Fig. 4 Multivariate principal component analysis of eight spiders on the basis of their ommochrome-related metabolites (F1: color of individuals and F2 nature of compounds). **a** Statistical analysis based on different metabolites showed two groups of crab spiders (W: white, group 1 and Y: yellow, group 2). **b** Statistical analysis showed a significant difference between the two groups of crab spiders of color of compounds and the color intensity of crab spiders: Colorless or translucent compounds (Tryp, kyn, KA), pale yellow compounds (3-OH, XA), and ommochromes (xantho and Dc-Xantho: yellow/brown and OmD: orange / red). Statistical analysis showed a significant correlation between the color of the crab spiders and the color of compounds, with a well grouped cluster of uncolored compounds in white crab spiders, and diverse ommochrome pigments in the yellow crab spiders

tion, suggesting that the presence of this compound is not due to degradation of xanthommatin.

After separation of compounds by HPLC, the distribution of metabolites between white and yellow crab spiders was different. Small quantities of tryptophan were found exclusively in white crab spiders, which is consistent with prior knowledge. Tryptophan is toxic in its free form (Linzen 1974) and, in the crab spider we studied, it is found in the integument and legs. Tryptophan precursors (kynurenine and 3-hydroxy-kynurenine) were found in abundance, both in the integument and in the legs, and the presence of tryptophan is inversely proportional for white and yellow crab spiders. Xanthommatin is a yellow-brown pigment made from condensation of two molecules of 3-hydroxy-kynurenine catalyzed by phenoxazinone synthetase (Phillips and Forrest 1980). Xanthommatin was found in yellow and white crab spiders, but in different locations in the two groups as described by Insausti and Casas (2008, 2009). Taking into account Dc-xanthommatin and the many other less abundant compounds reminiscent of ommochromes, we conclude that there is twice the amount of ommochrome-related products in yellow as compared to white spiders. Ommatin D, a red ommochrome pigment produced from xanthommatin by the addition of a sulphate group, was found only in yellow crab spiders. Our technique may, however, have

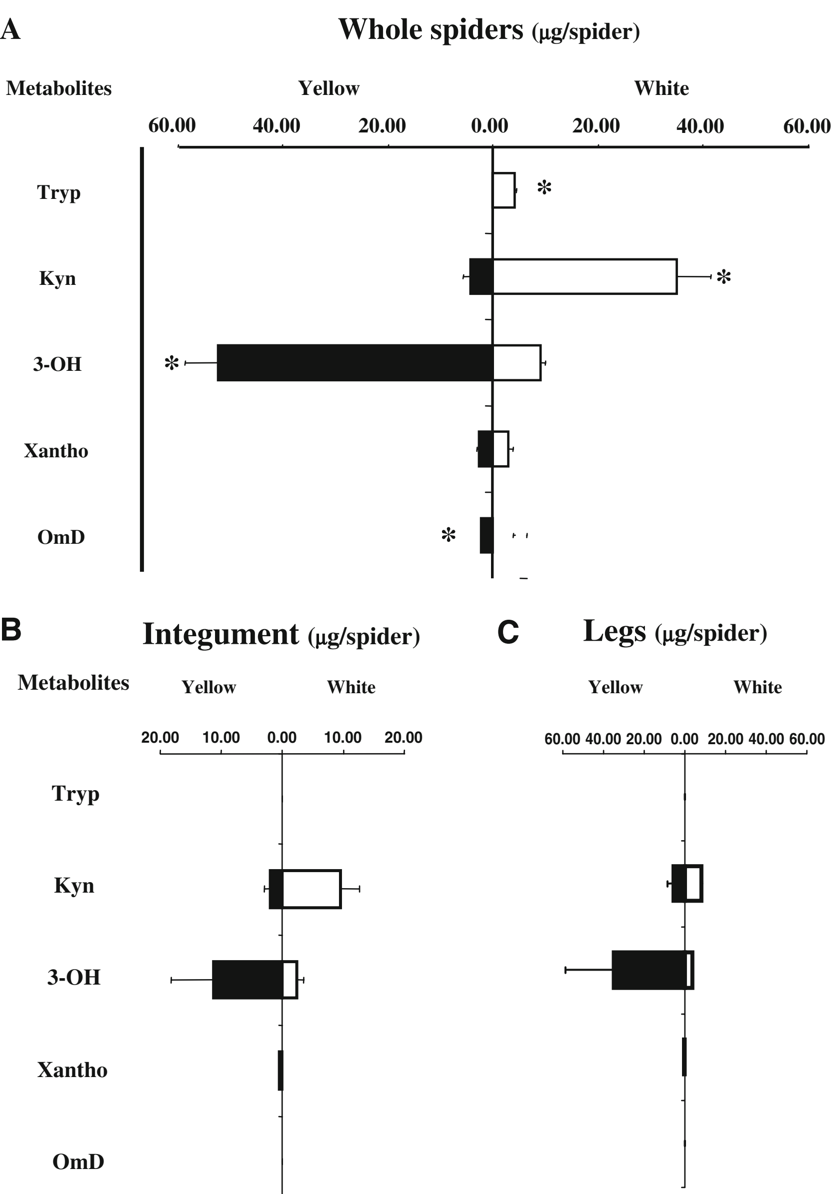

Fig. 5 Quantification of the main identified metabolites of whole spiders (**a**), integument (**b**) and legs (**c**), in white and yellow spiders (only known ommochrome pigments and precursors were analysed; abbreviations as in Table 3)

underestimated the amount of this metabolite present because, at the acid pH used for extraction, some ommatin D may have precipitated in the cytosol. Thus, the role of ommatin D in crab spider coloration is still uncertain, although its water solubility suggests that it is more easily removed than xanthommatin and, therefore, may be part of an elimination pathway.

