Identification of Species Within the C. carnea Group The widespread and abundant *C. carnea s.l.* is composed of several sibling, cryptic, and sympatric species (Henry et al. 2001). For their identification, we used several morphological traits of adults (Thierry et al. 1992, 1998; Henry et al. 1996, 2002, 2003). As we were aware of the debates about a valid nomenclature within the *C. carnea* group (Canard and Thierry 2005), we accepted the species names given by Henry et al. (1996, 2002, 2003).

Statistical Analyses The data units for the field experiments were number of insects caught/inspection. The catches from field trapping tests were transformed by using $(x+0.5)^{1/2}$ as suggested by Roelofs and Cardé (1977) for similar experiments. In many field trapping tests, trap catches are below ten or even zero, so this or a similar transformation is desirable (Tukey 1949, 1955). Data were analyzed by a Student's *t* test (two treatments only) or analysis of variance (ANOVA; more than two treatments). Treatment means were separated by the Games–Howell Test (Games and Howell 1976; Jaccard et al. 1984). Where one of the treatments caught no insects, the Bonferroni–Dunn test (Dunn 1961) was used to check that mean catches in other treatments were not significantly different from zero catch (see also table and figure legends). To analyze EAG responses, we used ANOVA followed by Fisher's protected least significant difference (LSD) for significance levels (Fisher 1966). All statistical procedures were conducted by using the software packages StatView® v4.01 and SuperANOVA® v1.11 (Abacus Concepts, Berkeley, CA, USA).

Results

EAG Response Spectra Both female and male antennae showed similar response intensities to the range of compounds tested (Fig. 1). The largest responses were evoked by (*E*)-cinnamaldehyde, and these responses were significantly different from all other compounds. This was followed in tendency by responses to methyl anthranylate, methyl salicylate, β-ionone, benzyl alcohol, and 2-phenylethanol, but responses to these compounds were not significantly higher than those to the phenethyl alcohol standard. Phenylacetaldehyde evoked medium large responses similar to those of the standard. The rest of the compounds evoked rather uniform, low to medium EAG responses.

Field Comparison Tests, Hungary In experiment 1A, traps baited with the binary combination of phenylacetaldehyde and acetic acid caught significantly more green lacewings than traps with only phenylacetaldehyde throughout the test period. Mean catches/trap/inspection (±SE) were 3.31±0.60 vs. 1.56±0.37, respectively (P=0.011 by Student's *t* test). Similar results were recorded in experiment 1B, the respective mean catches were 6.69±0.41 vs. 4.70±0.34 specimens (P=0.002 by Student's *t* test). Unbaited control traps caught a mean (±SE) of 0.00±0.00 (experiment 1A) or 0.02±0.01 (experiment 1B) lacewings, respectively.

In the ratio test (experiment 2), traps with the 1:1 blend of phenylacetaldehyde + acetic acid caught the highest number of *C. carnea*, and mean catch in these traps was significantly higher compared to traps with phenylacetaldehyde alone (Fig. 2). The 10:1 blend produced intermediate catches. Very little was captured with the 1:10 blend, and zero catches were recorded in traps with acetic acid only.

The known lacewing attractant β-caryophyllene (Flint et al. 1979) did not catch more than unbaited controls and did not influence catches when added to the binary phenylacetaldehyde + acetic acid combination (Table 1, experiment 3). Methyl salicylate (Molleman et al. 1997; James 2003) was also inactive on its own; however, it increased catches significantly when added to the binary phenylacetaldehyde + acetic acid blend (Table 1, experiment 3).

The synergistic action of methyl salicylate was confirmed in experiment 4 (Fig. 3). Addition of methyl salicylate in equal or ten times lower amounts compared to the other two compounds in the ternary blend produced higher catches than the binary phenylacetaldehyde + acetic acid mixture. Similarly high catches were observed when methyl salicylate was added in a separate dispenser or loaded together in the same dispenser. When the amount of phenylacetaldehyde + acetic acid was decreased in the ternary blend, catches decreased. Methyl salicylate on its own again showed no activity (Fig. 3).

When comparing efficacy of the 1:1:1 ternary blend with that of the described lacewing attractants 2-phenylethanol (Zhu et al. 1999, 2005) and 3-methyl eugenol (Suda and Cunningham 1970; Umeya and Hirao 1975), the ternary blend caught approximately one magnitude more than the single compounds, although both 2-phenylethanol and 3-

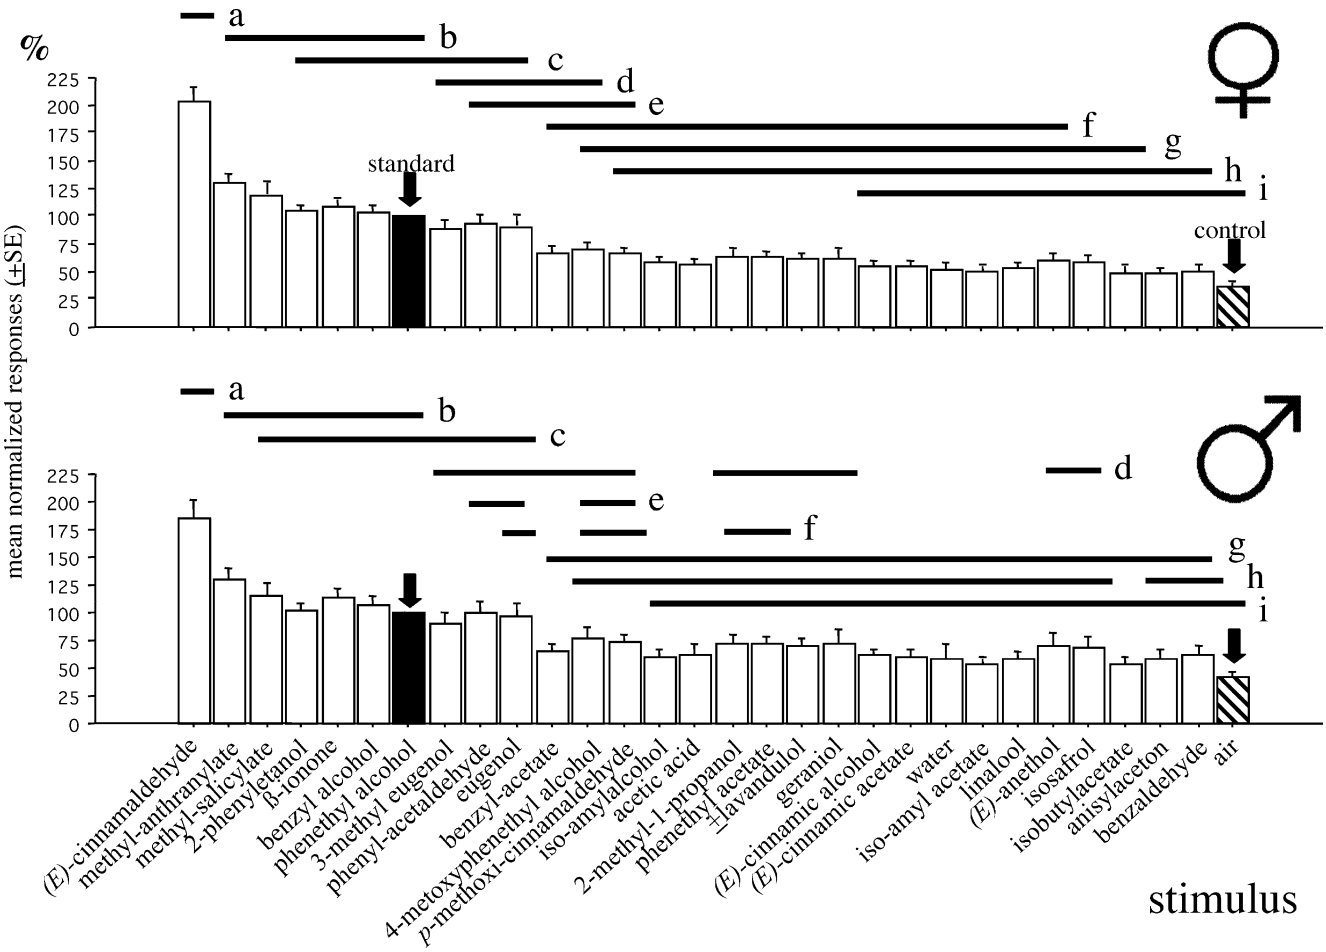

Fig. 1 Normalized EAG responses of female or male green lacewing antennae to a range of attractant candidate compounds. *Columns* show mean responses of antennae from nine female or 11 male insects tested. Responses were normalized to the response evoked by the standard phenethyl alcohol. *Columns with horizontal bars* not significantly different (α=0.05) by ANOVA, Fisher's Protected LSD test

Significant difference from zero catch (acetic acid on its own) was tested by Bonferroni–Dunn test

methyl eugenol showed significantly increased catches as compared to unbaited controls (Table 1, experiment 5). However, when these compounds were added to the ternary blend, no influence on catches was observed (Table 1, experiment 6).

Finally, when the activity of (*E*)-cinnamaldehyde and methyl anthranylate, both evoking high EAG responses from antennae of both sexes (Fig. 1) were studied, the single compounds showed significant attraction as compared to the unbaited traps (Table 1, experiment 7). However, their addition to the ternary blend did not increase catches. In fact, the quaternary mixture containing methyl anthranylate caught less than the ternary blend.

Subtraction tests aimed to study the relative importance of the components of the ternary phenylacetaldehyde + acetic acid + methyl salicylate blend yielded similar trends of catches in both experiment 8 and 9 (Fig. 4). Lowest catches were recorded with the acetic acid + methyl salicylate binary combination; however, catches in these traps were higher than in unbaited traps (in experiment 9, where unbaited traps

n.t. not tested

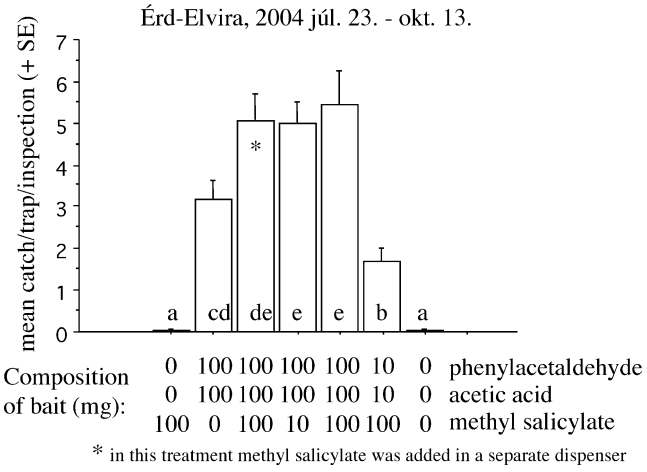

Fig. 3 Mean catches of green lacewings in traps baited with blends of phenylacetaldehyde, acetic acid, and methyl salicylate in different ratios or with the single compounds (experiment 4; total caught in test, 1,210 lacewings). *Columns with same letter* not significantly different (α=0.05) by ANOVA, Games–Howell test

were also operated). Phenylacetaldehyde on its own produced medium high catches. The binary phenylacetaldehyde + acetic acid blend showed a tendency of catching more than phenylacetaldehyde on its own. Largest catches were observed in the binary phenylacetaldehyde + methyl salicylate mixture or the ternary blend, and no significant difference was found between these blends.

Among randomly selected specimens caught in experiments 8 and 9 (138 and 941, respectively), 30.0% and 62.2% were females. There was no apparent difference in ratio of sexes caught among the different treatments.

A determination effort of a random sample of 205 (experiment 8, 92% out of a total of 222 captured) and 559 (experiment 9, 50.4% out of a total of 1,109 captured) lacewing specimens resulted in 84.1% and 49.1% of *C. carnea* s. str. (Stephens), 11.6% and 39.1% of *Chrysoperla lucasina* Lacroix, 4.3% and 9.9% of *Chrysoperla pallida* (Henry et al. 2002), respectively. The remaining 3.5% of specimens from experiment 9 were morphologically similar to *Chrysoperla agilis* (Henry et al. 2002); however, the occurrence of this species in the Hungarian fauna has not been reported previously. To sum it all up, all captured specimens investigated belonged to the *C. carnea* group.

Activity of the Optimized Attractant in Different European Regions In Rotondella, a total of 128 adult *C. carnea* were caught (83 females, 16 males, and 29 unsexed specimens) in traps with the ternary lure between 14th April and 27th July (16 inspections on five traps) resulting in a mean (±SE) of 1.60±0.18 adults/trap/inspection. Only five adults (four females and one male) were found in unbaited control traps.

In Ullensvang, Western Norway, a total of 18 adult *C. carnea* were caught in traps with the ternary lure between 16th May and 15th June (four inspections on ten traps) resulting in a mean (±SE) of 0.45±0.19 adults/trap/inspection. Between 16th June and 12th September, a total of 14 adults were caught (12 inspections on three traps) resulting in a mean (±SE) of 0.23±0.10. Further, a total of 287 eggs were found inside ten delta traps with baits between 16th May and 15th June, and a total of 26 eggs were found inside five delta traps with baits between 16th June and 12th September. No adults or eggs were found in

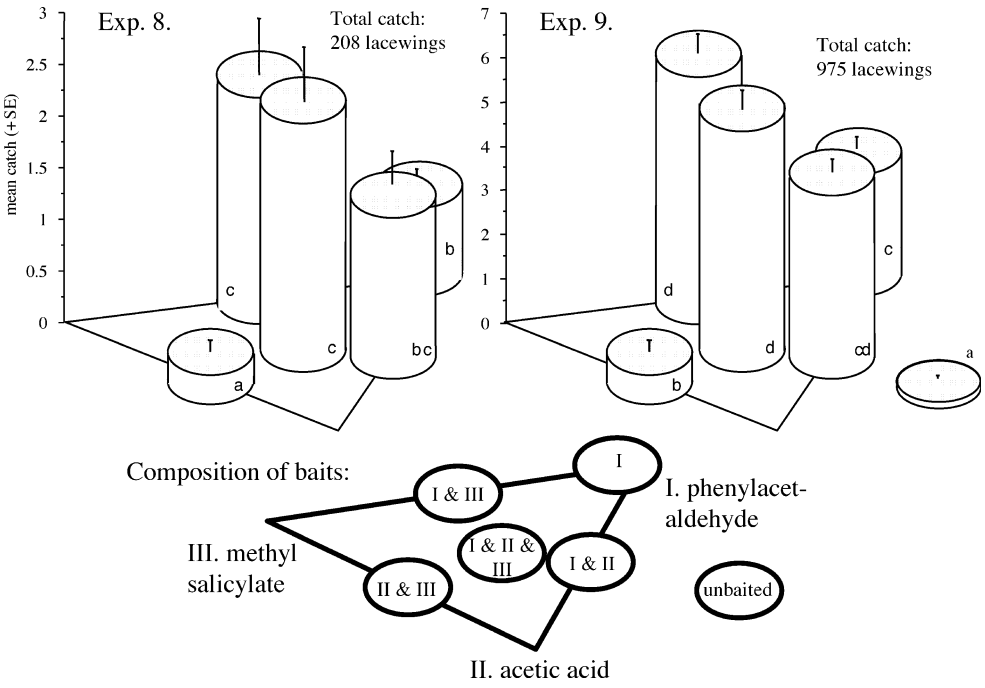

Fig. 4 Mean catches of green lacewings in traps baited with binary and ternary blends of phenylacetaldehyde, acetic acid, and methyl salicylate or with phenylacetaldehyde by itself (experiments 8 and 9; total caught in tests, 208 and 975 lacewings, respectively). *Columns with same letter* not significantly different (α=0.05) by ANOVA, Games–Howell test

unbaited control traps. In Søråsjordet, Ås (southeastern Norway), a total of 63 adults were caught in delta traps with the ternary lures between 29th May and 8th October (10 inspections on 5 traps) resulting in a mean (±SE) of 1.26± 0.22 adults/trap/inspection. In Norderåshagen, Ås (five inspections on seven traps), a total of 137 adults were caught between 29th May and 13th June (3.91±0.45 adults/trap/inspection). A total number of 99 and 156 eggs were found in the two fields, respectively, inside the traps during the corresponding periods. In the unbaited control traps, a total of one adult and two eggs were found.

Discussion

In this study, the addition of acetic acid clearly enhanced the behavioral activity of the previously known synthetic attractant phenylacetaldehyde. Acetic acid is known to be weakly attractive to several insect species (i.e., Yothers 1927; Keiser et al. 1976; Casana-Giner et al. 1999). Attractant combinations of acetic acid and other food- or host-derived volatile compounds have been reported to show increased activity in yellowjacket wasps (Landolt 1998), in noctuid or pyralid moths (Landolt and Alfaro 2001; Tóth et al. 2002; Landolt 2005), and, more recently, in the codling moth (Landolt et al. 2007). The presence of acetic acid usually is thought to indicate fermentation products, and attraction to acetic acid-emitting sources has been explained as orientation towards food sources by insects that feed on fermenting materials (Utrio and Eriksson 1977; Landolt et al. 2007). A similar hypothesis can explain the increased response of green lacewings to blends containing acetic acid.

Phenylacetaldehyde will produce (*E*)-2,4-diphenylbut-2-enal in the presence of acetic acid (Goetz et al. 1990). This reaction can be expected to take place when both compounds are loaded into the same dispenser. Because the addition of acetic acid resulted in a significant increase in catches both when the two compounds were presented in two different dispensers (experiment 1A) or when they were loaded into the same dispenser (experiment 1B), it suggests that the possible formation of (*E*)-2,4-diphenylbut-2-enal had no dramatic effect on behavioral activity. In this study, no attempt was made to examine in detail the possible influence of (*E*)-2,4-diphenylbut-2-enal on the activity of the phenylcetaldehyde + acetic acid blend, but this interaction should be clarified in future experiments.

We demonstrated in this work that trap catches to the binary mixture of phenylacetaldehyde and acetic acid can be further increased by the addition of methyl salicylate. This compound attracted *C. carnea* green lacewings in a test originally aimed at predators of the pear psylla (Molleman et al. 1997) and was also attractive to *Chrysopa nigricornis* Burmeister (James 2003). We did not observe any significant attraction to methyl salicylate on its own (Table 1, Fig. 3).

The compound β-caryophyllene has earlier been described as an attractant for *C. carnea* (Flint et al. 1979), but we did not confirm these findings. Caryophyllene has also been found to be behaviorally inactive in other studies (Zhu et al. 2005; Tóth et al. 2006). The reason for this discrepancy in attraction is not clear.

3-Methyl eugenol, which has been reported as attractive for some chrysopid spp. (Suda and Cunningham 1970; Umeya and Hirao 1975), showed some activity with *C. carnea* when presented alone in our tests. The attraction of *C. carnea* to 2-phenylethanol presented alone (e.g., Zhu et al. 2005) was also confirmed in our study. However, none of the above described compounds increased catches of *C. carnea* when added to the ternary blend optimized in this study.

We screened synthetic compounds by EAG to look for attractant candidates, as suggested by Dodds and McEwen (1998). Both compounds that evoked the highest responses, (*E*)-cinnamaldehyde and methyl anthranylate, were attractive in the field when presented alone. To our knowledge, neither has been reported to be attractive to lacewings. However, when (*E*)-cinnamaldehyde was added to the ternary blend optimized in this study, we observed no impact on the trap catches. Addition of methyl anthranylate possibly reduced catches (although this phenomenon should be confirmed through further testing).

There are other potential semiochemicals that might bear further study. For example, in a laboratory olfactometer bioassay, Van Emden and Hagen (1976) reported that tethered female green lacewings spent ca. 70% of the total time flying towards reaction mixtures thought to produce indole acetaldehyde, which led the authors to suggest that indole acetaldehyde was a lacewing attractant. However, Van Emden and Hagen (1976) never tested the synthesized pure compound in the laboratory or in the field.

Based on our results, it appears that the ternary blend described in this study is the most powerful synthetic attractant reported to date for *C. carnea*. Green lacewing populations from southern to northern and central Europe responded equally well in this study, and there was no indication of geographical differences in response, so this ternary attractant may prove to have widespread applicability. It remains to be seen whether *C. carnea* populations outside of Europe will also be as responsive.

From the subtraction tests of the ternary blend (experiments 8 and 9), it appears that the removal of phenylacetaldehyde had the most impact on the activity, whereas the removal of methyl salicylate resulted in a quantitative but not significantly lower reduction in trap catch. Removal of acetic acid did not lower trap catch. The combination of

methyl salicylate and phenylacetaldehyde was two to three times more attractive than phenylacetaldehyde alone was. More detailed studies should be carried out to evaluate whether acetic acid can be omitted altogether without seriously affecting efficiency.

Most insect predators show omnivorous feeding behavior, i.e., by feeding directly or indirectly on plant materials such as pollen or nectar (Jervis and Kidd 1996; Villenave et al. 2005). Green lacewings are adapted to unpredictable food supplies and larval habitats. Adult females perform obligatory migration flights where they do not react to olfactory stimuli. After the initial migration flight, females start responding to plant odors by a combination of appetitive down- and upwind flights (Duelli 1980, 2001).

The three "cryptic" lacewing species, *C. lucasina*, *C. pallida*, and *C. carnea* s. str. captured in baited traps in this study all belong to the *C. carnea* species complex. No other chrysopids were caught in significant numbers. An explanation could be that floral food sources are more important for green lacewing adults of genera *Chrysoperla* (and probably also for *Dichochrysa*), whose diet regime is palynoglycophagous, than for other chrysopids (Canard 2001).

The attractant described in this study appears to be highly attractive to females, which is advantageous from the point of view of applicability in biological control efforts. *C. carnea* females attracted by our ternary attractant may spend a long time in the vicinity of the bait dispenser, searching for a food source and oviposition sites. Preliminary observations of eggs deposited in traps indicate that the ternary attractant may give rise to major bouts of oviposition. If confirmed in more extensive experiments, this response may be advantageous in biological control. A large number of lacewing larvae will reduce aphid populations on that particular plant. The ternary attractant might also increase biological control by increasing lacewing numbers in overwintering boxes, a method widely used by organic growers.

In the closely related *C. oculata*, the synthetic main component of the aggregation pheromone, (1*R*,2*S*,5*R*,8*R*)-iridodial, attracted many males into traps (Zhang et al. 2004). More recently, Chauhan et al. (2007) reported that although few females entered traps baited with iridodial, they found many female insects in the vicinity of the traps. As the pheromonal communication and host attraction systems of the *C. carnea* complex become better known, combinations of pheromones with floral attractants may provide optimal management tools to exert better biological control by this group of beneficial insects.

Acknowledgments The present study was partially supported by grants from the Hungarian OTKA Foundation. Study trips of R. T. and T. M. were generously supported by the Bilateral Intergovernmental S&T Cooperation I-17/99 between Italy and Hungary.

The Role of Extrafloral Nectar Amino Acids for the Preferences of Facultative and Obligate Ant Mutualists

Marcia González-Teuber · Martin Heil

Received: 24 September 2008 / Revised: 17 March 2009 / Accepted: 27 March 2009 / Published online: 16 April 2009

Abstract Plants in some 300 genera produce extrafloral nectar (EFN) to attract ants as a means of indirect defence. Among Mesoamerican *Acacia* species, obligate myrmecophytes produce EFN constitutively to nourish symbiotic ant mutualists, while non-myrmecophytes induce EFN secretion in response to herbivore damage to attract non-symbiotic ants. Since symbiotic *Acacia* ants entirely depend on the host-derived food rewards while non-symbiotic ants need to be attracted to EFN, this system allows comparative analyses of the function of EFN components in ant nutrition and attraction. We investigated sugar and amino acid (AA) composition in EFN of two myrmecophytes (*Acacia cornigera* and *Acacia hindsii*) and two related non-myrmecophyte species (*Acacia farnesiana* and *Prosopis juliflora*). AA composition allowed a grouping of myrmecophytes vs. non-myrmecophytes. Behavioural assays with obligate *Acacia* inhabitants (*Pseudomyrmex ferrugineus*) and non-symbiotic ants showed that AA composition affected ant preferences at high but not at low AA/sugar ratios. Most interestingly, behavioural responses differed between the two types of ants tested: Symbiotic ants showed a clear preference for higher AA concentrations and preferred nectar mimics with those four AAs that most significantly characterised the specific nectar of their *Acacia* host plant. In contrast, non-symbiotic ants distinguished among nectars containing different sugars and between solutions with and without AAs but neither among nectars with different AA/sugar ratios nor among mimics containing different numbers of AAs. Our results confirm that both AAs and sugars contribute to the taste and attractiveness of nectars and demonstrate that the responses of ants to specific nectar components depend on their life style. AAs are a chemical EFN component that likely can shape the structure of ant–plant mutualisms.

Introduction

Nectar is an aqueous solution of substances that mainly comprise primary metabolites such as sugars and amino acids and generally serves the attraction of mutualistic animals to plants (Baker and Baker 1975; Baker et al. 1978). Resulting benefits for plants include pollination in the case of floral nectar and protection from herbivores through the attraction of carnivores in the case of extrafloral nectar (EFN; Koptur 1992; Heil 2007, 2008). EFN is usually secreted outside the flowers, and—in contrast to floral nectar—it is not involved in pollination (Bentley 1977; Koptur 1992).

EFN has been described for plants in more than 300 genera (Bentley 1977; Koptur 1992; see also URL: www.biosci.unl.edu/emeriti/keeler/extrafloral/worldlistfamilies.htm). Plant species secreting EFN to attract defending ants (De la Fuente and Marquis 1999; Heil and McKey 2003) are, therefore, commonly called 'myrmecophilic' (i.e. 'ant-loving'). Ants benefit from attending plants, since they use EFN as a nutritive resource and since they are guided to

herbivores in the case of herbivore-induced EFN flow. Compounds that are mainly regarded responsible for the attraction of ants are sugars (Baker and Baker 1973; Blüthgen and Fiedler 2004; Heil et al. 2005) and amino acids (Lanza 1988, 1991; Lanza et al. 1993; Blüthgen and Fiedler 2004). Ants generally appear to prefer sugar solutions that contain amino acids over pure sugar solutions (Lanza 1991), but even the detailed identity of amino acids could elicit varying ant responses to artificial EFNs (Blüthgen and Fiedler 2004).

Other plants, in contrast, secrete EFN in a slightly different functional context. Obligate myrmecophytes are inhabited by specialised ants (Heil and McKey 2003). In these cases, there is no need for the plant hosts to attract ants from the vicinity, while the nutritive value of EFN might be more important due to the dependency of the inhabiting ants on the host-derived food rewards. A comparative approach using a set of related ant–plants that are characterised by these different levels of specificity allows, thus, a deeper understanding of the function that certain EFN components might play in ant attraction and nutrition.

For the present study, we used Mesoamerican *Acacia* species. In this species group, the obligate myrmecophytes secrete EFN constitutively (Heil et al. 2004) to nourish symbiotic ant colonies. These ants, which belong to the *P. ferrugineus* group of the genus *Pseudomyrmex*, obligatorily inhabit particular host plants and are nutritionally adapted to (and entirely dependent on) the host-derived food sources (Heil et al. 2004, 2005; Clement et al. 2008; Kautz et al. 2009). In contrast, non-myrmecophyte species of *Acacia* and of the related genera secrete EFN only in response to herbivore attack (Heil et al. 2004) to attract non-symbiotic ants, i.e. generalist species from the vicinity (Heil and McKey 2003). Thus, although EFN of both myrmecophyte and non-myrmecophyte *Acacia* species fulfils nutritive functions, an attractive function appears important only for the non-myrmecophytes, while EFN of myrmecophytes has likely a higher nutritional importance for the symbiotic ants.

The aim of our study was to evaluate how soluble amino acids affect ant preferences. We predicted that both sugars and amino acids should differ among EFN of myrmecophyte and non-myrmecophyte plant species. Both compound classes were analysed by high-performance liquid chromatography (HPLC), and then, behavioural assays were applied to study the attractiveness of nectar mimics differing in the quantity and concentration of those single compounds that most strongly contributed to the chemical differences among EFNs. Thereby, we aimed to determine whether specific amino acids, their concentration, or their mere number have any specific function in shaping different types of ant-plant mutualisms.

Methods and Materials

Plant Material and Study Site

We investigated the chemical composition of EFN of two myrmecophytes [*Acacia hindsii* Benth. and *Acacia cornigera* (L.) Willendow], of one non-myrmecophyte *Acacia* [*Acacia farnesiana* (L.) Willendow] and of one non-myrmecophytic, sympatric species of another genus, yet the same subfamily, the Mimosoideae (*Prosopis juliflora* Swartz). EFN was collected from plants growing naturally in the coastal area of the state of Oaxaca (México), 5 km northwest of Puerto Escondido (Pacific coast; ~15°55′ N and 97°09′ W; elevation, 15 m), in March and April 2007 and 2008. Species were determined following Janzen (1974) and Seigler and Ebinger (1995) and by comparison with specimens held at the Herbario MEXU at UNAM (Mexico City).

Nectar Collection and Quantification

Branches of myrmecophytes were deprived of ants and other insects the day before nectar collection: thorns were cut off, ants were mechanically removed, and the branch was then placed in a mesh bag after isolating it from the rest of the plant by applying a ring of sticky resin (Tangletrap, The Tanglefoot Corp., Grand Rapids, MI, USA). Branches of non-myrmecophyte species were induced by applying 1 mmol aqueous jasmonic acid solution (Heil et al. 2004) and then placed in mesh bags. After 1 day, nectar production rates were quantified as amounts of soluble solids per 24 h and per gram leaf dry mass by quantifying the nectar volume with microcapillaries (Hirschmann Laborgeräte GmbH & Co. KG, Eberstadt, Germany) and the nectar concentration with a refractometer (Atago Co. Ltd.) as described previously (Heil et al. 2000, 2001). The leaves bearing the EFN were then collected and dried (50°C for 48 h). EFN was collected from five individuals per species, which, in earlier studies, (Heil et al. 2004, 2005) turned out a sufficiently high sample size to represent the chemical variability of EFN secretion in the populations under investigation.

Determination of Carbohydrates and Amino acids

EFN was stored at −20° until analysis. For carbohydrate analysis, 30 µL of nectar were diluted in 600 µL de-ionised water. After centrifugation and membrane filtration (Vivaspin 500, Vivascience Sartorius Group, Stonehous, UK), sugars were immediately separated by HPLC on an anion exchange column and quantified by pulsed amperometric detection (Dionex Series 4500 Chromatography System, Dionex, Idstein, Germany). For the analysis of amino acids,

30 µL of nectar were diluted in 200 µL de-ionised water. After centrifugation and membrane filtration, 100 µL of the supernatant were diluted with 20 µL sulfosalicylic acid (12.5%). After incubation at 4°C for 30 min and a second centrifugation, 50 µL of sample buffer were added to 100 µL of the supernatant. Samples were then analysed using an Amino Acid Analyzer LC 5001 (Biochrom 20 Plus, Cambridge, England). To control for differences in overall nectar concentration, the content of each amino acid was related to the sugar content of the respective sample and is expressed in millimole amino acid per millimole sugar. Differences in amino acid concentrations among the four species were evaluated with a Kruskal–Wallis analysis of variance (ANOVA) (N=5 individual per species). Different individuals were used as replicates to avoid pseudoreplication. Considering that data were not normally distributed, amino acid composition was evaluated with a non-metric multidimensional scaling (NMDS), in order to identify putative associations among the species (NMDS allows to reduce a multidimensional data set to two dimensions and thus appeared an appropriate approach for this question). Ordination was carried out using the following parameters: Bray–Curtis as distance measure, stability criterion of 0.005, 200 iterations, ten runs with real data and ten runs with randomised data. The software used for this analysis was PC-ORD v. 4.2 (McCune and Mefford 1999). Values of NMDS axes were compared among species using a univariate ANOVA.

Behavioural Assays

To study the behavioural responses of ants (symbiotic vs. non-symbiotic ants) to EFN with differing composition, 'cafeteria'-style experiments were carried out under field conditions. Such 'cafeteria' experiments allow to simultaneously offer different types of food sources to animals that freely can choose among them.

The NMDS of EFN amino acids revealed strongest differences between EFNs of *A. hindsii* and *Prosopis* (Fig. 3). We, therefore, focused on these two plant species for the behavioural assays and evaluated the attraction of obligate *Acacia* symbionts (*Pseudomyrmex ferrugineus* Smith F.) and of non-symbiotic ants to EFNs of these two plant species and to different artificial nectars that mimicked the major differences between the two plant species (see Table 1).

Experiment 1: High and Low AAs A first field eperiment was conducted in March 2007. EFN of *A. hindsii* and *Prosopis* was first collected from several individual plants (N=3–5) in the field and then pooled to achieve higher nectar volumes. Then, EFN collected of *A. hindsii* was adjusted with distilled water to a concentration of 4% (w/v), which was the highest concentration found in nectar of *Prosopis* in the field. Six nectar mimics were applied at the same concentration (4%): solution (sol.) 1 contained fructose (F)+glucose (G)+sucrose (S) at a ratio of 3:3:1 to mimick sugar ratio as found in the EFN of *Prosopis*, sol. 2 contained F+G at a ratio of 1:1, mimicking the sugars found in EFN of *A. hindsii*. Three nectar mimics were prepared with different AA compositions: Sol. 3 was a sugar solution (F/G=1:1) containing methionine, isoleucine, leucine, valine, threonine, phenylalanine, proline and serine (i.e., those AA that were highly correlated with Axis 1, see below, and that most strongly contributed to the chemical difference between EFN of *A. hindsii* and of *Prosopis*). Sol. 4 was a sugar solution (F/G=1:1) with those four AA that were highly dominant in EFN of *A. hindsii* (see below, Table 2), and sol. 5 was a sugar solution (F/G=1:1) containing phenylalanine and proline, which both appear particularly important AA in the physiology of insects (Chapman 1983; Dafni and Kevan 1994; Micheu et al. 2000). Pure water was offered as a control (sol. 6; Table 1).

These six artificial solutions and fresh EFNs of *A. hindsii* (sol. 7) and *Prosopis* (sol. 8) were offered to ants in their natural habitat. Two different AA/sugar ratios were used to evaluate whether ants are able to distinguish among different artificial solutions when these contain different AA/sugar ratios: (1) a ratio of each amino acid to fructose and glucose of 1:50 ('high-AA EFNs', N=10 cafeterias) and (2) a ratio of each amino acid to fructose and glucose of 1:1,000 ('low-AA-EFNs', N=17 cafeterias). The ratio 1:50 represents the values that we found in EFN of *Acacia* species (see Table 2).

Independent experiments were conducted for symbiotic and non-symbiotic ants. For *P. ferrugineus*, a 10-µl drop of each of the eight solutions was offered on a horizontal branch of an *A. hindsii* host plant (one cafeteria per plant). For generalist ants, the eight solutions were offered on branches of *Prosopis* that were cut off the plants and placed then on the soil to facilitate the access of generalist ants. In both cases, the individual droplets were offered 10–15 cm apart from each other, and the spatial order varied among the cafeterias. Solutions that had evaporated or that had been entirely consumed were replaced with a new drop of 10 µL. All ants feeding on the droplets were counted five times during the morning (between 10:00 A.M. and 13:00 P.M.). Each single count lasted 3 min, with an interval of 30–40 min between the individual censuses. Because ant abundance may differ among individual plants, numbers of ants that had been attracted to the individual cafeterias were summed up for every cafeteria to calculate the relative proportion of ants that had been attracted to each individual solution. This percentage of ants was subjected to univariate ANOVA (independent variable, solution

type) after arcsine transformation (Sokal and Rohlf 1995). A least significant difference (LSD) test was posteriorly applied.

Experiment 2: Number of AAs A second 'cafeteria experiment' was carried out in January 2009 to examine whether the ratio of AAs to sugars or the number of AAs is most important to determine ant preferences. Given that ants were only able to distinguish among solutions at higher AA concentrations (Fig. 4), solutions (4%) at ratios 1:10 and 1:50 of AAs to total sugars were prepared with different numbers of total AAs (2AA, 4AA and 8AA). The following six solutions were prepared: 1:10-2AA, 1:10-4AA, 1:10-8AA, 1:50-2AA, 1:50-4AA and 1:50-8AA. Solutions were

Statistical differences among the four species were evaluated for each AA with a Kruskal–Wallis ANOVA, and significance levels are indicated. For amino acid names, see Table 3. Total AAs refers to the sum of the 19 AAs for each species. Total sugars refer to the sum of fructose and glucose for *A. cornigera* and *A. hindsii* and of fructose, glucose and sucrose for *A. farnesiana* and *Prosopis* (see Fig. 1).

offered in independent experiments to symbiotic (N=10) and non-symbiotic ants (N=10). 'Cafeteria experiments' were conducted as described above. Differences in the percentage of ants attracted to each solution were analysed with univariate ANOVA, after arcsin transformation. LSD was applied then as post hoc test.

Experiment 3: AA/sugar ratios The third experiment was conducted January 2009 to determine which minimal ratio of AAs to total sugars allows ants to differentiate among mimics that contain and that do not contain AAs. Six different 4AA solutions (4%) for symbiotic ants (N=10) and six different 8AA solutions (4%) for non-symbiotic ants (N=10) were prepared at different ratios of AAs to total sugars (1:10, 1:50, 1:100, 1:500 and 1:1,000) and tested in 'cafeteria experiments'. Differences in ant preferences (percentage of ants) among solutions were analysed with univariate ANOVA, after arcsin transformation. A LSD test was posteriorly applied. 'Cafeteria experiments' were conducted as described above.

Results

Sugars and Amino Acids

Sucrose, fructose and glucose were the only sugars detected in EFN of *Acacia* and of the closely related *Prosopis*. EFNs of the two non-myrmecophyte species contained all three sugars, while EFNs of the myrmecophytes only contained the monosaccharides, fructose and glucose (Fig. 1). EFN secretion (in microgram soluble solids per gram leaf dry mass per 24 h) by the myrmecophyte, *A. cornigera*, was significantly higher than for the non-myrmecophyte species ($F_{3,21}$=6.08; P<0.005; univariate ANOVA; Fig. 2). No significant differences were observed in EFN secretion between *A. cornigera* and *A. hindsii* (P>0.05, Tukey test) and between *A. hindsii* and the non-myrmecophyte species (P>0.05, Tukey test).

Amino acid concentrations varied strongly among the four species, and 'species' was a significant source of variation in the concentrations of 17 of the 19 amino acids detected (Table 2). The qualitative compositions differed much less, as only two of the four species contained less than 19 amino acids (*A. cornigera*, arginine missing; *Prosopis*, methionine and proline missing), while in EFN of *A. hindsii* and *A. farnesiana*, all the 19 amino acids were present.

Non-metric Multidimensional Scaling

Both axes contributed significantly to the variation among the species (axis 1, $F_{3,16}$=63.0, P<0.001, univariate ANOVA; axis 2, $F_{3,16}$=22.4, P<0.001, univariate ANOVA), allowing a grouping of myrmecophyte vs. non-myrmecophyte species. *A. hindsii* and *Prosopis* were most distant from each other (Fig. 3). For axis 1, there were no significant differences among myrmecophyte species and among non-myrmecophytes, but the myrmecophtes differed significantly from the non-myrmecophytes. For axis 2, *Prosopis* was significantly different from all other three species.

Methionine, isoleucine, leucine, valine, threonine, phenylalanine, proline and serine were the components with the highest contribution to both axes (amino acids with higher correlation coefficients, see Table 3), suggesting that these eight amino acids did increase the C value and thus contributed most strongly to the differentiation among the species. All these eight amino acids where present at much higher concentrations in *A. hindsii* EFN than in EFN of *Prosopis* (Table 2).

Amino Acids and Ant Attraction

In the experiment using low AA EFNs (ratio of each AA to fructose=1:1,000 in the artificial mimics), mutualistic ants preferred EFN of *A. hindsii* over EFN of *Prosopis* (Fig. 4a), whereas non-mutualistic ants showed the opposite preference (Fig. 4b). In general, 'solution type' significantly affected the percentage of ants attracted to the different solutions. This remained true both for symbiotic ants ($F_{7,128}$=8.31; P<0.001; univariate ANOVA) and for non-symbiotic ants ($F_{7,128}$=7.49; P<0.001; univariate ANOVA). Nevertheless, neither symbiotic nor non-symbiotic ants discriminated among the various AA-containing artificial solutions (Fig. 4a, b). For high AA EFNs, the percentages of ants attracted to the different solution types also were significantly different both for symbiotic ants ($F_{7,72}$=10.89; P<0.001; univariate ANOVA) and non-symbiotic ants ($F_{7,72}$=10.83; P<0.001; univariate ANOVA; Fig. 4c, d). Moreover, ants under these conditions distinguished among the artificial solutions, since symbiotic ants significantly preferred the artificial solution with four amino acids (leucine, phenylalanine, proline and valine), while no significant differences were observed among the other artificial solutions. Again, symbiotic ants preferred EFN of *A. hindsii* over the EFN of *Prosopis* (Fig. 4c). On the other hand, non-symbiotic ants significantly preferred the sugar solutions with sucrose over the solution without sucrose, and the sugar–amino acid solutions over sugar-only solutions, although they did not discriminate among the different solutions with amino acids. Consistently with the first experiment, *Prosopis* EFN attracted more non-symbiotic ants than nectar of *A. hindsii* (Fig. 4d).

In the second experiment testing different AA/sugar ratios, significant differences among AA solutions were only observed for symbiotic ants ($F_{5,54}$=6.66; P<0.001; univariate ANOVA). These ants significantly preferred the solution 1:10 over all other solutions, and in fact, ant preference decreased continuously with decreasing AA concentration (Fig. 5a). In contrast, non-symbiotic did not differentiate significantly among solutions with different AA/sugar ratios ($F_{5,54}$=0.27; P>0.05; univariate ANOVA; Fig. 5b). Similar results were obtained in the third experiment, where symbiotic ants distinguished among the different solutions ($F_{5,54}$=0.47; P>0.05; univariate ANOVA, see Fig. 5a) and significantly preferred the solution with 4AAs over the other solutions at both 1:10 and 1:50 ratios ($F_{5,54}$=4.67; P<0.001; univariate ANOVA, see Fig. 5c). Again, non-symbiotic ants did not differentiate significantly among solutions ($F_{5,54}$=0.27; P>0.05; univariate ANOVA; Fig. 5d)

Discussion

EFN is secreted by many plants to attract ants and thus serves as a means of indirect defence (Heil 2008). Sugars and amino acids are generally known as the EFN compounds that are responsible for this attractive function (Koptur 1979; Lanza and Krauss 1984; Lanza 1991; Lanza

Table 3 Correlations between specific amino acids and the two NMDS axes in EFN of three *Acacia* species and *Prosopis*

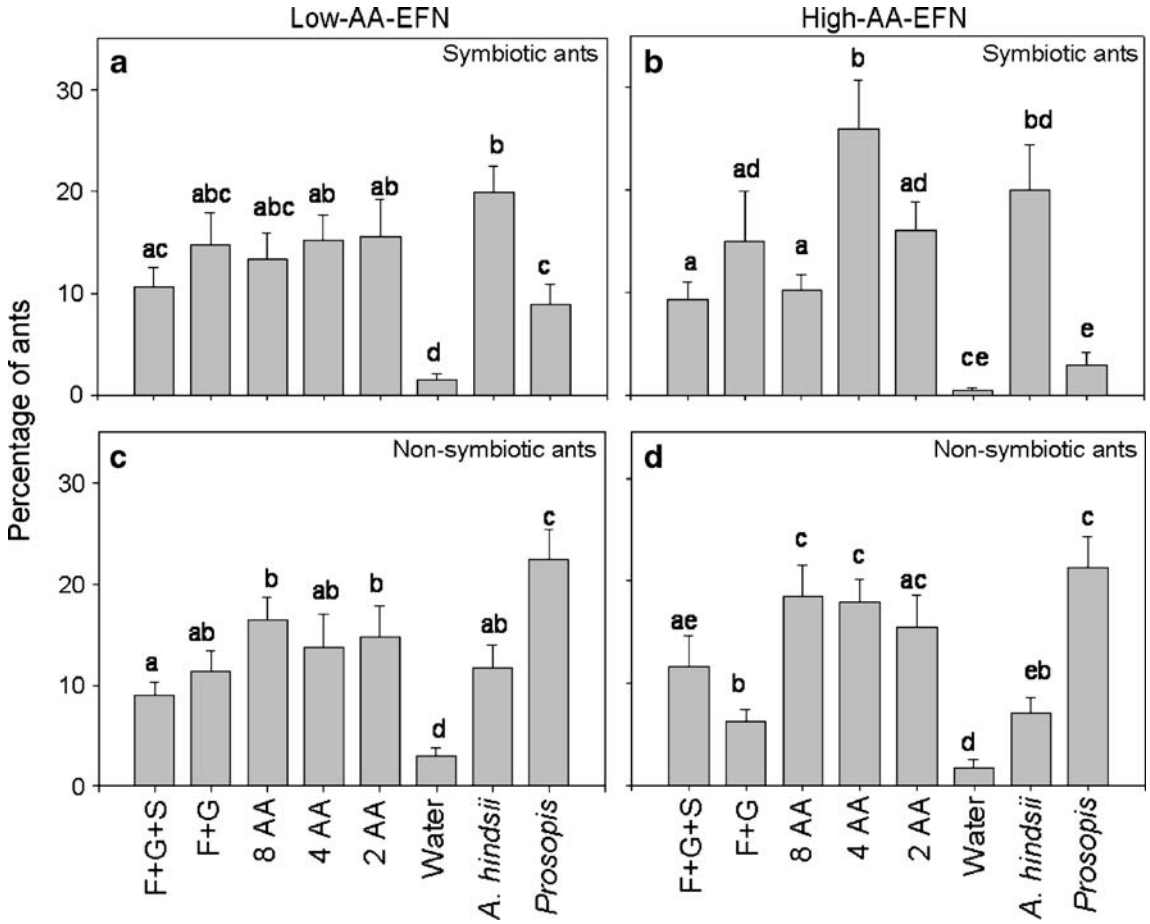

Fig. 4 Ant attraction to EFN mimics. Preferences of symbiotic and non-symbiotic ants to natural EFNs of *A. hindsii* and *Prosopis* and various EFN mimics with and without amino acids (AA). Solution compositions are indicated in Table 1. Low-AA-EFN (**a**, **b**) contained an AA/sugar ratio of 1:1,000 (sample size=17 cafeterias), whereas high AA EFNs (**c**, **d**) contained a ratio of 1:50 (sample size=10 cafeterias). Ant preferences are expressed as means+SE of the percentage of all feeding ants that were attracted to each solution. *Different letters* indicate significant difference in ant attracted among solutions ($P<0.05$ according to post hoc LSD test)

et al. 1993; Blüthgen et al. 2004), but ant preferences to sugars and amino acids may vary among ant species according to their nutritive needs and particularly among functionally different types of mutualisms.

NMDS analysis demonstrated a separation of myrmecophyte species vs. non-myrmecophytes according to the amino acid composition of their EFN: the myrmecophyte, *A. hindsii*, and the non-myrmecophyte, *P. juliflora*, turned out to be the most distant among the four investigated species. Interestingly, these chemical distances mirror the phylogenetic relations: a phylogenetic reconstruction based on chloroplast DNA markers (Heil et al. 2004) also revealed *A. hindsii* and *P. juliflora* to be most distantly related among the species tested in this study. Phenylalanine and proline appeared in much higher concentrations in EFN of the myrmecophytes, *A. cornigera* and *A. hindsii*, than in EFN of the two non-myrmecophytes, which is in line with the very low concentrations of these two amino acids found in EFN of the non-myrmecophyte, *Macaranga tanarius* (Heil et al. 2000) and in other EFNs (Baker et al. 1978; Inouye and Inouye 1980). These two amino acids were among those that most intensively contributed to the differentiation that NMDS revealed among the EFNs studied in this paper.

We found that free amino acids at high concentrations in EFN significantly affected preferences by different ants. Several studies have reported interspecific variability in ant preferences to amino acids (Lanza 1988; Lanza et al. 1993; Blüthgen and Fiedler 2004). Our results generally confirm these studies, since symbiotic and non-symbiotic ants differed in their preferences for artificial amino acid solutions. Nevertheless, differences in ant behaviour were only evident when the relative concentration of single amino acids to sugars were high (1:50), i.e., at concentrations as found in *Acacia* EFN. In contrast, neither symbiotic nor non-symbiotic ants discriminated among artificial mixtures at low amino acid concentrations (1:1,000). This result confirms the study by Lanza (1991), who showed that preferences of fire ants were most obvious when nectar mimics contained high levels of amino acids.

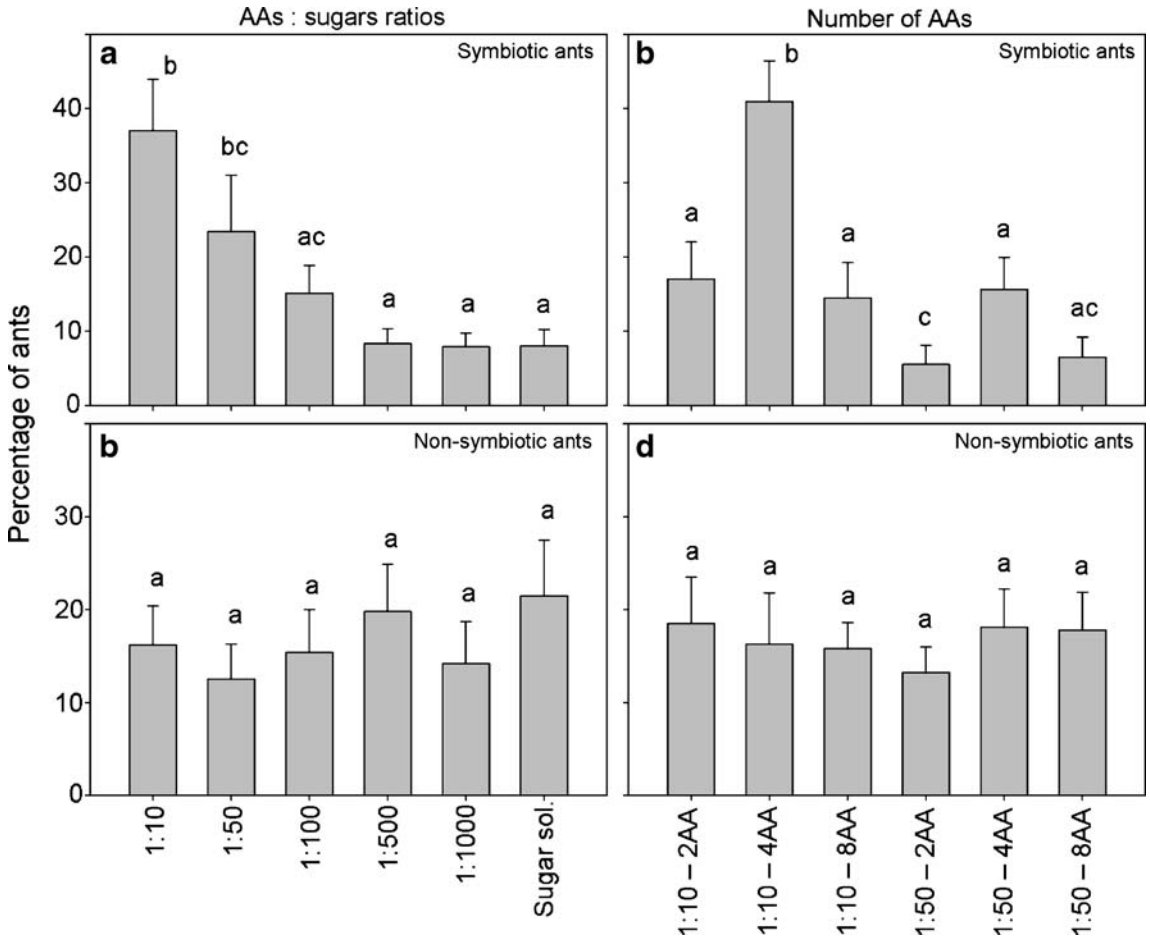

Fig. 5 Preferences of symbiotic and non-symbiotic ants to 4AA and 8AA solutions, respectively, with different AA/sugar ratios (**a**, **b**) (sample size=10 cafeterias) and to solutions with different number of AAs at two different AAs/sugars ratios (**c**, **d**) (sample size=10 cafeterias). Ant preferences are expressed as means+SE of the percentage of all feeding ants that were attracted to each solution. *Different letters* indicate significant difference in ant attracted among solutions ($P<0.05$ according to post hoc LSD test)

Therefore, our results support the general assumption that high concentrations of amino acids in nectar contribute notably to its taste (Gardener and Gillman 2002).

However, ant life history strongly affected whether and how ants responded to certain nectar components and AAs that affected the chemical grouping of myrmecophyte EFNs vs. non-myrmecophyte EFNs determined in part the observed behaviour of symbiotic and non-symbiotic ants. As expected, the symbiotic ants specifically preferred the solution containing those four amino acids that are highly concentrated in the EFN of their host plant (*A. hindsii*). Furthermore, symbiotic ants were able to distinguish this specific solution (1:10-4AA) from other solutions, suggesting that not only AA concentration but also their number and detailed identity determines preferences by symbiotic ants. In contrast, although non-symbiotic ants preferred the solution with eight amino acids in the first experiment, they did not distinguish among nectar mimics that differed only in the number or exact concentration of AAs, while the identity of sugars had a strong and significant effect. Apparently, for generalist ants, just the presence of amino acids in the nectar but not their detailed identity is important, while symbiotic ants are much more selective. Considering that non-symbiotic ants do not establish an obligate mutualism with plants, they must forage on different plant species, unlike symbiotic ants, which are constitutively nourished by one specific host. This different style of life between symbiotic and non-symbiotic ants affects their preferences and selectiveness with respect to detailed chemical composition of their food sources.

These results also suggest that those 4AAs that contributed most to separate myrmecophyte from non-myrmecophyte EFN and that significantly affected the behaviour of symbiotic ants should have a particularly important function for the nutrition of these ants. In fact, high concentrations of phenylalanine and proline have also been reported for different floral nectars (Carter et al. 2006; Petanidou et al. 2006) and thus might be typical for more important types of

nectar-mediated interactions. Phenylalanine is one of the ten essential amino acids for honeybees (Chapman 1983; Dafni and Kevan 1994), while proline is preferentially utilised by insect pollinators during the initial phases of insect flight (Micheu et al. 2000). For ants, comparable information is lacking, and further physiological studies are needed to determine the significance of specific essential amino acids for their metabolism.

Our study suggests that the detailed amino acid composition of EFN is important for its ecological function. Strikingly, behavioural responses differed between symbiotic ants and non-symbiotic ants, with symbiotic ants generally being more selective. Our results confirm that both amino acids and sugars contribute to the taste and attractiveness of nectars and demonstrate clearly that the responses of ants to specific nectar components depend on their life style. Therefore, amino acids are a chemical component of nectar that likely can shape the structure of ant–plant mutualisms.

Effects of Simulated Herbivory on Defensive Compounds in Forage Plants of Norwegian Alpine Rangelands

Eli R. Saetnan · George O. Batzli

Received: 20 November 2008 / Revised: 23 February 2009 / Accepted: 10 March 2009 / Published online: 14 April 2009

Abstract A field study on the effects of current grazing practices on plants in central Norway found no increase in either phenolic compounds or proteinase inhibitors in plants subjected to grazing by sheep. This could either reflect insufficient damage to the plants due to low grazing intensity or a lack of a long-term response of the plants to grazing. In this study, we tested the hypothesis that damage to forage plants used by sheep and rodents in Norwegian alpine rangelands can stimulate a long-term (at least 2-week) increase in levels of defensive compounds. We used clipping experiments to manipulate the severity and timing of damage to eight species of common plants used by herbivores in Norway. Under greenhouse conditions (i.e., climate-controlled), we subjected mature plants to one of four clipping treatments: control (0% leaf tissue removed), low (10–15% leaf tissue removed), high (70–75% leaf tissue removed), or sustained (15% of leaf tissue removed every other day up to a total removal of 75%, i.e., five clippings over 9 days). Samples were collected 2 weeks after final clipping and analyzed for concentrations of total phenolics, proteinase inhibitors, ratio of total phenolics to soluble proteins, and ratio of proteinase inhibitors to soluble plant proteins. As expected, the different species of plants responded differently to simulated herbivory, but most plants either showed no response to mechanical wounding and tissue loss or had reduced defensive compounds. Thus, our results do not support the hypothesis that herbivory induces a long-term increase in defensive compounds in alpine rangelands of Norway, a result consistent with those from field studies.

Introduction

Plants often increase levels of secondary metabolites in response to herbivory (an induced response), but responses to defoliation and browsing vary depending on nutrient availability, season and severity of the attack, species of plant, and species of herbivore (Crawley 1999). The production of defensive compounds constitutes a significant energetic cost to the plant and, therefore, may reduce seed production (Cates 1975) or lower growth rates (Zangerl et al. 1997; Donaldson et al. 2005). Such plants would be at a disadvantage when levels of herbivory are low, but habitats with variable levels of herbivory may favor plants that can increase their level of defense as herbivory increases (Adler and Karban 1994; Åström and Lundberg 1994; Müller-Schwarze and Thoss 2008). Indeed, induced responses often increase plant fitness (Agrawal 1998), which indicates that the benefits of induced defenses often outweigh the cost of producing defensive chemicals.

Induced responses occur in response to a wide range of herbivores, including mammals. For instance, severe winter browsing by hares causes feltleaf willow to revert to a juvenile phase that contains much higher levels of phenolic compounds (Bryant et al. 1985). Similarly, grazing by

livestock (cattle, sheep, and goats) stimulates production of leaf-surface terpenes in tarbush (Estell et al. 1998) and grazing by Soay sheep increases alkaloid levels in grasses on the island of St. Kilda (Bazely et al. 1997). Although many plants respond to herbivory with increased defensive compounds, some do not. Bilberry (*Vaccinium myrtillus*) in northern Norway lowers phenolic concentrations when heavily used by grey-sided voles (Oksanen et al. 1987). In other cases, the data do not agree. For instance, Seldal et al. (1994) report increased production of proteinase inhibitors in response to clipping for stiff sedge (*Carex bigelowii*) in Norway, but Lindgren et al. (2007) found no such increase from an extensive clipping experiment in northern Sweden.

Sheep and arvicoline rodents (lemmings and voles) occur together on Norwegian alpine rangelands where both forage mainly on graminoids and forbs (Mysterud and Warren 1991; Mysterud and Mysterud 2000; Mysterud and Austrheim 2005; Kausrud et al. 2006; Saetnan et al. 2009). Thus, sheep can potentially impact the quality or quantity of available forage for the rodents. Högstedt and Seldal (1998) suggest that grazing by even low densities of sheep (12/km^2) has detrimental effects on small herbivores because of lower forage quality. Arvicoline rodents do appear sensitive to changing levels of defensive compounds in preferred forage plants. Lemmings prefer plants low in proteinase inhibitors and with a low ratio of proteinase inhibitors to plant proteins (Bråthen et al. 2004), while voles prefer forage with lower phenolic concentrations (Hambäck et al. 2002; Strengbom et al. 2003).

A field study on the effects of current grazing practices on plants and rodents in central Norway reports no increase in either phenolic compounds or proteinase inhibitors in plants (including *C. bigelowii*) subjected to grazing by sheep (Saetnan 2008). This could reflect either insufficient damage to the plants or a lack of a long-term plant response to grazing. Both of the studies cited above report short-term, transient responses (hours to days) to *C. bigelowii* herbivory (Seldal et al. 1994; Lindgren et al. 2007). For increased defensive compounds to inhibit future grazing, higher concentrations must be maintained over a longer period, and maintenance of higher levels may require repeated damage (Gustafson and Ryan 1976), e.g., every 1–3 days if only transient responses occur.

This study tested the hypothesis that damage to forage plants used by sheep and rodents in Norwegian alpine rangelands can stimulate long-term (at least 2-week) increases in defensive compound levels. Plants contain a wide variety of defensive compounds that could be induced (Rosenthal and Berenbaum 1991), too many to include in one study. In this study, we concentrated on phenolic compounds and proteinase inhibitors, two kinds of compounds induced by herbivory in many plants. The test involved clipping experiments that manipulated the amount and repetition of damage to eight species of common plants used by herbivores in central Norway. We expected increased concentrations of phenolic compounds and proteinase inhibitors or changes in the ratios of these compounds to soluble plant proteins in response to high or sustained levels of damage.

Methods and Materials

Choice of Plants

Although sheep eat mainly graminoids and forbs, they also forage regularly on young shrubs, such as bilberry and willow (Mysterud and Warren 1991; Mysterud and Mysterud 2000; Mysterud and Austrheim 2005; Kausrud et al. 2006). The only detailed study of the diet of sheep in alpine rangelands provides a representative diet for similar habitats across southern and central Norway (Mysterud and Austrheim 2005) and forms the basis for the choice of plants used in this study. The dominant graminoids in alpine rangeland sheep diets include wavy hair grass (*Deschampsia flexuosa*), stiff sedge (*C. bigelowii*), and sweet vernal grass (*Anthoxanthum odoratum*). In addition, tufted hair grass (*Deschampsia cespitosa*), which dominates the meadow habitats of central Norway, provides a sizeable proportion of the diet. The most common species of forbs in sheep diets are common sorrel (*Rumex acetosa*) and wood cranesbill (*Geranium sylvaticum*). Goldenrod (*Solidago virgaurea*), though eaten in small amounts, occurs in a far larger proportion of the diet than its availability suggests. To complete the study, we included bilberry (*V. myrtillus*) as a representative of the dwarf shrubs eaten by sheep. Field voles (*Microtus agrestis*) in central Norway also eat a diverse diet of graminoids, forbs, and shrubs and overlap with sheep in several of their preferred species (Table 1). Norwegian lemmings primarily eat graminoids and mosses,

Table 1 Relative use of selected forage plants as indicated by occurrence in the diet of sheep, lemmings, and voles

Plant species	Sheep[a]	Lemmings[b]	Voles[b]

[b] Data for lemmings and voles from Saetnan et al. (2009)

including significant amounts of stiff sedge and tufted hair grass (Table 1).

Methods of Propagation

Because this experiment was conducted in a greenhouse at the University of Essex, England, we procured plants from commercial nurseries that specialize in wild plants. The only exception, *C. bigelowii*, was collected from the southerly slope of the Carneddau ridge in North Wales, a site identified by Britton et al. (2005). All plants were maintained in a greenhouse for a minimum of 1 month before the start of clipping trials, generally grew to triple their original height, and were flowering at the time of clipping. No signs of nutrient deficiency, such as slow growth or discoloration of tissue, occurred.

Upon accession, we transplanted all plants into plastic pots appropriate for their size, 0.5-L pots for *Carex*; 2-L pots for the three grasses, *R. acetosa* and *S. virgaurea*, and 5-L pots for *V. myrtillus* and *G. sylvaticum*. All pots contained Vapogro™ peat-based potting compost (Avoncrop, UK) and were kept well-watered throughout the study. No further nutrients were added. We maintained plants at 10–15°C with 20 h of daylight, cycling between warmer daytime and cooler nighttime temperatures, which simulated summer conditions in the alpine regions of central Norway.

Experimental Regime

Previous investigations of grazing pressure in alpine habitats of southern Norway showed that low densities of sheep (25/km^2) damaged 3–9% of forage plants, except for goldenrod, which had 25–43% of plants damaged. High densities of sheep (80/km^2) damaged 10–23% of plants overall, but 74% of goldenrods (Mysterud and Austrheim 2005). A previous clipping study of stiff sedge removed 10–15% of leaf tissue to simulate low-intensity herbivory and 60–70% to simulate high intensity of herbivory (Lindgren et al. 2007). Seldal et al. (1994) used a single clipping of stiff sedge with removal of 50% of leaves. To examine the potential impact of different levels of grazing on defense compounds, we compared four levels of clipping: control (0% removed), low (10–15% of all shoots removed), high (70–75% of all shoots removed), and a sustained high treatment (15% of all shoots removed every other day up to a total removal of 75%, i.e., five clippings over 9 days). Clipping consisted of trimming terminal portions of all shoots the required amount with a clean scissors, including leaves, stems, and flowers (if any). In all cases, samples (similar amounts of old and regrown leaves) were harvested from each of the six replicates for each treatment and species combination (a total of $6 \times 4 \times 8 = 192$ samples for each chemical test) 2 weeks after the final experimental clipping.

Chemical Analysis

All samples were frozen in liquid nitrogen immediately upon collection and ground to a fine powder using a mortar and pestle. Samples for total phenolic (TP) analysis were extracted in 80% aqueous methanol for 24 h, centrifuged, and the supernatant analyzed by using the Folin–Ciocalteau assay with a gallic acid standard (Singleton et al. 1999). To analyze for proteinase inhibitors (PI), a 10-mg sample was extracted in extraction buffer (1 mL, 40 mM Tris–HCL buffer, pH 8.1, with 2% *w*/*v* Triton X-100). Extracts were measured for PI activity by using a standard assay with trypsin (Bergmeyer and Gawehn 1974), so we may have only assayed trypsin inhibitors. Because previous work indicated lemmings may respond to the ratio of PI to soluble plant proteins (SPP), not simply PI (Seldal et al. 1994), we also assayed SPP, which we quantified by using a protein dye-binding method (Bradford 1976) with bovine serum albumin (Sigma) as the standard. We then calculated the ratio of PI to SPP for each sample and the ratio of TP to SPP. Because phenolic compounds often bind to proteins (Harborne 1991), we also calculated the ratio of TP to SPP.

Statistical Analysis

To test overall significance of treatments, results for all chemicals were analyzed together by using a two-way multivariate analysis of variance (MANOVA) with species and treatment as fixed factors. Roy's largest root was used for tests of overall significance because it provided the greatest power and the most robust test statistic for further post hoc tests (Scheiner 2001). After establishing overall significant patterns in the results, we analyzed differences among treatments, within species, by using a separate one-way MANOVA for each species with treatment as a fixed factor. We then tested mean values of specific chemicals for significant differences between treatments and between species with Tukey's post hoc tests. All statistical analyses were done with SPSS 14.0 (2005).

Results

The overall two-way MANOVA indicated that treatment effects ($F_{3,151}=12.1$, $P<0.001$), species effects ($F_{7,151}=1097.6$, $P<0.001$), and their interactions ($F_{21,151}=9.6$, $P<0.001$) were all significant for all chemicals with two exceptions. Neither the treatment effect for TP ($F_{3,151}=1.0$, $P=0.382$) nor the treatment effect for TP/SPP ($F_{3,151}=1.9$, $P=0.131$) were significant, although the species by treatment interactions were (TP: $F_{21,151}=8.3$, $P<0.001$; TP/SPP: $F_{21,151}=4.4$, $P<0.001$). Contrary to expectations, the control and low-intensity clipping treatments had higher

levels of proteinase inhibitors ($F_{3,151}$=15.8, P<0.001), but the species by treatment interaction ($F_{21,151}$=8.4, P<0.001) indicated that chemical responses to treatments differed among the plant species. The significant treatment effects for SPP and TI/SPP (SPP: $F_{3,151}$=7.5, P<0.001; TI/SPP: $F_{3,151}$=5.5, P=0.001) also differed from expectations being higher in the control and low-intensity clipping treatments, and again, the species by treatment interactions (SPP: $F_{21,151}$=2.7, P<0.001; TI/SPP: $F_{21,151}$=5.5, P=0.001) indicated different responses among species.

Within species, PI showed significant treatment effects only in *Solidago* and *Carex*, and these were not in the directions expected (Table 2). Compared to controls, PI increased in *Solidago* only at low clipping intensity and actually decreased in *Carex* at high and sustained levels of clipping.

Two species also showed a significant response to treatment in the concentration of SPP, although the overall treatment effect was also significant (Table 2). *D. flexuosa* had a lower SPP concentration in the sustained treatment than in the control, whereas *Rumex* had a higher SPP concentration in the high clipping treatment, but not in other treatments. *Vaccinium* had lower SPP at sustained clipping compared to high clipping, but neither treatment differed from the control.

The overall pattern for the ratio of PI to SPP was similar to that for PI, but in this case, five species showed a significant response to the treatments (Table 2). Compared to the controls, only *D. cespitosa* responded in the expected direction with an increased ratio, but only at high clipping intensity. *Solidago* and *Vaccinium* exhibited a higher ratio at low clipping intensity only, *Rumex* had a significantly lower ratio at high clipping intensity only (although low and sustained clipping produced the same trend), and *Carex* showed a lower ratio at high intensity and sustained clipping.

The significant species by treatment interaction for TP occurred because five species showed a variety of treatment effects (Table 2). Compared to the controls, two species could be regarded as responding in the expected direction, although the patterns were not consistent with one another. *Anthoxanthum* showed an increased TP at low and high intensities of clipping only, and *Geranium* had increased phenolics with sustained clipping only. Two species responded in the opposite direction. The TP content of *Rumex* decreased significantly at all levels of clipping, whereas that of *Vaccinium* decreased only with sustained clipping. The fifth species, *Carex*, had higher TP at high clipping than at sustained clipping, but neither differed from the control.

Similarly, the significant species by treatment interaction for TP/SPP occurred because three species showed varied treatment effects (Table 2). *Carex* had higher TP/SPP at high compared to sustained clipping, and *Rumex* had lower TP/SPP at all levels of clipping compared to the control, both mirroring the patterns for TP. *D. flexuosa* had higher TP/SPP with sustained clipping because of lower SPP with this treatment.

Discussion

As expected, the different species of plants responded differently to simulated herbivory. In general, the forage plants used in our experiment showed little propensity for increased concentrations of defensive compounds or their ratio to SPP in response to damage. Out of 32 cases (2 defensive chemicals×2 ratios to SPP×8 species), four responses to treatments showed increased concentrations at high or sustained damage compared to controls (PI/SPP ratio for *D. cespitosa*, TP for *Anthoxanthum* and *Geranium*, and TP/SPP for *D. flexuosa*), six were in the opposite direction (PI for *Carex*, PI/SPP for *Rumex* and *Carex*, TP for *Rumex* and *Vaccinium*, and TP/SPP for *Rumex*), and the rest showed increased concentrations only at low clipping (three cases) or no significant difference from the controls (19 cases).

Other studies, such as for *Solidago missouriensis* (Brown and Weis 1995) and *Brassica napus* (Cipollini and Bergelson 2000), have shown induced responses of dicotyledons after little damage, but no response after serious damage. A lack of response to severe damage in such cases might reflect resource limitation or lack of tissue for provision of the necessary jasmonic acid signal (Cipollini and Sipe 2001). The response of PI and PI/SPP in *Solidago* to low clipping only in our study could be a similar phenomenon, but that still leaves a preponderance of cases with no response or a response opposite to that expected for our treatments.

Differences in resource availability in the laboratory and the field could also explain the previous contradictory results for PI in *Carex*, a transient increase reported by Seldal et al. (1994), but no response reported by Lindgren et al. (2007). However, our longer-term results (decreased PI only at high and sustained damage) differed from both these studies. Curiously, concentrations of PI in our *Carex* controls were four times those reported in the field by Bråthen et al. (2004) and Lindgren et al. (2007). This may represent differences between laboratory and field conditions or differences in developmental stages that are known to affect allocations to these defensive chemicals (Bråthen et al. 2004).

Total phenolics responded more as expected, with two species (a grass and a forb) showing increased TP in response to simulated herbivory. At least one other grass, western wheatgrass (*Pascopyrum smithii*), has shown an

N=6 for all means. Different letters indicate significant differences between treatments for that species (P<0.05)

induced response in TP, in this case in response to heavy defoliation by grasshoppers (Redak and Capinera 1994). Still, most of our species did not exhibit the expected result. The reduction in TP in *Vaccinium* in response to sustained clipping has also been reported previously for *Vaccinium* on islands in northern Norway where repeated damage from voles led to reduced levels of TP (Oksanen et al. 1987).

Some of the results from our study could reflect the use of artificial clipping. Mechanical wounding may not stimulate the plant in the same way as natural herbivory (Baldwin 1990). Several studies have found plants to respond differently to mechanical wounding either in amount of response (Haukioja and Neuvonen 1985; Faeth 1986; Baldwin 1988) or in kind of response (Hartley and Lawton 1987; Neuvonen et al. 1987; Pontoppidan et al. 2005) compared to natural herbivory. Some plants may respond not only to the loss in leaf tissue, but also to some component of the herbivore saliva (Coleman et al. 2007) or pathogen invasion (Kavitha and Umesha 2008) at the site of wounding that is not replicated in simulated herbivory trials. However, the use of mechanical wounding does replicate results from natural herbivory in some systems. The response of *Vaccinium* in our study clearly conformed to the pattern seen in natural systems, and others have found simulated herbivory to provide a good indication of the effects of natural herbivory (Green and Ryan 1972; Karban 1986; Neuvonen et al. 1987). The applicability of simulated herbivory for predicting responses to natural herbivory likely depends on the species in question and the type of herbivory being investigated. Because it is easier to control, simulated herbivory, thus, provides a good starting point for further investigations in the field.

Variation among species in this study was larger than that seen for any treatment effects within a species. The level of secondary metabolites was relatively high for several of the species, all of which were preferred forage species for both sheep and voles. For instance, the level of PI in all species except *D. flexuosa* was higher than that avoided by lemmings in Canada (Bråthen et al. 2004). The levels of TP in both *Geranium* and *Vaccinium* were relatively high, yet voles (Saetnan et al. 2009) and sheep (Mysterud and Austrheim 2005) readily consumed both species. If palatable plants naturally have such high levels of secondary metabolites, it is unlikely that smaller effects in response to damage by herbivores would have a significant effect on diet choice.

Of course, we only examined two types of defensive compounds, and other chemicals could be important as induced defenses against mammalian herbivory. Recent studies on grasses have shown that increased accumulation of silica in response to grazing can affect the growth and reproduction of voles, which could influence their population dynamics (Massey and Hartley 2006; Massey et al. 2007). This possibility deserves further investigation, but our results do not support the hypothesis that herbivory induces a long-term increase of defensive compounds in important forage plants on alpine rangelands of Norway, a result consistent with those from field studies.

Acknowledgments Financial support for this project was provided by the Program for Ecology and Evolutionary Biology at the University of Illinois at Urbana–Champaign. All chemical analyses were completed at the University of Essex with the help of Richard Webster.

RAPID COMMUNICATION

Changes in Nutritional Value of Cyanogenic *Trifolium repens* Grown at Elevated Atmospheric CO_2

Roslyn M. Gleadow · Everard J. Edwards · John R. Evans

Received: 22 February 2009 / Revised: 20 March 2009 / Accepted: 20 March 2009 / Published online: 8 April 2009

Abstract Global food security in a changing climate depends on both the nutritive value of staple crops as well as their yields. Here, we examined the direct effect of atmospheric carbon dioxide on the toxicity of the important pasture crop, *Trifolium repens* L. (clover). Shoots of *T. repens* contain cyanogenic glycosides that break down to release toxic hydrogen cyanide when damaged. The ability of animals to tolerate cyanogenic compounds is dependent, in part, on their overall protein intake. We grew *T. repens* communities at ambient and approximately twice-ambient CO_2 in a controlled environment greenhouse experiment. We found that the ratio of total cyanogenic glycosides to total protein ratio was nearly two times higher in leaves of *T. repens* grown at elevated CO_2. This study highlights the importance of assessing the nutritive value of this and other plants in response to rising CO_2 so that steps can be taken to address any adverse consequences for herbivores.

Introduction

Two major problems facing the world today are climate change and population growth. Despite the large body of research on the effect of elevated CO_2 on primary productivity, few studies consider the overall nutritional value of plants. Typically, leaf nitrogen and protein concentrations are 10–20% lower in plants grown at twice-ambient CO_2 (Ainsworth and Long 2005; Taub et al. 2008). In addition, concentrations of carbon-based defense compounds such as phenolics are often higher (Lincoln et al. 1993), again decreasing the nutritive value.

Less is known about the effect of elevated CO_2 on cyanogenic glycosides. Cyanogenic glycosides are constitutive defense compounds found in about 5% of all plants (Jones 1998; Gleadow and Woodrow 2002). When plant tissue containing cyanogenic glycosides is crushed or chewed, the glycosides are mixed with endogenous β-glucosidases, and toxic hydrogen cyanide (HCN) is released. Given the high proportion of crop plants that are cyanogenic (c. 60%, Jones 1998), it is vital to know whether or not such plants will become more cyanogenic in the future and to compare that with predicted decreases in leaf protein levels.

Trifolium repens (white clover) is an important component of pastures in many parts of the world. It contains two cyanogenic glycosides, mostly linamarin (α-hydroxyisobutyronitrile-β-D-glucopyranoside) and a smaller proportion of lotaustralin (2-hydroxy-2-methylbutyronitrile-beta-D-glucopyranoside). To our knowledge, only one elevated CO_2 study of *T. repens* has included an analysis of the

endogenous cyanogenic glycosides (Frehner et al. 1997). Those results were inconclusive, as there was a lot of seasonal variation, and the workers did not measure leaf nitrogen. Gleadow et al. (1998), in a study of cyanogenic *Eucalyptus cladocalyx*, found that cyanogenic glycoside concentration per mass did not increase in leaves of seedlings grown at elevated CO_2, but there was a 40% decrease in leaf protein, increasing the overall leaf toxicity. The aim of this study, therefore, was to quantify the protein and cyanogenic glycoside concentrations in *T. repens* grown under ambient and twice-ambient CO_2 in order to predict the ability of pastures to support grazing animals in the future.

Methods and Materials

This experiment was part of a larger study described in detail by Edwards et al. (2006). Briefly, *Trifolium repens* cv. Haifa L. was grown in 36 plastic containers (525×370×450 mm) filled with steam-treated sand in temperature-controlled, naturally lit greenhouses (25°C/20°C; day/night) for 15 months. Each container was inoculated with *Rhizobium leguminosarum* bv. Trifolii strain ANU843. Greenhouses were supplied with air containing ambient (360 ppm) or twice-ambient (700 ppm) CO_2. Pots were watered daily and fertilized three times per week with 500 ml Rorison's solution, with the N components adjusted to contain low or high NO_3 (0 or 4 mM nitrate) (N=6). Cyanogenic glycosides were measured as evolved HCN on subsamples of freeze-dried leaf material, expressed as mg CN g^{-1}_{DW} (Woodrow et al. 2002). Remaining leaves were oven dried and then analyzed for total leaf nitrogen by using an EA 1110 CHN-O Carlo-Erba Elemental Analyzer (Carbo-Erba instruments, Milan, Italy) and total protein with the Lowry method. Data were analyzed with Minitab15.

Results and Discussion

This is the first study on the impact of elevated CO_2 on nutritional quality in cyanogenic pasture plants. We found that leaf nitrogen was c. 20% lower in foliage of *T. repens* grown at elevated CO_2 (P<0.05; Fig. 1a), and protein concentration was c. 25% lower (P<0.01; Fig. 1b). These findings are consistent with other studies of many other C3 plants, and usually those reflect some degree of down-regulation in photosynthesis (Ainsworth and Long 2005). Such acclimation is usually more pronounced when growth rates are limited by nitrogen supply (Gleadow et al. 1998; Ainsworth and Long 2005). In our study, there was no significant difference in the response to elevated CO_2 between the two N treatments, probably because *T. repens*

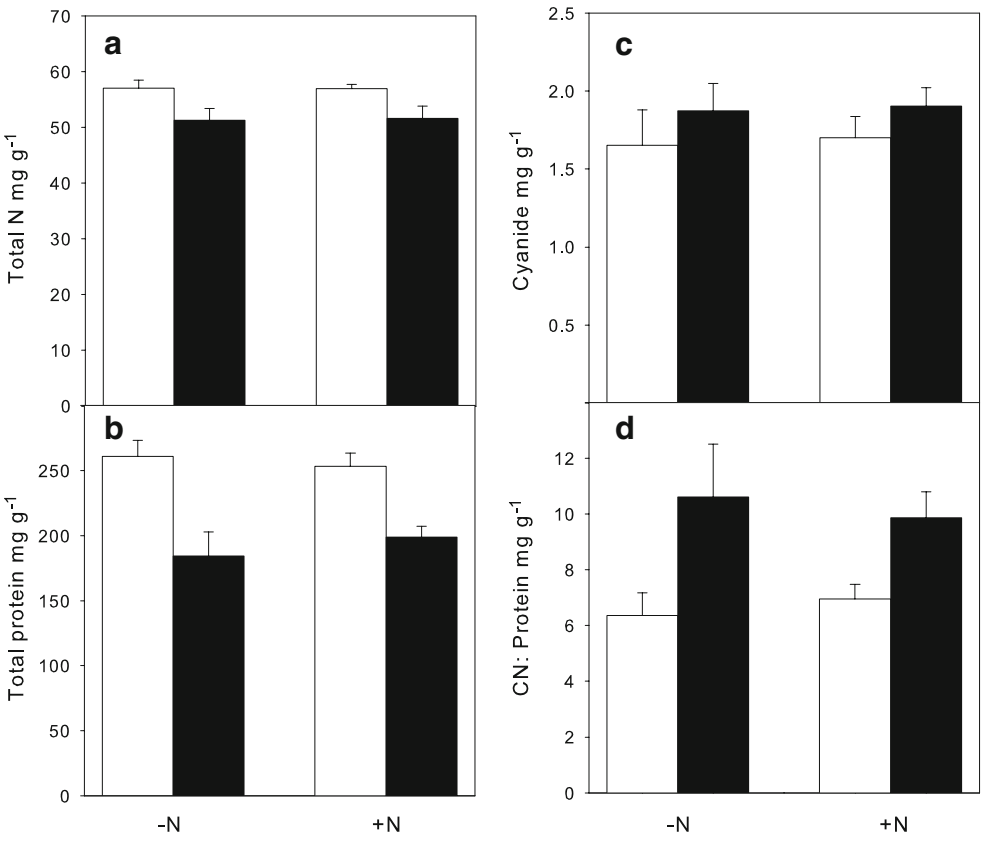

Fig. 1 Chemical composition of *Trifolium repens* grown at ambient (*open*) and elevated CO_2 (*closed*) and supplied with nutrient solutions containing nitrate (+N) or without nitrate (-N). **a** Total leaf nitrogen; **b** total protein; **c** cyanogenic glycosides (measured as evolved cyanide); **d** ratio of evolved cyanide to total leaf protein. All data are expressed on a dry weight basis

supplements its N requirements by fixing atmospheric N through symbiotic associations with *Rhizobium* bacterium (Edwards et al. 2006).

There have been, to our knowledge, only three published studies on the effect of atmospheric CO_2 on cyanogenic glycosides. We found here that total cyanogenic glycoside concentration in *T. repens* was not significantly different in plants grown at ambient and twice-ambient CO_2 (Fig. 1c), consistent with these earlier studies (Frehner et al. 1997; Gleadow et al. 1998; Bazin et al. 2002). By contrast, we did not detect a significant impact of the nitrate supply on cyanogenic glycoside concentration as has been observed by others (Gleadow et al. 1998), reflecting the consistent leaf N concentrations across treatments.

Animals have the ability to convert cyanide to the less toxic thiocyanate, but the capacity to do this is dependent on the rate of ingestion and the availability of sulfur-rich proteins (Westley 1988; Gleadow and Woodrow 2002). We calculated the cyanide-to-protein ratio as an index of the nutritional quality of *T. repens* grown at elevated CO_2. The amount of cyanide relative to protein increased by 40% in plants supplied with NO_3 and by 30% in plants not given additional NO_3 (Fig. 1d; $P<0.001$), although the NO_3 effect alone was not statistically significant. Forage with greater than 0.8 mg CN g^{-1}_{DW} generally is considered to be toxic to cattle under field conditions (Westley 1988), about half the value reported here (overall mean=1.7 mg CN g^{-1}_{DW}). Typically, *T. repens* occurs in mixed pastures, and animals would be unlikely to ingest toxic quantities. However, if cyanogenic glycoside concentration increases relative to the protein in the future, then the overall nutritional value of the pasture would be substantially less.

Protein content of food crops such as wheat and rice are predicted to contain to 15–20% less protein by the end of this century (Taub et al. 2008). Lower protein content of leaves of pasture plants is also of concern as this would mean that grazing animals would need to increase their consumption in order to maintain their current protein intake. Insect studies have shown that animals compensate for the lower protein content of plants grown at elevated CO_2 by eating more (Lincoln et al. 1993). If this is also true of grazing mammals, then they would ingest more cyanogenic glycosides along with the rest of the plants in mixed pastures. Other species in the pasture are likely to have higher concentrations of antifeedants such as phenolics as well, which are known to interfere with protein uptake (Lincoln et al. 1993; Taub et al. 2008). If these results hold true for other cultivars, it is possible that pastures rich in *T. repens* could become unsuitable for livestock if atmospheric CO_2 continues to increase. These results demonstrate the importance of testing the effect of climate change on the nutritive value of crop plants as well as yield.

Pretreatment of Clover Seeds with Nod Factors Improves Growth and Nodulation of *Trifolium pratense*

Dominika Maj · Jerzy Wielbo · Monika Marek-Kozaczuk · Stefan Martyniuk · Anna Skorupska

Received: 13 November 2008 / Revised: 26 March 2009 / Accepted: 27 March 2009 / Published online: 16 April 2009

Abstract The increase in legume production in sustainable agriculture depends not only on the effectiveness of the selected nitrogen-fixing inoculants but also on their competitiveness in a soil environment containing an indigenous rhizobial population. In this study, we investigated the effect of pretreatment of red clover seeds with specific Nod factor (LCOs) on germination, growth, and nodulation of clover growing under sterile conditions and in the soil. We demonstrated that, although the symbiotic ability and competitiveness of the inoculant strain RtKO17 was not improved under competitive soil conditions, LCOs treatment of clover seeds significantly enhanced clover nodulation and growth of plants.

Keywords Competitiveness · Nod factor · Symbiosis · *Rhizobium leguminosarum* bv. *trifolii*

Introduction

Rhizobia are gram-negative soil bacteria able to establish symbiosis with leguminous plants and reduce atmospheric nitrogen to ammonia that in turn is used by plants. Nodule formation is a highly specialized process that requires "cross talk" between the bacteria and the host plant. The first step of the interaction includes release of the host plant signal molecules, usually specific flavonoids, and the synthesis of bacterial signal molecules, lipochitooligosaccharides (LCOs), called Nod factors (for review, see Spaink 2000; D'Haeze and Holsters 2002). The Nod factors consist of a chitooligosaccharide backbone of three to five β-1,4-linked *N*-acetyl-D-glucosamine residues, substituted by a fatty acyl chain of varying lengths and with varying degrees of unsaturation, attached at the nonreducing end. Other diverse substitutions controlled by specific *nod* genes and present on both ends of the oligochitin chain make the Nod factors specific for plant hosts (Denarie and Cullimore 1993; Spaink et al. 1994). The biosynthesis of Nod factors is controlled by *nod* genes transcriptionally induced by a flavonoid-activated NodD protein. Recognition by the NodD protein of the particular flavonoids determines the first level of specificity in the symbiosis. Nod factors are secreted and elicit multiple responses in the root epidermis, cortex, and pericycle that lead to the nodulation of the appropriate host plants (Heidstra and Bisseling 1996). One of the earliest plant responses to Nod factors is an increase in the intracellular calcium level in root hairs, followed by calcium oscillations and alteration of the root hair cytoskeleton (for review, see Heidstra and Bisseling 1996; Gage 2004; Jones et al. 2007). These responses are followed by curling of root hairs to trap rhizobia and stimulation of root cortex cells to reinitiate mitosis. The rhizobia invade the roots through tubular structures called infection threads, which penetrate the root cortex and stimulate the nodule primordium formation. The nodule primordium develops into a nodule, while the bacteria differentiate into their endosymbiotic form, the bacteroids, that are able to fix nitrogen into ammonia, which are subsequently utilized by the plant.

Structurally appropriate Nod factors, apart from exopolysaccharide production, are required for an ongoing infection thread formation and elongation, as well as other plant responses in the indeterminate nodule-forming plants (Jones et al. 2007). Application of purified Nod factors to legume roots at nanomolar concentrations can elicit root hair deformation, cortical cell divisions, and in some cases, the formation of nodule-like outgrowth (Heidstra and Bisseling 1996).

The Nod factors of *Rhizobium leguminosarum* bvs. *trifolii* and *viciae* consist of three to five residues of a *N*-acetyl-D-glucosamine backbone to which a fatty acid chain is attached at the nonreducing end and various substituents that occur on the chitin-like backbone (Spaink et al. 1991). *R. leguminosarum* bv. *trifolii* produces a subset of Nod factors that bear a complex mixture of highly unsaturated fatty acyl chains, including $C_{18:3}$, $C_{20:3}$, and $C_{20:4}$, determined by the protein products of the region downstream of *nodEF* and *nodRL* (Bloemberg et al. 1995; Schlaman et al. 2006). The overall hydrophobicity of the highly unsaturated or hydroxylated fatty acyl moieties of the Nod factors has been shown to be essential for host-specific biological activity. Nod factors are structurally diverse and a single rhizobial strain may produce a range of metabolites (Spaink et al. 1995). They are recognized by plant receptors (Oldroyd and Downie 2004) and have a mitogenic effect, inducing the cortical cell division potential, thus leading to the formation of nodule primordium (Spaink et al. 1991). Purified LCOs can reinitiate cell division, giving rise to nodule-like structures (Stokkermans et al. 1995). There is also evidence that Nod factor (Nod Bj V C18:1, MeFuc) produced by *Bradyrhizobium japonicum*, as well as a number of synthetic LCOs, improve germination and early growth of soybean and nonlegume plants tested in greenhouse and in short-term field experiments (Prithiviraj et al. 2003).

Attempts to improve nodulation and nitrogen fixation in the soil often fail because of the out competition of inoculant strains by the indigenous rhizobial population that can generally be less efficient in nitrogen fixation but better adapted, with a higher infectivity potential, resulting in higher nodule occupancy (for review, see Triplett and Sadowsky 1992; Streeter 1994; Toro 1996). Thus, rhizobial strains used as inocula must not only be effective in nitrogen fixation but also highly competitive. In our previous work, we selected from among the indigenous soil rhizobial population *R. leguminosarum* bv. *trifolii* strains that were competitive and highly responsive to flavonoid induction (Wielbo et al. 2007, Maj et al. 2008).

The main objective of the current study was to assess whether a pretreatment of clover seeds with specific LCOs improves germination, growth, and nodulation under sterile conditions and whether this treatment affects the symbiotic ability and competitiveness of the inoculant strain under competitive soil conditions. We hypothesized that clover germination and growth improvement by LCO treatment, even under the competitive conditions, could facilitate a subsequent inoculation with the rhizobial strain RtKO17 previously selected as competitive and effective in nodulation and nitrogen fixation. Under these conditions, plant roots exposed to LCOs prior to infection would have been infected more readily by the inoculant strain than by its less robust competitors. To our knowledge, the effect of LCO treatment on clover growth and nodulation has not been studied thus far.

Methods and Materials

Bacterial Strains and Growth Conditions

R. leguminosarum bv. *trifolii* strain KO17 (RtKO17) was isolated from nodules of red clover (*Trifolium pratense* L. cv. Dajana) grown on cultivated soil in the region of Lublin, Poland. In the competition experiment, the derivative of RtKO17 carrying pJBA21Tc with constitutively expressed *gusA* gene was used (Wielbo et al. 2007). Rhizobial strains were maintained and grown on mannitol yeast extract agar 79CA medium (Vincent 1970). *Escherichia coli* strains were grown on Luria–Bertani (LB) medium (Sambrook et al. 1989). When needed, tetracycline was added to 79CA or LB media at the concentration 10 μg/mL.

Preparation of Exudate from Sprouted Seeds

Red clover (*T. pratense* L. cv. Dajana) seeds were surface-sterilized by immersion in 0.1% $HgCl_2$ for 3 min, rinsed with sterile distilled water, then treated with 70% ethanol for 3 min, followed by extensive washing with sterile water. The sterilized seeds were shaken in sterile water, in darkness, for 4 days at 28°C, and during this time, the seeds germinated. After the removal of the sprouted seeds, the supernatant was extracted with ethyl acetate in the ratio 10:1 (*v*/*v*). Ethyl acetate was evaporated, and the pellet was resolubilized in 95% ethanol and stored at 4°C. To determine the amount of the flavonoids, the ethanol extracts were dried and weighed. The approximate flavonoid concentration in seed exudate was calculated relative to the molecular weight of authentic flavone.

LCOs Isolation

Logarithmic cultures of *R. leguminosarum* bv. *trifolii* strain KO17 were induced with sterile clover seed exudate at a final concentration of 2 μM and incubated at 28°C for an additional 48 h. One liter of the activated culture was

extracted twice with 0.2 volume of *n*-butanol (Prithiviraj et al. 2003). The organic fraction was separated and dried under vacuum in a rotary evaporator (Rotavapor–R, Bűchi, Switzerland). The amount of Nod factors was determined by conversion of the amino sugars to methyl glycosides and gas chromatography/mass spectrometry (GC/MS) analysis. To 250 µg sample, 30 µg GalNAc was added as internal standard and hydrolyzed in 1 mL of 2 M trifluoroacetic acid (TFA) at 120°C for 2 h. The TFA was eliminated by washing the samples two times with Millipore water, following which the samples were dried under nitrogen. Free fatty acids were removed from the samples with 0.5 mL 10% (*v*/*v*) ether in hexane. This step was repeated three times. Samples were reduced by solid sodium borohydride ($NaBH_4$) at 0°C in darkness for 12 h. The excess of $NaBH_4$ was removed by sequential distillation with the following solutions: 200 µL 10% (*v*/*v*) acetic acid in water, 200 µL 10% (*v*/*v*) acetic acid in methanol, and 200 µL 1 M HCl in methanol. Samples were redistilled two times with methanol and dried under nitrogen. In the next acetylating step, 25 µL acetic anhydride and 50 µL pyridine were added to the dry sample and incubated at 85°C for 30 min and then dried under nitrogen. The sample was dissolved in a small volume of chloroform and applied to GC/MS (Hewlett-Packard HP 5890A) equipped with an HP.5MS capillary column coupled to a mass selective detector MSD HP 5971. The temperature program was as follows: initially 150°C for 5 min, then raised to 310°C (5°C/min), and the final temperature 310°C for 10 min. LCOs concentration was approximated based on the assumption that a single molecule of a Nod factor contains on average four residues of GlcNAc. The calculated content of GlcNAc in the LCOs preparation was 346 nM.

Root Hair Deformation Assay

To estimate the biological activity of isolated LCOs, a root hair deformation test was performed on red clover (*T. pratense* L. cv. Dajana). Surface-sterilized seeds of clover were germinated on Fåhraeus agar medium (Fåhraeus 1957) in Petri dishes in the dark at 28°C. After 24 h incubation, seedlings were transferred to microscope glass slides (two seedlings per slide) covered with 1 mL 0.4% Fåhraeus agar medium supplemented with serially diluted *R. leguminosarum* bv. *trifolii* LCO at the final concentration from 10^{-8} to 10^{-13} M. The initial content of GlcNAc in the LCOs preparation was 346 nM. Slides were placed in a moist chamber and incubated at 28°C in the dark. After 24 and 48 h, the growth and deformation of individual root hairs was assessed under a light microscope (Olympus BX41). Root hairs of at least ten plants were examined for each LCO dilution.

Radioactive Labeling of LCOs and TLC

To label LCOs in vivo, *R. leguminosarum* bv. *trifolii* strain KO17 was grown in M1 medium containing 18.7 mM NH_4Cl, 11.5 mM K_2HPO_4, 3.7 mM KH_2PO_4, 1.7 mM NaCl, 0.8 mM $MgSO_4 \cdot H_2O$, 0.01 mM $FeCl_3$, 1% glycerol, 1 µg/mL thiamine HCl, 0.5 µg/mL biotin, and 1 µg/mL pantothenate at 28°C to OD_{550} 0.4–0.5. One milliliter cultures were supplemented with clover seed exudate at a final concentration of 2 µM and incubated at 28°C for 2 h; 12.5 µCi [2-C^{14}] sodium acetate (50–60 mCi/mmol; Hartmann Analytic, Braunschweig, Germany) were added and further incubated for 16 h at 28°C. Radioactive LCOs were extracted with *n*-butanol and concentrated by evaporation. Pellets were dissolved in 40 µL *n*-butanol, and volumes of 1 µL were analyzed on reversed-phase C18-coated TLC silica plates (Merck, Darmstadt, Germany) using acetonitrile–water (1:1, *v*/*v*) as the mobile phase (Spaink et al. 1992). TLC plates were dried and exposed to Kodak X-OMAT K film for 45 days at room temperature.

Clover Germination in the Presence of LCOs

Seeds of clover (*T. pratense* L. cv. Dajana) were surface-sterilized and soaked in serially diluted LCO solution (from 10^{-7} to 10^{-13} M) for 30 min. Seeds were transferred to Petri dishes with Fåhraeus agar medium (50 seeds per dish) and placed in darkness at 28°C. Each treatment was conducted in three replicates. Germination was observed after 24 and 48 h, and the root length and the percentage of germinated clover seedlings were estimated.

Clover Growth Assays in the Presence of LCOs

Sterile seeds of clover were soaked in serially diluted LCOs as described above and transferred to plastic pots with sterile sand (600 g of sand per pot, ten seeds per pot). Pots were irrigated once with 50 mL Fåhraeus medium supplemented with 5 mM KNO_3 and then watered every 2 days. The growth chamber was set at a 16/8-h light/dark (L/D) regime and at 22°C/15°C day/night temperature. After 6 weeks of growth, clover plants were harvested and fresh and dry mass of shoots were estimated. Each treatment was carried out in ten replicates, and the experiment was repeated twice with similar results.

Effect of LCOs on *T. pratense–R. leguminosarum* bv. *trifolii* Symbiosis: The Greenhouse Experiment

Four different treatments of sterilized seeds of clover (*T. pratense* L. cv. Dajana) were prepared: (1) seeds soaked in water for 30 min; (2) seeds soaked in LCO solution (~10^{-10} M) for 30 min; (3) seeds soaked in water

and inoculated with 10 mL suspension of RtKO17 (~7×10^7 CFU/mL); (4) seeds soaked in LCO solution and inoculated with 10 mL suspension of RtKO17. Seeds were sown in plastic pots with sterile sand (600 g of sand per pot, ten seeds per pot). Pots were watered every 2 days. The growth chamber was set at a 16/8-h L/D regime and at 22°C/15°C day/night temperature. After 6 weeks, the plants were harvested, and the fresh and dry mass was estimated. Each treatment was carried out in five replicates, and the experiment was repeated twice with similar results.

Outdoor Experiment

The experiment was conducted at the Institute of Soil Science and Plant Cultivation, Puławy, Poland. Plants were cultivated in Mitcherlich pots filled with 7 kg of loamy sand (mixture of sand and loamy soil in the ratio 2:1). Pots were kept under a rainout shelter for 6 weeks in May and June 2008. The soil was maintained at about 60% water-holding capacity. In this experiment, the strain RtKO17 (pJBA21Tc) tagged with *gusA* marker was used to study its competitiveness in relation to indigenous rhizobia.

Four different treatments of nonsterilized seeds of clover (*T. pratense* L. cv. Dajana) were conducted: (1) seeds soaked in water for 30 min and sown in pots (20 seeds of clover per pot) to test clover infection by autochthonous rhizobia; (2) seeds soaked in LCO solution (~10^{-10} M) to test clover infection by autochthones in the presence of LCO; (3) seeds inoculated with 10 mL suspension of RtKO17(pJBA21Tc) (~7×10^7 CFU/mL) to test the competitiveness of the inoculant; (4) seeds soaked in LCO solution (10^{-10} M) and inoculated with 10 mL RtKO17 (pJBA21Tc) (~7×10^7 CFU/mL) to test for the effect of LCOs on inoculant competitiveness. Each treatment had seven replicates. After 2 weeks, clover from one pot per treatment was inspected for number of nodules, and the roots were stained for GUS^+ activity (in groups 3 and 4). Overall, 24 pots were examined, with 20 clovers per pot. After 6 weeks of growth, plants were removed, and the roots were gently washed in tap water, the shoots and roots were separated, and their fresh and dry mass was estimated. Samples of roots were stained for β-glucuronidase (GUS) activity in 50 mmol/L^{-1} sodium phosphate buffer (pH 7.2) with 50 μg/mL 5-bromo-4-chloro-3-indolyl-β-D-glucuronide (X-Glc), 0.1 mmol/L ethylenediaminetetraacetic acid, 0.38 mmol/L $K_3Fe(CN)_6$, and 0.38 mmol/L $K_4Fe(CN)_6$ for approximately 12 h at room temperature (Wilson et al. 1995). The competitive potential of strain RtKO17(pJBA21Tc) was determined by calculating the number of blue nodules (colonized by the *gusA*-tagged strain) and the number of white nodules (elicited by indigenous rhizobia).

Statistical Analysis

Statistical analysis was carried out by the analysis of variance and Tukey test using the STATISTICA software (Stat Soft, Tulsa, OK, USA).

Results

Biological Activity of LCOs Produced by Strain RtKO17

In this study, we used the *R. leguminosarum* bv. *trifolii* strain KO17 (RtKO17) which was previously selected as effective in plant growth promotion and a competitive field isolate (Wielbo et al. 2007; Maj et al. 2008). To isolate Nod factors (LCOs), strain RtKO17 growing in M1 medium supplemented with radioactive C^{14}-acetate was induced with red clover seed exudate instead of synthetic flavonoids in order to obtain less artificial conditions. LCOs were isolated as *n*-butanol extracts, and the samples were run on TLC plates for estimation of LCOs quality. Under the described conditions, after the induction of RtKO17 for 48 h, at least five spots were visible in comparison to the noninduced control (Fig. 1), signifying that different types of LCOs were produced. Comparison of LCOs production profile of flavonoid-induced RtKO17 with the previously published *R. leguminosarum* LCOs profiles (Tak et al. 2004) indicates that the spots could represent several forms of LCOs, likely consisting of four to five glucosamine

Fig. 1 Autoradiogram of thin-layer chromatography separation of LCOs from *R. leguminosarum* strain KO17 labeled with [2-C^{14}] sodium acetate. Cells were grown without inducer (*1*) or in the presence of 2 μM of flavonoid inducer for 48 h at 28°C (*2*)

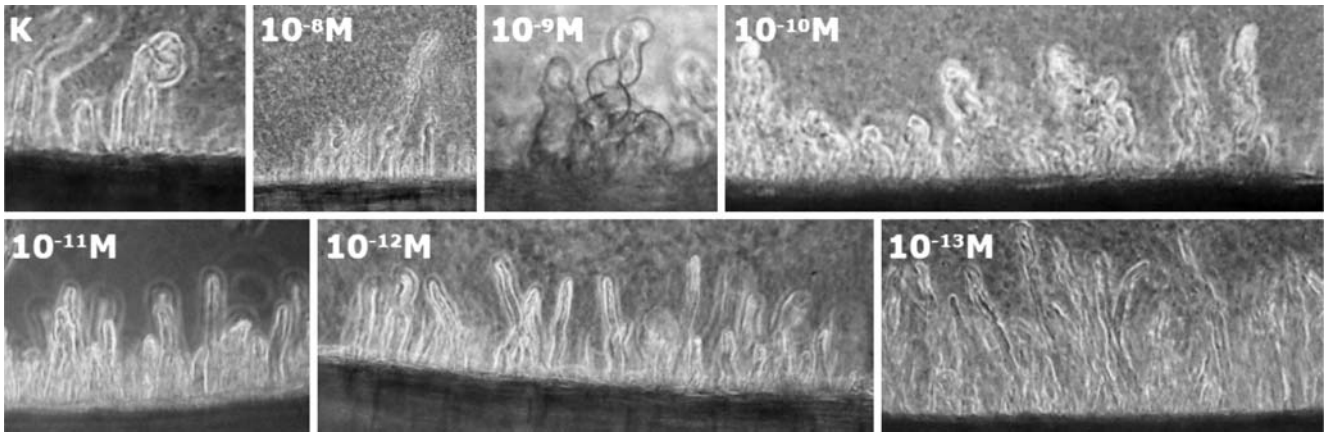

Fig. 2 Root hair deformation induced by appropriate concentration of LCOs isolated from *R. leguminosarum* strain KO17. Control showing typical root hair deformation after addition of strain RtKO17

residues bearing a complex mixture of highly unsaturated fatty acyl chains. For plant test assays, nonlabeled LCOs were isolated from a large volume of a culture growing under comparable conditions. The approximate amount of LCOs was estimated by GC chromatography, and its biological activity was examined in a root hair deformation assay (Heidstra et al. 1994). Crude *n*-butanol extract of RtKO17 flavonoid-induced culture was serially diluted, and clover root hair deformation was examined by microscopic observations as described in the "Methods and Materials" section. Root hair curling could be observed over a range of LCOs concentration (Fig. 2), but the most pronounced deformation occurred within the range 10^{-9} to 10^{-10} M.

Using LCOs isolated from RtKO17, we examined the effect of different concentrations of Nod factor on the germination of clover on Fåhraeus agar plates (Table 1). After seed treatments for 24 and 48 h, the germination and root lengths increased significantly when compared to the untreated control. The strongest and statistically significant effect both on germination and root length of clover was observed with the range 10^{-10} to 10^{-12} M LCOs after 2 days incubation.

Next, we examined the effect of LCOs treatment on the germination and growth of surface-sterilized clover seeds grown for 6 weeks in sterile sand under laboratory conditions. A statistically significant stimulation of shoot growth was found with 10^{-9} to 10^{-11} M LCOs and of roots with 10^{-9} to 10^{-12} M LCOs, whereas the differences in seed germination were not statistically significant (Table 2).

The experiments described above allowed us to determine the concentration of LCOs produced by strain RtKO17 that substantially stimulated the germination and growth of clover seedlings under sterile laboratory conditions during long-time cultivation. The most active concentration of crude extract of LCOs produced by strain RtKO17 was estimated at approximately 10^{-10} M.

Effect of LCOs on Growth and Nodulation of Clover Grown in Sterile Sand Inoculated with Strain RtKO17: The Greenhouse Experiment

We examined the growth and nodulation of clover seeds treated with LCOs (~10^{-10} M) grown in sterile sand and inoculated with the strain RtKO17 in comparison to uninoculated control plants (Table 3). In the case of LCO-treated seeds that were not inoculated with rhizobia (groups 1 and 2), a moderate stimulation of shoot growth was observed. Under these conditions, LCO treatment stimulated the growth of clover, however, the fresh and dry shoot mass was not statistically different when compared with seeds soaked in water and inoculated with the same strain (treatment groups 3 and 4). The number of nodules was also not significantly different in relation to control plants (Table 3).

Table 1 Effect of *R. leguminosarum* bv. *trifolii* KO17 Nod factor (LCOs) on the germination of clover seeds (*T. pratense*)

Effect of LCOs on Growth and Nodulation of Clover Inoculated with RtKO17-*gusA* Strain and Grown Under Competitive Conditions: The Outdoor Experiment

Finally, we studied the effect of LCO on the growth and nodulation of clover in soil. The clover seeds were soaked in LCOs of the same concentration as in the previous experiment (Table 3) and inoculated with strain RtKO17(pJBA21Tc). This strain was tagged with *gusA* to study its competitiveness in relation to an indigenous population of rhizobia (Table 4). The growth of LCO-treated clover infected by indigenous rhizobia was substantially improved, and the differences in fresh mass of shoots and roots were statistically significant (groups 1 and 2). Also, a 54% increase in total nodule number in relation to untreated seeds was observed. It is worth noting that the growth of clover roots in the presence of LCOs was more robust (1.64-fold) than shoots (1.37-fold) in relation to the untreated control plants.

Growth of LCO-treated clover seeds additionally inoculated with the selected inoculant strain RtKO17-*gusA* was comparable to the untreated control (groups 3 and 4) (Table 4). However, similarly to plants in groups 1 and 2, there was a significant increase in nodule number, about 60%. Generally, a broad variability in nodule number per plant was observed in groups of clover treated with LCOs, independent of the presence of the RtKO17 inoculant (groups 2 and 4), indicating different response of individual plants to LCOs treatment.

To study the effect of LCOs treatment on the competitiveness of RtKO17-*gusA*, we examined nodule occupancy by histochemical staining of whole root systems of clovers 2 and 6 weeks post inoculation (Table 5). After 2 weeks, we found 54% blue nodules in clover untreated with LCOs and 49% Gus^+ nodules formed by plants treated with LCOs. After 6 weeks of cultivation, the proportion of Gus^+ nodules decreased significantly, and strain RtKO17-*gusA* occupied only 14% of nodules in LCO-untreated plants and about 18% of nodules in LCO-treated seeds. These results indicate poor ability of the inoculant strain to compete with autochthonous rhizobial population during prolonged cultivation, unaffected by LCO treatment.

Taken together, the results of the experiment carried out in nonsterile soil revealed the potential of enhancing clover growth and nodulation by LCOs seeds treatment. However, the competitiveness of the selected strain RtKO17-*gusA* in relation to indigenous rhizobia was not enhanced even in seeds stimulated by LCOs.

Discussion

In this study, we describe the promotion of plant growth and nodulation due to treatment of clover seeds with specific Nod factors. In all plant tests, we used LCOs extracted from a culture of strain RtKO17 that had been previously selected as competitive and highly responsive to flavonoid induction as judged by the activation of *nod* genes (Wielbo et al. 2007; Maj et al. 2008). Based on the estimation of LCO biological activity conducted via root hair curling assay, we used a crude preparation of the Nod factor at approximately 10^{-10} M concentration as the most effective. Our study shows that soaking of clover seeds with LCOs RtKO17 causes a statistically significant enhancement of germination and growth of seedlings

Table 3 Effect of LCOs on the growth and nodulation of clover (*T. pratense*) grown in sterile sand and inoculated by RtKO17pJBA21Tc (greenhouse experiment)

Group	Treatment	Fresh mass of shoots (mg)	Fresh mass of roots (mg)	Dry mass of shoots (mg)	Number of nodules/plant

cultivated for 6 weeks in sand under sterile uncompetitive conditions. These results are in agreement with observations reported by Prithiviraj et al. (2003) who showed that LCO Bj V(C18:1,MeFuc) treatment of soybean seeds and nonleguminous plants from diverse botanical families grown for a short time (10 days) under sterile conditions, and also in soil, significantly promoted germination of the seeds and, subsequently, seedlings growth.

The observed increase in the germination of seeds and the growth of clover seedlings after LCOs application could be attributed to an enhanced cell cycle rate described in legumes and nonleguminous plants by several authors (de Jong et al. 1993; Stokkermans et al. 1995; Dyachok et al. 2000). Rhizobial LCOs influenced somatic embryogenesis in Norway spruce (*Picea abies*) and stimulated cell division in Norway spruce protoplasts in the absence of auxin and cytokinin (Dyachok et al. 2000). Nod factors were also shown to stimulate somatic embryogenesis of mutated carrot cell line (de Jong et al. 1993). It was shown that O-acetylated chitin oligosaccharides can induce root cortical cell divisions when these molecules are introduced inside the plant tissue by ballistic microtargeting (Schlaman et al. 1997). There is a possibility that endogenous LCOs analogous in structure to rhizobial Nod factors may be produced in plants (Dyachok et al. 2000).

In the case of RtKO17 inoculation of seeds treated with LCOs and grown in sterile sand, we did not observe a statistically significant increase of fresh and dry mass of shoots (Table 3). The number of nodules elicited by the inoculant strain was also comparable to the untreated control. A possible explanation for the lack of growth promotion could be the excess of Nod factor. In the sterile environment, the factors were also produced by the RtKO17 inoculant strain. The possible excess of Nod factors that are already active in nanomolar concentrations could be due to the lack of autochthonous bacteria that affect the level of Nod factors by production of chitinases capable of factor degradation (Staehelin et al. 1994). Castillo et al. (1999) constructed a derivative of *Sinorhizobium meliloti* strain 1021 with an amplifiable fragment of a symbiotic region, which produced LCOs in higher quantities. A moderate amplification (2.5 copies) of the symbiotic region significantly improved its symbiotic properties, and inoculation of alfalfa with this strain resulted in an enhancement of plant growth. In contrast, higher copy derivatives produced the Nod factor in greater quantities but also reduced nodulation, nitrogen fixation, and plant growth in relation to control plants. These data indicate a tight regulation of *nod* gene expression and are consistent with the previous observation that strains that bear multicopy plasmids containing *nod* genes show reduced nodulation (Knight et al. 1986).

In the outdoor experiment, we tested the possibility of promoting growth and nodulation by LCO treatment of

clover seeds grown for 6 weeks in nonsterile soil and the competitiveness of the selected strain RtKO17-*gusA* in relation to indigenous rhizobia (Tables 4 and 5). A statistically significant increase of fresh and root clover mass and the percentage of nodule number was the most important effect of LCO seed treatment. An additional inoculation of seeds with RtKO17 did not affect clover growth, but the nodule number increased by approximately 43%, which confirmed LCO stimulation of nodule organogenesis. Conversely, we did not observe any substantial effects of LCO treatment on the competitiveness of RtKO17, which remained low in the treated and untreated control.

Taken together, the effects of Nod factors treatment on seed germination and growth could be explained by a mitogenic effect, thus inducing cortical cell division in roots and leading to the formation of nodules in a compatible plant host (Spaink et al. 1991; Truchet et al. 1991). The most important finding from the presented results is that LCOs pretreatment of seeds before planting could enhance legume growth and nodulation, despite the fact that rhizobia that inhabit the soil are exposed to a mixture of several chemical signals, and the efficiency of nitrogen fixation is determined by the final symbiotic partner.

Phthalic Acid Induces Oxidative Stress and Alters the Activity of Some Antioxidant Enzymes in Roots of *Malus prunifolia*

Ru Bai · Fengwang Ma · Dong Liang · Xin Zhao

Received: 5 December 2008 / Revised: 20 February 2009 / Accepted: 10 March 2009 / Published online: 8 April 2009

Abstract Apple replant is a widespread agricultural problem documented in all of the major fruit-growing regions of the world. In order to better understand the phytotoxic mechanisms induced by allelochemicals involved with this problem, *Malus prunifolia* plants were grown hydroponically to the six-leaf-stage in the presence of phthalic acid (0 or 1 mM) for 5, 10, or 15 days. Apple plants were evaluated for: shoot and root length, fresh and dry weight, malondialdehyde (MDA) content, hydrogen peroxide (H_2O_2) content, superoxide radical ($O_2^{\cdot-}$) generation rate, and antioxidant enzyme activities. Shoot and root lengths and fresh and dry weights of *M. prunifolia* decreased in plants exposed to phthalic acid. MDA and H_2O_2 content increased in phthalic acid-treated plants as did the generation rate of $O_2^{\cdot-}$ in *M. prunifolia* roots. The activities of superoxide dismutase (EC 1.15.1.1), peroxidase (EC 1.11.1.7), catalase (EC 1.11.1.6), ascorbate peroxidase (EC 1.11.1.11), glutathione reductase (EC 1.6.4.2), dehydroascorbate reductase (EC 1.8.5.1), and monodehydroascorbate reductase (EC 1.6.5.4) increased in phthalic acid-stressed roots compared with control roots. These results suggest that activation of the antioxidant system by phthalic acid led to the formation of reactive oxygen species that resulted in cellular damage and the decrease of *M. prunifolia* growth.

Keywords Antioxidant enzymes · Growth inhibition · *Malus prunifolia* · Membrane damage · Oxidative stress · Phthalic acid

Introduction

Allelopathy is widely reported in agroecosystem and silviculture, and is implicated in problems such as exotic plant invasion, replant problems, and soil sickness (Lee et al. 2006; Hao et al. 2007; Fernandez et al. 2008). Allelopathic plants exert detrimental effects via the release of plant compounds (allelochemicals) through leaching, root exudation, volatilization, and/or decomposition of plant materials (Weir et al. 2004) and can interfere with the metabolism of other plants. If the effect of such compounds is harmful to plant growth and development, it becomes a biotic or allelochemical stress (Romero-Romero et al. 2005).

Under normal growth conditions, a dynamic equilibrium exists between the production and detoxification of free radicals in cell organelles. Biotic and abiotic stresses may cause the formation of reactive oxygen species (ROS) such as superoxide radical ($O_2^{\cdot-}$), hydroxyl radical ($OH^{\cdot-}$), and/or hydrogen peroxide (H_2O_2) that are commonly generated and accumulated in cells (Cho and Seo 2005). Enhanced ROS production can affect membrane permeability, damage DNA and proteins, induce lipid peroxidation, and ultimately lead to programmed cellular death (Ding et al. 2007). Plants have evolved mechanisms that protect cell and subcellular systems from the effects of ROS by using antioxidant systems such as superoxide dismutase (SOD), peroxidase (POD), catalase (CAT), ascorbate peroxidase (APX), glutathione reductase (GR), dehydroascorbate reductase (DHAR), and monodehydroascorbate reductase

(MDHAR). Tolerance to allelochemicals by various crop plants has been associated with an increase in the activity of antioxidant enzymes (Yu and Matsui 1997).

The apple replant problem is widespread. Studies have shown that allelochemicals in root exudates or decomposition of residues may play a role in this agricultural problem (Borner 1959; Zhang et al. 2007; Bai et al. 2009). However, the mechanisms involved have not been investigated extensively. Reports suggest that allelochemicals cause increased membrane leakage, and enhance H_2O_2 and MDA levels in the target plant tissues. For instance, cinnamic acid enhanced the generation of free radicals, increased lipid peroxidation, and oxidative membrane damage in cucumber and figleaf gourd plants (Ding et al. 2007). Similarly, 2-benzoxazolinone inhibited lettuce growth, caused membrane damage, and increased MDA and H_2O_2 production (Sanchez-Moreiras and Reigosa 2005). Most studies in this regard focused on vegetables and agronomic crops (Baziramakenga et al. 1995; Yu et al. 2003; Ye et al. 2006). However, it is not known whether the inhibitory effects were mediated through production of ROS in apple roots under allelochemical stress. Phthalic acid is a potent allelochemical and inhibits the growth of a number of plants such as *Lactuca sativa* L. (Lee et al. 2006), *Zea mays* L. (Chai and Feng 2007), and *Malus prunifolia* (Bai et al. 2009). Accordingly, its effect on plant growth, ROS generation rate, and ROS-antioxidant enzyme activity were investigated in *M. prunifolia* seedlings.

Methods and Materials

Plant Materials and Phthalic Acid Treatment Seeds of apple rootstock, *M. prunifolia*, were obtained from Fuping County (34°75′ N, 109°15′ E), Shaanxi Province. Seed sterilization was done according to Zhang et al. (2007) and involved surface-sterilization in 0.3% (*v*/*v*) H_2O_2 for 20 min, followed by several rinses with sterile H_2O. The sterilized seeds were stratified at 4°C for 85 days. Sprouted seeds were sown in plastic pots (9 cm in diameter, 12 cm high; three seeds per pot) filled with sterilized sand. All pots were placed in a greenhouse at the College of Horticulture, Northwest A&F University, Yangling (34°20′ N, 108°24′ E). Plants were grown without supplementary illumination with night and day temperatures at 20 to 25°C and relative humidity at 65–80%. Seedlings were watered once a week with Hoagland nutrient solution (Hoagland 1920), pH 6.0±0.2. When the seedlings reached the six-leaf-stage, batches of 45 uniform seedlings were transferred into a hydroponic system (plastic container; 45×37×22.5 cm) filled with 5 l half Hoagland nutrient solution at pH 6.0±0.2 and electrical conductivity at 1.2 ms/cm, respectively. The containers were placed in a controlled growth room with a L/D regime of 12/12 h, 25/20°C, and a photon flux density of 140–160 μmol m^{-2} s^{-1}. Seedlings were allowed to acclimate to the hydroponic conditions for 5 days. Phthalic acid (purchased from Yifang S&T Ltd. Tianjin, China), dissolved in ethanol, was added to the nutrient solution to concentrations of 0 or 1 mM. In the preliminary experiment, thinner *M. prunifolia* leaves and brownish root apices in parallel with a large amount of mucilage was secreted from roots 15 days after application of 1 mM phthalic acid. This indicates that phthalic acid at this concentration is lethal to *M. prunifolia* seedlings. The final concentration of ethanol in control and treatment solutions was 0.1% (*v*/*v*). The nutrient solutions in the containers were aerated continuously by air pumps. The solution in the plastic container was kept at the same level by adding half Hoagland nutrient solution at 24 h intervals. Each treatment was replicated three times in a completely randomized design. Root samples were taken from both control and phthalic acid-treated plants on days 5, 10, and 15 after treatment, and the tissue was frozen in liquid nitrogen and stored at −70°C until analysis. At the end of the experiment (15 days after treatment), root and shoot length and fresh and dry weight of seedlings were measured. The seedlings were dried in an forced-air oven at 60°C until constant mass was reached.

Measurement of MDA, H_2O_2, and $O_2^{\cdot-}$ Generation Lipid peroxidation was followed by measuring MDA accumulation using the method of Baziramakenga et al. (1995) with some modifications. Root samples (0.2 g) were homogenized in 0.1% of trichloroacetic acid in phosphate buffer (5 ml; pH 7.8) and centrifuged at 12,000×*g* for 15 min. Supernatant (1 ml) was added to 0.5% thiobarbituric acid in 20% trichloroacetic acid (4 ml). The mixture was placed in a water bath at 100°C for 10 min and then quickly cooled in an ice-bath for 15 min. Samples were centrifuged at 12,000×*g* for 5 min, and then the absorbance of the supernatant was measured at 450, 532, and 600 nm.

H_2O_2 in the supernatant was measured according to Patterson et al. (1984). Root samples (0.5 g) were homogenized in 5-ml pre-cooled acetone and centrifuged for 10 min at 1,500×*g*. Titanium chloride (0.1%, *w*/*v*) and concentrated ammonia (0.2 ml) were added into the supernatant (1 ml), the mixture was allowed to react (10 min at 25°C) and the reaction mixture was centrifuged at 1,500×*g* for 10 min. Absorbance at 410 nm was measured, and the H_2O_2 concentration was calculated according to a standard curve.

The rate of $O_2^{\cdot-}$ generation was measured as described by Elstner and Heupel (1976) with some modifications. Root tissue (1 g) was homogenized in 65 mM potassium phosphate buffer (3 ml; pH 7.8). The homogenate was centrifuged at (10,000×*g* for 15 min). The supernatant

(0.5 ml) was added to 65 mM potassium phosphate buffer (0.5 ml; pH 7.8) containing 10 mM hydroxylammonium-chloride (0.1 ml) and incubated (25°C for 20 min). Sulphanilic acid (58 mM; 1 ml) and α-naphthyl amine (7 mM; 1 ml) were added to the mixture, and it was allowed to incubate (25°C for 20 min). The final solution was mixed with an equal volume of chloroform and the absorbance of the pink phase was measured at 530 nm.

Extraction and Assay of Enzyme Activities Antioxidant enzymes (SOD, POD, and CAT) were extracted according to the method of Yu et al. (2003) with some modifications. Root samples (0.5 g) were homogenized in phosphate buffer (8 ml; 0.1 M; pH 7.5) containing 2% (*w*/*v*) polyvinylpyrrolidone. The homogenate was centrifuged (12,000×*g* for 20 min) and the supernatant was used for enzyme analysis. All assays were carried out at 2–4°C.

Superoxide dismutase activity was measured according to Beauchamp and Fridovich (1971) with minor modification. The assay medium (3 ml) contained phosphate buffer (50 mM; pH 7.8), EDTA-Na (0.1 mM), L-methionine (12 mM), riboflavin (2 μM), and nitrotetrazolium blue chloride (75 μM). Riboflavin was added last. The tubes were shaken and placed at a photosynthetic photon flux of 50 μmol m^{-2} s^{-1} for 15 min. The reaction was initiated and terminated by turning the light on and off, respectively. The A_{560} was measured on a spectrophotometer and tubes containing the assay mixture, but without the root extract (control), were illuminated to determine maximum A_{560}.

Peroxidase activity was measured according to Sofo et al. (2004) with some modification. The reaction solution (3 ml) contained phosphate buffer (2.9 ml, 50 mM; pH 7.0), guaiacol (50 μl; 10 mM), H_2O_2 (10 μl; 40 mM), and crude enzyme extract (40 μl). The Increase in A_{470nm} due to the oxidation of guaiacol was measured at 20°C.

Catalase activity was assayed by monitoring the decrease in A_{240nm} (Aebi 1984). The reaction mixture contained phosphate buffer (50 mM; pH 7.0) and H_2O_2 (30% *w*/*v*) and was started by adding the reaction solution to crude extract (10 μl).

AsA-related enzymes were extracted according to Nakano and Asada (1981). Generally, each 0.5 g of roots material was homogenized in KH_2PO_4-KOH (6 ml, 50 mM; pH 7.5) containing ethylenediaminetetraacetic acid (0.1 mM), Triton X-100 (0.3% *v*/*v*), and insoluble polyvinylpolypyrrolidone (4% *w*/*v*). The homogenate was centrifuged (16,000×*g* for 15 min at 2°C) and the supernatant was used for APX, GR, MDHAR, and DHAR analyses.

Ascorbate peroxidase was measured by monitoring the decrease in $A_{290\ nm}$ (Nakano and Asada 1981). The assay mixture (1 ml) contained Hepes–KOH (50 mM; pH 7.6), ethylenediaminetetraacetic acid (0.1 mM), H_2O_2 (0.2 mM, AsA 0.5 mM), and enzyme extract. The reaction was initiated by adding H_2O_2.

Glutathione reductase activity was monitored at $A_{340\ nm}$ in a 1 ml reaction mixture containing Tris–HCl (100 mM; pH 8.0), ethylenediaminetetraacetic acid (1 mM), oxidized glutathione (GSSG;1 mM), and NADPH (0.2 mM). The reaction was initiated by adding NADPH (Grace and Logan 1996).

Monodehydroascorbate reductase activity was assayed at 340 nm in a 1 ml reaction mixture containing Hepes–KOH (50 mM; pH 7.6), NADH (0.1 mM), AsA (0.25 mM), and AsA oxidase (EC 1.10.3.3; 0.25 U). The reaction was initiated by adding AsA oxidase (Miyake and Asada 1992).

Dehydroascorbate rductase activity was measured at 265 nm in a 1 ml assay solution containing Hepes–KOH (100 mM; pH 7.0), ethylenediaminetetraacetic acid (1 mM), GSH (2.5 mM), and DHA (0.2 mM). The reaction was initiated by adding DHA (Dalton et al. 1986).

Statistical Analysis All data were subjected to analysis of variance, followed by Tukey's Studentized Range Test (SAS Statistical package, version 8.2). Results are presented as the means±standard deviation (SD).

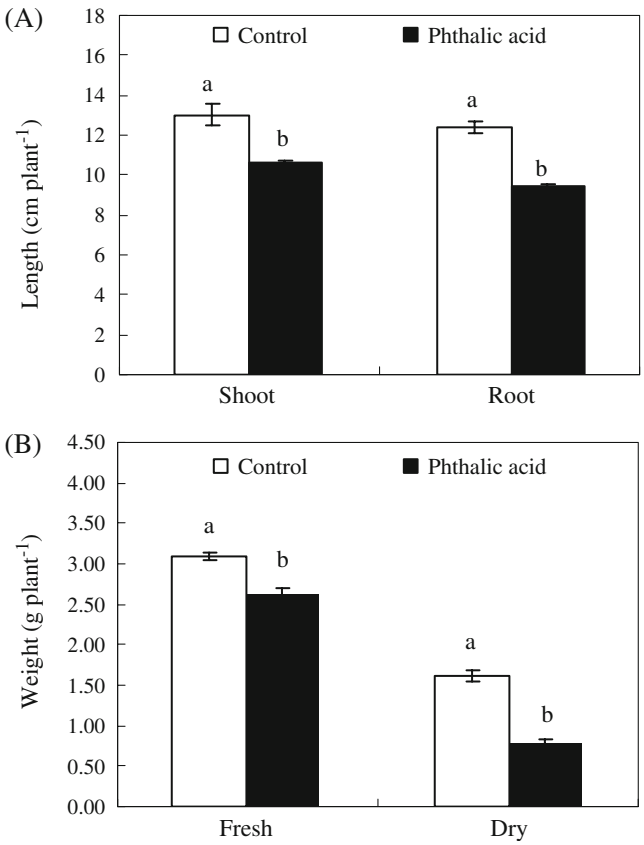

Fig. 1 Shoot and root length (**a**) and fresh and dry weight (**b**) of *Malus prunifolia* plants grown at 0 (control) or 1 mM phthalic acid. Samples were taken 15 days after treatment. Values are means of three replicates± standard error (SE). Significant difference ($P<0.05$ level) was tested between the control and 1 mM phthalic acid treatment for each dependent variable and indicated by different *letters above the bars*

Results

Effect on Plant Growth The toxic effect of 1 mM phthalic acid appeared after 15 days following treatment. The length of shoot and root of *M. prunifolia* plants had reduced shoot and root length compared to lower than controls (Fig. 1a). Fresh and dry weights were 3.09 and 1.61 g plant^{-1} in control plants compared to 2.63 and 0.79 g plant^{-1} for plants treated with 1 mM phthalic acid (Fig. 1b).

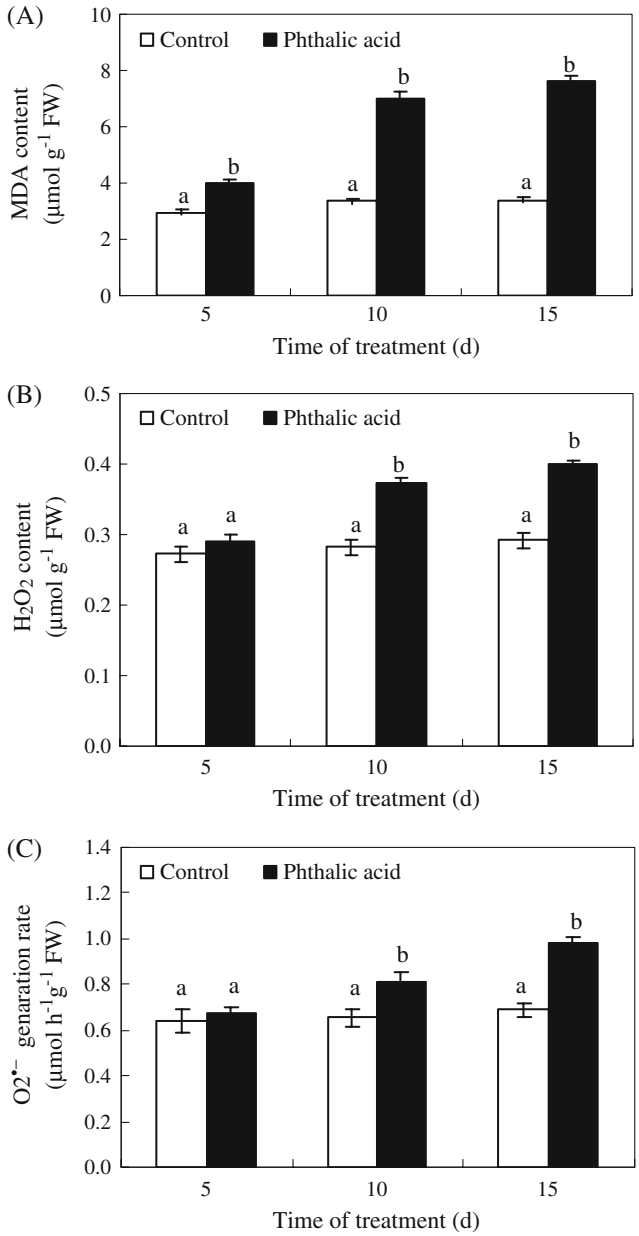

Fig. 2 MDA (**a**), H_2O_2 (**b**) content, and $O_2^{\cdot-}$ generation rate (**c**) in *Malus prunifolia* plants grown at 0 (control) or 1 mM phthalic acid. Values are means of three replicates±standard error (SE). Significant difference ($P<0.05$ level) was tested between the control and 1 mM phthalic acid treatment at each sampling date separately and indicated by different *letters above the bars*

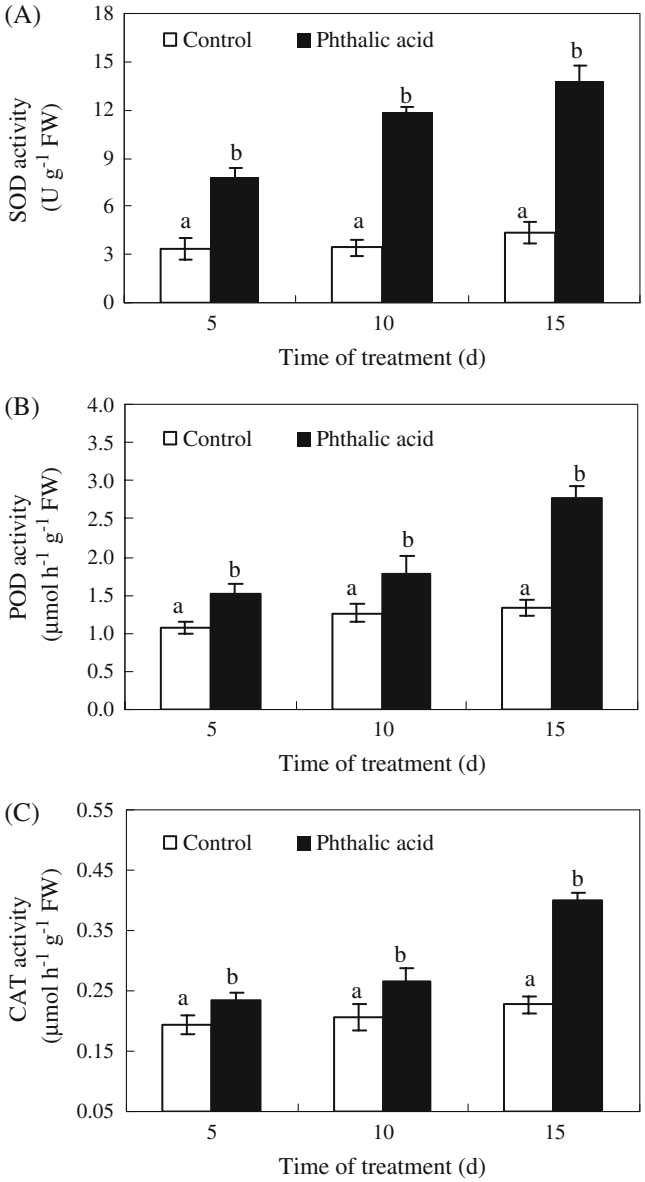

Fig. 3 SOD (**a**), POD (**b**), and CAT (**c**) activities of *Malus prunifolia* plants grown at 0 (control) or 1 mM phthalic acid. The values are means of three replicates±standard error (SE). Significant difference ($P<0.05$ level) was tested between the control and 1 mM phthalic acid treatment at each sampling date separately and indicated by different *letters above the bars*

Effect on MDA, H_2O_2, and $O_2^{\cdot-}$ Generation MDA concentration in *M. prunifolia* roots increased significantly after 5, 10, and 15 days of treatment (Fig. 2a). The maximum increase of 125.4% was observed after 15 days. Exposure to phthalic acid also resulted in an increase in the H_2O_2 content and $O_2^{\cdot-}$ generation rate, respectively (Fig. 2b, c). The maximum increases of 37.2% and 29.9%, respectively, were observed after 15 days.

Effect on Enzyme Activity In response to phthalic acid, activities of SOD, POD, and CAT, as well as enzymes in

ascorbate-glutathione cycle, e.g., APX, GR, MDHAR, and DHAR, all showed similar trends in the activity of root enzymes in response to phthalic acid. In general, enzyme activities increased progressively during the treatment period (days 5–15) compared to enzymes in the roots of plants not exposed to phthalic acid (Figs. 3 and 4).

Discussion

Phthalic acid treatment significantly decreases the growth of *M. prunifolia* plants (Fig. 1). This finding is in agreement with studies on *L. sativa* L. (Lee et al. 2006) and *Z. mays* L. (Chai and Feng 2007), and consistent with the inhibitory effects of other allelochemicals on plant growth reported previously (Lin and Kao 2000; Asao et al. 2004; Batish et al. 2008).

The formation of free radials in cells results in damage to cell membranes due to lipid peroxidation. Thus, the level of MDA, produced during lipid peroxidation, is a good indicator of oxidative damage that could be occurring within cells (Masia 2003). MDA accumulation due to lipid peroxidation has been reported in response to a variety of abiotic and biotic stresses (Dhindsa et al. 1981; Apel and Hirt 2004). In the present study, enhanced MDA (Fig. 2a) suggests that phthalic acid probably induces oxidative stress, and, as a result, disrupts cellular membrane structure, and causes a loss of cellular integrity. Similar results with other allelochemicals have been found (Wu et al. 2002; Batish et al. 2006; Ye et al. 2006). Many studies show that increased MDA content is associated with increased $O_2^{\cdot-}$ and H_2O_2 production following biotic and abiotic stresses (Forman et al. 2002; Lara-Nunez et al. 2006). Here, phthalic acid induced $O_2^{\cdot-}$ and H_2O_2 production in *M. prunifolia* roots (Fig. 2b, c), which suggests that phthalic acid could trigger ROS generation and induce oxidative stress in *M. prunifolia* roots. This observation is consistent with that obtained with mung bean treated with 2-benzoxazolinoen (Batish et al. 2006). Increases in SOD activity (Fig. 3a) also indicate that excessive generation of $O_2^{\cdot-}$ has been triggered by pthalic acid treatment, and, consequently, that SOD activity was up-regulated to mitigate the oxidative damage. Similar responses have been

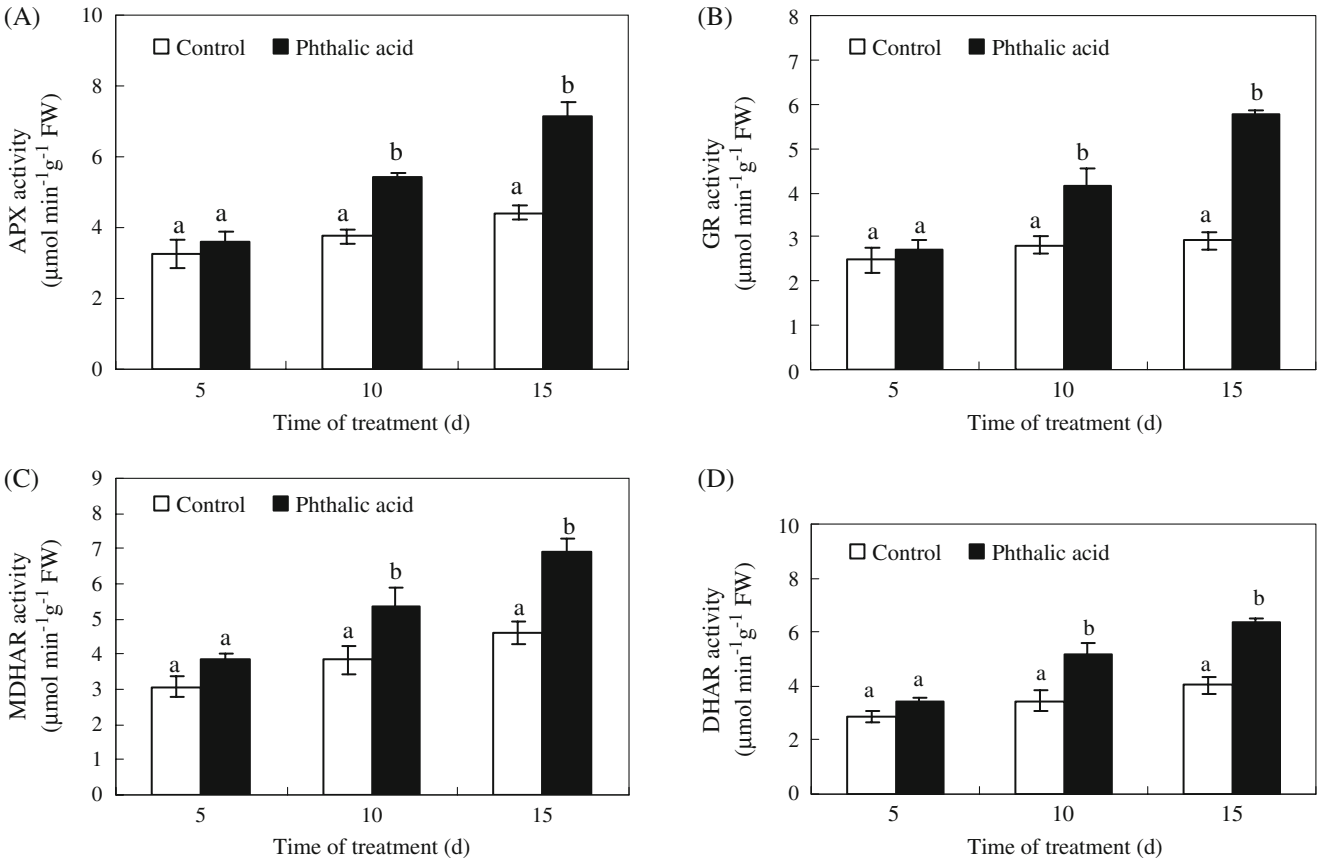

Fig. 4 APX (**a**), GR (**b**), MDHAR (**c**), and DHAR (**d**) activities of *Malus prunifolia* plants grown with 0 (control) or 1 mM phthalic acid. The values are means of three replicates±standard error (SE). Significant difference ($P<0.05$ level) was tested between the control and 1 mM phthalic acid treatment at each sampling date separately and indicated by different *letters above the bars*

observed in plants treated with other allelochemicals (Yu et al. 2003; Batish et al. 2006; Wu et al. 2002; Lin et al. 2007).

Accumulation of H_2O_2 in *M. prunifolia* roots in response to phthalic acid treatment enhances lipid peroxidation and causes a severe oxidative stress resulting in disruption of metabolic activities in the cell. Enhanced H_2O_2 levels are removed by the antioxidant enzymes such as CAT, APX, and POD (Blokhina et al. 2003), and glutathione-ascorbate cycle (Nakano and Asada 1981). In the present study, increases in the activities of these antioxidant enzymes paralleled the accumulation of MDA and H_2O_2 in *M. prunifolia* root after exposure to phthalic acid (Figs. 2–4). Our observations are consistent with those of Cruz-Ortega et al. (2002), who reported that allelochemical stress causes increases in the level of free radicals and the activity of antioxidant enzymes and suggests that increased induction of these enzymes is necessary to prevent lipid peroxidation (i.e., to counter the higher MDA and H_2O_2 in roots). Although there were increased levels of antioxidants in roots after exposure to phthalic acid, oxidative stress still occurred. Our data are consistent with those of Batish et al. (2006), who showed that exposure of mung bean to 2-benzoxazolinone increased APX, GR, and CAT activity. An increased POD activity in response to allelochemicals also has been demonstrated in cucumber root (Yu et al. 2003). Oracz et al. (2007) observed an increase in the cell membrane permeability, MDA level, H_2O_2 concentration, and SOD and CAT activity in mustard treated by sunflower extract. Furthermore, the activity and expression of most antioxidant enzymes is stimulated by ROS accumulation (Apel and Hirt 2004).

In summary, phthalic acid induces oxidative stress in *M. prunifolia* roots through the generation of ROS and decreases plant growth, despite the concomitant increase in antioxidant enzymes. This might be one of the mechanisms responsible for the apple replant problem. The increase in antioxidant enzymes could reflect a defensive response to the cellular damage provoked by phthalic acid treatment. However, this increase was not strong enough to eliminate all the deleterious effects provoked by phthalic acid, only alleviated the impact of stress.

Received: 23 February 2009 / Revised: 29 March 2009 / Accepted: 2 April 2009 / Published online: 21 April 2009

Abstract Invasive plants are by definition excellent competitors, either indirectly through competition for resources or directly through allelopathic inhibition of neighboring plants. Although both forms of competition are commonly studied, attempts to explore the interactions between direct and indirect competition are rare. We monitored the effects of several doses of extracts of *Alliaria petiolata*, a Eurasian invader in North America, on the growth of *Impatiens pallida*, a North American native, at several planting densities. The density-dependent phytotoxicity model predicts that as plant density increases, individual plant size will decrease, unless a toxin is present in the soil. In this case, individual plant size is predicted to increase as plant density increases, as plants share a limited toxin dose. We tested this model using fractions of an *A. petiolata* extract enriched in flavonoids or glucosinolates, as well as a combined fraction. The flavonoid-enriched fraction and the combined fraction suppressed *I. pallida* growth but only when applied at a dose eight times higher than that expected in the field. When treated with a dose equivalent to estimated field exposure levels, *I. pallida* growth was not distinguishable from that of control plants that received no extract, showing that indirect competition for resources was more important for determining the growth of *I. pallida* than direct allelopathic inhibition by *A. petiolata*. This is an important reminder that, even though many plants have the demonstrated potential to exert strong allelopathic effects, those effects may not always be apparent when other forms of competition are considered as well.

Keywords Allelopathy · Invasion · Glucosinolates · Flavonoid glycosides

Introduction

In natural communities, plants compete in complex ways as they vie for the same territory and resources. These interactions can be classified as direct or indirect competition and are difficult to distinguish experimentally since they operate in concert. Indirect competition is widely assumed to be the default natural condition, where two plants require access to a limited resource and the "winner" is more efficient at acquiring that resource (Connell 1990). Direct competition occurs through interference, with allelopathy being one of the most common mechanisms. Allelopathic plants release compounds into the environment that negatively impact surrounding plants, thus giving the allelopath a competitive advantage (Rice 1974).

Invasive plant species are by definition excellent competitors, whether by direct competition, indirect competition, or both. The distinction is important for several reasons. Simply removing the invader may control the spread of an invasion by indirect competition. However, in a site where direct competition is occurring, removal of the invader may not be enough. Allelochemicals released by the invader could remain in the soil and continue to inhibit

growth of other plants, even after removal of the allelopathic invader. For this reason, considerable attention has been paid to exploring the competitive mechanisms of invasive plants (Levine et al. 2004; Theoharides and Dukes 2007), including *Alliaria petiolata* (M. Bieb.) Cavara and Grande, Brassicaceae (garlic mustard; Meekins and McCarthy 1999; Bauer et al. 2005).

A. petiolata, an herbaceous biennial, was introduced into North America from Europe in the 1860s and has since become invasive in much of Canada and the northeast and Midwestern USA (Nuzzo 2002). The success of *A. petiolata* in North America has been attributed to its high propagule pressure (Cavers et al. 1979), escape from herbivores (Blossey et al. 2001), superior competitive ability (Meekins and McCarthy 1999), and allelopathic inhibition of surrounding plants (Vaughn and Berhow 1999; Roberts and Anderson 2001; Prati and Bossdorf 2004; Stinson et al. 2006; Wolfe et al. 2008). Given the broad range of bioactive secondary metabolites produced by garlic mustard (Haribal and Renwick 1998, 2001; Vaughn and Berhow 1999; Haribal et al. 2001; Renwick et al. 2001; Cipollini and Gruner 2007), it is not surprising that a large part of the effort spent studying the invasive success of this species has focused on allelopathic effects. Crude extracts and purified compounds from *A. petiolata* inhibited germination and growth of other plants and their symbiotic arbuscular mycorrhizal fungi (Vaughn and Berhow 1999; Roberts and Anderson 2001; Stinson et al. 2006; Callaway et al. 2008). Seeds of *Geum* spp. sown in soil conditioned by *A. petiolata* germinated better if the soil also contained activated carbon, presumably indicating the presence of inhibitory organic compounds in the soil (Prati and Bossdorf 2004). Cipollini et al. (2008b) also found positive effects of adding activated carbon on growth of *Impatiens capensis* growing with *A. petiolata* in the field. In contrast, *A. petiolata* extracts have failed to inhibit germination or growth of several plant species in some studies (McCarthy and Hanson 1998; Cipollini et al. 2008a). While *A. petiolata* clearly has the potential to act allelopathically, whether allelopathic effects are important in more realistic environments where resource competition is also occurring is largely unknown.

Activated carbon has been advocated for use as a soil amendment as a simple way to distinguish between allelopathy and resource competition because it should adsorb organic compounds with little effect on inorganic nutrients (Inderjit and Callaway 2003). However, it can alter nutrient levels in unpredictable ways (Lau et al. 2008), and other methods to verify the allelopathic potential of plant species are therefore necessary. Allelopathic effects are highly dependent on densities of target species and can be masked by resource competition at high densities (Weidenhamer et al. 1989; Weidenhamer 1996). According to the density-dependent phytotoxicity model, if resource competition is the dominating factor in an interaction, then individual plant mass will decrease as density increases. However, if allelopathy is the dominant factor, then individual plant mass will decrease more slowly, or even increase, as density increases, until a density is reached where resource competition among target plants becomes the dominant factor (Fig. 1). This model assumes that all plants present must share the available dose of an allelochemical, and as plant density increases the dose per plant decreases. At very high densities, each plant receives a dose so low that allelopathic inhibition disappears, and resource competition among target plants thus becomes dominant (Weidenhamer et al. 1989). This pattern has been observed for plants exposed to purified compounds (Hoffman and Lavy 1978; Andersen 1981; Weidenhamer et al. 1989), ground tissue from suspected allelopaths (Tseng et al. 2003), and soil conditioned by an allelopathic plant (Weidenhamer et al. 1989).

Allelopathic effects of *A. petiolata* may be masked by resource competition among target plants in some cases, and a better understanding of the dose–response relationship of secondary metabolites of *A. petiolata* would help clarify this issue. Synergism among allelochemicals also may be contributing to the inconsistency of results reported in the literature since fractions of extracts and even purified compounds have been used (Vaughn and Berhow 1999; Roberts and Anderson 2001). The objective of this experiment was to use a density-dependent phytotoxicity approach to determine the allelopathic potential of *A. petiolata* for a range of extract doses. We used fractionated extracts, enriched in either glucosinolates or flavonoid

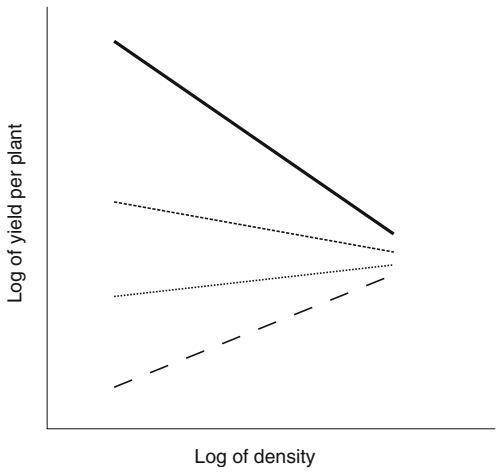

Fig. 1 Predictions of the density-dependent phytotoxicity model. The *bold line* represents expectations when resource competition is dominant, and the *dashed line* represents expectations when allelopathy is dominant. *Dotted lines* represent expected patterns at intermediate chemical doses

glycosides, to explore the contribution of different classes of compounds to observed allelopathic effects.

Methods and Materials

We chose *I. pallida* (Nutt.) Balsaminaceae (pale jewelweed) as the target plant for this study because it grows in the same habitats invaded by *A. petiolata* and has been susceptible to allelopathic effects of *A. petiolata* in prior studies (Barto, unpublished data). *I. pallida* seeds were collected from a population in Yellow Springs, OH, USA (39° 47.0' N, 83° 52.5' W), and nonsterilized seeds were stratified immediately in sterile water at 3°C to stimulate germination. Then, seedlings were transferred to 15-cm (1 L) pots containing sieved field soil mixed 1:1 with sand. The experiment was fully factorial with four densities (one, two, four, and eight *I. pallida* plants), three *A. petiolata* fractions (glucosinolate-enriched fraction, flavonoid-enriched fraction, and a combined fraction), and six concentrations (0.25*X*, 0.5*X*, 1*X*, 2*X*, 4*X*, and 8*X*) with *X* equaling 3.3-mg tissue equivalents per gram soil. This dose was chosen to represent expected exposure levels in the field (Callaway et al. 2008). A set of controls that received only water was planted at all four densities, and at least three replicate pots were planted for each treatment combination.

Extracts were prepared and fractionated, as in Callaway et al. (2008). We boiled *A. petiolata* tissues in ethanol, then filtered and dried the extract before defatting with hexane to remove chlorophylls. We wanted to focus on the glucosinolates and flavonoids, so the hexane fraction was discarded, even though it may have contained lipophilic

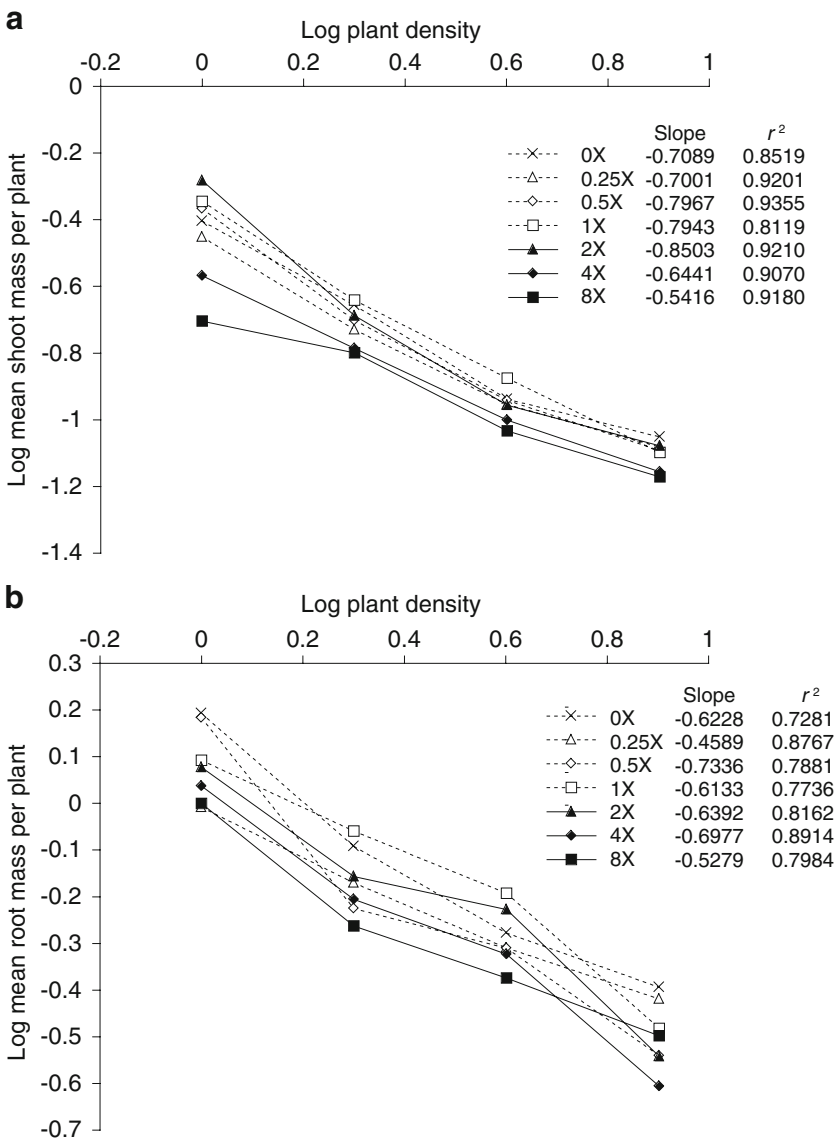

Fig. 2 Response of *Impatiens pallida* plants exposed to a flavonoid-enriched fraction of an *Alliaria petiolata* extract (*N*=2–3). **a** Relationship of log mean shoot mass per plant and log plant density. **b** Relationship of log mean root mass per plant and log plant density

allelochemicals. We dissolved the dried extract in water, then partitioned with *n*-butanol to separate the flavonoid glycosides and alliarinoside from the glucosinolates (Callaway et al. 2008). Both extracts were dried and redissolved in water before use. Pots were dosed weekly and watered as needed. Plants were harvested after 6 weeks and air-dried at 25°C for 1 week, and shoot and root dry masses were measured. Root-to-shoot ratios were calculated, and the log of root and shoot dry mass per plant and log of root-to-shoot ratios were regressed against the log of plant density per pot using PROC GLM with density and dose as factors, followed by Duncan's multiple-range test with α=0.05 (Weidenhamer et al. 1989). SAS version 9.1 (SAS Institute Inc., Cary, NC, USA) was used for all analyses.

Results

Across all other factors, mean shoot dry masses were higher in pots dosed with a glucosinolate-enriched fraction than those that received either a combined extract or a flavonoid-enriched fraction ($F_{2,\ 161}$=3.55, P=0.031). Mean root dry masses showed a similar pattern, and the effect was almost significant at the P=0.05 level ($F_{2,\ 161}$=2.88, P=0.059). Mean root and shoot mass per plant declined with increasing plant density at every dose.

Among pots dosed with a flavonoid-enriched fraction, plant density was the most significant factor that impacted shoot dry mass (t=−19.07, P<0.001; Fig. 2a, Table 1). Dose was also significant (t=−4.98, P<0.001), but shoot mass after exposure to the 8*X* dose was lower than that of control plants only at the lowest density. This suggests that, at densities greater than one plant per pot, resource competition among *I. pallida* plants was masking any allelopathic effects of *A. petiolata* extracts. The slopes of the regression lines were significantly different (t=2.16, P=0.034), supporting predictions of the density-dependent phytotoxicity model. However, the slope for the 1*X* dose could not be distinguished from that of the control, indicating that, at an ecologically relevant dose, allelopathic inhibition was not occurring. Plant density also was the most significant factor impacting root dry mass (t=−12.81, P<0.001) of plants exposed to a flavonoid-enriched fraction, but dose had no effect (t=−1.90 P=0.068; Fig. 2b, Table 1). Root dry mass was not affected by a flavonoid-enriched fraction since the slopes of the regression lines were not significantly different (t=0.26, P=0.797).

Effects were much less pronounced in pots dosed with a glucosinolate-enriched fraction. Plant density was again the most significant factor that affected mean shoot and root dry masses (shoot: t=−11.94, P<0.001; root: t=−14.02, P< 0.001; Fig. 3, Table 2). Dose impacted mean shoot dry masses (t=2.13, P=0.036), while mean root dry masses were unaffected (t=−0.25, P=0.802). As before, the slopes of the regression lines were not significantly different in either case (shoot: t=−0.17, P=0.866; root: t=1.13, P= 0.264), suggesting that resource competition among *I. pallida* plants was the dominant factor when they were exposed to glucosinolates alone.

Inhibitory effects were most pronounced in pots dosed with both flavonoid- and glucosinolate-enriched fractions, representing a more complete phytochemical profile of *A. petiolata*. Plant density again was the most significant factor

In dose column, *X* represents expected field levels of 3.3 mg *A. petiolata* tissue equivalents per gram soil

[a] Means with the same letter are not significantly different at α= 0.05 using Duncan's multiple-range test

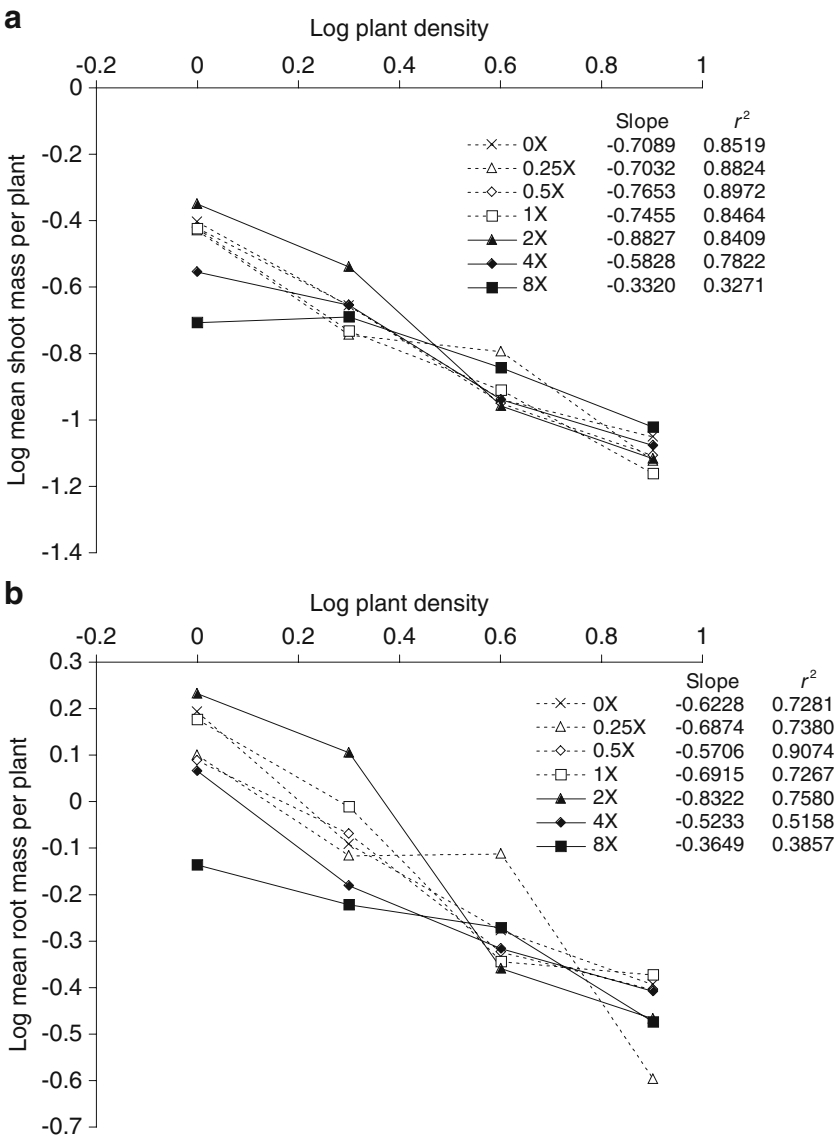

Fig. 4 Response of *I. pallida* plants exposed to a combined *A. petiolata* extract (N=2–3). **a** Relationship of log mean shoot mass per plant and log plant density. **b** Relationship of log mean root mass per plant and log plant density

impacting mean shoot and root dry masses (shoot: t=−15.34, P<0.001; root: t=−10.91, P<0.001; Fig. 4, Table 3). Extract dose significantly affected both mean shoot and root dry masses (shoot: t=−3.76, P<0.001; root: t=−3.35, P=0.001), with the strongest dose being the most inhibitory, but differences were significant only at the lowest density. Slopes of the regression lines for mean shoot mass and mean root mass against plant density were different (shoot: t=3.53, P<0.001; root: t=2.03, P=0.045) when pots received a combined extract (Fig. 4a). The highest dose led to the lowest slope, showing that at high doses allelopathic inhibition by *A. petiolata* is more important than resource competition between *I. pallida* plants. However, at the 1*X* dose expected to represent exposure levels in the field, the slope of the treatment regression lines could not be distinguished from that of control plants. Therefore, even though compounds produced by *A. petiolata* can inhibit *I. pallida* shoot and root growth, they do not appear to do so at an ecologically relevant dose.

The root-to-shoot ratios of plants exposed to a flavonoid-enriched fraction of an *A. petiolata* extract were affected by both density and dose (density: t=2.97, P=0.004; dose: t=2.16, P=0.034; Table 4). Root-to-shoot ratios were highest at a density of four plants per pot, indicating that, as *I. pallida* plants became more crowded, they invested resources preferentially in root growth, but these allocation patterns were not affected by exposure dose.

In *I. pallida* plants exposed to a glucosinolate-enriched fraction of an *A. petiolata* extract, root-to-shoot ratios generally were higher in plants exposed to low doses than

in plants exposed to high doses (t=−2.54, P=0.013), showing that at high exposure levels root growth was slower than shoot growth (Table 5).

Since combined *A. petiolata* extracts affected both shoot and root dry mass of *I. pallida* plants similarly, root-to-shoot ratios were not affected by density or dose (density: t=1.62, P=0.108; dose: t=−0.33, P=0.743; Table 6).

Discussion

A. petiolata has the potential to exert strong allelopathic effects on surrounding plants, as shown by the reduced *I. pallida* growth observed in this study after exposure to high doses of either a flavonoid-enriched fraction or a combined extract. However, in contrast to reports of inhibition by glucosinolates at doses as low as two times field levels (Vaughn and Berhow 1999), we found no inhibition due to glucosinolates, even using a dose eight times higher than expected field levels. Studies that use multiple fractions are rare, but our finding that a combined extract had greater biological effects than each of its component parts supports previous work (Callaway et al. 2008).

Despite the well-known potential for *A. petiolata* to be allelopathic (Vaughn and Berhow 1999; Roberts and Anderson 2001; Prati and Bossdorf 2004; Stinson et al. 2006; Callaway et al. 2008), intraspecific resource competition was the dominant process determining growth of the *I. pallida* plants used in this study. Levels of glucosinolates and flavonoid glycosides in soils beneath *A. petiolata* plants in the field are low and often undetectable (Barto and Cipollini 2009). Furthermore, the half-lives of the glucosinolates and their degradates are frequently less than 10 days in nonsterile field soil (Gimsing et al. 2006, 2007), although, in nonsterile soil water, sinigrin has a half-life greater than 120 days (Tsao et al. 2000). The flavonoid glycosides are much less stable with half-lives less than 12 h in nonsterile

field soil (Barto and Cipollini 2009). We did not assay the hexane fraction with lipophilic compounds, which may have contained more stable allelochemicals, although none have been reported for *A. petiolata*. We chose to use extracts instead of dried plant material so that our results would not be confounded by nutrient differences among the treatments. However, some allelochemicals may not have been extracted by our protocol and therefore would not have been applied to *I. pallida* plants. With these caveats, we can say that allelopathic effects due to the most abundant allelochemicals produced by *A. petiolata* are unlikely to be the most important factor contributing to its ability to displace *Impatiens* populations (McCarthy 1997). The 1*X* dose we used to represent expected field levels may be lower than actual field levels in sites with high *A. petiolata* densities or sites where degradation of allelochemicals is slowed. In such sites, allelopathy may still contribute to the invasive success of *A. petiolata*.

Invasive success may be explained by superior resource competition; however, seedlings of *I. capensis*, a smaller congeneric of *I. pallida*, were actually no less competitive than *A. petiolata* seedlings when both were planted at the same time (Meekins and McCarthy 1999). Although small *A. petiolata* seedlings did not outcompete *I. capensis*, *A. petiolata* is a biennial and bolts early in the spring of its second year before many other plants have grown substantially. Therefore, second-year *A. petiolata* plants likely are more competitive with an annual like *Impatiens* than *A. petiolata* seedlings and may be able to outcompete *I. pallida* seedlings. Superior resource competition was evident in a field study of second-year *A. petiolata* plants competing with *I. capensis*, but a portion of the competitive effects in that study were ameliorated by activated carbon (Cipollini et al. 2008b). Although we did not detect allelopathic effects on *I. pallida* at ecologically relevant doses, such effects may be more pronounced on target species that are less effective at competing for resources than *I. pallida*.

Further complicating matters are the interactions between direct (allelopathic) and indirect (resource competition) forms of competition. Resource competition can cause shifts in root-to-shoot ratios, which could alter levels of allelochemicals produced preferentially in roots or shoots (Goldberg 1990). Flavonoid glycosides are more abundant in the shoots of *A. petiolata*, while glucosinolates are more abundant in the roots (Vaughn and Berhow 1999). Other environmental factors such as soil texture, the presence of other soil contaminants, altitude, latitude, light levels, temperature, and pH of the soil also influence the production of allelochemicals (Blanco 2007). In *A. petiolata*, production of flavonoid glycosides varies seasonally (Haribal and Renwick 2001), and differences among populations may be due to environmental factors (Haribal and Renwick 2001) and/or be genetically controlled (Cipollini et al. 2005). Glucosinolate production also varies seasonally (Vaughn

Table 6 Root-to-shoot ratios of dry masses of *I. pallida* plants exposed to a combined *A. petiolata* extract

Dose	(mean±1 SE)[a]

[a] There were no significant differences among means using Duncan's multiple-range test (α=0.05)

and Berhow 1999) and is influenced by environmental factors (Cipollini 2002). There has been a historical division in the literature between advocates of allelopathy and resource competition, leading many to attempt to prove that either one or the other is dominant. In reality, both are facets of the same phenomena, competition, and attempts to incorporate both may prove more fruitful than focusing on either one independently.

Acknowledgements We thank Steph Enright for help in collecting *A. petiolata* in very unpleasant field conditions and for help in setting up and harvesting the experiment. Comments by two anonymous reviewers substantially improved this manuscript. Funding was provided by an Environmental Protection Agency Greater Research Opportunities Fellowship to K Barto (#91673701).

Defense by Volatiles in Leaf-Mining Insect Larvae

Jean-Luc Boevé · Gontran Sonet · Zoltán Tamás Nagy · Françoise Symoens · Ewald Altenhofer · Christopher Häberlein · Stefan Schulz

Received: 2 February 2009 / Revised: 27 March 2009 / Accepted: 2 April 2009 / Published online: 24 April 2009

Abstract The defense strategy of an insect toward natural enemies can include a trait that appears at first sight to contradict its defensive function. We explored phylogeny, chemistry, and defense efficiency of a peculiar group of hymenopteran sawfly larvae where this contradiction is obvious. Pseudodineurini larvae live in leaf mines that protect them from some enemies. Disturbed larvae also emit a clearly perceptible lemon-like odor produced by ventral glands, although the mine hampers the evaporation of the secretion. The mine could also lead to autointoxication of a larva by its own emitted volatiles. Citral was the major component in all Pseudodineurini species, and it efficiently repels ants. We conclude that full-grown larvae that leave their mine to pupate in the soil benefit from citral by avoiding attacks from ground-dwelling arthropods such as ants. In some species, we also detected biosynthetically related compounds, two 8-oxocitral diastereomers (i.e., (2*E*,6*E*)- and (2*E*,6*Z*)-2,6-dimethylocta-2,6-dienedial). Synthetic 8-oxocitral proved to be a potent fungicide, but not an ant repellent. The discrete distribution of 8-oxocitral was unrelated to species grouping in the phylogenetic tree. In contrast, we discovered that its presence was associated with species from humid and cold zones but absent in species favoring warm and dry environments. The former should be protected by 8-oxocitral when faced with a fungal infestation while crawling into the soil. Our work shows the importance of integrating knowledge about behavior, morphology, and life history stages for understanding the complex evolution of insects and especially their defense strategies.

Introduction

Predation pressure is a potent evolutionary force especially on insects, which are a basic element in most terrestrial ecosystems. As a consequence, defense strategies are widespread and diversified in insects and often rely on the use of noxious chemicals (Eisner 1970; Blum 1981). Chemical defense mechanisms have a profound impact on the entire biology of an insect species, as defense is coupled with other adaptations in morphology, physiology, niche use, behavior, etc. (Whitman et al. 1990). Other nonchemical defensive traits also interact in the evolution of insect species (Evans and Schmidt 1990). A trait in isolation may appear at first glance to be in contradiction to the others. For instance, conspicuousness renders insects more visible,

thus, more vulnerable; but this trait is used in defense strategies such as aposematism and mimicry, by relying on the predator's associative learning capabilities (Guilford 1990; Ruxton and Sherratt 2006).

We detected such a paradoxical situation in the biology of a group of phytophagous insects that not only live within a plant tissue but also emit defensive volatiles. The tribe Pseudodineurini belongs to the hymenopteran nematine (Tenthredinidae) sawflies (see Boevé (2008) for an introduction to the family). The larvae of this tribe are specialized leaf miners on plants mainly belonging to the buttercup family Ranunculaceae (Altenhofer 2003; Altenhofer and Pschorn-Walcher 2006; Table 1, Fig. 1). Compared to free-living sawfly larvae, endophytic larvae presumably are mechanically protected from some natural enemies (Price and Pschorn-Walcher 1988; Connor and Taverner 1997). Additionally, almost all larvae of the 1,200 highly diverse nematine species possess ventral glands that emit a volatile antipredator secretion (Boevé and Pasteels 1985). A typical lemon-like odor is perceived easily when Pseudodineurini larvae are disturbed. The odor intrigued us since volatiles often repel (at a distance) approaching and/or attacking small arthropods (Pasteels et al. 1983). For example, the odor of lemon eucalyptus repels insects such as mosquitoes (Moore et al. 2007). Further, several nematine species among the free-living *Nematus* and galling *Pontania* show a secondary reduction in gland size (Boevé and Pasteels 1985), no perceptible odor, only a trace of volatiles such as long chain hydrocarbons (Boevé et al. 1992), and thus probably a more or less functionless secretion. Pseudodinerini larvae are endophytic and emit repellents, and our aim was to understand this apparent redundancy of defensive traits. The latter trait is especially puzzling since the closed environment in which the larva lives hampers the evaporation of volatiles and could lead to autointoxication.

Pseudodineurini is a small tribe that comprises about 15 described Holarctic species (Taeger and Blank 2008). A dozen belong to the genus *Pseudodineura*, and larvae are known for seven Western Palaearctic species. Adults are about 5 mm in body length, and larvae up to 1 cm. Several species of the tribe are restricted locally and occur only during a short season (Altenhofer and Pschorn-Walcher 2006). However, we were able to gather enough material for chemical and phylogenetic analyses. Preliminary chemical analyses revealed the occurrence of two acyclic monoterpene diastereomers (*E*)-3,7-dimethyl-2,6-octadienal (geranial) and (*Z*)-3,7-dimethyl-2,6-octadienal (neral; the mixture of the two compounds is called citral) in the glandular secretion of *Pseudodineura* larvae. These compounds also occur in lemon, lemon grass, etc. and are important in the food and perfume industry. Their occurrence was expected in *Pseudodineura* due to the perceptible odor and because free-living *Nematinus* larvae also emit them (Boevé et al. 1984). However, two isomers of another unidentified monoterpene occurred in only some *Pseudodineura* species. In the present study, the chemical profile of the glandular secretion of this group was investigated in relation to phylogeny. Moreover, bioassays were performed to reveal the defensive efficiency of live larvae and to compare the bioactivity of citral and the other monoterpenes. The results lead us to an explanatory framework that brings together the evolution and ecology that includes biotic and abiotic factors. As a case study, it allows us to better comprehend how multifunctional traits can evolve.

Methods and Material

Sample Collection Sawflies were collected in the field, mainly in the province *Niederösterreich* of Austria (Table 1). The Pseudodineurini larvae were identified by EA, and voucher specimens of all sawfly samples are kept by JLB at the Royal Belgian Institute of Natural Sciences.

Phylogenetic Analyses Twenty-five specimens representing all West Palearctic Pseudodineurini species except *Pseudodineura heringi* were used for phylogenetic analyses. We also added one North American species (*Pseudodineura parva*). Six outgroup species were chosen on the basis of the subfamilial phylogeny of Nematinae proposed by Nyman et al. (2006).

Total genomic DNA was extracted by using DNeasy Mini Kits (Qiagen). The posterior half of the larvae (or the whole specimen when larvae were smaller than 5 mm) stored in 96% ethanol was used. Fragments of the mitochondrial cytochrome *b* gene (cob; aligned length: 433 bp) were amplified and sequenced by using the primers CB-J-10933: 5′-TATGTACTACCATGAGGACAAATATC-3′, and CB-N-11367: 5′-ATTACACCTCCTAATTTATTAGG AAT-3′ (Simon et al. 1994). The cytochrome *c* oxidase subunit I gene (COI; aligned length: 874 bp) was amplified and sequenced with the primers sym-C1-J-1718 (Nyman et al. 2006) and A2590 (Normark et al. 1999). A fragment of the nuclear 28S rRNA gene (28S; aligned length: 579 bp) was amplified and sequenced with the primers D2F: 5′-CGTGTTGCTTGATAGTGCAGC-3′ and D2R: 5′-TTG GTCCGTGTTTCAAGACGG-3′ (Schmidt et al. 2006). PCR products were sequenced on an ABI Prism 3130XL capillary sequencer. For detailed list of samples and GenBank accession numbers, see Table 1. DNA sequences of 28S rRNA were aligned with MAFFT 6 (Katoh et al. 2002; Katoh and Toh 2008) by using the Q-INS-i option. Mitochondrial gene sequences were aligned manually.

Phylogenetic analyses were carried out with PAUP* v4.0b10 (Swofford 2002), MrBayes v3.1.2 (Ronquist and Huelsenbeck, 2003), and BEAST v1.4.8. (Drummond and

Rambaut 2007). Trees were calculated with parsimony (gaps in 28S sequences were considered as fifth character), maximum likelihood (ML), and Bayesian (BI) methods based on each gene separately, on the concatenated sequences of two genes (COI and 28S), and on the concatenated sequences of three genes. The Akaike and the Bayesian information criteria implemented in jModeltest v0.1.1 (Posada 2008) were used to find appropriate nucleotide substitution models, and the recommended settings were used in the subsequent ML and BI analyses. In order to infer branch supports, we performed 2,000 bootstrap replicates under parsimony and 100 replicates under ML criteria using PAUP*. BI analyses were carried out with MrBayes running 2×10^6 generations. For the protein-coding genes (i.e., COI as in Fig. 2), we partitioned the dataset according to codon positions (first and second positions vs. third positions), and performed a Bayesian analysis in BEAST running 10^7 generations. In all Bayesian analyses, the first 25% of the sampled trees were discarded ("burn-in").

Chemical Analyses and Syntheses Full-grown Pseudodineurini larvae were taken out of their leaf mines, and samples containing 13 to 30 individuals were extracted for 5 min in approximately 0.5 ml hexane. For *Pseudodineura fuscula*, larvae as well as eonymphs were extracted in this way. Extracts were kept at −80°C until gas chromatography/mass spectroscopy (GC–MS) analysis.

Most analyses were performed on a Fisons 8060 GC system equipped with a nonpolar capillary column (DB-5, 30 m×0.32 mm I.D., film thickness 0.25 μm) and coupled to a Fisons MD800 quadrupole mass spectrometer. The extract was concentrated, up to 0.25 ml, when relatively few larvae were extracted. From each extract, 1 μl was injected, with a solvent delay of 3 min. The temperature program was 2 min at 60°C, then up to 280°C with 3°C min^{-1}, and then 30 min at 280°C. Spectra were obtained in EI mode.

To confirm the chemical composition of some extracts and to elucidate the structure of a monoterpene that remained unidentified, additional analyses were performed on a Hewlett Packard GC 6890 with split/splitless-injector and a fused silica capillary column (BPX5, SGE Inc., 25 m×0.22 mm I.D., film thickness: 0.25 μm) connected to a Hewlett Packard MSD 5973 quadrupole mass spectrometer operating in the EI mode. The temperature program was 1 min at 50°C, then up to 320°C with 10°C min^{-1}.

Neral (**c1**) and geranial (**c2**) were synthesized from nerol and geraniol via Swern oxidation (Omura and Swern 1978). The obtained **c1** and **c2** contained 1.4% of **c2** and 1.1% of **c1**, respectively. The 8-oxocitrals also were synthesized from nerol and geraniol. First, an allylic oxidation was performed by using catalytic amounts of selenium dioxide and tert-butyl hydroperoxide as cooxidant (Li et al. 1997). The resulting dialcohols then were oxidized via Swern oxidation (Omura and Swern 1978). (2*E*,6*Z*)-2,6-Dimethylocta-2,6-dienedial (**c3**) contained 25% of (2*E*,6*E*)-2,6-dimethylocta-2,6-dienedial (**c4**), and **c4** contained 10% of **c3**. As far as we know, no selective synthesis exists that would furnish these compounds in the same diastereomeric purity as obtained for the citrals. The 8-oxocitrals are relatively unstable, and they slowly isomerize upon standing. Only the C-6 double bond isomerizes, thus, showing the higher reactivity of 8-oxocitral at this position (Chan et al. 1968). Before performing the bioassays (see below), the relative proportion of the mixtures **c3** + **c4** had already changed from 3:1 to 1:1 and from 1:9 to 1:4. After these bioassays, which required several months, the mixtures were reanalyzed, and their relative proportions remained stable for the mixture 1:1, whereas the other mixture was largely degraded.

Bioassays Three types of bioassays were performed: sawfly larvae alive vs. ants, synthesized compounds vs. ants, and these same compounds vs. fungi.

The interactions between larvae of *Pseudodineura mentiens* and ant workers of *Myrmica rubra*—a common ant species in Europe, including Austria (Seifert 1988)—were observed in 9-cm diam Petri dishes. First, one leaf of *Hepatica nobilis* with a full-grown larva still in its mine was deposited in a Petri dish containing ten ants. Six replications were made. After 24 h, we observed whether the ants opened the mine. Second, ten ants per Petri dish were confronted with one larva just taken out of its mine. Seven full-grown and six penultimate instar larvae were tested. We counted after 15 min the number of ants that surrounded the larva, i.e., clearly making a mandibular contact with it. After the bioassay, we determined the instar by recording the head coloration and measuring the head capsule width (HCW). Full-grown larvae have a whitish head and HCW=1.0 to 1.18 mm, whereas larvae at penultimate instar have a dark head and HCW=0.85 to 1.0 mm.

To measure the repellent effect of the synthesized monoterpene isomers (see above) we used the ant *Crematogaster scutellaris* in an experimental setup described in Boevé (1988) and in which this ant species performed better than *M. rubra*. Forty ant workers were taken from a laboratory colony and left for 30 min in a 14-cm diam Petri dish coated on its inner border with Fluon® to prevent escape. Then, a 5×5-cm glass plate with a metallic podium of 1 cm diam and 0.5 cm in height fixed at its center was placed in the uncovered Petri dish. The plate had 75 μl of a 1:1 water/honey solution deposited on the glass around the podium. For 5 min, ants were allowed to find the solution and feed. The number of feeding ants then was counted for

[d] The Pseudodineurini larvae where always collected, per sample, in a small area, thus, clearly belonging to a single population. Their host-plants occurred as a small patch, especially *Clematis recta*, *Ranunculus platanifolium* from Groß Gerungs, and *Pulsatilla vulgaris*. Larvae used in chemical analyses are marked (+)

[e] For genetic analyses, we often used more than one individual from one sawfly population, each one being numbered (.1, .2, .3) as DNA individual. This specimen numbering is reused in Fig. 2

[f] GenBank accession numbers are given for COI, cob, and 28S; sequence could not be obtained (–)

Fig. 1 Sawfly larva of *Pseudodineura fuscula* on *Ranunculus platanifolium*. All *Pseudodineura* species are leaf miners of Ranunculaceae plants. Both leaf epidermis layers being translucent, the larva is visible as is the feces that accumulate in the mine. Photographed by J-L Boevé

the first time (t=0), and simultaneously, a piece of 5×5-mm filter paper embedded with 0.25 µl of the tested monoterpene was placed on the podium. The number of feeding ants was recounted, once per minute, up to t=10 min. This experiment, performed at 25°C, was replicated four times per monoterpene. Distilled water instead of a monoterpene was used as a control.

Antifungal testing of **c1**, **c2**, **c3** + **c4** (1:1 and 1:4) was performed with the yeast *Candida albicans* (strain: IHEM 9559) and the filamentous fungus *Aspergillus fumigatus* (IHEM 18963). These strains are referenced in the BCCM/IHEM Collection catalog (http://bccm.belspo.be/db/ihem_search_form.php). These two human pathogenic species were chosen because standardized reference methods are available for antifungal susceptibility testing (i.e., CLSI M27A (2002a) for yeasts and CLSI M38A (2002b) for filamentous fungi). These tests are performed in 96-well plates. We used an individual microplate per sample to avoid interferences due to the volatility of the compounds. Stock inoculum suspensions were prepared from a 24-h-old culture of *C. albicans* grown on Sabouraud medium, and from a 7-day-old culture of *A. fumigatus* grown on potato dextrose agar. As starting sample amounts, we used 3.75, 4.5, 5.0, and 3.0 mg of **c1**, **c2**, **c3** + **c4** (1:1), and **c3** + **c4** (1:4), respectively. The sample was solubilized in 200 µl of sterile saline. The microplate contained 100 µl of twofold serial dilutions of the sample and 100 µl of the fungal inoculum in twice concentrated RPMI medium (2% glucose, 0.165M MOPS). The final concentration of the inoculum was 2.5 10^3 CFU/ml for *C. albicans* and 5 10^3 CFU/ml for *A. fumigatus*. Growth and sterility controls were included in each experiment. Microplates were

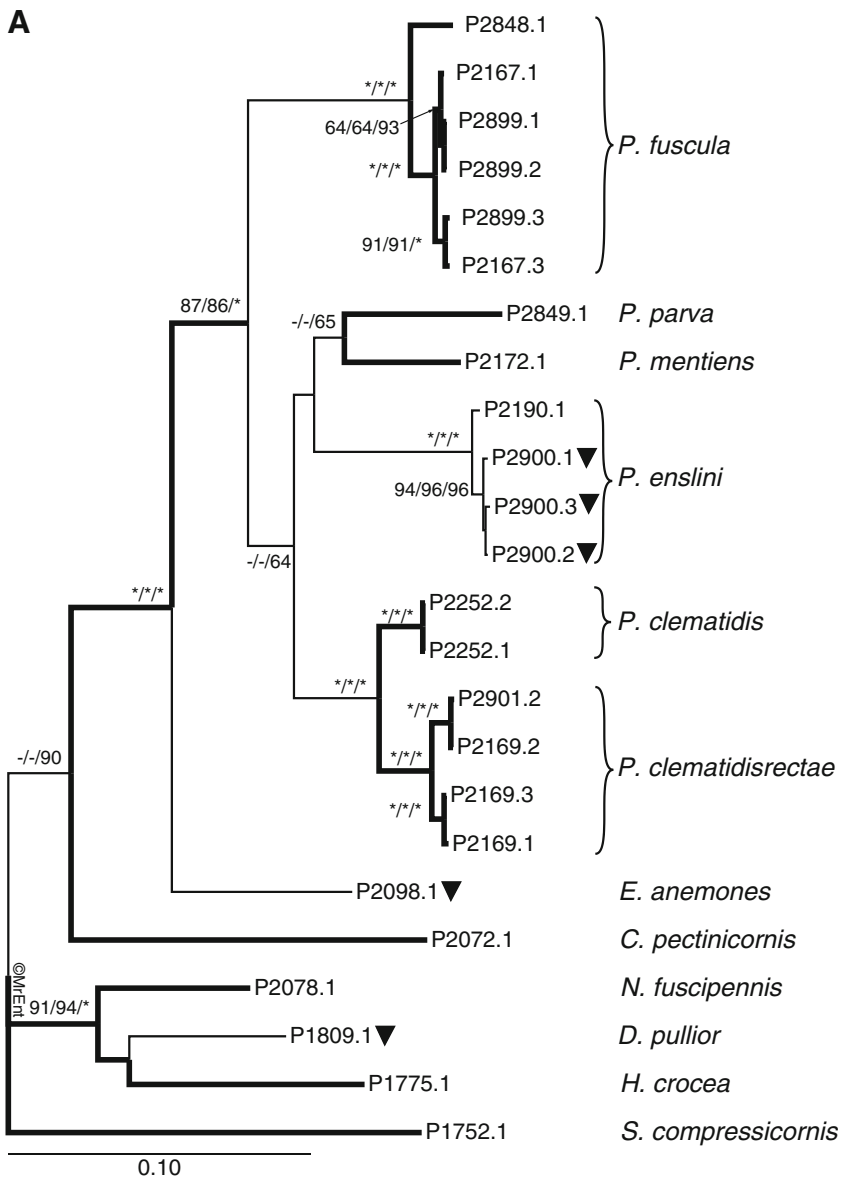

Fig. 2 Phylogenetic relationships of the Pseudodineurini (**A**) and *Pseudodineura* (**B**). In **A**, the tree was reconstructed using Bayesian inference for concatenated COI and 28S sequences (1,453 bp). Branches in *bold* show clades supported by the combined analyses of COI, cob, and 28 S sequences (1,886 bp). Taxa marked with *black inverted triangles* were not included in the latter analysis. Clade support values are: parsimony bootstraps (2,000 replicates)/maximum likelihood bootstraps (100 replicates)/ Bayesian posterior probabilities (2×10^6 generations). Values under 60% are not shown. Bootstrap values of 97–100% and posterior probabilities of 100% are replaced by *asterisks*. In **B**, the tree from COI sequences was reconstructed using BEAST, and posterior probabilities were calculated by running 10^7 generations. *Asterisks* replace values between 99% and 100%. Presence (*plus sign*) or absence (*minus sign*) of 8-oxocitral (**c3** and **c4**). Species documented as xerotherm (*Yes*) or not (*No*) in Altenhofer and Pschorn-Walcher (2006). Unknown or unclear (*question mark*)

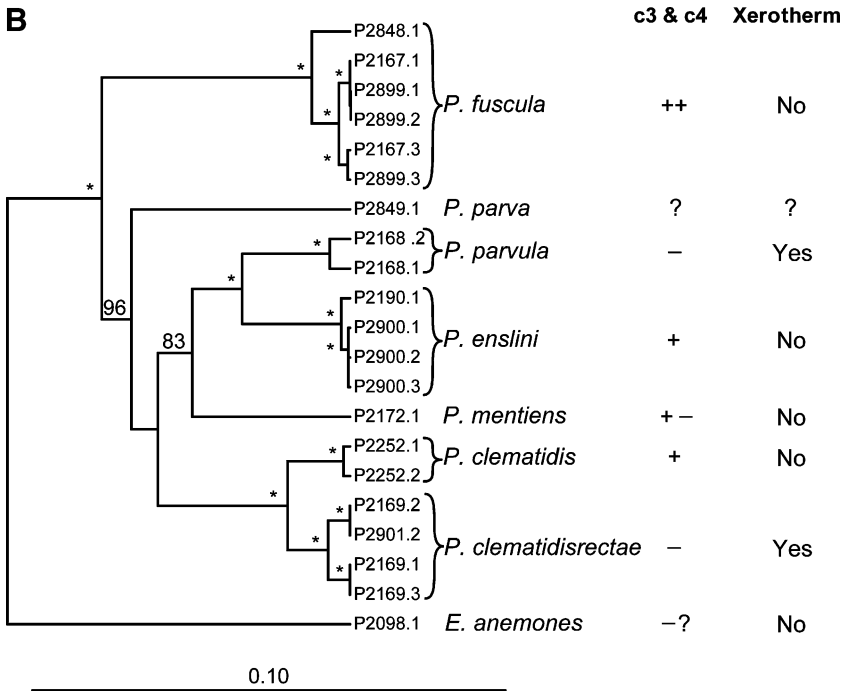
incubated at 35°C for 48 h and analyzed by spectrophotometry at 405 nm. The minimum inhibitory concentration (MIC)100 corresponds to a total growth inhibition, and MIC50 to a 50% growth inhibition. The minimum fungicidal activity (MFC) is the lethal concentration determined by inoculation on an agar plate of 20 µl aliquots from each well and that showed 100% growth inhibition compared to the growth control. Thus, the MFC is the lowest concentration resulting in no growth.

Results

Phylogenetic Analyses Complete datasets of COI, cob, and 28S sequences (total aligned length: 1866 bp) were obtained for representatives of ten species. For *Pseudodineura parvula*, only the amplification and sequencing of COI was successful; for *Endophytus anemones* and *Dineura pullior* we obtained COI and 28S sequences.

All combined and single-gene analyses (except 28S) supported monophyly of the genus *Pseudodineura* with highest bootstrap and posterior probability values (Fig. 2A). *Endophytus anemones* appeared to be the sister taxon of *Pseudodineura*. Phylogenetic relationships among *Pseudodineura* species could not be completely resolved despite the different evolutionary characteristics and amount of phylogenetic information of the three selected markers. Nonetheless, the sister-species relationship of *Pseudodineura clematidis* and *Pseudodineura clematidisrectae* consistently received highest support. Furthermore, COI analyses revealed a probable sister-species relationship between *Pseudodineura parvula* and *Pseudodineura enslini* (Fig. 2B).

Fig. 2 (continued)



Chemical Analyses The glandular secretion was composed mainly of monoterpenes (Fig. 3). Neral (**c1**) and geranial (**c2**) were the major compounds in all studied Pseudodineurini. In several *Pseudodineura* species, an uncommon monoterpene occurred as two isomers in medium amounts. The mass spectra showed a molecular mass 14 amu higher than that of citral, which is consistent with an additional methylene group or carbonyl function. The tabular data of the mass spectrum were comparable with those for (2*E*,6*E*)-2,6-dimethylocta-2,6-dienedial (**c4**) as described in literature (Veith et al. 1996). The structure then was confirmed by synthesis, followed by comparison of mass spectra and retention indices of the natural and synthetic compounds. The analogous (2*E*,6*Z*)-2,6-dimethylocta-2,6-dienedial (**c3**) was identified in the same way.

For each species, the relative abundance (in percentage) of **c1**, **c2**, **c3**, and **c4** was as follows (see also Fig. 2B): *P. clematidisrectae* (29, 53, 0, 0, respectively), *P. clematidis* (24, 67, 2, 3), *P. parvula* feeding on *Pulsatilla vulgaris* (34, 57, 0, 0), *P. enslini* (15, 63, 3, 10), *P. fuscula* feeding on *Ranunculus bulbosus* (35, 56, 1, 3), *P. fuscula* feeding on *Ranunculus platanifolium* (10, 55, 2, 13), *P. heringi* (31, 46, 0, 0), *P. mentiens* (25, 53, 1, 2 for a sample from June; 25, 32, 0, 0 for a sample from August; 25, 52, 0, 0 for eonymphs from this sample), and *E. anemones* (35, 65, 0, 0). Thus, the relative abundance varied between 10% and 37% for **c1**, 46–72% for **c2**, 1–3% for **c3**, and 3–13% for **c4**, which means that **c2** was always more abundant than **c1**, and **c4** more than **c3**.

Bioassays The six *P. mentiens* larvae left in their leaf mine survived well their 24 h confrontation with ant workers of *M. rubra*, since no mine was opened during this period. In the bioassay where larvae were experimentally taken from their mine, the mean number (± SD) of ants surrounding a single penultimate instar larva was 1.7 (± 0.8), but none surrounded a full-grown larva ($P<0.01$, Mann–Whitney U test).

The two isomers of citral (**c1** and **c2**) were significantly repellent for *C. scutellaris* ant workers, with compound **c1**

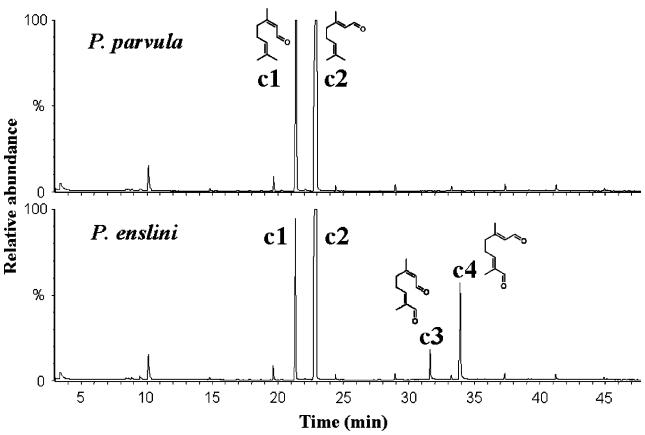


Fig. 3 Chromatograms of the volatiles emitted by two closely related *Pseudodineura* species, *P. parvula* and *P. enslini*. The monoterpene isomers correspond to citral (**c1** and **c2**) and 8-oxocitral (**c3** and **c4**). Other, smaller peaks correspond to alkanes: from dodecane with t_R= 10.13 to octadecane with t_R=44.95

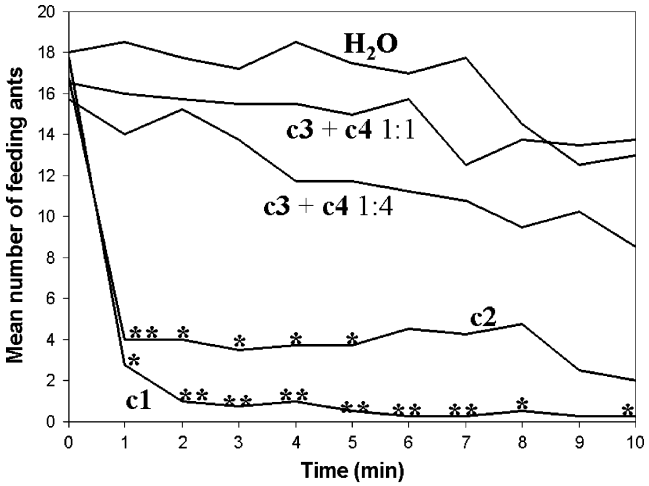

Fig. 4 Repellent activity of citral (**c1** and **c2**) and related 8-oxocitral (**c3** and **c4**) on the ant *C. scutellaris*. The monoterpenes were offered at $t=0$ on a small podium that was surrounded at its base by feeding ants. The number of feeding ants was counted every minute during 10 min. Water was used as a control. Standard deviation values are not shown, for clarity. $*P<0.05$, $**P<0.01$, Kruskall–Wallis test with post-test (corrected for ties), by comparing each volatile vs. water

being slightly more repellent than **c2**. In contrast, the mixture of the two isomers of 8-oxocitral (**c3** and **c4**) showed only a weak nonsignificant activity (Fig. 4).

The antifungal susceptibility tests revealed that all four synthesized monoterpenes were active against fungi (Table 2). The mixture **c3** + **c4** (1:1) showed the strongest fungicidal activity (with MFC=0.781 mg/ml), for both *C. albicans* and *A. fumigatus*, compared to the other tested monoterpenes. We consider activity values as similar between the two fungi species, taking into account that such values obtained from terpenes can vary even between strains of the same species (Sabini et al. 2006).

GC–MS analyses, performed after the bioassays, revealed that only the mixture **c3** + **c4** (1:1) remained stable over time, whereas **c3** + **c4** (1:4) was degraded. This may explain why a relatively low antifungal activity was observed with **c3** + **c4** (1:4), which is, however, closer to the natural mixture (see Fig. 3). It is possible that **c3** is more active than **c4**, which would increase the potency of **c3** + **c4** (1:1) mixture where **c3** is proportionally more concentrated.

Discussion

There are both advantages and disadvantages for an insect to feed as a leaf miner, as compared to an external leaf feeder (Connor and Taverner 1997). From the point of view of aggression from natural enemies, the risk of external disease infection is lower, whereas parasitoids inflict higher mortality due to a lower mobility of the leaf miner. Galling nematines may be less susceptible to this kind of parasitism than free-living species, since the mean number of parasitoid species is 4.0 for shoot-galling nematines, in contrast to almost 16 for free-living colonial nematines (Price and Pschorn-Walcher 1988; but see Nyman et al. 2007). Among the Pseudodineurini, 0–3 parasitoid species per host species were recorded (Altenhofer and Pschorn-Walcher 2006). Thus, it is likely that the leaf-mining habit allows Pseudodineurini larvae to avoid at least some parasitoids, such as tachinid flies. Considering predation, mining vs. external feeding habits seem to be similar in risks incurred (Connor and Taverner 1997). The mechanical protection offered by the mine was effective in our bioassay where larvae and mines remained intact for 24 h while surrounded by *M. rubra* workers. Mechanical protection appears to be insufficient, however, in the birch leaf mining sawfly *Fenusa pusilla*. It feeds in newly unfolding thin leaves and can be preyed upon by ants (Pezzolesi and Hager 1994). This sawfly species does not belong to the nematines and does not possess ventral glands. Thus, predation by ants may have a significant impact on sawfly leaf miners if the leaf epidermal layers are thin and if the larvae are not defended chemically.

