The impetus for a special issue on Human Impact and Chemical Ecology originated from a talk by David Wood at the 25th Anniversary Meeting of the International Society of Chemical Ecology held at Pennsylvania State University in 2008. In Professor Wood's historical review of the field of chemical ecology, he touched on many themes. They included reminders that: we would celebrate the 50th anniversary (in 2009) of the discovery of the first insect pheromone (the silk moth) by Butenandt and colleagues and the first use of the term "pheromone" by Karlson and Lüscher in the same year; the Journal of Chemical Ecology would celebrate its 35th Anniversary in 2010; from its origins in insect semiochemicals, Chemical Ecology has advanced into new frontiers as exemplified by previous specialized issues of the Journal devoted to such topics as Allelopathy (2000), Aquatic Chemical Ecology (2002), Molecular Chemical Ecology (2004), Mammalian Chemical Ecology (2006), and Olfactory Ecology (2008); and finally and importantly that the discoveries made under the broad umbrella of Chemical Ecology must continue to serve and benefit human survival.

Via an exchange of cocktail napkins during and after David's address, Wilhelm Boland and I came up with a working list identifying current topics of focus in Chemical Ecology that directly impact human well-being and survival. The subsequently seven solicited review papers gathered here cover a broad spectrum of topics that range from the challenges of global change, invasive species, and pollution, to disease vectors. Among the four selected contributed papers are two that relate to plant chemistry (global change and invasives), one to pheromone disruption, and one to the protective aspects of geophagy.

We could not address all aspects of human impact within our various sub-disciplines. Many facets that likely deserve review, but are missing, include obvious ones: benthic and pelagic effects in aquatic systems, such as coral reef deterioration and red tides; diminishing populations of beneficial insects, such as honey bees; and accelerated geographic speciation and extinctions.

Notwithstanding, the topics included here ought to give one pause to reflect on: our collective global concerns and challenges; the achieved modest successes in combating many of our self-created problems; and the hope that the future will be better for our efforts. We express our thanks both to the authors of the invited review articles, all of whom claimed it to be a difficult but rewarding task, as well as to the authors of the contributed papers. We hope that readers of the Journal will find the issue enlightening, and provoking, and that perhaps it may serve to focus future research.

REVIEW ARTICLE

Impacts of Elevated Atmospheric CO_2 and O_3 on Forests: Phytochemistry, Trophic Interactions, and Ecosystem Dynamics

Richard L. Lindroth

Received: 24 August 2009 / Revised: 2 December 2009 / Accepted: 8 December 2009 / Published online: 8 January 2010
© Springer Science+Business Media, LLC 2009

Abstract Prominent among the many factors now affecting the sustainability of forest ecosystems are anthropogenically-generated carbon dioxide (CO_2) and ozone (O_3). CO_2 is the substrate for photosynthesis and thus can accelerate tree growth, whereas O_3 is a highly reactive oxygen species and interferes with basic physiological functions. This review summarizes the impacts of CO_2 and O_3 on tree chemical composition and highlights the consequences thereof for trophic interactions and ecosystem dynamics. CO_2 and O_3 influence phytochemical composition by altering substrate availability and biochemical/physiological processes such as photosynthesis and defense signaling pathways. Growth of trees under enriched CO_2 generally leads to an increase in the C/N ratio, due to a decline in foliar nitrogen and concomitant increases in carbohydrates and phenolics. Terpenoid levels generally are not affected by atmospheric CO_2 concentration. O_3 triggers up-regulation of antioxidant defense pathways, leading to the production of simple phenolics and flavonoids (more so in angiosperms than gymnosperms). Tannins levels generally are unaffected, while terpenoids exhibit variable responses. In combination, CO_2 and O_3 exert both additive and interactive effects on tree chemical composition. CO_2-and O_3-mediated changes in plant chemistry influence host selection, individual performance (development, growth, reproduction), and population densities of herbivores (primarily phytophagous insects) and soil invertebrates. These changes can effect shifts in the amount and temporal pattern of forest canopy damage and organic substrate deposition. Decomposition rates of leaf litter produced under elevated CO_2 and O_3 may or may not be altered, and can respond to both the independent and interactive effects of the pollutants. Overall, however, CO_2 and O_3 effects on decomposition will be influenced more by their impacts on the quantity, rather than quality, of litter produced. A prominent theme to emerge from this and related reviews is that the effects of elevated CO_2 and O_3 on plant chemistry and ecological interactions are highly context- and species-specific, thus frustrating attempts to identify general, global patterns. Many of the interactions that govern above- and below-ground community and ecosystem processes are chemically mediated, ultimately influencing terrestrial carbon sequestration and feeding back to influence atmospheric composition. Thus, the discipline of chemical ecology is fundamentally important for elucidating the impacts of humans on the health and sustainability of forest ecosystems. Future research should seek to increase the diversity of natural products, species, and biomes studied; incorporate long-term, multi-factor experiments; and employ a comprehensive “genes to ecosystems” perspective that couples genetic/genomic tools with the approaches of evolutionary and ecosystem ecology.

Introduction

Forest ecosystems have played roles of unparalleled importance in the evolution and ecology of life on Earth. Currently, forests cover ~30% of the earth’s land surface, store ~45% of terrestrial carbon, and contribute ~50% of

terrestrial net primary production (Bonan 2008). They provide vital ecological, economic and social services, including regulation of biogeochemical cycles, production of food and fiber, preservation of biodiversity, governing of climate systems, and buffering against natural and anthropogenic disasters (Hassan et al. 2005; Millenium Ecosystem Assessment 2005).

Earth's forests are now subject to a veritable Pandora's Box of environmental evils, the magnitude and diversity of which have never occurred previously in human history. Worldwide, climate and land use changes, invasive species, pest outbreaks, and pollution are exacting an increasing toll on the health, biological diversity, and sustainability of forests (Laurence and Peres 2006; Hari and Kulmala 2008; Kurz et al. 2008; Raffa et al. 2008; van Mantgem et al. 2009). Against this backdrop of massive and seemingly intractably complex socio-environmental ills, the question arises: "of what relevance is chemical ecology?"

In a word, plenty. Naturally-produced chemicals, particularly phytochemicals, govern many, if not most, of the interactions that characterize community and ecosystem function. They *respond to* global environmental change; they *perpetuate*, via interaction networks, the consequences of global change; and they *feed back* to influence future global change. Consider, for example, the carbon cycle (Fig. 1). Enriched atmospheric CO_2 influences plant physiology, with consequences for plant production and chemical composition. Plant chemical composition in turn influences trophic interactions and decomposition, which ultimately feed back to affect atmospheric CO_2 concentrations (Peñuelas and Estiarte 1998; Beedlow et al. 2004; Lindroth and Dearing 2005). Or, consider the isoprenoids and related biogenic volatile organic carbons (BVOCs) released in large quantities by some species of trees (e.g., eucalypts, poplars, and conifers). These compounds are precursors for the formation of tropospheric ozone (O_3), which in turn negatively impacts plant production (Fig. 1) and human health (Fowler et al. 1999; Lerdau and Gray 2003; Monson 2003; Laothawornkitkul et al. 2009). An understanding of the roles of natural products as responders to, and effectors of, global change will improve our ability to predict ecosystem responses to future change, and inform management decisions with respect to mitigation and adaptation strategies.

Analogous in some respects to intestinal villi, forest trees provide structurally expansive and heterogeneous surfaces through which the exchange of chemicals between the atmosphere and biosphere is effected. The same properties enhance exposure of forest trees to gaseous pollutants. Two such gases, CO_2 and O_3, are considered the most important and ubiquitous, affecting forests worldwide (Saxe et al. 1998; Fowler et al. 1999; Felzer et al. 2004; Karnosky et al. 2005, 2007). Independent of their function as greenhouse gases, CO_2 and O_3 are directly and indirectly affecting forest ecosystems now, with increasingly pronounced impacts predicted for the future (Fig. 2). (Note that although both CO_2 and O_3 occur naturally, they are appropriately considered "pollutants" because of their anthropogenic production and effects on living systems.)

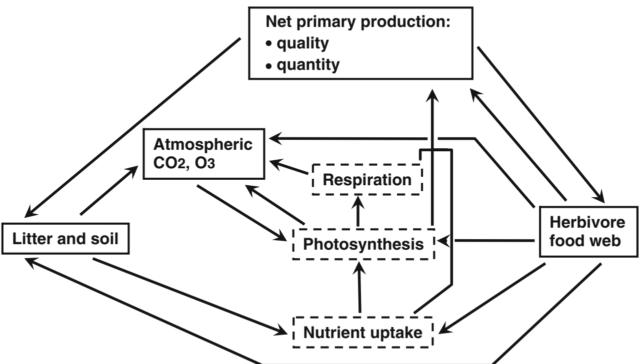

Fig. 1 Carbon cycling and storage in forest ecosystems. Solid boxes represent major pools; dashed boxes represent major plant physiological processes (adapted from Lindroth and Dearing 2005)

The purpose of this review is to assess the impacts of enriched atmospheric CO_2 and O_3, independently and interactively, on the chemical ecology of forest ecosystems. Several recent reviews provide an assessment of the effects of CO_2 and O_3 on plant chemistry; that information will be summarized and updated here. I will then explore the consequences of CO_2- and O_3-mediated changes in tree chemistry for trophic interactions (plant—animal—natural enemy) and ecosystem dynamics (rates of plant damage, organic substrate deposition and decomposition) (Fig. 1). I will not detail the links between ozone and plant volatiles, as those have been covered in several very recent reviews, including elsewhere in this issue (Laothawornkitkul et al. 2009; Pinto et al. 2010; Yuan et al. 2009). Finally, although CO_2 and O_3 are both greenhouse gases, the effects of climate change per se on ecological interactions (e.g., Bale et al. 2002; Parmesan 2006; Berggren et al. 2009; Dukes et al. 2009; Pelini et al. 2009) are beyond the scope of this review.

Temporal Trends in Concentrations of CO_2 and O_3

Concentrations of atmospheric CO_2 now approach 386 ppm, higher than at any time in the last 26 million years (Pearson and Palmer 2000) and 40% higher than at the dawn of the industrial revolution. Emissions scenarios predict a range of substantially elevated concentrations by the end of this century, from a low of 550 ppm to a high of 900 ppm (Karl et al. 2009). Over the last several decades, combustion of fossil fuels, coupled with a smaller contribution from manufacture of cement, have accounted for

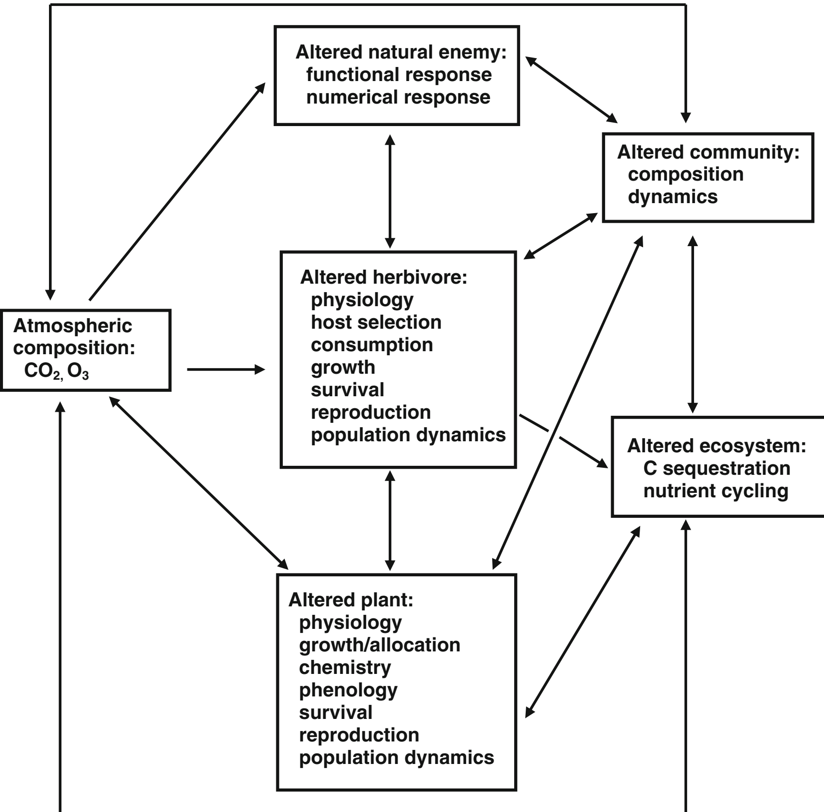

Fig. 2 Complex of interacting factors that feed forward and feed back to influence food webs, community and ecosystem structure and function, and atmospheric composition

approximately 80% of human-caused emissions. The remaining 20% has resulted from changes in land use, primarily deforestation (Denman et al. 2007; Karl et al. 2009).

Since the evolution and spread of large, vascular plants, about 380 MYA, forests have played prominent, regulating roles with respect to atmospheric CO_2 concentrations. They were largely responsible for the massive drawdown of atmospheric CO_2 (peaking at upwards of 5,000 ppm) in the late Devonian and Carboniferous Periods. Forests exerted two major effects on the global carbon cycle, both of which reduced atmospheric CO_2 concentrations (Berner 2005). First, they produced massive amounts of lignified tissue that was refractory to decomposition. This organic material, upon sedimentary burial, led to the formation of enormous coal deposits. Second, large and deep root systems greatly accelerated nutrient uptake from rock substrates, enhancing the weathering of Ca-Mg silicate minerals. Ca and Mg cations, in the presence of carbonic acid (derived from atmospheric CO_2 and water), formed Ca-Mg carbonates, which precipitated in ocean sediments to form limestone and dolomite.

Tropospheric ozone is recognized as the most damaging and widespread pollutant affecting agricultural and forest ecosystems in North America and Europe (Chameides et al. 1994; Ollinger et al. 1997; Skärby et al. 1998; Fuhrer and Booker 2003; Ashmore 2005; Karnosky et al. 2007; Wittig et al. 2009). Concentrations of O_3 have increased an average of 38% (range of 20–50%) since the pre-industrial age (Denman et al. 2007). Although O_3 is a regional pollutant, large areas of the earth already are impacted, background levels are steadily increasing, and 60% of the world's forests are expected to be affected detrimentally by the end of this century (Fowler et al. 1999; Vingarzan 2004; Denman et al. 2007).

O_3 is a secondary pollutant, produced via the catalytic oxidation of hydrocarbons (e.g., VOCs) by OH radicals, in the presence of nitrogen oxides and sunlight (Wennberg and Dabdub 2008). Because O_3 is highly reactive, it persists for short periods (hours to several weeks) in the atmosphere. Rapid degradation, coupled with substantial spatial and temporal variation in production, contribute to highly variable distribution of this pollutant. Regional VOC and NO_x emission control policies are expected to reduce peak O_3 levels in North American and Europe, whereas in Asia and other regions, emissions of these precursors are increasing (Ashmore 2005). Moreover, background levels of O_3 (not attributable to local origin) are increasing steadily worldwide (Vingarzan 2004).

Plant-derived, biogenic VOCs can be important contributors to the formation of O_3 (Sharkey and Lerdau 1999; Lerdau and Gray 2003; Laothawornkitkul et al. 2009; Yuan et al. 2009). When BVOCs such as isoprene, monoterpenes or methylbutenol are oxidized in the presence of NO_x,

substantial amounts of O_3 can be produced. Indeed, large inputs of BVOCs may handicap efforts to reduce ozone pollution through controlling emissions of anthropogenic VOCs. Moreover, ecological interactions may amplify ozone production. A modeling study by Litvak et al. (1999) indicated that even modest (10%) damage by defoliating insects in coniferous forests is sufficient to increase local concentrations of O_3.

In contrast, in the presence of low NO_x concentrations, BVOCs are oxidized by O_3, leading to a decrease in atmospheric O_3 and a concomitant increase in secondary organic aerosols (Laothawornkitkul et al. 2009). Thus, forest ecosystems can serve as effective quenchers of anthropogenic O_3, but in the process contribute to atmospheric aerosol loading that influences climate. Kurpius and Goldstein (2003) documented that for a *Pinus ponderosa* forest during summer, 51% of atmospheric O_3 is broken down via gas phase chemistry (reactions with BVOCs), 30% is lost to stomatal uptake, and 19% is lost to surface deposition.

Effects of CO_2 and O_3 on Plant Physiology and Growth

Carbon Dioxide

As the substrate for photosynthesis, and ultimate source of all carbon fixed via primary production, atmospheric CO_2 strongly influences plant physiology and growth. Photosynthesis is catalyzed by Rubisco (ribulose-1,5-bisphosphate carboxylase oxygenase), which fixes carbon to form carbohydrates. In C3 plants, including most forest tree species, enriched CO_2 atmospheres increase the intracellular CO_2:O_2 ratio, thus reducing photorespiration (oxygenation) and increasing photosynthesis (carboxylation). Carbohydrates then are transported throughout the plant and subsequently converted to various carbon-containing compounds required for plant metabolism, structure, storage and defense (Fig. 3).

The effects of elevated atmospheric CO_2 on tree physiology and growth have been covered in numerous reviews (e.g., McGuire et al. 1995; Saxe et al. 1998; Long et al. 2004; Ainsworth and Long 2005; Norby et al. 2005; Körner 2006; Leakey et al. 2009). In brief, N use efficiency improves as the N allocated to Rubisco (the largest single pool of N in leaves) can be re-allocated to other metabolic processes. Stomatal conductance generally declines, decreasing transpiration and improving water use efficiency. Enhanced photosynthesis, coupled with improved nitrogen and water use efficiencies, often accelerates plant growth, i.e., the “fertilizer effect” of enriched CO_2 (Beedlow et al. 2004). The growth stimulation afforded by enriched CO_2 is especially strong in young forest stands, characterized by abundant soil resources and open canopies. In contrast, studies in mature stands, where tree growth is tightly coupled to soil nutrients and canopies are closed, indicate smaller to zero growth enhancement (Asshoff et al. 2006; Körner 2006).

A key, unresolved issue in global change biology is to what extent improved tree growth can be sustained into the future, affording greater carbon sequestration and thereby mitigating climate change. To date, open-air FACE studies generally indicate that accelerated rates of photosynthesis and growth are sustained over the short to medium term and across a broad range of productivity (Long et al. 2004; Norby et al. 2005; Huang et al. 2007; but see Körner et al. 2005 for a contrary example with mature trees). Still, the duration of these studies is short compared with the lifespan of trees. The Progressive Nitrogen Limitation (PNL) hypothesis (Luo et al. 2004) posits that CO_2-enhanced growth and carbon sequestration will diminish over time: as storage of N in plant biomass and soil organic matter increases, available soil N becomes limiting to growth. If not nitrogen, then a host of other factors (climate change, fire, insects, ozone, etc.) is predicted to constrain the fertilization effect of atmospheric CO_2 enrichment (Beedlow et al. 2004; Huang et al. 2007). For example, Cole et al. (2009) reported that atmospheric CO_2 enrichment over the last 50 years has increased growth rates of natural stands of *Populus tremuloides* by an astonishing 53%, but enhancement is diminished in periods of low precipitation. Finally, elevated atmospheric CO_2 may, via climate change impacts, ultimately lead to reduced carbon sequestration at the landscape level. In Canada, for example, extensive areas of forest recently have transitioned from CO_2 sinks to CO_2 sources, due to insect outbreaks and fires (Kurz et al. 2008).

Ozone

Reactions of tropospheric O_3 with plant chemistry can occur in gaseous, solid, or liquid phases (Fuhrer and Booker 2003). Gaseous reactions with plant VOCs are described by Pinto et al. (2010). Solid phase reactions may occur, for example, with plant cuticular components. The most important reactions for plants, however, occur in the liquid phase, after ozone has entered through the stomata and diffused into the aqueous media of interstellar spaces (Fuhrer and Booker 2003).

O_3 elicits a cascade of damaging physiological consequences in plants, described in detail in numerous recent reviews (e.g., Andersen 2003; Fuhrer and Booker 2003; Ashmore 2005; Kangasjärvi et al. 2005; Wittig et al. 2007, 2009). Because it is so highly reactive, O_3 is minimally distributed following dissolution into intercellular fluids. It reacts with lipid and protein components of cell walls and plasma membranes, leading to the formation of aldehydes, peroxides and assorted reactive oxygen species (ROS). These products

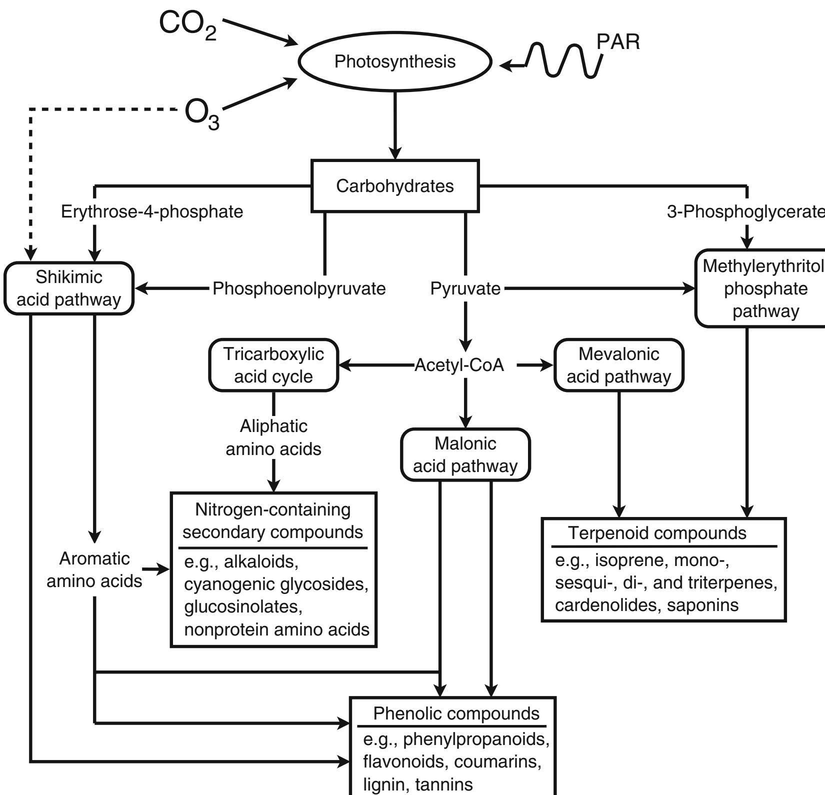

Fig. 3 Biosynthetic pathways for the production of the major classes of plant secondary compounds (adapted from Taiz and Zeiger 2002). Dashed lines indicate a control (signal transduction) pathway. PAR = photosynthetically active radiation

can then cause cell death, or activate various transduction pathways for defense responses, such as stomatal closure, production of anti-oxidants such as ascorbate and phenolics, and programmed cell death (a component of the hypersensitive response) (Fuhrer and Booker 2003; Valkama et al. 2007; Fig. 3). Reduced stomatal conductance, compromised photosynthesis, consumption of carbohydrates in localized tissue repair, and inhibition of phloem transport at the leaf level combine to decrease the supply of carbohydrates throughout the plant (Andersen 2003; Wittig et al. 2007, 2009). As a consequence, senescence is accelerated and whole-plant growth is inhibited.

A recent, comprehensive meta-analysis by Wittig et al. (2009) evaluated the effects of O_3 on the growth of trees representative of northern temperate and boreal forests. They found that, relative to preindustrial levels, current levels of tropospheric O_3 account for an average 7% reduction in tree biomass growth. Moreover, as O_3 levels continue to rise, further decreases of 11% and 17% are predicted for 2050 and 2100, respectively.

Understanding of the interactive effects of CO_2 and O_3 on tree growth is critically important to our ability to predict the efficacy of forests to serve as global carbon sinks in the future (Beedlow et al. 2004). A modeling study by Sitch et al. (2007) indicated that tropospheric O_3 may reduce terrestrial carbon sinks, and thereby effect indirect radiative forcing of climate change. This conclusion was subsequently corroborated by the work of Wittig et al. (2009), which indicated increasingly pronounced reductions in tree growth under elevated concentrations of O_3 in the future. To date, only one experiment has addressed the long-term (10+ years) effects of independent and combined CO_2 and O_3 treatments on forest trees. Karnosky et al. (2005) reported that at Aspen FACE (Wisconsin, U.S.A.), O_3 reduced the growth-enhancement effect of CO_2, although responses differed among tree species.

Effects of CO_2 and O_3 on Phytochemistry

CO_2 and O_3 directly and indirectly influence carbon assimilation and nutrient (e.g., N) acquisition, and thereby the pools and fluxes of key precursors for the production of secondary metabolites (Fig. 3). They also may influence the signal transduction pathways that govern gene expression and subsequent synthesis of secondary compounds. Not surprisingly then, growth under CO_2- or O_3-enriched atmospheres typically alters the chemical composition of forest trees.

Numerous reviews have addressed the effects of CO_2 and O_3 on plant chemistry (Kangasjärvi et al. 1994; Peñuelas et al. 1997; Bezemer and Jones 1998; Cotrufo et al. 1998a; Koricheva et al. 1998a; Peñuelas and Estiarte 1998; Norby et al. 2001; Zvereva and Kozlov 2006; Stiling and Cornelissen 2007; Valkama et al. 2007; Bidart-Bouzat and Imeh-

Nathaniel 2008; Wittig et al. 2009). Unless noted otherwise, the general trends for forest trees, summarized below, are drawn from that comprehensive set of reviews. Specific studies will be mentioned to illustrate particular patterns or highlight recent findings.

To date, research on the effects of CO_2 and O_3 on forest trees has been restricted to a small set of primarily temperate species. Most commonly studied are species of *Acer*, *Betula*, *Fagus*, *Pinus*, *Populus*, and *Quercus*. Although these are prominent, if not "foundation," genera, a major challenge to the global change research community is to broaden the taxonomic and geographic representation of trees, especially tropical species.

Carbon Dioxide

Enriched atmospheric CO_2 produces generally consistent effects on concentrations of primary metabolites in trees (Cotrufo et al. 1998a; Koricheva et al. 1998a; Saxe et al. 1998; Stiling and Cornelissen 2007). Foliar concentrations of nitrogen typically decline (on average, 14–17% relative to ambient CO_2), due to reductions in Rubisco concentrations and dilution by accumulating carbohydrates. Levels of simple sugars may or may not increase, whereas levels of starch generally increase substantially.

Studies of the effects of CO_2 on secondary metabolites in trees have been restricted to "carbon-based" compounds, particularly phenolics and terpenoids. Consequently, this research often has been framed in the context of source-sink balance hypotheses [e.g., carbon-nutrient balance hypothesis (Bryant et al. 1983), growth-differentiation balance hypothesis (Herms and Mattson 1992)]. These hypotheses predict that elevated CO_2 will increase plant concentrations of carbon-based secondary compounds, especially if soil nutrient availability is limiting to growth (Peñuelas and Estiarte 1998).

In general, results have not been as readily predictable as the hypotheses would suggest (reviewed in Koricheva et al. 1998a; Peñuelas and Estiarte 1998; Zvereva and Kozlov 2006; Stiling and Cornelissen 2007; Bidart-Bouzat and Imeh-Nathaniel 2008). Moreover, the shikimic acid pathway, leading to production of phenolics, is more strongly influenced by CO_2 levels than are the mevalonic acid and methylerythritol phosphate pathways, leading to production of terpenoids (Fig. 3). Enriched atmospheric CO_2 typically, but not invariably, increases tannin concentrations. Common, but less consistent, are increases in simple phenolics, including phenolic acids and glycosides (e.g., salicylates). Growth under elevated CO_2 also tends to increase lignin concentrations in tree leaves (Coûteaux et al. 1999; Norby et al. 2001), although more recent results, from long-term FACE studies, have shown no such effects (Finzi et al. 2001; Parsons et al. 2008; Liu et al. 2009). Overall, effects of CO_2 on terpenoid concentrations are minimal; although a few studies have revealed increases, most have found no change or decreases in concentrations.

The C/N ratio is a widely recognized, general index of overall tissue quality, relevant to both herbivory and decomposition. Enriched CO_2 atmospheres almost invariably increase C/N ratios in tree foliage (Coûteaux et al. 1999), due to a combination of decreased N concentrations and increased carbohydrate and phenolic concentrations.

Aside from such general indices, however, empirical studies have frustrated attempts to develop general, predictive models of the impacts of CO_2 on plant secondary chemistry. In short, a host of interacting factors have, over evolutionary time, combined to determine the chemical profiles of trees, and the effects of any one environmental factor can be masked by the direct or interactive effects of others.

One of the major confounding factors is taxon-specificity. Phytochemical responses of trees to CO_2 enrichment differ at the level of class (e.g., gymnosperm vs. angiosperm), species, and genotype (Julkunen-Tiitto et al. 1993; Lindroth et al. 2001, 2002; Zvereva and Kozlov 2006; Stiling and Cornelissen 2007; Bidart-Bouzat and Imeh-Nathaniel 2008). These differences represent taxonomic variation in evolutionary strategies that optimize solutions for the conflicting demands of carbon allocation toward growth, reproduction, and defense. For example, Cseke et al. (2009) recently compared leaf transcription profiles, physiology, and biochemistry between CO_2-responsive and unresponsive clones of *Populus tremuloides* grown at Aspen FACE. They found that the CO_2-responsive clone partitions carbon into pathways associated with "active" defense and stress responses, carbohydrate synthesis, and subsequent growth, whereas the unresponsive clone partitions carbon into pathways associated with cell wall compounds such as lignin, derived from the shikimic acid pathway.

Interactions with abiotic environmental factors also influence chemical responses of trees to CO_2. The availability of key resources (e.g., nutrients, water, light) can strongly shape plant chemical responses to CO_2, but, again, the magnitude and even direction of responses differ among chemical constituents and tree species (e.g., Lavola and Julkunen-Tiitto 1994; Kinney et al. 1997; McDonald et al. 1999; Booker and Maier 2001; Coley et al. 2002; Koike et al. 2006). Of particular importance in the context of global environmental change are potential interactions between atmospheric CO_2 and temperature. To that end, Zvereva and Kozlov (2006) conducted a meta-analysis of studies that assessed the simultaneous elevation of CO_2 and temperature on plant quality. Again, results were compound- and taxon-specific. Thus, responses to enriched CO_2 may be: 1) independent of temperature (e.g., foliar nitrogen and phenolics in Angiosperms); 2) offset by elevated temperature

(e.g., carbohydrates; foliar terpenes in gymnosperms); or 3) apparent only with elevated temperature (e.g., foliar nitrogen in gymnosperms, phenolics, and terpenoids in woody tissues). More recently, Veteli et al. (2007) reported for three tree species (*Betula* and *Salix*) that carbon allocation to phenolics was increased under elevated CO_2, decreased under elevated temperature, and unchanged under a combination of elevated CO_2 and temperature.

Interactions with biotic agents also may influence chemical responses of trees to CO_2, although much less research has been conducted with biotic than with abiotic factors. Herbivory frequently elicits induced chemical changes in trees, particularly in levels of phenolics (Nykänen and Koricheva 2004). Thus, enriched CO_2 atmospheres have been predicted to enhance induced chemical responses. Evidence to date, however, suggests that CO_2 does not modify induced chemical responses to defoliation in trees, although only a few studies have been conducted (Lindroth and Kinney 1998; Roth et al. 1998; Agrell et al. 1999; Rossi et al. 2004; Hall et al. 2005; Huttunen et al. 2008).

A final factor complicating attempts to draw general conclusions about the effects of CO_2 on tree chemistry is ontogeny (genetically-determined developmental changes). Many species of trees exhibit strong ontogenetic shifts in chemical composition (e.g., Bryant and Julkunen-Tiitto 1995; Donaldson et al. 2006), which reflect shifting physiological demands and defense strategies as trees mature (Boege and Marquis 2005). How ontogeny may interact with CO_2 to affect chemical profiles in trees is unknown. Such interactions may be one reason, however, for why chemical responses of plants in long-term FACE studies appear to be less pronounced than in short-term pot studies (Ainsworth and Long 2005; Lindroth, unpublished data).

Ozone

Elevated levels of tropospheric O_3 can modify plant chemical composition via several mechanisms. By disrupting photosynthesis, O_3 inhibits production of carbohydrates and the flow of precursors into pathways of primary and secondary metabolism (Fig. 3). Ozone also functions as a general abiotic elicitor of defense signaling pathways, particularly of phenolic compounds (Kangasjärvi et al. 1994; Heath 2008; Betz et al. 2009a). The two mechanisms may, of course, interact, as reductions in carbohydrate precursors for the shikimic acid pathway may constrain induced defensive responses. Moreover, these mechanisms may play out differently over different time scales, resulting in varying responses to acute versus chronic ozone stress.

The effects of O_3 on levels of primary metabolites vary among compounds and tree species. Levels of nutrients (e.g., N, P, K, Ca) may increase, decrease, or not change in response to O_3 fumigation. Levels of simple sugars generally are unaffected, whereas levels of starch typically decline in angiosperms, but not gymnosperms.

As is true for CO_2, studies of the effects of O_3 on secondary compounds in trees have been restricted almost entirely to phenolics and terpenoids. In general, elevated O_3 leads to increases in concentrations of phenolic acids and flavonoids in angiosperms but not in gymnosperms, and no overall change in concentrations of tannins. Foliar lignin concentrations also are generally unresponsive to O_3 fumigation (Boerner and Rebbeck 1995; Booker et al. 1996; Liu et al. 2005; Oksanen et al. 2005). Effects of O_3 on terpenoid levels have been studied in only a few tree species, and results are species-specific: increases in *Pinus sylvestris* and *Populus* species, and no change in *Picea abies* (Valkama et al. 2007; Blande et al. 2007). Moreover, the magnitude of response varies among types of terpenes, with diterpenes responding more strongly to O_3 than mono- or sesquiterpenes.

That O_3 elicits increases in the levels of some carbon-based secondary metabolites without corresponding increases in carbohydrates runs counter to the predictions of source-sink balance hypotheses (e.g., Bryant et al. 1983), and may be explained by the fact that ozone triggers up-regulation of antioxidant defense systems linked to the shikimic acid pathway (Valkama et al. 2007). Ozone causes oxidative damage, coupled to the proliferation of oxygen radicals. Gene transcription and activity of numerous enzymes in the shikimic acid pathway are elevated in response to O_3 exposure, leading to the production of antioxidants such as flavonoids and other simple phenolics, and shifts in the monomeric composition of lignin (Kangasjärvi et al. 1994; Heath 2008; Betz et al. 2009a, b). Indeed, ozone-induced phenolics have been considered potential bioindicators of O_3 stress in plants under natural conditions (Sager et al. 2005; Bidart-Bouzat and Imeh-Nathaniel 2008).

Ozone exposure also influences the amount and chemical composition (e.g., alkyl esters and fatty acids vs. alkanes and alkanols) of cuticular waxes in tree leaves (Karnosky et al. 2002; Kontunen-Soppela et al. 2007; Percy et al. 2009). These changes in turn determine the physical structure of the cuticular surface, with repercussions for leaf surface properties such as wettability.

In contrast to a large body of research with CO_2, little work has addressed how O_3 pollution interacts with other environmental factors to shape plant chemical profiles. Lindroth et al. (1993a) evaluated the effects of elevated O_3 and light intensity on several foliar constituents of hybrid poplar and sugar maple (*Acer saccharum*), and found that O_3 and light interacted to affect only concentrations of N in maple. Given that forest ecosystems are exposed to

multiple, simultaneous stress factors (e.g., climate change, insect outbreaks) in addition to increasing O_3 damage, and that some of those stressors induce the same chemical defense pathway as does O_3, such research is sorely needed.

Interactions Between CO_2 and O_3

The environmental factor that has been investigated most thoroughly in combination with O_3 pollution is CO_2. Enriched CO_2 may reduce ozone damage to trees both by decreasing stomatal conductance (and consequent oxidative stress) and by increasing carbohydrate pools for the synthesis of antioxidant compounds. The recent meta-analysis by Valkama et al. (2007) evaluated the effects of O_3, and O_3 combined with CO_2, on foliar chemistry of 22 species of trees. They found that enriched CO_2 can offset O_3-induced chemical changes, but their analysis did not differentiate between simple additive, versus interactive, effects of CO_2 and O_3.

Indeed, CO_2 and O_3 exert both independent (additive) and interactive effects on tree chemical profiles. Elevated O_3 concentrations exacerbated the CO_2-mediated reductions in N concentrations in *Betula papyrifera* (Kopper et al. 2001) and *Populus tremuloides* (Holton et al. 2003), but offset reductions in N in *Betula pendula* (significant $CO_2 \times O_3$ interactions). Peltonen et al. (2005) assessed the effects of CO_2 and O_3 on over thirty simple phenolics in *B. pendula*. They identified interactive effects in approximately three-quarters, and independent effects in one-quarter, of the cases. The interactive effects revealed that O_3-mediated induction of phenolics disappeared under elevated CO_2. Tannin levels also are influenced by both additive and interactive effects of CO_2 and O_3. Condensed tannin concentrations responded to the additive, independent effects of CO_2 and O_3 in *Fagus crenata* and various species of *Betula* (Kopper et al. 2001; Peltonen et al. 2005; Karonen et al. 2006), but to the interactive effects of CO_2 and O_3 in *Populus tremuloides* (Holton et al. 2003). Similarly, the effects of CO_2 and O_3 on monoterpenes and sesquiterpenes in *Pinus sylvestris* sometimes were additive and sometimes interactive (Sallas et al. 2001). In short, whether CO_2 and O_3 function in an additive or interactive manner depends on the particular chemical constituent and tree species studied.

Effects of CO_2 and O_3 on Trophic Interactions

Plant chemical composition is a strong ecological and evolutionary driver of trophic interactions, particularly between plants and herbivores. Given that green plants and phytophagous insects comprise nearly half of Earth's recognized species (Strong et al. 1984), it is not surprising that these taxa occupy the vast majority of all studies on plant-herbivore interactions. Several recent reviews have addressed the effects of CO_2 and O_3 on plant-insect interactions (Zvereva and Kozlov 2006; Stiling and Cornelissen 2007; Valkama et al. 2007; Bidart-Bouzat and Imeh-Nathaniel 2008). Composite results will be summarized below and supplemented with additional, relevant studies of tree-feeding herbivores.

Carbon Dioxide

Little evidence exists to suggest that elevated CO_2, upwards of 1,000 ppm predicted for this century, will directly affect insects (Coviella and Trumble 1999). Work by Stange (1997) showed that atmospheric CO_2 concentrations influence host location by *Cactoblastis cactorum*, but no similar work has been done with forest insects. Rather, the major effect of enriched CO_2 on herbivores will be indirect, mediated via changes in plant quality (Fig. 2). Overall, elevated CO_2 reduces the quality of tree foliage as food, due to decreases in nitrogen (an index of protein) and minerals, and increases in carbohydrates and phenolics. These changes typically, but not always, alter the preference and reduce the performance of herbivores.

CO_2 concentration influences selection of plants by insects and mammals. Elevated CO_2 reduced leafminer oviposition on *Populus tremuloides* (Kopper and Lindroth 2003a), but increased birch aphid oviposition on one of two clones of *B. pendula* (Peltonen et al. 2006). The few feeding studies conducted to date suggest that preferences of insects for ambient versus elevated CO_2 foliage are not easily predicted, as shifts in both directions, and no change, have been reported (Traw et al. 1996; Kuokkanen et al. 2003; Agrell et al. 2005; Knepp et al. 2007). Elevated CO_2 decreased the palatability of winter-dormant *Betula* species to hares and rabbits (Mattson et al. 2004), but not to voles (Kuokkanen et al. 2004). Of greater relevance in the universally CO_2-enriched world of the future, however, is whether enrichment alters relative preferences of herbivores for various host species. Minimal evidence to date suggests that such is the case. For example, Agrell et al. (2005) demonstrated that forest tent caterpillars switch relative preferences between *Populus tremuloides* and *Betula papyrifera*, as well as between *P. tremuloides* genotypes, grown in high CO_2 environments.

Elevated CO_2 also influences the individual performance of herbivores, although the effects are highly species-specific for both trees and insects. Among the more uniform (though still variable) of responses is food consumption. In general, insects increase both consumption rates, and total consumption, on CO_2-enriched foliage, ostensibly as a means to compensate for reduced N concentrations. Compensatory

feeding responses may be constrained, however, by the simultaneous consumption of higher concentrations of secondary metabolites such as phenolics. Approximate digestibility of food typically is not significantly affected, but conversion efficiencies of digested food into biomass generally decline. Little is known about how CO_2 environment affects insect detoxication capacities; a study with gypsy moths revealed enhanced oxidase, reductase, and esterase activities in larvae fed CO_2-enriched *P. tremuloides*, but not *Acer saccharum* (Lindroth et al. 1993b). Development times usually are prolonged, while growth rates and final pupal and adult weights decline or are unaffected, but rarely improve. Effects on reproduction have rarely been investigated. Lindroth et al. (1997) found no effect of CO_2 on the number and mass of eggs produced by gypsy moths, whereas Awmack et al. (2004) reported deceased fecundity in aphids on *B. papyrifera* under elevated CO_2.

Species-specificity in terms of insect herbivore responses to enriched CO_2 may be linked to differences among feeding guilds (e.g., chewers, miners, sap-feeders, seed-feeders). Bezemer and Jones (1998) identified such guild effects for plants and phytophagous insects in general. Too few studies have been conducted with tree-feeding insects to evaluate differences among guilds. However, the minimal, if not positive effects of CO_2 on tree-feeding aphids (Docherty et al. 1997; Awmack et al. 2004), in contrast to effects on chewing insects, suggest that guild-specific responses to CO_2 may exist for forest insects.

Just as interactions with various environmental factors influence the effects of CO_2 on plant chemistry, so may they modulate effects on herbivores. For example, the effects of elevated CO_2 on herbivore performance can be ameliorated or exacerbated by the availability of light, water, and soil nutrients (e.g., Kinney et al. 1997; Lawler et al. 1997; Roth et al. 1997; Hättenschwiler and Schafellner 1999; Agrell et al. 2000). Potential interactions with climate warming are of particular interest, as warm temperatures generally affect insects in a manner opposite that of CO_2, i.e., accelerated development and enhanced growth and reproductive performance (Bale et al. 2002). Indeed, Zvereva and Kozlov (2006) conclude from their recent meta-analysis that temperature increases are likely to mitigate predicted negative effects of enriched CO_2 on insects, and emphasize the need for future research to address the two factors in parallel.

In addition to the bottom-up effects of altered plant chemistry, elevated CO_2 may influence the top-down effects of natural enemies (predators, parasitoids, and pathogens) on insect herbivores (Fig. 2). Enriched CO_2 could affect natural enemies by altering the behavioral or physiological defenses of prey, modifying the quality of prey (e.g., insect size, concentrations of plant-derived toxins), or by altering the efficacy of host location and disease transmission. Few studies have addressed these possibilities, however, especially with forest systems. Elevated atmospheric CO_2 dramatically diminished the pheromone-mediated, predator escape behavior of aphids on *Populus tremuloides* (Mondor et al. 2004). In contrast, two studies have found the bottom-up effects of CO_2 on parasitoid performance (survivorship, development, and growth) to be minimal to nil (Roth and Lindroth 1995; Holton et al. 2003). The virulence of pathogens such as nuclearpolyhedrosis virus (NPV) is linked to host plant chemistry [e.g., tannins (Foster et al. 1992)], so CO_2-enriched atmospheres may influence the dynamics of disease outbreaks. CO_2-induced increases in condensed tannins in *P. tremuloides* did not, however, alter the susceptibility of gypsy moths to NPV (Lindroth et al. 1997). At this time insufficient information is available to predict whether the bottom-up effects of CO_2 on natural enemies will in general be buffered, amplified, or, more likely, context- and species-specific.

The impacts of elevated CO_2 concentrations on forest insects at the levels of populations and communities will be determined by a combination of bottom-up, top-down, and abiotic factors (Fig. 2). Historically, inferences about population-level responses have been drawn from studies of individual insects, but such conclusions can be misleading (Awmack et al. 2004). To date, however, few studies have addressed the impacts of elevated CO_2 at higher levels of organization. Several studies with tree-feeding aphids have shown no population-level effects (Docherty et al. 1997; Awmack et al. 2004), while another revealed positive effects of enriched CO_2 on aphid population size (Percy et al. 2002). In contrast, Stiling et al. (1999, 2002, 2003, 2009) found reduced densities (number per leaf) of herbivores, especially leafminers and leaftiers, in several woody species of a scrub-oak community exposed to elevated CO_2. Reduced herbivore densities were attributed to higher rates of both plant- and parasitoid-induced mortality, and were offset in several *Quercus* species by increased foliar production under high CO_2 (Stiling et al. 2009). Monitoring of aspen blotch leafminers (*Phyllonorycter tremuloidiella*) at Aspen-FACE indicated that elevated CO_2 roughly doubled plant-mediated mortality, substantially reduced predator-mediated mortality, and minimally influenced parasitoid-mediated mortality (Fig. 4).

Even fewer studies have addressed the effects of enriched CO_2 on speciose insect communities. Following 4 years of pan-trapping at Aspen FACE, Hillstrom and Lindroth (2008) reported that elevated CO_2 reduced abundance of phloem-feeding herbivores and increased abundance of chewing herbivores, although results were only marginally significant. Enriched CO_2 increased numbers of figitid and ichneumonid parasitoids, but not of braconid or chalcid parasitoids. Insect community composition differed between ambient and elevated CO_2 plots in 3 out of 4 years. In the most comprehensive study to

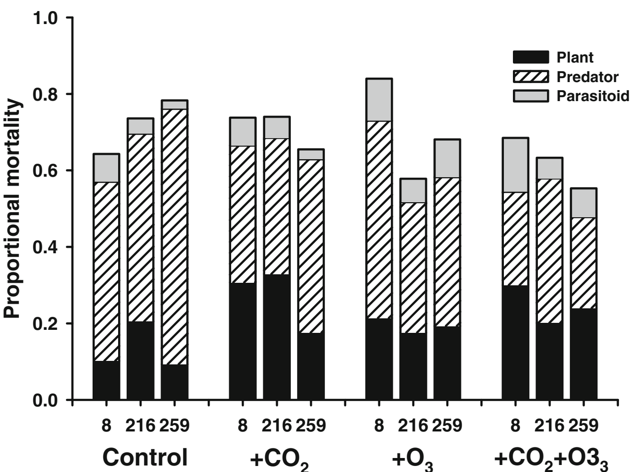

Fig. 4 Effects of CO_2 and O_3, in isolation and combination, on plant-, predator-, and parasitoid-induced mortality of aspen blotch leafminers (*Phyllonorycter tremuloidiella*). Data reveal major sources of mortality, prior to adult emergence, for miners on *Populus tremuloides*. Numerals below bars indicate aspen genotypes. Observations recorded in July 2001 at the Aspen FACE research site (Awmack and Lindroth, unpublished data)

date for forest canopy insects, Hillstrom and Lindroth (unpublished data) visually monitored insects on *Populus tremuloides* and *Betula papyrifera* over 3 years at Aspen FACE, cataloging over 36,000 insects from nearly 300 species. Overall, enriched CO_2 tended to increase the abundance of phloem-feeders and decrease the abundance of chewers and gallers on *P. tremuloides*, although effects were variable among species and over time. Few consistent effects on abundance were found, however, for insects on *B. papyrifera*. Elevated CO_2 did not affect species diversity of canopy insects, except for insects on *P. tremuloides* in 1 year. Elevated CO_2 also did not influence insect community composition, except for insects on *B. papyrifera* in 1 year.

Ozone

Increasing evidence suggests that tropospheric ozone pollution may affect directly insects. Gate et al. (1995) found that under elevated O_3, searching efficiency of a hymenopteran parasitoid, as well as the proportion of hosts parasitized, declined. O_3 likely interacts with the complex of BVOCs that function as "infochemicals" to govern key interactions between insects and both their hosts (plant or insect) and natural enemies (predators and parasitoids) (Laothawornkitkul et al. 2009; Yuan et al. 2009; Pinto et al. 2010, this volume). Chemical degradation or transformation of BVOCs by O_3 is likely to increasingly disrupt olfactory cues in atmospheres of the future.

Selection of plants as oviposition or food hosts is influenced by O_3 concentrations. O_3-treated foliage reduced leaf beetle oviposition onto *Populus deltoides* (Jones and Coleman 1988) and leafminer oviposition onto *Populus tremuloides* (Kopper and Lindroth 2003a). Few feeding studies have compared the preferences of insects for fumigated vs. nonfumigated foliage, and those indicate a range of responses. Leaf beetles preferred O_3-treated *P. deltoides* (Jones and Coleman 1988) and common leaf weevils preferred O_3-treated hybrid aspen (Freiwald et al. 2008), whereas forest tent caterpillars preferred untreated *P. tremuloides* (Agrell et al. 2005). Forest tent caterpillars greatly increased their preference for *Betula papyrifera*, relative to *P. tremuloides*, under elevated O_3, and also shifted their preferences among *P. tremuloides* genotypes (Agrell et al. 2005).

O_3 fumigation changes the individual performance of phytophagous insects, although, as for CO_2, effects are highly species-specific. The meta-analysis by Valkama et al. (2007) summarized results for 22 species of trees and ten species of insects. Food consumption rates typically are unaffected, as are survival and reproduction rates. Development times usually are reduced, and pupal masses increased, under elevated O_3. For example, Kopper and Lindroth (2003b) reported that for forest tent caterpillars reared on high-O_3 *Populus tremuloides*, development times decreased an average of 14% and pupal weights increased an average of 31% compared with insects on control trees. Relative growth rates of chewing, but not sucking, insects generally increase under elevated O_3. On average, insect fecundity is not affected by O_3, although Awmack et al. (2004) reported decreased fecundity for aphids on *Betula papyrifera*.

Under natural conditions, interactions between trees and herbivores likely are influenced by multiple, interacting stressors, including O_3 (Koricheva et al. 1998b). With the exception of interactions with CO_2 (addressed below), however, exceedingly little is known about how O_3 may interact with other environmental factors to influence trophic interactions. Lindroth et al. (1993a) reported that gypsy moth larval performance was influenced by the independent, but not interactive, effects of O_3 and light intensity. With the likelihood of increased pest damage to forests under future scenarios of global environmental change, assessments of the combined effects of ozone and other stressors should be a high priority.

A growing body of literature reveals that O_3 pollution likely will affect interactions between tree-feeding insects and their natural enemies. As indicated above and described elsewhere in detail (Yuan et al. 2009; Pinto et al. 2010), O_3 may directly affect the behavior and fitness of predators and parasitoids. Alternatively, elevated O_3 may alter the behavioral or physiological defenses of prey, or their quality as food. For example, Mondor et al. (2004) reported that at Aspen FACE, high O_3 environments markedly

enhanced predator escape behaviors of aphids on *Populus tremuloides*. Also at Aspen FACE, O_3 fumigation reduced survivorship of the parasitoid *Compsilura concinnata* (Holton et al. 2003). Decreased fitness was consistent with improved performance of its forest tent caterpillar host, which in turn was linked to decreased levels of phenolic glycosides in *P. tremuloides*.

Despite accumulating evidence for impacts of O_3 at the level of individual insect performance, little work has addressed impacts at the level of populations. Awmack et al. (2004) found that O_3 fumigation at Aspen FACE increased population densities of aphids on *Betula papyrifera* when protected from natural enemies, but not when unprotected. Also at Aspen FACE, elevated O_3 levels tended to increase plant-mediated mortality, reduce predator-mediated mortality. and increase parasitoid-mediated mortality of aspen blotch leafminers (*Phyllonorycter tremuloidiella*), although magnitudes of effects varied among insects on different aspen genotypes (Fig. 4).

At the level of insect communities, pan-trapping at Aspen FACE revealed positive effects of elevated O_3 on abundance of some phloem-feeding insects, and strong suppressive effects on a diversity of parasitoids (Hillstrom and Lindroth 2008). O_3 influenced the community composition of insects captured by traps in 2 out of 4 years. In our more recent visual censuses of canopy insects at Aspen FACE, we found that O_3 fumigation increased abundances of several species of chewing insects, but decreased numbers of several phloem-feeders, on *Populus tremuloides* (Hillstrom and Lindroth, unpublished data). O_3 did not, however, consistently affect abundances of insects on *Betula papyrifera*. O_3 also had generally little impact on the species diversity and community composition of canopy insects on several tree species, and across multiple years, at Aspen FACE.

Interactions Between CO_2 and O_3

Valkama et al. (2007) sought to differentiate the effects of O_3 alone, versus O_3 in combination with CO_2, on the performance of tree-feeding insects. Their meta-analysis revealed that many of the positive effects of O_3 on insect performance, especially for leaf chewers, are negated with simultaneous exposure to enriched CO_2. Their review did not, however, differentiate between simple additive, versus truly interactive, effects of CO_2 and O_3 on insects.

Indeed, relatively few studies have been designed to detect potential interactive effects of CO_2 and O_3 on forest insect performance, and those have shown mixed results. Several studies (Awmack et al. 2004; Peltonen et al. 2006) have assessed the independent and combined effects of CO_2 and O_3 on feeding, growth, and reproductive performance of aphids, and revealed no significant interactions. Similarly, no significant interactions were observed with respect to CO_2 and O_3 effects on leafminers on *Populus tremuloides* (Kopper and Lindroth 2003a), whitemarked tussock moths feeding on *Betula papyrifera* (Kopper et al. 2001), or forest tent caterpillar feeding preferences for *P. tremuloides* and *B. papyrifera* (Agrell et al. 2005). In contrast, CO_2 and O_3 interacted to influence development and growth of forest tent caterpillars on *P. tremuloides*: O_3-mediated enhancements in performance were greater at ambient than elevated CO_2. In short, the limited evidence to date suggests that the combined effects of CO_2 and O_3 on insect herbivores will be primarily additive, although the standard caveat of context- and species-specificity applies.

Effects of CO_2 and O_3 on Ecosystem Dynamics

At the level of forest ecosystems, plant chemistry plays a host of important roles, the most prominent of which arguably is regulation of the transfer of fixed carbon to herbivores and decomposers—the dominant pathways of material flow (Fig. 1). Accumulating evidence suggests that elevated concentrations of CO_2 and O_3 will modify the complex of physiological and ecological interactions that determine rates of plant damage, organic substrate deposition, and nutrient cycling. In short, the effects of CO_2 and O_3 on plant chemistry will in turn influence the sequestration and cycling of carbon and nutrients in forest ecosystems.

Forest Canopy Damage

Phytophagous insects generally remove 2–15% of primary production in temperate deciduous forests (Cebrian 1999; Cyr and Pace 1993; Cebrian and Lartigue 2004), although during outbreaks, nearly 100% can be consumed (e.g., Donaldson and Lindroth 2008). Canopy damage rates are a function of the host preferences, individual consumption rates, population densities, and community composition of herbivorous insects, all of which can be influenced by levels of atmospheric CO_2 and O_3.

The effects of CO_2 on loss of primary production to herbivores have been explored in only a few forest systems. In a Florida scrub oak community, enriched CO_2 decreased the frequency of damage to *Quercus myrtifolia* (Stiling et al. 2002). Later work in the same system documented a decline in the frequency of damage by 4 of 6 insect feeding groups, across three *Quercus* species, under elevated CO_2 (Hall et al. 2005). Working with four understory tree species at the FACTS-1 FACE site (loblolly pine—hardwood forest), Hamilton et al. (2004) reported declines of 10–46% in foliar damage rates in high CO_2 plots. These declines were driven largely, however, by the

response of one species (*Ulmus alata*); damage rates in other species were not statistically significant from those of control trees. Knepp et al. (2005) followed up that work by censusing foliar damage rates in twelve species of potted saplings at FACTS-1 FACE. Enriched CO_2 reduced damage rates across all species in 2001, but not in 2002–2003. In the most comprehensive study to date, Couture, Meehan, and Lindroth (unpublished data) evaluated damage rates on leaves collected from *Populus tremuloides* and *Betula papyrifera* over 3 years at Aspen FACE. Elevated CO_2 concentrations did not markedly affect herbivory rates in 1 year, but increased damage rates by 2–3-fold in 2 years of the study. Overall, these studies indicate that canopy damage rates are likely to change under CO_2 concentrations of the future. But, consistent with effects on individual insects, the magnitude and direction of change will be both species-specific and temporally variable.

To date, no published study has evaluated the effects of elevated tropospheric O_3 on community-wide, canopy damage in forest ecosystems. Our work at Aspen FACE (Couture, Meehan and Lindroth, unpublished data) revealed that high levels of O_3 reduced damage to both *Populus tremuloides* and *Betula papyrifera* in 2 of 3 years.

Calculations of losses to primary production based on leaf areas damaged by herbivores may significantly underestimate true reductions in production. Aldea et al. (2006) showed that in a variety of deciduous tree species, chewing damage caused modest and localized suppression of photosynthetic efficiency in adjacent, undamaged leaf tissue, whereas galling damage caused large and extensive suppression. The authors suggest that the spatial propagation of reduced photosynthesis may be influenced by enriched CO_2, but did not observe such effects in their study. More recently, however, P. Nabity and M. Hillstrom (pers. comm.) found that elevated CO_2 decreased the propagation of reduced photosynthesis caused by insects feeding on *Populus tremuloides* and *Betula papyrifera* at Aspen FACE.

Organic Substrate Deposition

Herbivorous insects mediate the transfer of organic materials from the forest canopy to the forest floor by depositing frass, greenfall, and insect biomass, and altering the timing and amounts of leachate througfall and leaf litterfall. These processes have received little attention in the context of global change research.

We recently evaluated the effects of fumigation treatments at Aspen FACE on the quality of frass produced by whitemarked tussock moth larvae feeding on *Populus tremuloides*, and the effects of both frass and greenfall on soil microbial respiration and nitrogen leaching (Hillstrom, Meehan, Kelly and Lindroth, unpublished data). Insect frass had slightly decreased N levels in high O_3 environments, and increased tannin levels in high CO_2 environments. However, neither frass nor greenfall quality affected microbial respiration (CO_2 efflux) or nitrogen (NO_3^-) leaching in soil microcosms. In contrast, the quantity of frass and greenfall added to microcosms markedly affected both respiration and N leaching, under all atmospheric conditions. Thus, insects may affect carbon and nitrogen mineralization in forests of the future more through their effects on the quantity (and timing), than quality, of substrate deposition.

Indeed, atmospheric CO_2 and O_3 concentrations appear to influence rates of insect-mediated organic substrate deposition in forests. At Aspen FACE, rates of combined frass and greenfall deposition were 35% higher in elevated vs. ambient CO_2 stands, and 13% lower in elevated vs. ambient O_3 stands, over three field seasons (Meehan, Couture, Bennett and Lindroth, unpublished data).

Finally, insect feeding and atmospheric composition both may alter the timing of litterfall in forest ecosystems. In general, feeding damage accelerates leaf abscission, whereas enriched CO_2 may either accelerate (Stiling et al. 2002) or decelerate (Karnosky et al. 2003) abscission rates. How herbivory and atmospheric chemistry may interact to influence the magnitude and timing of leaf abscission is unknown.

Soil Invertebrates

Soil invertebrates play important roles in the nutrient cycling dynamics of forest ecosystems, from the comminution and microbial inoculation of plant litter to the vertical transport of organic matter through soil horizons. These processes are governed both by the quality and quantity of litterfall, which in turn are influenced by atmospheric composition (Fig. 1).

Several studies have evaluated the effects of leaf litter from elevated CO_2 plots on feeding preferences of isopods. Using short-term (3 day) feeding choice studies, Cotrufo et al. (1998b) found that isopods (*Oniscus asellus*) consumed 16% less high-CO_2 litter than ambient-CO_2 litter from *Fraxinus excelsior*. Subsequently, Cotrufo et al. (2005a) fed isopods (*Porcellio* sp.) for 2 weeks on litter from six tree species grown under ambient and elevated CO_2, and found no difference in palatability for five species, and increased preference for high-CO_2 litter for one species. Using no-choice feeding studies and two species of isopods, Hättenschwiler et al. (1999) found increased consumption of high-CO_2 beech litter, but no effect of CO_2 on consumption of spruce litter. Hättenschwiler and Bretscher (2001) reported that growth of trees under elevated CO_2 altered the relative preference of *O. asellus* for different litter species—increasing preference for one, decreasing

preference for another, and not affecting yet another. Thus, as is the case for insects feeding on green leaves, the consequences of CO_2 for detritus-feeding invertebrates are species-specific.

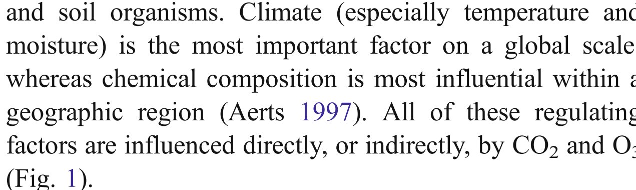
Additional studies have assessed the effects of leaf litter from elevated CO_2 or O_3 environments on fitness indices and population growth of soil invertebrates. Individual growth of juvenile earthworms (*Lumbricus terrestris*) was reduced when fed high-CO_2 or high-O_3 birch (*Betula pendula*) litter (Kasurinen et al. 2007), and high-CO_2 (but not high-O_3) aspen (*P. tremuloides*) litter (Meehan, Crossley and Lindroth, unpublished data). Growth and mortality rates of isopods, however, generally have been shown not to be affected by CO_2 or O_3 treatments (Hättenschwiler and Bretscher 2001; Kasurinen et al. 2007). Population growth of collembola (*Sinella curviseta*) decreased when reared on high-CO_2 aspen litter, but increased when reared on high-O_3 aspen litter (Meehan, Crossley and Lindroth, unpublished data).

Several studies have evaluated the effects of CO_2 and O_3 on soil invertebrate communities under field conditions. Hansen et al. (2001) investigated the effects of elevated CO_2 concentrations on soil microarthropods at the FACTS-1 FACE site. Over the first 19 months of CO_2 treatment, total microathropod abundance declined by 34% in high-CO_2 plots, relative to ambient plots. The decline was driven by changes in abundance of oribatid mites, and was attributed to factors other then changes in litter quality. Haimi et al. (2005) censused populations of enchytraeids, mites and collembola in soil samples surrounding chambered *Pinus sylvestris* trees. Elevated CO_2 concentrations contributed to low numbers of acaridid mites, but did not significantly affect other soil fauna. Loranger et al. (2004) assessed responses of soil invertebrates to CO_2 and O_3 enrichment at Aspen FACE. They found that numbers of collembola and Oribatid mites, but not various other soil animals, declined in elevated CO_2 plots. Mites, but not other fauna, also decreased in high O_3 plots.

In summary, CO_2- and O_3-mediated changes in litter quality are likely to influence the performance of soil invertebrates of forests in the future. Some evidence exists to suggest that reduced litter quality will negatively affect the fitness of soil animals. In turn, their roles in nutrient cycling and soil carbon sequestration are likely to be altered. Overall, however, as noted by Couteaûx and Bolger (2000), no general patterns of response have yet emerged, likely due to the species- and context-specific nature of these interactions.

Litter Decomposition

Rates of litter decomposition and attendant nutrient mineralization are governed primarily by climate, litter chemistry,



and soil organisms. Climate (especially temperature and moisture) is the most important factor on a global scale, whereas chemical composition is most influential within a geographic region (Aerts 1997). All of these regulating factors are influenced directly, or indirectly, by CO_2 and O_3 (Fig. 1).

Litter quality is determined by carbon availability (which ranges from labile sugars to recalcitrant lignin), mineral content, and chemical modifiers such as tannins (Swift et al. 1979; Anderson 1991). Tannins and related phenolic constituents alter decomposition by complexing with other litter components (e.g., amino acids) and/or by inhibiting the degradative activity of enzymes and soil fauna (Horner et al. 1988; Anderson 1991; Coûteaux et al. 1995). For similar litter types in common environments, nitrogen, lignin, and tannin concentrations appear to act as “a hierarchical series of controls” (Anderson 1991). In high quality, readily decomposable litters, tannins may be rate retardants, whereas in low quality, slowly decomposable litters, lignin concentration, or lignin: N ratio typically determine decomposition rates (Anderson 1991). Any factor that markedly affects the nitrogen or C-based secondary metabolite concentration of litter also will affect decomposition, and consequently, nutrient availability (Chapin 1991).

The “litter quality” hypothesis, introduced by Strain and Bazzaz (1983), proposed that CO_2 enrichment will decrease plant nitrogen (relative to carbon) concentrations, and thereby reduce litter decomposition and soil N availability. Progressive soil nitrogen limitation is anticipated to eventually feed back to reduce plant production (Luo et al. 2004; Johnson 2006). Thus, CO_2-mediated changes in the chemical quality of litter have been of key interest with respect to understanding the cycling and storage of carbon in forest ecosystems. Indeed, litter from trees grown under elevated CO_2 characteristically exhibits reduced N concentrations and increased lignin concentrations and C:N ratios (Ceulemans et al. 1999; Norby et al. 2001).

To date, however, studies of the effects of elevated CO_2 on litter decomposition (measured as mass loss or microbial respiration) have not demonstrated a consistent direction of response. A comprehensive meta-analysis by Norby et al. (2001), including data for 33 woody species, showed that data do not support the “litter quality” hypothesis of reduced decomposition rates for litter produced under elevated CO_2. Decomposition studies published since that review have been increasingly realistic, employing more long-term and field-based approaches with open-top chambers or FACE sites. Still, a consistent pattern has yet to emerge. Several studies have documented reduced decomposition of leaf litter produced under elevated CO_2. For example, litter from three *Populus* species grown under elevated CO_2 at POPFACE exhibited reduced decomposi-

tion rates (Cotrufo et al. 2005b), as did litter from *Betula papyrifera* and *Populus tremuloides* from young (sapling) forest stands grown under elevated CO_2 at Aspen FACE (Parsons et al. 2004, 2008). In contrast, CO_2 growth environment did not alter subsequent litter decomposition rates for *Quercus myrtifolia* in a scrub oak community (Hall et al. 2006), for five tree species at the FACTS-1 FACE site (Finzi et al. 2001), or for *B papyrifera* and *P. tremuloides* in older, closed-canopy stands at Aspen FACE (Liu et al. 2009). Diverse responses among experiments have been attributed to a number of factors, including soil fertility, decomposition environment, CO_2 exposure mechanism, study duration, stand development, and, genotype- and species-specific effects (Norby et al. 2001; Kasurinen et al. 2006; Hall et al. 2006; Liu et al. 2009).

Relatively little research has investigated the effects of atmospheric O_3 on litter quality and decomposition. Growth of three species of deciduous tree seedlings (Boerner and Rebbeck 1995; Scherzer et al. 1998) and two species of *Pinus* seedlings and saplings (Scherzer et al. 1998; Kainulainen et al. 2003) under elevated O_3 did not influence subsequent decomposition rates of leaf litter. Findlay et al. (1996), however, found that cottonwood leaves produced under high O_3 levels exhibited reduced decomposition rates (in aquatic microcosms), which were linked to increased phenolic concentrations. Similarly, Kasurinen et al. (2006) observed reduced decomposition in *Betula pendula* leaves produced under high O_3 concentrations. Parsons et al. (2008) found that early in stand development at Aspen FACE, growth under elevated O_3 reduced 2-year decomposition rates of *Populus tremuloides* litter, independent of CO_2 treatment. In contrast, elevated O_3 accelerated decomposition of *Betula papyrifera* litter from ambient CO_2 treatments, but decreased decomposition of litter from enriched CO_2 treatments (a significant $O_3 \times CO_2$ interaction). Later work at Aspen FACE, however, showed that elevated O_3 decreased the decomposition of *P. tremuloides* and *B. papyrifera* litter from closed-canopy stands during only the first year of a 2.6-year study (Liu et al. 2009). As is the case for atmospheric CO_2, the effects of elevated O_3 on litter decomposition appear to be species-, age-, and context-specific.

Although too early for definitive conclusions, the developing scientific consensus is that atmospheric CO_2 and O_3 will affect litter decomposition and subsequent nutrient cycling more through their effects on the quantity, than quality, of foliage produced, and by shifting the species composition of forests (Finzi and Schlesinger 2002; Cotrufo et al. 2005b; Liu et al. 2007, 2009; Hillstrom, Meehan, Kelly and Lindroth, unpublished data). For example, soil carbon sequestration at Aspen FACE appears to be more closely related to CO_2- and O_3-mediated changes in input quantity and species composition than to qualitative changes in litter chemical composition (Loya et al. 2003; Liu et al. 2007, 2009).

Conclusions and Recommendations for Future Research

Human-induced changes in the levels of atmospheric CO_2 and O_3 clearly influence the quantity and quality of primary production. In turn, changes in plant chemical composition cascade through above- and below-ground ecological interactions (e.g., herbivory, decomposition) to alter ecosystem structure and function, ultimately feeding back to affect terrestrial carbon sequestration and atmospheric composition. Many of these interactions are governed by processes that are fundamentally chemical in nature (double entendre intended). Thus, chemical ecologists have much to offer in terms of elucidating the mechanisms that integrate biological organization—from genomes to ecosystems—in a globally changing world.

An admittedly frustrating theme to emerge from this and other recent reviews (e.g., Stiling and Cornelissen 2007; Bidart-Bouzat and Imeh-Nathaniel 2008; Tylianakis et al. 2008) of global environmental change is that the effects of any single change factor on any particular ecological interaction are highly variable. Responses tend to be species- and context-specific, and thus appear idiosyncratic. Global change science must advance considerably further before predictions about impacts on natural systems can be made with accuracy and precision. The work of chemical ecologists should be central to such efforts: it will provide mechanistic insight into ecosystem function and provide data critical to the accurate parameterization of global change and risk assessment models.

Below I provide a non-exhaustive list of some of the more pressing needs for the contributions of chemical ecologists toward furthering our understanding of the effects of CO_2 and O_3 on forest ecosystems. Funding of large, long-term, multi-investigator projects is essential to the success of these efforts.

1. Increase the diversity of natural products studied. Our understanding of the effects of global change on the phytochemistry of forest ecosystems is based on a few classes of chemical compounds, primarily phenolics and terpenoids. Almost nothing is known about effects on other classes of secondary metabolites important to at least some tree species, e.g., alkaloids, cyanogenic glycosides, nonprotein amino acids, coumarins, and iridoid glycosides.
2. Broaden the representation of species and biomes investigated. To date, research has focused on a narrow range of deciduous and coniferous tree species and biomes, and mostly lepidopteran herbivores. Both

tropical and boreal forests are critically important to the global carbon cycle, and poorly represented in global change research. Future studies should emphasize foundation tree species (Ellison et al. 2005) and functional groups (e.g., insect borers, miners) and taxa (e.g., mammals) known to be important to the health and sustainability of forest ecosystems. The coniferous forests and irruptive bark beetles of western North America are a prime example (Raffa et al. 2008). In a similar vein, future research should address non-exploitative ecological interactions, such as mutualistic associations of plants with pollinators and mycorrhizae.

3. Emphasize simultaneous investigation of multiple global change drivers. As documented in this review and others (e.g., Tylianakis et al. 2008), the effects of any particular global change factor on ecological interactions are context-dependent. Multiple drivers should be investigated simultaneously to more realistically approximate future environments and to provide a diversity of conditions under which to test the effects of individual drivers (Tylianakis et al. 2008). Altered temperature and precipitation are arguably the most important additional factors to evaluate in the context of CO_2 and O_3 effects on forests.
4. Conduct long-term experiments. The majority of studies published to date have been executed over short time frames (up to several years), with only a few approaching 10 years—considerably less than the lifespan of forest trees. Some ecosystem processes (e.g., soil nutrient depletion and carbon storage) require assessment over the course of a decade or longer, logistical and funding constraints nothwithstanding. Long-term experiments also could allow for studies of evolutionary responses of insects to CO_2- and O_3-mediated changes in tree chemistry, which are conspicuously absent in the published literature and important to understanding the effects of global change on forest ecosystems.
5. Employ “genes to ecosystems” research perspectives. “Genes to ecosystems” research has emerged as a new disciplinary frontier in genetics and ecology (Whitham et al. 2006). It combines genetic/genomic tools with the approaches of evolutionary ecology to understand the functional significance of genes in ecological context and the dynamics of ecosystems in evolutionary context. The discipline of chemical ecology can play a key role in elucidating the “metabolomes” that link gene expression to ecosystem processes in the context of global environmental change.

Acknowledgments Two decades of global change science by my research group have been generously supported by grants from the National Science Foundation, U.S. Department of Agriculture (National Research Initiatives) and the U.S. Department of Energy (Office of Science; currently, grant DE-FG02-06ER64232). Comments from two reviewers, including Stephan Hättenschwiler, improved the manuscript. I am deeply appreciative of the contributions of numerous undergraduate, graduate, postdoctoral and technical associates who have contributed to nearly 20 years of global change research in the Lindroth Lab, and grateful to the Source of grace that, like rain, falls on us all.

Abstract Tropospheric ozone (O_3) is an important secondary air pollutant formed as a result of photochemical reactions between primary pollutants, such as nitrogen oxides (NO_x), and volatile organic compounds (VOCs). O_3 concentrations in the lower atmosphere (troposphere) are predicted to continue increasing as a result of anthropogenic activity, which will impact strongly on wild and cultivated plants. O_3 affects photosynthesis and induces the development of visible foliar injuries, which are the result of genetically controlled programmed cell death. It also activates many plant defense responses, including the emission of phytogenic VOCs. Plant emitted VOCs play a role in many eco-physiological functions. Besides protecting the plant from abiotic stresses (high temperatures and oxidative stress) and biotic stressors (competing plants, micro- and macroorganisms), they drive multitrophic interactions between plants, herbivores and their natural enemies e.g., predators and parasitoids as well as interactions between plants (plant-to-plant communication). In addition, VOCs have an important role in atmospheric chemistry. They are O_3 precursors, but at the same time are readily oxidized by O_3, thus resulting in a series of new compounds that include secondary organic aerosols (SOAs). Here, we review the effects of O_3 on plants and their VOC emissions. We also review the state of current knowledge on the effects of ozone on ecological interactions based on VOC signaling, and propose further research directions.

Introduction

Since the pre-industrial era, atmospheric O_3 concentration has increased. When globally averaged, this amounts to a 30% rise (IPCC 2007). Recent estimates (Sitch et al. 2007; The Royal Society 2008) project a continuous rise in tropospheric O_3 levels as a result of increases in anthropogenic precursor emissions. It has been estimated that O_3 concentrations increase by between 0.5 and 2% per year (Vingarzan 2004), and that by 2100 the mean monthly 24-h concentration will be above 40 ppb over most of the Earth, and above 70 ppb over some regions (Sitch et al. 2007). Currently, O_3 is the most important pollutant in rural areas (Ashmore 2005) due to long-range transport from polluted sites (IPCC 2007; Vingarzan 2004). Both acute and chronic exposures have a strong negative impact on plants. While acute exposure results in visible symptoms that reduce the economic value of crops (see Ashmore 2005, for a review), chronic exposure affects physiological processes with or without visible symptoms (Long and Naidu 2002), which results in decreased crop yields (see Ashmore 2005, for a review). In

turn, plant-mediated effects can impact on herbivore performance (Kopper and Lindroth 2003; Awmack et al. 2004) and behavior (Jones and Coleman 1988; Jackson et al. 1999; Agrell et al. 2005) as well as the performance and abundance of higher trophic levels e.g., predators and parasitoids of herbivores (Percy et al. 2002; Holton et al. 2003).

During recent years, there has been growing interest in assessing the atmospheric and ecological effects of O_3 on VOC emissions. In a process driven by positive feedback, O_3 exposure enhances the emission of VOCs to the atmosphere (Llusià et al. 2002), which in turn increases atmospheric O_3 concentrations, since VOCs take part in photochemical reactions that lead to O_3 formation (Atkinson and Arey 2003). This positive feedback may be enhanced by increasing temperatures. In field exposure experiments, very moderate temperature increases have been shown to significantly enhance phytogenic VOC emissions, and in particular green leaf volatiles (Hartikainen et al. 2009). Earlier research suggested isoprenoids (mostly isoprene and monoterpenes) act as scavengers of radical oxygen species (ROS) or membrane stabilizers under high temperature stress and thus improve plant thermotolerance (Peñuelas and Llusià 2003; Sharkey et al. 2008).

VOCs are also prone to ozonolysis (Fig. 1), a process that results in the formation of secondary organic aerosols (SOAs) (Seinfeld and Pandis 2006; Laothawornkitkul et al. 2009). From an ecological point of view, both increased emission and destruction of VOCs by O_3 may affect several of their multiple functions (Lerdau and Slobodkin 2002; Holopainen 2004; Yuan et al. 2009). VOCs protect plants from biotic stressors such as fungi and bacteria through antifungal and antimicrobial properties and may repel generalist herbivores (see Kesselmeier and Staudt 1999; Dudareva et al. 2006; Laothawornkitkul et al. 2009 for a review). They also inhibit seed germination and growth of neighboring plant species (Romagni et al. 2000) and thus decrease competition. In addition, VOCs attract pollinators to flowers, animal seed dispersers to odorous fruits (Dudareva et al. 2006), herbivores to host plants (Schoonhoven et al. 2006), and herbivore-induced VOCs mediate the orientation of micro- and macro-organisms from higher trophic levels towards their host or prey (Dicke 1999, for a review; Rasmann et al. 2005). Plant VOCs also are important in within-plant signaling as well as in plant-to-plant signaling (Karban et al. 2003; Frost et al. 2007; Heil and Silva Bueno 2007). As VOCs have significant ecological relevance, we review how O_3 affects their emission and subsequent ecological interactions. Based on current knowledge of O_3 effects on plant biochemistry and physiology and atmospheric chemistry, we identify the potential impact on ecological interactions based on VOCs and propose prospective areas for further research.

O_3 in the Atmosphere: The Photochemical Smog Formation Process

The photochemical formation of O_3 in the troposphere begins with the oxidation of nitric oxide (NO) to nitrogen dioxide (NO_2) under sun light, and then proceeds through reactions 1 and 2 ($O(^3P)$ indicates the ground–state

Fig. 1 The ozonolyzis of alkenes proceeds via an initial O_3 addition to the C–C double bond(s) of alkenes, followed by degradation of the resulting ozonide (**1**), which in turn may decompose and form the Criegee intermediate (**2**) and carbonyl (**3**). The energy-rich Criegee biradical (**2**) can be stabilized by collision, and thus, may react with water leading to carboxylic acid (**4**) formation

energy-rich biradical

oxygen). In unpolluted air, some NO undergoes oxidation leading to NO_2 regeneration (reaction 3). However, in polluted air, this cycle can be broken down by the action of organic (RO_2•) or hydro-peroxy (HO_2) radicals. The free radicals that oxidize NO to NO_2 (reactions 4 and 5) are formed during photo-oxidation of biogenic (from biological processes in both marine and terrestrial environments Fuentes et al. 2000) and anthropogenic VOCs excluding carbon monoxide (CO) and carbon dioxide (CO_2) (Finlayson-Pitts and Pitts 2000).

$$NO_2 + hv \rightarrow NO + O(^3P) \tag{1}$$

$$O(^3P) + O_2 + M \rightarrow O_3 + M \quad (M = \text{air, inert particle}) \tag{2}$$

$$O_3 + NO \rightarrow NO_2 + O_2 \tag{3}$$

$$RO_2\bullet + NO \rightarrow RO\bullet + NO_2 \tag{4}$$

$$HO_2\bullet + NO \rightarrow OH\bullet + NO_2 \tag{5}$$

The best way to understand O_3 production is to consider the oxidation of methane (CH_4), structurally the simplest VOC. The CH_4 oxidation cycle serves as a simplified model for the chemistry of the unpolluted troposphere (reactions 6–12). In the polluted atmosphere, the fundamental chemical principles are the same (Baird and Michael 2005). The oxidation of VOCs is triggered by hydroxyl radicals (OH•), and results in several alkyl peroxy (RO_2•) and hydroperoxy (HO_2•) radicals, which lead to the conversion of NO to NO_2, and hence, promotes O_3 accumulation and the efficient regeneration of the OH•. In turn these can react with other VOCs. The primary source of OH• in the atmosphere is the reaction of electronically excited O atoms, O ($_1$D), a result of O_3 photolysis, with water vapor. The reaction of electronically excited nitrogen oxide (NO_2*) with water is also an important source of OH•. The NO_2* breaks the O–H bond in water, leading to OH• and HONO formation (Li et al. 2009). In polluted areas, the photolysis of aldehydes (e.g., HCHO), nitrous acid (HONO) and hydrogen peroxide (H_2O_2) also can be significant sources of OH• or HO_2• that can rapidly be converted to OH• (Seinfeld and Pandis 2006).

$$CH_4 + OH\bullet \rightarrow CH_3\bullet + H_2O \tag{6}$$

$$CH_3\bullet + O_2 \rightarrow CH_3OO\bullet \tag{7}$$

$$CH_3OO\bullet + NO \rightarrow CH_3O\bullet + NO_2 \tag{8}$$

$$CH_3O\bullet + O_2 \rightarrow H_2CO + HO_2\bullet \tag{9}$$

$$H_2CO \rightarrow H\bullet + HCO\bullet \tag{10}$$

$$H\bullet + O_2 \rightarrow HO_2\bullet \tag{11}$$

$$HCO\bullet + O_2 \rightarrow CO + HO_2\bullet \tag{12}$$

The most important classes of compounds in the photochemical process, including O_3 formation, are alkanes, alkenes, aromatic hydrocarbons, carbonyl compounds (e.g., aldehydes and ketones), alcohols, organic peroxides, and halogenated organic compounds (e.g., alkyl halides). In urban areas, compounds representing all VOC classes are important for O_3 formation, but especially significant are the alkenes such as propene and butenes. In rural vegetated areas, biogenic non-methane VOCs emitted by plants tend to be the most important source (Guenther 1999). The major alkenes emitted by vegetation are isoprene (2-methyl-1,3-butadiene) and monoterpenes ($C_{10}H_{16}$) (Atkinson and Arey 2003).

The photochemical process is driven by NO_x (NO plus NO_2) levels, reactivity of VOCs as well as the amount of OH• in the atmosphere (Seinfeld and Pandis 2006; Wennberg and Dabdub 2009). At low NO_x levels, the net production of O_3 increases with increasing NO_x. However, at high NO_x levels, there is a net destruction of O_3 through reactions with NO. In addition, there is a transition stage in which O_3 shows only a weak dependence on NO_x levels (Seinfeld and Pandis 2006). Thus, the efficiency of O_3 production per unit of NO_x oxidized is generally highest in areas where NO_x levels are low, and it decreases with increasing NO_x concentration. Therefore, in urban areas, the ozone level is directly related to traffic, reaching higher values when truck traffic is lower due to NO_x level drops (Wennberg and Dabdub 2009).

O_3 Effects on VOCs: From the Cell to the Environment

O_3 can affect the biosynthesis and/or emission of VOCs by impacting the biochemistry and physiology of the plant (Rao et al. 2000; Long and Naidu 2002), as well as by reacting with plant surfaces (Fruekilde et al. 1998) and probably by altering their physico-chemical properties (Müller and Riederer 2005). It also can affect VOCs in the leaf boundary layer and in the atmosphere (Loreto et al. 2001; Pinto et al. 2007a, b, c) (Table 1), where VOCs become infochemicals for an array of micro- and macro-

Table 1 Ozone effects on different functional levels, which could affect voc-based signaling

Primary effect	Secondary effect	Related potential ecological outcome
Activation of defense genes and biochemical cascades (Baier et al. 2005; Kangasjärvi et al. 2005; Heath 2008).	Cross-effects of signaling transduction pathways (Rao et al. 2000; Pieterse et al. 2001). Effects on JA- and SA-induced defense responses (Pieterse et al. 2001); decreased/increased/altered VOC emissions (Rao et al. 2000; Blande et al. 2007).	Disruption of the activation of induced defenses, including induced emissions of VOCs.
Decreased photosynthesis (Long and Naidu 2002).	Less carbon for primary production (Sitch et al. 2007). Decreased/altered VOC emissions (Gouinguené and Turlings 2002).	Decreased olfactory cues for herbivores and natural enemies.
Formation of plant cellular injuries (Kangasjärvi et al. 2005).	Induction of VOCs (Heiden et al. 2003); increased/ altered VOC emissions (Heiden et al. 1999, 2003; Vuorinen et al. 2004a).	Alter the orientation of herbivores (increase or decrease herbivory). Alter plant–plant communication Disrupt induced indirect defenses.
Reaction with plant surfaces and leaf boundary layer (Holopainen 2004).	Alteration of the physico-chemical properties of plant surfaces (Müller and Riederer 2005); degradation of VOCs or O_3 quenching (Loreto et al. 2001); formation of new volatile compounds (Calogirou et al. 1999); decreased/altered VOC emissions (Loreto et al. 2004).	Altered herbivory. Effects on herbivore and parasitoid foraging
Reaction of VOCs in the atmosphere (Atkinson and Arey 2003)	Degradation of emitted VOCs (Atkinson and Arey 2003), formation of new volatile compounds (Calogirou et al. 1999), SOA formation (van Reken et al. 2006); decreased/altered VOC emissions (Pinto et al. 2007a, b, c; McFrederick et al. 2008), altered plant surface properties due to SOA (Cape 2008).	Reduced or altered signals to plants, pollinators, herbivores and carnivores (Pinto et al. 2007b; Himanen et al. 2009)

organisms. Quantitative or qualitative alterations to VOC profiles as a result of O_3 exposure may affect interactions between plants and pollinators, herbivores and natural enemies of herbivores (Gate et al. 1995).

Signal Transduction Pathways and Plant Defense Responses to O_3 Exposure

The development of visible symptoms following acute O_3 exposure is the result of a genetically controlled programmed cell death, which resembles the response occurring during incompatible plant-pathogen interactions (hypersensitive response, HR) (Fig. 2). In a recent study, Overmyer et al. (2008) used a range of Arabidopsis mutants to investigate the complexity of O_3 sensitivity, finding multiple phenotypic traits to be involved and to interact. In brief, O_3 gains its entrance to the leaf tissues through stomata. There is an initial increase in Ca^{2+} flux into the cytosol, and accumulation of ROS in the apoplasm. Different ROS are formed as a result of O_3 degradation, but hydrogen peroxide (H_2O_2) seems to be the major signaling molecule for the development of HR. However, there is evidence that superoxide anion radicals (O_2^-) and reactive nitrogen species (peroxynitrite, $ONOO^-$) also may act as signaling molecules. The initiation, development and containment of programmed cell death is controlled by the plant hormones salicylic acid (SA), ethylene (ET), and jasmonic acid (JA), respectively (for a review see Baier et al. 2005; Kangasjärvi et al. 2005). During the development of the HR, there is up and down regulation of many genes. Among others, O_3 induces the expression of genes that encode glutathione S-transferase, pathogenesis related proteins (PR- proteins), phenylalanine ammonia-lyase (PAL), and L-ascorbate peroxidase, which are all involved in defense responses (Baier et al. 2005; Heath 2008). The role of phytohormones in induced plant defenses is well known. SA and JA are particularly important signaling molecules in the activation of defense responses, including the induced emission of VOC after herbivore attack (Rao et al. 2000; Arimura et al. 2005 for a review). In general, the SA-pathway is activated mainly in response to microbial pathogens and is related to programmed cell death, whereas the JA-pathway is activated to a greater extent upon herbivore attack (Pieterse et al. 2001). There is increasing evidence, however, that sucking insects including aphids (Zhu and Park 2005), whiteflies (Kempema et al. 2007), and mirid bugs (Frati et al. 2009) induce methyl salicylate (MeSA) emissions. For instance, silverleaf whitefly (*Bemisia argentifolii* Bellows & Perring) nymphs elicit the activation of SA defense. In addition, they seem to be able to suppress the JA pathway (Kempema et al. 2007), which plays a major role in the induced production of plant VOCs (Arimura et al. 2008). There also are examples of microbial pathogens that activate JA-mediated plant defense (Pieterse et al. 2001 for a review). Cross-talk between signaling pathways is thought to be crucial for the

Springer

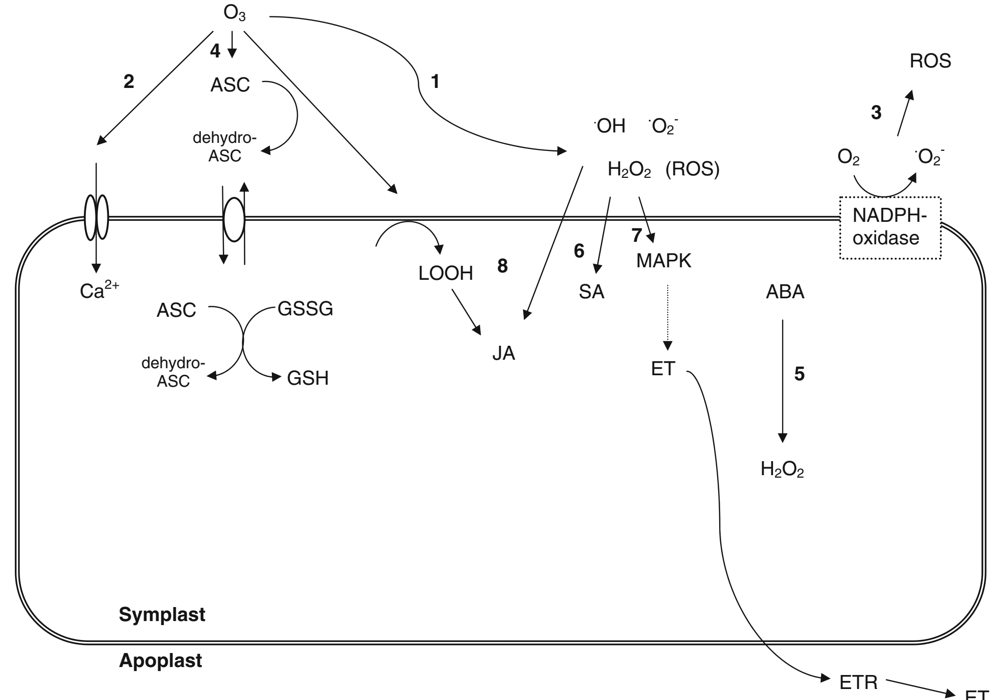

Fig. 2 O_3 degradation in the apoplasm results in the formation of reactive oxygen species (ROS) (**1**). There is an early increase in Ca^{2+} that leads to the activation of a mitogen-activated protein kinase (MAPK) and NADPH oxidase (**2**). This enzyme is responsible for the further production of ROS, and the spreading of the signal to other cells (**3**). A second peak of Ca^{2+} is concurrent with the expression of glutathione S-transferase. Antioxidants such as ascorbic acid (ASC) scavenge O_3, and its regeneration at the expense of glutathione also triggers changes in metabolism and gene expression (**4**). Abscisic acid (ABA)-induced closure of the stomata is the result of Ca^{2+} influx activation in the guard cells. ABA also can result in the production of H_2O_2, which in turn inactivates a protein phosphatase that inhibits ABA-induced stomata opening (**5**). The synthesis of salicylic acid (SA) is induced. SA is involved in the initiation of cell death (**6**). Ethylene (ET) is synthesized and is responsible for the propagation of the lesion (**7**). Jasmonic acid (JA) is synthesized from peroxidation of lipids (LOOH) in the membrane (**8**). The three hormones are involved in the expression of genes and further defense responses (Baier et al. 2005; Kangasjärvi et al. 2005)

optimal response of plants under different threats. Signaling pathways can affect each other in a positive manner; however, negative effects have been observed for plants under simultaneous attack by herbivores and fungal infection (Schoonhoven et al. 2006 for a review).

O_3 exposure elicits similar plant responses to fungal infection (Rao et al. 2000), and at biochemical and genetic levels there is overlap and interaction with signaling pathways involved in responses to different stresses (Heath 2008). Thus, the cross-talk between phytohormone-mediated signaling pathways may affect the induction of plant defense responses to biotic and oxidative stress under simultaneous herbivore attack and O_3 exposure. There are no studies that have strictly assessed the interaction between O_3- and herbivore-induced signaling pathways, but interactions between O_3 and herbivory have been observed in the emission of plant VOCs. Blande et al. (2007) reported increased emissions of some monoterpenes (α-pinene and/or β-pinene), and higher total monoterpene emissions from hybrid aspens (*Populus tremula* × *tremuloides* Michx.) grown under moderately elevated O_3 and infested by *Phyllobius pyri* L. compared to plants grown in ambient O_3 concentrations. In addition, Pinto et al. (2007a) found significant increases of MeSA in the headspace of Lima bean (*Phaseolus lunatus* L.) plants damaged by *Tetranychus urticae* Koch in O_3-enriched atmospheres (60 and 120 ppb) compared to damaged plants in filtered air. However, the mechanisms behind the interaction remain unknown.

O_3 Effects on Plant Photosynthesis: Less Carbon for Primary Production and VOC Biosynthesis

The starting point for the biosynthesis of VOCs is photosynthesis. Carbohydrates produced by photosynthesis are used mainly for primary plant metabolism, e.g., proteins, carbohydrates, and lipids involved in vital physiological functions, but they also are allocated to secondary plant metabolites. Volatile intermediates of primary metabolism, as well as volatile secondary metabolites, include isoprenoids (isoprene and terpenoids), fatty acid derivatives, phenylpropanoids/benzenoids, and other

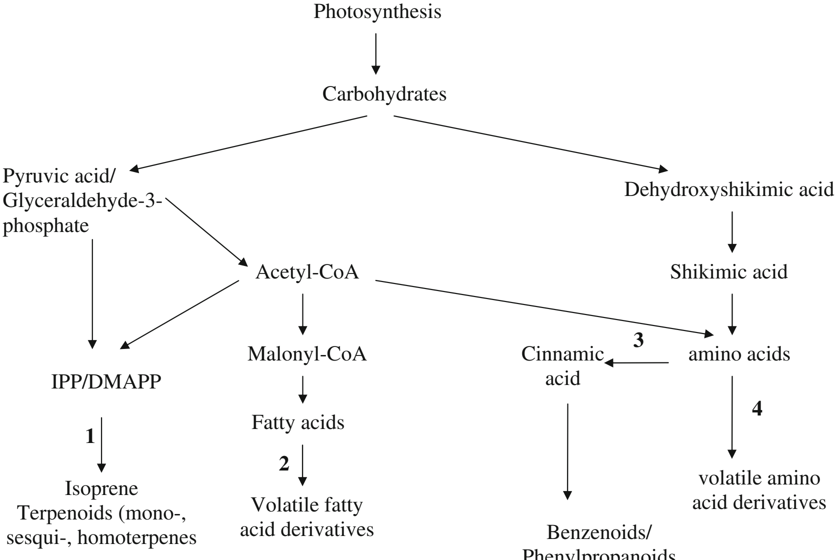

Fig. 3 Isoprenoids are formed from isopentenyl diphosphate (IPP) and its isomer dimethylallyl diphosphate (DMAPP). In the cytosol, IPP is synthesized from 3 molecules of acetyl-CoA (MVA pathway). Two molecules of IPP and one of DMAPP condense to form farnesyl pyrophosphate, precursor of sesquiterpenes. In plastids, IPP is derived from pyruvate and glyceraldehyde-3-phosphate (MEP pathway). Isoprene is synthesized from DMAPP. One molecule of IPP and one of DMAPP condense to form geranyl pyrophosphate, the precursor of monoterpenes, and three of IPP and one molecule of DMAPP condense to form geranylgeranyl pyrophosphate the precursor of diterpenes. Diversity is achieved by terpene synthases. Additional reactions lead to irregular homoterpenes (**1**). Fatty acid derivatives originate in cell membrane-derived fatty acids: linolenic or linoleic acid, which are oxygenated via the LOX pathway. Oxidation results in 9-hydroxyperoxy and 13-hydroxyperoxy derivates of polyenoic fatty acids, which are cleaved resulting in short chain C6 or C9 VOCs (GLVs). Alternatively, they can be metabolized by other enzymes. For example, 13-hydroperoxy-linolenic acid results in jasmonic acid and its volatile ester methyl jasmonate via the octadecanoid pathway (**2**). Phenylpropanoids/benzenoids are formed from L-phenylalanine, synthesized via the shikimic acid pathway. It is converted into (*E*)-cinnamic acid by the L-phenylalanine ammonia-lyase (PAL). In further steps of phenylpropanoid synthesis, (*E*)-cinnamic is converted into hydroxycinnamic acids, aldehydes, and alcohols, which in turn can form VOCs. Benzenoids are formed by the shortening of the (*E*)-cinnamic side chain (**3**). Other amino acids (alanine, valine, leucine, isoleucine, methionine) are precursors for aldehydes, alcohols, esters, acids, and nitrogen and sulfur-containing VOCs (**4**) (Dudareva et al. 2006; Schoonhoven et al. 2006)

volatile compounds derived from amino acids (Dudareva et al. 2006, for a review) (Fig. 3). At the physiological level, O_3 exposure results in a decline in the photosynthetic capacity of plants, alters the assimilate transport capacity from leaves to sinks, and, therefore, alters carbon allocation to storage organs and buds, which may affect the subsequent season in perennial species (Riikonen et al. 2008). Effects on photosynthetic processes explain the reduced concentrations of different types of carbohydrate (from soluble sugars to starch) observed in trees and cultivated species (Jackson et al. 1999; Valkama et al. 2007 for a review). O_3 can damage or inhibit almost every step of photosynthesis from light capture in photosystem II to starch accumulation in chloroplasts and phloem loading (Long and Naidu 2002 and references therein). Chronic exposure to O_3 leads to a reduction in photosynthetic pigments (chlorophyll a, b and carotenoids) (Leitao et al. 2007). It also negatively affects the levels and activity of Rubisco (ribulose-1,5-biphosphate carboxylase/oxygenase), the enzyme that catalyses the first step of net photosynthetic CO_2 assimilation (Long and Naidu 2002 for a review), as well as increasing the activity and quantity of PEPc (phosphoenolpyruvate carboxylase) (Dizengremel et al. 2008), the enzyme that catalyses the carboxylation of phosphoenolpyruvate to form oxaloacetate (Kai et al. 2003 for a review). O_3 exposure also can reduce stomatal conductance (see Fig. 3 for the biochemical processes involved) and the amount of intercellular CO_2 (Black et al. 2007). It has been forecasted that stomatal closure due to ozone exposure will decrease the gross primary production and carbon stocks in plants (Sitch et al. 2007). Although stomatal control has no effect on emission of compounds that diffuse through the leaf cuticle, or emissions from external glands and hairs, it has been suggested that this could affect the emission of newly synthesized compounds (Kesselmeier and Staudt 1999). Since the production of herbivore-induced VOCs correlates with photosynthetic activity (Paré and Tumlinson 1997; Gouinguené and Turlings 2002), adverse effects on the photosynthetic capacity of the plant may also result in a decrease in precursors needed for the biosynthesis of VOCs, including induced compounds (Arimura et al. 2008).

Formation of Plant Cellular and Tissue Injuries: Induction of VOC Emissions

As mentioned above, O_3-induced changes at the biochemical level lead to increased emission of VOCs. During the development of visible symptoms in plants, after acute and in some cases after chronic O_3 exposure, the induced/increased emission of VOCs has been observed as a common response (Rao et al. 2000). In general, O_3 increases VOC emissions from plants (Peñuelas et al. 1999) in a compound specific (Hewitt et al. 1994) manner. O_3-induced VOC blends include compounds that originate from different biosynthetic pathways, some of which are involved in the recruitment of predators and parasitoids, and in plant–plant interactions. For instance, the exposure of tobacco plants (*Nicotiana tabacum* L.) results in the induction of MeSA and an array of sesquiterpenes in both O_3-sensitive and O_3-tolerant cultivars (Heiden et al. 1999; Beauchamp et al. 2005).

The chronic exposure of Mediterranean woody plants (Llusià et al. 2002), *Pinus pinea* L. (Hewitt et al. 1994) and silver birch (*Betula pendula* Roth) (Vuorinen et al. 2005) to moderately elevated O_3 under field conditions resulted in emissions of individual terpenoids that increased, decreased, or remained unaffected. Under controlled conditions, fumigation of 3-year-old *Quercus ilex* L. plants for 5 days and single leaves for 4 h with elevated to extremely elevated O_3 concentrations (100 ppb up to 250 ppb) resulted in increased monoterpene emissions (Loreto et al. 2004). It has been suggested that such increases are involved in anti-oxidative stress responses (Loreto et al. 2004). The homoterpene (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), commonly emitted after herbivore attack (Karban and Baldwin 1997), also is induced by acute O_3 exposure in Lima bean plants (Vuorinen et al. 2004a).

In addition to isoprenoids, products of the lipoxygenase (LOX) pathway are induced by O_3 (Heiden et al. 1999). Heiden et al. (2003) found a positive relationship between the development of visible symptoms and the emission of LOX products. It is likely that the emission of LOX products is the result of LOX activity as part of the signal cascade that results in the visible symptoms. Lipoxygenase activity and accumulation of linoleic acid has been observed during programmed cell death triggered by O_3 exposure (Rao et al. 2000). Beauchamp et al. (2005) proposed that O_3 induced destruction of the hydroperoxides formed by lipoxygenases leads to the formation of volatile LOX products.

Effects of O_3 on VOCs in the Leaf Boundary Layer

Plant surfaces and the leaf boundary layer are of great importance in chemical ecology. Plant surfaces are the arenas for a number of ecological interactions between plants and other organisms, and their physicochemical properties determine the performance of and host recognition by microorganisms and arthropods (Müller and Riederer 2005; Schoonhoven et al. 2006 for a review). The leaf boundary layer is an approximately 5 mm thick layer adjacent to the leaf surface with relatively still, humid air (more humid than the surrounding air). VOC concentrations in the boundary layer are very high, and they are likely to affect the behavior of arthropods, and the proliferation of microorganisms (Holopainen 2004; Schoonhoven et al. 2006).

O_3 may alter VOC concentrations in the leaf boundary layer by affecting the biosynthesis of epicuticular waxes (Percy et al. 1992) or by reacting with them or with VOCs present in the boundary layer (Fruekilde et al. 1998; Loreto et al. 2004). Changes in the biosynthesis of epicuticular waxes may alter the physicochemical properties of the leaf surface (Müller and Riederer 2005), and consequently the emission of VOCs through diffusion. The ozonolysis of epicuticular waxes and VOCs in the leaf boundary layer may result in the production of new compounds from the carbonyl family such as ketones and aldehydes (Fruekilde et al. 1998; Calogirou et al. 1999). These reaction products may act as antagonists of olfactory cues (repellents). New compounds also may be adsorbed to plant surfaces (Müller and Riederer 2005). These likely could prevent oviposition or act as feeding deterrents to insect herbivores, but research on this topic is needed. VOC concentrations in the leaf boundary layer also may be reduced. Monoterpenes, for instance, quench O_3, in a process that has a defensive function against oxidative stress (Loreto et al. 2004). How the reduced concentrations of VOCs in the leaf boundary layer are affected by O_3 episodes, and the consequent effects on, for example, germination of pathogenic fungal spores or foraging activity of small herbivores like thrips, is so far unknown.

Ozonolysis of VOCs in the Atmosphere: Degradation and Secondary Organic Aerosol (SOA) Formation

Many VOCs emitted by plants are very reactive with oxidants such as O_3, hydroxyl radicals, and nitrate radicals in the atmosphere (Atkinson and Arey 2003). In the particular case of O_3, it has been estimated that oxidation of plant VOCs accounts for nearly 50% of the O_3 removal within a forest canopy, whereas stomatal uptake and deposition on surfaces together account for the rest (Kurpius and Goldstein 2003). These figures illustrate the importance of O_3 with regard to degradation of plant VOCs. It has been proposed that O_3 can affect plant–insect interactions through chemical destruction or transformation of olfactory cues (Gate et al. 1995; McFrederick et al. 2008). Indeed, the concentration of the

scent plume is severely affected in the O_3-polluted atmosphere (McFrederick et al. 2008), and differences in the reactivity of individual compounds results in the altered composition of VOC profiles (Pinto et al. 2007a, b, c). In particular, some terpenoids and GLVs are readily oxidized, and their lifetimes in the atmosphere are as short as a few minutes (Atkinson and Arey 2003). Variation in lifetimes is dependent on the number of C–C double bonds or the degree of unsaturation of the compound. Saturated compounds such as 1,8-cineole and camphor are not affected by O_3. At the other extreme, polyunsaturated compounds such as *d*-limonene, β-ocimene, and α-terpinene are significantly affected by O_3 (Calogirou et al. 1996).

The oxidation of terpenes has been reviewed by Calogirou et al. (1999). When oxidized by O_3, they can lead to the formation of a variety of compounds from the carbonyl group (mainly ketones, hydroxyketones, and aldehydes) as well as carboxylic acids (Calogirou et al. 1999; Souza et al. 1999). In brief, O_3 adds to the C–C double bond(s) of terpenes, which results in the formation of a primary unstable ozonide that in turn decomposes to form epoxides as well as an energy-rich biradical (Criegee intermediate, Fig. 1) and a carbonyl (Calogirou et al. 1999). The decomposition of the excited Criegee intermediate also leads to the formation of OH•, which also may have an impact on atmospheric chemistry (Aschmann et al. 2002). OH• also are able to react with terpenes (Atkinson and Arey 2003). A series of reactions leads to stabilized products. The stabilized Criegee intermediates may react with water molecules, thus resulting in the formation of organic acids (Calogirou et al. 1999; Seinfeld and Pandis 2006). Side-reactions also result in the production of aldehydes and H_2O_2 (Calogirou et al. 1999), which can cause direct damage to plants (Sant'Anna et al. 2008 and references therein). Several compounds that result from the reaction of O_3 with common floral VOCs are odorous volatile compounds that may interfere with foraging of bees (McFrederick et al. 2008).

In addition, some products, such as carboxylic acids, are compounds with low volatility that form new particles or condense onto pre-existing ones (gas/phase partitioning) (Seinfeld and Pandis 2006). One factor that influences the potential of VOCs to form SOAs is their chemical structure (Hoffmann et al. 1997; Lee et al. 2006). For instance, compounds with several C–C double bonds, such as limonene, can produce more particles than cyclic terpenes, which in turn can produce more particles than acyclic compounds (Hoffmann et al. 1997). Although the potential of isoprene and monoterpenes for forming SOAs has been the subject of many studies (Hoffmann et al. 1997; Yu et al. 1999; Claeys et al. 2004), the evidence that sesquiterpenes also could be a major source of particles in the atmosphere is accumulating (Bonn and Moortgat 2003; van Reken et al. 2006). These compounds could contribute to the nucleation process through the rapid formation of condensable products (Calogirou et al. 1999; Lee et al. 2006). Although to date no experiments have strictly assessed the effects of SOA on plant-insect interactions, it has been suggested that secondary organic aerosols may affect plant surfaces by deposition, and, therefore, impact interactions of plants with other biotic agents (Cape 2008).

O_3-induced VOCs: Impacts on Herbivores and Predators

O_3-induced VOCs may affect host location by herbivorous insects. O_3 can trigger the emission of individual compounds that make the plant more attractive or repellent to herbivores or higher trophic levels. Jackson et al. (1999) found that O_3 increases the oviposition preference of *Manduca sexta* (L.) on tobacco, which is not explained by O_3 effects on the tobacco leaf chemistry, but according to the authors may owe to changes in VOC emissions. On the other hand, Cannon (1990) found that O_3-induced VOCs from red spruce needles repel spruce budworm larvae. O_3-induced VOCs also may mask herbivore-induced VOCs, alter the emission of signaling compounds and change ratios of compounds in the VOC blend. Moreover, O_3 induces the emission of VOCs, e.g., MeSA (Heiden et al. 1999) and the homoterpene DMNT (Vuorinen et al. 2004a) that are acknowledged olfactory cues for organisms of higher trophic levels (Dicke et al. 1990; De Boer and Dicke 2004). To our knowledge, only one study has tested whether O_3-induced VOC can disrupt induced indirect defense. Vuorinen et al. (2004a) showed that in conditions of filtered air with O_3 removed, the predatory mite *Phytoseiulus persimilis* Athias-Henriot is able to discriminate between VOCs emitted by ozonated Lima bean plants and by ozonated plants simultaneously damaged by its prey, the two spotted mite *T. urticae*. Moreover, it did not discriminate between the ozonated plants and plants grown in filtered air, although O_3 exposure of the plants induced VOC emissions (Vuorinen et al. 2004a).

O_3 Effects on Plant–Plant Signaling

Within-plant and plant–plant signaling mediated by VOCs is a subject that has received significant attention in recent years. However, the results of this signaling and its importance can be subtle. Consequently, debate over its existence has been intense (Baldwin and Schultz 1983; Fowler and Lawton 1985; Karban and Baldwin 1997; Baldwin et al. 2002; Karban et al. 2003). Now, with analyses of gene activation, plant–plant signaling has been demonstrated convincingly (Arimura et al. 2000; Ton et al. 2007). The most commonly reported plant response is priming for more rapid defense against herbivore attack (Ton et al. 2007). However, it seems

fair to say that this signaling is one of the most sensitive processes to occur in nature.

Several chemical compounds from different biosynthetic pathways have been implicated as likely candidates for plant–plant and within-plant signaling. To date, these compounds include the green leaf volatiles [(*E*)-2-hexenal (Arimura et al. 2001; Farag and Paré 2002; Mirabella et al. 2008), (*Z*)-3-hexen-1-ol (Ruther and Kleier 2005), and cis-3-hexenyl acetate (Yan and Wang 2006; Frost et al. 2008)], the terpenes myrcene and blended ocimene volatiles [(*E*)-β-ocimene, (*Z*)-β-ocimene and allo-ocimene) (Godard et al. 2008)], and the phytohormones [methyl jasmonate (Farmer and Ryan 1990; Preston et al. 2001), MeSA (Shulaev et al. 1997), and ethylene (O'Donnell et al. 1996)]. Increases in O_3 and other reactive species in the atmosphere could have a profound impact on this process. A recent laboratory study with Lima bean plants, using extra-floral nectar as a measurable marker of plant–plant communication, indicated that increased O_3 concentration reduces the distance over which this communication can occur (Blande, unpublished). Previous studies have indicated that plant–plant communication provides receiver plants with a tangible defense benefit (Karban et al. 2003; Kost and Heil 2005). Consequently, we may expect plants that receive 'more secure' signals, for example less reactive VOCs or underground signals via root exudates (Guerrieri et al. 2002), to gain advantage under conditions of increasing O_3.

Multitrophic Effects

To date, few laboratory experiments have been conducted to assess whether degradation of VOCs by O_3 can affect tritrophic interactions between plant, herbivore and herbivore natural enemies (Pinto et al. 2007b, c; Himanen et al. 2009). The ozonolysis of major herbivore-inducible VOCs did not affect the orientation of *Cotesia vestalis* (Haliday) (=*Cotesia plutellae*) towards cabbage plants (*Brassica oleraecea*) or oilseed rape (*B. napus* L.) damaged by *Plutella xylostella* L. -(Lepidoptera: Yponomeutidae) (Pinto et al. 2007b; Himanen et al. 2009). The orientation of the predatory mite *P. persimilis* towards herbivore-damaged Lima bean plants also was unaffected (Pinto et al. 2007b). The results of VOC analysis in these studies showed that the most common herbivore-inducible terpenes and GLVs were degraded in O_3-polluted environments, but that there are more atmospherically stable herbivore-induced volatile compounds, such as benzyl cyanide, a nitrile in cabbage, and methyl salicylate in lima bean. It is likely that these stable compounds can provide important long-distance plant-carnivore signals and may be used by natural enemies of herbivores to orientate. However, on insect resistant Bt crops, O_3 episodes may harm the orientation behavior of moth parasitoids. *C. vestalis* prefers the odors of herbivore-induced VOCs in filtered air over those exposed to O_3 and cannot discriminate between VOCs of intact plants and herbivore-damaged plants from a genetically transformed line of oilseed rape in elevated O_3, when feeding damage is substantially reduced (Himanen et al. 2009). Overall, these results suggest that decreased concentrations (McFrederick et al. 2008) or altered ratios of compounds (Pinto et al. 2007a) due to elevated O_3 concentrations, may affect plant–animal interactions.

Further Directions

Plant Biology At the cellular level, research on cross-talk between signal transduction pathways should take into consideration the effects of O_3, as the signaling cascades it elicits overlap with those elicited by biotic stresses (Heath 2008). This is an important focus, and will lead to us gaining insight of how plants simultaneously activate their defense systems against abiotic and biotic stressors. Genetic engineering, for O_3 sensitive mutants for example, is an important tool for obtaining more information about this cross-talk and the possible consequences for plant processes in the field of chemical ecology. It would be interesting to know, for instance, how O_3 induced defense affects further emission of VOCs in an ecological context, in other words, whether O_3 exposure can prime or delay the activation of induced indirect defense.

Ecology To date, few studies have addressed the effects of O_3 on chemical ecology in field conditions (McFrederick et al. 2008; Pinto et al. 2008). There is a need to assess whether herbivory and mutualistic interactions that rely entirely on O_3 reactive compounds can be affected by this pollutant. For example, the effect of O_3 on reactive monoterpenes emitted by coniferous trees, plays an important role in the interaction between trees and bark beetles (Kesselmeier and Staudt 1999). In multitrophic interactions, the orientation of natural enemies under laboratory conditions may be based on herbivore-inducible VOCs that undergo little reaction with O_3 and may act as olfactory cues (Pinto et al. 2007a, b). VOCs are decreased greatly in O_3 polluted atmospheres, and it is important to assess the sustainability of insect chemical communication in the field, particularly in fragmented areas (McFrederick et al. 2008). So far, experiments have been conducted under controlled conditions that do not resemble nature, and therefore, the effects could have been underestimated. Field O_3 enhancement experiments have demonstrated the negative effects of O_3 on the abundance of natural enemies (Percy et al. 2002). Foraging by herbivores, pollinators, and parasitoids occurs over several meters, and therefore, O_3 and other oxidants such as OH, which is also formed during ozonolysis of VOCs, could be affected. In future atmos-

pheres, elevated CO_2 could further reduce VOC emissions from O_3-stressed plants (Vuorinen et al. 2004b; Calfapietra et al. 2008), which may lead to significantly reduced foraging efficiency of parasitoids (Vuorinen et al. 2004b).

Perception EAG and behavioral responses of herbivorous insects to reaction products of induced plant volatiles should be assessed. Typically, parasitoid wasps use their antennae to sense the volatiles in the leaf boundary layer and palpate plant surface chemicals after arrival on a plant infested by a potential host herbivore species. One possible methodology for assessment could be to collect SOA particles formed in a reaction chamber under O_3 exposure, with subsequent offering of inert filter discs to various herbivorous insects. The control discs would consist of condensated plant VOCs collected from a reaction chamber without O_3. Although there is little evidence that O_3 affects plant surfaces and VOCs in the boundary layer, such effects on ecological interactions remain unexplored. There is evidence that plant–fungi interactions can be altered (Percy et al. 2002), but there is a need to assess how O_3-altered boundary layers may affect interactions with arthropods.

Below-Ground Impacts It is unlikely that below-ground interactions can be affected directly by O_3, as the gas will be lost by dry deposition. However, O_3 exposure affects assimilate transport and root/shoot allocation (Grantz et al. 2006). Disturbed carbon allocation may in turn affect the composition and amount of VOCs emitted by roots, and consequently affect interactions between herbivores and natural enemies e.g., entomopathogenic nematodes (Rasmann et al. 2005), or other plants (Nishida et al. 2005).

Reactivity of Pheromones This review is based on the effects of O_3 on biosynthesis, release and atmospheric behavior of phytogenic VOCs that act as infochemicals to other organisms. Functionality of VOCs emitted by arthropods themselves e.g., sexual pheromones, alarm pheromones, and aggregation pheromones in future atmospheres also deserve attention. Particularly long distance sex pheromones of moths (McFrederick et al. 2009), which are comprised of alcohols, ketones, or aldehydes, could be highly vulnerable in O_3-polluted environments.

Abstract Atmospheric levels of carbon dioxide (CO_2) have been increasing steadily over the last century. Plants grown under elevated CO_2 conditions experience physiological changes, particularly in phytochemical content, that can influence their suitability as food for insects. Flavonoids are important plant defense compounds and antioxidants that can have a large effect on leaf palatability and herbivore longevity. In this study, flavonoid content was examined in foliage of soybean (*Glycine max* Linnaeus) grown under ambient and elevated levels of CO_2 and subjected to damage by herbivores in three feeding guilds: leaf skeletonizer (*Popillia japonica* Newman), leaf chewer (*Vanessa cardui* Linnaeus), and phloem feeder (*Aphis glycines* Matsumura). Flavonoid content also was examined in foliage of soybean grown under ambient and elevated levels of O_3 and subjected to damage by the leaf skeletonizer *P. japonica*. The presence of the isoflavones genistein and daidzein and the flavonols quercetin and kaempferol was confirmed in all plants examined, as were their glycosides. All compounds significantly increased in concentration as the growing season progressed. Concentrations of quercetin glycosides were higher in plants grown under elevated levels of CO_2. The majority of compounds in foliage were induced in response to leaf skeletonization damage but remained unchanged in response to non-skeletonizing feeding or phloem-feeding. Most compounds increased in concentration in plants grown under elevated levels of O_3. Insects feeding on *G. max* foliage growing under elevated levels of CO_2 may derive additional antioxidant benefits from their host plants as a consequence of the change in ratios of flavonoid classes. This nutritional benefit could lead to increased herbivore longevity and increased damage to soybean (and perhaps other crop plants) in the future.

Introduction

Atmospheric carbon dioxide (CO_2) levels have risen steadily since the start of the Industrial Revolution, from

280 to 387 ppm today (IPCC 2007). Current levels of atmospheric CO_2 are expected to double within the next 100 years (Ehhalt et al. 2001). Levels of ozone (O_3) also have been increasing in the lower atmosphere over this time period (Ehhalt et al. 2001). Numerous studies have been conducted on how various ecosystems might respond to changing atmospheric levels of these two gases (Kimball et al. 2002; Karnosky 2003; Booker et al. 2009; Lindroth 2010, this issue; Pinto et al. 2010, this issue). SoyFACE (Soybean Free Air gas Concentration Enrichment) is a research site at the University of Illinois, Urbana-Champaign, USA, for the study of the effects of elevated CO_2 and O_3 on a common midwestern agricultural ecosystem, that of *Glycine max* Linnaeus (soybeans). The United States produces 32% of the world's *G. max*, currently a $13 billion industry, and Illinois is one of the largest producers in the country (ASA 2008). Previous research conducted at this site revealed that damage by insect herbivores increased in elevated CO_2 treatments. This increase was associated with higher numbers of Japanese beetles (*Popillia japonica* Newman) found on those plants (Hamilton et al. 2005, Dermody et al. 2008). A subsequent study demonstrated that *P. japonica* fed a diet of *G. max* leaves grown in elevated CO_2 live longer and are more fecund than beetles that consume foliage grown under ambient conditions (O'Neill et al. 2008).

Changes in the antioxidant makeup of foliage under elevated CO_2 may be a factor that contributes to enhanced *P. japonica* longevity. Oxidative stress has been linked to aging, with the long-term build-up of oxidation products in the body leading to diminished cellular function (Harman 1956). This damage is countered by antioxidants, molecules that prevent oxidative damage in cells by quenching oxygen free radicals (Tang et al. 2006). Dietary constituents, including some phytochemicals, with antioxidant properties are associated with enhanced longevity in several insect species (Orr and Sohal 1994). Previous studies on plants grown under elevated CO_2 have determined that antioxidant content increases in fruits (e. g., strawberries, *Fragaria x ananassa* Dutch, Wang et al. 2003) and in foliage (e. g., European silver birch, *Betula pendula* Roth, Saleem et al. 2001). *Glycine max* contains several compounds with antioxidant properties, including flavonoids and isoflavonoids (Lee et al. 2006), but if and how foliar content of these compounds changes when plants are grown under elevated CO_2 has yet to be determined.

Flavonoids and isoflavonoids are biosynthesized via the phenylpropanoid pathway (key enzyme: phenylalanine ammonia-lyase = PAL) and contribute to plant defense against oxidative stressors (Dakora and Phillips 1996), such as pathogens, herbivores, or abiotic factors. Plant wounding induces these compounds (Hagerman and Butler 1991). Individual flavonoids in artificial diets can be detrimental to insect growth by virtue of their prooxidant properties (Ahmad and Pardini 1990). A study by Johnson and Felton (2001), however, indicated that the relative proportions of individual flavonoids in the food source are important in determining biological activity. The total complement of flavonoids can override the prooxidant trend and instead benefit herbivores by providing them with increased antioxidant protection. Quercetin in particular can stimulate feeding and promote herbivore growth (Ruuhola et al. 2001; Saleem et al. 2001). Isoflavonoids can have negative effects on herbivores (Simmonds and Stevenson 2001; Yu et al. 2003) irrespective of composition.

We measured flavonoid content of *G. max* foliage grown under elevated and ambient levels of CO_2 and O_3, singly and in combination. We hypothesized that elevated levels of CO_2, O_3, and herbivore damage will increase the products of the PAL pathway. The PAL pathway requires high levels of carbon to generate its products, including flavonoids (Tsai et al. 2006). Plants grown under elevated CO_2 have a greater C:N ratio than plants grown under ambient levels of CO_2 (Ainsworth et al. 2002), thus increasing the amount of carbon available to be transformed into phenolics. Increased exposure to O_3 is hypothesized to increase flavonoid production in *G. max* tissue and counteract potential oxidative damage. Ground level O_3 is an atmospheric pollutant that cycles seasonally and can have large effects on agricultural systems (Mauzerall and Wang 2001). Ozone is a powerful oxidative stressor, reducing *G. max* yield and increasing the incidence of early senescence (Morgan et al. 2006). Because production of flavonoids is known to vary with types of herbivory (Izaguirre et al. 2007), we measured changes in flavonoid content in response to damage from multiple herbivore feeding guilds (Mewis et al. 2006). Damage to plants grown under elevated levels of CO_2 was inflicted by phloem-feeders (*Aphis glycines* Matsumura, soybean aphid), leaf-chewers (*Vanessa cardui* Linnaeus, painted lady butterfly), and leaf-skeletonizers (*P. japonica*, Japanese beetle). Damage to plants grown under elevated levels of O_3 was inflicted by the Japanese beetle only.

Methods and Materials

Description of Field Site All herbivore feeding and tissue collection took place at the SoyFACE site (South Farms, University of Illinois, Savoy, IL, USA). SoyFACE is an open Free Air gas Concentration Enrichment system that exposes large field plots of *G. max* to elevated CO_2 and elevated O_3, individually or in combination in a full factorial design (Long et al. 2004). Crops at SoyFACE are rotated between corn (*Zea mays*) and *G. max* cv. Pioneer 93B15. Treatment plots (ambient air with 387 μmol mol^{-1}

CO_2, elevated CO_2 with a target of 550 μmol $mol^{-1}CO_2$, addition of 1.2 x ambient levels O_3, and combination of the elevated CO_2 and O_3 treatments) have a diameter of 20 m, cover 350 m^2, and are at least 100 m from any other plots. Treatments were replicated in a randomized block design. There were four plots for each treatment for a total of 16 plots present in the field. Average O_3 concentration during the 2005 season was 63.3 nmol/mol. Average CO_2 concentration during the 2005 season was 552 μmol/mol, during the 2006 season, 550.3 μmol/mol, and during the 2007 season, 553 μmol/mol. Ozone levels in the experimental plots were measured with an O_3 analyzer (model 49C; Thermo Scientific Instruments, Franklin, MA, USA) and the concentration of CO_2 in the plots was measured with an infrared gas analyzer (model SBA-1; PP Systems, Hitchin, UK). As there were no observed effects of feeding on *G. max* foliage grown under elevated O_3 on *P. japonica* longevity at this site, we discontinued measuring changes in flavonoid concentrations in foliage grown under elevated levels of O_3 with *V. cardui* and *A. glycines* feeding damage.

Herbivore Enclosures for P. japonica Adults and V. cardui Larvae Mesh cages for containing study species and excluding non-study species were constructed with 1× 4 mm plastic mesh material covering a PVC-pipe framework. Cages were raised over the course of the season with the height of the plants, with a maximum height of 1 m, 1 m wide, and 1 m deep covering ~30 plants and a total volume of 1 m^3. For *P. japonica* and *V. cardui*, two cages were erected in all elevated CO_2 and ambient plots, at opposite ends of the plot. For *P. japonica*, two cages were also erected in each elevated O_3 plot. *P. japonica* and *V. cardui* experiments were done separately, as natural populations of each species were present in the field at different points during the season.

Collection of P. japonica Emerging *P. japonica* adults were collected from the east side of Meadowbrook Park (Urbana, IL, USA) in the last week of June 2005. Sixty beetles were added to one of the two cages in each plot, 30 individuals on June 29, and 30 individuals on June 30. The second cage was left sealed to prevent any damage to the plants until sampled. Seventy additional beetles were added to cages on July 8, to replace those that had escaped.

Acquisition of V. cardui V. cardui larvae were obtained from Carolina Biological Supply (Burlington, NC, USA). Natural populations at the SoyFACE site were not large enough to use for this experiment, but we observed natural population cycles for the timing of placement of larvae onto the experimental plants. Ten larvae were bagged (1.4 mm mesh bags) over two neighboring trifoliate leaves chosen from the top four trifoliate leaves on each plant on July 14, 2006, with 10 plants bagged in one cage in each ambient and elevated CO_2 plot. The larvae were bagged on the plants in addition to being in the cage, as they were small enough to fit through the mesh of the cage. The second cage was left sealed to prevent any damage from occurring to the plants until they were sampled.

Collection of A. glycines A. glycines adults were obtained from a campus laboratory colony. Fifty aphids were bagged over one trifoliate chosen from the top four trifoliates on each of 10 plants on August 6, 2007, in each ambient plot and on another 10 plants in each elevated CO_2 plot. Plants without visible insect damage were selected. Ten plants were bagged without aphids for control tissue.

Collecting Leaf Tissue from Herbivore-Damaged and Control Plants Damaged and undamaged leaf tissues were sampled 2.5 d and 2 wk after beetles started feeding, 1 and 3 d after *V. cardui* larvae started feeding, and 1, 3, and 7 d after aphids started feeding. Tissue was sampled at multiple time points after herbivore feeding began because flavonoid and isoflavonoid levels are induced over time, and we

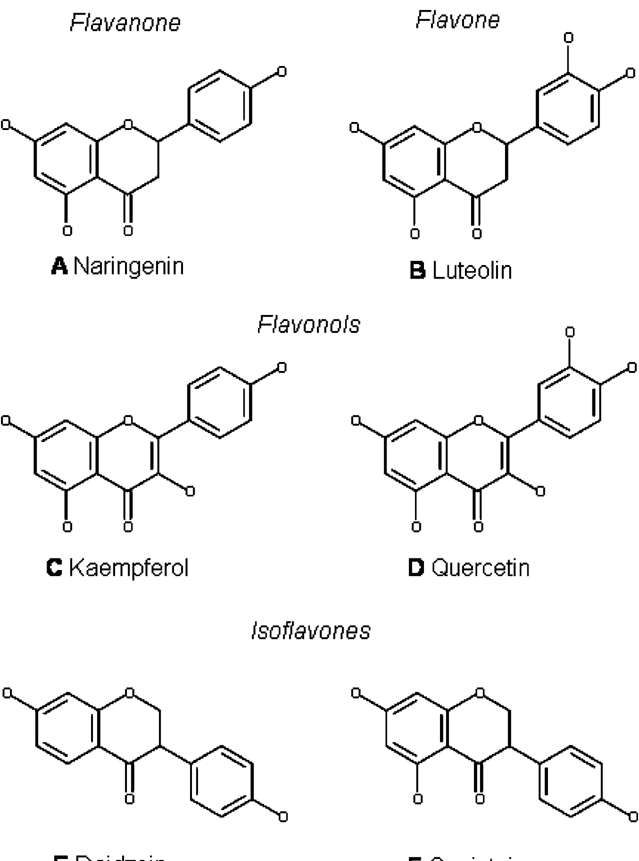

Fig. 1 Structures of the six flavonoid compounds identified in *Glycine max* foliage and phloem. **a**. Naringenin, **b**. Luteolin, **c**. Kaempferol, **d**. Quercetin, **e**. Daidzein, and **f**. Genistein. Figures drawn with SymyxDraw 3.2 (Symyx Solutions, Inc., San Ramon, CA)

wanted to capture their increase and decrease. Tissue always was selected from the top three leaf trifoliates of the sampled plants. On plants with herbivores, leaves exhibiting between 20–40% herbivore damage (as estimated by eye) but that did not have the herbivore currently feeding on them were selected. This allowed us to sample damaged tissue without disrupting feeding. For flavonoid analysis, four leaf disks were punched from one lateral leaflet from 5 plants with a metal cork borer (bore diam ~ 1.5 cm.). Leaf veins and spots of damage (either created mechanically or by herbivores) were avoided when leaves were punched so that equal leaf area was obtained in all disks. Disks from each cage were collected in paper envelopes that were immediately sealed and placed in liquid nitrogen.

Collecting Phloem from Aphid-Damaged and Control Plants A second leaf was selected from the top three leaf trifoliate leaves (again avoiding the trifoliate on which aphids were feeding) for phloem sap collection 1 d, 3 d, and 1 wk after aphids started feeding. Leaves were selected from aphid-damaged and control plants at each time point. Leaves were cut at the petiole, and the petiole was placed immediately in a 5-ml solution of 10 mM EDTA, pH 7 (Walter and DiFonzo 2007). The open tube tops and leaf petioles were Parafilm-wrapped to seal them, and the tubes were left in the dark at 5°C for 24 h. Phloem samples were kept at −80°C until analyzed.

Foliar Flavonoid Analysis for Herbivore-Damaged and Control Samples Six leaf disks (~1.77 cm^2 each) were taken from each sample, ground with a 6-mm glass bead (Fisher Scientific) in a Bead Beater (Wig L Bug, Crescent Dental Mfg. Co., Chicago, IL, USA), and combined with 500 µl methanol. Samples were vortexed and left at room temperature for 1 h. Samples then were sonicated for 1 min and centrifuged at 15,000 rpm for 5 min. Flavonoid compounds were separated on a reverse-phase high-pressure liquid chromatograph (HPLC) (712 WISP, Waters Corporation, USA) using a 250×4.6 mm ID 5 µm Capcell Pak C18 column (AG120, Shiseido Fine Chemicals, Japan) and a diode array detection system that has the capacity to

[a] Changes in flavonoid amounts across the control and beetle-damage treatments over time were compared in foliage grown under ambient and elevated levels of CO_2 and O_3 by double repeated measures *ANOVA*. Significant *P* values at the 0.05 level are in bold text. The repeated measures effects from this analysis are separately reported in Tables 2 and 3.

measure wavelengths in the 210–400 nm range. The mobile phase consisted of 0.05% formic acid in H_20 (solvent A) and 100% acetonitrile (solvent B) at a flow rate of 1 ml/min. The sample injection volume was 10 µl, and components were eluted with the following solvent gradient: from 0–1 min solvent A was 85%; from 1 to 10 min solvent A was decreased to 70%; from 10 to 20 min solvent A was decreased to 62%; from 20 to 25 min solvent A was decreased to 20%; from 25 to 30 min solvent A was maintained at 20%; finally, solvent A was increased to 85% for 5 min. Between each injection, a mixture of 85% solvent A and 15% solvent B was run for 15 min.

A sample containing all flavonoid peaks present in this soybean variety was analyzed by LC/MS (model 2010ev Shimadzu, Kyoto) and diode array detection by employing the same separation and column for quantitative analyses. Sample peak areas were measured at 254 nm. Mass spectra, UV spectra and retention times were used to identify compound peaks in each sample, and commercially available standards were employed to convert peak areas to µg/cm^2 leaf area. The amount of standard injected in g divided by the area of the peak produced was used as the calibration factor. The area of the sample peak multiplied by the calibration factor, then multiplied by the dilution factor (total extract volume divided by the volume injected), and all divided by the total leaf area extracted (number of disks multiplied by the area per disk) was the flavonoid amount in the plant, µg/cm^2 leaf area. Peaks were matched across samples, and concentrations were compared by double repeated measures analysis of variance (*ANOVA*) with a between-subject effect of CO_2 treatment, and a between-subject effect of O_3 treatment in the beetle experiments. Damage and date were considered as repeated measures because matched insect-damaged and control samples were taken from the same CO_2 and O_3 treatment plots for each time point (SPSS 9.0, Chicago, IL, USA).

Phloem Flavonoid Analysis of Aphid-Damaged and Control Samples Phloem samples were dried in a centrifugal evaporator (RC 10.22, Jouan Inc., USA). Five hundred µl of methanol were added to each sample, and samples were analyzed by HPLC using the same protocol as for foliage. Statistical analysis was conducted with the same protocol as used for foliage (SPSS 9.0, Chicago, IL, USA).

[a] Flavonoid amounts across the two atmospheric treatments over time were compared in control and beetle-damaged foliage by double repeated measures *ANOVA*. Significant *P* values at the 0.05 level are in bold text.

Results

The isoflavone genistein (Fig. 1f), the flavone luteolin (Fig. 1b), the flavanone naringenin (Fig. 1a), and the flavonols quercetin (Fig. 1d) and kaempferol (Fig. 1c) were identified in all foliage irrespective of damage, as were glycosides of these compounds.

Flavonoid Results for Beetle-Damaged and Control Tissues The only main effect of CO_2 involved a single flavonoid; one of the two quercetin diglycosides increased significantly under elevated CO_2 (Table 1). In contrast, seven (genistein, kaempferol, kaempferol triglycoside, luteolin diglycoside, naringenin methyl hexose, quercetin, and quercetin triglycoside) of the 12 flavonoids increased in plants exposed to elevated ozone (Table 1). Five compounds not belonging to any particular flavonoid class were significantly affected by interactions between CO_2 and O_3. These interactions were of one type; large increases in flavonoids associated with elevated ozone were wholly or largely suppressed in elevated CO_2 treatments (data not shown). There also was a significant interaction between CO_2 and time with kaempferol triglycoside doubling in concentration at ambient CO_2 (from 0.267±s.e. 0.052 to 0.480±s.e. 0.092, μg/cm^2 leaf area) but remaining unchanged at elevated CO_2 (from 0.337±s.e. 0.052 to 0.279±s.e. 0.092, μg/cm^2 leaf area) (d.f.=63, F=5.322, P=0.040).

Beetle damage induced significantly increased concentrations of naringenin methyl hexose, kaempferol diglycoside, kaempferol triglycoside, and quercetin triglycoside (Table 2). Over the course of the sampling period, concentrations of six compounds (genistein, kaempferol, kaempferol diglycoside, naringenin methyl hexose, quercetin, and quercetin triglycoside) increased from the first to the second collection date (Table 3).

Flavonoid Results for Caterpillar-Damaged and Control Tissues There were no significant effects of elevated CO_2 (Table 4) on flavonoid concentration, and no significant interactions between effects of elevated CO_2 and damage by caterpillars. Levels of genistein were significantly higher in foliage damaged by *V. cardui* (Table 5). Quercetin triglycoside decreased in abundance from the first to the second collection date (Table 6).

			Elevated	0.671	0.048
Quercetin triglycoside 2	0.690	0.175	Ambient	0.961	0.100
			Elevated	1.021	0.100

[a] Flavonoid amounts over time and across the control and caterpillar-damage treatments were compared in foliage grown under ambient and elevated levels of CO_2 by double repeated measures *ANOVA*. Significant *P* values at the 0.05 level are in bold text. The repeated measures effects from this analysis are separately reported in tables 5 and 6.

Flavonoid Results for Aphid-Damaged and Control Foliar Tissues Concentration of only one flavonoid, quercetin, increased under elevated CO_2 conditions (Table 7). Two of the quercetin triglycosides, kaempferol triglycoside, quercetin hexose, and genistein increased from the first to the third collection date, whereas luteolin diglycoside declined in abundance from the first to the third collection date (Table 8). There were no significant effects of aphid damage (Table 9), and no significant interactions between effects of elevated CO_2 and aphid feeding.

Flavonoid Results for Aphid-Damaged and Control Phloem The only confirmed flavonoid in phloem was the isoflavone daidzein (Fig. 1e). This isoflavone increased in concentration from the first to the third collection date (Table 8) and showed a marginally significant increase in concentration in response to aphid damage (Table 9). There were no significant interactions.

Discussion

Elevated CO_2 affected only concentrations of a single flavonoid in *G. max*. Plants grown under elevated amounts of CO_2 have higher quercetin:kaempferol ratios, and quercetin may be acting as an antioxidant for these plants,

quenching reactive oxygen species (ROS) (Qiu et al. 2008). Elevated levels of atmospheric CO_2 have been suggested to cause oxidative damage to plants, so additional amounts of antioxidants may well be produced to counter this increased damage (Cheeseman 2006). Ozone, a strong oxidizing agent, was a far more effective inducer of flavonoid production in this study. This inducing effect, however, was almost entirely absent when CO_2 also was elevated. One possible explanation for this interaction is that soybean leaf stomatal conductance is decreased in elevated CO_2 atmospheres, thus reducing ozone fluxes into the leaf and buffering its effects (Bernacchi et al. 2007; Mishra et al. 2008).

The significant increase in quercetin and the non-significant decrease of kaempferol changes the flavonoid ratios found in plants grown under elevated CO_2 and may change the total balance for herbivores also from prooxidant to antioxidant (Galati et al. 2002). Similar shifts in the quercetin:kaempferol ratio have been observed in plants grown under temperature stress (Albert et al. 2009). Quercetin has a higher quenching capability than kaempferol (Rice-Evans et al. 1996), and it was theorized that under temperature stress more quercetin was produced because of this quenching ability (Albert et al. 2009). Similar effects may occur in soybeans growing under

elevated CO_2 stress. Genistein levels in *G. max* were decreased under elevated CO_2 treatment at the $P=0.1$ level. This decrease in genistein content in plants grown under elevated CO_2 is fortuitous for most herbivores, as genistein reduces most insects' longevity and overall fitness (Piubelli et al. 2005). The multiple changes in *G. max* flavonoid content under elevated CO_2 conditions may contribute to the increased longevity experienced by *P. japonica* on *G. max* foliage grown under elevated carbon dioxide (O'Neill et al. 2008). This hypothesis could be tested by supplementing soybean foliage grown under ambient levels of CO_2 with enough quercetin to equal the quercetin:kaempferol ratio found in foliage grown under elevated levels of CO_2, even with the higher levels of kaempferol found in the foliage grown under ambient levels of CO_2.

The differential flavonoid response of *G. max* to leaf-skeletonization, non-skeletonizing leaf chewing, and phloem sucking feeding damage suggests that the induced defense responses of plants depend on the type of damage inflicted (Felton et al. 1994; Kaplan et al. 2008). Whereas leaf damage in the form of skeletonization induces changes in several flavonoid and isoflavonoid levels, feeding damage by the

[a] Flavonoid amounts across the two atmospheric treatments over time were compared in undamaged and aphid-damaged foliage by double repeated measures *ANOVA*. Significant *P* values at the 0.05 level are in bold text.

caterpillar *V. cardui* increased levels of one genistein glycoside, and feeding by the aphid *A. glycines* did not affect production of any compound. The increase in flavonoid content over time is to be expected as these compounds are induced by herbivore damage (Hagerman and Butler 1991), and by increased photooxidative stress, particularly in August when the aphid experiments were conducted (Stark et al. 2008).

The increase in flavonoid content in *G. max* tissue grown under elevated O_3 conditions is also expected as O_3 is a powerful oxidative agent (Sager et al. 2005). This increase is consistent with the results of other studies that have looked at changes in genes involved in the flavonoid biosynthesis pathway in *G. max* foliage in response to elevated O_3 conditions (Bilgin et al. 2008). The increase in content of all flavonoid compounds regardless of class could be utilized by the plant as a general response against adverse environmental conditions (Bilgin et al. 2008). This increase in content of all flavonoids in *G. max* foliage grown under elevated O_3 leaves the quercetin:kaempferol balance unchanged, helping to explain the lack of an effect on longevity of *P. japonica* feeding on this foliage (O'Neill et al. 2008) and contributing to the lack of an effect on herbivory on plants grown under elevated levels of O_3 at this research site (Dermody et al. 2008).

In a separate study, tissue from plants in the beetle treatments from this experiment was examined *via* microarray to investigate transcriptional responses to elevated CO_2 and leaf skeletonization (Casteel et al. 2008). Transcriptional changes involved in flavonoid and isoflavonoid biosynthesis supported our findings that abundance increased after beetle damage (e.g., putative flavonol synthase, 2′-hydroxydihydrodaidzein reductase, isoflavone reductase-like protein), with or without elevated CO_2, and increased flavonol biosynthesis (e.g., flavonol synthase-like oxidoreductase) under elevated CO_2 conditions (Casteel et al. 2008).

These changes in defense compound/antioxidant concentrations were examined in the context of damage inflicted by only a single herbivore; impacts of different types of damage inflicted simultaneously have yet to be determined. Given the multiplicity of responses that depend on the nature of feeding damage, the prediction of future impacts of global atmospheric changes on the soybean agroecosystem will be difficult. The changes in the quercetin: kaempferol ratio of *G. max* foliage under elevated CO_2 though, suggests that the benefits of *G. max* foliage to select herbivores may be great.

Acknowledgments This research was funded by USDA grant #2002-02723, by NSF grant #IBN-0236053 and by a grant from the Office of Science (BER), U.S. Department of Energy (#DE-FG02-04ERG3849). We thank Adam Austin for helping with the leaf sample HPLC processing. We thank Glen Hartman and Curt Hill for maintaining the *A. glycines* colony in the Department of Crop Sciences, UIUC.

REVIEW ARTICLE

Heavy Metal Pollutants and Chemical Ecology: Exploring New Frontiers

Robert S. Boyd

Received: 26 August 2009 / Revised: 20 November 2009 / Accepted: 14 December 2009 / Published online: 28 January 2010

Abstract Heavy metals are an important class of pollutants with both lethal and sublethal effects on organisms. The latter are receiving increased attention, as these may have harmful ecological outcomes. For example, recent explorations of heavy metals in freshwater habitats reveal that they can modify chemical communication between individuals, resulting in "info-disruption" that can impact ecological relationships within and between species. Info-disruption can affect animal behavior and social structure, which in turn can modify both intraspecies and interspecies interactions. In terrestrial habitats, info-disruption by metals is not well studied, but recent demonstrations of chemical signaling between plants via both roots and volatile organic molecules provide potential opportunities for info-disruption. Metals in terrestrial habitats also can form elemental plant defenses, in which they can defend a plant against natural enemies. For example, hyperaccumulation of metals by terrestrial plants has been shown to provide defensive benefits, although in almost all known cases the metals are not anthropogenic pollutants but are naturally present in soils inhabited by these plants. Info-disruption among microbes is another arena in which metal pollutants may have ecological effects, as recent discoveries regarding quorum sensing in bacteria provide an avenue for metals to affect interactions among bacteria or between bacteria and other organisms. Metal pollutants also may influence immune responses of organisms, and thus affect pathogen/host relationships. Immunomodulation (modification of immune system function) has been tied to some metal pollutants, although specific metals may boost or reduce immune system function depending on dose. Finally, the study of metal pollutants is complicated by their frequent occurrence as mixtures, either with other metals or with organic pollutants. Most studies of metal pollutants focus on single metals and therefore oversimplify complex field conditions. Study of pollutant impacts on chemical ecology also are difficult due to the necessity of studying effects at varying ecological scales: "dynamic scaling" of chemical ecology studies is rarely done completely. It is clear that much remains to be learned about how heavy metal pollution impacts organisms, and that exciting new research frontiers are available for experimental exploration.

Introduction

Humanity's ability to mine and use metals has played a major role in development of modern human society (Wilson 1996). Many metals have a wide range of uses, but these have come at a significant environmental price: some (generally called heavy metals) have serious negative environmental consequences, yet our dependence on them continues to result in large inputs into our environment (Han et al. 2002). Heavy metals are an important category of pollutants and as such have major detrimental impacts on both human health (Duruibe et al. 2007) and the health of terrestrial and aquatic communities and ecosystems (Sánchez 2008). A number of metals have been included in the term "heavy metal," but the term has not been used consistently in the literature (Sánchez 2008). The primary focus here will be on those commonly

studied as pollutants (Han et al. 2002), including Cd, Cu, Cr, Hg, Pb, Ni, and Zn.

Much research on heavy metal pollutants has focused on their direct negative effects on organisms. These direct effects stem from the general toxicity of heavy metals to a variety of biological processes. The negative effects often result in serious toxicological symptoms, including mortality. These effects are generally dose-dependent, but some heavy metals are required in relatively small amounts as micronutrients for many organisms, so that low doses can have positive direct effects (Lefcort et al. 2008). In addition to direct effects, pollutants may have indirect effects through their impact on the structure of food webs in communities (Fleeger et al. 2003). For example, Lefcort et al. (2002) reported that snails in a heavy metal-polluted lake were less sensitive to the metals than their internal parasites, so that parasite loads were markedly reduced in the polluted lake and this resulted in greater abundance of the snail. In another example, Stepanauskas et al. (2006) dosed freshwater microcosms with a range of Cd or Ni concentrations and found that bacterioplankton densities increased at very low metal concentrations. They explained this effect as a consequence of low metal doses suppressing growth of bacteriovore eukaryotes. There are many cases in which organisms differ in susceptibility to pollutants, and hence community structure is altered in polluted locations by both direct and indirect effects.

Recently, there has been recognition that serious sublethal direct effects of many pollutants (including heavy metals) can occur. These may have subtle impacts on species performance that in turn can lead to important indirect effects. "Info-disruption" is a recently defined category of sublethal direct effect (Lürling and Scheffer 2007) in which a pollutant interferes with the chemical communication networks that inform organisms about their biotic and abiotic environments. For example, a review by Lürling and Scheffer (2007) described the importance of the "smellscape" to organisms and how pollutants can alter their perception of it. Klaschka (2008) referred to info-disruption as the "infochemical effect" and provided an additional recent review of this burgeoning field. Klaschka (2008) points out that the ecological importance of info-disruption, in both laboratory and field studies, is greater than was previously believed. Both these reviews broadly illustrate how anthropogenic pollutants (including heavy metals) can affect organismal ecology and summarize recent advances in this area.

This mini-review is not intended to comprehensively cover the literature regarding all heavy metals and their ecological effects. Instead, I seek to extract from recent literature concepts regarding the biological effects of metal pollutants that might be of interest to chemical ecologists. My emphasis is in illustrating these concepts to demonstrate their potential ecological importance and as a stimulus for additional research. Because most of the research regarding info-disruption by pollutants has emerged from studies in freshwater aquatic systems (Lürling and Scheffer 2007; Klaschka 2008), those systems will be the starting place for this review. From there, I will move to terrestrial systems and examine how concepts being developed from aquatic systems might apply to relationships in terrestrial habitats. Then, I will summarize some of the recent excitement in microbiology regarding chemical communication (and potential social organization) in bacteria, thus illustrating the potential for heavy metals to impact these aspects of microbial biology and touching upon two other metal/microbial issues of great recent interest, antibiotic resistance and immunomodulation. Finally, I will review briefly some other issues that complicate our understanding of heavy metal pollutant effects on organisms and communities (including impacts of multiple pollutants, and how issues of scale add complexity to ecological studies), and conclude with a few considerations of future research directions.

Heavy Metals in Aquatic Communities

Heavy Metals and Predator/Prey Relationships Perhaps the most active research area regarding info-disruption by heavy metals in aquatic communities deals with the effects of metals on predator/prey interactions. The concern is that heavy metals can influence predator/prey interactions by degrading the ability of prey to respond to predators, ultimately resulting in decreased prey population sizes due to increased predator success (McPherson et al. 2004). Another reason for the interest in heavy metals and behavior in aquatic communities is that heavy metals may have behavioral effects at concentrations much less than at which they have lethal effects (Scott and Sloman 2004), suggesting that regulatory pollution limits based upon standard toxicological studies may be too high to prevent damage to aquatic communities through these sublethal behavioral effects. This realization has led to calls for increased integration of behavioral studies into ecotoxicological investigations (e.g., Clotfelter et al. 2004; Klaschka 2008).

With regard to predator/prey relations, a number of investigations have shown decreased ability of fish exposed to heavy metals to respond to skin extracts, which can serve as an alarm signal for prey species (Smith 1992; Kats and Dill 1998). Heavy metal pollutants for which these effects have been shown include Cu (Carreau and Pyle 2005; Pyle and Mirza 2007), Cd (Honda et al. 2008; Kusch et al. 2008), and Hg (Smith and Weiss 1997). Some studies have taken these investigations into the field to show that fish in metal-contaminated lakes respond differently from fish in

uncontaminated lakes. For example, McPherson et al. (2004) showed that prey fish in a Ni/Zn contaminated lake did not respond to skin extract of another prey species, whereas prey fish in an uncontaminated lake did. In other cases, fish from polluted and uncontaminated lakes have been brought into the laboratory for comparison of responses to skin extracts. Mirza et al. (2009) studied wild yellow perch (*Perca flavescens*) from a lake contaminated by a mixture of heavy metals (mainly Cu, Ni, and Zn), finding that the fish from the contaminated lake did not respond to a chemical alarm cue whereas those from an uncontaminated lake did.

Although the studies referred to above have focused upon ability of prey to detect and avoid predators, heavy metals may affect mechanisms other than escape behavior that are used by prey to avoid predation. For example, the bioluminescence ability of some marine organisms (or the presence of bioluminescent organisms as symbionts in hosts) is thought to be an anti-predator behavior (Buskey and Swift 1983; Jones and Nishiguchi 2004; Cronin 2005), and there is evidence that heavy metal pollution can affect bioluminescence ability. For example, Deheyn et al. (2000) collected individuals of an echinoderm, the brittle star *Amphipholis squamata*, along a heavy metal (Cd, Cu, Fe, Pb, Zn) gradient in a polluted bay in Spain. Those from the most polluted area had less intense and more slowly generated bioluminescence responses, and bioluminescence responses of individuals transferred from a less- to a more-polluted area became weaker and slower. The authors suggest that, since light production is a defense for some bioluminescent organisms, this defense would be less effective for this species in polluted areas. Bioluminescence of marine organisms also may play a role in mate attraction (Deheyn and Latz 2009) or attraction of prey (Cronin 2005), so that interference with bioluminescence by heavy metals may impact other organismal interactions.

While most studies show that info-disruption can result in lowered defensive ability and thus increased predation, info-disruption may act to enhance predator defense in some cases. I know of no case involving heavy metals in which prey defense against predation is enhanced by a metal pollutant, but Lürling (2006) reported that an organic pollutant (the surfactant FFD-6) affects a green alga (*Scenedesmus obliquus*) in a way that mimics effects of predator compounds that stimulate an anti-predator trait (formation of relatively large colonies of cells). Presumably, algal cells in the larger colonies formed in a polluted lake would be less susceptible to predation by zooplankton (Lass and Spaak 2003). Info-disruption also may benefit prey by negatively affecting predator search ability. For example, Smith and Weiss (1997) studied effects of Hg pollution on the behavior of mummichogs (*Fundulus heteroclitus*), a tidal creek fish that preys upon invertebrates but in turn is preyed upon by blue crabs (*Callinectes sapidus*). Fish from a polluted site attempted to capture prey less frequently than those from an unpolluted site, and the polluted site fish also were more likely to be captured by blue crabs. Although the effects of Hg were not shown to be due to info-disruption (rather than other sublethal effects), these results suggest that the net result of info-disruption will depend on the suite of species involved, their sensitivities to the pollutant, etc.

Another way by which a heavy metal can affect an organism negatively is for the metal to prevent that organism from detecting and avoiding areas that contain toxic heavy metal concentrations. Hansen et al. (1999a) found that low levels of Cu can damage olfaction in Chinook salmon (*Oncorhynchus tshawytscha)* and rainbow trout (*Oncorhynchus mykiss*), and fish actively avoided Cu-contaminated water. However, if fish were exposed to sublethal Cu levels that damaged their olfactory abilities, they were unable to detect waters containing lethally high Cu concentrations, thus suggesting that exposure to low levels of metal pollutants may result in mortality if fish are later exposed to greater concentrations.

Although I have emphasized studies of fish behavior in the previous sections, studies of invertebrates have shown heavy metal effects on their behavior as well. For example, Vuori (1994) concluded that sublethal concentrations of Cd changed behavior of caddisfly larvae. Larvae exposed to low (12 μg/L) Cd were less aggressive in intraspecific encounters, and behavior of both intruder and resident larvae that had been exposed to this low concentration of Cd differed from that of larvae not exposed to Cd. In a second example, Michels et al. (2000) showed that sublethal doses of Cd affected the phototactic behavior of the crustacean *Daphnia magna*. A recent review of chemically-induced predator defenses in plankton summarized a number of cases of behavioral predator defenses present in this invertebrate group (Lass and Spaak 2003), illustrating the potential for heavy metals to impact these and thus affect ecological relationships.

To this point I have discussed how heavy metals may influence predator/prey interactions via info-disruption, by affecting the ability of prey to detect predators or vice versa. Heavy metals may influence predator/prey interactions in ways other than through their effects on behavior, such as through effects on physical defenses. Physical defense (involving a change in morphology) is common in plankton (Lass and Spaak 2003), and a number of studies have reported morphological reactions of plankton species to the presence of predator kairomones. For example, *Daphnia* produce neckteeth that reduce the rate of predation

by *Chaoborus* midge larvae (Parejko 1991). Mirza and Pyle (2009) reported that low levels of Cu (10 μg/L) interfered with ability of *Daphnia* to respond to the *Chaoborus* midge kairomone that induces neckteeth formation. *Daphnia* exposed to Cu and kairomone had fewer and smaller neckteeth than those exposed to kairomone alone. These less well-defended offspring had lower survival when exposed to predators (*Chaoborus* midge larvae).

Heavy Metal Effects on Social Structure and Reproductive Behavior The effects of heavy metals on an animal species are likely complex, and one of the factors that can add to that complexity is the social structure of the organism(s) involved. Social structure is important in many organisms, especially vertebrates such as fish, and a recent review by Sloman (2007) of trace heavy metal effects on salmonid fish social hierarchies illustrates how sociality can influence pollutant effects on species. Her review shows that social status can change the physiology of an individual and, as a result, its susceptibility to pollutants. Furthermore, uptake may vary among heavy metals depending upon the physiological effects of a fish's social status. For example, she reported that dominant fish accumulated less Cu (Sloman et al. 2002; Sloman 2007) whereas studies of Cd showed that dominant fish accumulated more Cd (Sloman et al. 2003). In this case, the specific effect may depend on the mechanism by which the heavy metal is taken up by cells. Copper is taken up via Na transport pathways (Sloman et al. 2002), and subordinate fish have increased Na uptake due to increased social stress (Sloman et al. 2004). On the other hand, Cd crosses gills via Ca transport pathways (Sloman 2007). If dominant fish take up more Ca to support the higher growth rates that result from their social position, then Cd uptake may be greater than for subordinate fish (Sloman et al. 2003). In addition to an impact of hierarchical position on metal effects, heavy metal pollutants also can affect social hierarchy formation itself (Sloman 2007). For example, Sloman et al. (2003) showed that rainbow trout exposed to Cd formed social hierarchies more quickly. The reason for this more rapid hierarchy formation was unclear, as Cd both increased fish growth rate and also damaged olfactory sensing cells. Interestingly, waterborne Cu (Sloman et al. 2002) or Cd (Sloman et al. 2003) did not affect hierarchies that had been formed in fish populations prior to exposure to the heavy metals.

The route of exposure of a heavy metal may determine if social structure will affect metal concentration in a fish species (Sloman 2007). For example, if exposure is dietary rather than waterborne, then a fish's social status and a contaminated food item's perceived value may influence metal intake. This could occur if a dominant individual that monopolizes a prized but contaminated food source receives an increased dose, whereas a subordinate forced to eat less prized but less contaminated foods will have lesser exposure. This scenario suggests an interesting possibility for accelerated social turnover, where dominants are harmed by diet, become less aggressive and/or are less healthy, and are replaced by subordinates, which in turn become harmed, etc.

Reproductive behaviors are another arena in which heavy metals may exert negative effects on aquatic species. The above information regarding chemical cue detection and social hierarchies illustrates two ways in which metals may affect reproductive behaviors, since reproduction in aquatic animals often involves chemical cues (Paul and Ritson-Williams 2008) and may involve social hierarchies (Sloman 2007). However, heavy metals also may directly affect gamete interactions, as illustrated by a study of the effects of Cu on fertilization of eggs of an intertidal polychaete, *Galeolaria caespitosa* (Hollows et al. 2007). This worm is a broadcast spawner, so that the sperm are diluted rapidly over distance. Laboratory tests showed that Cu had stronger effects on fertilization at low sperm concentrations than at high ones. The authors also took their study into the field, finding that Cu also reduced fertilization success there. They concluded that eggs needed to be much closer to a sperm source in the presence of Cu for successful fertilization to occur in the field. Relatively sedentary aquatic species may require a minimum population density to be reproductively successful. This is an example of an Allee effect in population ecology, broadly defined as a positive relationship between individual fitness and population size or density (Stephens et al. 1999). Hollows et al. (2007) point out that their research on *Galeolaria caespitosa* shows that Cu pollution can magnify an Allee effect: the negative effect of Cu on fertilization success means that successful fertilization will occur at greater population densities than when Cu pollution is absent. Given that Allee effects are increasingly recognized as important in ecology and conservation biology (e.g., Levitan and McGovern 2005; Liu et al. 2008), potential effects of metal pollutants on reproductive processes deserve more investigation.

Mode of Action of Heavy Metals Reports of the effects of heavy metals on behavior have stimulated researchers to investigate the mechanisms by which those effects operate. Some studies of fish suggest that heavy metals directly damage sensing cells in the olfactory epithelium (e.g., Hansen et al. 1999b), but in some cases fish that return to unpolluted conditions recover their olfactory function (e.g., Beyers and Farmer 2001; Baldwin et al. 2003; Sandahl et al. 2006), depending on the degree and extent of exposure to the metals. More recent research has revealed cases of lasting damage from short-term embryonic exposure. For example,

Carreau and Pyle (2005) showed that short (5–7 days) embryonic exposure of fathead minnows (*Pimephales promelas*) to Cu caused decreased olfactory function several months after they were removed from Cu-contaminated conditions. A study by Blechinger et al. (2007), using embryos of zebrafish (*Danio rerio*) exposed for 3 hr to Cd, documented olfactory cell death, the effects of which decreased olfactory ability 4–6 weeks later.

Besides direct effects on sensing cells, there is an additional pathway by which heavy metal pollutants can interfere with fish senses. As summarized by Sloman (2007), certain metals (Cd, Hg, Ni, Mn) can be transported along nerves into more central portions of the nervous system and can exert disruptive effects there. Therefore, the examination of the olfactory epithelium for damage to detect olfactory impairment may not reveal functional failure. For example, Mirza et al. (2009) studied yellow perch from unpolluted and metal-contaminated lakes in Canada. They found that fish from the contaminated lakes had functional olfactory epithelium, but failed to respond to chemical alarm cues. They hypothesized that heavy metals of these chronically exposed fish may be accumulating in signal generating olfactory cells and interfering with signal processing rather than signal reception.

Heavy Metals as Elemental Defenses It also is possible that heavy metals have a direct chemical defense function. In general, studies of chemical defense in both marine (summarized in Pawlik 1993; Hay 1996) and terrestrial (summarized in Dearing et al. 2005; Schowalter 2006) environments have focused on the tremendous variety of organic chemicals (termed secondary chemicals) that are produced by organisms and that protect them from natural enemies. Elemental defense, a concept that has emerged mainly from studies of some terrestrial systems (see terrestrial system section below), suggests that certain elements present at high concentrations in an organism's tissues may protect it from natural enemies (Boyd 2004). In general, elemental defenses differ from secondary chemicals because they are not carbon-based structures synthesized via the metabolic pathways that generate secondary chemical defenses but instead are based upon other elements absorbed from the environment (Martens and Boyd 1994).

Elemental defense by heavy metals has been suggested in a few instances from studies in marine environments. For example, Capon et al. (1993) reported extremely high concentrations of Cd and Zn in an Antarctic marine sponge (*Tedania charcoti*) and demonstrated that those concentrations were capable of antibacterial effects. A recent survey of Antarctic sea spiders (Pycnogonida) found high levels of Cd, Cu, Ni, or Zn in some samples (Jöst and Zauke 2008): the authors suggested that the high Ni levels in some samples (up to 200 mg/kg on a dry mass basis) may have defensive effects, although no experimental investigation was done. In another example, Pawlik (1993) suggested that some tunicates that contain high levels of metals (notably V, but also Cr, Fe, Mg, Mn, Mo, and Ti) may be protected by those elements. In particular, feeding experiments with V (Stoecker 1980) showed that artificial food amended with V was less palatable to two species of representative generalist marine predators. Recently, Odate and Pawlik (2007) tested whether the high V concentration in a marine tunicate has a defensive effect. They were unable to confirm that V in the form present in the tunicate was defensively active, and suspected that low tissue pH was the primary chemical defense in the case they examined. Thus, unlike in terrestrial systems, there currently is little evidence that heavy metals (including metal pollutants) have defensive effects in marine systems. The topic, however, is not well explored.

Heavy Metals in Terrestrial Communities

Heavy Metals and Plant Behavior/Communication Whereas the literature from aquatic (particularly freshwater) communities suggests heavy metals may be important info-disruptors, similar effects have not been reported from terrestrial communities. This may be due to fundamental differences between aquatic and terrestrial habitats (Zimmer and Zimmer 2008): for example, heavy metals in above-ground terrestrial communities generally are not suspended in the medium (air) in high concentrations, whereas heavy metals in polluted aquatic communities usually are dissolved in the medium that bathes those organisms. On the other hand, effects of some heavy metals (e.g, Hg and Pb) on the nervous systems of terrestrial animals are well known, and these can include effects on behavior (Duruibe et al. 2007), illustrating a potential for heavy metal effects on terrestrial animal behavior.

The lack of information on heavy metal info-disruption in terrestrial communities might also stem from a lack of investigation. For example, the section above on effects of metals on aquatic animal behavior brings up the question of whether metals in soil might affect plant root behavior. Whether plants "behave" in a way that is analogous to animals is debatable (Trewavas 2009), but McNickle et al. (2009) have attempted to define common ground for studies of both animal and plant "behavior." In terms of plant root foraging, it has long been known that plant roots respond to heterogeneity in the soil environment (Hodge 2009), and research on the Zn hyperaccumulator plant *Thlaspi caerulescens* revealed existence of "zincophilic" foraging (Schwartz et al. 1999;

Haines 2002), the preferential proliferation of roots in high-Zn soil patches. Studies of plants that hyperaccumulate other metals (e.g., Liu et al. 2009) have documented similar cases of root proliferation in high-metal soil patches. The opposite situation, plant roots avoiding high-metal soil patches (perhaps in response to metal pollution of the soil), may exist for less metal tolerant species. Thus, soil heavy metal concentration may affect root growth patterns of plants and thus root behavior.

Direct response of plant roots to soil heavy metals may be analogous to direct responses of aquatic animals to waterborne heavy metals, but the more subtle info-disruption effects of heavy metals that are beginning to be identified in aquatic communities are difficult to relate to plants. Recent research, however, suggests plant roots may be more environmentally aware than previously thought. In particular, studies have suggested that roots can discriminate between self- and non-self roots (e.g., Falik et al. 2003; Gruntman and Novoplansky 2004). Furthermore, Dudley and File (2007) reported that roots of sea rocket (*Cakile edentula* var. *lacustris*) detect and respond to roots of conspecifics, and particularly suggested that they are capable of kin recognition. Debate has occurred regarding both the claim of kin selection by plants (Klemens 2008; Milla et al. 2009) and root mediated kin recognition (Hess and de Kroon 2007), but the field seems open for further experimental work (de Kroon 2007). Early work with desert plant roots suggested that *Larrea tridentata* and *Ambrosia dumosa* shrubs can detect roots of heterospecifics (Mahall and Callaway 1992, 1996) and the concept of chemical signaling between plant roots seems generally accepted (Hodge 2009).

Plant communication is not limited to the belowground realm. Communication between plants by volatile airborne chemicals has attracted interest since at least the 1970s, but the signals may be non-specific and susceptible to “eavesdropping” by neighboring plants (e.g., Karban et al. 2004). A recent report (Karban and Shiojiri 2009) showed that sagebrush (*Artemisia tridentata*) individuals discriminate between self-generated and non-self-generated signals. In this study, herbivore damage was significantly less when a clone of the target plant generated a volatile signal that induces herbivore chemical defense (compared to a volatile signal generated by a non-clone plant). Volatile chemical communication provides another pathway by which info-disruption may occur. The ability of a plant to detect volatile chemical signals may be changed due to exposure to heavy metals, most likely through impacts of metal-contaminated soil. Stress from exposure to the contaminated soil (Koricheva et al. 1998) may affect a plant’s physiology and thus the volatile chemical signaling system. Dry deposition of metal-containing dust is another avenue by which heavy metals can impact plants. Entry of metal-laden dust into stomata, or dissolution of metals from dust during rain or dew deposition, may allow metals to penetrate directly into tissues and ultimately cells (Greger 2004). How metal exposure may influence volatile chemical generation or detection remains to be explored.

The existence of chemical signaling between plants provides an opportunity for heavy metal pollutants to interfere with these signal mechanisms, perhaps in ways similar to the info-disruption documented in aquatic animal research. As in aquatic systems, signal disruption may occur in several ways: heavy metals may prevent the signal from reaching the receptor, interfere with the receptor’s reception, or interfere with signal transmission. To my knowledge there is no evidence of such info-disruption, but now that the question has been raised it can receive research attention.

Heavy metal pollutants, via other indirect pathways, also may influence plant interactions with natural enemies. As with other pollutants, heavy metal pollutants cause stress that changes plant characteristics, including secondary chemistry. Mithöfer et al. (2004) pointed out that heavy metals may stimulate production of oxylipins in plants: some of these, such as jasmonic acid, have well investigated roles as plant defense signals (e.g., Kessler et al. 2004). Koricheva et al. (1998) reviewed papers regarding the plant stress hypothesis: the concept that increased stress may cause changes in plant chemistry that favor natural enemy performance. They concluded that the hypothesis was supported in some cases but not in others, depending on many factors including the type of stress and insect feeding mode. It is clear from their review, however, that stress caused by heavy metal pollutants is another pathway by which plant ecological relationships with natural enemies can be impacted.

Heavy Metals as Elemental Defenses Heavy metal pollutants in terrestrial environments may directly affect plants by providing an elemental defense against plant natural enemies. The elemental defense hypothesis was originally applied to plants that accumulate extraordinary concentrations of elements, often heavy metals, in their tissues (Boyd and Martens 1992). These “hyperaccumulator” plants most often occur in habitats that contain naturally elevated levels of the element the plants accumulate. For example, many hyperaccumulators of Ni (Ni hyperaccumulators are the most numerous category of hyperaccumulators: Baker et al. 2000) occur on serpentine soils, and these often are naturally Ni-rich (Alexander et al. 2007). Tests of elemental defense (reviewed by Boyd 2007) have reported defensive effects (in some but not all cases) for a number of elements (As, Cd, Ni, Se, and Zn), most of which are heavy metals. These elements and others can be pollutants, leading to the question of whether a heavy metal

pollutant might form an elemental defense for a plant exposed to that pollutant.

I know of one study that may illustrate an elemental defensive effect by a pollutant. Scheirs et al. (2006) studied effects of Cd pollution on herbivory by a leaf-mining fly (*Chromatomyia milii*) on the grass *Holcus lanatus*. Plants were exposed to a range of relatively low Cd concentrations, and their suitability as hosts was determined by monitoring the performance of both adult flies and their offspring. Plant growth decreased in response to Cd treatments, and plant tissue Cd concentrations increased. Feeding and oviposition by adult flies, as well as performance of fly offspring, decreased as Cd concentration in plant tissues increased. Although this experiment showed plants exposed to Cd pollution were less suitable hosts, the authors were unable to determine if this was a direct effect of Cd or an indirect effect of plant host quality changes that occurred due to Cd exposure (in this case, for example, soluble sugar concentrations in plant tissues decreased with increasing Cd exposure). Thus, it cannot be concluded that the pollutant was directly responsible for the defensive effect, but this study does provide an example of a metal pollutant changing a plant-herbivore relationship in favor of the plant.

The concept of elemental defense is not limited to the producer trophic level. Elements (including heavy metals) found at relatively high concentrations in herbivores (or higher trophic levels) may have defensive benefits (Boyd and Martens 1998), but they have rarely been investigated. Nickel hyperaccumulator plants in serpentine ecosystems can be fed upon by specialized herbivores that themselves have high whole-body Ni levels (Boyd 2009). If high body Ni concentrations have defensive effects, these “high-Ni insects” (Boyd 2009), defined as those containing >500 µg Ni/g (on a whole-body, dry mass basis), are good choices for experimental tests of elemental defense against predators or pathogens. An initial investigation (Boyd and Wall 2001), that used the high-Ni mirid bug *Melanotrichus boydi,* found that mortality of crab spiders (*Misumena vatia*) was significantly greater when they were fed the high-Ni insect compared to those fed low-Ni prey. No defensive effect was found, however, for tests of two other predators (Boyd and Wall 2001) or for several pathogens (Boyd 2002), so that no general conclusion about elemental defense in this high-Ni herbivore could be reached. Elemental pollutants other than heavy metals also may have defensive effects in herbivores: Vickerman and Trumble (2003) showed that consumption of high-Se herbivore prey negatively affected the predacious bug *Podisus maculiventris*. Elemental defensive benefits likely will be positively correlated with heavy metal concentration. Biomagnification (sometimes used synonymously with bioconcentration) is generally defined as an increased element concentration in one trophic level relative to the previous one (Gray 2002). If biomagnification were to occur with a heavy metal, defensive metal effects would be more likely for organisms higher in a food web due to their higher body concentrations of that metal. Many studies have examined biomagnification, with mixed evidence that heavy metals biomagnify (e.g., Goodyear and McNeill 1999; Gray 2002; Burger 2008). Focus of elemental defense studies on systems that show biomagnification would be most likely to demonstrate elemental defense at higher trophic levels: yet even without biomagnification, differing abilities to bioaccumulate can result in defensive metal effects at higher trophic levels.

Heavy Metals and Pathogen/Microbial Communities

Heavy Metals as Pathogen/Microbial Info-disruptors Chemosensation is a vital way in which bacteria gain information about their environment. During the last 20 years, microbiologists have been excited to learn that chemical signaling among bacteria can be extensive and can lead to behaviors that suggest analogies to animal behaviors (West et al. 2007). For example, quorum sensing is the production of molecules by bacterial cells that indicate bacterial density and stimulate a population to act in a coordinated fashion (West et al. 2007; Williams et al. 2007). Discovery of this phenomenon stimulated much research into the mechanisms involved (Waters and Bassler 2005), the potential uses of these molecules in treating diseases (Ni et al. 2009), and even exploration of social phenomena (West et al. 2007) such as kin selection (Diggle et al. 2007) and cheating (Zhang et al. 2009) in bacteria. Although not all microbiologists are in agreement regarding the phenomenon’s behavioral analogies with eukaryotes (Turovskiy et al. 2007), it is interesting to consider how metal pollutants might impact the behavioral ecology of microbes.

Metals have some direct connections to quorum sensing. For example, Fe is an important and often limiting resource for bacteria, and they may produce chelating chemicals (siderophores) in order to sequester it from their environment (Challis 2005). These siderophores may have multiple functions, including acting as quorum sensors or antibiotics (Schertzer et al. 2009). Tolerance of some bacteria to heavy metals is increased greatly by formation of a bacterial biofilm, and biofilm formation can be controlled by quorum sensing molecules (e.g., Sarkar and Chakraborty 2008). At least one quorum sensing molecule contains a heavy metal (Zn) ion as part of its structure (Hilgers and Ludwig 2001).

Recognition of the importance of chemical signaling to microbes raises questions regarding the potential for heavy

metal pollutants to disrupt communication similar to those discussed for macrobiotic organisms in the preceding sections. Do heavy metal pollutants interfere with signal production, inactivate a signal, or interfere with signal reception? And, if they do, then what are the consequences for ecological relationships between organisms? Research on quorum sensing disruption appears to focus primarily on organic molecules: recent reviews (González and Keshavan 2006; Rasmussen and Givskov 2006; Ni et al. 2009) do not mention interference by heavy metals yet contain a plethora of examples involving organic compounds. The potential for pollutants to interfere with quorum sensing appears unevaluated, but there are tantalizing glimpses of how this could work. For example, the green alga *Chlamydomonas reinhardtii* produces organic chemicals that apparently mimic quorum sensing molecules produced by some bacteria (Teplitski et al. 2004). In another case, Manefield et al. (2002) report that a red alga (*Delisea pulchra*) produces organic chemicals (halogenated furanones) that interfere with quorum sensing of bacteria and may prevent algal biofilm formation on the surface of the algal thallus. There also are many examples in which chemicals produced by eukaryotes influence bacterial quorum sensing (e.g., González and Keshavan 2006; Ni et al. 2009), providing chemical interactions that might be influenced by heavy metal pollutants.

Heavy Metals and Antibiotic Resistance Another connection between heavy metals and disease incidence is concern that metal pollutants may act as co-selection agents for antibiotic resistance in bacteria. Co-selection occurs when selection for one trait simultaneously selects for a second trait: in this case, selection for metal resistance also selects for resistance to antibiotics (Baker-Austin et al. 2006). In fact, one explanation for the evolution of antibiotic resistance genes, some of which have had extensive evolutionary histories prior to widespread human uses of antibiotics, is their ability to function in heavy metal resistance (Aminov and Mackie 2007): essentially pre-adapting them to current human uses of antibiotics. Antibiotic resistance is a serious threat to human health, and how such resistance evolves and the role of the environment in this process is of increasing interest (Baquero et al. 2008). One reason for this interest is that antibiotics may degrade in the environment but metals do not, and heavy metal pollution continues to increase (Han et al. 2002). Thus, heavy metal pollution may help maintain antibiotic resistant bacterial strains even if input of antibiotics into the environment is reduced. For example, chloramphenicol has been banned in China since 1999 (Dang et al. 2008). A recent survey (Dang et al. 2008) of antibiotic-resistant bacteria found resistant bacteria remained in Jiaozhou Bay, and suggested that pollutants (including heavy metals) were providing a reinforcing selective pressure that maintained the antibiotic resistance of bacterial populations. This indicates that antibiotic resistance, once evolved, will be difficult to eradicate and thus will remain a serious human health concern.