The complete congruence of crab spider color and their color classification by using PCA of chemical composition is powerful evidence that ommochrome precursors and end products give rise to the yellow coloration. The PCA also highlights the chemical variability of the yellow coloration vs. that for white spiders. The hues of varying intensities might originate in the varying stages of color change in these spiders. The observed reversal in the ratio kynurenine/3-hydroxy-kynurenine is correlated positively with the ultra-structural changes observed in the opisthosoma and prosoma during color change (Insausti and Casas 2008, 2009), and conclusively associates the granule morphology identified by these authors with biochemical composition. We interpret *Type III* granules as ommochromes and *Type I* granules as kynurenine. 3-Hydroxy-kynurenine might be part of the heterogeneous *Type II granules*. The distribution of different metabolites in tissues was heterogenic whatever the color of crab spiders, and may be explained by the presence of ommin-binding proteins capable of transporting ommochromes and precursors, as described in insects (Sawada et al. 2006). It is presently unclear whether ommochromes are synthesized in the intestine and transported to the integument, or whether

tryptophan is transported and converted to ommochromes in the integument.

In summary, the pathway of either tryptophan degradation or ommochrome synthesis plays an important role in visual color of *M. vatia* crab spiders. However, it is not clear what triggers cryptic color change (Théry and Casas 2002; Brechbühl et al. 2009). The catabolic pathway of tryptophan also is involved in others physiological processes in arthropods, such as production of ATP and the regulation of ecdysone synthesis (Linzen 1974; Naya et al. 1991; Okech et al. 2006). In this study, 3-hydroxy-kynurenine is most abundant in yellow crab spiders, and may lead to precursors of xanthommatin synthesis. We hypothesise that the early degradation of kynurenine or 3-hydroxy-kynurenine (yellow precursors) to xanthralinic acid, 3-hydroxy-xanthralinic acid, and alanine (precursors without visible coloration) may explain the reversion of color in *M. vatia* crab spiders (yellow to white), without xanthommatin synthesis. In contrast, the synthesis and the catabolism of xanthommatin might produce degradation products of similar spectral and chemical behavior such as the numerous unknown metabolites reminiscent of ommochromes that are observed in yellow spiders. In this case, the yellow color of crab spiders seems be due to the summation of yellow ommochrome precursors (from yellow to brown according to concentration and pH).

In summary, as in insects, the metabolic pathway of tryptophan catabolism seems to play an important role in the physiology and behavior of crab spiders. *Misumena vatia* crab spiders appear able to control this metabolic pathway at different levels, thus utilizing these metabolic products for optimal crypsis.

Acknowledgments Dr. Mickaël Riou thanks Professor Jerome Casas for hosting him on his team. Abstract Queens and workers are not morphologically differentiated in the primitively eusocial wasp, *Ropalidia marginata*. Upon removal of the queen, one of the workers becomes extremely aggressive, but immediately drops her aggression if the queen is returned. If the queen is not returned, this hyper-aggressive individual, the potential queen (PQ), will develop her ovaries, lose her hyper-aggression, and become the next colony queen. Because of the non-aggressive nature of the queen, and because the PQ loses her aggression by the time she starts laying eggs, we hypothesized that regulation of worker reproduction in *R. marginata* is mediated by pheromones rather than by physical aggression. Based on the immediate loss of aggression by the PQ upon return of the queen, we developed a bioassay to test whether the queen's Dufour's gland is, at least, one of the sources of the queen pheromone. Macerates of the queen's Dufour's gland, but not that of the worker's Dufour's gland, mimic the queen in making the PQ decrease her aggression. We also correctly distinguished queens and workers of *R. marginata* nests by a discriminant function analysis based on the chemical composition of their respective Dufour's glands.

Key Words *Ropalidia marginata* · Queen pheromone · Potential queen · Dufour's gland · Reproductive monopoly

Introduction

The differentiation of adult colony members into fertile queens and functionally sterile workers is an important feature of insect societies of ants, bees, and wasps. In these highly eusocial insect species, which generally have large colony sizes (>>100 individuals), queens and workers are morphologically differentiated, with queens maintaining their reproductive monopoly with pheromones. On the other hand, in primitively eusocial species, colony sizes are usually small (<100 individuals), and queens and workers are morphologically indistinguishable, with queens believed to suppress worker reproduction by physical aggression (often referred to as dominance behavior) (Wilson 1971). *Ropalidia marginata*, the subject of this study, is classified as a primitively eusocial species, because of the absence of morphological differentiation between queens and workers. However, the queen in *R. marginata* is a strikingly non-aggressive and non-interacting individual that, nevertheless, maintains complete reproductive monopoly. Since the queen does not use physical aggression to suppress worker reproduction (Gadagkar 2001), we hy-

pothesized that *R. marginata* queens may use pheromones for this purpose.