Citral was the major compound in all analyzed Pseudodineurini species (Fig. 3), and it was detected in full-grown larvae still in their mine as well as in eonymphs in their

Table 2 In vitro susceptibility of two fungal species *Candida albicans* and *Aspergillus fumigatus* to citral (**c1** and **c2**) and mixtures of 8-oxocitrals (**c3** and **c4**)

Monoterpenes	Fungus	MIC50 (mg/ml)	MIC100 and MFC (mg/ml)[a]

MIC50 minimum inhibitory concentration 50%, *MIC100* minimum inhibitory concentration 100%

cocoons. It is an insect repellent (Boevé 1988; Vartak et al. 1994), fungicide, and a fungus growth inhibitor (Kuwahara et al. 1989; Lima et al. 2005; Sabini et al. 2006). These bioactivities were corroborated by our bioassays (Fig. 4, Table 2). We believe that citral will be used especially when the larva leaves a mine. The larva will then crawl into the soil to spin a cocoon (Hering 1951; Zinovjev and Vikberg 1998; Altenhofer and Pschorn-Walcher 2006) and may be easily attacked by foraging ground-dwelling arthropods such as ants. A similar situation is found in another endophytic nematine, the apple sawfly *Hoplocampa testudinea*, which also pupates in the soil. The size of ventral glands increases in an allometric way once the larva becomes full-grown, the glandular secretion then becomes obvious, and the defense is efficient against ants (Boevé et al. 1997). The ontogenic increase in *P. mentiens* chemical defense was reflected in our bioassays by the significant difference between full-grown larvae, which were not approached, and younger ones.

There seems to be no direct influence of the host-plant on the biosynthesis of monoterpenes by Pseudodineurini larvae. Citral is the major compound of the glandular secretion not only in the Pseudodineurini but also in the alder-feeding *Nematinus* species (Boevé et al. 1984), and it is detected in two spruce-feeding *Pristiphora* species, *Pristiphora compressa* and *Pristiphora pallida* (Boevé, personal observation). The independence between host-plant (chemistry) and chemical composition of the glandular secretion also is observed in other nematine sawflies: for benzaldehyde produced by *Nematus* and *Pristiphora* species and for dolichodial produced by *Nematus* and *Craesus* species (Boevé et al. 1992; Boevé and Heilporn 2009). Thus, these genera as well as Pseudodineurini probably produce the major compounds of their glandular secretion de novo.

Not all phylogenetic relationships among the studied Pseudodineurini species could be resolved. However, it is obvious that *P. clematidisrectae* and *P. clematidis* are sister species, as are probably *P. parvula* and *P. enslini*. The interesting point is that in both species pairs, one species produces the 8-oxocitral isomers, the other does not. This implies that the production of 8-oxocitrals is not a synapomorphic trait for a certain subgroup of Pseudodineurini. We hypothesize that one or more gene(s) have been switched on/off several times during evolution. Citral might be converted by enzymatic reaction into 8-oxocitral, but it is more likely that geraniol or nerol is first enzymatically oxidized at the terminal position to the respective 8-hydroxygeraniol or 8-hydroxynerol, which is subsequently enzymatically oxidized to the dialdehyde. Since citral occurred in the secretion of all Pseudodineurini, obviously derived from geraniol by oxidation, the same precursor for 8-oxocitral is available in each species. Thus, the on/off switching that leads to the presence or absence of the 8-oxocitrals would require an additional enzyme, namely an oxidase that acts on geraniol, while the final oxidation might be performed by the same enzyme in the case of citral and 8-oxocitral. A potential subsequent step is the cyclization of 8-oxocitral into dolichodial. This is a major compound of the glandular secretion in several nematine sawflies (Boevé et al. 1984, 1992; Boevé and Heilporn 2009). Traces of iridoids such as dolichodial were detected in the glandular secretion of Pseudodineurini larvae, but it is not clear how they are formed. The pathway that involves two enzymatic steps from geraniol or nerol to the dialdehyde is described in leaf beetles, which use these dialdehydes as precursors of defensive iridoids (Veith et al. 1996). 8-Oxocitral is also the precursor of iridoids in plants.

What is the adaptive value of 8-oxocitral, and why does it occur in only some Pseudodineurini species? This monoterpene is inefficient as a defense against attacking small arthropods (Fig. 4), but it is an efficient fungus inhibitor as well as a fungicide (Table 2). Such antifungal activities would be relevant when the larva lives in a mine since feces accumulate therein (Fig. 1), offering a substrate for the proliferation of fungi. Additionally, when a full-grown larva crawls into the soil, it again may be subject to fungal infestation. Living in leaf mines and pupating in the soil are life history traits common to all Pseudodineurini larvae, and it does not explain why only some *Pseudodineura* species produce 8-oxocitral. There is, however, a parallel between an abiotic factor in the biotope where species live, as recorded in Altenhofer and Pschorn-Walcher (2006), and the presence vs. absence of 8-oxocitral. The humid and cold zones species *P. clematidis*, *P. enslini*, and *P. fuscula* produce 8-oxocitral, whereas the xerotherm species *P. clematidisrectae*, *P. heringi*, and *P. parvula* do not (P=0.05, Fisher exact probability test; N=6 species, not considering *P. mentiens* that showed variable chemical data, see below). We, thus, think that larvae crawling into a relatively warm and dry soil are less susceptible to fungal infestation, and that the production of 8-oxocitral may be less necessary. Indeed, entomopathogenic fungi are rarer in dry zones than in humid ones (Hall and Papierok 1982), and they require a high relative humidity, of at least 92–93%, for sporulation and for spore germination on insect adults and larvae (Deacon 1997). In this context, it is noteworthy that only the geographic distribution of *P. enslini*, *P. fuscula*, and *P. mentiens* extends into the humid cold zones of North Europe (Viramo 1969), and these species produce 8-oxocitral. Once the mining habit and the production of citral evolved in the ancestor of the Pseudodineurini, the production of 8-oxocitral may have been opted by those species living in relatively humid and cold zones.

We have no clear answer whether the adaptation to produce 8-oxocitral happened at a specific or subspecific level. Two samples of *P. fuscula* larvae were chemically

analyzed. The larvae came from two different populations, one collected on *R. bulbosus* and the other on *R. platanifolium*. 8-Oxocitral was detected in both samples. In contrast, larvae from one population of *P. mentiens* contained 8-oxocitral, whereas another sample did not. Interestingly, these latter larvae were collected from the xerotherm biotope (location "Langenlois"; Table 1). This suggests that, at least for *P. mentiens*, the production of 8-oxocitral is an adaptation at the population level. The intraspecific variation that we observed at the genetic level in several species should be studied more carefully to see whether it is linked to the (sub)-specific production of 8-oxocitral.

Our study began by asking why a larva that lives concealed and protected in a mine also would produce a defensive volatile secretion. By investigating the occurrence of citral in the larvae, the discrete occurrence of the biosynthetically related 8-oxocitral was incidentally detected. This stimulated us to reconstruct the phylogeny of the insect group and to compare the bioactivities of both compounds. It was surprising that 8-oxocitral was detected, twice, in only one of two closely related species. Further, the bioassays were at first restricted to ant repellence tests. We expected a higher activity with 8-oxocitral than citral since the former compound possesses two (reactive) aldehyde groups. When the bioassay results showed the opposite antifungal tests were performed due to the observation that feces accumulate in a leaf mine. These results led to the conclusion that abiotic factors play an important role in selecting for 8-oxocitral, since it is present in species that live in cold and humid areas. The efforts of a multidisciplinary team were necessary in order to integrate this accumulation of unpredictable results and to construct a more comprehensive picture of the evolution of a particular defense strategy in insects. Finally, M. Hering who devoted his life to leaf-mining insects mentions as an epigraph a sentence by J. Swammerdam that is strangely connected to our work: *Ich habe mir sagen lassen*, *in heißen Ländern fände man zwischen den Blättern daumenlange Würmer* (Hering 1935-1937), i.e., "I was informed that in warm countries one can find inch-long worms between the leaves."

Acknowledgements JLB performed the GC–MS analyses in the lab of Monika Hilker (Berlin, Germany), with the technical assistance of Frank Müller. Filip De Block provided JLB with ants. Many thanks, also, to the collectors of sawfly specimens used in the genetic analyses and to Tommi Nyman, Herbert R. Jacobson, and two anonymous reviewers for critical and helpful reading of the manuscript. For phylogenetic analyses, funding was provided by the Joint Experimental Molecular Unit (project ECES_PSEU) that is supported by the Belgian Science Policy Office.

Received: 29 December 2008 / Revised: 11 March 2009 / Accepted: 13 April 2009 / Published online: 5 May 2009

Abstract A comparative study was conducted to assess the contact and fumigant toxicities of eleven monoterpenes on two important stored products insects—, *Sitophilus oryzae*, the rice weevil, and *Tribolium castaneum*, the rust red flour beetle. The monoterpenes included: camphene, (+)-camphor, (−)-carvone, 1-8-cineole, cuminaldehyde, (L)-fenchone, geraniol, (−)-limonene, (−)-linalool, (−)-menthol, and myrcene. The inhibitory effect of these compounds on acetylcholinesterase (AChE) activity also was examined to explore their possible mode(s) of toxic action. Although most of the compounds were toxic to *S. oryzae* and *T. castaneum*, their toxicity varied with insect species and with the bioassay test. In contact toxicity assays, (−)-carvone, geraniol, and cuminaldehyde showed the highest toxicity against *S. oryzae* with LC_{50} values of 28.17, 28.76, and 42.08 μg/cm^2, respectively. (−)-Carvone (LC_{50}= 19.80 μg/cm^2) was the most effective compound against *T. castaneum*, followed by cuminaldehyde (LC_{50}= 32.59 μg/cm^2). In contrast, camphene, (+)-camphor, 1-8-cineole, and myrcene had weak activity against both insects (i.e., LC_{50} values above 500 μg/cm^2). In fumigant toxicity assays, 1-8-cineole was the most effective against *S. oryzae* and *T. castaneum* (LC_{50}=14.19 and 17.16 mg/l, respectively). Structure-toxicity investigations revealed that (−)-carvone—, a ketone—, had the highest contact toxicity against the both insects. 1-8-Cineole—, an ether—, was the most potent fumigant against both insects. In vitro inhibition studies of AChE from adults of *S. oryzae* showed that cuminaldehyde most effectively inhibited enzyme activity at the two tested concentrations (0.01 and 0.05 M) followed by 1-8-cineole, (−)-limonene, and (L)-fenchone. 1-8-Cineole was the most potent inhibitor of AChE activity from *T. castaneum* larvae followed by (−)-carvone and (−)-limonene. The results of the present study indicate that (−)-carvone, 1,8-cineole, cuminaldehyde, (L)-fenchone, and (−)-limonene could be effective biocontrol agents against *S. oryzae* and *T. castaneum*.

Introduction

Monoterpenes are common essential oil constituents that provide the essence and the odor of a plant. Several hundred naturally occurring monoterpenes are known. They are biosynthesized from geranyl pyrophosphate, the ubiquitous acyclic C_{10} intermediate of the isoprenoid pathway (Windholz et al. 1983). Monoterpenes can be classified into two major groups: monoterpene hydrocarbons that include acyclic aliphatic, monocyclic aliphatic, and dicyclic aliphatic and oxygenated monoterpenes that include acyclic monoterpenoids, monocyclic monoterpenoids, and dicyclic

monoterpenoids. The latter group includes many alcohols, aldehydes, ketones, ethers, and acids (Templeton 1969).

Monoterpenes exert a wide spectrum of biological actions that are important in food chemistry, chemical ecology, and the pharmaceutical industry. Also, their insecticidal and herbicidal properties suggest their importance as potential pest control agents (Kohli et al. 1998; Isman 1999, 2000; Romagni et al. 2000). Monoterpenes possess acute contact and fumigant toxicity to insects (Shaaya et al. 1991; Grodnitzky and Coats 2002; Lee et al. 2004; Waliwitiya et al. 2005; Choi et al. 2006; Kordali et al. 2006; Samarasekera et al. 2008), repellent activity (Mason 1990; Watanabe et al. 1993), antifeedant activity (Hough-Goldstein 1990; Hummelbrunner and Isman 2001; Argandoña et al. 2002), as well as development and growth inhibitory activity (Gunderson et al. 1985; Karr and Coats 1992). These interesting biological activities are attributed to the physical–chemical properties of monoterpenes that include: (1) lipophilicity and low vapor pressure (resulting in their non-persistence in soil and limited leaching into ground water), (2) low mammalian toxicity, and (3) novel modes of action. As such, monoterpenes provide many prototypes for the synthesis of new pesticides (Dayan et al. 1999; Isman 2000).

Fumigant and contact toxicities of some monoterpenes on rice weevil adults, *Sitophilus oryzae* (L.) (Kim and Ahn 2001; Park et al. 2003) and the rust red flour beetle, *Tribolium castaneum* (Herbst) (Rice and Coats 1994; Prates et al 1998; Lee et al. 2001a, 2003, 2004) have been demonstrated. However, most of these studies were preliminary since the values of median lethal concentration (LC_{50}) for monoterpenes on both insects were not estimated. In addition, the inhibitory effect of monoterpenes on *S. oryzae* and *T. castaneum* acetylcholinesterase, a target enzyme of neurotoxic insecticides, were not reported.

Therefore, the aim of the present work was to study the comparative contact and fumingant toxicities of different classes of monoterpenes on *S. oryzae* and *T. castaneum*. The in vitro inhibitory effect of monoterpenes on acetylcholinesterase (AChE) activity was examined to explore the mode-of-action of these compounds and to elucidate structure–insecticidal activity relationships.

Materials and Methods

Chemicals The monoterpenes, camphene (95%), (+)-camphor (98%), (−)-carvone (98%), 1-8-cineole (99%), cuminaldehyde (98%), (L)-fenchone (98%), geraniol (98%), (−)-limonene (96%), (−)-linalool (95%), (−)-menthol (98%), and myrcene (90%) were purchased from Sigma–Aldrich Chemical Co., Steinheim, Germany. Chemical structures of test monoterpenes are shown in Fig. 1. Malathion (95%; American Cyanamid Co, USA) was used as a reference insecticide. Acetylthiocholine iodide (ATChI) and 5,5′-dithio-bis(2-nitrobenzoic) acid (DTNB) were purchased from Sigma–Aldrich Chemical Co., USA.

Test Insects All experiments were conducted in the laboratory with colonies of the rice weevil *Sitophilus oryzae* (L.) (Coleoptera: Curculionidae) and the rust red flour beetle *Tribolium castaneum* (Herbst) (Coleoptera: Tenebrionidae). Colonies were maintained in our laboratory for over 10 years without exposure to insecticides. *S. oryzae* was reared on sterilized whole wheat. *T. castaneum* was reared on wheat flour mixed with yeast (10:1, *w*/*w*). Insect rearing and all experimental procedures were carried out at 26± 1°C, 65±5% RH, and a L/D regime of 12:12 h. Adult insects used in toxicity studies were 2-week post-emergence.

Contact Toxicity Assay The insecticidal activity of eleven monoterpenes against the adults of *S. oryzae* and *T. castaneum* was evaluated by direct contact application assay (Qi and Burkholder 1981; Broussalis et al. 1999). A series of concentrations of each was prepared in acetone. One milliliter of each concentration was applied on the bottom of a glass Petri dish (9 cm diam) to give a range of concentrations (0.01–500 μg/cm^2). Solvent was allowed to evaporate for 2 min prior to introduction of insects. Twenty adults of each insect were separately placed into Petri dishes. Control dishes were treated with acetone alone. All treatments were replicated four times. Malathion was used as a reference insecticide. Mortality percentages were recorded after 24 h of treatment, and LC_{50} values were calculated according to Finney (1971).

Fumigant Toxicity Assay The toxicity of monoterpene vapors was tested against *S. oryzae* and *T. castaneum* adults by using a modified fumigant toxicity assay as described by Huang et al. (2000). Glass jars (1 l) were used as fumigation chambers. Monoterepenes were applied to filter paper pieces (2×3 cm) attached to the undersurface of the screw caps of jars at: 1, 2.5, 5, 10, 15, 20, 30, 40, 60, 80, 90, and 100 mg. The inner side of the jar's neck was painted with Vaseline to prevent direct contact of insects with monoterpenes. Caps were screwed tightly onto the jars containing 20 insects of *S. oryzae* or *T. castaneum* in each one. Control insects were kept under the same conditions without monoterpenes. Four replicates of each treatment were set up. The number of dead insects was counted after 24 h of treatment, and the mortality percentages and LC_{50} values were calculated according to Finney (1971).

AChE Activity Assay S. oryzae adults and *T. castaneum* larvae (0.5 g) were separately homogenized in 5 ml of 0.1 M ice-cold phosphate buffer (pH 7.0) using a Teflon glass tissue

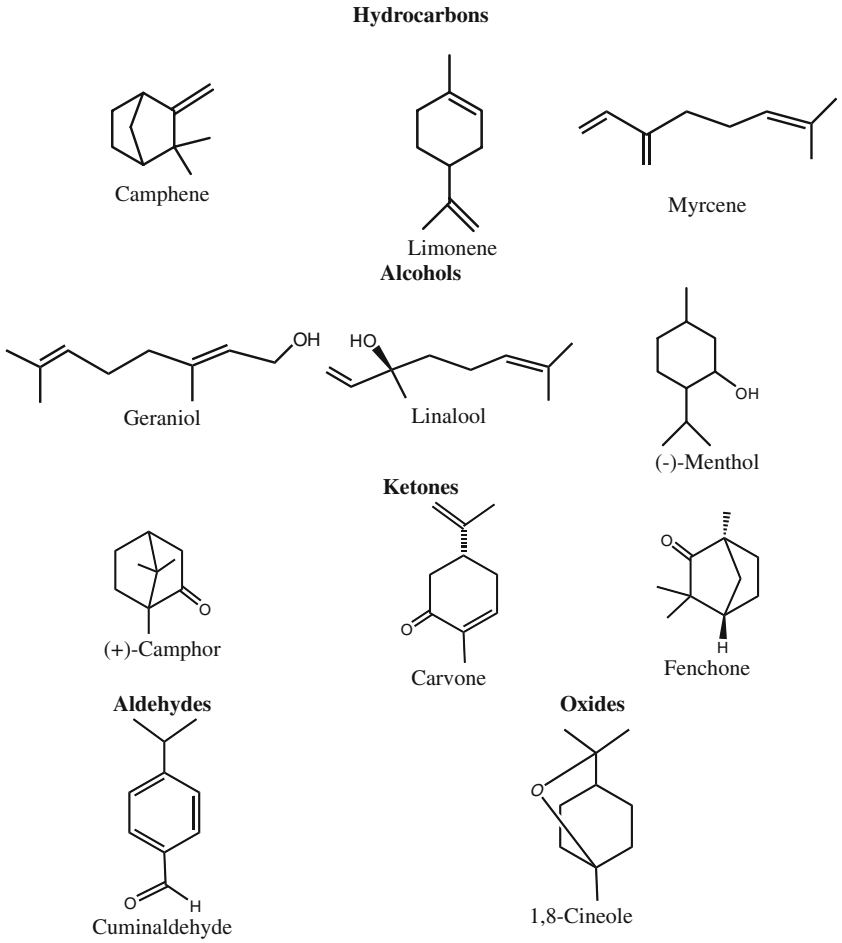

Fig. 1 The chemical structures of the monoterpenes tested

homogenizer. Homogenates were centrifuged (5,000 rpm for 20 min at 0ºC), and supernatants were used as the enzyme source for determination of AChE activity. Inhibition of AChE was determined by the colorimetric method of Ellman et al. (1961) using ATChI as substrate. Enzyme aliquots (50 µl) and DTNB (100 µl of 0.01 M) were added to 0.1 M phosphate buffer (pH 8.0; 2.8 ml). To this mixture, monoterpene test solutions (20 µl) prepared in dimethyl sulfoxide (DMSO) were added. Control treatments were prepared by the addition of DMSO (20 µl) in place of a monoterpene. Mixtures were incubated at 37ºC for 15 min. Reactions were started by adding ATChI (30 µl) followed by incubation at 37ºC for 10 min. Absorbance was measured at 412 nm using of Unico 1200-Spectrophotometer. Tested compounds were examined at two concentrations 0.01 and 0.05 M. Each test and control was corrected by blanks for nonenzymic hydrolysis. All the experiments were done in triplicate. Inhibition percentage of AChE activity was calculated as follows:

$$\text{AChE inhibition}(\%) = \frac{(OD_B - OD_T)}{OD_B} \times 100$$

where OD_B is the optical density of blank enzyme and OD_T is the optical density of treatment.

Statistical Analysis The concentration-mortality data were subjected to Probit analysis (Finney 1971) to obtain the LC_{50} values using the SPSS 12.0 software program (Statistical Package for Social Sciences, USA). The values of LC_{50} were considered to be significantly different, if 95% confidence limits did not overlap. The data of AChE inhibition was analyzed by one-way analysis of variance. Mean separations were performed by Student–Newman–Keuls (SNK) test and differences at $P<0.05$ were considered as significant.

Results and Discussion

Contact Toxicity The contact toxicity of 11 monoterpenes and a reference insecticide—malathion—was evaluated against *S. oryzae* and *T. castaneum* by using a residual film method. LC_{50} values, their 95% confidence limits expressed as microgram per square centimeter, and the slopes of toxicity regression lines are shown in Tables 1 and 2. (−)-Carvone and geraniol were the most effective among the monoterpenes tested against *S. oryzae* with LC_{50} values

of 28.17 and 28.76 μg/cm^2, respectively. Cuminaldehyde (an aldehyde monoterpene) and (−)-linalool (alcoholic monoterpene) also had relatively strong toxicities (LC_{50}= 42.08 and 66.74 μg/cm^2, respectively), while (−)-menthol (LC_{50}=221.68 μg/cm^2) and (L)-fenchone (LC_{50}= 291.80 μg/cm^2) elicited moderate toxic effects. Camphene and myrcene (hydrocarbon monoterpenes), (+)-camphor (a ketone monoterpene), and 1-8-cineole (an oxide monoterpene) had the lowest toxicity with LC_{50} values above 500 μg/cm^2. The alcoholic monoterpenes -, geraniol, (−)-linalool, and (−)-menthol—, possessed pronounced activity, whereas the hydrocarbon monoterpenes—, camphene, (−)-limonene, and myrcene—, were less active (Table 1).

Contact toxicity assays of monoterpenes on *T. castaneum* larvae shown in Table 2 revealed that (−)-carvone was the most effective compound, followed by cuminaldehyde and (−)-linalool, LC_{50} values of 19.80, 32.59, and 105.63 μg/cm^2, respectively. These results are similar to *S. oryzae* data (Table 1). (L)-Fenchone (a ketone monoterpene) and geraniol (alcoholic monoterpene) were of moderate toxicity against *T. castaneum* (LC_{50}=179.49 and 195.02 μg/cm^2, respectively). In contrast, camphene, (+)-camphor, 1-8-cineole, (−)-menthol, and myrcene had weak toxicity (i.e., LC_{50} values greater than 500 μg/cm^2).

Few studies have reported on monoterpene contact toxicities against *S. oryzae* and *T. castaneum*. For example, Park et al. (2003) found that treatment of *S. oryzae* adults with limonene and myrcene (260 μg/cm^2 after 2 days of contact) resulted in 36% and 10% mortality, respectively. This activity was comparable to the activity of limonene and myrcene reported here. The contact toxicities of fenchone to *S. oryzae* (Kim and Ahn 2001) and of 1-8-cineole and limonene to *T. castaneum* (Prates et al. 1998) have been reported. The activity found in this study for (−)-limonene, myrcene, and camphene on *T. castaneum* agrees with that reported by Garcìa et al. (2005), who stated that limonene had a moderate toxicity, while myrcene and camphene were inactive.

Fumigant Toxicity of Monoterpenes The toxicity of monoterpene vapors to *S. oryzae* and *T. castaneum* are summarized in Tables 3 and 4. Test compounds arranged by monoterpene class displayed varied toxicity against the two insects. 1-8-Cineole and (−)-carvone had the highest toxicity toward *S. oryzae* with LC_{50} values of 14.19 and 17.78 mg/l, respectively. (−)-Limonene, myrcene, and (L)-fenchone possessed lower fumigant activity (LC_{50}=26.92, 27.37, and 29.61 mg/l, respectively), while (−)-linalool, menthol, and cuminaldehyde had only moderate toxicity (LC_{50}=52.78, 61.75 and 71.40 mg/l, respectively). With LC_{50} values above 100 mg/l, camphene, (+)-camphor, and geraniol, were the least effective compounds.

Among monoterpenes tested against *T. castaneum,* 1-8-cineole had the lowest LC_{50} value of 17.16 mg/l (Table 4). The hydrocarbon monoterpenes myrcene and (−)-limonene had pronounced toxicity with LC_{50} values of 31.70 and 33.37 mg/l, respectively). Camphene, (+)-camphor, cuminaldehyde, geraniol, (−)-linalool, and (−)-menthol were

significantly less toxic with LC_{50} values greater than 100 mg/l.

The fumigant toxicity of some of the test monoterpenes (i.e., camphor, 1-8-cineole, geraniol, limonene, and linalool) have been examined previously against *S. oryzae* (Lee et al. 2001a, 2003). The toxicity of these compounds was in general agreement with the data presented in this report. However, 1-8-cineole, limonene, and fenchone also possessed fumigant toxicity against *T. castaneum* (Prates et al. 1998; Lee et al. 2003, 2004).

Toxicity of the test monoterpenes varied with insect species and bioassay method. For example, in contact assays, geraniol, (−)-linalool, and (−)-menthol were more toxic to *S. oryzae,* whereas (−)-carvone, cuminaldehyde,

and (L)-fenchone were more effective on *T. castaneum*. Camphene, camphor, 1-8-cineole, (−)-limonene, and myrcene had approximately the same toxicity against both insects. Most test compounds in fumigant assays were more effective toward *S. oryzae* than *T. castaneum,* except for camphene, camphor, and geraniol that had weak activity toward both insects. Differential toxicities to *S. oryzae* and *T. castaneum* by monoterpenes have been noted previously (Lee et al. 2003, 2004).

Assay method impacted the toxicity of monoterpenes. For example, 1-8-cineole and myrcene had pronounced fumigants toxicity toward *S. oryzae* but were weak contact toxicants. In contrast, geraniol was an effective contact toxicant against *S. oryzae*, but was a weak fumigant. With *T. castaneum*, 1-8-cineole and myrcene were among the most toxic compounds in fumigant assays, but the two compounds were only weakly toxic in contact assays. Cuminaldehyde, geraniol, and (−)-linalool had strong contact toxicity but weak fumigant activity, while (−)-limonene showed the reverse. It is clear that assay method impacts the toxicity and efficacy of the test monoterpenes. Similar conclusions have been reported regarding the insecticidal activity of monoterpenes against stored product insects (Prates et al. 1998; Park et al. 2003).

The contact and fumigant toxicities of various monoterpenes and how activity varies with structure was investigated. (−)-Carvone, a ketone, showed the highest contact toxicity, while an aldehyde (cuminaldehyde) and an alcohol ((−)-linalool) were more toxic than other oxygenated and non-oxygenated monoterpenes. In contrast, 1-8-

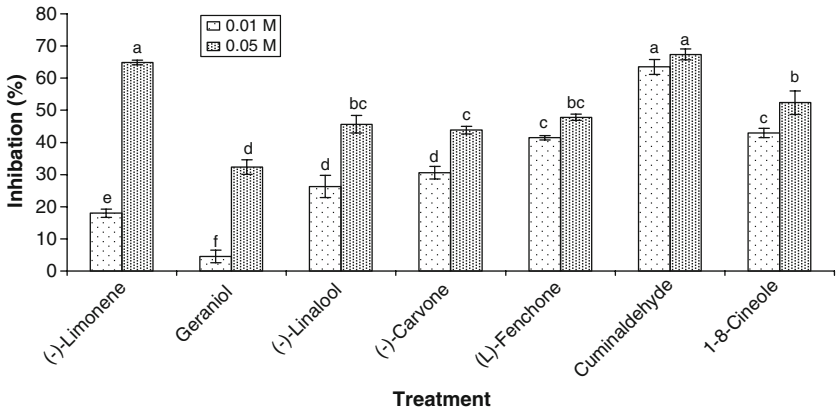

Fig. 2 In vitro inhibition of *Sitophilus oryzae* adult acetylcholinesterase activity by monoterpenes. Data are means ± SE of three replicates. *Different letters* are significantly different at 0.05 level

cineole, an ether-containing monoterpene, was the most potent fumigant. This finding agrees with Lee et al. (2003) who stated that 1-8-cineole was more toxic than some ketone compounds. Two hydrocarbons—, (−)-limonene (a monocyclic monoterpene) and myrcene (an acyclic monoterpene) were among the most active fumigant toxicants. (−)-Carvone and (L)-fenchone (both ketones) were more effective than either of the alcohols, i.e., (−)-linalool and geraniol. Similarly, Rice and Coats (1994) found that some ketones were more effective fumigants than alcohols. These observations raise the possibility that the presence of a carbonyl group augments toxicity.

Inhibitory Effect of Monoterpenes on AChE Activity The in vitro inhibitory effect of monoterpenes on AChE from adults of *S. oryzae* and larvae of *T. castaneum* was examined at 0.01 and 0.05 M (Figs. 2 and 3). Cuminaldehyde was the most effective inhibitor of *S. oryzae* AChE activity (63.50% and 67.35% at 0.01 and 0.05 M, respectively), followed by 1-8-cineole (42.96% and 52.37% at 0.01 and 0.05 M, respectively), and (−)-limonene (64.86% at 0.05 M). In contrast, geraniol was the least effective inhibitor of *S. oryzae* AChE at the two concentrations (4.51% and 32.33% at 0.01 and 0.05 M, respectively).

The inhibitory effects of monoterpenes on AChE derived from *T. castaneum* larvae indicated that a 1-8-cineole had the greatest inhibitory activity and there was no significant difference between the two concentrations (64.90% and 70.53% at 0.01 and 0.05 M, respectively). This was followed by (−)-carvone (56.79% and 70.20% inhibition at 0.01 and 0.05 M, respectively) and (−)-limonene (42.63% and 51.66% at 0.01 and 0.05 M, respectively).

Our results agree with the reports of others regarding the inhibitory activity of monoterpenes on AChE activity. Of four monomterpenes (1-8-cineole, (−)-carvone, (−)-limonene, or (−)-linalool, 1,8-cineole was the most inhibitory toward electric eel AChE activity (Picollo et al. 2008). In addition, monoterpenes have been shown to be effective inhibitors of AChE's from eel, housefly, and bovine erythrocyte (Gracza 1985; Grundy and Still 1985; Ryan and Byrne 1988; Miyazawa et al. 1997).

Comparing monoterpene toxicity against *S. oryzae* with the inhibitory effects on AChE activity from the same insect show that some of the monoterpenes possess strong insecticidal activity and potent AChE inhibitory activity—, e.g., cuminaldehyde, 1-8-cineole, (−)-limonene, and (L)-fenchone. However, other compounds (e.g., (−)-carvone and geraniol) have strong insecticidal activity but are weak inhibitors of AChE. Similarly, Lee et al. (2001b) did not find a direct correlation between insect toxicity and AChE inhibition by menthone or β-pinene. These findings suggest that AChE may be a target for monterpenes but does not rule out that there may be other targets.

The development of natural insecticides would help to decrease the negative impact of synthetic insecticides, such as residues, resistance, and environmental pollution. In this respect, natural insecticides may be effective, selective, biodegradable, and less harmful to the environment. In the present study, monoterpenes such as (−)-carvone, 1,8-cineole, cuminaldehyde, (L)-fenchone, and (−)-limonene showed strong contact and/or fumigant toxicities against *S. oryzae* and *T. castaneum*. Based on these findings, these or other monoterpenes may serve as viable alternatives to synthetic insecticides.

Enhanced Toxicity and Induction of Cytochrome P450s Suggest a Cost of "Eavesdropping" in a Multitrophic Interaction

Ren Sen Zeng · Zhimou Wen · Guodong Niu · Mary A. Schuler · May R. Berenbaum

Received: 19 January 2009 / Revised: 14 March 2009 / Accepted: 29 April 2009 / Published online: 12 May 2009

Abstract The inducibility of cytochrome P450 monooxygenases (P450s) and other xenobiotic-metabolizing enzymes is thought to reflect material and energy costs of biosynthesis. Efforts to detect such costs of detoxification enzyme induction, however, have had mixed success. Although they are rarely considered, ecological costs of induction may be a more significant evolutionary constraint on herbivores than material and energy costs. Because some P450-mediated metabolic transformations are bioactivation reactions that increase, rather than reduce, toxicity, maintaining high levels of P450 activity places an organism at risk of greater mortality in the presence of compounds that are bioactivated. We show that P450 inducibility in the generalist moth *Helicoverpa zea* in response to plant signaling substances, an adaptive response in a ditrophic interaction between herbivore and plant, becomes detrimental in the presence of a third trophic association with a plant pathogen that produces aflatoxin, a toxin that can be bioactivated by P450s. Consumption of plant signaling molecules, such as methyl jasmonate (MeJA) and salicylic acid (SA) enhanced the toxicity of aflatoxin B1 (AFB1) to *H. zea* that resulted in substantially more damage to larval growth and development. Among the P450 transcripts already cloned from this organism, two in the CYP6B and CYP321A subfamilies are shown to be induced in response to MeJA and SA, suggesting that they may mediate some of the observed bioactivations.

Introduction

As primary producers in most terrestrial trophic webs, plants are at risk of attack by a broad spectrum of consumers, including both pathogens and herbivores, and their principal defense is the production of toxic compounds. Different suites of defense genes are activated in response to potential consumers via several interacting signaling pathways in plants. In a wide variety of species, mechanical damage, including that inflicted by chewing herbivores, activates many genes that are responsive to jasmonic acid (JA) and related octadecanoids, including methyl jasmonate (MeJA) and 12 oxophytodienoic acid (OPDA) (Kessler and Baldwin 2002; Moran and Thompson 2001; Reymond et al. 2000, 2004). Feeding damage, along with insect-specific elicitors such as volicitin, a fatty acid conjugate, induces the synthesis of octadecanoid signals, which in turn can trigger production of toxins and antinutritive substances that deter further herbivory (Pechan et al. 2000; Lou and Baldwin 2004; Mewis et al. 2005). Similarly, infection by pathogens in many plant species leads to induction of salicylic acid, which in turn induces broad-spectrum protection against subsequent pathogen

infection through a variety of mechanisms (Yang et al. 1997; De Vos et al. 2005). Although mechanical damage does not lead to increased production of salicylic acid (SA) (DeMoraes et al. 2004), insect herbivory is in some cases associated with elevated SA production (Bi et al. 1997), and, because salicylate can inhibit JA production (Harms et al. 1998), cross-talk and interactions among these signaling pathways collectively determine patterns of plant chemical defense responses to herbivory.

Helicoverpa zea (Boddie) (Lepidoptera: Noctuidae) is a highly polyphagous caterpillar that utilizes over 100 plant species as hosts (Wiseman 1999). In this species, cytochrome P450s (P450s) are responsible for metabolizing a broad range of the allelochemicals encountered in the diet. Heterologous expression of individual P450s demonstrated that at least two of the P450s from this species, CYP6B8 and CYP321A1, are broadly substrate-specific (Li et al. 2004; Sasabe et al. 2004). That CYP6B8 transcripts can be induced by ingestion of JA suggests that *H. zea* can "eavesdrop" on the signaling systems of plants by responding to these signals via upregulation of particular sets of P450s prior to the biosynthesis of defense chemicals in plants (Li et al. 2002b).

Infestation by *H. zea* predisposes some plants to infection by fungi, particularly the *Aspergillus* ear molds that produce aflatoxins (Lillehoj 1992; Dowd 1998), dihydrofurocyclopentenones and dihydrofurolactones that form irreversible adducts to nucleic acids with concomitant inhibition of DNA replication and DNA-dependent transcription (Murray et al. 1982; Iyer et al. 1994). In vertebrates, some P450s catalyze the epoxidation of the terminal furan ring of aflatoxin B1 (AFB1) to yield AFB1-8,9-epoxide (AFBO), a highly genotoxic metabolite (Murray et al. 1982). In the Hikone-R strain of the fruit fly, *Drosophila melanogaster*, bioactivation of AFB1 is catalyzed by CYP6A2 (Saner et al. 1996). In contrast, however, the caterpillar *Amyelois transitella* (navel orangeworm), which frequents fungus-contaminated fruit tissue, produces aflatoxicol (AFL) as the major aflatoxin metabolite and does not produce AFBO as a metabolite at all, thus leading Lee and Campbell (2000) to suggest that the absence of this particular biotransformation is indicative of coevolution between kernel-feeding insects and toxin-producing fungi.

Helicoverpa zea larvae do not regularly encounter aflatoxins across their many hosts, and they are highly sensitive to low concentrations of these mycotoxins in their diet (Dowd 1988; Zeng et al. 2006), which suggests that P450-mediated metabolism of aflatoxins may result in bioactivation rather than detoxification in this species. Because "eavesdropping" on plant signaling systems results in increased transcription of particular sets of P450s in *H. zea* (Li et al. 2002b), we examined the transcript profiles for several P450s previously cloned in this species (Li et al. 2002a, b; Sasabe et al. 2004) in response to signaling substances and aflatoxin B1. We show here that P450 inducibility in *H. zea* in response to plant signaling substances appears to be detrimental, rather than beneficial, in the presence of a mycotoxin, which is produced as a consequence of an additional trophic association between a plant and its phytopathogen.

Methods and Materials

Chemicals Aflatoxin B1 (AFB1), methyl jasmonate (MeJA), and salicylic acid (SA) were obtained from Sigma-Aldrich (St. Louis, MO, USA). Analytical grade dimethyl sulfoxide (DMSO) was purchased from Fisher Scientific (Fair Lawn, NJ, USA). RQ1 DNase, RNasin, and AMV reverse transcriptase were from Promega (Madison, WI, USA), Taq polymerase and deoxynucleotide triphosphates (dNTPs) were from Invitrogen (Carlsbad, CA, USA), and the TRIzol reagent was from Gibco-BRL (Cleveland, OH, USA).

Insects A laboratory colony of *H. zea*, initiated from caterpillars collected in Champaign County, IL in sweet corn, was used for all studies. *H. zea* larvae were reared individually on a semi-synthetic control diet containing wheat germ (Waldbauer et al. 1984), and maintained in an insectary kept at 23–26°C with a photoperiod of 16:8 h | L:D. Caterpillars were collected within 12 h of new molting to ensure that they were homogeneous in their developmental age.

Bioassays Stock solutions of AFB1 were prepared at a concentration of 1 µg/µl in DMSO, SA was prepared at concentrations of 1 mg/µl and 12 µg/µl, and MeJA was prepared at concentrations of 100 µg/µl and 2.9 µg/µl, all in DMSO; these solutions were included in diets with final concentrations of DMSO not exceeding 0.2%. Newly molted fourth and fifth instars were assayed with 20 larvae per treatment, with two sets of experiments performed for each developmental stage. In the first set of SA experiments, larave were placed on diets containing either 0.2% DMSO (control), SA (1 mg/g, High SA [H-SA]; or 12 µg/g, Low SA [L-SA]), 1 µg/g AFB1 or [1 µg/g AFB1 + H-SA or L-SA]. In the second set of MeJA experiments, larvae were provided with diets containing either 0.2% DMSO (control), MeJA (100 µg/g, High MeJA [H-MeJA]; or 2.9 µg/g, Low MeJA [L-MeJA]), 1 µg/g AFB1 or [1 µg/g AFB1 + H-MeJA or L-MeJA]. Larvae exposed to the four different diets in each set of experiments were individually reared in 30-ml plastic cups in an insectary at 23–26°C with a photoperiod of 16:8 h | L:D. For fourth instars, mortality was recorded after 8 d. For fifth instars, weight gain was

measured after 3 d of treatments, and pupation was recorded every day. For individuals surviving through pupation, pupal weights were measured within 24 h of pupation. Each set of bioassays was independently replicated three times.

Statistical Analyses All data were evaluated by two-way factorial analysis of variance (ANOVA) with treatment differences among means tested at $P = 0.05$ by Tukey *post-hoc* test. Data for mortality are the means from three replicates with 20 larvae/treatment after 8 d of treatments.

Transcript Analysis Fifth instar *H. zea* larvae molting within a period of 12 h and within a weight range of about 170–270 mg were grouped randomly. Twenty larvae in each treatment group were switched to diets containing the plant signaling chemicals at the following concentrations: MeJA at 2.9 μg/g diet and 100 μg/g diet, and SA at 12 μg/g diet and 1 mg/g diet. The control was set with caterpillars feeding on a diet containing 0.2% DMSO because this solvent was used for each of the signaling chemicals added to diets. Forty-eight hours after feeding, larval midguts were excised and cleaned in 0.1 M sodium phosphate buffer (pH 7.8). Total RNA was extracted from each group of twenty pooled larvae by using TRIzol reagent treated with 5 U RQ1 DNase for 30 min at 37°C, cleaned up with a Qiagen RNeasy kit (Valencia, CA, USA), quantified by A_{260}, and stored at −80°C.

RT-PCR Southern Analysis RT-PCR Southern analyses were used to measure semi-quantitatively the induction of the *CYP6B8* and *CYP321A1* transcripts. To keep RT-PCR signals within their linear ranges, amplification conditions for P450 and actin (control) transcripts were checked by varying PCR cycle numbers and RNA amounts to achieve conditions not limited by any of the components within these reactions. The final 50 μl RT-PCR reaction mixtures contained 100 ng total RNA, 0.5 μl RNasin (40 U/μl), 0.5 μl AMV reverse transcriptase (10 U/μl), 0.25 μl Taq polymerase (5 U/μl), 25 μl 2x RT buffer containing dNTPs and 1 μl (10 μM) of each forward and reverse primer. The gene-specific forward/reverse primer sets used in these reactions were: 5′-TCTTGTGGACAGCATTATTAGC-3′ and 5′-CAAGTCCGAATGGTAAGTACGC-3′ for *CYP6B8*, 5′-TAGTGTGGAGGGTGACCAACTG-3′ and 5′-CGGACAACAAGCCAGTCGTAGGC-3′ for *CYP321A1*, and 5′-TGGGAYGAYATGGAGAAGATCTGG-3′ and 5′-TAGATGGGBACBGTGTGBGAGACA-3′ (with Y (C/T) and B (C/G/T)) for actin. The RT-PCR reactions were initiated with a reverse transcription step at 42°C for 50 min, followed by a denaturation step at 94°C for 5 min, 18 cycles of PCR amplification (94°C for 1 min, 60°C for 1 min, 72°C for 2 min) and a final extension step at 72°C for 5 min. Control reactions conducted with cloned CYP6B8 and CYP321A1 templates indicated that, under these conditions, these primer sets were completely gene-specific. For their final quantification, 10 μl of concentrated (6x) 40% sucrose loading dye were added to each reaction, and 20 μl of each PCR product mixture were run on a 1.0% agarose gel containing 1x TBE buffer. After gel-blotting, the Hybond-N membranes (Amersham-Pharmacia Biosciences, Uppsala, Sweden) were pre-hybridized and then hybridized with ^{32}P-labeled gene-specific probes at 42°C overnight in hybridization buffer containing 5x SSC, 5x Denhardt's solution, 50% formamide, 50 mM sodium phosphate (pH 7.0), and 0.5% SDS. Membranes were washed twice at low stringency in buffer containing 2x SSC, 0.1% SDS at 42°C each for 15 min and once at high stringency in buffer containing 0.2x SSC, 0.1% SDS at 62°C for 15 min. Finally, the membranes were autoradiographed and quantified by phosphoimager analysis by using a Typhoon 8600 variable model imager (Amersham-Pharmacia Biotech).

Results and Discussion

To determine the effects of encountering aflatoxin in the presence of plant signaling substances, two sets of experi-

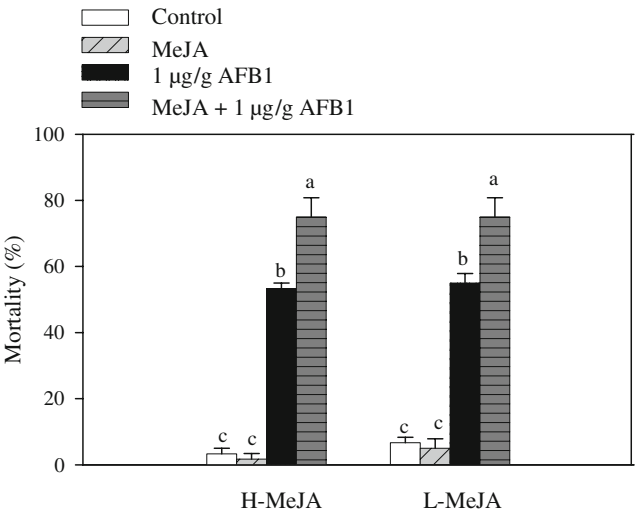

Fig. 1 Effects of methyl jasmonate (MeJA) on mortality of fourth instar *Helicoverpa zea* exposed to 1 μg/g aflatoxin B1 (AFB1) after 8 d. Caterpillars were reared on the diets containing either 0.2% DMSO (control), MeJA (100 μg/g, H-MeJA; or 2.9 μg/g, L-MeJA), 1 μg/g AFB1, or [1 μg/g AFB1 + H-MeJA or L-MeJA]. Values are means + standard error from three replicates with 20 caterpillars/treatment. Significant differences ($P < 0.05$ using Tukey *post-hoc* test) among treatments in a group are indicated by different letters above bars. Two-way ANOVA showed that effects of H-MeJA ($F = 9.6$, $P = 0.015$), AFB1 ($F = 365.1$, $P < 0.001$), and the H-MeJA×AFB1 ($F = 13.1$, $P = 0.007$) interaction were significant, and effects of L-MeJA ($F = 6.368$, $P = 0.036$), AFB1 ($F = 265.3$, $P < 0.001$), and the L-MeJA×AFB1 ($F = 8.895$, $P = 0.017$) interaction were significant

ments were performed on both fourth and fifth instars. In one set, larave were fed diets containing AFB1 in the presence and absence of the signaling substance MeJA; in the second set, larvae received artificial diets containing AFB1 in the presence and absence of the signaling substance SA. The signaling substances were incorporated into diets at low concentrations (MeJA at 2.9 µg/g and SA at 12 µg/g) approximating those produced by *H. zea* host plants as a consequence of herbivory or fungal infection (Seskar et al. 1998; Royo et al. 1999). High concentrations of the signaling compounds were selected to maximize the likelihood of detecting an upper limit on the response.

Although neither signaling substance alone in the diet had any detectable effect on fourth instar larvae for the duration of the bioassay, aflatoxin at a concentration of 1 µg/g affected mortality ranging from 35 to 55%. Both signaling substances further increased this toxicity. Inclusion of 100 µg/g MeJA (H-MeJA) and 2.9 µg/g MeJA (L-MeJA) in the diet increased mortality by 21.7% ($P = 0.006$) and 20%, respectively, compared with larvae exposed only to 1 µg/g AFB1 (Fig. 1). Exposure of fourth instars to diets containing 1 mg/g SA + 1 µg/g AFB1 and 12 µg/g SA + 1 µg/g AFB1 resulted in increases in mortality by 23.3% ($P = 0.021$) and 16.7% ($P = 0.141$) , respectively, compared with larvae exposed only to 1 µg/g AFB1 (Fig. 2).

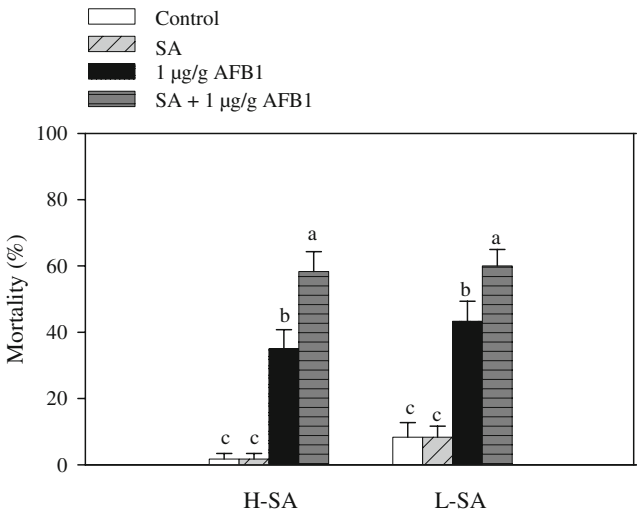

Fig. 2 Effects of salicylic acid (SA) on mortality of fourth instar *Helicoverpa zea* exposed to 1 µg/g aflatoxin B1 (AFB1) after 8 d. Caterpillars were reared on the diets containing either 0.2% DMSO (control), SA (1 mg/g, H-SA; or 12 µg/g, L-SA), 1 µg/g AFB1, or [1 µg/g AFB1 + H-SA or L-SA]. Values are means + standard error from three replicates with 20 caterpillars/ treatment. Significant differences ($P < 0.05$ using Tukey *post-hoc* test) among treatments in a group are indicated by different letters above bars. Two-way ANOVA showed that effects of H-SA ($F = 7.295$, $P = 0.027$), AFB1 ($F = 108$, $P < 0.001$), and the H-SA×AFB1 interaction ($F = 7.259$, $P = 0.027$) were significant, effects of L-SA ($F = 3.030$, $P = 0.119$) and the L-SA×AFB1 interaction ($F = 3.030$, $P = 0.120$) were not significant, the effect of AFB1 ($F = 81.939$, $P < 0.001$) was significant

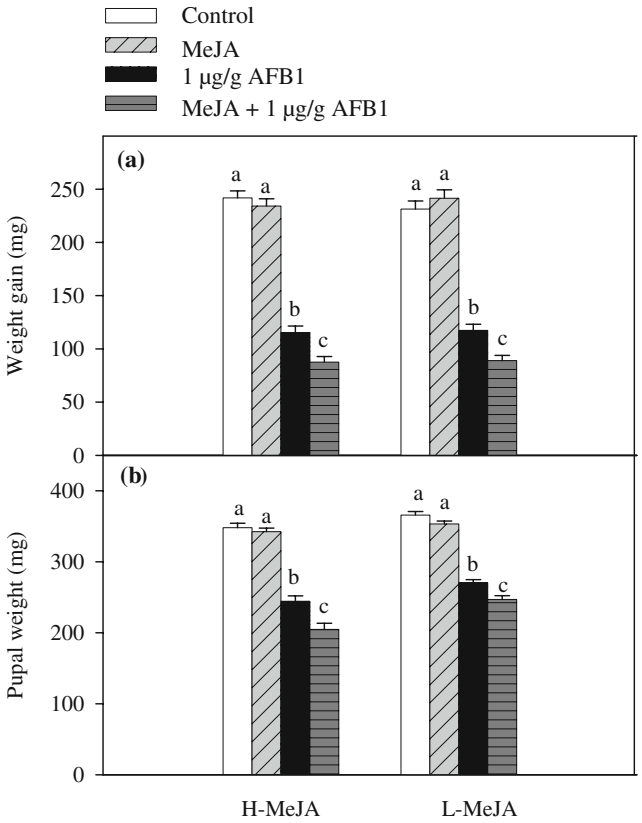

Fig. 3 Effects of methyl jasmonate (MeJA) on (a) weight gain after 3 d and (b) weight within 24 h of pupation for surviving larvae of fifth instar *Helicoverpa zea* exposed to 1 µg/g aflatoxin B1 (AFB1). Larvae were reared on the diets containing either 0.2% DMSO (control), MeJA (100 µg/g, H-MeJA; or 2.9 µg/g, L-MeJA), 1 µg/g AFB1, or [1 µg/g AFB1 + H-MeJA or L-MeJA]. Values for weight gain and pupal weight are means + standard error from three replicates with 20 larvae/ treatment. Significant differences ($P < 0.05$ using Tukey *post-hoc* test) among treatments in a group are indicated by different letters above the bars

An identical pattern was observed in bioassays with fifth instars. Fifth instar larave experienced declines in weight gain and pupal weight of 24.1% ($P = 0.011$) and 16.3% ($P < 0.001$), respectively, in the combined treatment of 100 µg/g MeJA + 1 µg/g AFB1 compared to treatment with 1 µg/g AFB1 alone (Fig. 3a,b). Inclusion of 2.9 µg/g MeJA in the AFB1 containing diet led to significant reduction in weight gain (24.3%, $P = 0.0179$) and pupal weight (8.8%, $P = 0.0016$) compared with larvae exposed only to 1 µg/g AFB1 (Fig. 3a, b). Exposure of fifth instar *H. zea* to diets containing 1 mg/g SA + 1 µg/g AFB1 resulted in a significant reduction in weight gain (36.1%, $P < 0.001$) and pupal weight (13.9%, $P < 0.001$) relative to larvae exposed only to 1 µg/g AFB1 (Fig. 4a, b). Similarly, exposure of fifth instars to diets containing 12 µg/g SA + 1 µg/g AFB1 resulted in significant reduction in weight gain (31.9%, $P < 0.001$) and pupal weight (13.7%, $P < 0.001$) compared with larvae exposed only to 1 µg/g AFB1 (Fig. 4a, b).

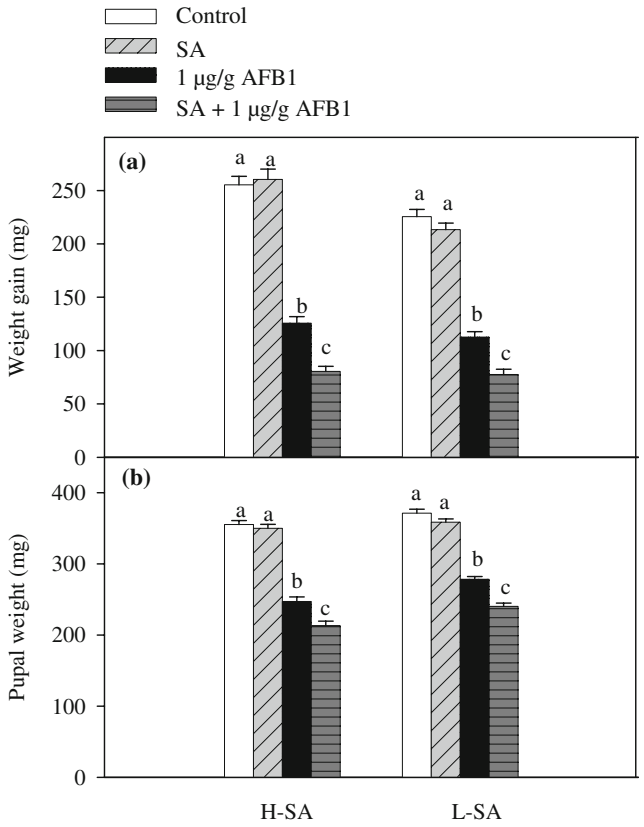

Fig. 4 Effects of salicylic acid (SA) on (a) weight gain after 3 d and (b) weight within 24 h of pupation for surviving larvae of fifth instar *Helicoverpa zea* exposed to 1 µg/g aflatoxin B1 (AFB1). Larvae were reared on the diets containing either 0.2% DMSO (control), SA (1 mg/g, H-SA; or 12 µg/g, L-SA), 1 µg/g AFB1, or [1 µg/g AFB1 + H-SA or L-SA]. Values for weight gain and pupal weight are means + standard error from three replicates with 20 larvae/treatment. Significant differences ($P < 0.05$ using Tukey *post-hoc* test) among treatments in a group are indicated by different letters above the bars

To determine the contributions of P450 upregulation to the increased toxicity of aflatoxin in the presence of signaling substances, transcript profiles for two P450s previously cloned in this species (Li et al. 2002a, b; Sasabe et al. 2004) were defined. RT-PCR analyses (Fig. 5) demonstrate that the *CYP6B8* and *CYP321A1* transcripts are induced to some extent in the presence of these plant signaling substances. Methyl jasmonate and salicylate induce *CYP6B8* and *CYP321A1* transcripts at least 2.1-fold. As mentioned, CYP6B8 and CYP321A1 are broadly substrate-specific enzymes (Li et al. 2004; Sasabe et al. 2004).

Bioactivation of aflatoxins by P450s has been demonstrated as a necessary step in bringing about most of their toxic effects in humans and other animals (Eaton et al. 1994). To date, no epoxide metabolite of aflatoxin has been identified in *H. zea*, although CYP321A1 expressed heterologously converts aflatoxin to aflatoxin P1, its O-demethylated product (Niu et al. 2008). The involvement of P450s in the bioactivation of aflatoxin in *H. zea* is supported by the significant decrease in the toxicity of AFB1 when the P450 inhibitor piperonyl butoxide (PBO) is included in the assay (Zeng et al. 2006), a result that is consistent with bioactivation of aflatoxin to more toxic derivatives by one or more P450s expressed in fourth and fifth instars. Molecular modeling data predict that aflatoxin can fit in the catalytic sites of CYP6B8 (Niu et al. 2008), which may be responsible for the bioactivation of aflatoxin in response to MeJA and SA.

Although evidence in support of a metabolic cost of inducing detoxification enzymes has been inconsistent (Neal 1987; Appel and Martin 1992; Cresswell et al. 1992; Kelley et al. 2002; Agrawal et al. 2002), this study suggests that "eavesdropping," or up-regulation of insect detoxification enzymes prior to plant biosynthesis of defense compounds, can exact a cost in situations where the defense compounds are bioactivated and not detoxified by P450s. The number of plant allelochemicals known to be bioactivated by P450-mediated reactions is limited to several classes that have relatively restricted distributions among plant families. Pyrrolizidine alkaloids, for example, which are bioactivated by P450s (Brattsten 1979), are effectively restricted to the Asteraceae, Fabaceae, and Boraginaceae (Seigler 1998; Stegelmeier et al. 1999). Thus, P450s of herbivorous insects up-regulated by plant signaling substances are likely to catalyze metabolic reactions

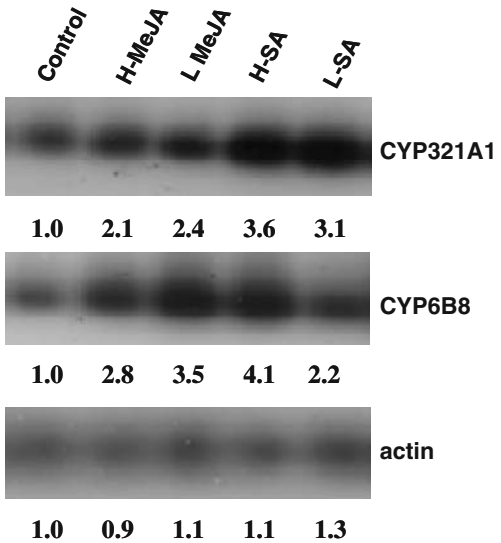

Fig. 5 P450 transcripts expressed in response to methyl jasmonate (MeJA) and salicylate (SA). Total *Helicoverpa zea* midgut RNA samples from the different diet groups (DMSO, 0.2% control solvent for all chemicals; H-MeJA, MeJA at 100 µg/g diet; L-MeJA, MeJA at 2.9 µg/g diet; H-SA, SA at 1 mg/g diet; L-SA, SA at 12 µg/g diet) were separately amplified by RT-PCR and analyzed as described in the Methods and Materials. The fold induction for each RT-PCR amplification after normalization to the constitutive actin transcript is shown below each lane

that bring about the detoxification of plant allelochemicals in the majority of cases.

In contrast with most plant chemicals, however, many mycotoxins, including aflatoxins, ochratoxin A, and zearalenone, are bioactivated by P450s or other oxidative enzymes (Dowd 1992; Ioannides 2000; Yiannikouris and Jouany 2002). The fungal toxin griseofulvin, synthesized by several *Penicillium* species, in fact appears to be bioactivated by P450s in *H. zea* (Dowd 1993). Producing toxins that are bioactivated by the principal Phase I metabolic enzymes used by the vast majority of animals may have been a key component of the adaptations of pathogenic fungi that allow them to defend their host resources against larger erstwhile consumers (Janzen 1977) (but see Sherratt et al. 2006). Plant signaling substances are well known to play distinct roles in mediating tritrophic interactions (Kessler and Baldwin 2002). In interactions between plants and insects, they initiate production of indirect defenses, i.e., volatile attractants that recruit predaceous natural enemies, and direct defenses, i.e., volatile repellents to herbivores (Heil 2004). In multitrophic interactions among plants, insects, and fungi, they may under some circumstances confer additional benefits to the plant by rendering insect consumers more vulnerable to fungal toxins. Whether this tritrophic interaction is a product of selection or is fortuitous is open to speculation.

Abstract We report the effects of some bisorbicillinoids isolated from biomass of the fungus *Trichoderma citrinoviride* on settling and feeding preference of the aphid *Schizaphis graminum*. Purification of the fungal metabolites was carried out by a combination of column chromatography and thin-layer chromatography using direct and reverse phases. Chemical identification was performed by spectroscopic methods including nuclear magnetic resonance and mass spectrometry. The identified bisorbicillinoids appeared to be bislongiquinolide, its 16,17-dihydro derivative, trichodimerol, and dihydrotrichodimerol. A feeding preference test with alate morphs of *S. graminum* was used to identify the active fractions. Among the four bisorbicillinoids, dihydrotrichodimerol and bislongiquinolide influenced aphid feeding preference, restraining specimens from settling on leaves treated with metabolites. Taste neurons sensitive to these compounds, particularly to bislongiquinolide, were located on tarsi of the *S. graminum* alate morphs.

Introduction

There has been growing interest in isolation of novel microbial metabolites for potential agricultural use (Tanaka and Ōmura 1993; Saxena and Pandey 2001). Microbial metabolites may reduce the selective pressure on crop pests due to the heavy and continuous use of synthetic agrochemicals and thus prevent the onset of resistant populations of plant pathogens and insects (Tanaka and Ōmura 1993). Furthermore, they are generally regarded as more environmentally friendly than their synthetic counterparts. The search for bioactive metabolites from microbes aims at the direct use of these compounds as agrochemicals as well as the discovery of new structural skeletons upon which to pattern synthesis of molecules with improved efficacy, stability, or biodegradability.

Fungi are an abundant source of secondary metabolites with various biological activities. In particular, fungal metabolites can affect different aspects of insect biology, such as survival, development, fecundity, and feeding

preference. The latter may have the ecological benefit of protecting fungal mycelium from mycophagous arthropods, such as springtails (Sabatini and Innocenti 2000). An eventual use of metabolites that are able to influence the feeding preference of insects in agriculture is conceivable. For instance, compounds that restrain aphids from feeding may reduce direct insect damage to crops and indirect damage due to infection with insect-transmitted viruses (Pickett et al. 1987). Data on such effects of fungal metabolites towards insect pests are limited (Wright et al. 1982; Mulè et al. 1992; Amiri et al. 1999; Ekesi et al. 2001; Ganassi et al. 2007). Ganassi et al. (2007) showed that some fungal isolates of the genus *Trichoderma* influenced the feeding preference of *Schizaphis graminum*, one of the most important pests of cereal crops, suggesting a potential antifeedant activity of these fungi towards aphids. The authors also showed that the biological activity of the fungal culture was from the water–methanol extractable of the fungal biomass, thus implying the presence of diffusible metabolites. Recently, two novel metabolites with potential antifeedant activity, citrantifidiene and citrantifidiol, were isolated from the culture extract of *Trichoderma citrinoviride* strain ITEM-4484 and characterized as a symmetrical disubstituted hexa-1,3-dienyl ester of acetic acid and a tetrasubstituted cyclohexane-1,3-diol, respectively (Evidente et al. 2008).

In this paper, we report the isolation and detection of four additional metabolites from strain ITEM-4484, all belonging to the bisorbicillinoids, a chemical family distinct from citrantifidiene and citrantifidiol. For two of them (trichodimerol and dihydrotrichodimerol), the genus *Trichoderma* is herein reported as a source for the first time. The effects on aphids of bisorbicillinoids from *T. citrinoviride* was studied by feeding preference tests and electrophysiological assays. These allowed us to characterize bislongiquinolide (**1**) and dihydrotrichodimerol (**4**) as two additional *Trichoderma* metabolites that influence aphid feeding preference, restraining them from settling on treated leaves.

Methods and Materials

Organisms

Fungus The fungal strain used was isolated from soil under *Abies* sp. in Tyrol (Austria). After re-isolation from a single germinated conidium, the strain was maintained in purity in the culture collection of the Institute of Sciences of Food Production, Bari, Italy, with the accession *T. citrinoviride* ITEM-4484. The strain was identified on the basis of morphological characters and by molecular techniques (sequence analysis of the internal transcribed spacer regions ITS-1 and ITS-2 of the nuclear rDNA, and a fragment of the translation elongation factor gene TEF-1α) as recently reported (Evidente et al. 2008).

Aphids The aphids used belonged to the species *S. graminum* (Rondani) (Hemiptera: Aphididae). The original *S. graminum* stock was collected in a cereal field located near Modena (Italy). Aphids were reared for several generations on wheat plants (*Triticum durum* Desf.) in a thermostatic chamber at 20°C under a 16:8 h light/dark cycle to induce parthenogenesis. Trials were carried out using alate adult morphs. Alate offspring were obtained in the laboratory by crowding.

Extraction and Purification of Fungal Metabolites Metabolites of *T. citrinoviride* ITEM 4484 were produced in a solid state fermentation as previously reported (Evidente et al. 2008). Briefly, the fungus was grown on autoclaved rice kernels brought to 45% moisture. Cultures were incubated at 25°C under a photoperiod of 12 h for 4 weeks and then oven-dried and finely ground. One kilogram of dried material was extracted with MeOH–H_2O (1% NaCl) mixture (55:45 *v*/*v*), defatted, and then extracted with CH_2Cl_2 as reported elsewhere (Evidente et al. 2008). The organic extracts were combined, dried (Na_2SO_4), and evaporated under reduced pressure, yielding a brown oil (15 g). The organic extracts (15 g) were fractionated by column chromatography (CC; eluent, $CHCl_3$-*i*-PrOH 85:15), and the fractions collected were analyzed by thin-layer chromatography (TLC) on silica gel (same solvent). Fractions showing the same chromatographic pattern were pooled yielding ten groups (A–L) of homogeneous fractions. The last fraction collected after fractions A–L was eluted with methanol.

A feeding preference test with alate morphs of the aphid *S. graminum* was used to identify active fractions in this and all subsequent purification steps. Residues of the B (1.58 g) and C (1.28 g) fraction groups were active in restraining aphids from settling on treated leaves (data not shown). The residue of fraction B (1.58 g) was purified by column chromatography (eluent, petroleum ether–Me_2CO 7:3), yielding ten groups (B1–B10) of homogeneous fractions. Only the residue of fraction B4 (94.7 mg) showed high activity and was purified further in two successive steps by preparative TLC on silica gel (eluent, $CHCl_3$-*i*-PrOH 9:1) and reversed-phase (eluent, EtOH–H_2O 6:4), yielding the most abundant active metabolite as a homogeneous solid. This was identified as dihydrotrichodimerol, (**1**, R_f 0.63 and 0.23, silica gel eluent, $CHCl_3$-*i*-PrOH 9:1, and reverse phase eluent, EtOH–H_2O 6:4, respectively, 15 mg). Purification by column chromatography (eluent, petroleum ether–Me_2CO

7:3) of the residue of fraction C (1.28 g) of the initial column gave nine groups of homogeneous fractions (C1–C9). The residues of fractions C2 (80.1 mg), C3 (431.6 mg), and C7 (54.6 mg) showed high activity. Purification of fraction C2 by preparative TLC (eluent, $CHCl_3$-*i*-PrOH 9:1) gave seven groups of homogeneous fractions (A1–G1). The residues of fractions D1 (15 mg) and G1 (8.8 mg) were active in feeding preference tests. Fraction D1 was purified by preparative TLC yielding citrantifidiene (Evidente et al. 2008), while fraction G1 (7.5 mg) by preparative TLC on reverse (eluent, EtOH–H_2O 6:4) yielded a homogeneous solid that was identified as trichodimerol (**2**, 4.6 mg R_f 0.4, reverse phase eluent, EtOH–H_2O 6:4). Purification of fraction C3 by a combination of column chromatography and TLC yielded citrantifidiol (Evidente et al. 2008). Finally, purification of fraction C7 by TLC on reverse phase (eluent, EtOH–H_2O 6:4) gave two homogeneous solids, the first yellow colored, and these were identified as bislongiquinolide (**3**, 7.5 mg, R_f 0.51 reverse phase eluent, EtOH–H_2O 6:4) and 16,17-dihydrobislongiquinolide (**4**, 12.0 mg, R_f 0.42 reverse phase eluent, EtOH–H_2O 6:4).

Identification Optical rotation was measured in $CHCl_3$ solution on a JASCO (Tokyo, Japan) P-1010 digital polarimeter; infrared (IR) and ultraviolet (UV) spectra were recorded as deposit glassy film and in MeCN solution, respectively, on a Perkin-Elmer Spectrum One Fourier transform-IR Spectrometer and a Perkin-Elmer Lambda 25 UV/Vis spectrophotometer (Norwalk, CT, USA). ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded at 600 (with a TCI cryoprobe™) and at 150 and 75 MHz, respectively, in $CDCl_3$ on Bruker spectrometers (Karlsruhe, Germany). Solvent was used as internal standard. Carbon multiplicities were determined by distortionless enhancement by polarization transfer (DEPT) spectra (Berger and Braun 2004). DEPT, correlation spectroscopy (COSY)-45, heteronuclear single quantum coherence (HSQC), and heteronuclear multiple bond correlation (HMBC) experiments (Berger and Braun 2004) were performed using Bruker microprograms. Electrospray ionization (ESI) and high-resolution (HR) ESI mass spectrometry (MS) spectra were recorded on Waters Micromass Q-TOF Micro spectrometer (Milford, MS, USA), while electron ionization (EI)-MS were taken at 70 eV on a QP 5050 Shimadzu spectrometer (Kyoto, Japan). Analytical and preparative TLC were performed on silica gel (Kieselgel 60 F_{254}, 0.25 and 0.50 mm, respectively, Merck, Darmstadt, Germany) or reverse-phase (Whatman, KC18 F_{254}, 0.20 mm, Maidstone, UK) plates; the spots were visualized by exposure to UV light and/or by spraying first with 10% H_2SO_4 in methanol and then with 5% phosphomolybdic acid in ethanol, followed by heating at 110°C for 10 min. Column chromatography: silica gel (Kieselgel 60, 0.063–0.200 mm Merck, Darmstadt, Germany).

Dihydrotrichodimerol (**1**) $[\alpha]_D^{25}$: +58.0 (*c* 1.4); IR ν_{max} cm^{-1} 3,423, 1,719, 1,634, 1,614, 1,548; UV λ_{max} nm (log ε) 360 (4.61), 298 (4.56), 234 (4.25); ^1H and ^{13}C NMR spectra were identical to those previously reported (Liu et al. 2005); HR ESI MS (+) *m/z*: 537 $[M+K]^+$, 521.2136 [$C_{28}H_{34}O_8Na$, calcd. 521.2151] $[M+Na]^+$, 499 $[M+H]^+$; ESI MS (−) *m/z*, 497 $[M-H]^-$; EI-MS (rel. int) *m/z*: 498 $[M]^+$ (15) 480 $[M-H_2O]^+$ (2), 401 $[M-CH_3-CH=CH-CH_2-CH_2-CO]^+$ (4), 384 $[M-CH_3-CH=CH-CH_2-CH_2-CO-OH]^+$ (1), 95 $[CH_3-CH=CH-CH=CH-C=O]^+$ (100), 55 $[CH_3-CH=CH-CH_2]^+$ (99).

Trichodimerol (**2**) $[\alpha]_D^{25}$: −408 (*c* 0.1); IR ν_{max} cm^{-1} 3,394, 1,613, 1,587, 1,415, 1,378; UV λ_{max} nm (log ε): 363 (4.60), 308 (4.30), 241 (4.15); ^1H and ^{13}C NMR spectra were identical to those previously reported (Liu et al. 2005); ESI MS (+) *m/z*: 519 $[M+Na]^+$, 497 $[M+H]^+$.

Bislongiquinolide (**3**) $[\alpha]_D^{25}$: +130 (*c* 0.2); IR ν_{max} cm^{-1} 3,434, 1,757–1,720, 1,630 1,576; UV λ_{max} nm (log ε) 373 (4.06), 290 (4.21) 261 (4.19); ^1H NMR spectrum was identical to that previously reported by Shirota et al. (1997) and Sperry et al. (1998); ESI MS (+) *m/z*: 519 $[M+Na]^+$.

Dihydrobislongiquinolide (**4**) $[\alpha]_D^{25}$: +350 (*c* 0.1); IR ν_{max} cm^{-1} 3,380, 1,729, 1,628, 1,570, 1,447, 1,379; UV λ_{max} nm (log ε) 369 (4.45), 259 (4.58); ^1H and ^{13}C NMR spectra were identical to those previously reported (Shirota et al. 1997); ESI MS (+) *m/z*: 521 $[M+Na]^+$.

Behavioral Bioassays The biological activity of the raw organic extract of *T. citrinoviride*, of the chromatographic fractions obtained in the purification process (data not shown), and of pure bisorbicillinoids (**1**–**4**), was assessed by feeding preference tests on alate morphs of the aphid *S. graminum.*

Extract, chromatographic fractions, and pure compounds were solubilized in 5% methanol to perform feeding preference tests as previously described (Ganassi et al. 2007). The raw organic extract of the fungal culture was tested at a concentration corresponding to 500 mg of rice culture per ml of 5% aqueous methanol; dihydrotrichodimerol (**1**) at concentrations of 2.5, 1.25, and 0.625 mg ml^{-1}; trichodimerol (**2**) at 0.82 mg ml^{-1}; bislongiquinolide (**3**) at 0.68 and 0.34 mg ml^{-1}; and dihydrobislongiquinolide (**4**) at 0.71 mg ml^{-1}. A 5% methanolic solution was used as control. For the tests, excised wheat leaves about 2 cm in length were dipped in the different solutions for 10 s. Then, leaves were placed on wet filter paper in 12 cm Petri dishes. Each dish contained two leaves, one treated with test

solution and one dipped in control solution, arranged in parallel at a distance of 4 cm. Aphids were placed between the two leaves with a fine brush, and their position was recorded every hour for 8 h, starting from the initial access that began less than 1 h after leaf excision.

For each treatment, five alate morphs were tested separately, and six replicates were run. The entire test was performed three times with the organic extract and twice with chromatographic fractions (data not shown) and pure metabolites.

Statistical Analysis The raw data obtained from feeding preference tests were analyzed by the Generalized Linear Model (GLM) repeated measures (time) procedure and compared by using a test of within-subjects effects, with SPSS release 15.01 for Windows software (SPSS, Chicago, IL, USA). The differences between the means of the number of aphids per leaf in each of the experimental treatments and those of the number of aphids on related controls over time were analyzed and adjusted with Bonferroni test for the number of comparisons.

Electrophysiological Bioassays Alate and apterous morphs of *S. graminum* obtained from laboratory rearing on host plants were used. Different concentrations (2.48, 1.24, 0.62, and 0.31 mg ml^{-1} in a 100 mM NaCl aqueous solution with 5% methanol) of the bisorbicillinoids, trichodimerol, dihydrotrichodimerol, and bislongiquinolide were tested. Methanol was added to solubilize the test compounds. Although methanol is thought to damage the nerve cells, which then does not allow for long recording durations, and most likely influences impulse frequencies, it has the advantage of dissolving material obstructing the pores and helping to obtain a good contact (Maher and Thiery 2004). Electrophysiological responses from the mesothoracic distal tarsomere were recorded by combining different techniques previously used to study single chemosensory sensilla (Hodgson et al. 1955; den Otter and van der Starre 1967; Marion-Poll and van der Pers 1996; Solinas et al. 2001; Maher and Thiery 2004; Ganassi et al. 2007). The indifferent electrode, a glass micropipette (tip 4–5 μm diameter) filled with a ringer solution (Kaissling 1995), was inserted into the aphid prothorax. The recording electrode, a glass micropipette (tip 2 μm diameter) containing one of the test stimuli, was connected to a sensillum. Action potentials were preamplified, filtered, and recorded with commercially available electrophysiological equipment (Tasteprobe Type DTP-1, Syntech, Hilversum, The Netherlands).

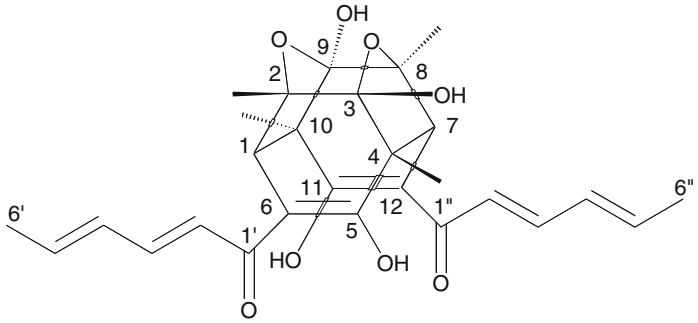
Test solutions were put into the micropipette 10 s before the experiment. Single-cell recordings were carried out at 22±2°C and 70±10% room humidity. Electrical activity was recorded for 1 s after stimulus onset, and 5 min was allowed to elapse between presentation of successive stimuli to the same sensillum. Test and control solutions were applied in a random series on the same sensillum. Action potentials (spikes) were stored on a magnetic tape (CditII, IEC II/Type II, High Bias 70 ms EQ, position chrome, Sony, Pontonx, sur l'Adour, France) by a double-channel recorder (Sony, TC-D5M) and successively analyzed with the AutoSpike™ 3.1 program (Syntech) on the basis of their amplitude, shape, and frequency.

Sensilla that failed to respond to the tested solutions were considered not functioning and were discarded (Crnjar and Prokopy 1982; Ganassi et al. 2007). Responses of the sensory cells were evaluated as spike frequency (spikes per second) during the first second of stimulation, 100 ms after stimulus onset. Firing frequencies were compared by means of the Student's *t* test.

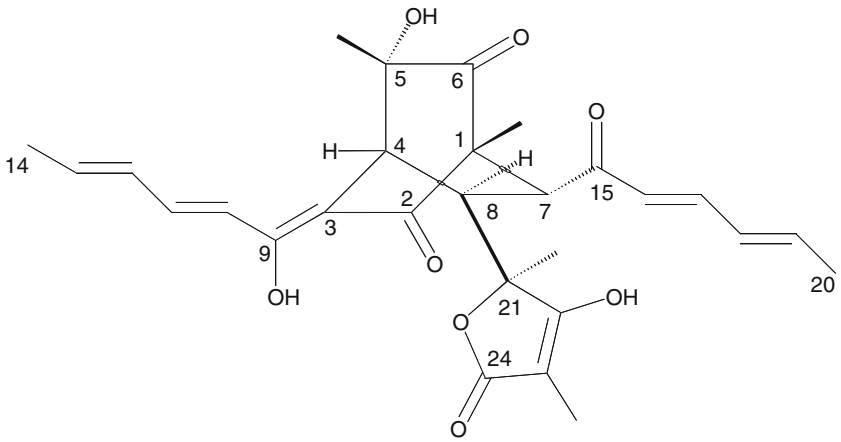
In order to verify the possible occurrence of olfactory responses, all compounds (25 μl of a 2.48 mg ml^{-1} solution) also were tested on antennae of living aphids. Stimuli were absorbed on a piece of filter paper (1 cm^2) inserted in a Pasteur pipette. Antennal responses were obtained by using a standard electroantennographic (EAG) technique (Ambrosi et al. 2001; De Cristofaro et al. 2004), and the green leaf volatile (*Z*)-3-hexen-1-ol (25 μl of a 1:10 *v/v* diluted solution in mineral oil) was used as an active control stimulus.

Results

The exhaustive extraction of a solid culture of *T. citrinoviride* (1 kg) yielded a crude organic extract that was active in restraining aphids from settling on treated leaves. This extract was purified by combined CC and TLC on direct and reverse phases and monitored by bioassays. This process led to the isolation of citrantifidiene and citrantifidiol, a symmetrical disubstituted hexa-1,3-dienyl ester of acetic acid, and a tetrasubstituted cyclohexane-1,3-diol, respectively, both with high activity towards aphids, and four additional metabolites as homogeneous solid compounds that did not crystallize. Preliminary ^{1}H and ^{13}C investigations showed that these metabolites were closely related and belonged to the family of bisorbicillinoids. Their structures were identified by using spectroscopic methods, essentially 1D (^{1}H and ^{13}C) 2D NMR (COSY, HSQC, HMBC) and EI and ESI MS techniques. The first metabolite was bislongiquinolide (**3**, Fig. 1, 7.5 mg kg^{-1}), based on its spectroscopic and physical properties. These were identical to those previously reported for this compound by Sperry et al. (1998), who originally characterized it from a strain of *Trichoderma longibrachiatum* isolated from *Haliclona* sp. from southwestern Indonesia. A second metabolite was identified as the 16,17-dihydroderivative of bislongiquinolide (**4**, Fig. 1, 12 mg kg^{-1}). The spectroscopic and physic properties were identical to those previously reported for **4** when first described by Shirota et al. (1997) as a metabolite



1 Dihydrotrichodimerol: 2',3'-dihydro
2 Trichodimerol



3 Bislongiquinolide
4 Dihydrobislongiquinolide: 16,17 dihydro

Fig. 1 Structures of dihydrotrichodimerol, trichodimerol, bislongiquinolide, and its 16,17-dihydroderivative (**1**–**4**)

of a *Trichoderma* sp. strain isolated from rice plant straw and named dihydrotrichotetronine. The third and the fourth metabolites were identified as dihydrotrichodimerol and trichodimerol (**1** and **2**, Fig. 1, 15 and 4.6 mg kg^{-1}, respectively). Their spectroscopic and physical properties were identical to those previously reported by Liu et al. (2005), who identified these compounds from a marine-derived strain of *Penicillium terrestre*.

Feeding Preference Tests on S. graminum Data obtained in tests carried out with wheat leaves treated with organic extract, with some of the chromatographic fractions from the purification process (data not shown), with pure metabolites, and with control leaves were analyzed with the GLM repeated measures procedure. This analysis determined if the interaction between the two conditions (treated and control) and the change over the time was statistically significant. The GLM analysis showed that the interaction between the number of aphids per leaf treated with organic extract of *T. citrinoviride* and the number of aphids per control leaf did not change over time; the Bonferroni adjustment for the number of comparisons revealed that the mean of the numbers of aphids counted on leaves dipped in organic extract was significantly smaller than the mean numbers of aphids counted on correspondent control leaves over time (Table 1).

GLM analysis of the data obtained in tests carried out with dihydrotrichodimerol (**1**) at the concentration of 2.5 mg ml^{-1} revealed no time × treatment interaction effects. The same analysis of the data obtained with a concentration of 1.25 mg ml^{-1} revealed time × treatment interaction effects, and also in this case the number of aphids counted on control leaves increased over the time of the trial. GLM analysis of the data obtained in tests carried out with a concentration of 0.625 mg ml^{-1} revealed no time × treatment interaction effects (Table 1). The Bonferroni test revealed that the average number of aphids on leaves treated with dihydrotrichodimerol at the concentrations of 2.5 and 1.25 mg ml^{-1} was significantly smaller than the number of aphids on correspondent control leaves, respectively, over time. The average number of aphids counted on leaves treated with dihydrotrichodimerol at a concentration of

GLM values describe the effect of time on aphid feeding preferences

ns not significant

*P<0.05; **P<0.01

[a] Values of P>0.05 for GLM indicate that the interaction between the two conditions (treated and control) and the change over time was not statistically significant

[b] Differences between the means of the number of aphids per leaf in each of the experimental treatments and those of the number of aphids on related controls over time were analyzed and adjusted with Bonferroni test for the number of comparisons

0.625 mg ml^{-1} was not significantly different from the number of aphids counted on control over time (Table 1).

GLM analysis of the data obtained in tests carried out with trichodimerol (**2**) at a concentration of 0.825 mg ml^{-1} revealed time × treatment interaction effects, as the difference between treated and controls changed during the trial. The Bonferroni test revealed that the average number of aphids on leaves treated was not different from the number of aphids on correspondent controls over time (Table 1).

GLM analysis and Bonferroni test of the data obtained in tests carried with the pure metabolite bislongiquinolide (**3**) at a concentration of 0.68 mg ml^{-1} and at a concentration of 0.34 mg ml^{-1} showed a time × treatment interaction effect. Indeed, the number of aphids on control leaves increased over time of the trial (Table 1).

GLM analysis and Bonferroni test of the data obtained in tests carried out with dihydrobislongiquinolide (**4**) at a concentration of 0.71 mg ml^{-1} did not show any time × treatment interaction effects (Table 1).

Electrophysiological Bioassays EAG study showed that the tested bisorbicillinoids were not able to stimulate the antennal olfactory sensilla of either alate or apterous morphs of *S. graminum*. The antennae, on the contrary, were stimulated (>1.0 mV) by the control stimulus, the green leaf volatile (*Z*)-3-hexen-1-ol.

Electrophysiological bioassays performed on the meso-thoracic distal tarsomere revealed that 31% of the alate and 15% of the apterous morph sensilla contacted gave rise to spike activity. Through applications of the control solution (100 mM NaCl), different action potentials were recorded. Methanol (5%) added to the control solution evoked spike frequencies similar to those obtained with the control solution alone (Table 2).

Each sensillum elicited action potentials by more than two different cells, but only the two larger ones in alate (a= 1.2 mV; b=0.7 mV) and apterous morphs (A=0.8 mV; B= 0.5 mV) were considered (Table 2). Responses from cells that elicited action potentials of lower amplitude (<0.5 mV) were not analyzable. In addition, higher concentrations of the test solutions induced deformations in spike shape and amplitude, so that responses could not easily be evaluated; lower concentrations evoked spike frequencies similar to the control.

On stimulation with the tested bisorbicillinoids, significant increases in spike frequency over controls were recorded. Cell a and b of alate *S. graminum* showed highly significant concentration-dependent responses to dihydrotrichodimerol and bislongiquinolide, respectively.

Table 2 Spike frequency (spikes per s±SD) recorded from cells with different action potential amplitudes (*a*=1.2 mV; *b*=0.7 mV; *A*=0.8 mV; *B*=0.5 mV) of *S. graminum* (alate and apterous morphs) tarsal sensilla (*N*=5) on stimulation with different doses of dihydrotrichodimerol, trichodimerol, and bislongiquinolide (**1**, **2** and **3**) and NaCl aqueous solution (100 mM), alone or added with methanol (5%)

Stimulus	Alate sensory cell		Apterous sensory cell	
	a	*b*	*A*	*B*
NaCl 100 mM	6.2±1.5	5.8±2.2	7.4±2.6	11.8±4.4
NaCl 100 mM+methanol 5%	6.4±2.0	6.3±3.2	8.2±2.2	10.6±4.8
Dihydrotrichodimerol, 2.48 mg ml^{-1}	38.8±6.6**	8.4±5.8	6.4±2.4	12.4±3.8
Dihydrotrichodimerol, 1.24 mg ml^{-1}	34.2±7.4**	8.2±4.0	8.6±2.8	9.8±5.4
Dihydrotrichodimerol, 0.62 mg ml^{-1}	20.0±5.6*	7.6±2.8	7.4±3.0	10.8±4.6
Dihydrotrichodimerol, 0.31 mg ml^{-1}	8.2±4.6	7.6±4.6	7.2±2.8	12.8±4.8
Bislongiquinolide, 2.48 mg ml^{-1}	6.4±4.0	82.4±10.6***	6.8±4.6	20.8±3.8*
Bislongiquinolide, 1.24 mg ml^{-1}	7.2±3.8	72.6±12.8***	7.4±2.6	10.6±4.6
Bislongiquinolide, 0.62 mg ml^{-1}	8.6±4.6	42.4±8.4**	8.2±2.6	12.6±3.4
Bislongiquinolide, 0.31 mg ml^{-1}	7.4±3.0	12.4±7.6	7.8±3.0	11.4±4.8
Trichodimerol, 2.48 mg ml^{-1}	23.6±7.2*	8.4±6.6	7.4±4.2	13.2±5.0
Trichodimerol, 1.24 mg ml^{-1}	20.8±6.6*	7.4±5.8	8.4±2.6	12.8±3.4
Trichodimerol, 0.62 mg ml^{-1}	12.6±8.2	6.4±4.4	7.6±2.2	11.2±4.6
Trichodimerol, 0.31 mg ml^{-1}	9.6±6.4	9.4±5.8	7.8±2.8	11.0±5.2

In each experiment, responses by the two cells showing the higher spike amplitudes were analyzed

Referred to the same column, Student's *t* test shows significant differences

*$P<0.05$; **$P<0.01$; ***$P<0.001$

Cell a was also stimulated by the two higher concentrations of trichodimerol. Sensory cells of the apterae morphs were not sensitive to the tested compounds, with the exception of a weak response of cell b to bislongiquinolide (Table 2).

Discussion

The four metabolites isolated from *T. citrinoviride* are related compounds belonging to the subgroup of dimeric methylated hexaketides, named bisorbicillinoids. This family includes the parent compound sorbicillinol and more than 30 monomeric and dimeric vertinoids isolated from *Verticillium intertextum*, *Penicilllium*, and *Trichoderma* spp. with different origins (Maskey et al. 2005). Many studies have been carried out on their isolation and chemical characterization (Trifonov et al. 1983, 1986; Gao et al. 1995; Andrade et al. 1997; Shirota et al. 1997; Abe et al. 1998, 1999; Sperry et al. 1998; Maskey et al. 2005), their biosynthesis (Sperry et al. 1998; Abe et al. 2002), as well as their synthesis and biomimetic synthesis (Nicolaou et al. 1999, 2000; Pitsinos et al. 2008). In particular, bislongiquinolide (**3**) was previously isolated, together with an epoxysorbicillinoid, a new vertinoid pigment, from a *T. longibrachiatum* strain isolated from the marine sponge *Haliclona* sp. (Sperry et al. 1998). In the same paper, the authors established that **3** and trichotetronine, which, consequently, was re-named bislongiquinolide, were identical. Trichotetronine had been previously described as a metabolite of a *Trichoderma* sp.; likewise, the 24,25-dihydroderivative named dihydrotrichotetronine (Shirota et al. 1997) corresponds to the dihydrobislongiquinolide isolated in the present paper (**4**). Interestingly, the species *T. longibrachiatum* and *T. citrinoviride* are closely related, as they both belong to the *Trichoderma* section *Longibrachiatum* and to the same phylogenetic clade (Bissett 1984, 1991; Samuels et al. 1998). Unfortunately, the third *Trichoderma* strain thus far known to produce bisorbicillinoids was not identified to species level (Shirota et al. 1997). It seems that the production of bisorbicillinoids is diffused among, if not restricted to, the species of the *Trichoderma* section *Longibrachiatum*. Should this observation be supported by further studies, it would be of importance for both the systematics of *Trichoderma* based on profiles of secondary metabolites (chemotaxonomy) and for screening of isolates producing new compounds that belong to this class of bioactive compounds. Both *T. longibrachiatum* and *T. citrinoviride* are soil inhabitants, especially abundant in natural and forest soils. Therefore, the production of fungal metabolites, which influence feeding preference of aphids, might be ecologically related to self-defense mechanisms against soil animals that eat

fungi. A definitive stereostructure was assigned to **3**, and a new skeleton numbering was assigned to these metabolites in agreement to that adopted for the dimeric bisorbicillinoid subgroup (Sperry et al. 1998). Trichodimerol and dihydrotrichodimerol previously were isolated, together with tetrahydrotrichodimerol, from a marine-derived strain of *P. terrestre*. Their cytotoxic effects were evaluated by the MTT method (Mosmann 1983) in P338 and A-459 cell lines using VP16 as a positive control (Liu et al. 2005). Not surprisingly, this diverse array of structurally related natural products has a broad range of biological activities. For instance, dihydrotrichodimerol (**1**) specifically activated peroxisome proliferator-activated receptor γ without affecting peroxisome proliferator-activated receptors α and δ. On the other hand, compounds **1** and **2** suppressed the production of tumor necrosis factor-α and nitric oxide in LPS-stimulated RAW264.7 cells to a similar extent (Lee et al. 2005)

Bisvertinolone, isolated from *Acremonium strictum*, is a novel antifungal agent that functions via inhibition of β-(1,6)-glucan biosynthesis (Nicolaou et al. 2000). In addition, bisorbicillinol, bisorbibutenolide, bisorbicillinoide, and birsorbibetanone exhibit antioxidant properties (Nicolaou et al. 2000).

The activity of influencing aphid feeding, restraining them from settling on treated leaves of bislongiquinolide and dihydrotrichodimerol, is reported herein from behavioral and electrophysiological tests, for the first time. These findings are in agreement with results previously observed by using powdered rice cultures of the fungus *T. citrinoviride* in a test with *S. graminum* (Ganassi et al. 2007).

EAG study showed that the tested compounds, however, were not able to stimulate the olfactory sensilla of *S. graminum*. In a previous paper, we showed that mixtures of metabolites of some species of *Trichoderma* are detected by tarsal sensory neurons (Ganassi et al. 2007). Results of single-cell recordings reported here indicate that the structures involved in the perception of bisorbicillinoids are taste cells located on the aphid tarsomeres. Single-cell responses to bislongiquinolide (cell b of the alate morphs) and dihydrotrichodimerol (cell a of the alate morphs) are dose-dependent and consistent with behavioral results. The biological meaning of the response of the cell a to trichodimerol is not clear. This compound did not elicit any activity in behavioral tests, and sensory responses could be due to its chemical structure, closely similar to that one of dihydrotrichodimerol. It has been argued that the different sensitivity of the two morphs of *S. graminum* might be due to the different distribution and number of adequate gustatory receptors (Ganassi et al. 2007). This hypothesis is largely supported both by the lower percentage of taste cells that evoke spike activity in apterous morphs and by the lack of responses to the tested compounds.

It has been reported that *T. citrinoviride* can cause infections in immunosuppressed humans (Kuhls et al. 1999). In practice, this may prevent the use of viable cultures of the fungus but not of its metabolites capable of influencing aphid feeding preference.

The findings reported in this paper show that the metabolites of the fungus *T. citrinoviride*, namely, bislongiquinolide and dihydrotrichodimerol, as well as citroantifidiene and citroantifidiol (Evidente et al. 2008) that have been previously isolated from the same source and belong to other classes of natural compounds, have a potential for the development of new agrochemicals for control of the aphid *S. graminum*.

Acknowledgment The NMR spectra were recorded at the NMR Service of the Istituto di Chimica Biomolecolare del CNR, Pozzuoli, Italy. Dr. G. Ricciardiello and Mrs D. Melck are gratefully acknowledged for technical assistance and Mrs. M. Zampa for recording MS spectra. The authors also acknowledge the assistance of Dr. Pasqualina Grazioso for statistical analysis. The work was supported by a grant from the Italian Ministry of University and Research (MIUR). Contribution DISSPAPA n. 162.

Identification of Host Attractants for the Ethiopian Fruit Fly, *Dacus ciliatus* Loew

Jeyasankar Alagarmalai · David Nestel · Daniela Dragushich · Ester Nemny-Lavy · Leonid Anshelevich · Anat Zada · Victoria Soroker

Received: 13 January 2009 / Revised: 10 April 2009 / Accepted: 20 April 2009 / Published online: 14 May 2009

Abstract The Ethiopian fruit fly, *Dacus ciliatus*, is an oligophagous pest of cucurbit crops, particularly melons, cucumbers, and marrows (summer squash). The present study aimed to identify host attractants for *D. ciliatus* and was guided by a behavioral bioassay and an electrophysiological assay. We tested volatile compounds from the fruits of a host plant, ripe and unripe Galia melon, *Cucumis melo* var. *reticulates*. Both sexes were attracted to melon volatiles. Those of ripe melon were preferred. Gas chromatography-electroantennographic detection analysis of the behaviorally active ripe melon volatiles consistently showed that 14 compounds elicited similar antennal responses from both sexes. Twelve compounds were identified by gas chromatography-mass spectrometry (GC-MS) using GC-MS libraries, retention indices (RI), and authentic standards. The electrophysiological activities of the compounds that were present at sufficient levels for identification, benzyl acetate, hexanyl acetate, (*Z*)-3-hexenyl acetate, (*Z*)-3-octenyl acetate, octanyl acetate, (*Z*)-3-decenyl acetate, and (*E*)-β-farnesene, were evaluated at six different dosage levels by using electroantennography (EAG). Benzyl and hexanyl acetates elicited dose responses only in males, while other tested compounds elicited dose responses in both sexes. The strongest responses were observed for doses between 100 ng and 10 μg. The dose response, in terms of attractiveness to synthetic compounds within the active range (as determined by EAG), also was evaluated in the behavioral bioassay. Synthetic acetates were attractive to both sexes when tested individually. Significant attraction was observed when individual compounds were applied in the bioassay arena at doses of 0.5–1 μg/dispenser. Blends of compounds in equal proportions also were attractive to the insects. The most attractive blend was a mixture of four or five identified acetates. The addition of an equal proportion of (*E*)-β-farnesene to this mixture had a deterrent effect.

Introduction

Fruit flies (Diptera: Tephritidae) are among the most important quarantine pests worldwide. Among these, the Ethiopian fruit fly, *Dacus ciliatus* Loew., is a serious pest of cucurbits in many countries, such as Egypt (Azab et al. 1970), South Africa (Hancock 1989), the island of Reunion, and other islands in the Indian Ocean (Dehecq 1995). This fly is classified as an A1 quarantine pest by the European and Mediterranean Plant Protection Organization (2008), requiring efficient monitoring and detection systems to reduce the probability of accidental introductions and export. Detection systems usually are based on strong olfactory attractants, which ideally are species-specific. In addition, lure-and-kill methods based on efficient attraction systems have proven valuable in the control of fruit flies (Aluja 1996; Hendrichs 1996; Koyama et al. 2004).

Little information is available regarding the chemical ecology of *D. ciliatus*, and no attractants have been identified for this species. There are several types of olfactory attractants for fruit flies: plant kairomones, parapheromones (that may include volatiles derived from host or nonhost plant species, such as trimedlure for *Ceratitis capitata* and methyl eugenol for many *Bactrocera* species),

food lures (that are usually protein hydrolyzate derivatives), and sex pheromones (Metcalf 1990; Jang and Light 1996). The attraction of *D. ciliatus* to some known parapheromones and essential oils was investigated several years ago by Qureshi et al. (1986). In that study, none of the investigated volatiles (e.g., Trimedlure, methyl eugenol, cue-lure, grapefruit oil, lemon oil, angelica seed oil, rose oil, etc.) attracted *D. ciliatus*. In a recent study performed in insect-proof screen cages in our laboratory, we confirmed the results of Qureshi et al. (1986), specifically regarding the lack of attraction of *D. ciliatus* to cue-lure, methyl eugenol, raspberry ketone, angelica seed oil, and Trimedlure (D. Nestel, unpublished results). We also observed low attraction to ammonia-releasing sources, such as BioLure, Buminal, etc. (D. Nestel, unpublished results).

Host and nonhost plants are the focal point of all fruit fly activities, such as feeding, lekking, mating, and egg-laying. Most of these activities are mediated by semiochemicals (Tan 2000). In particular, the attraction of fruit flies to their hosts is usually guided by volatile phytochemicals (Aluja and Mangan 2008), especially in species that exhibit host specificity such as oligophagous *D. ciliatus*. Indeed, a preliminary wind tunnel bioassay revealed that *D. ciliatus* is attracted to pieces of cucurbit fruits (e.g., melon and cucumber; D. Nestel, unpublished results).

Isolation and identification of specific attractants from fruit often is difficult due to blend complexity, which changes in composition during ripening. Rapid screening of multiple compounds of interest and the analysis of complex blends have been facilitated by coupled gas chromatography-electroantennogram detection (GC-EAD), which has been used successfully to identify attractants for a number of fruit fly species from several plant sources (Cosse et al. 1995; Zhang et al. 1999; Nojima et al. 2003a, b; Siderhurst and Jang 2006). The objective of the present study was to identify plant-derived attractants of *D. ciliatus* based on a behavioral bioassay coupled with gas chromatography-electroantennogram detection. Since the screening of volatiles by using a wind tunnel is a time-consuming process and field tests are problematic for quarantine pests, a cage choice bioassay was designed especially for this study.

Methods and Materials

Insect Culture Adult flies were obtained from a culture maintained at 27°C under strict quarantine conditions by the Plant Protection and Inspection Services of the Agricultural Research Organization (Israel Ministry of Agriculture), located in Bet Dagan, Israel. The culture was initiated 10 years ago from a wild population from the Arava valley. The culture is periodically refreshed with wild material. Larvae were reared on an artificial diet, as described in Nestel et al. (2004). Adults were provided with water and a mixture of sugar and yeast hydrolyzate. Sexually mature male and female flies, 10 to 16 days old, were selected prior to each experiment.

Fruits Ripe and unripe highly aromatic Galia melons, *Cucumis melo* var. *reticulates*, grown in open fields under commercial conditions were used. Melons were picked directly from the field and preserved for 3–4 h under cold conditions (~4°C) until volatile collection.

Collection of Volatile Compounds Host and nonhost fruits (ripe or unripe) were placed into jars of different sizes (0.5–5 l) with purified air passing through activated charcoal into the jar. Aerations were run for 48 h using a tube (3 cm×6 mm ID) of Super Q (Alltech Associates, Deerfield, IL, USA) held in place with glass wool plugs. The collected materials were extracted with 3 ml *n*-hexane (HPLC grade, Bio-Lab Israel, Jerusalem) and stored at 18°C for further assays.

Behavioral Bioassay Fly preferences for host volatiles were tested in a two-choice bioassay in a still-air arena. Plexiglas cages (40×40×30 cm^3) served as bioassay arena units. To avoid saturation with volatiles, the cages had two screened windows, each 10 cm wide. Experimental cages were located in a ventilated room, with a continuous interchange of air. Four traps, each consisting of a 20 ml glass vial plugged with a stainless steel funnel, were set in the corners of the cage floor. Two identical baited traps (treatment) and two control traps were set in opposing corners of each cage. To reduce the effects of directionality, baited and control traps were located within each replicate following a randomization protocol. Each bait (50–100 µl) (e.g., volatile preparations, different doses of individual compounds, or blends) and an appropriate control (*n*-hexane) were absorbed onto cotton wool wicks (1.9×1 cm ID). Bioassays consisted of releasing ten females or ten males in the center of a cage at around 1700 hours. Flies entering traps or remaining outside (alive or dead) were counted after 20 h. Each preparation was tested at least five times, usually simultaneously in different bioassay units situated side by side and exposed to the same illumination and environmental conditions. Initially, observations were made at 1 h intervals for the first 7 h and then again overnight. Data are reported as the percentage of flies entering either the treatment or the control traps overnight. The percentage of insects attracted to the tested preparation and to control treatment was calculated at each time interval by counting the cumulative number of flies in each kind of trap and dividing that number by the total number of trapped flies. Usually, for each replicate, seven to ten flies entered the traps after 20 h.

Identification of Antennae-Active Fruit Volatiles Electroantennographic responses to fruit volatiles were recorded with a Thermo Finnigan (Chrom-Card Trace-Focus GC, Milano, Italy) gas chromatograph coupled to a Syntech (IDAC-232, Hilversum, the Netherlands) electroantennogram detector system. The GC was equipped with a ZB-5 column (30× 0.25 mm ID×0.25 μm film thickness, Phenomenex (Torrance, CA, USA), with helium as the carrier gas at 2.0 ml/min and a make-up gas of 2 ml/min, which was added before the splitter. The injector, in splitless mode, and flame ionization detector (GC-FID) were kept at 250°C and 270°C, respectively. The oven was kept at 60°C for 2 min, and the temperature was then raised by 10°C min^{-1} to a final temperature of 230°C, which was maintained for 10 min.

For electroantenno-detection, the insect head was cut off, and a reference electrode was inserted into its base with a glass capillary tube filled with KCl (0.1 N). The distal end of the antenna was inserted into the tip of the recording glass capillary electrode. Antennae from both sexes were tested. Each antennal preparation was used only once. Humidified air (0.8 l/min) was used to carry effluent from the EAD transfer line to the antennal preparation. The signals generated by the EAD and FID were passed through a Syntech IDAC-232 high-impedance amplifier and analyzed with Syntech GC-EAD2000 software version 1.00. FID peaks that elicited EAD responses in at least seven runs were marked for identification by GC-mass spectrometry (GC-MS).

Electron Impact MS (70 eV) was conducted with an Agilent 6890 N GC coupled to an Agilent 5973 N Mass Selective Detector by a RTX-5SilMS (30×0.25 mm ID× 0.25 μm film thickness; Restek, Bellefonte, PA, USA) capillary column. Scanned masses ranged from 40 to 400 amu. The oven temperature was held at 50°C for 10 min, then heated at 15°C min^{-1} to 230°C, and kept at this temperature for 10 min. The injector was kept at 220°C in the splitless mode with helium (1.5 ml min^{-1}) as the carrier. Identification was conducted according to calculated Kovat's indices of the EAD runs, the mass spectra of EAD-active compounds that had been matched with MS libraries (NIST 5, Wiley 7 and Adams), literary Kovat's indices, and injections of authentic samples from synthesis or commercial sources as indicated below.

GC Analyses were conducted by using an Agilent 6890 GC equipped with a DB-23 30 m×0.25 mm ID×0.25 μm film-thickness polar column (J&W Scientific, Folsom, CA, USA) and a nonpolar HP-5 (J&W Scientific) capillary column, used in the splitless mode. The polar column was initially at 50°C for 3 min; the temperature was increased at a rate of 5° C min^{-1} to 220°C and was maintained at 220°C for 10 min. The nonpolar column was held at 50°C for 10 min, heated at 15°C min^{-1} to 230°C, and maintained at 230°C for 10 min. The injector was held at 230°C in the splitless mode with helium (1.5 ml min^{-1}) as the carrier. Pentadecanyl acetate was used as a standard for quantification.

The positions of the double bonds in hexenyl, octenyl, and decenyl acetates were determined by the microchemical reaction of dimethyl disulfide adducts according to the accepted procedure (Dunkelblum et al. 1985), followed by GC-MS analysis of the adduct products, as described above. The position of the double bond in dodecenyl acetate was not identified in the same way, since the amount of material available for reaction with dimethyl disulfide was too small. However, the double bond in this compound is most probably located at carbon 3, based on the results of our injections of seven different dodecenyl acetate standards, containing a double bond on carbon 3, 5, 7, 9, 10, or 11. The geometries of the double bonds in hexenyl, octenyl, decenyl, and dodecenyl acetates were determined by comparing the Rt values of corresponding standards with the natural sample in the polar column.

Chemicals Chemicals obtained from commercial sources were used without further purification: (*Z*)-3-hexenol, *n*-hexanol, *n*-octanol (Fluka, Buchs SG, Switzerland), (*E*)-3-decenylacetate and (*Z*)-3-decenyl acetate (Pherobank, Wageningen, The Netherlands), benzyl alcohol and (*Z*)-3-octenol (Sigma-Aldrich, Rehovot, Israel), (*E*)-β-farnesene (Bedoukian, Danbury, CT, USA), β-caryophyllene (Fluka, Buchs, Germany), (*Z*)-3-dodecenyl acetate (old sample from unknown supplier), pyridine, and acetic anhydride (Aldrich, Steinheim, Germany). Alcohols were converted into their acetates by overnight reaction with acetic anhydride in pyridine, which yielded the appropriate acetates (90–99% yield). Liquid flash chromatography was performed by using silica gel 60 (70–230 mesh) and pentane, with increasing amounts (1–5%) of ether used as eluting solvents.

Antennal Response to Different Concentrations of Active Volatiles The receptivity of the antennae of both sexes of *D. ciliatus* to serially diluted solutions of synthetic chemicals was investigated with electroantennography (EAG). For each tested compound, a dilution series was prepared starting with a 1:1 (*w*/*w*) dilution in hexane (AR-grade) followed by further 1:10 dilutions to yield the following concentrations: 100 μg/μl, 10 μg, 1 μg, 100 ng, 10 ng, and 1 ng per 1 μl solution. Antennal preparations for the EAG analysis were made as described in the previous section. We used the same antenna to test all of the concentrations of a single compound. Each compound was tested on eight antennae, using one antenna per fly. To prepare the tested solutions for EAG, a standard aliquot (1 μl) of each test dilution was pipetted onto a piece of filter paper (Whatman No.1), exposed to air for 20 s to allow the solvent to evaporate

and then inserted into a glass Pasteur pipette. A stimulus flow controller (CS-05; Syntech) was used to generate a 0.6-s stimulus at 1–2 min intervals, with a flow rate of 1.5 l/min. The signals generated by the antenna were passed through a high-impedance amplifier (IDAC-232, Hilversum, the Netherlands) and displayed on a monitor. Syntech software was used to process EAG signals.

Statistical Analysis Differences in the proportion of flies selecting the tested compound or the control in the behavioral bioassay were analyzed with the Wilcoxon signed rank test. Inferences regarding the response of antennae to different concentrations of tested compounds in EAG were analyzed by using a repeated measures model with the General Linear Model (Statgraph Plus, 2000, Manugistics, Inc. Rockville, MA, USA). Average antennal responses were separated using the least significant difference (LSD) method (α=0.05; Statgraph Plus, 2000).

Results

Both sexes were attracted to volatile compounds collected from ripe melon (Wilcoxon signed rank test, Z=−2.11, P<0.034, df=7 for females; Z=−2.66, P<0.008, df=8 for males; Fig. 1). Insects were not attracted to volatiles from unripe melon. In the choice bioassay, both male and female flies were able to discriminate between volatile compounds collected from ripe melons and volatile compounds from unripe melons and preferred the former (Wilcoxon signed rank test, Z=−2.8, P<0.005, df=9 for females; Z=−2.8, P<0.005, df=9 for males; Fig. 1).

GC-EAD analysis of headspace volatiles from ripe Galia melon revealed about 14 compounds that consistently elicited electrophysiological responses from the antennae of both sexes of *D. ciliatus* (see EAD trace in Fig. 2). Compounds that elicited EAD responses were identified by GC-MS and GC analysis on nonpolar and polar capillary columns. The identification process was completed by subsequent injections of authentic standards to the two different polarity GC columns, except for isopentyl hexanoate, germacrene D, and cadinene (unknown isomer). The mass spectra and retention indices (RI) of these compounds are identical with those reported in the literature (El-Sayed, 2008; NIST 5 MS library; and references therein). Among the 14 active peaks associated with the elicitation of EAD responses, 12 compounds were identified: (*Z*)-3-hexenyl acetate, hexanyl acetate, benzyl acetate, (*Z*)-3-octenyl acetate, octanyl acetate, isopentyl hexanoate, (*Z*)-3-decenyl acetate (and some (*E*)-3-decenyl acetate), β-caryophyllene, (*E*)-β-farnesene, germacrene D, cadinene (unknown isomer), and (*Z*)-3-dodecenyl acetate (Table 1). Among the EAD-active ripe melon volatiles, hexanyl acetate and (*Z*)-3-hexenyl acetate had the most abundant peaks. The identified acetates were not found among the volatiles collected from unripe melons.

The sensitivity of fly antennae to increasing doses of individual compounds was analyzed by using EAG. As shown in Fig. 3, the responses of both male and female antennae to most compounds were dose-dependent (P<0.05). For both female and male insects, the optimal responses to most of the compounds occurs around 1 μg quantities. For some of the compounds, the level of the response differed between sexes. Males were more sensitive to hexanyl acetate (F=14.9, df=1.48, P<0.01), benzyl acetate (F=6.17, df=1.42, P<0.01), and *E*-(β)-farnesene (F=11.1, df=1.42, P<0.01) but less sensitive to (*Z*)-3-hexenyl acetate (F=14.1, df=1.42, P<0.01). Antennal responses to octanyl acetate and (*E*) and (*Z*)-3-decenyl acetate were not sex-dependent (F=0.82; F=0.46; F=1.97, respectively, P>0.05). For the response to (*Z*)-3-octenyl acetate, we found a significant interaction between sex and dosage (F=3.03; df=5; 48, P<0.05).

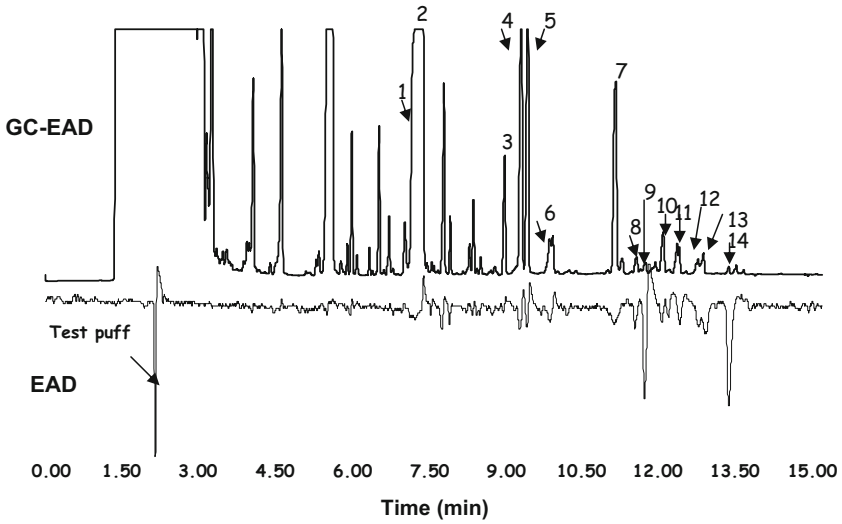

Fig. 2 GC-EAD profile of the ripe melon volatile extracts applied to the antennae of female *D. ciliatus*. The numbers represent peaks with EAD responses

The attractiveness of different doses of the identified EAD-active compounds was tested in a two-choice behavioral bioassay (Tables 2 and 3). In addition, 0.5 μg mixtures of active volatiles (increasing in compound content complexity) also were tested in the behavioral bioassay (Fig. 4). The results of the choice bioassay revealed that all of the acetates attracted flies of both sexes. For most compounds, significant attraction was observed when compounds were

[a] EAD values reflect the averages of five female and six male antennae depolarization records

[b] Compounds eliciting EAG responses in, or attracting other tephritids. The affected species are listed (*Al*, *A. ludens*; *Cc*, *C. capitata*; *Bd*, *B. dorsalis*; *Bt*, *Bactrocera tryoni*; *Rp*, *Rhagoletis pomonella*) (Cosse et al., 1995; Hull & Cribb, 2001; Hwang et al., 2002; Light et al., 1988; Malo et al., 2005; Nojima et al., 2003a; Siderhurst & Jang, 2006). Peaks marked by a and b are sequential with no base-line separation, therefore it is hard to determine which of them elicited the EAD-response. Pentadecanyl acetate was used as an external standard for quantification by FID.

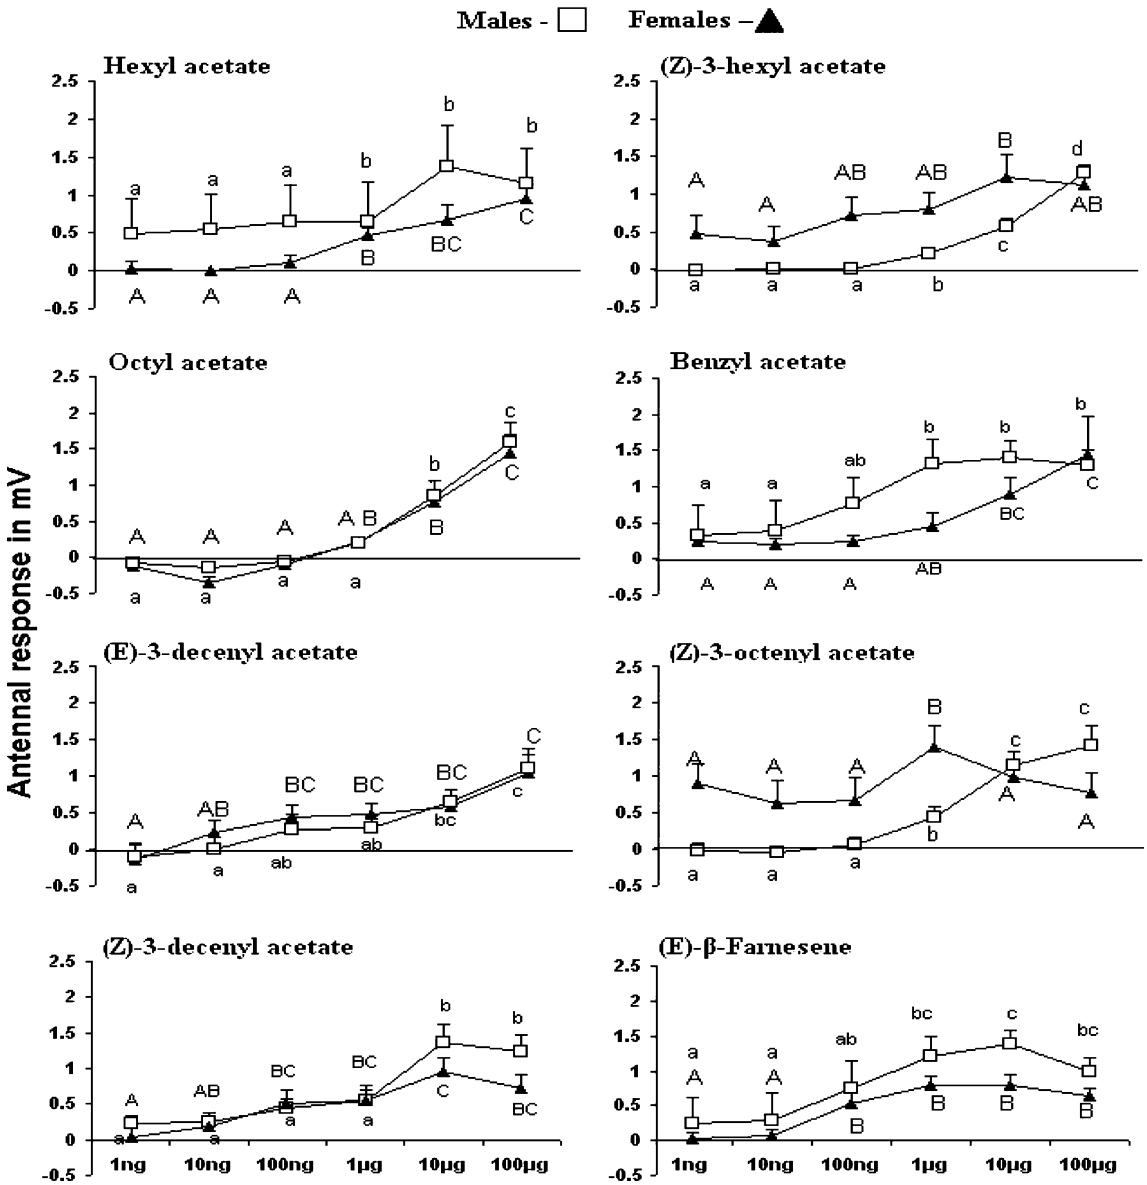

Fig. 3 EAG dose responses of female and male antennae of *D. ciliatus* to synthetic components of melon volatile blends. Results are average responses of at least eight antennae (expressed in mV). The response to hexane (blank) was subtracted from the data. Different letters (*capital letters* for females and *lower-case letters* for males) indicate significant differences in responses to ascending doses. GLM repeated measure following LSD analyses were conducted ($P<0.05$)

applied at doses around 0.5–1 µg. However, (*E*)-β-farnesene was slightly attractive (61%) to males (Wilcoxon signed rank test, $Z=-2.197$; $df=9$, $P=0.028$) but unattractive to females. Moreover, at some doses, it was even repellent.

Among the simple blends, the most effective attractant was a 1:1 mixture of octanyl acetate and (*Z*)-3-octenyl acetate (blend A; Fig. 4). Addition of (*E*)-β-farnesene to this mixture caused a decrease in attractiveness (blend C; Fig. 4). A blend of (*Z*/*E*)-3-decenyl acetate and hexanyl acetate (blend D) was even less attractive (Fig. 4). Overall, the most attractive blend for both sexes was a mixture of six acetates (blend G; Fig. 4). Benzyl acetate and (*E*)-β-farnesene were excluded from this mixture since, as mentioned above, the latter causes a decrease in attractiveness, especially to females, while the former was not that attractive to females in the dose–response behavioral bioassay (Table 3).

Discussion

Similar to many fruit flies, *D. ciliatus* was attracted to volatile compounds released by host fruit. In particular, volatile compounds from a climacteric melon variety (*C. melo* L. cv. *reticulates* group) were attractive to both sexes.

Attractive volatiles were collected from whole fruit aroma. Using a simple, though efficient, laboratory bioassay, we screened volatile preparations and demonstrated that the flies prefer volatiles from ripe melons that, in contrast to unripe fruit, are known to produce relatively large quantities of a wide variety of aromatic compounds (Beaulieu and Grimm 2001; Shalit et al. 2001).

The headspaces of ripe melons are characterized by volatile aldehydes, alcohols, and large quantities of acetate esters that are likely to be the key contributors to the unique aromas of melons (Shalit et al. 2001). GC-EAD of melon headspace revealed that the antennae of both sexes of *D. ciliatus* can detect at least 14 compounds in melon aroma, eight of which have been identified as acetates: benzyl acetate, hexanyl acetate, (*Z*)-3-hexenyl acetate, octanyl acetate, (*Z*)-3-octenyl acetate, (*Z*)-3-decenyl acetate, some (*E*)-3-decenyl acetate, and (*Z*)-3-dodecenyl acetate. The other identified compounds were isopentyl hexanoate, β-caryophyllene, (*E*)-β-farnesene, germacrene D, and cadinene (unknown isomer). Δ-Cadinene and β-caryophyllene were also described by Shalit et al. (2001) as components of the headspace of ripe Arava melon. Although the RI of the cadinene component in our samples was similar to that of Shalit et al. (2001), the MS spectrum matches better a structural isomer of γ-cadinene than δ-cadinene. Δ-Cadinene is known as one isomer; however, three γ-cadinene isomers are reported in the literature (Connolly and Hill 1991). It seems that the component in our sample is one of the

isomers of γ-cadinene and not δ-cadinene. Unfortunately, the wide range of the RIs reported in the literature (NIST 5) and the lack of standards prevent determining the exact isomeric structure of our cadinene component.

Further EAG studies confirmed the specific sensing of most of the identified compounds. Both hexanyl acetate and (*E*)-β-farnesene previously have been described as elicitors of EAG responses in polyphagous flies, such as *C. capitata* and *Bactrocera dorsalis* (Light et al. 1988; Hull and Cribb 2001; Siderhurst and Jang 2006). Additionally, hexanyl acetate was identified as an elicitor of an EAG response in *Anastrepa ludens* (Malo et al. 2005).

The maximal responses of the antennae of both sexes of *D. ciliatus* were similar, occurring around 1.5 mV. However, the sexes differed in their sensitivity to the isolated compounds. While the responsiveness of males' antennae to hexanyl and benzyl acetate was greater than that of females, the females were more responsive to (*Z*)-3-hexenyl acetate. In behavioral bioassays, the dose response to the identified compounds was not clear. However, except for (*E*)-β-farnesene, the tested concentrations of all identified acetates were attractive to both sexes. *E*-β-Farnesene was deterrent to females but was slightly attractive to males. In fact, screening of several melon volatile collections revealed that (*E*)-β-farnesene is rather uncommon. Moreover, Nigg et al. (1994) reported that this compound is a deterrent to *A. ludens*, suggesting that it may play a role in the fruit flies' assessment of suitable fruits (i.e., as an indicator of host status). This finding, which may have some possible applications, merits further investigation.

Our results also revealed interesting differences in the behavioral responses of male and female *D. ciliatus* to the volatiles they were exposed to. As an example, females were consistently attracted to (*Z*) and (*E*)-3-decenyl acetate, while males were attracted to lower concentrations of (*Z*)-3-decenyl acetate, instead of the (*E*)-isomer. Also, both sexes were strongly attracted to (*Z*)-3-hexenyl, (*Z*)-3-octenyl, and octanyl acetates, but the attractiveness of the latter two was limited to doses below 10μg. The fact that males were more attracted to benzyl acetate than females could be explained

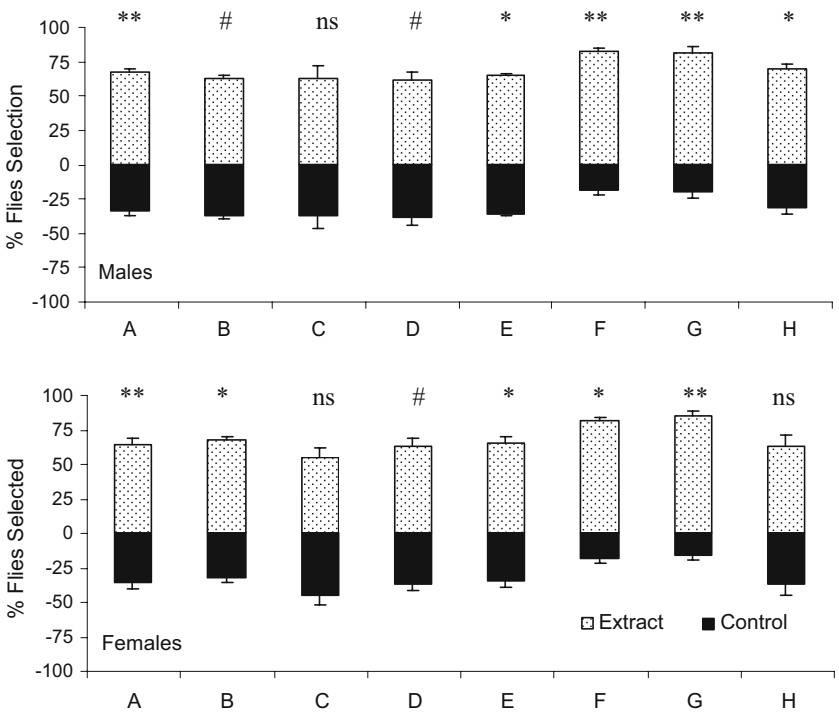

Fig. 4 Attraction of *D. ciliatus* to different mixtures of synthetic compounds (0.5 μg of each component per vial). Results are average percentages (±SE) of total flies trapped using each lure; *N*=number of cages tested for each two-choice set-up, consisting of a treatment mixture and a control (hexane); (a) males and (b) females. by males' higher antennal sensitivity to these compounds, as observed in EAG responses. However, there was no correlation between the antennal and behavioral responses in the cases of the other compounds.

At present, we do not have any explanation for the observed sexual differences in electrophysiological and behavioral responses to the examined volatile compounds. However, we suspect that the latter have evolved to fit sex-specific strategies and behaviors.

Despite the above-mentioned differences, the blend of identified compounds excluding benzyl acetate and (*E*)-β-farnesene (Fig. 4, blend G) proved attractive to both sexes. Excluding hexanyl acetate from the mixture (Fig. 4, blend F) did not reduce its attractiveness. The addition of benzyl acetate and (*E*)-β-farnesene to the blends decreased their attractiveness (Fig. 4, blend H), again strengthening the observation that (*E*)-β-farnesene seems to be a deterrent. However, we should keep in mind that, by using blends of compounds in equal proportions, we considerably raised the relative amount of (*E*)-β-farnesene, which is a minor component of melon emissions as observed in peak 9 of Fig. 2. Thus, under natural conditions, it is not expected to have negative effects. Since each of the six selected compounds were attractive and the difference in responses to the different blends was not high, it appears that the effect of blend components is not synergistic but may be additive. In any case, and based on the additive results observed for the blend, octanyl acetate and (*Z*)-3-octenyl acetate seem to be the two main identified attractants of *D. ciliatus*. These two compounds have not been reported previously as attractants for Tephritidae. On the other hand, hexanyl acetate was reported previously to be attractive to *B. dorsalis* (Siderhurst and Jang 2006), and benzyl acetate was attractive to males of the highly polyphagous *B. dorsalis*, *Bactrocera cucurbitae*, and *C. capitata* (Metcalf et al. 1986 and references therein).

Oligophagous flies, such as *D. ciliatus* that specialize on cucurbits, could be expected to respond to a narrow band of cues, presumably those specific to cucurbits. To address this issue, we need to evaluate volatile profiles of additional cucurbit hosts of *D. ciliatus*. However, our data indicate that a mixture of rather general volatiles is attractive to these flies. Thus, our results correspond well with the idea suggested by Bruce et al. (2005) for phytophagous insects, i.e., that the ratio-specific odor recognition, relying on a particular ratio of volatiles distributed generally among plants, is the more common mechanism of host recognition, rather than species-specific volatile–host recognition.

Our blends of six or seven acetates seem promising for field applications. However, we have to overcome the challenge of making a host-derived odor that is attractive under field conditions against a background of natural chemicals. In the case of *D. ciliatus*, the volatile profile of ripe melon may prove effective in fields of young, unripe melon. Moreover, if *D. ciliatus*, like the melon fly *B. cucurbitae*, exhibits daily movements among host plants and surrounding vegetation, attractants could be applied in perimeter traps, as suggested by Piñero et al. (2006). We currently are exploring this option. Our initial results indicate that blends may be attractive to the fly under field conditions (unpublished data). Other challenges include the need to understand the effect of fly physiological status (e.g., age and reproductive condition) on perception and attractiveness of the identified volatiles and incorporation of this information into a field application strategy. In particular, young and sexually immature females are expected to respond to cues differently from old and inseminated females. The former are looking for protein food sources for oogenesis (Kendra et al. 2005), whereas the latter may concentrate on searching for oviposition sites. Differential responses to volatiles may improve our understanding of their specific activity and may help to tailor appropriate blends, both for monitoring and control.

Acknowledgments We thank the Plant Protection and Inspection Services of the Ministry of Agriculture, Israel for providing the facilities necessary for this research. We also thank Dr. Jossi Burger (Neve Ilan Research Center, Israel) and Mr. Ami Maduel (Yair Field Station, Northern Arava) for providing the melon fruit used in this study and two anonymous reviewers for helpful comments. This research was supported by the Dr. Eva Ehrlich Memorial Fund, grant no. 131-1304.

Neonate Silkworm (*Bombyx mori*) Larvae Are Attracted to Mulberry (*Morus alba*) Leaves with Conspecific Feeding Damage

Allison C. Mooney · Hugh M. Robertson · Kevin W. Wanner

Received: 24 November 2008 / Revised: 29 March 2009 / Accepted: 13 April 2009 / Published online: 9 May 2009

Abstract The silkworm *Bombyx mori* is a molecular genetic model for the Lepidoptera. Its odorant receptor genes have been described, and preliminary studies suggest that several are expressed specifically in the larval caterpillar stage. This study was undertaken to identify olfactory behaviors specific to the larvae. A two-choice leaf disk bioassay with naive neonate larvae was used to evaluate the attractiveness of three types of mulberry leaf (*Morus alba*): newly flushed leaves from branch tips, mature leaves, and mature leaves with feeding damage caused by conspecific larvae. Mature leaves with feeding damage were the most attractive, newly flushed leaves were moderately favored, and undamaged mature leaves were the least attractive. Volatile odors collected from whole mulberry leaves by using solid-phase microextraction fibers were analyzed by gas chromatography-mass spectrometry. The volatile profile of newly flushed leaves and mature leaves damaged by conspecific larvae was more complex compared to undamaged mature leaves. By comparing the volatile makeup of each leaf type, a list of 22 candidate odors responsible for attracting the neonate larvae was generated; α-farnesene was particularly notable as a herbivore-induced volatile. These odors will be used in future in vitro studies to determine whether they activate larval-specific odorant receptors.

Introduction

Olfaction is one of the most important ways through which insects interact with their surroundings. Among its many functions, insects rely on chemoreception to locate both mates and food sources. For example, male Lepidoptera are able to locate females from long distances by sensing and orienting to female-produced sex pheromones (Schneider 1992). Female Lepidoptera use olfactory cues, including volatiles induced by feeding damage, to locate host plants when searching for oviposition sites (Renwick and Chew 1994). The silkworm *Bombyx mori* genome was sequenced in 2004 (Mita et al. 2004; Xia et al. 2004), and the silkworm is becoming a molecular genetic model species representing the Lepidoptera (Goldsmith et al. 2005). Approximately 50 different odorant receptor (Or) genes have been annotated from the silkworm genome (Wanner et al. 2007). Male-specific Ors activated by the sex pheromones bombykol and bombykal have been characterized (Sakurai et al. 2004; Krieger et al. 2005; Nakagawa et al. 2005) as well as female-biased Ors whose function remains uncertain (Wanner et al. 2007; Anderson et al. 2009). These studies represent initial efforts to link the molecular biology of insect olfaction with behavior and chemical ecology.

The females of many Lepidoptera species select the host plant for oviposition (Renwick and Chew 1994). However,

the hatching neonate larvae must contend with a variety of factors to locate and establish their feeding site, a behavior thought to be mediated primarily by olfaction (Zalucki et al. 2002). Many species of Lepidoptera disperse in the wind as early instars on silk threads, after which host plants and suitable feeding sites need to be located. Ablation experiments in the 1960s demonstrated that caterpillar antennae mediate olfactory attraction to odors located 10–30 cm distant (reviewed in Schoonhoven 1987). Due to its economic importance to sericulture, the olfactory behavior of silkworm larvae was studied extensively in the 1960s in Japan in relation to artificial diet and feeding behavior. Studies revealed that the terpenes found in mulberry leaves, such as citral, linalyl acetate, linalool, and terpinyl acetate, as well as terpene alcohols attract *B. mori* larvae (Hamamura and Naito 1961; Ishikawa et al. 1969). Citral and linalyl acetate were very attractive, while terpinyl acetate and hexanol were slightly less attractive.

The volatile profile of a plant often changes as a result of herbivore feeding damage (Dicke et al. 1988; Turlings et al. 1995; Pare and Tumlinson 1999; Kessler and Baldwin 2001). Herbivore-induced volatiles differ from those produced by mechanical damage (Dicke et al. 1988; Pare and Tumlinson 1999). The volatiles that are produced in response to herbivore feeding are often attractive to predators and parasites of the herbivores that induced the damage (Pare and Tumlinson 1999; Hoballah and Turlings 2005). The signaling function of the volatiles may have evolved as a secondary function of compounds that function to deter herbivore feeding behavior and prevent infection of damaged tissue (Turlings et al. 1995). By attracting predators, plants may be protected against further damage.

Herbivores themselves can use herbivore-induced volatiles as chemical cues, but this subject has been less well studied. Caterpillar feeding during the day can induce plant volatiles at night that deter oviposition by conspecific moths (De Moraes et al. 2001). Some lepidopteran larvae are attracted to food sources with conspecific feeding damage. Apple codling moth (*Cydia pomonella*) larvae are preferentially attracted to volatiles from apples that have been infested by other codling moth larvae compared to undamaged or mechanically damaged apples (Landolt et al. 2000). Similarly, fall armyworm (*Spodoptera frugiperda*) neonate larvae are more attracted to cowpea leaves damaged by conspecifics than to undamaged cowpea leaves (Carroll et al. 2008).

The order Lepidoptera includes many significant pest species of crop plants worldwide, and it is the larval caterpillar stage that causes feeding damage. Molecular genetic approaches to understanding host-seeking and selection behavior by larvae may help provide a foundation for the development of new pest management techniques. For example, plants have been genetically modified to produce volatiles that attract aphid parasitoids (Beale et al. 2006). Preliminary research has identified several silkworm Ors that appear to be expressed specifically in the larval antennae and not in adult antennae.

This study was conducted to identify larval-specific silkworm behaviors and the odors that mediate these behaviors to provide a basis to further study the molecular function of larval-specific Ors. The volatile profiles of three different categories of mulberry leaves (newly flushed leaves, mature leaves, and mature leaves with conspecific feeding damage) and their attractiveness to neonate silkworm larvae were evaluated.

Methods and Materials

Leaf Disk Assays White mulberry (*Morus alba*) leaves were collected daily (Champaign-Urbana, Illinois area) in the early morning typically between 7:00 and 9:00 A.M. each day that tests were conducted. Following collection, leaf disks were cut with an 18-mm cork borer. Three categories of leaf disk were prepared: mature (dark green) leaves, newly flushed (light green) leaves collected from branch tips, and mature leaves with feeding damage. Mature leaf disks with and without feeding damage were prepared by placing cut disks in a 25-mm Petri dish (lined with moistened filter paper to prevent desiccation) for 24 h. One set of Petri dishes included five neonate larvae that were allowed to feed for the 24-h-period. Prior to testing, the larvae and frass were removed. In some choice tests, the filter paper underneath the mulberry leaf disks also were used after it was cleaned of frass and larvae and folded into a small (approximately 1 cm) bundle. Filter paper underneath mature leaf disks without larval feeding was prepared by using the same procedure.

All choice tests were conducted with the same procedure, changing only the odor sources. Each replicate tested the odor preferences of naive neonate *B. mori* larvae that had hatched within 24 to 48 h. A batch of 10,000 silkworm eggs was purchased from Mulberry Farms (Fallbrook, CA, USA) and stored at 4°C. Larvae hatched from eggs as needed in plastic Petri dishes without food. Glass Petri dishes (80 mm diameter) were washed with dilute Liqui-Nox detergent (Fisher Scientific), rinsed with acetone, and baked at 240°C for at least 2 h before being used in choice tests. Two odor sources were placed on opposite sides of the glass Petri dish, and five neonate larvae were placed in the center of the dish with the lid in place. Larvae were allowed to crawl for 15 min after which their positions were noted (at odor source 1, at odor source 2, or in-between). If all five larvae reached an odor source before 15 min had expired, the test was stopped, and the position of the larvae

was noted. Two assays (five larvae per assay) were performed each day on five different days, for a total of ten replicates of five larvae in each replicate.

Six comparisons were conducted using leaf disks from: (1) mature leaves vs. mature leaves, (2) mature leaves vs. newly flushed leaves, (3) mature leaves vs. mature leaves with feeding damage, (4) mature leaves with feeding damage vs. newly flushed leaves, (5) filter paper underneath mature leaves vs. filter paper underneath mature leaves with feeding damage, and (6) mature leaves with feeding damage vs. the filter paper underneath mature leaf disks with feeding damage. The null hypothesis that equal proportions of larvae chose each type of odor source was tested with the chi-square statistic. Choice tests with single larvae also were conducted to rule out the possibility that larvae were interacting with each other when selecting the odor source.

Solid-Phase Microextraction Fiber Assay To collect the volatiles released from each type of mulberry leaf, a solid-phase microextraction fiber was used (SPME, Supelco Bellefonte, PA, USA; the fiber was coated with polydimethylsiloxane/divinylbenzene). Whole leaves with petioles attached were placed in a 125-ml Erlenmeyer flask and covered with aluminum foil. Flasks were thoroughly washed with dilute Liqui-Nox detergent, rinsed with acetone and baked for at least 2 h at 240°C between each use. The SPME fiber was inserted through the foil and exposed 2–4 cm from the surface of the sample material for 30 min. A 50-W full-spectrum plant light was directed at the flask from 30 in. away. The temperature of the flask was monitored and never exceeded 30°C.

Volatiles were collected from each sample material (12 g of whole leaves with petioles) on three different days. Newly flushed mulberry leaves are smaller and weighed less per leaf, and 10 g of leaves were analyzed for each replicate. Mature leaves with feeding damage were prepared by placing 12 g of whole mature leaves with petioles in a 125-ml flask with approximately 100–200 neonate larvae that were allowed to feed overnight, after which the larvae, frass, and silk were removed prior to volatile collection. Immediately after the 30-min exposure to the test material, the SPME fibers were analyzed with a gas chromatograph-mass spectrophotometer, GC-MS (HP Agilent 6890 Gas Chromatograph and HP 5973 Mass Spectrometer, Palo Alto, CA, USA), fitted with an HP-5MS column. The fiber was heated to 40°C for 1 min, increased 10°C/min to 250°C, and then held at 250°C for 5 min. SPME fibers were blanked (baked at 250°C for 5 min) immediately prior to collecting volatiles.

Volatile peaks that were identified with at least 80% confidence by Enhanced MSD Chemstation (version D.02.00.275, Agilent Technologies) software and the NIST Mass Spectral Database were considered candidates. The identity of the candidate volatiles were confirmed with standards purchased from Sigma-Aldrich (St. Louis, MO, USA) with purities typically greater than 98%. Small amounts of the pure standards were spotted onto filter paper in a flask, exposed to a SPME fiber for 5 min, and analyzed on the GC-MS using the same program. The identity of the leaf volatiles was confirmed if the retention times and mass spectra of the standard chemical and the peak in leaf volatile samples matched.

Results

Leaf Disk Assays To evaluate the two-choice leaf disk assay, two similar samples were compared (leaf disks cut from mature mulberry leaves). The naive neonate silkworm larvae did not exhibit any bias; equal proportions selected each of the two similar samples (chi-square=0.03, P=0.87). The same results were obtained when larvae were tested individually, supporting the subsequent use of larvae in groups of five (unpublished results). When presented with similar choices, a greater proportion of larvae failed to select either sample within the 15-min assay (Fig. 1).

Larvae demonstrated a clear preference for leaf disks cut from newly flushed leaves (74%) compared to disks from mature leaves (20%; Fig. 1, chi-square=15.5, P<0.001). The same preference for newly flushed leaves was demonstrated in preliminary experiments that used individual larvae (unpublished results). Mature leaf disks with conspecific feeding damage also were clearly preferred (80%) compared to mature leaf disks with no damage (12%; chi-square=25.1, P<0.001). Larvae preferred mature leaf disks with conspecific feeding damage (60%) compared to newly flushed leaf disks (32%), but the difference was less pronounced (Fig. 1, chi-square=4.26, P=0.04). In all three of these choice experiments, more than 92% of the larvae chose one of the treatments within 15 min.

Surprisingly, the moist filter paper used to keep leaf disks with feeding damage from desiccating was highly attractive in preliminary choice assays. We assayed the attractiveness of filter paper relative to mature leaf disks with feeding damage, the most attractive leaf type. Filter paper underneath leaf disks with feeding damage was significantly preferred (76%) compared to the filter paper (12%) underneath mature leaves with no feeding damage (Fig. 1, chi-square=23.3, P<0.001). Mature leaf disks with feeding damage appeared to be only slightly more attractive (50%) when compared to filter paper (38%) that they were placed on top off, and the difference was not statistically significant (chi-square=0.82, P=0.37). The odor(s) that

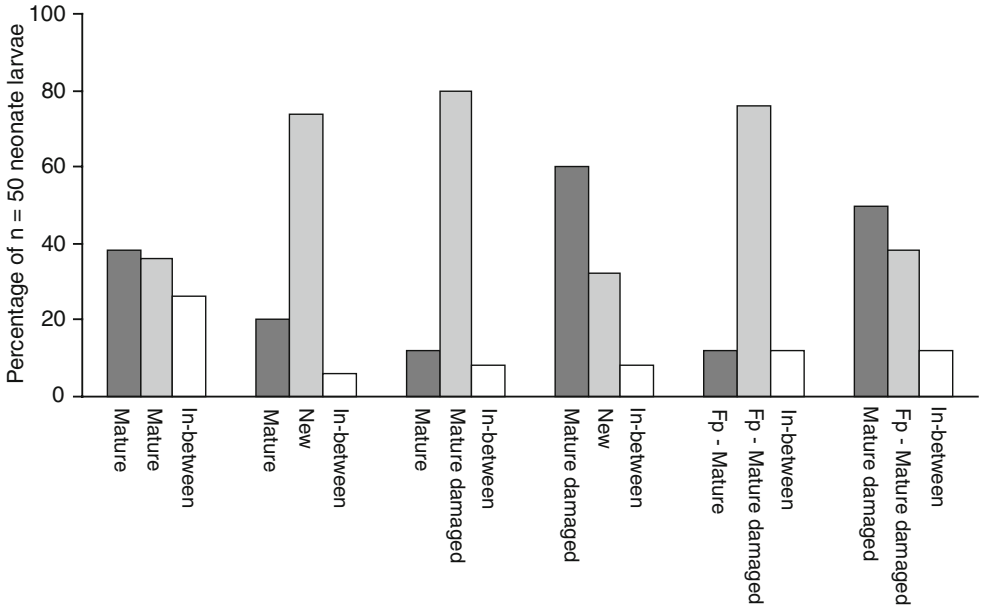

Fig. 1 Attraction of neonate silkworm larvae to different mulberry leaf types. Percentage *of N*=50 neonate larvae attracted to two different leaf disk types in six different choice experiments: (1) mature leaves vs. mature leaves (chi-square 0.03, P=0.87), (2) mature leaves vs. newly flushed leaves (chi-square 15.5, P<0.001), (3) mature leaves vs. mature leaves with feeding damage (chi-square 25.1, P< 0.001), (4) mature leaves with feeding damage vs. newly flushed leaves (chi-square 4.26, P=0.04), (5) filter paper exposed to mature leaves (*Fp-mature*) vs. filter paper exposed to mature leaves with feeding damage (*Fp-mature damage*; chi-square 23.3, P<0.001), and (6) mature leaves with feeding damage vs. the filter paper exposed to mature leaf disks with feeding damage (chi-square 0.82, P=0.37). Larvae that did not exhibit a preference after 15 min were termed in-between

absorbed into the filter paper were highly attractive even when compared to the most attractive leaf type.

SPME Fiber Assay SPME analysis of whole mulberry leaves with petioles attached (conducted in triplicate) yielded different volatile profiles for each category (Fig. 2, Table 1). Figure 2 illustrates the volatile profile of a typical replicate for each leaf type, and Table 1 lists the identities (confirmed using standard reference chemicals) and their proportional abundance. The mature mulberry leaves yielded a relatively simple volatile profile with two predominant peaks (#2 and #5) representing (*Z*)-3-hexen-1-ol and an unidentified compound. A third less abundant peak, #16, was identified as (*Z*)-3-hexenyl butyrate (Fig. 2, Table 1). These three volatiles were detected in all three leaf types; (*Z*)-3-hexen-1-ol and the unidentified peak were predominant, while (*Z*)-3-hexenyl butyrate was less abundant, particularly in newly flushed leaves.

Newly flushed leaves also produced a greater number of minor peaks yielding a more complex volatile profile (peaks #8–11, 13–15, and 20–22). However, with the exception of #13 ((*Z*)-β-ocimene), the abundance of these minor peaks (identified as a variety of terpenes including α-terpinene, *o*-cymene, D-limonene, eucalyptol, γ-terpinene, linalool, caryophyllene, and β-cubebene) was measurable in only one of the three replicates (Table 1). For example, while minor peaks #8 to 11 were identified in Fig. 2b, their abundance was below the software's detection threshold in all but one replicate. The proportional abundance of these minor peaks ranged from 1.1% to 4.4% of the total volatiles (percent of the total peak area, Table 1). The variability between replicates may be related to variability in the developmental stage of newly flushed leaves collected in the field.

Mature mulberry leaves with conspecific feeding damage produced more complex volatile profiles that were consistent between replicates (Table 1). In addition to the three common volatiles (peaks #2, 5, and 16), several short-chain alcohols, aldehydes, and acetates were produced by leaves with feeding damage, including (*E*)-2-hexenal, (*E*)-2-hexen-1-ol, 1-hexenol, hexyl acetate, and (*E*)-2-hexenyl acetate (peaks #1, 3, 4, 6, and 7). Other volatiles that were detected from leaves with feeding damage included eucalyptol, (*E*)-β-ocimene, (*Z*)-β-ocimene, linalool, (*Z*)-3-hexenyl butyrate, hexyl butyrate, methyl salicylate, (*Z*)-3-hexenyl 2-methylbutanoate, caryophyllene, β-cubebene, and α-farnesene (peaks #11–13, 15–22, Fig. 2 and Table 1). The abundance of eucalyptol, (*E*)-β-ocimene, methyl salicylate, and caryophyllene was measurable in one replicate only. Several of these volatiles may be associated with leaves that have feeding damage, including (*E*)-2-hexenal, (*E*)-2-hexen-1-ol, 1-hexenol, hexyl acetate, (*E*)-2-hexenyl acetate, (*E*)-β-ocimene, hexyl butyrate, methyl salicylate, (*Z*)-3-hexenyl 2-methylbutanoate, and α-

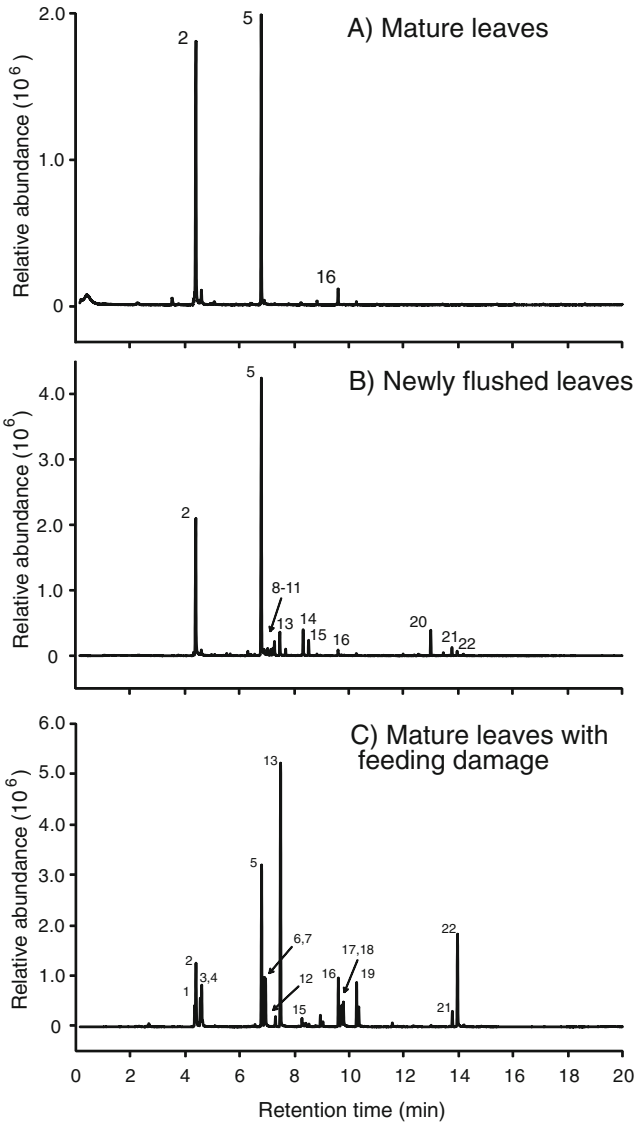

Fig. 2 Volatile profile of three mulberry leaf types. **a** Mature leaves, **b** newly flushed leaves, and **c** mature leaves with feeding damage from neonate silkworms. Each of the selected total ion current chromatograms are representative of three replicated experiments. The numbered peaks correspond to compounds identified in Table 1. Retention time (min) is labeled on the *x-axis*, relative abundance ($\times 10^6$) on the *y-axis*

farnesene (Table 1). Of particular note, α-farnesene was produced consistently in all three replicates of feeding-damaged leaves (proportional abundance ranged from 6% to12%), indicating that it may function as a herbivore-induced volatile, much as it is known to act in the apple coddling moth/apple tree system (Landolt et al. 2000). A small peak corresponding to α-farnesene was detected from newly flushed leaves, but its abundance was below threshold levels. Also notable, methyl salicylate was detected as a volatile specific to herbivore-damaged mulberry leaves although in one replicate only. Methyl salicylate is an important mobile signal for plant systemic acquired resistance (Park et al. 2007), and its ability to attract beneficial insects has been tested in field trials (James and Price 2004).

Discussion

Using a two-choice leaf disk assay, naive neonate silkworm larvae were found to be strongly attracted to mature mulberry leaves with conspecific feeding damage and also to newly flushed leaves, compared to undamaged mature leaves. The neonate larvae of Lepidoptera species commonly feed on newly flushed foliage, presumably because it is easier to digest, providing a plausible biological rationale for the attraction of neonate silkworms to newly flushed mulberry leaf disks. The attraction of neonate silkworms to mulberry leaves with conspecific feeding damage was strong and more difficult to explain. The behavior was robust enough that larvae placed on a lab bench all crawled towards leaves with feeding damage rather than undamaged leaves. Neonate apple codling moth (*C. pomonella*) larvae and neonate fall armyworm (*S. frugiperda*) larvae also have been found to be attracted to host plants damaged by conspecific feeding (Landolt et al. 2000; Carroll et al. 2008). The emission of specific plant volatiles in response to insect feeding damage and their role in attracting and recruiting natural enemies of the herbivore has been well documented (Dicke et al. 1988; Turlings et al. 1995; Pare and Tumlinson 1999; Kessler and Baldwin 2001; Hoballah and Turlings 2005). However, the response of the herbivores themselves to the volatiles induced by their feeding has not been as well studied (De Moraes et al. 2001). Locating and establishing suitable feeding sites is critical to the survival of neonate larvae (Zalucki et al. 2002). Larval aggregation in the Lepidoptera is not uncommon, and it is believed to confer advantages such as increasing foraging efficiency and aiding in defense (Zalucki et al. 2002). Neonate larvae have limited searching capacity, and damaged tissues that emit more volatiles might be easier to detect (Zalucki et al. 2002). Herbivore-induced volatiles may also provide information about host plant quality (Carroll et al. 2006). Conspecific feeding may be a marker of habitat fitness on the basis that other individuals have found a particular location to be suitable for feeding (Stamps and Krishnan 2005). Furthermore, when the concentration of conspecifics in an area increases, their ability to overcome plant defenses may increase (Prokopy and Roitberg 2001). Other behavioral aspects of caterpillar aggregation have been discussed recently in Carroll et al. (2006) and Carroll et al. (2008).

Compared to mature undamaged leaves, the volatile profile of newly flushed mulberry leaves and mature leaves

Table 1 GC-MS analysis of mulberry leaf volatiles collected by using SPME fibers

Peak #	Compound	Retention Time (min)	Proportion (%) of total peak area[a] (mean ± S.D.)		
			Mature	New	Eaten
1	(*E*)-2-Hexenal	4.35			3.9±3.6

Volatiles were collected and identified from three types of whole Mulberry leaf: (a) mature dark green leaves, (b) newly flushed light green leaves from branch tips, and (c) mature leaves with feeding damage from neonate silkworms. The abundance of each volatile is reported as a proportion of the total peak area. Numbered volatiles correspond to the peak numbers on the total ion current chromatograms in Fig. 2. The identity of 16 volatiles was verified by using standard reference chemicals with purities typically greater than 98%

[a] Bracketed numbers indicate that the volatile was detected in only one of three replicates

[b] Six volatiles for which standard chemicals could not be obtained

damaged by conspecific feeding was more complex. Of the 22 volatiles identified, two green leaf volatiles were common to most samples, (*Z*)-3-hexen-1-ol, and (*Z*)-3-hexenyl butyrate. Several other green leaf volatiles (6-carbon alcohols, acetates, and aldehydes), including (*E*)-2-hexenal, (*E*)-2-hexen-1-ol, hexyl acetate, (*E*)-2-hexanyl acetate, and hexyl butyrate were detected only from whole mulberry leaves that had sustained feeding damage from neonate silkworms for a period of approximately 18 h. Green leaf volatiles typically are released quickly after mechanical damage caused by biotic or abiotic factors. Green leaf volatiles associated with fresh mechanical damage subside quickly, and herbivore-induced volatiles such as terpenoids produced several hours later are indicative of older damage (Hoballah and Turlings 2005). The mulberry leaves used in this study had sustained feeding damage continuously up until the time that volatiles were sampled with SPME fibers, yielding a mixed fresh and older damage volatile profile.

In addition to the green leaf volatiles, several terpenoids were identified from leaves with feeding damage (Table 1). These included eucalyptol, (*E*)- and (*Z*)-β-ocimene, linalool, caryophyllene, β-cubebene, caryophyllene, and α-farnesene. Several terpenoids were identified from newly flushed leaves but at low abundance and inconsistently between replicates. Among these candidate odors, α-farnesene may be one of the more interesting volatiles since it was produced consistently by mulberry leaves with feeding damage. Neonate apple coddling moth larvae are attracted to α-farnesene, which is produced in response to feeding damage by conspecific larvae (Landolt et al. 2000). In our experiments, moist filter paper placed underneath the leaf disks with feeding damage also was highly attractive. A preliminary GC-MS analysis of the filter paper volatiles (Supple-

mentary Fig. 1) yielded α-farnesene as the predominant peak.

Also interesting was the fact that methyl salicylate, involved in resistance signaling in plants (Park et al. 2007), was detected only from mulberry leaves with feeding damage (however, in one replicate only). Recent research indicates that methyl salicylate also may influence the behavior of beneficial insects (Williams et al. 2008). However, when a variety of pure volatiles was tested in the two-choice assay (unpublished results), larval responses were weak and difficult to interpret. Linalool, abundantly induced by fall armyworm feeding on maize seedlings, was attractive to sixth instars on its own or as a supplement to whole plant odors (Carroll et al. 2006). To simulate a natural blend, we used mature leaf disks spiked with a range of concentrations of the candidate volatiles. However, we could not demonstrate a clear attraction to any one volatile. A blend of volatiles or more natural release rates may be required to replicate the attraction.

The attraction of neonate silkworms to mulberry leaves damaged by feeding occurred in the absence of prior feeding or olfactory experience with the host plant, suggesting that the behavior is innate. The attraction of neonate fall armyworms to cowpea seedlings also occurred in the absence of prior experience (Carroll et al. 2008). Neonate larvae have a limited time in which to successfully locate and establish a feeding site before starving. Pest management strategies that alter the chemosensory profile of the host plant might have potential for exploiting this vulnerable stage. Chemical cues that stimulate neonate dispersal from the host plant may increase mortality rates (e.g., (Varela and Bernays 1987; Carroll et al. 2006).

The fact that silkworms are attracted to herbivore-induced volatiles provides an opportunity to study the molecular mechanisms that underlie this behavior. The silkworm genome has been sequenced, and genetic tools continue to be developed, making it one model species that represents the Lepidoptera. Some *Drosophila* Ors are expressed specifically in the larval stage (Kreher et al. 2005) suggesting they detect odors that mediate larval-specific behaviors. The candidate odors identified in this study will be used as ligands to characterize the function of larval-specific silkworm Ors. Many of the molecular mechanisms of host seeking and selection behavior in the Lepidoptara are likely to be conserved, and research that used model species, such as the silkworm, can be applied to economically significant pest species.

Acknowledgments We thank the Hanks' lab for the use of the GC-MS and technical advice, Annie Ray and Emerson Lacey for their help with designing experiments and running the GC/MS, and Art Zangerl for assisting with volatile identification. We also thank the two anonymous reviewers for helpful comments that improved the manuscript. This research was funded by USDA NRI grant #2006-03826.

Gustatory Responsiveness to Six Bitter Tastants in Three Species of Nonhuman Primates

Matthias Laska · Rosa Mariela Rivas Bautista · Laura Teresa Hernandez Salazar

Received: 13 January 2009 / Revised: 17 March 2009 / Accepted: 6 April 2009 / Published online: 29 April 2009

Abstract Gustatory responsiveness of six adult squirrel monkeys, four spider monkeys, and five pigtail macaques to six bitter tastants was assessed in two-bottle preference tests of brief duration (2 min). Animals were given the choice between a 30-mM sucrose solution and defined concentrations of a bitter tastant dissolved in a 30-mM sucrose solution. With this procedure, *Saimiri sciureus*, *Ateles geoffroyi*, and *Macaca nemestrina* were found to significantly discriminate concentrations as low as 0.2, 0.05, and 0.1 mM quinine hydrochloride; 1, 1, and 0.05 mM caffeine; 20, 5, and 1 mM naringin; 5, 2, and 1 mM salicin; 0.01, 0.001, and 0.02 mM sucrose octaacetate; and 0.05, 0.01, and 0.5 mM denatonium benzoate, from the alternative stimulus. With the exception of naringin in the pigtail macaques, all three species rejected all suprathreshold concentrations of all bitter tastants tested. The spider monkeys and the pigtail macaques displayed the lowest taste avoidance thresholds with three of the six tastants each; in contrast, the squirrel monkeys displayed the highest taste avoidance thresholds with four of the six tastants. The across-tastant patterns of taste avoidance thresholds were identical in spider monkeys and squirrel monkeys; both species displayed the following order of sensitivity: sucrose octaacetate > denatonium benzoate > quinine hydrochloride > caffeine > salicin > naringin. All three primate species were more sensitive to the two artificial tastants (sucrose octaacetate and denatonium benzoate) compared to the four naturally occurring tastants. However, the concentrations detected by all three primate species with the four naturally occurring tastants are well below those reported in plants or arthropods consumed by these species suggesting that they may use bitterness as a criterion for food selection.

Introduction

The sense of taste has been investigated behaviorally (e.g., Glaser 1986; Pritchard et al. 1994; Hladik et al. 2002) and electrophysiologically (e.g., Hellekant and Ninomiya 1994; Scott et al. 1998, 1999) in a number of primate species. However, most studies have concentrated on detectability of the five basic taste qualities, mainly by using the alkaloid quinine hydrochloride as the only prototypic bitter stimulus. Only sparse information is available on the behavioral responsiveness of nonhuman primates to naturally occurring bitter tastants other than this alkaloid. This is all the more surprising given the wide variety of chemical classes that comprise naturally occurring bitter-tasting substances (DuBois 2007) and given that the vast majority of food-related toxins taste bitter to humans (Rouseff 1990). Further, both plants and arthropods frequently use bitter-tasting and often highly toxic compounds as deterrents against potential predators (Belitz and Wiester 1985; Eisner et al. 2005). Therefore, it should be adaptive for primates to detect bitter tastants at concentrations low enough to prevent ingestion of too high amounts of such potentially toxic compounds.

Given the presumed importance of bitter tastants for food selection in primates, it was the aim of the present

study to assess the gustatory responsiveness of three species of nonhuman primates to six bitter tastants belonging to different chemical classes. Four of these tastants, quinine hydrochloride, caffeine, naringin, and salicin, occur naturally in both plants and arthropods, whereas the other two, sucrose octaacetate and denatonium benzoate, have not been found so far in nature (Belitz and Wiester 1985).

As all primate species tested so far reject substances that taste bitter to humans, a two-bottle preference test of brief duration (2 min) was employed. This method makes it possible to measure directly preferences for or aversions to tastants and largely rules out the possibility of postingestive factors on the animals' ingestive behavior. Further, as all three primates used in the present study cooperated in tests of liquid consumption only as long as at least one of the alternatives was a sapid solution, we decided to use a 30-mM sucrose solution rather than water, both as the solvent for the tastant and as the alternative stimulus. This concentration of sucrose is only a factor of 3 above the taste preference threshold of the squirrel monkeys and the pigtail macaques, respectively, and a factor of 10 above that of the spider monkeys and thus represents a weak sweet stimulus that is unlikely to mask the bitter tastant.

The three primate species employed here, squirrel monkeys (*Saimiri sciureus*), spider monkeys (*Ateles geoffroyi*), and pigtail macaques (*Macaca nemestrina*), are known to differ—at least to some degree—in their dietary habits (Caldecott 1986; Lima and Ferrari 2003; Gonzalez-Zamora et al. 2009), thus allowing us to address the question whether possible differences in bitter taste responsiveness may reflect an evolutionary adaptation to dietary specialization. The ability to include two New World and one Old World primate species (the macaques) allowed us to address additionally the question whether the degree of phylogenetic relatedness rather than dietary specialization may affect the bitter taste responsiveness of nonhuman primates.

Methods and Materials

Animals Testing was carried out with six male adult squirrel monkeys (*S. sciureus*), two male and three female adult pigtail macaques (*M. nemestrina*), and four female adult spider monkeys (*A. geoffroyi*). Animals were housed as social groups in enclosures with adjacent single cages that could be closed by sliding doors to allow temporary separation of animals for individual testing (for details of maintenance, see Laska 1996, 2000; Laska et al. 1996). All animals were born in captivity and had no experience with natural vegetation. They were fed commercial monkey chow, fresh fruit, and vegetables ad libitum but were deprived of water overnight before testing on the following morning. The amount of food offered daily to the animals was such that leftovers still were present on the floor the next morning. Thus, it was unlikely that ravenous appetite affected the animals' ingestive behavior during the tests.

Taste Stimuli A set of six substances tasting bitter to humans was used: quinine hydrochloride (quinine is a naturally occurring alkaloid in the bark of cinchona trees; as it is a basic amine, it is presented as a salt, in this case as a hydrochloride, Chemical Abstracts Service # 130-89-2), caffeine (a naturally occurring xanthine alkaloid, e.g., in coffee plants, CAS# 58-08-2), naringin (a naturally occurring flavonoid glycoside, e.g., in grapefruit, CAS# 10236-47-2), salicin (a naturally occurring phenol glycoside in many Salicaceae, CAS# 138-52-3), sucrose octaacetate (an artificial acetylated sucrose derivative, CAS# 126-14-7), and denatonium benzoate (an artificial compound with the International Union of Pure and Applied Chemistry name phenylmethyl-[2-[(2,6-dimethylphenyl)amino]-2-oxoethyl]-diethylammonium benzoate, CAS# 3734-33-6). The rationale for using these substances was that they represent different chemical classes and are naturally occurring as well as artificial bitter tastants. All substances were obtained from Sigma-Aldrich (St. Louis, MO, USA) and were of the highest available purity.

Procedure Taste responsiveness to the six bitter tastants mentioned above was assessed by using a two-bottle preference test of short duration (Richter and Campbell 1940). Twice each day, approximately 2 and 1 h before feeding, the animals were separated and allowed 2 min to drink from a pair of simultaneously presented graduated cylinders with metal drinking spouts.

Animals were given a choice between a 30-mM sucrose solution and defined concentrations of the bitter tastants dissolved in a 30-mM sucrose solution. With quinine hydrochloride, caffeine, naringin, and salicin, testing started at a concentration of 10 mM and proceeded in the following steps (10, 5, 2, 1, 0.5, 0.2, 0.1 mM, etc.) until the animals failed to show a significant preference or aversion. With sucrose octaacetate and denatonium benzoate, testing started at a concentration of 1 mM and proceeded in the following steps (1, 0.5, 0.2, 0.1, 0.05 mM, etc.).

To maintain the animals' motivation and willingness to cooperate, testing did not follow a strict order of increasing or decreasing bitter tastant concentrations but followed a pseudorandomized scheme in which trials with taste mixtures containing high and thus presumably aversive concentrations of a bitter tastant were alternated with mixtures containing low and thus presumably less aversive concentrations of the same bitter tastant.

Each pair of stimuli was presented a total of ten times, and the position of the stimuli was pseudorandomized in

order to counterbalance possible position preferences. All animals had served in previous studies that use the same method (Laska and Hernandez Salazar 2004, Laska et al. 2008). They were trained to enter the single cages voluntarily and were completely accustomed to the procedure.

The experiments reported here comply with the *Guide for the Care and Use of Laboratory Animals* (National Institutes of Health Publication no. 86-23, revised 1985) and also with current German and Mexican laws.

Data Analysis For each animal, the amount of liquid consumed from each bottle was recorded, summed for the ten test trials with a given stimulus combination, converted to percentages (relative to the total amount of liquid consumed from both bottles), and 66.7% (that is, two thirds of the total amount of liquid consumed) was taken as criterion of preference. This rather conservative criterion was chosen for reasons of comparability of data, as the same criterion had been used in previous studies that used the same method with the same primate species (Laska 1994, 1996, 1997, 1999, 2000; Laska et al. 1996, 1998, 1999, 2000a, b, 2001, 2008; Laska and Hernandez Salazar 2004), and in order to avoid misinterpretation of data due to a too liberal criterion.

Additionally, two-tailed binomial tests (Siegel and Castellan 1988) were performed, and an animal was only regarded as significantly preferring one of the two alternative stimuli if it reached the criterion of 66.7% and consumed more from the bottle containing the preferred stimulus in at least eight out of ten trials (binomial test, $P< 0.05$). Accordingly, at the group level, a given species was regarded only as significantly preferring one of the two alternative stimuli if all animals tested reached the criterion of 66.7%, and all animals consumed more from the bottle containing the preferred stimulus in at least eight out of ten trials.

Preliminary tests showed that the animals generally rejected solutions containing relatively high concentrations of the bitter tastants. Following convention, the results nevertheless are expressed as percentage preference for the tastant and not for the solvent. Accordingly, 33.3% (that is, one third of the total amount of liquid consumed) was taken as criterion of aversion.

Preliminary analysis of the data indicated that there were no reliable differences in choice behavior and liquid consumption between males and females of a species and between the first and the second presentation of the day. Intraindividual variability of the amount of liquid consumed across the ten test trials with a given stimulus combination was low and averaged less than 20%. Thus, a theoretically possible bias in the overall preference score due to excessive drinking in aberrant trials did not occur. Therefore, data obtained in ten test trials from an individual animal of a given species with a given stimulus combination were combined and are reported as group means and standard deviations.

Results

Figures 1, 2, and 3 show the mean taste responses of squirrel monkeys, spider monkeys, and pigtail macaques, respectively, in the two-bottle preference tests with a 30-mM sucrose solution used both as solvent for the bitter tastants and as the alternative stimulus.

Squirrel monkeys significantly discriminated concentrations as low as 0.2 mM quinine hydrochloride, 1.0 mM caffeine, 20 mM naringin, 5 mM salicin, 0.01 mM sucrose octaacetate, and 0.05 mM denatonium benzoate from the alternative stimulus (group level). In most cases, interindividual variability of scores was low, as can be inferred from the SDs in Fig. 1. Thus, at the individual level, the avoidance threshold values for a given tastant maximally differed by a factor of 5 (quinine hydrochloride, naringin, and denatonium benzoate), and usually less, between subjects.

At the group level, the spider monkeys significantly discriminated concentrations as low as 0.05 mM quinine hydrochloride, 1.0 mM caffeine, 5 mM naringin, 2 mM salicin, 0.001 mM sucrose octaacetate, and 0.01 mM denatonium benzoate from the alternative stimulus. As for the squirrel monkeys, interindividual variability of scores was usually low (compare SDs in Fig. 2) and avoidance threshold values for a given tastant maximally differed by a factor of 5 (quinine hydrochloride), and in one case (caffeine) not at all, between subjects.

Pigtail macaques showed significant discrimination of concentrations as low as 0.1 mM quinine hydrochloride, 0.05 mM caffeine, 1 mM naringin, 1 mM salicin, 0.02 mM sucrose octaacetate, and 0.5 mM denatonium benzoate from the alternative stimulus (group level). Again, interindividual variability of scores was low in most cases (compare SDs in Fig. 3). Thus, at the individual level, the avoidance threshold values for a given tastant maximally differed by a factor of 5 (caffeine), and in two cases (quinine hydrochloride and denatonium benzoate) not at all, between subjects. Interestingly, the pigtail macaques preferred rather than rejected naringin at concentrations between 10 and 1 mM.

With all six bitter tastants and all three species, we observed that, in each trial, each animal sampled both alternatives at least once and, with the exception of the highest bitter tastant concentrations, even tended to switch between bottles more than once.

Comparison Among Species Among the three primates tested, the spider monkeys (with quinine hydrochloride,

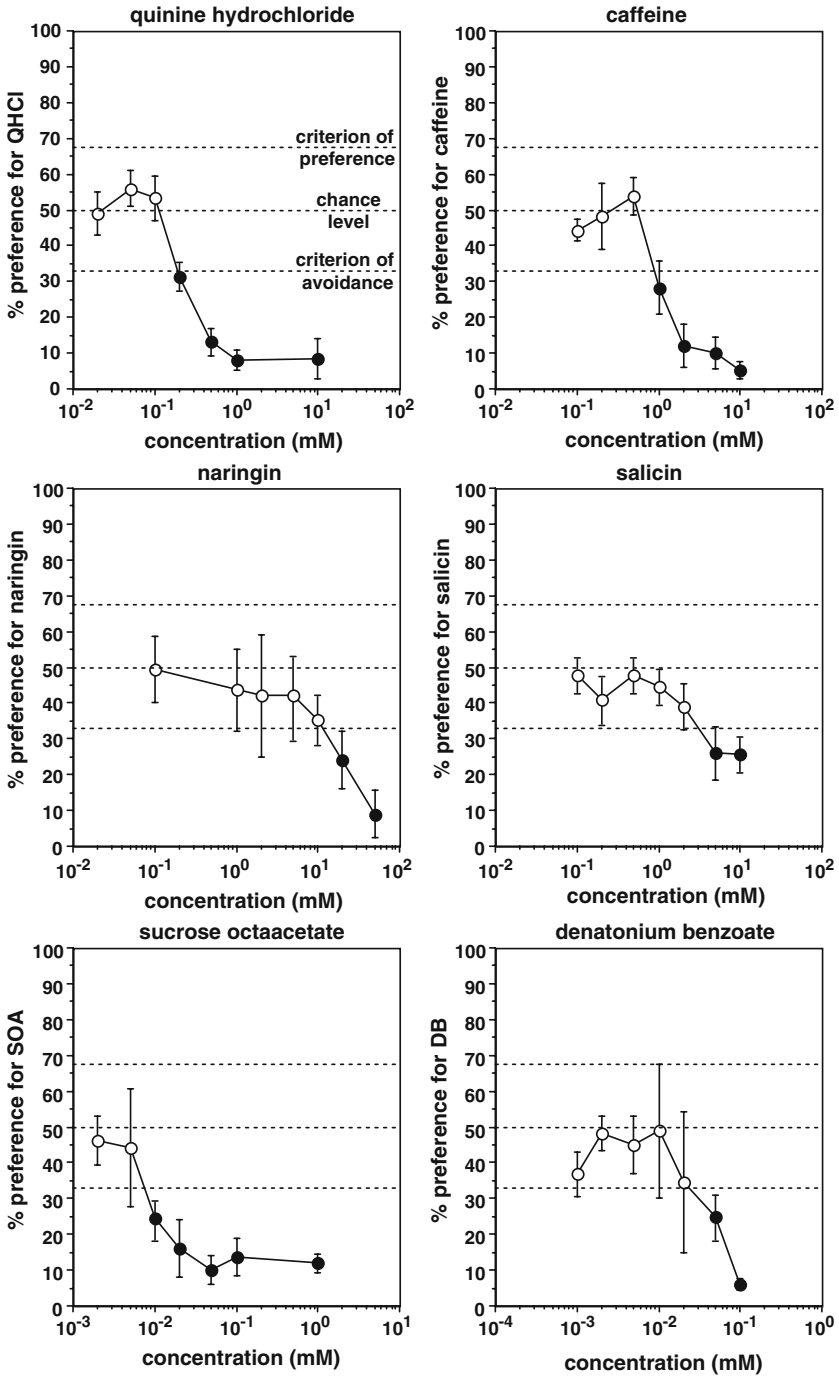

Fig. 1 Gustatory responsiveness of six squirrel monkeys to various concentrations of quinine hydrochloride, caffeine, naringin, salicin, sucrose octaacetate, and denatonium benzoate dissolved in a 30-mM sucrose solution and tested against a 30-mM sucrose solution as an alternative stimulus. Each data point represents the mean value (±SD) of ten test sessions of 2 min per animal. *Black* data points indicate concentrations at which all animals significantly rejected the bitter tastant (binomial test, $P<0.05$)

sucrose octaacetate, and denatonium benzoate) and the pigtail macaques (with caffeine, naringin, and salicin) showed the lowest taste avoidance thresholds with three of the six tastants each. The squirrel monkeys, in contrast, showed the highest taste avoidance thresholds with four of the six tastants (quinine hydrochloride, caffeine, naringin, and salicin). However, the across-tastant patterns of taste avoidance thresholds were identical between spider monkeys and squirrel monkeys, with both species displaying the following order of sensitivity: sucrose octaacetate > denatonium benzoate > quinine hydrochloride > caffeine > salicin > naringin. Accordingly, a significant positive correlation between the across-tastant patterns of sensitivity for the tastants tested with these two species was found (Spearman, $r_s=0.76$, $P<0.01$). The pigtail macaques displayed an across-tastant pattern of taste avoidance thresholds (sucrose octaacetate > caffeine > quinine hydrochloride > denatonium benzoate > salicin = naringin), which differed from that of the two other species. Accordingly, no significant correlation between the across-tastant pattern of *M.*

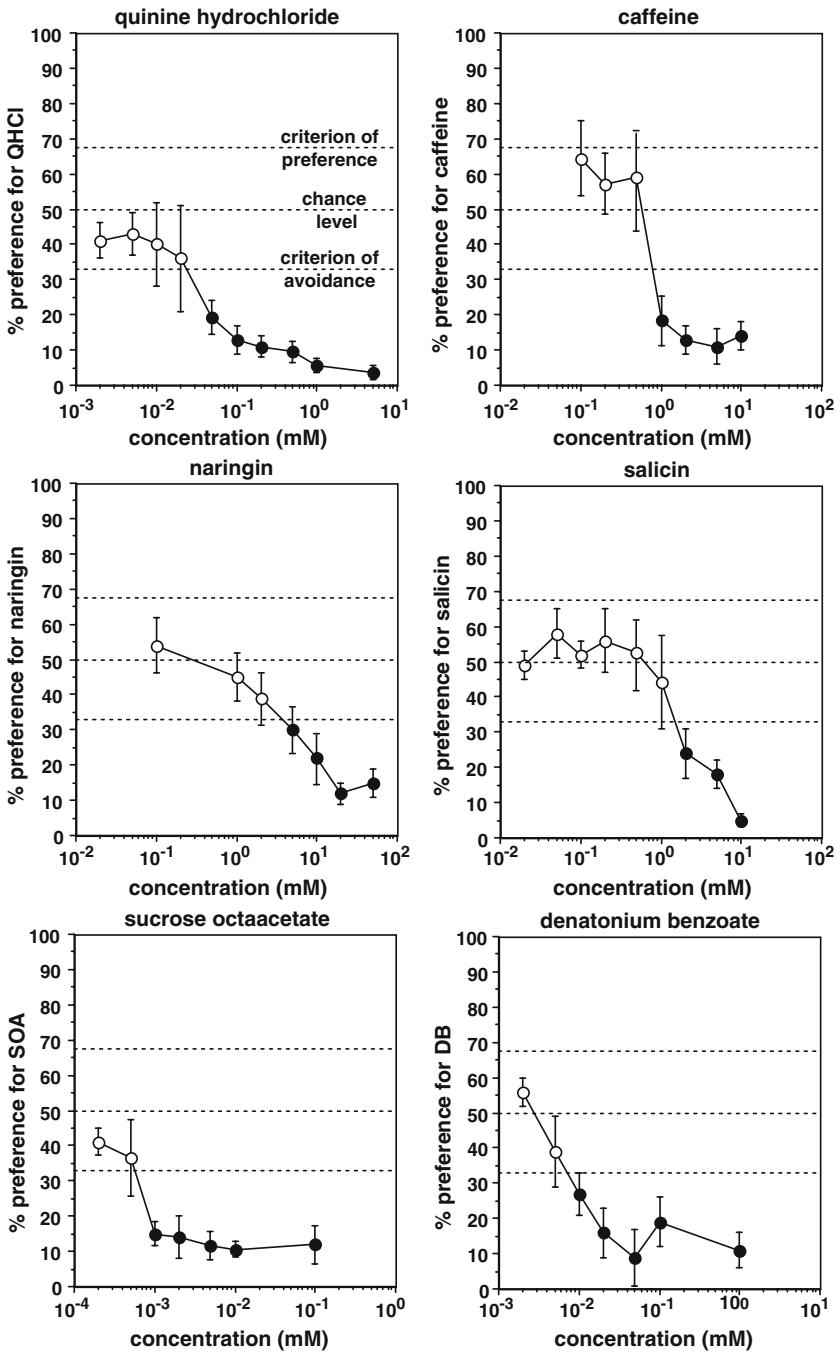

Fig. 2 Gustatory responsiveness of four spider monkeys to various concentrations of quinine hydrochloride, caffeine, naringin, salicin, sucrose octaacetate, and denatonium benzoate dissolved in a 30-mM sucrose solution and tested against a 30-mM sucrose solution as an alternative stimulus. Each data point represents the mean value (±SD) of ten test sessions of 2 min per animal. *Black* data points indicate concentrations at which all animals significantly rejected the bitter tastant (binomial test, $P<0.05$)

nemestrina and of *A. geoffroyi* (Spearman, $r_s=0.24$, $P>0.05$) and *S. sciureus* (Spearman, $r_s=0.26$, $P>0.05$) was found. Nevertheless, all primate species were most sensitive to sucrose octaacetate and least sensitive to naringin.

Discussion

The results of this study are a first and conservative approximation of the gustatory sensitivity of three primate species for the six bitter tastants tested. Although only between four and six animals per species were tested, the results appear robust as interindividual variability generally was low (see SDs in Figs. 1, 2, and 3). Further, with all tastants and all species, the lowest concentrations presented were consumed at equal amounts compared to the alternative stimulus, suggesting that the avoidance of (or, in the case of naringin with the pigtail macaques, preference for) higher concentrations of a stimulus was based on taste perception and not on other cues. However, the possibility of the tastants acting on olfactory and/or trigeminal receptors in the nose and/or the oral cavity cannot be

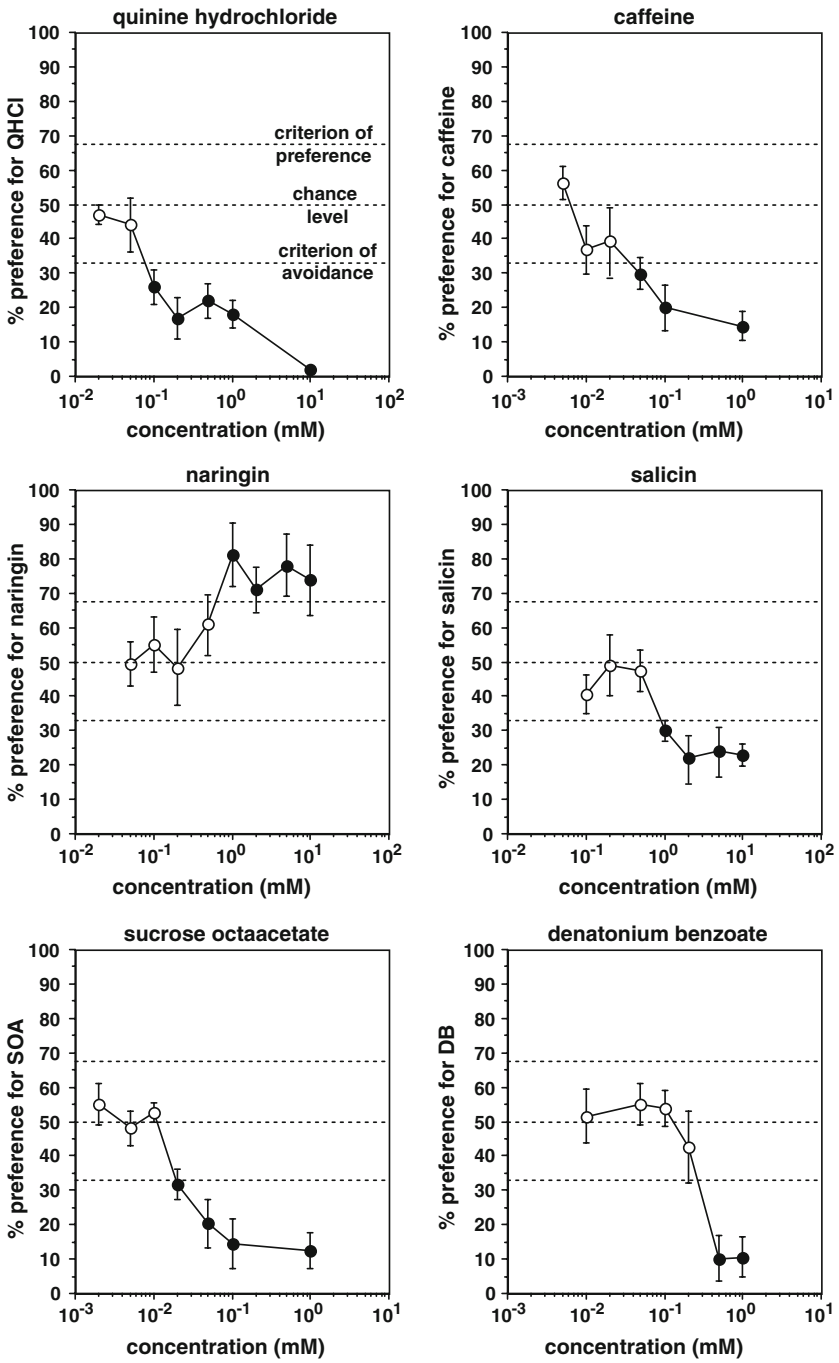

Fig. 3 Gustatory responsiveness of five pigtail macaques to various concentrations of quinine hydrochloride, caffeine, naringin, salicin, sucrose octaacetate, and denatonium benzoate dissolved in a 30-mM sucrose solution and tested against a 30-mM sucrose solution as an alternative stimulus. Each data point represents the mean value (±SD) of ten test sessions of 2 min per animal. *Black* data points indicate concentrations at which all animals significantly rejected (or, in the case of naringin, preferred) the bitter tastant (binomial test, $P<0.05$)

excluded. Similarly, the possibility that postingestive factors might have led to a conditioned aversion across trials that, in turn, might have affected the results cannot be excluded. There was no indication that the animals' avoidance of the bitter stimuli changed across trials. Taste qualities such as "bitter" are a human construct; it is not known whether other species experience the same percept as we do. Nevertheless, there is evidence of nonhuman primate taste receptors specialized to respond to and taste fibers, as well as cortical areas specialized to convey and process information about chemicals described as "bitter" by humans (Hellekant and Ninomiya 1994; Scott et al. 1999; Behrens and Meyerhof 2006).

Table 1 compares the taste avoidance thresholds of *S. sciureus*, *A. geoffroyi*, and *M. nemestrina* obtained here with data available from other species. Such across-species comparisons should take into consideration that different methods may lead to differing results. The present study employed a weak sucrose solution as solvent for the tastants, whereas other studies employed water. Similarly, in our study, the stimuli were presented for 2 min per trial, whereas some others have used different presentation times.

Additionally, the criterion used to define an avoidance threshold may differ among studies. All studies included in Table 1, however, employed two-bottle preference tests and were not conditioned to taste aversion or operant conditioning procedures and thus are basically the same method.

Whereas taste responsiveness to quinine hydrochloride has been tested with more than a dozen species of nonhuman primates and an even higher number of nonprimate mammals, data for the other tastants used in this study are sparse. The taste avoidance threshold of spider monkeys for quinine hydrochloride (0.05 mM) is one of the lowest values among the nonhuman primate species tested. It is interesting that the taste avoidance threshold of pigtail macaques for quinine hydrochloride (0.1 mM) is a factor 6–8 lower than that of the rhesus macaque and a factor of 10 lower than that of the long-tailed macaque, all species belonging to the same genus *Macaca*. All primate species tested here compare favorably in their responsiveness to quinine hydrochloride with the mouse. Other nonprimate mammals such as the cat (0.005 mM), the pig (0.002 mM), and the European mole (0.0005 mM) appear to be more sensitive for quinine hydrochloride than the primates tested here, whereas the horse (5.0 mM) and the rabbit (2.0 mM) show markedly higher avoidance threshold values and appear to be less sensitive than the primates tested here.

The only other data for any of the five other tastants used in the present study with other species of nonhuman primates were obtained with the rhesus macaque (Aspen et al. 1999). This Old World primate seems to be markedly less sensitive for caffeine (1.5 mM) than the pigtail macaque (0.05 mM) but similar to spider monkeys and squirrel monkeys (1.0 mM, respectively) and slightly more sensitive to denatonium benzoate (0.22 mM) than the pigtail macaque (0.5 mM), but less sensitive than the spider monkey (0.01 mM) and the squirrel monkey (0.05 mM).

The only species of nonprimate mammals for which data from all six tastants are at hand is the mouse. This rodent species appears to be less sensitive for caffeine and salicin and more sensitive for naringin than the three primates, but with avoidance threshold values for quinine hydrochloride, sucrose octaacetate, and denatonium benzoate falling into the range obtained with the three primate species. Although the across-tastant pattern of avoidance thresholds in the mouse (sucrose octaacetate > denatonium benzoate = quinine hydrochloride > naringin > caffeine = salicin) differs from those of the nonhuman primates tested, this species, too, appears to be more sensitive to the two artificial tastants compared to the four naturally occurring ones.

Our finding that the taste avoidance thresholds found here were about one (caffeine, naringin, and salicin) to four (denatonium benzoate) log units higher than the taste detection thresholds established in humans suggests that *Homo sapiens* is markedly more sensitive to bitter tastants than the primates tested here and, in fact, any nonhuman primate species tested so far (see Table 1). However, the sophisticated psychophysical signal detection methods employed with human subjects are likely to be more sensitive than the simple two-bottle preference test used with both nonhuman primates and nonprimate mammals. This assumption is supported by findings from Pritchard et al. (1995) who reported that taste thresholds obtained with a conditioning paradigm in *Macaca mulatta* are 1.6–2.2 log units lower than those obtained using a preference paradigm with the same species and are approximately 1.5 log units lower than human detection thresholds. This suggests that the sensitivity of the primates employed in our study might—at least for some of the tastants tested—be similar to or even match that of *H. sapiens*. The across-tastant pattern of taste detection thresholds obtained in humans (denatonium benzoate > sucrose octaacetate > quinine hydrochloride > caffeine > naringin > salicin) differs from those of the primates tested in our study, but humans, too, appear to be more sensitive to the two artificial bitter tastants compared to the naturally occurring ones.

Which factors might cause the differences in responsiveness within and between the species tested? It is well established that postingestive factors may influence an animal's ingestive behavior in subsequent encounters with the same type of food or liquid (Garcia and Hankins 1975). The method employed here, however, makes this possibility unlikely as the short duration of the tests (2 min per presentation) prevented animals from drinking amounts of liquid that are large enough to induce physiological effects that are perceptible.

Differences in dietary habits repeatedly have been shown to explain differences in taste performance among species (Kare 1971; Pfaffmann 1977; Spector 2000). Among New World primates, for example, the degree of frugivory correlates positively with sensitivity for food-associated monosaccharides and disaccharides (Laska 1996; Laska et al. 1996). Similarly, the proportion of animal matter in the diet of nonhuman primates correlates negatively with sensitivity for monosodium glutamate (Laska and Hernandez Salazar 2004). A comparison of 30 mammal species found a relationship between sensitivity for quinine hydrochloride and dietary specialization, with carnivores > omnivores > grazers > browsers (Glendinning 1994). This finding is consistent with the idea that animals with a relatively high occurrence of bitter and potentially toxic compounds in their diet, such as browsing herbivores, should have evolved a high bitter taste threshold (i.e., a low sensitivity) and, thus, a high tolerance to dietary toxins. In contrast, animals that rarely encounter bitter and potentially toxic compounds, such as carnivores, should have evolved a low bitter taste threshold (i.e., a high sensitivity) and, thus, a low tolerance to dietary toxins (Iason and Villalba 2006).

This idea is supported further by the fact that browsing herbivores that cannot afford to reject all foods that taste bitter usually have evolved physiological mechanisms that aid in detoxifying potential toxins upon ingestion, while carnivores are usually lacking such evolutionary adaptations in their gastrointestinal tracts (Belovsky and Schmitz 1991).

The three species tested in this study differ markedly in the proportion of animal matter in their diet. However, squirrel monkeys, the species showing the highest taste avoidance thresholds with the naturally occurring tastants, also have been reported to show the highest proportion of animal matter in their diet (72% of total intake) among the three species tested. Pigtail macaques, the species with the lowest avoidance threshold with three of the four naturally occurring tastants, on the other hand, include a considerably lower proportion of animal matter in their diet (13%). Spider monkeys, with an intermediate position in their bitter taste responsiveness, hardly consume any animal matter (1% of total intake; Caldecott 1986; Lima and Ferrari 2003; Gonzalez-Zamora et al. 2009). Thus, our findings do not seem to support the presumed positive correlation between bitter taste sensitivity and carnivory. However, animal matter consumed by squirrel monkeys consists mainly of arthropods rather than vertebrates. Arthropods frequently employ bitter-tasting secretions or hemolymph as deterrents against predators (Eisner et al. 2005). The relatively low bitter taste sensitivity observed in squirrel monkeys might be explained as an evolutionary adaptation to bitter-tasting arthropod deterrents. This idea is supported by the fact that the pigtail macaques, which displayed lower avoidance thresholds for quinine hydrochloride than two other members of the genus *Macaca*, include a lower proportion of arthropods in their diet than rhesus and long-tailed macaques (Caldecott 1986).

Old World and New World primates differ in their ability to perceive substances such as aspartame and thaumatin, which both taste sweet to humans, suggesting that phylogenetic relatedness also might account for differences or correspondences in taste perception among species (Nofre et al. 1996). However, in our study, spider monkeys and pigtail macaques, i.e., one New World and one Old World primate species, displayed the lowest taste avoidance thresholds with three of the six tastants. The possibility of phylogenetic relatedness as an explanation for the observed differences in responsiveness to the bitter tastants tested is unlikely.

Pigtail macaques did not reject detectable concentrations of naringin but rather preferred them over the alternative stimulus. Although our use of a 30-mM sucrose solution, both as the solvent for the tastants and as the alternative stimulus, might have contributed to this unusual pattern of performance, this seems unlikely, as this concentration of sucrose is only a factor of 3 above this species' preference threshold (Laska 2000) and thought to be weak enough to prevent massive masking effects or other types of qualitative interactions that may occur when applied in heterogenous taste mixtures (Stevens 1996). A more likely explanation for the observed preference of the pigtail macaques for naringin is that this substance may not have a purely bitter taste for this species but may evoke a mixed taste sensation involving a quality that is not bitter. Human psychophysical studies (Schiffman 2000) as well as electrophysiological recordings from single taste fibers in nonhuman primates (Hellekant and Ninomiya 1994) have demonstrated that a variety of substances evoke mixed taste sensations and elicit activity in more than one type of taste fibers, i.e., not only in bitter-best fibers.

The concentrations detected by the three primate species with the four naturally occurring tastants are well below those reported in fruits or other parts of plants that are consumed by these species (Nagy and Shaw 1980; Souci et al. 1989; Rouseff 1990). However, bitter tastants may not be distributed uniformly in plants but may be concentrated in specific regions of fruits, seeds, or leaves. Nevertheless, it seems reasonable to assume that the bitterness elicited by these compounds in the natural diet of *S. sciureus*, *A. geoffroyi*, and *M. nemestrina* plays a part in the food selection behavior of these species.

Cuticular Hydrocarbon Phenotypes Do not Indicate Cryptic Species in Fungus-Growing Termites (Isoptera: Macrotermitinae)

Andreas Marten · Manfred Kaib · Roland Brandl

Received: 20 November 2008 / Revised: 26 February 2009 / Accepted: 11 March 2009 / Published online: 28 April 2009

Abstract In several termite species, distinct differences in the composition of cuticular hydrocarbons among colonies correspond to high genetic divergence of mitochondrial DNA sequences. These observations suggest that hydrocarbon phenotypes represent cryptic species. Different cuticular hydrocarbon phenotypes also are found among colonies of fungus-growing termites of the genus *Macrotermes*. To determine if these hydrocarbon differences in *Macrotermes* also indicate cryptic species, we sequenced the mitochondrial CO I gene from species in West and East Africa. Among individuals of a supposed species but belonging to different cuticular hydrocarbon phenotypes, the genetic distances are much smaller than distances between species. Unlike what has been observed in other termites, *Macrotermes* hydrocarbon phenotypes do not represent cryptic species. Our findings suggest fundamental differences in the evolution and/or function of cuticular hydrocarbons among different termite lineages.

Introduction

Termites (Isoptera) have a complex social structure, similar to the social systems in some Hymenoptera, such as ants (Formicidae). However, these similar social structures are maintained through different intraspecific communication mechanisms. In ants, communication among nestmates is mediated by numerous glands and compounds (Hölldobler and Wilson 1990). In contrast, termites use a limited number of exocrine glands and few chemical compounds for communication (Billen and Morgan 1998; Kaib 2000; Peppuy et al. 2004). However, there is considerable evidence that termites use hydrocarbons on the epicuticle for nestmate and species recognition (e.g., Bagnères et al. 1991; Takahashi and Gassa 1995; Clément and Bagnères 1998; Kaib et al. 2002; Howard and Blomquist 2005). According to behavioral experiments, dissimilarity in the composition of cuticular hydrocarbons (CHC) are correlated with the level of agonistic behavior between colonies (e.g., Haverty and Thorne 1989; Haverty et al. 1999; Kaib et al. 2004a). Furthermore, inquilines, species from various insect orders that live within termite colonies, have a CHC composition similar to that of the host colony (Howard et al. 1980; Kaib et al. 2004b).

Insect CHCs range in chain length from C_{21} to C_{49} with saturated, unsaturated, and branched compounds (e.g., Lockey 1988; EstradaPena et al. 1994; Ye et al. 2007). This diversity allows for considerable qualitative and quantitative differences in the composition of CHCs among species or populations. Qualitative differences and large quantitative differences (CHC phenotypes) are interpreted to reveal variation among species, whereas moderate quantitative differences occur among conspecific populations (EstradaPena et al. 1994; Haverty and Nelson 1997; Takematsu and Yamaoka 1999; Page et al. 2002). Interspe-

cific differences in the composition of CHCs suggest that they are useful characters for species identification and taxonomy (Kaib et al. 1991; Bagine et al. 1994; Page et al. 2002; Ye et al. 2007). For example, in the termite genus *Reticulitermes* (Rhinotermitidae), CHC phenotypes correspond to mitochondrial DNA variation and provide evidence for cryptic species (Jenkins et al. 2000; Clément et al. 2001; Uva et al. 2004; Copren et al. 2005; Austin et al. 2007).

In several *Macrotermes* species, sympatric colonies have different CHC compositions (Bagine et al. 1994; Kaib et al. 2002, 2004a). The genus *Macrotermes* belongs to the fungus-growing Macrotermitinae within the most species-rich termite family Termitidae, also referred to as "higher termites". All other termite families are often labeled as "lower termites". To determine if qualitative CHC differences in higher termites also correspond to cryptic species, we sequenced the mitochondrial gene cytochrome *c* oxidase subunit I (CO I) from several *Macrotermes* species with differing CHC phenotypes.