Co-selection includes two mechanisms: co-resistance and cross-resistance. In co-resistance, a gene that confers heavy metal tolerance is present on the same genetic element as a gene for antibiotic resistance. Aminov and Mackie (2007) point out that antibiotic resistance genes may occur on plasmids large enough to include other genes, including heavy metal resistance genes. In such situations, a bacterium that possesses that plasmid would benefit from the physiological capability to resist both stresses. In cross-resistance, the same gene codes for resistance to both heavy metals and antibiotics. Baker-Austin et al. (2006) point out that cross-resistance is probably common because resistance to stresses induced by both heavy metals and antibiotics rely on similar cellular mechanisms. Co-selection also may occur because of a bacterial behavior (such as biofilm formation) that indirectly increases resistance to both heavy metals and antibiotics (Baker-Austin et al. 2006).

Evidence for co-resistance between heavy metal pollutants and antibiotics takes two forms. First, studies of metal polluted versus unpolluted areas show greater antibiotic resistance in bacteria from the polluted areas. For example, Stepanauskas et al. (2005) measured both heavy metal and antibiotic resistance of bacterial communities both before and after they were exposed to metal-polluted wastewater, finding significant increases in resistance to both stressors after metal exposure. In a study of freshwater microcosms, Stepanauskas et al. (2006) showed that bacteria from Cd- and Ni-treated microcosms were significantly more resistant to antibiotics than those from controls. A number of studies, in a variety of environments exposed to a variety of heavy metals, have shown similar results, suggesting that co-selection is widespread (Baker-Austin et al. 2006). Second, co-selection has been demonstrated experimentally by adding heavy metals to a system and measuring antibiotic resistance change. Berg et al. (2005) found that Cu-amended soils contained more Cu-resistant and antibiotic-resistant bacteria than unamended soils.

Heavy Metals as Immunomodulators The previous section regarding antibiotic resistance and heavy metals suggests a related issue that has been connected to metal pollutants: immunomodulation. Immunomodulation is a change in immune system function due to effects of a chemical (Lawrence and McCabe 2002), including pollutants such as heavy metals: it includes immunotoxicity (or immunodepression), a suppressing effect on the immune system, as well as immunostimulation (an accelerating effect). Either of these phenomena can negatively affect an organism's

health. As with other heavy metal effects, immune system effects can vary depending on metal dose (Lawrence and McCabe 2002). For example, low doses of some heavy metals, such as Cd, Hg, and Pb, can improve immune system function, whereas higher doses are suppressive (Cabassi 2007). Many studies have shown immunomodulation associated with sublethal metal exposure in the environment or in experimental laboratory settings (e.g., Lawrence and McCabe 2002; Dietert and Piepenbrink 2006; Ilbäck et al. 2008). Most studies have targeted vertebrates, but recent work has revealed negative effects of heavy metal pollutants on host defense response systems of marine invertebrates (e.g., Oweson and Hernroth 2009; Vijayavel et al. 2009) as well as terrestrial insects (e.g., Sorvari et al. 2007; van Ooik et al. 2008).

Although there are many reports of effects of heavy metals on immune system function, in general the ultimate mechanisms are not clear. One mode of action is for metals to affect directly the ability of the immune system to identify and respond to pathogen attack. In other words, the complicated chemical communication that occurs during generation of the immune response provides an opportunity for info-disruption by metals. In a simple example, phagocytic activities of cells, measured by their ability to engulf labeled particles, may decrease in the presence of some heavy metals (Fournier et al. 2000). Furthermore, Bishayi and Sengupta (2003) showed that chemotaxis was impaired in mouse splenic macrophages when animals were treated with As or Pb. It is not clear whether these effects stem from info-disruption or more direct effects of heavy metals on cellular health, but the potential parallel with the info-disruption issues being investigated by aquatic biologists is interesting.

Final Considerations

A complicating factor for studies of pollutants (including heavy metals) is that contamination by multiple pollutants often occurs (Fleeger et al. 2003). With regard to metals, these may be multiple metals or one or more metals mixed with one or more organic chemical pollutants. Despite the prevalence of mixtures, toxicological studies often focus on effects of single pollutants (Yang 1994) and so may not be realistic models for judging actual impacts. Generally, combinations of potentially toxic materials may act additively, synergistically, or antagonistically, and all of these effects have been observed in some cases for some heavy metals. For example, additive effects occur when one chemical acts independently of another. Jhee et al. (2006) explored the effectiveness of combinations of certain plant elemental defenses toward an herbivorous moth (*Plutella xylostella*) using an artificial diet amended with metals. When Zn was combined in a pairwise fashion with Cd, Ni, or Pb, toxic effects were additive, and the combination treatments caused greater mortality than single metals alone. Synergy occurs when chemicals interact in a way that increases their joint toxicity beyond that expected if their effects were additive. Jensen et al. (2006) reported an example of synergy of methylmercury and selenate in a study of effects of these chemicals on an insect detritivore (the fly *Megaselia scalaris*). Mixtures containing as little as the LC5 (Lethal Concentration 5%) of both chemicals resulted in 100% larval mortality. Finally, antagonism occurs when effects of one chemical can reduce a negative impact of another. For example, Sanchez-Dardon et al. (1999) studied effects of heavy metals on the immune system of rainbow trout. They found that individual doses of Cd, Hg, or Zn affected immune system function, but when Zn was combined with Cd or Hg no changes occurred. The positive effect of a small dose of a potentially toxic substance is termed a “hormetic effect” (Lefcort et al. 2008), and antagonism is one mechanism by which hormetic effects of a heavy metal pollutant can occur.

Another complicating factor for studies of pollutant impacts is that of scale. While the challenges of scale to ecological studies have been recognized for a long time, Zimmer and Zimmer (2008) point out that these are especially important in chemical ecology. In their recent review, Zimmer and Zimmer (2008) discuss dynamic scaling: the need to scale chemical ecology studies to the physical and chemical environments in which chemical ecology occurs. They point out that complete dynamic scaling is usually not done in laboratory or field studies and this can make it difficult to judge actual ecological effects. They also conclude that many chemical ecology studies have an organism-level emphasis, and point out that including population, community, and ecosystem scales is important to achieve a full understanding of ecological effects. These points certainly apply to studies of metals as info-disruptors, and illustrate the extensive and careful research needed to explore these aspects.

This mini-review has covered a number of ways in which anthropogenic heavy metal pollution may affect organisms and their interactions. It is interesting to consider how the human-generated increase in heavy metal concentrations in biological communities may be affecting evolution of species within them. It is clear that heavy metal pollution (or in fact, release of many pollutants) has provided an opportunity for some species to evolve tolerant populations. In the case of heavy metals, examples range from prokaryotes (e.g., Piotrowska-Seget et al. 2005) to eukaryotes (Janssens et al. 2009). In light of the concept of elemental defenses: is human-caused increase in heavy metal availability providing an opportunity for metal-based

defenses to become more frequent? There are two ways this may occur: 1) through changes in host traits (other than metal concentration) that occur as consequence of exposure to the heavy metal, 2) directly through increased heavy metal concentration serving as an elemental defense. The latter case (increased heavy metal concentration) occurs when organisms are exposed to heavy metal pollutants, and it depends on the balance of intake and excretion. The evolution of metal tolerance in organisms exposed to metal pollutants is a first step in formation of an elemental defense, allowing subsequent evolution of uptake and sequestration mechanisms that may result in concentrations of heavy metals adequate to deter natural enemies. It is difficult, however, to differentiate between direct and indirect effects of heavy metal pollutants. For example, in the section on terrestrial communities (above), the study of Scheirs et al. (2006) showed that Cd exposure of the grass (*Holcus lanatus*) negatively impacted an herbivore (the fly *Chromatomyia milii*). However, the authors were unable to determine if this was due to the direct effect of Cd on the fly, or an indirect effect of plant host quality changes that also changed due to Cd exposure.

Bioaccumulation of heavy metals may be another example by which metal pollutants can have defensive effects. In fact, in a sense this has been the case in some polluted locations where animals that contain dangerous levels of pollutants have been banned from human consumption. If this resulted in decreased human predation upon those animals, then a heavy metal pollutant would function as an elemental defense against humans. For example, in 2001 the U.S. government recommended that pregnant women limit intake of some fish (notably tuna) due to Hg contamination, and consumption by this target group decreased significantly (Oken et al. 2003). This apparently is not (at least not yet) an effective defense, as overfishing of tuna continues (e.g., MacKenzie et al. 2008), but it serves to illustrate a potential defensive consequence of heavy metal pollution.

Future Research Directions

Most of this mini-review has suggested future research directions, but I will close with some summary considerations. Research on direct toxic effects of heavy metals on organisms, a research area that has received much attention, needs further exploration. The discovery of important sublethal metal effects, however, provides a new area for research. The concept of info-disruption, now well established in freshwater systems, may be extended into other habitats and could uncover previously unrecognized heavy metal pollution impacts. For example, are there parallels between the effects of metals on immunomodulation in animals and effects of heavy metals on plant responses to pathogen attack? Poschenrieder et al. (2006) suggested there are, for example, pointing out that Cd treatment can induce production of plant signal molecules (e.g., jasmonic acid, ethylene) that mobilize plant defenses against natural enemies.

The concept of elemental defense is another research area in need of investigation. Examples from communities that are exposed to naturally elevated heavy metal levels, such as terrestrial serpentine communities (Boyd et al. 2009), suggest ways to explore similar questions in metal polluted situations. Finally, there are opportunities to explore the effects of heavy metal pollutants on ecological units larger than species. Communities and ecosystems are difficult to study due to their complexity, but a complete understanding of metal pollutant effects cannot be accomplished without such studies. Hopefully, a more complete understanding will enable us to limit harmful effects of anthropogenic heavy metal pollutants on Earth's biota.

Acknowledgments I thank Hugh Lefcort and two anonymous reviewers for helpful suggestions regarding an earlier version of this manuscript.

REVIEW ARTICLE

Direct and Indirect Effects of Invasive Plants on Soil Chemistry and Ecosystem Function

Abstract Invasive plants have a multitude of impacts on plant communities through their direct and indirect effects on soil chemistry and ecosystem function. For example, plants modify the soil environment through root exudates that affect soil structure, and mobilize and/or chelate nutrients. The long-term impact of litter and root exudates can modify soil nutrient pools, and there is evidence that invasive plant species may alter nutrient cycles differently from native species. The effects of plants on ecosystem biogeochemistry may be caused by differences in leaf tissue nutrient stoichiometry or secondary metabolites, although evidence for the importance of allelochemicals in driving these processes is lacking. Some invasive species may gain a competitive advantage through the release of compounds or combinations of compounds that are unique to the invaded community—the "novel weapons hypothesis." Invasive plants also can exert profound impact on plant communities indirectly through the herbicides used to control them. Glyphosate, the most widely used herbicide in the world, often is used to help control invasive weeds, and generally is considered to have minimal environmental impacts. Most studies show little to no effect of glyphosate and other herbicides on soil microbial communities. However, herbicide applications can reduce or promote rhizobium nodulation and mycorrhiza formation. Herbicide drift can affect the growth of non-target plants, and glyphosate and other herbicides can impact significantly the secondary chemistry of plants at sublethal doses. In summary, the literature indicates that invasive species can alter the biogeochemistry of ecosystems, that secondary metabolites released by invasive species may play important roles in soil chemistry as well as plant-plant and plant-microbe interactions, and that the herbicides used to control invasive species can impact plant chemistry and ecosystems in ways that have yet to be fully explored.

Keywords Invasive plants · Novel weapons hypothesis · Nutrient cycling · Allelopathy · Glyphosate

Introduction

Plants modify their environment in many ways that include the alteration of some of the most basic aspects of the physical and chemical substrates in which they grow. Through these effects, plants provide a crucial component of biogeochemical cycling, as they shape biogeochemical processes by producing "weathering agents", driving mineral cycles, and altering the hydrology of the soil (Kelly et al. 1998). Plants can affect soil structure (particle aggregation) by creating pores in soil, and plant growth promotes rapid wetting and drying cycles that cause shrinkage and strengthening of the soil (Angers and Caron 1998). This is amplified by root exudation of material that stabilizes the developing aggregations. Plants decrease the bulk density of soils through root channeling and litter deposition, thus making it easier for water and roots to penetrate (Tiedemann and Klemmedson 1986; Joffre and Rambal 1993; Callaway et al. 1991). However, the most thoroughly documented effects of plants on substrates involve resources, and in particular soil nutrients. Plants take up nutrients, but over long periods of time plant litter

and root exudates modify and build soils so that the potential for storage and retention of soil nutrients increases, and concomitantly total pools of most nutrients also increase (e.g., Crocker and Major 1955).

There is a substantial literature base that indicates exotic invasive plant species may alter nutrient cycles in ways that differ from resident natives. Many invasive plant species have high specific leaf areas, growth rates, and leaf nutrient concentrations, relative to the natives at the same sites, and these traits have the potential to increase rates of decomposition and nutrient cycling (Allison and Vitousek 2004). Recently, Liao et al. (2008) conducted a meta-analysis and found that on average, invaders were correlated with much higher litter decomposition rates and increases in soil nitrogen mineralization and nitrification (also see Ashton et al. 2005; Feng et al. 2009). Ehrenfeld (2004) and Ehrenfeld et al. (2001) suggested that unusual traits of many invasives, relative to local natives, might affect the particular way in which they alter ecosystem properties. These traits include greater size, higher growth rates and photosynthetic rates, higher live tissue and litter nutrient concentrations, and highly effective nitrogen-fixing symbioses. Rout and Callaway (2009) hypothesized that if invasive species enhance net primary productivity and nitrogen cycling in invaded ranges but not in their native ranges, the inherent traits of plants may be unlikely to drive these processes, because then the same ecosystem effects should occur in the native ranges. An alternative possibility is that once they are successful, invasive plants may undergo rapid natural selection for key leaf traits related to nutrient cycling. For example, Feng et al. (2009) provided evidence that the invasive *Ageratina adenophora,* native to Mexico but an invader throughout the subtropics, appears to have evolved leaves that are easier to decompose in its invaded range. Regardless, understanding whether exotic invasives alter ecosystems differently from native species will help resolve important questions in ecology, evolution, and conservation.

Plants to some degree affect their substrates through processes that are general to all plant species, such as driving nutrient cycles and increasing acidity through inputs of CO_2 into substrate (Kelly et al. 1998). However, plants have the potential to affect substrates, and thus, important ecosystem processes in a more species-specific way through the vast array of different secondary biochemicals and combinations of biochemicals that they produce and release into their environments. Secondary biochemicals are loosely defined as organic compounds that not directly involved in primary metabolic processes such as photosynthesis, cell respiration, cell division or cell growth (Metlen et al. 2009). Not only are these compounds highly diverse, but specific combinations may be species-specific. Ugolini and Sletten (1991) have argued that organic acids produced by plants, in general, have crucial roles in weathering through soil acidification, but we know little about how specific secondary metabolites might affect ecosystem processes in other ways. However, it is worth considering the possibility that organic compounds produced by invasive species may affect their substrates in unique ways. It has been proposed that some exotic invaders may gain an advantage by possessing secondary compounds that are novel to the invaded community—the "novel weapons hypothesis". This is the idea that that some invaders possess allelopathic, defensive, or antimicrobial chemicals to which native organisms have not adapted (Callaway and Aschehoug 2000; Mallik and Pellissier 2000; Callaway and Ridenour 2004; Cappuccino and Arnason 2006; Callaway et al. 2008). If indeed some invasives become dominant because of the novelty of their chemical composition, and if the secondary metabolite composition of particular species can uniquely affect soil biogeochemistry, then the potential for invasives to have unusual effects on soil chemistry through the novel biochemistry of their leachates, litter, volatiles, or root exudates may be high.

Invasive plants also may indirectly alter soil chemistry through the synthetic herbicides used to control them. For example, the most widely used herbicide in the world, glyphosate, has long been considered an ideal herbicide because of its rapid breakdown in the environment, low toxicity to animal species, and lack of carcinogenic or teratogenic effects (Baylis 2000; Borrgaard and Gimsing 2008; Duke and Powles 2008). Glyphosate has disadvantages for the control of invasive plants because it is toxic to a broad spectrum of plant species, but it is a common tool in the management of invaders both in native plant communities (e.g., Spencer et al. 2008) and in agricultural settings where there is increasing use of transgenic crops modified to be glyphosate-resistant (Duke and Powles 2008). Herbicides can affect the growth of non-target plants in treated areas (Crone et al. 2009), or through drift to neighboring untreated areas. Sublethal herbicide applications can alter plant secondary chemistry significantly (Lydon and Duke 1988), with consequences that are little understood. Herbicides can influence plant communities indirectly by changing soil microbial communities, and by altering plant chemistry and plant associations with microorganisms, particularly mycorrhizal fungi and nitrogen-fixing bacteria. Here, we review and discuss the literature on how exotic invasive plants affect soil chemistry, ecosystem processes, and community structure, with a focus on the secondary biochemistry of the invaders and herbicides used to eliminate them.

Direct Effects of Invasive Plants—Litter and Exudates

Plants produce and release constitutive levels of unique secondary compounds and unique combinations of compounds through leaf leachates, leaf litter, leaf volatiles, and root exudates and volatiles (Langenheim 1994; Lin et al. 2007; Ens et al. 2009a; Metlen et al. 2009; Jamieson and Bowers 2009). The production and release of these compounds, however, can be induced by environmental conditions (Agrawal 1998; Ormeño et al. 2007; Soler et al. 2007; Metlen et al. 2009). Importantly, many of these compounds have the potential to alter the fundamental nature of the substrates in which plants grow. For example, low nutrient availability and toxic metals in soils can elicit the production and release of secondary biochemicals from roots that increase nutrient availability and chelate toxic metals in soil (Li et al. 2007). When grown in phosphorus-poor conditions, *Vicia faba* acidifies its rhizosphere with malate and citrate, substantially lowering the pH of growth media and increasing phosphorus availability. *Banksia grandis*, *Lupinus albus*, and *Caustis blakei* also have been shown to exude specific blends of carboxylates (e.g., malate and citrate), in response to specific soil chemistry, to make phosphorus available (Lambers et al. 2002; Misson et al. 2005; Playsted et al. 2006; Wang et al. 2007, 2008). In turn, these exudates affect the biogeochemistry of their environment and competitive dynamics in these plant communities. Similarly, Tharayil et al. (2009) found that the roots of *Centaurea diffusa* exude an allelochemical, 8-hydroxyquinoline, on a diurnal basis, and in response to iron deficiency. *Centaurea diffusa* utilizes this phytotoxin for its own acquisition of iron in alkaline soils. These effects however, appear to be ephemeral, and few studies have attempted to understand the potential long-term effects of either exuded or litter-based chemicals on soil characteristics.

Higher soil phosphorus often is correlated with invasion (but see Martin et al. 2009), yet it is not usually clear whether invaders prefer microsites with high soil phosphorus or if they cause increases in available soil phosphorus. For example, Herr et al. (2007) found that plots in Europe with *Solidago gigantea* had lower soil pH and increased labile phosphorus fractions than plots without the invader (but see Scharfy et al. 2009). Thorpe et al. (2006) found that phosphorus concentration in the invasive forb *Centaurea maculosa*, growing in natural field conditions, was more than twice that of three abundant native species, and that at very low levels of soil phosphorus availability, phosphorus uptake by *C. maculosa* was six times greater than that by the native forb, *Lupinus argenteus*. However, natural field soil phosphorus levels were elevated in sites with *C. maculosa* relative to where the weed had been eliminated with herbicide, thus providing somewhat stronger evidence that the invader was actually the cause of the elevated phosphorus concentrations in the soil. Higher phosphorus under *C. maculosa* is consistent with increases in soluble phosphorus found in the rhizospheres of plants that exude phosphatases (Grierson and Adams 2000) or chelating compounds (Grierson 1992; Stevenson and Cole 1999). Roots of *C. maculosa* appear to exude the polyphenol catechin (Blair et al. 2006; Pollock et al. 2009; Triebwasser et al. 2009; but see Stermitz et al. 2009), and high concentrations can be found periodically in soils (Perry et al. 2007). Although the exudation of catechin by *C. maculosa* is debatable, catechins also are produced by many other plant species. Much like 8-hydroxyquinoline, catechin is phytotoxic (Inderjit et al. 2008a, b; Pollock et al. 2009; Thorpe et al. 2009 but see Duke et al. 2009), and also can chelate metals. Tharayil et al. (2008) found that 8-hydroxyquinoline and catechin mobilize metal-nutrients in soils, thus increasing metal-nutrient acquisition by plants. Catechin is highly ephemeral in soils and solutions (Pollock et al. 2009; Triebwasser et al. 2009), and thus seems unlikely to have long-lasting direct ecosystem effects; however, the indirect chelating effects on metal-nutrient compounds may last longer.

DeLuca et al. (2006) measured the effects of catechin on phosphorus availability in calcareous alluvial soils (pH=8) collected near Missoula, Montana, and the effects of aluminum and 8-hydroxyquinoline on phosphorus availability in aluminum rich soils (pH=6) collected near the Dalles, Oregon. In the Montana soils, phosphorus likely is bound primarily to calcium as calcium phosphates, while in the Oregon soils, phosphorus likely is bound to aluminum. Both soils were amended with a small amount of rock phosphate. They found that application of catechin substantially increased phosphorus availability in calcareous soils and that 8-hydroxyquinoline increased phosphorus availability in acidic soils. This may be due to chelation of calcium by catechin and of aluminum by 8-hydroxyquinoline. Interestingly, catechin had no effect on phosphorus availability in acidic, aluminum-rich soils, and 8-hydroxyquinoline had no effect in calcareous soils (T.H. DeLuca, unpublished data). Furthermore, adding “biochar” (charcoal derived from natural fires) eliminated or reduced the effects of these allelochemicals on phosphorus availability. These results demonstrated the potential for different secondary metabolites exuded from roots to have system-specific effects. The addition of biochar to phenolic-rich soils in natural ecosystems also has been shown to strongly affect nitrogen transformations in temperate and boreal forests (DeLuca et al. 2002; Gundale and Deluca 2006).

The effects of root exudates may be altered by interactions of plants with other organisms. Hamilton and Frank (2001) conducted a ^{13}C pulse-chase and simulated

herbivory experiment on *Poa pratensis* in grasslands of Yellowstone National Park and measured carbon flow into the soil rhizosphere, microbial biomass, and the associated effects on soil nitrogen dynamics. They found that grazing promoted root exudation of carbon, which was then assimilated by soil microbes, although they did not determine the nature of the exudate. Herbivore-induced carbon flow from roots affected soil nutrient pools, plant uptake, leaf concentrations of nitrogen, and photosynthesis.

Rather than releasing chelators, plants may release enzymes involved in phosphorus acquisition. Caldwell (2005) found that soils under *Cytisus scoparius* (scotch broom), a species that has invaded widely in the Pacific Northwest, had much higher activities of two soil enzymes involved in phosphorus availability, phosphatase and β-glucosidase, but lower phosphorus:carbon ratios under *C. scoparius* than in prairie vegetation, perhaps due to higher phosphorus uptake by the invader. Similarly, Blank and Young (2004) found that three invasive species increased calcium, magnesium, and nitrogen mineralization in soil solution of a "high-resource" soil and also greater enzyme activity in both high- and low-resource soils.

In some cases, the release of biologically active compounds by plants has been documented, but the ecological effects are unknown. *Pteridium aquilinum* (bracken fern) and *Heracleum mantegazzianum* (giant hog weed) are both exotic invaders in parts of the world (Kollmann et al. 2009). *Pteridium* produces ptaquiloside, a norsesquiterpene glycoside, and *Heracleum* produces furanocoumarins, and these compounds can affect surface and ground water quality. Kollmann et al. (2009) report that ptaquiloside is transferred to soil from where it can leach into aquatic systems. They also report that ptaquiloside is carcinogenic and that very low concentrations can be dangerous to humans in drinking water. When cows eat ptaquiloside, the toxin can accumulate in milk (Alonso-Amelot et al. 1998).

Some of the most salient aspects of highly invasive plant species are their powerful competitive effects in non-native ranges relative to effects in their native ranges (Hierro et al. 2005). There is evidence that this biogeographic shift in competitive impact may be directly contributed to by novel allelopathic effects (Callaway and Aschehoug 2000; Mallik and Pellissier 2000; McKenney et al. 2007; Ens et al. 2009b; He et al. 2009). Competition between native species can be affected by the indirect effects of secondary metabolites exuded by roots and contained in litter (Meier and Bowman 2008); however, little is known about how the indirect effects may operate in invaded ecosystems.

As noted above, whether through leachates, litter, or exudates, invasive plant dominance often is correlated with changes in ecosystem processes in soils. Also, these changes frequently are measured as increases in available nutrients and nutrient pools (Liao et al. 2008). For example, Duda et al. (2003) found that as the exotic *Halogeton glomeratus* invades native *Krascheninnikovia lanata*-dominated vegetation, soil concentrations of nitrate, phosphorus, potassium, and sodium increased with the cover of the invader. Rodgers et al. (2008) found that soils in North American temperate deciduous forest invaded by the European forb *Alliaria petiolata* were consistently and significantly higher in nitrogen, phosphorus, calcium, and magnesium availability, and soil pH. In the laboratory, the release of volatile compounds from the leaves of *A. petiolata* did not significantly alter soil nitrogen availability, nor did the colonization of native soils by *A. petiolata* roots alter soil nutrient cycling. However, in a leaf litter decomposition experiment, the leaves of *A. petiolata* significantly increased the rate of decomposition of native tree species, thus indicating that fundamental changes in nutrient cycling were more important than inhibitory effects of *A. petiolata* secondary compounds on the activity of the microbes that decompose the native litter. Sanon et al. (2009) also found that microbial communities may have a role in the ecosystem-scale changes in soil biochemistry caused by invasive plants. They found that invasion by *Amaranthus viridis* increased concentrations of nitrogen, carbon, total phosphorus, and soluble phosphorus in the top 15 cm of soil. Total phosphorus was almost three times higher in invaded soils, whereas soluble phosphorus was approximately twice as high in invaded soils. These increases were correlated with increases in bacterial abundance and soil microbial activity. However, despite this increase in important soil resources, arbuscular mycorrhizae (AM) fungi, rhizobial development, and the growth of native *Acacia* species were severely reduced in soil invaded by *A. viridis*.

McGrath and Binkley (2009) measured the soil chemical changes induced by the invasive *Microstegium vimineum* (Japanese stiltgrass) in acidic, nutrient-poor temperate forests. In a greenhouse study, soil pH under *M. vimineum* was significantly higher than that of soil without the exotic, and in invaded forests they found higher pH, phosphorus, levels of several cations, and lower aluminum beneath dense *M. vimineum* than when *M. vimineum* was not present. Similarly, *Lantana camara* invasion in India is correlated with increases in soil available nitrogen, ammonification, nitrification rate, and nitrogen mineralization, which in turn is correlated with high nitrogen, low lignin, low lignin:nitrogen ratios, and low carbon:nitrogen ratios in *L. camara* litter (Sharma and Raghubanshi 2009). Blank (2008) found that invasion by *Bromus tectorum*, a Eurasian annual grass that has spread throughout western North America, increased the availability of manganese, nitrogen, phosphorus, copper, iron, calcium, and potassium. They suggested that *B. tectorum* affects the flow of nutrients

through the soil system with the potential to alter the vertical distribution of nutrients in the soil profile (also see Evans et al. 2001). Similar increases have been reported in invasions by *Lepidium latifolium* in the western United States (Renz and Blank 2004). Dassonville et al. (2007) hypothesized that a substantial increase in a wide range of nutrients occurred under the canopies of the invasive *Fallopia japonica* through “nutrient uplift” and redistribution.

Dassonville et al. (2008; see also Vanderhoeven et al. 2005) examined the effects of seven invasive plant species in Europe on nutrient pools in the topsoil and found that the intensity of the impact and whether or not pools increased or decreased depended on the site. Strong increases in nutrient concentrations with invasion occurred primarily in sites that were initially nutrient poor, but decreases typically occurred in soils that initially were nutrient rich. In the nutrient-poor tropical forest of the Seychelles, Kueffer et al. (2008) did not find strong differences among ecosystem effects of native and invasive trees. They compared leaf traits and understory soil characteristics of six native and six invasive tree species. Litter of invasive canopy and pioneer species had higher specific leaf areas, and litter decomposition was faster than for comparable native species; however, these traits did not differ between native and invasive understory species (also see Batten et al. 2005). However, whether exotics demonstrated strong invasive tendencies or not was not clear. Allison and Vitousek (2004) also explored the effects of invaders on ecosystem processes in nutrient-poor substrates on an island (Hawai’i). They measured leaf litter properties, decomposition rates, and nutrient dynamics for five common native species and six clearly identified aggressive invasive species. They found far higher litter decay rates for invaders.

Invaders also appear to alter the way that native litter is processed through nutrient cycles in some cases. Standish et al. (2004) found that native litter placed under mats of the invasive *Tradescantia fluminensis* in a remnant of New Zealand lowland podocarp–broadleaf forest decomposed at almost twice the rate of litter placed outside the mat. They also pointed out that the effect of *Tradescantia* on such cycles could be seen in the smaller forest floor mass where *Tradescantia* was abundant. Also, nitrate availability was higher in plots with *Tradescantia.*

Interestingly, the frequent increases in soil nutrient concentrations that are observed over time with many invaders has been proposed as a sort of feedback process in which elevated concentrations of nutrients, especially nitrogen, promote the greater success of invaders relative to natives. Prober and Lunt (2009) took an especially creative approach to this possibility by investigating whether restored stands of the native tussock grass, *Themeda australis*, in southeast Australia could reduce soil nitrate concentrations that appeared to be promoting a suite of exotic invaders, and thus might increase resistance to invasion. They found that successful establishment of *Themeda* plots treated by fire or by adding carbon supplements reduced soil nitrate to levels comparable with non-invaded, *Themeda*-dominated sites, and significantly reduced exotic cover compared to controls. When plots were not seeded with *Themeda*, soil nitrate concentrations increased after carbon treatments ended, and invasive abundance increased to levels of the control plots. They argued that “*Themeda* is a keystone species that regulates nitrate cycling, thereby imparting ecological resistance to invasion by nitrophilic annuals”.

In sum, the literature indicates that exotic invasive plants can have strong effects on the biogeochemistry of ecosystems and that these effects can be caused by differences in leaf tissue composition or secondary metabolites. However, effects of secondary metabolites on soil ecosystem processes appear to be less important than the stoichiometric ratios of nutrients and structural and non-structural carbon.

Indirect Effects of Invasive Plants—The Effects of Herbicides

While the primary use of herbicides is the control of weeds in agricultural lands, herbicide treatment increasingly is used to control invasive weeds in non-agricultural settings. The spectrum of compounds used as herbicides and growth regulators is far less than that of secondary metabolites in plants, but the large quantities of these compounds applied annually certainly have the potential to impact ecosystem processes. Globally, more than 800 million kg of herbicides and plant growth regulators were used in 2001. More than 200 million kg were used in the United States, including 40 million kg of glyphosate (US Environmental Protection Agency 2009).

The effects of herbicides on soil microorganisms and ecosystem processes have been studied in many different systems, and addressed in numerous reviews and texts (e.g., Grover and Cessna 1991). Our intent here is not to review this literature comprehensively, but rather to point out some of the ways in which herbicides may affect ecosystem processes and plant communities as they are applied to control invasive weeds. We have emphasized the effects of glyphosate (N-(phosphonomethy)glycine) because it is the most widely used herbicide in the US, but we also review selected studies with other herbicides to illustrate some of the potential indirect effects that these compounds can have.

The impact of glyphosate on soil microbial communities has been widely studied in both agricultural and non-agricultural communities, and most studies have shown

little to no lasting effects (Wardle and Parkinson 1991; Haney et al. 2000; Busse et al. 2001; Ratcliff et al. 2006; Weaver et al. 2007). Santos and Flores (1995) evaluated the effect of glyphosate on nitrogen fixation by free-living *Azotobacter chroococcum* and *A. vinelandii* and observed no effect at recommended applications rates of glyphosate. Busse et al. (2001) measured microbial biomass, respiration, and metabolic diversity in three ponderosa pine communities following 9–13 years of glyphosate applications. Soils had varying clay and aluminum and iron oxide contents, providing a range of capacities for glyphosate binding . Minimal effects on soil microbial communities were detected. Weaver et al. (2007) examined the impact of glyphosate on microbial communities in an agricultural soil. Profiles of microbial fatty acid methyl esters showed no effect of glyphosate application. Further laboratory experiments in which high doses of glyphosate were applied (up to three times the recommended rate) had a detectable impact on soil microorganisms for less than 1 week. They concluded that the effects of glyphosate on soil microbes were “small” and “transient.”

However, other studies have shown subtle effects with the potential to impact plant communities. Feng and Thompson (1990) measured rapid initial degradation of glyphosate in soils, but detected residues of the herbicide and aminomethyl phosphoric acid (AMPA), the primary metabolite of glyphosate, for up to 360 days after application. Araújo et al. (2003) found that in vitro application of glyphosate to two Brazilian soils resulted in increases of fungal and actinomycete populations, but very small decreases in the abundance of soil bacteria. Carbon dioxide release from soil was increased by glyphosate application, and the glyphosate metabolite AMPA (aminomethyl phosphonic acid) was found in soils treated with glyphosate, indicating that the herbicide was broken down by soil microorganisms. Microbial degradation of glyphosate is well-established, and organisms capable of degrading it have been characterized (Moore et al. 1983; Pipke and Amrhein 1988), suggesting at least the potential for glyphosate to alter soil microbial composition. Widenfalk et al. (2008) applied four pesticides including glyphosate to sediment in experimental microcosms. Glyphosate was found to cause small but significant shifts in bacterial community composition over 1 month, and the effects of glyphosate were greater than those of isoproturon, the other herbicide included in the study. Lupwayi et al. (2009) measured the impacts of applications of 2,4-D and glyphosate to glyphosate-resistant canola prior to seeding, and observed that the functional structure of the soil bacterial community was changed and functional diversity was reduced by both herbicides. Microbial biomass C increased when these herbicides were applied, and they concluded that these changes, while minor, could affect soil biological processes and food webs. Zabaloy et al. (2008) found minor impacts on microbial populations and activities from additions of 2,4-D, metsulfuron-methyl and glyphosate at ten times the recommended label rates. Effects of glyphosate exceeded those of the other two herbicides, and at high doses glyphosate could influence soil microbes as a phosphorus source. The authors cautioned that because less than 1% of soil microbes are cultivable, it is unclear whether all significant changes to soil microbial community structure can be detected. Powell et al. (2009) found no permanent negative effects of glyphosate-tolerant crops and herbicide regimes on soil microbiota and litter decomposition. However, in some treatments, glyphosate increased the fungus: bacteria biomass ratio, and there was some indication of reduced litter decomposition rates, although results were inconsistent. These authors concluded that further work was needed to determine whether there might be longer term effects on organic matter accumulation and nutrient cycling. Tejada (2009) characterized microbial biomass and several enzyme activities up to 180 days following laboratory applications of glyphosate and the herbicide diflufenican to two soils. Herbicides were applied singly and in combination. The glyphosate-diflufenican mixture was the most toxic, reducing microbial biomass, and decreasing the activities of important metabolic indicators including dehydrogenase, urease, β-glucosidase, phosphatase, and arylsulfatase. Toxicity was observed up to 180 days following application, and also was greater in a sandy loam soil than in clay soil. Because glyphosate is often used in combination with other herbicides that provide residual activity, these results imply that the impact of glyphosate on soil microorganisms and biochemistry may be greater than currently recognized.

Herbicides also can indirectly affect plant growth through effects on rhizobium nodulation and mycorrhizal formation, although these effects have not often been investigated. Eberbach and Douglas (1989) examined how the nodulation of subclover *Trifolium subterraneum* L. was affected in nutrient culture by nine herbicides (2, 4-D, amitrole, atrazine, chlorsulfuron, diclofop-methyl, diquat, glyphosate, paraquat, and trifluralin). Diquat, paraquat, glyphosate, and chlorsulfuron inhibited growth of *Rhizobium trifolii*, and amitrol, diclofop-methyl, and glyphosate decreased nodulation. Busse et al. (2004) reported no effect of the herbicides triclorpyr, imazapyr, and sulfometuron on ectomycorrhizal formation of Ponderosa pine, Douglas fir, and white fir. The herbicides were applied at rates up to double the recommended application rate. While seedling growth was inhibited by many of the treatments, ectomycorrhizal formation was unaffected. In contrast, Abd-Alla et al. (2000) reported that the herbicides bromoxynil and paraquat reduced

nodulation and colonization of roots of three legumes by arbuscular mycorrhizal fungi. Accumulation of nitrogen, phosphorus, and potassium in affected plants was reduced. The effects observed varied by species and compound. In an interesting early report, Schwab et al. (1982) indicated that at concentrations above 1 mg kg^{-1} simazine, the non-mycorrhizal species *Chenopodium quinona* was induced to form arbuscular mycorrhizas.

Herbicides and herbicide drift to adjacent land can have substantial effects on non-target plants. Picloram is used to control invasion by spotted knapweed (*Centaurea maculosa*). Crone et al. (2009) followed the effects of picloram on the native arrowleaf balsamroot, *Balsamorhiza sagittata*, and found that a single application of picloram reduced flowering and seed set of this native wildflower for 4 years. Marrs et al. (1991) conducted experiments in which eight native dicot species were grown in experimental microcosms with and without the perennial grass *Lolium perenne* and exposed to drift of the herbicide mecoprop. Effects ranged from reduction of growth to stimulation, depending on species, and flowering performance of some species also was affected. The results imply that herbicide drift could impact competitive balance and fecundity of species in communities adjacent to sprayed sites. Måren et al. (2008) explored the impact of the herbicide asulam on native heathland vegetation. Asulam is the most popular strategy for restoration of heathlands invaded by bracken (*Pteridium aquilinum*). In a seven-year field study, asulam treatment did eliminate bracken, but had both positive and negative effects on several minor heathland species. A group of "bracken-suppressed, yet herbicide-sensitive" species, was identified, and it was argued that abundance of these native species could be reduced because of herbicide use.

Gove et al. (2007) studied the effect of low doses of glyphosate on six woodland understory species. Glyphosate treatment increased mortality and reduced biomass and fecundity for all species. Species differed in their sensitivity to glyphosate, and differences in species distribution were measured to a distance of 4 m into woodland margins. Neumann et al. (2006) demonstrated that non-target transfer of glyphosate can occur not only through drift but also by release from treated plants into the rhizosphere. Glyphosate applications at 6% of the recommended rate reduced iron and manganese uptake in non-target sunflower plants, suggesting that glyphosate has the potential to alter micronutrient nutrition in non-target plants (Eker et al. 2006).

Two recent papers report stimulatory effects of sublethal doses of glyphosate, which imply that glyphosate drift may affect competitive outcomes of affected plants in ways that are difficult to predict. Velini et al. (2008) found that low doses of glyphosate can stimulate the growth of crops (corn and soybean), an herb (*Commelina benghalensis*), and two tree species (*Eucalyptus grandis and Pinus caribea)*. The doses required for stimulation varied with species and tissue type, with both root and/or shoot stimulation observed depending on species. Cedergreen (2008) treated barley with low doses of glyphosate and found that the growth stimulation observed lasted for 6 weeks in comparison to untreated controls, but did not persist until harvest. It was suggested that competitive abilities of plants may be affected by glyphosate stimulation, but this hypothesis remains untested.

A potentially important effect of glyphosate is the alteration of plant secondary chemistry that can be caused by sublethal applications. In a study of the effects of sixteen herbicides on soybean, Hoagland and Duke (1983) found that concentrations of hydroxyphenolics and anthocyanins were either increased or decreased, depending on the herbicide. Glyphosate inhibits the shikimic acid pathway, and thus accumulation of certain plant metabolites is characteristic of glyphosate exposure. Lydon and Duke (1988) reported increases in concentrations of gallic acid, 4-hydroxybenzoic acid, and protocatechuic acid in response to treatment of velvetleaf (*Abutilon theophrasti*) with glyphosate. Effects were dramatic, with protocatechuic acid concentrations increasing from 1.8 to 112 ng/mg dry weight. Four other species tested showed varying impacts of glyphosate on phenolic metabolism. Lydon and Duke (1988) hypothesized that the release of high concentrations of certain secondary metabolites caused by glyphosate exposure could have allelopathic impacts, but this has not been investigated. Adding weight to this hypothesis, Einhellig (1996) reported additive inhibition in greenhouse experiments for combinations of the allelochemical ferulic acid with low levels of atrazine, alachlor, and trifluralin. Despite this intriguing report, the interactive effects of herbicides and allelochemicals remain largely unknown. Disruption of phenolic metabolism by glyphosate also has been shown for nodulated soybean (Hernandez et al. 1999). Both glucosinolate and phenolic metabolism of rapeseed (*Brassica napus)* was affected by glyphosate, with concentrations of glucosinolates affected in complex ways—methionine-derived glucosinolates increased at glyphosate concentrations exceeding 5 μM, but decreased at 1 μM concentration (Peterson et al. 2007). Sublethal doses of other herbicides also can impact plant secondary chemistry. Alla and Younis (1995) treated corn and soybean seedlings with five different herbicides (trifluralin, fluometuron, atrazine, alachlor, and rimsulfuron) and found that the herbicides affected concentrations of hydroxyphenolic compounds and anthocyanins. They increased or decreased depending on the particular compound and species combination.

Future Directions

Understanding whether and how exotic invasive plants change ecosystems in ways fundamentally different from native species can contribute to our understanding of plant-soil microbe interactions, the role of secondary metabolites in ecology in general, and the potential for regional evolutionary trajectories in different parts of the Earth (Callaway et al. 2005). This also is an important issue to resolve for accurate evaluation of the biological and economic impact of invaders. We have learned a great deal about general ecosystems effects and some of the operating mechanisms. However, little is known about the substantial potential for long-term effects through exuded or litter-based secondary metabolites on soil characteristics. Recent work demonstrates that plants respond to environmental conditions by releasing particular allelochemicals that can play a role in chelation or solubilization of nutrients, but it is not known how this mechanism or other mechanisms differ between invaded communities and those in native ranges of the same species. Active chelation of scarce nutrients presumably may alter competitive relationships among species, but the extent and importance of these effects is not known. Little is known also about how secondary metabolites may indirectly impact competitive relationships through effects on soil microbial and other processes. The literature demonstrates that invasive plant dominance often is correlated with changes in nutrient status and ecosystem processes in soils, but the relative importance of secondary metabolites relative to mineral composition in driving these effects is not well understood and needs further investigation.

Numerous reports suggest the importance of the indirect impacts of invasive species through the herbicides used to control them. Herbicide applications can alter plant secondary chemistry significantly, and impact important symbioses with nitrogen-fixing bacteria and mycorrhizae, but the consequences of these effects are not yet understood. While several reports provide evidence for differential decomposition of invasive plant litter, the alterations in plant chemistry that have been demonstrated in response to glyphosate applications suggest that there could be a significant impact on how litter from these plants is processed. The potential interactive effects of herbicides and plant allelochemicals, on plant-plant interactions and on soil microbiology and chemistry, are largely unknown. The potential impact of combinations of herbicides on soil microorganisms and soil chemistry and interactions with allelochemicals is another area where further study is needed.

In summary, invasive plants have the potential to directly affect soil chemistry and ecosystem function through the direct effects of secondary metabolites in their tissues, leachates, and exudates; and indirectly through chemical attempts to control them. In this context, much is known about highly local effects (e.g. in pots, common gardens, or smallplots), but little is known about the scale at which these effects function. Thus, scaling up from small scale experiments to large scale field-based monitoring of these sorts of effects will be a necessary step for a complete understanding of the impact of invasive plants on soil chemistry.

Abstract Invasive plant species can have significant ecological and economic impacts. Although numerous hypotheses highlight the importance of the chemical defenses of invasive plant species, the chemical ecology of many invasive plants has not yet been investigated. In this study, we provide the first quantitative investigation of variation in iridoid glycoside concentrations of the invasive plant Dalmatian toadflax (*Linaria dalmatica*). We examined variation in chemical defenses at three levels: (1) variation within and among populations; (2) variation due to phenology and/or seasonal differences; and (3) variation among plant parts (leaves, flowers, and stems). Further, we examined two biological control agents introduced to control *L. dalmatica* for the ability to sequester iridoid glycosides from this invasive plant. Results indicate that *L. dalmatica* plants can contain high concentrations of iridoid glycosides (up to 17.4% dry weight of leaves; mean = 6.28±0.5 SE). We found significant variation in iridoid glycoside concentrations both within and among plant populations, over the course of the growing season, and among plant parts. We also found that one biological control agent, *Calophasia lunula* (Lepidoptera: Noctuidae), was capable of sequestering antirrhinoside, an iridoid glycoside found in *L. dalmatica*, at levels ranging from 2.7 to 7.5% dry weight. A second biological control agent, *Mecinus janthinus* (Coleoptera: Curculionidae), a stem-mining weevil, did not sequester iridoid glycosides. The demonstrated variation in *L. dalmatica* chemical defenses may have implications for understanding variation in the degree of invasiveness of different populations as well as variation in the efficacy of biological control efforts.

Introduction

The invasion of non-native plant species has affected ecosystems throughout the world and represents a major threat to native biodiversity (Wilcove et al. 1998; Levine et al. 2003; Myers and Bazely 2003; Mitchell et al. 2006). Numerous hypotheses have been proposed to elucidate the mechanisms that underlie plant invasions. Many of these hypotheses, including the enemy release, evolution of increased competitive ability, novel weapons, and novel chemistry hypotheses, highlight the importance of plant defensive chemistry in the success and invasion dynamics of introduced species (Blossey and Notzold 1995; Keane and Crawley 2002; Callaway and Ridenour 2004; Cappuccino and Arnason 2006; Inderjit et al. 2006). Moreover, plant secondary compounds are known to play an important role in mediating species interactions, including plant-plant, plant-pathogen, and plant-herbivore interactions. Thus, research that examines the chemical ecology of invasive plants may contribute greatly to understanding factors that facilitate invasion success as well as factors that influence management and biological control efforts.

In this paper, we present the first quantitative investigation of the chemical defenses of Dalmatian toadflax, *Linaria dalmatica* (L.) P. Mill. (Plantaginaceae), which has been identified as both an ecologically and economically important invasive plant species (Duncan et al. 2004). This species contains iridoid glycosides (Handjieva et al. 1993; Ilieva et al. 1993; Franzyk et al. 1999), but its iridoid content has not been quantitatively examined. Iridoid glycosides are a group of cyclopentanoid monoterpene-derived compounds found in approximately 50 plant families (Bobbitt and Segebarth 1969; Jensen et al. 1975; El-Naggar and Beal 1980; Boros and Stermitz 1990). These compounds mediate plant interactions with both specialist and generalist herbivores, acting as deterrents and toxins for generalists and as attractants and feeding stimulants for certain specialists (review in Bowers 1991). Further, these compounds can be sequestered by some specialist insect herbivores and provide protection against their natural enemies (Bowers 1991; Rimpler 1991; Nishida 2002).

We quantified the two major iridoid glycosides, antirrhinoside and linarioside (Fig. 1), found in *L. dalmatica*, and examined three levels of variation in iridoid glycoside concentrations: (1) variation within and among populations; (2) variation due to phenology and/or seasonal differences; and (3) variation among plant parts (leaves, flowers, and stems). Additionally, we examined two introduced biological control agents, the toadflax defoliator, *Calophasia lunula* Hufnagel (Lepidoptera: Noctuidae) and the stem-mining weevil, *Mecinus janthinus* Germar (Coleoptera: Curculionidae), for their ability to sequester iridoids. We were interested especially in examining *C. lunula* because the bright coloration of larvae (white, black, and yellow) suggested aposematism and because a number of lepidopteran species are known to sequester iridoid glycosides that provide protection against natural enemies (Bowers 1991; Nishida 2002). For comparison, we also analyzed larvae of the common buckeye butterfly, *Junonia coenia* Hübner (Lepidoptera: Nymphalidae), for its ability to sequester iridoid glycosides from *L. dalmatica* because it is known to sequester other iridoid glycosides (Bowers and Collinge 1992) and will feed on *L. dalmatica* (pers. obs.).

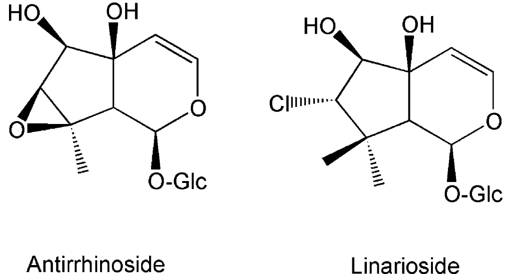

Fig. 1 Structures of the iridoid glycosides antirrhinoside and linarioside

Methods and Materials

Study System Linaria dalmatica is a perennial species native to Eurasia that escaped cultivation in North America during the early 1900's and since has become a land management concern throughout the western United States and Canada (Vujnovic and Wein 1997; Wilson et al. 2005). Synonyms of this species include *L. dalmatica* ssp. *dalmatica* and *L. genistifolia* ssp. *dalmatica* (Vujnovic and Wein 1997; Weber and Wittmann 2001; USDA 2009). *Linaria dalmatica* is designated as a noxious weed in 12 states throughout the western United States and has been reported to occur in at least 33 states (USDA 2009). Once established, *L. dalmatica* can be a strong competitor and may reduce the abundance of native grasses and forbs (Carpenter and Murray 1998).

Several iridoid glycosides have been identified in *L. dalmatica* and other *Linaria* species (Ilieva et al. 1992, 1993; Handjieva et al. 1993; Franzyk et al. 1999). *Linaria dalmatica* is reported to contain five iridoid glycosides: antirrhinoside, linarioside, isolinarioside, 5-O-glucosylantirrinoside, and 5-O-allosylantirrhinoside (Handjieva et al. 1993; Ilieva et al. 1993; Franzyk et al. 1999). To date, the iridoid content of *L. dalmatica* has not been investigated quantitatively; however, one study has examined other closely related *Linaria* species. Nikolova-Damyanova et al. (1994) used quantitative thin-layer chromatography (TLC) to estimate iridoid glycosides from the dried ground aerial plant tissue of *L. vulgaris*, *L. simplex*, *L. pelliseriana*, and *L. genistifolia*, and they found that antirrhinoside and linarioside represent the two major iridoids found in these species. In *L. genistifolia*, antirrhinoside represented approximately 60–70% of the total iridoid content and linarioside represented 10–20% (Nikolova-Damyanova et al. 1994).

Management of *L. dalmatica* by using chemical and mechanical control often is unsuccessful due to waxy leaves that protect the plant from herbicides as well as long taproots and the ability to reproduce vegetatively from root buds and fragments (Carpenter and Murray 1998; Wilson et al. 2005). Consequently, biological control may be the most effective management strategy for managing invasive populations of this species. Seven specialist herbivores of *L. dalmatica* have been introduced into North America, either intentionally as biological control agents or accidentally (Wilson et al. 2005). Iridoids are likely to play a role in mediating interactions between *L. damatica* and these specialist herbivores; however, little is known about the iridoid content and chemical ecology of this invasive plant.

Mecinus janthinus is a stem-mining weevil native to Eurasia, which was approved for release as a biocontrol agent in Canada and the US in the early 1990s (Wilson et

al. 2005). *Mecinus janthinus* larvae develop from early to mid-summer within the stems of *L. dalmatica*. Larvae pupate during late summer and overwinter in dead stems. Adults emerge the following spring and feed on the leaves and stems of the plant (Jeanneret and Schroeder 1992). Because *L. dalmatica* population growth appears to be limited by interspecific competition rather than seed availability, Grieshop and Nowierski (2002) suggest that biocontrol agents that reduce the competitive ability of plants by attacking stems and roots are most effective at reducing population densities. Furthermore, research by Peterson et al. (2005) demonstrated that *M. janthinus* larval injury had a significant deleterious effect on the primary physiology of *L. dalmatica*, whereas *Calophasia lunula* larval injury did not result in any significant physiological responses. Accordingly, *Mecinus janthinus* seems to be the most promising biological control agent for management of *L. dalmatica* populations.

Calophasia lunula is a defoliating lepidopteran, also native to Eurasia, which was introduced into North America in the early 1960's as a biocontrol agent for *L. dalmatica* and *L. vulgaris* (Wilson et al. 2005). Adult moths emerge in May, and caterpillars can be found feeding on *L. dalmatica* from late May through August. Depending on weather and the length of the growing season, *C. lunula* will complete one to three generations per year. This specialist herbivore is found throughout the range of *L. dalmatica* and its occurrence is widespread in the United States. Caterpillars can cause severe defoliation, but larval injury is likely only significant at the seedling stage, not at the adult stage of *L. dalmatica* (Wilson et al. 2005).

Junonia coenia is a lepidopteran native to North and Central America and is not a specialist on *L. dalmatica*, but it is a specialist on plants that contain iridoid glycosides (Bowers 1984). Common host plants of this species include native and cultivated snapdragons, *Antirrhinum majus* (Plantaginaceae) (Robinson et al. 2002). Moreover, larvae also will feed on *L. dalmatica* (pers. obs.). Snapdragons are known to contain antirrhinoside and other iridoid glycosides (Beninger et al. 2007). Although *J. coenia* larvae have been shown to sequester the iridoid glycosides aucubin and catalpol (Bowers and Collinge 1992), this species has not been examined for its ability to sequester antirrhinoside.

Sample Collection Plant samples were collected from three field sites in the northwestern region of Boulder County, Colorado, USA, in the spring and summer of 2006. Two field sites were located on Boulder County Parks and Open Space property: Rabbit Mountain (40° 14′ 13″ N; 105° 12′ 53″ W) and Hall Ranch (40º 12′ 42″ N; 105º 17′ 20″ W). The third site was located on private property in Lefthand Canyon (40° 7′ 14″ N; 105° 19′ 26″ W). Field sites ranged from 1675–2075 m in elevation and were characterized as dry and rocky foothills grassland habitat with vegetation dominated by mixed grasses, forbs, and shrubs. Plant samples were collected on three dates that spanned the major phenological stages of *L. dalmatica*: pre-flowering (late-May), peak flowering (mid-July), and during fruiting and seed set (mid-September). We collected plant samples from 10 patches at each field site (N=10 samples per date/site). Each sample was comprised of three ramets collected from a distinct patch. Because *L. dalmatica* reproduces vegetatively and from seed, it was not possible to determine whether ramets come from a single or multiple individuals without genetic analyses. Although *L. dalmatica* can hybridize with *L. vulgaris* in natural habitats (Ward et al. 2009), we are confident that our samples are pure *L. dalmatica* because *L. vulgaris* is not present at our study sites and the sampled plants in these populations clearly showed the morphology of *L. dalmatica*.

Mecinus janthinus adults (N=10) were collected from Lefthand Canyon in early June 2006. *Calophasia lunula* samples came from a lab culture started from eggs obtained from the Colorado Department of Agriculture Insectary (Palisade, CO). Larvae were reared in a growth chamber (model Percival 36-LLVL; interior volume = 0.84 m^3) with a 16:8 h L/D photoperiod and temperatures set to 25°C day and 20°C night. Larvae were fed *L. dalmatica* plants collected from a field population located behind the University of Colorado 30th St. Greenhouse, Boulder, CO during August 2006. Larvae were selected for sample preparation at three stages: newly molted 4th and 5th instars and midway through the 5th instar (larvae were starved for 12–18 h to empty gut contents). Male and female pupae, newly emerged adults, and eggs also were prepared for iridoid analyses. The sample size for each stage was N=10 individuals, except in the case of eggs, which were analyzed as 4 samples of 50–100 eggs. In addition to caterpillars, pupae, and eggs, we examined *C. lunula* hemolymph collected from 5th instar larvae (N=4) for the presence of iridoid glycosides. Hemolymph was collected with a 10 µl capillary tube from an incision made on a larval proleg. *Junonia coenia* larvae were obtained from a laboratory culture maintained at the University of Colorado, and were reared mid-August through mid-September 2006 from hatching until they molted to the 5th instar on either field collected *L. dalmatica* or garden collected *Antirrhinum majus* (N=10 individuals per host plant). For *J. coenia*, we analyzed iridoid glycoside concentrations for 5th instars only.

Sample Preparation Plant tissues were separated into leaves, stems, and flowers, oven-dried at 50°C to a constant mass, weighed to the nearest 0.01 g, ground into a fine powder, and then 25–30 mg of each plant sample was prepared for chemical analysis. Sample preparation

methods have been described previously (Gardner and Stermitz 1988; Bowers and Stamp 1993). Briefly, sample preparation involves extracting plant material in methanol, filtering out plant material from the methanol extract, evaporating extracts to dryness, and then partitioning the dried extract between water and ether to remove hydrophobic compounds.

Calophasia lunula and *J. coenia* samples were weighed fresh, killed by freezing at −40°C, ground and extracted fresh in methanol, and then prepared for iridoid analyses by using the same method as plant tissues. For *C. lunula* and *J. coenia* samples, a separate set of individuals at each life stage ($N=5$ per life stage) was weighed fresh, oven dried at 50°C to constant mass, reweighed, and data were used to calculate wet to dry weight conversion factors for the various life stages. *Calophasia lunula* eggs ($N=4$ composite samples) were weighed and extracted fresh (no conversion factors calculated). The 10 *M. janthinus* adults were combined into a single composite sample, weighed, and extracted fresh (no conversion factors calculated). These samples were then prepared for iridoid analysis as described above.

Chemical Analyses In this study, we compared two methods for examining iridoid glycosides: gas chromatography (GC) and high performance liquid chromatography (HPLC). Standards of antirrhinoside and linarioside were provided by Søren Jensen. Methods for analyzing iridoids using GC with phenyl-β-D-gluco-pyranoside (PBG) as an internal standard have been described previously (Gardner and Stermitz 1988; Bowers and Stamp 1993). For GC analysis, iridoid glycosides were derivatized to the corresponding trimethylsilyl derivatives by using Tri-sil Z™ (Pierce Chemical Company). GC analyses were performed on a Hewlett-Packard (HP) 5890A system (Agilent Technologies), and data were processed with HP ChemStation software (version A.03.34).

HPLC analyses were performed on a Hewlett-Packard 1090 system (Agilent Technologies) equipped with a diode array detector (DAD) and Apex (Jones Chromatography, U.K.) ODS 5 μm reverse phase C-18 column (250× 4.6 mm o.d.) protected with a guard column of the same material (7.5×4.6 mm). HPLC data were processed with HP ChemStation software (version A.10.02) that included a DAD spectral evaluation module. Our method for HPLC analysis was modified from a previous method described in Høgedal and Mølgaard (2000). Specifically, we used an isocratic method with a sample injection volume of 20 μl, mobile phase consisting of 3% acetonitrile in water (0.01% phosphoric acid added to bring pH to 4.0), flow rate of 1 ml/min, analysis time of 60 min, and spectrophotometric detection at 205 nm. Calibration curves were made using standard solutions with concentrations of 0.125–3.5 mg/ml. Standards included antirrhinoside, linarioside, and phenyl-β-D-gluco-pyranoside (PBG), which was the internal standard. The HPLC method was validated carefully and system suitability standards (<5% C.V for standard solution injections) were verified for each group of sample runs.

Statistical Analyses Iridoid glycosides were analyzed as proportions of dry weight (concentration). Data were arcsine square root transformed to meet assumptions of normality. Simple linear correlation analyses using Pearson correlation coefficients were performed to examine correspondence between iridoid glycosides measured with GC and HPLC methods and to determine if antirrhinoside and linarioside concentrations measured in plant tissues were correlated.

Because antirrhinoside and linarioside are potentially correlated, we used multivariate analysis of variance (MANOVA) to examine variation in iridoid glycoside concentrations due to (1) site and/or population differences, (2) date of sample collection and/or phenology, and (3) the part of the plant from which tissues were analyzed (flowers, leaves, or stems). We examined the main effects of date and plant part in separate analyses due to the unbalanced nature of our sampling design (i.e., iridoid glycoside concentrations from flowers and stems were measured only on one sampling date). The first MANOVA model, which examined iridoid glycoside concentrations of leaves only, included site, date, and a site by date interaction term. In the second MANOVA model, site, plant part, and a site by plant part interaction term were the main factors. MANOVAs were performed by using the general linear model (GLM) procedure in SYSTAT (version 11). When significant effects were detected by MANOVA, we followed up with univariate repeated-measures ANOVAs for each dependent variable (antirrhinoside and linarioside). Variation in iridoid glycoside concentrations (% dry weight) and total amount of iridoid glycosides (mg) of different life stages of *Calophasia lunula* were examined by ANOVA. For all univariate ANOVAs, Tukey's *post hoc* multiple comparisons tests were used to examine pairwise differences among groups when significant differences were detected. All statistical analyses were performed in SYSTAT (version 11).

Results

Comparison of GC and HPLC Methods Derivatized antirrhinoside and linarioside co-eluted when analyzed by GC, and the mean retention time for both compounds was 7.4 min. Derivatized PBG had a mean retention time of 4.1 min. With HPLC methods, separation of antirrhinoside

and linarioside peaks was achieved. Mean retention times for standard compounds were 20.1 min for antirrhinoside, 37.1 min for PBG, and 42.6 min for linarioside. Calibration curves indicated good linearity with standard solution concentrations between 0.125–3.5 mg/ml. The correlation coefficients for calibration curves were 0.995, 0.976, 0.995 for antirrhinoside, linarioside, and PBG, respectively. There was a highly significant positive relationship between GC and HPLC data (i.e., combined iridoid glycosides) (r=0.978; P<0.001; Fig. 2).

Iridoid Glycoside Variation in Linaria dalmatica Combined iridoid glycoside (antirrhinoside + linarioside) concentrations ranged from as high as 17.4% dry weight to as low as 0.2% dry weight of leaves (mean = 6.28±0.5 SE). We found antirrhinoside concentrations up to 16.5% (mean = 5.02±0.4 SE) dry weight of leaves and linarioside concentrations up to 6.7% (mean = 1.26±0.1 SE). The simple linear correlation analysis revealed a significant positive relationship between concentrations of antirrhinoside and linarioside (r=0.459; P<0.001; Fig. 3). On average, antirrhinoside represented 75.7% of the combined iridoid glycosides measured in leaves.

In our analysis of leaf tissue collected from plants on three sampling dates, we found significant variation in iridoid glycoside concentrations due to both site (*Wilks' λ*= 0.566, $F_{4,160}$=13.19, P<0.001) and date (*Wilks' λ*=0.378, $F_{4,160}$=25.07, P<0.001). There was no site by date interaction effect (*Wilks' λ*=0.958, $F_{8,160}$=0.43, P=0.900). Iridoid glycoside concentrations varied significantly both within and among populations (Fig. 4). Univariate ANOVAs revealed that antirrhinoside and linarioside showed similar patterns of variation among populations (site effect) and over the course of the growing season (date effect) (Table 1). Of the three populations, plants collected from Rabbit Mountain had the highest iridoid glycoside concentrations (Tukey's *post-hoc* pairwise comparisons: P<0.05 in both cases). In this one population, combined iridoid glycoside concentrations of leaf tissues ranged from 17.4 to 9.5% (mean = 12.97±0.7 SE) in May and from 14.2 to 0.5% (mean = 5.50±1.6 SE) in September, showing an average decline of 40% in the concentrations of these defense compounds over the course of the peak growing season. Across all field sites, iridoid glycoside concentrations were highest early in the growing season and declined over time (Fig. 4).

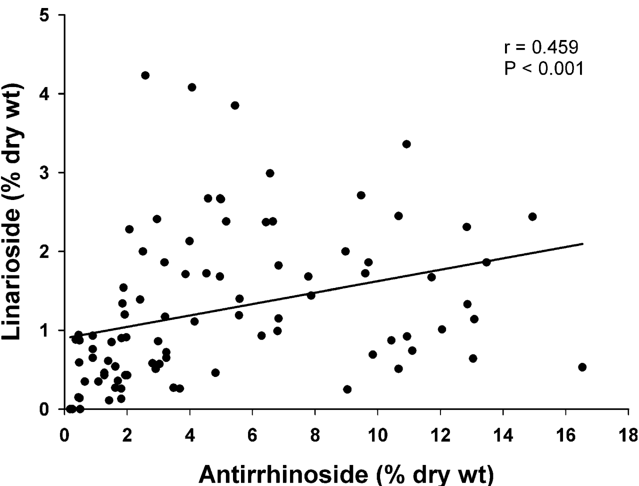

Fig. 3 Relationship between antirrhinoside and linarioside concentrations (% dry weight) measured in *Linaria dalmatica* leaves

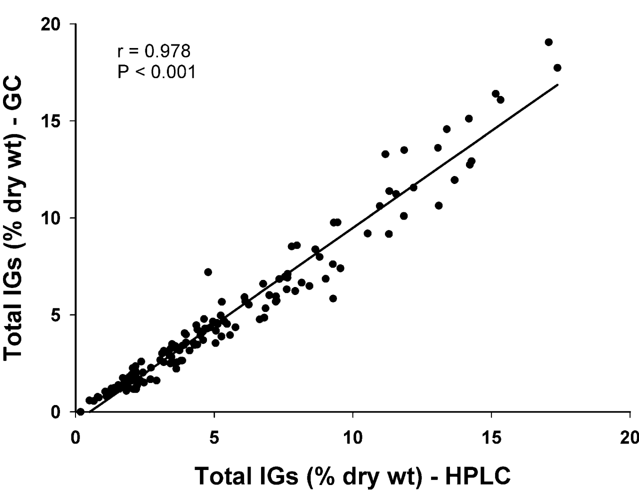

Fig. 2 Comparison of combined iridoid glycosides (antirrhinoside + linarioside) measured in *Linaria dalmatica* using GC and HPLC methods. Data are reported as % dry weight of leaf tissues. Antirrhinoside and linarioside co-eluted when analyzed by GC. Separation of compounds was acheived by HPLC

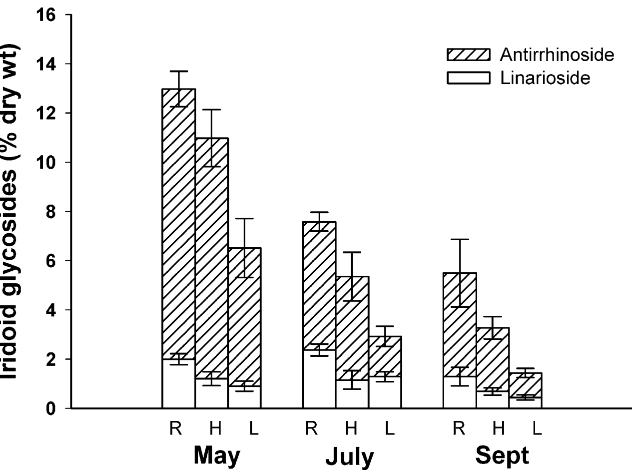

Fig. 4 Pattern of variation in iridoid glycoside concentrations of *Linaria dalmatica* leaves. Plant samples were collected in late-May, mid-July, and mid-September from three populations located in Boulder County, Colorado (USA): Rabbit Mountain (R), Hall Ranch (H), and Lefthand Canyon (L). Data reported are mean % dry weight ± SE (N=10 per site per date)

[a] Field sites (Rabbit Mountain, Hall Ranch, Lefthand Canyon) were located in Boulder County, Colorado (USA)

[b] Tissues from leaves, flowers, and stems were analyzed for samples collected in July of 2006 (N=10 per site)

Results of the second MANOVA, which examined iridoid glycoside concentrations of flowers, leaves, and stems, indicated effects of site (*Wilks'* λ=0.506; $F_{4,160}$=16.25; P<0.001) and plant part (*Wilks'* λ=0.358; $F_{4,160}$=26.90; P<0.001) as well as a site by plant part interaction effect (*Wilks'* λ=0.673; $F_{8,160}$=4.38; P<0.001; Fig. 5). Again, univariate ANOVAs revealed that antirrhinoside and linarioside demonstrated similar response patterns, this time in response to the effects of site, plant part, and the interaction of these two factors (Table 2). Across field sites, combined iridoid glycoside concentrations of flowers (mean = 5.20±0.3 SE) and leaves (mean = 5.29±0.5 SE) were more than double the concentrations found in stems (mean = 2.07±0.2). At Hall Ranch and Lefthand Canyon, flowers had similar iridoid glycoside concentrations compared to leaves (Tukey's *post-hoc* pairwise comparisons: P>0.05 in all cases); however, at Rabbit Mountain, flower tissues contained slightly higher concentrations of iridoid glycosides compared to leaves (P<0.05). Site-specific differences in iridoid glycoside concentrations of flowers compared to leaves resulted in the observed plant part site by interaction effect (Table 2).

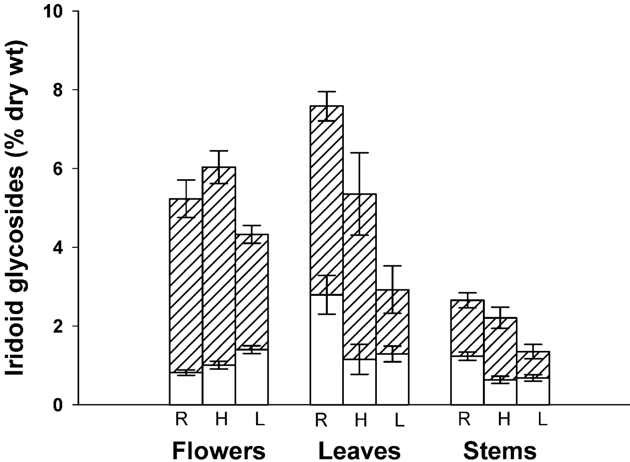

Fig. 5 Iridoid glycoside concentrations of flowers, leaves, and stems of *Linaria dalmatica*. Plant samples were collected in July 2006 from three populations located in Boulder County, Colorado (USA): Rabbit Mountain (R), Hall Ranch (H), and Lefthand Canyon (L). Data reported are mean % dry weight ± SE (N=10 per site)

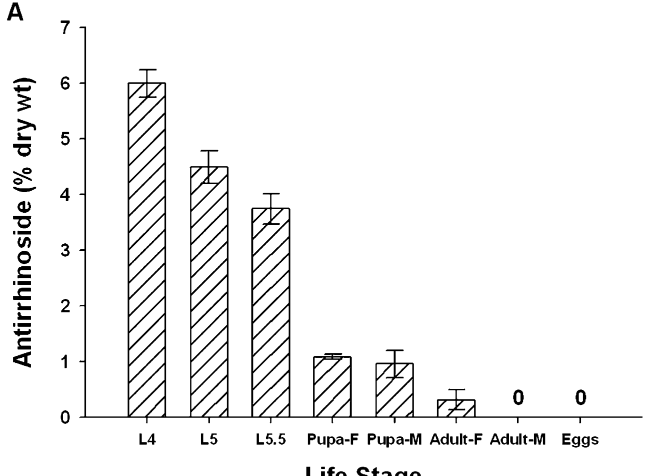
Iridoid Glycoside Sequestration by Herbivores We found no evidence of iridoid sequestration by *M. janthinus*. However, results indicated that both *C. lunula* and *J. coenia* sequestered antirrhinoside from *L. dalmatica*. Antirrhinoside was found in larvae, pupae, and adult females of *C. lunula*, but was not found in eggs or adult males. In adult females, only three of the 10 samples contained antirrhinoside. Both the concentrations (% dry weight) and total amounts (mg) of antirrhinoside varied significantly among different life stages (P<0.001 in both cases; Fig. 6). The highest levels of antirrhinoside were found in larvae, with concentrations ranging from 2.7 to 7.5% dry weight (mean = 4.8±0.3 SE), and total amounts equal to 0.64± 0.07 mg (mean ± SE) in the three larval stages analyzed. Antirrinoside amounts in hemolymph ranged from 1.5 to 5.5 µg/µl, indicating that hemolymph is one important site of iridoid storage in *C. lunula* larvae. *Junonia coenia* also sequestered antirrhinoside. For 5th instars reared on *L. dalmatica*, we found antirrhinoside concentrations as high as 15.7% dry weight (mean = 12.1±0.5 SE), and total antirrhinoside amounts were 2.72±0.17 mg (mean ± SE). For 5th instar larvae reared on *A. majus*, antirrhinoside represented 9.6% (±0.5 SE) of the larval dry weight, and total amounts were 2.06±0.15 mg (mean ± SE). We found no evidence for sequestration of linarioside by either *C. lunula* or *J. coenia*, despite the presence of this iridoid glycoside in *L. dalmatica* host plants.



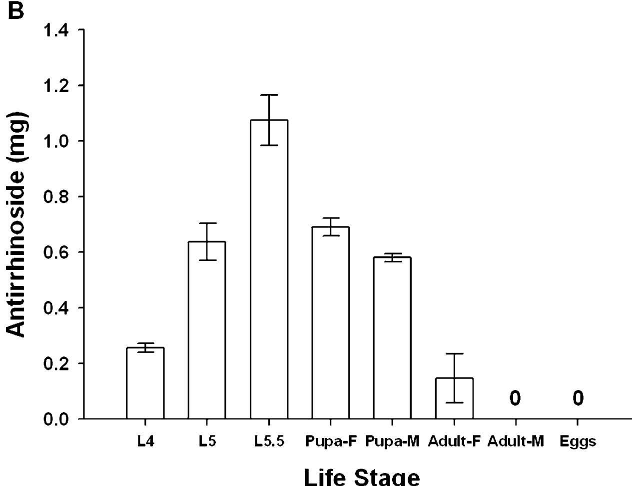


Fig. 6 Sequestration of antirrhinoside by *Calophasia lunula* (Noctuidae) at various life stages (**a**) concentration (% dry weight) (**b**) total amount (mg). N=10 individuals for each larval (L) stage, pupae, and adults. For eggs, N=4 samples each with 50–100 eggs

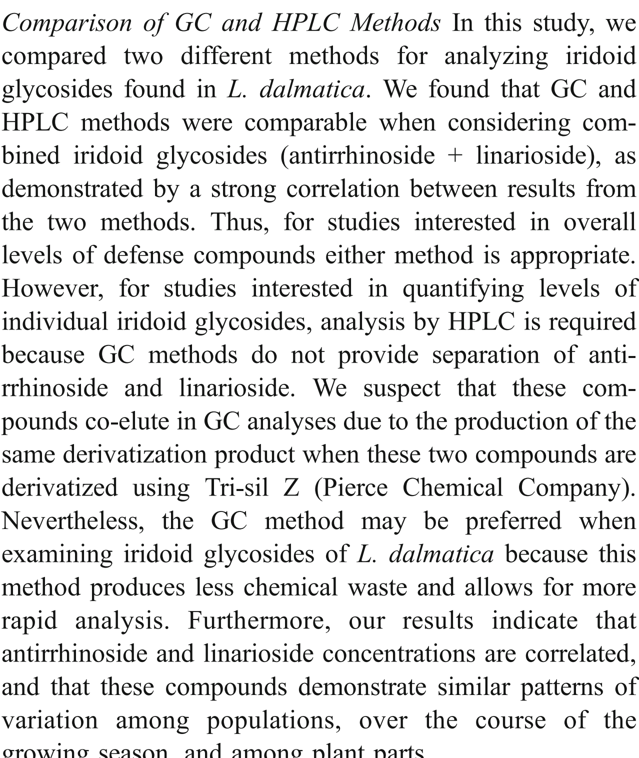
Discussion

Of the many plants introduced into novel habitats, few become established, and even fewer become invasive (Williamson and Fitter 1996). The novel chemistry and novel weapons hypotheses propose that some introduced plant species are successful invaders because natural enemies in the introduced range are not adapted to their unique chemical profiles (Callaway and Ridenour 2004; Cappuccino and Arnason 2006). Although many invasive plant species are thought to be phytochemically unique in their introduced range (Cappuccino and Arnason 2006), often little is known about the quantitative variation of defense compounds and the chemical ecology of plant-herbivore interactions for these species. Our research provides the first investigation of quantitative variation in the chemical defenses of the invasive plant *Linaria dalmatica.*



Comparison of GC and HPLC Methods In this study, we compared two different methods for analyzing iridoid glycosides found in *L. dalmatica*. We found that GC and HPLC methods were comparable when considering combined iridoid glycosides (antirrhinoside + linarioside), as demonstrated by a strong correlation between results from the two methods. Thus, for studies interested in overall levels of defense compounds either method is appropriate. However, for studies interested in quantifying levels of individual iridoid glycosides, analysis by HPLC is required because GC methods do not provide separation of antirrhinoside and linarioside. We suspect that these compounds co-elute in GC analyses due to the production of the same derivatization product when these two compounds are derivatized using Tri-sil Z (Pierce Chemical Company). Nevertheless, the GC method may be preferred when examining iridoid glycosides of *L. dalmatica* because this method produces less chemical waste and allows for more rapid analysis. Furthermore, our results indicate that antirrhinoside and linarioside concentrations are correlated, and that these compounds demonstrate similar patterns of variation among populations, over the course of the growing season, and among plant parts.

Iridoid Glycoside Variation in Linaria dalmatica We found that *L. dalmatica* contains high levels of iridoid glycosides, up to 17% dry weight with a mean of 6%. These results suggest that the species is well defended against generalist natural enemies, in particular naïve species. However, different generalist species can demonstrate varying responses to iridoid glycosides. For example, Beninger et al. (2008) found that gypsy moth larvae (*Lymantria dispar*: Lymantriidae) avoided leaves of cultivated snapdragon, *Antirrhinum majus* (Plantaginaceae), which contain antirrhinoside, and larval growth was reduced when fed a diet with 3.3% antirrhinoside concentrations. By contrast, cabbage looper (*Trichoplusia ni*: Noctuidae) larvae readily fed on *A. majus,* and larval growth actually increased on diets with antirrhinoside. The overall defensive nature of *L. dalmatica* iridoid glycosides against generalist herbivores requires further investigation.

Our study indicates that *L. dalmatica* plants are both spatially and temporally variable in levels of iridoid glycosides and that plant parts have varying concentrations of iridoid glycosides. Similar patterns of variation in iridoid glycoside concentrations have been documented for other plant species containing iridoid glycosides (e.g., Darrow and Bowers 1997). Although in contrast to *L. dalmatica*, Darrow and Bowers (1997) found that iridoid glycoside concentrations of *Plantago lanceolata* (Plantaginaceae) increased over the course of the growing season. Also, iridoid glycoside concentrations found in *P. lanceolata* were lower in general than those observed in *L. dalmatica*.

The results of our study suggest that there may be opportunities for generalist herbivores to avoid the deterrent or toxic properties of these compounds. For example, generalist herbivores, including both insects and grazing animals, may be able to utilize *L. dalmatica* as a resource in certain populations where plants produce lower levels of iridoid glycosides and at certain times of the year such as the later part of the growing season when levels are low. Also, stems are not well defended compared to leaves and flowers. Consequently, *L. dalmatica* may be especially susceptible to stem-mining or boring insects in the introduced range. It should be noted, however, that it is unknown whether iridoid glycosides found in *L. dalmatica* are inducible, as demonstrated in other plants that contain iridoids (e.g., Darrow and Bowers 1999; Fuchs and Bowers 2004).

Our research indicates that a number of factors, including genotype, ontogeny, phenology, and site differences may influence iridoid glycosides concentrations found in *L. dalmatica*. Genetic, ontogenetic, biotic, and abiotic environmental factors have all been shown to contribute to quantitative variation in iridoid glycosides in *Plantago* spp. (Bowers et al. 1992; Bowers and Stamp 1993; Adler et al. 1995; Darrow and Bowers 1999; Marak et al. 2002; Fuchs and Bowers 2004; Barton and Bowers 2006; Barton 2007; Wurst et al. 2008). Furthermore, such quantitative variation in these compounds has been shown to influence the degree to which individual plants are defended against generalist natural enemies, including pathogens and herbivores (e.g., Biere et al. 2004; Harvey et al. 2005).

In addition to influencing generalists, quantitative variation in iridoid glycosides of *L. dalmatica* also may affect specialists, including biological control agents used to manage *L. dalmatica* populations. Iridoid glycosides have been shown to act as feeding stimulants and oviposition cues, as well as to affect the performance of specialist insect herbivores (reviewed in Bowers 1991). In general, iridoid glycosides have been positively associated with both oviposition preference and performance of specialist insect herbivores (Bowers 1984; Pereyra and Bowers 1988; Bowers and Puttick 1989; Klockars et al. 1993; Nieminen et al. 2003; Harvey et al. 2005; Prudic et al. 2005; Saastamoinen et al. 2007; Reudler Talsma et al. 2008). Thus, iridoid glycosides may influence interactions between *L. dalmatica* and its biological control agents, potentially affecting host plant choice of ovipositing females as well as performance of offspring. Interestingly, we found that stems contain much lower levels of iridoid glycosides than flowers and leaves, which may have implications for biological control efforts, in particular for the use of *Mecinus janthinus*, which is a stem-miner. Gaining an understanding of the factors that contribute to variation in iridoid glycoside content of *L. dalmatica* may contribute to improving the management of this species.

Iridoid Glycoside Sequestration by Herbivores This study is the first to document sequestration of iridoid glycosides by *Calophasia lunula*. We found that *C. lunula* sequesters intermediate levels of antirrhinoside, on average about 5% of the caterpillar dry weight. At these concentrations, sequestered iridoid glycosides have been shown to be deterrent or toxic to a wide variety of predators, including birds, spiders, stink bugs, wasps, and ants (Bowers 1980; De la Fuente et al. 1994; Dyer and Bowers 1996; Strohmeyer et al. 1998; Theodoratus and Bowers 1999; Stamp 2001; Rayor and Munson 2002). We were surprised to find low levels of antirrhinoside in a few female adult moths; however, moths were frozen soon after emergence and may have retained some meconium, which can contain iridoid glycosides (Bowers and Puttick 1986; Bowers unpublished data). Variation in iridoid glycoside content of host plants has been shown to influence levels of iridoids found in sequestering species (e.g., Theodoratus and Bowers 1999; Prudic et al. 2005). Thus, factors that influence iridoid glycoside concentrations of *L. dalmatica* may also affect the degree to which *C. lunula* is defended against its natural enemies.

Compared to *Junonia coenia*, *C. lunula* is less efficient at sequestering antirrhinoside, as *J. coenia* larvae sequestered approximately twice as much antirrhinoside as *C. lunula* larvae. In general, *J. coenia* sequesters iridoid glycosides at high levels, with observed amounts up to 25% dry weight (Theodoratus and Bowers 1999). Larvae of three other lepidopteran species (*Meris paradoxa* Rindge (Geometridae), *Lepipolys perscripta* Gn (Noctuidae), and an undescribed species of *Lepipolys*) have been shown to sequester antirrhinoside at levels as high as 9.6 mg or 11.2% dry weight (Boros et al. 1991). Larvae of all three species feed on *Maurandya antirrhiniflora* (Plantaginaceae), which contains antirrhinoside in very high concentrations, up to 36% dry weight (Boros et al. 1991). Like *C. lunula*, these larvae are warningly colored; *M. paradoxa* is black, white, and yellow and the two *Lepipolys* species are gray with yellow, black, and white markings.

Plant defensive chemistry has been linked to the invasion success of numerous introduced species (Callaway and Aschehoug 2000; Callaway and Ridenour 2004; Cappuccino and Arnason 2006). Defense compounds are known to be of key importance in protecting plants from attack by generalist enemies and in host-plant selection by specialist enemies. However, as found in our study, plant defense compounds can demonstrate significant variation at multiple levels, including at the individual plant and population levels as well as over time. Such variation will ultimately influence the degree to which plants are

defended against generalist herbivores. Moreover, the influence of variation in plant chemical defenses on insect host plant selection and performance may contribute to variable success in biological control efforts. Thus, future studies that examine variation in the chemical defenses and chemical ecology of *L. dalmatica* may prove useful for understanding factors that influence the invasion success, impacts, and management of this species.

Acknowledgments We thank Timothy Seastedt for support with this research; Eowyn Burke, Kelly Sensequa, and Patrick Travers for field and laboratory assistance; Ken Keefover-Ring and Courtney Meier for help with HPLC method development; Boulder County Open Space and Parks for permission to use study sites; the Colorado Department of Agriculture Insectary for supplying study organisms. We also thank two anonymous reviewers and the Bowers lab group, in particular Evan Lampert, for suggestions and comments on this manuscript. We are especially grateful to Søren Jensen (Organic Chemistry, Lyngby, Denmark) for providing standards of antirrhinoside and linarioside. Funding for this project was provided by Boulder County Open Space and Parks, the Department of Ecology and Evolutionary Biology at the University of Colorado, the Hazel Schmoll Research Fellowship in Colorado Botany, and NSF grants DEB 0614883 and 0808473.

Sex Pheromones and Their Impact on Pest Management

Peter Witzgall · Philipp Kirsch · Alan Cork

Abstract The idea of using species-specific behavior-modifying chemicals for the management of noxious insects in agriculture, horticulture, forestry, stored products, and for insect vectors of diseases has been a driving ambition through five decades of pheromone research. Hundreds of pheromones and other semiochemicals have been discovered that are used to monitor the presence and abundance of insects and to protect plants and animals against insects. The estimated annual production of lures for monitoring and mass trapping is on the order of tens of millions, covering at least 10 million hectares. Insect populations are controlled by air permeation and attract-and-kill techniques on at least 1 million hectares. Here, we review the most important and widespread practical applications. Pheromones are increasingly efficient at low population densities, they do not adversely affect natural enemies, and they can, therefore, bring about a long-term reduction in insect populations that cannot be accomplished with conventional insecticides. A changing climate with higher growing season temperatures and altered rainfall patterns makes control of native and invasive insects an increasingly urgent challenge. Intensified insecticide use will not provide a solution, but pheromones and other semiochemicals instead can be implemented for sustainable area-wide management and will thus improve food security for a growing population. Given the scale of the challenges we face to mitigate the impacts of climate change, the time is right to intensify goal-oriented interdisciplinary research on semiochemicals, involving chemists, entomologists, and plant protection experts, in order to provide the urgently needed, and cost-effective technical solutions for sustainable insect management worldwide.

50 Years of Pheromone Research

Fifty years of curiosity driven pheromone research have yielded a profound understanding of sexual communication in insects. The discovery that minute amounts of species-specific chemical signals, encoded by discrete receptors on the antenna, instantaneously elicit a conspicuous upwind flight orientation behavior has been a source of inspiration for fundamental research on the insect olfactory system; research ranges from biosynthetic production of sex pheromones to peripheral perception by odorant receptor neurons, central processing of the olfactory input, and the resulting behavior (Jacquin-Joly and Merlin 2004; Jefferis et al. 2007; Xue et al. 2007; Cardé and Willis 2008; De Bruyne and Baker 2008).

The progress that has been made from the identification of the first sex pheromone in the silk moth by Butenandt and coworkers in 1959 to the identification of olfactory receptors in *Drosophila* (Clyne et al. 1999; Vosshall et al. 1999) and in the silk moth (Krieger et al. 2005) is spectacular. Pheromone communication, including the

generation of behavioral responses, is now being dissected at a molecular level (Benton et al. 2007; Dickson 2008). Our imagination is not sufficient to envision knowledge in insect olfaction and chemical ecology another 50 years from now, provided that researchers have the mandate and the resources to carry on this work.

Fundamental research derives, in part, its motivation and justification from the prospect of applying the acquired knowledge. A characteristic of insect chemical ecology is that the know-how can be transferred and used for the control of insects that are noxious to plants or animals. The interconnection between fundamental and applied research, the academic sector, chemical industries, agriculture, horticulture, and forestry, has been a driving force in fundamental and applied pheromone research. Many who began pheromone research in the sixties were influenced by the concept of integrated pest management (Stern et al. 1959) and Rachel Carson's (1962) plea for biorational pesticides. The use of synthetic pheromones for environmentally safe insect control was postulated soon after the discovery of silk moth pheromone (Butenandt et al. 1959; Wright 1964), well before pheromones of economically important insect pests were known.

Fifty years after bombykol, the database of insect pheromones and related attractants contains hundreds of chemicals (Arn et al. 1992; El-Sayed 2008). Pheromones are used as monitoring tools worldwide, and pheromone-based control applications cover large areas (Ridgway et al. 1990b; Howse et al. 1998; Baker and Heath 2004). Behavior-modifying chemicals are elegant tools for insect control, and the prospect of a wide range of future applications in agricultural and medical entomology continues to fuel research in insect olfactory physiology and chemical ecology (Van der Goes van Naters and Carlson 2006). The idea of replacing hazardous insecticides with environmentally benign and species-specific odorants is still a current research challenge, but the emphasis is shifting. The motivating force for green, sustainable insect control is no longer merely the health of the rural work force, the safety of agriculture and horticultural products, nor even the attempt to promote organic farming. The matter is more urgent than it was 50 years ago, and our concerns are the necessity of establishing sustainable insect control methods in times of increasing food insecurity.

Sustainable Insect Control and Food Security

Population growth, creating an increased demand for food, intensifies the pressure on our natural resources, and the adverse effects of climate change on agroecosystems further accentuates the magnitude of this challenge (Ehrlich et al. 1993). Foremost among the Millennium Development Goals endorsed by the United Nations is to eradicate extreme hunger and poverty and, more precisely, to halve between 1990 and 2015 the proportion of people who suffer from hunger. (www.un.org/millenniumgoals). Obviously, our endeavor to secure food for a growing population is closely related to another millennium goal, i.e., to reduce the loss of environmental resources and biodiversity. As we approach the deadline for the fulfillment of these goals, advances have begun to slow or even to reverse.

Environmental security and food security are closely interrelated and mutually dependent. Intensified pressure on ecosystems leads to depletion of resources that are vital for agriculture, including natural enemies of insect pests, pollinators, and carbon sequestration (Ehrlich et al. 1993; Thrupp 2000; van Mantgem et al. 2009). Moreover, future crops will grow under a different climate. The predicted associated effects of higher growing season temperatures and altered patterns of precipitation will have substantial impact on all forms of land use, from agriculture land and forests to aquatic environments. (Battisti and Naylor 2009; Schlenker and Roberts 2009).

Climate changes also will influence plant health and vigor, directly and indirectly through a modified reproductive performance of their associated herbivores. Climatic change will alter outbreak patterns and geographical ranges of insects, including those that vector diseases. The consequences are difficult to predict, especially in view of the complex interactions between crops, herbivores, and pathogens, but climate-related changes most likely will combine to reduce yields (Hunter 2001; Gregory et al. 2009). Forest insects have provided the first conspicuous examples of how insect outbreaks are intensified by global warming. Higher temperatures and drought are blamed for violent bark beetle attacks across Northern America that impact forest structure and in consequence carbon sequestration (Kurz et al. 2008; Van Mantgem et al. 2009).

Up to one third of worldwide food production is destroyed by insects, not including the damage done in storage. During decades of insecticide use, a permanent decrease in the abundance of targeted insect populations never has been achieved. Many of our top agricultural pests instead have been created by the use of pesticides that often have a stronger effect on natural antagonists than on the target species, and also because of widespread insecticide resistance (Pimentel et al. 1992; Elzen and Hardee 2003; Oerke 2006). This is particularly relevant in developing countries, where agricultural production must be increased to feed the population (Thrupp 2000; Pretty et al. 2003; Nwilene et al. 2008).

While crop protection against insects has long relied on insecticides, it is clear that they alone cannot provide a solution, not even by further intensification of their application. Shortcomings are particularly obvious in

regions with warm climates and long growing seasons. Recognition of pesticide limitations has, for example, led to the development of pheromone-based methods for control of the rice stem borer *Scirpophaga incertulas* in Bangladesh. Rice covers 70% of the land available for agriculture. Yield has increased by over 40% from 1996 to 2001, yet it does not match consumption. The annual insecticide application has increased from 7,000 t in 1997 to more than 16,000 t in the year 2000, some 90% of which is used in rice production. Even some agrochemical industries now have reached the view that a further increase is not feasible, and thus they support the development of mating disruption and mass trapping of rice stem borer in order to maintain a sustainable level of pesticide use (Cork et al. 2005b).

Chemical ecology produces the knowledge of non-toxic and species-specific pheromones and other semiochemicals that do not harm beneficial species and thus, the basis for efficient and sustainable insect management strategies. The paradox is that currently available know-how is not sufficiently exploited, and we may not be investing enough in research and development to provide breakthroughs quickly enough, especially in food-deficient countries in the developing world. Development aid to agriculture declined by almost 60% between 1980 and 2005, even though the total development aid bill increased over the same period (Fig. 1). In this review, one of our goals was to demonstrate that it is timely and meaningful to invest further in research on behavior-modifying chemicals for sustainable insect management.

Successes and Constraints of Pheromone-Based Methods

"There are many other reasons for using pheromones; one is that they are elegant" (Arn 1990). Three main elements account for the fascination of insect sex pheromones and their feasibility for insect management: 1) they are species-specific, 2) they are active in very small amounts, and 3) the vast majority are not known to be toxic to animals.

Pheromones are by definition species-specific, since the discrimination of conspecific and heterospecific pheromone signals is a key element in the evolution of specific mate recognition systems in many insects. Even synthetic, incomplete pheromone blends usually affect only the target, with the possible exception of taxonomically closely related species (Cardé and Haynes 2004).

Insects use extremely small amounts of pheromone for communication. For example, calling females of codling moth *Cydia pomonella* release pheromone at a rate of several ng/h. [In comparison, apple trees in orchards release one main volatile compound, (*E*,*E*)-α-farnesene, at an estimated rate of several g/ha/h (Witzgall et al. 2008)]. Pheromone trap lures used for detection and monitoring release typically ten to 100 times more than a calling female, and mating disruption dispensers used in orchards release up to 10,000 times more codlemone, which amounts to release rates of 10–100 mg/ha/h. The seasonal application rate of codlemone for mating disruption of codling moth in orchards is up to 100 g/ha. Worldwide annual production of codlemone is ca. 25.000 kg (Fig. 2), for codling moth control on ca. 210.00 ha.

Regulatory agencies in several countries consider it safe to use lepidopteran pheromones. This was corroborated by a recent evaluation by the California Environmental Protection Agency on the occasion of an area-wide eradication campaign against light brown apple moth (Ting 2009). Many pheromones have been registered for pest control, and there is no evidence of adverse effects on public health, non-target organisms, or the environment. Pheromones are applied in slow release formulations, thus resulting in low exposure; residues of lepidopteran pheromones in pheromone-treated food crops have not been detected (Tinsworth 1990).

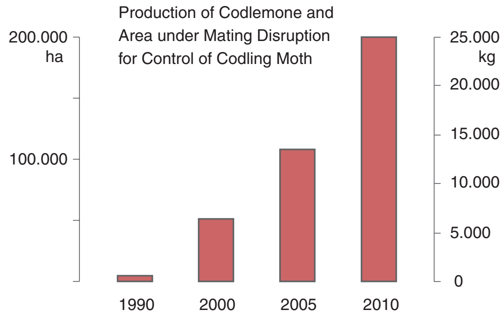

Fig. 2 Production of codling moth *Cydia pomonella* pheromone and area under mating disruption against codling moth worldwide (above; data courtesy of Shin-Etsu Chemical Co., Tokyo)

Insecticides vs. Pheromones

Insecticides do not achieve a long-term pest population decrease. In contrast, an observation shared by many working with pheromone-based control is that continuous long-term use *does* decrease population levels of target species (Fig. 3; Witzgall et al. 1999; Varner et al. 2001; Ioriatti et al. 2008; Weddle et al. 2009). This is attributable to a recovering fauna of beneficials, and to an increasing efficacy of pheromones at low population densities, when communication distance between sexes is increasing.

Insecticide overuse also induces outbreaks of secondary pests. Predatory and phytophagous mites provide the classic example of how the natural regulation of herbivores by their antagonists is disturbed by broad-spectrum pesticides (Agnello et al. 2003). Replacing insecticide with pheromone treatments in vineyards and orchards has rendered treatments against phytophagous mites superfluous, which compensates for the cost of the pheromone treatment (Louis et al. 1997; Waldner 1997; Jones et al. 2009). This emphasizes the contributing vital role of natural enemies for population control, and it corroborates that pheromone-based methods produce better results in the long run, due to recovery of the beneficial fauna.

Insects with hidden, protected lifestyles, including those with underground or woodboring larval habits, cannot easily be controlled with cover sprays of insecticides. Here, control with pheromones is advantageous, since it aims at the mobile adult life stage, and functions to prevent oviposition altogether. Examples of successful pheromone applications are provided in the sections below, and many of these concern insects that inflict severe damage and that are difficult or expensive to control with insecticides.

Slow Development of Pheromone-Based Pest Management

Despite their advantages, progress with practical implementation and commercial exploitation of pheromones has been slow. In Europe, pheromones have been used widely for almost two decades; against the grapevine moths *Lobesia botrana* and *Eupoecilia ambiguella* in Germany, Switzerland, and Northern Italy (Fig. 3; Arn and Louis 1996; Varner et al. 2001; Ioriatti et al. 2008) and against codling moth *Cydia pomonella* in Switzerland and Northern Italy (Mani et al. 1996; Waldner 1997). Although similar climatic, faunistic, and economic conditions exist in other

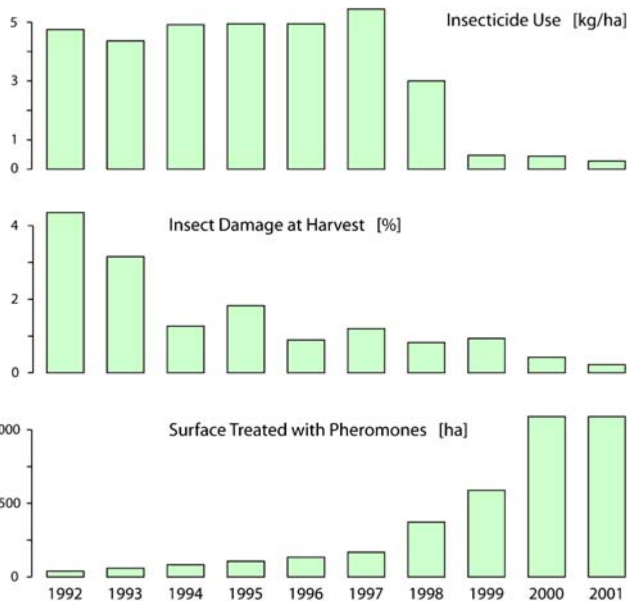

Fig. 3 Mating disruption in the Mezzocorona vineyards in Trento, Italy (Mauro Varner and Claudio Ioriatti, pers. comm.; photo by Mauro Varner)

European wine- and fruit-growing areas, pheromones have not been used much until very recently.

This suggests that motivation and determination among those involved in development and operation of pheromonal pest control methods is a key factor. A certain inertia in the pest control sector to adopt new technologies may be sustained by the lack of interest among research scientists in promoting and transferring existing knowledge. Ehrlich et al. (1993) convincingly argued that the historical separation of agriculture and pure biology at most universities has prevented the implementation of ecological principles in agriculture. To some extent, this may still be true today.

Another key to a more widespread use of pheromones is that the technologies currently in use must become more reliable. Continued goal-oriented research will lead to both more reliable and hence more widespread applications, but funding for applied research at academic institutions and extension services is being cut in many countries (Jones et al. 2009). Field implementation should become a focus of future pheromone research.

Few conventional chemical industries have invested in pheromones, and this lack of engagement has led to the belief that pheromone technology is not viable economically. More smaller companies that specialize in a particular product type, and have the flexibility and low overheads to make their investments in semiochemical products financially viable, are needed.

Practical pheromone applications depend on availability of efficient dispenser materials and on the economic synthesis of pheromone chemicals. The price of synthetic codlemone in the beginning of the nineties, for example, was far too elevated for commercial area-wide applications, but development of large-scale synthesis (Yamamoto and Ogawa 1989) made it possible to exploit it commercially. The annual production of codlemone, the main pheromone compound of codling moth, is on the order of 25 t (Fig. 2), and the price of codlemone is now well below 1,000 US$/kg.

Motives for Area-Wide Pheromone Use

The pheromone application concept goes beyond the conventional control paradigm of protecting plants against larval infestation with sprays of toxic compounds. Conditions for pheromone use are more favorable in area-wide programs, where the effect of immigrating, mated insect females becomes negligible. Successful use is frequently based on a joint effort that involves research scientists, extension entomologists, growers' associations, and also pheromone industries. Area-wide projects facilitate and provide support for this organizational effort (Ioriatti et al. 2008; Jones et al. 2009; Weddle et al. 2009).

The economic benefits of implementing sustainable techniques become evident at the landscape level. A close inspection of pheromone technologies that have been in place over several years shows that the price of pheromones vs. insecticides should not be confounded with economy of use. Farmers' efforts and successes in establishing sustainable production methods contribute to rural development (Ioriatti et al. 2008).

Safe insect control techniques not only improve product quality, but also contribute to the image of a region. Insecticide drift and run-off pollutes air and groundwater, and reduction of insecticide sprays alleviates growing conflicts between rural and urban areas. Orchards and vineyards, where pheromone-mediated mating disruption is widely used, are a part of cultural landscapes that produces, in addition to horticultural products, revenues by attracting tourists, enterprises, investors, and people who wish to inhabit this land.

Detection and Monitoring

The most widespread and successful applications of sex pheromones concern their use in detection and population monitoring. Captures in traps baited with synthetic pheromone lures accurately show whether a specific insect is present, and when its seasonal flight period starts. A simple and widespread strategy is to time insecticide sprays accordingly.

Population monitoring relates trap captures to the abundance of, or to the damage caused by an insect species. The magnitude of trap captures is used to determine thresholds, either for the timing of control procedures, or for making the decision whether or not remedial action is to be taken. One of the first widely used monitoring systems that include an action threshold based on trap captures was established for pea moth *Cydia nigricana* (Wall et al. 1987). Pheromone traps are sensitive enough to detect low-density populations, and are, therefore, effective for tracking invasive species in the establishment phase (El-Sayed et al. 2006; Liebhold and Tobin 2008).

Since pheromones lures are inexpensive and usually reliable, they facilitate the Integrated Pest Management (IPM) concept, which relies on frequent scouting of target species for planning of control measures and evaluating their efficacy. This is particularly so when more specific tools such as semiochemicals, microbials, or beneficials are used, rather than broad-spectrum insecticides.

Invariably, pheromone traps capture adults, and often only males, as is the case with lepidopteran pheromones. When trapping information is to be used in a predictive manner, such as in the damage done by the next generation of larvae, a good understanding of the biology of the pest and the effect of weather and crop stage on development is

needed. For pheromone-based monitoring it is further essential that a number of parameters, including the attractant, dispenser, trap design, and trap location are standardized and kept constant. The attractant and dispenser material must be under strict quality control, since release rates and chemical impurities, even in trace amounts, will strongly affect the attractiveness of a lure (Arn et al. 1997). Lure constancy, not overall attractiveness, is decisive.

One future goal is data capture. Insect monitoring can be facilitated by supplying farmers with additional information that includes current and historical seasonal records of trap catch, infestation rates, climate data, and possibly even the geographical distribution of the crop and target insect. This can be aided by the use of geographical information systems (GIS), for example, in area-wide control programs in forests (see below; Tobin et al. 2004, 2007).

Practical Use of Pheromone-Baited Traps

Hundreds of pheromone compounds have been identified, most of them in Lepidoptera, but also in other insect orders, particularly beetles and flies (Arn et al. 1992; El-Sayed 2008). Table 1 shows widely used pheromone lures. In several species, such as the tomato leafminer *Tuta absoluta* and in stored product insects, lures are used for both monitoring and mass trapping (see below). Lures are distributed by many companies worldwide, and there are no reliable data on the total number used, especially in emerging markets in Asia and South America. We estimate that at least 20 million pheromone lures are produced for monitoring or mass trapping every year. This includes all pest control sectors, horticulture, agriculture, stored products, forests, and also private use in households and gardens.

Gall midges (Diptera: Cecidomyiidae) are, because of their small size, difficult to see, and pheromones are cost-effective tools for tracking these tiny flies. Gall midge pheromone identifications require state-of-the-art analytical techniques, since they are produced in pico- to femtogram amounts. The chemical structures are carbon chains with one or two ester functionalities, and have been identified from several species including Hessian fly *Mayetolia destructor* (Andersson et al. 2009), swede midge *Contarinia nasturtii* (Hillbur et al. 2005), and raspberry cane midge *Resseliella theobaldi* (Hall et al. 2009). Swede midge traps have been deployed along the US-Canadian border to determine the geographical range of this invasive insect. A combination of a predictive model with pheromone traps accurately assesses and times control strategies (Hallett et al. 2009).

The tomato leafminer, *Tuta absoluta*, is an example of how the absence of an efficient conventional chemical control or other biological method encourages the use of an immature pheromone technology for insect control, merely because other methods are not available. *T. absoluta* is a multivoltine species that mines leaves and fruits of solanaceous plants. Effective chemical control is difficult to achieve (Pereyra and Sanchez 2006). Originally of neotropical distribution, *T. absoluta* recently has been introduced to Southern Europe and Northern Africa. This has fuelled the demand for monitoring lures, which are now employed in mass trapping campaigns in greenhouses. The main sex pheromone component is a triene, (E,Z,Z)-3,8,11-tetradecatrien-1-yl acetate (Svatos et al. 1996), but the lack of an economic synthesis currently precludes mating disruption tests.

Pheromone identifications in beetles are less advanced than in moths. Aggregation pheromones currently are used for mass trapping of weevils and scarabs (see below), and sex pheromones of several other families are under investigation. Larvae of click beetles are hard to control with pesticides due to their underground life habit. One main compound of click beetle pheromones is geranyl octanoate, and specific blends have been identified in several species. Pheromones have been used to survey species distributions and to monitor in the field, for example, *Agriotes* sp. in Europe and North America (Vernon and Toth 2007; Toth et al. 2008).

A number of pheromones have been elucidated in cerambycid beetles over the past decade. Even weak attraction to generic blends may be sufficient for monitoring distribution and phenology. However, some pheromones even attract females, and many of these species have long life cycles with short adult stages, which should favor the use of pheromones for control (Maier 2008; Ray et al. 2009; Rodstein et al. 2009). The coffee white stem borer *Xylotrechus quadripes* is a serious pest of coffee in South Asia. Male beetles have been shown to attract females, and (S)-2-hydroxy-3-decanone has been identified as the main attractive compound. Pheromone traps have been rapidly adopted for mass trapping (Table 1; Hall et al. 2006) reflecting exceptional grower interest in the absence of acceptable alternative control methods.

Mass Trapping and Annihilation

Control of insect populations with pheromones is achieved by two principle techniques, mating disruption and mass annihilation. Mating disruption (see below), causes disorientation and communication disruption between the sexes, and thus delays, reduces, or prevents fertilization of females. Mass annihilation, by mass trapping or attract-and-kill, relies on attraction of one or both sexes to a lure, in combination with a large-capacity trap or an insecticide-

Table 1 Use of sex pheromone lures for detection (D) and population monitoring (M), and for mass annihilation tactics, by mass trapping (MT) and attract-and-kill (AK)

Species	Purpose	Region	Lures/year

[b] Data concern South Asia only

impregnated target. Unlike detection and monitoring, where only a small proportion of a population needs to be sampled, mass annihilation requires the use of the most attractive lure.

For attract-and-kill strategies, two different approaches are taken. Either, a semiochemical formulation, consisting of an attractant and inert carriers, is deployed as an additive tank-mix to insecticide products, or an attractant and insecticide are incorporated into a fully integrated matrix that can be applied as a stand-alone intervention. Each approach has specific merits. The additive approach has an advantage in that registration of semiochemicals is facilitated. When applying an integrated matrix product, blanket spray coverage of the crop is not necessary, so the amount of insecticide can be significantly reduced. However, specialized application technology is required.

With female-produced sex pheromones, only males are caught. Since male insects typically mate more than once, a high proportion of the male population must be removed to produce an effect. Male protandry, eclosion before females, will improve the effect of removing males. In addition, even a delay in mating, via a reduction in the number of available males, may also contribute to population control, as has been shown in mating disruption studies (Vickers 1997; Fraser and Trimble 2001; Jones et al. 2008; Stelinski and Gut 2009). These studies underscore the importance of integrating population biology and life history data into development of pheromone-based control applications. Population control is a dynamic and quantitative phenomenon, as illustrated by the importance of the Allee effects in the management of biological invasions (Liebhold and Tobin 2008).

Features of the biology and ecology of the target species that determine the efficacy of annihilation techniques include: the duration of the life cycle, the number of generations per season, the duration of the flight period, and the rate of population growth. Univoltine insects with short seasonal flight periods and a limited host range are easiest to control. Annihilation techniques become far more efficacious when using lures that attract females or both sexes, and when they include male-produced pheromones, aggregation pheromones, floral or plant volatiles that serve as ovipositional cues.

Mass trapping and attract-and-kill are cost-effective compared to mating disruption, since much smaller amounts of pheromones are needed. The insecticide component is environmentally rather safe, since small amounts are used and since crop contamination during application is much reduced. Nonetheless, the insecticide component is an obstacle to public acceptability of attract-and-kill methods. Fungal or viral insect pathogens might be used instead, but their slow mode of action and the short field-life of formulations have not been solved.

Practical Use of Mass-Trapping

Brinjal Fruit and Shoot Borer Eggplant is an important vegetable in South Asia, commercially produced by approximately 700,000 farmers on 570,000 ha in India alone. In Bangladesh, 40% of all vegetables produced are eggplants, providing farmers with a regular, year-round income. Severe yield losses are caused by the fruit and shoot borer *Leucinodes orbonalis*. Insecticides appear to be largely ineffective for control of *L. orbonalis*, because of protection offered by the fruit itself and because of insecticide resistance. A pheromone-based mass trapping strategy has been developed, from optimization of the pheromone blend and dose, trap design, and placement to field implementation (Cork et al. 2001, 2003, 2005a). Mass trapping, without the use of insecticides, has led to a 50% and higher increase in marketable fruit, which has been attributed to the combined effects of mass trapping and enhanced impact of natural enemies. Additionally, secondary pests, such as mites and whitefly, were reduced in the pheromone plots. The yield increase translates to earnings of $1,000 US$ per ha and yr for resource-poor families. Given estimated sales of pheromone lures reported in India and Bangladesh (Table 1), at least 15% of all farmers have now adopted the technology, and this is increasing year on year (A. Cork, unpublished).

Bark Beetles Bark beetles are of tremendous importance in coniferous forests worldwide, and the discovery of the aggregation pheromones of the most destructive European and North-American species was soon followed by area-wide mass trapping campaigns (McLean and Borden 1979; Bakke 1982). A more recent study corroborates that mass trapping is indeed a viable control strategy. In an isolated 2,000-ha forest reserve in China, traps for the double-spined spruce bark engraver *Ips duplicatus*, baited with a 2-component pheromone blend of ipsdienol and *E*-myrcenol, were employed at a rate of 1 trap/25 ha for 3 years. Yearly beetle captures between 0.5 and 1.7 million strongly reduced average tree mortality to 17% according to a 20-year record (Schlyter et al. 2003). This particular forest is isolated, but treatments on larger areas that use the same trap density should produce the same effect.

Palm Weevils Palm weevils are the most destructive pests of palm trees and cannot be efficiently controlled with insecticides. Adult weevils are not very susceptible to toxic compounds, and mining larvae are protected inside tree trunks. They provide an outstanding example of sustainable area-wide insect control by mass trapping, covering thousands of hectares of palm in all growing regions, particularly in Central America, the Middle East, and South Asia (Table 1). The beetles use aggregation pheromones for sexual communication prior to mating, attracting both

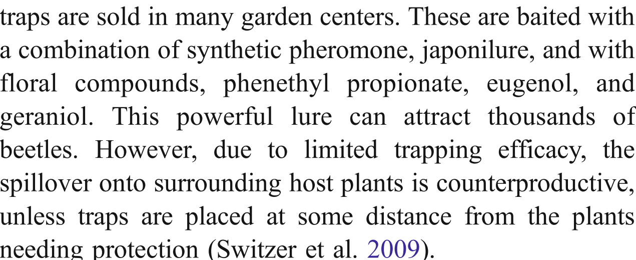
males and females. A facilitating factor is that overall population densities are lower than in smaller insects. Attractancy of the lures can be augmented by the use of plant and associated fermentation volatiles (Giblin-Davis et al. 1996; Oehlschlager et al. 2002).

Males of the American palm weevil, *Rhynchophorus palmarum*, release an aggregation pheromone, rhynchophorol: (4S)-2-methyl-(5E)-hepten-4-ol (Rochat et al. 1991; Oehlschlager et al. 1992). Captures with pure rhynchophorol increase considerably with the addition of plant material, leading to the development of an efficient control method based on mass trapping (Oehlschlager et al. 1993). Laboratory studies corroborate that aggregation is mediated by a male-produced pheromone and host-plant volatiles that include acetoin and ethyl acetate (Said et al. 2005). The American palm weevil is an important pest of several palm species in tropical America. Besides damaging the trees, it vectors a nematode that cause red ring disease. At less than one trap per 5 ha, even high palm weevil populations and nematode infestation rates have been reduced to very low infection levels, after only 1 year of trapping in combination with removal of infected palms (Oehlschlager et al. 2002).

The red palm weevil, *Rhynchophorus ferrugineus* originates in South-East Asia and is now widely distributed in Asia, Africa, and Oceania. It infests a range of tropical palms, including date, oil, and coconut palms. The larvae develop in the tree trunk, where they destroy the vascular system. Tens of thousands of date palm trees have been destroyed in the Middle East and North Africa since its appearance in the eighties because insecticide-based control is not sufficiently efficient (Soroker et al. 2005; Blumberg 2008). Mating in red palm weevil is mediated by an aggregation pheromone produced by the male weevil, composed of the main compound (4S,5S)-4-methyl-5-nonanol (ferrugineol) and 4-methyl-5-nonanone (Giblin-Davis et al. 1996; Perez et al. 1996). Traps loaded with ferrugineol, supplemented with ethyl acetate and plant volatiles, and a fermenting mixture of dates and sugarcane molasses, are placed at densities of up to 10 traps/ha for monitoring and mass trapping. Pheromone traps have played a significant role in the suppression of red palm weevil populations, for example in date palm plantations in Israel (Hallett et al. 1999; Soroker et al. 2005).

Banana Weevil The banana root borer *Cosmopolites sordidus* is a major pest of bananas throughout the world. The male-produced aggregation pheromone sordidin attracts both sexes, and mass trapping by using ground traps has the potential to replace inefficient insecticide treatments (Reddy et al. 2009).

Japanese Beetle The Japanese beetle is a devastating pest of urban landscape plants in the eastern United States and



traps are sold in many garden centers. These are baited with a combination of synthetic pheromone, japonilure, and with floral compounds, phenethyl propionate, eugenol, and geraniol. This powerful lure can attract thousands of beetles. However, due to limited trapping efficacy, the spillover onto surrounding host plants is counterproductive, unless traps are placed at some distance from the plants needing protection (Switzer et al. 2009).

Practical Use of Attract-and-Kill

Cotton Boll Weevil The cotton boll weevil *Anthonomus grandis* is a major pest of cotton in the Americas. Males produce an aggregation pheromone, grandlure (Tumlinson et al. 1969), that has been successfully incorporated into a pheromone-baited killing station known as "Boll Weevil Attract and Control Tubes". These tubes are produced in large numbers every year (Table 1). A density of 14 traps per ha achieves a strong reduction in weevil populations, at minimal crop damage. After successful control and eradication programs in the USA, bollweevil trapping is now also used in South America on at least 250,000 ha (Ridgway et al. 1990a; Smith 1998).

House Fly In addition to feeding attractants, house flies *Musca domestica* are attracted to pheromone, (Z)-9-tricosene (muscalure), which is widely used in combination with co-attractants in lure-and-kill approaches indoors and in livestock stables (Table 1; Butler et al. 2007; Geden et al. 2009).

Fruit Flies Male fruit flies (Diptera, Tephritidae) produce pheromones that attract females (Jang et al. 1994; Landolt and Averill 1999). However, these sex pheromones have not been a main research target, because of the efficacy of parapheromones and plant volatiles as attractants (methyl eugenol, trimedlure, cuelure, angelica seed oil, enriched ginger oil, raspberry ketone), and hydrolyzed protein baits (e.g., GF-120). These have been most widely used for monitoring and annihilation of several fruit flies, including Oriental fruit fly *Bacterocera dorsalis*, melon fly *Bacterocera cucurbitae*, and Mediterranean fruit fly, *Ceratitis capitata* for almost 50 years. Methyl eugenol, which is a male pheromone precursor, is a highly effective attractant and is used in IPM programs and for eradication of *Bactrocera* flies by male annihilation in the Pacific region, including Hawaii and California (Cunningham et al. 1990; Hee and Tan 2004; Vargas et al. 2008; El-Sayed et al. 2009).

A female-produced pheromone, a blend of (1,7)-dioxaspiro-[5,5,]-undane (olean), α-pinene, n-nonanal, and ethyl dodecanoate is exploited for control of the olive fly *Bactrocera oleae* by a lure-and-kill technology that incorpo-

rates the food attractant ammonium bicarbonate (Mazomenos and Haniotakis 1985; Broumas et al. 2002).

Orchard Tortricids A fully integrated attract-and-kill product, containing 0.16% pheromone and 6% permethrin, has provided control of codling moth at economic levels of less than 1% harvest infestation in apple orchards in Switzerland. Based on reductions in trap catch and the mating frequency of tethered moths, efficacy of the attract and kill droplets lasted 5–7 wk, requiring two seasonal applications. Subsequent experiments replaced permethrin with an alternative toxicant, the insect growth regulator, fenoxycarb, which has a sterilizing effect. Field tests showed that autosterilization, i.e., transfer of the insect growth regulator from a contaminated male to the female moth at mating, contributes to the control effect (Charmillot et al. 2000, 2002).

Studies of competition have shown that attracticide droplets are more attractive to male moths than calling females, and that the number of point sources is key to the ability of males to locate calling females (Krupke et al. 2002). Commercial applications require applications of 3,000 droplets per ha. At this rate, disruption of male orientation is likely to be a contributing mechanism. This has been substantiated with two further key orchard tortricids, Oriental fruit moth *Grapholita molesta* and lightbrown apple moth *Epiphyas postvittana* (Suckling and Brockerhoff 1999; Evenden and McLaughlin 2004).

Disorientation and Communication Disruption by Air Permeation

Insects rely on volatile sex pheromones to communicate for mating. Permeation of the crop with synthetic sex pheromone can disrupt chemical communication and thus prevent mating. Indeed, the mating disruption technique has become the most commonly utilized application of semiochemicals for population control (Baker and Heath 2004; Witzgall et al. 2008). Unlike with mass trapping, the natural pheromone is not required for mating disruption to be effective. Both attractive and non-attractive pheromone blends have been used, since off-blends can result in considerable cost savings (Bengtsson et al. 1994; Cork et al. 1996; Stelinski et al. 2008). Negative signals, including antiaggregation pheromones, have been combined with attractants into push-pull techniques (Borden 1997; Schlyter and Birgersson 1999; Cook et al. 2007).

The behavioral mechanisms by which mating disruption is achieved have been subject to investigation and discussion since Bartell (1982). If we understood the underlying mechanisms that cause or result in the behavioral modification that leads to disruption of mating, we will be better placed to understand why some applications are successful and others not (Cardé and Minks 1995; Sanders 1996, Miller et al. 2010). Attempts to interpret the behavioral response to air permeation treatments should, however, also build on field data on both the behavior of moths and molecules. Male moth behavior depends on a number of factors, including pheromone blend, release rate, and aerial concentration. Measurement of these factors and their contribution to efficacy will help to predict the outcome of mating disruption (Bengtsson et al. 1994).

Resistance to mating disruption is a remote risk in many species, because changes in female pheromone biosynthesis or male response are unlikely to lead to a new communication channel that is unaffected by synthetic pheromone treatments that do not precisely match the female-produced blend. However, resistance to treatments with a single pheromone component has occurred in the small tea tortrix *Adoxophyes honmai*. The efficacy of (Z)-11-tetradecenyl acetate, a ubiquitous leafroller pheromone component, decreased after 16 years. The composition of the pheromone blend produced by the females was unaltered, but the pheromone response was broader in resistant males. Efficacy of mating disruption returned to its former level, after changing to the natural 4-component pheromone blend (Mochizuki et al. 2002; Tabata et al. 2007a, b).

Commercial use of mating disruption became possible only after industrial scale synthesis became available at the end of the eighties. As a general guide, application rates of between 10 g and 100 g per ha per season are required to achieve communication disruption, thus resulting in aerial concentrations of at least 1 ng/m3 (Bengtsson et al. 1994; Cork et al. 2008).

A wide range of controlled release formulations has been developed for use in mating disruption. Early on, it had been assumed that a very high density of point sources was required to produce an effective fog of pheromone to disrupt male moths, and, therefore, formulations such as aqueous suspensions of micro-capsules and hollow fibers were developed. However, with the advent of hand-applied reservoir-type formulations, it was realized that fewer point sources that release higher quantities of pheromone could achieve the same result, by generating plumes with high concentrations of synthetic pheromone. Season-long field life is a main advantage of hand-applied dispensers. Renewed efforts to develop sprayable formulations is motivated by reduced application cost, either in combination with fungicides in orchards, or for applications on large areas (Leonhardt et al. 1990; Weatherston 1990; Trimble et al. 2003; Tcheslavskaia et al. 2005; Il'ichev et al. 2006).

A major flaw of current commercial pheromone dispensers is that pheromone release increases with ambient temperature. In apple orchards treated against codling moth,

ca. 90% of pheromone applied is released outside the diel flight period, mainly during daytime at peak ambient temperatures (Witzgall et al. 1999). In addition, dispensers must be applied early in season when population densities are still low and release rates decrease during the season, as population densities start to increase. These problems can be circumvented by using timed and metered pheromone sprayers that release constant and large amounts of pheromone only when the insects are active (Shorey and Gerber 1996; Mafra-Neto and Baker 1996; Fadamiro and Baker 2002). Such "puffers" are now increasingly used against navel orangeworm *Amyelois transitella* and codling moth.

Mating disruption is more efficacious over large areas. This is in part because large areas reduce the impact of gravid females that immigrate into treated plots, but also because homogenous air permeation is facilitated. Incomplete permeation with pheromone, especially along crop borders, is an obstacle. This has been confirmed by field EAG measurements of aerial pheromone concentrations (Milli et al. 1997). Border effects become negligible when large surfaces are treated. Indeed, dispenser spacing and overall pheromone application rate can be reduced as the treated area increases, resulting in considerable cost savings to farmers.

Adoption of mating disruption and reduction of insecticide leads to a decrease in the incidence of secondary pests due to conservation of natural enemies. In orchards and vineyards, mating disruption renders treatments against phytophagous mites superfluous since outbreaks are typically induced by the overuse of insecticides.

Other biological techniques rarely permit stand-alone containment of insects, and mating disruption, in addition to annihilation techniques, is often the only option when insecticides cannot be applied, as in organic crops, allotment gardens, or against insecticide-resistant insect populations (Suckling et al. 1990; Albert and Wolff 2000). From the nineties onwards, the area under mating disruption saw an almost exponential expansion into the first decade of this century (Fig. 2; Brunner et al. 2002; Ioriatti et al. 2008).

Mating Disruption in Vineyards

The history of mating disruption of grape moths in Europe, reviewed by Arn and Louis (1996) and Ioriatti et al. (2008), exemplifies the weight of interfacing research among extension people, growers, and pheromone industries for the development and implementation of this new technology.

The complete identification of the sex pheromones of the key European grape insects as a prerequisite for the development of mating disruption (Arn et al. 1986; Guerin et al. 1986; El-Sayed et al. 1999b) was the incentive for the development of techniques that still are widely used in chemical ecology research, such as the electroantennographic detector (Arn et al. 1975) and a wind tunnel bioassay with quantitative, controlled stimulus application (Rauscher et al. 1984; El-Sayed et al. 1999a, b).

A portable electroantennogram apparatus was designed for live measurements of ambient pheromone concentrations with an insect antenna, and for rapid optimization of pheromone dispenser placement (Sauer et al. 1992; Koch et al. 2009b). Field tents were used to determine the mating status of female moths and critical population densities, above which mating disruption is no longer effective (Feldhege et al. 1995). The latest methodological progress is appreciably simple but facilitates replicated field measurements of the behavioral effect of dispenser formulations or dispenser densities. Insects are released into portable 8.5 m^3 field cages that contain traps with live females and synthetic pheromone. The cages are placed in vineyards, into 20×20 m pheromone dispenser arrays that simulate full-scale vineyard treatments. The plot size is convenient for the investigation of experimental dispenser formulations (Koch et al. 2009a).

Experimental trials in vineyards were expanded to area-wide campaigns by involving plant protection entomologists, growers associations, and pheromone industries (Rauscher and Arn 1979; Neumann et al. 1993; Vogt et al. 1993). The coordination of mating disruption field campaigns is a complex task, indeed: 1,447 growers participated in Northern Italy in 1999 (Varner et al. 2001). By the end of the nineties, mating disruption had led to an area-wide reduction in population densities and it became widely accepted by growers in Germany, Switzerland, and Northern Italy (Fig. 3; Varner et al. 2001). A challenge in these European vineyards is now to develop novel strategies against new pests that are not affected by mating disruption, especially leafhoppers that vector plant diseases (Mazzoni et al. 2009).

Meanwhile, European grapevine moth *Lobesia botrana* has been found in Chile and Napa County, California. In Chile, 40,000 ha now are under mating disruption in an attempt to eradicate the newly established population (V. Veronelli, pers. comm.)

Mating Disruption in Orchards

Pheromone use in orchards concerns mainly the codling moth *Cydia pomonella*, Oriental fruit moth *Grapholita molesta* (Table 1), and lightbrown apple moth *Epiphyas postvittana*.

Lightbrown apple moth *Epiphyas postvittana* is native to Australia and New Zealand. It is a serious threat to agriculture, because of its polyphagous lifestyle on many fruit and ornamental crops and because it is a quarantine

pest in many countries. Suckling and Clearwater (1990) demonstrated that a 2-component blend provided better communication disruption than the main compound alone. Mating disruption then was conceived as a strategy to achieve, in combination with a reduced spray program, economically acceptable control in insecticide resistant populations in apple in New Zealand (Suckling et al. 1990; Suckling and Shaw 1995). More recently, efficient population control has been demonstrated in Australian citrus (Mo et al. 2006). Lightbrown apple moth now has been found in California. A mating disruption campaign uses ground-based sprays and hand-applied dispensers (Garvey 2008; Varela et al. 2008).

Codling moth *C. pomonella* exemplifies some main requirements for competitive pheromone use (Brunner et al. 2002; Witzgall et al. 2008). (1) The larvae damage the crop directly, and the economic damage threshold in apple, pear, and walnut is very low. (2) The hatching larvae are difficult to control with insecticides since they immediately bore into the fruit. A most efficient and widely used insecticide, azinphos-methyl, has been banned in many countries due to its acute neurotoxicity. Resistance problems have occurred with several other insecticides (Reyes et al. 2009). New insecticides, including neonicotinoids that provide more specific control than organophosphates are more costly and still harmful to beneficial arthropods (Beers et al. 2005; Brunner et al. 2005; Poletti et al. 2007). (3) Other, stand-alone biological control techniques are not available. (4) Overuse of insecticides is well-known to harm predatory mites and induce phytophagous mites (Waldner 1997; Epstein et al. 2000; Agnello et al. 2003). Miticide sprays are costly; avoiding them balances the cost of the pheromone treatment. (5) IPM was initiated in orchards and vineyards, and much emphasis has been placed on crop protection education. (6) Consumers are more wary of pesticide residues in fruit than in other food. (7) Sustainable pest control helps to reconcile conflicts between urban and adjacent rural areas, and corroborates the contribution of orchards to the aesthetic value of a region. The worldwide orchard area treated with codling moth mating disruption has now surpassed 200,000 ha, corresponding to, for example, almost half of the European orchard area (Table 2; Fig. 2).

Mating Disruption in Forests

Antipheromones and Bark Beetle Control Bark beetles, including mountain pine beetles *Dendroctonus* sp. can convert large regions of boreal and temperate forest from carbon sinks to carbon sources. It is, therefore, urgent to determine whether pheromones and other semiochemicals become effective in suppressing bark beetle outbreaks. Conifer-inhabiting bark beetles have evolved several olfactory mechanisms for finding, colonizing, and killing their hosts, and also for avoiding unsuitable, overcrowded host trees and resistant nonhost trees. The battery of semiochemicals, attractant and repellent, produced by beetles, host plants, and non-host plants is available for the design of innovative control technology (Borden 1997; Schlyter and Birgersson 1999; Zhang and Schlyter 2004; Seybold et al. 2006).

An alternative strategy to mass trapping with attractant pheromones (see above) are push-pull tactics. These combine aerial permeation of forest stands with anti-aggregation pheromone or repellent non-host volatiles with attractant pheromones. Recent tests confirm the potency of the anti-aggregation pheromones verbenone and methylcyclohexenone (MCH) in aerial forest treatments against mountain pine beetle *Dendroctonus ponderosae* and Douglas-fir beetle *D. pseudotsugae*, respectively (Gillette et al. 2009a, b). These compounds also have been combined with pheromone-based mass-trapping in a push-pull fashion, using hand-applied dispensers (Borden et al. 2006, 2007).

Gypsy Moth The largest application of mating disruption over many years is part of the area-wide management of gypsy moth *Lymantria dispar*, an invasive forest insect in the Eastern US. The "Slow the Spread" program has significantly reduced the spread of gypsy moth by detecting isolated populations in grids of pheromone-baited traps placed along the expanding population front. The detected populations are treated by using *Bacillus thuringiensis* or more frequently by mating disruption, by using aerial applications of plastic flakes (Sharov et al. 2002; Tcheslavskaia et al. 2005).

A prerequisite to the success of managing the spread or establishment of invasive insects is the availability of practical methods for detecting low-density populations. Much of the credit for the success of gypsy moth containment efforts is attributed to the availability of pheromone-baited traps that are inexpensive yet highly sensitive (Liebhold and Tobin 2008).

Area-Wide Programs

Natural insect populations are known to fluctuate in large-scale synchrony. Such spatio-temporal fluctuations are particularly conspicuous in unmanaged forest insects, which can defoliate entire regions (Peltonen et al. 2002). Population fluctuations have been largely neglected in horticultural and agricultural insects while conventional insecticides are the dominating management tactic. The knowledge of population changes on a regional scale is, however, vital for pheromone-based pest management programs (Kobro et al.

Table 2 Use of mating disruption and air permeation with pheromones and antipheromones

Species	Main crop	Region	Area (ha)
Mating disruption			
Gypsy moth *Lymantria dispar*	Forest	USA	230.000
Codling moth *Cydia pomonella* [a]	Apple, pear	Worldwide	210.000
Grapevine moth *Lobesia botrana*	Grape	EU, Chile	100.000
Oriental fruit moth *Grapholita molesta*	Peach, apple	Worldwide	50.000
Pink bollworm *Pectinophora gossypiella* [b]	Cotton	USA, Israel, South America, EU	50.000
Grapeberry moth *Eupoecilia ambiguella*	Grape	EU	45.000
Leafroller moths, Tortricidae	Apple, pear, peach, tea	USA, EU, Japan, Australia	25.000
Striped stem borer *Chilo suppressalis*	Rice	Spain	20.000
Other species	Fruit, vegetables		40.000
Total			770.000
Antipheromones			
Mountain pine beetle *Dendroctonus ponderosae*	Pine	USA, Canada	– [c]
Douglas-fir beetle *D. pseudotsugae*	Douglas-fir	USA, Canada	– [c]

[a] Annual estimated codlemone production is 25 tons (Fig. 2)

[b] Usage dropped significantly upon widespread adoption of transgenic cotton varieties

[c] No data available

2003). In addition, landscape ecology affects insect dynamics, and this should be taken into account for more efficient crop protection (Ricci et al. 2009).

Pheromone-based methods have been shown to produce reliable results especially in area-wide programs, and future applications should, therefore, be planned on a landscape level. Geographic information systems (GIS) make it possible to capture, organize and evaluate insect population data and to visualize spatial and temporal fluctuations on a regional scale. Geo-referenced insect monitoring data can, in addition be correlated with relevant parameters such as distribution of the crop and other vegetation, geography, climate, and insect control programs.

GISs are already in use, especially in forest insects, to document geographic variation, predict outbreaks, and to delimit invasive species (Tobin et al. 2004, 2007). The web adds yet another dimension to the analytical power of geographical information systems, as it provides worldwide connectivity. A web-based GIS permits one to quickly disseminate and share information, and it enables interactivity between end users, extension people, and researchers. A rigorous effort should be made to apply such techniques for landscape-level applications of semiochemical-based insect control.

Other Semiochemicals

Semiochemicals that attract insect females are tools for monitoring the occurrence and reproductive status of females. This is particularly important in species in which sexual communication relies on female-produced sex pheromones that attract only males. Moreover, some powerful annihilation strategies are based on female attractants (Table 3). Plant-derived chemicals also are known to improve attraction to pheromone lures (Giblin-Davis et al. 1996; Oehlschlager et al. 2002; Knight and Light 2005; Knight et al. 2005; Bengtsson et al. 2006; Schmidt-Büsser et al. 2009).

Even non-host volatiles may play a significant role in insect management, since some insects avoid volatiles of non-host plants. The know-how of negative plant volatile signals can be used to design push-pull techniques (Borden 1997; Zhang and Schlyter 2004; Cook et al. 2007).

Floral Compounds that Target Moths Floral scents play a key role in the coevolution of flowering plants and their pollinators (Raguso 2004; Bergström 2008). The bouquets of flowering plants, for example, Canada thistle and *Buddleja* butterfly bush, are strong attractants for Lepidoptera, Coleoptera, Diptera, and Hymenoptera (El-Sayed et al. 2008; Guedot et al. 2008). Synthetic floral attractants composed of phenylacetaldehyde and other volatiles, such as β-myrcene are known for several noctuid moths (Haynes et al. 1991; Heath et al. 1992; Landolt et al. 2006). Noctuids also respond to attractants that encode fermenting food sources, such as acetic acid and 3-methyl-1-butanol (Landolt and Alfaro 2001; Landolt et al. 2007).

A highly effective technique to control *Helicoverpa* spp. combines floral attractants and feeding stimulants with insecticide. The blend is sprayed on one out of 36 or 72 rows of a cotton field, thus minimizing the environmental

Table 3 Use of other semiochemicals in insect detection (D) and control by mass trapping (MT) and attract-and-kill (AK)

Species	Lure	Purpose	Region	Lures/year
Horticulture				
Mediterranean fruit fly *Ceratitis capitata*	Trimedlure	MT	Worldwide	3.000.000
Melon fly *Bactrocera cucurbitae*	Cue-lure	AK	South Asia, USA	300.000
Oriental fruit fly *Bactrocera dorsalis*	Methyl eugenol	AK	South Asia, USA	400.000
Agriculture				
Corn rootworm *Diabrotica spp.*[a]	Kairomone	AK	USA	40.000 ha
American bollworm *Helicoverpa armigera* [a]	Kairomone	AK	Australia	10.000 ha

impact of the insecticide component. The attractant primarily targets female moths and removes them from the crop ecosystem prior to oviposition, showing that plant volatiles can be used to control insect populations (Del Socorro et al. 2003, 2010a, b; Gregg et al. 2010). The dispersal activity of insects, which is generally perceived as an obstacle for mating disruption and mass trapping, can be turned into an advantage when using female attractants.

This breakthrough development is based on a paradigm shift, since the attractant does not mimic a particular plant, it is instead a combination of compounds from several plants, producing a supernatural floral blend not found in nature (Del Socorro et al. 2003, 2010a, b; Gregg et al. 2010). Clearly, olfactory space would accommodate different floral attractants, since noctuid moths have been exposed to a changing guild of flowers during evolution. It is conceivable, given a more complete knowledge of olfactory receptor ligands, that such synthetic blends can be created also for other insect species.

Social Wasps Blends of acetic acid, with either butyl butyrate, heptyl butyrate, or isobutanol elicit food-finding behavior in a range of social wasps (Landolt et al. 2000). Lures for these wasps are widely distributed for the home and garden market (Table 3).

Corn Rootworms Diabroticine chrysomelid beetles evolved in the prairie ecosystem with larvae that feed on grass roots and adults that feed on vegetative parts of a broad range of plants, including maize. The western corn rootworm, *Diabrotica virgifera virgifera* is a species that is of particular concern in Europe, since it was introduced into the Balkans (Hummel 2003). Adult beetles are attracted to the volatiles of squash blossoms (Cucurbitaceae), and compulsive feeding and arrestment responses on cucurbit foliage are triggered by cucurbitacin secondary plant compounds (Metcalf et al. 1980). This behavior is exploited in the development of floral-baited traps for monitoring (Toth et al. 2007) and flowable and sprayable bait formulations that contain insecticides for area-wide management (Siegfried et al. 2004; French et al. 2007).

Emerald Ashborer The metallic and bright coloration of the elytra of jewel beetles (Buprestidae) points to the significance of visual cues in mate finding. However, host finding is likely mediated by olfactory cues, since many buprestids oviposit on stressed or dying trees. This has been demonstrated in the genus *Melanophila*, where females, which oviposit on wood of trees freshly killed by fire, can detect substances emitted in smoke from burning wood (Schütz et al. 1999).

The emerald ash borer is a rapidly spreading invasive species in the Eastern USA that kills ash trees. The cooperative emerald ash borer project includes a considerable trapping program (Table 3) for early detection in and around the Great Lakes district. Bark volatiles from green ash *Fraxinus pennsylvanica* contain a range of antennal active sesquiterpenes. Natural oil distillates, containing high concentrations of some of these ash volatiles, are currently used as a lure (Crook et al. 2008; Crook and Mastro 2010

this volume). Emerald ash borer trapping is another example of how even immature technology is adopted, due to the absence of other management tools.

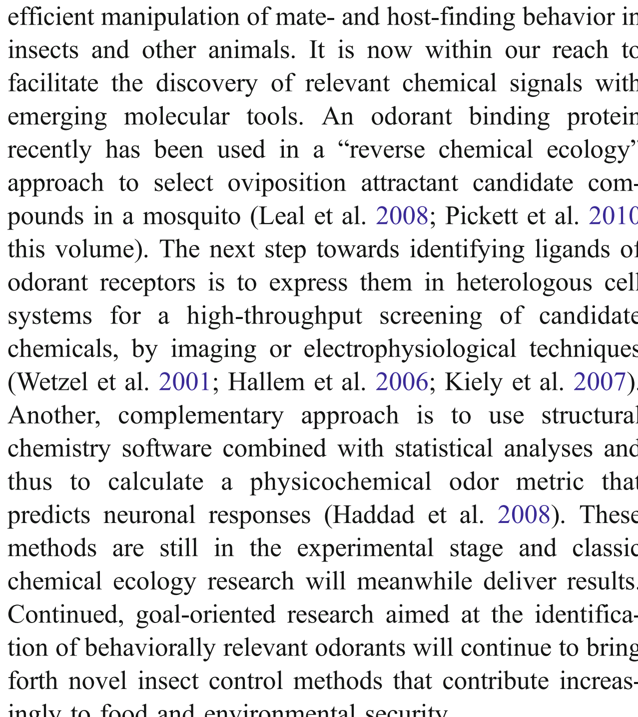
Tsetse Flies African trypanosomiasis is transmitted by tsetse flies *Glossina* spp., that are obligate haematophages. The prospect of eradicating tsetse over large areas has appeared to be a serious possibility because of the development of cost-effective semiochemical-based control technologies, notably odor-baited targets that mimic host odor. The search for further host volatiles is ongoing (Harraca et al. 2009). The best known attractant identified from cattle volatiles and buffalo urine comprises a blend of 3-n-propyl phenol, 1-octen-3-ol, and 4-methylphenol (p-cresol), and a separate dispenser containing methyl ethyl ketone or acetone, (Bursell et al. 1988; Vale et al. 1988). Importantly, the odor-baited targets are treated with a fast acting insecticide, typically deltamethrin, and provide visual cues, typically colored in panels of blue and black, that attract and elicit landing in tsetse flies (Torr et al. 1997). There has been a steady increase in the use of odor-baited targets for mass trapping in Southern Africa, with a concomitant insecticide treatment of cattle. In Zimbabwe, an area-wide vector management program reduced typanosomiasis in cattle from several thousand cases per year to two in 1995 (Lindh et al. 2009; Torr et al. 2010).

Sheep Blowflies Australian sheep blowfly *Lucilia cuprina* and related species are potentially controlled by a rather selective synthetic kairomone attractant (Table 3). Insecticidal control is problematic, because of the demand for residue-free wool and the resistance of blowflies to many insecticides. Fly population changes also are driven largely by climate, rather than by biotic factors, and are expected to increase under likely scenarios of climate change (Goulson et al. 2005).

Traditionally, blowfly traps have been baited with liver and sodium sulfide, but a synthetic kairomone, consisting of 2-mercaptoethanol, indole, butanoic acid, and a sodium sulfide solution is far more effective and selective for *L. cuprina* than the standard liver attractant. More importantly, the synthetic mix can be packaged in controlled-release dispensers to generate constant, prolonged release of the attractant. Field studies have confirmed that kairomone traps are a useful component of a blowfly control program (Ward and Farrell 2003; Urech et al. 2004, 2009).

Outlook

Future applications of pheromones and other semiochemicals depend on the availability of odorants that enable



efficient manipulation of mate- and host-finding behavior in insects and other animals. It is now within our reach to facilitate the discovery of relevant chemical signals with emerging molecular tools. An odorant binding protein recently has been used in a “reverse chemical ecology” approach to select oviposition attractant candidate compounds in a mosquito (Leal et al. 2008; Pickett et al. 2010 this volume). The next step towards identifying ligands of odorant receptors is to express them in heterologous cell systems for a high-throughput screening of candidate chemicals, by imaging or electrophysiological techniques (Wetzel et al. 2001; Hallem et al. 2006; Kiely et al. 2007). Another, complementary approach is to use structural chemistry software combined with statistical analyses and thus to calculate a physicochemical odor metric that predicts neuronal responses (Haddad et al. 2008). These methods are still in the experimental stage and classic chemical ecology research will meanwhile deliver results. Continued, goal-oriented research aimed at the identification of behaviorally relevant odorants will continue to bring forth novel insect control methods that contribute increasingly to food and environmental security.

Abstract The emerald ash borer (EAB), *Agrilus planipennis* Fairmaire (Coleoptera: Buprestidae) is a serious invasive pest that has caused devastating mortality of ash trees (*Fraxinus sp*., Oleaceae) since it was first identified in North America in 2002. Shortly after its discovery, surveys were conducted, based on the visual inspection of trees. The shortcomings of visual surveys have led to a critical research need to find an efficient survey method for detecting *A. planipennis* infestations. Here, we present a review of research that has led to the development of effective trapping methods for *A. planipennis*. Studies on the insect's biology and behavior have led to the identification of several potential attractants as well as the design of a visually attractive trap. The ongoing challenge in developing an optimally efficient trapping methodology for *A. planipennis* will involve finding the best combination of variables, such as trap shape, trap color (or other visual properties), trap placement, lure components, as well as the ratios and release rates of those components.

Keywords *Agrilus planipennis* · Coleoptera · Buprestidae · Behavior · Sesquiterpenes · Green leaf volatiles · Contact pheromone

Introduction

The emerald ash borer (EAB), *Agrilus planipennis* Fairmaire (Coleoptera: Buprestidae) is a serious invasive pest that has caused devastating mortality of ash trees (*Fraxinus sp*., Oleaceae) since it was first identified near Detroit Michigan, USA, and Windsor Ontario, Canada (Haack et al. 2002). It is not reported as a pest in its native range of China, Korea, Japan, Mongolia, Taiwan, or eastern Russia (Chinese Academy of Sciences, Institute of Zoology 1986; Yu 1992; Haack et al. 2002; Xu 2003; Gao et al. 2004; Wei et al. 2004). Despite intense suppression efforts by American and Canadian authorities, the beetle has increased its range rapidly, mainly due to the movement of logs, firewood, and nursery trees. More information on the introduction of *A. planipennis* into North America is provided in a thorough review by Poland and McCullough (2006). Since 2002 *A. planipennis* has been reported in Ohio and Maryland (2003), Indiana (2004), Illinois (2006), Pennsylvania and West Virginia (2007), and more recently in Virginia, Wisconsin, Missouri, Minnesota, Kentucky, and New York as well as Quebec, Canada (http://www.emeraldashborer.info). Since its introduction, *A. planipennis* has killed tens of millions of ash trees (*Fraxinus* spp.) in North America and Canada (http://www.emeraldashborer.info). North American ash species (in particular green ash *F. pennsylvanica* Marsh., white ash *F. Americana* L. and black ash *F. nigra* Marsh) are highly vulnerable to infestation by *A. planipennis*. When North American species have been planted in Asia (Liu et al. 2003), they have been shown to be highly susceptible to *A. planipennis* when compared to native asian ash species (mainly Chinese ash *F. chinensis* Roxb. and Manchurian ash, *F. mandshurica* Rupr.) (Eyles et al. 2007; Rebek et al. 2008). While Marshall et al. (2009b) reported that *A. planipennis* did not differentiate between different North American ash species in forest's, Anulewicz et al. (2008) found that *A. planipennis* preferred green over white ash, and white over blue ash in urban

environments. Laboratory studies also have found preferences among North American ash species (Pureswaran and Poland 2009a).

Studies of *Agrilus* species native to North America (Barter 1957, 1965; Cote and Allen 1980; McCullough and Katovich 2004; Cappaert et al. 2005a) reveal their biology and ecology are similar to those of *A. planipennis*. Larvae of *A. planipennis* feed in the phloem and cambial regions forming S-shaped galleries that disrupt nutrient and water flow, resulting in tree death, 2–3 years after first infestation (Liu et al. 2003). Larvae progress through four instars before overwintering as prepupae in the sapwood or outer bark. Pupation takes place in mid April before adults emerge in May and June through D-shaped exit holes (Bauer et al. 2004; McCullough and Katovich 2004). Adults emerge in May and June (in Michigan) with flight activity lasting until August. Adults feed on the margins of ash leaves throughout their lifetime and require a maturation period of ~1 week before females mate. Females continue to feed for another 5–7 days before they lay individual eggs (50–90) in bark crevices. Eggs hatch within 2 weeks (Bauer et al. 2004; Cappaert et al. 2005a). Adults continue to mate and feed for the remainder of their 3–6 week life span (Poland and McCullough 2006). A one-year life cycle is most common, but a two-year cycle does exist in China in the most northern reaches of its native range (Yu 1992; Marshall et al. 2009a). This 2 year larval development also has been reported in North America (Siegert et al. 2007; Tluczek et al. 2008; McCullough et al. 2009).

Agrilus planipennis—Mating Behavior and Pheromones

Although the genus *Agrilus* (Coleoptera: Buprestidae) includes thousands of species (Jendek 2000), it remains poorly understood, particularly with respect to chemical ecology and mating behavior. Once host trees are located, *Agrilus* beetles presumably find mates via one or more of the following signals: visual, auditory, vibration, tactile, or pheromonal (Fenton 1942; Carlson and Knight 1969; Gwynne and Rentz 1983; Dunn and Potter 1988).

Mating behavior of *A. planipennis* has been the subject of several studies. The primary mate-finding strategy appears to involve active visual searches by males for females (Lelito et al. 2007a, b, 2008; Rodriguez-Saona et al. 2007). Males will hover 0.3–1.0 m above conspecific beetles on ash leaves before rapidly and accurately descending onto them, and they respond similarly to naturally occurring or dead nonspecific's (Lelito et al. 2007b). Male mating behavior also has been tested using 'dummy' beetles that had been washed in dichloromethane (to remove any cuticular contact cues). Lelito et al. (2007b) found that males spent significantly less time attempting to copulate with pinned male or solvent washed female dummies than with unwashed females, indicating that a contact pheromone is utilized by males after the visual landing stage of mate location is completed. A detailed study on the distribution and structure of *A. planipennis* antennal sensilla showed that males had significantly more uniporous gustatory sensilla than females (Crook et al. 2008d), thus supporting the evidence that mate recognition by males involves female released contact cues. Sensory deprivation experiments in the laboratory using male—female pairs demonstrated that if male antennae were covered with paint they took significantly longer to find females and spent less time in copula compared to untreated males (Pureswaran and Poland 2009b). Blocking male eyes with paint did not appear to affect their mate finding capacity when compared to unpainted males, demonstrating that at short range (≤5 cm), olfactory cues were more important than visual ones.

Cuticular hydrocarbons recently were identified as contact pheromones for *A. planipennis* (Lelito et al. 2009; Silk et al. 2009). Lelito et al. (2009) identified 3-methyltricosane as being a potential contact pheromone. This long-chain hydrocarbon was present on the cuticle of mature females (10–12 days old) but found in only trace amounts on the cuticle of males or immature (3-day-old) females. In field assays, male *A. planipennis* spent significantly more time attempting to copulate with dead, pinned females coated with 3-methyltricosane (3 beetle equivalents) than with solvent-washed beetles, although males still spent the most time investigating pinned, dead, unwashed females. Lelito et al. (2009) suggested that the behavioral effect of 3-methyltricosane may be synergized by other compounds secreted onto the cuticular surface. Individual testing of the compound's two enantiomers may determine if chirality is important.

In another analysis of *A. planipennis* cuticular hydrocarbons, Silk et al. (2009) revealed nearly identical chemical profiles in males and females except for one compound, 9-methyl-pentacosane, which was exclusively present in 10–14 day old (sexually mature) females. Reapplication of synthetic 9-methyl-pentacosane to hexane rinsed female 'dummies' (at one female equivalent) restored almost all contact and male copulatory behavior in field bioassays. Time spent by males in contact with 9-methyl-pentacosane treated females and the time spent in attempted copulation was significantly greater than that observed with hexane washed females and not significantly different from unwashed female controls. 9-Methyl-pentacosane is, therefore, used as a contact pheromone component by male *A. planipennis*. This is interesting since 9-methyl-pentacosane also is a contact pheromone component of the cerambycid beetle *Xylotrechus colonus* F. (Ginzel et al. 2003).

Both 3-methyltricosane (Lelito et al. 2009) and 9-methyl-pentacosane (Silk et al. 2009) are more abundant or only present on the cuticle of 10–14 day old females, thus suggesting that their presence is associated with sexual maturation (or more specifically egg maturation). The relationship between insect sexual maturation and increased pheromone production is well documented with other insect species (Dillwith et al. 1983; Blomquist et al. 1987; Adams et al. 1995; Monnin et al. 1998; Schal et al. 2001; Howard and Blomquist 2005).

Olfactometer and behavioral data currently provide no evidence that *A. planipennis* uses long range pheromones (Otis et al. 2005; Rodriguez-Saona et al. 2006; Lelito et al. 2007b, 2008). A volatile, antennally active compound (for males and females), emitted primarily by female *A. planipennis*, was identified as (3*Z*)-dodecen-12-olide (3*Z*-lactone), but its biological activity has yet to be demonstrated (Bartelt et al. 2007; A. Cossé unpublished observations). Silk et al. (personal communication) synthesized both the 3*Z*-lactone and its stereoisomer (3*E*)-dodecen-12-olide (the 3*E*-lactone) and found that GC-EAD responses of *A. planipennis* were more consistent for the 3*E*-lactone. This is intriguing because the 3E-lactone has not yet been identified in male or female aeration samples. Despite the apparent lack of behavioral activity in preliminary field tests, the 3*E*-lactone (but not the 3*Z*-lactone) induced a significant orientation of males in preliminary olfactometer tests (P. Silk, personal communication). Female beetles were unresponsive in olfactometer tests. Further research is warranted but these results do indicate that (3*E*)-dodecen-12-olide (the 3*E*-lactone) could be a short range volatile pheromone for *A. planipennis.* This would support the observations of Pureswaran and Poland (2009b) who suggested that males can identify females at a short range (≤5 cm) before they come into contact with them.

This apparent lack of a useful pheromone for use in trap surveys has forced researchers to examine host volatile and visual stimuli in detail so that potential attractants can be identified and utilized.

Detection of *Agrilus planipennis*

The detection of *A. planipennis* at low population densities is the greatest challenge in being able to monitor and manage the beetle successfully (Marshall et al. 2009b). Without early detection, forest pests such as *A. planipennis* soon become well established, which in turn greatly limits the effectiveness of early control measures that would help limit the pest's movement to other areas (Liebhold et al. 1995; Marshall et al. 2009a, b). Shortly after its discovery in North America, *A. planipennis* surveys were conducted, based on the visual inspection of tree damage, as no traps, lures or other methods were available for operational use (McCullough et al. 2009). The detection of early *A. planipennis* infestations by using visual surveys proved exceedingly difficult for several reasons. Overt visible symptoms of *A. planipennis* infestation are bark cracks, woodpecker attacks, canopy dieback, and epicormic branching, but these are not clearly evident until ash trees are heavily attacked (Poland and McCullough 2006; McCullough et al. 2009). The D-shaped exit holes are visible earlier but are small and tend to occur in the upper canopy during the early stages of attack. The problems and inadequacies of visual surveys led to a research effort to develop a sensitive and efficient survey method for detecting newly established (and delimiting) infestations of *A. planipennis*.

Agrilus planipennis Attraction to Stressed Trees

Before *A. planipennis* was discovered in North America, very little was known about how buprestids locate potential mates and hosts. Buprestid mating appeared to be facilitated by host selection followed by visual, tactile, and possibly auditory cues, as opposed to involving a 'long distance' pheromone (Carlson and Knight 1969; Gwynne and Rentz 1983). Previous studies have shown that both the bronze birch borer (*A. anxius* Gory) and the two-lined chestnut borer (*A. bilineatus* Weber) colonize stressed trees rather than healthy or dead trees (Anderson 1944; Dunbar and Stephens 1976; Cote and Allen 1980; Haack and Benjamin 1982; Dunn 1985; Dunn et al. 1987; Katovich et al. 2001). To investigate stress-mediated attraction in *A. planipennis,* McCullough et al. (2009) compared the number of insects caught on sticky bands that were attached to healthy and stressed ash trees. Trees were stressed by herbicide injection or by mechanically girdling the tree (i.e., removing a 15-cm-wide band of outer bark and phloem, thereby disrupting nutrient translocation). They found a significantly higher number of *A. planipennis* adults on trees that had been stressed. As a result of these findings, girdled trees were used by survey agencies in Michigan, Ohio, and Indiana from 2004 to 2007 (McCullough et al. 2009) and they led to the detection of some previously unknown infestations. McCullough et al. (2009) suggested that girdled trees could also be used as 'trap trees' if they were destroyed after oviposition and before larvae completed development. One problem that limits the use of stressed trees in large-scale monitoring programs is that they must be felled and stripped of bark to determine presence or absence of larvae (Francese et al. 2008; Marshall et al. 2009a). This is labor intensive, destructive, expensive, and time consuming (Cappaert et al. 2005a). Also, suitable detection trees may not be available in areas

of interest (McCullough et al. 2009). Development of a practical trap and effective lure has, therefore, become a research priority for *A. planipennis* detection programs (Poland 2007).

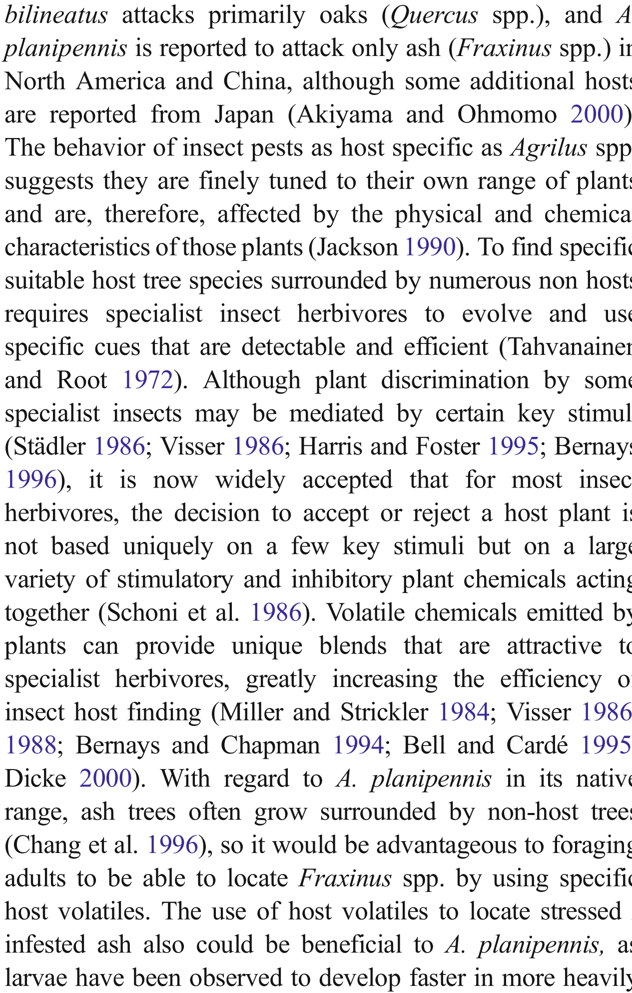
Traps—Design, Color and Placement Considerations

As pointed out by de Groot et al. (2008), an important component of any trap-based monitoring system is the trap itself. Recent studies based on color, visual cues, shape, and trap placement have led to good progress in developing an effective trap and trapping methods for *A. planipennis* (Francese et al. 2005, 2007, 2008; Otis et al. 2005; Crook et al. 2006, 2007, 2008a, b, c, 2009; Lelito et al. 2007a, b, 2008; McCullough et al. 2008; Marshall et al. 2009a, b). The trap currently used for *A. planipennis* survey is a prism-shaped sticky trap made from sheets of purple corrugated plastic (peak wavelengths of 430, 600, and 670 nm; trap described by Francese et al. 2008). This attraction to purple can be explained by recent electroretinogram (ERG) assays by Crook et al. (2009) who showed that while both male and female *A. planipennis* were sensitive to light in the blue (420–430 nm, 460 nm) range of the visible spectrum, females also were sensitive to light in the red (640–650, 670) range. Purple traps, accordingly, have typically caught more females than males (Francese et al. 2008; Crook et al. 2009).

Further ERG work by Crook et al. (2009) showed that *A. planipennis* are also sensitive to light in the green range (540–560 nm). In trapping assays, both dark and light green traps with a peak reflectance at 540 nm caught two to three times as many beetles as purple traps (either painted purple or made from purple plastic) when traps were hung at mid-canopy (~13 m). No significant differences were seen between purple and green traps at 1.5 m. The sex ratio on light and dark green traps, unlike purple, was heavily skewed toward males (Crook et al. 2009). Based on these results, Crook et al. (2009) suggested a green trap (placed at 13 m) for detecting incipient *A. planipennis* populations. Trap placement high in the tree canopy of tall trees, however, is logistically difficult and has not been widely adopted for large scale monitoring programs (Francese et al. 2008). When testing lures for *A. planipennis* for potential use in large scale monitoring programs, factors such as trap color and placement have to be considered, especially when interpreting sex ratio catch data on different treatments.

Host Volatiles and *Agrilus planipennis*

Agrilus buprestids typically have narrow host ranges; for example, *A. anxius* attacks only birch (*Betula* spp.), *A. bilineatus* attacks primarily oaks (*Quercus* spp.), and *A. planipennis* is reported to attack only ash (*Fraxinus* spp.) in North America and China, although some additional hosts are reported from Japan (Akiyama and Ohmomo 2000). The behavior of insect pests as host specific as *Agrilus* spp. suggests they are finely tuned to their own range of plants and are, therefore, affected by the physical and chemical characteristics of those plants (Jackson 1990). To find specific suitable host tree species surrounded by numerous non hosts requires specialist insect herbivores to evolve and use specific cues that are detectable and efficient (Tahvanainen and Root 1972). Although plant discrimination by some specialist insects may be mediated by certain key stimuli (Städler 1986; Visser 1986; Harris and Foster 1995; Bernays 1996), it is now widely accepted that for most insect herbivores, the decision to accept or reject a host plant is not based uniquely on a few key stimuli but on a large variety of stimulatory and inhibitory plant chemicals acting together (Schoni et al. 1986). Volatile chemicals emitted by plants can provide unique blends that are attractive to specialist herbivores, greatly increasing the efficiency of insect host finding (Miller and Strickler 1984; Visser 1986, 1988; Bernays and Chapman 1994; Bell and Cardé 1995; Dicke 2000). With regard to *A. planipennis* in its native range, ash trees often grow surrounded by non-host trees (Chang et al. 1996), so it would be advantageous to foraging adults to be able to locate *Fraxinus* spp. by using specific host volatiles. The use of host volatiles to locate stressed / infested ash also could be beneficial to *A. planipennis,* as larvae have been observed to develop faster in more heavily infested trees (Cappaert et al. 2005b).



Dunn (1985) reported that adult *A. bilineatus* were able to locate oaks within 24 hours of inducing a stress injury, suggesting that 'tree-stress' volatiles had an important role in tree colonization. This is supported by a further study that found that crude bark distillate of stressed oak trees, when used with sticky-banded trees and vane traps, caught significantly more *A. bilineatus* than did water controls (Dunn et al. 1986).

These findings on this related *Agrilus* species, along with the known attractancy of *A. planipennis* to girdled ash trees (Lyons et al. 2009; McCullough et al. 2009), suggested that the study of volatile attractants in stressed trees warranted further investigation.

Host Volatiles—Bark Sesquiterpenes

Crook et al. (2008b) collected headspace volatiles from the bark tissue at 0 and 24 h after manually girdling green ash (*F. pennsylvanica*) using methods similar to those of Zhang et al. (2000). Ratios of bark-emitted monoterpenes and sesquiterpenes were determined for both girdled and non-girdled

trees. Bark samples taken from girdled trees were seen to have elevated sesquiterpene levels. Gas chromatographic-electroantennographic detection (GC-EAD) revealed that six of the elevated compounds consistently elicited antennal responses in both male and female *A. planipennis*. Mated females gave larger and more consistent antennal responses than virgin females or males (D. J. Crook, unpublished observation), suggesting that mated females potentially used these volatile cues when searching for oviposition substrates.

Crook et al. (2008b) identified five of the antennally active compounds as α-cubebene, α-copaene, 7-epi-sesquithujene, *trans*-β-caryophyllene, and α-humulene (α-caryophyllene). The sixth antennally active compound was identified as eremophilene by Cossé et al. (2008). *Trans*-β-caryophyllene, α-humulene, and α-cubebene are systemic, as they have also been identified in green ash foliar volatiles that elicit antennal responses in *A. planipennis* (T. M. Poland, unpublished data).

These sesquiterpenes have been shown to be potentially important in several other plant-insect systems (Minyard et al. 1969; Pearce et al. 1975; Lanier et al. 1977; McKibben et al. 1977; Minks and Van Deventer 1978; Bejer 1979; Flint et al. 1979, 1981; Blight et al. 1980; Kamm and Buttery 1983; Millar et al. 1986; Vrkočová et al. 2000). Sesquiterpenes are notoriously difficult (and expensive) to isolate, identify, and synthesize (Gershenzon 1993), so natural sources were used for lure development and field testing. Crook et al. (2006, 2007, 2008a, b) found two sources of tree oils that contained high amounts of sesquiterpenes. The first, manuka oil, is a steam distillate from the New Zealand manuka tea tree *Leptospermum scoparium* J. R. and G. Forst (Myrtaceae). Manuka oil contains high amounts of four of the antennally active ash-bark sesquiterpenes: α-cubebene (35 g/liter), α-copaene (48 g/liter), *trans*-β-caryophyllene (24 g/liter), and ~3.4 g/liter of α-humulene. Eremophilene also is present in manuka oil in trace amounts (Cossé et al. 2008). Manuka oil lacks the sixth compound, 7-epi-sesquithujene (Crook et al. 2006, 2007, 2008a, b). The second oil, phoebe oil, is a steam distillate from Brazilian walnut, *Phoebe porosa* Mez. (Lauraceae), which grows in the Araucaria forests of Parana and Santa Catharina in Southern Brazil. This oil contains all six of the antennally active volatiles found in green ash in similar high quantities to manuka oil (Cossé et al. 2008).

Crook et al. (2008b) field tested manuka oil lures, using purple 'prism traps' (APHIS, USDA) set at 1.5 m, as they had previously been found to be visually attractive (described by Francese et al. 2008). Three daily release rates of manuka oil (5, 50, and 500 mg) were compared against unbaited controls. All three manuka oil treatments caught significantly more adult *A. planipennis* (both males and females) than unbaited traps, but there was no significant difference in insect catch among the three manuka oil release rates. Another field study that used purple traps placed at 1.5 m height, by Crook et al. (2008b), tested manuka oil (50 mg/day release rate), phoebe oil (50 mg/day release rate), manuka and phoebe oil (25 mg/day release rate each), and an unbaited trap. They found that all oil lure treatments caught significantly more adults than unbaited traps. Phoebe oil (84 mean trap catch) and manuka/phoebe oil (98 mean trap catch) baited traps caught significantly more insects than manuka oil (46 mean trap catch) traps and unbaited traps (32 mean trap catch). No significant differences were seen in trap catch between the two phoebe oil lure baited traps. Crook et al. (2008b) suggested that the increased catch on phoebe lure baited traps was due to the oil containing 7-epi-sesquithujene, which manuka oil lacked.

These findings showed that the antennally active 'ash' sesquiterpenes present in manuka oil and phoebe oil were attractive to *A. planipennis*. It appears that there is a change in the phloem chemistry of ash after girdling that causes a sudden increase in sesquiterpene levels. These levels are detectable and attractive to both male and female adult *A. planipennis*. Attractiveness of these oils to both sexes is not surprising, as both males and females respond to the sesquiterpenes found in girdled ash aerations, Manuka oil and phoebe oil when examined using GC-EAD techniques (Crook et al. 2008b).

Based on the consistent attractancy of manuka oil to *A. planipennis* in 2005–2007 field tests, the Emerald Ash Borer National Survey program (United States Department of Agriculture, Animal and Plant Health Inspection Service) implemented the use of purple prism traps baited with manuka oil for monitoring purposes in 2008 (Crook et al. 2009). Baited traps detected ten new infestations in 2008, including a new state record in Missouri (http://www.emeraldashborer.info). In 2009, the survey program used purple prism traps baited with a blend of manuka : phoebe oil (ratio 80:20, 50 mg/day nominal release rate). These traps detected 15 new infestations in counties within Kentucky, Pennsylvania, Ohio, Wisconsin, and West Virginia.

A recent study by Marshall et al. (2009b) quantified the capture rates and detection ability of manuka oil and phoebe oil baited traps (green and purple prism traps), along with girdled trap trees, in areas that had high and low population levels of *A. planipennis* (more typical of survey programs). In low beetle population sites, manuka oil baited purple traps, hung at 6 m, caught significantly more *A. planipennis* adults per day than girdled trap trees and green traps. Purple traps baited with phoebe oil or manuka oil had 70–88% detection rates (i.e., at least one adult caught) compared to 47% for girdled trap tree treatments. Adult catch on traps or trap trees was not compared to larval counts in trap trees (that had been peeled later, after the

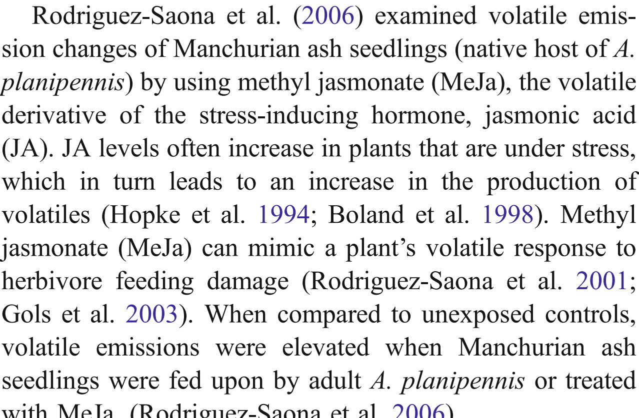
flight season). Marshall et al. (2009b) did mention that some sites with zero *A. planipennis* captured on traps had larvae in trap trees when examined later on. For detection surveys, it is recommended that girdled trees be peeled and examined for larvae because it increases their rate of detection.

Marshall et al. (2009b) also noted that there was a lack of significant differences with regard to traps associated with trees of different vigor ratings. This suggested for the first time that a baited trap may not be impacted by the ash tree from which it is hung. The lure and trap combination is, therefore, more important than the health and vigor of the tree in which it's hanging. Based on this study, baited purple traps (at 6 m) are currently, the most effective and practical method for detecting *A. planipennis* in newly established infestation areas.

There have been attempts to improve efficacy of the bark-oil distillate lures. One issue with the use of manuka and phoebe oil lures is that both oils are mixtures that include ~30 sesquiterpenes and triketones, some of which could potentially have negative effects on lure attractancy. The most recent research has concentrated on eremophilene and 7-epi-sesquithujene, which appear to be the most antennally active volatiles in aerations of both green ash (Crook et al. 2008b) and white ash aeration samples (Cossé et al. 2008). Unfortunately, neither of these biologically active sesquiterpenes are commercially available, and synthesis of 7-epi-sesquithujene is not practical. Eremophilene can, however, be obtained in fairly large, pure amounts through the chemical conversion of the natural ketone, eremophilone, which is commercially available in Buddha wood oil (*Eremophila mitchelli* Benth., *Myoporaceae*) as well as phoebe oil (Cossé et al. 2008). Recent field tests of lures that contain manuka oil and phoebe oil fractions (containing concentrated EAD active components) have not significantly improved trap catch when compared to standard phoebe oil based lures (D. J. Crook and A. Cossé unpublished results).

Host Volatiles—Ash Seedlings and Foliage

Green leaf volatiles (GLVs) are well-studied compounds released by deciduous trees. Their levels can become elevated due to stress from a variety of factors that can include physical damage and insect feeding (Ruther et al. 2000; Zhang and Schlyter 2004; Cossé et al. 2006; Rodriguez-Saona et al. 2006). GLVs can act as kairomones, pheromonal synergists, and host specific attractants for a number of coleopteran species (Dickens et al. 1990; Dickens 2000; Ruther et al. 2000, 2002; Reinecke et al. 2002, 2006; Ruther 2004; Cossé et al. 2006; Fernandez et al. 2007).



Rodriguez-Saona et al. (2006) examined volatile emission changes of Manchurian ash seedlings (native host of *A. planipennis*) by using methyl jasmonate (MeJa), the volatile derivative of the stress-inducing hormone, jasmonic acid (JA). JA levels often increase in plants that are under stress, which in turn leads to an increase in the production of volatiles (Hopke et al. 1994; Boland et al. 1998). Methyl jasmonate (MeJa) can mimic a plant's volatile response to herbivore feeding damage (Rodriguez-Saona et al. 2001; Gols et al. 2003). When compared to unexposed controls, volatile emissions were elevated when Manchurian ash seedlings were fed upon by adult *A. planipennis* or treated with MeJa. (Rodriguez-Saona et al. 2006).

Feeding by *A. planipennis* adults on Manchurian ash seedlings increased daytime volatile emissions by 6.8 times, which was similar to an increase of 6.3 times for MeJa treated seedlings. Olfactometer assays found that volatiles from beetle-damaged or MeJa-exposed ash were attractive to virgin female adult *A. planipennis*, suggesting that females were able to respond broadly to induced volatile emissions independent of the triggering factor. Mated female adults were not tested. Male *A. planipennis* did not respond significantly to insect damaged foliage or MeJa treated volatiles in olfactometer assays (Rodriguez-Saona et al. 2006).

Manchurian ash (considered a 'resistant' ash species that has co-evolved with *A. planipennis* in its native range) has been shown to release higher amounts of volatiles when compared to the highly susceptible North American green ash (Pureswaran and Poland 2009a). It is possible that low levels of volatile release indicate lower host resistance, and also that *A. planipennis* can detect that difference. In general, little is known about the underlying mechanisms that govern the behavior of *A. planipennis* with respect to ash tree resistance (Eyles et al. 2007; Rebek et al. 2008; Chen and Poland 2009).

Rodriguez-Saona et al. (2006) found at least 16 compounds from Manchurian ash that were antennally active to both male and female *A. planipennis*. GLVs elicited the strongest and most consistent antennal responses. Female *A. planipennis* showed a stronger electroantennogram (EAG) response to linalool than males. Male responses were greater to hexanal, (*E*)-2-hexenal, (*Z*)-3-hexenol, 3-methyl-butylaldoxime, 2-methyl-butylaldoxime, and hexyl acetate. Of these, (*Z*)-3-hexenol elicited the largest EAG response overall.

In another study by de Groot et al. (2008), eight GLV's were detected in both white and green ash foliar aeration extracts. These were (*Z*)-3-hexenal, (*E*)-2-hexenal, (*Z*)-3-hexenol, (*E*)-2-hexenol, hexanol, (*Z*)-3-hexenyl acetate, hexyl acetate, and hexanal. Of these, (*Z*)-3-hexenol and (*Z*)-3-hexenyl acetate made up over 80% of the total GLV volatiles emitted by both ash species. GC-EAD test results

were similar to those of Rodriguez-Saona et al. (2006) in that the GLV's were antennally active to both males and females. Males produced larger EAD responses to all the alcohols and aldehydes than females. Females were more responsive than males to hexyl acetate. There was no difference in responses when both sexes were tested with (*Z*)-3-hexenyl acetate. de Groot et al. (2008) also showed that (*Z*)-3-hexenol was by far the most stimulatory volatile among the GLV's tested on males. Male responses to (*Z*)-3-hexenol were two-fold greater than to (*E*)-2-hexenal or (*E*)-2-hexenol at the same test concentration of 7 ng/μl. For females, (*Z*)-3-hexenol was no more stimulating than other GLV's tested.

Between 2004 and 2006, various lure combinations and dosages of these potential GLV's were tested by de Groot et al. (2008) in six field experiments. Males consistently responded to (*Z*)-3-hexenol in four experiments. In an experiment that tested (*Z*)-3-hexenol at two dosages (48 mg/day and 330 mg/day), males showed a positive response to the lower release rate; however, in two other non-dose studies, the 330 mg/day lure was an effective male attractant. Further field tests to establish the most attractive GLV release rate for *A. planipennis* were recommended (de Groot et al. 2008). GC-EAD results by de Groot et al. (2008) did however suggest that male *A. planipennis* were more sensitive to low concentrations of (*Z*)-3-hexenol (<1 ng) and the other GLV's than to higher ones. Hexanol and (*E*)-2-hexenol were not attractive to *A. planipennis* in field tests, and they did not enhance the attractiveness of (*Z*)-3-hexenol. The aldehydes hexanal, (*E*)-2-hexenal, and nonanal were not attractive to male or female *A. planipennis* in field tests despite being active in GC-EAD assays. The development of a GLV lure for *A. planipennis* obviously is a difficult, time consuming, and challenging task when there are numerous GC-EAD active GLV's to field test (at different release rates and in different blends). Of the GLV's tested to date, (*Z*)-3-hexenol, appears to be the most attractive to *A. planipennis*, particularly males, which correlates well to the strong antennal responses seen in the lab (Rodriguez-Saona et al. 2006; de Groot et al. 2008). de Groot et al. (2008) suggested (*Z*)-3-hexenol may serve as an important cue for finding females on foliage in the canopy of ash trees. Interestingly, (*Z*)-3-hexenol also is reported to be a kairomone for chafers (Genus *Melolontha*) in conjunction with a female pheromone (Ruther et al. 2000, 2002; Ruther 2004).