If the queen is lost or removed from a colony, one of the workers becomes highly aggressive within a few minutes; if the queen is not returned, this individual develops ovaries and becomes the new queen of the colony within a few days. We have designated this individual as the potential queen (PQ; Premnath et al. 1996). However, if the queen is returned to the colony within a day of removal, the PQ decreases her aggression and swiftly returns to being a typical worker (Premnath et al. 1996; Kardile and Gadagkar 2002; Sumana and Gadagkar 2003; Deshpande et al. 2006). This suggests that the PQ perceives the absence of the queen within a few minutes. When workers are separated from their queen by a wire mesh screen, one of the workers establishes itself as the PQ and will lay eggs if the wire mesh is not removed (Sumana et al. 2007/2008). How then do workers perceive the presence or absence of their queen? One possibility is through physical interactions with the queen. However, we have shown that the rates of interaction of the PQ with the queen (both direct and indirect, via interactions with other workers) are not frequent enough to explain the rapidity with which the queen's absence is perceived (Bhadra et al. 2007). Another possibility is that the queen applies her pheromone to the nest surface. This possibility is supported by the observation that the queen, but not the workers, frequently rubs the ventral side of her abdomen on the nest surface (Bhadra et al. 2007). Because the Dufour's gland, which opens into the tip of the abdomen, is believed to be a source of the queen signal in honeybees (Katzav-Gozansky et al. 1997; Katzav-Gozansky et al. 2002; Dor et al. 2005), we examined the possibility that the queen pheromone of *R. marginata* is produced in the Dufour's gland.

Here, we demonstrated that a crude macerate of the queen's Dufour's gland mimics her presence in a bioassay, and that queens and workers can be classified correctly by a discriminant function analysis that uses the hydrocarbon profiles of their respective Dufour's glands.

Methods and Material

We collected post-emergence nests of *R. marginata* from various localities in Bangalore (13° 00' N and 77° 32' E), India, and transplanted them to the Vespiary at the Centre for Ecological Sciences, Indian Institute of Science, Bangalore. The nests were maintained in closed cages made of wood and fine mesh, and provided with food, water, and building material, ad libitum. All adults were uniquely color-coded with small spots of Testors® enamel paints (Gadagkar 2001). The queen was identified by egg-laying behavior prior to beginning the experiment.

Bioassay

We developed a bioassay for the queen pheromone based on the observation that the PQ immediately reduces her aggression when the queen is returned to the colony. Thus, we tested whether applying crude macerate of the Dufour's gland of the queen but not of the workers mimics the return of the queen by a similar reduction in the aggression of the PQ. The bioassay consisted of three observation sessions lasting 36 min. each. Each session consisted of six observation periods of 5 min. each, interspersed with a 1 min. break. After observing the normal queen-right colony in the first session (Queen-right Session), the queen and a randomly chosen worker were removed, and the queen-less colony was observed in the second session (Queen-less Session). Before beginning observations in the third session (Treatment Session), the contents of the Dufour's gland of the removed queen or a worker (each crushed in 30 µl of Ringer's solution) or 30 µl of Ringer's solution, were applied to the nest with a micropipette. The choice of treatment was decided by drawing random numbers and was unknown to the observer. A total of 25 nests were used in the experiment (8 queen extract; 9 worker extract, and 8 Ringer's solution). All statistical analyses were performed using the software package STATISTICA 7.

We used Ringer's solution because we observed that organic solvents, such as pentane or acetone, had an adverse effect when applied to the nest, with the wasps becoming agitated or even dying after contact with these solvents. Later, we validated the use of Ringer's solution by chemical analysis of crude macerates of glands crushed in Ringer's solution and found a similar chemical profile to that obtained by extracting glands in pentane.

Chemical Analysis

Preparation of Sample Seven additional colonies were used for chemical analysis. The queens of each colony and a total of 18 workers (2 to 5 per colony, depending on colony size) had their Dufour's glands dissected in distilled water under a stereomicroscope, after gently pulling out the sting. The gland was placed in a vial (chilled with dry ice and acetone), containing 5 µl pentane, and crushed with a needle.