Methods and Materials

We collected major workers from 27 colonies of *Macrotermes* from West and East Africa (Table 1) and divided the sample of each colony into two batches for chemical and genetic analysis, respectively. For each colony, we sequenced the CO I gene, a mitochondrial DNA fragment, which has been frequently used for the delimitation of taxonomic entities (Hebert et al. 2003; Smith et al. 2005; Aldrich and Kambhampati 2007). CHC composition was characterized for several of those colonies that were not previously analyzed in respect to DNA sequence variation (Kaib et al. 2002, 2004a). According to classical taxonomy, these colonies belong to four species. Colonies of the same

[a] Chemical work has been documented previously, and we give the colony codes and phenotype labels used in the original publications (Kaib et al. 2002, 2004a)

[b] We treated *M. subhyalinus* from the Ivory Coast and from Kenya as separate species (for further details see "Methods and Materials")

Macrotermes species often build characteristic mounds. However, *Macrotermes subhyalinus* mounds differ considerably between West and East Africa. In the former, mounds are closed, whereas in the latter mounds have conspicuous open ventilation chimneys. Furthermore, cytochrome *c* oxidase subunit II gene sequences of *M. subhyalinus* suggest that these groups belong to two different species (Brandl et al. 2007). Nevertheless, we have retained the classic nomenclature for consistency with previous publications (Kaib et al. 2002, 2004a) but have treated *M. subhyalinus* from West and East Africa as different species in the present analysis (Table 1).

Chemical Analysis Chemical analysis of CHCs followed Kaib et al. (2002, 2004a) and most of the considered CHC phenotypes were previously documented there (see Table 1). In short, we extracted CHCs from up to ten major workers of each colony with *n*-hexane. Extracts were air-dried and reconstituted with *n*-hexane for analysis. After purification, the CHC compounds were separated by gas chromatography. Peaks from different chromatograms were aligned by comparison of linear retention indices calculated on the basis of an interspersed *n*-alkane series from eicosane to hexatriacontane. Individual hydrocarbons were identified by coupled gas chromatography/mass spectrometry. For the determination of the double bond positions of unsaturated hydrocarbons, dimethyl disulfide derivatives were prepared (see Kaib et al. 2000). For a descriptive analysis, we performed ordinations (e.g., principal component analysis based on variance–covariance matrices among individuals) to visualize the variation within and between colonies (see Kaib et al. 2002). In such ordination plots, individuals formed distinct groups, and in some species we also found distinct clusters of colonies. We identified these clusters with clear differences in the composition of CHCs as phenotypes. To characterize the composition of each phenotype, we averaged the relative concentration of each compound within colonies and across colonies of a particular phenotype (Fig. 1).

DNA Isolation, Amplification, and Sequencing We extracted DNA from the limbs of major workers by using the DNeasy Tissue Kit (Qiagen, Hilden, Germany). A 658-bp fragment of the CO I gene was amplified with the primer pair HCO and LCO (Folmer et al. 1994) with a standard PCR protocol. Amplified DNA was purified by using the MinElute PCR Purification Kit (Qiagen, Hilden, Germany) and sequenced in both directions by a commercial company (GENterprise GmbH, Mainz, Germany).

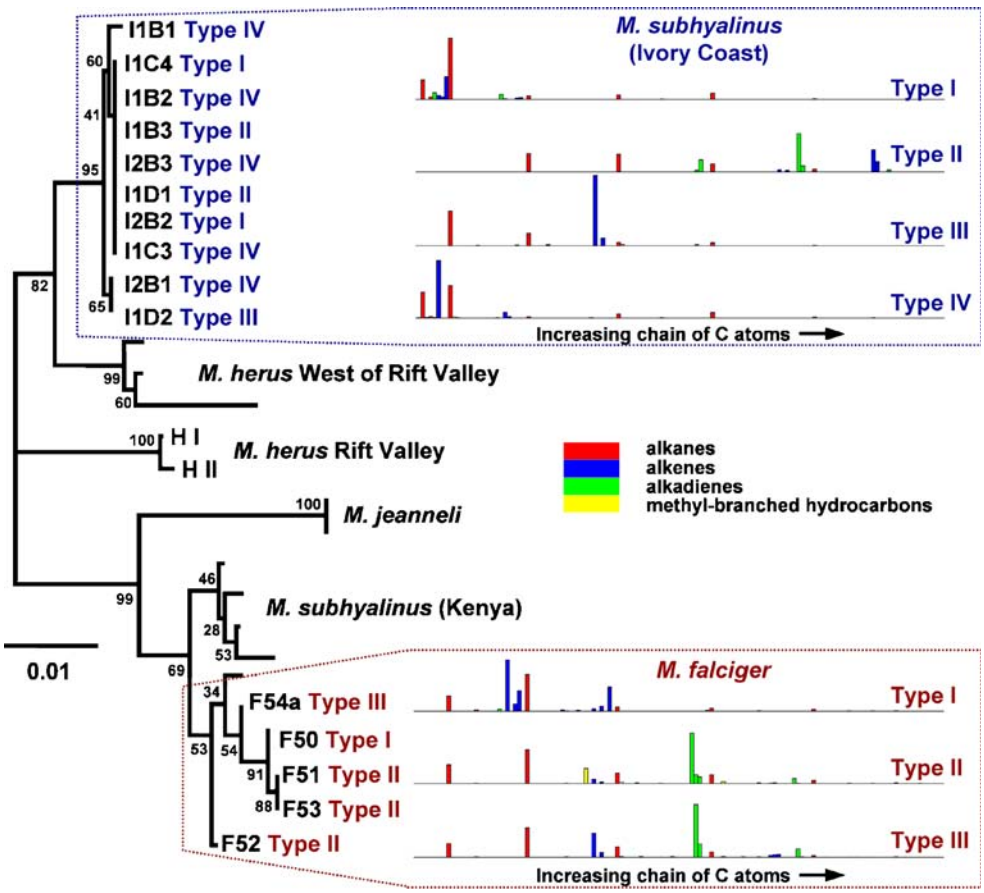

Fig. 1 Unrooted neighbor-joining tree of the CO I gene sequences obtained from *Macrotermes* colonies listed in Table 1 using the Kimura 2-parameter distance. Bootstrap support is shown at the nodes. For *M. subhyalinus* (Ivory Coast) and *M. falciger*, the relative composition of multiple CHC phenotypes (scale from 0% to 50%) is summarized. The legend indicates four different classes of hydrocarbons. For a detailed list of the compounds, see Kaib et al. (2002, 2004a)

Sequence Analysis The sequences were aligned with additional Macrotermitinae CO I sequences from GenBank (Supplementary material) by using ClustalW implemented in BioEdit 7.0.1 (Hall 1999) and visually checked. Kimura 2-parameter genetic distances among haplotypes were calculated in MEGA version 4 with the pairwise deletion option (Tamura et al. 2007). We accounted for the whole data set (own and published sequences) to calculate distances between certain CHC phenotypes, within species and between species pairs or genus pairs with the "within group means" and "between groups means" MEGA4 functions, respectively. The distance matrix for our own sequence data was used to construct a neighbor-joining tree, and support for the tree was evaluated with 1,000 bootstrap replicates. These simple methods were chosen for three reasons. First, we were interested in differences within and between congeneric species. The Kimura 2-parameter method increasingly underestimates distances with increasing differentiation. Therefore, our test is conservative for a comparison between distances within species (low downward bias) and distances between species or even higher taxa (high downward bias). Second, we were not attempting to determine the *Macrotermes* phylogeny. Instead, we were estimating the relative genetic differentiation between colonies with the same or different CHC phenotypes compared to the differentiation between species or genera. Finally, the Kimura 2-parameter distance required fewer parameters than other distance measures and had a lower associated error.

Results

Chemical Analysis The chemical composition differed little among major workers collected within the same colony (data not shown; for examples, see Kaib et al. 2002, 2004a). In addition, we showed for *Macrotermes herus* that minor and major workers have almost similar CHC profiles (data not shown). In contrast, in some cases CHC composition differed considerably among colonies of the same, morphologically defined species. For West African *M. subhyalinus*, four CHC phenotypes (Fig. 1) were identified (for further details see Kaib et al. 2004a). In contrast, East African *M. subhyalinus* showed no distinct phenotypes. In *Macrotermes falciger*, three unique CHC phenotypes were observed (Fig. 1, for further details see Kaib et al. 2002). Two *M. herus* colonies from the Rift Valley also had different phenotypes (data not shown). Within phenotypes, the variation of CHCs among colonies was small. Between colonies of a supposed species with different phenotypes, the composition of CHCs showed clear qualitative and quantitative differences, mainly in the unsaturated and branched compounds (Fig. 1).

Sequence Analysis We identified 62 variable sites in the CO I sequences. These sites resulted in 18 haplotypes among the 27 *Macrotermes* individuals (Table 1). The number of haplotypes per species ranged from 1 to 5. The most divergent haplotypes within a species differed by 21 transitions and seven transversions (haplotypes 6 and 9). These high values are due to differences between *M. herus* samples from the west of the Rift Valley in Kenya and samples within the Rift Valley (Fig. 1). The Kimura 2-parameter distance between the two groups was 0.035, whereas the distance within groups was 0.011 (west of the Rift Valley) and 0.0016 (within the Rift Valley; compare these values to Table 2). According to the CO I sequences, in Kenya *M. herus* may represent two different species, but the data are insufficient to draw conclusions. After excluding *M. herus*, haplotypes from the same species differed by at most three transitions and two transversions.

To determine the relationships among CHC phenotypes, we constructed a neighbor-joining tree (Fig. 1). Independent of CHC phenotypes, individuals of the same species clustered with high bootstrap support (>50%) in the tree. Different CHC phenotypes (e.g., phenotypes I, II, and IV of West African *M. subhyalinus*) even shared the same CO I haplotype (Fig. 1). Among the four categories where genetic distance was measured (among CHC phenotypes of a species, within species, between congeneric species,

[a] CHC phenotypes of *M. falciger, M. herus*, and *M. subhyalinus* (Ivory Coast) were considered (see Table 1)

[b] To calculate distances within species, we used only sequences where no CHC data were available (own and published data, see also Supplementary material).

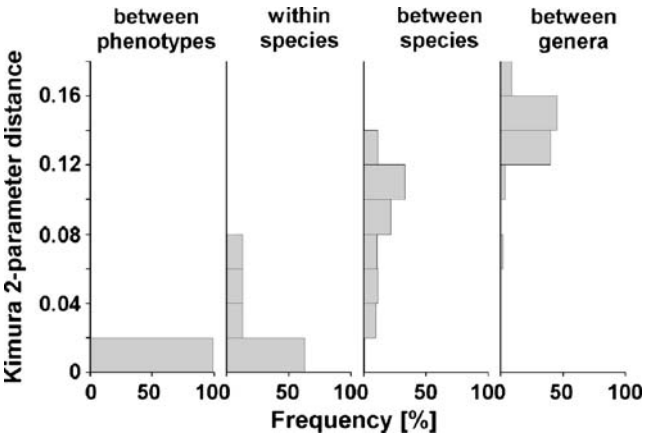

Fig. 2 Distribution of pairwise genetic distances among CHC phenotypes of *Macrotermes*, within species of Macrotermitinae, among congeneric species of Macrotermitinae, and between genera of Macrotermitinae (see also Table 2)

and between genera), distances between CHC phenotypes was the smallest (Fig. 2, Table 2). The maximum distance between conspecific CHC phenotypes (0.0031) was much smaller than the minimum distance between species (0.0105; Table 2).

Discussion

Based on the analysis of sequence variation of the CO I gene within and among species, CHC phenotypes in morphologically or geographically defined *Macrotermes* species do not represent cryptic species. This finding contrasts with what has been observed in lower termites. In lower termites, CHC phenotypes are supposed to represent cryptic species because of consistent differences in mitochondrial or nuclear DNA markers among phenotypes (e.g., Jenkins et al. 2000; Kutnik et al. 2004; Copren et al. 2005; Aldrich and Kambhampati 2007). CHC compositional differences within phenotypes are of similar magnitude in lower and higher termites (see Kaib et al. 2002, 2004a; Copren et al. 2005). Furthermore, genetic distances among species of Macrotermitinae are in the same range as those reported for lower termites (Park et al. 2006). Thus, fundamental differences in the evolution and function of cuticular hydrocarbons between lower and higher termites may exist.

We are aware that a single gene or locus on its own is not sufficient to detect cryptic species. However, the main goal of our study was to compare observations from lower termites with the situation in higher termites. Most of the studies on species specificity of CHC phenotypes in lower termites have used mitochondrial genes (Jenkins et al. 2000; Copren et al. 2005; Austin et al. 2007). Mitochondrial markers are sufficiently variable to resolve species-level differences, and such sequences also are valuable tools in termite taxonomy (Clément et al. 2001; Marini and Mantovani 2002; Szalanski et al. 2004; Uva et al. 2004; Park et al. 2006; Roy et al. 2006). For example, based on CO I gene differences, Aldrich and Kambhampati (2007) distinguished between subspecies of *Zootermopsis nevadensis* (Termopsidae). Furthermore, the CO I gene is an almost universal marker for the delimitation of species, and thus this gene is often used in barcoding studies (Hebert et al. 2003).

The suggested different role of CHC phenotypes in different termites is also exemplified by a difference in the geographic distribution of phenotypes. In lower termites, CHC phenotypes often occur in different populations (Haverty and Nelson 1997; Haverty et al. 1999; Page et al. 2002). Therefore, differences in CHC composition could be a passive consequence of other genetic differences or because of environmental differences. In contrast, in higher termites, CHC phenotypes may occur in the same population (Kaib et al. 2002, 2004a). Studies of CHC phenotypes in higher termites, however, are limited to the genus *Macrotermes*, and these patterns may not hold for all higher termites.

CHC compositional differences could be caused by genetic or environmental factors. In *Drosophila*, CHC composition is heritable (Takahashi et al. 2001). By using amplified fragment length polymorphism fingerprints, genetic differences in *M. subhyalinus* were correlated positively with differences in the composition of CHCs (Kaib et al. 2004a). Similar results, based on microsatellite data, were obtained for *Reticulitermes santonensis* (Dronnet et al. 2006). Although CHC composition may vary with environmental conditions, nesting material, and diet (e.g., Nielsen et al. 1999; Liang and Silverman 2000), even neighboring colonies may belong to different CHC phenotypes in *Macrotermes* (Kaib et al. 2002, 2004a). With such a small spatial distance among colonies, it is unlikely that environmental differences are the main factor for the occurrence of CHC phenotypes. Furthermore, *Macrotermes* species construct complex mounds with an effective ventilation system and constant microclimate conditions (Darlington 1985), and their CHC composition is not likely to reflect external environmental differences.

Regardless of the cause of CHC composition differences, interactions among workers from colonies with different phenotypes leads to aggression (Kaib et al. 2004a), indicating that CHCs play a role in nestmate recognition (Haverty et al. 1999; Kaib et al. 2002, 2004a, b). Nestmate recognition is essential to the social system because it guarantees colony integrity (see also Husseneder et al. 1998; Husseneder and Grace 2001). Because CHC composition is to some extent heritable and involved in nestmate recognition, divergent CHC composition could result in sympatric speciation, if alates use CHC for mate choice.

Alates are the colony members that swarm and mate with their counterparts from other colonies to establish new colonies. In *Macrotermes*, alates that establish new colonies are unrelated (Hacker et al. 2005). Because multiple CHC phenotypes occur in sympatry, there is a good chance that alates from different CHC phenotypes meet during nuptial flights. If alates are like workers, then CHC compositional differences among alates should lead to aggressive behavior. This aggression caused by different CHC phenotypes could lead to sympatric speciation. Reproductive individuals are often mutilated (Brandl et al. 2001, 2004), suggesting that aggressive behavior is common among reproductives, at least during the early stage of colony formation. However, our sequence data of the CO I gene suggest that the different CHC phenotypes do not represent distinct genetic lineages, and therefore CHC phenotypes are not mediating sympatric speciation. Rather than aggression as a mating barrier, in sympatric *Macrotermes* species, temporal separation of the nuptial flights and differences in sexual pheromones seem to prevent mating among closely related species (Peppuy et al. 2004).

Besides speciation, two other factors can explain the occurrence and evolution of CHC phenotypes in Macrotermitinae. First, CHC phenotypes may be influenced by symbionts. All *Macrotermes* species cultivate fungi in the colony for food (Pomeroy et al. 1991). Additionally, all termites harbor an abundant and diverse microbiota in their digestive tract (Brune 2006). If the fungi or the gut microbiota provide precursors for CHC synthesis, different fungal strains or differences in the composition of the gut microbiota could lead to different CHC profiles (Bagine et al. 1994). In this case, CHC phenotypes would result from fungal population structure or differences in the microbial gut community rather than from termite population structure. For example, it has been shown for the lower termite *Z. nevadensis*, that gut microorganisms supply precursors for methyl-branched hydrocarbon biosynthesis (Guo et al. 1991). In higher termites, however, a possible relationship between CHC composition and cultivated fungal strains or gut microbiota has never been tested. Second, the occurrence of CHC phenotypes might be influenced by inquilines. Termite colonies are long-lived and provide a rich, constant resource for inquilines. Colonies of fungus-growing termites often are invaded by termitophilous staphylinid or scarab beetles (e.g., Kistner 2001; Krikken 2008; own observations). If these inquilines become abundant, they can use up a significant portion of the food resources, thus lowering the fitness of the termite colony. Therefore, termites should have evolved strategies that limit colony access for inquilines. Inquilines have two possible strategies for access to the termite colony. Either inquilines are chemically neutral to the termites, or the inquilines acquire the recognition code of the colony. In support of the latter case, CHC composition of inquilines and termites was similar (Howard et al. 1980; Kaib et al. 2004b). However, this strategy would be risky for inquilines if different CHC phenotypes exist in a population of *Macrotermes* and inquilines have not evolved a fixed pattern of CHC composition that allows access to all colonies of a host species. Thus, the occurrence of different CHC phenotypes within populations of *Macrotermes* species might have evolved as a defense against inquilines.

Our COI gene sequence data suggest that CHC phenotypes do not represent species in *Macrotermes*. Therefore, in general, CHCs did not add new taxonomic information for species delimitation in this group (but see Kaib et al. 1991). It remains unknown if *Macrotermes* CHC composition is a consequence of the environment, symbiotic relationships, or if it is an evolutionary adaptation against unwanted visitors. Future studies need to investigate in *Macrotermes* the genetic population structure of symbionts as well as inquilines. Furthermore, we need more information on the genetic structure and CHC composition of other species of higher termites.

Acknowledgments During our work on CHC variation in *Macrotermes*, several people helped conduct fieldwork, performed behavioral tests, or helped to identify the hydrocarbons. In particular, we want to mention R. Bagine, J. Darlington, S. Franke, W. Francke, A. Halwas, and G. Kagezi. V. Traxel helped to improve the figures. We thank two anonymous reviewers and the editor for their comments. The work was supported by the German Science Foundation within the priority program 1127 (*Radiations—The origin of biodiversity*).

Comparison of Urinary Scents of Two Related Mouse Species, *Mus spicilegus* and *Mus domesticus*

Helena A. Soini · Donald Wiesler · Sachiko Koyama · Christophe Féron · Claude Baudoin · Milos V. Novotny

Received: 13 January 2009 / Revised: 11 March 2009 / Accepted: 1 April 2009 / Published online: 24 April 2009

Abstract Whereas the house mouse (*Mus domesticus*) has been studied extensively in terms of physiology/behavior and pheromonal attributes, the evolutionarily related mound-building mouse (*Mus spicilegus*) has received attention only recently due to its divergent behavioral traits related to olfaction. To date, no chemical studies on urinary volatile compounds have been performed on *M. spicilegus*. The rationale for our investigations was to determine if there are differences in urinary volatiles of intact and castrated *M. spicilegus* males and to explore further whether this species could utilize the same or structurally similar pheromones as the male house mouse, *M. domesticus.* The use of capillary gas chromatography/mass spectrometry (GC-MS) together with sorptive stir bar extraction sampling enabled quantitative comparisons between the intact and castrated *M. spicilegus* urinary profiles. Additionally, through GC-MS and atomic emission (sulfur-selective) detection, we identified qualitative molecular differences between intact *M. spicilegus* and *M. domesticus*. A series of volatile and odoriferous lactones and the presence of coumarin were the unique features of *M. spicilegus*, as was the notable absence of 2-sec-butyl-4,5-dihydrothiazole (a prominent *M. domesticus* male pheromone) and other sulfur-containing compounds. Castration of *M. spicilegus* males eliminated several substances, including δ-hexalactone and γ-octalactone, and substantially decreased additional compounds, suggesting their possible role in chemical communication. Some other *M. domesticus* pheromone components were also found in *M. spicilegus* urine. These comparative chemical analyses support the notion of metabolic similarities as well as the uniqueness of some volatiles for *M. spicilegus*, which may have a distinct physiological function in reproduction and behavior.

Introduction

There is an evolutionary connection between the common house mouse (*Mus domesticus*) and the mound-building mouse (*Mus spicilegus)*, with two pairs of closely related species and subspecies in the phylogenetic tree: *Mus musculus domesticus* and *Mus musculus musculus* in one pair and *M. spicilegus* and *Mus macedonicus* in the second one (Bonhomme et al. 1984; Sage et al. 1993). The *M. domesticus* living environment is interwoven with human habitats, whereas *M. spicilegus* species is feral, and in some cases, at least during the summer period, *M. spicilegus* may live in a close contact with *M. musculus musculus* (Orsini et al. 1983; Sokolov et al. 1998; Simeonovska-Nikolova 2007). Additionally, in its social structure and behavior, *M. spicilegus* has diverged far from the *M. domesticus*. Unlike *M. domesticus*, *M. spicilegus* individuals are monogamous (Patris and Baudoin 1998; Dobson and Baudoin 2002; Baudoin et al. 2005; Gouat and Féron 2005) and cooperatively build colonial mounds for overwintering (Orsini et al. 1983; Garza et al. 1997; Poteaux et al. 2008).

Moreover, *M. spicilegus* males display intense paternal care (Patris and Baudoin 2000; Féron and Gouat 2007).

M. spicilegus individuals appear to rely on olfaction in their social behavior and mate selection (Patris and Baudoin 1998; Patris et al. 2002; Heth et al., 2001, 2003). In this species, social and kin recognition through olfactory cues have been observed in several studies (Gouat et al. 1998; Dobson and Baudoin 2002; Baudoin et al. 2005; Busquet and Baudoin 2005; Todrank et al. 2005; Colombelli-Negrel and Gouat 2006). The odors, which are used for social communication in mice, have a number of glandular and nonglandular sources: preputial glands, ear glands, plantar glands, anal glands, coagulating glands, submaxillary glands, urine, and feces (Brown 1985). The salivary androgen-binding proteins (Laukaitis et al. 1997; Talley et al. 2001) and tear fluid peptides (Kimoto et al. 2005) also have been reported as sources of chemical messengers in *M. domesticus*. In the house mouse, the urine-mediated chemical signals have been relatively well-characterized over the years (for reviews, see Novotny 2003; Hurst and Beynon 2004). Behavioral tests have revealed that the odor cues (expected to originate mainly from urine) are used in communication (Patris and Baudoin 1998; Féron and Gheusi 2003; Busquet and Baudoin 2005; Colombelli-Negrel and Gouat 2006). Thus far, there have been no complementary reports for *M. spicilegus* on the chemical nature of such olfactory cues; to date, the chemical constituents used in communication and scent sources for *M. spicilegus* remain unknown.

The first purpose of this study was to structurally characterize and quantify individual chemical constituents of the urinary volatile profiles for the intact versus castrated *M. spicilegus* males. The second goal was to qualitatively compare the findings to the previously well-characterized male *M. domesticus* urinary compounds.

A quantitative comparison of the intact and castrated *M. spicilegus* male volatile profiles was performed to explore the metabolic end products that could be produced under testosterone control. Some of the endocrinologically controlled urinary constituents may act as chemical messengers regulating various reproductive and social functions. Additionally, the urinary volatile profiles of female and male *M. spicilegus* individuals were qualitatively compared in order to explore gender roles related to the urine-mediated chemical communication, such as those used in mate selection and individual recognition. This chemical characterization is expected to provide clues to the observed differences in social and behavioral characteristics between the two species.

To facilitate this study, we used the stir bar aqueous extraction method (Baltussen et al. 1999, 2002), which was followed by solventless sample introduction into a gas chromatograph-mass spectrometer (GC-MS) instrument. This methodology is compatible with screening for volatile organic compounds at low concentrations in biological samples and is well suited for compound identification and quantitative comparisons (Soini et al. 2005). In addition, a combination of gas chromatography with atomic emission detection (GC-AED) was utilized for the highly sensitive sulfur compound profiling. In this report, we also take our previously determined characteristics of the male *M. domesticus* (ICR, C57Black/B6 and C57Black/B10) urinary volatile components and qualitatively compare them with the new *M. spicilegus* chemical information obtained in this study. Analytical approaches for the *M. domesticus* and *M. spicilegus* samples were identical. All analyses were performed in the same laboratory.

Methods and Materials

Experimental Animals M. spicilegus mice were fifth-generation animals from a population collected in Gyöngyös, Hungary in October 1999. From the time of collection, the genealogy of every individual was known, and all breeding pairs had been formed in a way to avoid inbreeding. They were bred at the University of Paris 13 (University of Paris-Nord at Villetaneuse) under laboratory conditions (20±1°C) with a 14:10 h L/D cycle. Food (mouse pellets type M20, Special Diet Services, Witham, Essex, UK), water, and bedding material (sawdust and cotton) were provided. Mice were weaned at 28 days of age and housed in same-sex sibling groups from 35 days of age. Males and females were 3–6 months old when they were used as urine donors.

For the male–female mouse comparisons, six males and six females were isolated in standard polycarbonate cages (26×16 cm and 14 cm high) 1 week before urine collection in order to eliminate the social dominance effect (Féron and Baudoin 1993, 1998). With the male presence being required to induce sexual receptivity in *M. spicilegus* females (Féron and Gheusi 2003), we assumed that all the isolated females were in anoestrus.

For the comparisons between intact and castrated males, isolation occurred 3 weeks prior to urine collection. Twenty males were isolated in standard polycarbonate cages (26× 16 cm, 14 cm high). Six of them were then castrated under anesthesia induced by an intraperitoneal injection of a mixture of ketamine (Imalgène 500, Merial, France, 100 mg/kg) and xylazine (Rompun 2%, Bayer, Puteaux, France, 5 mg/kg).

Male *M. domesticus* urinary volatile profiles from inbred ICR albino mice, C57BL /B6 and C57BL /B10 black mice (Jackson Laboratories, Bar Harbor, ME, USA) were used for qualitative comparisons. The data obtained for *M. domesticus* have been previously reported by Harvey et al. (1989) and Novotny et al. (2007).

Urine Collection Animals were introduced individually into a clean polycarbonate cage and surveyed for urination at least every 5 min. Fresh individual urine was quickly collected with a syringe and frozen (−20°C). A preliminary study showed that this was the best process to handle these sensitive mice.

Ethical Note The experiments complied with the current French laws (authorization 93-0033 for C. Féron; laboratory approval was secured from the Prefecture of Seine Saint Denis (prefectorial decree 02-2651), complying with the Association for the Study of Animal Behaviour/Animal Behaviour Society Guidelines for the Use of Animals in Research.

Reagents and Analytical Methods All compound identifications were verified by comparisons to authentic standards. Standard compounds were purchased from Aldrich Chemical Company (Milwaukee, WI, USA), except 3-octen-2-one and β-farnesene were from TCI America (Portland, OR, USA) or synthesized in our laboratory according to the previously described synthetic methods for dehydro-*exo*-brevicomin (Wiesler et al. 1984), *sec*-butyl-4,5-dihydrothiazole (North and Pattenden 1990), and 6-hydroxy-6-methyl-3-heptanone (Novotny et al. 1999). Twister™ stir bars (10 mm in length, 0.5 mm film thickness, 24-μl polydimethylsiloxane volume) were used as the sorptive extraction devices. They were purchased from Gerstel GmbH (Mülheim an der Ruhr, Germany). Volatile and semivolatile compounds were extracted from 0.2 ml of urine in 20-ml capped glass vials for 60 min with a Twister™ stir bar. The urine samples were first diluted with 2.0 ml water (high-purity OmniSolv® water, EM Science, Gibbstown, NJ, USA). As an internal standard, 8 ng of 7-tridecanone (Aldrich, Milwaukee, WI, USA) was added in 10 μl of ethanol to each vial. Stirring speed was 800+rpm on the Variomag Multipoint HP 15 stirplate (H+P Labortechnic, Oberschleissheim, Germany). Prior to extraction, all glassware were washed with acetone and dried at 80°C. After extraction, stir bars were rinsed with a small amount of distilled water, dried gently on a paper tissue, and placed in the Thermal Desorption Autosampler (TDSA) tube (Gerstel GmbH, Mülheim an der Ruhr, Germany) for the GC or GC-MS analysis. GC equipment for the sulfur compound analysis consisted of an Agilent GC Model 6890 instrument with an Atomic Emission Detector (Model G2350A from Agilent Technologies, Wilmington, DE, USA), and a Thermal Desorption Autosampler (Gerstel) operated in a splitless mode. The separation capillary column was HP-5MS (30 m×0.25 mm, i.d., 0.25 μm film thickness) from Agilent. Samples were thermally desorbed in a TDSA automated system, followed by injection into the column with a cooled injection assembly. Temperature program for desorption was 20°C (0.5 min), then 60°C/min to 280°C (hold 10 min). Temperature of the transfer line was set at 280°C. The injector was cooled with liquid nitrogen to −60°C and, after desorption and cryotrapping, was heated at 12°C/s to 280°C with the hold time of 10 min. The injector inlet was operated in the solvent-vent mode, with a vent pressure of 14 psi, a vent flow of 30 ml/min, and a purge flow of 50 ml/min. The GC temperature program was 40°C (0.5 min) then 2°C/min to 200°C (hold 10 min). The carrier gas head pressure was 14 psi for a flow rate of 1.2 ml/min. The GC unit was operated in the constant-flow mode. The emission lines for carbon (193 nm), sulfur (181 nm), and nitrogen (174 nm) were monitored during the atomic plasma emission detection.

The GC-MS instrument used for the compound identification was an Agilent 6890 N gas chromatograph connected to the 5973i MSD mass spectrometer (Agilent Technologies). The GC column was a narrow-bore capillary with 180 μm, i.d.×20 m DB-5MS (0.18 μm film thickness, Agilent Technologies, Wilmington, DE, USA). The inlet head pressure was 12.5 psi for the helium flow of 0.7 ml/min. The system operated in the constant-flow mode. The temperature program was 50°C (2 min) at 4°C /min to 200°C (hold 1 min). Positive electron ionization (70 eV) mode was used with the scanning rate of 4.51 scans per second over the mass range of 35–350 amu. The MSD transfer line temperature was set at 280°C. The ion source and quadrupole temperatures were set at 230°C and 150°C, respectively. The TDSA-injector sample introduction setting was identical to that described above in connection with the GC-AED system, except that the injector trapping temperature was set at −80°C.

Quantitative Evaluations and Statistical Analyses As the basis for quantitative comparisons of urinary chromatographic profiles of the fresh urine collected on plates, the peak area integration was performed, and peak areas were normalized by dividing with the peak area of internal standard (7-tridecanone) for each separated component. Either GC-MS total-ion chromatograms (TIC) or selected-ion chromatograms obtained after the postrun modification of TICs were used for calculations. Normalized peak areas were statistically evaluated for the intact and castrated mouse groups. Student's *t* test was employed for pairwise comparisons. The sulfur compound profiles from the GC-AED were compared in a qualitative manner between the intact and castrated males. The quantitative data obtained in this study for the male *M. spicilegus* urine samples were compared semiquantitatively with the female *M. spicilegus* urine and qualitatively with the male *M. domesticus* urine data obtained previously in this laboratory.

Results

Male *M. spicilegus* urinary volatile compound profiles by GC-MS featured more than 100 components. Approximately 60 compounds showed sufficient spectral intensity and

*$P<0.05$ accepted significance; statistical significance for the compound level differences between intact (*I*) and castrated (*C*) male *M. spicilegus* urine

[a] Tentatively identified

[b] Unique urinary compounds for *M. spicilegus*, not found in *M. domesticus*

purity for the quantitative comparisons. Among these, 30 were identified, 15 were tentatively identified, while ten remain unknown (Table 1).

The characteristic feature for the profiles from *M. spicilegus* was the prominent presence of γ- and δ-lactones, ketones, alcohols, and acids. Characteristic urinary components found in *M. domesticus* are three dihydrofuran compounds (MW 126), which were shown previously to originate from a puberty-accelerating pheromone, 6-hydroxy-6-methyl-3-heptanone (Novotny et al. 1999) and its lactol form (see Table 1 for 5,5-dimethyl-2-ethyl-4,5-dihydrofuran, *Z*-5,5-dimethyl-2-ethylidenetetrahydrofuran and *E*-5,5-dimethyl-2-ethylidenetetrahydrofuran). These three furan derivatives were present in male *M. spicilegus* at levels comparable to those for *M. domesticus* reported earlier (Harvey et al. 1989; Novotny et al. 2007). In castrated *M. spicilegus*, the levels of these furan derivatives were significantly lower ($P<0.002$) than in intact *M. spicilegus* males. Another *M. domesticus* pheromone compound, dehydro-*exo*-brevicomin, also present in female urine in small amounts (Harvey et al. 1989; Jemiolo et al. 1991), was found at lower levels in urine from the intact and castrated male and also in female *M. spicilegus* urine (data not shown). Castration did not change dehydro-*exo*-brevicomin levels in *M. spicilegus* significantly in contrast to the suppressed levels of dehydro-*exo*-brevicomin in the samples from castrated *M. domesticus* (Novotny et al. 1980; Harvey et al. 1989). Trace levels of the dominant male mouse pheromone for *M. domesticus*, β-farnesene (Harvey et al. 1989), were detected in the intact male *M. spicilegus* urine but were not seen in female or castrated animals. *N*-(Methylthio) methylaniline was the only identified sulfur compound in the GC-MS TIC urine profiles from *M. spicilegus*, being more abundant in the intact male mouse urine when compared to the mouse urine of castrates ($P<0.01$). The representative structures of the main compounds distinguishing the two species are shown in Fig. 1.

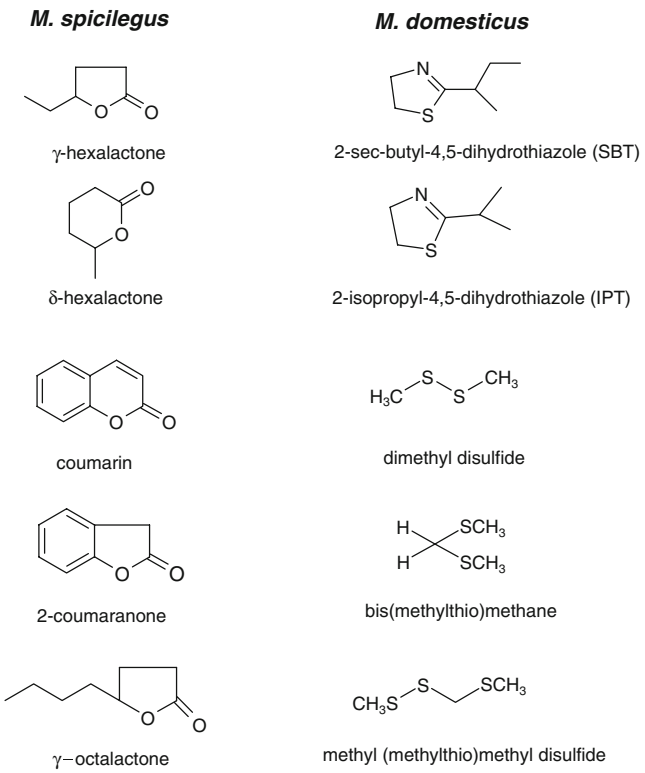

Fig. 1 Distinguishing chemical structures of volatile compounds in *M. spicilegus* and *M. domesticus* male urine

Castration of *M. spicilegus* males affected the volatile profiles in three ways: certain compounds, apparently under endocrine control, disappeared; while the levels of other compounds increased; and a set of previously undetected compounds became apparent (see Table 1). Figure 2 illustrates the representative urinary volatile profiles for intact and castrated *M. spicilegus* males and intact male *M. domesticus*. In addition to β-farnesene, castration removed 2-heptanone, δ-hexalactone, *N*-phenylformanilide, and γ-octalactone from the set of urinary volatiles. Some compound levels decreased after castration, including γ-hexalactone ($P<0.02$) and *N*-(methylthio)methylaniline ($P<0.01$), shown as normalized peak areas with standard deviation (SD) in Table 1. In contrast, after castration, levels of 2-coumaranone, a unique compound for *M. spicilegus*, increased ($P<0.001$). The absolute amounts of 2-coumaranone in castrated male urine were about 300± 200 ng/ml (standard deviation, SD, $N=6$), while in the intact mouse urine, the levels were just 2±2 ng/ml (SD, $N=14$). In addition, other constituents, including several lactones, were found at higher levels, and new compounds such as coumarin and several late-eluting lactones appeared in the urine of castrated males (see Table 1). Figure 3 shows a comparison of selected compound levels affected by castration. Individual variation for some of the compounds appeared relatively large (>70%, relative standard deviation (RSD), $N=6$–14), while some compounds varied only within the range of 12–30% (RSD, $N=6$–14) among the sampled individuals. Typically, the variation due to the sampling method was only 5–10% (RSD, $N=4$).

Qualitative comparisons in the GC-AED sulfur-selective profiles did not reveal any clear differences between intact

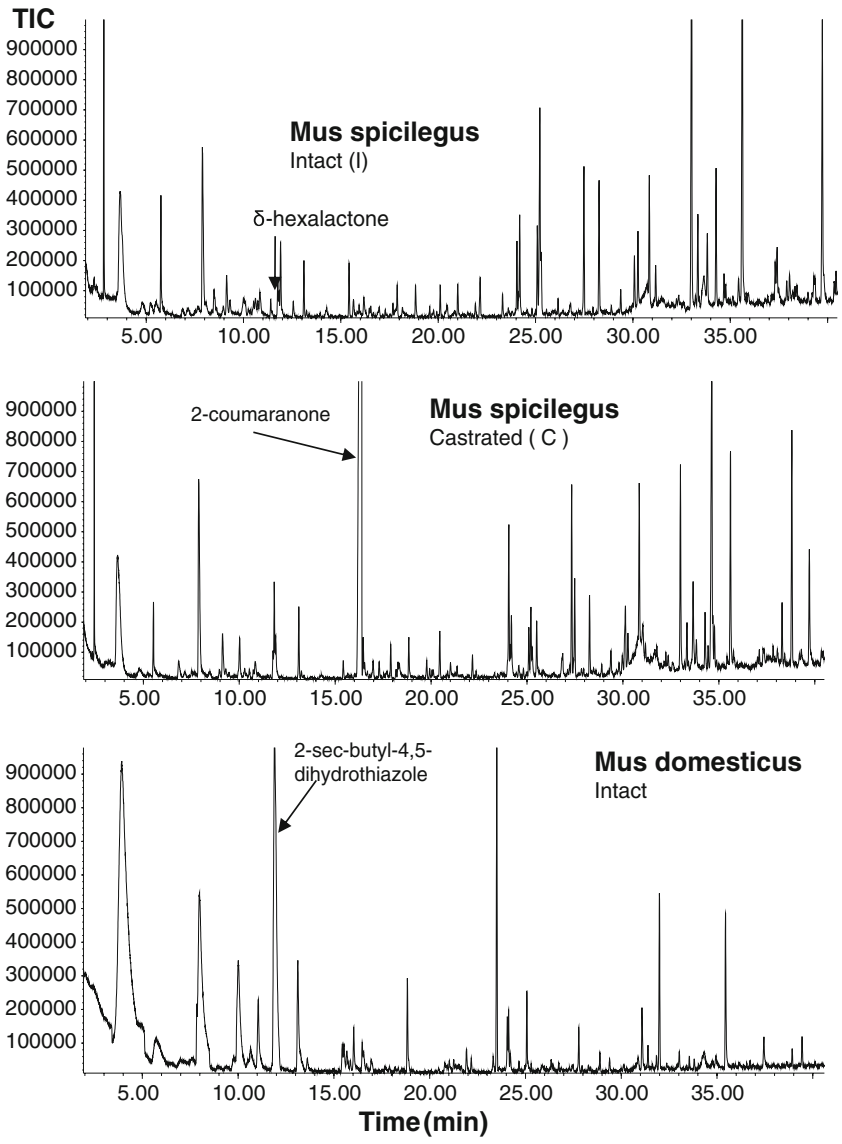

Fig. 2 Representative urinary (GC-MS total ion current) profiles of **a** intact and **b** castrated male *M. spicilegus*. **c** A comparative profile for male intact *M. domesticus*

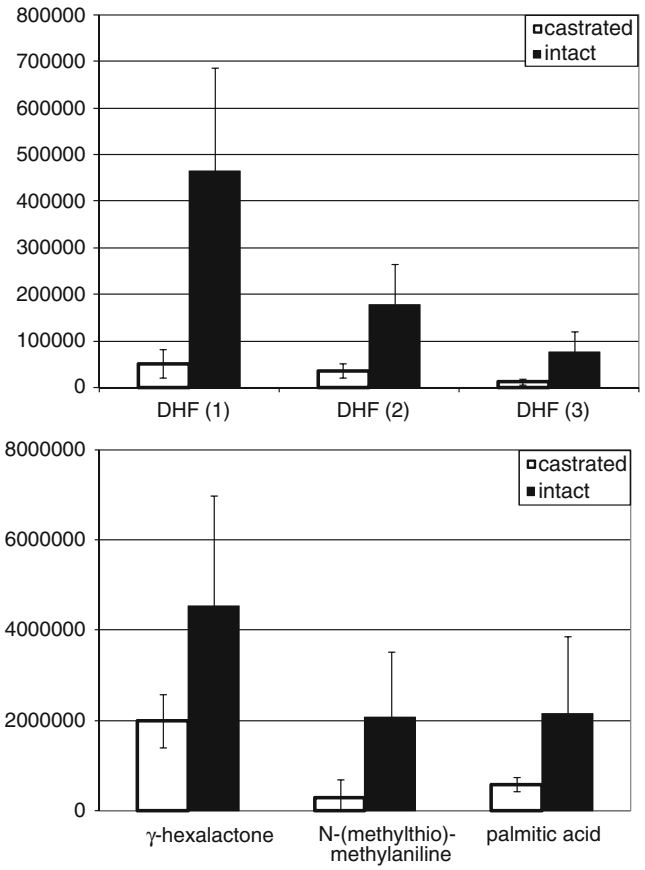

Fig. 3 Effect of castration on selected compound levels in urine (see Table 1). *Y-axis* corresponds to normalized peak areas. *Error bars* indicate standard deviation (SD)

and castrated animals. Relatively low-level (sub-picogram), sulfur-containing compounds (data not shown) were detected but could not be identified structurally.

Several of the previously reported *M. domesticus* urinary compounds (Novotny et al. 1990a, b, 2007) also were present in *M. spicilegus* profiles, including three characteristic dihydrofurans. It is notable that the *M. domesticus* male dominance signaling pheromone compound, 2-sec-butyl-4,5-dihydrothiazole, and its "structural relative," 2-isopropyl-4,5-dihydrothiazole (Novotny et al. 1985), were not detected in the *M. spicilegus* urine. Linear sulfur compounds, such as dimethyl disulfide, bis(methylthio) methane, and methyl(methylthio)methyl disulfide, typical for *M. domesticus* (Novotny et al. 2007), were also absent in *M. spicilegus* urinary volatile profiles. Furthermore, few *M. spicilegus* urinary ketones were present compared to those identified in *M. domesticus* urine (Novotny et al. 2007).

Discussion

Since castrated male *M. spicilegus* did not show β-farnesene, 2-heptanone, δ-hexalactone, *N*-phenylformanilide, or γ-octalactone among the urinary volatiles, it is suggested that the metabolic pathways involving these compounds may be under endocrine control. Behavioral tests with these compounds would be necessary to show what are the possible chemo-signaling and physiological functions of these compounds for male and female *M. spicilegus.* Castration also significantly affected the production of lactones, thus demonstrating an endocrine feedback for lactone biosynthesis. There is a strong possibility that some of the lactones may be mediators of chemical communication that involve reproduction. Furthermore, lactone levels were particularly varied among the individual intact males, suggesting that the lactone profile could be related to individual recognition. In their pure form, many of the lactones exhibit fruit- or berry-like aromas (Gatfield et al. 1993), which are relatively subtle odors in human perception, as opposed to the pungent smell in the *M. domesticus* male urine caused by the sulfur-containing compounds. The same unique lactone compounds were found in the female *M. spicilegus* urine in our qualitative screening (unpublished experiments).

Lactone biosynthesis involves C-18 hydroxyl fatty acids as precursors, which undergo β-oxidation steps followed by lactonization (Albrecht et al. 1992). Additionally, 9,10-oleic acid has been reported as a precursor for γ-dodecalactones in the yeast cultures (Haffner and Tressl 1996). This may imply that the metabolism of fatty acids leading to urinary lactone end products could play a prominent role in *M. spicilegus* metabolism. Contrarily, *M. domesticus* shows little presence of urinary lactones. The occurrence of urinary lactones previously has been reported in female and male pine voles (*Microtus pinetorum*) (Boyer et al. 1989). In female pine voles, γ-octalactone exhibited the greatest urinary level changes among the volatile compounds after estrogen treatment or ovariectomy.

Other biological sources for lactones have been reported for insects and microorganisms, such as the cephalic gland γ-octalactone of giant honeybee workers (*Apis laboriosa*; Blum et al. 2000) and δ- and γ-lactones emitted by marine *Alphaproteobacteria* (Dickschat et al. 2005). In these two studies, lactones were hypothesized as potential chemical signaling compounds within the giant honeybee colony and bacterial culture, respectively.

Urinary ketones in intact male *M. spicilegus* interestingly were sparse (Table 1). *M. domesticus* urinary ketones (e.g., 2-heptanone, 6-methyl-5-hepten-3-one, 5-hepten-2-one) previously have been found to correlate with the major histocompatibility complex mouse haplotypes (Novotny et al. 2007).

M. spicilegus originate from Eastern Europe. Several diagnostic genetic loci separate *M. spicilegus* and *M. domesticus* species (Bonhomme et al. 1984; reviewed in Sokolov et al. 1998). The genes in these loci code for enzymatically active proteins. Alcohol and malate dehy-

drogenases, esterases, carbonic anhydrase, and mannose and glucose phosphate isomerases are among these proteins. Consequently, some of the distinguishing coded enzymes may impact the metabolic pathways that lead to the excretion of urinary substances.

In addition to the lactones, urinary coumarin appears as an interesting "metabolic marker compound" for the *M. spicilegus* species. The presence of coumarin and abundance of 2-coumaranone in the urine of castrated *M. spicilegus* male also represent distinguishing metabolic pathways not found in *M. domesticus*. Coumarin could originate from different plants (reviewed in Bourgaud et al. 2006). In mammalian systems, coumarin generally exhibits toxic effects and is oxidatively metabolized (detoxified) by the cytochrome P450 mono-oxygenase enzyme system in liver microsomes (Creaven et al. 1965; Lewis and Lake 2002). The specific mouse enzyme for coumarin elimination through 7-hydroxylation is CYP2A5 (Miles et al. 1990). The CYP2A5 enzyme is also known to be inhibited by lactones and 2-coumaranone (Juvonen et al. 1991, 2000). In a study within the *M. domesticus* strains, P450 enzymes have been found genetically altered among these strains (Wood 1979). Furthermore, a single autosomal gene locus Gpi-1 (glucose phosphate isomerase-1) was found responsible for the differential hydroxylase activity of P450 (Wood and Taylor 1979). Since Gpi-1 also was found as one of the distinguishing genetic loci between *M. spicilegus* and *M. domesticus* (Bonhomme et al. 1984), the vastly different urinary volatile profiles of these species could be due, in part, to differential P450 oxidase activity, among other metabolic routes. For example, the distinguishing Es-2 loci controlling esterases have been found especially active in the kidney (Ruddle et al. 1969) and thus likely to affect some of the urinary metabolite excretion. However, separate genetic studies and metabolic mapping are necessary to link the genetic sources for the observed metabolic profile differences between *M. spicilegus* and *M. domesticus*, as exemplified by the urinary coumarin levels observed in this study. Furthermore, it seems desirable to investigate how these genetically induced changes in the urinary volatile constituents could facilitate chemical communication and social behavior in the "scent world" of the *M. spicilegus* species.

In summary, quantitative comparisons of the urinary volatile profiles for male *M. spicilegus* mice reveal several compounds that have previously shown biological activity as components of male-produced pheromones in the *M. domesticus* species. These similarities suggest that the two mouse species carry a certain genetic linkage that may be utilized in chemo-signaling. On the other hand, the total absence of the prominent *M. domesticus* male aggression pheromone, 2-*sec*-butyl-4,5-dihydrothiazole, in the *M. spicilegus* urine and the presence of unique δ- and γ-lactones and coumarin seem to indicate that these species have developed some distinctly separate metabolic pathways involving urinary constituents. Castration of *M. spicilegus* males removed δ-hexalactone and γ-octalactone among the identified urinary constituents. Their testosterone control suggests a possible involvement in chemical communication within the species. Behavioral tests are in progress to define possible roles of several urinary volatile organic compounds in *M. spicilegus* chemical communication.

Acknowledgments This work was sponsored jointly by the Lilly Chemistry Alumni Chair and the Indiana University METACyt Initiative, partially funded through a grant from the Lilly Endowment, Inc., as well as the French National Center for Scientific Research and the French Ministry for Higher Education and Research (University of Paris 13). We wish to thank Mr. K.E. Bruce (Institute for Pheromone Research, Indiana University) for assistance with the analyses and data collection and Professor A. Hefetz (Tel Aviv University, Israel) for comments on a previous version of the manuscript.

Identification and Synthesis of a Female-Produced Sex Pheromone for the Cerambycid Beetle *Prionus californicus*

Joshua Rodstein · J. Steven McElfresh · James D. Barbour · Ann M. Ray · Lawrence M. Hanks · Jocelyn G. Millar

Received: 15 December 2008 / Revised: 20 March 2009 / Accepted: 27 March 2009 / Published online: 25 April 2009

Abstract Females of the large cerambycid beetle *Prionus californicus* produce a powerful sex pheromone that attracts males. The pheromone was adsorbed on solid phase microextraction (SPME) fibers inserted into the ovipositor sheath and analyzed by coupled gas chromatography-electroantennogram detection and GC-mass spectrometry. The pheromone was identified as an isomer of 3,5-dimethyldodecanoic acid by a combination of retention index comparisons and mass spectral interpretation. The mass spectrum was misleading because it exhibited enlarged fragment ions that were not representative of branch points or other obvious stabilizing structural elements. The structure was verified by synthesis of 3,5-dimethyldodecanoic acid as a mixture of all four possible isomers, and this mixture was highly attractive to male beetles in field bioassays. The SPME extracts also contained several other compounds that were tentatively identified as chain-extended homologs of the main pheromone component. This pheromone should prove useful for sampling and management of the beetle, which is an important pest of hops, and an occasional pest in a variety of orchard crops. Although this is the first female-produced pheromone to be identified from the Cerambycidae, there is considerable evidence for pheromone production by females of other species in the subfamily Prioninae. Thus, this pheromone and the associated methodology used in its identification should be useful in the identification of female-produced attractant pheromones from other members of the subfamily.

Keywords 3,5-dimethyldodecanoic acid · 3,5-dimethyltridecanoic acid · 3,5-dimethylpentadecanoic acid · Cerambycidae · Prioninae · Coleoptera

Introduction

Prionus californicus Motschulsky (Coleoptera: Cerambycidae), commonly known as the California prionus, ranges throughout much of western North America, being found from Alaska south to Mexico and as far east as the Rocky Mountains and Colorado (Linsley 1962). The adults are among the largest longhorned beetles in North America (Linsley 1962). The beetle has a long life cycle (3–5 years or more), spending most of its life underground as a root-feeding larva. The fully developed larvae pupate in spring, and the adults appear in a relatively synchronized emergence from early- to mid-summer. The nonfeeding adult life stage is relatively short (a few weeks at most), and the adults must find mates and reproduce quickly before they exhaust their energy reserves and die (JDB, pers. obs.).

Prionus californicus has a broad host range, feeding on the roots of a wide variety of perennials, and is an occasional to chronic pest of oaks, apple, cherry, almond, and many other species of woody plants in natural, agricultural, and urban environments (Solomon 1984). It is a particularly serious pest in the production of hop, *Humulus lupulus* L. (Urticales: Cannabaceae), in the northwestern USA (Bishop et al. 1984). Infestations in crops are difficult to manage because the developing larvae are protected within the roots of the host crop. Furthermore, insecticides may be ineffective against the adults because they do not feed and have a heavily sclerotized cuticle. We initiated a project to identify the sex pheromone of *P. californicus* as a first step in the possible development of noninsecticidal methods of monitoring and managing this important pest.

In preliminary studies, we showed that female *P. californicus* produce a powerful sex pheromone that specifically attracts males (Cervantes et al. 2006). The pheromone appeared to be produced by structures associated with the ovipositor, and "calling" females exhibited a stereotypical behavior of rhythmic extension and contraction of the ovipositor, with the eversion of a small sac-like projection from the dorsal surface of the ovipositor (Barbour et al. 2006). Here, we report the identification, synthesis, and preliminary field testing of a sex pheromone of *P. californicus*. This is the first female-produced sex attractant pheromone to be identified from this large beetle family, with more than 30,000 described species (Lawrence 1982).

Methods and Materials

Insects Insects were reared individually with pieces of hop root in 19-l buckets buried in the ground at the Southwest Idaho Research and Extension Center, as previously described (Cervantes et al. 2006). Each bucket was covered with a screened lid, and adult beetles were collected as they emerged. Adult beetles were shipped within 24 h after emergence by overnight courier to UC Riverside (USDA-APHIS permit 71758), where they were held at ~4°C in individual vials with a piece of moistened paper towel until used in experiments. Insects were used within 7 days after arrival at UC Riverside and, therefore, were 2–9 days old when used in experiments. Female *P. californicus* are receptive to mating within 24 h after emergence (Barbour et al. 2007).

Collection and Analysis of Pheromone Dissection and examination revealed that the eversible sac-like projection of females was contained in the ovipositor sheath, so we sampled directly from this structure. Thus, a live virgin female was held firmly while the ovipositor was gently pulled out to its full extension and clamped with a hemostat. The tip of a solid phase microextraction device fiber (polydimethylsiloxane coated fiber, 100-µm thick film, Supelco, Inc., Bellefonte PA, USA) was then inserted into the opening from which the sac-like structure was everted and moved around to adsorb constituents by contact for ~1 min. One SPME fiber was used to sequentially sample from as many as 17 females to provide sufficient adsorbed material for analysis. SPME fibers were cleaned immediately before use by thermal desorbtion at 250°C for 10 min in the injector port of a gas chromatograph. Synthetic standards (see below) were adsorbed on SPME fibers by exposing the fibers to the headspace odors from a filter paper treated with a test compound and held in a vial sealed with aluminum foil.

The loaded SPME fibers were wiped gently with a paper tissue to remove any adhering materials before analysis. Loaded fibers initially were analyzed by coupled gas chromatography-electroantennogram detection (GC-EAD), using two Hewlett-Packard 5890 series II gas chromatographs (HP, Avondale PA, USA). The first GC was fitted with a DB-5 column (30 m×0.25 mm ID, 0.25 µm film, programmed from 100°C/1 min, 10°/min to 275°C for 15 min; J&W Scientific, Folsom, CA, USA), and the second with a DB-WAX column (30 m×0.25 mm ID, 0.25 µm film, 100°C/1 min, 10°/min to 240°). Loaded SPME fibers were desorbed in the injection port for 1 min prior to starting the temperature program. Helium was used as the carrier and makeup gas, and all injections were made in splitless mode. The column effluent was split equally with a glass X-shaped union (Restek, Bellefonte PA, USA) fitted with 0.32 mm ID sections of uncoated and deactivated GC column, with one section going to the flame ionization detector (FID), another to the electroantennogram detector (EAD), and the final section providing helium makeup gas (3 ml/min). The EAD branch passed through a heated conduit (250°C) and into the side of a 15 mm ID glass tube swept with humidified medical air (770 ml/min), with the air flow directed over the insect antennal preparation. Signals were recorded on either matched HP 3394 integrators or with an SRI model 202 PeakSimple chromatography data system running on a personal computer with PeakSimple v. 2.83 software (SRI Instruments, Torrance, CA, USA).

Males used in GC-EAD analyses were not chilled or anesthetized prior to use. The five terminal flagellomeres (out of total number of 12) of one antenna were cut off, and ~1 mm of the tip was removed with a razor blade. The section of antenna then was mounted between two glass capillary electrodes filled with Locke's saline (7.5 g NaCl, 0.21 g $CaCl_2$, 0.35 g KCl, 0.2 g $NaHCO_3$ per liter distilled water), with electrical contact to the amplifier being provided with 0.2-mm gold wires. The antennal preparation was centered in the effluent air stream from the GC, and antennal signals were amplified and filtered with a custom-built amplifier and recorded in parallel with the FID signals, as described above.

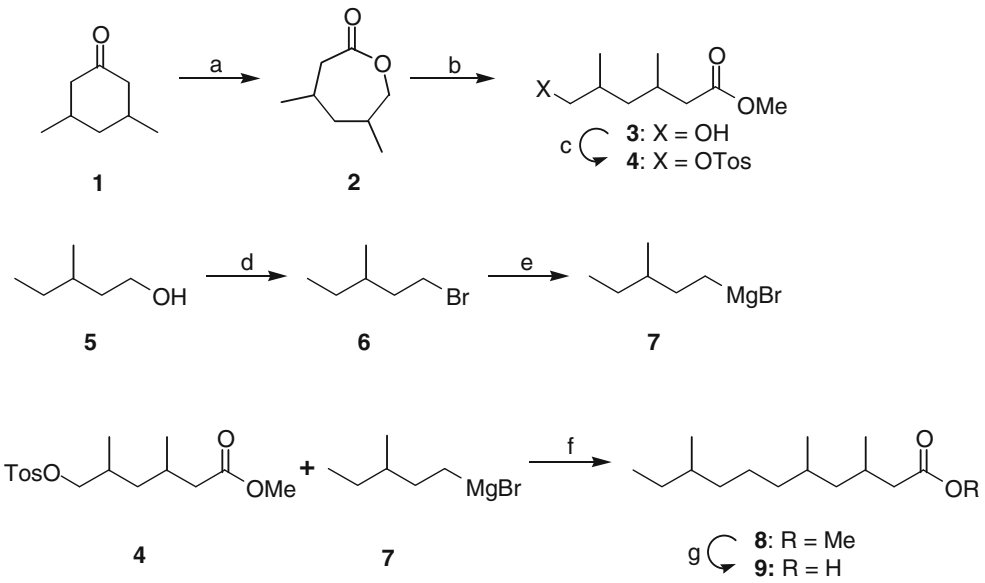
Loaded SPME fibers also were analyzed by GC-MS, using an HP 6890 GC interfaced to an HP 5973 mass selective detector (MSD), or an Agilent 6890N GC interfaced to a 5975C MSD, both fitted with HP5-MS columns (30 m× 0.25 mm ID, temperature program 40°C/0 min, 10°C/min to 280°C, hold 15 min). SPME fibers were desorbed for 30 s in splitless mode before beginning temperature programming. Kovats indices (Kovats 1965) of analytes were calculated with reference to straight-chain hydrocarbons.

Synthesis of the Pheromone and Analogs Tetrahydrofuran (THF) was distilled from sodium/benzophenone ketyl under argon. ^{1}H- and ^{13}C-NMR spectra were recorded with a Varian INOVA-400 (400 and 100.5 MHz, respectively) spectrometer, as $CDCl_3$ solutions. Chemical shifts are expressed in ppm relative to $CDCl_3$ (7.27 and 77.23 ppm for ^{1}H and ^{13}C NMR, respectively). Worked-up solutions were dried over anhydrous Na_2SO_4, and concentrated by rotary evaporation under reduced pressure. Crude products were purified by flash or vacuum flash chromatography on silica gel (230–400 mesh). Mass spectra of synthetic intermediates were obtained with a Hewlett-Packard 5890 GC interfaced to an HP 5970 mass selective detector, in EI mode (70 eV) with helium carrier gas. The GC was equipped with an HP5-MS column (25 m×0.20 mm ID ×0.33-µm film). Reactions with air- or water-sensitive reagents were carried out in dried glassware under argon atmosphere.

Syntheses of Trimethylundecanoic and 3,5-Dimethyldodecanoic Acids: Synthesis of 3,5,9-Trimethylundecanoic Acid

4,6-Dimethyl-2-Oxepanone **(2)** A solution of 3,5-dimethylcyclohexanone **1** (6.341 g, 50 mmol), *m*-chloroperbenzoic acid (approximately ~67% by weight, 12.93 g, ~50 mmol), and trifluoroacetic acid (0.384 g, 5 mmol) in methylene chloride (140 ml) was stirred in an ice bath for 1 h, then warmed to room temperature and stirred until the reaction was complete (~24 h). The mixture was then held at ~4°C overnight to precipitate most of the *m*-chlorobenzoic acid and then filtered with suction, rinsing with hexanes. The filtrate was stirred with dilute sodium bisulfite solution (75 ml) for 4 h to destroy any remaining *m*-chloroperbenzoic acid. After separation of the layers, the organic layer was washed twice with saturated sodium bicarbonate solution and brine then dried and concentrated, yielding 6.11 g (86%) of 4,6-dimethyl-2-oxepanone **2**, 96% pure by GC. This was used in the next step without further purification. ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.92 (d, J= 6.9 Hz, 3H), 0.98–1.10 (m, 1H), 1.04 (d, J=6.6 Hz, 3H), 1.25 (t, J=6 Hz, 1H), 2.0 (m, 3H), 2.49 (m, 2H), 4.05 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 19.1, 24.3, 30.0, 34.2, 42.3, 47.0, 74.4, 175.1. MS: *m*/*z* (%): 170 (2), 142 (3), 112 (55), 97 (29), 83 (9), 69 (100), 56 (45), 55 (55), 43 (28), 42 (75), 41 (89; Scheme 1).

*Methyl 6-Hydroxy-3,5-Dimethylhexanoate (**3**)* Sodium metal (0.210 g, 9 mmol) was added to dry MeOH (40 ml) in a dry three-neck flask under argon at 0°C, and the mixture was stirred until the Na had completely dissolved. 4,6-Dimethyl-2-oxepanone **2** (6.11 g, 43 mmol) was added dropwise, and the reaction was stirred at room temperature for 2.5 h, then quenched with 1 M HCl (100 ml) and extracted three times with ether. The combined ether extracts were washed sequentially with water, saturated aqueous sodium bicarbonate, and brine, then dried and concentrated. The crude methyl 6-hydroxy-3,5-dimethylhexanoate **3** (5.47 g, 87% pure by GC, 73% crude yield) was used in the next step



Scheme 1 Synthesis of 3,5,9-trimethylundecanoic acid. *a* *m*-chloroperbenzoic acid, TFA, CH_2Cl_2; *b* NaOMe, MeOH; *c* TosCl, pyridine, DMAP; *d* PBr_3, ether; *e* Mg turnings, THF; *f* Li_2CuCl_4, tosylate **4**, THF; *g* KOH, MeOH/H_2O

without further purification. ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.92 (d, J=6.8 Hz, 3H), 0.95 (d, J=6.5 Hz, 3H), 1.01 (m, 2H), 1.32–1.42 (m, 1H), 1.63–1.73 (m, 1H), 1.75 (br. s, 1H), 2.0–2.08 (m, 1H), 2.11 (dd, J=14.9, 7.5, 1H), 2.30 (dd, J=14.9, 6.0, 1H), 3.48 (d, J=5.6 Hz, 2H), 3.66 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 17.6, 20.7, 27.8, 33.2, 40.7, 41.4, 51.7, 67.9, 174.1. MS *m/z* (%): 161 (5), 115 (6), 101 (9), 97 (5), 83 (17), 74 (100), 69 (12), 59 (22), 55 (30), 43 (29), 42 (13), 41 (39).

*Methyl 6-[[(4-methylphenyl)sulfonyl]oxy]-3,5 dimethylhexanoate (**4**)* *p*-Toluenesulphonyl chloride (10.3 g, 53 mmol) was added to a solution of 6-hydroxy-3,5-dimethylhexanoate **3** (5.47 g, 31 mmol) and dimethylaminopyridine (0.425 g, 3.4 mmol) in 40 ml pyridine at room temperature, and the mixture was stirred 12 h. The mixture was then poured into excess 1 M HCl and extracted with ether. The ether layer was washed with saturated aqueous sodium bicarbonate and brine. The sodium bicarbonate and brine layers were back extracted with ether, and the combined organic layers were dried and concentrated. The crude residue was purified by vacuum flash chromatography (95:5 hexanes:EtOAc, then 100% EtOAc) to yield 6.01 g (58.2%) of tosylate **4** of 74% purity by gas chromatography, along with 13% of recovered 4,6-dimethyl-2-oxepanone **2**. A smaller sample was repurified to obtain spectral data, yielding tosylate **4** as a 93:7 mixture of diastereomers (total, 96% chemically pure by GC). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.91 (d, J~5.6 Hz, 3H), 0.92 (d, J~6.8 Hz, 3H), 0.85–1.04 (m, 1H), 1.31 (m, 1H), 1.80–2.02 (m, 2H), 2.04 (dd, J=14.7, 8.3 Hz, 1H), 2.23 (dd, J=14.7, 5.2 Hz, 1H), 2.46 (s, 3H), 3.67 (s, 3H), 3.79 (dd, J=9.5, 6.5 Hz, 1 H), 3.90 (dd, J=9.5, 5.3 Hz, 1H), 7.36 (d, J=8.3 Hz, 2H), 7.80 (d, J=8.3 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 17.3, 20.5, 21.8, 27.8, 30.6, 37.8, 37.8, 40.2, 41.3, 51.7, 75.0, 128.1, 130.0, 133.3, 144.9, 173.4. MS: *m/z* (%): 328 (3), 297 (8), 254 (1), 232 (9), 173 (9), 155 (35), 141 (26), 125 (13), 114 (17), 111 (12), 101 (16), 96 (25), 91 (80), 83 (100), 74 (19), 69 (38), 55 (60), 41 (55).

*1-Bromo-3-methylpentane (**6**)* PBr_3 (4.84 g, 17.8 mmol) was added dropwise to a solution of 3-methylpentanol **5** (5.02 g, 48.8 mmol) in dry ether (65 ml) at 0°C, shielding the reaction from light. The reaction was allowed to warm to room temperature and stirred overnight. The reaction was then poured into ice water and extracted with ether. The ether layer was washed sequentially with saturated aqueous sodium bicarbonate and brine, then dried and concentrated by fractional distillation of the ether with a short Vigreux column. The resulting oil was Kugelrohr distilled (oven temp. ~70°C, 3–4 Torr) to yield 3.904 g (48.4%) of bromide **6** as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.90 (t, J=7.4 Hz, 3H), 0.90 (d, J=6.5 Hz, 3H), 1.18 (m, 1H), 1.36 (m, 1H), 1.5–1.75 (m, 2H), 1.88 (m, 1H), 3.43 (m, 2H). MS *m/z* (%): 166 (2), 164 (2), 137 (1), 135 (2), 109 (3), 107 (5), 95 (2), 93 (2), 85 (53), 69 (25), 57 (90), 41 (100).

*Methyl 3,5,9-trimethylundecanoate (**8**)* Freshly ground magnesium turnings (1.149 g, 46 mmol) were added to a dry three-neck flask under argon, and a ~4-ml aliquot of a solution of 1-bromo-3-methylpentane **6** (3.223 g, 23.6 mmol) in 20 ml dry THF was added. The mixture was stirred until the Grignard reaction started, followed by addition of the remainder of the solution by syringe pump over 1 h. After the addition was complete, the mixture was stirred for an additional 1 h then allowed to stand so that fine solids could settle out.

Dry THF (16 ml), lithium tetrachlorocuprate solution (7 ml, 0.1 M in THF, 0.7 mmol), and tosylate **4** (5.047 g, 15.3 mmol) were added to a dry three-neck flask under argon, and the mixture was chilled in an ice bath. The freshly prepared solution of 3-methylpentylmagnesium bromide **7** was added dropwise, maintaining the temperature at ~0°C. After the addition was complete, the reaction was stirred 1 h at 0°C, and then allowed to warm slowly to room temperature overnight. The reaction was then quenched with 1 M HCl, and the mixture was extracted with ether. The ether layer was washed sequentially with saturated aqueous sodium bicarbonate and brine, then dried and concentrated. The residue was purified by column chromatography (95:5 hexanes/ethyl acetate), yielding 0.45 g of the desired product **8** (12.2%) and 3.36 g (10.2 mmol, 66%) of unreacted tosylate **4.** ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.86 (m, 9 H), 0.93 (d, J=6.2 Hz, 3H), 0.95–1.17 (m, 4H), 1.18–1.38 (m, 7H), 1.46 (m, 1H), 2.05 (m, 2H), 2.31 (m, 1H), 3.67 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$): 11.59, 19.37, 19.45, 20.24, 20.29, 20.58, 24.44, 28.08, 29.63, 29.78, 30.22, 30.26, 34.60, 37.05, 37.12, 37.21, 41.75, 44.85, 44.91, 51.52, 174.03. MS: *m/z* (%): 185 (12), 143 (10), 131 (2), 115 (7), 101 (88), 83 (30), 74 (100), 59 (25), 55 (51), 41 (72).

*3,5,9-Trimethylundecanoic Acid (**9**)* A mixture of methanol (31 ml), water (3.4 ml), KOH (0.94 g, 17 mmol), and methyl 3,5,9-trimethylundecanoate **8** (0.201 g, 0.82 mmol) was refluxed 1 h, then cooled to room temperature. The mixture was acidified with 1 M HCl, then extracted three times with ether. The combined ether layers were washed with brine, then dried and concentrated, to yield 3,5,9-trimethylundecanoic acid **9** as a mixture of stereoisomers (0.169 g, 88.9%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.86 (m, 9H), 0.97 (two overlapped d, 3H), 0.98–1.52 (m, 10H), 2.08 (m, 2H), 2.36 (m, 1H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 11.60, 19.38, 20.22, 20.5, 24.42, 27.91, 29.64, 29.78, 34.60, 37.12, 41.50, 44.75, 44.82, 179.01. MS: *m/z* (%): 199 (5), 129 (100), 111 (33), 97 (22), 89 (22), 83 (10), 71 (87), 43 (37).

Synthesis of 3,5,7-Trimethylundecanoic Acid (13)

Methyl 6-iodo-3,5-dimethylhexanoate (10) A solution of methyl 6-hydroxy-3,5-dimethylhexanoate **3** (2.3 g, 13.2 mmol) and triethylamine (3.70 ml, 26.4 mmol) in ether (66 ml) was cooled to −5°C in an ice-salt bath, and methanesulphonyl chloride (1.24 ml, 15.8 mmol) was added dropwise. The reaction was stirred for 30 min, then quenched with dilute sodium bicarbonate. The organic layer was separated and washed sequentially with 1 M HCl, water, and brine, then dried and concentrated. The crude mesylate was taken up in acetone (66 ml), and NaI (6.92 g, 46 mmol) was added. The mixture was stirred 8 days at room temperature then concentrated by rotary evaporation. The residue then was partitioned between water and ether. The ether layer was washed with brine, dried, and concentrated. The residue was purified by flash chromatography (hexane/EtOAc 95:5) yielding 3.07 g (81%) of iodide **10**. ^{1}H NMR (400 MHz, CDCl3): δ 0.96 (d, 2H, J=6.5 Hz), 0.99 (d, 2H, J=6.5 Hz), 1.1 (m, 1H), 1.35 (m, 1H), 1.55 (m, 1H), 2.04 (m, 1H), 2.16 (dd, 1H, J=14.6, 8.0 Hz), 2.30 (dd, 2H, J=14.6, 5.6 Hz), 3.15 (dd, 1H, J=11.7, 5.9 Hz), 3.25 (dd, 1H, J=11.7, 4.2 Hz), 3.68 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 17.6, 20.2, 21.4, 28.0, 32.1, 41.7, 43.7, 51.7, 173.5. MS *m*/*z* (%): 284 (trace), 253 (6), 235 (2), 183 (2), 157 (40), 141 (3), 125 (32), 97 (36), 83 (100), 73 (17), 69 (21), 55 (92), 41 (87).

*3,5,7-Trimethylundecanoic acid (***13***)* A dry three-neck flask was loaded with freshly ground magnesium turnings (0.86 g, 35.2 mmol) and THF (17 ml) under argon. 2-Bromohexane (2.80 g, 17 mmol; Alfa Aesar) was purified immediately before use by vacuum flash chromatography on silica gel, eluting with pentane. After concentration, the bromide was added dropwise over 1 h to the slurry of Mg turnings, and the mixture was stirred a further 3 h after the addition was complete. The resulting 2-hexylmagnesium bromide solution **11** was then added dropwise to an ice-bath-cooled solution of lithium tetrachlorocuprate (1.8 ml, 0.18 mmol), THF (5 ml), and methyl 6-iodo-3,5-dimethylhexanoate **10** (1.0 g, 3.51 mmol). The reaction was held at ~0°C for 2 h then allowed to warm slowly to room temperature overnight. The mixture was quenched with 1 M HCl and extracted with ether. The ether layer was washed sequentially with saturated sodium bicarbonate and brine, dried, and concentrated. The resulting crude methyl 3,5,7-trimethylundecanoate **12** was refluxed 1 h in a mixture of methanol (100 ml), water (10 ml), and KOH (4.02 g, 71.6 mmol). After cooling, the mixture was diluted with water and any unreacted methyl ester and Wurtz coupling dimerization products from the Grignard reagent were removed by extracting the mixture twice with ether. The remaining aqueous layer was then acidified with HCl and extracted three times with ether. The combined ether extracts were washed with brine, dried, and concentrated, yielding 240 mg of crude acid **13**. ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.78–0.92 (m, 9H), 0.93–0.99 (m, 3H), 0.99–1.14 (m, ~4H), 1.14–1.37 (m, ~7H), 1.37–1.51 (m, 1H), 1.51–1.62 (m, 1H), 2.07 (m, 2H), 2.37 (m, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 14.40, 19.57, 20.14, 20.31, 20.54, 20.59, 20.73, 20.78, 23.23, 23.74, 27.52, 27.62, 27.77, 27.87, 29.33, 29.54, 30.06, 30.15, 36.41, 37.99, 38.01, 41.34, 41.69, 44.48, 44.88, 45.25, 45.60, 179.40. MS *m*/*z* (%): 228 (1), 210 (1), 192 (5), 171 (7), 169 (7), 153 (12), 143 (6), 139 (4), 129 (33), 111 (32), 101 (23), 87 (100), 69 (49), 57 (45), 43 (62).

Synthesis of 3,5-Dimethyldodecanoic Acid (**18**)

*1-Bromo-2-methylnonane (***15***)* Mesyl choride (9.58 ml, 123 mmol) was added dropwise to a chilled solution (~10°C in an ice-salt bath) of 2-methylnonanol **14** (18.72 g, 112 mmol) in methylene chloride (280 ml) and triethylamine (23.2 ml, 168 mmol). The resulting mixture was stirred 1 h at ~−10°C then filtered with suction. The filtrate was washed sequentially with 1 M HCl, saturated $NaHCO_3$, and brine, then dried and concentrated. The crude mesylate was taken up in acetone (280 ml), and LiBr (29.11 g, 336 mmol) was added in three portions (exothermic!), allowing the mixture to cool between additions of each portion. The mixture was stirred 3 h at room temperature then heated to 60°C overnight. After cooling to room temperature, the mixture was filtered with suction, and the filtrate was concentrated. The crude reaction mixture was diluted with pentane and washed with water and brine. After concentration, the residue was purified by vacuum flash chromatography on silica gel, eluting with pentane. The purified 1-bromo-2-methylnonane **15** then was Kugelrohr distilled (oven temp ~65°C: 1.6 Torr), yielding 21.68 g of colorless oil (85%), 91% pure by GC. ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.89 (t, J=6.78 Hz, 3H), 1.01 (d, J=6.62 Hz, 3H), 1.28 (m, 10H), 1.45 (m, 1H), 1.80 (m, 1H), 3.33 (dd, 1H, J=9.75, 6.24 Hz), 3.40 (dd, 1H, J=9.75, 4.94 Hz). ^{13}C NMR (100 MHz, $CDCl_3$): δ 14.29, 18.99, 22.85, 27.08, 29.44, 29.86, 32.04, 35.07, 35.41, 41.83. MS *m*/*z* (%): 113 (trace), 98 (16), 85 (17), 71 (31), 57 (86), 41 (100).

*3,5-Dimethyldodecanoic Acid (***18***)* 1-Bromo-2-methylnonane **15** (11.57 g, 52.3 mmol) was added dropwise to a slurry of Mg turnings (3.64 g, 150 mmol) in dry THF (96 ml) under argon over ~2 h. The resulting solution of Grignard reagent **16** was then added by syringe to a slurry of CuI (0.678 g, 3.56 mmol) and dry THF (10 ml) in a dry three-neck flask cooled to 0°C under argon. Then, β-butyrolactone **17** (5.38 g, 62.5 mmol) in dry THF (44.6 ml) was added

dropwise over 60 min. The mixture was stirred at 0°C for 30 min and then warmed to room temperature overnight. The reaction was quenched with 1 M HCl and extracted with ether three times. The combined ether extracts were washed twice with 1 M NaOH. The resulting combined aqueous layers then were acidified with 3 M HCl, and extracted twice with ether. The combined ether layers were washed with brine, dried, and concentrated to give 6.7 g of crude acid **18** (47%). Attempted Kugelrohr distillation of a portion of the crude acid resulted in decomposition, and so the remainder (6.7 g) was purified by flash chromatography (hexanes/EtOAc 3:1, with 1% acetic acid), giving 6.1 g of 3,5-dimethyldodecanoic acid **18** of 96% purity by GC. ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.86 (t, 3H, J=6.6 Hz), 0.88 and 0.90 (dd, 3H, J=6.7 Hz), 0.95 and 0.97 (dd, 3H, J=6.4 Hz), 1.00–1.20 (m, 2H), 1.27 (m, 12H), 1.47 (m, 1H), 2.10 (m, 1H), 2.3 (m, 1H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 14.3, 19.5, 19.6, 20.2, 20.5, 22.9, 27.0, 27.2, 27.9, 27.9, 29.6, 30.1, 30.2, 32.1, 36.8, 37.9, 41.5, 42.4, 44.5, 44.8, 179.1, 179.3 (MS: see Fig. 2C).

Field Bioassay of Synthetic Pheromone A field bioassay of the synthetic 3,5-dimethyldodecanoic acid was conducted at Placerita Canyon Natural Area (Los Angeles Co., CA), an area where adult *P. californicus* frequently are collected in light traps during summer months (I. P. Swift, pers. obs.). The bioassay was deployed from 12 to 17 June 2008 (clear skies, no precipitation, maximum air temperatures 21–36°C). Traps consisted of 19-l polypropylene buckets (38 cm tall× 30 cm diam) fitted with aluminum funnels (model 2815B, BioQuip, Rancho Dominguez, CA, USA) that were buried with the top of the funnel flush with the soil surface. Lures consisted of clear low density polyethylene press-seal bags (Bagette model 14770, 5.1×7.6 cm, 0.05 mm wall thickness, Cousin Corp., Largo, FL, USA) that were loaded with 100 mg of synthetic 3,5-dimethyldodecanoic acid (as the mixture of four stereoisomers) in 900 µl ethanol. Control lures consisted of bags loaded with 1 ml of pure ethanol. Lures were hung inside trap funnels with wire. Traps were set up in a westerly transect in an area wooded with mature *Quercus agrifolia* Neé (position of first trap N 34°22′42″ W 118°28′53″, 462 m elevation). There were two sets of traps in the transect, each including two traps baited with pheromone and two control traps, with traps spaced ~8 m apart, and with the sets separated by 60 m. Traps were checked for beetles daily at ~8:00 AM.

Differences between treatments in numbers of beetles captured were tested with the nonparametric Friedman's test (blocked by set and day, PROC FREQ with CMH option; SAS Institute 2001) because a mean of zero for controls violated assumptions of analysis of variance (Sokal and Rohlf 1995). We used a mark-recapture technique to estimate the local abundance of male *P. californicus*. All beetles that were removed from traps on 13–16 June 2008 were marked with a spot of blue fingernail polish on the pronotum and were released in wooded areas at least 20 m from traps. We recorded the number of marked individuals that were recaptured and used the Lincoln-Peterson index to estimate the size of the local population based on the accumulated number of marked beetles that had been released (Southwood and Henderson 2000).

Voucher specimens of *P. californicus* have been deposited at the Entomology Research Museum at the University of California, Riverside, CA.

Results

Identification of the Pheromone Gas chromatography-electroantennogram detection analyses of the compounds collected from female beetles by contact SPME showed that the antennae of male *P. californicus* responded strongly to a compound present in nanogram quantities (estimated from peak size in GC-MS total ion current chromatograms) in the extracts (Fig. 1, peak 2), with additional responses to several other components (Fig. 1, peaks 1, 3, and 4). Analyses of SPME samples by GC-MS produced a mass spectrum (Fig. 2A) that suggested that the most active compound had a probable molecular weight of 228 Da, for a possible molecular formula of $C_{14}H_{28}O_2$, which would accommodate one site of unsaturation. The distorted peak

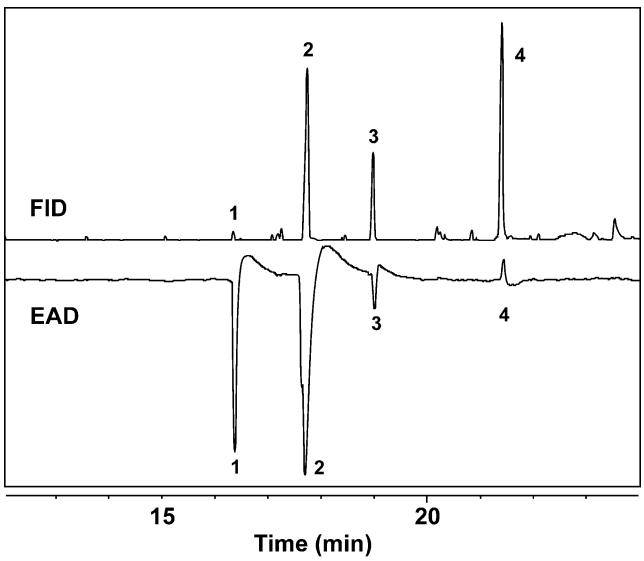


Fig. 1 Representative coupled gas chromatography-electroantennogram analysis of a contact SPME extract of the ovipositor of a female *P. californicus*. *Upper trace* is the chromatogram from a DB-5 GC column, *lower, inverted trace* is the antennal response. *Peak 1* = methyl 3,5-dimethyldodecanoate; *peak 2* = 3,5-dimethyldodecanoic acid; *peak 3* = 3,5-dimethyltridecanoic acid; *peak 4* = 3,5-dimethylpentadecanoic acid

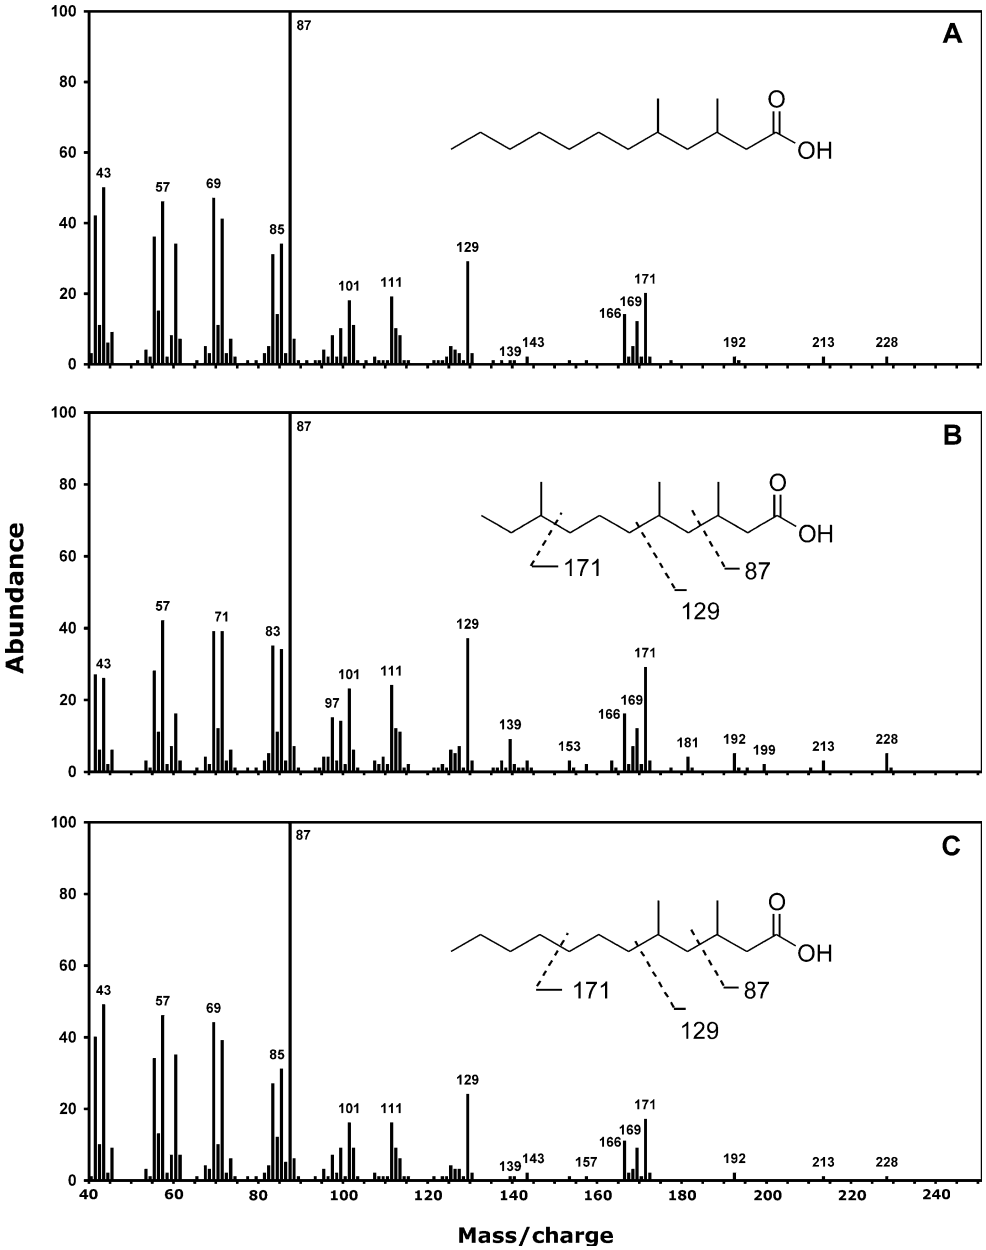

Fig. 2 Electron impact ionization mass spectra of: **A**) the compound from the SPME extract of female ovipositor that elicited the largest antennal response from males (Peak 2 in Fig. 1, 3,5-dimethyldodecanoic acid), **B**) a stereoisomer of 3,5,9-trimethylundecanoic acid, and **C**) the synthetic diastereomer of 3,5-dimethyldodecanoic acid with the same retention time as the insect-produced compound

shape suggested a polar analyte such as a diol or carboxylic acid. Further evidence of a polar analyte was obtained by comparison of the Kovats indices (KI; Van den Dool and Kratz 1963; Kovats 1965) of the compound on a nonpolar DB-5 column (1636) vs. the KI value on a polar DB-WAX column (2541). The large difference between the two columns (905 KI units) was virtually identical to the corresponding difference in KI values for a model compound, tridecanoic acid, on DB-5 (1677) and DB-WAX (2585, difference 908 KI units). The carboxyl function accounted for the single site of unsaturation, indicating that the compound could have no other double bonds or rings. Furthermore, the fact that the KI values of the insect-produced compound were actually lower than those of tridecanoic acid, even though tridecanoic acid contained one less carbon, indicated that the compound was a branched rather than a straight-chain structure.

Detailed examination of the mass spectrum (Fig. 2A) provided further information. The base peak at *m/z* 87 was tentatively assigned to a carboxylic acid with a methyl branch at the carbon ß to the carboxyl function (C_3). A second significant fragment at *m/z* 129 suggested a second methyl branch at C_5. The ion at *m/z* 171 suggested a third methyl branch at either C_7 or at C_9 if cleavage had occurred closer to the end of the chain. Other useful fragments included a relatively strong *m/z* 60 ion, from loss of acetic acid, and even-mass ions at *m/z* 192 (loss of $2\times H_2O$) and 166 (loss of $C_2H_6O_2$).

The additional component that elicited the first antennal response (Fig. 1, peak 1) was tentatively identified as the methyl ester of the major pheromone component and provided further support for some of the structural elements of the parent compound. Its mass spectrum was characterized by a base peak at *m/z* 74 from McLafferty rearrangement of a methyl ester with two hydrogen on the carbon α to the carbonyl group, a large fragment at *m/z* 101 (65%) from cleavage of a methyl ester with a methyl branch on C_3, a weak molecular ion at *m/z* 242 (2%), and two significant fragments at *m/z* 143 (10%) and 185 (9%), analogous to the fragments at *m/z* 129 and 171 in the spectrum of the parent acid, after accounting for the additional 14 mass units from the methyl ester.

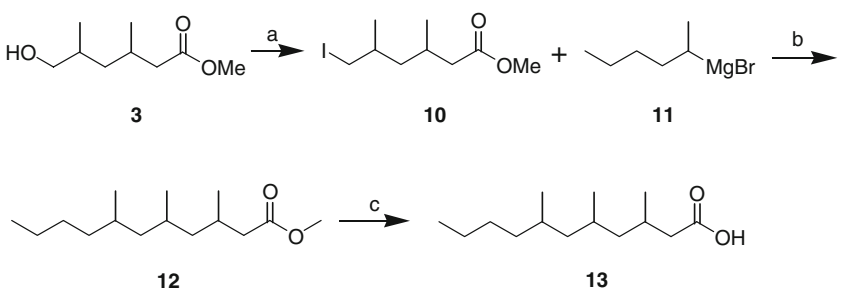
Based on the above data, the 3,5,9-trimethylundecanoic acid structure was deemed the most likely structure, and this compound was synthesized as a mixture of all eight stereoisomers, which appeared as three broad, overlapping peaks on GC analysis. The mass spectra of the synthetic 3,5,9-trimethylundecanoic acid isomers were similar but not quite identical to that of the insect-produced compound (Fig. 2B). One of the key discriminating factors was the difference in the ratio of the low intensity ions at *m/z* 139 and 143 between the spectra of all of the 3,5,9-trimethylundecanoic acids and the natural compound. Because of the uncertainty in measuring the Kovats indices of these broad and overlapping peaks, which also were concentration-dependent, the mixture of acids was methylated, and the KI values of the methyl esters were compared to that of the trace amount of the methyl ester of the pheromone that was present in the insect extract (Fig. 1, peak 1). The mixture of methyl ester diastereomers appeared as two peaks on the DB-5 column, and the KI values of both were significantly shorter (1558 and 1567) than that of the insect-produced compound (1600), proving that the 3,5,9-trimethylundecanoic acid structure was not correct. Furthermore, the synthetic material was virtually inactive in both laboratory and field bioassays (JDB, unpublished data).

We reasoned that another trimethyl branched alternative, i.e., 3,5,7-trimethylundecanoic acid, was even less likely to be correct because shifting the outermost methyl group inwards towards the middle of a hydrocarbon chain would further decrease the retention time. This was verified by synthesis of standards; the KI values of the four diastereomeric methyl esters (1518, 1526, 1538, 1547) were all considerably lower than that of the insect produced compound, and the mass spectra were all obviously different than that of the natural product.

A third trimethyl-branched alternative, 3,5,9-trimethylundecanoic acid, also was ruled out by synthesis of standards; the mass spectrum of the natural compound and those of the synthetic isomers were markedly different, and the Kovats indices on DB-5 (1569, 1574, 1608) of the three peaks from the methyl esters of the mixture of synthetic stereoisomers did not match that of the insect-produced compound.

Having eliminated what seemed to be the most reasonable structures based on the mass spectral data, and with the information that the Kovats indices suggested a longer chain with fewer branch points, we then considered which dimethyldodecanoic acids might fit the data. Of the significant mass spectral fragments, the assignment of the *m/z* 87 base peak as a fragment arising from cleavage of a carboxylic acid with a methyl branch at C_3 seemed robust, based on examination of database spectra of saturated carboxylic acids with a methyl group in the three position. Thus, the most likely positions for the remaining methyl group were at either C_5 (supporting the fragment at *m/z* 129) or C_8 (supporting the fragment at *m/z* 171), with biosynthetic considerations favoring the former. Nonstereoselective synthesis of 3,5-dimethyldodecanoic acid resulted in a mixture in which the *syn* and *anti*-diastereomers were separable by GC, with the later eluting peak matching the natural compound in both Kovats index and mass spectrum (Fig. 2A vs C). Further confirmation of the identification was obtained from the excellent match between the mass spectrum and Kovats index of the corresponding methyl ester with those of the insect-produced methyl ester (Fig. 1, peak 1). In total, these data confirmed that the pheromone was one of the stereoisomers of 3,5-dimethyldodecanoic acid and that the ion at *m/z* 171, despite its prominence, was not indicative of a branch point.

In addition to 3,5-dimethyldodecanoic acid and its methyl ester (Fig. 1, peaks 2 and 1, respectively), the insect extracts also contained two compounds tentatively identified as the homologs, 3,5-dimethyltridecanoic and 3,5-dimethylpentadecanoic acid (Fig. 1, peaks 3 and 4, respectively) based on the facts that their Kovats indices were approximately 100 and 300 units greater than that of the major pheromone component, and the analogies between their mass spectra and the mass spectra of 3,5-dimethyldodecanoic acid. In particular, their mass spectra were similar to that of 3,5-dimethyldodecanoic acid in the lower mass ranges, being characterized by base peaks at *m/z* 87 and significant ions at *m/z* 129, indicative of methyl branches on C_3 and C_5, and a significant *m/z* 60 ion from loss of acetic acid. However, their molecular ions were integer multiples of 14 mass units higher than that of 3,5-dimethyldodecanoic acid, and the cluster of ions at *m/z* 166, 169, and 171 corresponding to losses of 62, 59, and 57 Da from the molecular ion of 3,5-dimethyldodecanoic acid at *m/z* 228, was replaced with analogous clusters of ions at *m/z* 180, 183, and 185 Da, and 208, 211, and 213 Da, respectively. A trace amount of the corresponding 3,5-dimethyltetradecanoic acid was also tentatively identified from its base peak at *m/z* 87, a large *m/z* 129 ion, and a cluster of ions at *m/z* 194, 197, and 199. These identifications have not yet been confirmed



Scheme 2 Synthesis of 3,5,7-trimethylundecanoic acid. *a* MesCl, Et_3N, ether; NaI, acetone; *b* CuI, iodide **10**, THF; *c* KOH, $MeOH/H_2O$

by synthesis, but the presence of the diagnostic patterns of ions and the Kovats index values provide substantial support for the proposed structures. The full EI mass spectra of these and related compounds are provided in the online supplement.

Syntheses of Trimethylundecanoic and 3,5-Dimethyldodecanoic Acids A nonstereoselective synthesis of 3,5,9-dimethyldodecanoic acid was developed (Scheme 1) so that all possible isomers would be represented in the resulting mixture. Thus, 3,5-dimethylcyclohexanone was subjected to Baeyer–Williger oxidation with *m*-chloroperbenzoic acid, yielding 4,6-dimethyl-2-oxepanone **2**. The lactone was transesterified with sodium methoxide in methanol to provide methyl 6-hydroxy-3,5-dimethylhexanoate **3**, which was then converted to tosylate **4**. A second synthon was constructed by conversion of 3-methylpentanol **5** to bromide **6** by treatment of **5** with PBr_3. The Grignard reagent **7** prepared from bromide **6** was then reacted with tosylate **4** with Li_2CuCl_4 catalysis, to produce methyl 3,5,9-trimethylundecanoate **8**. Basic hydrolysis of the ester in aqueous ethanol gave the free acid **9**.

The second possibility, 3,5,7-trimethylundecanoic acid, was constructed using similar methodology (Scheme 2). Thus, methyl 6-hydroxy-3,5-dimethylhexanoate **3** from the above synthesis was converted to the corresponding iodide **10** via the mesylate. Reaction of the iodide with 2-hexylmagnesium bromide, with CuI catalysis, produced methyl 3,5,7-trimethylundecanoate **12**. Basic hydrolysis of the ester gave the free acid **13**.

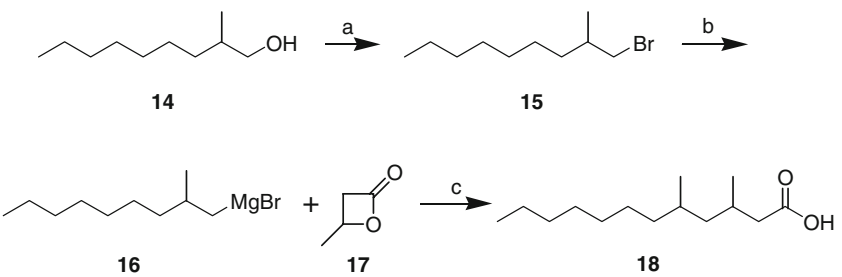
3,5-Dimethyldodecanoic acid was synthesized nonstereoselectively (Scheme 3) by ring opening of ß-butyrolactone with 2-methylnonylmagnesium bromide, with copper catalysis (Sato et al. 1980), yielding 3,5-dimethyldodecanoic acid **19** in a single step.

Field Bioassay Synthetic 3,5-dimethyldodecanoic acid as the mixture of all four stereoisomers attracted male *P. californicus* in a field bioassay. An average (± SE) of 3.5± 0.34 male beetles per trap per day were captured in traps baited with the synthetic pheromones (total over 5 days, 72 beetles), whereas no beetles were captured in control traps (means significantly different; Friedman's $Q_{1,39}=27.6$, $P<0.001$). No females were captured. In the mark-recapture portion of the assay, we recaptured only eight males that had been marked with paint and released, and Lincoln–Peterson estimates of local population size averaged (± SD) 280±230 male *P. californicus*.

Discussion

Whole body extracts of female *P. californicus* have been shown to be highly attractive to males (Barbour et al. 2006), but they contain a plethora of cuticular hydrocarbons and other contaminants that obscure possible pheromone components. Similarly, attempts to collect sufficient pheromone for analysis by using dynamic headspace collection, trapping odors released by unmated female beetles on activated charcoal, were unsuccessful; after elution with both polar and nonpolar solvents, the resulting extracts were minimally attractive to male beetles. Analyses of the compounds absorbed from the inside of the ovipositor, however, showed that the main pheromone component had been collected in detectable amounts by this method, along with several homologs.

The identification of the pheromone was confounded by the small amounts of pheromone that could be recovered in insect extracts, and by the fact that the contact SPME method of extracting and analyzing the pheromone provided



Scheme 3 Synthesis of 3,5-dimethyldodecanoic acid. *a* MesCl, Et_3N, CH_2Cl_2; LiBr, acetone; *b* Mg turnings, THF; *c* CuI, ß-butyrolactone **17**

only mass spectral and retention time data. The combination of both types of data proved crucial in finally identifying the correct structure. The remarkable similarity between the mass spectra of the synthetic 3,5,9-trimethylundecanoic acid and the pheromone at first led us to believe that this structure was correct, but retention time comparisons on both the polar and nonpolar columns, with both the free acids and the corresponding methyl esters, proved that this was not possible. Detailed examination of the mass spectra showed that there were indeed small but reproducible differences between the spectra. Nevertheless, the presence of the misleading *m/z* 171 ion, and the corresponding ions in the homologs, is noteworthy. In fact, it had been previously noted that even straight-chain carboxylic acids display periodic enlarged fragment ions in the middle of the aliphatic chain, with no obvious source of stabilization to account for the fragmentation (McLafferty and Turecek 1993, p. 218).

Only male beetles were caught in traps baited with the synthetic 3,5-dimethyldodecanoic acid, thus verifying that this compound is a sex pheromone. The substantial number of beetles captured also suggests two other points. First, the fact that the beetles were attracted to the mixture of all four stereoisomers of 3,5-dimethyldodecanoic acid suggests that none of the "unnatural" stereoisomers are likely to be strongly antagonistic. The lack of antagonism will be a tremendous benefit for the commercialization of the pheromone for monitoring and/or control of the beetle, because as described above, 3,5-dimethyldodecanoic acid can be readily prepared in multigram quantities in a single step from two simple precursors. The relatively strong attraction obtained with 3,5-dimethyldodecanoic acid also suggests that the other compounds in the extracts from females are not crucial components of the pheromone, and that racemic 3,5-dimethyldodecanoic acid as a "single" component is a satisfactory trap bait.

To our knowledge, the work described here represents the first identification of a pheromone for a species in the longhorned beetle subfamily Prioninae. However, there is considerable circumstantial evidence that female-produced sex attractant pheromones are widespread within the Prioninae (e.g., Rotrou 1936; Edwards 1961; Benham and Farrar 1976; Gwynne and Hostetler 1978), so we anticipate that pheromones of other species, particularly congeners of *P. californicus*, will soon be reported, now that the basic methods and a "lead" compound have been characterized. It should also be noted that the pheromone of *P. californicus* is entirely different in structure from the male-produced pheromones of species in other subfamilies of the Cerambycidae (e.g., Hanks et al. 2007; Ray et al. 2009), and female-produced pheromones of two species that are apparently closely related to the Cerambycidae: *Migdolus fryanus* Westwood and *Vesperus xatarti* Dufour (Leal et al. 1994; Boyer et al. 1997; taxonomy according to Napp 1994; Bense 1995; Dong and Yang 2003).

There is still considerable work to be done to complete the identification of the pheromone of *P. californicus*, and to use it most effectively for insect management. First, further details of the pheromone itself (e.g., which stereoisomer[s] are produced by the beetle, and the possible role of the other components in extracts) need to be worked out. Second, operational details of using the pheromone efficiently for sampling and control of this insect require optimization. Unlike some other groups of insects for which numerous pheromones are known and for which traps and pheromone release devices have been well studied, relatively little has been done with pheromone trapping of cerambycids. For example, the carboxylic acid chemistry of the *P. californicus* pheromone is unusual among insect pheromones, and release devices such as the rubber septa that are commonly used for many insect pheromones do not work well with this compound (unpub. data). Furthermore, our field observations suggest that the beetles may walk or fly towards pheromone sources, so traps should be designed to be accessible to both walking and flying insects. These and related questions will be addressed in ongoing research, so that this novel pheromone can be fully developed for management of *P. californicus* in crops where it is a chronic problem.

The online supplement to this manuscript includes the full EI mass spectra of EI mass spectrum of 3,5,7-trimethylundecanoic acid, 3,5,9-trimethylundecanoic acid, 3,5-dimethyldodecanoic acid, 3,5-dimethyltridecanoic acid, 3,5-dimethylpentadecanoic acid, methyl 3,5,7-trimethylundecanoate, methyl 3,5,9-trimethylundecanoate, and methyl 3,5-dimethyldodecanoate.

Identification of Chemicals Emitted by Calling Males of the Sapote Fruit Fly, *Anastrepha serpentina*

David C. Robacker · Martin Aluja · Robert J. Bartelt · Joseph Patt

Received: 14 August 2008 / Revised: 4 November 2008 / Accepted: 2 December 2008 / Published online: 9 May 2009

Abstract Emissions from sexually active *Anastrepha serpentina* males were collected by solid-phase microextraction. Calling behavior of wild-type males showed no clear peak during the day, except that it was evident less frequently immediately after daybreak and just before dark. Calling by laboratory males was highest between 8 and 11 h after onset of the photophase, and mating by wild flies occurred mostly between 6 and 10 h after onset of the photophase. Two major components of male emissions were identified as 2,5-dimethylpyrazine (DMP) and 3,6-dihydro-2,5-dimethylpyrazine (DHDMP). DHDMP was synthesized, and the identity of the natural product confirmed by comparison of gas chromatographic retention times and mass spectrum. Emissions of DMP and DHMP were greatest during peak calling behavior, with males emitting up to 1.8 and 3.3 μg/h of DMP and DHDMP, respectively. A minor component, which did not vary with time of day, was identified as 2,3,5-trimethylpyrazine. To our knowledge, this is the first report of 3,6-dihydro-2,5-dimethylpyrazine in nature.

Keywords Solid phase microextraction (SPME) · Sex pheromone · Pyrazine · Dihydropyrazine · Diptera · Tephritidae

Introduction

Anastrepha serpentina is known as the "Sapote (Zapote in Spanish) fruit fly" as it principally infests fruit within the Sapotaceae [e.g., *Calocarpum mammosum* (L.) P. Royen, *Chrysophyllum mexicanum* Brandegee ex. Stand, *Chrysophyllum cainito* L., *Bumelia sebolana* Lundell, *Manilkara zapota* (L.) P. Royen, *Pouteria campechiana* (Kunth) Baehni, *Pouteria glomerata*, *Pouteria obovata* H.B.K., *Pouteria hypoglauca* (Standley) Baehni, *Sideroxylon capiri* (A.DC.) Pittier] (Baker et al. 1944; Aluja et al. 1987, 2000b, 2003; Norrbom 2004). On occasion, it has been reported to infest citrus [e.g., *Citrus aurantium* L., *Citrus sinensis* (L.) Osbeck, both Rutaceae], mango (*Mangifera indica* L., Anacardiaceae), peaches and pears [*Prunus persica* (L.) Batsch, and *Pyrus communis* L., respectively, both Rosaceae] (Baker et al. 1944, Aluja et al. 1987, Norrbom 2004), and is thus considered a pest of quarantine significance (Sharp et al. 1989). It is distributed from southern USA to Argentina, excluding the Caribbean Islands (Hernández-Ortíz and Aluja 1993).

The sex and aggregation pheromones of *Anastrepha* fruit flies have been investigated for only a few pest species of the nearly 200 species in the genus (Heath et al. 2000). The

first chemicals identified from male emissions in this genus were (*Z*)-3-nonenol and (*Z,Z*)-3,6-nonadienol from *Anastrepha ludens* (Esponda-Gaxiola 1977). The same alcohols and two novel diastereomeric pairs of enantiomeric bicyclic lactones, which were subsequently named anastrephin and epianastrephin, were next identified from *Anastrepha suspensa* and *A. ludens* (Nation 1983; Battiste et al. 1983; Stokes et al. 1983). Later, a novel macrolide, subsequently named suspensolide (Chuman et al. 1988), and (*E,E*)-α-farnesene were identified from both of these species, and β-ocimene and β-bisabolene were found in emissions of *A. suspensa* (Rocca et al. 1992; Heath et al. 2000). Several of these compounds and their combinations were attractive to sexually active female flies in laboratory assays (Nation 1975, Robacker and Hart 1985), but many of the chemicals have not been tested.

Work on pheromones of other *Anastrepha* has been less extensive. During the early 1990s, pheromones from additional species were investigated for the purpose of developing attractants as well as understanding phylogenetic relationships within the genus. Heath et al. (2000) collected and quantified emissions from *Anastrepha obliqua*, *Anastrepha striata*, *Anastrepha fraterculus* (Central American populations), and *A. serpentina*, but none of the chemicals were tested for pheromonal activity. Principal compounds in emissions of *A. obliqua* were (*Z*)-3-nonenol, (*E,E*)-α-farnesene, and (*Z,E*)-α-farnesene, of *A. striata*, linalool, ethyl hexanoate, and ethyl octanoate, and of *A. fraterculus*, nonenols, anastrephin, and epianastrephin. De Lima et al. (1996) reported (*Z,E*)-α-farnesene, (*E,Z*)-α-farnesene, suspensolide, and a series of pyrazines in male salivary glands of Brazilian *A. fraterculus*. Pheromonal activity was not demonstrated for any of these.

Although collections of male emissions were made for *A. serpentina*, no male-specific chemicals were reported (Heath et al. 2000). Lek formation in this species, and behavior of flies in leks under natural conditions (Aluja et al. 1989), as well as a description of the microbehaviors that together make up "calling" (Aluja et al. 2000a) have been studied. Briefly, calling includes puffing of the pleural areas of the abdomen, eversion of a presumed pheromone gland from the abdominal tip and touching the gland to a leaf surface, and rapid wing vibrations often accompanied by the male spinning on the leaf surface. In addition, Castrejon-Gomez et al. (2007) investigated other aspects of the calling behavior of this fly, reporting effects of age, time of day, and male density on calling by mass-reared and wild males. Nothing has been published about the chemical composition of the emissions of calling males.

The purpose of this work was to identify the principal male-specific chemicals in emissions of male *A. serpentina*. For this work, we collected male emissions by using solid-phase microextraction, a technique different from those used previously for this and the other species of *Anastrepha*.

Methods and Materials

Insects and Test Conditions Observations of calling behavior were conducted with feral flies collected from *Chrysolphyllum mexicanum* collected in the vicinity of Teocelo, Veracruz, Mexico (19°23′ N, 96°58′ W) and from *M. zapota* collected in the vicinity of Metapa de Domínguez, Chiapas, Mexico (14°50′ N, 92°11′ W). Fruit was transported to the laboratory in Xalapa, Veracruz and placed in plastic baskets that, in turn, were placed over plastic washbowls containing vermiculite as a pupating medium. All pupae were weighed and sorted by size. To reduce any size effect on sexual performance, we used only pupae that weighed between 10 and 20 mg.

All other work was conducted with flies from a laboratory culture that originated from mamey fruit (*Pouteria sapota*; Sapotaceae), a native host of the fly, collected in Chiapas in 2000, and reared on artificial diet for at least 25 generations. Diet ingredients include maseca, torula yeast, sucrose, vitamins, beck's salt, methyl paraben, sodium benzoate, agar, HCl, and cholesterol. Flies were segregated by sex 2–3 days after eclosion. Flies in the laboratory culture have not been observed to mate before 7 days after eclosion. Males used for collections of volatiles were put into Plexiglas cages (20.5× 20.5×20.5 cm) with screened tops. Cages were provisioned with a protein/sugar mixture and additional sugar in a separate container, as well as water. Laboratory conditions for holding and testing flies were 24±2°C, 60±20% relative humidity, and a 13-h photophase that began at 0330 h and ended at 1630 h, with exceptions specified later. Volatiles collections were conducted in the same room where adult test flies were held. The room contained inlet and outlet vents to bring new air into the room from the outdoors and expel air from the room. Complete air replacement in the room occurred eight times per hour. Overhead lighting was provided by fluorescent "cool white" lights (F40CW, General Electric).

Observations of Calling Behavior of Males in Field Cages At 8 days of age, all individuals, sorted by geographical origin (i.e., Veracruz and Chiapas) were marked with a distinctive color on the pronotum (Veracruz—white, Chiapas—green) with water-based paint (Vinci, Vinci de Mexico S.A. de C. V. Mexico; Aluja et al. 2001). Observations were carried out inside a cylindrical field cage (3 m diam.×3 m height) placed inside a climate-controlled room (25±2°C, 70% RH and 0–120 lx light intensity, simulating daily patterns) at the Instituto de Ecologia, A.C., Xalapa, Veracruz (19°30′ N and 96°55′ W, 1,300 m elevation). To simulate a patch of

host and non-host trees, sapodilla (*M. zapota*), tropical plum (*Spondias mombin* L., Anacardiaceae), orange (*C. sinensis*), and mango (*M. indica*) potted trees were placed on wooden stools and arranged in the center of the field cage as described in Aluja et al. (2001).

Over a 5-day period, ten virgin females and ten virgin males from each population (total of 40 flies) were released into the cage daily and removed at the end of the day. Males were released the night previous to testing (21:00 h) and females the day of testing (05:30 h). Starting at 06:00 h and until 20:00 h, all calling males and mating pairs were counted every 15 min. A male was considered to be calling if the pheromone gland was everted from the abdomen tip, or if he engaged in rapid wing vibrations.

Collection and Gas Chromatographic Analysis of Male Emissions Volatiles emitted by sexually mature males were collected by using solid phase microextraction (SPME) with a polydimethylsiloxane (PDMS) coated fiber (100 μm coating; Supelco, Inc., Bellefonte, PA, USA). Twenty sexually mature, virgin males (8–23 days old) were put into a 2-neck 500-ml round-bottom flask with ground glass joints, early in the morning of the day when collections were to be conducted. Collections of volatiles were also done using 20 virgin, sexually mature females (15–18 days old) three times on each of 2 days. Compressed air entered the flask through a ground glass gas inlet tube that extended into the flask to within 2 cm of the flask wall on the opposite side. Flow rate was set to 200 ml min^{-1} by using a VICI Condyne flow controller (Valco Instruments Co., Inc., Houston, TX, USA). Air exited the flask through the second neck via a ground glass hose adapter, modified by replacing the hose connector with a 4.5-mm i.d. glass tube. This arrangement allowed the air to sweep through the entire flask before exiting. The glass tubes for incoming and exiting air were loosely packed with a piece of tissue as a barricade to the flies. The flask was turned upside down so that incoming air tube emptied onto the upper wall of the flask and outgoing air exited on the bottom. Calling flies congregated on the upper wall because a large green leaf was taped onto the top on the outside of the flask so as to allow flies to sit on the "underside" of a leaf, a typical site for calling *Anastrepha* on trees (Aluja et al. 2000a). Additional light was provided above the leaf with a 75-W incandescent light bulb, creating shadow on the underside of the leaf.

Volatiles were collected by inserting the SPME sheath 2 cm into the 4.5-mm ID tube and extending the PDMS fiber for 1 h per sampling. Most samplings were done from 0800 to 1630 h at 24°C. These times corresponded to 4.5 h after onset until the end of the photophase. For some collections, the onset of the photophase was adjusted to later in the day so that emissions early in the photophase could be sampled conveniently. Volatiles were analyzed by gas chromatography (GC) after thermal desorption from the PDMS fiber by on-column injection at 220°C in a 15-cm retention gap (0.53 mm ID deactivated fused-silica) connected to the analytical column by a GlasSeal™ connector (Supelco). The analytical column was a J&W DB-1 (30 m, 0.32 mm ID, 5 μm film; Agilent Technologies, Inc., Santa Clara, CA, USA). Column oven temperature was 50°C for 5 min, then programmed at 5°C min^{-1} to 200°C. Carrier gas was helium at a linear velocity of 30 cm s^{-1}. Analyses were conducted by using a Shimadzu GC-17A (Shimadzu Scientific Instruments, Inc., Columbia, MD, USA) equipped with both flame ionization (FID) and flame thermionic (Model FTD-17) detectors (FTD). Detection was by FID for all analyses used to quantify emissions at different times of the day, and by FTD for three analyses to determine presence of nitrogen in eluted peaks. GC peak areas were measured using Empower™ 2 Chromatography Data Software (Waters Corporation, Milford, MA, USA). Kovats indices were calculated for putative pheromone peaks.

Gas Chromatography–Mass Spectrometry Analyses of Chemicals in Male Volatiles Volatiles were collected by SPME for a 1-h period, 9–10 h after onset of photophase, the time of day when the largest peaks were observed. Chemicals were thermally desorbed from the fiber for 1 min by splitless injection at 250°C, with the injector purged after 1 min. A DB-1 column (60 m, 0.25 mm ID, 0.25 μm film; Agilent), with helium at 26 cm s^{-1} as carrier gas, was used for the analyses. Column oven temperature was programmed from 50°C to 200°C at 5°C min^{-1}. Gas chromatography–mass spectrometry (GC–MS) data were acquired with a Hewlett Packard 6890 GC coupled with an HP 5973 Network Mass Selective Detector [in electron ionization (EI) mode at 70 eV] over a mass range of 20–550 amu. Identification of 2,5-dimethylpyrazine (**1**) (DMP) and 2,3,5-trimethylpyrazine (**3**) (TMP) was by computer matching with spectra in the NIST 98 Library of Mass Spectra and Subsets (Hewlett-Packard) and by GC and MS comparison to commercial samples of 2,3-, 2,5-, and 2,6-dimethylpyrazine and 2,3,5-trimethylpyrazine (Aldrich Chemical Co., Milwaukee, WI, USA). The mass spectrum of the unknown peak that was eventually identified as 3,6-dihydro-2,5-dimethylpyrazine (**2**) (DHDMP) did not match with any spectrum in the NIST 98 Library database. DHDMP in male emissions was identified by using its molecular weight as determined by GC–MS, GC-FTD analysis, and matching its GC retention times and mass spectrum with those of synthetic DHDMP.

Synthesis of DHDMP Oximinoacetone (**6**, Fig. 1) was first prepared, as described by Krems and Spoerri (1947): Ethyl

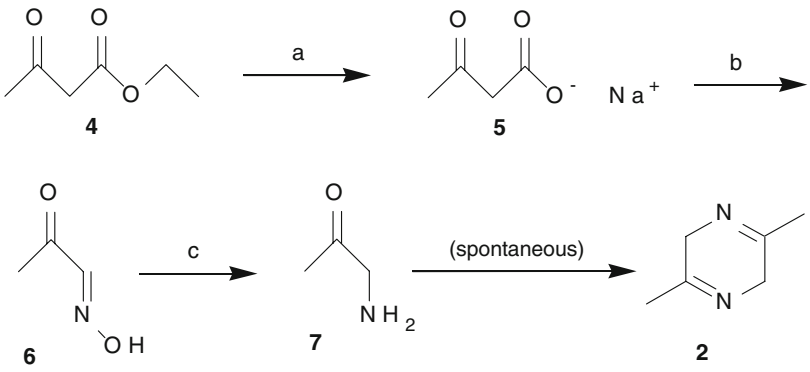

Fig. 1 Synthesis of 3,6-dihydro-2,5-dimethylpyrazine (DHDMP) (**2**). Reaction conditions: *a* 5% aqueous NaOH, 30 min, room temperature; *b* H_2O, HOAc, $NaNO_2$, 0°C to room temperature, 1 h; *c* Al/Hg, tetrahydrofuran, 0°C, 30 min

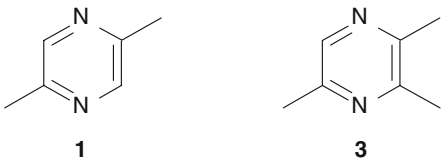
Other male-specific compounds from *Anastrepha serpentina*



acetoacetate (**4**) (5 g, 0.038 mol) was added to a 5% aqueous solution of NaOH (50 ml, containing 0.063 mol base) and stirred at room temperature for 30 min. The solution, now containing sodium acetoacetate (**5**), was cooled over ice, and acetic acid (7.5 ml) added slowly. A twofold excess of sodium nitrite (5.24 g, 0.076 mol) was added slowly to the acidified solution and stirred for 1 h at room temperature. Oximinoacetone (**6**) was extracted with diethyl ether (25 ml, three times), and the combined extracts dried over anhydrous magnesium sulfate and filtered. Solvent was removed gently by rotary evaporation. EI mass spectra (70 eV) were acquired on a Hewlett Packard 5971A Mass Selective Detector with GC inlet. Nuclear magnetic resonance (NMR) spectra were obtained on a Bruker Avance 500 MHz instrument. One-dimensional ^1H and ^{13}C data are reported, but two-dimensional HSQC and HMBC experiments also were run to aid in assignment of resonances to the proper compounds. Oximinoacetone (**6**): EI-MS: *m/z* (%)= 87 (M^+, 25), 72 (7), 55 (3), 43 (100). ^1H NMR (500 MHz, C_6D_6): 2.31 (s, 3H), 7.92 (s, 1H). ^{13}C NMR (125 MHz, C_6D_6): 24.9, 149.1, 195.6.

Oximinoacetone (**6**) then was reduced to aminoacetone (**7**) with aluminum amalgam as described by Ferris et al. (1968). Aminoacetone dimerized and dehydrated spontaneously to give DHDMP (**2**) (Krems and Spoerri 1947). Aluminum amalgam was prepared by covering aluminum foil (ca. 0.1 g, cut into small pieces) with an aqueous solution of mercuric chloride (5%, 5 ml) for about 1 min, resulting in grayish turbidity in the solution as metallic mercury began to deposit on the foil surface. The solution was decanted off, and the foil quickly rinsed twice with water (5 ml) and two times with tetrahydrofuran (THF, 5 ml). The foil was placed in fresh THF (5 ml) and stirred at ice temperature. Oximinoacetone (**6**) (ca. 0.1 g) was added in one portion. Reaction soon set in, accompanied by the formation of a greenish turbidity in the solution. After 30 min, the solution was transferred to a vial and tightly capped and stored in the freezer. Aliquots were removed and diluted with hexane for GC studies. In addition to compound **2**, the solution contained the air oxidation product, DMP (**1**) and unreacted oximinoacetone (**6**). Purification of **2** was impracticable because it readily oxidizes in air, but the impurities were easily separable from product **2** by GC.

Mass and NMR spectra were acquired for the product mixture as described for oximinoacetone. 3,6-Dihydro-2,5-dimethylpyrazine (**2**): EI-MS: *m/z* (%)=110 (M^+, 34), 95 (1), 69 (100), 54 (19), 42 (89), 41 (48). ^1H NMR (500 MHz, C_6D_6): 1.71 (s, 3H), 3.66 (s, 2H). ^{13}C NMR (125 MHz, C_6D_6): 23.5, 51.6, 166.6. 2,5-Dimethylpyrazine (**1**): EI-MS: *m/z* (%)=108 (M^+, 100), 81 (12), 66(2), 52 (5), 42 (93). ^1H NMR (500 MHz, C_6D_6): 2.26 (s, 3H), 8.15 (s, 1H). ^{13}C NMR (125 MHz, C_6D_6): 20.6, 143.4, 150.5.

Determination of Emission Rates of DMP and DHDMP

Collections of volatiles and GC analyses were conducted as described above. Emission rates were calculated by using the methods and principles found in Bartelt (1997) and Bartelt and Zilkowski (1999). Emission of volatiles from the flies was assumed to be fairly constant during the 1-h sampling periods suggesting that the volatiles in the round bottom flask had achieved a steady rate (i.e., that the volatile concentration within the flask was constant, and thus, that the emission rate from the flies was equivalent to the emission rate through the exit port; Bartelt and Zilkowski 1999). The SPME calibration factor, *K*, for DMP was

previously measured as 11.2 ml (Bartelt 1997), and this value also was used in calculations for DHDMP because the two compounds are of similar volatility. One-hour sampling allowed DMP and DHDMP to equilibrate fully with the SPME fiber (Bartelt 1997), so that their concentrations in the exit air stream were simply proportional to their amounts in the fiber coating (measured by GC). The transfer of sample from the fiber to the GC column was assumed to be quantitative. The response factor for the FID was calibrated by using quantitative standard solutions of DMP. The absolute emission rates were calculated by using the GC-measured amounts, *K*, and the air flow rate past the SPME fiber (Bartelt and Zilkowski 1999).

Statistical Analyses Means and standard errors were calculated for percentages of males calling and mating at various times of the day. Emissions (GC peak areas) of DMP, DHDMP, and TMP from calling males were analyzed to determine the effect of time of day on amount emitted. The effect of time of day was tested by ANOVA by using 1-h time periods as a discrete independent variable. Effect of test day was also partitioned out of the total sum of squares. ANOVAs were conducted by using SuperANOVA (Abacus Concepts 1989).

Results

Diurnal Rhythm of Calling and Mating Wild males began calling within 2 h after sunrise (Fig. 2). Calling behavior of males from Veracruz occurred during most of the photophase, peaking from 9 to 12 h after sunrise. Calling by males from Chiapas followed a similar pattern, but levels were lower and no distinct peak was observed. Laboratory males used in the collection of volatiles also followed a similar pattern (note that no observations were made for this during hours 1–5 and 14 as they were exposed only to 13 h of daylight), with the percentage of males calling generally higher than for the wild insects.

Mating of wild flies from Veracruz followed a pattern similar to calling of laboratory and Veracruz males (Fig. 3). Mating by wild flies from Chiapas appeared to peak earlier in the day. Frequencies of matings were low in these observations, making all comparisons tentative.

Identification of Putative Pheromones in Male Emissions GC analysis indicated that emissions by males varied with time of day for only three compounds. Two of these were tentatively identified as DMP and TMP by computer matching of their mass spectra with spectra in the NIST 98 Library of Mass Spectra and Subsets. The identities of these compounds were confirmed by matching GC retention times and mass spectra with those of authentic compounds. Both produced larger relative responses on the FTD than on the FID, confirming the presence of N bonded to C.

The third chemical was emitted at the highest rate by males, but its mass spectrum (Fig. 4a) did not match any spectra in the library. It also yielded a larger response by the FTD than the FID, indicating the presence of N. Its retention time was longer than that of DMP but close enough to suggest a similar molecular weight (Kovats indices: DMP, 895; unknown, 965). Its probable molecular weight was 110 amu, and the likely molecular formula was $C_6H_{10}N_2$, from isotopic analysis based on the relative abundances of the M+1 ion and the molecular ion, and because an even molecular weight would correspond to an even number of nitrogen atoms. Because the molecular weight was 2 amu greater than the molecular weight of

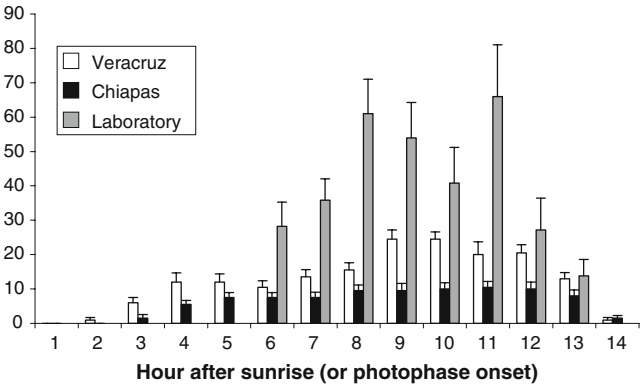


Fig. 2 Mean percentage of male *Anastrepha serpentina,* originating from a laboratory colony and two wild populations (from Veracruz and Chiapas, Mexico), exhibiting calling behavior in the laboratory with respect to time of day. For the laboratory colony, no observations were made during hours 1–5 and 14 (i.e., there were only 13 h of daylight). *Lines atop bars* are SEM

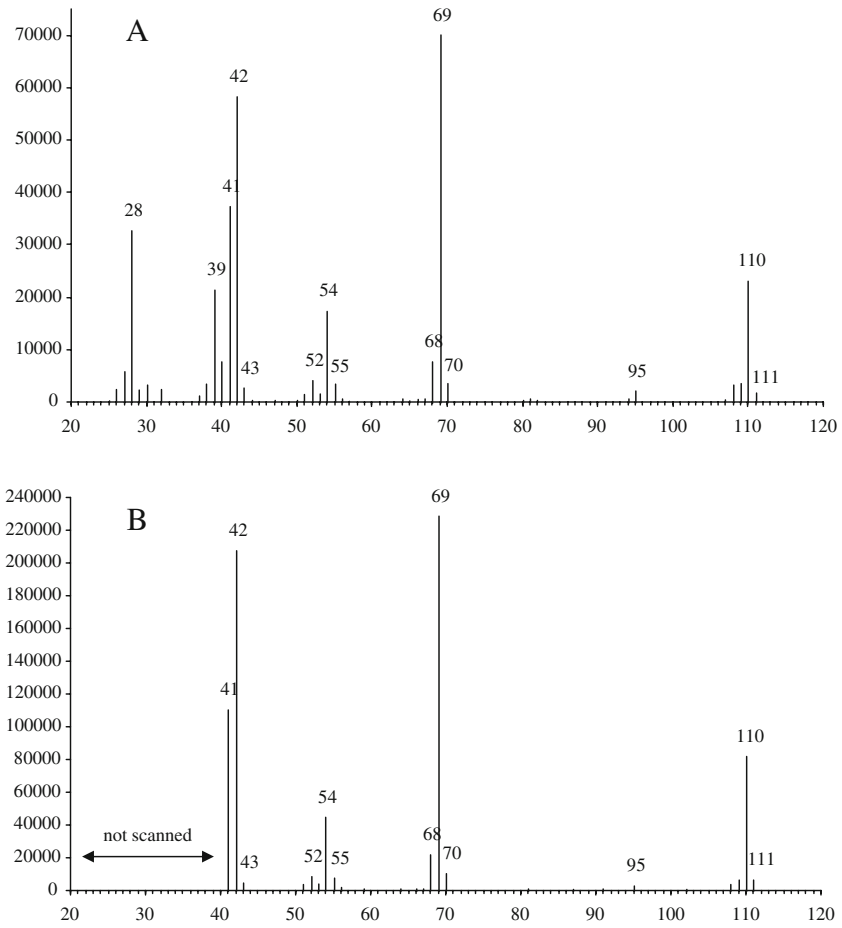

Fig. 4 Electron ionization mass spectra of 3,6-dihydro-2,5-dimethylpyrazine (DHDMP) (**2**). **a** Chemical with Kovats retention index 965 in emissions of calling male *Anastrepha serpentina*. **b** Chemical with Kovats retention index 965 in product of reaction of oximinoacetone (**6**) on aluminum amalgam

DMP and the molecular formula was the same as that of DMP plus two H atoms, the unknown was tentatively identified as a dihydro-dimethylpyrazine, and standards were synthesized to determine exactly which compound it was. Fortuitously, the first standard, 3,6-dihydro-2,5-dimethylpyrazine matched the unknown by mass spectrum (Fig. 4b) and GC retention times, and we concluded that the *A. serpentina* compound was probably DHDMP.

DMP and DHDMP were not found in emissions of females. A small amount of TMP was present in collections from females. The amount was about 2% of the amount found in male emissions, and it could have resulted from imperfect fiber cleaning after a GC determination of male emissions.

Male Emissions vs. Time of Day Emissions of DMP and DHDMP by males in laboratory experiments showed definite peaks about 7–11 h after onset of the 13-h photophase (Fig. 5). Emissions of DMP were significantly greater at 9 and 11 h than at any other time except 10 h (F=4.2; df=10, 53; P< 0.001). Emissions of DHDMP were greater between 9 and 11 h than at any other times (F=5.5; df=10, 53; P<0.001). There were no significant differences with time of day for emission of TMP. A chromatogram of male emissions at 10 h after the onset of photophase is shown in Fig. 6.

Actual emission rates were determined for DMP and DHDMP. Peak emission of DMP was calculated as 1.8 µg/h/male (N=9), 11 h after onset of photophase, and 3.3 µg/h/male (N=9) for DHDMP, 10 h after the onset of photophase.

Discussion

Evidence for the most abundant compound emitted by male *A. serpentina* being DHDMP is strong. The natural and synthetic compounds were identical by GC retention, mass spectrum, and responses on the FTD. It is unlikely that other isomers (with respect to methyl position, nitrogen position, or double-bond position) would match all these criteria. Furthermore, the synthetic scheme (head-to-tail dimerization of oximinoacetone), the NMR spectra, and presence of DMP as a reaction by-product (due to oxidation of DHDMP in air) are entirely consistent with the desired isomer of DHDMP that was made. NMR of the natural compound would have given further confirmation of structure, but this was not feasible because the lability of DHDMP would make it difficult to collect and purify enough material. After a thorough search of the literature, we conclude this to be the first report of DHDMP as a natural product.

The identifications of the less abundant, fly-derived compounds, DMP and TMP, were also based on MS and GC comparison to synthetic standards. These were considered unequivocal because double-bond position was not an issue, and because standards were available for all of the possible methyl group positions.

In this study, males used for the collection of emissions were fed a combination of sugar and protein. Aluja et al. (2001) reported that male-mating performance was influenced strongly by adult diet. For example, *A. serpentina* males with varying adult feeding histories (adults fed from the time of emergence on dry sucrose, open fruit, a mixture [3:1] of dry sucrose and hydrolyzed protein, or a mixture of dry sucrose and bird feces) that were competing for access to females in a field cage, exhibited greatly differing rates of copulatory success. Those with access only to sucrose never mated, while those with access to the sucrose/protein mixture mated the most (greatest proportion) and were able to mate repeatedly over a 3-day period. The latter is pertinent, as it has been shown that adult diet influences the composition of the sex pheromone of *A. suspensa* (Epsky and Heath 1993). In the case of *A. serpentina*, in which all of the putative pheromone components contain nitrogen, the need for protein in order for males to produce these chemicals in the high quantities reported above seems especially important.

The presence of pyrazines in male emissions of *A. serpentina* has precedence in Tephritidae. Baker et al. (1985) stated that they found nine components of male Mediterranean fruit fly emissions, including 2-ethyl-3,5-dimethylpyrazine, although no chemical data were given, and this compound was not tested for biological activity. Jang et al. (1989) found 2,5-dimethyl-3-ethylpyrazine as a trace component of male emissions of this fly. This compound elicited a small electroantennogram response from female antennae. Baker et al. (1990) identified 2,3-dimethylpyrazine and DMP in anal glands of Mediterranean fruit fly. These pyrazines were attractive in field tests, but the tests did not determine if the response was sexual attraction. However, Flath et al. (1993) did not find pyrazines in emissions of male Mediterranean fruit flies. In the case of the Mexican fruit fly, sexually inactive males and females are attracted to both DMP (Robacker and Flath 1995) and TMP (Robacker and Bartelt 1997).

De Lima et al. (1996) indicated that pyrazines had been detected as pheromone components in *Bactrocera dorsalis*, but gave no specific reference. Baker et al. (1982) identified methylpyrazine, TMP, and tetramethylpyrazine from rectal glands of melon fly (*Bactrocera cucurbitae*), but Nishida et al. (1990) did not find these chemicals in melon fly, possibly due to strain differences. However, Perkins et al. (1990) reported that Lewis (1987) confirmed the presence of TMP and tetramethylpyrazine but could not find methylpyrazine.

Chuman et al. (1987) identified 2-methyl-6-vinylpyrazine as the sex pheromone of the papaya fruit fly (*Toxotrypana curvicauda*), a species closely related to *Anastrepha*. De Lima et al. (1996) found DMP, TMP, 3-ethyl-2,5-dimethylpyrazine, and 3-butyl-2,5-dimethylpyrazine in salivary glands of male *A. fraterculus*. These chemicals were not tested for pheromonal activity. Calling males of other species in the *fraterculus* group, including *A. suspensa*, *A. obliqua*, and *A. ludens*, are not known to emit pyrazines (Heath et al. 2000).

DHDMP is in a class of compounds called dihydropyrazines that have not been reported as chemicals emitted by calling Tephritidae. Moreover, DHDMP has never been reported in nature. While the structurally related pyrazines are generally stable, dihydropyrazines are not. The stability of pyrazines results from the aromatic nature of the six-

membered ring (analogous to benzene, but with N in place of C at the 1 and 4 positions). The instability of dihydropyrazines, in general (Krems and Spoerri 1947), and of DHDMP in particular (Wilen 1970), follows from the tendency to lose two hydrogens and aromatize. Even contact with air can cause this conversion. As shown in this work, DHDMP is stable enough to be released from living flies and to be captured by an SPME fiber, but it is apparently not stable enough to survive protracted or relatively harsh volatile collection procedures.

One of the significant implications of this work is that dihydropyrazines might be common in insects, perhaps serving as pheromones or pheromone precursors, but have never been found because of the methodology constraints discussed above. If this is the case, then it is also possible that the pyrazines found in this work, and in other Tephritidae (see above), actually may not be produced by the flies but are present only in male emissions as artifacts of the breakdown of dihydropyrazines.

As a possible consequence of the instability of dihydropyrazines, Heath et al. (2000) reported no chemicals associated with calling behavior of male *A. serpentina*. These authors collected male-emitted chemicals by passing male emissions through Porapak Q, an adsorbent that has been used extensively by numerous insect chemical ecologists to identify pheromones and other semiochemicals. Apparently, SPME PDMS used in the present work was better suited than Porapak Q for collecting emissions of *A. serpentina*, at least in part because of the lability of DHDMP. The handling of DHDMP, including collection on Porapak Q, solvent extraction, sample focusing by solvent evaporation, and storage, likely resulted in nearly complete breakdown of DHDMP. Why Heath et al. (2000) did not report finding DMP and TMP is difficult to explain, but may be a function of affinities of PDMS and Porapak Q for pyrazines.

Because these compounds (**1**–**3**) are emitted in the greatest amounts at the time of day when calling and mating of flies are greatest, we suggest that they may be sex pheromone components. Testing of the behavioral activity elicited by these compounds will be a topic of future research.

Acknowledgments We thank Maura Rodriguez and Rosa Ruiz (USDA ARS, Weslaco, Texas) and Darío García-Medel and Alberto Anzures Dadda (Instituto de Ecología, A.C.) for technical assistance. Martín Aluja received financial support from the Mexican Campaña Nacional contra las Moscas de la Fruta (Secretaría de Agricultura, Ganadería, Desarrollo Rural y Pesca—Instituto Interamericano de Cooperación para la Agricultura (SAGARPA-IICA), the Consejo Nacional de Ciencia y Tecnología (Project CONACyT—SEP-2004-C01-46846) and the Instituto de Ecología, A.C. (Xalapa, Veracruz, México). MA also acknowledges support from CONACyT through a Sabbatical Year Fellowship (Ref. 79449). Karl Vermillion of USDA ARS NCAUR, Peoria, IL, acquired the NMR spectra. The use of a product brand in this work does not constitute an endorsement by the USDA.

Aggregation Pheromone of the Qinghai Spruce Bark Beetle, *Ips nitidus* Eggers

Qing-He Zhang · Jian-Hai Ma · Feng-Yu Zhao · Li-Wen Song · Jiang-Hua Sun

Received: 18 October 2008 / Revised: 13 April 2009 / Accepted: 15 April 2009 / Published online: 1 May 2009

Abstract Volatiles from hindgut extracts of males of the Qinghai spruce bark beetle, *Ips nitidus*, from different attack phases (phase 1: unpaired males and phases 2–4: males joined with one to three females) and hindgut extracts of mated females were analyzed by gas chromatography–mass spectrometry (GC–MS)/flame ionization detection (FID) with both polar and enantioselective columns. The GC–MS/FID analyses demonstrated that unpaired males from attack phase 1 (nuptial chamber constructed) produced 2-methyl-3-buten-2-ol, approx. 74%-(−)-ipsdienol, and (−)-*cis*-verbenol as major hindgut components, and (−)-*trans*-verbenol, (−)-ipsenol, (−)-verbenone, myrtenol, and 2-phenylethanol as minor or trace components. The quantities of 2-methyl-3-buten-2-ol and especially ipsdienol decreased after mating during phases 2–4, whereas the quantities of (−)-*cis*- and (−)-*trans*-verbenol did not change. In contrast, the quantity of (−)-ipsenol seemed to increase as mating activity progressed. After mating with three females (harem size=3; phase 4), only trace to small amounts of male-specific compounds were detected from *I. nitidus* male hindguts. Chemical analysis of the hindgut extracts of mated females showed only trace amounts of semiochemicals. A field-trapping bioassay in Qinghai, China showed that the four-component "full blend" containing the three major components, 2-methyl-3-buten-2-ol, (±)-ipsdienol, and (−)-*cis*-verbenol, plus a minor component, (−)-*trans*-verbenol, caught significantly more *I. nitidus* (♂/♀=1:2.2) than did the unbaited control and two binary blends. The replacement of (±)-ipsdienol with nearly enantiomerically pure (−)-ipsdienol in the "full blend" significantly reduced trap catches, which suggests that both enantiomers are needed for attraction. On the other hand, removal of (−)-*trans*-verbenol from the active "full blend" had no significant effect on trap catches. Our results suggest that the three major components, 2-methyl-3-buten-2-ol, 74%-(−)-ipsdienol, and (−)-*cis*-verbenol (at 7:2:1), produced by unpaired fed males, are likely the aggregation pheromone components of *I. nitidus*, thus representing the first characterization of an aggregation pheromone system of a bark beetle native solely to China.

Introduction

The Qinghai spruce bark beetle, *Ips nitidus* Eggers (Coleoptera: Scolytidae), was first described in 1933 from specimens collected by Eggers from Muke Tatslenlu (Kangding), Sichuan Province, China. Fu (1983) recorded

I. nitidus from several species of spruce (*Picea*) in five western provinces of China (Gansu, Qinghai, Sichuan, Xinjiang, and Yunnan). In the 1970s, *I. nitidus* was recognized as one of the dominant bark beetle species in Qinghai spruce forests [*Picea crassifolia* (Kom.)] of the Qilian Mountain, Gansu Province (Fu 1983). This bark beetle infests weakened, wind-thrown, or burned trees, and at high population densities, it attacks healthy spruce trees. Recently, *I. nitidus* together with two other newly described sympatric bark beetles, *Ips shangrila* Cognato and Sun (Cognato and Sun 2007) and *Pseudips orientalis* (Wood & Yin) (Cognato 2000), were identified as the most destructive forest pest insects in the Maixiu Forest Park of Qinghai Province, China; where, since 2001, their outbreaks (independent or mixed) have caused significant tree mortality both in plantations and natural stands of *P. crassifolia* (Xue et al. 2003; Liu et al. 2007, 2008).

During the outbreaks in 2001–2005, the species was mis-identified as *Ips typographus* (L.) by Chinese entomologists (Xue et al. 2003), but in 2006, it was correctly identified by Milos Knížek (Forestry and Game Management Research Institute, Czech Republic) as *I. nitidus*. The basic biology and host colonization behavior of this species in natural spruce forests were recently described (Liu et al. 2007, 2008). First attempts to catch adult beetles with traps baited with *I. typographus* pheromone lures during their dispersal flights were made in the mid 1980s by Zhou et al. (1995) in Gansu Province with some positive results (assuming the captured beetle species was correctly identified). Additional bouts of field screening of potential attractants (for future monitoring or mass-trapping operations) with the known *Ips* aggregation pheromone components and their various combinations have been undertaken by local forest departments in recent years, but these efforts have yielded little success.

In contrast to the previous focus on screening semiochemicals by evaluating flight responses, our objectives were to (1) identify the aggregation pheromone of *I. nitidus*, (2) analyze the quantitative variation of pheromone components from different attack phases, (3) determine the enantiomeric compositions of major chiral pheromone components, and (4) test the behavioral activity of the key male-specific compounds as flight attractants in the field in Qinghai, China.

Methods and Materials

Collection and Preparation of Samples Live adult *I. nitidus* of different subcortical attack phases [phase 1: unpaired male in nuptial chamber; phase 2: one mated male with one female; phase 3: one mated male with two females; and phase 4: one mated male with three females in the galleries] were collected between 22 and 25 May 2008 from two naturally attacked wind-thrown Qinghai spruce trees [*P. crassifolia*)] at Maixiu Forest Park (35°08′–35°30′ N; 101° 33′–102°03′ E; ca. 2,900–3,000 m elevation), Huangnan Tibetan District, Qinghai Province, China. Beetles from the same family gallery system were placed in a 2-ml polyethylene centrifuge tube (Fisher Scientific, Pittsburgh, PA, USA) and immediately put into an outdoor cooler (ca. 4°C). The centrifuge tubes were separated into categories of attack phases on the same day of collection in the laboratory, and the hindguts were dissected quickly. Sexes were distinguished based on their elytral spine differences (Third elytral spine of males is much larger and more strongly capitate than the other three spines, whereas in females there are no obvious differences among the second, third, and fourth spines; Song et al. unpublished data) and presence of the aedeagus (male) or eggs (female) in cases where the spines were damaged. Male hindguts from the same attack phase and the same sample tree were extracted immediately with 1 ml redistilled pentane (with 2 μg of heptyl acetate as internal standard) in a 2-ml amber glass vial. Female hindguts from various attack phases and both sample trees were pooled and extracted in the same fashion as the male hindguts. Hindgut extracts (four to 27 guts/sample for males from different attack phases and 19 guts/sample for mated females) were shipped to the USA by express mail and kept at −20°C until analyzed chemically [gas chromatography with mass spectrometric detection (GC–MS) and gas chromatography with flame ionization detection (GC–FID)].

GC–MS Analysis All hindgut samples were analyzed on a combined Agilent 6890N gas chromatograph (GC) and an Agilent 5973N mass selective detector equipped with a polar column (INNOWax; 60 m×0.25 mm×0.5 μm film thickness; Agilent Technologies, Wilmington, DE, USA). The GC oven was programmed at 50°C for 1 min, with a rise to 230°C at a rate of 10°C/min, and held at 230°C for 25 min. Injector and transfer line temperatures were both 250°C. Helium was used as carrier gas at a constant flow of 26 cm/s. Compounds were identified by comparison of retention times and mass spectra with those of authentic standards (see Chemical Standards below). All of the analytes are previously known bark beetle semiochemicals.

GC–FID Analysis Hindgut samples also were injected into a Varian CP-3800 GC equipped with a polar column (INNOWax; 30 m×0.53 mm×1.0 μm film thickness; Agilent Technologies, Wilmington, DE, USA) and FID for compound quantification based on the internal standard (IS 2 μg of heptyl acetate in each sample; assuming similar or identical response factors between the analytes and the IS). Helium was used as the carrier gas at a constant flow of

26 cm/s, and the injector and detector temperatures were 220°C and 300°C, respectively. Column temperature was 50°C for 1 min, rising to 240°C at 10°C/min, and then held for 10 min.

Enantioselective GC–FID The enantiomeric analyses of male hindgut extracts (from phases 1 to 2), and a synthetic mixture of several key *Ips* pheromone compounds including (±)-ipsenol, (±)-ipsdienol, (1*S*,2*S*)-(−)-*cis*-verbenol, (1*S*,2*R*)-(−)-*trans*-verbenol, amitinol, (1*S*)-(−)-verbenone, and *E*-myrcenol (50 ng/μl each in hexane) were conducted by injecting the samples splitless on a Varian CP-3800 GC equipped with an Rt-bDEXm™ column (30 m×0.25 mm×0.25 μm film thickness; Restek, Bellefonte, PA, USA). Helium was used as carrier gas, and the injector/detector temperatures were both 230°C. Column temperature was 80°C for 1 min and rose to 200°C at 2°C/min. Elution orders of the (−)- or (+)-enantiomers of ipsenol and ipsdienol [(−)- eluted before (+)- for both compounds] were determined by injecting SPME (CAR/PDMS, 75 μm; Supelco, Bellefonte, PA, USA) samples of synthetic 97%-(+)-ipsdienol and 97%-(−)-ipsenol onto the same column, which confirmed the previous reports with a similar stationary phase (Seybold et al. 1995b; Macías-Sámano et al. 1997; Savoie et al. 1998). Since no pure (+)-enantiomers of *cis*- or *trans*-verbenol, and verbenone were available for comparison, our suggestions on their enantiomeric assignments were based entirely on the retention time matches to the synthetic (−)-enantiomers. Therefore, these assignments should be considered provisionary.

Chemical Standards Synthetic compounds were obtained from various commercial and noncommercial sources: (±)-ipsenol (95%, chemical purity: cp), (±)-ipsdienol (95% cp), (−)-*cis*-verbenol (98% cp, unknown enantiomeric purity-ep), and (−)-verbenone (99% cp, unknown ep; Bedoukian Research Inc., Danbury, CT, USA); amitinol (98% cp, W. Francke, Universität Hamburg, Hamburg, Germany); *E*-myrcenol (95.2% cp, SciTech, Prague, Czech Republic); 2-methyl-3-buten-2-ol (97% cp, Acros, Morris Plains, NJ, USA); (−)-ipsenol (97.3% cp; 97.5% ep), (+)-ipsdienol (96% cp; 98.2% ep), (−)-ipsdienol (95% cp; 97% ep) and (−)-*trans*-verbenol (>95% cp, unknown ep) [Pherotech (now Contech) International, Inc., Delta, BC, Canada]; heptyl acetate (>98% cp, food grade) and (±)-1,3-butanediol (99% cp) (Sigma-Aldrich, St. Louis, MO, USA).

Field Trapping To assay for behavioral activity of the potential semiochemicals, a field-trapping experiment was carried out from 30 July to 24 August 2008 at the Maixiu Forest Park, which is the same park from where the *I. nitidus* hindgut samples were collected. Three sets of cross-barrier type traps (Sino-Czech Trading Co. Ltd. Beijing, China; see photo insert in Fig. 3) were set up along the edge of a *P. crassifolia* forest stand on a northern slope next to a creek at Douheyan, with >30 m between trap sets and ca. 10 m between traps within each set, and >10 m from the nearest trees. Within each set, eight traps were baited with different blends (full or partial blends; racemic or enantiomerically pure) of the key male-produced volatile compounds in their natural production ratios; a ninth trap was left unbaited as a negative control (Table 1). Release rates of the potential semiochemicals varied from <0.3 to 30 mg/day (Table 1). The positions of traps together with dispensers within each set were assigned randomly, and to minimize any positional effects, the dispensers' positions were re-

Table 1 Semiochemical treatments and dispensers for field-trapping experiment with the Qinghai spruce bark beetle, *Ips nitidus*, Qinghai Province, China, 30 July–24 August, 2008

Chemical	Treatments and loading (mg/dispenser)[a]								
	A	B	C	D	E	F	G	H	I
2-Methy-3-buten-2-ol[b]	2,000	2,000	2,000	2,000	2,000	2,000	2,000	2,000	0
(−)-*cis*-Verbenol[c]	15	15	15	15	0	0	0	0	0
(−)-Ipsdienol (97%) [c]	30	0	30	0	30	0	30	0	0
(±)-Ipsdienol [c]	0	30	0	30	0	30	0	30	0
(−)-*trans*-Verbenol [c]	7	7	0	0	7	7	0	0	0
1,3-Butanediol (inert solvent)	750	750	750	750	750	750	750	750	750

[a] Loading ratios were based on the natural ratios of these chemicals produced by unpaired males from phase 1 (Table 2)

[b] 2-Methyl-3-buten-2-ol alone was released from a 2-mil polyethylene bag (7×5 cm) with felt. Release rate was 30 mg/day measured at 22°C in a laboratory fumehood

[c] These semiochemicals (individuals: G/H or in combinations: A/B/C/D/E/F) were dissolved in 750 ml of 1,3-butanediol (as an inert solvent) and loaded in a 2-mil polyethylene bag (3×5 cm) with felt. The exact release rates of these chemicals were not determined with normal gravimetric methods due to the hygroscopic nature of the inert solvent. Estimated release rates by solid phase microextraction (SPME) followed by GC analysis indicated a low overall release rate (<0.3 mg/day) for individual components or mixtures of ipsdienol, and *cis*- and *trans*-verbenol

randomized after each replicate (Byers 1991) when >10 beetles were caught in the traps with the most attractive bait.

Statistical Analyses Trap catch data were converted to proportion (P) of total captured beetles within each replicate. Data then were transformed by arcsin$\sqrt{P}$ to meet the assumptions of normality and homogeneity of variances for ANOVA. Means were compared by ANOVA followed by the Ryan–Einot–Gabriel–Welsh (REGW) multiple Q test (SPSS 16.0 for Windows) at α=0.05 (Day and Quinn 1989). Due to the zero responses to the unbaited control and the two binary blends, these three treatments were not included in the ANOVA and range tests. Trap catch data (untransformed) were also analyzed with the nonparametric Kruskal–Wallis ANOVA on ranks followed by the Student–Newman–Keuls test to separate means of the treatments with and without zero catches (Zar 1984).

Results

Chemical Analysis Eleven volatile compounds from the extracts of male hindguts were identified by GC–MS and quantified by GC–FID. These compounds included 2-methyl-3-buten-2-ol, ipsdienol, and *cis*-verbenol (at 7:2:1) as major components, and *trans*-verbenol, ipsenol, and verbenone as minor or trace components (Fig. 1, Table 2). Myrtenol and 2-phenylethanol, found in several *Ips* beetles (Zhang et al. 2000), but not confirmed as pheromone components, also were detected as minor components (Fig. 1, Table 2). 3-Hydroxy-2-butanone, 1-heptanol, and isobutyric acid were present in all samples.

GC–FID analysis with an enantioselective stationary phase of the hindgut extracts of the *I. nitidus* males from phases 1 to 2 and a synthetic mixture of *Ips* pheromone compounds showed that *I. nitidus* males produced 74±3%-(−)-ipsdienol (mean±SE; N=4; Fig. 2). The predominant enantiomers of other chiral compounds were tentatively determined as (−)-*cis*- and (−)-*trans*-verbenol, (−)-verbenone, and likely (−)-ipsenol (Fig. 2).

Mean amounts (N=2) of the three major components (2-methyl-3-buten-2-ol, ipsdienol, and *cis*-verbenol) from phase 1 were 2,800, 760, and 330 ng/male (ca. 7:2:1 ratio), respectively, which are 2–100 times higher than the three minor components (*trans*-verbenol, ipsenol, and verbenone; Fig. 1, Table 2). Although no statistical analysis was performed because of the limited data set, the quantities of 2-methyl-3-buten-2-ol and especially ipsdienol decreased after mating (i.e., during phases 2–4), whereas the quantities of *cis*- and *trans*-verbenol, myrtenol, and 2-phenylethanol showed no obvious changes (Fig. 1, Table 2).

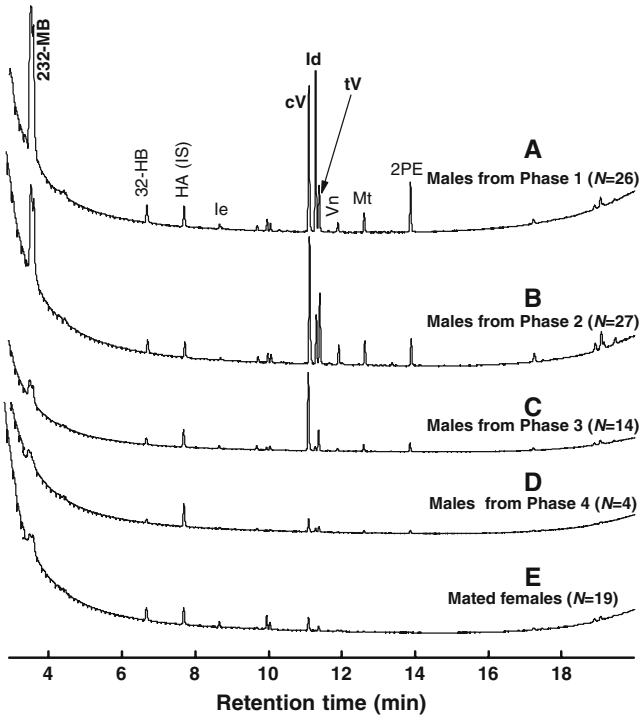

Fig. 1 Representative gas chromatograms (polar column with FID detection) of compounds in hindgut extracts of male *Ips nitidus* from different attack phases (*A–D*) and mated females from mixed phases (*E*). Heptyl acetate (HA; 2 µg/sample) was added as an internal standard to the hindgut extracts. Analytes included 2-methyl-3-buten-2-ol (*232-MB*), *cis*-verbenol (*cV*), ipsdienol (*Id*), ipsenol (*Ie*), *trans*-verbenol (*tV*), (−)-verbenone (*Vn*), 3-hydroxy-2-butanone (*32-HB*), myrtenol (*Mt*), and 2-phenylethanol (*2PE*)

Interestingly, the quantity of ipsenol seemed to increase as the mating activity progressed (Table 2).

In the hindgut extracts of mated females (taken from mixed phases), only trace amounts of male *Ips*-related semiochemicals were detected by GC–MS or GC–FID (Fig. 1 E). These traces may have been due to contamination in the gallery from semiochemical-producing males. In female extracts, we detected quantities of 3-hydroxy-2-butanone, 1-heptanol, and isobutyric acid that were similar to those in male extracts (Table 2).

Field-Trapping Experiment Due to extremely low populations of *I. nitidus* sister broods and heavy winds and rains during the period of our field study (late July to mid August), only six replicates were obtained from two sets of traps (sets 2–3). Traps and dispensers in set 1 were damaged by a flood or partially missing, thus giving no valid data. The unbaited control traps and traps baited with the binary blends (Table 1, treatments G and H): 2-methyl-3-buten-2-ol plus (±)-ipsdienol or (−)-ipsdienol, did not catch any beetles (Fig. 3). Ternary blends with 97%-(−)-ipsdienol caught only a few beetles and seemed to be less attractive than ternary or quaternary blends with (±)-

ipsdienol (Fig. 3). The four-compoment "full blend" containing 2-methyl-3-buten-2-ol, (±)-ipsdienol, (−)-*cis*-verbenol, and (−)-*trans*-verbenol, caught the most beetles. This response was significantly higher than that to the quaternary blend that contained 97%-(−)-ipsdienol (Table 1, treatment A, Fig. 3). Subtraction of (−)-*trans*-verbenol from the most active "full blend" [containing (±)-ipsdienol] slightly reduced trap catches, but this response was not significantly different from that to the quaternary blend (Fig. 3). The sex ratio of captured beetles was estimated as 1:2.2 (♂/♀), based on the pooled sub-samples.

Discussion

This is the first chemical and behavioral analysis of the aggregation pheromone system of the Qinghai spruce bark beetle, *I. nitidus*. GC–MS and GC–FID results demonstrate that males from attack phase 1 (nuptial chamber constructed, unpaired) produced 2-methyl-3-buten-2-ol, ipsdienol, and *cis*-verbenol as major hindgut components, and *trans*-verbenol, ipsenol, and verbenone as minor or trace components (Fig. 1 A, Table 2). Other compounds frequently found in many *Ips*, but not confirmed as pheromone components,

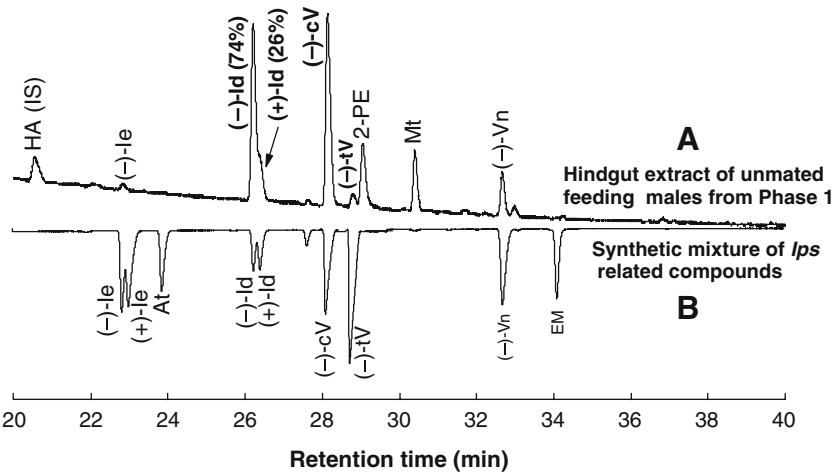

Fig. 2 Enantioselective GC–FID analyses (Rt-bDEXm™ column) of *A* compounds in a hindgut extract of unpaired male *Ips nitidus* from attack phase 1 and *B* a synthetic mixture of *Ips*-related compounds, including (±)-ipsenol (*Ie*), (±)-ipsdienol (*Id*), amitinol (*At*), (−)-*cis*-verbenol (*cV*), (−)-*trans*-verbenol (*tV*), (−)-verbenone (*Vn*), and (*E*)-myrcenol (*EM*; ca. 50 ng/each compound). Amitinol and *E*-myrcenol are achiral. Heptyl acetate (HA; 2 μg/sample) was added as an internal standard to the hindgut extract

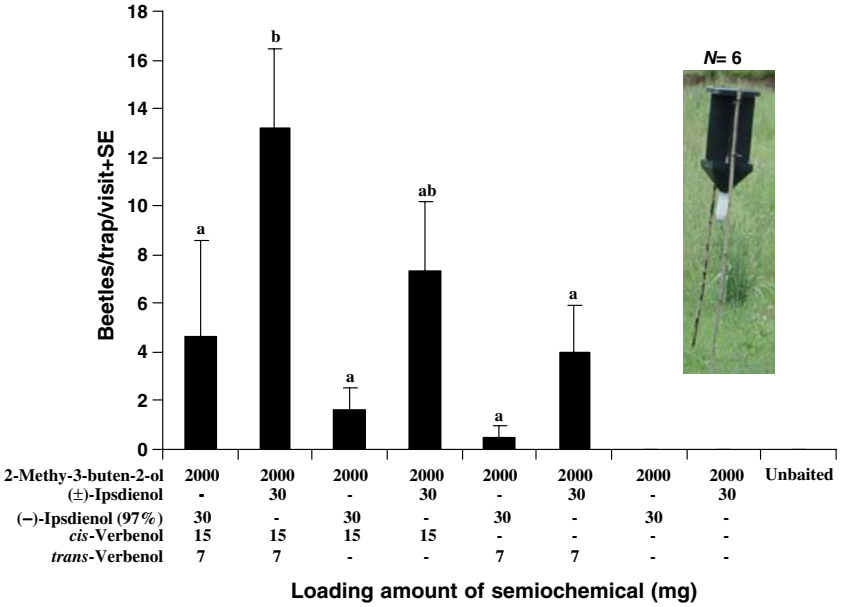

Fig. 3 Mean captures (N=6) of *Ips nitidus* in cross-barrier traps (*photo insert*) baited with different combinations (Table 1) of the key male-produced volatile compounds in their natural production ratios, July 30 to August 24, 2008, Douheyan, Maixiu Forest Park, Qinghai, China. An unbaited trap served as the negative control. *Bars with the same letter* are not significantly different (P>0.05) by REGW multiple Q test after ANOVA on the arcsin$\sqrt{P}$ transformed data of the relative catches, i.e., proportion (P) of total captured beetles within each replicate. Due to the zero responses to the unbaited trap and the two binary blends, these three treatments were not included in the ANOVA and range tests, but were further compared by using the nonparametric Kruskal–Wallis ANOVA on ranks followed by Student–Newman–Keuls test to separate means of the treatments with and without zero catches

such as myrtenol and 2-phenylethanol, also were detected as minor components (Birgersson et al. 1984; Zhang et al. 2000, 2007; Fig. 1, Table 2). 3-Hydroxy-2-butanone, 1-heptanol, and isobutyric acid, commonly related to insect fat tissues (Zhang et al. 2006), were present in all samples, and presumably are not part of the male-produced aggregation pheromone system. Chemical analysis of the hindgut extracts of mated females showed trace quantities of these semiochemicals (Fig. 1 E, Table 2), in agreement with the preponderance of studies that indicate that female *Ips* do not produce behaviorally relevant amounts of aggregation pheromones during attacks (Wood 1982; Byers 1989b).

GC–FID analyses indicated a large variation in the quantities of male-produced volatiles during different attack phases. The maximum production of the major components occurred in phases 1–2, when the nuptial chamber was finished, or only one female was accepted (Fig. 1 A, B). Mating reduced production of the male-specific major hindgut volatiles, especially for 2-methyl-3-buten-2-ol and ipsdienol, whereas the quantities of ipsenol appeared to increase as colonization progressed (Table 2). This might indicate a potential repellent effect of ipsenol during the development of attacks, as reported for *I. typographus* (Schlyter et al. 1992). After mating with three females (harem size=3; phase 4), only trace to tiny amounts of male-specific compounds were detected in *I. nitidus* male hindgut extracts, suggesting that males in this phase may not be capable of attracting females or other males (Fig. 1 D).

Enantioselective GC analysis indicated that *I. nitidus* males produced approx. 74%-(−)-ipsdienol (Fig. 2). This enantiomeric composition is different from those reported for other Eurasian *Ips* spp. (Kohnle et al. 1988, 1991; Zhang et al. 2007), including its sibling species *I. typographus* [95%-(−)] (Kohnle et al. 1991) and the sympatric *I. shangrila* [99%-(+)] and *P. orientalis* [67%-(+)] (Zhang et al., unpublished). However, this enantiomeric ratio is similar to that of eastern populations of North American *Ips pini* (Seybold et al. 1995a). Other chiral compounds were tentatively determined as follows: (−)-*cis*- and (−)-*trans*-verbenol, (−)-verbenone, and likely (−)-ipsenol, based on the retention time comparison with the synthetic standards (Fig. 2), which are similar to the reported absolute configurations for many *Ips* bark beetles (Kohnle et al. 1988).

Our field-trapping data showed that the four-component "full blend" containing the three major components, 2-methyl-3-buten-2-ol, (±)-ipsdienol, and (−)-*cis*-verbenol, plus a minor component, (−)-*trans*-verbenol, caught significant numbers of *I. nitidus* (both females and males; Fig. 3). Replacing (±)-ipsdienol with 97%-(−)-ipsdienol in the "full blend" significantly reduced trap catches, indicating that both enantiomers of ipsdienol might be needed for attraction. This response preference to both enantiomers is

supported by a naturally occurring blend of 74%-(−)-ipsdienol extracted from male hindgut tissue (from phases 1 to 2; Fig. 2). It remains unknown if the natural ratio of ipsdienol enantiomers will prove superior to racemic ipsdienol. Subtraction of (−)-*trans*-verbenol from the active "full blend" (Byers 1992) had no significant effect on trap catches. In fact, this compound also was detected in other Eurasian *Ips* species as a minor component, such as *I. typographus* (Birgersson et al. 1984), and *I. duplicatus* (Byers et al. 1990; Schlyter et al. 1992; Zhang et al. 2007), but was not considered to be part of their aggregation pheromone systems (Schlyter et al. 1987).

I. nitidus and *I. typographus* form a monophyletic group and are sibling species (Cognato and Sun 2007). The proposed aggregation pheromone for *I. nitidus* contains three components: 2-methyl-3-buten-2-ol, ipsdienol, and *cis*-verbenol, whereas the aggregation pheromone system for *I. typographus* contains two components: 2-methyl-3-buten-2-ol and *cis*-verbenol (Kohnle et al. 1988). Ipsdienol is produced as a minor component by mated male *I. typographus* during late attack phases (Birgersson et al. 1984), but has not been considered as part of its aggregation pheromone system (Schlyter et al. 1987; Kohnle et al. 1988). The enantiomeric compositions of ipsdienol isolated from the two species differ [95%-(−) for *I. typographus* (Kohnle et al. 1991) and 74%-(−) for *I. nitidus* (Fig. 2)]. Any differences in the enantiomeric compositions of *cis*-verbenol from these two species have not been reported. Thus, there appears to be some level of disparity in the aggregation pheromone attractants for *I. nitidus* and *I. typographus* that may allow these species to maintain their reproductive isolation within their zone of sympatry (e.g., native spruce forests in Qinghai and Gansu Provinces, China). These differences in the pheromone systems may not be as pronounced as predicted by the saltational evolution hypothesis proposed by Symonds and Elgar (2004), i.e., within certain phylogenetic constraints, pheromone evolution in bark beetles is characterized by large saltational shifts, resulting in substantial phenotypic (i.e., pheromonal composition) differences between sibling species. In fact, this hypothesis is not supported either by experimental data on cross-attraction in the field between two sympatric sibling *Ips* species, *Ips hoppingi* and *Ips confusus*, in the southwestern USA (Cane et al. 1990) or by data on laboratory responses to pheromones by 17 species of *Ips* (Lanier and Wood 1975). *I. nitidus* and two other sympatric bark beetles, *I. shangrila* and *P. orientalis*, share a common or similar spatial and temporal niche(s) in *P. crassifolia* (Liu et al. 2007). This may result in strong interspecific competition and reproductive isolation pressures (Lanier and Wood 1975; Wood 1982). The latest effort and progress on identification of the aggregation pheromone systems of *I. shangrila* and *P. orientalis* indicates that these two newly described species produced different aggregation pheromone blends from each other and from *I. nitidus* (Zhang et al., in preparation). Such a disparity in pheromone systems (discrimination among their pheromone blends) among the sympatric (competitive or cooperative) bark beetle species and their potential semiochemical interactions may play an important role in maintaining their mass attack sequences (e.g., partial niche separation) and reproductive isolation, and regulating spatial and temporal competition (Birch and Wood 1975; Lanier and Wood 1975; Byers and Wood 1980; Cane et al. 1990; Švihra et al. 1980; Paine et al. 1981; Wood 1982; Byers 1989a, b; Schlyter et al. 1992; Zhang et al. 2008).

Our results suggest that the three major components, 2-methyl-3-buten-2-ol, 74%-(−)-ipsdienol, and (−)-*cis*-verbenol (at 7:2:1), produced by unpaired fed males, are likely the aggregation pheromone components of *I. nitidus*. Another semiochemical found in male hindgut tissue, (−)-*trans*-verbenol, may not be part of the aggregation pheromone system, but it merits further field bioassays to determine its potential functionality. This is the first characterization of an aggregation pheromone system of a bark beetle that is native solely to China. More field-trapping experiments on optimal component ratios (including the enantiomeric ratios of ipsdienol), release rates, and dispenser technology are underway. Traps baited with synthetic aggregation pheromone lures will have great potential as a monitoring and mass-trapping tool in integrated pest management directed against this serious forest pest (Schlyter et al. 2001).

Acknowledgments The technical support of Mr. Han Fu-Zhong and his colleagues at the Maixiu Forest Park, Qinghai, China is appreciated. We thank Dr. A. I. Cognato, (Michigan State University) for the help on species ID in the field; Dr. Steven J. Seybold (USDA Forest Service, Davis, CA) for the gift of (+)-ipsdienol; Prof. Dr. Wittko Francke for the gift of amitinol; and Dr. J. A. Byers (USDA-ARS) for reviewing an earlier version of this manuscript. This study was supported by a special grant from Foreign Expert Bureau of Qinghai Province.

Variability in Pheromone Communication Among Different Haplotype Populations of *Busseola fusca*

Received: 14 September 2007 / Revised: 6 March 2009 / Accepted: 26 April 2009 / Published online: 12 May 2009

Abstract The relationship between pheromone composition and mitochondrial haplotype clades was investigated by coupling DNA analyses with pheromone identification and male mate searching behavior among different geographic populations of *Busseola fusca*. The within-population variations in pheromone blend were as great as those observed between geographic populations, suggesting that the female sex pheromone blend was not the basis of reproductive isolation between the geographic clades. Furthermore, while data from wind tunnel experiments demonstrated that most of the tested males were sensitive to small variations in pheromone mixture, there was considerable within-population variability in the observed response. The study identified a new pheromone component, (*Z*)-11-hexadecen-1-yl acetate, which when added to the currently used three-component synthetic blend resulted in significantly higher traps catches. The new recommended blend for monitoring flight phenology and for timing control measures for optimal efficacy of *B. fusca* is (*Z*)-11-tetradecen-1-yl acetate (62%), (*E*)-11-tetradecen-1-yl acetate (15%), (*Z*)-9-tetradecen-1-yl acetate (13%), and (*Z*)-11-hexadecen-1-yl acetate (10%).

Introduction

The maize stemborer, *Busseola fusca* (Fuller, 1901) is a major pest of *Sorghum bicolor* Moench and *Zea mays* L. in sub-Saharan Africa (Kfir et al. 2002) and now is found rarely on wild host plants (Le Rü et al. 2006; Ong'amo et al. 2006). Due to the internal feeding habit of larvae, insecticide treatments are ineffective unless applied before the young larvae penetrate into the stem (Ndemah and Schulthess 2002). However, sex-pheromone-baited traps could be used to monitor adult flight phenology of *B. fusca* and to determine the timing of pesticide sprays for optimal efficacy. Furthermore, pheromone-based management strategies such as mating disruption or attract- and- kill technology could be developed for use. The sex pheromone of *B. fusca* females was identified by Nesbitt et al. (1980) as a mixture of (*Z*)-11-tetradecen-1-yl acetate (Z11-14:Ac), (*E*)-11-tetradecen-1-yl acetate (E11-14:Ac), and (*Z*)-9-tetradecen-1-yl acetate (Z9-14:Ac), at a ratio of 10:2:2. However, in Kenya and other African countries, this attractant was abandoned as a pest management tool because of poor efficacy.

Recently, Sezonlin et al. (2006) identified three clades of mitochondrial haplotypes of *B. fusca:* W collected from West Africa (Mali, Benin, Ghana, and Togo), and two distinct clades from East Africa: clade I minor and clade II major. Most of the moths collected in Kenya belonged to

clade II. The divergence of these clades occurred around one and a half million years ago (Sezonlin et al. 2006). In this study, we examined the pheromone composition and male response windows both within and between mitochondrial clades, as these parameters are elements of the Specific Mate Recognition Systems (SMRS) sensu Paterson (1985), which may act as strong forces in reproductive isolation in other Lepidoptera species (Frérot and Foster 1991; Pelozuelo et al. 2004).

Methods and Materials

Insects Male and female *B. fusca* were obtained either from the mass rearing unit of ICIPE in Nairobi (Kenya) or from field collected larvae in various localities of Kenya (East Africa) and several countries of West Africa (Table 1). Larvae were fed on artificial diet and, upon pupation, were sent to INRA in Versailles (France), where they were sexed and held in individual containers on moist vermiculite. Adults were collected daily, and males were housed in groups of ten in rectangular crystal polystyrene boxes, while females were placed in individual containers for testing at 2–3 days old. All materials were held at 25°C, 85± 10% rh, under a 12:12 h light/dark reversed photoperiod, and the experiments were carried out during the mating period, which starts in the fifth hour of the scotophase under these conditions (Calatayud et al. 2007).

Chemical Analyses The pheromone glands of calling virgin females were extruded with a thin forceps, and the gland tegument area was gently rubbed for 5 min with the adsorbent part of a 65 µm of Carbowax™-Divinylbenzene (CW/DBV) (SUPELCO) solid-phase microextraction (SPME) fiber (Frérot et al. 1997). The SPME collection of each female was analyzed by gas chromatography (GC) using a Varian 3400 CX with a split-spitless injector heated at 240°C and a FID detector at 260°C. The fiber was subjected to thermal desorption in the injector. A 30 m× 0.32 mm i.d. Rtx®-Wax column (Restek®, France) was used with the oven temperature being ramped from 60°C to 100°C at 15°C/min, then to 245°C at 5°C/min. Helium was the carrier gas (15 psi). GC-MS analyses were carried out on a Varian ion trap Saturn II coupled to a 3400 CX GC. The MS conditions were as following: electron impact (IE) mode, 70 eV, 40 to 330 amu. The GC injector split-splitless was held at 250°C, and the RTX-5 Sil-MS (Restek®, France), 30 m×0.32 mm i.d. column temperature ramped from 50°C to 300°C at 8°C/min. Pheromone compounds were identified by comparing retention times and mass spectra of SPME samples collected from the gland with synthetic reference compounds. We examined, either by GC or GC-MS, 24 females from the ICIPE rearing unit, 21 wild females from various localities in Kenya, and 28 from several West African countries.

Table 1 The quantity (µg) of different synthetic compounds in different *Busseola fusca* pheromone lures (A, B, C, D, E, F) used in wind tunnel experiments

	Female	A	B	C	D	E	F
Z11-14:Ac	80	80	80	80	80	80	75
E11-14:Ac	22	20	20	20	10	10	20
Z9-14:Ac	12	10	5	5	10	20	5
Z11-16:Ac	12	10	10	5	10	10	10

The natural pheromone blend was determined using GC-MS

Wind Tunnel Bioassays The experiments were carried out in a half-cylinder (190 cm long × 80 cm wide × 45 cm high) wind tunnel with an airflow set at 0.6 m/s at 23±2°C and approximately 45% rh. A constant red incandescent light source above the tunnel allowed observations and video recording.

Naive males, placed in individual capped wire mesh cages (3 cm diam × 6 cm), were released from a 12-cm-high platform, 150 cm downwind of the source. Each assay lasted 5 min or ended earlier if the male contacted the pheromone source. Flight behaviors were recorded on video (Panasonic AG-7330) with a Hitachi KP 161 CCD black and white camera equipped with a Nikon objective AF Micro Nikkor 60 mm 1:2.8 D. Tapes were transcribed onto computerized video files and analyzed with The Observer 5.0 software (Noldus, Wageningen, The Netherlands, 2004). The attractiveness of the sources was assessed by using the following parameters (1) latency time, which is the time elapsed from the moment a male was placed on the platform to take-off (LT); (2) upwind flight in the first half (FH); (3) flight to the half-way point (HW); or (4) flight in the second half (SH) of the wind tunnel; and (5) an approach (few millimeters; SA) or either contact or attempt to copulate with the source (C). Males that did not respond were excluded only if their antennae and wings were in bad condition; otherwise, they were classified as not responding.

Stimuli The pheromone glands of two virgin calling females immobilized by a pressure on wing muscles were kept extruded by using crocodile clips, and the insects were placed on a 15-cm-high metal support in the wind tunnel. For any given pair of females, the responsiveness of five males was tested. Synthetic lures for the wind tunnel (Table 1) were prepared with synthetic chemicals applied onto rubber septa (Sigma-Aldrich). All chemicals used were 100% pure for Z9-14:Ac and Z11-16:Ac and about 97% for Z11- and E11-14:Ac.

Field Trapping Field trapping was carried out at Maimahiu (Rift Valley, Kenya). The lures (Table 2), at final concentrations of 1-000 µg loaded onto rubber septa (Sigma-Aldrich), were placed inside multicolored Unitrap traps (Biosystèmes France, SARL; green cover, yellow top, and white bottom) at the edge of maize fields, approximately 1.5 m above the ground and at least 30 m apart. Traps were checked every 2 days, and the lures were renewed every 2 weeks. Each treatment was replicated three times, and traps were checked for five consecutive weeks (N=15) from May 1 to June 20 in 2004.

Genetic Analyses All females used for pheromone identification and males used for wind tunnel bioassays were preserved subsequently in absolute alcohol immediately after the experiment, and total genomic DNA was extracted from their thoraxes and legs by using a DNeasy Tissue Kit (QIAGEN®). A 965-bp fragment of the mitochondrial gene encoding cytochrome *b* was amplified with primers CP1 (5′GAT GAT GAA ATT TTG GAT C 3′) and Tser (5′TAT TTC TTT ATT ATG TTT TCA AAA C 3′). Polymerase chain reactions were performed using a Biometra® thermocycler: initial denaturation for 5 min at 94°C; 40 cycles of 94°C for 1 min, 46°C for 1 min 30 s, and 72°C for 1 min 30 s; and 5 min final extension at 72°C. The reaction mixture contained 5 µl of 5× buffer, 3 µl $MgCl_2$ (25 mM), 1 µl primers (10 mM), 0.6 µl dNTPs (10 mM), 1 µl PCR DNA, and 1 U of Promega *Taq* polymerase per 25 µl of reaction mixture.

For females and males, East and West mitochondrial clades were distinguished by PCR-RFLP using *Bsu*36I restriction digests of the amplified DNA fragment (restriction site: CC-TTAGG), while separation of clades I and II clades was based on *Xho*II restriction digests of the amplified DNA fragment (restriction site: A-GATCC). Reaction mixtures were incubated for 6 h at 37°C, and restriction fragments were separated by agarose gel electrophoresis.

Statistics Data on pheromone identification were analyzed using GLM, while those relating to male behavior data were compared with Student's t test on R 2.4.0 software (Chambers et al. 2006). The mean numbers of moths caught in each field treatment were compared by using Kruskal–Wallis test. For field trapping, the ranks were generated with proc Rank of SAS 9.1 (SAS Institute 2003), analyzed with proc General Linear Model, and then separated by using Tukey–Kramer comparison procedure. For all tests, the significance level was set at $P \leq 0.05$. To determine whether the different populations could be separated on the basis of the pheromone chemical profile, we compared the relative composition of the three minor pheromone components, E11-14:Ac, Z9-14:Ac, and Z11-16:Ac by using principal component analysis (PCA; Georgin 2002).

Results

Chemical Analyses Four different compounds were found in the ICIPE colony females (N=24) (Fig. 1): three tetradecene acetates (1, 2, 3) (m/z=43 (100%), 55 (45%), 67 (97%), 81 (98%), 194 (M^+-60, 24%)) and one hexadecene acetate (4) (m/z=43 (94%), 55 (60%), 67 (100%), 81 (94%), 222 (M^+-60, 17%)). These were identified as (*Z*)-9-tetradecen-1-yl acetate (Z9-14:Ac, 15% (±6.09)), (*E*)-11-tetradecen-1-yl acetate (E11-14:Ac, 27% (±3.70)), (*Z*)-11-tetradecen-1-yl acetate (Z11-14:Ac, 100%), and (*Z*)-11-hexadecen-1-yl acetate (Z11-16:Ac, 14% (±9.58)), by comparing their retention times and mass spectra with those of synthetic compounds.

GC and GC-MS analyses of females revealed that all populations, irrespective of origin, shared the same four components. The component ratios were not significantly different among populations (P<0.05), which was not surprising given the high intra-population variability (Table 3).

PCA results showed that two minor components, Z9-14:Ac and E11-14:Ac, explain 63.4% and 21.9% of the pheromone variability, respectively, while the third component, Z11-16:Ac, explained only 14.6% (data not

represented). The PCA analyses did not clearly separate either geographical or mitochondrial populations (Fig. 2).

Wind Tunnel Bioassays The flight behavior of *B. fusca* males to conspecific females (N=20) was similar to that described for most Lepidoptera (Baker 1990; Baker and Haynes 1996). After a highly variable period of latency (mean LT = 51 s; range 10 to 116 s), 85% of the males took flight and exhibited locking-on behavior, with 80% subsequently flying upwind in a low-amplitude zigzag pattern (mean flight time = 69 s; range 10 to 186 s) and touching the female and/or attempting to copulate.

The synthetic lure A, with the same composition as the naturally observed pheromone, was not as attractive as the exposed glands of virgin females, and even minor modifications in the ratio of the minor components reduced upwind flight and/or contact with the source (Fig. 3). The removal of any of the minor components from the identified pheromone mixture abolished the upwind flight response,

Ratios are calculated considering the major component, Z11-14 Ac, being 100%

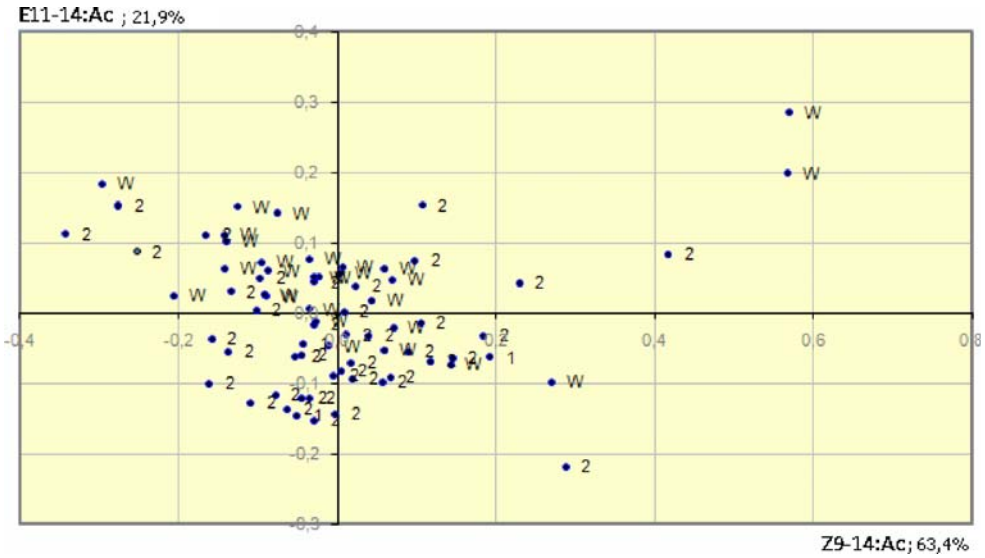

Fig. 2 PCA with two of the four components of *B. fusca* female pheromone: E11-14:Ac and Z9-14:Ac. The three mitochondrial clades are represented as *1*, *2*, and *W* for East I, East II, and West clades, respectively

and low variations in ratio of Z9-14:Ac and E11-14:Ac affected the male responses.

Field Trapping At a loading of 1,000 µg, the addition of Z11-16:Ac (10%) to the previously described three-component blend resulted in significantly higher numbers of males being caught (H=47.9 P<0.001; Table 2). The exclusion in the blend of either Z9-14:Ac or the E11-14:Ac significantly lowers the number of male captures (Table 2).

Genetic Analyses The molecular analyses of 72 *B. fusca* females used for the pheromone identification confirmed the existence of the three, previously described mitochondrial clades (Sezonlin et al. 2006). All females collected in West Africa (N=28) belonged to clade W, while three and 41 East African females fell into clades I and II, respectively. Females from all clades shared the same pheromone components, and the inter-population differences in ratios were not significantly different from intra-population ones (Table 3).

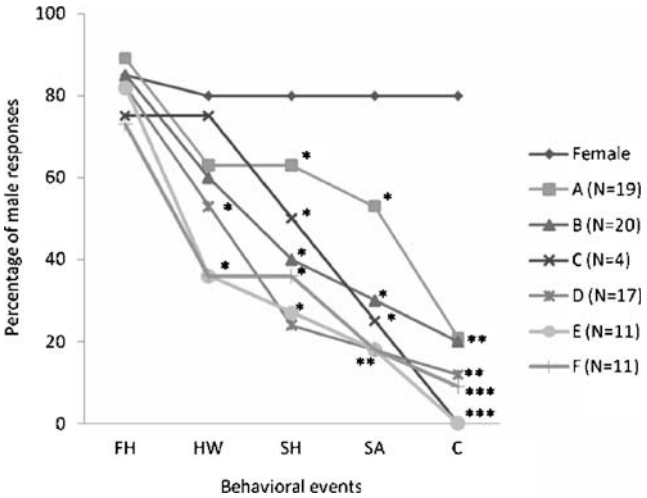

Fig. 3 The response of *B. fusca* males in wind tunnel experiments to the conspecific female sex pheromone and synthetic pheromone mixtures *A*, *B*, *C*, *D*, *E*, and *F*: upwind flight in the first half of the wind tunnel (*FH*); flight to the half-way point (*HW*); flight in the second half of the tunnel (*SH*); source approach (*SA*); contact with the pheromone source or copulation attempts (*C*). Data followed by *asterisk* are significantly different from each other according to Student's *t* test (P<0.05)

Discussion

The addition of the newly identified sex pheromone component, Z11-16:Ac, to the three component blend (Nesbitt et al. 1980) significantly increased *B. fusca* male responses in the wind tunnel. However, despite this improvement, the four-component lure was still less attractive in wind tunnel than the natural female pheromone, even though no other potentially important trace compounds were detected by GC-MS, using single ion monitoring mode. This suggests that the observed behavioral differences can probably be related to wind tunnel conditions that differ from field conditions in Africa and/or to release rate or concentration differences between the septa and female glands. However, the four-component blend of (*Z*)-11-tetradecen-1-yl acetate (62%), (*E*)-11-tetradecen-1-yl acetate (15%), (*Z*)-9-tetradecen-1-yl acetate (13%), and (*Z*)-11-hexadecen-1-yl acetate (10%) was the most effective in the field and offers an improved lure for monitoring *B. fusca* flight activity in IPM programs.

There were no significant interclade pheromone differences, even for clades I and II, which occur in sympatry. Furthermore, while the wind tunnel results showed that even if most of *B. fusca* males were sensitive to small variations of component ratios, the range of male response

windows was high within any given population. Such a plasticity of the male response may explain why the polymorphism of pheromone mixtures does not appear to play a role in reproductive success.

According to Sezonlin et al. 2006, East (clade I and II) and West (W clade) African *B. fusca* populations have been geographically separated for about 1.5 million years. However, we could not relate any particular pheromone blend to a particular mitochondrial clade, suggesting that the female sex pheromone composition did not influence the divergence seen in DNA studies. The sex pheromone mixture and the male responses did not play a role in either reproductive isolation between the sympatric clades, nor for divergence of the SMRS between the now allopatric East and West populations.

Acknowledgments We are grateful to Peter Mwatha Njoroge and Joseph Njoroge Mwatha for helping us run the field trapping at Maimahiu (Rift Valley, Kenya). Thanks are also given to Peter O. Ahuya for help and to Anthony Wanjoya and Hervé Guénégo for technical assistance. The authors are grateful to Jeremy Mc Neil and Fritz Schulthess for all valuable comments and revision of English.

Visualizing a Plant Defense and Insect Counterploy: Alkaloid Distribution in *Lobelia* Leaves Trenched by a Plusiine Caterpillar

Craig B. Oppel · David E. Dussourd · Umadevi Garimella

Received: 23 December 2008 / Revised: 5 May 2009 / Accepted: 8 May 2009 / Published online: 26 May 2009

Abstract Insects that feed on plants protected by latex canals often sever leaf veins or cut trenches across leaves before feeding distal to the cuts. The insects thereby depressurize the canals and reduce latex exudation at their prospective feeding site. How the cuts affect the distribution and concentration of latex chemicals was not known. We modified a microwave-assisted extraction technique to analyze the spatial distribution of alkaloids in leaves of *Lobelia cardinalis* (Campanulaceae) that have been trenched by a plusiine caterpillar, *Enigmogramma basigera* (Lepidoptera: Noctuidae). We produced sharp two dimensional maps of alkaloid distribution by microwaving leaves to transfer alkaloids to TLC plates that were then sprayed with Dragendorff's reagent to visualize the alkaloids. The leaf prints were photographed and analyzed with image processing software for quantifying alkaloid levels. A comparison of control and trenched leaves documented that trenching reduces alkaloid levels by approximately 50% both distal and proximal to the trench. The trench becomes greatly enriched in alkaloids due to latex draining from surrounding areas. Measurements of exudation from trenched leaves demonstrate that latex pressures are rapidly restored proximal, but not distal to the trench. Thus, the trench serves not only to drain latex with alkaloids from the caterpillar's prospective feeding site, but also to isolate this section, thereby preventing an influx of latex from an extensive area that likely extends beyond the leaf. Microwave-assisted extraction of leaves has potential for diverse applications that include visualizing the impact of pathogens, leaf miners, sap-sucking insects, and other herbivores on the distribution and abundance of alkaloids and other important defensive compounds.

Introduction

When damaged, many plants release defensive exudates such as latices, resins, oils, or mucilages from elongate canal systems. Latex is especially common, occurring in over 20,000 species of plants in 40 families (Lewinsohn 1991), approximately 8% of known plant species. Latex canals are formed of living cells called laticifers that ramify throughout the plant, usually associated with the vascular bundles (Esau 1965; Fahn 1979; Hagel et al. 2008). Latex typically is stored under pressure (Buttery and Boatman 1976); plant injury results in the flow of canal contents down a pressure gradient to the site of damage. Insect herbivores attempting to feed upon latex-defended plants encounter an immediate outflow delivered directly to mouthpart receptors. Latex exudates typically are rich in deterrents and toxins (Farrell et al. 1991; Dussourd 2003; Konno et al. 2004, 2006; Hagel et al. 2008; Sethi et al. 2009); they also congeal rapidly, threatening prospective herbivores with entrapment (Zalucki and Brower 1992; Dussourd 1993, 1995).

Although the double-edged sword of poisons and adhesives delivered by bulk flow is unquestionably an

effective defense against most herbivores, several lineages of insects have evolved behavioral adaptations that circumvent defensive canals (Dussourd 2009 and references cited). The insects often sever leaf veins or cut trenches prior to feeding distal to the cuts (Dillon et al. 1983; Compton 1987; Dussourd and Denno 1991; Dussourd 1999; Evans et al. 2000; Darling 2007). In each case, the vein cuts or trenches reduce exudation beyond the cuts where the insect feeds. Whereas the effects of canal cuts on latex outflow have been well established, little is known about how these injuries alter the distribution and concentration of chemicals in leaves. We used a microwave-assisted extraction technique to visualize and quantify the distribution of alkaloids in leaves of cardinal flower, *Lobelia cardinalis* (Campanulaceae), that have been trenched by a plusiine caterpillar *Enigmogramma basigera* (Lepidoptera: Noctuidae) (Fig. 1). Alkaloids within the latex matrix serve as a tracer that allows us to elucidate how trenching affects the laticifer system and the distribution of latex constituents in the leaf.

Like other plants in the Campanulaceae, *Lobelia* has anastomosing articulated laticifers composed of stacked cells in which the interconnecting walls are partially or completely absent; the resulting tubes are interconnected by cross channels that form a web-like anastomosing structure (Esau 1965; Metcalfe and Chalk 1983). The laticifers in *Lobelia* occur mainly within the phloem tissue, but branches extend into the mesophyll of the leaves (Fraser 1931).

Lobelia cardinalis contains the piperidine alkaloid lobeline at high levels (7.1 mg lobeline/g dry weight, Krochmal et al. 1972) that are comparable to amounts in the closely related medicinal plant *L. inflata* (Indian tobacco). Lobeline acts on nicotinic acetylcholine receptors (Felpin and Lebreton 2004). Overdoses in humans cause stupor, muscle tremors, paralysis, convulsions, coma, and eventually death (Duke 1985). Despite risks of poisoning, *L. inflata* has been used for centuries as a respiratory stimulant and for other medical applications; lobeline currently is being studied as a potential treatment for methamphetamine addiction, dementia and other CNS disorders (Felpin and Lebreton 2004). In addition to lobeline, cardinal flower contains at least three other alkaloids (Chaubal et al. 1962; Krochmal et al. 1972); lobinaline is reportedly the most abundant alkaloid in the plant (Gupta and Spenser 1971).

Fig. 1 Penultimate instar *Enigmogramma basigera* feeding on the tip of a *Lobelia cardinalis* leaf after transecting the leaf with a trench

Cardinal flower in central Arkansas often is heavily damaged by the plusiine caterpillar *Enigmogramma basigera* (Walker), the pink-washed looper (Fig. 1). *Enigmogramma basigera* is classified in the tribe Argyrogrammatini (LaFontaine and Poole 1991) together with other known trenchers such as *Trichoplusia ni* (cabbage looper) and *Pseudoplusia includens* (soybean looper) (Dussourd and Denno 1994). Curiously, late instar *E. basigera* cut trenches while facing the leaf petiole, unlike other trenching plusiines that usually trench facing the leaf tip.

Using *L. cardinalis* and the caterpillar *E. basigera* as a model system, we tested if trenching reduces alkaloid levels at the feeding site distal to the trench. Our approach was to extract alkaloids from *L. cardinalis* leaves by using an adaptation of the protocol developed by Nitao and Zangerl (2004). They used microwaves to extract furanocoumarins from parsnip, *Pastinaca sativa* (Apiaceae), onto phase separation paper to create two dimensional maps of furanocoumarin distribution in entire leaves. Furanocoumarins in parsnip are sequestered primarily within oil ducts found within the leaf veins. Chambers et al. (2007) subsequently published a microwave print of a parsnip leaf trenched by the cabbage looper, *Trichoplusia ni*. The print shows a substantial accumulation of furanocoumarins along the trench, presumably due to drainage of the oil ducts. We significantly modified the microwave technique to extract alkaloids and developed a method for quantifying the distribution of alkaloids in trenched and control (non-trenched) leaves.

Methods and Materials

Study Organisms Lobelia cardinalis L. plants were started from seed (Easyliving wildflower, Willow Springs, MO, USA) and grown in environmental chambers (Model E15, Conviron, Ottawa, Canada) under high pressure sodium and metal halide lamps. Plants were provided with a 12 h day length and a maximum light intensity of 700 µmol/m^2/sec for 4 h; light intensities on either side of the daily maximum

were ramped up/down to simulate natural conditions. Environmental chamber temperatures ranged from 15ºC at night to a daytime high temperature of 25ºC. Plants were fertilized bi-monthly with a 100 ppm nitrogen solution (Scott, Maryville, OH, USA). All experiments used ~9-month-old plants in the rosette stage.

A lab colony of *E. basigera* was established with larvae collected on *L. cardinalis* and adults attracted to mercury vapor lamps in Conway, Arkansas. For experiments, caterpillars were reared from egg hatch until the mid-penultimate instar on potted *L. cardinalis* at low density, thus ensuring that all caterpillars used in the bioassays were experienced trenchers. Trenched leaves were obtained by caging larvae individually on leaves, allowing them to complete a trench that transected the leaf blade, then removing each larva at the first sign of feeding. In all experiments, caterpillars were used only once.

Microwave-assisted Extraction Protocol Twenty *L. cardinalis* plants were randomly assigned to the control or trenched treatment. To maximize efficiency of microwave extraction, only large, flat leaves (> 7.5 cm length, >1.8 cm wide) were selected. For the trenched treatment, caterpillars were allowed to complete a trench (one trench/plant), then the leaf was removed immediately. Ten control and ten trenched leaves were harvested by cutting and cauterizing the petiole with a red-hot scalpel; as documented in a subsequent experiment, this step minimized latex loss from ruptured laticifers.

Alkaloid visualization and analysis involved four steps: 1) partially drying the leaf, 2) microwave-assisted transfer of alkaloids from leaf to TLC plate, 3) developing color by spraying the TLC plates with Dragendorff's reagent, and 4) digital imaging and processing. The excised leaf was first dried at 50ºC for 45 min to reduce water content and thus facilitate alkaloid extraction. The leaf then was sandwiched between two acetate-backed thin layer chromatography (TLC) plates (20×20 cm Whatman silica gel-G cut into 10×10 cm squares, 250 µm thick, no indicator, Fisher Scientific, Pittsburgh, PA, USA). The TLC squares were saturated with toluene, which greatly increased the efficiency of alkaloid extraction from the partially dried leaves. We conducted extensive testing of alternate media for the microwave extraction, including KC-18 reverse phase preparatory TLC plates, alumina oxide preparatory TLC plates, 1PS phase separation paper, SG-81 cation exchange paper, DE-81 anion exchange paper, and P-81 silica impregnated paper (all Whatman media; Fisher Scientific). The different media were tested in combination with solvents (hexane, methylene chloride, chloroform, ethyl acetate, isopropanol, ethanol, methanol, and water). Silica-gel G TLC plates with toluene and cation exchange paper used with acidified solvents both provided high quality leaf prints; we opted for the TLC plates because of their superior resolution.

The *L. cardinalis* leaf pressed between two TLC plates was placed between two 20×20 cm cardboard blotters and two 5 mm thick, 20×20 cm Pyrex glass plates. The leaf assembly was transferred to a 1200 watt microwave oven (Panasonic Model NN-H504BF); a 4.4 kg sand weight in a Pyrex dish was placed on top to compress the assembly and maximize contact between the leaf and TLC plate. The entire assembly was microwave extracted at 30% power for 11 min (the Panasonic magnetron cycles on and off to produce an overall average of 30% power). Long extraction times at lower average power minimized the lateral movement of dissolved alkaloids, which would distort the spatial prints of alkaloid distribution. After microwaving, both the top and bottom TLC plates were sprayed with freshly prepared Dragendorff's reagent (Harborne 1984) yielding a top and bottom print of alkaloid distribution for each leaf extracted (Fig. 2a, b). Leaf prints were allowed to develop for 1 h, then were photographed on a copy stand with a 6 megapixel Minolta Maxxum 7D digital SLR camera equipped with a 70–200 mm zoom lens. To prevent loss of pixel intensity data due to software compression, the images were captured as RAW files, then converted to TIFF format. TIFF images were imported into Adobe Photoshop elements 2.0 where the characteristic yellow background color imparted by Dragendorff's reagent was removed by using a color deconvolution plug-in (Berger et al. 2006). The modified images retained only the orange color that Dragendorff's reagent produces in response to alkaloids (Fig. 2c). This image was converted to eight bit grayscale with black indicating high alkaloid levels, white denoting low levels, and 254 shades of gray representing intermediate levels. The grayscale image was imported into Image J v. 1.37c (National Institute of Health) for quantifying alkaloid levels in the leaf by averaging gray values (Fig. 2d).