Several field studies have tested *A. planipennis* attraction to GLV based lures with manuka oil lures. McCullough et al. (2008) used a purple "double-decker trap" (a 10 foot tall PVC pipe with two purple prism traps attached at 1.8 and 3 m) to test various lure treatments. These traps were tested in full sunlight away from the edge of ash woodlots, which likely reduced competition from volatiles of nearby ash trees. A four-component leaf-blend lure (*Z*)-3-hexanol, (*E*)-2-hexanol, (*E*)-2-hexanal, and hexanal) developed by Poland et al. (2006) was tested with and without manuka oil lures. Their results showed that the traps baited with the GLV blend or the GLV blend + manuka oil lures caught significantly more *A. planipennis* than manuka oil baited traps. In addition, double-decker traps baited with the GLV blend + manuka oil were able to attract and intercept dispersing *A. planipennis* at least 300 m away from very lightly infested ash trees.

Crook et al. (2008b) tested the same four GLV components used by McCullough et al. (2008) with and without manuka oil lures (50 mg per day release) on individual purple traps at 1.5 m and 13 m heights, along the edges of infested ash stands. A GLV blend was released from individual bubble cap devices (daily release rates were (*Z*)-3-hexenol=3.8 mg, (*E*)-2-hexenol=3.8 mg, (*E*)-2-hexenal=13 mg, and hexanal=13 mg). Unbaited purple prism traps were tested along with three lure treatments (manuka oil + GLV blend, manuka oil alone, GLV blend alone). Overall, traps baited with manuka oil + GLV blend caught significantly more beetles than traps baited with the GLV blend or unbaited traps, but responses to the lures differed somewhat with trap height. When trap data were examined separately by trap height, at 13 m, manuka oil baited traps, with or without GLV lure, caught significantly more beetles than unbaited or GLV-baited traps, and the GLV lure did not measurably enhance effectiveness of the manuka lure. At 1.5 m, traps baited with manuka-oil or GLV caught significantly more *A. planipennis* than unbaited traps but were not significantly different when compared to each other; however, the manuka oil + GLV-baited traps caught significantly more *A. planipennis* than any other treatment. These results showed that the four-component GLV lure could enhance attraction to manuka oil, but its effectiveness appeared to be dependent on trap height. Effectiveness of the GLV lure at 13 m may have been compromised by volatiles from the surrounding ash foliage. Overall, traps caught significantly more beetles at 13 m than at 1.5 m, indicating that there is more *A. planipennis* activity higher in the ash canopy. Similarly, other studies have found that greater numbers of *A. planipennis*, as well as other buprestids, are caught in the canopy as opposed to near the ground (Francese et al. 2007, 2008; Wermelinger et al. 2007) along with observations on beetle behavior in the field (Lance et al. 2007; Lelito et al. 2007a, b; Rodriguez-Saona et al. 2007). Correlation between trap capture and the feeding, breeding, and dispersal habits of other beetle species is not uncommon (Atkinson et al. 1988; Safranyik et al. 2000).

Based on the most recent developments in lures (Crook et al. 2008b; de Groot et al. 2008), trap color (Crook et al. 2009), and trap placement (Francese et al. 2008), Grant et

al. (2009) evaluated (*Z*)-3-hexenol and manuka oil lures in two separate field trials. Phoebe oil based lures were not tested with (*Z*)-3-hexenol. Their first field trial tested lures on purple traps placed at 1.5 m above the ground; the second tested lures on light green traps hung on the lower canopy of small trees (approximately 3 m above the ground). The first test included two other GLV's, (*Z*)-3-hexenal and (*Z*)-3-hexenyl acetate, which had not been field tested previously (de Groot et al. 2008).

On purple traps hung at 1.5 m, (*Z*)-3-hexenol (7.6 mg/day) caught significantly more male beetles than females. Manuka-oil (50 mg/day) baited traps attracted equal numbers of males and females. The addition of (*Z*)-3-hexenal or (*Z*)-3-hexenyl acetate did not enhance purple trap catch in either binary or tertiary mixtures.

On green traps, 7.6-mg and 80-mg daily release rates of (*Z*)-3-hexenol caught significantly more males than females, and more males than the unbaited controls or manuka-oil baited traps. Female counts were similar for all treatments. A combination of the manuka oil and (*Z*)-3-hexenol did not enhance or reduce trap catch when compared to traps baited with just (*Z*)-3-hexenol.

Overall, (*Z*)-3-hexenol produced measurable increases in capture of male *A. planipennis* on sticky traps, and that effect was independent of trap height or color (Grant et al. 2009). Both low and high releases of (Z)-3-hexenol (7.6 and 80 mg) were equally attractive.

The studies by Crook et al. (2008b) and Grant et al. (2009) indicate that bark-released sesquiterpenes and GLV's act independently and affect males and females differently. This most recent study by Grant et al. (2009) supports findings by de Groot et al. (2008) that (*Z*)-3-hexenol does appear to have a role in canopy and/or mate finding by males. In comparison, sesquiterpene emissions from bark tissue may indicate the presence of a stressed ash tree and appear to attract both sexes. GC-EAD responses also suggest males are particularly sensitive to (Z)-3-hexenol (Rodriguez-Saona et al. 2006; de Groot et al. 2008), whereas mated females are more sensitive than males to sesquiterpenes (Crook et al. 2008b). Sesquiterpenes could have an important role for mated females when ovipositing on ash bark. More females than males are usually seen on the bark tissue of ash trees (Lelito et al. 2007b), including freshly girdled ash trees (D. J. Crook unpublished observations).

The one disadvantage of essential oils such as Manuka oil in monitoring programs (which require a standardized bait) is that the chemical composition can vary depending on the geographic region, cultivar, and growing conditions of the extracted plant material (Porter and Wilkins 1999). Despite this, manuka oil and phoebe oil are recommended as an efficient and cost effective attractant for the redbay ambrosia beetle, *Xyleborus glabratus* as they contain high levels of sesquiterpenes found in redbay wood, *Persea borbonia* L. Spreng (Hanula and Sullivan 2008). In comparison to essential oils, (Z)-3-hexenol and other GLV's, are single components that are easily synthesized, relatively inexpensive, and available commercially (Grant et al. 2009).

Final Comments

Despite its continued spread throughout North American ash resources, the known areas of *A. planipennis* infestation have been expanded due to the improvement of detection methods. Effective detection of adults (rather than larvae) now allows for the earlier planning and implementation of silvicultural management strategies by state, provincial and federal, regulatory, and natural resource agencies. This, working in conjunction with public outreach and education activities, will help to delimit and slow the spread of this devastating invasive pest in North America.

Effectiveness of monitoring and detection tools for *A. planipennis* will continue to improve as we learn more about the insect's behavior and biology. The ongoing challenge in developing an optimally efficient trapping methodology for *A. planipennis* will involve finding the best combination of variables such as trap shape, trap color (or other visual properties), trap placement, lure components, as well as the ratios and release rates of those components.

Acknowledgments We would like to thanks Dave Lance and Joseph Francese (APHIS USDA, Otis ANGB) for reviewing earlier drafts of this review. We would also like to thank the three anonymous reviewers for their much appreciated comments and suggestions.

Abstract Infectious diseases affecting livestock and human health that involve vector-borne pathogens are a global problem, unrestricted by borders or boundaries, which may be exacerbated by changing global climate. Thus, the availability of effective tools for control of pathogen vectors is of the utmost importance. The aim of this article is to review, selectively, current knowledge of the chemical ecology of pathogen vectors that affect livestock and human health in the developed and developing world, based on key note lectures presented in a symposium on "The Chemical Ecology of Disease Vectors" at the 25th Annual ISCE meeting in Neuchatel, Switzerland. The focus is on the deployment of semiochemicals for monitoring and control strategies, and discusses briefly future directions that such research should proceed along, bearing in mind the environmental challenges associated with climate change that we will face during the 21st century.

Introduction

Infectious diseases affecting livestock and human health that involve vector-borne pathogens are a global problem, unrestricted by borders or boundaries, which may be exacerbated by changing global climate. The global burden of disease through the impact of pathogens and other infectious organisms, including those transmitted by vectors, can be measured using a number of parameters. For farm animals, this can be measured directly as a reduction in the amount of available food (FAO 2005). This can contribute directly to food insecurity and poverty on a global scale. For human populations, the global burden of disease can be measured in disability adjusted life years (DALYs). Approximately 40% of all DALYs lost can be attributed specifically to vector-borne diseases, along with other major diseases including acute respiratory infections, HIV/AIDS, and TB (WHO 2000). In view of these startling figures, the availability of a range of tools for control of vectors of pathogens is of the utmost importance. The aim of this article is to review, selectively, current knowledge of the chemical ecology of vectors of pathogens that affect livestock and human health in developed and developing countries, based on key note lectures presented in a symposium on "The Chemical Ecology of Disease Vectors" at the 25th Annual ISCE meeting in Neuchatel, Switzerland, with a view to the deployment of semiochemicals for monitoring and control strategies, and to discuss briefly future directions that such research should proceed along, bearing in mind the environmental challenges associated with climate change that we will face during the 21st century.

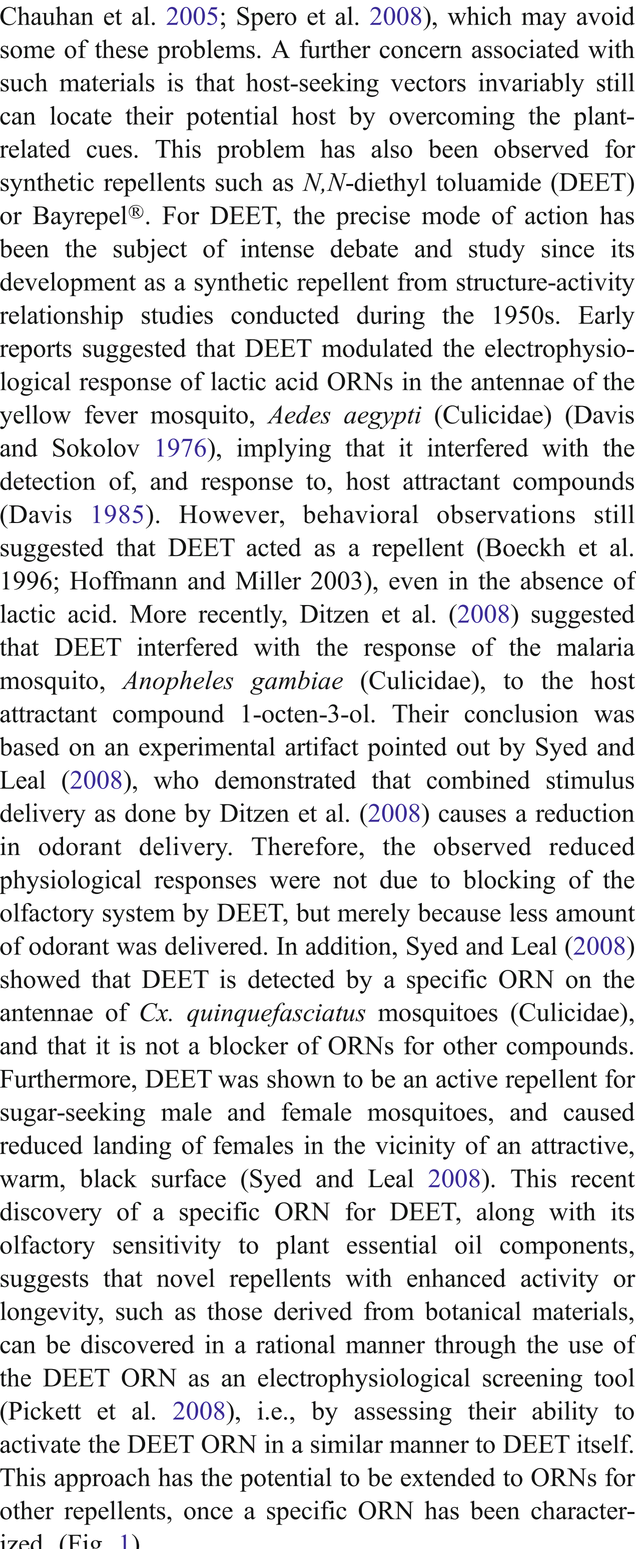
Compounds that act as broad-spectrum toxicants, i.e., insecticides, started to provide the main intervention against pathogen vectors during the latter half of the 20th century, and still do so. These include the synthetic pyrethroid

insecticides, which were largely invented during the 1960s and 1970s by Michael Elliott and his colleagues at Rothamsted (Elliott et al. 1973). However, due to a number of factors, such as the development of insecticide resistance, their perceived negative environmental impact upon human health and the environment, and the cost of maintaining registration of insecticides for pest control, such materials may no longer be acceptable for control of pathogen vectors. In spite of this, the insect nervous system still remains a major target for insect control. The emphasis now, however, relates to non-toxic mechanisms for interfering with pest behavior and development, e.g., host and mate-seeking behavior and oviposition site selection. These are mediated predominantly by the detection of small, lipophilic molecules (semiochemicals) that are detected by specialized olfactory receptor neurons (ORNs) located either on the antennae or on the maxillary palps (Pickett et al. 2009). The potential for manipulating the behavior of vectors of pathogens in host, mate, and oviposition site selection *via* olfactory detection of semiochemicals presents opportunities for their control, *via* the development of novel repellents and attractants, provided they can be deployed through an integrated management strategy, e.g., the push-pull strategy, which has been used highly successfully for pest management in some arable crop systems(Cook et al. 2007; Hassanali et al. 2008).

Hypotheses for Developing Novel Repellents for Pathogen Vectors

The ability to manipulate pathogen vector behavior can be exploited by developing repellents based on hypotheses that relate to evolution of repellency. These fall into three classes: (1) botanicals, (2) non-host species, and (3) host-derived repellents.

Botanicals In conveying a strong plant cue, botanicals interfere with host location by haematophagous (blood-sucking) and biting flies and other arthropods. Although botanically-derived materials such as citronella oil, *Eucalyptus* spp. oils containing *p*-menthane-3,8-diol and eucamalol, and gum resins from members of the Burseraceae have been investigated for use as repellents for human or livestock protection (Nishimura and Satoh 1999; Peterson and Coats 2001; Birkett et al. 2008), the active components are highly volatile, can be readily lost, and therefore lose efficacy at a rapid rate (Lindsay et al. 1996; Chou et al. 1997). Furthermore, these agents also can cause dermatitic problems, so repeated application is not a viable option. However, iridoid nepetalactones produced by *Nepeta* spp. plants (Lamiaceae), and structurally-related compounds, have been investigated as repellents (Bernier et al. 2005;



Chauhan et al. 2005; Spero et al. 2008), which may avoid some of these problems. A further concern associated with such materials is that host-seeking vectors invariably still can locate their potential host by overcoming the plant-related cues. This problem has also been observed for synthetic repellents such as *N,N*-diethyl toluamide (DEET) or Bayrepel®. For DEET, the precise mode of action has been the subject of intense debate and study since its development as a synthetic repellent from structure-activity relationship studies conducted during the 1950s. Early reports suggested that DEET modulated the electrophysiological response of lactic acid ORNs in the antennae of the yellow fever mosquito, *Aedes aegypti* (Culicidae) (Davis and Sokolov 1976), implying that it interfered with the detection of, and response to, host attractant compounds (Davis 1985). However, behavioral observations still suggested that DEET acted as a repellent (Boeckh et al. 1996; Hoffmann and Miller 2003), even in the absence of lactic acid. More recently, Ditzen et al. (2008) suggested that DEET interfered with the response of the malaria mosquito, *Anopheles gambiae* (Culicidae), to the host attractant compound 1-octen-3-ol. Their conclusion was based on an experimental artifact pointed out by Syed and Leal (2008), who demonstrated that combined stimulus delivery as done by Ditzen et al. (2008) causes a reduction in odorant delivery. Therefore, the observed reduced physiological responses were not due to blocking of the olfactory system by DEET, but merely because less amount of odorant was delivered. In addition, Syed and Leal (2008) showed that DEET is detected by a specific ORN on the antennae of *Cx. quinquefasciatus* mosquitoes (Culicidae), and that it is not a blocker of ORNs for other compounds. Furthermore, DEET was shown to be an active repellent for sugar-seeking male and female mosquitoes, and caused reduced landing of females in the vicinity of an attractive, warm, black surface (Syed and Leal 2008). This recent discovery of a specific ORN for DEET, along with its olfactory sensitivity to plant essential oil components, suggests that novel repellents with enhanced activity or longevity, such as those derived from botanical materials, can be discovered in a rational manner through the use of the DEET ORN as an electrophysiological screening tool (Pickett et al. 2008), i.e., by assessing their ability to activate the DEET ORN in a similar manner to DEET itself. This approach has the potential to be extended to ORNs for other repellents, once a specific ORN has been characterized. (Fig. 1).

Non-host Species The response of vectors to compounds from related non-host species is considered more adaptively valuable in their behavioral ecology than the response to botanically-derived repellents. Although there are plenty of anecdotal data to support this, scientific evidence is scarce.

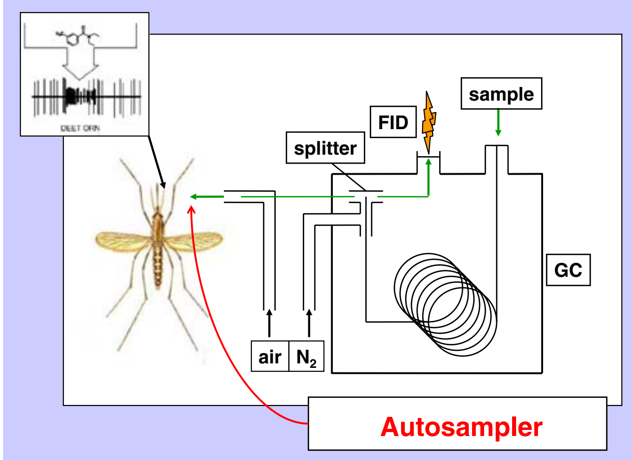


Fig. 1 Active compounds in samples from naturally repellent sources can be identified by gas chromatography (GC)-coupled electrophysiology. By replacing the GC with an autosampler and using a single olfactory neuron (e.g. one which responds to a known plant repellent and also responds to a synthetic repellent such as DEET or a repellent insecticide) compound libraries could be screened for new types of repellent

Evidence is provided, however, from the Morsitans group of tsetse flies, *Glossina* spp. (Glossinidae) that transmit trypanosomiasis (nagana) in cattle (Bovidae). Here, elegant chemical ecological studies have shown that the vertebrate non-host waterbuck, *Kobus defassa* (Bovidae), produces potent non-host repellents for this group of flies (see section below on Afro-tropical vectors). The hypothesis that underpins this work has allowed development of repellents in aquatic ecosystems, for example against the salmon louse, *Lepeophtheirus salmonis* (Copepoda: Caligidae), a major arthropod pest that affects farmed and wild Atlantic salmon, *Salmo salar*, (Salmonidae) populations (Bailey et al. 2006; Mordue (Luntz) and Birkett 2009). It was shown that the non-host fish, the turbot, *Scophthalmus maximus* (Scophthalmidae), produces two compounds, 4-methylquinazoline and 2-aminoacetophenone, which when added to salmon (host)-conditioned seawater, interfere with *L. salmonis* host-seeking behavior (Bailey et al. 2006). Although unclear in this scenario, certainly for Dipterous flies, it is still possible for hosts to be detected in the presence of non-host species. For example, human beings are located easily by anthropophilic mosquitoes such as *An. gambiae*, even when surrounded by cattle (Costantini et al. 2001).

Host Derived Repellents Individuals within an animal population can be extremely unattractive, even to arthropods highly adapted to those species. Similar to the situation for related non-host species described above, there have been plenty of anecdotal accounts to support this hypothesis, but again only recently has evidence been provided on a scientific basis, specifically for Diptera. For dairy cattle, the loading of nuisance and pathogen-vectoring cattle flies (Muscidae) is uneven across a herd of same-breed individual heifers, *Bos taurus* (Jensen et al. 2004; Oyarzun et al. 2009), with the hypothesis being that differential fly-loads are mediated by volatile semiochemicals. Subsequent studies have shown that reduced fly-loads are due to the enhanced production and release of 6-methyl-5-hepten-2-one (MHO), and that addition of slow-release formulations that release this compound to “attractive” cattle could reduce fly loads (Birkett et al. 2004). The presence of “inappropriate” host signaling has been investigated in human beings. Field studies using odor-baited entry traps (OBETs) have shown that the addition of human-specific compounds (*E*)-, (*Z*)-3-methyl-2-hexenoic acid and 7-octenoic acid, major components of human axillary sweat, significantly reduce trap catches of *Anopheles gambiae* s.l. (Costantini et al. 2001). The differential attractiveness of human beings to mosquitoes (Culicidae) and biting midges (Ceratopogonidae) has been studied extensively (Logan et al. 2008, 2009). For the yellow fever mosquito, *Aedes aegypti*, and the Scottish biting midge, *Culicoides impunctatus*, differential attraction has been demonstrated and shown to be due to the presence of enhanced “inappropriate” host signaling, mainly *via* MHO, geranylacetone, octanal, nonanal, and decanal. The ability to reduce upwind flight activity of *Ae. aegypti* by using nanogram levels of compounds is indicative of how such signaling is adaptively valuable in the host-seeking ecology of this mosquito species (Logan et al. 2008, 2009).

Host-Derived Attractants and Attractant Pheromones

For the control of pathogen vectors, host-derived attractants and attractant pheromones can be exploited further by combined use of trapping with repellents as part of a push-pull strategy (Cook et al. 2007; Logan and Birkett 2007; Hassanali et al. 2008). Many pathogen vector species respond to attractants that are derived from host excretory products, such as urine, dung, exhaled breath, and skin secretions, including CO_2, lactic acid, ammonia, acetone, and fatty acids (Logan and Birkett 2007). Studies on the Morsitans group of tsetse flies, *Glossina* spp., (Glossinidae), have identified kairomones from cow odors (Hall et al. 1984) and urine (Owaga et al. 1988). These have been used in baited traps and targets for effective suppression of *Glossina* spp. populations (e.g., POCA; 3-n-Propylphenol: 1-Octen-3-ol: *p*-Cresol: Acetone) (Vale et al. 1988; Brightwell et al. 1991). However, such blends appear to be partially attractive, compared to natural host (cattle) odor, implying that other attractants need to be identified in order to provide full activity.

Pheromones, which although not always directly related to the vectoring component of the pathogen vector life-cycle, are highly species-specific, and, therefore, offer a potent means of vector control, through their deployment in trapping systems. Examples of pheromones for vectors are rare, but *Culex* spp. mosquitoes that are responsible for the transmission of West Nile Virus along with other viruses, and filarial nematodes, utilize an oviposition pheromone, (5*R*,6*S*)-6-acetoxy-5-hexadecanolide, to assess the suitability of an oviposition site (Laurence and Pickett 1982, 1985). This pheromone, which is released from the apical droplets of egg rafts, has been tested successfully in many field trials in several countries in afflicted regions (Otieno et al. 1988; Mboera et al. 2000a, b), and now is commercially available for trapping systems. The pheromone can be deployed effectively if used in conjunction with environmentally benign larvicides, such as the insect growth regulator pyriproxyfen or larvae-specific pathogens such as the fungus *Lagenidium giganteum* Couch (Pickett and Woodcock 1996). Use of the pheromone in such circumstances is tempered by three factors.

First, optimal activity requires use in conjunction with site-derived oviposition cues such as 3-methylindole (skatole), which is derived from stimuli such as decaying organic material or pit latrine water (Mordue (Luntz) et al. 1992; Blackwell et al. 1993; Mboera et al. 2000a), or other compounds such as trimethylamine and nonanal, which also are generated by decaying food material (Leal et al. 2008).

Second, *Culex* spp. mosquitoes habituate to local oviposition site cues. This was illustrated by the adaptation of mosquitoes based at the London School of Hygiene and Tropical Medicine to local, i.e., London, tap water (Pickett and Woodcock 1996). Thus, it appears that local oviposition cues need to be identified prior to their local application. While this may seem initially to be technically challenging, the development of new analytical techniques, e.g., stir bar sorptive extraction (SBSE), offers opportunities for rapid identification of further oviposition cues (Carson et al. 2009).

Third, the production of pheromone for their deployment, while being affordable in developed countries, represents a financial and technical challenge for local production. Thus, higher plants offer alternative, cheap, and renewable resources for production of pathogen vector pheromones in afflicted countries. These include production of the *Culex* spp. oviposition pheromone from the seed oil of *Kochia scoparia* (Chenopodiaceae) (Olagbemiro et al. 1999, 2004), and the sandfly, *Lutzomyia longipalpis*, pheromone, (*S*)-9-methylgermacrene-B, from the essential oil of *Geranium macrorrhizium* (Geraniaceae) (Hooper et al. 2006).

Host Shifts in Pathogen Vectors

Studies on the semiochemicals produced by human and birds hosts of *Culex* spp. mosquitoes revealed that one compound, nonanal, is a significant component of human, pigeon (*Columbia livia*), and chicken (*Gallus gallus*) odor (Syed and Leal 2009). Furthermore, this compound, along with others in host odor, is detected with extreme sensitivity by ORNs on the antennae of *Cx. quinquefasciatus*. Nonanal was detected by a large array of sensilla, and was by far the most potent stimulus. It has been suggested that *Cx. quinquefasciatus* can detect humans and birds, thereby facilitating host shifts, and thus, transmission of West Nile virus among human populations (Syed and Leal 2009). In field experiments, a combination of nonanal and CO_2 acts in a synergistic manner, leading to significantly higher catches of *Culex* mosquitoes in binary traps, compared to individual traps (Syed and Leal 2009).

Molecular Recognition Processes Underlying Pathogen Vector Behavior

The mechanisms that underlie olfactory reception of semiochemicals by insects currently are receiving much attention, with a view to providing new opportunities for pest control, including pathogen vectors. These are primarily targeted at two levels, odorant-binding proteins (OBPs) and olfactory receptors (ORs).

Odorant-binding proteins have been proposed as key agents involved in the movement of semiochemicals across the antennal sensillum lymph towards ORs (Pickett et al. 2009). Genes and cDNAs encoding the OBPs of a number of insect species have been cloned, including pathogen vectors, and recombinant OBPs that have been generated *via* suitable expression systems. The first OBP to be isolated from a mosquito was from *Cx. quinquefasciatus* (Ishida et al. 2002). Subsequent immunohistochemistry studies have shown that this OBP, termed CquiOBP1, is expressed in trichoid sensilla on the antennae that house an ORN sensitive to the oviposition pheromone, (5*R*,6*S*)-6-acetoxy-5-hexadecanolide (Leal et al. 2008). Furthermore, CquiOBP1 exists in monomeric and dimeric forms, with the monomer binding the oviposition pheromone in a pH-dependent manner, with a change in pH resulting in an apparent loss of binding due to changes in secondary structure (Leal et al. 2008). Interestingly, binding studies with enantiomers of the pheromone have shown that the non-naturally occurring antipode have higher affinity than the natural stereoisomer. Since the initial isolation of CquiOBP1, similar OBPs have been isolated from other *Culex* spp., including *Cx. tarsalis* (Ishida et al. 2003), *Cx. pipiens* and

Cx. molestus (Leal et al. 2008). cDNAs for putative OBPs have been isolated from *An. gambiae* (Biessmann et al. 2002).

The availability of genome sequences for mosquitoes has enabled the identification of genes that encode putative OBPs *via* genome and EST database searches. Their expression is detected in antennae by using quantitative real time PCR, and their production by using recombinant technology. These include genes for so-called "Plus-C" OBPs in *An. gambiae* (Zhou et al. 2004), genes for OBPs in anthrophilic *An. gambiae* s.s. and zoophilic *An. arabiensis* (Li et al. 2005), *Ae. aegypti*, and *An. gambiae* (Zhou et al. 2008), and for *Cx. quinquefasciatus* (Pelletier and Leal. 2009). Despite the discovery of putative OBPs for these pathogen vectors and other insects, the molecular recognition processes that involve OBP binding of semiochemicals are yet to be elucidated, Thus, experimental approaches are required that allow measurement of binding and specificity. To this end, several techniques have been developed to measure the non-covalent interaction between OBPs and semiochemicals. These include: (1) fluorescence binding assays, which have been used most recently to study the binding properties of OBPs from *Ae. aegypti* (Li et al. 2008) and the silkworm moth, *Bombyx mori* (Zhou et al. 2009), (2) cold-binding assays, which have been used to study the interaction between native and mutated pheromone-binding proteins (PBPs) from *B. mori*, and the pheromone bombykol (Leal et al. 2005), and (3) electrospray ionization mass spectrometry (ESI-MS), which was used to study the interaction between the *B. mori* pheromone-binding protein BmorPBP1 and bombykol (Oldham et al. 2000). Recently, high-throughput ESI-MS analysis of BmorPBP1 incubated with its' pheromone components (bombykol and bombykal) and analogues has been developed (Hooper et al. 2009). The availability of a high-throughput assay would allow *in vitro* screening of OBPs against compounds identified as pathogen vector semiochemicals, and would provide a means of searching libraries of compounds for new semiochemicals with enhanced activity. However, despite evidence that OBPs appear to be abundant in pathogen vectors and have the potential to be used in their control, functional evidence for the role of OBPs in mediating odor selectivity is still quite sparse, and *in vivo* evidence of their role is required. Studies on insect ORNs (see below) by Carlson and co-workers have apparently shown that ORNs are not matched to their cognate OBPs. This led to a suggestion that OBPs do not play a large role in specifying odor selectivity or sensitivity, at least in *Drosophila melanogaster*.

The identification and functional characterization of ORNs in pathogen vectors also offers new opportunities for control. The peripheral receptor system for *Cx quinquefasciatus*, i.e., maxillary palps and antennal ORNs, has been mapped, with all the sensilla on the palps being shown to house 3 ORNs and respond to CO_2 and plant/floral odors (Syed and Leal 2007). Antennal ORNs were shown in later studies to respond to a variety of chemicals (Syed and Leal 2009). High throughput electrophysiological assays have been used to identify volatile compounds that activate, inhibit, or block ORNs for *D. melanogaster*, with active compounds being tested for behavioral activity (Hallem and Carlson 2006; Kreher et al. 2008). Specialized ORNs that mediate the detection and avoidance of CO_2 have been identified in *D. melanogaster*, and recent studies by Turner and Ray (2009) have proposed that this phenomenon is due to inhibition of the CO_2 ORNs by volatile compounds present in food odor. The authors also report similar inhibition of CO_2 ORNs in *Culex* spp. mosquitoes, and highlight the important role that appropriate inhibitory odorants could have in disrupting CO_2-mediated host seeking behavior in pathogen vectors (Turner and Ray 2009). Similar to the OBP story, this approach potentially can be applied to search for new semiochemicals with superior activity. However, as peripheral responsiveness to stimuli must be integrated by the organism to mediate behavior, this suggests a potential limitation in developing such a strategy.

New Chemical Ecology Studies on Afro-Tropical Pathogen Vectors

The impact of pathogen vectors upon livestock and human health is greatest in sub-Saharan African countries. Chemical ecological research in these countries has been dominated by studies on the attraction of the Morsitans group of *Glossina* spp. tsetse flies, and *Anopheles* / *Culex* spp, mosquitoes to host odors and oviposition cues, as exemplified elsewhere in this review. Nevertheless, novel research is being undertaken that aims to identify: (1) semiochemicals from non-hosts that can be developed for livestock protection, (2) semiochemicals from hosts for the control of vectors of neglected diseases that can be deployed in the protection of livestock belonging to resource-poor farmers, e.g., nomadic communities, who are unable to access more advanced approaches to pathogen vector control, and (3) novel oviposition semiochemicals.

While host-derived attractants have been identified for the Morsitans group of *Glossina* spp. from host breath and urine (see above), more recent studies have focused on feeding preferences, including the existence of non-host allomones produced by the non-preferred host waterbuck, *K. defassa* (Gikonyo et al. 2000). Analysis of the odor composition of preferred (buffalo, *Syncerus caffer*, and ox, *Bos indicus*) and non-preferred (*K. defassa*) species, and electrophysiological studies, have shown that the odors of the two preferred hosts are comparable. They comprise medium-chain, saturated or unsaturated aldehydes and

Springer

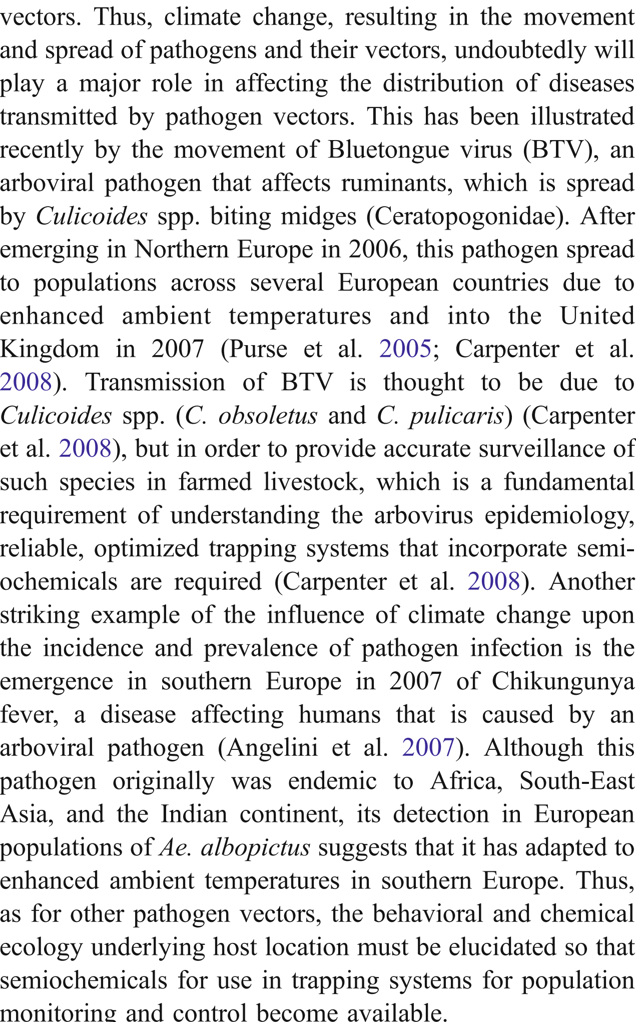
phenolic compounds, with the non-host odor containing fewer aldehydes but more phenolic components and a series of 2-ketones (C_8–C_{13}) and δ-octalactone, and moderate amounts of C_5–C_9 straight chain fatty acids. The electrophysiological responses of *Glossina* spp. show that 2-ketones and the lactone from the non-host odor are physiologically active (Gikonyo et al. 2002). Subsequent behavioral studies have shown that when presented with EAG-active components found specifically in the non-host odor, typical upwind flight behavior of flies is disrupted, with flies avoiding the non-host blend (Gikonyo et al. 2003). The behavioral responses of *Glossina* spp. to putative repellents based on guaiacol (2-methoxyphenol), a known mild repellent, also have been investigated, with the aim of identifying analogues with more potent repellent activity (Saini and Hassanali 2007). Of the compounds tested, the 4-methyl-substituted analogue (4-methylguaiacol) elicited stronger repellent effects, compared with guaiacol. Furthermore, the 4-methyl derivative reduced significantly trap catches of attractant-baited traps, and when applied to ox hosts, reduced the proportion of flies feeding on the host. Application of the repellent to approximately 75% of cattle herds has been shown to protect entire cattle herds (Saini and Hassanali 2007).

The Palpalis group of tsetse flies are responsible for the transmission of Human African Trypanosomiasis (HAT) across sub-Saharan Africa. In order to develop cost-effective control methods for *Glossina fuscipes* spp., the most important HAT vector, the responses of *G. fuscipes fuscipes* to host odors have been investigated in Kenya. Field trapping studies showed that odors from the monitor lizard, *Varanus niloticus*, significantly increased landing responses from *G. f. fuscipes* compared to ox and human odor, thereby suggesting that attractants in the lizard odor can be exploited in developing traps for controlling this major HAT vector (Omolo et al. 2009).

The oviposition behavior of gravid *An. gambiae* mosquitoes, in response to quality of oviposition site water and the density of larvae already at the site, has been investigated. The presence of larvae in distilled water deterred oviposition, but in natural breeding site water, a low density of larvae increased oviposition, whereas a higher density inhibited oviposition. These data suggest that a volatile pheromone is emitted by conspecific larvae, and that a non-olfactory cue deters oviposition at sites with high larval densities (Sumba et al. 2008).

Future Directions

For any vector-borne pathogens, the incidence and prevalence of pathogen infection in animals and human beings is dependent upon the distribution and abundance of their



vectors. Thus, climate change, resulting in the movement and spread of pathogens and their vectors, undoubtedly will play a major role in affecting the distribution of diseases transmitted by pathogen vectors. This has been illustrated recently by the movement of Bluetongue virus (BTV), an arboviral pathogen that affects ruminants, which is spread by *Culicoides* spp. biting midges (Ceratopogonidae). After emerging in Northern Europe in 2006, this pathogen spread to populations across several European countries due to enhanced ambient temperatures and into the United Kingdom in 2007 (Purse et al. 2005; Carpenter et al. 2008). Transmission of BTV is thought to be due to *Culicoides* spp. (*C. obsoletus* and *C. pulicaris*) (Carpenter et al. 2008), but in order to provide accurate surveillance of such species in farmed livestock, which is a fundamental requirement of understanding the arbovirus epidemiology, reliable, optimized trapping systems that incorporate semiochemicals are required (Carpenter et al. 2008). Another striking example of the influence of climate change upon the incidence and prevalence of pathogen infection is the emergence in southern Europe in 2007 of Chikungunya fever, a disease affecting humans that is caused by an arboviral pathogen (Angelini et al. 2007). Although this pathogen originally was endemic to Africa, South-East Asia, and the Indian continent, its detection in European populations of *Ae. albopictus* suggests that it has adapted to enhanced ambient temperatures in southern Europe. Thus, as for other pathogen vectors, the behavioral and chemical ecology underlying host location must be elucidated so that semiochemicals for use in trapping systems for population monitoring and control become available.

Pheromones (sex, aggregation, and oviposition), which although not always directly related to the pathogen transmission stage of the life cycle, also can be incorporated into optimized trapping systems. Although the underlying mechanisms associated with the chemical ecology of oviposition behavior have been studied extensively for *Culex* spp. mosquitoes, e.g., the oviposition pheromone and site-derived cues, such mechanisms need to be appropriately investigated for other vector species.

As stated above, host-derived attractants, and pheromones, can be used in trapping systems for vector population monitoring and control. However, their potential can be fully realized only when used in conjunction with repellents for livestock and human protection. The identification of host-derived repellents, as exemplified by the discovery of 6-methyl-5-hepten-2-one and geranylacetone from human beings (Logan et al. 2008), potentially will provide a new class of repellents that are highly active due to their ecological role in non-host avoidance. Deployment of such repellents that use slow-release formulations is technically challenging, but the availability of novel dispenser technologies will facilitate their commercial

development. A more sustainable approach is to enhance the production of repellents in hosts, by exploring their biosynthesis, and therefore, the genetic factors that are responsible for repellent production.

In addition to identifying new semiochemical tools for improved trapping systems, investigations into the olfactory processes that underlie the perception of semiochemicals also will potentially provide opportunities for improved detection of pathogen vectors, through the development of biosensors based either on whole insects, e.g., honeybee, *Apis mellifera*, olfaction (Pickett et al. 1998), or on over-expressed insect OBPs or ORs. Furthermore, the development of physical sensors such as portable, miniature mass spectrometers, for the detection of pathogen vector semiochemicals also provides a potential route to improved vector detection (Birkett and Pickett 2006).

In summary, in a changing global climate, the movement of vector-borne pathogens requires generation of additional scientific knowledge surrounding their chemical ecology. New and efficient tools for population monitoring and control will be needed that will both be acceptable to the general public, and affordable even to the poorest of communities in afflicted regions. This will be a grand challenge, on a global scale, for chemical ecologists in the 21st century.

Abstract Trail pheromone disruption of invasive ants is a novel tactic that builds on the development of pheromone-based pest management in other insects. Argentine ant trail pheromone, (*Z*)-9-hexadecenal, was formulated as a micro-encapsulated sprayable particle and applied against Argentine ant populations in 400 m^2 field plots in Hawai'i Volcanoes National Park. A widely dispersed point source strategy for trail pheromone disruption was used. Traffic rates of ants in bioassays of treated filter paper, protected from rainfall and sunlight, indicated the presence of behaviorally significant quantities of pheromone being released from the formulation for up to 59 days. The proportion of plots, under trade wind conditions (2–3 m s^{-1}), with visible trails was reduced for up to 14 days following treatment, and the number of foraging ants at randomly placed tuna-bait cards was similarly reduced. The success of these trail pheromone disruption trials in a natural ecosystem highlights the potential of this method for control of invasive ant species in this and other environments.

Keywords Argentine ant · Trail pheromone · Disruption · Trail integrity · Invasive species

Introduction

The Argentine ant, *Linepithema humile* (Mayr), is a highly invasive species that has numerous negative impacts on native arthropods (Gillespie and Reimer 1993; Human and Gordon 1997; Liebherr and Krushelnycky 2007), including other ant species (Human and Gordon 1996; Holway 1999). When a species such as *L. humile* invades remote islands or other ecologically sensitive areas, native arthropod populations may be eliminated quickly causing problems for other organisms, such as plants, which may lose their native pollinators (Cole et al. 1992) and seed dispersers (Christian 2001). In human-modified landscapes, Argentine ants are both a nuisance (Vega and Rust 2001; Holway et al. 2002) and an agricultural pest, impacting the effectiveness of biological control agents in orchards (Moreno et al. 1987; Itioka and Inoue 1996). Poison baits have not proven entirely reliable for control of these pests (e.g., Krushelnycky and Reimer 1998; Hooper-Bui and Rust 2000; Klotz et al. 2000; Greenberg et al. 2006) and also pose risks to pets and wildlife. Thus, more effective and environmentally benign control tactics are needed for the management and control of these invasive ants.

Sensitive ecosystems require appropriate pest-control formulations to avoid non-target impacts at the landscape level. Pheromone-based pest management (e.g., El-Sayed 2009) offers both target specificity and low hazard. This approach could be used for managing invasive ants, such as Argentine ants, in urban or natural ecosystems. To date, exploration of the potential for using pheromones or other odorants for control of ant species has been limited

mainly to leaf cutting ants (Robinson and Cherrett 1978), the red imported fire ant (*Solenopsis invicta*), and the Argentine ant (Robinson and Cherrett 1978; Shorey et al. 1992).

Argentine ants use a trail pheromone, consisting of (*Z*)-9-hexadecenal (Z9-16:Ald) (Cavill et al. 1979), to orient to food and communicate the location of food to nest mates. The compound Z9-16:Ald also is a sex pheromone component of a number of moth species (El-Sayed 2009) and is readily available commercially. Wright (1964) first proposed the use of synthetic pheromones for mating disruption of moths, but until recently there has been no effort to expand this concept to flightless insects, such as foraging ants, through trail pheromone disruption.

Trail-following behaviors of Argentine ants have been well examined (Van Vorhis Key et al. 1981; Van Vorhis Key and Baker 1982). Van Vorhis Key and Baker (1982) recognized that it might be possible to modify trail following behavior by using synthetic compounds, although they did not elaborate on a possible method. The recent demonstration of close-range disruption of Argentine ant trails by using pheromone contained in “twist-tie” polyethylene tubing dispensers showed reduced ant traffic in small plots (Tatsuki et al. 2005; Tanaka et al. 2009). This type of polyethylene-tubing formulation has been used for mating disruption of moths, usually at a density up to one thousand discrete point sources per hectare in orchards and other crops (Suckling and Angerilli 1996; Suckling 2000). However, a discrete point-source approach may not give an effective concentration of trail pheromone to prevent trail following over large areas, except under very still conditions, because pheromone concentration from these dispensers is a function of application height (Suckling et al. 1999). Moreover, the boundary layer, which is the target for trail disruption of ants, is likely to receive the lowest concentration of pheromone.

In previous work, we quantified the integrity of Argentine ant trail-following behavior by video analysis of movement and track angles (Suckling et al. 2008). Trail integrity, defined as r^2 for the position of ants in a video frame, was devised as a measure of the ability of workers to follow a reasonably straight trail, before and after the application of a point source of synthetic trail pheromone. Well-formed trails were completely disrupted indoors by using a crude wax-based formulation. However, due to rapid pheromone release from the wax-coated quartz sand, only several hours of disruption was achieved in small (1 m^2 and 4 m^2) plots (Suckling et al. 2008).

In this study, we examined whether a more durable, sprayable formulation, containing Z9-16:Ald, could be used to disrupt trail-following behavior of Argentine ants in a hot and windy field setting. We used a widely dispersed point-source strategy within the boundary layer where the ants were actively foraging. A micro-encapsulated formulation was chosen for testing because a similar product is commercially available for mating disruption of moth species (Stelinski et al. 2007). The research followed two approaches: 1) laboratory bioassay and micro-plot testing of short-range disruption of trail-following behaviors, and 2) larger field trials to examine impact of disruption on trail formation and recruitment to baits.

Methods and Materials

Chemicals (*Z*)-9-Hexadecenal (94% isomeric purity) was obtained from Bedoukian Research (Danbury, CT, USA) and formulated into a micro-encapsulated sprayable product. The pheromone formulation was prepared by Suterra LLC (Bend, OR, USA), and was similar to that used for light brown apple moth in California (www.cdfa.ca.gov) and other moths (Stelinski et al. 2007), with ca 20% active ingredient as micro-encapsulated particles in water. This formulation had the advantage of being readily dispersible in the field with relatively even coverage of pheromone in the plots.

Field Site The field study took place at ca 1,200 m elevation in an exposed landscape with high Argentine ant populations, windy conditions, and occasional heavy rainfall, on friable cinder soil and rock. The area of Hawai‘i Volcanoes National Park called Broomsedge Burn (19°25′ 59.6″ N, 155°17′35.2″ W; Fig. 1) is mesic to dry ohia (*Metrosideros polymorpha*) woodland now dominated, after fires, by the invasive grasses broomsedge bluestem (*Andropogon virginicus*) and bush beardgrass (*Schizachyrium condenstum*). It is exposed to prevailing trade winds,

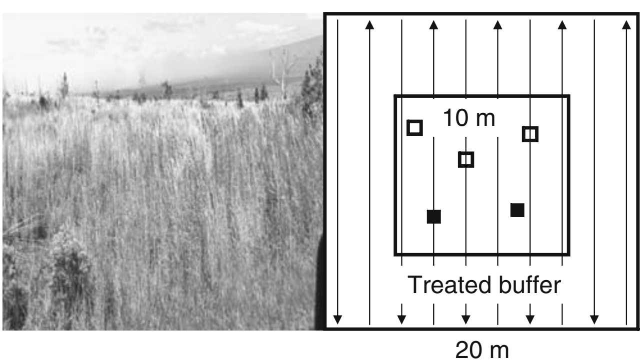

Fig. 1 Layout for trial testing the application of micro-encapsulated Argentine ant trail pheromone, (*Z*)-9-hexadecenal, in Moana Loa in Hawai‘i Volcanoes National Park (*left*), showing 400 m^2 plots treated by 10 swathes using a garden sprayer. Ant trailing and foraging at bait cards were made in the central square (5 m from the plot boundary). Locations were either fixed (*black squares*) at the same location, or randomly (*unfilled squares*) located within the assessment area on each sampling date

averaging 2–3 m s^{-1}, because of sparse canopy cover (Suckling et al. 2008). During the trial, daytime air temperatures of 15–29°C (mean 20.4°C) and ground temperatures of 13–30°C (mean 20.1°C) were experienced. Wind speed at 1 m above ground level ranged from 0.3 to 3.7 m s^{-1} (mean 1.5 m s^{-1}), while at ground level (1 cm) wind speed ranged from 0 to 2.4 m s^{-1} (mean 0.9 m s^{-1}).

Pre-treated Micro-plot Disruption We anticipated that forager numbers would be reduced under pheromone disruption conditions. A dose-response experiment was conducted over a square of paper on aluminum foil-covered boards (21.5×21.5 cm). The papers were treated with 0, 3.7, 37.5, 375, or 3,750 g a.i./ha of sprayable pheromone by using a low-pressure hand sprayer. The top rate was undiluted and only applied for calibration of deposition (7 replicates). Densities of particles on the board were determined with a stereomicroscope. Magnetic stirring of particles was needed because of the buoyancy (flotation) of the pheromone product. Twenty-eight pre-treated boards (5 m separation) were baited with approximately 1 ml of 1:1 macerated tuna (Bumblebee Foods, San Diego, CA, USA) and Karo Light Corn Syrup (ACH Food Companies, Memphis, TN, USA), centered on a plastic-coated card (3× 5 cm). Baits were protected from sunlight and heat with an inverted plastic plate (25 cm diam.) suspended 15 cm above the ground. Counts of ants on the cards were made one hour after bait placement.

Impact on Traffic Rates To test the longevity of the sprayable pheromone, a bioassay that measured the effect of the pheromone formulation on Argentine ant trail traffic was conducted on a 6-m section of ant trail on an external painted cinder block wall in Hawai‘i Volcanoes National Park. Pheromone was sprayed from a height of 1 m onto five 9 cm-diam. circular black craft paper discs (Pacon Corp., Appleton, WI, USA), for ca 0.5 s on 19 February 2008. Bioassays used treated half circles placed opposite each other, 2 cm either side of a vertical ant trail, at 0.5, 2, 4, 24, 48, and 72 h after treatment, then at approximately weekly intervals, for a total duration of 9 week. At each test time, a pre-treatment count of ant movement in a single direction along the trail was made for 1 min by using a bisected unsprayed disc placed along the trail as a control, followed by treated paper. For each observation (5 per date), two measurements of traffic rates were made, each 1 min apart, and pooled as pseudo-replicates (Hurlbert 1984) for analysis. It was expected that the short duration of the bioassay and the lack of complete disruption would enable 5 independent repeats at different locations along the trail but, to be certain, the data were analyzed for a downward trend in traffic. After the counts were completed, the half circles were removed from the trail and stored indoors at ambient temperature until the next test.

Small Field Plot Tests (400 m^2) To test whether treatment of larger areas would facilitate more sustained trail and/or foraging disruption, trials were conducted in 20×20 m plots, each with a 10×10 m central square (Fig. 1). Eight plots, 80 m apart from each other, were randomly designated as treatment (*N*=4) or as control (*N*=4). Trail following and foraging of ants was measured within the central square; the outer area acted as a buffer zone for any influence of wind. Pheromone was applied at a rate of 375 g a.i./ha by using a 3.8 liter garden sprayer (RL Flo-Master®, Root-Lowell Manufacturing Co., Lowell, MI, USA). The pheromone was divided into 10 equal portions so as to ensure uniform delivery of pheromone across the plot (Fig. 1). The sprayer was agitated continuously during application. Control plots were untreated.

Some 2.5 h prior to application of pheromone, five cards, baited with the 1:1 tuna-corn syrup mixture, were randomly placed within the 100 m^2 centers of treatment and control plots (Fig. 1), The number of ants on each card and the presence or absence of trails to each card were determined 0.02 d before pheromone treatment, and 0.02, 0.08, 0.16, 1, 2, 3, 8, 10, 14, 21, 28, and 35 d after treatment. Two of the 5 cards on each plot were randomly selected from those at which well-developed trails had been established (“fixed” locations). At later sampling dates, bait cards were placed at these fixed locations and at 3 new, randomly selected positions (Fig. 1). This differential placement of cards within plots was designed to challenge the ability of the ants to use established trails and to create new trails. Card placement simulated food resources that had either been previously identified by the ants or newly located on each sample date. The 2 fixed or 3 randomized cards from each plot were considered pseudo-replicates (Hurlbert 1984) and pooled for analysis.

The study was initiated on 29 January 2008, with two treatment and two control plots. The other 4 plots were started on 11 February 2008 because of poor weather.

Statistical Analysis Traffic rates and ant counts were log-transformed after initial inspection of the data indicated that this was warranted to stabilize the variance. Disruption in the bioassay and small plot test was calculated as = 100 – (count in the Treatment / count in the Control) * 100. Two-way ANOVA on log-transformed counts of ants was used to analyze the traffic rates for main effects (time and treatment) testing the longevity of the pheromone. Log-transformed counts of ants at baits in the micro-plot experiment were analyzed using two-way ANOVA. The experimental design for the small-plot test was a random-

ized complete block with two factors (treatment and bait card location) at two levels (control, treatment; fixed, random). A general linear model was conducted on log-transformed counts of ants at bait cards to stabilize the variance. The proportion of ant trails at the bait cards in the randomized and fixed plots was predicted using binary logistic regression (Quinn and Keough 2002). This predicted the probability of trail presence at the baits. The dependent-response variable was the presence or absence of ant trails to the cards, modeled using three explanatory factors: randomized/fixed cards, time, and treatment. The data were modeled against reference categories for each explanatory factor; reference categories, randomized = “fixed”, time = “before”, treatment = “no pheromone”. The predicted odds ratio, exp(β), indicated the odds of trail presence for the explanatory factors compared to their respective reference categories (see Stringer et al. 2007 for further explanation). For example, if the odds ratio, exp(β), is 20 for a point in time, then the odds of trail presence is 20 times greater than the reference time (before). A value of 1 would indicate that trail presence after application did not differ from that before. Only the main effects were modeled, as there were no significant interaction effects. Data were analyzed in GenStat (GenStat 2007) and SAS (2004).

Results

Pre-treated Micro-plot Disruption No evidence was found for short distance disruption in recruitment of ants to bait cards ($F_{3,24}$=2.47, P=0.09, mean ± standard deviation 89.6± 49.7 ants/card). There was no correlation between ant counts and the number of particles found on sample papers (r^2=0.15; range 0–6 particles per 38.5 cm^2).

Bioassay of Impact on Traffic Rates Two-way ANOVA revealed a significant effect for treatment ($F_{1,136}$=142.3, P<0.001) and time ($F_{16,136}$=3.41, P=0.001), with no significant interaction between the two factors. There was no impact of untreated cards on traffic rates (number of ants/min) over the course of the study, and no trend in traffic rate among repetitions (P>0.999, df=84). A significant downward trend in traffic rate with time since pheromone treatment was found (% reduction in traffic over time = −0.5083x + 72.92, where x = dose of pheromone treatment; r^2=0.63, P<0.01) (Fig. 2).

Small Field Plot Tests (400 m^2) Argentine ant trails were significantly disrupted shortly after pheromone application and up to 14 days later, measured by a reduction in the presence of visible trails in plots with both types of bait

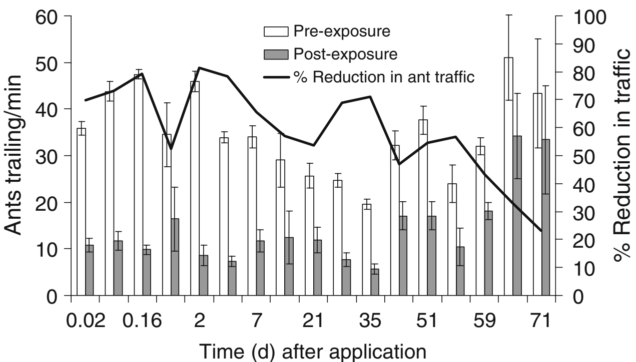

Fig. 2 Effect of application of micro-encapsulated synthetic trail pheromone, (*Z*)-9-hexadecenal, on Argentine ant trail-following over time; measured as mean (± SEM) traffic rates (*left axis*) and % reduction (compared to controls, pre-exposure) of ant counts, post-exposure (*right axis, line*)

locations and treatments (Fig. 3). Following pheromone application, there was a significant reduction in trail presence, with the odds ratio being 28 times less than for trail presence before pheromone application. The predicted odds of trail presence at randomized baits was eight times lower than at fixed bait positions, regardless of treatment (Table 1).

Randomizing the location of baited sites influenced ant counts at baits ($F_{(1,6)}$=19.25, P<0.005), with a reduction in worker number in the treated plots (Fig. 4). However, inspection of results on individual dates showed that the pheromone treatment disrupted ant trail formation on cards (as evidenced by the proportions of cards with trails) longer than it disrupted the counts of ants on cards (Figs. 3, 4, 5). Bait predation by introduced mongoose, *Herpestes javanicus*, occurred in several plots on Day 8. No error bars are shown on this day because of the resultant lack of degrees of freedom.

Discussion

We have demonstrated, using a micro-encapsulated trail pheromone formulation in a natural ecosystem, that significant disruption of trail following by Argentine ants is possible over at least a 14-day period. This is an improvement in longevity of disruption over the wax-based dispersible formulating originally tested, which disrupted visual trails and foraging at bait cards in 4-m^2 plots for only 24 h (Suckling et al. 2008). We also were able to demonstrate significant disruption of foraging by Argentine ant workers for bait cards.

Our bioassay that examined traffic rates proved to be a robust and reliable measure of trail disruption from a point source (Suckling et al. 2008; Tanaka et al. 2009). The

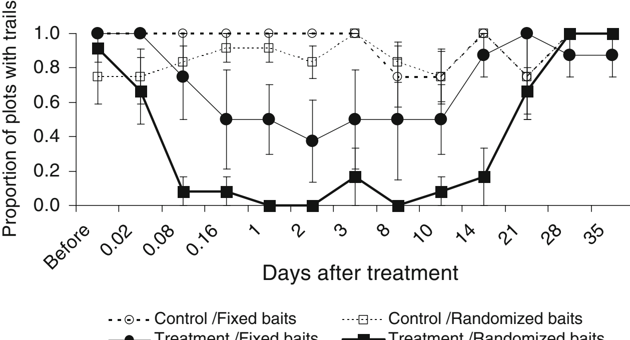

Fig. 3 Proportion of plots with visible Argentine ant trails before and after the 400-m^2 test areas were treated with micro-encapsulated synthetic trail pheromone or left as untreated control. Periodic 1 min observations for presence of trails were made, commencing 30 min after treatment, near baits placed repeatedly in the same location (fixed baits) or replaced at random positions (randomized baits). *Bars* indicate one standard error

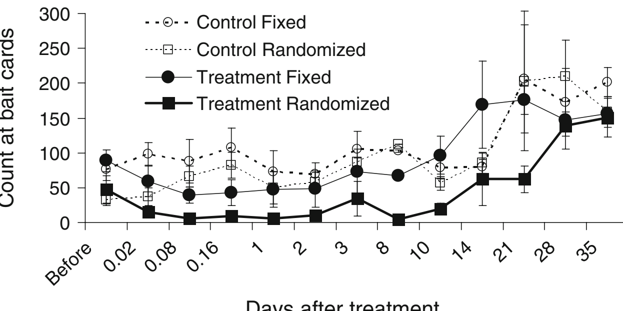

Fig. 4 Mean (±SEM) count of Argentine ants at bait cards before (control) and after synthetic trail pheromone treatment. Cards were placed in the field, repeatedly either at the same location (fixed) or randomly (randomized) within the central 10×10 m of the plot, 2 h before counts. *Bars* indicate one standard error

results showed that the treated bioassay cards, stored in the absence of sunlight or rainfall, maintained their efficacy at disrupting trail following for many weeks. Testing under less favorable conditions should be carried out to determine the robustness of the formulation in the field.

The micro-plot experiments offered a minimum walking distance of 6.3 cm from the edge of the sprayed area to the central bait card for disruption. That complete disruption was not achieved under these conditions, suggests that ant trails were formed near the treated boards, and that foraging ants regrouped onto trails in the vicinity of the bait. Argentine ants can orientate using cues other than trail pheromones to find food resources. For instance, they are known to use food odors (Wolf and Wehner 2000; Stanley et al. 2008), but not vision (Aron et al. 1993), to orient toward food sources. As trail following from the edge of the disrupted boards to the central food was unsuccessful, it appears likely that multiple individual discoveries of the food source were made, rather than a single discovery (or few discoveries) complemented by recruitment through trail pheromone.

The effect of disruption in the larger plots was less pronounced in the situation in which baits were replaced in the same locations (fixed), compared to when their positions were re-randomized. This suggests that ant nests may have learned the location of the fixed baits by associating different cues such as food olfactory cues (Wolf and Wehner 2000) or different pheromones (Dussutour et al. 2009) with the resource. It is not clear whether the responses of the ants to the fixed or randomized baits in this study are typical of ant responses to food supplies such as floral nectar or honeydew from homopterans. Finding of

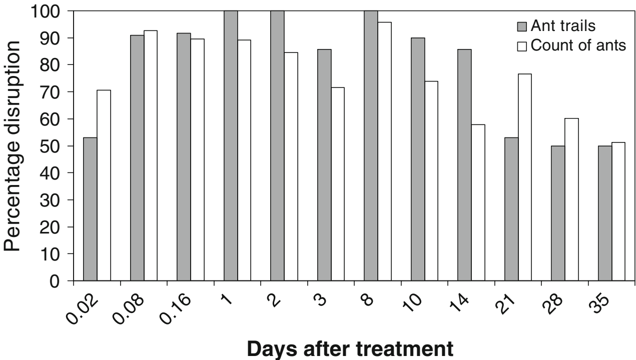

Fig. 5 Percentage trail pheromone disruption (relative to untreated controls) of Argentine ants in small plots (400 m^2) over time, as measured by reduction in presence of trails and ant counts at randomized bait cards

the randomized bait cards probably represents the opportunistic foraging efforts of the nest (i.e., the nest's ability to detect and use new food sources); reduced trail formation and forager numbers to such opportunistic food sources likely results in lesser utilization, and possibly an impact of nest productivity.

With our demonstration of the feasibility of long-duration disruption of Argentine ant trail following using sprayable pheromone, future research should concentrate on improving the efficacy of the method through studying the mechanisms involved both in trail following and disruption of the behavior. Additionally, disruption could be improved by the identification and utilization of other compounds involved in trail following (Cavill et al. 1979). We will continue examining the potential of disruption of pheromone trail integrity as a stand-alone pest management tactic against Argentine ants and as a tactic integrated with other control methods.

Differences and Commonalities in Physical, Chemical and Mineralogical Properties of Zanzibari Geophagic Soils

Abstract The function of human geophagy has long been questioned. We sought to test hypotheses concerning its potential physiological effects through analysis of soils and patterns in geophagy behavior. Eleven samples of geophagic soils consumed by pregnant women on Pemba Island, Zanzibar, Tanzania, were characterized according to their color, texture, major element chemistry, trace element chemistry, bulk mineralogy, and clay mineralogy. An epidemiological study ($N=2367$) and ethnographic interviews ($N=57$) on Pemba yielded information about geophagic behaviors and socio-demographic and biological characteristics of those who consumed earth. The soils varied widely in color, ranging from light red to white through various shades of brown and yellow, and texture ranged from clay to sand. Major element chemistry of the soils also varied greatly; most were low in Fe and Ca. Trace elements, whether of biological or non-biological significance, were uniformly low when compared with normal ranges of mineral soils. The sole commonality among the samples is that all clay fractions were dominated by a kaolin mineral: kaolinite, halloysite, or a mixture of both. Geophagy behavior also varied greatly, with one major exception: a greater proportion of pregnant women (7.1%) and young children (4.5%) consumed earth than non-pregnant women (0.2%) or men (0%). The presence of kaolin mineral in all samples, its palliative and detoxifying properties, and the highest prevalence of geophagy among those most biologically vulnerable suggest that geophagy may be a protective behavior.

Introduction

Geophagy, the purposeful consumption of earth, has long been a source of fascination and puzzlement. Geophagy is a specific type of pica, which is defined as the craving and subsequent consumption of non-food substances. The motivation and consequences of this behavior remain unclear. Geophagy has been documented in many human cultures (Laufer 1930; Anell and Lagercrantz 1958) and throughout the animal kingdom (Jones and Hanson 1985; Kreulen 1985; Krishnamani and Mahaney 2000). It is a very old practice; the first written account of geophagy was by Hippocrates in the 4th century BCE (Hippocrates 1849), but archaeological evidence suggests it dates back to Homo habilis (Clark 2001).

There are three major groups of hypotheses concerning the physiological causes of pica: hunger, micronutrient

deficiency, and protection from toxins and pathogens (Young et al. 2008).

1. The hunger hypothesis posits that people consume non-food substances because they do not have anything else to eat (Laufer 1930).
2. The micronutrient deficiency hypothesis posits that people with micronutrient deficiencies eat non-food substances in an attempt to increase micronutrient intake of Fe (Hunter 1973), Zn (Smith and Halsted 1970), or Ca (Wiley and Katz 1998). Another version of this hypothesis is that a micronutrient deficiency causes disturbed taste sensitivities or malfunctioning of appetite-regulating brain enzymes that cause non-food substances to become appealing (von Bonsdorff 1977). In this scenario, pica is a consequence of micronutrient deficiency, but not an attempt to remedy it.
3. The protection hypothesis states that pica is motivated by an attempt to mitigate the harmful effects of plant chemicals or microbes (Johns 1986; Profet 1992). It is proposed that pica substances protect by either adsorbing pathogens and toxins within the gut lumen or by coating the surface of the intestinal endothelium, thereby rendering it less permeable to toxins and pathogens. According to this hypothesis, overt gastrointestinal distress, which can be the result of exposure to either toxins or pathogens (Simjee 2007), also trigger pica. Additionally, this hypothesis implies that pica substances would be ingested during periods of rapid growth, i.e., the times of greatest need for protection from toxins and microbes. Under this hypothesis, childhood and pregnancy, especially early pregnancy [which is the critical period of organogenesis (Moore and Persaud 1998)], are the periods when pica most likely would occur (Flaxman and Sherman 2000). Pregnant women, who are immunologically suppressed (Formby 1995; Fessler 2002), also may need protection from substances that would normally be harmless.

A limited number of studies have tested these hypotheses, fewer have studied the health status of those practicing pica, and rarer still are studies that have correctly examined the physical, chemical, and mineralogical nature of the soils consumed. In reviewing previous analytical work done on geophagic samples, there are a number of limitations that deserve special attention.

Most published chemical analyses of geophagic earths are not useful for testing the nutritional hypothesis because they are confined typically to the total elemental content, without consideration of the extent to which these elements are biologically available (Wilson 2003; Young et al. 2008). Human gut pH varies from pH 1–2 in the stomach to pH 7–8 in the small intestine, the site of the bulk of nutrient absorption. This fluctuation has major consequences for the bioavailability of elements, and must be considered when drawing conclusions about nutritional benefits.

Second, the amounts of the soils consumed need to be precisely specified; previous researchers have made calculations about intake based on amounts reported from another study, even if that study took place on a different continent, several decades in the past, or in a different age group (e.g., Hunter 1973; Smith et al. 1998).

Third, although it is critical to establish the mineralogy of geophagic samples, especially in relation to the protection hypothesis, previous studies have been vague in the characterization of their mineralogy. For example, halloysite is identified specifically as the main clay mineral in the soils consumed by humans (Aufreiter et al. 1997) and various primates (Mahaney et al. 1993, 1995a, b, 1997; Aufreiter et al. 2001), although Wilson (2003) concluded that the identification of the clay mineral in these papers was ambiguous. The distinction between different kaolin minerals could be important, as kaolinite and halloysite have different particle morphologies (flat platy vs. tubular or spheroidal), which could affect their dispersion/flocculation behavior (Itami and Fujitani 2005), as well as their viscosity and flow characteristics (Yuan and Murray 1997). These properties could be significant in affecting the ability of the clays to coat the gut wall, thereby acting as a barrier to harmful chemicals and microorganisms (Allen and Leonard 1985) and as a stimulant to mucus secretion (Leonard et al. 1994; Theodorou et al. 1994; Gonzalez et al. 2004). Additionally, it may be inferred from some studies of geophagic soils that animals and humans can distinguish halloysitic from kaolinitic soils (Wilson 2003), and knowledge of the exact mineralogy of the soil clays would provide useful information for testing this inference.

In this work, we attempted to increase our understanding of geophagy by a careful characterization of the physical, chemical, and mineralogical properties of 11 samples of consumed earth and then link it to epidemiological and ethnographic data on geophagy behavior. We performed these analyses to identify commonalities that may yield clues to the physiological motivation for the selection and consumption of these materials.

Methods and Materials

Study Site and Sample Collection Pemba was chosen as an appropriate research site because geophagy is a well-established practice there (Young and Ali 2005). Pemba is the second largest island in the Zanzibar archipelago located 50 km off the coast of Tanzania. The archipelago is part of the ancient Miocene Rufiji/Ruvu delta, and most

of Pemba is underlain by alluvial formations of Miocene age (Stockley 1942). Similar Miocene alluvial formations host the Pugu kaolinite deposits to the west of Dar es Salaam on the East African mainland. In general, the culture and ecology of Pemba are similar to the rest of coastal East Africa (Middleton 2004).

The geophagic earths for analysis were selected based on results from a large epidemiological study of maternal anaemia and pica in an obstetric population conducted between 2004 and 2006 (N=2367). Additionally, in-depth interviews about pica were conducted with a sample of 57 individuals who had professed their pica behavior. Participants in in-depth interviews were either pregnant participants in the larger study or resident in a study participant's household. Four respondents were male, and recounted their pica behaviors during childhood.

The 4 types of earth consumed in Pemba are known in Swahili as *udongo*, *mchanga*, *vitango pepeta* and *ufue* (Fig. 1). *Udongo* is a fine reddish-brown clayey earth that is found close to the surface or in termitaria, and is used in making structures like house walls. *Mchanga* is the sandiest of the earths eaten, and is collected close to the surface. It is often exposed during the construction of wells or latrines. *Vitango pepeta* (also called *vitango mlima*) consists of large soft light-colored chunks of earth, and is obtained from closer to the surface of the earth than *ufue*. *Ufue* is much whiter than *udongo* and is found by digging from 5 to 50 cm into the earth's surface. The terms *ufue* and *vitango pepeta* are frequently used interchangeably by consumers.

In the large epidemiological study, women were asked about their pica behavior in two questions: if they ate *udongo* and if they ate *vitango pepeta* or *ufue*. *Mchanga* was not inquired about because it was consumed far less frequently. The interviews with those who had engaged in pica lasted from 30–75 min, and covered the many pica materials consumed in Pemba, including the 4 earths. A number of other pica substances are consumed on Pemba, including uncooked rice, charcoal, ash, ice, chalk, and ground shell, but are beyond the scope of this paper (Young 2008).

During interviews, participants were asked how samples were identified, collected, stored, and prepared, as well as about the attractiveness of various qualities, e.g., color, texture, flavor. After the interview, a Pemban fieldworker and/or an author (SLY) accompanied participants to the source of the pica substance if they were still engaging in pica. The consumer then collected precise amounts of the materials they consumed, as well as a large amount for subsequent analysis. Of the 57 participants in in-depth interviews, 26 had eaten *udongo*, 10 had eaten *ufue*, 13 had eaten *vitango pepeta*, and 2 had eaten *mchanga*.

The samples chosen for laboratory analysis were selected to reflect the frequency of consumption reported of each type of earth in the interviews. In this study, five *udongo* samples (2 from house walls and 3 from soil exposures), two *ufue* samples (both soil exposures), three *vitango pepeta* samples (all soil exposures) and one *mchanga* sample (soil exposure) were characterized (Table 1). The study would have been strengthened by the analysis of undesirable samples, i.e., samples that were not considered suitable for consumption. This will be rectified in subsequent studies.

Sample analysis The color of the samples was established objectively by reference to a Munsell chart, which describes colors in order of their hue (actual color), value (degree of lightness), and chroma (strength of color). Soil pH measurements were made by an electrometric method that used glass-calomel electrodes on soil suspensions in a soil: water ratio of 1:2.5 following the procedure for agricultural soils outlined by Peech (1965). Particle size analysis was made by laser light scattering (diffraction) by using a Malvern Mastersizer 2000.

Determination of both the major and minor elements in the geophagic samples was done by X-ray fluorescence analysis (XRF). This is the method of choice for inorganic materials because the instrumentation is widely available and has become the standard method for the analysis of major and trace elements of rocks following the procedures developed by Norrish and Hutton (1969) and Leake et al. (1969). XRF analysis is performed on pressed-powder discs and involves no pre-treatment other than a simple crushing and milling procedure.

The mineralogy of the geophagic materials was determined by X-ray diffraction (XRD) methods. Bulk samples were micronized in water in a McCrone mill, and the resulting slurries spray dried as described by Hillier (1999). XRD patterns were obtained from the spray dried random

[a] Not all participants discussed all facets of their geophagic behavior, so the information in each cell does not always sum to the number of respondents

powder samples by scanning from 2 to 75°2Θ, in 0.02 steps, counting for 2 seconds per step on a Siemens D5000, using Co Kα radiation, selected by a diffracted beam monochromator. Bulk mineralogical composition was determined by a full pattern fitting reference intensity ratio method as described in detail in Omotoso et al. (2006). For further characterization of the clay minerals, <2 micron clay fractions were separated from the bulk samples by sedimentation, and dried down onto glass slides. The resulting oriented preparations were scanned on the D5000 diffractometer, from 2–45°2Θ, with 0.02° steps, counting for 1 second per step, in the air-dried state, following solvation with ethylene glycol by a vapor pressure method and after heating to 300°C for 1 hour (Wilson 1987).

Identification of certain clay minerals requires the use of supplementary treatments. Distinguishing halloysite from kaolinite is done through the rapid formation of an intercalation complex with formamide (Churchman et al. 1984). Clay fractions sedimented onto glass slides were examined before and after treatment with formamide to determine the presence of halloysite. These samples were run on a Panalytical X-pert Pro diffractometer, using Ni-filtered Cu Kα radiation with an X-celerator position sensitive detector. Both the air-dried and the subsequently formamide-saturated clay samples were scanned from 2–45° 2Θ, the total scan taking approximately 7 minutes to complete. Formamide treated specimens were scanned 30 minutes after contact with formamide.

Coherent fragments of the materials were mounted onto standard SEM stubs using carbon paint as the adhesive coated with gold. The prepared samples were analyzed by using a Philips XL30 Field Emission Scanning Electron Microscope (FEG-SEM) operating at an accelerating voltage of 20 kV. Characterisation of the various minerals was aided by Energy Dispersive Spectroscopy (EDS), which provides an elemental composition of the material analyzed. The EDS detector is equipped with an ultra-thin window that allows detection of elements down to carbon.

Results

Geophagy in Pemba There was great variety in the collection and consumption of soils (Table 1). Most participants collected their own soils. There were many sites from which they could be obtained, including the walls of houses, agricultural fields, and hills. Some soils were prepared carefully by heating or cleaning, while others were eaten as found. Most consumers were not able to explain why they had cravings for earth, although a few mentioned nausea and excess salivation. The amounts consumed ranged from 18.4 to 180.2 g, and the frequency of daily consumption ranged from 1 to 20 times. Consumers frequently were enthusiastic about liking the smell and taste of the soils, but in non-specific ways. Many answers to inquiries about what they liked about it were variations of "It's just so good!". To better understand the smell and taste they experienced, we asked if there were items that the soil reminded them of.

One clear commonality in behavior is that most geophagy occurs during pregnancy. Of the 2,367 pregnant women interviewed, 169 (7.1%) stated that they had eaten earth in the course of their current pregnancy. Of children 2–5 years old, 4.5% engaged in geophagy, 0.2% of non-pregnant women engaged in geophagy, and no adult men or elderly men or women engaged in pica (Young 2008). No data are available on the behavior of 5–18 year olds. The marked relationship between geophagy and pregnancy was reinforced by participants' comments; many of them ceased craving earth after giving birth and thought that geophagy was "good" only if pregnant (Table 1).

Physical Characteristics Macroscopic Appearance Although the geophagic materials typically are described as "soils", a more accurate description for some would be "saprolites" in that they resemble decomposed and easily disaggregated rock, such as that often found at the base of soil profiles developed by *in situ* weathering (Table 2). Colors were highly variable, ranging from white to different shades of brown and red. Large textural differences also were apparent, with *udongo* and *mchanga* samples being sandy, whereas the *ufue* and *vitango pepeta* ones were more clay-rich. The latter appeared to consist of weathered shale or clay, while *udongo* and *mchanga* probably represented alluvial sandy material.

pH and Clay Content There was a surprisingly large range of pH values and proportion of clay and non-clay fractions (Table 3). Alkaline pH values characterized the *udongo* and *mchanga* samples, with one sample (835) yielding a pH of

Table 2 Color and macroscopic description of 11 geophagic samples from Pemba

Sample number	Name	Munsell color	Description
818	*Udongo*	Very pale brown (10YR 8/3)	Coarse blocky structure; sandy texture; contains fragments of carbonized wood; slakes immediately in water.
832	*Udongo* (house)	Light yellowish brown (2.5Y 6/3)	Sandy material containing white inclusions and organic matter; slakes immediately in water.
835	*Udongo* (house)	Dark grayish brown (10YR4/2)	Sandy material received in crushed disaggregated state; some white grains observed.
839	*Udongo*	Light brownish gray (2.5Y 6/2)	Blocky, slightly indurated sandy material; porous structure with some rootlets; slakes immediately in water.
849	*Udongo* (house)	Light red (2.5YR 6/6)	Coarse blocky decomposed material of silty texture; light and porous; slakes immediately in water.
833	*Ufue*	White (5Y 8/1)	Clayey sand; disperses easily but doesn't slake.
845	*Ufue*	White (7.5YR 8/1) with pinkish white (7.5YR 8/2) variegations	Soft decomposed clayey material; very coarse blocky; disperses easily but doesn't slake.
834	*Vitango pepeta*	Reddish yellow (7.5YR 7/6) with some red patches (10R 4/6), others pinkish white	Coarse blocky material, soft and decomposed; strongly variegated and patchy in color; clayey/silty texture.
812	*Vitango pepeta*	Pale whitish yellow (2.5Y 8/3) with yellowish (10YR 8/8) mottles	Coarse platy structure; weathered shale; clayey; disperses easily but doesn't slake immediately.
842	*Vitango pepeta*	White (7.5YR 8/1) with pink (7.5YR 8/2) patches on weathered surfaces	Soft decomposed clayey material; coarse crumbs (>10 mm) and medium blocks (10–20 mm); disperses easily but doesn't slake.
838	*Mchanga*	Pale yellowish (2.5YR 7/3)	Fine sandy material.

Table 3 pH and particle size analysis (%) data of 11 geophagic samples from Pemba

Sample number	Material	pH (H_2O)	<2 μm	2–20 μm	20–2000 μm
818	*Udongo* (field)	7.20	8.2	7.5	84.2
832	*Udongo* (house)	7.62	11.0	11.7	77.3
835	*Udongo* (house)	10.44	12.8	11.9	75.3
839	*Udongo* (field)	8.17	6.5	5.3	88.1
849	*Udongo* (field)	4.72	13.8	7.9	78.3
833	*Ufue*	5.02	4.8	15.6	79.6
845	*Ufue*	4.95	25.9	12.3	61.8
834	*Vitango pepeta*	4.94	22.9	25.2	51.9
812	*Vitango pepeta*	4.80	33.6	31.6	34.8
842	*Vitango pepeta*	4.54	17.6	23.0	59.4
838	*Mchanga*	8.45	0.7	1.4	97.9

10.4. This sample came from a house wall to which lime may have been added. In contrast, the *ufue* and *vitango pepeta* materials were distinctly acidic with pH values in the 4.54–5.02 range. Analysis of the clay contents confirmed the impression gained from the assessment of texture, with the *mchanga* sample containing <1% clay in contrast to *vitango pepeta* with 23–34% clay.

Chemical Characteristics. Major Elements Both *udongo* and *mchanga* samples were very siliceous; total silica contents ranged from 77 to 94% and with correspondingly low alumina and ferric oxide contents (Table 4). Values for alkalis and alkaline earths were variable. In contrast, the *ufue* and *vitango pepeta* samples were less siliceous and more aluminous. In the former, ferric oxide contents were comparable to those of *udongo*, and alkalis and alkaline earths showed a slightly smaller range of values. The *vitango pepeta* samples, however, were more iron-rich than any of the samples, with ferric oxide ranging from 1.56 to 8.06%.

Trace Elements Total trace element contents of the geophagic soils (Table 5) usually were lower than the range of values found for mineral soils with <5% organic matter derived from all types of parent materials, as assessed by Mitchell (1964). Not all trace elements analyzed are of biological significance from either a nutritional or toxicity point of view, but for the sake of completeness all results are shown. Trace elements of interest in the context of human nutrition, Co, Cu, I, and Zn, are all in the low or normal range when compared to the usual range in mineral soils. The same is true of trace elements such as As and Pb, which are associated with toxicity.

Mineralogical Characteristics. Bulk Soil Analysis Mineral analyses of the bulk soils (Table 6) were reasonably consistent with the results of bulk chemical analysis (Table 4). The *udongo* and *mchanga* samples were quartz-rich with contents ranging from 69–92% and corresponding closely with SiO_2 values. In contrast, the clay-rich *vitango pepeta* samples contained smaller amounts of quartz (4–35%) and higher kaolin contents (58–95%) corresponding to their lower SiO_2 (52–62%) and higher $A_{12}O_3$ (23–35%) values. The *ufue* samples occupied a position intermediate between *udongo* and *vitango pepeta* with respect to quartz and kaolin contents. The main iron oxide mineral in the geophagic soils was goethite [FeO(OH)] rather than hematite (Fe_2O_3), with *vitango pepeta* samples being the most goethitic (8–11%) and correspondingly having the highest ferric oxide content (1.6–8.2% Fe_2O_3). There is a general correspondence between amounts of calcite and K-feldspar, particularly at the high end of the range, with CaO and K_2O values, respectively.

Clay Mineral Analyses Clay fractions of the geophagic soils were all dominated by kaolin-type minerals (Table 6). Representative XRD traces of the clay fractions from the various geophagic soils are shown in Fig. 2. In determining the relative kaolinite/halloysite contents of the soils, an initial assessment was made by comparing the intensities of the basal reflection at ~10 Å, due to the formation of the formamide/halloysite complex with the basal reflection at ~7Å, which represents the uncomplexed kaolinite mineral. From this, it was evident that kaolinite was dominant in 5

Table 6 Relative kaolinite/halloysite contents in the clay fractions of the geophagic soils as assessed from visual inspection of the XRD patterns before and after formamide treatment

A small amount of gibbsite is indicated (peak at 4.85Å). Two *Ufue* soil (sample 833) showing dominance of halloysite (strong peak at 10Å) over kaolinite (weak peak at 7Å) after formamide. A small amount of gibbsite is indicated (peak at 4.85Å)..*Vitango pepeta* soil (sample 812) showing dominance of halloysite (strong peak at 10Å) over kaolinite (weak peak at 7Å after formamide). Other features of these patterns suggest that this clay may be interstratified with smectite*, Vitango pepeta* soil (sample 834) showing dominance of kaolinite (strong peak at 7Å) over halloysite (weak peak at 10Å) after formamide

of the 11 samples, halloysite was dominant in 3 samples and sub-dominant in 1 sample (Table 6). In 2 samples, there were roughly equal amounts of both minerals. Both *ufue* and *vitango pepeta* samples could be either kaolinite dominant or halloysite dominant. *Udongo* tended to be kaolinite dominant whereas *mchanga* was more halloysitic. Quantification of the two minerals by a full pattern fitting method yielded results that were consistent with this initial assessment (Table 7), apart from sample 812 that had special features concerning mixed layering. Most clays also contained minor to trace amounts of gibbsite ($Al(OH)_3$), a mineral characteristic of highly weathered soils.

SEM Observations Geophagic materials examined by SEM included one sample of *udongo* (818), one of *ufue* (833), and two of *vitango pepeta* (812, 834) (Fig. 3). At low magnification, the *udongo* sample was found to consist of dense masses of aggregated clay arranged in a sub-parallel fashion that coated and bound together the majority sand-size particles (Fig. 3a). Clay coatings often have a globular appearance, but high magnification showed that they are composed primarily of individual, equant, flat, platy particles ~100–500 nm diameter (Fig. 3b). Occasional elongated particles also were observed. EDS analysis of the fine-grained particles revealed a dominance of Si and Al in roughly equal proportions, consistent with their identification as a kaolin mineral and with the XRD analysis of the clay fraction as being kaolinite-dominant.

The *ufue* sample also showed individual sand grains bound together by globular aggregates of clay. In some cases, the clay was observed to coat relatively fresh surfaces of feldspar (Fig. 3c). Higher magnification revealed that the coatings consisted of spherical micro-aggregates about 5 μm diameter and consisted of radially-arranged tube-like or lath-like particles that imparted a pin-cushion appearance to the micro-aggregate as a whole (Fig. 3d). Individual particles are 1–2 μm long and

Total-clay is sum of kaolin/smectite, kaolinite, and halloysite

Fig. 3 SEM images and EDS spectra of selected samples **a**: *Udongo* (818) showing aggregated clay coating and binding sand particles together. **b**: *Udongo* (818) showing platy morphology and small size of constituent particles. **c**: *Ufue* (833) showing clay layer with globular morphology coating relatively unweathered feldspar grain. **d**: *Ufue* (833) showing delicate tubular morphology of halloysite with a pure Al, Si, and O composition. **e**: *Vitango pepeta* (834) showing open sandy texture and binding network of clay. **f**: *Vitango pepeta* (834) showing crinkled mass of platy clay particles containing minor Mg in their composition. **g**: *Vitango pepeta* (812) showing aggregated clay texture. H: *Vitango pepeta* (812) showing crinkled platy morphology and curled edges of constituent clay particles, also containing minor Mg in their composition

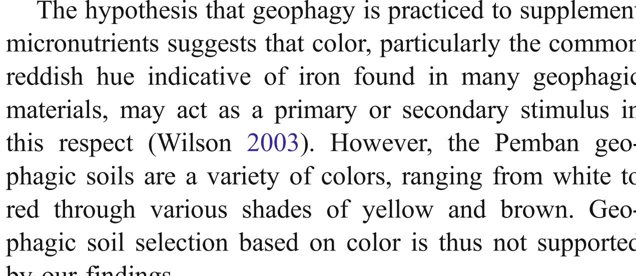
~0.2 μm diameter. The morphology of these particles is identical with that of tubular halloysite. Identification as halloysite is consistent with both the EDS analysis that showed Si and Al in equal proportions, and with the XRD analysis of the clay fraction.

The two *vitango pepeta* samples examined by SEM had somewhat different clay contents and, according to both clay fraction and bulk sample XRD analyses, also differed in the relative importance of kaolinite, halloysite, and mixed-layer kaolin. Sample 834 was kaolinite-dominant whereas sample 812 appeared to consist mainly of mixed-layer kaolin/smectite of halloysitic character with respect to the formamide test. Low magnification SEMs of 834 showed sandy material with abundant pore space held together by a meshwork of clay coatings over relatively fresh quartz and feldspar grains (Fig. 3e). The clay itself was composed of a crinkled mass of flat, platy particles, often with curled edges, about 1–2 μm diameter (Fig. 3f). There was abundant micro-pore space between the platy particles. The clay-rich nature of sample 812 is evident from low magnification SEMs, the whole consisting of crinkled flakes and aggregates arranged in sub-parallel fashion and with abundant void space (Fig. 3g). The constituent particles were mostly of an equant, platy shape, often bent or sinuous with curled edges, and ranged from ~0.5 to 2 μm diam (Fig. 3h). These crinkled, curled, and sinuous morphologies lend support to the identification by XRD of kaolin/smectite in the *vitango pepeta* samples. Furthermore, in both samples EDS analysis showed that the composition of the clay particles may be different from those described for *ufue* and *udongo* above in that they have a slightly higher Si:Al ratio and minor, but obvious, K, Mg, and Fe contents. Although minor in amount, the presence of Mg in the *vitango pepeta* clay particles is significant because it is consistent with the relatively high MgO content of the bulk *vitango pepeta* samples as determined by XRF (Table 4).

Discussion

In general, the geophagic soils we analyzed were highly variable in color and chemical composition, and had low concentrations of trace elements. The sole commonality was the presence of a kaolin mineral. Geophagy was practiced almost uniquely by pregnant women and young children.

No respondents described eating earth as a response to hunger or because other food was not available (Table 1). There was no significant difference in economic status or food intake between geophagists and non-geophagists (Young 2008). Therefore, hunger does not explain geophagy in this population.



The hypothesis that geophagy is practiced to supplement micronutrients suggests that color, particularly the common reddish hue indicative of iron found in many geophagic materials, may act as a primary or secondary stimulus in this respect (Wilson 2003). However, the Pemban geophagic soils are a variety of colors, ranging from white to red through various shades of yellow and brown. Geophagic soil selection based on color is thus not supported by our findings.

A second piece of evidence against the micronutrient deficiency hypothesis is the highly variable major chemical composition of the geophagic soils. *Ufue* and *vitango pepeta* soils are extremely low in Ca (<0.2% CaO), whereas the concentration in *udongo* soils is variable. Indeed, the correlation of CaO with calcite in *udongo* samples from house walls suggests that the CaO content is a result of lime addition during construction, rather than a property of the original soil. As for Fe, the *vitango pepeta* samples are notably rich in this element (1.6–8.1% Fe_2O_3), whereas all of the other soils, with one exception, are poor (<1% Fe_2O_3).

Furthermore, the concentrations of trace elements of biological significance in the soils are uniformly low when compared to the usual range found in all types of mineral soils. It is difficult to conceive that such a negative similarity could act as stimulus to the selection of soils to be consumed. Furthermore, micronutrient cravings have yet to be identified in humans (Johns and Duquette 1991).

Our research would be strengthened by determining the bioavailability of these trace elements. However, it is probable that none of them is bioavailable to any significant extent because of the highly weathered nature of the soils. Weathering tends to remove mobile or "available" nutrients leading to a highly leached soil where any nutrient elements are associated with resistant minerals not susceptible to decomposition. Furthermore, the dominant mineral form of Fe is goethite, which is the least soluble of any of the common iron oxide minerals (Schwertmann and Taylor 1989). It seems unlikely that geophagists are regularly obtaining any mineral nutrients from these soils.

It has been suggested that geophagic soils are selected because of their pleasant unctuous texture associated with richness in clay (Wilson 2003). Clayey soils are consistent with the protection hypothesis; a number of clays have been proven efficacious at quelling gastro-intestinal distress and detoxifying harmful pathogens and chemicals (Gonzalez et al. 2004; Leonard et al. 1994; Theodorou et al. 1994). However, our data show that the texture of these soils is extremely diverse ranging from sand, i.e., *udongo* and *mchanga* materials that consist predominantly of quartz, to clay i.e., *vitango*

pepeta largely made up of clay minerals. The *ufue* soils form an intermediate group between these two extremes. Selection of these geophagic soils simply on the basis of overall clay mineral content is not supported by the findings presented here, although it is notable that the four Swahili names are obviously correlated with total clay mineral content as determined by XRD.

Despite the many differences, the samples have one similarity: clay mineralogy. All clay fractions are dominated by a kaolin-type mineral, either kaolinite, halloysite, or a mixture of both. Additionally the *vitango pepeta* samples contain a significant amount of kaolin/smectite. Thus, it seems that the dominant type of kaolin mineral in the Zanzibar geophagic soils could be kaolinite, halloysite, or kaolin/smectite. This mineralogical similarity is consistent with the protection hypothesis, given that kaolin minerals have long been used in pharmaceutical formulations to both treat the causes and the symptoms of gastrointestinal distress (Vermeer and Ferrell 1985; Wakibara et al. 2001; Carretero 2002). The beneficial role of the kaolin minerals is based upon their ability to coat and adhere to the gastric and intestinal mucus membrane, thus protecting against toxins, bacteria, and viruses, and adsorbing excess water in the feces. (Allen and Leonard 1985; Leonard et al. 1994; Theodorou et al. 1994; Gonzalez et al. 2004).

It is plausible that the occurrence of kaolin-type minerals in all Zanzibari geophagic soil samples serves to protect the health of the consumer. The high prevalence of geophagy during pregnancy and early childhood, the times during which individuals experience the greatest biological vulnerability, lends support to this hypothesis. However, future analyses of Pemban soils must include mineralogical analysis of those not eaten, to ascertain that the clay mineralogy of all soils in Pemba is not dominated by kaolin.

No one has yet elucidated a mechanism by which humans can identify the presence of kaolin minerals in soils. One clue perhaps is the importance of smell in the selection of geophagic materials. The scent of earth, especially when wet, has been mentioned by many geophagists around the world (Hooper and Mann 1906; Forsyth and Benoit 1989; McIntyre 2000). Further study of human's capacity to identify and distinguish between odors of different clay minerals could be done easily, and may contribute further to our understanding of the selection and function of geophagy.

In summary, the geophagic soils of Pemba Island are diverse in color, texture, major element chemistry, and clay mineral content. The trace element contents of the soils, whether of biological or non-biological significance, are uniformly low, and the bioavailability of those that are present is dubious. The two commonalities observed among these soils is the dominance of kaolin in the clay fraction and the practice of geophagy by those who are biologically vulnerable. The palliative, protective and detoxifying properties of kaolin lend support to the hypothesis that geophagy is a protective behavior.

Semiochemical-Mediated Oviposition Avoidance by Female House Flies, *Musca domestica*, on Animal Feces Colonized with Harmful Fungi

Abstract House flies, *Musca domestica*, utilize ephemeral resources such as animal feces for oviposition and development of larval offspring, but they face competition with fungi that colonize the same resource. We predicted that house flies avoid oviposition on feces well-colonized with fungi, thereby reducing fungal competition for larval offspring. Working with fungal isolates from chicken feces, we have previously shown that prior establishment of *Phoma* spp., *Fusarium* spp., or *Rhizopus* spp. on feces significantly reduced oviposition by house flies. Here, we report that, in the headspace volatiles of these three fungal genera, five compounds (dimethyl trisulfide, an unknown, 2-phenylethanol, citronellal, norphytone) elicit responses from house fly antennae. In behavioral bioassays, dimethyl trisulfide and 2-phenylethanol significantly reduced oviposition by house flies. We conclude that fungus-derived volatiles serve as semiochemical cues that help house flies avoid resources colonized with fungal competitors for the development of larval offspring.

Keywords House flies · *Musca domestica* · *Phoma* spp. · *Rhizopus* spp. · Fungi · Animal feces · Resource competition · Oviposition · Semiochemicals · Dimethyl trisulfide · 2-Phenylethanol

Introduction

Microorganisms competing with insect larvae for ephemeral resources can adversely affect larval development, particularly when these microorganisms are first to colonize the resource. For example, microorganisms have been shown to curtail the number of burying beetle, *Nicrophorus quadripunctatus*, offspring that complete development (Wilson et al. 1984). Competition with fungal (Fuentes-Contreras et al. 1998; Askary and Brodeur 1999), viral (Hochberg 1991), or bacterial (Chilcutt and Tabashnik 1997) pathogens of host insects adversely affects even parasitoid larvae, which exploit living organisms. The outcome of this competition is dependent upon the relative timing of infection. Within pea aphids, *Acyrthosiphon pisum*, the presence of bacteria is so detrimental to larvae of the parasitoid *Aphidius ervi* that these bacteria persist as beneficial endosymbionts of the aphid (Oliver et al. 2003).

Competition with fungi is particularly costly for larvae of the house fly, *Musca domestica.* Females lay their eggs on fleeting organic resources such as manure (Keiding 1974; Fatchurochim et al. 1989). Larvae hatch within 24 h and develop through three instars in 5–7 days. After a 5-d pupal period, adult males and females eclose. When fungi were established on a fleeting resource 3 days before house flies oviposited, all of the resulting larvae perished (Zvereva 1987).

When the relative timing of resource colonization strongly affects the outcome of competition, harmful competitors often are recognized and avoided. Many parasites and parasitoids recognize host-marking pheromones and avoid oviposition on the same host (Li 2006; Stelinski et al. 2007). The mistletoe-feeding pierid butterflies *Delias argenthona* and *D. nigrina* have overlapping host ranges, but they oviposit more selectively on specific host species when heterospecific competitors are present (Orr 2008). Mosquitoes avoid larval habitats with intra- or interspecific competitors (Munga et al. 2006). Adult ladybirds avoid oviposition on plants with other aphid predators already present (Sarmento et al. 2007). Leaf beetles

(Roeder et al. 2007) and Australian weevils (Rayamajhi et al. 2006) avoid plants already colonized with a rust fungus, and larvae and adults disperse rapidly when placed on fungus-infected host plants. Finally, the hymenopteran parasitoid *Aphidius ervi* avoids oviposition on plants where aphid hosts were killed by the entomopathogenic fungus *P. neoaphidis* (Baverstock 2005).

All the above examples are interactions between specific insects and microorganisms. House flies, in contrast, face diverse fungi as resource competitors, each with a different establishment rate and competitive effect on house fly larvae. To determine whether houseflies have adapted to avoid fungus-infested resources, we isolated fungal strains from different types of animal feces, and tested the hypotheses that house flies avoid oviposition on feces that is colonized with competitive fungi, and that the avoidance is due to fungus-derived semiochemicals.

Methods and Materials

Experimental Insects Adult house flies were kept in cages at 50–80% relative humidity (RH), 22–30°C and a 16L:8D photoperiod, and were provisioned with water, sugar cubes, and skim milk powder *ad libitum*. House fly eggs were collected on glass Petri dishes (50×10 mm) containing sterile skim milk agar (SMA; 15 ml water, 0.12 g nutrient broth powder, 0.24 g skim milk powder, 0.3 g agar) and reared to adult insects in artificial diet prepared from wheat bran (400 g), brewers yeast (15 g), molasses (15 ml), and water (700 ml), with a supplemental protein paste prepared from skim milk powder and water (Lam et al. 2007).

Isolation and Identification of Fungal Strains To isolate feces-colonizing fungi, feces pats from free-range organic chickens, sheep, horses, and wild barn swallows were collected at the Wind's Reach Farm, Langley, B.C., Canada. A sterile inoculating loop was inserted into the center of each pat and streaked across Petri plates (90×15 mm) containing feces agar (20 ml water, 2.5 g chicken feces that had been sterilized by stirring and autoclaving >3 times at 121°C for 45 min, plus 0.4 g agar). This procedure was to select for fungi that can grow on chicken feces nutrients alone. Mycelia from separate fungal colonies were isolated and incubated on Petri plates (90×15 mm) containing potato dextrose agar (PDA; 20 ml water, 0.48 g potato dextrose broth powder, 0.4 g agar) at 24°C and 85% RH. To identify the fungi that expressed behavioral activity in experiments 1–6, each strain was grown in a Sabouraud dextrose broth, and a Qiagen DNA extraction was performed using the QIAamp® DNA Mini Kit (Qiagen®, Canada, Cat. No. 51304) according to the manufacturer's instructions. Sequencing of 18S rRNA was performed using Fun 1 and Fun 2 primers (unpublished; designed by Dr. Bryne, Animal Health Centre, Abbotsford, B.C., Canada). Fungi were identified based on colony morphology and by comparing 18S rRNA sequences to the Genbank database.

Hypothesis 1: House Flies Avoid Oviposition on Feces that is Colonized with Fungi In two-choice experiments 1–6 (N=10 each), we compared oviposition by house flies on sterilized feces (control) and sterilized feces mixed with one of six fungal isolates (treatment) as follows: *Phoma* sp., *Rhizopus* sp., *Fusarium* sp. (SFU-1), *Fusarium* sp. (SFU-2), Unknown 1, and unknown 2.

Chicken feces pats (0-24 h old) were blended and sterilized. An 8-g aliquot of treatment feces then was thoroughly mixed with the mycelia and spores (if present) of a 1-wk-old PDA culture of one fungal isolate. An 8-g aliquot of control feces was mixed without addition of fungi. Aliquots (8 g) of each feces mixture were packed tightly into separate sterile plastic Petri dishes (35×10 mm). To generate an attractive crevice for oviposition, a 5-mm diam well was poked into the center of each dish with a sterile metal spatula.

Control and treatment dishes then were incubated separately for 3 d in a sterile glass chamber (15 cm ID× 28 cm) through which filtered and humidified air was drawn at 0.5 l/min. Control and treatment dishes were placed in randomly assigned opposite corners of a mesh cage (30×30×45 cm) containing 20 male and 20 female house flies. When oviposition ceased after 3–6 h, the eggs on each dish were removed and weighed or counted (~15,000 eggs/g).

The weights/counts of eggs deposited on treatment and control oviposition sites within each replicate pair were converted to two separate percentages adding up to 100% of total eggs deposited. This approach was chosen because of variation in the total amount of eggs deposited by the flies in each replicate. Two-tailed one-sample bootstrap tests on the means were conducted to determine whether the mean percentages of eggs deposited on treated feces was significantly different from 50%. For each bootstrap test, 1000 bootstrap samples were randomly generated with replacement, and each sample contained the same number of replicates as the original data set. The mean percentage of the original data set was then compared with the mean percentages of its bootstrap samples (SAS, ver. 9.1; SAS Institute, Cary, NC, U.S.A.) with α=0.05.

Hypothesis 2: Fungi Produce Semiochemicals that Inhibit Oviposition by Houseflies; Acquisition of Headspace Volatiles Ten Petri plates (90×15 mm) containing Potato Dextrose+ Feces agar (20 ml water, 0.48 g potato dextrose broth powder, 2.5 g sterilized chicken feces, 0.4 g agar) were

inoculated with mycelia of a fungal isolate that inhibited oviposition in experiments 1–6. Plates in staggered form were placed into a sterile glass chamber (15 cm ID×28 cm) through which filtered and humidified air (see next paragraph) was drawn at 1.0 l/min for 1 wk. Volatiles were adsorbed on 0.2 g of Porapak Q (50–80 mesh, Waters Associates Inc. Milford, MA, USA) inside a Pyrex glass tube (3.8×40 mm), and desorbed with 2 ml of pentane. Headspace volatiles of sterile potato dextrose+feces agar served as a control and were also adsorbed on Porapak Q.

To ensure that clean air entered the autoclaved aeration chamber and to prevent introduction of bacteria onto the fungal plates, air was filtered through 3.5 g of autoclaved (45 min at 121°C) and oven-dried (overnight at 110°C) Porapak Q that was tightly packed into a glass tube (140×8 mm ID). Each day, agar plates were visually monitored for bacterial and fungal contamination, and none was observed.

Analyses of Headspace Volatiles To identify volatiles that elicited responses from house fly antennae, Porapak Q extracts were concentrated and 1-µl aliquots analyzed by coupled gas chromatographic-electroantennographic detection (GC-EAD) (Arn et al. 1975; Gries et al. 2002). Analyses employed a Hewlett Packard (HP) 5890A gas chromatograph equipped with a GC column (30 m×0.25 mm ID) coated with DB-5 (J&W Scientific, Folsom, CA, USA) and helium as a carrier gas (35 cm s^{-1}) with the following temperature program: 50°C (1 min), 20°C/min to 280°C. For GC-EAD recordings, an antenna was pulled from a live female house fly and suspended between two glass capillary electrodes (1.0×0.58×100 mm) (A-M Systems, Inc., Carlsborg, WA, USA) filled with saline solution (Staddon and Everton 1980). Mass spectra of antenna-stimulating components were obtained with a Saturn 2000 Ion Trap (Varian) fitted with a DB-5 column. Compounds were identified by comparing their retention indices (Van den Dool and Kratz 1963) and mass spectra with those reported in the literature [dimethyl trisulfide (Swearingen et al. 2006), phenylacetaldehyde, norphytone (Pherobase 2010), citronellal, 2-phenylethanol (Adams 1989)], and with those of authentic samples.

Two-choice Experiments with Candidate Semiochemicals Experiments 7–11 (N=10–24 each) tested each of the candidate semiochemicals (dimethyl trisulfide, phenylacetaldehyde, 2-phenylethanol, cironellal, norphytone) to determine its effect on oviposition by house flies. Two glass Petri dishes (50×10 mm) containing sterile skim milk agar (15 ml water, 0.12 g nutrient broth powder, 0.3 g agar) served as oviposition sites. A thin strip of agar (width< 5 mm) was excised across the middle of the plate to provide a crevice conducive for oviposition. The candidate neat semiochemical was released from a 5-µl micro-capillary tube which was sealed with plasticine at one end and placed within the crevice such that the open end was near the center of the plate. An empty tube was prepared analogously and placed into the crevice of the control plate. In each replicate, the two plates were randomly assigned to opposite corners of a mesh cage (30×30×45 cm) that contained 20 male and 20 female house flies. Resulting egg counts/weights were analyzed as described above. In all replicates, release rates (µg/h) of candidate semiochemicals were determined volumetrically by measuring with a digital calliper the capillary tubes' length of released chemical, and by taking into account (*i*) the total length of the tube (40 mm), (*ii*) its total holding capacity (5 µl), (*iii*) the compound's density, and (*iv*) the duration (16 h) of the bioassay.

Results

Hypothesis 1: House Flies Avoid Oviposition on Feces Colonized with Fungi In experiments 1 and 2, sterilized feces inoculated with *Phoma* sp. or *Rhizopus* sp. received significantly fewer eggs from female house flies than sterilized feces with no added fungi (Fig. 1, P<0.001). In contrast, in experiments 3–5, the presence of *Fusarium* sp. (SFU-1 or SFU-2) or Unknown Fungal Isolate 1 had no effect on oviposition decisions (Fig. 1, P>0.05). In experiment 6, feces inoculated with Unknown Fungal Isolate 2 received significantly more eggs than feces devoid of fungi (Fig. 1, P<0.05).

Hypothesis 2: Fungi Produce Semiochemicals that Inhibit Oviposition by House Flies GC-EAD analyses of headspace volatile extracts of *Phoma* and *Rhizopus* fungi (which strongly inhibited oviposition by female house flies) and of *Fusarium* sp. (SFU-1) (which appeared to have some effect on oviposition), revealed six compounds that consistently elicited responses from house fly antennae (Fig. 2). By comparing their mass spectra and retention indices with those of authentic standards, antenna-stimulatory components 1, 2, 4, 5, and 6 were identified as dimethyl trisulfide, phenylacetaldehyde, 2-phenylethanol, citronellal, and norphytone, respectively. Component 3 remains unknown. Of these six components, only phenylacetaldehyde also was found in headspace volatiles of sterile feces agar (data not shown). Thus, phenylacetaldehyde was excluded form experiments 7–10 that tested the effect of each of the fungal volatiles dimethyl trisulfide, 2-phenylethanol, citronellal, or norphytone on oviposition decisions by house flies In experiments 7–10, dimethyl trisulfide and 2-phenylethanol strongly reduced oviposition by females (Fig. 3A, experiments 7–9), whereas neither citronellal nor norphytone had a behavior-modifying effect (Fig. 3A, experiment 9,10). These

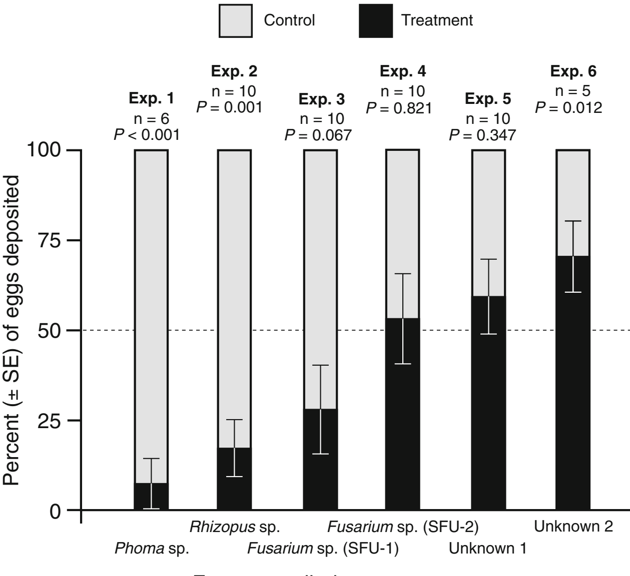

Fig. 1 Percent of house fly eggs oviposited on sterile chicken manure incubated for 3 days with (treatment) and without (control) experimental infestation with a fungal strain. Replicates in which no oviposition occurred were omitted

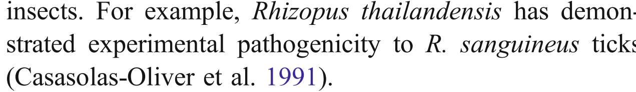
contrasting results could not be attributed to contrasting release rates of semiochemicals because citronellal and norphytone had greater release rates than the oviposition-inhibiting semiochemicals (Fig. 3B).

Discussion

Our data show that female house flies avoid oviposition on ephemeral resources that have been colonized by specific fungal resource competitors, likely due to detection of fungal volatiles.

The presence of particular genera of fungi such as *Phoma* and *Rhizopus*, rather than just the presence of any fungus, affected oviposition by house flies on feces. *Phoma* is a genus of common soil fungi that contains many plant pathogenic species that cause rots and blight (Gray et al. 2008; Davidson et al. 2009), but it also contains species affecting insects. *Phoma aspidioticola*, for example, is highly pathogenic to the scale insect *Aspidiotus destructor* but not to the plant host *Syzygium cumini* (Narendra and Rao 1974). *Rhizopus* is a genus of molds that includes fungi found in soil, decaying fruit and vegetables, old bread, and animal feces (El-Mougy et al. 2008; Rodriguez et al. 2008; Serrano-Garcia et al. 2008; Takahashi et al. 2008). However, some species are plant pathogens (Prom and Perumal 2008; Zhao et al. 2008), cause infections in humans and animals (Landlinger et al. 2008), or affect



insects. For example, *Rhizopus thailandensis* has demonstrated experimental pathogenicity to *R. sanguineus* ticks (Casasolas-Oliver et al. 1991).

By avoiding oviposition sites colonized with potentially pathogenic fungi, female house flies make choices that enhance their fitness. Larval diet inoculated with mycelia and/or spores of the oviposition-inhibiting fungi *Fusarium* spp., *Phoma* spp., and *Rhizopus* spp. had detrimental effects on the number of house fly larvae that completed development (Lam et al. 2009). This decrease in larval survival may not occur with other fungi [e.g., *Fusarium* spp. (SFU-1)] that had little or no impact on oviposition by female house flies. Alternatively, these fungi may simply lack the semiochemical cues that indicate the presence of (harmful) fungi.

Release rates of synthetic semiochemicals from glass capillary tubes in oviposition experiments 7–10 exceeded those from agar cultures of *Rhizopus* spp. by 100–500 times. This, however, seemed justified because levels of semiochemical emission from *Rhizopus* spp. are likely to have varied greatly during the 7-d aeration period, with peak emissions assumed to have coincided with a short (~1 d) period of rapid fungal growth (when nutrients were plentiful), and with much lower levels of emissions before and after that period.

Each fungal isolate with adverse effects on the development of house fly larvae (Lam et al. 2009) emitted dimethyl trisulfide and 2-phenylethanol, each of which strongly reduced oviposition by house flies on feces. Neither of these two semiochemicals has been reported to affect oviposition decisions by flies, but 2-phenylethanol is a bacteria-derived putative oviposition semiochemical for *Anopheles gambiae* mosquitoes (Lindh et al. 2008).

Dimethyl trisulfide and 2-phenylethanol are well known in diverse ecological contexts. For examples, 2-phenylethanol is released from the hair pencils of courting males in noctuid and pyralid moths (Kuwahara 1980; and references cited therein). As a plant semiochemical, 2-phenylethanol adds to the attractiveness of plants to their respective herbivores (e.g., Zilkowski et al. 1999), pollinators (e.g., Knudsen and Tollsten 1993), or predators in tritrophic systems (e.g., Zhu and Park 2005). Dimethyl trisulfide is a major constituent of the flower of the voodoo lily, *Sauramutum guttatum,* and of the stinking mushroom, *Phallus impudicus* (Borg-Karlson et al. 1994). It is also present in floral volatiles of bat-pollinated plants, and in the essential oils of garlic, *Allium sativum* (Harborne et al. 1999; Kim et al. 2004). It is a major aroma component of cooked brassicaceous vegetables (Maruyama 1970), an indicator of decaying meat (Brown 1982), and a semiochemical of the dead-horse arum, *Helicodiceros muscivorus,* a plant which fools flies into pollinating it by emitting a smell like a rotting carcass (Stensmyr et al. 2002). Dimethyl trisulfide is also a volatile odor constituent of

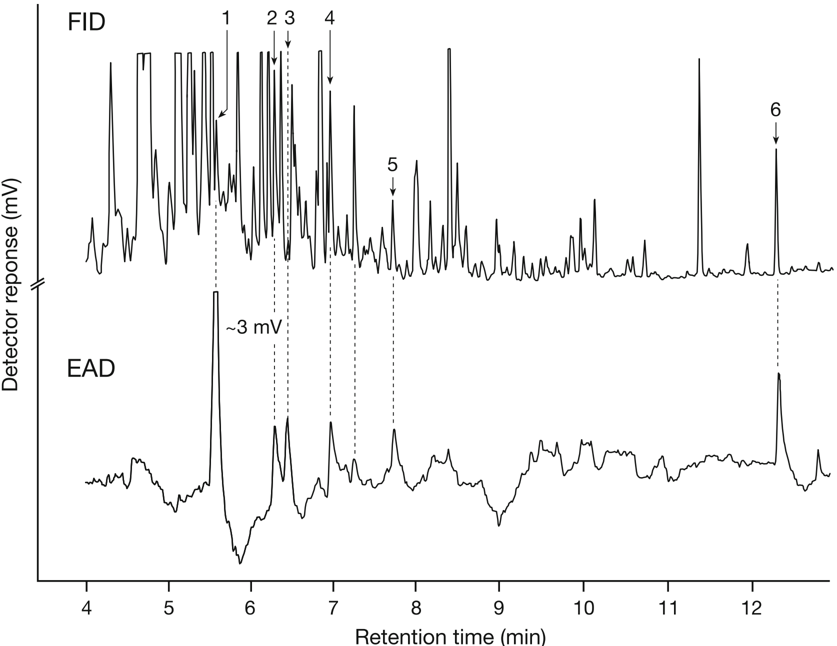


Fig. 2 Results of gas chromatographic-electroantennographic detection analysis of headspace volatiles captured from *Rhizopus* spp. growing on feces agar. No additional responses from house fly antennae were observed with the volatiles of the other two oviposition-inhibiting fungal strains (data not shown). Compounds that consistently (N=3) elicited antennal responses are marked with arrows and are labeled: (1) dimethyl trisulfide; (2) phenylacetaldehyde; (3) unknown; (4) 2-phenylethanol; (5) citronellal; and (6) norphytone. Phenlyacetaldehyde was found in headspace volatiles of *sterile* manure agar, and thus was omitted from experiments 7–10

various types of animal manure (Cai et al. 2007), and, as a single component, it is known to attract some calliphorid and one muscid fly (Nilssen et al. 1996).

Feces-emitted dimethyl trisulfide may, at least in part, be produced by fungi colonizing it. That some flies are attracted to dimethyl trisulfide (Nilssen et al. 1996) implies that it may serve as a foraging cue indicative of food or oviposition sites. Feces is rich in protein and could provide nutrients to adult flies even though they may not use it as a resource for larval offspring.

It would now be intriguing to determine whether volatile profiles of fungal isolates that are harmful or harmless to larval offspring of house flies differ, and how the differences might facilitate oviposition choices by female flies. It would

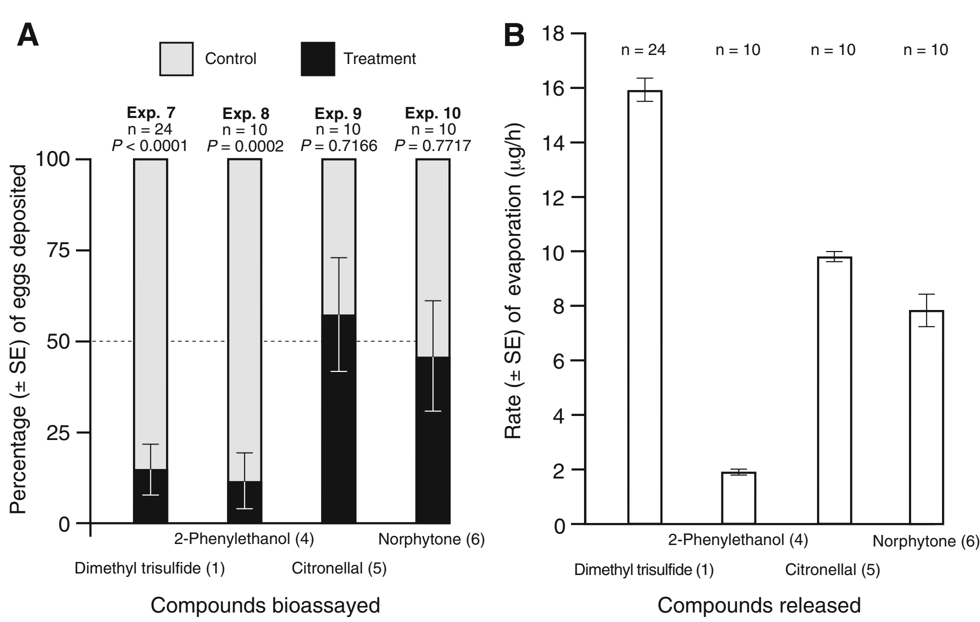

Fig. 3 **A** Percent of house fly eggs oviposited on artificial agar oviposition sites with (treatment) or without (control) a candidate semiochemical released from a micro-capillary tube at the centre of the oviposition site; **B** Rates of evaporation of each candidate semiochemical from micro-capillary tubes (5 µm ID×40 mm)

also be worth investigating whether the semiochemicals, or the fungi producing them, could be exploited as a tactic within programs for managing house flies in livestock production facilities.

Sequestration of Glucosinolates and Iridoid Glucosides in Sawfly Species of the Genus *Athalia* and Their Role in Defense Against Ants

Sebastian E. W. Opitz · Søren R. Jensen · Caroline Müller

Received: 7 November 2009 / Revised: 4 January 2010 / Accepted: 6 January 2010 / Published online: 2 February 2010

Abstract In this study, the larval sequestration abilities and defense effectiveness of four sawfly species of the genus *Athalia* (Hymenoptera: Tenthredinidae) that feed as larvae either on members of the Brassicaceae or Plantaginaceae were investigated. Brassicaceae are characterized by glucosinolates (GLSs), whereas Plantaginaceae contain iridoid glucosides (IGs) as characteristic secondary compounds. *Athalia rosae* and *A. liberta* feed on members of the Brassicaceae. Larvae of *A. rosae* sequester aromatic and aliphatic GLSs of *Sinapis alba* in their hemolymph, as shown previously, but no indolic GLSs; *A. liberta* larvae with a narrower host range sequester aliphatic as well as indolic GLSs from their host plant *Alliaria petiolata*. Larvae of *A. circularis* and *A. cordata* are specialized on members of the Plantaginaceae. *Athalia circularis* utilizes mainly *Veronica beccabunga* as host plant, whereas *A. cordata* feeds additionally on *Plantago lanceolata*. Both sawfly species sequester the IGs aucubin and catalpol. In *V. beccabunga*, catalpol esters and carboxylated IGs also occur. The high catalpol concentrations in hemolymph of *A. circularis* can only be explained by a metabolization of catalpol esters and subsequent uptake of the resulting catalpol. The carboxylated IGs of the plant are excreted. The IG-sequestering sawfly species are able to accumulate much higher glucoside concentrations in their hemolymph than the GLS-sequestering species, and the concentration of IGs in hemolymph increases constantly during larval development. The defensive effectiveness of hemolymph that contains GLSs or IGs and of the respective glucosides was tested in feeding-bioassays against a potential predator, the ant *Myrmica rubra* (Hymenoptera: Formicidae). Hemolymph of IG-sequestering cryptic *A. cordata* larvae has a higher deterrence potential than hemolymph of the GLS-sequestering conspicuous *A. rosae* larvae. The results show that glucoside sequestration is widespread in the genus *Athalia,* but that the specific glucoside uptake can result in different defense effectiveness against a predator species.

Introduction

Most plant families contain secondary plant metabolites that are characteristic at the taxon level (Schoonhoven et al. 2006). These metabolites can act as a defense against generalist herbivores, however, some adapted specialized insect species are able not only to tolerate, but even to use these secondary metabolites for their own advantage. These species have evolved the ability to take up, accumulate, and store the plant-derived metabolites, a process referred to as sequestration (Duffey 1980). Sequestering insects often are conspicuously colored, which is interpreted as an alarm signal to predators (Rothschild 1973; Bowers 1993). Sequestration is a fairly widespread mechanism to deal with harmful plant metabolites and is commonly found in several phytophagous insect orders, mainly within the Coleoptera, Lepidoptera, and Heteroptera/Sternorryncha but also in Hymenoptera (for review see Opitz and Müller

2009). Within tenthredinids, sequestration of plant metabolites in the larval hemolymph has been described for several species (Bowers et al. 1993; Schaffner et al. 1994; Müller et al. 2001; Prieto et al. 2007) and seems to be related to the phenomenon of 'easy bleeding' (Boevé and Schaffner 2003). Thereby hemolymph is presented rapidly upon attack of biting predators through the easily disrupted integument of the larvae. Several potential predators are deterred by the hemolymph, whereas the sawfly larvae survive the attack (Boevé and Müller 2005).

Within the genus *Athalia* (Hymenoptera: Tenthredinidae), herbivorous larvae of *A. rosae* L. feed on various species of the Brassicaceae and are known to sequester glucosinolates (GLSs) up to a certain concentration level in the hemolymph (Müller et al. 2001; Müller 2009). Subsequently, GLSs are metabolized mainly in the larval body and to a minor extent excreted intact with the frass (Müller and Wittstock 2005). GLSs are amino acid derived ß-thioglucoside-*N*-hydroxysulfates with aromatic, aliphatic, or indolic side chains. They are characteristic for Brassicaceae and a few other plant families, and they differ species—specifically in their qualitative composition (Fahey et al. 2001). In *A. rosae* hemolymph, aromatic GLSs such as sinalbin (*p*-hydroxybenzyl GLS, **9**, Fig. 1) and glucotropaeolin (benzyl GLS) as well as aliphatic GLSs such as sinigrin (2-propenyl GLS) **10** have been found in high concentrations (Müller et al. 2001). In contrast, indolic GLSs such as glucobrassicin (indol-3-ylmethyl GLS) **11** are detectable only in traces in individuals fed on plants containing high indolic GLS concentrations (Müller 2009). The hemolymph of *A. rosae* has been shown to be deterrent against predatory insects, such as *Myrmica rubra* L. (Hymenoptera: Formicidae) and *Vespula vulgaris* L. (Hymenoptera: Vespidae). The defensive principle is, in part, based on the GLSs present in the hemolymph (Müller et al. 2002; Müller and Brakefield 2003). Sequestration of GLSs also is known for one bug and two aphid species (Aliabadi et al. 2002; Bridges et al. 2002).

In Europe, the genus *Athalia* comprises 17 species that are specialized on different plant families (Liston 1995). Several species, including *A. rosae* and *A. liberta* (Klug), feed on members of the Brassicaceae, whereas others, including *A. cordata* Lepeletier and *A. circularis* (Klug), feed on members of the chemically different Plantaginaceae, which are characterized by iridoid glucosides (IGs). These cyclopentanoid monoterpene-derived compounds are produced by the mevalonic acid pathway, and usually are *O*-linked to glucosides at C-1 (Jensen 1991; von Poser et al. 2000). Aucubin **1** and catalpol **2** are the most common IGs. Catalpol also can occur esterified with different acids forming catalpol esters. The 6-*O*-catalpol esters are limited to the genera *Veronica*, *Paederota*, *Picrorhiza* (Plantaginaceae), and some Bignoniaceae (Taskova et al. 2006; von Poser et al. 2000; Jensen et al. 2005). Sequestration of IGs has been found in species of different insect orders (for review see Opitz and Müller 2009), and renders some of

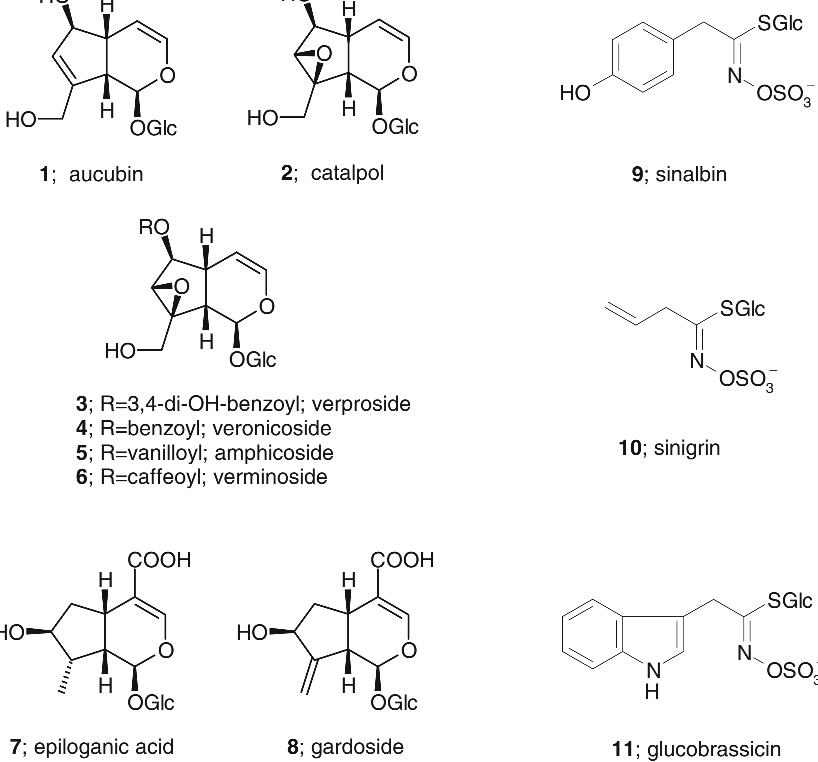

Fig. 1 Chemical structures of the main glucosides found in the investigated plant species. The IGs aucubin (1) and catalpol (2) occur in *Plantago lanceolata* and *Veronica beccabunga* (Plantaginaceae), whereas the latter also contains the carboxylated IGs epiloganic acid (7) and gardoside (8) as well as four catalpol esters (3 to 6). The diversity of GLSs in Brassicaceae is much higher and only one representative of each of the three main classes are shown; the aromatic sinalbin (p-hydoxybenzyl GLS, 9) as main component of *Sinapis alba*, the aliphatic sinigrin (2-propenyl GLS, 10) as main component of *Alliaria petiolata* and the indolic GLS glucobrassicin (indol-3-ylmethyl GLS, 11) occurring in both species

these species unpalatable to bird predators (Bowers 1980, 1992; Bowers and Farley 1990). The catalpol esters have not been found to be sequestered, and the corresponding esterifying acids are excreted with the frass in *Euphydryas anicia* (Doubleday and Hewitson) (Lepidoptera: Nymphalidae) (Gardner and Stermitz 1988).

In Brassicaceae, GLSs co-occur with myrosinases, plant thioglucosidases that hydrolyze the GLSs upon tissue damage into toxic, volatile isothiocyanates and other products via an unstable aglucone (Fahey et al. 2001). IGs can be hydrolyzed by insect β-glucosidases in the gut forming unstable aglyca with differing biological activity (Bowers 1991). Thus, sequestration of both glucoside types is possible only if these degradation processes are at least in part circumvented (Konno et al. 1999). Apart from *A. rosae* (Müller 2009), nothing is known about the sequestration abilities of other *Athalia* spp., nor about their defense effectiveness against predators. Therefore, this study aimed to investigate the sequestration ability of four *Athalia* species, *A. rosae*, *A. liberta*, *A. cordata*, and *A. circularis* that feed on two different glucoside-containing plant families (Brassicaceae and Plantaginaceae). Further, the defense capability of sequestered glucosides was examined against the ant *Myrmica rubra*. The glucoside concentrations were quantified and tracked over the entire larval development in IG-sequestering insects. Results are discussed with regard to the conspicuousness of the different species.

Methods and Materials

Plant and Insect Rearing White mustard (*Sinapis alba* L. cv. Silenda, Brassicaceae), garlic mustard [*Alliaria petiolata* (M. Bieb.) Cavara & Grande, Brassicaceae] and brooklime [*Veronica beccabunga* L., Plantaginaceae (earlier Scrophulariaceae)] were grown in a greenhouse at 20°C and a photoperiod of L16:D8. Ribwort plantain (*Plantago lanceolata* L., Plantaginaceae) was grown in a climate chamber (20°C, 70% r. h., L16:D8). Seeds of *S. alba* were obtained from Kiepenkerl (Norken, Germany), seeds of *P. lanceolata* from Rühlemann's (Horstedt, Germany), and seeds of *A. petiolata* and *V. beccabunga* from the Botanical Garden of Berlin, Germany. *Veronica beccabunga* was sown once, and subsequently was propagated by cuttings.

Adults of four *Athalia* species, *A. rosae*, *A. cordata*, *A. liberta*, and *A. circularis*, were collected in the surroundings of Würzburg (Bavaria, Germany). The Brassicaceae-feeder *A. rosae* was reared on flowering plants of *S. alba*, and *A. liberta* on 1st-year, non-flowering *A. petiolata* plants in the greenhouse. The Plantaginaceae-feeder *A. cordata* was reared on non-flowering *P. lanceolata*, and *A. circularis* on non-flowering plants of *V. beccabunga*. Adults were allowed to oviposit on potted plants of the respective species in cages (51×36×35 cm and 61×61×66 cm for *A. rosae*) kept in the greenhouse. Larvae were reared on these plants until pupation in the soil. Adults were provided with a mixture of honey and water (1:10). New plants were added to the cages when necessary. A colony of the ant *M. rubra* was transferred from the surrounding of Bielefeld University, Germany, and maintained in the laboratory (22°C, 70% r.h., and L16:D8).

Collection of Insect Samples and Plant Material Hemolymph samples were taken from *Athalia* spp. larvae (last feeding instar) that had fed on their respective host plants. Hemolymph was collected from living individuals (6 to 7 replicates per species) by piercing the integument carefully with a needle without damaging the gut. Exuded hemolymph was collected from every individual with glass capillaries in 1.5 ml Eppendorf tubes. Additionally 10 to 15 larvae were transferred in Petri dishes without food for 3 h, and their frass was collected (5 to 6 replicates), thereby avoiding any contamination with plant material. Moreover, six male adults of each species were taken shortly after emergence. In order to evaluate sequestration qualities and quantities, 3 to 7 replicates of mature leaf material of the four host plant species, *S. alba*, *A. petiolata*, *P. lanceolata*, and *V. beccabunga*, were sampled as well. All samples were weighed, frozen in liquid nitrogen, lyophilized, and analyzed for their glucoside contents either by HPLC-DAD or GC-MS (see below).

Analysis of Development-Dependent Sequestration of Iridoid Glucosides in A. circularis and A. cordata The time-course of GLS-sequestration throughout larval development is known for *A. rosae* (Müller and Wittstock 2005). To compare this pattern with that of IG-sequestering species, hemolymph samples of individual *A. cordata* larvae of mixed sex reared on *P. lanceolata* were analyzed 7, 9, and 11 d (N=4 to 6 per day) after larval hatching. It was not possible to collect hemolymph of younger (smaller) larvae or of pre-pupae (eonymphs), which occurred at the twelfth day. Similarly, male *A. circularis* larvae were reared on *V. beccabunga*, and their hemolymph was analyzed 8 (larval stage L3), 10 (L4), and 12 d (L4) after larval hatch (N=8 per day). To quantify the total IG amount in larvae throughout development, every other day *A. circularis* larvae of mixed sex (N=3 per day) were taken from larval hatch until reaching the eonymph stage after 14 d (males 5 instars, females 6 instars). The larvae were starved 1.5 to 1.8 h before sampling. All samples were weighed, frozen in liquid nitrogen, and processed as described below. A Kruskal-Wallis analysis of ranks followed by a multiple comparison test was used to compare the hemolymph

concentrations at different developmental times in *A. cordata* and *A. circularis*.

Analysis of Glucosinolate and Iridoid Glucoside Concentrations For analysis of GLSs, larval hemolymph, frass, adults, and leaf samples were extracted in 80% methanol with sinigrin (for samples related to *S. alba*) and sinalbin (for *A. petiolata*), respectively, as internal standards (both obtained from Phytoplan Diehm & Neuberger GmbH, Heidelberg, Germany). GLSs were converted to desulfo GLSs as described previously (Agerbirk et al. 2001). Analysis of desulfo GLSs was carried out on an HPLC (1200 series, Agilent, Santa Clara, CA, USA) with a Supelcosil LC-18 column (Supelco, Bellefonte, PA, USA) with a gradient (solvent A: water, solvent B: methanol) of 5–10% B within 10 min, 10–38% B within the next 14 min, 38–50% B in 2 min, and 50–60% B in 4 min, followed by a cleaning cycle. For identification, retention times and UV-spectra were compared to those of standards. GLSs sequestered by *A. rosae* had been identified earlier by LC-MS (Müller et al. 2001). For quantification, response factors were applied (aromatic GLS: 0.5, benzyl GLS 0.86, aliphatic GLS: 1, indolic GLS: 0.26).

For IG analysis, samples were extracted in 80% methanol with phenyl-β-D-glucopyranoside (Sigma-Aldrich, St. Louis, MO, USA) as internal standard. After drying of samples in a rotation vacuum concentrator (RVC 2-18, Martin Christ, Osterode am Harz, Germany), they were re-dissolved in 500 µl water (TKA MicroPure, Niederelbert, Germany). An aliquot of 100 µl was transferred in GC-vials and evaporated to dryness under a nitrogen stream. For derivatization, 100 µl silylation agent (*N*-trimethylsilylimidazole:pyridine 1:4, Sylon TP Kit, Supelco, USA) were added, and samples were heated to 80°C for 30 min in a thermoblock (Reacti-Therm, Pierce, Rockford, IL, USA). GC-MS analyses were performed on a Focus GC-DSQ II (Thermo Electron S.p.A., Rodano, Italy), equipped with a VF-5 ms column (30 m×0.25 mm ID, 10 m guard column, Varian, Palo Alto, CA, USA) in electron impact ionization mode. The injection mode was splitless at a temperature of 225°C with a helium flowrate of 1.2 ml/min. Samples were analyzed with two different programs adapted from Gardner and Stermitz (1988). For the analysis of aucubin and catalpol only, temperature program A was applied, for the less volatile catalpol esters and carboxylated IGs, program B. Program A started at 100°C for 1 min, the first ramp of 70°C/min was heating to 200°C with 1 min hold, followed by a second ramp of 3°C/min to 250°C with a 1 min hold. The final temperature of 280°C was reached with a ramp of 5°C/min followed by a 5 min hold. Program B also started at 100°C for 1 min and heated with a 70°C/min ramp to 200°C with 1 min hold, but was followed by a 12°C/min ramp to 260°C with a 6 min hold. The third ramp of 20°C/min to the final temperature of 325°C ended with a hold of 20 min. IGs were identified by comparison of MS spectra and retention times to those of purified authentic standards. Aucubin **1** and catalpol **2** were obtained from Phytoplan (Diehm & Neuberger GmbH, Heidelberg, Germany), while the catalpol esters verproside **3**, veronicoside **4**, amphicoside **5**, and verminoside **6** and carboxylated IGs (epiloganic acid **7**, and gardoside **8**) were isolated from dry plant material of *V. beccabunga*. Plant material was extracted with ethanol, and the water-soluble fraction was purified by preparative chromatography using a Merck Lobar RP-18 column size B (Merck, Darmstadt, Germany). The initial eluent was H_2O followed by H_2O:MeOH mixtures (15:1 to 1:1) and finally by MeOH. The isolated compounds were identified by means of ^{1}H NMR spectroscopy (Jensen et al. 2005).

Deterrence Bioassay against Ants The response of ants towards larval hemolymph and towards purified glucosides was tested with *M. rubra* ant workers according to Müller et al. (2002). Single worker ants were placed in a glass Petri dish (4 cm diam) and offered a 4 µl test and a 4 µl control droplet (droplets 0.7 cm apart). For preparing the hemolymph solutions, 2 µl of freshly collected hemolymph of *A. rosae* or *A. cordata* larvae, respectively, were dissolved in 23 µl of 0.1 M sucrose solution (resulting dilution factor of 1:12.5). This was subsequently diluted further with 0.1 M sucrose solution. The test droplets of hemolymph-sucrose solution were tested for *A. rosae* in dilutions of 1:125 or 1:625 (Müller et al. 2002) and for *A. cordata* in dilutions of 1:312 and 1:1,562. The control droplets consisted of hemolymph-equivalent amounts of water diluted in 0.1 M sucrose solution, thus resulting in the same sucrose concentrations. Glucoside standards were tested in a concentration of 0.8 mM for sinalbin and 0.08 mM for catalpol. Number of visiting events and time spent drinking at the test or the control droplet were recorded for 14–15 ants for a period of 5 min.

To compare the defense effectiveness of GLS and IG sequestering larvae directly, the ant response was tested to larval hemolymph solutions of *A. rosae* and *A. cordata* offered as described above against each other in dilutions of 1:125 and 1:625, respectively. Three batches containing pooled hemolymph of three *A. rosae* larvae (reared on *S. alba*) were compared to three batches containing pooled hemolymph of three *A. cordata* larvae (reared on *P. lanceolata*). For each batch, 6 ants were recorded, in total 18 ants for each dilution. Differences in the drinking duration of ants on the two sucrose solution droplets were tested by Wilcoxon matched-pairs signed-rank tests. Hemolymph samples were divided before use to determine the GLS and IG concentrations of the respective samples by HPLC and GC-MS as described above.

Results

Sequestration Pattern in Athalia Species Sequestration abilities were studied in four *Athalia* species after rearing them on their primary host plants (Fig. 2). All species showed a similar glucoside (IGs or GLSs, respectively) sequestration pattern. Highest concentrations of glucosides were found in larval hemolymph, followed by adult sawflies, whereas the frass contained the lowest concentrations or only traces of glucosides. Regarding the sequestration efficiency, *A. cordata* and *A. circularis* that fed on Plantaginaceae were able to sequester much higher concentrations of glucosides in the hemolymph than the species feeding on members of Brassicaceae (100–250 µmol IG/g FW as compared to 10–40 µmol GLS/g FW; Fig. 2). Glucoside concentrations varied highly within each of the four plant species. However, glucoside concentrations of the larval hemolymph were not related to the concentrations present in the respective host plants across species.

Leaves of *A. petiolata* contained only low concentrations (below 1 µmol/g FW) mainly of sinigrin, whereas *S. alba* provided around 10 times higher concentrations of aromatic GLSs (sinalbin and glucotropaeolin). Comparably low concentrations of GLSs were found in larval hemolymph

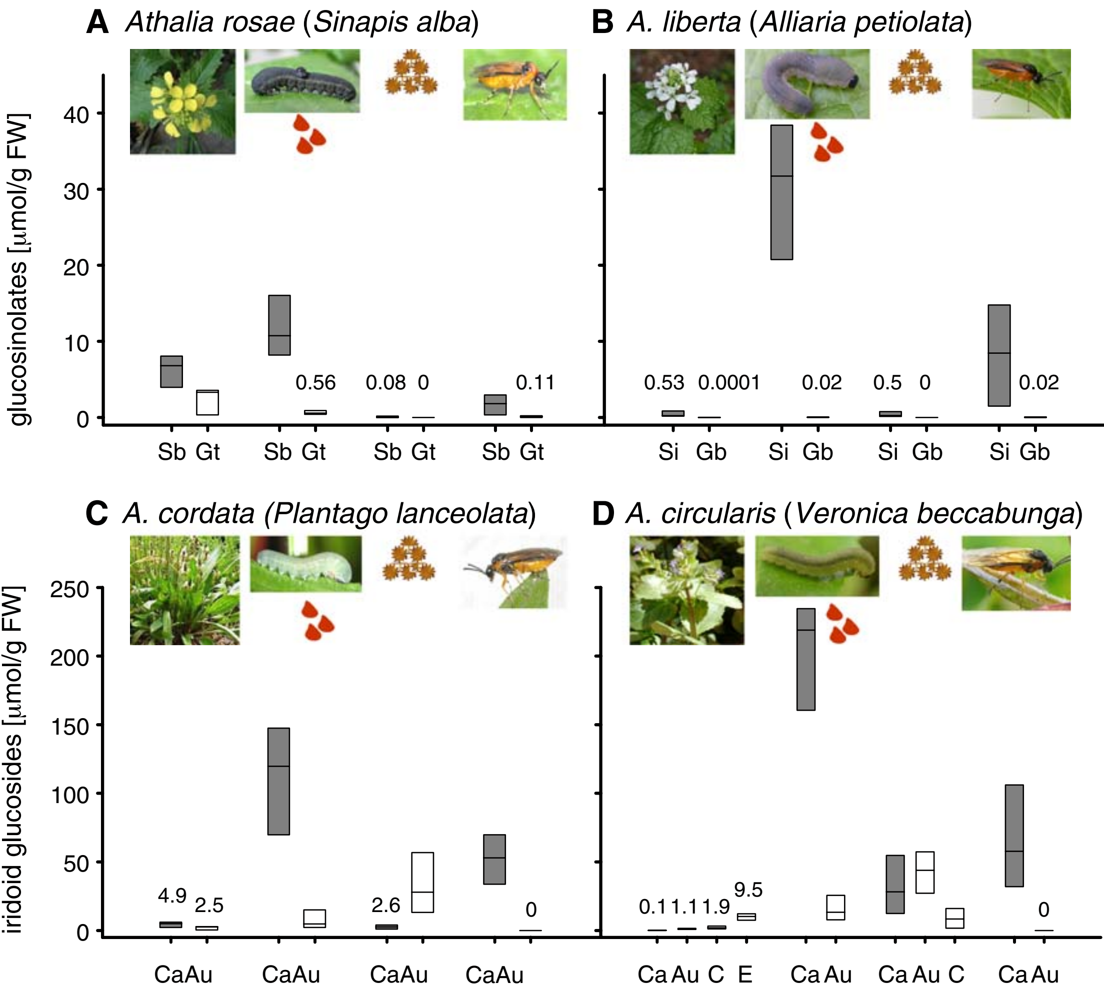

Fig. 2 Glucoside concentrations (median, 25th and 75th percentiles) of the prominent glucosides (*grey*: dominant sequestered glucoside) in the respective host plant species (*N*=3 to 7), larval hemolymph (*N*=6 to 7) and frass (*N*=5 to 6) of last feeding instar larvae and in adults (*N* =5 to 6) of four *Athalia* species: (**a**) *A. rosae* fed on *Sinapis alba*, (**b**) *A. liberta* fed on *Alliaria petiolata*, (**c**) *A. cordata* fed on *Plantago lanceolata*, and (**d**) *A. circularis* fed on *Veronica beccabunga*. For the Brassicaceae, only the main plant glucosides [for *S. alba*: Sb, sinalbin (*p*-hydroxybenzyl GLS), Gt, glucotropaeolin (benzyl GLS); for *A. petiolata*: Si, sinigrin (2-propenyl GLS), Gb, glucobrassicin (indol-3-ylmethyl GLS)] were taken into account. For the Plantaginaceae, the IGs aucubin (Au) and catalpol (Ca) found in *Plantago lanceolata* and *Veronica beccabunga* and the carboxylated IGs (C, sum of epiloganic acid, gardoside, arborescosidic acid and low concentrations of mussaenosidic acid) and catalpol esters (E, sum of verproside, veronicoside, amphicoside, and verminoside) of *V. beccabunga* were quantified. Small pictures of the host plant species, larval hemolymph (blood droplets), the frass and adults indicate the corresponding results and visualize the differences in the larval coloration as well as the similarities in coloration of the adults. Median values of very low concentrations are written above the respective boxes

as well as in adults of *A. rosae* (Fig. 2a). In contrast, *A. liberta* larvae concentrated sinigrin of their host plant *A. petiolata* 30-fold in their hemolymph. Moreover, indolic GLSs, e.g., glucobrassicin, always were detectable in the larval hemolymph and in adult sawflies of *A. liberta*, although indolic GLSs were present in the plant only in low concentrations (Fig. 2b). Only minute concentrations of GLSs were excreted with the frass in both *A. rosae* and *A. liberta*.

Within the Plantaginaceae, leaves of *P. lanceolata* contained the IGs aucubin and catalpol in substantial concentrations. Leaves of *V. beccabunga* contained only low concentrations of these IGs but high concentrations of various catalpol esters, i.e., verproside and veronicoside, small amounts of amphicoside and verminoside, and carboxylated IGs, e.g., epiloganic acid and gardoside (Fig. 2c, d). Larvae of *A. cordata* that fed on *P. lanceolata* sequestered 15-times higher concentrations of catalpol than aucubin in their hemolymph. The frass contained more aucubin than catalpol. Adult *A. cordata* contained catalpol only (Fig. 2c). The catalpol esters and carboxylated IGs of *V. beccabunga* were not sequestered by *A. circularis*; the larvae sequestered only aucubin and very high concentrations of catalpol (Fig. 2d). The host plant IGs were concentrated in the hemolymph up to 100-fold. Additionally, catalpol esters were not detected in the frass, but the carboxylated IGs and up to 50 µmol/g FW of aucubin and less catalpol were excreted. Furthermore, minor concentrations of 3,4-dihydroxy benzoic acid, the esterifying acid of verproside, also were detectable in the frass (data not shown). Adults of *A. circularis* contained only catalpol, as found for *A. cordata*.

Development-Dependent Sequestration of Iridoid Glucosides in A. cordata and A. circularis The development-dependent investigation of IG sequestration in both species revealed a cumulative uptake of IGs. The concentration of IGs (aucubin and catalpol) increased significantly over time in hemolymph of *A. cordata* larvae reared on *P. lanceolata* (Fig. 3a) and in hemolymph of *A. circularis* fed on *V. beccabunga* (Fig. 3b), respectively. In accordance, the total amount of IGs in whole larvae of *A. circularis* reared on *V. beccabunga* increased constantly during larval development (Fig. 3c). After 7 days, the total IG concentration in the hemolymph was around 30 µmol/g FW in *A. circularis* and reached concentrations up to 200 µmol/g FW after 11 days. In eonymphs, the total IG amount dropped to the level found in larvae around day 5. The eonymphs of *A. circularis* contained only catalpol (Fig. 3c) in a concentration range similar to that found in adults (about 50 µmol/g FW) (see above, Fig. 2d). Note that sequestration values of Figs. 2 and 3 can not be compared directly because the sequestration was investigated in larvae feeding on different host plant batches at different times.

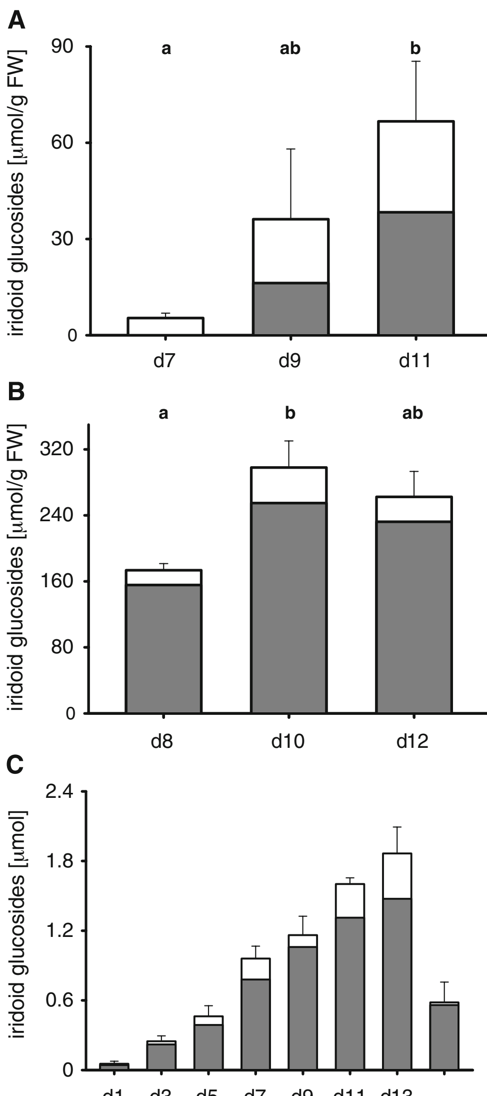

Fig. 3 Mean concentrations of IGs (+ s.e.) in (**a**) hemolymph of *Athalia cordata* larvae (N=4 to 6) at day 7, 9 and 11 after hatching and (**b**) hemolymph of *A. circularis* larvae (N=8) at day 8, 10 and 12 after hatching. (**c**) Mean total IG amounts (+ s.e.) in *A. circularis* larvae at different days after hatching and in eonypmhs (N=3 individuals per time point). *Stacked bars*: *grey*: catalpol, *white*: aucubin. Larval hemolymph concentrations were compared by Kruskal-Wallis analysis of ranks (*A. cordata*: $H_{(2,\ N=16)}=6.93$, $P=0.03$ for total IGs, *A. circularis*: $H_{(2,\ N=24)}=9.36$, $P=0.009$ for total IGs), followed by multiple comparisons tests; *lower case letters* denote significant differences ($P<0.05$); *FW* fresh weight, *Eo* eonymph

Defense Effectiveness of Hemolymph and the Sequestered Glucosides Against Ants Hemolymph of *A. rosae* (main glucoside sinalbin) and *A. cordata* (main glucoside catalpol) as well as sinalbin (GLS) and catalpol (IG) were tested for their deterrent activity against the generalist predator *M. rubra*. The response of individual workers differed highly, as indicated by the high standard errors. Sucrose solution embittered with either of the two hemolymph samples

evoked a clear deterring effect; the ants preferred to drink the pure sucrose solution. Different dilutions were tested to determine the deterrence limit of the two hemolymph samples. The hemolymph of *A. rosae* was still significantly deterrent in a dilution of 1:125, but not in a dilution of 1:625 (data adapted from Müller et al. 2002). The hemolymph of *A. cordata* was deterrent in a dilution of 1:312 and even in a dilution of 1:1,562 (Table 1). The glucoside concentrations in the tested hemolymph droplets were equal approximately to 0.1 mM sinalbin in the 1:125 dilution of *A. rosae* hemolymph and 0.09 mM catalpol in the 1:1,562 dilution of *A. cordata* hemolymph (calculated from empirical sequestration values). Similarly, sucrose droplets containing 0.8 mM sinalbin or 0.08 mM catalpol were less ingested than the control droplets, demonstrating that the glucosides of the sawfly hemolymphs were at least in part responsible for the deterrent effects on the ants. In addition, catalpol was deterrent even in a 10-fold lower concentration as compared to sinalbin (Table 1).

Finally, the deterrent effectiveness of hemolymph of *A. rosae* and of *A. cordata* was tested against each other. In a dilution of 1:125, ants preferred to drink sucrose solution with *A. rosae* hemolymph as compared to droplets with *A. cordata* hemolymph. One batch with a particularly high GLS concentration in *A. rosae* hemolymph (20 µmol/g FW) resulted in an overall low drinking duration on both droplets. Overall, the drinking period was comparably low when the hemolymph samples of *A. rosae* and *A. cordata* were tested against each other. In these cases, the ants showed a cleaning of mouth parts and antennae after feeding on the deterrent test dilutions offered in both concentrations. In a higher dilution, ants did not discriminate between hemolymph samples of either species.

Discussion

All investigated *Athalia* species are able to sequester glucosides from their host plant species of different plant families and able to concentrate them in their hemolymph regardless of the glucoside class. However, high quantitative differences became evident among the sequestration patterns of the four species. IGs were much higher concentrated in larval hemolymph of Plantaginaceae-feeders than GLSs in hemolymph of Brassicaceae-feeders. Larvae of *A. rosae*, for which GLS sequestration has been shown previously (Müller et al. 2001), had the lowest sequestration ability among the four *Athalia* species. Generally, they contained the lowest glucoside concentra-

Table 1 Drinking duration of individual *Myrmica rubra* ant workers in dual-choice assays

	N	Mean drinking duration (± SE) on test droplet [s][a]	Mean drinking duration (± SE) on control droplet [s][b]	*P*-value[c]
Athalia rosae hemolymph[d] Dilution 1:125[e]	14	10.6±6.0	85.8±16.1	0.004

[f] Hemolymph samples were gained from *A. cordata* larvae reared on *P. lanceolata*

tions in larval hemolymph and in adults despite the highest glucoside concentrations available in the host plant *S. alba*. GLS uptake in *A. rosae* occurs only to a certain level, which is, however, also related to the GLS concentration of the host plants (Müller et al. 2003; Müller and Wittstock 2005; Müller and Sieling 2006). Moreover, GLSs are degraded rapidly and excreted after some hours as unknown metabolites in *A. rosae* (Müller and Wittstock 2005). This can explain the comparably low GLS concentrations in the hemolymph. Larvae of *A. rosae* are able to sequester aromatic GLSs from *S. alba* and aliphatic GLSs from other Brassicaceae, but almost no indolic GLSs (Müller et al. 2001; Müller 2009). In contrast, *A. liberta* stored three to ten times higher GLS concentration than its host plant *A. petiolata* in larval hemolymph and adults. Besides the dominant sinigrin, considerable concentrations of gluco-brassicin (indolic GLS) also were sequestered, although only low concentrations of this indolic GLS were present in the host plant. Another Brassicaceae feeder, *A. lugens* (Klug), also is able to sequester indolic GLSs from *B. rapa* (Opitz, personal observation), thus indicating different sequestration abilities among the *Athalia* spp. specialized on members of Brassicacae. It is unknown whether GLSs also are metabolized and degraded in *A. liberta*. Adults of the Japanese subspecies *A. rosae ruficornis* (Jakovlev) are known to feed pharmacophagously on e.g., *Ajuga decumbens* Thunb. (Lamiaceae) and to sequester clerodane diterpenoids from this plant species (Nishida et al. 2004). It needs to be studied whether the *Athalia* spp. investigated in the present study are also pharmacophagous on species of Lamiaceae or other plant families.

In *A. rosae* larvae, GLS concentrations varied in a fluctuating manner throughout larval development (see Müller and Wittstock 2005). In contrast, the IG concentration of the Plantaginaceae-feeders *A. cordata* and *A. circularis* increased in the hemolymph constantly throughout larval development. This resulted in very high concentrations of IGs in the last instar (Fig. 3). The IGs found in both *Athalia* species that fed on Plantaginaceae were always comprised of high amounts of catalpol, although other IGs were present in the host plants as well. Usually, *P. lanceolata* contains more aucubin than catalpol, with lower concentrations in older leaves (Bowers 1988, 1991). This relation is highly variable, however, and the mature leaves of *P. lanceolata* were found to contain five-times higher concentrations of catalpol than aucubin in the present study. These subsequently increased in the larvae of *A. cordata* to a ratio of 30:1 catalpol:aucubin (Fig. 2c). The presence of high concentrations of catalpol in the hemolymph of *A. cordata* as compared to aucubin could be due both to higher catalpol concentrations in the host plants and to a higher sequestration efficiency of catalpol. Two additional IGs, 8-epiloganic acid and gardoside, were found in *P. lanceolata* in low concentrations in another study (Willinger and Dobler 2001). None of these IGs was detected in the samples of *P. lanceolata* or in the hemolymph of *A. cordata* in this study. The high catalpol concentrations in *A. circularis* probably are acquired differently. Whereas *V. beccabunga* contains only low concentrations of catalpol, the main IG fraction in the genus *Veronica* is comprised of several catalpol esters and carboxylated IGs (Jensen et al. 2005). The four identified catalpol esters of *V. beccabunga*, verproside, veronicoside, amphicoside, and verminoside, were not detectable in larval hemolymph of *A. circularis* and were not excreted with the frass either. Most likely, the catalpol esters were hydrolyzed and the released catalpol was sequestered, thus resulting in high catalpol concentrations in the larval hemolymph of *A. circularis*. In accordance with this hypothesis, the esterifying acid of the dominant catalpol ester verproside, 3,4-dihydroxybenzoic acid, was detectable in the frass of some *A. cordata* samples (3 out of 7) after verproside had been fed in high concentrations to the larvae (data not shown). A similar way of coping with catalpol esters has been shown earlier for butterfly species of the genus *Euphydryas* (Gardner and Stermitz 1988). In both *A. cordata* and *A. circularis*, the higher amount of catalpol as compared to aucubin in larval hemolymph also may be due to an epoxidation of the precursor aucubin into catalpol. Unfortunately, *Athalia* spp. cannot be reared on artificial diet to test this hypothesis. Caterpillars of *Precis* (*Junonia*) *coenia* Hübner (Lepidoptera: Nymphalidae) did not convert aucubin to catalpol or *vice versa*, when they were fed on an artificial diet containing the respective IGs (Bowers 1992).

Only traces of GLSs were detectable in frass of the two Brassicaceae-feeders, which suggests an efficient transport system of the hydrophilic GLSs through the gut membrane and an almost complete degradation of GLSs before excretion in *A. rosae* and *A. liberta*. In contrast to the GLS-sequestering species, frass of the Plantaginaceae-feeding *Athalia* species contained considerably more IGs, with generally more aucubin than catalpol. This finding indicates a favored, but not complete uptake of catalpol in these species. Other IG sequestering insect species likewise preferably take up catalpol, but aucubin is sequestered as well (for review see Opitz and Müller 2009). In few insect species, other IGs are sequestered in low amounts, but no catalpol esters or carboxylated IGs (Stermitz et al. 1986; Nishida and Fukami 1989; Boros et al. 1991; Mead et al. 1993).

As found previously for *A. rosae* (Müller and Wittstock 2005), the glucoside amount in *A. circularis* dropped drastically from the last feeding instar to the eonymph (Fig. 3c). This indicates that glucosides are either metabolized to a large extent before pupation or eliminated with the molt to the eonymph. In adults of all four species,

glucoside concentrations were relatively low. Furthermore, only catalpol was present in adults of both Plantaginaceae-feeders. Either these species eliminated aucubin, metabolized it to catalpol before pupation, or the concentrations of aucubin were below the detection threshold. In the IG sequestering species *Poladryas minuta* Edwards (Lepidoptera: Nymphalidae), large amounts of catalpol are excreted with the meconium (L'Empereur and Stermitz 1990).

For tenthredinid sawflies, sequestration seems to be a common way to handle plant secondary metabolites (Boevé and Schaffner 2003), and is often related to easy bleeding in this taxon. All investigated *Athalia* species show the phenomenon of easy bleeding as larvae, by which they immediately after injury confront an attacking predator with the glucosides in their hemolymph. Within this genus, IG sequestration resulted in a higher defense potential than GLS sequestration against a potential predator, the ant *M. rubra* (Table 1). The hemolymph of *A. cordata* significantly deterred ants from drinking embittered sucrose solution in higher dilutions (1:1,562) than the hemolymph of *A. rosae* (1:125). When offered together in comparable concentrations to ant workers, the hemolymph of *A. cordata* was more deterrent than hemolymph of *A. rosae*. In accordance, catalpol still evoked a high deterrence when tested in a tenfold lower concentration than sinalbin. The drinking duration of ants generally was low on hemolymph solutions of both species, and they often showed cleaning behavior after contacting a hemolymph solution. In general, the glucoside concentration in the hemolymph of all species is sufficient to offer protection against this generalist predator. The superior defense of the IG sequestering species (high activity of catalpol as well as high IG concentration in hemolymph) is puzzling because of their rather cryptic lifestyle. Larvae of *A. cordata* as well as *A. circularis* are camouflaged, and their green–grayish coloration merges well with the plant coloration. Moreover, *A. circularis* larvae often hide at the basis of the plant or even in the soil especially during the first larval days (personal observation). In contrast, *A. rosae* larvae promote their unpalatability with a blackish, conspicuous coloration (Ohara et al. 1993), whereas *A. liberta* is grey and rather inconspicuous. Furthermore, *A. rosae* larvae move during larval development to the yellow flowers of *S. alba* (Bandeili and Müller 2010), where the contrast is even stronger as compared to larvae feeding on leaves. Of all investigated species, *A. rosae* is most visible to visually-hunting predators, although it is the species least effective in sequestration. Other selection pressures must be assumed for the evolution of this prominent coloration of *A. rosae*.

To our knowledge, nothing is known about the exact mechanism of GLS or IG sequestration. Although the polar, non-volatile GLSs and IGs differ in their structure, both are glucosidically-bound hydrophilic metabolites, whereby the chemistry of the glucose moiety might be sufficient to facilitate sequestration. A transporter may be needed for their uptake, as has been postulated for the uptake of the hydrophilic glucoside salicin in order to pass the gut membrane in larvae of *Chrysomela populi* L. (Coleoptera: Chrysomelidae) (Discher et al. 2009). In contrast, the rather lipophilic cardenolides do not seem to need a transporter in *Oncopeltus fasciatus* (Dallas) (Heteroptera: Lygaeidae); studies on this system postulated a passive diffusion across the gut membrane (Isman 1977; Scudder and Meredith 1982). The specificity of glucoside uptake in *Athalia* spp. needs to be investigated in more detail to determine whether the transport is dependent on the glucosidic nature of the compounds. This would include testing whether the *Athalia* species also are able to sequester respective glucosides from non host plant families. Such investigations might further allow one to postulate the ancestral and derived host plant family use in the genus *Athalia* and to reveal phylogenetic relationships of sawfly species on the basis of their differing sequestration abilities.

Acknowledgments The authors thank the Botanical Garden of Berlin, Germany, for providing seeds of *Alliaria petiolata* and *Veronica beccabunga*, D. Balten, B. Kruckemeyer and R. Sutter for help in plant cultivation and insect rearing and K. Arand for help with bioassays. This work was funded by the grant MU1829/1-1 of the Deutsche Forschungsgemeinschaft.

Naphthoquinones and Anthraquinones from Scent Glands of a Dyspnoid Harvestman, *Paranemastoma quadripunctatum*

Günther Raspotnig · Verena Leutgeb · Miriam Schaider · Christian Komposch

Received: 24 June 2009 / Revised: 02 November 2009 / Accepted: 12 January 2010 / Published online: 2 February 2010

Abstract Extracts of *Paranemastoma quadripunctatum* (Opiliones, Dyspnoi, Nemastomatidae) contained seven components, all of which likely originated from the secretion of well-developed prosomal scent glands. The two main components (together accounting for more than 90% of the secretion) were identified as 1,4-naphthoquinone and 6-methyl-1,4-naphthoquinone. The minor components were 1,4-naphthalenediol, two methoxy-naphthoquinones (2-methoxy-1,4-naphthoquinone, and 2-methoxy-6-methyl-1,4-naphthoquinone) and two anthraquinones (2-methyl-9,10-anthraquinone and a dimethyl-9,10-anthraquinone). While some chemical data on scent gland secretions of the other suborders of Opiliones (Cyphophthalmi, palpatorean Eupnoi, and Laniatores) already exist, this is the first report on the scent gland chemistry in the Dyspnoi. Naphthoquinones are known scent gland exudates of Cyphophthalmi and certain Eupnoi, methoxy-naphthoquinones and anthraquinones are new for opilionid scent gland secretions.

Introduction

Large prosomal sac-like glands—so-called repugnatorial or scent glands—represent the main exocrine system in harvestmen, and they are a synapomorphic character of all Opiliones. These glands typically open to the body outside via one large orifice on the lateral margins of the carapace, either dorsal to coxae I (Palpatores), dorsal to coxae II (Laniatores), or atop tubercles ("ozophores") that protrude from the prosoma (Cyphophthalmi). Scent glands are primarily thought to serve chemical defense (e.g., Martens 1978) although, in certain groups, additional functions may have evolved (Holmberg 1986; Machado et al. 2002). Since the 1950s, the chemistry of scent gland secretions of various opilionids has been investigated sporadically, nevertheless leading to a considerable amount of chemical data (review in Gnaspini and Hara 2007): Specific sets of benzoquinones and phenols occur in gonyleptoid Laniatores (Grassatores) (e.g., Hara et al. 2005), while terpenes, esters, and nitrogen-containing compounds have been found in one representative of travunioid Laniatores (Insidiatores) (Ekpa et al. 1984). In the Palpatores, chemical knowledge on scent glands is biased: In Eupnoi (at least in some Sclerosomatidae), acyclic components such as ethyl ketones and their corresponding alcohols are common (Ekpa et al. 1985), while naphthoquinones were reported from Phalangiidae (Wiemer et al. 1978). Recently, both acyclic ketones and naphthoquinones were also detected in Cyphophthalmi (Raspotnig et al. 2005). By contrast, data on the chemical composition of scent gland exudates in the Dyspnoi are lacking.

Dyspnoid scent glands generally are more inconspicuous and cryptic than in other groups and show many aberrant features. Ozopores may be hidden or covered (instead of being exposed, as characteristic for defensive glands), and in the majority of Dyspnoi, noticeable emission of secretion from ozopores, as occurs in other Opiliones, does not occur at all. In some taxa, scent glands obviously produce and store solid secretion; this may be true for Ischyropsalididae (Juberthie et al. 1991) and Trogulidae (Schaider and Raspotnig 2009). In these cases, the emission of secretion is thought to be gaseous, by slow sublimation of solid glandular contents (Juberthie et al. 1991). In species of *Trogulus*, however, emission has never been detected, not even under heavy mechanical disturbance (Pabst 1953). Scent gland features in Dyspnoi have led to doubts concerning their defensive nature (Schaider and Raspotnig 2009), with the chemistry of secretion remaining a major open question. Since scent gland secretions and their chemical profiles, respectively, also seem to constitute phylogenetically useful information (e.g., Roach et al. 1980; Hara et al. 2005), and since the relationship of Palpatores and Laniatores is still uncertain (Shultz and Regier 2001; Giribet et al. 2002), the scent gland chemistry of Dyspnoi may help clarify phylogenetic questions.

We here present the first chemical analysis of a dyspnoid scent gland secretion using the model nemastomatid species, *Paranemastoma quadripunctatum*.

Methods and Materials

Specimens of *Paranemastoma quadripunctatum* (Perty 1833) (Opiliones, Dyspnoi, Nemastomatidae) were collected by hand in Styria and Carinthia (Austria). Extraction of scent gland secretions was performed from living specimens. In total, individual extracts from 18 adults of both sexes were prepared by two methods: 1) by dabbing scent gland secretion on filter paper pieces that were subsequently extracted in 100 µl of hexane for 10 min (8 extracts); 2) by whole body extraction of individuals in 150 µl of hexane or ethyl acetate for about 30 min (10 extracts). With respect to the latter method, in 8 of 10 cases, the solvent was heated to 60°C and sonicated to dissolve the components. Aliquots of extracts (2 µl) were subject to gas chromatographic-mass spectrometric (GC-MS) analysis, using a Trace GC2000 coupled to a Voyager MS (both from Thermo, Vienna, Austria). The GC was equipped with a ZB-5MS fused silica capillary column (30 m×0.25 mm i.d., 0.25 µm film thickness, Phenomenex, Germany). Injection was splitless with helium (at 1.5 ml min^{-1}) as carrier gas. The column temperature was programmed from 50°C (held for 1 min) to 200°C at 10°C min^{-1}, and then to 300°C at 15°C min^{-1}. The ion source of the MS and the transfer line were kept at 170°C and 310°C, respectively. Electron impact (EI) spectra were recorded at 70 eV.

Reference compounds for comparisons of GC-MS data were purchased from Sigma (Vienna, Austria) (1,4-naphthalenediol, 1,4-naphthoquinone, 2-methoxy-1,4-naphthoquinone, 2-methyl-9,10-anthraquinone). For authentic 6-methyl-1,4-naphthoquinone, we used a natural source, namely the scent gland secretion of another opilionid, *Phalangium opilio*, in which 6-methyl-1,4-naphthoquinone was identified by both MS and NMR-studies (Wiemer et al. 1978).

Results

Chemical Identification of Extract Components Seven components (A–G) were detected in the extracts by GC (Fig. 1; Table 1). The two major compounds (A and C), together accounting for about 90% of the extract profile, were known previously from a study with the cyphophthalmid harvestman *Cyphophthalmus duricorius* (Raspotnig et al. 2005), and appeared to be 1,4-naphthoquinone and 6-methyl-1,4-naphthoquinone, respectively. For final identification, we compared both their MS patterns as well as GC retention times to those of the authentic standards, finding full correspondence. The remaining minor components were identified either: 1) by comparison of mass spectra and retention times to commercially available compounds (compounds B, D, and F) or 2) tentatively only, by interpretation and comparison of mass spectra to spectra from the NIST-library (compounds E and G) (Table 1).

The mass spectrum of compound B clearly was related to that of compound A (1,4-naphthoquinone), and was identified as 1,4-naphthalenediol. Compounds D and E also appeared to be homologous naphthoquinones, namely methoxy-naphthoquinones. Compound D was identified as 2-methoxy-1,4-naphthoquinone (M^+ at *m/z* 188). Compound E exhibited a comparable mass spectrum, but with fragment ions in the higher mass range, all shifted 14 mass units higher (M^+ was at *m/z* 202), indicating the presence of an extra methyl-group. The position of the additional methyl-group in compound E was not determined but, by analogy to component C (6-methyl-naphthoquinone), we tentatively identify this compound as 2-methoxy-6-methyl-1,4-naphthoquinone. Components F and G are anthraquinones, namely a 2-methyl-9,10-anthraquinone (M^+ at *m/z* 222; component F), and a homologous component that again differs only by the presence of an additional methyl-group (M^+ at *m/z* 236; compound G). The latter compound is probably a dimethyl- or an ethyl-anthraquinone.

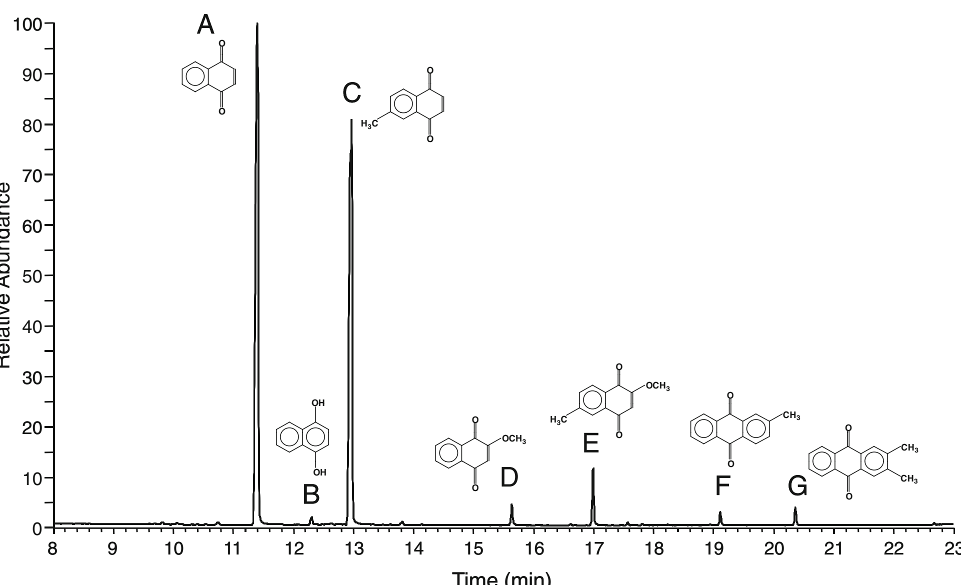

Fig. 1 Typical gas chromatographic profile of a droplet loaded with scent gland secretion dabbed onto filter paper from the mouth of a *Paranemastoma quadripunctatam* male. Components: Peak A (1,4-naphthoquinone), B (1,4-naphthalenediol), C (6-methyl-1,4-naphthoquinone), D (2-methoxy-1,4-naphthoquinone), E* (2-methoxy-6-methyl-1,4-naphthoquinone), F (2-methyl-9,10-anthraquinone), G* (2,3-dimethyl-9,10-anthraquinone). [Components E and G, marked with an asterisk were only tentatively identified (see text).]

Chromatographic Profiles and Secretory Glands The compounds found in the extracts are most likely from the scent glands that open to the body outside via one large ozopore on either side of the prosoma in the region of coxae I. In whole body-extracts obtained from short extraction times (30 min) at room temperature and hexane or ethyl acetate as a solvent, the chemical profile observed from filter-paper extraction was detected only in two out of 10 individuals. The remaining eight individuals (where no secretion was detected) were extracted again in hot hexane for 1 h, followed by ultrasonic treatment (10 min), and these extracts contained the same set of components as in filter-paper extracts, but in reduced amounts. In particular, the anthraquinones were found present only in trace amounts. In order to link unequivocally the extracted components with the scent glands, living specimens were squeezed gently with a forceps, which led to the emission of a droplet of clear enteric fluid from the mouth. Subsequently, and beginning from the lateral sides of the droplet, color was mixed into the enteric fluid, until the whole droplet became brownish. GC profiles of filter-paper extracts of this droplet clearly showed the full chemical profile of all seven components as described above. Such droplets were dabbed from eight individuals, and each exhibited a consistent chemical profile corresponding to the profiles obtained from whole body-extracted individuals (Fig. 1). No differences in secretion profiles were recognized between males and females. If clear droplets were examined (dabbed from

Components in bold are main components of the secretion; components marked with * have been identified tentatively (on the basis of their mass spectra) only. Quantification of components is based on the relative abundance of peak areas (whole secretion=total of all peak areas = 100%).

the mouth before the colored secretion was mixed in), none of the profile-components was detected.

Discussion

As outlined in the introduction, problems in extracting dyspnoid secretions are due to: 1) their possibly solid nature and, 2) the general reluctance of Dyspnoi to release secretions. Thus, after several previous unsuccessful attempts to extract and analyze secretions of some Dyspnoi (e.g., species of *Trogulus* and *Anelasmocephalus*), we present here the first example of dyspnoid scent gland chemistry. Behavioral experiments with *P. quadripunctatum* could not easily evoke emission of secretion; in fact, observable discharge of secretion from ozopores (common in many other Opiliones) did not occur. In case of disturbance, however, individuals of *P. quadripunctatum* regurgitate a droplet from the mouth, which subsequently is mixed with scent gland secretion, indicated by a gradual color change of the droplet from clear to brownish. A similar situation is known for certain Laniatores where a regurgitated droplet runs from the mouth to the ozopores, mixing with scent gland secretion, thereby also gradually changing color (Eisner et al. 2004). In *P. quadripunctatum*, we might have observed the reversed emission sequence; secretion from scent glands may run towards the mouth region where it is dissolved in a regurgitated droplet of enteric fluid. Another possibility is that regurgitated enteric fluid runs first to the ozopores, partly dissolving (viscous or even solid) scent gland exudates. Subsequently, the scent gland secretion-enteric fluid mixture may run back to the mouth, finally mixing with more enteric fluid, thus creating an applicable defensive droplet. Since the chemistry indicates a viscous or partly solid exudate, the latter scenario may be the most probable. In either case, secretion or a secretion-fluid-mix reaches the regurgitated droplet at the mouth from both sides at the same time, as indicated by the change of color beginning at the lateral margins of the oral droplet. Additionally, the location of ozopores is consistent with this view; i.e., ozopores in *P. quadripunctatum* (dorsal to coxae I as in all Palpatores) are hidden beneath a dorso-lateral fold of the carapace, and are directed ventrally. Thus, secretion, or a secretion-enteric mixture, is discharged towards coxae I, and flows ventrally towards the mouth. The scent gland secretion-enteric fluid mixture in *P. quadripunctatum* may be applied to a potential predator with the chelicerae. As such, application of secretion may represent a special kind of "leg dabbing" as known from Cyphophthalmi and certain laniatoreans (Juberthie 1961; Eisner et al. 2004).