Gas Chromatographic-Mass Spectrometric Analysis After adding another 5 µl pentane to the vial containing the crushed gland, 2 µl extract was injected into an Agilent 6890 gas chromatograph coupled with an Agilent 5973 mass selective detector. A fused-silica capillary column, coated with 100% dimethyl polysiloxane (Agilent HP-1, 60 m×250 µm×0.25 µm), was used for the gas chromatography-mass spectrometry (GC-MS) analyses. The injector port and transfer line were set at 250°C, and

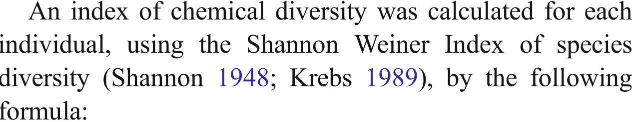
helium was the carrier gas. The column oven was programmed from 100–275°C at 7°C min^{-1}, held for 5 min, and then to 280°C at 5°C min^{-1} held for 33 min. Analyses were performed in split mode (split ratio 10:1). Straight-chain and methyl-branched hydrocarbons were identified from their characteristic mass spectral fragmentation patterns, produced by electron impact ionization at 70 eV. The compounds identified were either straight-chain or branched hyrdrocarbons, the spectra of which are very clear and can be interpreted unambiguously. For example, branching at carbon 11 (11-methylHC) gives a distinct peak fragment at m/z 168 with a complementary fragment depending on the chain length of the compound. Likewise, 14-methylHC has a pronounced peak fragment at m/z 196, etc. For dimethyl compounds, we have two branching points and therefore 4 complementary peak fragments, the m/z of which are characteristic to the compound. The spectra of most of these compounds have been previously published with a list of the ions characteristic to the branching points. A blank run with 2 µl pentane confirmed that none of the detected compounds was present as impurities in the solvent.

Statistical Analyses Both multivariate and univariate analyses were carried out. To reduce the number of peaks used in the multivariate analyses, only those present in at least 70% of all individuals were considered. Before applying any multivariate test, the areas under each peak were transformed by √(X=+0.5) to eliminate zero values (Zar 1999). Before applying the transformation, we confirmed that group variances were proportional to the means. The transformed data were subjected to the further transformation:

$$Z_{p,j} = \ln\left[\frac{A_{p,j}}{g(A_j)}\right]$$

where, $A_{p,j}$ is the area of the peak p for individual j, $g(A_j)$ is the geometric mean of all peaks considered for analysis in individual j, and $Z_{p,j}$ is the transformed area of peak p for individual j (Reyment 1989). These transformed areas then were subjected to principal components (PC) analysis, followed by stepwise discriminant function analysis. All peaks had communality <0.8 on PC1 and were considered subsequently for discriminant analysis. The significance of Wilk's λ (for canonical discriminant function), and the percentage of correct assignments (for classification discriminant functions) were used to evaluate the validity of the discriminant functions. For univariate analysis, the areas under each peak were transformed into percentages of total area under all peaks for each individual, and Mann-Whitney *U* tests were carried out to determine whether queens and workers differed for each compound.

An index of chemical diversity was calculated for each individual, using the Shannon Weiner Index of species diversity (Shannon 1948; Krebs 1989), by the following formula:



$$H' = -\left(\sum_{i=1}^{S} p_i \ln p_i\right)$$

where H' is the index of chemical diversity, S is the total number of peaks in the respective individual, p_i is the relative abundance of each peak (i.e., the area under the respective peak divided by total area under all peaks in that individual). A Mann-Whitney *U* test was carried out to test whether queens and workers differed with respect to indices of chemical diversity.

Squared Euclidean distances were calculated to estimate the chemical distances between all possible pairs of individuals, using the standardized percentages of area under each peak (percentages calculated out of total area under all peaks as mentioned earlier). Z scores for the matrices were used to standardize the percentages, and the differences between groups were analyzed by Mann-Whitney *U* tests. Statistical analyses used the software packages StatistiXL, version 1.7 and Mystat 12.

Validation of Bioassay

Because we carried out the bioassay using Ringer's solution, and the chemicals we identified from the Dufour's gland are insoluble in Ringer's, we determined whether the Ringer's solution macerates used in the bioassays actually contained the Dufour's gland compounds or not. Each gland was crushed in 30 µl Ringer's solution, as in the bioassay, and the contents transferred to a clean glass vial. The Ringer's solution was evaporated from the vial in an oven at 30°C, the dry vial chilled, and 10 µl pentane added to it. Two microliters of this extract were analyzed by GC using an Agilent 6890 gas chromatograph equipped with a flame ionization detector and a fused silica capillary column coated with 5% phenyl methyl siloxane (Agilent HP-5, 30 m × 320 µm × 0.25 µm). General GC conditions were the same as those in the GC-MS analyses. The Ringer's solution was analyzed similarly to rule out any organic compounds that might be present as impurities. Peaks were identified by analyzing a sample of 21 glands in 20 µl pentane by both GC-MS and GC.

Further, to rule out the possible involvement of other compounds in the Dufour's gland-Ringer's solution that are insoluble in pentane, we analyzed glands crushed in acetone. GC conditions were identical to those used in the pentane extracts, and blank runs were also carried out to exclude solvent-based impurities.