To estimate alkaloid content, a standard curve was generated by using eight solutions (10 mg/ml to 0.09 mg/ml) of L-lobeline HCl (Sigma-Aldrich, St. Louis, MO, USA) in methanol. Preliminary testing determined that concentrations in excess of 12 mg/ml resulted in average gray values approaching zero, which effectively set the upper limit of the standard curve. Conversely, lobeline solutions of less than 0.09 mg/ml resulted in average gray values approaching the highest possible value (255), thus setting the lower detection threshold possible by using eight bit digital images. Replicated 30 µl aliquots of the eight solutions were dispensed onto TLC plates identical to the plates used for leaf prints. The plates were sprayed with Dragendorff's reagent, allowed to dry at room temperature for 1 h, then were photographed and processed as previously described with the leaf prints. Image J was used

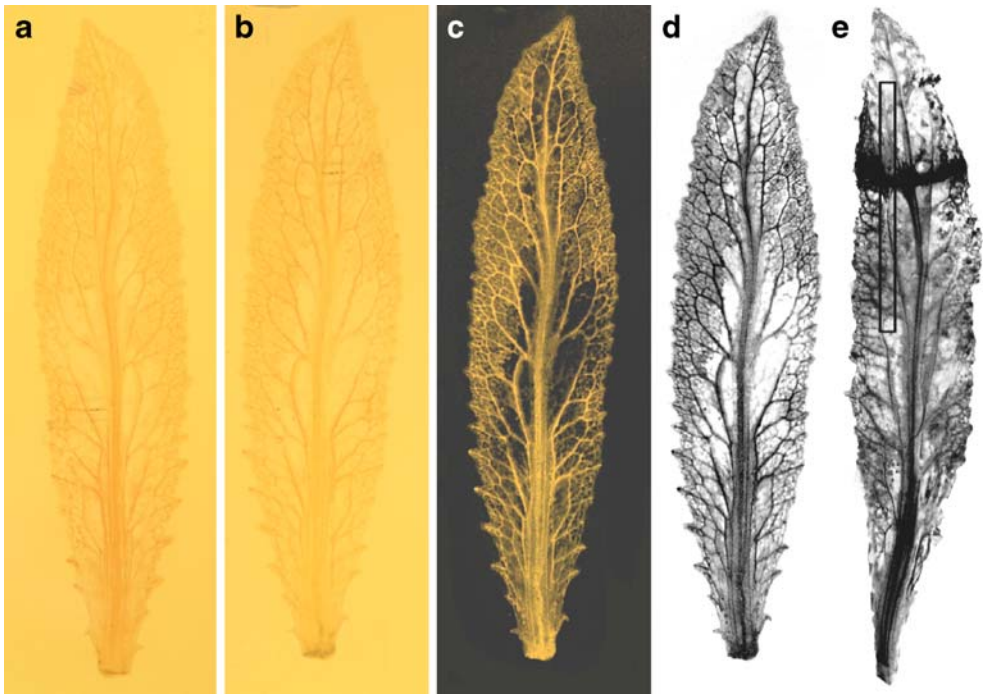

Fig. 2 Alkaloid distribution in *Lobelia cardinalis* leaves as visualized by the microwave extraction procedure. Top (**a**) and bottom (**b**) print of a control leaf. (**c**) The same print as b after removal of the yellow background with color deconvolution. (**d**) Final gray scale image of the same print. (**e**) Gray scale image of a trenched leaf showing alkaloid deposition in the trench. The rectangular sample box is shown to the left of the midrib

to measure the average gray value within a 0.5 cm^2 circle around each 30 µl sample spot. The log_{10} transformed mass of L-lobeline HCl in each spot was regressed against the mean average gray values obtained from image J to produce the regression formula (Log_{10} (Mass of L-Lobeline)=−0.0071(Average gray)+2.5002; R^2=0.96). This formula was used to convert average gray values from leaf prints to alkaloid levels. The calculated alkaloid level was adjusted for area. For example, for a given average gray level, a 0.1 cm^2 sample box was assumed to contain 1/5 of the alkaloid found in the 0.5 cm^2 circle used with the standards.

The quantification of alkaloids in leaf prints is possible because the orange color produced by the Dragendorff reaction increases in intensity as alkaloid titers increase and digital images encode intensity information in numeric form. We spatially calibrated microwave leaf prints by using a metric ruler photographed with each digital image and the scale function of image J. A rectangular sample box measuring 0.25 by 5.0 cm was positioned parallel to the leaf midrib. On trenched leaves, the sample box was situated such that 2 cm of the sample box lay on the distal side of the trench toward the leaf tip, and 3 cm extended proximal to the trench toward the leaf petiole (Fig. 2e). The distance from leaf tip to trench averaged 3.1 cm; therefore, control leaves were sampled by aligning the 2 cm mark of the sample box at 3.1 cm from the leaf tip. Average gray values were sampled along the length of the sample box by using the "plot profile" function of image J, which samples and collects average gray values of pixels every 0.01 cm. We smoothed this raw data by averaging gray values every 0.1 cm. Thus, each 5.0 cm sample box resulted in 50 measurements for every leaf print. For each 0.1 cm slice, the average gray value was converted to mass of lobeline per 0.025 cm^2 (the area of the slice) by using the standard curve. The alkaloid content of corresponding slices from top and bottom leaf prints were added to calculate total alkaloids. Finally, average alkaloid concentrations for both trenched and control leaves were plotted against distance along the sample transect (Fig. 3). We used this graph to separate the leaf into three regions determined by the intersection points of the lines for trenched and control leaves. We designated the section from 0–1.1 cm as the distal (leaf tip) region, from 1.2–2.3 cm as the trench region, and the remaining section from 2.4–4.9 cm as the proximal leaf region.

To test if trenching alters the spatial distribution of alkaloids, we used a 2-way *ANOVA* with fixed effects design. The main effects were treatment (trenched or control) and leaf region (distal, trench, and proximal). The alkaloid content of slices in each leaf region was averaged for each plant resulting in a balanced design with 60 alkaloid measurements (three leaf regions, ten plants/treatment, and two treatments).

One-way *ANOVAs* were used to test the effects of leaf region on alkaloid levels independently for trenched and control leaves. Variances were not homogenous, so we used *Tamhane T-2 post-hoc tests* to compare leaf regions in alkaloid levels. Independent sample *t*-tests were used to compare alkaloid levels across treatments (trenched vs. control) for each leaf region. All statistical analysis was conducted using SPSS v. 11.0. Further details on the

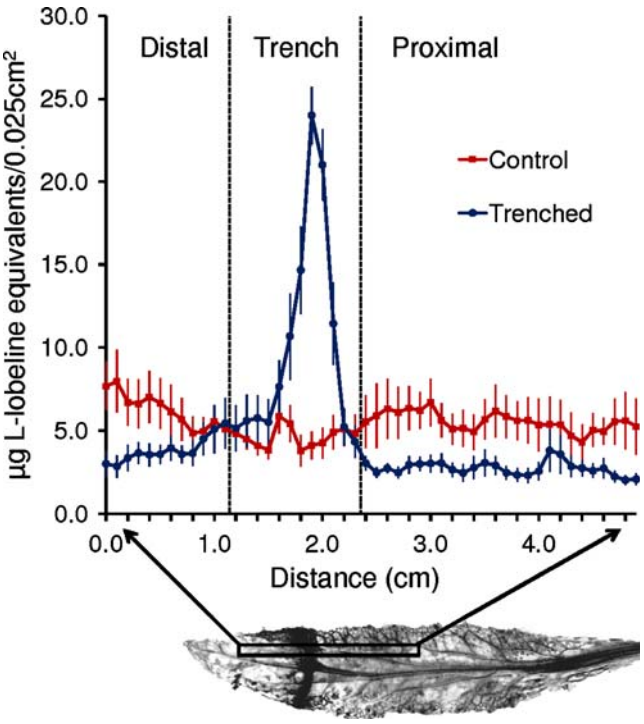

Fig. 3 Distribution of alkaloids in rectangular sample boxes from 10 trenched (blue) and 10 control (red) leaves. The 0.25×5.0 cm sample boxes were divided into fifty 0.25×0.1 cm slices. Each data point represents the average alkaloid content of a slice from ten plants. Alkaloid levels are quantified as lobeline equivalents per 0.025 cm^2 slice; bars represent±one standard error. The trench is clearly denoted by a marked increase in alkaloid levels. Three regions were defined for statistical analysis: a distal region (toward the leaf tip on the left), the trench, and a proximal region (toward the leaf base on the right). These regions were demarcated by the intersections of the control line with the trenched line

microwave extraction protocol and alkaloid quantification can be found in Oppel (2008).

Effect of Petiole Cautery on Latex Loss To determine if cauterization trapped latex within leaf laticifers, we quantified the amount of latex that exuded from *L. cardinalis* petioles. A single mature leaf on 60 plants was randomly assigned to one of three treatments: 1) petiole cut once without cauterization, 2) petiole cauterized, then re-cut without cauterization, or 3) petiole cut twice without cauterization. In the cut once treatment, leaf petioles were severed with a sharp scalpel, and latex exuding from the petiole of the detached leaf was collected on pre-weighed filter paper. Latex on the scalpel blade also was wiped on the filter paper. The petiole of cauterized leaves in treatment 2 was cut and cauterized with a red-hot scalpel to stop latex flow from the severed laticifers. After 2 min, the petiole was cut again ~2 mm above the cauterized cut, this time with a scalpel at room temperature; the exuding latex was collected as described previously. In the cut twice treatment, the leaf petiole was severed with a scalpel at room temperature and allowed to exude latex for 2 min; latex flow ceased well before the 2 min period finished. None of the latex was collected. The petiole then was severed without cautery~2 mm above the initial cut. This time the exuding latex was collected and quantified. If cauterization seals laticifers with no loss of latex, then treatments 1 and 2 should emit similar quantities of latex. If cauterization reduces latex loss, then treatment 2 should release more latex than treatment 3. If cauterization does not seal laticifers due to internal or external bleeding, then treatments 2 and 3 should exude similar quantities of latex. Treatments were compared using a *one-way ANOVA*. Since variances were not homogeneous, *Tanhame's T-2 tests* were used for *post-hoc* comparisons.

Effect of Trenches on Distal Latex Exudation To determine how trenching affects latex exudation beyond the trench where the caterpillars feed, we measured the amount of latex exuding from simulated feeding on trenched leaf tips and paired control leaves. One mature leaf on 10 *L. cardinalis* plants was trenched by a penultimate instar *E. basigera*, whereas another leaf on each plant served as a control. The leaf tip beyond the trench was cut repeatedly in~2 mm slices perpendicular to the leaf midrib, progressing from the leaf tip to the trench. Latex exudate from both sides of each cut was collected onto pre-weighed filter paper; the scissors were wiped on the filter paper between each cut. The same procedure was used with the paired control leaf; slices were removed the same distance from the tip as in the trenched leaf. Leaves were randomly assigned to treatment, and the order of sampling also was randomly determined. The wet weights of latex collected from control and trenched leaves were compared using a paired *t*-test.

Latex Exudation Distal and Proximal to Trench The microwave experiment documented that trenching reduces alkaloid titers on both sides of the trench. Caterpillars feeding on the two sides would presumably ingest comparable amounts of alkaloid unless latex pressures are unequal. To determine if pressures differ, we measured latex exudation from each side. Penultimate instar *E. basigera* larvae were allowed to trench mature *L. cardinalis* leaves (N=10 plants; one caterpillar and one leaf per plant). When the trench was complete, the leaf was cut in~2 mm slices perpendicular to the leaf midrib. After each cut, latex exuding from both sides of the cut was collected and weighed. Sampling progressed either from the leaf tip to the trench (distal) or from the trench toward the leaf petiole (proximal). Whether the distal or proximal regions were sampled first was determined randomly. An identical number of cuts were made on each side of the trench. The

wet weights of latex collected were compared by using a paired sample *t-test*.

Results

Alkaloid Distribution Microwaving leaves provided high resolution two dimensional maps of alkaloid distribution (Fig. 2). Leaf edges were sharp in the prints, indicating that alkaloids did not bleed sideways distorting the prints. The highest concentrations occurred in the leaf veins where laticifers are concentrated in *Lobelia* (Fraser 1931). Alkaloid levels measured for entire top and bottom prints did not differ (t=0.478, df=19, P=0.638), indicating that extraction occurred equally from both leaf surfaces.

The total alkaloid content of trenched leaves (41.8±7.4 μg/cm^2) and control leaves (46.2±6.2, mean±1se) did not differ significantly (t=0.454, df=18, P=0.655). However, trenching profoundly altered the distribution of alkaloids in the sample rectangles. In trenched leaves, alkaloids drained from both distal and proximal leaf regions into the trench. This movement resulted in a significant interaction between treatment (control or trenched) and leaf region (distal, trench, and proximal) in the two-way ANOVA (Fig. 4). Alkaloid content did not differ between leaf regions in the control leaves (one-way ANOVA, $F_{2,\ 27}$=0.599, P=0.557), but did differ in trenched leaves (one-way ANOVA $F_{2,\ 27}$=176.167, P<0.001). In trenched leaves, the distal and proximal leaf regions did not differ in total alkaloids (*Tamhane T-2*, P=0.476); however, each of these regions was lower in alkaloids than the trenched section (*Tamhane T-2*, distal P=0.05, proximal P=0.002)(Fig. 4). In our sample rectangle, alkaloid movement in trenched leaves caused an average loss of 24.02 μg L-lobeline HCl equivalents from the distal region (38% loss), an increase of 53.87 μg L-lobeline HCl equivalents in the trenched region (114% gain), and a decrease of 28.30 μg L-lobeline equivalents in the proximal leaf region (51% loss). The total loss from the proximal and distal regions (52.32 μg) approximately equaled the increase in the trenched region (53.87 μg).

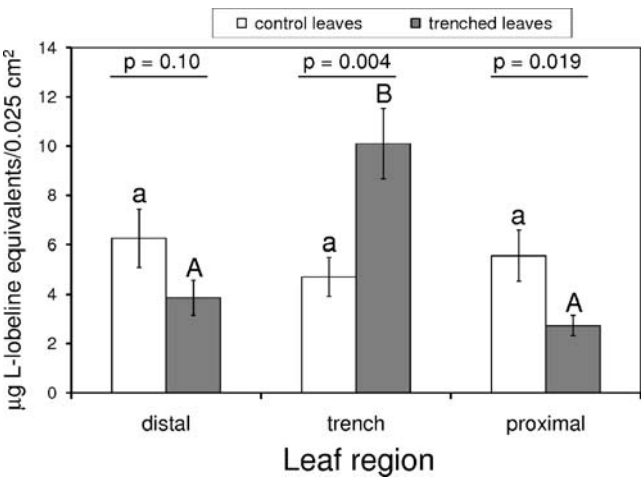

Fig. 4 Alkaloid levels in rectangular sample boxes from 10 trenched and 10 control *Lobelia cardinalis* leaves. Each box was separated into three leaf regions: distal to the trench, trenched section, and proximal to the trench. Alkaloid levels for each region were quantified as average lobeline equivalents per 0.25×0.1 cm slice. Each bar represents the mean±1SE for ten plants. Significant differences between the three leaf regions are denoted by different letters above the bars (lowercase letters for control leaves, uppercase letters for trenched leaves) (one-way ANOVAs; *post-hoc* Tamhane T-2). Significant differences between control and trenched leaves for each leaf region are indicated above the line connecting the contrasting pair (independent sample *t*-tests)

Comparisons between trenched and control leaves revealed that the trenched region was significantly higher in alkaloids than the comparable area in control leaves (t=3.281, df=18, P=0.004), whereas trenching reduced alkaloid levels in the proximal leaf region (t=2.568, df=18, P=0.019) (Fig. 4). The trench drained ~51% of the total alkaloids from the proximal section, suggesting that at least half of the alkaloids in leaves are contained within the latex. Surprisingly, trenched and control leaves did not differ significantly in the alkaloid content of the distal region (t=1.755, df=18, P=0.100). However, alkaloid levels in trenched and control leaves were similar near the trench, but differed substantially farther from the trench (closer to the leaf tip) (Fig. 3).

Alkaloid content in the proximal leaf section of the trenched leaves changed little along the sample box, implying that the area of the leaf drained by the trench extends well beyond our sample box (Fig. 3). Extrapolated linear regression lines for control and trenched leaves in the proximal region intersect at~20 cm from the trench, thus suggesting that trenching drains latex from the entire leaf, perhaps even beyond the petiole. In the distal region of trenched leaves, the low alkaloid levels furthest from the trench likewise imply that latex also has drained from more distant regions.

Effect of Petiole Cautery on Latex Loss Cauterizing petioles reduced, but did not eliminate latex loss from excised leaves. The three treatments differed in the amount of latex emitted from severed petioles (Fig. 5, *one-way ANOVA* $F_{2,57}$=20.48, P<0.001). Leaves cut one time exuded significantly more latex than cauterized leaves (*Tahame T-2*, P=0.007) or leaves cut two times without cautery (*Tahame T-2*, P<0.001). Cauterized leaves exuded more latex than leaves cut two times (*Tahame T-2*, P=0.001). The cauterized leaves released~1.7 times more latex than the leaves cut twice, documenting that cauterization maintained latex pressures within the laticifers. However, the cauterized leaves released substantially less

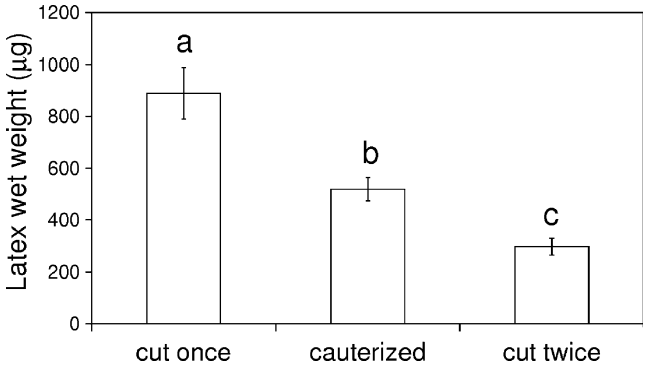

Fig. 5 The amount of latex (mean±1 SE) emitted from *Lobelia* leaf petioles in three treatments: 1) petiole cut once, 2) petiole cauterized, then re-cut, and 3) petiole cut two times (N=20 leaves/treatment). In treatments 2 and 3, latex was collected only from the second cut. Different letters indicate significant differences at the 0.01 level (one-way ANOVA; post-hoc Tamhane T-2)

latex than the control (cut once) leaves, indicating that some latex pressure was lost due to internal or external bleeding (Fig. 5).

Effect of Trenches on Distal Latex Exudation Trenching caused a decrease in the amount of latex that exuded from the leaf tip distal to the trench (paired t=2.757, df=9, P=0.022) (Fig. 6). The trench reduced the wet weight of latex emitted by 92.7%.

Latex Exudation Distal and Proximal to Trench The distal section of the trenched leaf emitted less latex than the proximal region (paired t=3.349, df=9, P=0.009) (Fig. 6). Any caterpillar that tried to feed on the proximal side would encounter ~13 times more latex (wet weight).

Discussion

Our leaf prints document that trenching drains alkaloids from both sides of the trench. As a result, the trench becomes greatly enriched in alkaloids. Although leaves of *L. cardinalis* emit only small amounts of latex (~1–2 µl), the raw latex reacts strongly with Dragendorff's reagent, thus suggesting high alkaloid concentrations. Furthermore, extracts of cardinal flower latex purified by solid-phase extraction and analyzed by using reverse-phase high performance liquid chromatography (HPLC) show a compound with a retention time and maximum absorbance comparable to the (-) lobeline HCl standard (Oppel and Kelley, unpublished data). These observations support the conclusion that *L. cardinalis* sequesters alkaloids within the latex, and that laticifers deliver the alkaloids to the trench. Indeed, during trenching, white latex is clearly observed entering the trench. Alkaloid-producing plants often concentrate alkaloids within laticifers (Wink and Roberts 1998). In the opium poppy, *Papaver somniferum* (opium poppy), for example, morphine levels may exceed 25% of the dry weight of latex exudates (Hartmann 1991).

The low alkaloid levels at the most distant locations from the trench in our sample boxes indicate that the area drained by the trench exceeds the area of our sample box. Previous studies have reported latex drainage from distances of at least 70 cm in severed stems of *Cryptostegia grandiflora* (Apocynaceae) and from a similar distance in tapped rubber trees, *Hevea brasiliensis* (Euphorbiaceae) (Buttery and Boatman 1976). If latex in *Lobelia* likewise flows from distant reserves into leaves during trenching, it is reasonable to expect higher total alkaloid levels in trenched leaves. Yet, there was no significant difference between trenched and control leaves in our study. This apparent contradiction likely can be attributed to an underestimation of alkaloids in the trench. Alkaloid levels above threshold produce the maximum saturation with Dragendorff's reagent and are underestimated by our methods. An alternative explanation for the similar alkaloid levels in trenched and control leaves is that the laticifers in each leaf are isolated as a separate reservoir. However, when *L. cardinalis* petioles are severed, latex drains from both sides of the cut, wherever the petiole is cut, suggesting that laticifers in the stem extend into the leaf.

The reaction of laticifers upon being breached has been studied in *Hevea brasiliensis* and other plants (Buttery and Boatman 1976; Milburn et al. 1990; Pickard 2008). Rupture of the pressurized latex tubes causes latex flow to the injury site down the resulting pressure gradient. Concurrently, water from surrounding tissues flows into the laticifers due to the large difference in water potential. The dilution of latex further facilitates latex flow. The dilution effect can be seen readily in *L. cardinalis* laticifers; the repeated cutting of a stem results in latex exudation that changes from an opaque, viscous, white fluid to a much clearer, watery fluid.

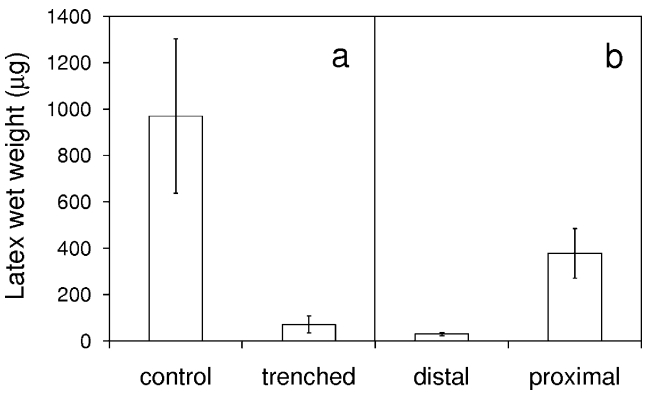

Fig. 6 **a** Amount of latex (mean±1 SE) emitted from (a) paired control and trenched *Lobelia* leaf tips, and **b** distal and proximal to trenches (N=10 leaves/treatment)

Drainage eventually ceases due to plugging (Buttery and Boatman 1976).

In the sample rectangles of our trenched leaves, alkaloid concentrations did not differ distal and proximal to the trench. Evidently, the influx of water into laticifers during drainage diluted the latex similarly on both sides of the trench. Why then do *E. basigera* caterpillars invariably feed on the distal side? Our exudation measurements documented that latex pressures are much lower on the distal side (Fig. 6). Laticifers proximal to the trench are partially recharged quickly because they remain connected to the extensive network of pressurized laticifers that extend throughout the plant. Although trenching drains and dilutes latex from both sides of the trench, only the distal side remains depressurized. The trench thus serves two purposes: it depletes and dilutes latex distal to the trench where the caterpillar feeds, and it prevents the influx of latex to this site from the plant's vast laticifer network. Dussourd and Denno (1991) proposed that trenching functions primarily to block the flow of latex to the feeding site, not to drain latex from the feeding site. Our current analysis documents both blockage and drainage in *L. cardinalis* leaves, illustrates the overwhelming importance of blockage, and shows clearly that latex is not a static defense. Any caterpillar attempting to feed on the proximal side of the trench would experience latex delivered directly to mouthpart receptors from pressurized laticifers. Caterpillars feeding on the distal side can consume the contents of the depressurized laticifers diluted with water and mixed with other leaf chemicals.

The trench drained~51% of the alkaloids from the proximal section of the leaves (Fig. 4), suggesting that at least half of the leaf alkaloids occur in the latex. The remaining alkaloids in trenched leaves must either be residuals not drained from the laticifers or alkaloids sequestered outside of the latex system. That the veins of trenched leaves still reacted strongly to Dragendorff's reagent suggests that most or all of the alkaloids are sequestered within the laticifers, which are closely associated with phloem bundles (Fraser 1931). However, it is conceivable that some alkaloid in *L. cardinalis* is located in the xylem or phloem, and that these tube systems contribute to the delivery of alkaloids to the trench. Alkaloid transport via xylem and phloem have both been documented (Wink and Roberts 1998). The pyrrolidine alkaloid nicotine, a close functional analog of the piperidine alkaloid lobeline, is transported in the xylem of *Nicotiana* (Solanaceae). Conversely, the quinolizidine alkaloids produced by plants in *Lupinus* (Fabaceae) are transported in the phloem, as are the pyrrolizidine alkaloids found in *Senecio* (Asteraceae).

We can readily exclude the xylem as a source of alkaloids moving into the trench in our experiments. The xylem during the day is under negative pressure. Rupture at the trench would cause rapid movement of xylem sap away from the trench as air entered the xylem tubes. Drying the leaf before microwaving should have prevented possible expansion and flow of this sap into the trench during heating in the microwave. In addition, analysis of stomatal conductance beyond *E. basigera* trenches in *L. cardinalis* indicates that many xylem vessels are not severed by the trench (Oppel, unpublished data); thus, bulk flow of xylem sap into the trench during microwaving seems unlikely. Unlike the xylem, the phloem sap is under positive pressure; it could potentially drain into the trench together with latex. Drainage would cease soon due to the formation of phloem protein (p-protein) plugs on the sieve plates (Oparka and Santa Cruz 2000). Nevertheless, we can not exclude a possible contribution of the phloem to the high alkaloid levels noted in the trench in our microwave prints.

Reduced exposure to latex during feeding presumably benefits *E. basigera* larvae. In the closely related cabbage looper, *Trichoplusia ni*, larvae are unable to develop on intact *L. cardinalis* plants, but feed and develop readily on excised leaves that are partially drained of latex (Dussourd 2003). The alkaloid lobeline is strongly deterrent to *T. ni* and triggers trenching behavior (Dussourd 2003). In contrast, *E. basigera* larvae develop and feed readily on intact *L. cardinalis*, although they grow more quickly on excised leaves (Dussourd, unpublished data). Whether lobeline and other piperidine alkaloids in *L. cardinalis* negatively affect *E. basigera* larvae has not yet been tested. Lobeline is known to deter feeding by a ctenuchid caterpillar, *Syntomis mogadorensis*, and by honeybees, *Apis mellifera* (Wink and Schneider 1990; Detzel and Wink 1993).

The microwave extraction protocol has advantages and limitations. The technique is uncomplicated, relatively rapid, and inexpensive when compared to other chemical analysis techniques such as HPLC and GCMS. Additionally, the microwave method yields high resolution, quantitative, two dimensional maps of alkaloid distribution in leaves. Few other techniques provide such detailed information on the distribution of secondary compounds in entire leaves (Nitao and Zangerl 2004). Microwave extraction of alkaloids and quantification should be possible with diverse plant species and diverse secondary compounds where visualization reagents are available. The technique has promise for studying the effects of pathogens, leaf miners, galls, mandibulate and haustellate insects, and various abiotic factors on alkaloid distributions in leaves. The method also might be used for analyzing alkaloid distributions in other flat substrates such as butterfly or moth wings.

Limitations of the microwave method include its inability to quantify very low or high alkaloid concentrations; low levels are undetectable, whereas high levels

are indistinguishable if they exceed the maximum response from Dragendorff's reagent. Intensifiers for Dragendorff's reagent such as sodium nitrite (Rubia and Gomez 1977) might be used to enhance sensitivity for low levels. Shorter microwave times could be used to extract alkaloids at low efficiency for quantifying high concentrations. Since Dragendorff's reagent is known to react with steroids, triterpenes, and some proteins, in addition to alkaloids, false positive responses may occur (Anderson et al. 1977). In *L. cardinalis*, lobeline and other alkaloids are known to occur at high concentrations (Krochmal et al. 1972), and we confirmed that lobeline is indeed found in the latex (Oppel and Kelley, unpublished data). Additional shortcomings of our technique include the inevitable loss of latex from the petiole cut during leaf removal. We explored other methods of minimizing latex loss that include ligating the leaf petiole, which was ineffective in stemming latex loss. Freezing the leaf with liquid nitrogen caused the leaf to crack; alkaloids diffused from the cracks during microwaving. Cautery appears to be the best method. Finally, the extraction efficiency of our microwave procedure remains unknown; therefore, the values reported should be considered as relative amounts, not total alkaloid levels. Nitao and Zangerl (2004) did test the effectiveness of their furanocoumarin protocol and found that microwaving parsnip leaves extracted furanocoumarins with efficiencies varying from 21–67%.

In summary, this study represents to our knowledge the first time that the effect of trenching on the two dimensional distribution of a secondary compound has been quantified. Our technique for visualizing and quantifying alkaloid distribution should have broad application in studies of insect-plant interactions, in monitoring how biotic and abiotic factors affect alkaloid production in economically important plants such as tobacco and poppy, and as a teaching tool accessible to both high school and college students.

Acknowledgments Many thanks to M.D. Kelley, K.C. Larson, and A.R. Zangerl for helpful advice and to R.D. Noyes and two anonymous reviewers for improving the manuscript. Antitermitic Activities of Abietane-type Diterpenes from *Taxodium distichum* Cones

Norihisa Kusumoto · Tatsuya Ashitani · Yuichi Hayasaka · Tetsuya Murayama · Koichi Ogiyama · Koetsu Takahashi

Received: 29 December 2008 / Revised: 13 April 2009 / Accepted: 3 May 2009 / Published online: 29 May 2009

Abstract Eight known abietane-type diterpenes were isolated from the weak acidic fraction of the *n*-hexane extract from cones of *Taxodium distichum*, one of the extant, living fossil conifers. They were identified as 6,7-dehydroroyleanone (**1**), taxodal (**2**), taxodione (**3**), salvinolone (**4**), 14-deoxycoleon U (**5**), 5,6-dehydrosugiol (**6**), sandaracopimaric acid (**7**), and xanthoperol (**8**). The structures of these compounds were determined by comparison of NMR spectral data with published data. The antitermitic (termicidal and antifeedant) activities of the compounds **1**–**8** against the subterranean termite, *Reticulitermes speratus* Kolbe, were evaluated. Compounds **1** and **3** showed potent termicidal activity, and **5** and **8** showed potent antifeedant activity. Compound **1** was found to be one of the representative bioactive compounds in the *n*-hexane extract of *T. distichum* cones. Compounds **1**–**8**, with the exception of **7**, were oxides of ferruginol (**9**). Therefore, the presence of various oxidation forms of the abietane-type structure reflects their various bioactivities.

Introduction

Taxodium distichum Rich (Taxodiaceae), commonly known as "bald" or "swamp" cypress, is well known as an extant deciduous, living fossil conifer indigenous to the southern part of North America. *T. distichum* heartwood is used for building materials, and has been reported to resist the attacks of the subterranean termite, *Coptotermes formosanus* Shiraki (Scheffrahn et al. 1988). The cones and seeds of *T. distichum* tend to be discovered from ancient stratum, and there are several reports concerning the fossil conifer and sediments of ancient flora (Otto et al. 2003, 2005). The cones produced by the conifers are essential parts for self-propagation. Consequently, the potential for having anti-feedant, antifungal, as well as other phytochemical activities against external influences is suggested (Yano and Furuno 1994).

Abietane-type diterpenes are widely distributed in the plant kingdom as natural compounds. They reveal characteristic bioactivities including cytotoxic, anti-tumor, anti-microbial, and anti-bacterial effects (Gao and Han 1997; Ulubelen et al. 1999; Gigante et al. 2003; Son et al. 2005; Marques et al. 2006). From previous studies, it is known that the abietane-type diterpenes are the major compounds in the cones of *Taxodium* species (Otto et al. 2003). The isolation of several kinds of abietane-type diterpenes from the cones of *T. distichum* has been reported (Yamamoto et al. 2003). Some of the compounds isolated, such as taxodione, taxodone, and taxodistine A and B, have been reported to have anti-tumor and cytotoxic activity (Kupchan et al. 1969; Hirasawa et al. 2007). Taxodione has been reported to exhibit antibacterial activities against methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* (VRE) as well (Yang et al. 2001). In addition, nezukol,

ferruginol, and manool, which have been isolated from the *T. distichum* heartwood (Scheffrahn et al. 1988), were shown to have antitermitic activities (Kang et al. 1993; Kano et al. 2004).

Natural compounds isolated from Taxodiaceae extant fossil conifers, such as from the genus *Metasequoia* and *Taxodium*, mostly have been taken from the leaf (Si et al. 2005) or the heartwood (Sato et al. 1966; Enoki et al. 1977). Only a few reports have considered bioactive compounds in living fossil conifer cones. Their bioactive compounds might have been important for the persistence, and thus, evolutionary success of *T. distichum.*

The aim of this research was to investigate the bioactive compounds of *T. distichum* cones and to evaluate their antitermitic activities by using a bioassay with the subterranean termite *Reticulitermes speratus* Kolbe. Subterranean termites are important decomposers in the terrestrial environment, and there has been interest in the activities of natural compounds against these termites (Bultman et al. 1979; Cornelius et al. 1997; Bläske and Hertel 2001). The termites *R. speratus*, *C. formosanus*, and *Cryptotermes domesticus* are harmful insects that damage wooden structures of buildings in Japan (Kang et al. 1993; Fukumoto et al. 2007).

Methods and Materials

Termite Collections Colonies of *Reticulitermes speratus* Kolbe were collected in Tsuruoka city, Yamagata prefecture, and maintained in well-humidified chambers at 27°C± 1°C for 1 month before the bioassay.

Termicidal and Antifeedant Tests Termicidal and antifeedant activities were tested simultaneously. Samples were applied to paper discs (Advantec, 8 mm diam, 1.5 mm thickness, ca. 30 mg disk weight) according to a previously described method (Tellez et al. 2002; Ganapaty et al. 2004). Paper discs were treated with 60 μl of each sample solution (5.0 mg/ml in MeOH). After being dried in a vacuum desiccator for 24 h, the weights of the paper discs were measured. The concentration of the sample in the dried paper disc was prepared to 1.0% (sample weight/paper disc weight×100). This dried paper disc was put on top of sea sand (3 g) that was spread uniformly at the bottom of a glass petri dish (45 mm diam, 20 mm high). Ten *R. speratus* workers were placed in the petri dish. The sea sand was kept moistened with water by using a sprayer. These petri dishes were maintained in a well-humidified chamber at 27°C±1°C for 10 d together with blank paper discs (no samples) and controls (no paper discs). Each of the tests included three replicates. The mortality of termites was recorded every 24 h, and termicidal activities were evaluated from the mortality average. The mass loss of each paper disc was measured at the end of the experimental period. Antifeedant activities were evaluated from the average of the mass that one termite fed per 24 h (mass loss of paper disc in 10 d/total number of termites in 10 d), and the relative rates were calculated from the blank readings.

Plant Material The fallen cones of *T. distichum* (Taxodiaceae) were gathered in the Yamagata Field Science Center (Faculty of Agriculture, Yamagata University, Japan). Identification was confirmed by the above institution.

General Experimental Procedures GLC analysis was performed with a HITACHI G-3000 Gas Chromatograph under the following conditions: DB-1 capillary column (30 m×0.32 mm i.d.; 0.25 μm film thickness; J&W Scientific, Folsom, CA, USA); column temperature from 180°C (0 min) to 280°C (15 min) at 4°C/min; injection temperature 250°C: detection temperature 250°C. GC/MS data were measured with a SHIMADZU QP-5000 GC-MS: DB-1 capillary column (30 m×0.32 mm i.d.; 0.25 μm film thickness; J&W Scientific, Folsom, CA, USA); column temperature from 100°C (1 min) to 320°C (10 min) at 5°C/min; injection temperature of 230°C: detection temperature of 250°C; acquisition mass range of 450-50 amu using helium as the carrier gas (3.6 ml/min). 1D and 2D NMR spectra were measured with a JEOL JNM-EX400 (^{1}H 400 MHz/^{13}C 100 MHz) spectrometer. The IR spectra were taken by a HORIBA FT-710 IR spectrometer with KBr pellets. UV spectra were taken by a SHIMADZU UV-1600PC spectrometer. Optical rotation values were measured by a HORIBA SEPA-300 polarimeter.

Extraction and Isolation The *n*-hexane extract of air-dried *T. distichum* cones (800.0 g) was extracted by the same method as previously reported (Kusumoto et al. 2008). The *n*-hexane soluble fraction (88.6 g) was extracted by partition extraction with saturated $NaHCO_3$, 10% $NaCO_3$, and 1% NaOH aqueous solution in a separatory funnel to yield 1.4 g, 1.2 g, and 11.2 g fractions, respectively, along with 74.8 g residue fraction. Part of the weak acidic fraction (11.0 g) was applied to silica gel 60 N (spherical 63–210 μm, neutral, Kanto Chemical Co., Japan) column chromatography (CC) with solvent systems of *n*-hexane / EtOAc (100:1 to EtOAc only), and eight fractions (fr. A–H) were collected. Fractions C, D, and E (566.3 mg, *n*-hexane / EtOAc, 100:1) were recrystallized by using benzene to give a red needle of 6,7-dehydroroyleanone (**1**, 306.3 mg). Further, fr. G (541.9 mg, *n*-hexane / EtOAc, 100:3) was recrystallized by using *n*-hexane to give a colorless needle of taxodal (**2**, 44.6 mg). Fraction F (304.7 mg, n-hexane /

EtOAc, 100:1 to 50:1) was purified by silica gel 60 N CC with a solvent system of *n*-hexane / chloroform (3:1 to chloroform only), and 40 fractions (fr. 1–40) were collected. Fractions 9, 10, 11, and 12 (110.0 mg, *n*-hexane / chloroform, 3:1) were purified by silica gel 60 N CC using a solvent system of *n*-hexane / chloroform (3:1) to give a dark yellow amorphous solid of taxodione (**3**, 29.0 mg). Fraction H (10.2 g) contained a polymerized mixture, which was separated to yield the EtOAc soluble (9.8 g) and insoluble fractions (333.7 mg). The EtOAc soluble fraction (6 g) was applied to silica gel 60 N CC using chloroform, and 48 fractions (fr. H1-H48) were collected. Fractions H9, H10, and H11 (233.1 mg) were recrystallized by using benzene, which gave a pale yellow powder of salvinolone (**4**, 123.2 mg). Successively, fractions H16, H17, H18, and H19 (461.1 mg) were recrystallized by using benzene, which yielded a pale yellow crystal of 14-deoxycoleone U (**5**, 182.8 mg). Fractions H23 to H27 (921.8 mg) were applied to silica gel 60 N CC using a solvent system of benzene / acetone (9:1) to a give pale yellow needle of 5,6-dehydrosugiol (**6**, 21.3 mg), a dark brown needle of sandaracopimaricacid (**7**, 11.6 mg), and a yellow needle of xanthoperol (**8**, 37.6 mg), respectively. Ferruginol (**9**) and sugiol (**11**) were isolated from *Cryptomeria japonica* in previous studies (Nagahama et al. 2000; Ashitani et al. 2001). 6,7-Dehydroferruginol (**10**) was synthesized from **11** by a chemical conversion according to a previous report (Matsui et al. 2004).

Results and Discussion

Bioactivities of the Compounds from T. distichum Cones The *n*-hexane soluble fraction (88.6 g) of *T. distichum* cones was separated by partition extraction and yielded strong (1.59%), medium (1.39%), and weak (12.61%) acidic fractions and a neutral fraction (84.41%). Termicidal activities of these four fractions were tested, and the results are shown in Table 1. The medium (33.3±20.3%) and the weak (33.3±12.0%) acidic fractions exhibited potent termicidal activity during a 10-d bioassay period. Based on the amount of extraction and the results of the bioassays, the weak acidic fraction seemed to contain the bioactive compounds. Therefore, it was further examined by silica gel column chromatography.

On a preparative scale, compounds **1**–**8** (Fig. 1) were isolated from the weak acidic fraction. The structures of these compounds, 6,7-dehydroroyleanone (**1**) (Hensch et al. 1975; Tezuka et al. 1998), taxodal (**2**) (Kusumoto et al. 2008), taxodione (**3**) (Kupchan et al. 1969; Tezuka et al. 1998), salvinolone (**4**) (Lin et al. 1989; Yamamoto et al. 2003), 14-deoxycoleon U (**5**) (Hueso-Rodriguez et al. 1983; Yamamoto et al. 2003), 5,6-dehydrosugiol (**6**) (Kupchan et al. 1969; Lin et al. 1989), sandaracopimaric acid (**7**) (Wenkert and Buckwalter 1972), and xanthoperol (**8**) (Kondo et al. 1963; Li et al. 2003), were determined by EI mass spectra, IR data, melting points, and NMR spectral data, and these were compared with published data. This is the first report of **2**, **7**, and **8** from *T. distichum* cones. Compounds **1**–**8**, except **2** and **7**, were diterpenes with an abietane-type structure.

[a] The concentration of the sample in the dried paper discs was prepared to 1.0% (sample weight/paper disc weight×100). *N*=3 replicates. 100%=30 termites. Means ± SE are given. Mortality rates were recorded every 24 h during the test periods

[b] No mortality observed

[c] None tested

[d] The mass of paper discs fed by one termite per 24 hr (calculated by mass loss of paper disc in 10 d divided by total number of feeding termites in 10 d)

[e] Relative rates were calculated from blank reading (100×mass of each sample/mass of blank)

The termicidal and antifeedant activities of compounds **1**–**8** against *R. speratus* were tested, (except for **7**, which was isolated in too low amounts), together with ferruginol (**9**), 6,7-dehydroferruginol (**10**), and sugiol (**11**). The results are shown in Table 2. Compounds **9**–**11** are well-known abietane-type diterpenes that exist in Taxodiaceae (Otto et al. 2002). Compound **9** has been shown previously to have antitermitic and antifungal activities (Kofujita et al. 2001; Kano et al. 2004).

When testing termicidal activity, **1** caused strong mortality (46.7±3.33% in 5 d, 70.0±10.0% in 10 d). Compound **3** also caused notable mortality after 10 d (20.0±11.6%), with the same value as **9**. The mortality rates caused by **8** after 10 d (10.0±5.77%) and the rates observed in the "no feed" assay (13.3±3.33%) were similar.

When testing antifeedant activity, **8** showed effective activitiy against *R. speratus*. The termites fed on paper treated with **8**. Compounds **3** and **5** also showed potent relative activities in the antifeedant test.

From these results, we conclude that *T. distichum* cones contain strong bioactive compounds (**1**, **3**, **5**, and **8**). In particular, **1** is a specific bioactive compound in the *n*-hexane extract of *T. distichum* cones, and has a quinone structure at the C ring (Fig. 2). The abietane-type diterpenes, which have quinone structures at the C rings, such as cryptoquinone and 7-hydroxy-11,14-dioxo-8,12-abietadiene, previously have been reported to show anti-fungal and cytotoxic activities (Kofujita et al. 2002, 2006). Herein, we report that **1**, the abietane-type quinone, exhibited strong activities against subterranean termite.

Bioactivities of the Oxidized Abietane-type Compounds It was assumed that the bioactive compounds **1**–**8** were oxides of **9** (Yamamoto et al. 2003). In order to compare the bioactive value of **9** with its oxides, the oxidation routes of **9** and the relative values on the basis of **9**, as a standard compound, are indicated in Fig. 2.

First, we discuss the termicidal activity (Fig. 2a). The activity decreased with dehydrogenation of C-6 and C-7 at **10**, but the activity increased with the synthesis of a quinone structure in the oxidation progression to **1** or **3**. Activity also decreased at **11**, but increased again through oxidation to **4**, **6**, and **8**. Moreover, oxidation of **4** to **5** resulted in loss of all activity.

Second, a similar change was observed with antifeedant activity (Fig. 2b). The activity of **3** was stronger than that of **1**. Furthermore, the activity completely disappeared at **11**, but high activities were obtained through oxidation to **5** or **8**.

These findings suggest that the various forms of the abietane-type structure due to the degree of oxidation reflect their various bioactivities. As several compounds that are active against *R. speratus* were discovered, they may be related to the defense of *T. distichum*. Hence, we consider that this may be one of the important factors that explains why *T. distichum* have prospered on the earth.

The Biogeographical Distribution of Duncecap Larkspur (*Delphinium occidentale*) Chemotypes and Their Potential Toxicity

Daniel Cook · Dale R. Gardner · James A. Pfister · Kevin D. Welch · Benedict T. Green · Stephen T. Lee

Received: 23 December 2008 / Revised: 19 April 2009 / Accepted: 26 April 2009 / Published online: 21 May 2009

Abstract Larkspurs (*Delphinium* spp.) are poisonous plants found on rangelands in western North America. Larkspur's toxicity has been attributed to the norditerpenoid alkaloids, which are divided into two main structural groups: the highly toxic (*N*-methylsuccinimido) anthranoyllycoctonine type (MSAL type) and the less toxic 7,8-methylenedioxylycoctonine type (MDL type). Plants high in the MSAL-type alkaloids are thought to be the most toxic to cattle, and the concentrations of these alkaloids have been used as a predictor of plant toxicity. Duncecap larkspur, *Delphinium occidentale*, occurs throughout much of the Intermountain West and Northwestern United States. Specimens from field collections and herbaria deposits were evaluated taxonomically and chemically. Two distinct alkaloid profiles were identified: one that contains the MSAL-type alkaloids and one that contains little, if any, MSAL-type alkaloids. Thus, plants with these two alkaloid profiles should differ in their toxic potential. Each profile was unique in its geographical distribution. These findings have important implications in grazing management decisions on *D. occidentale*-infested rangelands, and they demonstrate that botanical classification alone is not a good indicator to determine the toxic risk of *D. occidentale*.

Keywords Larkspur · MSAL-type alkaloids · Norditerpene · *Delphinium occidentale* · Methyllycaconitine

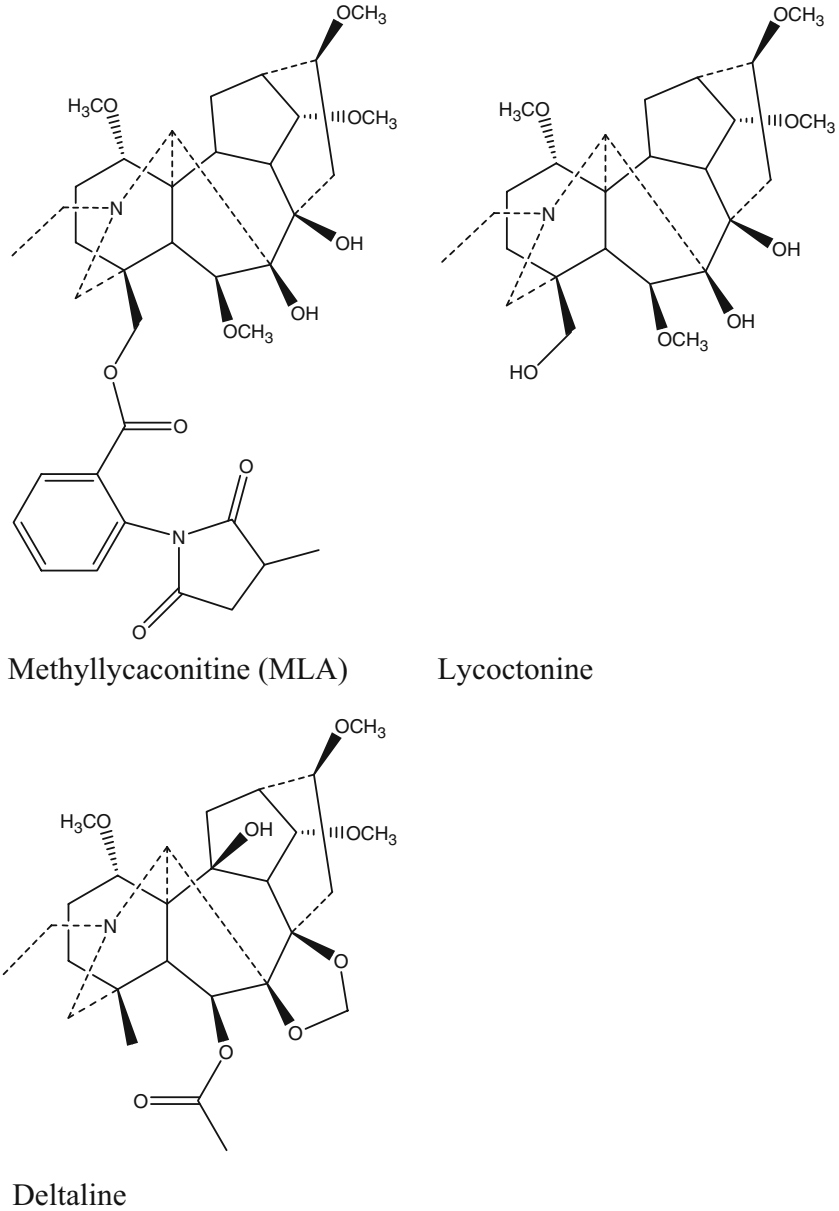
Introduction

Larkspurs (*Delphinium* spp.) are poisonous plants on rangelands in the western USA. They are responsible for significant losses to the cattle industry and are the subject of extensive research (Marsh et al. 1916, 1934; Pfister et al. 1999, 2002). Total cost to the livestock industry from cattle deaths attributed to larkspur poisoning is estimated to be millions of dollars annually (Nielsen et al. 1994). Larkspurs are divided into three groups based principally upon their height: low larkspurs, plains larkspurs, and tall larkspurs. The tall larkspurs are responsible for a greater number of cattle losses than either the plains or low larkspur.

Larkspur-induced poisoning in cattle is attributed to the diterpenoid alkaloids that can represent up to 3% of the plant dry weight. There are two main structural groups of norditerpene alkaloids, the *N*-(methylsuccinimido) anthranoyllycoctonine type (MSAL-type) and the 7,8-methylenedioxylycoconine type (MDL-type) norditerpenoid alkaloids (Fig. 1; Olsen et al. 1990). The MSAL-type are approximately 20 times more toxic than the MDL-type based upon the LD_{50} of the individual compounds in a mouse model (Manners et al. 1993, 1995; Panter et al. 2002). Acute larkspur poisoning has been attributed to the MSAL-type alkaloids (Aiyar et al. 1979; Pfister et al. 1999), and plants high in the MSAL type are thought to be the most toxic to cattle. The concentrations of these alkaloids have been used as a predictor of plant toxicity (Pfister et al. 2002; Ralphs et al. 2002). The most abundant member of the MSAL-type alkaloids in the tall larkspurs is methyllycaconitine (MLA; Gardner et al. 2002).

Two synopses of the genus *Delphinium* found in North America have been published, the first by Ewan (1945) and the second by Warnock (1995, 1997). Three tall larkspur species (*Delphinium barbeyi*, *Delphinium occidentale*, and

Fig. 1 Structure of select norditerpene alkaloids in *Delphinium occidentale*



Delphinium glaucum) of particular interest received different taxonomic treatment by both authors. Recent research from standard systematics (Welsh and Ralphs 2002), chemotaxonomy (Gardner et al. 2002), and molecular markers (Li et al. 2002) support the treatment given to these three species by Ewan (1945). All of these species can contain the MSAL-type alkaloids with MLA being the major member.

An observation of particular interest made by Gardner et al. 2002 was the identification of two alkaloid profiles in *D. occidentale*. One alkaloid profile lacked or displayed small amounts of the MSAL-type alkaloids, whereas the other profile displayed large amounts of the MSAL-type alkaloids. The objective of this study was to determine the extent of these two profiles throughout the geographical distribution of *D. occidentale*. We report here that *D. occidentale* has two definable chemotypes, with distinct geographical boundaries, that should differ in potential toxicity. These results have implications for grazing management decisions in *D. occidentale*-infested rangelands, and they demonstrate that taxonomic classification alone is not a good indicator to determine the toxic risk of *D. occidentale*.

Methods and Materials

Plant Materials Analytical samples were prepared from plant material collected from herbarium specimens and resident populations of *D. occidentale*. Herbarium specimens were provided by the Intermountain Herbarium at

Utah State University, the Stanley L. Welsh Vascular Plant Herbarium at Brigham Young University, the University of Colorado Museum Herbarium, the Rocky Mountain Herbarium at the University of Wyoming, the University of Washington Herbarium, and the Herbarium at Oregon State University. Specimens of questionable identification were verified to be authentic *D. occidentale* specimens by staff at the Intermountain Herbarium at Utah State University or the Stanley L. Welsh Vascular Plant Herbarium at Brigham Young University. Leaf and flower material were sampled from herbarium specimens and subsequently ground by using a Retsch mixer mill MM301 (Haan, Germany).

Field samples of *D. occidentale* populations (1,464 plants representing 118 accessions) were collected in the summer of 2007 and 2008. Accessions were collected throughout the geographical distribution of *D. occidentale* including the states of Utah, Idaho, Montana, Wyoming, Colorado, Nevada, and Oregon. Samples immediately were placed on dry ice after collection and stored at −80°C upon return to the laboratory. Samples were frozen for possible use in subsequent research. Samples were freeze-dried and ground to pass through a 2-mm screen using a Wiley mill.

Sample Extraction and Alkaloid Analysis Individual plant samples were extracted and analyzed by electrospray mass spectrometry by using procedures previously described (Gardner et al. 1999). In summary, 25-mg plant material from herbarium samples was extracted in 6 ml of methanol for 16 h. Reserpine (125 µg) was added as an internal reference. The sample was mixed then centrifuged. A 200-µl sample was diluted into 800 µl of 1:1 methanol/1% acetic acid. For plant samples collected in the field in the summers of 2007 and 2008, 100-mg plant material was extracted in 6 ml of methanol for 16 h. Reserpine (500 µg) was added as an internal reference. The sample was mixed then centrifuged. A 50-µl sample was diluted into 950 µl of 1:1 methanol/1% acetic acid.

Mass spectra were recorded for each sample over a range of 150–800 *m*/*z* and averaged across all scans taken at 40% of peak height (total ion current). Data were calculated by recording the abundance of all ions above a relative area of 0.1%. The amount of a compound (as represented by a single mass unit) detected was calculated based on the relative abundance of the internal standard reserpine (MH^+=609). The resulting mass spectral data were reduced and tabulated to a final set of quantitative values for 57 different protonated molecules by using a method similar to that reported by Gardner et al. (2002) (Table 1).

Data Analysis Each sample was assigned into group A (samples with MLA concentrations greater than 100 µg/mg) or group B (samples with MLA concentrations less than 100 µg/mg). This cutoff was chosen because it clearly separated the two alkaloid profiles observed previously by Gardner et al. (2002). MANOVA and discriminant analysis of the two assigned groups were performed as a pairwise comparison by using BioNumerics 4.6 (Applied Maths, Inc.). Two parameters were reported: (1) *L* (Wilk's Lambda likelihood ratio test) is the likelihood of the obtained discrimination with the assumption that the groups are drawn from the same population. A low *L* value infers that the groups are likely to be drawn from different populations. (2) *P* is the probability that a random grouping of the groups would yield the same degree of discrimination. *t* tests were performed by using Microsoft Excel. All multivariate and univariate statistical comparisons were made from plants of the same developmental stage.

Results

Field collections (1,464 specimens representing 118 accessions) of *D. occidentale* were made in the summer of 2007 and 2008. Samples were representative of the reported geographical distribution of *D. occidentale.* In addition, 599 herbarium specimens of *D. occidentale* from the cooperating herbaria were sampled. These specimens were collected from the late 1800s to the current year, and they also were representative of the reported geographical distribution of *D. occidentale*. All samples were analyzed by electrospray mass spectrometry. The resulting mass spectral data were reduced and tabulated to a final set of quantitative values for 57 different masses (Table 1).

Initially, each sample was scored for the presence of MLA (>100 µg/mg) or reduced amounts of MLA (<100 µg/mg). A total of 698 samples were identified that contained greater than 100 µg/mg MLA. A total of 1,365 samples were identified that contained less than 100 µg/mg MLA. To confirm that these two groups were unique, multivariate statistical methods (MANOVA and discriminant analysis) were used to test for grouping. The pairwise MANOVA revealed that the two groups were different (*P*= 0.001%, *L*=0.15). Discriminant analysis also was performed by comparing the two groups as a pairwise comparison. Discriminant analysis showed clear separation of the two groups based upon multiple alkaloids. The five most important discriminants were the following masses: *m*/*z* 683 (MLA), 715, 739, 753, and 699. These two multivariate methods demonstrated that the two groups were different. As a result, samples with greater than 100 µg/mg MLA will hereafter be termed chemotype A and those samples that have less than 100 µg/mg MLA will hereafter be termed chemotype B. Representative mass

[b] Alkaloid identification taken from Pelletier et al. (1981, 1989), Joshi et al. (1988, 1989), Kulanthaivel et al. (1988, 1990), and Manners et al. (1996, 1998)

[c] Relative alkaloid concentrations per 100 mg of plant material. Concentrations were normalized to an internal reserpine standard

spectra of the two chemotypes are shown in Fig. 2. Chemotype A contains the MDL- and MSAL-type alkaloids including MLA, while chemotype B contains principally the MDL-type alkaloids and very little, if any, MLA.

A *t* test was used to identify masses whose concentrations are different between the two chemotypes. The mean concentration of each mass for each chemotype and the possible alkaloid each mass may represent are listed in Table 1. A conservative approach was taken for identifying masses whose concentrations are different by using the Bonferroni *P* value at $\alpha=0.05/57=0.0009$. By using these criteria, 36 masses were identified whose concentrations were different between the two chemotypes. The concentrations of 16 masses were greater in chemotype A and the concentrations of 20 were greater in chemotype B. The alkaloids that accumulated to greater amounts in chemotype A were other MSAL-type alkaloids in addition to MLA, while those alkaloids that accumulated to greater amounts in chemotype B were the MDL-type alkaloids.

The geographical distribution of each chemotype was investigated by state and counties within each state. Table 2 shows the number of samples analyzed from each state, county, and the number of samples assigned to each chemotype. A distribution map of the two chemotypes is shown in Fig. 3. Most counties had only samples of one chemotype. However, a number of counties such as Caribou (ID), Lincoln (WY), Sublette (WY), and Fremont (WY) have samples of each chemotype, indicating that they serve as a transition zone from south to north. Although these counties have plants with both chemotypes, individual populations from field collections in each county were either chemotype A or B in most cases. Likewise, counties that are in the transition zone from east to west, such as Juab and Box Elder counties of Utah, also have samples of both chemotypes but are spatially separated: chemotype A to the west and chemotype B to the east.

Discussion

Previous research has demonstrated that the MSAL-type alkaloids are more toxic than the MDL-type in a mouse model (Manners et al. 1993, 1995; Panter et al. 2002; Welch et al. 2008). The MSAL-type alkaloids are thought to be the most toxic to cattle, and their concentrations have been used as a predictor of plant toxicity (Ralphs et al. 2002; Pfister et al. 2002). Consequently, current management recommendations for grazing cattle on larkspur containing ranges are based primarily on the concentration of MSAL-type alkaloids (Pfister et al. 2002; Ralphs et al. 2002).

In considering these facts, a finding of particular interest made by Gardner et al. (2002) was the identification of two alkaloid profiles in *D. occidentale*. One profile lacked or displayed small amounts of the MSAL-type alkaloids, and another that displayed larger amounts of the same alkaloids. However, no information regarding the relative distribution of these two profiles was provided. Therefore, the objective of this study was to define the distribution of these two profiles throughout the geographical distribution of *D. occidentale* by using field collections and herbarium specimens.

Two chemotypes of *D. occidentale* were identified, thus supporting the preliminary finding of Gardner et al. (2002). Chemotypes A and B contain similar MDL-type alkaloids but at different concentrations (Table 1). However, no MDL-type alkaloid was chemotype specific, and differences in the MDL-type alkaloids between chemotypes were due to the large sample size. Localized populations of each chemotype may not contain statistically different amounts of the MDL-type alkaloids. The major MDL-type alkaloids in both chemotypes based upon concentration are those with masses (*m/z*) 454, 468, 482, 494, 508, 552, and 578 (Table 1). Deltaline ($MH^+=508$) is the major MDL-type alkaloid in most samples of both chemotypes; however, the

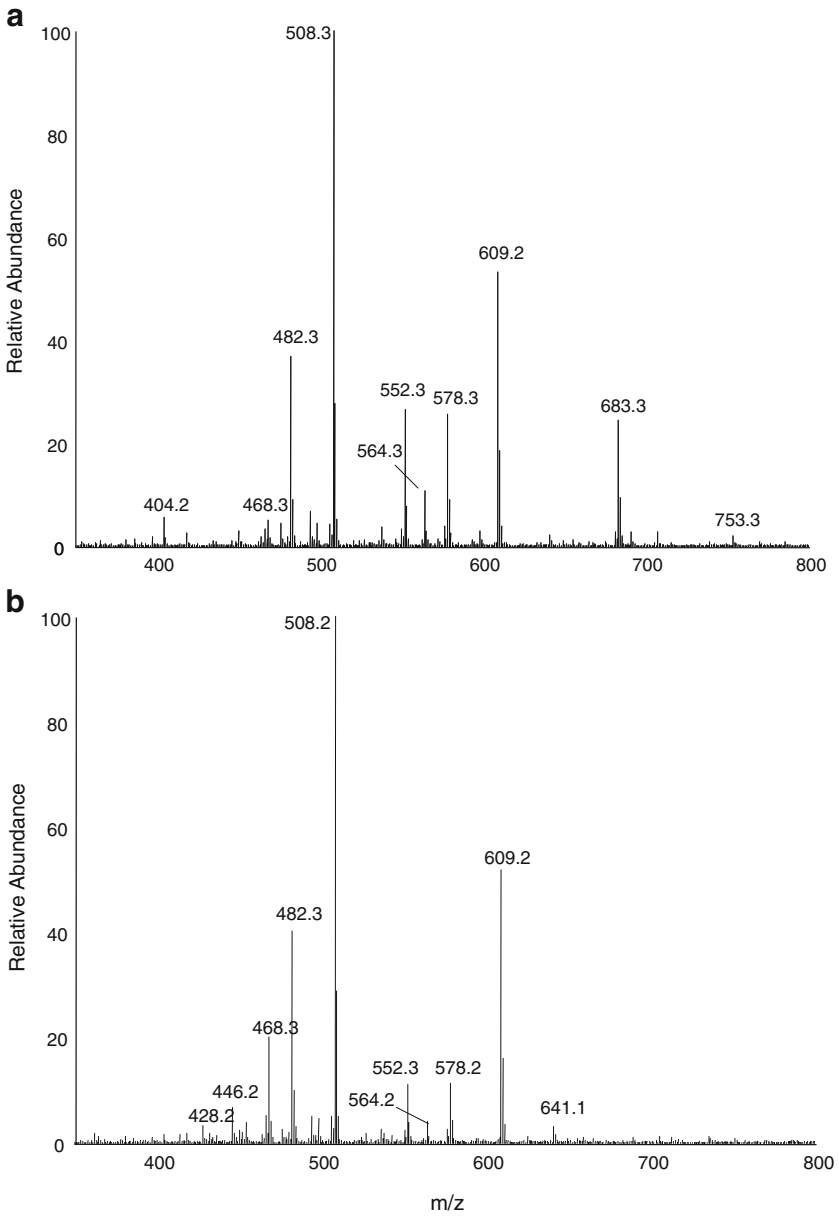

Fig. 2 Electrospray mass spectra from representative samples from each *Delphinium occidentale* chemotype

ratio of deltaline to other MDL alkaloids varies among locations. For example, in some locations masses (*m*/*z*) 454, 552, and 578 may be the major MDL-type alkaloid. Chemotypes A and B contain different concentrations of the MSAL-type alkaloids. Concentrations of the other MSAL-type alkaloids such as nudicauline, geyerline, 14-deacetynudicauline, and others are different between the two chemotypes but like the MDL-type alkaloids are not chemotype specific. This is due to the fact that some of these minor MSAL-type alkaloids are not found in all populations of chemotype A. Methyllycaconitine (MH^+= 683) concentration, which was used as the basis for assigning the two groups, was chemotype specific by definition. Three conclusions can be drawn from these data.

First, plants that represent chemotype B containing very low amounts or no detectable MSAL-type alkaloids would likely pose little risk to grazing cattle based upon current models and recommendations. Current management recommendations state that plants with greater than 3-mg MSAL-type alkaloids per gram plant material pose the greatest risk to cattle (Pfister et al. 2002). Alternatively, plants that represent chemotype A containing the MSAL-type alkaloids may pose considerable risk to cattle based upon current models and recommendations. However, poisoning is always dependent upon the dose and duration. Chemotype B plants contain the less toxic MDL-type alkaloids. Therefore, at the proper dose and duration, there is a possible risk of poisoning livestock.

Second, in general, each chemotype had a distinct distribution with defined boundaries (Table 2 and Fig. 3). In some cases, the chemotypes are separated by notable geographic features. For example, the east to west transition is separated by the desert that runs north to south on the west side of the state of Utah (Fig. 3). On the other hand, the north to south transition zone of the two chemotypes is not separated by any notable geographic features. In fact, two populations in Lincoln County, Wyoming that represent the two different chemotypes occurred on the same watershed less than 5 miles apart.

Third, the data suggest that the qualitative nature of the alkaloid profiles in *D. occidentale* remains constant at a given location. This conclusion is supported by field collections that have the same qualitative alkaloid profiles as the herbarium specimens from identical locations that were collected up to 100 years earlier. In addition, the data suggest that the alkaloid composition of herbarium specimens is not modified as a result of long-term storage at room temperature. Thus, herbarium specimens may serve as useful resources in determining risk of other larkspur species. However, quantitative amounts of these alkaloids may vary among years, and quantitative assessment of the alkaloids over time due to environment and other factors merits further investigation. For example, in *D. barbeyi*, a closely related tall larkspur species, both the MDL- and MSAL-type alkaloids decline as the plant matures and

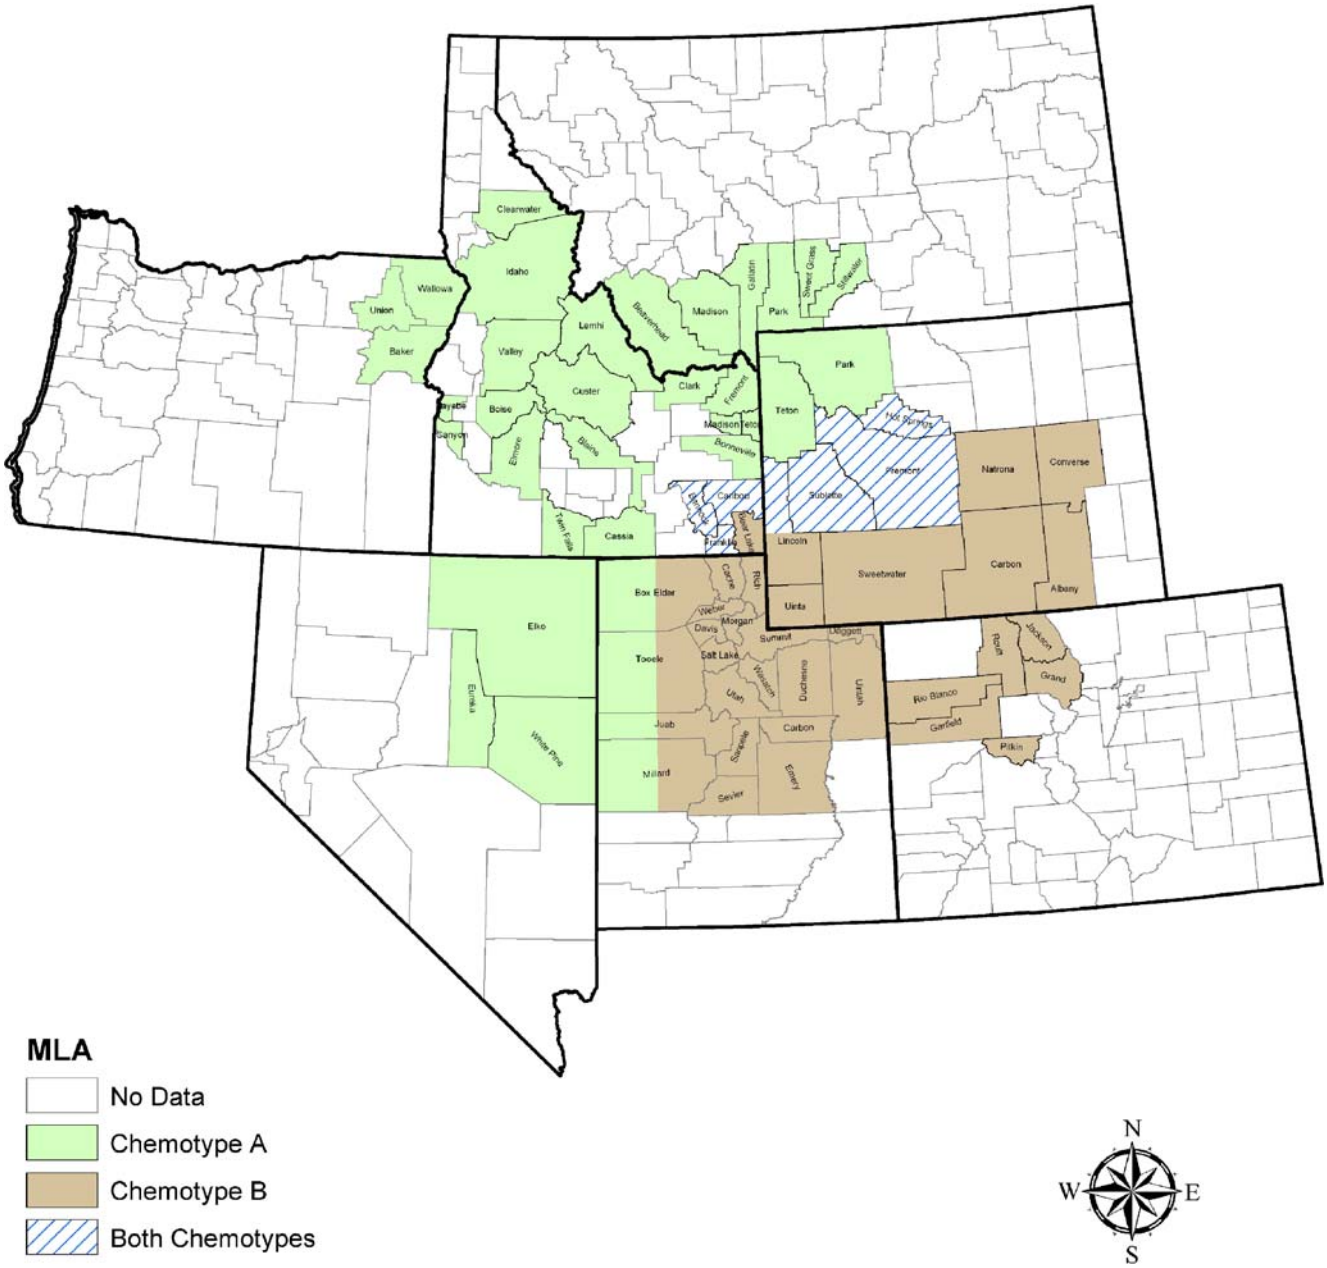

Fig. 3 Distribution map of chemotypes A and B throughout the geographical distribution of *Delphinium occidentale*

accumulate to different amounts in differing plant tissues (Ralphs and Gardner 2003). Additionally, environmental factors such as light, defoliation, and herbivory by insects have been shown to influence norditerpene alkaloid concentrations and pools (Ralphs et al. 1998a, b; Ralphs and Gardner 2001b). Such causes could be responsible for or play some part in the observed differences between the two chemotypes as well as their distribution.

We currently are not able to explain why there are two unique chemotypes of *D. occidentale* with such a defined geographical distribution, although some possibilities merit consideration. First, these chemotypes may represent unique *Delphinium* species or varieties, although no obvious morphological features used for taxonomic separation of the two groups have been noted. Second, the chemotypes may have originated due to environmental differences among locations. Previous research has shown that *D. occidentale* with chemotype A and *D. barbeyi* have distinct alkaloid profiles. However, when reciprocal gardens were established with these two species, the variation in profiles disappeared (Ralphs and Gardner 2001a). Third, these chemical profiles may be the result of natural phytochemical evolution of plants in the presence of herbivores. Frequency-dependent selection by herbivores may result in the evolution of differing chemical phenotypes (Schmeller et al. 1994). Furthermore, in certain

instances, plants with one chemotype have been shown to be more susceptible to herbivory than those of another chemotype (Berenbaum and Zangerl 1988; Bowers and Puttick 1988). It appears likely that plants with chemotype B may be more susceptible to herbivory due to their lack of methyllycaconitine, a potent insecticide (Jennings et al. 1986). Finally, chemotype B may be derived from hybridization between chemotype A of *D. occidentale* and *D. barbeyi* as suggested previously (Ralphs and Gardner 2001a; Gardner et al. 2002; Li et al. 2002). In fact, chemotype B may overlap with *D. barbeyi* in parts of Sevier, Sanpete, and Emery counties in Utah, all the counties in Colorado, and Albany and Carbon counties in Wyoming (Ralphs and Gardner 2001a; Gardner et al. 2002). Hybridization can result in either the gain of novel secondary compounds or the loss of secondary compounds (Orians 2000). If chemotype B were derived from hybridization, it is possible that a loss of function in the biosynthetic pathway leading to the MSAL-type alkaloids occurred, which could result in the accumulation of the MDL-type alkaloids. To address such possibilities, we are initiating further studies that include phylogenetic analysis and reciprocal gardens.

In summary, the MSAL-type alkaloids, such as MLA, are the primary factors responsible for the toxicity of larkspur plants. We report here that *D. occidentale* has two defined chemotypes: one (chemotype A) contains significantly more MSAL-type-alkaloids, and one lacks or contains very small amounts of the MSAL-type alkaloids (chemotype B). In general, the plants with these chemotypes grow in distinct geographical locations; however, there are counties that contain populations of both chemotypes. In addition, this study demonstrates that taxonomic identification of *D. occidentale* is not sufficient to determine risk. Lastly, based upon current toxicity models, the results from this study have implications for making management decisions for D. *occidentale*-infested rangelands. Additional research, however, is needed to determine the exact risk to livestock of each chemotype before these management recommendations can be further refined.

Acknowledgments We thank Jessie Roper, Clint Stonecipher, Scott Larsen, Kendra Dewey, and Katie Lott for technical assistance. We appreciate the herbarium at the University of Washington, Oregon State University, University of Wyoming, University of Colorado, Brigham Young University, and Utah State University for providing specimens that were sampled for chemical analysis. We thank Susan Durham for statistical support.

RAPID COMMUNICATION

Drones of the Dwarf Honey Bee *Apis Florea* Are Attracted to (2E)-9-Oxodecenoic Acid and (2E)-10-Hydroxydecenoic Acid

Narayanappa Nagaraja · Axel Brockmann

Received: 9 April 2009 / Revised: 7 May 2009 / Accepted: 2 June 2009 / Published online: 16 June 2009

Abstract The queen mandibular gland component (2E)-9-oxodecenoic acid (9-ODA) has been suggested to function as the major sex pheromone component in all honey bee species. In contrast to this hypothesis, chemical analyses showed that in the Asian dwarf honey bee species, *Apis florea*, a different decenoic acid, (2E)-10-hydroxydecenoic acid (10-HDA), is the major component in the mandibular gland secretion. We show here that *A. florea* drones are attracted to 9-ODA as well as to 10-HDA. However, 10-HDA attracted higher numbers of drones at lower dosages than 9-ODA, and also was more attractive when directly compared to 9-ODA in a dual attraction experiment. We conclude that 10-HDA has to be viewed as the major sex pheromone in *A. florea*. The result that both pheromone components are capable of attracting drones when presented alone was unexpected with regard to existing sex pheromone attraction experiments in honey bees.

Keywords Sex pheromone · Mandibular gland · (2E)-9-oxodecenoic acid · (2E)-10-hydroxydecenoic acid · *Apis florea* · Honey bee

Introduction

Sex pheromone communication in honey bees is thought to be similar among the different species, and the general idea is that all species use (2E)-9-oxodecenoic acid (9-ODA), a queen mandibular gland component, as the major sex pheromone (Koeniger and Koeniger 2000). However, chemical analyses of queen mandibular gland secretions have shown that 9-ODA is not the major component in all species and all virgin queens (Plettner et al. 1997; Keeling et al. 2000). Virgin and mated *Apis florea* queens as well as virgin queens of the Western honey bee, *Apis mellifera*, synthesize higher amounts of (2E)-10-hydroxydecenoic acid (10-HDA) than 9-ODA (Plettner et al. 1997). In *A. mellifera*, 9-ODA attracts drones when presented alone, and 10-HDA increases the attractiveness of 9-ODA (Brockmann et al. 2006). Electroantennogram recordings and gene expression analysis showed a specialization of the drone olfactory system to detect 9-ODA (Brockmann et al. 1998.Wanner et al. 2007). Reports on sex pheromone communication in *A. florea* are contradictory. Sannasi et al. (1971) reported evidence that *A. florea* drones are attracted to 9-ODA, whereas other authors stated that attempts to attract *A. florea* drones with 9-ODA had failed (see Oldroyd and Wongsiri 2006). Because there is a close match between the signals produced by the sender and the behavioral responsiveness of the receiver in animal communication systems, we decided to test whether drones of *A. florea* are attracted to 9-ODA or 10-HDA.

Methods and Materials

The drone attraction experiments were conducted at Gandhi Krishi Vignan Kendra (GKVK) campus of the University of Agricultural Sciences, Bangalore, South India during March 2006. Synthetic samples of (2E)-9-oxodecenoic acid (9-ODA) and (2E)-10-hydroxydecenoic acid (10-HDA) were purchased from Phero Tech Inc. (Delta BC, Canada). At first, we performed attraction experiments to generate

dose response curves for each pheromone component. Altogether, we tested eight dosages of 9-ODA (0.25, 0.5, 0.75, 1.0, 1.25, 1.5, 1.75, and 2 mg/ml) and five dosages of 10-HDA (0.1, 0.3, 0.5, 0.75, and 1.0 mg/ml). Dilution of 9-ODA and 10-HDA were prepared with absolute ethanol according to the manufacture's protocol. We used cotton wicks as pheromone dispensers, which were impregnated with 1 ml of the respective pheromone solution. Baits were lifted about 3 m into the air with a helium-filled balloon at known drone congregation areas (Nagaraja and Brockmann unpubl.). Each pheromone dosage was tested in 3–5 attraction experiments, and presentation of pheromone components and dosages were randomized. In all experiments, drone attraction was measured as the number of drones counted in the vicinity of the pheromone bait during 10 min by using binoculars. In a second series of experiments (N=6), we compared directly the attractiveness of 9-ODA vs. 10-HDA (and as a control 10-HDA vs.10-HDA) using the concentrations that attracted the highest number of drones in the dose response experiments (1.5 mg/ml for 9-ODA; 0.5 mg/ml for 10-HDA). The two baits were attached to separate helium filled balloons flying in the air about 2.0 to 2.5 m apart. Finally, to confirm that our visual identification of *A. florea* drones was correct, we performed control experiments (N=6) in which we compared the number of drones visually observed with the number of drones caught when presenting 9-ODA (1.5 mg/ml) or 10-HDA (0.5 mg/ml). For this purpose, we attached pheromone impregnated cotton wicks to glue plates (Trubble gum®, Pest control India Ltd., Bangalore, India). Although we caught a significantly lower number of drones with the glue plates than we had visually observed, this control experiment confirmed that the visual identification of *A. florea* drones was correct (see Fig. 1d).

All experiments were done over a period of several days. Each experimental day we conducted 5–10 attraction experiments during the daily drone flight time from 11:30 to 14:00 h. Results of the dose response curves were analyzed statistically by using a one-way ANOVA and a Tukey *post hoc* test for pair wise comparisons, and results of the dual attraction experiments were analyzed by using a paired t-test.

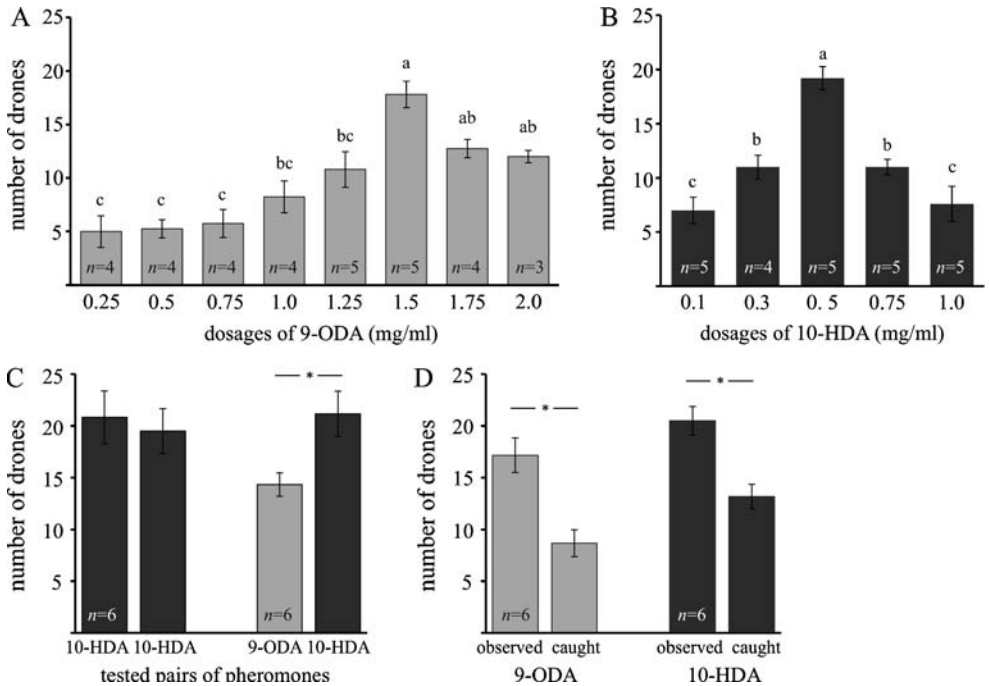

Fig. 1 **a** Dose-response curve for 9-ODA. **b** Dose-response curve for 10-HDA. 9-ODA attracted a maximum number of drones (17.8±1.2 SE) at dosages of 1.5–2.0 mg/ml (one-way ANOVA, df=7, F=12.481, P<0.001). In contrast, 10-HDA attracted a similar maximum number of drones (19±1.1 SE) at a dosage of 0.5 mg/ml (one-way ANOVA, df=4, F=17.295, P<0.001; Tukey test P<0.05). The highest dosage of 10-HDA led to a decrease in the number of drones attracted (Tukey test P<0.05). **c** Dual attraction experiment comparing attractiveness of 9-ODA (1.5 mg/ml) and 10-HDA (0.5 mg/ml). A lower dosage of 10-HDA attracted a significantly higher number of drones than a higher dosage of 9-ODA (paired t-test: t=−2.64, df=5, P two-tailed <0.05). **d** Single component attraction experiments comparing number of drones visually observed and caught. Number of drones, which were caught with the glue plate, were significantly lower that number of drones, which were visually observed close to the glue plates for both pheromone components (9-ODA: paired t-test: t=4.0194, df=10, P two-tailed <0.01; 10-HDA: paired t-test: t=4.0100, df=10, P two-tailed <0.01). Columns indicate average number of drones (±SE), grey columns are responses to 9-ODA, black columns are responses to 10-HDA; N indicates number of pheromone attraction experiments

Results and Discussion

Both mandibular gland components, 9-ODA and 10-HDA, attracted drones when presented alone. However, 10-HDA attracted a maximum number of drones at lower dosages than 9-ODA in the dose response curve experiments (Fig. 1a/b), and 10-HDA also attracted higher numbers of drones than 9-ODA when we directly compared the most attractive dosages of both components (Fig. 1c). On the basis of these results, we conclude that 10-HDA has to be viewed as the major sex pheromone component in *A. florea*. This finding correlates nicely with the fact that *A. florea* queens synthesize more 10-HDA than 9-ODA (Plettner et al. 1997; Keeling et al. 2000).

The result that 10-HDA and 9-ODA both attracted drones was surprising. Most, if not all, sex-pheromone studies so far have revealed two different types of male behavior; either males are attracted by the whole species-specific pheromone blend, or the detection of the major pheromone component is sufficient to elicit male search flights and mating. In the latter case, the minor pheromone components increase the behavioral response, but minor components are incapable of inducing mating flights (Linn et al. 1986).

There are two possible interpretations for our results. First, we cannot definitely exclude that the attraction of drones to 9-ODA might be an experimental artifact. 9-ODA is present in low amounts in the mandibular glands (Plettner et al. 1997; Keeling et al. 2000), whereas we used high dosages in our experiments. Thus, it is possible that off-range dosages of 9-ODA resulted in activation of 10-HDA sensitive olfactory sensory neurons or upstream neural circuits, which lead to an artificial activation of the behavioral response to 10-HDA. Unfortunately, nothing is known about the receptor and neural processing for 10-HDA and possible interactions with 9-ODA.

The other possible interpretation is that our findings demonstrate a species specific behavioral response of *A. florea* drones, namely that they are responding to both 10-HDA and 9-ODA when presented as single compounds. *A. florea* drones are unique in that they have a strongly reduced sex-pheromone olfactory subsystem compared to drones of other honey bee species (Brockmann and Brueckner 2001, 2003). For example, *A. florea* drones only have about 1,200 olfactory poreplate sensilla compared to 14,700 in *A. mellifera* drones (Brockmann and Brueckner 2003). These quantitative differences in the peripheral olfactory system are in part due to the considerable differences in body size among honey bee species. As there is a high selection pressure on the drones' capability to detect queens, the responses to both pheromone components might suggest that *A. florea* drones have evolved unique sensory and central neural mechanisms to overcome limitations of their body size.

Abstract This work was undertaken to identify floral compound(s) produced by honeysuckle flowers, *Lonicera japonica* (Thunberg), that mediate the attraction of New Zealand flower thrips *Thrips obscuratus* (Crawford). Volatiles were collected during the day and night and analyzed by gas chromatography–mass spectrometry (GC-MS) to determine their emission over these two periods. Nine compounds were identified in the headspace; the main compound was linalool, and the other compounds were germacrene D, *E*,*E*-*alpha*-farnesene, nerolidol, *cis*-jasmone, *cis*-3-hexenyl acetate, hexyl acetate, *cis*-hexenyl tiglate, and indole. There was a quantitative difference between day and night volatiles, with *cis*-3-hexenyl acetate, hexyl acetate, *cis*-hexenyl tiglate, and *cis*-jasmone emitted in higher amounts during the day compared to the night. When the compounds were tested individually in field trapping experiments, only *cis*-jasmone attracted New Zealand flower thrips in a significant number. In another field trapping experiment, *cis*-jasmone caught similar numbers of New Zealand flower thrips compared to a floral blend formulated to mimic the ratios of the compounds emitted during the day, while catch with the night-emitted floral blend was not significantly different from the control. Subsequently, two field trapping experiments were conducted to determine the optimal attraction dose for *cis*-jasmone, a range of 1–100 mg loaded onto a red rubber stopper was tested, and the highest catches were in traps baited with 100 mg loading. A higher range of 100–1000 mg loaded into polyethylene vials was tested, and the highest catch was in traps baited with 500 mg. In another experiment aimed at comparing the attraction efficacy of *cis*-jasmone with the two other known thrips attractants (ethyl nicotinate and *p*-anisaldehyde), ethyl nicotinate showed the highest trap catch followed by *cis*-jasmone. A smaller number of *Thrips tabaci* (Lindeman) was attracted to traps baited with *cis*-jasmone. These results suggest that *cis*-jasmone might act as a kairomone that mediates the attraction of New Zealand flower thrips to the flowers of the Japanese honeysuckle.

Keywords *Thrips obscuratus* · *Thrips tabaci* · Japanese honeysuckle · *cis*-Jasmone · Ethyl nicotinate · Kairomone · Thysanoptera · Thripidae

Introduction

Thrips generally are considered economically important pests in vegetable, fruit, floriculture, and plant production throughout the world. New Zealand flower thrips, *Thrips obscuratus* (Crawford) damages nectarines by feeding on fruitlets (McLaren 1992). Adult *T. obscuratus* also are attracted to ripening stone fruits, causing quarantine problems for export fruits (McLaren and Fraser 2002). Some thrips can transmit viral, fungal, and bacterial

pathogens to plants (Fermaud et al. 1994; Mound 2005). Insecticides are used to control thrips populations on nectarines (McLaren and Fraser 2000). The spray threshold is based on manual monitoring of thrips (McLaren and Fraser 2002). However, success with this technique is dependent on weather patterns, and it has associated sampling errors. Thus, the development of a practical synthetic attractant for *T. obscuratus* could help to determine accurately the level of thrips present and help reduce the use of insecticides or could be used directly in a control tactic, e.g., mass trapping or lure and kill (El-Sayed et al. 2006, 2009).

Many flower-dwelling thrips species feed on pollen and nectar of various plants, which suggests that they may play a role in the pollination of these species. The efficacy of thrips as pollinators has not been studied systematically. However, there is a tendency to consider thrips as pollen thieves rather than effective pollinators (Mound 2005). New Zealand flower thrips, *T. obscuratus*, has been found in the flowers, leaves, and fruits of many native and exotic plants in New Zealand (Norton 1984; Teulon and Penman 1990). It has been suggested that the attraction of thrips to host plants is regulated by both olfactory and visual cues (Teulon et al. 1999). Several plant volatile compounds attract different thrips species in the field (see El-Sayed 2008). For example, ethyl nicotinate attracts *T. obscuratus* in New Zealand (Penman et al. 1982; Teulon et al. 1993). *p*-Anisaldehyde is attractive to several species of flower-dwelling thrips in England (Kirk 1985) and *Frankliniella occidentalis* (Pergande) in New Zealand (Teulon et al. 1993). Methyl anthranilate attracts two species of flower-dwelling thrips species, *Thrips coloratus* (Schmutz) and *Thrips hawaiiensis* (Morgan) in Japan (Murai et al. 2000). Elucidation of the behavioral activity of these compounds has been based on field screening experiments of compounds, rather than on the classical experimental approach to identify behaviorally active compounds from natural sources, in this case flowers. Thus, the ecological basis for attraction of thrips to ethyl nicotinate or similar compounds is poorly understood.

The honeysuckles (family Caprifoliaceae) have pleasant-scented flowers on vines in the genus *Lonicera*. There are more than 190 species worldwide that are distributed mainly in the Northern Hemisphere. The volatile constituents of some species have been investigated due to their commercial potential in the perfume industry, e.g., *Lonicera periclymenum* L. (Lamparsky 1985), *Lonicera americana* (Koch) (Mookherjee et al. 1990), and *Lonicera japonica* (Thumb) (Schlotzhauer et al. 1996; Miyake et al. 1998). Although these studies showed quantitative and qualitative variation in volatiles among different species, the volatiles were represented mainly by linalool and linalool derivatives such as linalool oxides, aldehydes, *cis*-jasmone, *cis*-jasmone lactone, and sesquiterpenes. Various odor blends that were formulated based on the constituents of flowers of the Japanese honeysuckle were attractive to many lepidopteran species in field trapping experiments (Pair and Horvat 1997).

Our objective, within the context of applications of attractants for insect pest management and border biosecurity surveillance programs in New Zealand, is to develop environmentally friendly semiochemicals that can be used for monitoring and control of insect pests and new invasive species. Many thrips species are aggressively invasive and can cause serious damage in newly invaded habitats. Therefore, the development of attractants for thrips would allow for monitoring, detection, delimitation, and surveillance. We have observed the attraction of significant numbers of *T. obscuratus* to the flowers of the Japanese honeysuckle, although this plant is not native to New Zealand. This work was undertaken to identify the chemical signal. We report in this study the results of the chemical analysis of volatiles of the Japanese honeysuckle flowers that were attractive to New Zealand flower thrips. In addition, we report the results of several field trapping experiments aimed at the identification of compound(s) that mediate the attraction.

Materials and Methods

Chemicals Linalool (>95%), *cis*-3-hexenyl acetate (98%), hexyl acetate (99%), indole (99%), *cis*-hexenyl tiglate (97%), and nerolidol (98%) were obtained from Sigma-Aldrich Chemical Company (St Louis, MO, USA). *cis*-Jasmone (99.5%) was obtained from Bedoukian Research Inc. (Danbury, CT, USA). Ethyl nicotinate (>99%), *p*-anisaldehyde (98%), and germacrene D (60%) were obtained from Fluka, (Steinheim, Germany), Aldrich (Milwaukee, WI, USA), and R.C. Treatt and Co. Ltd (Suffolk, UK), respectively. *E,E-alpha*-farnesene (99%) was extracted from apples as described in Murray (1969). All chemicals were stored at −5°C until used.

Volatile Collection and Analysis Volatiles were collected from flowers in the field by using a dynamic headspace collection method followed by sorbent extraction. Collection was conducted under natural light conditions and ambient temperature and was conducted in two subsequent time periods to determine the emission during the day (0800–1900 hours) and night (1900 to 0800 hours). Intact flower heads with few leaves was housed in an oven bag (Pams oven bag, polyester, Auckland, New Zealand, i.d. 4.0 cm, 6.0 cm high). A charcoal-filtered air stream was pulled over the flowers, and the headspace was collected on an adsorbent trap containing 50 mg of Tenax-GR 35/60

(Alltech Associates Inc.) in a 15-mm long×10-mm diameter glass tube. Tenax traps were thermally conditioned at 200°C under a stream of nitrogen before use. Airflow in the headspace collection system was 2 l/min, and each collection session lasted for 24 h. Control samples were collected from the above system but without flowers to distinguish between floral compounds and ambient contaminants. After volatile collection, Tenax traps were transported to the lab and extracted with 1 ml of hexane (5×200 µl aliquots, *n*-hexane analaR BDH, Laboratory Supplies, Poole, England). Quantification of compounds was conducted by using external standard methods. Sample volumes were reduced to 10 µl at ambient temperature under a stream of argon. Samples were sealed and stored at −80°C until used. The concentrated extracts of headspace from flowers were analyzed with a Saturn 2200 GC-MS (Varian Inc., Walnut Creek, CA, USA). The GC-MS system was equipped with a 30 m×0.25 mm i.d.×0.25 µm, VF5-MS capillary column (Varian Inc.). Helium was used as carrier gas. Spectra were recorded at an ionization voltage of 70 eV over a mass range *m*/*z* of 20 to 499. The transfer line and the ion trap were held at 250°C and 180°C, respectively. Compounds were identified by comparing their mass spectra with the authentic standards and the NIST MS library, as well as coincidences for Kovats retention indices published in the literature (El-Sayed 2008). For analysis of liquid samples, the oven was programmed from 40°C (held for 2 min) to 240°C at 4°C/min. Samples were injected in splitless mode, and the temperature of the injector was maintained at 220°C.

Field Trapping Experiments

Testing Individual Compounds The relative attractiveness of the individual compounds identified in the headspace of (*cis*-3-hexenyl acetate, hexyl acetate, linalool, indole, *cis*-hexenyl tiglate, *cis*-jasmone, germacrene D, *E,E-alpha*-farnesene, and nerolidol) were tested in a peach orchard (Yumyeong) near Lincoln, Canterbury for attraction of *T. obscuratus* in January of 2006. Traps were deployed for 2 weeks. Ten milligrams of each compound dissolved in 200-µl hexane were loaded into the well of 8-mm diameter red rubber septa (Thomas Scientific Inc., Philadelphia, PA, USA), and the solvent was allowed to evaporate in a fume hood. Septa were stored at −20°C until use. Lures were replaced after 5 days around the middle of the test period. Red delta traps made of plastic corflute contained a white adhesive-coated panel (Suckling and Shaw 1992) baited with individual compounds and were placed in five rows with three replicates of each treatment. Red delta traps were used because they are less attractive to thrips, as well as non-target species including bees and bumble bees compared to white traps. Traps were positioned 1.7 m above the ground in each trap tree and were spaced 10 m apart in each row. Each treatment was assigned randomly to a trap tree within each row of trees. Septa were placed in the center of the white sticky base lying on the sticky surface. Sticky bases were removed weekly during the experimental period for later counting. Stereomicroscopy was used to aid the identification and counting of thrips caught on the sticky bases. A trap with a blank lure was used as control.

Testing blends of compounds In subsequent experiment, the relative attractiveness of two floral blends that reflected day and night floral compounds were formulated and tested for 2 weeks in January 2009 by using a randomized complete block design. Lures were replaced after 5 days around the middle of the test period. Based on the result of the first experiment, *cis*-jasmone was used as a positive control, and a trap baited a blank lure was used as a negative control. The loadings of two floral blends and *cis*-jasmone are given in Table 2. Floral odors tested were released using 12-mm diameter polyethylene vials (La Packaging, Yorba Linda, CA, USA). The polyethylene vials containing the odor blend were stored at −20°C until use. The experimental design and protocol were identical to the above experiment.

Dose–Response Experiments The effect of three doses of *cis*-jasmone (1, 10, and 100 mg) loaded into red rubber septa on the number of *T. obscuratus* captured in *cis*-jasmone-baited traps was assessed in a peach orchard (Yumyeong) near Lincoln, Canterbury, for 2 weeks in February 2006 by using a randomized complete block design. *cis*-Jasmone was loaded into red rubber septa. A septa was loaded with 1, 10, or 100 mg of *cis*-jasmone dissolved in 200 µl hexane, and the solvent was allowed to evaporate in a fume hood. The septa were stored at −20°C until use. Traps were placed in five rows with five replications for each treatment at 15 m spacing between treatment rows. Septa were placed in the center of the white sticky base lying on the sticky surface. One of each of the four treatments was randomly assigned to a trap tree within each row of trees. In a separate experiment, with Yumyeong peaches separated by shelter belts from the first dose–response test, the effects of higher doses of *cis*-jasmone (100, 500, and 1,000 mg) loaded into polyethylene vials were assessed for 2 weeks in February 2006. The three higher doses 100, 500, and 1000 mg of *cis*-jasmone were loaded directly into polyethylene vials. The experimental design and protocol in the second experiment were identical to that of the first dose–response experiment. In both experiments, a trap with a blank lure was used as control.

Table 1 Mean amounts (ng)± SE of volatiles identified in the headspace of the Japanese honeysuckle flowers, *Lonicera japonica*

Compound	[a]Kovats	Amount (ng)		*P* value
		Day	Night	
cis-3-hexenyl acetate	1006	6.8±1.13	2.3±0.38	0.01
Hexyl acetate	1011	2.6±0.49	1.2±0.27	0.04
Linalool	1103	108.6±23.8	101.4±18.34	0.81
Indole	1288	1.4±0.56	0.5±0.17	0.14
cis-3-hexenyl tiglate	1327	1.5±0.28	0.5±0.11	0.01
cis-Jasmone	1393	6.9±1.30	2.7±0.38	0.01
Germacrene D	1480	21.4±4.80	31.6±5.24	0.23
E,E-alpha-farnesene	1489	17.1±4.90	11.3±2.30	0.31
Nerolidol	1093	14.9±4.58	7.7±2.54	0.23

Compound identities were confirmed by comparison of MS and retention time of authentic standards and the published kovats value

[a] Kovats index on a DB-5 column

Relative Attractiveness of cis-Jasmone vs. Known Thrips Attractants The relative attractiveness of *cis*-jasmone, ethyl nicotinate, and *p*-anisaldehyde was tested in field trapping experiments in peach orchards for 2 weeks in early March 2006 in Canterbury. Five hundred milligrams each of *cis*-jasmone, ethyl nicotinate, and *p*-anisaldehyde were loaded directly into 12-mm-diameter polyethylene vials. A trap with a blank lure was used as a control. A randomized complete block experimental design was used, with a layout and experimental design similar to that described above for the dose response experiments.

Data Analysis

The variance of the mean quantity of each compound emitted by honeysuckle flowers during the day and night or the mean captures obtained with each treatment was stabilized by using the $\sqrt{x}$ or $\sqrt{(x+1)}$ transformation, respectively. The significance in the quantity of compounds emitted or the treatment effect in the field experiments were tested by using analysis of variance (SAS Institute Inc. 1998). Significantly different means were identified by using Fisher's protected least significant difference.

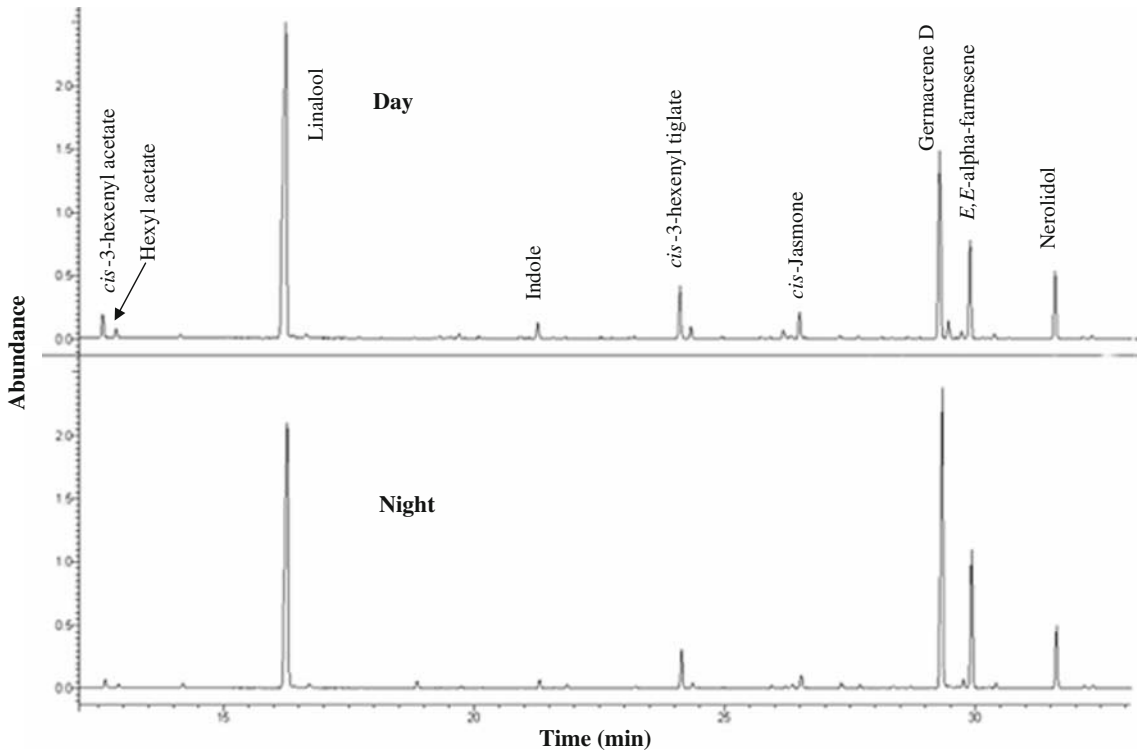

Fig. 1 GC traces of extracts of headspace volatile chemicals collected from of the Japanese honeysuckle flowers, *Lonicera japonica* during two periods (day and night)

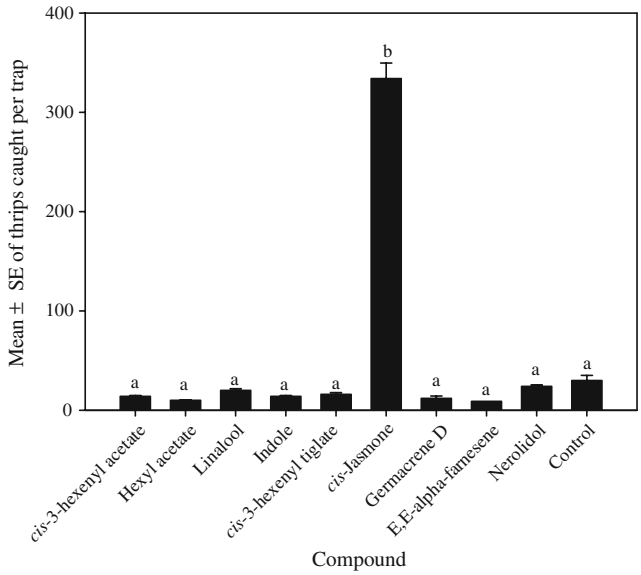

Fig. 2 Mean catch±SE of New Zealand flower thrips, *Thrips obscuratus* in traps baited with compounds (10 mg each) identified in the headspace of the Japanese honeysuckle flowers, *Lonicera japonica*. *Letters on columns* indicate significant differences ($P<0.05$)

Results

Headspace Chemical analyses of the headspace of the honeysuckle flowers from the dynamic headspace collection method are given in Table 1. Nine compounds were identified (Fig. 1) with the main compound, linalool, contributing up to 60% and 64% of total headspace volatiles emitted during the day and the night, respectively (Table 1). The other compounds were germacrene D, *E,E-alpha*-farnesene, nerolidol, *cis*-jasmone, *cis*-3-hexenyl acetate, hexyl acetate, *cis*-hexenyl tiglate, and indole. There was a quantitative difference between day and night volatiles, with *cis*-3-hexenyl acetate (treatment $F_{1,8}=14.22$, $P>0.01$), hexyl acetate (treatment $F_{1,8}=6.4$, $P>0.01$), *cis*-hexenyl tiglate (treatment $F_{1,8}=10.6$, $P>0.01$), and *cis*-jasmone (treatment $F_{1,8}=9.7$, $P>0.01$) emitted in higher amounts during the day.

Testing Individual Compounds and Blends of Compounds When the compounds were tested individually, only *cis*-jasmone attracted New Zealand flower thrips in significant numbers compared to control (treatment, $F_{9,20}=23.5$, $P<0.001$, Fig. 2). The catch in traps baited with floral blend volatile mimics emitted during the day and with *cis*-jasmone was significantly higher than control (Table 2). The catch in traps baited with day blend volatiles was similar to *cis*-jasmone alone. However, the catch in traps baited with blend volatiles emitted during the night was not different from the catch in control traps (Table 2).

Dose–Response Experiments The amount of *cis*-jasmone loaded onto red rubber septa affected the number of *T. obscuratus* captured in the two experiments (treatment, $F_{3,16}=15.1$, $P<0.05$ for the lower dose; treatment, $F_{3,16}=8.94$, $P<0.01$ for the higher dose). In the experiment, the greatest number of thrips was captured at the 100 mg loading (Fig. 3A). There was no difference in the mean numbers of thrips captured using the 0, 1, and 10 mg loading, while increasing the loading from 10 to 100 mg resulted in a significant increase in the mean number of *T. obscuratus* captured (Fig. 3A). In the second dose–response test, the greatest number of thrips captured was at the 500 mg loading (Fig. 3B). Increasing the loading from 100 to 1,000 mg resulted in a significant increase in the mean number of *T. obscuratus* (Fig. 3B).

Table 2 Mean±SD of catch of New Zealand flower thrips, *Thrips obscuratus* in traps baited with two floral odor blends represent odor emission in two periods (day and night) from the Japanese honeysuckle flowers, *Lonicera japonica*, and *cis*-jasmone

Chemical	Blend (mg)			Control
	Day	Night	One-component	
cis-3-hexenyl acetate	8	3	10	
Hexyl acetate	2	2		
Linalool	118	127		
Indole	2	1		
cis-3-hexenyl tiglate	2	1		
cis-Jasmone	10	2		
Germacrene D	24	40		
E,E-alpha-farnesene	18	14		
Nerolidol	16	10		
Mean catch of *T. obscuratus**	386 a	142 ab	412 a	105 b
±SE	55.6	7.2	84.5	23.1

Mean catch followed by the same letter are not significantly different ($P>0.05$)

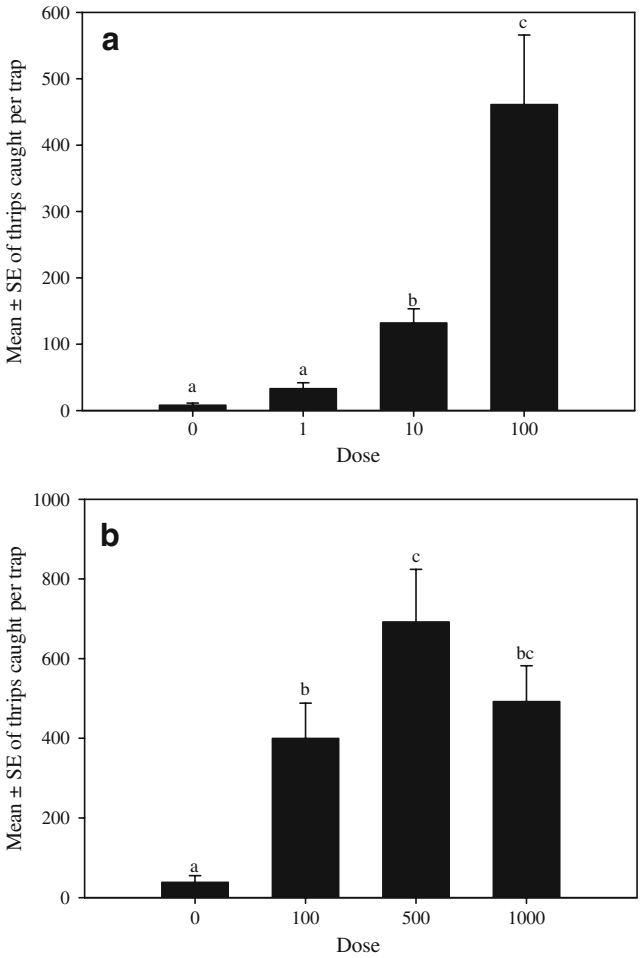

Fig. 3 Mean catch±SE of New Zealand flower thrips, *Thrips obscuratus* in red delta traps baited with various dosages of *cis*-jasmone: **A** 0, 1, 10, and 100 mg loaded into red rubber septa; **B** 0, 100, 500, and 1000 mg loaded into polyethylene vials. *Letters on columns* indicate significant differences ($P<0.05$)

Relative Attractiveness of cis-Jasmone vs. Known Attractants The relative attractiveness of *cis*-jasmone, ethyl nicotinate, and *p*-anisaldehyde to *T. obscuratus* is shown in Fig. 4. More thrips were caught in red delta traps baited with ethyl nicotinate than *cis*-jasmone or *p*-anisaldehyde (Treatment $F_{3,16}=24.6$, $P<0.01$). *Cis*-jasmone attracted more thrips than *p*-anisaldehyde and control traps. There was no significant difference between attraction to *p*-anisaldehyde and control trap.

Discussion

Although nine compounds were positively identified in the headspace of the honeysuckle flowers, other compounds were present in trace amounts. The number of compounds emitted from flowers was less than the compounds identified in the flower extracts (Schlotzhauer et al. 1996). Except for *cis*-3-hexenyl acetate, all compounds found in the headspace were present in the flower extracts (Schlotzhauer et al. 1996). There was similarity between the ratios of the compounds found in the flower headspace and the ratios found in steam distilled floral extracts. Linalool was the main compound in both the extracts and the headspace samples, while germacrene D was the second main component. Miyake et al. (1998) tentatively identified six compounds in the flower headspace of Japanese honeysuckle, with linalool as the main one and others including indole, germacrene D, nerolidol, *cis*-hexenyl tiglate, and decanal present in much lower amounts. *E,E-alpha*-farnesene was not reported, while it was present in our headspace samples. Miyake et al. (1998) showed that there is a rhythmic emission of volatiles from honeysuckle flowers where both linalool and germacrene D are emitted in large quantities around midnight. In contrast, in our analysis, there was no difference in the emission of linalool and germacrene D between the two collection periods. This difference could be due to the sampling method; we estimated the emission during 12-h periods, while they sampled at 3-h intervals.

When the compounds in the headspace were tested individually, only *cis*-jasmone attracted thrips in significant numbers. A floral blend formulated to mimic the odor produced by honeysuckle flowers during the day attracted similar numbers of thrips as *cis*-jasmone alone, while the attraction to the floral blend formulated to mimic the odor produced by flowers during the night was similar to the control. This suggests that *cis*-jasmone is the only active compound in the floral blends tested. Mookherjee et al.

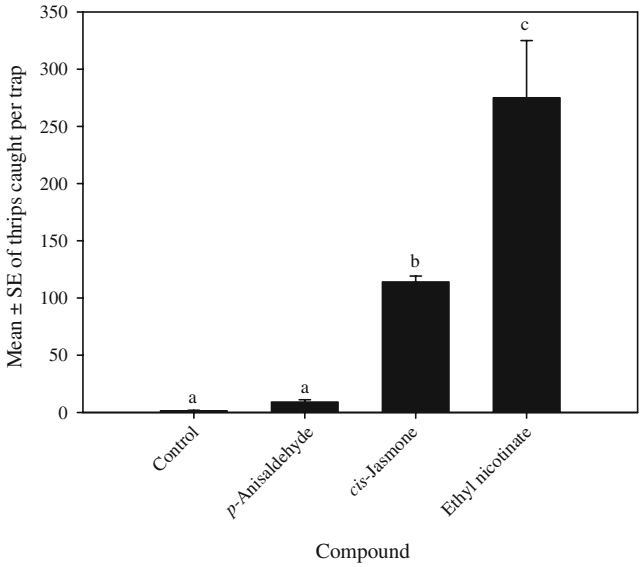

Fig. 4 Mean catch±SE of New Zealand flower thrips, *Thrips obscuratus* in red delta traps baited with 500 mg of *cis*-jasmone, ethyl nicotinate, and *p*-anisaldehyde. *Letters on columns* indicates difference ($P<0.05$)

(1990) showed that both *cis*-jasmone and indole levels maximize during the day in the flower of *L. americana*. In our analysis, *cis*-3-hexenyl acetate, hexyl acetate, *cis*-3-hexenyl tiglate, and *cis*-jasmone levels all maximized during the day with the latter likely attracting the diurnally active New Zealand flower thrips (McLaren and Fraser 2002).

cis-Jasmone attracted New Zealand flower thrips in the field, and its attraction can be considered moderate compared to ethyl nicotinate. Ethyl nicotinate was reported as a potent attractant for New Zealand flower thrips by Penman et al. (1982). *p*-Anisaldehyde, another known thrips attractant (Kirk 1985), was not attractive to *T. obscuratus* in our study. In contrast, *p*-anisaldehyde was attractive to the Western flower thrips, *F. occidentalis* (Kirk 1985; Teulon et al. 1993). The behavioral basis of attraction of New Zealand flower thrips to ethyl nicotinate is not clearly understood and needs to be resolved. It is known that both olfactory and visual cues are important components in host-finding behavior of New Zealand flower thrips (Teulon et al. 1993), and it is likely that both senses are used for host location. *T. obscuratus* is an indigenous species of New Zealand and has a wide host range (Norton 1984; Teulon and Penman 1990), being attracted to flowers and ripe stone fruits such as peaches, which suggest that odors are an important cue for host location. Thus, *cis*-jasmone might act as a kairomone used by thrips as a foraging cue.

cis-Jasmone is produced by damaged plants, and there is evidence that it plays a role in plant defense against herbivores (Birkett et al. 2000; Bruce et al. 2003). It was found repellent to the lettuce aphid, *Nasonovia ribisnigri* (Mosh) in olfactometer bioassays and to the damson-hop aphid, *Phorodon humuli* (Schrank) in the field (Birkett et al. 2000). It was found also to be repellent to the alatae of the grain aphid, *Sitobion avenae* (Fabricius) in an olfactometer bioassay (Bruce et al. 2003). Application of *cis*-jasmone on wheat reduced the population of cereal and grain aphids, *S. avenae*, and the plant was less susceptible to attack by aphids (Birkett et al. 2000 and Bruce et al. 2003). Additionally, *cis*-jasmone was attractive to the predacious seven-spot ladybird, *Coccinella septempunctata* L., in an olfactometer, and to the aphid parasitoid, *Aphidius ervi* (Haliday), in wind tunnel studies (Birkett et al. 2000). *cis*-Jasmone also was attractive to the Japanese beetle, *Popillia japonica* (Newman) in field trapping experiments (Loughrin et al. 1998). It seems unlikely that the attraction of New Zealand flower thrips, *T. obscuratus* to *cis*-jasmone is related to plant defense mechanisms, as in this case, *cis*-jasmone is released by undamaged flowers, whereas in other plant species such as cotton or potato, it is released more after damage.

cis-Jasmone has been reported in the floral odor of many plant species (see http://www.pherobase.com/database/floral-compounds/floral-taxa-compounds-detail-cis-jasmone.php). Examples include the kiwifruit flower, *Actinidia chinensis* (Planch.) (Tatsuka et al. 1990), which is usually visited by *T. obscuratus* and leads to infection by the botrytis bunch rot, *Botrytis cinerea* (Fermaud et al. 1994). *cis*-Jasmone also has been found in the flowers of *Nicotiana tabacum* (L.) (Solanaceae) (Loughrin et al. 1990). The onion thrips, *Thrips tabaci* (Lindeman) is a cosmopolitan species and is known to attack a wide range of host plants including tobacco *N. tabacum*. Interestingly, we have caught a smaller number of *T. tabaci* in traps baited with *cis*-jasmone in the peach orchard. The occurrence of *cis*-jasmone in the flowers of *N. tabacum* and the attraction of *T. tabaci* to *cis*-jasmone might support our view on the behavioral mechanism that underlies attraction of thrips to *cis*-jasmone as a response to host volatile compounds. The finding that it attracted *T. tabaci* in a peach orchard suggests the need for further investigation of the attraction of *cis*-jasmone to *T. tabaci* in regard to host plant selection (i.e., onion, tomatoes, and tobacco). Although *cis*-jasmone has been identified in the headspace of flowers of several plants, we did not find evidence in the literature to indicate that this compound attracts pollinator insects.

Both odor and color play a role in attraction of thrips to host plants (Teulon et al. 1999), and New Zealand flower thrips show a preference for white over any other color (McLaren 1995). It would be interesting to study the interaction between different colors and *cis*-jasmone in the attraction of *T. obscuratus*. *cis*-Jasmone and ethyl nicotinate have attracted *T. obscuratus*, so it would also be interesting to study the interaction between the two compounds in a binary blend. Comparing the potency of both compounds on thrips attraction over the entire flight season would also be valuable. Although *cis*-jasmone showed moderate activity compared to ethyl nicotinate, it is more environmentally friendly and less hazardous to human and animal health than ethyl nicotinate, which has hazardous properties (Fisher Scientific Inc. 2007). Our researchers have to wear masks during the deployment of ethyl nicotinate lures. This advantage makes a *cis*-jasmone lure more desirable for *T. obscuratus* population monitoring.

Received: 9 January 2009 / Revised: 27 April 2009 / Accepted: 13 May 2009 / Published online: 22 May 2009

Abstract The effects of moderately elevated ozone (ca. 35 ppb) on the growth and secondary chemistry of the leaves of two soil-grown Finnish hybrid aspen (*Populus tremula* L. x *Populus tremuloides* Michx.) clones with different ozone sensitivities were studied at an open-air exposure field in Kuopio, Finland. Stomatal conductance, photosynthetic rate, and chlorophyll fluorescence were measured during the third growing season. Foliar phenolic concentrations, ergosterol concentration of fine roots, and final dry mass of the trees were determined at the end of the third growing season. Elevated ozone increased the ectomycorrhizal status of the fine roots but had no effect on gas exchange or on the final biomass of either of the clones, indicating equal sensitivity to ozone and no effect of elevated ozone on the intraspecific competitive ability of the clones after three growing seasons. However, in agreement with the data from potted plants of the same clones after two growing seasons, significant differences between the clones were found in all parameters measured. A negative correlation between growth and high concentrations of foliar phenolics indicated that allocation to secondary chemistry also was costly in terms of growth under high resource availability.

Introduction

Populus species are fast-growing pioneer trees of the temperate forests and are used in the wood industry for the production of paper, plywood, and matches (Zsuffa et al. 1996). They are also good candidates for biomass production for energy, as well as for phytoremediation of heavy metal-polluted soils (Hermle et al. 2007; Christersson 2008). Hybrid aspen, which is a cross between European aspen (*Populus tremula* L.) and North American trembling aspen (*Populus tremuloides* Michx.), has shown superior growth and wood quality compared with native European aspen (Yu et al. 2001). Plantations of selected hybrid aspen clones have been established in Sweden, Estonia, and Finland for pulpwood and bioenergy production

(Rytter and Stener 2005; Tullus et al. 2007; Luoranen et al. 2006 and references therein). However, there is large clonal variation in hybrid aspen in response to environmental conditions (Oksanen et al. 2001; Yu and Pulkkinen 2003; Häikiö et al. 2007, 2008). In a changing climate, it is important to find stress-tolerant genotypes for large-scale plantations.

Ground-level atmospheric ozone (O_3) remains a global air pollution problem despite precursor (NOx) emission reduction measures in industrialized countries during the last decades. Despite the reductions in short-term peak levels of ozone, background ozone concentrations have increased by 2 ppb per decade to the present concentrations of 35–40 ppb in the Northern Hemisphere (The Royal Society 2008). *Populus* species have been reported to be one of the most sensitive species to elevated tropospheric ozone concentrations (Wittig et al. 2007). Significant reductions in total biomass were observed in a trembling aspen stand after 7 years of exposure to elevated ozone (King et al. 2005). We previously studied the responses of eight hybrid aspen clones and two native aspen clones in an open-field experiment with moderately elevated ozone concentrations (ca. 35 ppb). We found a significant genotype x ozone interaction in the performance of potted saplings of hybrid aspen after two growing seasons, with elevated ozone reducing the growth of four of the clones and having no effect or enhancing the growth of the other four clones after two growing seasons (Häikiö et al. 2007).

In this study, parallel to an experiment with potted saplings of the same hybrid aspen clones, saplings of one moderately ozone-tolerant and one moderately ozone-sensitive clone (Oksanen et al. 2001; Häikiö et al. 2007) were planted in soil to study the effects of elevated ozone concentrations on their competitive ability. Exposure to elevated ozone concentrations was reported to cause changes in the intraspecific competitive ability of sensitive or tolerant aspen genotypes, with poor competitors having an added disadvantage under elevated ozone (Kubiske et al. 2007; Zak et al. 2007). We hypothesized that belowground competition together with long-term elevated ozone exposure would increase the competitive ability of the more ozone-tolerant clone relative to the more ozone-sensitive clone. We also hypothesized that the higher resource (nutrient) availability of the soil-grown trees would result in lower foliar phenolic concentrations compared with the potted trees, as reported by Kleiner et al. (1998) and Osier and Lindroth (2001). Phenolic concentrations were unaffected by nitrogen fertilization in our earlier study with potted hybrid aspen saplings (Häikiö et al. 2008). We also wanted to study the differences between the clones in the foliar phenolic composition observed earlier (Häikiö et al. 2008) in more detail.

Methods and Materials

Plant Material The material of the experiment consisted of two hybrid aspen (*Populus tremula x P. tremuloides*) clones included in the Finnish hybrid aspen breeding programme. Clones 55 and 110 were produced originally in 1952 and 1962, respectively, by crossing female *P. tremula* from Southern Finland with male *P. tremuloides* from Canada, and selected in 1998 from progeny trials in Anjalankoski (60°45′ N, 26°59′ E) and Lapinjärvi (60°37′ N, 26°11′ E), respectively. The clones were produced by micropropagation at the Finnish Forest Research Institute Haapastensyrjä Breeding Station and planted in soil as 1-yr-old saplings (30–40 cm in height) in June–July 2002 on an open-air exposure field at Kuopio University Research Garden (62° 53′ N, 27°37′ E). The soil was a former agricultural field and it was tilled, fertilized, and mixed with forest peat and sand before planting. Twenty four plants per clone were planted with 50 cm spacing on each of four replicate ozone exposure plots and four control plots. Saplings were grown under a natural microclimate without watering or fertilization except for one nitrogen fertilization in 2003 to level off differences in soil nitrogen status among the plots. Soil water content during the growing season was measured with a ThetaProbe ML2 (Delta-T Devices Ltd., Cambridge, UK). The volumetric soil water content varied between 0.30 m^3m^{-3} and 0.40 m^3m^{-3} during the growing season 2004 (data not shown). The biggest broad-leaved weeds were removed once in a growing season. For all samplings and measurements, first-flush leaves from primordia formed during the previous growing season were used.

Ozone Exposure A free-air ozone exposure system with four elevated ozone plots and four control plots was used to manipulate experimentally the ozone concentrations in the field. Ozone was produced from pure oxygen by an ozone generator (G21, Pacific Zone Technology Inc., Brentwood, CA, USA). It was released into exposure rings through vertical vent pipes from the upwind direction. Ozone fumigation was run 24 h day^{-1} in 2002–2003, and between 08:00–22:00 in 2004, and it was turned off during heavy rain, dew, low or high wind velocities, and when the ambient ozone concentration was less than 10 ppb. The fumigation was run from bud opening in May until leaf fall in October. Ozone concentrations were monitored at the canopy level in the center of the ozone exposure rings with two Dasibi 1008-RS ozone analyzers (Dasibi Environmental Corp., Glendale, CA, USA) and on the control rings with an Environnement S.A. O342M ozone analyzer (Environnement S.A., Poissy, France), which were intercalibrated. The realized ozone enhancement during the growing seasons 2002–2004 was 1.3–1.4 times the ambient

ozone concentration (approximately 35 ppb). Cumulative ozone exposures AOT00 and AOT40, together with the mean monthly temperatures for the growing seasons in 2002–2004, are given in Table 1. The mean daily ozone concentrations in 2002–2004 are presented in Fig. 1.

Leaf Nitrogen Concentration Samples for total leaf organic nitrogen concentration were collected in mid-June, 2004, and analyzed by the standard Kjeldahl method (Allen 1989). From each plot, 2 leaves from 5 trees per clone were taken and pooled for analysis, i.e., one sample per clone per plot (altogether 16 samples).

Chlorophyll Fluorescence, Stomatal Conductance, and Net Photosynthesis One sun leaf from 4 trees per clone per plot (altogether 64 leaves) in the middle of the canopy was selected and used in all fluorescence, conductance, and photosynthesis measurements. Measurements were made in dry, sunny weather between 10:00 and 16:00 h.

Chlorophyll fluorescence was measured four times in 2004 (June 23, July 12, July 27, and August 5) with a portable pulse-modulated FMS2 fluorometer (Hansatech Instruments Ltd., Norfolk, UK). After a 30-min dark adaptation, dark-adapted minimal fluorescence (F_0) was measured. A saturating pulse (0.7 s) of light (about 11 000 μmol m^{-2} s^{-1}) was applied, and maximal photochemical efficiency of PSII (F_v/F_m, where F_m is dark-adapted maximal fluorescence and F_v is F_m–F_0), was recorded.

Stomatal conductance (g_s) was measured four times in 2004 (June 17, July 19, July 22, and August 3) with LI-1600 Steady State Porometer (LI-COR Inc., NE, USA).

Leaf-level net photosynthesis (A_{sat}) was measured 5 times during the growing season 2004 (July 2, July 8, July 21, August 4, and August 17) using a CI-510 Portable Photosynthesis System (CID Inc., Vancouver, WA, USA). Photosynthesis was measured in saturating light (>1 000 μmol m^{-2} $s^{-}1$) after determining the light-saturation point of photosynthesis. In the last three measurements, a light attachment module (CI-510LA) was used because of unfavorable weather conditions.

Foliar Phenolics Samples for phenolic analyses were collected on August 4–9, 2004. Three leaves were taken and pooled from 3 trees per clone per plot (altogether 48 samples). The leaves were dried at room temperature with

Table 1 Ozone exposure and mean monthly temperatures during the growing seasons 2002–2004

		2002	2003	2004
AOT00 (ppm.h)	ambient O_3	60.8	76.5	46.3
	elevated O_3	77.4	116.3	65.4
AOT40 (ppm.h)	ambient O_3	0.5	1.3	0.9
	elevated O_3	16.6	17.7	10.4
mean O_3 exposure (ppb)	ambient O_3	36		
	elevated O_3	26		
mean temperature (°C)	May	–	12.3	9.0
	June	16.7	12.4	13.1
	July	19.2	20.2	16.9
	August	17.4	13.8	15.5
	September	10.0	10.2	11.5

Ozone exposure is expressed as accumulated over threshold of 0 ppb (AOT00) or 40 ppb (AOT40) for 24 h day^{-1}. Mean monthly temperatures were calculated from 24 h daily mean values

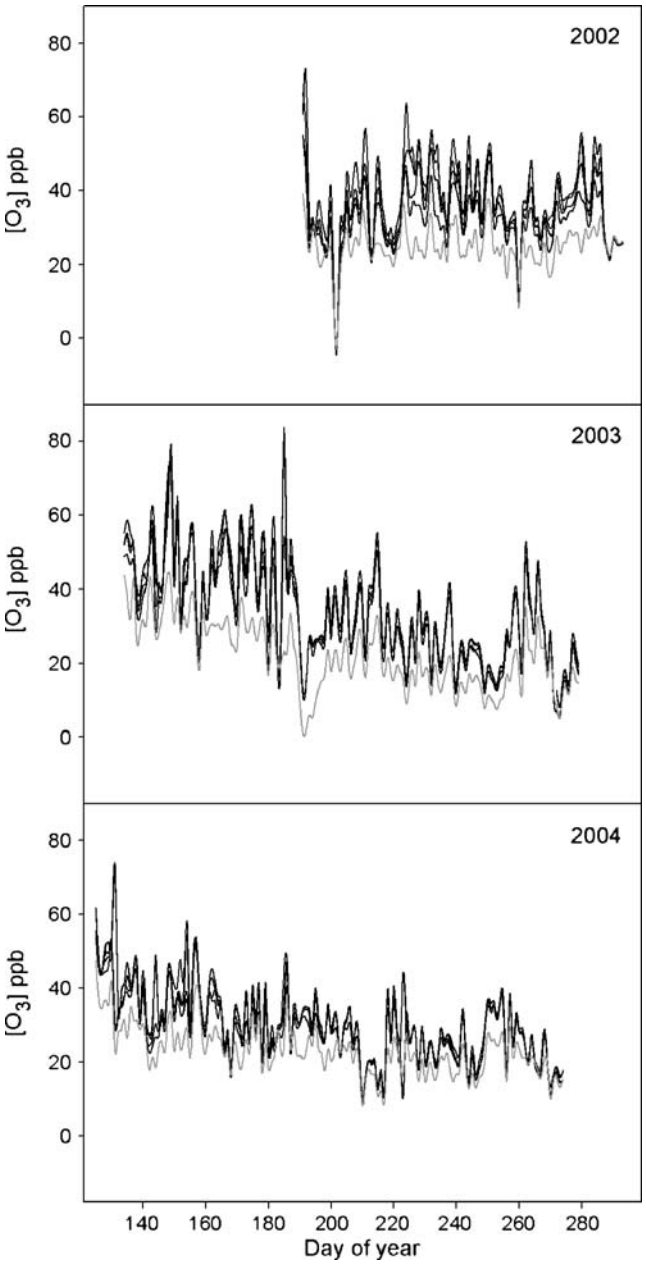

Fig. 1 Daily mean ozone concentrations (ppb) for 24 h day^{-1} in 2002–2004. *Black lines* = elevated ozone, *gray line* = ambient ozone

RH < 20%, and were ground to powder without the petiole and midvein. Dry samples were stored at −20°C until analyses. For extraction, 8 mg of leaf sample were mixed with 600 ml of ice-cold methanol. The sample was vortexed, left to stand on ice for 15 min, and centrifuged (3 min, 13 000 rpm). The supernatant was collected, and the residue was extracted another four times. Supernatants were combined, the methanol was evaporated under nitrogen flow, and the dry sample was stored at −20°C.

For HPLC analysis, the sample was redissolved in 600 ml methanol:H_2O (1:1). Phenolics were analyzed by using HPLC (HP 1050 Series HPLC, Palo Alto, CA, USA) with a binary pump, an autosampler, and a photo diode array detector, combined with ChemStation for LC 3D (Rev. A.09.01; Agilent Technologies). A 3 µm HP Hypersil ODS column (60×4.6 mm ID) was used. Eluents were aqueous 1.5% tetrahydrofuran + 0.25% *o*-phosphoric acid (=A) and 100% methanol (=B). The following gradient was used: 0–5 min: 100% A, 5–10 min 85% A, 10–20 min 70% A, 20–47 min 50% A, 47–65 min 100% B. The flow rate was 2 ml min^{-1}, and the injection volume was 15 µl. HPLC runs were monitored at 220 and 320 nm. HPLC-chromatograms from the HPLC analysis showed the main peaks at 220 nm (salicylates and catechins) and 320 nm (flavonoids) (Fig. 2). Initial identification of compounds was based on comparisons of retention times and spectral characteristics. Commercial standards were used for quantification of the identified compounds: (+)-catechin (Aldrich Chemicals Co, Milwaukee, WI, USA) for (+)-catechin and gallocatechin; chlorogenic acid (Aldrich) for neochlorogenic acid and chlorogenic acid; kaempferol 3-glucoside (Extrasynthèse, Genay, France) for kaempferol derivatives; quercetin 3-galactoside (Apin Chemicals Ltd, Abingdon, UK) for quercetin derivatives; myricetin 3-rhamnoside (Apin Chemicals Ltd.) for myricetin derivatives, isorhamnetin 3-glucoside (Apin Chemicals Ltd.) for the isorhamnetin derivative; salicin (Sigma, Steinheim, Germany); and tremulacin (Roth, Karlsruhe, Germany). Salicortin, disalicortin, and tremuloidin were based on purified standards obtained from prof. Beat Meier, ETH, Zürich, Switzerland (salicortin was used as a standard for both salicortin and disalicortin). Soluble condensed tannins were determined from an aliquot of the HPLC extract using the acid-butanol test (Porter et al. 1986). Tannin purified from hybrid aspen leaves was used as a standard. The mean value of three samples per clone per plot was used as a statistical unit.

For verifying the identification of compounds, one sample of each clone was analyzed by HPLC/API-ES mass spectrometry (HP 1100 Series LC/MSD, Hewlett-Packard, Palo Alto, CA, USA). A 3 µm HP Hypersil ODS column (100×2.1 mm ID) was used. Eluents were aqueous 1.5% tetrahydrofuran + 0.25% acetic acid (=A) and 100% methanol (=B). The following gradient was used: 0–5 min: 100% A, 5–10 min: 85% A, 10–20 min: 70% A, 20–60 min: 50% A, 60–62 min: 100% B. The injection volume was 5 µl, and flow rate was 0.4 ml min^{-1}. For electrospray ionization, the capillary was set at 4000 V, the nebulizer pressure was 30 psig, the drying gas temperature was 350°C with a flow of 12 l min^{-1}, and the fragmentation voltage was set at 80 V. Four novel phenolics were indentified: quercetin 3-arabinoglucoside (619 M+23; 465, M+1, quercetin-glucoside; 303, M+1, quercetin), quercetin 3-arabinoglucuronide (633, M+23; 479, M+1, quercetin-glucuronide; 303, M+1, quercetin), kaempferol 3-arabinoglucoside (603, M+23; 287, M+1, kaempferol), and isorhamnetin 3-glucuronide (493, M+21; 515, M+23; 317, M+1, isorhamnetin).

Biomass Analysis Twelve plants per clone per plot were harvested during August 20–24, 2004. Trees were measured for height, base diameter, and diameter at breast height (1.3 m). Plant parts were separated into leaves, stems (with branches), and roots, and the roots were washed. Only the main part of the coarse roots was collected from 3 trees per clone per plot. Plant parts were dried to constant weight at 60°C, and the dry weights of leaves, stems, and coarse roots were measured. Total leaf area was calculated from the dry weight of the leaves, after determination of dry weight/area ratio for each clone from sample leaves (3 leaves per clone per plot). The mean value of 12 plants per clone on each plot was used as a statistical unit, except for coarse roots, where the mean value of 3 plants per clone per plot was used. In addition, samples were collected to determine differences in fine root biomass between ozone and control plots since it was not possible to separate the fine roots of the two clones. Four samples per plot with a diameter of 5.3 cm and depth of 15 cm were cored in the middle of the plots between the trees in September 8, 2004. The samples were stored at −20°C until washed. Roots were separated into fine roots (< 2 mm diam) and coarse roots, dried to constant weight, and the dry weight was measured. The mean value of 4 samples per plot was used as a statistical unit.

Mycorrhizal Root Status The mycorrhizal status of the fine roots was determined by ergosterol analysis as described in Salmanowicz and Nylund (1988) and later modified by Nylund and Wallander (1992) and Markkola (1996). Briefly, four samples per plot with a diameter of 5.3 cm and depth of 11 cm were cored from the soil in the middle of the trees between August 26 and September 9, 2004. The fine roots were washed immediately after coring and stored at −80°C until analyses. The frozen fine roots were vacuum-dried and ground to powder in liquid nitrogen. Twenty five to 50 mg of the sample were mixed with 10 ml of 95% ethanol. The sample was shaken for 2 min, and 2 ml of 60% KOH was added for saponification. After incubation in a 95°C water bath for 45 min, the supernatant

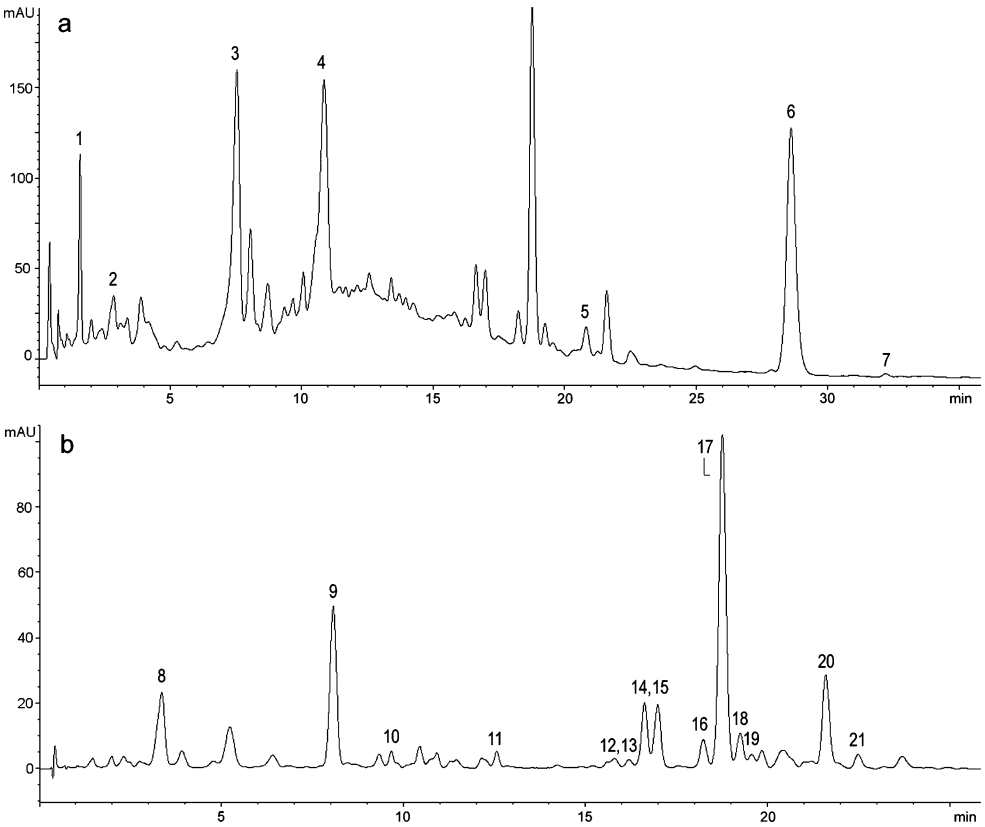

Fig. 2 HPLC chromatograms of identified hybrid aspen leaf phenolics at (**a**) 220 nm and (**b**) 320 nm. For identification of peaks, see Table 3

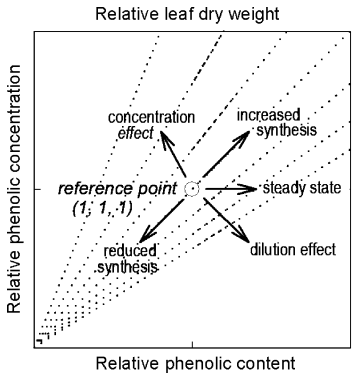
was decanted into a new tube with 3 ml of deionized water. The free ergosterol in the precipitate was extracted with 3, 2, and 1 ml pentane, and the pentane phases with the free sterols were collected into a new tube. Pentane was allowed to evaporate to dryness, and the dry samples were stored at −20°C. For HPLC analysis, ergosterol samples were dissolved in 500 µl of 100% methanol, and incubated at 50°C for 20 min. After centrifugation, the supernatant was transferred into the autosample vial. HPLC analysis was done by using a reverse-phase column (Hewlett-Packard, LiChrospher 100 RP-18) with 100% methanol as eluent. Twenty µl sample were injected and run at 1.6 ml per minute. Provitamin D2 (5,7,22-ergostatrien-3β-ol) was used as a standard.

Statistical and Graphical Analyses In the statistical analyses, the main effects and interactions of two levels of ozone and two clones were tested. In all analyses, the mean value per clone per plot was used as a statistical unit. To test for main effects and interactions of ozone and clone on biomass and growth, and on concentrations of phenolic compounds of leaves, linear mixed model analysis of variance using SPSS for Windows 14.0 (SPSS Inc. 2005) was performed, with ozone and clone as fixed factors, and plot as a random factor. For determinations of fine root biomass and ergosterol concentration, ozone was used as a fixed factor and plot as a random factor since clonal effects could not be studied. In the repeated measurements analyses (fluorescence, stomatal conductance, and photosynthesis), ozone, clone, and measuring date were used as fixed factors, and plot as a random factor. In the case of statistically significant interactions, pairwise *post hoc* comparisons were used for interpretation of the effects of different factors. For all statistical tests, the significance level was set at $P<0.05$.

Treatment and clone effects on foliar phenolics were analyzed also by using a graphical vector analysis (GVA; Haase and Rose 1995) to determine whether the induced/reduced accumulation of a compound is the result of increased/decreased synthesis, or concentration/dilution of the compound due to a change in leaf biomass (Koricheva 1999). Relative values of mean concentrations were plotted against mean contents per leaf, with the diagonal lines representing the relative mean foliar dry weights. Vectors were drawn by using either the ambient ozone treatment or clone 110 as the reference point (1, 1, 1), and the direction and magnitude of the vectors were used to interpret the impacts of ozone or clone on the phenolic compounds, respectively (Fig. 3).

Correlations between the two hybrid aspen clones, foliar phenolic compounds, and growth-associated variables were studied with principal component analysis (PCA) using SIMCA-P 11.5 software (Umetrics AB, Umeå, Sweden). After unit variance scaling of the variables, a model with four principal components that explained 89% of the variation was extracted. The input data matrix consisted



Content	Concentration	Leaf dry weight	Interpretation
+	0	+	Steady state (increase)
+ / 0	-	+	Dilution effect
-	-	+ / 0 / -	Reduced synthesis
-	0	-	Steady state (decrease)
0 / -	+	-	Concentration effect
+	+	+ / 0 / -	Increased synthesis

Fig. 3 Interpretation of directional shifts in the phenolic content (*x* axis), concentration (*y* axis) and leaf dry weight (*diagonal lines*) in a graphical vector analysis. Adapted from Haase and Rose (1995) Koricheva (1999) and Peltonen et al. (2005)

of 16 observations (2 clones × 8 plots) and 26 variables (22 phenolic compounds, stem and root dry weight, height growth, radial growth, and A_{sat}, F_v/F_m, and g_s measured in the beginning of August).

Results

Leaf Nitrogen Concentration Leaf nitrogen concentration was on average 32.6 mg g^{-1}. There were no statistically significant differences between the clones or between ozone treatments (data not shown).

Chlorophyll Fluorescence, Stomatal Conductance and Photosynthetic Rate Ozone had no main effect on F_v/F_m, g_s or A_{sat} of the clones (Table 2, Fig. 4). However, there was a significant O_3 x date interaction in A_{sat} showing higher photosynthetic rates in response to elevated ozone in the first measurement in July (P=0.026), but no differences between the ozone treatments in the rest of the measurements (Fig. 4). There were statistically significant differences between the clones in F_v/F_m, and A_{sat} but not in g_s (Table 2), with higher values in clone 110. There was a significant clone x date interaction in F_v/F_m, with clone 110 having higher F_v/F_m values than clone 55 except at the first measuring date (Table 2, Fig. 4).

Table 2 Main effects and interactions of ozone, clone, and measuring date on leaf-level net photosynthesis (A_{sat}), stomatal conductance (g_s), and maximum efficiency of PS II (F_v/F_m) of two clones of soil-grown hybrid aspen saplings

Foliar Phenolics We extracted and analyzed, in addition to condensed tannins, 21 individual phenolic compounds from hybrid aspen leaves. Among them, four compounds, quercetin 3-arabinoglucoside, quercetin 3-arabinoglucuronide, kaempferol 3-arabinoglucoside, and isorhamnetin 3-glucuronide, were tentatively identified for hybrid aspen. Elevated ozone affected significantly only the concentrations of neochlorogenic acid, which were 57% and 28% higher in elevated ozone in clones 110 and 55, respectively (Table 3). Instead, there were statistically significant differences between the clones in all phenolic compounds, except for salicin and quercetin 3-arabinoside (Table 3). In total, clone 55 contained 83% higher concentrations of phenolics than clone 110. Of the main phenolic groups, salicylates comprised 45% and 57% of the total phenolics in clones 55 and 110, whereas condensed tannins and catechins comprised 46% and 29% of the total phenolics of clones 55 and 110, respectively. Phenolic acids together with flavonol glycosides comprised less than 14% of the total phenolics. Concentrations of most individual phenolic compounds were higher in clone 55, and only disalicortin, neochlorogenic acid, kaempferol diglycoside, kaempferol 3-glucuronide, and myricetin 3-glucoside + glucuronide were found in higher concentrations in clone 110 than in clone 55 (Table 3).

Vector analysis showed that elevated ozone resulted in increased accumulation of most phenolics, as shown in Table 3, but since the effects were not statistically significant, except for neochlorogenic acid, the results are not shown. Dry weights of single leaves were not different between the clones (0.11 g for clone 55 and 0.13 g for clone 110; P=0.209). Thus, when clone 55 was compared to clone 110 (Fig. 5 a–g), vector analysis showed that the higher concentrations of total phenolics, salicylates, and especially tannins and catechins in clone 55 were the result of increased synthesis and not a concentration effect (Fig. 5 a–c). A slight concentration effect in clone 55 is

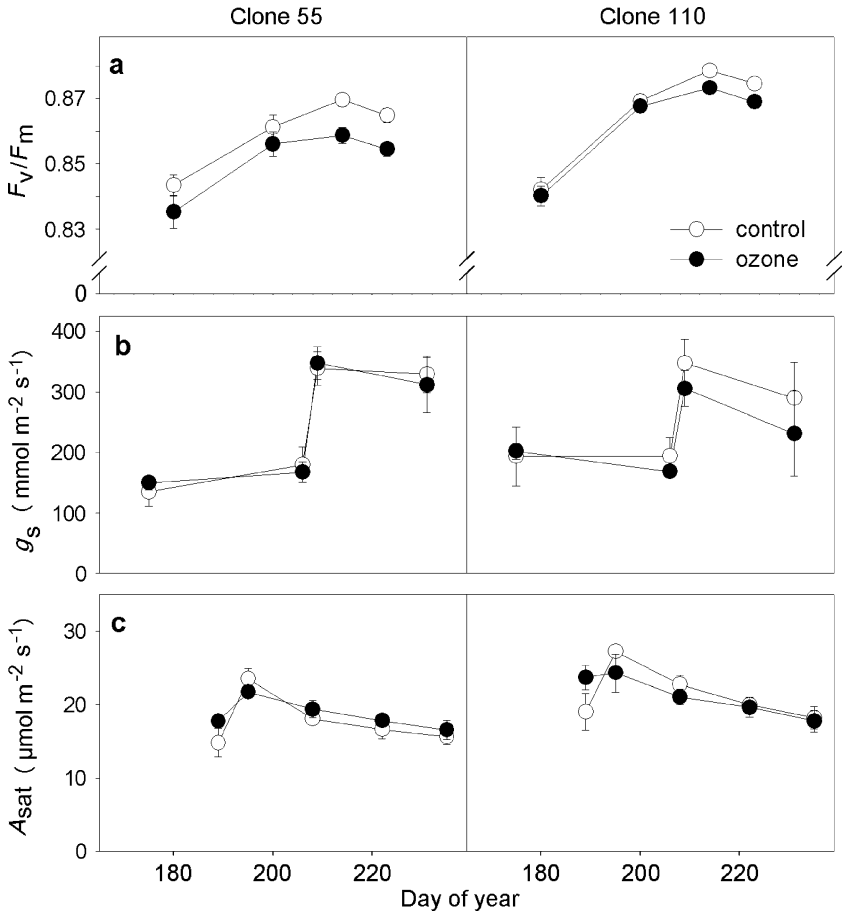

Fig. 4 Mean (**a**) maximum efficiency of PS II (F_v/F_m), (**b**) stomatal conductance (g_s), and (**c**) leaf-level net photosynthesis (A_{sat}) of two clones of soil-grown hybrid aspen saplings (N=4) during the third growing season in ambient ozone (*open circles*) and elevated ozone (*closed circles*). Error bars are SEs

seen in total flavonol glycosides (Fig. 5 e). Reduced accumulation of neochlorogenic acid, and considerably greater accumulation of chlorogenic acid in clone 55 compared with clone 110 was observed (Fig. 5 f–g).

Biomass and Mycorrhizal Root Status There were no significant differences in growth or dry mass in clones between the ozone treatments in the soil-grown trees (Table 4a). Instead, there were differences between the clones in all growth and biomass parameters (Table 4a). The total biomass of clone 110 was 65% greater than that of clone 55. The final height was 15% greater in clone 110, whereas the base diameter and diameter at 1.3 m were 34% and 40% greater, respectively, in clone 110 than in clone 55. The difference in the dry mass of fine roots (< 2 mm in diam) and coarse roots (> 2 mm) between ozone and control plots was not statistically significant (Table 5). The ergosterol content of the fine roots was significantly (41%) higher in elevated ozone plots than in control plots (Table 5).

We also reanalyzed the biomass data from the pot experiment of clones 55 and 110 (Table 4b). Even though clone 55 was clustered among the ozone-tolerant clones, and clone 110 among the ozone-sensitive clones (Häikiö et al. 2007), no effects of elevated ozone concentrations on the growth or biomass of either clone were observed, except for a statistically significant reduction in coarse root biomass in elevated ozone in clone 110 (Table 4b). Elevated ozone tended to reduce the stem dry mass more in clone 110 than in clone 55, and increased the final height of clone 55, whereas no effect of elevated ozone on the final height of clone 110 was observed (Table 4b). We found differences between the clones in the dry mass of stem and roots, and in the final base diameter, which were significantly greater in clone 110 than in clone 55 (Table 4b).

Principal Component Analysis PCA was used to study the relationships between the clones, different growth variables, and foliar phenolic composition (Fig. 6). The first PC explained almost 60% of the data, and was characterized by high scores in biomass attributes associated with clone 110 on the positive side, and the bulk of phenolic compounds associated with clone 55 on the negative side (Fig. 6). Growth was negatively correlated with catechins, condensed tannins, chlorogenic acid, and many quercetin derivatives (Fig. 6). No correlation between growth and A_{sat} or g_s was found (Fig. 6).

Discussion

Elevated Ozone Concentrations Did Not Affect the Competitive Ability of the Two Hybrid Aspen Clones Because our earlier studies with potted saplings of eight hybrid aspen clones showed significant ozone x clone interactions in most biomass attributes after two growing seasons (Häikiö et al. 2007), we expected to find differences in growth responses after three growing seasons between the more ozone-tolerant clone 55 and the more ozone-sensitive clone 110 growing in soil. However, no effects of elevated ozone in any of the growth parameters were found on either clone. Also, reanalysis of the potted saplings of clones 55 and 110 showed no significant differences in the growth responses to ozone, except for the dry mass of coarse roots showing 17% and 29% reductions in response to elevated ozone in clones 55 and 110, respectively. Significant differences in growth of both the potted and the soil-grown trees were found only between the two clones, not between the ozone treatments. This is in contrast with the observations of King et al. (2005) who found a 22% reduction in the standing biomass of trembling aspen after 7 years of ozone exposure. This might be due to the relatively low ozone enhancement and shorter time scale of our experiment compared with the studies of King et al. (2005). Clones 55 and 110 also were not among the most ozone tolerant or sensitive hybrid aspen clones used in our previous experiments (Oksanen et al. 2001; Häikiö et al. 2007). We also did not find changes in fitness in response to elevated ozone in the two hybrid aspen clones as shown by the lack of ozone x clone interaction in growth-associated parameters. Clone 110 was a better competitor than clone 55 in both ambient ozone and elevated ozone concentrations as shown by the greater biomass of clone 110 at the end of the experiment. Differences in growth responses to elevated ozone among clones of trembling

Table 5 The differences between ambient ozone and elevated ozone plots in the dry mass of fine roots (< 2 mm), coarse roots (> 2 mm) and ergosterol concentrations of fine roots

	Ambient O_3	Elevated O_3	*P* values

Ergosterol (ng mg-1 DW)	606.0±39.1	856.4±81.4	**0.032**

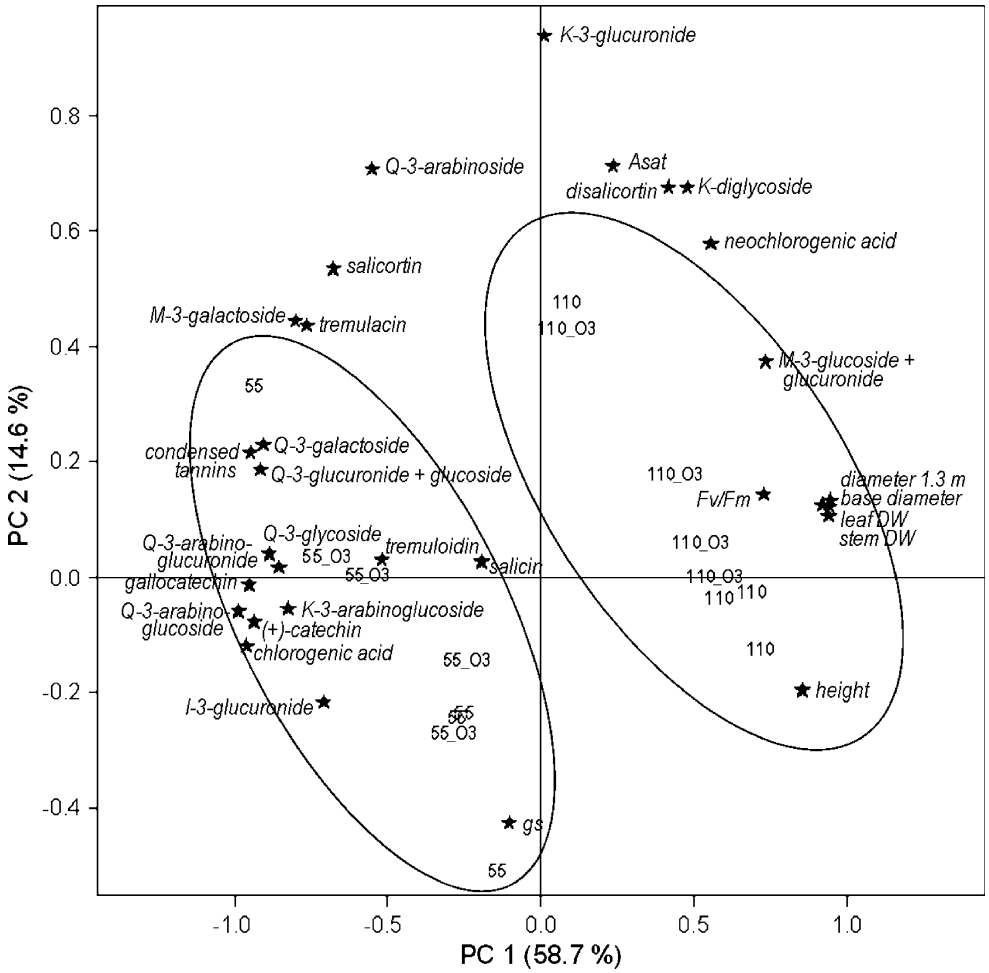

Fig. 6 The PCA biplot diagram showing the loading plot (*star symbols*) of phenolic compounds, biomass (leaf and stem dry weight, base diameter and diameter at 1.3 m, and final height), chlorophyll fluorescence (F_v/F_m), and gas exchange (A_{sat} and g_s), superimposed on the score plot of hybrid aspen clones indicated by clone numbers (each observation represents a mean value per clone per field). The variances explained by principal components 1 and 2 are shown in parentheses

aspen were reported by Karnosky et al. (2005), and after 7 years of ozone exposure, the extremely ozone-tolerant trembling aspen clone 8 L had a better competitive ability in elevated ozone than in the control treatment, whereas the poorest competitor was more strongly inhibited in elevated ozone than the other clones (Kubiske et al. 2007).

Elevated ozone concentrations usually reduce carbon allocation to roots (Grulke et al. 1998; Andersen 2003), which was also reported in our study with potted plants (Table 4b; Häikiö et al. 2007). Because of the difficulties in extracting coarse root systems of individual trees growing in soil, we determined the fine root biomass from each plot by collecting soil samples at random locations between the trees. Fine roots, which may comprise >75% of the root length in trees (Pregitzer et al. 2002), play the most important role in nutrient and carbon cycling in forests, even though they represent only a small fraction of total tree biomass. We did not find significant differences in fine root or coarse root dry mass between the ozone treatments. Consistent with our results, no changes in root biomass in response to elevated ozone concentrations were reported after two growing seasons in trembling aspen (King et al. 2001), or after three growing seasons in birch (Kasurinen et al. 2005). However, the response can change over time, and after eight growing seasons, increased fine-root biomass of trembling aspen in elevated ozone has been observed (Pregitzer et al. 2008). Increased numbers of both mycorrhizal and non-turgescent fine roots after 2 years of elevated ozone exposure in a mature beech stand were also reported by Grebenc and Kraigher (2007). Our root samples were collected on one sampling occasion at the end of August, and because fine root production is usually greater in spring and early summer than in autumn (Hendrick and Pregitzer 1996; Grulke et al. 1998), the responses may have been confounded by the temporal variation in fine root production and mortality. On the other hand, we did not observe a reduction in photosynthetic capacity of our clones in response to elevated ozone, and since the structural development of roots is dependent on current photosynthate (Andersen 2003), the lack of significant effects of ozone on root biomass is not surprising.

Ergosterol concentration of the fine roots was 41% higher in the elevated-ozone plots compared with control plots. Increases in the mycorrhizal status of the roots in response to elevated ozone has been reported in birch by Kasurinen et al. (2005) and in beech by Grebenc and

Kraigher (2007), who attributed the differences to changes in species composition and the relative abundance of ectomycorrhizal fungi. *Populus* species are colonized by both ectomycorrhizae (EM) and arbuscular mycorrhiza (AM; Smith and Read 1997; Neville et al. 2002), and ergosterol has been shown to be absent in AM fungi (Olsson et al. 2003). Therefore, ergosterol analysis can be used only for a coarse estimation of mycorrhizal biomass.

The nitrogen status of the soil-grown trees was good based on the high foliar nitrogen concentrations (> 30 mg g^{-1}) in both clones. Even though the trees were not systematically watered or fertilized during the three growing seasons, soil nutrient and water availability in the soil-grown trees were good compared with the potted plants, which probably suffered from both root restriction and drought, especially during the hot summer of 2003. When the final heights of the clones at the end of the second growing season were compared, no difference in height between potted and soil-grown trees was observed in clone 55 (P=0.550), whereas in clone 110, the soil-grown trees were 15% higher than the potted trees (P=0.002). This indicates that, when growing in soil, clone 110 was able to exploit the ample soil resources and increase its competitive ability. We found differences between the clones in the potted saplings in response to nitrogen amendment (Häikiö et al. 2007). There was a 26% increase in total dry mass in the high-N plants of clone 110, whereas no difference in total dry mass was found between the two nitrogen treatments in clone 55 (data not shown). This suggests that other resources than nitrogen restricted the growth of clone 55. Because *Populus* species are high isoprene emitters, volatile isoprene synthesis can lead to great losses of carbon fixed by photosynthesis (Monson and Fall 1989; Geron et al. 2001). In this experiment, however, no differences between the two clones in the concentrations of emitted isoprene were observed that could account for differences in carbon allocation for growth between the two clones (Blande et al. 2007).

High Concentrations of Leaf Phenolics Were Negatively Correlated with Growth Salicylates and condensed tannins comprise the majority of the phenolics in the leaves of *Populus* species, and have been studied in many experiments in context with herbivory, elevated ozone or elevated carbon dioxide (e.g., Holton et al. 2003; Agrell et al. 2005). We now have elucidated the whole phenolic profile, including the phenolic acids and flavonol glycosides, of hybrid aspen leaves in detail.

Previously, we reported high clonal variation in the foliar phenolic profile of eight hybrid aspen clones (Häikiö et al. 2007). The present study supports the finding that genotype and not ozone causes most of the variation in the secondary chemistry of the leaves (see also Kontunen-Soppela et al. 2007). Salicylates, condensed tannins, flavonol glycosides (derivatives of quercetin, kaempferol, and myricetin), and hydroxycinnamate derivatives may comprise up to one-third of the dry mass of aspen leaves (Tsai et al. 2006). Salicylates have been reported to be highly dependent on genotype, whereas the concentrations of condensed tannins vary across environmental conditions (Hemming and Lindroth 1999; Osier and Lindroth 2001, 2006). Higher concentrations of condensed tannins in elevated ozone were found in the foliage of loblolly pine (Jordan et al. 1991) but in a meta-analysis, no effects of elevated ozone alone on the concentrations of condensed tannins were reported (Valkama et al. 2006). In this study, we detected no effect of ozone on either salicylates or condensed tannins, which is in contrast with our previous study with potted trees, where higher concentrations of condensed tannins and their precursor (+)-catechin, as well as chlorogenic acid, were found in ozone-fumigated hybrid aspen saplings (Häikiö et al. 2007). Instead, the only phenolic significantly increased by elevated ozone in the soil-grown plants was neochlorogenic acid, which was more abundant in clone 110 than in clone 55. The caffeoyl moiety of chlorogenic acid or neochlorogenic acid may act as a precursor to lignins, and ozone-induced increases in lignins, which may act as barriers or have an antioxidant effect on reactive oxygen species, have been reported in *Populus* leaves and stem wood (Cabane et al. 2004; Kaakinen et al. 2004). The chlorogenic acids are also powerful antioxidants (Grace et al. 1998), and increased levels of chlorogenic acid under ozone stress have been observed in birch (Saleem et al. 2001; Peltonen et al. 2005).

The clonal differences in the foliar phenolic profiles can be seen easily in the PCA biplot (Fig. 6), where most phenolics are associated with clone 55. Clone 110 had 30% lower concentrations of salicylates, 66% lower concentrations of catechins and condensed tannins, and 15% lower concentrations of flavonol glycosides than clone 55. GVA showed that the higher concentrations of phenolics in clone 55 were the result of increased synthesis and not the result of concentration due to smaller leaf dry weight. As indicated by PCA, high concentrations of phenolics, especially catechins and condensed tannins, were negatively correlated with growth. A negative correlation between growth and condensed tannins was also found by Donaldson et al. (2006) and Häikiö et al. (2007). The biosynthetic costs of condensed tannins or salicylates are not very high when presented as grams of glucose required per gram of compound (Gershenzon 1994), but considering the high concentrations of these compounds in the leaves, the net cost of production of phenolics of clone 55 was twice as high as that of clone 110. Even though elevated ozone concentrations did not affect the competitive ability of the clones, the slower growth of clone 55 compared with clone 110 may have led to an increase in resource limitation and a decrease

in competitive ability, which could have resulted further in greater allocation to secondary compounds instead of growth. In our studies, phenolics comprised 19% of the dry weight of the leaves in the potted trees, compared with 12% in the soil-grown trees. This may be explained by nutrient limitation (P, K) or drought stress which may have shifted carbon allocation towards phenolics in the potted plants (Donaldson et al. 2006). Clone 55 was also infected by a fungal disease (tentatively identified as *Marssonina* blight) from the start of the experiment, which likely affected the secondary chemistry of the leaves. In *Melampsora*-infected hybrid poplar, the condensed tannin pathway was induced (Miranda et al. 2007), and in *Salix*, enhanced synthesis of catechin, salicortin, and chlorogenic acid in response to *Melampsora* infection have been reported (Hakulinen 1998; Hakulinen et al. 1999).

To summarize, elevated ozone concentrations did not affect the gas exchange or the final dry mass of the two hybrid aspen clones studied, indicating that the clones did not differ in their ozone sensivitity. This was confirmed by renanalyzing clonal data from a previous experiment with potted plants of the same clones. There were no changes in the ozone sensitivity affecting the competitive ability of either clone after 3 years of moderately elevated ozone exposure. Instead, high carbon allocation to phenolics (mostly condensed tannins and salicylates) resulted in poor growth and significant differences in the final biomass between the two clones. Higher resource availability resulted in markedly lower foliar phenolic concentrations in the soil-grown trees compared with the potted trees of the same clones.

Acknowledgements This study was funded by the Academy of Finland project 51758 (E. H. and M. M.), North Savo Regional Fund of the Finnish Cultural Foundation (E. H.), Jenny and Antti Wihuri Foundation (E. H.), the Graduate School in Forest Science (V. F.), Finnish Cultural Foundation (T. S.), and the Academy of Finland project 106538 (V. P.). We thank Timo Oksanen for ozone fumigations and technical assistance, Vesa Kiviniemi for statistical advice, and Dr. Minna Kivimäenpää for valuable comments on the manuscript.

Effects of Phenylcarboxylic Acids on Mitosis, Endoreduplication and Expression of Cell Cycle-Related Genes in Roots of Cucumber (*Cucumis sativus* L.)

Yun Zhang · Min Gu · Xiaojian Xia · Kai Shi · Yanhong Zhou · Jingquan Yu

Received: 2 March 2009 / Revised: 4 May 2009 / Accepted: 5 May 2009 / Published online: 21 May 2009

Abstract Several benzoic and cinnamic acid derivatives were identified from cucumber root exudates. The effects of these phenylcarboxylic acids on root growth and cell cycle progression were examined in germinated seeds of cucumber. All 12 phenylcarboxylic acids (0.25 mM) tested significantly inhibited cucumber radicle growth, and cinnamic acid exerted a dose-dependent inhibitory effect. At 6 h after exposure to the acids, transcript levels of the cell cycle-related genes, including two cyclin-dependent kinases (CDKs) and four cyclins were reduced. Among them, transcript of *CycB*, a marker gene for mitosis showed a remarkable reduction. The temporal analysis showed that expression of mitotic genes (*CDKB*, *CycA*, and *CycB*) were reduced throughout the experiment, while the reduction of the other genes (*CDKA*, *CycD3;1*, and *CycD3;2*) were observed only at earlier time points. At 48 h after treatment with benzoic and cinnamic acids, an enhancement of endoreduplication was observed. Further time course analysis indicated that endoreduplication started as early as 6 h after exposure to cinnamic acid. These results provide evidence that exposure to benzoic and cinnamic acids can induce rapid and dramatic down-regulation of cell cycle-related genes, thus leading to root growth inhibition. Meanwhile, the block of mitosis caused by phenylcarboxylic acids also induced an increased level of endoreduplication.

Introduction

Plants synthesize an array of chemicals that are involved in a variety of plan-plant, plant-microbe, and plant-herbivore interactions (Inderjit and Duke 2003; Weir et al. 2004). The allelochemicals that are responsible for plant-plant allelopathy are delivered into the rhizosphere mainly through leaching, volatilization, decomposition, and root exudation (Rice 1984; Singh et al. 1999). Allelopathy is usually interspecific (Weidenhamer et al. 1989; Callaway and Aschehoug 2000), but also may occur within the same species, which is called autotoxicity (Singh et al. 1999, Yu et al. 2000). The problem of autotoxicity is common in croplands, and is one of the major reasons for growth reduction in monocropping (Singh et al. 1999; Yu et al. 2000). Although autotoxicity has long been recognized, little is known about its exact action mode.

Investigation of the chemical composition of allelopathic plants reveals that a great number of secondary metabolites serve as allelochemicals. Among them, benzoic and cinnamic acid derivatives are frequently identified from soils or root exudates (Yu and Matsui 1994; Blum 1996; Inderjit and Duke 2003). Root growth inhibition by benzoic and cinnamic acids has been widely observed (Chon et al. 2002; Iqbal et al. 2004; Hiradate et al. 2005; Rudrappa et al. 2007; Batish et al. 2008). Furthermore, exogenous addition of allelochemicals can influence physiological and biochemical reactions, such as photosynthesis, respiration, water and nutrient uptake, and generation of reactive oxygen species (Hejl et al. 1993, Hejl and Koster 2004; Gonzalez et al. 1997; Yu and Matsui 1997; Ding et al.

2007), as well as induce changes in gene expression (Golisz et al. 2008). All such physiological, biochemical, and transcriptional changes are implicated directly or indirectly in plant growth inhibition.

Plant growth ultimately is driven by the process of cell division coupled with the subsequent expansion and differentiation of the resulting cells (Beemster et al. 2003; Jakoby and Schnittger 2004). Cell division plays a role both in the developmental processes that create plant architecture and in the modulation of plant growth rate in response to the environment (Cockcroft et al. 2000; Beemster et al. 2002). The normal cell cycle mode is characterized by a round of DNA replication (S phase) followed by mitosis and cytokinesis (M phase), and separated by two gap phases (G_1 and G_2) (Inzé 2005). Cyclin-dependent kinases (CDKs) and their cyclin partners regulate the G_1/S- and G_2/M-phase transitions as well as progression through and exit from the cell cycle (Menges et al. 2002; Beemster et al. 2005; Inzé and De Veylder 2006). Studies have shown that regulation of cell cycle-related gene expression in different phases is an important mechanism for control of progression through the cell cycle (Menges et al. 2002; Beemster et al. 2005). At present, little is known about the relationship between allelopathy and cell division. Cell cycle progression has been proposed as a target (Burgos et al. 2004; Nishida et al. 2005; Sánchez-Moreiras et al. 2008). However, no data are available concerning the influence of allelochemicals such as phenylcarboxylic acids on the regulation of cell cycle progression by investigation of cell cycle-related gene expression.

Poor plant growth in monocropping of cucumber is supposedly related to autointoxication partly arising from root exudates (Yu et al. 2000). Phenylcarboxylic acids including benzoic and cinnamic acids have been identified from root exudates of cucumber plants, and they had detrimental effects on ion uptake and enhanced the incidence of *Fusarium* wilt by triggering oxidative stress in cucumber (Yu and Matsui 1994, 1997; Ye et al. 2004, 2006; Ding et al. 2007). This study was performed to investigate the influences of benzoic and cinnamic acids on cucumber root growth and cell cycle progression in radicle tips.

Methods and Materials

Plant Material Cucumber (*Cucumis sativus* L. cv. Jinyan No.4) seeds were germinated at 25°C in darkness. Fifty seeds were imbibed in petri dishes (diameter=15 cm) on two layers of Whatman filter paper saturated with 15 ml distilled water. When the radicle had begun to emerge, germinating seeds were transferred to another petri dish with different solutions of derivatives of benzoic and cinnamic acid (benzoic, vanillic, *p*-hydroxybenzoic, *o*-hydroxybenzoic, 3,4-dihydroxybenzoic, gallic, cinnamic, 3-phenylpropionic, caffeic, *p*-coumaric, ferulic, and sinapic acids) at 0.25 mM for another 48 h. Distilled water served as the control. To study concentration effect of cinnamic acid, germinating seeds were transferred to petri dishes containing cinnamic acid at 0.05, 0.1, 0.25, and 0.5 mM for another 48 h. Radicle length was determined at 48 h after exposure to different phenylcarboxylic acids, and inhibition rates of radicle length were calculated. Each experiment was carried out with three independent replicates.

Nuclei DNA Content Analysis We analyzed the relative nuclei DNA content of cucumber radicle tips (0–2 mm) at 48 h after treatments with different kinds of derivatives of benzoic and cinnamic acids (0.25 mM). Afterwards, changes in nuclei DNA content with different concentrations of cinnamic acid (0.05, 0.1, 0.25, and 0.5 mM) were investigated in the radicle tips of cucumber seeds at 48 h after treatment. Additionally, temporal changes in nuclei DNA content of radicle tips were determined at 6, 24, and 48 h after treated with cinnamic acid (0.25 mM). Samples were chopped with a razor blade in 1 ml of ice-cold buffer (45 mM $MgCl_2$, 30 mM sodium citrate, 20 mM MOPS, pH=7, and 1% Triton X-100) (Galbraith et al. 1983), filtered over a 45-μm nylon mesh, and stained with 4,6-diamidino-2-phenylindole. Stained nuclei were analyzed by a FACSCalibur flow cytometer (Becton, Dickinson and Company, USA). Calibration of C-values was made with nuclei from young leaves of cucumber.

Data were analyzed with CellQuest software to determine the ploidy distribution. Mean C-value (MCV) was calculated as the sum of the number of nuclei of each ploidy level multiplied by its endoreduplication cycle and divided by the total number of nuclei (Barow and Meister 2003), where C-value represents the DNA content of the monoploid chromosome set of an organism (Greilhuber et al. 2005; Greilhuber 2008).

RNA Extraction Total RNA was extracted from 0–2 mm radicle tips of cucumber with different treatments with TRIZOL reagent (Sangon, China) according to the manufacturer's instructions at various time after treatments. After extraction, total RNA was dissolved in diethyl pyrocarbonate-treated water.

Transcript Level Estimation with qRT-PCR Quantitative real-time PCR (qRT-PCR) assays were performed to determine the relative transcript level of each cDNA. Gene-specific primers for qRT-PCR were designed based on EST sequences for six cell cycle-related genes, *CDKA* (cyclin-dependent kinase A), *CDKB* (cyclin-dependent kinase B), *CycA* (A-type cyclin), *CycB* (B-type cyclin),

CycD3;1 (D-type cyclin), and *CycD3;2* (D-type cyclin). The specific sets of primers used for the amplification of each cDNA are summarized in Table 1. The first-strand cDNA used as template for qRT-PCR was synthesized by using a RevertAid^{TM} first strand cDNA Synthesis Kit (Fermentas) from 2 µg of total RNA purified by using a RNeasy Mini Kit (Qiagen).

qRT-PCR was performed with an iCycler iQ Multicolor Real-time PCR Detection System (Bio-Rad, Hercules, CA, USA). Each reaction (20 µl total volume) consisted of 10 µl iQ SYBR Green Supermix, 1 µl of diluted cDNA, and 0.1 µM of forward and reserve primers. PCR cycling conditions were as follows: 95°C for 3 min, 40 cycles of 95°C for 10 s, and 58°C for 45 s. Fluorescence data were collected during the 58°C step. The cucumber *actin* gene was used as an internal control. Relative gene expression was calculated as described by Livak and Schmittgen (2001).

Statistical Analysis Seeds were arranged in three randomized blocks with three replicates per treatment. All results were subject to analysis of variance (Statistica 6.0, Microsoft Corp., 1995), and the means were compared by the Tukey' HSD test at a significance level of $P \leq 0.05$.

Results

Effects of Benzoic and Cinnamic Acids on Radicle Elongation of Cucumber The effects of benzoic acids (benzoic, vanillic, *p*-hydroxybenzoic, *o*-hydroxybenzoic, 3,4-dihydroxybenzoic, and gallic acids) and cinnamic acids (cinnamic, 3-phenylpropionic, caffeic, *p*-coumaric, ferulic, and sinapic acids) at 0.25 mM on cucumber radicle elongation were examined at 48 h after treatments (Table 2). Exposure to these acids all resulted in a reduction in radicle length. The inhibition rates ranged from 20.69 to 59.43%, as compared to the control treated with distilled water. Among the 12 acids assayed, cinnamic acid had the greatest inhibitory effect while benzoic acid had the lowest. Comparatively, benzoic acids showed less inhibitory effects (20.7–36.0%) than cinnamic acids (34.8–59.4%). Additionally, the concentration effect of cinnamic acid, an important autotoxin of cucumber, on cucumber radicle growth was investigated. Cinnamic acid at 0.05 mM had only slight inhibitory effects on radicle elongation while cinnamic acid at 0.1 mM significantly inhibited radicle length (Fig. 1). Exposure to cinnamic acid at 0.25 mM and 0.5 mM resulted in a more marked reduction of radicle length by 52.4% and 69.3%, respectively.

Effects of Benzoic and Cinnamic Acids on Relative Nuclei DNA Content in Cucumber Radicle Tips To examine the effects of benzoic and cinnamic acids on mitosis and endoreduplication in cucumber radicle tips, nuclei DNA content was measured by flow cytometric analysis in cucumber radicle sections 2 mm apart in the radicle tip, the zone with most active cell division in the radicle. The first peak of nuclei observed in the histogram for cucumber was defined as 2C, and the following peaks were 4C, 8C, and so on according to Gilissen et al. (1993). Nuclei with 2, 4, and 8C were all found in control radicle tips, and the MCV was relatively constant (3.83–3.99) (Tables 3, 4, and 5). As shown in Table 3, all tested benzoic and cinnamic acids significantly decreased the proportion of 2C but increased the proportion of 8C. Among them, radicles exposed to sinapic, caffeic, and cinnamic acids showed higher 8C values than those exposed to other acids. However, these acids had little effect on the proportion of 4C. The MCV increased from 3.96 for the control to

Table 2 Inhibition of radicle elongation of cucumber plants exposed to 0.25 mM phenylcarboxylic acids for 48 h

Phenylcarboxylic Acids	Inhibition Rate of Radicle Length (%)
Control	0.0 g
Benzoic Acid	20.7 f
Vanillic Acid	35.2 d
p-Hydroxybenzoic Acid	30.4 e
o-Hydroxybenzoic Acid	36.0 d
3,4-Dihydroxybenzoic Acid	33.2 de
Gallic Acid	33.0 de
Cinnamic Acid	59.4 a
3-Phenylpropionic Acid	48.6 b
Caffeic Acid	43.4 c
p-Coumaric Acid	34.8 d
Ferulic Acid	35.5 d
Sinapic Acid	48.2 b

Numbers with different letters refer to significant differences among the treatments ($P \leq 0.05$). The concentration of each phenylcarboxylic acid was 0.25 mM. Each treatment was carried out using three independent biological replicates.

4.43 and 4.66 after exposure to benzoic and cinnamic acids, respectively. Accordingly, exposure to all these acids resulted in an increased level of endoreduplication in radicle tips.

Table 4 shows that cinnamic acid at 0.05 mM had no significant influence on the MCV but significantly decreased the proportion of 2C. When the concentration of cinnamic acid reached ≥0.1 mM, the proportion of 2C decreased and the proportion of 8C increased. The MCV increased by 14.7%, 17.8%, and 23.5% in the 0.10, 0.25, and 0.5 mM cinnamic acid treatments, respectively, as compared to the control. A time course study showed that exposure to cinnamic acid at 0.25 mM resulted in a decrease in 2C proportion and an increase in 8C proportion from 6 h after treatment, leading to a significant increase in MCV. Compared with the control, the MCV index increased by 6.0, 11.5, and 10.2% at 6, 24, and 48 h after treatment with 0.25 mM cinnamic acid, respectively (Table 5).

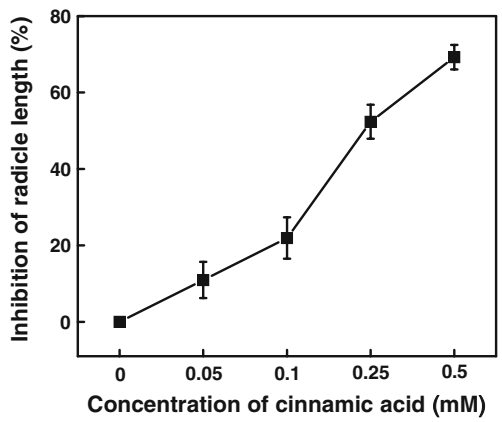

Fig. 1 Effects of different concentrations (0, 0.05, 0.1, 0.25, and 0.5 mM) of cinnamic acid on inhibition of cucumber radicle elongation (%) at 48 h after treatment

Effects of Benzoic and Cinnamic Acids on Cell Cycle-related Genes Expression To gain insight into the mechanism by which these acids regulate the cell cycle, the expression of six cell cycle-related genes, *CDKA*, *CDKB*, *CycA*, *CycB*, *CycD3;1*, and *CycD3;2* were examined in cucumber radicle tips (2 mm) after treatments. Transcript levels of all examined genes were reduced in radicles after exposure to 0.25 mM benzoic, vanillic, *p*-hydroxybenzoic, *o*-hydroxybenzoic, cinnamic, 3-phenylpropionic, and *p*-coumaric acids. Exposure to 3,4-dihydroxybenzoic and gallic acids reduced the transcript level of *CycB* but had negligible effects on transcript levels of other genes (Fig. 2). Caffeic acid had little effect on transcript levels of *CDKA*, *CycA*, and *CycD3;1* but greatly reduced transcript levels of *CDKB*, *CycB*, and *CycD3;2*. Similarly, ferulic and sinapic acids reduced the transcript levels of *CDKA*, *CDKB*, *CycB*, *CycD3;1*, and *CycD3;2* but had negligible effects on transcript levels of *CycA* (Fig. 2).

We further analyzed the changes in transcript levels of cell cycle-related genes in cucumber radicles in response to different concentrations of cinnamic acid at 6 h after treatment, as well as at various time after treatment with 0.25 mM cinnamic acid. As shown in Fig. 3, transcript levels of all six cell cycle-related genes decreased with the increase in the concentration of cinnamic acid. Transcript levels of *CDKA*, *CDKB*, *CycA*, *CycB*, *CycD3;1*, and *CycD3;2* decreased to 61.2, 57.7, 62.2, 20.5, 61.5, and 52.71% of the control, respectively, in radicles after 6 h-exposure to 0.25 mM cinnamic acid (Fig. 3). The inhibition in the expression of six cell cycle-related genes was detectable earlier (at 3 h) after exposure to 0.25 mM cinnamic acid (Fig. 4). The expression of *CDKA* gene was repressed at 3 h after exposure to cinnamic acid, and a more dramatic decrease was observed at 6 h after treatment. Transcript levels of *CDKB*, *CycA*, and *CycB* were down-regulated throughout the treatment time. *CycD3;1* and

Numbers with different letters in the same column refer to significant differences among the treatments ($P \leq 0.05$). The proportions of 2C, 4C, and 8C nuclei were measured on 10 000 nuclei. The concentration of each phenylcarboxylic acid was 0.25 mM. Each treatment was carried out using three independent biological replicates.

CycD3;2 genes were down-regulated at 3 and 6 h, and then, their transcript levels increased gradually (Fig. 4).

Discussion

In the present study, we used benzoic and cinnamic acid derivatives identified from cucumber root exudates (Yu and Matsui 1994; Asao et al. 1999), to investigate their impact on cucumber root growth and cell cycle regulation. Germinated seeds were used since radicles or the young roots usually are the first organs to obtain contact with autotoxic agents. The results showed that all phenylcarboxylic acids caused strong inhibition in cucumber radicle elongation (Table 2), which is consistent with previous studies (Yu and Matsui 1994, 1997; Yu et al. 2003; Dos Santos et al. 2008; Batish et al. 2008; Tharayil et al. 2008). Cinnamic acid, an important autotoxin of cucumber, showed a higher inhibitory effect than other compounds, as has been observed in other plants (Yu and Matsui 1997; Hiradate et al. 2005). It is worth noting that cinnamic acid was applied at reasonable concentrations (0~0.5 mM) in this study since the concentration of autotoxins was 0.1 mM in soils after cucumber cultivation and may reach much higher levels in soils enriched in plant residues (An et al. 2001a, 2001b; Yu et al. unpublished data). The presence of a variety of autotoxins exuded from cucumber roots likely would exhibit synergism (Yu and Matsui 1994; An et al. 2001b). All tested compounds caused significant inhibition in radicle length to different degrees (Table 2), which was possibly due to chemical characteristics such as water solubility (Yu and Matsui 1997; Tharayil et al. 2008).

The elaboration of plant form and function depends on the ability of a cell to divide and differentiate (Inzé 2005). Benzoic and cinnamic acids differently induced down-regulations of two CDKs (*CDKA* and *CDKB*) and four cyclin (*CycA*, *CycB*, *CycD3;1*, and *CycD3;2*) genes at the transcript level (Figs. 2, 3, and 4). Among them, expression of *CycB*, a marker gene for mitosis and specific to the G_2/M phase of the cell cycle (Hemerly et al. 1992; Ferreira et al. 1994), was the most reduced, suggesting that the transition of G_2 to M was blocked by the phenylcarboxylic acids; thus, the ability of cells to enter cell division was impaired (Cools and De Veylder 2009). This is consistent with a report that benzoxazolin-2(*3H*)-one selectively retards cell cycles at the G_2/M checkpoint in lettuce seedling root meristems (Sánchez-Moreiras et al. 2008).

Table 4 Effects of different concentrations of cinnamic acid on relative nuclei DNA content and mean c-value in cucumber radicle tips at 48 h after treatment

Concentrations (mM)	2C (%)	4C (%)	8C (%)	Mean C-Value
0	33.7a	52.4a	13.9c	3.9c

48	Control	35.8a	48.5	15.8b	3.9b
	Cinnamic Acid	28.3b	49.6	22.2a	4.3a

Numbers with different letters in the same column refer to significant differences between the treatments ($P \leq 0.05$). The proportions of 2C, 4C, and 8C nuclei were measured on 10 000 nuclei. The concentration of cinnamic acid is 0.25 mM. Each treatment was carried out using three independent biological replicates.

It also has been demonstrated that salt stress and fungal elicitors also induce the repression of the B-type cyclin gene expression (West et al. 2004; Suzuki et al. 2006). Similar to *CycB* gene, expression of *CycA* gene, an A-type cyclin involved in the control of S-to-M phase, was reduced by the phenylcarboxylic acids. Possibly, cinnamic and other acids induce generation of reactive oxygen species that suppress the transcript level of *CycA*, since the expression of *CycA* gene is sensitive to oxidative stress (Reichheld et al. 1999; Ding et al. 2007). *CDKB* gene is specific to the G_2 and M phases (Magyar et al. 1997; Porceddu et al. 2001) while the *CDKA* gene plays a pivotal role in both the G_1-to-S and G_2-to-M transition points, and its activity is rate limiting for the plant cell cycle (Hemerly et al. 1995; Inzé 2005). Similar to other studies under salt stress, water stress, and cold night conditions (Setter and Flannigan 2001; West et al. 2004; Rymen et al. 2007), the expression of *CDKA* and *CDKB* genes was down-regulated by the tested phenylcarboxylic acids, especially *CDKB*, which showed a constant down-regulation pattern during the treatment time. This also suggests that mitosis was more seriously inhibited.

D-type cyclins are thought to regulate the G_1-to-S transition (Menges et al. 2006). The reduced transcript levels of *CycD3;1* and *CycD3;2* in cucumber radicles after exposure to phenylcarboxylic acids suggested that they

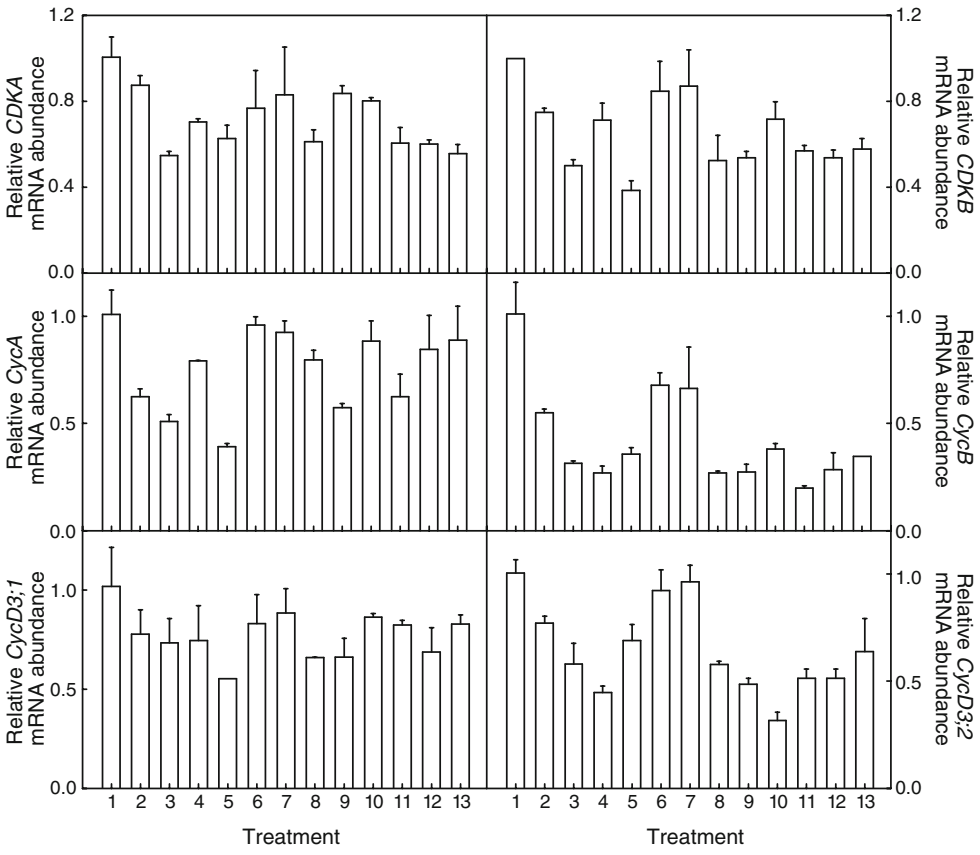

Fig. 2 Expression of cell cycle-related genes in cucumber radicle tips at 6 h after exposure to 12 phenylcarboxylic acids. The numbers of the 1–13 displaying on the horizontal axis represent different treatments with distilled water, benzoic acid, vanillic acid, *p*-hydroxybenzoic acid, *o*-hydroxybenzoic acid, 3,4-dihydroxybenzoic acid, gallic acid, cinnamic acid, 3-phenylpropionic acid, caffeic acid, *p*-coumaric acid, ferulic acid, and sinapic acid, respectively. The concentration of each phenylcarboxylic acid was 0.25 mM. Expression levels by qRT-PCR are expressed as a ratio of the control, which is set as 1

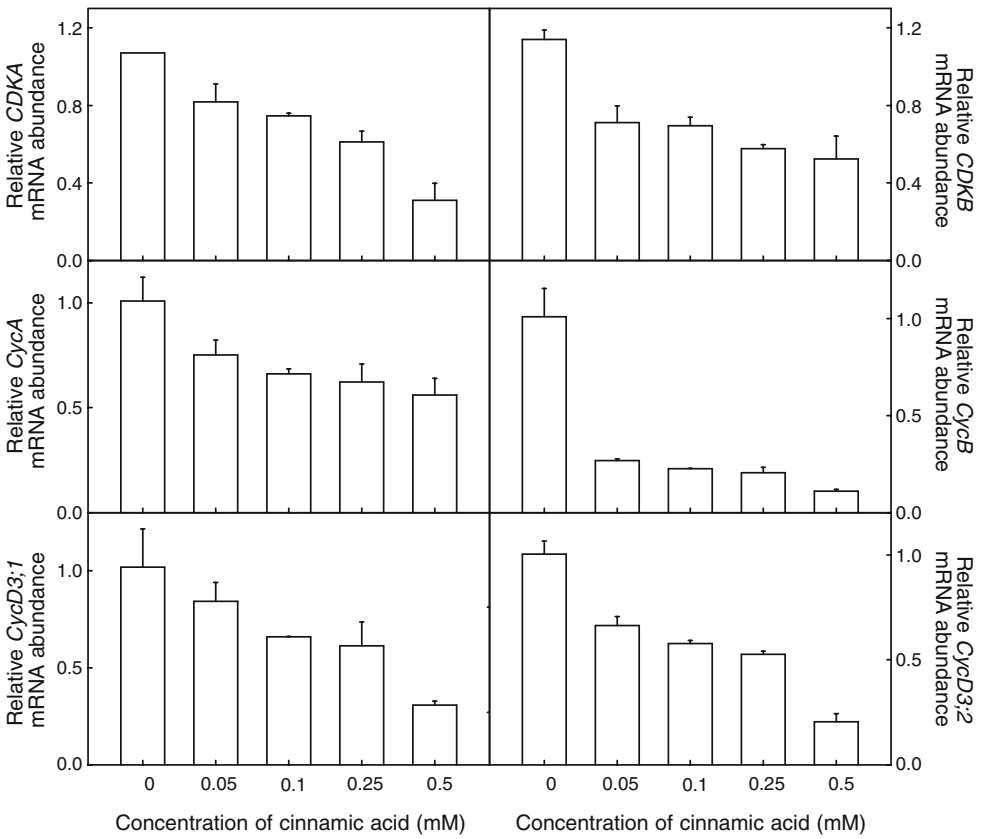

Fig. 3 Expression of cell cycle-related genes in cucumber radicle tips at 6 h after exposure to different concentrations of cinnamic acid. The concentrations of cinnamic acid used were 0.05, 0.1, 0.25, and 0.5 mM, respectively. The control was treated with distilled water. Expression levels by qRT-PCR are expressed as a ratio of the control, which is set as 1

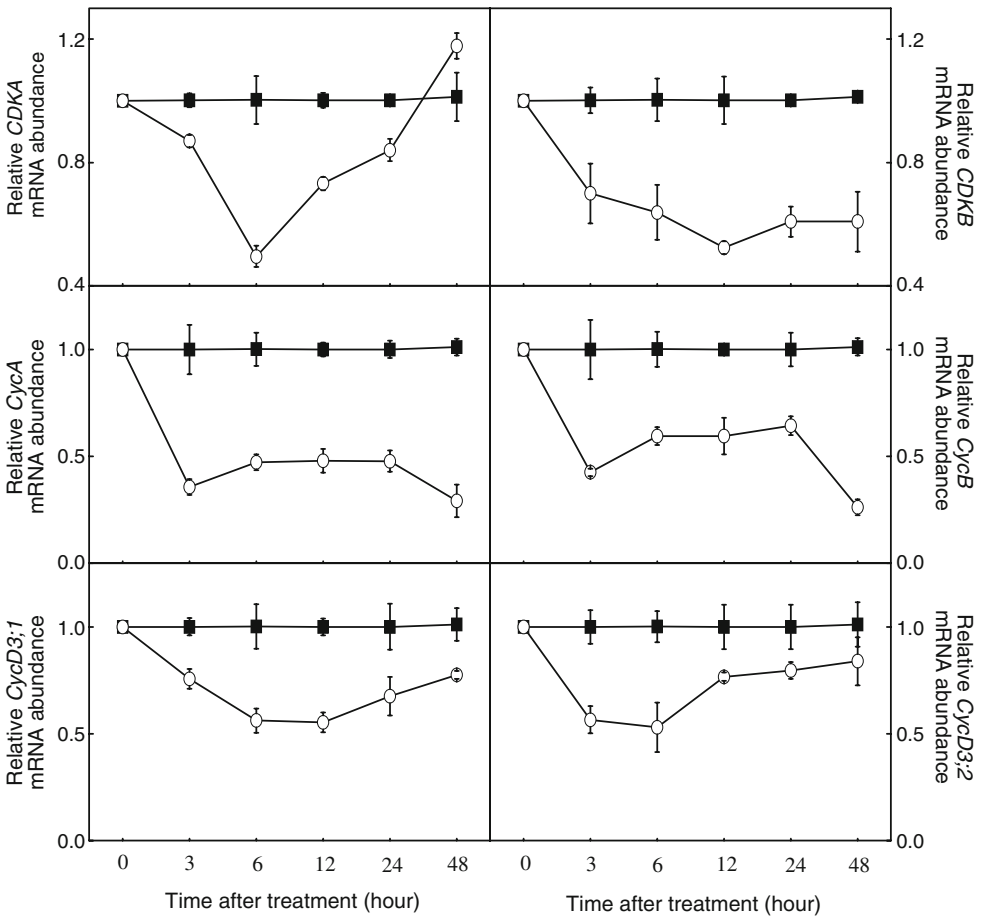

Fig. 4 Expression of cell cycle-related genes in cucumber radicle tips at different hours after exposure to cinnamic acid. The concentration of cinnamic acid was 0.25 mM. Expression levels by qRT-PCR are expressed as a ratio of the control, which is set as 1. The control (filled rectangular), 0.25 mM cinnamic acid (open circle)

altered the G_1-to-S transition process. However, it is interesting to note that both the expression of *CDKA* and *CycD3* genes increased from 12 h after treated with 0.25 mM cinnamic acid, which was different from the expression patterns of *CDKB*, *CycA*, and *CycB* genes in our study (Fig. 4). It is likely that *CDKA* and *CycD3* genes also play roles in the process of endoreduplication since they are active in the G_1/S phase (see below).

The existence of 2, 4, and 8C cells in cucumber radicles suggested the occurrence of endoreduplication, as observed in a previous study (Gilissen et al. 1993). Endoreduplication is another mode of the cell cycle. The mitotic cell cycle comprises the duplication and subsequent distribution of chromosomes between two daughter cells, whereas endoreduplication involves repetitive chromosomal DNA replication and marks the exit from the cell division program, leading to an increase in the ploidy level (Joubès and Chevalier 2000; Cools and De Veylder 2009). In this study, we found that all the tested phenylcarboxylic acids induced higher levels of endoreduplication compared with the control. The enhancement of endoreduplication that occurred after phenylcarboxylic acids treatments was possibly a protective and adaptive mechanism to environmental stress as has been observed in cadmium stress (Fusconi et al. 2006; Repetto et al. 2007).

Previous studies have shown that senescence can induce a higher level of endoreduplication, and both benzoic and cinnamic acids can trigger the generation of reactive oxygen species and ultimately cause loss of root viability (Galbraith et al. 1991; Ding et al. 2007). It is possible that the induction of significant amounts of reactive oxygen species by cinnamic acid could consequently result in the process of early senescence and cause a higher level of endoreduplication. Down-regulation of mitotic genes induced by benzoic and cinnamic acids then may directly result in a different distribution of the nuclei class of ploidy in the differentiated roots. *CDKB* and *CycB* genes are actively involved in the cell mitosis phase, whereas reduced expression of these genes is accompanied by the onset of enhanced endoreduplication (Schnittger et al. 2002; Boudolf et al. 2004; Cools and De Veylder 2009). In our study, *CDKB* and *CycB* were significantly and constantly repressed at the transcript levels when exposed to phenylcarboxylic acids (Figs. 2, 3, and 4), indicating a significant inhibition of the mitotic phase. Since the mitotic phase was blocked, the initiation of the endoreduplication phase was enhanced (Tables 3, 4, and 5).