Furthermore, the anthraquinones found in the *P. quadripunctatum* exudate are highly unusual compounds for exocrine secretions of arthropods, since these are solid, poorly soluble compounds under normal ambient temperatures. Thus, dissolving or diluting scent gland exudates in enteric fluid may be necessary in order to release secretion quickly. The rapid solubility of the scent gland exudates of *P. quadripunctatum* in enteric fluid is, nevertheless, remarkable because attempts to extract these exudates from whole bodies by using different solvents at elevated temperature with sonication did not produce concentrated extracts. In the rare cases where we found large amounts of the scent gland components in whole-body extracts, we suppose that we extracted individuals at the very moment of "loading" droplets of enteric fluid with scent gland secretion. Large amounts of these components were detected in droplets of both sexes, excluding the participation of male cheliceral glands as a possible source of chemical material (these glands are present in male nemastomatids, see e.g., Martens and Schawaller 1977).

We have preliminary data that the use of enteric fluid to dissolve (viscous or even solid) scent gland exudates may be characteristic of Dyspnoi. Even in trogulids and ischyropsalidids, this mechanism of secretion release appears to be more likely than the hitherto proposed slow sublimation of solid scent gland contents (e.g., Juberthie et al. 1991). In any case, the *Paranemastoma* exudate may represent a "prestage" to these completely solid secretion boli in the groups mentioned above. From a chemosystematic point of view, anthraquinones and methoxy-naphthoquinones are new for opilionid scent gland secretions but are expected to occur in other Dyspnoi as well. By contrast, 1,4-naphthoquinone and 6-methyl-1,4-naphthoquinone (the two main components of the *Paranemastoma* exudate) may be widespread, and are previously known from scent glands of Cyphophthalmi (Raspotnig et al. 2005), and from glands of at least one representative of Eupnoi, *Phalangium opilio* (Wiemer et al. 1978).

Abstract Alarm pheromones in social insects are an essential part of a complex of pheromone interactions that contribute to the maintenance of colony integrity and sociality. The alarm pheromones of ants were among the first examples of animal pheromones identified, primarily because of the large amount of chemical produced and the distinctive responses of ants to the pheromone. However, the alarm pheromone of the fire ant, *Solenopsis invicta*, eluded identification for over four decades. We identified 2-ethyl-3,6-dimethylpyrazine as an alarm pheromone component of *S. invicta*. Worker fire ants detect the pyrazine alarm pheromone at 30 pg/ml, which is comparable to alarm pheromone sensitivities reported for other ant species. The source of this alarm pheromone are the mandibular glands, which, in fire ants, are not well developed and contain only about 300 pg of the compound, much less than the microgram quantities of alarm pheromones reported for several other ant species. Female and male sexuals and workers produce the pyrazine, which suggests that it may be involved in fire ant mating flight initiation, as well as the typical worker alarm response. This is the first report of 2-ethyl-3,6-dimethylpyrazine from a *Solenopsis* species and the first example of this alkaloid functioning as an alarm pheromone.

Introduction

In social insects, maintenance of colony cohesiveness, sociality, and defense depends on sophisticated pheromonal communication. Worker/worker chemical interactions include recruitment, colony immigration, alarm, and nestmate recognition. Male and female alate sexuals use pheromones to induce mating flights and mediate mating behaviors. Workers are attracted to queen-produced releaser pheromones that are related to queen grooming, feeding and care of eggs (Vander Meer and Alonso 1998). Queens also release primer pheromones that influence sexual competition, directly or through the workers (Vargo 1998; Vander Meer and Alonso 2002). Pheromone diversity in social insects is matched by the diversity of their exocrine glands. Sixty three different glands have been described for social insects; in ants (Formicidae), alone, there are at least 39 described exocrine glands (Billen and Morgan 1998).

Alarm pheromones are a major class of social insect releaser pheromone, which have no direct benefit to the recipient but serve to put other colony members in a high state of alertness. In response to alarm pheromone, a variety of alarm behaviors have been described, including rapid running, attraction to the source, colony dispersal, and aggressive postures (Vander Meer and Alonso 1998). The chemistry of ant alarm pheromones is diverse, but components typically have a molecular weight of 100–200 and have 5–10 carbons. The low molecular weight, and consequent high volatility, of alarm pheromones is necessary for a quick and highly transient information transfer. Alarm pheromones can be terpenoids, alcohols, aldehydes,

ketones, esters, nitrogen heterocycles, sulfur-containing compounds, or other types of molecules (Hölldobler and Wilson 1990; Billen and Morgan 1998).

The highly evolved fire ant, *Solenopsis invicta* Buren, uses a complex of pheromones, including a recruitment pheromone (Vander Meer 1986) and a queen-produced recognition pheromone (Glancey et al. 1984). Decades ago, Wilson (1962) defined alarm behavior in fire ants as the rapid, erratic movement of workers toward a disturbed worker, and suggested that the source was from the head and, secondarily, from Dufour's gland components. Interestingly, alarm pheromones also are likely involved in fire ant mating flights. Fire ant mating flights are characterized by the opening of the normally closed nest tumulus, and frenzied, alarm-like, activity by workers (sterile), and male and female sexual alates, prior to the alates taking flight (Markin et al. 1971; Obin and Vander Meer 1994). The alarm-like behavior of workers and alate sexuals is mediated by a releaser pheromone linked to the mandibular gland (Obin and Vander Meer 1994; Alonso and Vander Meer 1997).

Elucidation of the structure(s) of the alarm pheromone of *S. invicta* has been a perplexing problem since it was first described over four decades ago (Wilson 1962). We present here the isolation, identification, and source of an alarm pheromone component from workers, and female and male sexual fire ants.

Methods and Materials

Source of S. invicta Colonies All colonies were monogyne and queenright (functional queen, brood, and workers), and derived from newly mated queens or from monogyne colonies collected from the Gainesville, FL, USA area, at least one year previously. Colonies were maintained as previously described (Banks et al. 1981), fed crickets three times a week, and had access to a test tube containing water and a test tube containing 10% aqueous sucrose solution.

General Alarm Bioassay Ten to 15 colonies were used for each bioassay, unless otherwise specified. At least 2 h prior to beginning an experiment, approximately 100–200 workers and some brood from each colony were added to small plastic containers with the inside walls coated with Fluon® to prevent escape. Additionally, a piece of red cellophane was placed over one end of the container to simulate dark conditions and to encourage the ants to move their brood and settle into a quiescent group; the experiment was not started if the worker ants had not settled into quiescent groups. All treatments and controls were placed in 20-ml scintillation vials. Just prior to the time of evaluation, the vial cap was removed and 3 ml of headspace were quickly drawn into a 5-ml plastic syringe (Henke-Sass Wolf Co.). A single syringe was used for each control and treatment. One milliliter of headspace air then was discharged over a group of quiescent ants, at a rate for which clean air (blank) would not generate a response, and the response of the ants observed and recorded. The response was evaluated on a scale of 1 to 4, with 1 = no response, 2 = some antennation, 3 = one to three workers running out of the resting group, and 4 = >3 workers running erratically from the resting group. Each evaluation lasted no longer than the length of time required to exhaust 1 ml of control air without alarming the ants. The experiment was conducted blind, with one person preparing the headspace sample and a second applying an unknown sample and reporting the response. All ant bioassay units were tested with all of the controls and treatments. Bioassay units were evaluated in sequence, but the samples given to the evaluator were randomized. In this way, a test unit that was alarmed had enough time to recover prior to the next test. To avoid complicating intra-colony responses, the workers in the bioassay units did not receive headspace samples from their own colony in the treatment/control vials. If negative or positive controls did not elicit the appropriate response, the experiment was terminated.

The *McNemar* test for significance of changes was used to analyze the alarm bioassay data. For analysis, bioassay scores of 1–2 were considered no reaction and scores of 3–4 were counted as alarm. The number of worker groups that displayed an alarm reaction to the test sample, but not to the negative control, was compared to the number of workers that reacted to the negative control but not to the test sample.

Shaken vs. Unshaken Workers Quiescent fire ant workers have an alarm response to headspace volatiles from shaken workers, but not to unshaken workers or clean air (Vander Meer et al. 2002). Unless specified otherwise, shaken and unshaken workers (100–200 in 20-ml glass scintillation vials coated on the upper inside surface with Fluon®) served as positive and negative controls, respectively. Air drawn from an empty 20-ml vial served as another negative control.

Amount of Venom Alkaloids in Shaken Ant Vials We tested whether shaking caused fire ant workers to release venom alkaloids. A thin layer of Fluon® was painted on the upper quarter of the inside surface of 20-ml scintillation vials, and about 100 fire ants were placed in each vial and weighed. The vials were shaken vigorously for 3–5 sec, and the ants were removed. *n*-Pentacosane (200 ng in 20 µl hexane) was added as an internal standard to the vial, which was then rinsed × 3 with hexane (100 µl each). The rinses were combined and the samples concentrated, if necessary, with

a gentle stream of nitrogen. A Varian 3700 GC, equipped with a flame ionization detector (FID) and a DB-1 fused silica column (0.32i.d.×30 m, 0.25 µm film thickness, J&W Scientific, Folsom, CA, USA), programmed from 150 to 285°C at 10°C min^{-1}, following a 2 min hold, was used for analysis. Injector and detector temperatures were 300°C. The data were analyzed with a Turbochome data analysis Workstation (Perkin-Elmer). Peak assignments were based on retention times of authentic *S. invicta* alkaloids, obtained by soaking workers in hexane overnight (see Ross et al. 1987). The total alkaloid quantity, relative to the internal standard, was determined This procedure was repeated five times.

Fire Ant Alarm Response to Venom Components Fire ant worker venom sacs were dissected (Vander Meer et al. 2002) and extracted in hexane at concentrations that approximated the amount found in vials from shaken ants (0.01 WE/10 µl hexane; WE = worker equivalent) and at 1 WE (per 10 µl hexane), used previously by Wilson (1962). Extracts (10 µl) were deposited on 1-cm square pieces of filter paper, the solvent allowed to evaporate, and the squares placed in 20-ml scintillation vials. The solvent control was prepared in the same way. Samples were evaluated in the alarm bioassay, as described above, along with shaken-ant positive controls.

Amount of Recruitment Pheromone in Shaken Ant Vials Shaken ants may release recruitment pheromone from their Dufour's glands, which could induce an alarm reaction in quiescent ants, as described by Wilson (1962). A sensitive recruitment orientation bioassay (modified from Barlin et al. 1976; Jouvenaz et al. 1978) was used to detect Dufour's gland products from shaken ants. This method utilizes a natural fire ant food trail that goes from the floor of the foraging area up a tongue depressor connected to two plastic platforms, the first platform used for the bioassay observation and the second containing food (crickets and 20% sucrose solution absorbed unto pieces of cotton). The base of each platform was coated with Fluon® to prevent ants from diverting their food trail down the sides of the platforms. A piece of paper (trail paper), the size of the platform, was placed on top of the first platform while the trail was developing. Pieces of paper (the same size as the platform) were marked with arcs on both sides, with both ends of the two arcs meeting. Ten microliters of treatment or control were applied to the two marked arcs of the paper (bioassay paper), and the solvent was allowed to evaporate. The bioassay paper was exchanged with the trail paper and the behavior of the ants observed. If at least one of the trailing ants followed the treatment trail from beginning to end, the test was scored positive; however, if the ants were confused at the two ends of the trail and no ants followed the test trail, the bioassay was scored negative. Due to the volatility of the recruitment pheromone, the bioassay was terminated after 2 min.

Three separate Dufour's gland extracts were prepared (Vander Meer et al. 2002) and diluted to a concentration of 0.1 WE/10 µl hexane. This concentration was subjected to bioassay and repeated dilution by a third until activity was lost. This allowed us to determine the approximate minimum Dufour's gland concentration needed for a positive bioassay. Extracts of shaken ant vials were prepared as described above, except no internal standard was added. Samples of these extracts were concentrated to 20 µl, with 10 µl used in the initial bioassay and the remaining 10 µl used for dilutions, if necessary. Responses of ants to these extracts were compared with responses of ants to the standard Dufour's gland dilutions, allowing determination of the approximate Dufour's gland concentration in WE.

Fire Ant Alarm Response to Recruitment Pheromone Dufour's glands were dissected as previously described (Vander Meer et al. 2002). Two concentrations were prepared: a) 1 WE/10 µl hexane, used by Wilson (1962) and b) 0.01 WE/10 µl hexane, the approximate amount released by shaken ants (see Results). Dufour's gland extract (10 µl) was deposited on a 1-cm square piece of filter paper, the solvent allowed to evaporate (ca. 20 sec), and the paper placed in a 20-ml scintillation vial. The solvent control was prepared in the same way. Samples were evaluated in the alarm bioassay as described above.

Solid Phase Micro Extraction (SPME) Collection Black (Carboxen/ Polydimethylsiloxane) SPME fibers (Supelco, Belefonte, PA, USA) were used to collect and desorb alarm pheromone volatiles for analysis. The fibers were thermally cleaned in the injection port of a GC for 2 h at 290°C or overnight at 280°C, prior to and after use. Approximately 1–1.2 g of worker ants were placed in a 20-ml glass scintillation vial, lined with Fluon® along the upper quarter to prevent escape. Each vial was sealed with a cap containing a small hole (large enough for insertion of the SPME needle) in the center. The ants were allowed to settle for approximately 1 h before headspace collection. For the unshaken ant treatment, a vial with worker ants was placed carefully under the SPME holder, and the fiber was lowered into the vial; volatiles were collected for 1 min. The SPME fiber then was retracted and the process repeated nine more times prior to desorption. For the shaken-ant treatment, a vial, containing worker ants, was shaken vigorously for 5 sec and then sampled by SPME, as described for unshaken ants.

Compounds absorbed onto the SPME fiber were analyzed initially on an Agilent 6890 GC, equipped with a FID (250°C), splitless injector (250°C), and a 30 m× 0.25 mm i.d. DB-23 capillary column. The column oven was

programmed from 40°C to 100°C at then 5°C min^{-1}, then to 250°C at 25°C min^{-1}. The SPME fiber was retracted 2.5 min. after insertion into the injector. SPME fibers also were analyzed by gas chromatography-mass spectrometry (GC-MS), using the same model GC and conditions, interfaced with an Agilent Mass Selective Detector 5973 (Palo Alto, CA) in the electron impact (EI) mode.

Identification of the Pyrazine Released by Shaken Fire Ant Workers The tentatively identified alarm pheromone component, 2-ethyl-3,5-dimethylpyrazine, was commercially available as a mixture with the 2-ethyl-3,6-dimethylpyrazine isomer (Aldrich Chemical Co, Milwaukee, WI, USA). Samples of these two isomers also were obtained (purified by preparative gas chromatography and 99% pure individually; Buttery and Ling 1997) from the laboratory of Dr R. M. Buttery. The identity of the natural alarm pheromone compound was established by co-injection and comparison of its retention time with those of the standards.

Synthetic chemicals were tested in the alarm bioassay at 1 ng/µl and 100 ng/µl in light mineral oil (Fisher Scientific, Fairlawn, NJ, USA). The oil did not elicit an alarm reaction and acted to slow the release of the volatile pyrazines. The negative controls for these tests were mineral oil, air, and unshaken ants. The positive control was the shaken ants. For all mineral oil bioassays, 1 ml of test material was placed in a 20-ml scintillation vial and tightly capped until use.

Quantification of Pyrazine Concentration in Headspace of Mineral Oil Standards Solutions of 100, 66, 33, 10, 6, and 3 pg/µl, in hexane, of 2-ethyl-3,6(3,5)-dimethylpyrazine were analyzed on the Agilent 6890 N-5973, in the Selective Ion Monitoring (SIM) mode, monitoring *m/z* 39, 42, 56, 81, 108, 135, and 136, in order to generate a standard curve. Since the standard consisted of two isomers, the ion abundances for each isomer were added to generate the standard curve. To determine synthetic pyrazine concentrations in the headspace of the mineral oil treatments used in the alarm bioassay, standards in light mineral oil, of concentration 100, 50, 25, 10, and 1 ng/µl, were prepared, and 1 ml of each was transferred to separate 20-ml scintillation vials. The headspace from each of these standards was used in the alarm bioassay, while another set of identically prepared standards was analyzed by GC-MS (sampling 100 µl of headspace) and used to determine pyrazine headspace concentration by comparison with the standard curve.

Qualitative Analysis of 2-Ethyl-3,6-Dimethylpyrazine in Mandibular Gland, Head and Thorax Quantities of the pyrazine in mandibular gland extracts from male and female alate sexuals and workers were determined. Female or male alate sexuals, or large workers, were collected in a scintillation vial with the upper quarter inner surface painted with Fluon®. The ants were allowed to become quiescent for at least 20 min and then frozen in a dry-ice acetone bath. An ant was placed on a watch glass, resting on ice under the microscope, with dorsal side up, and the top of the head punctured, and the cuticle layer was peeled away toward the front. The remaining (bottom) part of the head exoskeleton was held, and one of the mandibles was pulled gently. If the mandible disengaged from the associated musculature and there was no visible lumen, the sample was discarded. If the mandible was pulled out with some musculature and/or a visible lumen, it was transferred to a clean probe and placed in hexane in a vial insert. Twenty mandibles were accumulated per sample, and each sample was extracted in 50 µl hexane at 4°C overnight prior to analysis. An internal standard (IS), 2-methyl-3-ethyl pyrazine (100 pg), was added to the samples. Later, in order to shorten the time required for mandibular gland dissections, we dissected a minimum frontal part of the head that included mandibular glands, but excluded the postpharyngeal gland and antennae. Head and thorax samples (20 of each) of female and male alates, and workers also were collected and extracted as above.

Samples were analyzed by GC-MS using the DB-23 column, with helium as carrier gas. The GC oven was held at 40°C for 2 min, then increased to 150°C at 15°C min^{-1}, held for 5 min., then increased to 250°C at 10°C min^{-1}. Compounds were quantified by SIM, monitoring *m/z* 121 and 122 (for the IS) and 108, 135, and 136 (for 2-ethyl-3,6-dimethylpyrazine). Quantification of the alarm pheromone was achieved by comparing the total ion area of the pyrazine component to the total ion area of the IS. Analyses were carried out on workers (N=16), female alates (N=19), and male alates (N=10). The results were analyzed by non-parametric analysis as ranks (Fisher PLSD, ANOVA) using Statview 5.0 software.

Results

Amount of Venom Alkaloids in Shaken Ant Vials The mean weight of ca. 100 worker ants was 73.3±4.4 mg (mean ± SE, N=5). The mean weight of venom alkaloids released by the ants onto the vial after being shaken was 211.0±48.6 ng per vial (mean ± SE, N=5). Each venom sac contains ca. 30 µg of total alkaloid (Vander Meer 1988); therefore, the shaken ants deposited only 0.007 poison sac equivalents onto the glass vial.

Amount of Recruitment Pheromone in Shaken Ant Vials The lowest detectable Dufour's Gland equivalent from standard Dufour's gland extracts in the bioassay was 0.0033±0.0013 WE (mean ± SE, N=3). This represents

approximately 1.3±0.8 pg of *Z,E*-α-farnesene per cm of trail, (mean ± SE, N=3), since a worker Dufour's gland contains approximately 4 ng of *Z,E*-α-farnesene (RVM, unpublished). Recruitment orientation bioassays with residues in the vials from shaken ants showed no activity in 2 of 3 replicates. The active replicate showed minimal activity (one ant completely followed the trail within the 2 min. time limit of the bioassay), and activity was lost with the next serial dilution. Therefore, shaken ants probably release extremely low levels of recruitment pheromone, between 0.0067 and 0.0033 WE of a Dufour's gland.

Fire Ant Alarm Response to Poison Sac and Dufour's Gland Components Headspace from 1 WE poison sac samples elicited a lower alarm response in fire ant workers than the shaken ant positive control (G=4.167, P=0.041, df=1, N=15), but elicited a significantly greater response than the air negative control (G=6.125, P=0.013, df=1, N=15) (Fig. 1). The alarm response from the lower poison sac concentration (0.01 WE) was not different from the air negative control (G=0.8, P=0.371, df=1, N=15) (Fig. 1). One WE of poison sac can generate an alarm response in fire ants; however, the small amount of poison sac contents released by shaken ants did not contribute significantly to the observed alarm response induced by the headspace above shaken ants (Fig. 1). Dufour's gland extracts at 1.0 WE gave an alarm response that was not different from the alarm response from shaken ants (G=1.333, P=0.248, df=1; N=14). When the concentration was reduced to 0.01 WE of a Dufour's gland, the alarm response was not different from that of the negative air control (G=0.000, P=1.000, df=1; N=14). The alarm response of the 1.0 WE Dufour's gland concentration was greater than the response of the 0.01 WE concentration (G=8.100, P=0.004, df=1; N=14). As shaken fire ant workers release less than 0.01 WE of Dufour's gland products, these results suggest that the alarm reaction from shaken ants is not due to the release of Dufour's gland products.

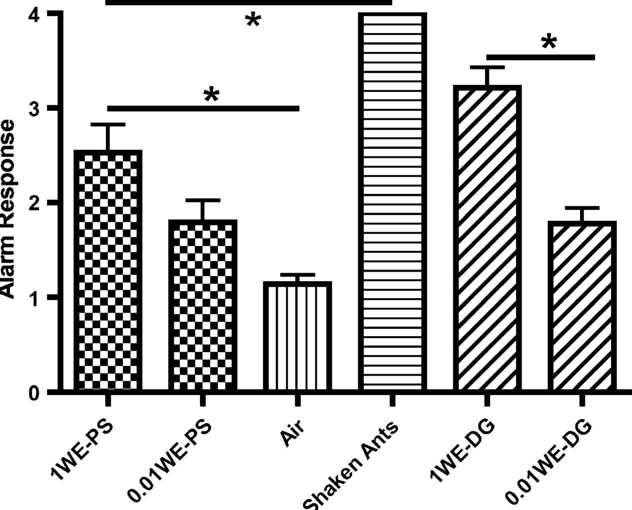

Fig. 1 Fire ant worker alarm responses to the headspace above, two poison sac extract concentrations (*WE* worker equivalent), two Dufour's gland (*DG*) extract concentrations, a positive control (shaken ants), and a negative control (air). The mean + SEM are shown (N=15). An * between two columns indicates a statistical difference (P< 0.05 *McNemar*'s Test)

Fig. 2 Structures of the two pyrazine isomers, 2-ethyl-3,6-dimethylpyrazine and 2,6-dimethyl-3-ethylpyrazine

Analysis of SPME Absorbed Volatiles Comparison of GC profiles from quiescent and shaken workers showed a difference of one major compound. The mass spectrum of this peak had a fragmentation pattern that matched 2-ethyl-3,5-dimethylpyrazine (2,6-dimethyl-3-ethylpyrazine; NIST 98 Mass Spectral Library, Rev.D.02.00, Palo Alto, CA, USA). Gas chromatographic analysis of the standards of this compound and the 2-ethyl-3,6-dimethylpyrazine isomer (Fig. 2), on a polar column, showed that the 2-ethyl-3,6-dimethylpyrazine eluted first (Buttery and Ling 1997). Our GC analysis showed that the natural compound co-eluted with this compound.

Alarm Pheromone Bioassay of 2-Ethyl-3,6-Dimethylpyrazine and 2-Ethyl-3,5-Dimethylpyrazine The alarm bioassay results for the commercial mixture of 2-ethyl-3,5(3,6)-dimethylpyrazine (ca. 60% 3,5-dimethyl isomer and 40% 3,6-dimethyl isomer) and the individual isomers are shown in Fig. 3. Responses to 1 ng/µl 2-ethyl-3,6-dimethylpyrazine were not significantly different (G=3.20, df=1, P=0.074, N=15) from the responses to the positive control of shaken ants, but were significantly greater (G=6.125, df=1, P=0.013, N=15) than those to the negative control of unshaken ants. In contrast, the alarm response to the 1 ng/µl synthetic mixture of 2-ethyl-3,5(3,6)-dimethylpyrazine was less (G=6.125, df=1, P=0.013, N=15) than that to the shaken ant positive control, but not different from that to the negative control of unshaken ants (G=3.2, df=1, P=0.074, N=15). By inference, the alarm response induced by the headspace above 1 ng/µl 2-ethyl-3,5-dimethylpyrazine was significantly less than that induced by the shaken ants, and not different from that by the unshaken ants. Responses to all 100 ng/µl treatment samples were not significantly different from the shaken ant positive control. In summary, 2-ethyl-3,6-dimethylpyrazine, had a lower active alarm response threshold than the 2-ethyl-3,5-dimethylpyrazine isomer and the mixture of the two isomers.

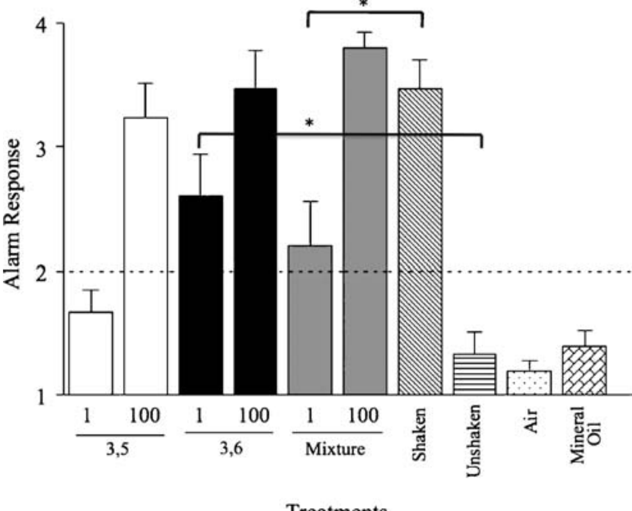

Fig. 3 Alarm responses of worker fire ants to two concentrations (in mineral oil) each of 2-ethyl-3,5-dimethylpyrazine (3,5), 2-ethyl-3,6-dimethylpyrazine (3,6), and a commercially available mixture of the two isomers (Mixture), negative controls (unshaken ants, air and mineral oil), and a positive (shaken ants) control. An * between two columns indicates a statistical difference ($P<0.05$, *McNemar*'s Test). An alarm response below the dashed line represents no alarm and alarm responses above the dashed line represents an alarm reaction

Alarm Response to Pyrazine Alarm Pheromone Concentration The fire ant alarm response to the headspace from a series of concentrations of the synthetic mixture of 2-ethyl-3,6(3,5)-dimethylpyrazine is shown in Fig. 4. The alarm response elicited from the headspace above the 1 ng/µl mixture was greater than that to the headspace above unshaken ants ($G=4.900$, $df=1$, $P=0.027$, $N=15$), but not different from that to headspace of the positive shaken ant control ($G=3.200$, $df=1$, $P=0.074$, $N=15$). By inference, all concentrations of the synthetic mixture of 2-ethyl-3,6(3,5)-dimethylpyrazine evaluated produced a greater alarm response than volatiles from the headspace above unshaken ants, with the exception of the lowest concentration, 100 pg/µl ($G=0.167$, $df=1$, $P=0.683$, $N=15$).

By using the standard curve ($y=1.3*10^6\times-628$; $R^2=0.9974$), derived from GC analysis of concentrations of the synthetic pyrazine mixture in hexane, the headspace concentrations of 100, 50, 25, 10, 1, and 0.1 ng/µl of the 2-ethyl-3,6(3,5)-dimethylpyrazine mixture in light mineral oil were determined as 0.5, 0.36, 0.24, 0.1, 0.03, and not detectable, pg/µl, respectively.

Pyrazine Alarm Pheromone in Adult Fire Ants Extracts of female and male alate and worker heads, and mandibles plus mandibular glands, all contained detectable amounts of 2-ethyl-3,6-dimethylpyrazine. In contrast, this compound was undetectable in thoracic extracts from these insects, demonstrating its specificity to the mandibular glands.

Workers contained significantly less 2-ethyl-3,6-dimethylpyrazine (316.6±42 pg/ant, $N=16$) than either female (746.9±80.8 pg/ant, $N=19$) or male (959.4±215.3 pg/ant, $N=10$) alates (Fisher PLSD, ANOVA, $P=0.002$ and $P<0.001$, respectively). The amounts of 2-ethyl-3,6-dimethylpyrazine in male and female alates were not significantly different (Fisher PLSD, ANOVA, $P=0.197$) (Fig. 5).

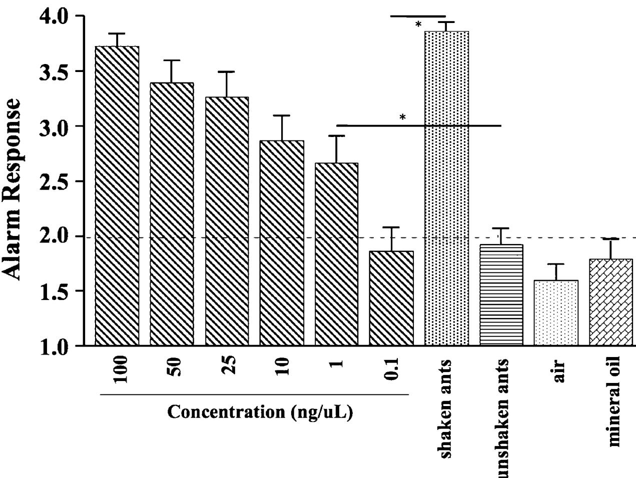

Fig. 4 Fire ant worker alarm responses to headspace above different concentrations of 2-ethyl-3,5(3,6)-pyrazine (in light mineral oil), negative controls (unshaken ants, air and mineral oil), and a positive (shaken ants) control. An * between two columns indicates a statistical difference ($P<0.05$, *McNemar*'s Test). An alarm response below the dashed line represents no alarm and alarm responses above the dashed line represents an alarm reaction

Discussion

Ant alarm pheromones are biosynthesized in a variety of exocrine glands and consist of chemicals of diverse

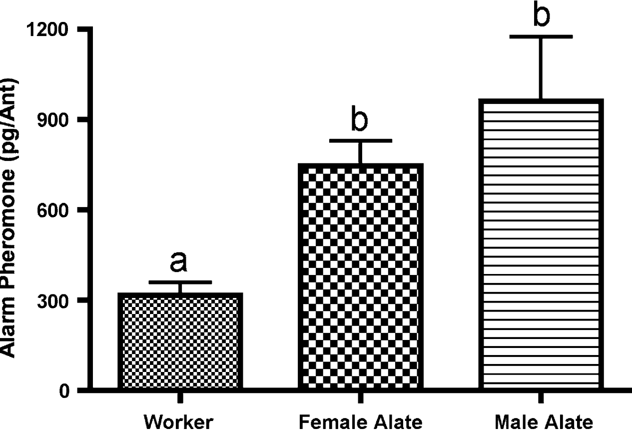

Fig. 5 The amount (mean + SEM) of 2-ethyl-3,6-dimethylpyrazine in fire ant workers (sterile females, $N=16$), and female ($N=19$) and male ($N=10$) sexual alates. Different letters above columns indicates means that are statistically different (*Fisher PLSD, ANOVA*, $P<0.05$)

structures (Vander Meer and Alonso 1998). Our identification of 2-ethyl-3,6-dimethylpyrazine as an alarm pheromone component of *S. invicta* increases the known diversity of ant alarm pheromones.

Pyrazines have been reported to have a variety of functions, including trailing (recruitment), defense, and alarm (El-Sayed 2009). The pyrazine reported here, 2-ethyl-3,6-dimethylpyrazine, has been reported primarily from the ant Subfamily Myrmicinae, which includes the genus *Solenopsis*, and also from the Ectatomminae, Dolichoderinae, and Ponerinae. In all cases, the function attributed to 2-ethyl-3,6-dimethylpyrazine is trailing (recruitment). While there are reports of 2-ethyl-3,6-dimethylpyrazine in mandibular glands of ants, no function has been attributed previously to this compound in ants (Cavill et al. 1984; Morgan et al. 1999). Another isomer, 2-ethyl-3,5-dimethylpyrazine, however, has been reported to be a part of the alarm pheromone of *Odontomachus brunneus* (Longhurst et al. 1978). This is the first report of 2-ethyl-3,6-dimethylpyrazine from a *Solenopsis* species, and is the first report of this alkaloid functioning as an ant alarm pheromone.

Although responses of fire ants to alarm pheromone previously have been documented (Wilson 1962), and the primary source of the pheromone known to be a cephalic gland, with attraction derived from a combination of the cephalic gland and Dufour's gland (Wilson 1962), the chemical identification of the fire ant alarm pheromone has eluded scientists. Our previous work had demonstrated that excited fire ant female and male sexual alates produce an alarm reaction in workers and that mandibular glands were the source of the alarm pheromone (Alonso and Vander Meer 1997). The ephemeral nature of fire ant alarm pheromones was demonstrated when headspace taken immediately after worker ants in a vial were electrically stimulated, elicited an alarm reaction. However, leaving the vial open for 2 min resulted in no alarm reaction (Vander Meer et al. 2002). This also partly explains the inability of some researchers to verify a cephalic source for fire ant alarm pheromones (Blum 1980).

Shaking a vial of worker ants revealed that both Dufour's gland and poison sac contents were deposited onto the vial, but at an amount less than one hundredth of a gland equivalent. This concentration did not elicit an alarm response from worker ants, although one Dufour's or poison gland equivalent did produce a significant alarm reaction. These results support the early alarm pheromone report by Wilson (1962), who used crushed worker body parts (one WE) to determine that the head, and probably the Dufour's gland, induced fire ant alarm responses. However, our results indicate that at physiologically relevant levels, neither Dufour's gland nor poison gland products are involved in eliciting the natural alarm response in fire ants, and that fire ant mandibular glands are the source of the alarm pheromone.

Because of the difficulty in obtaining behaviorally active extracts from worker mandibular glands, we used SPME to compare headspace above quiet and shaken workers to identify 2-ethyl-3,6-dimethylpyrazine as a unique component released from shaken fire ant workers. We then were able to detect and quantify this compound in the mandibular glands of workers, and male and female sexual alates. Our results showed that workers contain only about 300 pg of the pyrazine, which is consistent with the morphological description of fire ant mandibular glands as small and comprised of only a few secretory cells (Phillips and Vinson 1980; Billen 1990). The small quantity of alarm pheromone from fire ant workers is in sharp contrast to the microgram quantities (>3,000 fold more) of alarm pheromone found in other ant species, e.g., *Lasius alienus* Dufour's gland contains microgram quantities of alarm pheromone (Regnier and Wilson 1969). The high volatility of the fire ant pyrazine and the small quantity produced explains why isolation and identification of the alarm pheromone of *S. invicta* had proven difficult.

Fire ants respond to the pyrazine mixture at a concentration of 30 pg/cm^3, or 1.3×10^{11} molecules/cm^3, which is comparable to the alarm sensitivity of 10^{10}–10^{13} molecules/cm^3 predicted by a model (Regnier and Wilson 1968), and to alarm threshold measurements of $>10^{11}$ molecules/cm^3 for *Pogonomyrmex badius* (Wilson 1958). The detection threshold of 2-ethyl-3,6-dimethylpyrazine by humans is extremely low, roughly 3.8×10^{13} molecules/cm^3 (Buttery and Ling 1997). In comparison, the fire ant is about 300 times more sensitive to this compound.

Ants produce a wide variety of alkaloids (see El-Sayed 2009). Fire ants produce a variety of 2-methyl-6-alkyl or alkenylpiperidines (MacConnell et al. 1971) that are used by workers in a variety of defensive contexts (Obin and Vander Meer 1985) and for prey procurement. These alkaloids are produced by the poison gland and stored in large quantities in the venom sac (Vander Meer 1988) and have a variety of physiological functions e.g., insecticidal, antimicrobial, and herbicidal (Obin and Vander Meer 1985; Escoubas and Blum 1990). The patterns of piperidine alkaloid homologues have been shown to be species-specific and are useful taxonomic tools (Brand 1978; Vander Meer and Lofgren 1988). Our identification of a pyrazine alarm pheromone component, produced by mandibular glands of fire ants, adds to our knowledge of the variety of alkaloid biosynthesis in glands of ants.

Future research will focus on the ontogeny of 2-ethyl-3,6-dimethylpyrazine production in the fire ant, isolation and identification of additional fire ant alarm pheromone components, and the species specificity of 2-ethyl-3,6-dimethylpyrazine.

Acknowledgements We thank M. Custer, T. Krueger, and D. Milne for technical support, and Drs. S Allan and S. D. Porter for critically reviewing the manuscript. We are grateful to Dr. Buttery for graciously providing synthetic samples of the two pyrazines.

Abstract *Bracon hebetor* is a larval ectoparasitoid that utilizes several pests belonging to the family Pyralidae (Lepidoptera) as hosts. In the present study, we analyzed the kairomonal response of this wasp to the male-produced sex pheromone of a host, the greater wax moth *Galleria mellonella*, an economically important pest of honeybees, *Apis mellifera*. Coupled gas chromatography-electroantennographic detection (GC-EAD) revealed three compounds in headspace collections from male *G. mellonella* that elicited responses from *B. hebetor* antennae: decanal and the previously identified sex pheromone components, nonanal and undecanal. Y-tube olfactometer tests that used naïve, mated wasps showed that females, but not males, were highly attracted to (a) male *G. mellonella* headspace samples, (b) two synthetic blends of nonanal and undecanal (in ratios matching that found in male moth samples), and (c) the two aldehydes tested individually. Further, female wasps did not discriminate between a blend of aldehydes and male *G. mellonella* headspace. In dose-response trials that used octanal, nonanal, decanal, and undecanal, no difference in EAG responses of the two sexes was observed, except for undecanal at the second highest dose, for which female antennae showed significantly larger responses than did male antennae. When the two binary blends were tested at different doses, female wasps were significantly attracted to the two highest doses (1 µg and 10 µg), but not to the lowest dose (100 ng). Our results show that females of this economically important parasitoid utilize the male-produced sex pheromone of a host as an indirect cue to guide them to potential oviposition sites.

Introduction

The greater wax moth, *Galleria mellonella* (L.) (Lepidoptera: Pyralidae), is an economically important pest of the honeybee, *Apis mellifera* (L.). Larval stages of the moth feed on wax, pollen, and honey, thus causing heavy economic damage as they burrow through the comb. One of the main biological control agents of *G. mellonella* is *Bracon hebetor* Say (Hymenoptera: Braconidae), a cosmopolitan, gregarious larval ectoparasitoid of many pests belonging to the family Pyralidae (Lepidoptera), including the Mediterranean flour moth, *Ephestia kuehniella* (Zeller), the Indian meal moth, *Plodia interpunctella* (Hübner), and the almond moth, *Cadra cautella* (Walker) (Benson 1973; Taylor 1988; Brower and Press 1990; Parra et al. 1996; Gündüz and Gülel 2004). The broad host range, high reproductive rate,

and short generation time of *B. hebetor* makes it an excellent candidate for biological control of many pyralid pests, including *G. mellonella*.

During host foraging, hymenopteran parasitoids commonly use semiochemicals emitted by the host, sources indirectly associated with the presence of the host (e.g., microorganisms), or the host habitat (Madden 1968; Vinson 1986; Godfray 1994; Rutledge 1996; Colazza et al. 2004; Laumann et al. 2009). Successful parasitism depends on appropriate habitat identification (i.e., long-range host location or host-habitat location), followed by short-range host location that includes host finding, host acceptance, host suitability assessment, and host regulation (Vinson et al. 1998). Parasitoids may use different semiochemicals emitted from different sources at various stages of the host selection process. In general, host habitat cues are most important at long distances, while cues from the host itself are more important at short distances (Weseloh 1981).

Sex pheromones released by host species have been shown to serve as kairomones in host location by a number of egg parasitoids, e.g., *Trichogramma* spp., *Telenomus* spp., *Chrysonotomyia ruforum* (Krausse), *Dipriocampe diprioni* (Ferrière), and *Ooencyrtus pityocampae* (Mercet) (Powell 1999; Bruni et al. 2000; Hilker et al. 2000; Reddy et al. 2002; Fiaboe et al. 2003), and by several larval/pupal parasitoids, e.g., *Apanteles ruficrus* (Haliday), *Microplitis rufiventris* (Kok), and *Eupelmus vuilleti* (CRW) (Powell 1999). Sex pheromones of aphids also are utilized as kairomones by several parasitoids, including *Diaeretiella rapae* (McIntosh), *Praon* spp., and *Aphidius* spp. (Powell 1999; Birkett and Pickett 2003; Powell and Pickett 2003). The parasitoids *Aphytis* spp., *Aphytis chilensis* (Howard), and *Encarsia perniciosa* (Tower), which attack the California red scale, *Aonidiella aurantii* (Maskell), the Oleander scale, *Aspidiotus nerii* (Bouché), and the San José scale, *Diaspidiotus* (=*Quadraspidiotus*) *perniciosus* (Comstock), respectively, also respond to host sex pheromone (Dunkelblum 1999; Powell 1999). All these interactions involve female-produced sex pheromones of the host; few studies have reported attraction of a parasitoid to an identified male-produced sex pheromone of the host (but see Borges et al. 1999; Silva et al. 2006).

Previously, it was not known whether the sex pheromone of *G. mellonella* is exploited by *B. hebetor* during the location of host larvae. Males of *G. mellonella* produce a sex pheromone in specific glands located on their forewings (Barth 1937; Roller et al. 1968), which has been identified as a mixture of nonanal and undecanal (Leyrer and Monroe 1973; Finn and Payne 1977; Romel et al. 1992). In this study, we evaluated the electrophysiological and behavioral responses of naïve, mated females and males of *B. hebetor* to the sex pheromone of male *G. mellonella*.

Methods and Materials

Insect Origin and Rearing The stock culture of *G. mellonella* originated from infested honeycomb stored in a warehouse in Samsun, Turkey, in 1997, and it has been maintained since on the same diet in the Laboratory of Animal Physiology at Ondokuz Mayıs University, Turkey. For the experiments, adult moths were collected from the stock culture and held in 1-liter glass jars, along with honeycomb for oviposition. Last instars were transferred to containers with fan-folded pieces of stiff paper and kept in an environmental chamber at 23°C, 60% r.h. and 16:8 L:D photoperiod. Individuals were separated by sex during the pupal stage.

Bracon hebetor was collected from a stock culture of *G. mellonella* in 1997 and has since been maintained on *G. mellonella* infesting honeycomb. Individuals used in the electrophysiological experiments, and the behavioral experiments with the 7:3 nonanal:undecanal blend (see results), were reared on *C. cautella*, whereas individuals used in the remaining behavioral experiments were reared on *G. mellonella* or *E. kuehniella*, from stock cultures in our laboratories. One *G. mellonella* last instar, or 1–3 *E. kuehniella*/*C. cautella* last instars, was introduced into a glass vial containing a honey-saturated cotton pad. One pair (female and male) of *B. hebetor* (<24-h-old) was introduced into the vial and allowed to attack the host for 48 h. Mated females and males were obtained by placing newly emerged female parasitoids with males in vials for 72 h. All parasitoids used in bioassays were 3 to 5-d-old. The test insects were reared in a controlled environment chamber at 25°C, about 60% r.h., with a 14:10 L:D photoperiod.

Preparation of Odor Stimuli Headspace collection was performed using small Teflon filters (3 mm i.d.), filled with adsorbent and connected to a battery-driven air pump (GroTech, Gothenburg, Sweden) via an aquarium hose. Initially, collection was performed on 10 male *G. mellonella* for 7 h, after the moths had been kept in the rearing jar for several days. In this experiment, 30 mg of SuperQ (Alltech, PA, USA, catalogue #2735) were used as adsorbent. Additional, 2–4 h collections (N=4) were later performed on 1–2 males placed in 50-ml glass jars. In these collections, 40 mg of Tenax GR 60/80 (Alltech, PA, USA, catalogue #4937) were used as adsorbent. The opening of the collection chamber was covered with part of an oven bag (Toppits®, Melitta Scandinavia AB, Klippan, Sweden). The flow rate of the pump was set to 200 ml min^{-1}, and odor collections were performed at the beginning of the scotophase at 25°C, 60% r.h., and 100 Lux red light. Collections from empty jars served as controls to identify possible contaminants.

After collection, filters were eluted with 200 µl of hexane with methyl stearate (10 ng/µl) added as an internal

standard. Prior to analysis by coupled gas chromatography and mass spectrometry (GC-MS), samples were concentrated to 50 µl with a stream of N_2. Synthetic aldehydes (nonanal, decanal, undecanal, of purity 95–99%) were purchased from Aldrich Chemical Ltd. (Dorset, England) or PolyScience Corp. (Niles, IL, USA). Male *G. mellonella* samples were diluted to match the concentrations of synthetic nonanal and undecanal in binary blends used in behavioral experiments.

Chemical Analysis Male *G. mellonella* headspace samples were analyzed with a Hewlett-Packard 5890 gas chromatograph, equipped with a non-polar HP-1 column (30 m×0.25 mm i.d., 0.25 µm film thickness; J&W Scientific, USA), linked to an HP 5972 mass spectrometer. Helium was used as carrier gas at a velocity of 40 cm sec^{-1}, and injector temperature was 220°C. Oven temperature was programmed from 50°C (held for 2 min.) to 250°C at 10°C min^{-1}. Aldehydes in headspace samples were identified by using mass spectral libraries and by comparison of retention times and mass spectra with those of synthetic standards.

Electrophysiology Coupled gas chromatography-electroantennographic detection (GC-EAD) was used to identify physiologically active compounds in headspace samples of male *G. mellonella*. The head of a *B. hebetor* wasp was cut and mounted to a PRG-2 EAG (10× gain) probe (Syntech, Kirchzarten, Germany), with the head placed on one electrode and the tips of both antennae placed on the other electrode with conductive gel (Blågel, Cefar, Malmö, Sweden). Charcoal-filtered and humidified air, at 0.5 m sec^{-1}, passed over the antennae via a glass tube (0.6 cm i.d.), located 10 mm from the preparation. Headspace samples, or a blend of synthetic nonanal, decanal, and undecanal (10 ng/µl of each compound) were injected into a Hewlett-Packard 5890 Series II plus gas chromatograph, equipped with the non-polar HP-1 column. The effluent from the column was split, 1:1, between the flame ionization detector (FID) and a heated transfer line (230°C) that led to the antennal preparation. Hydrogen, at 40 cm sec^{-1}, was used as carrier gas. Oven temperature was programmed from 50°C (held for 2 min.) to 250°C at 10°C min^{-1}. A wasp preparation was used only for a single GC-EAD run.

In addition to GC-EAD, electroantennogram (EAG) dose-response tests were performed on female and male *B. hebetor* antennae by using octanal [found in male *G. mellonella* from Russia (Lebedeva et al. 2002)], nonanal, decanal, and undecanal, in hexane, as stimuli. A Pasteur pipette, containing 10 µl of the test stimulus on a strip of filter paper, was inserted through a hole in the glass tube, 10 cm before the outlet. The pipette was linked to an air-control system (Syntech, Kirchzarten, Germany), which generated 0.5 sec puffs through the pipette into the air stream of the glass tube. The amount of aldehyde loaded into a pipette ranged from 10 ng to 10 µg. Pipettes loaded with 10 µl of hexane served as controls. A dose-response trial for a specific aldehyde always started with the lowest dose and finished with the highest dose, and was always followed by a control stimulus. Each antennal preparation was stimulated with all four aldehydes at all four doses, but the order of aldehydes tested was randomized among antennal preparations.

Data obtained from GC-EAD and EAG experiments were analyzed with Autospike Version 3.3 (Syntech, Kirchzarten, Germany). In dose-response experiments, the EAG amplitude for each dose of a test compound was divided by the amplitude of the control stimulus associated with that compound, and the calculated ratios used in the statistical analyses. For each compound and dose, responses of female and male antennae were compared by using unpaired *t*-tests (SPSS 11.5).

Behavioral Experiments A Y-tube glass olfactometer was used to test the attraction of naïve, mated female and male *B. hebetor* to headspace samples, as well as to the two sex pheromone components of male *G. mellonella* (nonanal and undecanal) that showed EAD/EAG responses for both sexes of wasps (see Results). All bioassays were conducted during the photophase, between 0900 and 1700 h. The bioassay room was maintained at 28±1°C, with r.h. between 50% and 70%.

The olfactometer consisted of a central tube (15 cm long, 1 cm i.d.) and two lateral arms (5 cm long, 1 cm i.d.), which were separately connected to an extending glass tube (10 cm long, 1 cm i.d.). Humidified and purified air, at 150 ml min^{-1}, was passed into the extending glass tube through a Teflon connection. Illumination was provided by hanging an office lamp (20 W) vertically, 50 cm above the olfactometer. In each experiment, we used strips of filter paper (1 x 1 cm) loaded with either 10 µl of the test stimulus or hexane (control) as lures.

Based on the analysis of headspace samples (see Results), the following test stimuli (Table 1) were used: male *G. mellonella* headspace sample (stimulus #1), two synthetic nonanal:undecanal blends at a total dose and ratios matching those found in different headspace sampling methods (#3 and #6), and nonanal (#8) and undecanal (#9) at doses matching those found in headspace samples. In addition, to test the dose-response relationship of *B. hebetor* to the host sex pheromone components, the two binary blends were tested at three concentrations each (#2–4, and #5–7).

For each bioassay, a single parasitoid was introduced individually into the central arm of the Y-tube. We recorded

Table 1 Odor stimuli used in behavioural assays with *Bracon hebetor*

Stimulus	Amount applied onto filter paper (µg)	
	Nonanal	Undecanal
1. Male *Galleria mellonella* headspace sample	≈0.4	≈0.6
2. Two-component blend[a] (7:3) low	0.07	0.03
3. Two-component blend (7:3) medium	0.7	0.3
4. Two-component blend (7:3) high	7.0	3.0
5. Two-component blend (2:3) low	0.04	0.06
6. Two-component blend (2:3) medium	0.4	0.6
7. Two-component blend (2:3) high	4.0	6.0
8. Nonanal	0.7	–
9. Undecanal	–	0.3

[a] Ratio in parentheses refers to nonanal:undecanal

the initial choice of each wasp that walked into one of the arms (choice chambers) and remained there for at least 30 sec. If a wasp did not make a choice within 8 min. after being released into the olfactometer, it was considered as a non-responder and excluded from the analysis. After five wasps had been tested, the olfactometer arms were rotated 180°, to randomize any positional effects, and the filter strips were changed. After ten wasps had been bioassayed, the olfactometer was exchanged for a clean one. Olfactometer data were analyzed by chi-square tests (SPSS 11.5).

Results

Chemical Analyses All headspace samples of *G. mellonella* males contained large amounts of nonanal and undecanal, small amounts of the corresponding primary alcohols and fatty acids, as well as intermediate amounts of decanal and 6,10,14-trimethylpentadecan-2-one. The nonanal:undecanal ratio in the sample from male moths in a rearing jar was approximately 7:3, whereas the average ratio (±s.d.) in four samples from male moths in empty glass jars was 0.58±0.04. Based on these data, headspace samples with a nonanal:undecanal ratio of ≈2:3, and two synthetic blends with a nonanal:undecanal ratio of 7:3 or 2:3, were tested in behavioral experiments (see below). Decanal was probably a contaminant, as this compound was found in similar amounts in male headspace samples and control samples.

Electrophysiology Three compounds in male *G. mellonella* headspace samples consistently elicited responses from female wasp antennae: nonanal, decanal, and undecanal (Fig. 1). The GC-EAD activity of these compounds was confirmed by using a synthetic mixture of the three aldehydes (Fig. 1). In the dose-response trials using the three aldehydes and octanal, no difference in EAG responses was observed between sexes, except to undecanal at the second highest dose (1 µg), to which female antennae showed significantly higher responses than male antennae ($P<0.01$; Fig. 2).

Behavioral Experiments In the Y-tube bioassay, naïve mated *B. hebetor* males did not respond to male headspace ($\chi^2=0.36$; $P>0.05$; Fig. 3), or to the mixture of nonanal and

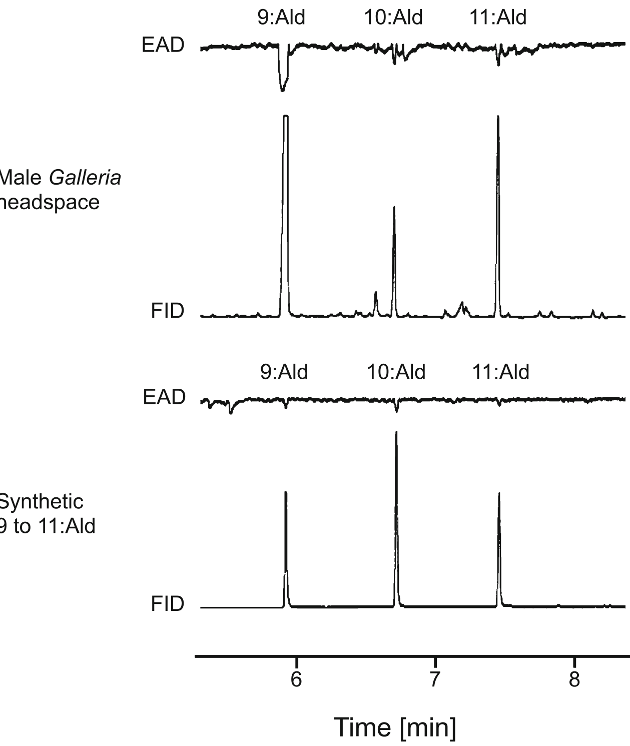

Fig. 1 Gas chromatography-electroantennogram detection (GC-EAD) responses of antennae of female *Bracon hebetor* to nonanal (9:Ald), decanal (10:Ald), and undecanal (11:Ald) in male *Galleria mellonella* headspace sample (*upper graph*) and synthetic reference compounds (*lower graph*). *FID* flame ionization detection

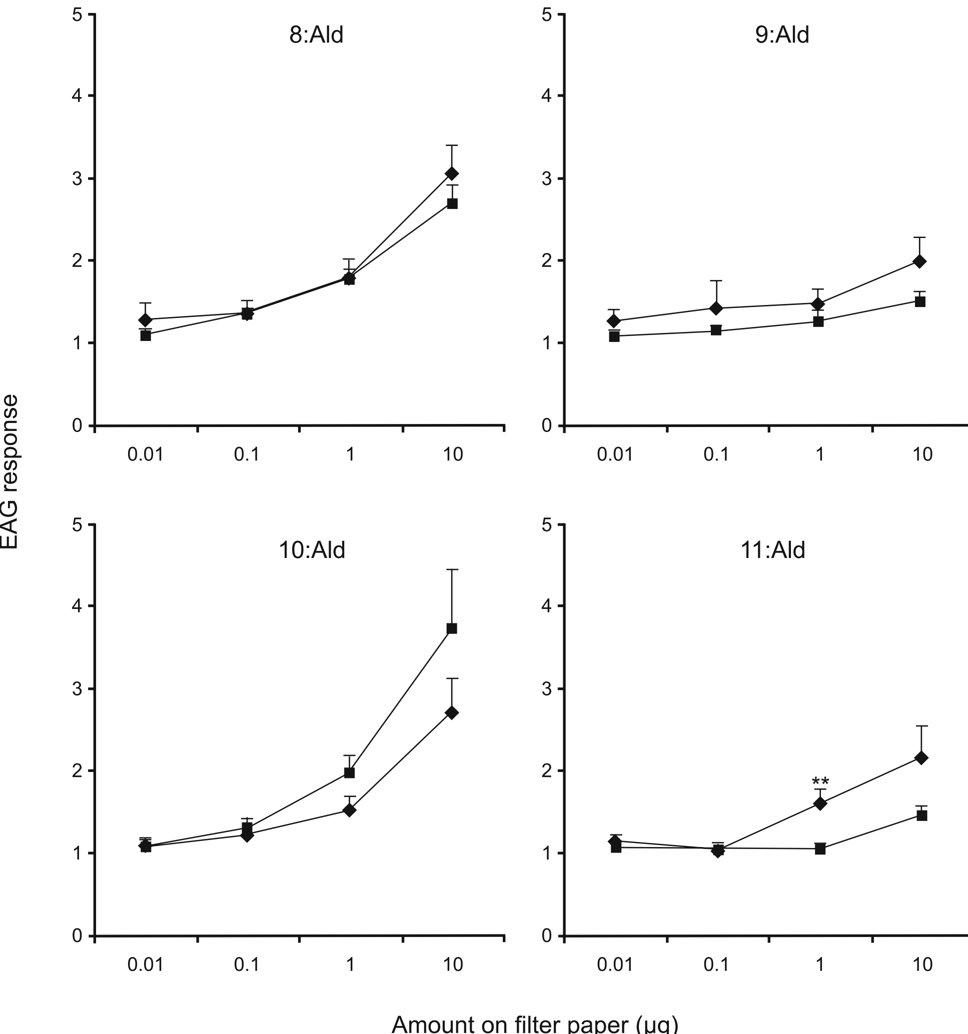

Fig. 2 Electroantennogram (EAG) responses of female (♦ N=14) and male (■ N=15) antennae of *Bracon hebetor* upon stimulation with various doses of octanal (8:Ald), nonanal (9:Ald), decanal (10:Ald), and undecanal (11:Ald). EAG responses were calculated as the ratio of the stimulation amplitude (test compound) to the control amplitude (air). *Error bars* show the standard error of the mean. The *asterisks* indicate a significant difference in response between sexes at a specific dose (unpaired *t*-test: ** $P<0.01$)

undecanal at the same dose (1 µg) as the headspace sample (7:3 ratio: χ^2=2.6; $P>0.05$; 2:3 ratio: χ^2=0.40; $P>0.05$; Fig. 3). In contrast, naïve, mated *B. hebetor* females were attracted significantly to the headspace sample (χ^2=14.4; $P<0.001$; Fig. 3), as well as to both synthetic binary blends at 1 µg (7:3 ratio: χ^2=4.8; $P<0.05$; 2:3 ratio: χ^2=9.0; $P<0.01$). When the headspace sample was tested against the binary blend at a nonanal:undecanal ratio of 2:3, at the same total amount of compounds (1 µg), no difference in attraction of female wasps was observed (χ^2=1.0; $P>0.05$, Fig. 3). Interestingly, when tested individually, both nonanal at 700 ng (χ^2=9.0; $P<0.01$) and undecanal at 300 ng (χ^2=4.8; $P<0.05$) were attractive to female wasps (Fig. 4). Dose-response trials that used the two binary blends showed that female wasps were attracted to the highest dose (10 µg; 7:3 ratio: χ^2=6.5; $P<0.05$; 2:3 ratio: χ^2=9; $P<0.01$), but not to the lowest dose (100 ng; 7:3 ratio: χ^2=0.13; $P>0.05$; 2:3 ratio: χ^2=0.04; $P>0.05$), of these mixtures (Fig. 4). In general, there were few non-responders ("No choice" in Figs. 3 and 4).

Discussion

Semiochemicals play an important role in mediating the interactions between parasitoids and their hosts. In some cases, these chemical cues are not directly associated with the attacked host stage, but help the parasitoids through restricting the search area. This is the case in several systems in which parasitoids utilize the host's sex pheromone to search an area where host mating is in progress and where oviposition has probably taken place or is soon to occur (Vet and Dicke 1992; Godfray 1994). In the present study, we demonstrated that an economically important parasitoid, *B. hebetor*, uses the male-produced sex pheromone components of its host, *G. mellonella*, as a kairomone for locating potential oviposition sites.

Electrophysiological analyses revealed that antennae of *B. hebetor* responded selectively to three compounds in male *G. mellonella* headspace samples: the two previously identified pheromone components, nonanal and undecanal (Barth 1937; Roller et al. 1968), as well as decanal. Other

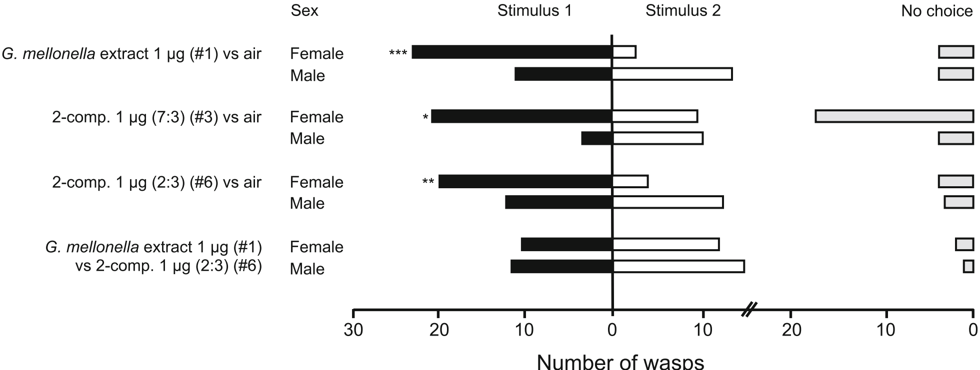

Fig. 3 Responses of naïve, mated females and males of *Bracon hebetor* to headspace sample of male *Galleria mellonella*, and to 7:3 and 2:3 mixtures of nonanal:undecanal (2-comp), in Y-tube olfactometer experiments. The total amount of aldehydes applied to the filter paper is shown (*chi-square* test: * $P<0.05$, ** $P<0.01$, *** $P<0.001$). The numbers of wasps that did not walk into one of the arms of the olfactometer and remain there for at least 30 sec are shown as "No choice"

compounds found in headspace samples in this study and in previous studies [1-nonanol, 1-undecanol, nonanoic acid, undecanoic acid (Romel et al. 1992), and 6,10,14-trimethylpentadecan-2-one (Lebedeva et al. 2002)] did not elicit antennal responses. Naïve mated female wasps were attracted significantly to two different blends of nonanal and undecanal in Y-tube tests. Further, female wasps did not discriminate between the synthetic binary blend and the headspace sample of male *G. mellonella*. This attraction to the compounds apparently was independent of the host species on which the test individuals were reared upon as larvae.

Few studies have reported attraction of female parasitoids to male-produced volatiles of the host. The egg parasitoid *Trissolcus basalis* (Wollaston) is attracted to volatiles released from virgin males of its host, *Nezara viridula* (L.) (Colazza et al. 1999). The same pattern has been observed for the congener *T. brochymenae* (Ashmead) that attacks *Murgantia histrionica* (Hahn) (Conti et al. 2003). However, the chemicals that mediate parasitoid attraction in these interactions were not identified. The only studies we know that show parasitoid attraction to an identified male sex pheromone of the host are by Borges et al. (1999) and Silva et al. (2006). They demonstrated that *Telenomus podisi* (Ash.) was attracted to methyl 2,6,10-trimethyltridecanoate, the male-produced pheromone of *Euschistus heros* (Fabr.) (Borges et al. 1998).

We used two different blends of aldehydes in the behavioral tests, based on the contrasting ratios obtained from the two different collection procedures (i.e., 10 males kept in the rearing jar for several days before collection was performed, or 1–2 males kept in a glass jar only during the time of odor collection). The nonanal:undecanal ratio of 7:3, obtained by the former method, was the same as that reported by Leyrer and Monroe (1973), who collected headspace from 50 males over 1 or 2 days. This ratio probably reflects the faster accumulation of the more volatile nonanal, relative to the less volatile undecanal, over longer collection periods. In contrast, the ratio of 2:3 obtained in the latter experiments is similar to that reported by Romel et al. (1992), who collected headspace for just a few hours. Regardless, female wasps were attracted similarly to both ratios in Y-tube experiments.

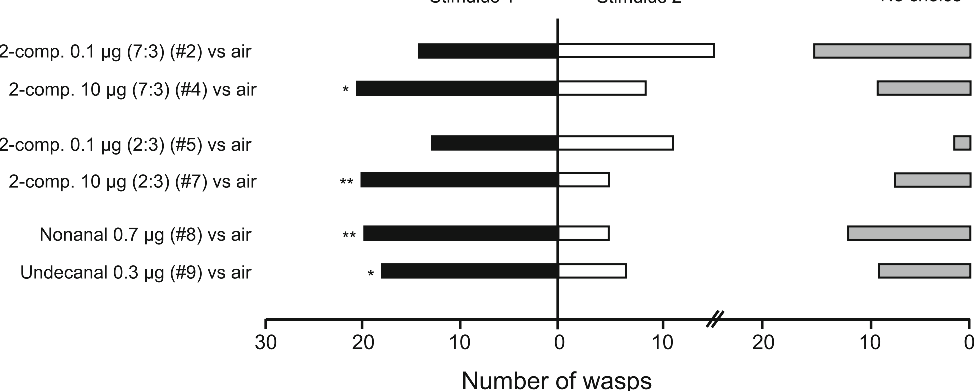

Fig. 4 Responses of naïve, mated females of *Bracon hebetor* to nonanal, undecanal, and 7:3 and 2:3 ratios of nonanal:undecanal (2-comp), in Y-tube olfactometer experiments. The total amount of aldehydes applied onto the filter paper is shown (*chi-square* test: * $P<0.05$, ** $P<0.01$). The numbers of wasps that did not walk into one of the arms of the olfactometer and remain there for at least 30 sec are shown as "No choice"

Another indication of a flexible response by female *B. hebetor* to the *G. mellonella* sex pheromone was its attraction to both aldehydes, individually, in contrast to many other parasitoid-host interactions for which mixtures of host sex pheromone components are needed to elicit parasitoid attraction. Another example of parasitoid attraction to individual component(s) of host sex pheromone is *Trichogramma chilonis* (Ishii). This parasitoid utilizes several moth species as hosts, including *Plutella xylostella* (L.) and *Ostrinia furnacalis* (Guenée). Female *T. chilonis* are attracted to (*Z*)-11-hexadecenyl acetate, a sex pheromone component of *P. xylostella* (Reddy et al. 2002), as well as to (*E*)-12-tetradecenyl acetate, a sex pheromone component of *O. furnacalis* (Boo and Yang 2000). Other natural enemies of *P. xylostella*, such as *Cotesia plutellae* (Kurdjumov) and *Chrysoperla carnea* (Stephens), respond only to more complete blends of the *P. xylostella* pheromone and not to individual components (Reddy et al. 2002).

The kairomonal response of *B. hebetor* females to the *G. mellonella* sex pheromone appears to be innate, as the wasps had no previous experience with odors of that host. Glinwood et al. (1999) demonstrated that naïve (i.e., received no experience of aphids or sex pheromone prior to testing) *Aphidius ervi* (Haliday) responded to aphid sex pheromone in olfactometer bioassays, providing further evidence that the response is innate. Innate responses to species-specific odor cues, such as adult sex pheromones, were reported by Mbata et al. (2004) for the generalist parasitoid *Pteromalus cerealellae* (Ashmead). This species is known to utilize insect hosts from two orders and four families (Brower 1991). Steidle et al. (2001, 2003), reported that a related generalist parasitoid, *Lariophagus distinguendus* (F.), also responded innately to the pheromone of one of its hosts.

Despite the sexual dimorphism in behavioral responses to host odors, no major difference in antennal sensitivity was observed between female and male *B. hebetor*, suggesting that the response difference was not a result of sexual dimorphism in the peripheral olfactory system (see Dweck and Gadallah 2008). Instead, our data imply that the behavioral differences arose from different processing by female and male central nervous systems of similar sensory input. Similar findings have been shown for the pteromalid bark beetle parasitoids, *Roptrocerus xylophagorum* (Ratzeburg) and *Rhopalicus tutela* (Walker) (Pettersson et al. 2000; Pettersson 2001).

Our study is not the first to demonstrate the use of semiochemicals for host location by *B. hebetor*. Parra et al. (1996) suggested that the species is attracted to grain moth infestations by volatile chemicals emanating from *E. kuehniella* frass. In addition, female *B. hebetor* are attracted to frass extracts from several host species (Dweck, Gündüz, Svensson, Anderbrant, unpubl. data). This use of olfactory cues by *B. hebetor* for location of hosts may be able to be exploited in pest control programs that utilize this parasitoid.

Acknowledgments The study was financed by a joint research grant under The Middle East and North Africa—Swedish Research Links Programme to EAG and OA.

Abstract This study was conducted to determine if constitutive levels of jasmonic acid (JA) and other octadecanoid compounds were elevated prior to herbivory in a maize genotype with documented resistance to fall armyworm (*Spodoptera frugiperda*) and other lepidopteran pests. The resistant inbred Mp708 had approximately 3-fold higher levels of jasmonic acid (JA) prior to herbivore feeding than the susceptible inbred Tx601. Constitutive levels of *cis*-12-oxo-phytodienoic acid (OPDA) also were higher in Mp708 than Tx601. In addition, the constitutive expression of JA-inducible genes, including those in the JA biosynthetic pathway, was higher in Mp708 than Tx601. In response to herbivory, Mp708 generated comparatively higher levels of hydrogen peroxide, and had a greater abundance of NADPH oxidase transcripts before and after caterpillar feeding. Before herbivore feeding, low levels of transcripts encoding the maize insect resistance cysteine protease (Mir1-CP) and the Mir1-CP protein were detected consistently. Thus, Mp708 appears to have a portion of its defense pathway primed, which results in constitutive defenses and the ability to mount a stronger defense when caterpillars attack. Although the molecular mechanisms that regulate the constitutive accumulation of JA in Mp708 are unknown, it might account for its enhanced resistance to lepidopteran pests. This genotype could be valuable in studying the signaling pathways that maize uses to response to insect herbivores.

Introduction

Numerous arthropod pests attack maize, an important crop grown throughout the world. Some of the most devastating of these insects are larvae in the order Lepidoptera, and they include various corn borers (*Ostrinia nubialis*, *Diatraea grandiosella*, *Sesamia nonagrioides*), the corn earworm (*Helicoverpa zea*), and fall armyworm (*Spodoptera frugiperda*). Although transgenic technology has vastly improved control of these pests, it is not always publicly

acceptable. Consequently, the development of host plant resistance to insect herbivores, especially against lepidopteran larvae, is an alternative and/or supplement to transgenic technology and chemical control methods. Over a number of years, the maize inbred lines Mp704 and Mp708 that are resistant to fall armyworm and southwestern corn borer (*Diatraea grandiosella*) have been developed using classical plant breeding (Williams et al. 1990b). These maize inbreds exhibit a remarkable resistance to a number of lepidopteran pests (Davis et al. 1988) in both field and laboratory tests, and they are often designated multiple-borer-resistant genotypes. The germplasm used to develop these lines originated in Antigua, where it was probably selected for its ability to yield well under high insect pressure. The phenotype exhibited by these lines is a reduction in larval weight by approximately 50%. Larvae recovered from resistance plants grown in the field are significantly smaller than are those reared in laboratory bioassays on fresh or freeze-dried material (Williams et al. 1990a). Not only are larvae reared on whorl tissue from resistant plants smaller, their development is delayed and they pupate later. This results in smaller larvae that are susceptible to predators and parasitoids in the field for a longer period of time.

A number of studies using Mp704 and Mp708 have been conducted to elucidate the mechanism of resistance, which is a multigene trait regulated by approximately 12 QTL (Brooks et al. 2005, 2007). The plants do not contain significant levels of secondary compounds like DIMBOA (Hedin et al. 1984), but there are differences in protein and hemicellulose levels that are associated with resistance (Williams et al. 1998). Other studies have shown that larval feeding results in the accumulation of a cysteine protease, Mir1-CP, at the wound site in the yellow-green region of the maize whorl (Pechan et al. 2000). Transgenic plant material expressing Mir1-CP inhibited fall armyworm larval growth by approximately 80% (Pechan et al. 2000). The LC_{50} for purified recombinant Mir1-CP ranged from 0.6 to 8.0 ppm depending on the lepidopteran species (Mohan et al. 2008). Both in vitro and in vivo studies indicated that Mir1-CP perforates the insects' peritrophic matrix (PM), which is an acellular structure that surrounds the food bolus and protects the midgut microvilli from chemical and physical damage (Pechan et al. 2002; Mohan et al. 2006). Physiological studies have shown that larvae feeding on whorl tissue from resistant plants are less able to utilize nutrients from ingested and digested food (Chang et al. 2000), which could be attributed to disruption of the PM that prevents nutrient recycling and accounts for the reduction in larval growth (Pechan et al. 2002).

Because resistance in these lines is a multigene trait, it would be useful to determine what other characteristics contribute to the resistance phenotype. Since chemical signals play a vital role in protecting plants from insect herbivores, they might account for some of the resistance found in Mp704 and Mp708. Some chemicals attract insect predators, others prime the plant for subsequent herbivory, while others trigger a signaling cascade within the plant that results in the accumulation of a plethora of defensive molecules (Walling 2000; Kessler and Baldwin 2002; Frost et al. 2008; Zhu-Salzman et al. 2008). These signals include jasmonic acid (JA), its conjugates, and other molecules in the octadecanoid pathway that signal plant responses to both abiotic and biotic stresses and regulate plant developmental pathways (see recent reviews by Wasternack 2007; Balbi and Devoto 2008; Browse and Howe 2008; Howe and Jander 2008; Kazan and Manners 2008). However, one of the crucial functions of JA is to transmit the signals that enable the plant to mount defenses against insect herbivores (Wasternack 2007; Browse and Howe 2008; Howe and Jander 2008). As would be expected for a signaling compound, JA biosynthesis is tightly regulated, and its concentration in plants prior to insect infestation generally is low (Hildebrand et al. 2000). However, JA levels dramatically increase in response to herbivory resulting in the increased expression of enzymes in the JA biosynthesis pathway and other defensive molecules. Although the JA signaling pathway has been studied extensively in dicot plant species, far less is known about it in monocots (Kazan and Manners 2008). Little is known about the role of JA and other octadecanoids in maize response to herbivory, especially at the midwhorl growth stage approximately five weeks after planting, when plants are particularly vulnerable to lepidopteran feeding in the field. The role of JA in positively regulating the accumulation of Mir1-CP in Mp708 recently has been demonstrated (Ankala et al. 2009). JA-treatment increased the expression of Mir1-CP and its transcripts, whereas blocking the octadecanoid pathway with ibuprofen or salicylic acid (SA) prevented its accumulation and resulted in plants more susceptible to herbivory (Ankala et al. 2009). Although the accumulation of Mir1-CP in Mp708 in response to caterpillar feeding or JA application is rapid and abundant, it has been observed consistently that low amounts of the protein and its transcripts are present prior to feeding (Pechan et al. 2000; Ankala et al. 2009). In addition, maize whorls collected in the field prior to herbivory and immediately lyophilized also retard caterpillar growth by 50% (Williams et al. 1990a). These observations suggested that parts of herbivore defense pathways are constitutively expressed in the resistant genotypes and that these plants may be "primed" to respond to herbivore attack. Priming has been defined as "the physiological state that enables plants to activate better or stronger defense responses" (Beckers and Conrath 2007). Generally plants are primed by external factors such as volatile organic compounds (Engelberth et al. 2004; Ton et al. 2006; Frost et al. 2008), but in this case it appears that the

insect resistant genotype Mp708 may be "naturally or genetically primed". We propose that Mp708 has constitutively elevated JA levels that cause the expression of certain defense genes prior to herbivory and that allows the plants to mount a rapid and strong response to subsequent herbivore feeding. In this study, we measured the levels of JA and *cis*-12-oxo-phytodienoic acid (OPDA) in the resistant and susceptible inbreds prior to and during herbivory. We also examined the expression of key genes that lead to the production of defensive proteins in maize, as shown in our model of the herbivore-defense signaling pathway, to determine if their transcript levels were elevated prior to herbivore attack (Fig. 1). These included genes in the JA-biosynthetic and signal transduction pathways and several genes that encode proteins involved in direct defenses.

Methods and Materials

Plant Materials and Fall Armyworm Feeding Two inbred lines of maize (*Zea mays*) Mp708 and Tx601 that are resistant and susceptible to fall armyworm feeding, respectively, were used (Williams et al. 1990b). Mp708 was selected from a cross between the resistant inbred Mp704 and Tx601 (Williams et al. 1990b). In numerous studies over 15 years, we have not detected the expression of Mir1-CP or its transcript in Tx601. However, Tx601 does have a defense response that includes the induction of defense gene expression in response to fall armyworm feeding (see Fig. 4). Plants were grown under greenhouse conditions at the Plant Science Research Center, Mississippi Agricultural and Forestry Experiment Station (Mississippi State University, USA). Fall armyworm larvae were reared on artificial diet at the Corn Host Plant Research Unit Insect-Rearing Laboratory of the USDA-Agricultural Research Service. Larvae that were 5-7-d post hatch (*ca*. 3rd instar) were used and seven larvae were placed in the whorl of 4–5-wk-old corn plants. This experiment was repeated three times with five plants for each time point and genotype. Tissue surrounding the feeding area in the yellow-green region of the whorl was collected at 0 time (no feeding) or after 1.5 or 24 h of feeding. Collected samples were frozen immediately in liquid nitrogen and stored at −70°C until use.

Quantification of Jasmonates and Salicylate Approximately, 100 mg of each sample tissue (frozen in liquid

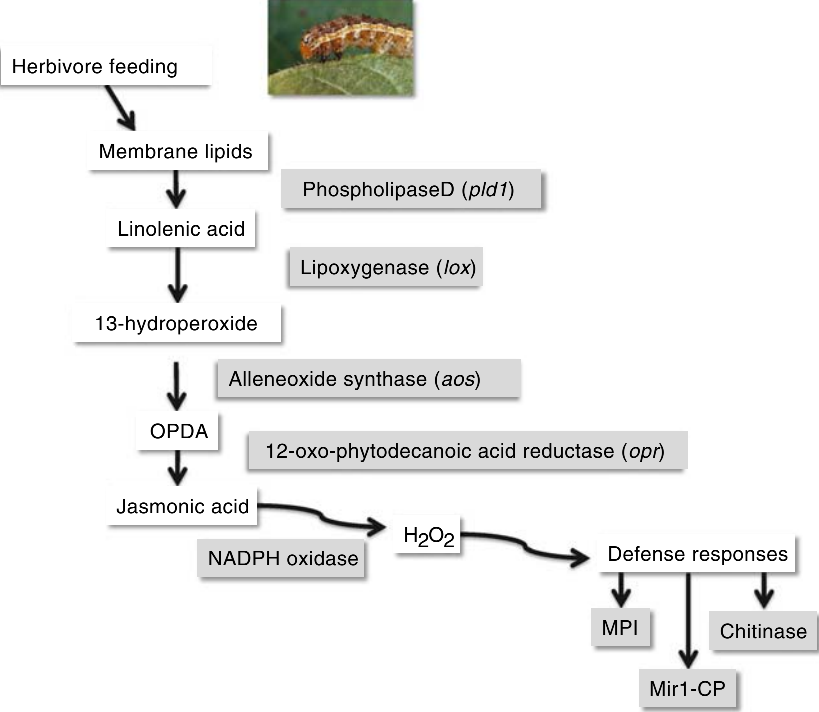

Fig. 1 A generalized diagram of the steps that occur in response to caterpillar feeding and that lead to the production of plant proteins involved in direct defenses. The enzyme phospholipase D releases linolenic acid from membranes. Linolenic acid is converted to jasmonic acid (JA) through a series of reactions. Key enzymes catalyzing some of the reactions are lipoxygenase (LOX), allene oxide synthase (AOS), and 12-oxo-phytodecanoic acid reductase (OPR). NADPH oxidase forms superoxide that is converted to the signaling molecule H_2O_2, which in turn triggers the production of maize protease inhibitor (MPI), maize insect resistance 1 cysteine protease (Mir1-CP), and chitinase. Transcript levels for the genes encoding the enzymes in the gray boxes and the three defense proteins were measured in this study

N_2) were used for the extraction and quantification of JA, OPDA, and SA as described previously (Engelberth et al. 2003). After extraction, the samples were analyzed by Chemical Ionization (CI)-GC/MS (Engelberth et al. 2003; Schmelz et al. 2003). Because appropriate internal standards are not commercially available, OPDA was quantified by comparison with an external standard curve as described previously (Schmelz et al. 2003).

RNA Extraction and Reverse Transcription Total RNA was isolated from the frozen leaf samples ground in liquid nitrogen using the Rneasy mini-kit (Qiagen) as per manufactures protocol. RNA quality was verified electrophoretically on 1% agarose gels followed by ethidium bromide staining. RNA samples were quantified spectrophotometrically by absorbance at 260 nm. Synthesis of cDNA and RT-PCR was carried out using the ThermoScript RT-PCR System (Invitrogen). cDNA synthesis was carried out with Oligo $(dT)_{20}$ primers using 500 ng of each RNA sample. RT-PCR conditions were optimized for each primer in a gradient thermocycler (Master Cycler, Gradient, Eppendorf) with regard to annealing temperatures. RT-PCR products were analyzed on a 1% agarose gel, and the optimized annealing temperatures were used for quantitative real-time PCR (qRT-PCR) experiments.

Quantitative RT-PCR qRT-PCR was carried out in a Roche Light Cycler 2.0 instrument using 0.5 μM each of forward and reverse primers (HPLC purified) (Table 1), 2 μl of Fast Start DNA Master SYBR Green I (Roche Diagnostics), and 1 μl cDNA (equivalent to 25 ng of mRNA). A no-template negative control was run with each set of samples to check for primer dimers or contaminants in the reagents. The following Light Cycler protocol was used. Pre-incubation (95°C for 10 min); amplification and quantification (95° for 10 sec, annealing temperature for specific primer for 10 sec, 72° for 5 sec) repeated 45 cycles: melting curve (65°–95° with 0.1°C/sec heating rate). A trial run was carried out for each primer set with all samples, and the one showing the highest expression (lowest CP) was used for construction of a standard curve using serial dilutions. Primer efficiency was determined for each primer from the standard curve (Pfaffl 2001). The relative expression for each target gene was calculated using the mathematical model proposed by Pfaffl (Pfaffl 2001). Ubiquitin was used as the reference gene. Specificity of RT products was confirmed by agarose gel electrophoresis of the product as well as evaluation of the melting curve.

Statistical Analysis Jasmonate and salicylate quantification data were obtained from three sets of experimental repeats

where each experiment had four to five biological repeats for each time point and each genotype. qRT-PCR data are from three biological repeats for each genotype and time point. Statistical analysis was carried out with a mixed model analysis of variance using the MIXED procedure of SAS (SAS Institute, Cary NC, USA).

Immunoblot Analysis Immunoblot analysis was conducted from whorl samples as previously described (Pechan et al. 2000).

Detection of H_2O_2 in Leaves Presence of H_2O_2 was detected by using 3,3- diaminobenzidine (DAB) as a substrate (Orozco-Cardenas and Ryan 1999) The DAB solution (1 mg/ml) was prepared by stirring DAB in PBS buffer of pH 3.2 for 5 h and adjusting the final pH to 5.6 with KOH.

Detection of H_2O_2 in Wounded Leaves The plants were cut at the soil level, and the cut stems were placed separately in these solutions for 12 h: (a) DAB solution; (b) DAB solution containing 100 μM diphenylene iodonium (DPI), an inhibitor of NADPH oxidase (Frahry and Schopfer 1,998); or (c) DAB solution containing 10 mM ascorbic acid, an antioxidant. The whorl region was crushed with a hemostat five times. This resulted in severe wounding to the tissue, but the plants remained structurally intact. The damaged whorl region was collected 10 min after wounding. The leaf segments were boiled in ethanol for 10 min to decolorize the leaves allowing clear visualization of the reddish brown color formed by the polymerization of DAB in the presence of H_2O_2. As control, unwounded leaves were stained in DAB solution and boiled in ethanol.

Detection in Fall Armyworm Infested Tissues The outer leaves of 5-day old plants were gently peeled off to expose the yellow-green region of the whorl region. Five-d-old fall armyworm larvae that had been starved for 6 h were placed in the whorl region and were allowed to feed for 3 or 24 h. The feeding site then was dipped in a Petri dish containing 15 ml of DAB solution for 3 min while the leaf was still attached to the plant. This was done to ensure that the peroxide formed was due to larval feeding and not to wounding caused by cutting the leaf. A separate replicate was performed with DAB solution containing 10 mM ascorbic acid. The stained area was cut from the plant and was boiled in ethanol for 10 min.

Results and Discussion

JA and OPDA Levels in Mp708 and Tx601 Three time points were selected for the determination of JA levels in Mp708 and Tx601. Since the primary objective of this study was to determine if JA levels in Mp708 were higher than those in Tx601 prior to herbivore feeding, samples were collected at the control time point (0 h). The 1.5 h time point was used because this is the minimum amount of time needed to detect the accumulation of Mir1-CP protein in response to fall armyworm feeding. The 24 h time point was selected because prior investigations indicated that Mir1-CP transcripts (*mir1*) were present prior to herbivory and did not increase during the first 24 h of feeding, which suggested that endogenous JA levels might maintain elevated transcript levels during this time. When both *cis*- and *trans*-JA levels were determined in whorls of the resistant and susceptible inbreds prior to herbivory, the results indicated that the resistant line Mp708 had *ca.* 3 to 4-fold higher levels of *cis*-JA and *trans*-JA than Tx601 (Fig. 2a, b). In addition to higher JA levels, OPDA, an intermediate in the JA biosynthetic pathway, was *ca.* 4-fold higher in Mp708 than Tx601 (Fig. 2c, d). In Mp708 and Tx601, *cis*-JA levels increased in response to fall armyworm feeding from 0 to 24 h and its levels were almost equal in both genotypes after 24 h of feeding (Fig. 2b). In Mp708, there was a larger increase in *cis*-OPDA as well as *trans*-OPDA in response to herbivory at 24 h (Fig. 2c, d). The susceptible genotype Tx601 had a "typical" response to herbivory marked by low constitutive levels of *cis*-JA and *cis*-OPDA prior to herbivory followed by an increase in both after larval feeding (Fig. 2b, d). Tx601 did not show an increase in *trans*-OPDA in response to larval feeding. Hence, it appears that herbivore defense in Mp708 could employ both JA and OPDA. OPDA can trigger the JA signal transduction pathway, and both compounds are needed for complete activation of the wound response (Böttcher and Pollman 2009). In addition OPDA can activate the expression of a unique set of defense genes not regulated by JA (Böther and Pollman, 2009).

In addition to OPDA and *cis*-JA, the level of the phytohormone salicylic acid (SA), which is also involved in plant defense signaling, was determined at 0 and 1.5 h after infestation (Fig. 2e). While JA plays a major role in defense against feeding by chewing insects, SA plays a central role in defense against pathogens (Ryals et al. 1996). Although there is evidence for both positive and negative interactions between the JA and SA pathways, the primary mode of interaction appears to be mutual antagonism. Reduction in SA levels has been shown to increase the JA response and vice versa. The significantly reduced level of SA in Mp708 relative to Tx601 at these two time points supports the mutual antagonism that has been observed in other plants. Unfortunately, SA levels were not determined at subsequent time points and we do not know if this trend continues at 24 h.

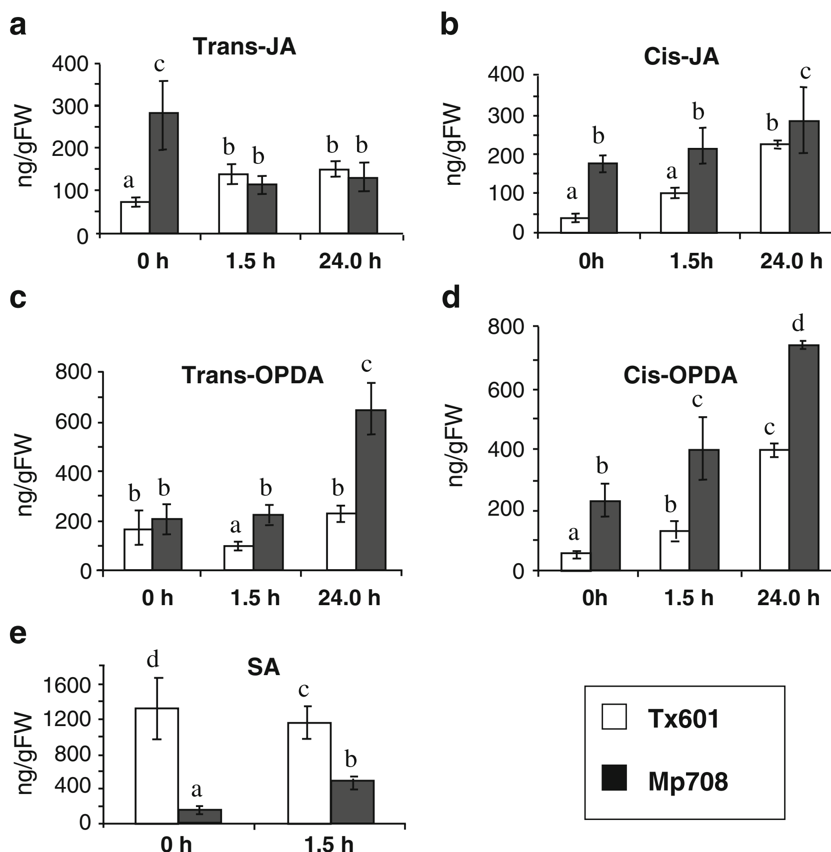

Fig. 2 Quantification of jasmonic acid (JA), 12-oxo-phytodienoic acid (OPDA), and salicylic acid (SA) in maize whorls. Larvae were allowed to feed on 5-wk-old plants of Mp708 and Tx601 for 1.5 and 24 h. Leaf tissue surrounding the feeding site was harvested, whereas tissue in the same position of the whorl of uninfested plants was collected as control. *Trans*-JA (**a**), *cis*-JA (**b**), *trans*-OPDA (**c**), *cis*-OPDA (**d**), and SA (**e**) were measured with CI-GC/MS. There were five samples per treatment, and the experiment was repeated three times. The lines on each bar represent standard error

Transcript Levels of JA Biosynthetic Pathway Genes Correlate with Higher Constitutive Levels of JA in Mp708 To determine if the constitutively elevated JA levels were affecting the expression of genes involved in herbivore defense response, the transcript abundance of key genes in the JA signaling, biosynthesis and response pathways was examined. Figure 1 shows a schematic diagram of the proposed JA signaling pathway leading to plant defense responses. Upon caterpillar feeding, phospholipase D (PLD) releases linolenic acid from the chloroplast membrane (Wang et al. 2000). Linolenic acid then is converted to JA in a series of reactions that occur in the chloroplast and peroxisome. Although there are many steps in this pathway, we measured the abundance of transcripts that encode a few key enzymes in the pathway, lipoxygenase (LOX), allene oxide synthase (AOS), and 12-oxo-phytodecanoic acid reductase (OPR). The JA signaling pathway ultimately activates NAPDH oxidase leading to the production of H_2O_2, which in turn, triggers the plant to accumulate proteins involved in direct defenses. We measured the transcript levels of NADPH oxidase and three proteins involved in direct defense, Mir1-CP, chitinase and maize protease inhibitor (MPI).

PLD catalyzes the first step in the signaling pathway. The transcript abundance for PLD was significantly higher in Mp708 at both 0 and 24 h (Fig. 3a, $P<0.001$). The abundance of transcripts for a lipoxygenase gene, *ZmLOX1,* was determined because this gene is induced by wounding and MeJA (Kim et al. 2003). In addition, the enzyme encoded by *ZmLOX1* produces a 13-LOX product that could be the precursor for JA (Kim et al. 2003). Message levels for *ZmLOX1* were higher in Mp708 at both time points (Fig. 3b, $P<0.001$). In fact, transcript levels of *ZmLOX1* were > 100-fold higher in Mp708 than in Tx601 after 24 h of insect feeding. The second *LOX* gene studied was *ZmLOX3*, which was selected because it is involved in maize defense against root nematodes (Gao et al. 2008). The expression of *ZmLOX3 also* was higher in both control and herbivore fed plants (Fig. 3c, $P<0.001$). In addition transcripts for *AOS* , which encodes an enzyme in the JA biosynthesis pathway, were higher in Mp708 than in Tx601 at both 0 and 24 h (Fig. 3d, $P<0.001$). These results indicate that in Mp708 key transcript levels in the herbivore-induced signaling pathway are constitutively elevated when compared to Tx601. Furthermore, the levels of these transcripts are elevated more in Mp708 than Tx601 following 24 h of herbivory, thus suggesting that priming is occurring in Mp708, but not Tx601.

The next enzyme involved in JA biosynthesis is 12-OPDA reductase (OPR). Several OPR genes have been identified in maize including *ZmOPR7,* which has been predicted to encode one of the specific maize OPRs

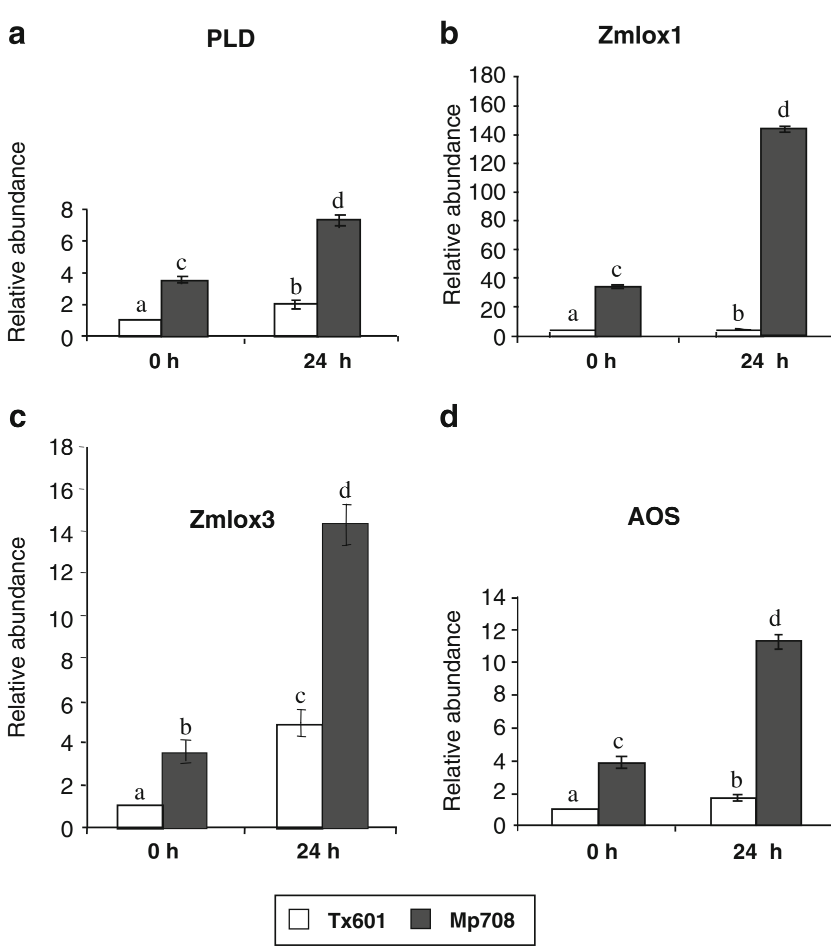

Fig. 3 Relative abundance of transcripts for enzymes in the JA signaling and biosynthetic pathway. RNA was extracted from the whorl region of 5-wk-old Mp708 and Tx601 plants infested with 3rd instar fall armyworm larvae for 24 h and from uninfested plants (0 h). cDNA was synthesized from these samples using oligo-dT primers. qRT-PCR was performed to determine the relative transcript abundance of *PLD* (**a**), *ZmLOX1* (**b**), *ZmLOX3* (**c**), and *AOS* (**d**). The relative abundance was calculated using the Pfaffl model with ubiquitin as reference gene. There were three biological and three technical replicates for each treatment. The lines on each bar represent standard error

involved in JA biosynthesis (Zhang et al. 2005). Consistent with the higher levels of *cis*- JA and *cis*-OPDA seen in control Mp708 plants, transcript levels for *OPR7* were higher in Mp708 than in Tx601 prior to herbivory (Fig. 4a, $P<0.001$). Larval feeding increased *OPR7* transcript levels in Tx601 ($P<0.001$), whereas *OPR7* transcript levels decreased in response to herbivory in Mp708 ($P<0.001$).

Expression of Other OPR Genes A significant increase in both *ZmOPR1* and *ZmOPR2* transcript levels was observed in response to larval feeding in Mp708 but not in Tx601 (Fig. 4b, c, $P<0.001$). These OPRs are similar to the *Arabidopsis OPR1* and *OPR2*, which do not participate in the JA biosynthetic pathway (Schaller 2001). *OPR1* appears to be activated by mechanical wounding (Biesgen and Weiler 1999). In maize, *ZmOPR2* expression increases in response to treatment with green leafy volatiles, mechanical wounding, or the regurgitant elicitor from beet armyworm (*Spodoptera exigua*) larvae (Engelberth et al. 2007). In Mp708, the large increase in OPDA without the commensurate increase in JA correlates with the increased abundance of transcript for *OPRs* that are not involved in JA biosynthesis. Although it remains to be tested, this suggests that OPDA might regulate an alternative herbivore defense pathway in Mp708. Both genotypes responded to feeding by reducing the expression of *OPR6* transcripts Fig. 3d, $P<0.001$), which is cytoplasmic and wound-inducible (Farag et al. 2005). Treatment of maize leaves with green leafy volatiles as well as crude regurgitant from beet armyworm larvae also failed to induce increase in *OPR6* transcripts (Engelberth et al. 2007).

Induction of Other Defensive Proteins In many plants, wound-induced synthesis of JA leads to activation of genes that encode proteinase inhibitors and other defensive proteins (Farmer and Ryan 1992). Therefore, transcript levels for maize protease inhibitor (*mpi*) (Cordero et al. 1994), a chitinase (*PRm3*) (Rakwal et al. 2004), and *mir1* (Pechan et al. 2000) were examined. *mpi*, which is induced by wounding and exogenous JA, was expressed at low levels in the controls of both genotypes, and fall armyworm feeding resulted in increased transcript levels in both genotypes, but the increase was larger in Mp708 (Fig. 5a, $P<0.001$). If the induction of *mpi* is dependent solely on JA, high constitutive expression in Mp708 would be expected. However, this was not the case, and this suggests that the induction of *mpi* in both Mp708 and Tx601

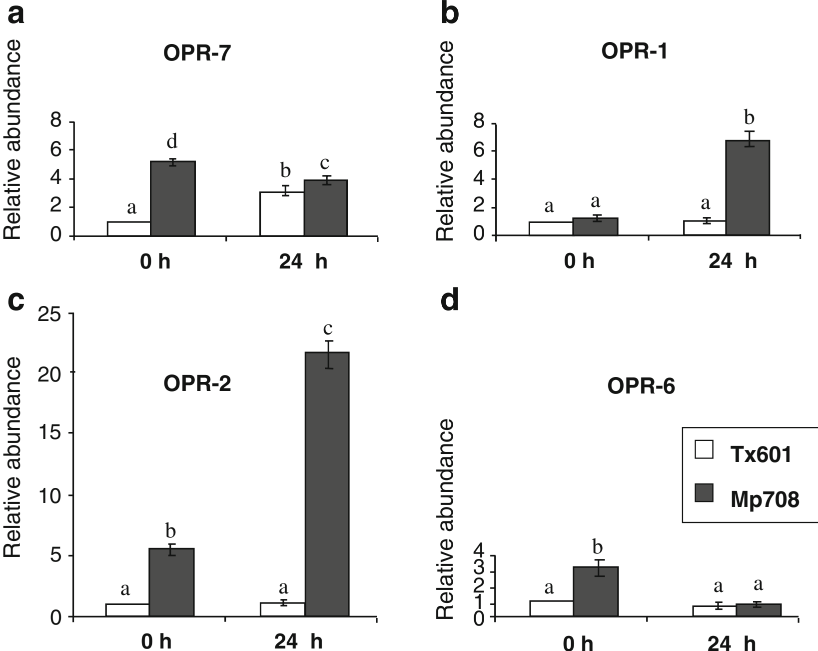

Fig. 4 Relative abundance of transcripts for several *OPR* genes. RNA was extracted and cDNA was synthesized as described in Fig. 3. qRT-PCR was performed to determine relative abundance for transcripts of *ZmOPR7* (**a**), *ZmOPR1* (**b**), *ZmOPR2* (**c**), and *ZmOPR6* (**d**). The relative abundance was calculated using the Pfaffl model with ubiquitin as reference gene. There were three biological and three technical replicates for each treatment. The lines on each bar represent standard error

requires another signal in addition to JA. It has been shown that blocking ethylene perception or synthesis decreases the accumulation of Mir1-CP and increases the susceptibility to herbivory in both Mp708 and Tx601 (Harfouche et al. 2006; Ankala et al. 2009). Thus, it is likely that ethylene is also required for MPI accumulation.

Although chitinases have been classified as antifungal proteins (Rakwal et al. 2004), they have been shown to be effective against aphid herbivory in sugarcane (Falco et al. 2001) and wheat (van der Westhuizen et al. 1998). In addition, chitinases that are induced by herbivory may attack the lepidopteran peritrophic matrix (PM), which is rich in chitin. Transcript levels of *PRm3*, which encodes a maize chitinase, were higher in Mp708 than Tx601 prior to herbivory (Fig. 5b, $P<0.001$), and although message abundance increased in response to herbivory in both genotypes, the level in Mp708 was much larger than in Tx601 (Fig. 5b, $P<0.001$). These results suggest that high chitinase expression in Mp708 could contribute to the PM perforation that is observed when fall armyworm feeds on this maize inbred (Pechan et al. 2002).

Mir1 Expression in Response to Fall Armyworm Feeding Low basal levels of Mir1-CP protein and its transcripts have been detected consistently in control plants prior to herbivore feeding (Fig. 6a, Pechan et al. 2000, Ankala et al. 2009). Upon larvae feeding, Mir1-CP begins to accumulate in the whorl within 1 h (Pechan et al. 2000). Despite this rapid accumulation, there is no commensurate increase in *mir1* transcripts at 30 min or 3 h (Fig. 6b). In fact, *mir1* transcripts appeared to decrease between 30 min and 24 h as shown by RT-PCR and real-time PCR (Fig. 6b, c). The paradox of rapid Mir1-CP accumulation in the absence of increased transcript levels during the first 24 h of herbivory could be due to post-transcriptional regulation of expression. However, a more likely explanation is that Mir1-CP is transported to the feeding site from the maize roots (Lopéz et al. 2007). This is supported by data indicating that 1, Mir1-CP accumulates in the roots in response to foliar herbivory, 2, it is found in the xylem and phloem of Mp708, and 3, root removal limits its accumulation in the whorl in response to herbivory (Lopéz et al. 2007). This suggests that there is communication between the above and below parts of maize in response to herbivore attack, which is consistent with the results of Erb et al. (2009).

Mp708 Appears to Generate More H_2O_2 and Accumulate More NADPH Oxidase Transcripts than Tx601 H_2O_2 has been shown to be a secondary messenger in JA-mediated defense signaling that acts downstream from JA (Orozco-Cardenas et al. 2001). Because JA and OPDA levels were elevated in Mp708 prior to herbivory, we speculated that there also might be increased production of H_2O_2. We visualized H_2O_2 by DAB staining and found that Mp708

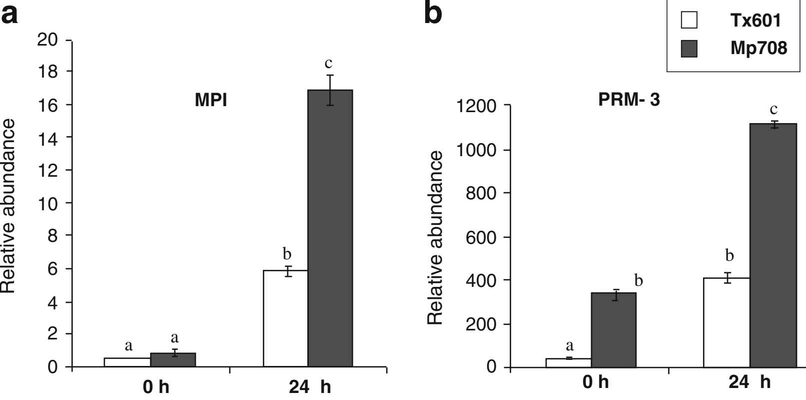

Fig. 5 Relative abundance of transcripts for *MPI* and *PRm3* (chitinase). RNA was extracted and cDNA was synthesized as described in Fig. 3. qRT-PCR was performed to determine the relative transcript abundance for *MPI* (**a**), and *PRm3* (**b**), was calculated using the Pfaffl model with ubiquitin as reference gene. There were three biological and three technical replicates for each treatment. The lines on each bar represent standard error

generated more H_2O_2 compared to Tx601 in response to wounding (Fig. 7a) or insect feeding (Fig. 7b). The release of H_2O_2 in response to wounding occurred within 10 min (Fig. 7a), but its production in response to feeding was slower and barely detectable in either genotype after 3 h (Fig. 7b). However, after 24 h of herbivory, there was intense red coloration surrounding the damaged areas of Mp708, whereas there was little coloration in Tx601 (Fig. 7b), which also suggests that Mp708 is able to mount a stronger defense after herbivory than Tx601.

A membrane-bound NADPH oxidase catalyzes the production of wound-induced superoxide (O_2^-), which then

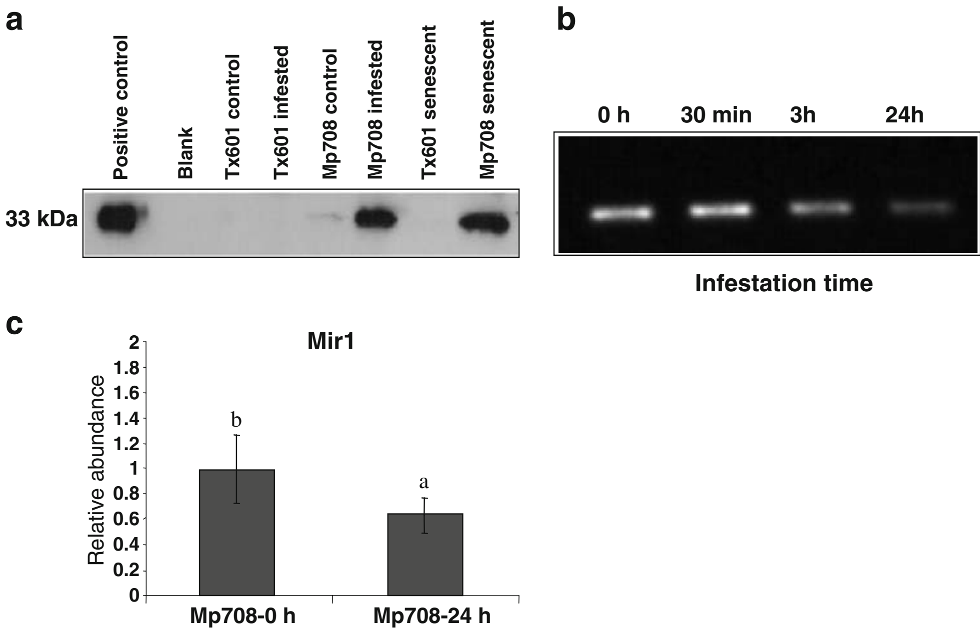

Fig. 6 *Mir1* expression and Mir1-CP accumulation in Mp708. **a** Immunoblot analysis of Mir1-CP expression in Mp708 and Tx601 plants. Total protein was extracted from samples collected near the larval feeding site or from senescing leaves. Controls were collected from the whorls of uninfested plants. The positive control is a protein extract from callus generated from Mp708 embryos. **b** RT-PCR of products generated with primers for *mir1* using RNA extracted from whorls of Mp708 around the feeding site after 0 h, 30 min, 3 h and 24 h feeding by 3rd instar fall armyworm larvae. **c** Relative abundance of transcripts for *mir1*. RNA was extracted and cDNA synthesized as described in Fig. 3. qRT-PCR was preformed to determine the abundance of *mir1* and ubiquitin transcripts. Relative abundance was calculated as the ratio between *mir1* and ubiquitin expression. The relative abundance was calculated using the Pfaffl model with ubiquitin as reference gene. There were three biological and three technical replicates for each treatment. The lines on each bar represent standard error

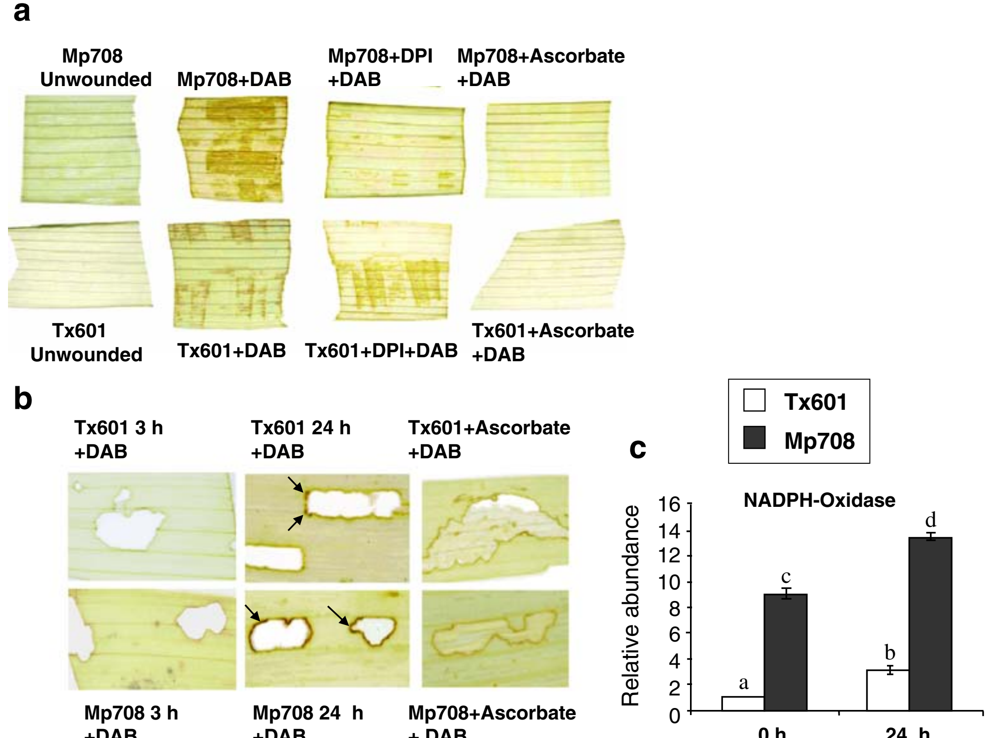

Fig. 7 H_2O_2 generation in wounded (**a**) and fall armyworm infested whorls (**b**). For the wounding experiment, plants were treated with DAB, DPI, and ascorbate as described in Materials and Methods, and the whorl region was crushed with a hemostat. For feeding experiments, 3rd instar fall armyworm larvae were placed on the yellow-green whorl region of 4-week old plants and caged to restrict the feeding area. Larvae were removed at specified times, and feeding areas were stained with DAB or DAB containing ascorbic acid. **c** NADPH oxidase transcript levels were measured by qRT-PCR conducted with cDNA synthesized as described in Fig. 3. The relative abundance was calculated using the Pfaffl model with ubiquitin as reference gene. Arrows indicate the reddish brown coloring in the wounded and fed areas. There were three biological and three technical replicates for each treatment. The lines on each bar represent standard error

is dismutated to H_2O_2 (Doke et al. 1996). When diphenyleneiodonium sulfate (DPI) was used as an inhibitor of NADPH oxidase (Frahry and Schopfer 1998), there was no detectable release of H_2O_2 in Mp708 in response to wounding (Fig. 7a), while its generation in Tx601 remained unchanged (Fig. 7a). These results suggest that H_2O_2 generation in these two inbreds could occur via two different pathways with NADPH oxidase functioning in Mp708 and other enzymes such as cell wall peroxidases functioning in Tx601. Absence of reddish brown coloration in the presence of the free radical scavenger ascorbic acid confirms that the coloration was due to H_2O_2 reacting with DAB. Prior to herbivory, NADPH oxidase transcript levels were higher in Mp708 than in Tx601, and they increased slightly in response to larval feeding (Fig. 7c). In Tx601, the level of NADPH oxidase transcripts increased due to feeding, but the overall expression levels were lower than those of Mp708 ($P<0.001$).

The maize inbred Mp708 was selected for its resistance to caterpillar feeding in the field. We propose that a portion of its resistance stems from expression of genes in the JA-induced defense pathway prior to herbivore attack and a response to subsequent larval feeding with even higher levels of defense gene transcripts than the susceptible inbred Tx601. These findings are consistent with the idea that Mp708 is genetically primed to withstand herbivore attack. Currently the cause of the JA over-production in Mp708 is unknown. Although there are a number of mutations in *Arabidopsis* that impair JA synthesis, conjugation to isoleucine, and perception (Wasternack 2007; Balbi and Devoto 2008; Browse and Howe 2008; Howe and Jander 2008; Kazan and Manners 2008), there are fewer known mutations that cause JA to be over-produced or to accumulate in the absence of wounding or herbivory (Cano-Delgado et al. 2000, 2003; Ellis and Turner 2001; Hilpert et al. 2001; Ellis et al. 2002; Jensen et al. 2002; Ko et al. 2006; Bonaventure et al. 2007a, b). The *fou2* mutant of *Arabidopsis* has a lesion in the Two Pore Channel 1 gene that encodes a Ca^+ permeant non-selective cation channel that produces more JA than wild type both constitutively and upon wounding. This mutant also has increased ability to catalyze the synthesis of LOX metabolites, and the

expression of a suite of JA and defense genes is up-regulated (Bonaventure et al. 2007a, b). Several other mutations resulting in constitutive JA production and constitutive defense appear to be involved in some aspect of cell wall deposition (Ellis et al. 2002; Cano-Delgado et al. 2003; Ko et al. 2006). Mutations that affect cellulose synthesis appear to alter the cell wall structure and result in continuous JA production (Ellis et al. 2002). Interestingly, there are differences in cell wall composition between Mp708 and Tx601. The resistant plants had more cellulose and hemicellulose than susceptible plants (Williams et al. 1998). The hemicellulose from resistant lines contained more neutral sugars and higher cross-linking than that from susceptible lines (Hedin et al. 1984). Although there could be a number of alternative scenarios, we speculate that changes in cell wall composition might alter its structure, which could result in the increased constitutive levels of JA and defense gene expression that we observed in Mp708.

In this study, we compared the defense responses of two maize inbreds that have different levels of resistance to caterpillar feeding. Mp708 is unique because it has a high level of resistance to herbivory, hence, we cannot extrapolate these results to all maize inbred lines. Nevertheless, the results of this study show that constitutive *cis*-JA and *cis*- OPDA levels are elevated in the caterpillar-resistant inbred Mp708, and the transcripts of many genes in the octadecanoid defense pathway are more abundant in resistant plants both prior to and after herbivory. Furthermore, Mp708 appears to rapidly generate higher levels of peroxide than the susceptible maize line. Hence, the remarkable ability of Mp708 to resist caterpillar feeding is probably because the entire herbivore defense signaling pathway, from PLD to H_2O_2, is primed prior to herbivory, suggesting that these plants are on constant alert and poised to mount a rapid and strong defense to caterpillar attack.

Abstract Feeding by herbivores can change plants in ways that make them more resistant to subsequent herbivory. Such induced responses are better-studied in a number of model dicots than in rice and other cereals. In a series of greenhouse and field experiments, we assessed the effects of prior herbivory by the fall armyworm, *Spodoptera frugiperda* (J.E. Smith) and of exogenous applications of jasmonic acid (JA) on the resistance of rice plants to the rice water weevil, *Lissorhoptrus oryzophilus* (Kuschel), the major pest of rice in the United States. Prior feeding by *S. frugiperda* and treatment of plants with exogenous JA resulted in increases in the resistance of plants to the weevil. Increases in resistance were manifested as reduced numbers of eggs and first-instars associated with armyworm-injured or JA-treated plants relative to control plants. In field experiments, there was a transient but significant reduction in the number of immature *L. oryzophilus* on JA-treated plants relative to untreated plants. To our knowledge, this is the first example of direct induced resistance in rice demonstrated in small-plot field experiments. We discuss the potential for the use of elicitor induced resistance in rice.

Introduction

Feeding by arthropod herbivores often causes changes in the expression of resistance-related genes and traits in plants, and these changes often make the plants less suitable for subsequent herbivores. This phenomenon has been termed induced resistance (Karban and Baldwin 1997). Induced resistance to herbivory can be broadly classified as direct or indirect. Direct induced resistance refers to changes that have direct negative effects on herbivore behavior, growth, or physiology. These effects can be manifested in a multitude of ways, such as reduced feeding, oviposition, fecundity, and survival of herbivores on previously damaged plants (Walling 2000). Indirect induced resistance refers to changes that attract or retain natural enemies of herbivorous arthropods (Dicke et al. 2003). Direct and indirect induced resistance has been reported in a wide variety of plants. However, such responses are less studied in rice and other economically important monocots (Kogel and Langen 2005; Karban and Chen 2007).

Jasmonic acid (JA) is a plant hormone that mediates the expression of both direct and indirect defenses against herbivory (Thaler et al. 2002; Wasternack 2007; Browse and Howe 2008). Jasmonic acid accumulates rapidly in plant tissues near the site of herbivore attack (Korth and Thompson 2006). Increases in endogenous JA lead, through a series of intermediary steps, to changes in the expression of resistance-related genes and metabolites, and to enhanced resistance to herbivory (Korth and Thompson 2006; Bruinsma and Dicke 2008). Consistent with its role as an endogenous signal, treating plants with exogenous JA often simulates the changes induced by natural herbivory (Farmer and Ryan 1990; Kessler and Baldwin 2002; Browse and Howe 2008).

The broad-spectrum nature of induced resistance in many plants (Stout and Bostock 1999) and the ability to stimulate induced resistance by applying exogenous elicitors like JA has raised the possibility of using induced resistance in agriculture. One way it could be used in agriculture is to use elicitors like JA to stimulate resistance at appropriate times in the life cycles of the pest and crop (Stout et al. 2002). Most tests of this idea have been conducted in greenhouses, and few studies have shown significant reductions in the preference, feeding, and survival of pests in field settings (Thaler et al. 1996; Black et al. 2003).

Rice, which serves as a staple food for a large portion of the world's population, has been relatively neglected as a model for the study of induced resistance to herbivorous arthropods (Karban and Chen 2007). What research that has been done has primarily focused on indirect induced resistance and/or induced responses to feeding by sucking insects (Bentur and Kalode 1996; Seino et al. 1996; Matsumura and Suzuki 2003; Xu et al. 2002, 2003; Kanno et al. 2005; Lou et al. 2005; Satoh et al. 2005; Senthil-Nathan et al. 2009). Recently, however, Stout et al. (2009) demonstrated direct induced resistance in rice to a chewing insect, the fall armyworm (*Spodoptera frugiperda* J.E. Smith), following earlier feeding by the same insect. Resistance to the fall armyworm also was induced by exogenous JA. The fall armyworm defoliates a wide assortment of plants, including rice, but rarely achieves pest status in rice in the United States.

The experiments described herein extend the prior work on direct induced resistance in rice by studying the effects of prior fall armyworm herbivory and exogenous JA on the resistance of rice to its major early-season insect pest in the United States, the rice water weevil, *Lissorhoptrus oryzophilus* Kuschel. Adult rice water weevils move from overwintering sites to rice fields in early spring and feed on rice leaves, resulting in longitudinal feeding scars that run parallel to leaf veins. Oviposition is triggered by flooding of rice fields, which typically occurs within five weeks of planting (Everett and Trahan 1967; Stout et al. 2002). Upon hatching, neonate larvae migrate down the plant to roots, where they feed and pass through four instars in 21–27 days (Zou et al. 2004). Feeding by adults generally does not result in economic injury, but root pruning by larvae can severely reduce both the growth and yield of rice (Smith 1983; Zou et al. 2004). In Louisiana, yield losses typically exceed 5% and can approach 25% or more (Stout et al. 2000). The objectives of this study were to determine if *S. frugiperda* herbivory and exogenous application of jasmonic acid induce resistance to *L. oryzophilus* in both greenhouse and small plot field experiments.

Methods and Materials

Plant and Insect Culture A total of four experiments were conducted in a greenhouse on the campus of Louisiana State University, Baton Rouge. For each experiment, seeds were planted in a soil mix (2:1:1, soil: peat moss: sand) in 11.4 cm^2 square pots, and plants were maintained in greenhouse conditions under ambient lighting at approximately 29°C–33°C. Approximately 1.2 g of 19:6:12 controlled release fertilizer (Osmocote, Scotts Miracle-Gro, Marysville, OH, USA) was added to soil at planting. Plants were grown, and experiments were conducted in large wooden basins lined with heavy black plastic that allowed plants to be flooded. Plants were thinned to a density of three plants per pot five to 7 d after planting.

Adult rice water weevils used in these experiments were collected from rice fields at the LSU AgCenter's Rice Research Station in Crowley, Acadia Parish, Louisiana, 1 d prior to use in experiments. Weevils were maintained from collection until use in plastic containers with water and rice leaves. In order to ensure equal ratios of males and females, weevils were captured in-copula and placed in small plastic cups just prior to use.

Fall armyworm larvae used to damage plants were obtained from a colony maintained year-round on artificial diet in the laboratory. The colony originated from larvae collected in bermudagrass pastures near Baton Rouge in 1997. Insects collected from pastures or rice fields are added annually to the colony to maintain genetic variability and vigor.

Two separate experiments were conducted to investigate whether feeding by *S. frugiperda* larvae induces resistance to *L. oryzophilus*. In the first, the rice cultivar 'Rosemont' was used; in the second, the cultivar 'Jackson' was used. These varieties were used because prior studies had shown them to be responsive to fall armyworm feeding and JA treatment (Stout et al. 2009). Rice seedlings were grown to the early three-leaf stage as described above. Pots then were randomly assigned to two treatment groups, 'control' and 'damaged'. Plants in the latter group were damaged by confining one 4th to 5th instar *S. frugiperda* larvae per plant in cages constructed of clear plastic cylinders (8.5 cm diam, 23 cm height) with one end inserted into the soil and the top end covered with a mesh-screen lid. Cylinder cages had two mesh-lined holes to allow for air circulation. Larvae were allowed to feed for 4–6 h, and on average, consumed between 20% and 30% of total leaf area, typically damaging portions of every leaf. Cages with no larvae were placed over plants assigned to the control group. Cages and larvae were removed from plants after 4–6 h of feeding, and plants were maintained in the greenhouse for later evaluation of resistance to *L. oryzophilus*.

Evaluations of resistance to *L. oryzophilus* were conducted 13–15 d after injury by *S. frugiperda*. By this time a new leaf or, in some cases, two new leaves had emerged on both damaged and control plants. Four pots of each treatment were placed into infestation cages, which were constructed of cylindrical wire frames (46 cm diam, 61 cm tall) covered with a mesh fabric screening. A total of 5 cages were used in each experiment. Weevils were then placed in cages at a density of one male:female pair per plant (24 pairs per cage). Basins were flooded to a depth of approximately 24 cm, and weevils were allowed to feed, mate, and oviposit on plants in cages for 4 d. Plants then were removed from cages and any weevils found on plants were removed.

Densities of eggs and 1st instars on or associated with plants were used to estimate levels of weevil infestation. Procedures for estimating egg and larval densities were adapted from Heinrichs et al. (1985) and Stout and Riggio (2002). Estimating egg densities provides information regarding oviposition preference, and estimating larval densities provides further information on oviposition preference and possibly on survival of eggs and early instars. Densities of eggs were determined by removing one plant from each pot. Soil was removed carefully from the roots, and plants were then labeled and placed in 75% ethanol until bleached. The numbers of eggs on plants were determined by carefully examining plants under a dissecting microscope (Meiji Techno Co. Ltd, Tokyo, Japan).

The densities of 1st instars emerging from plants were determined by removing two plants from each pot, carefully washing soil from the roots, and suspending individual plants in test tubes containing distilled water. Test tubes were labeled, arranged in a rack, and placed in a growth chamber (28°C,14:10 h L:D). Weevils infesting plants treated in this manner hatch from eggs, emerge from leaf sheaths, and settle on the bottom of test tubes (Heinrichs et al. 1985). First instars were removed by shaking roots free of larvae and then pouring water from test tubes into a Petri dish for counting. Plants were placed back into their respective test tubes immediately after counting and replenished with distilled water. Larvae were counted daily until no larvae were found for three consecutive days.

Two additional experiments were conducted to investigate JA induced resistance, each using the two rice cultivars 'Jasmine' and 'Rosemont.' Elicitor treatments were prepared by dissolving 21 mg (1 mM) or 105 mg (5 mM) jasmonic acid (Sigma-Aldrich, St. Louis, MO, USA) in 1 ml of 95% ethanol and adding the ethanol solution to 100 ml distilled water. Three weeks after planting, 6 pots of each cultivar were assigned to treatment groups and were sprayed until run-off with 100 ml of 1 mM or 5 mM JA solutions or with 100 ml of water containing 1 ml of ethanol (control) using a hand held aerosol sprayer. Each plant received approximately 5.5 ml of elicitor or control solutions. The following day, one pot of each treatment/cultivar combination was placed in each of 6 infestation cages, resulting in 6 pots per cage, and plants were infested with weevils as described earlier. Estimation of larvae and egg densities were carried out as previously described, except that egg densities were not determined in the second experiment.

Analysis of Data Data for each of the four experiments described above were analyzed separately. For each experiment, counts of eggs and 1st instar larvae were taken using separate plants, thus providing independent measures of plant resistance. Data from *S. frugiperda* experiments were analyzed as a randomized complete block design using a mixed-model analysis of variance (ANOVA) (PROC MIXED) in SAS (SAS Institute 2007), with damage treatment (damaged or control) as a fixed effect and cage as a random effect. Data from JA experiments were analyzed as a 2×3 factorial using PROC MIXED, with infestation cage as a random effect and cultivar ('Rosemont' and 'Jackson') and JA concentration (0, 1, and 5 mM) as fixed effects. Means were separated using least significant differences (LSD) test.

Two experiments were conducted during the 2008 growing season at the Louisiana State University Agricultural Center Rice Research Station, Crowley, Acadia Parish, Louisiana. In both experiments, rice was planted by placing seeds into soil using a plywood template measuring1.5× 1.5 m, with 3 cm diam holes spaced 7.5 cm apart and arranged in five rows and five columns. Two seeds were inserted into each hole at a depth of approximately 2 cm. The area defined by the template was considered a plot, and plots were spaced 1 m apart in a completely randomized design. In the first experiment, seeds of the cultivar 'Jackson' were hand planted on 8 April with 6 plots (replicates) of each of 3 treatments. Treatments consisted of exogenous applications of 1 mM and 5 mM solutions of JA and an untreated control; JA and control solutions were prepared as described in greenhouse experiments. On 29 April, 21 d after planting, plots were fertilized at a rate of 68 kg per acre of nitrogen as urea, and plants were subsequently sprayed with JA until runoff. A permanent flood was established 1 wk after JA treatment.

A second experiment using the rice cultivar 'Rosemont' was planted on 10 June using the same templates as above with 1.8 m spacing between plots. The experimental design was a completely randomized design with two treatments—control and JA (5 mM)—with 15 replicates for each treatment. On 10 July, 30 d after planting, plots were fertilized at a rate of 68 kg per acre of nitrogen as urea, and plants were subsequently sprayed with JA until runoff and permanent flood was established the following day.

In the first field experiment, plants were sampled for eggs 6 and 12 d after establishment of permanent flood (13 and 19 d after JA treatment). In the second experiment, plants were sampled for eggs 2 d after permanent flood was established (3 d after JA treatment). For egg sampling, two plants from each plot were removed, and soil was washed from roots. Plants were labeled and stored in 75% ethanol until bleached. The numbers of eggs on plants were determined by examining the leaf sheaths under a dissecting microscope (Meiji Techno Co. Ltd, Tokyo, Japan).

Densities of *L. oryzophilus* larvae and pupae in plots were determined by using a soil-root core sampler with a diam of 9.2 cm and a depth of 7.6 cm. Core samples were taken 19 and 27 after permanent flood in the first experiment, and 14 and 19 d after permanent flood in the second experiment. For each sampling date, 1 to 4 core samples were taken from each plot. Core samples were processed by placing them in a sieve bucket (40-mesh screen) and washing soil from roots. Buckets then were placed into plastic basins containing salt water, which facilitated larval and pupal counts as they floated to the water surface (N'Guessan et al. 1994).

Prior to analysis, the number of immature *L. oryzophilus* observed in each core sample was converted to number of larvae per plant by dividing the total number of immature larvae by the number of plants in each core sample. Generally, one or two plants were contained in each core sample. Data were analyzed as completely randomized design experiments by one-way ANOVA using PROC MIXED with treatment (JA or control) as a fixed effect. Means were separated using least significant difference (LSD) test.

Results

Characterization of Induced Resistance Following Fall Armyworm Herbivory In the first experiment, significantly fewer first instars emerged from 'Rosemont' rice plants previously damaged by *S. frugiperda* than from undamaged plants (Fig. 1; $F_{1,33}$=5.30, P=0.028). Numbers of eggs per plant did not differ between control and damaged plants ($F_{1,33}$=1.66, P=0.21) in this experiment. In the second experiment, densities of both eggs ($F_{1,33}$=8.78, P=0.006) and first instars ($F_{1,33}$=15.02, P<0.001) of *L. oryzophilus* were significantly lower in cultivar 'Jackson' that were previously injured by *S. frugiperda* than in undamaged plants (Fig. 2).

Characterization of Induced Resistance Following JA Applications In the first experiment with exogenous JA, densities of eggs were lower in plants treated with 1mM and 5mM JA than in control plants of both varieties (Fig. 3; $F_{2,50}$=12.39, P<0.001). In addition, there were fewer eggs per plant on 'Rosemont' than on 'Jasmine' ($F_{1,50}$=5.89, P=0.02), but the interaction between cultivar and treatment was not significant ($F_{2,50}$=0.39, P=0.68), indicating that the effect of JA did not differ between cultivars. The high rate of exogenous JA also reduced the number of first

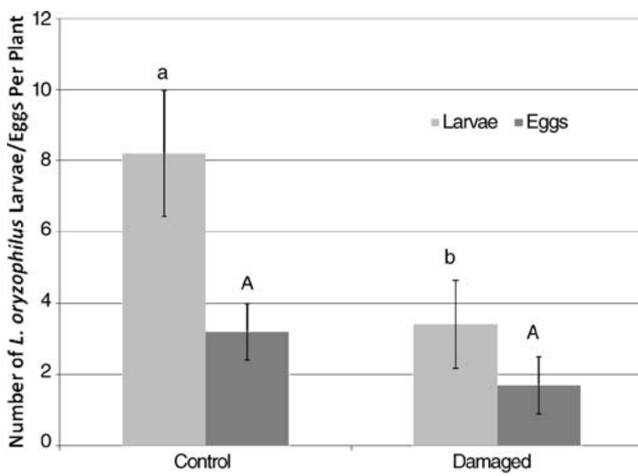

Fig. 1 Mean number of *Lissorhoptrus oryzophilus* larvae and eggs per plant (± se) in initial experiment using *Spodoptera frugiperda* damaged and undamaged plants of rice cultivar Rosemont. Plants were damaged by allowing one 4th–5th instar *S. frugiperda* to feed on each plant for 4–6 h. *Bars* accompanied by different *upper case letters* (eggs) or *lower case letters* (larvae) indicate that means differ significantly (P≤0.05)

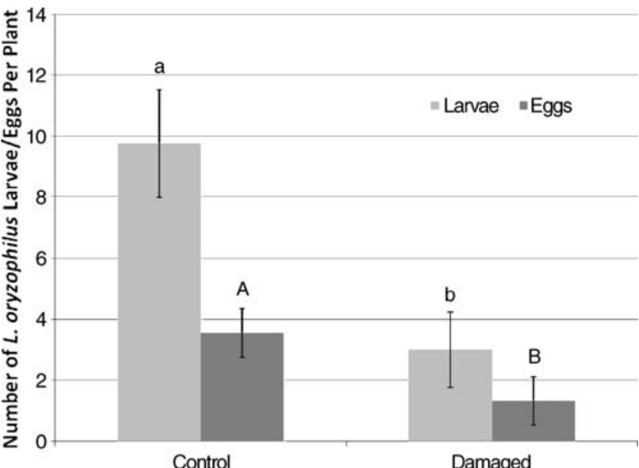

Fig. 2 Mean number of *Lissorhoptrus oryzophilus* larvae and eggs per plant (± se) in second greenhouse experiment using *Spodoptera frugiperda* damaged and undamaged plants of rice variety 'Jackson.' Plants were damaged by allowing one 4th–5th instar *S. frugiperda* to feed on each plant for 4–6 h and assays for weevil resistance were conducted 15 d later. *Bars* accompanied by different *upper case letters* (eggs) or *lower case letters* (larvae) indicate that means differ significantly (P≤0.05)

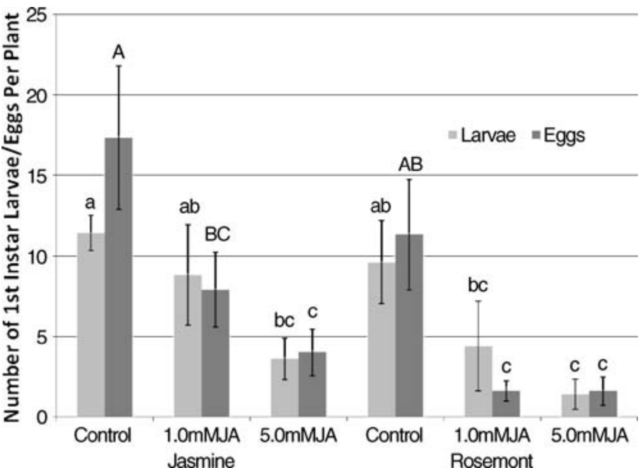

Fig. 3 Mean number of *Lissorhoptrus oryzophilus* eggs and larvae per plant (± SE) in greenhouse two-way experiment using two different varieties and three different concentrations of exogenous JA applications. *Bars* accompanied by different *lower case* (eggs) or *upper case* (larvae) letters indicate that means differ significantly ($P \leq 0.05$)

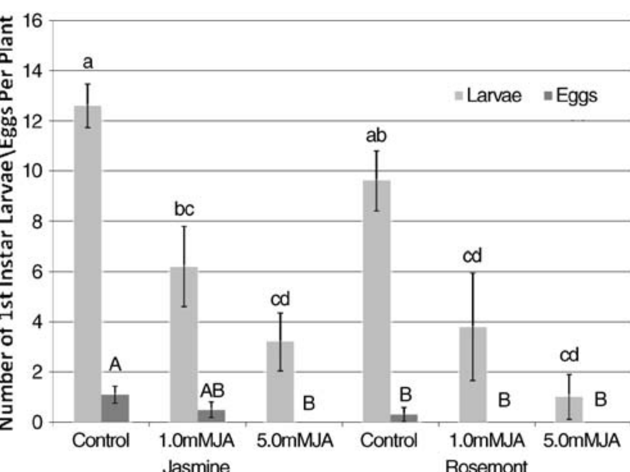

Fig. 4 Mean number of *Lissorhoptrus oryzophilus* larvae (±SE) per plant in second greenhouse experiment using two different varieties and three different concentrations of exogenous JA applications. *Bars* accompanied by different *letters* indicate that means differ significantly ($P \leq 0.05$). The effect of variety is also significant (P=0.038)

instars relative to the 1mM and untreated plants (Fig. 3; $F_{2,20}$=6.82, P=0.006). No cultivar effect on first instars was observed ($F_{1,20}$=2.51, P=0.13), and the interaction between cultivar and treatment was not significant ($F_{2,20}$=0.21, P=0.81).

In the second JA experiment, densities of larvae in both the 1mM and 5mM JA treatments were reduced compared to untreated plants (Fig. 4; $F_{2,20}$=21.57, $P<$ 0.001). A varietal difference in larval densities was also observed ($F_{1,20}$=4.92, P=0.038), but the interaction between cultivar and treatment was not significant ($F_{2,20}$=0.04, P=0.96).

Field Experiments In the first field experiment (cultivar 'Jackson'), numbers of eggs per plant did not differ among treatments at 6 and 12 days after flood (Table 1; $F_{2,15}$=0.53, P=0.60 and $F_{2,15}$=0.15, P=0.86 at 6 and 12 d after JA treatment, respectively). Numbers of *L. oryzophilus* larvae per plant in the first core sampling were reduced by 52% (1 mM) and 62% (5 mM) in the JA treated plants compared to control (Table 1; $F_{2,15}$=3.90, P=0.04). In the second core sampling, numbers of larvae per plant were not significantly different among treatments ($F_{2,14}$=0.71, P=0.51).

In the second field- experiment (cultivar 'Rosemont') JA treatment did not significantly reduce egg densities. Numbers of *L. oryzophilus* larvae per plant in the first core sampling were lower in the JA-treated plots than in control plots (Table 2; $F_{1,20}$=4.23, P=0.05). The second core sampling showed no treatment effect on the number of larvae per plant ($F_{1,18}$=0.36, P=0.55).

Discussion

While there is a growing body of literature pertaining to induced responses to insects in rice (Karban and Chen 2007), most of this research has involved piercing-sucking insect pests or indirect resistance (Xu et al. 2002; Matsumura and Suzuki 2003; Zhou et al. 2003; Lou et al. 2005). Rice thus remains relatively under-utilized for the study of direct induced resistance to chewing insects. This is a critical lack of knowledge, as many of the most important pests of rice in the U.S. and globally are chewing insects. Recently, Stout et al. (2009) showed that feeding by *S. frugiperda* and exogenous JA induced a long-lasting systemic resistance to subsequent feeding by *S. frugiperda.* The results of this prior study led us to hypothesize that *S. frugiperda* herbivory and exogenous JA would induce resistance to *L. oryzophilus*, the most important insect pest of rice in the United States (Smith 1983; Way 1990). The goal of this study was to provide further information on the nature and importance of direct induced resistance in rice and its possible use in pest management.

Our results demonstrate that feeding by *S. frugiperda* induces resistance to an unrelated insect species (*L. oryzophilus*), which is consistent with the broad spectrum nature of induced resistance in many systems (Stout and Bostock 1999). Female *L. oryzophilus* laid 37–53% fewer eggs on plants damaged by fall armyworm 13–15 days earlier than they did on undamaged plants. Additionally, 30–40% fewer *L. oryzophilus* first instars were recovered from previously damaged plants than from undamaged plants. This reduction in densities of *L. oryzophilus* eggs and first instars on armyworm-damaged plants is likely due

Table 1 Mean number of *Lissorhoptrus. oryzophilus* eggs and larvae per plant (± SE) in field samples using rice cultivar 'Jackson.' Egg samples were taken 13 and 19 d after exogenous JA applications. Core samples were taken 19 and 27 d after permanent flood was established. Means within the same column followed by different letters indicate a significant difference ($P<0.05$)

Treatment	First egg sample Eggs/Plant	Second egg sample Eggs/Plant	First core sample Larvae/Plant	Second core sample Larvae/Plant
Control	0.83±0.74a	2.17±1.48a	4.84±1.32a	7.4±1.7a
1.0 mM JA	0.17±0.16a	1.82±0.8a	2.31±0.50b	4.76±0.75a
5.0 mM JA	0.67±0.33a	4.10±1.8a	1.92±0.50b	6.32±1.1a

to an induced response rather than a reduction in oviposition sites for weevils because *L. oryzophilus* females oviposit inside leaf sheaths and not in leaf blades (Stout and Riggio 2002), the primary tissue removed by armyworm feeding. Also, plants had put on between 1 and 2 new leaves between the time of armyworm feeding and weevil infestations, and weevils prefer the sheaths of younger leaves for oviposition (Stout et al. 2002).

Exogenous JA also stimulated resistance to rice water weevils. Plants treated with 1 mM or 5 mM exogenous JA received 54 to 66% fewer eggs on 'Jasmine' and 'Rosemont', respectively, than untreated plants. Moreover, exogenous JA reduced the number of *L. oryzophilus* larvae per plant by 23% (1 mM) to 69% (5 mM) in 'Jasmine' and 54% (1 mM) to 85% (5 mM) in 'Rosemont'. There also was a significant effect of cultivar in one of the JA experiments (more eggs and larvae were found on 'Jasmine' than on 'Rosemont'), but the effect of JA on egg and larval mortality was stronger than the effect of cultivar. Our results are consistent with research in many dicot species that has found the activation of the JA pathway can provide generalized protection against an assortment of herbivorous insects (Inbar et al. 1988; Thaler 1999; Omer et al. 2000, 2001).

Our demonstration of direct induced resistance in rice contributes to a growing body of literature that documents responses induced by chewing insects in rice. Recently, Yuan et al. (2008) identified genes that underlie enhanced volatile emission from rice plants damaged by *Spodoptera frugiperda* (F.) herbivory. They also demonstrated that induced volatiles from *S. frugiperda* herbivory were highly attractive to female *Cotesia marginiventris* (Cresson) parasitoids. Xu et al. (2002) demonstrated increased volatile emission following *S. litura* herbivory compared with *Nilaparvata lugens* (Stål) damaged, mechanically damaged, and undamaged rice plants. Moreover, *S. litura* females avoided plants infested with *N. lugens* in a dual-choice flight tunnel bioassay.

The ability of JA to induce resistance to *L. oryzophilus* in greenhouse experiments led us to hypothesize that exogenous JA would induce resistance in field grown plants. Although adult rice water weevils can be found in rice fields before flooding, oviposition and larval infestations largely commence after flooding (Everett and Trahan 1967; Stout et al. 2002). Densities of eggs in rice fields in Louisiana generally are highest 1 to 3 weeks after flooding, while peak larval densities usually occur two to three weeks later (Stout et al. 2000; Zou et al. 2004). Because our greenhouse experiments had shown that JA-induced resistance reduces oviposition, applications of JA were made 7 days and 1 day prior to flooding in the first and second field experiments, respectively. Although densities of rice water weevil eggs were not significantly reduced in JA treated plants compared with untreated plants in either experiment, consistent trends in the data suggest that JA-treatment made plants less attractive for oviposition (see Tables 1 and 2). Most probably, sampling of eggs was not extensive enough (both in terms of number of plants sampled and frequency of sampling) to detect transient JA-induced differences in egg densities. This interpretation is particularly likely in light of the results of the core sampling, which in both experiments were consistent with the hypothesis that JA treatment induces a transient increase in rice resistance to rice water weevils. In both experiments, initial core samplings, which were conducted 15 to 28 days after flooding, revealed significant

Table 2 Mean number of *Lissorhoptrus. oryzophilus* eggs and larvae per plant (± SE) in field samples using cultivar 'Rosemont.' Egg samples were taken 3 d after exogenous JA applications. Core samples were taken 14 and 19 d after permanent flood was established. Means within the same column followed by different letters indicate a significant difference ($P<0.05$)

Treatment	First egg sample Eggs/Plant	First core sample Larvae/Plant	Second core sample Larvae/Plant
Control	2.18±0.7a	2.88±0.68a	8.12±2.56a
5.0 mM JA	0.88±0.43a	1.46±0.34b	6.54±1.33a

and substantial (up to 60%) reductions in densities of larvae and pupae in JA treated plants compared to untreated plants. However, weevil densities in the second core sampling were not reduced in JA treated plants compared to untreated plants in either experiment.

There are few studies that have examined the use of JA on economically important crops in field settings (but see Thaler 1999; Black et al. 2003), and, to our knowledge, the results reported here are the first to describe direct, JA-induced resistance in rice to herbivores in field-based experiments. The use of chemical elicitors, such as JA, holds potential as a tool for use in agriculture (Stout et al. 2002). Negative effects associated with a reliance on conventional insecticides, such as the development of insecticide resistance, environmental contamination, and threats to human safety, can be mitigated by the use and exploitation of elicitor-induced host plant resistance. Elicitors can stimulate broad-spectrum resistance to a variety of pests; in rice, for example, this study and prior studies (Mei et al. 2006; Senthil-Nathan 2009; Stout et al. 2009) have shown that exogenous JA induces resistance against a variety of important insect and disease pests. In addition, the use of elicitors allows producers to manage both the intensity and timing of induction. However, the relative high cost of elicitors compared to insecticides, coupled with the transient nature of elicitor-induced resistance, may serve as limiting factors in the widespread adoption and use of elicitors in agriculture.

RAPID COMMUNICATION

Elucidation of a Diurnal Pattern of Catechin Exudation by *Centaurea stoebe*

Nishanth Tharayil · Daniella J. Triebwasser

Received: 23 December 2009 / Revised: 12 January 2010 / Accepted: 15 January 2010 / Published online: 16 February 2010

Abstract The exudation of secondary metabolites at phytotoxic concentrations has been proposed as a mechanism of invasion for some exotic plant species. Catechin is a natural flavanoid implicated in the potential allelopathic interactions of *Centaurea stoebe*. However, recent studies have shown that catechin is highly unstable and not likely to accumulate in growing medium at phytotoxic concentrations. All previous studies that investigated the allelopathic potential of catechin assumed a continuous exudation of this compound by *C. stoebe*. Contrary to this, but similar to many other plant secondary metabolites, we hypothesized that catechin exudation may exhibit a pulsed pattern that could facilitate its transient accumulation. Further, we aimed at optimizing a more sensitive detection technique. We tested the hypothesis by quantifying the diurnal pattern of catechin release by *C. stoebe* in a hydroponic system. Using sample processing, based on a solid phase extraction technique, and more sensitive fluorescent detection parameters, we were able to quantify catechin in the picomolar range from the growing medium. Catechin exudation exhibited a possible diurnal rhythm with respect to light intensity, with the highest concentration at 6 h after exposure to sunlight. Catechin also was found to undergo a degradation reaction resulting in a transient abundance of pyrocatechol in our system.

Keywords *Centaurea stoebe* · *Centaurea maculosa* · Spotted knapweed · Allelopathy · Catechin · Fluorescence spectroscopy · Allelochemical

Introduction

Plants produce and exude a diverse array of secondary metabolites, under various environmental conditions. These exuded compounds can modify species competition in favor of donor plants by providing uncontested access to the limited resources (Rice 1984), by increasing chemical nutrient foraging efficiency (Tharayil et al. 2009), by preventing intraspecific competition through autotoxicity (Ervin and Wetzel 2000), and by facilitating root navigation in soil (Falik et al. 2005). *Centaurea stoebe*, spotted knapweed, is a noxious and economically destructive exotic weed that has invaded 2.9 Mha in North America (DiTomaso 2000). Roots of *C. stoebe* appear to exude the polyphenol catechin (Blair et al. 2005), but early reports of exudation have not been reproducible (Stermitz et al. 2009). Catechin has been reported at very low concentrations in the rhizosphere soil of *C. stoebe* (Blair et al. 2005, 2006) but high concentrations may occur periodically (Perry et al. 2007).

Exudation of metabolites by plant roots and their concentration in growth medium is a dynamic process, as the exudates are degraded, transformed, or resorbed. Hence, the time of sampling and the sensitivity of sampling procedures are major determinants in understanding the magnitude of root exudates by plants. In a previous study, we demonstrated that the exudation of 8-hydroxyquinoline by the related species *C. diffusa* follows a diurnal pattern of light intensity (Tharayil et al. 2009). Many plant metabolites are subjected to similar diurnal patterns of light

intensity (Urbanczyk-Wochniak et al. 2005), which can be linked to the diurnal regulation of photosynthetic carbon metabolism (Geiger and Servaites 1994). Methods used in previous studies that investigated the exudation of catechin seemed to assume a continuous exudation of this compound by *C. stoebe* (Blair et al. 2005). In contrast, in the present study we hypothesized that catechin could exhibit a pulsatile exudation pattern. Further, we used a more sensitive detection technique for catechin.

Methods and Materials

Plant Material Seeds of *Centaurea stoebe* were collected from Missoula, MT, USA during 2004. The root exudates were quantified in hydroponic cultures. Although hydroponic cultures oversimplify the complex interactions that exudates undergo in soil matrices, they were superior for the objectives of this study due to the less complex matrix influence (thus providing a realistic measure of root exudates) and also due to the convenience of repeated sampling at relatively short intervals. *Centaurea stoebe* were grown in a system similar to that used for growing *C. diffusa* as described in Tharayil et al. (2009) [Supplementary material]. Plants were grown for 10 wk in hydroponics to obtain enough root biomass for catechin quantification. At the day of harvest, after twice thoroughly washing the roots, plants were transferred to the appropriate half-strength Hoaglands solution (2 l, only distal half of roots immersed). We monitored the catechin exudation pattern in relation to the diurnal variation in sunlight intensity by harvesting root exudates of nutrient-sufficient plants (batches of 12) 2, 5, 7, 10, 14, and 24 h after nutrient solution replacement (nutrient solution changed 7:00 am [time zero], light intensity crossed 10 μmol S^{-1} m^{-2} at 8:00 am).

Catechin Analysis The fluorescent spectra of an aqueous solution of catechin were studied with a PerkinElmer Fluorescence Spectrometer (LS-45) with an excitation-emission scan range from 200–800 nm and at a scan speed of 5 nm S^{-1}. Raman scatter lines were removed by subtracting a background (DI-H_2O) from the sample.

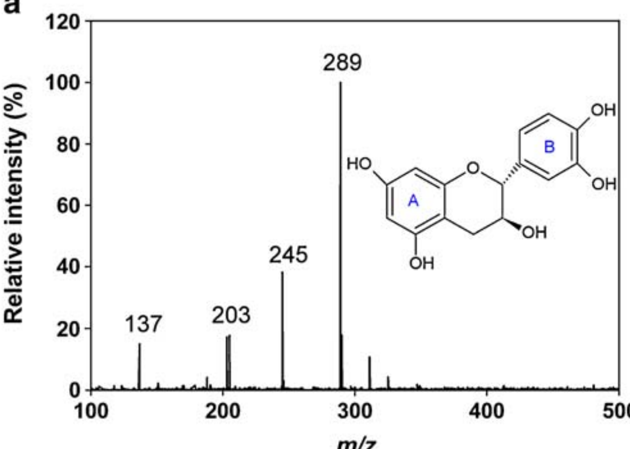
Analysis of Exudates Exudate solutions were filtered through a 1.8-μm glass fiber filter (metal-free) followed by a 0.45-μm cellulose acetate membrane filter. Samples were concentrated by solid-phase extraction using Strata-X 33-μm polymeric reversed phase cartridges (200 mg/3 ml; Phenomenex, Torrance, CA, USA); samples were loaded on a preconditioned column (4 ml min^{-1}), thereafter the cartridges were washed with 25% (v/v) MeOH, and the retained catechin was eluted with a 1.5 ml mixture of MeOH and MeCN (20:60%; v/v). The elutent was concentrated further under nitrogen to 0.5 ml before analysis. Preliminary studies with spiked (5 picomolar; 4 l) sample matrix gave 90% recovery of catechin. All samples were analyzed with a Shimadzu quaternary pump HPLC system equipped with an autosampler, inline degasser, UV–visible diode array detector (DAD) and fluorescence detector. Separations were performed on a Gemini C_{18} column (5 μm $110A^0$; 250 mm×4.6 mm I.D.; Phenomenex, Torrance, CA, USA). Absorbance of samples was monitored at 280 nm with the DAD and at excitation-emission wavelength of 205–316 nm and 280–316 with the fluorescent detector. The photo multiplier tube gain of fluorescence detector was adjusted to 4. The mobile phase consisted of MeCN : acetic acid: water (15 : 0.5 : 84.5, v/v). Standards were prepared in solid-phase elution solvent to avoid interference by the sample matrix during quantification of the analyte. Sample peaks were identified by comparing their retention time and spectra with those of authentic standards. Peaks of interests were collected and further identified qualitatively by using a liquid chromatograph (Waters ACQUITY UPLC™ system, Waters Corp., MA, USA) coupled with electrospray ionization quadrupole, orthogonal acceleration time-of-flight tandem mass spectrometer (Micromass MS Technologies, Manchester, UK, ion source- 3,000 V, detector 1,200 V, Lockmass: NaFormate, scan range from 100 to 800 *m/z*), operating in negative ion mode.

Statistics Data were analyzed using one-way ANOVA, and significance is reported at the 95% confidence interval. All statistical tests were performed with SAS 9.1 (SAS Institute, Cary, NC)

Results and Discussion

The presence of catechin and catechol in the growing medium was positively determined based on mass spectra of fractions of interest. Catechin was identified based on following the fragmentation pattern in negative ion mode (Fig. 1a): 289 $[M-H]^-$, 245 subsequent loss of –CH2–CHOH–, 203 subsequent loss of C_2H_2O, 137 results from A-ring fragment of catechin (retro-Diels-Alder cleavage of heterocyclic flavanoid ring, Stöggl et al. 2004; Tharayil et al. 2008). Catechol was identified based on *m/z* 109 which corresponds to $[M-H]^-$.

Considering the minute and transient exudation of most plant secondary metabolites, the analytical techniques adopted for their qualitative and quantitative determination should be robust in the extraction, pre-concentration, and cleanup steps. Automated methods for purification and concentration of catechin from tea leaves using in-tube



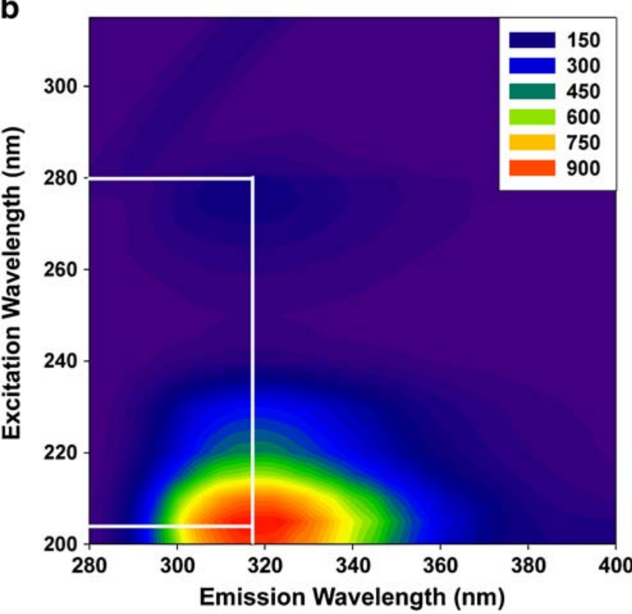


Fig. 1 Spectra of catechin. **a** LC-ESI-MS/MS of catechin and its molecular structure Refer to result section for spectral interpretation. **b** Background-corrected fluorescent spectrum of catechin showing higher fluorescence emission (at 316 nm) when excited with 205 nm compared to 280 nm. The contours represent the relative fluorescence intensity

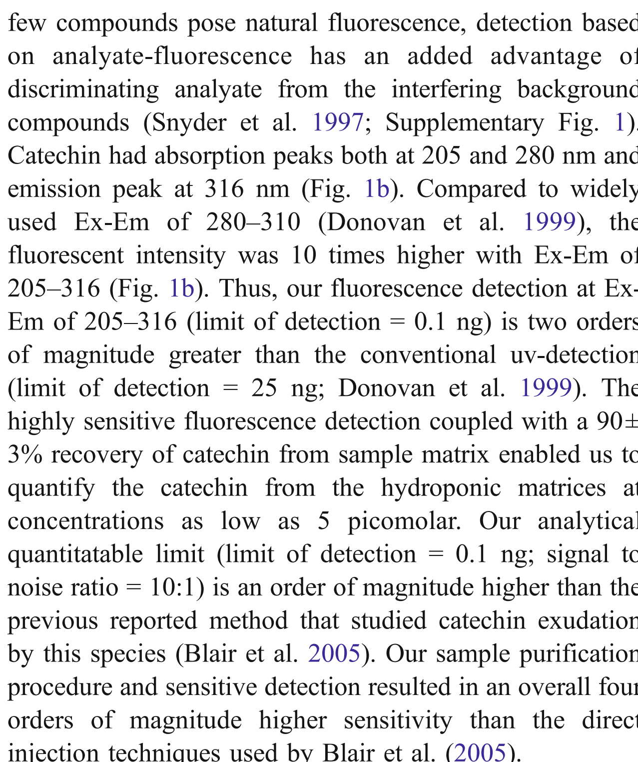
solid phase microextraction (SPME) have been previously published (Wu et al. 2000). Our method, although more cumbersome than the automated method, results in superior extraction efficacy (90%) compared to 10.1 % using SPME (Wu et al. 2000). Additionally, in-tube SPME cannot be employed when sample size is large, which is typical of any soil-less root exudate studies. Mass-spectrometer detection that uses a gas-chromatograph, although more sensitive (Donovan et al. 1999), requires careful derivatization with *N,O*-bis(trimethylsilyl)-trifluroacetamide (BSTFA), which can be cumbersome.

Compared to uv-dectection, fluorescence detection generally is three orders of magnitude more sensitive. Since



few compounds pose natural fluorescence, detection based on analyate-fluorescence has an added advantage of discriminating analyate from the interfering background compounds (Snyder et al. 1997; Supplementary Fig. 1). Catechin had absorption peaks both at 205 and 280 nm and emission peak at 316 nm (Fig. 1b). Compared to widely used Ex-Em of 280–310 (Donovan et al. 1999), the fluorescent intensity was 10 times higher with Ex-Em of 205–316 (Fig. 1b). Thus, our fluorescence detection at Ex-Em of 205–316 (limit of detection = 0.1 ng) is two orders of magnitude greater than the conventional uv-detection (limit of detection = 25 ng; Donovan et al. 1999). The highly sensitive fluorescence detection coupled with a 90± 3% recovery of catechin from sample matrix enabled us to quantify the catechin from the hydroponic matrices at concentrations as low as 5 picomolar. Our analytical quantitatable limit (limit of detection = 0.1 ng; signal to noise ratio = 10:1) is an order of magnitude higher than the previous reported method that studied catechin exudation by this species (Blair et al. 2005). Our sample purification procedure and sensitive detection resulted in an overall four orders of magnitude higher sensitivity than the direct injection techniques used by Blair et al. (2005).

Centaurea stoebe produced actively growing roots in our system (root : shoot ratio of 8:1; fresh weight; Supplementary Fig. 2). Previous studies have expressed catechin exudation based on its concentration in culture media (Blair

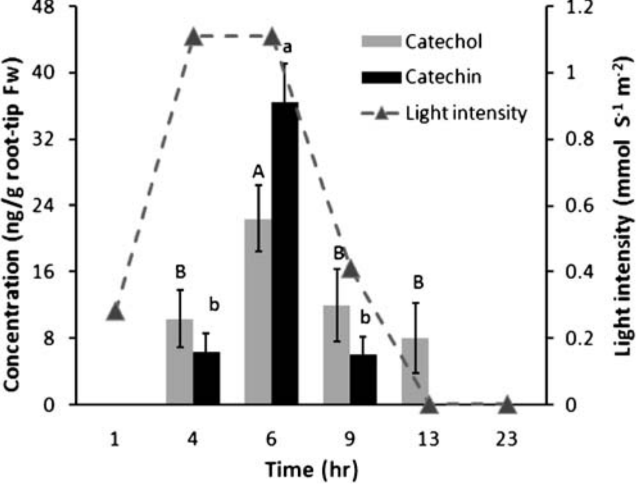


Fig. 2 Appearance of catechin and catechol in hydroponic medium as a function of diurnal light intensity. *Bars* represent mean value ± SD (*N*=4). X-axis represent the time in hours of six sample harvest after the light intensity crossed 10 µmol S^{-1} m^{-2} (8:00 am). Since only the distal half of the roots were immersed in sampling solution, catechin production is normalized based on fresh weight of root tips. Catechin concentration at 1, 13, and 23 h and catechol concentration at 1 and 23 h were below our detection limit. *Triangles* represent the mean sunlight intensities at respective sampling periods. *Bars* with the same letter are not significantly different (*P*<0.05, *N*=4; Duncan's New Multiple Range Test)

et al. 2005). Since the amount of compounds secreted would be directly proportional to the active root-biomass, and since only the distal half of the roots were immersed in sampling medium, the exudation of catechin was normalized to root-tip-fresh-weight collected at the end of the experiment. This overcame the dilution effect due to the amount of media. Root-tip biomass on an average consisted of 30–38% of total root fresh weight.

Centaurea stoebe exhibited a diurnal pattern in catechin exudation, and exudation reached a maximum at 6 h duration of light exposure (7 h after time zero, Fig. 2, $P < 0.05$, $N=4$). The exhibited diurnal pattern could be explained by the fact that flavan-3-ols (catechins) are derived from flavanones, and flavonoid biosynthesis takes place in the presence of light (Seigler 1995).

Catechin was found to undergo a degradation reaction that resulted in a transient abundance of catechol in our system (Fig. 2). Further, both catechin and catechol were unstable in the medium, and the concentration dropped below the detection limit overnight (Fig. 2). To test whether the catechol in the media is a degradation product of catechin, catechin was added to 24 h sample-containers after removing the plants, and the catechin concentrations and catechol were monitored. In a subset of containers, sucrose was added as a source of carbon (200 μg ml^{-1}). Disappearance of the added catechin and a corresponding but transient appearance of catechol identified the source of catechol as catechin. Although the experiments were not conducted in axenic conditions, the absence of catechin in the above plant-less cultures suggests that the source of catechin would be *C. stoebe* rather than microbes.

Catechol is more persistent in the hydroponic media (up to 13 h) compared to catechin (Fig. 2), which further suggests that catechol is a degradation product of catechin. Previous studies in soil media have demonstrated a similar breakdown of exogenously applied catechin to catechol with an accompanying increase in nutrient-mobility attributed to the chelation properties of catechol (Tharayil et al. 2008). Catechin production in our system was below the detection limit on cloudy days (>0.1 mmols S^{-1} m^{-2}). The exudation measured in our system is an order of magnitude lower than the previous conservative estimates by Blair et al. (2005). Apart from the high variability in catechin production by individual Centaurea plants (Blair et al. 2005), another explanation for low concentrations in our system could be possible microbial degradation. Considering the lower catechin phytotoxicity in soil-less medium observed in previous studies (Blair et al. 2005; Tharayil et al. 2008), the catechin concentration in our system would be below that required for phytotoxic concentration.

Pulsed release could increase the bioavailability of a compound by temporarily overwhelming the biological and chemical degradative capacity of soil (Tharayil et al. 2009). Additionally, catechin has been shown to be more persistent in a sandy loam soil when present along with phenolic acids that are released during litter decomposition of *C. stoebe* (Tharayil et al. 2008). Hence, how a pulsed release of catechin could interact with other soil edaphic and biotic factors needs further investigation. Since most earlier studies assumed continuous exudation, our results showing the diurnal pattern could provide some explanation for the previously reported highly variable catechin concentration in natural soils and in growing media. This affirms the importance of the sensitivity of sampling techniques and the time of sampling for studying plant secondary metabolites exuded through roots.

Acknowledgements The authors thank Ragan Callaway and Giles Thelen for supplying the *Centaurea maculosa* seeds for this study, Frank Stermitz, Harsh Bais, Jorge Vivanco, Ragan Callaway, Ruth Hufbauer, and two anonymous reviewers for providing constructive comments on an earlier version of this manuscript. This study was partially funded by the SC LIFE project. Technical Contribution No. 5751 of the Clemson University Experiment Station.

RAPID COMMUNICATION

Reduced Photosynthetic Activity is Directly Correlated with 2-(3*H*)-benzoxazolinone Accumulation in Lettuce Leaves

Adela M. Sánchez-Moreiras · Alberto Oliveros-Bastidas · Manuel J. Reigosa

Abstract 2-(3*H*)-Benzoxazolinone (BOA) is a secondary plant metabolite previously found to inhibit plant growth and development. The phytotoxic activity of BOA has been extensively demonstrated over the last years. However, the relation of BOA phytotoxicity with BOA accumulation in plant leaves has not been thoroughly investigated. In this work, BOA phytotoxicity on photosynthesis (ΦPSII and *P*n) of lettuce (*Lactuca sativa* L. cv. Great Lakes) was studied, and these results were correlated with BOA quantities in the leaves. BOA-treated plants showed reduced photosynthesis rate 6 h after the beginning of the treatment, and the efficiency of photosystem II started to be affected 10 h after treatment. These results were correlated with an increasing concentration of BOA in leaves that starts 6 h after treatment and shows a maximum at 96 h.

Keywords BOA action · HPLC · Photosynthetic activity · Phytotoxicity

Introduction

2-(3*H*)-Benzoxazolinone (BOA) is a stable decomposition product derived from the highly reactive and toxic but unstable plant secondary metabolite 2,4-dihydroxy-7-methoxy-2*H*-1,4-benzoxazin-3(4*H*)-one, especially found in cereals. This benzoxazolinone is a potent allelochemical in rye and other plant species, and it has been shown previously to have phytotoxic activity (Baerson et al. 2005). This classical Gramineae compound has been associated with dose-dependent germination and growth inhibition and more in-depth effects on energy metabolism in higher plants. Recent studies demonstrated BOA-reduced seedling length, which was associated with detailed morphological characteristics and impacts on cell division in the radicles (Sánchez-Moreiras and Reigosa 2008). Furthermore, a model of action related to oxidative damage has been proposed for BOA on adult plant metabolism (Sánchez-Moreiras et al. 2005; Batish et al. 2006). These studies concluded that BOA induces the generation of oxidative stress with high levels of lipid peroxidation and concomitant cell damage.

These previous studies demonstrate clear effects of BOA treatment. However, the relation between allelochemicals effects and the presence of the allelochemicals in the target organ has not been documented often. The ability of the cells to metabolize, accumulate, and extrude the natural compounds increases the probability that the toxicity measured after allelochemical application is due to some derivative compound and not necessarily to the 'original' allelochemical (Macías et al. 2006). The different strategies for avoiding allelochemical damage (extracellular excretion, vacuolar sequestration, vesicle transport, accumulation of the metabolite in a non-toxic form) usually are present in the plants as resistance mechanisms. Several studies on the detoxification of BOA in plant cells have concluded that, once into the cell, the cyclic hydroxamic acid can be metabolized by oxidation or hydroxylation and fast glycosylation to obtain a detoxification product storable in the vacuole (Friebe et al. 1998; Hofman et al. 2006). The intermediate toxic compounds generated during these

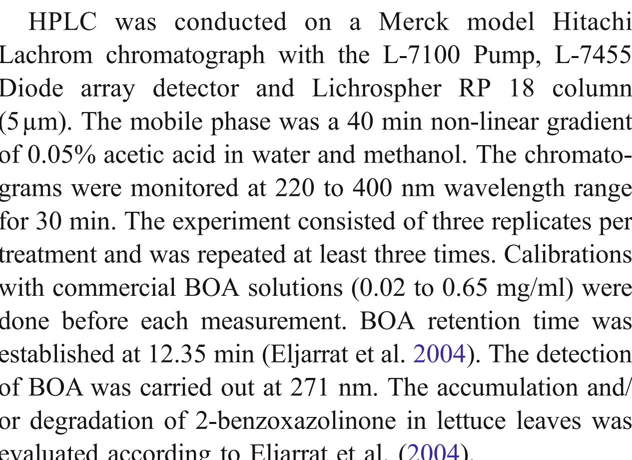
detoxification reactions (i.e., BOA-6-OH) could interfere and distort the measurement of BOA effects (Sicker et al. 2001; Schulz et al. 2006). Most of these studies, however, were done on roots of treated plants, and little information is available about the amount of BOA that reaches the leaves, the stability of this benzoxazolinone in the cells, and the correlation of BOA and phytotoxicity. Chiapusio et al. (2004) measured the translocation and accumulation of radio-labelled BOA in radish seeds and seedlings. They concluded that cotyledons were the sink organ for this allelochemical. However, these results were obtained in BOA-germinating seedlings, which makes it difficult to predict at which precise moment BOA reaches the leaf and to what extent this presence can be correlated with the observed phytotoxicity. Although BOA shows stronger effects on germinating seedlings, its impact on adult plant development also is important due to its continuous presence in the field when the BOA-containing crops are used as cover crops, mulch, smother crops, green manure, or grown in rotational sequences (Dhima et al. 2006). The ecological meaning of BOA action is based on its small but constant effect, which can be highly effective in plant to plant interactions.

Therefore, our goal in this study was to measure the presence of BOA in lettuce leaves after treatment and to correlate these results with the effects on photosynthesis. HPLC was used to measure BOA in leaf extracts, and phytotoxicity was assessed by photosynthesis and fluorescence measurements.

Methods and Materials

BOA solutions (2-benzoxazolinone; Aldrich Chem.Co. 15,705-8) were prepared with distilled water (pH 6.0) at 600 µM and 1 mM concentrations. Seeds of *Lactuca sativa* L. cv. Great Lakes (California) were placed in a thermostatically controlled chamber (16/8 h photoperiod at 150 µmol m^{-2} s^{-1} and 18/8 ºC and germinated in plastic trays with perlite, and 500 ml nutrient solution were added every other day. One week after germination, seedlings were treated with three different treatments. BOA concentrations were based on the dose-response curve for BOA (Sánchez-Moreiras et al. 2008): control, 600 µM BOA (first BOA concentration with significant effects), and 1 mM BOA (I_{50}). All solutions were prepared in 1:1 Hoagland's solution with 0.1% EtOH as solvent.

About 1 g fresh weight leaf tissue was harvested (3 samples per treatment) at 0, 2, 6, 12, 24, 48, 72, and 96 h after BOA exposure for quantification of BOA in leaves by high performance liquid chromatography (HPLC). For HPLC analyses, fresh lettuce leaves were cut into small pieces and immediately treated with ultrasounds at 50 ºC in a solution of 2% HOAc-MeOH for 10 min. The extract was filtered and dissolved to 5 ml.



HPLC was conducted on a Merck model Hitachi Lachrom chromatograph with the L-7100 Pump, L-7455 Diode array detector and Lichrospher RP 18 column (5 µm). The mobile phase was a 40 min non-linear gradient of 0.05% acetic acid in water and methanol. The chromatograms were monitored at 220 to 400 nm wavelength range for 30 min. The experiment consisted of three replicates per treatment and was repeated at least three times. Calibrations with commercial BOA solutions (0.02 to 0.65 mg/ml) were done before each measurement. BOA retention time was established at 12.35 min (Eljarrat et al. 2004). The detection of BOA was carried out at 271 nm. The accumulation and/or degradation of 2-benzoxazolinone in lettuce leaves was evaluated according to Eljarrat et al. (2004).

Photosynthesis rate (*P*n) was measured in the whole plant with an infrared gas analyser LI-6400 (Li-Cor model 6400, Lincoln, NE, USA). Photosynthesis values (µmol m^{-2} s^{-1}) were recorded in triplicate at 800 µmol m^{-2} s^{-1} quantum flux density (provided by a 6400-02B led light source), leaf temperature close to 20ºC, and a CO_2 flow value of 400 µmol s^{-1}. Immediately after gas-exchange measurements, the influence of BOA (1 mM) on the functional state of the photosynthetic apparatus and the ability of the plant to respond to this situation was investigated by the *in vivo* chlorophyll fluorescence of whole plants with a fluorescence monitoring system from Hansatech Ltd. Plants were exposed to ambient light for short time when the measurements were done during night period (see Figs. 1 and 2). Negative control (water) was used in order to ensure the correct development of the experiment (supplemental data). Data were subjected to analysis of variance, with a multiple range test (LSD) for subsequent pairwise comparisons. Data homocedasticity was tested with Levene's statistics.

Results and Discussion

The photosynthetic efficiency was monitored over a 96 h treatment period in order to get a clear picture of the evolution of BOA effects on lettuce leaves (as a model system). Figure 1 shows the monitored *P*n (photosynthetic rate) in plants treated with BOA and untreated controls. Photosynthetic activity clearly was enhanced briefly after treatment.

Figure 2 shows the monitored ΦPSII (chlorophyll *a* fluorescence) and *P*n (photosynthetic rate) in the plants after 1 mM BOA exposure. BOA started to affect photosynthetic rate about 6 h after treatment (day period), and reached the lowest rates 8 h after treatment. The *P*n transiently increased between 8 and 10 h, and then decreased during the night period. *P*n recovered after 16 to 18 h, and was relatively high 36 h after treatment. Probably the plant was coping with the stress produced by BOA application by compensating (most likely by heat

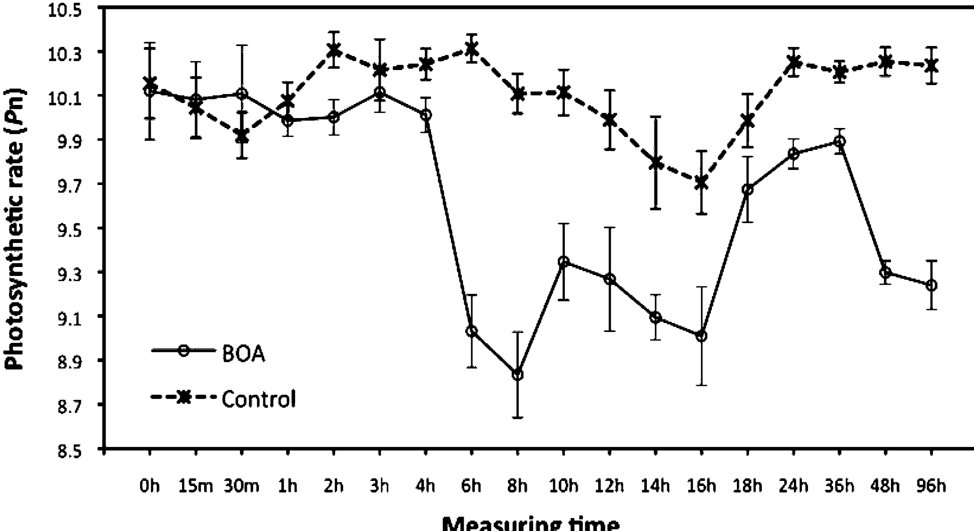


Fig. 1 Photosynthetic rate of control and BOA (1mM)-treated plants over 96 h treatment period (N=3 for each data point; means±SE are given)

dissipation) the excess energy. However, this was a short time of recovery, and the decline in *P*n became even more drastic after the second day of treatment. *P*n decreased between 36 and 48 h and remained low for the remainder of the experiment. At this time (48 h), no visible symptoms of BOA phytotoxicity were detected in the leaves. Finally, plants showed very low *P*n and Fv/Fm values 96 h after treatment, the last measurement time, when BOA-treated plants showed smaller size and more senescent leaves than control plants.