Results

The Bioassay

In all nests, a PQ was obvious after queen removal, due to a significant increase in its aggression from the Queen-right Session to the Queen-less Session (Wilcoxon matched pairs signed-ranks test: $P=0.012$ for queen-gland and Ringer's-solution treatments, and $P=0.007$ for worker-gland treatment). There was a significant reduction in the PQ's aggression from the Queen-less Session to the Treatment Session (Fig. 1) in nests treated with the queen's Dufour's gland macerate ($P=0.012$). However, in nests treated with worker-gland macerate or Ringer's solution, the PQ did not show any change in aggression from the Queen-less Session to the Treatment Session ($P=0.593$ for worker and $P=0.401$ for Ringer's).

Chemical Analysis

Of 18 workers, two were eliminated from statistical analyses because they had poorly developed glands, and most compounds in their glands were below the detectable limit of the GC-MS analysis. All queens had well developed glands. The Dufour's gland contained a series of linear, monomethyl and dimethyl branched alkanes with 21 to 33 carbon atoms in the main chains. We did not find any unsaturated compounds. Considering all individuals, we found about 30 different compounds (Fig. 2 and Table 1). We did not find any compound or set of compounds present exclusively in queens or in workers.

We found that: 1) queens had a significantly greater percentage peak area than workers for three compounds (peaks #16, #24, and #29; Mann-Whitney U test, $U=96$, $P=0.003$ for peak #16; $U=91$, $P=0.009$ for peak #24; and $U=96.5$, $P=0.002$ for peak #29); 2) a significantly lower percentage peak area than workers for one compound (peak #13; $U=83$, $P=0.038$; and 3) they were indistinguishable from workers in percentage peak areas for the remaining compounds ($P>0.05$). When the queens and workers of each colony were examined separately, the differences based on these compounds were not consistent. There was no compound that was consistently greater or lower in any queen compared to all the workers tested from her colony. The differences between queens and workers became significant only when all queens were pooled together and compared with all workers pooled together. However, when we added up the percentage areas under peaks 16, 24, and 29, for which queens had higher percentage areas than workers, queens of each colony were greater than workers from their respective colonies, except for one colony, which was a small colony with only three workers, out of which two were newly eclosed. Queens and workers did not differ with respect to total area under all peaks ($U=59$, $P=0.871$) or total number of peaks present ($U=64.5$, $P=0.579$).

We differentiated all queens and workers by a stepwise discriminant analysis (Wilk's $\lambda=0.214$, $P<0.001$, classification analysis: 100% correct classification; Fig. 3). Peak

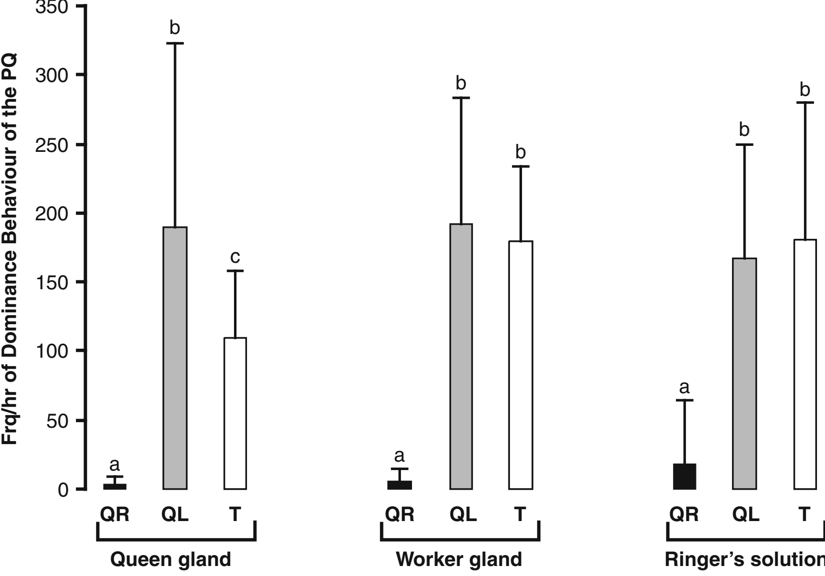


Fig. 1 Mean and standard deviation of the frequency per hour of dominance behavior exhibited by the potential queen from *Ropalidia marginata* nests in the three sessions of the bioassay (Queen-right, Queen-less and Treatment; $N=8$, 9, and 8, respectively) when the nest was exposed to queen Dufour's gland macerate, worker Dufour's gland macerate or Ringer's solution (control). Comparisons are by Wilcoxon matched pairs signed-ranks test among the three sessions within each treatment. Different letters denote significant difference among bars ($P<0.05$)

Fig. 2 Total ion mass chromatograms of a *Ropalidia marginata* worker and a queen from the same colony. Asterisk signifies contaminant present in blank run. Peak numbers correspond to compounds identified in Table 1

numbers 8, 13, 14, 15, 16, 21, and 22 were selected in the discriminant analysis. Analysis of index of chemical diversity showed that queens had higher indices of diversity than workers (Mann Whitney U=82, P=0.044), but the difference was not universal. There were two colonies in which the queen had a lower diversity index than a worker from the respective colony. Both of these colonies were small, one had three workers, out of which two were newly eclosed (see above), and the other with four workers out of which three were newly eclosed. Analysis of chemical distances showed that queen-worker distances were significantly greater than worker-worker distances (Mann-Whitney U=8237, P=0.001). Queen-queen distances were, however, not different from queen-worker distances (U=1266, P=0.583), but were greater than worker-worker distances (U=1660, P=0.01).