In summary, this study demonstrated that benzoic and cinnamic acid derivatives caused rapid and dramatic down-regulation of cell cycle-related genes in cucumber radicles, leading to radicle growth inhibition. Meanwhile, they induced an increased degree of endoreduplication due to the blocking of mitosis. This is possibly a protective mechanism against stress.

Two Regulatory Mechanisms of Monoterpenoid Pheromone Production in *Ips* spp. Of Bark Beetles

Jeremy C. Bearfield · Anastasia G. Henry · Claus Tittiger · Gary J. Blomquist · Matthew D. Ginzel

Received: 16 April 2009 / Revised: 3 June 2009 / Accepted: 11 June 2009 / Published online: 25 June 2009

Abstract Bark beetles use aggregation pheromones to coordinate host colonization and mating. These monoterpenoid chemical signals are produced *de novo* in midgut cells via the mevalonate pathway, and pheromone production is induced when an adult beetle feeds on phloem of a host tree. In *Ips pini*, juvenile hormone (JH) III influences key regulatory enzymes along the mevalonate pathway that leads to pheromone production. In fact, topically applied JH III is sufficient to stimulate pheromone production in unfed males. In this study, we explore the influence of feeding and JH III treatment on pheromone production in male *Ips confusus,* the pinyon Ips. We also characterize the influence of feeding and JH III treatment on transcript levels and activity of three key enzymes involved in pheromone biosynthesis: 3-hydroxy-3-methylglutaryl-CoA (HMG) synthase (HMGS), HMG-CoA reductase (HMGR) and geranyl diphosphate synthase (GPPS). We also extend the current understanding of the regulation of pheromone biosynthesis in *I. pini,* by measuring the influence of feeding and JHIII treatment on enzymatic activity of HMGS and GPPS. Feeding on host phloem alone strongly induces pheromone production in male *I. confusus*, while JH III treatment has no effect. However, feeding and JH III both significantly up-regulate mRNA levels of key mevalonate pathway genes. Feeding up-regulates these genes to a maximum at 32 h, whereas with JH III-treatment, they are up-regulated at 4, 8, and 16 h, but return near to non-treatment levels at 32 h. Feeding, but not JH III treatment, also increases the activity of all three enzymes in *I. confusus,* while both feeding or treatment with JH III increase HMGS and GPPS activity in *I. pini.* Our data suggest that pheromone production in *Ips* is not uniformly controlled by JH III and feeding may stimulate the release of some other regulatory factor, perhaps a brain hormone, required for pheromone production.

Introduction

In *Ips* species, production of aggregation pheromones is induced when a pioneering adult beetle feeds on host phloem while attacking a tree. If a sufficient number of beetles respond to these chemical signals, host defenses can be overcome and the tree colonized. For example, male *I. confusus* produce a pheromone of monoterpenoid alcohols ipsenol, ipsdienol, and *cis*-verbenol (Birch et al. 1977). In *I. pini,* ipsenol and ipsdienol are produced *de novo* in midgut tissues via the mevalonate pathway (Seybold et al. 1995b; Ivarsson et al. 1998; Hall et al. 2002a). It is clear that in *I. pini* and other *Ips* species juvenile hormone (JH) III influences key regulatory enzymes along the mevalonate pathway that leads to pheromone production (see Fig. 1; Byers and Birgersson 1990; Ivarsson et al. 1993; Seybold et

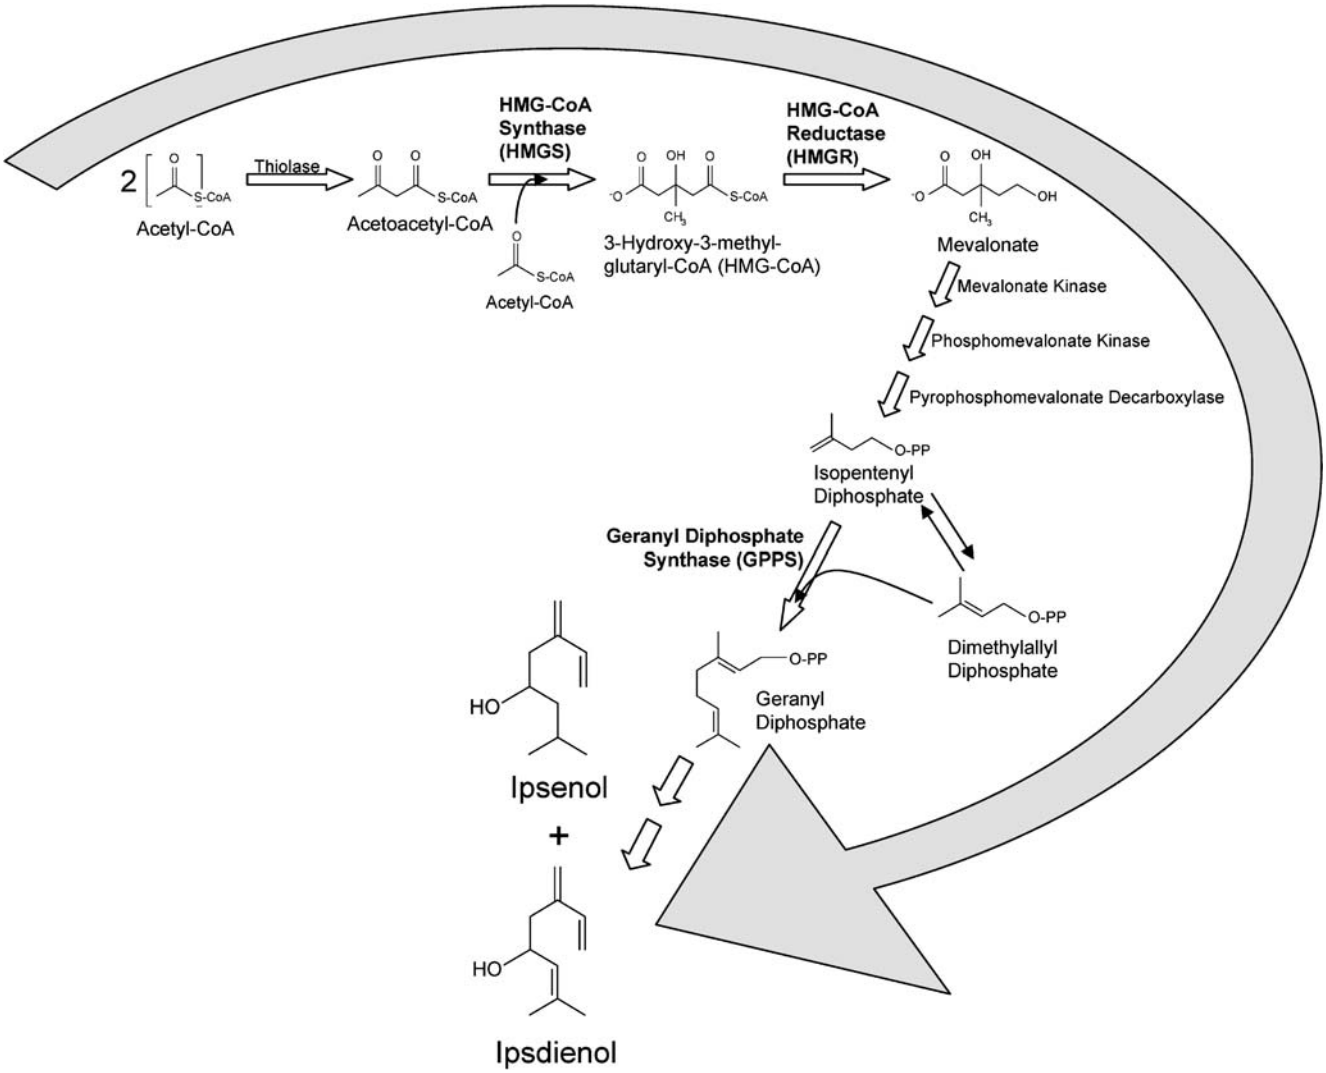

Fig. 1 Mevalonate pathway genes and associated enzymes involved in biosynthesis and regulation of pheromone production in *Ips* spp

al. 1995a; Seybold et al. 1995b; Tillman et al. 1998). In male *I. paraconfusus* and *I. pini,* JH III regulates mRNA levels of 3-hydroxy-3-methylglutaryl-CoA (HMG) reductase (HMGR) (Tittiger et al. 1999), the first committed and a highly regulated step in the mevalonate pathway. Moreover, feeding and JH III treatment strongly upregulate levels of HMGR transcript in the anterior midgut tissues of *I. pini* (Keeling et al. 2004). From these studies, it appears that in *I. pini* feeding on host phloem stimulates JH III synthesis by the *corpus allatum*, which, in turn, increases the expression level and enzyme activity of HMGR in the mevalonate pathway resulting in high levels of pheromone production (Tillman et al. 1998). In addition, JH III also upregulates transcription of other mevalonate pathway genes, including HMG-CoA synthase (HMGS) and geranyl diphosphate synthase (GPPS), in male *I. pini* (Gilg et al. 2005; Bearfield et al. 2006; Keeling et al. 2006).

Although JH III strongly regulates HMGR activity in *I. pini*, it has no influence on enzymatic activity in other *Ips* species. In assays measuring the conversion of ^{14}C-HMG-CoA to ^{14}C-mevalonolactone by fed and JH III treated males in several species, JH III treatment caused large increases in HMGR activity in *I. pini* but had no effect in *I. paraconfusus* (Tillman et al. 2004). However, feeding strongly increased the enzymatic activity of HMGR in both species; suggesting that members of the *grandicollis* subgeneric group (*e.g., I. paraconfusus*) are quite different from *I. pini* with regard to the regulation of pheromone production by juvenile hormone. Interestingly, *Ips confusus* is closely related to *I. paraconfusus* and falls into the same *grandicollis* group based on multiple gene analysis (Cognato and Vogler 2001) and mitochondrial cytochrome oxidase I DNA sequences alone (Cognato and Sperling 2000).

In this study, we use biochemical and molecular approaches to test the hypothesis that JH III does not exclusively regulate pheromone production in *Ips confusus,* a member of the *grandicollis* subgeneric group. We also evaluate for the first time the effect of JH III treatment and feeding on the transcriptional regulation of key mevalonate pathway genes in male *I. confusus*.

Materials and Methods

Insects Immature *I. confusus* were obtained from infested *Pinus monophylla* bolts collected from the Bureau of Land Management (BLM) land east of Carson City, Nevada, USA. We also collected bolts of *Pinus jeffreyi* infested with immature *I. pini* from the University of Nevada Whittell Forest, NV and from within the Lake Tahoe Basin Management Unit, South Lake Tahoe, CA. The insects were reared to adults in a greenhouse according to Browne (1972) and emerged adults were collected daily. Adult beetles were separated by sex according to Lanier and Cameron (1969) and stored for up to two weeks at 4°C in moist paper towels until used in experiments.

Influence of JH and Feeding on the Production of Key Pheromone Components We assessed the influence of JH III on the production of key pheromone components, ipsenol and isdienol, by collecting headspace volatiles of adult beetles on an absorbent. Individual male beetles (N= 30) were topically treated with either 10 μg of racemic JH III (Sigma-Aldrich, St. Louis, MO) dissolved in 0.5 μl of acetone or acetone alone (control) applied to the abdominal venter. Each group of beetles was then placed in a modified glass septum-inlet adaptor (29/32 joint, Sigma-Aldrich) and an absorbent filter containing 100 mg of 50/80 mesh Super Q® (Alltech Associates, Deerfield, IL) was attached to one end of the chamber with a 3 cm section of Tygon® tubing. Humidified and charcoal-purified air was pulled through the apparatus at a rate of ~500 ml/min. The beetles were aerated in the dark for 20 hr and then the Super Q® filters were eluted with 1 ml of pentane: ether (1:1) spiked with *n*-octanol (20 μg), as an internal standard. The resulting extracts were analyzed by gas chromatography (GC) using a Hewlett-Packard 5890 Series II GC equipped with an HP-INNOWax (J&W Scientific) capillary column (30 m × 0.25 mm × 0.25 μm film thickness) in splitless mode with a constant column flow of 1.5 ml He/min. The oven temperature was ramped from 60 to 150°C at 5°C/min, then 150 to 240°C at 10°C/min with a 5 min hold at 240°C. The identity of ipsenol and ipsdienol present in the samples was confirmed by comparing their retention times to those of authentic standards.

To determine the influence of feeding on the production of ipsenol and ipsdienol by male *I. confusus,* we treated 30 male beetles with 0.5 μl of acetone each and then placed them into individual 4 mm holes drilled through the bark of a small bolt of pinyon pine (~10 cm diameter and 15 cm long). The infested bolt was then placed in an inert oven cooking bag supported by a cylindrical wire cage (25 cm height, 20 cm diameter) and the beetles were allowed to feed. Humidified and charcoal-purified air was drawn out of the bag (~1 l/min) and volatile compounds were collected for 20 hr on an absorbent filter made of 100 mg of 50/80 mesh Super Q®. As a control, we also collected volatiles from an uninfested bolt of pinyon pine into which 30 holes had been drilled. The filters were then eluted and the resulting extract analyzed by GC as described above. The amount of ipsenol and ipsdienol produced by beetles in each treatment was compared by one-way ANOVA, followed by Fisher's least significant difference (LSD) test (STATSOFT 2005; Sokal and Rohlf 1995). We sampled volatiles three times for each treatment.

Gene Expression Analysis by Real-time PCR Male *I. confusus* were either treated with JH III (10 μg in 0.5 μl acetone), fed on *P. monophylla* phloem, or treated with 0.5 μl of acetone alone (control), or left untreated. All insects were kept at room temperature throughout the experiment. After 4, 8, 16, and 32 hr, the anterior midguts were excised from the beetles in water, purged of their contents, frozen immediately in liquid nitrogen and stored at -80°C. Each treatment was replicated six times for each time point with five midguts were used per replicate per time point.

Total RNA was prepared from the midgut tissue using the RNeasy Mini plant kit (Qiagen). A portion of the RNA was reverse-transcribed into first strand cDNA template using Superscript III RNase H- reverse transcriptase and random hexamer primers (Invitrogen). *Ips confusus cytoplasmic actin* was chosen as the endogenous control gene because it is unresponsive to JH III treatment or feeding in *I. pini* midguts (Keeling et al. 2004, 2006). After cloning *cytoplasmic actin* from *I. confusus*, semi-quantitative RT-PCR was used to confirm its lack of response to JH III or feeding. Moreover, further studies using quantitative real time (qRT-PCR) also confirmed that *I. confusus cytoplasmic actin* is a suitable normalizing gene (Sandstrom et al. 2008). Fragments of *I. confusus* HMGR, HMGS, and GPPS were isolated using degenerate primers based on previously reported sequences, and then sequenced to design specific real-time primers. All gene-specific primers were chosen only after first being identified with the Primer Express software program (Applied Biosystems, version 2.0) and then analyzed using Vector NTI Advance software (Invitrogen, version 9.1) to decrease the possibility of primer dimer formation. PCR amplifications were performed on an ABI Prism 7000 Sequence Detection System (Applied Biosystems) following the manufacturer's protocol. Each

reaction was prepared in a separate well containing cDNA template, 300 nM of both forward and reverse primers and SYBR Green PCR Master Mix (Applied Biosystems). Relative gene expression was determined using the ΔΔCT method (Livak and Schmittgen 2001).

Influence of JH III Treatment and Feeding on Enzyme Activity of HMGS, HMGR, and GPPS We assessed the enzymatic activity of HMGS, HMGR and GPPS in groups of male *I. confusus* treated with 0.5 µl of acetone and allowed to feed in a bolt of pinyon pine for 4, 8 and 16 hr. Beetles were placed in holes predrilled into the phloem and strips of aluminum screen were secured over the holes to prevent the insects from leaving the log. Males were also treated with JH III (10 µg JH III in 0.5 µl of acetone) and incubated in the dark at room temperature for 4, 8 and 16 hr. The same number of beetles treated with 0.5 µl of acetone and incubated in the dark served as controls for each time point. We also measured the enzymatic activity of HMGS and GPPS in male *I. pini* treated as described above. The enzymatic activity of HMGR in response to feeding and JH III treatment has recently been reported for *I. pini* (Tillman et al. 2004) and was not further studied here.

HMG-CoA Synthase Activity Midguts of ~ 30 individual beetles for each treatment were dissected, stored in liquid nitrogen and homogenized with a mortar and pestle in 20 ml of homogenization buffer (0.25 M sucrose, 0.1 mM EDTA, 2.0 mM Hepes, and 100 mM of PMSF, pH 7.2). Microsomes were separated by differential centrifugation and enzyme activity assayed as described by Clinkenbeard et al. (1975) and revised by Scharnagl et al. (1995). In this assay, 100 µg of microsomal protein was combined with 120 µm acetoacetyl-CoA in 200 µl of assay buffer (0.1 M Tris-HCl (pH 8.0), 0.1 mM EDTA and 20 mM $MgCl_2$). The reaction mixture was then incubated for 2 min in a 30°C water bath and 400 µM total acetyl-CoA (~55,500 dpm/reaction) was added. The reaction then remained in the water bath and after 9 min (linear range) was stopped by pipetting a 50 µl aliquot of the mixture into scintillation vials containing 200 µl of 6 N HCl. The tubes were then placed in a 90°C sand bath for 2 hr. Under these conditions, CoA thioesters are hydrolyzed and non-reacted [^{14}C] acetate is evaporated, and only [^{14}C] HMG acid, from enzymically formed HMG-CoA, remains. The amount of labeled HMG acid formed during the reaction by HMG-CoA synthase was then determined using a TRI-CARB 2900 TR liquid scintillation analyzer. Samples were run in triplicate and, as an appropriate control, we also measured the amount of radiolabeled HMG acid formed in reactions that contained no enzyme protein.

HMG-CoA Reductase Activity HMG-CoA reductase activity was assayed using a protocol modified from Casals et al. (1996) and Tillman et al. (2004). In this assay, midguts were dissected from ~ 90 adults for each treatment, placed in liquid nitrogen, and homogenized in 500 µl of assay buffer (100 mM sucrose, 40 mM K_2PHO_4, 30 mM EDTA, 50 mM KCl, 10 mM DTT, pH 7.4). Microsomes were then isolated by serial centrifugation (HMGR protein is located in the endoplasmic reticulum). The tissue homogenate was first centrifuged at 7740×*g* for 5 min at 4°C to remove large debris, and the resultant supernatant was further centrifuged at 12,100×*g* for 20 min to remove the mitochondria. To pellet the microsomal fraction, the supernatant from the 12,100 x *g* spin was ultracentrifuged at 165,000×*g* for 69 min at ~ −5ºC. The resulting pellet was then resuspended in 20 µl of assay buffer (50 mM K_2PHO_4, 5 mM EDTA, 200 mM KCl, 5 mM DTT, pH 7.4) and total protein concentration was determined by the Bradford method (1976) using bovine serum albumin (1 mg/ml) as an external standard.

3-Hydroxy-3-methylglutaryl-CoA reductase activity was determined by measuring the conversion of [3-^{14}] HMG-CoA to [3-^{14}] mevalonolactone. Specifically, the reaction mix contained 175 µM total HMG-CoA (1:1 labeled: unlabeled; ~44,000 dpm), 10 mM NADPH, ~ 100 µg of microsomal protein in 200 µl of assay buffer (N=3 assay samples from one preparation of microsomes). The mixture was incubated for 10 min in a 37ºC water bath with shaking and then the reaction was terminated with the addition of 20 µl of 5 M HCl. The samples were then incubated for another 30 min in the 37ºC water bath to catalyze the cyclization of linear mevolonate to mevalonolactone (MLL). Following the incubation, the reaction mixture was extracted three times with 5 ml aliquots of diethylether which were combined over Na_2SO_4. The combined ether extracts were then concentrated to ~ 200 µl and the [^{14}C] mevalonolactone was separated from the unreacted [^{14}C] HMG-CoA by silica paper chromatography using a solvent development system of 1:1 hexane:acetone. A MLL standard was also run along with the radiolabeled reaction products. The migration (R_f value) of the radiolabeled compounds along the silica plate were determined using a BioScan Imaging Scanner System 200-IBM (Bioscan, Inc., Washington, D.C.). The position of the [^{14}C]mevalonolactone on the silica plate was determined by comparing its R_f value to that of the MLL standard. The portion of silica containing the labeled MLL was then scraped from the plate and the radioactivity was quantified using a Packard TRI-CARB 2900 TR (Perkin Elmer, Germany) liquid scintillation analyzer (LSA).

GPPS Activity Prenyltransferase activity was measured as per Gilg et al. (2005) with modifications. A standard acid-lability assay was used to measure the incorporation of [1-^{14}C] isopentenyl diphosphate (IPP) into polyprenyl

products. Specifically, ~ 100 µg of soluble beetle tissue extract (~30 beetles per treatment) was combined with allylic substrate (50 µm DMAPP) and 10 µM [1-^{14}C] total IPP (55 µCi/µmol) in 200 µl of assay buffer (20 mM Hepes (pH 7.2), 2.5 mM $MgCl_2$, 5 mM KF, 1 mM DTT, 10% glycerol, and protease inhibitor). The reaction mixture was then incubated for 1 h at 32ºC. The resulting acid was hydrolyzed by adding10 µl of 5 N HCl and reincubating the mixture for 30 min at 32ºC. After the incubation period, the reaction products were extracted with 300 µl ddH_2O and 1 ml hexane and the radioactivity of 500 µl of the organic/hexane phase radioactivity measured using a Packard TRI-CARB 2900 TR (Perkin Elmer, Germany) liquid scintillation analyzer (LSA).

We also used reverse phase-high performance liquid chromatography (HPLC) to confirm that isoprenyl diphosphate was the product of the reaction. The reaction was carried out as described above, but terminated by boiling the samples for 5 min and then spinning them at 16,000×*g* for 5 min. Clear homogenates (injection volume 200 µl: 100 µl of reaction sample mixed with 75 µl of buffer and 25 µl of authentic mixed standards (DMAPP, GPP, FPP, GGPP; 1:1:0.5:0.5) were directly loaded onto a Discovery 250×4.6 C_{18}, 5 µm, silica column (Supelco) using a HP 1050 series HPLC. Phosphorylated short-chain isoprenyls were cleanly separated using a solvent system of 25 mM NH_4HCO_3 pH 7.0: acetonitrile as described by Zhang and Poulter (1993). Samples were eluted at a flow rate 1 ml/min by using a linear gradient program: 100% 25 mM NH_4HCO_3 for 5 min and 0–100% acetonitrile for 30 min. Eluent was monitored by UV (214 nm). One milliliter fractions were collected by using an Amersham Pharmacia LKB-FRAC-100 Fraction Collector (Amersham Pharmacia Biotech), and fractions corresponding to IPP/DMAPP,GPP, FPP, and GGPP peaks (retention times 4, 16, 20, and 25 min, respectively) were assayed for radioactivity by using a TRI-CARB 2900 TR LSA.

Statistical Analysis of Enzyme Activity The activity of HMGS, HMGR, and GPPS in response to feeding and JH III treatment was expressed as a fold increase in enzymatic activity compared to acetone-treated controls (see Schiefelbein et al. 2008). Data are reported as means±S.E. and enzymatic activity over time by treatment was compared using a nested analysis of variance (nested ANOVA, Dunnett's method; STATSOFT 2005).

Results

Influence of Feeding and JH on the Production of Key Pheromone Components GC analysis of volatiles collected from fed and JH III-treated male *I. confusus* revealed that ipsenol and ipsdienol are produced only in response to feeding (one-way ANOVA, $F_{4,\ 10}$=45.6, P<0.0001). In response to feeding for 20 h, males released 563.4±31.1 ng of ipsenol (mean±SE) and 194.3±65.2 ng of ipsdienol; these data suggest that JH III alone is not sufficient to stimulate pheromone production in male *I. confusus.*

Expression Analysis Partial cDNA clones were obtained for *I. confusus* HMGR (IcHMGR; accession no. FJ536869), HMGS (IcHMGS; accession no. FJ536868), GPPS (IcGPPS; accession no. FJ536870), and *cytoplasmic actin* (IcActin; accession no. FJ536867) using *I. pini* gene-specific primers and degenerate primers in conjunction with homology-based PCR techniques. The effect of a 10 µg dose of JH III on the mRNA levels of the three mevalonate pathway genes in the anterior midgut of male beetles was determined at multiple time points using quantitative real-time PCR. In male *I. confusus*, feeding and JH III treatment were both sufficient to raise transcript levels for the three genes examined (Fig. 2). For male beetles, each gene demonstrated slightly different transcript values at each time point, but the expression patterns over time were very similar. In general, the mRNA levels following JH III-treatment showed a modest increase and peaked at either 8 or 16 hr and gradually decreased thereafter, reaching a level at or below the 4 hr time point at 32 hr post-treatment (Fig. 2). In comparison, transcript levels following feeding demonstrated a similar pattern as JH III treatment at the first two time points, but the induction was not as pronounced. Whereas the induction of the mevalonate pathway genes begins to decline at the latter time points (16 and 32 hr) with JH III treatment, feeding causes a marked increase in mRNA levels, reaching their highest values at 32 hr post treatment.

HMG-CoA Synthase Activity In both male *I. confusus* and *I. pini* there was a significant increase in enzyme activity over time by treatment (ANOVA, *I. confusus,* $F_{6,\ 18}$=168.6, P< 0.001; *I. pini*, $F_{6,\ 18}$=22.9, P<0.001; Fig. 3). In male *I. pini,* both JH III and feeding caused significant increases in HMGS activity over the acetone-control at the 16 hr time point (2.32±0.89 and 4.23±0.32 fold increases, respectively; ANOVA, Dunnett's method, P<0.001). However, only feeding alone caused a significant increase in enzymatic activity over the acetone-treated control in male *I. confusus* (4.85±0.25 fold increase; ANOVA, Dunnett's method, P<0.001).

HMG-CoA Reductase Activity There was a significant increase in enzymatic activity of HMGR with time by treatment (ANOVA, $F_{6,\ 17}$=3.65, P<0.05; Fig. 4), and feeding caused a significant increase in enzyme activity over the control at the 8 and 16 hr time points (ANOVA,

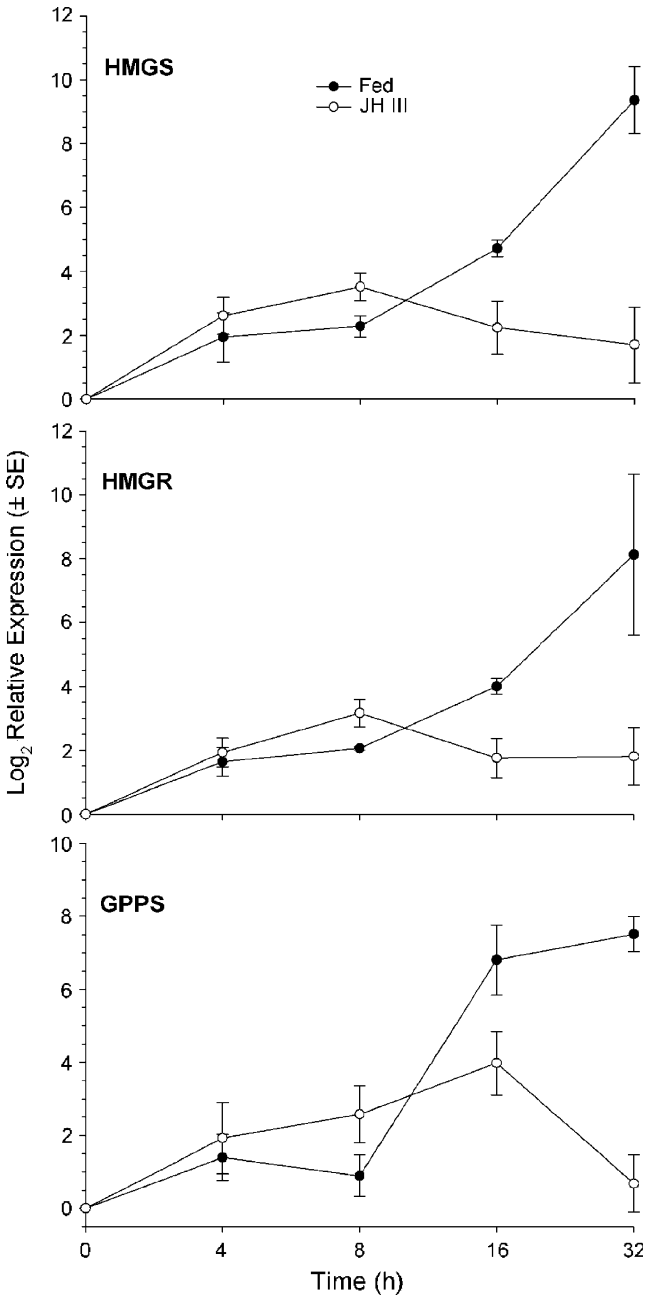

Fig. 2 Effect of JH-III treatment and feeding on the relative expression of *HMGS* (top), *HMGR* (middle), and *GPPS* (bottom) in midguts of male *I. confusus* as measured by qRT-PCR. Expression (Log_2) is relative to either acetone-treated males for JH-III treatment or unfed controls for fed males

Dunnett's method, $P < 0.001$ and $P < 0.05$, respectively). In fact, HMGR activity was increased by 1.32±0.29 fold over the control at 8 h and 0.86±0.41 fold at 16 hr. Treatment with JH III, however, caused no significant increase in activity over the acetone treated controls at all time points (Fig. 4).

GPPS Activity GPPS activity increased with time by treatment for both *I. confusus* and *I. pini* (ANOVA, *I. confusus,* $F_{6,\ 18}=8.85$, $P<0.001$; *I. pini*, $F_{6,\ 18}=15.1$, $P<0.001$; Fig. 5). For *I. pini,* both JH III-treatment and feeding caused a significant increase in activity over the acetone-treated control at 16 hr (1.28±0.32 and 0.987±0.18 fold increases, respectively; ANOVA, Dunnett's method, $P<0.001$). Interestingly, feeding alone caused an increase in GPPS activity at 8 and 16 hr post treatment in male *I. confusus* (0.44±0.13 and 1.16±0.09 fold increases, respectively; ANOVA, Dunnett's method, $P<0.05$). Moreover, it was confirmed by HPLC analysis that GPP was the only short-chain isoprenyl diphospate product of these assays.

Discussion

The present results support the hypothesis that in *I. confusus*, a member of the *I. grandicollis* subgeneric group, JH III does not exclusively regulate pheromone production.

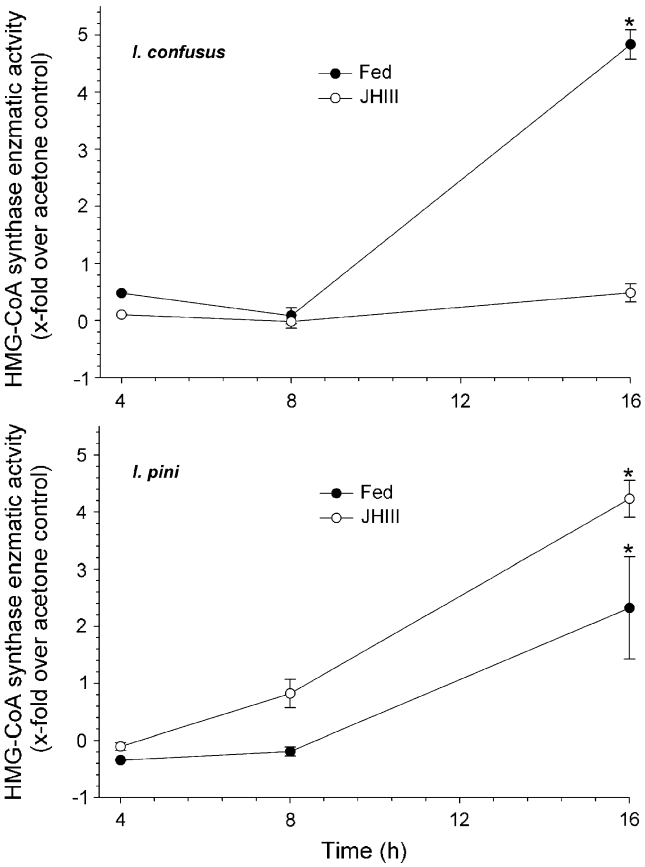

Fig. 3 Effect of feeding and JH III treatment on the enzymatic activity of HMG-CoA synthase in male *I. confusus* (top) and *I. pini* (bottom). An *asterisk* denotes a significant difference in enzyme activity relative to acetone-treated controls (Dunnett's method, $P<0.05$)

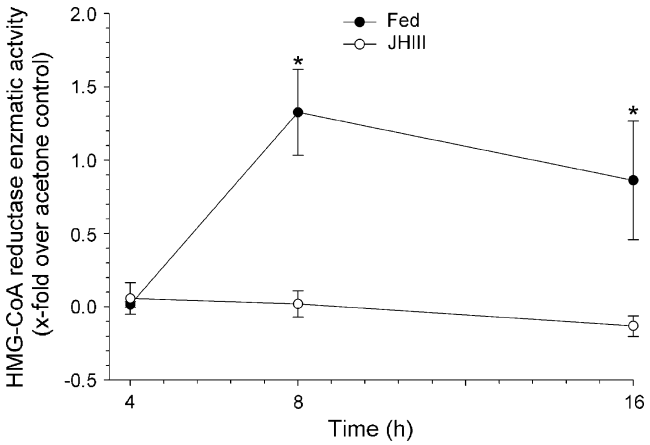

Fig. 4 Effect of feeding and JH III treatment on the enzymatic activity of HMG-CoA reductase activity in male *I. confusus*. An *asterisk* denotes a significant difference in enzyme activity relative to acetone-treated controls (Dunnett's method, $P<0.05$)

Here, we show that feeding, but not JH III treatment, stimulates pheromone production in male *I. confusus*. Previous work by Borden et al. (1969) demonstrated that gut extracts of male *I. paraconfusus* (then referred to as *I. confusus*) become highly attractive to female beetles after topical application of synthetic JH (Borden et al. 1969). However, large non-physiological doses (50–100 µg) of hormone were required to attain a strong response, and females were not attracted in bioassays to midguts treated with 10 µg of JH, the amount used in our study (Borden et al. 1969). Moreover, females were attracted to as little as 0.02 male equivalents of extract from males which had fed on host phloem, while extract from hormone-treated males elicited only a weak response (Borden et al. 1969).

The induction of mevalonate pathway genes in male bark beetles often precedes an increase in protein production, enzyme activity, and pheromone production (Tillman et al. 2004; Bearfield et al. 2006). In male *I. confusus,* either JH III treatment or feeding is sufficient to increase *HMGS*, *HMGR*, and *GPPS* transcript levels in the anterior midgut (Fig. 2). At the 4 h and 8 h time points, the transcript levels of the fed-group were slightly lower and likely due to the time necessary for JH III to be synthesized and released following feeding. At the 16 hr and 32 hr time points, however, expression levels of JH III-treated males began to decline likely due to the hormone dose being metabolized while the fed beetles showed large increases in all three genes studied (Fig. 2). Although each gene shows a modest induction of transcript at 32 hr following JH III treatment, the relative expression patterns at 32 hr post-feeding are 100 to 200-fold higher than unfed controls (Fig. 2). In addition to the transcriptional effects of JH III, these results suggest that a supplemental factor released following feeding may further induce the expression of mevalonate pathway genes in male *I. confusus*.

Feeding induces the coordinated gene expression of several earlier steps in monoterpenoid pheromone biosynthesis in both male and female *I. pini*, including *HMGS* and *HMGR*, but *GPPS,* a later step in the pathway, is induced only in males (Keeling et al. 2004). In male *I. confusus*, the differences in transcriptional regulation between JH III treatment and feeding were generally more pronounced further along the biosynthetic pathway and the disparity was most dramatic at 32 hr for all three genes (Fig. 2). The increases in relative expression with feeding were ~65-, 55-, and 120-fold above JH III-treated males for *IcHMGS*, *IcHMGR*, and *IcGPPS*, respectively (Fig. 2). Therefore, it appears that in *Ips* species, the early biosynthetic steps are more coordinately regulated by both feeding and JH III treatment than the terminal steps in the mevalonate pathway. A developmental factor may also contribute to the alternate regulation of pheromone biosynthesis due to the higher basal levels of mevalonate pathway genes. Specifically, basal *GPPS* mRNA levels in male *I. pini* are 400-500-fold above female levels (Keeling et al. 2006), suggesting that the last steps of the pathway are more

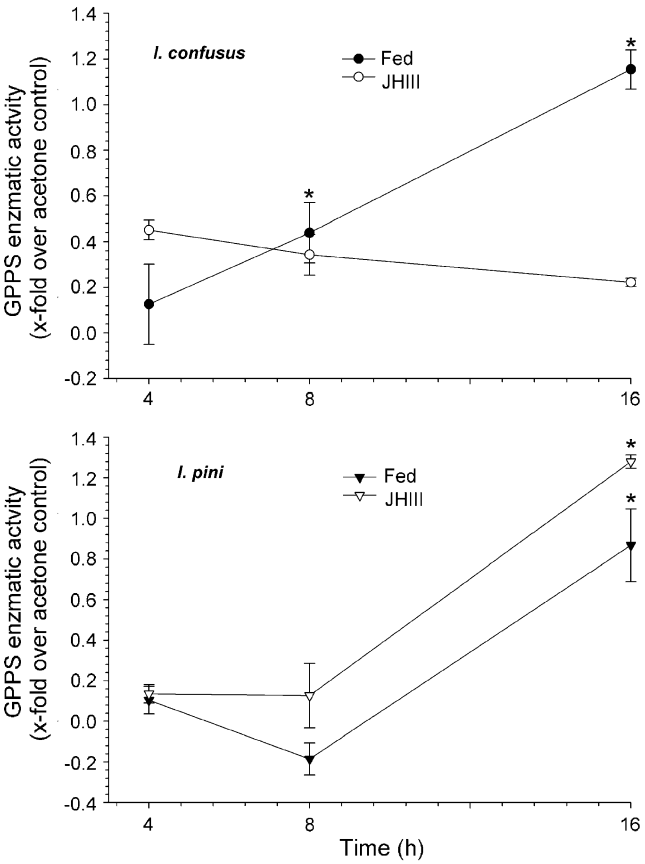

Fig. 5 Effect of feeding and JH III treatment on GPPS enzyme activity in male *I. confusus* (top) and *I. pini* (bottom). An *asterisk* denotes a significant difference in enzyme activity relative to acetone-treated controls (Dunnett's method, $P<0.05$)

developmentally regulated than *HMGS* and *HMGR*. In *I. confusus*, however, all genes studied here demonstrated only a two-fold difference in basal transcript levels (data not shown). Although not studied in as much detail, the same coordinate regulation between sexes does not exist in *D. jeffreyi* as only males demonstrate an induction of *HMGS* and *HMGR* with JH III treatment (Hall et al. 2002b; Tittiger et al. 2000, 2003). Male *D. jeffreyi* produce a mevalonate-derived aggregation pheromone component, frontalin, in response to exogenous treatment with JH III (Barkawi et al. 2003)

In *I. confusus*, feeding also caused an increase in HMGS, HMGR, and GPPS enzymatic activity in male beetles (Figs. 3, 4, and 5). Although mRNA levels were induced by JH III treatment in male *I. confusus* (Fig. 2), there was no concomitant increase in enzyme activity (Figs. 3, 4, and 5) or production of ipsdienol and ipsenol in treated insects. Similarly, the mRNA induction of *HMGR* with JH III treatment in male *I. paraconfusus*, measured by northern blot analysis, is not followed by a subsequent increase in enzymatic activity of HMGR or pheromone production (Tillman et al. 2004). In this study, we also determined that the enzymatic activity of HMGS and GPPS in *I. pini* and *I. confusus* are not uniformly regulated by JH III. Unlike *I. pini*, the activity of HMGS and GPPS in male *I. confusus* was not influenced by hormone treatment.

Tillman et al. (2004) demonstrated a difference in the regulation of pheromone production between species in the *pini* and *grandicollis* subgeneric groups. The work presented here further supports the existence of a dichotomy in the regulation of pheromone production among *Ips* species. It has also been suggested that feeding by male *I. paraconfusus* may cause the release of a brain hormone by *corpora cardiaca* which, in turn, may stimulate pheromone production (Hughes and Renwick 1977; Lu 1999). Interestingly, in preliminary experiments brain extracts from fed male *I. confusus* were sufficient to cause a modest increase in ipsenol production in JH III-treated males (unpub. data). Further study will likely reveal regulatory factors influencing pheromone biosynthesis in members of the *grandicollis* group of bark beetles.

Received: 12 March 2009 / Revised: 27 May 2009 / Accepted: 2 June 2009 / Published online: 20 June 2009

Abstract Age-related changes of antennal-active components of male labial gland extracts were studied in two closely related bumblebee species, *Bombus terrestris* and *B. lucorum*. In *B. terrestris,* compounds eliciting electroantennogram (EAG) responses of virgin queens were ethyl dodecanoate, 2,3-dihydrofarnesal, 2,3-dihydrofarnesol, hexadecan-1-ol, octadeca-9,12,15-trien-1-ol, and geranylcitronellol. Compounds that elicited EAG responses from queens of *B. lucorum* were ethyl dodecanoate, ethyl tetradec-7-enoate, ethyl tetradec-9-enoate, ethyl hexadec-9-enoate, hexadecan-1-ol, hexadec-7-enal, octadeca-9,12-dien-1-ol, octadeca-9,12,15-trien-1-ol, and octadecan-1-ol. Quantities of these compounds in the labial glands changed significantly over the lifetime of the respective males of the two species. In both species, concentrations of the respective compounds reached their maximum within seven days after eclosion. Subsequently, a rapid decrease in the amount of EAG-active compounds occurred in *B. terrestris*, whereas in *B. lucorum* the amount of active compounds stayed approximately constant or decreased at a slow rate. Microscopy showed that in *B. terrestris* secretory cells of the labial glands undergo apoptosis from the fifth to the tenth day of life, whilst in *B. lucorum* labial gland cells remain unchanged throughout the life of the males.

Introduction

The most common European bumblebee species, *Bombus terrestris* (Linnaeus 1758) and *Bombus lucorum* (Linnaeus 1761), both belong to the subgenus *Bombus sensu stricto*. As observed for other bumblebee species during premating behavior, *B. terrestris* and *B. lucorum* males scent-mark prominent objects on their flight routes with a species-specific sex pheromone ('patrolling behavior'; Calam 1969; Schremmer 1972; Svensson 1980; Lloyd 1981; Morse 1982; Villalobos and Shelly 1987) that attracts conspecific virgin queens to the marked spots for mating (Kullenberg et al. 1970; Bergström et al. 1981; Bergman 1997).

The male-produced pheromones of these bumblebees are produced in the cephalic part of the labial gland (Kullenberg et al. 1973; Bergman and Bergström 1997). Volatile components of the gland secretion are deposited on prominent objects on the flight routes or on perches (Bergman and Bergström 1997; Kindl et al. 1999). The secretion is a complex mixture, comprised of many compounds, usually with one or two major components (Valterová and Urbanová 1997; Terzo et al. 2003). In closely related bumblebee species, the secretions may be similar but usually differ in dominant components and/or compound proportions. Although the main components of the secretion are presumed to comprise the sex pheromone, behavioral roles of specific components in female attraction have yet to be demonstrated. Thus, the actual male-produced pheromone components in secretions of bumblebee species are unknown.

The composition of bumblebee labial gland secretions is used as a tool for taxonomic identification and species and subspecies discrimination (Paterson 1993; Terzo et al. 2005; Rasmont et al. 2005; Bertsch et al. 2005; Coppée et al. 2008). However, there is great inter-individual variability in the composition of secretion components within a single species (Svensson and Bergström 1977; Ågren et al. 1979; Šobotník et al. 2008), which can make differentiation difficult, especially among related species. Recently, changes of cephalic labial gland ultrastructure in relation to age of males were reported for *B. terrestris* (Šobotník et al. 2008). It was found that the secretory activity of the gland cells is high in newly emerged males, but drops as males age. Five days after eclosion of the adult male bumblebee, the biosynthetic activity within the gland stops, and the secretory cells degenerate (Šobotník et al. 2008). Maximal gland content occurred in 2–7 day-old males, and decreased in older males. This age-related change in gland content was paralleled by the ability of gland extracts from different age males to elicit electroantennogram (EAG) responses from queen antennae. Although the study by Šobotník et al. (2008) demonstrated changes in the volume of gland content with age, there was no detailed chemical analysis of changes in the quantities of components of the secretion. They did, however, perform coupled gas chromatogram-electroantennogram detection (GC-EAD) experiments, using male labial gland secretions and queen antennae, and found at least six antennal-active compounds, ethyl dodecanoate, 2,3-dihydrofarnesal, 2,3-dihydrofarnesol, hexadecanol, octadecatrienol, and geranylcitronellol, that could potentially play a role in male sex pheromone signaling (Šobotník et al. 2008; Valterová et al. 2007).

Qualitative analysis of the labial gland extract from *B. lucorum* has previously been performed (Bergström et al. 1973; Urbanová et al. 2001). However, no attention has been paid to age of males. There are a few reports on seasonal variation in the secretion composition of other bumblebee species (Kullenberg et al. 1970; Svensson and Bergström 1977; Ågren et al. 1979), but thus far the phenomenon of age-related changes in composition has not been studied systematically.

In the present study, we report age-dependent quantitative changes of major EAG-active components of the labial gland of two related bumblebee species, *B. lucorum* and *B. terrestris*. This allowed us to determine whether the relatively time-limited labial gland secretion activity observed in *B. terrestris* also occurs in another species in the subgenus *Bombus sensu stricto.*

Methods and Materials

Insects Colonies of *B. lucorum* and *B. terrestris terrestris* (L.) were established by the two-queens cascade method (Ptáček et al. 2000). All mother queens were taken from their natural habitats during the nest-searching period in order to minimize the possible negative influence of artificial conditions on the progeny. Bumblebee colonies were kept in plastic boxes of 0.6–1 L volume and fed with honeybee pollen pellets and concentrated sugar solution (sucrose:fructose 1:1). When colonies started to produce males, male cocoons were removed from the parental hives and left to mature separately under the care of several workers supplied with food (Ptáček 1999). Freshly emerged males were removed and kept according to age. Animals of the following age were studied. *Bombus terrestris*: shortly after eclosion, 1, 2, 3, 4, 5, 7, 10, 12, 17, 20, 24, and 33 days after eclosion (five individuals of each age); *B. lucorum*: shortly after eclosion, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 15, 20, 25, and 30 days after eclosion (5–6 individuals of each age). Males were killed by freezing (−18°C) and were kept frozen prior to dissection. Labial glands were dissected and extracted with hexane (100 µl per gland) containing 1-bromodecane as internal standard (1.79 mg/ml for *B. terrestris* and 2.13 mg/ml for *B. lucorum*). Glands, in solvent, were shaken for 30 min after which the extracts were transferred to clean vials and kept at −18°C prior to analysis.

Identification of Compounds Extracts were analyzed by gas chromatography-mass spectrometry (GC-MS) using a splitless injector (200°C), mass detector (200°C, Fisons MD 800) and autosampler AI3000 (Thermo). A DB-5 ms column (30 m × 0.25 mm, film thickness 0.25 µm, Agilent Technologies) and helium gas (constant flow of 1 ml min^{-1}) were used for separations. The temperature programs differed for samples of the different species: for *B. terrestris*, 70°C (2 min. delay) to 320°C at 10°C min^{-1}; for *B. lucorum*, 70°C (2 min. delay) to 140°C at 40°C

min^{-1}, to 240°C at 2°C min^{-1}, and then to 320°C at 4°C min^{-1}. Compounds were identified based on their mass spectra and on co-chromatography with synthetic or commercially available standards.

Gas chromatography-electroantennogram detection GC-EAD experiments were performed with a 5890A Hewlett-Packard gas chromatograph (GC) equipped with a DB-5 column (30 m×0.25 mm, film thickness 0.25 µm, J & W Scientific). The column was split by a Graphpack 3D/2 four-arm splitter. The splitter led the eluate to flame ionization (FID) and EAD detectors. N_2 make-up gas at 20 ml min^{-1} was introduced via one arm of the splitter. Labial gland extracts (1–5 µl) were injected in the splitless mode. The GC was temperature programmed from 50°C (2 min. delay) to 270°C at 30°C min^{-1}. The temperature of the injector and FID were set to 230 and 260°C, respectively. The EAD detector consisted of a queen antenna connected via two glass Ag/AgCl electrodes to a universal AC/DC 10XProbe (Syntech, Hilversum, The Netherlands). The EAD and FID signals were fed to a computer via the serial IDAC interface box (Syntech) and analyzed by using GC-EAD software (Syntech). The antenna was exposed to compounds that eluted from the GC via an Effluent Conditioner Tube (Syntech) heated to 180°C. Virgin queens (N=4) used for GC-EAD recording were kept at low temperature (5°C) and high humidity until use. Isolated antennae, with the distal tips excised, were used for recordings. Each antenna was used only once.

Chemicals The following standards were used for the quantification of EAG-active components of the labial gland secretions: (*E*)-farnesol (Firmenich, Geneva, Switzerland), geranylgeraniol (ICN, Irvine, CA, USA), ethyl tetradec-9-enoate (Nu-Check-Prep, Elysian, MN, USA). (*Z,Z,Z*)-Octadeca-9,12,15-trien-1-ol, ethyl dodecanoate, hexadecan-1-ol, octadecan-1-ol, (*Z,Z*)-octadeca-9,12-dien-1-ol, and ethyl hexadec-9-enoate were purchased from Sigma (St Louis, MO, USA). (*Z*)-Hexadec-9-enal was prepared earlier in our laboratory.

Quantitative Analyses Only EAD-active compounds were quantified. For *B. terrestris*, 2,3-dihydrofarnesol, 2,3-dihydrofarnesal, geranylgeraniol, geranylcitronellol, (*Z,Z,Z*)-octadeca-9,12,15-trien-1-ol, and ethyl dodecanoate were quantified; *B. lucorum:* ethyl dodecanoate, ethyl tetradec-7-enoate, ethyl tetradec-9-enoate, ethyl hexadec-9-enoate, hexadecanol, hexadec-7-enal, octadecan-9,12-dienol, octadecan-9,12,15-trienol, and octadecanol were quantified. Quantification was carried out in Total Ion Current mode of the mass detector and based on peak areas. Because the different compounds were present in samples at widely differing concentrations, we had to avoid overloading the mass detector with the most abundant component. Separation of ethyl tetradec-7-enoate and ethyl tetradec-9-enoate under the conditions used was poor. Therefore, these two isomers were quantified together according to the external calibration for ethyl tetradec-9-enoate. Previous studies (Urbanová et al. 2001) showed that the concentration ratio of these isomers in the labial gland extracts was: $\mathrm{area}_{\mathrm{ethyltetradec-9-enoate}} / \mathrm{area}_{\mathrm{ethyltetradec-7-enoate}} = 187.5$. We assumed that the difference in responses of these isomers in the mass detector was less than 5%, and the concentration ratio remained constant over a bumblebee's life.

The calibration curve for (*Z*)-hexadec-7-enal was constructed by using (*Z*)-hexadec-9-enal, as the correct isomer was not available. 2,3-Dihydrofarnesol and 2,3-dihydrofarnesal quantification was calibrated by using farnesol, and geranylcitronellol was calbrated by using geranylgeraniol, due to unavailability of standards. Considering the close similarities in structures between calibrants and compounds, we assumed the quantification error to be low. Octadeca-9,12-dienol and octadeca-9,12,15-trienol could not be separated, but the same approach and assumption as used for ethyl tetradec-7-enoate and ethyl tetradec-9-enoate were used for the samples and quantitative calibration.

The same internal standard (IS; 1-bromodecane, ~2 mg/ml) was used for both calibration and sample sets. Calibration curves were constructed from peak area (ratios of standard/IS). Second degree polynomial equations were used to fit the obtained data. Unknown sample concentrations were calculated by using the calibration curve equations and expressed in µg per gland for each component. Mean values and standard errors were calculated for each male age group.

Microscopy Fixed cephalic parts of labial glands of *B. lucorum* originated from males of ages, pharate imago (darkly colored males enclosed in pupal cuticle shortly before eclosion), <1 d, 1, 2, 3, 4, 5, 6, 9, and 13 days. Two to four samples of each age were studied using optical microscopy and, as only slight differences were observed over the adult life of a male, only a single sample of each age was studied by transmission electron microscopy. Dissection took place in a droplet of fixative (2% glutaraldehyde and 2.5% formaldehyde in 0.1 M phosphate buffer), in which the tissue stayed for 1 day at ambient temperature. After post-fixation in 1.5% OsO_4 in 0.1 M phosphate buffer, the samples were dehydrated by passing through a series of ethanol-water mixtures (50, 75, and finally 100%). Tissues were then embedded into standard Spurr resin. Semithin sections (1 µm) were stained with Azure II and observed under Amplival (Zeiss) optical microscope (equipped with Canon EOS 300D camera). Ultrathin sections were studied with a Jeol 1011 transmission electron microscope.

Results

Gland Microscopy Microscopy of the cephalic labial gland showed differences between the two species. Unlike *B. terrestris*, the labial gland of *B. lucorum* remained functional throughout the life of the adult male. Additionally, in *B. lucorum*, the production of lipid secretion by the smooth endoplasmic reticulum (SER) started earlier (at time of emergence) (c.f., in *B. terrestris* production started on the 2nd day after emergence). The lipids were continuously secreted at the cell apices and, as their volume increased, were accompanied by swelling of the lumen and a decrease in cell layer thickness (Fig. 1a–c; optical microscopy).

The active transport of precursors from the hemolymph was observed in young males of both species, with the transport stopping during the third day after eclosion in *B. terrestris* (Šobotník et al. 2008), but continuing in males of *B. lucorum* up to the 13th day after eclosion. This

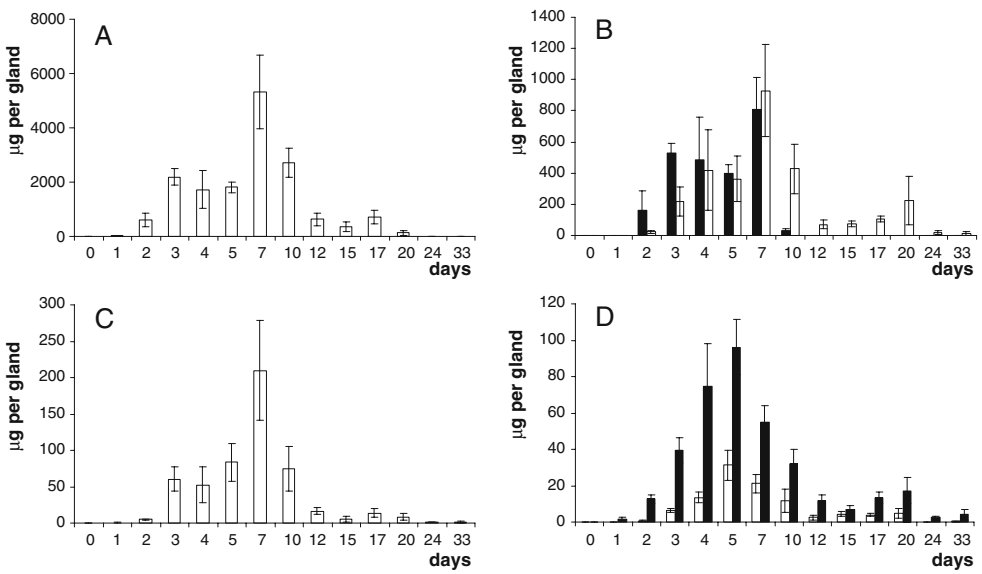

Fig. 4 Concentration changes, with regard to age of adult male, of electroantennogram-active compounds in the cephalic labial gland of *Bombus terrestris* males (mean ± standard error). **a** 2,3-dihydrofarnesol; **b** geranylcitronellol (white bars) and ethyl dodecanoate (black bars); **c** hexadecan-1-ol; **d** 2,3-dihydrofarnesal (white bars) and octadeca-9,12,15-trien-1-ol (black bars)

difference is associated with the different fates of the secretory cells in both species. The cells died after several days of secretory activity in *B. terrestris* (between the 5th and 10th day, Fig. 1d), whereas they conitnued to produce secretion throughout the life of adult *B. lucorum* males. However, even in older *B. lucorum* males, flattening of cells, lower volume of SER, and fewer droplets of secretion in the cell cytoplasm were observed (Fig. 2a,b; electron microscopy) indicating a decreasing rate of secretion production.

GC-MS, GC-EAD, and quantitative analyses In the labial gland of *B. terrestris,* the EAD-active compounds were identified as ethyl dodecanoate, 2,3-dihydrofarnesal, 2,3-dihydrofarnesol, hexadecanol, octadeca-9,12,15-trienol, and geranylcitronellol (Fig. 3a). In *B. lucorum*, ethyl dodecanoate, ethyl tetradec-7-enoate, ethyl tetradec-9-enoate, ethyl hexadec-9-enoate, hexadecanol, hexadec-7-enal, octadeca-9,12-dienol, octadeca-9,12,15-trienol, and octadecanol elicited antennal responses in conspecific queens (Fig. 3b).

The EAD-active compounds of both species were quantified. In *B. terrestris*, the most abundant EAD-active component of the extract was 2,3-dihydrofarnesol (Fig. 4a). Males produced small quantities (ca. 20 µg/gland) of this compound on the day of eclosion. The quantity of this compound increased up to 2 mg/gland over the next two days, and remained roughly constant at this level for three more days. On the 6th and 7th days following eclosion, the concentration increased almost three times to ca. 6 mg/gland. Subsequent to this, the amount of 2,3-dihydrofarnesol decreased dramatically, such that at 10 days after eclosion, it fell to ca. 0.5 mg/gland. By day 20, 2,3-dihydrofarnesol was present in the gland at a very low amount (2 µg/gland). A similar pattern was observed for geranylcitronellol (1 µg–1 mg/gland, Fig. 4b) and hexadecanol (0.5 µg–200 µg/gland, Fig. 4c). A different age-dependent pattern was observed for ethyl dodecanoate, which appeared in the secretion later than the terpenes (at 2 days, 0.5 µg/gland), increased to its maximum concentration (800 µg/gland) on day 7, and then dropped to 0.7 µg/gland by day 20 (Fig. 4b). The remaining EAD-active compounds, octadecatrienol and 2,3-dihydrofarnesal, reached a maximum concentration around day five (100 µg/gland and 30 µg/gland, respectively, Fig. 4d).

The concentration profiles of the most abundant EAD-active compounds (i.e., ethyl tetradec-7-enoate and ethyl tetradec-9-enoate) present in the gland of *B. lucorum*, (Fig. 5a), differed from those in *B. terrestris.* In *B. lucorum*, no significant maxima were observed in the profile of the most abudnant EAD-active compounds, with the quantities remaining relatively constant over the adult life of the males. Ethyl tetradec-7-enoate and ethyl tetradec-9-enoate were both present (ca 0.9 mg/gland) in the gland on the day after eclosion, with maximum quantities (total of 1.5 mg/gland) occurring between days 7–20. The quantities of these two compounds declined significantly by day 25. Other EAD-active compounds, ethyl dodecanoate and hexadecanol (Fig. 5b), were present at roughly one tenth the amount (113 and 91 µg/gland, respectively) of the main component, but their concentration profiles exhibited a similar pattern with no significant maximum or changes between days 4–10. However, by day 15, the amount of hexadecanol increased, especially in comparison to ethyl dodecanoate, and reached a maximum in 25-day old males (185 µg/gland). Patterns in concentration changes similar to that of hexadecanol were observed for ethyl hexadec-9-enoate and hexadec-7-enal (Fig. 5c). The alcohols octadeca-9,12-dienol, octadeca-9,12,15-trienol (Fig. 5d),

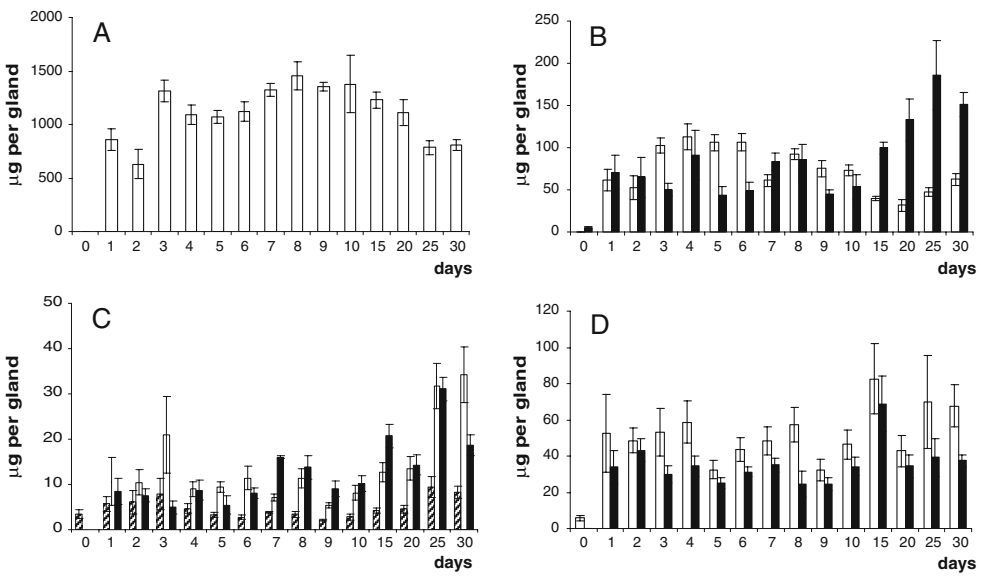

Fig. 5 Concentration changes, with regard to age of adult male, of electroantennogram-active compounds in the cephalic labial gland of *Bombus lucorum* males (mean ± standard error). **a** total ethyl tetradec-7-enoate and ethyl tetradec-9-enoate; **b** ethyl dodecanoate (white bars) and hexadecan-1-ol (black bars); **c** octadecan-1-ol (hatched bars), ethyl hexadec-9-enoate (white bars), and hexadec-7-enal (black bars); **d** octadeca-9,12-dien-1-ol (white bars) and octadeca-9,12,15-trien-1-ol (black bars)

and octadecanol (Fig. 5c) remained at a similar concentration (30–70 μg/gland) throughout the life of the male.

Discussion

The patterns in the quantitative profiles of the various EAD-active compounds corresponded well with the physiological and morphological changes observed in the labial glands for both species. While in *B. lucorum*, the secretory activity of the acinar cells continued over the lifetime of adult males, in *B. terrestris*, production stopped in males older than 10 days. The reasons behind the profound differences in labial gland morphlogy and chemical production between the closely related species are not clear and cannot be explained by lifetime of males, since laboratory observations show no difference in longevity (~50 days) of both species.

We speculate that the age-dependent changes in gland content may play a role in mate selection. Maximal labial gland content (and activity of secretory cells) was found in 3–5 day-old males of *B. terrestris*, which corresponds well with the time when males usually leave their natal nests (fifth day after eclosion) and start to mark and patrol. Additionally, maximal content in the gland matches maximal sperm content (6th day post-emergence; Tasei et al. 1998). In the laboratory, *B. terrestris* males mate between day 6–27 with the probability of successful mating dropping dramatically after day 11 (Tasei et al. 1998). Information about optimal reproductive behavior and physiology in *B. lucorum* is not available, but it would be interesting to know whether it matches the greater duration of labial gland content of EAD-active compounds found in this study.

It has been hypothesized that virgin queen bumblebees searching for a mate are likely to be more attracted to locations where higher amounts of secretion have been deposited by patrolling males (Ågren et al. 1979). Thus, given our results, it is possible that younger males of *B. terrestris* may have an advantage, over older males, in attracting queens, because their scent marks are likely to contain higher amounts of labial gland secretions than those of older males. Such an advantage would not be expectecd in *B. lucorum*, since young and old males have similar quantities of labial gland secretions.

Earlier reports on the variation in composition of the labial gland secretions of bumblebees are scarce. Kullenberg et al. (1970) described considerable seasonal variation in the diterpene content in the glands of *B. hortorum* and *B. hypnorum*. Svensson and Bergström (1977) found that diterpenic components in the labial gland secretion of *B. pratorum* males appear later in the season. Ågren et al. (1979) studied changes in labial gland secretion of various bumblebees species. No labial gland secretion compounds were observed in pupae of *B. hypnorum*. The compounds appeared from day 1 after emergence, and their amounts increased rapidly over the next 4–7 days. For *B. lapidarius*, measurements of gland content were not made until 7 days after eclosion. Secretion content had dropped 14 days after eclosion and further declined to undetectable by 19 –29 days. A similar declining trend was observed for *B. hortorum* males (Ågren et al. 1979). Although this study utilized an analytical technique (TLC) that did not allow precise quantifications of compounds to be made, the results are consistent with our observations for *B. terrestris*.

Although attractiveness of the male labial gland secretion for young queens has been demonstrated by Bergman (1997), roles of individual components in the blend have not been studied. Our study on the quantitative changes of EAG-active chemicals has identified a number of potential pheromone components, which should be tested in bioassays.

Finally, our results show that the production and composition of the labial gland secretion of male bumblebees vary considerably with age. Thus, chemotaxonomic studies that use labial gland secretions to distinguish between closely related species should take this variation into account, perhaps by analyzing solely mature and sexually active males. Such chemotaxonomic studies are best combined with other techniques such as morphology and genetic analysis, for differentiating clsoely related species (Bertsch et al. 2005).

Received: 5 December 2008 / Revised: 13 April 2009 / Accepted: 1 May 2009 / Published online: 21 May 2009

Abstract The honey locust gall midge, *Dasineura gleditchiae* Osten Sacken 1866 (Diptera: Cecidomyiidae) is the main pest of ornamental varieties of the honey locust tree, *Gleditsia triacanthos* L., in North America, and is now becoming a pest of concern in Europe. Female midges were observed to emerge in the early morning with their ovipositor extended until they mated. Volatiles were collected from virgin females in a closed-loop stripping apparatus and analyzed by gas chromatography (GC) coupled to electroantennographic (EAG) recording from the antenna of a male midge. A single EAG response was observed, which was assumed to be to the major component of the female sex pheromone. This was identified as (*Z*)-2-acetoxy-8-heptadecene by comparison of its mass spectrum and GC retention times on different columns with those of synthetic standards and by micro-analytical reactions. This compound was synthesized, and the individual enantiomers were produced by kinetic resolution with lipase from *Candida antarctica*. Analysis of the naturally-produced compound on a cyclodextrin GC column indicated it was the *(R)*-enantiomer. In EAG dose-response measurements, the *(R)*-enantiomer alone or in the racemic mixture evoked significant responses from the antennae of male *D. gleditchiae*, whereas the *(S)*-enantiomer did not. In field trapping tests, the *(R)*-enantiomer attracted male *D. gleditchiae.* The racemic compound was equally attractive, but the *(S)*-enantiomer was not attractive. Both the pure *(R)*-enantiomer or racemic (*Z*)-2-acetoxy-8-heptadecene, applied to red rubber septa in a dose range of 3–30 μg, constitute a strongly attractive bait in sticky traps for monitoring the flight of *D. gleditchiae.*

Introduction

The honey locust gall midge, *Dasineura gleditchiae* Osten, Sacken 1866 (Diptera: Cecidomyiidae), already known as the most important pest of honey locust tree, *Gleditsia triacanthos* L., in North America (Thompson et al. 1998), has now appeared in several European countries, e.g., the Netherlands (Nijveldt 1980), Italy (Bolchi and Volonte 1985), Great Britain (Halstead 1992), Switzerland (Fischer and Pivot 1992), Serbia (Simova-Tossic and Skuhravá 1995), and Hungary (Ripka 1996). Soon after its appearance in Hungary, it severely damaged the aesthetic value of thornless, *inermis* cultivars of *G. triacanthos*, which are favoured ornamental trees in urban green areas, and public concern prompted the search for control methods. The developing larvae are hidden and protected inside the galls. Morever, only a few pesticides are registered for application in urban areas, and their use is restricted, such that often only a single treatment is permitted. These constraints underline the importance of the exact timing of application

of control measures, for which pheromone traps could be suitable tools. Monitoring the flight by means of pheromone-based trapping would be particularly advantageous in view of the sharply-synchronized, extremely short flight periods, typically lasting no longer than a few days, and of the development of several subsequent generations in the course of a season.

Here, we report the identification of the female-emitted sex pheromone of *D. gleditchiae* and field trapping tests with the synthetic pheromone.

Methods and Materials

Insects Insects were collected as mature larvae or pupae inside galls on infested leaves of *G. triacathos* "Sunburst" trees located in Budapest, Hungary. Infested leaves were placed in cylindrical glass containers (15 cm diam, 20 cm high) at room temperature under 18:6 hL:D photoperiod at a relative humidity 80–90%. Emerging adults were collected daily and separated by sex on the basis of the morphological differences in their antennae (Skuhravá 1997). Females mate in the morning hours of the day of emergence, lay eggs on the same day, and die soon afterwards. Thus, midges were collected early in the morning, and were assumed to be unmated.

Calling, Diel Dependence and Length of Mating Freshly-emerged adults were used for the observations, and tests were conducted in a greenhouse in Budapest under ambient conditions with one wall open but sheltered from direct sunlight. A single female was placed in a Petri-dish (20 cm diam) containing a freshly cut leaflet of *G. triacanthos* "Sunburst", and allowed to acclimatize for a few minutes. Then, 5 males were introduced into the Petri dish (25 replicates). Copulatory behavior was observed, and the duration of copula measured. For statistical analyses, a *t*-test was used.

Collection of Volatiles Freshly-emerged, unmated females were transferred from the emergence chambers into the glass tube (125 ml) of a closed-loop stripping apparatus (CLSA) (Brechbühler AG, Schlieren, Switzerland), equipped with a MB-21E metal bellows vacuum pump (Metal Bellow Corporation, Sharon, MA, USA) and collection filter containing activated charcoal (1.5 mg). Collections were run from 9.00 h to 14.00 h to coincide with the mating period in the experimental greenhouse where the observations of mating were performed. Collections were conducted over 3 consecutive days, and dead females were replaced daily by fresh ones. Two such collections were made using totals of ca. 400 and 1,800 females, respectively. Trapped volatiles were eluted from the charcoal filter with hexane (40 µl; "ProAnalysi", Merck, Darmstadt, Germany).

Electroantennography (EAG) EAG responses were recorded with glass electrodes (1.17 mm i.d.; Syntech, Hilversum, The Netherlands) pulled to a fine point and filled with Ringer solution (Beadle and Ephrussi 1936). These were attached to silver/silver chloride electrodes held in MP15 micromanipulators and connected to an IDAC 232 amplifier (Syntech). The reference electrode was inserted into the back of the isolated head of a male *D. gleditchiae*, and the intact tip of one antenna was inserted into the recording electrode, which was cut to give a close fit. The required amounts of synthetic or natural pheromone in hexane (10 µl) were applied to filter paper (1 × 1 cm). The natural pheromone was quantified by gas chromatography with flame ionization detection (GC-FID), based on comparison of the area of the peak on the GC trace corresponding to the EAG-active component with those of standard acetates. The amount of the racemic pheromone was doubled with respect to the single enantiomers at each dose level, so that the amounts of each enantiomer would correspond to amounts of the individual enantiomers tested. Stimuli were delivered by puffing air (1 ml) through a Pasteur pipette that contained the filter paper into a moistened air stream (660 ml/min) directed towards the antennae. The series of stimuli was tested on 5 antennal preparations. For statistical analysis, responses to synthetic samples were normalized to the response evoked by an aliquot of volatile collection containing ca. 2.8 ng of natural pheromone, corresponding to ca. 150 female equivalent hours (FEH). Data were transformed to log(x+1), and subjected to ANOVA. If the *F* value was significant, differences between means were tested for significance by the Games-Howell *post-hoc* test, using the program SuperANOVA® (Abacus Concepts Inc., Berkeley, CA, USA).

For gas chromatographic analyses with simultaneous electroantennographic detection (GC-EAD), the above EAG was linked by an effluent conditioning assembly (Syntech) to a 6890 N GC (Agilent Technologies Inc., Santa Clara, CA, USA) equipped with a DB-Wax column (30 m × 0.32 mm × 0.25 µm film thickness; J&W Scientific). Injections were made in splitless mode (220°C). The oven temperature was held at 60ºC for 1 min, then programmed at 10ºC/min to 220ºC and held for 20 min. The carrier gas was helium (4.0 ml/min).

Gas Chromatography Linked to Mass Spectrometry (GC-MS) GC-MS analyses were carried out on a CP 3800 gas chromatograph linked to a Saturn 2200 ion trap mass spectrometer (Varian, Oxford, UK) operated in electron impact mode. Samples were analyzed with fused capillary columns (30 m × 0.25 mm i.d. × 0.25 µm film thickness) coated with polar (Supelcowax-10, Supelco, Gillingham, Dorset, UK) or non-polar (VF5, Varian) phases. Oven temperature was held at 50°C for 2 min, then programmed at 6°C/min to 250°C

and held for 5 min. Helium was used as the carrier gas (1.0 ml/min), and injection was splitless (200°C). Retention times were converted to retention indices relative to the retention times of *n*–alkanes or acetates (Zellner et al. 2008).

Enantioselective Gas Chromatography For analytical separation of enantiomers, an HP6890 gas chromatograph was used, fitted with a fused silica capillary column (30 m × 0.32 mm i.d.) coated with CP-Chirasil-DexCB (Varian) and FID (250°C). Carrier gas was helium (2.4 ml/min), injection was splitless (200°C), and the oven temperature was held at 60°C for 2 min, then programmed at 10°C/min to 170°C.

Microanalytical Reactions For hydrogenation, 10% palladium on charcoal catalyst was washed twice with hexane, and then one drop of the suspension was added to a collection of volatiles (5 µl) from female *D. gleditchiae* in hexane. Hydrogen was bubbled into the suspension for 2 min through a length of deactivated fused silica tubing (20 cm, 0.32 mm i.d.), and the product was analyzed by GC-MS on the polar column.

For reaction with dimethyl disulfide (DMDS), an aliquot (5 µl) of a collection of volatiles from female *D. gleditchiae* containing approximately 25 ng of the EAG-active component was mixed with DMDS (10 µl; SigmaAldrich, Gillingham, Dorset, UK) and a solution of iodine in diethyl ether (2 µl, 0.1%) (Leonhardt and DeVilbiss 1985). After standing 6 h at 40°C, the reaction mixture was treated with hexane (100 µl) and aqueous sodium thiosulfate solution (20 µl, 5%), and the layers were mixed until the iodine color had disappeared. The hexane layer was removed, dried with magnesium sulfate, and analyzed by GC-MS on the non-polar column.

Synthesis Nuclear Magnetic Resonance (NMR) spectra were recorded in $CDCl_3$ on a JEOL EX270 machine at 270 MHz for ^1H and 67.8 MHz for ^{13}C. Infrared (IR) spectra were recorded as thin films with a Perkin Elmer 881 grating spectrophotometer (Perkin Elmer, Beaconsfield, Bucks., UK).

(*Z*)-2-Acetoxy-8-heptadecene was synthesized by addition of methylmagnesium iodide to (*Z*)-7-hexadecenal followed by acetylation of the resulting alcohol (Fig. 1). The racemic material was resolved by hydrolysis with lipase from *Candida antarctica* that gave unreacted (2*S*)-acetate and the (2*R*)-alcohol, which was acetylated to give the corresponding acetate (Fig. 1).

Thus, a sample of (*Z*)-7-hexadecenyl acetate prepared previously at Natural Resources Institute, University of Greenwich, Chatham Maritime, Kent, UK, (NRI) by a standard acetylenic route was hydrolyzed with potassium carbonate in methanol, and the resulting alcohol was oxidized to the aldehyde with pyridinium chlorochromate in dichloromethane (Corey and Suggs 1975). Methyl magnesium iodide was prepared by addition of methyl iodide (2.84 g, 20 mM) in dry diethyl ether (10 ml) to magnesium turnings (0.6 g, 25 mM) in diethyl ether (20 mM) under nitrogen.

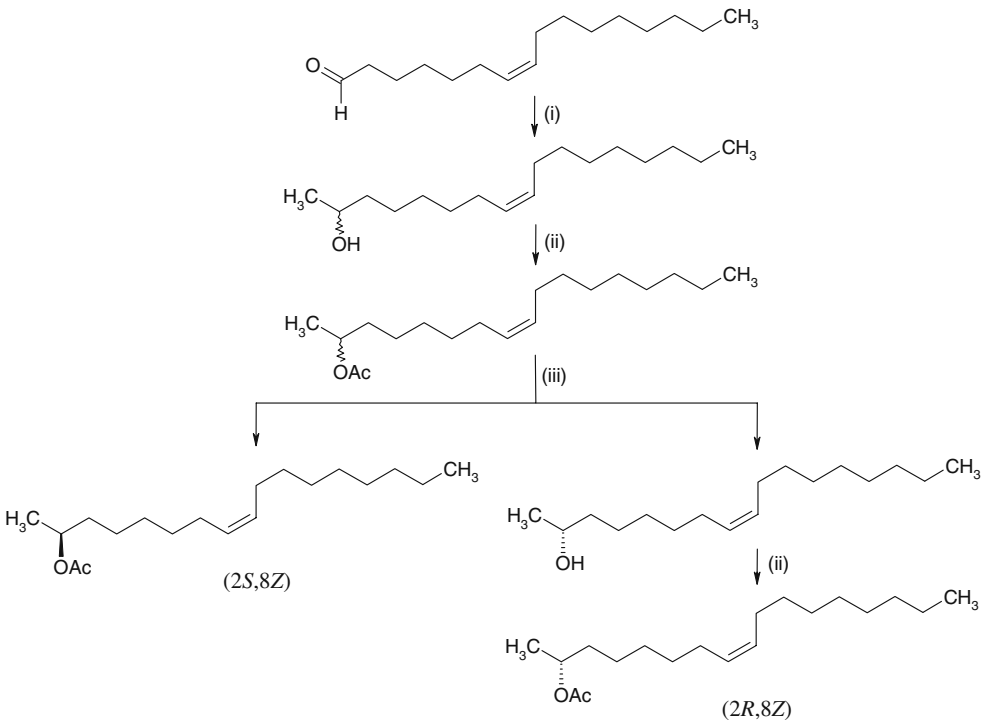

Fig. 1 Synthesis and resolution of (*Z*)-2-acetoxy-8-heptadecene (reagents: (i) MeMgI in diethyl ether; (ii) acetic anhydride/pyridine; (iii) lipase from *Candida antarctica* in phosphate buffer pH 7)

Titration indicated the resulting solution was 0.76 M. To this solution (7.5 ml, 6 mM) was added (*Z*)-7-hexadecenal (0.714 g, 3 mM) in diethyl ether (10 ml) dropwise with stirring and ice cooling. Standard aqueous workup and Kugelrohr distillation gave (*Z*)-8-heptadecen-2-ol (b.p. 140°C, 0.04 mm Hg; 0.7 g, 93%). IR (film): ν 3420 cm^{-1} (O-H); MS: *m/z* (%) 254 (M^+, 6), 236 (M-H_2O, 3), 138 (8), 137 (7), 125 (11), 124 (11), 111 (8), 110 (27), 109 (31), 97 (26), 96 (64), 95 (60), 83 (22), 82 (52), 81 (100), 69 (23), 68 (21), 67 (100), 57 (12), 55 (38), 54 (12), 45 (29), 43 (21), 41 (38).

The alcohol (0.254 g, 1 mM) was acetylated with acetic anhydride (0.2 ml) in pyridine (0.2 ml) for 5 h at room temperature. Standard aqueous workup and Kugelrohr distillation gave (*Z*)-2-acetoxy-8-heptadecene containing approximately 5% of the *E* isomer (b.p. 160°C/ 0.04 mm; 0.25 g, 85%). IR (film): ν 1735 cm^{-1} (C=O); ^{1}HNMR: δ 0.88 (t, *J* = 6.8 Hz, 3H, C$\underline{H}_3$-CH_2), 1.20 (d, *J* = 6.2 Hz, 3H, C$\underline{H}_3$-CH), 1.2–1.4 (br m, 20H, -C$\underline{H}_2$-), 1.95–2.05 (br m, 4H, C$\underline{H}_2$-CH=), 2.02 (s, 3H, C$\underline{H}_3$-C=O), 4.88 (hex, J = 6.2 Hz, 1H, CH_3-C$\underline{H}$-O), 5.3–5.4 (m, 2H, C=C$\underline{H}$); ^{13}C NMR: δ 14.12, 19.97, 21.39, 22,69, 25.32, 27.11, 27.24, 29.11, 29.34, 29.54, 29.63, 29.78, 31.92, 35.92, 71.07, 129.63, 130.11, 170.78.

(Z)-2-Acetoxy-8-heptadecene (0.16 g, 0.54 mM) was stirred with dipotassium hydrogenphosphate buffer (0.1 M, pH 7; 3 ml) and lipase acrylic resin from *Candida antarctica* (Sigma-Aldrich; 25 mg) overnight at room temperature. The mixture was extracted twice with 10% diethyl ether in petroleum ether (10 ml), and the extracts were washed once with brine (10 ml) and dried over magnesium sulfate. After removal of solvent on a rotary evaporator, the residue (0.15 gm) was chromatographed on silica gel (7 g) eluted with a gradient of diethyl ether in petroleum ether from 2% to 20%. The unreacted acetate fraction contained (2*S*,8*Z*)-2-acetoxy-8-heptadecene (70 mg) with enantiomeric excess (ee) of 99.0%. The alcohol fraction was acetylated with acetic anhydride (0.1 ml) in pyridine (0.1 ml) at room temperature overnight. Standard aqueous workup gave (2*R*,8*Z*)-2-acetoxy-8-heptadecene (70 mg) with 99.1% ee.

2-Acetoxyheptadecane was prepared from 2-heptadecanone synthesized previously at NRI by addition of methyl lithium to hexadecanoic acid in ether (Jorgenson 1970). The ketone was reduced to 2-heptadecanol with sodium borohydride in aqueous ethanol and acetylated with acetic anhydride in pyridine (b.p. 140°C/0.04 mm Hg). IR (film): ν 1735 cm^{-1}; MS: *m/z* (%) 255 (1), 254 (1), 180 (2), 166 (2), 152 (4), 139 (4), 138 (4), 125 (13), 124 (8), 111 (35), 110 (11), 98 (8), 97 (53), 96 (16), 95 (8), 85 (12), 84 (9), 83 (41), 82 (15), 81 (13), 71 (17), 70 (18), 69 (39), 67 (16), 61 (7), 57 (28), 56 (15), 55 (40), 43 (100), 42 (7), 41 (38).

All other positional isomers of acetoxyheptadecane were synthesized by reduction and acetylation of the corresponding heptadecanones, which were available commercially or were synthesized by addition of an organolithium to a carboxylic acid (Jorgenson 1970). (2*S*,12*Z*)-2-Acetoxy-12-heptadecene, the pheromone of the pistachio twig borer, *Kermania pistaciella* (Gries et al. 2006), was kindly provided by Prof. Gerhard Gries.

Field Trapping Tests Synthetic compounds were applied to red rubber dispensers (MSZ 9691/6, TAURUS, Budapest, Hungary) in hexane (20 μl). Delta-shaped traps with transparent walls (Csalomon® RAG, Plant Protection Institute Hungarian Academy of Sciences, Budapest, Hungary) were used with exchangeable inserts (10 x 16 cm) coated with adhesive (Tangle Trap, Tanglefoot Co., Grand Rapids, MI, USA). Traps were placed in the foliage of *G. triacathos* "Sunburst" trees at "Lágymányosi hid", Budapest, Hungary, 2 m above ground and 10 m apart. In the first experiment, catches in traps baited with racemic (*Z*)-2-acetoxy-8-heptadecene (20 μg) and the *(R)*- or *(S)*-enantiomers (10 μg) were compared in a randomized complete block design with 7 replicates from 1–3 June 2007. In the second experiment, catches with the *(R)*- or *(S)*-enantiomers of (*Z*)-2-acetoxy-8-heptadecene and a 1:1 mixture were compared at various doses with three replicates from 14–17 June 2008. Mean catches were transformed to log(x+1) in order to normalize variances before carrying out analysis of variance (ANOVA). If the *F* value was significant for treatments ($P < 0.05$), differences between means were tested for significance by the Games-Howell *post-hoc* test, using the program SuperANOVA® (Abacus Concepts Inc., Berkeley, CA, USA).

Results

Mating Behavior Freshly-hatched *D. gleditchiae* females were observed to keep their ovipositors extended while sitting on fresh leaflets waiting for males. Otherwise, no specific calling posture was observed. Females were ready to copulate immediately after emergence. Copulations took place most frequently in the morning hours between 0800 – 1200 h under the experimental conditions. Copulations lasted on average for 19.64 sec ± 1.74 sec S.E. ($N = 25$). After mating, the female withdrew her ovipositor.

Electrophysiological Analysis of Collected Volatiles The EAG response evoked from the antenna of a male *D. gleditchiae* by stimulation with a 200 FEH aliquot of the collection of volatiles from virgin females was 0.250 mV ± 0.016 mV S.E., which was significantly stronger than that to the hexane stimulus 0.043 mV ± 0.004 mV ($P < 0.05$).

GC-FID/EAD analysis of a 150 FEH aliquot of the volatile collection from females revealed a single EAG

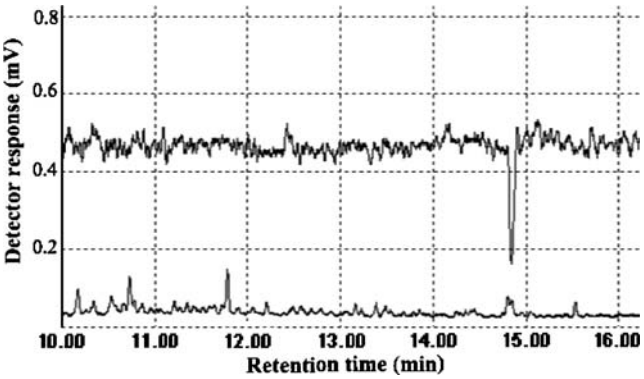

Fig. 2 Analysis by gas chromatography with flame ionization detection and simultaneous electroantennographic detection (GC-FID/EAD) of a collection of volatiles from unmated *Dasineura gleditchiae* females collected in a closed-loop stripping apparatus (CLSA). (150 female equivalent hours (FEH) injected)

response from the male antenna at 14.84 min corresponding to a noticeable peak in the FID trace (Fig. 2), and this was assumed to be a component of the female sex pheromone. Retention times of synthetic standards in parallel runs were: decyl acetate 8.80 min; tetradecyl acetate 12.99 min; hexadecyl acetate 14.87 min. Thus, the retention index of the EAG-active peak relative to saturated acetates was 1597 (Table 1).

Analyses by GC-MS GC-MS analyses of volatiles collected from female *D. gleditchiae* on the polar GC column showed a peak at retention index 1590 relative to straight chain acetates (Table 1). The mass spectrum (Fig. 3) showed ions at *m/z* 43 and 61, characteristic of acetate esters, and the highest ion at *m/z* 236. A compound having the same mass spectrum was observed at retention index 1588 relative to acetate esters in analyses on the non-polar GC column (Table 1). The similarity in retention indices relative to acetate esters on the two columns indicated the compound was probably a mono-acetate rather than di-acetate. The ion at *m/z* 236 would thus correspond to a 17–carbon acetate with one double bond after loss of acetic acid.

A small peak (4% relative to the above component) was observed in GC-MS analyses of volatile collections having mass spectrum and retention times on both GC columns identical to those of 2-acetoxyheptadecane (Table 1), and no traces (< 0.2%) of other acetoxyheptadecanes were detected. It was considered that the acetoxy group of the main pheromone component was probably in the 2-position, and this was confirmed by catalytic hydrogenation of a collection of volatiles which gave 2-acetoxyheptadecane only.

Reaction of an aliquot from the volatile collections with DMDS and subsequent analysis by GC-MS gave a derivative with strong ions at *m/z* 390 (M^+), 173, and 157 (Table 1 and Fig. 3). The latter ions correspond to $(C_8H_{17}\text{-}CHSCH_3)^+$ and $(C_7H_{13}\text{-}CHSCH_3)^+$, respectively, indicating that the double bond was in the 8-position.

(*Z*)-2-Acetoxy-8-heptadecene (Z8-17:2Ac) was synthesized via addition of methylmagnesium iodide to (*Z*)-7-hexadecenal, and had identical retention times (Table 1) and mass spectrum (Fig. 3) to those of the natural EAG-active compound. The (*E*)-2-acetoxy-8-heptadecene, present as a minor impurity of the *Z* isomer, and (*Z*)-2-acetoxy-12-heptadecene eluted later on both GC columns (Table 1).

As mentioned above, 2-acetoxy-heptadecane was present in collections of volatiles from female *D. gleditchiae* at approx 4% of the (*Z*)-2-acetoxy-8-heptadecene. (*Z*)-8-Heptadecen-2-ol could not be detected (< 0.5%). The best collection of volatiles made from 1,800 female *D. gleditchiae* contained approximately 200 ng of pheromone, corresponding to approximately 0.11 ng per female.

Absolute Configuration of Pheromone The enantiomers of (Z)-2-acetoxy-8-heptadecene were resolved easily on a cyclodextrin GC column (Fig. 4; retention times *(S)*- 19.74 min, *(R)*- 20.15 min). The individual enantiomers were prepared in high enantiomeric excess by kinetic resolution with the lipase from *Candida antarctica*, which selectively hydrolyses or acetylates the *(R)*-enantiomer (e.g., Xiao and Kitazume 1997; Gries et al. 2006). Analysis of a collection

Table 1 GC Retention indices for natural and synthetic compounds

Compound	Polar GC column[a]		Non-polar GC column[b]	
	RI[c]	KI[d]	RI[c]	KI[d]
EAD-Active compound in GC-EAD	1597			
EAD-Active compound in GC-MS	1590	2292	1588	1996
(*Z*)-2-Acetoxy-8-heptadecene	1590	2292	1588	1996
(*E*)-2-Acetoxy-8-heptadecene	1594	2296	1595	2002
(*Z*)-2-Acetoxy-12-heptadecene	1610	2311	1603	2011
(*Z*)-8-Heptadecen-2-ol	1649	2351	1480	1888
2-Acetoxyheptadecane	1573	2272	1614	2024
DMDS derivative of active compound			2226	2634

[a] DB-Wax for GC-EAD; Supelcowax 10 for GC-MS; [b] VF5; [c] GC retention time relative to retention times of acetate esters of primary, straight-chain alcohols; [d] GC retention times relative to retention times of *n*-alkanes

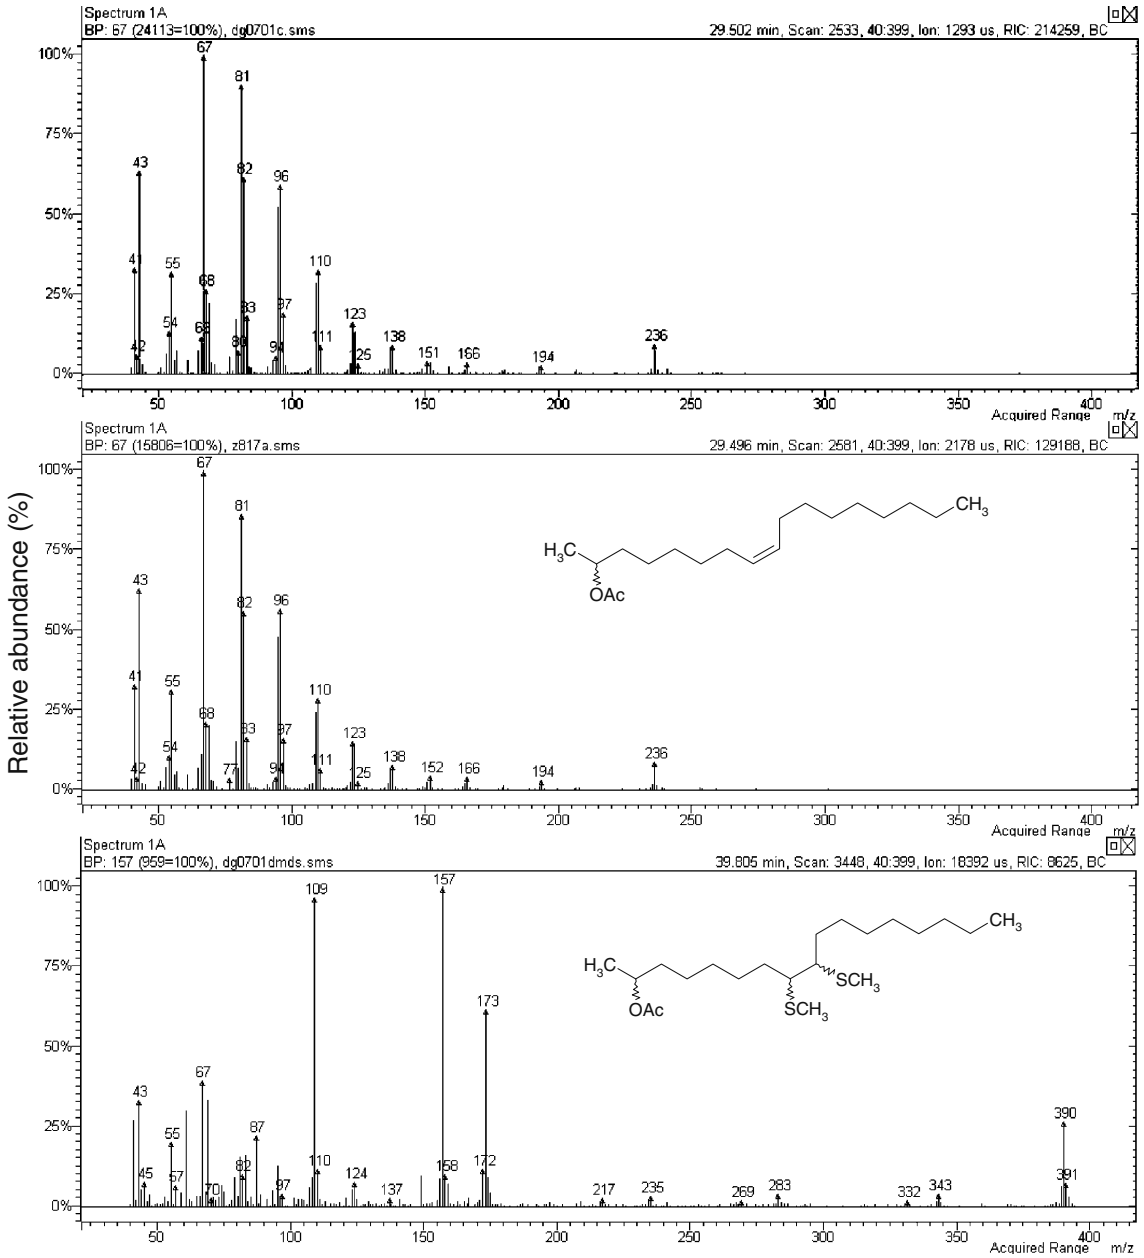

Fig. 3 Mass spectra of EAG-active compound in volatiles collected from virgin female *Dasineura gleditchiae* (upper), synthetic (*Z*)-2-acetoxy-8-heptadecene (middle) and DMDS derivative of EAG-active compound (lower)

of volatiles from female *D. gleditchiae* showed a peak at the retention time of the *(R)*-enantiomer and essentially none (< 1%) of the *(S)*-enantiomer. This was confirmed by co-chromatography of the natural compound and synthetic *(R)*-enantiomer (Fig. 4).

Electroantennography of Synthetic Compounds Both racemic (*Z*)-2-acetoxy-8-heptadecene and the *(R)*-enantiomer evoked stronger antennal responses ($P < 0.05$) from male *D. gleditchiae* than the hexane solvent across the dose range of 1 – 10 ng (Fig. 5). The *(S)*-enantiomer elicited a stronger response than hexane ($P < 0.05$) only at the 3 ng dose. The racemic sample evoked stronger responses ($P < 0.05$) than the *(S)*-enantiomer at 3 and 10 ng doses. The response evoked by an aliquot of the hexane solution of the collection of volatiles from virgin female *D. gleditchiae* containing ca. 2.8 ng of the EAG-active component fits well into the range of responses evoked by the *(R)*-enantiomer at the corresponding dose range.

Field Trapping Tests In experiment 1, traps baited with racemic (*Z*)-2-acetoxy-8-heptadecene or with the *(R)*- or *(S)*-enantiomer attracted different numbers of male *D. gleditchiae* midges ($F_{3,24} = 101.2$, $P = 0.001$). The *(R)*-enantiomer was

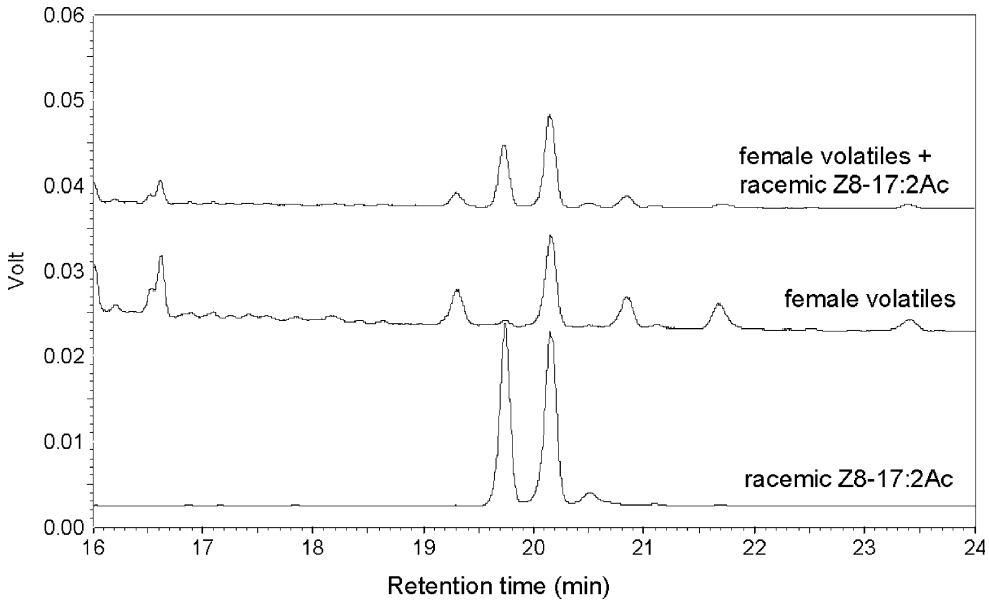

Fig. 4 GC analyses of EAG-active compound in volatiles collected from virgin female *Dasineura gleditchiae* and (*Z*)-2-acetoxy-8-heptadecene (Z8-17:2Ac) on an enantioselective cyclodextrin column

more attractive than the racemate ($P < 0.05$) (Table 2). Traps baited with the *(S)*-enantiomer caught 34 times fewer male midges than those baited with the racemate, although this was still significantly more than in unbaited control traps ($P < 0.05$), possibly due to the small amount of *(R)*-enantiomer present (Table 2).

In experiment 2, although the ANOVA indicated significant differences between treatments ($F_{8,18} = 6.436$; $P < 0.001$), traps baited with the *(R)*-enantiomer of (*Z*)-2-acetoxy-8-heptadecene at 1, 3, 10, or 30 μg or the racemate at 2, 6, 20, or 60 μg captured similar numbers of male midges ($P > 0.05$) (Fig. 6). For all these treatments, except the racemate at 2 μg or 6 μg, catches of midges were significantly greater ($P < 0.05$) than those in unbaited traps.

Discussion

We observed that the precopulatory and mating behaviors of *D. gleditchiae* were rather similar to those of several

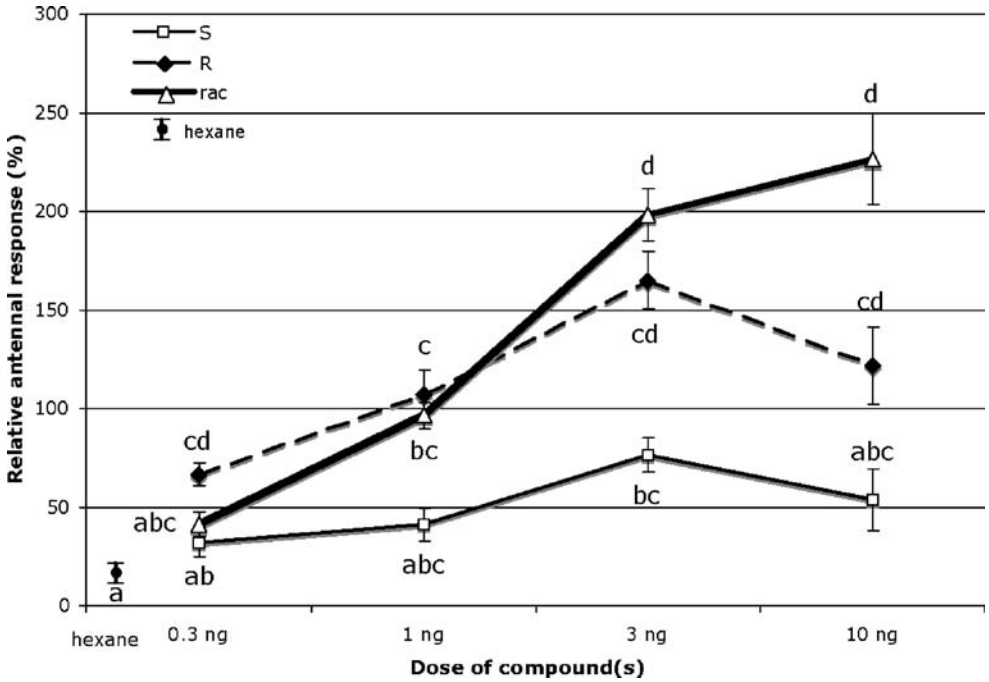

Fig. 5 EAG responses from antennae of male *Dasineura gleditchiae* to different doses of *(S)*- and *(R)*-enantiomers and racemic (*Z*)-2-acetoxy-8-heptadecene (values normalized to response to 2.8 ng natural pheromone = 100%; $N = 5$; points with different letters are significantly different at the 5% probability level after ANOVA on data transformed to log(x+1) followed by the Games-Howell test)

Table 2 Mean catches of male *Dasineura gleditchiae* with enantiomers of (*Z*)-2-acetoxy-8-heptadecene in Budapest (1-3 July, 2007, 7 replicates)

Compound	Loading (μg)	Mean catch ± SE[a]
(2*R*,8*Z*)-2-Acetoxy-8-heptadecene	10	223.0 ± 44.2 a

other cecidomyiid species with respect to the posture of females' extruded ovipositors, readiness of mating soon after emergence, diurnal rhythm of mating taking place in the sunny morning hours, and length *in copula* (Harris and Foster 1999 and references therein).

In GC-EAD analyses of collections of volatiles from virgin female *D. gleditchiae,* a single response from male antennae was consistently observed, and this corresponded to a small peak in the FID trace. This compound was assumed to be the major component of the female sex pheromone. GC-MS analyses on both polar and non-polar columns suggested this was a secondary 17-carbon acetate with one double bond, and microanalytical reactions indicated the acetoxy function was in the 2-position and the double bond in the 8-position. (*Z*)-2-Acetoxy-8-heptadecene had an identical retention time and mass spectrum compared to the natural compound. Analyses on an enantioselective GC column indicated this consisted of exclusively the *(R)*-enantiomer.

Electroantennographic dose-response measurements of the synthetic *(S)*- and *(R)*-enantiomers and racemic (*Z*)-2-acetoxy-8-heptadecene revealed that the *(R)*-enantiomer alone or mixed with the *(S)*-enantiomer evoked significant responses from the antennae of male *D. gleditchiae,* whereas the *(S)*-enantiomer did not. In field experiments, the *(R)*-enantiomer alone or the racemic mixture were attractive to males, but the *(S)*-enantiomer was not.

Taken together, these results support the conclusion that (2*R*,8*Z*)-2-acetoxy-8-heptadecene is the major component of the female sex pheromone of *D. gleditchiae*. A trace of 2-acetoxyheptadecane was found in volatiles from the females, but (*Z*)-8-heptadecen-2-ol could not be detected. This is a novel pheromone component, but is consistent with the type of structures found in other midge sex pheromone components. It has an odd number of carbon atoms and an alkanoyloxy function on the 2-carbon (Hillbur et al. 2005 and references therein). The *Z*-8 double bond seems to be particularly common, also occurring in pheromone components of the apple leaf curling midge, *Dasineura mali*, (Cross and Hall 2005; Suckling et al. 2007), the Chinese chrysanthemum gall midge, *Rhopalomyia* spp. (Liu et al. 2007), the pear leaf curling midge, *D. pyri* (Amarawardana et al. 2006), and the blackcurrant leaf midge, *D. tetensi* (unpublished). It is of interest to note that *D. gleditchiae* produces the *(R)*-enantiomer, whereas the *(S)*-enantiomer has so far been found more commonly in other midge species, and even in a moth species, *Kermania pistaciella* Ams. (Lepidoptera: Oinophilidae) (Gries et al. 2006).

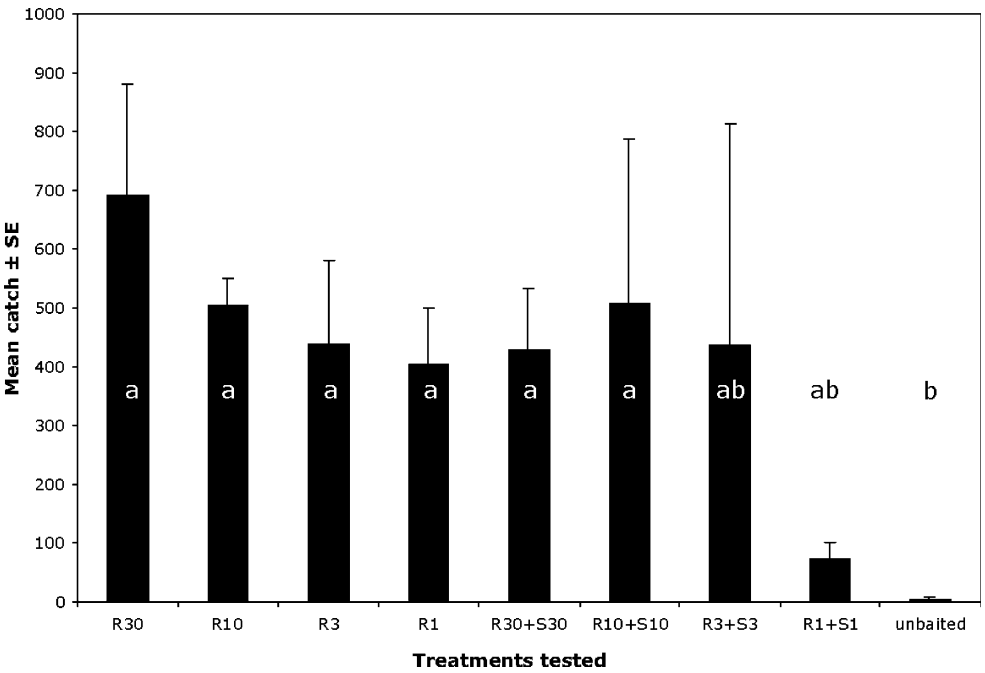

Fig. 6 Mean catches (± SE) of male *Dasineura gleditchiae* in sticky traps baited with the *(R)*-enantiomer and racemic (*Z*)-2-acetoxy-8-heptadecene at different doses at Lágymányosi hid, Budapest, Hungary. (14-17 June 2008; 3 traps/treatment. In abbreviations of treatments, the letter and number refer to the enantiomer(s) and dose, respectively, that were tested. Columns marked by the same letter do not differ significantly at the 5% probability level after ANOVA on data transformed to log(x+1) followed by the Games-Howell test)

(2*R*,8*Z*)-2-Acetoxy-8-heptadecene or the racemic material applied to red rubber septa in a dose range of 3–30 μg provides an effective bait in sticky traps for monitoring of the flight of *D. gleditchiae*. Further work is required to optimize the dose of pheromone and investigate the effects of trap positioning.

Acknowledgements This work was sponsored in part by a grant of NKFP 4/012/2004 and by a grant of the Hungarian Scientific Research Fund (OTKA) K 72767 to G. Szőcs. The GC-EAD apparatus was financed by GVOP-3.2.1-2004-04-0153/3.0 (major part) and by OTKA T37355 (minor part) to G. Szőcs. We are grateful to G. Gries for a sample of (2*S*,12*Z*)-2-acetoxy-12-heptadecene.

Received: 13 February 2009 / Revised: 19 May 2009 / Accepted: 19 May 2009 / Published online: 25 June 2009

Abstract The sex pheromone of the chrysanthemum gall midge, *Rhopalomyia longicauda* (Diptera: Cecidomyiidae), the most important insect pest in commercial plantations of chrysanthemum, *Dendranthema morifolium (Ramat.) Tzvel.,* in China, was identified, synthesized, and field-tested. Volatile chemicals from virgin females and males were collected on Porapak in China and sent to the United Kingdom for analysis. Coupled gas chromatographic–electroantennographic detection (GC-EAG) analysis of volatile collections from females revealed two compounds that elicited responses from antennae of males. These compounds were not present in collections from males. The major EAG-active compound was identified as 2-butyroxy-8-heptadecene by gas chromatographic (GC) retention indices, mass spectra, in both electron impact and chemical ionization modes, hydrogenation, epoxidation, and derivatization with dimethyldisulfide. The lesser EAG-active compound was identified as the corresponding alcohol. The ratio of butyrate to alcohol in the collections was 1:0.26. Racemic (*Z*)-8-heptadecen-2-ol and the corresponding butyrate ester were synthesized from (*Z*)-7-hexadecenyl acetate, and the synthetic compounds found to have identical GC retention indices and mass spectra to those of the natural, female-specific components. Analysis of the volatile collections on an enantioselective cyclodextrin GC column showed the natural pheromone contained (2*S*,8*Z*)-2-butyroxy-8-heptadecene. Field tests showed that rubber septa containing racemic (*Z*)-2-butyroxy-8-heptadecene were attractive to *R. longicauda* males. The (naturally occurring) *S*-enantiomer was equally as attractive as the racemate, while the *R*-enantiomer was not attractive to males, and did not inhibit the activity of the *S*-enantiomer. The attractiveness of the butyrate was significantly reduced by the presence of even small amounts of the corresponding alcohol.

Introduction

Chrysanthemum gall midge, *Rhopalomyia longicauda* (Diptera: Cecidomyiidae), is the most important insect pest of commercial plantations of chrysanthemum, *Dendranthema morifolium (Ramat.) Tzvel.,* in China (Cheng et al. 1990; Liu et al. 2003; Wu et al. 2007), and has also been found on wild species of chrysanthemum in Jeju Island, Korea (Sato et al. 2009). This species was first identified as

Epimgia sp. (Liu et al. 1987) in China, but was recently renamed as *Rhopalomyia longicauda* by K. M. Harris (International Institute of Entomology, UK; pers. comm.) and J. Yukawa (Entomological Laboratory, Faculty of Agriculture, Kyushu University, Japan; pers. comm.). Females lay eggs singly or in clusters near the shoot tips, the young leaves, and the flower buds. Larvae bore into and feed on the tissues of the plant, producing the conspicuous cone-shaped galls. Larval feeding causes severe distortion and stunting of the plants, resulting in a reduction in numbers and quality of flowers. Yield losses frequently exceed 40% of flowers. There are five generations of the insect per year in China, with the last generation overwintering as pupae in cocoons in the soil.

Rhopalomyia longicauda is currently controlled in China by sprays of methamidophos, oxid-dimethoate and monocrotophos as soon as galls are seen, but these insecticides are becoming less effective and are highly toxic to other organisms. It would be beneficial for control of this pest if one could predict the emergence and flight period of the adults accurately, and hence determine if and when to spray. Traps baited with sex pheromone have been developed for monitoring several other species of midge (Hillbur et al. 2000; Bruce et al. 2007; Cross et al. 2008, 2009). Here, we report identification, synthesis, and field testing of the female-produced sex pheromone of *R. longicauda*.

Methods and Materials

Experimental Insects On 30 July 2006, cone-shaped galls were picked from chrysanthemum plants in a commercial plantation in Anguo, Hebei Province, China. Pupae of *R. longicauda* were collected from these galls and transferred individually into plastic centrifuge tubes (5 ml) that contained a piece of moist filter paper. The tubes were kept at approximately 25°C and L16:D8 h. Adult midges started to emerge on 1 August. Most females emerged during 22:00–24:00 h. About 5 min after emergence, virgin females began to extend their ovipositors and apparently to release pheromone. Thus, adults were sexed and transferred to the entrainment vessel as soon as possible after emergence, so they would likely be unmated.

Collection of Volatiles Volatiles were collected from female and male *R. longicauda* placed separately in glass chambers (15×5 cm) with a glass frit at the upwind end (Hamilton Laboratory Glass, Margate, Kent, UK) at 25°C and L16:D8 h. A vacuum pump drew charcoal-filtered air (200 ml min^{-1}) through the chamber, with volatile chemicals trapped on Porapak Q (200 mg; 50/80 mesh; Waters Associates Inc., Milford, MA, USA) held between plugs of silanized glass wool in a Pasteur pipette (4 mm i.d.). The life span of adult *R. longicauda* is 1–2 d so, each day, dead midges were removed and fresh live midges introduced into the chambers. The collection filters were renewed after volatiles from approximately 300 female midges had been collected, approximately every 4 d. The collection filters were mailed to the UK where the trapped chemicals were eluted from the Porapak Q with dichloromethane (Pesticide grade; 3×0.5 ml) and concentrated to one-fifth the original volume by a gentle stream of nitrogen.

Analysis by Gas Chromatography (GC) Samples were analyzed by gas chromatography on an HP 6850 instrument (Agilent Technologies, Reading, Berks., UK) with a fused silica capillary column (30 m×0.32 mm i.d.×0.25 µm film thickness) coated with a polar phase (Wax10, Supelco, Gillingham, Dorset, UK). The oven temperature was programmed from 60°C for 2 min, then at 10°C min^{-1} to 250°C. Carrier gas was helium (2.4 ml min^{-1}), injection was splitless (220°C), and detection was by flame ionization (FID; 250°C). For all GC analyses, retention times were converted to Retention Indices (RI) relative to those for *n*-alkanes.

Analysis by Gas Chromatography-Electroantennography (GC-EAG) GC-EAG analyses were carried out with an HP 6890 instrument (Agilent) with capillary GC columns (30 m×0.32 mm i.d.×0.25 µm film thickness) coated with polar (Wax10; Supelco) and non-polar (SPB1; Supelco) phases. The oven temperature was programmed from 50°C for 2 min, then at 10°C min^{-1} to 250°C. Carrier gas was helium (2.4 ml min^{-1}), and injection was splitless (220°C). The GC column effluent was split (1:1) with a push-fit Y-piece between the FID (250°C) and a silanized glass T-piece in the column oven. Nitrogen (200 ml min^{-1}) was blown continuously over the EAG preparation, and every 17 sec this was diverted through the T-piece for 3 sec, blowing the contents over the EAG preparation, as described by Cork et al. (1990).

For the EAG preparation, the wings and legs of a male midge were excised, and the whole insect was suspended between glass electrodes containing electrolyte (0.1 M potassium chloride with 10% polyvinylpyrrolidone added to reduce evaporation). The ends of both antennae were inserted into the recording electrode and the body into the reference electrode. The electrodes were attached to silver/silver chloride electrodes held in micromanipulators on a portable EAG device developed by Syntech (INR-02; Syntech, Hilversum, The Netherlands). Both FID and EAG signals were collected and analyzed with EZChrom software (Elite v3.0; Scientific Software Inc., Pleasanton, CA, USA).

Gas Chromatography Linked to Mass Spectrometry (GC-MS) GC-MS analyses were carried out on a Carlo Erba

5130 GC (Thermoelectron, Hemel Hempstead, Hertfordshire, UK) linked directly to an ion trap detector (Finnigan ITD 700; Thermoelectron) operated in electron impact (EI), or chemical ionization (CI) with isobutane, modes. The polar GC column (30 m×0.25 mm i.d.×0.25 μm film thickness) was coated with Wax 10 (Supelco). The carrier gas was helium (0.5 kg cm^{-2}), injection was splitless (220°C), and the oven temperature was programmed from 50°C for 2 min, then at 6°C min^{-1} to 250°C.

GC-MS analyses were also carried out on an HP 6890 GC (Agilent) coupled to an HP 5973 MSD (Agilent) operated in EI mode. The GC column (30 m×0.25 mm i.d.×0.25 μm film thickness) was coated with a non-polar phase (SPB1; Supelco). The carrier gas was helium (1 ml min^{-1}), injection was splitless (220°C), and the oven temperature programmed from 60°C for 2 min, then at 6°C min^{-1} to 250°C.

Micro-analytical Reactions For hydrogenation, a sample of the concentrated volatile collection (in 20 μl dichloromethane, containing approx. 20 ng of pheromone) from female midges was placed in a conical vial (1.1 ml; Chromacol Ltd, Welwyn Garden City, UK). Most of the solvent was removed by a stream of purified nitrogen before hexane (50 μl) was added. The hydrogenation catalyst (10% palladium on charcoal; 100 mg) was placed in another vial, washed twice with hexane (1 ml), and then suspended in hexane (1 ml). An aliquot of the suspension (1 drop) was added to the hexane solution of the collected volatiles. Hydrogen was then bubbled into the mixture through a piece of fused silica capillary column for 1 min. The mixture was allowed to stand for 5 min, and then was analyzed by GC-MS using both polar and non-polar columns.

For epoxidation, a solution of 3-chloroperbenzoic acid in dichloromethane (5 μl, 1 mg ml^{-1}) was added to an aliquot of a concentrated volatile collection (in 20 μl dichloromethane, containing approx. 20 ng) from female midges. After standing at room temperature for 2 h, the reaction mixture was analyzed directly by GC-MS by using both polar and non-polar columns (Bierl-Leonhardt et al. 1980).

For reaction with dimethyldisulfide (DMDS), a sample of the concentrated collection (in 20 μl dichloromethane, containing approx. 20 ng) from female midges was transferred to a conical vial (1.1 ml). Most of the solvent was removed by a stream of purified nitrogen before hexane (20 μl) was added, followed by DMDS (20 μl; SigmaAldrich, Gillingham, Dorset, UK) and a solution of iodine in diethyl ether (2 μl; 6 mg ml^{-1}). The mixture was allowed to stand overnight at approximately 40°C. Hexane (50 μl) was added, followed by aqueous sodium thiosulfate solution (5%; 50 μl). The two layers were mixed until the iodine color had disappeared, and the lower aqueous layer was removed with a syringe. The resulting solution was dried over magnesium sulfate and analyzed by GC-MS on the non-polar column (Buser et al. 1983; Leonhardt and DeVilbiss 1985).

Enantioselective Gas Chromatography GC analyses were also carried out on a column (30 m×0.32 mm i.d.×0.25 μm film thickness) coated with a chiral cyclodextrin stationary phase (Chirasil-Dex CB; Varian, Oxford, UK). The oven temperature was programmed from 60°C for 2 min, then at 20°C min^{-1} to 165°C. Injection was splitless at 220°C with helium as the carrier gas (2.4 ml min^{-1}).

Synthesis Nuclear Magnetic Resonance (NMR) spectra were recorded in $CDCl_3$ on a JEOL EX270 machine at 270 MHz for ^{1}H and 67.8 MHz for ^{13}C. Infrared (IR) spectra were recorded as thin films with a Perkin Elmer 881 grating spectrophotometer (Perkin Elmer, Beaconsfield, Bucks., UK).

(*Z*)-2-Butyroxy-8-heptadecene was synthesized by addition of methylmagnesium iodide to (*Z*)-7-hexadecenal, followed by conversion of the resulting alcohol to the butyrate (Fig. 1). The racemic material was resolved by hydrolysis with lipase from *Candida antarctica*, which gave unreacted 2*S*-butyrate and the 2*R*-alcohol, which was separated and converted to the corresponding butyrate (Fig. 1).

(*Z*)-7-Hexadecenyl acetate, prepared previously at NRI by a standard acetylenic route, was hydrolyzed with potassium carbonate in methanol, and the resulting alcohol was oxidized to the aldehyde with pyridinium chlorochromate in dichloromethane (Corey and Suggs 1975). Methyl magnesium iodide was prepared by addition of methyl iodide (2.84 g, 20 mM) in dry diethyl ether (10 ml) to magnesium turnings (0.6 g, 25 mM) in diethyl ether (20 mM) under nitrogen. Titration indicated the resulting solution was 0.76 M. To this solution (7.5 ml, 6 mM) was added (*Z*)-7-hexadecenal (0.83 g, 3.5 mM) in diethyl ether (10 ml) dropwise with stirring and ice cooling. Standard aqueous workup and Kugelrohr distillation gave (*Z*)-8-heptadecen-2-ol (b.p. 140°C, 0.04 mm Hg; 0.7 g, 80%). IR (film): ν 3420 cm^{-1} (O-H); MS: *m/z* (%) 254 (M^{+}, 6), 236 (M-H_2O, 3), 138 (8), 137 (7), 125 (11), 124 (11), 111 (8), 110 (27), 109 (31), 97 (26), 96 (64), 95 (60), 83 (22), 82 (52), 81 (100), 69 (23), 68 (21), 67 (100), 57 (12), 55 (38), 54 (12), 45 (29), 43 (21), 41 (38).

The alcohol (0.254 g, 1 mM) was mixed with butyric acid (0.132 g, 1.5 mM) and N,N-dimethylaminopyridine (10 mg) in dichloromethane (5 ml) and N,N'-dicyclohexylcarbodiimide (0.3 g, 1.4 mM) added in portions. After stirring for 5 h at room temperature, diethyl ether (5 ml) was added, the mixture filtered, and solvents were removed on a rotary evaporator. The residue was chromatographed

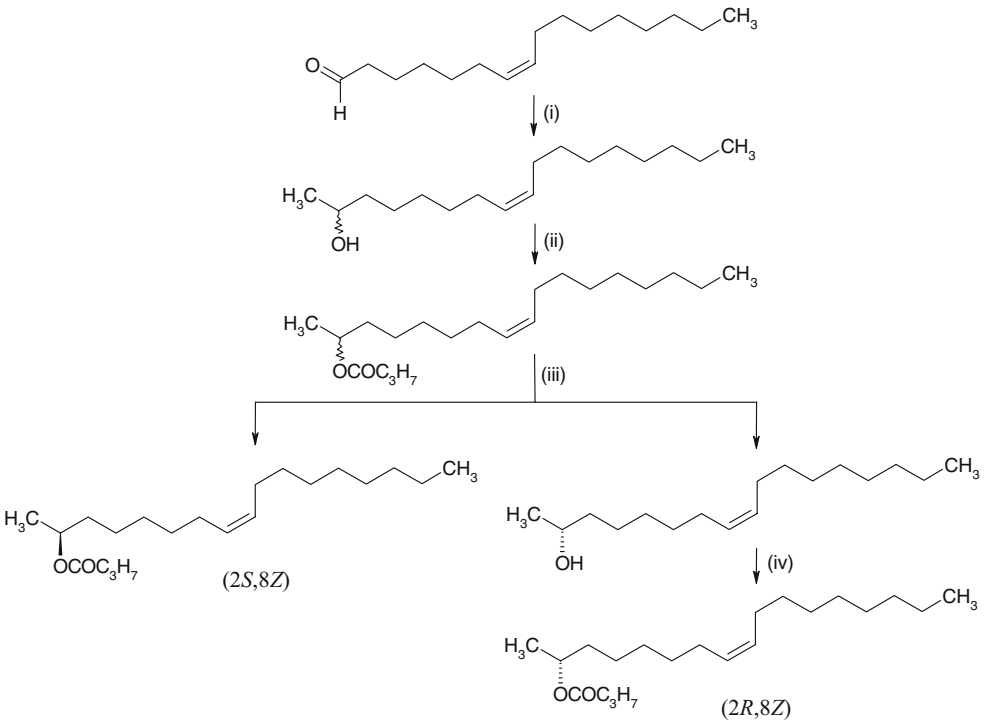

Fig. 1 Synthesis and resolution of enantiomers of (*Z*)-2-butyroxy-8-heptadecene. Reagents: (i) MeMgI in diethyl ether; (ii) butyric acid/ N,N-4-dimethylaminopyridine/ N,N'-dicyclohexylcarbodiimide in dichloromethane; (iii) lipase from *Candida antarctica* in phosphate buffer pH 7; (iv) butyryl chloride/pyridine in dichloromethane)

on silica gel (12 g) using 2% diethyl ether in petroleum ether, and the product was distilled in a Kugelrohr apparatus to give (*Z*)-2-butyroxy-8-heptadecene containing approximately 5% of the *E* isomer (b.p. 180°C/ 0.04 mm Hg; 0.25 g, 78%). IR (film): ν 1735 cm^{-1} (C = O); ^{1}HNMR: δ 0.88 (t, *J*=6.8 Hz, 3H, CH_3-CH_2), 0.95 (t, *J*= 7.3 Hz, 3H, CH_3-CH_2-CH_2-CO), 1.20 (d, *J*=6.6 Hz, 3H, CH_3-CH), 1.2–1.4 (br m, 18H, -CH_2-), 1.4–1.4 (br m, 2H), 1.65 (hex, *J*=7.6, 2H, CH_3-CH_2-CH_2-CO), 1.95–2.05 (br m, 4H, CH_2-CH=), 2.25 (t, 2H, *J*=7.6, CH_3-CH_2-CH_2-CO), 4.90 (hex, J=6.2 Hz, 1H, CH_3-CH-O), 5.3–5.4 (m, 2H, C = CH); ^{13}C NMR: δ 13.68, 14.12, 18.60, 20.05, 22,69, 25.33, 27.11, 27.24, 29.11, 29.34, 29.54, 29.64, 29.78, 31.92, 35.95, 36.67, 70.72, 129.65, 130.09, 173.38.

(*Z*)-2-Butyroxy-8-heptadecene (0.25 g, 0.8 mM) was stirred with dipotassium hydrogenphosphate buffer (0.1 M, pH 7; 3 ml) and lipase acrylic resin from *Candida antarctica* (Sigma-Aldrich; 25 mg) overnight at room temperature. The mixture was extracted twice with 10% diethyl ether in petroleum ether (10 ml), and the extracts were washed once with brine (10 ml) and dried over magnesium sulfate. After removal of solvent on a rotary evaporator, the residue (0.25 gm) was chromatographed on silica gel (10 g), and eluted with a gradient of diethyl ether in petroleum ether from 2% to 20%. The unreacted ester fraction contained (2*S*,8*Z*)-2-butyroxy-8-heptadecene (0.11 g) with an enantiomeric excess (ee) of 99.8% by GC analysis on the enantioselective column. The alcohol fraction (0.11 g) was dissolved in dichloromethane, and pyridine (50 mg) and butyryl chloride (100 mg) were added. After stirring at room temperature overnight, standard aqueous workup gave (2*R*,8*Z*)-2-butyroxy-8-heptadecene (0.12 g) with 99.1% ee. (2*S*,8*Z*)-8-Heptadecen-2-ol for use in field tests was prepared by hydrolysis of (2*S*,8*Z*)-2-butyroxy-8-heptadecene (20 mg) with potassium hydroxide in ethanol (0.1 N, 1 ml) for 8 h.

2-Butyroxyheptadecane was prepared from 2-heptadecanone synthesized previously at NRI by addition of methyl lithium to hexadecanoic acid in ether (Jorgenson 1970). The ketone was reduced to 2-heptadecanol with sodium borohydride in aqueous ethanol, and reacted with butyric acid, N,N-dimethylaminopyridine and N,N'-dicyclohexylcarbodiimide in dichloromethane (b.p. 160°C/ 0.03 mm Hg). IR (film): ν 1735 cm^{-1}; MS: *m/z* (%) 238 (5), 139 (3), 125 (7), 115 (21), 111 (14), 97 (23), 89 (33), 85 (12), 83 (20), 71 (100), 69 (19), 67 (5), 57 (44), 55 (38), 43 (77), 41 (34).

(2*S*,12*Z*)-2-Acetoxy-12-heptadecene, the pheromone of the pistachio twig borer, *Kermania pistaciella* (Gries et al. 2006), was kindly provided by Professor Gerhard Gries. A sample was hydrolyzed with potassium carbonate in methanol to give (2*S*,12*Z*)-8-heptadecen-2-ol, and this was reacted with butyryl chloride and pyridine in dichloromethane to give a sample of (2*S*,12*Z*)-2-butyroxy-12-heptadecene.

Field Experiments Field experiments were conducted in commercial chrysanthemum plantations in Angou, Hebei Province, China. Dispensers were red rubber septa (20× 10 mm o.d., International Pheromone Systems Ltd., Wirral,

UK) impregnated with the test chemical(s) applied in petroleum ether (0.1 ml) containing 2,6-di-*tert*-butyl-4-methylphenol (BHT, 99%; Sigma-Aldrich) as an antioxidant, at 20% the amount of the major test component. Traps were sticky delta traps (20 cm long×17 cm sides) with the septum fixed 2 cm above the sticky insert. Experiments employed a randomized complete block design with 3 replicates each, and traps were placed at 20-m intervals.

Experiment 1 was carried out from 30 June to 3 July 2007, when plants were 25–35 cm high. Traps were hung 30 cm above the ground. Treatments were (A) racemic (*Z*)-2-butyroxy-8-heptadecene (20 µg); (B) (*Z*)-2-butyroxy-8-heptadecene (20 µg)+(*Z*)-8-heptadecen-2-ol (3 µg); (C) (2*S*,8*Z*)-2-butyroxy-8-heptadecene (10 µg); (D) (2*S*,8*Z*)-2-butyroxy-8-heptadecene (10 µg) + (2*S*,8*Z*)-8-heptadecen-2-ol (1.5 µg); (E) (2*R*,8*Z*)-2-butyroxy-8-heptadecene (10 µg); (F) (2*R*,8*Z*)-2-butyroxy-8-heptadecene (10 µg) + (2*R*,8*Z*)-8-heptadecen-2-ol (1.5 µg); and (G) unbaited control.

Experiment 2 was carried out from 19 to 23 September 2007 when plants were 70–80 cm high. Traps were hung 75 cm above the ground. There were 7 treatments: (2*S*,8*Z*)-2-butyroxy-8-heptadecene (10 µg), five two-component blends of (2*S*,8*Z*)-2-butyroxy-8-heptadecene (10 µg) with (2*S*,8*Z*) -8-heptadecen-2-ol at 1, 2, 5, 10, and 15% of the major component, and unbaited control.

Catches of male *R. longicauda* were transformed to log(x+1) to improve the equality of variances, as judged by plots of residuals against estimated means, and subjected to two-way analysis of variance (ANOVA), excluding treatments in which no midges were caught (Genstat for Windows version 10, VSN International Ltd., Hemel Hempstead, UK). Differences between means were tested for significance at the 5% level by the Least Squares Difference (LSD) test.

Release Rate Measurements For release-rate measurements, two rubber septa dispensers were loaded with a 1:1 blend of racemic (*Z*)-2-butyroxy-8-heptadecene and (*Z*)-8-heptadecen-2-ol (50 µg each), and maintained in a laboratory windtunnel at 27°C and 8 km/h windspeed. At intervals, volatiles were collected from each septum separately as described for collection of volatiles from live insects, except that the septa were held in smaller glass vessels (10×3 cm) constructed from Quickfit adapters. Volatiles were collected on Porapak for 24 h at a flow rate of 2 l min^{-1}. Collected volatiles were eluted with dichloromethane, pentadecyl acetate (200 ng) was added as an internal standard, and the solution was analyzed by GC-MS on the polar column.

Results

Pheromone Identification GC-FID analyses of three collections from female *R. longicauda* midges and three collections from male midges, using a polar GC column, showed two compounds present in all the collections from females; neither of these components were present in collections from males. GC-EAG analyses of volatiles from virgin female *R. longicauda* on both polar and non-polar GC columns revealed two compounds that elicited responses from the antennae of males (Fig. 2); again, these compounds were not detectable in collections from virgin males. RIs for the EAG-active compounds are shown in Table 1.

Collections of volatiles from female midges were analyzed by GC-MS using both polar and non-polar columns. The EI fragmentation pattern of the major EAG-active compound (Fig. 3) suggested that it was a butyrate, as evidenced by ions at *m/z* 71 ($C_3H_7CO^+$) and *m/z* 89 ($C_3H_7COOH_2^+$). The ion at *m/z* 236 corresponded to loss of butyric acid from a 17-carbon butyrate with one double bond (molecular weight 324). The CI mass spectrum showed ions at *m/z* 326 and 237 confirming this.

After catalytic hydrogenation of a sample of volatiles from female *R. longicauda*, GC-MS analysis showed the major compound had disappeared and was replaced by a butyrate ester having GC RIs and mass spectrum identical with those of 2-butyroxyheptadecane (Table 1). The EI mass spectrum of this compound showed ions at *m/z* 238 and at *m/z* 115 (CH_3-CH-$OOCC_3H_7^+$), confirming that the butyrate was in the C-2 position.

Epoxidation of a sample from female *R. longicauda* gave a product (RI 2363 on the non-polar GC column, 2822 on the polar column) with an EI mass spectrum that showed an ion at *m/z* 252, corresponding to loss of butyric acid from the epoxide of a monounsaturated 17-carbon butyrate. Ions at *m/z* 155 (C_8H_{17}-$C_2H_2O^+$) and *m/z* 109 [loss of butyric acid from CH_3-CH($OOCC_3H_7$)-$(CH_2)_5$-$C_2H_2O^+$] indicated that the double bond in the original compound was in the C-8 position. This was confirmed by reaction of a sample from female *R. longicauda* with DMDS, which gave a product (RI 2809 on the non-polar column) with a mass spectrum that showed a molecular ion at *m/z* 418, corresponding to addition of one DMDS molecule (94) to a compound with molecular weight of 324. Diagnostic ions at *m/z* 173 [$CH_3(CH_2)_8$-$CHSCH_3^+$] and *m/z* 137 [loss of butyric acid from CH_3-CH($OOCC_3H_7$)-$(CH_2)_5$-$CHSCH_3^+$] confirmed that the double bond was located at the C-8 position. (*Z*)-2-Butyroxy-8-heptadecene was synthesized and found to have identical RIs and mass spectra to those of the major EAG-active compound in volatiles from female *R. longicauda*. The RIs were different from those of the corresponding *E*-isomer, present as an impurity in the *Z*-isomer, and those of (*Z*)-2-butyroxy-12-heptadecene, derived from (*Z*)-2-acetoxy-12-heptadecene, the pheromone of the pistachio twig borer, *Kermania pistaciella* (Gries et al. 2006) (Table 1).

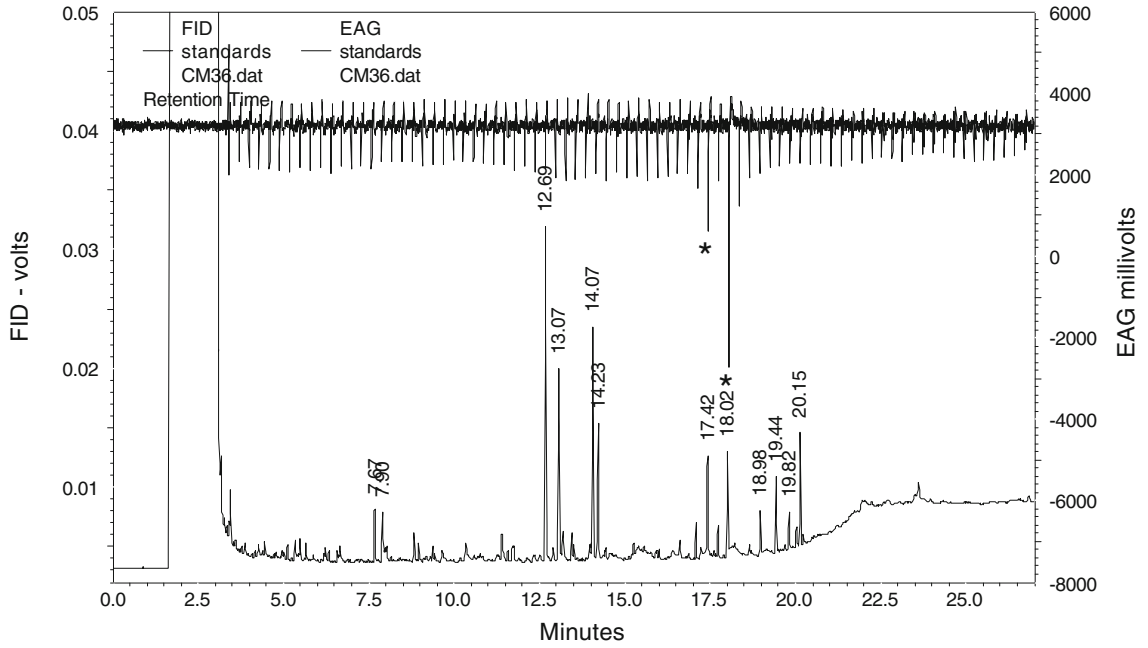

Fig. 2 Coupled gas chromatographic–electroantennographic (GC-EAG) detection analysis of volatiles collected from virgin female *Rhopalomyia longicauda* using a male electroantennogram preparation and a polar column (EAG responses are marked with *)

The mass spectrum of the minor EAG-active compound showed a molecular ion at *m/z* 254 and an ion at *m/z* 237 (M-17), indicating a monounsaturated 17-carbon alcohol. An ion at *m/z* 45 [CH_3-$CH(OH)^+$] was consistent with the alcohol group being at the C-2 position. Synthetic (*Z*)-8-heptadecen-2-ol was found to have identical GC RIs (Table 1) and mass spectrum to those of this compound (Table 1).

The proportion of the minor, relative to the major, compound in the volatiles from female *R. longicauda* was 0.26:1±0.06 (SEM; *N*=3), determined by integration of the total ion trace in GC-MS analyses on the polar column. The minor compound co-chromatographed with an impurity on the column used for GC-EAG analyses in Fig. 2. Comparison of peak areas with those of standard acetate esters

Table 1 Gas chromatographic retention indices (RI), relative to *n*-alkanes, for the major and minor electroantennogram-active components in the volatile collections of female *Rhopalomyia longicauda* and various synthetic compounds, on polar (Wax10) and non-polar (SPB1) columns

	RI	
Compound	Wax10	SPB1
Major electroantennogram-active component	2418	2171
Minor electroantennogram-active component	2348	1885
(*Z*)-2-butyroxy-8-heptadecene (I)	2418	2172
(*E*)-2-butyroxy-8-heptadecene	2423	2178
(*Z*)-2-butyroxy-12-heptadecene	2442	2188
(*Z*)-8-heptadecen-2-ol (II)	2353	1885
(*Z*)-12-heptadecen-2-ol	2311	1907
2-heptadecyl butyrate	2399	2197
2-heptadecanol	2331	1909

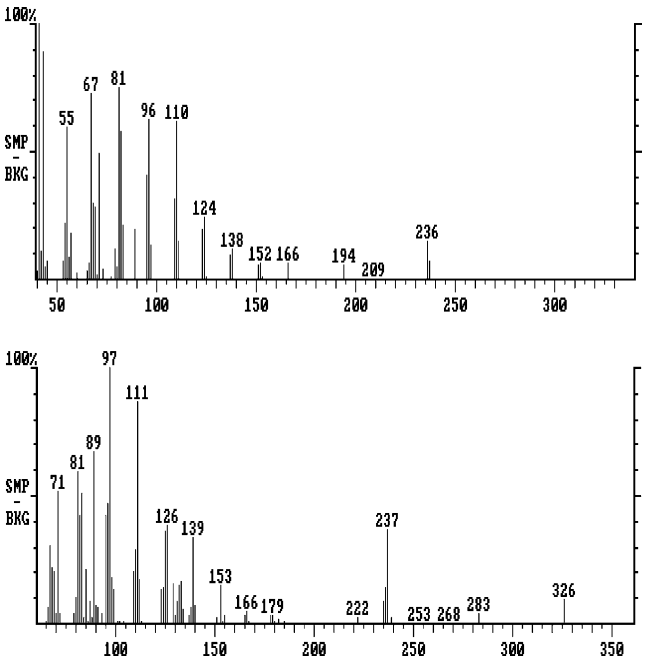

Fig. 3 Mass spectra of the major pheromone component of *Rhopalomyia longicauda* using electron impact (upper) and chemical ionization (lower)

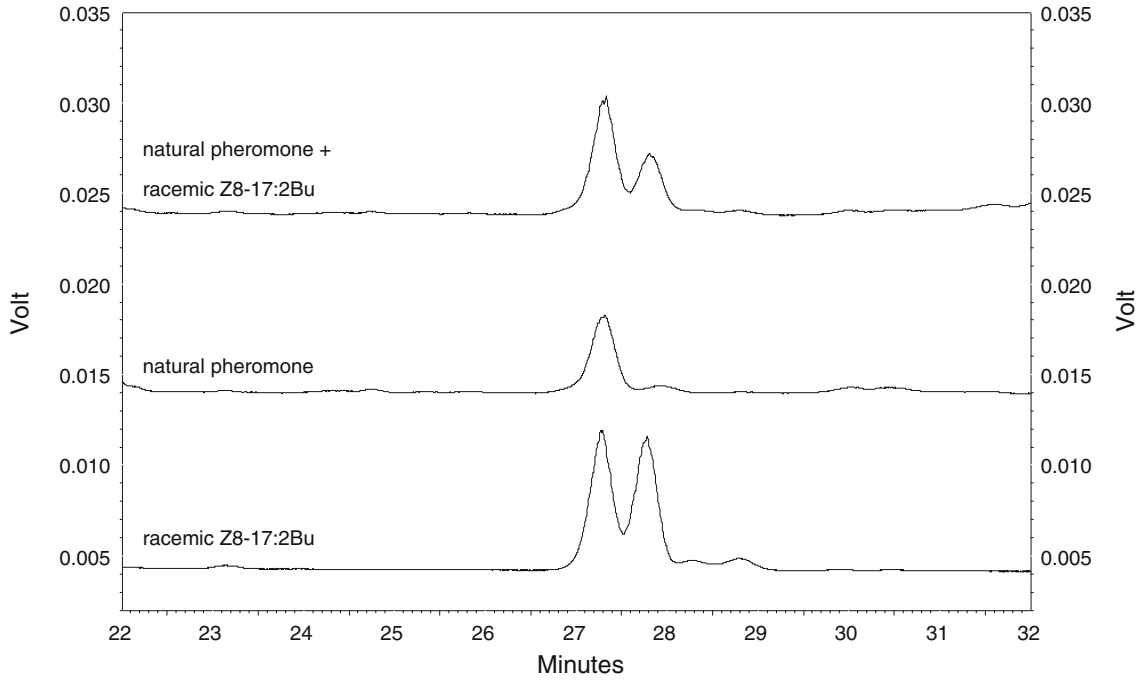

Fig. 4 Gas chromatography (GC) analyses of natural and synthetic pheromone components on an enantioselective GC column: racemic (*Z*)-2-butyroxy-8-heptadecene (Z8-17:2Bu) (lower); volatiles from female *Rhopalomyia longicauda* (middle); coinjection of racemic (*Z*)-2-butyroxy-8-heptadecene and volatiles from female *R. longicauda* (upper)

indicated that the amount of the major compound produced was up to 0.7 ng/female over a life of 1–2 days.

Configuration of the Two Components The two enantiomers of synthetic (*Z*)-2-butyroxy-8-heptadecene were separated on a cyclodextrin column, with the *S* enantiomer eluting at 27.25 min and the *R* enantiomer at 27.75 min (Fig. 4). The identities of the two enantiomers were resolved following enantioselective hydrolysis with lipase from *Candida antarctica*, which selectively hydrolyses the *R*-enantiomer (e.g., Xiao and Kitazume 1997; Gries et al. 2006). Analysis of volatiles from female *R. longicauda* showed a peak at the same retention time as the first (i.e., the S-enantiomer) of the peaks in the racemate, and no peak corresponding to the second-eluting (i.e., R-) enantiomer (Fig. 4). The natural chemical co-chromatographed with the first-eluting enantiomer, confirming its identity as (2*S*,8*Z*)-2-butyroxy-8-heptadecene (Fig. 4). The two enantiomers of (*Z*)-8-heptadecen-2-ol could not be separated on this column.

Field Tests Field-trapping tests were conducted to determine the activity of synthetic (*Z*)-2-butyroxy-8-heptadecene, (*Z*)-8-heptadecen-2-ol, and their blends. In Experiment 1, differences among treatments were highly significant (Fig. 5; $F=11.78$, df 5,10, $P<0.001$). Traps baited with synthetic racemic (*Z*)-2-butyroxy-8-heptadecene (A) or (2*S*,8*Z*)-2-butyroxy-8-heptadecene (C) caught equal numbers of male *R. longicauda* ($P>0.05$), while traps baited with (2*R*,8*Z*)-2-butyroxy-8-heptadecene (E) caught no males. Addition of the alcohol to the butyrate at a ratio of 0.15:1, corresponding to the ratio found in volatiles from female *R. longicauda* midges, completely suppressed trap

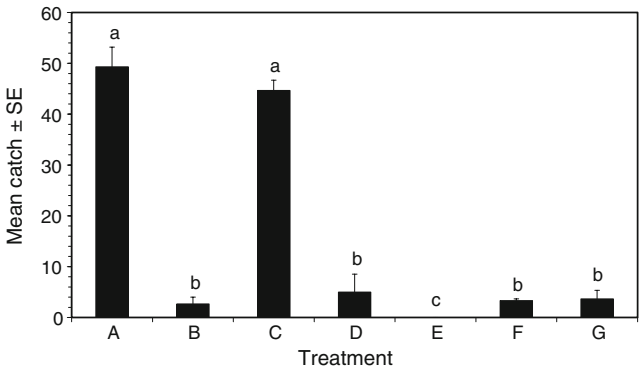

Fig. 5 Mean catchers (±SE) of male *Rhopalomyia longicauda* captured in traps baited with synthetic candidate pheromone components: (A) racemic (*Z*)-2-butyroxy-8-heptadecene (20 μg); (B) (*Z*)-2-butyroxy-8-heptadecene (20 μg) + (*Z*)-8-heptadecen-2-ol (3 μg); (C) (2*S*,8*Z*)-2-butyroxy-8-heptadecene (10 μg); (D) (2*S*,8*Z*)-2-butyroxy-8-heptadecene (10 μg) + (2*S*,8*Z*)-8-heptadecen-2-ol (1.5 μg); (E) (2*R*,8*Z*)-2-butyroxy-8-heptadecene (10 μg); (F) (2*R*,8*Z*)-2-butyroxy-8-heptadecene (10 μg) + (2*R*,8*Z*)-8-heptadecen-2-ol (1.5 μg); and (G) unbaited control. Trial carried out from 30 June – 3 July 2007; 3 replicates; totals with different letters are significantly different, $P<0.05$

capture of male midges. Thus, traps baited with racemates of both compounds (B), with the *S*-enantiomers of both compounds (D), or with the *R*-enantiomers of both compounds (F) caught numbers of males that were not significantly different from those captured in unbaited traps (G) ($P>0.05$) (Fig. 5).

Determination of release rates of (*Z*)-2-butyroxy-8-heptadecene and (*Z*)-8-heptadecen-2-ol from a rubber septum loaded with equal amounts of the two compounds (50 μg each) showed that the mean ratio of the alcohol to the butyrate in the volatiles released was 13.3:1 after 2 d, 13.3:1 after 4 d, 12.1:1 after 9 d and 10.4:1 after 15 d. Thus, a blend containing 0.02:1 alcohol:butyrate on a septum would be expected to give a release ratio of components similar to the 0.26:1 blend released by female *R. longicauda*. Experiment 2, therefore, examined the effect on trap catches of adding (2*S*,8*Z*)-8-heptadecen-2-ol to (2*S*,8*Z*)-2-butyroxy-8-heptadecene at five different ratios from 0.01:1 to 0.15:1. All blends were significantly less attractive ($P<0.05$) than (2*S*,8*Z*)-2-butyroxy-8-heptadecene alone; the 0.1:1 and 0.15:1 blends caught no male midges at all (Fig. 6; $F=43.62$, *df* 3,6, $P<0.001$).

Discussion

(2*S*,8*Z*)-2-Butyroxy-8-heptadecene is released by virgin female *R. longicauda* midges and not by males. This compound elicited an EAG response from conspecific males and was highly attractive to male midges in field trapping tests, although no direct comparison with the attractiveness of live females or extracts of the pheromone glands of females was performed. Thus, this compound is the major component of the sex pheromone produced by female *R. longicauda*. The *R*-enantiomer of this compound was unattractive to males, and did not appear to affect the attractiveness of the *S*-enantiomer when the racemate was tested.

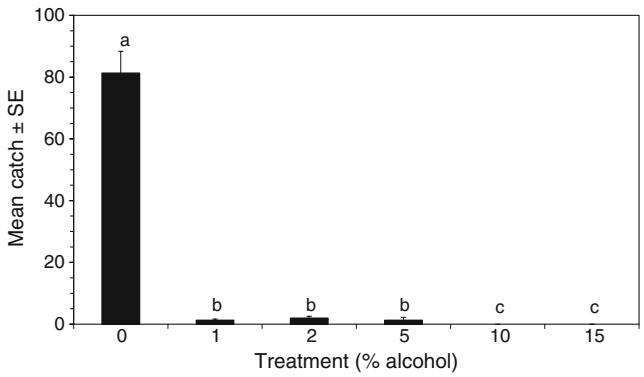

Fig. 6 Mean catches (±SE) of male *Rhopalomyia longicauda* captured in traps baited with blends containing different ratios of candidate pheromone components (2*S*,8*Z*)-2-butyroxy-8-heptadecene (10 μg) and (2*S*,8*Z*)-8-heptadecen-2-ol. Trial carried out from 19–23 September 2007; 3 replicates; totals with different letters are significantly different, $P<0.05$

The corresponding alcohol, (*Z*)-8-heptadecen-2-ol also was present in volatile collections from female *R. longicauda* midges in a ratio of approximately 0.26:1, relative to the butyrate, and this compound also elicited an EAG response from antennae of male midges. Determination of relative release rates of the butyrate and alcohol from the rubber septa used as dispensers in field tests indicated that a ratio of 0.02:1 alcohol: butyrate on the septum should release a blend approximating that found in volatile collections from female midges. However, even at ratios as low as 0.01:1, the presence of the alcohol suppressed the attractiveness of the butyrate to males in field trials.

Since the alcohol appears to inhibit attraction to the butyrate, its presence in the volatile collections is surprising. It is unlikely that the alcohol arose from the butyrate by decomposition during the collection process. Re-examination of traces from GC-FID analyses of samples immediately after extraction from the collection filters showed the presence of the alcohol in similar relative proportions to those observed during GC-EAG analyses carried out on samples stored for three months. The enantiomers of the alcohol could not be separated on the enantioselective GC column used, and it was assumed that the female midges produced the *S*-enantiomer exclusively as they do for the butyrate. Hence, we tested only the S-enantiomer or the racemic mixture, which both suppressed trap capture when added to the butyrate. Another possibility is that the *R*-enantiomer of the alcohol is attractive and the *S*-enantiomer is strongly inhibitory. This should be investigated in future studies.

Neither (2*S*,8*Z*)-2-butyroxy-8-heptadecene nor the corresponding alcohol have been reported as insect pheromone components. However, the structure of these compounds conforms to the general pattern of structures found in pheromone components of other cecidomyiid midges. The backbone has an odd number of carbon atoms with an oxygenated functionality in the 2-position (Hall et al. 2009). The opposite enantiomer of the corresponding acetate, (2*R*,8*Z*)-2-acetoxy-8-heptadecene, is the pheromone of the honey locust gall midge, *Dasineura gleditchiae* (Molnár et al. 2009), and (*Z*)-13-acetoxy-8-heptadecen-2-one is the pheromone of the apple leaf curling midge, *D. mali* (Cross and Hall 2005; Suckling et al. 2007; Cross et al. 2009). The butyrate ester functionality has also been found in the sex pheromone component, (2*S*,7*S*)-2,7-dibutyroxynonane, of the orange wheat blossom midge, *Sitodiplosis mosellana* (Gries et al. 2000).

The role of (*Z*)-8-heptadecen-2-ol in the pheromone of *R. longicauda* remains to be determined, but traps baited with (2*S*,8*Z*)-2-butyroxy-8-heptadecene or the racemic mixture can be used to monitor this pest.

Acknowledgements This work was funded by the National Science and Technology Support Projects in the 11th Five-year Plan of China (No. 2006BAD15B03, 2006BAD08A03 and 2006BAD02A16-4) and in part by the UK Horticultural Development Council and the Worshipful Company of Fruiterers. We thank Dr. K. M. Harris (former director of International Institute of Entomology, UK) and Prof. Junichi Yukawa (Entomological Laboratory, Faculty of Agriculture, Kyushu University, Japan) for identifying this insect species.

Identification and Synthesis of the Sex Pheromone of the Madeira Mealybug, *Phenacoccus Madeirensis* Green

Hsiao-Yung Ho · Yu-Ting Su · Chi-Hung Ko · Ming-Yu Tsai

Received: 14 February 2009 / Revised: 6 May 2009 / Accepted: 2 June 2009 / Published online: 16 June 2009

Abstract Two components were identified from aeration extracts of the virgin female Madeira mealybug, *Phenacoccus madeirensis* as *trans*-(1*R*,3*R*)-chrysanthemyl (*R*)-2-methylbutanoate and (*R*)-lavandulyl (*R*)-2-methylbutanoate (with a ratio of 3:1) by a combination of gas chromatography retention time matches, mass spectrometry, and microchemical tests. The structures and chirality of the compounds were confirmed by comparing with synthetic compounds. The synthetic *trans*-(1*R*,3*R*)-chrysanthemyl (*R*)-2-methylbutanoate was highly attractive to males in laboratory bioassays; the synthetic (*R*)-lavandulyl (*R*)-2-methylbutanoate was weakly attractive. No synergistic effect was observed when the mixture of the two compounds was tested.

Keywords Mealybug · *Trans*-(1*R*,3*R*)-chrysanthemyl (*R*)-2-methylbutanoate and (*R*)-lavandulyl (*R*)-2-methylbutanoate · Hemiptera · Pseudococcidae · *Phenacoccus madeirensis*

Introduction

The Madeira mealybug, *Phenacoccus madeirensis* Green, is one of the most polyphagous of all mealybug species, having been reported from more than 42 host families (USDA 2006 and references therein). Its range includes nearly all temperate areas of the world, but it has limited distribution in Australasian and Oriental regions (CAB International 2000). However, it has recently invaded Taiwan (Yeh et al. 2006).

Although parasitoids of the Madeira mealybug have been studied (Chong and Oetting 2008), no work has been done to identify the sex pheromone of this species. Sex pheromones of the related species *Planococcus citri* (Risso) and *Planococcus ficus* Signoret have been identified, and now are widely used in pest management (Moreno et al. 1984; Millar et al. 2002; Walton et al. 2006). Sex pheromones of several other mealybug species have been identified recently, including *Pseudococcus maritimus* (Ehrhorn) (Figadere et al. 2007), *Planococcus minor* (Maskell) (Ho et al. 2007), and *Planococcus kraunhiae* (Kuwana) (Sugie et al. 2008). For a pest as important as *P. madeirensis*, identification of the sex pheromone for use in pheromone-baited monitoring traps would be helpful for detection and management. We report here the identification of two female-specific components of *P. madeirensis* in Taiwan as *trans*-(1*R*,3*R*)-chrysanthemyl (*R*)-2-methylbutanoate [IUPAC name: 2R-Methyl-butanoic acid (1'R, 3'R)-2',2'-dimethyl-3'(2-methyl-propenyl)-cyclopropylmethyl ester] and (*R*)-lavandulyl (*R*)-2-methylbutanoate. The biological activity of the synthetic compounds was verified in laboratory bioassays.

Methods and Materials

Insects A colony of *P. madeirensis* was started from bugs collected from painted copperleaf, *Acalypha wilkesiana* Muell.-Arg, on the campus of National Taiwan University, Taipei, Taiwan in 2006. The mealybugs were reared on sprouted potatoes (Solanaceae: *Solanum tuberosum* L.) in an incubator maintained at 28°C, relative humidity 40–

80%, and under a photoperiod of 12:12 h (L:D). The identity of the species was confirmed by Dr. S. P. Chen of Department of Applied Zoology and Entomology, Taiwan Agricultural Research Institute, Taichung, Taiwan.

Sprouted potatoes were infested with ovisacs to start new cohorts (10–15 ovisacs for each potato). After 10–14 d, female nymphs were separated from male nymphs by transferring female nymphs with a fine brush to a new sprouted potato to ensure virginity after emergence. The sex of the mealybug could be distinguished by appearance and behaviors of the second-instar nymphs (Chong et al. 2003; Yeh et al. 2006). At this stage, male nymphs become pink and secrete waxy filamentous cocoons, whereas female nymphs remain pale yellow and lack cocoons.

Males of *P. madeirensis* nymphs were separated by the method of Negishi et al. (1980) and Arai (2000) as follows. Male nymphs that crawled off the potato sprouts to pupate on the paper towels that covered the potatoes were collected. The pupae-containing paper towels were put into a container (21.5 cm ID×6.5 cm in depth) and kept in the incubator. Two to 3 days after emergence, males were used in bioassays.

Collection of Pheromone Extracts Sprouted potato tubers infested with virgin females (about 200–350 females per potato) were aerated in a 1,000 ml glass aeration chamber by passing purified air through the chamber. The headspace volatiles were trapped on collectors that consisted of glass tubes packed with activated charcoal (2.5 cm×8 mm ID), and collections continued for 5–7 d. A total of 1,000–2,000 female-day-equivalents (hereafter FDE) of the female-specific compounds were collected per collector. Extracts from aerations of uninfested sprouted potato tubers served as controls.

Analysis of Pheromone Extracts The collectors were eluted with pentane, and the resulting extracts were analyzed by splitless coupled gas chromatography-mass spectrometry (GC-MS) with a ThermoQuest Trace GC interfaced to a Finnigan Trace mass spectrometer (electron impact ionization, 70 eV). The GC oven was held at 40°C for 1 min, programmed at 10°C/min to 250°C, with injector and transfer line temperatures of 200°C and 250°C, respectively. DB-5MS, DB-1, and DB-23 columns (all 30 m×0.25 mm ID, J & W Scientific, Folsom, CA, USA) were used, with helium as carrier gas. The Kovats indices of the unknowns were calculated in relation to straight-chain alkanes. For determination of the absolute configurations of the compounds, a chiral Rt-bDEXsm capillary column (30 m×0.25 mm ID, Restek, Bellefonte, PA, USA) was used. NMR spectra were recorded on Bruker Avance 400 spectrometer.

Isolation of the Pheromone High performance liquid chromatography (HPLC) was employed to isolate the sex pheromone, using an ECOM® Beta 10 Gradient Pump (Prague, Czech Republic), a silica gel column (250× 4.6 mm, 5 μ) (LDC/Milton Roy, Riviera Beach, FL, USA), a Rheodyne Model 7125 sample injector, and a DAD230 photo diode array detector (set at 200–650 nm) (ChromTech, Singapore). Aeration extracts of infested and uninfested potatoes were eluted with a solvent gradient of pentane and diethyl ether (1.0 ml/min), starting with 100% pentane for 2 min, and then decreasing to 0% pentane in 55 min with the addition of diethyl ether. Fractions were collected every 1 min with a fraction collector. The collected fractions were concentrated under a stream of nitrogen and then analyzed by GC/MS.

Hydrolysis of the Unknown The concentrated fraction that contained the unknown (1 μg) was dissolved in 300 μl of ethanol, and two drops of 1 N NaOH were added. The reaction mixture was kept in a water bath at 35°C for about 30 min before 1 N HCl was added to neutralize the solution. The product was extracted with hexane. The hexane solution was dried by passing through a short plug of anhydrous $MgSO_4$. After concentration under a stream of nitrogen, the product was analyzed by GC/MS.

Chemicals Racemic 2-methylbutanoic acid, (*S*)-2-methylbutanoic acid, chrysanthemol (mixture of *trans* and *cis*), lithium aluminum hydride solution in THF, succinic anhydride, (±)-lavandulol, 4-dimethylaminopyridine (DMAP), 1,3-diisopropylcarbodiimide (DIC), and dicyclohexylcarbodiimide (DCC) were obtained from Sigma-Aldrich Co. (Milwaukee, WI, USA). *Trans*-(+)-chrysanthemic acid (CAS # 4638-92-0) was purchased from Acros Organics (Belgium). Pig pancreatic lipase (30.1 U/mg) was purchased from Fluka. Diethyl ether was dried by distillation from sodium-benzophenone ketyl.

Separation of trans- and cis-Chrysanthemol The *trans*- and *cis*- isomers were separated by using semipreparative HPLC on a silica gel column (5 μ, 250×10 mm Luna, Phenomenex) with a solvent gradient of pentane and diethyl ether (2.0 ml/min), starting with 100% pentane for 3 min, and then decreasing to 65% ether in 5 min, to 62% in 80 min, decreasing to 0% pentane in 82 min with the addition of diethyl ether. The *trans*- and *cis*- isomers eluted at around 29 min and 26 min. ^{1}H NMR ($CDCl_3$, 400 MHz) of *trans*-chrysanthemol: δ 0.82 (m, 1H), 1.04 (s, 3H), 1.09 (m, 1H), 1.14 (s, 3H), 1.66 (s, 3H), 1.69 (s, 3H), 3.55 (m, 1H), 3.76 (m, 1H) and 4.85 (d, 1H). ^{1}H NMR ($CDCl_3$, 400 MHz) of *cis*-chrysantheol: δ 1.03 (s, 3H), 1.06 (m, 1H), 1.07 (s, 3H), 1.37 (t, 1H), 1.68 (s, 3H), 1.71 (s, 3H), 3.62 (m, 2H), and 4.95 (d, 1H). The stereo-chemistry was assigned according to the NMR data of the two compounds (Bramwell et al. 1969).

Resolution of (R)-2-Methylbutanoic Acid from Racemic 2-Methylbutanoic Acid Racemic 2-methylbutanoic acid

(58 mg, 0.57 mmole) in 0.5 ml $CHCl_3$ was added to a solution of dicyclohexylcarbodiimide (DCC) (119 mg, 0.57 mmole, in 1 ml $CHCl_3$) cooled in an ice-bath (Kaneda 1986). Then, 70 mg (0.57 mmole) (*S*)-α-methylbenzylamine were added. The solution was heated in a 50°C bath for 1 h. The reaction mixture was cooled and concentrated. Ethyl acetate was added to the residue, and the mixture was filtered. The diastereomeric amide products were in the ethyl acetate filtrate. The diastereomers were separated by using semipreparative HPLC on a silica gel column (5 μ, 250×10 mm Luna, Phenomenex) with a solvent gradient of pentane and diethyl ether (1.0 ml/min), starting with 100% pentane for 2 min, and then decreasing to 0% pentane in 30 min with the addition of diethyl ether. The diastereomers eluted at around 7 min and 8.5 min. Each pure compound was hydrolyzed by refluxing the amide (45 mg) in 1 ml 70% H_2SO_4 for 3 h. After cooling to room temperature, 5 ml water were added, and the mixture was extracted with diethyl ether (10 ml×2). The ether layer was extracted with 2 M NaOH, and the basic aqueous layer was acidified with 1 N HCl, then extracted with diethyl ether. The resolved acid was in the ether layer. After comparison of the resolved acids with authentic (*S*)-2-methylbutanoic acid (from Sigma-Aldrich Co.) on a chiral GC column (r.t. for (*S*)-2-methylbutanoic acid 18.5 min, (*R*)-2-methylbutanoic acid 18.69 min), the compound that eluted first on the HPLC was identified as the amide of (*R*)-2-methylbutanoic acid.

Resolution of (R)-Lavandulol from Racemic Lavandulol The procedure of Zada and Dunkelblum (2006) was followed. Briefly, racemic lavandulol (231 mg, 1.5 mmole), succinic anhydride (300 mg, 3 mmole), and pig pancreatic lipase (340 mg, 30.1 U/mg) were added to 10 ml dry ether, and the mixture was stirred in the room temperature for 24 h. After filtration, the filtrate was diluted with 10 ml of ether and then stirred with 1 M Na_2CO_3 (10 ml) for 30 min. After separation from the aqueous solution, the ether layer was concentrated, yielding 57 mg of (*R*)-lavandulol of 97% optical purity. Absolute configuration of (*R*)-lavandulol was determined according to Zada and Dunkelblum (2006). Because (*S*)-lavandulol will react with the succinic anhydride and become half acid, which was separated from the unreacted (*R*)-lavandulol, (*R*)-lavandulol was in the ether layer. On a chiral GC column, the (*R*)-lavandulol elutes later than the (*S*)-lavandulol (Zhang et al. 2004). The r. t. of the compound in the ether layer was 30.78 min and r.t. of (±)-lavandulol were 29.92 min and 30.78 min, so the compound in the ether layer was identified as (*R*)-lavandulol.

Reduction of Trans-(+)-Chrysanthemic Acid *Trans*-(+)-Chrysanthemic acid (48 mg) was dissolved in 2 ml THF and 0.5 ml of $LiAlH_4$ in THF (2.4 M) was added. After heating at 40°C for 2 h, the mixture was cooled in an ice bath, and quenched by slow, dropwise addition of saturated $NaHCO_3$ (foams!). After gas evolution ceased, 10 ml of diethyl ether were added, and the reaction mixture was stirred at room temperature for 1 h. The ether layer was separated, filtered, dried over $MgSO_4$, and concentrated to yield 37 mg of *trans-(1R,3R)*-chrysanthemyl alcohol.

Preparation of Trans-(1R,3R)-Chrysanthemyl 2-Methylbutanoate and (R)-Lavandulyl (R)-2-Methylbutanoate The *trans-(1R,3R)*-chrysanthemyl alcohol (10 mg, 0.065 mmole), 2-methylbutanoic acid (6.6 mg, 0.065 mmole), 4-dimethylaminopyridine (DMAP) (1.6 mg, 0.013 mmole) and 1,3-diisopropylcarbodiimide (DIC) (9 mg, 0.07 mmole) were combined in dichloromethane (400 μl) and stirred for 1 h at room temperature. After evaporation of the dichloro-

methane, water was added, and the product was extracted with ether. The compound was purified by semi preparative HPLC on a silica gel column (5 μ, 250×10 mm Luna, Phenomenex) with a solvent gradient of pentane and diethyl ether (1.0 ml/min), starting with 100% pentane for 2 min, and then decreasing to 0% pentane in 30 min with the addition of diethyl ether. ^{1}H NMR ($CDCl_3$, 400 MHz) of *trans-(1R,3R)*-chrysanthemyl 2-methylbutanoate: δ 0.82 (2H, m), 0.89 (3H, t, *J*=7.6 Hz), 1.02 (3H, s), 1.13 (3H, s), 1.15 (3H, d, *J*=6 Hz), 1.45 (2H, quintet, *J*=6.8 Hz), 1.65 (3H, br. s), 1.68 (3H, br. s), 2.34 (1H, sextet, *J*=7.2 Hz), 3.93 (1H,dd, *J*=8.8, 11.6 Hz), 4.29 (1H, dd, *J*=6.8, 11.6 Hz), 4.85 (1H, d, *J*=7.6 Hz). ^{13}C NMR ($CDCl_3$, 75 MHZ): δ 11.6, 16.7, 18.2, 21.5, 22.3, 22.4, 25.6, 26.8, 29.0, 31.0, 41.1, 65.3, 122.9, 133.5, and 176.9. The same procedure was used for the preparation of (*R*)-lavandulyl (*R*)-2-methylbutanoate. ^{1}H NMR ($CDCl_3$, 400 MHz) of (*R*)-lavandulyl (*R*)-2-methylbutanoate: δ 0.87 (3H, t, *J*=7.6 Hz), 1.10 (3H, d, *J*=7.2 Hz), 1.44 (2H, m), 1.58 (3H,s), 1.66 (3H, s), 1.68 (3H, s), 2.06 (2H, m), 2.33 (1H, m), 2.38 (1H, m), 4.03 (2H, d, *J*=6.8 Hz), 4.71 (1H,s), 4.8 (1H, s), 5.05 (1H, t, *J*=6 Hz). ^{13}C NMR ($CDCl_3$, 75 MHZ): δ 11.6, 16.6, 17.8, 19.9, 25.7, 26.7, 28.6, 41.2, 46.2, 65.5, 112.4, 121.7, 132.8, 144.9, and 176.7.

Dynamics of Pheromone Release To determine the diurnal pattern of pheromone release, a cohort of 450 virgin female mealybugs of known age were aerated, and the collectors were changed every 5 h between 19:00 and 15:00, with another collector being used to collect the volatiles between 15:00 and 19:00. Aerations were continued for 3 d. Collectors were eluted as described above, and internal

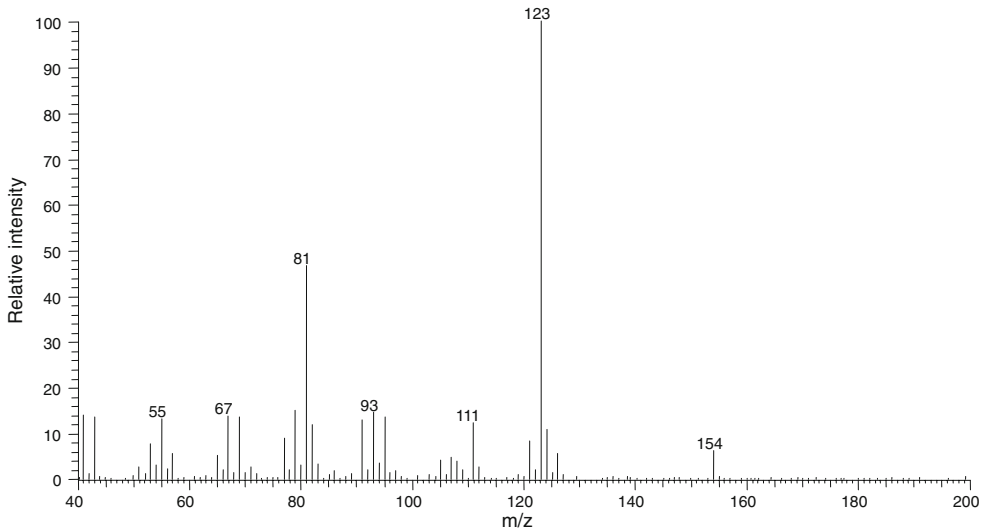

Fig. 3 EI mass spectrum of the hydrolyzed product of compound A

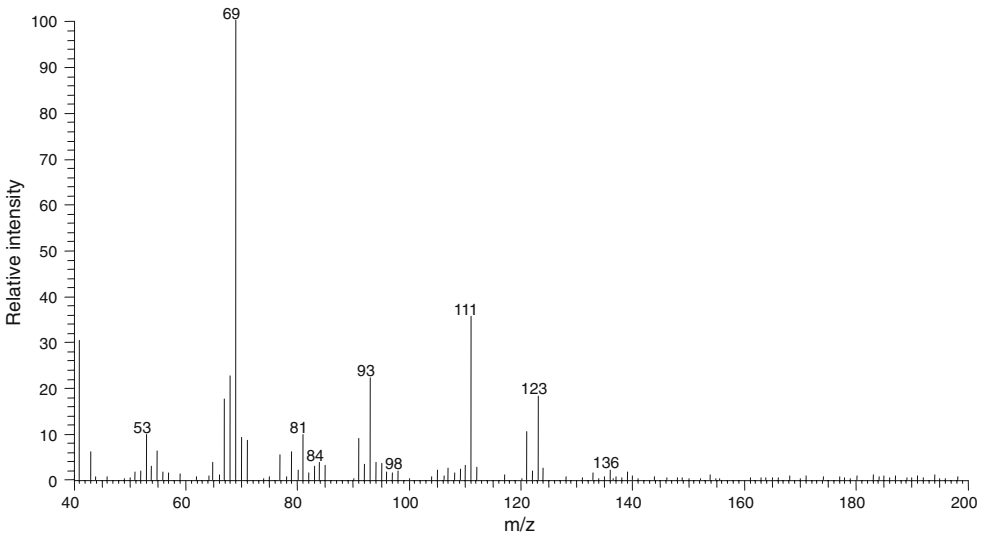

Fig. 4 EI mass spectrum of the hydrolyzed product of compound B

standard (benzophenone, 600 ng) was added to the pentane extract. The amount of the major compound was estimated by comparison of GC peak areas. The amounts of the major compound were recorded in the aeration chamber for a consecutive 24 h period. The data for each time period were combined, and means and standard deviations were calculated. The data are reported as nanograms per hour produced by the 450 female bugs during each time interval. Data were analyzed by ANOVA.

Laboratory Bioassay Bioassays were performed in plastic Petri dishes (14 cm ID; 2 cm in depth) during 19:00–21:00 in a room with fluorescent lights (Tashiro et al. 1969, Lanier et al. 1989, Arai 2000, Zada et al. 2003). Adult males (24–37) that had emerged 1–2 d earlier, together with two pieces of filter paper (2×1 cm) moistened with water, were introduced into the Petri dish about 1–2 h before the bioassay began. Two pieces of filter paper (1×1 cm), one treated with pheromone compound(s) in pentane, and the other with an equivalent amount of pentane as control, were placed in the Petri dish. The numbers of males on each 1 cm^2 paper were recorded 11 times at intervals of 10 min. Treatments included natural extract, synthesized *trans*-(1*R*,3*R*)-chrysanthemyl (*R*)-2-methylbutanoate (compound A), synthesized (*R*)-lavandulyl (*R*)-2-methylbutanoate (compound B) (about 6.7 ng/paper), and a mixture of synthesized compounds A and B in a ratio of 3:1 (6.9 ng: 2.3 ng per paper). The percentage of the males on the filter papers (both the

treatment and the control) was calculated for each reading. An average of the 11 readings for each bioassay was recorded as the percentage of male bugs on the treatment or control filter paper. The data were analyzed by t-test.

Results

Analysis Comparison of the extracts of volatiles from mealybug-infested and uninfested potato sprouts revealed two significant insect-produced compounds. The Kovats Index (KI) values of the two compounds were 1727 (compound A) and 1748 (compound B) on the DB-23 column, 1490 (compound A) and 1501 (compound B) on the DB-1 column, and 1492 (compound A) and 1502 (compound B) on the DB-5MS column. The mass spectrum of compound A (Fig. 1) showed significant fragments at *m/z* (%): 57 (100), 81 (35), 85 (48), 93 (32), 107 (14), 121 (98), 123 (76), 136 (4), 156 (19), 169 (4) with a small molecular ion at *m/z* 238 (3). The mass spectrum of compound B (Fig. 2) showed significant fragments at *m/z* (%): 57 (70), 69 (74), 80 (28), 85 (23), 93 (100), 107 (14), 121 (36), 136 (15), 156 (3), also with a small molecular ion at *m/z* 238 (1). The presence of a significant fragmentation ion at *m/z* 85 ($C_4H_9C{\equiv}O^+$) and 136 (M^+-C_4H_9COOH) for both compound A and compound B, suggested that the unknowns could be esters of 5-carbon, saturated carboxylic acids.

The mass spectrum of the hydrolyzed product of compound A (Fig. 3) showed fragment ions with *m/z* (%): 55 (14), 67 (14), 81 (46), 93 (14), 95 (13), 111 (12), 123 (100), and 124 (10), and a molecular ion of *m/z* 154 (6). The mass spectrum of the hydrolyzed product of compound B (Fig. 4) showed fragment ions with *m/z* (%): 53 (10), 55 (8), 69 (100), 81 (10), 93 (24), 111 (36), 121(10), 123 (18), and 136 (4) (M^+-18). The molecular weight of the hydrolyzed product of both compound A and B was 102 mass units less than that of the unknowns, supporting the hypothesis that the unknowns were esters of five-carbon saturated acids. Another compound after hydrolysis showed fragment ions of *m/z* (%): 41 (23), 57 (37), 73 (18), 74 (100), 87(31), and 102 (0.4). Comparison of the mass spectrum of the hydrolyzed products with the NIST mass spectral database, suggested possible structures for the hydrolyzed product of compound A as chrysanthemol, lavandulol for the hydrolysis product of compound B, and the acid part of the ester as 2-methylbutanoic acid.

Both *trans*- and *cis*-chrysanthemol were esterified with 2-methylbutanoic acid, and the esters were compared with compound A from the aeration extract on a DB-23 column. Compound A was confirmed as *trans*-chrysanthemyl 2-methylbutanoate.

The mass spectrum of compound B showed the same fragmentation of the pheromone component as the published spectrum of a component of the pheromone of the pink

Table 2 Percentage of male mealybugs attracted to various treatments in Petri dish bioassays

Treatment	Percentage of males attracted to treatment (mean ± S. D.)	Percentage of males attracted to control (mean ± S. D.)	Difference P value[b]
Compound isolated from mealybug volatiles (6.7 ng[a])	24.5±5.5 (n=5)	3.0±2.2 (n=5)	<0.001
Compound A (*trans*-(1*R*,3*R*)-chrysanthemyl (*R*)-2-methylbutanoate) (6.7 ng)	47.7±9.4 (n=5)	0.7±0.8 (n=5)	<0.001
Compound B ((*R*)-lavandulyl (*R*)-2-methylbutanoate) (6.7 ng)	10.5±6.8 (n=5)	0.9±1.2 (n=5)	0.03

Mixture of compound A and B (3:1, 6.9 ng:2.3 ng)[c]	19.9±6.9 (n=9)	18.8±5.5 (n=9)	0.72

Controls consisted of filter papers treated with solvent

[a] Amount of the major component, chrysanthemyl methylbutanoate (6.7 ng), together with the minor compound lavandulyl methylbutanoate (2.2 ng)

[b] P value after t-test

[c] The control treatment in this experiment is the single compound A (6.9 ng)

hibiscus mealybug, *Maconellicoccus hirsutus* (Zhang, et al. 2004). After comparison of the lavandulyl 2-methylbutanoate with the unknown on DB-23 column, compound B was confirmed as lavandulyl 2-methylbutanoate.

The absolute configuration of the natural pheromone components was unambiguously determined by comparison of retention times of the natural 2-methylbutanoic acid, lavandulol, and chrysanthemol with synthetic isomers on a chiral Rt-bDEXsm capillary column (Table 1). As shown in the table, the pheromones are composed of esters of (*R*)-2-methylbutanoic acid and (*R*)-lavandulol, and *trans*-(1*R*,3*R*)-chrysanthemol, respectively. The structures of the two compounds, A and B are shown in Fig. 5.

Bioassay of Natural Extract and Synthetic Pheromone The diurnal pattern of production of sex pheromone is shown in Fig. 6. Production was the greatest during the scotophase, peaking at 19:00–24:00. Chong et al. (2003) also observed that the males were active during the scotophase, so bioassays were carried out from 19:00 to 21:00. The results for bioassays of the synthesized materials, the compound from volatiles of female mealybugs, and controls are shown in Table 2. Synthetic *trans*-(1*R*,3*R*)-chrysanthemyl (*R*)-2-methylbutanoate (compound A) was highly attractive. (*R*)-Lavandulyl (*R*)-2-methylbutanoate (compound B) and the mixture of the two compounds (in ratio of 3:1) were also attractive to male mealybugs. There was no significant difference between the attractiveness of A and the mixture of compound A and B (last row of Table 2) indicating no additive or synergistic effects between these two compounds.

Concentration of 10 ng to 1×10^{-5}ng of the synthetic compounds and the natural materials were tested in the dose-response experiment and the results are shown in Tables 3 and 4. Within this dosage range, the effectiveness of the compounds increases as the concentration increases. The attractiveness of the synthetic compounds and the natural materials at the dosage of 10^{-3}ng was compared, and the result shown in Table 5 indicates that the synthetic compounds are as effective as the natural material.

Table 3 Percentage of male mealybugs attracted to various dosages of synthetic materials in Petri dish bioassays

Dosage[a]	Percentage of males attracted to treatment (mean ± S. D.) (n=3)	Percentage of males attracted to control (mean ± S. D.) (n=3)	Difference P value[b]
10 ng	31.6±3.8	0.6±0.4	0.004
1 ng	20.0±5.0	0.7±0.6	0.02
1×10^{-1}ng	13.4±0.4	2.1±1.8	<0.001
1×10^{-2}ng	14.4±0.5	1.3±0.6	<0.001
1×10^{-3}ng	7.5±2.5	1.0±0.2	0.04

Discussion

The structures of the major and minor components isolated from female *P. madeirensis* represent further examples of the irregular terpenoid motif of the sex pheromones of pseudococcid species. For example, the sex pheromone of *Pseudococcus viburni* (Millar et al. 2005) is a monoterpene that incorporates a cyclopentane unit. Sex pheromones of *Pseudococcus cryptus* (Arai et al. 2003) and *P. citri* (Bierl-Leonhardt et al. 1981) are monoterpenes with a cyclobutane moiety. The sex pheromone of *P. ficus* (Hinkens et al. 2001), *P. minor* (Ho et al. 2007), and *P. kraunhiae* (Kuwana) (Sugie et al. 2008) are acyclic monoterpenes with the same basic

carbon skeleton formed from an unusual linkage of two isoprene units. All of the species mentioned above appear to use single components as attractants. It is also interesting to note that the major sex pheromone component we identified here is a monoterpene with a cyclopropane moiety. Chrysanthemol and derivatives have not been found in insects, although they have been isolated from plants (Alexander and Epstein 1975; Gunawardena et al. 2002).

One of the sex pheromone components of pink hibiscus mealybug (PHM), *Maconellicoccus hirsutus*, is (*R*)-lavandulyl (*S*)-2-methylbutanoate (Zhang et al. 2004). Thus, the pheromone components of PHM and Madeira mealybug consist of the same enantiomer of lavandulol, but are esterified with different 2-methylbutanoic acid enantiomers. Zhang et al. (2006) also found that (*R*)-lavandulyl (*R*)-2-methylbutanoate (the compound in the sex pheromone of Madeira mealybug) significantly reduced attraction to (*R*)-lavandulyl (*S*)-2-methylbutanoate (the compound in the sex pheromone of PHM). Because Madeira mealybug produces (*R*)-lavandulyl (*R*)-2-methylbutanoate, it should not cross-attract PHM, thus helping to assure the reproductive isolation of the two species.

The related San Jose scale insect, *Quadraspidiotus perniciosus* (Comstock), produces three components, 7-methyl-3-methylene- 7-octen-1-yl propanoate, (*Z*)-3,7-dimethyl-2,7-octadien-1-yl propanoate, and (*E*)-3,7-dimethyl-2,7- octadien-1-yl propanoate, with each compound being active as a single component, and no apparent synergism in blends of the components (Anderson et al. 1981). However, in the PHM, the two-component blend is needed to attract male PHM.

In summary, we identified two compounds from the aeration extracts of the female Madeira mealybug, *P. madeirensis,* a major pest of economically important crops. Females produce the two components in a 3:1 blend. Compound B is only weakly attractive vs. a blank control, and it does not act additively or synergistically with the major component. Thus, it appears that the active pheromone is a single compound, as in most other mealybugs (except PHM). The importance of the chirality of the components and the role of compound B will be studied further in our laboratory.

Male-Produced Aggregation Pheromones of the Cerambycid Beetles *Xylotrechus colonus* and *Sarosesthes fulminans*

Emerson S. Lacey · Jocelyn G. Millar · Jardel A. Moreira · Lawrence M. Hanks

Received: 20 January 2009 / Revised: 20 March 2009 / Accepted: 4 April 2009 / Published online: 15 May 2009

Abstract Adults of both sexes of the cerambycid beetles *Xylotrechus colonus* (F.) and *Sarosesthes fulminans* (F.) were attracted to odors produced by male conspecifics in olfactometer bioassays. Analyses of headspace volatiles from adults revealed that male *X. colonus* produced a blend of (*R*)- and (*S*)-3-hydroxyhexan-2-one and (2*S*,3*S*)- and (2*R*,3*R*)-2,3-hexanediol, whereas male *S. fulminans* produced (*R*)-3-hydroxyhexan-2-one and (2*S*,3*R*)-2,3-hexanediol. All of these compounds were absent in the headspace of females. Two field bioassays were conducted to confirm the biological activity of the synthesized pheromones: (1) enantiomerically enriched pheromone components were tested singly and in species-specific blends and (2) four-component mixture of racemic 3-hydroxyhexan-2-one plus racemic 2-hydroxyhexan-3-one and the four-component blend of the stereoisomers of 2,3-hexanediols were tested separately and as a combined eight-component blend. In these experiments, adult male and female *X. colonus* were captured in greatest numbers in traps baited with the reconstructed blend of components produced by males, although significant numbers were also captured in traps baited with (*R*)-3-hydroxyhexan-2-one alone or in blends with other compounds. Too few adult *S. fulminans* were captured for a statistical comparison among treatments, but all were caught in traps baited with lures containing (*R*)-3-hydroxyhexan-2-one. In addition to these two species, adults of two other species of cerambycid beetles, for which pheromones had previously been identified, were caught: *Neoclytus a. acuminatus* (F.) and its congener *Neoclytus m. mucronatus* (F.). Cross-attraction of beetles to pheromone blends of other species, and to individual pheromone components that are shared by two or more sympatric species, may facilitate location of larval hosts by species that compete for the same host species.

Introduction

Aggregation or sex pheromones produced by males have been identified for 12 species of longhorned beetles of the subfamily Cerambycinae (Coleoptera: Cerambycidae; Lacey et al. 2004, 2007b; Hanks et al. 2007; Ray et al. 2009a, b, and references therein). Pheromone components of most of these species are typically six to ten carbons long with hydroxyl or carbonyl groups at C_2 and C_3 (Lacey et al. 2004, 2007b; but see Lacey et al. 2008; Hanks et al. 2007; Ray et al. 2009a, b). In addition, minor components that are different from this general structural motif may be important synergists in the pheromone (Fettköther et al. 1995; Reddy et al. 2005; Lacey et al. 2008).

In this article, we describe investigations of the chemical ecology of two sympatric and synchronic cerambycine

species of the tribe Clytini, X*ylotrechus colonus* (F.) and *Sarosesthes fulminans* (F.). Larvae of both species develop in woody tissues of stressed, moribund, and damaged (often wind-thrown) trees of a variety of hardwood species (especially of the genera *Caryae* and *Quercus*; for general biology, see Linsley 1964). Both species are native to eastern North America. Adults are active in spring and summer and are crepuscular, flying from ~16:00 to 22:00 h (ESL, personal observation). Adult male and female *X. colonus* commonly aggregate, in numbers that may exceed 30 individuals per group, on larval hosts. Adult *S. fulminans* may be present on the same larval hosts, but in much smaller numbers (ESL, personal observation). Adult male *X. colonus* and *S. fulminans* have pores on the surface of the prothorax that are characteristic of pheromone production in other species of cerambycines (Ray et al. 2006). Male *X. colonus* sometimes also display a characteristic posture that has been associated with pheromone release in other cerambycine species (the "push-up stance"; Lacey et al. 2007a).

We tested the hypotheses that male *X. colonus* and *S. fulminans* produce aggregation pheromones that conform to the structural motif of other cerambycines and that complete blends of synthetic pheromone components are more attractive to beetles than individual components. We also tested the responses of both species to traps baited with blends of all regio- and stereoisomers of the main pheromone components. These blends are more economical to synthesize than enantiomerically enriched pheromone components and have proven effective as attractants for other cerambycine species (Hanks et al. 2007).

Methods and Materials

Source of Insects Adult *X. colonus* and *S. fulminans* were collected by hand on 6 June 2004 from a wind-thrown white oak, *Quercus alba* L., at Allerton Park (Piatt Co., IL, USA), a 600-ha mixed hardwood forest owned by the University of Illinois. Adults were housed individually in the laboratory (12:12 h L:D, ~20°C, ~50% RH) in cylindrical cages, constructed of aluminum window screen, with plastic Petri dishes at top and bottom, and provided with 10% sucrose in water. Beetles used in bioassays were active and apparently healthy.

Olfactometer Bioassays We tested for volatile attractants in both species by using a horizontal glass Y-tube olfactometer (6 cm diameter, main tube 26 cm long, arm length 22 cm, and 70° angle between arms). We conducted olfactometer studies outdoors in partial shade because all cerambycine species that we have bioassayed to date did not respond in Y-tube olfactometer bioassays conducted under laboratory conditions (see Lacey et al. 2004, 2007b, 2008). A 2-L plastic chamber, containing a cylinder of aluminum screen for a perch, was attached to each arm of the Y-tube. When bioassaying *X. colonus*, one chamber held six males and the other held six females. Only three *S. fulminans* of each sex were used as odor sources in their respective bioassay, because this species was less abundant. Ambient air was pulled through the olfactometer (air speed 2.5 m s^{-1}) with a 0.75 kW vacuum cleaner connected to a variable voltage power supply. For each trial, a beetle was released at the base of the Y-tube and allowed 10 min to respond (crossing a line 18 cm down one arm) to an odor source. Chambers were alternated between Y-tube arms every three trials to control for positional bias. The chambers and olfactometer were washed with unscented laboratory detergent (Alconox® powder, Alconox, Inc., NY, USA) and rinsed with acetone each day. We bioassayed 20 *X. colonus* of each sex between 17:00–20:00 h on 9, 10, and 13 June 2004 and 13 female and seven male *S. fulminans* during the same hours on 11 and 12 June 2004 (skies clear, air temperatures ~24–30°C). For each species, numbers of each sex responding to treatments were compared with the χ^2 goodness-of-fit test corrected for continuity (Sokal and Rohlf 1995).

Identification of Pheromone Components Volatile compounds produced by adult *X. colonus* and *S. fulminans* were collected by placing five adult females and males in separate glass vacuum traps (0.3 L, manufactured by the glass shop, School of Chemical Sciences, UIUC) that were lined with aluminum screen to provide perches. A glass tube (6 cm long×9.5 o.d.×4 mm i.d.) containing 100 mg of 80/100 mesh SuperQ® (Alltech Associates, Deerfield, IL, USA) was attached to one nipple of each chamber with an 8-cm long section of Teflon® tubing. Charcoal-purified air was pulled through the apparatus with a water aspirator (1 L min^{-1}). Males and females of each species were aerated simultaneously on a laboratory windowsill from 16:00 to 22:00 h: *X. colonus* on 11, 12, and 13 June and *S. fulminans* on 14, 15, and 16 June 2004. We selected these time periods for collecting volatiles from beetles because they corresponded to activity periods in the field (ESL, personal observation). Collectors were eluted into silanized glass vials (Cat. #27114, Supelco®, Bellefonte, PA, USA) with three 0.5-ml aliquots of methylene chloride. The resulting extracts were analyzed with a Hewlett-Packard® (Sunnyvale, CA, USA) 6890 gas chromatograph (GC) coupled to a 5973 mass selective detector (MS). The GC was fitted with a DB5-MS column (30 m×0.25 mm, 25 µm film thickness; Agilent Technologies, Santa Clara, CA, USA) and programmed from 40°C (held for 1 min) to 250°C at 10°C min^{-1} (held for 15 min), with an injector temperature of 250°C. Injections were made in the splitless mode. When it became clear that one or more of the

compounds in the extract might be thermally unstable (see Leal et al. 1995; Lacey et al. 2007b), the injector temperature was lowered to 100°C, and the temperature program was changed to 20°C (held for 2 min) to 250°C at 10°C min^{-1} (held for 15 min). Absolute configurations of the insect-produced compounds were determined by analysis of aliquots on a Cyclodex-B GC column (30 m× 0.25 mm, 0.25 micron film thickness, J&W Scientific, Folsom CA, USA) with the GC programmed from 50°C (held for 1 min) to 200°C at 5°C min^{-1}, injector 100°C, detector 200°C. Identifications of peaks were confirmed by coinjections of extracts with authentic standards.

Field Bioassays of Synthetic Pheromone In Experiment 1, bioassays of reconstructed blends of male-specific volatiles for each of the two species, as well as of the individual components, were conducted on 9 days between 11 June and 27 July 2006 and 5 days between 29 May and 14 June 2007. Bioassays were carried out at Allerton Park and Brownfield Woods (Champaign Co., IL; skies clear to partly cloudy, maximum air temperatures ~22–30°C, wind speed ~8–20 kph), the latter a 26-ha mixed deciduous forest owned by the University of Illinois. We used two different sites because we observed that trap catches of cerambycine species at individual sites decline over time, possibly because trapping depletes local populations (ESL, unpublished data). Both of the sites had populations of *X. colonus* and *S. fulminans* (ESL, personal observation) and replications of the experiment were assigned randomly to sites.

Traps were black cross-vane flight intercept panel traps (1.2 m tall×0.30 m wide, Intercept™, model PT, APTIV, Inc., Portland, OR, USA). Traps were suspended from hangers constructed of 1.27 cm i.d. PVC pipe (D1785, Schedule 40, Charlotte Pipe and Foundry Co., Charlotte, NC, USA), with a 1.5 m long upright connected with a T fitting to a 20-cm long arm with a loop of wire at the end to which the trap was attached. The upright was mounted on a 1.5 m section of 1.27 cm diameter steel reinforcing bar driven into the ground. Traps were positioned 10 m apart in a straight line approximately perpendicular to the prevailing wind direction. Traps were set up at ~14:00 h and beetles were removed from traps at ~11:00 h the following day.

Enantiomerically enriched hydroxyhexanones (94% ee; Lacey et al. 2007a, b) and hexanediols (>98% stereoisomerically pure, Lacey et al. 2008) were synthesized as previously described. Each treatment was dissolved in 1 ml of absolute ethanol. We randomly assigned each of the following nine treatments to traps: (1) *X. colonus* blend (see "Results"): (*R*)-3-hydroxyhexan-2-one (8 mg), (*S*)-3-hydroxyhexan-2-one (1.25 mg), (2*R*,3*R*)-2,3-hexanediol (2.5 mg), and (2*S*,3*S*)-2,3-hexanediol (0.5 mg); (2) *S. fulminans* blend (see "Results"): (*R*)-3-hydroxyhexan-2-one (8 mg) and (2*S*,3*R*)-2,3-hexanediol (1.25 mg); (3) (*R*)-3-hydroxyhexan-2-one (8 mg); (4) (*S*)-3-hydroxyhexan-2-one (8 mg); (5) (2*S*,3*S*)-2,3-hexanediol (8 mg); (6) (2*R*,3*R*)-2,3-hexanediol (8 mg); (7) (2*S*,3*R*)-2,3-hexanediol (8 mg); (8) ethanol control (1 ml); and (9) blank control (empty emitter).

Pheromones were loaded into release devices that consisted of modified 1.5-ml microcentrifuge tubes (#05-406-16; Fisher Scientific, Pittsburg, PA, USA). A section of polyethylene tubing (25 mm long, 4 mm o.d., 2 mm i.d.) was inserted through a 4 mm hole drilled through the tube cap and cemented in place with quick setting epoxy glue such that 8 mm of tubing extended beyond the cap. A 5-cm long section of pipe cleaner (cotton fiber and steel wire, 2.5 mm diameter) was inserted through the tubing such that one end reached the bottom of the microcentrifuge tube and the other end extended 5 mm beyond the end of the polyethylene tubing (modified from Hanks et al. 2007). Ethanol is an efficient carrier of hydroxyhexanones and hexanediols (Hanks et al. 2007) and the lures released ~1 ml of ethanol solution over the course of 1 day under field conditions (unpublished data). Lures were hung with wire in the open central slot of panel traps.

Differences among treatments in numbers of beetles captured (sexes combined) were tested with the nonparametric Friedman's test (blocked by site and day; PROC FREQ with CMH option, SAS Institute, 2001) because assumptions of analysis of variance were violated by heteroscedasticity (Sokal and Rohlf 1995). Differences between pairs of means were tested with the REGWQ means-separation test to control maximum experiment-wise error rates (SAS Institute, 2001). Replications that captured fewer than two beetles overall (N=9) were excluded from the statistical analyses for a given species. Differences between numbers of females and males captured within treatments were tested with the χ^2 goodness-of-fit test (Sokal and Rohlf 1995).

We conducted a further trial ('Experiment 2') to test the responses of *X. colonus* and *S. fulminans* to blends of stereoisomers of the chemicals to determine whether unnatural regio- and/or stereoisomers had an inhibitory effect. This bioassay was conducted on 25 days between 13 June–31 August 2006 and 18 days between 5 May–15 August 2007 at Allerton Park and Brownfield Woods using the methods described above. Treatments were as follows (compounds synthesized as described in Hanks et al. (2007) and diluted to 1 ml with absolute ethanol): (1) ~1:1:1:1 blend of enantiomers of 3-hydroxyhexan-2-one and 2-hydroxyhexan-3-one (100 mg total load, 25 mg of each isomer; henceforward referred to as "generic hydroxyhexanones"); (2) ~1:1:1:1 blend of all four stereoisomers of 2,3-hexanediol (100 mg total load, 25 mg of each isomer; henceforward "generic hexanediols"); (3) 1:1 combination

of generic hydroxyhexanones and generic hexanediols (200 mg total load); (4) ethanol control (1 ml); and (5) blank control (empty emitter).

The mixtures were loaded into lures and differences among treatments in numbers of beetles captured per species were tested as in the previous bioassay. Replications that captured fewer than two beetles of a given species were excluded from statistical analysis (N=28). On days when enantiomerically enriched pheromones and generic pheromones were bioassayed simultaneously, trap lines were separated by >1 km.

Results

Olfactometer Bioassays In olfactometer bioassays, 17 female *X. colonus* were attracted to odors emitted by live males, compared to only two that responded to odors of live females (χ^2=11.8, P< 0.001). Male *X. colonus* showed a similar response, with 16 responding to odors of live males compared to only one responding to odors from live females (χ^2=13.2; P< 0.001). Both sexes of *S. fulminans* were attracted to odors produced by male conspecifics, with 12 females responding to males and only one responding to females (χ^2=9.31; P< 0.01) and all seven males responding to males (χ^2=7.00; P< 0.05). These findings confirmed that males of both species produce volatile pheromones that attract both sexes.

Identification of Pheromone Components GC-MS analyses of volatiles collected from male *X. colonus* revealed two major peaks in the total ion chromatogram that were absent in the analogous headspace of females. The retention time and mass spectrum of the larger peak (base peak at *m/z* 55, other significant fragments at *m/z* 43 [78%], 73 [53%], and 45 [26%]) matched those of a synthetic standard of 3-hydroxyhexan-2-one. The retention time and mass spectrum of the smaller peak (base peak at *m/z* 55, other significant fragments at *m/z* 75 [10%], 73 [61%], 72 [34%], 45 [26%], and 43 [35%]) matched those of a synthetic standard of 2,3-hexanediol. The stereoisomeric compositions of the insect-produced compounds were determined to be ~70% (*R*)- and 10% (*S*)-3-hydroxyhexan-2-one and 17% (2*S*,3*S*)- and 3% (2*R*,3*R*)-2,3-hexanediol by analysis on the Cyclodex-B column, with the enantiomers being resolved to baseline (for elution order of all hydroxyketones and 2,3-hexanediols, see Ray et al. 2009b). Analogous collection and analysis of headspace volatiles from both sexes of *S. fulminans* revealed that males produced ~83% (*R*)-3-hydroxyhexan-2-one and 17% (2*S*,3*R*)-2,3-hexanediol as the only detectable male-specific components (identified as described above).