Pulse-modulated fluorescence was recorded for the same replicates per treatment used for gas-exchange measurements (Fig. 2). The photochemical yield of Photosystem II (PSII) was established by measuring the quantum yield of

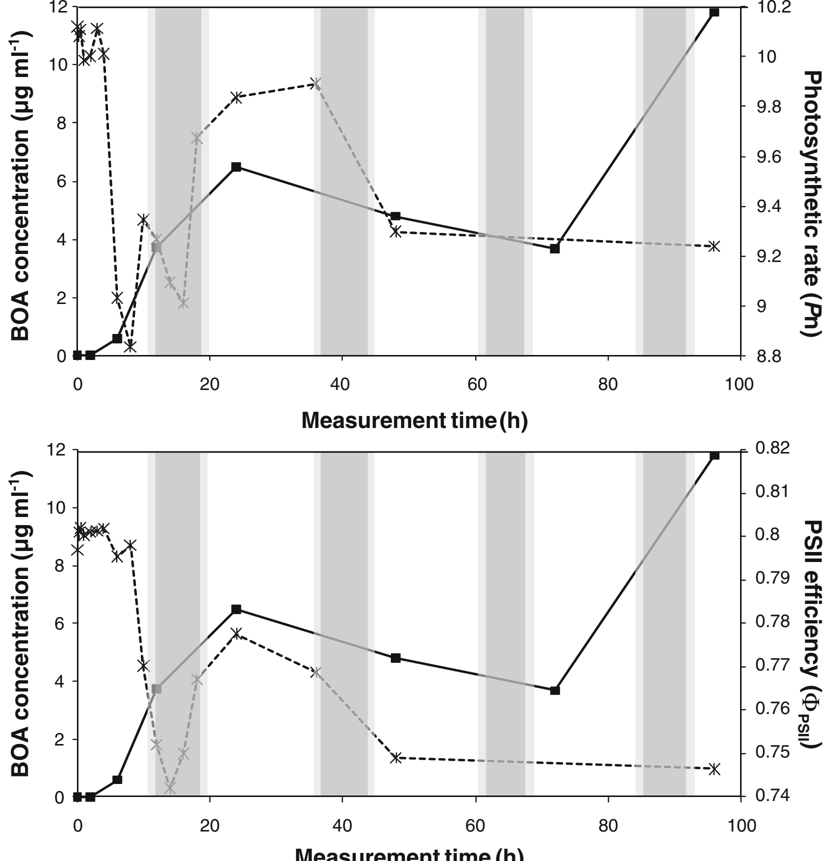

Fig. 2 BOA concentration and photosynthetic activity in lettuce leaves over 96 h treatment. Continuous line represents BOA concentration in the leaves (μg ml^{-1}) and dotted line represents photosynthetic activity (*P*n and Φ_{PSII}). Dark areas represent night periods and day-night transition periods

Table 1 Correlations between photosynthetic parameters and BOA quantities in lettuce leaves after BOA treatment (1mM)

	Correlations	ΦPSII	*P*n	[BOA]
ΦPSII	Pearson Correlation	1	0.546([a])	−0.773([a])
	Sig. (2-tailed)	–	0.000	0,000
*P*n	Pearson Correlation	0.546([a])	1	−0.464([b])
	Sig. (2-tailed)	0.000	–	0.013

[a] Correlation is significant at the 0.01 level (2-tailed)

[b] Correlation is significant at the 0.05 level (2-tailed)

Photosystem II photochemistry (Φ_{PSII}). The quantum yield of electron flow through PSII *in vivo*, i.e., the overall efficiency of PSII reaction centers in the light (Φ_{PSII}), measures the proportion of absorbed energy that is used in photochemistry (the reached efficiency). The inhibition of Φ_{PSII} values insinuates a weak efficiency of PSII reaction centers and indicates an alteration of the rate of linear electron transport, suggesting that the proportion of photons absorbed by PSII and used for photosynthesis is being reduced (Hall and Rao 1999). The temporal profile for ΦPSII was similar to that of *P*n but it started later. Decrease of PSII efficiency started 10 h after treatment and stayed statistically low for the overall period. Moreover, we detected a similar tendency for recovery at 36 h for ΦPSII and *P*n, although the recovery observed in ΦPSII was a trend only with statistically different values with respect to the control.

To quantify BOA concentration in lettuce leaves, HPLC measurements were conducted in plants treated with 600 µM and 1 mM BOA concentrations and in untreated plants as a negative control. Figure 1 shows BOA content in lettuce leaves at eight different exposure times after 1 mM BOA treatment. BOA accumulation in leaves slowly increased to a first peak of concentration 24 h after the treatment. BOA concentration in the leaves was highest 96 h after BOA exposure. Values obtained for 600 µM were similar to those found for 1 mM BOA treatment but in a lower range of values (data not shown).

When considering *P*n, ΦPSII, and HPLC measurements, we see a clear correlation between presence of BOA in the leaves and decreased photosynthetic activity (Table 1). The first time point at which BOA was detected in the leaves (6 h) correlates perfectly with the first time at which photosynthesis was strongly affected (6 h). When photosynthesis is low, BOA concentration in the leaves is high. In this way, Pearson's coefficient gave statistically significant correlations for these three measurements. BOA accumulation showed significantly inverse correlation with ΦPSII and *P*n non-stressed values (−0.773 and −0.464, respectively) while, as expected, ΦPSII showed a highly significant correlation with *P*n values. No new peaks were detected in the chromatograms over this time period although previous studies have shown the ability of lettuce to enzymatically detoxify BOA (Schulz et al. 2006). We conclude that the phytotoxicity observed in lettuce leaves at this time was due to the activity of BOA and not to some derivative or other degradation compounds. Nevertheless, the time course data demonstrated that photosynthetic rate (*P*n) dropped as BOA was first detected in the leaves, which also suggests that the signal or damage that reduced *P*n occurred in the roots and moved up to the leaves along with BOA. Altogether, the effect observed on lettuce after BOA treatment is directly correlated with addition and presence of BOA in the plants.

Acknowledgements The authors are grateful to Oliver Weiss for help in the photosynthesis measurements, and Eva Diéguez and Francisco Macías from the University of Cádiz for their help with the HPLC measurements and their wise advice.

Abstract Capacity for terpene production may confer advantage in protection against abiotic stresses such as heat and drought, and also against herbivore and pathogen attack. Plant invasive success has been intense in the Hawaiian islands, but little is known about terpene content in native and alien plant species on these islands. We conducted a screening of leaf terpene concentrations in 35 native and 38 alien dominant plant species on Oahu island. Ten (29%) of the 35 native species and 15 (39%) of the 38 alien species contained terpenes in the leaves. This is the first report of terpene content for the ten native species, and for 10 of the 15 alien species. A total of 156 different terpenes (54 monoterpenes and 102 sesquiterpenes) were detected. Terpene content had no phylogenetic significance among the studied species. Alien species contained significantly more terpenes in leaves (average ± SE=1965±367 μg g^{-1}) than native species (830±227 μg g^{-1}). Alien species showed significantly higher photosynthetic capacity, N content, and lower Leaf Mass Area (LMA) than native species, and showed higher total terpene leaf content per N and P leaf content. Alien species, thus, did not follow the expected pattern of "excess carbon" in comparison with native species. Instead, patterns were consistent with the "nutrient driven synthesis" hypothesis. Comparing alien and native species, the results also support the modified Evolution of Increased Competitive Ability (EICA) hypothesis that suggests that alien success may be favored by a defense system based on an increase in concentrations of less costly defenses (terpenes) against generalist herbivores.

Introduction

Plant invasion is an important component of current global change (Mooney and Hobbs 2000). Chemical factors such as terpenes can be involved in the competition between alien and native plant species. For example, Barney et al. (2005) stated that the terpene production capacity of *Artemisia vulgaris* can be a key factor in its establishment and proliferation in introduced habitats by phytotoxic effects on native species.

Many studies have investigated the physiological and ecological significance of terpenes in plants. Protection, defense, and infochemical function have been highlighted as roles of terpenes (Llusià and Peñuelas 2001; Wheeler et al. 2002; Peñuelas and Llusià 2003, 2004). Examples of these roles are photoprotection (Peñuelas and Munné-Bosch 2005), thermotolerance (Sharkey and Singsaas 1995; Peñuelas and Llusià 2001, 2002; Copolovici et al. 2005; Peñuelas et al. 2005), protection against drought stress

(Llusià and Peñuelas 1998; Kainulainen et al. 1991), and non-specific antioxidative capacity, whereby terpenes protect photosynthetic membranes against peroxidation and reactive oxygen species such as singlet oxygen (Loreto and Velikova 2001; Peñuelas and Llusià 2002; Loreto et al. 2004; Munné-Bosch et al. 2004; Llusià et al. 2005).

Although relative performance often depends on growth conditions, invaders are more likely to have higher leaf area and lower tissue construction costs that increase productivity, and also greater phenotypic plasticity that is advantageous in disturbed environments (Daehler 2005). Foliar traits such as higher photosynthetic capacity per dry mass (A_{mass}) and lower leaf construction costs associated with a lower leaf mass per area (LMA) partly explain the success of alien plant species (Baruch and Goldstein 1999; Funk and Vitousek 2007), since they may contribute to faster growth rates for invaders and confer a competitive advantage over native species (Reich et al. 1997; Peñuelas et al. 2010). Similarly, invasive plant species in Hawai'i have been found to have higher foliar N and P concentrations than native species (Peñuelas et al. 2010).

Changes in nutrient availability can affect terpene production (Son et al. 1998; Kainulainen et al. 2000; Lee et al. 2005). Greater terpene production in plants with higher nutrient concentration and photosynthetic rates can be expected from the "nutrient-driven synthesis" hypothesis that predicts a larger enzyme production with greater cellular N and P availability. Higher nutrient availability usually is expected to translate into higher carbon fixation and activity of the enzymes involved in isoprenoid production (Harley et al. 1994; Litvak et al. 1996). In contrast, a lower production of terpenes as carbon based secondary compounds under higher nutrient availabilities can be expected from the "carbon based secondary compounds" (CBSC) hypthesis and the source-sink "carbon-nutrient balance" or "excess carbon" (CNB) hypothesis (Loomis 1932; Bryant et al. 1983; Herms and Mattson 1992; Peñuelas and Estiarte 1998). These hypotheses assert that plants allocate carbon to secondary metabolism only after growth requirements are met, and that growth is constrained more by nutrients than by photosynthesis. According to these theories, the excess carbohydrates that accumulate in nutrient-limited plants when photosynthesis outpaces growth are diverted to the production of carbon-based secondary compounds (e.g., terpenes and phenolics).

Phenotypic plasticity has been an important mechanism that enables alien plants to colonize exotic habitats, and recent studies indicate that alien plants also can evolve quickly (Maron et al. 2004). Some invasive trees and herbs have proved to be able to evolve in periods from 1 to 3 hundred years or less, reaching a faster growth capacity, and changing their chemical defense strategies (Rogers and Siemann 2004; Siemann et al. 2006). The main cause of this increase in fitness has been proposed as the Evolution of Increased Competitive Ability (EICA) hypothesis (Blossey and Nötzold 1995). It predicts that introduced species, which lose contact with their natural specialist herbivores, may evolve, thus decreasing their investment in anti-herbivore chemical defenses. This way, resources no longer needed for defense can be reallocated to other functions that provide a selective advantage in the novel habitat. Recent modifications in the development of increased competitive ability (EICA) hypothesis propose that since invasive genotypes still may experience attack by local generalist herbivores (Müller-Schärer et al. 2004), selection may favor a reduction in the expression of metabolically expensive chemical defenses effective against specialist herbivores, and increase the concentrations of less costly qualitative defenses, such as terpenes, that may be more toxic to generalist herbivores (Joshi and Vrieling 2005; Stastny et al. 2005). In this context, Johnson et al. (2007) have observed that when North American native populations of *Solidago gigantea* grow under the same environment conditions as alien European population of the same species, the native plants have lower monoterpene and diterpene contents than invasive plants. This suggests that terpene content might be related to alien success.

The Hawaiian archipelago is the most isolated terrestrial region on Earth (Vitousek and Walker 1989), and is especially vulnerable to invasions by non indigenous species (Harrington and Ewel 1997). Alien plants in Hawai'i have strong impact on native Hawaiian ecosystems and their highly endemic flora (Mack and D'Antonio 2003; Hughes and Uowolo 2006). In these Islands, around 861 flowering plant species (47% of total Hawaiian angiosperm flora) are naturalized alien species (Wagner et al. 1999). As a result, approximately 25% of the Hawaiian native flora, 90% of which is endemic, has been listed as threatened or endangered. In fact, all tropical island ecosystems appear to be especially vulnerable to invasive species, and some experiments suggest that the high resource availability and the poor ability of native species to capture these resources, contributes to the vulnerability of island communities to the establishment and spread of alien species (Allison and Vitousek 2004).

There are published reports of terpene contents in species that are aliens in Hawai'i, but these studies have been conducted in other parts of the world (Ogunkoya et al. 1972; Schapoval et al. 1998; Kikuzaki et al. 2000; Wheeler et al. 2002; Chiang and Kuo 2002; Pino et al. 2005; Randrianalijaona, et al. 2005; Fernández and Torres 2006; Pachanawan et al. 2008). Generally, apart from scarce reports (Komai and Tang 1989) little is known about terpene content in Hawaiian native and alien flora.

In this study, we conducted a screening of leaf terpene content in 35 native and 38 alien dominant Hawaiian plant

species. Our aims were to: (i) estimate terpene content and composition of native and alien species that are dominant in Oahu, (ii) compare the mono- and sesquiterpene content of the 35 native plants with the content of 38 alien plants, (iii) compare the relationships of terpene content with the leaf traits defining "leaf economics spectrum" (Wright et al. 2004), such as photosynthetic rates (A_{mass}), leaf mass area (LMA), and C, N, P, and K leaf concentrations among native and alien species, and (iv) test the "nutrient driven synthesis", "excess carbon", and "modified EICA" hypotheses for terpene content in native and alien species.

Methods and Materials

Field Sites The study was conducted in May 2007 on Oahu, the third largest of the Hawaiian Islands. As typical of larger Hawaiian Islands, the climate is characterized by steep rainfall gradients over short distances (Müller-Dombois and Fosberg 1998). Lowlands at the leeward side have a pronounced dry summer season, while precipitation is distributed almost uniformly in lowland and mountain rain forests. Due to the oceanic tropical climate, interannual temperature oscillations are small with winters having on average 2–3°C cooler temperatures than summers. As large differences in the composition of native and alien vegetation occur in response to rainfall gradients, four sites with distinct precipitation regimes were selected for plant sampling in the leeward lowlands of Oahu, and at the leeward side of Koolau mountains (Table 1 and see detailed decription of the sampling sites, their climate and the studied species in Peñuelas et al. 2010).

The four key soil types found across the sites rank according to the state of soil weathering as *oxisols*>*ultisols*>*mollisols*>*inceptisols* (Uehara and Ikawa 2000; Deenik and McClellan 2007). *Mollisols* exhibit the highest fertility, while more leached *oxisols* and *ultisols* with lower pH are among the soils with lowest fertility (Uehara and Ikawa 2000; Deenik and McClellan 2007). *Inceptisols*, the youngest soils, typically show weak profile development, and, depending on genesis, exhibit tremendous variability in fertility (Deenik and McClellan 2007). The Tantalus series *inceptisols* are of moderate to high fertility, while the *inceptisols* in rocky soils and mountainous land are of low fertility. Thus, in our study, the broad soil classes rank according to fertility as *mollisols* > *inceptisols* (Tantalus) > *oxisols* ≅ *ultisols* > *inceptisols* (mountainous soils).

Study Species Altogether, 73 dominant,(35 native, and 38 alien) species were studied at four sites (Peñuelas et al. 2010). All native species sampled were evergreen, but in dry sites (St. Louis Heights, Hahaione Valley), four alien species were drought-deciduous (*Desmodium incanum*, *Falcataria moluccana*, *Senna surattensis*, *Tabebuia rosea*), and two were semi-deciduous (*Haematoxylum campechianum*, *Leucaena leucocephala*). The deciduous and semi-deciduous aliens were legumes, except for *Tabebuia rosea* (*Bignoniaceae*). Of the 73 studied species, 36 were trees, 29 shrubs, 3 woody vines to shrubs, 3 woody vines, one herb to subshrub, and one parastitic mistletoe (*Korthalsella complanata*). The distribution of species among the key life form classes was similar among native and alien species (14 alien and 15 native shrubs, 21 alien and 15 native trees; Peñuelas et al. 2010).

Each species was sampled in triplicate, with twigs or small branches taken from 3 individuals for each species. Samples were cut with a sharp knife and cut again immediately with the excised stem under water, to prevent ingress of air to the xylem vessels and subsequent stress. In the lab, the excised stems were enclosed loosely in plastic bags to prevent water loss by transpiration prior to terpene extraction. Leaf extractions were conducted during the next 12 h. Species coordinates and sampling altitude were noted in each site by using GPS, and this information was used to link species locations to specific soil types and to derive location-specific climatic data. Long-term average monthly and annual precipitation, precipitation of the three driest months and annual precipitation, and average, maximum

Table 1 Description of the study sites

Site	Coordinates	Average ± SD[a] altitude (m)	Average ± SD precipitation (mm)		Average ± SD annual temperature (°C)				
			Annual	Three driest months	Minimum	Maximum	n	N	A

N number of species, *N* native species, *A* alien species

[a] averages are based on the number of species sampled and species-specific locations. In statistical analyses, exact species-specific environmental data were used

and minimum temperatures were estimated from high resolution climatic grids by using the database developed and continuously updated by Giambelluca and associates (Giambelluca et al. 1986; Cao et al. 2007). ARCGIS 9.1 was used to extrapolate between the isohyets (10 m square cells in the grid with appropriate elevation model), as applied previously in Hawaiian ecosystems (Porder et al. 2005; Dunbar-Co et al. 2009).

Species were classified according to site preference as dry, dry-mesic, mesic, dry-wet, mesic-wet, and wet forest species. Species invasiveness was scored by using a four-level scale as 0 (native species), 1 (low invasiveness), 2 (moderate-high), and 3 (very high). These simplified scores were based on the Australia/New Zealand weed risk assessment (WRA) system (Pheloung et al. 1999) modified to Hawai'i and other Pacific Islands (Daehler et al. 2004). For Hawaiian Islands, these scores are reported in Pacific Island Ecosystems at the Risk (PIER) project online database, maintained by U.S. Forest Service's Institute of Pacific Islands Forestry (http://www.hear.org/pier/), and on recent updates on species invasive potential in Oahu (Daehler and Baker 2006). The weed risk assessment is based on up to 49 questions about species biology. For 9 species that have not been scored in these assessments, weed risk assessment scores were derived based on the risk questionnaire (http://www.hear.org/pier/). As the risk assessment provides information of possible species invasiveness, but not on whether the species actually becomes invasive in the specific new habitat, finally, a simplified 3-level scale (1–3) was used to group aliens with varying invasive potential and known invasiveness throughout Oahu. (Daehler et al. 2004; Daehler and Baker 2006).

Leaf Terpene Extraction and Analysis Leaf samples were crushed in liquid nitrogen with a Teflon pestle in a Teflon tube until a homogeneous powder was obtained. Between 2–4 ml of pentane (depending on the leaf type) were added before the pulp defrosted. The Teflon tubes were maintained airtight at 25°C during 24 h for full extraction. After this, a sample of each extract was put into a 300 μl glass vial. Samples were injected automatically into the GC-MS following a split of 0.5:80, thus allowing only 0.625% of the injected sample to enter the column. The column was an HP-5 crosslinked 5% PH Me Silicone (Supelco Inc.). Solvent delay was 3 min. The initial temperature of 40°C was increased immediately with a ramp of 30°C min^{-1} to 60°C. The second ramp was 10°C min^{-1} to 150°C, which was maintained for 3 min. The third ramp was 70°C min^{-1} to 250°C, which was maintained for 5 min. Carrier gas was helium at 0.7 ml min^{-1}. The mass detector was used with an electron impact of 70 eV. Identification of monoterpenes was conducted by GC-MS and comparison with authentic standards from Fluka (Buchs, Switzerland), literature spectra, and GCD Chemstation G1074A HP. Calibration with common terpenes α-pinene, 3-carene, β-pinene, β-myrcene, *p*-cymene, limonene, sabinene (monoterpene), and α-humulene (sesquiterpene) standards was carried out once every 5 analyses. Standards were purchased from Sigma Aldrich (Gilingham, Dorset, UK). Terpene calibration curves (N=4 different terpene concentrations) were always highly significant (r^2>0.99 for the relationships between signal and terpene concentrations). The most abundant terpenes had similar sensitivity (differences were less than 5%). Quantification of the peaks was conducted according to the amount of ion 93 in the compound and by using the calibration of the most similar mono- or sesquiterpene standard depending on the compound investigated. The total GC run time was 23 min. All sampling and analytical procedures were applied in the same way for native and alien species.

Statistical Analyses The program Phylomatic (Webb and Donoghue 2005) was used to build a phylogenetic tree of the species studied (Fig. 1) as explained in Peñuelas et al. (2010). The stadistical significance of the genetic differences among different species in explaining the variability of the studied variables was calculated by employing Matlab 7.6.0 with the PHYSIG module developed by Blomberg et al. (2003).

Altitude was significantly correlated with all the main climate variables of each respective site (total annual precipitation, the precipitation of the three driest months, mean annual temperature, annual mean of the daily minimum temperatures, annual mean of the daily maximum temperatures, annual mean of monthly difference between the maximum and minimum temperature and annual mean of the coldest monthly temperature) (data not shown).

To analyze the effects of all studied characteristics on foliage terpene contents, we conducted a general linear model (GLM) with site (4 different sample sites), species origin (native and alien), and soil type (5 different soil types) as independent categorical variables, altitude as independent continuous variable, and in the case of variables with phylogenetic fingerprinting, phylogenetic distances also were included as continuous independent factors. We introduced the factor site in the GLM design to extract the variability due to site. Since the origin of the studied species (native vs. alien) showed a significant phylogenetic signal (k=0.309, P=0.022) mainly due to the high abundance of alien species of the Orders *Rosales*, *Lamiales*, and *Laurales*, we conducted all the statistical analyses that had the origin of species as the independent factor both by an ordinary GLM without phylogenetic distance matrix and also with phylogenetic distance matrix even when the dependent variable had no significant phylogenetic signal. Thereafter, the model with a lower

Fig. 1 Phylogenetic tree of the studied woody plant species obtained from PHYLOMATIC programme (Webb and Donoghue 2005). The scale depicts millions of years. The field sampling site is depicted between brackets to the right of each species. (SLH = St. Louis Heights. HV = Hahaione Valley. T = Tantalus. WR = Williwillinui Ridge). The origin (N = Native. A = Alien) is also depicted

Akaike information criterion (AIC) was selected. To conduct these analyses we used Matlab 7.6.0 with REGRESSIONV2 module (Lavin et al. 2008). We also conducted a PCA analysis with leaf economics spectrum variables (nutrients, A_{mass} and LMA) and the different sets of species as cases. Then, we looked at the correlation between the factor scores that characterized the functional spectrum and total leaf terpene contents by using Statistica 6.0 software package (StatSoft, Inc. Tule, OK, USA).

We employed the same rationale to analyze potential differences between native and alien species in terpene contents vis-à-vis leaf chemical, physiological, and anatomical traits. To analyze what variables are differently correlated between alien and native species, we conducted discriminant analysis among leaf total terpene contents and leaf traits by using Matlab 7.6.0 with REGRESSIONV2 module (Lavin et al. 2008) and Statistica 6.0 software (StatSoft, Inc. Tule, OK, USA). To analyze the effects of leaf economics spectrum on terpene emisssion and whether there were different relationships between native and alien species, we also conducted a PCA analysis with the species as cases and leaf economics spectrum (nutrients, amass, and LMA) as variables and calculated the factor scores for each species. Thereafter, we conducted a correlation between the factor scores that characterized the functional spectrum and the total terpene contents.

To compare possible differences in the proportion of species that produced and accumulated terpenes between the alien and native species set, we conducted a *Chi-square* test by using Statistica 6.0 software package (StatSoft, Inc. Tule, OK, USA).

Results

Foliage Terpene Concentration. Alien vs. Native Species Twenty-five (10 natives and 15 alien) of the 73 studied species contained at least one terpene (concentration above the detection limit of 0.6 ng g^{-1} in their leaves; Tables 2 and 3). No terpenes were detected in 48 of the 73 studied species (Appendix 1). Total terpene and total monoterpene concentrations were higher in the entire set of alien species than in the entire set of native species (P=0.02 and P=0.04, respectively) (Table 4, Fig. 2). In alien species, total terpene concentration was 1965±367 μg g^{-1} (4524±1225 μg g^{-1} when considering only storing species) and in native species it was 830±227 μg g^{-1} (2905±650 μg g^{-1} when considering only storing species). Total sesquiterpenes, cyclic monoterpenes, cyclic sesquiterpenes, and aromatic monoterpenes were also higher in alien than in native species but the differences were not significant (Table 4, Fig. 2). The greater average total terpene content in alien than in native species was due mainly to higher leaf monoterpenes in moderately-high invasive species and to higher sesquiterpenes in highly invasive species than in native species (Fig. 2). Neither the sampling site nor soil type had any significant effect on total terpene content (Table 4). The proportion of species that accumulated terpenes, although higher in alien species, was not significantly different between native (29%) and alien species (39%) (χ^2=0.97, P=0.42).

Several mono- and sesquiterpene compounds were found in 10 native species (*Cheirodendron trigynum*, *Melicope clusiifolia*, *Melicope peduncularis*, *Metrosideros macropus*, *Metrosideros polymorpha*, *Metrosideros rugosa*, *Metrosideros tremuloides*, *Myrsine lessertiana*, *Myrsine sandwicensis*, *Syzygium sandwicensis*), which had not been described previously as terpene accumulators to our knowledge. *Syzygium sandwicensis* accumulated 3 monoterpenes (camphene, E-β-ocimene, 3,7 dimethyl-octa-1,3,7-triene) and 11 sesquiterpenes (Tables 2 and 3) in its leaves. In the species of the genus *Metrosideros*, three monoterpenes (sabinene, 1,3,6-octatriene, 3,7-dimethyl E-β-ocimene) and 18 sesquiterpenes (Tables 2 and 3) were detected. In the two species of the genus *Myrsine*, 2 monoterpenes (limonene, myrcene) and 33 sesquiterpenes (Tables 2 and 3) were observed. In *Cheirodendron trigynum*, 11 monoterpenes and 11 sesquiterpenes were found (Tables 2 and 3). Finally, in the two *Melicope* species, 24 monoterpenes and 29 sesquiterpenes were found (Tables 2 and 3).

Among the 15 alien species that accumulated terpenes in their leaves, three species *Heliocarpus americanus* (1 monoterpene, 7 sesquiterpenes, Tables 2 and 3), *Schinus terebinthifolius* (7 monoterpenes, 9 sesquiterpenes), and *Persea americana* (7 monoterpenes, 3 sesquiterpenes) had not been reported previously as terpene accumulators.

Phylogenetic influence on the values of the variables was present only in 6 of the 156 different detected terpenes: β-cubebene, β-maaliene, epi-bicyclo-sesqui-phellandrene, γ-elemene, β-ocimene and l-β-pinene. Total terpene contents did not show a phylogenetic effect (data not shown).

Relationships of Leaf Terpenes to A_{mass}, LMA and Nutrient Leaf Concentrations and Climate No significant relationships of total terpenes with climatic characteristics and A_{mass} were observed in the corresponding GLM analysis either in native or alien species (data not shown). Discriminant analysis of the total terpenes (TT) and leaf traits: LMA (Wilk's Lambda = 0.58 and P=0.002), leaf N concentration (Wilk's Lambda = 0.65 and P=0.008), leaf K concentration (Wilk's Lambda = 0.82 and P=0.1) and A_{mass} (Wilk's Lambda = 0.67 and P=0.019), separated native and alien species (Fig. 3), showing that the set of native species had greater LMA and lower leaf economic traits and leaf terpenes than the set of alien species. Relationships of total

terpene contents with the main leaf economic and structural traits did not differ between native and alien species (Fig. 3). There was no significant correlation between total leaf terpenes and the PC1 scores of each species obtained in the PCA analysis of leaf economic traits (LMA, Amass, N, K) within native plants (R=0.17, P=0.64) nor within alien plants (R=0.090, P=0.77) (Fig. 3).

Discussion

Terpenes in Hawaiian Plants This study provides novel information about terpene contents in Hawaiian native plant species. It also contributes to advance our understanding of terpene content in several alien species that have worldwide distributions (Sharma et al. 1999; Olajide et al. 1999; Ghisalberti 2000; Kikuzaki et al. 2000; Wheeler et al. 2002; Pino et al. 2005; Zhao et al. 2009).

None of the 10 native species that accumulated terpenes has been reported previously as terpene-containing, at least to our best knowledge. At the genus level, only some species of the genus *Syzygium* had been reported as terpene accumulators (Chang et al. 1999). Among the 15 alien terpene-containing species, six had been previously identified as mono and sesquiterpene-containing species (*Psidium guajava*, Olajide et al. 1999; *Lantana camara*, Sharma et al. 1999; Ghisalberti 2000; *Pimenta dioica*, Kikuzaki et al. 2000; *Melaleuca quinquenervia*, Wheeler et al. 2002; *Mangifera indica*, Pino et al. 2005; *Ageratina adenophora*, Zhao et al. 2009). In these cases, the terpenes reported previously and those found in the present research generally were the same, but with some differences. Some terpenes found in *Lantana camara*, such as α-gurjunene or zingiberene, had not been reported previously in this species. Similarly, in *Melaleuca quinquenervia*, we found 7 terpenes (viridiflorol, 1–8 cineole, α-terpineol, α-pinene, β-pinene, γ-terpinene, α-terpinene) of the 10 already previously reported in this species (Wheeler et al. 2002), but in addition we also found 8 more monoterpenes and 22 sesquiterpenes (Tables 2–3). It is possible that the sampling technique may have induced some stress, which might have resulted in the production of these extra compounds. Five of the 17 alien species that accumulated several mono- and sesquiterpenes, *Cinnamomum burmannii, Eucalyptus robusta*, *Psidium cattleianum*, *Rubus rosifolius*, and *Syzygium cumini* (Tables 2–3) had not yet been reported as terpene-accumulator species, although members of the same genus have been described as terpene accumulators (Chang et al. 1999; Olajide et al. 1999; Moore et al. 2004; Chao et al. 2005; Yang et al. 2005; Malowicki et al. 2008). In another species, *Pluchea carolinensis*, known to have medical properties, terpene content has been suggested, but had not been described (Fernández and Torres 2006). In this study, 1 monoterpene and 3 sesquiterpenes were detected in this species. Finally, three alien species *Heliocarpus americanus*, *Schinus terebinthifolius* and *Persea americana* had not been reported previously as terpene accumulators. We did not detect a phylogenetic effect in the total terpene content among the set of studied species, nor in the content of the individual terpenes.

Higher Terpene Content in Alien Species and No Relationship to Leaf Economics In regard to the number of species that accumulate terpenes, although the difference was not significant, the proportion of species that accumulated terpenes in leaves was slightly higher in alien (39%) than in native (29%) species. In regard to the absolute terpene leaf accumulation, alien species accumulated greater amounts in leaves, and also had greater N and P leaf concentrations than native species, and their ratio of terpene contents to the concentrations of these two elements were higher than in native species. Thus, the differences between alien and native species were proportionally greater in leaf terpene accumulation than in N and P leaf content. Collectively, these data suggest a greater investment in terpene production with respect to nutrient absorption and carbon fixation in alien compared with native species. Thus, alien species in Hawai'i may have more productive leaves and invest more of their leaf primary production in terpene accumulation than native species.

The discriminant analyses based on the relationships between total terpene accumulation and LMA and nutrient content significantly separated alien from native plants, thus reflecting that alien species have greater total terpene contents, N and K concentrations, and A_{mass} and lower LMA than native species. When comparing native with alien species, a significantly higher leaf nutrient and terpene content are observed in alien species. This segregation suggests that these species may be using different resources and might also have greater capacities to capture and use nutrients. Despite this, however, there were no significant relationships between leaf terpene accumulation and leaf economic spectrum in either native or alien species.

"Nutrient Driving", "Excess Carbon" and "EICA Related" Hypotheses The comparison of alien and native species did not support the "excess carbon" hypotheses (Loomis 1932; Bryant et al. 1983; Herms and Mattson 1992; Peñuelas and Estiarte 1998). Alien species had higher N leaf contents but did not have lower terpene concentrations. Decreases of terpene production have been reported when leaf nutrient concentrations increase (Son et al. 1998). Kainulainen et al. (1996) observed that N fertilization had no effect on monoterpene concentrations in growing needles of *Pinus sylvestris*, but in mature needles, N fertilization significantly decreased concentrations of some individual and total monoterpenes. There also are reports of no relationships at

Table 2 Foliar contents of aromatic, cyclic, and non-cyclic monoterpenes (μg g^{-1}) detected in the studied native and alien species in Oahu (Hawai'i). The species lacking detectable amounts of aromatic and cyclic monoterpenes are shown in Appendix 1. A = alien; N = native

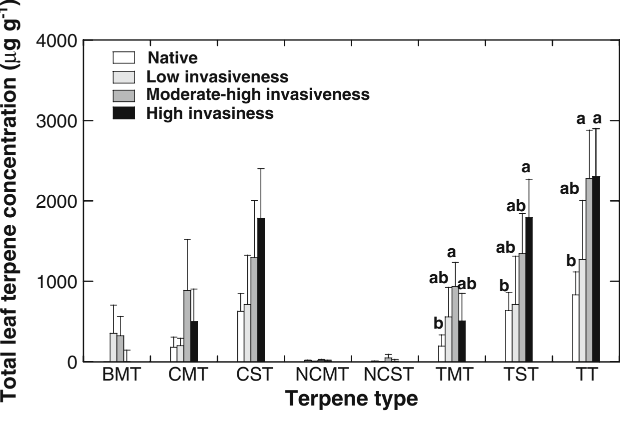

Fig. 2 Foliar benzenic monoterpene (BMT), cyclic monoterpene (CMT), cyclic sesquiterpene (CST), non-cyclic monoterpene (NCMT), non-cyclic-sesquiterpene (NCST), total monoterpene (TMT), total sesquiterpene (TST), and total terpene (TT) concentrations (μg g^{-1}) in native and alien species grouped according to their invasiveness index. Different letters indicate statistically significant differences at P<0.05 among species groups with differing invasiveness index

all between soil nutrients and terpene contents (Heyworth et al. 1998). Our results support the "nutrient driving synthesis hypothesis", which expects higher nutrient availability to translate into higher carbon fixation and activity of the enzymes involved in isoprenoid production (Harley et al. 1994; Litvak et al. 1996). Other studies have reported a significant and positive relationship between leaf terpene content and N availability in *Pinus halepensis* (Kainulainen et al. 2000), and NPK fertilization has shown to increase terpene contents in *Chrysanthemum boreale* (Lee et al. 2005). On the other hand, our results also support the modified EICA related hypothesis that suggests that alien success may be favored by an increase in the concentrations of less costly defenses such as terpenes that may be more toxic to generalist herbivores (Joshi and Vrieling 2005; Stastny et al. 2005), as has been observed in some previous studies (Johnson et al. 2007).

Terpene Content and Success of Aliens The results suggest that alien success may be related to higher levels of leaf terpene content that can have protective effects in response to environmental stress and/or prevent the attack of generalist herbivores and pathogens. The possible role of terpenes as cause of alien success due to herbivorism protection, however, should be taken with caution because the few studies that have examined herbivory pressure in Hawai'i are inconclusive. For example, a study by DeWalt et al. (2004) found little fungal and insect damage on one invader; however, Joe and Daehler (2008) found significant slug damage on several rare native species. Terpenes may produce advantages by other mechanisms, e.g., overall higher terpene production and accumulation in alien species could be involved in allelopathic or protective mechanisms

Fig. 3 Discriminant analysis using Leaf total terpenes (TT) vs. Photosynthetic capacity (A_{mass}), TT vs. Leaf mass per area (LMA), TT vs. leaf nitrogen concentration (N), TT vs. Leaf potassium concentration, TT and TT vs. PC1 first principal component factor scores of 'leaf economics spectrum' (covariation among leaf traits; LMA, A-mass, N, K) as independent continuous variables, and species origin: native (in black - bold) and alien (in red – light gray) as the dependent categorical factor. Only terpene containing species are considered in the discriminant analyses shown here. Similar results were found for the whole set of species studied including both terpene containing and non-containing species. (Ag = *Ageratina adenophara*, Cb = *Cinnamonium burmanii*, Ct = *Cheirodendrum trigynum*, Er = *Eucapyptus robusta*, He = *Heliocarpus americanus*, Lc = *Lantana camara*, Ma = *Metrosideros macropus*, Mc = *Melicope clusiifolia*, Md = *Myrsine lessertiana*, Me = *Metrosideros polimorpha*, Mi = *Magnifera indica*, Mp = *Melicope peduncularis*, Mq = *Melicope quinquenervia*, Mr = *Metrosideros rugosa*, Ms = *Myrsine sandwicensis*, Mt = *Metrosideros tremuloides*, Pc = *Pluchea carolinensis*, Pd = *Pimenta dioica*, Pe = *Persea Americana*, Pg = *Psidium guajava*, Pt = *Psidium cattleionum*, Ru = *Rubus rosifolius*, Sc = *Syzygium cumini*, St = *Schinnus terebinthifolius*, Sy = *Syzygium sandwisensis*)

that would confer competitive advantage with respect to native species, compensating for their greater nutritive value and palatability that results from their higher nutrient contents and lower LMA. Additionally, terpenes have other functions that can confer competitive advantage to aliens. For example, they have infochemical and communication roles (Peñuelas et al. 1995; Wheeler et al. 2002; Peñuelas and Llusià 2003, 2004), and confer photoprotection (Peñuelas and Munné-Bosch 2005) and thermotolerance (Sharkey and Singsaas 1995; Peñuelas and Llusià 2001 and 2002; Peñuelas et al. 2005). They also may confer protection against drought stress (Kainulainen et al. 1991; Llusià and Peñuelas 1998), and may act as general antioxidants, protecting vital membranes against peroxidation and reactive oxygen species such as singlet oxygen (Loreto and Velikova 2001; Peñuelas and Llusià 2002; Loreto et al. 2004; Munné-Bosch et al. 2004; Llusià et al. 2005).

In summary, total terpene contents were greater in alien than in native species. The frequency of leaf terpene-containing species, however, was not significantly greater in alien than in native species. The results also suggest that

the percentage of species that contain terpenes in leaves in Oahu is probably comparable with other floras. Alien species presented higher terpene contents, and also greater N and K leaf concentrations, and A_{mass}, but lower LMA than native species. These differences between alien and native species did not support the "exces carbon" and the "traditional EICA" hypothesis but were in accordance with the "nutrient driven synthesis" and with the "modified EICA related" hypotheses. The results suggest a possible different time-stage of adaptation to a novel Oahu habitat between native (old-alien-invaders) and recent alien plants. The different patterns in production and content of terpenes in native and alien species merit further investigation, given that plant invasive success is an emerging global phenomenon.

Acknowledgements ÜN was holding G. P. Wilder Chair at the Department of Botany, University of Hawai'i at Manoa, Hawai'i during the time of the study. We also thank the students, faculty, and staff of that Department for making available laboratory space and equipment for this research. Abstract Biological pesticides based on nucleopolyhedroviruses (NPVs) can provide an effective and environmentally benign alternative to synthetic chemicals. On some crops, however, the efficacy and persistence of NPVs is known to be reduced by plant specific factors. The present study investigated the efficacy of *Helicoverpa armigera* NPV (*Hear*NPV) for control of *H. armigera* larvae, and showed that chickpea reduced the infectivity of virus occlusion bodies (OBs) exposed to the leaf surface of chickpea for at least 1 h. The degree of inactivation was greater on chickpea than that previously reported on cotton, and the mode of action is different from that of cotton. The effect was observed for larvae that consumed OBs on chickpea leaves, but it also occurred when OBs were removed after exposure to plants and inoculated onto artificial diet, indicating that inhibition was leaf surface-related and permanent. Despite their profuse exudation from trichomes on chickpea leaves and their low pH, organic acids—primarily oxalic and malic acid—caused no inhibition. When *Hear*NPV was incubated with biochanin A and sissotrin, however, two minor constituents of chickpea leaf extracts, OB activity was reduced significantly. These two isoflavonoids increased in concentration by up to 3 times within 1 h of spraying the virus suspension onto the plants and also when spraying only the carrier, indicating induction was in response to spraying and not a specific response to the *Hear*NPV. Although inactivation by the isoflavonoids did not account completely for the level of effect recorded on whole plants, this work constitutes evidence for a novel mechanism of NPV inactivation in legumes. Expanding the use of biological pesticides on legume crops will be dependent upon the development of suitable formulations for OBs to overcome plant secondary chemical effects.

Introduction

Helicoverpa armigera (Hubn.) is a major crop pest in Asia, Africa, and Australasia attacking a wide range of important crops including cotton, maize, tomato, peppers, chilies, and legumes such as chickpea and pigeonpea (King 1994; Gowda 2005). Its status as arguably the world's most important agricultural pest can be attributed to its wide geographical and host range coupled with its ability to develop high levels of resistance to chemical insecticides (Armes et al. 1992b; Kranthi et al. 2002). The baculovirus biopesticide *Helicoverpa armigera* nucleopolyhedrovirus (*Hear*NPV) is an ecologically benign alternative to chemical insecticides that is effective and can overcome problems of chemical insecticide resistance (Moscardi 1999; Grzywacz et al. 2005). *Hear*NPV is now commercially produced in Australia, Thailand, India, and China for control of *H. armigera* (Singhal 2004; Buerger et al. 2007, Sun and Peng 2007). However, the utility of baculoviruses for insect pest management is compromised by the fact that

some host plants adversely influence the severity of viral disease in insects and so reduce pest control efficacy (Felton and Duffey 1990; Duffey et al. 1995; Hoover et al. 1998a; Cory and Hoover 2006). It has for some time been recognized that *Heliothis zea* NPV, a closely related baculovirus, performed poorly on some crops such as cotton (Young and Yearian 1974; Forschler et al. 1992), a phenomenon linked to the direct action of glandular secretions in reducing the persistence of occlusion bodies (OBs) the infective stage of the virus (Young and Yearian 1977; Ellerman and Entwistle 1985). OBs are a protective crystalline protein matrix in which virions are embedded during transmission and in hostile environments (Hunter-Fujita et al. 1998). The maintenance of OB integrity is crucial to viral persistence outside the host and for initiating infections in new host insects. Host plant effects on biological pesticides are not restricted to baculoviruses, as plants such as cotton have been shown to reduce the efficacy of other biopesticides, especially *Bacillus thuringiensis* (Kushner and Harvey 1962; Johnson 1982; Ali et al. 2004). Inhibition of NPV infections on cotton also has been attributed to high peroxidase activity and subsequent free radical generation, which was associated with an increase in the sloughing off of midgut cells that are the point of entry for the NPV virions, thereby reducing virus-induced mortality (Hoover et al. 1998a, b, 2000). While the use of *Hear*NPV has been shown to be effective on chickpea (Jayaraj et al. 1987; Rabindra et al. 1992; Cherry et al. 2000), field trials have indicated OB persistence and activity to be much lower on chickpea leaf surfaces than on other crops such as tomato (Rabindra et al. 1994), suggestive of some degree of adverse interaction on chickpea. Chickpea produces copious glandular secretions rich in organic acids, and the leaf surface can subsequently have a low pH (<3) (Rembold and Weigner 1990; Stevenson and Aslam 2006). This could make it a challenging host plant for biopesticide use, as earlier work on *Lymantria dispar* NPV has shown that larvae can be less susceptible to OBs when inoculated on highly acidic (pH 3.8–4.6) oak foliage rather than other less acidic aspen foliage (Keating and Yendol 1987) an effect associated with low pH and high levels of organic acids (Keating et al. 1989).

The present study was undertaken to investigate the efficacy of *Hear*NPV on chickpea in comparison with tomato, a known favorable host (Forschler et al. 1992; Farrar and Ridgway 2000), and cotton, a host plant known to impair OB infectivity. We hoped to better understand what plant factors affect virus efficacy with a view to developing better recommendations for the efficacy of NPV-based insecticides on legume crops and to assist in the development of a suitable formulation for OBs for use on crops such as chickpea.

Methods and Materials

Virus The virus strain (NRI#0210) was provided by Professor R.J. Rabindra of Tamil Nadu Agricultural University, India, and stored at −80°C. This strain is typical in activity of strains of *Hear*NPV used in biopesticide products in India, having a mean LC_{50} of 2.78×10^3 OB ml^{-1} for neonate larvae. This is similar to that reported by others including Somasekar et al. (1993) and that had been used previously in field trials on chickpea in India (Cherry et al. 2000). It was multiplied up in third instars of *H. armigera*, then harvested and purified by using a standard NPV purification protocol (Hunter-Fujita et al. 1998). The virus was enumerated by using a standard Neubauer haemocytometer and phase contrast microscope at X400 magnification (Wigley 1980). The identity of the source and progeny of the virus was checked by using a standard DNA restriction analysis protocol for NPVs with EcoR1 (Hunter-Fujita et al. 1998).

Insects Insects for the bioassays were derived from a culture of *H. armigera* provided by the NERC Centre for Ecology and Hydrology at Oxford that had been maintained there for a number of years. The insects were reared at 26±2°C with a relative humidity of 50±5% and a 14:10 hL:D regime. Larvae were reared in groups in 250 ml plastic pots on an artificial wheatgerm casein diet until the second instar, and then individually in 30 ml plastic pots on wheatgerm diet using a method previously described (Armes et al. 1992a).

Plants Plants used were cotton (*Gossypium hirsutum*,) variety Ankur 651 (Ankur Seeds Ltd. Nagpur, India), chickpea (*Cicer arietinum*) variety ICC 11322 provided by ICRISAT, Hyderabad, India, and tomato (*Lycopersicon esculentum*) 'Moneymaker' variety. All were grown in plastic pots on John Innes no. 2 potting compost at 28±2°C in a glasshouse with a 14:10 hL:D cycle and a relative humidity of 60%. Plants were 5 wk old. The surface area of leaves was measured with a Quantimet 520-image analyzer (Leica Microsystems Cambridge Ltd., UK). Thus, the concentration of different compounds in a sample could be equated to an area of leaf surface to ensure that insects were presented with naturally occurring concentrations during feeding bioassays. These data together with the chemical analysis were used to calculate chemical concentration of leaf extracts in terms of unit area so that surface contamination bioassays could be calibrated to match concentrations found on leaf surfaces.

Viral Bioassays To assess OB activity, both leaf dip and surface contamination neonate larval bioassays were used under standard larval rearing conditions, 26°C with

a 14/10 hL:D cycle. In the leaf dip assays, a standard methodology was used (Evans and Shapiro 1997). The *Hear*NPV stock suspensions were prepared as fivefold dilution series in 50 ml of 0.02% Triton X-100 immediately prior to use in bioassays. Leaves were cut from the plant at the stem and dipped in the *Hear*NPV dilutions. Control leaves were dipped in 0.02% Triton X-100 only. After dipping, the stem of the treated leaves was mounted in molten agar in 250 ml round plastic containers, either one cotton leaf, two tomato leaves, or six compound chickpea leaves were used per container; fifty neonate larvae less than 18 h old were used for each treatment with 25 being placed in each container. Larvae were allowed to feed on the leaves for 24 h, after which they were transferred to 25 ml individual pots and reared individually on clean artificial diet, the mortality was recorded after 5 and 7 d. To ascertain OB activity separately from leaf surfaces OB treatments the mass surface contamination bioassay was employed (McKinley 1985; Jones 2000). Again, fivefold series dilutions of OBs in distilled water were prepared and then dispensed as 75 µl aliquots onto the surface of artificial diet in 30 ml plastic pots, spread evenly by tilting and left to dry. Two larvae were added to each pot, reared for 7 d under standard conditions, and mortality was counted on d 5 and 7. Fifty larvae were used for each treatment replicate. All assays were replicated 5–7 times with each assay including a control and a stock solution positive control. The results were subjected to probit analysis (Finney 1971) in SPSS. Comparisons of LC_{50} were performed on log transformed data, to equalize variances, using ANOVA procedure in SIGMASTAT software. Treatment means were compared by using the LSD test. In some bioassays where means differed by several orders of magnitude, transforming the data did not normalize variances, so the non-parametric Kruskal-Wallis test with Tukey multiple comparison procedure was adopted.

Effect of Exposure of HearNPV to Cotton, Tomato and Chickpea Leaf Surfaces To study plant surface chemistry and its effect on *Hear*NPV, OBs suspended in distilled water were applied to the leaf surfaces on whole plants at a concentration of 3×10^{7} OB ml^{-1} in 0.02% triton by using a hydraulic hand sprayer. They were applied at a rate sufficient to evenly wet the leaves. Plants used in experiments were, after application of OB, maintained in the laboratory at 26°C under the 14/10 hL:D cycle, and the virus was then left on the leaves for 1 or 24 h after which OBs were recovered by using a standard washing technique in water containing 0.1% sodium dodecycl sulphate for 1 h (Jones 1988). The samples and the OBs were concentrated by centrifugation at 2500 g at 5°C for 30 min (Hunter-Fujita et al. 1998). The supernatant was discarded, and the OBs were re-suspended in distilled water, then stored at −20°C prior to counting and bioassay. This procedure was found to have no significant effect on the LC_{50} of virus, and recovery of OBs from leaf surfaces was ascertained to be >95%; similar to that reported by other workers using this technique (McKinley 1985; Jones 1988).

Analysis of Organic Acids in Methanol Extract of Chickpea Leaf Surface by GC-MS The surfaces of 50 leaves were extracted in 300 ml methanol and analyzed by GC-MS. Purification of the organic acid fraction was carried out according to Stumpf and Burris (1979). The residue was resuspended in pyridine (50 µl) (Sigma-Aldrich) with a glutaric acid internal standard (1 mg ml^{-1}) (Sigma-Aldrich). Ten min before injection, 25 µl of *N, O*-bis (tri-methylsilyl)-acetamide (Supelco) were added; the vial was shaken and left to stand at room temperature for 5 min before injection. GC-MS was carried out on a Hewlett Packard HP6890 GC linked to an ion detector (HP 5973 Mass Selective Detector) operated in Electron Ionization (EI) mode. A fused silica capillary column (30 m×0.25 mm i.d., coating 0.25um) coated with non-polar HP-5MS (5% Phenyl Methyl Siloxane, Agilent 1909 IS-433) was used with a split/splitless injector with helium as carrier gas (0.5 kg cm^{-2}). The oven temperature was held at 60°C for 2 min and then raised to 250°C at 6°C per min. Compounds were identified by comparing EI-MS and GC retention indices with synthetic standards under the same operating conditions. A set of organic acid standards as reported to occur on chickpea leaf surfaces (Rembold and Weigner 1990) was prepared in sterile distilled water, derivatized and analyzed as described above.

Effect of Organic Acids Present on the Chickpea Leaf Surface on the Infectivity of OBs against H. armigera Neonates Organic acids (Sigma Aldrich, USA) were mixed at the concentration present on leaf surface as determined above, in 10 ml of sterile distilled water. A sample of *Hear*NPV (1×10^{10}OB) was added to the organic acid solution and then left in a rotator at 30 rpm for 1 h. OBs were recovered by centrifuging at 2500 g for 30 min, then re-suspended in 5 ml of distilled water, and then were counted. Serially diluted suspensions of OBs in distilled water were bioassayed alongside a control OB suspension not exposed to the organic acids.

HPLC Analysis of Chickpea Leaf Extracts after Spraying with OB Suspension To determine the effect of *Hear*NPV OBs on chickpea leaf chemistry, a suspension of 3×10^{7} OB ml^{-1} in 0.02% Triton was sprayed onto to the leaf surfaces of whole plants with a hydraulic hand sprayer sufficient to evenly wet the leaves. Control plants were sprayed with 0.02% Triton. Leaves were excised within 5 min or after 1, 4, or 24 h after spraying, and the surface

was extracted in methanol for 40 s. Extracts were filtered (Whatman No. 1), and evaporated to dryness under reduced pressure. Dried extracts were redissolved in 1 ml of 100% HPLC grade methanol for analysis. Aliquots (10 ul) were injected onto a reverse-phase column (Spherisorb 5ODS analytical column, 4.6 mm i.d. x 250 mm) and eluted at 1 ml min^{-1} using the gradient 90% A: 10% B at t=0 min to 50% A: 50% B at t=20 min to 20% A: 80% B at t=25 min to 100% B at t=30 min and 90% A: 10% B at t=37 min (A is 2% acetic acid and B is 2% acetic acid in acetonitrile).

Isolation of Leaf Surface Compounds and Their Effect on Activity of HearNPV OBs against H. armigera Larvae Compounds **1** and **2** were isolated by repetitive HPLC as described above, and fractions were collected manually at approximately 22 and 29 min. Combined fractions were evaporated under reduced pressure and weighed. LC-MS was carried out on a Thermo-Finnigan LC/MS/MS system consisting of a 'Surveyor' autosampling LC system interfaced to a LCQ Classic quadrupole ion trap mass spectrometer. Chromatographic separation was performed on a 150 mm×4.6 mm i.d. (5 μm particle size) Phenomenex Luna C18 column using a linear mobile phase gradient of 1 ml min^{-1} flow rate with water (A): MeOH (B): 5% Acetic Acid in MeOH (C). Initial conditions were 80% A, 0% B, and 20% C changing to 0% A, 80% B, and 20% C at t=20 min and maintained at these conditions to t=25 min. Injection volume was 10 μl, and data analysis was performed using Xcalibur 1.2 software. The ion trap MS was fitted with an Atmospheric Pressure Chemical Ionization (APCI) source operated under standard conditions; i.e., vaporizer temperature 450°C, needle current 5 mA, heated capillary temperature 150°C, sheath and auxiliary nitrogen gas pressure 80 and 20 psi, and the source voltages tuned for the optimal transmission of protonated rutin. The ion trap was set to monitor ions from m/z 125–1200 with collision energy of 45%. Authentic samples of genistein, daidzein, pratensein, biochanin A, and formononetin (Aldrich-Sigma) were co-chromatographed with methanol leaf extracts of chickpea leaf surface that had been sprayed with *Hear*NPV (suspended in 0.02% Triton X-100) and indicated that **2** was biochanin A. Compound **1** had a similar UV spectrum to **2** but eluted earlier (22 min) indicating a more polar nature and suggesting a glycoside. An aliquot of **1** that had been isolated from the leaf extracts as described above was analyzed by LC-MS and recorded a molecular ion signal in positive mode $[M+H]^+$ at m/e=447 indicating the molecular weight of 446 and a molecular formula $C_{22}H_{22}O_{10}$. Comparison of the mass spectrum with the library confirmed the structured to be biochanin A 7-*O*-glucoside (sissotrin) with good match in the lower range (m/e=100–300) of the spectrum. For example, the signal observed at $[M+H]^+$ m/e=285 indicated loss of a glucose moiety $[M\text{-}162 + H]^+$ and corresponded to biochanin A with a base peak at m/e=270 correlating to the loss of glucose and a methyl from the methoxy at C-4′ and a further fragment at m/e= 253 correlating to $[M\text{-}162\text{-}OCH_3]^+$ with the loss of the methoxy group. Subsequent co-chromatography using an authentic standard of sissotrin from natural products collection at Royal Botanic Gardens, Kew, confirmed this identification.

1 **2**

Compounds **1** and **2** were used subsequently in bioassays to evaluate their effects on *Hear*NPV.

The surface area of the leaves was measured as described above. A 200 μl aliquot of sissotrin (25 μg ml^{-1}) in methanol containing the equivalent sissotrin from 1250 mm^2 of chickpea leaf surface and equal to the surface area of artificial diet in a 30 ml container was placed onto the diet surface and allowed to evaporate. The control diets were treated with 200 μl methanol. *Hear*NPV concentrations on a five-fold dilution scale were prepared in distilled water. A control dose containing only distilled water also was prepared. An aliquot of each virus concentration was dispensed in a volume of 75 μl onto the surface of the diet and allowed to dry, after which 10 neonate larvae were released into each of the five pots. Larvae were allowed to feed for 24 h and then were transferred to clean artificial

diet pots at a rate of two per pot and reared under standard conditions. Mortality was recorded after 7 d. The experiment was replicated three times.

Effect of Biochanin A on the Efficacy of HearNPV against H. armigera Larvae Biochanin A (Sigma Aldrich, USA) was diluted to 500, 250, 100, and 10 ppm in distilled water, and was also tested against *Hear*NPV. A 200 µl aliquot of biochanin A at 500, 250, 100, or 10 ppm was spread over the surface of artificial diet. Control pots were treated with same amount of biochanin A. Bioassays were carried out as described above for sissotrin with 50 larvae treatment^{-1}, and the experiment again was replicated three times.

Results

Effect of Cotton, Tomato and Chickpea Plants on HearNPV against H. armigera Larvae using a Leaf Dip Bioassay Method The leaf dip bioassay showed that exposure of *Hear*NPV on chickpea leaf could impair *Hear*NPV activity. The LC_{50} values (Fig. 1) for the different plants were different (F=14.6, df=2,20, P=<0.001), and the LC_{50} for *Hear*NPV on chickpea of 3.96×10^4 OB ml-1 was significantly higher than that on tomato (2.65×10^3 OB ml^{-1}) and cotton (9.36×10^3 OB ml^{-1}). The result on tomato was not different from the mean LC_{50} of this virus strain obtained on artificial diet, which was 2.78×10^3 OB ml^{-1}. The bioassays of *Hear*NPV OBs exposed to tomato, cotton, and chickpea leaf surfaces also showed highly significant differences after 1 h (H=10.851, df=3, P=0.017) and 24 h (H=11.033, df=3, P=0.012) (Fig. 2); OBs on chickpea were markedly less infectious than OBs on tomato or cotton, which did not differ significantly from the LC_{50} of unexposed control OBs. Thus, exposure of OBs to the surface of chickpea for 1 and 24 h resulted in inactivation even after OBs were removed from the leaf surface. The LC_{50} values of *Hear*NPV OBs exposed to chickpea for 1 and 24 h did not differ significantly, indicating that the observed inactivation reaches its maximum effect within 1 h and exposure beyond that does not further affect OB infectivity.

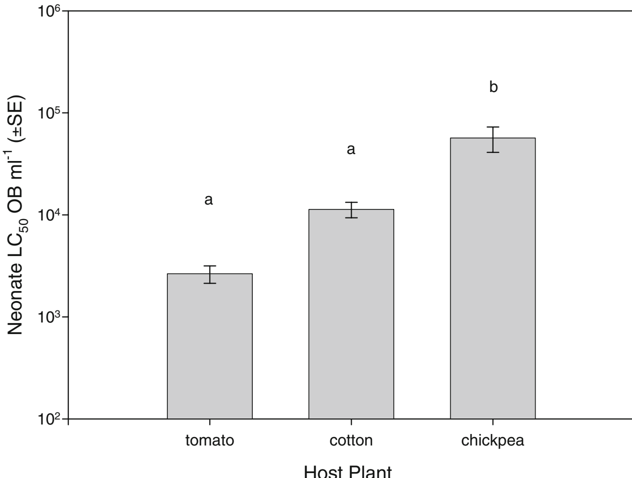

Fig. 1 Comparison of median lethal concentrations ($LC_{50}\pm$SE,) of *Hear*NPV against *Helicoverpa armigera* neonates bioassayed on leaves of cotton, tomato and chickpea with the leaf dip bioassay. Bars with different letters are statistically significant at $P<0.05$ (see detail in text)

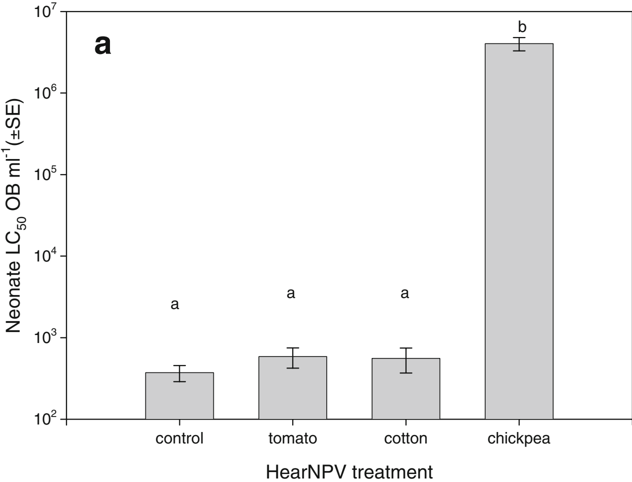

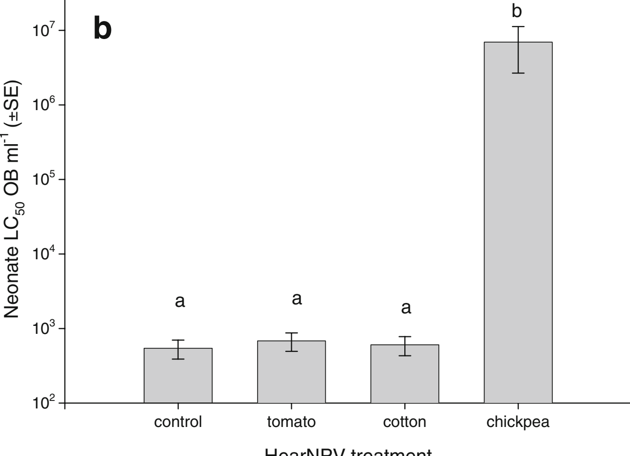

Fig. 2 Comparison of median lethal concentrations ($LC_{50}\pm$SE) of untreated *Hear*NPV and *Hear*NPV OB exposed to cotton, tomato and chickpea leaf surfaces for 1 hr (**a**) and 24 hr (**b**) bioassayed against *Helicoverpa armigera* neonates on artificial diet. Bars with different letters are statistically significant at $P<0.05$ (see detail in text)

Analysis of Organic Acids in Methanol Extract of Chickpea Leaf Surface by GC-MS The leaf surfaces of chickpea extracted with 100% methanol contained oxalic, malonic, malic, citramalic, and citric acid (Fig. 3). The compounds with retention times 13.47–13.48, and 16.01 min were silane impurities, while those at 24.80–24.81 min were sugars. Glucose-6-phosphate, oxalacetate, succinic, and

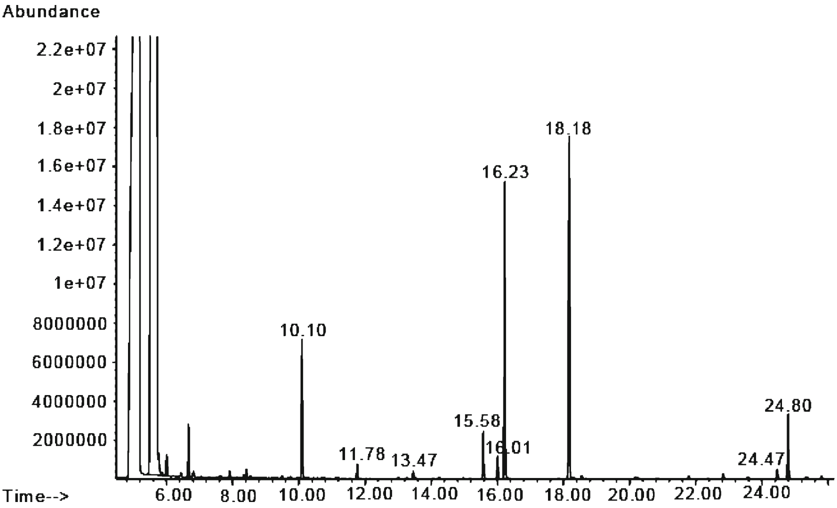

Fig. 3 Total ion gas chromatogram of chickpea leaf surface extract in methanol

Retention time (min)	Compound
10.10	Oxalic acid
11.78	Malonic acid
13.47	Silane impurities
15.58	Citramalic acid
16.01	Silane impurities
16.23	Glutaric acid
18.18	Malic acid
24.47	Citric acid
24.80	Sugars

fumaric acids were not found in any of the solvent extracts despite having been identified earlier by Rembold et al. (1980).

Effect of Organic Acids Present on the Chickpea Leaf Surface on the Efficacy of HearNPV against H. armigera Neonates The mean LC_{50} values of *Hear*NPV exposed to organic acids and for untreated *Hear*NPV by using a surface contamination bioassay system to neonates of *H. armigera* were 8.05×10^2 OB ml^{-1} and 6.16×10^2 OB ml^{-1}, respectively, and were not significantly different (t=0.484, P=0.762).

HPLC Analysis of Chickpea Leaf Surfaces after Spraying with NPV Chickpea plants were sprayed with *Hear*NPV in a 0.02% Triton X-100 suspension (to optimize spreading) and surface extracted in methanol within 5 min and after 1, 4, and 24 h. After 1 h, there was a more than four-fold increase in the concentration of **1** to 22 μg cm^{-2} compared with unsprayed leaf surfaces (5 μg cm^{-2}) in which the presence of **1** is constitutive. After 2, 4, and 24 h, the concentration of **1** was similar to pre spray quantities and remained there up to 24 h. Analysis of control plants that were sprayed with 0.02% Triton also showed only higher levels of **1** after 1 h, indicating that the process of spraying in the absence of virus was itself sufficient to induce the production of this compound and that it was not induced by the presence of the *Hear*NPV.

Effect of Sissotrin on the Efficacy of HearNPV against H. armigera Larvae The mean LC_{50} after exposure of *Hear*NPV to sissotrin for 1 h at a concentration equivalent to that found on the leaf surface after spraying was 1.23×10^4 OB ml^{-1}, and this was significantly higher than untreated *Hear*NPV at 2.30×10^3 OB ml^{-1} (F=44.24, df=1,4, P=0.003). However, this increase in LC_{50} for sissotrin treated *Hear*NPV is small compared to the LC_{50} values when *Hear*NPV OBs were exposed to chickpea plant surface for 1 h, thus suggesting that sissotrin does reduce the efficacy of *Hear*NPV but does not account for all the inhibition observed when *Hear*NPV was applied to the leaf.

The mean LC_{50}s of *Hear*NPV after exposure to different concentrations of biochanin A are shown in Fig. 4. There was a difference (F=4.16, df=4, 10, P=0.031) between the treatments, and it was shown by using least significant difference tests that mean LC_{50} values for *Hear*NPV exposed to biochanin A were not significantly different from each other but were significantly greater than the untreated sample. This indicates that biochanin A was effective even at concentrations as low as 10 ppm. As with

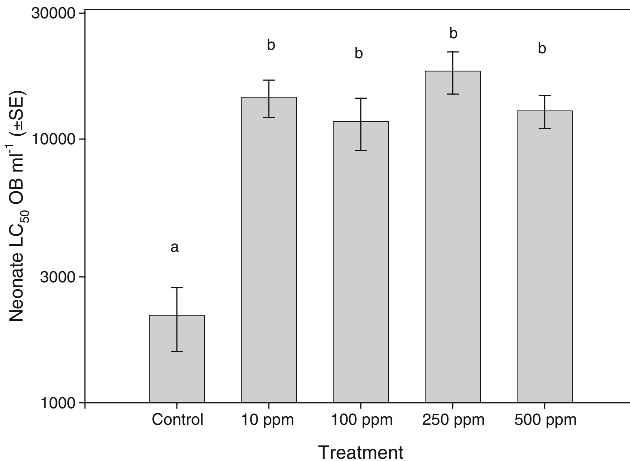

Fig. 4 Median lethal concentration (LC_{50}±SE) for *Hear*NPV exposed for 1 hr to different concentrations of biochanin A as determined by diet surface contamination bioassay on *Helicoverpa armigera* neonates. Bars with different letters are statistically significant at $P<0.05$ (see detail in text)

sissotrin, however, the effect of biochanin A does not explain fully the 5-fold increase in LC_{50} seen in *Hear*NPV after exposure on chickpea plants, suggesting that other factors must be involved.

Discussion

This study showed that the efficacy of *Hear*NPV OBs was inhibited considerably more on chickpea than on cotton, and that the effect was caused, at least in part, by surface isoflavonoids and not by organic acids. This was surprising since chickpea leaf surfaces have pH of <3 due the presence of organic acids (Rembold and Weigner 1990), and there is a well known association between low pH with NPV inactivation (Ignoffo and Garcia 1966). This study also has demonstrated that the inactivation of OBs on leaves is caused by their direct interaction with surface chemicals since OBs that had been exposed to the leaf surface were still inactive once removed. Thus, this differs from the mechanism of peroxidase inactivation reported previously for cotton (Hoover et al. 1998a, b,). The present work does not support an earlier proposition that the reduced efficacy of *Hear*NPV on chickpea could be related to a slower feeding rate of *H. armigera* on chickpea, thereby reducing the rate of OB ingestion (Rabindra et al. 1992). Sissotrin accumulated on the leaf surface at least for a short period of time after plants were sprayed with the OB suspension in 0.02% Triton or even with the 0.02% Triton control. This indicates that the process of spraying was sufficient to induce the production of these compounds, and was not induced by the presence of the *Hear*NPV. Thus, the induction of these compounds is not a response specific to the application of *Hear*NPV, but rather a response to either wetting or the presence of surfactant. The increased secretion of biologically active antimicrobial compounds by chickpea in response to wetting would be biologically explicable, as chickpea is subject to damaging fungal diseases such as Botrytis grey mould during periods of heavy dew or precipitation (Pande et al. 2005).

Plant chemicals previously have been shown to inhibit OB dissolution by binding irreversibly to OB structural proteins (Schultz and Keating 1991), a mechanism that is enhanced at least for orthodihydroxy moieties in the presence of peroxidases and polyphenoloxidases, particularly in damaged plant tissues (Felton and Duffey 1990). The present data do not shed light on the mechanism by which isoflavonoids impair NPV infectivity. Further work to understand this would be useful since the inactivation mechanism reported here may impact on other biological pesticides such as Bt or entomopathogenic fungi, given that chickpea isoflavonoids are toxic to numerous organisms including viruses, bacteria, fungi, and insects (Stevenson et al. 1997; Stevenson and Haware 1999; Simmonds and Stevenson 2001; Ito et al. 2003; Getti et al. 2006; Aslam et al. 2009). The identification of a new group of compounds that affect OBs, however, adds to the existing literature on this topic. The importance of the finding is highlighted by the LC_{50}s of OBs exposed on leaf surfaces being 3–5 orders of magnitude greater than that reported in cotton in both the present and earlier studies (Young and Yearian 1974; Forschler et al. 1992). It is not known if this mechanism is present or is as profound in all chickpea varieties. However, selective breeding for disease resistance (Pande et al. 2005) may have resulted in varieties with more biologically active compounds, and may explain the high OB inactivation reported here.

This study showed that *Hear*NPV OBs were inactivated when consumed on cotton leaf material, but showed no sign of inactivation when bioassayed on diets after exposure on and then removal from cotton; a result that concurs with those of Hoover et al. (1998a, b). However, there was no evidence of the OB inactivation by ionic cotton gland secretions reported previously (Ellerman and Entwistle 1985) on Ankur 651, the cotton variety tested here. This again may be explained by varietal differences in the chemistry of Ankur 651 and the Deltapine varieties studied earlier. Some Indian cottons are reportedly more detrimental to OB infectivity than chickpea (Rabindra et al. 1994).

While sissotrin and biochanin A have a significant inactivating action, the magnitude of inactivation by these compounds did not fully account for the effects observed on leaf surface assays. Therefore, other chemicals are likely to contribute to this inactivation and further work will be required to identify these.

In considering the results reported here, it may be surprising that *Hear*NPV is effective as a biopesticide on chickpea (Jayaraj et al. 1987; Rabindra et al. 1989; Cherry et al. 2000; Ahmed and Chandel 2004). However, on some crops, 90% of *H. armigera* larvae killed by *Hear*NPV sprayed onto plants acquire the infection within 1 h of application (D Murray, pers. comm.). The interaction of *Hear*NPV with chickpea also may be influenced by the variety of chickpea. Cowgill and Bhagwat (1996) for example reported a field trial in which *Hear*NPV was more effective at killing *H. armigera* when applied to the *H. armigera* susceptible genotype (ICCC 37) of chickpea than on a *H. armigera* resistant genotype (ICC 506). This may have been due to differences in their chemistry since the production of isoflavonoids in chickpeas is known to vary among cultivars at least in association with resistance to plant pathogens such as *Botrytis* and *Fusarium* (Stevenson et al. 1997).

Additives, including milk powder, casein, molasses, and Robin blue dye are reported to improve *Hear*NPV performance on chickpea (Rabindra et al. 1989). Although it has been assumed that they improved UV stability (Rabindra and Jayaraj 1988), given the present findings, it is possible that some additives also may contribute to improving OB efficacy by inhibiting chemical inactivation of OBs or by encouraging feeding and rapid viral acquisition before the OB inactivation processes have taken effect.

Acknowledgement We gratefully acknowledge the Higher Education Funding Council for England for funding and the generous advice and assistance of Prof. David Hall, Dr. Geoffrey Kite and Dudley Farman in the chemical analysis.

Flavonoids Have Differential Effects on Glucose Absorption in Rats (*Rattus norvegicus*) and American Robins (*Turdis migratorius*)

Abstract Mounting evidence suggests that small birds rely largely on non-mediated intestinal absorption of glucose through the paracellular pathway, while non-flying mammals rely on mediated absorption across the enterocyte membranes by using glucose transporters SGLT-1 and GLUT-2. Relying on non-mediated transport of glucose may decrease its absorption rate at low glucose concentrations but may release small birds from the effects of glucose transport inhibitors. We evaluated transport by using flavonoids known to inhibit glucose transport in vitro. Quercetin, isoquercetrin, and phloridzin were tested in rats (*Rattus norvegicus*) and robins (*Turdis migratirius*), and naringenin, naringenin-7-glucoside, genistein, epigallocatechin gallate (EGCG), and phloretin were used only in rats. By using a pharmacokinetic approach that involves serial blood collection and area under the curve calculations, we determined the bioavailability of 3-0-methyl D-glucose, the non-metabolized analogue of D-glucose. Six of the eight flavonoids tested in rats significantly decreased the absorption of 3-0-methyl D-glucose, while none of the flavonoids tested in robins significantly decreased the bioavailability of 3-0-methyl D-glucose. We conclude that flavonoids effectively decrease glucose absorption in rats, which rely on mediated absorption of glucose, but that flavonoids do not have an effect in robins, which rely on non-mediated absorption of glucose.

Introduction

Glucose is absorbed in the small intestine via the transcellular and paracellular pathways. Transcellular absorption is mediated by membrane-bound transporter proteins such as the sodium dependent glucose transporter (SGLT-1), found on the apical membrane of enterocytes, that actively absorbs glucose from the gut lumen. GLUT-2, a glucose transporter found on the basolateral membrane of enterocytes facilitates the diffusion of glucose out of the enterocytes and into the blood. Paracellular absorption involves movement of glucose through the tight junctions (TJs) of adjoining cells by diffusion or by solvent drag (Pappenheimer and Reiss 1987). This non-mediated route is quantitatively important in some species. For example, paracellular absorption accounts for the majority of glucose absorption in at least two avian species (Chang and Karavsov 2004; McWhorter et al. 2009). Paracellular absorption accounts for significantly more glucose absorption in small birds (<400 g) than in similar-sized non-flying mammals (Lavin and Karasov 2008). Enhanced paracellular absorption may compensate for the relatively small intestinal size in birds compared to nonflying mammals (Caviedes-Vidal et al. 2007).

The reliance on mediated absorption of glucose either by SGLT-1 or GLUT-2 ensures efficient and complete absorption from the intestine, but it requires energy either to drive

active transport or to produce and insert the transporter into the enterocyte membrane. Furthermore, reliance on mediated absorption of glucose makes mammals susceptible to transport inhibitors. Non-mediated transport, such as the paracellular pathway, may be less costly energetically than mediated absorption, but it may also be less efficient when glucose levels in the intestine are low. However, the use of non-mediated absorption of glucose may free small birds from susceptibility to transport inhibitors.

Flavonoids are widely distributed in higher land plants, and have numerous biological effects, including inhibition of glucose transporters. Phloretin and phloridzin are chalcones that inhibit GLUT-2 and SGLT-1, respectively. Numerous in vitro studies have demonstrated that tea catechins isoflavones, flavonols, and flavanones inhibit glucose transport (Song et al. 2002; Johnston et al. 2005; Kwon et al. 2007; Araujo et al. 2008). These in vitro experiments demonstrate only what might occur in the whole animal. For example, inhibition may not occur in vivo if flavonoids are greatly diluted by intestinal secretions or if lengthy intestinal residence time compensates for reduced membrane absorption rate. In vivo studies are needed to show whether flavonoids that inhibit glucose transport in vitro will also inhibit transport in vivo.

We tested whether flavonoids inhibit glucose absorption in vivo in laboratory rats (*Rattus norvegicus*) and robins (*Turdis migratorius*). We hypothesized that mammals would be more susceptible to the potential inhibitory effect of flavonoids than birds. We tested eight flavonoids from five different subclasses as inhibitors of glucose absorption in vivo in rats and three flavonoids from two different subclasses in robins. We employed a pharmacokinetic approach by using a non-metabolized, radiolabeled analogue of D-glucose, 3-0-methyl D-glucose (3OMD-glucose), to determine if flavonoids decrease glucose absorption from the intestine. 3OMD-glucose is used commonly along with other glucagogues to study glucose absorption in vivo (Uhing and Kimura 1995; Debru et al. 2001). By comparing the plasma concentration of 3OMD-glucose after oral dosing to the plasma concentration after injection, we calculated the bioavailability and elimination rate of orally administered 3OMD-glucose with or without flavonoids present. By using standard pharmacokinetic analysis, we determined the inhibitory potential of some common flavonoids in vivo in rats and robins.

Methods and Materials

Animals and Housing Male Sprague Dawley rats (Harlan) weighing 300–350 g were housed individually in shoebox cages. The room in which the rats were housed was maintained at an average ambient temperature of 22°C and an average relative humidity of 30%. Rats were fed rodent blocks (Teklad) ad libitum. There is evidence of diurnal rythmicity of SGLT-1 function (Tavakkolizadeh et al. 2001) so rats were placed on a reverse light cycle of 12D:12L to allow experiments to occur during their active period.

Adult American robins (*Turbidus migratorius*) with an average body mass of 69.2±1.4 g were captured with mist nets at the University of Wisconsin - Madison campus during 2003 and 2004. Robins were housed individually in wire cages (0.75 m×0.5 m×0.5 m) at an average ambient temperature of 22°C and an average relative humidity of 30%. The robins were fed a banana mash diet (Denslow et al. 1987) and water ad libitum. All procedures described followed established guidelines for the care and handling of laboratory animals and were approved by the Research Animal Resource Center Animal Care Committee at the University of Wisconsin - Madison.

Experimental Design Rats were assigned randomly to 4 groups of 4 rats per group. Each group received 4 randomly assigned treatments, consisting of an injection treatment and 3 oral treatments, at least 1 wk apart. The oral treatments included a control treatment plus two flavonoid treatments. Eight flavonoids: quercetin, naringenin, genistein, epigallocatechin gallate (EGCG), phloridzin, phloretin, naringenin-7-glucoside, and isoquercetrin were tested (Fig. 1). Naringenin-7-glucoside and isoquercetrin were from Indofine, while all other flavonoids tested were from Sigma-Aldrich.

A total of 8 robins were assigned randomly to 5 treatments, consisting of an injection treatment and 4 oral treatments at least 1 wk apart. The oral treatments included a control plus three flavonoid treatments. The three flavonoids tested were phloridzin, quercetin, and isoquercetrin. Unlike the omnivorous rat, insectivorous/frugivorous robins are unlikely to have any ecologically relevant exposure to the flavonoids naringenin, naringenin-7-glucoside, genistein, EGCG, and phloretin that are found in citrus, soy, green tea, and apples Therefore, we tested only the flavonoids that were ecologically most relevant in the robin, quercetin and isoquercetrin, and phloridzin as a positive control because it is a potent inhibitor of SGLT-1.

Solution Composition The glucose analog 3-0-methyl [^{14}C (U)] D-glucose with a specific activity of 250 mCi/mmol was obtained from American Radiolabeled Chemicals. The injection treatment solution consisted of 5 μCi of ^{14}C 3OMD-glucose in 200 μl (rats) or 100 μl (robins) of isotonic saline. The oral control treatment solutions contained 5 μCi of ^{14}C 3OMD-glucose in 2 ml (rats) or 750 μl (robins) of 10 mM aqueous glucose containing 2% (*v*/*v*) dimethyl sulfoxide (DMSO, Sigma-Aldrich). For the

Fig. 1 Structures of flavonoids tested for inhibition of glucose absorption

flavonoid treatment solutions, the flavonoid was dissolved in DMSO and then diluted into the control oral treatment solution to yield 10 mM flavonoid and 2% (*v*/*v*) DMSO.

Experimental Procedure Food was withheld from the rats and robins for 15 h prior to experiments to allow their stomachs and small intestines to empty. The rats and robins were either gavaged with a blunt end feeding needle for the oral treatments or they were given an intramuscular (IM) injection in the caudal thigh muscle (rats) or the pectoralis muscle (robins) for the injection treatment. Dosing syringes were weighed immediately before and after dosing on an analytical balance to determine the exact mass of the treatment solution for each individual. Blood samples were taken from rats at 0, 10, 20, 30, 45, 60, 90, 150, and 240 min post administration (injection or oral). Blood (70–100 μl) was collected from rats with a 26 gauge, 0.5 in needle (Fisher Scientific) inserted into the tail vein of the rat, and a heparinized capillary tube was used to collect blood from the luer lock of the needle. Blood samples were taken from robins at 0, 5, 10, 15, 20, 45, 90, and 150 min post administration. Blood (~40 μl) was collected from the robins with a 26 gauge, 0.5 in needle inserted into the brachial vein of the robins, and heparinized capillary tubes were used to collect the blood from the luer lock of the needle. The capillary tubes were centrifuged at 4,000 rpm to separate the plasma. Plasma was transferred into pre-weighed 7 ml scintillation vials (Fisher Scientific), and the vials were reweighed to determine the plasma mass. Samples were counted on a Wallac WinSpectral 1414 liquid scintillation counter after adding 5 ml of scintillation fluid to each sample (Ecolume, ICN).

Pharmacokinetic Analysis The radioactivity in each plasma sample at time *t* was normalized to the mass of the sample (C_t, dpm/g plasma) and plotted against sampling time. The area under this curve (AUC_t) represents the amount of radiolabeled probe that has been absorbed from time zero up to time *t*, whereas AUC_{total} denotes the total amount of probe absorbed from time zero to infinity (∞).

Following typical procedures in pharmacokinetics (Gibaldi and Perrier 1982), the area from $t = 0$ to $t = x$ min (when the final blood sample was taken) was calculated by using the trapezoidal rule. The area from $t = x$ min to $t = \infty$ was calculated as:

$$AUC^{x\rightarrow\infty} = C_t(\text{at}\, t = x)/K_{el} \quad (1)$$

where K_{el} is the elimination rate constant, which can be determined for each animal in each experiment as the slope of the terminal portion of its plot of log (plasma ^{14}C concentration) vs.time (Riviere, 1999). K_{el} was determined typically from the last three log transformed values (Lavin et al. 2008; McWhorter et al. 2009). The total $AUC^{0\rightarrow\infty}$ was obtained by summing the two areas. Bioavailability (B) for each probe was estimated as the ratio of the area for oral gavage experiments to the area for injection experiments ($AUC_{injection}$) normalized to the dose given to the animal:

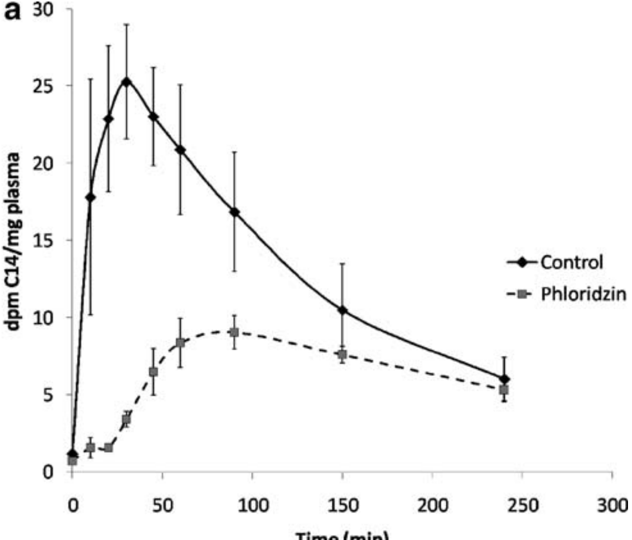
$$\text{Bioavailability}(B) = (AUC_{oral}/\text{dose}_{oral})/(AUC_{injection}/\text{dose}_{injection}) \quad (2)$$

This method of calculating B is favored because it makes no major assumptions about compartments or kinetics of absorption or elimination (Welling 1986). The dose of ^{14}C 3OMD-glucose was determined by liquid scintillation counting of 5 µl aliquots of the treatment solutions that were weighed and corrected to the mass of material actually administered.

Statistical Analysis Bioavailability data were normalized by arcsine square root transformations. Bioavailability and elimination rate were analyzed within species by repeated measure analysis of variance (ANOVA) with treatment as a factor using SYSTAT (Wilkinson and Coward 2000). *Post-hoc* pairwise comparisons using pooled variances were used to determine which flavonoid treatments significantly affected bioavailability or elimination rate compared to control within species. For between species comparisons, Bonferroni corrected two-tailed t-tests were used to determine if bioavailability and elimination rates differed. Data are represented as mean ± standard deviation (SD) unless otherwise stated. A P-value of 0.05 or less was used to establish significance.

Results

Bioavailability Rats and robins showed qualitatively similar uptake kinetics of ^{14}C 3OMD-glucose in the absence of flavonoids (Fig. 2). The bioavailability of ^{14}C 3OMD-glucose in rats was decreased ($P<0.05$) by six of the eight flavonoids tested (Table 1). The phloridzin treatment decreased absorption 38%, whereas bioavailability in the



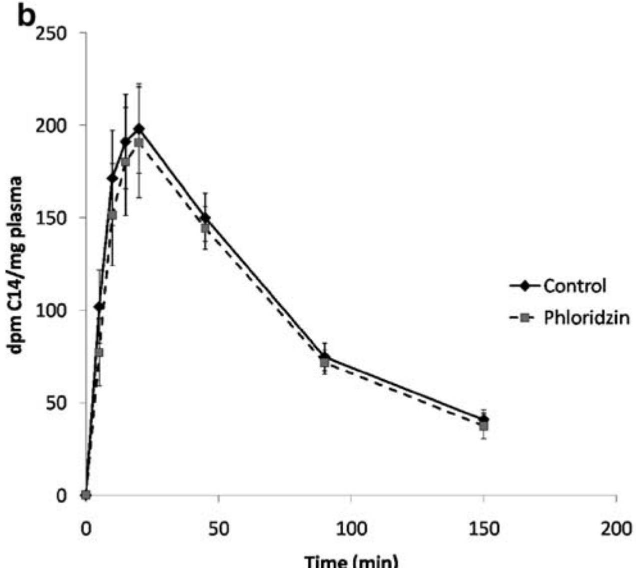


Fig. 2 **a** Absorption of orally administered ^{14}C 3OMD-glucose in laboratory rats. The presence of phloridzin in the oral treatment solution extended the absorption phase of ^{14}C 3OMD-glucose. Data represented are the means ± SE of the plasma ^{14}C at each time point (N=4). When rats were orally dosed with the control treatment (5 µCi ^{14}C 3OMD-glucose, 10 mM D-glucose) the plot is characterized by an early rapid increase in plasma ^{14}C that peaks around 45 minutes. When rats were orally dosed with the phloridzin treatment (10 mM phloridzin, 5 µCi ^{14}C 3oMD-glucose, and 10 mM D-glucose) the plot is instead characterized by an early slower increase in the plasma ^{14}C that does not peak until after 60 minutes. **b** Absorption of orally administered ^{14}C 3OMD-glucose in robins. The presence of phloridzin (10 mM) in the oral treatment solution (5 µCi ^{14}C 3OMD-glucose, 10 mM D-glucose) did not affect the absorption of ^{14}C 3OMD-glucose in robins. Data represented are the means ± SE of the plasma ^{14}C at each time point (N=8)

presence of quercetin was not significantly different from its respective control. The bioavailability of ^{14}C 3OMD-glucose in robins was not significantly affected by quercetin, isoquercetin, or phloridzin ($F_{3,21}$=0.447, P=

Table 1 The bioavailability of ^{14}C 3-O-methyl d-glucose was decreased in the presence of flavonoids in rats

Treatment	Bioavailability (%) mean ± SD	Repeated measure ANOVA using arcsine sqrt transformed FA data		Pairwise comparisons post-hoc using pooled variance	
		F	*P*-value	*F*	*P*-value
Group 1 (*n*=4)		10.263	0.012		
Control	97.0±3.9				
Quercetin	93.9±4.4			1.715	0.282

[a] Significantly decreased the bioavailability of 3OMD-glucose $P<0.05$

0.722), in contrast to in rats in which both isoquercetin and phloridzin reduced absorption (Figs. 2 and 3).

The bioavailability of ^{14}C 3OMD-glucose was higher in rats than in robins in the control treatments ($P=0.004$; Fig. 3). The overall mean bioavailability for the control treatments in rats ($N=16$) was 95.3±8.4% while in robins ($N=8$) it was 75.1±9.3%.

Elimination Rate We also tested for treatment effects on elimination rate because SGLT-1 is responsible for reabsorption of glucose in kidney tubules. If the flavonoids reach the kidney, they might decrease the rate of glucose reabsorbtion and, thus, increase the rate of elimination. None of the flavonoids tested significantly altered the elimination rate of ^{14}C 3OMD-glucose in robins (Table 2,

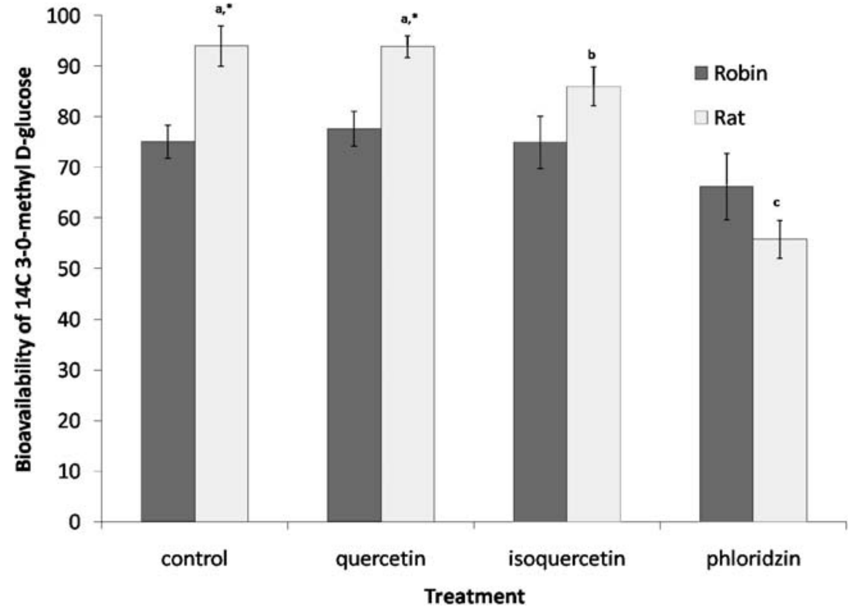

Fig. 3 Bioavailability of orally administered ^{14}C 3OMD-glucose in rats and robins. [a] Rate constants are expressed as dpm of ^{14}C per mg plasma per min, and are presented as mean ± SD

[b] Significantly different from rat ($P<0.05$)

[c] Significantly different from all other rat treatments $P<0.05$)

$F_{4,28}=1.612$, $P=0.199$), and only phloridzin appeared to have a significant effect in rats (Table 2). Apparently, phloridzin slowed the absorption rate of ^{14}C 3OM D-glucose to such an extent that absorption was still occurring at the last three blood sampling time points (Fig. 2a; notice the 3rd to last plasma sample was in the peak). Therefore, the apparent elimination rate constant estimated for the phloridzin treatment that used the last three time points was likely influenced by absorption, and probably underestimated the true elimination rate constant.

Robins had higher apparent elimination rates of ^{14}C 3OMD-glucose than rats in all treatments (Table 2, Fig. 4). The overall mean apparent elimination rate constant for the injection treatments in rats ($N=16$) was 0.007±0.0001 dpm-mg^{-1}-min^{-1} while in robins ($N=8$) it was 0.012±0.002 dpm-mg^{-1}-min^{-1}.

Discussion

We found that flavonoids inhibited in vivo glucose absorption in rats but not in robins. We discuss the importance of testing the inhibitory activity of flavonoids in vivo, and possible ecological/evolutionary ramifications of differential effects of flavonoids on glucose absorption in rats vs. robins.

While numerous in vitro studies have determined that many flavonoids inhibit glucose transporters, only a handful

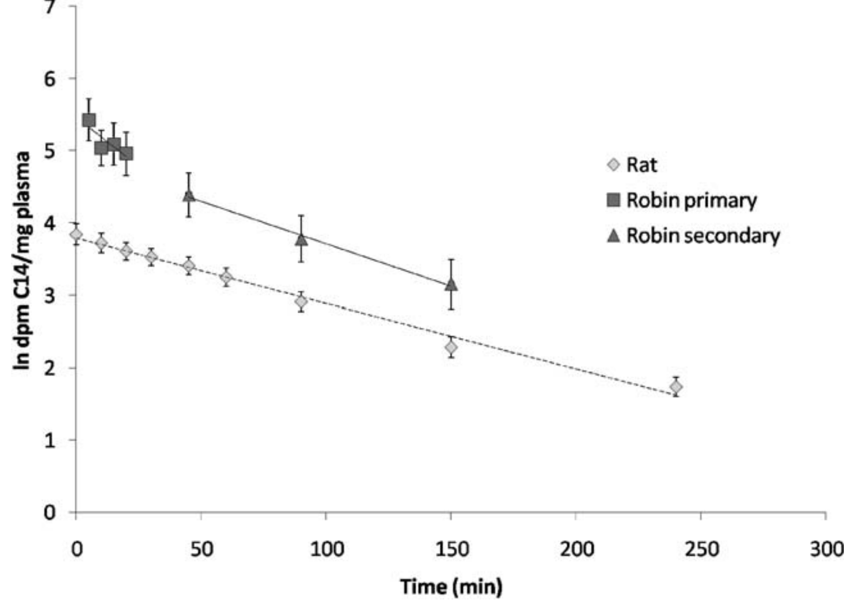

Fig. 4 Elimination rates of ^{14}C in rats and robins when injected intramuscularly with 5 µCi ^{14}C 3OMD-glucose. Data represented are the means ± SE of the plasma ^{14}C at each time point. In the robins the elimination of ^{14}C 3OMD-glucose is bi-exponential so only the last three time points 45, 90 and 150 minutes, which are labeled as robin secondary, were used from both the injection as well as oral treatments to calculate the elimination rate. Robins had a significantly faster elimination rate than the rats ($P<0.05$)

have investigated their in vivo effects. For example, in vivo studies have been performed to investigate the effect on blood glucose levels of apple juice (Johnston et al. 2002), quercetin (Song et al. 2002), and various herbal extracts that historically are used as treatments for diabetes (Shi et al. 1998; Ahmad et al. 2000; Yoshikawa and Matsuda 2000; Aybar et al. 2001; Ndong et al. 2007). In some of these studies, blood glucose concentrations were determined after dosing with extracts or flavonoids, while in others glucose tolerance tests were used to determine if the extracts dampened the spike in blood glucose following oral glucose loading. Neither method distinguishes between pre- and post-absorptive effects of the test chemicals.

By employing standard pharmacokinetic techniques, we demonstrated that six of eight flavonoids significantly decreased bioavailability of ^{14}C 3OMD-glucose in rats (Table 1). Differences in bioavailability may be due to changes in absorption or changes in rate of elimination (Riviere 1999). One flavonoid, phloridzin, decreased the apparent elimination rate (Table 2), but we believe this was an artifact. Apparently phloridzin decreased the absorption rate to such an extent that absorption was still occurring during the time points used to determine the elimination rate, thus leading to underestimation of the elimination rate constant (Fig. 2a). Crespy et al. (2001) estimated the bioavailability of phloridzin in rats to be approximately 10%, with no intact phloridzin found in the plasma, only unconjugated and conjugated phloretin. It is, therefore, not likely that phloridzin affected the elimination rate through systemic effects. Given the artifacts in our measurement, inhibition of glucose absorption by phloridzin may actually be larger than the 35% estimated in this study, and in fact phloridzin inhibited glucose uptake by around 66% when samples were taken over a longer time interval (Skopec 2003).

Robins and other small birds rely on non-mediated absorption of glucose (Chang and Karavsov 2004; McWhorter et al. 2009). Small birds have significantly less surface area in their small intestines than similarly sized non-flying mammals (Lavin et al. 2008). Less surface area may physically constrain the number of glucose transporters. Therefore, birds may need to rely on the paracellular pathway in order to absorb glucose. While non-mediated absorption may be a spatially and energtically efficient way to absorb glucose, it is not as efficient as mediated absorption for low levels of glucose. In our study, with low glucose concentrations in the treatment solutions, the 3OMD-glucose bioavailability was 20% lower in robins than in rats (Fig. 3). In house sparrows (*Passer domesticus*), which are similar in size to robins and, which also primarily utilize non-mediated absorption of glucose, bioavailability of 3OMD-glucose is 26% lower under low glucose concentrations (no D-glucose in the gavage solution) than with saturating levels of glucose (200 mM D-glucose in the gavage solution) (Chang and Karavsov 2004).

Another difference between the rats and robins was that robins eliminated 3OMD-glucose more rapidly than the rats (Table 2, Fig. 4). The robins were significantly smaller than the rats (70 g compared to 300–350 g), and elimination rates are typically slower in larger animals (Riviere 1999).

There may be several ecological/evolutionary ramifications of differential effects of flavonoids on glucose absorption in small birds vs. non-flying mammals. For mammals or large birds with well developed hindguts, inhibition of glucose absorption from the small intestine by dietary flavonoids may have little to no effect. In the presence of the inhibitor, glucose would be efficiently fermented in the hindgut, and much of the energy from the fermentation would be passed onto the animal. However, inhibition of glucose absorption by flavonoids might have negative consequences for frugivores. Frugivorous birds such as Yellow-rumped warblers, Cedar waxwings, and American robins have limited hindgut fermentative capacity and subsist for at least part of the year almost exclusively on fruit (Afik et al. 1997; Martinez Del Rio et al. 1992). In these birds, glucose that is not absorbed in the small intestine due to inhibition by flavonoids present in fruit would be lost in feces, significantly decreasing energy acquisition.

Non-mediated absorption of glucose from the intestine in small birds may have two benefits: It may allow decreased surface area and volume of the small intestine that may lead to lighter guts necessary for flight (Lavin et al. 2008). In addition, non-mediated glucose absorbtion may make small frugivorous birds tolerant to the inhibitory effects of the flavonoids present in their food.

RAPID COMMUNICATION

Knockdown of a Mosquito Odorant-binding Protein Involved in the Sensitive Detection of Oviposition Attractants

Julien Pelletier · Aline Guidolin · Zainulabeuddin Syed · Anthony J. Cornel · Walter S. Leal

Received: 18 January 2010 / Revised: 5 February 2010 / Accepted: 5 February 2010 / Published online: 27 February 2010
© The Author(s) 2010. This article is published with open access at Springerlink.com

Abstract Odorant-binding proteins (OBPs) were discovered almost three decades ago, but there is still considerable debate regarding their role(s) in insect olfaction, particularly due to our inability to knockdown OBPs and demonstrate their direct phenotypic effects. By using RNA interference (RNAi), we reduced transcription of a major OBP gene, *CquiOBP1*, in the antennae of the Southern house mosquito, *Culex quinquefasciatus*. Previously, we had demonstrated that the mosquito oviposition pheromone (MOP) binds to CquiOBP1, which is expressed in MOP-sensitive sensilla. Antennae of RNAi-treated mosquitoes showed significantly lower electrophysiological responses to known mosquito oviposition attractants than the antennae of water-injected, control mosquitoes. While electroantennogram (EAG) responses to MOP, skatole, and indole were reduced in the knockdowns, there was no significant difference in the EAG responses from RNAi-treated and water-injected mosquito antennae to nonanal at all doses tested. These data suggest that CquiOBP1 is involved in the reception of some oviposition attractants, and that high levels of OBPs expression are essential for the sensitivity of the insect's olfactory system.

Introduction

Odorant binding proteins (OBPs) were identified almost three decades ago (Vogt and Riddiford 1981), but their roles in insect olfaction are still a matter of considerable debate. That OBPs are involved in odorant reception was disputed after odorant receptors (ORs) were demonstrated to respond to semiochemicals when expressed in heterologous systems These expression systems, however, have limitations in addressing the role(s) of OBPs in olfaction. The heterologous expression system that uses *Drosophila* empty neurons (Dobritsa et al. 2003) includes surrogate OBPs, i.e., OBPs expressed in the ab3 sensilla, whereas in non-insect cell systems[1] (Forstner et al. 2009) odorants are solubilized with organic solvent or with the addition of recombinant OBPs. Thus, ultimately the role(s) of OBPs in insect olfaction must be addressed by examining insects with reduced levels (knockdowns) or devoid of a test OBP (knockouts). In *Drosophila*, analysis of a mutant defective for expression of an OBP revealed that DmelOBP76a (aka LUSH) is required for the activation of pheromone sensitive neurons by (*E*)-11-vaccenyl acetate and associated behavior (Xu et al. 2005), but other insect species are not amenable to this type of genetic manipulation. Previously, we employed the empty neuron system of *Drosophila* to express the pheromone receptor from the silkworm moth, *Bombyx mori*, BmorOR1 alone or co-expressed with a pheromone-binding protein, BmorPBP1 (Syed et al. 2006). Despite the low levels of BmorPBP1 expression in this heterologous system, we demonstrated clearly that PBPs enhance the sensitivity of the insect olfactory system (Syed

[1] We apologize for not being able to cite all the relevant literature due to reference limitations of a rapid communication.

et al. 2006). Recently, it was shown that addition of a recombinant PBP to a heterologous system that expresses a pheromone receptor from *Antheraea polyphemus* increases both sensitivity and selectivity (Forstner et al. 2009).

Given that our previous attempts to knockdown PBP expression in the silkworm moth were unsuccessful (Leal and Ishida, unpublished data), we explored knocking down OBP expression in mosquitoes. We then focused on CquiOBP1, which is highly expressed in the antennae of the Southern house mosquito *Culex pipiens quinquefasciatus* (=*Cx. quinquefasciatus*) (Ishida et al. 2002). Recently, CquiOBP1 was shown to bind a mosquito oviposition pheromone (MOP) (Laurence and Pickett 1982) in a pH dependent manner and to be expressed in antennal sensilla sensitive to this pheromone (Leal et al. 2008). In the present study, we used CquiOBP1 as a target in RNA interference (RNAi) experiments to examine its function in the reception of oviposition attractants. Mosquitoes injected with double strand RNA (dsRNA) showed reduced levels of *CquiOBP1* transcripts as well as reduced antennal responses to MOP, skatole, and indole when compared to water-injected controls. Interestingly, antennal response to nonanal, a major host cue detected with extremely high sensitivity by *Cx. quinquefasciatus* antennae (Syed and Leal 2009), was not significantly affected. These findings suggest that CquiOBP1 is involved in the detection of multiple oviposition attractants and plays a key role in the sensitivity of the mosquito olfactory system.

Methods and Materials

CquiOBP1 RNA Interference Full-length CquiOBP1 dsRNA was synthesized by in vitro transcription from purified PCR product that contained T7 promoter sequences in inverted orientations and purified by using RNeasy MinElute Cleanup Kit (Qiagen). Approximately 100 nl (350 ng) of dsRNA were injected through the intersegmental thorax membranes into 1-to-48 h-old *Cx. quinquefasciatus* female mosquitoes with a microINJECTOR™ System MINJ-1 (Tritech Research, Los Angeles, CA, USA). dsRNA-injected, water-injected, and non-injected mosquitoes were generated. Individual female heads were dissected in liquid nitrogen 4 d post-injection, RNA from each head was extracted with RNeasy Mini Kit (Qiagen), and individual cDNAs were synthesized from 0.1 μg of RNA using 100u SuperScript® II reverse transcriptase (Invitrogen). Real-time quantitative PCR (qPCR) was carried out by using EXPRESS SYBR® GreenER™ qPCR Super-Mix Universal (Invitrogen) in a final volume of 20 μl. Reactions were run with a standard cycling program, 50°C for 2 min, 95°C for 2 min, 40 cycles of 95°C for 15 s, and 60°C for 1 min, on an AB7300 real-time PCR system (Applied Biosystems). Determination of transcripts abundance was based on two independent replicates for each sample. CquiOBP1 expression was normalized to the expression levels of an endogenous control, the ribosomal protein that encodes gene S7 (CquiRpS7). Relative quantification analysis based on the comparative C_t method ($\Delta\Delta C_t$) was performed using AB7300 system SDS software (Applied Biosystems). Non-injected mosquitoes were used for calibration purposes. Non quantitative PCR was carried out from the same cDNAs by using 2u GoTaq® DNA polymerase (Promega) in a final volume of 25 μl. CquiRpL8 amplification was used as a control of cDNA integrity.

Electrophysiological Recordings An excised head of an adult *Cx. quinquefasciatus* female was mounted on a Syntech EAG platform equipped with micromanipulator-12 and a high-impedance AC/DC preamplifier (Syntech, Germany). Chloridized silver wires in drawn-out glass capillaries filled with 0.1% KCl and 0.5% polyvinylpyrrolidone (PVP) were used for reference and recording electrodes. The recording electrode accommodated the two antennae of the excised head after the tips of the antennae were clipped to provide a better contact. Preparation was bathed in a high humidity air stream flowing at 20 ml/s to which a stimulus pulse of 2 ml/s was added for 500 ms. Any change in antennal deflection induced by the stimuli or control puffs was recoded for 10 s. Indole and 3-methyl indole (skatole) were purchased from Acros (USA) and were 95% pure; nonanal (99%) was from Sigma-Aldrich; racemic 6-acetoxy-5-hexadecanolide (MOP) was a gift from Bedoukian Research Incorporated, USA. Chemicals were dissolved in dichloromethane (DCM), wt/vol, to make a stock solution of 10 μg/μl and decadic dilutions were made. An aliquot (10 μl) of a stimulus was loaded onto a filter paper strip, the solvent was evaporated for 30 s, and the strip was placed in a 5 ml polypropylene syringe from which various volumes were dispensed. Solvent alone served as control. Data presented are from a pool of mosquitoes injected and tested in three different batches on different days. In each session, EAG responses of at least three of RNAi-treated and water-injected mosquitoes were recorded.

Results and Discussion

We employed a combination of RT-PCR and real-time quantitative PCR (qPCR) to examine mRNA levels of *CquiOBP1* in heads of RNAi (dsRNA-injected) and control (water-injected, non-injected) mosquitoes using *CquiRpS7* as a control gene. RT-PCR analysis showed a clear reduction of *CquiOBP1* transcript levels in dsRNA-injected mosquitoes, as compared to water-injected and non-injected mosquitoes (Fig. 1a). We then examined by

electroantennogram (EAG) the responses of sham-and RNAi-treated female mosquitoes to oviposition attractants. Silencing the *CquiOBP1* gene clearly affected antennal responses to MOP and indole, a putative oviposition attractant (Millar et al. 1992) (Fig. 1b), but the response to nonanal was not significantly affected. Next, we quantified the reduction of transcripts by qPCR (Fig. 1c), which confirmed the trend observed by a semi-quantitative method (Fig. 1a). dsRNA-injected mosquitoes displayed reduction of *CquiOBP1* transcript levels (average 59.9%) when compared to both water-injected (sham-treated) mosquitoes (average 97.3%) and non-injected controls (normalized to 100%). dsRNA-Injected individuals displayed significant reduction of *CquiOBP1* transcripts (47% to 65%) (Fig. 1c). Furthermore, water-injected and non-injected mosquitoes displayed almost equivalent levels of *CquiOBP1* transcripts, thus demonstrating that RNAi treatment is responsible for the observed reduction of *CquiOBP1* mRNA levels (Fig. 1c). This partial silencing of *CquiOBP1* shown by qPCR analysis demonstrates the feasibility of significantly reducing even highly expressed olfactory genes like OBPs by using the RNAi approach.

Fig. 1 PCR and EAG data. **a** RT-PCR analysis indicating that *CquiOBP1* transcripts were reduced in RNAi-treated females (RNA1 & RNA2) when compared to the transcript levels in water-injected (Water) and non-injected (NON) females. CquiRpL8, control gene. **b** EAG traces recorded from antennae of water- and RNAi-treated female mosquitoes challenged with MOP (100 µg), indole (10 µg), and nonanal (10 µg). Bars on the top of traces indicate the duration of the 500 ms stimulus. **c** Relative expression of *CquiOBP1* by qPCR using EXPRESS SYBR® Green ER™. RNAi-treated, water-injected, and non-injected mosquitoes (each $N=5$). **d**, **e**, **f** Dose-response EAG curves for skatole, indole, and nonanal, respectively ($N \geq 10$). The scale for skatole (**d**) and indole (**e**) graphics is the same, but the high sensitivity of nonanal (**f**) required a different scale

Correlation with EAG data (Fig. 1b) also suggests that ~50% transcripts reduction is enough to generate reduced responses to several semiochemicals.

Finally, we compared the responses of sham- and RNAi-treated female mosquitoes to various doses of these oviposition-related compounds. EAG responses of RNAi-treated females to MOP were below the detection limit, but the dose required to generate consistent EAG signals with water-treated or untreated mosquitoes was high (100 µg). In contrast, reduction of *CquiOBP1* transcripts led to a significantly reduced response to skatole (N=10, P<0.05) at all doses tested (Fig. 1d). Likewise, EAG responses to indole by RNAi-treated females were significantly lower than the responses recorded from water-treated female mosquitoes at all doses tested (Fig. 1e). Lastly, we observed an apparent trend towards smaller EAG responses to nonanal by RNAi-treated compared water-treated female mosquitoes, but the differences were not significant (Fig. 1f).

The simplest explanation for these findings is that OBPs play an important role for the sensitivity of the insect's olfactory system. Although we were not able to completely silence *CquiOBP1*, probably because of the high level of transcription, the partial knockdown clearly affected antennal response to physiologically relevant compounds. Previously, we demonstrated by in vitro assays that CquiOPB1 binds MOP in a pH-dependent manner, and we showed its expression in antennal sensilla sensitive to this oviposition attractant (Leal et al. 2008). These RNAi experiments are the first evidence in vivo that CquiOBP1 is involved in the reception of *Culex* mosquito oviposition attractants. Although it is tempting to speculate that CquiOBP1 is selective because responses to nonanal were not significantly different in sham- and RNAi-treated mosquitoes (Fig. 1f), the level of transcript reduction achieved by our RNAi treatments may not be high enough to affect EAG responses of semiochemicals such as nonanal for which the olfactory system responds with remarkable sensitivity (Syed and Leal 2009). By contrast, the reduced levels of *CquiOBP1* transcripts affected the responses of compounds with higher thresholds, thus allowing us to conclude that CquiOBP1 is indeed involved in the detection of oviposition attractants, and that high levels of OBPs expression are essential for the sensitivity of the insect's olfactory system.

Abstract Herbivorous insects searching for a host plant need to integrate a sequence of multimodal sensory inputs. We conducted a series of no-choice experiments in a laboratory wind tunnel to examine the behavioral response of the specialist fruit fly, *Neoceratitis cyanescens* (Diptera: Tephritidae), to host visual and olfactory stimuli presented singly or in combination (e.g., colored fruit model with or without host fruit odor). We also studied the influence of wind flow, age, and sex on the response of flies. In two-choice experiments, we evaluated the ability of mature females to discriminate between two fruit models emitting host vs. non-host fruit odor or clean air. *Neoceratitis cyanescens* mature females can use independently or interactively olfactory and visual stimuli to locate their host, whereas immature females and males respond primarily to host fruit odor. In the absence of wind, mature females mainly use visual information to locate the host fruit. In wind, host fruit odor significantly increases the probability and speed of locating the host fruit. In a two-choice situation between two bright orange spheres, flies accurately detected the sphere emitting host fruit odor vs. non-host fruit odor or odorless air. Nevertheless, they preferred to land on the bright orange sphere when the sphere emitting host fruit odor was blue. Furthermore, when odor source and fruit model were spatially decoupled (90 or 180°), >50% flies that landed on the fruit model initially performed an oriented flight toward the odor source, then turned back to the fruit model while in flight or after one landing, thus suggesting visual information to be the ultimate indicator of host fruit.

Introduction

Finding and selecting suitable targets for egg laying, mating, feeding, or resting, is a key issue for reproductive success in insects (Schoonhoven et al. 2005). In phytophagous insects, orientation, including searching and finding host plants, involves the integration of a sequence of multimodal sensory inputs (Bernays and Chapman 1994; Bell et al. 1995; Cardé and Willis 2008). These inputs are received through peripheral receptors such as antenna and compound eyes, and then processed in the brain. Finch and Collier (2000) developed the hypothesis that once phytophagous insects have located the habitat by use of plant volatile chemical information, visual stimuli then govern the next phase of host plant location.

Frugivorous fruit flies (Diptera: Tephritidae) have evolved mechanisms that use plant volatiles and spectral properties during the host finding process (Roitberg 1985). In the specialist apple maggot fly, *Rhagoletis pomonella* (Walsh), fruit-seeking females are attracted at long distance by a blend of volatile esters from ripening fruit (Fein et al. 1982; Zhang et al. 1999), whereas vision is predominant at close range, within the host habitat (Prokopy and Owens 1983; Averill et al. 1988; Aluja and Prokopy 1992; Green et al. 1994). However, olfactory cues can interact in short-range searching for host fruit in the tree canopy when fruit are less apparent or scarce (Prokopy and Roitberg 1984;

Aluja and Prokopy 1993). Recent studies indicate that specific volatile blends, including non-host fruit volatiles, are used by apple, hawthorn, and flowering dogwood-infesting *Rhagoletis* flies to discriminate host fruit (Nojima et al. 2003a,b; Linn et al. 2003, 2004, 2005; Forbes and Feder 2006). The relative importance and the sequence by which these stimuli mediate host location at short distance, and how flies adapt their searching behavior in response to information, are not well known. Furthermore, the decision to engage in searching a plant is based not only on the perception of suitable information but also on the insect's physiological status (for a review, see Barton Browne et al. 1990). For various species, responses to visual and olfactory stimuli from host plants have been shown to be influenced by age and reproductive status. In *R. pomonella*, the age and sexual maturity of females significantly affect the probability and time to discover fruit models (Duan and Prokopy 1994).

As an oligophagous species specialized on solanaceous plants, the tomato fruit fly *Neoceratitis cyanescens* (Bezzi) (Diptera: Tephritidae) is a relevant model system to study the role of visual and olfactory cues and their interaction in guiding females to the host plant at short range. Classified in the subfamily Dacinae and the tribe Ceratitidini (Hancock and White 1997), this species is widespread throughout the Indian Ocean region, including Madagascar, Mauritius, Reunion, and Mayotte islands (OEPP/EPPO 1997). Females usually lay their eggs in fruit, causing serious damage to vegetable crops, particularly field-grown tomato (*Lycopersicum esculentum* Mill.), whereas wild plants such as bugweed (*Solanum mauritianum* Scop.) serve as natural reservoirs. Previous studies showed that flower and fruit volatiles assist gravid females (but also immature females and males) in finding the host plant (Brévault and Quilici 2010). At short range, i.e., within the host plant habitat, gravid females (but neither immature females nor males) are strongly attracted to fruit-mimicking bright orange spheres (Brévault and Quilici 1999, 2007a,b).

Because olfactory and visual cues were presented separately in these experimental settings, it is not clear how they interact during the fruit finding process at short range. Furthermore, many signals in nature are complex and multimodal, consisting of components from two or more sensory modalities, and the question of why organisms use multimodal signals remains poorly studied (Kulahci et al. 2008). We tested the following hypotheses: (a) visual stimuli are sufficient to elicit orientation response to host fruit; (b) the integration of more specific olfactory cues can improve the host finding efficiency in terms of speed and accuracy, especially when visual cues are inadequate or poor (obstructed or weakly attractive), or when visual cues are similar to those of non host plants; (c) conversely, since turbulence is likely to affect olfactory information, flies may rely on visual stimuli to locate host fruit when olfactory cues are inadequate or poor.

Using a laboratory wind tunnel, we studied the behavioral response of individually tested flies to an array of visual and olfactory cues presented singly or in combination (e.g., fruit model with or without host fruit odor). We also investigated the effect of wind flow, age (sexual maturity), and sex of flies on the response to a combination of visual and olfactory stimuli. In two-choice experiments, we evaluated the ability of gravid females to discriminate between two fruit models that emit host or non-host fruit odor, or clean air. The behavioral traits of *N. cyanescens* are discussed in the light of adaptive strategy and pest management.

Methods and Materials

Insects

Larvae of *Neoceratitis cyanescens* were collected from field-grown tomatoes in the western part of Reunion Island. Flies of both sexes emerged in 30×30×30 cm screen Plexiglas cages under controlled conditions (25±1°C, 70± 10% RH, and a LD 12:12 h photocycle). They had free access to granulated sugar, enzymatic yeast hydrolysate (ICN Biomedicals, Costa Mesa, CA, USA), and water until the time of testing. Behavioral experiments were conducted on laboratory-reared adult flies (generations 2 to 6) (Etienne 1973). The responses of 2-d-old immature females, 8-d-old mature females, and 6-d-old mature males were recorded. Based on Brévault and Quilici (2000a), 8-d-old females were supposed to have a high oviposition drive, as opposed to 2-d-old immature females. The flies used in all experiments were naive to fruit and plant odors and fruit visual cues, i.e., they were not allowed any contact with host-plant material and had no ovipositional experience prior to testing.

Laboratory Wind Tunnel

A semi-cylindrical plastic tunnel was used to assess the behavioral response of flies to olfactory cues (Fig. 1). A fan placed at the downwind end of the tunnel produced an adjustable wind flow of 0–60 cm sec^{-1}, measured with a telescopic 830 anemometer (TSI Inc., St. Paul, MN, USA). Clean air was pumped from above the building roof, and once passed through the tunnel was pushed outside. Two fabric filters placed in the upwind and downwind sections of the tunnel provided a laminar air flow. Grey adhesive bands were placed randomly on the tunnel floor to provide visual flow for the flying insects (Cardé 1984). Two sliding windows allowed the introduction and removal of insects from the tunnel. A neon ramp placed 50 cm above the

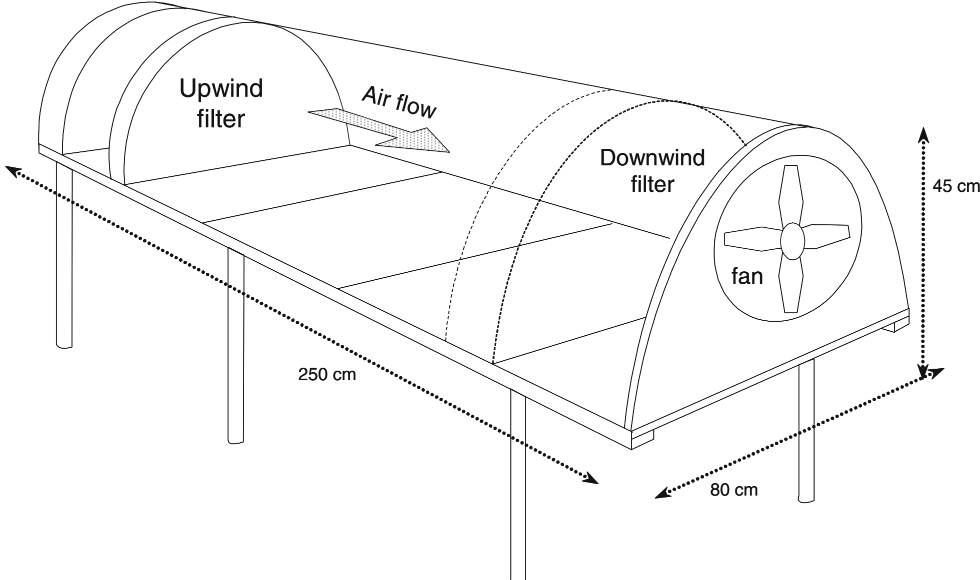

Fig. 1 Laboratory wind tunnel used to investigate the response of fruit flies to visual and olfactory cues

tunnel provided an illumination of 400 lux, and temperature was maintained at 25±1°C.

The behavioral response of flies to the combination of visual and olfactory stimuli was tested in no-choice or two-choice experiments. In both types of experiments, the odor sources were placed outside the tunnel in a sealed plastic bag (PET) with an inlet and outlet for air (Fig. 2). The inlet was connected via a silicon pipe to a vacuum pump that injected air at a flow of 1.0 l min^{-1}, whereas the outlet was connected to a sphere (3.7 cm diam) pierced with small holes (1 mm diam) and placed in the flight tunnel at 2 cm height (Fig. 2). As a result, odor was swept from the bag to the flight tunnel. Based on previous studies, air speed in the tunnel was fixed at 25 cm s^{-1} (Brévault and Quilici 2010).

Experimental Trials

In the first no-choice experiment (Exp. 1), the odor source was composed of unripe berries of bugweed (100 g), host fruit known to be highly attractive for *N. cyanescens* flies (Brévault and Quilici 2010), or an empty bag as control (clean air). Odor was conveyed to a colored sphere at location ‘0’ in the tunnel (100 cm from the released fly, Fig. 2), or no sphere as control. The color of the sphere was alternatively blue, yellow, or bright orange, respectively representing weak, moderate, and strong host fruit stimuli for mature females (Brévault and Quilici 2007a). In Exp. 2, flies were offered only a bright orange sphere at location ‘0’, with or without host fruit odor, in wind (30 cm sec^{-1}),

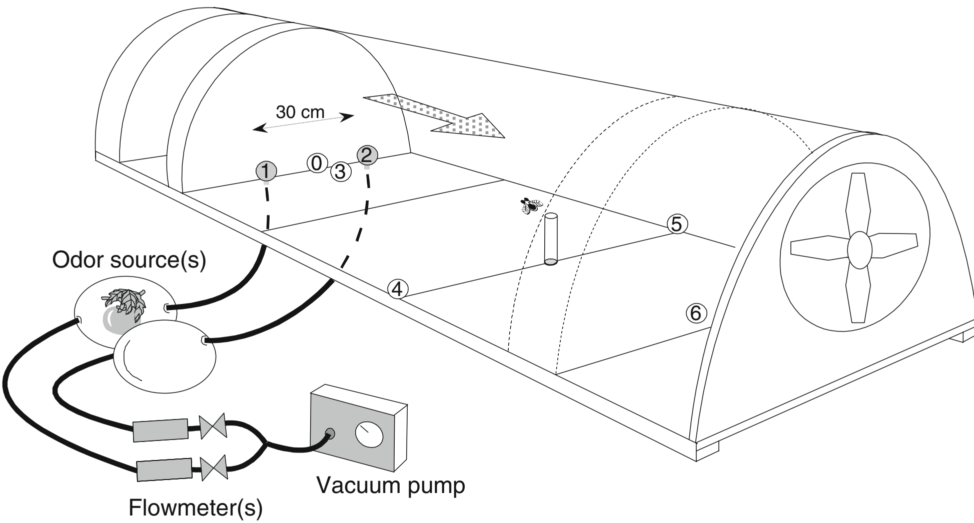

Fig. 2 Experimental trials designed for assessing behavioral response of flies to a combination of visual and olfactory stimuli. The odor source is placed in a sealed plastic bag and headspace is swept to the tunnel at locations 0–6. The release vial containing one individual fly is placed gently into the wind tunnel. Observations begin when the fly climbs onto the top of the release vial. Behavioral sequences and location of insects are time recorded using ‘The observer version 3.0’ software

or in still air (0 cm sec^{-1}). In Exp. 3, flies were offered only a bright orange sphere at location '0' (0°, 100 cm from the released fly, Fig. 2), on one side at location '4' or '5' (90°, 40 cm from the released fly, Fig. 2), or in the downwind end of the tunnel at location '6' (180°, 50 cm from the released fly, Fig. 2), with host fruit odor emitted at location '0' (Fig. 2).

In the two-choice experiments, a pair of spheres was presented in wind flow (25 cm sec^{-1}) to individually tested 8-d-old mature females. In Exp. 4, two bright orange spheres were placed at location '1' and '2' (30 cm between spheres, 100 cm from the released fly, Fig. 2). One odor source was composed of unripe berries of bugweed (100 g), and the other was composed of either unripe host fruit (tomato, *L. esculentum*), unripe non-host fruit (zucchini, *Cucurbita pepo* L., orange, *Citrus sinensis* L.), or clean air (empty bag as control). Bugweed odor vs. clean air also was tested in the absence of wind flow. In Exp. 5, a yellow or blue sphere emitting host fruit odor replaced the bright orange sphere emitting host fruit odor. In Exp. 6, a bright orange or yellow sphere without odor was placed at location '3', 10 cm in front of the bright orange sphere emitting host fruit odor at location '0' (Fig. 2).

Behavioral Observations

In the no-choice experiments, individual flies were gently transferred into a small glass vial (5×1.5 cm) that was deposited downwind at 100 cm of location '0' (Fig. 2). Observations started as soon as the fly climbed onto the top of the vial, and lasted 2 min, or less when the fly reached the sphere or the upwind section of the tunnel in the absence of any sphere. Behavioral sequences, locomotion, and location of flies were time recorded with 'The Observer version 3.0' software (Noldus Information Technology, Wageningen, The Netherlands). Only typical postures were analyzed, i.e., scan (motion around the tip of the release vial), orientation toward odor source ('arrestment'), lag time (time before leaving the vial), upwind flight (in the opposite direction of the wind flow), direct flight and landing on the sphere. In the two-choice experiments, observations also lasted 2 min or ended sooner when flies landed on a sphere. Behavioral observations lasted 1 min more after landing, to assess egg-laying behavior (Exp. 4) or landing on the other sphere (Exp. 6).

A minimum of 30 flies per treatment were tested. Flies were tested only once, individually, in series of 5 individuals per randomized treatment. Between treatments, the wind tunnel was ventilated with clean air for 5 min to prevent odor contamination. Observations were conducted in the afternoon between 2:30–5:30 pm when females usually seek for host fruits to lay their eggs (Brévault and Quilici 2000b).

Data Analysis

Quantitative data were analyzed using non parametric *Kruskal-Wallis* one-way *ANOVA*, because assumption of normality was not met. Behavioral frequencies were compared by χ^2-*tests* and Marascuilo procedure using XLSTAT (Fahmy 2006). To determine whether there was any interaction between olfactory and visual stimuli, a χ^2-*test* was used for a two-way contingency table (combinations of absence and presence of odor and visual stimuli).

Results

Do Visual and Olfactory Cues Interact during the Host Finding Process?

Orientation toward the odor source was more frequent in flies exposed to host fruit odor than to clean air (χ^2_7=99.4 for 8-d-old females; χ^2_3=83.6 for 2-d-old females; χ^2_3= 90.2 for 6-d-old males; P<0.001), and negatively associated to scan behavior (r_6=0.95, P<0.001) and lag time (r_6= 0.92, P=0.001) on the release vial (Fig. 3a, Table 1). Flies

The sphere and odor source were placed at location '0', 100 cm distance from the released fly (Fig. 3a).

SEM standard error of mean. *N* number of tested flies

Data of the same experiment in the same column followed by different letters are significantly different according to *χ2-test* or *Kruskal-Wallis ANOVA**. The source of host fruit odor was composed of 100 g unripe berries from bugweed (*Solanum mauritianum*).

that oriented toward the odor source did not scan their environment and left the release vial earlier. Conversely, the presence of a sphere with clean air, regardless of its color, did not affect significantly those parameters (χ^2_{1-3}=0.1–6.1, P=0.107–0.702). Host fruit odor *per se* significantly triggered an upwind flight regardless of the age or sex of flies (Table 1). Accordingly, host fruit odor had a significant effect on the percentage of flies that reached the upwind section of the flight tunnel (χ^2_7=97.0 for 8-d-old females; χ^2_3=53.8 for 2-d-old females; χ^2_3=33.6 for 6-d-old males; P<0.001).

In the absence of host fruit odor, the percentage of 8-d-old females that reached the upwind section was higher in the presence of a bright orange or a yellow sphere than in the absence of sphere (χ^2_7=12.5, P=0.006). Furthermore, there was a significant additive interaction between olfactory and visual stimuli for the percentage of flies that engaged in an upwind flight and that reached the upwind section (χ^2_7=10.1, P=0.002; χ^2_7=7.6, P=0.006, respectively). However, the presence of a sphere did not affect the percentage of 2-d-old females and 6-d-old males that reached the upwind section (χ^2_3=1.1, P=0.295 for 2-d-old females; χ^2_3=0.9, P=0.350 for 6-d-old males). Only 2.5% of 2-d-old females and 6.7% of 6-d-old males landed on the bright orange sphere in the absence of host fruit odor, compared to, respectively, 32.5 and 43.3% when fruit odor was combined. The bright orange sphere *per se* significantly triggered landing of 8-d-old females on the sphere (37.5%) compared to the yellow (5.0%) or the blue sphere (0.0%), and this percentage increased synergistically when host fruit odor was combined with the bright orange sphere (75%), as compared to the yellow (27.5%) or blue (10.0%) sphere (χ^2_7=3.9, P=0.048; χ^2_7=4.8, P=0.028, respectively). In addition, flies reached the bright orange

sphere earlier in the presence (15±4 sec) than in the absence (49±10 sec) of host fruit odor.

In the absence of wind flow or host fruit odor, most 8-d-old females scanned their environment (Fig. 3a, Table 2). Conversely, in both wind flow and host fruit odor, most flies oriented themselves towards the odor source so that lag time on the release vial was significantly reduced (Table 2). In addition, there was a significant synergistic interaction between olfactory and wind stimuli for the percentage of flies that scanned their environment or orientated toward the source, and the mean time before leaving the release vial (χ^2=12.4, P< 0.001; χ^2_3=8.4, P<0.001; χ^2_3=5.2, P<0.001, respectively). A significant synergism was found between olfactory and wind stimuli for the percentage of flies that landed on the sphere (χ^2_3=13.9, P<0.001). Host fruit odor significantly increased the probability of locating the bright orange sphere in wind but not in still air. In the absence of host fruit odor, the percentage of flies that landed on the sphere in still air (45.0%) was higher than that in wind (27.5%). Time to reach the sphere was significantly reduced in the presence of host fruit odor and wind flow.

Within the 2 min assigned to behavioral observations, the percentage of flies that landed on the orange sphere was higher when the sphere was placed in the odor plume at 0° (90.6%) or outside the plume at 90° (78.1%) than in the plume at 180° (40.6%) (Fig. 3b, Table 3). At 0°, 86.2% of flies that landed on the sphere performed a direct flight. At 90°, 40.0% of flies that landed on the sphere performed a direct flight, whereas 52.0% turned back while in flight toward the odor source. At 180°, 46.2% of flies that landed on the sphere performed a direct flight, whereas 23.1% turned back while in flight toward the odor source, and 30.8% with at least one landing transition. The mean time to reach the sphere was significantly lower at 0° than at 90° and 180° (Table 3).

Does Host Fruit Odor Mediate Discrimination between Fruit Models?

In the absence of wind flow, 8-d-old females did not land preferentially on the bright orange sphere emitting host fruit odor (62.5%), but 66.6% of flies that first landed on the sphere emitting clean air left the sphere within 1 min (Fig. 3c, Table 4). Conversely, 80.0% of flies that landed on the sphere emitting host fruit odor drew their ovipositor. In wind (25 cm sec^{-1}), flies preferentially landed on the sphere emitting host fruit odor rather than on the sphere emitting clean air or non host fruits such as zucchini or orange odor (77.8, 83.3, and 80.6%, respectively), but did not show any preference when the second sphere emitted host fruit odor from unripe tomatoes (Table 4). Most flies extended their ovipositor regardless of the nature of the fruit (57.1–71.4%), and few left the odor-emitting sphere (0.0–14.3%).

Flies significantly preferred to land on the bright orange sphere when presented together with a yellow or a blue sphere (Fig. 4). However, they did not discriminate between the bright orange and the yellow sphere when the yellow sphere emitted host fruit odor, but continued to prefer the bright orange sphere to the blue one emitting host fruit odor. When a bright orange sphere emitting clean air was placed 10 cm in front of a bright orange sphere emitting host fruit odor, flies preferentially landed on the odorless sphere (83.3%) but this stop constituted a transitional step, as 90% of females switched to the sphere emitting the fruit odor within 1 min. When a yellow sphere was placed in front of the bright orange sphere emitting host fruit odor, 70% of flies flew around the yellow sphere and

landed on the bright orange sphere as a first choice (Fig. 3d, Table 5).

Discussion

Our results demonstrate that: 1) *N. cyanescens* gravid females can use independently or interactively olfactory and visual cues to locate host fruit; 2) olfactory information when carried by wind improves searching efficiency at short range, both in terms of speed and accuracy, but visual cues are predominant in the decision of landing; and 3) immature females and males respond primarily to olfactory cues. Consistent with previous reports on *N. cyanescens* responses to fruit models (Brévault and Quilici 2007a, b) and host fruit odor (Brévault and Quilici 2010), we observed that both bright orange spheres and host fruit odor in wind independently elicited positive responses of fruit-seeking females. The bright orange sphere *per se* significantly triggered landing of 8-d-old females (37.5%) compared to the yellow sphere (5.0%) or the blue sphere (0.0%), and this percentage increased synergistically when

N number of tested flies

The two bright orange spheres and the odor sources were placed at location '1' and '2', 100 cm distance from the released fly (Fig. 3c). A *χ2-test* was performed to compare the distribution of landings of flies with a theoretical distribution (50–50%). The other frequencies were analyzed by using *χ2-tests*. The source of fruit odor was composed of 100 g unripe fruit from host plants (bugweed, *Solanum mauritianum*; tomato, *Lycopersicon esculentum*) or non host plants (zucchini, *Cucurbita pepo*; orange, *Citrus sinensis*).

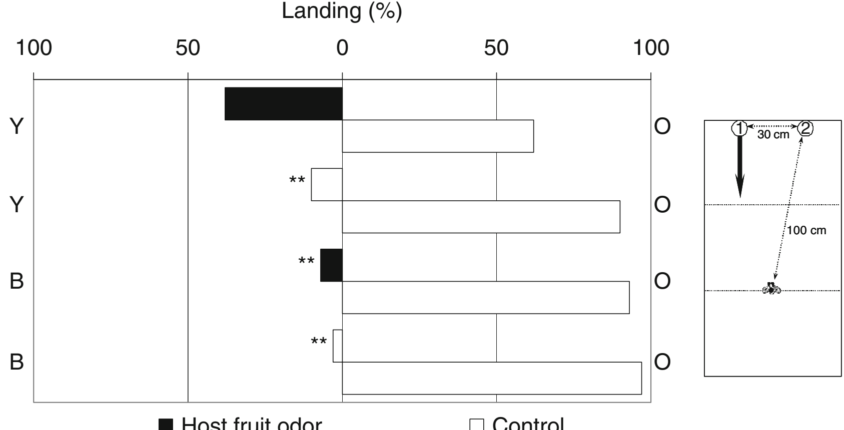

Fig. 4 Behavioral response of individually tested *Neoceratitis cyanescens* 8-d-old mature females to a combination of visual (B-blue, Y-yellow, or O-bright orange spheres) and olfactory (host fruit odor) cues in 2-choice tests. *N*=30 flies. The two spheres and the odor source are placed at location '1' or '2', 100 cm distance from the released fly. A χ*2-test* is performed to compare the distribution of landings of flies with a theoretical distribution (50–50%). The source of fruit odor is composed of 100 g unripe fruit from bugweed (*Solanum mauritianum*)

host fruit odor was combined with the bright orange sphere (75%).

In the specialist fruit fly *R. pomonella*, host fruit odor also interplays in stimulating visual search activity during host finding by females when fruit are less apparent or scarce (Aluja and Prokopy 1993). Szentesi et al. (1996) observed that olfactory stimulation favored landing of adults of the grasshopper, *Melanoplus sanguinipes* (F.) (Orthoptera, Acrididae) on visual models, with more directional searching flight and less time. Similar additive interactions between visual and olfactory stimuli in host location have been reported for the mountain pine beetle *Dendroctonus ponderosae* Hopkins (Campbell and Borden 2006) and the pine weevil, *Hylobius abietis* L. (Coleoptera, Scolytidae) in finding an undamaged conifer seedling (Björklund et al. 2005). In the leafhopper *Dalbulus maidis* (De Long and Wolcott) (Homoptera, Cicadellidae), plant volatiles act as a synergist by increasing the number of contacts made by insects with green light (Todd et al. 1990). Searching activity of parasitoids such as *Microplitis croceipes* (Cresson) (Wackers and Lewis 1993), *Diachasmimorpha longicaudata* (Ashmead) (Hymenoptera, Braconidae) (Jang et al. 2000), and *Apocephalus paraponerae* Borgmeier (Diptera, Phoridae) (Morehead and Feener 2000) increase when olfactory cues are combined with visual cues. In *Manduca sexta L.* (Lepidoptera, Sphingidae), a nectarivorous nocturnal hawkmoth attracted by a range of stimuli including floral volatiles and visual display, Goyret et al. (2007) showed that transient olfactory stimulation before visually guided approach (temporal decoupling) enhanced responsiveness to an odorless visual target. Under natural conditions, the integration of bi- or multi-modal information may be viewed as adaptive, as it improves the searching efficiency within resource patches of variable and complex environments.

In the absence of wind to carry the olfactory information, *N. cyanescens* mature females relied on visual information to locate the bright orange sphere. In a two-choice situation between two bright orange spheres, flies were able to detect

Table 5 Behavioral response of individually tested *Neoceratitis cyanescens* 8-d old mature females to a combination of visual (yellow or bright orange spheres) and olfactory (host fruit odor) cues in 2-choice tests

Color of sphere	Sphere location	Odor source	*N*	Landing site as first choice (%)	Landing site 1 min later (%)

Bright orange	0	Host fruit		16.7	90.0
		χ^2_1 *(P)*		7.5 (0.006)	11.4 (0.001)
Yellow	3	control	30	30.0	0.0
Bright orange	0	Host fruit		70.0	100.0
		χ^2_1 *(P)*		2.5 (0.114)	20.0 (<0.001)

N number of tested flies

The two spheres were placed at location '0' or '3', respectively 100 and 90 cm distance from the released fly. The odor source was placed at location '0' (Fig. 3d). A χ*2-test* was performed to compare the distribution of landings of flies with a theoretical distribution (50–50%). The source of fruit odor was composed of 100 g unripe fruit from bugweed (*Solanum mauritianum*).

the sphere emitting the host odor only in the wind, suggesting that host fruit odor can assist flies to locate the adequate fruit when visual stimuli are similar to those of non host plants. However, flies did not discriminate between an odorless bright orange sphere and a yellow sphere (poor signal) with host fruit odor, but they preferred to land on the odorless bright orange sphere when presented with a blue sphere with host fruit odor. This result indicates a dominance of visual cues in the decision of landing.

Furthermore, flies preferentially landed on the odorless bright orange sphere (83.3%) placed 10 cm in front of that emitting host fruit odor, although this stop constituted a transitional step. When the odorless orange sphere was replaced by a yellow sphere, flies landed preferentially on the bright orange sphere. When odor source and fruit model were spatially decoupled, most flies engaged in an oriented flight toward the odor source. However, some were able to turn back while in flight or after landing to orient themselves toward the fruit model, thus suggesting visual information to be the ultimate indicator of host fruit. In a comparable dual-choice experiment, *M. sexta* moths showed a strong bias for the visual display over the odor plume, suggesting the former to be the ultimate indicator of a nectar source (Goyret et al. 2007).

Efficiency of host finding by insects entails the use of informative, accurate and easy to assess multimodal cues (Fawcett and Johnstone 2003). Flies initially may use specific volatiles emitted by host fruit (including flower blends) and carried by wind to locate an appropriate habitat, by tracking wind-borne odor known as odor-guided optomotor anemotaxis (Schoonhoven et al. 2005; Cardé and Willis 2008) and 'aim-then-shoot' tactics (Brévault and Quilici 2010). Olfactory cues emitted by the host foliage then could be an indicator of an appropriate habitat, leading flies to search for a visual image to detect individual fruit at a short distance (Brévault and Quilici 2007b).

However, integration of olfactory signals enhances searching efficiency, both in terms of speed and accuracy. Synergism between olfactory and visual cues supports the more general hypothesis that foragers may benefit by integrating multimodal information of the plants they encounter in nature (Campbell and Borden 2006). Flies can be guided by the odor plume when fruit are scarce or obstructed by dense canopy, whereas visual orientation will enable them to stay on course when it loses the odor trail. The response of immature females and males to olfactory stimuli could favor, respectively, long range dispersal towards potential host plants, or the search for a sexual partner.

The positive response of flies to olfactory plant stimuli in the wind tunnel (quantity and reliability of odor release) may not reflect the natural situation that flies experience at a short distance to a host plant. Furthermore, complete absence of turbulence is rare under natural conditions where volatiles are carried away from the source with the prevailing direction of air flow and will be dispersed as pockets of odor. Moreover, host plants may be scattered between non-host plants (Schoonhoven et al. 2005). In this study, we observed the behavioral response of naive host-seeking flies that had no previous contact with the host plant. Experience may enhance decision-making or induce changes in preference due to enhanced egg maturation resulting from contact with hosts (Papaj 2000) or through behavioral changes such as sensitization (Bell 1990; Schoonhoven et al. 2005). For example, *Bactrocera dorsalis* (Hendel) females previously exposed to kumquats locate more easily this fruit than females exposed to various other hosts (Prokopy et al. 1990). Similarly, learning influences the visual ability of *R. pomonella* females to detect host fruit (Prokopy et al. 1994). Experience with the host then may modify the ranking and specificity of host location stimuli, so that a more specific search image and perhaps olfactory cues are used subsequently (Rausher 1978; Vet et al. 1990, 1995; Wackers and Lewis 1993; Landolt and Molina 1996).

As opposed to most tephritids of economic significance on Reunion Island, no effective lure or bait is known for *N. cyanescens*. Knowledge of the interaction between visual and olfactory stimuli involved in host location could be useful for developing trapping systems (Katsoyannos 1989). In commercial orchards, red sticky spheres mimicking apples were improved by the addition of specific volatile compounds for monitoring *R. pomonella* females seeking host fruit (Zhang et al. 1999). Our next step will be to identify and formulate the minimal blend of volatile compounds that causes attraction of *N. cyanescens* mature females.

Abstract Damage by the Russian wheat aphid (RWA), *Diuraphis noxia*, significantly reduces wheat and barley yields worldwide. In compatible interactions, virulent RWA populations flourish and susceptible plants suffer extensive leaf chlorophyll loss. In incompatible interactions, RWA reproduction and population growth are significantly reduced and RWA-related chlorophyll loss in resistant plants is minor. The objectives of this study were to develop an understanding of the molecular and phytochemical bases of RWA resistance in plants containing the *Dnx* resistance gene. Microarray, real-time polymerase chain reaction, and phytohormone assays were conducted to identify transcriptome components unique to RWA-infested *Dnx* plants and susceptible (*Dn0*) plants, and to identify and characterize putative genes involved in *Dnx* plant defense responses. We found that RWA-infested *Dnx* plants upregulated >180 genes related to reactive oxygen species, signaling, pathogen defense, and arthropod allelochemical and physical defense. The expression of several of these genes in RWA-infested *Dnx* plants increased significantly from 6- to 24-h post infestation (hpi), but their expression in *Dn0* plants, when present, was delayed until 48- to 96 hpi. Concentrations of 16- and 18-carbon fatty acids, *trans*-methyl-12-oxophytodienoic acid, and abscisic acid were significantly greater in *Dnx* foliage than in *Dn0* foliage after RWA infestation, suggesting that *Dnx* RWA defense and resistance genes may be regulated via the oxylipin pathway. These findings provide a foundation for the elucidation of the molecular basis for compatible- and incompatible plant-aphid interactions.

Introduction

Aphids (Order Homoptera) are major arthropod pests of agriculture worldwide, damaging crops by removing photoassimilates and vectoring numerous devastating plant viruses. The limited tissue damage caused during aphid feeding and the prolonged interactions of aphid mouthparts with plant cells make plant responses to phloem-feeding aphids distinct from those of chewing insects (Walling 2000). Many species of aphids are resistant to insecticides (Devonshire and Field 1991), and some have developed virulence to plant aphid

resistance genes. Environmental concerns linked to insecticide use have led to the development and cultivation of many aphid-resistant crop varieties during the past century (Panda and Khush 1995; Smith 2005).

The Russian wheat aphid (RWA), *Diuraphis noxia*, is a serious pest of wheat, *Triticum aestivum*, and barley, *Hordeum vulgare*, and with the exception of Australia, the aphid has been introduced globally since the early 1900s (Quisenberry and Peairs 1998). In compatible interactions with RWA, susceptible wheat plants react to the injection of RWA saliva by rolling the leaves longitudinally around the main leaf vein to form a tubular refuge that protects aphids from predators. As a result, RWA populations flourish and plants suffer extensive leaf chlorophyll and carotenoid loss (Burd and Elliott 1996; Heng-Moss et al. 2003). These reductions also are manifested as significant reductions in photosynthetic efficiency that results in weakened plants with substantially lower grain yields (Smith et al. 1991). In incompatible interactions that involve plants containing the RWA-resistance genes, RWA reproduction and population growth are significantly reduced, and chlorophyll loss is minor.

Heritable resistance to pest insects has been widely documented in many cereal, forage, fruit, and vegetable crop plants (Smith 1989) and single resistance (R) genes inherited as dominant traits control resistance in both monocots and dicots (reviewed in Smith 2005). Resistance may be categorized as antibiosis (an adverse effect on insect biology—including mortality), antixenosis (an adverse effect on insect behavior), or tolerance (the ability of a plant to withstand insect damage). Many insect-resistant plants, including RWA-resistant barley and wheat, contain multi-category resistance (reviewed in Berzonsky et al. 2003; Smith 2005).

Ten RWA (*Dn*) resistance genes from cereal crops have been identified (Smith 2004; Liu et al. 2005) and are being deployed in the U.S. (Quick et al. 1996) and South Africa (Prinsloo 2000). However, RWA virulence occurs in Africa (Malinga et al. 2007; Tolmay et al. 2007), Asia (Dolatti et al. 2005), Europe (Basky 2003), North America (Burd et al. 2006), and South America (Smith et al. 2004).

An understanding of the molecular bases of plant-aphid interactions is progressing, albeit slowly, based on the identification of plant genes that control aphid resistance. The NBS-LRR gene *Mi-1.2* from *Lycopersicon peruvianum* controls resistance to the potato aphid, *Macrosiphum euphorbiae* (Thomas), and to three species of the root knot nematode, *Meloidogyne* spp. (Kaloshian et al. 1997; Vos et al. 1998). No monocot insect R genes have been cloned, but the transcript levels of NBS-LRR genes are affected in plants infested by aphids (Lacock et al. 2003; Klingler et al. 2005; Botha et al. 2006; Park et al. 2006). Aphid feeding activates plant defense signals similar to those involved in response to pathogen infection (Tjallingii and Hogen-Esch 1993; Walling 2000; Kaloshian 2004), but the origin of aphid elicitors of these signals is poorly understood (Urbanska et al. 1998; Miles 1999; Forslund et al. 2000).

The recognition of aphid probing and sustained feeding results in transmission of defense response signal cascades that involve jasmonic acid (JA), salicylic acid (SA), ethylene (ET), abscisic acid (ABA), and gibberellic acid (GA) (Smith and Boyko 2006). At the onset of aphid-plant interactions, aphid feeding results in the altered activation of peroxidases, intercellular chitinases, and β-1,3-glucanases involved in the release of plant cell wall oligosaccharides (Smith and Boyko 2006). Reactive oxygen species (ROS) elicitors that respond to aphid feeding may also upregulate the activity of these enzymes. Peroxidase (PER), glutathione transferase (GST), catalase (CAT), nitrate reductase, and quinone oxidoreductase genes are upregulated in aphid-infested plants (Martinez de Ilarduya et al. 2004; Zhu-Salzman et al. 2004; Divol et al. 2005; Boyko et al. 2006; Park et al. 2006; Couldridge et al. 2007).

Interactions between aphids and their host plants elicit the activation of both the JA and SA defense response pathways and the related upregulation of genes controlled by each of these plant hormones. Examples of these interactions include greenbug feeding on sorghum (Zhu-Salzman et al. 2004), the peach potato aphid (PPA), *Myzus persicae*, feeding on *Arabidopsis thaliana* and potato, *Solanum tuberosum* (Fidantsef et al. 1999; Moran and Thompson 2001; Moran et al. 2002), and potato aphid feeding on potato and tomato (Fidantsef et al. 1999; Martinez de Ilarduya et al. 2004). Results of experiments with RWA feeding on wheat, and the tobacco aphid, *Myzus nicotianae*, feeding on wild tobacco, *Nicotiana attenuate*, indicate the involvement of JA signaling but only marginal activity of SA signals in these interactions (Voelckel et al. 2004; Boyko et al. 2006).

Ethylene production increases significantly after aphid feeding on the foliage of aphid-resistant barley or wheat plants compared with susceptible plants (Miller et al. 1994; Argandona et al. 2001; Boyko et al. 2006), and sequences that code for proteins involved in ET production are over-expressed in aphid-infested *Arabidopsis* and celery, *Apium graveolens*, plants (Moran et al. 2002; Divol et al. 2005). Jasmosinc acid and ET are synergistic in the defense responses of *Arabidopsis* resistance to the peach potato aphid (Dong et al. 2004) and in the induction of defense responses in squash, *Cucurbita moschata*, foliage to feeding by the silver leaf whitefly, *Bemisia argentifolii*, (van de Ven et al. 2000). WRKY proteins (with the conserved amino acid sequence WRKYGQK) modulate JA-SA interactions in *Arabidopsis* pathogen response (Li et al. 2004) and *WRKY* upregulation in tobacco plants infested by the tobacco aphid suggests that JA-SA interactions also play a role in plant defense responses to aphids (Voelckel et al. 2004). Sequences putatively involved in ABA and GA biosynthesis are

upregulated in aphid-infested foliage of celery, sorghum, and wheat (Zhu-Salzman et al. 2004; Divol et al. 2005; Boyko et al. 2006; Park et al. 2006).

The objectives of this study were to develop an understanding of the molecular and phytochemical bases of RWA resistance in wheat plants that contain the *Dnx* RWA resistance gene. Microarray, real-time PCR, and phytohormone assays were used to identify transcriptome components and phytohormones that were differentially regulated in RWA-infested *Dnx* plants and susceptible (*Dn0*) plants. Previous research (Dong et al. 2004; Voelckel et al. 2004; Boyko et al. 2006; Park et al. 2006), led us to hypothesize that unique components of the *Dnx* transcriptome in the ROS, oxylipin, ABA, and terpenoid pathways are activated by RWA feeding, and that these proteins may function to mediate the expression of the *Dnx* plant phenotype.

Methods and Materials

Plant Genotypes and Aphids A wheat landrace from Afghanistan (USDA Plant Introduction 220127) (Harvey and Martin 1990) containing the RWA resistance gene *Dnx* (Liu et al. 2001) was crossed to the RWA-susceptible wheat genotype 'Sando's Selection 4040' (*Dn0*), originally developed at Oklahoma State University. F_2-derived F_3 family plants originating from this cross were bulked into groups of 10 resistant plants and 10 susceptible plants according to their reaction to RWA biotype 1 (RWA1) infestation (Liu et al. 2001). Bulk lines were advanced to the F_4 generation. Seeds of resistant and susceptible F_4 lines were planted in 12 cm diam plastic pots containing Jiffy® potting mix and grown in the greenhouse during July 2005 at 30°C day: 22°C night, and a photoperiod of 14:10 (L:D). Supplemental lighting was provided from sodium halide lamps. Experiments were conducted in the greenhouse under the same conditions. Seed stocks are currently maintained by the Plant Resistance Laboratory, Department of Entomology, Kansas State University (KSU), Manhattan, KS, USA. RWA biotype 1 (RWA1) used in all experiments originated from a culture established with aphids collected from Hays, KS, in 2004, courtesy of Dr. J. P. Michaud, KSU Dept. of Entomology, Hays, KS. The culture was maintained on RWA-susceptible 'Jagger' wheat plants at the environmental conditions described above for plant growth.

In total, 140 plants with the *Dnx* gene and 110 plants lacking the gene (*Dn0*) were assessed across five different experiments. These included plant phenotyping experiments to classify plant and aphid responses to each other (20 plants of each genotype), a microarray experiment to assess wheat EST expression (90 *Dnx* plants, 60 *Dn0* plants), northern blot verification of microarray results (9 plants of each genotype), real-time PCR verification of microarray results (9 plants of each genotype), and phytohormone experiments (12 plants of each genotype).

Phenotype Evaluations The previously reported resistance of *Dnx* and susceptibility of *Dn0* plants to RWA1 (Liu et al. 2001; Boyko et al. 2006) was confirmed in experiments to measure phenotypic damage expression, tolerance resistance, and antibiosis resistance with protocols of Boyko et al. (2006). Pre-germinated *Dnx* and *Dn0* F_4 seeds were planted in pots and allowed to grow to the two-leaf stage. Plants were paired for height and growth (*Dnx* with *Dnx*, *Dn0* with *Dn0*), and one plant of each pair was infested with five RWA1 late stage nymphs. The remaining plant of each pair was not infested and used as a control. All pots were covered with individual nylon-mesh cages, and 10 pairs (replicates) of plants were arranged in a randomized complete block design. When the infested *Dn0* plants showed complete leaf rolling and 95% chlorosis of the youngest leaf (~21 d), cages were removed and leaf chlorosis, leaf rolling and leaf folding damage sustained from RWA1 feeding was rated on a 0–3 scale for each symptom; where 0 = no damage, 1 = <50% symptoms, 2 = >50% symptoms and 3 = 100% symptoms/ dead plant) (Smith et al. 1991).

Tolerance resistance, the ability of a plant to withstand arthropod damage and yield significantly greater dry mass than a susceptible plant under similar conditions of infestation (Smith 2005), was measured by calculating the proportional plant dry weight change (DWT) of *Dnx* and *Dn0* plants as $DWT = [(WC - WT)/WC] \times 100$, where WC was the dry weight of the uninfested control plant, and WT was the dry weight of the infested plant (Reese et al. 1994). The shoots from uninfested and infested plants were cut at the soil surface, placed in aluminum foil pouches, dried in an oven at 75°C for 72 h, and tissue weights were determined.

Antibiosis resistance, in which the plant adversely affects the growth and development of the arthropod, was determined by counting the numbers of RWA1 on the infested plants in each of the pairs of plants in the tolerance experiment. Aphids produced on infested plants of each genotype were removed with a camel's-hair brush, collected on wax paper, funneled into vials of 95% EtOH, and counted. A tolerance index (TI) was calculated by using the equation: plant DWT/number of aphids produced on the infested plants (Reese et al. 1994). The plant TI was determined to compensate for the confounding effect of differing numbers of RWA1 on infested plants. Genotypes with TI values significantly lower than those of the susceptible control plants were considered tolerant. Data for plant damage, plant DWT, plant TI, and RWA1 population development were subjected to ANOVA by using the SAS GLM procedure (SAS 2001). Where significant, treatment means were separated by using the LSD at α=0.05.

RNA Extraction For the microarray hybridization experiments, RNA was extracted from leaves of *Dnx* and *Dn0* plants at the two-leaf stage of growth when the 3rd leaf was beginning to unfurl. Plants were grown in the greenhouse as mentioned previously and were not under drought stress. There were three replications of *Dnx* infested plants, three replications of *Dnx* uninfested plants, two replications of *Dn0* infested plants, and two replications of *Dn0* uninfested control plants. Each replicate of each treatment contained 15 plants. Each of the 15 treatment plants was infested with approximately 50 RWA1 late stage nymphs and adults. In each treatment replicate, leaves of all plants were harvested 24 h after infestation, pooled, quick frozen in a freezer at −80°C, and ground in liquid N_2. Total RNA was extracted from pooled leaves with TRI Reagent™ following the manufacturer's protocol (Molecular Research Center Inc., Cincinnati, OH, USA). RNA samples were purified with a RNease Kit following the manufacturer's instruction from QIAGEN Inc. (Valencia, CA, USA). RNA concentrations were measured by using a NanoDrop-1000 Spectrophotometer from NanoDrop Technologies (Wilmington, DE, USA). RNA quality was checked with an Agilent 2100 Bioanalyzer following the Reagent Kit guide from Agilent Technologies (Foster City, CA, USA).

Microarray Hybridization and Data Analysis The Affymetrix GeneChip® Wheat Genome Arrays (Santa Clara, CA, USA) contain 61,127 probe sets representing 55,052 transcripts for all 42 chromosomes in the wheat genome on a single array. The array includes ESTs from *T. monococcum, T. turgidum*, and *Ae. tauschii,* and GenBank® full-length mRNAs from all species through May 18, 2004. Labeling and hybridization of arrays were performed according to the standard protocol provided by Affymetrix. (www.affymetrix.com/support/technical/manual/expression_manual.affx). After hybridization and washing, arrays were scanned with an Affymetrix GeneChip Scanner 3000. Hybridization quality was verified by scaling factor, overall hybridization rate, and signal strength of several bacterial spike controls. The spike controls were hybridized with labeled targets in different concentrations resulting in particular ratios between different spikes.

Image acquisition, image settings, and raw data generation were accomplished with Affymetrix GeneChip® Operating Software (GCOS). After alignment of the image settings for each chip, raw data were extracted and marked as "present" (well above the background), "marginal," or "absent" (similar to, or below the background) under default settings. The overall target signal intensity of each chip was scaled to 500 and then loaded into GeneSpring GX 7.3.1 software (Agilent Technologies, Palo Alto, CA, USA) for further analysis. The data were pre-normalized to the 50th percentile per chip and then normalized based on per-gene normalization with the median method, from which the signal of each gene in a particular sample was divided by the median signal of the same gene in all samples.

Normalization per gene and per chip of the log2 values was performed to allow the comparison of the independent replicates performed in the experiment. Normalization was performed for all measurements by using the flags ("present," "marginal," or "absent") assigned by Affymetrix treatment of the arrays. However, only those transcripts that were declared present or marginal in at least 4 of the 6 microarrays hybridized with RWA-resistant *Dnx* probes and 3 of the 4 arrays hybridized with RWA-susceptible *Dn0* probes were taken into account. This procedure facilitated the elimination of transcripts with very low signals in both treatments (declared "absent").

The resulting genes that exhibited significant changes in expression in comparisons between treated and control *Dnx* or *Dn0* plants were selected by applying a *t*-test (one-way ANOVA Welch *t*-test, $P>0.05$ with "Benjamini and Hochberg False Discovery Rate" for multiple comparisons $\alpha=0.05$). A cutoff value of a 2-fold change, commonly used for microarray analysis, was used to discriminate the expression of genes that were differentially altered in response to RWA feeding. Fold change values were calculated between treatment and control samples based on the normalized average measurement of the signal intensity. The number of sequences examined was further narrowed after eliminating those with raw expression values of <600 units.

Comparisons of changes in differential up- or downregulation of gene expression between RWA-infested *Dnx* and *Dn0* plants were discriminated by using the CEDA (Comparative EST Data Analysis) virtual subtraction procedure developed by Wang and Zhang (2004). Genes expressed in uninfested control plants were removed from those in infested plants with the formula: [(*Dnx* infested-*Dnx* control)-(*Dn0* infested-*Dn0* control)] for *Dnx* plants, and [(*Dn0* infested-*Dn0* control)-(*Dnx* infested-*Dnx* control)] for *Dn0* plants. The CEDA output provided a list of candidate up- or downregulated genes, uniquely expressed in *Dnx* infested plants or *Dn0* infested plants, and sorted by the statistical significance of change in gene expression.

The nucleotide sequences identified after probing and hybridization of arrays were clustered by using the CAP3 software tool with default settings (Huang and Madan 1999). From 61,290 array probe sequences, a non-redundant dataset containing 7,511 contigs and 42,863 singletons was obtained that allowed the comparison of the expression of different probes mapped to a single contig. To understand gene function, non-redundant sequences were searched against the UniProt reference database (Bairoch et al. 2005) with the BLASTX program downloaded from the NCBI site (ftp://ftp.ncbi.nih.gov/blast/). Queried sequences were annotated by using the best hit in UniProt with an E value threshold of 1^{e-5}. Functional annotation included text

description as well as gene ontology terms of each matched reference sequence (Camon et al. 2003), to understand the biological processes involving genes of interest. Unique known transcripts in *Dnx* and *Dn0* plants were compared for similarity to known genes, and these genes were classified by function.

Northern Blot Analyses To validate the expression of ESTs in the microarray hybridzation experiment, a separate northern blot experiment was conducted with total RNA isolated from fresh leaf tissue of RWA-infested resistant (containing the *Dnx* gene) and susceptible (containing the *Dn0* gene) wheat plants infested with 20 RWA biotype 1 late stage nymphs per plant. Tissues were collected at 6-, 12-, 24-, 72-, and 120 h post-infestation, and RNA was extracted with TRI reagent™ (Molecular Research Center). Each treatment consisted of RNA pooled from two biological replicates, and each replicate contained leaf tissue from 3 plants, for a total of 6 plants. Three separate uninfested *Dnx* plants and 3 separate uninfested *Dn0* plants served as non-infested controls. Tissues were collected from plants at each time point. Five µg of total RNA from each treatment were subjected to electrophoresis in denaturing 1.5% agarose gels containing formaldehyde and transferred onto a GeneScreen membrane (Perkin-Elmer Life Science Inc., Boston, MA, USA). Gels were stained with ethidium bromide, and rRNA levels were compared to control for equal loading. Membranes were baked at 80°C for 2 h to fix the RNA and then hybridized separately to individual probes. Primers for PCR amplification were generated at the KSU Core Biotechnology Facility by using selected sequences from the Affymetrix GeneChip® Wheat Genome Array EST files (Table 1). Probes were derived by PCR amplification of plant template cDNAs and labeled with ^{32}P-dCTP by using the random labeling kit from Stratagene (La Jolla, CA, USA). Prehybridization (4 h) and hybridization (overnight) were carried out at 42°C in hybridization buffer (Chen et al. 2004). Membranes then were washed at medium stringency [2x SSC at room temperature for 30 min, 2x SSC, 1% sodium dodecyl sulphate (SDS) at 65°C for 30 min, and 0.1x SSC, 0.1% SDS at room temperature for 30 min]. Blots were placed against X-ray film (Kodak) and hybridization patterns were visualized by autoradiography.

Real-time Quantitative PCR Analyses Real-time PCR was used to confirm the expression of six stress response or cellular metabolism genes in leaf tissues from both *Dnx* and *Dn0* plants. These genes had been shown previously to be highly downregulated in the transcriptome of *Dnx* plants at 24 hpi. Genes included Q9P3N1 (hypothetical stress response protein), Q5ZD81 (calmodulin-like protein), Q6Z1A3 (putative NAC1 stress response protein), Q6Z1A3 (putative cytochrome P450), Q7XN01 (transcription protein), and Q6I5G9 (mitochondrial ATP synthase). Primers were designed based on Affymetrix™ Gene Chip EST sequences and GeneBank by using the software package Beacon Designer. Primers sequences are shown in Table 1.Wheat actin (AB181991) was used as an internal control. Total RNA was isolated as described for northern blotting. After purification with TURBO™ DNA-free (Ambion, Austin, TX), 2 µg total RNA were reverse transcribed into cDNA by using a SuperScript III First-Strand cDNA Synthesis System (Invitrogen) following the manufacture's protocols.

The change in expression of these genes was determined at 6-, 12-, 24-, 72-, 96-, and 120 hpi in tissues from *Dnx* and *Dn0* plants infested with 20 RWA biotype 1 late stage nymphs per plant. For each post-infestation—genotype treatment, RNA was collected from two biological replicates, each consisting of leaves pooled from 3 plants. Three separate uninfested *Dnx* plants and 3 separate uninfested *Dn0* plants served as non-infested controls. Real-time PCR was performed with iQ™ SYBR Green Supermix (BIO-RAD) by using the flowing amplification protocol: 5 min denaturation at 95°C, 40 cycles of 30 s at 95°C, 20 s at 53°C, and 45 s at 72°C. This was followed by product melt to confirm a single PCR product. Gene downregulation fold change was calculated as: $2^{\Delta\Delta Ct}[\Delta\Delta Ct = (Ct_{GOI}In - Ct_{GOI}Un) - (Ct_{HKG}In - Ct_{HKG}Un)]$, where GOI = gene of interest, In = infested sample, Un = uninfested sample, HKG = wheat-actin gene. Data for mean downregulation of each gene were subjected to ANOVA by using the SAS GLM procedure (SAS 2001). Where significant, treatment means were separated by using the LSD at α=0.05.

Phytohormone Analyses Individual two leaf stage plants containing *Dnx* or *Dn0* were grown in 10 cm diam. plastic pots filled with Pro-MixBx® potting mix, in the greenhouse [24°C day: 20°C night, photoperiod of 14:10 (L:D)]. Six *Dnx* or 6 *Dn0* plants were each infested for 12-, 24-, 48-, or 96 h with 20 to 30 RWA1 late stage nymphs and adults per plant. Six uninfested *Dnx* or *Dn0* plants collected at 24 h post-infestation served as uninfested controls for all infested *Dnx* or *Dn0* treatments. At the end of each infestation period, all above ground foliage from plants in each treatment were harvested, placed a in freezer at −80°C, ground to powder in liquid N_2, weighed, and analyzed.

Plant powders were extracted in 300 µl cold 1-propanol : H_2O : HCl (2:1:0.005), centrifuged for 1 min, the organic layer transferred to a glass tube, and diluted with 20 µl of 2 M trimethylsilyldiazomethane:methylene chloride (1:4). Each extract then was combined with 20 µl of (12:88 acetic acid:hexane) : methylene chloride (1:4) and allowed to stand overnight to quench methylation. Samples were placed in SuperQ columns, where phytohormones were

removed by vapor phase extraction and eluted from columns with 100–200 µl of methylene chloride into GC vials. The residual solvent from each SuperQ column was removed and added to each sample vial with a N_2 stream. Due to sampling errors from damage to tissues or sample loss during vapor phase extraction, the number of replications analyzed for each phytohormone treatment varied from N=3 to N=6.

Samples were subjected to quantitative analyses by using an HP 6890 gas chromotograph and HP 5973 mass spectrometer in the KSU Lipidomics Research Center. Total ion counts were acquired and processed by using Agilent Chemstation software, AMDIS (www.amdis.net), and MET-IDEA (Broeckling et al. 2006; http://www.noble.org/plantbio/ms/MET-IDEA/index.html). Plant tissue data were normalized by fresh weight, and sample ion counts were expressed as per cent ng/g standard. Spectral data were subjected to log e transformation and analyzed by using SAS PROC GLM with unequal variance (SAS 2001). The procedures used for tissue preparation, extraction, sample acquisition, and GC-MS analyses are detailed in Schmelz et al. (2004).

Samples were evaluated for content of the following phytohormones and fatty acids: methyl abscisic acid (ABA); methyl benzoate (BA); methyl *trans*-cinnamate (CA); methyl salicylate (SA); *cis*- and *trans* methyl jasmonate (JA); *cis*- and *trans*-methyl-12-oxophytodienoic

acid (12-OPDA); the saturated 16:0 and 18:0 fatty acids, and the 16:1, 16:3, 18:1, 18:2, and 18:3 unsaturated fatty acids. Internal standards were as follows: ABA – (*S*)-5-(1-hydroxy-2, 6, 6-trimethyl-4-oxo-2-cyclohexen-1-yl)-3-methyl-(2Z,4E)-pentadienoic acid; BA—(ring-$^{13}C_6$) benzoic acid methyl ester; CA – (E)-3-phenyl-2-propenoic acid methyl ester; SA – 2-hydroxybenzoic acid methyl ester; and JA – 3-oxo-2-(2-pentenyl) cyclopentaneacetic acid. The CA internal standard was used to calculate the amount of each methyl fatty acid, OPDA-Me trans, and OPDA-Me cis. In several previous experiments, the relative instrument response of CA/methyl 19:0 fatty acid was 0.137 ng/ng.

Results

Phenotype Evaluations F_4 plants containing the RWA1 resistance gene *Dnx* displayed limited leaf rolling symptoms (1.8±0.62, mean ± SE) and leaf chlorosis symptoms (1.8±0.13, mean ± SE), compared to F_4 plants lacking *Dnx* (*Dn0*) (mean ± SE leaf rolling=2.9±0.12, mean ± SE chlorosis=3.0±0.34). (Both symptoms rated on a 0–3 scale; 0=no damage, 3=100% symptoms).

Both antibiosis and tolerance function in RWA1 resistance imparted by other *Dn* genes (Hein 1992; Smith et al. 2004; Voothuluru et al. 2006), and in tolerance experiments infested *Dnx* plants sustained significantly ($P<0.009$) smaller changes in proportional plant dry weight (DWT) compared with *Dn0* plants (Fig. 1b). However, when RWA1 population sizes on *Dnx* and *Dn0* plants were used to compute a tolerance index (TI) to compensate for different population sizes, the observed differences in plant DWT were not significant (data not shown). Nevertheless, leaves of *Dnx* plants exhibited significantly less leaf rolling and leaf chlorosis compared to *Dn0* plants, thus demonstrating their ability to tolerate RWA1 feeding and chloroplast destruction.

Dnx and Dn0 Plant Transcriptomes There were distinct and dramatic quantitative differences in the unannotated transcriptomes of RWA1-infested plants and uninfested plants containing *Dnx* and *Dn0*. Infested *Dnx* plants upregulated 1,137 genes and downregulated 171 genes that were expressed at significantly ($P\leq0.05$) greater levels compared to uninfested control plants (Table 2). In contrast, infested *Dn0* plants significantly upregulated only 201 genes and downregulated 16 genes.

The CEDA virtual subtraction procedure (Wang and Zhang 2004) was applied to the data in Table 2 to identify genes uniquely expressed in *Dnx* infested plants or *Dn0* infested plants. This was accomplished by using the formulae [(*Dnx* infested-*Dnx* control)-(*Dn0* infested-*Dn0* control)] for *Dnx* plants, and [(*Dn0* infested-*Dn0* control)-(*Dnx* infested-*Dnx* control)] for *Dn0* plants. CEDA subtraction yielded 551 upregulated genes and 43 downregulated genes in infested *Dnx* plants (≥2-fold expression differences, $P\leq0.05$). Of these genes, 401 of the upregulated transcripts and 27 of the downregulated transcripts were of unknown function. After ontology and grouping, 161genes unique to RWA1-infested *Dnx* plants were significantly upregulated and only 17 genes were significantly downregulated (Table 3). After virtual subtraction of the *Dn0* transcriptome, followed by ontology and grouping, 38 genes were found to be significantly upregulated and 14

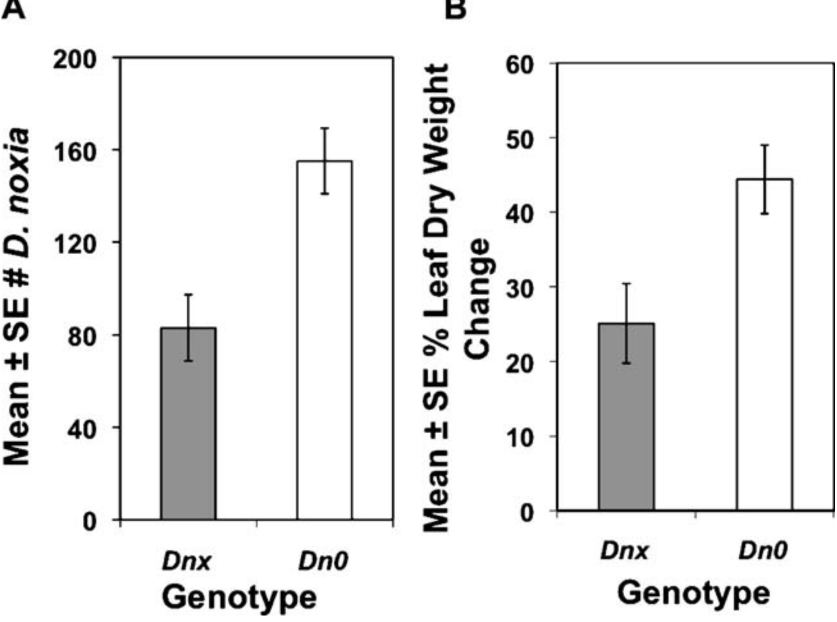

Fig. 1 Phenotypic responses of Russian wheat aphid biotype 1 (RWA1) and RWA1-resistant (*Dnx*) and susceptible (*Dn0*) plants at 21 d post infestation: (**a**) Mean ± S.E. RWA population development (differences significant at $P=0.001$); (**b**) Mean ± S.E. percent proportional leaf dry weight changes as determined by DWT = [(dry wt. of uninfested control plant−dry wt. of infested plant)/dry wt. of uninfested control] ×100 (differences significant at $P=0.009$); $N=10$

Table 2 Numbers of genes exhibiting significant changes in expression[a] in comparisons between infested[b] and uninfested plants of wheat genotypes resistant (*Dnx*) and susceptible (*Dn0*) to Russian wheat aphid biotype 1

Genotype/treatment comparison	Number of upregulated genes	Number of downregulated genes
Dnx infested versus *Dnx* uninfested control	1,137	171
Dn0 infested versus *Dn0* uninfested control	201	16

[a] $P \leq 0.05$, minimum 2-fold change

[b] 24 h post infestation

genes were found to be significantly downregulated (Table 3). The putative functions of affected transcripts in both genotypes were related to plant cell wall disruption; the initiation of defense responses; ROS production; ABA-, ET-, JA-, and SA signaling; phytopathogen defense responses; and arthropod allelochemical and physical defenses (Table 3). We found differences in the *Dnx* and *Dn0* transcriptomes after annotation (Table 3), compared to before annotation (Table 2), as well as before and after application of the CEDA virtual subtraction procedure.

Plant Cell Wall Disruption Numerous transcripts with putative functions in the cell wall were 2- to 6-fold upregulated in infested *Dnx* plants (Supplemental Data Table 1). These transcripts include cereal β-1,3-glucanase (*GLG*), chitinase (*Chia)*, protein kinase, and WIR1 (*WIR1*) membrane proteins based on sequence similarity. Among them, *GLG* and *Chia* were completely absent in infested *Dn0* plants. On the other hand, infested *Dn0* plants expressed two membrane proteins (Supplemental Data Table 2) that were not expressed in infested *Dnx* plants.