Validation of Bioassay

Glands crushed in Ringer's solution gave similar GC-MS profiles to those obtained using pentane extracts of glands (Supplementary material S1 and S2). GC analysis of glands crushed in acetone also gave profiles similar to those obtained using pentane (Supplementary material S3).

Discussion

We have shown that applying an extract of the queen's Dufour's gland onto the nest surface results in the PQ behaving as if the queen has returned to the nest. We also have shown that queens and workers can be classified

Table 1 Peak numbers, retention times, identity and average percent areas and standard deviations of dufour's gland compounds of queens and workers in *Ropalidia marginata*

Peak #	Retention Time (min)	Identity of compound	% area of each compound mean±standard deviation	
			workers	queens

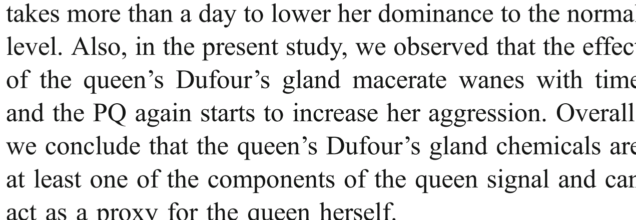
correctly based on the contents of their Dufour's glands. These results are consistent with the hypothesis that, in *R. marginata*, the workers (at least the PQ) perceive the presence of their queen through contents of the Dufour's gland that she applies to the nest surface. It should be noted that our ability to classify queens and workers correctly required that we consider the effect of several compounds simultaneously with no single compound being adequate for this purpose. We do not rule out the role of other compounds or indeed of other mechanisms contributing to queen recognition by colony members. We do not have direct evidence that the compounds tested here are responsible for the lack of ovarian development of the workers in the presence of the queen. However, if workers use an honest signal of their queen's fertility to refrain from reproduction, as suggested by Keller and Nonacs (1993), the compounds we identified also may be involved in reproductive regulation in *R. marginata,* thus permitting the queen to maintain reproductive monopoly in spite of her docility.

Analysis of chemical diversity showed that queens, in general, had higher indices than workers, implying that queens have either greater numbers of compounds, or a more even distribution (i.e., less variable ratios, within individuals) of compounds. Since we did not find any difference between queens and workers with respect to numbers of compounds present, it is likely that the distribution of relative proportions of compounds is more even in the case of queens and less even in the case of workers. The two

Fig. 3 Scores on discriminant function analysis for gas chromatographic analyses of Dufour's glands of *Ropalidia marginata* queens and workers (n_{queens}=7, $n_{workers}$=16, Wilk's λ=0.214, P<0.001, classification analysis: 100% correct classification)

colonies in which the queen did not have the highest index value were small colonies with only one mature worker, with the rest of the workers being newly eclosed. Chemical profiles of old, well established queens could be different from those of newly established queens, as queens are known to be behaviorally dominant during the nest initiation period or pre-emergence phase (Gadagkar 2001). Also, in this species, the old queen sometimes gets overthrown with a worker becoming the PQ and ultimately taking over as the new queen of the colony, a phenomenon known as queen turnover in natural colonies (Gadagkar 2001). It is possible that queens that are on the verge of being overthrown have a declining queen signal and are chemically different from normal queens. Since we do not have any information on the history of each colony, and also did not measure the ovarian development of the queens used in our GC-MS analyses, we cannot make any conclusive statement as to why these colonies were different from the others. Chemical distances show that queen-worker distances are higher than worker-worker distances, indicating that queens and workers are more different from each other than workers are from other workers. However, queen-queen distances are different from worker-worker, but not queen-worker distances, implying that more variability in peak area (relative amount) occurs among queens (between individuals).

Suppression of the PQ's dominance is not complete after applying the queen's Dufour's gland extract to the nest, although the level of dominance is significantly higher than that observed in the queen-right condition. It should be noted that in earlier studies (Sumana and Gadagkar 2003) we saw that, after keeping the queen away from her colony for a day followed by queen reintroduction on the next day, the dominance of the PQ remained significantly higher than in the normal queen-right condition, suggesting that the PQ



takes more than a day to lower her dominance to the normal level. Also, in the present study, we observed that the effect of the queen's Dufour's gland macerate wanes with time and the PQ again starts to increase her aggression. Overall, we conclude that the queen's Dufour's gland chemicals are at least one of the components of the queen signal and can act as a proxy for the queen herself.