Field Bioassays of Synthetic Pheromone In Experiment 1, testing chiral synthetic pheromone components, traps captured 79 adult *X. colonus* of both sexes, but only ten adult *S. fulminans* (Table 1). Treatments differed significantly in numbers of *X. colonus* captured (Fig. 1; Friedman's $Q_{8,79}$=52.3, P<0.001). Only traps baited with (*R*)-3-hydroxyhexan-2-one alone or in a blend (i.e., the *X. colonus* and *S. fulminans* blends) were significantly attractive compared to ethanol and blank controls (Fig. 1). The blend

Table 1 Results of experiment 1

	Xylotrechus colonus		*Sarosesthes fulminans*		*Neoclytus a. acuminatus*	
Treatment	♀	♂	♀	♂	♀	♂

(9) Blank control						
Total	46	33	7	3	27	18

Numbers of cerambycid beetles of three species caught in traps baited with enantiomerically enriched candidate pheromone components (N=9 replicates for *Xylotrechus colonus* and *Sarosesthes fulminans*; N=10 replicates for *N. a. acuminatus*). The blend of components specific to *X. colonus* contained (*R*)- and (*S*)-3-hydroxyhexan-2-one and (2*R*,3*R*)- and (2*S*,3*S*)-2,3-hexanediol. The *S. fulminans* blend contained (*R*)-3-hydroxyhexan-2-one and (2*S*,3*R*)-2,3-hexanediol. Treatment numbers correspond to treatments in Fig. 1. Sex ratio of total numbers within species were not significantly different from 1:1 (χ^2, P>0.05).

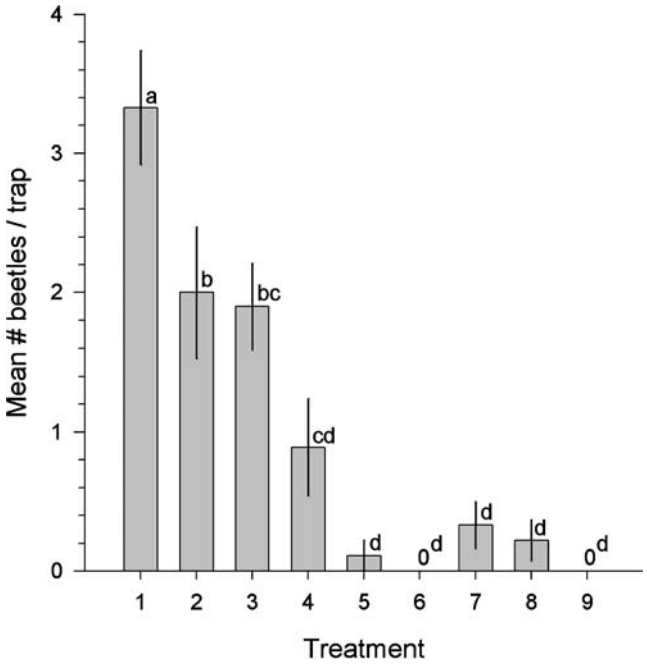

Fig. 1 Mean (±SE) numbers of adult *Xylotrechus colonus* (N=9 trials) captured per trap (sexes combined) with respect to composition of the lure (N=9 trials). The blend of components specific for *X. colonus* contained (*R*)- and (*S*)-3-hydroxyhexan-2-one with (2*R*,3*R*)- and (2*S*,3*S*)-2,3-hexanediol, the *Sarosesthes fulminans* blend contained (*R*)-3-hydroxyhexan-2-one and (2*S*,3*R*)-2,3-hexanediol. Treatment numbers correspond to treatments in Table 1: (*1*) *X. colonus* blend, (*2*) *S. fulminans* blend, (*3*) (*R*)-3-hydroxyhexan-2-one, (*4*) (*S*)-3-hydroxyhexan-2-one, (*5*) (2*R*,3*R*)-2,3-hexanediol, (*6*) (2*S*,3*R*)-2,3-hexanediol, (*7*) (2*S*,3*S*)-2,3-hexanediol, (*8*) ethanol control, and (*9*) blank control. Means with different letters are significantly different (REGWQ test; P<0.05)

of pheromone components specific for *X. colonus* captured the greatest number of beetles (Fig. 1). Too few adult *S. fulminans* were captured for statistical analysis of treatments; however, all ten beetles were captured with lures that contained the most abundant component of its volatile collection, (*R*)-3-hydroxyhexan-2-one (Table 1).

During Experiment 1, we also trapped adults of another cerambycine species, *Neoclytus acuminatus acuminatus* (F.) (Table 1), the male-produced pheromone of which is composed solely of (2*S*,3*S*)-2,3-hexanediol (Lacey et al. 2004). Treatments differed in numbers of *N. a. acuminatus* captured (Friedman's $Q_{8,45}$=64.2, P<0.001, ten replicates), with only traps baited with (2*S*,3*S*)-2,3-hexanediol catching significantly more beetles (3.60±0.54, sexes combined) than ethanol and blank controls (means=0 for both).

In Experiment 2, testing the generic blends of pheromone stereoisomers, we captured 111 adult *X. colonus* of both sexes (Table 2) but only eight *S. fulminans*. Treatments again differed in numbers of adult *X. colonus* captured (Fig. 2, top; Friedman's $Q_{4,111}$=70.98, P<0.001), with significantly greater numbers in traps baited with generic hydroxyketones, alone or in combination with generic hexanediols, than in solvent or blank controls. No adult *X. colonus* were captured in traps baited with only the generic hexanediols. Again, too few adult *S. fulminans* were captured for statistical analysis, although all were captured in traps with lures that contained generic hydroxyketones (Table 2).

In Experiment 2, traps baited with generic pheromone lures also captured 121 adult *N. a. acuminatus* of both sexes, as well as 50 adult males and females of a congener, *Neoclytus m. mucronatus* (F.) (Table 2). The male-produced pheromone of *N. m. mucronatus* is composed of only (*R*)-3-hydroxyhexan-2-one (Lacey et al. 2007b). Treatments differed in numbers of *N. a. acuminatus* and *N. m. mucronatus* captured (Fig. 2; Friedman's $Q_{4,121}$=89.3, P< 0.001; $Q_{4,50}$=36.3 P<0.001, respectively). Significantly more *N. a. acuminatus* were captured in traps baited with generic hexanediols, alone or in combination with hydrox-

(5) Blank control								
Total	54	57	5	3	49	72	31	19*

Numbers of cerambycid beetles of four species caught in traps baited with generic pheromone blends (N=31, 28, 28, and 18 replicates for *Xylotrechus colonus*, *Sarosesthes fulminans*, *N. a. acuminatus*, and *N. m. mucronatus*, respectively). The blend of hydroxyhexanones contained equal amounts of (*R*)- and (*S*)-3-hydroxyhexan-2-one and (*R*)- and (*S*)-2-hydroxyhexan-3-one, and the blend of hexanediols contained approximately equal amounts of (2*R*,3*R*)- (2*S*,3*S*)- (2*R*,3*S*)- and (2*S*,3*R*)-2,3-hexanediol. The treatment designated 'Ketones + Diols' contained equal amounts of the blends of hydroxyhexanones and hexanediols. Treatments are numbered to correspond to treatments in Fig. 2.

*P<0.05 (χ^2) next to total number of males indicates sex ratio of beetles captured within species that is significantly different from 1:1

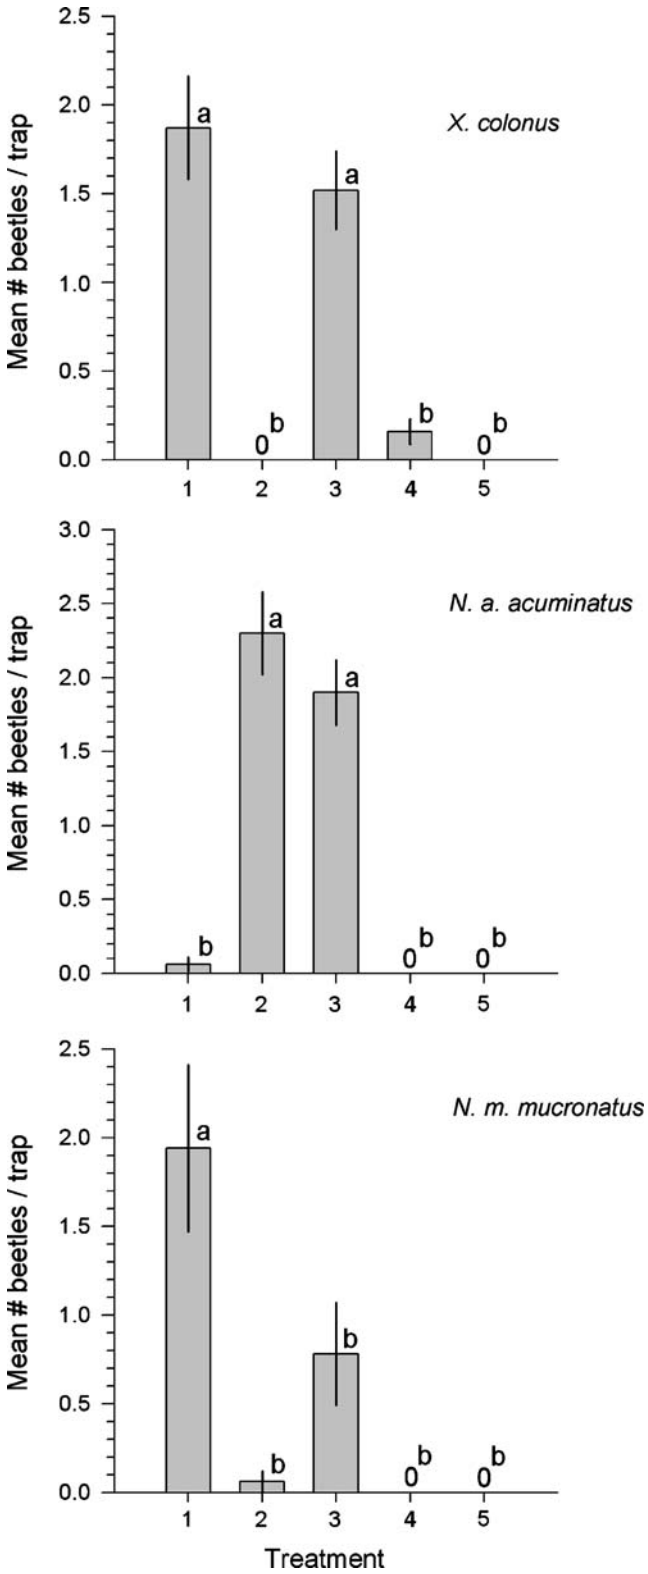

Fig. 2 Mean (±SE) numbers of adults (sexes combined) of three species of cerambycid beetles captured with respect to composition of the lure: *top*, *Xylotrechus colonus* (*N*=31 trials); *middle*, *Neoclytus a. acuminatus* (*N*=28 trials); and *bottom*, *Neoclytus m. mucronatus* (*N*=18 trials). Treatment numbers correspond to treatments in Table 2: (*1*) generic hydroxyhexanones; (*2*) generic hexanediols; (*3*) 1:1 mixture of generic hydroxyhexanones and hexanediols; (*4*) ethanol control; and (*5*) blank control. Means with different letters are significantly different (REGWQ test; $P<0.05$)

yhexanones (Fig. 2, middle), than in control traps or traps baited with generic hydroxyketones. Conversely, adult *N. m. mucronatus* were only significantly caught in traps baited with generic hydroxyhexanones (Fig. 2, bottom).

In both field bioassays, traps baited with the synthetic pheromone components also captured small numbers (total catch <8 individuals) of an additional 11 species of cerambycids, including seven species in the subfamily Cerambycinae (*Anelaphus pumilus* [Newman], *Cyrtophorus verrucosus* [Olivier], *Knulliana cincta* [Drury], *Neoclytus caprea* [Say], *Neoclytus scutellaris* [Olivier], *Phymatodes amoenus* [Say], *Xylotrechus convergens* LeConte), three species of the subfamily Lamiinae (*Liopinus alpha* [Say], *Psenocerus supernotatus* [Say], and *Urographis fasciatus* [Degeer]), and one species of subfamily Parandrinae (*Neandra brunnea* [F.]). Traps captured few insects other than the species reported here.

Discussion

Attraction of both sexes of *X. colonus* and *S. fulminans* to odors from conspecific males in olfactometer bioassays provided the first evidence that males of both species produce aggregation pheromones. Traps baited with synthetic pheromone captured similar numbers of male and female *X. colonus*, confirming that males produce an aggregation pheromone (Tables 1 and 2). The small number of *S. fulminans* captured is consistent with its scarcity in the habitats where we conducted our bioassays (ESL, personal observation). The structure of the pheromone components of *X. colonus* and the putative pheromone compounds of *S. fulminans* are consistent with the ketone/diol structural motif of other cerambycine species (see "Introduction") and provide further support for the hypothesis that this structural motif has been conserved within the Cerambycinae (see Lacey et al. 2004, Hanks et al. 2007). Nevertheless, recent studies have shown that some cerambycine species have pheromone components of entirely different chemical classes (Hanks et al. 2007; Lacey et al. 2008; Ray et al. 2009a). Our study also provides further evidence that the presence of gland pores on the prothorax of males (in *X. colonus*, *S. fulminans*, *N. a. acuminatus*, and *N. m. mucronatus*; Ray et al. 2006, Lacey et al. 2007b) and calling behavior of males (in *X. colonus*, *N. a. acuminatus*, and *N. m. mucronatus*; Lacey et al. 2007a, b) reliably indicate that volatile pheromones play a role in mate location in cerambycine species.

In both field experiments, all treatments that contained (*R*)-3-hydroxyhexan-2-one attracted significant numbers of adult *X. colonus* (Figs. 1 and 2 (top)). However, *X. colonus* were caught in greatest numbers in traps baited with its species-specific blend (Fig. 1), suggesting that the full blend is necessary for optimal attraction. In the absence of (*R*)-3-hydroxyhexan-2-one, adult *X. colonus* responded weakly, or did not respond (Fig. 1) to the minor components of the blend produced by males [including (*S*)-3-hydroxyhexan-2-one and (2*R*,3*R*)- and (2*S*,3*S*)-2,3-hexanediols]. Unnatural isomers apparently did not inhibit attraction of *X. colonus* to (*R*)-3-hydroxyhexan-2-one, as evidenced by the significant number of beetles captured in traps baited with the *S. fulminans* lure or the generic hydroxyketones (Figs. 1 and 2 (top)). Attraction of adult males and females of a congener, *Xylotrechus nauticus* (Mannerheim), to synthetic pheromones also is not inhibited by unnatural isomers (Hanks et al. 2007).

(*R*)-3-Hydroxyhexan-2-one now has been shown to be an important component of male-produced pheromones of 14 species of cerambycine beetles (including *X. colonus* and possibly *S. fulminans*; see Hanks et al. 2007). Overlap in pheromone composition among sympatric cerambycine species can result in cross-attraction (Hanks et al. 2007). Cross-attraction was evident in the present study, with both sexes of *X. colonus* caught in traps baited with treatments representative of reconstructed blends of the pheromone produced by *S. fulminans* (Fig. 1), as well as the other species caught in traps baited with compounds identified in the two focal species of this study. *X. colonus*, *S. fulminans*, *N. a. acuminatus*, and *N. m. mucronatus* are sympatric, overlap in phenology, and share larval hosts (Linsley 1964). In fact, adults of all four species may aggregate on the same downed host tree (ESL, personal observation) and adult *X. colonus* and *N. m. mucronatus*, at least, are attracted to odors emanating from dying hosts (Ginzel and Hanks 2005). Larvae of all four species require hosts that are severely weakened or moribund (Linsley 1964) and competition for these resources (with other insect species and saprophytes), results in rapid degradation of hosts (Hanks 1999). Species that rely on such ephemeral hosts may be under selective pressure to locate hosts quickly and oviposit (Hanks 1999). Thus, these species may exploit the pheromones of other species in their feeding guild as kairomones. Closely related species of bark beetles (Curculionidae: Scolytinae), as well as closely related species of sap beetles (Nitidulidae), share pheromone components, respectively, resulting in cross-attraction among species (e.g., Zilkowski and Bartelt 1999; Haberkern and Raffa 2003). Perhaps not coincidentally, males of these bark and sap beetle species also produce aggregation pheromones (Zilkowski and Bartelt 1999; Haberkern and Raffa 2003) such as those produced by male cerambycine beetles.

The responses of beetles of three species, *X. colonus*, *N. a. acuminatus*, and *N. m. mucronatus*, to generic lures (Table 2, Fig. 2) again demonstrates that these blends could be used to collect live specimens of various cerambycine species, for analysis and identification of the pheromone blends that they actually produce. In this context, even weak attraction to generic blends may be sufficient for collecting adults for pheromone identification or even monitoring the distribution and phenology of economically important species of interest for which a pheromone has yet to be identified.

Natural Ligands of Porcine Olfactory Binding Proteins

Chrystelle Le Danvic · Gaelle Guiraudie-Capraz · Djamel Abderrahmani · Jean-Pierre Zanetta · Patricia Nagnan-Le Meillour

Received: 20 February 2009 / Revised: 8 May 2009 / Accepted: 15 May 2009 / Published online: 22 May 2009

Abstract Knowledge of endogenous ligands of olfactory binding proteins is a prerequisite for studying their role in odor and pheromone transduction. Here, we report the extraction, derivatization, and characterization by gas chromatography-mass spectrometry of the natural ligands of pig, *Sus scrofa* (L.), Von Ebner's Gland protein (VEG) and odorant binding protein (OBP). We identified two isoforms (VEG1 and VEG2), which differed only by the linkage of an *O*-N-acetylglucosamine (*O*-GlcNac) group on VEG1. The natural ligands of VEG1 were characterized as two isomers of testosterone, whereas ligands of VEG2 and OBP were fatty acids or their derivatives. Our findings suggest that the binding specificity of VEG1 for steroids is governed by the presence of an *O*-GlcNac moiety on the protein. This specificity was confirmed by the binding of radiolabeled testosterone only by VEG1 in an in-gel binding assay. This is the first evidence for a post-translational modification in the process of odorant discrimination by olfactory binding proteins.

Introduction

Olfactory binding proteins are small soluble proteins secreted in a variety of tissues and organs related to chemical communication (Tegoni et al. 2000). They are probably an adaptation to terrestrial life, as members of this protein group seem to be absent in fish, but widespread in insects, mammals, and reptiles. Their physiological role depends on their localization: 1) binding and transport of odors and pheromones in most tissues and fluids, as odorant binding proteins (OBP) of saliva (Marchese et al. 1998) and amniotic fluid (Guiraudie-Capraz et al. 2005), hamster aphrodisin (Singer et al. 1986), or tear lipocalin in mammals (Garibotti et al. 1995; Redl 2000), and 2) odor and pheromone transduction in olfactory organs, as pheromone-binding proteins (PBP) in insects (Xu et al. 2005). This latter physiological role is better understood in insects than in mammals, where the involvement of olfactory binding proteins in odor discrimination remains to be elucidated. Binding to specific ligands has only been demonstrated for the sub-class of pheromone-binding proteins such as Major Urinary Proteins (MUP) of rodents (Robertson et al. 1993), salivary lipocalin (SAL) in the pig, *Sus scrofa* (L.) (Marchese et al. 1998; Scaloni et al. 2001) and aphrodisin in hamsters (Briand et al. 2004). In these species, the identification of the natural endogenous ligands of these proteins was a prerequisite for studying their binding properties and understanding their physiological role.

Porcine olfactory binding proteins have been studied extensively because one of the first mammalian OBP was identified in this species (Dal Monte et al. 1991; Paolini et al. 1998). Besides porcine OBP (pOBP), two other proteins [SAL and Von Ebner's Gland protein (VEG)] were identified and characterized from nasal tissue (Scaloni et al. 2001) and the vomeronasal organ (VNO) (Guiraudie et al. 2003). The natural ligands of SAL were identified as androstenol and androstenone, the two components of the boar sex pheromone (Marchese et al. 1998; Loebel et al. 2000). pOBP extracted from nasal tissue does not bear a ligand (Paolini et al. 1998), contrary to the bovine OBP, which contains 1-octen-3-ol as its natural ligand (Ramoni et al. 2001). Finally, attempts to identify the natural ligand of porcine VEG were unsuccessful (Garibotti et al. 1995; Burova et al. 2000; Scaloni et al. 2001). The human counterpart of porcine VEG, the tear lipocalin, was found to contain fatty acids, cholesterol, triacylglycerol, and fatty alcohols (Glasgow et al. 1995), which were not bound or were only weakly bound by porcine VEG in binding assays (Scaloni et al. 2001).

In a previous study, we used an in-gel binding assay to examine the partitioning of several ligands (fatty acids and steroids) among olfactory binding proteins (OBP, SAL, and VEG) of the respiratory mucosa and the VNO of the pig (Guiraudie et al. 2003). In both tissues, two isoforms of VEG displayed different affinities for the ligands: the slower migrating form (VEG1) bound the steroid progesterone but not fatty acids, whereas the faster migrating form (VEG2) only bound fatty acids. We hypothesized that the natural VEG1 ligand could be a steroid. Here, we report the extraction, derivatization, and characterization by gas chromatography coupled to mass spectrometry (GC-MS) of the natural ligands of porcine VEG1, VEG2, and OBP.

Methods and Materials

Protein Extraction from Biological Samples Animals (Large White pre-pubertal male pigs) were slaughtered in agreement with UE directives about animal welfare. VNO were dissected immediately after death and stored at −80°C (Guiraudie et al. 2003). Native proteins were extracted from 10 mg of VNO by adding 800 µl of a 2:1 solution of chloroform/methanol (v:v) to the tissue in Eppendorf tubes on ice. After a brief vortex homogenization, samples were centrifuged at 13,000×*g* for 10 min at 4°C, to separate the different phases. As the tissues contained water, three phases were obtained: the upper chloroform phase (containing lipids), the water interface containing the tissue, and the methanol phase containing proteins. The methanol phase was dried under vacuum (Speed-Vac, Eppendorf, Le Pecq, France) and stored at −20°C until use.

Binding Assay with Radiolabeled Analogs of Steroids The principle of the in-gel binding assay and its protocol have been fully described (Guiraudie et al. 2003). Tritiated testosterone (17-β-hydroxy-4-androsten-3-one, (1,2,6,7-^{3}H[N])) and progesterone (4-pregen-3,20-dione; (1,2,6,7-^{3}H[N])) were from Sigma-Aldrich (La Verpillière, France) and had a specific activity of 3.7 TBq/mmol and 3.4 TBq/mmol, respectively. An aliquot of VNO extract in sample buffer (identical to Fig. 1) was incubated for 30 min on ice with an ethanolic solution of either tritiated testosterone or tritiated progesterone (5 µl, 3×10^{7} Bq), before analysis by electrophoresis, blotting, and fluorography (Guiraudie et al. 2003).

Identification of the Binding Proteins by In-Gel Digest, Peptide Extraction, and Matrix Assisted Laser Desorption Ionization-Time of Flight Mass Spectrometry (MALDI-TOF MS) Analysis An aliquot of each biological sample used for ligand extraction was loaded onto a 0.75 mm thick gel, and electrophoresis was run in non-denaturing conditions to check the identity of proteins by peptide mapping (Nagnan-Le Meillour et al. 2009). Peptides resulting from the trypsin digestion were extracted by adding 30 µl of a 0.1% trifluoroacetic acid (TFA) solution in 50% acetonitrile. A solution of α-cyano-4-hydroxycinnamic acid (Sigma-Aldrich) at a concentration of 10 mg/ml in 0.1% 2:1 acetonitrile/TFA (v:v) was used as matrix. The peptides were analyzed on a Voyager DE Pro MALDI-TOF mass spectrometer (Applied Biosystem, Courtaboeuf, France), in positive linear mode. An external calibration of peptides covering the 1,000–4,000 mass range was performed for each measurement. Protein identification was achieved by comparison of measured peptide masses with the theoretical OBP (GenBank accession number NP_998961) and VEG (S77587) peptide maps (http://expasy.org/tools/peptide-mass.html). The SAL was

not included in this study as its endogenous ligands are known.

Extraction of Endogenous Ligands and Derivatization Protein extracts were submitted to electrophoresis in non-denaturing conditions as previously described (Guiraudie et al. 2003). Gels (1.5 mm thickness) were stained with colloidal Coomassie blue (Guiraudie et al. 2003) until the bands just appeared. Placing the gels in water stopped staining, and the band slices were cut immediately with a razor blade and put into an Eppendorf tube. As a control, portions of the gel corresponding to the sample buffer without proteins also were dissected. Band slices were loaded with 500 µl of 2:1 chloroform/methanol (v:v) and ground by using a conical pestle at room temperature. After a brief centrifugation (13,000×*g* for 5 min at room temperature), the supernatant was recovered and dried at room temperature in a rotary evaporator. At room temperature and under harsh extraction, the proteins were denatured, and they liberated their ligands. The remaining water was eliminated in the same conditions as an acetonitrile/water azeotrope obtained after addition of 500 µl acetonitrile dried previously on calcinated calcium chloride (Zanetta et al. 1999).

The dry residue was taken up in 200 µl of dried acetonitrile, and 50 µl of heptafluorobutyric anhydride (HFBAA) (Fluka, Sigma-Aldrich) were added. The samples were submitted to a flash acetylation for 1 min in a sand bath at 150°C. Before GC/MS analyses, individual samples were dried under a stream of nitrogen and supplemented with 100 µl of dried acetonitrile. In order to verify the nature of the fatty ligands, after GC-MS analyses, the samples were evaporated under a stream of nitrogen, then

supplemented with 200 µl anhydrous methanol and 200 µl of a diazomethane solution in diethyl ether. The samples were left for 1 h at room temperature, dried under a stream of nitrogen, taken up in dried acetonitrile, and analyzed by GC-MS under the same conditions.

Identification of the Ligands by Gas chromatography Coupled to Mass Spectrometry (GC-MS) Ligands were separated by using a Carlo Erba GC 8000 gas chromatograph equipped with a 25 m×0.32 mm CP-Sil5 CB Low bleed/MS capillary column, 0.25 µm film phase (Chrompack, Les Ulis, France). The temperature of the Ross injector was 260°C, and the samples were analyzed with the following temperature program: 90°C for 3 min, then 5°C/min until 260°C, followed by 20 min at 260°C. The column was coupled to a Finnigan Automass II mass spectrometer (mass detection limit 1000). Analyses were performed routinely in the electron impact (EI) mode (ionization energy 70 eV; source temperature 150°C). In order to preserve the filament of the ionization source, GC/MS records were performed 5 min after the injection of the sample. The EI mode of MS analysis was chosen because it provided fundamental information on the structure of the compound(s) and allowed a general representative total ion current (TIC) response for the different kinds of compounds. Data were recovered between 45 and 1000 *amu.* Integrations of the peaks were performed on the TIC chromatogram with Xcalibur software (Thermo Fisher Scientific, Courtaboeuf, France). The standard compounds (testosterone, fatty acids) were from Sigma-Aldrich.

Characterization of the O-N-acetylglucosamine Moiety The YinOYang server at www.cbs.dtu.dk/services/YinOYang/ (*via* www.expasy.org) was used to predict potential sites of *O*-N-acetylglucosamine (*O*-GlcNac) modification. The presence of *O*-GlcNac was investigated experimentally by using beta-elimination. This reaction occurs when *O*-GlcNac beta-linked serine and threonine residues of proteins are exposed to strongly alkaline conditions (Oda et al. 2001). For beta-

elimination, proteins were separated by native-PAGE as described above, then electroblotted onto PVDF membrane (Immobilon P, Millipore, Saint-Quentin-en-Yvelines, France) as described in Guiraudie et al. (2003). The two bands containing the VEG isoforms were cut with a razor blade and placed immediately (to avoid drying) in a solution of 0.5 M $NaBH_4$, 0.1 M NaOH for 18 h at 45°C. The reaction was stopped by the dropwise addition of acetic acid on ice. After evaporation under nitrogen, methanol was added, then evaporated again to eliminate the methylborates (repeated x 3). The dry sample was resuspended in 1 ml acetic anhydride for 4 h at 100°C to peracetylate the alditols that resulted from the beta-elimination. The peracetylated alditols were extracted with chloroform and analyzed by GC-MS by using a BPX70 capillary column (30 m×0.32 mm) coupled to a Finnigan Automass II mass spectrometer (Thermo Fisher Scientific). The temperature program was from 150°C to 230°C at 3°C/min, then 230°C to 250°C at 5°C/min.

Results

Characterization of Binding Proteins An aliquot of each of the VNO extracts used for ligand identification was loaded onto a 0.75 mm-thick gel in parallel for peptide mapping to

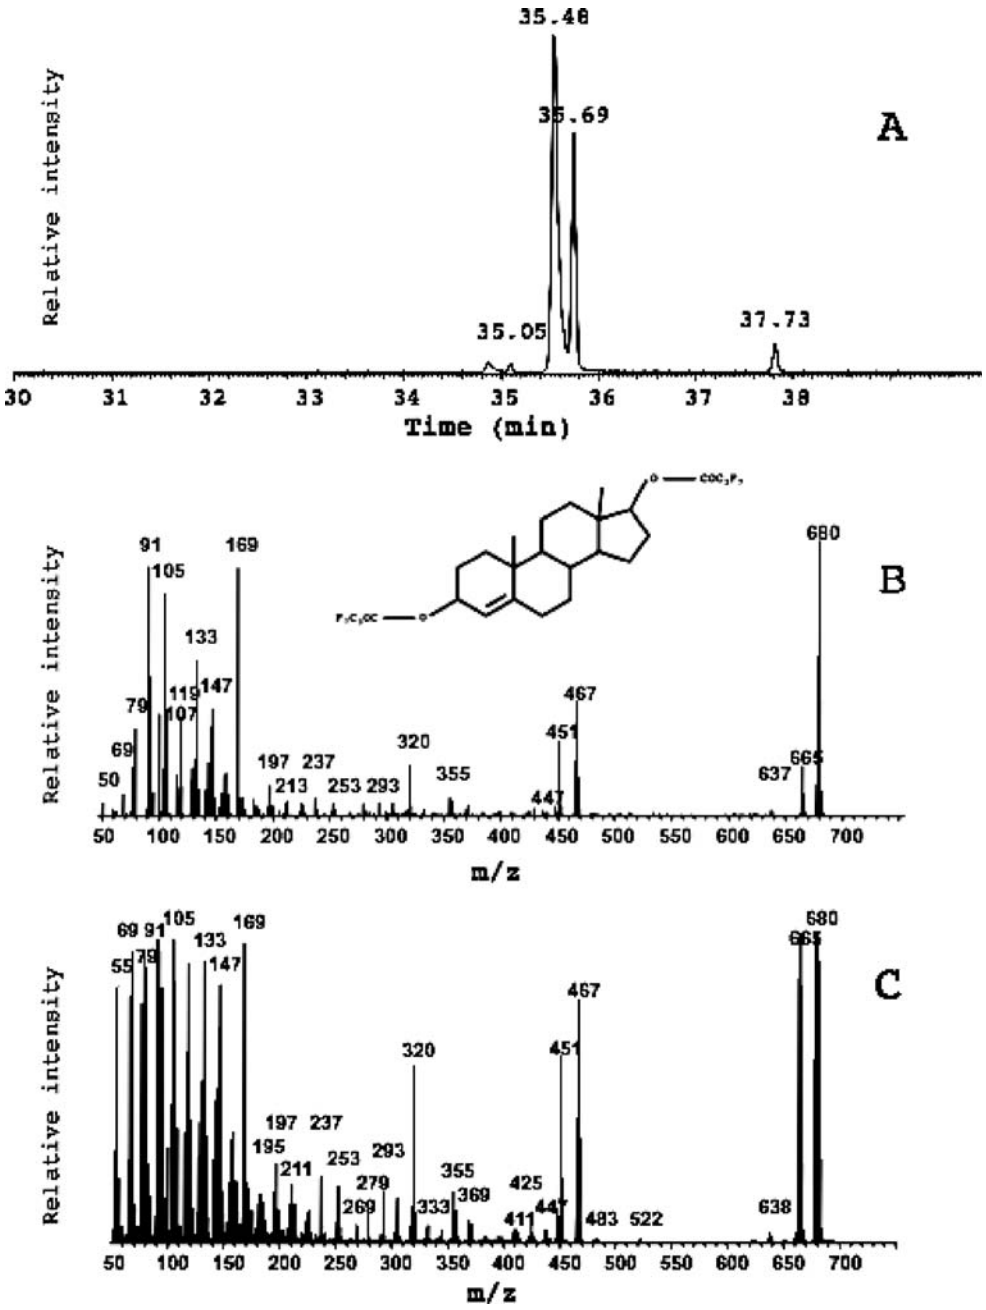

Fig. 6 Characterization of VEG1 ligands. **A)** Total ion chromatogram of ligand extraction from pig VEG1. **B)** Mass spectrum of the peak with R_t = 35.69 min. **C)** Mass spectrum of derivatized standard testosterone (Sigma-Aldrich)

confirm the identity of the proteins used for ligand extraction (Fig. 1). Bands 1 to 3 were analyzed to check the presence of VEG and OBP (Guiraudie et al. 2003). MALDI-TOF MS analysis confirmed the presence of VEG1 in band 1, VEG2 in band 2, and OBP in band 3. A comparison of the peptides from the tryptic digestion of bands 1 and 2 from the VNO to the theoretical peptides from VEG digestion by the same enzyme revealed that the VEG sequence was covered at 68.15% in band 1 and 82.16% in band 2 (Table 1). The difference between the two VEGs is the absence in VEG1 of the peptide 138–157 (*m/z*: 2,140.0087, Figs. 2 and 3) typical of the C-terminus of the protein (Guiraudie et al. 2003). Because the presence of extra-groups linked to peculiar amino acids may explain the absence of peptides (e.g., SAL bears N-glycosylations branched on Asn53, Scaloni et al. 2001), we searched for

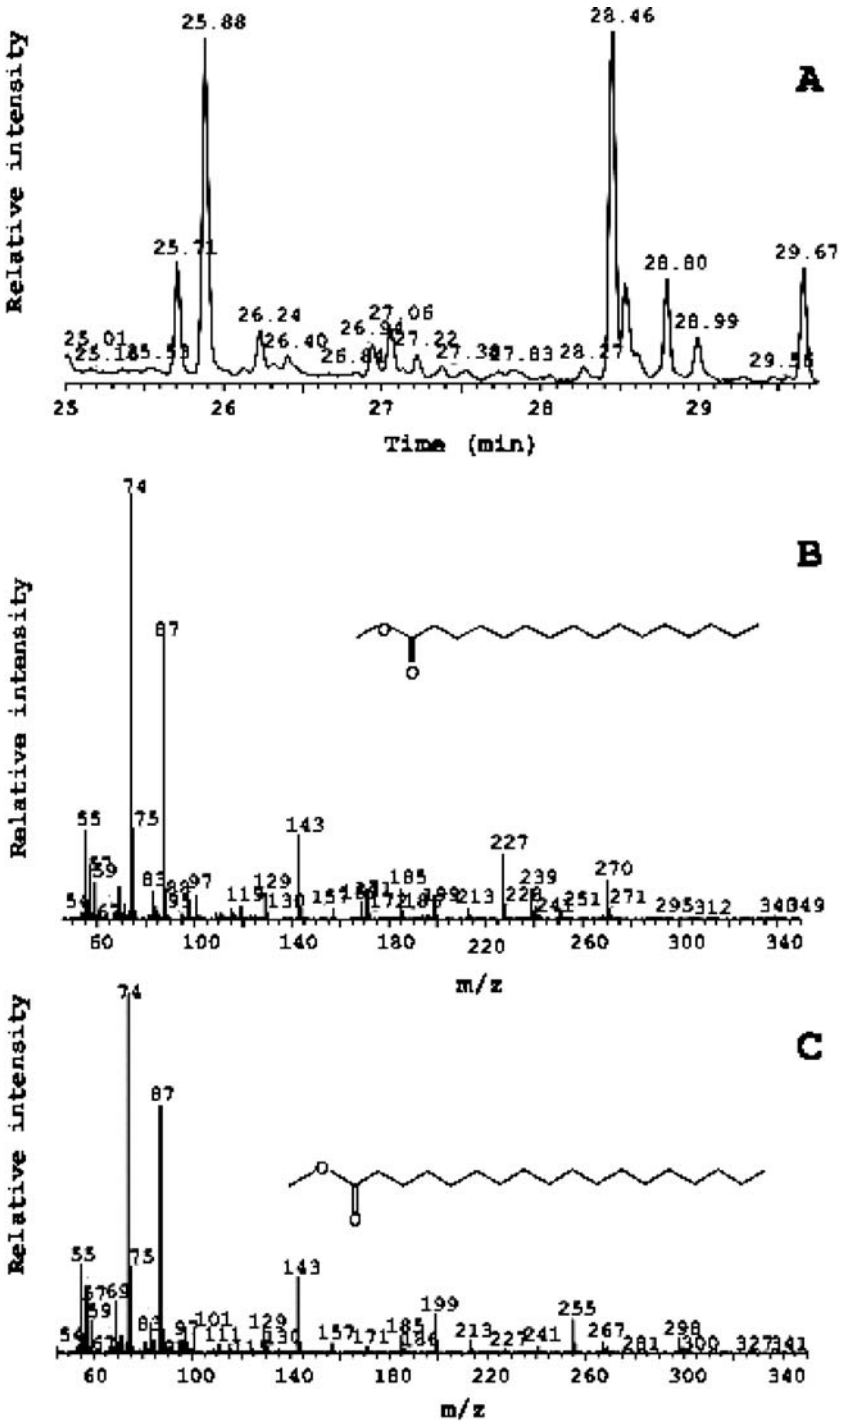

Fig. 7 Characterization of pig VEG2 ligands. **A)** Total ion chromatogram of ligand extraction from VEG2. **B)** Mass spectrum of peak with Rt = 25.71 identified as hexadecanoic acid methyl ester. **C)** Mass spectrum of peak with Rt = 29.67, identified as octadecenoic acid methyl ester. Peaks of Rt = 25.88 and Rt = 28.80 were identified as phthalates, peak of Rt = 28.46 as oleanitrile, all retrieved in the control

potential sites of post-translational modifications in the proteomic database www.expasy.org. The YinOYang server indicated only the possibility of *O*-N-acetylglucosaminylation on Ser149, with a high score (0.67 with a threshold of 0.35). We, thus, performed a beta-elimination on the entire proteins (VEG1 and VEG2) electroblotted onto PVDF, and the presence of glycans was investigated by GC-MS. Ions of *m/z* 84, 102, and 318, typical of the peracetylated *O*-N-acetylglucosamine fragmentation (*O*-GlcNac, Fig. 4A) were searched and retrieved at the retention time of 31.58 min (Fig. 4B) in VEG1 chromatogram. No such ions were found in the VEG2 chromatogram. Standard *O*-GlcNac was injected in the same GC-MS conditions and eluted at a retention time of 31.50 min (data not shown). The mass spectra of the experimental peak of R_t 31.58 and standard *O*-GlcNac were compared, and confirmed the presence of a *O*-GlcNac moiety on the protein (Fig. 4C). Peptide mapping on band 3 of the VNO (Fig. 5) revealed that the peptide sequence of OBP was covered at 100% (Table 2).

Identification of Binding Protein Ligands by GC-MS Bands corresponding to the two isoforms of VEG, and OBP were submitted to ligand extraction, the resulting supernatants were derivatized, and analyzed by GC-MS. The chromatogram of the VEG1 extraction displayed two major peaks of R_t 35.48 and 35.69 (Fig. 6A), whose mass spectra suggested steroids. No data were available for HFB derivatives in the NIST library, but the published analysis

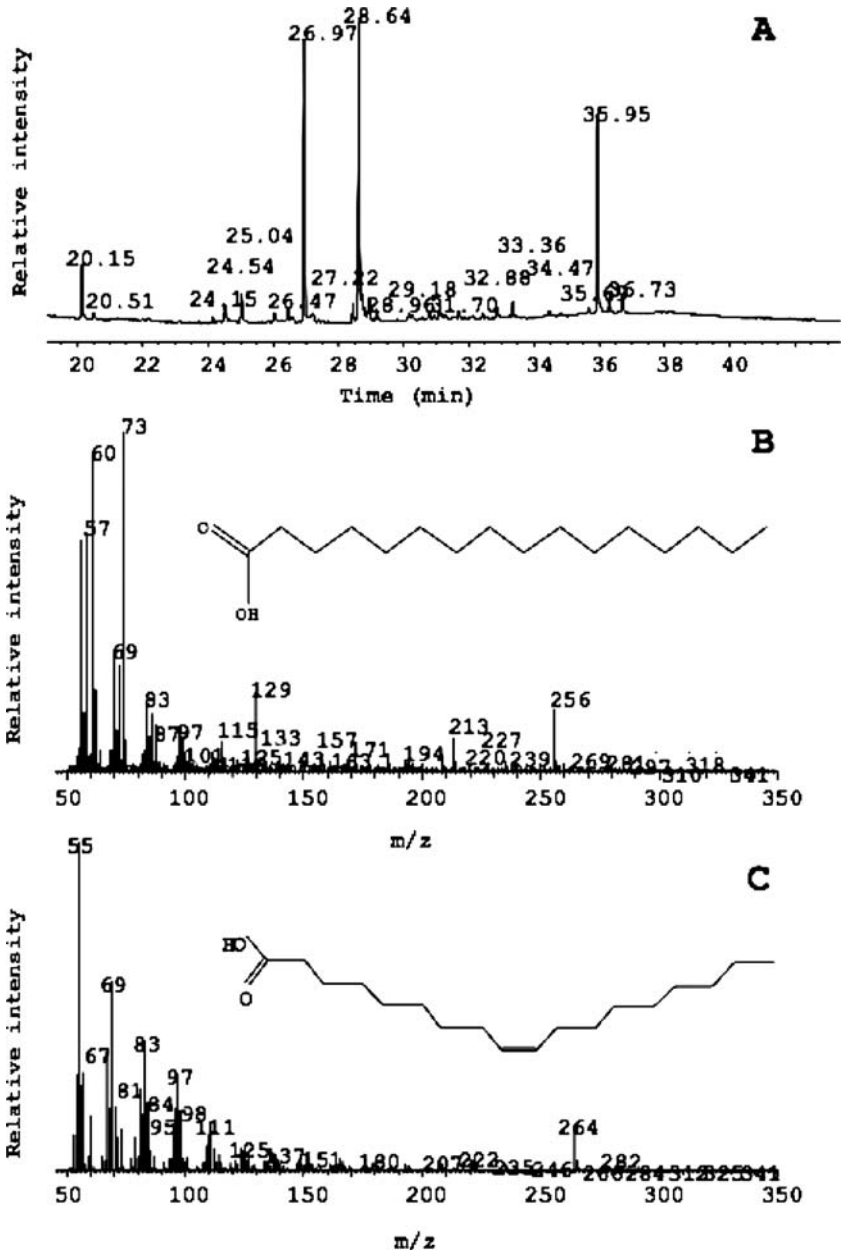

Fig. 8 Characterization of pig OBP ligands. **A)** Total ion chromatogram of ligand extraction from band 3. **B)** Peak with R_t = 26.97 was identified as hexadecanoic acid by comparison with R_t and mass spectrum of the standard. **C)** Peak of R_t = 28.64 was identified as octadecenoic acid. Peaks of R_t = 20.15 min and of R_t = 35.95 corresponded to phthalates

of anabolic steroids of cattle, derivatized with HFBAA (Daeseleire et al. 1998) indicated that the presence of four selected ions (*m/z*: 680, 467, 320, and 355) is typical of testosterone (Fig. 6B). Standard testosterone was derivatized and analyzed under the same conditions. Its mass spectrum (Fig. 6C) was identical to the mass spectrum of the compound with R_t = 35.69 (Fig. 6B). Since the mass spectrum of the compound with R_t = 35.48 was identical, we hypothesize that it corresponds to a testosterone isomer, dihydroxytestosterone, which is secreted together with testosterone, and is the biologically active steroid (see Discussion).

Analysis of the VEG2 ligands (Fig. 7A) showed several peaks of contaminants that also were retrieved in the control sample (oleanitrile and phthalates). We did not detect any steroid. Two fatty acid methyl esters were characterized (match of 100% with the NIST spectra), hexadecanoic acid methyl ester at R_t = 25.71 min (Fig. 7B), and octadecenoic acid methyl ester at R_t = 29.67 min (Fig. 7C).

The chromatogram of OBP ligand extraction showed four major peaks (Fig. 8A). The one at R_t = 26.97 was identified as palmitic acid (hexadecanoic acid, Fig. 8B) and the peak at R_t = 28.64 as oleic acid [(*Z*)-9-octadecenoic acid, Fig. 8C]. Two phthalates were identified at R_t = 20.15 and R_t = 35.95.

Binding Assay with Radiolabeled Analog of Testosterone The results reported above indicated that the chemical structure of ligands bound by VEG1 and VEG2 were different, suggesting a strong specificity in binding properties of the two VEG isoforms. The specific binding of VEG1 to progesterone and of VEG2 for fatty acids had already been demonstrated (Guiraudie et al. 2003). To validate these data, we performed a binding assay with tritiated testosterone, the endogenous ligand of VEG1, and progesterone, as a positive control (Fig. 9). As expected, testosterone was only bound by VEG1, whereas progesterone was strongly bound by VEG1 and weakly bound by VEG2 and OBP.

Discussion

We used HFBAA derivatization to characterize the endogenous ligands of the porcine olfactory binding proteins (VEG isoforms and OBP) because it is a standard method for the GC and/or GC-MS analysis of steroid derivatives (e.g., Daeseleire et al. 1998). Because we did not purify the putative ligands, the samples contained some contaminants coming from electrophoresis sample buffer, principally Tris, sucrose, and also phthalates from Eppendorf tubes (polypropylene), which were easily identified by using EI detection in mass spectrometry (typical 149 ion). These contaminants did not interfere with the identification of the ligands.

We characterized the endogenous ligands of VEG isoforms and OBP from pig VNO, which endogenous ligands were able to displace in a binding assay (Guiraudie et al. 2003; this study). Our analysis showed that VEG2 and OBP ligands are fatty acids or their derivatives, already found in the human counterpart of VEG, the tear lipocalin (Redl 2000). These data also are in accordance with published results obtained from an in-gel binding assay, where VEG2 and OBP bound different fatty acids of the porcine maternal pheromone (Guiraudie et al. 2003). We also have demonstrated that the steroid progesterone was bound only by VEG1, suggesting a strong binding specificity for steroids. Indeed, we have identified the previously unknown natural ligand of VEG1 as testosterone, differing from progesterone by the substitution of an alcohol instead of a methyl-ketone on carbon 17. Testosterone is the major compound secreted by the testes and is metabolized into dihydrotestosterone, which is transported *via* the blood to the submaxillary gland (Babol et al. 1996) by binding to various proteins (sex hormone binding globulin and in a lesser extent, albumin). The expression of VEG is associated with glands and organs involved in sexual communication. Its high concentration in saliva, together with androstenone and androstenol, suggests a role in mating behavior of pigs that could be investigated by behavioral assays. In this context, VEG1 of the VNO has to be considered as a pheromone-binding protein [as is the case with SAL (Marchese et al. 1998; Loebel et al. 2000)]. The presence in the same compartment of both components involved in sexual communication and OBP has been documented in insects. In *Drosophila*, the fatty acid derivative *cis*-vaccenyl acetate is transferred from the male to the female during copulation bound to a CSP (Jallon et al. 1981; GenBank accession number U08281). In the Lepidoptera, CSPs are expressed in the pheromonal gland, at least to solubilize pheromone components, which are fatty acid derivatives (Jacquin-Joly et al. 2001).

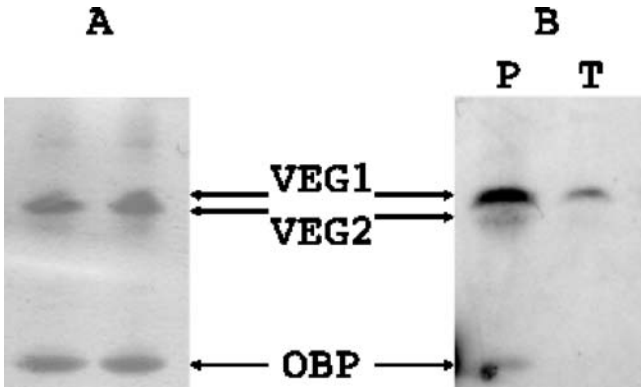

Fig. 9 In-gel binding assay between pig VNO extract and tritiated steroids. **A)** PVDF membrane stained with Ponceau red after electroblotting of VNO proteins. Position of VEG1, VEG2 and OBP is indicated. **B)** Fluorography after a 1-wk exposure, indicating the location of the radiolabeled progesterone (P) and testosterone (T)

As the only difference that we identified between VEG1 and VEG2 is the *O*-GlcNac moiety on VEG1, we assume that the binding specificity of VEG1 to steroids is linked to the presence of the *O*-GlcNac group on the protein. This result is unusual: indeed, the *O*-linked N-acetylglucosaminylation of proteins is described as a nuclear and cytoplasmic modification (Torres and Hart 1984) and is not supposed to occur on secretory proteins, i.e., proteins synthesized *via* the endoplasmic reticulum, that bears a signal peptide as olfactory binding proteins. *O*-N-acetylglucosaminylation and phosphorylation can occur on the same Ser and Thr residues in a reversible mechanism called YinOYang (Corner and Hart 2001). The enzyme responsible for the *O*-GlcNac linkage (*O*-GlcNac transferase, OGT) was not retrieved in the reticulum compartment (Hart et al. 2007). Although there is evidence for the phosphorylation of extracellular proteins by ectokinases (e.g., Nath et al. 2008), to date no protein localized in the extracellular pathway has been described to bear *O*-GlcNAc residues. However, the linkage of *O*-GlcNac to an olfactory binding protein was already reported for hamster aphrodisin (Briand et al. 2000). This surprising result, however, was not discussed by these authors, despite the fact that two potential *O*-GlcNac sites (S58, T148) are predicted by the YinOYang server (SwissProt accession number Q9Z1I7). This unusual post-translational modification for secretory proteins could be a special feature of Bowman's gland secreting cells and the study of VEG1 biosynthesis pathway in such cells is currently ongoing.

Until now, the impact of post-translational modifications on the binding properties of OBPs (*sensu largo*) has not been fully investigated. The *O*-GlcNac modification creates several isoforms of OBPs, which possess different and specific binding affinities for pheromone components. The existence of such variants extends the possibility of coding for odorants by OBPs, and it suggests that the binding of odorants by OBPs is an initial discrimination step, preceding binding to olfactory receptors. This hypothesis is novel for the field of Mammalian olfaction where OBPs have been considered mainly as passive carriers of odorant molecules.

Phosphorylation of Native Porcine Olfactory Binding Proteins

Patricia Nagnan-Le Meillour · Chrystelle Le Danvic · Fanny Brimau · Philippe Chemineau · Jean-Claude Michalski

Received: 19 February 2009 / Revised: 10 June 2009 / Accepted: 21 June 2009 / Published online: 7 July 2009

Abstract The identification of various isoforms of olfactory binding proteins is of major importance to elucidate their involvement in detection of pheromones and other odors. Here, we report the characterization of the phosphorylation of OBP (odorant binding protein) and Von Ebner's gland protein (VEG) from the pig, *Sus scrofa*. After labeling with specific antibodies raised against the three types of phosphorylation (Ser, Thr, Tyr), the phosphate-modified residues were mapped by using the beta-elimination followed by Michael addition of dithiothreitol (BEMAD) method. Eleven phosphorylation sites were localized in the pOBP sequence and nine sites in the VEG sequence. OBPs are secreted by Bowman's gland cells in the extracellular mucus lining the nasal cavity. After tracking the secretion pathway in the rough endoplasmic reticulum of these cells, we hypothesize that these proteins may be phosphorylated by ectokinases that remain to be characterized. The existence of such a regulatory mechanism theoretically increases the number of OBP variants, and it suggests a more specific role for OBPs in odorant coding than the one of odorant solubilizer and transporter.

Introduction

Despite extensive studies of their structure and binding properties, the role of odorant binding proteins (OBPs) in the detection of odorant molecules still is not completely understood (Tegoni et al. 2000). These small soluble proteins are secreted in the mucus that lines the nasal cavity in mammals where olfactory receptor neurons are located. One major unresolved question about OBPs is their interaction with olfactory receptors, and the nature of the olfactory receptor ligands. Two major hypotheses have been proposed: 1) The ligand is the odorant molecule itself, solubilized and transported to the receptor by OBPs. In this scheme, the binding between odorant molecules and OBPs is unspecific, and this implication is supported by the low number of OBPs found in the mucosa of each animal species, and by their broad spectrum of binding of

hydrophobic molecules (Dal Monte et al. 1993; Herént et al. 1995). OBPs also are assumed to concentrate odorants and/or to scavenge them from receptors in a deactivation process (Pelosi 2001). 2) The ligand is the complex formed by the specific binding between a given odorant molecule and a specific OBP. This hypothesis involves a conformational change of the OBP upon ligand binding, which confers an "activated" form to the complex, able to interact with a specific receptor. It also implies that the number of OBPs should be higher than yet described. The micro diversity of OBPs has not been fully investigated. However, Paolini et al. (1998) reported that the porcine OBP is the major OBP of nasal mucosa, although perhaps not the only one. Microheterogeneity of OBPs related to primary structure differences has also been reported in porcupine (Ganni et al. 1997).

We have used a ligand-oriented approach to identify the proteins involved in the specific binding of pheromone components in the nasal mucosa of pre-pubertal pigs, *Sus scrofa* (Guiraudie et al. 2003). Three OBPs were identified as Salivary Lipocalin (SAL), Von Ebner's gland protein (VEG), and porcine odorant binding protein (pOBP), by immunodetection with specific antibodies, peptide mapping, and cloning of the encoding cDNA. The binding assay, performed in non-denaturing conditions, revealed two isoforms of VEG, with different binding properties (Guiraudie et al. 2003). We have shown recently that the binding specificity of VEG1 isoform for steroids is governed by the presence of an *O*-GlcNac moiety on the protein (Le Danvic et al. 2009). Such a specificity of ligand binding, linked to OBPs isoforms, strongly favors the hypothesis that specific complexes could exist between odorants and OBPs. Furthermore, we observed that the purification of olfactory binding proteins by anion exchange HPLC provided several isoforms eluted at different NaCl concentrations, suggesting different charges coming from post-translational modifications (unpublished results). Here, we report the identification, characterization, and localization of post-translational modifications of porcine OBP and VEG.

Methods and Materials

Protein Extraction from Respiratory Mucosa Animals (Large White adult sows of *Sus scrofa*) were slaughtered in agreement with UE directives about animal welfare. Respiratory mucosa (RM) was dissected immediately after death and stored at −80°C. Native proteins were extracted from 10 mg of RM with 800 µl of 2:1 chloroform/methanol (v:v, Sigma-Aldrich, La Verpillière, France) on ice. After a brief homogenization by vortexing, the samples were centrifuged at 12,100×*g* for 10 min at 4°C. The methanol phase was dried under vacuum (Speed-Vac, Eppendorf, Le Pecq, France) and stored at −20°C until use.

Dephosphorylation Enzymatic Treatment RIPA buffer (150 mM NaCl, 1% NP40, 0.5 mM DTT in 50 mM Tris/HCl pH=8.5) was added to protein samples and incubated 16 h at 37°C with 2 units of alkaline phosphatase (rAPid alkaline phosphatase, Roche Diagnostics, Meylan, France) for 10 µg of total protein.

Polyacrylamide Gel Electrophoresis (PAGE) and Western Blotting Samples were analyzed by 16.8% PAGE gels in denaturing and reducing conditions (SDS-PAGE) as previously described (Guiraudie et al. 2003; Nagnan-Le Meillour et al. 2009). Gel staining (overnight in Coomassie blue R solution) and Western blotting were performed as described in Guiraudie et al. (2003), except that for the Western blot, membranes were saturated with 5% non-fatty milk before incubation with anti-pOBP and -VEG antibodies, or with 3% bovine serum albumin (BSA, Sigma-Aldrich) for anti-phosphorylation antibodies. Rabbit polyclonal antibodies anti-phosphoserine, anti-phosphothreonine, and anti-phosphotyrosine were used at 1:500, 1:500, and 1:2,000 dilutions, respectively, following recommendations of the manufacturer (Zymed laboratories, Invitrogen, Cergy-Pontoise, France). Rabbit polyclonal antibodies were raised in our laboratory against recombinant purified pOBP (Nagnan-Le Meillour et al. 2009). They were used at a 1/20,000 dilution, and rabbit polyclonal anti-VEG antibodies at a 1/10,000 dilution (provided by Professor Paolo Pelosi). Membranes then were incubated with secondary antibodies at a 1:50,000 dilution (anti-rabbit horseradish peroxidase-labeled antibodies, Amersham Biosciences, GE Healthcare, Templemars, France). Detection was carried out with ECL Plus Western Blotting Detection Kit (Amersham Biosciences).

Characterization of Native Proteins by In-gel Digest, Peptide Extraction and MALDI-TOF MS Analysis Band slices containing pOBP and VEG were treated as previously described (Nagnan-Le Meillour et al. 2009), with Trypsin Gold (Mass Spectrometry grade, Promega, Charbonnières, France, 10 ng/µl). Peptides resulting from the trypsin digestion were extracted with two incubations in 45% acetonitrile in 10% formic acid at 30°C for 15 min, followed by an incubation in 95% acetonitrile in 5% formic acid at room temperature (RT) for 15 min. The extracts were dried under vacuum and solubilized in 5 µl of 0.1% trifluoroacetic acid (TFA) before desalting and concentration on a C18 column (Vivapure C18, microspin columns, Sartorius, Palaiseau, France). Peptides were eluted with different percentages of acetonitrile (12.5, 25, 50, and 80%) directly into the matrix (α-cyano-4-hydroxycinnamic acid, Sigma-Aldrich) prepared at a concentration of 10 mg/ml in

50% acetonitrile, 0.1% TFA, and were analyzed on a Voyager DE Pro MALDI-TOF mass spectrometer (Applied Biosystems, Courtaboeuf, France). The instrument was used in reflector mode, measuring peptide masses in a range of 500 to 4,000 Da. Calibration points were based on the masses of the matrix cluster or trypsin autolysis products (*m/z* 842, 2211). Protein identification was performed by comparison of measured peptide masses with the theoretical porcine OBP (GenBank accession number NP_998961) and VEG (S77587) peptide maps (http://expasy.org/tools/peptide-mass.html).

Mapping Phosphorylation Sites in Proteins As a first approach, the NetPhos server at http://www.cbs.dtu.dk/services/NetPhos/ (Blom et al. 1999) was used to predict potential phosphorylation sites in pOBP and VEG sequences. The sites of phosphorylation were experimentally determined by using a method involving mild beta-elimination followed by Michael addition of dithiothreitol (BEMAD) adapted from Wells et al. (2002). Proteins were extracted and treated as they were for peptide mapping (above), except that they were not reduced and alkylated before treatment with trypsin, to avoid the addition of DTT on cysteines. Peptides resulting from trypsin digestion were suspended in 50 mM Tris/HCl containing 1 mM $MgCl_2$ and alkaline phosphatase (1 U/10 µl). The reaction was incubated overnight at 37°C, then dried in a speed-vac. Dried peptides were β-eliminated and subjected to Michael addition with DTT by resuspension in 200 µl of BEMAD solution (1% triethylamine, 0.1% NaOH, 20% ethanol, 10 mM DTT) and incubated at 50°C for 2.5 h. The reaction was stopped by addition of TFA to a 1% final concentration. Peptides were cleaned up via reverse-phase Vivapure C-18 micro columns (Sartorius) with different acetonitrile percentages in 0.1% TFA (12.5, 25, 50, and 80%) and dried. DTT modified peptides were enriched by thiol affinity chromatography according to Whelan and Hart (2006). Thiopropyl Sepharose 6B resin (Amersham Biosciences) was swelled and washed in column buffer containing 150 mM NaCl and 1 mM EDTA in 20 mM Tris/HCl, pH 7.6 (TBS/EDTA). The resin was transferred into a Vivaclear Mini Clarifying filter (Sartorius) and washed with 7 ml of TBS/EDTA by centrifugation. Peptides were resuspended in 200 µl TBS/EDTA and loaded onto the thiol column for 4 h at RT by rotation. The column then was washed with 15 ml of TBS/EDTA, and peptides were eluted by three washes of 150 µl TBS/EDTA containing 20 mM of free DTT. They were acidified by 0.1% TFA and cleaned up with reverse phase Vivapure C-18 Micro spin columns (Sartorius). Peptides were eluted directly into the matrix (10 mg/ml of α-cyano-4-hydroxycinnamic acid in 0.1% TFA, 50% acetonitrile) and analyzed by MALDI-TOF MS as above.

Results and Discussion

Heterogeneity of Porcine OBP and VEG The respiratory mucosa (RM) extracts were submitted to electrophoresis in native (Fig. 1A) or denaturing conditions (Fig. 1B), and the respective positions of pOBP and VEG were determined by peptide mapping. Both spectra (Fig. 2) and reconstituted maps (Table 1) indicated that the two proteins co-migrate in the same band in denaturing conditions (Fig. 1B). This result is in accordance with the calculated molecular weights of the proteins (17,935 Da for pOBP and 17,441 Da for VEG) and with previous data obtained by using the same electrophoresis conditions for pOBP (Nagnan-Le Meillour et al. 2009). Each peptide could be assigned unambiguously to one or the other protein, as none of them was found to be common to pOBP and VEG (Table 1). After electrophoresis in native conditions, pOBP and VEG displayed reproducible heterogeneity (Fig. 1A), which was not detected under reducing and denaturing conditions of SDS-PAGE (Fig. 1B). These different forms can result from different global charges, due to post-translational modifications, such as phosphorylation on Ser, Thr, and Tyr residues. The NetPhos server (www.cbs.dtu.dk/services/NetPhos/) indicated that several sites in the primary structure could potentially be phosphorylated: Ser13, Ser24, Ser41, Ser67, Tyr78, and Tyr82 in pOBP, and Ser24, Ser35, Ser149, Thr23, and Tyr97, in VEG. We, thus, performed Western blotting with commercial specific antibodies, raised against the three types of phosphorylation, to test the hypothesis that both proteins are phosphorylated.

Immunodetection of Phosphorylations with Specific Antibodies Preliminary experiments were run under native conditions, where the diversity of binding proteins is the

◀ **Fig. 2** Monoisotopic mass spectra from MALDI-TOF MS analysis of reduced and carboxymethylated band slice containing pOBP and VEG (SDS-PAGE) of the pig, *Sus scrofa*, respiratory mucosa (RM) extract after trypsin digestion (untreated sample). Peptides were eluted with different percentages of acetonitrile: 12.5% (**1**), 25% (**2**), 50% (**3**), and 80% (**4**)

most detectable. Unfortunately, phosphate groups often are buried into the folded protein and unreachable by antibodies. As expected, under these conditions, the Western blot with the three antibodies was negative. A Western blot then was performed after SDS-PAGE, and the band containing the two co-migrating proteins (Fig. 3A) was labeled by antiphosphoserine (Fig. 3B), antiphosphotyrosine (Fig. 3C), but not by antiphosphothreonine, which is consistent with the prediction of the NetPhos server of only one potential phosphorylation site on VEG Thr23. To verify the accuracy of the labeling, half of the RM sample was treated with alkaline phosphatase (AP) to remove any phosphate group, and both treated and untreated samples were submitted to Western blot analysis with the three specific antibodies. With antiphosphoserine antibodies, we observed a significant reduction of the signal after AP treatment (Fig. 4A), unless a total knock out. We obtained the same results with antiphosphotyrosine antibodies (data not shown). In both cases, we checked for the presence of pOBP and VEG after treatment by Western blot with anti-pOBP and anti-VEG antibodies (Fig. 4B and C, respective-

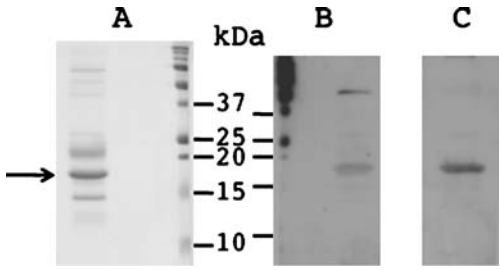

Fig. 3 Immunodetection of phosphorylated proteins in respiratory mucosa (RM) samples of the pig, *Sus scrofa*, by Western blot and ECL Plus detection. **A** Coomassie blue staining of the same sample as used for Western blot analysis. Arrow indicates the band containing pOBP and VEG. **B** antiphosphoserine antibodies (1:500 dilution, 2 min exposure). **C** antiphosphotyrosine antibodies (1:2,000 dilution, 2 min exposure). Discrepancy between relative positions of molecular weight markers in A and B/C comes from the swelling of the gel (**A**) in water

ly). The corresponding band was cut from a SDS-PAGE gel run under the same conditions, and it was submitted to peptide mapping. The use of different percentages of acetonitrile allowed elution of most of the expected peptides. Indeed, the VEG sequence was recovered at 84.1%, and the pOBP one at 84.7% with or without AP treatment, indicating that the proteins were not degraded by the dephosphorylation (Table 1). These data indicated that one of the two proteins, or both, are phosphorylated.

Mapping of Phosphorylation Sites in pOBP and VEG Experiments described above did not permit us to conclude whether one or both proteins are phosphorylated. Thus, the sites were located in proteins experimentally by the BEMAD method followed by MALDI-TOF MS analysis. In MALDI-TOF MS, the *O*-linked phosphate groups are labile and decayed by the laser during desorption of peptides from the matrix (Mann et al. 2002). The use of beta-elimination of phosphate from Ser, Thr, and Tyr residues by alkaline phosphatase, followed by the attack of the nucleophile DTT confers a tag of defined molecular mass (136.2 Da) to the peptides bearing phosphate groups, that are subsequently enriched by the use of thiol columns. The band slice containing pOBP and VEG was submitted to enzymatic digestion and BEMAD modification. The measured masses of resulting peptides were compared to a theoretical list of potential DTT-modified peptides calculated from the pOBP and VEG protein sequences (Table 2). Two different enzymes (Trypsin-T or Chymotrypsin-CT or both) were used for the site analysis. When using either T or CT, many ambiguous sites remained, and it was necessary to perform T and CT treatments successively to obtain the pOBP and VEG phosphorylation sites. Mass spectral analysis of peptides eluted with 50% acetonitrile after T + CT treatment, BEMAD and thiol column enrichment, revealed that in addition to DTT-modified peptides (Table 2), some unmodified peptides, typical of the pOBP and VEG digestion were present (Fig. 5). Five peptides resulted from the pOBP digestion with T + CT (mass 655.3903 corresponding to peptide 51–55), or T (mass 2224.0593, peptide 134–152; mass 2239.8924, peptide 138–157, and mass 2296.9473, peptide 138–157 with Cys_CAM:155) and VEG digestion with T (mass 2265.9512, peptide 93–111). The ratio between DTT-modified and unmodified peaks could not be determined, as the modified peptides were enriched by the use of thiol columns. We suggest that phosphorylated peptides are present in small quantities in the RM extracts, as the unmodified peaks are much more abundant than modified ones, even after enrichment (e.g., mass 2224.0593). The other DTT-modified peptides (Table 2), were obtained with other acetonitrile percentages (12.5, 25, and 80%) and different enzymatic treatment (T or CT). The corresponding spectra are provided in Supplementary data.

In pOBP, the phosphorylation of the following residues was predicted by the NetPhos software: Ser13, Ser24, Ser41, Ser 67, and Tyr82 (Ser24, Ser149, Tyr97, and Thr23 in VEG), whereas Ser23, Ser49, Ser57, Tyr52, Thr71, and Thr122 were not predicted (Ser91, Ser153, Thr54, Thr151, and Tyr87 in VEG). The occurrence of masses indicating the phosphorylation of one or more residues in the same

peptide (21–38 and 41–50 in pOBP, 21–31 and 140–157 in VEG) suggests that several isoforms of phosphorylation co-exist for each protein. Finally, despite the combined use of two enzymes, the phosphorylation sites of peptides 59–72 in pOBP (Ser67 or Thr71) and 140–157 in VEG (Ser149 or Ser153 or Thr151) remained ambiguous. We considered the use other enzymes or chemical methods (CNBr) to assign the phosphorylation to one or the other residue, but none of these methods was suitable, as the theoretically generated peptides still contain all of the potentially phosphorylated residues. The sites could be determined by site-directed mutagenesis followed by heterologous expression in eukaryotic cells (Nagnan-Le Meillour et al. 2009), and by site mapping with the BEMAD method.

Phosphorylation of Extracellular Proteins This work demonstrated that two olfactory binding proteins (pOBP and VEG) are phosphorylated, which is a novel and unexpected result. Indeed, pOBP and VEG are secreted in the nasal mucus by the exocrine Bowman's glands via the secretion pathway. This pathway occurs in the rough endoplasmic reticulum (RER) where the signal peptide permits the translocation of proteins through the RER membrane to be processed and secreted. Thus, hypothetically these proteins are not exposed to nuclear and cytoplasmic kinases and phosphatases involved in the phosphorylation/dephosphorylation of cellular proteins. However, Jordan et al. (1994) and others have provided evidence for the existence of extracellular enzymes (ecto-enzymes) located in the extracellular space. In particular, the occurrence of ecto-kinases and ecto-phosphatases has been demonstrated in various cell types, i.e., in goat spermatozoa where they modulate sperm motility (Nath et al. 2008). Such enzymes could be responsible for the phosphorylation of OBPs after

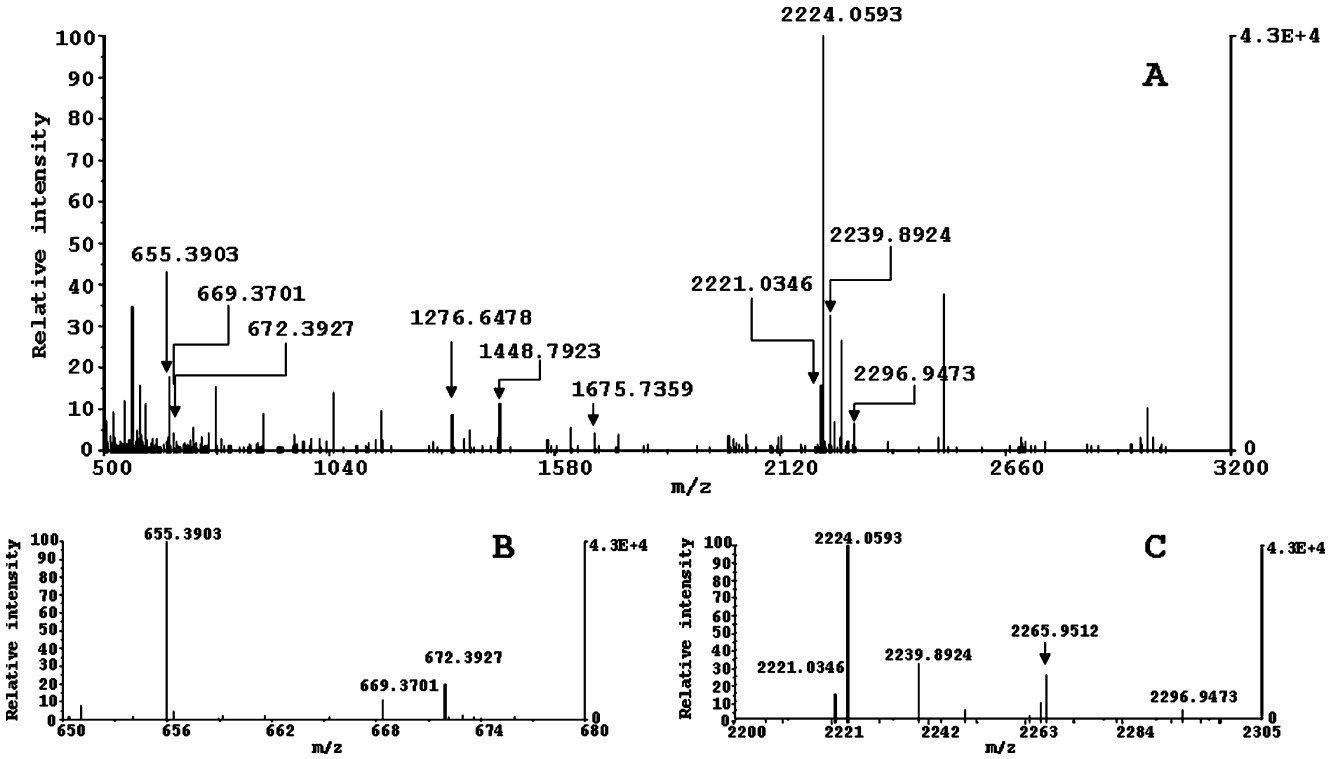

Fig. 5 Monoisotopic mass spectrum of MALDI-TOF MS analysis of carboxymethylated band containing pOBP and VEG (SDS-PAGE) of the pig, *Sus scrofa*, respiratory mucosa (RM) extract after BEMAD. **A** Peptides elution with acetonitrile 50%, after T + CT treatment. **B** Magnification of the 650–680 *m/z* zone. **C** Magnification of the 2,200–2,300 *m/z* zone. OBP (C + CT) 51–55 (*m/z*=655.3903). VEG (T)-93–111 (*m/z*=2265.9512). DTT-modified peptides are listed in Table 2

their extracellular secretion. Hypothetically, ecto-enzymes may have the potential for intercellular regulation or reception and transduction of external stimuli. Phosphorylation is a dynamic, reversible mechanism that results in a conformational change in the structure of many enzymes and receptors, causing them to become activated or deactivated. Accordingly, the phosphorylation of pOBP and VEG creates a variety of isoforms that could possess different and specific affinities for pheromones or other odors. We recently have demonstrated that the binding specificity of the VEG1 isoform of the pig vomeronasal organ for steroids is governed by the linkage of an *O*-GlcNac moiety on the protein (Le Danvic et al. 2009). The same result was obtained with the RM tissue (data not shown). *O*-N-acetylglucosaminylation and *O*-phosphorylation can occur on the same protein and, in several instances, they map to the same (YinOYang) or adjacent sites (Comer and Hart 2000). In any case, the two modifications are dynamic and reversible, and increase the number of possible combinations for isoforms. Interestingly, Ser149 in VEG, which is phosphorylated, is also predicted by the YinOYang server (at www.expasy.org) to be *O*-GlcNac-modified. We plan to map the *O*-GlcNac sites on VEG molecules, but the results will be much more difficult to obtain than for phosphorylation, as the sub-population of glycosylated VEG is probably a minor part of the entire population. Enrichment by using affinity columns with anti-*O*-GlcNac antibody will be necessary prior to BEMAD treatment.

The existence of such variants extends the possibility of odorant coding by OBPs, strongly suggesting that this interaction is the first discrimination step, prior to the binding with olfactory receptors. The possibility of regulation of pOBP and VEG binding properties by phosphorylation and glycosylation opens new ways to study their role in perireceptor events in olfaction, as well as their genesis via biosynthesis as secreted proteins in exocrine glands.

Acknowledgments We warmly thank Dr Frédéric Lévy for his skillful dissection of pig RM, and Professor Paolo Pelosi for his kind gift of anti-VEG antibodies. We are also grateful to Michael Thant and Djamel Abderrahmani for their contribution to preliminary experiments. We thank two anonymous referees and Dr. S.J. Seybold for their help to improve the manuscript.

Mate Finding in the Parasitic Wasp *Cephalonomia tarsalis* (Ashmead): More than one way to a Female's Heart

Jana Collatz · Till Tolasch · Johannes L. M. Steidle

Received: 30 October 2008 / Revised: 14 May 2009 / Accepted: 19 June 2009 / Published online: 9 July 2009

Abstract The parasitic wasp, *Cephalonomia tarsalis* (Hymenoptera: Bethylidae), parasitizes larvae of the saw-toothed grain beetle, *Oryzaephilus surinamensis* (L.) (Coleoptera: Silvanidae), and is used for biological control of this worldwide pest of stored grain. To study the hypothesis that *C. tarsalis* not only mates at its natal patch but also uses olfactory cues to find mating partners elsewhere, we investigated semiochemical use by male *C. tarsalis*. Olfactometer experiments revealed that male *C. tarsalis* are arrested by odors emanating from the cocoons of conspecifics, from young unmated females, and from feces of the host. Dodecanal, which was identified from extracts of filter paper contaminated by young females, had an arresting effect on males but not on females and was, therefore, considered as a sex pheromone. These findings indicate that *C. tarsalis* is a species with partial local mate competition. Males mate with females: 1) at the emergence site following location of females by sex pheromones from their cocoons, and 2) after dispersal from the natal patch following location of females directly by dodecanal and indirectly by unidentified sexual kairomones from host feces.

Introduction

The parasitic wasp, *Cephalonomia tarsalis* (Hymenoptera: Bethylidae), is a specialist parasitoid of larvae of the sawtoothed grain beetle, *Oryzaephilus surinamensis* (Coleoptera: Silvanidae) (Powell 1938), and the merchant grain beetle, *O. mercator* (Fauvel). Wasps use chemical cues to locate their host larvae, attack and paralyze the hosts, and oviposit on the outside of the host. The larva feeds ectoparasitically on the host and pupates in a cocoon next to it. Because both host species are worldwide pests of stored grain and other commodities, *C. tarsalis* is used for their biological control in Europe (Zimmermann et al. 2008). However, many aspects of the wasp's biology are still unknown, and more knowledge could contribute to improve its use as a biological control agent.

One aspect that is unclear is the mating strategy of *C. tarsalis*. Females usually search for and paralyze several hosts, which they hide in a sheltered place before they begin to oviposit (Howard et al. 1998). As in many other bethylids (Griffith and Godfray 1988), this oviposition patch is aggressively defended against conspecific females (personal observations). Within the patch, females lay between one and four eggs on one host larva, depending on the number of available hosts (Powell 1938). If one egg is laid, it typically results in female offspring (Cheng et al. 2003). If more than one egg is deposited, progeny are usually of both sexes (Powell 1938). Therefore, *C. tarsalis* can be considered as a quasi-gregarious species, and most *C. tarsalis* males hatch in the vicinity of their sisters. It has been shown that these males emerge one to 2 days earlier than the females and enter their sister's cocoons for mating (Powell 1938). According to the theory of local mate competition, a strongly female-biased sex ratio in offspring would be expected in such a single foundress situation, if

all matings occur at the natal patch (Hamilton 1967). However, in *C. tarsalis*, females were found to lay one female and one male egg together on one host, i.e., to have a sex ratio of 1:1 (Powell 1938). Similarly, Cheng et al. (2003) reported a proportion of 57% females and Zimmermann et al. (2008) reported a sex ratio of 60% in large commercial breedings. Thus, the sex ratio of *C. tarsalis* seems to be low as compared to other species with local mate competition, where strong competition between males is avoided by strongly female-biased sex ratios (Thornhill and Alcock 1983), e.g., 5:1 in *Lariophagus distinguendus* (Charnov et al. 1981), 10:1 in *Nasonia vitripennis* (Werren 1980), and 4:1 in *Cephalonomia hyalinipennis* (Pérez-Lachaud and Hardy 1999). Another possible means for reducing competition between males is for not all matings to occur locally (Taylor and Bulmer 1980). This could be true in *C. tarsalis*, where 1) unmated females produce isolated sons (Powell 1938) or 2) males disperse from the natal patch after all females have been mated and have a chance to find mates in other patches (Nunney and Luck 1988). In contrast to many other bethylid species, this latter scenario is conceivable for *C. tarsalis*, since males are winged, often large and capable of dispersal. Furthermore, host- and natal patches of females often are close together due to aggregation of the host-species *O. surinamensis*, and male *C. tarsalis* live about 6 d, which seems long enough to disperse from the natal patch and find other patches. Therefore, we hypothesized that *C. tarsalis*, in contrast to many other bethylid species (Griffith and Godfray 1988) might display partial local mate competition. Under this hypothesis, some matings take place at the emergence site with siblings, and some matings occur at other patches, where non-related females emerge or are searching for hosts (Werren and Simbolotti 1989). In this case, we would expect that males use semiochemicals that are suitable to locate unmated sisters in the emergence patch, as well as semiochemicals that are suitable for the location of emerged females on other host patches (see Fauvergue et al. 1999). In order to test this hypothesis, we used bioassays to study the semiochemicals used by male *C. tarsalis* to locate its mating partners, and we used bioassays as well as coupled gas chromatography-mass spectrometry (GC-MS) to identify a female-produced sex pheromone.

Methods and Materials

Insects Specimens for cultures of *C. tarsalis* and *O. surinamensis* were collected in august 2005 from a flour-mill near Pforzheim, Germany. Cultures were kept at 23°C (*C. tarsalis*) and 27°C (*O. surinamensis*) in glass jars (height 10 cm, diam 8 cm). To rear *O. surinamensis*, approximately 500 adults were kept on a mixture of 70 g rolled oats and 100 g crimped wheat with one teaspoon of dried yeast for oviposition. The grain mixture was moistened up to 14% water content. After 7 d, the grain-mixture containing eggs and larvae was separated from adults by sieving with two sieves (2 mm and 0.63 mm mesh-size). To rear *C. tarsalis*, about 30 newly emerged wasps were placed into glass jars together with 3rd-instar larvae (3 wk-old) of *O. surinamensis*. The wasps were kept in these jars for 2 wk and were then removed. After 21 to 24 d, the next generation of parasitoids emerged and was collected every other day. To obtain samples for chemical analyses and bioassays, these parasitoids were allowed to mate within a glass vial. To obtain old mated females, these females then were allowed to oviposit on host larvae in glass jars for 2 wk. Afterwards, females were recollected and used for experiments. Cocoons and young virgin females were obtained by placing ten clean host larvae into glass-vials containing several pieces of filter paper. Mated female wasps were allowed to oviposit onto these larvae. Cocoons of developing next generation wasps were used in bioassays two weeks later. Young virgin females were obtained from cocoons 16–20 d after oviposition by daily collection from vials where no males had hatched.

To obtain information on sex ratio in our cultures, we allowed single females to oviposit on groups of 50, 100, 200, and 400 *O. surinamensis* larvae of mixed age in glass vials containing rearing medium. Offspring of *C. tarsalis* were sexed and counted afterwards. The experiment was repeated three times.

Bioassays The reaction of wasps to volatile stimuli was tested in a four-chamber-olfactometer (Steidle and Schöller 1997). This was made of heat resistant, opaque Plexiglas ® and consisted of a cylinder (height 4 cm high, diam 19 cm) divided by vertical plates into four chambers (Fig. 1). On the top of the cylinder, a walking arena (height 1 cm high, diam 19 cm) consisting of plastic gauze (mesh 0.2 mm) with a rim of heat resistant Plexiglas ® (0.9 cm high) was covered with a glass plate. No airflow was generated. A Petri dish containing an odor sample was placed beneath the arena in one chamber. The opposite chamber either contained an empty Petri dish or a Petri dish with another odor sample (see Fig. 1. T2/C3). The other chambers remained empty as transition zones. The olfactometer was illuminated from above. At the beginning of each experiment, a wasp was placed in the center of the walking arena. The behavior (walking, resting) and the position of the wasp were recorded for 420 s by using computer software "The Observer 5.0" (Noldus, Wageningen, The Netherlands). To avoid biased results due to side preferences of the parasitoids, the position of the olfactometer was rotated clockwise after every wasp. No more than ten wasps of the

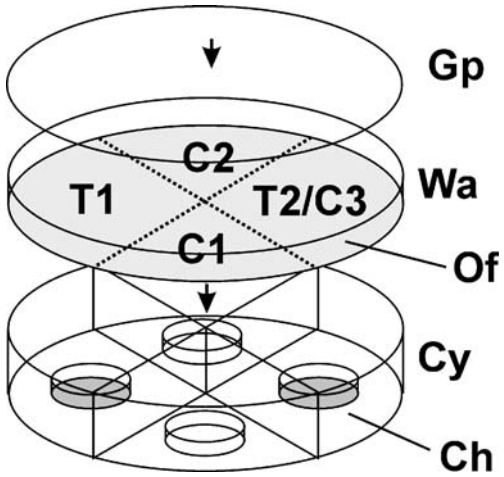

Fig. 1 Olfactometer for testing the response of wasps towards different odor sources. Height 5 cm, diam 19 cm. Abbreviations: Gp—glass plate; Wa—walking arena; Of—odor fields; Cy—cylinder; Ch—chambers; T1: test field above odor sample; C1 and C2: transition zones above empty Petri dishes; T2/C3: field opposite of T1 with odor sample in Petri-dish or with empty Petri dish

same batch were tested in one experiment, and several treatments (see below) were tested on the same day, with wasps randomly assigned to each treatment. The times that each wasp spent walking in the test and control fields of the walking arena were compared statistically by the Wilcoxon-matched pairs test by using the software package Statistica for Windows 6.0 (StatSoft Inc. 2003). All bioassays were performed with 1 to 2-d-old males (experiments 1, 3–10) or females (experiments 2, 11), which were freshly collected from rearing jars. The following samples and combinations of samples were tested:

Bioassays for Attractive Stimuli

1. To investigate the short-range response of males to cocoons, ten pupal cocoons of *C. tarsalis* (COC) were tested against the empty control (CON; *N*=25). Cocoons contained wasps 2 to 4 d before emergence.
2. To check for contamination of cocoons with larval feces, ten pupal cocoons of *C. tarsalis* (see above) were tested against the empty control. This experiment was performed with female wasps (*N*=20).
3. To test if males are arrested by feces of females hosts, 1 g rearing medium infested with *O. surinamensis*, including grain and host frass (IRM), was tested against 1 g uninfested rearing medium (URM; *N*=25).
4. To test if males are arrested by females hosts, ten 3rd-instar larvae of *O. surinamensis* (LAR) were tested against the empty control (*N*=25). To exclude contamination of host larvae with feces, the larvae were kept on filter paper for 6 hr before the experiments and were then transferred to another clean Petri dish.
5. To test if males are arrested by odors from the habitat of females hosts, ten mechanically damaged grains (MDG) were tested against empty controls (*N*=22). Mechanically damaged grains were obtained by crushing seeds with a coffee grinder.
6. To test for differences in arresting effect, five young virgin females (YVF) were tested against five old mated females (OMF; *N*=25).
7. To test if females leave male arresting residues while walking, filter paper (2.5×2.5 cm) on which ten young virgin females were allowed to walk for 15 min (FTY) was tested against filter paper on which ten old mated females had walked for the same time (FTO; *N*=25).

Bioassays for Identification of Attractive Substances Taking into account the low volatility of some of the substances and the distance of wasps from the odor source in the olfactometer, a twenty-fold higher concentration of substances was used in the bioassays than quantified from female residues (Table 1).

8. To test if fatty acids are responsible for the arresting effect of female residues on males, filter paper with a mixture of fatty acids (FAM; nonanoic acid 1.7 µg, tetradecanoic acid 6.4 µg, (*Z*)-9-hexadecenoic acid 2.9 µg, hexadecanoic acid 13.9 µg; values refer to the total amount of substance applied on filter paper in 10 µl dichloromethane) was tested against filter paper with 10 µl of dichloromethane (DCM; *N*=25).
9. To investigate if 1-tetradecene is the arresting compound, filter paper with 1-tetradecene (TDC; 24 ng total amount of substance dissolved in 10 µl of dichloromethane applied on filter paper) was tested against filter paper with 10 µl of dichloromethane (*N*=25).
10. To test if dodecanal is the arresting compound, filter paper with dodecanal (DOD; 28 ng total amount of substance dissolved in 10 µl dichloromethane applied on filter paper) was tested against filter paper with 10 µl of dichloromethane (*N*=25).
11. To test if dodecanal acts specifically on male, but not on female wasps, filter paper with dodecanal (28 ng total amount of substance dissolved in 10 µl dichloromethane applied on filter paper) was tested against filter paper with 10 µl of dichloromethane on female wasps (*N*=20).

Bioassays to Establish the Reaction Threshold To assess the reaction threshold of male *C. tarsalis* to dodecanal, either 9, 6, or 3 ng dissolved in 10 µl dichloromethane (test) and 10 µl dichloromethane (control) were applied on pieces of filter paper (2.5×2.5 cm). After solvent evaporation, the

Table 1 Compounds from residues of young virgin females on filter paper, which were absent or present in minor amounts in residues of old mated females

Number in chromatogram	Compound	Total amount released (ng/hr)
1	Nonanoic acid	87.1
2	1-Tetradecene	1.2
3	Dodecanal	1.4
4	Tetradecanoic acid	320
5	(*Z*)-9-Hexadecenoic acid	147.5
6	Hexadecanoic acid	695

filter papers were placed into a glass Petri dish and a male wasp was introduced into the Petri dish. The time of contact and the behavior of the wasp on test and control filter paper were recorded for 300 s and analyzed as described above (N=15).

Extracts To obtain extracts from female residues, pieces of filter paper (2.5×2.5 cm) were pre-cleaned by rinsing with dichloromethane. After solvent evaporation, either ten young virgin females (see above) or ten old mated females (see above) were allowed to walk on the filter paper for 1 h. Subsequently, filter papers were rinsed with 2 ml of dichloromethane. Extracts were concentrated to 500 µl in a water bath at 60°C. Before chemical analysis, each extract was checked for an arresting effect on males (N=7–10). Attractive extracts were further concentrated to 50 µl for chemical analyses (N=3).

To obtain extracts from cocoons, ten cocoons containing wasps 2 to 4 d prior to emergence were extracted in 1 ml of dichloromethane for 1 h. The extract was filtered and concentrated to 50 µl in a water bath at 60°C for chemical analyses (N=3).

Chemical Analyses Extracts were analyzed by coupled gas chromatography-mass spectrometry (GC-MS) employing a 6890 GC gas chromatograph linked to a 5973 N MSD (both Agilent Technologies, Santa Clara, CA, USA) in electron impact mode at 70 eV with helium as carrier gas (1.2 ml/min). Separations were done by using an HP-5MS column (30 m, 0.25 mm i.d., 0.25-µm film thickness; Agilent) that was operated at 60°C for 3 min, increased to 300°C at a rate of 3°C /min, and finally held at this temperature for 10 min. Both the injector and the transfer line between GC and MS were heated to 250°C. For identification, mass spectra and retention times of candidate peaks were compared to mass spectra and retention times of commercially available standard compounds.

Comparison of Substances from Old Mated and Young Virgin Females Extracts of trails from old mated females and young virgin females were compared to an extract of clean filter paper. Peaks occurring in the extract of clean filter paper were excluded from the analysis. Remaining peaks were compared semi quantitatively by using relative peak areas. Each peak analyzed in a sample was standardized by dividing its area by the total of analyzed areas in the sample with Primer 6 software package (Primer-E Ltd. 2006). Mean percentages of peak areas from old mated females were subtracted from mean percentages of peak areas from young virgin females. Peaks with mean peak area higher in extracts from young females were identified, and substances were tested in bioassays for arrestment. The threshold was set at 0.5% difference in relative peak area.

Quantification of Potential Semiochemicals To quantify substances from female residues on filter paper, 100 ng of synthetic substances were applied on pre-cleaned filter paper. After 1 h, substances were recovered by rinsing the filter paper with 1 ml dichloromethane and analyzed by GC-MS. Resulting peak areas were compared to peak areas obtained from female trails after females were allowed to walk on filter paper for 1 h (N=3). To assess the amount of dodecanal found on filter paper after the presence of single females within a shorter period of time, females were allowed to walk on filter paper for 15 min. The filter paper was analyzed and dodecanal was quantified as described above.

Chemicals Chemicals and solvents were purchased from Sigma-Aldrich (Munich, Germany) or Merck (Darmstadt, Germany) and were of highest purity available.

Results

Breeding experiments of *C. tarsalis* revealed an actual sex ratio of 1: 2.29 ± 1.09 (Mean ± s.d.; male: female) in our cultures. There was no correlation between sex ratio and host availability (Spearman rank r=0.00, N=15, P=1.0).

Silk cocoons of *C. tarsalis* containing wasps 2 to 4 d before emergence, which had developed in the absence of grains and host feces, had an arresting effect on male wasps (Fig. 2a). Female wasps, which were tested to control for the contamination of the cocoons with host feces, did not react to the cocoons (Fig. 2b). In addition, male wasps were

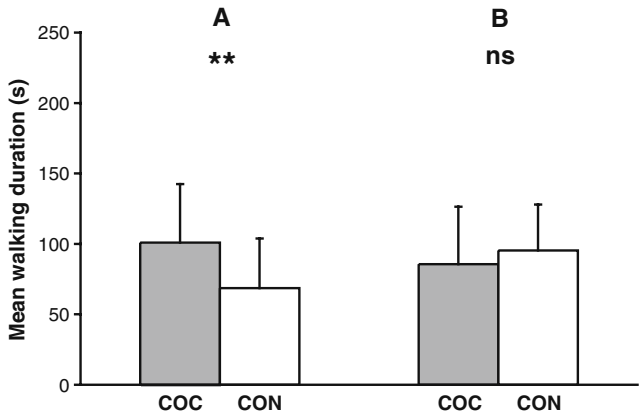

Fig. 2 Walking time (mean ± s.d.) of male (**a**) and female (**b**) *Cephalonomia tarsalis* in the odor field of an olfactometer with ten pupal cocoons of *C. tarsalis* and an empty control field. strongly arrested by the infested rearing medium of *O. surinamensis* and significantly preferred the respective olfactometer field to the field with uninfested rearing medium (Fig. 3a). Mechanically damaged grains (Fig. 3c) as well as larvae of *O. surinamensis* (Fig. 3b) showed no arresting effect on males of *C. tarsalis*. Therefore, host feces are the component in the grain-host-complex that induces arrestment.

Young virgin females had an arresting effect on males when old mated females were placed in the opposite olfactometer field (Fig. 4a). Similarly, filter paper that had been walked on by young virgin females was highly arresting when compared to filter paper that had been walked on by old mated females (Fig. 4b). Extracts of these filter papers with dichloromethane analyzed by GC-MS

revealed six compounds that occurred in higher amounts in extracts from young as compared to old females (Fig. 5, Table 1). Based on the comparison of mass spectra and retention times, these compounds were identified as four fatty acids (nonanoic acid, tetradecanoic acid, (*Z*)-9-hexadecenoic acid, and hexadecanoic acid), 1-tetradecene, and dodecanal. Neither a mixture of the four fatty acids

(Fig. 6a) nor 1-tetradecene (Fig. 6b) arrested male wasps in the olfactometer. In contrast, dodecanal significantly arrested males (Fig. 7a). Females did not react to dodecanal (Fig. 7b).

Experiments to quantify the amount of dodecanal on filter paper after female visits revealed that 15 min of contact by one female results in the deposition of about 3 ng dodecanal on the filter paper. Experiments where wasps had direct contact to dodecanal on filter paper demonstrated that 6 ng of dodecanal were sufficient to obtain a significant arrestment response in male *C. tarsalis*, whereas 3 ng did not elicit a significant reaction (Fig. 8). Dodecanal was present only in trace amounts in cocoons 2 to 4 d prior to wasp emergence.

Discussion

This study revealed that males of the parasitic wasp *C. tarsalis* are significantly arrested in the olfactometer by odors that originate from cocoons containing conspecifics up to a distance of several centimeters. This result supplements earlier studies that showed that males of *C. tarsalis* were arrested when in direct contact with cocoons (Howard 1998). It is likely that these odors emanating from cocoons are used for mate location. To test if feces contamination from the host larvae in the cocoons might be responsible for the arrestment, we also studied the response of female wasps to the cocoons. Earlier studies revealed that host feces have a strong arresting effect on females (Collatz and Steidle 2008). In these control experiments, females did not react to the cocoons. Thus, it is unlikely that the cocoons are contaminated with feces from the host larvae. To check if dodecanal (see below) might be responsible for the reaction of males to conspecific cocoons, cocoons were chemically analyzed. Dodecanal was found only in minimal trace amounts and, therefore, is likely not responsible for the attractiveness of cocoons. Thus, the identity of the behavioral chemical or chemicals that emanate from the cocoons bears further study.

In addition to female cocoons, males of *C. tarsalis* were arrested in the olfactometer by young virgin females as well as by filter paper that had been walked on by young virgin females. These young females likely release arresting volatiles, which are either absent or released in lesser amounts by old females. Because young virgin females were compared to old mated females, it remains unclear if mating status or age are responsible for the difference. However, males do not prefer virgin to mated females of the same age, and females mate several times within 24 h

after emergence (Cheng et al. 2004). Therefore, it is reasonable to assume that the difference is due to age rather then to mating status of the wasps.

Chemical analyses revealed several compounds that were present in larger amounts in the residues of young females on filter paper as compared to old females. Of these, only dodecanal had an arresting effect on male, but not on female wasps in the olfactometer. The amount of dodecanal released by a single female per 15 min was around 3 ng, and behavioral experiments revealed a reaction threshold by male *C. tarsalis* to dodecanal between 3 and 6 ng. Thus, considering analytical constraints due to the low amount of substance, the male reaction threshold is within the same range as the amount of dodecanal released by one female. Therefore, we suggest that dodecanal is a sex pheromone *sensu* Landolt and Phillips (1997), which acts specifically on the behavior of the opposite sex (males) and enables mate finding. It is unclear so far, if dodecanal is deposited on the ground as a trail pheromone or released in the air and subsequently adsorbed on the filter paper. According to its chemical nature, dodecanal would be suitable as a trail pheromone. Its volatility is low enough to remain on the substrate for a certain time but also high enough to form an odor-space above the substrate. Sexual trail pheromones are known from other parasitoid species, e.g., *Aphytis melinus* (Bernal and Luck 2007), *Trichogramma brassicae* (Pompanon et al. 1997), and *Aphelinus asychis* (Fauvergue et al. 1995). However, to our knowledge, none of the parasitoid trail pheromones has yet been identified.

Interestingly, substrate-borne semiochemicals are not only used by males of *C. tarsalis* for mate location, but by also by females for host finding. Chemical cues released by wandering host larvae of *O. surinamensis* arrest female wasps only for up to 30 min, thus adding a time-specific component to the host-finding process of *C. tarsalis* (Collatz and Steidle 2008). We hypothesize that a similar mechanism is involved with the female sex pheromone of *C. tarsalis*, especially when considering the tight agreement between reaction threshold and amount of pheromone released.

In addition to sex pheromones from cocoons and female residues, males of *C. tarsalis* also reacted positively to odors from feces of the host *O. surinamensis*. Odors from the host (in absence of feces) and from mechanically damaged grains (i.e., the host habitat) had no effect on male response. Because female *C. tarsalis* also use odors of host feces to locate their hosts (Collatz and Steidle 2008), these odors guide males to the female's oviposition site and thus agree with the definition of a sexual kairomone *sensu* Ruther et al. (2002). According to this definition, a sexual kairomone is composed of one or more allelochemicals, which are used by the benefiting organism for sexual purposes. The use of host kairomones in parasitoids for mate finding is known from several parasitoid species. For example, males of the parasitic wasp *Lariophagus distinguendus* use volatiles emitted by the larvae of its host, the granary weevil, *Sitophilus granarius* (Steiner et al. 2007). In the parasitoid *Venturia canescens*, female pheromones were three times more attractive to males when they were combined with host-related odors, whereas the latter were not attractive by themselves (Metzger 2008).

Taken together, males of *C. tarsalis* use semiochemical cues from different sources to locate females at different sites for mating. They use sex pheromones released by conspecific cocoons to locate sisters at the emergence site; they react to dodecanal, a female sex pheromone to locate females over some distance; and they use sexual kairomones from the feces of the host to find host-feeding and oviposition sites of females away from the emergence site. These findings support the hypothesis that in contrast to other bethylids, *C. tarsalis* is a species with partial local mate competition, with matings at the emergence site and matings after dispersal from the natal patch. This might explain the observed sex ratio of one male to 2.29 females in *C. tarsalis*, which is lower than the more female-biased sex ratios of other parasitic wasps, where local mate competition is more pronounced.

Acknowledgments We greatly appreciate the contribution of Kerstin Hacker and Wolfgang Spohn to part of the olfactometer experiments. This work was supported by the German Research Foundation Project number STE 841/6-1.

A Two-Component Female-Produced Pheromone of the Spider *Pholcus beijingensis*

Yonghong Xiao · Jianxu Zhang · Shuqiang Li

Received: 5 January 2009 / Revised: 27 May 2009 / Accepted: 17 June 2009 / Published online: 7 July 2009

Abstract Chemical signaling plays an important role in spider sexual communication, yet the chemistry of spider sex pheromones remains poorly understood. Unlike insects and mammals, the identification of spider pheromones has seldom been attempted, and no multicomponent pheromones have been found. Empty webs of sexually receptive females of *Pholcus beijingensis* were more attractive to male conspecifics as compared to webs of sexually unreceptive females or to mature males. Coincidently, chemical analysis revealed that (*E,E*)-farnesyl acetate, diisobutyl phthalate, and hexadecyl acetate of the spider webs exhibited higher relative abundances in sexually receptive females than in sexually unreceptive females or males, indicative of possible pheromone components. Two-choice behavioral assays verified that the blend of (*E,E*)-farnesyl acetate and hexadecyl acetate (w/w: 2:1) attracted males at a dosage equivalent to the amounts of these compounds in one spider web, whereas neither compound alone aroused males. In addition, diisobutyl phthalate (a likely contaminant from contact with plastic) alone or in combination with either of the acetates did not evoke the males' attraction. The behavioral data suggest that (*E,E*)-farnesyl acetate and hexadecyl acetate comprise a two-component female-produced sex pheromone in *P. beijingensis*, the first multicomponent pheromone found in spiders.

Introduction

Spiders generally are aggressive and cannibalistic. They have evolved elaborate means to communicate with each other during courtship. The exchange of chemical signals is probably the first type of communication in spiders that bring the males and females together (Weygoldt 1977). Chemical signaling plays an important role in spider sexual communication, and contact between the emitter and the receiver is not necessary (Gaskett 2007). Silk-bound pheromones are important in courtship. For example, in some species, a mate-searching male rapidly cuts the thread of a virgin female's web or packs the silk into a tight mass. This behavior may hinder evaporation of the sex pheromone thereby reducing the chances of another male reaching the web (Watson 1986; Schulz and Toft 1993). Male wolf spiders, *Schizocosa ocreata,* show significantly more and longer bouts of chemosensory and courtship behaviors on the silk of adult, unmated female spiders than on any other stimulus treatment (Roberts and Uetz 2005).

Silk-bound sex pheromones occur in several arachnid families (Dondale and Hegdekar 1973; Suter and Renkes 1982; Searcy et al. 1999; Michael and Maydianne 2004; Roberts and Uetz 2004, 2005). However, the chemistry of these remains poorly understood, especially in comparison with those of crustaceans and insects, and some mammals,

reptiles, and fishes. There are only three species of spiders for which pheromones have been identified. The pheromone compounds (*R*)-3-hydroxybutyric acid (HBA) and its dimer, (*R*)-3-[(*R*)-3- hydroxybutyryloxy]-butyric acid (HBBA), occur in a sheet-web spider *Linyphia triangularis* (Schulz and Toft 1993). The wandering spider, *Cupiennius salei*, and the orb-web spider, *Agelenopsis aperta*, have two other sex pheromones: (*S*)-1,1′-dimethyl citrate (Papke et al. 2000; Tichy et al. 2001) and 8-methyl-2-nonanone (Papke et al. 2001). Structurally unrelated to other known pheromones, both HBA and (*S*)-1,1′-dimethyl citrate seem to be unique to spiders. The pheromone 8-methyl-2-nonanone resembles a component of insects, that include the caddisfly, *Hesperophylax occidentalis,* and the Asian palm weevil, *Rhynchophorus ferrugineus* (Hallett et al. 1993; Bjostad et al. 1996). Herein, we explored the structure, function, and chemical mechanism(s) of sexual communication in spiders.

Pholcid spiders (Araneae, Pholcidae) often are found in houses and buildings, especially in basements and cellars. *Pholcus beijingensis* is common in various caves in the vicinity of Beijing. They usually spin untidy webs in corners or on the stone walls of cave entrances. Sexual selection occurs in pholcids (Uhl 1998; Uhl et al. 2005). The species is polygamous, and males and females alike have multiple mating partners. During the reproductive season, males abandon their webs to search for potential mates, while the females wait on their webs for males. The approach of a mature male rarely triggers predatory or aggressive behavior in sexually receptive females. In natural populations, immature and adult spiders overlap during much of the active breeding season (Chen and Li 2005; Chen et al. 2008). Selection may favor males that distinguish conspecific, sexually receptive females during the reproductive season, otherwise they would be eaten. We isolated chemical signals from the web thread of *P. beijingensis*, and identified the sex pheromone components.

Methods and Materials

Subjects

Juvenile and adult *P. beijingensis* were collected in March and May of 2007 at the entrance of a bat cave located southwest of Beijing, China (39º42.350′N, 115º42.825′E). Each spider was kept in a glass cuvette (4 cm i.d.×12 cm high) with a small moistened wad of cotton on the bottom to provide humidity. Cuvettes were put in a climatic chamber (RXZ-268B, Ningbo Jiangnan Instrument Factory) under a 14:10 h (L/D) photoperiod regime at 25°C (day) and 22°C (night). About 10–15 fruit flies (*Drosophila melanogaster*) were provided to each spider for food once a week.

Test for Attraction to Silk of Females

We screened the following classes of *P. beijingensis*: juveniles, sexually receptive females, egg-holding females, and mate-searching males. To determine whether the adults were reproductively active or not, we paired each male with an adult female on the female web, and checked for courtship behavior (Table 1). We removed the male from the web when it unfolded its pedipalps to the female. These sexually receptive females and males were chosen for the experiments. Egg-holding mothers were taken as sexually unreceptive females because they always held their egg sac with their chelicerae until the spiderlings hatched; generally, they remained sedentary and would not copulate with males during this phase. We randomly paired 30 females with 30 males until mating occurred. Thus, we also obtained gravid spiders.

We tested the hypotheses that the silk of sexually receptive females was attractive to mate-searching males by using a two-choice arena composed of three quadrates consisting of plastic chambers (upper dimensions: 16.5×11 cm; lower: 14.5×9 cm, height: 5.5 cm), each of which component was removable (Fig. 1). A hole was cut into one side of each choice chamber, and in both ends of the release chamber. A selecting male was released into the central chamber and could move freely into the left or right choice chamber.

We completed three sets of trials. The silk of sexually receptive females was presented in all sets, while either silk from juvenile spiders, silk from mate-searching males, or silk from egg-holding females was presented as the alternative choice. Male *P. beijingensis* were introduced into the central release chamber and allowed to acclimate to the surroundings for 1 h before the trials. The silk stimuli consisted of empty webs (no spider present) woven by test spiders. The order of treatments in the arena system was randomized. All male attraction tests were completed at night (usually from 20:00 to 22:00 h). We observed movement of the selecting males under infrared light, and recorded which chamber it first chose during a 2 h observation period. We deleted trials when a selecting male was disturbed and escaped into a choice chamber as soon as the choice arena system was connected. Each selecting male was used in only one trial of one test. A minimum of 15 males was tested in each trial set.

We also tested the attractiveness of extracts of silk from females. Pheromone from the silk of sexually receptive females was extracted with dichloromethane (5 µl for each web). A piece of filter paper containing the extract was placed in one of the choice chambers; the other choice chamber contained a filter-paper with an equal quantity of dichloromethane only. The choice chambers were occupied alternatively with the silk extract and the solvent only. Selecting males were allowed 2 h to discriminate between the silk extract and the solvent treatments.

Table 1 Sequence of courtship behavioral patterns displayed in the spider, *Pholcus beijingensis*

Behavior pattern	Description
Level 1	**Detection and location (♂)**
Pedipalps waggle	Shaking pedipalps up and down
Abdomen vibration	Shaking abdomen, usually immediately following pedipalps shaking
Adjust position	Picking up legs and shuffling body within same location
Search	Shoot jerky movements on web with frequent direction shifts and then turn towards the female
Level 2	**Signaling and approaching (♂)**
Flex	Slow or quick push on web with walking legs while raising body, followed by leg retraction with body lowering to make vibration of the web
Body tremor	High frequency dithering on the web to cause shoot and rapid quiver of the web during walk
Approach	Walk towards female spider with a few interruption for rubbing walking legs with his chelicerae
Pluck web	Short pull on silk threads with one of front legs alternatively in front of the female till she reacts (e.g. plucking back, adjusting direction) alternately, with rarely touching the female legs
Level 3	**Preparation and mate initiation (♂ & ♀)**
Leg spread	Male faces female from a distance of < 2 cm, with femurs of all walking legs spread backward in a line, forming a right angle with the web
Pedipalp unfolding	Male unfolds pedipalps up and forwards with abdomen cocked and legs spread backward, keeping this posture and waiting for approaching female
Contact	Female approaches male, both female and male contact each other with front part of cephalothorax or first pair of walking legs and frequently adjust body position
Mate initiation	Male clamps female's epigynum with his chelicerae and his two pedipalps inserts into the female's genital pore, at the same time female raises all her walking legs together to support her abdomen.

Levels refer to temporal stages within the courtship sequence from transition analysis of *Agelenopsis aperta* presented by Singer (Singer et al. 2000) and *Pholcus beijingensis* presented by Chen (Chen and Li 2005).

Silk Sample Collection and Extraction

Sexually receptive females, mate-searching males, and sexually unreceptive female spiders (egg-holding females) supplied silk samples. Square boxes made of cardboard (22 cm l.×22 cm w.×8.5 cm h.) were used for the spiders to weave webs. A glass Petri dish with cotton soaked in distilled water was set in each box to supply humidity. All boxes were cleaned with alcohol (99%) and air-dried before use. We released the spiders into the boxes individually.

Fig. 1 Two-choice arena system used in assessment of the attraction of the silk and the potential pheromones. The three chambers were upended and spliced with a hole on one or two sides. The selecting male was released in the central chamber and could move freely to the left or right choice chamber

After 48 h, the web silk was curled into a very small ball and put into a glass capillary (1.8 mm i.d.×3 cm l.), which had been fused at one end. The capillary containing silk was then sealed in a screw-cap vial (Agilent Technologies, USA). Compounds from each silk sample were extracted with 5 μl dichloromethane (purity > 99.5%, Beijing Fine Chemical Company, Ltd., Beijing, China) for 48 h. Following extraction, we removed the silk, and stored the remaining solution at −20°C until analysis by gas chromatography-mass spectrometry (GC-MS).

GC-MS Analysis

Analytical GC-MS was performed on an Agilent Technologies Network 6890N GC system coupled with 5973 Mass Selective Detector with the NIST/EPA/NIH Mass Spectral Library (2002 version; Agilent Technologies 2002). Chemstation software (Windows 2000) was used for data acquisition and processing. The GC was equipped with a 30 m HP5-MS capillary column (0.25 mm i.d.×0.25 μm film thickness). Helium was used as the carrier gas at a flow rate of 1.0 ml/min. The temperature of the injector was set at 280°C. One μl of sample was injected in the splitless mode. The oven temperature was programmed from 80°C to 240°C at 5°C/min. Then, the temperature was increased

by 10°C/min up to 280°C and held for 10 min. Electron impact ionization used 70 eV, and the scanning mass ranged from 30 to 450 amu. Compounds were identified tentatively by matching their gas chromatographic retention times and mass spectra with authentic analogs of the mass spectral library. (*E,E*)-Farnesyl acetate (FA, 95%; Sigma-Aldrich, Inc., St. Louis, MO, USA), diisobutyl phthalate (DIBP, 99.0%; Laboratories of Dr. Ehrenstorfer GmbH, Germany) and hexadecyl acetate (HA, 95%; Sigma-Aldrich, Inc., St. Louis, MO, USA) were used to confirm identification of unknown products after separation on a non-polar column (HP5-MS) and a polar column (HP-INNOWax, 30 m long, 0.25 mm i.d. × 0.25 μm film thickness).

Statistical Analysis

All statistical analyses were conducted using SPSS for Windows (version 15.0; SPSS Inc. 1999). We formed two hypotheses to test statistically. The first stated that no sexual dimorphism occurred in the relative abundances of crude extract compounds from webs. The second stated that there was no difference in the relative abundances of the compounds in the crude extracts from receptive females and sexually unreceptive females. To test the hypotheses, we measured the relative abundance of each compound by converting the peak area of a particular compound into a percentage of the sum peak areas from the 14 main GC peaks. If a given GC peak was too small to display the diagnostic MS ions, which rarely occurred, its area was taken as zero. Subsequently, the relative abundances of the compounds were analyzed by using either parametric tests, when the data were normally distributed, or non-parametric tests, when the data were not normally distributed. To analyze differences in the relative abundances of the compounds, we used Mann–Whitney *U* test for compound 8 when comparing differences between sexually receptive females and mate-searching males, and compound 14 in comparing differences between sexually receptive females and egg-holding females, which did not have normally distributed raw data. Other compounds were analyzed with an independent two-tailed *t* test when the raw data were normally distributed. The Chi-square test was used to analyze observed counts to the expected counts for male choice data.

Titer Analysis of Putative Pheromone Components

We determined the content of each putative pheromone component on a female's web. FA, HA, and DIBP each were diluted sequentially in dichloromethane to concentrations of 0.0001, 0.001, 0.01, 0.1, and 1 μg/μl. We injected 1 μl of each prepared solution into the GC-MS. GC detection showed that the peak areas of these compounds in female silk extract were close to those of the test samples at 0.01 μg/μl. Therefore, we injected 1, 2, 3, 4, and 5 μl of authentic sample at 0.01 μg/μl in GC to obtain the calibration regression equation. The quantity of each putative pheromone component on a female's web was calculated by comparing the peak area with that of the synthetic standard sample.

Test for Biological Activity of the Potential Pheromone Components

Bioassay of the potential pheromone components involved three steps. First, attractiveness of each compound to mate-

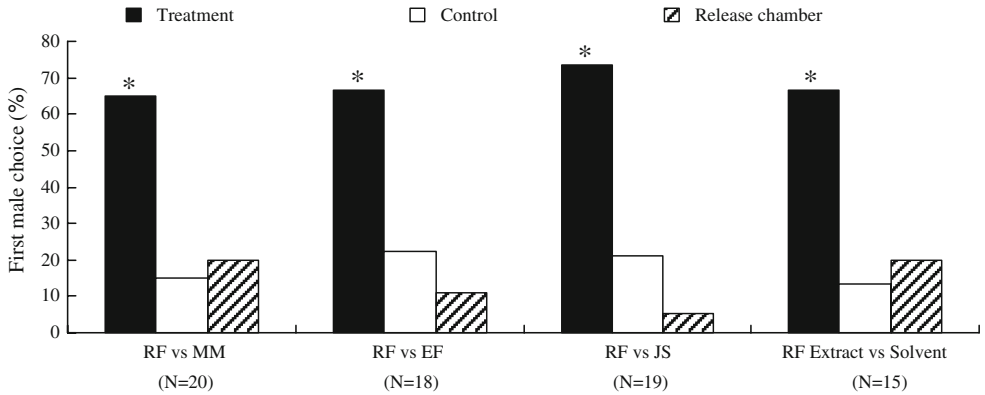

Fig. 2 Results of male *Pholcus beijingensis* attraction to sexually receptive female silk and the silk extract. Trials were completed in the two-choice arena system (Fig. 1). *RF* web of the sexually receptive female; *MM* web of the mate-searching male; *EF* web of the egg-holding female; *JS* web of the juvenile spider; *RF Extract* silk extract of the sexually receptive female; *Solvent* an equivalent amount of dichloromethane to the silk extract. The catalogue 'treatment' refers to sexually receptive female webs in all trials; 'Control' refers to webs of other spiders including mate-researching male, egg-holding female, and juvenile spider in corresponding trials; 'Release chamber' refers to males that within the 2 h observation period failed to leave the central arena into which they had been introduced 1 h before the start of the trial. * indicates $P < 0.05$

searching males was tested in the two-choice arena. Second, attractiveness of the tertiary blend involving FA, HA, and DIBP was tested. Third, we tested binary blends to check whether attractiveness to males was retained as follows: FA and DIBP; FA and HA; and HA and DIBP. The relative quantity of each component in all trials was equivalent to that naturally contained in a female's web.

Because the blend of FA and HA was significantly attractive to males, we diluted FA and HA in dichloromethane to concentrations of 0.001, 0.01, 0.1, and 1 μg/μl, and we used 10 μl FA and 5 μl HA of the series to determine the attractiveness of differing concentrations. An equivalent amount of dichloromethane was applied as the solvent control. We observed the movement of the males under infrared light for 2 h, and recorded which chamber they chose first.

We also determined whether the pheromone would elicit male courtship. We placed a filter-paper with the pheromone (10 μl FA and 5 μl HA at a concentration of 0.01 μg/μl) on an empty egg-holding female web, and then introduced a male. We observed each male for 2 h to detect whether the male displayed courtship signaling or not. We also observed male mate-searching behavior on empty webs produced by sexually receptive females.

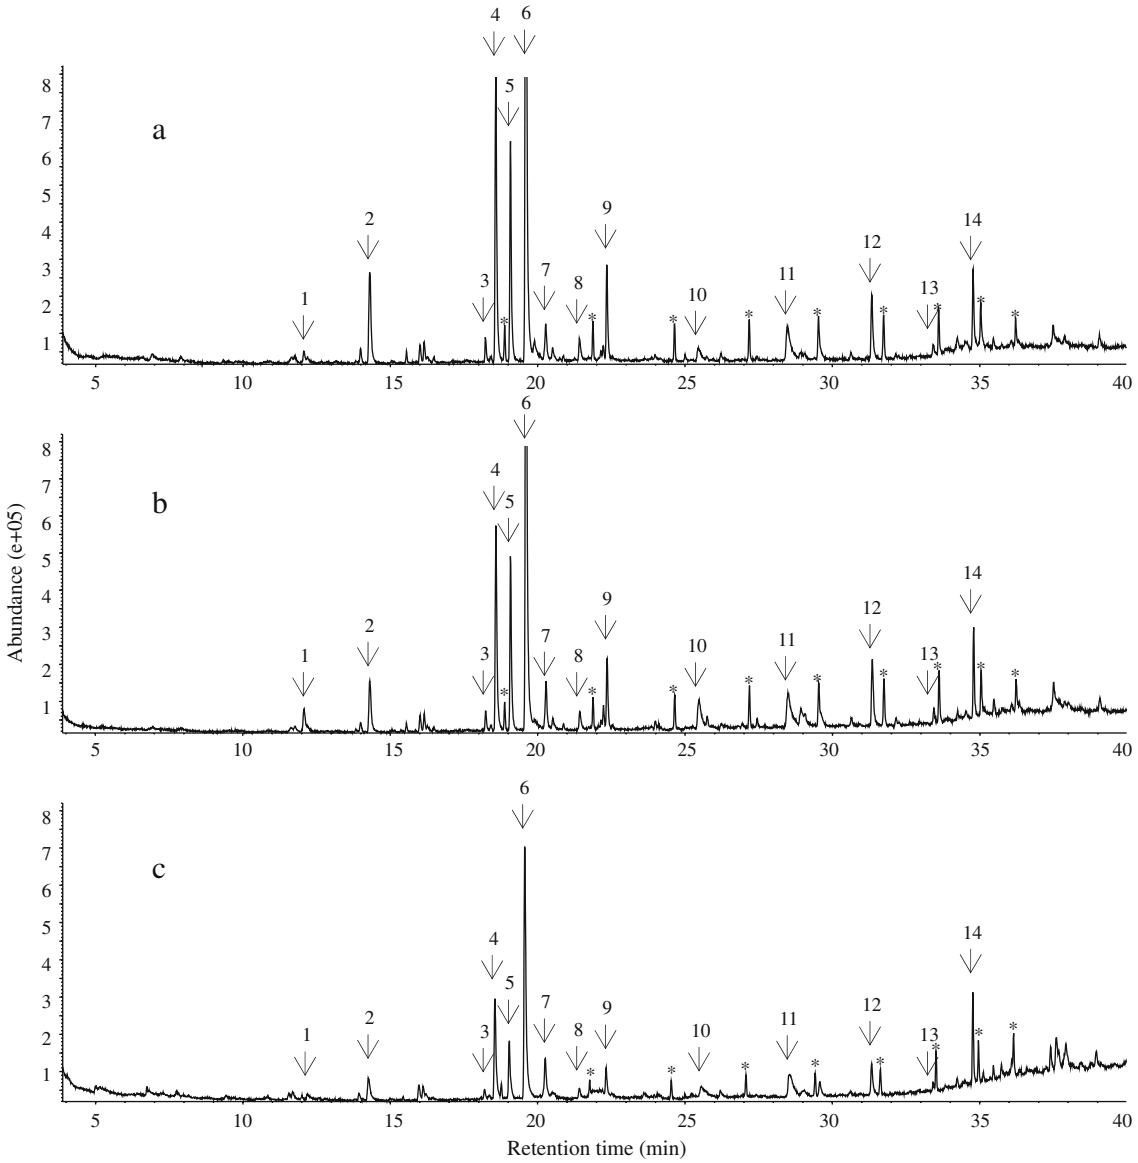

Fig. 3 Representative gas chromatograms of the crude extract of sexually receptive female silk **a**, mate-searching male silk **b** and egg-holding female **c**. The numbers that label the GC peaks correspond to peak numbers in Table 2. * denotes the Si-containing compounds that are regularly presented in the chromatograms. These silaceous compounds were not considered as potential pheromone components but contaminants from the GC column

Results

Male Attraction to Sexually Receptive Females' Silk and Silk Extract

The results of the two-choice arena trials are presented in Fig. 2. Adult male *P. beijingensis* were significantly attracted to webs produced by sexually receptive females (Chi-square test: X_1^2=6.250, P<0.05; X_1^2=4.000, P<0.05; X_1^2=5.556, P<0.05, respectively; Fig. 2). Dichloromethane extract of the silk from sexually receptive females also attracted mate-searching males (X_1^2=5.333, P<0.05; Fig. 2). The selecting males moved from the release chamber directly into the chamber previously occupied by sexually receptive females, and most males would stay on the empty females' webs until the next morning.

Identification of Potential Pheromone Components

More than 20 different compounds were regularly detected (some in low quantities) in silk samples of *P. beijingensis*, including some silaceous compounds. These were present in all samples and are considered most likely to be contaminants from the column; therefore, they were dismissed (Fig. 3).

We tentatively identified 14 compounds detected in the silk samples by matching GC retention times and mass spectra with analogs in the mass spectral library (Table 2). No qualitative differences were observed in chromatograph peaks among the silk extracts of the sexually receptive and egg-holding females and the mate-searching males. Egg-holding females usually spun less silk than sexually receptive females and mate-searching males. The total peak area detected from the silk extract of egg-holding females was less than those obtained from the other sample groups.

Quantitative analyses of relative abundances of the relevant compounds are presented in Table 2. Relative areas of peaks 5, 6, and 9 occurred in significantly greater proportions in silk extracts of the sexually receptive females than those of mate-searching males. These compounds also displayed significant differences between receptive females and egg-holding females, and they were less abundant in the silk extract of egg-holding females (Table 2). Therefore, they were considered as putative pheromone components of *P. beijingensis*. The mass spectra (Fig. 4) matched those of synthetic standards following separation with non-polar and polar columns. Thus, compounds 5, 6, and 9 were (*E,E*)-farnesyl acetate (FA), diisobutyl phthalate (DIBP), and hexadecyl acetate (HA), respectively.

RF Sexually receptive female; *MM* Mate-searching male; *EF* Egg-holding female

[a] Compounds were verified with synthetic standard samples after separation with a non-polar column and a polar column; other components were identified tentatively by comparison with spectra listed in the NIST (Agilent Technologies 2002) mass spectral library and analogous data except for the unidentified compounds, whose mass spectra has low matching degree with those suggested by the MS library (NIST 2002)

[b] *P* values were tested by using Mann–Whitney U test; others were tested by using independent *T* test

[c] Relative abundances of these components in silk extract of sexually receptive females was significantly more than those in silk extracts of mate-searching males and egg-holding females

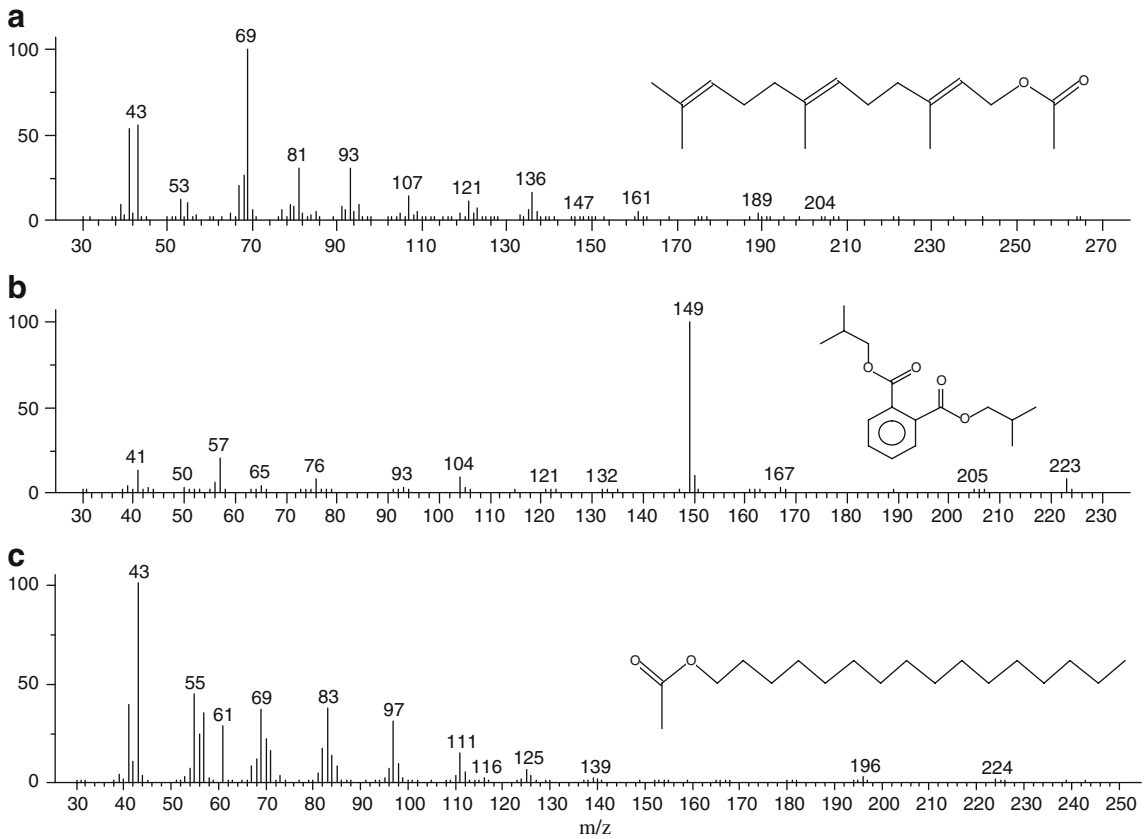

Fig. 4 Mass spectra of **a** compound 5, **b** compound 6, and **c** compound 9 of the silk sample. They were identified as (*E,E*)-farnesyl acetate, diisobutyl phthalate, and hexadecyl acetate, respectively, by comparing retention times and mass spectra with those of the authentic standards

Titer Analysis of the Putative Pheromone Components

The quantities of FA and HA on female webs (N=8) was determined by external regression analysis of concentration ranges for synthetic standards of these compounds. Sexually receptive females produce about 0.052 and 0.025 μg/web of FA and HA, respectively.

Biological Activity of the Potential Pheromones

Bioassay results showed that male *P. beijingensis* displayed no choice for a particular chamber in the trials involving the single compounds FA, DIBP, or HA (X_1^2=0.529, P>0.05; X_1^2=0.222, P>0.05; X_1^2=0.474, P>0.05, respectively; Fig. 5). However, when we combined the three compounds, the tertiary blend of FA, HA, and DIBP was attractive to selecting males (X_1^2=4.263, P<0.05; Fig. 5). The binary blend of FA and HA also showed significant attraction to males (X_1^2=4.000, P<0.05; Fig. 5), while the other two binary blends did not attract males (X_1^2=0.053, P>0.05; X_1^2=0.818, P>0.05) ; Fig. 5). Whereas FA and HA were required to attract males, DIBP was not, even if it occurred in a large amount in the silk. As the silk samples were collected from the cardboard boxes with a slice of plastic paper filmed in the inner wall, we cut down a small chip of the plastic paper (3×3 mm) and extracted it with dichloromethane. GC-MS detection result showed that the phthalate compounds including diisobutyl phthalate, dibutyl phthalate, and diisooctyl phthalate were presented in the extraction. Therefore, the phthalates must be contaminants introduced on the webs by the spiders coming in contact with the plastic.

Attractiveness of the binary blend of FA and HA in different concentrations was tested (Fig. 6). Male *P. beijingensis* significantly preferred the chamber containing FA and HA at concentrations of 0.01 and 0.1 μg/μl (X_1^2= 4.571, P<0.05; X_1^2=7.118, P<0.05, respectively; Fig. 6). Males showed no significant choice between the treatment chamber and control chamber in the trials involving the binary blend at concentration of 0.001 μg/μl and the highest concentration of 1 μg/μl (X_1^2=1.143, P>0.05; X_1^2=2.579, P>0.05; Fig. 6).

Most males displayed exploratory behavior (Table 1, Level 1) but no males displayed courtship signaling (Table 1, Levels 2 and 3) when presented with pheromone solutions on filter-paper on the webs made by egg-holding females. Likewise, only searching behavior, and no courtship signaling, was exhibited by males on the webs produced by sexually

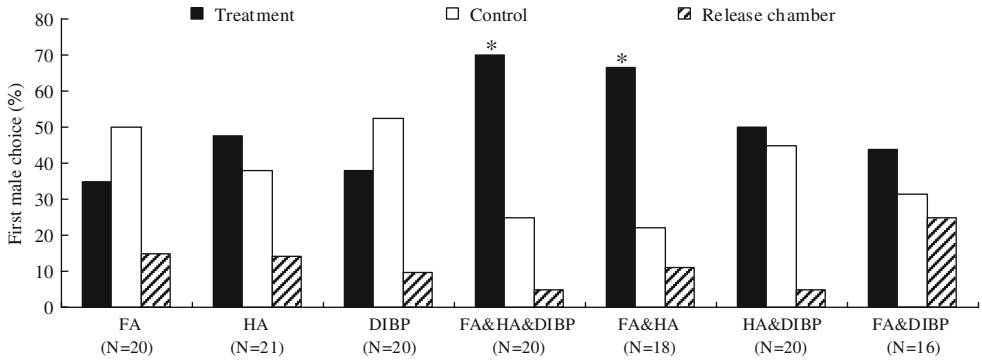

Fig. 5 Results of the attractiveness for male *Pholcus beijingensis* to single putative pheromone component and the blends. Trials were completed in the two-choice arena system (Fig. 1). Dosage of the chemicals applied in the treatments was equal to those obtained from one female web. 'Control' means equal quantity dichloromethane to corresponding applied chemicals. 'Release chamber' refers to males that within the 2 h observation period failed to leave the central chamber into which they had been introduced 1 h before the start of the trial. * indicates $P < 0.05$

receptive females. Male *P. beijingensis* initiated signaling only when a sexually receptive female was on the web.

Discussion

The sex pheromone of *P. beijingensis* consists of a 2:1 ratio of (*E,E*)-farnesyl acetate (FA) and hexadecyl acetate (HA), deposited on the web by sexually receptive females. By triggering male searching behavior, the pheromone plays an important role in guiding males to females' webs. Male *P. beijingensis* showed no attraction response to either FA or HA alone. Although both females and males of *P. beijingensis* can emit the pheromone, sexually receptive females release much more than males. FA is relatively abundant on the female's silk, averaging 0.052 μg per web, while HA averages 0.025 μg per web. Mixtures of FA and HA at or below 0.01 μg and 0.005 μg, respectively, failed to attract selecting males. Thus, male *P. beijingensis* have an 'olfactory detection threshold' for finding potential mates. Pheromone in a slightly higher concentration than that generally found on the web of a sexually receptive female attracted males and stimulated mate-searching behavior (Fig. 6). However, males were not attracted when the pheromone dosage was much higher than that of a sexually receptive female's web.

In other species of spiders, however, single pheromone compounds bound to the silk act as sex attractants (Papke et al. 2000, 2001; Tichy et al. 2001). The first reported spider sex pheromone, that of *Linyphia triangularis*, comprised two compounds, (*R*)-3-hydroxybutyric acid (HBA) and (*R*)-3-[(*R*)-3-hydroxybutyryloxy]-butyric acid (HBBA), and either compound alone could trigger the web reduction behavior of males. The dimer (HBBA) and the monomer (HBA) are relatively unstable compounds, such that HBBA slowly disintegrates into the monomer, HBA. Thus, HBBA

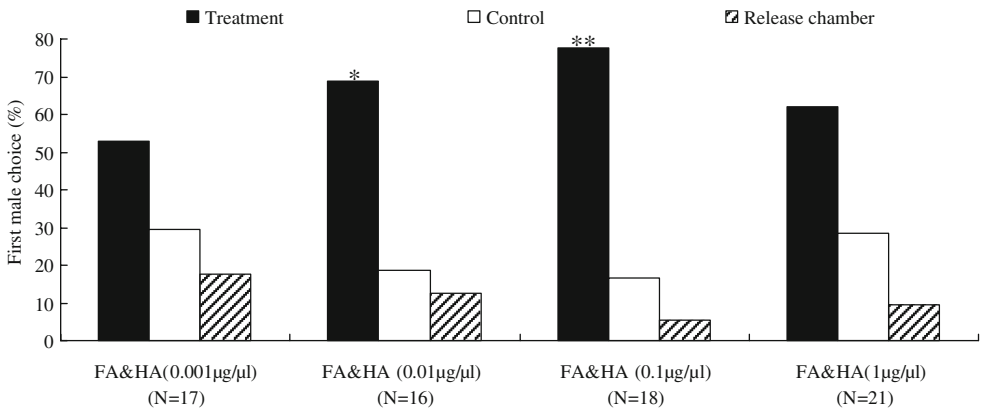

Fig. 6 Results of the attractiveness for male *Pholcus beijingensis* to four concentrations of the two-component blend and each component of the blend. Trials were completed in the two-choice arena system. FA is (*E,E*)-farnesyl acetate and HA is hexadecyl acetate. The category 'treatment' refers to one of the stepwise concentrations of the binary blend. 'Control' refers to equivalent dichloromethane to treatment. 'Release chamber' refers to males that within the 2 h observation period failed to leave the central arena into which they had been introduced 1 h prior to the start of the trial. * indicates $P < 0.05$. ** indicates $P < 0.01$

may be the precursor of HBA (Schulz and Toft 1993). (*R*)-HBA occurs in three closely related genera of spiders: *Linyphia*, *Microlinyphia*, and *Neriene* (Schulz and Toft 1993).

The major pheromone component of *P. beijingensis* (FA), was identified previously as a sex pheromone component of the click beetle, *Agriotes proximus* (Coleoptera: Elateridae) (Yatsynin et al. 1980, 1996). This compound also was reported from male Scandinavian bumblebees, *Bombus pratorum* (Bergman and Bergström 1997), the rock honeybee *Apis dorsata* (Blum et al. 2000), and the stingless bee *Melipona beecheii* (Cruz-López et al. 2005). Recently, FA was described as a sex pheromone component in the preputial gland of male Brandt's voles, *Lasiopodomys brandtii*, where it attracts females (Zhang et al. 2007b). HA also was described as a pheromone component in voles (Brinck and Hoffmeyer 1984; Welsh et al. 1988; Zhang et al. 2007a). Straight-chain acetates usually containing 12–18 carbons are common pheromone components in other insects (Roelofs 1995; Byers 2002).

Most insect sex pheromones are blends of chemicals that consist of a number of different components, and they function only when combined in a particular ratio (Wyatt 2003). Multicomponent pheromones also occur in vertebrates, such as goldfish, mice and other mammals; here too, individual components of the blend usually are inactive (Novotny et al. 1999; Sorensen and Stacey 1999). It is not uncommon that some pheromone components are used by several, distantly related species. The Asian elephant, *Elephas maximus*, shares its female sex pheromone with 140 species of moth (Rasmussen et al. 1996). Zhang et al. (2007b) reported that most of the castration-suppressed compounds in preputial gland secretions of male Brandt's voles were described previously as pheromone components of insects. The sex pheromone compounds from the spider *L. triangularis* (HBA and its dimer HBBA) also have been found in an ascomycete fungus, *Hypoxylon truncatum* (Quang et al. 2003). The coincidence of pheromone components among different species illustrates not only the ubiquity of pheromones, but also their biochemical convergence (Wyatt 2003).

Acknowledgments The manuscript benefited greatly from comments by Jeffrey R. Aldrich (USDA-ARS Research Entomologist, USA), Robert W. Murphy (University of Toronto, Canada) and two anonymous referees. Response of *Mythimna unipuncta* Males to Components of the *Sesamia nonagrioides* Pheromone

Matilde Eizaguirre · Carmen López · Albert Sans · Dolors Bosch · Ramon Albajes

Received: 28 May 2008 / Revised: 23 January 2009 / Accepted: 22 June 2009 / Published online: 12 July 2009

Abstract Several sympatric lepidopteran species feed on maize plants, and the different components of their species-specific female sex pheromones may play a role in attracting conspecifics and/or deter heterospecific males. In this study, we analyzed the content of *Mythimna unipuncta* pheromone glands and tested the response of males to components of their own pheromone blend and that of *Sesamia nonagrioides* in the wind tunnel. Whole pheromone glands, and lures where (Z)-9-hexadecenyl acetate, Z)-11-hexadecen-1-ol or (Z)-9-hexadecenyl acetate + (Z)-11-hexadecen-1-ol were added to the major component, (Z)-11-hexadecenyl acetate, elicited significantly higher responses by *M. unipuncta* males than lures with main component alone, although the levels varied with concentration. In the field a rather different outcome was observed, as the addition of other compounds found in the female pheromone gland did not improve trap catch over lures with only (*Z*)-11-hexadecenyl acetate. The addition of (*Z*)-11-hexadecenal, a compound of the *S. nonagrioides* pheromone, to (*Z*)-11-hexadecenyl acetate significantly reduced attraction of *M. unipuncta* males both in the wind tunnel and in the field, as well as the number of sympatric clover cutworm, *Discestra trifolii*, under field conditions. The addition of (Z)-9-hexadecenyl acetate, a minor component of the *M. unipuncta* pheromone blend, reduced the number of *S. nonagrioides* captured in field traps that were baited with the *S. nonagrioides* lure. The significance of such inhibition in the reproductive isolation of sympatric species that attack maize is discussed.

Introduction

Pheromone mediated mating is common in insects, especially in nocturnal Lepidoptera. Species-specific pheromone blends not only facilitate mate location by conspecifics, but may also inhibit responses by heterospecific adults, serving as a reproductive isolating mechanism and reducing costly mating mistakes. However, such effects on heterospecific males have been reported, not only by closely related species with common components in the respective female sex pheromone blends, but also between taxonomically distant species with totally different pheromones. For example, Eizaguirre et al. (2007) found that the two principal components of the European corn borer (ECB), *Ostrinia nubilalis* pheromone inhibited the response of the *Sesamia nonagrioides* males to their conspecific pheromone. Similarly, when one component of the *S. nonagrioides* pheromone was added to the corn borer pheromone, it inhibited the response of ECB males. They hypothesized that this form of inhibition either could play a role in interspecific competition or be part of reproductive isolation mechanisms that involve a third species that is sympatric with the other two (Greenfield 2002).

In previous field studies (Albajes et al. 1988), traps baited with *S. nonagrioides* lures or virgin females attracted males of the sympatric noctuid, *Mythimna unipuncta*, a species that shares two common pheromone components with *S. nonagrioides* (Steck et al. 1980, 1982; Streng et al. 1985). Furthermore, the addition of ECB pheromone to the *S. nonagrioides* lure inhibited the responses of both *S.*

nonagrioides and *M. unipuncta* males (Eizaguirre et al. 2002). We, therefore, undertook both laboratory and field studies to determine the response of *M. unipuncta* males to lures that contain their own pheromone alone and when mixed different components of *S. nonagrioides* sex pheromone.

Methods and Materials

Mythimna unipuncta eggs were obtained from field collected females, and the resulting larvae were reared individually at 25°C, 16 L8 h D, 60% RH on an artificial diet (Shorey and Hale 1965). Pupae were sexed and then stored at 8°C until required. For the different experiments, male and female pupae were reared in two separate incubators at 21°C, 16 L8 h D, 60% RH, and the adults emerging each day were held in cages with a supply of 10% sucrose solution.

Identification of Female Sex Pheromone Samples of female *M. unipuncta* sex pheromone were obtained by gently extruding the glands and wiping the surfaces for 25 min with an SPME fibre (100 mm polydimethylsiloxane, Supelco), as described by Frerot et al. (1997). Each sample, taken from two to five individuals, was collected during the scotophase, using only females that were exhibiting calling behavior. The samples were analysed on a DB-Wax capillary column (30 m×0.25 mm ID×0.25 mm film thickness)(J & W Scientific, CA, USA) with an Agilent Technologies 6890 N gas chromatograph in splitless injection mode (45 s) coupled to an Agilent Technologies 5973 N mass spectrometer. The injector temperature was set at 250°C, and the GC oven temperature was programmed from 100°C (1 min) to 225°C at 5°C/min and then held at this temperature for 10 min. The SPME fibre was desorbed into the injector for 5 min. The pheromone components were subsequently identified by comparing retention times and fragmentation patterns with those of synthetic standards: [(*Z*)-11-hexadecenyl acetate, (*Z*)-11-hexadecen-1-ol, (*Z*)-11-hexadecenal, dodecyl acetate, (*Z*)-9-hexadecenyl acetate, and hexadecyl acetate] purchased from SEDQ SA (Barcelona, Spain). All were found to be >96% isomerically pure by GC analysis. The N-hexane used, purchased from Acros Organics (Geel, Belgium), was of pesticide residue grade.

Male Responses in a Wind Tunnel Assays were carried out in a laminar flow wind tunnel (Gemeno et al. 2006) at 21± 1°C, 50% RH and a wind velocity of 0.2 m/s during the 3–5th h of the scotophase (the peak response period, unpublished data). The tunnel was illuminated with a fluorescent red light resulting in a 1.8 and 1.5 lux intensity at the ceiling and floor, respectively.

Two series of assays were done by testing various combinations of the compounds identified in *M. unipuncta* female pheromone glands, and those from the *S. nonagrioides* pheromone blend. All compounds tested in the assays (see Table 1) were applied to cardboard female mimics, previously washed with hexane, suspended from the center of the ceiling at the upwind end of the tunnel. When the natural pheromone sources were tested, glands from two calling females were excised and immediately placed on the mimic to be tested. Individual males were released 1.4 m downwind of the pheromone source to be tested, and were observed for a maximum of 5 min, with the following behaviors being recorded: taking flight (TF), oriented upwind flight (ZZ), and contacting the source (CT). The proportion of males any given behavior was calculated by using only those individuals that completed the previous step and not the total number used in a given assay. Five to ten males were flown to any given source during an assay, with a total of 30–40 males tested to each source during the entire experiment. Males varied in age from 3–6 days-old, with each individual being tested only once.

Field Trials Trials were carried out in the Lleida region of Spain (utm-31n, *X*=291035 *Y*=4620587) from July 26 to October 11 in 2006 and July 18 to November 7 in 2007, using a randomised block design, with blocks being separated by >300 m. Econnex®-type universal moth traps, with dichlorvos to kill the captured insects, were hung on 1.5-m-high wooden stakes, placed 20 m apart within each block. The compounds tested (see Table 1) were applied to rubber septa (Sigma-Aldrich Química, S. A.) that had previously been washed with hexane for 1 h, and attached with wire from the ceiling of the trap. Lures were not replaced during the trapping period. The number of *M. unipuncta*, *S. nonagrioides*, *O. nubilalis*, and *Discestra. trifolii* (a noctuid that feeds on alfalfa and is usually caught in traps baited with *S. nonagrioides* pheromone) males were recorded weekly.

Statistical Analyses There were no differences in the proportion of males taking flight when exposed to the different lures, so only the percentages of males that exhibited oriented flight (ZZ) and contacted the lure (CT) were compared. Furthermore, as there was no effect of age on male response to any given lure, the behaviors of all males for any given treatment were pooled before analyses by using the normal approximation of the binomial tests.

Trap catch data were transformed (square root [x+0.5]) and then analyzed with a split-split-plot-like model (Gomez and Gomez 1984), and the means compared by using LSD. Statgraphics (1997) was used for all analyses.

Results

Five different components were found in the gland extracts (Fig. 1), that by comparison with the retention times and MS fragmentation patterns of synthetic standards, were identified in order of relative quantities as (*Z*)-11-hexadecenyl acetate (100%), hexadecyl acetate (15–20%), (*Z*)-11-hexadecen-1-ol (2–3%), (*Z*)-9-hexadecenyl acetate (1%), and hexadecenol (1%). The sixth peak (marked with * in Fig. 1) is probably an impurity, as its mass spectra did not match any typical pheromonal component of Lepidoptera, and according to the NBS75K mass spectra library (from NIST), the best match (83%) was for glycerine.

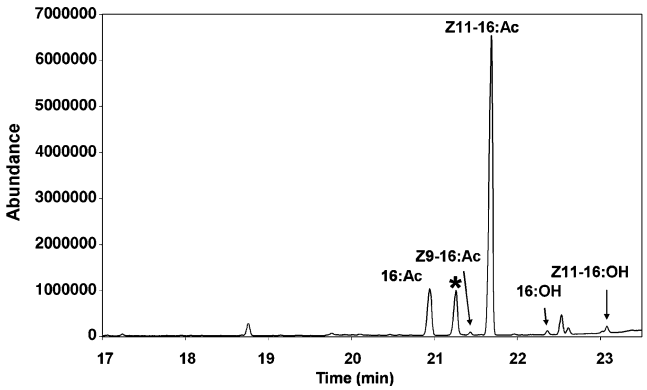

Fig. 1 Chromatogram obtained from an SPME wipe of 3 pheromone glands from 3- to 4-day-old calling *Mythimna unipuncta* females during the 4–5 h of the scotophase. The peak marked with an * is probably an impurity

The proportion of males taking flight was the same for all treatments (χ^2 test, $P=0.507$), so clearly none of the compounds tested in any of the wind tunnel assays inhibited flight behavior. Consequently, only the proportions of males that exhibited upwind flight and reached the source were considered.

In the first series of assays that tested the pheromone glands of both *S. nonagrioides* and *M. unipuncta* pheromone glands, as well as various combinations of synthetic blends, (*Z*)-11-hexadecenyl acetate + (*Z*)-11-hexadecenal, the *Sesamia* pheromone, (*Z*)-9-hexadecenyl acetate, or control mock females did not elicit any upwind flight by *M. unipuncta* males (data not shown). The highest responses of *M. unipuncta* males that oriented by flying upwind and reaching the source were observed with the conspecific female pheromone gland. The addition of either (*Z*)-9-hexadecenyl acetate or (*Z*)-11-hexadecen-1-ol to (*Z*)-11-hexadecenyl acetate resulted in a significantly higher proportions of males exhibiting upwind flight compared to the major pheromone component alone (Fig. 2), but only the presence of (*Z*)-9-hexadecenyl acetate resulted in a significant increase in the proportion contacting the source. Very few *M. unipuncta* males exhibited oriented flight, and none touched the source

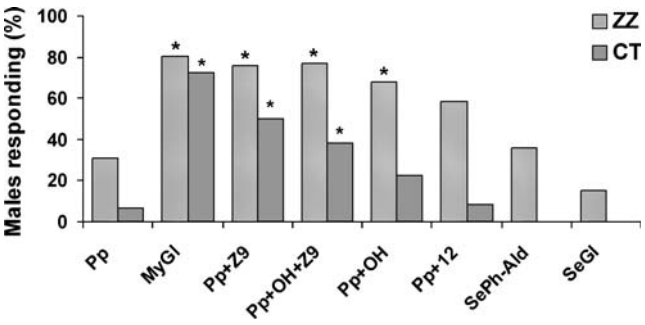

Fig. 2 Percent of *Mythimna unipuncta* males flying upwind in a zig-zag (ZZ) and contacting the source (CT) to different compounds embedded in a mock female in the wind tunnel. MyGl indicates two *M. unipuncta* female glands; Pp is 0.1 μg of the major *M. unipuncta* pheromone component (*Z*)-11-hexadecenyl acetate, while Pp+OH, 12, or Z9 indicate the addition (*Z*)-11-hexadecen-1-ol, dodecyl acetate or (*Z*)-9-hexadecenyl acetate (5% and 1%, respectively). SeGl indicates two *Sesamia nonagrioides* female glands while SePh-Ald indicates the commercial pheromone blend for *S. nonagrioides* without (*Z*)-11-hexadecenal;. Columns with * indicate significantly different response in comparison with the major component alone ($P<0.05$)

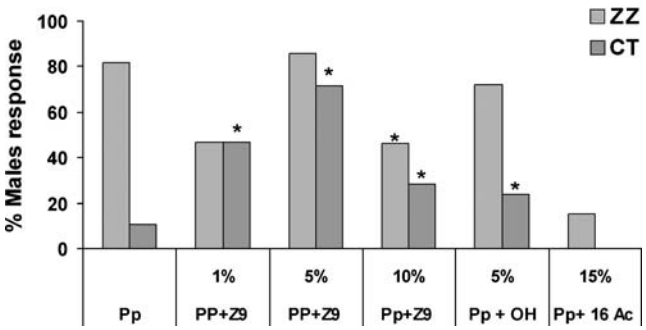

Fig. 3 Percent of *Mythimna unipuncta* males flying upwind in a zig-zag (ZZ) and contacting the source (CT) to different compounds embedded in a mock female in the wind tunnel. Pp is 0.1 μg of the major *M. unipuncta* pheromone component (*Z*)-11-hexadecenyl acetate, while Pp + Z9, OH, or16 indicate the addition of (*Z*)-9-hexadecyl acetate, (*Z*)-11-hexadecen-1-ol, or hexadecyl acetate to the major component, in the proportions shown. Columns with * indicate significantly different response in comparison with the major component alone ($P<0.05$)

when exposed to models with *S. nonagrioides* pheromone glands or to this species' synthetic blend, even when (*Z*)-11-hexadecenal was not included.

In the second set of assays, males exhibited no upwind flight when the major component, (*Z*)-11-hexadecenyl acetate, was combined with 10% of either (*Z*)-11-hexadecen-1-ol or hexadecyl acetate found in *M. unipuncta* pheromone glands, or with 1% or 5% (*Z*)-11-hexadecenal found only in the *S. nonnagrioides* pheromone blend (data not shown). However, for the other combinations, there were significant differences in both the proportions that exhibited upwind flight and contacted the source (Fig. 3). The proportion of males exhibiting upwind flight to the major component alone, was much higher than in the first series of assays (Fig. 2). The combinations of (*Z*)-11-hexadecenyl acetate with 1% and 5% (*Z*)-9-hexadecenyl acetate elicited the highest responses, although the addition of 10% (*Z*)-9-hexadecenyl acetate or 5% (*Z*)-11-hexadecen-1-ol still resulted in significantly more males reaching the source than with (*Z*)-11-hexadecenyl acetate alone. The addition of 15% hexadecenyl resulted in fewer males showing an upwind flight response, and none reached the source.

Field Trials In contrast to the wind tunnel results, the addition of different components identified from the pheromone gland of *M. unipuncta* did not increase trap catch, when compared to lures that contained just the major component, (*Z*)-11-hexadecenyl acetate. In fact, the addition of (*Z*)-11-hexadecen-1-ol resulted in significantly lower numbers of males being caught (Fig. 4). While the addition of (*Z*)-11-hexadecenal, one of the two components of the *S. nonagrioides* pheromone not found in the *M. unipuncta* gland, significantly reduced trap catches, the other, dodecyl acetate, had no effect (Fig. 4).

The pheromone blend identified by Sans et al. (1997) was the most attractive to *S. nonagrioides* males. Captures were low with (*Z*)-11-hexadecenyl acetate alone and while the addition of (*Z*)-11-hexadecenal did significantly increase the number of males captured, the addition of either (*Z*)-11-hexadecen-1-ol, (*Z*)-9-hexadecenyl acetate, or dodecyl acetate did not (Fig. 5). The addition of (*Z*)-9-hexadecenyl acetate, found only in the glands of *M.*

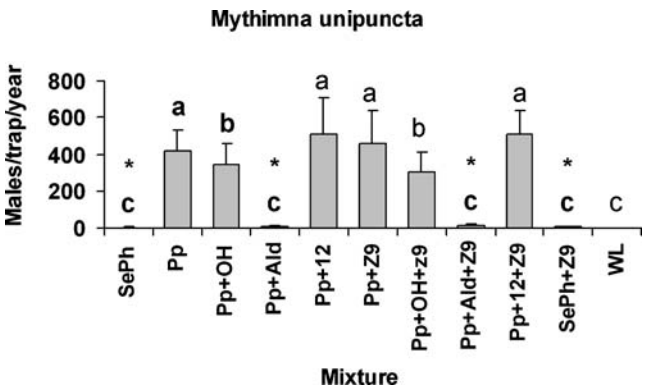

Fig. 4 Number of males (+S.E.) of *Mythimna unipuncta* caught per trap per year. All lures except WL contained (*Z*)-11-hexadecenyl acetate, the major pheromone component of *M. unipuncta* and *Sesamia nonagrioides*. Pp represents 100 μg of (*Z*)-11-hexadecenyl acetate, while Pp + OH, Ald or 12 indicate the addition of (*Z*)-11-hexadecen-1-ol, (*Z*)-11-hexadecenal, or dodecyl acetate (5 μg), respectively. Z9 indicates the addition of 1 μg of (*Z*)-9-hexadecenyl acetate, SePh is the complete pheromone of *S. nonagriodes* (Sans et al. 1997), and WL indicates empty traps. Catches in traps where the lures contained (*Z*)-11-hexadecenal are marked with an asterisk. Different letters on the top of bars indicate significant differences in the numbers of males captured

unipuncta, to the complete *S. nonagrioides* blend resulted in a significantly lower trap catch compared with the complete blend alone (Fig. 5).

The lures that contained various components of *M. unipuncta* pheromone were all equally attractive to *D. trifolii* males (Fig. 6) but, as observed in *M. unipuncta* (Fig. 4), the addition of (*Z*)-11-hexadecenal caused a decrease in the number of males caught.

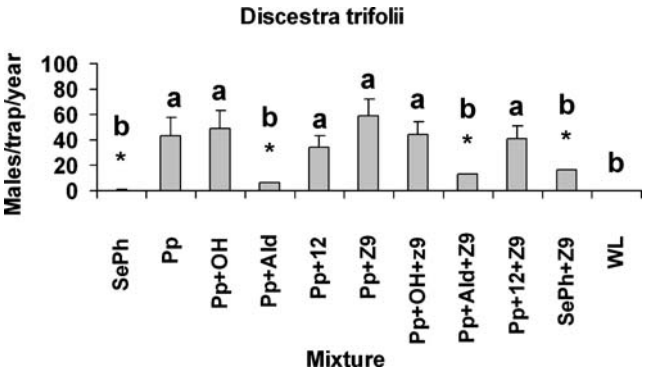

Fig. 6 Number of males (+ S.E.) of *Discestra trifolii* caught per trap per year. All lures except WL contained (*Z*)-11-hexadecenyl acetate, the major pheromone component of *Mythimna unipuncta* and *Sesamia nonagrioides*. Pp represents 100 µg of (*Z*)-11-hexadecenyl acetate, while Pp + OH, Ald, or 12 indicate the addition of (*Z*)-11-hexadecen-1-ol, (*Z*)-11-hexadecenal, or dodecyl acetate (5 µg), respectively. Z9 indicates the addition of 1 µg of (*Z*)-9-hexadecenyl acetate. SePh is the complete pheromone of *S. nonagriodes* (Sans et al. 1997), and WL indicates empty traps. Catches in traps where the lures contained (*Z*)-11-hexadecenal are marked with an asterisk. Different letters on the top of bars indicate significant differences in the number of males captured

Discussion

To date, five compounds have been identified from the pheromone glands of *M. unipuncta* (McDonough et al. 1980; Steck et al. 1980, 1982; Farine et al. 1981; Kamm et al. 1982). However, based on a number of different studies, only the major component (Z)-11-hexadecenyl acetate and (Z)-11-hexadecen-1-ol appear to play a major role in attracting males to lures. Even the role of (Z)-11-hexadecen-1-ol is somewhat unclear; while its addition to the main component did increase the number of males contacting the source in our wind tunnel experiments and has increased trap catches in some field studies (Steck et al. 1980; Turgeon et al. 1983), in others it did not (Farine et al. 1981; Kamm et al. 1982, this study). As noted by Turgeon et al. (1983), there are a number of non-mutually exclusive reasons for this apparent contradiction, including trap type, the height of the traps, the cropping system, and the position of the lure. A number of biotic and abiotic conditions may impact pheromone-mediated mating behavior (McNeil 1991) so the outcome may be affected by differences in the duration of trapping period, the local population densities, the frequency with which traps are emptied, and how the data are analyzed. For example, Turgeon et al. (1983) compared daily trap catch data, while in this study we emptied traps weekly and considered total numbers/trap for the entire season.

The majority of compounds found in the pheromone blend of a species are believed to play an intraspecific role in the long and/or short range responses of individuals searching for conspecific partners (Haynes and Birch 1985; David and Birch 1989). However, taken together, the results of various experiments conducted to date on the armyworm would support the idea put forward by Kamm et al. (1982) stating " it may be that *M. unipuncta* only utilizes (Z)-11-hexadecenyl acetate for long range attractancy". (Z)-11-Hexadecenyl acetate is a pheromone component in a number of Lepidoptera (McDonough et al. 1980; Sreng et al. 1985; Batiste-Pereira et al. 2006), many of which are sympatric. Thus, if specific components found in the pheromone gland of *M. unipuncta* do not serve in intraspecific mate location they could serve interspecifically to reduce the probability of heterspecific matings between sympatric species (Farine et al. 1981).

Clearly, the addition of (Z)-9-hexadecenyl acetate, a minor component found in the pheromone blend of *M. unipuncta* significantly reduced the effectiveness of the *S. nonagrioides* lure (Fig. 5), while not affecting *M. unipuncta* responses when added to (Z)-11-hexadecenyl acetate (Fig. 4). The addition of (Z)-11-hexadecenal, a minor component found in *S. nonagrioides* female pheromone glands and that is an essential component of the most effective *S. nonagrioides* lure (Sans et al. 1997), resulted in

a significant decline in the attractiveness of (Z)-11-hexadecenyl acetate for *M. unipuncta* (Fig. 4) and *D. trifolii* (Fig. 6). These results are in contrast to previous findings that traps baited with *S. nonagrioides* females captured *M. unipuncta* males (Albajes et al. 1988), and further field research is needed to determine under what ecological conditions such attraction might occur.

Interestingly, (Z)-9-tetradecenyl acetate, a pheromone component of *S. cretica* that inhibits *S. nonagrioides* males (Germinara et al. 2007), has also been reported to significantly reduce the responsiveness of *M. unipuncta* males to (Z)-11-hexadecenyl acetate, although the reported concentrations required to do so varies from >5 (Steck et al. 1980) to >20% (Kamm et al. 1982). However, *M. unipuncta* does not share any pheromone components with *O. nubilalis*, so the hypothesis that pheromone cross-inhibition between *S. nonagrioides* and *O. nubilalis* evolved to avoid attraction to a third sympatric species (Eizaguirre et al. 2007), would not involve the common armyworm.

Thus, there is a great deal of research required to determine to what extent the different acetates, and other pheromone components, serve in intra-specific attraction and/or inter-specific reproductive isolation in a number of sympatric species found in maize ecosystems. This information would not only provide basic information on the role of sex pheromones in mate choice, but would be of considerable importance in the use of pheromones in pest management programs that target a number of different species attacking the same host crops.

Abstract Larvae of the bollworm *Helicoverpa zea* (Boddie) show some tolerance to *Bacillus thuringiensis* (*Bt*) Cry1Ac, and can survive on Cry1Ac-expressing *Bt* cotton, which should increase resistance development concerns. However, field-evolved resistance has not yet been observed. In a previous study, a population of *H. zea* was selected for stable resistance to Cry1Ac toxin. In the present study, we determined in laboratory bioassays if larvae of the Cry1Ac toxin-resistant *H. zea* population show higher survival rates on field-cultivated *Bt* cotton squares (= flower buds) collected prebloom—bloom than susceptible *H. zea*. Our results show that Cry1Ac toxin-resistant *H. zea* cannot complete larval development on Cry1Ac-expressing *Bt* cotton, despite being more than 150-fold resistant to Cry1Ac toxin and able to survive until pupation on Cry1Ac toxin concentrations greater than present in *Bt* cotton squares. Since mortality observed for Cry1Ac-resistant *H. zea* on *Bt* cotton was higher than expected, we investigated whether Cry1Ac interacts with gossypol and or other compounds offered with cotton powder in artificial diet. Diet incorporation bioassays were conducted with Cry1Ac toxin alone, and with gossypol and 4% cotton powder in the presence and absence of Cry1Ac. Cry1Ac toxin was significantly more lethal to susceptible *H. zea* than to resistant *H. zea*, but no difference in susceptibility to gossypol was observed between strains. However, combinations of Cry1Ac with gossypol or cotton powder were synergistic against resistant, but not against susceptible *H. zea*. Gossypol concentrations in individual larvae showed no significant differences between insect strains, or between larvae fed gossypol alone vs. those fed gossypol plus Cry1Ac. These results may help explain the inability of Cry1Ac-resistant *H. zea* to complete development on *Bt* cotton, and the absence of field-evolved resistance to *Bt* cotton by this pest.

Introduction

Bollworm, *Helicoverpa zea* (Boddie), has a naturally high tolerance to the *Bacillus thuringiensis* (*Bt*)-derived Cry1Ac protein compared to other target pests of *Bt* cotton in the US such as tobacco budworm, *Heliothis virescens* (F.), and pink bollworm, *Pectinophora gossypiella* (Saunders) (MacIntosh et al. 1990b; Sivasupramaniam et al. 2008). This relatively high tolerance, coupled with preferential feeding on tissues that express lower levels of *Bt* protein (Brickle et al. 2001), and toxin attenuation due to abiotic stress and plant phenology (e.g., postbloom), can result in complete larval development on Cry1Ac cotton, especially when insect populations are large (Jackson et al. 2004a). Additionally, *H. zea* is exposed to the *Bt* Cry1Ab protein in Cry1Ab-expressing corn, which is similar in structure and function to

Cry1Ac (Crickmore et al. 1998). This relatively high selection pressure increases the likelihood of resistance evolution (Gould 1998), and it was thus not surprising that early mathematical models predicted resistance development to *Bt* cotton in *H. zea* within 3–7 yr (Harris 1991; Roush 1997). Furthermore, the capacity for *H. zea* to develop resistance to Cry1Ac has been demonstrated in laboratory-selected strains (Luttrell et al. 1999; Jackson et al. 2004b; Anilkumar et al. 2008a). However, contrary to these results and predictions, field-evolved resistance has not occurred in *H. zea* even after 12 yr of intensive commercial use of *Bt* cotton in the USA (Ali et al. 2008; Moar et al. 2008).

Although numerous Cry1Ac-resistant strains of *H. virescens* (Gould et al. 1992, 1995), *P. gossypiella* (Liu et al. 1999; Tabashnik et al. 2000), and *Helicoverpa armigera* (Hubner) (Akhurst et al. 2003) have been developed in the laboratory, very few strains have been able to pupate and produce fertile adults on *Bt* cotton (Tabashnik et al. 2003; Bird and Akhurst 2004). Of those lepidopteran strains that can develop to fertile adults on *Bt* cotton, there is little correlation between the relative susceptibility of these strains to Cry1Ac, the level of Cry1Ac resistance in these resistant strains, and the relative survivorship of these resistant strains on *Bt* cotton (Liu et al. 1999; Akhurst et al. 2003; Tabashnik et al. 2003; Bird and Akhurst 2004). Possible explanations for this low correlation include interactions between *Bt* proteins and secondary plant metabolites (Carrière et al. 2004), use of a form of *Bt* protein for resistance selection not exclusively found in *Bt* cotton (Liu et al. 1999; Tabashnik et al. 2000; Akhurst et al. 2003; Henneberry and Jech 2007; Anilkumar et al. 2008a), increased consumption of plant tissues compared to consumption of artificial diet (Woods 1999), loss of genes or a reduction in expression of compounds necessary to survive on cotton during laboratory rearing and *Bt* resistance selection, or fitness costs associated with *Bt* resistance (Tabashnik et al. 2003; Gassmann et al. 2009).

Anilkumar et al. (2008a) reported a population of *H. zea* that was selected for stable and moderately high levels of resistance to the Cry1Ac toxin in the laboratory. Because *H. zea* is relatively tolerant to Cry1Ac, and arguably the most polyphagous of all target lepidopteran pests of *Bt* cotton that express Cry1Ac in the US, research was conducted to determine if larvae of the Cry1Ac toxin-resistant *H. zea* population show higher survival rates or can at least survive to a greater instar than susceptible *H. zea* on field-cultivated *Bt* cotton squares (= flower buds) collected during prebloom—bloom stage. Furthermore, this study explored the interaction of Cry1Ac with gossypol and cotton powder in artificial diet to help explain the higher than expected mortality observed for Cry1Ac-resistant *H. zea* on *Bt* cotton.

Methods and Materials

Insect Strains A laboratory susceptible colony of *Helicoverpa zea* (SC) was established in September 2004 from a laboratory colony from Monsanto (Union City, TN, USA). A resistant strain (AR) was the product of selecting SC for resistance by exposing individual neonates to an artificial diet containing up to 500 µg *Bt* Cry1Ac toxin/g diet for 25 generations (Anilkumar et al. 2008a). Seven d after exposure to the Cry1Ac toxin, surviving molted larvae were transferred to untreated diet and reared until pupation (Ali et al. 2006; Anilkumar et al. 2008a; Sivasupramaniam et al. 2008). Resistance to Cry1Ac toxin was assessed at selected generations (Anilkumar et al. 2008a), and the AR strain was >150-fold resistant (based on artificial diet bioassays) when survivorship bioassays on *Bt* and non-*Bt* cotton squares were initiated.

In order to avoid complete loss of the AR strain due to fitness costs associated with Cry1Ac resistance selection and rearing in the laboratory for 26 generations (Anilkumar et al. 2008b), AR was crossed with a new Monsanto susceptible strain (from Union City, TN), SC1, resulting in a strain designated AR1. SC1 had higher LC_{50} (31.25 µg Cry1Ac toxin/g diet) values than SC (8.89–15 µg Cry1Ac toxin /g diet; Anilkumar et al. 2008a). Although both reciprocal crosses were attempted, only AR[♀] X SC1[♂] yielded a viable F_1 population due to mating costs associated with AR males (Anilkumar et al. 2008b). Because Cry1Ac resistance in *H. zea* is inherited as a co-dominant character (Burd et al. 2003; Anilkumar et al. 2008b), high levels of resistance (resistance ratio >50-fold compared to SC1) were observed in the F_1 generation (data not shown) confirming that AR1 was resistant to Cry1Ac toxin. AR1 was selected at the regular selection concentration of Cry1Ac (500 µg Cry1Ac toxin/g diet) for two generations (Anilkumar et al. 2008a).

Cry1Ac Toxin An *E. coli* strain expressing Cry1Ac protoxin from *B. thuringiensis* subsp. *kurstaki* strain HD-1 (provided by L. Masson, Biotechnology Research Institute, National Research Council, Montreal, Canada) was cultured, and the activated toxin prepared as indicated elsewhere (Pusztai-Carey et al. 1994; Moar et al. 1995b).

Lyophilized Leaf Tissue Powder Studies Lyophilized cotton (*Gossypium hirsutum*, C312) leaf tissue powder was supplied by Monsanto (St. Louis, MO, USA).

Cotton Plants Bt cotton, *Gossypium hirsutum* (DPL555) and the near isogenic non-*Bt* cotton (N*Bt*) (DPL491) were planted at the Prattville Agricultural Research Unit, Alabama Agricultural Research Station, Prattville, AL, U. S.A.. Planting dates for *Bt*- and N*Bt*-cotton were April 23rd

and 24th, 2007, respectively. Cotton plants were cultivated as per typical practices. N*Bt*-cotton plants were treated with imidacloprid at 1 oz/A on both July 13 and July 24, 2007 for aphid control, and tissues were used 5 d after treatment for bioassays. Cotton plants were >85 d old (prebloom-bloom) when squares were harvested. Pin-head to midpoint-stage squares (7–14 d old) were collected, transported to the laboratory, and stored at 4–7°C until needed, up to a maximum of 13 d.

Cry1Ac Protein Quantification in Plants Beginning on the day of field collection, and on days when cotton squares were removed from refrigeration and used in bioassays, a random sample of 10 *Bt* squares was placed at −80°C. After all bioassays were completed, all −80°C samples were shipped to Monsanto (St. Louis, MO, USA) for Cry1Ac protein quantification. Square tissues were lyophilized, and Cry1Ac expression was determined using ELISA and compared against a positive *Bt* cotton standard as described in Greenplate (1999) and Sivasupramaniam et al. (2008). Three replicate assays were conducted for each sample.

Bioassay: H. zea Survival and Development on Cotton Squares Moist cotton balls were immersed in distilled water, squeezed to remove excess water, and placed in petri dishes (35×10 mm) to reduce cotton square desiccation. Individual neonates from both *H. zea* strains were placed on the outside of square bracts on one square in each petri dish, and squares were changed every 3 d (replacing larvae on bracts) until the end of the experiments. For both *Bt* and N*Bt*-cotton tests, larvae and squares were transferred to 30 ml cups that contained three to five squares when larvae reached 4th instar, and rearing was continued until pupation. Larval mortality and stadia were recorded beginning on the 4th d, and subsequently at 3 d intervals. Larval weights were recorded after 7 d, and tests were continued until survivors reached pupation. Bioassay trays were incubated at 27±1°C, RH 50%, and a photoperiod of 14:10 (L:D) h. Thirty larvae from each strain were tested in each replication. Experiments were repeated three times.

Bioassays: H. zea Survival and Development on Differently Treated Food General Gossypol and/or Cry1Ac toxin were added when the diet temperature was <60°C, and the diet was mixed thoroughly. Diets were filled into 128-well bioassay trays (CD-International, Pitman, NJ, USA) at about 1 g per well. Neonate larvae of strains AR1 and SC1 were transferred individually into each well and covered with ventilated covers. Bioassay trays were incubated at 27±1°C, RH 50%, and a photoperiod of 14:10 (L:D) h. Larval mortality and stadia were recorded beginning on the 4th d, and subsequently at 3 d intervals, up to 25 d. IC_{50} values (μg Cry1Ac/g diet) were determined as those inhibitory concentrations at which half of the larvae failed to molt to the 3rd instar after 7 d. Larval weights were recorded after 7 d, and tests were continued until survivors reached pupation. EC_{50} or EC_{90} (μg Cry1Ac/g diet) were determined as those effective concentrations at which larval weight was reduced by 50% or 90% compared to larvae fed on an untreated control diet (Jalali et al. 2004). Thirty-two larvae were tested for each treatment. Three replicates were conducted for the diet with Cry1Ac and the diet with Cry1Ac plus gossypol; six replicates were run for the diet with Cry1Ac plus lyophilized cotton powder.

(a) *Artficial diet with Cry1Ac*. Larvae were exposed to a level of Cry1Ac toxin four to six times greater than detected in fresh *Bt* cotton squares by ELISA, i.e., 15 μg Cry1Ac toxin/g diet.
(b) *Artficial diet with Cry1Ac and gossypol*. Larvae were exposed to diet containing 3.75 μg, 7.5 μg, or 15 μg Cry1Ac/g diet, or 0.0375%, 0.075%, or 0.15% gossypol (95% in acetic acid crystals, Sigma, St. Louis, MO, USA), and a 1:1 combination of Cry1Ac and gossypol (at respective dilutions from the maximum concentration used). For control, larvae were kept on a diet without Cry1Ac and gossypol additions. Because gossypol was dissolved in 1.0 % dimethylsulfoxide (DMSO), all diets contained a final concentration of 1.0% DMSO.
(c) *Artificial diet with Lyophilized cotton powder and Cry1Ac*. Larvae were exposed to 4% cotton powder, 15 μg Cry1Ac/g diet, and their 1:1 combinations in two generations.

Quantification of Gossypol Uptake by Larvae Five larvae from each replication that survived after 7 d in bioassays that contained gossypol (gossypol alone, gossypol plus Cry1Ac) or cotton powder (cotton powder alone, cotton powder plus Cry1Ac) were weighed and placed individually into 30 ml plastic cups that contained no diet for 10–12 h to allow for purging of gut contents. Insects were transferred individually to a microcentrifuge tube and frozen at −80°C. Gossypol content per insect was determined as described by Orth et al. (2007).

Data Analysis

Effect of Storage on Cry1Ac Stability in Plants Plant age at sampling was considered a fixed classification effect, and duration of storage as a fixed effect covariate nested with age to analyze the effect of storage on Cry1Ac stability. The sole random effect in the model was replicate(age), and Proc Mixed predicted a separate intercept for each age class with the no intercept option (SAS Institute 2003).

Larval Feeding upon Cotton Squares Larval mortality was arcsine square root transformed and analyzed by repeated measures ANOVA with SAS Proc GLM using the normal distribution function. The effect of diet on larval development (instars 3 and 4) was modeled with SAS Proc GLIMMIX with a binomial distribution function and the logit link function. Strain, treatment, and their interactions were fixed effects and replicate the sole random effect. The degrees of freedom for *t*-tests and confidence intervals were calculated as the number of group means minus the number of fitted parameters (Schabenberger and Pierce 2004).

Larval Feeding upon Diet with Cry1Ac Larval mortality was arcsine square root transformed and analyzed by repeated measures ANOVA with SAS Proc GLM using the normal distribution function.

Larval Feeding upon Diet with Gossypol and Cry1Ac Mortality of larvae that feed upon these diets was modeled by logistic regression with SAS Proc NLmixed using the binomial distribution function. The CONTRAST statement was used to evaluate the statistical significance of toxin differences within strains and ESTIMATE to calculate IC_{50} values (see above) plus associated 95% confidence intervals, as well as the contrasts between strains. For larval weight data, replicate x strain interaction means in response to toxin rate were modeled with SAS Proc NLmixed by using an exponential decay model with a lower asymptotic limit and a normal distribution function. EC_{50} and EC_{90} values were estimated from this analysis (see above). Interactions of effects Cry1Ac and gossypol on larvae were evaluated as described by Salama et al. (1984). Differences in observed mortality and theoretical mortality for the mixture of Cry1Ac and gossypol were analyzed with χ^2 tests. Interaction was considered 1) synergistic, if observed mortality was more than expected mortality coupled with significant chi square values, 2) additive, if observed mortality was more than expected mortality coupled with non significant chi square values, 3) antagonistic, if observed mortality was less than expected mortality coupled with significant chi square values.

Larvae Feeding upon Diet with Lyophilized Leaf Tissue Powder and Cry1Ac Larval mortality was modeled with SAS Proc GLIMMIX with a normal distribution function. The residual variance was modeled by using the group option to account for heterogeneous variances among treatments. Larval weight and gossypol concentration/mg larva were modeled using the same procedure but with lognormal distribution function, which was necessary as residuals under the normal assumption were extremely right-skewed. Treatment, strain, and their interaction were treated as fixed effects. However, random effects were different for each of parameter. For larval weight, generation, replicate (generation), and their interactions with fixed effects. For larval mortality, generation and replicate (generation) were considered to be random effects. Least squares diet × strain interaction means were calculated. The slicediff (for larval weight and mortality), pdiff (gossypol concentration/larvae), and simulation options were employed to assess differences among strains and diets while controlling the Type I error rate. Analysis of synergism between Cry1Ac and cotton powder was evaluated as explained above.

Quantification of Gossypol in Larvae Since the distribution of gossypol concentration per larva was right skewed, data were analyzed with a generalized linear models framework that utilized SAS Proc GLIMMIX. The lognormal distribution function resulted in a symmetrical distribution of residuals. Strain and toxin were fixed effects class variables, and toxin rate was treated as a fixed effects covariate. Differences among toxin x strain combinations then were predicted at toxin rates 375, 750, and 1,500 using the AT option of the LSmeans statement with the simulation adjustment to control the Type I error rate.

Results

Cry1Ac Expression in Cotton Squares The concentration of Cry1Ac in our field-collected *Bt* cotton squares (flower buds) was not significantly different from levels of Cry1Ac found in Monsanto's positive control, DP50 Bollgard® squares used to determine if commercially grown Bollgard® is producing acceptable levels of Cry1Ac (Fig. 1). Cry1Ac expression was reduced (F_5=248.75, P< 0.001) by 45% from 86 d (July 18) to 124 d (August 25) after planting; and storage at 4–7°C did not affect the stability of the Cry1Ac for all samples except the July 18th samples (P=0.049).

Survivorship of Helicoverpa zea Larvae of AR and SC Strains on Bt Cotton and NBt Cotton Only tissue type (*Bt* and N*Bt*) ($F_{1,8}$=140.02, P<0.001), but not strains ($F_{1,8}$= 2.65, P=0.143) or their interactions ($F_{1,8}$=4.48, P=0.067) had a significant effect on cumulative mortality at 31 d (Fig. 2a). Mean (± SE) cumulative mortality on *Bt* cotton for SC larvae at 4 d and 7 d was 60.00 (±8.33) and 76.67 (±6.01) percent, respectively, and was significantly (P<0.05) higher compared to AR larvae (34.45±1.92 and 54.45 ± 1.93% at 4 d and 7 d, respectively). No significant differences were observed in cumulative mortality on 10 d, 13 d, and 16 d between AR (70.00±7.26, 77.78±6.94, and 81.11±7.51%) and SC larvae (86.67±4.41, 88.89±4.19, and 95.56±2.55%) on *Bt* squares. All SC larvae on *Bt* squares were dead by

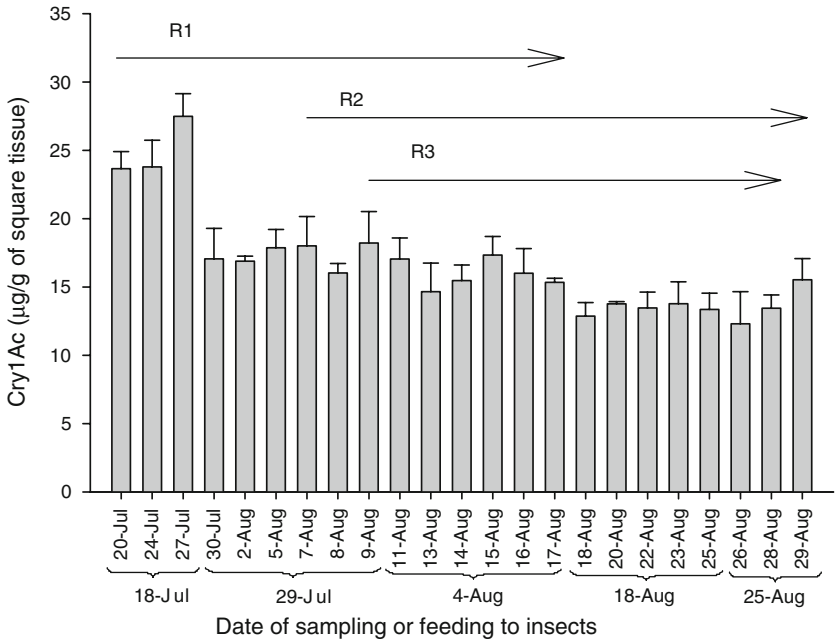

Fig. 1 Quantity of Cry1Ac protein (µg Cry1Ac/g lyophilized tissue) expressed in *Bt* cotton squares measured using ELISA. R1-3 = replicates 1–3. *Squares* were harvested July 18–Aug 25, and *squares* were refrigerated at 4–7°C until fed to *Helicoverpa zea* from July 20–Aug. 29. Means and SD of three replicates are given

19 d compared to 84.45±6.74% mortality for AR larvae, and these differences were significant ($P<0.05$). Both AR and SC larvae survived equally well on N*Bt* cotton; neither duration nor total survivorship varied between strains.

Larval weight after 7 d was different when comparing their food (*Bt* and N*Bt* cotton tissues ($P<0.001$), but not when comparing AR and SC strains ($P=0.406$): Neither was the interaction of food tissue and strain significant ($P=0.125$) (Table 1). When considering larval mortalitiy, tissue ($P<0.001$) and its interaction ($P=0.028$) with strain, but not the strain alone ($P=0.099$) had an effect on the number of larvae reaching 3rd instar. The proportion of larvae reaching 3rd instar differed significantly between AR and SC on *Bt*, but not on non-*Bt* tissues, and only AR-larvae reached 4th instar on *Bt* cotton squares.

Effect of Cry1Ac in Artificial Diet All factors such as strains ($F_{1,8}=22.32$, $P=0.002$), type of diet (Cry1Ac treated or untreated) ($F_{1,8}=80.20$, $P<0.001$), and their interactions ($F_{1,8}=40.56$, $P<0.001$) had effects on cumulative mortality after 25 d (Fig. 2b). For within subject effects, only duration of exposure ($F_{7,2}=49.92$, $P=0.020$) and its interaction with type of diet ($F_{7,2}=34.57$, $P=0.028$) had an effect on mortality over time. However, no differences were observed for interaction of duration of exposure with strains ($F_{7,2}=5.12$, $P=0.173$) nor for their combined interaction with type of diet ($F_{7,2}=11.18$, $P=0.085$). Larvae of SC1 and AR1 strains performed similarly on untreated diet resulting in 10–17% mortality after 25 d. SC1-larvae feeding on 15 µg Cry1Ac toxin/g diet had 92% mortality after 25 d, whereas AR1-larvae had only 45% mortality feeding on 15 µg

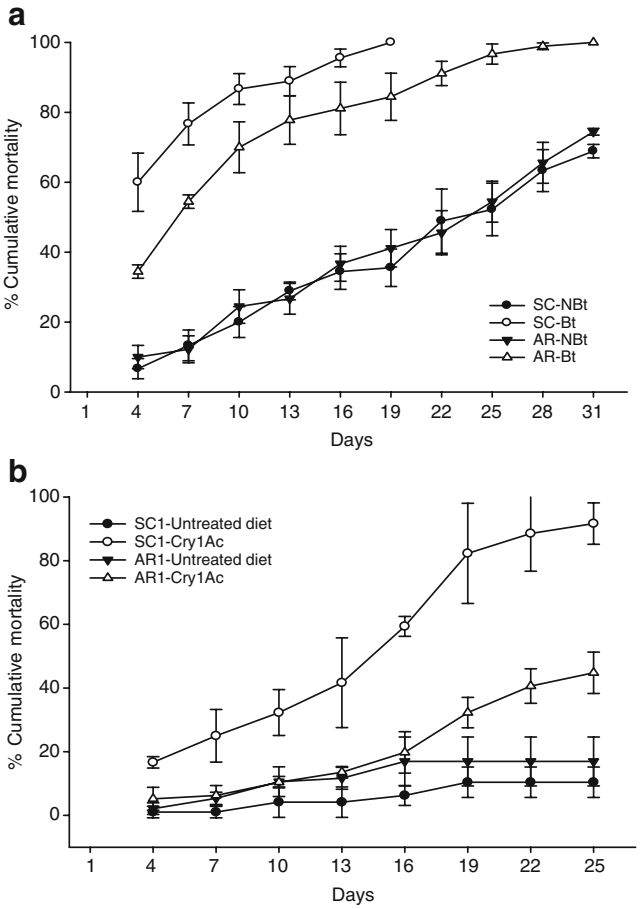

Fig. 2 Cumulative % mortality of susceptible (SC) and Cry1Ac-resistant (AR) *Helicoverpa zea* on **a** *Bt* (DPL-555) and N*Bt* (DPL-491) cotton squares and **b** untreated diet and diet treated with 15 µg Cry1Ac/g diet. Means and SD of three replicates are given

[a] Values in the parenthesis are 95% confidence intervals

Cry1Ac toxin/g diet after 25 d. After 25 d, only 8.33% SC1-larvae reached pupation as compared to 55% pupation in AR1. For both strains, the largest increase in mortality occurred between 16–19 d. At this time mortality of AR1-larvae feeding upon Cry1Ac toxin increased significantly compared to the untreated control.

Effect of Cry1Ac and Gossypol in Artificial Diet IC_{50} values (i.e., Cry1Ac toxin concentration at which 50% of larvae fail to molt to third instar) were significantly different between AR1 (17.56) and SC1 (7.07) larvae. With the addition of gossypol to Cry1Ac toxin, however, the IC_{50} value for AR1-larvae (10.04) decreased significantly and was not significantly different (P=0.05) from SC1-larvae on Cry1Ac alone (Table 2). The IC_{50} value for SC1-larvae with the Cry1Ac plus gossypol combination did not significantly decrease (P=0.05) compared to Cry1Ac alone (Table 2). EC_{50} values (i.e., Cry1Ac toxin concentration at which larval weight was reduced by 50%) for AR1 (1,172) and SC1-larvae (1,204) were similar for gossypol, and were significantly higher than the values for Cry1Ac toxin (AR1=0.99, SC1=0.97) and their mixtures (AR1=1.35, SC1=0.94) (Table 3). Gossypol concentration in larvae did not differ significantly between strains at any concentration (375 µg/g diet, 750 µg/g diet and 1,500 µg/g diet) of gossypol in the presence or absence of Cry1Ac after 7 d (Fig. 3a). However, irrespective of strain, larvae feeding on 0.15% gossypol in the presence of 15 µg Cry1Ac toxin/g diet had significantly less gossypol/mg body weight.

Effect of Cry1Ac and Cotton Powder Strain (F_1=32.48, P< 0.001), treatment (F_3=602.14, P<0.001), and the strain X treatment interaction (F_3=71.38, P<0.001) had a significant effect on the percentage of larvae molting to third instar (Table 4). Differences between strains were observed with Cry1Ac toxin (P < 0.001). However, no differences

were observed between strains on untreated diet (P=0.933), nor on 4% cotton powder in the presence (P = 0.051) or absence (P=0.262) of Cry1Ac. Gossypol concentration in larvae did not differ between strains (F_1=0.0, P=0.985), and there was no significant interaction with treatment (F_2=0.70, P=0.501). However, larvae feeding on different treatments had significantly (F_2=243.84, P<0.001) different levels of gossypol (Fig. 3b). Treatments (F_3= 103.91, P<0.001), strains (F_1=6.24, P=0.018), and their interactions (F_3=12.35, P<0.001) influenced larval weight significantly (Fig. 4). AR1 and SC1 larval weights differed on Cry1Ac toxin alone (P<0.001), but not in other treatments.

Synergistic Interactions Significant synergistic interactions of Cry1Ac toxin with cotton powder and gossypol were

[c] Cotton powder incorporated at 4% wt/wt

observed for AR1-larvae, but not for SC1-larvae when assessing percent failure to molt to third instar (Table 5). However, there was an additive interaction only at lower levels of Cry1Ac and gossypol for both insect strains.

Discussion

When reared on N*Bt* cotton, *Helicoverpa zea* larvae of AR and SC strains did not differ in survivorship nor in time required for pupation. In contrast, Cry1Ac-resistant *H.*

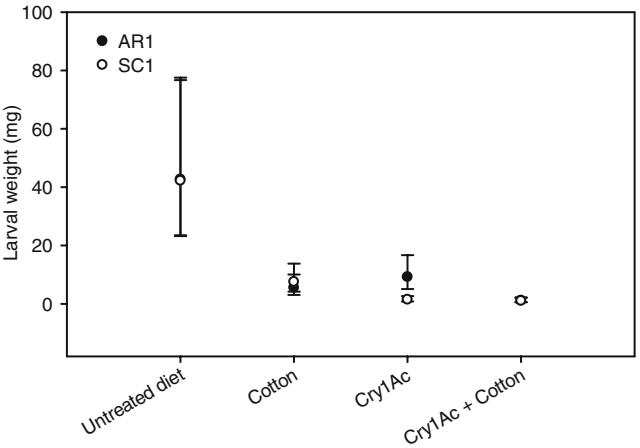

Fig. 4 Effect of 4% cotton powder in the presence and absence of 15 µg Cry1Ac/g diet on larval weight in Cry1Ac-resistant (AR1) and susceptible (SC1) *Helicoverpa zea*. The data represent the mean of three replications and standard errors are back-transformed values from logarithmic scale

[b] Expected mortality is calculated from observed mortalities in different treatments after adjusting for control mortality

virescens (Tabashnik et al. 2003), *H. armigera* (Bird and Akhurst 2004), and *P. gossypiella* (Liu et al. 1999) showed significantly slower larval development on N*Bt* cotton than susceptible individuals (Bird and Akhurst 2004). These results suggest that the *H. zea* AR-strain differs from the *H. zea* SC-strain primarily by the ability to survive higher concentrations of Cry1Ac toxin.

Bt cotton squares used for this study contained commercially acceptable concentrations of Cry1Ac toxin as measured by ELISA. ELISA results are particularly important for this study since cotton Cry1Ac toxin levels may change due to drought or treatment of samples after collection. Indeed, mean Cry1Ac expression levels were reduced by 45% from 86 d to 124 d after planting during a very hot and dry season. Greenplate (1999) found a similar reduction of Cry1Ac expression with the increase in the age of cotton plants. In contrast, refrigeration of harvested squares at 4–7°C for up to 13 d did not result in a significant reduction in Cry1Ac levels. These results may help future investigations in which *Bt* cotton squares will need to be refrigerated for extended periods prior to use.

Cry1Ac toxin was tested at 15 μg/g diet, the minimum concentration observed in lyophilized *Bt* cotton squares by using ELISA. However, fresh *Bt* cotton tissue contains about six to eight fold less Cry1Ac toxin compared to lyophilized tissue (SS unpublished data). Therefore, even at a concentration four to six fold higher than found in fresh *Bt* cotton squares (typically 2–4 μg/g; SS unpublished data), 55% of AR1-larvae could develop to pupation thus suggesting that AR-larvae should be able to develop to pupation on *Bt* cotton especially if larvae feed selectively on tissues that express lower Cry1Ac concentrations (such as bracts) than squares (KJA and WJM unpublished data; Sivasupramaniam et al. 2008). However, no AR-larvae reached pupation on *Bt* cotton even though the AR strain showed significant decreases in mortality compared to SC at 4 d and 7 d. Similar results were found by Tabashnik et al. (2008). Our results suggest that testing the survivability of putative Cry1Ac-resistant insects on tissues that express Cry1Ac for a time that is not sufficient for pupation may overestimate the capability for field-evolved resistance.

Because the nutritional value of plant material is significantly lower than nutritionally-rich artificial diet, larvae can consume up to 6–8-fold more plant material compared to artificial diet (Naeem et al. 1992; Woods 1999). Therefore, both susceptible and resistant *H. zea* would be expected to consume much higher levels of Cry1Ac toxin when feeding on *Bt* cotton squares than with similar toxin concentrations incorporated into diet, thus resulting in much higher than expected mortality (which was observed). This is primarily the reason why a six to eight fold increase in Cry1Ac toxin concentration (15 μg/g diet) was chosen as the highest concentration representing *Bt* cotton squares. When the AR1 strain was reared on 100 μg Cry1Ac toxin/g diet (about 16–42 times the level of Cry1Ac toxin found in *Bt* cotton squares) from 3rd instar to 5th instar after being selected on 500 μg Cry1Ac toxin/gram diet, many larvae died before pupation, and those larvae not dead were severely stunted (WJM, unpublished data). Furthermore, increased consumption of plant secondary compounds such as gossypol (that have been shown to synergize Cry1Ac toxin), in addition to Cry1Ac toxin, could also help explain the increased mortality of AR-larvae on cotton squares as compared to artificial diet. Thus, consideration of the actual amount of insecticidal compounds consumed is critical when comparing toxicities from different diets.

Results from Cry1Ac mixtures with gossypol and cotton powder showed synergistic interactions at the highest concentration tested for AR1, but not for SC1. The highest concentration of gossypol tested (0.15%) was the mean of the two concentrations of gossypol tested by Carrière et al. (2004), and it is representative of the gossypol concentration in cottonseed in Pima and Upland cotton varieties (as discussed in Carrière et al. 2004). In addition, 4% cotton

powder was synergistic in its activity with Cry1Ac toxin against AR1 even though it contained only 6 µg gossypol/g (data not shown). Other than gossypol, cotton plants produce many other insecticidal secondary metabolites such as heliocides H_1 and H_2, and hemigossypolone (Hedin et al. 1991). These compounds also could potentially interact to reduce AR survivorship on *Bt* cotton. Sachs et al. (1996) showed that cotton plants that express high levels of terpenoids (e.g., gossypol) along with Cry1Ab had reduced survivorship of tobacco budworm, *H. virescens*, compared to cotton plants that expressed low to conventional levels of terpenoids. Interestingly, the use of corn powder instead of cotton powder in combination with Cry1Ac also resulted in a synergistic response with Cry1Ac-resistant, but not with susceptible larvae (data not shown), suggesting that a more generalized plant effect (not limited to cotton) is interacting with Cry1Ac against resistant insects. Because *Bt* toxin is known to have antifeedant activity (Whalon and Wingerd 2003), AR-larvae would be expected to consume more diet that contains either Cry1Ac or Cry1Ac + gossypol than SC-larvae, thus agreeing with the observation that synergism between Cry1Ac toxin and gossypol or cotton powder should occur only for AR, However, because no differences in effects of different gossypol concentrations on AR and SC-larvae were observed, the synergism of Cry1Ac toxin and gossypol or cotton powder in AR-larvae should be related to the increased consumption of Cry1Ac toxin, not gossypol.

This is the first report of plant compounds other than protein inhibitors that synergize the activity of *Bt* proteins, especially against Cry1Ac-resistant insects. To date, most compounds that are synergistic with *Bt* Cry proteins are other *Bacillus* spp. or *Bt* products such as spores or spore crystal mixtures (Liu et al. 1998; Moar et al. 1989, 1995a), zwittermicin A (Broderick et al. 2000), β-exotoxin (Moar et al. 1986), CytA (Wirth et al. 1997), and a peptide expressed in *E. coli* that contains a corresponding *Bt* binding sequence (Chen et al. 2007). However, plant protease inhibitors and several chemical insecticides also have been reported to synergize *Bt* proteins (Herfs 1965; MacIntosh et al. 1990a). Gossypol occurs naturally in an enantiomeric mixture of both (+)-gossypol and (−)-gossypol, and the ratio varies among commercial cotton cultivars. Both of these forms reduced the survivorship of *H. zea*, and a racemic mixture of 1:1 had a synergistic effect at 0.16% (Stipanovic et al. 2006). The gossypol obtained from Sigma used in the current study was extracted from cotton seeds, and the ratio of enantiomeric forms of gossypol was not provided. Therefore, further studies are warranted to quantify the ratios of enantiomers and to evaluate their interactions with Cry1Ac.

The synergistic interaction of gossypol and cotton powder with Cry1Ac observed in AR1-larvae may help explain the inability of AR-larvae to survive and produce fertile adults on *Bt* cotton. Carrière et al. (2004) suggested that increased susceptibility of Cry1Ac-resistant *P. gossypiella* to gossypol was linked to the cadherin mutation resistance mechanism (Morin et al. 2003; Carrière et al. 2006). However, AR-larvae have no observable differences in Cry1Ac binding (essentially eliminating a cadherin mutation as a potential resistance mechanism), and appear to have altered proteolysis as a resistance mechanism (Anilkumar et al. 2008a; WJM and KJA unpublished data). Additionally, the AR1 strain was not differentially susceptible to gossypol alone compared to the SC1 strain, nor did AR1-larvae contain more gossypol than SC1-larvae, as has been suggested for Cry1Ac-resistant *P. gossypiella* (Carrière et al. 2004). One possible explanation for synergistic effects of gossypol and Cry1Ac only on AR-larvae is that gossypol is degraded by upregulation of a cytochrome P450 in *Helicoverpa armigera* (Mao et al. 2007). Typically, overexpression of detoxification enzymes results in fitness costs (Matsumura 1985). Assuming that Cry1Ac-resistance in AR-larvae is due to proteolysis, (most likely overexpression of a digestive protease), overexpression of two enzymes may result in increased fitness costs, which were observed in AR-larvae (Anilkumar et al. 2008b). A change of midgut protease activity also could affect nutritional protein digestion which could also influence larval growth, as was observed for AR1 (Gassmann et al. 2009). Because synergism was determined only for AR1-larvae based on their failure to molt to third instar, differences in observed development also could be influenced by changes in hormone [such as juvenile hormone (JH) 1] concentrations caused by competition with gossypol for JH1 binding sites, as has been suggested by Carrière et al. (2004). Therefore, future studies are warranted to determine how resistance mechanisms not associated with binding (or fitness costs involved with Cry1Ac selection) are affected by the presence of gossypol and other plant compounds.

The prediction of field-evolved *Bt* resistance on the basis of laboratory bioassays has always been difficult. Field-evolved resistance has not occurred in *H. zea* even after 12 y of commercial use of *Bt* cotton in the USA (Ali et al. 2006, 2008; Moar and Anilkumar 2007; Moar et al. 2008) even though laboratory experiments have shown that *H. zea* does have the capability to become resistant to the *Bt* protein (Cry1Ac) in *Bt* cotton (Luttrell et al. 1999; Jackson et al. 2004b; Anilkumar et al. 2008a). Results presented in this study help to illustrate that the actual hurdles that *H. zea* must overcome to become resistant to *Bt* cotton in the field are complex, and they help to explain the absence of field-evolved resistance in this pest.