On northern blots, *GLG*, *Chia-3*, and *WIR1B* exhibited a similar expression pattern (Fig. 2a). They were expressed very little in uninfested *Dnx* plants, upregulated slightly at 6 hpi, and strongly at 12 hpi in infested *Dnx* plants. The elevated transcript levels in infested *Dnx* plants gradually decreased after 24 hpi. These three genes were either not upregulated or much less upregulated in infested *Dn0* plants until 72 or 120 hpi, when a significant elevation of the level of these transcripts was observed.

ROS Production Several genes related to *ROS* metabolism, including *GST*, Ca^{++} and Fe^{++} binding proteins, *CYP450*, oxidoreductases, and peroxidases, were 2- to 8-fold upregulated in infested *Dnx* plants responding to RWA1

Table 3 Numbers of annotated genes in different functional classes expressed[a] in wheat plant leaves containing the *Dnx* resistance gene or *Dn0* susceptibility gene after phloem feeding by Russian wheat aphid biotype 1[b] as determined by the Comparative EST Data Analysis virtual subtraction procedure[c]

Gene functional class	Number of upregulated genes		Number of downregulated genes	
	Dnx	*Dn0*	*Dnx*	*Dn0*

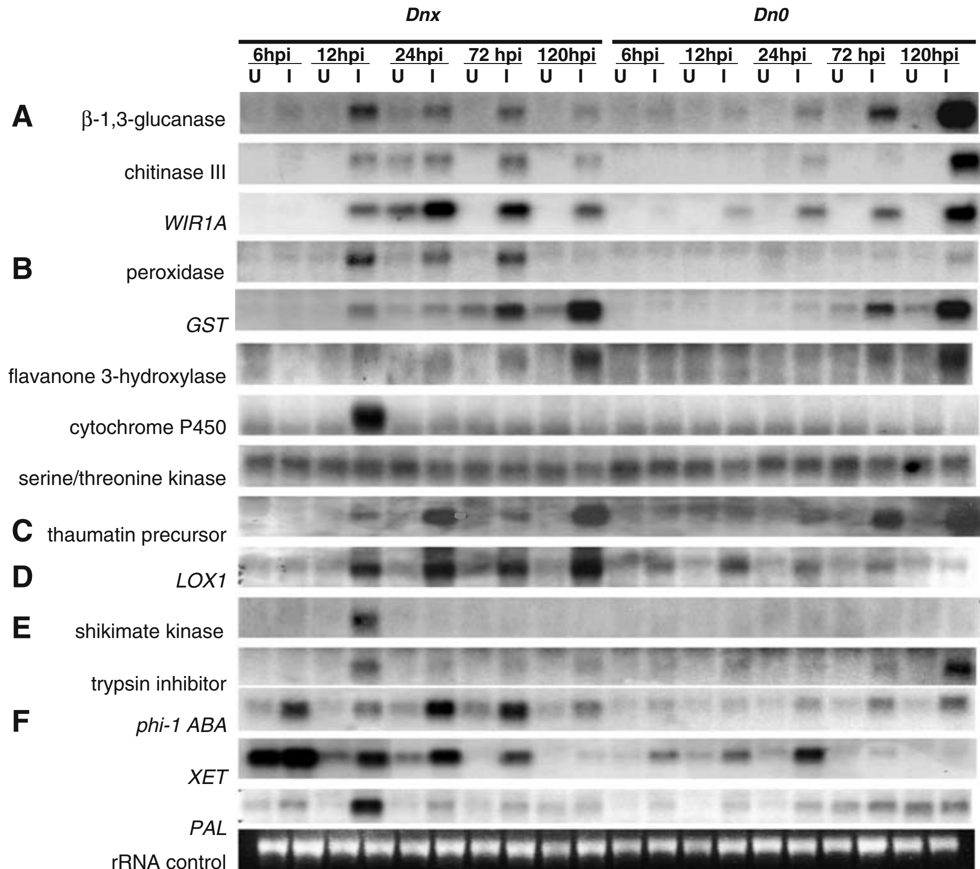

Fig. 2 Temporal upregulation of wheat transcripts from Russian wheat aphid biotype 1 (RWA1)—infested (I) and control uninfested (U) plants containing the RWA1 resistant (*Dnx*) or susceptible (*Dn0*) genes. (**a**) Membrane protein genes—Q9XEN7 *β*-1,3-glucanase, Q8W427 chitinase III, Q01482 *WIR1A* membrane protein; (**b**) ROS response genes—Q43212 peroxidase precursor, Q8S702 glutathione S-transferase, Q8H8H7 flavanone 3-hydroxylase, Q9AVM3 cytochrome P450, Q5BQ31 serine/threonine kinase; (**c**) P27357 thaumatin-like protein PWIR2 precursor (SA metabolism); (**d**) P29114 *LOX1* lipoxygenase 1 (JA precursor); and (**e**) Aphid anti-digestion/toxin genes—Q5NTH3 shikimate kinase 2, P12940 Bowman-Birk trypsin inhibitor; F. Dehydration response genes—Q6Z676 *phi-1* ABA dehydration signaling, P93671 *XET* xyloglucan endotransglycosylase, Q43210 *PAL* phenylalanine ammonia lyase. Northern blot analysis of 5 µg of total RNA from the leaves of *Dnx* or *Dn0* plants at 6-, 12-, 24-, 72- and 120 h post infestation (hpi) with RWA biotype 1 adults. Filters were hybridized with probes derived from cDNA clones of Affymetrix EST sequences encoding each gene shown on left. Gels were stained with ethidium bromide and rRNA levels compared to control for equal loading (shown is representative loading on a single gel). Each lane represents RNA pooled from two biological replicates, each consisting of leaves from three plants

feeding (Table 3, Supplemental Data Table 1), but their expression was approximately one-half that level in *Dn0* plants (Table 3, Supplemental Data Table 2). On northern blots, the levels of these transcripts were strongly upregulated in infested *Dnx* plants at least at one post infestation time point (Fig. 2b). The levels of these transcripts were either unaffected or less elevated in infested *Dn0* plants.

Defense Signaling Results of microarray analyses produced transcripts putatively associated with the SA signaling pathway. These included Pathogenesis-Related-1 (*PR1*), *PR4*, *PR5*, and *WRKY* (Yalpani et al. 1991; Dong et al. 2003), which were 2- to 7-fold upregulated in infested *Dnx* plants (Supplemental Data Table 1). In contrast, transcripts associated with the JA signaling pathway including *FAD3C*, *DAD1 LOX1*, *ACS1*, *12-OPR,* OPDA hydrolases, 12-OPDA ABC transporters (Dhondt et al. 2000; Ishiguro et al. 2001; Liechti and Farmer 2002; Theodoulou et al. 2005) were 2- to 4-fold upregulated in infested *Dnx* plants (Supplemental Data Table 1). Transcripts associated with ABA and ET signaling pathways increased from 2- to 4-fold in infested *Dnx* plants (Supplemental Data Table 1). These included EIN-3-like proteins, AP2 domain-containing transcription factors, C2 GRAM domain-containing proteins, and putative phi-1 proteins (Zhu 2002; Zhang et al. 2004) (Supplemental Data Table 1). None of these genes were upregulated in infested *Dn0* plants (Supplemental Data Table 2).

Pest/Pathogen Defenses Dnx-based resistance to RWA is manifested as reduced aphid population growth (Boyko et al. 2006; Khan et al. 2009; Lazzari et al. 2009), which may be a result of suppressed aphid feeding, an inhibition of aphid

digestion or a combination of both. Plant secondary metabolites suppress insect feeding, and several transcripts associated with secondary metabolite production including cycloartenol synthase, monoterpene synthase, and shikimate kinase were upregulated 2–4 fold in RWA1-infested *Dnx* plants (Supplemental Data Table 1). On northern blots, the transcript coding for shikimate kinase was expressed in infested *Dnx* leaves at 12 hpi but was absent in *Dn0* plants at all post-infestation time points (Fig. 2e). Further, the transcript encoding a UDP-glucose glucosyltransferase, an enzyme that transfers glucose UDP-glucose to terpenes (Xiong et al. 2001, Scharrenberg et al. 2003), was upregulated 2- to 4-fold (Supplemental Data Table 1). Various enzyme inhibitors limit digestion in the insect gut (Gatehouse and Boulter 1983). A transcript encoding a Bowman-Birk trypsin inhibitor was upregulated at 12 hpi in *Dnx* infested plants, but this transcript was not significantly affected by RWA1 feeding in *Dn0* plants until a very late time point (120 hpi) (Fig. 2e). Interestingly, several phytoalexin and pathogen resistance genes underwent 2- to 4-fold upregulation in infested *Dnx* plant foliage, including *ACRE, HHT, SMM:HSM, and SNAP* (Supplemental Data Table 1), but these transcripts were not expressed in *Dn0* infested plants (Supplemental Data Table 2).

Downregulated Transcripts Transcripts downregulated in plants of each genotype possessed various functions (Table 3, Supplemental Data Tables 3 and 4) and several representative downregulated transcripts were chosen for real-time PCR to confirm microarray results (Fig. 3, Supplemental Data Figs. 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13 and 14.). There were no significant differences in downregulation of the stress response protein in either *Dnx* or *Dn0* tissues at 6-, 12-, 24-, or 72 hpi (Fig. 3a). A calmodulin-like gene displayed similar patterns, and in both *Dnx* and *Dn0* infested tissues, downregulation was significantly greater at 24- and 120 hpi than at 6- or 12 hpi (Fig. 3b). A transcript encoding a NAC domain pathogen response protein (Collinge and Boller 2001) was strongly downregulated in infested *Dnx* plants (Fig. 3c), and was significantly greater in *Dnx* tissues at 72- and 120 hpi than at 6-, 12-, or 24 hpi. There were no differences in expression between any post-infestation times in *Dn0* tissues. Expression of *CYP450* CA619079 was relatively low in *Dnx* and *Dn0* tissues (Fig. 3d), but was significantly greater in *Dnx* infested tissues at 24- and 120 hpi compared to 6- and 12 hpi. There were no differences in expression between *Dnx* infested tissues collected at 72 hpi and any other post-infestation time (Fig. 3d). In *Dn0* infested tissues, there were no differences in the expression of CYP450 at any post-infestation time. Downregulation of a transcription protein and a mitochondrial ATP synthase in *Dnx* plants was significantly greater in *Dnx* tissues at 120 hpi than at 6 hpi (Fig. 3e, f). There were no significant temporal differences in downregulation of either protein in *Dn0* tissues.

Phytohormone Analyses The concentration of the 16:1 fatty acid in infested *Dnx* and *Dn0* plants increased significantly ($P<0.001$) at 12-, 24-, and 48 hpi, but returned to the control level at 96 hpi (Table 4). The concentration of 16:3 fatty acid increased dramatically in infested *Dnx* and *Dn0* plants at 48 hpi, where it was significantly greater in *Dnx* plants than *Dn0* plants. There were comparatively fewer significant differences between treatments for the 18:1 and 18:3 fatty acids. The 18:1 fatty acid content of both *Dnx* and *Dn0* infested tissues was significantly ($P<0.001$) greater than uninfested controls at 96 hpi. The 18:3 fatty acid content of *Dnx* infested plants was significantly ($P<0.001$) greater than the uninfested control at 12 hpi, and in *Dn0* plants, significantly ($P<0.001$) greater than the control at 12- and 24 hpi. This trend was similar for the 18:2 fatty acid, but the only significant increase in *Dnx* tissues over *Dn0* tissues occurred at 12 hpi (data not shown). There were no significant differences between two genotypes at any time point for 16:0 or 18:0 fatty acids (data not shown).

The *cis*- and *trans*-Me-OPDA content differed significantly ($P<0.001$) between post infestation times in leaves of *Dnx* and *Dn0* plants, and between the genotypes at each post infestation time (Table 5). In *Dnx* plants, *cis*-Me-OPDA content increased dramatically to 2.3% at 24 hpi, and was significantly ($P<0.001$) greater than the uninfested control or any other *Dnx* post infestation time. In contrast, *cis*-Me-OPDA content in *Dn0* plants was reduced at each hpi time compared to that produced in uninfested plants, and reductions were significant ($P<0.001$) at 12- and 24 hpi (Table 5). With the exception of the 24 hpi treatment, *cis*-Me-OPDA content was significantly greater in *Dn0* plants (including uninfested controls) than the corresponding *Dnx* plant treatments. Expression of *trans*-Me-OPDA was more pronounced than *cis*-Me-OPDA. In *Dnx* plants, *trans*-Me-OPDA content was significantly greater at 12-, 24-, and 48 hpi than in uninfested controls, and decreased to the level of the 0 h uninfested control at 96 hpi. As with *cis*-Me-OPDA, production of *trans*-Me-OPDA in uninfested *Dn0* plants was significantly greater than in uninfested *Dnx* plants (Table 5). However, the *trans*-Me-OPDA content of *Dn0* infested plants at all hpi intervals was significantly less than untreated *Dn0* control plants and significantly lower than that of each corresponding *Dnx* plant hpi time. In contrast to Me-OPDA, there were no significant trends in differences in *cis*- or *trans*-methyl jasmonate (meJA) content at different time points or between *Dnx* and *Dn0* plants (data not shown).

Abscisic acid (ABA) content in *Dnx* plant foliage was significantly ($P<0.001$) greater at 12- and 48 hpi than in uninfested plants (Table 6) and was significantly greater in

Fig. 3 Temporal downregulation (mean ± S.E fold change) of wheat transcripts from plants containing the RWA resistant (*Dnx*) or susceptible (*Dn0*) gene at 6-, 12-, 24-, 72- and 120 h post infestation with RWA biotype 1 adults. (**a**) Q9P3N1 hypothetical stress response protein; (**b**) Q5ZD81 calmodulin-like protein; (**c**) Q6Z1A3 NAC1 stress response protein; (**d**) Q6YXE1 cytochrome P450 (**e**) Q7XN01 transcription protein; and (**f**) Q6I5G9 mitochondrial ATP synthase. Each treatment mean represents two biological replicates, each consisting of leaves pooled from three *Dnx* or *Dn0* plants

Dnx plants than in *Dn0* plants at 48 hpi. ABA content in the foliage of *Dn0* plants was elevated at 12- and 24 hpi, but these amounts were no different from those of the uninfested control. The leaf content of benzoate, a salicylic acid intermediate, increased significantly ($P<0.001$) in *Dnx* foliage at 12-, 24-, and 48 hpi compared to the 0 h control, and a similar trend was absent in *Dn0* plants (Table 6). In addition, the benzoate content of infested *Dnx* plants was significantly

Table 4 Mass (% ng/g standard) of unsaturated 16:1 (7-hexadecenoic), 16:3 (7,10, 13-hexadecatrienoic), 18:1 (9-octadecenoic), and 18:3 (9,12,15-octadecatrienoic) fatty acids in leaves of Russian wheat aphid biotype 1—resistant (*Dnx*) and susceptible (*Dn0*) wheat genotypes at 12-, 24-, 48-, and 96 h post-aphid infestation (hpi), and in 0 h uninfested control plants

[a] For each fatty acid, means within a column followed by the same letter are not significantly different at $P<0.001$

greater than in *Dn0* plants at one time point (48 hpi). However, there were no differences in methyl salicylate leaf content between any of the *Dnx* or *Dn0* post infestation treatments (data not shown). The amounts of the related SA intermediate *trans*-cinnamate also increased over time in both *Dnx* and *Dn0* plants, but the quantities were no different from those of uninfested control plants (data not shown).

Discussion

Plant resistance to insects is a complex process, often involving numerous plant biochemical pathways. We hypothesized that the products of unique defense proteins in the *Dnx* plant transcriptome are activated by RWA1 feeding probes, resulting in expression of the *Dnx* plant phenotype. Results from microarray hybridizations, northern blot and real-time PCR assays, and vapor phase extraction of foliar phytohormones support this hypothesis. The results that we obtained identify unique differences in the molecular responses of resistant *Dnx* plants to RWA attack in comparison with those of susceptible *Dn0* plants, and suggest that 16 carbon membrane fatty acids; oxylipins, ABA, and ET defense response signals; and downstream defense proteins are likely components for *Dnx*-mediated resistance to RWA. Most transcripts potentially involved in resistance were upregulated more rapidly and at a greater magnitude than in susceptible plants, suggesting a more rapid and stronger induction of a *Dnx*-mediated gene network as a likely mechanism for *Dnx* resistance. This mechanism has been observed with several plant resistance responses to various pathogens (van Loon et al. 2006).

Table 5 Mass (% ng/g standard) of *cis*- and *trans*-methyl-12-oxo-phytodienoic acid (12-OPDA) in leaves of Russian wheat aphid biotype 1—resistant (*Dnx*) and susceptible (*Dn0*)wheat genotypes at 12-, 24-, 48-, and 96 h post-aphid infestation, and in 0 h uninfested control plants

Several results suggest the SA pathway to be less important in mediating *Dnx* resistance to RWA than the JA pathway. Fewer SA-related transcripts were upregulated in *Dn0* plants (3) versus *Dnx* plants (16), and none of those upregulated in *Dnx* plants was expressed in *Dn0* plants. Over five post-infestation time points, there were no differences between tissues of *Dnx* and *Dn0* infested plants in the content of the *trans*-cinnamate or SA. Content of the SA intermediate benzoate in *Dnx* plants was significantly greater than in *Dn0* plants at only 48 hpi.

The levels of expression of the majority of transcripts were similar between *Dnx* and *Dn0* plants. However, approximately 30% of the transcripts contained in the microarray were upregulated in *Dnx* plants, and most of them are plant defense-related genes (Table 3). In comparison, only 19% of the transcripts were upregulated in *Dn0* plants, and the proportion of these upregulated transcripts associated with plant defense was much lower. The transcripts upregulated in susceptible plants, therefore, may be related to general plant stress responses. Most, if not all ABA, ET, and JA signaling genes upregulated in *Dnx* plants were absent in *Dn0* plants. On the other hand, approximately 9% of the upregulated *Dn0* transcripts were related to auxin (AUX) signaling and these were absent in *Dnx* plants (Table 3). The expression of AUX-related transcripts may result in *Dn0* plants increasing their ROS production, as demonstrated by Boyko et al. (2006) and Kawano (2003). An additional 27% of the upregulated *Dn0* transcripts included metabolism genes (Table 3), which were not upregulated in *Dnx* plants. The downregulation of metabolic transcripts in *Dnx* plants at 120 hpi (Fig. 3) may decrease some plant metabolic activities that can enable the production of *Dnx*-related defense compounds. A related downregulation of stress response transcripts in *Dnx* plants could be due to a reduced need for these transcripts, in favor of downstream plant defenses.

At the onset of insect feeding, components of the cell wall membrane such as *GLG* and *Chita*, which were highly expressed in infested *Dnx* plants, participate in insect defense responses in plants (Kempema et al. 2007; Park et al. 2007; see review of Smith and Boyko 2006). The increased upregulation of defense response transcripts related to ROS metabolism in *Dnx* leaves (Fig. 2b) is similar to that induced by other plant feeding insects (Schmidt et al. 2005; Couldridge et al. 2007). The expression of *GLG*, *Chita*, and ROS-related transcripts in *Dnx* infested tissues suggests their involvement in *Dnx* defense responses to RWA feeding probes.

Further, the putative role of WIR1 membrane proteins in *Dnx* resistance is strengthened by the results of Gaupels et al. (2008), who identified a WIR1A-like protein in barley phloem sap, obtained from stylets of actively feeding *Rhopalosiphum padi* aphids. Our results were similar to those of Zhu-Salzman et al. (2004) and Park et al. (2006), who demonstrated expression of CYP450 monooxygenase (MO) in aphid-resistant sorghum plants. The precise role of the CYP450MOs in *Dnx*-infested plants is difficult to determine, because these compounds function in the synthesis of JA, SA, chemical defenses, and the detoxification of exogenous chemicals such as RWA salivary components.

LOX, a gene whose transcripts are associated with the JA signaling pathway, is strongly induced by foliar feeding of numerous insects (Sardesai et al. 2005; and see Smith and Boyko 2006 review), but plant JA-induced defense responses may be antagonized by those induced by SA (Spoel et al. 2003; Koornneef et al. 2008). For example, silver leaf whitefly herbivory suppresses *LOX2* and *FAD* expression and elevates *PR1* and *PR5* expression (Kempema et al. 2007). However, the upregulation of JA- and SA-related transcripts in *Dnx*-infested plants was similar to that noted by Salzman et al. (2005), in sorghum response to mechanical wounding and by Li et al. (2008) in soybean plant response to aphid feeding. We observed induction of homologs of genes composing much of the JA and SA pathways but expression of SA transcripts was ~ 2x greater than expression of JA synthesis transcripts (Supplemental Data Table 1). Nevertheless, although SA transcripts were more highly expressed in micro-

arrays than JA transcripts, results of northern blot and phytohormone assays indicated that SA does not contribute to *Dnx* resistance (Fig. 2c, Table 6). Liu et al. (2007) reported similar results in Hessian fly resistant wheat plants.

Aphid feeding stimulates *WRKY* expression (Voelckel et al. 2004; Park et al. 2006; Li et al. 2008) (Supplemental Data Table 1), yet *WRKY* transcription factors suppress JA (Kalde et al. 2003; Li et al. 2004; Mao et al. 2007), indicating that *WRKY* expression in *Dnx* tissues may partially explain the comparatively reduced expression of JA-signaling genes. Wound-induced JA production is regulated by the supply of substrate available to allene oxide synthase (Turner et al. 2002). Thus, the minimal foliar damage and related chloroplast loss sustained by *Dnx* plants in our experiments (Fig. 1b), may have limited the release of fatty acids from chloroplast lipids for JA metabolism.

Oxylipin analyses suggest that *LOX*, *trans*-OPDA, and the 18- and 16 carbon OPDA fatty acid precursors function in *Dnx* resistance (Fig. 2d, Tables 4 and 5). The direct role of OPDA in insect defense responses (Stintzi et al. 2001) and the production of OPDA-specific response gene homologs by mechanical wounding (Taki et al. 2005) support these results. Expression of oxylipin metabolites in *Dnx* plants appears to stimulate production of downstream feeding inhibitors and toxins (Fig. 2e), several of which have been reported as resistance factors (Moraes et al. 2000; Miller et al. 2005; Lou and Baldwin 2006; Smith and Boyko 2006; Liu et al. 2007). RWA1 phloem ingestion decreases markedly on *Dnx* plants within 8 hpi (Lazzari et al. 2009), further supporting the possibility that *Dnx* feeding inhibitors and/or toxins contribute to the significant ($P<0.001$) antibiotic effects exhibited in the reduced RWA1 population development shown in Fig. 1a. These antibiotic effects shown by RWA1 substantiate similar results of Khan et al. (2009) with plants containing *Dnx* in different genetic backgrounds. The ~50% RWA1 population reduction on *Dnx* plants in Fig. 1a is similar to that observed by Boyko et al. (2006) (57%, 66%) and Khan et al. (2009) (34%).

The lack of leaf wilting and interveinal collapse in RWA1 incompatible interactions indicates that *Dnx* resistance also may result from reduced tissue and water loss. For example, *PAL* and *CAD5*, which mediate lignin synthesis, were highly expressed in infested *Dnx* tissues (Fig. 2f), and both have been implicated in insect resistance (Ciepiela 1989; Kempema et al. 2007; Liu et al. 2007). Elevated expression of latex-abundant-, fiber (CA609522), and sorbitol transporter (BT009301) proteins (Supplemental Data Table 1) provide additional evidence of physical components of *Dnx* resistance and an additional explanation of the low tissue dry weight changes occurring in RWA-infested *Dnx* plants (Fig. 1b).

ABA- and ET- dehydration responses were uniquely upregulated in *Dnx* plants during RWA feeding (Fig. 2f, Table 6), as reported by Salzman et al. (2005) and Park et al. (2006). ABA- and ET over-expression in response aphid-infested plants (Moran et al. 2002; Divol et al. 2005; Boyko et al. 2006) and the upregulation of the ET signaling genes in *Dnx* plants (Supplemental Data Table 1) strongly suggests their role in *Dnx* resistance. Related dehydration response transcripts were highly expressed, and one - *XET*—was differentially expressed in *Dnx* plants (6–72 hpi) and *Dn0* plants (12–24 hpi) (Fig. 2f), also demonstrating their contribution to *Dnx* resistance.

Our results indicating the upregulation of homologs of the pathogen resistance genes *ACRE, AP, Bet, HHT*, and *SNAP* in RWA1-infested *Dnx* tissues is the first report of their expression in response to insect feeding. Validation of the role(s) of these genes and other candidate genes in *Dnx* resistance awaits functional confirmation experiments, likely involving gene silencing. In the interim, more than 400 *Dnx* expressed transcripts are presently of unknown function. Elucidation of their function will provide additional information about putative genes and their expression patterns involved in wheat plant responses to RWA herbivory.

Acknowledgments We thank Nanyan Lu for helpful comments and support in the Affymetrix array data acquisition. This research was supported by a Kansas Crop Improvement Association grant to CMS and is contribution No. 08-151-J of the Kansas Agricultural Experiment Station. This research was performed in the Gene Expression Facility at Kansas State University, which is supported through the National Science Foundation grant, DBI 0421427. Plant phytohormone analyses were performed at the Kansas Lipidomics Research Center Analytical Laboratory, supported by the Functional Genomics Consortium initiative of Kansas State University's Targeted Excellence Program. The Kansas Lipidomics Research Center is supported by National Science Foundation (EPS 0236913, MCB 0455318, DBI 0521587), Kansas Technology Enterprise Corporation, K-IDeA Networks of Biomedical Research Excellence (INBRE) of National Institute of Health (P20RR16475), and Kansas State University.

Abstract Three saponins and two sapogenins had differential effects on food consumption in five near-isogenic flea beetle lines, which differ in their ability to utilize a novel host plant, *Barbarea vulgaris* (Brassicaceae). The ability to live on this plant is controlled by major, dominant R-genes in the flea beetle, *Phyllotreta nemorum* (Coleoptera: Chrysomelidae: Alticinae). A susceptible genotype (rr) is unable to live on the plant, whereas resistant genotypes (RR and Rr) can utilize the novel host plant. Among compounds isolated from *B. vulgaris*, hederagenin cellobioside (hederagenin-3-O-(4-O-β-D-glucopyranosyl)-β-D-glucopyranoside) inhibited feeding, whereas the effect of oleanolic acid cellobioside was much weaker. The aglycones (sapogenins) were inactive. Although hederagenin cellobioside was active against all flea beetle lines, its effect on food consumption was much stronger on the susceptible genotype (rr) compared to the resistant genotype (Rr). Susceptible and resistant flea beetle genotypes were equally sensitive to a non-host saponin, α-hederin (hederagenin-3-O-(2-O-α-L-rhamnopyranosyl)-α-L-arabinopyranoside). These results suggest that R-alleles in flea beetles might be specific adaptations to defensive saponins in *B. vulgaris*. A possible mechanism of action of the R-alleles might be to encode for an enzyme (e.g. a glucosidase), which is able to cleave glycosidic bonds in hederagenin cellobioside, but not in α-hederin. The potential role of saponins as defensive compounds in *B. vulgaris* and as targets for counter-adaptations in flea beetles and other insects is discussed.

Keywords *Barbarea vulgaris* · Brassicaceae · Flea beetle · *Phyllotreta nemorum* · Chrysomelidae · Alticinae · Host plant resistance · Host shift · Deterrents · Triterpenoids · Saponins · Hederagenin cellobioside

Introduction

Green plants produce a large variety of secondary compounds that have important roles in the interaction between the plant and its environment (Hartmann 1996). Many of these compounds are toxic to or deter feeding in herbivorous insects, and plants that contain these compounds may have a selective advantage in habitats where herbivorous insects are abundant. Insects, on the other hand, may evolve counter-adaptations to particular secondary compounds, i.e., they may be able to detoxify them or tolerate them in their tissues without harmful effects (Schoonhoven et al. 2005).

The idea of a stepwise "coevolutionary arm's race" between plants and insects was first formulated by Ehrlich and Raven (1964) and later these ideas were expanded upon by Futuyma and Keese (1992) and Thompson (1994, 2005). This theory can explain the apparently paradoxical observations that: 1) green plants produce large amounts of chemicals with no obvious functions for plant growth and

reproduction in the absence of enemies (Hartmann 1996), and 2) that the host range of many herbivorous insects is restricted by the occurrence of secondary plant compounds, which may have positive as well as negative effects on insect behavior and performance (Schoonhoven et al. 2005). Coevolution can explain broad patterns of distribution of plant defenses and host use in herbivorous insects, but many processes still are not well understood, and there are only few examples, where reciprocal selection in natural populations has been rigorously proven (Thompson 2005; Gomulkiewicz et al. 2007).

The interaction between the plant *Barbarea vulgaris* ssp. *arcuata* (Opiz.) Simkovics (Brassicaceae) (hereafter called *Barbarea*) and the flea beetle, *Phyllotreta nemorum* L. (Coleoptera: Chrysomelidae: Alticinae) seems to be particularly well suited for studies of processes involved in coevolutionary interactions between two trophic levels, since both the plant and the insect are polymorphic. The pubescent P-type of *Barbarea* is susceptible to all known genotypes of the flea beetle, whereas the glabrous G-type is resistant to the most common flea beetle genotypes found in Denmark (Nielsen 1997a, b; Agerbirk et al. 2003b). The inheritance of resistance to flea beetles in *Barbarea* still is not fully understood, although levels of resistance in hybrids (F1) between the G- and the P-type are intermediate between those of the parents, whereas the full range from complete susceptibility to complete resistance is expressed in a segregating F2 population (Kuzina et al. 2009).

The flea beetle, *P. nemorum*, is an oligophagous species, which utilizes a few species from the crucifer family (Brassicaceae) as natural host plants. Although the G-type of *Barbarea* is resistant to most flea beetle genotypes, it is a major host plant for the species in some localities (Nielsen and de Jong 2005; de Jong et al. 2009). Local flea beetle populations that live on the G-type of *Barbarea* have high frequencies of particular resistance genes (named R-genes), whereas frequencies of these genes in populations that live on other host plants are lower (Nielsen and de Jong 2005). The R-genes, which may be sex-linked or autosomal, are dominant, since the genotypes RR and Rr develop equally well on the G-type of *Barbarea*, whereas rr does not grow at all on this plant type (Nielsen 1997a, b; de Jong et al. 2000). In order to study the effect of individual R-genes, a number of near-isogenic lines were developed by repeated back-crossing of the genotypes RR and Rr with rr. Detailed investigations of one of these lines demonstrated that its particular R-gene should be considered as an adaptation to defenses in *Barbarea*, since it conferred ability to live on this particular species but not to any other crucifer (Nielsen 1999).

Members of the crucifer family are characterized chemically by their content of glucosinolates. Being present in all members of the Brassicaceae, these compounds may be considered as a first generation of defensive compounds in the family (Feeny 1977; Nielsen 1978; Renwick 2002). Glucosinolates, however, do not protect the plants against a number of specialist insects that have evolved means to detoxify them (Ratzka et al. 2002; Wittstock et al. 2004) and indeed use them as host specific cues (Renwick 2002). As a putative response to renewed selection pressures imposed by herbivorous insects, a number of crucifers have evolved a second generation of defensive compounds, e.g. cucurbitacins in *Iberis* spp. and cardenolides in *Cheiranthus* and *Erysimum* species. These compounds are feeding deterrents for a number of flea beetles (Nielsen et al. 1977; Nielsen 1978), and in *Pieris* spp. they serve as feeding deterrents for caterpillars and as oviposition deterrents for adult females (Huang et al. 1993; Sachdev-Gupta et al. 1993a, b; Huang and Renwick 1994). These compounds can explain the differential utilization of *Iberis*, *Cheiranthus*, and *Erysimum* species by several herbivorous insects (Nielsen 1978; Renwick 2002).

The relationship between chemical content and suitability to insects in the genus *Barbarea* is less well understood. The P- and the G-type of *Barbarea* contain different optical isomers of 2-hydroxy-2-phenylethylglucosinolate (glucobarbarin and glucosibarin), but no correlation (neither quantitative nor qualitative) between glucosinolate content and resistance to flea beetles has been documented (Agerbirk et al. 2001, 2003b). More recently, resistance to flea beetles has been correlated with the content of a number of triterpenoid saponins in a segregating F2 population from a cross between the G- and the P-type (Kuzina et al. 2009). Two triterpenoid saponins previously have been isolated and identified from *B. vulgaris* (Shinoda et al. 2002; Agerbirk et al. 2003a). The major compound in the G-type is hederagenin-3-O-(4-O-β-D-glucopyranosyl)-β-D-glucopyranoside (hederagenin cellobioside), whereas oleanolic acid-3-O-(4-O-β-D-glucopyranosyl)-β-D-glucopyranoside (oleanolic acid cellobioside) is found in lower concentrations (Kuzina et al. 2009). These compounds are absent in the P-type, but occur in variable concentrations in the G-type and in F2 plants from a cross between the G- and the P-type (Kuzina et al. 2009). They are both potent feeding deterrents against caterpillars of the diamond back moth, *Plutella xylostella* (Shinoda et al. 2002; unpublished results), while their effects on flea beetles have yet to be evaluated.

The purpose of the present work was to determine whether resistance to flea beetles in *Barbarea* might be mediated by saponins. Saponins and their aglycones (sapogenins) have been recognized as defensive compounds in plants against several herbivorous insects and pathogenic fungi. In many cases, the biological effects were closely linked to the carbohydrate moiety. Removal of individual sugars might increase as well as decrease the biological activity (Bowyer et al. 1995; Osbourn 1996; Adel et al. 2000). In the present study, feeding deterrent activity of the two known triterpenoid

saponins from *B. vulgaris* were compared with the effects of the aglycones, hederagenin and oleanolic acid, and of a hederagenin glycoside (α-hederin) with a different carbohydrate moiety (Fig. 1). Furthermore, we investigated whether R-genes in flea beetles might be considered as adaptations to saponin mediated defenses in *Barbarea*.

The study addressed the following questions: 1) do saponins reduce feeding in *P. nemorum*? 2) are the aglycones more or less active than the parent glycosides? 3) Is there any relation between biological activity and the structure of the aglycone or the carbohydrate moiety of saponins? and 4) do near-isogenic flea beetles that are either susceptible or resistant to defenses in *B. vulgaris* show differential responses to saponins?

Methods and Materials

Plants Radish plants were grown in a growth chamber at 20±2°C and a L18:D6 photoperiod as described previously (Nielsen 1999).

Insects Feeding responses of five near-isogenic flea beetle lines were compared. A susceptible line from Taastrup (ST) originated from beetles collected on radish in Taastrup (Nielsen 1999). Beetles from this line (rr genotype) are unable to survive on *Barbarea*. Imagines of the ST-line were kept in groups of 15–25 beetles that were allowed to mate randomly. Larvae as well as adults were reared on radish leaves as described previously (Nielsen 1999).

Feeding responses of the susceptible ST-line were compared with those of four near-isogenic resistant lines that express R-genes from different Danish and Swiss populations. All the resistant lines are able to survive on the G-type of *Barbarea*. They are heterozygous (Rr genotype), and the lines were maintained by repeated backcrossing with the ST-line. When one heterozygous male (Rr) was mated with an ST-female (rr), 50% of their offspring was Rr. This genotype was selected by rearing the offspring on the G-type of *Barbarea*, since Rr genotypes survived on this plant, whereas rr did not. At least ten generations of backcrosses had been made with the lines used in the present study.

Four different resistant lines were maintained: 1) YE contained a Y-linked R-gene from Ejby, which only occurs in males and is inherited from fathers to sons (Nielsen 1997b, 1999); 2) the AE line contained an autosomal gene from Ejby (Nielsen 1997b); 3) the AK-line contained an autosomal gene from Kværkeby (de Jong et al. 2000); and 4) the DE-line contained a gene from Delemont (Switzerland) which was inherited autosomally under laboratory conditions (Nielsen, unpublished results). The founders of the YE, AE, and AK lines were collected in populations that use the G-type of *Barbarea* as a natural host plant, whereas the founders of the DE line were collected on *Sinapis arvensis* (Nielsen, unpublished results). Feeding responses of females from the AE, AK, and DE lines were compared with those of males

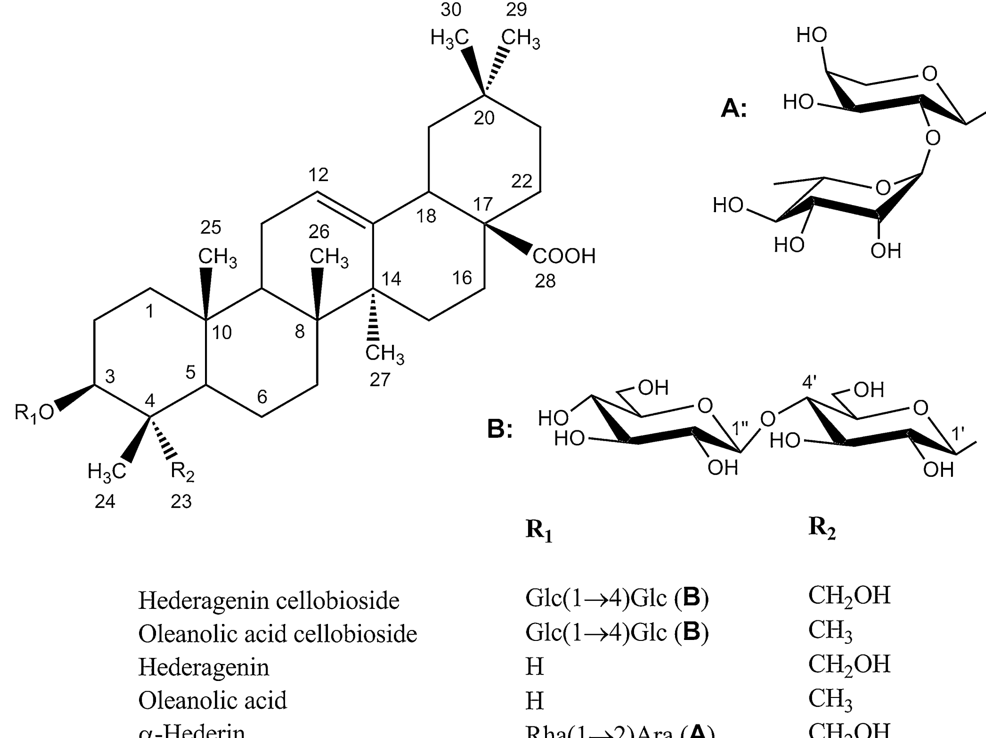

Fig. 1 Saponins and sapogenins evaluated as feeding deterrents against the flea beetle, *Phyllotreta nemorum*

from the YE line and females and males from the ST line. Beetles used in the bioassays were 3–7 d-old and had been feeding on radish leaf discs until the bioassays were initiated.

Chemicals Hederagenin cellobioside was isolated from *B. vulgaris* as described previously (Shinoda et al. 2002). Oleanolic acid cellobioside was isolated, and the structure was determined as follows: Fresh leaves (2.8 kg) of *B. vulgaris* var. *variegata* (Chiltern Seeds, England) were extracted with MeOH (14 l) and the aqueous MeOH ext. was partitioned with $CHCl_3$. The $CHCl_3$ layer was evaporated off and chromatographed on silica gel ($CHCl_3$ -> 20% MeOH/$CHCl_3$) to separate 12 fractions. The compound (96 mg) was purified as a white powder from Fr. 7 (1.3 g; 10% MeOH/$CHCl_3$ eluate) by the chromatography of silica gel ($CHCl_3$:MeOH:H_2O=150:30:2), reversed phase silica gel (YMC-GEL ODS-120A, 85% MeOH), and prep. HPLC (Shiseido Capcellpak C18, 82.5% MeOH). FAB-MS was obtained by using a JEOL HX-110 mass spectrometer, ^{1}H and ^{13}C NMR spectra were recorded on a JEOL A-500 spectrometer, and optical rotation was measured on a JASCO DIP-360 polarimeter.

Spectral data: A white powder, $[\alpha]_D^{26}$+18.2° (MeOH; *c*. 1.2). Positive ion FAB-MS (glycerol matrix) *m/z* 803.4551 $([M + Na])^+$, $C_{42}H_{68}NaO_{13}$ requires 803.4558. Negative ion FAB-MS (glycerol matrix) *m/z* 779 ($[M–H]^-$), 617 ($[M–glc-H]^-$), 455 ($[M–2glc-H]^-$). ^{1}H NMR (500 MHz, C_5D_5N): 0.84 (3H, *s*, H-25), 0.96 (3H, *s*, H-29), 1.00 (6H, *s*, H-24 and H-26), 1.02 (3H, *s*, H-30), 1.31 (6H, *s*, H-23 and H-27), 3.34 (1H, *dd*, *J*=4, 12 Hz, H-3), 3.95 (2H, *m*, H-5′ and H-5″), 4.01 (1H, *dd*, *J*=8, 8 Hz, H-2′), 4.09 (1H, *dd*, *J*=8, 8 Hz, H-2″), 4.18 (2H, *dd*-like, H-3″ and H-4″), 4.26 (1H, *dd*, *J*=8 Hz, H-3′), 4.27 (1H, *dd*, *J*=6, 12 Hz, H-6″a), 4.30 (1H, *dd*, *J*=8, 8 Hz, H-4′), 4.49 (1H, *dd*, *J*=3, 12 Hz, H-6″b), 4.50 (1H, *dd*, *J*=2, 12 Hz, H-6′a), 4.55 (1H, *dd*, *J*=4, 12 Hz, H-6′b), 4.86 (1H, *d*, *J*=8 Hz, H-1′), 5.18 (1H, *d*, *J*=8 Hz, H-1″), 5.48 (1H, *dd*, *J*=3, 3 Hz, H-12). ^{13}C NMR (125 MHz, C_5D_5N): 15.4 (C-25), 16.9 (C-24), 17.3 (C-26), 18.4 (C-6), 23.6 (C-16), 23.7 (C-11), 23.7 (C-30), 26.1 (C-27), 26.4 (C-2), 28.2 (C-23), 28.3 (C-15), 30.9 (C-20), 33.1 (C-7), 33.2 (C-22), 33.2 (C-29), 24.2 (C-21), 37.0 (C-10), 38.7 (C-1), 39.4 (C-4), 39.7 (C-8), 42.0 (C-18), 42.1 (C-14), 46.5 (C-19), 46.6 (C-17), 48.0 (C-9), 55.8 (C-5), 62.4 (C-6′), 62.4 (C-6″), 71.5 (C-4″), 74.8 (C-2″), 75.2 (C-2′), 76.2 (C-5′), 76.9 (C-3′), 78.2 (C-3″), 78.4 (C-5″), 81.6 (C-4′), 88.9 (C-3), 104.9 (C-1″), 106.4 (C-1′), 122.5 (C-12), 144.8 (C-13), 180.1 (C-28).

The high resolution FAB-MS analysis established the molecular formula, $C_{42}H_{68}O_{13}$. This molecular formula and the NMR spectral data suggested that the compound was an oleanolic acid 3-*O*-glycoside having two hexosyl groups as its sugar moiety (Nagao et al. 1991). The identification of the sugar moiety by using acid hydrolysis and methanolysis was performed as described previously (Shinoda et al. 2002). The linkages between the aglycon and sugar moieties were determined from correlations in the HMBC spectrum between H-3 (3.34) and C-1′ (C-1 of inner glucosyl group; 106.4), H-1′ (4.86) and C-3 (88.9), H-4′ (4.30) and C-1″ (C-1 of terminal glucosyl group; 104.9), and between H-1″ (5.18) and C-4′ (81.6). The spectral data are nearly identical to those published previously by Agerbirk et al. (2003a) that used slightly different conditions, and they confirm that the isolated compound is oleanolic acid-3-O-(4-O-β-D-glucopyranosyl)-β-D-glucopyranoside (oleanolic acid cellobioside).

α-Hederin was purchased from Extrasynthese, France, hederagenin from Carl Roth GmbH, Germany, and oleanolic acid from ICN Biomedical, USA.

Bioassays Saponins and sapogenins were dissolved in 75% ethanol. Radish leaf discs (11 mm diam) were treated on both sides with 15 μl of these solutions by using an automatic pipette. Control leaf discs were treated with solvent only. When the solvent had evaporated, the leaf discs were transferred to plastic containers (*V*=185 ml) with gypsum-charcoal bottom layers that supplied high humidity. Two leaf discs that had received the same treatment were transferred to each container (non-choice situation). In each container, one beetle was exposed to two leaf discs for 24 h at 24±2°C and a L18:D6 photoperiod. The leaf area consumed was measured under a stereo microscope.

In order to avoid biases due to day-to-day variations in availability of beetles from different lines and in radish leaf quality, the following measures were taken: 1) bioassays were made only on days when at least two different lines were available, and 2) consumption rates of individual beetles on radish leaf discs treated with saponins or sapogenins were adjusted with consumption rates on control leaf discs tested on the same day (see statistics).

Statistical Analysis Consumption by one beetle on two leaf discs for 24 h was treated as one replicate (C_i). From each replicate, a relative consumption rate (RCR) was calculated as 100×C_i / average consumption on control leaf discs tested on the same day. Confidence limits (95%) around RCR were calculated as $t_{0.975}$ × SE. Test and control treatments are significantly different when the 95% confidence interval around RCR does not include 100, which is the theoretical RCR if consumption rates of test and control leaf discs are equal. Analysis of variance (ANOVA) was performed with the GLM procedure in SAS on square root transformed values of RCR in order to obtain homogeneity of variances.

Results

Relative consumption rates (RCR) on treated radish leaf discs depended on compound, concentration and flea beetle

genotype (Tables 1, 2). Analysis of variance (ANOVA) on all data and on various subsets of them provided further information on the sources of variation. In the analysis of all data, a significant effect of flea beetle line was found (Table 2). This effect disappeared when data from resistant genotypes (Rr; lines: YE, AE, AK, and DE) and susceptible genotypes (rr; ST females and males) were analyzed separately (Table 2). This means that the variation observed among flea beetle lines in the overall ANOVA could be explained as a difference between on the one hand the susceptible ST line, and on the other hand all the resistant lines, whereas there were no significant differences among the resistant lines depending on the origin of the R-gene.

The two saponins isolated from *Barbarea vulgaris*, hederagenin cellobioside and oleanolic acid cellobioside had different effects on RCR in flea beetles. High concentrations of hederagenin cellobioside (2.0 mM and 0.5 mM) had significant, negative effects on RCR in all lines, since confidence intervals around RCR never included 100 (the theoretical value when consumption rates on treated and control leaf discs are equal) (Table 1). The effect of hederagenin cellobioside was much stronger on the susceptible ST-line compared to the resistant lines (see below). The effect of oleanolic acid cellobioside was weaker and in many cases not significant (Table 1). The aglycones (sapogenins) were inactive (Table 1). These

Table 1 Relative consumption rates (RCR) in near-isogenic lines of the flea beetle, *Phyllotreta nemorum,* on radish leaf discs treated with different concentrations of saponins or sapogenins. Deterrent effects of the saponins and sapogenins are significant, when RCR + c.l. < 100, since 100 is the theoretical value of RCR, when there is no difference between treated and control leaf discs

[a] hederagenin cellobioside and α-hederin

results demonstrate that the major saponin in *Barbarea*, hederagenin cellobioside, is a feeding deterrent for all flea beetle genotypes, and that the biological activity depends on structure of the aglycone and on the presence of a carbohydrate moiety.

There were differences among lines in RCR on radish leaf discs treated with higher concentrations of hederagenin cellobioside (2 mM: $F=10.80$; $df=4$; $P<0.001$, and 0.5 mM: $F=11.37$; $df=4$; $P<0.001$). No significant differences among lines were found in responses to lower concentrations of this compound nor to oleanolic acid cellobioside or to the aglycones (data not shown). Differences among lines in RCR on leaf discs treated with hederagenin cellobioside could be attributed to a difference between the genotypes rr (ST females and males combined) and Rr (YE, AE, AK, and DE combined) (2 mM: $F=37.48$; $df=1$; $P<0.001$, and 0.5 mM: $F=25.80$; $df=1$; $P<0.001$). These results suggest that hederagenin cellobioside is an important defensive compound in *Barbarea* against susceptible genotypes, and that the R-genes in flea beetles might be adaptations to defenses in *Barbarea* mediated by this compound.

The importance of glycosylation pattern of saponins in defenses in *Barbarea* and counter-adaptations in flea beetles was illustrated further by beetle responses to the non-host compound α-hederin, which contains the same aglycon as hederagenin cellobioside, but differs in glycosylation pattern (Fig. 1). α-Hederin reduced RCR in all flea beetle lines (Tables 1, 2). Although hederagenin cellobioside and α-hederin influenced RCR in all lines, there were differences in the effects of the two compounds on susceptible and resistant genotypes. Hederagenin cellobioside and α-hederin had similar effects on RCR in the ST-line (rr), whereas α-hederin was significantly more inhibitory than hederagenin cellobioside to all the resistant lines (Table 2). Differential responses of resistant genotypes to hederagenin cellobioside and α-hederin strengthen the assumption that R-genes are adaptations to defenses in *Barbarea* mediated by saponins with a specific glycosylation pattern.

Discussion

The results presented here illustrate some of the chemical and metabolic changes that seem to have occurred in *Barbarea* and flea beetles as an outcome of evolutionary interactions between them.

Until now, *Barbarea* is the only genus of Brassicaceae known to contain saponins (Shinoda et al. 2002; Agerbirk et al. 2003a; Kuzina et al. 2009). The restricted distribution of saponins in the family suggests that they originated later than the glucosinolates, which have a wider distribution in the family. Hederagenin cellobioside was the most abundant saponin in the G-type and in hybrids from crosses between the G- and the P-type, whereas oleanolic acid cellobioside and other yet unidentified saponins were found in smaller quantities (Kuzina et al. 2009). There were significant, negative correlations between survival of flea beetle larvae and concentrations of hederagenin cellobioside, oleanolic acid cellobioside, and several minor saponins in a segregating F2 population from crosses between the G- and the P-type (Kuzina et al. 2009). The range of concentrations where hederagenin cellobioside was active in the present study was well within the range found for this compound in *B. vulgaris* (Shinoda et al. 2002; Nielsen et al. unpublished results). These results suggest that hederagenin cellobioside is an important part of the defenses in *Barbarea* against flea beetles, since it is both the most abundant and the most active compound. Further studies are necessary to unravel the role of less active oleanolic

acid cellobioside and the minor saponins in plant defenses against flea beetles. Since all these saponins are biosynthetically related, they tend to occur in the same plants, and it is still uncertain whether combinations of hederagenin cellobioside with oleanolic acid cellobioside and some of the minor saponins are more active than hederagenin cellobioside alone.

Both saponins isolated from *Barbarea* inhibit feeding in larvae of the diamond back moth, *Plutella xylostella* (Shinoda et al. 2002, unpublished results). This crucifer specialist readily accepts *B. vulgaris* for oviposition, but larvae do not survive on it (Badenes-Perez et al. 2006). *Barbarea* species also are less preferred hosts for several other crucifer specialists (Börjesdotter 2000; Renwick 2002), and some of these insects discriminate between G- and P-type plants (Renwick 2002; Nielsen, unpublished results). It is, therefore, likely that saponins contribute to defenses in *Barbarea* against several herbivorous insects, although in some cases other mechanisms also may be important (van Leur et al. 2008).

Mechanisms of the action of saponins on insects are not well understood. Saponins have been found to reduce feeding in adult flea beetles, but the present study did not allow any clear distinction between pre- and postingestive effects on food consumption (Glendinning 2002). *Barbarea* is acceptable for initial feeding by adult flea beetles and for mine initiation by larvae (Nielsen 1997a, b). The termination of feeding after a short meal might indicate that defensive compounds in *Barbarea* exert a toxic, post-ingestive effect that inhibits further feeding behavior. Behavioral as well as toxic effects of saponins have been demonstrated in other interactions between plants and insects (Adel et al. 2000; Golawska 2007).

This study demonstrates that glycosides are more active than aglycones, whereas the identity of the diglycosidic sugar moiety was less important against non-adapted flea beetles. Unfortunately, hederagenin-monoglycosides were not available to be tested. Saponin monoglucosides were not abundant in *Barbarea* (Kuzina et al. 2009), but they might be formed during degradation of the cellobiosides as part of a putative detoxification process in flea beetles (see below). Aglycones were more active than their parent glycosides from *Medicago* spp. against the generalist insect, *Spodoptera littoralis* (Adel et al. 2000) and against plant parasitic nematodes (Argentieri et al. 2008). Hederagenin glycosides with three sugar units had higher molluscicidal activity than saponins with only one sugar unit (Huang et al. 2003). These variable outcomes suggest that saponins may exert various effects on herbivores, and further studies are needed in order to understand the relationships between chemical structure and biological effects.

Presence of defensive compounds in plants may mediate counter-adaptations in herbivorous insects. Glucosinolates often are considered as a first generation of defensive compounds in members of Capparales (Feeny 1977; Nielsen 1978; Renwick 2002), and a number of specialist insects have evolved counter-adaptations to them and may use them as host specific cues (Renwick 2002). *Phyllotreta nemorum* is stimulated to feed by glucosinolates, and since all known host plants for the species contain glucosinolates (Nielsen 1978), it is likely that alleles that confer adaptations to glucosinolates have become fixed in the species.

Saponins belong to a second generation of defensive compounds in Capparales, and crucifer specialist insects have had a shorter time to adapt to them. The present study suggests that R-alleles in flea beetles represent specific adaptations to saponins in *Barbarea*. This is in agreement with previous observations that R-alleles confer improved performance on *Barbarea* but not on any other glucosinolate-containing plant (Nielsen 1999). R-alleles are, thus, considered to be derived traits, which have evolved in flea beetles as an outcome of natural selection imposed by the presence of defensive saponins in a potential, novel host plant, *Barbarea*. Different R-genes may have originated from independant mutations on different chromosomes, i.e., on an autosome in the gene(s) found in the AE, AK, and DE lines or on the Y-chromosome in the gene found in the YE line. Alternatively, they may have all originated from a single mutation on an autosome, and the Y-linked gene was later translocated to the Y-chromosome. The similarity of effects of R-alleles on feeding behavior on saponin-treated leaf discs suggests that their mode of action is similar, i.e., they may belong to the same gene family. *Phyllotreta nemorum* is polymorphic with respect to R-alleles, which are abundant in populations living on the G-type of *Barbarea*, but is relatively rare in populations that live on other host plants (Nielsen and de Jong 2005).

The present study indicates that enzymic degradation of hederagenin cellobioside might be a potential mode of action of R-alleles. The susceptible genotype (rr) of flea beetles is more sensitive to hederagenin cellobioside than the resistant genotype (Rr), whereas both genotypes are insensitive to the aglycone, hederagenin. This difference among genotypes could be explained if R-alleles encode for an enzyme (e.g., a β-glucosidase), which can cleave glycosidic bonds in hederagenin cellobioside. The partial sensitivity of resistant beetles to hederagenin cellobioside then could be explained as an effect of accumulation of the compound in the guts of flea beetles if consumption rates are higher than the rates of degradation. Resistant and susceptible genotypes of flea beetles were equally sensitive to the non-host compound, α-hederin. This observation provides further support for the idea that R-alleles encode for a specific enzyme, which can remove one or two glucose units from hederagenin cellobioside, but not

rhamnose or arabinose units from α-hederin. Deactivation of saponins by means of β-glucosidases or other glycohydrolase enzymes has not been demonstrated in any insect species, whereas detoxification of saponins by removal of sugars is an integral part of the infection process in many pathogenic fungi (Bowyer et al. 1995; Osbourn 1996; Morrissey et al. 2000; Morant et al. 2008).

This study has identified saponins as defensive compounds in *Barbarea* and as targets for counter-adaptations in flea beetles. Saponins may confer resistance in the plant against a number of herbivores, and no information is available yet on effects of individual herbivore species on evolution of defenses in *Barbarea*. The study identified R-alleles in flea beetles as derived traits that confer counter-adaptations in flea beetles to saponins in *Barbarea*. Improved knowledge of the chemical aspects of the interactions between *Barbarea* and flea beetles may provide further insight into the factors that influence the distribution and abundance of susceptible and resistant plants, and of the R-alleles in natural flea beetle populations that live on different host plants. Furthermore, there is geographic variation in host plant use by *P. nemorum* and in flea beetle abundance on local patches of *Barbarea* (Nielsen and de Jong 2005; de Jong et al. 2009). For this reason, the interaction between *Barbarea* and flea beetles offers excellent opportunities for investigations of several aspects of the geographic mosaic theory of coevolution (Thompson 2005).

Abstract Salicylate-containing phenolic glycosides (PGs) are abundant and often play a dominant role in plant-herbivore interactions of *Populus* and *Salix* species (family Salicaceae), but the biosynthetic pathway to PGs remains unclear. Cinnamic acid (CA) is thought to be a precursor of the salicyl moiety of PGs. However, the origin of the 6-hydroxy-2-cyclohexen-on-oyl (HCH) moiety found in certain PGs, such as salicortin, is not known. HCH is of interest because it confers toxicity and antifeedant properties against herbivores. We incubated *Populus nigra* leaf tissue with stable isotope-labeled CA, benzoates, and salicylates, and measured isotopic incorporation levels into both salicin, the simplest PG, and salicortin. Labeling of salicortin from [$^{13}C_6$]-CA provided the first evidence that HCH, like the salicyl moiety, is a phenylpropanoid derivative. Benzoic acid and benzaldehyde also labeled both salicyl and HCH, while benzyl alcohol labeled only the salicyl moiety in salicortin. Co-administration of unlabeled benzoates with [$^{13}C_6$]-CA confirmed their contribution to the biosynthesis of the salicyl but not the HCH moiety of salicortin. These data suggest that benzoate interconversions may modulate partitioning of phenylpropanoids to salicyl and HCH moieties, and hence toxicity of PGs. Surprisingly, labeled salicyl alcohol and salicylaldehyde were readily converted to salicin, but did not result in labeled salicortin. Co-administration of unlabeled salicylates with labeled CA suggested that salicyl alcohol and salicylaldehyde may have inhibited salicortin biosynthesis. A revised metabolic grid model of PG biosynthesis in *Populus* is proposed, providing a guide for functional genomic analysis of the PG biosynthetic pathway.

Introduction

Salicylate-containing phenolic glycosides (PGs) are important mediators in ecological interactions of *Populus* and *Salix* species with their respective herbivore communities. While PGs function as chemical deterrents and toxicants against certain herbivores, their foliar concentration can be high (up to 25%) in some genotypes, posing a potential trade-off to growth (Osier and Lindroth 2001). Investigating the biosynthesis and turnover of PGs will be essential for understanding the growth-defense trade-off associated with PGs in these species.

Several studies suggest that PGs are derived from cinnamic acid (CA) (Fig. 1). For example, administering 2-aminoindan-2-phosphonic acid (AIP), an inhibitor of phenylalanine ammonia lyase (PAL), the enzyme that catalyzes conversion of phenylalanine to CA, drastically reduced PG accumulation in shoot tips of *Salix pentandra*

Fig. 1 Salicylate-containing phenolic glycosides, putative precursors, and isotope labeling patterns

plantlets (Ruuhola and Julkunen-Tiitto 2003). Additionally, radioisotope-labeled CA and benzoic acid (BA) were incorporated into salicin, a salicyl alcohol glycoside (Fig. 1), based on administration to *Salix purpurea* leaf disks (Zenk 1967). Labeled benzyl alcohol and salicyl alcohol were converted to salicin as well, although administration of salicyl alcohol also resulted in formation of isosalicin, which was not present in untreated leaf disks (Zenk 1967). Isosalicin is not found in most *Populus* and *Salix* species (Palo 1984), but it has been observed in bark extracts of *Salix daphnoides* (Kammerer et al. 2005). Administering radiolabeled *o*-coumaric acid resulted in substantial radioactivity in salicyl alcohol, suggesting an alternate possible PG pathway, in which 2-hydroxylation of CA occurs prior to shortening of the propenyl side-chain. However, salicylic acid (SA), the well-known plant defense signal, was not readily converted to salicyl alcohol (Zenk 1967). Based on the ability of salicylaldehyde to compete with labeled CA for incorporation into salicin, Zenk (1967) suggested that salicylaldehyde is glucosylated to form helicin as a potential precursor for salicin and all other PGs. However, this hypothesis has not been tested.

The biosynthesis of higher-order PGs, such as salicortin, remains unclear, as well. Their potent biological activity has been attributed to the 6-hydroxy-2-cyclohexen-on-oyl (HCH) moiety, which is released by hydrolysis in the insect gut (Lindroth and Hwang 1996; Ruuhola et al. 2001). It is thought that salicin is an intermediate, which is conjugated

to the HCH precursor, 1-hydroxy-6-oxo-2-cyclohexene-1-carboxylic acid (HCC), to produce salicortin (Fig. 1). In the present study, we administered stable-isotope labeled CA, benzoates and salicylates to *Populus nigra* leaf disks, and measured incorporation of label into both salicin and salicortin, the two primary forms of PGs detected in this species. Salicortin is of particular interest, because it is nearly ubiquitous among *Salix* and *Populus* species, and because of its role in mediating ecological interactions in these species. Based on our findings, we propose revisions to the current model of the PG biosynthetic pathway.

Methods and Materials

Isotope Labeled Precursors All isotopic materials were purchased from Cambridge Isotope Laboratories (Cambridge, MA, USA), except salicylaldehyde and salicyl alcohol. All were uniformly labeled with ^{13}C (99 atom % ^{13}C) at each of the 6 phenyl carbons (e.g., [$^{13}C_6$]-CA; see Fig. 1), except [$^2H_5$]-BA and [$^2H_6$]-CA. [$^2H_5$]-BA was uniformly labeled with deuterium (99 atom % ^{2}H) at each of the five H positions on the phenyl ring, whereas [$^2H_6$]-CA was labeled similarly but has an additional ^{2}H at the β-carbon of the propenyl side-chain (98 atom % ^{2}H).

[$^{13}C_6$]-Salicylaldehyde was synthesized from [$^{13}C_6$]-phenol, using the modified Reimer-Tiemann reaction described by Mokle et al. (2006). Briefly, [$^{13}C_6$-]-phenol (99 atom % ^{13}C) was refluxed with 60% concentrated sodium hydroxide, 6% ethanol, and 34% chloroform at 65°C for 20 min. The solution was acidified with HCl, and then extracted with diethyl ether. Salicylaldehyde product was isolated by flash chromatography (normal phase), using hexane:ether (19:1, v/v) as the mobile phase. Fractions were collected and preliminarily evaluated by normal phase thin layer chromatography (TLC) with hexane:ether (9:1, v/v) mobile phase. Fractions containing a TLC band with Rf corresponding to authentic salicylaldehyde (Sigma, St Louis, MO, USA) were combined, and then roto-evaporated to remove solvent. The purified product was evaluated by HPLC-MS (negative ion mode) on a C18 reversed phase column (as described below), using authentic standard salicylaldehyde. The synthetic [$^{13}C_6$]-salicylaldehyde had the same retention time as the authentic standard, with the base peak at *m/z* 127, $[M-1+6]^-$ which is 6 units higher than the base peak of the natural abundance standard salicylaldehyde, *m/z* 121 $[M-1]^-$, as expected. Based on HPLC-MS, we calculated that the [$^{13}C_6$]-salicylaldehyde was 99 atom % ^{13}C.

[$^{13}C_6$]-Salicyl alcohol was synthesized by reducing [$^{13}C_6$]-salicylaldehyde in sodium borohydride, modified from (Setamdideh and Zeynizadeh 2006). We heated [$^{13}C_6$]-salicylaldehyde in 95% ethanol and sodium borohydride (1:1 molar ratio of salicylaldehyde:sodium borohydride) and refluxed for 20 min. The solution was cooled and concentrated under a stream of N_2 gas, and then ethanol was evaporated completely under vacuum centrifugation. The resulting powder was resuspended in water, acidified with 10% HCl, and extracted in methylene chloride. After evaporating the methylene chloride extract, the resulting salicyl alcohol was resuspended in ethanol, and checked by HPLC-MS. The synthetic [$^{13}C_6$]-salicyl alcohol at *m/z* 129, $[M-1+6]^-$ (99 atom % ^{13}C) co-eluted with the natural abundance authentic standard at *m/z* 123, $[M–1]^-$.

Plant Material Populus nigra NC5271 plants were propagated by rooted cuttings and then grown to a height of at least 0.5 m in a glasshouse before use in experiments. Supplemental lighting (600 μmole m^{-2} s^{-1} at mid canopy) was used to extend the day length in the fall and winter (14 :10 h light:dark). The leaf plastochron index (LPI) was used according to Larson and Isebrands (1971), with LPI 0 defined as the first fully unfolded leaf greater than 1 cm in length. LPI 3 leaves were used for the administration experiments because salicortin biosynthesis was active, based on preliminary testing, and the leaves provided ample, soft material for facile extraction of PGs.

Leaf Disk Administration Leaf disks were taken from LPI 3 leaves, avoiding the leaf margins and veins, where leaf tissues were less uniform. Typically, we tested 3 independent leaf disks per treatment group for each experiment. Each 6 mm diam leaf disk was submerged in 0.2% sodium bicarbonate solution with the appropriate isotope-labeled compound, and infiltrated by using gentle aspiration for 10 min. The concentration of labeled compounds varied depending on the experiment and is specified in the results section. Labeled compounds were administered at 99% isotopic purity. To aid infiltration, 0.01% Tween 20 and 1% ethanol were included. Following infiltration, the solution was replaced with 0.2% sodium bicarbonate and labeled compound, without Tween 20 or ethanol. Incubation under 100 μmole m^{-2} s^{-1} light was conducted for 6 h based on preliminary tests, thus indicating that a 4–6 h administration time was required for consistent detection of label incorporation from [$^{13}C_6$]-CA into salicin and salicortin. All experimental comparisons were made with similarly treated control leaf disks. In all samples analyzed (with or without phenolic compound administration), total salicin and salicortin levels detected in leaf disks were similar to those detected from intact tissues (i.e., tissues harvested directly into methanol or snap-frozen immediately), suggesting that the effect of cutting the leaf disks on PG accumulation, if any, was minimal during the short administration periods.

HPLC-MS Analysis Following incubation, each leaf disk was blotted dry, washed briefly with hexane, and then

extracted with cold methanol for 12 min in a 4°C ultrasonicator bath. An aliquot of the methanol extract was analyzed directly by reverse-phase using an Agilent 1100 HPLC equipped with DAD UV/VIS detector and single quadrapole mass spec (Agilent, Santa Clara, CA, USA). To discriminate between labeling of the salicylate ring and the HCH ring of salicortin, the remaining half of the methanolic extract was subjected to mild alkaline hydrolysis, and salicortin breakdown products were analyzed. The hydrolytic procedure was developed by using an authentic salicortin standard (kindly provided by R.L. Lindroth, University of Wisconsin). Briefly, the methanolic extract was mixed with 1:10 vol/vol 0.5 M sodium carbonate (pH 11.45) for hydrolysis at 60°C for 20 min. Under these conditions, all of the salicortin was hydrolytically cleaved, liberating salicin and HCH (Ruuhola et al. 2003). Since salicin also occurs naturally in *Populus* leaves, the amount of salicin prior to hydrolysis was subtracted from the amount of salicin after hydrolysis to estimate the amount of salicin specifically hydrolyzed from salicortin. Since an authentic HCH standard was not available, the data for putative HCH is presented in absorbance units for relative comparisons.

Each extract or hydrolysate (10 µl) was loaded onto an Eclipse XDB-C18 column (150 x 2.1 mm, Agilent, Santa Clara, CA, USA) equipped with an Eclipse XDB-C8 guard column (12.5 x 4.6 mm). Compounds were resolved using a 0.2 ml min^{-1} flow rate of mobile phase A (10 mM formic acid, pH 3.3) and mobile phase B (acetone), with the following gradient: 0–15 min (linear 0–70% B), 15–17 min (linear 70–100% B), and 17–19 min (100% B). Samples were analyzed by a DAD detector (recorded spectrum at 200–400 nm, and chromatographic signal at 215, 255, 270, 310, and 350 nm), as well as MS detection. The MS detector (negative ion mode) was set to API-ES ionization mode, *m/z* 90–800, with a drying gas temperature of 350°C, a flow rate of 10.0 l min^{-1}, and a voltage cap of 3,000 V. Due to the use of negative polarity, ions typically were detected as $[M–1]^-$. Additionally, some ions were observed at *m/z* 46 units higher than expected based on formula mass, due to formation of formide adducts $[M-H+HCOOH]^-$, from the formic acid mobile phase. Isotope labeled and unlabeled PG concentrations were determined from standard curves of authentic salicin and salicortin, using extracted ion chromatogram peak areas, and are presented as the concentration on a dry weight basis (µmol g^{-1} dry weight).

Statistical Analysis For each experiment, analysis of variance was performed using SigmaStat software version 3.5 (Systat Software, Inc., San Jose, CA, USA). When *ANOVA* indicated a significant effect of administration treatments or co-administration treatments, data were analyzed further by using a multiple comparison test. For labeled cinnamate, salicylate, and benzoate administration, all treatments were compared pairwise using a Fisher's protected *LSD* (α= 0.05). For co-administration experiments, a Holm-Sidak multiple comparison test was performed, with all treatments compared to the control, which was $[^{13}C]$-CA administration with no co-administration.

Results

Incorporation of Stable Isotope Labeled CA into PG We administered 0.5 mM $[^{13}C_6]$-CA to the leaf disks and evaluated isotope incorporation into PG. The [M+6] differential allowed us to distinguish clearly between the $[^{13}C_6]$-labeled and natural abundance forms of salicin and salicortin. When $[^{13}C_6]$-CA was administered to leaf disks for 6 h, a new ion indicating labeled salicin (*m/z* 337) $[M+6-H+HCOOH]$ appeared with the same retention time (11.5 min) as $[^{12}C]$-salicin (Fig. 2a and b). Authentic standard salicin was detected at *m/z* 331 $[M-H+HCOOH]^-$, consistent with detection of the formide adduct of salicin, due to formic acid in our HPLC solvent. This confirmed that CA is a precursor for salicin. Three ions of salicortin were detected at the same retention time (13.25 min) following administration (Fig. 2c). These included unlabeled salicortin at *m/z* 423 $[M–H]^-$, and two new ions that were 6 and 12 units larger (*m/z* 429 $[M-H+6]^-$ and *m/z* 435 $[M-H+12]^-$). Only the 423 ion was detected in extracts from control leaf disks (Fig. 2d). This indicated that the CA tracer was incorporated into salicortin, and that both the salicyl and HCH rings were derived from CA. Hereafter, the occurrence of the 429 ion is referred to as single-ring labeled salicortin, while the 435 ion is referred to as double-ring labeled salicortin.

A hydrolytic procedure was used to confirm tracer incorporation into the HCH or salicyl moieties of salicortin (see Methods and Materials). The hydrolysis of salicortin resulted in 2 major peaks on the HPLC chromatogram, including salicin (*m/z* 331) and an unidentified peak (*m/z* 187). The *m/z* 187 of the unidentified peak is consistent with the mass of 1-hydroxy-6-oxo-2-cyclohexene-1-hydroxymethane (HCH-alcohol) with a formide adduct $[M-H+HCOOH]$. Administering $[^{13}C_6]$-CA resulted in *m/z* 337 and *m/z* 193 following hydrolysis, consistent with labeled salicin and HCH-alcohol, respectively. For leaf extracts, there was an additional major peak with *m/z* 177 following hydrolysis, but the UV absorbance maxima (310 and 320 nm) suggested that this peak was derived from hydroxycinnamates. Hereafter, we treat the 187 ion as the putative HCH-derived hydrolysis product of salicortin, and the 193 ion as its $^{13}C_6$ labeled homolog.

Peak areas of labeled salicin and salicortin were smaller than those of the unlabeled forms (Fig. 2a and c). This was

Fig. 2 Salicylate glycoside labeling from [$^{13}C_6$]-cinnamic acid. Labeled (*m/z* 337, dashed line) and unlabeled (*m/z* 331, solid line) salicin, as well as single (*m/z* 429, dashed line) and double (*m/z* 435, dotted line) ring labeled salicortin and unlabeled salicortin (*m/z*=423, solid line) following **a**, **c** [$^{13}C_6$]-CA administration, or **b**, **d** control incubation. Chromatograms show overlays of mass-spec detector (MSD) extracted ion signals for the unlabeled ions on the primary y-axis, and for the labeled ions on the secondary y-axis (note the smaller scale on the secondary y-axes)

observed over a time course of 2, 4, and 6 h of administration, which showed a continual slow accumulation of labeled salicortin up to 0.7 µmol/g over 6 h, relative to 50–60 µmol/g unlabeled salicortin. Double-ring labeled salicortin was more abundant than single-ring labeled salicortin when [$^{13}C_6$]-CA was administered at 0.5 mM, but the reverse was true at the lower administration level of 0.1 mM (Fig. 3b). More double- than single-ring labeling at high administration levels may indicate that [$^{13}C_6$]-CA was present in the leaf cells at higher concentrations than the endogenous, unlabeled pool. This would suggest that the uptake of [$^{13}C_6$]-CA was not limiting, but the low percentage of labeled salicortin was due to slow biosynthesis.

Incorporation of Labeled Benzoates and Salicylates into PG Because they are putative intermediates in salicin biosynthesis, [$^{13}C_6$]-labeled benzyl alcohol, benzaldehyde, salicyl alcohol, and salicylaldehyde, as well as [$^2H_5$]-BA

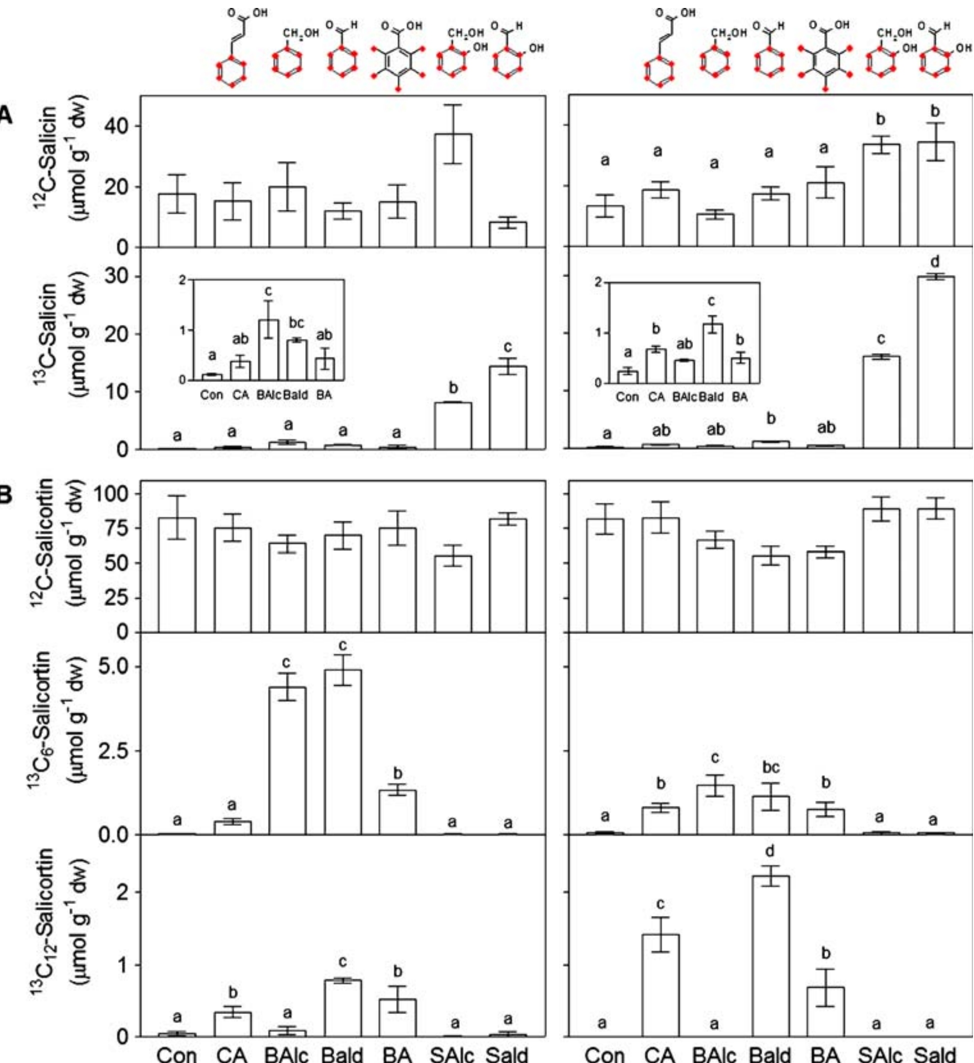

Fig. 3 Incorporation of stable isotope from labeled compounds into **a** salicin, and **b** salicortin. *Populus nigra* leaf disks were incubated in 0.2% sodium bicarbonate (Con) and with [$^{13}C_6$]-cinnamic acid (CA), [$^{13}C_6$]-benzyl alcohol (BAlc), [$^{13}C_6$]-benzaldehyde (Bald), [D_5]-benzoic acid (BA), [$^{13}C_6$]-salicyl alcohol (SAlc) or [$^{13}C_6$]-salicylaldehyde (Sald) administered at 0.1 mM (left panels) or 0.5 mM (right panels) for 6 h. Bars indicate means ± standard errors (N=3). Fisher's protected LSD was used to compare all treatments pairwise. Like letters above bars indicate a lack of significant difference. A separate analysis was conducted for insets

(Fig. 1) were administered to *P. nigra* leaf disks. Administering [$^2H_5$]-BA resulted in [$^2H_4$]-salicin (*m/z* 335, $[M-H+HCOOH+4]^-$), as well as [$^2H_4$]- and [$^2H_8$]-salicortin (*m/z* 427 $[M-H+4]^-$ and *m/z* 431 $[M-H+8]^-$, respectively). Administering labeled SA was not conducted, because preliminary administration of unlabeled SA yielded only SA glucoside (SAG) (Suppl. Fig. 1). We anticipated this result since transgenic knockdown of SA in *Populus* reduced SAG concentrations, but not those of salicin, salicortin, or tremuloidin (Morse et al. 2007).

Tracer from salicyl alcohol, salicylaldehyde, BA, benzyl alcohol, and benzaldehyde was incorporated into salicin, as was previously observed by Zenk (1967). Administration of labeled salicylaldehyde also resulted in trace levels of its labeled glucoside, helicin (RT 12.5 min; *m/z* 335) $[M-H+HCOOH+6]^-$, confirmed based on retention time and mass spectrum of authentic helicin. Unlabeled helicin was not detected in any other leaf samples. This indicates that salicylaldehyde is converted mostly to salicyl alcohol before conversion to salicin, with helicin as a minor artifact (via nonspecific glycosyltransferase activities). Alternatively, salicylaldehyde is glycosylated to form helicin first before being reduced rapidly to form salicin, thus leaving a small standing pool of helicin. Helicin has been suggested previously to be an intermediate in salicin biosynthesis (Zenk 1967). Accumulation of labeled salicin was 13–75 fold higher for salicyl alcohol and salicylaldehyde than for BA, benzyl alcohol, benzaldehyde or CA administration (Fig. 3a). Labeling of salicin from salicyl alcohol and salicylaldehyde increased with the administration concentrations from 0.1 mM to 0.5 mM, but remained constant and comparatively low from BA, benzyl alcohol, benzaldehyde, or CA at both administration concentrations. Administering salicylaldehyde and salicyl alcohol also resulted in accumulation of [$^{13}C_6$]-isosalicin (*m/z* 291) $[M-H+6]^-$, which was not present in the control leaf disks (Suppl. Fig. 2). The identity of isosalicin was based on comparison to the retention time and mass spectrum of authentic unlabeled isosalicin (*m/z* 285) $[M–H]^-$ (kindly provided by Dr. Bernd Schneider, Max Plank Institute for

Chemical Ecology). Although the molecular mass of isosalicin and salicin are the same, the difference in *m/z* (285 for isosalicin vs. 331 for salicin) indicates that electrospray ionization did not result in a formide adduct of isosalicin. Administration of benzyl alcohol and benzaldehyde also resulted in a new peak (not shown), putatively the labeled glucoside of benzyl alcohol, benzyl-glucoside, based on *m/z* 315 $[M - H + HCOOH + 6]^-$.

Label from salicyl alcohol and salicylaldehyde administered at either 0.1 mM or 0.5 mM was not incorporated into salicortin (Fig. 3b; Suppl. Fig. 2B and C). However, administration of labeled CA, BA, and benzaldehyde each resulted in double- and single-ring labeled salicortin. Interestingly, benzyl alcohol administration resulted in only single-ring labeled salicortin (Fig 3b). Analysis of hydrolyzed leaf extracts confirmed isotopic labeling of both the salicyl and HCH moieties of salicortin from labeled CA, BA, and benzaldehyde (Suppl. Fig 2B and C). On the other hand, tracer from benzyl alcohol was found only in the salicyl ring. With respect to salicortin biosynthesis, the data suggest that salicin and HCH may be derived from BA or benzaldehyde, but that enzymatic conversion of BA and/or benzaldehyde to benzyl alcohol could favor synthesis of the salicyl moiety.

Co-administration of Salicylates and Benzoates Affected PG Biosynthesis from $^{13}C_6$-cinnamate In preliminary co-administration experiments, $[^{13}C_6]$-CA was administered along with unlabeled salicylates, cinnamates, benzoates, and salicin (Suppl. Fig. 3). For preliminary testing, $[^{13}C_6]$-CA was administered at 0.5 mM, while the unlabeled compounds were provided at 0.5 mM and 1.0 mM. BA, 4-hydroxy-BA, *p*-coumaric acid, SA, and salicin had no effect on concentrations of labeled or unlabeled salicortin. In contrast, benzyl alcohol, benzaldehyde, salicyl alcohol, and salicylaldehyde had the most pronounced effects, reducing the labeling of salicin and salicortin (Suppl. Fig. 3). Therefore, dose response experiments were conducted for benzyl alcohol, benzaldehyde, salicyl alcohol and salicylaldehyde, to aid in the interpretation of the label incorporation experiments.

Unlabeled salicyl alcohol, salicylaldehyde, benzaldehyde, and benzyl alcohol, at concentrations ranging from 0.01 to 1 mM, were co-administered along with 0.5 mM $[^{13}C_6]$-CA for dose response experiments (Fig. 4). Unlabeled salicyl alcohol and salicylaldehyde resulted in a drastic increase in the concentration of unlabeled salicin *m/z* 331, but a decrease in the amount of salicin that was labeled *m/z* 337 (Fig. 4c and d). This is consistent with label dilution due to facile glucosylation of the administered salicylates. Additionally, a portion of the salicyl alcohol that was administered was also converted into unlabeled isosalicin (Suppl. Fig. 4C) *m/z* 285. Similarly, co-administering salicylaldehyde also resulted in a dose-dependent increase in unlabeled isosalicin *m/z* 285, but also resulted in labeled isosalicin (Suppl. Fig. 4D) *m/z* 291.

Salicyl alcohol and salicylaldehyde also reduced incorporation of label from CA into salicortin (Fig. 4g and h) *m/z* 429 and *m/z* 435. The response was weakly apparent at 0.1 mM, and the labeling was reduced further with increasing salicylaldehyde or salicyl alcohol concentrations.

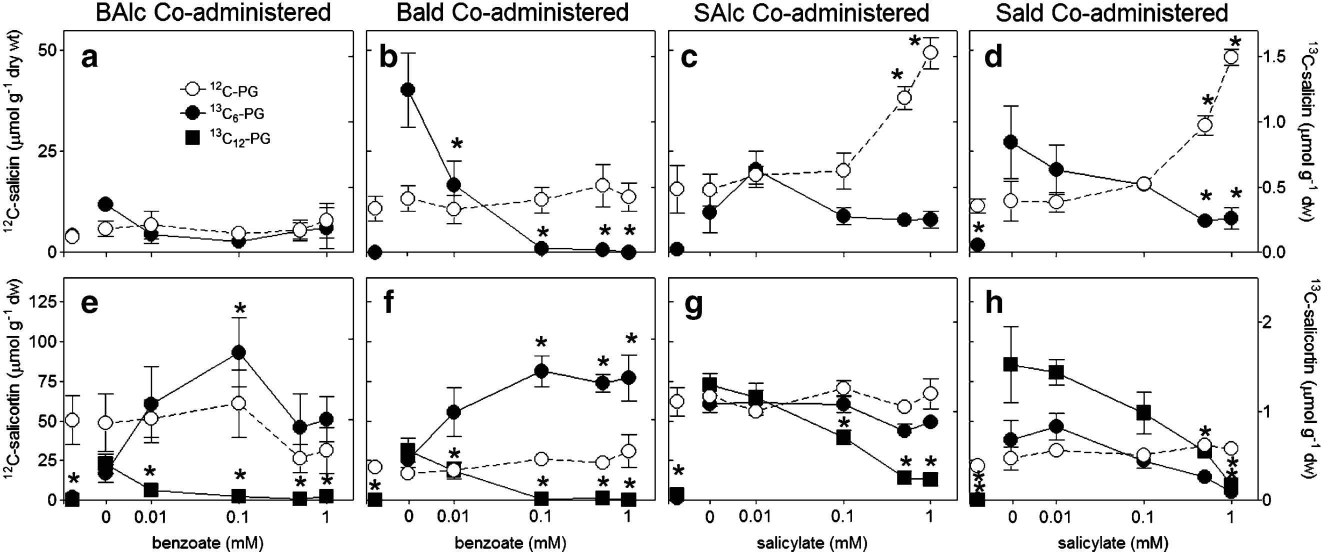

Fig. 4 Response of PG biosynthesis to co-administration of different concentrations of unlabeled BAlc, Bald, SAlc, and Sald. *De novo* PG biosynthesis was determined as $[^{13}C_6]$-CA conversion to $[^{13}C]$-PG. Values for no isotope controls are shown to the left of the response curves within each graph. Salicin is shown above **a**–**d**, and salicortin below **e**–**h**. Symbols and error bars indicate means and standard errors (N=3). Asterisks above symbols indicate significant differences from the no co-administration ^{13}C-CA control, using Holm-Sidak multiple comparison procedure

Analysis of hydrolysates indicated that labeling of both salicyl and HCH rings was decreased (Suppl. Fig. 4G, H, K and L). Together with the findings that label from salicyl alcohol and salicylaldehyde was not incorporated into salicortin (Fig. 3b), the reduction in [$^{13}C_6$]-CA-dependent labeling of salicortin in the co-administration experiment was consistent with inhibition or downregulation of *de novo* salicortin biosynthesis following salicyl alcohol and salicylaldehyde administration. Total salicortin concentrations did not decrease, probably because it is a relatively stable metabolite *in vivo*.

Co-administration of either unlabeled benzaldehyde or benzyl alcohol did not increase salicin levels or lead to accumulation of isosalicin (Fig. 4a, b; Suppl. Fig. 4A and B). However, both benzaldehyde and benzyl alcohol reduced incorporation of label from [$^{13}C_6$]-CA into salicin *m/z* 337, when co-administered at concentrations as low as 0.01 mM (Fig. 4a and b). Interestingly, formation of single-ring labeled salicortin *m/z* 429 from [$^{13}C_6$]-CA was stimulated (Fig. 4e and f), while double-ring labeled salicortin *m/z* 435 was reduced at 0.01 mM, and was essentially eliminated at 0.1 mM or higher concentrations of benzaldehyde and benzyl alcohol. The decreases in double-ring labeling of salicortin were due to decreased label incorporation into the salicyl moiety (Suppl. Fig. 4E and F). Thus, benzaldehyde and benzyl alcohol are both likely to be intermediates in the biosynthesis of the salicyl moiety. We observed a stimulation of HCH labeling that paralleled the increase in single-ring salicortin labeling, following benzyl alcohol and benzaldehyde co-administration (Suppl. Fig. 4I and J vs. Fig. 4e and f). At higher concentrations, benzyl alcohol appeared to have a negative effect as salicortin labeling decreased. However, benzaldehyde did not have the same effect, since salicortin labeling remained stable. These results are consistent with a sensitivity of the salicyl and HCH pathways to benzoate substrate availability.

Shortening the CA Propenyl Side Chain Deuterated (^{2}H) CA was administered to leaf disks to track the side-chain modification and hydroxylation reactions that lead to salicylate PGs. Each of the 5 hydrogen atoms at the phenyl ring, as well as the hydrogen at the β-carbon of the propenyl side-chain, was substituted with ^{2}H ([$^2H_6$]-CA; Fig. 1). The removal of the ^{2}H at the C-2 position of the phenyl ring is expected upon *O*-hydroxylation, based on the results of [$^2H_5$]-BA administration (see above). The removal of the ^{2}H on the β-carbon can indicate that the propenyl side chain shortening of cinnamate proceeds via a β-oxidative route (Jarvis et al. 2000). Upon administering [$^2H_6$]-CA, [$^2H_4$]-salicin *m/z* 335 $[M - H + HCOOH + 4]^-$ as well as $^2H_4$- and $^2H_8$-salicortin *m/z* 427 $[M - H + 4]^-$ and 431 $[M - H + 8]^-$ were detected (Supp Fig. 5), suggesting that a second deuterium was indeed removed from the β-carbon.

Discussion

Salicortin, a salicylate-containing phenolic glycoside (PG), plays an important role in ecological interactions and growth of *Populus* (Hwang and Lindroth 1997; Donaldson et al. 2006), but little is known about its biosynthetic pathway. Using stable isotope labeled prescursors, we provide the first direct empirical evidence that not only the salicyl moeity, but also the HCH moiety, of salicortin may be derived from CA, with benzoates as intermediates.

Salicin, the 2-*O*-glucoside of salicyl alcohol, has been considered a possible precursor of the salicyl moiety of salicortin (Ruuhola and Julkunen-Tiitto 2003). While administering labeled salicylaldehyde and salicyl alcohol resulted in accumulation of labeled salicin, it did not result in labeled salicortin at either concentration tested. Two possible explanations can be offered. First, salicylaldehyde and salicyl alcohol are precursors to salicortin, but exogenous salicylaldehyde and salicyl alcohol cannot gain entry to the salicortin biosynthetic pathway due to either metabolic channeling or abnormal sub-cellular localization. Metabolic channeling is known to be important for certain phenylpropanoid branch pathways (Winkel 2004). Exclusion of exogenous salicylaldehyde and salicyl alcohol from entering into PG pathways would not preclude glucosylation of salicylaldehyde or salicyl alcohol, since the glucosyltransferases that catalyze this type of reaction are known for their promiscuity in substrate affinity (Vogt and Jones 2000). Glucosylation of salicylaldehyde and salicyl alcohol in an abnormal sub-cellular context could have impeded their subsequent conjugation to HCH for salicortin synthesis, since glucosylation is known to alter sub-cellular localization of phenolics (Dean et al. 2003). If salicylaldehyde and salicyl alcohol were excluded from the salicortin biosynthetic pathway, the reduction of salicortin labeling from [$^{13}C_6$]-CA by co-administering unlabeled salicylaldehyde and salicyl alcohol cannot be explained by biosynthetic competition, but might be explained by down-regulation of the pathway or competition for a common pool of glucose or UDP-glucose. Second, it is plausible that salicylaldehyde and salicyl alcohol, and hence salicin, are not intermediates in salicortin biosynthesis. Since label from BA, benzaldehyde, and benzyl alcohol was incorporated into the salicyl group of salicortin, it is possible that salicortin biosynthesis may, instead, involve formation of a benzyl conjugate (e.g., benzyl-HCH or benzyl-benzoate) first, and then conversion of the benzyl moiety to a salicyl moiety by 2-hydroxylation (Fig. 5).

Among the benzoates, benzyl alcohol would be the most likely precursor of the salicyl ring of salicortin, since HCH is conjugated to the alcohol moiety of the salicyl group in salicortin (Pearl and Darling 1970, 1971). Consistent with this, co-administration of unlabeled benzaldehyde, benzyl alcohol, and, to a much lesser extent, BA, reduced labeling

Fig. 5 Revised working model of the salicortin biosynthetic pathway, or metabolic grid. Solid black arrows indicate pathways proposed previously in willow, tobacco, petunia and snapdragon (Zenk 1967; Jarvis et al. 2000; Ruuhola and Julkunen-Tiitto 2003; Boatright et al. 2004; Orlova et al. 2006; Long et al. 2009. Dashed black arrows indicate newly hypothesized pathways, including a CA/benzoate origin for 1-hydroxy-6-oxo-2-cyclohexene-1-carboxylic acid (HCC), the possible free acid precursor of the HCH moeity of salicortin (Pierpont 1994)

of the salicyl moiety of salicortin from [$^{13}C_6$]-CA. Administration of labeled BA and benzaldehyde resulted in labeled HCH and salicyl moieties, whereas labeled benzyl alcohol resulted only in a labeled salicyl moiety. Taken together, the results support a pathway in which CA is sequentially converted to BA and/or benzaldehyde, then to benzyl alcohol, and then to the salicyl moiety of salicortin. Further work will be necessary to resolve whether endogenous free salicylaldehyde and salicyl alcohol are intermediates in salicortin biosynthesis.

Isotope labeling suggests that BA and benzaldehyde, but not benzyl alcohol, may be intermediates in the conversion of CA to the HCH moiety of salicortin. However, co-administration of BA or benzaldehyde did not reduce label incorporation from [$^{13}C_6$]-CA into HCH. This suggests that benzoates might participate in a tangential, but interchangeable pathway, rather than as direct intermediates in the biosynthesis of HCH and its proposed immediate precursor, HCC (Fig. 5; Pierpont 1994). Emerging evidence from petunia suggests that benzoyl-CoA may be a precursor to

benzoic acid (grey box, Fig. 5). In petunia, CA may be converted to benzoyl-CoA via the β-oxidative pathway (Boatright et al. 2004; Orlova et al. 2006; Long et al. 2009). Most of the BA resulting from the β-oxidative pathway is actually derived from hydrolysis of benzyl-benzoate, itself the product of benzoyl-CoA conjugation with benzyl alcohol (Boatright et al. 2004; Orlova et al. 2006; Long et al. 2009). The benzoate pool also may be derived from two separate non-β-oxidative pathways via conversion of CA directly to benzaldehyde, or of phenylpyruvate directly to benzaldehyde (Boatright et al. 2004; Orlova et al. 2006; Long et al. 2009). In petunia, at least, both β-oxidative and non-β-oxidative pathways appear to be active simultaneously, although with differential flux and diurnal regulation (Boatright et al. 2004; Orlova et al. 2006). It is not yet clear whether either or both β-oxidative and non-β-oxidative pathways also exist in other distantly related species, such as *Populus*. The deuterium label at the β-carbon of [$^{2}H_{6}$]-CA administered to leaf disks was lost during the conversion to PGs, for both salicyl and HCH moieties, providing evidence in favor of a β-oxidative pathway in *Populus*. This result is similar to previous findings for tobacco (Jarvis et al. 2000), but we cannot rule out a contribution from a non-β-oxidative pathway, particularly under different environmental conditions (e.g., dark cycle).

The findings that both the salicyl and HCH moieties may be synthesized from the benzoates point to the importance of benzoate pool transformations in regulating salicortin biosynthesis. In *Salix pentandra* roots, which contained no PGs, administration of benzoic acid resulted in salicortin accumulation, providing further support for the central involvement of benzoates in the biosynthesis of both salicyl and HCH rings (Ruuhola and Julkunen-Tiitto 2003). Interestingly in this regard, co-administering unlabeled benzoic acid did not decrease HCH labeling from [$^{13}C_{6}$]-CA, while benzaldehyde and benzyl alcohol increased HCH labeling with a concomitant reduction in salicyl ring labeling. Unlabeled benzaldehyde and benzyl alcohol likely competed with the [$^{13}C_{6}$]-CA-derived pool for incorporation into the salicyl moiety, thereby reducing salicyl labeling, and shunting [$^{13}C_{6}$]-CA-derived metabolites toward the HCH pathway. If conversion to free benzoates is tangential to HCH biosynthesis, as discussed above, co-administering benzoates may be less likely to reduce HCH labeling directly. This would also be consistent with the structural complexity of HCH, implicating a multi-step conversion from the benzoate precursors, as opposed to the more facile conversion from benzoates to the salicyl moiety. On the other hand, if co-administration stimulated metabolism of benzoates through alternative pathways, the proportional labeling of the benzoate pools might have been higher than expected. Although it is unclear whether an alternative pathway was stimulated, benzaldehyde and benzyl alcohol administered to leaf disks were converted to benzyl-glucoside, indicating that at least one alternative pathway for benzoates was active. A synthesis of these scenarios is that there is great flexibility in the maintenance of salicyl:HCH balance due to the dynamic nature of benzoate and hydroxycinnamate pool size and complexity. The increased HCH labeling upon benzaldehyde and benzyl alcohol co-administration also suggests a possible signaling role of benzoates in maintaining the salicyl:HCH balance, which warrants further investigation.

PGs are diverse (Tsai et al. 2006), so the pathway is likely to be complex, and may vary in a species- and genotype-dependent manner. Ruuhola et al. (2003) suggested a metabolic grid for PG biosynthesis, rather than a strict pathway model. This would allow the possibility of multiple pathways of salicortin biosynthesis (e.g., salicyl alcohol-dependent and independent) that could function simultaneously or under different conditions. For example, administration of radiolabeled *o*-coumaric acid resulted in radioactive salicyl alcohol in *S. purpurea* (Zenk 1967). In our study, unlabeled *o*-coumaric acid appeared to compete with labeled CA for incorporation into both salicyl and HCH moieties of salicortin, although we cannot rule out that this result was due to inhibition rather than competition. Since 2-hydroxylation of benzoates can occur in *Populus*, as indicated by [$^{2}H_{5}$]-BA administration, *o*-coumaric acid might lie at the head of another pathway within the PG biosynthetic grid. Future studies will be necessary to test the extent to which 2-hydroxylation normally occurs before and after shortening of the propenyl side chain of CA.

By our revised model, the salicin biosynthetic pathway may need to be considered as a branch separate from the salicortin biosynthetic pathway, at least in some cases. Label from both salicylaldehyde and salicyl alcohol was incorporated into salicin. Co-administering unlabeled salicylaldehyde and salicyl alcohol reduced, but did not eliminate, label incorporation from CA into salicin, and it resulted in accumulation of high concentrations of unlabeled salicin, suggesting multiple pathways to salicin. However, administering unlabeled benzaldehyde or benzyl alcohol eliminated label incorporation from [$^{13}C_{6}$]-CA into salicin, indicating that all pathways to salicin required benzaldehyde and benzyl alcohol intermediates in our experimental system. Label from benzoates was also incorporated into salicin, but at a much lower rate than for salicylaldehyde and salicyl alcohol administration, suggesting that conversion from benzoates to salicylates may have been a rate limiting step. In addition, the proportion of salicortin that was labeled during benzoate administration was equal or greater than the proportion of salicin that was labeled. If salicin is an intermediate in

salicortin biosynthesis, then there may be more than one pool of salicin to account for the lack of labeling dilution in salicortin. A higher abundance, low turn-over pool (e.g., vacuolar storage) would explain the low percent labeling of salicin, while a smaller, high-turnover pool of salicin, that serves as intermediates for salicortin biosynthesis, could account for the higher than expected labeling in salicortin if salicin is an intermediate. Therefore, we conclude that a metabolic grid needs to be considered for salicin biosynthesis.

Salicin, while not incorporated into salicortin in the present study, cannot be excluded as a possible precursor for other PG derivatives, such as tremuloidin, that are not present in the experimental *P. nigra* clone. The HCH-devoid tremuloidin consists of a BA conjugated to the glucose moiety of salicin, and could be derived from a separate biosynthetic route than salicortin.

In summary, our results indicate that both the salicyl and the HCH rings of salicortin are of phenylpropanoid origin. CA is routed through benzyl alcohol in biosynthesis of the salicyl moiety, but is diverted upstream at benzaldehyde, BA, and/or benzoyl-CoA for synthesis of HCH. The sequenced *Populus trichocarpa* genome (Tuskan et al. 2006) and associated resources now offer the possibility of targeting specific gene families for functional genomic study (e.g., hydroxylases, glycosyltransferases) to begin identifying genes involved in the PG biosynthetic pathway. Future studies to identify PG-related genes should be designed that give consideration to all of the hypothetical pathways in our revised metabolic grid model. One novel addition to the metabolic grid of salicortin biosynthesis consists of addition of a benzoate group at the alcohol moiety of benzyl alcohol, followed by conversion of the benzoate moiety to HCH, 2-hydroxylation to form salicyl-HCH, and then glucosylation at the 2-hydroxyl group of the salicyl alcohol ring.

Abstract Some lichen compounds are known to deter feeding by invertebrate herbivores. We attempted to quantify the deterring efficiency of lichen compounds against a generalist vertebrate, the bank vole (*Myodes glareolus*). In two separate experiments, caged bank voles had the choice to feed on lichens with natural or reduced concentrations of secondary compounds. We rinsed air-dry intact lichens in 100% acetone to remove extracellular compounds non-destructively. In the first experiment, pairs of control and rinsed lichen thalli were hydrated and offered to the bank voles. Because the lichens desiccated fast, we ran a second experiment with pairs of ground control and compound-deficient thalli, each mixed with water to porridge. Eight and six lichen species were tested in the first and second experiment, respectively. In the first, bank voles preferred compound-deficient thalli of *Cladonia stellaris* and *Lobaria pulmonaria*, but did not discriminate between the other thallus pairs. This was likely a result of deterring levels of usnic and stictic acid in the control thalli. When lichens were served as porridge, significant preference was found for acetone-rinsed pieces of *Cladonia arbuscula*, *C. rangiferina*, *Platismatia glauca,* and *Evernia prunastri*. The increased preference was caused mainly by lower consumption of control thalli. Grinding and mixing of thallus structures prevented bank voles from selecting thallus parts with lower concentration of secondary compounds and/or strengthened their deterring capacity. We conclude that some lichen secondary compounds deter feeding by bank voles.

Introduction

Lichens are photosynthetic organisms adapted to environments that are too low in nutrients, too cold, and/or too dry for vascular plants. Globally, as much as 8% of the land surface is dominated by lichens (Larson 1987). Lichen-dominated ecosystems are widespread in alpine and northern areas, but lichen herbivores are few. They include species of molluscs, oribatide mites, and moth larvae, as well as rodents, reindeer/caribou (*Rangifer tarandus*), and musk deer (*Moschus moschiferus*).

Few herbivores are adapted to lichen consumption. Compared with most forage plants, arboreal lichens regularly eaten by flying squirrels (*Glaucomys sabrinus*) and red-backed voles (*Myodes gapperi*) in Idaho, USA, are deficient in lipids, nitrogen, and several trace elements (Dubay et al. 2008). These animals have a low ability to digest and utilize nitrogen from lichens and are unable to maintain their N balance when feeding on lichens alone. In addition, most lichen species contain high amounts of carbon-based secondary compounds. Most of these lichen compounds are polyphenols that originate via the polyketide pathway (Culberson et al. 1977). They are produced by the fungal partner (Leuckert et al. 1990; Culberson and Armaleo 1992) by using the photosynthates delivered from the algae. More than 800 lichen compounds have been

identified (Huneck and Yoshimura 1996), and 0–5 compounds commonly are present in each lichen species. Many lichen secondary metabolites are biologically active and may protect the organisms against various pests (Huneck 1999; Romagni et al. 2000; Manojlovic et al. 2002) and environmental stresses (Bialonska and Dayan 2005). Some compounds also are known to deter grazing by invertebrates (Lawrey 1983a; Emmerich et al. 1993; Gauslaa 2005; Pöykkö et al. 2005). In a study of food choice by the slug *Pallifera varia*, Lawrey (1983a, b) observed that lichen species with the lowest concentrations of N and P were preferred. Lichens rich in N and P had a stronger chemical herbivore defense in terms of lichen compounds. In 2004, 400–500 free ranging elk (*Cervus elaphus*) developed paresis and died in Wyoming, USA, probably due to intoxification by the lichen *Xanthoparmelia chlorochroa* (Cook et al. 2007). Reindeer and caribou, on the other hand, survive on a winter diet that consists exclusively of lichens (Klein 1982; Aagnes and Mathiesen 1994; Terry et al. 2000; Storeheier et al. 2002). Recently, Sundset et al. (2008) identified a reindeer rumen bacterium that was able to tolerate and grow in the presence of various common lichen compounds, including the very common usnic acid. This suggests that reindeer are lichen feeding specialists, capable of detoxifying lichen compounds.

Earlier published experiments on the defensive role of lichen compounds have focused on invertebrates. Our aim was to test deterence against an herbivorous vertebrate, the bank vole (*Myodes glareolus*). The bank vole is a mixed granivorous-folivorous rodent. In Fennoscandia, it is most common in forests (Hansson 1978, 1983). In contrast to the central European bank vole that eats mostly easily digestible food and nutritious seeds, the Scandinavian bank vole feeds on forbs in summer, berries in late summer, fungi in summer-autumn, dwarf-shrubs (*Vaccinium* spp.) in autumn-winter, and lichens at least in winter-spring (Hansson 1985; Esseen and Renhorn 1998). Alectorioid lichens may constitute a significant part of the bank vole diet in old forests where they often occur in great abundance, but their dietary importance varies among years (Hansson and Larsson 1978; Hansson 1979).

By rinsing air-dry lichen thalli in 100% acetone, a substantial part of the secondary compounds can be extracted non-destructively (Solhaug and Gauslaa 1996, 2001). Thereafter, we can offer bank voles a choice between pairs of lichen pieces with and without assumed defensive compounds. This approach has been used in studies both with generalist (Gauslaa 2005) and specialist (Pöykkö et al. 2005) invertebrates, but not with vertebrates. By using pairs with control thalli and acetone-rinsed thalli of eight lichen species, we tested the hypothesis that reduced lichen compound concentrations lead to increased bank vole consumption of lichen material.

Methods and Materials

The Herbivore Ten adult bank voles, 4 males and 6 females, were captured in Vegårshei, Aust-Agder, S Norway, during 28 March–14 May 2005. The voles were named with letters A to J for identification, and were kept separately in 30×50×13 cm large cages. Between experiments they were fed every 2nd day with apples and bread. Water was always available in petri dishes.

Collection and Preparation of Lichens Eight species were collected in SE Norway in 2005 and used in the experiments from May to December 2005. *Cladonia arbuscula* (Wallr.) Flot. and *Cladonia rangiferina* (L.) F.H. Wigg were from a clear-cut in Siljan, Telemark, while *Cladonia stellaris* (Opiz.) Pouzar & Vězda was collected in an open pine forest in Atna, Hedmark. *Evernia prunastri* (L.) Ach. was sampled from oak trees near cultivated fields in Ås, Akershus. *Parmelia saxatilis* (L.) Ach. was picked from boulders in Ås, while *Platismatia glauca* (L.) W.L Culb. & C.F. Culb. originated from birch twigs in a spruce forest at Kittilbu, Gausdal, Oppland. *Lobaria pulmonaria* (L.) Hoffm. was collected on *Populus tremula* stems in Siljan, while *Umbilicaria spodochroa* (L.) Hoffm. was found on sea cliffs in Drøbak, Akershus.

After collection, sampled thalli were dried at room temperature for 48 h and then stored in a freezer (−20°C) until start of the experiment. One day before an experiment started, one species was taken from the freezer, all debris removed, and 20 randomly selected pieces of 1–2 g were prepared. They then were stored overnight, before dry weight was determined.

Ten randomly selected pieces were rinsed in 100% acetone. Each sample was put into a beaker placed in a fume cap. Acetone was added until it covered the entire lichen, by using either 100 or 200 ml, depending on the size of the thallus. Beakers were covered to avoid evaporation of acetone. After 20 min, the acetone with extracted compounds was transferred immediately to an empty glass flask closed by a lid. The procedure was repeated twice, and the supernatants were combined. An aliquot of 5 ml of the extract was transferred to a marked vial and left overnight to evaporate. Dried extracts were stored in freezer until HPLC analyses.

Before feeding lichens to the voles, all samples were weighed again, and moistened with water. Two different feeding experiments that used pairs of controls and compound-deficient lichens were done; 1) intact and hydrated thalli were offered to the voles, or 2) hydrated thalli finely ground in a ball mill (Retsch) for 3 min and mixed with more water were offered as porridge served in petri dishes. The latter approach was added because we observed that intact thalli dried within 2–3 h in the vole

cages, and desiccated thalli appeared less attractive than moist thalli. The porridge remained moist for 10–12 h. Two species, *L. pulmonaria* and *P. saxatilis*, were not served as porridge. We did not have enough material of *L. pulmonaria* from the same population, while the *P. saxatilis*-powder was highly hydrophobic and did not form porridge.

Feeding Experiments Between experiments, voles were fed with bread and apples. Before the start of a new experiment, all remaining food was removed from the cages. During the porridge experiments, we also removed sawdust and vole feces to avoid such debris from mixing with the fodder. The fodder was served in the cage in two permanently open traps so that the vole could go in and out, but the entrance was too small for the vole to drag the petri dish out of the trap and mix the two samples. One trap contained an acetone-rinsed sample, the other an unrinsed control. The feeding lasted from 3.30 PM to 08.00 AM the following day in experiments that used whole lichen thalli, and from 11.00 PM to 08.00 AM the following day in experiments with lichen porridge. Feeding experiments were run late evening and in the night when voles are most active, and disturbance by human activities is minimal. After the experiment, samples were collected from e cages and left to dry at room temperature for 1 D. All debris was removed before weighing. Each experiment was performed twice, as we had only 10 traps. This means that 5 voles were given the choice between treated and non-treated samples of one lichen species on one day, and the following day 5 new voles went through the same experiment ($N=10$).

High Performance Liquid Chromatography (HPLC) Analysis Dry lichen extracts from the acetone rinsing were redissolved in 500 µl of acetone and analysed on an 1100 Series HPLC (Agilent Technologies, Waldbronn, Germany) that included a 1040 M diode array detector. Separation was achieved on an ODS Hypersil 60×4.6 mm column. Oven and injector temperature were 25 and 22°C, respectively. The injection volume was 10 µl, and the flow rate 2 ml min^{-1}. Solvent A consisted of 0.25% orthophosphoric acid and 1.5% tetrahydrofuran in HPLC pure water, while solvent B was 100% methanol. The run started with 30% B. Within 15 min, solvent B was increased to 70% and further to 100% within15 min, and then isocratically in 100% B for a further 5 min. At the end of the run, solvent B was reduced to 30% within 1 min, and the column was flushed with 30% B for 10 min before the next run started.

The detection wavelength was 245 nm, and the identification of compounds was based on retention times, online UV-spectra, co-chromatography of commercial standards [atranorin, evernic acid, fumarprotocetraric acid (Apin Chemicals), usnic acid (Sigma)], and standards of tenuiorin, gyrophoric acid, salazinic acid, and stictic acid kindly provided by Dr. H.J. Sipman (Botanischer Museum

Berlin-Dahlem, Berlin, Germany). Compounds were quantified against response curves of the above-mentioned standards. We were not able to get standards of perlatolic acid and caperatic acid, and so response curves of usnic acid and atranorin, respectively, were used for quantification of these compounds. Constictic, peristictic, cryptostictic, norstictic, and methyl norstictic acids were all calculated from the response curve of stictic acid. Gyrophoric acid derivatives were calculated from the response curve of gyrophoric acid.

Efficiency of the Acetone Rinsing Method McEvoy et al. (2006) have shown that not all extractable secondary compounds are fully rinsed from whole thalli by acetone. We tested the efficiency of the extraction method by doing a full extraction of 3 thalli of each species. After the normal acetone-rinsing procedure, we ground the thalli to powder in a ball mill, took out subsamples of about 15 mg, added 500 µl of acetone, and vortexed the mixture for 30 sec. Samples then were left to stand for 10 min before they were centrifuged for 3 min at 15,000 rpm. The supernatants were collected, and the procedure repeated three times. Test extractions revealed that after 4 extractions, no HPLC-detectable secondary compounds were left in the lichen pellets. The combined supernatants were evaporated to dryness, 500 µl of acetone were added and analyzed by HPLC as described above.

Statistical Analysis The data were analysed in a pairwise *t*-test with the statistical software SYSTAT 10 (SPSS Inc., Chicago, U.S.A.).

Results

Lichen Compounds The studied lichen species contained 2–6 different secondary compounds, and the amounts removed by the original acetone rinsing varied from 3.38 mg g^{-1} DW in *P. glauca* to 52.3 mg g^{-1} DW in *U. spodochroa* (Table 1). A subsequent full extraction of previously acetone rinsed thalli documented species-specific rinsing efficiencies (Table 1). Acetone rinsing removed 100% of the secondary compounds from *U. spodochroa*, and 82–90% from *C. arbuscula*, *C. stellaris*, *L. pulmonaria,* and *E. prunastri*. In contrast, only 50–57% was removed from *C. rangiferina*, *P. glauca,* and *P. saxatilis*. We also checked whether or not the rinsing efficiency varied among different compounds and between positions in the lichen thallus (cortical or medullary compounds), but only small variations were found (data not shown).

The chemical composition of *C. arbuscula*, *C. rangiferina*, *C. stellaris*, *E. prunastri,* and *P. glauca* corresponded well with the literature for Nordic populations of the species (e.g.,

The level of significance ($P<0.05$) in bold is given according to a pairwise t-test of rinsed and unrinsed thalli.

Krog et al. 1994). Each contained two or three primary lichen substances. *Lobaria pulmonaria* contained six detectable compounds, all belonging to the stictic acid chemosyndrome (cf. Elix and Tønsberg 2006), with stictic acid itself being the most abundant. *Parmelia saxatilis* contained atranorin (minor) and salazinic acid (major) as reported by Krog et al. (1994), but chloroatranorin and one unidentified compound also were detected. *Umbilicaria spodochroa* contained gyrophoric acid (major) and atranorin (minor). Two minor unidentified compounds with spectra resembling gyrophoric acid may be lecanoric acid and hiasic acid, which can be expected in all characterized chemical races of the species (Posner et al. 1992).

Lichen Herbivory When intact lichens were served, acetone rinsing increased DW consumption only in *L. pulmonaria* and *C. stellaris* (Table 2). No significant preference was observed among rinsed and unrinsed pairs of the other species. However, when serving lichen as porridge (Fig. 1), acetone rinsing also increased consumption in *C. arbuscula*, *C. rangiferina*, *E. prunastri,* and *P. glauca*, but decreased consumption in *C. stellaris* (Table 2). *Lobaria pulmonaria* and *P. saxatilis* were not tested in the porridge experiment due to lack of material. The two species with the lowest total consumption (*U. spodochroa* and *P. saxatilis)* were the only species where no preference was found. In general, voles did not eat more lichen porridge than they did intact lichens (except for rinsed *E. prunastri* thalli). Grinding reduced the consumption of control thalli (Table 2).

Discussion

Many lichen species produce large amounts of secondary compounds that restrain grazing from invertebrates (Lawrey 1983a; Emmerich et al. 1993; Gauslaa 2005; Pöykkö et al. 2005). The present study is the first to show that lichen secondary compounds also may reduce grazing of a vertebrate herbivore (Fig. 1, Table 2).

When offered as porridge, the bank vole had a preference for lower concentration of lichen compounds in four of the tested lichen species. We expected that lichens would be more attractive and edible for voles in the moist state. Instead, either grinding or the addition of water made the porridge of control thalli less attractive in most of the species (Table 2). The reason for this is not clear. However, by quantifying the acetone rinsing efficiency, we showed that the extractability of secondary compounds in most lichen species is increased during grinding to powder. Since grinding releases and exposes the compound to crystalization, a bank vole may feel a stronger repulsiveness to the compounds. Furthermore, deterrent substances are not evenly distributed inside a lichen thallus. In the *Cladina*-species used in this experiment, the total concentration of lichen compounds was up to three times higher in the apical 10 mm of the podetia compared with other living parts (Nybakken and Julkunen-Tiitto 2006). When offered whole lichen thalli, voles had the option of selecting and eating the less toxic parts, while preparation of porridge may have reduced the variation in palatability within control thalli. Since lichen secondary compounds are not soluble in water, addition of water as such is not likely to enhance the smell or taste of lichen compounds.

Rinsing intact lichen thalli in acetone clearly reduced the concentration of secondary compounds, although extraction efficiency varied among species (Table 1). When lichens were served as intact thalli, the total concentration of compounds may have played a role. In both species where the voles preferred rinsed thalli (*C. stellaris* and *L. pulmonaria*), 90% of the secondary compounds were removed. However, acetone rinsing also was highly effective for other species (*C. arbuscula*, *E. prunastri,* and *U. spodochroa*) without influencing the vole's preference. This suggests that the presence and the concentration of

Fig. 1 The porridge experiment. Lichens were ground to powder, mixed with water and served to the bank voles in petri dishes. The photo shows petri dishes with *Evernia prunastri* after one night of feeding. Upper panel: Controls. Lower panel: acetone-rinsed thalli

specific compounds is important. Usnic acid is the most frequently studied lichen substance, and it has well documented deterrent effect in some herbivores (reviewed by Cocchietto et al. 2002). It occurred in high amounts in *C. stellaris* and in much lower concentrations in *C. arbuscula* and *E. prunastri* (Table 1). The low consumption of control thalli of *C. stellaris* compared with the two other species (Table 2) points at an antiherbivore role of usnic acid at high concentrations. *Lobaria pulmonaria,* the other species in which acetone-rinsing increased grazing in intact thalli, has a special chemistry (Table 1). In a study of snail herbivory on *L. pulmonaria* and *Pseudocyphellaria crocata*, Gauslaa (2008) observed a negative correlation between concentrations of stictic and constictic acids and frequency of grazing marks. Stictic acid was the compound rinsed out in highest amounts from our thalli, and it has been suggested previously as an antiherbivore compound (Lawrey 1980). Therefore, we postulate that stictic acid prevented the bank voles from feeding on the control thalli of *L. pulmonaria*.

Despite the fact that *U. spodochroa* contained the highest concentration of secondary compounds and that these were 100% extracted, no significant preference was measured in either of the two feeding experiments. The bank voles hardly sampled any of the served forms of this lichen (Table 2). Gyrophoric acid, the major compound, has been mentioned as a possible antiherbivore compound (Nimis and Skert 2006). However, as its removal did not increase feeding, this species probably uses other defense mechanisms (e.g., hard texture, un-extractable chemicals inside living cells, low nutritive value).

In summary, we have shown that some lichen secondary compounds function as deterrents against a generalist vertebrate herbivore. Some of these seem to deter herbivores across taxonomic groups, e.g., mammals, insects, and gastropods.

Acknowledgements We thank Annie Aasen and Camilla Iversen, Dept. of Ecology and Natural Resource Management, Norwegian University of Life Sciences for invaluable help in the lab. Furthermore, we are grateful to Prof. Lars Fröberg, University of Lund, Sweden and an anonymous reviewer for useful comments on the manuscript. The permission to catch and use bank voles in the study was given by the Norwegian Directorate for Nature Management.

Abstract The spruce seed moth, *Cydia strobilella* L., is a serious pest on cones of spruce (*Picea spp.*) in the Holarctic region. Previous studies from different parts of its area of distribution have reported conflicting results on the composition of its sex pheromone. By gas chromatography with electroantennographic detection, coupled gas chromatography-mass spectrometry, a Y-tube olfactometer bioassay, and field trials, the sex pheromone of Swedish populations of the species was identified as (8*E*,10*E*)-dodecadienyl acetate and (8*E*,10*Z*)-dodecadienyl acetate. About 0.5 pg of each pheromone component was extracted per female. The most attractive blend of *EE*- and *EZ*-isomers was about 6:4, respectively, and 0.3 µg of the blend per rubber septum was the most attractive dosage for field trapping. Monounsaturated components previously reported as sex pheromone components/attractants for *C. strobilella*, (*E*)-8-dodecenyl acetate in Canadian populations and (*Z*)-8-dodecenol in Polish and Dutch populations, did not attract any *C. strobilella* in this study. Large numbers of *C. jungiella* Clerck were trapped by using (8*E*,10*Z*)-dodecadienyl acetate alone, whereas (*Z*)-8-dodecenol attracted *Pammene splendidulana* Guenée and *P. rhediella* Clerck.

In memoriam of professor Jan Löfqvist and in recognition of his contributions to insect chemical ecology.

Introduction

The spruce seed moth, *Cydia strobilella* L. [formerly *Laspeyresia strobilella* L., *C. youngana* Kearfott, and *L. youngana* Kearfott] (Lepidoptera: Tortricidae), is a serious cone pest of spruce in the Holarctic region; for instance Norway spruce, *Picea abies* (L.) H. Karst, in Europe; and white spruce, *P. glauca* (Moench) Voss, and black spruce, *P. mariana* (Miller) Britton, Sterns and Poggenburg, in North America. The flight phenology of this diurnal species is more or less synchronized with the pollination period of spruce hosts. Female calling and mating take place in the early photophase. The eggs are laid between the scales of female flowers, and the larvae feed on the maturing seeds, and cause great damage to the seed harvest without leaving any external evidence of infestation (e.g., Bakke 1963; Seifert et al. 2000). Studies have shown that *C. strobilella* is difficult to control as larvae (e.g., Annila 1973; Rosenberg and Weslien 2005). Thus, monitoring the flight of adults is a necessary element of integrated pest management strategies for control of this species.

Attempts to identify the sex pheromone of *C. strobilella* were initiated more than 30 years ago, but failed (C. Löfstedt, J.N.C Van der Pers, and J. Löfqvist, unpublished). Since then, several different compounds have been reported as sex attractants for the species. (*Z*)-8-Dodecenol (*Z*8–12:OH) was reported as an attractant in the Netherlands (Booij and Voerman 1984), and in Poland (Skrzypczynska et al. 1998). In Canada, (*E*)-8-dodecenyl acetate (*E*8–12:OAc) was demonstrated to be an attractant (Grant et al. 1989), and

later this compound was confirmed as a sex pheromone for *C. strobilella* (Bédard et al. 2002; Trudel et al. 2006). In China, where the species heavily infests cones of Korean spruce, *P. koraiensis* Nakai, field trapping tests revealed an attractant blend of *Z*8–12:OH, (*E*)-8-dodecenol (*E*8–12:OH), and (8*Z*,10*E*)-dodecadienol (*Z*8,*E*10–12:OH) (Sun et al. 2001).

In Sweden, as part of a large screening project of attractants for tortricid moths, a mixture of (8*E*,10*E*)-dodecadienyl acetate (*E*8,*E*10–12:OAc) and (8*E*,10*Z*)-dodecadienyl acetate (*E*8,*Z*10–12:OAc) was found to be attractive, but trap catches were low (Witzgall et al. 1996). More recently, mixtures of *E*8,*E*10–12:OAc and (8*E*,10*E*)-dodecadienol (*E*8,*E*10–12:OH), or *E*8,*Z*10–12:OAc and (8*E*,10*Z*)-dodecadienol (*E*8,*Z*10–12:OH), were reported to attract significant numbers of *C. strobilella* males (Witzgall et al. 2009).

A properly identified sex pheromone is still missing for European populations of *C. strobilella*, which has hampered the use of sex pheromones for monitoring and control of this moth in seed orchards. In the present paper, we report our identification of a two-component sex pheromone, which is highly efficient for trapping of *C. strobilella* in Sweden.

Methods and Materials

Insects Previous-year cones of Norway spruce were collected at Ålbrunna (59°30′N, 17°32′E), Uppland Province, Sweden, in March 2009. Cones were stored first at 6°C, 55% r.h. and a 18:6 L:D cycle. To trigger emergence of *C. strobilella*, cones were transferred later to 15°C, 60% r.h. and a 17:7 L:D cycle, and placed in small wooden boxes (16×16×15 cm) with a sealed glass exit tube inserted to facilitate collection of emerged insects as they moved towards the light. The boxes were checked every h during the photophase. Newly emerged moths were collected as soon as they appeared, separated by sex, and kept individually in small plastic tubes until used in experiments.

Chemicals Reference compounds of different origin and purity were available for the identification work from our laboratory collection of pheromone compounds. Compounds used for behavioral experiments included *E*8–12:OAc (chemical purity 99.4%), *Z*8–12:OH (chemical purity 98.1%), *E*8,*E*10–12:OAc (chemical purity 99.0%; isomeric purity 99.3%), and *E*8,*Z*10–12:OAc (chemical purity 95.8%; isomeric purity 96.3%). The dienic compounds were synthesized and purified as described in Witzgall et al. (1993).

Pheromone Gland Extraction Calling and mating behavior of *C. strobilella* were observed by putting newly emerged adults (6♀ × 6♂) into an outdoor transparent plastic cage (35×30×60 cm) with a spruce branch. Female calling (extrusion of the pheromone gland) was observed 2–5 h into the photophase, and mating was observed during this calling period. The pheromone glands of 0-to-2-d-old virgin females were dissected in the early photophase as soon as the calling behavior was observed. Up to 20–30 glands were combined and extracted together for 30 min in 20 µl of redistilled hexane. For quantification of pheromone titer by gas chromatography-mass spectrometry (GC-MS), combinations of 160, 222, and 230 female equivalent extracts were prepared and analyzed.

Electrophysiology Gas chromatography with electroantennographic detection (GC-EAD) was used to identify physiologically active compounds in female gland extracts. One-to-2-d-old males were analyzed. The head and both antennae, with their tips cut off, were used in preparations, and mounted to a PRG-2 EAG (10x gain) probe (Syntech, Kirchzarten, Germany) using conductive gel (Blågel, Cefar, Malmö, Sweden). Charcoal-filtered and humidified air passed over the antennal preparation from a glass tube outlet at 5 mm distance from the preparation. The GC effluent to the antennae passed through a heated transfer line set at 230°C.

Female pheromone gland extracts containing ≈20 calling females were placed in micro-vials with hexane before being used for GC-EAD screening. In addition, synthetic standards of putative pheromone compounds for *C. strobilella* that had been reported for other *Cydia* species also were used [*E*8–12:OAc, *Z*8–12:OAc, *E*8–12:OH, *Z*8–12:OH, *E*8,*E*10–12:OH, and a mixture of the isomers *Z*8,*E*10–12:OAc (34%), *E*8,*E*10–12:OAc (23%), *E*8,*Z*10–12:OAc (41%), *Z*8,*Z*10–12:OAc (2%)] at concentrations of 17 ng/µl, 2 ng/µl, and 0.2 ng/µl. Samples were injected into an Agilent 7890A GC (Agilent Technologies), equipped with either a medium-polar HP-INNOWax column (30 m×0.25 mm i.d., and 0.25 µm film thickness; J&W Scientific, USA) or a non-polar HP-5 column (30 m×0.32 mm i.d., and 0.25 µm film thickness; J&W Scientific, USA). A split at the end of the column allowed a 1:1 division of the GC effluent to the flame ionization detector (FID) and to the antennal preparation. Hydrogen was used as carrier gas at a flow rate of 43 cm/sec, and injector temperature was 225°C. The column temperature was maintained at 80°C for 2 min after injection, and then was increased by 10°C/min to 220°C. Each antennal preparation was used for a single GC-EAD trial. Data were analyzed with the GC-EAD Pro Version 4.1 software (Syntech, Kirchzarten, Germany).

As the amounts of *E*8,*E*10–12:OAc and *E*8,*Z*10–12:OAc (the only EAD-active compounds found in female extracts, see results) were below the detection limit for the FID, a calibration curve was obtained to calculate the approximate relative ratio of the two compounds in female glands. Synthetic mixtures of the isomers (≈0.1 ng/µl) were

prepared in five different ratios, and GC-EAD analyses were performed to estimate the relative FID peak areas and corresponding EAD response amplitudes, for the isomers in these mixtures. These data were then fitted to a curve with the best correlation coefficient. By using this curve, the relative EAD amplitudes that corresponded to the isomers could be used to calculate the relative ratio of the compounds in seven female gland extracts to estimate mean and median *EE*/*EZ* ratios.

Gas chromatography-Mass Spectrometry The pheromone gland extracts were analyzed with a Hewlett-Packard 5975 mass-selective detector coupled to a Hewlett-Packard 6890 GC, equipped with a capillary column of either HP-INNOWax (30 m×0.25 mm i.d., and 0.25 μm film thickness; J&W Scientific, USA), or HP-5MS (30 m× 0.25 mm i.d., and 0.25 μm film thickness; J&W Scientific, USA). The HP-INNOWax column was programmed from 80°C for 1 min, 10°C/min to 200°C, hold for 10 min, and then to 230°C at 10°C/min, hold for 10 min. The HP-5MS column was programmed from 80°C for 1 min, 10°C/min to 150°C, then to 200°C at 4°C/min, hold for 10 min, and finally to 250°C at 10°C/min, holding for 10 min. Injector and transfer line temperatures were 250°C and 280°C, respectively, and helium was used as carrier gas.

Selected ion monitoring (SIM) was used to monitor the pheromone component candidates. The characteristic ions *m*/*z* 61($CH_3CO_2H_2^+$), 79, 81, 164($M\text{-}60^+$), and 224(M^+) were used for monitoring the 8,10-dodecadienyl acetate isomers, by comparing both retention time and ion ratios with those of the authentic synthetic compounds. The above SIM mode was also used for quantification when *E*8,*E*10–12:OAc was used as the external standard, with a concentration range of 0.01–0.1 ng. The absolute amounts of *E*8,*E*10–12:OAc and *E*8,*Z*10–12:OAc in female gland extracts were obtained by integrating the abundance of ion *m*/*z* 164 on the polar column and then calculating by the polynomial regression equation $y=6.37x^2 + 11.93x + 58.27$ ($r^2=0.997$), which was obtained based on the fragment abundance of ion *m*/*z* 164 in the external standard. Under these conditions, the limit of detection for the dodecadienyl acetate isomers is 4 pg with a signal/noise ratio (S/N) of 3:1.

Behavioral Experiments A glass Y-maze (15 cm length × 15 mm i.d.) (Scientific Glass, Löberöd, Sweden) was used to study the attraction of male moths to the *EE* and *EZ* isomers, individually or in a blend. The olfactometer was connected to a battery-driven air pump (GroTech, Gothenburg, Sweden), and the 200 ml/min was set to 20 ml/sec. The test stimulus was applied on a strip of filter paper inserted in a 10 ml plastic syringe and connected to the stimulus arm. The test stimulus always was applied at a volume of 10 μl. A second syringe loaded with 10 μl of hexane served as a control. Filters were replaced every 30 min. Four treatments were tested: the two isomers individually at a dose of 10 ng, and the binary blend (*EE*/*EZ* ratio of 4:3) at a total dose of 0.7 ng or 7 ng.

Experiments were performed 1–3 h into the photophase at 5,000 lux, 21°C and ≈45% r.h.. The olfactometer was placed in 45° angle in relation to the table, with the arms at 10 cm higher elevation compared to the area of the tube where the moths were introduced. This tilted position of the olfactometer triggered more walking behavior in moths compared to when the Y-tube was kept horizontally. One-to-3-d-old males were used for behavioral tests. After being transferred to the Y-tube, a male was given 5 min to respond; i.e., walk at least 1 cm into either of the two arms of the olfactometer. Moths not responding within the given time period were considered as non-responders and were excluded from the analysis. Each moth was used only once. For each experiment, the position of the stimulus and control arms was alternated to avoid position effects. Data on olfactory responses were analyzed with a binomial test (Siegel and Castellan 1998) against the null hypothesis that moths would be attracted equally to both arms of the olfactometer. Between experiments, Y-tubes were baked in an oven at 300°C for 2 h to remove traces of compounds.

Field Experiments Field trapping experiments were conducted in two spruce seed orchards in Sweden: Maltesholm, (55°54′N, 13°59′E), Skåne Province, and Ålbrunna (see above), in spring 2009. Custom-built Delta-traps or traps purchased from either PheroTech Inc. (Delta, BC, Canada) or AgriSense BCS Ltd (Pontypridd, UK), all with sticky inserts, were used. Synthetic blends were prepared in hexane, and 100 μl solution were added to red rubber septa (Catalogue no. 224100-020, Wheaton Science Products, Millville, NJ, USA) to be used as lures.

The first field trial was conducted in Maltesholm from 7 to 19 May, and in Ålbrunna from 7 May to 1 June. In this experiment, rubber septa were loaded with the *E*8,*E*10–12:OAc and *E*8,*Z*10–12:OAc isomers, either individually (*EE*: 4 μg, *EZ*: 3 μg) or as a blend in a 4:3 ratio (same amounts of the isomers as when applied individually). In addition, lures were loaded with *E*8–12:OAc (3 μg) or *Z*8–12:OH (3 μg), which have been reported to be attractive to *C. strobilella* in Canada and Poland/The Netherlands, respectively. Septa loaded only with hexane served as controls. Five trap replicates were used.

The second field test was conducted from 13 to 29 of May in Maltesholm, and from 19 May to 1 June in Ålbrunna. In this experiment, different ratios of *E*8,*E*10–12:OAc and *E*8,*Z*10–12:OAc isomers (i.e., intended ratios of 100:0, 90:10, 75:25, 50:50, 25:75, 10:90, and 0:100) were applied to rubber septa at a total dosage of 3 μg per lure. Five trap replicates were used. The actual ratios of the

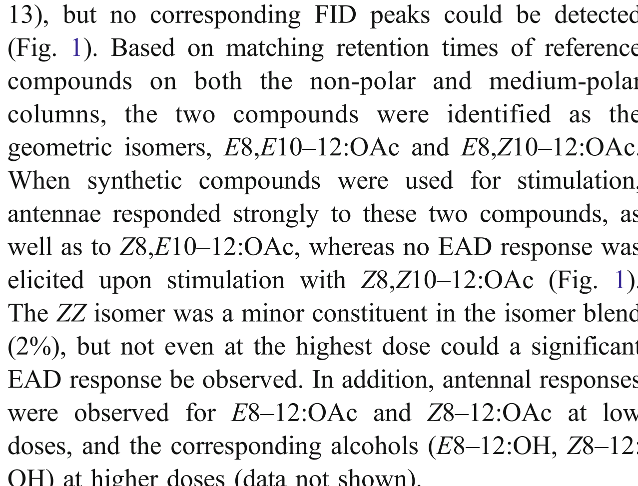
isomer blends were checked subsequently by both GC-MS on an HP-INNOWax column and GC-FID on an HP-1 column. To investigate the isomerization of compounds under field conditions, the 3 wk field-aged rubber septa were collected at the end of this experiment, and the wide-bore cavity of a septum was filled with 200 µl of hexane. The hexane was recovered from the septum after 5 min, concentrated to approximately 40 µl, and passed through a 1.5×0.5 cm column of Florisil (250 mg, 100–200 mesh) for purification. The column was washed with 1 ml of hexane, and the concentrated eluate was analyzed by GC-MS on an HP-INNOWax column (see above).

The third trial was conducted from 19 to 29 of May in Maltesholm and from 27 of May to 8 of June in Ålbrunna. It was designed to determine the optimal total dose of the two-component blend at an *EE*/*EZ* ratio of 60:40 (which was shown to give the highest trap catches during the first two checks in the ratio experiment in Maltesholm). Dosages of 0.1, 0.3, 1, 3, 10, and 30 µg per rubber septum were tested. Four trap replicates were used. The actual *EE*/*EZ* ratio used in this experiment was confirmed as 61:39 by both GC-FID (HP-1 column) and GC-MS (HP-INNOWax column).

Traps were suspended from spruce branches at 2–4 m height and at least 10 m apart within each replicate in Maltesholm, and at 1.3–2 m height and 7 m apart within each replicate in Ålbrunna. Traps were checked every 2nd day and redistributed, with exception of trial one and two in Ålbrunna that were not redistributed. The trapped tortricid moths were identified according to Svensson (2006) and Razowski (2003). Genital preparations from selected specimens were examined to confirm species identifications (courtesy of Ingvar Svensson, Österslöv, Sweden). A subsample of voucher specimens is kept in the laboratory for reference. Statistical analyses were based on the catches recorded on each occasion that a trap was checked. Traps then were redistributed, and the number of replicates thus was obtained as the number of physical replicates times the number of times the traps were checked. During the 1st and 2nd experiments in Ålbrunna, traps were not redistributed. Thus, the number of replicates was equal to the number of traps, and the total catch in a specific trap over the whole trapping period was treated as a replicate. Differences in trap catch among treatments were compared by using analysis of variance on log (x+1) transformed data, followed by multiple comparisons according to the Bonferroni *post hoc* test with adjusted levels for significance. All analyses were performed using SPSS ver. 16.

Results

GC-EAD Antennae from males responded exclusively and strongly to two compounds in female gland extracts (*N*=



13), but no corresponding FID peaks could be detected (Fig. 1). Based on matching retention times of reference compounds on both the non-polar and medium-polar columns, the two compounds were identified as the geometric isomers, *E*8,*E*10–12:OAc and *E*8,*Z*10–12:OAc. When synthetic compounds were used for stimulation, antennae responded strongly to these two compounds, as well as to *Z*8,*E*10–12:OAc, whereas no EAD response was elicited upon stimulation with *Z*8,*Z*10–12:OAc (Fig. 1). The *ZZ* isomer was a minor constituent in the isomer blend (2%), but not even at the highest dose could a significant EAD response be observed. In addition, antennal responses were observed for *E*8–12:OAc and *Z*8–12:OAc at low doses, and the corresponding alcohols (*E*8–12:OH, *Z*8–12:OH) at higher doses (data not shown).

The FID-EAD curve, obtained from GC-EAD analyses of five synthetic blends with different *EE*/*EZ* ratios, showed a good correlation between the ratios for EAD responses and FID peaks for the two isomers ($y=0.32^{0.42x}$; $r^2=0.99$). Based on this relationship, we established the FID peak ratios of the isomers in seven female gland extracts by plotting onto the curve the observed ratios of EAD responses for the *EE* and *EZ* isomers. These FID peak ratios ranged from 0.6 to 2.3, but had the same mean and median value (1.3). Based on the median FID ratio obtained from the curve, an *EE*/*EZ* ratio of 4:3 was used in the olfactometer tests and the first field trapping experiment.

Chemical Analysis of Pheromone Gland Extract GC-MS analyses of pheromone gland extracts revealed high amounts of heneicosane, tricosane, and heptacosane (8.6 ng, 7.2 ng,

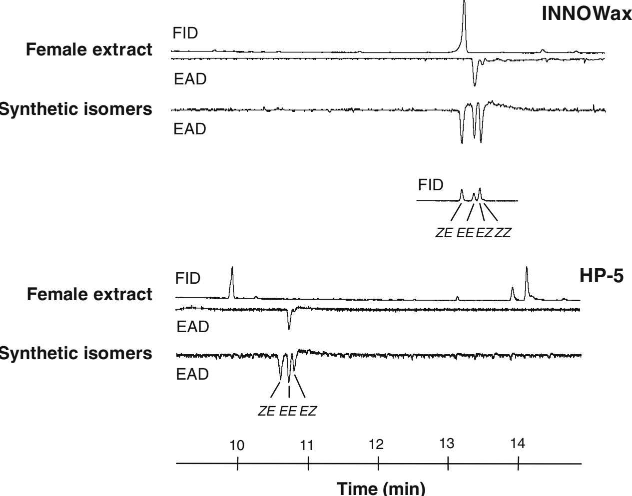


Fig. 1 Gas chromatography with flame ionization detection and electroantennographic detection (EAD) using male *Cydia strobilella* antennae responding to gland extracts of females or a synthetic mixture of *Z*8,*E*10–12:OAc (*ZE* 34%), *E*8,*E*10–12:OAc (*EE* 23%), *E*8,*Z*10–12:OAc (*EZ* 41%), and *Z*8,*Z*10–12:OAc (*ZZ* 2%). Two different column types were used (HP-INNOWax and HP-5)

and 18.3 ng per female gland, respectively), as well as small amount of hexadecanal and octadecanal (compounds identified based on matching mass spectra and retention times on both columns, data not shown). However, the EAD-active dodecadienyl acetates, *E*8,*E*10–12:OAc and *E*8,*Z*10–12:OAc, were not detected in full-scan mode, but in SIM mode, both components were confirmed by using both the polar and the non-polar columns. The two insect-derived compounds eluted at the same retention times as the two authentic standards, and exhibited the diagnostic fragments at *m*/*z* 61, 79, 81, and 164 in the same ratios. The subsequent quantification showed an average titer of 0.42±0.07 pg of *E*8,*E*10–12:OAc, and 0.55±0.10 pg of *E*8,*Z*10–12:OAc per female equivalent (calculated from three extracts containing 160, 222, and 230 female equivalents, respectively). The average (±S.D.) *EE*/*EZ* ratio was found to be 43±3%, which differed somewhat from the ratio obtained from the FID-EAD curve (see above).

Bioassays Preliminary flight tunnel analyses revealed that male moths did not fly upwind to either the two-component blend at various doses or to calling females. In Y-tube experiments, males showed significant attraction to the two-component blend at both doses tested ($P<0.01$; Fig. 2). In addition, significantly more males chose the treatment arm vs. the control arm when the *EZ* isomer alone was used as stimulus ($P<0.05$; Fig. 2), but many males did not respond by walking upwind in the olfactometer in these experiments and, thus, were excluded from the analysis. No significant attraction was observed when using the *EE* isomer alone as stimulus, and many non-responders were observed in these experiments as well.

Field Trapping Results from the first field test (Fig. 3) showed that *E*8,*Z*10–12:OAc alone at a dosage of 3 µg per septum, or a 4:3 blend of *E*8,*E*10– and *E*8,*Z*10–12:OAc at a total dosage of 7 µg per septum attracted significant numbers of male *C. strobilella* at both locations, whereas the other treatments were unattractive to this species. Interestingly, the same two treatments also attracted another *Cydia* species; *C. jungiella* Clerck (formerly *Grapholita jungiella*). Trap catch of this species was much higher for *E*8,*Z*10–12:OAc alone compared to the binary blend (total catch Maltesholm: 31 (*EZ*) vs. 2 (*EE*+*EZ*); total catch Ålbrunna: 1,053 (*EZ*) vs. 43 (*EE*+*EZ*)). Traps baited with *Z*8–12:OH were not attractive to *C. strobilella*, but instead trapped significant numbers of two *Pammene* species, which were only attracted to this compound: *P. splendidulana* Guenée with a total catch of 67 at Maltesholm (no moths trapped at Ålbrunna), and *P. rhediella* Clerck with at total catch of 14 at Maltesholm and 45 at Ålbrunna. *E*8–12:OAc did not attract any moths in this study.

The optimal *EE*/*EZ* ratio for attraction of *C. strobilella* was investigated in a second experiment. In Maltesholm, all ratios except pure *EE* isomer attracted high numbers of males, with ratios ranging from 50% to 90% *EE* trapping the highest numbers (Fig. 4). In Ålbrunna, similar results were obtained. Analysis of the field-aged rubber septa at the end of the Maltesholm field test showed that after three weeks in the field, the percentage of *EE* isomer in the rubber septa had increased regardless of the initial ratio, except for one group in which the initial *EE* percentage was 99.3% but decreased to 97.5% after three weeks in the field (Fig. 5). Baits aimed to contain 0–75% *EE* after three weeks of aging in the field also contained a smaller but significant amount of the *ZE* isomer (3–13%), whereas this isomer could not be quantified reliably in the two mixtures with the highest original amount of *EE* isomer. This isomerization, plus the impurity of ca. 3.6% of the *EE* isomer in *E*8,*Z*10–12:OAc, makes it hard to carry out a strict test of precise ratios between the candidate pheromone components.

In the third experiment, the 6:4 blend of *EE* and *EZ* isomers attracted male *C. strobilella* at doses from 0.1 µg to 3 µg, whereas almost no males were attracted to the two highest doses (Fig. 6). The 0.3 µg dose attracted the highest numbers of males at both localities, whereas significantly fewer males were attracted to the two highest doses compared to the lower doses at Maltesholm. Trap catches at Ålbrunna were not significantly different because of too low total catches and high variation among traps within the same treatment. However the response profiles were identical in both places, revealing highest attraction to the lower doses.

Discussion

Our study demonstrates conclusively that a 6:4 mixture of *E*8,*E*10– and *E*8,*Z*10–12:OAc, a ratio of the components that

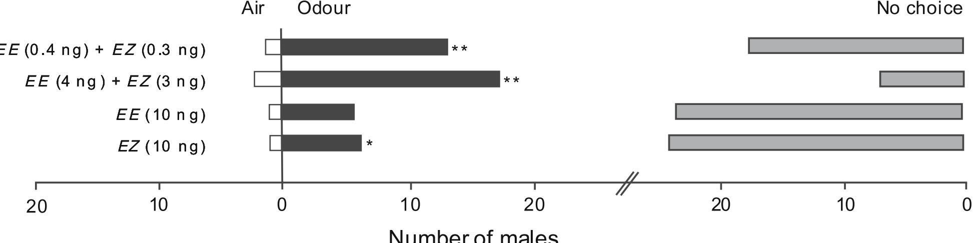

Fig. 2 Response of male *Cydia strobilella* to *E*8,*E*10–12:OAc and *E*8,*Z*10–12:OAc, individually or in a 4:3 mixture, in Y-tube olfactometer tests (Binomial test; * $P<0.05$, ** $P<0.01$)

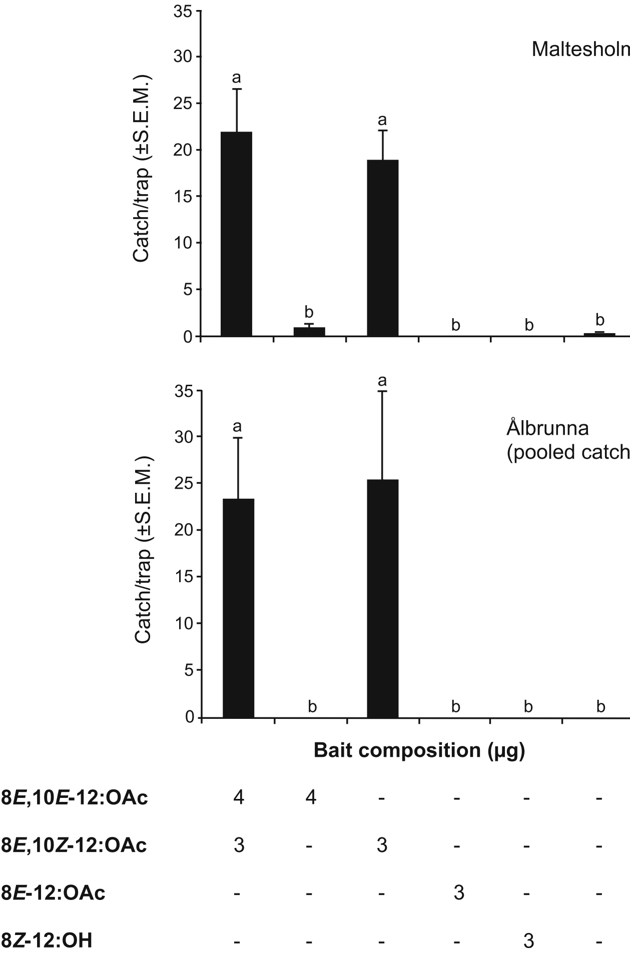

Fig. 3 *Cydia strobilella* males caught in traps using different pheromone candidate components at two field sites in Sweden. Analysis of data from Maltesholm is based on catch per trap per check (N=25), whereas the analysis of data from Ålbrunna is based on pooled catches per trap (N=5). *Bars with different letters* indicate significantly different catches (analysis of variance on log (x+1) transformed data, followed by multiple comparisons according to the Bonferroni *post hoc* test (α<0.0036))

comes close to that found in extracts of females, is an efficient attractant for male *C. strobilella* in Sweden. In a field screening of attractants for tortricids in Italy and Sweden, Witzgall et al. (1996) reported a few *C. strobilella* attracted to a 1:1 blend of *E*8,*E*10–12:OAc and *E*8,*Z*10–12:OAc at a dosage of 20 µg per lure (on average 5 males per replicate, N=8). Considering the fact that 0.3 µg was the most attractive dose for the species in our experiment, and that the catches using dosages above 3 µg were significantly lower, the low catches in the previous study can be explained by the excessive dosage used to bait the earlier traps.

In a more recent screening study, Witzgall et al. (2009) found that traps baited with a 1:1 blend of *E*8,*E*10–12:OAc and the corresponding alcohol *E*8,*E*10–12:OH, or *E*8,*Z*10–12:OAc and *E*8,*Z*10–12:OH, in a dosage of 20 µg per trap, attracted *C. strobilella* males, with the *E*,*Z*-combination being the most active. In our GC-EAD analyses of gland extracts of females, we did not record any responses at the expected retention times of those corresponding alcohols. In the GC-EAD experiments with synthetic standards, the antennae of males responded to three of the four dodecadienyl acetates (*Z*8,*E*10–12:OAc, *E*8,*E*10–12:OAc, and *E*8,*Z*10–12:OAc), and to two monounsaturated dodecenyl acetates (*E*8–12:OAc and *Z*8–12:OAc). However, males' antennae did not respond to the dodecadienol *E*8,*E*10–12:OH even when a relatively high dose of the synthetic compounds was used. Of course, this does not rule out the possibility that small amounts of the alcohols corresponding to the female-produced dienic acetates may still be released by calling females and act as behavioral synergists, but so far our results suggest that the female-produced sex pheromone of *C. strobilella* is a mixture of the two acetates.

When stimulated with gland extract of females, males' antennae responded exclusively to the *E*8,*E*10– and *E*8,*Z*10–12:OAc (Fig. 1), whereas there was no EAD response at the expected retention time of the *ZE* acetate isomer.

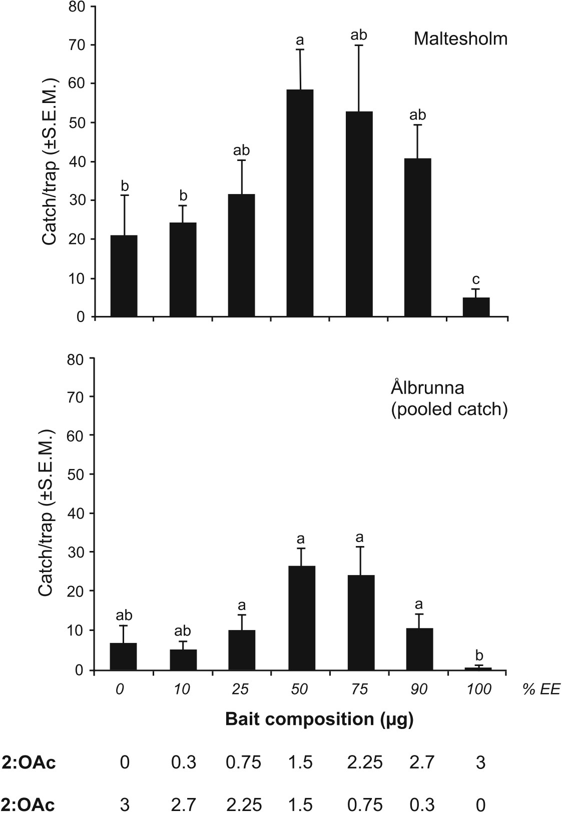

Fig. 4 Trap catch of *Cydia strobilella* males using different ratios of *E*8,*E*10–12:OAc and *E*8,*Z*10–12:OAc at two field sites in Sweden. Analysis of data from Maltesholm is based on catch per trap per check (N=38), whereas the analysis of data from Ålbrunna is based on pooled catches per trap (N=5). *Bars with different letters* indicate significantly different catches (analysis of variance on log (x+1) transformed data, followed by multiple comparisons according to the Bonferroni *post hoc* test (α<0.0025))

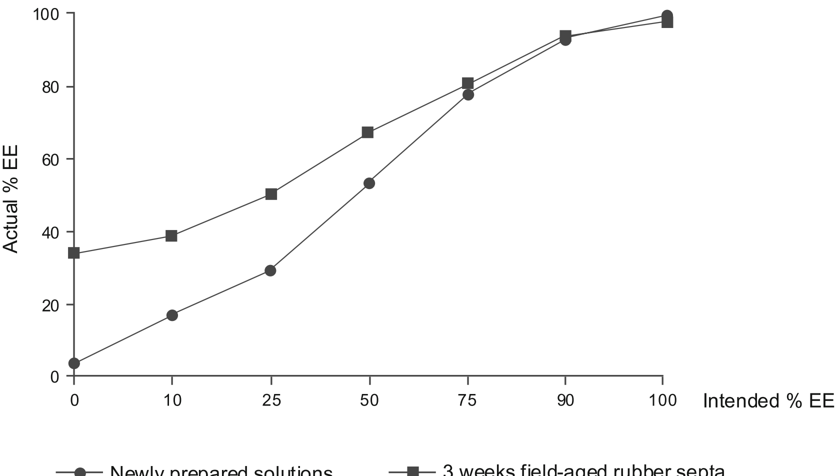

Fig. 5 Comparison of 8,10-dodecadienyl acetate isomer ratios (% *EE* isomer in a total amount of *EE* and *EZ* isomers) in newly prepared solutions for field tests (intended and actual) and in rubber septa aged for 3 wk in the field

Among *Cydia* species, the geometric isomers of 8,10-dodecadienyl acetate play different roles. For instance, in *C. jungiella*, which was observed flying in the course of our experiments with *C. strobilella, Z*8,*E*10–12:OAc was identified previously as a powerful attractant (Witzgall et al. 1996), whereas in the pea moth, *C. nigricana* F., *Z*8,*E*10–, *E*8,*Z*10–, and *Z*8,*Z*10–12:OAc isomers were not detected in gland extracts of females, and strongly inhibited male attraction to the sex pheromone compound *E*8,*E*10–12:OAc (Witzgall et al. 1993). We hypothesize that *Z*8,*E*10–12:OAc is a sex pheromone antagonist to *C. strobilella*, because of the strong GC-EAD response by antennae of males in spite of the absence of this compound in the female pheromone gland.

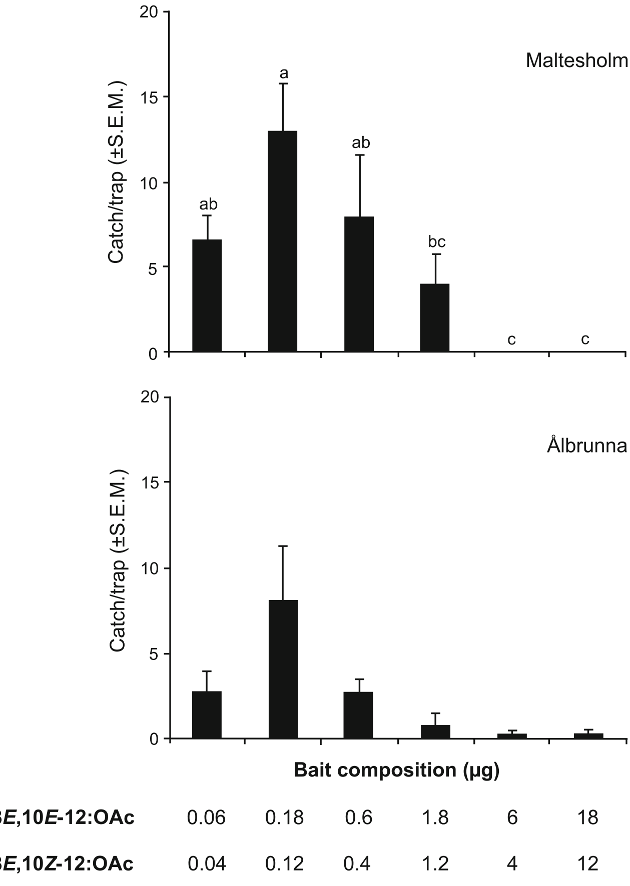

Fig. 6 Trap catch of *Cydia strobilella* males using different doses of a 6:4 blend of *E*8,*E*10–12:OAc and *E*8,*Z*10–12:OAc at two field sites in Sweden. Analyses of data from Maltesholm (*N*=23) and Ålbrunna (*N*=16) are based on catch per trap per check. *Bars with different letters* indicate significantly different catches (analysis of variance on log (x+1) transformed data, followed by multiple comparisons according to the Bonferroni *post hoc* test ($\alpha<0.0036$))

The composition of the identified sex pheromone for Swedish populations of *C. strobilella* in the present study differs from those previously reported for this species. Canadian populations of *C. strobilella* use only *E*8–12:OAc as a sex pheromone (Grant et al. 1989; Bédard et al. 2002). Although Brown and Miller (1983) synonymized the North American (formerly *C. youngana*) and European *C. strobilella* based on characters of the genitalia, it is tempting to suggest that, based on the marked difference in their sex pheromone composition, the two populations are, indeed, different species. This hypothesis could be tested by molecular phylogeographic analyses. The European situation should also be reexamined. Booij and Voerman (1984) and Skrzypczynska et al. (1998) reported *Z*8–12:OH as a sex pheromone for *C. strobilella*. In the present study, *P. splendidulana*, which is morphologically similar to *C. strobilella*, was attracted to traps baited with *Z*8–12:OH, but not to traps baited with any other compounds. Examination of genital preparations was required to confirm the species identity of trapped moths, and to show that *C. strobilella* and *P. splendidulana* were selectively attracted to different odor treatments in our field trials. However, at this point it cannot be ruled out that the pheromone composition of *C. strobilella* shows geographic variation.

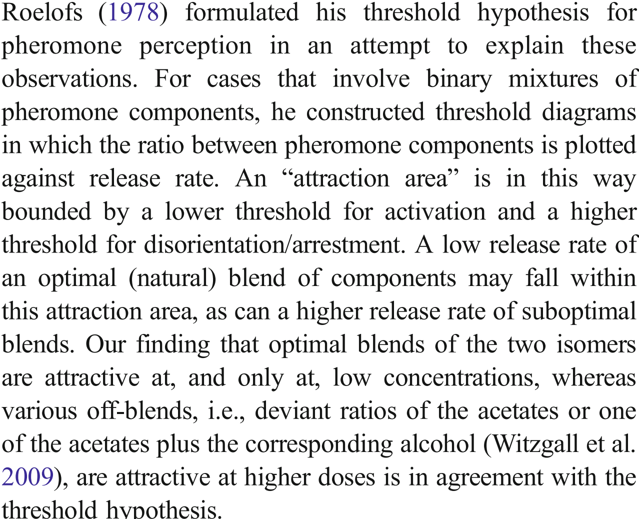
In the first field experiment, male *C. strobilella* were captured in traps that used both the binary blend and *E*8,

*Z*10–12:OAc alone, although GC-EAD analyses indicated that both components should be important for attraction (Fig. 3). Similar results were obtained in the indoor bioassays (Fig. 2). When checking possible isomerization of compounds after the second field experiment, we found that after three weeks in the field, the percentage of *EE* isomer in rubber septa generally increased except for the group in which the initial *EE*/*EZ* ratio was 99.3% (Fig. 5). This is in agreement with earlier findings of the isomerization of highly pure (99.4%) *EE* isomer on red rubber septa in the lab (Witzgall et al. 1993), and on polyethene dispensers in the field (Bengtsson et al. 1994) where in total 10% of the other three isomers were formed after ca. 20 days. It has been shown that the rate of isomerization of the *EE* isomer can be even faster in the field (25.1% *EZ*, 14.2% *ZE*, and 4.2% *ZZ* after four weeks; Davis et al. 1984). Isomerization, plus the impurity of ca. 3.6% of the *EE* isomer in *E*8,*Z*10–12:OAc, explains why this single component was attractive to *C. strobilella* in our first field test, as well as in our indoor bioassays. Similar extensive isomerization of 8,10-dodecandienyl acetate in rubber septa was found previously in the identification of the sex pheromone of the filbertworm, *C. latiferreanus* Walsingham (formerly *Melissopus latiferreanus*, Davis et al. 1984).

The third field test revealed that male *C. strobilella* are attracted to the sex pheromone at very low doses, which correlated well with the minute amounts of compounds produced by females. The most efficient dose for trapping was 0.3 µg per rubber septum, and the two highest doses tested (10 µg and 30 µg) trapped very few males. This sensitivity to the pheromone components in *C. strobilella* could explain the relatively low catches of males in the first experiment that used the 7 µg binary blend. A similar sensitivity in the pheromone communication system was observed in Canadian populations of *C. strobilella*, where the pheromone *E*8–12:OAc was produced in too small amounts by individual females to be detectable by FID, and where the optimal dose for attraction of males in field trials ranged from 0.3 µg to 3 µg (Grant et al. 1989; Bédard et al. 2002).

On the other hand, according to the sex pheromone identifications in tortricids to date, including the genus *Cydia*, the female-released sex pheromone titer in this family is normally at the nanogram level. For example, the codling moth *C. pomonella* (L.) produces the main sex pheromone component codlemone, *E*8,*E*10–12:OH (Roelofs et al. 1971), at an average amount of 8.7 ng per female (Witzgall et al. 2001). Among those tortricid moths for which the pheromone titer has been reported, only a few species, including the hickory shuckworm, *C. caryana* Fitch (McDonough et al. 1990) and *C. nigricana* (Greenway 1984), store the pheromone components in subnanogram levels.

It was observed earlier that male moths of some species were not always trapped in field tests by the ratio of pheromone components produced by the female moths.



Roelofs (1978) formulated his threshold hypothesis for pheromone perception in an attempt to explain these observations. For cases that involve binary mixtures of pheromone components, he constructed threshold diagrams in which the ratio between pheromone components is plotted against release rate. An "attraction area" is in this way bounded by a lower threshold for activation and a higher threshold for disorientation/arrestment. A low release rate of an optimal (natural) blend of components may fall within this attraction area, as can a higher release rate of suboptimal blends. Our finding that optimal blends of the two isomers are attractive at, and only at, low concentrations, whereas various off-blends, i.e., deviant ratios of the acetates or one of the acetates plus the corresponding alcohol (Witzgall et al. 2009), are attractive at higher doses is in agreement with the threshold hypothesis.

In summary, the lack of an efficient sex pheromone for European populations of *C. strobilella* has hampered the use of odor-based monitoring and control of this species in seed orchards, and our identified two-component sex pheromone hopefully may solve this problem. Mating disruption by means of synthetic pheromone may be an efficient way of controlling populations of *C. strobilella* in seed orchards. Because of the extremely high sensitivity of males to the pheromone, and the low female pheromone production, efficient mating disruption may be easier to obtain for *C. strobilella* compared to many other moth species. Trudel et al. (2006) used this technique in white spruce seed orchards in Canada to reduce cone damage by *C. strobilella*. Male captures in pheromone traps were reduced by up to 98%, and cone damage was reduced by up to 69% in pheromone-treated areas compared to control areas, thus showing the potential of the mating disruption technique to control populations of *C. strobilella* in European seed orchards as well.

Acknowledgements We are grateful to Ingvar Svensson for assistance with identification of the trapped insects. The research was supported by a grant from The Swedish Tree Breeding Association, and a grant from the vice chancellor at Lund University for cooperation between Lund University and the Swedish Agricultural University at Alnarp.

Sex Pheromone of *Agriotes acuminatus* (Stephens, 1830) (Coleoptera: Elateridae)

Till Tolasch · Maximilian von Fragstein · Johannes L. M. Steidle

Received: 30 November 2009 / Revised: 1 February 2010 / Accepted: 10 February 2010 / Published online: 27 February 2010

Abstract The click beetle species *Agriotes acuminatus* is distributed in open deciduous forests throughout a large area in Europe. In order to identify its sex pheromone, gland extracts of female beetles were investigated by using GC/MS. Neryl butanoate and 2,6-dimethyl-(*Z*,*E*)-2,6-octadien-1,8-diol dihexanoate, in a ratio of approximately 1:5, were the only volatile compounds present in the extracts. Structures of both esters were confirmed by synthesis. Field experiments revealed a strong attraction of *A. acuminatus* males towards neryl butanoate, which could be synergistically enhanced by addition of 2,6-dimethyl-(*Z*,*E*)-2,6-octadien-1,8-diol dihexanoate. The latter compound alone did not show any attractive effect. While all *Agriotes* spp. investigated to date use geranyl and/or (*E*,*E*)-farnesyl esters as sex pheromones, the nerol derivatives of *A. acuminatus* are the first (*Z*)-2-configurated pheromones within this genus.

Introduction

Agriotes acuminatus is a fairly common click beetle species that inhabits a large part of Europe. Its distribution ranges from Spain in the west to the Caucasus in the east, and from Italy and Greece in the south up to Denmark and Great Britain in the north (Cate 2007).

With a body length of 6.5–7.5 mm, a light brown color with a dark longitudinal stripe in the middle of the elytra, the lighter colored hind angles of the pronotum and especially its much more slender form, the appearance of *A. acuminatus* clearly differs from the other Central European species of its genus. In contrast, it strongly resembles the closely related and very common *Dalopius marginatus* (L.), from which it can be distinguished in the field by the finer punctated and, therefore, shinier pronotum (cf. Lohse 1979). Furthermore, the larva of *A. acuminatus* shows a longitudinal wrinkled sculpturing on the abdominal tergites (Rudolph 1974; Klausnitzer 1994), similar to *Agriotes pallidulus* (Illiger), but unlike all other Central European *Agriotes* spp.

Adults of *A. acuminatus* occur in open deciduous forests, especially on their edges and on glades, from lowlands to the montane zone. In contrast to agriculturally important species such as *A. lineatus* (L.), *A. obscurus* (L.), and *A. sputator* (L.), which develop in open areas, the larvae of *A. acuminatus* inhabit forest soil, where they presumably feed on roots of various plants (Rudolph 1974). Since *A. acuminatus* usually occurs in much lower numbers than economically important species and is absent from open agricultural areas, it is not classified as a pest insect.

In this study, the identification and synthesis of the sex pheromone of *Agriotes acuminatus* is reported, and the results of the corresponding field experiments are shown. The aim of our investigation was to complete the knowledge concerning sex pheromones of the Central European members of the genus *Agriotes*, and to provide an effective monitoring tool for faunistic purposes where the species is rare.

Methods and Materials

Insects Adult beetles of *Agriotes acuminatus* were collected in July 2004 by using a sweep net and a beating tray near Göppingen/Baden-Württemberg/Germany along a small river that cuts through an old beech forest. Beetles were sexed in the lab by observing the last abdominal segments, and a total of 22 female *A. acuminatus* were used for preparing extracts.

Extracts Beetles were frozen for 20 min, and allowed to thaw for another 20 min to room temperature. Subsequently, the ovipositor was extricated from the abdomen with forceps, and the now visible paired pheromone glands, similar to those described by Merivee and Erm (1993) for the click beetle *Agriotes obscurus*, were removed. Separate extracts were prepared for each beetle by transferring the glands to 300 µl CH_2Cl_2.

Chemical Analyses Analyses of natural extracts were carried out by coupled gas chromatography–mass spectrometry (GC/MS) in electron impact mode at 70 eV, 230°C, using a 6890 GC/5973 N MSD quadrupole instrument (Agilent Technologies, Santa Clara, CA, USA). Using helium as carrier gas, separations were achieved with a 30 m× 0.25 mm ID, 0.25-µm film HP5-MS fused silica column (Agilent), starting at 60°C for 3 min, then programmed to 300°C at a rate of 3°C /min, and finally held at 300°C for 40 min. Nuclear magnetic resonance (NMR) spectra of synthetic compounds were recorded with a Varian INOVA 500 instrument (Varian, Palo Alto, CA, USA).

Chemical Syntheses Chemicals and solvents were purchased from Aldrich or Merck and were of the highest purity available. Purification of synthetic products was carried out by flash chromatography on silica gel (silica 32–63, 60 Å, ICN-Biomedicals, Eschwege, Germany) at 1.3 bar using mixtures of ethyl acetate and hexane.

Neryl butanoate (**1**) and neryl hexanoate were prepared from nerol and the appropriate acid chlorides according to known methods (Tóth et al. 2003). Neryl hexanoate was oxidized to (*E*)-8-hydroxyneryl 1-hexanoate using SeO_2 and *tert*-butyl hydroperoxide, following Arm et al. (1986). Esterification of this product with hexanoyl chloride gave (*E*)-8-hydroxyneryl 1,8-dihexanoate (**2**) in a total yield of 57%.

In the NMR data, carbon atom numbers of the acid moieties in position 1 are indicated by one, in position 8 by two apostrophes.

Bait Dispensers and Traps Dispensers were prepared as described earlier (Tolasch et al. 2007) from 0.2 ml PCR tubes (ThermoTube™, Peqlab, Germany) that had been pierced with an insect pin 0.5 mm diam at the front side 2 mm below the lid. Dispensers were filled with three types of baits: **A**: 3 mg neryl butanoate (**1**), **B**: 15 mg 2,6-dimethyl-(*Z*,*E*)-2,6-octadien-1,8-diol dihexanoate (**2**), and **C**: 3 mg **1** + 15 mg **2**, resembling the natural ratio of these compounds found in the glands (1:5). Under laboratory conditions, the odor dispensers had a stable mean release rate of approximately 8–10 µg per day, regardless of the amount in the tubes (determined by weighing, unpublished data). Due to their different physical properties, the particular release rates of **1** and **2** may be different in lure **C**; however, we assumed that the ratio is similar to that of the natural pheromone.

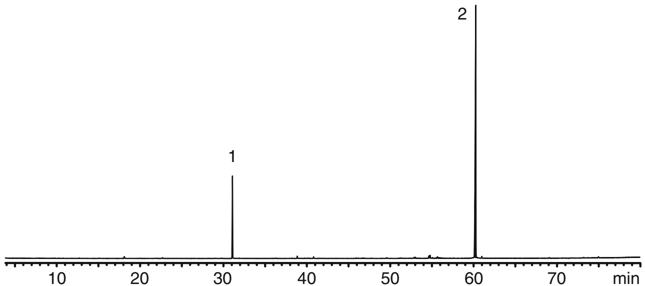

Fig. 1 Representative gas chromatogram (total ion current) of a gland extract from a female *Agriotes acumiatus* (30 m HP5-MS capillary column, 3 min at 60°C, then 3°C/min to 300°C)

Funnel traps were the same as described before (Tolasch et al. 2007). Each collecting bottle was filled with brine (200 ml) to preserve the beetles and minimize the possible attraction of further individuals to those already captured.

Field Experiments Two separate field tests were performed in 2006 and 2009. To check the general attractiveness of the synthetic blend of **1** and **2** resembling the natural ratio found in the glands, field experiments were carried out from 23 May to 13 June 2006 along a small river cutting through an old beech forest (*Fagus sylvatica* L.) near Göppingen/Baden-Württemberg/Southwest Germany. Sixteen traps were grouped into 8 sets, each set containing a trap baited with lure **C** and an unbaited control. Traps were suspended ca. 1.5–2.0 m above the ground from branches at the edge of the forest. The distance between traps within one set was about 5 m, while the distances between the sets were at least 50 m.

A second field bioassay, designed to examine the activity of the single compounds vs. the mixture, was performed

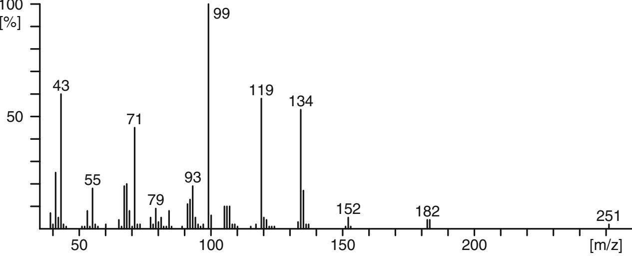

Fig. 2 70 eV–mass spectrum of the *Agriotes acuminatus* extract compound eluting after 60 min, subsequently identified as 2,6-dimethyl-(*Z*,*E*)-2,6-octadien-1,8-diol dihexanoate (**2**)

Fig. 3 Structures of the two pheromone gland compounds identified in *Agriotes acuminatus*, neryl butanoate (**1**) and 2,6-dimethyl-(*Z*,*E*)-2,6-octadien-1,8-diol dihexanoate (**2**)

from 9–30 June 2009 in a mixed lowland forest at the river Körsch near Plieningen/Baden-Württemberg/Southwest Germany. Predominant trees were black alder (*Alnus glutinosa* (L.) Gaertn.), willow (*Salix* spp.), poplar (*Populus* spp.), and black cherry (*Prunus serotina* Ehrh.). A total of 24 traps were grouped into 6 sets, each set comprised of three baited traps with lure **A**, **B**, **C**, respectively, and an empty control. Traps were suspended as described above, but the distances between the traps were larger (~15 m within one set, ~100 m between the sets). In both field tests, traps were checked weekly, captured beetles were removed and the brine was replaced. The numbers of male beetles were compared between traps by the Wilcoxon matched-pairs test using Statistica 6.1 (StatSoft, Tulsa, USA).

Results

GC/MS analysis revealed two compounds present in all gland extracts in a ratio of approximately 1:5, with only small quantitative variation between the samples of different females (Fig. 1). The minor compound, eluting at 31.1 min under the conditions described, was identified as neryl butanoate (**1**) by comparison with a synthetic sample. The major compound exhibited a mass spectrum resembling the spectrum of (*E*)-8-hydroxygeranyl diisovalerate (previously found in *Agriotes litigiosus* (Rossi), see Tóth et al. 2003), with the base peak shifted from *m/z* 85 to *m/z* 99 pointing to a dihexanoate (Fig. 2). A synthetic sample of (*E*)-8-hydroxygeranyl dihexanoate, prepared from geranyl hexanoate via the route described above (data not shown), eluted almost 1 min later than the natural product, however, the mass spectra were almost identical. Given that esters of nerol usually show very similar mass spectra but slightly shorter retention times than the corresponding geranyl esters, 2,6-dimethyl-(*Z*,*E*)-2,6-octadien-1,8-diol dihexanoate (**2**) (= (*E*)-8-hydroxyneryl dihexanoate) finally was proposed, which turned out to be identical with the natural product. The structures of both gland compounds are depicted in Fig. 3. The absolute amount of neryl butanoate (**1**) was estimated to be 92.8±18.5 ng/female, and for 2,6-dimethyl-(*Z*,*E*)-2,6-octadien-1,8-diol dihexanoate (**2**) 427.8±62.3 ng/female (*N*=4, respectively).

In the first set of field tests, performed in 2006, a 1:5-mixture of **1** and **2** proved highly attractive for males of *A. acuminatus*. In traps baited with lure **C**, a total of 548 ♂♂ were caught, while only 6 ♂♂ were found in the unbaited controls, showing a highly significant difference ($P<0.001$, Fig. 4, left). The second field test (2009), designed to investigate the activity of the single compounds **1** and **2** vs. the mixture, revealed a strong attractiveness for neryl butanoate (**1**, lure **A**), which captured a total of 313 males. Catches with the mixture (lure **C**) were almost 3 times higher (902 ♂♂), showing a strong synergistic effect of **2**. Lure **B** attracted no beetles at all, while 9 ♂♂ were found in the control traps (Fig. 4, right).