Our results add to the growing evidence for chemical communication between queens and workers in primitively eusocial wasps. For example, Downing (1991) demonstrated that the contents of the Dufour's gland in *Polistes fuscatus* act as an egg-marking pheromone. Sledge et al. (2001) showed that queens and workers in *Polistes dominulus* differ in their cuticular hydrocarbon signatures. Dapporto et al. (2007) suggested that the contents of the Van der Vecht's gland may function as a queen pheromone in *Polistes gallicus*. Unlike *Polistes* queens, that are also aggressive in addition to producing a chemical cue signaling their presence, *R. marginata* queens appear to rely more heavily on pheromones for communication with workers, as they are non-aggressive and interact directly with other members of their colonies relatively infrequently. Our results are similar to the situation in honeybees in which queens are non-aggressive and where there is good evidence for the contents of Dufour's glands as signals of fertility (Katzav-Gozansky et al. 2002).

Acknowledgements We thank the Department of Science and Technology, the Department of Biotechnology, the Council for Scientific and Industrial Research and the Ministry of Environment and Forests, Government of India for financial assistance, and Robin Crewe for helpful comments and encouragement. We also thank Anjali Rajasekharan, Pooja Muralidharan and Gautam Pramanik, Centre for Ecological Sciences, Indian Institute of Science, Bangalore, for technical assistance with the GC-MS analyses and, Prasanta Das, Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore, for providing useful suggestions regarding interpretation of mass spectra. AB carried out the behavioral observations. SAD, KC, and AM did the dissections and prepared the extracts. AM carried out the chemical analysis, with help and guidance from DGN and AH. The paper was co-written by AB, AM, and RG, and RG supervised the overall work. All experiments reported here comply with the current laws of the country in which they were performed.

Variation in and Responses to Brood Pheromone of the Honey Bee (*APIS mellifera* L.)

Bradley N. Metz · Tanya Pankiw · Shane E. Tichy · Katherine A. Aronstein · Robin M. Crewe

Abstract The 10 fatty acid ester components of brood pheromone were extracted from larvae of different populations of USA and South African honey bees and subjected to gas chromatography-mass spectrometry quantitative analysis. Extractable amounts of brood pheromone were not significantly different by larval population; however, differences in the proportions of components enabled us to classify larval population of 77% of samples correctly by discriminant analysis. Honeybee releaser and primer pheromone responses to USA,Africanized and–European pheromone blends were tested. Texas-Africanized and Georgia-European colonies responded with a significantly greater ratio of returning pollen foragers when treated with a blend from the same population than from a different population. There was a significant interaction of pheromone blend by adult population source among Georgia-European bees for modulation of sucrose response threshold, a primer response. Brood pheromone blend variation interacted with population for pollen foraging response of colonies, suggesting a self recognition cue for this pheromone releaser behavior. An interaction of pheromone blend and population for priming sucrose response thresholds among workers within the first week of adult life suggested a more complex interplay of genotype, ontogeny, and pheromone blend.

BP brood pheromone

Introduction

Honey bees, *Apis mellifera* L., are distributed naturally throughout Africa, Asia, Europe, and the Middle East (Ruttner 1988). European honey bees in the US are a mixture of approximately seven subspecies introduced by English and Spanish settlers in the 1600s and by bee breeders in the late nineteenth and early twentieth centuries (Sheppard 1989). The gene pool reflects these introductions in both the commercial and feral populations (Schiff et al. 1994; Schiff and Sheppard 1995). In 1956, a South African sub-species, *A. m. scutellata*, was introduced to Brazil, and queens from this sub-species mated with European males producing the Africanized honey bee, a genetic admixture of *A. m. scutellata* and European honey bees (Pinto et al. 2005). The first Africanized colony was discovered in the USA in 1990 (Pinto et al. 2005). As a consequence, there are two behaviorally different types of honey bees found in the Americas, referred to as Africanized and European honey bees.

The comparative study of differences in pollen foraging behavior of these two types (Winston 1987) can help us understand the proximal mechanisms that regulate foraging activity. When fostered together in the same European colony, Africanized bees are more likely to forage for pollen and water than European bees (Danka et al. 1987; Pesante et al. 1987; Fewell and Bertram 2002; Pankiw 2003).

Along with other factors (reviewed in Page and Erber 2002), a mixture of larval chemicals, called brood pheromone (BP), influences various pheromone releaser responses in honey bee colonies, including the proportion of pollen foragers, pollen load weight, and pollen foraging trip frequency (Pankiw and Page 2001; Pankiw 2004a, 2007; Sagili 2007). Brood pheromone also elicits primer responses (Pankiw 2004b) such as, for example, affecting the age of first foraging; bees in colonies treated with a relatively low amount of BP forage at significantly younger ages than bees in colonies treated with a relatively high amount of BP (Le Conte et al. 2001; Sagili 2007).

Africanized bees forage at younger ages than European bees in common colony-rearing studies (Pankiw 2003). First foraging at a younger age and a greater probability to forage for pollen is associated with a greater sensitivity to sucrose (Page and Erber 2002; Pankiw et al. 2002; Pankiw 2003). Africanized bees have significantly lower response thresholds compared to European bees, when newly emerged or prior to any feeding experience (Pankiw 2003). Sucrose-response thresholds are modulated by BP, such that a relatively low amount of BP increases sucrose sensitivity and a relatively high amount decreases sucrose sensitivity (Pankiw and Page 2001; Pankiw 2004b; Pankiw et al. 2004). Treatment with a low dose of BP for 30 days increases the amount of brood area reared by colonies vs. controls, probably as a result of the combined suite of primer and releaser effects outlined above (Pankiw et al. 2004; 2008b; Sagili 2007).