Oxidative Responses of St. Augustinegrasses to Feeding of Southern Chinch Bug, *Blissus insularis* Barber

Murugesan Rangasamy · Bala Rathinasabapathi · Heather J. McAuslane · Ronald H. Cherry · Russell T. Nagata

Received: 5 March 2009 / Revised: 2 June 2009 / Accepted: 22 June 2009 / Published online: 9 July 2009

Abstract Southern chinch bug, *Blissus insularis* Barber (Hemiptera: Blissidae), is a serious insect pest of St. Augustinegrass, *Stenotaphrum secundatum* (Walt.) Kuntze, a turfgrass commonly grown in the southeastern United States. Resistance to southern chinch bug has been identified in the polyploid St. Augustinegrass varieties 'Floratam' and 'FX-10', and the diploid 'Captiva'. However, southern chinch bug in Florida and elsewhere has overcome Floratam's resistance. This research investigated the potential role of selected plant oxidative enzymes in resistance/susceptibility to southern chinch bug in two polyploid varieties (FX-10 and Floratam) and two diploid varieties (Captiva and Palmetto). Oxidative enzyme activity was estimated spectrophotometrically from plant samples collected 1, 3, 5, and 8 days after southern chinch bug infestation and from uninfested control plants. Resistant FX-10 and Captiva had significantly higher peroxidase activity, while Captiva had significantly higher polyphenol oxidase activity 5 and 8 days after infestation compared to uninfested controls. FX-10 had higher lipoxygenase activity 3, 5, and 8 days after infestation compared to uninfested controls. Catalase activities did not differ between infested and control plants in any of the varieties tested. Native gels stained for peroxidase indicated that certain isozymes in FX-10 and Captiva were induced 5 and 8 days after infestation. Isozyme profiles of polyphenol oxidase and lipoxygenase did not differ between control and infested FX-10, Floratam, Captiva, and Palmetto. Potential mechanisms to explain the correlation of resistance to southern chinch bug in FX-10 and Captiva with higher activities of oxidative enzymes are discussed.

Introduction

St. Augustinegrass, *Stenotaphrum secundatum* (Walt.) Kuntze, is the most widely planted turfgrass in Florida and the southeastern USA. This turfgrass species accounts for 85% of total sod production in Florida, is currently planted on more than one million acres, and is worth more than $262 million annually (Haydu et al. 2005). The southern chinch bug, *Blissus insularis* Barber (Hemiptera: Blissidae), is a major challenge to the production and use of St. Augustinegrass (Crocker 1993), and necessitates numerous insecticide applications annually to maintain the turf's aesthetic value. Unfortunately, this insect has developed resistance to several insecticides (Reinert and Portier 1983; Cherry and Nagata 2005, 2007).

Host plant resistance to southern chinch bug has been an important component of integrated management of this insect for many years. Floratam, a polyploid variety of St. Augustinegrass with resistance to southern chinch bug, was released in Florida and other Gulf Coast states in 1973 (Horn et al. 1973). However, in 1985, a population of

chinch bug in Florida was reported to have overcome Floratam's resistance (Busey and Center 1987); this ability to use Floratam as a host is now widespread throughout Florida (Nagata and Cherry 2003).

As potential alternatives to Floratam, two southern chinch bug resistant St. Augustinegrass varieties were developed: a polyploid line, FX-10 (Busey 1993) and a diploid line, Captiva (Nagata and Cherry 2003). We have shown that both FX-10 and Captiva deter feeding of southern chinch bugs (i.e., through antixenosis) (Rangasamy et al. 2006). Captiva also had adverse effects on the biology of the southern chinch bug (i.e., antibiosis) (Rangasamy et al. 2006), suggesting a metabolic basis for insect resistance.

Currently, the biochemical or physical mechanisms of resistance in these varieties are unknown. Our goal is to decipher mechanisms that will facilitate efforts to breed St. Augustinegrass varieties with durable chinch bug resistance. The mechanisms of plant resistance against phloem-feeding aphids have been studied extensively, compared to other phloem feeders (Thompson and Goggin 2006); however, aphids feed on their host plants by probing intercellularly, while phloem-feeding southern chinch bugs probe intracellularly and, likely, this results in more and different kinds of cellular damage and plant response. Thus, a study of the plant response to chinch bug feeding is warranted. One prominent plant response to insect herbivore attack is the induction of oxidative enzymes, such as polyphenol oxidase (PPO), peroxidase (POX), lipoxygenase (LOX), and catalase (CAT) (Green and Ryan 1972; Hildebrand et al. 1986; Felton et al. 1989, 1994a, b; Stout et al. 1999; Constabel et al. 2000; Chaman et al. 2001; Ni et al. 2001; Heng-Moss et al. 2004). These enzymes, because of their potential roles in plant signaling, synthesis of defense compounds, and/or in oxidative stress tolerance, have been implicated in plant resistance to insect herbivores.

The objective of this investigation was to compare the enzymatic responses of resistant vs. susceptible varieties of diploid and polyploid St. Augustinegrass to feeding by a population of southern chinch bug that has overcome Floratam resistance. Our study focused on the induction of the oxidative enzymes POX, PPO, CAT, and LOX in four cultivars of St. Augustinegrass challenged by adult southern chinch bugs feeding.

Methods and Materials

Plants, Insects, Sample Collection St. Augustinegrass varieties selected for comparison included two diploids (Captiva, chinch bug-resistant, and Palmetto, chinch bug-susceptible) and two polyploids (FX-10, resistant and Floratam, susceptible), all provided by R.T. Nagata (Everglades Research and Education Center, Belle Glade, FL, USA). Rooted sprigs from single node cuttings were grown in plastic pots (12.5 cm diam×12.5 cm depth) containing a 1:1 (*v*/*v*) mixture of sand and Fafard mix #2 (Conrad Fafard, Agawam, MA, USA). Plants were grown in a glass house with ambient light at a temperature of 28°C (24–32°C), 70% RH (65–75% RH) and fertilized with Osmocote Plus 15-9-12 (Scotts-Sierra Horticultural Products Company, Marysville, OH, USA) at the rate of 5 g kg^{-1} of growing medium. Stolons (approx. 30 to 40 cm in length and a minimum of 3 nodes) were used in experiments. Plants were 6–8 week-old.

Southern chinch bugs were collected from Royal Palm Beach (Palm Beach County, FL, USA) for all experiments. Insects were collected by vacuuming southern chinch bug-infested St. Augustinegrass lawns, as described by Cherry (2001). In the laboratory, fifth instars and adults were separated from the debris, placed into 20-l plastic buckets, provided with fresh Floratam runners, and maintained at 18°C in growth chambers until use. Twenty adult chinch bugs (1:1 sex ratio) were confined in organdy sleeve cages on the youngest three nodes of one stolon of a potted St. Augustinegrass plant. Chinch bugs were removed from the stolon before collecting the sample for biochemical analysis. A 2-g amount of a sample of auxiliary shoot (including leaf sheaths and blades) was excised from each stolon and collected 1, 3, 5, and 8 days after chinch bug infestation. Thes amples were frozen immediately in liquid nitrogen and stored at −80°C until analysis. Five replicate plants of each variety were used for each chinch bug infestation period along with an equal number of control plants whose stolons were confined in cages without chinch bugs.

Sample Preparation

Frozen St. Augustinegrass samples were ground into powder in a mortar chilled with liquid nitrogen. Soluble proteins were extracted using HEPES (4-(2-hydroxymethyl)-1-piperazineethanesulfonic acid) buffer (20 mM; 5 ml; pH 7.2) containing protease inhibitors [0.3 ml g^{-1} plant tissue: a mixture of 1 μM bestatin, 0.2 mM 4-(2-aminoethyl) benzenesulfonyl fluoride, 1 μM pepstatin A, 1 μM E-64, 10 μM leupeptin, 1 mM 1, 10-phenanthroline (Sigma, St. Louis, MO, USA), and 1% (wt/v) polyvinylpyrrolidone]. The homogenate was filtered through a 4X muslin cloth and centrifuged at 10,000×g (10 min at 4°C). The supernatant was collected, desalted using a PD-10 desalting column (Sephadex G-25M, Amersham Biosciences Inc., Piscataway, NJ, USA), and stored at −80°C until protein and enzyme analyses.

Estimation of Total Protein

Total protein content and enzyme activities were determined with a Beckman Model DU 640 Ultraviolet-Visible

spectrophotometer. Total protein content was determined by following the modified method of Lowry et al. (1951) using the Folin-Ciocalteau phenol reagent (Pierce Chemical, Rockford, IL, USA) and bovine serum albumin as a standard.

Enzyme Activities

Soluble POX specific activity was measured with guaiacol (Sigma, St. Louis, MO, USA) as a substrate. Increase in absorbance at 470 nm was monitored for 2 min using a protocol modified from Hildebrand et al. (1986) and Hori et al. (1997). Reactions were started by adding H_2O_2 (30% *v/v*; 10 µl) into a quartz cuvette containing HEPES-KOH (250 mM; 100 µl; pH 7.0), protein extract (5 µl); guaiacol (18 mM; 300 µl), and distilled water (585 µl). POX specific activity (µmoles mg protein^{-1} min^{-1}) was calculated using the molar absorptivity of guaiacol at 470 nm (ε = 26.6M^{-1} cm^{-1}).

Catalase-specific activity was determined following a modified protocol from Hildebrand et al. (1986). The reaction was conducted in a quartz cuvette, started by adding protein extract (200 µl) with HEPES-KOH (250 mM; 100 µl; pH 8.0), H_2O_2 (75 mM; 100 µl), and distilled water (600 µl). The reaction was monitored at 240 nm for 2 min; CAT specific activity was determined using the molar absorptivity of H_2O_2 at 240 nm (ε = 43.6M^{-1} cm^{-1}) and expressed as µmoles mg protein^{-1} min^{-1}.

PPO activity was measured using a protocol modified from Hori et al. (1997). The reaction was started in a cuvette by adding protein extract (25 µl) to HEPES-KOH (250 mM; 100 µl; pH 6.0), catechol (1.6%; 500 µl; Sigma, St. Louis, MO, USA) and distilled water (375 µl). PPO activity was monitored at 470 nm for 2 min and calculated as the change in A_{470} mg protein^{-1} min^{-1}.

LOX activity was determined by using a protocol modified from Skorzynska-Polit and Krupa (2003). Linoleic acid (Fluka, St. Gallen, Switzerland) substrate was prepared by following a protocol described in Koch et al. (1992). A stock solution of sodium linoleate was prepared by mixing linoleic acid (10 mM; 14 µl), Tween-20 (14 µl), and oxygen-free distilled water (2 ml). The mixture produced a milky emulsion after drawing mixing with a Pasteur pipette. The emulsion was cleared by addition of 0.5M NaOH (0.11 ml). The volume was made up to 5 ml with oxygen-free distilled water and dispensed into 2-ml screw-capped vials that were flushed with N_2 and stored at −20°C. The reaction was started in a quartz cuvette by adding linoleic acid (10 mM; 10 µl) to the protein extract (50 µl), HEPES-KOH (250 mM; 100 µl; pH 7.0), and distilled water (860 µl). The change in absorbance at 234 nm was recorded for 5 min. LOX activity was expressed as the change in A_{234} mg protein^{-1} min^{-1}.

Isozyme Profiles

Native gel electrophoresis (Mini-Protean III, Bio-Rad Laboratories, Inc., Hercules, CA, USA) was used to study isozyme expression of POX, PPO, and LOX. Equal amounts of protein (30 µg/well) were loaded into discontinuous 10-well polyacrylamide gels [4.5 % (w/v) and 7.5% (w/v)] for POX and PPO, and 5.0% (w/v) and 12.5% (w/v) gels for LOX. Gels were run for 120 min (at 30 mA at 4°C) using a tris-glycine (pH 8.3) continuous buffer for POX and PPO isozymes. The gels containing POX and PPO enzymes were stained using a protocol modified from Vallejos (1983); LOX isozymes were stained according to a protocol by Heinisch et al. (1996).

Gels to be stained for POX activity were incubated in sodium acetate buffer (50 mM, pH 5.0) and run at 25±2°C on a platform shaker (50 rpm). After 10 min of incubation, H_2O_2 (30%; 20 µl) and 4-chloronaphthol (10 mg dissolved in 0.5 ml methanol) were added to the buffer. Peroxidase activity was visualized as dark blue bands after approx. 20 min. Gels stained for PPO activity were soaked in HEPES buffer (20 mM; pH 7.2) containing DL-β-(3,4-dihydroxyphenylalanine DOPA (5 mM; Sigma, St. Louis, MO, USA) for 30 min at 25±2°C on a platform shaker (50 rpm). PPO activity was visualized after 30 min as dark brown bands on a clear background.

Gels to be stained for LOX activity were rinsed briefly in distilled water, incubated (30 min; 4°C) in linoleic acid substrate solution—prepared in the dark by mixing linoleic acid (50 µl) and 95% ethanol (50 µl)—and placed on a platform shaker (50 rpm). The gel was rinsed again in distilled water and incubated on a shaking platform (50 rpm at 25±2°C for 10 min). Gels were stained with sodium borate buffer (0.2 M; 20 ml; pH 9.0) containing *N*, *N*-dimethyl-*p*-phenylenediamine (0.5 g), methanol (4.5 ml), and acetic acid (0.5 ml; 1:1, acid:water), and diluted to 50 ml with distilled water. The isozymes were observed as pink bands.

Statistical Analysis

The study was designed as a completely randomized split-plot in time where insect infestation was the whole-plot treatment, and time after infestation was the sub-plot treatment with five replications. Mean enzyme activities in infested and control plants were compared within ploidy levels (polyploid varieties, FX-10 and Floratam; diploid varieties, Captiva and Palmetto) using PROC GLM (SAS 1999). The means of POX and PPO activities were log (x)-transformed to correct for nonhomogeneity of variances. Tukey's test was used for mean separations.

Results

Total Protein Content

There were no significant differences in total extractable protein between chinch bug-infested and control plants for any of the St. Augustinegrass varieties at any time period after infestation ($P > 0.05$); samples averaged 8.75 mg protein g^{-1} fw.

Peroxidase Activity

Polyploid FX-10 plants infested with southern chinch bug had nearly two-fold higher POX-specific activities 5 and 8 days after infestation compared to uninfested control FX-10 plants and infested and uninfested susceptible Floratam plants ($F_{3,48}$ = 43.20, $P<0.001$) (Fig. 1). There was no interaction between polyploid St. Augustinegrass varieties and infestation period. Similarly, diploid Captiva plants infested with southern chinch bugs had a two-fold increase in POX-specific activities 5 and 8 days after infestation compared to uninfested controls and infested or uninfested southern chinch bug-susceptible Palmetto ($F_{3,48}$ = 27.42, $P<0.001$). There also was no interaction between diploid St. Augustinegrass varieties and infestation period.

Polyphenol Oxidase Activity

There were no differences in PPO specific activity between the infested and control plants of the polyploid varieties, FX-10 and Floratam, at any time period after infestation (Fig. 2). However, PPO specific activity differed among control and infested Captiva and Palmetto ($F_{3,48}$ = 5.32, P= 0.003). The southern chinch bug-infested Captiva plants had higher PPO activity 5 and 8 days after infestation compared to their respective control plants. However, there were no differences in PPO activities among infested and control Palmetto plants.

Lipoxygenase Activity

Polyploid FX-10 plants infested with southern chinch bug had higher LOX specific activity 3, 5, and 8 days after infestation compared to their respective control plants and Floratam plants, whether infested or not ($F_{3,48}$ = 485.26, $P<0.001$) (Fig. 3). There was an interaction between polyploid St. Augustinegrass variety and duration of infestation ($F_{9,48}$ = 36.31, $P<0.001$); LOX specific activity in southern chinch bug-infested FX-10 plants peaked 3 days after infestation. It was 2-fold higher than 1 day after infestation, and then declined 5 and 8 days after infestation. The LOX specific activities in southern chinch bug-infested and control Floratam plants were not significantly different. However, chinch bug-infested FX-10 plants had higher LOX activity than uninfested FX-10 controls, Floratam controls, and infested plants 1 and 3 days after infestation. There were no differences in LOX specific activities between infested and control plants of the diploid varieties, Captiva and Palmetto, at any of the time periods studied.

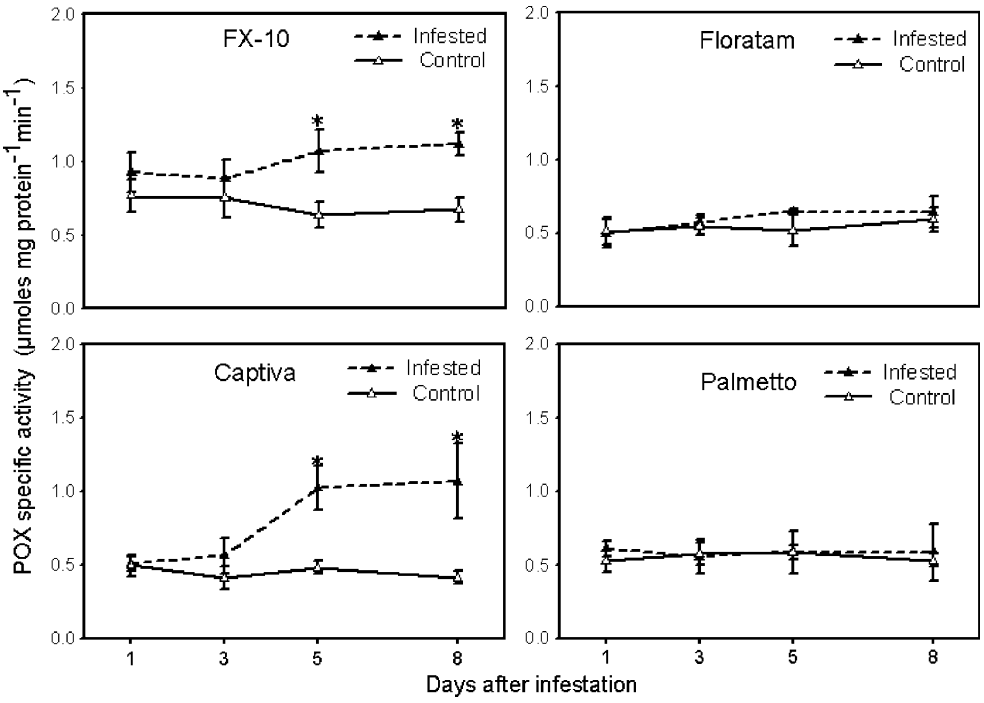

Fig. 1 Levels of peroxidase (POX) specific activity in polyploid (FX-10 and Floratam) and diploid (Captiva and Palmetto) St. Augustinegrass varieties 1, 3, 5, and 8 days after initiation of southern chinch bug feeding. Values are means ± SEM of five replicates. Means marked with * differ significantly between control and infested treatments ($P<0.05$, Tukey's test)

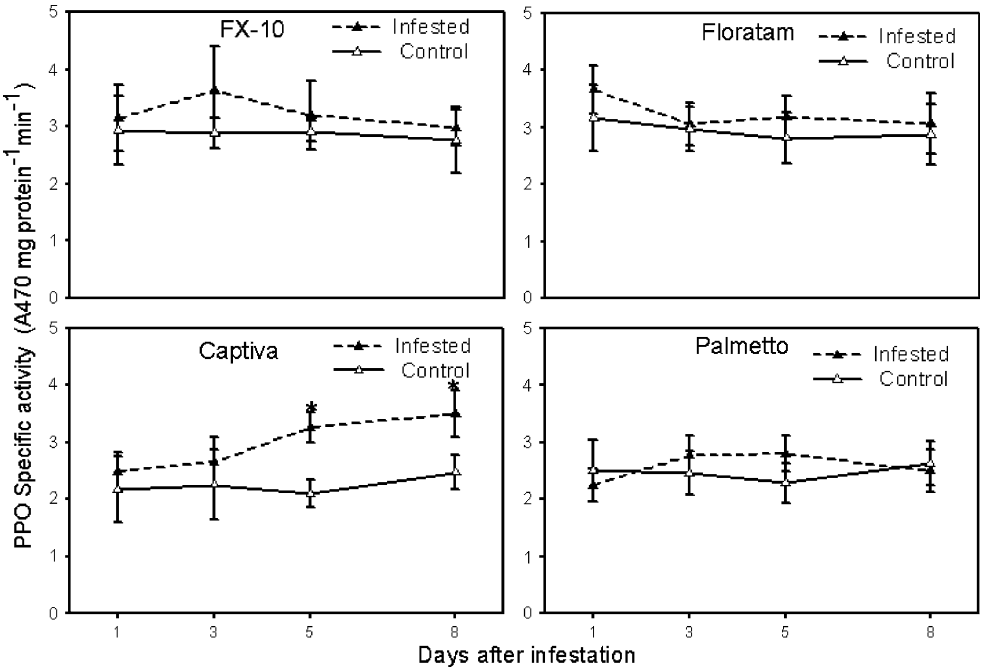

Fig. 2 Levels of polyphenoloxidase (PPO) specific activity in polyploid (FX-10 and Floratam) and diploid (Captiva and Palmetto) St. Augustinegrass varieties 1, 3, 5, and 8 days after initiation of southern chinch bug feeding. The values shown are means ± SEM of five replicates. Means marked with * differ significantly between control and infested treatments ($P<0.05$, Tukey's test)

Catalase Activity

There were no differences observed in CAT specific activity between southern chinch bug-infested and control plants at any time period after infestation in any of the St. Augustinegrass varieties studied ($P>0.05$, data not shown). The mean CAT specific activity in infested and control plants of the four St. Augustinegrass varieties was 5.99 μmoles mg protein^{-1} min^{-1}.

Isozyme Profile Studies

Native gels stained for POX-specific activity showed 5 and 3 isozymes in FX-10 and Captiva, respectively; two of them were induced 5 and 8 days after infestation compared to their respective controls (Fig. 4). There were 3 POX isozymes in Palmetto and 5 in Floratam with no visible difference between infested and control plants at any of the times after infestation (Fig. 4).

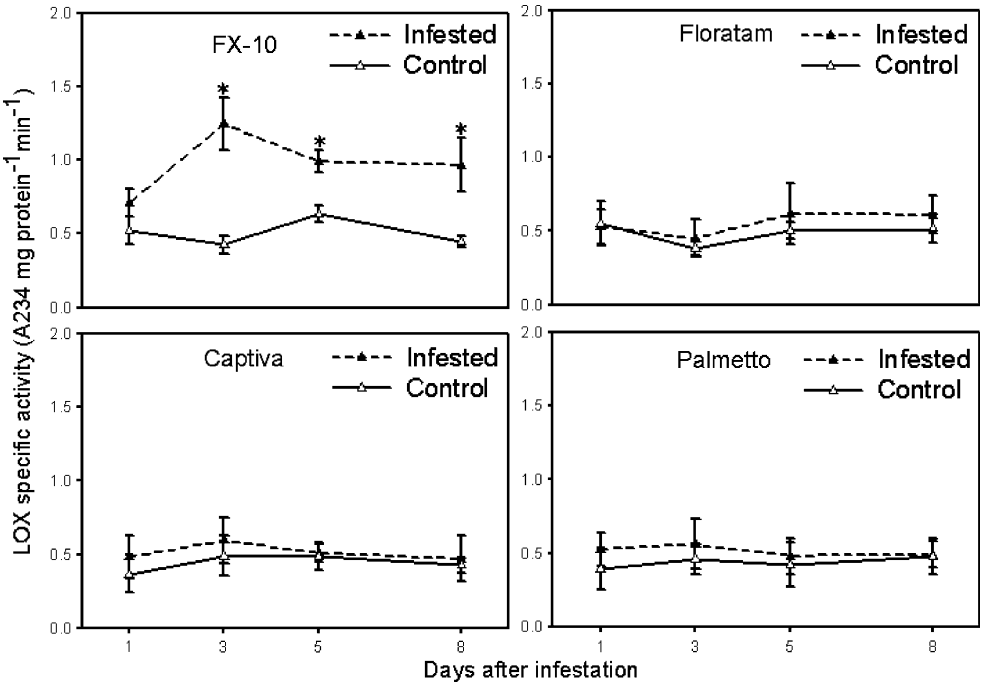

Fig. 3 Levels of lipoxygenase (LOX) specific activity in polyploid (FX-10 and Floratam) and diploid (Captiva and Palmetto) St. Augustinegrass varieties 1, 3, 5, and 8 days after initiation of southern chinch bug feeding. Values are means ± SEM of five replicates. Means marked with * differ significantly between control and infested treatments ($P<0.05$, Tukey's test)

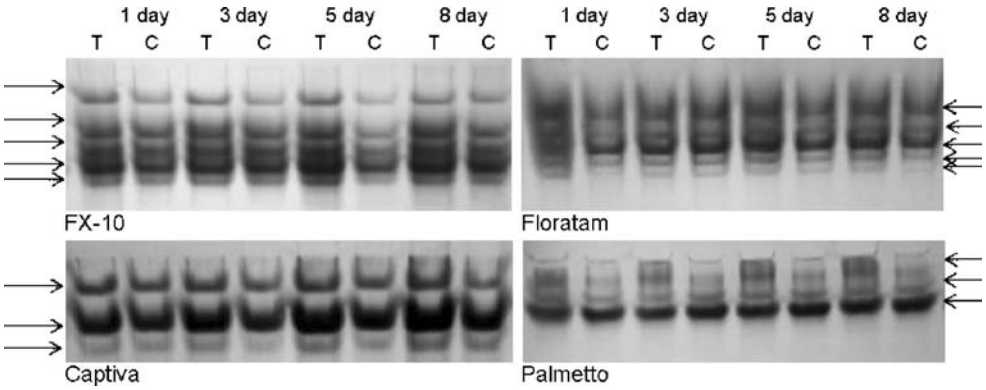

Fig. 4 Native gels stained for POX activity in polyploid (FX-10 and Floratam) and diploid (Captiva and Palmetto) St. Augustinegrass varieties 1, 3, 5, and 8 days after initiation of southern chinch bug feeding. T and C refer to the infested (i.e., treated) and control samples, respectively. Arrows indicate POX isoforms

Native gels stained for PPO activity showed 2 isozymes in Captiva, Palmetto, and Floratam and 3 in FX-10 with no apparent difference between southern chinch bug-infested and control plants at any of the time periods studied (Fig. 5). There were 3 LOX isozymes observed in FX-10, 2 in Captiva and Palmetto, and one in Floratam (Fig. 6). There were no apparent differences in LOX isozyme intensity or number between southern chinch bug-infested and controls plants.

Discussion

Infestation by southern chinch bugs neither increased nor decreased the total extractable protein content of four St. Augustinegrass varieties when measured 1, 3, 5, or 8 days after infestation. Our results agree with those of Heng-Moss et al. (2004) who found no increase in total protein content of resistant buffalograss varieties (Cody and Tatanka) after infestation by the western chinch bug, *Blissus occiduus* Barber. However, Ni et al. (2001) reported an increase in total protein in wheat varieties infested with the Russian wheat aphid, *Diuraphis noxia* (Mordvilko), and the corn leaf aphid, *Rhopalosiphum padi* (L.), in contrast to an earlier report of a two-fold decrease in total protein 2 days after infestation by *D. noxia* (van der Westhuizen and Pretorius 1995). The difference in results may be due to different methods used for determining protein concentration.

We found that both chinch bug-resistant varieties, FX-10 and Captiva, had a nearly two-fold increase in POX specific activity 5 and 8 days after infestation compared to uninfected control plants. Our results agree with many previous reports that POX specific activity increases after herbivore infestation (Hildebrand et al. 1986; Felton et al. 1994a, b; van der Westhuizen et al. 1998; Chaman et al. 2001; Ni et al. 2001; Heng-Moss et al. 2004; Khattab 2007). In contrast, while lupin varieties resistant to green peach aphid, *Myzus persicae* (Sulzer), had significantly different constitutive levels of POX and PPO activity, protease inhibitors and soluble phenolics, the levels of PPO and POX were not increased in response to aphid infestation (Cardoza et al. 2005).

Herbivore damage induces production of H_2O_2 in plants (Dowd and Lagrimini 1997). Oxidative enzymes such as POX and CAT regulate the level of H_2O_2, and POX activity is dependent on the supply of H_2O_2 *in vitro* (Duffy and Felton 1991). A high level of H_2O_2 produced in response to mechanical wounding of tomato plants acted as a secondary messenger and activated later-expressed defense genes,

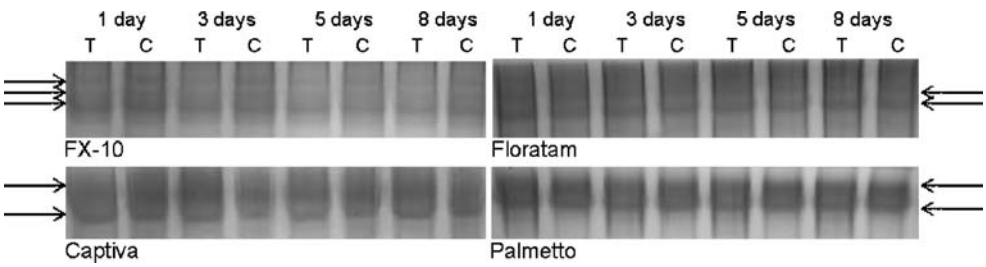

Fig. 5 Native gels stained for PPO activity in polyploid (FX-10 and Floratam) and diploid (Captiva and Palmetto) St. Augustinegrass varieties 1, 3, 5, and 8 days after initiation of southern chinch bug feeding. T and C refer to the infested (i.e., treated) and control samples, respectively. Arrows indicate PPO isoforms

such as those coding for proteinase inhibitors and polyphenol oxidase (Orozco-Cardenas et al. 2001). An increase in POX activity in insect-resistant plants may help to detoxify the peroxides, thus reducing plant tissue damage when compared to susceptible plants (Hildebrand et al. 1986). Peroxidase enzymes are involved with plant cell wall-building processes, by mediating the oxidation of hydroxycinnamyl alcohols into free radical intermediates, cross-linking of polysaccharides and extensin monomers, lignification, and suberization (Chittoor et al. 1999). Brisson et al. (1994) suggested that oxidative cross-linking of the plant cell wall could enhance its ability to slow pathogen ingress. Such a reinforcement of the cell wall in response to insect feeding may serve as a mechanical barrier and prevent insect stylets from reaching their feeding sites (i.e., phloem sieve elements in the case of southern chinch bug). Enhancement of POX isozyme activity in maize (*Zea mays* L.) increased resistance to herbivores and pathogens (Dowd and Lagrimini 1997).

Plant catalases scavenge mitochondrial and peroxisome H_2O_2, and reduce it to H_2O and O_2. Zhu-Salzman et al. (2004) found that CAT genes were down-regulated in resistant sorghum infested with greenbug, and speculated that reduced CAT activity could help the plant maintain high H_2O_2 levels that damage the insect midgut. Park et al. (2006) also found that CAT genes were down-regulated in greenbug resistant sorghum varieties. However, Heng-Moss et al. (2004) reported a loss in CAT activity in response to *B. occiduus* on susceptible buffalograss varieties. Our study found no association between CAT-specific activity levels and southern chinch bug resistance in St. Augustinegrasses, and supports previous reports that used other plant-insect combinations that also indicated no relationship between CAT activity and resistance (Faccioli 1979; Matkovics et al. 1981; Hildebrand et al. 1986).

The association of PPO activity with host plant resistance to insects occurs in many plants including tomato, potato, coffee, and poplar (Duffy and Felton 1991; Constabel et al. 1996; Chaman et al. 2001; Wang and Constabel 2004; Thipyapong et al. 2006). In our studies, only Captiva had higher levels of PPO specific activity as a result of southern chinch bug infestation, whereas FX-10 showed no induction. Heng-Moss et al. (2004) found no association between PPO activity in buffalograsses and their resistance to *B. occiduus*.

Our studies indicate that FX-10 had a two-fold higher LOX-specific activity 3 days after southern chinch bug infestation, and a reduced, but still higher activity 5 and 8 days following infestation compared to control plants (Fig. 4). Increased LOX activity has been reported in soybean in response to two-spotted spider mite infestation (Hildebrand et al. 1986) and attack by *Helicoverpa zea* larvae (Boddie) (Felton et al. 1994a). Increased levels of LOX activity caused oxidative damage in midgut epithelial cells of *H. zea* larvae and reduced their growth (Felton et al. 1994a). Bi et al. (1997) showed an increase in LOX in *H. zea* damaged cotton squares along with altered phenolic contents. Gene expression studies showed that LOX transcripts were elicited in tomato plants in response to attack by the aphid *Macrosiphum euphorbiae* (Thomas) and *M. persicae* (Fidantsef et al. 1999). Gene expression was locally upregulated in *Nicotiana attenuata* Torrey ex Watson after *Macrosiphum nicotianae* Blackman infestation (Voelckel et al. 2004). LOX-deficient *N. attenuata* plants, when planted into native habitats, became more vulnerable to adapted herbivores such as *Manduca sexta* (L.) and attracted new opportunistic herbivores, such as *Empoasca* spp. leafhoppers (Kessler et al. 2004).

Lipoxygenases are ubiquitous enzymes that catalyze the hydroperoxidation of polyunsaturated fatty acids having *cis, cis*-pentadiene moieties (Hildebrand et al. 1986). Linoleic acid and linolenic acid are the major LOX substrates in plants (Hildebrand et al. 1986). Lipid peroxidation by LOX results in formation of fatty acid hydroperoxides that may be degraded to highly reactive aldehydes, γ-ketols, and epoxides (Gardner 1991), hydroxyl radicals, singlet oxygen, superoxide ion and peroxyl, acyl, and carbon-centered radicals (Kanofsky and Axelrod 1986) either through enzymatic or chemical means.

Gardner (1979) mentioned that the interactions between lipid hydroperoxides and proteins results in protein-protein cross linking, and amino acid damage. These chemical changes in proteins may affect the assimilation of insect amino acids. Lipid peroxidation end products could be deterrent to insect feeding and operate via antixenosis, or be toxic and function via antibiosis (Felton et al. 1994a). Both modalities of resistance occur in St. Augustinegrass against the southern chinch bug (Rangasamy et al. 2006). Shukle and Murdock (1983) demonstrated that LOX could act directly as a defense against insect attack in soybean. Lipoxygenases also are involved in inducible herbivore resistance. Oxidation of linolenic acid by LOX is the first step in the jasmonic acid signaling pathway, which has been implicated in the coordination of direct plant defense [e.g., production of oxidative enzymes and protease inhibitors (Staswick and Lehman 1999; Mao et al. 2007)] and indirect plant defense [e.g., production of volatiles (Dicke et al. 1999; Thaler 1999)]. Rayapuram and Baldwin (2006) investigated the performance of *M. sexta* larvae on *N. attenuata* plants silenced in LOX3 expression and jasmonic acid signaling. They found that LOX3-mediated defense in wild plants reduced larval growth, consumption, and frass production compared to the mutant. Mao et al. (2007) transformed maize plants with the wheat oxalate oxidase gene and reported that the up-regulated LOX transcripts and 14-fold higher free phenolics in transgenic plants were positively associated with resistance to the European corn borer (*Ostrinia nubilalis* H.) compared to control plants.

While enzyme induction has been examined in this work, other biochemical adaptations including enzyme inhibition, activation, and substrate availability also may be important factors in determining this trait. We associate the increased levels of POX and LOX in FX-10 and POX and PPO in Captiva with southern chinch bug resistance in these varieties. Increased POX activity seems to be due to the induction of specific isozymes. The fact that enzyme induction differs between the two resistant cultivars suggests that the mechanisms of resistance also differ. This corroborates our finding (Rangasamy et al. 2006) that while FX-10 shows antixenosis to southern chinch bug, Captiva exhibits both antixenosis and antibiosis. Together, our results support the hypothesis that oxidative enzymes play a vital role in herbivore resistance in plants. Our data suggest that identification of genes that encode inducible PPO, POX, and LOX enzymes could be the first step in understanding southern chinch bug resistance in St. Augustinegrass and will be valuable markers for breeding southern chinch bug resistant varieties. Our research supports the hypothesis that chinch bug resistance in St. Augustinegrass has a metabolic basis and highlights the possible involvement of lignification and oxidative enzymes in secondary product synthesis for chinch bug resistance in St. Augustinegrass.

Acknowledgements We thank Dr. Marty Marshall (Food Science and Human Nutrition Department, University of Florida) for use of his spectrophotometer and Dr. Eric Schmelz (USDA ARS, Center for Medical, Agricultural, and Veterinary Entomology, Gainesville, Florida) for comments on an earlier draft of the manuscript. This research was supported by the Florida Agricultural Experiment Station and a Wedgeworth Fellowship to R. C.

Interactive Influence of Leaf Age, Light Intensity, and Girdling on Green Ash Foliar Chemistry and Emerald Ash Borer Development

Yigen Chen · Therese M. Poland

Received: 18 May 2009 / Revised: 17 June 2009 / Accepted: 19 June 2009 / Published online: 2 July 2009

Abstract Biotic and abiotic environmental factors affect plant nutritional quality and defensive compounds that confer plant resistance to herbivory. Influence of leaf age, light availability, and girdling on foliar nutrition and defense of green ash (*Fraxinus pennsylvanica* Marsh) was examined in this study. Longevity of the emerald ash borer, *Agrilus planipennis* Fairmaire (Coleoptera: Buprestidae), adults reared on green ash foliage subjected to these factors was assayed. Mature leaves generally were more nutritious with greater amino acids and a greater ratio of protein to non-structural carbohydrate (P:C) than young leaves, in particular when trees were grown in shade. On the other hand, mature leaves had lower amounts of trypsin and chymotrypsin inhibitors, and total phenolics compared to young leaves. Lower defense of mature leaves alone, or along with higher nutritional quality may lead to increased survival and longevity of emerald ash borer feeding on mature leaves. Sunlight reduced amino acids and P:C ratio, irrespective of leaf age and girdling, and elevated total protein of young foliage, but not protein of mature leaves. Sunlight also dramatically increased all investigated defensive compounds of young, but not mature leaves. Girdling reduced green ash foliar nutrition, especially, of young leaves grown in shade and of mature leaves grown in sun. However emerald ash borer performance did not differ when fed leaves from trees grown in sun or shade, or from girdled or control trees. One explanation is that emerald ash borer reared on lower nutritional quality food may compensate for nutrient deficiency by increasing its consumption rate. The strong interactions among leaf age, light intensity, and girdling on nutrition and defense highlight the need for caution when interpreting data without considering possible interactions.

Keywords *Fraxinus pennsylvanica* · *Agrilus planipennis* · Abiotic factors · Foliar nutrition · Plant defense

Introduction

Low nutritional quality and occurrence of plant secondary metabolites in many cases contribute to plant resistance to herbivory. For example, herbivores that feed upon plants with higher nutritional quality generally grow faster and perform better (i.e., have greater reproductive potential and longevity) than those reared on lower quality plants (Mattson 1980; Chen et al. 2008a. In addition, many plant allelochemicals adversely affect herbivore colonization and life histories (Ryan 1990).

Levels of nutrients and defensive compounds change in response to biotic and abiotic factors. One factor is age of leaves. Young and expanding tissues generally are believed to contain higher concentrations of nutrients because these tissues require more resources to support their rapid growth (Mattson 1980; Harper 1989). Regarding defenses, it is widely accepted that plant parts with higher fitness values should be better defended (Optimal Defense theory; McKey 1979). The greater fitness value of young expanding leaves over older leaves has been demonstrated experimentally in some plants (McKey 1979; Strauss et al. 2004), as has the elevated accumulation of chemical defenses in these leaves (Ohnmeiss and Baldwin 2000; Chen et al. 2008b).

Light is another factor that may affect plant nutritional and defensive compounds. Reduced light intensity results in low absorbance of solar energy in the light-dependent stage of plant photosynthesis. The resultant low storage of chemical energy may impair capture of CO_2 from the atmosphere and its conversion to photosynthates in the light-independent stage, and subsequent allocation of photosynthates to growth and defense. Plant response to a shaded environment is similar to 'carbon stress' described by the carbon-nutrient balance (CNB) hypothesis (Bryant et al. 1983) an idea that has increasingly lost credibility in recent years (Hamilton et al. 2001; Cipollini et al. 2002; Koricheva 2002; Nitao et al. 2002). According to this hypothesis, trees grown under shaded environments would be more carbon-limited and have lower amounts of carbon-based defensive compounds, while amounts of nitrogen-based defensive compounds would be higher.

Girdling, removal of a ring of bark and phloem around the outer circumference, is a practice used worldwide in agriculture, horticulture, and forestry, with various purposes (Noel 1970; Lahav et al. 1986; Mostafa and Saleh 2006). Girdling interrupts the transport of photosynthates to the roots and has a variety of physiological and biochemical effects on plants such as accumulation of carbohydrates above the girdle and a decline of carbohydrates below the girdle (Noel 1970; Roper and Williams 1989; Li et al. 2003; Mostafa and Saleh 2006). An accumulation of amino acids above the girdle has been reported in *Salix fragilis* twigs (Mittler 1958). Plants are also known to induce defensive chemicals following mechanical wounding and insect herbivory (Stout et al. 1998; Reymond et al. 2000; Lawrence and Koundal 2002), although the effects of girdling on the induction of defensive compounds are little known. Therefore, girdling might alter plant resistance to herbivory due to changes in nutritional qualities and defense.

In this study, we examined the effects of leaf age, light intensity, and girdling on green ash (*Fraxinus pennsylvanica* Marsh) resistance to emerald ash borer (EAB), *Agrilus planipennis* Fairmaire (Coleoptera: Buprestidae), from a nutritional and defensive chemistry perspective. EAB is an exotic species first detected around Detroit Michigan, USA and Windsor Ontario, Canada in 2002, and is threatening the ash resource in North American (Haack et al. 2002; Poland and McCullough 2006). EAB attacks ash trees (*Fraxinus* spp.) of all species and sizes from large mature trees to trees that are 2 cm in diameter (Cappaert et al. 2005). Adults feed on foliage, and females lay eggs in bark cracks and crevices. The larvae tunnel in the cambial region disrupting the flow of nutrients and girdling the tree. Progress has been made on EAB host range (Anulewicz et al. 2007, 2008), biology (Bauer et al. 2004; Cappaert et al. 2005), behaviors (Rodriguez-Saona et al. 2006; Lelito et al. 2007), and chemical ecology (Rodriguez-Saona et al. 2006; Eyles et al. 2007; Crook et al. 2008; de Groot et al. 2008). EAB adults have been observed to prefer trees grown in open areas over those in the shady ones (Poland et al. 2005). Girdled trees are more attractive to EAB than non-girdled trees (Poland et al. 2005; McCullough et al. 2006, 2009). However, little is known to date about mechanisms that underlie these EAB behaviors and ash tree resistance to EAB, except that certain phloem phenolics might account for the relatively higher resistance of Manchurian ash (*F. mandshurica*) to EAB (Eyles et al. 2007). Elucidation of these mechanisms contributes to ash tree breeding programs to develop resistant varieties or hybrids.

We quantified the nutritional and defense compounds trypsin and chymotrypsin inhibitors, and total phenolics of green ash foliage, and we evaluated adult EAB performance reared on green ash foliage subject to various biotic and abiotic factors. Specifically we tested the following hypotheses: (1) young leaves have higher nutritional qualities and greater defensive compounds than mature leaves; (2) shaded trees have higher foliar nutrients and nitrogen-based defensive compounds (i.e., proteinase inhibitors) but lower carbon-based defensive compounds (phenolics), according to the CNB hypothesis; (3) girdled trees have elevated carbohydrate levels and defensive protease inhibitors and phenolics, but reduced P:C ratio; and 4) adult EAB will have greater longevity on leaves with higher nutritional quality and lower defense compounds.

Materials and Methods

Green Ash Green ash seedlings (2-yr-old and ca. 15–30 cm tall) were used for the ease of manipulation of the treatments. Seedlings were purchased from Lawyer Nursery Inc. (West Plains, MT, USA) in February, 2008, and stored in a dark room at 4°C until potting. Seedlings were potted with TPOT2 tree pots (Width: 15 cm; Height: 41 cm; Volume: 6.23 L; Stuewe & Sons, Inc., Corvallis, OR, USA) using BACCTO® High Porosity Professional Planting Mix (Michigan Peat Co., Houston, TX, USA) and soil at a ratio of 3:1 as planting medium. Seedlings were grown during July–August, 2008 (ca. L16:D8 h) in a greenhouse set at approximately 25±2°C and supplemented with 400-Watt high-pressure sodium lamps from 10:00 pm to 6:00 am. The greenhouse is located on campus of Michigan State University, East Lansing, MI, USA. Osmocote 14-14-14 Classic fertilizer (Scotts Company LLC., Marysville, OH, USA) was mixed with the planting medium at ca. 4 kg m^{-3} soil. Seedlings were watered as need.

Approximately 5 weeks after potting when seedlings had 4–6 fully expanded compound leaves and 3–6 expanding leaves, seedlings were subjected to light intensity (2 levels:

Shade and Sunny) and girdling (2 levels: Girdled and un-girdled) treatments. Shade treatment was a 1.2×0.7×1.1 m (L×W×H) cage built with 1.9 cm (inner diam) PVC pipes (Charlotte, NC, USA) covered with 80% TapeKnit shade cloth (American Nettings & Fabric Inc., Ferndale, WA, USA). The shade cloth reduced the amount of sunlight available to the trees by approximately 70–80%. The sunny treatment did not have a shade cloth cage. Two light intensity levels were assigned randomly to four whole plots arranged in a straight line. Twenty seedlings of similar size were randomly assigned to each of the four whole plots. Half (10) of the seedlings assigned to each whole-plot were randomly selected and girdled (i.e., a 2.5 cm band of phloem removed on the stem at a height of 15 cm from the soil), and the other half were left un-girdled. At the end of the experiments (2 weeks following these treatments), one young (Young: expanding leaves less than 3-weeks-old) or one mature (Mature: fully expanded leaves that were 4- to 6-weeks-old) compound leaf was randomly collected from each plant. Therefore, the experimental design was a completely randomized split-plot design with light intensity as whole plots. The split plots were girdling and leaf age arranged as a 2×2 factorial.

Insects EAB infested ash trees were felled at the end of 2007 and early 2008 and cut into 90-cm long logs. Logs were held in cold storage at 4°C. As beetles were required for experiments, they were allowed to emerge in rearing tubes at 25°C. Upon emergence they were separated by sex and used for bioassay.

Effects on F. pennsylvanica Growth and Leaf Chlorophyll Contents To examine the effects of shade and girdling on green ash growth, heights (from soil to meristem) of green ash seedlings were determined at the onset of treatments and again at the end (2 weeks following treatments). Because leaf chlorophylls are the most important photosynthetic pigments of higher plants and are positively correlated to photosynthetic potential (Filella et al. 1995; Markwell et al. 1995; Richardson et al. 2002), leaf chlorophyll content was measured by using a Minolta SPAD-502 (Konica Minolta Sensing, Inc., Japan) at the end of experiments. Chlorophyll content (μmol m^{-2}) was calculated according to a standard curve for corn (*Zea mays*) plants, chlorophyll (μmol m^{-2})=10 $^{(M^{\wedge}\ 0.261)}$, where M is the chlorophyll meter reading (Markwell et al. 1995). The experiment was a split-plot design as described above.

Effects on F. pennsylvanica Nutritional Chemistry Seedlings were grown as described above. Approximately 2 weeks after treatments, one mature (3–4 weeks after full expansion) or one young (within 2 weeks following sprouting; ca. 20–50% size of mature leaflets) compound leaf from each tree was cut and flash frozen in liquid nitrogen. Samples were brought to the laboratory in a cooler containing dry ice, and 2–4 leaflets of the collected compound leaf were ground to fine powder with mortar and pestle in liquid nitrogen. The ground plant tissue was stored at −20°C until bioassayed.

Approximately 40–80 mg of ground plant tissue were used for extraction. Extraction of total soluble protein, amino acids, and soluble non-structural carbohydrate (glucose, fructose, and sucrose) followed Bi et al. (2003) and Chen et al. (2009). Extraction of non-soluble non-structural carbohydrate (starch) followed Marquis et al. (1997) and Chen et al (2009). Total protein content was determined following the Bradford protein assay, and calculated with a standard curve established by using bovine serum albumin (Ni et al. 2001). Amino acid content was colorimetrically determined using the cadmium (Cd)-ninhydrin procedure (Doi et al. 1981). The amino acid content was calculated from a standard curve generated using glycine as a standard. Glucose, fructose, and sucrose contents were determined by using glucose assay kit (Sigma-Aldrich, St. Louis, MO, USA) and calculated from a standard curve generated using D-glucose as a standard. The starch content was estimated in glucose equivalents. All chemicals used in this experiment and the following were purchased from Sigma-Aldrich (St. Louis, MO, USA), or Fisher Scientific (Pittsburgh, PA, USA).

Effects on F. pennsylvanica Protease Inhibitors and Total Phenols Leaf samples were collected and prepared as in the preceding experiment. Trypsin and chymotrypsin inhibitors extraction followed Stout et al. (1998). Ground and weighed plant tissue was mixed with a Tris-HCl buffer (pH 7.8) containing 7% polyvinylpolypyrrolidone, 1.67 mM phenylthiourea, 0.3 mM KCl, and 0.4 mM ascorbic acid. The mixture was centrifuged at 10,000×g for 10 min. The supernatant was used for assay.

The trypsin inhibitor assay followed Walsh and Wilcox (1970), and Broadway (1993). Bovine trypsin (0.2 mg ml^{-1} in 1 mM HCl) was mixed with an equal volume of plant extract and incubated at room temperature for 10 min. Eighty microliters of the mixture was added to 3 ml substrate solution [1.04 mM *Nα-p*-tosyl-L-arginine methyl ester (TAME) in 0.05 M Tris-HCl buffer]. The activity of trypsin that remained after reaction with trypsin inhibitors in the sample was monitored at 247 nm for 3 min with a Shimadzu UV Mini-1240 spectrophotometer at 25°C and was converted to amount of trypsin from a standard curve using Bovine trypsin within the linear range (0~0.1 mg ml^{-1}). The amount of trypsin inhibitors was expressed as amount of inhibited trypsins, and was calculated by subtracting the trypsins remaining after the

reaction from the amount of trypsin (8 μg) used in the beginning of assay.

The chymotrypsin inhibitor assay followed Walsh and Wilcox (1970), and Broadway (1993). *Nα*-Tosyl-Lys-chloromethylketone (TLCK)-treated bovine chymotrypsin (0.2 mg ml^{-1} in 1 mM HCl) was mixed with an equal volume of plant extract and incubated at room temperature for 10 min. Eighty microliters of the mixture were added to 3 ml substrate solution containing 0.5 mM *N*-benzoyl-L-tyrosine ethyl ester (BTEE), 5% methanol, and 0.05 M Tris-HCl buffer. The activity of chymotrypsin that remained after the reaction with chymotrypsin inhibitors was monitored at 256 nm for 3 min with a Shimadzu UV Mini-1240 spectrophotometer at 25°C and was converted to amount of chymotrypsins from a standard curve using Bovine chymotrypsin within the linear range (0~0.1 mg ml^{-1}). The amount of chymotrypsin inhibitors was expressed as amount of inhibited chymotrypsins, and was calculated by subtracting chymotrypsins remaining after the reaction from the amount of chymotrypsin (8 μg) used in the beginning of assay.

Total phenol extraction followed Hagerman (1988) and Cork and Krockenberger (1991). Determination of total phenol followed Graham (1992). Briefly, ground and weighed plant tissue was extracted ×3, each time with 1 ml 70% acetone at 4°C in the dark for 30 min. The supernatant after each centrifugation was pooled and its concentration [m*mol* g^{-1} fresh weight (FW)] determined using a modified Prussian blue assay. An external standard curve with gallic acid within the linear range was constructed to calculate sample concentration.

EAB Performance in Response to Green Ash Foliage To evaluate effects of leaf age, shade, and girdling on green ash foliar nutritional and defensive chemistry, adult EAB longevity reared on foliage subject to these treatments was assayed. One newly emerged adult EAB male and one female were placed in a sealed 295-ml plastic drinking cup where they were fed excised compound leaves from different treatments (treatments were as described above for the previous experiment). A 5×7 cm area on the side of the cup was cut away and sealed with 1×1 mesh for ventilation. The petioles of excised leaves were placed into 20-ml glass vials filled with water before being placed into cups. Leaves were exchanged with fresh leaves of the same treatment every 2–3 days. Survival of EAB was monitored daily until all EAB were dead. Each treatment was replicated ten times (cups). Cups were kept in chambers set at 25±2°C and 70% relative humidity with a photoperiod of L14:D10h.

Statistical Analyses All experiments were completely randomized split-plot designs with light intensity as whole plots, and girdling and leaf age (arranged as a 2×2 factorial) as split plots. Leaf cholorphyll, foliar total proteins, amino acids, TNC, protein:TNC ratio, trypsin inhibitors, chymotrypsin inhibitors, total phenolics, and EAB longevity were analyzed by PROC MIXED in SAS (SAS Institute 1999) with the interaction of light intensity and its replication as a random effect. Protein:TNC ratio data were log transformed before being subject to analysis. Survival of EAB adults was analyzed with repeated measure ANOVA (PROC GLM in SAS) with date as the repeated measure. Comparison was separately conducted between Young and Mature leaf treatments, between Sunny and Shady treatments, and between Control and Girdled treatments. In all analyses, the type I error α was controlled at 0.05.

Results

Effects on Green Ash Growth and Leaf Chlorophyll Content Green ash seedling height was not affected by light intensity or girdling (data not shown). Effects of leaf age, light condition, and wound status on leaf chlorophylls are shown in Table 1. Mature leaves had higher leaf chlorophyll than young leaves. For mature leaves, exposure to sunny conditions decreased leaf chlorophyll levels, while girdling had no effect. For young leaves, sunny conditions decreased leaf chlorophyll levels of girdled trees, but had no effect on chlorophylls of control trees; girdling decreased chlorophylls of trees under sunny conditions, while it did not affect chlorophylls of trees under shady conditions.

Effects on Green Ash Foliage Nutritional Chemistry Total proteins, amino acids, TNC, and P:C in relation to leaf age, light, and girdling treatments are shown in Table 2. Leaf age and girdling did not affect the amount of proteins. Exposure to sunny conditions increased proteins of young but not mature leaves. Mature leaves had significantly greater amino acids than young leaves, regardless of light and girdling treatments. Shading increased amino acid quantity, while girdling did not affect amino acids.

Leaves from trees grown under sunny conditions had higher TNC levels, irrespective of leaf age and girdling. Girdling increased TNC levels when trees were grown under sunny conditions, but not under shady conditions. Mature leaves had greater TNC than young leaves when trees were under sunny conditions. In contrast, young leaves had greater TNC content under shady conditions.

Girdling generally decreased P:C. The reduction in P:C was especially obvious in young leaves grown under shady conditions and in mature leaves grown under sunny conditions. Under sunny conditions, P:C was almost

[e] A 2.5 cm band of phloem removed from stem at a height of 15 cm from the soil.

Effects on Green Ash Foliage Defensive Compounds Trypsin and chymotrypsin inhibitors, and total phenolics of *F. pennsylvanica* foliage in response to light, girdling, and leaf age are shown in Table 3. The level of trypsin inhibitors was more than 30% greater in young leaves than in mature leaves. Light exposure and girdling had no significant influence on levels of trypsin inhibitors. The interaction between light and leaf age on chymotrypsin inhibitors was significant. Under sunny conditions, young leaves had more than three times higher chymotrypsin inhibitor levels, compared to mature leaves. However, under shady conditions, the difference in chymotrypsin inhibitors was not significant. Growth under sunny conditions more than doubled chymotrypsin inhibitor levels of young leaves, but had no significant effect in mature leaves.

The amount of total phenols in foliage from the sunny treatment was more than twice as high as in foliage from the shade treatment. Light exposure interacted with leaf age: under sunny conditions, young leaves had more than twice the level of total phenols compared to mature leaves; however, under shady conditions, mature leaves had greater total phenols than young leaves. Girdling decreased total phenolics of young leaves under shady conditions, while it elevated total phenolics of mature leaves under sunny conditions.

EAB Performance in Response to Green Ash Foliage Subject to Age, Shade, and Girdling Survival of EAB adults feeding on green ash foliage of various treatments over time is shown in Fig. 1A–C. Survival of EAB grown on mature leaves was greater than that on young leaves (Fig. 1A). There was no significant difference in survival of EAB feeding on foliage grown under sunny compared to shady conditions (Fig. 1B), or foliage from girdled vs. control trees (Fig. 1C). Similarly, only leaf age significantly influenced EAB adult longevity, which was greater on older leaves (Fig. 1D).

Discussion

Effects of Leaf Age on Plant Nutritional Quality and Defense Young and growing tissues generally are believed to contain higher quantities of nutrients (Mattson 1980; Harper 1989; White 1993), because these tissues require more resources to support their rapid growth. Total soluble protein accounted for less than 1.6% of the fresh weight of leaf tissues in this study, which might indicate the scarcity of nitrogen sources for arthropods feeding on green ash foliage. The amounts of total soluble protein did not differ between young and mature leaves (Table 2). However, mature leaves had greater levels of amino acids than young leaves, which is contrary to what is typically believed. Amino acid levels in plants and animals are in many cases

elevated by stress (Good and Zaplachinski 1994; Bischof 1996; Dadmarz et al. 1998). We were not aware of any stress other than shade and girdling that the experimental seedlings experienced in this study. Therefore, higher amount of total amino acids in mature than young green ash leaves may be intrinsic. Nutrient balance, especially the ratio of protein to digestible carbohydrate (P:C) also has been shown to be important for the development of many insects; several of them chose higher P:C over lower P:C when given choices in the laboratory using artificial diets (Lee et al. 2002; Bede et al. 2007). The effects of leaf age on P:C interacted with the effect of light exposure: under sunny conditions, young leaves had greater P:C than mature leaves, especially in girdled trees, because young leaves had less TNC than mature leaves. On the other hand, under shady conditions mature leaves had higher P:C compared to young leaves, because older leaves had less TNC than young leaves. Interactive effects of leaf age and light condition on tannin concentration have been observed in *Inga oerstediana* seedlings (Nichols-Orians 1991). Thus, light condition may need to be considered when studying the effect of leaf age on nutritional qualities and defensive chemistry.

Young leaves had greater levels of trypsin and chymotrypsin inhibitors, and total phenolics than mature leaves in this study (Table 3). This is *consistent* with Optimal Defense theory, predicting that plant parts with higher fitness value should be better defended (McKey 1979). The greater fitness value of young expanding leaves over older leaves has been experimentally demonstrated in other study systems (McKey 1979; Strauss et al. 2004), as has the elevated accumulation of chemical defenses in these leaves (Ohnmeiss and Baldwin 2000; Chen et al. 2008b).

Effects of Light or Shade on Plant Nutritional Quality and Defense Exposure to sunlight elevated total proteins of

young green ash leaves, whereas it did not affect proteins of mature leaves in the study. The increased proteins in young leaves under sunny conditions might be partly attributable to trypsin and chymotrypsin inhibitors because the pattern of protein changes in young leaves under sunny conditions parallels that of trypsin and chymotrypsin inhibitor levels (discussed below). In contrast, exposure to sunlight decreased amino acid levles and P:C ratio, irrespective of leaf age and girdling. The lower P:C of leaves in the sun is due to a greater rate of increase in TNC in these leaves rather than an increase in total proteins. Although sunlight exposure reduced leaf chlorophyll levels (Table 1), it brought about net accumulation of TNC in foliage grown in the sun. On the other hand, although shading increased leaf chlorophyll content in compensation for lower sunlight, it brought about a net decline of TNC. Sunlight sharply elevated amounts of chymotrypsin inhibitors (nitrogen-based defensive chemicals) and total phenolics (carbon-based defensive compounds) of young leaves, but not mature leaves. A similar pattern of light effects on tannin levels of young and mature leaves has been observed in *Inga oerstediana* (Nichole-Orians 1991). The tannin levels of young *I. oerstediana* leaves grown to maturity in 20% of full sunlight was increased compared to young leaves grown to maturity in 2% of full sunlight. However, light intensity did not change tannin content of already mature leaves. The increase in chymotrypsin inhibitors for young leaves in the sun was *inconsistent* with the predictions of the CNB hypothesis that argues that trees grown under sunny environments should have lower nitrogen-based defensive but higher carbon-based defensive compounds (Bryant et al. 1983), while the elevation of total phenolics in young leaves in the sun followed the CNB predictions. The fact that defensive compounds, both carbon- and nitrogen-based, were elevated only in young leaves, highlights the need for caution when interpreting data without considering possible interactions such as leaf age. This also indicates the need to consider as many interactions as possible when developing hypotheses.

Effects of Girdling on Plant Nutritional Quality and Defense Girdling reduced leaf nutritional quality, in particular of young leaves grown in the shade and of mature leaves grown in the sun. The reduction of P:C was mainly due to accumulated TNC. Girdling is known to elevate TNC amounts above the girdled sites in many plant species including white ash, *F. Americana* (Noel 1970; Roper and Williams 1989; Li et al. 2003). The interactive effects of girdling, leaf age, and sunlight intensity on TNC indicated that the effects of girdling on foliage TNC were dependent on leaf age and growing conditions of seedlings. The greater photosynthetic capacity of mature leaves over young leaves grown in the sun (higher leaf chlorophyll levels; Table 1) might explain the accumulation of TNC in mature leaves from girdled trees in the sun. However, the increased accumulation of TNC in young leaves from girdled trees in the shade is contradictory to the higher photosynthetic capacity of mature leaves over young leaves from girdled trees grown in the shade, which is also indicated in Table 1. One explanation is that girdling makes TNC in young leaves grown in the shade more demanding, and TNC synthesized in mature leaves is exported to young leaves. No significant changes in protease inhibitors and total phenolics were observed following girdling. This is surprising since a variety of plant defensive chemicals are known to be induced after mechanical wounding and insect herbivory inflicted on leaves (Stout et al. 1998; Chen et al. 2008b). One possible explanation is that plants may respond differently to foliar damage and phloem injury.

EAB Adult Performance in Response to Green Ash Foliage Subjected to Various Treatments Increased EAB adult longevity was observed only on mature leaves compared to young and expanding leaves. This was probably attributable mainly to weaker defense (lower protease inhibitors and total phenolics) of mature leaves. Greater amino acids and P:C ratio of mature leaves, especially, higher P:C ratio in the shade, might also confer better performance of EAB adults on mature leaves. Reduction of light elevated amino acid and P:C ratio. However, EAB longevity was not affected by light intensity. A similar pattern was observed between girdled and control trees in that girdling decreased the nutritional quality of foliage, but EAB performance was not affected. The failure to detect EAB performance difference between low and high nutritional food might be explained by compensatory feeding of EAB adults that fed upon low quality foliage, since defensive compounds between these treatments were not significantly affected. Compensatory feeding of many herbivores on low quality host plants has been documented (Mattson 1980; Scriber and Slansky 1981).

In summary, leaf age, light exposure, and girdling interactively affected green ash nutritional and defensive compounds. Both nutritional quality and defensive compounds might contribute to EAB adult performance in this study and feeding preferences reported elsewhere (Poland et al. 2005; McCullough et al. 2006). However, the role of TNC in EAB preferences deserves special attention because the accumulation of TNC in foliage from girdled trees and trees grown in the sunny areas parallels EAB adult preference to these trees over corresponding un-girdled trees and trees grown in the shady areas. Additionally, although girdling and sun exposure altered nutritional and defensive chemistry of green ash foliage, EAB adult performance in the no-choice tests was not affected. The underlying mechanisms need further investigation. Eluci-

dation of these mechanisms contributes to ash tree breeding programs to develop resistant varieties or hybrids.

Acknowledgments Tina Ciaramitaro and Deborah Miller maintained the EAB colony and trees in the greenhouse. Drs. Dan Herms (Department of Entomology, the Ohio State University, OH), James Miller (Department of Entomology, the Michigan State University, MI), and two anonymous reviewers provided critical reviews of an earlier draft of the manuscript. Statistical Consulting Center (College of Agriculture and Natural Resources in Michigan State University) assisted with part of the statistical analyses. The authors thank all of these individuals and organizations. The research was supported by the USDA Forest Service, NA FHP.

The Influence of Eastern North American Autumnal Migrant Monarch Butterflies (*Danaus plexippus* L.) on Continuously Breeding Resident Monarch Populations in Southern Florida

Amy Knight · Lincoln P. Brower

Received: 2 March 2009 / Revised: 5 June 2009 / Accepted: 12 June 2009 / Published online: 7 July 2009

Abstract In Florida, the eastern North American population of the monarch butterfly exhibits geographic variability in population structure and dynamics. This includes the occurrence of migrants throughout the peninsula during the autumnal migration, occasional overwintering clusters that form along the Gulf Coast, remigrants from Mexico that breed in north-central Florida during the spring, and what have been assumed to be year-round, resident breeding populations in southern Florida. The work reported here focused on two monarch populations west of Miami and addressed four questions: Are there permanent resident populations of monarchs in southern Florida? Do these breed continuously throughout the year? Do they receive northern monarchs moving south during the autumn migration? Do they receive overwintered monarchs returning via Cuba or the Yucatan during the spring remigration from the Mexican overwintering area? Monthly collections and counts of spermatophores in the bursa copulatrices of females established that a resident population of continuously breeding monarchs exists year-round in southern Florida. It was determined through cardenolide fingerprinting that most of the butterflies had bred on the local southern Florida milkweed species, *Asclepias curassavica.* During the autumn migration period, however, some monarchs had fed on the northern milkweed, *Asclepias syriaca*. It appears that instead of migrating to Mexico, these individuals travel south through peninsular Florida, break diapause, mate with and become incorporated into the resident breeding populations. None of the monarchs captured in spring had the *A. syriaca* cardenolide fingerprint, which is evidence against the southern Florida populations receiving overwintered remigrants from Cuba, Central America or Mexico.

Introduction

In North America, monarch butterflies *Danaus plexippus* L. (Nymphalidae) breed east of the Rocky Mountains to the Atlantic Coast and undergo a southward migration of up to 3,900 km from the northern United States and Canada to overwintering sites in central Mexico, followed by a spring remigration back into the U.S.A. of up to an additional 2,100 km (Brower et al. 2006). A smaller population breeds west of the Rockies and migrates to numerous overwintering sites along the California coast (Frey and Schaffner 2004). Monarchs also migrate in eastern Australia (review in James 1993), where they were introduced in the 1870s (Ackery and Vane-Wright 1984). In contrast, non-migratory, continuously breeding populations occur throughout the Neotropics and the West Indies (Urquhart 1960; Barcant 1970; Brower 1985) and in introduced populations on several Pacific islands and in parts of Australia (James 1993).

A long debated question that bears on the evolutionary exploitation of a temperate flora by an essentially tropical insect (Brower 1995; Ackery and Vane Wright 1984) is whether continuously breeding, non-migratory monarch

e-mail: brower@sbc.edu

butterfly populations occur in the southern United States. Reasons for this debate were Williams' (1958) contention that North American monarchs do not reproduce in their overwintering areas, and the subsequent confusion between overwintering and breeding populations reported from southern Texas (Urquhart 1960), southwestern Arizona (Funk 1968), southern California (Urquhart et al. 1970), and Florida (Urquhart 1960). Brower (1962) added to the debate by reporting what he considered local breeding populations during the spring in south-central Florida. Subsequent research determined that these populations were most likely a new spring generation established by remigrants returning from overwintering sites in Mexico (Knight 1998; Knight et al. 1999).

Limited evidence of breeding during the winter in southern Florida at one of the sites described in this study (Site 1) was presented by Brower (1985). He determined that 15 of 17 females collected on 5 December 1975 had mated, and also noted five mating pairs. Farrey and Davis (2004) reported monarch larvae on milkweeds growing in a southern Florida garden in January. The possibility exists then, that populations of monarchs in southern Florida may breed year-round. Other unresolved issues are the extent to which southern Florida monarch populations may be derived from the eastern North American migratory population, the possibility that they originated as immigrants from resident breeding populations in the West Indies, or that introgression may occur from both sources.

To resolve these issues, this study was carried out on two monarch populations in southern Florida immediately west of Miami, on the eastern edge of the Everglades. Four questions are addressed: Are the populations present throughout the year? Do they breed during all months of the year? Do they receive northern monarchs moving south during the autumn migration? Do they receive monarchs remigrating northward through the Florida peninsula during the spring?

To answer the first two questions, monarchs were censused nearly every month from September 1994 to November 1995 and their breeding status was determined by dissecting females and counting the number of spermatophores in their bursa copulatrices. The last two questions were addressed by analyzing chemical fingerprints of cardenolides present in individual monarchs collected from the two Miami populations throughout the same period. This technique utilized thin-layer chromatography (TLC) to visualize the arrays of cardenolides extracted from individual butterflies that reflect the species-specific pattern of these poisons that are present in the milkweed species (Asclepiadaceae) on which the monarch fed while a larva (Brower et al. 1982). Because different milkweed species have distinct thin-layer chromatography patterns, it is often possible to determine the general geographic area where a monarch adult was born, based on the milkweeds' discreet geographic distributions (Woodson 1954).

This method allows differentiation of autumn migrant monarchs that would have fed as larvae on northern milkweeds, predominantly *Asclepias syriaca* L. (Malcolm et al. 1993; Wassenaar and Hobson 1999), from monarchs that would have fed on southern Florida milkweeds, principally *A. curassavica* L. *Asclepias syriaca* is the most abundant eastern North American milkweed species and is distributed from southern Canada to Virginia (Woodson 1954). Because of human influence, it recently has extended its range to north central Georgia, but not Florida (Wyatt 1996). *Asclepias curassavica* occurs widely in the Neotropics and on the Caribbean islands (Woodson 1954). It is also abundant in cattle pastures in southeastern Florida (Cohen 1983, 1985). Several other species of milkweed occur in southern Florida and are discussed below.

Methods and Materials

Monarch Collections and Sampling Sites Adult monarchs were collected from two field sites near Miami, Florida. The butterflies were netted, placed in glassine envelopes, and kept continually on ice in a cooler, then frozen in a standard laboratory freezer until analyzed.

Site 1, the main collecting area was a ≈ three ha pasture in Hialeah, Florida (25°53′N, 80°22′W) and surrounded a water filled limestone quarry. The pasture contained large patches of *A. curassavica* as well as two other less abundant milkweeds, *A. incarnata* Walt. and *Sarcostemma clausum* (Jacq.) Schult. The site was bordered to the south by a stand of large live oaks, *Quercus virginiana* L. (Fagaceae), in which monarchs were observed roosting and as resting mated pairs. *Sida* sp. (Malvaceae) also grew in the pasture and was a potential nectar source. Censuses were made in March–April 1990 and monthly from September 1994 to November 1995, except for November 1994 and June and August 1995. Reference to Google Earth, "Graham Baptist Church", access date 9 May 2009, indicates that the old field vegetation surrounding the quarry was destroyed, probably around 2002.

Site 2 (25°48′N, 80°20′W) was ≈ three ha area 10 km south of Site 1. It consisted of a fenced cattle pasture containing abundant but scattered *A. curassavica* plants, and a larger, ungrazed old-field that contained a few *A. curassavica* and a variety of composites (Asteraceae) that served as nectar sources. Monarchs were monitored from February to May 1995, and one sample was collected here for thin-layer chromatography analyses on 7 Nov 1995.

Wing Condition and Mating Status Wing condition for each butterfly was rated visually from 1 (fresh, virtually no scales missing) to 5 (worn, many scales missing) in increments of 0.5. Mating frequency was determined for

all females collected in 1994 and 1995 by dissecting their bursa copulatrices and counting spermatophores, following the method of Van Hook (1999). Butterflies collected in 1990 were too desiccated for bursa copulatrix dissections.

Chemical Procedures In order to perform TLC analyses and determine the foodplants that the butterflies had fed upon as larvae, butterflies were assayed for cardenolide contents as follows. They were dried at 60°C for 16 h in a forced draft oven and weighed on a Mettler AK 160 balance (Mettler-Toledo, Inc., Columbus, OH, USA). Following Alonso-Mejia et al. (1997), each dried butterfly was ground in petroleum ether to extract the lipids. Following Malcolm et al. (1989), cardenolides were ethanol-extracted from the individually defatted butterflies in 10 ml volumetric flasks and spectroassayed to determine gross concentration as µg/0.1 g of dry butterfly material. A Lambda IIs dual beam spectrophotometer (Perkin Elmer Corporation, Norwalk, CT, USA) was used for all spectroassays.

Seven ml of each remaining ethanol extract were cleaned of plant pigments for TLC in order to visualize the component cardenolides by using the tetranitrodiphenyl (TNDP) reagent (Brower et al. 1982; Malcolm et al. 1989; Moranz and Brower 1998). Chromatography was performed on the extracts of a total of 408 monarchs. Each TLC plate was spotted with 14 monarch extracts along with 10 µg of digitoxin and digitoxigenin cardenolide standards spotted on the center and sides of each plate (Fig. 1a and b). Following visualization, each plate was photographed on Kodachrome 25 film, and the images were transferred digitally to a compact disc. Adobe Photoshop (ver. 2.0) was used to sort individual butterflies by cardenolide pattern, as described in Moranz and Brower (1998).

Discriminating Cardenolide Fingerprints of Monarch Adults that Fed as Larvae on Various Milkweed Species The various fingerprints were sorted by comparing the cardenolide spot intensities and mobilities with published fingerprints of the monarch and/or queen butterfly (*Danaus gilippus* Cramer) reared on several milkweed species. The two most critical fingerprints are those found in monarchs that fed as larvae either on the southern Florida *A. curassavica* (Fig. 1a and b) or the northern *A. syriaca* (Fig. 1b). Published *A. curassavica* fingerprints are in Cohen 1983; Brower 1984; Malcolm et al. 1989; Knight 1998, while published *A. syriaca* fingerprints are in Brower 1984; Seiber et al. 1986; Malcolm et al. 1989; Knight 1998. Several other species of milkweeds occur in central to

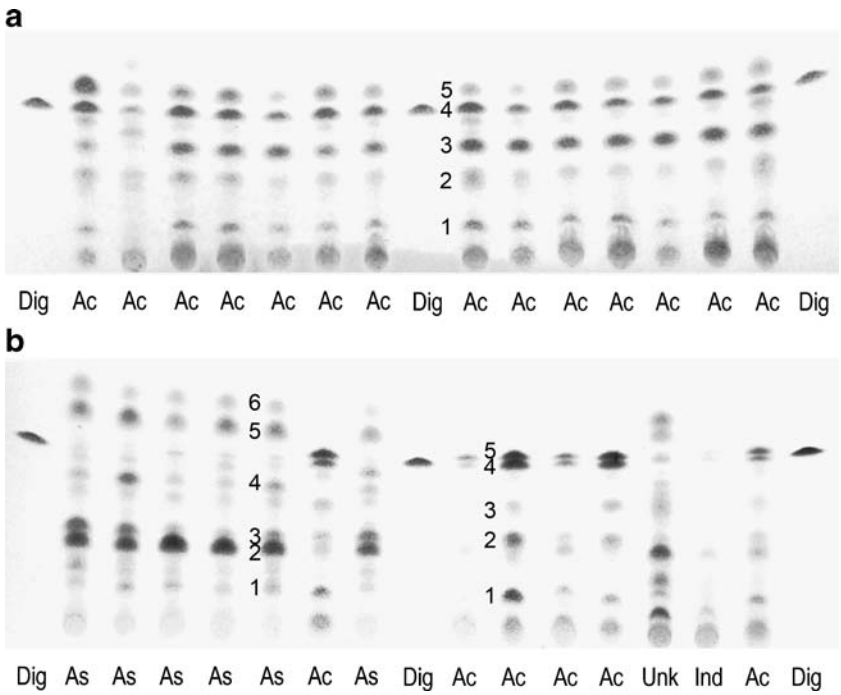

Fig. 1 **a** Thin-layer chromatogram plate of 14 monarchs captured in southern Florida at Site 1 on 1 January 1995, with 10 µg of digitoxin (Dig) standards. The butterflies were all females from which 75 µg of extracted cardenolide were applied to the single plate. Unnumbered spots are not cardenolides. All butterflies have the *Asclepias curassavica* (Ac) cardenolide fingerprint. **b** Thin-layer chromatogram plate of 14 monarchs captured in southern Florida at Site 2 on 7 November 1995, with 10 µg of digitoxin (Dig) standards. Unnumbered spots are not cardenolides. From left to right, the first three channels are from males, and the rest from females; only 7 µg were available for nos. 8 and 10, 3 µg for no. 13, and 32 µg for no. 14; the applied amount for the rest of the channels was 75 µg. Six butterflies exhibit the *Asclepias curassavica* (Ac) cardenolide fingerprint, seven the *A. syriaca* (As) fingerprint, one butterfly is *indeterminate* (Ind), and one has an as yet unknown (Unk) fingerprint

southern Florida (Woodson 1954). These include *A. perennis* Walt., *A. longifolia* Michx., *A. viridis* Walt., *A. humistrata* Walt., *A. lanceolata* Walt., and three vinaceous milkweeds, *Matelea gonocarpa* Walt. (Shinners), *Cynanchum scoparium* Nutt., and *C. angustifiolium* Pers. All of these produce monarchs and/or queens with fingerprints that are qualitatively distinct from monarchs that feed on *A. curassavica* or *A. syriaca* (Martin et al. 1992; Moranz and Brower 1998). Two other common Florida species are *A. incarnata* L. with only small amounts of cardenolide, and *A. tuberosa* L. that has virtually none (Malcolm 1991; Brower, Seiber, and Nelson, unpublished data). Both produce faint to no monarch fingerprints that are distinct from *A. curassavica* and *A. syriaca*. Cardenolide fingerprints have not been determined for three other southern Florida milkweeds: *A. verticillata* L., *A. pedicellata* Walt., and the vine, *Sacrostemma clausum* (Jacq.) Schult. The first two are relatively uncommon, and *A. pedicellata* is Florida's smallest milkweed that has little foliage to support a monarch larva. It is probable that *Sarcostemma*, like *Cynanchum* and *Matelea* (Moranz and Brower 1998), has similar weak fingerprints, vividly distinct from both *A. syriaca* and *A. curassavica.*

The monarch fingerprints were designated as indeterminate when there was an insufficient amount of cardenolide on the TLC plate to determine a clear pattern, or as unknown when a pattern was clear but could not be matched to a known one.

Results

Cardenolide Fingerprints Thin-layer chromatography revealed that at least 84% of the 379 adult monarchs collected in 12 of the 13 months at Site 1 had the *A. curassavica* cardenolide fingerprint, with 100% having this fingerprint in six of the months (Table 1; Fig. 1). In November 1995, eight of 11 individuals (73%) had the *A. curassavica* fingerprint, and three (27%) had the *A. syriaca* fingerprint. In total, 11 monarchs from Site 1 had fed as larvae on *A. syriaca*. Significantly, all *A. syriaca* monarchs were collected in autumn: six in October 1994, three in November 1995, and one each in December 1994 and October 1995. Three had fingerprints that were indeterminate, and two had unknown fingerprints.

TLC results for the Site 2 collection of 29 monarchs on 7 November 1995 had a higher proportion of *A. syriaca* monarchs (58%) than did the collection made at Site 1 one day earlier (28%); Table 1; Fig. 1). Excluding the two indeterminate individuals and the one unknown, this difference is significant (Site 2, 17/26=65%; Site 1, 3/11=27%; $\chi_1^2=4.90$, $P<0.05$). The indeterminate monarchs probably had also fed on *A. syriaca* plants that had low cardenolide concentrations. Monarchs that feed on this milkweed vary from low to high concentrations both in migrants (Knight 1998) and in those collected from across the northern summer breeding range (Malcolm et al. 1989). Overall, only eight of the 408 monarchs analyzed could not be fingerprinted to a known milkweed species; 91% had fed on *A. curassavica*, and 7% on *A. syriaca*.

Frequency of Female Mating Of the 139 females dissected from Site 1, 133 (96%) had mated (Table 2). Five of the six virgins had excellent wing condition (1 or 1.5), suggesting that they had bred locally, and that enough time had not elapsed since eclosion for them to have mated. Of the 133

females that had mated, 113 (85%) were multiply mated, with a maximum of ten spermatophores counted in one individual. The mean number of spermatophores ranged from 2.2 in May 1995 to 5.5 in February 1995. The high frequency of multiple matings in all months indicates that mating occurs throughout the year in this population.

Of the nine *A. syriaca* females collected at Site 1, all had mated, and seven (78%) had multiply mated. These northern migrants had thus broken diapause and must be exchanging genes with the Miami population. Mating frequency also was high for the 16 females collected at Site 2, with 88% mated and 56% multiply mated. Twelve of these 16 females (75%) had the *A. syriaca* cardenolide fingerprint, ten (84%) were mated, and six (50%) were multiply mated. The two unmated females had wing conditions of 2.0, suggesting that they may have been recently arrived migrants from the north that still were in reproductive diapause.

Wing Condition Mean wing condition for all monarchs captured was 2.6 (SD=1.0). Monarchs with excellent (1.0 or 1.5) wing condition were captured in every month sampled except November 1995, Site 1, where the best condition was 2.0.

Discussion

This study addressed whether resident monarch populations occur in southern Florida, and, if so, whether they breed continuously through the year. Monthly collections confirmed that two populations on the eastern edge of the Everglades near Miami occur year-round, and periodic research at one of these sites indicates that monarchs as well as abundant *A. curassavica* and *A. incarnata* plants have occurred there for at least 20 years, in December 1975 (Brower 1985), December 1981 (Cohen 1983), September 1984 (Malcolm and Brower 1986), March–April 1990 (this paper), and September 1994–November 1995 (this paper).

Monarchs were collected in every month visited from September 1994 to November 1995. Although no visits were made in June and August of 1995, the population appeared stable throughout the study, as indicated by the numbers of monarchs captured during each visit. The capture and bursa dissection results, along with the constant presence of *A. curassavica* as a food plant and the *A. curassavica* cardenolide fingerprint in the butterflies collected at both sites are evidence for a viable, year-round continuously breeding resident monarch population in this part of southern Florida.

Bursa copulatrix dissections of female monarchs confirmed that the monarchs breed year-round. Sixty-seven to 100% of the females were mated in all months, with most multiply mated. Similarly, Brower (1985; unpublished data) found that 15 of 17 females captured at Site 1 on 5 December 1975 had mated from two to seven times, saw four mating pairs, and also determined that two fresh females had not mated. These results are similar to those found in resident populations of monarchs in Trinidad, West Indies, where mating frequency in the summer was 96%, with 52% multiply mated (Pliske 1973), and for summer breeders both in Massachusetts, U.S.A. and in Australia where 98% of the females were mated, with 80 and 95% multiply mated, respectively (Brower 1985; Suzuki and Zalucki 1986). Finally, the wing condition also provided evidence that new generations are being produced

throughout the year: at least some individuals in each non-autumn month had wing conditions of 1.0 or 1.5, indicating recent eclosion.

Year-round breeding of monarchs may not be possible throughout much of the southeastern U.S. because of warm summer temperatures. Based on the laboratory findings of Zalucki (1982) and Rawlins and Lederhouse (1981) that constant temperatures between 31 and 35.5°C are lethal for monarch larvae, Malcolm et al. (1987) deduced that high early summer temperatures in the Gulf coastal states force the new spring generation produced during late March and April to move north, which they do in early May (Knight et al. 1999). It seems likely, however, that maximum summer temperatures in the Miami area are slightly below this threshold most of the time. The mean monthly maximum temperature for 30 years (1961–1990) from April to September at the Miami airport was 31.7°C (Anon. 1999). Further north in Florida, however, temperatures may exceed the threshold sufficiently often to be lethal. For example, in Gainesville approximately 480 km north of Miami, the mean monthly maximum temperature for 30 years (1961–1990) from April to September was 32.6°C (Anon. 1999).

In contrast, warm temperatures are required for monarchs to breed year-round and thus sustain a population in southern Florida because neither the butterflies nor their larval food plants can survive severe freezing temperatures (Ackery and Vane-Wright 1984; Larsen and Lee 1994; Anderson and Brower 1996) that periodically affect north Florida and the Gulf Coast (Brower 1995). Although warm temperatures also occur throughout the winter in the southwestern United States, where winter breeding has been reported, these areas probably cannot sustain a permanent year-round breeding population due to the dieback of milkweeds during the autumn and winter (Funk 1968; Urquhart et al. 1970). This is not the case, however, in southern Florida, where the climate is sufficiently warm and wet to sustain year-round populations of *A. curassavica*, a nearly ubiquitous neotropical milkweed (Woodson 1954) that is the principal food plant of monarchs throughout the West Indies, Central and South America (Barcant 1970; Haber 1993). Thus, the combination of warm temperatures and a constant host plant supply, which promotes year-round reproduction in southern Florida, resembles conditions in the tropics where continuously breeding, resident monarch populations occur widely.

This study also addressed whether southern Florida populations receive migratory monarchs from the north during the autumn. The TLC results for October and November 1994 and 1995 show clearly that the southern Florida resident population receives an influx of autumnal migrant monarchs that have fed on the northern milkweed, *A. syriaca*. Moreover, 90% of these *A. syriaca* females were mated or multiply mated, indicating that they had broken reproductive diapause and were becoming incorporated into the resident southern Florida population. The two unmated females appeared to be recent arrivals still in reproductive diapause, which is characteristic of most autumn migrants along the Florida Gulf coast and at the overwintering sites in Mexico (Herman et al. 1989, Van Hook 1999). Mating frequencies of autumnal migrants along the northern Florida Gulf Coast have been observed at 29% (Brower 1985) and 38% (A. Knight and L. P. Brower, unpublished), which are much lower than those reported here for the migrants at the southern Florida sites.

Environmental factors strongly influence reproductive activity in monarchs. Based on physiological experiments, Barker and Herman (1976) proposed that monarchs in the Gulf coast states remain in reproductive arrest as long as average temperatures are below 28°C. Along with the evidence from the present study, this suggests that the migrants must become reproductively active when they reach the warmer, southern areas such as southern Florida and the West Indies (Urquhart 1960; Brower 1985). The incorporation of these autumnal migrants into the southern Florida population is further indicated by the fingerprint results that no monarchs that had fed on *A. syriaca* were present in March and April, 1990 or in January to September, 1995.

The final question addressed by this study is whether there is evidence for a spring remigration of monarchs that had overwintered in Cuba or the Yucatan into these southern Florida populations, as originally postulated by Urquhart and Urquhart (1976). The lack of the *A. syriaca* fingerprint in any of the southern Florida samples collected during March through May argues against this hypothesis. *A. syriaca* monarchs do appear regularly each spring in north-central Florida, but these are likely individuals returning from the Mexican overwintering sites. As far as is known, all Caribbean and southern Florida monarch populations are resident and non-migratory, and the possibility that they migrate northward is not supported by a long-term study of migration patterns of Florida butterflies (Walker 2001), nor by any evidence cited in reviews of the migration biology of the monarch butterfly (Brower 1985, 1995).

Research by Dockx et al. (2004) on monarchs collected in Cuba is in agreement. These authors combined cardenolide fingerprinting with stable isotope analyses and determined that 62% of 152 monarchs that were collected at three Cuban sites during November in 1993, 1995, 1996, and 1997 had migrated there from southeastern Canada or the northeastern United States. Of these, 18 were determined to have fed as larvae on *A. syriaca.* As in the southern Florida samples, no *A. syriaca* butterflies were found in a March sample.

The evidence from both studies provides support for the hypothesis (Brower 1985, 1995) that autumn migrants

flying south through the Florida peninsula are off the normal course to their overwintering area in central Mexico. These individuals, in effect, become physiologically trapped, break reproductive diapause, and, rather than remigrating northward the following spring, they and their offspring become assimilated into the resident breeding populations.

In summary, monthly collections confirmed that monarchs on the eastern edge of the Everglades occur year-round, and bursa copulatrix dissections of females indicated that the population is continuously reproductive. Cardenolide fingerprinting revealed that, except in the autumn, virtually all monarchs had fed as larvae on *A. curassavica*, a neotropical milkweed that grows extensively in southern Florida but does not occur naturally in the monarch's northern range. Taken together, the findings provide evidence for a year-round breeding population and for its persistence through the years.

Cardenolide fingerprints of *A. syriaca* present in butterflies collected during October–December established that northern migrants enter the Miami population during the autumn. Moreover, 90% of these *A. syriaca* females were mated or multiply mated, indicating that they had broken reproductive diapause and were becoming incorporated into the resident southern Florida population. The lack of the *A. syriaca* fingerprint in any of the spring butterflies is evidence against a spring remigration of northeastern monarchs that have migrated to and overwintered in Cuba or the Yucatan back into these southern Florida populations.

Finally, although the cardenolide fingerprints in our samples were distinct and their interpretation straightforward, multivariate analysis of fingerprint patterns could further confirm these results. We propose to conduct High Performance Liquid Chromatography (HPLC) by using remaining cardenolide extracts from these samples and to develop a statistical interpretation method.

Acknowledgement We thank Cal Dodson for showing Brower the locations of various southern Florida monarch populations in 1968 and Reverend Jack Hill of Graham Baptist Church for allowing us to use his facilities. We also thank Dan Hipes, Cristina Dockx, Ray Moranz, and Natalia Arango-Velez for help with field work, and Carmen Lanciani, Thomas Walker, Dan Hipes, and Linda Fink for critiquing the manuscript. Shannon Gibbs and Ray Moranz helped develop the Adobe Photoshop-based sorting system used to distinguish the fingerprint patterns. The research was supported by U.S. NSF grant DEB 922091 to the University of Florida, with L. P. Brower as principal investigator, and by the Wildlife Conservation Society of New York.

Stigmasterol and Cholesterol Regulate the Expression of Elicitin Genes in *Phytophthora sojae*

Lina F. Yousef · Ahmed F. Yousef · Joseph S. Mymryk · Warren A. Dick · Richard P. Dick

Received: 5 February 2009 / Revised: 21 May 2009 / Accepted: 11 June 2009 / Published online: 9 July 2009

Abstract Sterol acquisition by soilborne plant pathogens of the genus *Phytophthora* is presumed to involve extracellular proteins belonging to class-I elicitins. However, little is known about the relationship between sterol availability and elicitin secretion. The objective of this study was to determine the expression of class-I elicitin genes in *Phytophthora sojae* when grown in a medium containing stigmasterol or cholesterol. *P. sojae* growth was stimulated by nanomolar concentrations of stigmasterol and cholesterol, which also resulted in the down-regulation of its elicitin genes over time when expression profiles were monitored using real time Reverse Transcription Polymerase Chain Reaction (RT-PCR). The down-regulation of elicitin genes in response to the two sterols also coincided with a reduction in the amount of elicitins detected in spent filtrates. Our study is the first to show the influence of sterols on elicitin gene expression in *Phytophthora*, which is important with respect to the ecology of elicitin secretion as sterol carrier proteins in the environment.

Introduction

Oomycetes are a diverse group of eukaryotic organisms that include the genus *Phytophthora*, many species of which are destructive plant pathogens in agricultural and forest ecosystems (van West et al. 2003). Members of *Phytophthora* all lack sterol biosynthetic pathways and acquire sterols exogenously from their environment to support their growth and sexual reproduction (Hendrix 1975; Elliot and Knights 1981; Nes and Stafford 1983; Ponchet et al. 1999; Marshall et al. 2001). It is speculated that these organisms acquire sterols from the environment via extracellular proteins belonging to class-I of elicitins (Ponchet et al. 1999). These are small (10 kDa) hydrophilic secreted proteins that were classified as sterol carrier proteins because some exhibited sterol and lipid carrier activity *in vitro* (Mikes et al. 1997, 1998; Vauthrin et al. 1999; Osman et al. 2001a, b).

Elicitins are proteins unique to the genus *Phytophthora,,* and are encoded by a large multi-gene family that is divided into at least eight different classes based on sequence homology and protein motif diversity (Jiang et al. 2006a, b). Class-I elicitins are the best characterized, and are considered structurally simple when compared to other elicitin classes (Jiang et al. 2006b). They encode only a conserved 98 amino acid sequence (known as the elicitin domain) and a signal peptide that is post translationally removed (Ponchet et al. 1999; Jiang et al. 2006b), whereas other classes may also encode a variable c-terminal domain that may contain a membrane-spanning domain (Jiang et al. 2006a, b). Elicitin genes are highly conserved across the entire genus of *Phytophthora* (Kamoun et al. 1997a, b; Qutob et al. 2003; Jiang et al. 2006a, b); all species of *Phytophthora* studied so far secrete elicitins abundantly into

their growth medium (Ponchet et al. 1999), suggesting a significant role for elicitins in the biology of these organisms, presumably in sterol uptake.

Class I elicitins became of interest when it was shown that these proteins induced a plant hypersensitive response (HR) when infiltrated on tobacco leaves (Ponchet et al. 1999). Consequently, further research was done to establish whether elicitin genes are avirulence genes that determine host range (Ponchet et al. 1999; Kamoun 2001). As a result, studies on elicitins have focused largely on elicitor activity on plants (e.g., Baillieul et al. 2003), characterization of protein structure (Lascombe et al. 2004), and discovery of new elicitins secreted by *Phytophthora* spp. (Churngchow and Rattarasarn 2000). However, there are no studies on the significance of elicitin secretion with respect to sterol availability and *Phytophthora* ecology. In soil, sterols are described as labile organic compounds (Bull et al. 2000); *in vitro* studies show that *Phytophthora* spp. assimilate exogenously supplied sterols into their membranes (Elliot and Knights 1981), but the relationship between sterol availability and elicitin secretion has not been established. Therefore, the objective of this study was to examine the expression profile of class-I elicitin genes in the model oomycete and pathogen of soybean, *Phytophthora sojae*, when two sterols of different origin, stigmasterol (plant) and cholesterol (animal), are supplemented in its growth medium.

Methods and Materials

The *Phytophthora sojae* culture (race 1) was obtained from Dr. Dorrance (OARDC, Wooster OH, USA). Cultures were maintained on non-clarified V8 agar (18% v/v V8 agar juice, 0.3% $CaCO_3$, and 2% agar) at 25°C in the dark. For growth response bioassays and gene expression experiments, plugs (6 mm or 10 mm diam) were transferred from the edge of actively growing *P. sojae* into a defined minimal medium (Wu et al. 2003) modified to contain glucose (10 g/l). The growth medium was solidified with 2% w/v agar (growth response experiments) or kept in liquid state (gene expression experiments). Cultures were incubated in the dark at 25°C until terminated.

Biological Assays Stigmasterol and cholesterol (95–99% purity) (Sigma-Aldrich, St. Louis, MO USA) were added to the growth medium at a final concentration of 1,000 nM, 100 nM, or 10 nM with chloroform (final 0.01% v/v) as the solvent. For growth response bioassays, single plugs (6 mm diam) were transferred from the edge of actively growing *P. sojae* on V8 agar to the center of experimental agar plates, and incubated in the dark at 25°C. Colony diameter was measured over time with a metric ruler. For gene expression and protein profile experiments, single plugs (10 mm diam) were inoculated into Erlenmeyer flasks (50 ml) that contained experimental media (20 ml). *P. sojae* mycelia were harvested over time by vacuum filtration through pre-weighted nylon membranes (0.2 μm), and replicates were either processed immediately for RNA extraction or dried in an oven overnight (45°C) for dry biomass measurements. All experiments were repeated independently twice. Experiments included three biological replicates. For gene expression experiments, RT-PCR data was generated from three technical replicates of two biological replicates.

Primer Specificity for Elicitin Amplification P. sojae contains at least nine elicitin genes (Qutob et al. 2003), two of which are class-I and named *SOJA* and *SOJB* (referred to as *sojein* in Mao and Tyler 1996 and Becker et al. 2000). The letters A and B following *SOJ* further classify the elicitins according to their isoelectric (pI) points as either acidic (A, pI<5) or basic (B, pI>5), depending on the total number of Lys residues present in the elicitin domain (Ponchet et al. 1999; Qutob et al. 2003). Moreover, four isotypes of the *SOJ*A gene are present, (originally named sojein 1–4 in Mao and Tyler 1996 and Becker et al. 2000) that differ from each other by a few amino acid substitutions within the elicitin domain, which results in a slightly different amino acid content. Primers for the *SOJA* and *SOJB* elicitin genes were designed from their cDNA sequences available on the National Center for Biotechnology Information (NCBI) web-site (Table 1), whereas primers for the internal control Actin gene (*ActA*) were designed from sequences of the gene available for *P. sojae* on the US Department of Energy's Joint Genome Initiative (JGI) web-site (Table 1).

Designing primers that are specific for each individual *SOJA* isotype is difficult because differences in the nucleotide sequences are minor. Instead, we designed primers to regions that are homologous to the elicitin domain in all four *SOJA* isotypes, which would amplify a 298 bp fragment of the expressed genes. Elicitin genes lack introns (Mao and Tyler 1996; Ponchet et al. 1999), which allowed us to use genomic DNA from *P. sojae* as a template to test the specificity our elicitin primers. The elicitin domain of *SOJA* is highly conserved and contains nucleotide sequences that are similar to *SOJB* and other elicitin classes present in *P. sojae*. To determine if our *SOJA* primers would amplify other elictin genes having homologous sequences, we cloned the PCR products into *E.coli* and submitted ten individual colonies selected at random for sequencing. Using BLAST, nine of the sequenced clones were identified as *Sojein2* (*SOJA-2*), and one was identified as *Sojein3* (*SOJA-3*). For *SOJB*, primers were designed to amplify a 120 bp fragment of the

3′untranslated region (UTR) of the gene because the 3′ UTR region is reported to be variable in elicitin genes (Jiang et al. 2006a, b).

Cloning of SOJA Elicitin Genes The *SOJA* elicitin genes were amplified from genomic DNA of *P. sojae* by regular PCR using the following primers; 5′ATCGAATTC ACCACGTGCACCTCG 3′ (forward) and 5′ AAT CTC GAG TTA CAG CGA CGC GCA CGT GGA CGA GAA 3′ (reverse). These primers are similar to the ones used for gene expression assays, but include *Eco*RI (forward primer) and *Xho*I (reverse primer) sites for cloning and sequencing to confirm the specificity of amplification. The underlined sequences correspond to the elicitin gene flanked by a restriction enzyme site. The cycle conditions were 94°C for 2 min, followed by 35 cycles of 92°C for 1 min, 56°C for 1 min, 72°C for 30 s, and a final extension at 72°C for 5 min. The amplicons were cut with *Eco*RI and *Xho*I, purified on 1% agarose, and ligated into a PGEX-4T-1 vector (GE Health Care, Piscataway, NJ, USA). *E. coli* DH5α was transformed with the construct, and ten individual clones from each amplification reaction were sequenced at the Robarts Research Sequencing facility (The University of Western Ontario, London, ON, Canada).

RNA Extraction and cDNA Synthesis RNA was extracted from mycelia of *P. sojae* using the RNeasy Plant Mini Kit (Qiagen cat # 74904) according to the manufacturer's protocol. The concentration of RNA was determined by using the Quant-iT ^{Tm} Ribogreen RNA assay kit (Invitrogen cat# R11490) via a NanoDrop ND-3300 Fluorospectrometer. Equivalent amounts of starting RNA (approximately 0.3 μg) from each sample were used as template for first strand cDNA synthesis with the QuantiTect Reverse transcription kit (Qiagen cat# 205311). A preliminary step to remove any contaminating genomic DNA prior to cDNA synthesis is included in the QuantiTect Reverse transcription kit.

RT-PCR Amplification and Analysis Amplification of cDNA was carried out in a final volume of 25 μl that contained 3 μl of a 10-fold dilution of the first strand cDNA, and 0.25 μM primers (*SOJA*) or 0.5 μM primers (*SOJB* or *ActA*) and 12.5 μl iQ™ SYBR Green super mix (Bio-Rad cat# 170-88805). Reactions were performed with a iQ5 multicolor real-time thermal cycler (iQ™ 5 optical module, Bio-Rad, Hercules, CA, USA) for 2 min at 94°C followed by 40 cycles of 94°C for 40 s, annealing at 67°C (*SOJ*A and *SOJ*B) or 59°C (*Act*A) for 40 s, and extension at 72°C for 30 s. The $2^{-\Delta\Delta C}$T method for relative quantification of gene expression was validated as described in (Livak and Schmittgen 2001) prior to the evaluation of elicitin gene expression. Untreated controls (*P. sojae* only receiving delivery solvent) served as calibrators for the treatments, whereas *Act* A served as an internal control to normalize for any variation in the amount of RNA that was initially added to the reverse transcription reaction. Amplification of specific transcripts was confirmed by melting curve analysis provided by the LightCycler instrument and length of PCR products on agarose gels (1.5%). The amplified products also were confirmed at least once by sequencing at the Plant Microbe Genetics facility (The Ohio State University, Columbus, OH, USA).

Protein Analysis The Bradford protein assay (Bradford 1976) was used to quantify the total amount of protein in the spent filtrates of *P. sojae* using γ-globulin as standard. Spent filtrates from replicates of each treatment subsequently were pooled into one sample, and each pooled sample (15 μl) was analyzed on 4–12% gradient Bis-Tris sodium dodecyl sulfate polyacrylamide gel (Invitrogen cat# NP0322BOX) with MES as the running buffer (Invitrogen cat# NP0002) using the XCell SureLock^{Tm} Mini cell system (Invitrogen, Carlsbad, CA, USA) at 200 V. Protein gels were silver stained with the SilverXpress silver staining kit (Invitrogen cat# LCG100) according to the manufacturer's protocol.

For 2D-PAGE analysis, proteins present in 5 ml of spent filtrates from day 13 of controls were precipitated from solution with four volumes of cold acetone (−20°C) according to a protocol published in a technical resource (PIERCE -TR00490.0, Rockford, IL, USA) and dissolved in 4.4% (w/v) CHAPS (200 µl) and urea solution (8 M). The entire volume was used to rehydrate a 3–10 pH IPG strip via a passive rehydration step (1 h) followed by an active rehydration step at 50 V (14 h). The rehydration step was followed by focusing the proteins on the IPG strip overnight at 60,000 vhr. Following focusing, the strips were equilibrated in urea (6 M), Tris buffer (0.375 M; pH8.8 for 25 min), and then in SDS(2% w/v), glycerol (20% w/v), DTT (2% w/v) for 25 min. The equilibrated IPG strips subsequently were run onto pre-cast criterion gels (10–20%) in TGS buffer at 200 V for 60 min, then fixed in methanol (10%) and acetic acid (7%) for 30 min prior to being stained overnight with Sypro Ruby (Bio-Rad cat# 170-3126) according to the manufacturers protocol. Three putative elicitin bands were excised from the gel, placed into water and submitted to the Mass Spectrometry and Proteomics Facilty (The Ohio State University, Columbus, OH, USA) for digestion and analysis by capillary-liquid chromatography-nanospray tandem mass spectrometry (Nano-LC/MS/MS) prior to identification using MASCOT (Matrix Science version 2.2.1, Boston, MA, USA), a search engine that uses MS data to identify proteins from primary sequence databases such as NCBI.

Statistical Analysis Colony diameter measurements, gene expression assay, biomass measurements, and extracellular protein assays from experiments were analyzed by factorial *ANOVA* followed by a *Bonferroni* or *LSD pairwise* comparison of means (α=0.05) using Statistix™ analytical software (P.O. Box 12185, Tallahassee, FL, USA).

Results

Response of P. sojae Sterols Stigmasterol is structurally similar to cholesterol, differing only by the presence of an additional 24-ethyl group and a *trans*-22-double bond (Fig. 1). The sensitivity of *P. sojae* to different concentrations of stigmasterol and cholesterol was determined by dose response growth assays (Fig. 2). Although the pathogen did grow in the absence of sterols, supplementation of growth medium with sterols enhanced the growth rate, as evident by an enhanced stimulation of its mycelium (Fig. 2).

Concentrations of stigmasterol or cholesterol ranging from 1 µM to 1,000 µM stimulated *P. sojae* mycelia equally well (data not shown). However, we were interested in determining the lowest concentration threshold required to stimulate *P. sojae* growth. Interestingly, *P. sojae* appears to be 10-fold more sensitive to stigmasterol than to cholesterol, as 10 nM of stigmasterol was the lowest concentration required to cause a significant (P<0.001) growth difference compared to controls (Fig. 2) vs. 100 nM needed for cholesterol to cause a similar response (Fig. 2).

Transcripts for both *SOJA* and *SOJB* elicitin genes were detected from cDNA generated from *P. sojae* mRNA, indicating both isoforms were expressed by the organism (Fig. 3). This was also confirmed by 2D-PAGE analysis of spent filtrates from control cultures (Fig. 4), which showed three protein bands with a molecular weight of approximately 10 kDa and pI's in the range of 3, 6, and 9. These proteins were confirmed to be elicitins of *P. sojae* after tryptic digestion and analysis of the individual bands using LC/ MS-MS) (data not shown).

By using a dilution series of cDNA from control cultures, we optimized PCR conditions to obtain equivalent amplification efficiencies for the target genes and the internal control gene used to normalize treatments. RT-PCR conditions for amplification of the targets (*SOJA* and *SOJB*) and internal reference gene (*ActA*) were optimized to yield respective amplification efficiencies of 104, 94, and 99% for the *SOJA, SOJB,* and *ActA* transcripts respectively. The amplification efficiency values for target genes fall within approximately 5% of the E value of the internal reference gene. This allowed the use of the $2_T^{-\Delta\Delta C}$ method (Livak and Schmittgen 2001) for the relative expression analysis of elicitin genes. Running the qPCR products on a 1.5% agarose gel showed the presence of a single band at approximately 300 bp, 250 bp, and 100 bp for *SOJ*A, *Act*A, and *SOJ*B, respectively (data not shown). The identity of the qPCR bands was confirmed by sequencing, and the characteristic melting temperatures for *SOJ*A, *SOJ*B, and *Act*A qPCR products were 90.5°C, 80.5°C, and 88.5°C, respectively.

Elicitin Gene Expression in Response to Stigmasterol and Cholesterol The class-I elicitin genes, *SOJA and SOJB*, are constitutively expressed in *P. sojae*, as transcripts for these genes were present in sterol untreated control samples. However, supplementing the growth medium of *P. sojae* with cholesterol or stigmasterol resulted in a differential expression profile of class-I elicitin genes compared to control samples. Generally, class-I elicitin genes became significantly (P<0.001) down-regulated over time compared to untreated controls (Fig. 3), but there appears to be a temporal delay in the down-regulation of *SOJA* and *SOJB* elicitin genes in response to cholesterol when compared to stigmasterol (Fig. 3). Specifically, elicitin genes became significantly (P<0.001) down-

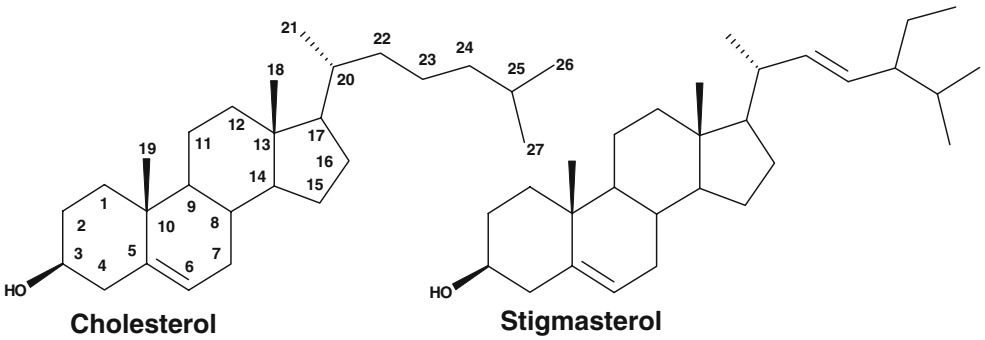

Fig. 1 Chemical structure of the sterols used to supplement *Phytophthora sojae* growth medium. Both sterols are structurally similar except that stigmasterol contains a trans-22 double bond and a 24-ethyl group in the side chain

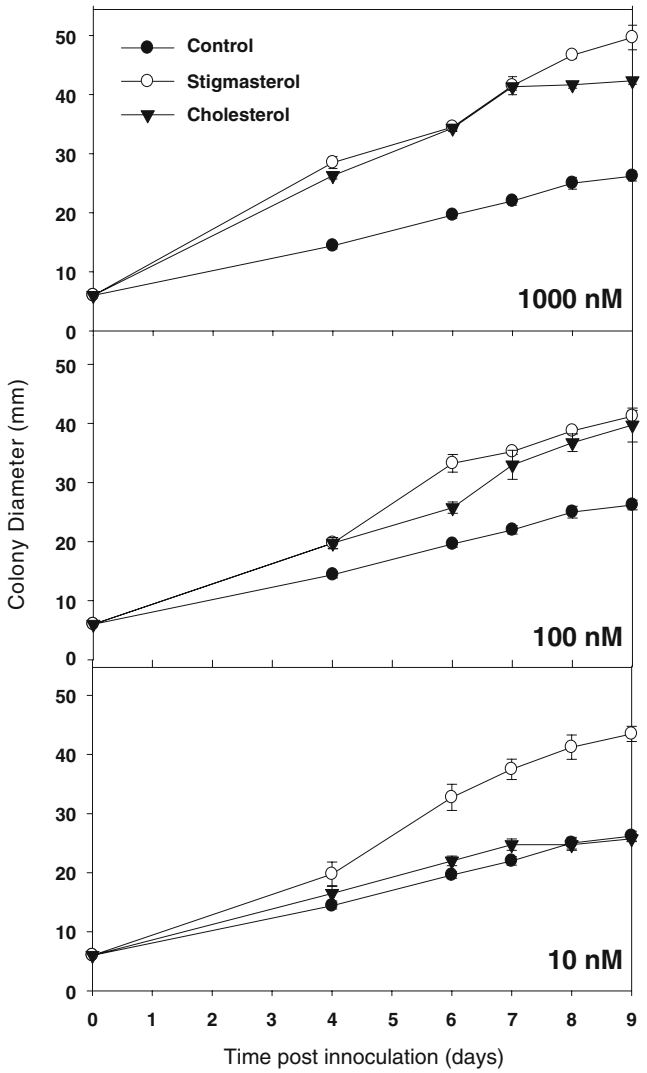

Fig. 2 *Phytophthora sojae* growth measurement (hyphal extension) over time after its growth medium was supplemented with a log-based gradient concentration of 1,000 nM, 100 nM, or 10 nM of either stigmasterol or cholesterol. Data plots represent three replicates ± SE from one experiment. ANOVA followed by a bonferroni pair-wise comparison of means identified significant differences (α=0.05, $P<$ 0.001) in colony diameter measurements between the 10 nM stigmasterol treatment and control, and between the 10 nM stigmasterol and 10 nM cholesterol treatments. No significant difference was identified between the 10 nM cholesterol treatment and the control

regulated on day-9 in response to stigmasterol (Fig. 3), whereas a similar magnitude in elicitin down-regulation occurred on day-13 for cholesterol (Fig. 3).

Expression of class-I elicitin genes appears to be controlled by both negative and positive feedback mechanisms that are dependent on environmental sterol concentrations. An example of negative feedback that is dependent on sterol concentration is observed in the *SOJA* expression profile in response to stigmasterol (Fig. 3). On day-3, *SOJA* genes were down-regulated significantly in response to 1,000 nM of stigmasterol, whereas the down-regulation event was delayed and only observed on day-9 for the lower stigmasterol concentrations of 10 nM and 100 nM (Fig. 3). An example of positive feedback is observed on day-3 in the *SOJA* and *SOJB* expression profile in response to cholesterol (Fig. 3), and *SOJB* expression in response to stigmasterol (Fig. 3), in which the genes were significantly ($P<0.001$) up-regulated compared to untreated controls.

Extracellular Proteins in Spent Filtrates of P. sojae The total amount of secreted proteins in relation to dry biomass of *P. sojae* was determined over time (Table 2). Extracellular protein profiles were examined by 1D-PAGE analysis (Fig. 5). The goal was to determine if the down-regulation in *SOJA* and *SOJB* genes in response to sterols coincided with a reduced amount of secreted elicitin proteins in the spent filtrates of *P. sojae*. Elicitins are reported to be the most abundant proteins in filtrates of *Phytophthora* spp. (Ponchet et al. 1999). This is consistent with our results for *P. sojae*, as the only protein detected in spent filtrates was a single 10 kDa band that was confirmed as an elicitin of *P. sojae* by LC/MS-MS.

The amount of protein in the spent filtrates of control cultures continued to increase and reached a maximum concentration of 5 μg ml^{-1} on Day-13 (Table 2). The detection limit of the silver stain kit is 0.7 ng $band^{-1}$. Therefore, the concentration of proteins in spent filtrates prior to day 13 (1–2 μg ml^{-1}) was likely below the detection limit of the silver stain. The 10 kDa band detected from control filtrates on Day-13 cultures was absent in spent filtrates of the 1,000 nM cholesterol and stigmasterol

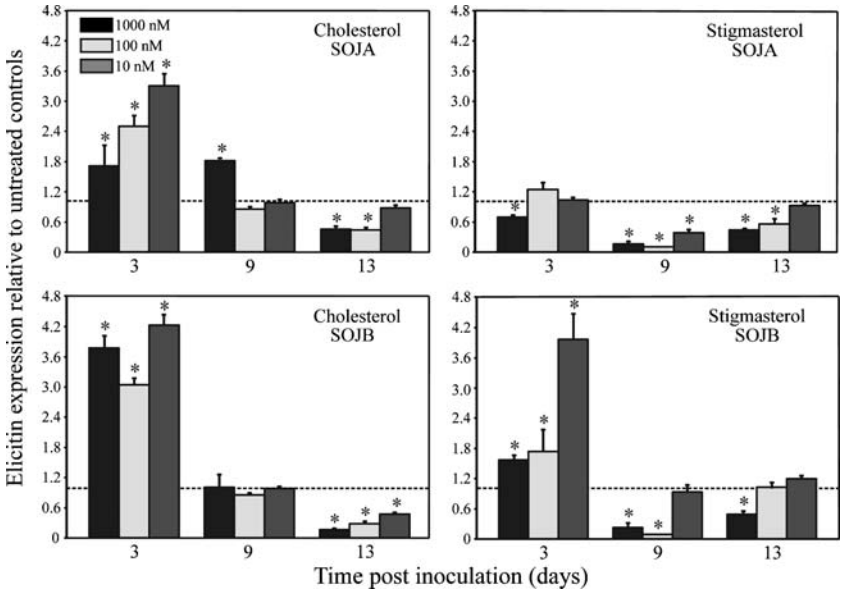

Fig. 3 *Phytophthora sojae* expression of class-I elicitin *SOJA and SOJB* genes was monitored over time in response to a log-based concentration gradient of 1,000–10 nM of cholesterol or stigmasterol using real-time RT-PCR. The y-axis shows expression relative to untreated controls (*P. sojae* not receiving sterol) after normalization to the internal control gene *Act*A(a value of 1.0 indicates no difference between treatment and control, a value greater than 1.0 indicates up-regulation of elicitin genes, and a value less than 1.0 indicates a down-regulation of elicitin genes). Bar graphs represent means of three technical replicates obtained from two biological replicates ± SE from two independent experiments. Bar graphs with a (*) indicate values significantly different from untreated controls after ANOVA followed by an LSD pair-wise comparison of means (α=0.05, P<0.001)

treatments (Fig. 5a) even though there was approximately 1.5 times more biomass in the same volume of experimental media compared to controls (Table 2). The reduced amount of proteins in the sterol treated samples (Fig. 5a) is supported by an analysis of the total amount of protein produced per biomass of *P. sojae* (Table 2). On Day-13, only 0.2 μg mg^{-1} protein was produced in the presence of 1,000 nM stigmasterol and 1.1 μg mg^{-1} for the same concentration of cholesterol compared to a higher amount (i.e., 4.2 μg mg^{-1}) produced by control cultures (Table 2).

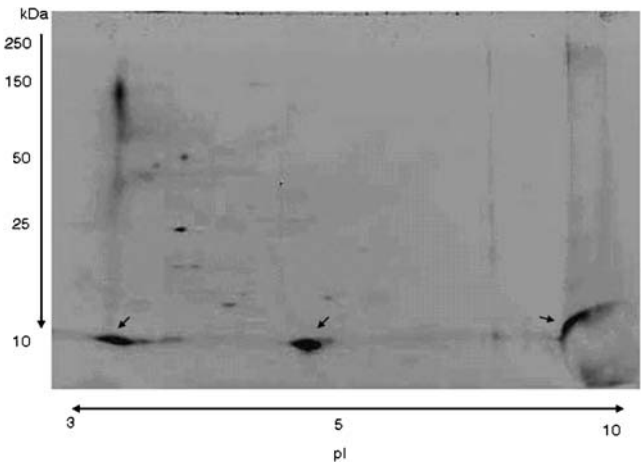

Fig. 4 Two-dimensional SDS-PAGE analysis of *Phytophthora sojae* extracellular proteins (25 μg) present in filtrates after 13 days of growth in a minimal medium in the absence of sterols. Proteins were separated according to their pI (x-axis) and size (y-axis). Arrows point to three putative elicitin isoforms with approximate pI values of 3, 5, and 9, and a molecular weight of 10 kDa. The identity of the proteins was later confirmed to be *P. sojae* elicitins by LC/MS/MS

The 10 kDa elicitin band was not detected in *P. sojae* spent filtrates treated with stigmasterol over the entire concentration range of 1,000 nM to 10 nM (Fig. 5), whereas it was detected when a cholesterol concentration of 100 nM (Fig. 5b) or 10 nM was used (Fig. 5c). Moreover, the staining intensity of the 10 kDa protein band reached levels similar to controls at the lowest cholesterol concentration (i.e., 10 nM) (Fig. 5c). This also is supported by the lack of differences in the amount of proteins produced per biomass between control cultures and those treated with 10 nM cholesterol (Table 2). This observation is in agreement with the biological dose response assays we conducted that showed the growth of *P. sojae* is more sensitive to stigmasterol compared to cholesterol (Fig. 2).

Discussion

Phytophthora sojae is a hemibiotroph that can survive in the soil as a saprotroph or as a heterotroph in the soybean host (Tyler 2007). In soil, the concentration of sterols varies between 0.2 ppm to 30 ppm and depends on the presence of

Table 2 Total proteins in spent filtrates of *phytophthora sojae* in response to stigmasterol and cholesterol over time

Values followed by the same letter are not significantly different from each other using ANOVA followed by a Bonferroni comparison of means ($P< 0.05$)

*ND indicates no protein detected

**Protein per biomass was calculated according to 20 ml of total experimental volume

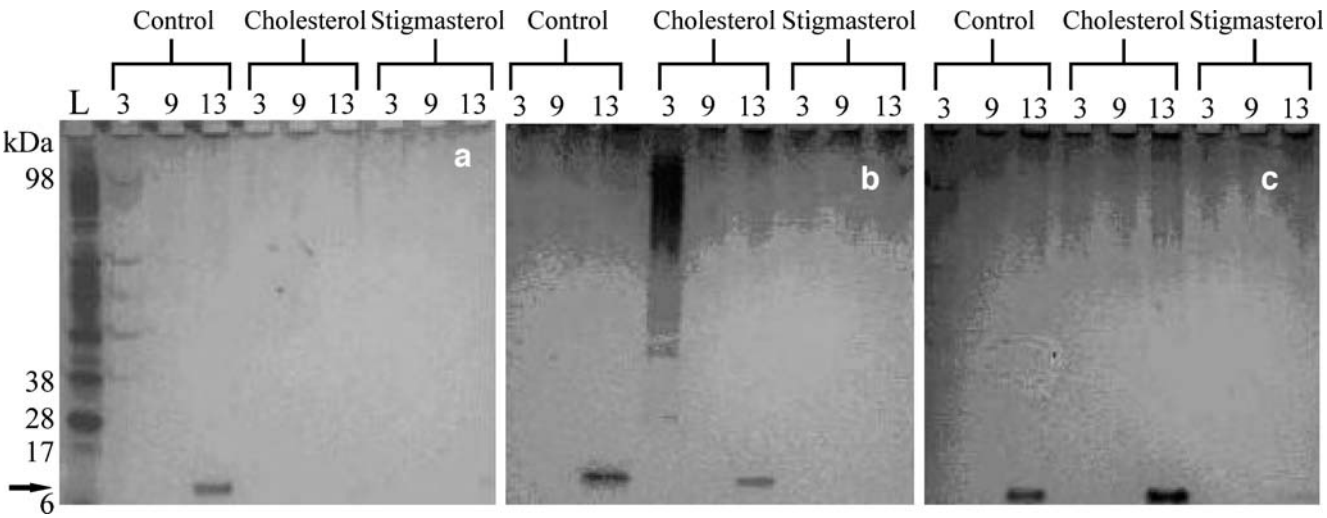

Fig. 5 Extracellular proteins present in filtrates of *Phytophthora sojae* grown in a minimal medium after 3 days, 9 days, or 13 days of growth in the absence of sterol (control), in the presence of 1,000 nM (**A**), 100 nM (**B**), or 10 nM (**C**) of either cholesterol or stigmasterol. The letter L shows standard protein markers with an approximate size range of 98 kDa to 6 kDa (SeeBlue Plus2 pre-stained standard, Invitrogen), whereas the numbers 3, 9, and 13 indicate days post inoculation of *P. sojae* into the experimental media. Spent filtrates (15 μl) containing a maximum amount of 75 ng total protein (e.g., control day 13) were separated on a 4–12% MES-SDS-PAGE gel and stained with silver nitrate. The arrows point to putative elicitin bands with a molecular size of approximately 10 kDa

soil organisms, plant matter, and organic fertilizer inputs (Puglisi et al. 2003). In soybean, sterol concentrations depend on the physiological stage of plant development, and vary between approximately 0.0002–0.005% of plant weight (Fenner et al. 1986). In this study, we evaluated mycelial extension and class-I elicitin gene expression of *P. sojae* in response to varying concentrations of stigmasterol and cholesterol. Mycelial extension of *P. sojae* was stimulated at nanomolar concentrations in response to both sterols, but was 10-times more sensitive to stigmasterol than to cholesterol. These results are significant and show that *P. sojae* (1) is exquisitely sensitive to the presence of sterols, responding to them at very low concentrations, and (2) apparently can discriminate between sterols with small structural differences. Our results are different from other sterol studies with *Phytophthora* (Wood and Gottlieb 1978; Nes and Stafford 1983; Marshall et al. 2001) because we utilized sterol supplement concentrations that are approximately 250 or 2,500 times lower than the lowest concentration of sterol supplements used in other studies to examine a physiological response. The ability of *P. sojae* to respond to sterols at nanomolar concentrations indicates that it is efficient in utilizing sterols, even at low concentrations in the environment.

Studies involving *P. parasitica* (pepper pathogen) (Colas et al. 2001) and *P. infestans* (potato pathogen) (Kamoun et al. 1997b) reported that the expression of elicitin genes in these organisms was down-regulated during plant infection. Colas et al. (2001) and Kamoun et al. (1997b) did not consider sterols as potential regulators of elicitin gene expression in *P. parasitica* or *P. infestans*. In our study, class-I elicitin gene expression in *P. sojae* appears to be controlled by both negative and positive feedback mechanisms that are dependent on sterol concentration and structure. Generally, a reduction in elicitin biosynthesis was observed when either stigmasterol or cholesterol was included in the growth medium of *P. sojae*. However, differences in the expression profile of *SOJA* and *SOJB* elicitin genes was observed in response to each sterol, which may be related to different binding efficiencies for these two sterols with elicitins encoded by the *SOJA* and *SOJB* genes.

Overall, cholesterol was less effective than stigmasterol in down-regulating elicitin expression since the kinetics of down-regulation by cholesterol were slower (Fig. 3). Moreover, the up-regulation of class-I elicitin genes in response to cholesterol on day-3 (Fig. 3) may have occurred to compensate for the slow kinetics of any of (1) elicitin binding with cholesterol, (2) elicitin-sterol complex binding to receptors on *P. sojae* membranes, or (3) metabolism of sterol once incorporated into cells. Following the same argument, the up-regulation of *SOJB,* but not *SOJA* elicitin genes, in response to stigmasterol may have occurred because the basic class-I elicitins encoded by the *SOJB* gene are less efficient in stigmasterol uptake than the acidic class-I elicitin proteins. A different study that involved the soilborne pathogen *P. cactorum* showed that the organism incorporated sitosterol into its mycelium more rapidly than it did cholesterol when a mixture of these two sterols was present in the growth medium (Elliot and Knights 1981), i.e., a mechanism involving elicitins maybe at play. Interestingly, a common observation made between this study and that of Elliot and Knights (1981) is both *P. sojae* and *P. cactorum* are plant pathogens that appear to process plant sterols (stigmasterol and sitosterol) more efficiently over cholesterol —a predominantly animal sterol. It maybe possible that *Phytophthora* plant pathogens have evolved to preferentially utilize sterols commonly present in their host.

In summary, our study shows that class-I elicitin genes of *P. sojae* are regulated by nanomolar concentrations of sterols, and that an apparent differential in temporal gene regulation occurs in response to small structural differences in sterol type (stigmasterol vs. cholesterol). Nonetheless, these results indicate that elicitins play a role in sterol uptake in *P. sojae*. It remains to be determined whether sterols act as diffusible factors that connect elicitin genes to the environment, or whether down-stream mechanisms with putative *P. sojae* elicitin receptors on membranes are involved.

Acknowledgements This work was supported by an Alumni Grant for Graduate Research and Scholarship from the Ohio State University (first author) and the USDA National Needs Graduate Fellowship Program. We appreciate the generosity of Dr. Anne Dorrance for providing the *Phytophthora sojae* isolate. The first author appreciates advice received from Dr. Terry Graham.

Received: 20 February 2009 / Revised: 05 June 2009 / Accepted: 11 June 2009 / Published online: 2 July 2009

Abstract Arbuscular mycorrhizal fungi can strongly influence the metabolism of their host plant, but their effect on plant defense mechanisms has not yet been thoroughly investigated. We studied how the principal direct defenses (iridoid glycosides) and indirect defenses (volatile organic compounds) of *Plantago lanceolata* L. are affected by insect herbivory and mechanical wounding. Volatile compounds were collected and quantified from mycorrhizal and non-mycorrhizal *P. lanceolata* plants that underwent three different treatments: 1) insect herbivory, 2) mechanical wounding, or 3) no damage. The iridoids aucubin and catalpol were extracted and quantified from the same plants. Emission of terpenoid volatiles was significantly higher after insect herbivory than after the other treatments. However, herbivore-damaged mycorrhizal plants emitted lower amounts of sesquiterpenes, but not monoterpenes, than herbivore-damaged non-mycorrhizal plants. In contrast, mycorrhizal infection increased the emission of the green leaf volatile (*Z*)-3-hexenyl acetate in untreated control plants, making it comparable to emission from mechanically wounded or herbivore-damaged plants whether or not they had mycorrhizal associates. Neither mycorrhization nor treatment had any influence on the levels of iridoid glycosides. Thus, mycorrhizal infection did not have any effect on the levels of direct defense compounds measured in *P. lanceolata*. However, the large decline in herbivore-induced sesquiterpene emission may have important implications for the indirect defense potential of this species.

Introduction

About 80% of all terrestrial plants form associations with arbuscular mycorrhizal fungi (AMF) (Wang and Qiu 2006). These are fungal symbionts that are well known to improve plant nutritional status by enhancing the uptake of essential nutrients such as phosphorous and nitrogen and by improving the water supply through an increase in root surface area (Smith and Read 1997). In return, fungi receive carbon in the form of photosynthates from the plant.

For both the establishment and the maintenance of the symbiotic association between plants and AMF, it is essential that both partners recognize each other. These recognition processes are initiated *via* molecular cross-talk mediated by changes in the gene expression and production of signal compounds in both partners (Harrison 2005). On the plant side, altered gene expression in the presence of AMF can influence other aspects of metabolism and even result in the induction of chemical defenses (Gange et al. 2007). A number of studies in the recent past have reported the effects of AMF on plant defensive compounds, such as volatile terpenoids (Akiyama and Hayashi 2002; Rapparini et al. 2008), essential oils (Copetta et al. 2006; Khaosaad et al. 2006) and glucosinolates (Vierheilig et al. 2000).

Furthermore, effects of AMF on salicylic acid (SA) and jasmonate dependent signaling pathways have been reported, suggesting that AMF modulate plant defenses (review by Pozo and Azcòn-Aguilar 2007 and references therein). AMF invasion triggers a general plant response to pathogen attack (Dumas-Gaudot et al. 2000), causing a transient accumulation of SA and activation of the SA-dependent signaling pathway at the early stages of the association. These responses then seem to be repressed once the compatibility of the symbionts is recognized (reviewed by Garcìa-Garrido and Ocampo 2002).

Two major forms of plant anti-herbivore defenses can be distinguished: direct defenses, which are toxic to the herbivore or deter feeding, and indirect defenses, which protect the plant by attracting natural enemies of the herbivore, either parasitoids or predators. Direct and indirect defenses can be constitutively expressed or induced by mechanical damage or herbivore feeding. The literature on mycorrhizal influence on direct and indirect defenses and the consequences for insect herbivores is scarce (Gange et al. 2007; Hartley and Gange 2009), although some studies that show the effects of AMF on direct defenses have been published (e.g., Marak et al. 2002; Fuchs and Bowers 2004). A major group of indirect plant defenses are volatile organic compounds (VOCs) that consist principally of green leaf volatiles (GLVs) and mono- and sesquiterpenes (Pichersky and Gershenzon 2002; Degenhardt et al. 2003). Herbivore-induced VOCs play an important role in attracting natural enemies of insect herbivores (e.g., Dicke et al. 1990; Turlings et al. 1990; Kessler and Baldwin 2001). Furthermore, herbivore-induced VOCs act as both intra- and inter- plant signals, and can result in priming and induction of plant defenses (e.g. Kost and Heil 2006; Frost et al. 2007; Heil and Silva Bueno 2007).

Naturally occurring VOC emissions have been compared in mycorrhizal vs. non-mycorrhizal plants. For example, mycorrhization of *Artemisia annua* L. with two AMF species did not affect the amount of total terpenes emitted, but there were slight changes in the relative quantities of single compounds (Rapparini et al. 2008). In addition, an unspecialized fungal root endophyte (*Acremonium strictum*) reduced terpene emission of tomato plants with consequences for insect oviposition preference (Jallow et al. 2008). However, no study to date has investigated how herbivore damage alters the production of defenses in AMF vs. non-AMF plants, even though herbivory is known to have marked effects on VOC emission profiles and the levels of other defense compounds.

Plantago lanceolata L. is a perennial forb with a cosmopolitan distribution and commonly forms associations with a large number of AMF species (Johnson et al. 2004; Oehl et al. 2004). The main group of secondary metabolites in *P. lanceolata* is the iridoid glycosides, with two dominant compounds, namely aucubin and catalpol. These compounds function as feeding and oviposition stimulants for specialized insects, and as deterrents or toxins for generalist herbivores (e.g., Bowers and Puttick 1988, Biere et al. 2004). Antimicrobial functions of these monoterpene derivatives also have been documented (Marak et al. 2002). The association of *P. lanceolata* with AMF can modify plant defense properties. In a study by Gange and West, the levels of the two iridoid glycosides (IGs), aucubin and catalpol, increased when the plants were associated with AMF (Gange and West 1994). However, the effects of AMF on other groups of defensive compounds in *P. lanceolata*, such as green leaf volatiles or volatile terpenoids, have not yet been documented.

In this study, we investigated the effects of the arbuscular mycorrhizal fungus *Glomus intraradices* (N.C. Schenck & G.S. Sm.) on *P. lanceolata* by focusing on two groups of compounds, IGs and VOCs, that typically act as direct and indirect plant defenses, respectively. In an experiment with a full factorial design, we compared VOC emissions and the IG contents of AMF-inoculated and non-inoculated *P. lanceolata* individuals after mechanical wounding and caterpillar herbivory with those of non-treated control plants.

Mycorrhizal fungi could influence a plant's allocation to defense in different ways: 1) *Altering nutritional status of the host plant:* Greater nutrient availability could lead to an increase in primary productivity that provides more resources for the plant to use in the biosynthesis of defensive metabolites, such as IGs or VOCs. On the other hand, harboring AMF is no guarantee of increased productivity, since in return for nutrients, plants provide symbiotic fungi with photosynthates. If the outflow of photosynthates to the fungal symbionts is greater than the increase in productivity due to enhanced nutrient supply, there may be a net decrease in carbon supply that could lead to a decline in defense metabolism. This decline might affect the production of direct vs. indirect defenses differently depending on the relative value of these defensive strategies under different nutritional conditions. 2) *Altering signalling pathways:* Independent of plant nutritional status, the presence of microorganisms, including AMF, could alter defense signalling. Microbial infection generally is known to activate many types of defense responses, although mycorrhizal fungi usually elicit only attenuated responses (Garcìa-Garrido and Ocampo 2002).

Methods and Materials

Plant, Fungus and Insect Material Seeds of *P. lanceolata* (Rieger & Hofmann, Germany) were sown in trays filled with commercially available sowing soil (Stender

Vermehrungssubstrat A210, Stender, Germany) that was previously autoclaved for 20 min at 121°C, in order to kill potential AMF propagules. *P. lanceolata* germinated and grew in a greenhouse (day:night temperatures 20–22°C: 18–20°C, 30–55% humidity, 16 h light, photosynthetically-active radiation ca. 180 µmol $m^{-2}s^{-1}$).

To prepare a growing medium, soil from a meadow in proximity to the greenhouse (in Jena, Germany) was mixed with sand in a 1:1 (w w^{-1}) proportion, and autoclaved for 20 min at 121°C. Thereafter, 178 pots (14.4 cm diam, 1.3 l) were each filled with 300 ml of the soil-sand mixture and watered with 10 ml soil suspension (500 g fresh soil suspended in 5 l tap water, filtered through a 25 µm Whatman filter to exclude AMF propagules) in order to allow the establishment of a new microbial community in the sterile soil mixture (Schroeder and Janos 2004). Afterwards, all pots were covered with gauze to prevent the soil from desiccation.

Glomus intraradices inoculum was purchased from Amykor (Germany) (strain AMYKOR1), and half of it was autoclaved for 30 min at 121°C. Half of the 178 pots were then inoculated with 5 g of AMF vital inoculum each ("mycorrhizal plants"), the other half were mock inoculated with the same quantity of AMF autoclaved inoculum ("non-mycorrhizal" plants). The inoculum was mixed with the upper layer (3–4 cm) of the soil-sand mixture, and the *P. lanceolata* seedlings were transplanted individually into the pots.

Due to a thrips infestation, all plants were treated once with Conserve (Dow AgroSciences LLC, USA) (Conserve 0.075 %, 0.5 l spray for all the 178 plants) 5 wk after transplantation.

Caterpillars of the generalist feeder *Spodoptera littoralis* Boisd. (Lepidoptera: Noctuidae) (Syngenta, Basel, Switzerland), were reared on an artificial bean diet at 21°C. The diet was prepared by mixing 1 l tap water with 1 kg beans, 18 g ascorbic acid, 10 g 4-ethylbenzoic acid, 18 g α-tocopherol (7.1% in germ oil), 8 ml 3.7% formaldehyde, and 2.4 l of a 5% agar solution) at 21°C. Third-instar caterpillars were starved for 24 h before they were used in the experiment.

Experimental Setup and Plant Treatments Plants were divided between mycorrhizal and non- mycorrhizal treatments, and 15 plants of a single treatment were placed in one tray (60×40 cm). The trays were positioned on a greenhouse bench in two rows, one with mycorrhizal plants and the other without, in order to avoid cross infection of AMF. Tray position on the greenhouse bench was shifted weekly to control for any differences in light or temperature conditions.

The experiment started 52 days after seedling transplantation and lasted for 18 d. Treatment of the plants started in the evening, and was performed as follows: six to seven mycorrhizal and the same number of non-mycorrhizal plants were randomly chosen and moved separately to two different trays. Plants in each tray then were divided into three groups that underwent the following treatments: Group 1 – Mechanical wounding (MW): young and old leaves were evenly damaged by punching ten 4 mm holes per plant with a ticket puncher. The same treatment was repeated on the following day, before the volatile collection started. Group 2 – Herbivory (H): six third-instar *S. littoralis* caterpillars per plant were allowed to feed overnight on the foliage. Group 3 – Control (C): control plants received no damage. The foliage of both the treated and the control plants was enclosed within a cellophane bag (205 x 380 mm, Unipack, Germany) to prevent caterpillars from escaping. In total, 32 mycorrhizal and 32 non-mycorrhizal plants underwent the MW treatment, 29 mycorrhizal and 29 non-mycorrhizal plants underwent the H treatment, and 28 mycorrhizal and 28 non-mycorrhizal underwent the C treatment.

The following morning volatile organic compounds were collected from all plants. Cellophane bags and caterpillars were removed before the volatile collection started.

Plant Volatiles Volatile organic compounds emitted by *P. lanceolata* after herbivory, mechanical wounding, or control treatment were collected in a dynamic headspace collection system located in a growth chamber set at 20°C, 55% relative humidity and 85±5 µmol $m^{-2}s^{-1}$ photosynthetically-active radiation.

Approximately 16 h after the start of the treatments (H, MW, and C), each potted plant was placed individually in a 3 l glass desiccator (Schott, Germany). Each desiccator was tightly closed with a glass lid equipped with a valve that allowed air, which was previously purified through a charcoal filter, to enter the enclosure. The incoming air flux was adjusted to 2±0.3 $lmin^{-1}$. After being in contact with the plant, the air exited the glass cylinder through a collection trap (4 mm diam glass tube containing 30 mg Super Q (ARS, Gainesville, FL, USA), positioned in an opening in the lid.

All VOC collections were performed within a six-hour timeframe from around 10 am to 4 pm to minimize variation in volatile emissions due to plant diurnal rhythm. After 4 ½ h VOC collection, the Super Q traps were eluted with 150 µl dichloromethane that contained 1500 ng nonylacetate as an internal standard.

VOCs were identified with a Hewlett-Packard model 6890 gas chromatograph employing the carrier gas He at 1 ml min^{-1}, splitless injection (injection temperature: 220°C, injection volume: 1 µl), a DB-5MS column (30 m×0.25 mm×0.25 µm film, J & W Scientific, Folsom, USA), and a temperature program from 40°C (2 min hold) to 300°C (2 min hold) with a first gradient of 7°C min^{-1} to

155°C and a second gradient of 60°C min^{-1} to 300°C. Coupled to the gas chromatograph was a mass spectrometer (Hewlett-Packard model 5973) with a quadrupole mass selective detector; transfer line temperature, 270°C; ionization potential, 70 eV; and a scan range of m/z 40–350. For quantification, a GC was coupled to a FID detector operating at 250°C, using the same conditions described above.

VOCs were first identified on the GC-MS by reference spectra in the Wiley and National Institute of Standards and Technology libraries and in the literature (Joulain and König 1998) and by comparison of retention times and mass spectra to those of standards in our collection and others kindly supplied by Wilfried A. König, Hamburg (essential oils of *Oreodaphne porosa* and *Aloysia sellowii*). Quantification of the identified compounds was carried out by comparing the peak areas in the FID traces with that of the internal standard, applying a response factor of 1 for the internal standard, 1.11 for (*Z*)-3-hexenyl acetate, 0.75 for (*E*)-β-ocimene and (*E*)-4,8 dimethyl-1,3,7-nonatriene (DMNT), and 0.74 for all the sesquiterpenes (calculated according to the effective carbon number concept (Scanion and Willis 1985)). In addition to the 6 major compounds discussed in the "*Results"* section, other compounds were identified in a subgroup of the 29 plants subjected to herbivory treatment (*N*=number of individuals from which the particular VOC was identified): limonene (*N*=11), α-copaene (*N*=12), β-elemene (*N*=5), α-humulene (*N*=5), α-muurolene (*N*=2), δ-cadinene (*N*=2). As the sum of these terpenoids never exceeded 7% of the total volatiles, they were not included in further analyses.

Plant Performance After VOC collection, the aboveground parts of all plants were cut at ground level, and the number of leaves and fresh weight were recorded for each plant. In order to estimate the amount of leaf area lost due to caterpillar feeding in the herbivore treatment, the leaves from these plants were aligned on a white board together with a reference area of 2.25 cm^2 and photographed with a digital camera. Digital images were analyzed with Adobe Photoshop (Adobe Systems Incorporated, USA). By referring to the amount of pixels in the reference area, actual remaining leaf areas were determined. Leaf area loss due to caterpillar feeding then was reconstructed by using the remaining leaf area as a template. After photographing, leaves of all plants were frozen in liquid nitrogen and freeze dried. Then, the dry weight of each individual was measured.

Iridoid Glycosides Iridoid glycosides were extracted from 25 mg of freeze dried, finely ground leaf material with 1.8 ml methanol. After 6 h extraction, leaf material was centrifuged at 16000 g, and the supernatant was transferred into clean tubes and evaporated to dryness under nitrogen. The pellet was redissolved in 500 µl of a 20% methanol solution and centrifuged at 16000 g (modified from Marak et al. 2002). Separation of iridoid glycosides was achieved on a Hewlett Packard HP 1100 Series HPLC system with autosampler and diode-array detector. The procedure employed a C-18 reversed phase column (Supelcosil LC18, 250×4.6 mm i.d., 5 µm particle size, Supelco) operated at 1 ml min^{-1} and 25°C. Injection volume was 20 µl. Elution was accomplished with a gradient (solvent A: 0,05% trifluoroacetic acid, solvent B: MeCN) of 0–15 % B (15 min), followed by a cleaning cycle (15–100 % B in 0.5 min, 2.5 min hold, 100 to 0 % B in 0.1 min, 5 min hold). Eluting compounds were monitored at 200 nm, and peaks were identified by match of retention time and UV spectrum with those of commercial standards (catalpol, Wako Chemicals; aucubin, Carl Roth, Germany). Additionally, the identity of catalpol and aucubin was confirmed by LC-MS. Concentrations of iridoid glycosides were calculated by using response curves generated with external standards of catalpol and aucubin.

Mycorrhization Rates For the determination of mycorrhization rate, a subset of 30 mycorrhizal and 30 non-mycorrhizal plants was sampled so that an equal number of individuals from each treatment (H, MW, and C) and from each day of volatile collection were included. Immediately after removal of the leaves, roots were rinsed carefully to wash off the soil, fixed in formaldehyde–acetic-acid [FAA: 6.0% formaldehyde, 2.3% glacial acetic acid, 45.8% ethanol and 45.9% H_2O (v v^{-1})], and stored at 4°C. Fixed roots were washed with distilled water, cut in segments of approximately 1.5 cm, and heated at 90°C for 10 min in 10% KOH. Afterwards, roots were rinsed in tap water, acidified to 3.7% HCl for 10 min, and stained for 11 min in a ready-to-use lactophenol blue solution (Fluka, Switzerland) (Phillips and Hayman 1970). The stain in excess was removed in 50% lactic acid. Total mycorrhizal colonization rates (percentage of the examined root segments with mycorrhizal structures) were determined microscopically using the line intersect method (Phillips and Hayman 1970), modified after Schmitz et al. (1991). Stained root segments from one single plant were densely packed on a microscope slide. A minimum of 300 visual fields per slide were observed at 200×magnification.

Plant and Soil Nutrient Analysis Freeze dried, finely ground plant material (300 mg) and the sand-soil mixture in which the plants grew (500 mg) were analyzed for total carbon and nitrogen content with an elemental analyzer (Vario MAX CNS, Elementar, Hanau, Germany).

Statistical Analysis In order to analyze the influence of mycorrhization and treatments (H, MW, and C) on the amount of 1) the individual volatile compounds, 2) the total amount of terpenes, and 3) the amount of GLVs emitted and corrected for the dry weight of the plants at the same time, analysis of covariance (ANCOVA) was used. Type of treatment and presence of mycorrhiza were considered as fixed factors, and dry weight was fitted in the model as a continuous covariate. Data were either cube root (total terpenes and GLV) or log transformed (single volatiles), and quantities equal to zero were excluded from the analysis of single volatiles to match the prerequisites for ANCOVA. Whenever possible, models were simplified by removing non-significant terms (Crawley 2007). Significance of differences between factor levels were tested by Tukey multiple comparisons of means.

As for volatiles, the influence of mycorrhization and treatments was analyzed on catalpol and aucubin levels. Since IGs are constitutively produced compounds known to accumulate during plant development (Barton 2007), time was fitted to the model as a covariate. Time was indicated as the number of days (1 to 18) from the start of the experiment, i.e., from the day of the treatment of the first set of plants. Catalpol quantities were square-root transformed before analysis to fulfil the requirements for ANCOVA.

Significance of differences in aboveground biomass (dry weight), leaf number, herbivory rates, and carbon and nitrogen content between mycorrhizal and non-mycorrhizal plants was tested by Student's *t*-test.

All statistical analyses were performed with software package R (R Development Core Team (2008), R: A language and environment for statistical computing. R Foundation for Statistical Computing, Vienna, Austria. ISBN 3-900051-07-0, URL http://www.R-project.org.).

Results

Plant Volatiles Plantago lanceolata plants emitted a volatile bouquet dominated by the green leaf volatile (GLV), (*Z*)-3-hexenyl acetate, as well as terpenoids of different classes. In order to assess the effect of mycorrhization and different treatments on the volatile emission of *P. lanceolata*, we quantified the six major volatile compounds, which together make up between 70–90% of the total mixture in herbivory treated and mechanically wounded plants. These include the green leaf volatile (*Z*)-3-hexenyl acetate, the monoterpene (*E*)-β-ocimene, the C_{11} homoterpene (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), and the sesquiterpenes (*E*)-β-caryophyllene, (*E*)-α-bergamotene, and (*E*)-β-farnesene. The volatile organic compound (VOC) emission profile of *P. lanceolata* was significantly different among plants in the different treatments (Fig. 1a, Table 1). Most strikingly, herbivore-damaged plants emitted much higher levels of terpenoids than mechanically-damaged plants or undamaged controls (Fig. 1a, Table 1).

There were significant differences between mycorrhizal and non-mycorrhizal plants. Mycorrhizal plants emitted about 55% less total terpenoids compared to non-mycorrhizal plants in the herbivory treatment (mycorrhiza: $F_{1,171}=5.11$, $P=0.039$; interaction mycorrhiza:treatment: $F_{2,171}=8.14$, $P<0.001$; Fig. 2a). Among the classes of terpenoids, the emission of sesquiterpenes was 63% lower in mycorrhizal compared to non-mycorrhizal plants after herbivory (Table 1), but the emission of monoterpene, (*E*)-β-ocimene, was not affected by this treatment ($F_{1,83}=0.04$, $P=0.845$, Table 2).

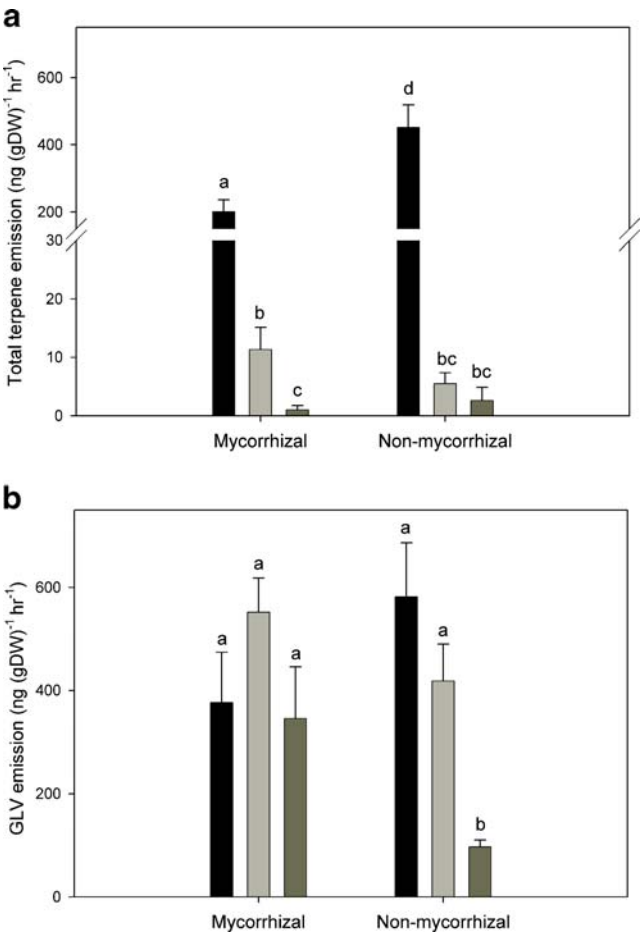

Fig. 1 Total emission of terpenes **(a)** and green leaf volatiles (GLV) **(b)** from *Plantago lanceolata* after herbivory (black bars) and mechanical wounding (light gray bars) in comparison to untreated control plants (dark grey bars). Bars represent means±SE. Different letters indicate significant differences between the means according to ANCOVA followed by Tukey test (adjusted $P<0.05$)

[a] These volatiles were emitted by a single plant, therefore the SE has not been calculated

For (*Z*)-3-hexenyl acetate, the only major GLV detected, mycorrhizal infection increased emission of undamaged plants more than 3-fold compared to undamaged non-mycorrhizal plants. Herbivory and mechanical wounding of mycorrhizal plants caused no further increase in the emission of this GLV, while these treatments did increase emission from non-mycorrhizal plants by over 5-fold (Fig. 1b).

The ANCOVA showed no significant interactions between the quantity of any of the terpenes and plant dry weight. However, a significant interaction of dry weight and mycorrhization ($F_{4,170}$=4.36, P=0.038, Table 2) was found for (*Z*)-3-hexenyl acetate. This means that the effect of mycorrhization on GLV emission varied according to plant biomass. In small plants, mycorrhization increased (*Z*)-3-hexenyl acetate emission, while it had the opposite effect on larger plants (Fig. 2).

Plant Performance The total aboveground biomass of mycorrhizal plants was on average 8.5% lower than non-mycorrhizal plants (fresh weight: $t_{1,175}$=−3.19, P=0.002, dry weight: $t_{1,176}$=3.87, P<0.001) (Fig 3). This result might be attributed to a drain of fixed carbon toward the fungus in mycorrhizal plants. In fact, mycorrhizal plants contained less carbon in their leaves compared to non-mycorrhizal plants (average C%: mycorrhizal plants= 41.4%, non-mycorrhizal plants=42.3%; Student's *t*-test, $t_{1,24}$=−3.98, P<0.001), but nitrogen content did not vary between leaves of mycorrhizal and non-mycorrhizal plants (N%=0.81% in both groups). The C/N ratio of the sand-soil mixture where the plants were grown was 23.15±0.35 (mean±SE, N=4). Non-mycorrhizal plants had on average a higher number of leaves compared to the mycorrhizal plants (mean non-mycorrhizal: 12.10, mean mycorrhizal: 11.40, $t_{1,162}$=−1.87, P=0.063).

Mycorrhization did not influence the feeding behaviour of *S. littoralis* caterpillars. The amount of leaf tissue consumed overnight was the same in mycorrhizal and non-mycorrhizal plants. ($t_{1,53}$=−0.83, P=0.411).

Iridoid Glycosides The two main iridoid glycosides (IGs) catalpol and aucubin did not show any significant change in

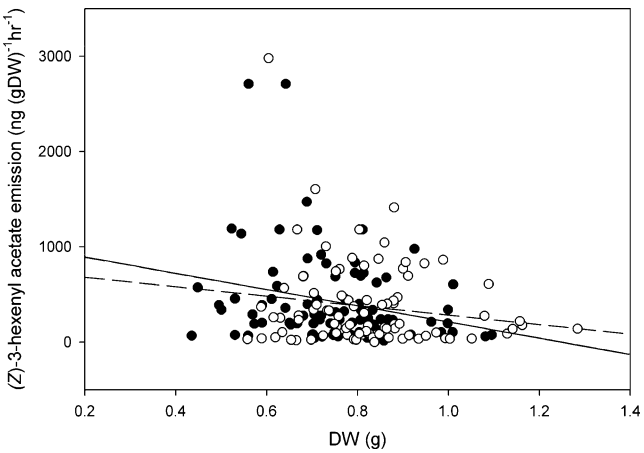

Fig. 2 Linear regression of (*Z*)-3-hexenyl acetate emission and plant dry weight for mycorrhizal (solid line) and non-mycorrhizal (dashed line) plants. Black dots represent all mycorrhizal plants (herbivory-treated, mechanically wounded and untreated), while open dots represent all non-mycorrhizal plants (herbivory-treated, mechanically wounded and untreated)

Table 2 ANCOVA summary table for the effects of mycorrhization, treatment and dry weight on the VOC emission of *Plantago lanceolata*

VOC	Factors				Covariate		df residuals
	Mycorrhiza (df=1)		Treatment (df=2)		Dry weight (df=1)		
	F	*P* [a]	*F*	*P*	*F*	*P*	
(*Z*)-3-hexenyl acetate	2.45	0.119[b]	15.47	**<0.001**[b]	1.34	0.242[b]	170
(*E*)-β-ocimene	0.04	0.845	46.85	**<0.001**	6.78	**0.011**	82
DMNT	7.68	**0.008**	8.55	**0.005**	1.20	0.279	48
(*E*)-β-caryophyllene	11.20	**0.001**	12.98	**<0.001**	3.00	0.089	50
(E)-α-bergamotene	18.14	**<0.001**	1.74	0.185	1.84	0.180	54
(*E*)-β-farnesene	7.57	**0.008**	1.066	0.353	1.19	0.281	46

[a] Bold numbers indicate significant effects

[b] For (*Z*)-3-hexenyl acetate two interactions were significant: mycorrhiza x treatment (F=8.41, P<0.001) and mycorrhiza x dry weight (F=4.36, P= 0.038). There was no significant interaction for any of the other volatile organic compounds

quantity, either between the treatments or between mycorrhizal and non-mycorrhizal plants (catalpol: treatment: $F_{2,173}$=0.065, P=0.937, mycorrhiza: $F_{1,173}$=0.021, P= 0.884; aucubin: treatment: $F_{2,173}$=2.09, P=0.127, mycorrhiza: $F_{1,173}$=0.98, P=0.322) (Table 1). The cofactor 'time' was significant for both catalpol ($F_{1,173}$=11.91, P<0.001) and aucubin ($F_{1,173}$=8.14, P=0.005), indicating that the concentration of IGs in the leaves slightly increased over time.

Mycorrhization Rates At the moment of harvest, all inoculated plants were infected by AMF. On average, we found 68% of the root system colonized by the fungus. No mycorrhizal structures were detected in roots of non-mycorrhizal plants.

Discussion

Mycorrhizal symbiosis is known to affect many plant parameters, including chemical defense (Gange et al. 2007; Hartley and Gange 2009). To understand fully the effects of this symbiosis on chemical defense, it is necessary to investigate compounds involved in both direct and indirect defense. Indirect defense is often manifested by the herbivore-induced release of volatile organic compounds (VOCs) that attract herbivore enemies. The results from our study show that *P. lanceolata* produces a large increase in volatile terpenoids after herbivory that may serve in indirect defense. However, the association of *P. lanceolata* with the arbuscular mycorrhizal fungus (AMF) *G. intraradices* significantly modifies the release of herbivore-induced VOCs from the plant by reducing the emission of the three major sesquiterpenes and the C_{11} homoterpene, DMNT. As DMNT and sesquiterpenes are prominent components of volatile blends known to act in indirect defense (Turlings et al. 1990), AMF may decrease the ability of herbivore-damaged plants to attract herbivore enemies. Consistent with these results, Jallow and co-workers (2008) recently reported that the inoculation of tomato plant roots with the endophytic fungus *Acremonium strictum* lead to a reduction in total terpenoid emission. In *Artemisia annua*, Rapparini et al. (2008) reported that infection with different *Glomus* species constitutively reduced the amounts of sesquiterpenes produced by undamaged plants compared to non-infected control plants. In contrast, infection had no effect on the amount of monoterpenes emitted by *A. annua*. These findings are consistent with our results from caterpillar-infested *P. lanceolata* plants where the major emitted monoterpene ((*E*)-β-ocimene) did not differ in its relative release rate between mycorrhizal and non-mycorrhizal plants.

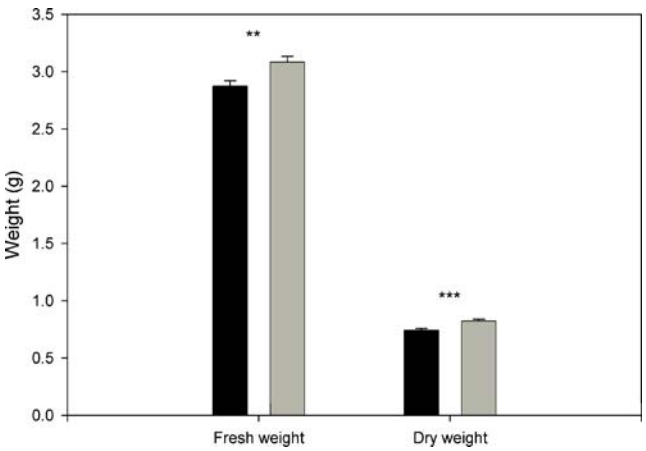

Fig. 3 Aboveground biomass of *Plantago lanceolata*. Fresh weight was recorded once for each plant, on the day the volatile collection was performed. Black bars=mycorrhizal plants, grey bars=non-mycorrhizal plants. Bars represent means±SE. Asterisks represent significant differences according to Student's *t*-test (**P<0.01, ***P<0.001)

Although there is as yet no evidence in the literature that AMF can alter plant indirect defenses, there are reports of the effects of mycorrhization on the major direct defense compounds of *P. lanceolata*, the constitutively produced iridoid glycosides (IGs), aucubin and catalpol. In our study, the levels of IGs were unaffected by mycorrhization. In contrast, a positive effect of mycorrhization on the IG content of *P. lanceolata* was reported by Gange and West (1994), who recorded higher levels of IGs in mycorrhizal compared to non-mycorrhizal plants. The authors attributed this result to the relatively higher fixed carbon levels in the shoots of mycorrhizal plants compared to non-mycorrhizal plants, which allowed more substrate to be allocated to IG production. In contrast, no effect of mycorrhization by *G. intraradices* was found on the catalpol content of *P. lanceolata* leaves by Wurst et al. (2004). Moreover, these authors observed a decrease in leaf carbon content after mycorrhization. We also observed a decrease in leaf carbon levels in the present study, and saw no increase in IG content. This finding supports the hypothesis that IGs are produced in higher amounts after mycorrhization only when symbiosis leads to greater amounts of fixed carbon in the leaves.

Not only did we find a reduction of total leaf carbon content in mycorrhizal plants, but also the aboveground biomass of mycorrhizal plants was lower than that of non-mycorrhizal plants. Although positive effects of AMF on their symbionts' productivity seem to be commonplace (Johnson et al. 1997), neutral or negative effects of mycorrhization on plant growth parameters and biomass also have been documented for *P. lanceolata* (Ayer et al. 1992; Klironomos 2003; Reynolds et al. 2005) and a number of other plant species (see Johnson et al. 1997 and references therein). That AMF can function as carbon sinks in plants has already been documented (Wurst et al. 2004; Reynolds et al. 2005; Ayres et al. 2006). If the growth of the fungus limits the carbon available to the plant for its basic metabolic requirements, the association could turn from symbiosis into parasitism, a phenomenon that has been attributed by some authors to nutrient-rich substrates, low temperatures, or limiting light conditions (reviewed by Smith and Smith 1996, Purin and Rillig 2008) or to particularly high mycorrhization rates (Gange et al. 1999 and references therein). In addition, AMF can be detrimental in association with particular hosts (Klironomos 2003), and the predisposition of a given fungal strain to parasitism rather than symbiosis seems to be at least partially under genetic control (Johnson et al. 1997). When confronted with a non-beneficial AMF association, plants might reallocate their resources among growth, defense, reproduction, and other functions. In this study of young *P. lanceolata*, there was a decline in growth, and a reduction in indirect defenses (volatile terpenes), but no change in the level of direct defenses (iridoid glycosides). These findings support our hypothesis that a net decrease in carbon availability caused by the fungus can cause a reduction in allocation to defense (in this case indirect defense). Maintaining high levels of direct chemical defenses in early developmental stages is a strategy adopted by a number of plant species, for example *Arabidopsis thaliana* (L.) Heynh. (Brown et al. 2003) and *Nicotiana sylvestris* Spegazzini and Comes (Ohnmeiss and Baldwin 2000). The reduction in indirect defenses observed can also be interpreted as a consequence of the general repression of defenses due to AMF colonization. In the first stages of the association, AMF seem to be able to modulate the defense signaling cascades in the plant, and lower the production of defense compounds (reviewed by Garcìa-Garrido and Ocampo 2002).

The mechanisms that underlie the induction of volatile terpene emission in *P. lanceolata* after biotic stresses such as herbivore feeding have not yet been elucidated. Terpene biosynthesis is carried out by condensation of C_5 isoprenoid units, which, in plants, can derive from two pathways: the methylerythritol phosphate (MEP) pathway, considered the principal route to monoterpene production, and the mevalonate (MVA) pathway, thought to be responsible for the production of sesqui- and triterpenes. The MEP pathway also leads to the production of carotenoids and eventually apocarotenoids, some of which are responsible for the yellow-colored roots seen in a number of species after mycorrhization (Strack et al. 2003). Interest in the function of this yellow pigment has stimulated study of the MEP pathway during mycorrhizal formation. Mycorrhization enhances the transcription of genes encoding 1-deoxy-D-xylulose 5-phosphate synthase (DXS), the enzyme that catalyzes the initial step of the MEP pathway in several species including *Medicago truncatula* L., *Nicotiana tabacum* L., *Zea mays* L., *Lycopersicon esculentum* Mill., and *Triticum aestivum* L. (Walter et al. 2000, 2002). An accumulation of transcripts for 1-deoxy-D-xylulose 5-phosphate reductoisomerase (DXR), the enzyme immediately downstream from DXS in the MEP pathway, also has been reported in wheat roots after *G. intraradices* infection (Walter et al. 2000). This AMF-mediated activation of the MEP pathway has not yet been examined with respect to the formation of monoterpenes, assumed to be MEP pathway-derived. After mycorrhizal infection of *P. lanceolata*, we observed no change in volatile monoterpene emission or the accumulation of the IGs, which derive from the same biosynthetic route as monoterpenes. Instead, a decrease in sesquiterpenes and DMNT, assumed to be derived from the MVA pathway, was detected. There are no reports in the literature on how the mevalonate pathway is altered by AMF infection.

The production of IGs is known to be strongly dependent on plant age in *P. lanceolata* (Fuchs and Bowers

2004; Barton 2007). In the study by Gange and West (1994), who found higher levels of IGs in mycorrhizal compared to non-mycorrhizal plants, IGs were extracted from four-month-old plants, which had been associated with AMF for 14 weeks. In contrast, the plants in the study by Wurst et al. (2004), where the IG content did not change with mycorrhization, and in our study were harvested between 9 and 12 weeks of age with a mycorrhizal period of 7 or 10 weeks, respectively. According to Fuchs and Bowers (2004), the concentration of IGs in *P. lanceolata* starts increasing 9 weeks after germination, while Barton (2007) found a strong increase in constitutive levels of IGs already after 6.5 weeks, and furthermore detected a positive correlation between growth rate and daily IG production. Direct comparisons of our results with the literature are difficult because of differences in growing conditions and the genetic properties of the plant material. Nevertheless, it seems plausible that the lack of increase in IGs on mycorrhization observed in our plants is due to harvest at a relatively early developmental stage.

The production of the GLV (*Z*)-3-hexenyl acetate in undamaged mycorrhizal-infected plants was comparable to that in herbivore or mechanically damaged individuals whether or not they were infected with mycorrhizae (Fig 2). Like many volatile terpenes, GLVs have been indicated in attracting insect parasitoids (Hoballah and Turlings 2005; Shiojiri et al. 2006), and can, therefore, be considered indirect defense signals. By increasing the emission of levels of GLVs in undamaged plants, mycorrhizal infection turns these typically induced volatiles into constitutive ones. This constitutively high GLV emission could be a possible explanation for the enhanced attractiveness of mycorrhizal vs. non-mycorrhizal plants to herbivore parasitoids observed by Guerrieri et al. (2004).

Considering the broad distribution and the importance of AMF associations in terrestrial ecosystems in general (Treseder and Cross 2006; van der Heijden et al. 2008) and more specifically in agricultural systems (Sawers et al. 2008), there is a need for further studies to analyze the impacts of mycorrhizal associations on plant defense in a broad range of species and the regulatory mechanisms responsible for these changes. Based on the present results, such investigations should also include an assessment of the mycorrhizal effects on the attraction of herbivore enemies. Since this attraction can vary when a combination of fungal species are associated with one plant (Gange et al. 2003), the effect of simultaneous association of different AMF on plant chemical defenses should also be investigated.

Acknowledgments We thank Carsten Renker, Udo Kornmesser, Andreas Weber and the gardeners of the MPICÖ, Daniel Rosenberger, Amelie Zander, Tobias Köllner, Grit Kunert, and Tim Walter for their assistance in various aspects of this work. Furthermore, we thank the two anonymous reviewers for the comments on the manuscript. The study was supported by the Max Planck Society.

Chemotaxis Disruption in *Pratylenchus Scribneri* by Tall Fescue Root Extracts and Alkaloids

Ada A. Bacetty · Maurice E. Snook · Anthony E. Glenn · James P. Noe · Padmaja Nagabhyru · Charles W. Bacon

Received: 27 March 2009 / Revised: 8 June 2009 / Accepted: 12 June 2009 / Published online: 3 July 2009

Abstract Tall fescue (*Festuca arundinacea*) forms a symbiotic relationship with the clavicipitalean fungal endophyte *Neotyphodium coenophialum*. Endophyte-infected grass is tolerant to nematode, but the factors responsible are unknown. One objective of this work was to determine if root extracts of tall fescue effected chemoreceptor activity of *Pratylenchus scribneri* by using an *in vitro* chemoreception bioassay. Another objective was to determine if specific ergot alkaloids (ergovaline, ergotamine, a-ergocryptine, ergonovine), and loline alkaloids, all produced by the fungal endophyte, altered chemotaxis with this bioassay. Methanolic extract from roots altered chemotaxis activities in this nematode but only from roots of plants cultured 45 ≥ d, which repelled nematodes. Extracts prepared from noninfected grasses were attractants. This assay indicated that the alkaloids were either repellents or attractants. N-formylloline was an attractant at concentrations of 20 μg/ml and lower, while at higher concentrations it was a repellent. Ergovaline, the major ergot alkaloid produced by the endophyte, was repellent at both high and low concentrations and caused complete death of the nematodes.

Introduction

Tall fescue (*Festuca arundinacea,* synonyms *Lolium arundinaceum* = *Schedonorus arundinaceus*) is a major perennial, cool-season turf and forage grass species that has been established as having a symbiotic relationship with a fungal endophyte *Neotyphodium coenophialum* Glenn, Bacon, & Hanlin (Bacon et al. 1977; Glenn et al. 1996). Subsequent research established that this symbiotum was mutualistic in which the fungus conferred biotic and abiotic defensive metabolites within the relationship (Lyons et al. 1986). The fungal symbiont produces non-conidiating, symptomless intercellular infections of tissue of the leaf sheaths, inflorescence stems, and seeds of tall fescue. The root and leaf blade are not infected. This biotrophic clavicipitalean fungus is the hybrid anamorphic state of several *Epichloe* species that can produce diseases in other grasses and sedges. In tall fescue, the association is entirely symptomless and the fungal symbiont is seed disseminated.

Symbiotic tall fescue is tolerant to numerous abiotic and biotic stresses and diseases, which is attributed to the interactive nature of the endophytic fungus. Of particular importance is that tall fescue is resistant to nematodes (McGlohon et al. 1961). Recent research has suggested that endophyte presence in tall fescue is associated with reduced numbers of various plant-parasitic nematodes in the soil and on grass roots (Bernard et al. 1997). West et al. (1988) and Kimmons et al. (1990) compared population densities of *P. scribneri* in the roots and soil surrounding tall fescue

plants with and without the endophyte. They found fewer nematodes in the endophyte-infected grass roots than in endophyte-free roots, and fewer nematodes were in the surrounding soil of endophyte-infected grass than in endophyte-free grass. This nematode population reduction supports previous findings that endophyte-infected tall fescue may be resistant or tolerant to several species of nematodes (Gwinn et al. 1992). The mechanisms responsible for the above tolerance to nematode infection remain uncertain, but in a recent study (Bacetty et al. 2007; Bacetty 2008), we established that ergot and other alkaloids, as well as tall fescue metabolites, are interactive in the nematode toxicity when measured by an *in vitro* toxicity system.

The lesion nematode, *Pratylenchus scribneri* Steiner, commonly is associated with forage grasses, and has been shown to reproduce on tall fescue (Kimmons et al. 1990; Bernard et al. 1997). *P. scribneri* is an obligate parasite that feeds and migrates in the cortical tissue of plant roots (West et al. 1988; Kimmons et al. 1990; Bernard et al. 1997). They continuously travel within their host's roots, feeding and moving from cell to cell, and can move in and out of the roots traveling freely in the rhizosphere (Bernard et al. 1997). This movement leads to secondary invasion of roots by other soilborne pathogens, which can result in root necrosis. Negative impacts on roots require several mechanisms that are either attractants or deterrents to the feeding activities of this and other nematodes (Roberts et al. 1992).

Since nematode behavior relies on chemoreception to locate potential hosts and other host related interactions (Perry 1996), it is important to know how the endophyte and its associated plant toxins influence nematode behavior. This research was designed to determine the semiochemical nature of specific tall fescue extracts and secondary metabolites from the endophyte to *P. scribneri* in order to provide some insight into the role symbiotic metabolites play in altering chemotaxis of this nematode. This was undertaken with the use of an *in vitro* bioassay that measures the behavior of *P. scribneri*. The specific objectives included: 1) assessing the attraction or repellency of total root exudates from symbiotic and nonsymbiotic tall fescue to *P. scribneri,* and 2) assessing the attraction or repellency to purified alkaloids known to accumulate in symbiotic tall fescue.

Methods and Materials

Nematode Culture Sterile cultures of *P. scribneri* were generously provided by Dr. Susan Meyer (USDA, ARS, Beltsville, MD). These nematodes were cultured on sterile corn root explants following the procedure of Meyer et al. (1990). Corn (*Zea mays* L.) cv. Pioneer 3223 seed were surface disinfected for 10 min in 100% commercial bleach (5.25% sodium hypochlorite) followed by a 15 min soak in 95% ethanol. Nine to ten surface sterilized seeds were placed onto 1.5% water agar (15 g/L, Difco, Detroit, MI, USA) plates and allowed to incubate in the dark at 25°C for 3–5 days. Primary roots were cut and transferred to pH adjusted (5.7) Gamborg's B5 agar (15 g/L) (Gibco, Carlsbad, CA, USA). Plugs from the original Meyer plate were transferred onto the fresh sterile roots. Prior to experiments, *P. scribneri* were extracted from the culture plates by pipetting sterile, distilled water (ca. 25°C) onto the surface of the B5 medium and transferring the nematode solution to sterile conical tubes for a stock solution. Nematodes were diluted and counted to desired numbers for experimental use.

Plant Cultures Twenty 2 wk-old tall fescue, cv. Jesup, seedlings (ten infected and ten non-infected with *N. coenophialum*) were transplanted to individual 20 cm plastic azalea pots filled with sterilized Fafard Professional Potting Mix. The pots were randomly arranged in the Russell Research Center greenhouse in Athens, Ga. Pots were watered 4 days per week to maintain soil moisture and fertilized with Osmocote's Slow Release Plant Food (Marysville, OH, USA) (19-6-12, NPK). Six weeks post transplanting, each pot was repotted into 26 l-plastic pots that would allow for extensive root growth for the entire length of the experiment, usually 10 mo culture. Both plant groups were randomly selected and screened for confirmation of endophyte infection by microscopic examination of the outermost leaf sheath (Hinton and Bacon 1985).

Root Extracts and Alkaloid Preparations Two independent pot culture experiments were conducted to identify the attractive or repellent nature to *Pratylenchus scribneri* from root of *Neotyphodium*-infected and non-infected plants. Samples were taken on 0 day, 30 days, 45 days, and 60 days for total root extract analysis. Total root extracts were prepared from 1.29 g and 9.61 g of roots that were ground in 500 ml of methanol by using a Polytron tissue grinder, filtered (Whatman #2), and the methanol was evaporated to dryness under a vacuum by using a rotoevaporator at 45°C. The residues were weighed, and a stock solution was prepared by dissolving the residue in sterile distilled water and filter sterilized (Acrodisc Syringe Filter 0.2 μm HT Tuffryn Membrane). Stock solutions of total extracts were adjusted with sterile distilled water to yield final test concentrations of 400 μg/ml, 200 μg/ml, 100 μg/ml, 50 μg/ml, 20 μg/ml, 10 μg/ml, and 5 μg/ml, and their effects on nematode behavior were determined by observing movement tracks on 0.4% water agar. One hundred-μl of root extracts were pipetted into 1 cm wells on opposite sides of a 5 cm Petri dish that contained the 0.4% water agar. Approximately 6 nematodes were placed

in the center of the water agar and allowed to move freely for 2 h while incubated in the dark at 25°C and observations were made with the Nikon microscope-camera setup. All experiments were performed in the dark and repeated at least three times.

All ergot alkaloids were obtained from Sigma Inc., St. Louis, MO, USA, as the free bases, with the exception of ergovaline, which was synthetically prepared as the salt of sodium tartrate (Department of Chemistry, Auburn University). These standards were stored under nitrogen at −20°C until use. The loline alkaloid was prepared from seed of endophyte-infected tall fescue, which was formylated with ethylformate and purified by silica gel chromatography that resulted in 94% pure N-formylloline. All compounds were dissolved in sterile distilled water, and these stocks solutions were filter sterilized and appropriate dilutions made with sterile distilled water as indicated below. All solutions and distilled water used as controlled solution were adjusted to pH5.5, which is the resulting pH of extracts obtained from roots during the grinding process. All stock and working solutions of ergot alkaloids were stored at −20°C until use, and these solutions were stable during the 2–4 h observation periods.

Nematode Chemotaxis Assay The effects on nematode behavior were compared by observing movement tracks in thin agar plates, following the procedure of Wuyts et al. (2006). Ergot and loline alkaloids, and extracts prepared as described above from roots of the *Neotyphodium*- infected and non-infected tall fescue cv. Jesup were used in this procedure. To determine at what concentration nematodes were attracted to or repelled by a test compound, 100 μl of the sterile ergot alkaloid solutions including ergovaline, ergotamine, ergonovine, α-ergocryptine, and loline were individually tested at concentrations of 200, 100, 50, 20, 10, 5, and 1 μg/ml. Controls consisted of sterile distilled water, and tartaric acid. A positive control consisted of concentrations of $CaCl_2$.

Observations were made with a Nikon SMZ1500 microscope with a Nikon DXM1200C digital camera attachment. Photographs were downloaded to PowerPoint, and the tracts were traced for ease in presentation. Compounds were determined to be an attractant or a repellent by using the definition and the sixteen-segment grid developed by Wuyts et al. (2006). The grid was placed on an agar plate to record the presence = 1, or absence = 2 of nematode tracks. The technique used to calculate the chemotaxis factor (Cf) was modified to include dividing the sum of scores of the attractant zones by those of the repellent zones. A Cf greater than 2 denoted an attraction, while values lower than 0.5 resulted in the compound being a nematode repellent.

Statistical Analysis Bioassay data were analyzed with regression analyses (SAS v. 9.1, SAS Institute, Carry, NC, USA) to determine significant differences between root extracts and fractions of endophyte-infected or non-infected fescue and their effects on *P. scribneri* motility. Regression testing (SAS v. 9.1) was used to determine significant differences of data generated from *in vitro* bioassays that tested the effects of alkaloids, on *P. scribneri* motility.

Results and Discussion

To reveal more about the biology of nematode suppression, an *in vitro* bioassay was used to evaluate the secondary metabolites within the roots of *N. coenophialum*-infected tall fescue on nematode behavior. From the results (Fig. 1), we determined that nematode behavior is affected by the secondary metabolites produced in this fungal-grass association, and that these factors are significant compared to

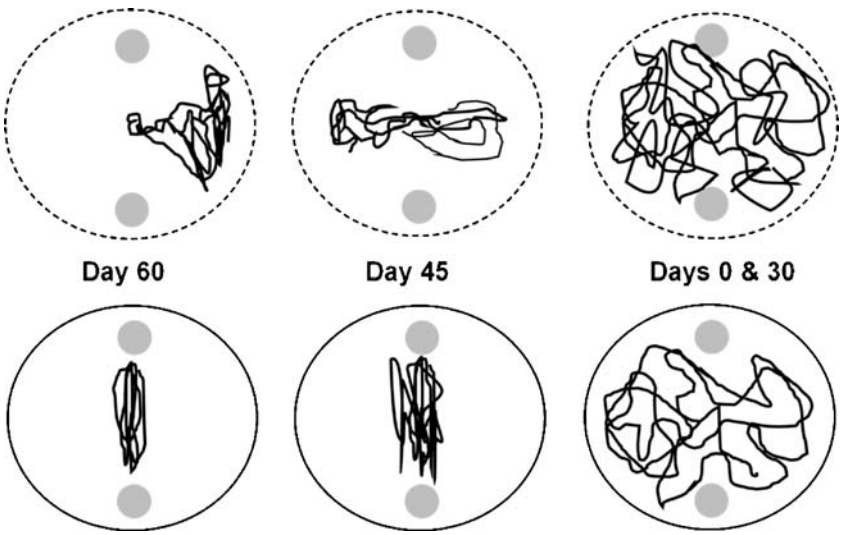

Fig. 1 Chemotaxis in *Pratylenchus scribneri* exposed to a methanolic extract of tall fescue root harvested from endophyte-infected (*dash circles*) and non-infected (*solid circles*) plants cultured over a 60-day growth period. Observations were made during a 2-h observation period

controls ($P<0.05$). After calculating the chemotaxis factors (Cf), extracts from days 0 and 30 exhibited a neutral effect on *P. scribneri* behavior in both the endophyte-infected and non-infected samples. Clear differences between endophyte status treatments occurred with extracts from the 45 day and 60 day sampling periods. Methanol extract of the endophyte-infected roots of 45 day-old tall fescue exhibited strong repellency at 100–400 μg/ml concentrations with Cf scores of 0, while the lower 5–50 μg/ml concentrations were weaker repellents with Cf scores of 0.3. In contrast, non-infected root extracts were strong attractants across all concentrations tested (Cf=3). Day 60, extracts exhibited similar strong nematode attraction across all concentrations (Cf=3). However, in the endophyte-infected root extracts, concentrations 50–400 μg/ml were all strong repellents (Cf=0), while 5–20 μg/ml remained weak repellents (Cf=0.3). Thus, a chemoreceptor substance is temporally expressed in the roots of infected tall fescue. Controls performed as expected, $CaCl_2$, a positive control, was an attractant (Cf=3); sterile distilled water had no effect on behavior as evidenced by nematodes' movement over the entire plate, and tartaric acid at the concentrations used was negative but at concentrations of 0.25% and greater was a strong repellent (Cf=0).

Using the same chemotaxis bioassay system, nematode behavior was examined when exposed to purified alkaloids that are produced in *N. coenophialum*-infected tall fescue. Representative chemotaxis responses to some concentrations are presented in Fig. 2. All produced significant effects ($P<0.05$) compared to comparable controls. Ergovaline, the principal ergopeptide alkaloid of endophyte-infected fescue, is a strong repellent (Cf=0) at the 100–200 μg/ml concentrations and a weak (Cf=0.3) repellent from 1–50 μg/ml. Following the 2-h incubation period, *P. scribneri* at the 10–200 μg/ml ergovaline treatments were found clustered together dead inside the agar. However, we determined that at the 1–5 μg/ml concentrations ergovaline was toxic (Bacetty et al. 2007). Since ergotamine and α-ergocryptine are also ergopeptides, it was expected that they would act as nematode repellents. Across all concentrations, ergotamine was an attractant (Cf=2.5–4), and this attractant resulted in nematode mortality at concentrations of 50–200 μg/ml. Alpha-ergocryptine was a weak (Cf=0.2–0.4) nematode repellent between 50–200 μg/ml and an attractant (Cf=3) between 1–20 μg/ml. Ergonovine was an effective but weak (Cf=0.25–0.3) repellent, and nematode mortality was not affected across concentrations.

The pyrrolizidine alkaloids affected *P. scribneri* behavior in a similar fashion to the ergopeptides, ergovaline and α-ergocryptine. The loline alkaloid produced a strong repellent (Cf=0), between 10–200 μg/ml and a weak repellent (Cf=0.3) at 1–5 μg/ml concentrations. As with ergovaline, nematode mortality was adversely affected. In the 20–200 μg/ml treatments, *P. scribneri* were found clustered together and dead after apparently moving a short distance from the inoculation site. Mortality was not affected at the

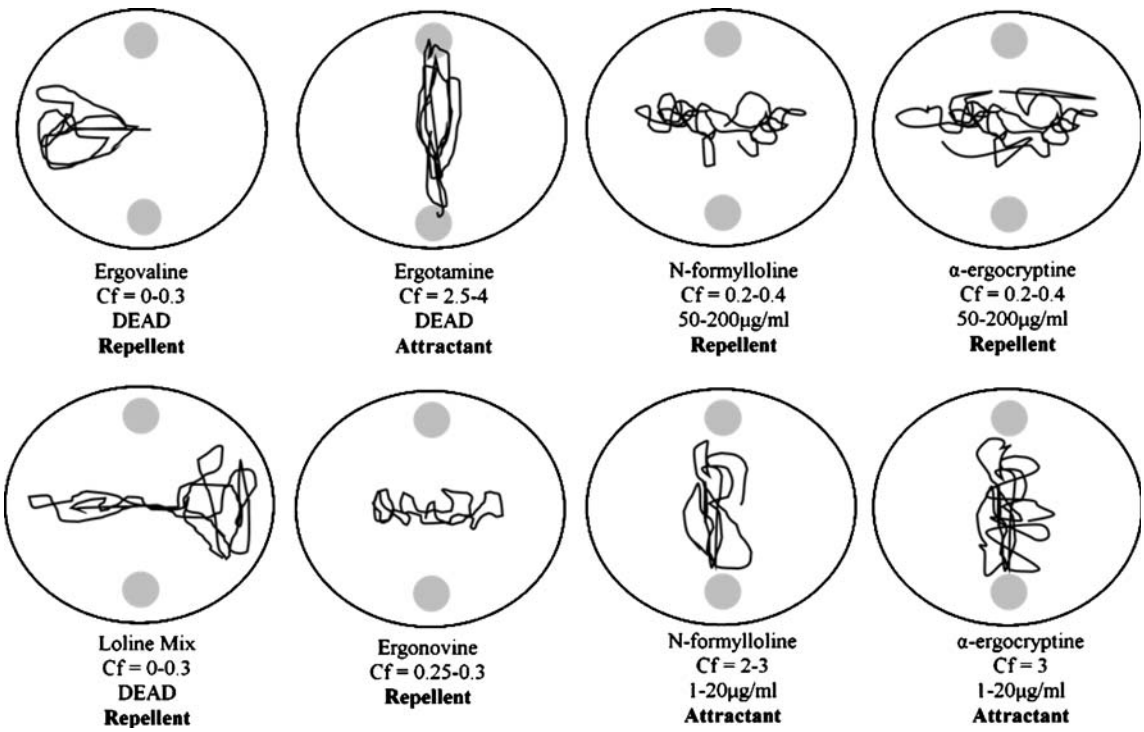

Fig. 2 Selected chemotaxis patterns displayed by *Pratylenchus scribneri* exposed to purified ergot and loline alkaloid concentrations. Observations were made during a 2-h observation period

lower 1–10 μg/ml concentrations. N-formylloline (loline) affected nematode behavior similarly to α-ergocryptine. The higher concentrations, 50–200 μg/ml, were weak (Cf= 0.2–0.4) nematode repellents, while the lower, 1–20 μg/ml, treatments acted as attractants (Cf=2–3). Nematode mortality was not adversely affected across concentrations. All controls (distilled water, pH adjusted distilled water, $CaCl_2$, and 0.01% tartaric acid) had no altering effects on nematode behavior. The data indicate that among the alkaloids the following order of repellency: Ergovaline > Ergonovine > Ergotamine > N-Formyloline > α-Ergocryptine. However, the qualitative and quantitative content of ergot alkaloids contained in leacheates from symbiotic plants within a given pasture situation is dependent on the genetics of the fungal endophyte and its individual grass tiller (Agee and Hill 1994; Hiatt and Hill 1997; Leuchtmann et al. 2000; Salminen and Parwinder 2002, Salminen et al. 2003), which as indicated by these data will produce variations in any disruptive behavior if the desire is for nematode control.

The most biologically active compounds for this nematode are the ergot alkaloids, which are found in abundance in leaves and seed of tall fescue. The natural effects of foliage toxins on a root parasite must be explained if their natural roles in the ecology of root parasitisms are to be understood. *Pratylenchus* species are economically important plant parasites worldwide with a wide host range of monocots and dicots, and depending on species, host, and temperature, the life cycle can be completed in 5–8 weeks. Eggs of this species are laid inside roots, and juveniles go through four molts in a single life cycle. All stages, except the egg, are vermiform, motile, and infective to plant host roots, and as a lesion nematode, migratory endoparasitic behavior results in spending a greater percentage of time within roots, feeding intracellularly within the root cortex. Nematodes are versatile as they can also migrate in and out of the root and sometimes feed as ectoparasites. The result of such destructive behavior alters root anatomy, leading to an unregulated flow of translocates such as ergot alkaloids downward. Further, the feeding behavior of nematodes also serves as a directed sink, pulling above ground substances downward to the roots. Thus, while the ergot alkaloids are produced in the foliage where the endophyte dwells, feeding by this and other species should result in a downward flow of substances, creating root and soil leacheates that contain these and other constituents of symbiotic grasses that are not necessarily translocated downwardly into non-nematode parasitized tall fescue roots. Plant leacheates produced by feeding nematode feeding occur in effective concentrations as they have been attributed to an increase in soil microbial biomass (Denton et al. 1999). Roots of endophyte-infected tall fescue do contain a small amount of ergot alkaloids, although they also contain a significant amount of both N-acetyl and N-formyl loline alkaloids (Bush et al. 1993). However, there are no data on the occurrence and quantities of such compounds in roots of tall fescue parasitized by nematodes species.

The neurotransmitters dopamine, serotonin, and acetylcholine have been detected in several nematode species (Sharp and Akinson 1980; Stewart et al. 2001) where they play a role in several aspects of nematode behavior. In *Caenorhabditis elegans,* the free-living nematode, exposure to exogenous dopamine causes numerous negative effects including paralysis, as well as inhibition of egg laying and defecation (Schafer and Kenyon 1995; Weinshenker et al. 1995). Acetylcholine is involved in locomotion, controlling wave initiation during movement, egg laying, pharyngeal pumping, and in male mating behavior (Hallam et al. 2000; Garcia et al. 2001). Serotonin also is involved in various nematode behaviors such as locomotion, egg laying, and pharyngeal pumping (Loer and Kenyon 1993; Schafer and Kenyon 1995; Weinshenker et al. 1995). Treatment of *C. elegans* with exogenous serotonin caused paralysis, stimulation of pharyngeal pumping in the absence of food, and stimulation of premature egg laying (Loer and Kenyon 1993; Schafer and Kenyon 1995; Weinshenker et al. 1995).

The ergoline ring system of ergot alkaloids is a structural homologue to the neurotransmitters epinephrine, norepinephrine, dopamine, and serotonin. The structural similarities may explain why some ergot alkaloids act as agonists or antagonists on neurotransmitter receptor sites. Based on structures alone, the biogenic amines, dopamine and serotonin, suggest modes of actions due to the ergots ergoline ring. It has been demonstrated that ergovaline, the major ergot alkaloid produced in endophyte-infected tall fescue, acts on a serotonin receptor (Dyer 1993; Larson et al. 1995). In livestock, ergot alkaloids mimic dopamine and exert an agonistic interaction with the D2 dopamine receptor to inhibit acetylcholine and dopamine release, depress chemosensory activity, inhibit norepinephrine release, and reduce prolactin secretions (Cross et al. 1995). The pyrrolizidines (lolines) alkaloids in infected tall fescue are a class of alkaloids that are of fungal origin, structurally distinct, but functionally similar to those found in vascular plants. The biological activity of the individual lolines has not been tied to livestock toxicosis; however, alone or in combination, they exhibit strong anti-insect activity. While N-formyllolline and N-acetylloline did not express any binding affinity to the D2 dopamine receptor (Larson et al. 1999), there are studies that have demonstrated that the lolines do bind to acetylcholine and/or serotonin receptors (Mattocks 1986).

The bioassay used here determined nematode responses to components of root and a fungal endophyte, which are important in terms of developing control strategies based on

disruption of chemoreception of nematodes, indicating the importance of chemotaxis in regulating the movements of nematode species. We have demonstrated that the *in vitro* migratory behavior of *P. scribneri* is altered in the presence of specific ergot and loline alkaloids, as well as tall fescue root extracts. While the *in planta* situation is unknown, the prior published reports of resistance to nematode and the behavior to root extracts from this work add support that substances from roots are responsible for the observed resistance. Analogs of these semiochemicals may have potential as controls for this and other nematodes. We base this hypothesis on our discussion of the possible mechanisms of action relative to structure-activity relationships of the ergot alkaloids and the perception of these substances by this species, which may serve as the basis for the search for other structures that can serve as allelochemicals for nematode control. The mode of action might be related to receptor sites in nematodes, which were not demonstrated in this work, but are expected to vary according to nematode species. If this is correct, it could account for species specificity observed for the tall fescue populations and the varied reactions of nematode species, thus producing an even greater impact as biocontrol strategies.

Acknowledgements We thank D. M. Hinton, USDA, ARS, for technical advice; C. Schardl, Univ. Kentucky, USDA-ARS Specific Cooperative Agreement Grant 200506271031 Department of Plant Pathology, University of Kentucky for his assistance and donation of loline; Dr. Susan Meyer for assistance concerning the sterile nematode culture and care used in this work; and H.R. Harrison, Jr. for supplying an authentic sample of 3,5-dicaffeoylquinic acid. We also acknowledge the assistance of Trevor Mitchell, USDA, ARS, with chemical analyses and Donald Woods, Crop and Soil Sciences Department, University of Georgia for assistance with the tall fescue cultivar Jesup.

Benthic Herbivores are not Deterred by Brevetoxins Produced by the Red Tide Dinoflagellate *Karenia Brevis*

Erik E. Sotka · Amanda McCarty · Emily A. Monroe · Nicole Oakman · Frances M. Van Dolah

Received: 20 April 2009 / Revised: 12 June 2009 / Accepted: 18 June 2009 / Published online: 11 July 2009

Abstract Gulf of Mexico blooms of the dinoflagellate *Karenia brevis* produce neurotoxic cyclic polyethers called brevetoxins. During and after a red tide bloom in southwestern Florida, *K. brevis* cells lyse and release brevetoxins, which then sink to the benthos and coat the surfaces of seagrasses and their epiphytes. We tested the possibility that these brevetoxin-laden foods alter the feeding behavior and fitness of a common benthic herbivore within Floridean seagrass beds, the amphipod *Ampithoe longimana*. We demonstrated that coating foods with *K. brevis* extracts that contain brevetoxins at post-bloom concentrations (1 μg g^{-1} drymass) does not alter the feeding rates of Florida nor North Carolina populations of *A. longimana,* although a slight deterrent effect was found at eight and ten-fold greater concentrations. During a series of feeding choice assays, *A. longimana* tended not to be deterred by foods coated with *K. brevis* extracts nor with the purified brevetoxins PbTx-2 and PbTx-3. Florida juveniles isolated with either extract-coated or control foods for 10 days did not differ in survivorship nor growth. A similar lack of feeding response to brevetoxin-laden foods also was exhibited by two other generalist herbivores of the southeastern United States, the amphipod *A. valida* and the urchin *Arbacia punctulata*. Given that benthic mesograzers constitute a significant portion of the diet for the juvenile stage of many nearshore fishes, we hypothesize that the ability of some mesograzers to feed on and retain brevetoxins in their bodies indicates that mesograzers may represent an important route of vertical transmission of brevetoxins through higher trophic levels within Gulf of Mexico estuaries.

Introduction

Gulf of Mexico blooms of the planktonic dinoflagellate *Karenia brevis* are among the oldest reported harmful algal blooms known (Landsberg et al. 2005), and some evidence indicates that their blooms have increased in both frequency and severity over the past 50 years (Alcock 2007). In the eastern Gulf of Mexico, *K. brevis* blooms typically originate on the west Florida shelf and are carried into coastal waters by prevailing wind and currents (Steidinger et al. 1998). Coastal blooms often are maintained in nearshore waters and shallow-water estuaries for months before subsiding, and thus, can have extensive impact on pelagic and benthic communities across large spatial scales (Tester and Steidinger 1997). The primary ecological impacts associated with *K. brevis* blooms are profound mortality events involving finfish, birds, and mammals (Van Dolah et al. 2001; Flewelling et al. 2005). The toxic

effects of *K. brevis* are due largely to brevetoxins, lipophilic cyclic polyethers that bind to and activate voltage-dependent sodium channels (VDSC), and thereby disrupt regulation of respiration and circulation (Baden 1989; Baden et al. 2005).

Adverse effects of brevetoxins can occur after either direct inhalation or consumption of brevetoxin-laden prey. Although distinguishing the relative importance of inhalation vs. consumption can be difficult, there is evidence that vertical transmission via consumption plays a primary role (Poli et al. 2000; Tester et al. 2000; Van Dolah et al. 2001; Doucette et al. 2005; Fire et al. 2008). In the pelagos, *K. brevis* cells commonly are consumed by zooplanktivorous herbivores (e.g., Naar et al. 2007), even though *K. brevis* is a relatively poor-quality food (Turner and Tester 1997; Tester et al. 2000; Prince et al. 2006) and alters copepod fitness (Breier and Buskey 2007) and swimming behaviors (Cohen et al. 2007). These zooplankton then are consumed by fishes that can accumulate brevetoxins within their own tissues.

On the benthos, brevetoxins are known to pass through benthic food webs via two trophic pathways (see reviews by Van Dolah et al. 2001; Doucette et al. 2005). Filter-feeding bivalves readily consume *K. brevis* cells and accumulate brevetoxins without increasing their mortality rates, thereby facilitating transmission to bivalve consumers such as omnivorous gastropods, fishes, and crabs. In addition, herbivorous fishes and manatees directly consume seagrasses and epiphytes that are coated with brevetoxins as dying cells sink to the benthos, break open, and release brevetoxins. Brevetoxin loads on these benthic plants can be substantial. For example, after a 2002 bloom in southwestern Florida, brevetoxin loads on seagrasses averaged approximately 1 μg g^{-1} drymass, and reached 3.1 μg g^{-1} drymass (Flewelling et al. 2005). The majority of this brevetoxin (~85%) coated epiphytic algae and persisted for more than ten weeks after *K. brevis* cells disappeared. Brevetoxin accumulation on seagrasses and their epiphytes subsequently has been found to be a widespread and common occurrence in southwest Florida during and after *K. brevis* blooms (Flewelling 2008; L. Flewelling, personal communication).

We propose a third pathway by which brevetoxins may be transmitted through benthic food webs, but that has received relatively little attention. Small benthic herbivores known collectively as mesograzers (e.g., amphipods, isopods, and polychaetes; cf. Brawley 1992) live and feed on brevetoxin-laden seagrass and epiphyte tissue, accumulate the toxins, and subsequently transfer brevetoxins to their own predators. Mesograzers are the primary consumers of seagrass epiphytes in many estuarine systems (Jernakoff et al. 1996; Hughes et al. 2004), tend to live several months during which they could potentially accumulate brevetoxin after a bloom relaxes, and are among the predominant prey items of omnivorous and carnivorous fishes, crabs, and shrimps in seagrass beds proximal to the Gulf of Mexico (e.g., Darnell 1961; Virnstein 1987; Motta et al. 1993; Luczkovich et al. 2002). Importantly, juvenile stages of several fish species depend almost entirely on a mesograzer diet (Stoner 1979), thus increasing the likelihood that mesograzers may serve as an important brevetoxin vector in estuarine food webs.

An untested assumption underlying this hypothesis is that benthic herbivores are willing to consume brevetoxin-laden foods. To address this, we pursued a series of feeding and performance assays with the herbivorous amphipod *Ampithoe longimana*, one of the most common herbivores in seagrass beds of the southeastern United States (Nelson 1980; Brooks and Bell 2001; A. McCarty and E. Sotka, personal observation), and we focused on the following questions: First, do amphipods alter their feeding behavior when offered foods coated with *K. brevis* chemical extracts or purified brevetoxin? Second, is amphipod survivorship or growth altered when isolated with foods coated with brevetoxin-laden extracts or with seawater containing solubilized brevetoxins? Third, do amphipods that are continuously fed brevetoxin-laden tissues for days contain measurable levels of toxin? Finally, do other benthic herbivores (the amphipod *Ampithoe valida* and the purple sea urchin *Arbacia punctulata*) show similar feeding responses toward *K. brevis* extracts similar to *A. longimana* ? Our results generally support the notion that benthic herbivores like *A. longimana* readily consume brevetoxin-laden foods, and indicate that benthic mesograzers could serve as important vectors for brevetoxin transmission through estuarine food webs.

Methods and Materials

Collection and Preparation We collected the amphipod *A. longimana* on the west coast of Florida (Tampa Bay 27° 45′ N, 82° 36′ W), the east coast of Florida (Fort Pierce 27° 28′ N, 80° 17′ W), and Bogue Sound, North Carolina (34° 41′ N, 76° 41′ W). In Tampa Bay, amphipods were collected at Lassing Park within seagrass beds of *Thalassia testudinum* and *Halodule wrightii*. Fort Pierce amphipods were collected on the seaweeds *Caulerpa sertulariodes*, *Padina gymnospora*, and *Hincksia feldmania* or in seagrass beds of *Thalassia testudinum* and *Halodule wrightii* at Stan Blum Boat Launch or Jaycee Park. In Bogue Sound, *A. longimana* and *A. valida* were collected at Radio Island Jetty largely from the seaweed *Sargassum filipendula*. The urchin *Arbacia punctulata* was collected from floating docks within Bogue Sound.

All animals were brought to the Grice Marine Laboratory in Charleston, SC, and kept in plastic tubs that

contained unfiltered seawater from Charleston Harbor at ~20°C with a salinity of 26–30 ppt. The water was aerated constantly, and changed approximately once a week. All amphipods were raised on a varied diet of the seaweeds *Sargassum filipendula*, *Hypnea musciformis, Gracilaria tikvahiae,* and *Ulva* (syn. *Enteromorpha*) *intestinalis* collected from Bogue Sound, NC. All seaweeds were washed in freshwater for at least two 30 s intervals in order to eliminate any *Ampithoe longimana* existing on the plants. Cultures were allowed to breed for one to several generations before the experiments began.

The *Ulva intestinalis* tissues used in feeding assays were collected at Radio Island Jetty. The seaweed was rinsed, cleaned of all other biota, and frozen. The frozen alga then was lyophilized at Hollings Marine Laboratory in Charleston, SC, ground into a fine powder with a Wiley mini-mill, and stored at −20°C until use.