Discussion

The results of our study show clearly that the sex pheromone of *Agriotes acuminatus* consists of neryl butanoate (**1**) and (*E*)-8-hydroxyneryl dihexanoate (**2**). While **1** is essential to provide a general attractiveness, **2** acts synergistically and strongly enhances the activity. Compound **2** alone did not show any attractive effect.

Interestingly, occasional catches of low but significant numbers of *A. acuminatus* males with traps for *A. brevis* and *A. sputator*, containing geranyl butanoate, have been reported in the literature (Tóth et al. 2003; Subchev et al. 2006). Most likely, this cross-attraction may be explained by traces of neryl butanoate as an impurity in the geranyl butanoate employed.

Neryl butanoate (**1**) has not been described as a component of a click beetle pheromone before. However,

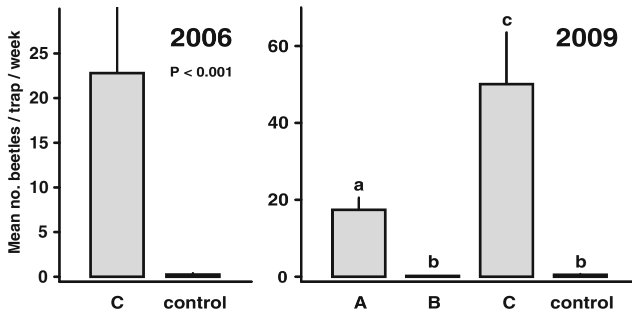

Fig. 4 Mean (+ SE) trap catches / week / trap of male *Agriotes acuminatus* in 2006 (*N*=24) and 2009 (*N*=18). Columns with different lowercase letters are significantly different at $P<0.001$ (Wilcoxon matched-pairs test)

it has been identified as a behaviorally inactive trace component among the volatiles of the pheromone gland of *A. sputator* (Tóth et al. 2003). (*E*)-8-Hydroxyneryl dihexanoate (**2**) represents an entirely new natural product.

Apart from the former subgenus *Ectinus* Eschscholtz (Tolasch 2008), the sex pheromones of the genus *Agriotes* are known to date form a relatively homogenous group with respect to their structural features: They are made up of one or two geranyl- and/or (*E*,*E*)-farnesyl esters of short fatty acids with equal chains (2–8 carbon atoms). If two compounds are involved, they differ either in the alcohol or in the acid moiety, but not in both (see Tóth et al. 2002, 2003). Representing acyclic monoterpene esters, the compounds reported here fit into this general scheme, however, there are two remarkabe differences: First, they show exclusively (*Z*)- instead of (*E*)- geometry at carbon 2 of the terpene unit. Second, they differ from each other in both the alcohol- and the acid moiety. This, along with the morphological features of the larvae and the adults mentioned above, points to a unique position of *A. acuminatus* within its genus, which is probably shared with the morphologically related *A. pallidulus* (Illiger) (pheromone hitherto unknown).

As mentioned in the introduction, *A. acuminatus* usually does not cause economical losses in agriculture or forestry. Nevertheless, the synthetic sex pheromone may serve as monitoring tool if the species should reach pest status. For the faunistic research, the pheromone could be useful for gathering records in places where the species is rare and/or reaches the limit of its distribution.

Abstract Fatty acid amino acid conjugates (FACs) have been found in noctuid as well as sphingid caterpillar oral secretions; in particular, volicitin [*N*-(17-hydroxylinolenoyl)-L-glutamine] and its biochemical precursor, *N*-linolenoyl-L-glutamine, are known elicitors of induced volatile emissions in corn plants. These induced volatiles, in turn, attract natural enemies of the caterpillars. In a previous study, we showed that *N*-linolenoyl-L-glutamine in larval *Spodoptera litura* plays an important role in nitrogen assimilation which might be an explanation for caterpillars synthesizing FACs despite an increased risk of attracting natural enemies. However, the presence of FACs in lepidopteran species outside these families of agricultural interest is not well known. We conducted FAC screening of 29 lepidopteran species, and found them in 19 of these species. Thus, FACs are commonly synthesized through a broad range of lepidopteran caterpillars. Since all FAC-containing species had *N*-linolenoyl-L-glutamine and/or *N*-linoleoyl-L-glutamine in common, and the evolutionarily earliest species among them had only these two FACs, these glutamine conjugates might be the evolutionarily older FACs. Furthermore, some species had glutamic acid conjugates, and some had hydroxylated FACs. Comparing the diversity of FACs with lepidopteran phylogeny indicates that glutamic acid conjugates can be synthesized by relatively primitive species, while hydroxylation of fatty acids is limited mostly to larger and more developed macrolepidopteran species.

Introduction

It is well documented that constituents of insect oral secretions can trigger plant responses, such as elicitation of induced *de novo* synthesis and release of volatile organic compounds (VOCs) (Turlings et al. 1990; Paré et al. 1998; Kessler and Baldwin 2001). The best known and most studied of insect-produced elicitors are the fatty acid amino

acid conjugates (FACs), first identified from beet armyworm *Spodoptera exigua* larvae (Alborn et al. 1997). In a recent study of a range of plant species, FACs and especially volicitin [*N*-(17-hydroxylinolenoyl)-L-glutamine] showed the broadest effects on plant hormone levels as well as induction of plant volatiles compared with caeliferin A16:0 and inceptin, two recently identified new classes of insect-produced elicitors of inducible plant defenses (Schmelz et al. 2006, 2009; Alborn et al. 2007). It also has been shown that application of volicitin to a mechanically wounded site selectively and transcriptionally activated genes for indole-3-glycerol phosphate lyase (*Igl*) and specific sesquiterpene cyclase (*stc1*), and that this activation also occurred systemically in undamaged leaves (Frey et al. 2000; Shen et al. 2000). However, previous studies (Truitt and Paré 2004; Truitt et al. 2004) showed that volicitin did not on its own serve as a mobile messenger for systemic VOCs emissions, but rather that a volicitin binding protein-ligand interaction may initiate plant defenses in response to herbivory.

Since glutamine-based FAC components initially were identified in oral secretions from *S. exigua* larvae, several other noctuid caterpillars have been reported to have the same glutamine-based FACs (Pohnert et al. 1999; Mori et al. 2001, 2003; De Moraes and Mescher 2004). In addition, oral secretions from some noctuid larvae such as *S. littoralis* also contain traces of glutamic acid-based FACs. Glutamine conjugates also are the major FACs in species of Geometridae, and one sphingid species (Pohnert et al. 1999; Mori et al. 2003). In contrast, glutamic acid conjugates are the dominant FACs in the sphingid tobacco hornworm, *Manduca sexta*, (Alborn et al. 2003) and tomato hornworm, *M. quinquemaculata* (Halitschke et al. 2001). Paré et al. (1998) showed that the fatty acid moiety of the FAC molecule originates from the diet of the caterpillar. Consequently, the fatty acid composition of the FACs roughly reflects the fatty acid composition in the host plant, although there seems to be a preference for linolenic and linoleic acid in the FAC synthesis (Aboshi et al. 2007).

Since the isolation and identification of FACs as elicitors of defensive reactions in plants, one intriguing question still remains to be answered: How do the insects benefit from producing FACs? Recently, we discovered that, at least for *S. litura*, glutamine-containing FACs play an active role in nitrogen assimilation by regulating the glutamine supply in the larval midgut (Yoshinaga et al. 2008). Enriching artificial diet with linolenic acid not only resulted in an increased FAC synthesis, but also promoted a 50% increased glutamic acid to glutamine conversion, ultimately resulting in a significantly increased amount of glutamine in the whole body. Thus, the ability to utilize FACs in the digestive system might be one way that lepidopteran larvae optimize their growth rate. However, it is not known if all lepidopteran larvae utilize FACs. Furthermore, differences in physiology or metabolism associated with glutamine-FACs vs. glutamic acid-FACs are not understood. These questions are not easy to answer, since only a limited number of insect species (mainly of agricultural interest) have been investigated for FAC content so far. Consequently, we decided to collect and analyze gut contents from an environmentally, taxonomically, and physiologically diverse group of lepidopteran larvae consisting of 29 species from16 families.

Materials and Methods

Caterpillar Source Colonies of *Spodoptera litura*, *Mythimna separate,* and *Hyphantria cunea* were maintained successively in the laboratory, and *Helicoverpa armigera* was supplied by Dr. Kenji Fujisaki, *Anadevidia peponis* by Dr. Tetsu Ando, *Samia cynthia ricini* by Dr. Masatoshi Ichida, and *Agrius convolvuli* by Dr. Masami Shimoda. Commercially available *Bombyx mori* were purchased from Mukin Yosan System Institute (Kyoto, Japan), *Agrotis ipsilon* eggs were purchased from Benzon Research Inc. (PA, USA), and *Manduca sexta* from North Carolina University, NC, USA. Another 18 wild species were collected in Kyoto, Osaka, Mie, and Tokushima prefectures in Japan. *Malacosoma americanum* was caught in Pennsylvania, USA, all identified by their morphological traits and food habitats. *Epiphyas postvittana* from New Zealand were from a recently-established colony fed on apple. *Hy. cunea* and *An. peponis* were fed on artificial diet (Insecta-LFS, Nihon Nosan Kogyo Ltd., Yokohama, Japan), while other species, including laboratory-reared species, were fed on their host plants. Last-instars of each species were frozen at −4°C to extract gut contents.

Gut Content Extraction and Sample Preparation At least three insects were used from one species (one insect per sample). The frozen gut contents were dissected out as earlier described (Mori et al. 2003), placed in plastic tubes, and immediately boiled for 20 min to avoid enzymatic decomposition of FACs (Mori et al. 2001). To each sample was added an equal volume of 50% water/acetonitrile solution (v/v) (an addition of 10–300 µl, dependent on the amount of gut content). The samples were then roughly homogenized with a plastic homogenizer and centrifuged at 14,000*g* for 5 min. Ten-fold dilutions of the supernatants with 50% acetonitrile solution were analyzed by LCMS.

LC/MS Analyses Mass spectral measurements were carried out with an LCMS-2010A instrument (Shimadzu, Kyoto, Japan) combined with an HPLC system (LC-10ADvp pump, CTO-10ACvp column oven, and SCL-10AVvp system

controller, Shimadzu). Three μl of sample solution were injected into a reversed-phase column (Cosmosil $5C_{18}$-AR-II, 50×2.0 mm I.D., Nacalai tesque, Kyoto, Japan) eluted for 15 min at (0.2 ml/min) with a solvent gradient of 40–95% CH_3CN containing 0.08% acetic acid, in water containing 0.05% acetic acid. The column temperature was maintained at 40°C (CTO-10Avp column oven, Shimadzu), and the column eluant was monitored by continuous MS total ion current trace. The CDL temperature was 250°C, the voltage was 1.5 kV, the nebulizer gas flow was 1.5 l/min, and the analytical mode was ESI negative scan from *m/z* 150–500. The negative ionization mass spectra gave characteristic $(M-1)^-$ ions for volicitin at *m/z* 421, *N*-hydroxylinolenoyl-L-glutamic acid *m/z* 422, *N*-hydroxylinoleoyl-L-glutamine *m/z* 423, *N*-hydroxylinoleoyl-L-glutamic acid *m/z* 424, *N*-linolenoyl-L-glutamine *m/z* 405, *N*-linolenoyl-L-glutamic acid *m/z* 406, *N*-linoleoyl-L-glutamine *m/z* 407, and *N*-linoleoyl-L-glutamic acid *m/z* 408. The position of the hydroxyl group in the hydroxylated FACs was not determined.

For some species, a few FACs were detected only in trace amounts. In such cases, we increased sample numbers, and determined an FAC was present only when it was detected in more than three replicates.

Results

Linolenic and linoleic acid were the dominant fatty acids in FACs. Although we also detected *N*-oleoyl-L-glutamine, and other less abundant fatty acids conjugated with glutamine reflecting the proportion of dietary fatty acids (Aboshi et al. 2007), we focused our analysis on conjugates based on these acids.

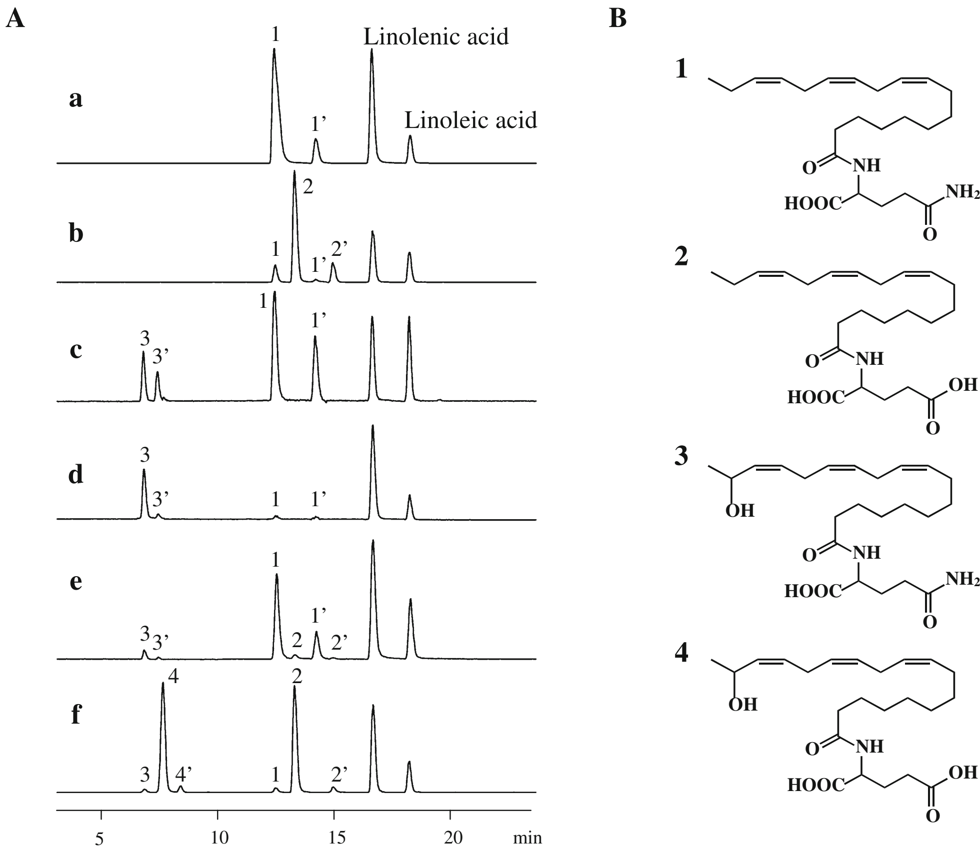

Fig. 1 (**A**) Typical extracted ion chromatograms of gut contents from (a) *Locastra muscosalis*, (b) *Phalera flavescens*, (c) *Xanthodes transversa*, (d) *Lymantria dispar*, (e) *Agrotis ipsilon*, and (f) *Acherontia styx*, and (**B**) chemical structures of compounds 1-4. A reversed-phase column was eluted for 15 min with a 40–95% solvent gradient of CH_3CN in water containing 0.05% acetic acid. ESI-negative MS scan at *m/z* 150–500. 1, *N*-linolenoyl-L-glutamine (*m/z* 405); 1′, *N*-linoleoyl-L-glutamine (*m/z* 407); 2, *N*-linolenoyl-L-glutamic acid (*m/z* 406); 2′, *N*-linoleoyl-L-glutamic acid (*m/z* 408); 3, *N*-hydroxylinolenoyl-L-glutamine (*m/z* 421); 3′, *N*-hydroxylinoleoyl-L-glutamine (*m/z* 423); 4, *N*-hydroxylinolenoyl-L-glutamic acid (*m/z* 422); 4′, *N*-hydroxylinoleoyl-L-glutamic acid (*m/z* 424)

and chemical structures of the major FACs. Noticeable differences in FAC composition among the species are first that *L. dispar* larvae (Fig. 1Ad) have more of the hydroxylated compounds (3, 3′) than glutamine conjugates (1, 1′), while for *X. transversa* (c) these ratios are reversed.

Second, *P. flavescens* (b), *Ag. ipsilon* (e) and *Ac. styx* (f) synthesize glutamic acid conjugates (2, 2′) as well as glutamine conjugates (1, 1′), but glutamine conjugates are the major compounds in *Ag. ipsilon,* while glutamic acid conjugates are dominant in *P. flavescens* and *Ac. styx*. Third, as seen in Fig. 1A, the linolenic/linoleic acid ratios in FACs are parallel to those corresponding free fatty acids as expected if the ratio simply depended on dietary fatty acid compositions rather than on an enzymatic substrate preference (Aboshi et al. 2007).

Table 1 shows the FAC components found in 29 lepidopteran species, including 10 species in which no FACs were found. Clearly, FACs are not specific to a certain lepidopteran group but synthesized by widely different families. As expected, closely related species in the same family tended to have the same or very similar FAC patterns. Interestingly, glutamine conjugates (1, 1′) were found commonly in all these 19 species. Based on this, all FAC patterns were classified into 4 types: ① glutamine only (Fig. 1Aa), ② addition of glutamic acid (b), ③ addition of hydroxylation (c, d), ④ addition of glutamic acid and hydroxylation (e, f) (Table 1).

Discussion

In this investigation, we were interested mainly in each species' ability to synthesize various FAC compounds regardless of diet. Considering the fact that linolenic acid-FACs are more active as plant volatile elicitors than linoleic acid-FACs, this ratio may have ecologically important

meaning for each species (De Moraes and Mescher 2004). However, we found no indication that the ratio of linolenic/linoleic acid in insect FACs differed from the ratio of the free fatty acids in the gut contents. This result suggests that there is no appreciable bias for fatty acid selection during FAC synthesis. Consequently, we focused this investigation on the difference between glutamine and glutamic acid and the hydroxylation status, rather than the fatty acids. No species have glutamic acid-FACs (2, 2′) without glutamine-FACs, nor hydroxylated FACs (3, 3′) without glutamine-FACs. This suggests that glutamine-FACs are the evolutionarily older FACs, and that the presence of glutamic acid conjugates, as well as hydroxylated acyl conjugates, are two independent indicators of FAC diversification. For the hydroxylation, we found clear differences between species, but it is worth noting that the ratio of hydroxylation can be variable even within a species. Previously, we reported hydroxylated FACs (3, 3′) as the major FACs in *S. litura* (Mori et al. 2003), but recently we found that *S. litura* larval gut contents have more *N*-linolenoyl-L-glutamine (1) than volicitin (3) (Yoshinaga et al. 2005). Even within an individual larva feeding on the same diet we have seen variation depending on the time course after the meal (data not shown). We also have noticed that a high abundance of dietary lipid increased the relative abundance of hydroxylated compounds in *M. sexta* (data not shown). Thus, the hydroxylation/non-hydroxylation ratio might be, at least partially, diet related. Since glutamine conjugates (1, 1′) are precursors of hydroxylated FACs (3, 3′) (Yoshinaga et al. 2005), the composition also will be influenced by the kinetics of 3 enzymes: conjugase, hydrolase, and hydroxylase. The glutamine/glutamic acid ratio appears to be more stable. In this investigation, *P. flavescens* and *Ac. styx*, had the same FAC proportions as *M. sexta*, with substantial amounts of glutamic acid-FACs, and only minor glutamine-FACs peaks. At least for *M. sexta*, an insect with which we have worked for several years, this ratio has been consistent and independent of the diet. We have no idea of the decisive factor for this, but it indicates a critical regulation of the proportions of these two types of FAC compounds.

The data we present here provide a broad base of information about FAC diversification in lepidopteran caterpillars. Figure 2 shows the distribution on the lepidopteran family tree (based on the Tree of Life web project database: http://tolweb.org/tree/) of the four FAC types from the 29 lepidopteran species described in this paper and nine other species studied earlier: three Geometridae species (Pohnert et al. 1999); *S. frugiperda* (③), *S. littoralis* (④) (Pohnert et al. 1999); *Heliothis virescens* (③), *Helicoverpa zea* (③) (Mori et al. 2001); *Helio. subflexa* (③) (De Moraes and Mescher 2004) in Noctuidae; *M. quinquemaculata* (④) in Sphingidae (Halitschke et al. 2001). All FAC-containing species had glutamine-based FACs in common but, surprisingly, only two species were of group ①: *L. muscosalis* and *B. triannulella*. The fact that *B. triannulella* is evolutionarily the most ancestral species among these FAC-containing species supports our hypothesis that glutamine conjugates are the evolutionarily older FACs, although more data for ancestral species are essential to corroborate this conclusion. Equally surprising, group ②, characterized by glutamic acid conjugates, can be seen in relatively primitive lepidopteran families such as Cossidae and Tortricidae. In contrast, group ③ and ④, which include hydroxylated FACs, are limited to Macrolepidoptera, which is considered to be the most advanced lepidopteran group. These species typically are characterized by their relatively large body size. However, since there are some large-sized species that do not synthesize FACs at all, these compounds can not be correlated simply with size and weight. Alternatively, species in group ③ and ④ may be associated with a broad range of host plants. Li et al. (2003) suggested that host plant diversity can be related directly to P450 activity and inversely related to substrate specificity. It is, therefore, likely that a cytochrome P450 enzyme is responsible for the FAC hydroxylation as represented by volicitin (Ishikawa et al. 2009).

Possibly, there is an evolutionary interplay between a plant's ability to detect and respond to different FACs and the insect's dependence on these same compounds for maximized nitrogen assimilation. We have shown that glutamine-FACs are involved in this process, but the function of, and even the biosynthesis of, glutamic acid conjugates still remain unknown. In this study, glutamic acid conjugates were not limited to *M. sexta* or *M. quinquemaculata,* but were found also in relatively primitive lepidopteran families. Furthermore, we have already reported FACs in the gut content of crickets and larval fruit flies in a pattern similar to that of *M. sexta* or *Ar. styx* (Yoshinaga et al. 2007), in which glutamic acid conjugates are dominant, with only trace amounts of glutamine conjugates. It appears that glutamine, as well as glutamic acid FACs, play important roles in insects, but we do not know if the role is the same in all these different insect species.

Despite the apparent physiological benefit of FACs, we also found 10 lepidopteran species where the gut content did not contain detectable amounts of any FACs. If the main function for FACs is to maximize nitrogen uptake and subsequently maximize growth rate, then we would expect that these FAC-free insects all should be characterized by long developmental times, but this is not the case. *Bombyx mori* and *Ar. coerulea* grow fast and achieve large body size, while Cossidae species (which make glutamic acid conjugates) grow slowly, boring into the trunk of salixes or apples, and require years before pupation. Curiously, there is a tendency for FAC-free caterpillars to have specific defensive strategies: *Hyphantria cunera* and *Malacosoma americanum* are gregarious on a host tree and make nests. Two Crambidae species also make nests by using leaves to wrap themselves.

Fig. 2 FAC-pattern classification and the phylogenetic relationship of Lepidoptera. [The phylogenetic tree is based on the Tree of Life Web Project. 2003. Lepidoptera. Moths and Butterflies. Version 01 January 2003 (temporary). http://tolweb.org/Lepidoptera/8231/2003.01.01 in The Tree of Life Web Project, http://tolweb.org/.] ① gutamine conjugates only; ② glutamine and glutamic acid-type FACs; ③ hydroxylated glutamine-type FACs; ④ hydroxylated glutamine and glutamic acid type FACs; O no FACs detected

Atrophaneura alcinous, *Parasa lepida lepida*, and *Pryeria sinica* are all notoriously toxic. *Pryeria sinica* also has an escape strategy that involves releasing thread to hang down from a tree branch. *Theretra oldenlandiae* has a threatening bull's-eye pattern that mimics snakes. *Arcte coerulea*, which was the only FAC-free species found in the Noctuidae so far, is famous for its characteristic threatening behavior, vigorously shaking its upper body and spitting slimy gut contents. Only domesticated silkworms have no such means of protection, but they no longer live in nature. In contrast, most of the FAC-containing species show no direct defensive reactions, with a few exceptions as shown in the case of *E. postvittana,* which also uses thread to escape from parasitoids (Suckling et al. 2001). Noctuidae and Sphingidae

species seem to especially focus on feeding and sleeping to grow faster, which characterizes them as serious pests (Fig. 2).

In summary: in this investigation we found that volicitin-related compounds are more commonly synthesized in lepidopteran larvae than was previously known but also that not all Lepidoptera utilize FACs. We were able to classify the FAC pattern into 4 groups: 1, glutamine conjugates only; 2, glutamic acid variation; 3, hydroxylated glutamine-type FACs; and 4, hydroxylated glutamine and glutamic acid type FACs. All FAC-containing species had *N*-linolenoyl-L-glutamine and/or *N*-linoleoyl-L-glutamine, which might be evolutionarily older FACs. Although the data provided here are biased toward noctuid and sphingid species, a comparison of the diversity of FACs with lepidopteran phylogeny indicates that glutamic acid conjugates can be synthesized by relatively primitive species, while hydroxylation of fatty acids is mostly limited to larger and more developed macrolepidopteran species.

This paper has highlighted the need to intensify our studies of FACs in Lepidoptera as well as other insects in order to obtain a new perspective and understanding of the multifaceted functions of FACs in the insect world.

RAPID COMMUNICATION

Rapid Communication: Experimental Evidence that Juvenile Pelagic Jacks (Carangidae) Respond Behaviorally to DMSP

Jennifer L. DeBose · Gabrielle A. Nevitt · Andrew H. Dittman

Received: 2 December 2009 / Revised: 19 January 2010 / Accepted: 21 January 2010 / Published online: 23 February 2010

Abstract Dimethylsulfoniopropionate (DMSP) is produced by marine algae and released during foraging activity by zooplankton and fish. Pelagic fishes depend on patchily distributed foraging opportunities, and DMSP may be an important signaling molecule for these events. We have previously shown that the abundance of carangid jacks is positively associated with elevated DMSP levels over coral reefs in the Gulf of Mexico, suggesting that these fishes may use spatial and temporal variation in DMSP to locate foraging opportunities. Here, we extend this work by demonstrating that juveniles of two species of pelagic jack, crevalle jack, *Caranx hippos*, and bluefin trevally, *C. melampygus*, detect and respond to DMSP in a flow-through tank in the laboratory. Juveniles of these species showed elevated swimming activity in response to ecologically relevant concentrations of DMSP (10^{-9} M). These results provide further evidence that this chemical may serve as a chemosensory cue for carangid species.

Introduction

Dimethylsulfoniopropionate (DMSP) is a soluble compound produced by marine algae and released during planktivorous foraging events (reviewed by Simo 2004). High DMSP concentrations are recorded in seawater around areas of high primary productivity and foraging activity, such as frontal zones or seamounts where phytoplankton tend to aggregate. Foraging aggregations often are characterized by large numbers of plankton, including phytoplankton and zooplankton, surrounded by planktivorous fishes, which are then corralled by predatory fish. Planktivorous fishes aggregate in response to DMSP (DeBose et al. 2008), and increased numbers of predatory jacks are correlated with increases in combined DMSP and dimethylsulfide (DMS) over coral reefs (DeBose and Nevitt 2007). Laboratory studies further indicated that high concentrations of DMSP (10^{-2}–10^{-3} M) in food increased striking frequency and weight gain in two species of saltwater fish (Nakajima et al. 1990). Predatory fishes generally are assumed to rely on visual cues. Thus, we wanted to test whether or not they can detect ecologically relevant concentrations of dissolved DMSP, with the goal of understanding the use of chemical cues in driving foraging events, and ultimately, trophic cascades. Specifically, the aim of the current study was to use a simple behavioral assay to verify whether jacks can detect DMSP.

Methods and Materials

Experimental Animals We tested behavioral responses of juveniles of two species of jack, crevalle jack, *Caranx hippos*, and bluefin trevally, *C. melampygus*, to DMSP by using a flow-through Plexiglas tank (Hara 2006). Crevalle jack are reef-associated pelagic, schooling fish from the

Atlantic Ocean, and bluefin trevally are a commercially important Pacific Ocean species. Adult crevalle jack and bluefin trevally feed mostly on fish and crustaceans (Lieske and Myers 2001), although at the juvenile stage we tested, both species feed on plankton.

Juvenile bluefin trevally [~2-mo-old; size range: 45.65–82.15 mm total length (TL)] were hatched and originally reared at the Oceanic Institute (Waimanalo, HI, USA), and then transported to the Northwest Fisheries Science Center, NOAA-Fisheries, Mukilteo Research Station, Mukilteo, WA, USA, for this study. Fish were housed in circular tanks (1.3–2.0 m diam.) supplied with sand-filtered flow-through seawater (21–23°C). Juvenile crevalle (~1-2-mo-old; 57.30–72.80 mm TL), associated with Sargassum mats, *Sargassum natans*, were collected near Galveston, TX, USA, and held in rectangular seawater tanks (1.8×0.8×0.7 m) at the Moody Gardens Aquarium Quarantine facility in Galveston, TX, USA.

Flow Tank Specifications All experiments were conducted in a 51 l flow-through tank (157×30×14 cm) with a flow rate of 5–7 l/min and a water depth of 10.8 cm. Water flow was smoothed by a flow-straightener (FS) made of straws (length: 9 cm; diam: 1.1 cm) glued together to form a 'honeycomb' of channels, located 10 cm downstream from the intake. Stimuli were introduced into the tank upstream of the FS, where an airstone thoroughly mixed the injected stimuli prior to flowing into the experimental arena of the tank. An airstone is a piece of porous stone whose purpose is to gradually diffuse oxygen into aquaria, thus eliminating the noise and large bubbles of conventional air filtration systems. The entire tank was housed under black plastic to reduce visual cues, but the tank was illuminated by infrared lights to allow recording of fish movements with an infrared camera (Sony DCR-TRV-17).

Testing Protocol Behavioral trials for DMSP responses were conducted from June to September 2006 with a total of 10 crevalle and 8 bluefin trevally. Prior to each trial, a single fish was fasted for 24 h and then placed in the downcurrent end of the flow table for an 8 h acclimation period. After acclimation, fish movement patterns along the length of the flow table (see *Behavioral Scoring and Analysis* below) were recorded for 10 min immediately prior to stimulus release (DMSP or ASW). Stimulus water was metered into the flow table for 1 min, and behavior was recorded for an additional 10 min. After a 30 min recovery period, the process was repeated with the second stimulus. In pilot studies, 30 min was sufficient for the experimental stimulus to vacate the tank and fish to resume background levels of activity. Fish were used in only one trial, experiencing both stimuli. The order of stimulus delivery was switched every trial.

Chemical Stimuli Two stimuli were tested during each trial: 10^{-9} M DMSP and artificial saltwater (ASW, Instant Ocean®, Mentor, OH, USA). ASW or DMSP (1.0×10^{-7} M) were delivered via intravenous medical bags positioned outside the black plastic blind. Stimuli were injected at a rate of 60 ml/min into the pre-FS reservoir for 1 min. Complete mixing, confirmed by dye release studies (Bright Dyes®, Miamisburg, OH, USA), yielded a final concentration of 1.0×10^{-9} M DMSP in the reservoir. This concentration is within the natural range of DMSP measured over coral reefs (Jones et al. 2007: 0.43–27 nM). DMSP solutions were prepared in artificial saltwater (ASW) matched to background salinity (±1 ppt) with a YSI meter (MODEL 85, YSI Inc., Yellow Springs, OH, USA). Working DMSP solutions were prepared immediately before each trial from stock solutions of DMSP (10^{-3} M) (Chemische Laboratoria, Rijksuniversiteit Groningen, Groningen, The Netherlands) stored at −20°C. All solutions were equilibrated to background water temperature (22.0±0.10°C for bluefin trevally, 26.8±0.11°C for crevalle jack) before each experimental trial.

Behavioral Scoring and Analysis Recorded trials were scored with J-Watcher software (V1.0, Macquarie Univer-

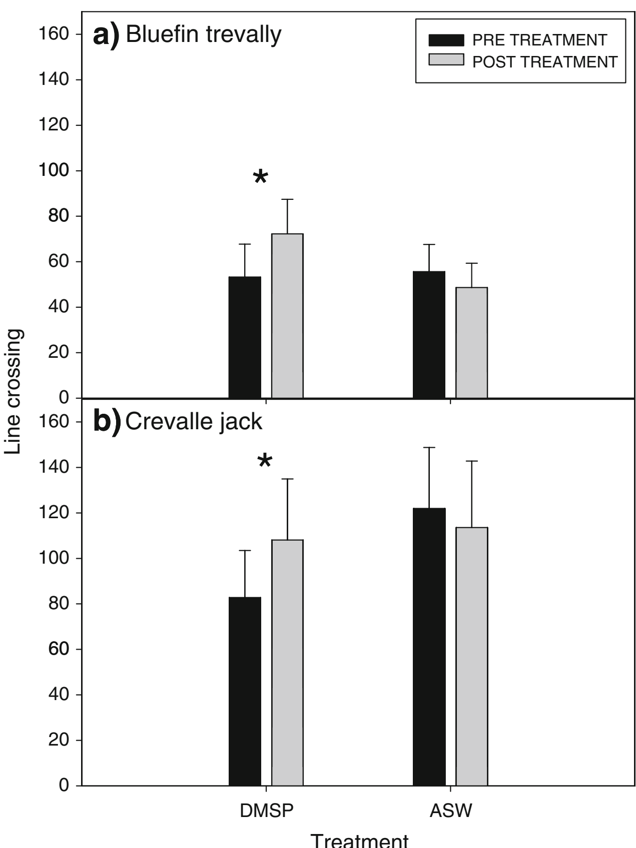

Fig. 1 Bluefin trevally (**a**) and crevalle jack behavioral response (**b**) to artificial salt water (ASW) and 10^{-9} M DMSP. Asterisk denotes significant difference in line crossing behavior between time periods associated with pre- (black bar) and post- (gray bar) treatment stimuli

sity and UCLA) by an observer blind to the treatment. The responses before and after stimuli exposure were defined as the number of lines crossed 10 min before and 10 min after stimuli presentation. The number of lines crossed was determined by using 10 cm grid lines on the bottom of the tank. Line crossings were defined by the entire head of the fish crossing the grid line. Data (before/after responses) were analyzed by paired *t*-test ($\alpha=0.05$) with before-stimulus responses as individual controls.

Results and Discussion

Both bluefin trevally and crevalle jack increased their number of line crosses in response to 10^{-9} M DMSP but not ASW (bluefin trevally: Fig. 1a, DMSP: $P<0.01$; ASW: $P=0.28$, $N=8$; crevalle: Fig. 1b, DMSP: $P<0.05$; ASW: $P=0.71$, $N=10$). Pre-stimulus activity levels were similar for both DMSP and ASW (bluefin trevally: $P=0.901$; crevalle: $P=0.353$), with fish moving throughout the test arena during the pre-stimulus period. Results indicate that *Caranx* spp. detected 10^{-9} M DMSP in a laboratory setting.

The ability to detect DMSP could be advantageous in finding food and/or habitat under laboratory and natural conditions; by increasing activity in the presence of this compound, jacks could use DMSP to locate foraging opportunities. DMSP was present in the commercial feeds fed to these jacks ($2.7–3.1\times10^{-7}$ M (extract); DeBose 2008) and wild crevalle jack used in these studies were captured under Sargassum mats, which also produce DMSP (Broadbent et al. 2002). In previous studies, we measured concentrations of total DMSP over coral reefs in the Gulf of Mexico and Caribbean (DMSPt, dissolved + particulate: $10^{-8}–10^{-9}$ M; DeBose and Nevitt 2007; DeBose 2008). Dissolved DMSP concentrations in the waters over the Great Barrier Reef are reported to be in the $10^{-7}–10^{-9}$ M range (Broadbent et al. 2002; Jones et al. 2007).

Our results provide evidence that two species of carangid jack detect ecologically relevant concentrations of DMSP, thus supporting the hypothesis that this compound, released during feeding interactions, might be an effective sensory cue for these fish in their natural environments. Overall, however, we are only beginning to understand the role of DMSP as a signal molecule in marine ecosystems. This study, combined with previous work (Nakajima et al. 1990; DeBose and Nevitt 2007; DeBose et al. 2008), provides intriguing evidence that pelagic fishes detect DMSP and may use this algal-produced compound as a foraging or habitat-associated cue in their natural environment. Reef-associated jacks must find habitat and foraging opportunities as they range over the reef and beyond into blue water, and most likely they use a suite of chemical and other sensory cues for orientation. By cueing to the release of DMSP associated with foraging activities of zooplankton and planktivorous fishes (Hill and Dacey 2006; DeBose et al. 2008), pelagic jacks could use this chemical to locate transient and localized foraging opportunities. The role of chemical cues in the behavior of pelagic fishes such as jacks is only beginning to be recognized. Although this study implicates DMSP as a compound of interest, others (e.g., amino acids, amines, etc.; Hara 2006) also are known feeding stimuli. Further work is needed to fully understand the multitude of ways that these fish may use chemical compounds to forage and navigate in their marine environment.

Acknowledgments We thank the Oceanic Institute, specifically C. Laidley and staff, for providing bluefin trevally. We also thank P. Swanson, M. Havey, D. May, M. Rust, T. Scott, P. Plesha, and F. Sommers, of the Northwest Fisheries Science Center, NOAA, for help in acquiring and maintaining trevally. Thanks to Moody Gardens Aquarium, especially R. Drinnen, B. Christie and staff, B. Dailey, and M. Weber, for collecting and housing crevalle jacks. We also thank S. Strom (Shannon Point Marine Center) for GC use. Experiments were conducted under UCD ACUC #12050. Funding was provided by a PEO Scholar Award and by a NSF-GRF (JLD) and by a grant from NOAA Fisheries (AHD).

Abstract Experiments were conducted to determine whether allelochemicals released by the important medicinal plant *Scutellaria baicalensis* Georgi help to explain why *S. baicalensis* performs poorly when continuously cropped. Based on high performance liquid chromatography, the concentration of baicalin (the major compound released by *S. baicalensis* roots) in the soil where *S. baicalensi* had been grown for 3 years was 0.97 μg.g^{-1}. Both the crude extracts from *S. baicalensis* roots and purified baicalin at 0.97 μg.g^{-1} increased the mortality of *S. baicalensis* seedlings in an autotoxicity test. This concentration stimulated the growth of two soilborne pathogens (*Pythium ultimum* and *Rhizoctonia solani*) on agar, and their growth and pathogenic activity in sand. Seedling mortality and damping-off caused by both pathogens were greater in sand where *S. canadensis* had previously grown than in sand where it had not previously grown. Mortality and damping-off of *S. baicalensis* seedlings also were significantly higher in soil collected from an *S. baicalensis* field than in soil collected from a *Nicotiana tabacum* L. field. The results are consistent with the hypothesis that allelochemicals released by *S. baicalensis* negatively affect *S. baicalensis* directly by inducing autotoxicity and indirectly by increasing pathogen activity in the soil.

Introduction

Autotoxicity, a form of intraspecific allelopathy, is defined as a process in which a plant species releases toxic chemicals that inhibit or delay germination and growth of other plants of the same species (Miller 1996; Singh et al. 1999). Autotoxicity occurs in natural ecosystems and is considered to have ecological significances in regulating plant population density (Canals et al. 2005; Sinkkonen 2007). Autotoxicity also is believed to be an obstacle to continuous cropping by causing regeneration failure in crop growth and yield in managed ecosystems (Chou and Lin 1976; Rice 1984; Batish et al. 2001; Hao et al. 2007; Liu et al. 2007; Fernandez et al. 2008).

Increasingly, studies have shown that root exudates can influence plant growth not only directly by acting as autotoxins (Mahall and Callaway 1992; Yu et al. 2000; Pramanik et al. 2001; Kong et al 2008; He et al. 2009) but also indirectly by affecting the soil microbial community (Christie et al. 1974; O'Donnell et al. 2001; Matamala et al. 2003; Bais et al. 2004; Yao and Allen 2006; Wu et al. 2009). Root exudates may affect soil microorganisms, which in turn influence the plant by initiating and manipulating biological and physical interactions between roots and other soil organisms (Kandeler et al. 2002; Bais et al. 2004); root exudates can, thus, affect the interactions between plants and soil microorganisms (Miethling et al.

2000). Although several studies have demonstrated that root exudates enhance soilborne pathogens by providing substrates for saprophytic growth (Nicol et al. 2003; Manici et al. 2004; Bonanomi et al. 2007), whether and how allelopathy influences soil microorganism communities to produce positive or negative feedback to the plants still is incompletely understood.

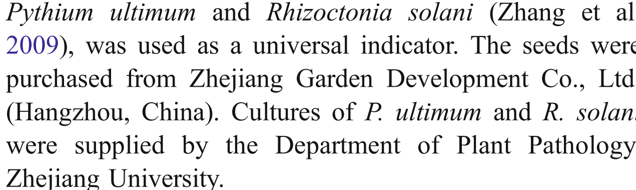
The dried root of the flowering plant *Scutellaria baicalensis* Georgi is used as a drug in Chinese traditional medicine (Yamamoto 1991), and the plant is widely grown as a crop in Eastern Asia (Qu et al. 2007). As a drug, the dry root of *S. baicalensis* is called Radix Scutellariae, and is officially listed in the Chinese Pharmacopeia (Kovacs et al. 2004). *Scutellaria baicalensis* contains large amounts of flavones, and the flavone baicalin (7-glucuronic acid, 5, 6-dihydroxy-flavone), which is one of the major effective components in dried roots of *S. baicalensis*, accumulates in the rhizosphere soil (Bochoráková et al. 2003). In the production of Radix Scutellariae, *S. baicalensis* suffers from a serious replant problem in that substantial yield reduction occurs after 2 years or 3 years of continuous cropping. Increasing evidence indicates that *S. baicalensis* suffers from diseases caused by the pathogens *Pythium ultimum* and *Rhizoctonia* spp. during continuous cropping (Benizri et al. 2005; Chang et al. 2007), suggesting that an increase in numbers of soilborne pathogens contributes to the replant problem.

We hypothesized that allelochemicals released by *S. baicalensis* negatively affect the source plant by inducing autotoxicity and by increasing pathogens in the soil. To test this hypothesis, we first quantified the concentration of baicalin in a field where *S. baicalensis* had been grown for 3 years. Based on that concentration of baicalin, we then conducted a series of experiments to determine: (1) whether baicalin directly reduces germination and growth of *S. baicalensis* seedlings; (2) whether baicalin promotes soilborne pathogens and thereby indirectly reduces germination and growth of *S. baicalensis* seedlings due to disease incidence.

Methods and Materials

Plants, Pathogens, and Chemicals Seeds of *Scutellaria baicalensis* Georgi were collected from the field site (see next section). For use as standards for quantitative analysis of flavonoids, high purity (>99%) baicalin, wogonoside, baicalein, and wogonin were obtained from the National Institute for the Control of Pharmaceutical and Biological Products, Beijing, China. Crude extracts of Radix Scutellariae (containing 16.7±1.3% baicalin) also were provided by the same institute.

Tomato (*Lycopersicon esculentum* Mill) variety Qianhong No.1, which is susceptible to the soilborne pathogens



Pythium ultimum and *Rhizoctonia solani* (Zhang et al. 2009), was used as a universal indicator. The seeds were purchased from Zhejiang Garden Development Co., Ltd. (Hangzhou, China). Cultures of *P. ultimum* and *R. solani* were supplied by the Department of Plant Pathology, Zhejiang University.

Study Site and Sampling The study was conducted in Wolong Town, Linqu County, Shandong Province, China (36°27′N, 118°38′E), where *S. baicalensis* is the major economic crop and has been grown by farmers for years. *Scutellaria baicalensis* had been grown on the study site, which is 5 ha, for the preceding 3 yr. The site is in the south temperate zone, and has a mean annual temperature of 12.4°C and a mean annual rainfall of 710 mm. The soil from the *S. baicalensis* field is a sandy loam with a pH of 6.89 (2.5:1, KCl aqueous solution:soil), an organic matter content of 17.17 $g{\cdot}kg^{-1}$, a total nitrogen content of 0.96 $g{\cdot}kg^{-1}$, an extractable phosphorus content of 60.90 $mg{\cdot}kg^{-1}$, and an extractable potassium content of 292.36 $mg{\cdot}kg^{-1}$. The field where *Nicotiana tabacum* had been grown had a pH of 7.07 (2.5:1, KCl aqueous solution: soil), an organic matter content of 20.15 $g{\cdot}kg^{-1}$, a total nitrogen content of 1.16 $g{\cdot}kg^{-1}$, an extractable phosphorus content of 31.55 $mg{\cdot}kg^{-1}$, and an extractable potassium content of 207.95 $mg{\cdot}kg^{-1}$.

For determination of the baicalin concentration in the study site soil, 30 soil cores (10 cm diam and 15 cm deep) in five sampling areas (2×2 m) were separately collected from the rhizospheres of *S. baicalensis* plants in November, 2008. In each of five sampling areas, six soil cores from one area were collected and combined to give one sample per area. The five soil samples were subjected immediately to slow air-drying, thus mimicking conditions that would occur during natural drying. Any obvious plant or animal debris was removed.

Quantification of Baicalin in the Soil For each 300-mg subsample per soil sample, baicalin was extracted with 30 ml of 70% MeOH for 60 min in an ultrasonic bath; the extraction procedure was repeated × 3 for each subsample. The methanolic extracts for each subsample were combined and evaporated to dryness *in vacuo*. The viscous residue was dissolved in 100 ml of MeOH and passed through a 0.45-μm nylon filter (Millex-HN, Ireland) before injection for HPLC analysis.

Standard curves were calibrated by using the linear least-squares regression equations derived from the peak areas of five injections. HPLC analysis was performed on an Aglient 1100 series system with a G1311A Quatpump, a G1314A variable wavelength detector, and a Chemstation (Rev. A. 10. 02) (Agilent Technologies, Waldbronn, Germany). The mobile phase was a gradient of (A) MeOH

and (B) H_2O-H_3PO_4 (99.9:0.1, v/v). The gradient was as follows: 0–42 min, 45–69% eluent A. Flow rate was 1.0 ml/min. Sample injection volume was 20 µl. Flavonoids were separated by using a Zorbax SB-C_{18} column (4.6×250 mm i.d., 5-µm particle), with a security guard column, Phenomenex C_{18} ODS (4×3.0 mm i.d.). Absorbance was recorded at 280 nm (Su et al. 2008).

Experiment 1: Germination of S. baicalensis Seedlings as Affected By Baicalin and Crude Extracts This experiment tested the toxicity of *S. baicalensis* and baicalin in Petri dish cultures. To separate phytotoxic effects from the carbon source effect of baicalin and to test whether baicalin is the major effective allelochemical, we designed four treatments (distilled water, glucose, baicalin, and crude extract). The final concentrations of glucose, baicalin, and crude extract were 0.97 $mg \cdot l^{-1}$, 0.97 $mg \cdot l^{-1}$, and 5.81 $mg \cdot l^{-1}$, respectively. The concentration of baicalin used in the experiment was based on the concentration found in the rhizosphere soil of *S. baicalensis* at the field site. The concentration of crude extract was based on the concentration of baicalin in the crude extract, which was 16.7±1.3%.

Seeds of *S. baicalensis* were surface-sterilized by soaking the seeds in 70% ethanol for 2.5 min, followed by four rinses in sterilized distilled water. They were then soaked in 2.5% sodium hypochlorite solution for 15 min, followed by five rinses in sterilized distilled water. Then 50 surface-sterilized seeds of *S. baicalensis* were dispersed on Whatman No. 40 filter paper in 9 cm Petri dishes (experimental unit), and 6 ml of each solution (distilled water, baicalin, glucose, or crude extract) were added. The Petri dishes were sealed with parafilm to prevent moisture loss and contamination. Seeds were germinated in incubators (Safe Experimental Instrument Company, Haishu, Ningbo, China) with a photoperiod of 16 h light and 8 h dark at 28°C (day) and 18°C (night) and 90% relatively humidity.

Seed germination was defined as when the radicle had extended 1 mm beyond the seed coat 5 d after sowing (Steinmaus et al. 2000). Recording ceased when there was no change in seed germination counts for more than 3 d.

The response index (RI), which indicates autotoxicity (Willamson 1988), was calculated by using germination rate. $RI = 1 - C/T$, where T is germination rate in treatments and C is germination rate of the control. RI values range from +1 to −1, RI>0 means stimulation, RI<0 means inhibition.

RI was analyzed with a one-way ANOVA by using the general linear model procedure in SPSS (V.10.0). LSD test at the 5% significance level was used to the compare the means.

Experiment 2: Growth of Pathogens in Agar Culture as Affected By Baicalin and Crude Extracts This experiment tested the effects of allelochemicals from *S. baicalensis* on the growth of pathogens in Petri dish cultures. We also designed four treatments (distilled water, glucose, baicalin, and crude extract) in this experiment as in experiment 1.

Agar media were prepared by mixing 9 ml of sterilized potato dextrose agar (PDA) at 60°C with 1 ml of each solution (distilled water, baicalin, glucose, and crude extract); these 10 ml were then added to each 9-cm diam Petri dish. Thus, the final concentrations in the Petri dishes were in accordance with the concentration of baicalin detected in the field soil. Before they were combined with agar, the solutions were sterilized by passing them through a 0.22-µm millipore filter.

Prepared inocula (5 mm diam agar plugs) were placed in the center of the Petri dishes, and the cultures were kept in a growth chamber (Safe Experimental Instrument Company, Haishu, Ningbo, China) in the dark at 28°C and 90% relatively humidity. The area of each colony was measured every 6 hs for 4 d (Fang 1998). The effect of the glucose, baicalin, and crude extract on growth of the pathogens was determined by calculating a PR (promotion rate): $PR = (At - Ac)/Ac$, in which At is the area of the colony treated with glucose, baicalin, or crude extract, and Ac is the area of the colony treated with distilled water.

There were six replicate Petri dishes for each solution. Because the main comparisons in this experiment were among the solution types within the *P. ultimum* or *R. solani* treatments, PR were analyzed with a one-way ANOVA for each pathogen. When an ANOVA was significant, an LSD test at the 5% significance level was used to the compare the means. SPSS V.10.0 was used for all statistical analyses in this study.

Experiment 3: Activity of Pathogens and Seedlings of S. baicalensis in Sand Culture as Affected By Baicalin and Crude Extract This experiment tested toxicity of *S. baicalensis* and the effects of baicalin and crude extract on activity of *P. ultimum* and *R. solani*. Both tomato (Rafin and Tirilly 1995; Yangui et al. 2008) and *S. baicalensis* were used to indicate pathogen activity.

A factorial experiment was designed with four solutions (distilled water, glucose, baicalin, and crude extract as in experiment 1) and with three pathogen treatments (no pathogen, *P. ultimum*, and *R. solani*). Each combination of solution and pathogen was applied to a 50-cm^3 plastic pot that contained sterilized fine sand (see next paragraph). There were six replicate pots per combination, giving a total of 72 pots.

Fine sand (0.45–1 mm diam) was soaked in a solution of NaClO for 24 h, washed with tap water, and sterilized at 120°C for 8 h in an oven. Each pot was filled with 150 g of sterilized sand. The solutions were diluted with distilled water as in experiment 1. Inoculum of *P. ultimum* and *R. solani* was prepared by growing the pathogens on cooked rice grains (Zhang et al. 2009). Immediately after a solution

was added to a pot, four rice grains colonized by *P. ultimum* or *R. solani* were added to the pot; the rice grains were buried 2 cm in the sand. For the pathogen-free treatment, pots received four rice grains treated in the same way as the colonized grains except that they were not exposed to the pathogens. After 1 wk at 22°C (to allow the pathogens to grow in the sand), 20 tomato or *S. baicalensis* seeds were planted in each pot. All pots were kept in a growth chamber with a photoperiod of 16 h light and 8 h dark at 22°C (day) and 18°C (night) and 90% relatively humidity. After seeds were sown, Hoagland's nutrient solution was added every 2 d to maintain normal seedling growth.

Numbers of germinated seeds and of damped-off seedlings were recorded daily for 21 d and 28 d. The mortality rate was calculated as follows: mortality rate (%)=(1−number of living seedlings/number of sown seeds)×100. The damping-off rate was calculated as follows: damping-off rate (%)=(number of damped-off seedlings/number of germinated seeds)×100 (Zhang et al. 2009).

The effects of the solution and pathogen on mortality rate and damping-off rate of tomato and *S. baicalensis* were determined with a two-way ANOVA (solution types and pathogens as factors). An LSD test at the 5% significance level was used to compare all treatment means for each combination of pathogen and plant species.

Experiment 4: Activity of Pathogens and S. baicalensis in Sand in Which S. baicalensis Had Grown Experiment 4 tested how sand in which *S. baicalensis* had grown affected seedlings and the pathogenic activity of *P. ultimum* and *R. solani*. A factorial experiment was designed with two plant levels (no plants and *S. baicalensis*) and three pathogens (no pathogen, *P. ultimum*, and *R. solani*). There were six replicate pots for each combination, giving a total of 36 pots.

The experiment was starting by growing *S. baicalensis* (four seeds per pot) or no plants in sterilized sand for 4 mo. The pots and sterilized fine sand used were the same as in experiment 2, except that each pot contained 500 g rather than 150 g of sterilized sand. Pots were placed in a growth chamber maintained at 30±1°C during the day and 25±1°C at night. The light was maintained at the photosynthetically active radiation flux (540 µmol m^{-2} s^{-1}) with a day length of 13 h. Air temperature, light density, and day length were similar to those experienced by *S. baicalensis* under the natural conditions that are optimum for its growth. Every 7 d, plants were fertilized with full-strength Hoagland's nutrient solution (Hoagland and Arnon 1950).

After 4 mo, the aboveground portion of each plant was removed, and pots were inoculated with *P. ultimum*, *R. solani*, or no pathogen using rice grains as described in experiment 2. After 1 wk (to allow the pathogens to grow into the sand). 20 tomato or *S. baicalensis* seeds, which had been surface sterilized with H_2O_2 (5%, v: v), were planted in each pot. All pots were kept in a growth chamber maintained as described for experiment 2. After seeds were sown, Hoagland's nutrient solution was added every 2 d. The experiment ended 21 d and 28 d after the seeds were added. Seed germination and seedling damping-off were quantified, and mortality rate and damping-off rate were calculated as in experiment 2.

The effect of plant and pathogen on mortality and damping-off rate of tomato and *S. baicalensis* was determined with a two-way ANOVA. Because the interaction between sand (no plant sand vs. *S. baicalensis* sand) and pathogen (no pathogen, *P. ultimum*, and *R. solani*) was significant (Table 1), an LSD test at the 5% significance levels was used to compare means for each combination of sand and pathogen treatment for each kind of plant.

Experiment 5: Seed Mortality and Seedling Damping-Off in Rhizosphere Soils from Fields Where S. baicalensis or N. tabacum Had Grown Experiment 5 tested whether *S. baicalensis* stimulates soilborne pathogens by comparing pathogenic activity in rhizosphere soils from fields where *S. baicalensis* or *N. tabacum* had grown for 3 yr.

Table 1 Significance of factors and factor interactions on mortality and damping-off based on two-way ANOVAs in experiments 3 and 4*

Experiment and variables	*d. f.*	Mortality rate		Damping-off rate	
		Scutellaria baicalensis	Tomato	*S. baicalensis*	Tomato
Experiment 3

*Significance level: *P<0.05; **P<0.01

Soil cores were collected from the *S. baicalensis* and *N. tabacum* field sites (30 cores per site with 60-cm^3 of soil per core) and immediately transported to the laboratory. Each soil core was placed in a 50-cm^3 plastic pot. Each pot was inoculated with either *P. ultimum* or *R. solani* as described in experiment 2. After 10 d, 20 tomato seeds or and *S. baicalensis* seeds, which had been surface disinfected with H_2O_2 (5%, v:v) were planted in each pot. All pots were kept in a growth chamber with the same conditions as in experiment 2. The experiment ended 21 d and 28 d after the seeds were added. Seed germination and seedling damping-off were quantified, and mortality and damping-off rate were calculated as in experiment 2.

The effect of rhizosphere field soil (*S. baicalensis* vs. *N. tabacum*) on mortality and damping-off rate of tomato and *S. baicalensis* was determined with a one-way ANOVA. Following this analysis, we performed an independent *t*-test of mortality rate and damping-off rate of tomato and *S. baicalensis* growing in soil from the *S. baicalensis* field vs. in soil from the *N. tabacum* field.

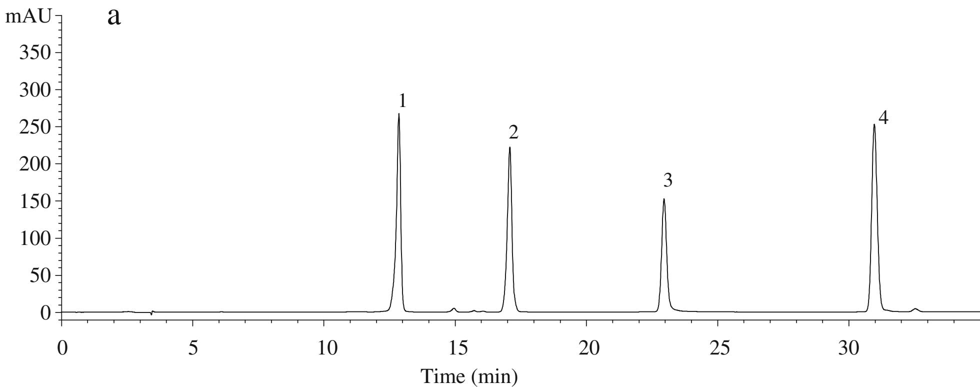
Results

Baicalin Concentration in Field Site Based on HPLC analysis, the soil extracts from the *S. baicalensis* field site contained 0.000097±0.000012% baicalin, or 0.97 μg of baicalin per g of soil (Fig. 1).

Experiment 1 Germination of S. baicalensis Seedlings as Affected By Baicalin and Crude Extracts In experiment 1, baicalin, glucose, or the crude extracts significantly impact germination of *S. baicalensis* (Fig. 2, $P<0.05$). The response index (RI) showed that both baicalin and the crude extracts inhibited the germination of *S. baicalensis*, whereas glucose stimulated the germination.

Experiment 2: Growth of Pathogens in Agar Culture as Affected By Baicalin and Crude Extract In experiment 2, the growth of both pathogens was significantly greater in agar containing baicalin, glucose, or the crude extract than in the nonamended agar distilled water. For both pathogens, the increase in growth relative to the nonamended agar was greater with baicalin and with the crude extract than with glucose (Fig. 3). The increase in growth did not differ between the baicalin and the crude extract treatments.

Experiment 3: Activity of Pathogens and S. baicalensis in Sand Culture as Affected By Baicalin and Crude Extract In experiment 3, baicalin, glucose, and the crude extract significantly affected seed mortality in sand (Table 2). When no pathogens were present, the mortality rate of both *S. baicalensis* and tomato seedlings was higher with



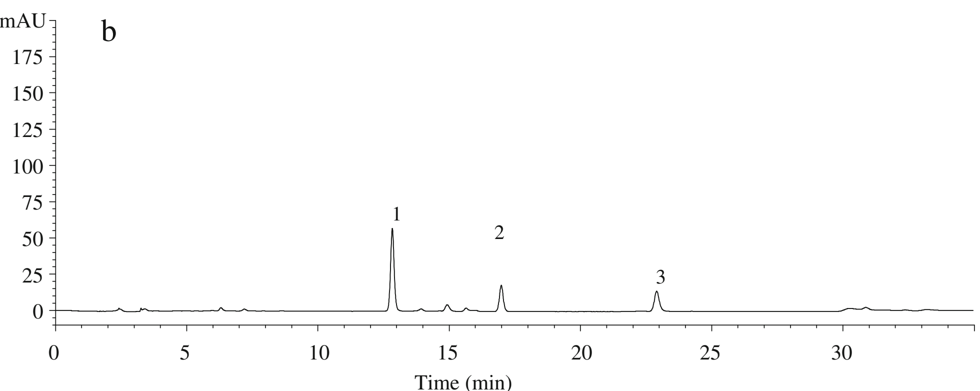


Fig. 1 Typical HPLC chromatograms of flavonoids. *a* Mixture of standards, *b* Soil samples of *Scutellaria baicalensis* on an Agilent Zorbax SB-C_{18} column (250 mm×4.6 mm i.d., 5 μm particle) and precolumn (3.0 mm×4.0 mm i.d.; Phenomenex C_{18} ODS). A gradient prepared from mixtures of MeOH and H_2O-H_3PO_4 (99.9:0.1, v/v) was used as mobile phase (0–42 min. 45–69% eluent A); the flow rate was 1.0 mL/ min and UV detection was performed at 280 nm (1 = baicalin; 2 = wogonoside; 3 = baicalein; 4 = wogonin)

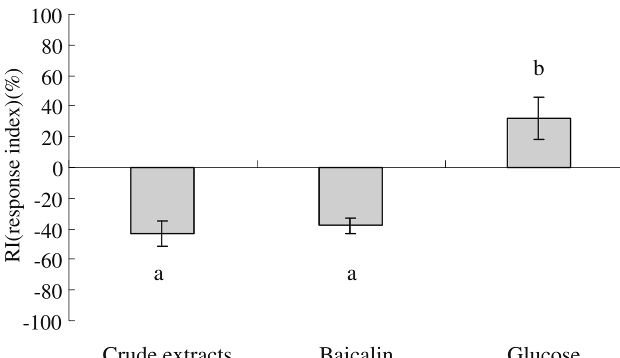

Fig. 2 Response index of germination of *Scutellaria baicalensis* affected by baicalin, crude extracts of Radix Scutellaria from *S. baicalensis*, and glucose in Petri dishes. Values indicate the response in germination relative to the control. Values are means±SE of four replicate Petri plates. For each treatment, values followed by the different letter are significantly different from the control at $P<0.05$

baicalin and crude extract than with water or glucose; in addition, *S. baicalensis* seeds incurred substantially higher mortality than tomato with baicalin and crude extract. Mortality of both plants was substantially greater with the pathogens than without, and the effect of the pathogens on mortality was enhanced by baicalin and crude extract (Table 2). There also was a tendency for glucose to enhance the mortality of *S. baicalensis* seeds but not the mortality of tomato seeds (Table 2).

No damping-off occurred in experiment 3 unless pathogens were added (Table 3). The damping-off rate caused by the pathogens was greater with baicalin and crude extract than with water and glucose, but the rate did not differ between baicalin and crude extract (Table 3).

Experiment 4: Activity of Pathogens and S. baicalensis in Sand in Which S. baicalensis Had Grown When no pathogen had been added to the sand in experiment 4, the mortality and damping-off of *S. baicalensis* seedlings but not of tomato seedlings was greater in soil previously planted with *S. baicalensis* than in soil that was not previous planted with *S. baicalensis* (Table 4). When pathogens were added, the mortality and damping-off of both *S. baicalensis* and tomato seedlings were greater in soil previously planted with *S. baicalensis* than in soil that was not previous planted with *S. baicalensis* (Table 4).

Experiment 5: Seed Mortality and Seedling Damping-Of in Rhizosphere Soils from Fields Where S. baicalensis or N. tabacum Had Grown In experiment 4, mortality rates of both *S. baicalensis* and tomato seedlings were significantly higher in the field soil collected from the rhizosphere of *S. baicalensis* than in the field soil collected from rhizosphere of *N. tabacum* (Table 5). Damping-off did not occur with tomato but damping-off of *S. baicalensis* was greater in the *S. baicalensis* soil than in the *N. tabacum* soil (Table 5).

Discussion

Experiments have shown that the roots of some plant species release allelochemicals that can accumulate in the soil and directly inhibit the same plant species (Ben-Hammouda et al. 2002; Liu et al. 2007). Our study demonstrated that baicalin (7-glucuronic acid, 5, 6-dihydroxy-flavone) released from the plant *S. baicalensis* accumulated in the soil. After *S. baicalensis* had been grown three consecutive years, the soil contained 0.97 $\mu g \cdot g^{-1}$ of baicalin (Fig. 1) measured in November when *S. baicalensis* has been harvested for 1 month. This concentration of baicalin might be lower than that before November since allelochemicals in the soil could be degraded by soil microorganisms (Inderjit 2005). However,

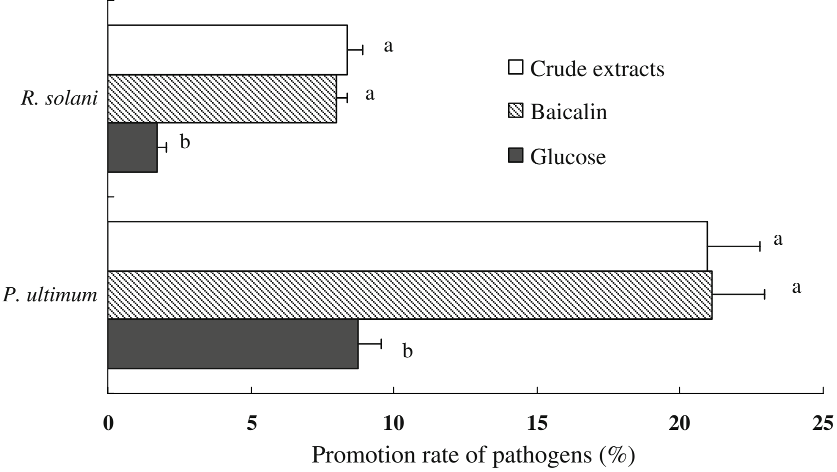

Fig. 3 Promotion rate of pathogen growth by baicalin, crude extracts of Radix Scutellaria from *Scutellaria baicalensis*, and glucose in agar culture. Values indicate the increase in growth relative to the control. Values are means±SE of six replicate Petri plates. For each pathogen, values followed by the different letter are significantly different at $P<0.05$

Table 2 Mortality of tomato and *Scutellaria baicalensis* seeds caused by pathogens (*Pythium ultimum* and *Rhizoctonia solani*) in sand culture as affected by baicalin and crude extract of Radix Scutellaria (experiment 3)[a]

we still used this concentration to test the baicalin effects. The reason for that is that baicalin may remain somewhat constant from November to March due to the low temperatures during this period at our study site (major production site of *S. baicalensis* in China). Qiu et al. (2004) have reported baicalin is stable in solution with a pH 6.8 and temperatures below 20°C. *Scutellaria baicalensis* usually is planted around April when baicalin in soil (having a similar concentration to that in November) may begin to have effects on germination and seedling growth directly and indirectly through affecting soilborne pathogens. As hormesis is common with antifungal compounds (Calabrese and Baldwin 2003), we also tested whether the concentrations of baicalin at lower or higher concentration than 0.97 $\mu g \cdot g^{-1}$ led to different effects (promotion at lower concentrations or inhibition at higher concentration). We measured the effects with four concentrations 0.097 $\mu g \cdot g^{-1}$, 0.97 $\mu g \cdot g^{-1}$, 5, and 10 $\mu g \cdot g^{-1}$ on pathogens growth in Petri-dish cultures. We did not find inhibition within these concentrations (data not shown). Thus, we used the baicalin concentration (0.97 $\mu g \cdot g^{-1}$) that we measured in November.

Both baicalin at 0.97 $\mu g \cdot g^{-1}$ in a pure solution and a crude extract of *S. baicalensis* roots that contained this same baicalin conentration inhibited the germination of *S. baicalensis* in both the Petri dish culture and sand culture. Experiments 2 and 3 demonstrated that baicalin and crude extracts both stimulated the growth on agar of two common soilborne pathogens and enhanced damping-off of *S. baicalensis* and tomato seedlings growing in sand. Even in the absence of pathogens in experiment 3, the baicalin and crude extract solution inhibited germination of *S. baicalensis* and tomato, suggesting both intraspecific allelopathy (autotoxicity) and interspecific allelopathy. There were no differences between the effects of baicalin and crude extract, suggesting that baicalin may be the principal active component in the crude extract.

It is not clear that whether the effects of root exudates are due to their serving as carbon sources (Nicol et al. 2003). Glucose was included in experiments 2 and 3 to determine whether the effects of baicalin and crude extract on the pathogens and seedlings may have resulted from a general increase in carbon availability. In most cases, the effects of baicalin and crude extracts on the pathogens and on the seedlings were much greater than those of glucose, suggesting that the *S. baicalensis* root secretions did more than simply provide carbon. The mechanism by which secretions from *S. baicalensis* stimulate pathogens, however, requires further investigation.

In this regard, we designed experiment 4 to separate direct allelopathic effects from indirect effects by growing *S. baicalensis* in sterilized sand with and without *R. solani* and *P. ultimum*. Results showed that even in the absence of the pathogens, seed germination was reduced and seedling damping-off was increased when *S. baicalensis* was grown in sand in which *S. baicalensis* had previously grown rather than in sand in which *S. baicalensis* had not previously grown, i.e., there was an effect of a previous *S. baicalensis* soil on subsequent *S. baicalensis* plants. When pathogens were present, seed germination usually was reduced and seedling damping-off increased when either *S. baicalensis* or tomato was grown in sand in which *S. baicalensis* had

previously grown rather than in sand in which *S. baicalensis* had not previously grown. In other words, chemicals released into the rhizosphere by *S. canadensis* had an indirect effect on other plants of the same or different species in that they enhanced disease incidences (Table 4).

The soilborne pathogens *R. solani* and *P. ultimum* commonly infect *S. baicalensis* tissues (Benizri et al. 2005; Chang et al. 2007). Although we did not quantify the populations of *R. solani* and *P. ultimum* in the *S. baicalensis* or *N. tabacum* field soils in this study, disease severity of both *S. baicalensis* and tomato were greater when in soil collected from the *S. baicalensis* field than in soil from the *N. tabacum* field (experiment 5). This finding is consistent with the idea that *S. baicalensis* promotes soilborne pathogens by releasing allelochemicals into the rhizosphere. The fields, of course, could have differed in other ways that could affect pathogen numbers and activities.

Our study increases the understanding of how plant-conditioned soils affect other plants of the same or different species through allelochemicals. It is known that plants and plant products can dramatically affect the structure, size, and activity of the soil microbial community (Bastida et al. 2008; Qu and Wang 2008), and that plants and plant products are primary drivers of soil microbial dynamics (Janssens et al. 1998; Larkin 2008). The effects of plants on soil microbial communities are presumed to result primarily from the release of different secondary compounds from roots and also from the breakdown of plant residues (Curl and Truelove 1986; Grayston et al. 1998; Pedrol et al. 2006). Van der Putten et al. (1993) and Bever (2003) have suggested that well-established plant succession may depend more on the accumulation of harmful (Bonanomi et al. 2005; Eppinga et al. 2006) and beneficial (Bezemer et al. 2006) rhizosphere organisms than on altered abiotic soil properties because biotic plant-soil feedback can be highly specific (Packer and Clay 2000; van der Putten 2003). Previous research has documented that root-derived phytochemicals promote soil pathogens (Ye et al. 2004; Mangla et al. 2008), which mediate the growth and survival of plants (Beckstead and Parker 2003; Ridenour and Callaway 2003). In this study, *S. baicalensis* stimulated soil pathogen accumulations apparently by releasing baicalin into the soil, thus generating negative feedback to *S. baicalensis* itself. This result provides additional supporting evidence that allelochemicals are important in mediating plant-soil feedbacks.

Our study also contributes to the understanding of problems associated with continuous cropping. For many crops, autotoxicity is believed to be a major cause of poor

Table 5 Mortality and damping-off of tomato and *Scutellaria baicalensis* plants growing in rhizosphere soils from fields where *S. baicalensis* or *Nicotiana tabacum* had grown

Plant	Mortality (%)		Damping-off (%)	
	N. tabacum soil	*S. baicalensis* soil	*N. tabacum* soil	*S. baicalensis* soil

performance when the same crop is repeatedly grown in the same soil (Rice 1984; Batish et al. 2001; Liu et al. 2007). Our study suggests that secretions accumulating in the soil have profound effects on pathogen dynamics, thus inducing high disease incidences, which may contribute to problems with continuous cropping.

In summary, we found that baicalin released from the medicinal plant *S. baicalensis* accumulates in soil. In addition to directly inhibiting the growth of *S. baicalensis* seedlings (autotoxicity), baicalin also stimulates soil pathogens and may thus increase diseases of *S. baicalensis*. Continuous cropping of *S. baicalensis* may result in poor performance of this crop because baicalin is released from *S. baicalensis* roots and accumulates in the soil.

Abstract The role of extracellular fatty acids in the interference between two algae, *Chlorella vulgaris* Beijerink and *Pseudokirchneriella subcapitata* (Korshikov) Hindak, was assessed by the co-cultivation of the two selected strains, as well as by the chemical analysis of exudates from the culture media of single strain cultures. The effect of culture age and phosphate limitation was evaluated. The experiments showed that the composition and amount of fatty acids, released by *C. vulgaris* and by *P. subcapitata*, both in a batch and in a continuous monoculture, depend on the culture age and on the phosphate concentration in the culture medium. We also found that the amount of chlorellin generated in the two algae co-culture increased and was almost exclusively constituted by a mixture of C18 fatty acids. By using the evaluated concentrations of these fatty acids, an artificial chlorellin was prepared. The toxicity of this mixture to *P. subcapitata* appears to be similar to that of the natural chlorellin. For both algae, a stimulation of growth was observed at low concentrations of the natural chlorellin, whereas higher concentrations produced inhibitory effects on both species. However, *P. subcapitata* was much more sensitive than *C. vulgaris*. By using some of these new experimental results, two new mathematical models have been used to describe the toxicity of chlorellin to *C. vulgaris* and to the interference between *C. vulgaris* and *P. subcapitata*, respectively.

Introduction

The green unicellular coccoid alga *Chlorella vulgaris* Beijerink was the first plant species in which a release of substances affecting other organisms was observed (Pratt and Fong 1940). Further investigations revealed that not a single compound, but a mixture of fatty acids and hydrocarbons (Spoehr et al. 1949), named chlorellin, was responsible for the toxicity towards bacteria and algae (McCracken et al. 1980). Such a joint action seems to be a widespread phenomenon in allelopathy and, according to Einhellig (1996), all allelopathic activities are due to a mixture of two or more compounds. Fatty acid mixtures frequently have been reported toxic in aquatic environments (Ikawa 2004). Chiang et al. (2004) found that blooms of the green unicellular alga *Botryococcus braunii* Kützing produce high amounts of fatty acids, which are severely toxic

to fish. Furthermore, Wu et al. (2006) demonstrated that the cytotoxicity of free fatty acids towards green algae and cyanobacteria affects primarily the plasma membrane.

Generally speaking, it is difficult to assess the role of allelopathy in the interference between two algal populations in the field, because it is difficult to evaluate the bioactive concentration of allelopathic substances, and also because too many environmental factors may influence their release from the donor organism (Blum et al. 1999). Furthermore, the sensitivity of the target species may vary, depending on the mode of action of the allelochemicals and environmental conditions (Inderjit and Duke 2003).

It is therefore more appropriate to study allelopathic phenomena under controlled laboratory conditions, where many variables can be kept constant, provided that the laboratory environment can mimic the natural environment sufficiently. This applies, for instance, for many open aquatic ecosystems, which often can be quite well simulated with chemostat laboratory cultures (Smith and Waltman 1995). This approach has been used previously by Fergola et al. (2007), and is used in the present paper. Fergola et al. (2007) found that *Pseudokirchneriella subcapitata* (Korshikov) Hindak became extinct in mixed cultures with *C. vulgaris* grown under phosphate-limiting conditions. A constant release of chlorellin-like material by *C. vulgaris* was observed during the time course of those experiments, and preliminary analyses confirmed that the exudates were composed primarily of various fatty acids. Here, by employing some new experimental results, two new mathematical models were used to describe the toxicity of chlorellin to *C. vulgaris* and to the interference between *C. vulgaris* and *P. subcapitata*, respectively.

Mathematical modelling is making increasingly significant contributions to many research areas. Mathematical models of biological and biochemical processes often represent a successful tool to better understand complex phenomena. Analysis (mathematical and numerical) can permit a deeper understanding both by predicting new scenarios and by suggesting new experiments. In the context of population dynamics, the influence of toxicants on the growth of populations and on competition among species has been widely studied in the last few years (Hallam et al. 1983; Hallam and Ma 1986, 1987a, b; Freedman et al. 1989; Smith and Waltman 1995; Hsu and Waltman 1998; Mukhopadhyay et al. 1998, 2003; Braselton and Waltman 2001). In particular, importance has been given to the competition that takes place in a chemostat-type environment. Such competitions have been mathematically represented essentially according to two different types of modelling approaches, adopted by Chattopadhyay (Mukhopadhyay et al. 1998, 2003), and Waltman (Smith and Waltman 1995; Braselton and Waltman 2001; Fergola et al. 2004, 2006), respectively. The two models used here follow this latter approach and give a representation of the dynamics of the interference taking place between the two algal species.

The main issue addressed in this study was to assess whether the age of culture, phosphate depletion, or co-occurrence of another species affected the composition of chlorellin and its release by *C. vulgaris*. Moreover, the biological activity of the natural exudate mixtures isolated from the co-culture of *C. vulgaris* and *P. subcapitata*, was compared to artificial chlorellin added to the chemostat culture, obtained by mixing the four main fatty acids in the proportion found in the exudates. On the basis of these results, a data analysis was performed. Additionally, some numerical simulations were performed by assigning to the parameters of the two considered models, numerical values obtained from some of the laboratory experiments described both in this paper and in Fergola et al. (2007).

Methods and Materials

Selection of Strains and Culture Conditions Two axenic strains were used: *C. vulgaris* CCAP 211/11b and *P. subcapitata* UTEX 1648 from ACUF (Algal Collection of the University Federico II, Naples). The algal strains were cultivated for 2 wk on Bold Basal Medium (BBM) (Nichols 1973) with an inorganic phosphate (Pi) concentration of 25 g l^{-1}. For *P*-limited cultures, the Pi concentration was reduced to 0.5 mg l^{-1} (Chen et al. 1997). Cultures were maintained in 100 ml Erlenmeyer flasks, at 23°C on shaking incubators at 40 rpm. Continuous illumination, with an irradiance of 80 μE m^{-2} sec^{-1}, was supplied by cool white fluorescent tubes (Philips TLD 39 w/55). Batch experiments, either with each single species or with mixed cultures of both species, were performed under the same conditions. The growth of population of *C. vulgaris* or *P. subcapitata* was followed using a spectrophotometer (Secoman 250) at λ=550 nm. When the experiments were carried out with mixed culture of the two algae, cells were counted by using a Burker hemocytometer, under an optical microscope (Nikon Eclipse 800).

Chemostat Cultures Algal competition for a limiting nutrient (phosphate) was examined in a chemostat culture system. The culture vessel was a standard chemostat containing 1,200 ml of culture media. Nutrient was pumped at a constant rate into the culture flasks by means of a peristaltic pump (GILSON–MINIPLUS 3) at a rate of 600 ml d^{-1} to give a washout rate of 50% a day. Experiments were carried out either on unialgal or mixed cultures. Continuous illumination (80 μE m^{-2} sec^{-1}) was provided by cool fluorescent lamps (Philips TLD 39 w/55). Sterile humidified air was bubbled through the cultures.

The air flow produced by an air compressor was controlled by a flow-meter and conveyed into two flasks of sterile water. Each culture was stirred continuously with a mixer (Heidolph). All experiments were performed using a BBM medium with a Pi concentration of 0.5 mg l^{-1}, as suggested by Chen et al. (1997). For the competition experiments, the two species were grown initially in different flasks to give a fixed cell number of 300,000 cells ml^{-1} for both strains. Successively, samples of both algae were withdrawn from 4-d-old cultures, and aseptically inoculated in the chemostat.

Analysis of Chlorellin Batch cultures either of *C. vulgaris* or *P. subcapitata* were carried out in 5,000 ml cylinders under continuous light at (80 μE m^{-2} sec^{-1}) at 23°C. The algal cultures were stirred continuously and air bubbled through the cells that were grown under *P*-sufficient (25 g l^{-1}) or *P*-limiting (0.5 mg l^{-1}) conditions. Aliquots of the cultures (2,500 ml) were collected and filtered during the mid-exponential phase (6,650,000 cells ml^{-1}) and at the beginning of the stationary phase of growth (14,000,000 cells ml^{-1}). In the co-cultures grown in the chemostat, the outflow was collected daily and stored at −20°C. All culture media were concentrated with an evaporator to 200 ml, and exhaustively extracted with methylene chloride (3×150 ml; recovery rate ~90%, 8%, <1%, respectively). The organic fraction was concentrated to dryness to obtain a lipoid fraction. This was derivatized with ethereal diazomethane and analyzed with a GC (Gas Chromatography) by using an RTX-5 capillary column (Restek; 30 m×0.25 mm inside diam, flow rate 10 ml min^{-1}, N_2 used as carrier gas). Analysis was performed with the following temperature program: 140°C for 5 min, from 140°C to 240°C at 4°C min^{-1}, and 240°C for 60 min. Fatty acid methyl esters (FAMEs) were identified by comparing their retention times with those of 19 commercial fatty acid standards purchased from SUPELCO, with the Limit of Quantitation of 14 ppb. Fatty acids yield and composition were studied also in co-cultures of *C. vulgaris* and *P. subcapitata* grown in *P*-limiting cultures. Individual algae from continuous cultures (300,000 cells ml^{-1}) were mixed at a 1:1 ratio, and after 4 d, when *C. vulgaris* was at a concentration of 1,200,000 cells ml^{-1} and *P. subcapitata* at 100,000 cells ml^{-1}, the composition of the medium was analyzed.

Toxicity Bioassays In order to analyze the composition and evaluate the toxicity of natural chlorellin, the culture medium (4 l) of *C. vulgaris* and *P. subcapitata* co-cultures was collected, concentrated with an evaporator to 200 ml, and exhaustively extracted with methylene chloride (3× 150 ml). The mixture of fatty acids extracted was dried and re-dissolved in 5 ml of dimethyl sulfoxide (DMSO). The solution was stirred for 2 h in the dark at room temperature. Test solutions were prepared by mixing the appropriate volumes of the DMSO stock solutions with culture media. The concentration of DMSO in culture media was 2 ml l^{-1} at the highest concentration of chlorellin tested (52 mg l^{-1}). Liquid growth inhibition tests against this extracted, natural mixture of fatty acids were performed with *P. subcapitata* or *C. vulgaris*. Inocula corresponding to 10,000 cells ml^{-1} (ISO protocol 1987) from cultures of each strain in mid exponential phase (4-d-old) were grown in 100 ml Erlenmeyer flasks containing 50 ml of BBM. Liquid inhibition tests also were carried out with chemostat cultures of *P. subcapitata* with the same initial cell concentration (300,000 cells ml^{-1}) against chlorellin at a constant concentration of 1.90 mg l^{-1}, and number of cells, photosynthetic rate, and Chlorophyll *a* concentration were monitored daily. For this purpose, pre-cultures of *P. subcapitata* were grown on *P*-sufficient BBM medium (concentration mg l^{-1}). When the algae were in mid-exponential growth phase (4-d-old), an inoculum (10 ml) was centrifuged, washed two times in sterile 0.9% NaCl solution, and then added to a culture vessel of a standard chemostat containing 1,200 ml of *P*-limited BBM (Pi 0.5 mg l^{-1}). Algae were grown in the chemostat according to the conditions described above (section *Chemostat Cultures*). Preliminary tests carried out on *P. subcapitata* gave evidence that cells that have been treated according to this protocol and re-suspended in *P*-sufficient BBM grew at rates comparable to those of control cultures. To assess the relationship between fatty acid toxicity and cell concentrations at very low cell densities, *P. subcapitata* cultures at an initial inoculum concentration ranging from 500 to 5,000 cells ml^{-1} were exposed to 1.90 mg l^{-1} of chlorellin isolated from co-cultures of *C. vulgaris* and *P. subcapitata*.

Fatty acids extracted from the medium of co-cultures of *C. vulgaris* and *P. subcapitata* were tested at concentrations ranging from 0.40 to 52 mg l^{-1}. A mixture of the four main fatty acids found in the natural chlorellin extract also was prepared by using stearic acid (C18:0, >99%), oleic acid (C18:1n9c, >98%), linoleic acid (C18:2n6c, 97%), and linolenic acid (C18:3n3c, 99%) (Sigma–Aldrich, Germany). It was dissolved in DMSO to give the same ratio found in a natural extract (linoleic acid 46.4%, linolenic acid 21.0%, oleic acid 19.2%, and stearic acid 13.2%). All bioassays and BBM analyses, controls and positive controls (containing only 2 ml l^{-1} DMSO) were carried out in triplicate in axenic conditions at 23°C with continuous illumination of 80 μE m^{-2} sec^{-1}. At the end of the incubation, the final pH was also measured. No difference in growth was observed among controls. Chlorophyll *a* was measured according to Lazzara et al. (1990), and photosynthetic rate was measured according to Pollio et al. (1993).

Statistical Evaluation For liquid growth inhibition tests, the effect of concentration, which differs significantly from that of the control, was determined by multi comparison Dunnett's tests, after verifying the Shapiro–Wilk's test for normality and the Hartley's test for homogeneity of variance ($P>0.5$). Calculations were performed using TOXSTAT 3.0 software (Gulley et al. 1989).

Mathematical Modelling Here, we introduce two deterministic mathematical models constituted by Ordinary Differential Equations, which represent the influence of chlorellin on *C. vulgaris* and *P. subcapitata* both in mono- and mixed culture. The two models are based on data obtained with several experiments performed in our laboratories. Our experiments gave us the opportunity to understand and quantitatively represent the following four crucial features (Fergola et al. 2007): a) nutrient uptake rates; b) yields (ratios between the amounts of produced biomass and absorbed nutrient); c) rate of allelochemical production; and d) the inhibitory effects of allelochemicals.

Mathematical Modelling of Inhibition Effects of Chlorellin We tested two mathematical models, both based on experimental data, to represent the inhibition effects of chlorellin on *P. subcapitata* and *C. vulgaris*. For the inhibitory effects on the growth rate of *P. subcapitata*, Eq. (1) was a suitable model fitting the experimental data (Fergola et al. 2007):

$$f_1(S)e^{-\gamma p} \tag{1}$$

where $f_1(S)$ is the growth function in the absence of toxicant, p is the concentration of chlorellin in the environment, and γ is a measure of the inhibiting effect of chlorellin $\gamma=7.81$ $\mathrm{l^2\ mg^{-2}}$). In Fergola et al. (2007) the influence of chlorellin on *C. vulgaris* was not included. Here, on the basis of new experiments, this process is taken into account and Eq. (2) is proposed as a suitable representation of the growth rate of *C. vulgaris* (LAB Fit software):

$$f_2(S)e^{-\alpha p^2} \tag{2}$$

where $f_2(S)$ is the growth function in absence of toxicant and computed at a given value of the nutrient concentration, and α is a measure of the inhibiting effect of chlorellin $\alpha>0$).

The estimate of the parameter α is chosen to minimize the χ^2 merit function given by the sum of squared residuals $\sum_i e_i^2$. This iterative fitting procedure is based on a modified Levenberg–Marquardt algorithm (Meyer and Roth 1972).

The Effect of Chlorellin on C. vulgaris in Chemostat Culture In order to describe the growth of *C. vulgaris* we considered three Ordinary Differential Equations (ODE), which represent the mass balance equations for the concentrations respectively of:

the nutrient,

$$\frac{dS}{dt} = \left(S^0 - S\right)D - f(S)e^{-\alpha p^2}\frac{N}{\eta} \tag{3}$$

the algae,

$$\frac{dN}{dt} = N\left[(1 - kN)f(S)e^{-\alpha p^2} - D\right] \tag{4}$$

and the chlorellin,

$$\frac{dp}{dt} = kf(S)e^{-\alpha p^2}N^2 - Dp \tag{5}$$

where d/dt denotes the time derivative, $S = S(t)$ is the phosphate concentration at time t, $N = N(t)$ is the biomass of *C. vulgaris* at time t, $p = p(t)$ is the concentration of chlorellin in the environment at time t, η is the constant yield of the population (Smith and Waltman 1995), S^0 is the constant input rate of the limiting nutrient concentration ($S^0>0$), D is the constant washout rate ($D>0$), $f(S) = \frac{mS}{a+S}$ is the functional response of *C. vulgaris* (Michaelis–Menten model) with the semi-saturation constant a ($a>0$), and m ($m>0$) the maximal specific growth rate of *C. vulgaris*, and α is a measure of the inhibiting effect of chlorellin ($\alpha>0$).

Finally we note that, according to Fergola et al. (2007), the term $kNf(S)$ is the rate of allelochemical production and is represented by the fraction of potential growth devoted to produce the chlorellin ($0<kN<1$). As in Fergola et al. (2007) we assume that the overall energy available to *C. vulgaris* arises only from nutrient consumption. Moreover, it is not completely available for the algae growing process, but is devoted partially to the production of chlorellin. In other words, we assume that a sort of energy conservation law holds, and furthermore, that the production of allelochemicals is proportional to the concentration of algae and thus represented by a linear function, which includes the constant k.

By performing the following scaling of the parameters (Smith and Waltman 1995)

$$\begin{aligned} &S = \overline{S}S^0, N = \overline{N}\eta S^0, p = \overline{p}S^0\eta, m = \overline{m}D, t = \frac{\tau}{D}, \\ &a = \overline{a}S^0, \alpha = \frac{\overline{\alpha}}{S^{02}\eta^2}, f(S) = \overline{f}\left(\overline{S}S^0\right), \overline{k} = k\eta S^0 \end{aligned} \tag{6}$$

we obtain from the Eqs. (3)–(5) a dimensionless system for the state variables S, N, p, which can be written, by removing the bars, in the form

$$\begin{cases} \frac{dS}{dt} = 1 - S - f(S)e^{-\alpha p^2}N \\ \frac{dN}{dt} = N\left[(1 - kN)f(S)e^{-\alpha p^2} - 1\right] \\ \frac{dp}{dt} = kf(S)e^{-\alpha p^2}N^2 - p \end{cases} \tag{7}$$

By standard techniques, we can prove the following two lemmas:

Lemma 1 Any solution of (7), with positive initial conditions, remains positive whenever it exists.

Lemma 2 Any solution of (7) is bounded (See proof in Appendix).

In view of the results concerning the growth of species in a chemostat-like environment (Smith and Waltman 1995), we suppose $m_i>1$, $i=1, 2$ and state the following theorem without the proof.

Theorem 1 System (7) admits the steady state solution E=(1, 0, 0) for all values of the parameters.

Theorem 2 If $\frac{m}{a+1} > 1$ then system (7) admits one positive equilibrium $E^*=(S^*, N^*, p^*)$. (See proof in Appendix)

Local Stability The stability analysis of the generic equilibrium $\overline{E} = (\overline{S}, \overline{N}, \overline{p})$ can be performed by means of the characteristic equation associated to the linearized system of (7)

$$\begin{cases} \dot{x}_1 = \left(-1 - f'(\overline{S})\overline{N}e^{-\alpha\overline{p}^2}\right)x_1 - f(\overline{S})e^{-\alpha\overline{p}^2}x_2 + 2\alpha f(\overline{S})\overline{p}\overline{N}e^{-\alpha\overline{p}^2}x_3 \\ \dot{x}_2 = f'(\overline{S})\overline{N}e^{-\alpha\overline{p}^2}(1 - k\overline{N})x_1 + \left[(1 - 2k\overline{N})f(\overline{S})e^{-\alpha\overline{p}^2} - 1\right]x_2 - 2\alpha\overline{p}\overline{N}(1 - k\overline{N})f(\overline{S})e^{-\alpha\overline{p}^2}x_3 \\ \dot{x}_3 = f'(\overline{S})\overline{N}^2ke^{-\alpha\overline{p}^2}x_1 + 2k\overline{N}f(\overline{S})e^{-\alpha\overline{p}^2}x_2 + \left(-2\alpha\overline{p}\overline{N}kf(\overline{S})e^{-\alpha\overline{p}^2} - 1\right)x_3 \end{cases} \tag{8}$$

whose characteristic equation can be written as follows

$$\det\begin{bmatrix} \left(-1 - f'(\overline{S})\overline{N}e^{-\alpha\overline{p}^2}\right) - \rho & -f(\overline{S})e^{-\alpha\overline{p}^2} & 2\alpha f(\overline{S})p\overline{N}e^{-\alpha\overline{p}^2} \\ f'(\overline{S})\overline{N}e^{-\alpha\overline{p}^2}(1 - k\overline{N}) & \left[(1 - 2k\overline{N})f(\overline{S})e^{-\alpha\overline{p}^2} - 1\right] - \rho & -2\alpha\overline{p}\overline{N}(1 - k\overline{N})f(\overline{S})e^{-\alpha\overline{p}^2} \\ f'(\overline{S})\overline{N}^2ke^{-\alpha\overline{p}^2} & 2k\overline{N}f(\overline{S})e^{-\alpha\overline{p}^2} & -2\alpha\overline{p}\overline{N}kf(\overline{S})e^{-\alpha\overline{p}^2} - 1 - \rho \end{bmatrix} = 0. \tag{9}$$

We can prove that:

Theorem 3 The following statements hold true: (See proof in Appendix)

(i) If $m < a + 1$, then the equilibrium E_0 turns out locally asymptotically stable;
(ii) If E^* exists, then it turns out locally asymptotically stable.

A New Model for the Interference between C. vulgaris and P. subcapitata In the system (3) of Fergola et al. (2007) the influence of chlorellin on *C. vulgaris* was not included. Here, according to the previous section, we assume that chlorellin also can act on *C. vulgaris*, and we propose to model the interference between the two algae with the following new system

$$\begin{cases} \frac{dS}{dt} = (S^0 - S)D - f_1(S)e^{-\gamma p}\frac{N_1}{\eta_1} - f_2(S)e^{-\alpha p^2}\frac{N_2}{\eta_2} \\ \frac{dN_1}{dt} = N_1[f_1(S)e^{-\gamma p} - D] \\ \frac{dN_2}{dt} = N_2\left[(1 - kN_2)f_2(S)e^{-\alpha p^2} - D\right] \\ \frac{dp}{dt} = kf_2(S)e^{-\alpha p^2}N_2^2 - Dp \end{cases} \tag{10}$$

where the inhibition effects of chlorellin on the two algae have been modeled in different ways and, according to what was suggested in the Discussion in Fergola et al. (2007), the two functions $f_1(S)$ and $f_2(S)$ are both of the Michaelis–Menten type.

Results

Concentration and Composition of Fatty Acids Released by C. vulgaris under Different Culture Conditions Experiments evaluated whether the chlorellin production of *C. vulgaris* is affected by age of culture, phosphate concentration in the culture medium, or co-occurrence of another algal strain. The lipoidic material recovered from the medium (*P*-sufficient) of *C. vulgaris* was 0.41 mg l^{-1} 10^{-6} cells in mid-exponential phase cultures and 0.70 mg l^{-1} 10^{-6} cells in stationary phase cultures. From *P. subcapitata* cultures, 0.08 mg l^{-1} 10^{-6} cells in the mid-exponential phase and 0.11 mg l^{-1} 10^{-6} cells in the stationary phase of growth were recovered (Table 1).

The GC analysis of the exudates showed the presence of fatty acids, identified by comparison with commercial standards. Under *P*-sufficient conditions, *C. vulgaris* batch cultures released fatty acids, ranging from C8 to C18, during their exponential growth phase, but a significantly

Table 1 Amounts of fatty acids (mg/l/10^6 cells) recovered from culture medium of *Chlorella vulgaris* Beijerink and *Psuedokirchneriella subcapitata* (Korshikov) Hindak. a) exponential growth phase, batch culture, *P*-sufficient; b) stationary growth phase, batch culture, *P*-sufficient; c) exponential growth phase, chemostat culture, *P*-limiting conditions; d) a mixed culture of *C. vulgaris* and *P. subcapitata* (initial ratio 1:1) in chemostat under *P*-limiting conditions, exponential growth phase

changed fatty acid composition during their stationary phase that showed a higher degree of polymerization (C14 to C22 acids). *Pseudokirchneriella subcapitata* cultures produced, during the mid-exponential growth phase, a mixture whose major components were C12, C18, C20, and C22 fatty acids; the same compounds, except C20 and C22, also were found in the medium collected from the stationary phase of growth.

These data indicate that the amounts and kinds of fatty acids were different for the two algae cultures (Tables 1, 2). The experiments on a single culture of the selected algae also were carried out in a chemostat, under *P*-limiting conditions. Fatty acids isolated from *C. vulgaris* under these conditions yielded 0.85 mg l^{-1} 10^{-6} cells (Table 1). Their composition was compared with that found in *P*-sufficient cultures during the exponential and stationary growth phases. The comparison showed an increase of acid compounds ranging from C8 to C18 (Table 2). Additionally, in the *P. subcapitata* culture, an increase of fatty acid concentrations was observed (0.25 mg l^{-1} 10^{-6} cells) (Table 1) in respect to the values obtained from batch cultures, and the fatty acid composition was represented by different compounds ranging from C8 to C20 (Table 2).

Fatty acid yield and composition also were studied in co-cultures of *C. vulgaris* and *P. subcapitata* grown in *P*-limiting cultures and with an initial inoculum of 300,000 cell ml^{-1} each. After four days, the composition of the medium was analyzed. At that time, we observed an increased growth of *C. vulgaris* (1,200,000 cells ml^{-1}) and a partial extinction of *P. subcapitata* (100,000 cells ml^{-1}). The isolated fatty acid mixture yielded 1.90 mg l^{-1} 10^{-6} cells ml^{-1}, which was the highest fatty acid concentration observed in our experiments (Table 1). The co-culture of the two algae grown under phosphorus deficiency also influenced the fatty acid composition of the mixture found in the culture medium (Table 2), which in this case

Table 2 Qualitative composition of the fatty acid mixture recovered from different culture media and growth conditions of *Chlorella vulgaris* and *Pseudokirchneriella subcapitata*. a) exponential growth phase, batch culture, *P* sufficient; b) stationary growth phase, batch culture, *P* sufficient; c) exponential growth phase, chemostat culture, *P*-limiting conditions; d) a mixed culture of *C. vulgaris* and *P. subcapitata* (initial ratio 1:1) in chemostat under *P*-limiting conditions; (x = present; ± = in trace)

was constituted almost exclusively by the following C18 fatty acids: stearic acid (13.2%), oleic acid (19.2%), linoleic acid (46.4%), and linolenic acid (21.0%).

Effect of Fatty Acids Mixture on C. vulgaris and P. subcapitata Growth The toxicity of chlorellin isolated from the co-culture of the two algae was assayed separately either on *P. subcapitata* or *C. vulgaris* grown in batch cultures. The range of concentrations tested was 0.4–52 mg l^{-1}. Figure 1 shows the concentration-response relationship of the two algae following 96 h exposure to the fatty acid mixtures. A stimulation of growth at low concentrations of chlorellin was observed for both algae. However, *P. subcapitata* was much more sensitive than *C. vulgaris* to chlorellin concentration. In the case of this latter organism, fatty acids elicited slight growth stimulation at concentrations ranging from 0.4 to 13.0 mg l^{-1}, and exerted a toxic action only at the highest concentrations tested, whereas *P. subcapitata* growth was appreciably stimulated only at the lowest concentrations tested and was strongly inhibited from 6.5 mg l^{-1} onward.

Although chlorellin isolated from algal co-cultures contained traces of other unidentified substances, we prepared a synthetic mixture of the four commercially available C18 fatty acids only, at the same ratio found in natural exudates. The mixture was assayed against *P. subcapitata* and *C. vulgaris*, giving the results reported in Fig. 2. For both species, we observed a growth stimulation at low concentrations and an inhibitory effects at high concentration. Kruskal–Wallis one way analysis of variance on ranks showed that there was no significant difference between the toxicity of chlorellin and the artificial fatty acid mixtures (P=0.171). The results shown in Figs. 1 and 2 also indicate that, under the experimental conditions of batch assays, a concentration of 1.90 mg l^{-1} of the fatty acid mixture was not toxic to *P. subcapitata* (1.90 mg l^{-1} is the amount found in co-culture). Two further experiments were carried out to better understand whether or not even lower cell densities are affected by such a concentration of fatty acids. In the first, the relationship between fatty acid toxicity and cell concentration showed no inhibition of growth in any of the inocula tested. In the second, the influence of *P*-limiting conditions together with a chlorellin concentration of 1.90 mg l^{-1} was evaluated on *P. subcapitata* grown in a chemostat. Although the experimental environment was equivalent to that described for previous experiments of co-culture with *C. vulgaris*, no inhibition was observed. The results of the experiments were used to develop a revised mathematical model that describes the nature of interference between *C. vulgaris* and *P. subcapitata*.

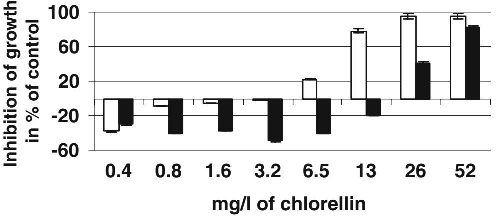

Fig. 1 Effects of chlorellin isolated from co-cultures of the two algae on *Chlorella vulgaris* or *Psuedokirchneriella subcapitata* growth (after 96 h exposure), grown in chemostat under *P*-limiting conditions. (black square *C. vulgaris*; white square *P. subcapitata*); *error bars* indicate the standard deviation

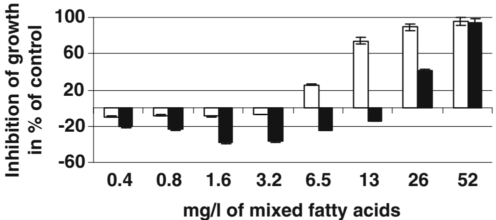

Fig. 2 Effects of fatty acids mixture (stearic, oleic, linoleic and linolenic acids) on *Chlorella vulgaris* or *Pseudokirchneriella subcapitata* growth (after 96 h exposure), grown in chemostat under *P*-limiting conditions; (black square *C. vulgaris*; white square *P. subcapitata*); *error bars* indicate the standard deviation

Mathematical Modelling The model (2) was fitted to the experimental data contained in Table 3 by using a non-linear minimization function (Nonlinear Regress) of the software package Mathematica (Wolfram-Research 1988). In this way, we computed α=4.38 l^2 mg^{-2} with an asymptotic standard error of 0.75 (Fig. 3). The variance was estimated to be 0.2×10^{-2}.

With respect to other models quoted in literature, the two considered here [(1), (2)] were selected mainly because of the advantage of mathematical tractability, simplicity, and the lowest residual standard error. The numerical simulation obtained from Eqs. (3)–(5) is given in Fig. 4. It shows good agreement between the experimental data of *C. vulgaris* growth in the chemostat and the numerical curve.

In a previous study (Fergola et al. 2007), we performed simulations of co-cultures of *C. vulgaris* and *P. subcapitata*, grown in a chemostat under phosphorus limitation. We found that *P. subcapitata* was excluded from the culture within nine days. The model developed to describe the interference between the two algae suggested that both competition for nutrients and toxic action of fatty acids, excreted by *C. vulgaris*, were responsible for the final exclusion of *P. subcapitata*.

For this investigation, some numerical simulations were performed. However, by comparing the numerical simulations obtained through system (10) of this paper with the experimental data of the laboratory interference, currently collected, there was not much difference from that obtained using system (3) of the Fergola et al. (2007).

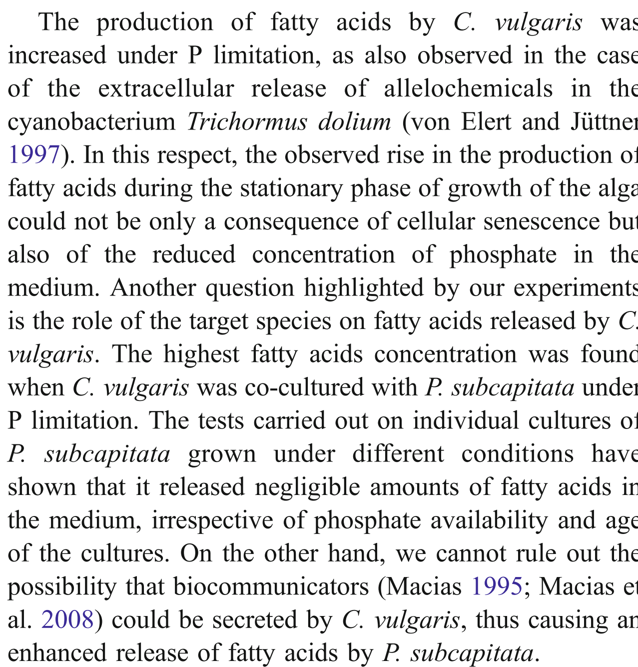
Table 3 The experimental *Chlorella vulgaris* growth rates in correspondence of different toxicant concentrations

Chlorellin (mg/l 10^2)	0	0.002	0.004	0.0078	0.0156	0.03125	0.0625	0.125	0.25	0.52
Growth rate (d^{-1})	0.64	0.70	0.67	0.70	0.71	0.72	0.72	0.69	0.41	0.19

In other words, the effect of chlorellin on *C. vulgaris* in system (10) does not seem to play an important role on the interference between the two algae, unless, once again, the amount of chlorellin produced throughout the experiment was so small that it was not sufficient to produce an observable inhibitory effect. It should be noted, however, that in contrast to the outcome of the laboratory experiments in mono-culture with synthetic chlorellin, the mathematical model predicts, in the experiment in co-culture, an inhibition of the *P. subcapitata* growth by the naturally produced chlorellin.

Discussion

One of the points addressed in this study deals with the chemical characterization of chlorellin. Since the works of Spoehr et al. (1949) and Scutt (1964), only few contributions to the characterization of this mixture have been attempted (Sushchik et al. 2001). Moreover, little information is available on environmental factors that influence the production and release of chlorellin. Sushchik et al. (2003) reported that the composition of extracellular free fatty acids released by *C. vulgaris* did not vary when the algae were grown at different temperatures. The results of our study suggest that the production and the composition of released fatty acids by *C. vulgaris* and *P. subcapitata* are influenced by *P*-supply and/or growth phases, and also by the presence and absence of a competitor.



The production of fatty acids by *C. vulgaris* was increased under P limitation, as also observed in the case of the extracellular release of allelochemicals in the cyanobacterium *Trichormus dolium* (von Elert and Jüttner 1997). In this respect, the observed rise in the production of fatty acids during the stationary phase of growth of the alga could not be only a consequence of cellular senescence but also of the reduced concentration of phosphate in the medium. Another question highlighted by our experiments is the role of the target species on fatty acids released by *C. vulgaris*. The highest fatty acids concentration was found when *C. vulgaris* was co-cultured with *P. subcapitata* under P limitation. The tests carried out on individual cultures of *P. subcapitata* grown under different conditions have shown that it released negligible amounts of fatty acids in the medium, irrespective of phosphate availability and age of the cultures. On the other hand, we cannot rule out the possibility that biocommunicators (Macias 1995; Macias et al. 2008) could be secreted by *C. vulgaris*, thus causing an enhanced release of fatty acids by *P. subcapitata*.

The profile of the fatty acid mixture was shown to be dependent on cultural conditions. Our data indicate that there was a shift towards C18 fatty acids when *C. vulgaris* was cultured under stress conditions. Furthermore the fatty acids mixture isolated from *C. vulgaris* culture under *P*-depleting conditions and in the presence of the competitor *P. subcapitata* was composed mainly of four C18 fatty acids with different degrees of unsaturation. These compounds have been found to be major components of the toxic mixtures released by a number of microalgae

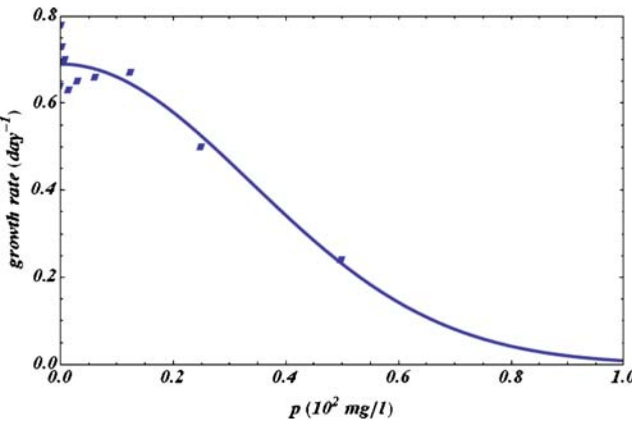


Fig. 3 Dependence of *Chlorella vulgaris* growth rate on the chlorellin concentration p. Comparison between experimental data and the exponential function $f_2\left(S\right)e^{-\alpha p^2}$ where α=4.38 (l^2/mg^2)

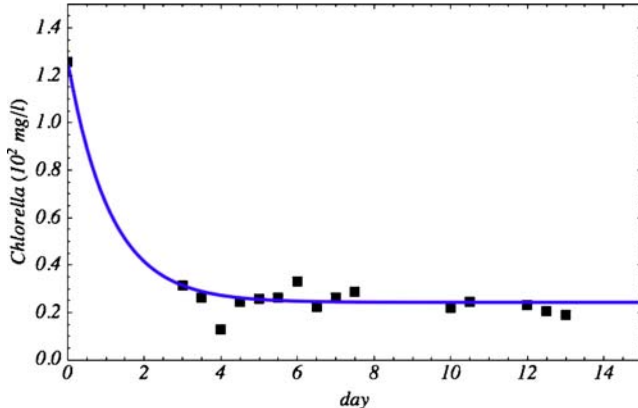

Fig. 4 In the picture, the *points* represent the chemostat experimental data and the *continuous line* is obtained through numerical simulations of Eqs. (3)–(5) with the following parameter values: D=0.9, S^0=0.52, m=1.16, a=0.004, k=0.4, η=0.5, α=4.38

belonging to Chlorophyta, such as *Chlamydomonas reinhardtii* (McCracken et al. 1980), *Chlorococcus* sp., and *Dunaliella primolecta* (Ohta et al. 1995).

The toxicity of fatty acids often has been attributed to their degradation products derived through photoxidation (Spoehr et al. 1949; Murata et al. 1989), but Aliotta et al. (1990) showed that an inhibitory activity of free fatty acids cannot be ruled out. Recently, Bosma et al. (2008) reported that the growth of the Xanthophyte *Monodus subterraneus* was inhibited severely by palmitoleic and oleic acids.

There is increasing evidence of the ecological role played by allelopathic interference in aquatic ecosystems and particularly by fatty acids and their products of photoxidation (Gross 2003, Ianora et al. 2006). However, their effective concentration under natural conditions remains of pivotal importance. The concentration of the fatty acid mixture isolated from single species culture of *C. vulgaris* varied from 0.4 to 0.85 mg l^{-1} in our experiments. In the mixed culture (*C. vulgaris* and *P. subcapitata*), the concentration was much higher (1.90 mg l^{-1}), which is close to those found in some freshwater lakes, where fatty acids are found within a range of 1 and 2 mg l^{-1} (Ikawa 2004). Concentrations of about 0.5 mg l^{-1} were inhibitory to *Phormidium tenue* (Yamada et al. 1993), but it is known that different species exhibit different sensitivities to fatty acid mixtures (Figueredo et al. 2007). In our experiments, chlorellin at 1.90 mg l^{-1} did not significantly influence the growth of *P. subcapitata*. However, in the field, a long exposure to sub-lethal concentrations of fatty acids could affect microalgal species succession. As demonstrated for other classes of compounds (Ianora et al. 2006), there is a high species-specific variability in the effects of allelochemicals on microalgae. Low concentrations of a metabolite can stimulate the growth-rate of some species, but also can be slowly accumulated within the cell, leading to adverse effects in other less resistant species (Ikawa 2004).

The experiments have shown that in the presence of chlorellin the growth of the two algae is modified. To be more precise, we observed that it is slightly stimulated at low concentrations and strongly inhibited as the chlorellin concentration increases. In the models, we did not include the stimulating effect of chlorellin on the two algae, since related experiments are currently in progress.

The simulations obtained on the basis of the suggested mathematical models predicted the experimental results well. Therefore, we reasonably conclude the following:

1) Chlorellin at concentrations above 6.5 mg l^{-1} is autotoxic for *C. vulgaris*. The autotoxic action of a free fatty acid mixture also should be evaluated in the field because, for diatom-derived unsaturated aldehydes, it has been demonstrated that they can act as a diffusible bloom-termination signal (Ianora et al. 2006).
2) *Pseudokirchneriella subcapitata* does not produce sufficient amounts of chlorellin in single species cultures to be ineffective in the competition of the two algal species under chemostat-like conditions. However, experiments are necessary to exclude the idea that biocommunicators produced by *C. vulgaris* or other parameters could enhance the productivity of chlorellin by *P. subcapitata* in co-cultures.
3) The inhibitory effects of a given concentration of natural chlorellin on *P. subcapitata* are similar and qualitatively equivalent to those produced by the same concentration of synthetic chlorellin, prepared as a mixture of the four C18 fatty acids (stearic, oleic, linoleic, and linolenic acids). This is relevant for future experiments, because it allows the use of artificial chlorellin, which is available in large amounts, instead of natural chlorellin, which is usually produced in very small quantities (Fergola et al. 2007).

Appendix

Proof (Lemma 2) If we set

$$z(t) = S(t) + N(t) + p(t) \tag{11}$$

due to system (7), we get

$$\dot{z}(t) = 1 - S - N - p = 1 - z(t), \tag{12}$$

and by integrating from 0 to t, we obtain

$$z(t) = z(0)e^{-t} + 1 - e^{-t},$$

and then

$$\lim_{t \to +\infty} z(t) = 1 \tag{13}$$

thus proving, for any initial condition, the boundedness of the solutions of (7).

Proof(Theorem 2) In order to prove the theorem, we look for positive steady state solutions ($S^*>0$, $N^*>0$, $p^*>0$) and we solve the system obtained by setting the right-hand side of system (7) equal to zero. In this way, we get

$$N^* = \frac{1 - S^*}{k(1 - S^*) + 1}, \qquad p^* = \frac{k(1 - S^*)^2}{k(1 - S^*) + 1} \tag{14}$$

and

$$\left(1 - S^*\right)\left[1 - \frac{f(S^*)}{k(1 - S^*) + 1} e^{-\alpha\left(\frac{k(1-S^*)^2}{k(1-S^*)+1}\right)^2}\right] = 0 \tag{15}$$

with a few calculations from (14) we find that $N^*>0$, $p^*>0$, if and only if $S^*<1$. We have to exclude the value $S^*=1$

because it makes both p^* and N^* equal to zero. Therefore (by omitting the star), we study the solutions of the equation

$$k(1-S)+1-f(S)e^{-\alpha\left(\frac{k(1-S)^2}{k(1-S)+1}\right)^2}=0 \quad (16)$$

if we define

$$h(S)=k(1-S)+1 \quad \text{and} \quad g(S)=f(S)e^{-\alpha\left(\frac{k(1-S)^2}{k(1-S)+1}\right)^2} \quad (17)$$

then the problem of finding the solution of (15) is changed into finding the solution of $h(S)=g(S)$. Remembering that $S<1$, it is easy to show that in the interval [0, 1], $h(S)$ is strictly decreasing whereas $g(S)$ is strictly increasing.

Therefore, because $h(1)=1$ and $g(1)=\frac{m}{a+1}$ the two curves admit only one intersection point with abscissa $S^*<1$ (Fig. 5).

Proof (Theorem 3)

(i) The roots of Eq. (9) computed in $E_0=(1, 0, 0)$ are

$$\rho_1=-1,\ \ \rho_2=f(1)-1,\ \ \rho_3=-1.$$

Therefore, the steady state E_0 turns out asymptotically stable if

$\rho_2<0 \Rightarrow f(1)<1$ that is $m<a+1$.

(ii) In $E^*=(S^*, N^*, p^*)$, Eq. (9) can be written as follows

$$\begin{aligned}&\rho^3+(a_{11}+a_{22}+a_{33})\rho^2\\&\quad+(a_{12}a_{21}+a_{11}a_{22}-a_{13}a_{31}+a_{23}a_{32}+a_{11}a_{33}+a_{22}a_{33})\rho+\\&\quad+a_{12}a_{21}a_{33}+a_{11}a_{22}a_{33}-a_{12}a_{23}a_{31}+a_{11}a_{23}a_{32}\\&\quad-a_{13}a_{22}a_{31}-a_{13}a_{21}a_{32}=0\end{aligned} \quad (18)$$

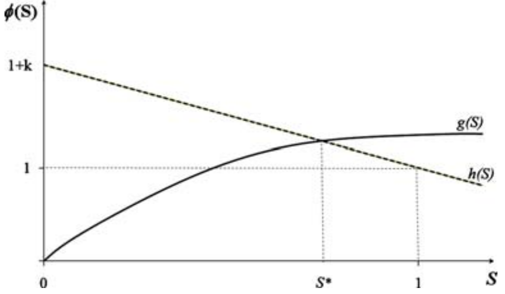

Fig. 5 Here we represent the plots of the two functions $h(S)$ and $g(S)$ defined in (12) in the proof of Theorem 4. These *curves*, as shown, admit only one intersection point with abscissa $S^*<1$

where

$$\begin{aligned}&a_{11}=-\frac{a+S^{*2}}{S^*(a+S^*)},\ a_{12}=-\frac{1-S^*}{N^*},\ a_{13}=2\alpha p^*\left(1-S^*\right),\\&a_{21}=\frac{aN^*}{S^*(a+S^*)},\ a_{22}=-k\left(1-S^*\right),\ a_{23}=-2\alpha p^*N^*,\\&a_{31}=\frac{ap^*}{S^*(a+S^*)},\ a_{32}=2k\left(1-S^*\right),\ a_{33}=-1-2\alpha p^{*2}\end{aligned}$$

are positive constants. In order to study the stability properties of the equilibrium, we can use the Routh–Hurwitz criterion. We observe that, being

1. $a_{11}+a_{22}+a_{33}>0$
2. $a_{12}a_{21}a_{33}+a_{11}a_{22}a_{33}-a_{12}a_{23}a_{31}+a_{11}a_{23}a_{32}-a_{13}a_{22}a_{31}-a_{13}a_{21}a_{32}=\dfrac{-\left(1-S^*\right)\left(-\frac{a+ak+kS^{*2}}{S^*\left(a+S^*\right)}-2kp^*\left(p^*+2N^*\right)\right)}{\alpha}>0$
3. $(a_{11}+a_{22}+a_{33})(a_{12}a_{21}+a_{11}a_{22}-a_{13}a_{31}+a_{23}a_{32}+a_{11}a_{33}+a_{22}a_{33})-(a_{12}a_{21}a_{33}+a_{11}a_{22}a_{33}-a_{12}a_{23}a_{31}+a_{11}a_{23}a_{32}+-a_{13}a_{22}a_{31}-a_{13}a_{21}a_{32})>0$

then all the hypotheses of the Routh–Hurwitz criterion are satisfied and the local stability of the equilibrium E^* follows.

Arbuscular Mycorrhizal Fungi Protect a Native Plant from Allelopathic Effects of an Invader

Kathryn Barto · Carl Friese · Don Cipollini

Received: 2 November 2009 / Revised: 24 February 2010 / Accepted: 2 March 2010 / Published online: 13 March 2010
© Springer Science+Business Media, LLC 2010

Abstract The allelopathic potential of the Eurasian invasive plant *Alliaria petiolata* has been well documented, with the bulk of the effects believed to be mediated by arbuscular mycorrhizal fungi (AMF). We exposed the herbaceous annual *Impatiens pallida*, which is native to North America, to fractionated *A. petiolata* extracts at four developmental stages (germination, presymbiosis growth, symbiosis formation, and symbiosis growth) by using exposure levels expected to be similar to field levels. Surprisingly, we found strong direct effects on *I. pallida* germination and growth, but no indirect effects on *I. pallida* growth mediated by AMF. We also observed strong synergistic effects with a complete *A. petiolata* extract that inhibited *I. pallida* germination and presymbiosis root growth more than either a glucosinolate or flavonoid enriched fraction alone. In fact, the flavonoid enriched fraction tended to stimulate germination and presymbiosis root growth. In contrast to these strong direct effects, *I. pallida* plant growth during both the symbiosis formation and symbiosis growth phases was unaffected by *A. petiolata* extracts. We also found no inhibition of AMF colonization of roots or soils by *A. petiolata* extracts. We show that AMF can actually ameliorate allelopathic effects of an invasive plant, and suggest that previously observed allelopathic effects of *A. petiolata* may be due to direct inhibition of plant and fungal growth before symbiosis formation.

Key Words Allelopathy · Glucosinolates · Flavonoid glycosides · Invasive plants

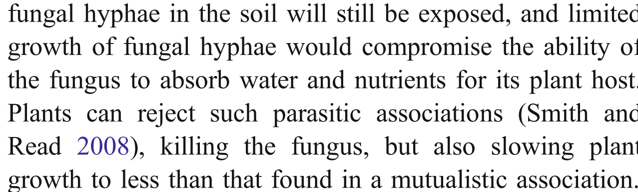
Introduction

Allelopathy has historically been defined as direct inhibition of plant growth by organic compounds produced by a donor plant (Choesin and Boerner 1991; Barkosky et al. 1999). These compounds act through several mechanisms that include causing DNA mutations (Hashimoto et al. 1984; Hashimoto and Shudo 1996; Wu et al. 2000), blocking photosynthesis (Einhellig et al. 1993; Gonzalez and Estevez-Braun 1997), and/or triggering programmed cell death (Bais et al. 2003). While these mechanisms clearly act directly on the target plants, many potential mechanisms of indirect inhibition exist as well (Inderjit and Weiner 2001). For example, compounds released by a donor plant can influence nutrient availability in a way that is more beneficial for the donor plant (Inderjit and Mallik 1999). Also, microbial populations supported by a donor plant can selectively inhibit growth of surrounding plants (Kaminsky 1981), or microbes that benefit surrounding plants can be inhibited by a donor plant (Stinson et al. 2006). Such beneficial microbes include the arbuscular mycorrhizal fungi (AMF), with which more than 80% of plants surveyed associate (Smith and Read 2008). AMF are obligately symbiotic and provide their host plants with

mineral nutrients and water in exchange for photosynthate (Smith and Read 2008). Many plants depend on AMF for normal growth, and any inhibition of AMF, therefore, would also indirectly slow plant growth.

Alliaria petiolata (M. Bieb.) Cavara and Grande (garlic mustard), a Eurasian native that is invasive in North America, can inhibit seed germination and growth of native plant species, and AMF and ectomycorrhizal germination and growth (Vaughn and Berhow 1999; Roberts and Anderson 2001; Prati and Bossdorf 2004; Stinson et al. 2006; Callaway et al. 2008; Wolfe et al. 2008; Barto and Cipollini 2009b), although inhibition does not always occur (McCarthy and Hanson 1998; Cipollini et al. 2008; Barto and Cipollini 2009a). Many of these results are based on seed and spore germination assays, or exposures that began before seed and spore germination. Stinson et al. (2006) observed reductions in colonization of woody species exposed to *A. petiolata* during the symbiosis formation phase, but a herbaceous plant exposed during the symbiosis formation phase was unaffected (Barto and Cipollini 2009a). Allelopathic effects of *A. petiolata* have been attributed to glucosinolates and isothiocyanates (Vaughn and Berhow 1999), but extracts enriched in alliarinoside and several flavonoid glycosides, known anti-herbivory compounds from *A. petiolata* (Haribal and Renwick 1998; Haribal et al. 2001), reduced AMF spore viability more than a glucosinolate enriched fraction (Callaway et al. 2008). Plant responses to alliarinoside and the flavonoid glycosides before symbiosis formation have not yet been determined.

We explored the effects of *A. petiolata* extracts on the four major developmental stages of a plant-mycorrhizae association (1. germination, 2. presymbiosis growth, 3. symbiosis formation, and 4. symbiosis growth), each in a separate experiment. The germination phase includes any stratification requirement up to and including emergence of the radicle from the seed. Growth of the plant before colonization by AMF is included in the presymbiosis growth phase. Although the non-mycorrhizal condition is usually rare in the field, sites with a long invasion history are likely to have low AMF colonization potential (Roberts and Anderson 2001), and this experiment demonstrates how well a re-introduced native grows when exposed to *A. petiolata* extracts without the benefit of AMF. During the symbiosis formation phase, contact between AMF and the plant is initiated and fungal structures begin to form inside the plant root. Allelopathic compounds could interfere with signaling between host plants and AMF, thereby limiting the formation of the symbiosis. Finally, the symbiosis continues to operate throughout the remainder of the plant's lifetime in the symbiosis growth phase. Once a symbiosis is formed, fungal structures inside the root are likely to be somewhat insulated from allelopathic effects. However,



fungal hyphae in the soil will still be exposed, and limited growth of fungal hyphae would compromise the ability of the fungus to absorb water and nutrients for its plant host. Plants can reject such parasitic associations (Smith and Read 2008), killing the fungus, but also slowing plant growth to less than that found in a mutualistic association.

The objectives of this experiment were to assess the effects of glucosinolate and flavonoid glycoside enriched fractions of *A. petiolata*, alone and in concert, on growth of a North American native plant and its associated AMF. These effects were assessed across multiple life stages in order to determine the importance of AMF in mediating any observed allelopathic effects. We expected glucosinolate and flavonoid enriched fractions to inhibit growth of *I. pallida*, primarily indirectly through inhibition of AMF in later life stages.

Methods and Materials

Extracts were prepared from first year *A. petiolata* plants randomly collected from the Wright State University Nature Preserve (39°48.0′N, 84°1.0′W) during late Spring, when the establishment of mycorrhizal symbioses with host plants is occurring actively. Plant tissues, leaves and roots, either were extracted immediately after collection, or flash frozen and stored at −20°C to maintain a standard lot of material for extract preparation. It is unclear whether secondary metabolites produced by *A. petiolata* enter the environment as root exudates, leaf leachates, or both, so we used both leaves and roots to prepare our extracts. Glucosinolates were separated from the flavonoid glycosides by using a butanol/water fractionation as described in Callaway et al. (2008), yielding glucosinolate enriched and flavonoid enriched fractions. The glucosinolates and flavonoids were by far the most abundant compounds in their respective fractions, but it was not our intention to purify these compounds because we wanted the combined treatment of glucosinolate and flavonoid enriched fractions to represent the complete *A. petiolata* phytochemical profile. All experiments were dosed at a rate equivalent to 3.3 mg *A. petiolata* tissue equivalents per g assay media, a dose that was estimated by assuming equivalent transfer rates of glucosinolates from plants to soils for *A. petiolata* as reported for Brassicaceae used as biofumigants (Callaway et al. 2008).

Impatiens pallida Nutt. (pale jewelweed) was chosen as the target plant because it grows in the same woodland habitats invaded by *A. petiolata* and is dependent on AMF for normal growth (K Barto, personal observation). While AMF generally are not thought to be host specific, certain plant-fungus associations are more effective than others (Stampe and Daehler 2003; Johnson et al. 2004), so we used naturally associated AMF of *I. pallida*. Mycorrhizal inocu-

lum consisted of finely chopped *I. pallida* roots collected from a population in Yellow Springs, Ohio (39 °47.0′N, 83 °52.5′W). *Impatiens pallida* seed were collected from the same population for all experiments. Inoculum was prepared in the fall and stored at 5°C until needed.

The seed germination experiment was conducted in small glass dishes (9 cm diam), which were stored at 3°C throughout the experiment. The presymbiosis growth experiment and the symbiosis formation and symbiosis growth experiments were conducted in root-viewing chambers made of 13×30×0.15 cm glass plates held ½ cm apart by silicon on 3 sides (Friese and Allen 1991). All experimental chambers, glass dishes, and root-viewing chambers, were filled with a 1:1 mix of field soil and sterile coarse sand or the same mix with activated carbon (AC) added at a rate of 20 ml/l soil, as has been used in other experiments with *A. petiolata* (Prati and Bossdorf 2004). Activated carbon sorbs organic compounds and serves as an additional experimental control to verify that effects are due to allelochemicals (Inderjit and Callaway 2003). Field soil, collected from an *A. petiolata* free area of the Wright State University Nature Preserve, has a high proportion of clay, and forms impenetrable bricks in the chambers without the addition of sand (K. Barto, personal observation). Root-viewing chambers were covered with foil and stored at a slight angle to encourage root and hyphal growth along one glass plate (Friese and Allen 1991). With the exception of the seed germination experiment, all chambers were placed under fluorescent grow-lights (130 μmol PAR/m^2/sec) at ~22°C in a growth room. Four separate experiments were conducted, examining one developmental stage per experiment.

Germination We examined the effects of treatments on germination by concurrently adding test fractions and ungerminated seeds to glass dishes. Seed germination was assessed by placing 5 *I. pallida* seeds on the soil surface, and applying doses every other week. Dishes were covered but not sealed to allow oxygen to circulate. Germination was scored weekly for 6 mo. We used 4 extracts (glucosinolate enriched fraction, flavonoid glycoside enriched fraction, combined fraction, and water control) crossed with 2 activated carbon treatments (with or without). There were 5 replicate chambers for each treatment combination. Final percent germination was analyzed using ANOVA with activated carbon and extract as fixed factors, followed by Tukey's HSD test where indicated. Data did not need to be transformed to meet assumptions of normality and homogeneity of variances, and were analyzed using R 2.7.1 (R Development Core Team 2008).

Presymbiosis Plant Growth We examined the presymbiosis growth stage by simultaneously adding test fractions and germinated seeds to root-viewing chambers. *Impatiens pallida* seeds were germinated in sterile water at 3°C (Leck 1979). Preliminary experiments showed that seedlings quickly became colonized with AMF in field soils, so chambers were treated with 190 mg/l of the fungicide chlorothalonil (Daconil®, Syngenta Crop Protection, Inc, Greensboro, NC, USA) every other day to maintain the uncolonized status of seedlings in this experiment. Chlorothalonil can inhibit plant growth at high does, so we conducted preliminary experiments and determined that this dosage schedule would block mycorrhizal colonization of seedlings without directly impacting *I. pallida* growth (K. Barto, unpublished data). Presymbiosis seedling growth was assessed by placing one newly germinated *I. pallida* seed on the soil surface while adding test compounds. Doses were applied once a week throughout the experiment by injecting 5 ml of extract into the chamber through each of three injection sites, located 7.5, 15, and 23 cm from the top of the chamber, along the 30.5 cm side. This volume was sufficient to wet the entire soil volume without forcing water out of the base of the chamber. The roots were traced onto transparency film and digitized every 3 d until a root reached the bottom of the chamber.

Total root length and area of the root system were quantified using ImageJ (NIH: http://rsb.info.nih.gov/ij/). We also measured the box-counting fractal dimension (FD), which quantifies exploration efficiency of the system independently of rhizosphere size (Walk et al. 2004), using the FracLac plugin for ImageJ (http://rsb.info.nih.gov/ij/plugins/frac-lac.html) (Barto and Cipollini 2009b). Height of the aboveground portion of *I. pallida* also was recorded once a week. Many plants died before the end of the experiment, so we also recorded life span. Growth rates for plant height, root length, and rhizosphere area, along with the box-counting fractal dimension of the root system and the life span of the plants, were analyzed using PROC GLM and ANOVA with activated carbon and extract as fixed factors followed by Tukey's HSD test where indicated. Data were transformed as necessary to meet assumptions of ANOVA and analyzed with SAS Version 9.1 (SAS Institute Inc., Cary, NC, USA).

Symbiosis Formation We examined the symbiosis formation stage by injecting compounds into inoculated root-viewing chambers with one growing *I. pallida* seedling. *Impatiens pallida* seeds were stratified in water at 3°C to stimulate germination, then planted in chambers. Mycorrhizal inocula, which consisted of chopped roots of field-collected *I. pallida*, was mixed with the soil at a rate of 1 g inocula/100 g soil before filling chambers. Injections began as soon as seeds were added, and doses were applied once a week throughout the experiment. Mycorrhizal structures were identified non-destructively in the chambers by their

fluorescence after excitation with 460 nm light (Friese and Allen 1991). Observations were made with an Eclipse TE 2000-S microscope with a B-2E/C filter cube.

Chambers were observed along horizontal 6 cm transect lines centered at the middle of the chamber and spaced vertically 5 cm apart. The first transect line was 2.5 cm below the top of the chamber, and additional lines were observed as the roots grew down through the chamber. In order to quantify AMF abundance inside roots, we scanned along each transect line and scored uncolonized and colonized roots. Then, we calculated the percentage of colonized roots observed in each chamber. In order to quantify AMF abundance outside of plant roots, we also scanned along each transect line, but due to time constraints we could not quantify hyphal abundance along the entire transect line. Instead, in every third field of view that did not contain a root, we scored for presence of absence of AMF hyphae. Only non-septate hyphae were counted as AMF. Then we calculated the percentage of fields of view containing AMF hyphae.

Height of the above ground portion of *I. pallida* also was recorded each week. Plants were harvested at the end of the experiment, dried at 30°C to constant mass, and root and shoot dry mass were measured. There were 4 treatments (glucosinolate enriched fraction, flavonoid glycoside enriched fraction, combined fraction, and water control) for each of two carbon amendments (with or without). There were ten replicate chambers per treatment combination yielding 80 chambers total. Data were analyzed as described for the presymbiosis growth experiment, excluding life span. Also, dry mass of the root, shoot, and the root to shoot ratio were analyzed by ANOVA with activated carbon and extract as fixed factors followed by Tukey's HSD test where indicated. Data did not need to be transformed and were analyzed with SAS Version 9.1 (SAS Institute Inc., Cary, NC, USA). In addition, percent colonization of the root and soil (untransformed) were analyzed using a repeated measures ANOVA with activated carbon and extract as fixed factors using STATISTICA Version 8.0 (StatSoft, Inc.).

Symbiosis Growth We examined the symbiosis growth stage by injecting compounds into chambers with already established symbioses between *I. pallida* and its associated mycorrhizal fungi. Established symbioses were generated by growing *I. pallida* seedlings in root-viewing chambers in field soil containing mycorrhizal inoculum. When seedlings were 4 wk old, colonization was verified by fluorescence microscopy before beginning injections of compounds. Injections were repeated weekly thereafter until the end of the experiment. Fungal development characteristics were monitored as in the symbiosis formation experiment. Plates were monitored weekly with observations beginning when plants were 3 wk old. Plants were harvested at the end of the experiment, dried at 30°C to constant mass, and root and shoot dry mass were measured. There were 4 treatments (glucosinolate enriched fraction, flavonoid glycoside enriched fraction, combined fraction, and water control) for each of 2 carbon amendments (with or without). There were 10 replicate chambers per treatment combination yielding 80 chambers total. Growth rate for plant height, percent colonization of roots and soil, dry mass of the root, shoot, and the root to shoot ratio were analyzed as for the symbiosis formation experiment.

Results

Germination Impatiens pallida seeds began to germinate after 20 weeks of stratification, and no additional seed germinated after 24 weeks. Exposure to a flavonoid or glucosinolate enriched fraction alone had no significant effect on germination. However, germination was lower in dishes dosed with a combined extract than either control dishes or those receiving a flavonoid enriched fraction (Fig. 1, $F_{3,32}$ = 3.71, P=0.021). Activated carbon did not affect germination rates ($F_{1,32}$ = 0.08, P=0.779), and there was no interaction between AC and extract ($F_{3,32}$ = 1.36, P=0.273).

Presymbiosis Growth Impatiens pallida plants in chambers with AC grew faster than plants in chambers without AC (Fig. 2a, Table 1). *Alliaria petiolata* extracts had no effect on *I. pallida* height (Table 1). Total root length of *I. pallida* plants increased more quickly in plants grown in soil containing AC than in plants grown without AC (Fig. 2b,

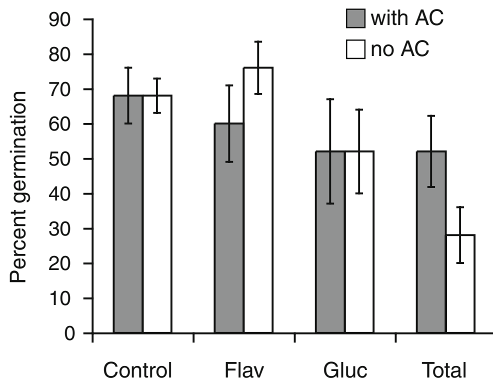


Fig. 1 Percent germination of *Impatiens pallida* seeds exposed to *Allairia petiolata* extracts during stratification, means ± 1 SE. Control—Chambers treated with water only. Table 1). Root growth varied with extract treatment, and only the combined extract significantly reduced root growth (Fig. 2b, Table 1). Since these plants were not yet colonized by AMF, these impacts represent direct effects of *A. petiolata* extracts on root growth. Patterns for growth of rhizosphere area followed those of root length (Table 1).

Root structure of *I. pallida* plants also was affected by *A. petiolata* extracts. The planar box-counting fractal dimension, which quantifies the exploration efficiency of the root system, was significantly higher in chambers with AC than in chambers without (Fig. 2c, Table 1). As for root length and rhizosphere area, the fractal dimension was highest in chambers that received a flavonoid enriched fraction and lowest in chambers treated with a combined extract (Fig. 2c, Table 1). The interaction between AC and extract also was significant (Table 1), with AC increasing the fractal dimension significantly only in chambers dosed with a glucosinolate enriched fraction (Fig. 2c).

Impatiens pallida plants grown in soil with AC lived longer than plants in soil without AC (Fig. 2d; Table 1). The glucosinolate enriched fraction and the combined *A. petiolata* extract significantly shortened *I. pallida* life span, while a flavonoid enriched fraction had no effect (Fig. 2d; Table 1). This inhibition was seen only in chambers without AC (Fig. 2d; Table 1).

Symbiosis Formation During the symbiosis formation phase, growth rates of *I. pallida* height, root, and rhizosphere area were unaffected by AC or *A. petiolata* extract (Table 2). Root structure of *I. pallida* plants was unaffected by AC (Table 2). However, regardless of AC treatment, root systems of plants exposed to a glucosinolate

Table 1 Results of ANOVA for growth rates of height, root length, rhizosphere area, and final box-counting fractal dimension, and life span of *Impatiens pallida* plants exposed to *Alliaria petiolata* extracts during the presymbiosis phase, with AC (activated carbon) and extract as factors. enriched fraction had significantly higher fractal dimensions (mean ± SE; 1.24±0.015) than those exposed to a combined fraction (1.18±0.020; Table 2). Root systems of control plants (1.21±0.011) or those exposed to a flavonoid enriched fraction (1.19±0.013) had fractal dimensions indistinguishable from either extreme. Shoot and root dry masses of plants at the end of the experiment, and the root to shoot ratio, were unaffected by AC or *A. petiolata* extracts (Table 2).

Arbuscular mycorrhizal colonization of *I. pallida* roots was higher in chambers containing AC than those without throughout the experiment, even though colonization declined with time in all chambers (Fig. 3a, Table 3). Hyphal abundance in the soil was unaffected by *A. petiolata* extract, but increased with time in chambers containing AC while remaining relatively constant in chambers without AC (Fig. 3b, Table 3).

Symbiosis Growth During the symbiosis growth phase, plant height increased more quickly in chambers without AC (mean ± SE; 6.63±0.42 cm/week) than in chambers with AC (5.41±0.25 cm/week; Table 4). Growth rate was unaffected by *A. petiolata* extracts, and there was no interaction between AC and extract (Table 4). Since *I. pallida* were given a month in the chambers before dosing began, roots had filled the chambers to such an extent that it would have been extremely difficult to track further development. Root morphology data, therefore, was not collected.

Arbuscular mycorrhizal fungal colonization was higher in roots of plants grown in soils containing AC than in soils without (Fig. 4a, Table 5), but fewer hyphae were found in soils containing AC than in soils without (Fig. 4b, Table 5). Root colonization declined over time (Fig. 4a, Table 5). Root dry mass was higher in chambers without AC (mean ± SE; 0.19±0.026 g) than in chambers with AC (0.15±0.032 g), as was shoot dry mass (without AC: 0.11±0.0076 g, with AC: 0.08±0.0047 g; Table 4). Both were unaffected by *A. petiolata* extracts (Table 4). The root to shoot ratio was not affected by *A. petiolata* extracts (Table 4).

Discussion

As expected, glucosinolate and flavonoid enriched fractions from *A. petiolata* extracts inhibited the growth of *I. pallida*. Synergistic effects of the flavonoid and glucosinolate enriched fractions were observed in the germination and presymbiosis growth phases, but not in either symbiosis phase. The flavonoid-enriched fraction had no effect alone, but appeared to enhance the slight toxicity of the glucosinolate enriched fraction, leading to the very low germination or growth rates observed after exposure to a combined fraction. These effects likely are due to the glucosinolates and flavonoids themselves, given their abundance in the extracts, but it is possible that unidentified compounds in the extracts also contributed to effects. Synergistic interactions among allelopathic compounds also occur in *Triticum*, where phenolic compounds increase cell permeability in root tips, allowing greater uptake of mutagenic benzoxazinoids (Blum et al. 1992; Hashimoto and Shudo 1996). Synergistic mechanisms also operate in *Desmodium* and *Sorghum,* which block parasitism by *Striga* plants by concurrently stimulating germination of *Striga* seeds while inhibiting further root growth (Chang et al. 1986; Weston et al. 1989; Yoder 2001; Tsanuo et al. 2003). While the specific mechanism of action remains to be elucidated, synergistic effects among compounds produced by *A. petiolata* clearly limited plant and AMF growth during the early stages of development.

We frequently observed declines in root colonization over time, potentially because as the plants aged and their roots filled the soil volume, assistance from AMF became less necessary. Plants have some control over intraradical fungal growth (Smith and Read 2008) and could have limited fungal development as the plants became root bound. This is supported by the decline in root colonization values in chambers containing AC, as well as control chambers receiving only water. Soil colonization values remained relatively constant throughout the symbiosis growth phase, and even increased in chambers containing AC during the symbiosis formation phase, suggesting that extraradical fungal structures are less dependent on the age

or status of the symbiosis than intraradical fungal structures. The plant likely has more control over intraradical fungal structures than extraradical, and the continued growth of extraradical structures may represent growth by the fungus away from its host in the face of decreasing support, via intraradical structures.

Activated carbon sorbs organic compounds and should rescue plants from allelopathic inhibition when incorporated into soils (Inderjit and Callaway 2003). Surprisingly, AC had no effect on germination. Extracts were added to test soils every other week since *A. petiolata* metabolites generally are not stable in non-sterile soils (Gimsing et al. 2006, 2007; Barto and Cipollini 2009c), but sinigrin has a half-life in excess of 120 d in non-sterile soil water (Tsao et al. 2000). Although low temperatures did not limit degradation of flavonoids (Barto and Cipollini 2009c), it is possible that compounds accumulated over the course of the six month experiment to levels that saturated the AC present in the soils. As expected, AC additions in the presymbiosis experiment rescued plants exposed to *A. petiolata* extracts. Plants exposed to extracts that were also growing in soils containing AC were not distinguishable from control plants receiving only water. Activated carbon effects during the symbiosis formation and symbiosis growth stages were less consistent, further suggesting that allelopathic inhibition was not as important in these life stages.

We found extensive evidence of inhibition of seed germination and presymbiosis plant growth in the absence of AMF. The lack of these non-AMF mediated inhibitory effects during the symbiosis formation and growth phases suggests that the AMF may actually be protecting the plant from the allelopathic compounds. This is not simply an age effect, where a larger plant is more able to resist inhibition than a small plant, because the presymbiosis and symbiosis formation experiments both began with germinated seed. The only difference was that the soil for the symbiosis formation experiment also contained AMF inocula with no previous exposure to *A. petiolata*.

In contrast to prior work that demonstrated inhibition of AMF by *A. petiolata* (Roberts and Anderson 2001; Stinson et al. 2006; Callaway et al. 2008; Barto and Cipollini 2009b), we found no evidence for impacts on AMF. However, earlier research monitored AMF that were not associated with a host plant (Roberts and Anderson 2001; Stinson et al. 2006; Callaway et al. 2008), or began dosing AMF in the presymbiosis phase (Barto and Cipollini 2009b), where we saw inhibition also. When exposures began in the symbiosis formation phase, Barto and Cipollini (2009a) did not see inhibition of *I. pallida* growth

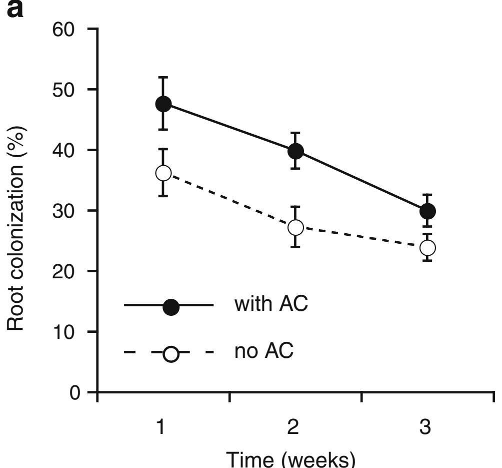
by the same *A. petiolata* extracts used here. Roberts and Anderson (2001) relied on spore and seed germination assays, and used a dose about eight times higher than that used in our study, so results cannot be compared directly. Stinson et al. (2006) used doses of *A. petiolata* extracts twice as high as those used here, which could account for the inhibition observed in that study. Ideally, allelopathy studies should use exposure levels equivalent to those found in the field. However, *A. petiolata* metabolites degrade rapidly, and rarely reach detectable levels in natural soils (Barto and Cipollini 2009c). This likely means that the actual bioactive compounds are degradates of the compounds produced by the plant. We, thus, used doses estimated to be realistic field levels (Callaway et al. 2008). Soil levels under naturally occurring plants likely are even lower than our estimated values, and any impacts not seen at these doses are unlikely to be important in the field.



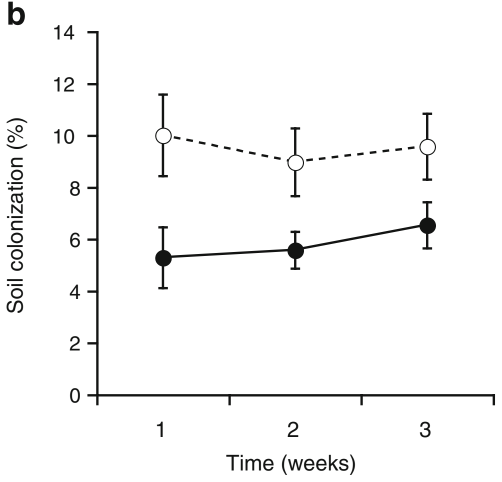


Fig. 4 Responses of *Impatiens pallida* plants exposed to *Alliaria petiolata* extracts during the symbiosis growth phase, means ± 1 SE. with AC—Chambers contained activated carbon. no AC—Chambers did not contain AC. **a** Percentage of root length colonized by AMF over time (N=8–10). **b** Percentage of soil area containing AMF hyphae over time (N=8–10)

Stinson et al. (2006) also observed reduced AMF colonization of tree seedlings in conditioned soils, which could be a legacy effect of very low inoculum potential due to direct suppression of spore viability and germination (Roberts and Anderson 2001; Stinson et al. 2006; Callaway et al. 2008), rather than allelopathic inhibition of colonization in the plant. Callaway et al. (2008) used a soil conditioning approach, and found reduced AMF spore viability and infectivity, and reduced emergence of plant seedlings in soil conditioned by *A. petiolata*. However, all of these endpoints occur before the symbiosis is established. The final biomass of plants grown in conditioned soil was lower than that of plants grown in control soil, suggesting that even after the beneficial mycorrhizal

symbiosis becomes established, the direct inhibition incurred during early life stages cannot be overcome.

We suggest that observed allelopathic inhibition by *A. petiolata* is due to legacy effects of direct inhibition of plant and fungal partners before the symbiosis is established, rather than to inhibition of colonization during an established symbiosis. This may seem like a purely mechanistic distinction because the end result of reduced AMF colonization and reduced plant growth is still the same, but direct inhibition is more easily addressed during restoration, especially when healthy AMF can ameliorate allelopathic effects. The strongest allelopathic effects occur during seed and spore germination and presymbiosis growth, thus suggesting that bypassing these life stages during restorations will be more successful than traditional methods of sowing ungerminated seed. More work is needed to determine whether or not other plant species, especially the woody species used by Stinson et al (2006), also are more sensitive to allelopathic inhibition before associating with mycorrhizal fungi then after the symbiosis has been initiated. Field studies that incorporate germinated seed and fresh AMF inocula also could be used to distinguish between legacy effects and ongoing allelopathic inhibition.

Subterranean Herbivore-induced Volatiles Released by Citrus Roots upon Feeding by *Diaprepes abbreviatus* Recruit Entomopathogenic Nematodes

Jared G. Ali · Hans T. Alborn · Lukasz L. Stelinski

Abstract Herbivore-induced volatile emissions benefit plant hosts by recruiting natural enemies of herbivorous insects. Such tritrophic interactions have been examined thoroughly in the above-ground terrestrial environment. Recently, similar signals have also been described in the subterranean environment, which may be of equal importance for indirect plant defense. The larvae of the root weevil, *Diaprepes abbreviates*, are a serious pest of citrus. Infestations can be controlled by the use of entomopathogenic nematodes, yet the interactions between the plant, insect and nematode are poorly understood and remain unpredictable. In bioassays that used a root zone six-arm olfactometer, citrus roots ('Swingle citrumelo' rootstock) recruited significantly more entomopathogenic nematodes (*Steinernema diaprepesi*) when infested with root weevil larvae than non-infested roots. Infested plants were more attractive to nematodes than larvae alone. Roots damaged by weevil larvae attracted more nematodes than mechanically damaged roots and sand controls. By dynamic *in situ* collection and GC-MS analysis of volatiles from soil, we determined that four major terpene compounds were produced by infested plant roots that were not found in samples from non-infested roots or soil that contained only larvae. Solvent extracts of weevil-infested roots attracted more nematodes than extracts of non-infested roots in a two choice sand-column bioassay. These findings suggest that Swingle citrus roots release induced volatiles as an indirect defense in response to herbivore feeding, and that some of these induced volatiles function as attractants for entomopathogenic nematodes.

Key Words Entomopathogenic nematodes · *Diaprepes abbreviatus* · Herbivore induced volatiles · Below-ground tritrophic interactions · *Steinernema diaprepesi*

Introduction

Plants produce an array of signals with diverse roles, thus providing them with responses necessary to survive in their dynamic environment. Examples of plants luring organisms and thereby facilitate their reproductive requirements are ubiquitous and often taken for granted (Pichersky and Gershenzon 2002). Less acknowledged is the ability of a plant to manipulate the behavior of organisms to serve defensive roles (Turlings and Wäckers 2004). However, examples of such tritrophic interactions, among plants, herbivores, and natural enemies are common (Agrawal and Rutter 1998; Agrawal and Karban 1999; Baldwin and Preston 1999; Dicke et al. 2003).

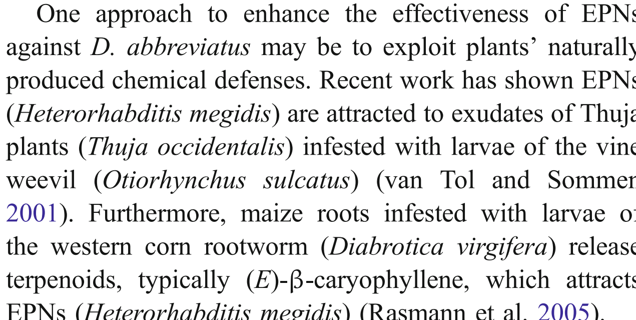
Herbivore feeding on plants results in release of volatile compounds, which may attract arthropod predators and/or parasitoids. For instance, lima bean plants (*Phaseolus lunatus*), release volatiles when infested with spider mites (*Tetranychus urticae*), which attract the predatory mite *Phytoseiulus persimilis* (Takabayashi and Dicke 1996). Oviposition can also stimulate plant exudates that are attractive to egg parasitoids; the legume, *Vicia faba* emits volatiles that attract the egg parasitoid, *Trissolcus basalis* after oviposition by the Pentatomid, *Nezara viridula*

(Colazza et al. 2004). Specific compounds from both the plant and salivary elicitors from the herbivore have been shown to mediate these interactions (Alborn et al. 1997). For example, methyl salicylate attracts herbivore predators (e.g., De Boer and Dicke 2004). Volicitin, found in oral secretions of caterpillars (*Spodoptera exigua*), has been well characterized and induces volatile production in maize (Alborn et al. 2000; Turlings et al. 2000). As the details of above-ground tritrophic interactions have become substantially resolved (Vet et al. 1991; Vet and Dicke 1992), recent attention has focused on analogous communication systems in the subterranean environment.

Volatile signaling by plant roots can contribute to belowground defense by acting as antimicrobial or anti-herbivore substances (Tumlinson et al. 1992, 1999; Neveu et al. 2002; Bais et al. 2006). Plants also can benefit by releasing herbivore-induced volatile emissions that recruit natural enemies of subterranean herbivores, as shown by van Tol and Sommen (2001), Aratchige et al. (2004), and Rasmann et al. (2005). The pressure from belowground pests of plants is significant and likely imparts selection pressure for evolution of induced plant responses.

Diaprepes abbreviatus (L.) is a significant belowground pest of plant roots on more than 290 plant species including citrus, sugarcane, vegetables, potatoes, strawberries, woody field-grown ornamentals, sweet potatoes, papaya, guava, mahogany, containerized ornamentals, and non-cultivated wild plants (Simpson et al. 2000). *Diaprepes abbreviatus* was first introduced into Florida in 1964 (Beavers and Selhime 1975). Over the past 40 years, it has contributed significantly to the spread of disease and damage to citrus, ornamental plants, and other crops causing approximately $70 million in damage annually (Weissling et al. 2002). *Diaprepes abbreviatus* damage the vegetative portion of plants by notching young leaves (Fennah 1940). Mature adults lay eggs between older leaves and emerging first instars drop to the soil where they develop and feed on roots causing the most severe damage to plants (Fennah 1940; Schroeder 1992). Currently, the most effective method for controlling the larval stage is with entomopathogenic nematodes (EPN), from the genera *Heterorhabditis* or *Steinernema* (Downing et al. 1991; Schroeder 1992).

EPNs are obligate parasites that kill their host with the aid of a symbiotic bacterium (Poinar 1990). Mass-produced EPNs have been used for control of *D. abbreviatus* by citrus growers for over 20 years (Duncan et al. 1999). Mass release of EPNs can effectively reduce larval populations of *D. abbreviatus* (Downing et al. 1991; Schroeder 1992; Bullock et al. 1999). However, the reported efficacy of EPNs against *D. abbreviatus* ranges from 0% to >90% suppression (Adair 1994; Bullock et al. 1999; McCoy et al. 2000), and thus improved consistency of this tactic is desired.



One approach to enhance the effectiveness of EPNs against *D. abbreviatus* may be to exploit plants' naturally produced chemical defenses. Recent work has shown EPNs (*Heterorhabditis megidis*) are attracted to exudates of Thuja plants (*Thuja occidentalis*) infested with larvae of the vine weevil (*Otiorhynchus sulcatus*) (van Tol and Sommen 2001). Furthermore, maize roots infested with larvae of the western corn rootworm (*Diabrotica virgifera*) release terpenoids, typically (*E*)-β-caryophyllene, which attracts EPNs (*Heterorhabditis megidis*) (Rasmann et al. 2005).

In this investigation, we quantified the behavior of the entomopathogenic nematode, *Steinernema diaprepesi* Nguyen & Duncan, in response to citrus plants damaged by larval *D. abbreviatus*. We show that EPNs are attracted to weevil-damaged roots, but not so to mechanically damaged roots, undamaged roots or larvae alone. We also identified volatile compounds induced by weevil feeding and showed that EPN response is specifically mediated by solvent extracts of infested roots.

Methods and Materials

Insects *Diaprepes abbreviatus* larvae were obtained from a culture at University of Florida's Citrus Research and Education Center (CREC) in Lake Alfred, FL, USA. This culture was periodically supplemented from a large culture maintained at the Division of Plant Industry Sterile Fly Facility in Gainesville, FL, USA. Larvae were reared on an artificial diet developed by Beavers (1982) using procedures described by Lapointe and Shapiro (1999). Larvae used in experiments were 3rd to 6th instars.

Nematodes *Steinernema diaprepesi* were isolated from *D. abbreviatus* larvae buried in a commercial citrus orchard in Florida. The nematodes were then reared in last-instar greater wax moth larvae, *Galleria mellonella* (L.) (Lepidoptera: Pyralidae), at approximately 25°C according to procedures described in Kaya and Stock (1997). Infective juveniles (IJs) that emerged from insect cadavers into White traps (White 1927) were stored in shallow water in transfer flasks at 15°C for up to 2 wk prior to use.

Plants 'Swingle citrumelo' (*Citrus paradisi* Macf. × *Poncirus trifoliata* L. Raf.) rootstock is prominent in commercial citrus production. The prevalence of this genotype is due to its tolerance to blight, citrus tristeza virus, plant parasitic nematodes, and *Phytophthora* spp., as well as cold tolerance (Stover and Castle 2002). The extensive use of this rootstock in commercial citrus production justified its use in this investigation. All plants were grown and maintained at the CREC in Lake Alfred, FL, USA in a greenhouse at 26°C, and 60–80% RH.

Olfactometer EPN response to *D. abbreviatus*-infested roots was tested with a root zone olfactometer (Analytical Research Systems, Gainesville, FL, USA) according to the design described in Rasmann et al. (2005). The olfactometer consists of a central glass chamber (8 cm diam and 11 cm deep) attached by six side arms to six glass pots (5 cm diam and 11 cm deep) in which various plants/ treatments were tested. The side arms are joined to the six treatments pots with Teflon connectors fitted with a fine mesh filter impervious to nematodes (2300 mesh, Smallparts, Inc., Miramar, FL, USA). For all tests, the olfactometer was filled with sand that had been autoclaved for 1 hr at 250°C and then adjusted to 10% moisture (dry wt. sand:water volume; W/V). In tests involving plants, seedlings were given 3 d to adjust to their sand filled olfactometer for each experiment.

In the first experiment, we tested nematode response to weevil-infested plants vs. non-infested controls. Infested plants were subjected to 3 d of feeding by 3rd–6th instar weevil larvae. Non-infested plants were not exposed to weevils. Three of the arms of the olfactometer were assigned randomly to a weevil-infested plant, while the remaining three received the non-infested control. IJ nematodes (2,500) were released into the central olfactometer chamber. Twenty-four hours after nematode release, the olfactometer was disassembled, and nematodes from each connecting arm were recovered from soil using Baermann extractors; extracted nematodes were collected and counted with a dissection scope. The tests were replicated with ten nematode releases for each treatment.

In the second experiment, we compared the response of EPNs to weevil-infested plants with larvae alone in sand. The bioassay consisted of three chambers with plants infested with six larvae each (as above) and three chambers containing six larvae in sand only. The experimental protocol and sampling procedures were otherwise identical to experiment 1.

In a third experiment, EPN response was assayed to weevil-infested plants (as above) vs. mechanically damaged roots. The treatments compared consisted of two mechanically damaged plants, two infested plants, and two sand only control arms. Treatments were assigned randomly to chambers. Plant roots were damaged mechanically by stabbing them five times daily with a metal corkborer for 3 d prior to nematode release (7 mm diam). This damage procedure was used because it visually resembled the type of damage inflicted by feeding *D. abbreviatus* larvae after 72 h. All other experimental and sampling procedures were identical to those described for experiment one.

Volatile Collections The objective of this experiment was to identify volatiles emitted by citrus roots damaged by weevil larvae. Volatiles were collected from 1) sand alone (negative control), 2) larvae alone in sand, 3) non-infested plant roots, and 4) weevil-infested roots. Each treatment was prepared within a chamber and connecting arm of the 6-chambered olfactometer and filled with the same 10% moistened sand as in the bioassays. Larvae, non-infested plants, and infested plants were maintained for 3 d before sampling. All plants were maintained in the olfactometer chambers for 3 d prior to weevil infestation. Thereafter, each chamber of the olfactometer containing a treatment was connected to a vacuum pump (ARS, Gainesville, FL, USA) for 24 hr with a suction flow of 0.8 ml/min. Compounds emitted from chambers were collected on adsorbent traps filled with 50 mg Super-Q,800–1000 mesh (Alltech Deerfield, IL, USA) held in glass fittings between the chamber and vacuum pump. Thereafter, Super-Q traps were rinsed with 150 µl of dichloromethane into individual 2.0 ml clear glass vials (Varian, Palo Alto, CA, USA, part number: 392611549 equipped with 500 µl glass inserts).

GC-MS Analysis A 1 µl aliquot of each dichloromethane extract was injected onto a GC-MS gas chromatograph (HP 6890) equipped with 30 m×0.25-mm-ID, 0.25 µm film thickness DB-5 capillary column (Quadrex, New Haven, CT, USA), interfaced to a 5973 Mass Selective Detector (Agilent, Palo Alto, CA, USA), in both electron impact and chemical ionization modes. The column was held at 40°C for 1 min after injection and then programmed at 10±°C/min to 260°C. The carrier gas used was helium at a flow average velocity of 30 cm/sec. Isobutane was used as the reagent gas for chemical ionization, and the ion source temperature was set at 250°C in CI and 220°C in EI. EI Spectra library search was performed using a floral scent database compiled at the Department of Chemical Ecology, Göteborg Sweden, the Adams2 terpenoid/natural product library (Allured Corporation, Adams 1995) and the NIST05 library. When available, mass spectra and retention times were compared to those of authentic standards.

EPN Response to Root Extracts The objective of this experiment was to compare EPN response to solvent extracts of citrus roots before and after weevil feeding. Citrus plants were placed individually into chambers of the 6-arm olfactometer for 3 d as previously described. Thereafter, volatiles were collected from chambers for 24 hr as described above in the volatile collections procedure. Six larvae were placed into each chamber containing a plant and allowed to feed for 3 d. Thereafter, volatiles were collected a second time from the intact feeding system for 24 hr. The adsorbent Super-Q traps from both treatments (before and after feeding) were extracted by rinsing with 150 µl of dichloromethane directly after their 24 hr collections as described above.

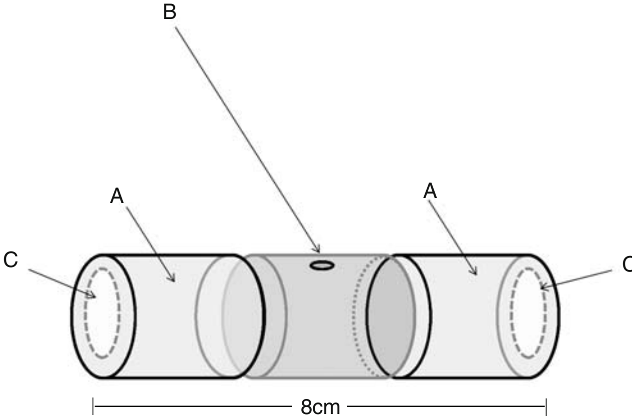


Fig. 1 Schematic diagram of sand column assay unit. Glass jar (17 ml) with samples at base (**a**), connecting tube (3 cm) with hole for nematode application (**b**), extracts placed on filter paper (**c**), arena was filled with heat sterilized sand at 10% moisture for all assays

To quantify EPN response to the root extracts collected, a two choice sand-filled olfactometer was used (Fig. 1). The olfactometer consists of three detachable sections: two opposing glass jars (Fig. 1a) (16 ml BTL, sample type 111, CLR, SNAPC, Wheaton, Millville, NJ, USA), which contained treatments and a central connecting tube 3 cm in length (Blue Max™ 50 ml polypropylene conical tube 30×115 mm, Becton Dickinson Labware, Becton Dickinson Company, Franklin Lakes, NJ, USA), with an apical hole into which nematodes were applied (Fig. 1b). Extracts were placed on filter paper, which was allowed to dry 30 sec for solvent evaporation. Thereafter, filter papers were placed on the bottoms of each glass jar (Fig. 1c), which subsequently were filled with 10% saturated, sterilized sand as described above. The central chamber connecting the two jars (arms of the olfactometer) also was filled with sterilized and moistened sand. The entire olfactometer was 8 cm in length when assembled with two possible extract treatments at opposite ends of the nematode release point. Nematodes (200 IJs) were applied into the central orifice of the connecting tube and given 8 hr to respond. Thereafter, the column was disassembled and the contents of the two collection pots were sampled using Baermann extractors; extracted nematodes were collected and counted. The experiment was replicated ten times.

Statistical Analysis Paired *t*-tests were used to compare nematode response in experiments testing root extracts in the two-choice olfactometers (df=9). Data from experiments using the six-arm olfactometer were analyzed with a log-linear model. Given that these data did not conform to simple variance assumptions implied in using the multinomial distribution, quasi-likelihood functions were used to compensate for the over dispersion of nematodes within the olfactometer (Turlings et al. 2004). The model was fitted by maximum quasi-likelihood estimation in the software package R (R Development Core Team 2004).

Results

Olfactometer Bioassays Significantly more EPNs were found attracted to *D. abbreviatus*-infested roots than non-infested control roots (F=12.76, df=1, 58, P<0.001) (Fig. 2a). Infested roots attracted more EPNs per arm than those containing larvae alone (F=13.78, df=1, 58, P<0.001) (Fig. 2b). More EPNs were attracted to *D. abbreviatus*-infested roots than to either mechanically damaged roots or the sand control (F=12.34, df=2, 57, P<0.001) (Fig. 2c).

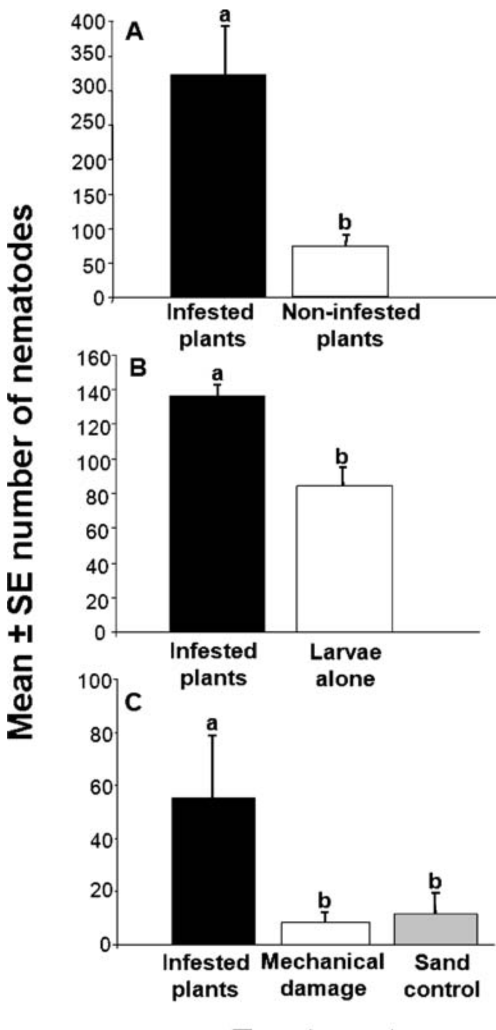

Fig. 2 Mean number of *Steinernema diaprepesi* attracted to chambers containing weevil-infested plants vs. non-infested control plants (**a**), weevil-infested plants versus larvae alone (**b**), weevil-infested plants, mechanically damaged plants or sand control (**c**). Each panel represents a separate experiment (N=10) conducted in a 6-arm olfactometer. Different letters indicate statistical significance at P<0.001

Table 1 GC-MS identification of volatiles from Swingle citrumelo rootstock (*Citrus paradise* × *Poncirus trifoliate*)

Peak #	RT	Name	CAS#	Infested root	Non-infested root	Larvae only
1	7.50	α-pinene[a,b]	000080-56-8	+	+	−
2	8.08	β-pinene[a,b]	000127-91-3	+	+	−
3	10.81	Geijerene[b]	006902-73-4	+	−	−
4	12.93	Pregeijerene[b]	020082-17-1	+	−	−
5	14.75	α-Santalene[b]	000512-61-8	+	−	−
6	14.93	α-Z-Bergamotene[b]	018252-46-5	+	−	−

[a] Synthetic standard comparison. [b] Indentification was based on comparisons of retention times with standard and spectral data from Adams, EPA, and Nist05 Libraries

There was no significant attraction to mechanically damaged roots as compared with the sand control (P=0.34) (Fig. 2c).

GC-MS Analysis Both α-pinene and β-pinene were identified in non-infested and infested plant roots by GC-MS (Table 1). *Diaprepes abbreviatus*-infested roots released four additional unique compounds that were not present in non-infested roots (Table 1). Two C_{12} terpenes were the most abundant, and they were consistently present in infested roots. These were geijerene and its precursor pregeijerene (Fig. 3). On-column GC/MS analyses showed significantly less geijerene and a comparable increase of pregeijerene, strongly suggesting a thermal degradation of pregeijerene to geijerene during GC analyses with splitless injection. It is therefore an open question how much geijerene might actually be released by the infested roots. The above six compounds were absent from pots containing larvae alone (Table 1).

EPN Response to Root Extracts Significantly more EPNs were found in arms containing solvent extracts of *D. abbreviatus*-infested roots than non-infested roots (P=0.03) (Fig. 4).

Discussion

Interactions between EPNs and their host insects, competitors, and natural enemies are well documented, but the degree to which herbivore-induced plant signals alter EPN orientation is largely unknown (Jaffee and Strong 2005; Duncan et al. 2007). Carbon dioxide has long been known

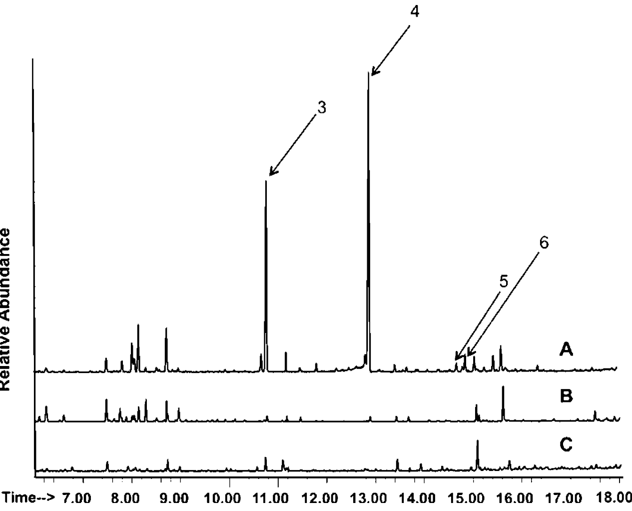

Fig. 3 Example chromatograms showing volatile profiles of *Diaprepes abbreviatus*-infested plants, non-infested plants and larvae alone. Volatile profile of infested *Citrus paradise* × *Poncirus trifoliate* rootstock (**a**) Volatile profile of non-infested *Citrus paradise* × *Poncirus trifoliate* rootstock (**b**) Volatile profile of *D. abbreviatus* alone in sand (**c**). All samples were collected for a 24 hr. Geijerene (3), Pregeijerene (4), α-Santalene (5), α-Z-Bergamotene (6). (Compound numbers correspond to Table 1)

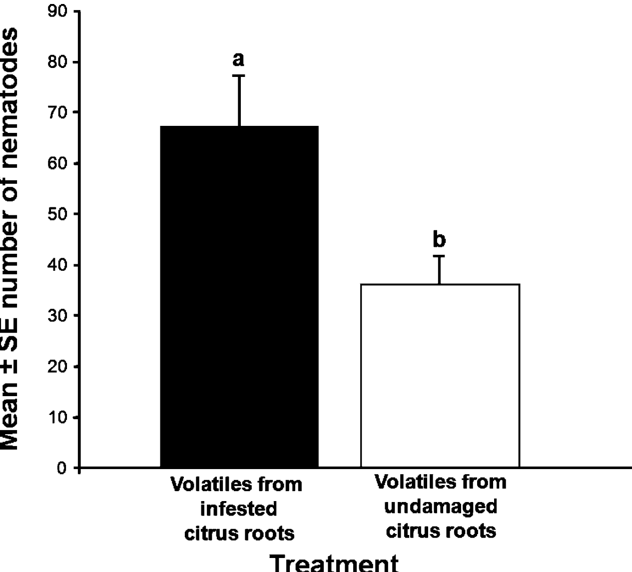

Fig. 4 Mean number of nematodes attracted to volatiles from *Diaprepes abbreviatus*-infested roots compared with volatiles from undamaged roots. Different letters indicate statistical significance at P=0.03

to attract nematodes to plant roots (Gaugler et al. 1980; Prot and Van Gundy 1981). However, functioning alone, such an ambiguous signal might not allow efficient host location by EPNs. van Tol and Sommen (2001) postulated that plants produce induced compounds that attract EPNs; this hypothesis has been confirmed in two systems (Boff et al. 2002; Rasmann et al. 2005). Furthermore, (*E*)-β-caryophyllene has been identified as the specific EPN recruitment signal emitted by maize roots damaged by corn rootworms (Rasmann et al. 2005).

The current results indicate that Swingle citrumelo rootstock releases herbivore induced volatiles that recruit EPNs. Our results also suggest that 'geijerenes' mediate this response. These C_{12} terpenes have not been described for citrus previously; however, they are known for insecticidal, antifeedant, and oviposition deterrent effects in leaves of other rutaceous plant species (Kiran et al. 2006; Kiran and Devi 2007). Geijerenes also have been described in hairy root cultures of *Pimpinella anisum* (Santos et al. 1998). Although these compounds were consistently present in infested root samples and are presumed candidate attractants for *S. diaprepesi*, we have yet to confirm the behavioral activity of the individual compounds. Solvent extracts of infested roots attracted *S. diaprepesi* suggesting that one or a blend of these compounds may be active. Fractionation studies of the induced compounds via preparative gas chromatography in concert with two choice bioassays of the partitioned profile may enable us to resolve the role of individual compounds on EPN behavior.

Recent identification of an EPN recruitment chemical is in the initial stages of application for crop protection and has been promising (Degenhardt et al. 2003, 2009; Turlings and Ton 2006). Direct application of (*E*)-β-caryophyllene to soil has been shown to reduce rootworm damage through enhanced action of their EPNs (Rasmann et al. 2005). Furthermore, recent advances in biochemistry/molecular genetics have made it possible to engineer cultivated maize that releases (*E*)-β-caryophyllene and recruits EPNs, thus protecting roots from herbivore damage (Degenhardt et al. 2003, 2009; Hiltpold et al. 2010). The currently investigated citrus rootstock system is different from the annual maize cropping system for which EPN recruitment is already being developed for corn rootworm management. Perennial systems characterized by fewer disturbances are believed to support more effective biological control than annually disturbed crops (Southwood and Comins 1976). Thus, augmenting the impact of *S. diaprepesi* in a perennial tree fruit system by application of recruitment chemicals may prove even more effective than in annual crops.

It also will be informative to investigate the parent lines of the Swingle rootstock, *Citrus paradisi* and *Poncirus trifoliata* to determine if either or both lines exhibit the herbivore-induced EPN recruitment seen in the hybrid. We plan also to investigate if other non-citrus hosts of *D. abbreviatus* release induced recruitment signals. Given the wide host range of *D. abbreviatus,* it will be important to determine the breath of this EPN recruitment response among its diverse host plants.