A crude brevetoxin extract was prepared from a *K. brevis* Wilson isolate by using a standard solid-phase SPEC extraction (Twiner et al. 2007). In brief, 200 ml of *K. brevis* culture were applied to a pretreated SPEC C18SAR disc (Varian Chromatography, Lake Forest, CA, USA). After a wash with 60 ml of Milli-Q water and 5 min of drying, brevetoxins were eluted from the discs with 20 ml methanol. A total of four extracts were produced from the same culture. The solution concentrations were quantified by using mass spectrometry (Twiner et al. 2007) and an ELISA antibody protocol (Maucher et al. 2007), which has an estimated detection limit of 100 pg / ml. Approximately 97% of the brevetoxins within these extracts was PbTx-1 and PbTx-2, as identified by liquid chromatography / mass spectrometry (following Wang et al. 2004; Zhihong Wang, unpublished data). Purified PbTx-2 and PbTx-3 were obtained from World Ocean Solutions, Wilmington, NC, USA; PbTx-1 was unavailable.

Feeding Assays Assays were performed with *K. brevis* lipophilic extracts that contained brevetoxins or purified brevetoxins. We never offered live *K. brevis* cells because to our knowledge, the cells rarely, if ever, accumulate on seagrass and its epiphytes. We assessed whether *K. brevis* extracts altered herbivore feeding rates by isolating *Ampithoe longimana* individuals on a single food (i.e., a no-choice assay) that was coated with extracts at known concentrations of crude brevetoxin (0.1, 1, and either 8 or 10 μg g^{-1} drymass, depending on the assay) or with ether only. To prepare the brevetoxin-laden food, the correct volume of brevetoxin in methanol was dried by using nitrogen gas, then dissolved in 20 ml of anhydrous ethyl ether and mixed with 1 g of freeze-dried and powdered *Ulva intestinalis*. Ether was removed under rotary evaporation. A solution of 0.18 g agar in 5 ml distilled water was heated to boiling in a microwave oven, cooled, and mixed with 1 g of brevetoxin-coated *Ulva* powder added to 4 ml water. The 10 ml mixture then was poured over window screen and flattened between two pieces of wax paper. After cooling for 30–60 min, the mesh was cut into grids of 6X10 cells (approximately 2 cm^2) and offered to individual amphipods in plastic cups that contained 50 ml of seawater. Ether-only control foods were prepared by rotary-evaporating 20 ml of anhydrous ethyl ether from 1 g of *Ulva* tissue as above. Twenty amphipods from each population were isolated individually with each treatment or control, and placed in the dark at 25°C for approximately 48 h. Previous work had indicated that feeding rates in the dark were higher relative to daytime feeding rates (Amanda McCarty, unpublished data). The number of squares consumed was recorded for all replicates, and a series of nonparametric Kruskal-Wallis tests were performed by using *R* (http://www.r-project.org/) to assess overall differences in feeding rate between control and brevetoxin-coated foods. *Post-hoc* differences were assessed with a series of nonparametric pairwise Wilcoxsan tests.

We assessed whether feeding preference was altered by the presence of crude brevetoxin extracts by offering amphipods a choice of *Ulva* tissue coated with extracts at known concentrations of brevetoxin or with ether only. Foods were created as described for no-choice assays. One 6×5 grid of the brevetoxin treatment (at either 1 or 8 μg g^{-1} drymass) and one control grid were offered to amphipods placed individually in small plastic cups (N=40). For each replicate, the number of cells cleared of food was recorded twice a day, and a replicate was removed from the assay when either nine cells had been removed from either the treatment or the control, or when the sum total of cells removed was ten or more. For each assay, a paired *t*-test was performed by using *R* to determine whether control and treatment foods were differentially consumed.

The application of heated agar did not appear to change the structure of brevetoxins used to produce the test foods, which is consistent with their description as heat-stable toxins (Baden et al. 2005). When heated agar was applied to several samples of purified PbTx-2 and PbTx-3, LC-mass spectrometry detected only these two compounds and a methanol adduct of PbTx-2 that arises from reaction with methanol. There was no detectable open A ring PbTx- 2, 3, oxidized PbTx -2, or open A ring oxidized PbTx-2 (Zhihong Wang, personal communication).

Performance Assay We also assessed the effects of brevetoxin consumption on the survivorship and growth of Florida *A. longimana*. Twenty females carrying eggs were isolated in Petri dishes and allowed time to release their offspring. The mother was removed after the first recorded appearance of juvenile amphipods. The juvenile amphipods were allowed approximately two weeks to grow on a mixed diet of *Sargassum* and *Ulva* before the performance assay began. A dash of cetyl alcohol powder was placed within

each dish to minimize the risk of juvenile amphipods being trapped in surface tension. After two weeks, the juveniles were isolated into separate Petri dishes and allowed one week to feed on fresh *Ulva* collected in Charleston, SC. The amphipods were then placed separately in plastic cups and raised on freeze-dried *Ulva* coated with or without extracts containing 8 μg/g brevetoxin. Because cetyl alcohol powder may preferentially bind to this lipid (T. Leighfield, personal communication), the powder was not added to these experimental cups. The assay was performed on eight juveniles from the Ft. Pierce population and 50 juveniles from the Tampa Bay population, divided evenly between the control and the treatment (n=29). Low numbers of the Ft. Pierce population is attributable to availability in our cultures. The food was prepared as described above in *Feeding Assays* and food and water were changed on day four and eight. The assay persisted for 10 days and was monitored daily for mortality.

To assess growth, pictures of each living amphipod were taken with a Nikon camera at the start of the assay and again at the end of the assay. In each picture, head height was measured at the end of the assay by using ImageJ (http://rsbweb.nih.gov/ij/) and corrected for degree of image magnification. Treatment effects on head height were assessed via an unpaired t-test. Because no females dropped their eggs in either control or treatment groups, we could not assess female fecundity. At the completion of the assay, 13 amphipods from the brevetoxin and control groups were flash-frozen and preserved at −80°C. To confirm that our feeding assays succeeded in exposing these amphipods to brevetoxins, the concentration of brevetoxin in these amphipods then was determined via ELISA. Because the small size of amphipods precluded ELISA analysis of individuals, we grouped one to five amphipods per replicate vials (N=4 and N=3 for brevetoxin and control groups, respectively).

Because brevetoxins can persist in the water column for weeks after a *K. brevis* bloom terminates, we tested the possibility that *A. longimana* amphipod survivorship would be affected by solubilized purified brevetoxins at one and 10 ng / ml. These concentrations were taken from levels recorded during and after a 2002 *K. brevis* bloom in Tampa Bay (Flewelling et al. 2005). However, brevetoxin concentrations in the water column are notoriously variable. For example, during the middle of a 2006 *K. brevis* bloom in northwestern Florida, Naar et al. (2007) measured brevetoxin concentrations in the water column up to ~80 ng / ml. Tester et al. (2008) similarly recorded vertically and horizontally variable brevetoxin concentrations from non-detect to 72 ng/ml in transects through blooms in southwest Florida. Thus, our survivorship assay mimics bloom conditions, but does not assess amphipod response to maximal concentrations that are sometimes found during exceptional blooms. Individual amphipods were isolated within 50 ml seawater inoculated with methanol (at 0.05% concentration), for a final concentration of 0, 1, and 10 ng/ml solubilized purified brevetoxin. We used 2:1 ratio of purified PbTx-2 to PbTx-3, which approximates ratios measured in senescing blooms (Tester et al. 2008). The sample sizes at the inception of the experiment were 32, 26, and 22 for the 0, 1, and 10 ng / ml treatments, respectively. Mortality was assessed every one to four days for 10 days, and analyzed via a χ^2 test.

Results

In a series of no-choice feeding assays, *Ampithoe longimana* individuals from three locations (St. Petersburg and Fort Pierce, Florida and Morehead City, North Carolina) consumed statistically equivalent amounts of control foods or foods coated with *K. brevis* extracts at brevetoxin concentrations of 0.1 and 1 μg g^{-1} (Fig. 1). Given that the brevetoxins persisted on epiphytes scraped from seagrass blades at concentrations up to 3 μg g^{-1} (Flewelling et al. 2005), these results indicate that observed post-bloom concentrations of brevetoxin do not tend to alter feeding rates of this benthic herbivore. At concentrations several-fold greater than observed post-bloom concentrations (i.e., 8 and 10 μg g^{-1}), there was a tendency for Florida and North Carolina individuals to feed at lower rates on foods coated with *K. brevis* extracts relative to control foods. However, the inhibitory effect of the *K. brevis* extract on Florida populations was not consistent across populations. For example, the St. Petersburg population fed significantly less on foods coated with 10 μg g^{-1} during one assay (Fig. 1a), but showed no tendency for lower feeding rates when foods were coated at 8 μg g^{-1} during an assay performed several months later (Fig. 1b).

When offered a choice between control foods or extract-coated foods with brevetoxin concentrations of 1 μg g^{-1}, all three populations of *A. longimana* amphipods consumed significantly more control foods (Fig. 2). Surprisingly, however, when the assay was repeated two days later at a higher concentration (8 μg g^{-1}), Florida populations fed on control and extract-coated foods at statistically equivalent rates. A likely explanation for inconsistent feeding deterrency in no-choice (Fig. 1) and choice (Fig. 2) assays using *K. brevis* extracts is the presence of unstable deterrent compounds that elute with 100% methanol and that are unrelated to the brevetoxins. We, therefore, tested the effects of purified brevetoxins on *A. longimana* feeding behavior by offering two Florida populations feeding choices between foods coated with PbTx2 or PbTx3 at 1 μg g^{-1} and control foods. Amphipods did not discriminate between control and PbTx2-coated foods, and significantly preferred the PbTx3-coated to control foods (Fig. 3).

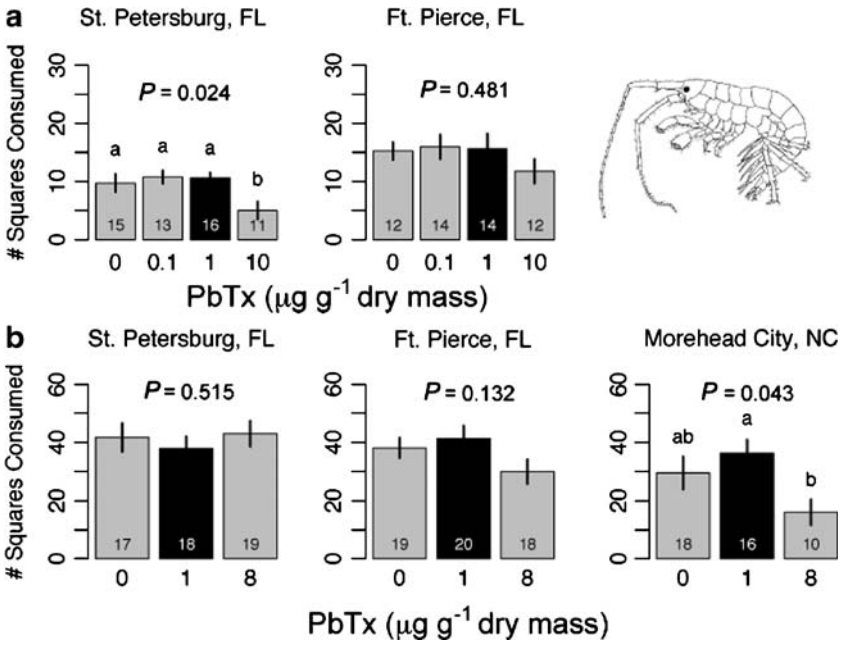

Fig. 1 No-choice feeding assays in which the lipophilic extract of *Karenia brevis* was offered to populations of the herbivorous amphipod *Ampithoe longimana*. Individual amphipods were isolated on freeze-dried *Ulva* (syn. *Enteromorpha*) *intestinalis* tissue coated with ether only ("0"), or with *K. brevis* extracts at a concentration of 1, 8, or 10 μg brevetoxin (g^{-1} dry mass). The *P*-values for Kruskal-Wallis non-parametric tests are indicated, and letters indicate treatments that are statistically indistinguishable by a pairwise Wilcoxan tests. **a**) and **b**) represent assays on independent *K. brevis* extracts and amphipod cultures. The dark bars (1 μg g^{-1}) represent observed concentrations of brevetoxins after bloom events in western Florida

In order to assess whether consuming *K. brevis* extracts has consequences for the survivorship and growth of *A. longimana*, we isolated individual juveniles with foods coated with extracts at 8 μg g^{-1} brevetoxin concentration or control foods. After 10 days, survivorship of Florida *A. longimana* did not differ between treatments (Fig. 4a: χ^2 test: $P>0.100$), nor did size [Mean growth in head height ± S.E. on control foods (0.113±0.021 mm) and extract-coated foods (0.135±0.023 mm); unpaired t-test $P=0.488$)].

To confirm that our feeding assays succeeded in exposing these amphipods to brevetoxins, we froze the juveniles at the end of the performance assay and measured brevetoxin loads within tissues. Juveniles fed brevetoxin-coated foods contained between 2–6 ng g^{-1} wetmass of brevetoxin ($N=4$; data not shown), while juveniles without foods had no detectable brevetoxins ($N=3$). Because individual amphipods averaged 2.8 mg wet mass, each amphipod contained approximately 0.01 ng brevetoxin. Our methods did not distinguish whether these brevetoxins were held in the gut, amphipod tissue, or both.

We also tested whether there was significant mortality when adult amphipods were exposed to seawater with observed concentrations of solubilized brevetoxin (1 or 10 ng ml^{-1}). After 10 days of exposure, control and brevetoxin-laden waters did not alter the survivorship of adult amphipods (Fig. 4b; χ^2 test: $P>0.100$).

To assess whether the lack of a feeding response to brevetoxin-coated foods is common to other generalist benthic

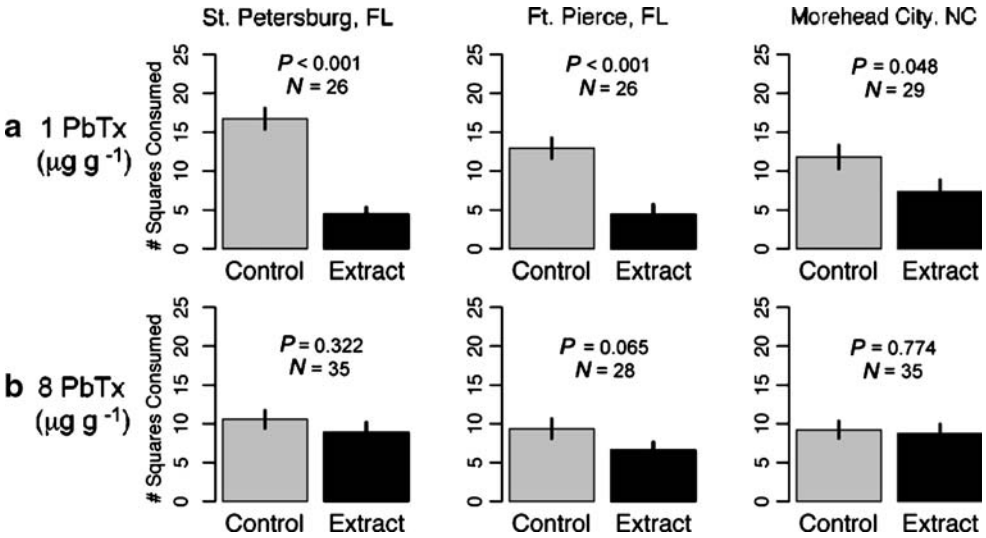

Fig. 2 Pairwise feeding choice by populations of the herbivorous amphipod *Ampithoe longimana*. Individuals were offered a feeding choice between freeze-dried *Ulva* (syn. *Enteromorpha*) *intestinalis* tissue coated with ether only (i.e., Control) or coated with *Karenia brevis* extracts at a concentration of **a**) one or **b**) eight μg brevetoxin (g^{-1} dry mass). Sample sizes and *P*-values from paired *t*-tests are indicated

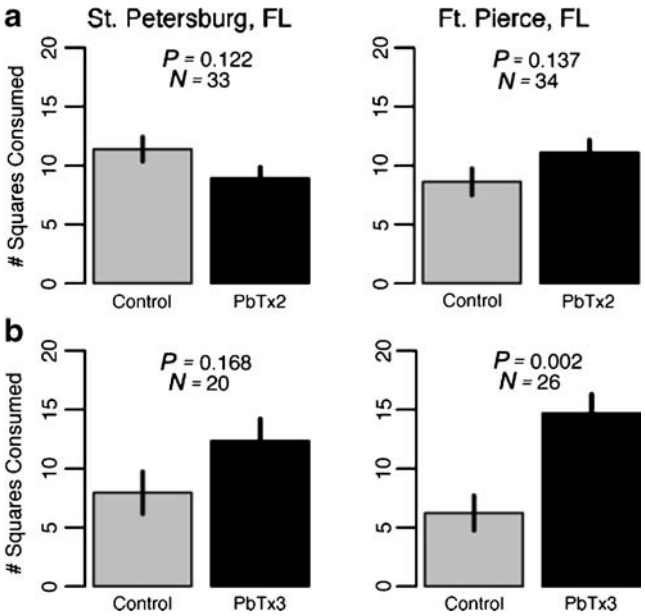

Fig. 3 Pairwise feeding choice by populations of the herbivorous amphipod *Ampithoe longimana*. Individuals were offered a feeding choice between freeze-dried *Ulva* (syn. *Enteromorpha*) *intestinalis* tissue coated with ether only (i.e., Control) or coated with **a**) PbTx2 or **b**) PbTx3 at a concentration of 1 μg brevetoxin (g^{-1} dry mass). Sample sizes and *P*-values from paired *t*-tests are indicated

herbivores, we offered a feeding choice between control and brevetoxin-coated foods at 1 μg g^{-1} to North Carolina populations of the sea urchin *Arbacia punctulata* and amphipod *Ampithoe valida.* Both herbivores readily consumed brevetoxin-coated foods at a rate equivalent to control foods (Fig. 5).

Discussion

As a first step toward understanding the potential importance of mesograzers in the vertical transmission of brevetoxins through benthic food webs of the Gulf of Mexico, we demonstrated that foods coated with observed 'post-bloom' concentrations of brevetoxins do not generally alter the feeding behaviors, survivorship, or growth of the benthic herbivorous amphipod *Ampithoe longimana* (Fig. 1–3, 4a). Moreover, adult amphipods revealed no decline in survivorship when exposed to solubilized brevetoxin at concentrations observed after blooms (Fig. 4b). We also found no detectable effects of *K. brevis* extracts on the feeding choices of two other benthic herbivores, the amphipods *A. valida* and purple sea urchin *Arbacia punctulata* (Fig. 5). Together, these results indicate that after *K. brevis* red tides, benthic herbivores readily feed on brevetoxin-coated foods, survive, and grow in brevetoxin-contaminated waters, and can, therefore, potentially transmit these brevetoxins to their predators.

Although the overall pattern is one of a lack of feeding deterrency, crude *K. brevis* extracts occasionally and inconsistently deterred amphipod feeding (see Results). Several lines of evidence suggest that this inconsistent feeding deterrence is mediated by unstable compounds eluted with 100% methanol extracts that are not brevetoxins. First, we found no change in total brevetoxin concentrations in the crude extracts over eight months of storage and handling (data not shown). Second, a direct test indicated that *A. longimana* was never deterred by purified brevetoxins at observed post-bloom concentrations (Fig. 3). In fact, the presence of PbTx-3 at 1 μg g^{-1} was a feeding attractant to a Fort Pierce population. Finally, we know that our methods were successful in offering brevetoxin-coated foods to the amphipods, because we detected brevetoxins within the tissues and/or guts of amphipods that were isolated on brevetoxin-laden foods for several weeks (see Results). The presence of unstable non-brevetoxin feeding deterrents similarly was inferred by Kubanek et al. (2007) when studying the feeding behaviors of rotifers.

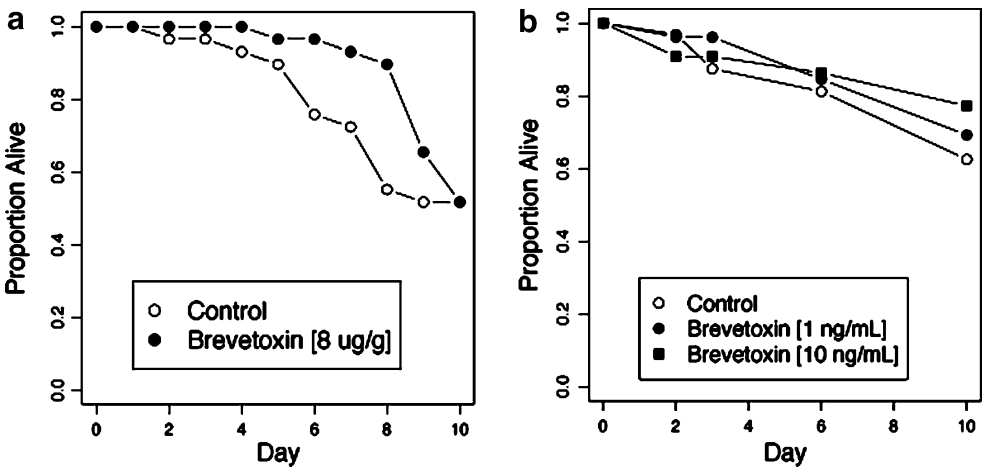

Fig. 4 Survivorship of Florida *Ampithoe longimana* when exposed to brevetoxins. **a**) Survivorship of juvenile amphipods when isolated on *Ulva* (syn. *Enteromorpha*) *intestinalis* tissue coated with ether only (i.e., Control) or *Karenia brevis* extracts at a concentration of eight μg brevetoxin (g^{-1} dry mass). **b**) Survivorship of amphipods when exposed to water with ethanol only (control), or observed (1 or 10 ng ml^{-1}) concentrations of purified brevetoxins

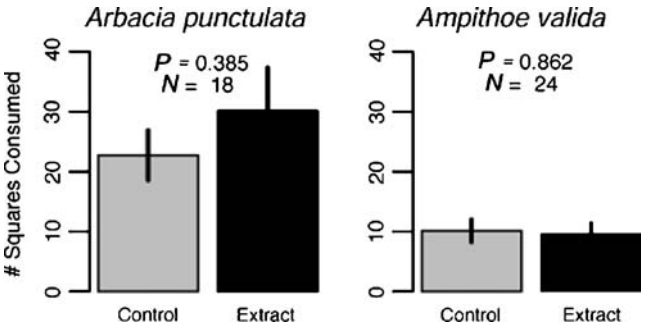

Fig. 5 Pairwise feeding choice by the temperate urchin *Arbacia punctulata* and the amphipod *Ampithoe valida*. Individuals were offered a feeding choice between freeze-dried *Ulva* (syn. *Enteromorpha*) *intestinalis* tissue coated with ether only (i.e., Control) or coated with *Karenia brevis* extracts at a concentration of one μg brevetoxin (g^{-1} dry mass). Sample sizes and *p*-values from paired t-tests are indicated

The lack of deterrent or deleterious effects of brevetoxins is surprising for several reasons. First, these results are inconsistent with observations of elevated mortality among benthic invertebrates when *K. brevis* blooms enter nearshore estuaries (e.g., Simon and Dauer 1972). However, it is difficult to assess whether our data and the mortality events truly are in conflict because brevetoxins loads were not measured during such events, and alternative or compounding explanations also could account for the catastrophic mortality event (e.g., hypoxia: Santos and Simon 1980). Second, the lack of a feeding deterrence seen in *A. longimana* appears to contrast strongly with the strongly deterrent effects of brevetoxins on other marine organisms. *Karenia brevis* cells and extracts appear to alter the behavior and fitness of pelagic rotifers (Kubanek et al. 2007) and copepods (Turner and Tester 1997; Landsberg et al. 2005; Prince et al. 2006; Breier and Buskey 2007; Cohen et al. 2007). In benthic habitats, *K. brevis* cells alter the feeding behavior, abundance and/or fitness of bivalves (Summerson and Peterson 1990; Keppler et al. 2006; Leverone et al. 2006; Haubois et al. 2007; Leverone et al. 2007). The causes of differences in feeding response toward *K. brevis* between groups of herbivores remain unclear, but we find it interesting that the previously studied herbivores consume live *K. brevis* cells, while the benthic herbivores studied here consume brevetoxin-laden epiphytes and seagrasses. Live *K. brevis* may occur occasionally on benthic plants, but unlike *Gambierdiscus* on tropical macroalgae (Cruz-Rivera and Villareal 2006), *K. brevis* does not sustain benthic populations.

We were also surprised that we could not detect significant differences in feeding behavior among amphipod populations that are annually exposed to *K. brevis* blooms (i.e., Tampa Bay; (Brand and Compton 2007) versus populations that rarely experience such blooms [i.e., Fort Pierce, Florida and Morehead City, NC; (Summerson and Peterson 1990)]. We had expected such microevolution to occur, because this amphipod has evolved population-level differences in feeding behaviors and fitness when isolated with lipophilic secondary metabolites produced by the brown seaweed *Dictyota* (Sotka and Hay 2002; Sotka et al. 2003; Sotka and Whalen 2008), and because some populations of a benthic clam (*Mya arenaria*; Bricelj et al. 2005) and pelagic copepod (*Acartia hudsonica*; Colin and Dam 2002) have evolved tolerance toward harmful algal blooms in the genus *Alexandrium*. It remains possible that population-level variation in *A. longimana* fitness traits is present (e.g., female fecundity) but this was not tested here.

A review by Landsberg (2002) concluded that the overall effects of harmful algal blooms (or HABs) "on food webs and ecosystems are probably the least understood of all impacts," and that "the pathways of algal-toxin transmission (are) complex and incompletely known" (pg. 188; see also Hay and Kubanek 2002; Cruz-Rivera and Villareal 2006). We propose that mesograzers and other benthic herbivores may represent an underexplored set of pathways by which brevetoxins produced by Gulf of Mexico *K. brevis* red tide blooms are transmitted vertically through estuarine food webs. Central to our hypothesis is the fact that mesograzers are a vitally important component of the diet for a variety of nearshore fishes (Motta et al. 1993; Luczkovich et al. 2002; Marancik and Hare 2007), including the extremely abundant pinfish *Lagodon rhomboides* (Stoner 1979). Moreover, the importance of mesograzers as a diet is greater for juvenile than adult life stages, suggesting that younger fish will be particularly vulnerable to brevetoxin transmission via mesograzer consumption. In support of our hypothesis, Naar et al. (2007) and Fire et al. (2008) document substantial loads of brevetoxins within *L. rhomboides* and other fishes in western Florida estuaries when collected weeks after a *K. brevis* blooms had relaxed.

We recognize that acceptance of benthic mesograzers as an additional mode of brevetoxin transmission requires answers to several outstanding questions. We do not know whether natural populations of mesograzers are laden with brevetoxins. We also do not know the rates at which bioaccumulation (if present) and depuration occurs in mesograzers. The brevetoxin load we report is much lower than that detected for pelagic copepods under laboratory conditions (~25 ng brevetoxin per copepod; Tester et al. 2000), although it is not clear whether these experiments (including the present study) utilized ecologically-realistic feeding rates. Moreover, we have not demonstrated that consumption of brevetoxin-laden mesograzers by fishes actually yields accumulation in fishes (e.g., Tester et al. 2000; Naar et al. 2007). Nevertheless, the present study does indicate that mesograzers deserve attention in our efforts to predict bioaccumulation rates and ecological impacts of brevetoxins within nearshore systems.

RETRACTION NOTE

Intraspecific and Interspecific Interactions Mediated by a Phytotoxin, (-)-Catechin, Secreted by the Roots of *Centaurea maculosa* (Spotted Knapweed)

Tiffany L. Weir · Harsh Pal Bais · Jorge M. Vivanco

Published online: 16 July 2009

Erratum to: J Chem Ecol (2003) 29:2397–2412
DOI 10.1023/A:1026313031091

This article has been retracted by Tiffany L. Weir and Jorge M. Vivanco.

Reason: After a reevaluation of this work, we no longer have confidence in several key observations and therefore, retract this paper. Specifically, the reported finding in Perry et al. (J of Chemical Ecology 33:2337–2344, 2007) of catechin in experimental blanks, suggest an exogenous source of catechin in our laboratory. The absence of experimental blanks in the current study along with the unreproducibly high levels of catechin reported from *in vitro* grown *C. maculosa* plants have led us to believe that the reported catechin may have originated from non-plant sources. In addition, a finding that some of our commercially purchased catechin was contaminated with 2,4-D along with our observation that catechin caused callus formation in some seedlings suggests that at least some of these experiments may have been conducted using a contaminated source. Because we cannot be sure that contaminated catechin was not used, the results of the phytotoxicity and germination inhibition experiments are meaningless.

Abstract *Phyllium westwoodii* is a phasmid insect (Order Phasmatodea) belonging to the Family Phylliidae (leaf insects). These rather large and ornate creatures are known for their morphological resemblance to plant leaves for camouflage. Pyrazines are a common class of compounds used or produced by a wide variety of organisms, even humans. When an individual of *P. westwoodii* is disturbed, it sprays an opaque liquid from a pair of prothoracic glands, which are utilized by other phasmid species for defense. The current study has found that this liquid contains glucose and a mixture of 3-isobutyl-2,5-dimethylpyrazine, 2,5-dimethyl-3-(2-methylbutyl)pyrazine, and 2,5-dimethyl-3-(3-methylbutyl)pyrazine. This is the first report of pyrazines found in the defensive gland spray of phasmid insects, and the first chemical analysis of glandular material from family Phylliidae.

Keywords Insect · *Phyllium westwoodii* · Phasmatodea · Phasmid · Phylliidae · Chemical defense · Dimethyl alkylpyrazine · 3-isobutyl-2,5-dimethylpyrazine · 2,5-dimethyl-3-(2-methylbutyl)pyrazine · 2,5-dimethyl-3-(3-methylbutyl)pyrazine · Glucose

Introduction

Chemical defense in walkingstick insects (also called stick insects, or "phasmids"; Order Phasmatodea) has been studied for decades. However, the chemical composition of defensive sprays from only a few species has been analyzed (Schneider 1934; Meinwald et al. 1962; Smith et al. 1979; Chow and Lin 1986; Ho and Chow 1993; Bouchard et al. 1997; Eisner et al. 1997; Dossey et al. 2006, 2007; Schmeda-Hirschmann 2006). The first analysis of a phasmid defensive spray was published in 1934 on *Agathemera crassa* (Schneider 1934) (referred to by Schneider as *Paradoxomorpha crassa*). Possibly, due to analytical limitations of that time, the chemical structure was likely incorrect, as the defense compound of another species in that genus (*Agathemera elegans*) was more recently determined to be 4-methyl-1-hepten-3-one (Schmeda-Hirschmann 2006). Subsequent to the work by Schneider in 1934, the next species studied was *Anisomorpha buprestoides* in classic works by Eisner, Meinwald, and co-workers (Meinwald et al. 1962; Eisner 1965). *Anisomorpha buprestoides* produces at least three stereoisomers of a monoterpene first identified by Meinwald et al. (Meinwald et al. 1962; Dossey et al. 2006; Dossey et al.

2008) and named anisomorphal. Since then, other phasmids have been shown to produce monoterpenes such as: iridodial (*Graeffea crouani*) (Smith et al. 1979), nepetalactone (*G. crouani*) (Smith et al. 1979), actinidine [*Megacrania alpheus* (Chow and Lin 1986) and *Megacrania* tsudai (Ho and Chow 1993)], limonene (*Sipyloidea sipylus*) (Bouchard et al. 1997), parectadial (a novel monoterpene first identified from the phasmid *Parectatosoma mocquerysi*) (Dossey et al. 2007), dolichodial (isomer of anisomorphal found in young *A. buprestoides*) (Dossey et al. 2008), peruphasmal (isomer of anisomorphal from *Peruphasma schultei*) (Dossey et al. 2006, 2008), and others as minor components (Ho and Chow 1993; Bouchard et al. 1997). In addition to monoterpenes, 4-methyl-1-hepten-3-one (as mentioned above) (Schmeda-Hirschmann 2006) and quinoline (from *Oreophoetes peruana*) (Eisner et al. 1997) also have been found in phasmid insect defense gland sprays.

Besides these secondary metabolites, glucose has been reported in the defensive spray of *A. buprestoides* (Dossey et al. 2006; Zhang et al. 2007), *P. schultei* (Dossey et al. 2006), and *P. mocquerysi* (Dossey et al. 2007). The presence of glucose may be of significance in the biosynthesis and/or transport of defensive substances into the glandular reservoir of these insects (see "Discussion") (Dossey et al. 2006, 2007). It also has been shown that *A. buprestoides* has the ability to biosynthesize its defensive monoterpenes from acetate and mevalonate (Meinwald et al. 1966) and *de-novo* from glucose (Dossey et al. 2008). To date, despite the range of small molecules already found in phasmids, no pyrazines have been isolated from insects in the order Phasmatodea.

Leaf insects (Order Phasmatodea, Family Phylliidae) make up a small group of anciently diverged phasmids that comprises 46 known species, all characterized by remarkable cryptic morphological and behavioral adaptations. They have dorso-ventrally flattened bodies and foliaceus lobes on legs that resemble leaves. Females are always much longer and proportionally broader than males, and their antennae also are particularly dimorphic. Adult males have long and densely setose antennae, while adult females possess very short antennae that bear on the third segment a stridulatory apparatus used for the production of defensive sounds (Henry 1922; Bedford 1978; Zompro and Grösser 2003, and references therein). Members of this family now occur in tropical Asia and Australia, with presumably introduced populations in eastern Africa, Madagascar, and adjacent islands, but they once lived as far away as Europe (Wedmann et al. 2007).

Phyllium (Phyllium) westwoodii (Wood-Mason 1875) (Fig. 1A) is a leaf insect that occurs in the Andaman Islands, China, Laos, Myanmar, Thailand, and Vietnam. When threatened, females of *P. westwoodii* enter into an immobile behavioral state known as catalepsy. If the threatening stimulus persists, they begin to stridulate with the antennae, and release an opaque-milky spray from a pair of glands at the anterior of their prothorax (Fig. 1B). This secretion is sprayed at moderate distance over the dorsal surface of the head and thorax. Many other phasmid species produce chemical sprays from homologous glands in response to being disturbed (Schneider 1934; Meinwald et al. 1962; Eisner 1965; Bedford 1978; Smith et al. 1979; Chow and Lin 1986; Ho and Chow 1993; Bouchard et al. 1997; Eisner et al. 1997; Thomas 2001; Dossey et al. 2006, 2007; Schmeda-Hirschmann 2006), and in certain cases these sprays function to repel potential predators (Eisner 1965; Carlberg 1985a b, 1986, 1987; Chow and Lin 1986; Bouchard et al. 1997; Eisner et al. 1997). The odor of *P. westwoodii* defensive spray has a striking similarity to that of chocolate.

Pyrazines are produced by a wide range of organisms (Wheeler and Blum 1973; Brown and Moore 1979; Cross et al. 1979; Blum 1981; Moore et al. 1990; Dickschat et al. 2005a, b). For insects, they often function as pheromones. Alkyldimethyl-pyrazines are used as pheromones by a number of insect species in the Order Hymenoptera (ants, bees, and wasps). Specifically, as trail [leaf cutter ant, *Atta sexdens rubropilosa* (Cross et al. 1979)] and alarm (Wheeler and Blum 1973; Brown and Moore 1979) pheromones by some ant species, and they are found commonly in ant glandular secretions (Blum 1981). Other pyrazines, such as methoxyalkylpyrazines, also protect some insects from predation by functioning as anti-feedants in combination with bright coloration in aposematic species (Moore et al. 1990). These have been found in crude extracts of insects other than phasmids such as grasshoppers [genus *Poekilocerus*, (Moore et al. 1990)] belonging to the Order Orthoptera, a distinct taxon from Order Phasmatodea (Terry and Whiting 2005).

Pyrazines have different uses for humans. They are often associated with characteristic aromas and flavors of some of our favorite foods (Maga and Sizer 1973; Adams et al. 2002). The Flavor and Extract Manufacturer's Association (FEMA) reports that 2,135 kg of pyrazine flavor additives are used in the United States annually (Adams et al. 2002). Alkyldimethylpyrazines function as odorants in foods such as chocolate (Welty et al. 2001) and are produced in the Maillard reaction during the roasting of cocoa beans (Arnoldi et al. 1988). Pyrazines also contribute to the flavor and aroma of roasted peanuts, beef, and other cooked foods (Maga and Sizer 1973).

This study reports the identification of three alkyldimethylpyrazines (Fig. 2), along with glucose, in less than 1 μl of the defensive spray from a single female *P. westwoodii*. Specifically, 3-isobutyl-2,5-dimethylpyrazine (**1**), 2,5-dimethyl-3-(2-methylbutyl)pyrazine (**2**), and 2,5-dimethyl-3-(3-methylbutyl)pyrazine (**3**) (Fig. 3) were

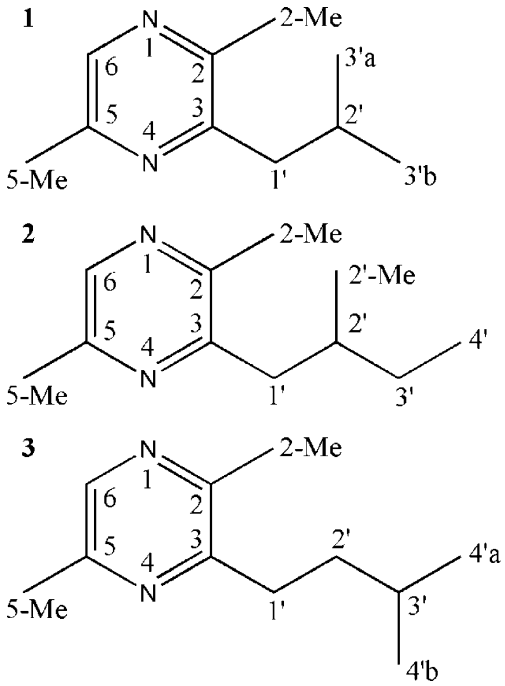

Fig. 2 Three alkyl dimethylpyrazines identified in the defensive spray of *Phyllium westwoodii*. 3-isobutyl-2,5-dimethylpyrazine (**1**), 2,5-dimethyl-3-(2-methylbutyl)pyrazine (**2**), and 2,5-dimethyl-3-(3-methylbutyl)pyrazine (**3**). Each structure is shown with corresponding carbon atom labeling

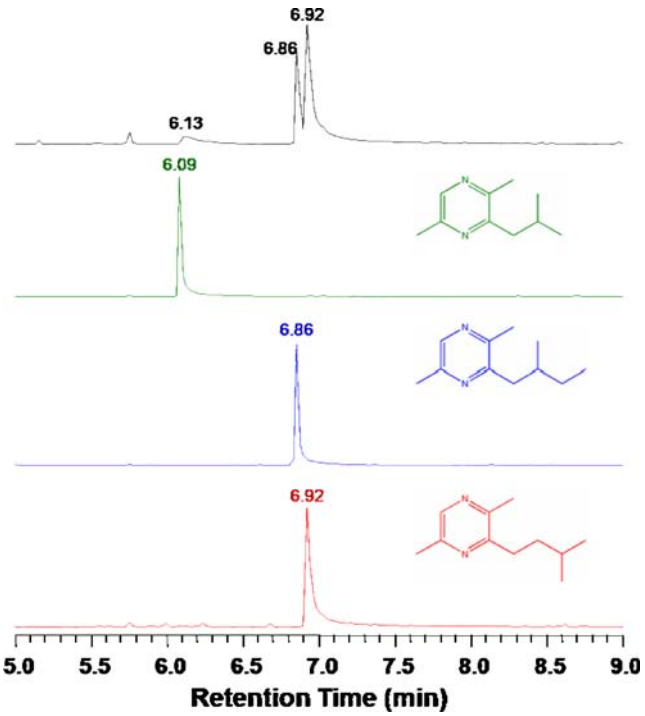

Fig. 3 GC-CI-MS total ion current chromatograms of natural *Phyllium westwoodii* defensive spray (black) compared with authentic synthetic standards: 3-isobutyl-2,5-dimethylpyrazine (top), synthetic (*S*)-2,5-dimethyl-3-(2-methylbutyl)pyrazine (middle), and synthetic 2,5-dimethyl-3-(3-methylbutyl)pyrazine (bottom). Each trace represents the injection into the GC apparatus of 4 μl of a sample made by extracting 2 μl of a D_2O NMR sample with 50 μl of methylene chloride (CH_2Cl_2). The NMR samples of synthetic reference compounds were 1 μl of pure neat material dissolved in 1 ml of D_2O

identified in the mixture using synthesis and gas chromatography (Fig. 3), mass spectrometry (Fig. 4), and NMR (Figs. 5, 6 and 7). This work demonstrates the increasingly apparent diversity of compounds produced by phasmid insects and the uniqueness of Phylliidae among the Phasmatodea.

Methods and Materials

Animal Material and Sample Collection A laboratory culture of *P. westwoodii* originated from Chiang Rai Province in northern Thailand, where the species thrives in tropical rain forest ecosystems. Rearing was conducted in a ventilated cage at a mean temperature of 23.5 °C, moderate humidity conditions, and a photoperiod of 12 h. Leaf insects were fed on *Quercus robur* and *Rubus ulmifolius*. To obtain the original sample of defensive spray (less than 1 µl), one adult female *P. westwoodii* was milked two times by placing a clean 1.5 ml glass vial over the glandular openings, and slightly agitating the insects. A second sample (approximately 2–4 µl), that consisted of seven milkings was obtained the same way from two adult females.

The smaller of the two samples mentioned above (less than 1 µl from a single female *P. westwoodii*) was dissolved in approximately 15 µl of D_2O and used for NMR analysis. Approximately 2 µl were removed from this sample after collection of NMR data, and extracted with CH_2Cl_2 for GC-MS analysis. Since it was unknown whether the compounds in the mixture contained exchangeable protons, an additional 2 µl sample was mixed with ~100 µl of H_2O and extracted with CH_2Cl_2 for GC-MS analysis.

Analytical Procedures NMR experiments were performed with a 600 MHz 1-mm triple resonance high temperature superconducting (HTS) cryogenic probe that was developed through collaboration between the University of Florida, the National High Magnetic Field Laboratory (NHMFL), and Bruker Biospin (Brey et al. 2006). Each sample was loaded into a 1-mm×100-mm capillary NMR tube (Norell, Inc.) with a 10 µl syringe with a removable 110-mm×30-gauge blunt needle. During NMR experiments, the capillary tube was held in a standard 10-mm spinner by using a Bruker MATCH™ device, and the capillary-MATCH-spinner combination was lowered vertically into the magnet on an air-column. The sample temperature was maintained at 20 °C. The spectrometer used for all NMR experiments was a Bruker Avance II 600. Additional NMR data acquisition parameters can be found in the Supplemental Material with their respective spectra. All data acquisition, processing, and analysis were done with Bruker TopSpin© 2.0 software. Chemical shift assignments were made by referencing the natural *P. westwoodii* ^{1}H and ^{13}C chemical shifts of the anomeric ^{1}H to 5.22 and ^{13}C to 94.8 ppm of alpha glucose based on the reported values for these resonances in the BMRB Metabolomic database (http://www.bmrb.wisc.edu/metabolomics/) (Ulrich et al. 2008). In order to verify the components in *P. westwoodii* defensive spray that were tentatively identified by

GC-EIMS and to assign ^{1}H and ^{13}C chemical shifts to those compounds (Tables 1, 2 and 3), one- and two-dimensional (1D and 2D, respectively) datasets were recorded (Figs. 5, 6 and 7, and Supplemental Material Figs. S2–S5). Specifically, COSY, TOCSY, NOESY, and natural abundance ^{13}C HMQC and HMBC datasets were collected.

GC-MS analyses were performed with a Thermo Scientific Trace DSQ mass spectrometer, equipped with a Restek Rxi™-5 ms column (15 m×0.25 mm ID×0.25 um df) and with helium as carrier gas (flow rate=1 ml/min). Four µl of each sample were injected in splitless mode, for 2 min, followed by a split flow rate of 50 ml/min. The GC oven temperature was maintained at 40 °C for 3 min, and then increased at a rate of 20 °C/min to 260 °C. The injector and transfer line were set at 250 °C, while the ion source was at 180 °C. Compounds that eluted from the column underwent electron ionization (EI) at 70 eV, and ions from *m/z* 50 to 700 were detected. The electron-ionization mass spectra (EI-MS) of these peaks were used to query the NIST/EPA/NIH Mass Spectral Library of known compounds using the NIST MS Search (ver. 2) software (Stein et al. 1987–2002).

Synthesis of Pyrazines: General Procedure The Grignard reagent was prepared by slow addition of the appropriate alkyl bromide (1.0 equiv.) to a stirred mixture of magnesium turnings (1.2 equiv.) in dry ether (1.0 M) at room temperature. The resulting mixture was stirred for 2 h at room temperature, and then titrated with 2-hydroxybenzaldehyde phenylhydrazone (Love and Jones 1999). Commercial 3-chloro-2,5-dimethylpyrazine (1.0 equiv.) was added to a solution of Fe$(acac)_3$ (0.05 equiv.) in THF-NMP (9:1, 0.25 M), and the mixture was cooled to 0 °C in an ice-water bath. Grignard reagent (1.5 equiv) in ether was added dropwise to this solution. The resulting mixture was stirred for an additional 30 min, and then quenched by the addition of water. The aqueous layer was extracted with diethyl ether. The combined organic extracts were dried over $MgSO_4$, clarified with charcoal, filtered, and the solvent was removed under

reduced pressure. The crude product mixtures were purified by silica gel column chromatography, using a solution of 5% ethyl acetate in hexane.

3-Isobutyl-2,5-dimethylpyrazine (1) Yield: 42% (3.463 g, 21.08 mmol). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.94 (d, *J*= 6.8 Hz, 6 H), 2.12 (non, *J* = 6.8 Hz, 1 H), 2.48 (s, 3 H), 2.51 (s, 3 H), 2.65 (d, *J*=7.2 Hz, 2 H), 8.14 (s, 1 H); ^{13}C NMR (100 MHz, $CDCl_3$): δ 21.3, 21.7, 22.6, 28.8, 43.7, 140.7, 149.0, 150.1, 154.4; IR (film): *v* 2957, 2869, 1450, 1370, 1288, 1168, 1074 cm−1; EI-MS 165.1386, HRMS-ESI (*m/z*): [M+] calcd for $C_{10}H_{16}N_2$ 165.1386, found 165.1390. Spectroscopic values for synthetic **1** were in agreement with reported literature values (Dickschat et al. 2005a).

(S)-2,5-Dimethyl-3-(2-methylbutyl)pyrazine (2) Yield. 46% (546 mg, 3.06 mmol). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.87 (d, *J*=6.8 Hz, 3 H), 0.92 (t, *J*=7.6 Hz, 3 H), 1.26 (m, 1 H), 1.42 (m, 1 H), 1.90 (m, 1 H), 2.49 (s, 3 H), 2.51 (s, 3 H), 2.56 (dd, *J*=8.4, 13.2 Hz, 1 H) 2.78 (dd, *J*=6.0, 13.2 Hz, 1 H), 8.13 (s, 1 H); ^{13}C NMR (100 MHz, $CDCl_3$): δ 11.6, 19.0, 21.3, 21.6, 29.7, 34.9, 42.0, 140.7, 149.0, 150.1, 154.5; HRMS-ESI (*m/z*): [M+] calcd for $C_{11}H_{18}N_2$ 179.1543, found 179.1545, specific optical rotation: $[\alpha]_D^{25}$ = +8.8 (*c*=2.535, CH_2Cl_2). Spectroscopic values for synthetic **2** were in agreement with reported literature values (Dickschat et al. 2005a).

2,5-Dimethyl-3-(3-methylbutyl)pyrazine (3) Yield: 55% (2.458 g, 13.79 mmol). ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.97 (d, *J*=6.8 Hz, 6 H), 1.53 (m, 2 H), 1.67 (sept, *J* = 6.8 Hz, 1 H), 2.47 (s, 1 H), 2.51 (s, 1 H), 2.75 (m, 2 H), 8.13 (s, 1 H); ^{13}C NMR (100 MHz, $CDCl_3$): δ 21.2, 22.6, 28.5, 33.4, 37.8, 140.8, 148.5, 150.2, 155.3; IR (film): *v* 2956, 2927, 2870, 1536, 1452, 1320, 1278, 1254, 1169, 1080, 1034, 999, 942, 738; HRMS-ESI (*m/z*): $[M+H]^+$ calcd for $C_{11}H_{18}N_2$ 179.1543, found 179.1546. Spectroscopic values of synthetic **3** were in agreement with reported literature values (Dickschat et al. 2005b).

Results

In the GC-MS chromatogram of *Phyllium westwoodii* defensive spray, three main peaks were detected (Fig. 3). Two samples extracted from D_2O and H_2O preparations both showed nearly identical mass spectra, suggesting that they contained no exchangeable protons (Fig. 4 and data not shown).

Mass spectra from all three peaks matched those of known alkyldimethylpyrazines with high scoring database

hits (Fig. 4 and Supplemental Material Fig. S1) (Stein et al. 1987–2002). Additionally, the mass spectra match those of synthetic standards (Fig. 4). However, some isomers of the highest scoring compounds also were close matches (Supplemental Material Fig. S1). Additionally, similar mass spectra might be obtained from molecules with different relative placement of the alkyl chains and methyl groups on the pyrazine ring. Previous studies have shown phasmid defensive sprays to contain glucose (Dossey et al. 2006, 2007; Zhang et al. 2007), which is not directly amenable to study by GC-MS. Thus, NMR experiments were performed on both the natural defensive spray of *P. westwoodii* and synthetic reference standards in order to alleviate ambiguity in the identification of chemical components and to identify non-volatiles.

First, as with other phasmids, *P. westwoodii* defensive spray contained a significant amount of glucose: approximately 27% for one sample and 42% for an independent replicate sample of the total material observed by integration of the 1D ^{1}H NMR spectrum: anomeric resonances of glucose compared to the vinyl and ring methyl resonances for pyrazines (Fig. 5 and data not shown). Additionally, three sets of spin systems consistent with the aliphatic constituents of the alkyl pyrazines identified by GC-MS were the major peaks observed in 2D TOCSY NMR spectra (Fig. 7). However, considerable overlap was observed between some key resonances common to the three compounds (Fig. 6). Thus, all three substances were synthesized and examined in pure form in D_2O by NMR to verify their identity in the spectra of the natural product sample. 2,5-Dimethyl-3-alkylpyrazines **1**, **2**, and **3** were synthesized *via* iron-catalyzed cross-coupling (Furstner et al. 2002) of 3-chloro-2,5-dimethylpyrazine with the appropriate Grignard reagent, as described by Dickschat et al. (Fig. 8) (Dickschat et al. 2005a, b). Enantiopure (*S*)-(+)-1-bromo-2-methylbutane was used for formation of the Grignard reagent in the synthesis of **2** under the presumption that the pyrazine derives biosynthetically from *L*-isoleucine.

One-dimensional (1D) NMR spectra of the natural defensive mixture from *P. westwoodii* and the three synthetic pyrazines in D_2O are compared in Fig. 6. The

alkyl and aromatic methyl region of the spectrum from 0.6–3.1 ppm (Fig. 6B) shows reasonably well-resolved resonances for the alkyl sidechains. A comparison of the spectrum of the mixture to those of the synthetic pyrazines in Fig. 6 indicates that the aromatic methyl resonances for all three compounds have nearly identical chemical shifts in the 2.4–2.5 ppm region. Additionally, the aromatic ^{1}H region at about 8.15 ppm shows at least three resonances, two of which almost completely overlapped. Thus, analysis of 2D spectra for the natural mixture and of the individual synthetic compounds was employed to resolve the ambiguity caused by the overlapping regions and obtain complete ^{1}H and ^{13}C chemical shift assignments for all three pyrazines.

Figure 7 shows the aromatic methyl and alkyl sidechain resonances of TOCSY spectra of the natural mixture (black) and the three synthetic pyrazines in color overlays (**1** green, **2** blue, and **3** red). Overlaying of two-dimensional NMR spectra can be a powerful and robust way to identify individual known substances in natural product mixtures. In the TOCSY spectrum of the mixture, three distinct alkyl spin systems were observed. For compound **1**, TOCSY correlations were observed between resonances at 2.68 ppm and the following: 2.00, and 0.90 ppm. COSY correlations were observed between resonances at 2.68 ppm and 2.00 ppm and between 2.00 ppm and 0.90, but not between 2.68 ppm and 0.90 ppm. For compound **2**, TOCSY correlations were observed between the resonance at 2.82 ppm and the following resonances: 2.58, 1.78, 1.36, 1.25, 0.88, and 0.83 ppm. Strong COSY correlations were observed between 2.82 and 2.58 ppm; 1.36 and 1.25 ppm; 1.36 ppm and 0.88 ppm; and 1.25 ppm and 0.88 ppm. Weaker COSY correlations are seen between the following resonances: 2.82 and 1.78; 2.58 and 1.78; 1.78 and 0.83 ppm. Oddly, no COSY ^{1}H-^{1}H correlations were observed in spectra from either natural or synthetic compound **2** between the methine 2′ resonance (1.78 ppm) and methylenes at 1.36 or 1.25 pm (Supplemental Material Fig. S3). However, distinct TOCSY correlations were observed between these pairs of resonances as expected (Fig. 7 and Supplemental Material Fig. S2). For compound **3**, TOCSY correlations were observed between 2.78 ppm and the following resonances: 1.47, 1.63, and 0.93 ppm. A strong COSY correlation was observed between the methylenes at 2.78 and 1.47 ppm and between the methyl and methylene resonances (1.47 and 0.93, respectively). However, only very weak COSY correlations were observed between the methylene resonance at 1.47 ppm and methyne at 1.63 ppm.

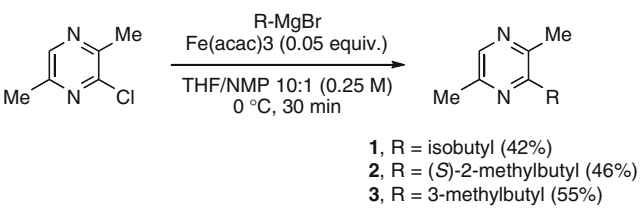

Fig. 8 Synthetic scheme for alkyldimethylpyrazines **1**–**3**

An overlapped set of spin systems with correlations between resonances at about 2.4–2.5 ppm and 8.15 ppm also were observed in TOCSY spectra. There were no clear ^{1}H-^{1}H correlations between those spin systems and the three alkyl ones (Fig. 7). However, the HMBC of the three pure synthetic pyrazines analyzed showed correlations between the 1′ ^{1}H and the 2 and 3 ^{13}C resonances (Supplemental Material Fig. S6). Additionally, the HMBC of the mixture showed a weak correlation between 2.78 and 158.5 ppm, demonstrating connectivity between the alkyl and other spin systems (Supplemental Material Fig. S5). Finally, in the HSQC experiment which was used, the signs (+/−) of the correlations were both sensitive to and consistent with the proposed methine, methylene, and methyl groups (Supplemental Material Fig. S4).

In addition to chemical analysis, a video was recorded which illustrates some features of the defensive behavior of *P. westwoodii* (Supplemental Material Fig. S7). This behavior is well established in the literature for other species in the same genus (Henry 1922; Bedford 1978; Zompro and Grösser 2003, and references therein). First, the insect was removed from the cage and placed on a stick for observation. This action sufficiently disturbed the insect causing it to freeze in a pose as if to play dead or possibly to resemble a leaf. The legs were positioned in a seemingly disordered conformation and were not all used to hold onto the stick. Next, when the offending stimulus was continued more aggressively, the insect compressed, became more active, attempted to escape, and produced stridulatory sounds by using its antennae. It is at this point that the insect released its defensive spray. Although the amount of secretion produced by *P. westwoodii* is small, to the human observer, its intense odor can be strongly perceived even at a distance of at least 30 cm. This odor was noticed only when *P. westwoodii* defended against attack or disturbance.

Discussion

These data demonstrate that the defensive spray of *Phyllium westwoodii* contains 3-isobutyl-2,5-dimethylpyrazine (**1**), 2,5-dimethyl-3-(2-methylbutyl)pyrazine (**2**), and 2,5-dimethyl-3-(3-methylbutyl)pyrazine (**3**), and α- and β-glucose. The release of this spray from *P. westwoodii* happens concurrently with a characteristic defense behavior (Supplemental Material Fig. S7 and described in the "Introduction") when approached by a human, which likely resembles an attack of natural predators of this species such as slow lorises and other primates (Francis Seow-Choen,

personal communication). Additionally, chemical sprays from homologous glands in other phasmid species have been shown experimentally to be effective in repelling potential predators such as ants, frogs, and birds (Eisner 1965; Carlberg 1985a, b, 1986, 1987; Chow and Lin 1986; Bouchard et al. 1997; Eisner et al. 1997). Thus, the prothoracic glandular spray from *P. westwoodii* is likely to be used predominantly for defense. However, it has not been shown if **1**, **2**, or **3** function as repellants of predators in the natural habitat of *P. westwoodii*.

Interestingly, these compounds are found widely in the aromas and flavors of foods that humans find pleasing (Maga and Sizer 1973). Some insects use these and other similar pyrazines as pheromones (Cavill and Houghton 1974; Cross et al. 1979; Blum 1981; Tengo et al. 1982). Also, the amount produced by *P. westwoodii* in response to being disturbed is small. Many phasmids produce only very small quantities of prothoracic glandular spray (Tilgner 2002), and the chemistry of their spray can vary over development (Dossey et al. 2008). Thus, it has been postulated that some species may use these substances for functions other than defense (Tilgner 2002; Dossey et al. 2008). It cannot be excluded that *P. westwoodii*, as well as other Phylliidae, use them for intraspecific communication. However, such a hypothesis is beyond the scope of this study and, as far as we are aware, has not yet been tested.

Other phasmid species produce monoterpenes (Meinwald et al. 1962; Smith et al. 1979; Chow and Lin 1986; Ho and Chow 1993; Bouchard et al. 1997; Dossey et al. 2006, 2007), a straight chain ketone (Schmeda-Hirschmann 2006), quinoline (Eisner et al. 1997), and other small secondary metabolites in their prothoracic defensive glands. However, this is the first report of pyrazines from these glands in any phasmid. In addition to *P. westwoodii* in this study, glucose also has been found in defensive sprays from other phasmids (Dossey et al. 2006, 2007; Zhang et al. 2007). Some Coleoptera of the family Chrysomelidae (leaf beetles) use precursors that are conjugated with glucose for monoterpene biosynthesis and transport into the defense glands (Feld et al. 2001; Laurent et al. 2003; Burse et al. 2007;Kunert et al. 2008). The common occurrence of glucose in insect defensive secretions, especially phasmids such as *P. westwoodii*, suggests that it may be similarly utilized in defensive secondary metabolite processing and/or transport. If so, this may represent a previously unreported mechanism for pyrazine production. This hypothesis requires further investigation.

The peculiar morphological features that characterize fossil and extant leaf insects (Zompro 2004; Wedmann et al. 2007) as well as the findings presented here, support the view that Phylliidae occupy a unique position among Phasmatodea. This study demonstrates yet another distinguishing feature of this unique group of phasmids. Many other phasmids produce monoterpenes or other secondary metabolites in their defensive spray, but the apparently homologous glands in *P. westwoodii* produce pyrazines, a class of compounds not previously reported from Phasmatodea. Pyrazines found in the chemical defense glands of *P. westwoodii* might even be considered an evolutionarily derived (apomorphic) feature of Phylliidae that further supports the monophyly of the taxon. The presence of glucose in walkingstick defensive sprays, along with the large size and ease of culture for these creatures, suggests their potential value as a model for the study of their biosynthetic pathways. Additionally, discovery of the functional role of pyrazines in *P. westwoodii* may shed new light on the role of secreted small molecules used by insects.

Acknowledgement We thank James R. Rocca at the Advanced Magnetic Resonance Imaging and Spectroscopy, University of Florida, for helpful technical assistance on NMR experiments. The GC-MS analysis reported in this study was developed and conducted by Dr. Maria Cristina Dancel of the Mass Spectrometry Facility, Department of Chemistry, University of Florida, who also helped with data interpretation. Funding was provided by NIH P41RR016105, the Human Frontier Science Program (ASE), and the NSF-supported National High Magnetic Field Laboratory, and Scripps Florida (WRR). NMR data were collected in the AMRIS facility in the McKnight Brain Institute of the University of Florida.

Temperature and Food Availability Differentially Affect the Production of Antimicrobial Compounds in Oral Secretions Produced by Two Species of Burying Beetle

Received: 6 February 2009 / Revised: 2 July 2009 / Accepted: 24 July 2009 / Published online: 19 August 2009

Abstract Carrion beetles of the subfamily Nicrophorinae search and bury a carcass that they utilize for reproduction. After burial, the carcass is coated with oral secretions that delay its decomposition. Previously, oral secretions of *Nicrophorus marginatus* were found to show antimicrobial activity, whereas secretion of *N. carolinus* lacked significant activity. Here, we tested the effects of temperature, sex of the beetle, and food type on the antimicrobial properties of oral secretions of both species. Unlike previous findings, we found that oral secretions of *N. carolinus* had antimicrobial activity. Temperature had significant effects on the amount of secretion protein. When protein concentrations were standardized to 1 μ/ml, *N. marginatus* secretions had higher antimicrobial activity at cooler temperatures, while *N. carolinus* had higher activity at warmer ones. The sex of the beetle did not affect antimicrobial activity for either species. Beetles of both species that were fed whole rats contained more protein in their oral secretions than beetles fed with equally sized pieces of raw ground beef. After standardizing the resulting protein concentrations to 1 μg/ml, antimicrobial activity of oral secretion increased for *N. carolinus* after rat feeding, but not for *N. marginatus*. Our results highlight key ecological differences between these closely related species. In addition, they demonstrate the importance of experiments being conducted under varying environmental conditions when evaluating species for potential antimicrobial compounds.

Introduction

Insects come into contact with millions of microorganisms and rely mainly on their innate immunity to avoid infection from pathogens (Clarke 1973; Gupta 1979; Lamberty et al. 1999; Lavine and Strand 2002). In addition to avoiding individual infection, some insects also produce antimicrobial compounds that protect their eggs or limit decay of carrion or dung that they use for reproduction. For example, the termite *Pseudacanthotermes spiniger* depends upon a symbiotic fungus for nutrition; the fungus grows on the fecal material of the termites. The termites coat their eggs with saliva that contains antimicrobial peptides, and this protects their eggs from the fungi (Lamberty et al. 2001). Another example is that of the European beewolf that applies the contents of its postpharyngeal gland to its prey of paralyzed honeybees where it delays fungal infestation (Strohm et al. 2008).

Carrion beetles (Coleoptera: Silphidae) also have an antimicrobial oral secretion (Hoback et al. 2004). Silphid beetles respond to carrion that they externally digest by secreting extracellular enzymes produced in the salivary gland (Ratcliffe 1996; Rana et al. 1997). Members of the subfamily Nicrophorinae often are referred to as 'burying beetles' because they arrive at the carcass during the early stages of decomposition and then bury and tend the carcasses (Milne and Milne 1976; Ratcliffe 1996). After interment, burying beetles coat the carcass with secretions that contain antimicrobial activity that delays the decom-

position of the carcass ensuring a reproductive source (Milne and Milne 1976; Ratcliffe 1996; Scott 1998; Hoback et al. 2004).

Burying beetles exhibit a unique form of bi-parental care where a male and female pair tend the carcass (Scott 1998). When a suitable carcass is found, a pair of beetles bury the carcass 10 cm or more deep by excavating underneath the carcass until it is completely covered (Ratcliffe 1996). Once buried, the pair will strip it of fur or feathers and shape it into a ball, known as the brood ball (Ratcliffe 1996; Trumbo 1996). Once the brood ball is formed, the beetles coat the outside with oral and/or anal secretions that help control decomposition.

Carcasses that were treated by silphid beetles were less contaminated by mold than those that were untreated, even after the beetles were removed (Suzuki 2001). This suggests that the chemical effects of the secretion remain active when no beetles are present. Rana et al. (1997) found the oral secretion of *Nicrophorus marginatus* to contain phospholipase A_2 (PLA_2). PLA_2 is responsible for the pre-oral hydrolyzing of fatty acids. The oral PLA_2 may preserve the carcass by directly attacking bacterial membranes (O'Leary 1962).

In a study of 10 species of *Nicrophorus* beetles from Nebraska, antimicrobial activity was found in the oral secretions of all but 2 species (Hoback et al. 2004). The results showed that the secretions of *N. orbicollis, N. americanus, N. obscurus, N. tomentosis,* and *N. marginatus* exhibited antimicrobial properties that significantly reduced the amount of bacteria by 20 to 40%. The antimicrobial activity worked against both gram-positive and gram-negative bacteria, and it appeared to be proteinaceous as its activity was diminished by heat and proteinase treatment (Hoback et al. 2004). Oral secretions of *N. pustulatus* and *N. carolinus* failed to reduce the number of bacteria.

The lack of antimicrobial activity in the secretion of *N. pustulatus* may be explained by its reproductive strategy, which is to parasitize the brood ball of another species (Wilson and Knollenberg 1984). The lack of antimicrobial activity in the oral secretion of *N. carolinus* is more difficult to explain and does not appear to correlate with size, habitat association, or phylogeny. However, Hoback et al. (2004) did not control for beetle sex when collecting secretions, nor did they directly test the effects of environmental temperature or type of carrion on secretion activity.

In an attempt to elucidate conditions that may explain the lack of antimicrobial activity of oral secretion from *N. carolinus* in our earlier study, we examined the effects of the temperature at which the beetles are held, the sex of the beetle, and the food type given to the beetle on the antimicrobial properties of saliva from *N. carolinus* and *N. marginatus*.

Methods and Materials

Insect Collection During the summers of 2005 and 2007, adult *N. marginatus* and *N. carolinus* beetles were collected in Kearney and Lincoln Counties in Nebraska, U.S.A., using baited pitfall traps, as outlined in Bedick et al. (1999). These traps consisted of 5 gallon (21 l) buckets that were baited with rotted jumbo rats purchased from RodentPro.com. Beetles were collected each morning before 10:00 a.m., and rats were replaced every 3 d. Beetles were identified according to Ratcliffe (1996) and transported to the laboratory at the University of Nebraska at Kearney.

Secretion Collection When carrion beetles are harassed, most will excrete oral and anal secretions, while some produce defensive anal sprays (Rana et al. 1997; Scott 1998). Secretions were collected by placing a sterile cotton swab between the mandibles, while applying gently pressure to the abdomen. An individual sample consisted of oral secretion from 10 beetles placed into 1 ml of 0.1 M Tris buffer at pH 7, a variation of the protocol of Hoback et al. (2004). Samples were centrifuged at 10,000 rpm for 1 min, and the supernatant was collected. Secretions were sterilized by using a 0.22 μm syringe filter with a 0.80 μm pre-filter (Pall Corporation, Ann Arbor, MI, USA) and stored at −20°C until assays were conducted.

Protein Quantification The concentration of protein in the secretions was quantified with BCA Protein Assay Kits (Pierce Biotechnology, Inc., Rockford, IL, USA) using bovine serum albumin as a standard. Samples were read at 562 nm with a Beckman DU-640 spectrophotometer (Beckman Coulter, Fullerton, CA, USA) with distilled water as a blank. Protein content from each sample was standardized to 1.0 μg/ml before toxicity analysis was conducted.

Statistical analysis for the temperature samples was conducted using SigmaStat 3.1 (Systat Software, Inc.). Means were tested with Kruskal-Wallis *ANOVA* followed by Dunn's Method for mean separation ($P<0.05$). For the effects of sex and food type on protein content, SigmaStat's Student *t*-test was used ($P<0.05$).

Toxicity Analysis Samples were assayed with a Microtox Model 500 Analyzer (SDI, Newark, DE, USA). The Microtox quantifies the survival of the bacterium, *Vibrio fisherii,* by measuring decrease in bioluminescence associated with cell death. All samples were standardized to 1 μg/ml protein concentration and assayed in triplicate with the 2% screening test, following the procedure in the MicrotoxOmni™ Software (AZUR Environmental, Newark, DE, USA) using 10.0 μl of 0.1 M Tris buffer at pH 7 as a control. Statistical analysis was done by using an

[a] Number of replications: $N=6$ for *N. marginatus* and $N=4$ for *N. carolinus* run in triplicate. Difference of means were tested using Kruskal-Wallis analysis of variance, followed by a Dunn's test when significant differences were detected ($P<0.05$). Different letters represent a significant difference between means.

[b] Number of replications: $N=14$ for *N. marginatus* and $N=5$ for *N. carolinus* run in triplicate. Difference of means were tested using Student t-test ($P<0.05$). Different letters represent a significant difference between means.

[c] Number of replications: $N=6$ for *N. marginatus* and $N=4$ for *N. carolinus* run in triplicate. Difference of means were tested using Student t-test ($P<0.05$). Different letters represent a significant difference between means.

ANOVA followed by a Tukey Test when differences were detected ($P<0.05$).

Temperature Assay Beetles were maintained as Hoback et al. (2004) by separating species and housing them in plastic containers with moistened soil from their habitat. Beetles were placed in one of five environmental chambers set at 4°, 10°, 15°, 25°, and 30°C, respectively, with a 15/9 h light/dark cycle. When beetles encounter a whole carcass, a suit of behaviors is initiated where an individual male and female fight off other beetles and bury the carcass for use in reproduction (Milne and Milne 1976). To standardize food availability and feeding status while examining the effects of temperature, we used commercially available raw 85% lean ground beef. Ground beef was weighed and fed to beetles daily. Any uneaten ground beef was removed daily.

Oral secretions were collected after 3 d in the environmental chambers. For each temperature at which beetles were kept, 6 samples of *N. marginatus* were collected and 4 samples of *N. carolinus.* All assays were conducted in triplicate. Once 3-d-incubation was complete, all beetles were released so that no beetle would be housed in the laboratory more than 3 d.

Sex Assay Adult beetles were sexed following the protocol of Trumbo (1996). The oral secretion was collected immediately, and the beetles released. For *N. marginatus*,

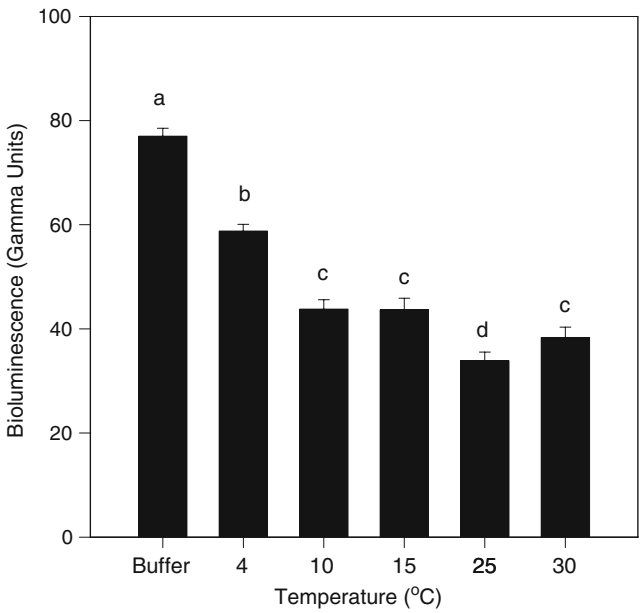

Fig. 1 Antimicrobial activity of oral secretion from *Nicrophorus carolinus* when maintained at five temperatures as compared to a Tris only buffer sample. Antimicrobial activity was measured using the Microtox 500 Analyzer which measures the bioluminescence in Gamma Units of *Vibrio fischerii*. Plotted are the mean + SE of $N=3$ experiments measured in triplicate. Data were statistically analyzed using ANOVA followed by a Tukey test when significance was detected ($P<0.05$). Different letters represent a significant difference between bars

a total of 14 secretion samples of each sex was collected and tested for antimicrobial activity. For *N. carolinus*, a total of 5 secretion samples was collected and tested for activity. All assays were conducted in triplicate.

Food Differences Beetles were separated into groups of 15 (both male and female) and placed into 30 X 15 X 20 cm glass containers containing moistened soil from their habitat. As a food source, beetles either were given a freshly thawed large rat at room temperature or raw 85% lean ground beef (Hamburger) that weighed approximately the same as the rat. All experiments were conducted at room temperature (21–24°C) in a fume hood to reduce odor. Secretions were collected after 3 d. A total of 6 secretion samples were collected from *N. marginatus* and tested for antimicrobial activity. For *N. carolinus*, a total of 4 secretion samples were collected. All assays were conducted in triplicate. Once the 3-d-incubation was complete, all beetles were released so that no beetle would be housed in the laboratory more than 3 d.

Results

Temperature Assays Our assays on the effect of temperature on protein content of oral secretion of *N. carolinus* revealed that beetles kept at 4°C produced significantly less protein than the 15°C and 25°C samples ($P<0.05$) (Table 1). After standardizing the protein content to 1.0 µg/ml, antimicrobial activity was quantified using the Microtox assay. *N. carolinus* oral secretions significantly inhibited growth compared to the buffer only control at all temperatures (Fig. 1). The highest antimicrobial activity was found for samples from beetles held at 25°C, with a 56% reduction in bioluminescence, significantly higher than samples from all other temperatures ($P<0.05$). The lowest antimicrobial activity was found in the 4°C sample with a 23.7% reduction in bioluminescence.

Protein content of oral secretions of *N. marginatus* was highest when beetles were kept at 4°C and lowest in the 30°C samples (Table 1). After standardizing protein content, all oral secretion samples had significantly reduced bacterial growth as compared to the buffer only control ($P<0.05$). The oral secretions with the greatest activities were collected from the beetles held at 4°C and 10°C with reduction of bioluminescence of 67.7% and 64.83%, respectively. These samples were not significantly different from each other, but they were significantly different from all other samples taken from beetles kept at other temperatures (Fig. 2).

Sex Assays No differences ($P>0.05$) were found between protein content of male and female oral secretions for either species (Table 1). The protein content from the oral secretions isolated from *N. marginatus* was slightly, but not significantly higher than of *N. carolinus.* No significant differences ($P>0.05$) were found between male and female antimicrobial activity from oral secretions in either species, but antimicrobial activity from oral secretions in both sexes was significantly different from the controls with buffer only (Fig. 3a and b).

Food Differences Oral secretion of rat-fed *N. carolinus* beetles contained 3.93 times more ($P<0.05$) protein than the secretion of the ground beef-fed beetles (Table 1). After standardization, the ground beef (Hamburger)- and rat-fed samples exhibited significantly different ($P<0.05$) antimicrobial activity as compared to the buffer control, but they did not differ from each other (Fig. 4a).

Oral secretion of *N. marginatus* contained 4.59 times more ($P<0.05$) protein than secretion of the ground beef-fed beetles (Table 1). After standardization of protein content, the antimicrobial activity of the oral secretions from *N. marginatus* given rat was significantly different ($P<0.05$) from both the buffer control and the ground beef (Hamburger)-fed samples, but samples from the ground beef-fed beetles were not significantly different from the buffer only control (Fig. 4b).

Discussion

Two environmental conditions were identified that influence the production of antimicrobial proteins found in oral secretion. Secretions from beetles of *N. carolinus* contained more protein and exhibited greater antimicrobial activity when beetles were kept at higher temperatures (25°C) (Table 1; Fig. 1), while the secretion of *N. marginatus* contained more protein and exhibited greater antimicrobial activity when beetles were kept at lower temperatures (4–10°C) (Table 1; Fig. 2). Although sex of the beetles did not influence antimicrobial activity of the secretion for

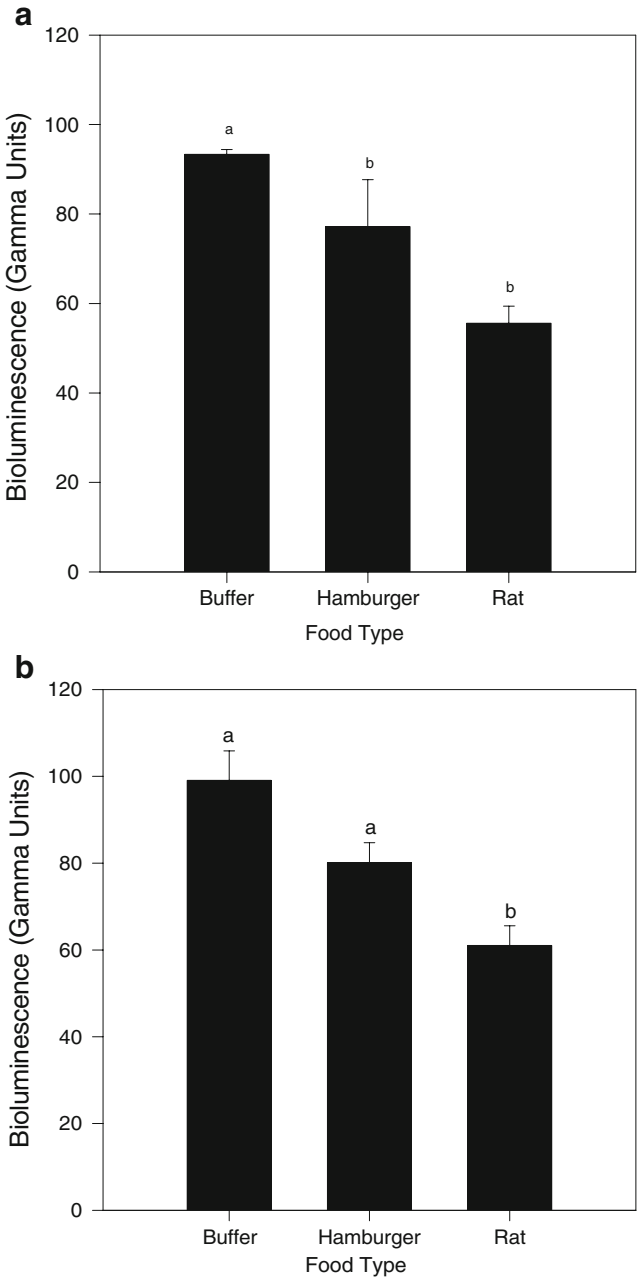

Fig. 4 Antimicrobial activity of oral secretion from *Nicrophorus carolinus* (4**a**) and *N. marginatus* (4**b**) beetles using two different food types (rat; Hamburger=ground beef) as compared to a Tris only buffer. Antimicrobial activity was measured using the Microtox 500 Analyzer which measures the bioluminescence in Gamma Units of *Vibrio fischerii*. Plotted are the mean+SE of $N=3$ experiments measured in triplicate. Data were statistically analyzed using ANOVA followed by a Tukey Test when significance was detected ($P<0.05$). Different letters represent a significant difference between bars

either species, food type altered antimicrobial activity of the secretion. Both species had significantly more protein in their oral secretions when provided with a rat as compared to ground beef (Table 1). The antimicrobial activity of the secretion also increased for *N. marginatus* fed on rats, but *N. carolinus* activity did not increase (Fig. 4). These data indicate that not only environmental conditions influence antimicrobial activity of the oral secretion, but different species also vary in their responses to these conditions.

Nicrophorus beetles generally become active when nighttime temperatures are above 13°C (Trumbo 1996). The reproductive season of the two species tested in this study almost completely overlap. In Nebraska, the active season of *N. marginatus* begins in February and ends in October. The active season of *N. carolinus* also ends in October, but activity begins in March (Ratcliffe 1996). According to the National Weather Service (2006), the average temperature for February 2006 was −2.2°C and 2.6°C for March 2006. Because *N. marginatus* begin their active season when the temperature is cooler, the optimum temperature of reproduction for *N. marginatus* may be lower than that of *N. carolinus*.

Hoback et al. (2004) found the antimicrobial activity of the oral secretions of burying beetles to be proteinaceous in nature, and protein activity is dependent upon temperature (Somero 1978; and Jaenicke et al. 1990). Antimicrobial activity in the oral secretion of *N. carolinus* was highest when beetles were kept at 25°C (Fig. 1), and the protein concentration was greatest for the 25°C samples, but only significantly greater than the 4°C samples (Table 1). These data also are supported by the ecology of *N. carolinus*. In Nebraska, *N. carolinus* is most common in the western part of the state in sandier soils (Anderson and Peck 1985; Ratcliffe 1996; Bishop et al. 2002). This environment would be hotter and drier than the preferred habitat of *N. marginatus*, which uses loam soils.

All of the samples for *N. marginatus* exhibited antimicrobial activity, with the 4°C and 10°C samples exhibiting the highest activity. As the temperature increased, a decrease in antimicrobial activity was observed (Fig. 2). The protein content of the oral secretion of *N. marginatus* also showed that the 4°C and 10°C samples had significantly more protein than the 30°C sample (Table 1). From the current findings, the antimicrobial activity of the beetles' oral secretions is most active at temperatures below 20°C. Bedick et al. (2006) reported a 50% mortality rate due to water loss for *N. marginatus* beetles when kept above 20°C in low humidity conditions for 10 h.

Parental supply of antimicrobial oral secretion is essential for larval success. Both parents are equally capable of producing antimicrobial oral secretion. In our experiment, beetles were collected, they were sexed, and their oral secretions were collected on the same day. Neither species showed significant differences between the antimicrobial activity or the protein content of the oral secretion produced by male or female beetles (Fig. 3; Table 1). This supports the findings of Scott (1989) who reported no differences in number, total weight, or survival of larvae when reared with single silphid males or females.

Because carrion is a rare resource (Eggert and Muller 1992), beetles cannot be selective, and numerous types of carrion have been found to attract burying beetles to traps (Bedick et al. 1999). The secretions of *N. carolinus* fed by either food type showed no difference in antimicrobial activity, and oral secretions of beetles fed by both food types showed significant antimicrobial activity (Fig. 4a). However, the secretions of *N. marginatus* showed a significant difference in antimicrobial activity when fed ground beef as compared to carrion. Although food type did not significantly affect antimicrobial activity of the oral secretion of *N. carolinus*, a significantly greater amount of protein was found in oral secretions from individuals fed rat carcasses than in secretions of those fed ground beef. The same was true for *N. marginatus*. The oral secretion from the rat fed beetles contained more than twice the amount of protein than the secretions from the ground beef fed beetles (Table 1). By producing larger quantities of protein, beetles would likely be able to protect successfully a brood ball from decomposition, even if the activity of the secretion does not change.

The results of this study indicate the importance of studying insects and potentially other groups under a variety of experimental conditions when investigating antimicrobial activity of their secretions. Temperature and carrion both were linked with changes in protein content of oral secretions of two carrion beetle species, but temperature also changed antimicrobial activity of the secretions. These factors are important in understanding under which conditions these beetles will be able to successfully reproduce. Other factors in the environment and beetle biology may also play a role in changing antimicrobial activity of the secretions, and these differences may be seen with other *Nicrophorus* species.

Acknowledgments We thank Darby Carlson, Rachel Anschutz, T. J. Walker, and Jessica Jurzenski for aid in collecting and identifying beetles. We also thank the Kuebler family for allowing us to trap beetles on their property. Abstract *Caenorhabditis elegans*, a bacterivorous nematode, lives in complex rotting fruit, soil, and compost environments, and chemical interactions are required for mating, monitoring population density, recognition of food, avoidance of pathogenic microbes, and other essential ecological functions. Despite being one of the best-studied model organisms in biology, relatively little is known about the signals that *C. elegans* uses to interact chemically with its environment or as defense. *C. elegans* exudates were analyzed by using several analytical methods and found to

Author contributions Fatma Kaplan and Dayakar V. Badri contributed equally and led the study; Fatma Kaplan, Aaron T. Dossey, Ramadan Ajredini, Hans Alborn and Michael Stadler intellectually contributed to the worm exudate protocol which was developed in the ASE laboratory; Fatma Kaplan, Ramadan Ajredini, and Rathika Nimalendran collected exudates; Dayakar V. Badri conducted bacterial bioassays; Hans Alborn collected LC-MS data; Fatma Kaplan and Cherian Zachariah collected NMR data; Fengli Zhang, Steven L. Robinette and Rafael Brüschweiler did COLMAR analysis; Fatma Kaplan, Cherian Zachariah, Michael Stadler, and Aaron T. Dossey manually analyzed NMR data. Sanja Roje and Francisco Sandoval analyzed amino acids by HPLC; Lanfang H. Levine analyzed young adult exudates by GC-MS; Wei Zhao did principle component analysis; Fatma Kaplan, Dayakar V. Badri, Arthur S. Edison and Jorge M. Vivanco analyzed the data and wrote the paper with help from the entire team.

contain 36 common metabolites that include organic acids, amino acids, and sugars, all in relatively high abundance. Furthermore, the concentrations of amino acids in the exudates were dependent on developmental stage. The *C. elegans* exudates were tested for bacterial chemotaxis using *Pseudomonas putida* (KT2440), a plant growth promoting rhizobacterium, *Pseudomonas aeruginosa* (PAO1), a soil bacterium pathogenic to *C. elegans*, and *Escherichia coli* (OP50), a non-motile bacterium tested as a control. The *C. elegans* exudates attracted the two *Pseudomonas* species, but had no detectable antibacterial activity against *P. aeruginosa*. To our surprise, the exudates of young adult and adult life stages of *C. elegans* exudates inhibited quorum sensing in the reporter system based on the *LuxR* bacterial quorum sensing (QS) system, which regulates bacterial virulence and other factors in *Vibrio fischeri*. We were able to fractionate the QS inhibition and bacterial chemotaxis activities, thus demonstrating that these activities are chemically distinct. Our results demonstrate that *C. elegans* can attract its bacterial food and has the potential of partially regulating the virulence of bacterial pathogens by inhibiting specific QS systems.

Introduction

Caenorhabditis elegans was the first metazoan to have its genome sequenced (Wilson et al. 1994), and has one of the best annotated animal genomes (www.wormbase.org). Its entire cell lineage from a single fertilized egg to an adult is known and has been related to the animal's anatomy (Sulston et al. 1983), and its anatomical ultrastructure has been described comprehensively by thin-section electron microscopy (White et al. 1986). *C. elegans* is particularly tractable for genetic studies (Brenner 1974), and as a result many signal transduction pathways have been identified. Several biomedically important discoveries have been made using *C. elegans* that include apoptosis (Ellis et al. 1991; Yuan et al. 1993), RNAi (Fire et al. 1998), and the *in vivo* application of the green fluorescent protein (Chalfie et al. 1994). In short, *C. elegans* is one of the best-understood animals in science. Natural *Caenorhabditis* species can be isolated from compost heaps, soil, decaying fruits, and even carrier invertebrates (Barriere and Felix 2006). Despite the wealth of genetic, cellular, and anatomical information, relatively little is known about *C. elegans* in its natural environment.

Small molecules are the primary mode of communication for most organisms. Bacteria, fungi, and plants release a variety of chemicals that attract or deter other organisms (Adler 1966; Mesibov and Adler 1972; Adler et al. 1973; Tso and Adler 1974; van der Drift et al. 1975; Hedblom and Adler 1983; Lugtenberg et al. 1999; Singh and Arora 2001; Bacilio-Jiménez et al. 2003; Kumar et al. 2007). Plant roots produce exudates that are capable of killing microbes, and these antimicrobial exudates can be up-regulated in response to pathogens (Walker et al. 2004; Bais et al. 2005). Several species of bacteria release acyl homoserine lactones to determine their local cell density (quorum sensing—QS), activate virulence factors at high cell density, and aggregate into biofilm (Miller and Bassler 2001; Williams et al. 2007). Some bacterial QS signals have been shown to attract *C. elegans* (Beale et al. 2006). Some species of plants (Givskov et al. 1996; Persson et al. 2005) and fungi (Rasmussen et al. 2005b) produce compounds that inhibit bacterial QS. Similar to bacteria, *C. elegans* also sense their own population density *via* dauer pheromones (Golden and Riddle 1982), which are ascaroside sugars with modified fatty acid groups (Jeong et al. 2005; Butcher et al. 2007, 2008; Srinivasan et al. 2008). These pheromones regulate the formation of a specific larval stage called dauer by integrating chemical cues from both the pheromone and an unknown chemical cue from their bacterial food source (Golden and Riddle 1982). *C. elegans* hermaphrodites also produce a chemical cue that attracts males (Simon and Sternberg 2002; White et al. 2007), and this mating cue recently was discovered to consist of a synergistic mix of known dauer pheromones called ascr#2 and ascr#3 (Butcher et al. 2007) and a glycosylated analogue called ascr#4, which is active at concentrations much lower than that required for dauer formation (Srinivasan et al. 2008). Recently, additional *C. elegans* ascarosides have been discovered with both dauer and mating activities (Pungaliya et al. 2009). Despite extensive recent research into *C. elegans* chemical signaling, relatively little is known about how *C. elegans* chemically interacts with microorganisms in its environment or even its natural food (Avery and Shtonda 2003; Shtonda and Avery 2006).

In this study, we present a comprehensive analysis of the chemical composition of *C. elegans* exudates by using several analytical techniques, which allowed the identifica-

tion of several amino acids, sugars, and organic acids that are released by the nematode into its environment. The majority of these chemicals were amino acids, and we present a quantitative analysis of changes in amino acid concentration as a function of development. The *C. elegans* exudates contained several compounds that cause bacterial chemotaxis, and we show that at least two species of bacteria, including the pathogenic *Pseudomonas aeruginosa*, were attracted to the exudates. This observation suggested the possibility that *C. elegans* exudates may employ a mechanism that helps protect them from pathogens. We found that *C. elegans* exudates produce a compound that inhibits quorum sensing in the reporter system based on the *LuxR* quorum sensing system (Andersen et al. 2001; Rasmussen et al. 2005a), and this compound is developmentally regulated and distinct from the compounds that cause bacterial chemotaxis. These results suggest a rich and complex set of chemical interactions between *C. elegans* and its environment.

Methods and Materials

Sample Preparation C. elegans exudates were collected at defined life stages (L1, L2, L3, L4, young adult and adult). Synchronized *C. elegans* (N2 Bristol) with a worm density of ~10,000 worms/ml were co-cultured with *Escherichia coli* (strain HB101) at 22ºC at 250 rpm on S-complete medium. The worms were harvested and separated from the medium and *Escherichia coli* by centrifugation or gravity, followed by rinsing three times over a nylon filter. They were then allowed to digest bacteria in their gut for 30 min in M9 buffer, rinsed three times in water, and incubated in water for 1 hr at density of ~30,000 worms/ml, as previously described (Jaffe et al. 1989; Johnstone 1999; Stiernagle 1999; Srinivasan et al. 2008). We recently were able to isolate and identify the *C. elegans* mating pheromone by using a similar preparation with the same relatively high worm density (Srinivasan et al. 2008). The primary purpose of the high density of worms is to collect enough material for efficient analytical characterization. All of the quantitative results shown below are normalized to the material produced by one worm in 1 h (defined as 1 worm equivalent: WE). Therefore, the density of the worm culture will not affect the outcome unless the exudates are themselves dependent on worm density. To rule out the possibility that the chemicals might be coming from dead worms, they were checked under the light microscope to verify whether they were alive before and after they were placed in water. As a negative control, we also made a similar preparation with only *E. coli* HB101 without worms. It should be noted that we are unable to distinguish whether the exudates were from regulated secretions or from defecation. The bacterial controls without worms allow us to rule out bacteria as the direct source of the exudates. For almost all experiments described below, we used the same replicate sample preps, three at each developmental stage. The exception was for the data shown in Fig. 4 in which we needed to produce additional replicates for C18 fractionation and bioassays.

NMR Data Collection from C. elegans Exudates For each life stage, *C. elegans* exudates from two independent experiments were lyophilized, and each sample was dissolved separately in 25 µl deuterium oxide (D_2O). A total volume of 12 µl containing ~54,000 worm equivalents (WE) and 0.25 mM 3-(trimethylsilyl)propionic acid-d4, a proton chemical shift reference standard (TSP=0.0 ppm), was transferred to a 1×100 mm capillary NMR tube (Norell, Inc., NJ, USA). NMR spectra of worm exudates were collected at 600 MHz on a Bruker Avance II 600 console in a 14.1 T magnet, using a 1-mm triple resonance high temperature superconducting (HTS) cryogenic probe (Brey et al. 2006). The NMR data were collected with a sample temperature of 300 ºK and spectral width of 7,211.53 Hz. The carrier frequency of ^1H was centered on residual water, which was eliminated by presaturation or by gradient methods. Two-dimensional total correlation spectroscopy (TOCSY) data were collected by using the DIPSI-2 mixing sequence (Shaka et al. 1988) with 60 or 90 ms mixing time, 2,048 complex data points along the direct and 1,024 or 512 complex data points along the indirect dimension, respectively. TOCSY data were processed with NMRPipe (Delaglio et al. 1995) by eliminating residual water by deconvolution, followed by apodization using a cosine squared function, zero-filled two times, Fourier transformed, and baseline corrected along both the dimensions. Data were analyzed and assigned with NMRview (Johnson 2004). To manually identify known metabolites by NMR, TOCSY spectra were overlaid with spectra of standard compounds downloaded from the BMRB metabolomics database (Markley et al. 2007). To confirm the different compounds identified in worm exudates, the samples were spiked with 1 to 2 mM of the respective authentic compound in D_2O, followed by the acquisition of both 1D and 2D NMR spectra.

Semi-automated Compound Identification by NMR Chemical constituents were identified using the webserver-based COLMAR protocol (Robinette et al. 2008), which provides processing and analysis of 2D NMR spectra of metabolic mixtures (http://spinportal.magnet.fsu.edu). The 2D TOCSY data were processed by using a covariance algorithm (Brüschweiler and Zhang 2004; Trbovic et al. 2004) that yields spectra with equally high resolution along both frequency dimensions. The covariance TOCSY spectra were then deconvoluted by COLMAR DemixC (Zhang

and Brüschweiler 2007; Zhang et al. 2007), which extracts 1D spectral traces that represent individual compounds by identifying spin systems with minimal likelihood of overlaps between different compounds in the covariance TOCSY spectra of the intact mixtures. In the final step, chemical shifts from individual spin systems derived from the DemixC traces were screened against the BMRB metabolomics spectral database (Seavey et al. 1991) using our COLMAR query webserver (Robinette et al. 2008; Snyder et al. 2008), which outputs a ranked list of the highest scoring compounds.

Gas Chromatography and Mass Spectrometry (GC-MS) Analysis To increase the number of identified compounds and to verify automated compound identification by NMR, we used GC-MS. We lyophilized 1 ml of young adult exudates (30,000 WE/ml) and *E. coli* (HB101) controls from three independent experiments, and chemically derivatized the lyophilized material using a two-step approach (Fiehn et al. 2000; Roessner et al. 2000; Wagner et al. 2003). Forty µl of 20 mg/ml methoxyamine hydrochloride in pyridine containing ribitol as an internal standard were directly added to the dried samples and vigorously mixed at 30°C for 1.5 h. Subsequently, 80 µl of *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA) containing a mixture of C_{12}, C_{15}, C_{19}, C_{22}, C_{28}, C_{32}, C_{36} n-alkanes were added and incubated at 37°C for 30 min. Derivatized samples were analyzed immediately by a TRACE DSQ GC-MS system (Thermo Finnigan Corp. Austin, TX, USA). Chromatograms were analyzed with the software AMDIS (version 2.64) in retention time index (RI) calibration mode. Metabolite identification was achieved by searching a user-library from the Max Planck Institute of Molecular Plant Physiology, Golm, Germany (Dr. Joachim Kopka, personal communication) that contains both retention time index and electron impact (EI) mass spectrum for each target component. Compounds were considered identified if their matching factor was greater than 800 on a scale of 0–1,000 and RI deviation was less than 3.0. Quantitative information for each component was extracted from the chromatogram by using the AMDIS software and a customized MACRO (http://www.lssc.nasa.gov/als/chemistry, then view features→metabolomics tool) and subsequently normalized to ribitol's response.

Quantification of Amino Acids by High Performance Liquid Chromatography (HPLC) To quantify the concentrations of amino acids present in worm exudates, an HPLC fluorescent detection methodology (Cohen and Michaud 1993) was employed. Three independent replicates of 3 ml of exudates at each developmental stage were lyophilized and resuspended in 150 µl of water. To make the amino acids fluorescent, samples were derivatized with 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate (AQC, AccQ•Fluor™ Reagent Kit, Waters, Milford, MA, USA) following the manufacturer's protocol with minor modifications as indicated below. Reconstituted exudates (2.5 µl) were mixed with 17.5 µl of AccQ•Fluor borate buffer followed by the addition of 5 µl of AccQ•Fluor Reagent. The resulting mixture was incubated at 55°C for 10 min in a heating block. Prior to HPLC separation, the derivatized samples were diluted to 50 µl with water and were filtered through a 0.22-µm PVDF membrane.

The resulting fluorescent derivatives were separated on a SunFire C_{18} column (4.6×150 mm, 3.5 µm) or a Nova-Pak C_{18} column (3.9×150 mm, 4.0 µm) using a Waters Alliance 2695 separation module and were measured by a Waters 2475 fluorescence detector using an excitation wavelength of 250 nm and an emission wavelength of 395 nm. Two separation procedures under gradient conditions (Supplementary Tables S2 and S3) were used to ensure accurate identification and quantification of amino acids. Solvent composition consisted of A, water; B, acetonitrile; C1, 140 mM sodium acetate and 17 mM triethylamine, pH 5.05; C2, 100 mM sodium acetate and 5.6 mM triethylamine, pH 5.7; D, 100 mM sodium acetate and 5.6 mM triethylamine, pH 6.8. The volume of sample injected was 10 µl. The AQC-amino acid derivatives were identified and quantified by comparison with standards.

Liquid Chromatography and Mass Spectrometry (LC-MS) Analysis To search for specific known metabolites, we utilized LC-MS. One ml (30,000 WE) of worm exudates from defined developmental life stages was lyophilized and then dissolved in 50 µl of methanol. Ten µl were analyzed using a Thermo Finnigan LCQ Deca XP Max with electrospray ionization in positive and negative ion modes. Additionally, 1 nmol of commercially available patulin (MP Biomedicals, OH, USA) and penicillic acid (Acros organic, NJ, USA) were analyzed under the same conditions as above to establish retention times and diagnostic ions for screening worm exudates for these compounds.

Principal Component Analysis (PCA) We used PCA to cluster exudates from different larval stages using measurements of 14 amino acids that were quantified by HPLC. The concentrations of amino acids in worm exudates varied greatly, both among different amino acids and among the different *C. elegans* life stages for a given amino acid. For example, the concentration of Met ranges from about 0 to 0.19 pmol/WE, while Ala ranges between about 0 and 6 pmol/WE. When data are not properly scaled, the performance of PCA is dominated by high concentration

metabolites, because they constitute most of the variance. To give each metabolite an equal weight in the analysis, we scaled the data by first subtracting the mean from each metabolite and then dividing by root-mean-square. The scaled metabolite measurements have mean 0 and variance 1. PCA analysis (Johnson and Wichern 2001) was performed on the scaled data using R software (http://www.r-project.org/).

Chemotaxis Assay A slightly modified agarose plug method (Yu and Alam 1997) was used to test for bacterial chemotaxis activity of worm exudates. Briefly, bacteria grown in LB medium overnight were used as a starter culture and inoculated again in the fresh LB at a dilution of 1:50. Rifampicin (20 μg/ml) was added to *P. aeruginosa* (PAO1), because this strain is resistant to that antibiotic. No antibiotics were added to *Pseudomonas putida* (KT2440) or *E. coli* (HB101) cultures. This culture was placed in a shaker incubator until reaching an OD_{600} of 0.4–0.6, the cell density corresponding to the maximum proportion of motile cells. The cells were collected by centrifugation, washed twice with chemotaxis buffer (10 mM potassium phosphate, pH 7.0, 0.1 mM EDTA, 1 mM $MgSO_4$) and resuspended to an OD_{600} of 0.1 for the chemotaxis assay. A 10 μl drop of 2% agarose solution made with chemotaxis buffer and 10 μl of worm exudate (~300 WE) were mixed and placed on the center of the acetone cleaned microscopic slide, framed with two plastic strips (16 mm apart) and covered with a cover slip to create a chemotaxis chamber. The slide was allowed to stand for 1 min to solidify the agarose plug. Once this was achieved, 120 μl of bacterial suspension was added to the chamber surrounding the agarose plug and incubated at room temperature for 15–30 min. Following incubation, the distribution of cells immediately adjacent to the agarose plug was observed under a phase-contrast microscope and recorded with a charge-coupled device camera. Positive and negative controls were with agarose plugs containing just LB medium and chemotaxis buffer, respectively. For each trial, at least three agarose plugs were used for each developmental stage of *C. elegans* exudates. These experiments were conducted in triplicate with three independent worm exudate preparations.

Antimicrobial Assay A modified agar diffusion method (Bauer et al. 1966) was used to test for antimicrobial activity of worm exudates against the opportunistic pathogen *P. aeruginosa* (PAO1). Luria-Bertani (LB) (Bertani 1951) agar plates were prepared and spread homogenously with 100 μl of an overnight grown culture of *P. aeruginosa* (PAO1) at a density of 0.02 (10^7 cfu/ml) suspended in 10 mM $MgSO_4$ buffer. The plates were dried for 5 min under a sterile hood. Thereafter, sterile Whatman filter paper discs, 7 mm diam, were placed on the surface of seeded agar plates and loaded with 50 μl and 100 μl of filter-sterilized exudates (~1,500 and 3,000 WE) and air dried. Sterile filter paper discs, loaded with 100 μl of sterile distilled water, were used as a negative control. After the plates were incubated at 37°C for 16 h, they were examined for the presence of zones of bacterial growth inhibition. These experiments were conducted in triplicate.

Quorum Sensing (QS) Inhibition Assays We used both a QSIS1 reporter system (Rasmussen et al. 2005a) and a green fluorescent protein (GFP)-based N-acyl homoserine-lactone (AHL) sensor system (Andersen et al. 2001) to test for the QS inhibition (QSI) activity of worm exudates. Both reporter constructs are based on the LuxR system of *Vibrio fischeri* and are plasmids expressed in *E. coli* for efficient screening of QSI activity. Both assays were conducted in the presence of activating AHLs. In the QSIS1 system, a toxic gene is expressed unless an inhibitor is added, so QSI activity is required for *E. coli* growth. In the GFP-based system, GFP is expressed with AHLs, and the amount of GFP expression and thus fluorescence is reduced with added QSI activity. The medium used for this assay was ABT minimal medium supplemented with 0.5% glucose and 0.5% Casamino acids (AB medium containing 2.5 mg of thiamine/l) (Clark and Maaole 1967). Ampicillin (100 μg/ml) was added to prevent contamination of the *E. coli* assay systems. A total of 50 μl of exudate (~1,500 WE) for QSIS1 was tested. Additionally, 50 μl of chamomile extracts and sterile water served as positive and negative controls, respectively, for QSIS1.

For the *gfp*-based AHL sensor system, we used a microtiter dish and tested the QSI activity of worm exudates in the presence of 100 nM *N*-3-oxohexanoyl-L-homoserine lactone. Each well contained 100 μl of test samples, 100 μl of diluted bacterial culture (*E. coli* MT102 harboring pJBA132) in ABT medium, and 100 nM *N*-3-oxohexanoyl-L-homoserine lactone. The final bacterial density (OD_{450}) was adjusted to 0.05. GFP fluorescence was monitored at an excitation wavelength of 475 nm, and emission detection at 515 nm along with bacterial density at OD_{450} every 20 min for 7 h at 30°C using a Synergy 4 microplate reader (BioTek, Winooski, VT, USA). Sterile water and 12.5 μM 4-nitropyridine N-oxide (4-NPO) (Sigma-Aldrich) were negative and positive controls, respectively. The test samples included prefractionated young adult *C. elegans* exudates (~3,000 WE), exudate fractions that were separated by C18 solid phase extraction into flow through, 50% methanol (MeOH), and 90% MeOH fractions (Srinivasan et al. 2008), and a reconstituted fraction in which the flow through, 50 and 90% MeOH fractions were recombined.

QS-dependent Virulence Factor Assays in P. aeruginosa We also used three assays—pyocyanin, elastase, and protease—to test for QSI activity of worm exudates in *P. aeruginosa*.

The details of these assay methods and results are provided in the Supplementary Material.

Results

Chemical Composition of C. elegans Exudates We used three techniques—NMR spectroscopy, HPLC, and GC-MS—to identify the major compounds in worm exudates. These complementary techniques allowed us to identify 36 low molecular weight compounds including sugars, amino acids, and other organic acids (Table 1). Qualitative changes in exudates during *C. elegans* development can be seen in the 1D ^{1}H NMR spectra in Fig. 1. These spectra show that worm exudates contain a relatively complex mixture of compounds, some of which are constant, and some variable in concentration throughout development. The most striking changes were in methyl resonances with chemical shifts around 1 ppm (Fig. 1). These signals were strong from L2 to young adult, but significantly diminished in adult animals. Resonances with chemical shifts around 8.3 ppm, presumably from aromatic compounds, were present in adult exudates but not in those from other life stages.

Initial compound identification was achieved by overlaying TOCSY spectra of common metabolites downloaded from the BMRB metabolomics database. We also used COLMAR DemixC, a recently developed semi-automated method to analyze NMR spectra of complex mixtures (Zhang and Brüschweiler 2007; Zhang et al. 2007). About 20% of the compounds could be identified using COLMAR, including sugars (glucose and trehalose), lactic acid, and amino acids (Val, Lys, Leu, Ile, Glu) (Supplementary Fig. S2 and Table S1). All NMR identifications were verified using NMR by spiking the exudates with known pure compounds. Some additional compounds were identified by manual analysis of NMR datasets and spiking experiments with known compounds.

GC-MS profiling (Fiehn et al. 2000; Roessner et al. 2000; Wagner et al. 2003) identified 29 compounds in young adult exudates, including the 8 identified by COLMAR. These water-soluble *C. elegans* exudates include several sugars, organic acids, and amino acids (Table 1). The NMR and GC-MS analyses both demonstrate that several free amino acids are in *C. elegans* exudates. As noted above, the NMR spectra also showed that some amino acid concentrations—most obviously the methyl resonances of Val, Leu, and Ile—significantly change with development (Fig. 1). We therefore quantified amino acid concentrations by HPLC. Principal component analysis (PCA) was performed on the amino acid profile data to assess overall experimental quality and variation between each developmental stage. PCA revealed that the three highest-ranking components accounted for 90.1% of the total variance within the dataset. The first two components (81% of the total variance) were enough to distinguish the individual life stages (Fig. 2a), thus demonstrating that development is a significant factor in the variation observed in *C. elegans* exudates. Furthermore, the variance from experiment to experiment was small in

Table 1 Chemical composition of *Caenorhabditis elegans* young adult exudates[a]

Sugars	Amino acids (continued)	Other compounds
Fructose[d]	Glycine[d]	2-Ketoglutaric acid[d]
Glucose[d,c]	L-Alanine[b,e,d]	Allontoin[d]
Glucose-6-P[d]	L-Glutamic acid[b,e,d]	Anthranilic acid[d]
Trehalose[b,d]	L-Isoleucine[b,e,d]	Betaine[b]
	L-Leucine[b,e,d]	Citric acid[d]
	L-Lysine[b,e,d]	Erythronic acid[d]
Amino acids	L-Phenylalanine[b,e,d]	Fumaric acid[d]
2-Aminoadipic acid[b,e,d]	L-Serine[d]	Glutaric acid[d]
Beta-Alanine[b,e,d]	L-Threonine[e,d]	Lactic acid[b,d]
N-Acetylglutamic acid[e]	L-Tyrosine[e,d]	Malic acid[d]
Ornithine[c,e]	L-Valine[b,e,d]	myo-Inositol[d]
Proline[e]	Aspartate[e]	Threonic acid[d]
Methionine[e]	Arginine[e]	Urea[d,e]

[a] Metabolites were identified by combined approaches of NMR, GC-MS, and HPLC. [b] Identified and verified by NMR, [c] Identified but not verified by NMR, [d] identified by GC-MS, [e] identified by HPLC. Three independent experiments were done starting from worm growth for GC-MS, HPLC and only two of those used for NMR. We also analyzed four additional young adult and adult samples by HPLC. As a control, *E. coli* (HB101) was treated the same way as the worms to determine any contamination from food source. Identification of glucose-6-P is with 80% confidence.

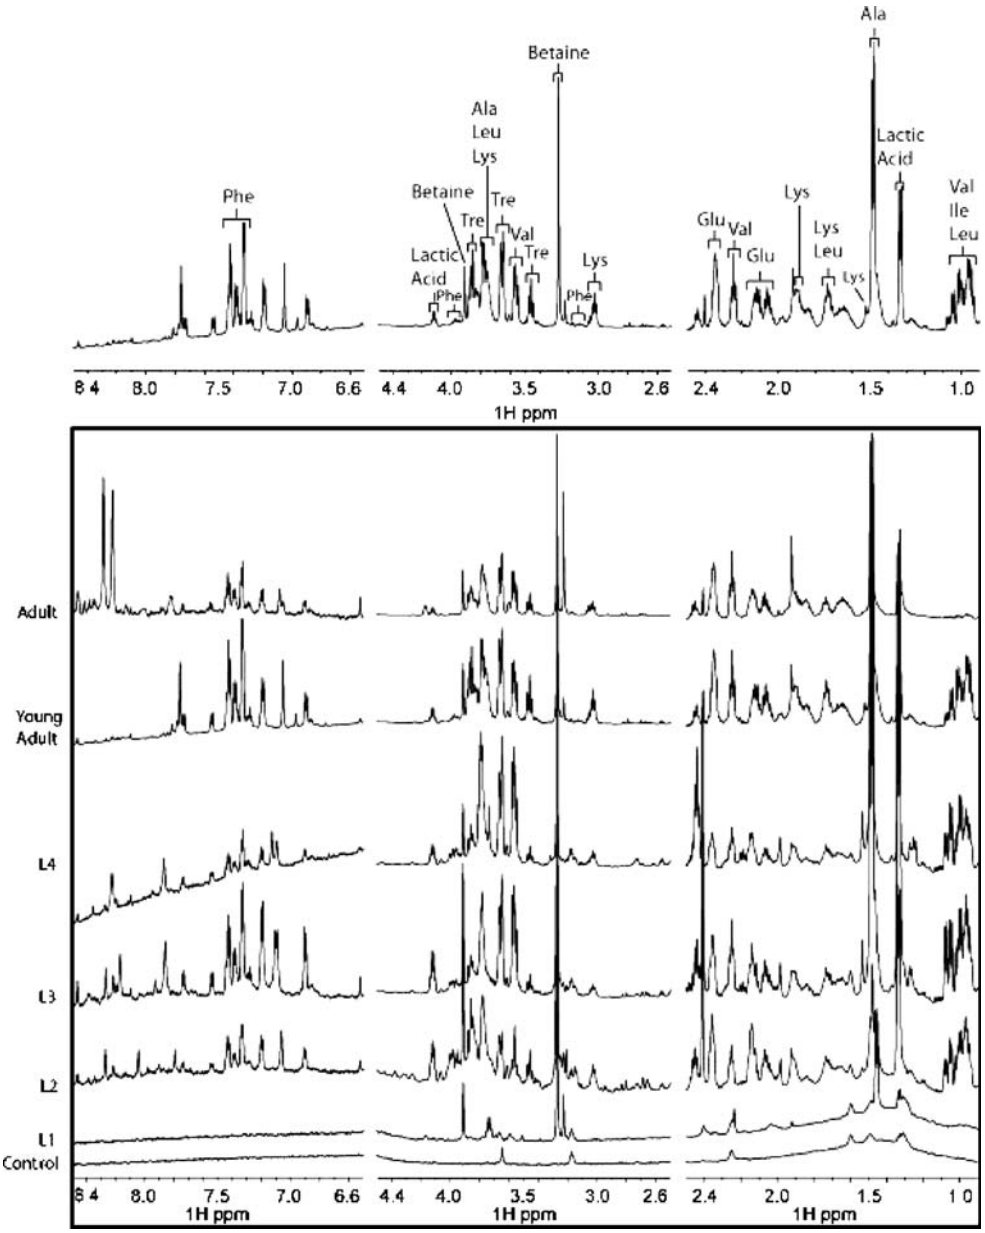

Fig. 1 NMR spectra of *Caenorhabditis elegans* exudates as a function of development. One-dimensional ^{1}H NMR spectra containing 54,000 WE from different *C. elegans* developmental stages were collected from three independent preparations of each developmental stage. The data shown are from one preparation and are representative of the others. Three regions of the spectra are shown, demonstrating a large amount of variation in chemical composition as a function of development. The annotations at the *top* are on the young adult exudates. The compounds were identified using either the semi-automated COLMAR analysis or manual analysis and spiking experiments, as described in the text

L1 and L2, but increased as the development progressed. This may be due in part to small differences in initial synchronization of worms that propagate with time.

The concentration of every amino acid in *C. elegans* exudates changed with development (Fig. 2b). Of all the developmental stages, L1 contained the fewest amino acids, with only 7 (Ala, Glu, Asp, Ile, Leu, Lys, Phe) detected and present at low concentrations. Every amino acid increased in concentration from L1 to L2 and from L2 to L3. For most developmental stages, Ala and Glu were the most abundant amino acids, with Ala at an approximately 10-fold average higher concentration than most of the others. Several amino acids (Ile, Leu, Thr, Pro, Phe, Met, Tyr, and Ala) have a profile that is highest at the L3 and young adult stages with a slight decrease at L4. With the exception of Asp, Lys, and ornithine (Orn), all amino acid concentrations decreased from young adult to adult stages. The concentration of Orn steadily increased through adult (Fig 2b).

To rule out the possibility that the identified molecules originated from the bacterial food source, we repeated the HPLC and GC-MS experiments on a control preparation that contained bacteria without worms; this sample was prepared identically to the worm exudate preparations, and we did not observe any amino acids or other compounds in Table 1. Additionally, the variation in metabolite profiles among different *C. elegans* life stages also suggests that bacteria, a constant in the experiments, are not the direct source of the observed metabolites. In summary, *C. elegans* exudates contain at least 36 amino acids, sugars and organic

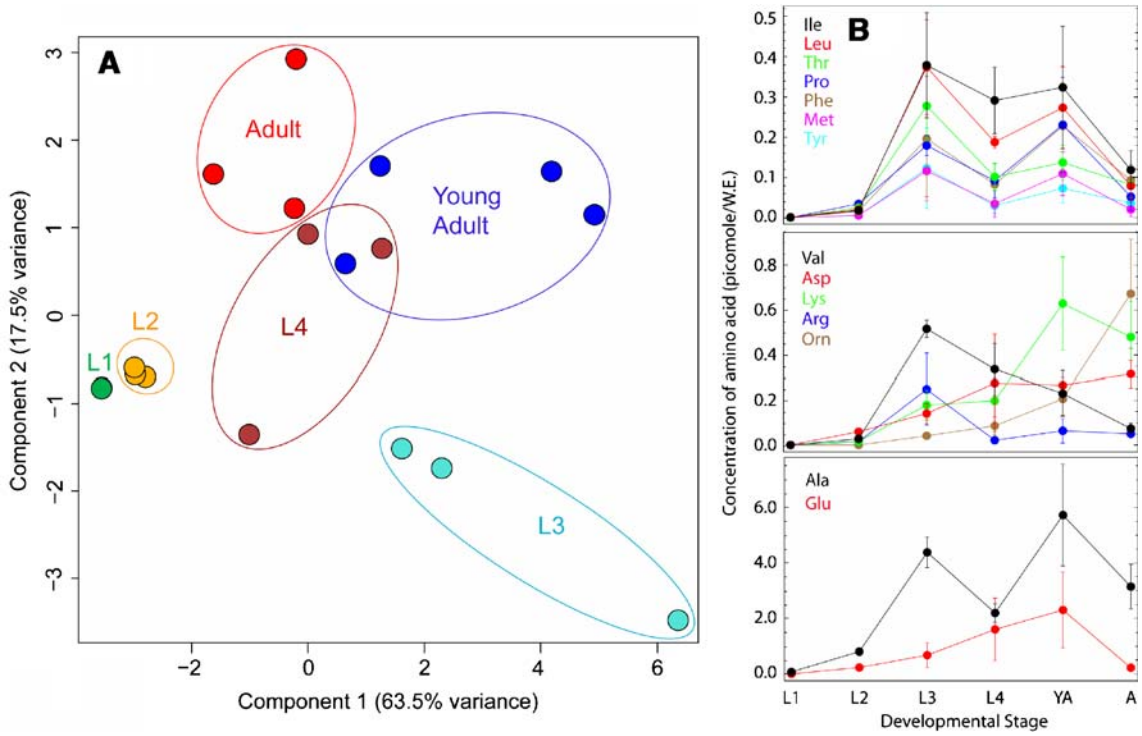

Fig. 2 Quantitative analysis of amino acids released by *C. elegans* at different developmental stages. Three independent preparations of exudates from each developmental stage were analyzed by HPLC. **a** Principal component analysis of all developmental stages. Each *circle* represents an independent experiment. The L1 data include three datasets that had very small variance among the three experiments. Components 1 and 2 account for 81% of the variation in the HPLC dataset. **b** Plots of amino acid concentrations (picomoles per worm equivalent) as a function of development. Note that the vertical concentration scale in each of the panels in **b** is different. Each point is the average and standard deviation of the three independent sample preparations and HPLC measurements. The amino acids are grouped according to overall shape of their concentration profile. The 7 in the *top* panel (Ile, Leu, Thr, Pro, Phe, Met, and Tyr) all have a peak at L3, a slight dip at L4, a slight increase at young adult (YA) and a drop at adult (A) stages. The group of four amino acids in the *middle* panel (Val, Asp, Lys, and Arg) are more variable, and the two amino acids at in the *bottom* panel (Ala and Glu) are produced in significantly higher concentrations

acids, and the concentrations of many of these compounds vary with development.

Bacteria Chemotax towards C. elegans Exudates Several species of bacteria, including *E. coli*, chemotax in response to various small molecule cues (Adler 1966; Mesibov and Adler 1972; Adler et al. 1973; Tso and Adler 1974; van der Drift et al. 1975; Hedblom and Adler 1983; Lugtenberg et al. 1999; Singh and Arora 2001; Bacilio-Jiménez et al. 2003; Kumar et al. 2007). For example, *E. coli* is attracted to Asp, Ser, Glu, Ala, Asn, Gly, Cys, Met, Thr, and trehalose (Adler et al. 1973; Hedblom and Adler 1983; Mesibov and Adler 1972) and repelled by Leu, Ile, Val, Trp, Phe, Gln, and His (Tso and Adler 1974). *C. elegans* lives in a complex soil environment with both beneficial and pathogenic microbial communities, and the chemical composition of *C. elegans* exudates suggests that the worms might attract bacteria. To test this hypothesis, exudates from young adult animals were tested qualitatively for bacterial chemotaxis by using the agarose-in-plug bridge method (Yu and Alam 1997). We tested three bacterial species: *P. aeruginosa* (PAO1), a bacterial species pathogenic to *C. elegans* (Darby et al. 1999; Aballay and Ausubel 2002), *Pseudomonas putida* (KT2440), a plant growth promoting rhizobacterium (Molina et al. 2000; Ramos-González et al. 2005), and *E. coli* (OP50), a widely used food source for *C. elegans* that is defective in motility. *P. aeruginosa* (PAO1) and *P. putida* (KT2440) both exhibited positive chemotaxis (Fig. 3a). This result is consistent with the presence of Ser, Glu, alpha-keto glutarate, succinate, citrate, and glucose in young adult exudates, as they have all been shown to attract *P. aeruginosa* (Moulton and Montie 1979). As a negative control, we tested *E. coli* (OP50), because it is widely accepted that this strain of bacteria is defective in motility (P. Sternberg, personal communication); this bacterium showed no response, consistent with our expectations (data not shown). Because beneficial and harmful bacteria were attracted to *C. elegans* exudates, we also tested the exudates for antibacterial activity against *P. aeruginosa* (PAO1). The exudates showed no antibacterial activity in our assays (data not shown). This is not surprising because previous studies documented higher bacterial activity and growth when

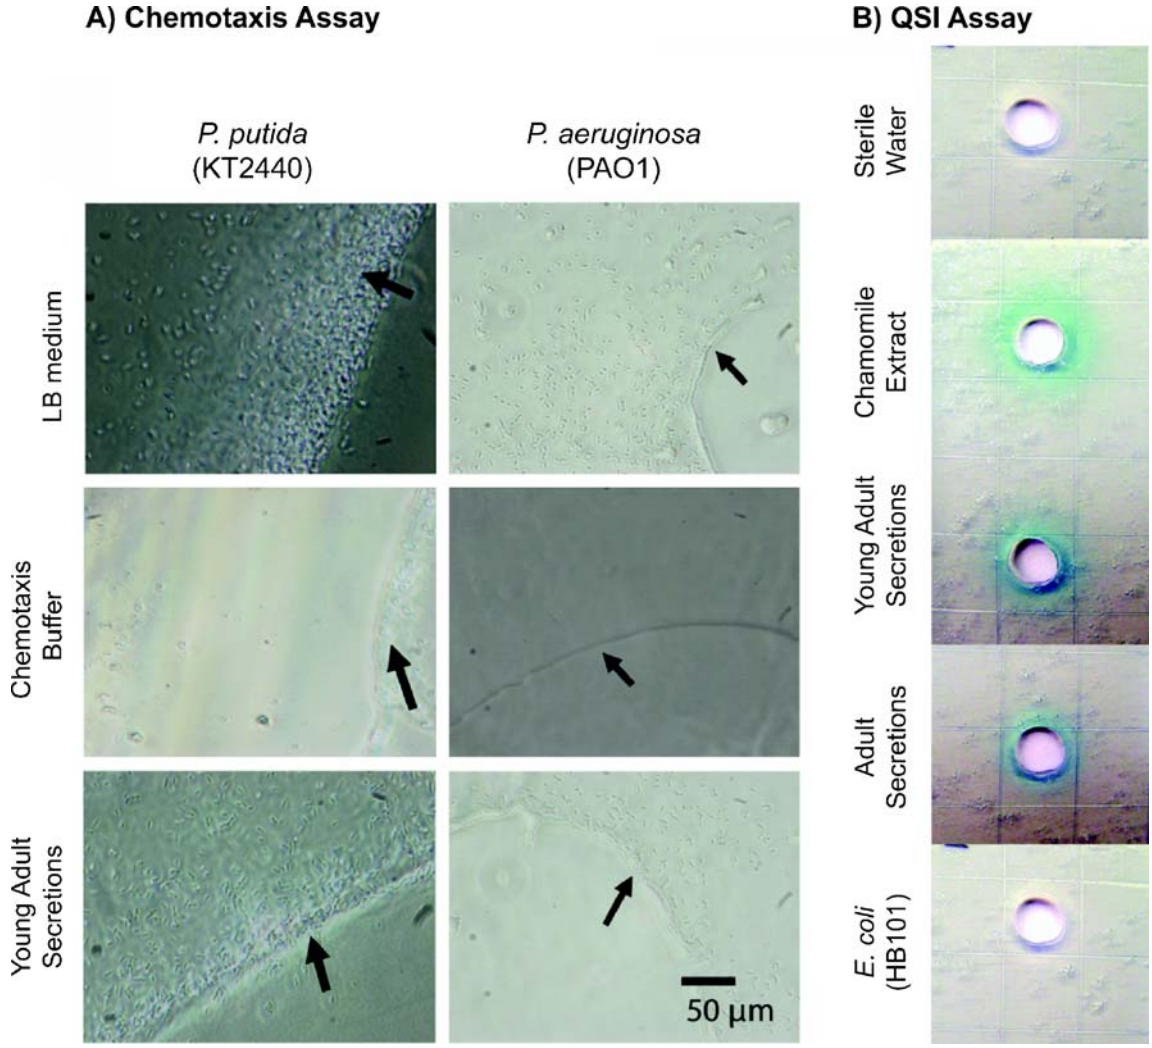

Fig. 3 Qualitative assays for bacterial chemotaxis and quorum sensing inhibition activity of *Caenorhabditis elegans* exudates. **a** Chemotaxis of *P. putida* (KT2440) and *P. aeruginosa* (PAO1). The *arrow marks* indicate the margin of the agarose plug. *Dark spots* near the margin of agarose plug are the bacterial cells. The bacterial cell density around an agarose plug that contained the exudates of interest was observed with a 40X phase-contrast objective (GX microscope) 30 min after introduction of a bacterial suspension. One plane of focus adjacent to the plug was photographed with a CCD camera on the microscope. LB media is a positive control and chemotaxis buffer is a negative control. **b** The QSIS1 reporter system (Rasmussen et al. 2005a) was employed for these qualitative assays. *Blue color* around the well indicates QSI activity. The *top* (sterile water) and *bottom* (*E. coli*) panels are negative controls, and chamomile extract is a positive control. *C. elegans* young adult and adult exudates showed positive QSI activity. For both the chemotaxis and QSI assays, three independent preparations of worm exudates were produced, and three assays were conducted on each preparation, for a total of nine assays. The figures are representative examples of one of these assays for each activity

Pseudomonas fluorescens and *Bacillus subtilis* were co-cultured with *C. elegans* (Huixin et al. 2001).

C. elegans Exudates Inhibit Bacterial Quorum Sensing (QS) We tested worm exudates for QS inhibition (QSI) activity, which would attenuate the bacterial pathogenicity, but not the growth and development (Bjarnsholt and Givskov 2007; Dong et al. 2007). All stages of *C. elegans* exudates were tested, and no activity was observed in larval stages (L1–L4). However, exudates from both young adult and adult animals showed QSI activity, as indicated by the presence of the bacterial growth around the well (Fig. 3b). Although the assay used in Fig. 3b is qualitative, the bacterial zone of growth (indicated by the blue color) is larger in exudates from young adults than adults. This suggests that *C. elegans* QSI activity is developmentally regulated.

We then tested *C. elegans* exudates for their ability to interfere with specific pathways in the production of virulence factors in *P. aeruginosa* QS. The exudates did not affect the production of elastase and protease, but induced a small amount of pyocyanin production (Supplementary Fig. S1) (Pearson et al. 1997; Fothergill et al.

2007). This small increase could be due to either an increase in release of pyocyanin, increase in biosynthesis, or both. We were unable to detect the known and commercially available QS inhibitors (patulin and penicillic acid) in *C. elegans* exudates (data not shown); these compounds have been shown to inhibit the *P. aeruginosa* QS system (Rasmussen and Givskov 2006). These results suggest that the *luxR* QSI activity of *C. elegans* exudates observed in the QSIS1 reporter system (Fig 3b) does not significantly affect the *P. aeruginosa* QS system.

Chemical Fractionation of Bacterial Chemotaxis and QSI Activities To our knowledge, the data in Fig. 3 are the first demonstration of either bacterial chemotaxis or QSI activity of *C. elegans* exudates. Based on extensive studies of bacterial chemotaxis, most of that activity could

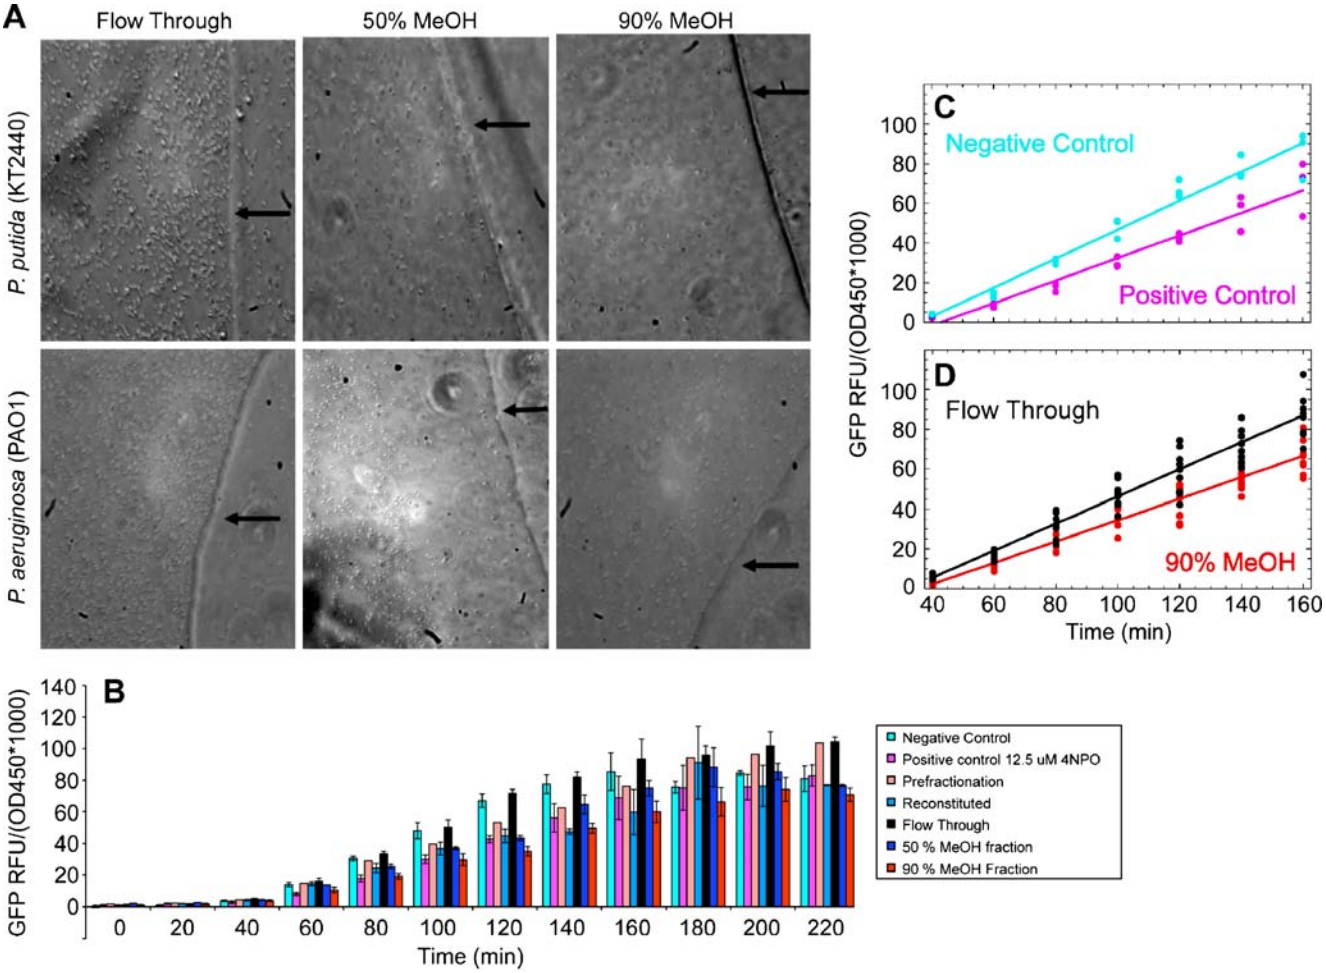

Fig. 4 Fractionation of bacterial chemotaxis and QSI activity. Young adult *Caenorhabditis elegans* exudates were separated into flow through, 50% methanol (MeOH), and 90% MeOH fractions by C18 solid phase extraction. **a** Chemotaxis of *P. aeruginosa* (PAO1) and *P. putida* (KT2440), as described in Fig. 3. The chemotaxis assay was repeated 3 times on 2 different sample preparations for a total of six replicates. Each of the assays showed the greatest bacterial chemotaxis towards the hydrophilic flow through fractions and very little chemotaxis to the most hydrophobic 90% MeOH fractions. The figures in **a** are a representative dataset. **b**, **c**, and **d** Quantitative QSI assay of young adult *C. elegans* C18 fractions (Andersen et al. 2001). **b** is a complete 220 min time course with the GFP fluorescence normalized to the bacterial optical density monitored at 450 nm. The increase in fluorescence is reduced by compounds with QSI activity, as seen by comparing the blue sterile water negative control with the pink 12.5 μM 4-nitropyridine N-oxide (4NPO) positive control. The data shown in **b** represent 3 replicate assays on 1 sample preparation. **c** and **d** show the data and linear fits from 40 to 160 min for negative and positive controls (**c**) and the flow through and 90% MeOH fractions (**d**). The negative and positive controls in **c** were from 3 replicates, and the exudate fractions in **d** were from 3 replicate measurements of 3 independent samples (total of nine measurements). The slopes, intercepts, and fitting statistics for the data shown in **c** and **d** as well as all the other conditions from **b** are in Table 2. We also compared the differences between each sample set using the model comparison technique under the linear model framework, and the statistical *P* values are shown in Table 3. The *C. elegans* flow through fraction had no QSI activity when compared with negative control ($P=0.5$), and there is no significant difference between the 90% MeOH fraction and positive control, showing that the hydrophobic fraction has QSI activity. The statistical analyses were performed using R2.8.0

Table 2 Parameters from linear regression analysis of QSI data from Fig. 4c and d[a]

Sample	Slope (STD)	Intercept (STD)	R^2
Flow through	678.7 (20.1)	−21,593.9 (3,170.1)	0.95
Negative control	729.0 (32.9)	−26,314.2 (3,540.0)	0.96
Positive control	567.7 (33.6)	−24,444.3 (3,615.1)	0.94
Prefractionation	579.3 (19.7)	−18,866.7 (2,119.2)	0.98
Reconstituded	553.0 (22.5)	−17,641.0 (3,352.4)	0.94
50% MeOH	616.4 (20.3)	−22,427.2 (3,349.5)	0.94
90% MeOH	535.2 (16.4)	−19,133.7 (3,107.7)	0.95

[a] All fits had P values <0.001.

be explained by several of the polar compounds in Table 1. In order to demonstrate that chemotaxis and QSI are caused by different chemicals, we fractionated young adult *C. elegans* exudates with a C18 solid phase extraction column (Srinivasan et al. 2008) and tested the activities of flow through as well as the 50% and 90% methanol (MeOH) fractions. The flow through contains polar compounds like many amino acids, organic acids, and sugars, which are known bacterial attractants, while the 50 and 90% MeOH fractions contain more hydrophobic compounds. Figure 4a shows that both *P. aeruginosa* (PAO1) and *P. putida* (KT2440) chemotax robustly to the flow through, less to the 50% MeOH, and very little to the 90% MeOH fractions. This is consistent with the literature on bacterial chemotaxis.

To test exudate fractions for QSI activity, we used a reporter system that could be more easily quantified and adapted to high-throughput testing than the assay used in Fig. 3b. In the assay shown in Figs. 4b, c, and d, fluorescence from the green fluorescent protein (GFP) was monitored as a function of time in a 96 well plate format. If no QSI inhibitor is present, the GFP fluorescence is maximal, and QSI inhibitors will reduce the intensity (Andersen et al. 2001). The QSI data shown in Fig. 4 were normalized to the overall cell growth monitored by the optical density at 450 nm to account for any general effects that the tested compounds have on *E. coli* cell growth. Figure 4b shows a complete time course that starts with a lag phase to about 40 min, is linear in GFP fluorescence from 40 to about 160 min, and remains stable after 160 min. Figures 4c and d are linear fits from 40 to 160 min of control (4C) and *C. elegans* flow through and 90% MeOH (4D) samples. The linear fitting parameters and correlation coefficients (R^2) and the slopes for all samples assayed in Fig. 4b are shown in Table 2, and P value comparisons of QSI activity between each sample are shown in Table 3.

The negative control (water) and *C. elegans* flow through fractions were similar (P=0.5; Table 3), demonstrating that the flow through has no QSI activity. The positive control (12.5 μM 4-nitropyridine N-oxide) and 90% MeOH fractions were also similar (P = 0.3), and the 90% MeOH fraction was distinct from both the negative control and flow through (P<0.001). These results demonstrate that the QSI activity results from a non-polar compound(s), in contrast to the polar flow through compounds that are responsible for bacterial chemotaxis. The 50% MeOH fraction has intermediate QSI activity (Tables 2 and 3). We also compared exudates before fractionation, and we reconstituted after fractionation to verify that the C18 column did not degrade or irreversibly bind to the compound responsible for the QSI activity, and these both are significantly different from the negative control (P < 0.001) (Tables 2 and 3).

Discussion

We have shown that *C. elegans* releases a variety of sugars, organic acids, and amino acids into its environment (Table 1) and that the concentrations of the amino acids are dependent upon development. Many of these compounds also are found in the exudates of other organisms including bacteria (Park et al. 2003; Zahradníčková et al. 2007), fungi (Singh and Arora 2001), and several species of

Table 3 The *Caenorhabditis elegans* flow through has no QSI activity, and the 90% MeOH fraction has similar activity to the 12.5μM 4NPO positive control

	NC	PC	Pre	Rec	50% MeOH	90% MeOH
Flow through	5.10E-01	<0.001	<0.001	<0.001	<0.001	<0.001
Negative Control (NC)		<0.001	<0.001	<0.001	<0.001	<0.001
Positive Control (PC)			<0.001	1.27E-02	<0.001	3.17E-01
Prefractionation (Pre)				5.43E-01	6.79E-01	4.56E-03
Reconstituted (Rec)					1.19E-01	3.97E-02
50% MeOH						<0.001

[a] The entries are P values, and numbers greater than 0.05 indicate that the two samples are not statistically different. The highlighted boxes show that the *Caenorhabditis elegans* flow through has no QSI activity and that the 90% MeOH fraction has similar activity to the 12.5 μM 4NPO positive control.

plants (Lugtenberg et al. 1999; Bacilio-Jiménez et al. 2003; Kamilova et al. 2006; Kumar et al. 2007). Additionally, many plant root exudates, and fungal or bacterial exudates attract bacteria (Bacilio-Jiménez et al. 2003; Kumar et al. 2007; Lugtenberg et al. 1999; Singh and Arora 2001; Park et al. 2003). Given their chemical composition, it was not surprising that *C. elegans* exudates examined in this work attracted bacteria. Previous experiments have shown that *C. elegans* enhance the growth of *Pseudomonas fluorescens* and *Bacillus subtilis* (Huixin et al. 2001). This suggests a hypothesis that *C. elegans* plays an active role in soil chemical ecology and may have evolved chemical systems for attracting and promoting growth of its own food source. Relatively little is known about the range of bacterial species that *C. elegans* eats in its native environments (Avery and Shtonda 2003; Shtonda and Avery 2006), so the hypothesis of "bacterial farming" by *C. elegans* remains to be tested. It should be noted that we investigated only water-soluble compounds that are released from the worms, and other compounds may interact with the hydrophobic cuticle or may be volatile.

If *C. elegans* non-specifically attracts bacteria, it is possible that pathogenic species have evolved to take advantage of this otherwise beneficial survival mechanism. Depending on the bacterial composition in a particular environment, one might predict that *C. elegans* would also need, therefore, to employ some sort of defense against pathogens or colonize soil patches that are devoid of pathogens. However, we were unable to detect any *C. elegans* antibacterial activity against the pathogenic bacterium *P. aeruginosa*, despite the fact that this same pathogen was attracted to *C. elegans* exudates. Since *P. aeruginosa* is resistant to many antibiotics (Stover et al. 2000), we cannot completely rule out the possibility that *C. elegans* produces antibacterial compounds, or that antibacterial compounds might be present in the intestine or on the cuticle of the nematode rather than released. Even though the data and literature are best explained by the absence of antibacterial compounds in *C. elegans* (Huixin et al. 2001), a result that is ecologically consistent with a bacterivorous nematode, this does not eliminate the possibility that *C. elegans* may have an inducible system to produce antibacterial activity.

Many pathogenic bacteria, including *P. aeruginosa*, regulate virulence through quorum sensing (Bjarnsholt and Givskov 2007; Dong et al. 2007), and *P. aeruginosa* (PAO1) is lethal to *C. elegans via* a toxin produced through the *LasR* QS system (Darby et al. 1999). Many species of bacteria, fungi, and plants employ a variety of mechanisms that inhibit bacterial QS, including enzymatic degradation of QS signaling molecules and direct inhibition (Walker et al. 2004; Bais et al. 2005; Dong et al. 2007). We showed that *C. elegans* exudates inhibited a *LuxR* QS system that was derived from *Vibrio fischeri*. However, the worm exudates did not affect common biomarkers of QS in *P. aeruginosa* (PAO1), the production of elastase and protease, and they had only a small influence on pyocyanin production (Supplementary Fig. S1). The *C. elegans* QSI activity appears developmentally regulated with maximal activity at the young adult stage. Perhaps *C. elegans* has evolved a mechanism by which it can avoid infection by certain pathogenic species of bacteria without employing antibiotics. These results are consistent with the observations that *C. elegans* exudates attract several bacterial species, as the QSI activity would provide the nematodes with a chemical defense without killing their food source.

In summary, *C. elegans* releases many common small molecules that can modulate its environment, and many of these compounds are developmentally regulated. These compounds may play important roles in the ecology of *C. elegans* in its natural habitat. Our data suggest that these molecules can provide a means for the worms to interact with bacterial food sources and potentially to defend against bacterial pathogens. It remains an open question whether the bacterial chemoattractants or quorum sensing inhibitor(s) are evolutionary adaptations or are byproducts of another process, such as metabolism. The identification of the QSI will help address this question and may open up new areas of research into the chemical ecology of nematodes.

Acknowledgement Funding was provided through the Human Frontier Science Program (ASE), the NIH (1R01GM085285-01 to ASE), the NSF (MCB-0429968 to SR), and the NSF funded National High Magnetic Field Laboratory (DMR-0654118). We thank Dr Michael Givskov for providing the GFP-based AHL sensor system and QSIS1 reporter system. We thank Drs. Paul Sternberg and Jagan Srinivasan for helping to establish biological activity of worm water and Drs. David Powell, Mario de Bono, Frank Schroeder, and Peter Teal for helpful ideas in the worm water protocol and Alex K. Brasher for his help collecting worm exudates. NMR data were collected in the University of Florida AMRIS Facility, and we thank Jim Rocca for his help with NMR data collection and interpretation.

RAPID COMMUNICATION

Identification of Secretory Compounds from the European Callipodidan Species *Apfelbeckia insculpta*

Božidar P. M. Ćurčić · Slobodan E. Makarov · Vele V. Tešević · Milka B. Jadranin · Ljubodrag V. Vujisić

Received: 2 July 2009 / Revised: 26 July 2009 / Accepted: 30 July 2009 / Published online: 19 August 2009

Abstract Defensive secretions of the callipodidan species *Apfelbeckia insculpta* contain a *p*-cresol as the main component and phenol in traces. This is the first identification of these compounds in a European callipodidan species. The repugnatory glands of *A. insculpta* are of the spirobolid type and consist of a spherical reservoir, a simple duct, and a valvular cuticular infolding that opens onto the lateral surface of the millipede via a pore.

Keywords Defensive secretion · Callipodida · *Apfelbeckia insculpta* · *p*-cresol · Phenol · Diplopoda

Introduction

Defense glands are present in all millipedes except for Penicillata, Sphaerotheriida, Chordeumatida, and Glomeridesmida (Hopkin and Read 1992; Shear et al. 2007). Julida, Spirostreptida, and Spirobolida were called by Eisner et al. (1978) "quinone millipedes" due to the universal presence of quinones in their defensive fluids. The orders Spirobolida and Spirostreptida emit secretions that contain mainly 1,4-benzoquinone and hydroquinone derivatives (Omura et al. 2002). The order Polydesmida was called by Eisner et al. (1978) a "cyanogenic order" because it includes millipedes that produce hydrogen cyanide, benzaldehyde, and mandelonitrile (Omura et al. 2002). Mandelonitrile is considered to be a biogenetic precursor of benzaldehyde and hydrogen cyanide. Some polydesmidan species also emit phenol derivatives (Blum et al. 1973; Duffey et al. 1977). Secretions from representatives of the orders Glomerida and Polyzoniida contain characteristic alkaloids (Omura et al. 2002). There are only a few published data concerning defensive secretions in members of the order Callipodida (Eisner et al. 1963; Shear et al. 2007).

The order Callipodida Bollman 1893 contains a wide variety of disjunct forms probably with relict status. The given order comprises three suborders (Sinocallipodidea Shear 2000; Callipodidea Pocock 1894; and Schizopetalidea Hoffman 1973), seven families, 35 genera, and 133 (sub-) species (Stoev et al. 2008). According to published data, a defensive secretion has been documented only in three callipodidan species found in the Southern Appalachians in the United States—*Abacion magnum* (Loomis 1943), *Tetracion jonesi* Hoffman 1956, and *Delophon georgianum* Chamberlin 1943—belonging to the suborder Schizopetalidea and family Abacionidae Shelley 1979 (Shear et al. 2007). These three species produce only *p*-cresol as a defensive secretion (Shear et al. 2007).

There is no published report of defensive secretions in European callipodidans. For these reasons, we focused our research on the species *Apfelbeckia insculpta* (L. Koch 1867), which belongs to the genus *Apfelbeckia* Verhoeff

1900, suborder Schizopetalidea and family Schizopetalidae Verhoeff 1909. This species is troglophilic (distributed on the Balkan Peninsula), and when disturbed emits a secretion with a strong smell of cresols. The present study represents the first attempt to clarify the chemical composition of the secretion in a European callipodidan species.

Methods and Materials

Millipedes of the species *Apfelbeckia insculpta* at subadult and adult stages were collected in March of 2008 from two caves in Western Serbia: Hadži-Prodanova Pećina Cave, village of Raščići, near Ivanjica; and Mlađenovića Megara Cave, village of Stapari, near Užice. The collected millipedes were sexed (five males, five females, and five juveniles from both localities) and separated in plastic dishes (20 cm diam×10 cm in height) with cave substrates. The millipedes were kept in the laboratory for a few days at 10°C in darkness under humid conditions created by spraying water every day.

For collection of defensive secretions, each millipede was soaked individually in methanol (1 ml) for 3 min. The methanol extract was removed by decantation and filtered through a 0.45 μm poly-tetrafluoroethylene (PTFE) filter (Agilent Technologies). To eliminate the effects of composition-altering oxidation and degradation of compounds, a portion of the extracts was subjected to GC-MS analysis immediately after preparation.

The GC-MS analyses were performed on an Agilent Technologies 5975C mass spectrometer coupled with a 7890A gas chromatograph by using an HP-5 MS capillary column (Agilent Technologies, 0.25 mm I.D.×30 m, 0.25 μm film thickness) under programmed conditions of temperatures that were varied from 60°C to 290°C at a rate of 10°C/min with an initial 2-min hold. Samples were injected using a splitless mode at 240°C and He as the carrier gas (constant flow, 1 ml/min). Mass spectra were obtained by electron ionization at 70 eV, the ion source temperature being 230°C.

Results

Gas chromatography-mass spectrometry (GC-MS) of the methanol extracts in all specimens (males and females, as well as juveniles) of *A. insculpta* from both localities showed two volatile compounds, *p*-cresol as the main component and phenol in traces. These compounds were identified by comparison of mass spectra in the NIST MS Search 2.0 computerized mass spectral library and confirmed by comparison with the retention time (t_R) and mass spectra of authentic standards.

Discussion

Apfelbeckia insculpta possesses a pair of repugnatorial glands on each of the pleurotergites. Only the first five pleurotergites and the last one (or two) are devoid of glands. The defense glands consist of a spherical sac or reservoir that contains secretory cells, a simple duct, and a valvular cuticular infolding that opens onto the lateral surface of the millipede via a pore (Fig. 1). The same type of repugnatorial gland was found in the callipodidan species *Abacion magnum* (Eisner et al. 1963) (the authors assigned the genus *Abacion* to the group of 'chordeumoid' millipedes; it belongs to the order Callipodida). This type of gland also is present in millipedes of the orders Spirobolida, Spirostreptida, Julida, Platydesmida, and Polyzoniida (Hopkin and Read 1992) and is classified as the spirobolid type. During collection, we observed that when disturbed, *A. insculpta* coils up into a tight spiral, keeping its head in the center. If further disturbed, the millipede discharges a defensive secretion. A second type of glands in millipedes (the polydesmid type) consists of a reservoir, duct, vestibule, and external opening. This type is characteristic of the order Polydesmida (Hopkin and Read 1992).

p-Cresol has been reported previously from three callipodidan species, viz., *Abacion magnum*, *Tetracion jonesi*, and *Delophon georgianum* (Abacionidae) (Shear et al. 2007). We found it in methanol extracts of a schizopetalid species, *A. insculpta*. Such a finding supports the idea (Shear et al. 2007) that from the known chemical composition of defensive secretions in these millipedes,

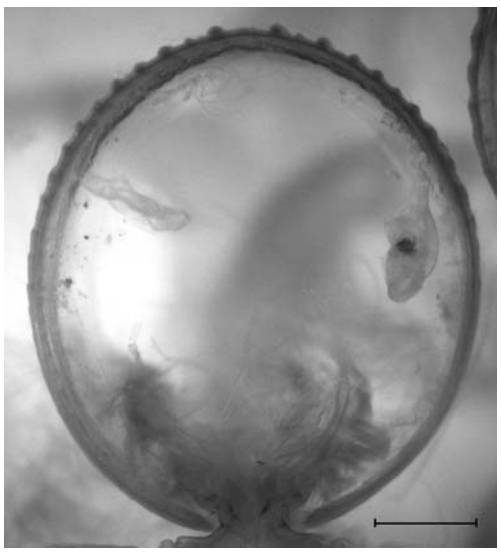

Fig. 1 Defense glands in one midbody pleurotergite in a male of *Apfelbeckia insculpta* (L. Koch 1867) from Hadži-Prodanova Pećina Cave, village of Raščići, near Ivanjica, Serbia, anterior view. Scale line=2 mm

p-cresol is probably the main characteristic secretion of all callipodidans. Apart from Callipodida, *p*-cresol is found also in millipedes of the order Polydesmida and in parajulid julidan *Oroiulus venustus* (Wood) (Eisner et al. 1978; Shear et al. 2007).

Little information is available regarding natural predators of *A. insculpta*. However, unlike almost all other millipedes, *A. insculpta* is a predator that feeds on earthworms, flies, spiders, and centipedes (Hoffman and Payne 1969). In the analyzed cave systems, the number of potential predators of adult specimens of this species is limited. Only early postembryonic stages may be a target of some spiders or carabids inhabiting the same caves from which *A. insculpta* was collected. On the other hand, cave systems represent an important shelter ensuring relatively safe reproduction (this is supported by the fact that in both cave systems studied, we found almost all postembryonic stages of *A. insculpta*).

On the basis of the aforementioned facts, we suggest that *p*-cresol in *A. insculpta* functioned as a defensive allomone. *p*-Cresol is known to be an effective repellent of ants and probably other insects (Eisner et al. 1978). It also repels lizards, jays, and grasshopper mice (Eisner et al. 1963), and may damage the potential predator. It may be important during the early postembryonic development of *A. insculpta*, as well as in adult stages if they ever leave the cave shelter. Furthermore, it is known that *p*-cresol and phenol exert antifungal activity by suppressing mycelia growth and spore germination (Roncadori et al. 1985). It is important in connection with this that in both cave-systems during collection of specimens, we registered abundant fungal populations. Other potential roles of *p*-cresol (chemical messenger or pheromone) will be the subject for further investigation.

Acknowledgments The present study was supported by the Ministry of Science and Technology of Serbia (Grants Nos. 143053 and 142053).

Sensory Imbalance as Mechanism of Orientation Disruption in the Leafminer *Phyllocnistis citrella*: Elucidation by Multivariate Geometric Designs and Response Surface Models

Stephen L. Lapointe · Lukasz L. Stelinski · Terence J. Evens · Randall P. Niedz · David G. Hall · Agenor Mafra-Neto

Received: 24 March 2009 / Revised: 22 June 2009 / Accepted: 26 July 2009 / Published online: 11 September 2009

Abstract Experimental designs developed to address mixtures are suited ideally to many areas of experimental biology, including pheromone blend studies, because such designs address the confounding of proportionality and concentration intrinsic to factorial and one-factor-at-a-time designs. Geometric multivariate designs coupled with response surface modeling allowed us to identify optimal blends of a two-component pheromone for attraction and trap disruption of the leafminer moth, *Phyllocnistis citrella*, a major pest in citrus growing areas around the world. Field trials confirmed that the natural 3:1 blend of (*Z,Z,E*)-7,11,13-hexadecatrienal:(*Z,Z*)-7,11-hexadecadienal was most effective as an attractant for male moths. However, the response surface generated in mating orientation trials revealed that the triene component alone was more effective than the natural blend in disrupting trap catch. Each individual component was effective at disrupting orientation in field trials, but (*Z,Z,E*)-7,11,13-hexadecatrienal was approximately 13 times more effective, at the same concentration, compared with (*Z,Z*)-7,11-hexadecadienal alone. In addition, the application of geometric design and response surface modeling to field studies provided insight into a possible mechanism of mating disruption and supported sensory imbalance as the operating mechanism for this species.

Introduction

Many insects, particularly moths, rely upon pheromonal communication for recognizing and locating potential mates (Cardé and Minks 1995). Although some species use a single compound as a sex pheromone (Novak and Roelofs 1985), most deploy a blend of compounds in species-specific ratios. The production of synthetic sex pheromones to disrupt mating in insect pest species has become a sizeable industry that contributes to a reduced reliance on insecticides in integrated crop protection strategies. Synthetic sex pheromones for mating disruption of crop pests are used on an estimated 662,000 ha of land worldwide (Witzgall et al. 2008).

At least two general models have been proposed to explain the mechanism by which treatment of crops with sex pheromones results in disruption of sexual communication and subsequent reduction in population densities. Competitive models suggest that sources of synthetic

pheromone compete with calling females. Under this scenario, disruption occurs when males follow false plumes and are, therefore, unable to locate females (Miller et al. 2006a). Non-competitive models hold that permeation of the air space with synthetic pheromone interferes with perception of the female's signal by camouflage, desensitization, and/or sensory imbalance (Miller et al. 2006a). Experimental approaches for distinguishing competitive from non-competitive disruption have been proposed based on transformations of moth catch data in traps as a function of pheromone dispenser density per unit area of crop (Miller et al. 2006a, b).

While it is generally understood that proportionalities of multi-component pheromone blends are important in insect attraction, it is not clear whether mating disruption is best achieved by using the natural pheromone blend or some other "unnatural" ratio (Minks and Cardé 1988). The development of mating disruption technology remains largely an empirical process of testing blends and concentrations (Cardé 1990).

Studies of blends, in general, and pheromone blends in particular, often confound the effects of proportionality and amount by allowing them to vary in parallel [cf. Evens and Niedz (2008) for a discussion on confounding in proportion-amount experimental designs]. Distinguishing between proportionality and concentration effects requires a special design known as a "mixture-amount" experiment (Cornell 2002), wherein proportionality and concentration are treated independently. In addition, commonly applied experimental designs such as factorial or one-factor-at-a-time approaches are either inherently confounded or fail to explore the experiment's design space adequately. For rational development of mating disruption technology, an experimental approach is required that distinguishes between proportion and amount, efficiently allocates treatments through a potentially complex multidimensional design space, and accounts for complex interactions between variables in multi-component pheromone systems.

The leafminer, *Phyllocnistis citrella* Stainton (Lepidoptera: Gracillariidae), is a major pest of citrus throughout the world (Heppner 1993). Larvae feed within leaves, producing serpentine mines that result in distortion and loss of photosynthetic capacity, thereby reducing yield (Peña et al. 2000). In addition to direct damage, mining by *P. citrella* increases the susceptibility of citrus leaves to infection by citrus canker, *Xanthomonas axonopodis* pv. *citri*, an important disease of citrus (Gottwald et al. 2007). Our interest was to determine optimal pheromone blends for attraction and mating disruption and to gain insight into the mechanism of disruption for control of *P. citrella* through application of appropriate experimental design. We used mixture-amount designs to quantify optimal pheromone blends and concentrations for both attraction to traps and orientation disruption in a series of field experiments conducted in Florida citrus groves. We believe the methods employed here to be of wide applicability, within this field and many other fields of biological inquiry, in which responses to proportion and amount of mixture components are measured.

Methods and Materials

Pheromone Synthesis

(*Z,Z,E*)-7,11,13-Hexadecatrienal and (*Z,Z*)-7,11-hexadecadienal (referred to also as triene and diene, respectively) were synthesized by ISCA Technologies Inc. Riverside, CA, USA, as previously described (Leal et al. 2006; Moreira et al. 2006), resulting in (*Z,Z,E*)-7,11,13-hexadecatrienal of 94% chemical purity (90% isomeric purity) and (*Z,Z*)-7,11-hexadecadienal of 86% chemical purity (72% isomeric purity).

Attraction Trial

Red, 11-mm natural rubber septa (West Pharmaceutical Services Co., Lionville, PA, USA) were loaded with hexane solutions (100 µl) of test blends of *P. citrella* sex pheromone, to yield 23 treatments consisting of varying proportions and amounts of the triene and diene (Fig. 1a). Thirteen of the treatments were replicated twice to estimate pure error. Blend proportion varied from 100% triene to 100% diene, and the amount of blend loaded onto each septum varied from 0.01 to 1.0 mg. Individual septa containing the pheromone blends were placed in traps (Pherocon VI, Trécé, Inc., Adair, OK, USA), with sticky card liners, and randomly assigned to field locations within a 12 ha mature production block of Duncan grapefruit trees, near Ft. Pierce, FL, USA, on 22 May 2008. Traps were placed at 45 m intervals within rows, with three traps per row. Rows with traps were separated (45 m) by six rows without traps. Adhesive liners were replaced and examined for the presence of *P. citrella* 24 h after deployment and weekly thereafter.

Disruption Trial

A commercial emulsified-wax matrix designed to provide slow release of semiochemicals (SPLAT^{TM}, ISCA Technologies) was formulated with varying proportions and amounts of (*Z,Z,E*)-7,11,13-hexadecatrienal and (*Z,Z*)-7,11-hexadecadienal. Proportions varied from 100% triene to 100% diene, and amount varied from 0.02 to 2.0 g/kg (0.002 to 0.2%) of formulated SPLAT (Fig. 1b) for a total of 17 proportion/amount combinations in separate plots and 3 control plots (no SPLAT). Eight of the treatments

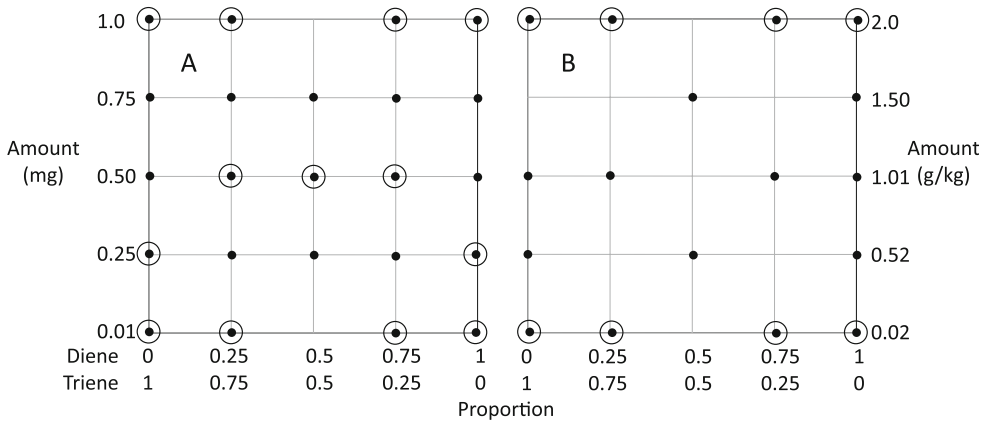

Fig. 1 A: Mixture/amount experiment design space showing 23 design points, consisting of varying ratios and amounts of (*Z,Z,E*)-7,11,13-hexadecatrienal (triene) and (*Z,Z*)-7,11-hexadecadienal (diene), to assess response of *Phyllocnistis citrella* males to pheromone-baited traps in a Florida citrus grove. The thirteen circled points were replicated twice for a total of 36 proportion-amount combinations (runs). B: Design space containing 17 design points, of varying ratios and amounts of triene and diene, to assess response of *P. citrella* males to pheromone-baited traps within 0.2 ha plots treated with a slow-release pheromone delivery system (SPLAT®) in a Florida citrus grove. The eight circled points were replicated twice for a total of 28 runs

were replicated twice to estimate pure error. SPLAT treatments and controls were randomly assigned to 0.2 ha plots of 77 trees (7 rows x 11 trees/row), equally spaced within a 24-ha mature production block of Duncan grapefruit trees, near Ft. Pierce, FL. SPLAT treatments were applied on 23 April 2008 using hand-held applicators calibrated to deliver 1 g dollops. Point source density and concentration were based on results previously reported for the 3:1 triene:diene blend (Stelinski et al. 2008). Within plots, each tree received 3 dollops of SPLAT at approximately a 1.5 m height. Perimeter trees received 4 dollops.

Trap shutdown, the disruption of male catch in traps baited with synthetic lures containing the natural blend of sex pheromone, was employed to quantify disruption. To measure trap shutdown, two Pherocon VI traps, each baited with a single rubber septum (West Pharmaceutical Services Co., Lionville, PA, USA) loaded with 130 µl of a hexane solution containing 130 µg of a 3:1 blend of (*Z,Z,E*)-7,11,13-hexadecatrienal and (*Z,Z*)-7,11-hexadecadienal, were placed in the center row of each plot equidistant from each other and the plot perimeter (trees 4 and 8 in rows of 11 trees each). Lures were deployed in traps on 23 April 2008 and replaced weekly.

Experimental Design

D-Optimality criteria were used to minimize the number of factor/component combinations necessary to provide accurate estimates of the coefficients of a quadratic x quadratic Scheffé polynomial model (Cornell 2002; Box and Draper 1971). Specifically, sufficient treatments or 'design points' (Fig. 1) were selected with Design Expert® software (v7.0.3, Stat-Ease, Inc. Minneapolis, MN, USA) such that the determinant of the $(X'X)^{-1}$ matrix was minimized; this has the net result of minimizing the volume of the confidence ellipsoid for the coefficients of the selected model (Piepel 1982). Several design points were added to estimate the lack of fit (LOF) between the response surface models and design points not used to generate the model fits (Weisberg 1985). A number of treatments were duplicated in order to: 1) attain sufficient degrees of freedom (df) to estimate pure error across the design space; 2) provide estimates of block effects; and 3) reduce the potential effect (s) of high leverage points. In all, there were 36 runs (proportion-amount treatments) for the attraction study and 25 runs for the disorientation study.

Statistical Analyses

A detailed description of the statistical methods used to analyze the data can be found in Lapointe et al. (2008). Briefly, all possible models from the mean to cubic polynomial were calculated with Design Expert® v.7.0.3. Initial model selection was based on a battery of adequacy tests (Anderson and Whitcomb 2005). Normality and constant variance were determined graphically; a Box-Cox plot was used to choose the correct transformations (Box and Cox 1964). Overly influential data points were identified with DFFITS and DFBETAS plots (Belsley et al. 1980). Adequate model precision was determined by comparing the range of predicted values at design points ($\hat{y}$) to the average variance (V-bar) of the prediction (Anderson and Whitcomb 2005). Potential outlier points were checked with externally studentized "outlier-t" (Weisberg 1985; Myers 1990) and Cook's Distance (Cook and Weisberg

1982) graphical plots. R^2, adjusted-R^2 (R_{adj}^2), and predicted-R^2 (R_{pred}^2), were estimated for each selected model [cf. Myers and Montgomery 2002)].

Test of High Diene SPLAT Disruptant

An estimated relative cost of synthesis of the diene and triene provided by ISCA Technologies was included in a model of results from the disruption trial. The resulting plot suggested that diene alone, if deployed at a much higher concentration, might function as a disruptant of trap catch as well as the triene alone. Therefore, a separate field trial was conducted in October 2008 to test the efficacy of a high concentration of the diene component for disrupting trap catch compared with the triene-only treatment identified as optimal in the disruption trial. Plots (0.2 ha) in a mature citrus grove were as described above for the disruption trial. SPLAT formulations consisted of 2.0 and 20.0 g/kg of diene, and 1.5 g/kg of triene. Four replicates of each of the three SPLAT treatments were applied on 3 October 2008. Four replicates with no SPLAT were included as controls. Two traps baited with the natural 3:1 blend were deployed in the center of the plots to assess trap shutdown as described above. Counts of trap liners were conducted every 3 to 4 d for a period of 26 d. Linear regression was used to describe the percent disruption of trap catch obtained in the treated plots compared with the control plots.

Results

Attraction Trial

There were no significant models that included amount of (*Z*,*Z*,*E*)-7,11,13-hexadecatrienal and (*Z*,*Z*)-7,11-hexadecadienal on capture of male moths (*P*-values ranged from 0.07 to 0.91). Therefore, amount effects were averaged across this dimension, which resulted in a highly significant (*P*-value <0.001) cubic x mean polynomial response surface model (RSM) for the number of male moths captured in pheromone-baited traps (Table 1; Fig. 2). Data were transformed (1/sqrt) based on the best lambda value from the Box-Cox plot [see Lapointe et al. (2008) for complete statistical methods]. The three R^2 statistics (R^2, R_{adj}^2 and R_{pred}^2) were ≥0.92. The greatest trap catch was obtained at a 3:1 triene:diene pheromone blend. "Pure" blends consisting of various amounts of the diene component alone were not attractive. While pure blends of triene showed some attraction (6% of the maximum 3:1 blend), trap catch decreased markedly as the lure blend diverged from the 3:1 ratio (Fig. 2) in either direction of the blend ratios.

Disruption Trial

The disruption trial produced a highly significant (*P*-value <0.001) linear x linear polynomial RSM (Table 1; Fig. 3) for trap shutdown, calculated as trap catch expressed as a percent of the control (no SPLAT pheromone applied). There was a highly significant interaction between triene proportion and amount, and also a significant interaction between diene proportion and amount (Table 1). No significant blending effect between diene and triene was observed; the highest level of trap shutdown occurred with pure triene (Fig. 3).

Test of High Diene SPLAT Disruptant

The high concentration of diene in SPLAT contained 40x the amount of diene in the highest concentration of the natural 3:1 blend tested in the disruption trial. Percent trap shutdown obtained in plots treated with the high concentration of diene (20 g/kg) and triene (1.5 g/kg) was similar (Fig. 4). The high diene treatment resulted in 89% reduction of moth catch in traps relative to untreated control plots over the 26 d duration of the trial. The 0.15% triene treatment resulted in an 83% reduction over the same period.

Discussion

Experimental designs developed to study mixtures (Cornell 2002) are ideally suited for pheromone blend studies. An inherent difficulty in quantifying main effects and interactions of mixture components is the confounding effects of proportionality and concentration, intrinsic to traditional factorial experimental designs. Confounding occurs when two or more quantities are varied together in a manner that makes it mathematically impossible to identify their unique effects (Evens and Niedz 2008). To overcome this, blends can be conceptualized as mixtures in which the sum of the component proportions is one. Because of the proportionality constraint, the resulting experimental design space has *n*-1 dimensions. The addition of one additional dimension to account for amount completes the design space. For example, the two-component pheromone system of *P. citrella* requires only a two-dimensional design space, one dimension for the mixture (i.e., ratio) of the two components, and one dimension for amount. Current computer hardware and software make it possible to design, execute, and analyze efficient experiments that systematically sample multidimensional experimental design space and generate mathematical equations that describe response variables across the entire design space with a minimum number of runs. Such an approach is more cost effective

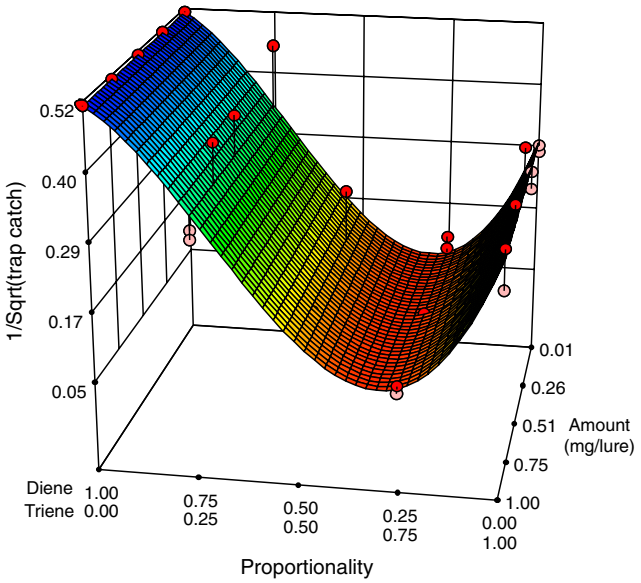

Fig. 2 Three-dimensional plot of the inverse of the square root of number of male *Phyllocnistis citrella* moths caught in pheromone-baited traps at two weeks after deployment, as a function of pheromone component proportionality and total pheromone amount. Greatest trap catch was achieved with the natural 3:1 ratio of (*Z,Z,E*)-7,11,13-hexadecatrienal (triene): (*Z,Z*)-7,11-hexadecadienal (diene)

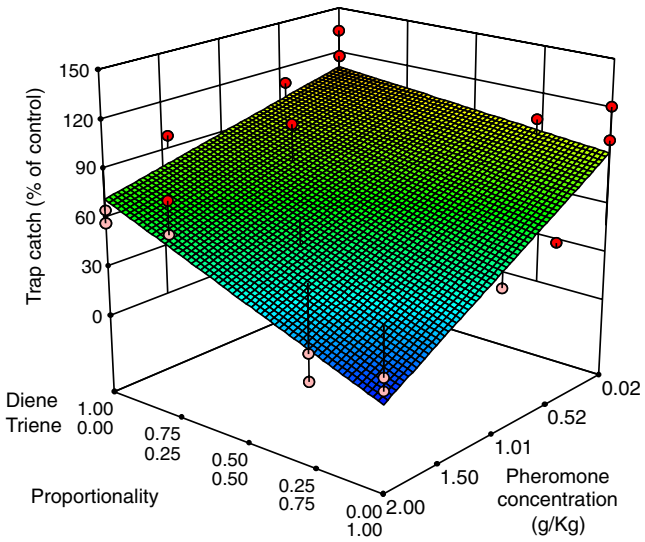

Fig. 3 Three-dimensional plot of trap catch within disruptant-treated plots expressed as percent of control trap catch at two weeks after deployment of SPLAT treatments. The lowest number of male *Phyllocnistis citrella* were captured in traps [baited with a 3:1 (*Z,Z,E*)-7,11,13-hexadecatrienal (triene): (*Z,Z*)-7,11-hexadecadienal (diene) lure] in plots treated with (*Z,Z,E*)-7,11,13-hexadecatrienal

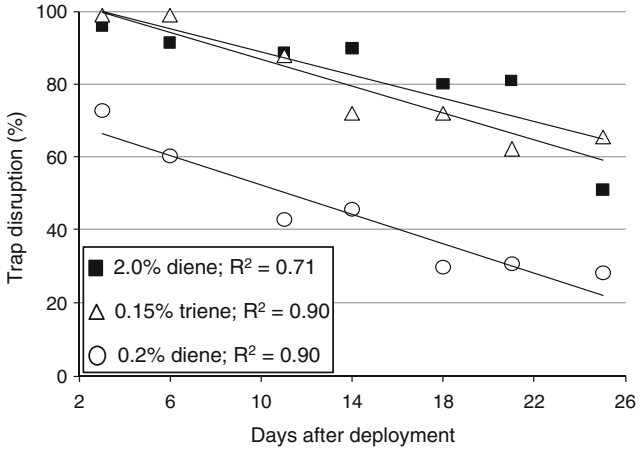

Fig. 4 Decay of trap disruption (%) over time of three SPLAT formulations containing single pheromone components: (*Z,Z*)-7,11-hexadecadienal (diene) or (*Z,Z,E*)-7,11,13-hexadecatrienal (triene). Disruption of trap catch was measured as the number of male *Phyllocnistis citrella* captured in traps baited with a 3:1 triene:diene lure in plots treated with a disruptant (diene or triene) expressed as a percent of the trap catch in the control plots

than traditional factorial designs (Lapointe et al. 2008) and, in the case of pheromone studies, can contribute insight into underlying mechanisms associated with mating disruption. Geometric multivariate approaches to mixture problems have wide applicability for experimental biology, as recently shown for insect diets (Lapointe et al. 2008), studies of ion-specific effects (Evens and Niedz 2008), and plant growth media (Niedz and Evens 2008).

Studies of disruption of moth species using various blends and concentrations of pheromone components, in general, have incompletely sampled experimental space defined by proportionality and amount (Charlton and Cardé 1981; Bellas and Bartell 1983; Flint and Merkle 1983; Moreira et al. 2006). We suggest that a more complete picture of the role of individual pheromone compounds in blends and their interactions, and important insight into mechanisms of mating disruption, can be obtained through use of non-confounded designs. Moreover, this approach minimizes the number of runs required in expensive and labor-intensive field trials that often are limiting for product development.

The natural ratio of two sex pheromone components (3:1 triene:diene) of *P. citrella* (Leal et al. 2006; Moreira et al. 2006) is a potent attractant in the field (Lapointe et al. 2006). In our study, attraction of males to baited traps declined markedly as the blend ratio departed from this natural ratio, with little interaction between proportion and amount (Fig. 2). Our geometric design surveyed the experimental space and produced a response surface that confirmed the work of Moreira et al. (2006) that the 3:1 blend is optimal for attraction at least over the release rates employed in this study.

The response surface generated in the disruption trial, however, was markedly different from that of the attraction trial. The straight line described by the response surface, corresponding to the highest pheromone concentration (0.2%) and X1-X2 axis (Fig. 3), demonstrated that trap shutdown increased in direct proportion to concentration of the triene with no synergistic or antagonistic blending effects between diene and triene. This lack of blending in the disruption trial suggests that an unnatural ratio consisting of one or the other of the single components could be as effective as the natural blend for mating disruption. This, together with the general lack of congruence between response surfaces, supports the conclusion of Stelinski et al. (2008) that disruption in this species is a non-competitive phenomenon.

The linear response of trap catch of *P. citrella* to individual components in binary blends deployed as disruptants may be analogous to the disorientation thresholds that define the "attraction area" according to the threshold hypothesis for pheromone perception proposed by Roelofs (1978). By applying Roelofs' "attraction area" concept to *P. citrella*, our results suggest that changes in binary proportions, away from the natural blend ratio, would produce a disorientation line with a steep slope for the diene and a much smaller slope for the triene. Considered this way, the amount of diene required to achieve disruption would be much greater than the amount of triene required, as demonstrated. Roelofs' threshold diagrams predict that, for species that utilize a binary pheromone mixture for upwind orientation, the natural blend should be most effective at low concentrations. Therefore, we might expect mating disruption to be more effective at lower release rates of the binary blend compared with either component alone. Our results with *P. citrella* do not support this extrapolation, at least within the concentrations tested in our investigation. Disruption, as measured in our field tests by reduced trap catch (Fig. 3), did not decline at low pheromone concentrations as the proportionality of the disruptant moved from the natural ratio to pure triene.

Under the competitive theory of mating disruption, males are predicted to follow false plumes associated with pheromone dispensers (Miller et al. 2006a). If disruption is non-competitive, no such orientation occurs. Typically, direct observation of male orientation to pheromone dispensers in the field is required to determine attraction. However, the response surfaces for *P. citrella* for attraction and disruption (Figs. 2, 3) demonstrate visually that the single triene component was equal to or greater in disruptive ability compared to the natural blend, even though males were not attracted to either component (diene or triene) singly. Effective trap shutdown was obtained with the natural blend (0.02%), the triene alone (0.015%), and

the diene alone (0.2%). Males of *P. citrella* were not attracted at close range in the field to SPLAT treatments that contained the natural blend or single component applications of SPLAT (LS, personal observation).

Therefore, our data suggest that disruption of male *P. citrella* occurred by a non-competitive mechanism (Stelinski et al. 2008). The non-competitive mechanisms of mating disruption are camouflage, desensitization, and sensory imbalance, as defined by Bartell (1982). Our data indicate that the 3:1 blend was highly attractive to males at a release rate approximating a female, whereas the triene or diene alone were not attractive. Based on current, as well as previous (Stelinski et al. 2008) research, we know that disruption of orientation by male *P. citrella* to traps by the 3:1 blend, triene alone, or diene alone occurs at certain concentrations of pheromone above the threshold for male activation and orientation. Furthermore, our data revealed that the triene is a superior disruptor of male *P. citrella* orientation compared with the 3:1 blend. Camouflage can be eliminated as a mechanism of disruption in our trials because, if it were operating, its effectiveness (i.e., disruption) should increase as the synthetic pheromone blend approximates the natural blend (Cardé 1990). Our results did not show such an effect (Fig. 3).

Desensitization, as a mechanism of disruption, can occur following prolonged exposure to an unnaturally high stimulation with synthetic pheromone, at the level of the peripheral (adaptation) or central (habituation) nervous system or both (Bartell 1982; Miller et al. 2006a). The two-component blend should be expected to cause greater desensitization of male *P. citrella* than the triene alone, because the blend acts on more receptors in total than does a single component. However, desensitization of a portion of receptors may be highly effective if it interferes with integration in the central nervous system. Thus, although our results indicate that disruption with the triene was superior to the 3:1 blend, desensitization as the mechanism of disruption cannot be ruled out. We believe that our field trapping and disruption results are most consistent with the sensory imbalance mechanism of disruption for *P. citrella*. Sensory imbalance involves males receiving a signal out of balance with the one their sensory system is optimized to perceive (Miller et al. 2006a). We found that the pure triene formulation was superior to the 3:1 blend in the disruption trial, and that we could disrupt trap catch with either pheromone component individually.

Minks and Cardé (1988) explored the question of whether optimal mating disruption of moths could be obtained through deployment of natural or unnatural ratios of pheromone components. They argued that available evidence suggested that natural blends should be most effective at the lowest dose and that, given the constraints of available information, pursuit of unnatural blends was unwise unless field trials demonstrated otherwise. Cardé and Minks (1995) reported that the majority of documented cases suggested that the natural blend provided best disruption at the lowest dose. As those authors note, none of the cases had been fully substantiated. We argue that with adequate experimental design and execution, optimal blend ratios and dosages for disruption can be identified and, further, may show that the natural blend may not be the most efficacious at low release rates. Furthermore, if the cost differential of synthesis of individual blend components is large, then economic considerations will drive practical decisions regarding product development for mating disruption applications. The case presented here for *P. citrella* demonstrates both of these points. First, the mixture-amount design allowed for exploration of the design space defined by proportionality and concentration of the two pheromone components. Second, the much lower cost of synthesis of the diene, compared to the triene, suggests that use of the diene, at a release rate an order of magnitude greater than that which would generate equivalent trap shutdown by the triene alone, may be warranted on economic grounds.

Acknowledgments We thank Evans Properties, Vero Beach, FL for use of their grapefruit groves. David Melius, Kelsey Stevens, Alex Pheneger, Kathy Moulton, Matt Hentz and Anthea Diamondis (USDA-ARS, Ft. Pierce) and Ian Jackson, Angel Hoyte and Wendy Meyer (UF, Lake Alfred) assisted with field trials. ISCA Technologies provided lures and SPLAT formulations. Partial funding was provided by USDA's IR-4 Project.

compounds were washed off prior to the assay (Ruther et al. 2002; Roux et al. 2007). However, lifeless dummies are inadequate during bioassays when the range of responses from each interacting individual depends on the behavior of the others (Gamboa et al. 1991; Roulston et al. 2003).

A good way to avoid this problem consists of inserting live insects into a glass vial whose inner walls were previously coated with an extract. Although this method has been used successfully with honey bees, which rub their wings, thorax, and abdomen on the coated insides of the walls (Dani et al. 2005), the technique is not suitable for transferring semiochemicals to non-flying insects that walk on the walls.

There are non-destructive, nontoxic extraction techniques, such as solid phase micro extraction (SPME), which consists of gently rubbing the insects with a glass fiber coated with a membrane with an affinity for cuticular compounds. The fiber then is introduced into the gas chromatograph injector where the compounds are desorbed. Results obtained through this method are similar to those obtained with solvent extracts (Monnin et al. 1998; Turillazzi et al. 1998; Tentschert et al. 2002). Turillazzi et al. (1998) adapted this method by replacing the fiber with a clean piece of cotton wool or filter paper. After rubbing the insects with substrate, the compounds are rinsed from the cotton wool or filter paper with a solvent, and then analyzed. These extractions by "abrasion" allow the insects to be kept alive so as to monitor variations in their cuticular profiles at different stages of their lives; it provides results similar to those of solvent extracts (with some variations in relative proportions: Turillazzi et al. 1998). In addition to the cost and fragility of SPME fibers, it is difficult to use these techniques on small and/or fragile insects; moreover, the analyses must follow the extraction as quickly as possible because the time during which compounds can be conserved is limited. Adaptation with cotton wool allows some of these disadvantages to be avoided, but cotton wool is slightly less sensitive and can catch on spurs on the cuticle.

Another non-destructive, nontoxic extraction method involves rinsing individuals with water and using the aqueous extract in behavioral assays. Andrews (1911) noted that water-washed termites were attacked by nestmates as well as by alien individuals. Fresneau (1980) successfully transferred recognition signals in *Pachycondyla villosa*, a ponerine ant. By rinsing workers belonging to two different colonies, and then soaking them in baths already used to wash alien individuals, he was able to induce aggressiveness among nestmates and tolerance between alien workers. This method was used by Dejean et al. (1990) to test learning behavior in *P. villosa* workers that adopt a posture of prudence when encountering termite soldiers, but not termite workers. Rinsed termite workers soaked in the "bath" water of soldiers triggered a posture of prudence in ants; whereas, rinsed termite soldiers soaked in the "bath" water of workers did not induce any prudence, so that termite soldiers viciously bit the ants. The authors concluded that compounds, here serving as kairomones, were transferred (after emulsion) between the termite soldiers and workers.

Henderson et al. (1990) wanted to test several methods for removing nestmate discrimination pheromones and then suppressing aggressive behavior between alien *Formica montana*. The methods used included washing the ants with distilled water; however, this technique yielded poor results in comparison to hexane or pentane washes because water does not wash as well as "classical solvents." Indeed, after a water-based wash, many cuticular compounds remain on the insect cuticle, so this method does not always allow the aggressive behavior of non-nestmate individuals to be completely inhibited (O.R. pers. obs.). In these reports, the insects were rinsed by vigorously shaking them in vials half-filled with water to emulsify their cuticular hydrocarbons. The insects, at first numbed, recovered after a few minutes and could subsequently be used in bioassays. However, no chemical analyses then were performed to verify which compounds were transferred.

In this study, we tested the hypothesis that cuticular compounds can be extracted and transferred between ants by using water followed by analysis of the chemical composition of the extracts and behavioral assay of the ants' responses in the laboratory.

Methods and Materials

Insects The study was conducted with *Camponotus blandus* (Smith 1858) (Formicinae) and *Solenopsis saevissima* (Smith 1855) (Myrmicinae) (both Hymenoptera: Formicidae), two Neotropical species found frequently in open habitats. In October 2007 and February 2009, we gathered workers belonging to one colony from each species located about 20 m from each other along a forest trail situated near the Petit Saut dam (French Guiana).

Cuticular Compound Extraction Cuticular compounds were extracted by using two methods. First, twelve individuals from each species were freeze-killed, and the compounds extracted by placing the ants into 500 µl of hexane in a 2 ml glass vial for 5 min. The solvent was evaporated under a nitrogen stream, and the sample was re-suspended in 20 µl of hexane. Second, we used a method designed to allow the insects to be kept alive wherein thirty individuals were placed into a 30 ml glass vial along with about 20 ml of ultra pure water (34°C) and hand shaken vigorously for 5 min with the

aim of emulsifying the cuticular hydrocarbons. The ants were removed, and the aqueous emulsion was extracted with 500 µl of hexane by shaking the vials for 10 sec before allowing the contents to settle for 1 min. The hexane supernatant was transferred to a 2 ml glass vial, removed under a nitrogen stream, and the residue re-suspended in 20 µl of hexane for gas chromatographic-mass spectrometric (GC-MS) analysis.

Applying Cuticular Hydrocarbons to the Ants Camponotus blandus Workers were applied with the cuticular compounds of *S. saevissima* workers in two different ways. In both cases, about 70 workers from the two species were rinsed separately in 20 ml of water as described previously. The ants then were removed and placed into plastic boxes whose walls were coated with fluon® to prevent them from climbing out, and whose floor was lined with absorbent paper on which the ants dried. For the first application method, rinsed *C. blandus* were placed directly into the emulsion of *S. saevissima* cuticular compounds, shaken for 10 sec, and then left in the emulsion for 5 min. They then were removed and placed again into a plastic box where they were redried. To see how effectively the cuticular compounds were transferred, some individuals were freeze-killed, and their cuticular compounds extracted with hexane prior to GC-MS analysis. For the second application method, the water-based emulsion was extracted with hexane as previously described, and the residual hexane was carefully removed and the "bath" water transferred to a clean vial. Only then were the rinsed *C. blandus* placed into the water from which the hexane fraction (containing compounds with a greater affinity for hexane than water) was removed. This second technique was used to test the action of the aqueous emulsion alone.

Chemical Analysis Chemical analysis and the identification of compounds were conducted with a Finnigan Trace GC-MS 2000 Series chromatograph directly coupled to a mass spectrometer quadrupole detector. The entire system was operated by using the Xcalibur data system, version 1.2. MS spectra were recorded in the EI mode (70 eV) over a mass range of 50–550 mass units with two scans per second. One µl was injected into the splitless mode with an injector temperature of 280°C and a detector temperature of 300°C. An apolar Rtx®-5MS-MS capillary column (30 m×0.25 mm i.d.× 0.25 µm film thickness, 5% diphenyl and 95% dimethylpolysiloxane) was used. Elution was carried out with helium at 1 ml/min. The oven temperature was programmed from 80°C (for 30 sec) to 200°C at 20°C/min, from 200°C to 240°C at 3°C/min, from 240°C to 300°C at 30°C/min, and left at 300°C for 19 min. As it is important only to check if the compounds in the water-based extract are the same as in the hexane-based extract, only tentative identifications were made by comparing them with a spectral database, retention indices, a series of standard linear alkanes, and the calculation of methyl positions on the basis of mass spectra. Then, these tentative identifications of the compounds were provided for informational purposes only; some were cross-checked with mass spectra found in the literature. Then, the alkaloids were identified based on comparisons with the work of MacConnell et al. (1971), Brand et al. (1972) and, more recently, Chen and Fadamiro (2009a, b). Some methylalkanes were identified through comparisons with the results obtained by Nelson et al. (1980) on the cuticular methylalkanes of some *Solenopsis* species.

Behavioral Assays To test the effectiveness of our extraction and application methods, five sets of ants were prepared: (1) Untreated *C. blandus* workers; (2) untreated *S. saevissima* workers; (3) *C. blandus* workers with the application method 1 thought to contain the cuticular extracts of *S. saevissima* workers; (4) *C. blandus* workers with application method 2 consisting of the water-based extract of the *S. saevissima* workers without compounds soluble in hexane; and (5) "blank" *C. blandus* workers, i.e., individuals that were rinsed in two different baths of clean water.

Behavioral interactions were tested between the following workers: (1) untreated *C. blandus vs*. untreated *C. blandus*; (2) untreated *C. blandus vs*. "blank" *C. blandus*; (3) untreated *C. blandus vs. C. blandus* with application method 2; (4) untreated *C. blandus vs. C. blandus* with application method 1; (5) untreated *S. saevissima vs*. *C. blandus* with application method 1; and (6) untreated *C. blandus vs*. untreated *S. saevissima*. All tested *C. blandus* workers belonged to the same colony. For each behavioral interaction, two workers were placed together for 5 min in a neutral arena (a Petri dish; 60 mm diam and 20 mm deep) whose walls were coated with Fluon® to prevent the ants from climbing out. We scored the interactions as follows: 1 = antennal contact (physical contact, but no aggressive response; may include trophallaxis), 2 = escape (sudden U-turn and running quickly), 3 = aggressiveness (brief biting by one or both of the workers; may include jerking and opening the mandibles), and 4 = fighting (prolonged aggressiveness, including prolonged biting and stinging [*Solenopsis*] or venom spraying [*Camponotus*]). We repeated each kind of confrontation 60 times, keeping the highest value noted for each series of 5-min observations, and used each worker only once. Because *S. saevissima* is active around the clock and *C. blandus* is typically diurnal (Orivel and Dejean 2002), all bioassays were performed during the day.

Statistical Analyses Levels of aggressiveness between interacting ants were compared by using the Kruskal–Wallis test. A *post-hoc* test (Dunn's multiple pairwise comparisons test) was then performed to isolate the dyadic interactions that differed from the others. All statistical analyses were performed with GraphPad Prism 4.03 software (GraphPad Software Inc 2005).

Results

Chemical Analysis and Extraction Methods The two methods of extraction produced both quantitatively (in terms of proportions) and qualitatively similar GC-MS profiles for both ant species (Fig. 1).

The GC-MS profiles of the two ant species were different (Fig. 1a–d). The GC-MS profiles for *C. blandus* contained 23 compounds, all hydrocarbons, ranging from C27 to C40 (Table 1). The *S. saevissima* profile had 34 compounds; the eight early eluting compounds, representing the bulk of the extracts, were piperidine alkaloids typical of *Solenopsis* venom (MacConnell et al. 1971; Brand et al. 1972). The later eluting compounds were all hydrocarbons ranging from C23 to C32. Only heptacosane (peak 26) was common to both species, but present at trace levels.

Application Methods The gas chromatogram obtained from rinsed *C. blandus* treated with the emulsion of *S. saevissima* cuticular compounds was not a perfect blend of the cuticular signatures of the two species (Fig. 1e). The *S. saevissima* alkaloids were transferred poorly to the rinsed

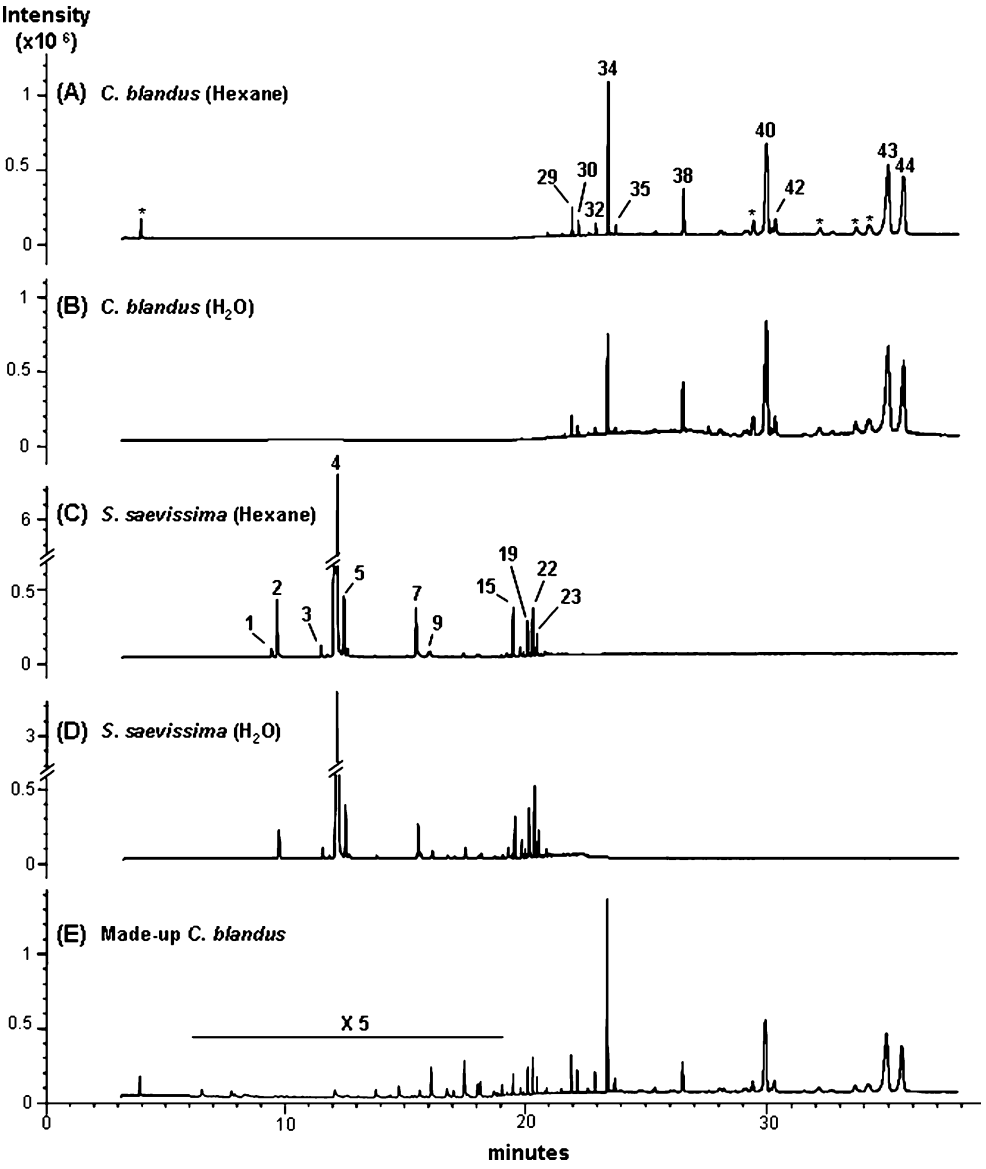

Fig. 1 Gas chromatographic-mass spectrometric traces of extracts from *Camponotus blandus* and *Solenopsis saevissima* workers. Analyses were conducted on extracts prepared by two methods (**a**–**d**), as well as on a hexane-based extract from *C. blandus* workers "made-up" with the emulsion of *S. saevissima* cuticular compounds (**e**); the area under the horizontal line is enlarged five times; * = contamination; see Table 1 for peak assignments

C. blandus, whereas all of the hydrocarbons from *S. saevissima* (peaks 9–27) were transferred efficiently, and the proportions of the transferred hydrocarbon components were comparable to those in the native extracts in most cases (except for compounds 15, 19, 22, and 23, which were recovered in smaller proportions than in the extracts of the worker *S. saevissima*, Table 1).

Behavioral Assays We typically noted the absence of aggressiveness (level 1; i.e., antennation and trophallaxis; Fig. 2) among untreated *C. blandus* nestmates that is significantly different from the high level of aggressiveness that occurred among untreated *C. blandus* and untreated *S. saevissima* workers (mean aggressiveness levels: 1±0 and 2.46±0.09, respectively; $P<0.001$; Fig. 2). The latter triggered some fighting and they mainly raised and vibrated their gaster ("flagging"), a behavior corresponding to the airborne dispersal of venom (see Obin and Vander Meer 1985). As a result, *C. blandus* workers ran, jerked away, or fought when contact became frequent. Interactions between untreated and "blank" *C. blandus* (to test the effect of double rinsing) were not significantly different from those observed between untreated nestmates (mean aggressiveness levels: 1±0 and 1.06±0.04, respectively; *NS*; Fig. 2). Inversely, interactions between untreated *C. blandus* workers and those with the "S make-up" resulted in levels of aggressiveness significantly higher than the two previous situations involving *C. blandus* workers (mean aggressiveness levels: 1±0 and 2.15±0.13, respectively; $P<0.001$; Fig. 2). Nevertheless, interactions between untreated *C. blandus* workers and *C. blandus* workers with "S-H make-up" were not different from interactions with untreated or "blank" *C. blandus* workers (Fig. 2). The interactions between untreated *C. blandus* workers and *C. blandus* workers with application method 1 were not significantly different from interactions between untreated *C. blandus* workers and untreated *S. saevissima* workers (mean aggressiveness levels: 2.15±0.13 and 2.46±0.09, respectively; *NS*; Fig. 2). Also, interactions between untreated *S. saevissima* workers and *C. blandus* workers with application method 1 were not significantly different from those between *C. blandus* workers and *C. blandus* workers with application method 1 (mean aggressiveness levels: 2±0.15 and 2.15±0.13, respectively; *NS*; Fig. 2), but they were different from those between untreated *C. blandus* and untreated *S. saevissima* workers (mean aggressiveness levels: 2±0.15 and 2.46±0.09, respectively; $P<0.001$; Fig. 2). Untreated *C. blandus* workers mainly ran away after encountering *S. saevissima* workers as well as *C. blandus* workers with the application method 1 (level 2 of aggressiveness), but *C. blandus* workers with the application method 1 did not run away when they encountered untreated *S. saevissima* workers (behavioral observations not shown).

Discussion

Our study demonstrates that it is possible to extract cuticular compounds from live tropical ants by using a tepid water bath, and that the extracted workers remain active even after being rinsed twice. Also, this method permits the cuticular extracts to be reapplied onto other live tropical ants with the aim, as in our study, of transferring a part or all of the cuticular recognition signals.

That ants living in equatorial countries survived our rinsing treatment is not surprising as they are adapted to living in areas with heavy rain, particularly ground-nesting species whose nests can be flooded. When flooded, the colonies of several species form rafts that float on the flooding waters. This frequently has been reported for fire ants (*Solenopsis invicta*, *S. saevissima*, and *Wasmannia auropunctata*), *Pheidole* spp. (all Myrmicinae) and the Argentine ant (*Linepithema humile*; Dolichoderinae) (Hölldobler and Wilson 1990; Morrison 1998; Holway et al. 2002; Haight 2006).

Water is a polar solvent and so is not theoretically adapted to extracting non-polar compounds. It also is well known that cuticular lipids are mainly made up of hydrocarbons, which are not water-soluble compounds. Nevertheless, our study has shown that by "relatively vigorously" shaking the glass vial containing the water and the ants, tepid water can be used to extract cuticular hydrocarbons in a way that is similar to using hexane. In fact, these non-polar compounds were not solubilized, but emulsified and floating on the surface of the water. To explain how the emulsion can transfer cuticular lipids on the ants, Dejean et al. (1990) used the comparison of birds caught in an oil slick, with the cuticular lipids acting as the oily film on the surface of the water and the live ants as the birds that were coated with the "pollutant." Even if water cannot extract all of the cuticular lipids (in terms of quantity), it is powerful enough to extract part of them, and to produce qualitatively the same extracts as hexane; moreover, the quantity extracted and reapplied is enough to induce the expected behaviors. In addition, the extraction of cuticular compounds from the "bath" water of *S. saevissima* workers by adding hexane prior to applying the cuticular compounds of *C. blandus* (application method 2) showed that the transferred signal really is contained in the hexane fraction and could be hydrocarbons.

We point out that the volume of water used in the application experiment is less important than the diameter of the vial. Indeed, as we were dealing with an emulsion,

Table 1 Tentative identification and relative quantities[a] of cuticular compounds from *Camponotus blandus* and *Solenopsis saevissima* by using two different methods of extraction and for application of *S. saevissima* cuticular extract to *C. blandus* workers

the smaller the diameter of the vial, the greater the height of the layer of the supernatant, facilitating the transfer of compounds to the ant cuticle. In the choice of the vial, then, there is a trade-off between diameter and the volume of water able to contain, in this case, 70 ants.

The main problem with using live insects in a water or polar solvent rinse is that, in addition to the expected cuticular hydrocarbons, extracts can contain exocrine gland secretions and regurgitated and excreted items. However, Vander Meer and Morel (1998) pointed out that solvent extracts of dead insects also contain such compounds. In our study, cuticular hydrocarbons and alkaloids from the venom gland of *S. saevissima* were obtained through hexane- and water-based extractions. Like hydrocarbons, fire ant alkaloids are not water-soluble and less dense than water (Blum et al. 1958). Nevertheless, they were poorly transferred to the *C. blandus* cuticle, probably due to their greater polarity.