Several nematode species attack *D. abbreviatus*. *Steinernema glaseri*, *S. carpocapsae*, and *Heterorhabditis bacteriophora* were investigated initially as possible control agents (Downing et al. 1991; Schroeder 1992). Of the species evaluated in laboratory bioassays and greenhouse trails, *S. riobrave* and a Florida isolate of *H. indica* were the most effective (Shapiro-Ilan and McCoy 2000). Currently, *S. riobrave* and *H. indica* are formulated for commercial application against *D. abbreviatus* in Florida citrus. These two EPN species, in addition to *S. diaprepesi*, will be evaluated and compared in similar future studies to determine whether the tentatively identified EPN recruitment signals are specific to the natively occurring EPN associated with the weevil or whether these signals function more broadly for other EPN species.

We report here for the first time an *in situ* method for sampling subterranean herbivore-induced volatiles during real time insect feeding. Previously used methods involve freeze-drying and crushing root samples (Rasmann et al. 2005), which will affect and misrepresent volatile production from intact roots. The currently described method allows identification of belowground volatiles as they are released over time without disturbance to the system.

The current results indicate that a commercially used citrus rootstock emits induced volatile chemicals in response to herbivore feeding that attract beneficial nematodes. Identification of the specific active compounds may lead to the development of an augmentive EPN recruitment tactic that improves biological control of *D. abbreviatus*. Also, such identification would be the first step towards development of genetically-engineered citrus rootstocks for enhanced recruitment of EPNs. Alternatively, it is possible that engineering plants for increased release of terpenes in general may prove effective (Schnee et al. 2006).

Acknowledgements We thank Dr. L. Duncan (University of Florida) for help with initiation of nematode cultures. We thank Dr. P. Teal (USDA-ARS-CMAVE) for facilitating access to laboratory space and equipment. Comments from Drs. L. Duncan and R. Campos-Herrera (University of Florida) and two anonymous reviewers improved a previous version of the manuscript. This work was partially supported by a USDA-CSREES special grant to LLS.

Induction of Phenolic Glycosides by Quaking Aspen (*Populus tremuloides)* Leaves in Relation to Extrafloral Nectaries and Epidermal Leaf Mining

Brian Young · Diane Wagner · Patricia Doak · Thomas Clausen

Abstract We studied the effect of epidermal leaf mining on the leaf chemistry of quaking aspen, *Populus tremuloides*, during an outbreak of the aspen leaf miner, *Phyllocnistis populiella*, in the boreal forest of interior Alaska. *Phyllocnistis populiella* feeds on the epidermal cells of *P. tremuloides* leaves. Eleven days after the onset of leaf mining, concentrations of the phenolic glycosides tremulacin and salicortin were significantly higher in aspen leaves that had received natural levels of leaf mining than in leaves sprayed with insecticide to reduce mining damage. In a second experiment, we examined the time course of induction in more detail. The levels of foliar phenolic glycosides in naturally mined ramets increased relative to the levels in insecticide-treated ramets on the ninth day following the onset of leaf mining. Induction occurred while some leaf miner larvae were still feeding and when leaves had sustained mining over 5% of the leaf surface. Leaves with extrafloral nectaries (EFNs) had significantly higher constitutive and induced levels of phenolic glycosides than leaves lacking EFNs, but there was no difference in the ability of leaves with and without EFNs to induce phenolic glycosides in response to mining. Previous work showed that the extent of leaf mining damage was negatively related to the total foliar phenolic glycoside concentration, suggesting that phenolic glycosides deter or reduce mining damage. The results presented here demonstrate that induction of phenolic glycosides can be triggered by relatively small amounts of mining damage confined to the epidermal tissue, and that these changes in leaf chemistry occur while a subset of leaf miners are still feeding within the leaf.

Key Words *Populus tremuloides* · *Phyllocnistis populiella* · Epidermal leaf mining · Induced defense · Phenolic glycosides · Extrafloral nectaries · Alaska

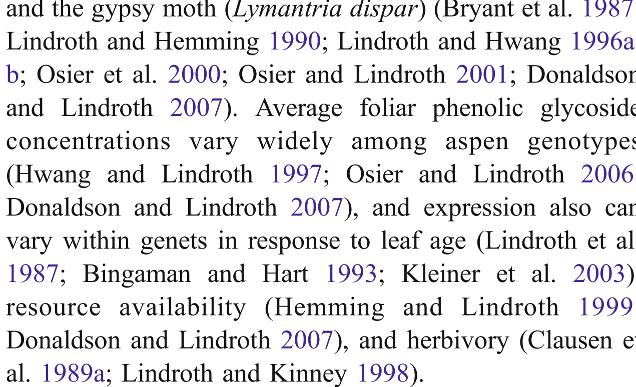
Introduction

Some plants respond to herbivore damage by increasing production of chemical, physical, or biotic defenses, responses that can help protect the remaining tissue against further damage (Karban and Baldwin 1997). Induction of resistance traits may have evolved in response to the costs of resistance. Such costs may include tradeoffs in resource allocation between growth and resistance and enhanced apparency to specialist herbivores that use resistance traits to locate hosts (Rhoades 1979; Strauss et al. 2002). For trees such as immature *Populus* spp., which must grow quickly to avoid being shaded by competitors or consumed by browsers (Bokalo et al. 2007), cost savings may allow a greater proportion of resources to be invested in early growth and survival.

Quaking aspen (*Populus tremuloides* Michx.) is a fast-growing forest tree subject to attack by a variety of vertebrate and invertebrate herbivores, including several

insect species subject to large-scale population outbreaks (Mattson et al. 2001). Since the late 1990s and continuing through 2009, aspen in Alaska and western Canada have experienced a severe outbreak of the aspen leaf miner (*Phyllocnistis populiella* Chambers, Lepidoptera: Gracillariidae) (Fig. 1a) (U.S. Forest Service 2006, 2007, 2008). Unlike most leaf miner taxa, which feed on the photosynthetic tissue of the mesophyll, *P. populiella* feeds only on the cells of the leaf epidermis, removing very little leaf biomass (Condrashoff 1964) (Fig. 1b). Although feeding damage is restricted to the epidermis, at high density *P. populiella* can reduce photosynthesis and slow the growth of aspen ramets (Wagner et al. 2008).

The leaves of aspen trees produce phenolic glycosides, which can provide resistance against some herbivores (Philippe and Bohlmann 2007). Four types of phenolic glycosides appear in aspen leaves, salicin, salicortin, tremuloidin, and tremulacin, with salicortin and tremulacin having greater biological activity than the others (Lindroth et al. 1987). Phenolic glycosides can reduce the growth rate and survivorship of several of aspen's most devastating pests, including the large aspen tortrix (*Choristoneura conflicta*), the forest tent caterpillar (*Malacosoma disstria*),



and the gypsy moth (*Lymantria dispar*) (Bryant et al. 1987; Lindroth and Hemming 1990; Lindroth and Hwang 1996a, b; Osier et al. 2000; Osier and Lindroth 2001; Donaldson and Lindroth 2007). Average foliar phenolic glycoside concentrations vary widely among aspen genotypes (Hwang and Lindroth 1997; Osier and Lindroth 2006; Donaldson and Lindroth 2007), and expression also can vary within genets in response to leaf age (Lindroth et al. 1987; Bingaman and Hart 1993; Kleiner et al. 2003), resource availability (Hemming and Lindroth 1999; Donaldson and Lindroth 2007), and herbivory (Clausen et al. 1989a; Lindroth and Kinney 1998).

In addition to phenolic glycosides, aspen also produce extrafloral nectaries (EFNs). Studies of other plant species indicate that EFNs can function as an indirect defense by attracting arthropod predators and parasitoids of herbivores to the plant (Bentley 1977; Koptur 1992; Röse et al. 2006). In some populations, EFNs increase plant fitness by reducing tissue loss to herbivores (Heil et al. 2004; Rudgers et al. 2004). EFN expression in aspen is extremely variable. EFNs occur on only a subset of aspen leaves, and the frequency of EFN expression varies among shoots, ramets, and genets (Doak et al. 2007). At the level of the leaf, the expression of EFNs and phenolic glycoside concentrations co-vary (Young et al. 2010). After controlling for mean differences among sites, ramets, and shoots, concentrations of foliar phenolic glycosides are about 30% higher in leaves with EFNs than in leaves lacking them (Young et al. 2010). On short aspen ramets, leaves bearing EFNs sustain lower levels of epidermal leaf mining than leaves lacking EFNs (Doak et al. 2007), but this difference may be caused by the higher phenolic glycoside content of EFN-bearing leaves, rather than by the indirect defense of EFN-bearing leaves by the leaf miner's natural enemies (Mortensen 2009; Young et al. 2010).

In this study, we tested whether leaf mining damage restricted to the epidermis induces the production of phenolic glycosides salicortin and tremulacin in leaves with and without EFNs. By comparing the phenolic glycoside concentrations of leaves collected serially from ramets with natural and reduced levels of leaf mining, we tracked the time course of phenolic glycoside expression in young aspen leaves and investigated whether induction has the potential to impact the performance of *P. populiella*.

Methods and Materials

Natural History Quaking aspen is widely distributed in North America (Mitton and Grant 1996) and reproduces both sexually and asexually, resulting in the formation of clonal stands. In the interior of Alaska, it tends to grow on south facing hillsides and along ridgelines.

The EFNs of *P. tremuloides* are located at the junction of the petiole and the leaf (Trelease 1881). The number of EFNs on a leaf can vary from 0 to 6, with most leaves possessing 0 or 2 (Doak et al. 2007). Among the preformed leaves, the first 5 to 8 leaves to emerge in spring (Critchfield 1960), EFNs are consistently expressed on the most proximal leaf, with frequency of expression decreasing distally along the shoot (Doak et al. 2007). In contrast, the neoformed leaves, which emerge later and extend the growing shoot, typically all possess EFNs (Doak et al. 2007). We focused on the preformed leaves in this study.

The aspen leaf miner *P. populiella* overwinters as an adult and emerges in early to mid May, prior to bud break. Oviposition begins as soon as the protective bud scales are shed, exposing the furled aspen leaves, and continues for about 10 d. Eggs are laid singly on both the upper and lower surfaces of young leaves. The eggs sink into the leaf tissue, and about a week after oviposition the larvae hatch directly into the epidermal tissue. The developing larvae feed on the cells of the leaf epidermis, leaving obvious tracks or mines. Larvae remain on the leaf surface on which they hatched and feed for 9–15 d (Condrashoff 1964). In the final instar, which lasts ≤2 d, larvae cannot feed and form leaf folds in which to pupate (Condrashoff 1964). During the years of this study (2006 and 2007), the median preformed leaf at the study site hosted a single leaf fold (Doak and Wagner, unpublished survey data).

Field Method To investigate the effects of epidermal leaf mining on aspen phenolic glycoside concentrations, we first (2006) experimentally reduced leaf miner densities on a set of aspen ramets by using an insecticide, and we contrasted the mean foliar phenolic glycoside concentration of insecticide-sprayed and naturally-mined ramets at a single point in time. The following year (2007), we measured the concentration of phenolic glycosides on insecticide-sprayed and naturally-mined ramets at intervals during the period of active feeding by the leaf miner.

In early June of 2006, we randomly chose a set of 12 small ramets (0.8–1.2 m in height) near the summit of Ester Dome (64°52′56″N, 148°03′57″W, elevation 720 m) near Fairbanks, Alaska. Ramets were located within a 20× 20 m area and exhibited similar physical characteristics; however, we cannot be certain that they all belonged to a single clone. Of the 12 ramets, half were assigned at random to receive an insecticide treatment. Just as the *P. populiella* eggs began to hatch, the treatment ramets were sprayed with the insecticide spinosad (Conserve; Dow AgroSciences, Indianapolis, IN.USA; concentration 1.56 ml l^{-1}; applied with a hand-powered pump sprayer until runoff). The insecticide was reapplied 6 d later. When the treatment ramets were sprayed with the insecticide, the remaining ramets were sprayed with an equal quantity of water.

This experiment relied on the assumption that the application of insecticide does not prevent aspen from producing an induced response to damage. To test this assumption, we took advantage of the ability of aspen leaves to mount a rapid, localized induction of phenolic glycosides in response to mechanical leaf damage (Clausen et al. 1989a). One day before we planned to harvest the insecticide-sprayed and naturally-mined leaves, we damaged 6 randomly-chosen leaves, from leaf positions 1–5 from two separate shoots, on each of the ramets that had been sprayed with insecticide by cutting them in half diagonally across the mid vein with scissors.

We harvested all leaves (naturally-mined, sprayed, and sprayed and mechanically damaged) 11 d following the approximate onset of leaf mining. At this point, 80–90% of the leaves on the naturally-mined ramets possessed one or more pupal folds, indicating that most of the aspen leaf miner larvae had ceased to feed (Condrashoff 1964). We sampled preformed leaves from the 5 most proximal leaf positions from 3 randomly-chosen shoots per ramet. Leaves were snipped at the petiole and immediately immersed in 10 ml of 50% aqueous MeOH . Cold 50% aqueous MeOH effectively extracts phenolic glycosides from aspen leaves (Bryant et al. 1987; Lindroth and Pajutee 1987). We maintained the leaf samples in solution at 2°C±1°C for 24 h. The leaves were then removed from the extract solution and pressed in a plant press for subsequent analysis of herbivore damage. The extract was stored at −40°C until analysis was conducted.

For each leaf, we counted the number of EFNs and visually estimated leaf mining on the top and bottom surfaces of the leaf and the percent of leaf tissue missing and/or damaged by other herbivores to the nearest 5.0 %. Our visual estimates of mining correlated strongly with measurements made using image analysis software (R^2> 0.9, Doak et al. 2007). For simplicity, we report % total leaf surface mined, calculated as the average of % mining on the top and bottom surfaces. Leaves were scanned using a desktop scanner and leaf area was measured using the image analysis program Scion Image (Fredrick, MD, USA). Leaves were dried at 60°C for 1 wk and weighed to the nearest 0.1 mg.

To determine how foliar phenolic glycoside concentrations changed on a finer time scale during the period of feeding by *P. populiella*, we conducted a second experiment at the same study area in May 2007. We chose 42 ramets ranging in size from 0.5 to 1.6 m in height; all located within a 25×25 m area adjacent to the 2006 site. Again, the genetic identity of the plants was not known. We assigned half of the ramets at random to receive an insecticide treatment. On the day that it appeared that the majority of

leaf miner eggs had hatched, we applied insecticide to treatment ramets and water to the others. The method of insecticide application was identical to the previous year. To accommodate repeated sampling while avoiding the removal of excessive numbers of leaves from individual ramets, we used a larger number of ramets than in 2006 and sampled each ramet on only two occasions. Leaf samples were collected on days 1, 2, 4, 5, 6, 9, and 12 after the onset of leaf mining. On each sampling day, we sampled preformed leaves from leaf positions 2 and 3 on a single shoot from 6 naturally-mined and 6 insecticide-sprayed ramets, chosen at random from the set of ramets that had not yet been sampled. Leaves were again sampled by cleanly snipping leaves at the petioles. Mattson and Palmer (1988) did not find a chemical response of the ramet when the leaf was sampled in this manner. When each ramet had been sampled once, we resampled each ramet a second time, using a different shoot. All leaf samples were handled and processed as in the previous year.

Chemical Analysis We prepared the aspen leaf extracts for analysis by filtering a 1.0 ml aliquot of extract through a 0.45 μm pore poyproplyene membrane syrine filter (Acrodisc, Thermo Fisher Scientific, Waltham, MA, USA). Samples were injected onto a 4.6×250 mm XDB-C8 column (Agilent) attached to a High Performance Liquid Chromatography (HPLC) (Agilent 1100) equipped with a UV/VIS diode array detector (Agilent) and analyzed at 230 nm. The phenolic glycosides were separated using a mobile phase gradient of acetonitrile (CH_3CN) and H_20 with a constant flow rate of 1.0 ml/min. The gradient elution was: 1% CH_3CN (0–4 min), 1–60% CH_3CN (4–10 min), 60–80% CH_3CN (10–15 min), 100% CH_3CN (15–22 min), and 100–1% CH_3CN (22–27 min). This was followed by a 10 min period at 1% CH_3CN prior to the injection of next sample. Salicortin and tremulacin were quantified using purified reference standards (Clausen et al. 1989b).

Statistical Analyses For both 2006 and 2007 data sets, we compared the % leaf mining damage, and the % leaf damage caused by other herbivores, on insecticide-sprayed vs. naturally-mined ramets using Wilcoxon tests.

Preliminary data analysis showed that concentrations of salicortin and tremulacin were highly correlated within leaves (R=0.8, df=166, P<0.01), responded similarly to treatment, and changed in similar ways over time. For simplicity, we therefore report total phenolic glycoside concentrations, calculated as the sum of salicortin and tremulacin.

To test whether insecticide treatment prevented induction of phenolic glycosides in response to damage, we compared the phenolic glycoside concentration of experimentally cut and uncut leaves (2006 data) using a mixed model analysis of covariance (ANCOVA) with mechanical damage as a fixed effect, leaf position as a covariate, and ramet and shoot as random effects.

To test the effect of leaf mining on foliar phenolic glycoside concentration (2006 data, leaves mined for 11 d) we again used ANCOVA, with insecticide treatment, EFNs (dichotomous: absence vs. presence), and their interaction as fixed effects, leaf position as a covariate, and shoot and ramet as random effects.

We tested when induction occurred (2007 data) by comparing the phenolic glycoside concentrations of leaves from naturally-mined and insecticide-sprayed ramets within each sampling date. We first ran a mixed model ANCOVA with insecticide treatment, day sampled, and their interaction as fixed effects, leaf position as a covariate, and shoot and ramet as random effects. We then conducted planned contrasts of the mean foliar phenolic glycoside concentration of naturally-mined and insecticide-sprayed ramets within each sampling day.

Phenolic glycoside concentrations were log transformed to meet parametric assumptions. Mixed model analyses applied the restricted maximum likelihood method and were conducted using JMP IN version 5.1.2 using the Kenward and Roger (1997) method to calculate denominator degrees of freedom (SAS Institute, Cary, NC, USA).

Results

The insecticide treatment prevented all detectable leaf mining damage by *P. populiella* on the treated ramets during both 2006 and 2007 (Table 1). Across all experimental trees, leaf mining represented by far the greatest source of leaf damage, although a small amount of chewing, skeletonizing, and galling damage were also observed (Table 1). Leaf damage due to herbivores other than *P. populiella* was not reduced significantly by the insecticide treatment (Table 1).

Foliar phenolic glycosides were induced in insecticide-sprayed leaves in response to mechanical leaf damage. One day after leaves on sprayed ramets were cut with scissors, the cut leaves had higher concentrations of phenolic glycosides than un-cut leaves ($F_{1,\ 113}$=6.45, P=0.012). The average phenolic glycoside concentration of the cut leaves was 37% higher then the undamaged leaves (back-transformed least square means; damaged leaves=27.3 mg/g, undamaged leaves=19.9 mg/g).

Leaf mining by *P. populiella* induced foliar phenolic glycosides. Eleven days after the approximate onset of leaf mining in 2006, the foliar phenolic glycoside concentration was, on average, 125% higher for ramets that had sustained natural levels of leaf mining damage than for ramets

Table 1 Percent leaf damage (mean±SE) by *Phyllocnistis populiella* and other herbivore taxa after experimental reduction in leaf miner abundance 11 days post treatment. "Other damage" is the sum of chewing, skeletonizing, and galling

sprayed with insecticide (Fig. 2; $F_{1,\ 10}=7.58$, $P<0.001$). Across all naturally-mined and insecticide-sprayed ramets, leaves with EFNs contained on average 26% higher concentrations of phenolic glycosides than leaves lacking EFNs (Fig. 2; $F_{1,\ 148}=5.40$; $P=0.021$). EFN presence and treatment did not interact ($F_{1,\ 145}=0.08$; $P=0.77$), indicating that leaves with and without EFNs were similar in their ability to induce phenolic glycosides in response to mining. Foliar phenolic glycoside concentrations increased along the shoot, with the most distal leaves having the highest concentrations (Fig. 3; $F_{1,\ 144}=6.14$; $P<0.01$).

By monitoring the time course of induction during the next growing season (2007), we found that induction occurred approximately 6–9 days after the onset of mining. Because on each collection day we harvested many fewer leaves ($N=12$) than in the 2006 experiment ($N=180$), we had less statistical power to detect differences between treatments. In the overall ANCOVA model, the mean phenolic glycoside content of leaves varied over time ($F_{6,\ 50}=2.85$, $P=0.01$), but there was no statistically significant effect of insecticide treatment ($F_{1,\ 37}=2.30$, $P=0.14$) or interaction between treatment and time ($F_{6,\ 50}=1.12$, $P=0.36$). However, the results of planned contrasts within days provided information about the timing of induction. During the first six days, average phenolic glycoside concentrations in both naturally-mined and insecticide-sprayed leaves rose, peaking at day 4, and then declined (Fig. 4a). Contrasts within sampling day revealed no significant differences in phenolic glycoside concentration between naturally-mined and insecticide-sprayed leaves up to and including day 6 ($P>0.05$). However, after day 6 the two groups diverged, and the average phenolic glycoside concentration was higher in naturally-mined leaves than in insecticide-treated leaves on day 9 (Fig. 4a, $F_{1,\ 67}=4.42$, $P=0.04$). The average phenolic glycoside concentration of both insecticide-treated and naturally mined ramets increased somewhat between days 9 and 12. While average phenolic glycoside concentration of the mined trees still exceeded that of insecticide-treated trees on day 12, the difference was no longer statistically significant (Fig. 4a, $F_{1,\ 69}=3.32$, $P=0.07$). Leaf mining damage extended over approximately 5% of the leaf surface at the time induction was noted (Fig. 4b).

Values are back transformed least squared means±SE. There was a significant effect of insecticide treatment ($P<0.001$) and EFN presence ($P<0.05$), and no interaction between insecticide treatment and EFNs ($P>0.05$)

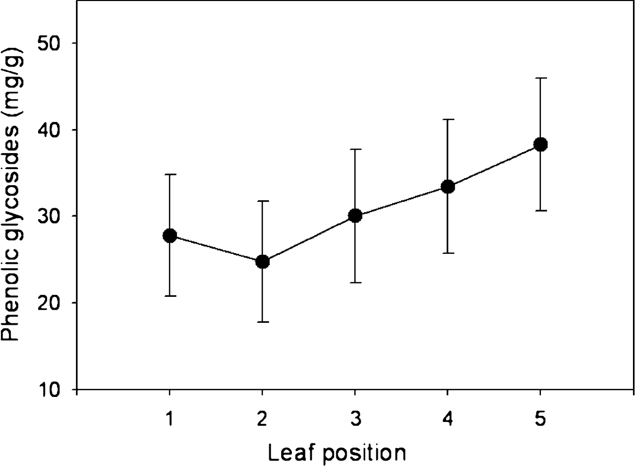

Fig. 3 Concentrations of foliar phenolic glycosides from leaf positions 1 through 5 during the summer of 2006. Values are back transformed least squared means±SE

Although some leaf miner larvae had ceased to feed by the time induction was detected, a subset of larvae apparently ingested leaves containing induced levels of phenolic glycosides. About 25% of sampled leaves possessed at least one pupal leaf fold (indicating that feeding had ceased) on day 6, and this percentage rose to 42% by day 9 (Fig. 4c), the day we observed induced levels of phenolic glycosides (Fig. 4a). On day 12, 92% of leaves had at least one pupal fold, indicating that approximately half of the leaves still contained feeding larvae on day 9 (Fig. 4c). Moreover, a substantial amount of feeding damage occurred post-induction (Fig. 4b), indicating that some larvae continued to feed following the damage-induced increase in phenolic glycoside concentration between days 9 and 12.

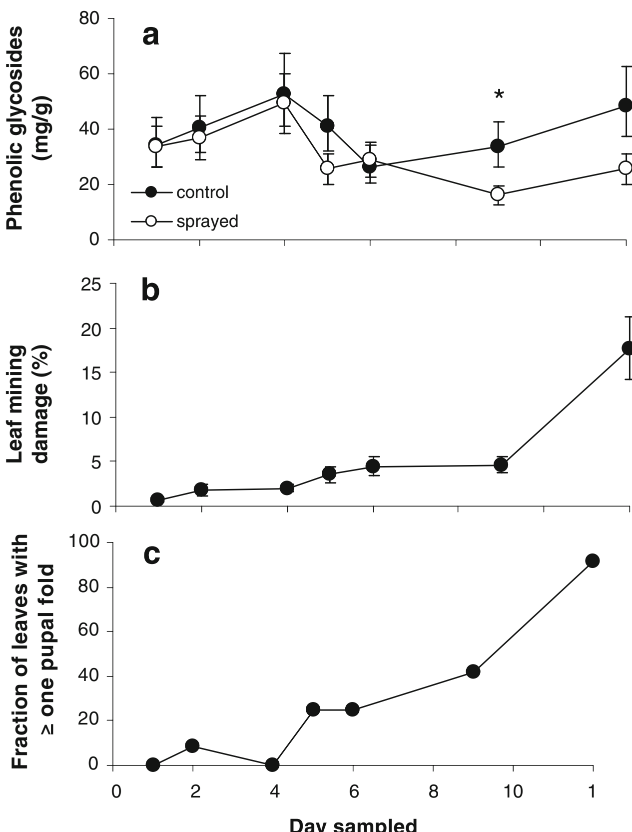

Fig. 4 Variation over time in **a** total foliar phenolic glycoside concentration (back transformed least squared means±SE) of naturally-mined (*filled symbols*) and insecticide-sprayed (*open symbols*) ramets; **b** mining damage (means±SE) on naturally-mined ramets and (**c**). the fraction of leaves sampled from naturally-mined ramets on which at least one leaf miner had ceased to feed and formed a pupal fold. Data are from summer 2007. The asterisk indicates that, on this sampling date, the contrast between average phenolic glycosides in naturally-mined and insecticide-sprayed leaves was statistically significant at $P<0.05$

Discussion

Damage to the epidermis caused by the mining activity of *P. populiella* led to the induction of phenolic glycosides in aspen leaf tissue. Epidermal leaf mining, while geographically widespread and ecologically important, is taxonomically restricted to a small subset of leaf miner taxa (Hering 1951). Consequently, few studies have investigated the physiological consequences of this form of herbivory for plants. In contrast, the vast majority of leaf mining species feed primarily on the photosynthetic cells of leaf mesophyll (Hering 1951). Studies investigating the effect of mesophyll mining on the chemistry of a variety of plant species report that mining can cause induced responses (Stout et al. 1994; Karban and Adler 1996; Inbar et al. 1999), although investigations of the induction of phenolic compounds in particular generally have reported negative results (Fisher et al. 2000; Ramiro et al. 2006).

Our results suggest that phenolic glycosides were induced while many leaf miner larvae were still feeding and growing and before the majority of the mining damage was inflicted on leaves (Fig 4). Phenolic glycosides are expressed in the epidermal tissue of aspen (Kao et al. 2002), thus it appears that *P. populiella* larvae ingest phenolic glycosides as they feed. Phenolic glycosides have negative effects on growth and survivorship of several generalist lepidopteran herbivores of aspen (Bryant et al. 1987; Hemming and Lindroth 1995; Hwang and Lindroth 1997; Osier and Lindroth 2001), but specialist herbivores, such as *P. populiella*, often are resistant to the effects of host plant secondary chemistry. However, natural patterns of leaf mining on leaves varying in phenolic glycoside concentration support the hypothesis that phenolic glycosides reduce *P. populiella* feeding damage (Young et al. 2010).

Treatment with insecticide did not prevent aspen leaves from inducing phenolic glycosides in response to mechanical damage. One day after mechanical damage was imposed, insecticide-sprayed leaves that were cut had 37% higher phenolic glycoside concentrations than sprayed leaves that were not cut. Clausen et al. (1989a) found that mechanically damaged aspen leaves contained 15% more phenolic glycosides (salicortin and tremulacin combined) than undamaged leaves one day post-damage. The data suggest that the difference in foliar phenolic glycoside concentration between aspen ramets sprayed with insecticide and ramets naturally damaged by leaf miners reflects induction caused by leaf mining, rather than an artifact of the insecticide treatment.

The concentration of phenolic glycosides was 26% higher in leaves with EFNs than in leaves lacking EFNs, in both the damaged and undamaged states. There was no

evidence that leaves with EFNs induced phenolic glycosides more strongly than leaves without EFNs; rather, leaves with and without EFNs both increased in phenolic glycoside concentration by approximately 125% in response to leaf mining (Fig. 2). High levels of phenolic glycosides in EFN-bearing leaves may help to explain the previously reported pattern of lower mining on these leaves (Doak et al. 2007). The association between EFNs and phenolic glycosides is addressed in greater detail elsewhere (Young et al. 2010).

In this study, approximately 9 days of mining damage accumulated before phenolic glycoside induction was observed. The newly-unfurled leaves may have been too young to mount an induced response. Alternatively, a threshold amount of damage may be required before aspen leaves respond by up-regulating phenolic glycoside expression (Underwood 2000). At the onset of induction in our study, approximately 5% of the total leaf epidermis was mined. While low, this level of damage falls within the range of damage levels documented to trigger induced resistance among species (Karban and Baldwin 1997).

Aside from the induction response, we observed considerable ontogenetic variation in the phenolic glycoside content of leaves. This also has been observed in previous studies (Lindroth et al. 1987; Osier et al. 2000). Foliar concentrations of phenolic glycosides varied more than 2-fold during the first six days of sampling and prior to the herbivore-induced response (Fig 4a). It is possible that the generally high concentrations of phenolic glycosides observed during the first four sampling days were induced by damage caused by eggs or newly hatched leaf miner larvae prior to insecticide application. However, we find this unlikely because the phenolic glycoside concentration subsequently declined between days 4 and 6 on both insecticide-sprayed and naturally-mined trees. More likely, the increase in concentration between days 1 and 4 reflected up-regulation of phenolic compounds during early leaf development, and the subsequent decrease in the concentration of phenolic glycosides after sampling day 4 reflected dilution of phenolic glycosides as the leaf gained mass (Jones and Hartley 1999). Regardless of the mechanism, high constitutive concentrations of phenolic glycosides in these newly-developing leaves, albeit short-lived, could present a challenge to some early spring herbivores.

Induced defenses can be costly to deploy (Agrawal et al. 1999). For aspen, detection of a cost of allelochemical expression depends upon the environmental conditions (Stevens et al. 2007). However, tradeoffs between aspen allelochemical expression and growth have been reported by several studies (Hwang and Lindroth 1997; Osier and Lindroth 2006; Stevens et al. 2007) suggesting that the production of phenolic glycosides may be costly. Aspen ramets naturally mined by *P. populiella* grew more slowly than those treated with insecticide to reduce mining damage (Wagner et al. 2008). In addition to the direct costs of herbivory that stem from decreased photosynthesis and early leaf abscission in mined leaves (Wagner et al. 2008), the cost of induction of phenolic glycosides in response to *P. populiella* mining damage may have contributed to the slow growth of naturally-mined ramets.

In summary, our results demonstrate that *P. populiella* mining damage to a small fraction (<10%) of the epidermis of aspen leaves induced the production of phenolic glycosides. The induction response did not occur immediately upon initiation of mining, suggesting that a threshold amount of damage was necessary to trigger the induction response. The onset of induction occurred while many of the leaf miners were still feeding; hence, induction of phenolic glycosides may increase aspen resistance to *P. populiella* herbivory. Higher constitutive and induced concentrations of phenolic glycosides on leaves with EFNs, relative to those without EFNs, may contribute to previously-reported lower mining damage on leaves bearing EFNs (Doak et al. 2007).

Acknowledgment We thank Shandra Miller and Sara Young for assistance with data collection. Colin McGill provided technical assistance and advice with the HPLC. We also thank Diana Wolf and Julie McIntyre for valuable insight and input. This research was funded by NSF DEB 0543632 to DW and PD. B. Young was partially supported by TASK (Teaching Alaskans, Sharing Knowledge), an NSF supported GK-12 Program.

Abstract We examined the effects of water and nutrient availability on the expression of the defense pyrrolizidine alkaloids (PAs) in *Senecio jacobaea* and *S. aquaticus*. *Senecio jacobaea*, and *S. aquaticus* are adapted to different natural habitats, characterized by differing abiotic conditions and different selection pressures from natural enemies. We tested if PA concentration and diversity are plastic over a range of water and nutrient treatments, and also whether such plasticity is dependent on plant species. We also tested the hypothesis that hybridization may contribute to PA diversity within plants, by comparing PA expression in parental species to that in artificially generated F_1 hybrids, and also in later generation natural hybrids between *S. jacobaea* and *S. aquaticus*. We showed that total PA concentration in roots and shoots is not dependent on species, but that species determines the pattern of PA diversification. Pyrrolizidine alkaloid diversity and concentration are both dependent on environmental factors. Hybrids produce a putatively novel PA, and this PA is conserved in natural hybrids, that are backcrossed to *S. jacobaea*. Natural hybrids that are backcrossed several times to *S. jacobaea* are with regard to PA diversity significantly different from *S. jacobaea* but not from *S. aquaticus*, while F_1 hybrids are in all cases more similar to *S. jacobaea*. These results collectively suggest that PA diversity is under the influence of natural selection.

Key Words Hybridization · Secondary metabolite diversity · Plant resistance · Alkaloid composition · Phenotypic plasticity

Introduction

Plants mediate interactions with herbivores and pathogens by production and distribution of secondary metabolites among various plant tissues. Herbivores are either deterred by (van Dam et al. 1995; Macel et al. 2005) or attracted to (Rauscher 2001) secondary metabolites. The community of soil organisms in the plant rhizosphere also is often determined by the composition of secondary metabolites in plant roots (Hol et al. 2004; Kowalchuk et al. 2006), and such metabolites can decrease growth of particular microbial species, and stimulate the growth of others (Hol and van Veen 2002). A single plant species often possesses many structural variations within single classes of secondary metabolites, and often it has been hypothesized that diversity of secondary metabolites is partially explained by selection pressure by herbivores and pathogens (Hol and van Veen 2002; Adler and Kittelson 2004; Macel et al. 2005; Albrechtsen et al. 2007). In many cases, environmental factors also are correlated with large variations in concentration, allocation, and diversity of secondary metabolites (Holton et al. 2003; Close et al. 2005; Loney et al. 2006).

Pyrrolizidine alkaloids (PAs) occur in a number of families including Apocynaceae, Asteraceae, Boraginaceae, and Orchidaceae (Hartmann and Witte 1995). They are toxic to generalist mammalian (Cheeke 1988) and insect (van Dam et al. 1995; Macel et al. 2005) herbivores, and may play a role in pathogen resistance (Hol and van Veen 2002; Kowalchuk et al. 2006). Pyrrolizidine alkaloid

composition, including concentration and diversity, exhibits some plasticity, and can alter in response to plant developmental cues (Schaffner et al. 2003), abiotic environment (Macel and Klinkhamer 2009), and interactions with natural enemies (Hol et al. 2004).

The *Senecio* genus (Asteraceae) contains more than 1500 species and, the production of PAs is widespread. In *Senecio*, PAs are synthesized as senecionine *N*-oxide in plant roots (Hartmann and Toppel 1987). Senecionine *N*-oxide is transported through the phloem to the shoots (Hartmann and Dierich 1998) where diversification into a number of related PA structures occurs. PA diversification is species specific, such that the suite of PAs within a plant species is generally unique (e.g., Pelser et al. 2005). Furthermore, significant variation in PA composition and concentration within *Senecio* species has been observed (Trigo et al. 2003; Macel et al. 2004).

We investigated the effects of both the abiotic environment, and of plant hybridization on the concentration and diversity of PAs expressed in the roots and shoots of *Senecio aquaticus* and *Senecio jacobaea*. The habitats of *S. jacobaea* and *S. aquaticus* are largely differentiated based on the organic and water content of the soil (Kirk et al. 2005b). Additionally, selection pressure by herbivores differs between the two species, partially because the wet soils found around natural *S. aquaticus* populations do not support the lifecycles of many invertebrate herbivores (see below).

We expect that differences in PA expression among species are due to different selection pressures over time. Because the environments of *S. jacobaea* and *S. aquaticus* are different, we also expect that these species may differentially alter production, allocation, and diversification of PAs according to environmental cues (e.g., Hol et al. 2003). For example, seasonal inundation excludes some root-associated herbivores from the habitat of *S. aquaticus*, and we thus expect that PAs associated with those herbivores are regulated differently in the roots of *S. aquaticus* from in *S. jacobaea*. Several studies have shown that environmental factors have an impact on PA expression in *S. jacobaea* (Macel 2003; Hol et al. 2003; Macel and Klinkhamer 2009).

Furthermore, *S. jacobaea* hybridizes in nature with *S. aquaticus* (Kirk et al. 2004). Natural hybrids between *S. jacobaea* and *S. aquaticus*, first observed at the Zwanenwater nature reserve in The Netherlands in 1979 (Ruud van der Meijden, personal communication), can be found in a narrow zone spanning a bank at the edge of a lake, which is intermediate to parental sites with regards to soil organic content and humidity (Kirk et al. 2005b). A previous study showed that natural hybrids are similar to *S. jacobaea* with regard to growth characteristics when subject to drought and flood-like conditions, while F_1 hybrids possess the drought resistant characteristics of *S. jacobaea*, and the flood resistant characteristics of *S. aquaticus* (Kirk et al. 2005b).

It has been postulated that hybridization may provide a mechanism for rapid evolution of resistance to parasites, including herbivores and pathogens. Hybridization creates a greater range of phenotypic variation than is found in parental species (Rieseberg et al. 1999; Kirk et al. 2005a; Wissemann 2007). If resistance traits exhibit higher variation among hybrid individuals than among parental species, hybrids may be more responsive to selection pressure than pure parental species. This hypothesis has been supported empirically (though not in relation to parasite resistance) in *Drosophila*, for which several studies have shown that variation in abiotic stress resistance can be higher in hybrid lines than in parental lines (Hercus and Hoffman 1999), such that hybrids may evolve more quickly in response to stress than parental species. Additionally, epistatic interactions among genes combined from both parents may create unique resistance traits, such as novel secondary metabolites (Fritz 1999; Orians 2000), and hybrid lines or hybrid genes may be selectively favoured.

Here, we investigated the effects of species by environment interactions on quantitative and qualitative expression of PAs in *S. jacobaea*, *S. aquaticus*, and their hybrids. We asked: i) Are there quantitative and qualitative differences in the expression of PAs between *S. jacobaea*, *S. aquaticus*, and their hybrids? ii) Do environmental factors affect PA expression in *S. jacobaea*, *S. aquaticus*, and their hybrids? iii) Is there evidence that novel PAs are produced in hybrids?

Methods and Materials

Study System Viable hybrids between *S. jacobaea* L. and *S. aquaticus* Hill have been reported from a number of locations including the United Kingdom (Stace 1975), Germany (Christian Düring, personal communication), and The Netherlands (Kirk et al. 2004). In this investigation, we studied *S. jacobaea*, *S. aquaticus*, and natural hybrids individuals sampled from the Zwanenwater reserve, located immediately to the South of Callantsoog, The Netherlands (52˚50′00”N, 004˚41′00”E). Composed mostly of sand dunes, the Zwanenwater reserve contains a small lake around which a hybrid population exists (see Kirk et al. 2005b for diagram). *Senecio jacobaea* is abundant in the dunes surrounding the lake, while *S. aquaticus* occurs infrequently at the lake fringe.

Selection pressure by specialist herbivores on *S. jacobaea* may be quite high, since a number of specialist herbivores, including *Tyria jacobaeae* and *Longitarsus jacobaeae*, cause extreme damage to above ground and

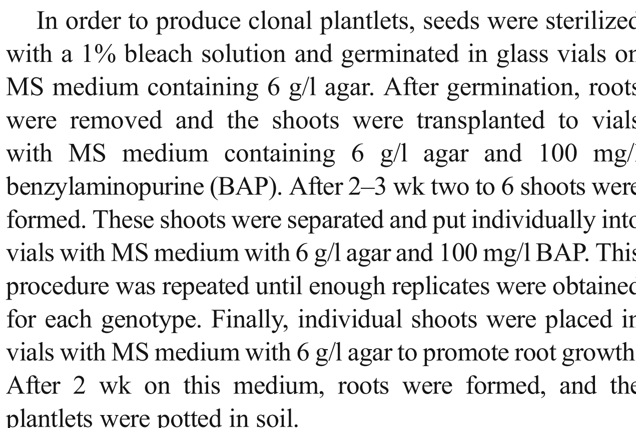
below ground plant parts. *Senecio aquaticus* is not subject to attack by *T. jacobaeae*, and other specialists that pupate in the soil around the plant, because pupae do not survive in the moist environments where *S. aquaticus* is found (personal observation). Thrips appear to be common in the *S. aquaticus* population (personal observation). Preliminary tests showed that in climate chamber experiments, *S. aquaticus* and *S. jacobaea* were equally susceptible to *T. jacobaeae* (Macel et al. 2002), and the generalist lepidopteran herbivore *Spodoptera exigua* (personal observation), but *S. aquaticus* was more resistant to the generalist thrips species *Thrips tabaci* than *S. jacobaea* (Kirk et al. 2005a).

Senecio aquaticus usually is found in seasonally waterlogged, humic, chalk-poor, and nutrient-rich soils (Weeda and Van Deursen 1994), while *S. jacobaea* prefers sunny environments with sparse vegetation (Weeda and Van Deursen 1994). *Senecio jacobaea* is able to elongate its roots rapidly in response to drought, in order to reach water sources that are unavailable to *S. aquaticus*, and *S. aquaticus* is resistant to flooding, while *S. jacobaea* is not (Kirk et al. 2005b).

Seeds of *S. jacobaea*, *S. aquaticus*, and natural hybrids were collected from plants in the field during 2001 and 2002. Putative hybrids were identified based on leaf lobe and flower morphology, and were later confirmed to be hybrids based on diagnostic amplified fragment length polymorphism (AFLP) markers (Kirk et al. 2004).

F_1 hybrids were produced by collecting from the field second year rosettes of parental plants that exhibited the development of flowering stems. Second year rosettes were collected because parental plants generally do not flower until their second year of growth, after vernalization (Kirk et al. 2005c). To minimize chances that introgressive genes were present in experimental parents, *S. aquaticus* individuals were collected from a marshy agricultural grassland approximately 500 m from the hybrid zone, and *S. jacobaea* individuals were collected from dunes located approximately 300 m from the hybrid zone. Plants from both species were placed in a greenhouse, allowed to flower, and were crossed in pairs of *S. jacobaea*×*S. aquaticus* by rubbing flower heads together. Both species are self-incompatible (Kirk et al. 2005c). Seeds were harvested from both parental plants to be certain that maternal effects are not involved in patterns of PA expression in F_1 hybrid offspring.

Effects of Environmental Factors on PA Expression We selected five *S. aquaticus* genotypes, five *S. jacobaea* genotypes, and five natural hybrid genotypes for experimental use. We also included 10 F_1 genotypes, including five pairs of full-sibs. Each pair of sibs was comprised of one genotype harvested from a *S. aqaticus* mother, and one genotype harvested from a *S. jacobaea* mother.



In order to produce clonal plantlets, seeds were sterilized with a 1% bleach solution and germinated in glass vials on MS medium containing 6 g/l agar. After germination, roots were removed and the shoots were transplanted to vials with MS medium containing 6 g/l agar and 100 mg/l benzylaminopurine (BAP). After 2–3 wk two to 6 shoots were formed. These shoots were separated and put individually into vials with MS medium with 6 g/l agar and 100 mg/l BAP. This procedure was repeated until enough replicates were obtained for each genotype. Finally, individual shoots were placed in vials with MS medium with 6 g/l agar to promote root growth. After 2 wk on this medium, roots were formed, and the plantlets were potted in soil.

One equal sized clonal plantlet from most genotypes was transplanted into each of 6 experimental columns (1 m length, 15 cm diam), yielding a total of 136 experimental plants. We aimed for 150 plants, but due to variance in sizes and difficulties with cloning, only 136 plants were used, giving an average of 22 plants per experimental treatment. For each treatment, we aimed to include 5 genotypes of each parental species, 5 natural hybrid genotypes, and 10 F_1 hybrid genotypes.

The experiment was established to test a combination of two nutrient and three water treatments. One meter tall columns were filled with sieved dune sand. In half the columns, the dune sand was mixed with 'Osmocote' slow release fertilizer (N:P:K = 15:11:13+2 MgO) at a concentration of 1.3 g/l sand to provide a nutrient rich medium. After establishment of seedlings, the bottoms of the columns were placed in water of three different depths: 5, 50, and 100 cm. A previous study (Kirk et al. 2005b) showed that columns placed in 5 cm of water created drought-like conditions. Columns placed in 50 cm of water created conditions, which did not subject plants to water-related stress, and columns were placed into 100 cm of water mimicked flooding (soil saturation). Columns were placed in a climate chamber for the duration of the experiment (light 16 h, temperature 20/15°C, relative humidity 70%).

All columns were given sufficient water at the beginning of the experiment to allow for seedling establishment. At the beginning of the experiment, soil throughout the total length of the column was moist. Experimental conditions were established 2 wk after seedlings were transplanted to columns, and the experiment was subsequently continued for 10 wk. Plants were not watered from the top during this period. Roots and shoots were harvested separately, and were dried in an oven for 3 d at 50°C.

PA Extraction and Identification All dried leaves and roots from each plant were separately milled to a fine powder and homogenized. Milled samples were stored in a freezer at −0°C until use. For extraction, approximately 15 mg of

plant material were extracted according to a modified version (de Boer 1999) of the acid-base extraction method (Hartmann and Zimmer 1986). Extractions were dissolved in methanol containing heliotrine at a concentration of 1 μg/ml(Latoxan, France) as an internal standard and analyzed by gas chromatography (GC). Final concentrations of each PA within the sample were calculated by integrating the GC peaks and converting these areas to concentration by using the known concentration of the internal standard. Conditions (injector 250°C, temperature program 220°C–250°C 5°C/min, split mode 1:30, carrier gas N_2 0.9 ml min^{-1}, pressure 56 kPa; detector NPD) were controlled by a Hewlett Packard gas chromatographer (model 6890). GC peaks were compared with known references to identify sample composition. Identities of PAs from known reference samples were previously confirmed by using GC-MS (Macel et al. 2002). PA_1 and PA_2 were confirmed to be PAs, and florosenine was identified by GC-MS according to Witte et al. (1992).

Statistics We tested PA concentrations and diversity separately for roots and shoots, since PAs may interact both with root and with shoot pathogens and herbivores. We analyzed diversity in two ways. First, we counted the absolute number of PAs produced in shoots and roots of each plant group across differing treatments. This is biologically relevant because the production of each PA requires the activation of at least one new enzymatic pathway within the plant (e.g., Pelser et al. 2005). We refer to this measure of diversity as PA richness throughout the remainder of the text. Differences in both PA richness and total PA concentration were analyzed with ANOVAs, including interaction terms, for which we identified the fixed factors as water treatments, nutrient treatments, and taxa. Taxa denote parental species, F_1 hybrids, and natural hybrids. Shoot to root ratio was used as a covariate because it was assumed that root biomass is proportional to PA production, and because the size of the shoots is not related to PA production (Hol et al. 2003). Relatively large shoots may lead to a dilution of PAs. We first tested for maternal effect on PA expression in F_1 hybrids, by including only F_1 hybrids in the analysis. Previous research has shown that maternal effects can affect both growth (Kirk et al. 2005b) and reproductive fitness (Kirk et al. 2005c) of F_1 hybrids between *S. jacobaea* and *S. aquaticus*. Since we found that the maternal parent was never a significant factor in the analyses, we treated all F_1 hybrids as one group for subsequent ANOVAs by using the entire data set.

We also analyzed PA diversity by applying principal component analysis (PCA) to quantitative PA data, which is likely most ecologically relevant from the perspective of plant defense. We applied ANOVAs to each principal component (PC) to test whether nutrient and water treatments and plant taxa had significant effects on PA composition. We then identified individual PAs that were highly correlated with each PC. All tests were performed with SPSS 8.0 (SPSS Inc. 1998).

Results

Eleven PAs were identified during our analyses (Table 1). We found eight PAs that commonly occurred in *S. jacobaea* (eight in the shoots, and eight in the roots). Additionally, PA_1 was present in low amounts in two plants of *S. jacobaea* and florosenine (Fig. 1) in one plant. To our knowledge, neither of these PAs has been reported previously from *S. jacobaea* individuals, and may represent PAs introgressed from the Zwanenwater hybrid zone. Ten PAs were present in *S. aquaticus*, of which the rare PA otosenine (Fig. 1) was found only in *S. aquaticus*. In contrast to findings for *S. jacobaea*, PA_1 almost always was present in *S. aquaticus* shoots. The reverse was true for jacobine. All eleven PAs were present among both natural hybrid and artificial hybrid genotypes. Florosenine appeared to be specific to hybrids, although trace amounts were expressed by one *S. jacobaea* plant.

There was no significant effect of, or interaction involving plant taxa on either shoot or root PA concentrations (Table 2 Fig. 2). In shoots, PA concentration was affected by both water, and an interaction between water and nutrient treatments. Pyrrolizidine alkaloid concentrations were approximately equal in all nutrient-rich treatments (regardless of water treatment), while in sand without nutrients, concentrations were high in the intermediate water treatment compared to other treatments. In roots, PA concentration was affected by both water and nutrient effects (Table 2). PA concentration increased with increasing soil wetness, and was higher in sand without nutrients than in sand with nutrients (Fig. 2).

PA richness in the shoots differed significantly among taxa (Table 3). Averaged over all treatments, the number of PAs per plant (± SE) were, respectively, 3.96±0.35, 3.59± 0.33, 4.13±0.33, 4.80±0.24 for *S. jacobaea*, *S aquaticus*, natural hybrids, and F_1 hybrids. In shoots, PA richness also was affected by an interaction between nutrient and water treatments and interactions between nutrient treatment and taxa (Table 3). The latter interaction is caused mainly by low PA richness of *S. aquaticus* in medium and dry nutrient rich conditions. In the roots, water and taxa were both significant factors; PA richness was higher in wetter conditions, and *S. aquaticus* and F_1 hybrids exhibited higher PA richness than *S. jacobaea*, with variable PA richness in natural hybrids (Fig. 3).

PCA yielded 2 components (Table 4) for PAs in plant shoots, which cumulatively explained 85.6% of the varia-

Table 1 Mean concentration (mg/g)±se of 11 pyrrolizidine alkaloids in the roots, and shoots of *senecio jacobaea*, *senecio aquaticus*, natural hybrid, and f_1 hybrid genotypes. data shown is pooled over all treatments

tion in PA expression. The first component (PC1) mostly explained variation in the least metabolically derived alkaloids identified in this experiment [i.e., was significantly correlated with senecionine (*r*= *0.68*), seneciphylline (*r*= *0.99*), and integerrimine (*r*= *0.74*), and to a lesser extent variation in jacobine (*r*= *0.21*), jacoline (*r*= *0.47*), and erucifoline (*r*= *0.38*) (Table 4)]. The second component (PC2) explained variation in jacobine (*r*= *0.98*), florosenine (*r*= *0.44*), PA_1 (*r*= *-0.29*), senecionine (*r*= *−0.31*) (Table 4). PC1 was affected significantly by all abiotic conditions and their interaction. Scores for PC1 were higher in sand without nutrients, and were low in wet and high in intermediate (moisture) conditions. PC2 was affected significantly by taxa with the parents that showed the most extreme scores (*S. jacobaea*: 0.34±0.17a, *S. aquaticus*: −0.61±0.17b). Mean hybrid scores were intermediate to those of parental species, but natural hybrids were statistically equal to *S. aquaticus*, while F_1 hybrids were statistically equal to *S. jacobaea* (natural hybrids −.04±0.17b, F_1 hybrids 0.16±0.12a; different letters indicate significant differences). Another significant main effect was found for nutrients with scores for nutrient rich conditions (0.31±0.11) higher than for sandy soils (−0.38±0.11).

Two principal components (PCs) accounted for 88.9% of the variation in root PA expression. As in the shoots, the first component (PC1) mostly explained variation in the least metabolically derived alkaloids [i.e., senecionine (*r*= *0.95*), seneciphylline (*r*= *0.66*), and integerrimine (*r*= *0.77*), and to a lesser extent variation in jacoline (*r*= *0.47*), and erucifoline (*r*= *0.25*) (Table 4)]. The second component (PC2) explained variation in senecionine (*r*= *−0.31*), seneciphylline (*r*= *0.75*), integerrimine (*r*= *0.26*), jacoline (*r*= *0.6*), PA_2 (*r*= *0.5*), and erucifoline (*r*= *0.48*). All three main effects (taxa, water, nutrients) were significant for PC1. Again, parents showed the most extreme scores (*S. jacobaea*: 0.53±0.18a, *S. aquaticus*: −0.31± 0.17b). Natural hybrids statistically were equal to *S. aquaticus*, while F_1 hybrids had intermediate mean scores, but statistically were equal to both parents (natural hybrids: −.21±0.17b, F_1 hybrids: 0.01±0.12ab; different letters indicate significant differences). Scores for PC1 decreased with dryer conditions and were lower in nutrient rich soils. PC2 showed significant mains effects of taxa and nutrients and a significant interaction between water and nutrients. Parental taxa showed the most extreme scores (*S. jacobaea*: −0.84±0.17a, *S. aquaticus*: 0.42±0.16b). Hybrid means

Discussion

We found that both environmental and taxa effects mediate the expression of PAs in the roots and shoots of the plant species presented here.

Environmental Factors Total PA concentration in roots and shoots is influenced by both soil moisture and nutrient availability (Salmore and Hunter 2001; Hol et al. 2003). According to the resource availability hypothesis, which postulates that plants should make higher investments in defense in the absence of abundant resources (Coley et al. 1985), PA concentrations are expected to be higher when nutrient availability is low. This was the case in our study; trends showed higher PA concentrations in sand without nutrients compared to sand with nutrients. This finding corroborates evidence presented by Hol et al. (2003) that PAs were diluted when *S. jacobaea* plants were grown on nutrient-rich media, due to rapid accumulation of biomass in relation to PA production.

The influence of soil moisture and nutrients on PA richness in the shoots was relatively small. In the roots, PA richness increased with increasing soil moisture. This suggests that differences in PA richness may play a large

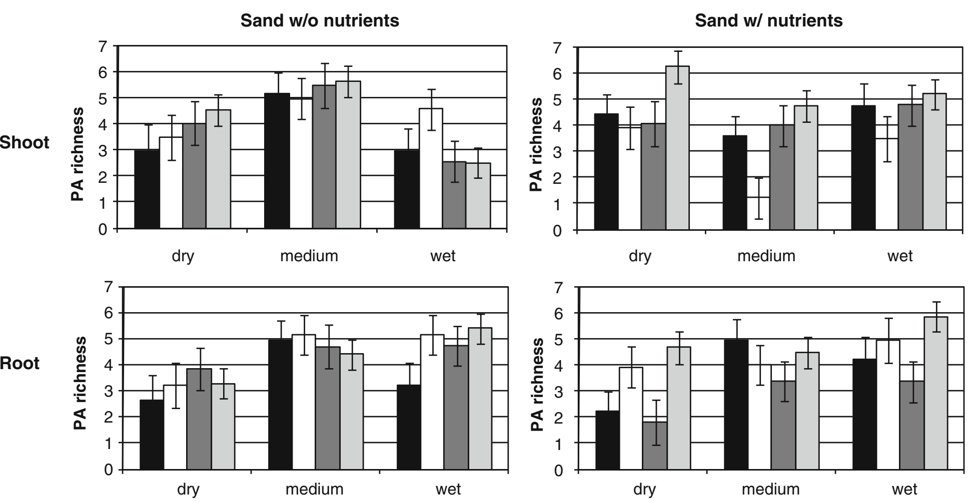

Fig. 3 Pyrrolizidine Alkaloid (PA) richness, defined as the number of PAs detected within each sample, in the shoots and roots of *Senecio jacobaea* (*black*), *Senecio aquaticus* (*white*), natural hybrids (*dark grey*), and F_1 hybrids (*light grey*) in a factorial design with two nutrient levels and three water levels. Vertical bars represent standard error

role in below-ground plant defense because pathogenic pressure will rise with increasing soil moisture (e.g., Shafer and Kotonan 2003). Based on limited data, below-ground defense seems to be more important for some species than others; Brassicaceous plants produce greater concentrations and a higher diversity of glucosinolates in roots than in shoots, and at least one glucosinolate has higher toxicity below-ground than above-ground (van Dam et al. 2009). In contrast, Milkweed allocates more resources to above-ground plant defense compared to below-ground defense (Rassman et al. 2009).

Nutrients and water conditions had a strong effect on PA expression in shoots and roots for both PCAs. In the shoots seneciphylline (PC1) and jacobine (PC2), and in the roots senecionine (PC1) and seneciphylline (PC2), were correlated strongly with PCA scores suggesting that the concentrations of these PAs are most influenced by environmental conditions. Concentration of jacobine in the shoots more than doubled when nutrient concentrations increased, although total PA concentration decreased. This might have implications for plant defense because jacobine has been shown to be more effective against thrips than all other PAs found in *S. jacobaea* (Leiss et al. 2009).

Taxa Plant taxa (including hybrid groups) never showed differences in *total* PA concentration in plant shoots or

[2] Indicates PAs that are significantly correlated with each PC ($P<0.05$)

[3] Significant factors represent single factors and/or interactions that had significant effects on PC values in ANOVA analyses

roots. This suggests that selective pressure by different natural enemies does not play a large role in determining total PA concentration, because *S. aquaticus* and *S. jacobaea* grow in different environments (nutrient rich and moist vs. nutrient poor and dry), with a different host of herbivores and soil bacteria and fungal communities (Kirk et al. 2005b; Singh et al. 2009). In contrast to total PA concentration, PA *richness* (diversity) was significantly different between taxa for shoots and roots. PA richness tended to be higher in shoots and roots of the F_1s compared to the parental species, and the natural hybrids and the F_1s contained PAs from both *S. aquaticus* and *S. jacobaea*. PA expression was affected significantly by taxa in both shoots and roots. Based on principal component analysis, we found that taxa was a significant factor with regard to PC2 in the shoots, which is explained mostly by variation in jacobine content. For PC1, which was highly correlated with seneciphylline in the shoots, there was no effect of taxa. In plant roots, taxa was a significant factor for both principal components. The effects of selective pressures by natural enemies on secondary metabolite composition have been difficult to demonstrate experimentally (i.e., Macel et al. 2005; Albrechtsen et al 2007), and the comparative method used here is a promising avenue of further research.

Novel Compounds With regard to hybridization between *S. jacobaea* and *S. aquaticus*, both F_1 and natural hybrids produce the PA florosenine, which may be a novel product of hybridization in the Zwanenwater population. Florosenine has been reported previously from the South American *Senecio* species *S. glaber* (Reina et al. 1993) and *S. leptolobus* (Mendez et al. 1990), as well as from a Swiss population of *S. aquaticus* (Pelser et al. 2005). Florosenine was never found in *S. aquaticus* from the Zwanenwater nature reserve during this current study, or during previous ones (Kirk et al. 2004). Trace amounts of florosenine were found in one *S. jacobaea* individual here, but this occurrence may represent introgression, since this PA has never been reported from other *S. jacobaea* populations, and was not found in either Zwanenwater *S. jacobaea* genotypes, or control populations from a variety of European locations analyzed in a previous study (Kirk et al. 2004). Florosenine is the O-acetyl derivative of otosenine. Mechanistically, it is possible that hybridization combines the ability of *S. jacobaea* to acetylate PAs, and the ability of *S. aquaticus* to synthesize otosenine. If such inter-specific epistatic interactions between enzymes and substrates can result in the production of unique PA structures, then hybridization within the genus *Senecio* may be a mechanism for structural PA diversification.

This study system is useful for studying variation in PA expression. Environmental conditions play an important regulatory role in PA concentrations in above-and below-ground plant parts, and these interactions seem mainly to be governed by senecionine, seneciphylline, and jacobine. A general problem with these types of experiments is that it is not yet possible to distinguish between the direct effects of the treatments and the indirect effect of the treatments caused by changes in the microbial community in the soil. Although the induced changes in PA expression in richness are likely to be relevant for plant defense, this still remains to be tested experimentally. The evaluation of natural selection on different hybrid genotypes that possess different combinations of PAs may be extremely useful for elucidating the role of PA diversity or expression of other secondary metabolites in plants (e.g., Lexer et al. 2003).

Acknowledgements Heather Kirk thanks the Natural Sciences and Engineering Research Council of Canada (NSERC) for financially supporting her research. Also thanks to Jung van der Meulen, Margriet Peet, and Helene de Vos for technical assistance, and Thomas Hartmann for assistance in identifying PA structures. We thank three anonymous reviewers for useful comments on the manuscript.

Abstract The tea weevil, *Myllocerinus aurolineatus* (Voss) (Coleoptera: Curculionidae), is a leaf-feeding pest of *Camellia sinensis* (O.Ktze.) with aggregative behaviors that can seriously reduce tea yield and quality. Although herbivore-induced host plant volatiles have been shown to attract conspecific individuals of some beetle pests, especially members of the Chrysomelidae family, little is known about the volatiles emitted from tea plants infested by *M. aurolineatus* adults and their roles in mediating interactions between conspecifics. The results of behavioral bioassays revealed that volatile compounds emitted from tea plants infested by *M. aurolineatus* were attractive to conspecific weevils. Volatile analyses showed that infestations dramatically increased the emission of volatiles, (*Z*)-3-hexenal, (Z)-3-hexenol, (*E*)-β-ocimene, linalool, phenylethyl alcohol, benzyl nitrile, indole, (*E*, *E*)-α-farnesene, (*E*)-nerolidol, and 31 other compounds. Among the induced volatiles, 12 chemicals, including γ-terpinene, benzyl alcohol, (*Z*)-3-hexenyl acetate, myrcene, benzaldehyde, (*Z*)-3-hexenal, and (*E, E*)-α-farnesene, elicited antennal responses from both sexes of the herbivore, whereas (*E*)-β-ocimene elicited antennal responses only from males. Using a Y-tube olfactometer, we found that six of the 13 chemicals, γ-terpinene, benzyl alcohol, (*Z*)-3-hexenyl acetate, myrcene, benzaldehyde, and (*Z*)-3-hexenal, were attractive to both males and females; two chemicals, (*E/Z*)-β-ocimene and (*E, E*)-α-farnesene, were attractive only to males; and four chemicals, (*E*)-4,8-dimethyl-1,3,7-nonatriene, phenylethyl alcohol, linalool, and (Z)-3-hexenol, were attractive only to females. The findings provide new insights into the interactions between tea plants and their herbivores, and may help scientists develop new strategies for controlling the herbivore.

Introduction

Herbivore-induced plant volatiles (HIPVs) have many functions: they can act as an indirect defense by attracting natural enemies of the herbivores (Vet and Dicke 1992; Dicke and Vet 1999; Turlings and Wäckers 2004), as a direct defense by deterring attack of the subsequent herbivores (Delphia et al. 2007), as a synergistic agent with sex or aggregation pheromones (Wakefield et al. 2005; Erbilgin et al. 2007), or as an attractant for conspecific or non-conspecific herbivores (Loughrin et al. 1996; Bolter et al. 1997; Kalberer et al. 2001; Otálora-Luna1 et al. 2009). Many species of Coleoptera beetles with aggregative behaviors attract conspecifics (Loughrin et al. 1996; Bolter et al. 1997; Kalberer et al. 2001), but the active chemicals involved have not been identified.

In Curculionidae beetles, some species use host plant volatiles as pheromone synergists or to locate host plants (Ndiege et al. 1996; Perez et al. 1997; Wang and Kays

2002; Wakefield et al. 2005). The addition of volatiles from sugarcane stalks to pheromone lures, for example, enhances lure effectiveness for trapping the West Indian sugarcane weevil *Metamasius hemipterus sericeus* (Oliv.) (Perez et al. 1997). Carob volatiles not only acted synergistically with aggregation pheromones in 3 weevil species, *Sitophilus zeamais* (Motsch.), *S. granarius* (L.), and *S. oryzae* (L.) but also directly attracted *S. zeamais* and *S. oryzae* (Wakefield et al. 2005). Volatile extracts from storage roots and aerial parts of the sweet potato were attractive to female sweet potato weevils (Wang and Kays 2002). Surprisingly, few studies have determined the role of HIPVs in mediating conspecific interactions in Curculionidae beetles. To date, only *Diaprepes abbreviatus* (L.) has been verified to be attracted to the volatiles from host plants infested by conspecific weevils. Otálora-Luna et al. (2009) discovered that (±)-linalool and carvacrol were emitted from citrus plants infested by the tropical root weevil *D. abbreviatus*; combined with a green leaf volatile (Z)-3-hexenol at a dose of 25:2.5:25 μg, these compounds attracted conspecific females, but, were repellent for males.

Myllocerinus aurolineatus (Voss) (Coleoptera: Curculionidae) is one of the main leaf-feeding insects on tea plantations (Zhu et al. 1988). Native to China, adult weevils feed on young, tender leaves, seriously deteriorating the yield and quality of tea. Although chemical control is effective against *M. aurolineatus*, it poses health and environmental risks associated with the residues that remain on tea leaves and the resistance that herbivores may develop, which in turn may lead to the resurgence of primary pests and outbreaks of secondary pests. Alternative strategies for controlling this weevil are needed.

The composition of volatiles from tea plants infested by *M. aurolineatus* adults and their roles in mediating interactions between conspecifics have not been investigated. To elucidate the role of tea volatiles induced by feeding of *M. aurolineatus* adults in host-searching behavior, we first measured the weevil response to intact plants, *M. aurolineatus* frass, and *M. aurolineatus* adults. Then, we collected and identified the volatiles released by plants infested with *M. aurolineatus* adults and the volatiles released by control plants. Finally, we screened and tested the attractiveness of the active components from the collected volatiles to *M. aurolineatus* adults.

Methods and Materials

Tea Plants One year before the experiment commenced, 1-yr-old Longjing tea plants were individually planted in plastic pots (14×15cm), irrigated every other day, and fertilized once a month. Plants were kept in a controlled climate room at 26±2°C and 70–80% relative humidity with a 12-h light cycle to provide plants with about 450 μmol photons/m^2/sec.

Insects Adult weevils of mixed age and sex and of unknown mating status were collected from damaged plants on the Tea Experimental Plantation (Tea Research Institute, Chinese Academy of Agricultural Sciences, Hangzhou Xihu Longjing First-degree Reserve, China). The insects were kept in a box for 2 d, then separated into males and females according to morphological characters and maintained in separate plastic containers (11.5×13 cm) with fresh tea leaves. Containers were put into a controlled climate chamber at 25±2°C and 70±5% relative humidity, with a photoperiod of 13 hL:11 h D. Two weeks later, weevils were starved for 2 h and used in the experiments.

Olfactometer Test Responses of *M. aurolineatus* adults to odors released from different sources or synthetic compounds were measured in a Y-tube olfactometer consisting of a Y-shaped glass tube (2.5 cm diam) consisting of a 12 cm base tube and two 12 cm arms at a 75° angle. Each arm was connected in series to an odor source container, a humidifier bottle, a tube with activated charcoal, and a flow meter. Both arms were connected to the exhaust of a common vacuum pump that controlled the air flow through the system at 800 ml min^{-1}. Weevils were allowed to walk through the base tube towards the odor sources. The Y-tube olfactometer was placed in a green box and each edge of the top was illuminated by a single 25-W lamp. All bioassays were conducted between 15:00 and 20:00 h in a room that was maintained at 25–27°C.

Each weevil was introduced individually into the base tube. Choice for an odor source was defined as a weevil crossing a line 8 cm after the division of the base tube and remaining there for at least 1 min. If a weevil did not make a choice within 5 min, it was considered a non-responding individual and recorded as “no choice”. After 2 weevils were tested, the olfactometer tube was washed with 98% acetone and then heated at 100°C for 5 min. The position of odor source containers in relation to each arm was reversed after each replication to eliminate directional bias. To avoid contamination, the connections of the odor chamber to the flow meter were rinsed with 98% acetone and then heated at 100°C for 5 min after each replication.

Response to Individual Components of the Plant—Weevil Complex In this experiment, the following odor sources were prepared:

1. Intact plants (IP). Potted plants were washed with running water and then put in glass chambers, which were the same as those in which volatiles were collected (see below). Four days later, the plants were used as an odor source for bioassays.

2. Plant-*M. aurolineatus* adult complex (PMA). Plants were prepared as in the above treatment (1) and 3 d later were infested individually with 100*M. aurolineatus* adults (female:male=1:1). One day later, the plants carrying 100*M. aurolineatus* adults were used as an odor source.
3. *M. aurolineatus* adults (MA). One hundred *M. aurolineatus* adults (female:male=1:1) were collected and used as an odor source.
4. Frass: Plants were individually infested with 100*M. aurolineatus* adults (female:male=1:1). One day later, frass was collected carefully with a clean brush, and 2 g were placed on a small Petri dish (5 cm diam) as an odor source.
5. Chemical standards. Silicon rubber septa were used as odor dispensers by adding 10 μl of one chemical to a septum, airing for 5 h, and storing the loaded septum at −20°C until it was individually placed in an odor container. Each septum was used for experiments for less than 3 h. Within that time, the release rates of the various chemicals from the septa were stable. All chemicals used were at least 98% pure and were obtained from the commercial suppliers listed in Table 1.

The behavioral responses of the weevils to the following pairs of odors were tested in the olfactometer: (1) purified air vs. IP, frass, MA, and PMA, respectively; (2) IP vs. PMA; (3) MA vs. PMA; (4) purified air vs. (*Z*)-3-hexenyl acetate, (*Z*)-3-hexenol, (*Z*)-3-hexenal, benzaldehyde, myrcene, benzyl alcohol, β-ocimene, γ-terpinene, linalool, phenylethyl alcohol, (*E*, *E*)-α-farnesene, or (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), respectively. The sex ratios of the weevil adults tested in (1), (2), and (3) were 1:1 (female:male). The weevil adults used in (4) were sexed according to their morphological characteristics.

Collection and Identification of Tea Volatiles The collection system (Fig. 1) consisted of a vertical cylindrical glass tube (18 cm i.d.×25 cm height) resting on a glass plate with a hole in its center. A halved rubber stopper with a 0.6 cm i.d. hole allowed the stem of the plant to pass through the hole in the plate, so that the living aerial part of the plant in the cylinder was separated from the pot (Fig. 1). At the top of the cylinder, another glass plate with a hole in the center was closed with a rubber plug that had two holes (0.8 cm i.d.). The inlet port was a glass tube (0.6 cm i.d.×30 cm) that was inserted through the stopper to about 1.5 cm above the bottom plate. The outlet port was another glass tube (0.6 cm i.d.×6.5 cm) inserted just to the bottom edge of the rubber plug. Purified air was pulled into the cylinder over the plant at a rate of 1.36 $l min^{-1}$. Incoming air was filtered through a silica gel for dryness, an activated charcoal filter for purification, a flow meter for measuring and regulating the airflow, and another activated charcoal filter for secondary

The names of the compounds followed by different letters indicate different methods for confirming identities: [a–g] comparison of retention times and mass spectra with those of authentic standards as follows: [a] Roth; [b] Sigma-Aldrich; [c] Fluka; [d] TCI; [e] Acros; [f] Pherotech; [g] gift from Taro Maeda; [h] comparison of Kovats Indices (KI) on DB-5, [i] comparison of mass spectra with the database. Data represent the mean of four replications ± SE.

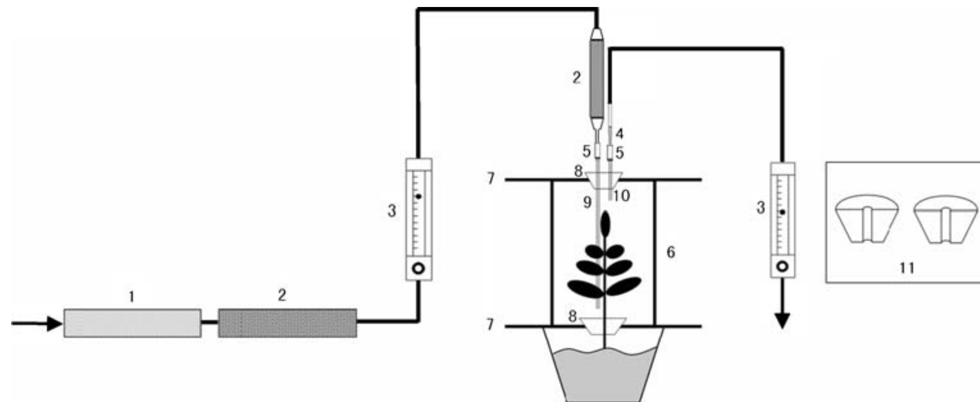

Fig. 1 Apparatus for collection of volatiles. 1. silica gel filter, 2. activated charcoal filter, 3. flow meter, 4. superQ trap, 5. teflon tubing, 6. cylindrical glass tube, 7. glass plate, 8. rubber plug, 9. inlet port, 10. outlet port, 11. details of rubber plug

purification. The blend of volatiles was trapped in a glass tube (0.4 cm i.d.×10 cm) that contained 35 mg of 80/100 mesh SuperQ absorbent (Alltech Associates., Inc., Deerfield, IL, USA). Teflon tubing was used to connect the flow meter to the inlet port, the outlet port to the trap, and the other end of the trap to a flow meter and vacuum pump. During collection, room temperature was 27±1°C, and the system was illuminated by two fluorescent lamps with a photoperiod of 13 hL:11 h D.

Volatiles emitted from intact plants and plants that were infested with 100*M. aurolineatus* adults (female:male=1:1) were collected. We also collected volatiles from a pot of soil without plants to determine whether the system was clean. Collection started 24 h after treatment and lasted 1 h. After each collection, traps were rinsed with 500 µl methylene dichloride, and 50 ng of ethyl decanoate were added to each sample as an internal standard. Each treatment was replicated four times. The amounts of volatile compounds were expressed as percentages of peak areas relative to the internal standard.

Analyses were carried out with a coupled gas chromatograph-mass spectrometer QP2101 (Shimadzu, Japan) equipped with an automated on-column injection system and a DB-5 MS capillary column (60 m×0.25 mm i.d., 0.25 µm film J&W Scientific, Folsom, CA, USA). The injection port was operated in splitless mode with a constant helium flow of 1 ml min^{-1}. The injector temperature was 250°C, the ionization potential was 70 eV, and the scan frequency was 2 sec^{-1}. Following injection, the column temperature was maintained at 45°C for 2 min, ramped at 5°C min^{-1} to 210°C, ramped at 25°C min^{-1} to 260°C, and held for 10 min. Data were collected with Shimadzu GC ChemStation software. The limitation of detection (LOD) is approximately 2.0 ng±0.4 ng.

For data analysis, GC-MS solution software (Shimadzu, Japan) was used, including the mass spectra library NIST 02 (National Technical Information Services). Library matches revealed candidate compounds. Identities were confirmed by comparing retention times and mass spectra with those of authentic standards (when available) or by comparing Kovats Indices (KI) on DB-5 if the chemical standards were not available.

Electrophysiological Recording and Chemical Analysis To distinguish the active components of weevil-induced volatiles, a GC-EAD instrument was used. An Agilent 7890 gas chromatograph (Agilent Technologies, Santa Clara, CA, USA) equipped with a DB-5 capillary column (30 m×0.25 mm i.d., film thickness 0.25 µm; J&W Scientific, Folsom, CA, USA) was coupled to electro-antennographic detection (GC-EAD system). Samples used for the EAD tests were collected as described above from the plants carrying 100*M. aurolineatus* adults (female: male=1:1). Each sample was concentrated under nitrogen (99.999%) to about 2 µl for injection. The injection port was operated in splitless mode. The temperature program was the same as that described for GC-MS analyses. The column effluent was split 1:1, with one part going to the flame ionization detector of the GC and another to the EAD through a heated (230°C) transfer line (Syntech, Hilversum, Netherlands). The EAD outlet was introduced into a glass tube with a constant air flow (0.5 ml min^{-1}). The humidified and purified supplemental airstream for the EAD was supplied continuously at 400 ml min^{-1} and directed at an excised tea weevil antenna. Two glass capillary recording Ag-AgCl electrodes filled with 0.5 M KCl solution were brought into contact with the distal and basic segments of the antenna, the end of which was cut carefully. Antennal signals were amplified and converted by using an interface box (Auto Spike, IDAC 2/3, Syntech), Krichzarten, Germany) before they were recorded. The FID and EAD signals were monitored simultaneously and stored on a personal computer for subsequent analysis with Electro-AntennoGraphy software (professional version, Syntech).

Statistical Analysis All statistical analyses were performed using the Statistica program (Statistica, SAS, Institute Inc., Cary, NC, USA). The differences between electrophysiological responses from the antennae of male and female weevil adults were analyzed for significance by *t*-test. The differences between the number of *M. aurolineatus* males and females entering each arm of the olfactometer for each paired treatment were analyzed by the *Kruskal-Wallis* test (χ^2 approximation).

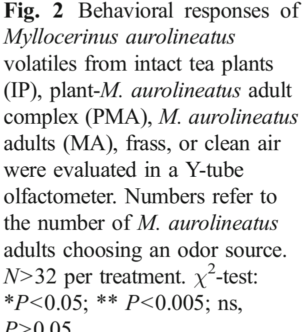

Fig. 2 Behavioral responses of *Myllocerinus aurolineatus* volatiles from intact tea plants (IP), plant-*M. aurolineatus* adult complex (PMA), *M. aurolineatus* adults (MA), frass, or clean air were evaluated in a Y-tube olfactometer. Numbers refer to the number of *M. aurolineatus* adults choosing an odor source. $N>32$ per treatment. χ^2-test: *$P<0.05$; ** $P<0.005$; ns, $P>0.05$

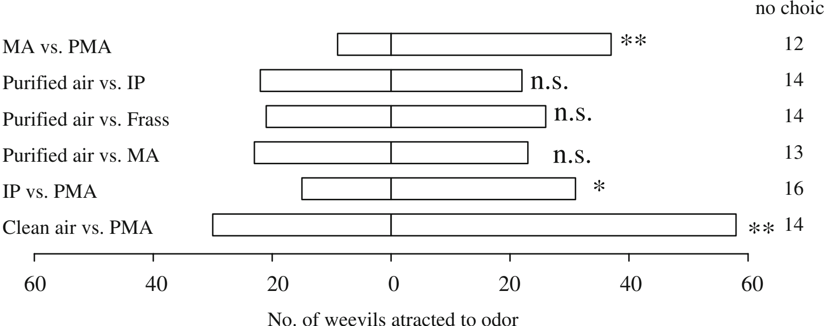

Results

Responses of M. aurolineatus Adults to Different Odors Volatiles emitted from the tea plant-weevil complex were significantly more attractive to the weevils than were clean air or the volatiles from weevils, frass, or intact tea plants (Fig. 2).

Volatile Analysis When plants were infested by adult weevils for one day, the quantity and number of volatiles dramatically increased compared to the volatiles released from intact plants (Table 1, Fig. 3). More than 40 compounds were emitted from plants infested with *M. aurolineatus* adults, including 9 fatty acid derivatives, 7 amino acid derivatives, 20 terpenoids, and 5 unknown compounds (Table 1, Fig. 3).

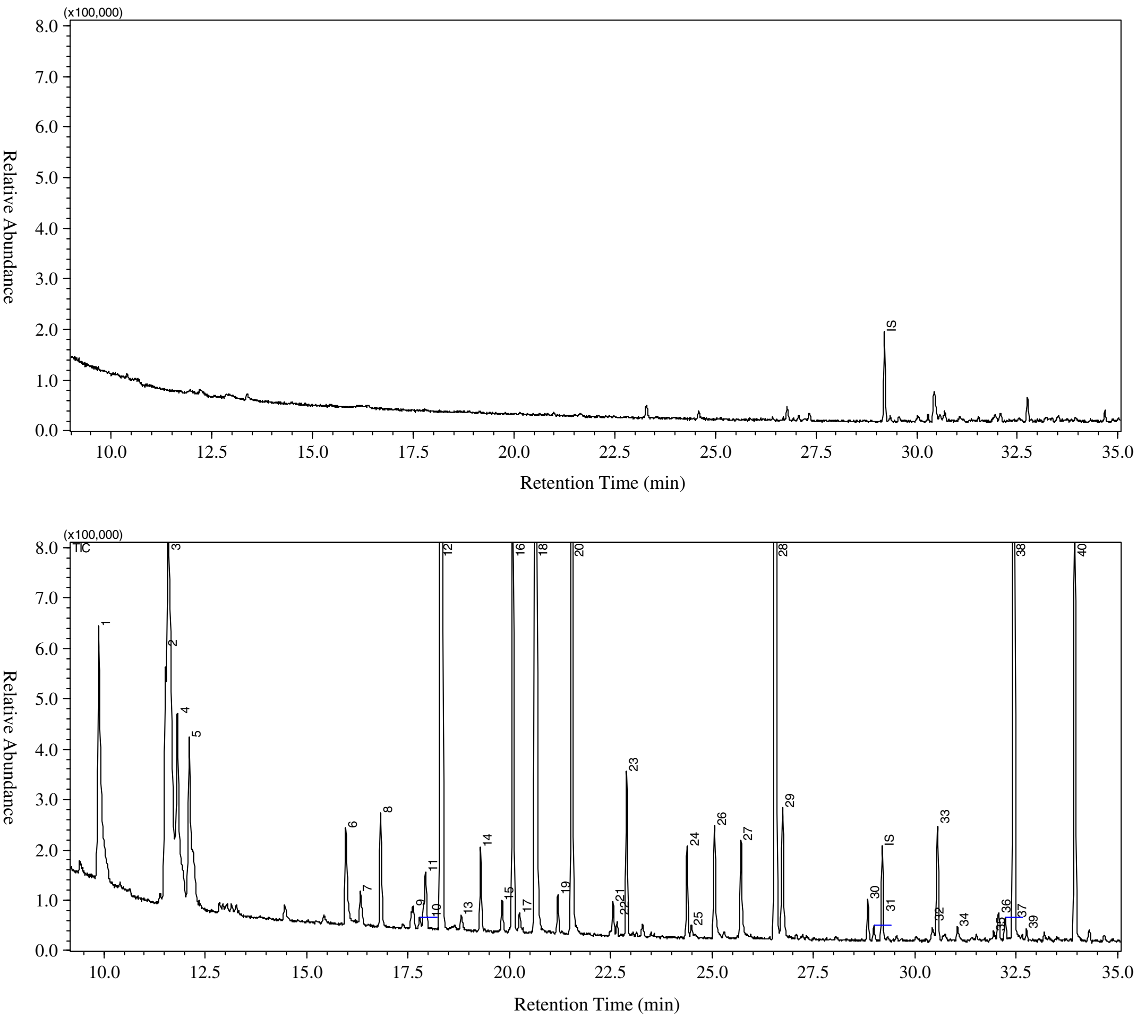

Fig. 3 Typical chromatograms obtained from headspace collections of volatiles from intact tea plants (IP) and plant-*Myllocerinus aurolineatus* adults complex (PMA)

[a] Identification is based on comparing mass spectra and retention times of authentic standards with the volatiles induced by weevils.

[b] Based on five different volatile samples.

* *t*-test comparing male response to female response, $P<0.05$.

(*E*)-β-Ocimene, phenylethyl alcohol, or DMNT were the most abundant. These volatiles were not detected in the headspace from intact plants.

Gas Chromatography-electroantennography Analysis In the blend of volatiles, there were 13 and 12 compounds that elicited antennal responses from male and female weevils, respectively (Table 2, Fig. 4). Among these, two compounds, (*Z*)-3-hexenal and (Z)-3-hexenol (peaks 1 and 2) elicited strong and consistent electrophysiological responses from the antennae of both sexes of *M. aurolineatus* adults, and 7 chemicals (peaks 3–5, 7, 9–11) elicited weak electrophysiological responses from the antennae of both sexes (Table 2 , Fig. 4). Among these, only (*Z*)-3-hexenal (peak 1) elicited significantly different electrophysiological responses from the antennae of male and female weevil adults.

Behavioral Responses of M. aurolineatus Adults to EAD-Active Compounds Twelve EAD-active compounds were tested in a Y-tube olfactometer (Fig. 5). Compared with clean air, both males and females were significantly attracted to γ-terpinene, benzyl alcohol, (*Z*)-3-hexenyl acetate, myrcene, benzaldehyde, and (*Z*)-3-hexenal. Two chemicals, (*E, E*)-α-farnesene and (*E/Z*)-β-ocimene, were attractive only to males, and 4 compounds, DMNT, phenylethyl alcohol, linalool, and (*Z*)-3-hexenol, were attractive only to females.

Discussion

Our results show clearly that the tea weevil, *M. aurolineatus,* was attracted to tea plants infested by conspecifics but not to undamaged tea plants, conspecific herbivores, or frass

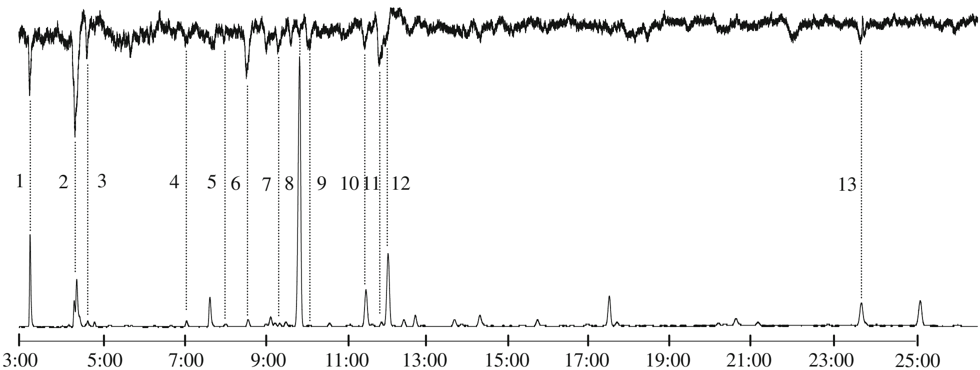

Fig. 4 Simultaneous responses of flame ionization detector (FID) and electroantennographic detection (EAD) recording of female *Myllocerinus aurolineatus* adult antennae response to the volatiles collected from the headspace of tea plants infested by *M. aurolineatus*. Thirteen EAD active compounds were identified as follows: 1. (*Z*)-3-hexenal, 2. (*Z*) -3-hexen-1-ol, 3. Unknown, 4. Benzaldehyde, 5. Myrcene, 6. (*Z*)-3-hexenyl acetate, 7. Benzyl alcohol, 8. (*E*)-*β*-ocimene, 9. γ-terpinene, 10. Linalool, 11. Phenylethyl alcohol, 12. DMNT, 13. (*E*, *E*)-α-farnesene

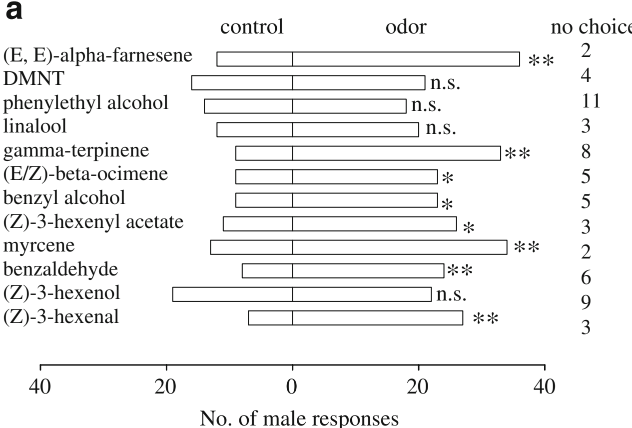

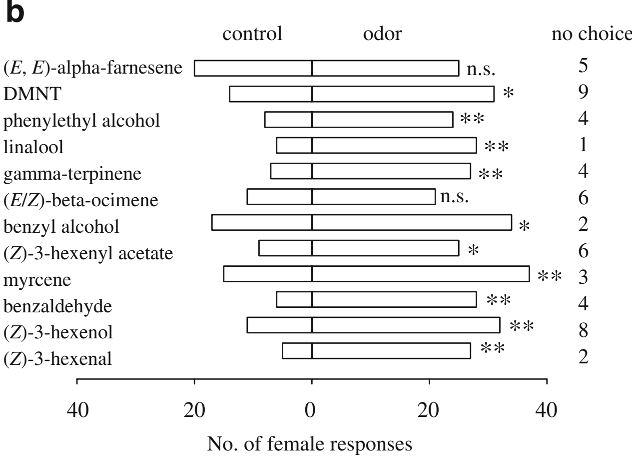

Fig. 5 Behavioral responses of *Myllocerinus aurolineatus* (A) males and (B) females to twelve synthetic compounds *vs*. clean air evaluated in a Y-tube olfactometer. Numbers refer to the number of *M. aurolineatus* adults choosing an odor source. $N>32$ per treatment. χ^2-test: *$P<0.05$; ** $P<0.005$; ns, $P>0.05$

from conspecifics. This suggests that *M. aurolineatus* adults use volatiles induced by conspecific feeding as olfactory cues when foraging for hosts, and it may in part explain the aggregation behavior of these herbivores in the field. Similar findings have been reported for other species of beetles in the Chrysomelidae (e.g., the Colorado potato beetle, *Leptinotarsa decimlineata* (Say) (Bolter et al. 1997) and the leaf beetle, *Oreina cacaliae* (Schrank) (Kalberer et al. 2001)), Scarabaedae (e.g., *Popillia japonica* (Newman) (Loughrin et al. 1996)); and in the Curculionidae (e.g., *D. abbreviatus* (Otálora-Luna et al. 2009)), as well as in the larvae of some lepidopteran families (Carroll et al. 2006).

The tea weevil may benefit from its response to volatiles from conspecific-damaged tea plants. First, the behavioral response may result in mass attacks that may decrease or even overwhelm the host plant's resistance. This has been reported in other beetles, especially the bark beetle (Lieutier 2002). Second, such behavior results in aggregations of both sexes on individual plants, which may in turn increase the probability of mating and the number of mates from which to choose, as shown in *O. cacaliae* by Kalberer et al. (2001), *Popillia japonica* Newman by Loughrin et al. (1996), and *L. decemlineata* by Bolter et al. (1997). Finally, the aggregation behavior may dilute the effect of natural enemies, as shown for the female diamondback moth *Plutella xylostella* (Linnaeus) (Shiojiri and Takabayashi, 2003). Our study suggests that the volatiles emitted from tea plants damaged by *M. aurolineatus* provide weevils with information about the host and conspecifics. These chemical signals may enhance host-searching efficiency, thus facilitating the survival and reproduction of *M. aurolineatus* under natural conditions.

After infestation with *M. aurolineatus* adults, tea plants released more than 40 chemicals, including green leaf volatiles, amino acid derivatives, and terpenoids. Not all of these compounds are unique to the induction of adult *M. aurolineatus* infestation, as (*Z*)-3-hexenol, benzaldehyde, (*E*)-2-hexenal, (*Z*)-3-hexenyl acetate, ocimene, and linalool have been reported as components of tea shoot–aphid complexes (Han and Chen 2002). Using GC-EAD analysis combined with Y-tube olfactometer bioassays, we found 6 chemicals, γ-terpinene, benzyl alcohol, (*Z*)-3-hexenyl acetate, myrcene, benzaldehyde, and (*Z*)-3-hexenal, which were attractive to both male and female *M. aurolineatus* adults; 2 chemicals, (*E*/*Z*)-β-ocimene and (*E, E*)-α-farnesene, which were attractive only to males; and 4 chemicals, DMNT, phenylethyl alcohol, linalool, and (*Z*)-3-hexenol, which were attractive only to females. Nine of the 12 compounds identified in this study have been reported previously as attractants for other insects. Campbell et al. (1993) found that the damson-hop aphid *Phorodon humuli* (Schrank) was attracted by (*Z*)-2-hexenal and β-caryophyllene, and deterred by methyl salicylate, and that these chemicals are emitted by conspecifics feeding on the hop host, *Humulus lupulus* L. Faccoli et al. (2008) found that myrcene, a component of HIPVs, modulates the host-seeking behavior of *Tomicus destryens* (Wollaston).

Unique combinations of odor components may provide a substantial degree of specificity for the host-seeking process of phytophagous insects. For instance, the Colorado potato beetle is attracted by a blend of (*Z*)-3-hexenyl acetate, (±)-linalool, and methyl salicylate (Dickens 2000). The blend of (±)-linalool, (Z)-3-hexenol, and carvacrol (25:25:2.5 μg) is attractive to the female tropical root weevil *D. abbreviatus*, but repellent to males (Otálora-Luna et al. 2009). However, linalool released from *Zea mays* plants infested by sixth-instars of *Spodoptera frugiperda* (Smith) was attractive to conspecific larvae (Carroll et al. 2006). An attractive function has been described in a number of insects for the following four compounds: DMNT for *S. frugiperda* (Carroll et al. 2008), phenylethyl alcohol for mosquito *Culex pipiens pipiens* Linnaeus (Jhumur et al. 2007), benzaldehyde for *Chrysopa sinica*

Tjeder, *Aphidius sp*., (*E, E*)-α-farnesene for the codling moth, *Cydia pomonella* (L.) (Yan et al. 2003; Landolt and Guédot 2008) and *Coccinella septempunctata* Linnaeus (Han and Chen 2002). To our knowledge, γ-terpinene, (Z)-3-hexenal, and benzyl alcohol have not been found to attract any insects.

Our results suggest that herbivore-induced host plant volatiles may have potential application in the monitoring and control of *M. aurolineatus* adults. Therefore, future research should be carried out in the field to assess the potential trapping effectiveness of the semiochemicals identified here.

Acknowledgments We thank Taro Maeda for providing chemical standards of DMNT; Dr. Jonathan David Sweeny for revising the English and providing suggestions for further investigation; and Emily Wheeler for editorial assistance. We thank Liang Su and Wen Zhang , who came from Jilin Agricultural University and Yangtze University as summer students in our group, for collecting and rearing weevils. The study was sponsored by the National Natural Science Foundation of China (200930771449), and the Science and Technology Department of Zhejiang Province (2009C32052).

Abstract A study was carried out on the allelopathic potential of four forest species, *Tectona grandis*, *Aleurites fordii*, *Gliricidia sepium*, and *Maytenus buxifolia*. The most active species, *T. grandis*, was selected to perform a phytochemical study. A new compound, abeograndinoic acid, was isolated, and elucidation of its structure showed that this compound has an unusual carbon skeleton. A further 21 known terpenoids—including 4 sesquiterpenoids, 8 diterpenes and 9 triterpenes—also were isolated. A biosynthetic scheme for the presence of the new compound is proposed. Bioactivity profiles that used etiolated wheat coleoptiles and phytotoxicity bioassays on the isolated compounds were conducted. The compounds that presented the highest phytotoxic activity are the diterpenes **9** (2-oxokovalenic acid) and **12** (19-hydroxyferruginol).

Key Words Allelopathy · Verbenaceae · *Tectona grandis* · Terpene · Clerodane

Introduction

Exotic plant species represent the core of agricultural production in many countries. Cuba is no exception, since most of the agricultural species grown in the country are exotic, having been introduced at some point in the past. A number of exotic timber trees were introduced into Cuba from tropical and subtropical regions. The scientific literature supports the ethnobotanical use of such species as sources of bioactive substances of both pharmacological and agrochemical interest. Examples of this phenomenon include neem (*Azadirachta indica* A. Juss) (Atawodi and Atawodi 2009), chinaberry (*Melia azedarach* L.) (Charleston et al. 2006), tamarind (*Tamarindus indica* L.) (Khanzada et al. 2008), gliricidia (*Gliricidia sepium* Jack) (Ramamoorthy and Paliwal 1993), wild indigo (*Indigofera suffruticosa* Mill) (Barros and Teixeira 2008), and sugar-apple (*Annona squamosa* L.) (Naik et al. 2008).

Better utilization of non-wood forest products (NWFPs) requires knowledge of the ecological relationships of introduced alien species and their potential as sources of bioactive compounds, especially agrochemical and allelopathic potential. The families *Celastraceae*, *Fabaceae*, *Euphorbiaceae*, and *Verbenaceae* have a wide variety of tree species with a number of biological activities. Several species within these families are distributed in Cuba, and these include *Tectona grandis* (Verbenaceae), *Aleurites fordii* (Euphorbiaceae) (Fozdar et al. 1989), *Gliricidia sepium* (Fabaceae) (Herath et al. 1997), and *Maytenus buxifolia* (Celastraceae) (González et al. 1997). These species are economically important and have been used in agroforestry systems or for various ethnobotanical applications. However, the possible environmental impact that arises from the introduction of these species has not been

evaluated, nor has the possible use of these species as a source of natural chemicals.

Herein, we describe a study of the allelopathic potential of these forest species. The species with the highest allelopathic activity, i.e., teak (*T. grandis) (Verbenaceae),* was selected for a phytochemical study with the aim of isolating and characterizing the metabolites responsible for the biological activity. Few compounds have been isolated from teak, and most of these are quinones and triterpenes (Rimpler and Christiansen 1977). The family Verbenaceae is characterized in chemical terms by the presence of low levels of diterpenes, with tectograndinol as the only example previously isolated from the genus *Tectona* (Joshi et al. 1977; Marwani et al. 1997).

The characterization of chemical components from *Tectona grandis* and the assessment of their activity are likely to provide information to explain the success of this tree culture where it has been used in agroforestry (taungya system). This system involves combining crops such as corn, cotton, cassava, ginger, peanut, soybean, upland rice, and beans with young teak plantations, an approach that results in higher crop yields and better control of the weeds (Wiersum 1982). From an ecological point of view, a move towards sustainable agriculture where weeds can be controlled to some extent by forest species such as *T. grandis* is desirable. The increased forest area is not only as a source of wood, but as a new potential tool for pest control.

Previously, we reported the isolation of seven apocarotenoids from *T. grandis* and elucidated the structures of two of them, tectoionols A and B (Macias et al. 2008). As a continuation of our study of this species, a bioassay-guided fractionation of extracts from *T. grandis* was carried out in order to isolate and identify the chemical constituents and to characterize their potential phytotoxic activities. We report here the isolation and structure elucidation of a new compound, abeograndinoic acid, which has an unusual carbon skeleton. A further 21 known terpenoids, including 4 sesquiterpenoids, 8 diterpenes, and 9 triterpenes, also were isolated. The bioactivity profiles of the isolated compounds were studied.

Methods and Materials

General IR spectra (KBr) were recorded on a Perkin-Elmer FT-IR Spectrum 1000 or a Matton 5020 spectrophotometer. NMR spectra were run on Varian INOVA-400 and Varian INOVA 600 spectrometers. Chemical shifts are given in ppm with respect to residual ^{1}H signals of $CHCl_3$-d_1 and acetone-d_6 (δ 7.25 and 2.04, respectively), and ^{13}C signals are referenced to the solvent signal (δ 77.00 and 29.80, respectively). Optical rotations were determined by using a Perkin-Elmer model 241 polarimeter (on the sodium D line). HRMS were obtained on VG AUTOESPEC mass spectrometer (70 eV). HPLC was carried out on a Merck-Hitachi instrument, with RI detection, using three different Merck LiChrospher columns: RP-18 (10 µm, 250×10 mm), SI 60 (5 µm, 250×4 mm), and SI 60 (10 µm, 250×10 mm).

Plant Material and Aqueous Extracts Leaves and bark of *Tectona grandis*, leaves and flowers of *Gliricidia sepium*, and leaves of *Maytenus buxifolia* and *Aleurites fordii* were collected between the months February and March (2003) in Ciudad de La Habana and were identified by MsC. Lutgarda González. Voucher specimens of each species (80613, 80614, 80921, and 80922, respectively) were deposited at the Jardín Botánico de Cuba.

Vegetal material was dried at room temperature in the shade. Dried materials of each species (50 g) were extracted with water (450 ml) for 24 h at room temperature in the dark—except for leaves of *G. sepium* and *A. fordii*, which were extracted with 900 ml of water.

Extraction and Isolation Dried leaves of *Tectona grandis* (5 kg) were extracted with water (35 l) for 24 h at room temperature in the dark. The aqueous solution was extracted with CH_2Cl_2 and then with EtOAc at room temperature. Details of the extraction procedure and the bioassays on the extract have been described previously (Macias et al. 2008). DCM/H_2O and DCM extracts were the most active.

The DCM/H_2O extract (8.8 g) was chromatographed on SiO_2 using mixtures of hexane/EtOAc of increasing polarity, acetone and methanol to afford twelve fractions: A_1–L_1.

Fraction E_1 (0.750 g, hexane/EtOAc, 17:3–1:4) was subjected to CC on Sephadex LH-20 using mixtures of n-hexane/chloroform/methanol (3:1:1) in order to remove chlorophylls and other high molecular weight compounds. The residue was separated by CC and HPLC on silica gel using mixtures of chloroform/acetone and hexane/EtOAc to yield compounds **1** (5.0 mg), **2** (0.4 mg), and **3** (4.8 mg). Fraction F_1 (0.800 g, hexane/EtOAc, 1:4) was subjected to CC on Sephadex LH-20 using a mixture of hexane/chloroform/methanol (3:1:1). Further purification by C-18 HPLC (water/methanol, 7:13) yielded compound **4** (2.8 mg). Fraction I_1 (0.750 g) was subjected to CC on silica gel using mixtures of chloroform/acetone of increasing polarity and methanol. The largest fraction, $I_1$6 (0.300 g), was purified by CC on silica gel using mixtures of hexane/acetone to yield compound **21** (1.1 mg).

The DCM (120 g) extract was chromatographed on silica gel (2.0 kg) using hexane/ethyl acetate mixtures of increasing polarity to yield eight fractions: A_2–H_2.

Fraction C_2 (15.00 g) was subjected to CC on silica using 1.5 l of each solvent (hexane, chloroform, ethyl

acetate, acetone, and methanol) to afford five fractions: C_21–C_25. Fraction C_22 (0.906 g, $CHCl_3$) was chromatographed by CC on silica gel, using mixtures of hexane/chloroform and chloroform/acetone. Purification by silica gel HPLC yielded **15** (2.3 mg), **5** (2.8 mg), and **13** (60 mg). Fraction C_24 (4.900 g, acetone) was subjected to CC on silica gel, using mixtures of hexane/chloroform and chloroform/acetone. Further purification by CC using hexane/ethyl acetate mixtures on silica gel and hexane/chloroform/methanol (3:1:1) on Sephadex LH-20 , that was the stationary phase that best separated these compounds, afforded compounds **12** (12.5 mg), **16** (5.0 mg), **14** (3.2 mg), and **6** (3.3 mg).

Fraction D_2 (hexane/EtOAc, 3:2, 7.46 g) was subjected to CC on silica gel, using mixtures of n-hexane/chloroform and chloroform/acetone. Fraction D_22 (0.930 g) was chromatographed using mixtures of n-hexane/chloroform and chloroform/acetone to afford, after further purification by HPLC, compounds **17** (3.0 mg), **8** and **10** (3.6 mg). Fraction D_23 (1.800 g, n-hexane/chloroform 1:3) was subjected to CC on silica gel using mixtures of n-hexane/chloroform and acetone to afford six fractions D_23A–D_23F. Fractions D_23B (0.485 g, chloroform) and D_23C (0.492 g, chloroform) were purified by CC on silica gel using mixtures of n-hexane/acetone and by HPLC to yield compounds **9** (18 mg) and **7** (15.5 mg). Fraction D_24 (1.200 g, chloroform/acetone 19:1) was subjected to CC on silica gel, using mixtures of n-hexane/acetone and chloroform/acetone. Compound **4** (3.6 mg) and an isomeric mixture of **18** and **19** (16 mg) were isolated from fraction D_24C after silica gel CC chromatography and C-18 HPLC. Fraction D_24E (0.059 g) was subjected to CC on silica gel using mixtures of n-hexane/chloroform and chloroform/acetone to yield compound **20** (4.9 mg) after purification by silica gel HPLC. Further chromatography of fraction D_24F (0.110 g) by CC and HPLC on silica gel, using mixtures of chloroform/acetone and acetone, afforded **11** (0.7 mg).

Abeograndinoic Acid (**11**), colorless oil; $[\alpha]_D^{25}$ −12.9 (*c* 0.01, $CHCl_3$); IR (KBr) ν_{max} 3410 (OH), 1735 (C=O), 1696 (C=O), 1650 (C=C) cm^{-1}. ^1H NMR data (400 MHz) $CHCl_3$-d_1: δ 9.78 (d, 1.2, H-3), δ 5.67 (br s, H-14), δ 4.13 (dd, 10.2, 4.4, H-2), δ 2.39 (ddd, 10.2, 10.2, 18.0, H-1), δ 2.36 (dd, 10.2, 10.2, H-10), δ 2.16 (d, 3H, 1.2, H-16), δ 2.13 (ddd, 12.9, 12.9, 4.2, H-12), δ 2.05 (ddd, 12.9, 12.9, 4.8, H-12′), δ 1.76 (ddd, 18.0, 10.2, 4.4, H-1′), δ 1.69 (ddd, 12.9, 12.9, 4.8, H-11), δ 1.60 (m, H-8), δ 1.40 (dddd, 13.4, 11.0, 11.0, 4.4, H-7), δ 1.31 (dddd, 13.4, 3.5, 3.5, 3.5, H-7′), δ 1.27 (ddd, 13.4, 4.4, 3.5, H-6′), δ 1.24 (m, H-11), δ 1.19 (m, H-6), δ 1.10 (s, 3H, H-18), δ 1.05 (s, 3H, H-19), δ 0.88 (s, 3H, H-20), δ 0.82 (d, 3H, 6.8, H-17); ^{13}C NMR data (100 MHz) $CHCl_3$-d_1: δ 208.3 (CH, C-3), δ 164.3.0 (C, C-15), δ 164.1 (C, C-13), δ 114.1 (CH, C-14), δ 78.0 (CH, C-2), δ 65.0 (C, C-4), δ 46.9 (CH, C-10), δ 46.8 (C, C-5), δ 36.7 (C, C-9), δ 36.0 (CH_2, C-12), δ 35.9 (CH, C-8), δ 35.2 (CH_2, C-1), δ 31.8 (CH_2, C-11), δ 30.9 (CH_3, C-6), δ 26.2 (CH_2, C-7), δ 25.7 (CH_3, C-20), δ 20.2 (CH_3, C-19), δ 19.4 (CH_3, C-16), δ 15.3 (CH_3, C-17), δ 12.2 (CH_3, C-18); HREIMS *m/z* 336.2311 (calc. for $C_{20}H_{32}O_4$ *m/z* 336.2300).

Coleoptile Bioassay Wheat seeds (*Triticum aestivum* L. cv. Duro) were sown in 15 cm diam Petri dishes misted with water and grown in the dark at 22±1ºC for 3 d (Hancock et al. 1964). Roots and caryopses were removed from the shoots. Shoots were placed in a Van der Weij guillotine and the apical 2 mm were cut off and discarded. The next 4 mm of the coleoptiles were removed and used for the bioassay. All manipulations were performed under a green safelight (Nitsch and Nitsch 1956). Compounds were predissolved in DMSO and diluted to the final bioassay concentration with a maximum of 0.1% DMSO. Parallel controls with water and DMSO at the same concentration also were run.

Crude extracts, fractions, or pure compounds to be assayed for biological activity were added to test tubes. Assays were carried out in duplicate. Phosphate-citrate buffer (2 ml) containing 2% sucrose (Nitsch and Nitsch 1956) at pH 5.6 was added to each test tube. Five coleoptiles were placed in each test tube (3 tubes per dilution), and the tubes were rotated at 0.25 rpm in a roller tube apparatus for 24 h at 22ºC in the dark. Coleoptiles were measured following digitalization of their images. Data were statistically analyzed using Welch's test (Martín Andrés and Luna del Castillo 1990). Data are presented as percent difference from control. Thus, zero represents the control, positive values represent stimulation of the studied parameter, and negative values represent inhibition.

Phytotoxicity Bioassays The selection of target plants was based on an optimization process developed by us in our search for a standard phytotoxicity bioassay (Macías et al. 2000). Several Standard Target Species (STS) were proposed, including the monocot *Allium cepa* L. (onion) and dicots *Lycopersicon esculentum* Will. (tomato), *Lepidium sativum* L. (cress), and *Lactuca sativa* L. (lettuce), which were assayed for this study.

Bioassays were conducted using Petri dishes (50 mm diam) with one sheet of Whatman No.1 filter paper as a support. Germination and growth were conducted in aqueous solutions at controlled pH using 10^{-2}M 2-[*N*-morpholino]ethanesulfonic acid (MES) and 1 M NaOH (pH 6.0). Compounds to be assayed were dissolved in DMSO (0.2, 0.1, 0.02, 0.01, and 0.002 M), and these solutions were diluted with buffer (5 µl DMSO solution/ml buffer) so

that test concentrations for each compound (10^{-3}, $5{\cdot}10^{-4}$, 10^{-4}, $5{\cdot}10^{-5}$, and 10^{-5}M) were reached. This procedure facilitated the solubility of the assayed compounds. The number of seeds in each Petri dish depended on the seed size. Twenty seeds were used for tomato, lettuce, cress, and onion. Treatment, control or internal reference solution (1 ml) was added to each Petri dish. A similar procedure was used for wheat in 90 mm diam Petri dishes with 10 seeds. Four replicates were used for tomato, cress, onion, and lettuce (80 seeds).

After adding seeds and aqueous solutions, Petri dishes were sealed with Parafilm to ensure closed-system models. Seeds were further incubated at 25ºC in a Memmert ICE 700 controlled environment growth chamber in the dark. Bioassays took 4 d for cress, 5 d for lettuce, tomato, and wheat, and 7 d for onion. After growth, plants were frozen at −10ºC for 24 h to avoid subsequent growth during the measurement process.

The commercial herbicide Logran®, a combination of *N*-(1,1-dimethylethyl)-*N*′-ethyl-6-(methylthio)-1,3,5-triazine-2,4-diamine (terbutryn, 59.4%) and 2-(2-chloroethoxy)-*N*-{[(4-methoxy-6-methyl-1,3,5-triazin-2yl)amino]carbonyl} benzenesulfonamide (triasulfuron, 0.6%), was used as an internal reference in accordance with a comparison study reported previously (Macías et al. 2000). This herbicide was used at the same concentrations (10^{-3}, $5{\cdot}10^{-4}$, 10^{-4}, $5{\cdot}10^{-5}$, and 10^{-5}M), and under the same conditions as the compounds reported here. Control samples (buffered aqueous solutions with DMSO and without any test compound) were used for all of the plant species assayed.

Evaluated parameters (germination rate, root length, and shoot length) were recorded using a Fitomed© system (Castellano et al. 2001), which allowed automatic data acquisition and statistical analysis by use of the associated software. Data were analyzed statistically using Welch's test, with significance fixed at 0.01 and 0.05. Results are presented as percent difference from the control. Zero represents control, positive values represent stimulation, and negative values represent inhibition.

IC_{50} values were obtained after adjusting phytotoxicity data to concentration (logarithmic scale), to a sigmoidal dose-response curve, defined by equation:

$$Y = Y_{\min} + \frac{Y_{\max} - Y_{\min}}{1 + 10^{\log EC50 - X}}$$

Where X indicates the logarithm of concentration, Y indicates the response (phytotoxicity), and $Y_{\max}$ and $Y_{\min}$ are the maximum and minimum values of the response, respectively. Goodness of fit is described by the determination coefficient (r^2). The adjustment and r^2 values were obtained using GraphPad Prism® software v. 4.00 (GraphPad Software Inc.).

Results and Discussion

Six aqueous extracts were obtained from leaves and bark of *T. grandis* (**TL**, 6 g; **TB**, 4 g), leaves and flowers of *G. sepium* (**GL**, 13 g; **GF**, 11.5 g), leaves of *A. fordii* (**AL**, 8.5 g) and leaves of *M. buxifolia* (**ML**, 1.2 g). The extracts were subjected to a bioassay of etiolated wheat coleoptiles. Five dilutions were used in the assay (1,000, 500, 250, 125, and 75 ppm) and these were prepared from the dried aqueous extracts.

The results obtained in the bioassay are shown in Fig. 1, where activity levels correlate with the concentration expressed in ppm. Extracts that showed higher activity levels were **TL**, **ML**, **TB,** and **GF**, which showed the highest inhibition values at 1,000 ppm, with values of −69, −66, −63, and −60%, respectively. The aqueous extracts of leaves from *A. fordii* (**AL**) and *G. sepium* (**GL**) at the highest concentrations showed lower inhibitory activity (−41 and −36%, respectively). Among the most active extracts, only the extract from leaves of *T. grandis* retained activity levels at lower concentrations, and these were close to those observed at the highest concentration. Thus, the activities of these extracts at 500 and 250 ppm were **TL** (−56 and −53%), **ML** (−48 and −45%), **TB** (−45 and −33%), and **GF** (−38 and −28%). In light of the observed values; its successful use in agroforestry systems; its bioavailability; and the possibility of exploiting non-timber forest products, the leaves of *T. grandis* were selected for further phytochemical study.

The study of the allelopathic potential of *Tectona grandis* was initiated with the study of the DCM extract obtained from the aqueous extract and the DCM extract

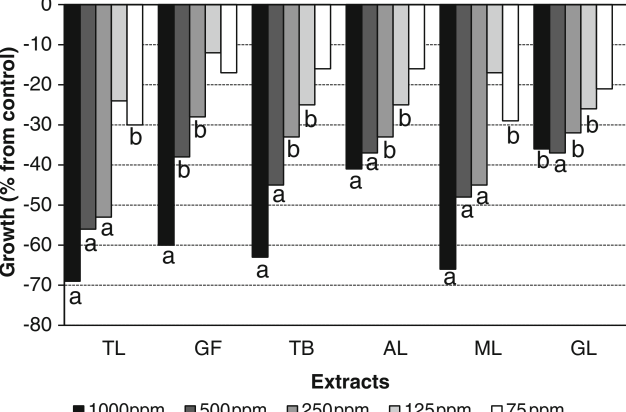

Fig. 1 Effect of aqueous extracts on the elongation of etiolated wheat coleoptiles. Values are expressed as percentage from the control and are not significantly different with $P>0.05$ for the Mann–Whitney's test. **a** Values significantly different with $P<0.01$. **b** Values significantly different with $0.01<P<0.05$. **TL** (leaves of *Tectona grandis*), **TB** (bark of *T. grandis*), **GL** (leaves of *Gliricidia sepium*), **GF** (flowers of *G. sepium*), **AL** (leaves of *Aleurites fordii*) and **ML** (leaves of *Maytensus buxifolia*)

Fig. 2 Terpenes isolated from *Tectona. grandis*

obtained by direct maceration of the dry leaves. Both extracts were selected on the basis of the bioactivity levels shown in the wheat coleoptile bioassay (Macías et al. 2008).

Spectroscopic data for sesquiterpenes **1** (Gutierrez and Herz 1988), **2** (Zhang et al. 2003), **3** and **4** (Niwa et al. 1978), diterpenes **5** (Zulueta et al. 1995), **6** (Urones et al. 1987), **7** (Marsaioli et al. 1975), **8** (Dekker et al. 1988), **9** (Hasan et al. 1982), and **12** (Cambie et al. 1984), as well as triterpenes **13** (Dellagreca et al. 1990), **14** (Aliotta et al. 1991), **15** (Wenkert et al. 1978), **16** (Brandao et al. 1992), **17** (Seebacher et al. 2003), **18**, **19** (Pungitore et al. 2005), **20** (Biessels et al. 1974), and **21** (Takahashi et al. 1974) were identical to those reported previously (see Fig. 2 for structures). This is the first time that sesquiterpenes have been described for the genus *Tectona* and the first time that compounds **2**–**6**, **8**–**10**, **12,** and **21** have been isolated from

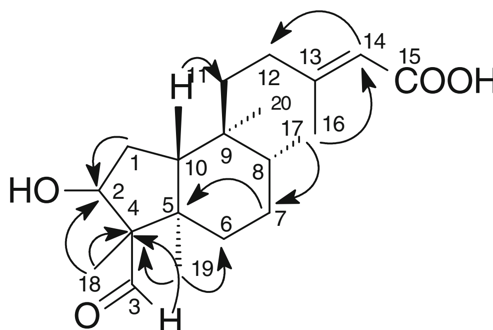

Fig. 3 ^{1}H-^{13}C correlations observed in the g-HMBC experiment on compound **11** (Abeograndinoic acid)

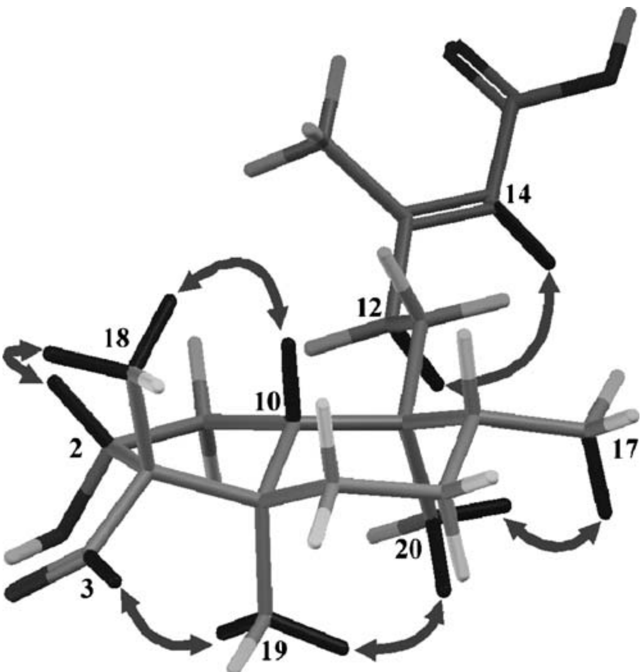

Fig. 4 nOe effects observed for the most stable conformer of **11** (abeograndinoic acid) using PM3 calculations

Fig. 5 Proposed biosynthetic scheme for compound **11** (abeograndinoic acid)

the family *Verbenaceae*. Compound **11** is also described for the first time in the literature.

Compound **11** was isolated as a colorless oil from the DCM extract. The mass spectrum of **11** shows a molecular ion at *m/z* 336.2311, corresponding to a formula $C_{20}H_{32}O_4$. The IR spectrum shows a band at 3,410 cm^{-1} due to the hydroxyl group, which along with the intense band at 1,696 cm^{-1} establishes the existence of an acid group in the molecule. Signals at 1,735 and 1,650 cm^{-1} are assigned to a carbonyl group and a double bond, respectively.

In the ^{1}H-NMR spectrum a characteristic set of signals is observed for the angular methyl groups present in the clerodane diterpene: two signals at δ 0.88 (s, 3H) and 1.05 (s, 3H), corresponding to the methyl groups attached to a quaternary carbon, are assigned to H-20 and H-19, a doublet methyl signal at δ 0.82 (d, 3 H, 6.8) corresponds to H-17 and a signal due to a methyl on a double bond with an *E* geometry at δ 2.16 (d, 3 H, 1.2, H-16). Moreover, the ^{1}H-NMR spectrum of **11** is similar to that of solidagonal (**10**) (Bohlmann et al. 1985), with a broad singlet at δ 5.67 (bs, H-14), suggesting the presence of a trisubstituted double bond, and a signal due to an aldehyde group at 9.78 (d, 1.2). These data suggest that this compound could have an abeoclerodane skeleton. The most significant differences observed in the spectrum in comparison to that of **10** are the signal at δ 1.10 (s, 3H), which corresponds to the H-18 methyl located on a quaternary carbon instead of a double bond, and the presence of a signal at δ 4.13 (dd, 10.2, 4.4) due to a proton geminal to a hydroxyl group (g-HSQC C-2 at δ 78.0).

The ^{1}H-NMR-2D-COSY experiment allowed us to establish the following correlations: the signal at δ 4.13 (dd, 10.2, 4.4, H-2) shows coupling with signals at δ 2.39 (ddd, 10.2, 10.2, 18.0, H-1) and δ 1.76 (ddd, 4.4, 10.2, 18.0, H-1′), corresponding to two geminal protons, which in turn are coupled with the signal at δ 2.36 (dd, 10.2, 10.2, H-10). These data imply that the formyl group cannot be attached at C-3, as it is in solidagonal (**10**).

The presence in the ^{1}H-NMR spectrum of a singlet assigned to H-18 and the correlations observed in the g-HMBC spectrum (Fig. 3) between the signals of H-18 at δ 1.10 and the quaternary carbon at 65.0 (C-4), as well as between C-3 and the aldehydic proton, allow us to place the aldehyde group geminal to C-18. These correlations, together with the previous data, lead us to suggest an unusual carbon skeleton for this compound. The correlations observed in the g-HMBC spectrum (see Fig. 3) allowed us to assign unambiguously all signals in the ^{1}H-NMR and ^{13}C-NMR spectra.

In order to determine the relative stereochemistry of the molecule, a series of 1D NOESY-NOESY experiments was carried out. The observed nOe effects are shown in Fig. 4. The nOe effect between H-14 and H-12 confirms an *E* stereochemistry for the double bond (Fig. 4).

The spectroscopic data for **11** suggest that this compound has the structure presented in Fig. 2, and we have named this abeograndinoic acid. This diterpene has a rearranged clerodane skeleton. Some furoclerodane compounds with a analogous carbon skeleton and very different functionalization have been described from the family

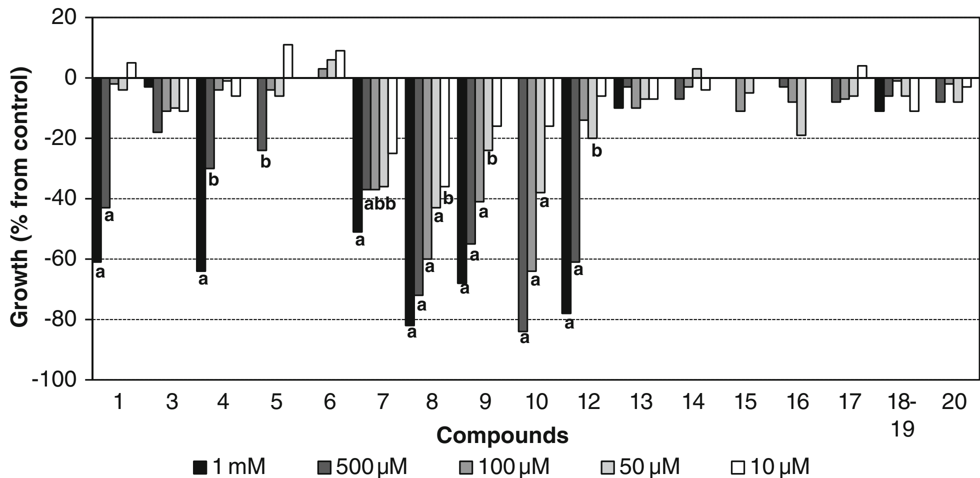

Fig. 6 Effects of compounds **1**–**20** on etiolated wheat coleoptiles. Values are expressed as percentage from the control and are not significantly different with $P > 0.05$ for the Mann–Whitney's test. **a** Values significantly different with $P < 0.01$. **b** Values significantly different with $0.01 < P < 0.05$

Asteraceae (Jakupovic et al. 1986; Bohlmann and Mungai 1990; Zdero et al. 1990a, b). A biosynthetic route through a pinacolinic rearrangement from the corresponding 3,4-dihydroxy derivative was proposed for these compounds. It also has been proposed that the biosynthetic origin of **10** is from a clerodane with a double bond between C-4 and C-5, after subsequent oxidative rupture, cyclization, and dehydration (Bohlmann et al. 1985). In the case of **11**, the biosynthesis could start with a clerodane skeleton, which has a double bond between C-2 and C-3. Oxidative rupture of the double bond and subsequent aldolic cyclization would afford compound **11** (Fig. 5).

Coleoptile Bioassay Results Etiolated wheat coleoptiles bioassay is a fast test (24 h), which is sensitive to a wide range of bioactive substances (Cutler et al. 2000) including plant growth regulators, herbicides (Cutler 1984), antimicrobials, mycotoxins, and assorted pharmaceuticals.

Fig. 7 Effects of compounds **7**–**9** and **12** on growth of standard target species. Values are expressed as percentage from the control and are not significantly different with $P>0.05$ for the Mann–Whitney's test. **a** Values significantly different with $P<0.01$. **b** Values significantly different with $0.01<P<0.05$

(Jacyno and Cutler 1993). The bioactivities on coleoptiles of these compounds were evaluated when sufficient quantities were avaliable (i.e., all cases except **2**, **11**, and **21**). The highest concentration tested for **1**, **3**, **4**, **7**–**9**, **12**, **13**, and **18**–**19** was 10^{-3} M, whereas **5**, **6**, **10**, **14**–**17**, and **20** were tested from $5{\cdot}10^{-4}$ M. It can be seen from Fig. 6 that sesquiterpenes **1** and **4** show inhibitory activity greater than −50% at the maximum concentration.

The results show that compounds **8**, **9**, and **12** inhibit coleoptile elongation by more than −60% at 10^{-3} M. In particular, **8** and **12** present values close to −80% at this concentration. It should be pointed out that compound **10** shows an inhibition value of −84% at $5{\cdot}10^{-4}$ M, which is the highest concentration tested. On the other hand, **5** and **6** show activity levels that are not particularly significant.

The most active compounds were the diterpenes **7**, **8**, **9**, **10**, and **12**. The activity of **12** decreases rapidly on dilution. The profile of the activity with dilution suggests that the presence of this α,β-unsaturated carbonyl group in the bicyclic system is influential in the activity, whereas the double bond and the carboxylic acid group on the lateral chain are less important. Thus, compound **7** shows an inhibition of −37% at $5{\cdot}10^{-4}$ M, whereas **8**, **9,** and **10** inhibit the elongation by −72, −55, and −84%, respectively, at the same concetration. Furthermore, the inhibition values are higher than −60% in the cases of **8** and **10** at 10^{-4} M.

Neither triterpenes nor steroids isolated in this work show relevant activity in this bioassay and, as a consequence, they were not selected for evaluation of phytotoxic activity.

In order to compare compound activities, IC_{50} values were calculated using the sigmoidal dose-response model. This approach allows comparison of the inhibitory activity of active compounds even when the starting concentrations are different. The order of increasing activity of the tested compounds in this bioassay is: **10** (IC_{50}=0.078 mM, R^2=0.984)>**8** (IC_{50}=0.31 mM, R^2=0.965) > **12** (IC_{50}=0.41 mM, R^2=0.983)>**9** (IC_{50}=0.65 mM, R^2=0.97) > **1** (IC_{50}=0.67 mM, R^2=0.998)>**4** (IC_{50}=0.96 mM, R^2=0.976)>**7** (IC_{50}=2.1 mM, R^2=0.975).

Phytotoxicity Bioassay Results The most active compounds were selected for phytotoxicity evaluation. Compounds **1**, **4,** and **10** were not included in the phytotoxicity bioassay due to the small amounts available (Fig. 7). The concentrations tested were identical to those in the previous bioassay. Standard target species (STS) were *Lactuca sativa* (lettuce), *Lycopersicum esculentum* (tomato), *Lepidium sativum* (cress), and *Allium cepa* (onion).

Regarding the dicotyledonous species, the tested compounds did not cause significant effects on germination or growth of *Lepidium sativum*. The behavior of the evaluated compounds in the germination and growth of *Lactuca sativa* is inhibitory in almost all cases. The highest inhibitory effects on the germination were caused by **9**, which shows activity values similar to the herbicide Logran® at the highest concentrations (10^{-3} M, −89%; $5{\cdot}10^{-4}$ M, −86%; 10^{-4} M, −68%) and higher values at lower concentrations ($5{\cdot}10^{-5}$ M, −48%; 10^{-5} M, −36%). With regard to the third dicotyledonous species, *Lycopersicum esculentum*, the effects on germination were of low significance. Root growth of tomato was stimulated by diterpenes **9** and **12**, with values higher than 20% for all concentrations, whereas the effects on shoots were not relevant.

In the monocotyledon species *Allium cepa*, the most affected parameter was root growth. Compounds **9** (10^{-3} M, −55%; $5{\cdot}10^{-4}$ M, −33%) and **12** (10^{-3} M, −44%) were inhibitory, with **9** being the most active. The effects on germination and shoot development were not significant, with **12** being the most active compound with values around −40% at the highest concentration.

In summary, the compounds that present the highest phytotoxic activity are the diterpenes **9** (2-oxokovalenic acid) and **12** (19-hydroxyferruginol). In addition, the general activity of the diterpene **10** (solidagonal acid), with an IC_{50} value of 78 μM, has to be highlighted, although due to the small amount isolated its phytotoxic activity could not be evaluated.

Abstract The phytotoxic effects of the lichen secondary metabolite—usnic acid on cultures of free living alga—*Scenedesmus quadricauda* (UTEX 76) and aposymbiotically grown lichen photobiont *Trebouxia erici* (UTEX 911) were assessed. We found a relatively strong inhibition effect of usnic acid on the growth of alga *Scenedesmus*, accompanied by an increase of cell size, an alteration of assimilation pigment composition, followed by strong degradation of chlorophyll *a*, a decrease of chlorophyll *a* fluorescence, and an increase of reactive oxygen species in the cells. The content of soluble proteins remained a stable parameter. Phytotoxicity of usnic acid on cultures of *Trebouxia* photobiont was significantly lower. Usnic acid in lichens may act as an allochemical that controls the division of photobiont cells, thereby regulating the balance between the photobiont and mycobiont forming thallus. Higher tolerance to usnic acid in *Trebouxia* cultures may be an adaptation resulting from the long term co-evolution of these algae with fungi that produce secondary metabolites.

Introduction

Lichens are a stable and self-supporting association between fungi (mycobionts) and photoautotrophic algae or cyanobacteria (photobionts). Interactions within a lichen thallus are, however, complex, and lichens may be considered more like an ecosystem or community than a typical organism (Fahselt 2008).

Lichens produce many unique compounds that are considered to have important biological and ecological roles. These roles include antimicrobial activity, allelopathy, antiherbivory, chelating of heavy metals, light screening, and other proposed functions not yet sufficiently supported by experimental evidence under laboratory conditions (Lawrey 1986; Pöykkö et al. 2005; Latkowska et al. 2006; Hauck et al. 2009; Solhaug et al. 2009). Secondary metabolites may be responsible for the ecological success of lichenization, allowing lichens frequently to be the dominant organisms in environments characterized by extreme ecological conditions. Lichen compounds are secreted by the fungal partner, and they are deposited on the surface of hyphae, as well as on lichen algae, typically constituting 0.1 to 5.0% (w/w) of thallus dry weight (Fahselt 1994).

Usnic acid, a yellowish pigment and dibenzofuran derivative, is a common lichen metabolite, especially abundant in members of the genera *Alectoria*, *Usnea*, or *Xanthoparmelia*. The antibiotic, antiviral, antimycotic, antiprotozoal, antiherbivoral, antiproliferative, anti-inflammatory, analgesic, antipyretic, allelopathic, and UV protecting effects of usnic acid have been stated previously (for review see Cocchietto et al. 2002).

There is little doubt that the presence of secondary metabolites, including usnic acid, has significant influence on lichen survival. Lichens are slow growing and long lived organisms, and due to the toxic effect of usnic acid to a wide range of organisms, their thalli are relatively well protected against pathogens and herbivores. However, usnic acid potentially can be toxic to cells that come in direct contact with it, even the algal partner of the lichen that produces it. Crystals of lichen cortical secondary metabolites may be deposited directly on the surface of photobiont cells (Sarret et al. 1998). Previous studies have suggested that the presence of usnic acid may regulate photobiont populations (Bačkor et al. 1998; Buďová et al. 2006). Production of usnic acid may be a critical step of maintaining the required ratio of mycobiont to photobiont biomass in thalli for mutualistic symbiosis.

The mechanisms of the phytotoxic effects of usnic acid on plants, including on its own photobionts are not understood sufficiently; however, inhibition of chlorophyll *a* fluorescence (F_V/F_M), decrease of carotenoid and chlorophyll levels in the cells, and decrease of viability have been demonstrated as responses of plants to the presence of usnic acid (Cardarelli et al. 1997; Endo et al. 1998; Buďová et al. 2006). Decrease of biomass production also has been demonstrated (Bačkor et al. 1998; Buďová et al. 2006; Lechowski et al. 2006).

Concentrations of secondary metabolites around photobiont cells are high, and lichen photobionts are in direct contact with cortical metabolites produced by the mycobiont (Takahagi et al. 2008). Although lichen compounds may act as allelochemicals and are responsible for maintaining balance between bionts inside lichen thalli, photobionts must be protected from the toxicity of these compounds. We hypothesized that lichen photobionts have evolved protective mechanisms against phytotoxicity of secondary metabolites through co-evolution with lichen mycobionts. To test this hypothesis, we evaluated the potential phytotoxic effect of usnic acid on the aposymbiotically grown lichen photobiont *Trebouxia erici*. For assessment of the potential differences in phytotoxicity of usnic acid to free-living algae without evolutionary experience with the presence of lichen secondary metabolites, *Scenedesmus quadricauda* also was chosen.

Methods and Materials

Organisms and Culture Conditions Free-living alga *Scenedesmus quadricauda* (Turp.) Bréb. (UTEX 76) and aposymbiotically grown lichen photobiont *Trebouxia erici* Ahmadjian (UTEX 911) were used. Both species belong to Chlorophyta, a division of green algae. Algae were cultivated on agar medium (1.5%) previously developed for cultivation of lichen algae by Ahmadjian (1993). This was Bold's Basal Medium (BBM 3N) plus 10 g casein acid hydrolyzate and 20 g glucose per liter with the pH adjusted to 6.5 (Bačkor et al. 2004). Cultures were maintained at 22°C under a 16:8 hr, L:D photoperiod and 30 $\mu mol.m^{-2}.s^{-1}$ artificial irradiance ("cool white" tubes).

Toxicity Assay Algae were cultivated on the surface of Whatman CF/C filters (glass fiber filter disks, 25 mm diam). Glass fiber filter disks were used instead of the cellulose-acetate disks, previously used for lichen photobiont cultivation (Bačkor et al. 2003, 2004). Glass fiber filter disks may be used directly for disruption in the mortar of algal cells grown on their surfaces. Crystals of usnic acid on the surface of fibers of the disk simulate the situation in natural lichens, where extracellular secondary metabolites located on the surface of hyphae are in the contact with algal cells in the photobiont layer. Briefly, cells from both algal species (approximately two inoculation loops) grown on stock solid *Trebouxia* media were transferred into 50 ml of liquid *Trebouxia* media in an Erlenmeyer flask. Cells were suspended by gentle stirring on a magnetic stirrer for 1 hr. Cultures were maintained for 5 d in a cultivation room under conditions described previously, with daily stirring on a magnetic stirrer for about 1 hr. Homogeneity of the algal suspension was verified microscopically, and the number of cells was calculated by using a standard haemocytometer. Cell density of cultures was adjusted to approximately 10^6 cells ml^{-1} of medium before quantitative cultivation of algae.

For cultivation of both algal species, sterilized Whatman CF/C filters (25 mm diam) were subjected to three different pretreatments. Usnic acid (0.01 and 0.1 mg / disk) dissolved in acetone (volume 30 µl) was applied by automatic pipette on the surface of disks, while the same volume of acetone was applied to control disks. We used (+)-usnic acid enantiomer (Sigma-Aldrich). After evaporation of acetone for 4 hr, one disk was transferred to the surface of solid *Trebouxia* medium in a separate Petri dish, (6 cm diam), and 20 µl of algal suspension were inoculated into the center of each disk. Disk pores allowed supplemental nutrient media to pass through the disk and permitted growth to be determined easily from changes in biomass (Bačkor et al. 2003, 2004). The total mass of cultures was calculated by subtracting the mean fresh weight (fw) of a

Whatman CF/C disk saturated by identical medium, from the fw of a disk supporting algal cultures after 14 d. Each treatment was replicated eighteen times for both algal species assessed.

Pigment Analysis and Measurement of Chlorophyll a Integrity The influence of usnic acid on the algae was determined by using cultures grown on Whatman CF/C disks. Weighed disks were extracted in the dark for 1 hr at 65°C in 5 ml of dimethyl sulfoxide (DMSO). To maximize chlorophyll extraction, cell aggregates were homogenized with a mortar, and glass fibers of disks facilitated disruption of cell walls of algae. After cooling to ambient temperature, the absorbance of the extract, as a reflection of turbidity, was determined at 750 nm with a spectrophotometer to be certain that it was always less than 0.01. Absorbance of extracts was read at 665, 649, 435, and 415 nm to assess chlorophyll content and the possibility of chlorophyll *a* degradation (Barnes et al. 1992; Wellburn 1994). To utilize the linear portion of the response curve, extracts from disks with very high cell densities (absorbance at 665 nm higher than 0.8) were diluted with fresh DMSO to fall into the absorbance range 0.2–0.8. To determine the content of “total” carotenoids, absorbance was read at 480 nm. Chlorophyll *a*, chlorophyll *b*, chlorophyll *a+b*, and total carotenoids were calculated by using equations derived from specific absorption coefficients for pure chlorophyll *a* and chlorophyll *b* in DMSO. Chlorophyll *a/b* was used to assess the physiological competence of algal cells.

The ratios of absorbances at 435 and 415 nm (A 435/A 415), termed the phaeophytinization quotient, were calculated as a reflection of the ratio of chlorophyll *a* to phaeophytin *a* and to provide an indication of integrity of photobiont chlorophyll. Each treatment was replicated three times.

Activity of Photosystem II Chlorophyll *a* fluorescence was measured in algae grown on Whatman CF/C disks on the surface of *Trebouxia* agar medium. While still on the surface of the medium in Petri dishes (to minimize desiccation), algae were dark-adapted for 30 min prior to measurement. The potential quantum yield of photosystem II (PSII) was measured with a Plant Stress Meter (PSM Mark II, Biomonitor, SCI AB), with a sensor 5 mm diam, and results were expressed as F_V/F_M calculated as the maximal fluorescence (F_M) less the minimal fluorescence (F_0), divided by F_M of dark adapted plants: $(F_M - F_0) / F_M = F_V/F_M$. Chlorophyll fluorescence parameters were taken from three separate positions on each disk, and the mean value used as one observation. Each treatment was replicated three times.

Content of Soluble Proteins Algae grown on Whatman CF/C disks (controls, as well as with addition of usnic acid on the surface of disks) were homogenized with disks in an ice-cold mortar in phosphate buffer (50 mM). After centrifugation at 15,000 g at 4°C for 20 min, the water-soluble protein content of supernatants was measured using the Bradford (1976) method. Supernatants (100 µl) were pipetted into 900 µl of Bradford assay kit (Biorad) in a spectrophotometric cuvette and mixed. After 10 min, absorbance of samples was spectrophotometrically measured at 595 nm. Bovine serum albumin was used as calibration standard. Each treatment was replicated three times.

Detection of Oxidative Status Hydrogen peroxide and superoxide were measured in homogenates with potassium phosphate buffer prepared for assay for determination of soluble proteins. Hydrogen peroxide was quantified by the $TiCl_4$ method (Kováčik and Bačkor 2007). Superoxide was estimated according to Elstner and Heupel (1976) by monitoring formation of nitrite from hydroxylamine at 530 nm. Reaction mixture contained 0.27 ml of potassium phosphate buffer, 0.03 ml of 10 mM hydroxylamine, 0.3 ml of supernatant, 0.3 ml of 17 mM sulphanilamide, 0.3 ml of 7 mM α-naphthylamine, and 0.3 ml of diethyl ether. Each treatment was replicated three times.

Cell Size Algae grown on Whatman CF/C disks from each treatment were separated gently from the surface of the disks by a scalpel. Cells were suspended immediately in 5 mM HEPES buffer, pH 6.5 and viewed under a light microscope at 800×. Cell size parameters (width and length in the case of *S. quadricauda* cells, or length in the case of *T. erici* spherical cells) were measured with an eyepiece micrometer. Twenty individual cells from each treatment and both algal species were evaluated.

Statistical Analysis The one-way analysis of variance and Tukey’s pairwise comparisons (MINITAB Release 11, 1996) were applied to determine significance ($P<0.05$) of differences in all measured parameters. In addition, two-way ANOVA with interactions (SPSS version 16, 2008) was applied to evaluate species effect (species), usnic acid effect (UA), and interactions between species effect and UA effect (species × UA) where applicable.

Results

Biomass production of the control *Scenedesmus* cultures was almost five times higher after 2 weeks of cultivation when compared to control *Trebouxia* cultures (Table 1). Presence of usnic acid on the disks significantly affected biomass production of both algal cultures in a dose dependent manner. However, a 0.01 mg/disk of usnic acid decreased biomass production of *Scenedesmus* cultures by a factor of 4,

Table 1 Biomass production (mg fw/disk), chlorophyll integrity (435/415), chlorophyll *a/b* ratio (A/B), total carotenoid/total chlorophyll ratio (CAR/CHL) and chlorophyll *a* fluorescence (F_V/F_M) of 2 week old *Secenedesmus* and *Trebouxia* cultures cultivated on disks with addition of usnic acid (0, 0.01 and 0.1 mg)

	Usnic acid conc. (mg/disk)	Biomass (mg fw/disk)	435/415	A/B	CAR/CHL	F_V/F_M

	P value	*P*=0.008	*P*=0.36	*P*=0.351	*P*=0.468	*P*=0.018

Values in vertical lines followed by the same letter(s) are not significantly different according to Tukey's test (*P*<0.05)

and a 0.1 mg/disk decreased biomass production by a factor of 11, while in *Trebouxia* culture biomass production was decreased only at the highest tested usnic acid dose of a 0.1 mg/disk by a factor of approximately 2.2 (Table 1). Two-way ANOVA for biomass production: species (*F*=63.25, *P*<0.001), UA (*F*=52.98, *P*<0.001), species × UA (*F*=40.98, *P*<0.001).

The highest tested usnic acid doses significantly decreased chlorophyll *a* integrity in *Scenedesmus* cultures, while in *Trebouxia* cultures none of the tested usnic acid concentrations significantly altered chlorophyll integrity (Table 1). Two-way ANOVA for chlorophyll *a* integrity: species (*F*=40.75, *P*<0.001), UA (*F*=10.84, *P*=0.006), species × UA (*F*=23.75, *P*<0.001).

Similarly, the highest tested usnic acid doses significantly decreased chlorophyll *a/b* of *Scenedesmus* cultures. In the *Trebouxia* cultures, we did not observe significant changes of chlorophyll *a/b* under any of the tested concentrations (Table 1). Two-way ANOVA for chlorophyll *a/b*: species (*F*=10.26, *P*=0.002), UA (*F*=1.88, *P*=0.194), species × UA (*F*=24.11, *P*<0.001).

Total carotenoid/total chlorophyll ratio was stable in both algal cultures regardless of usnic acid application (Table 1). Two-way ANOVA for total carotenoid/total chlorophyll ratio: species (*F*=2.32, *P*=0.139), UA (*F*=0.13, *P*=0.716), species × UA (*F*=4.81, *P*=0.03).

When calculated per unit of fresh weight (mg/g fw) of algal biomass, we observed a significant decrease of chlorophyll *a*, chlorophyll *b*, chlorophyll *a*+*b*, and total carotenoids in *Scenedesmus* cultures with the presence of a 0.1 mg/disk of usnic acid (Table 2). In the *Trebouxia* cultures, we did not observe any decrease in these parameters when calculated per unit fresh weight (Table 2). Two-way ANOVA for chlorophyll *a*: species (*F*=11.04, *P*=0.002), UA (*F*=20.69, *P*<0.001), species × UA (*F*=6.73, *P*=0.01). Two-way ANOVA for chlorophyll *b*: species (*F*=3.91, *P*=0.049), UA (*F*=14.81, *P*=0.002), species × UA (*F*=0.44, *P*=0.651). Two-way ANOVA for chlorophyll *a*+*b*: species (*F*=8.74,

Table 2 Chlorophyll *a* content (A, mg/g fw), chlorophyll *b* content (B, mg/g fw), chlorophyll *a*+*b* content (A+B, mg/g fw) and content of total carotenoids (TOT CAR, mg/g fw) of 2 week old *Secenedesmus* and *Trebouxia* cultures cultivated on disks with addition of usnic acid (0, 0.01 and 0.1 mg)

Values in vertical lines followed by the same letter(s) are not significantly different according to Tukey's test (P<0.05)

P=0.004), UA (F=19.48, P<0.001), species × UA (F=4.15, P=0.042). Two-way ANOVA for total carotenoids: species (F=9.08, P=0.004), UA (F=14.93, P=0.002), species × UA (F=8.14, P=0.005).

Usnic acid decreased the F_V/F_M ratio of *Scenedesmus* cultures. Presence of a 0.1 mg/disk decreased the F_V/F_M ratio more than four times, while in *Trebouxia* cultures the F_V/F_M ratio decreased only 1.15 times at the highest tested usnic acid dose of 0.1 mg/disk (Table 1). Two-way ANOVA for F_V/F_M: species (F=91.20, P<0.001), UA (F=55.38, P<0.001), species × UA (F=49.48, P<0.001).

Increase of usnic acid on the disk did not cause a significant decrease in the soluble protein content of algal cultures calculated per unit fresh weight according to one-way ANOVA (Table 3). Two-way ANOVA for soluble protein content: species (F=0.492, P=0.623), UA (F=29.12, P<0.001), species × UA (F=5.60, P=0.019). According to two-way ANOVA, significant UA, as well as species × UA effects were observed.

The highest tested usnic acid dose of 0.1 mg/disk caused a significant increase of hydrogen peroxide content in *Scenedesmus* cultures (Table 3). In the cultures of *Trebouxia*, we also observed an increase of hydrogen peroxide content at a dose of 0.1 mg/disk, however, the increase was not strong enough to be significant (Table 3). Two-way ANOVA for hydrogen peroxide content: species (F=16.16, P<0.001), UA (F=11.80, P=0.004), species × UA (F=1.96, P=0.183).

The highest tested usnic acid dose of 0.1 mg/disk caused a significant increase of superoxide in cultures of both algal species tested (Table 3). Two-way ANOVA for superoxide content: species (F=15.49, P<0.001), UA (F=0.42, P=0.526), species × UA (F=0.21, P=0.815).

Both tested usnic acid doses caused significant increases of width and length of *Scenedesmus* cells. In *Trebouxia* cultures, we did not observe any significant increase of cell size at any of the tested usnic acid concentrations (Table 3). Two-way ANOVA for width: species (F=6.70, P=0.002), UA (F=8.53, P=0.005), species × UA (F=3.86, P=0.026).

Discussion

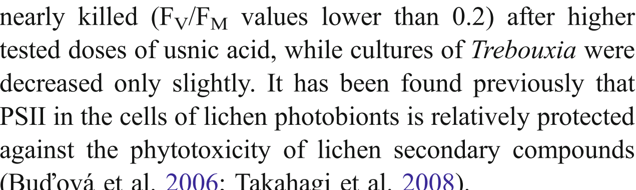
Influence of Usnic Acid on Algal Growth Usnic acid appears to have phytotoxic effects on vascular plants (Cardarelli et al. 1997; Lechowski et al. 2006) as well as on the algal partner of lichens (Bačkor et al. 1998; Buďová et al. 2006). In the present study, we found that control cultures of free-living alga *Scenedesmus* grew better when compared to aposymbiotically grown control cultures of *Trebouxia*. Presence of usnic acid on the surface of fibers caused a dose-dependent decrease of the growth of both algal cultures, however, the decrease was more pronounced in cultures of *Scenedesmus* compared to cultures of *Trebouxia*. Lower toxicity of usnic acid for photobiont cells may be a result of co-evolution of *Trebouxia* photobionts with filamentous fungi over a long period of time, perhaps hundreds of millions of years (Yuan et al. 2005). Usnic acid possesses antimitotic effects that have been demonstrated in taxonomically diverse organisms (Cardarelli et al. 1997). Surprisingly, presence of usnic acid in this study caused a significant increase of cell size of *Scenedesmus* cultures. This may be a result of the effect of usnic acid on the spindle apparatus during mitosis (Al-Bekairi et al. 1991). Although a similar trend was observed in the *Trebouxia* cells, the effect was not strong enough to be significant.

Influence of Usnic Acid on Algal Metabolic Processes The mechanisms of phytotoxic effects of usnic acid still are mostly unknown. It has been demonstrated that viability of the protoplasts of *Nicotiana tabacum* decreases due to the presence of usnic acid (Cardarelli et al. 1997). Buďová et al. (2006) demonstrated that viability of the *Trebouxia erici* photobiont cells decreased due to increased doses of usnic acid.

Changes in composition of assimilation pigments, as well as in chlorophyll *a* fluorescence of aposymbiotically grown lichen photobionts previously have been found to be excellent markers for assessment of the influence of xenobiotics, including metals (Bačkor et al. 2003). One of the most frequently used parameters in lichen stress physiology is chlorophyll degradation, expressed as the phaeophytinization quotient, which reflects the ratio of chlorophyll *a* to phaeophytin *a* (Bačkor and Loppi 2009). This is defined as the ratio of optical densities at 435 nm and 415 nm (OD_{435}/OD_{415}). In healthy lichens and photobionts, the OD_{435}/OD_{415} ratio is about 1.4, and the presence of xenobiotics, including heavy metals, may cause a marked decrease of this value (Ronen and Galun 1984; Bačkor and Loppi 2009). In the present study, none of the tested usnic acid concentrations caused a significant decrease of phaeophytinization quotient in *Trebouxia* cultures, while the highest tested dose of 0.1 mg/disk caused a significant decrease of the phaeophytinization quotient in the cultures of *Scenedesmus*. An identical trend was observed for the ratio of chlorophyll *a/b*, where only the highest tested dose of usnic acid in the cultures of *Scenedesmus* caused a significant decrease; chlorophyll *a* of *Scenedesmus* cells was more sensitive than chlorophyll *b*. However, when we compared changes of total chlorophyll content to total carotenoid content due to presence of usnic acid, we did not find significant differences in either algal species.

Irrespective of the previously noted parameters, we observed a decrease in the content of chlorophyll *a*, chlorophyll *b*, chlorophyll *a*+*b*, and total carotenoids of *Scenedesmus* calculated per unit of fresh weight. Although chlorophyll *a* and chlorophyll *b* differ only in the composition of side chain (chlorophyll *a* contains a methyl group and chlorophyll *b* a formyl group), decrease of chlorophyll *a* was notable. Previous studies suggested that plants exposed to pollutants, including acid rain, heavy metals, and herbicides respond by decrease of chlorophyll *a* rather than chlorophyll *b* (Hendry et al. 1987). Degradation of chlorophyll *a* here was accompanied by increased phaeophytinization. Han et al. (2004) demonstrated that usnic acid is toxic to cultured hepatocytes and disrupts electron transport in mitochondria and induces oxidative stress in the cells. A previous study suggested that production of the reactive oxygen species in the cells of the lichen photobiont *Trebouxia erici* caused increase of membrane lipid peroxidation (Bačkor et al. 2007).

The reduced F_V/F_M values measured in our usnic acid treated cultures indicate damage to PSII. Endo et al. (1998) demonstrated a decrease of chlorophyll *a* fluorescence in spinach leaves due the presence of lichen-derived secondary metabolites. However, we found a differential sensitivity of algae to usnic acid as cultures of *Scenedesmus* were



nearly killed (F_V/F_M values lower than 0.2) after higher tested doses of usnic acid, while cultures of *Trebouxia* were decreased only slightly. It has been found previously that PSII in the cells of lichen photobionts is relatively protected against the phytotoxicity of lichen secondary compounds (Buďová et al. 2006; Takahagi et al. 2008).

Xenobiotics, including metals, may alter the composition of soluble proteins in cultures of lichen photobionts (Bačkor and Fahselt 2008). Although we observed a significant decrease of protein content due to usnic acid when analyzed for individual disks (data not shown), we did not observe significant changes in soluble protein content calculated per unit of algal biomass either in *Scenedesmus* or in *Trebouxia* cultures. Caviglia et al. (2001) demonstrated that usnic acid in lichen *Parmelia soredians* may act as an antioxidant that detoxifies reactive oxygen species produced by the application of the herbicide Paraquat. However, Han et al. (2004) demonstrated that usnic acid itself may induce oxidative stress in the cells. In the present study, we found that the highest tested dose of usnic acid significantly increased hydrogen peroxide content in cultures of *Scenedesmus*, as well as superoxide radicals in cultures of both tested algal species.

In summary, we confirmed that usnic acid has a phytotoxic effect on algae, but that algae are differentially sensitive, and that the lichen photobiont *Trebouxia* is significantly less affected than *Scenedesmus*. These conclusions are based on analyses of physiological processes including biomass production, composition of assimilation pigments (mostly by decrease of chlorophyll *a* content and increase of its phaeophytinization), chlorophyll *a* fluorescence, soluble proteins, and reactive oxygen species. Higher tolerance of *Trebouxia* cultures to usnic acid may be an adaptation resulting from the long term co-evolution of these algae with fungi that produce secondary metabolites. These also may act as allelochemicals that control cell division of photobiont cells inside lichen thalli, thus regulating balance between symbionts forming lichens.

Abstract Mimicry is used widely by arthropods to survive in a hostile environment. Often mimicry is associated with the production of chemical compounds such as pigments. In crab spiders, the change of color is based on a complex physiological process that still is not understood. The aim of this study was to identify and quantify the ommochrome pigments and precursors responsible for the color change in the mimetic crab spider *Misumena vatia* (Thomisidae). A modified high performance reverse phase ion-pair chromatography technique enabled us to separate and quantify the ommochrome pigments, their precursors, and related metabolites in individual spiders. Compounds such as tryptophan, kynurenine, and kynurenic acid occurred only or mainly in white crab spiders. In contrast, compounds such as 3-hydroxy-kynurenine, xanthommatin, and ommatin D occurred only or mainly in yellow crab spiders. Factor analysis ranked the different color forms in accordance with their metabolites. The biochemical results enabled us to associate the different phases of formation of pigment granules with specific metabolites. Yellow crab spiders contain many unknown ommochrome-like compounds not present in white crab spiders. We also found large quantities of decarboxylated xanthommatin, whose role as precursor of new pathways in ommochrome synthesis needs to be assessed. The catabolism of ommochromes, a process occurring when spiders revert from yellow to white, warrants further study.

Keywords Crypsis · 3-Hydroxy-kynurenine · Xanthommatin · High Performance reverse phase ion-pair chromatography technique

Introduction

Color changes play many roles in the behavioral ecology of animals (Morse 2007; Brechbühl et al. 2009), but neither the biochemical and physiological mechanisms of color production nor the underlying genetic basis of this phenomenon have been studied thoroughly. The crab spider, *Misumena vatia*, can change its color reversibly from white to yellow, matching the color of the flowers on which it perches, which supposedly helps increase prey capture (Morse 2007; Ings and Chittka 2008; Théry and Casas 2009). In butterflies, color changes also play an important role in camouflage against predators, reproduction, and sensory physiology (Reed et al. 2008). The biochemistry and nutrient budget that underlie color changes in crab spiders is not well understood. This work investigated the relationship in a crab spider between ommochromes and visual crypsis.

Color changing crab spiders of the family Thomisidae, in particular *Misumena vatia* and *Thomisus onustus*, have been studied with respect to their pigmentation for well over a hundred years (Heckel 1891). These spiders are

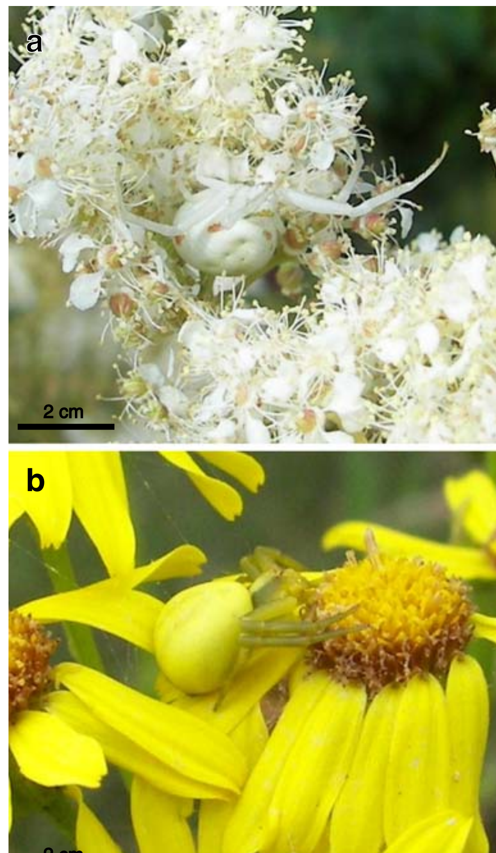

Fig. 1 White and yellow adult females of *Misumena vatia* on flowers of a fruit tree (*white form*) and *Rudbeckia* spp. (*yellow form*)

unusual, as they are able to change color reversibly, within a few days, from white to yellow (Fig. 1). The crypsis of these spiders is astonishing. For example, bees often are deceived with fatal consequences (Chittka 2001; Théry and Casas 2002; Chittka and Osorio 2007; Théry 2007; Ings and Chittka 2008; Taylor and Pfannenstiel 2008). This form of mimicry also may protect the spiders from detection by birds and other predators (Chittka and Osorio 2007; Théry and Casas 2009). Although the physiological and ecological mechanisms for color change in cryptic spiders have been discussed in detail previously (Insausti and Casas 2008, 2009), the biochemistry of color changes in spiders and other organisms has not been pursued vigorously. Older work assumed that the yellow color of *Misumena vatia* was due to carotenoids (Millot 1926), but ommochromes later were found to be the pigments responsible for this color change (Seligy 1972; Insausti and Casas 2008). Most research on ommochrome pigments occurred in the 1970's and 80's (Linzen 1974; Needham 1974; Fuzeau-Braesch 1985; Kayser 1985). Since then, there has been some related research on the developmental biology of butterfly wing patterns (Koch 1993; Nijhout 1997; Reed and Nagy 2005), the physiology of mosquito eyes (Beard et al. 1995; Rasgon and Scott 2004), and tryptophan metabolism (Kato et al. 2006; Han et al. 2007). Ommochrome pigments are the main chromogenic class in the pathway from tryptophan to catabolic compounds (Scheme 1). These pigments range from yellow (xanthommatin), red (ommatin), purple, violet, to black. The chemically characteristic property of ommochromes is their reduction-oxidation (redox) behavior, absorption of ultraviolet and visible light, and low solubility in aqueous medium. The reduced (bathochromic) forms of ommochromes are red, while the corresponding oxidized form is usually yellow. Redox properties of ommochromes enable them to act not only as functional pigments (e.g., in the eyes and integument), but also as an electron accepting or donating system, and as metabolic end products (Scheme 1; Linzen 1974; Needham 1974).

Ommochrome pigments can be divided into three groups whose criteria are based on structure (Linzen 1974): ommins, ommatins, and ommidins and cryptommidins (only found in the eyes of migratory locust *Locusta migratoria*) (Scheme 1).

We hypothesize that the ommochrome biochemical pathway is responsible for the yellow/white reversible color change in *M. vatia*. However, the biochemical pathway involved is more complex than that described by Linzen (1974). In *M. vatia*, tryptophan is derived from digested protein, mainly of insect origin. Tryptophan is the precursor of the first catabolic pathway leading to the production of ommochromes but it does not accumulate (Grob K. and Linzen B. unpublished), rather it is catabolized. In insects, one pathway leads to the synthesis of kynurenine and 3-hydroxy-kynurenine metabolites needed for ommochrome synthesis. According to the physiological state of the crab spider, biosynthesis can favor production of kynurenic acid, xanthurenic acid, anthranilic acid, 3-hydroxyanthralinique acid, or alanine. Kynurenine is a precursor of ommochromes; however, it also may function as a yellow pigment (Seligy 1972; Oxford and Gillespie 1998). 3-Hydroxy-kynurenine also can serve as a pigment (Seligy 1972; Koch 1993; Oxford and Gillespie 1998), and this compound is the major route of the metabolism of tryptophan. 3-Hydroxy-kynurenine is labile, readily transforming into xanthurenic acid (which is stable), or 3-hydroxyanthralinic acid and alanine, and may produce the first ommochrome (xanthommatin) in the chain reaction. Xanthommatin can be metabolized into two other ommochrome pigments: rhodommatin (dihydro-xanthommatin-O-beta-D-glucoside) and ommatin D (dihydro-xanthommatin sulfate, or OmD). These pigments are red and resistant to oxidation in air (Linzen 1974).

The aim of this work was to identify and quantify, in the same run and on the same animals of varying coloration, the relative amounts of ommochrome precursors and pigments associated with color change in crab spiders. In

this process, we developed a simple and sensitive high performance liquid chromatography method for these types of compounds.

Methods and Materials

Crab Spiders White and yellow *M. vatia* adult female crab spiders (Thomisidae) were collected on flowers in the surroundings of Tours, France, during spring and summer (Fig. 1). Upon capture, they were maintained individually in plastic vials with water (cotton plug) for 3 d (without changing color) and fed a fly every day (*Lucillia* spp.). They then were separated in two groups on the basis of color appearance, and were left 2 d without food before being frozen at −80°C. Yellow crab spiders were rare in the field compared to white crab spiders. The *M. vatia* group corresponding to white with red strips was not used for this study.

Chemicals and Standard Solutions All chemicals were of analytical grade. Acetonitrile, heptanesulphonate, methanol, and hydrochloric acid were obtained from VWR International (Pessac, France). Tryptophan, kynurenine, 3-hydroxy-kynurenine, kynurenic acid, xanthurenic acid, sodium phosphate monobasic, and orthophosphoric acid were obtained from Sigma-Aldrich (St. Quentin, France).

Xanthommatin and the ommatin D were prepared by the method of Butenandt and Schaefer (1962), and verified by high-performance liquid chromatography (HPLC) coupled with mass spectrometry (MS). An HP1946B quadripole MS (Agilent 66 Technologies, SantaClara, CA, USA) equipped with an electrospray ionization source working in positive mode was used. Standard solutions were prepared from 1 mg of the synthesized product dissolved in 2 ml of acidified methanol (hydrochloric acid at 0.5%, pH 2), giving a 0.5 mg/ml solution. A standard mixture was made from the precursors (7 µg/ml) and ommochromes (35 µg/ml).

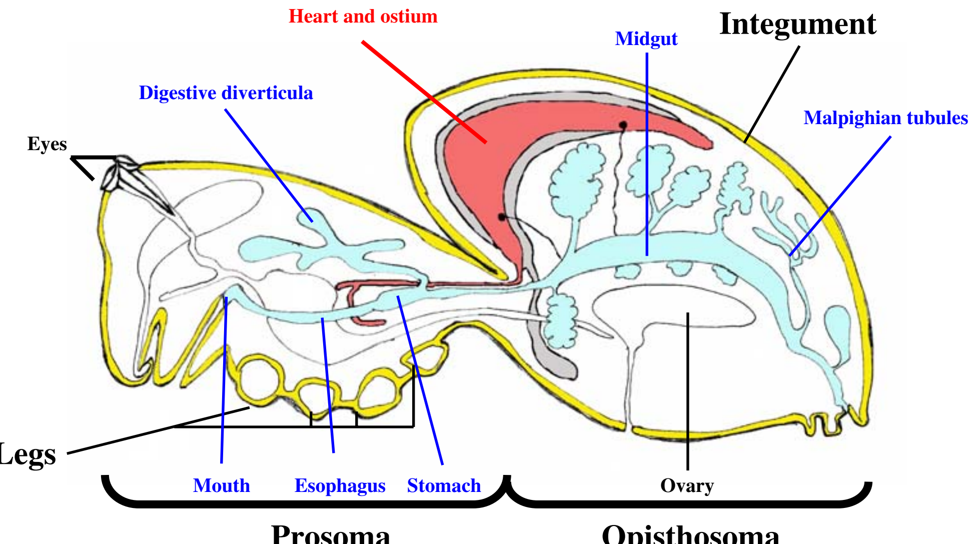
Tissue Preparation and Extraction of Precursors and Ommochromes Four whole yellow and 4 whole white spiders were analyzed. Each was dissected into the legs and the entire opisthosomal hypodermis (Scheme 2), and these tissues were frozen at −80°C until use. For analysis, each sample was crushed in 2 ml of acidified methanol using a Wheaton glass tissue grinder (Fisher-Bioblock, Elancourt, France), transferred to a 2 ml Eppendorf tube, incubated overnight at room temperature, and centrifuged for 15 min at +4°C at 10,000 g. The supernatant was passed through a 0.22 µm filter (Millex GV®, Millipore, Saint-Quentin, France), and condensed by lyophilization (Hyophilisateur, Christ-Alpha, Bioblock Scientific, Illkirch, France).

HPLC Analysis The chromatographic method was based on an ion-pairing technique described previously (Iwahashi and Ishii 1997; Arnault et al. 2003). A Waters HPLC system (Milford, MA, USA) was used, consisting of a 600E quaternary gradient pump, a 996 diode array detector, and a 717 autoinjector. The UV absorbance spectral data were collected from 200 to 500 nm, and the data were acquired and processed using Millenium 3.1 software. Compounds were separated on a Hypurite Elite reversed phase C18 column (150 mm length × 3 mm i.d., 3 µm particle size; Thermo Hypersil, Keystone, Bellafonte, PA, USA). The elution gradient was based on a binary solvent system (time in min [% eluant A/ % eluant B]: 0 min [100/0]; 5 min [70/30]; 25 min [46/54]; 26 min [0/100]; 28 min [0/100]; 30 min [100/0], and 40 min [100/0]). Solvent A consisted of 20 mM sodium phosphate monobasic + 10 mM heptanesulphonate (pH 2.1 adjusted with 85% orthophosphoric acid), and solvent B consisted of 50% acetonitrile / 50% solvent A (v/v), at pH 2.1. Before use, the mobile phase was filtered as above. The column temperature was set at 38°C, and the flow rate was constant at 0.4 ml/min. The detection limit was defined as three times the background noise (American Chemical Society 1980); only areas exceeding this background noise were kept for further analysis.

Statistical Analyses Statistical analyses were performed by using XLstat software, 2007 version (Addinsoft, New-York, USA). Comparisons of means among different groups of crab spiders were carried out by the Mann-Whitney test for small samples (non-parametric test). The correlation between the metabolites and the color of the individual was carried out by using a multivariate principal component analysis (PCA).

Results

Identification and Quantification of Ommochrome Pigments and Precursors The chromatogram in Fig. 2 shows



Scheme 2 Diagrammatic longitudinal section of a spider

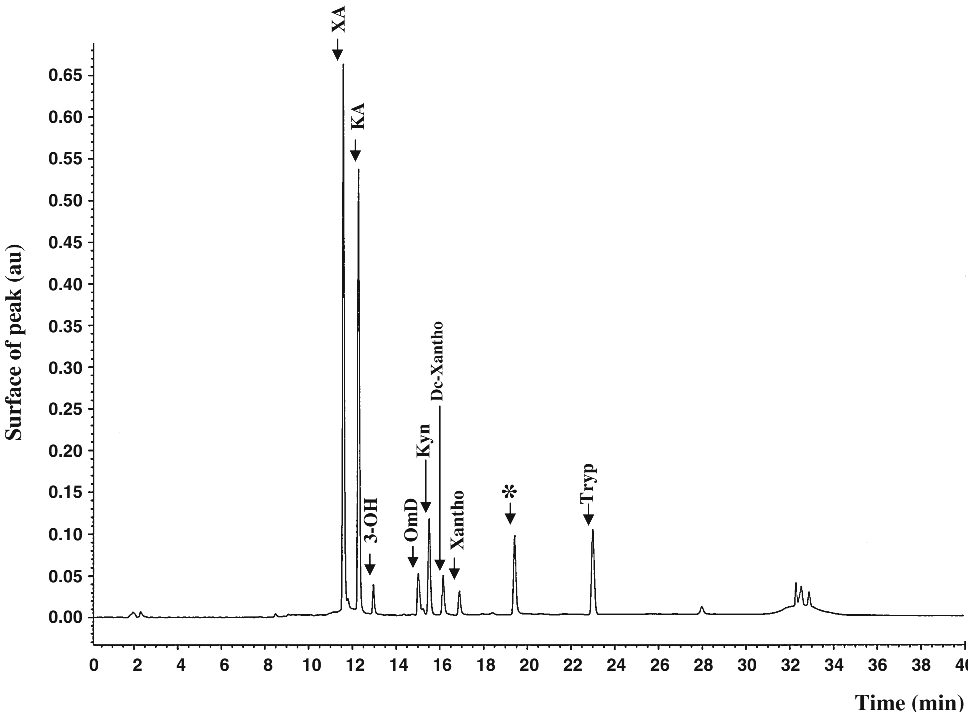


Fig. 2 Chromatogram of the 10–24 min range of the standard solution of eight synthetic ommochromes and metabolites (*degradation product)

the five precursors (Tryptophan “Tryp”, Kynurenine “Kyn”, 3-OH-Kyn-kynurenine “3-OH”, kynurenic acid “KA”, and xanthurenic acid “XA”), and three ommochromes (xanthommatin “Xantho”, ommatin D “OmD”, and decarboxy-xanthommatin “Dc-Xantho”) in the standard solution. One other compound (*; RT 19.50) also was detected. Retention times, absorbance spectra, and maximum absorbance wavelengths for standards are shown in Table 1.

Chromatograms from extracts of whole white (A) and yellow (B) crab spiders exhibited the same substances, but in different quantities (Fig. 3). Table 2 shows the mean quantities of each detected metabolite in each group of four crab spiders. Both precursors and ommochromes were detected but with strong variability among individuals, particularly in yellow crab spiders. Tryp, Kyn, and KA were statistically more abundant in white crab spiders; 3-OH and OmD were more abundant in yellow crab spiders ($P<0.05$, Table 2). Xantho and XA were similar in the two groups. Dc-Xantho was detected in both white and yellow crab spiders, sometimes in large quantities. Many non-identified substances (NIS) with UV spectra and retention times similar to ommochromes were detected in yellow crab spiders; NIS are expressed as a percentage of each substance compared to the total of all extracted substances (Table 3). The NIS with similar chemical properties to Xantho represent approximately 15% of the metabolites in yellow crab spiders, and only 3% in white spiders. Some metabolites are typical of a specific color group, such as the NIS-1 for white spiders or NIS-5, NIS-7 and NIS-10 for yellow spiders ($P<0.05$, Table 3).

Relationship between Spider Color and Constituents Figure 4 illustrates the multivariate PCA for eight crab spiders for the known metabolites (A) or all the compounds detected (B). Two PCE groups were distinguished clearly (Pearson correlation test) on the basis of a match with the visual color appearance (F1: color of individuals) and the different metabolites (F2: time of retention, spectra, and the chemical nature of compounds) (Fig. 4a). The nature of the substance is related directly to the color of the individual (Fig. 5b); however, the variability of the yellow crab spiders was higher than that for white crab spiders. The relationship between color of the crab spider and substance was 66% and, if only the known substances were taken into account in the PCA analysis, this relationship reached 81% correlation (data not shown).

Localization of Ommochrome Metabolites In whole spiders, Tryp was found exclusively in white individuals (Fig. 5), while OmD was found only in yellow spiders (see also Table 1, $P<0.05$). Kyn was the most abundant metabolite, not only in the whole body but also in the integument and legs of white crab spiders (Fig. 5, $P<0.05$). In contrast, 3-OH was present in much larger amounts in yellow spiders, both in whole animals and in their integument and legs. Xantho was found in the whole body of both types of crab spider, but was restricted to the legs and integument in yellow crab spiders.

Table 1 Characteristics of the crab spider ommochrome metabolites (standard solution; spectral range of 200–500 nm)

Peak number	Time of retention (min)	Name of metabolite	λ max (nm)	Spectra Y: arbitrary unit X: λ max (nm)
1	11.59	Xanthurenic acid	348	
2	12.24	Kynurenic acid	332	
3	12.93	3-hydroxy-kynurenine	373	
4	14.85	Ommatin D	486	
5	15.52	Kynurenine	363	
6	16.15	Dc-xanthommatin	453	***
7	16.89	Xanthommatin	459	
8	22.99	Tryptophan	286	

*Footnotes: ***: The spectrum of Dc-xanthommatin was identical to that xanthommatin.*

Discussion

Color change in crab spiders is a complex and still poorly understood process. Earlier research showed that compounds such as the 3-hydroxy-kynrenine and the xanthommatin are responsible for the visual color *M. vatia* crab spiders, and play a role in cryptic mimicry (Heckel 1891; Millot 1926; Seligy 1972; Linzen 1974; Needham 1974; Brown and Nickla 1977; Théry and Casas 2002). Xanthommatin also seems to play a role in optical perception of ultraviolet light in crab spiders (Bhaskara et al. 2009), but metabolic pathways by which these pigments are produced and degraded are not known precisely. The ability to change color is rare in crap spiders; according to Linzen (1974), only 1/4 of crab spiders change color. Reversible color change seems to be a strategy that camouflages crab spiders from both their predators and their potential prey (Théry and Casas 2009). The HPLC technique developed here allowed us to identify and quantify several ommochrome precursors and metabolites in a single run on small samples. Our results are in agreement with the sub-cellular localization of compounds described by Insausti and Casas (2008, 2009).

By using our HPLC procedure, we confirmed the presence of ommochrome pigments and their precursors in crab spiders, first identified by Seligy (1972). In addition, we detected new ommochrome metabolites (particularly in yellow crab spiders), many of which remain unidentified. Several of these metabolites might be pigments associated with ommochromes. First, the extraction technique, based on extremely acid pH, is rather selective for the ommochromes. It is, therefore, unlikely that other

pigments such as pterins, carotenoids, guanine, or uric acid were present in our samples. Whole pterins and carotenoid pigments were not found in another study of crab spiders (Oxford and Gillespie 1998). Guanine and uric acid crystals have been recovered in white and yellow crab spiders (Oxford and Gillespie 1998; Insausti and Casas 2008), and the presence of guanine crystals in the opisthosoma and uric acid crystals in the prosoma have been associated with a white color (Insausti and Casas 2008). Second, the 450–520 nm spectral profiles of these unidentified compounds are reminiscent of those for known ommochromes. It is unclear if Dc-xanthommatin is an artifact of processing the samples or a true metabolite present in living spiders. Vogliardi et al. (2004) suggest that this compound could be a precursor of new pathways to ommochrome production. In this study, the principal component analysis revealed that the amounts of Dc-xanthommatin are independent of the amounts of other metabolites that give the yellow colora-

Table 2 Quantification of ommochrome metabolites in whole adult female crab spiders

		Mean quantity of metabolites (μg / crab spider)		
		Color of *Misumena vatia*		
Type of metabolites	Name of metabolites	White means (*N*=4)	Yellow means (*N*=4)	Significant level correlation of Pearson
Precursors	Tryptophan	4.17±0.34	0.00±0.00	*P*<0.05