Differences in a suite of pollen foraging behaviors between European and Africanized honey bees results in the Africanized bees collecting more pollen, rearing more brood, and their colonies reproducing more frequently in a tropical and subtropical environment (Winston 1992). This has led to the domination of the Africanized mitotype in Texas and much of the southern USA (Pinto et al. 2005; USDA-ARS 2008). Given that BP infleunces this suite of pollen foraging behaviors, a possible mechanism regulating differential pollen foraging between Africanized and European is variation in BP produced by the respective larvae, or differential response to BP by the respective adults.

Brood pheromone is composed of a blend of the methyl and ethyl esters of palmitic (16:0), stearic (18:0), oleic (18:1 Δ^{9}), linoleic (18:2 $\Delta^{9,12}$), and linolenic (18:3 $\Delta^{9,12,15}$) acids; the pheromone blend and extractable amounts vary with larval age and caste (reviewed in Pankiw 2004b and references therein). To date, all published studies on the effects of synthetic BP have been performed using the blend characterized from larvae of France (Le Conte et al. 1994; Pankiw 2004b), with most studies using colonies of European or mixed European lineage in the USA (Le Conte et al. 2001; Pankiw and Page 2001; Pankiw 2004a, b, 2007; Pankiw et al. 2004, 2008b). To date, there have been no published studies on variation in blend or amount of BP among different populations of same-stage larvae. Furthermore, the consequent behavioral or physiological effects of different blends of BP have been explored only superficially by using whole hexane extracts of larvae (Pankiw and Rubink 2002) or by not separating the effects of blend and dose (Pankiw and Page 2001).

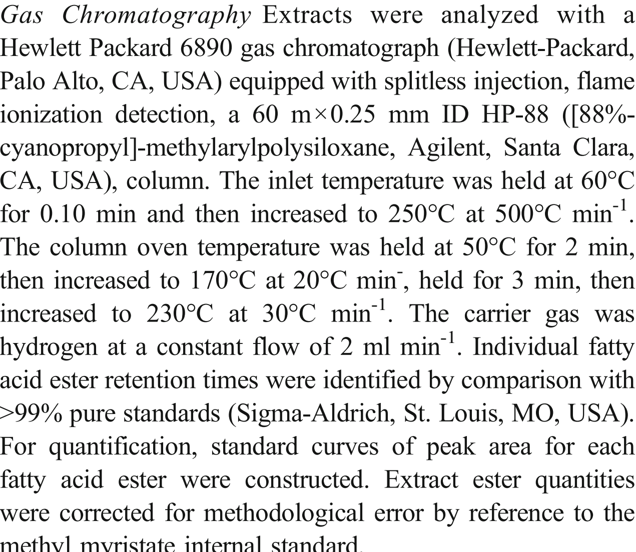
The goal of this study was to examine BP blend variation and behavioral responses to any variation in three populations of bees characterized by geographical location and mitochondrial lineage: honey bees having European mitochondrial DNA from Texas and Georgia, USA, and bees having African mitochondrial DNA from Texas, USA and Pretoria, South Africa. We characterized BP blends by chromatography-mass spectrometry (GC-MS), and we examined differences in blend by using a discriminant analysis model. Because releaser and primer responses are modulated by different physiological systems (Pankiw 2004b), the effects of BP blends were cross-tested among the different populations of bees in a pollen foraging bioassay (releaser response) and a sucrose response threshold bioassay (a primer response).

Methods and Materials

Bee/Larval Sources Four bee populations were used. European queens and package bees were purchased from a breeder in Moultrie, Georgia, USA where no record of the African mitotype has been reported (USDA-ARS 2008). Africanized colonies were collected from Mission, Texas, USA. Texas-European honey bees were from Navasota, Texas, USA and had European mitochondrial DNA. The prevalence of Africanized bees in Texas suggested that introgression of African nuclear DNA in colonies with European mitochondrial DNA was likely (Pinto et al. 2005), meaning that this population may be intermediate. European and African mitochondrial lineage was confirmed by the method of Pinto et al. (2003). Texas-Africanized, Texas-European, and Georgia-European colonies were all maintained in a College Station, Texas apiary (30° 6′ N; 96° 32′ W). African (*A. m scutellata*) colonies were maintained in an apiary at the University of Pretoria, Pretoria, South Africa (25° 45’ S; 28° 14’ E). All the queens in this study were unrelated to each other and naturally mated.

Collection of Larvae for Chemical Analysis Larvae were collected from 8 Texas-Africanized, 8 Georgia-European colonies, 11 Texas-European colonies, and 7 South African colonies. Single frames containing larvae were removed from the colonies and brought within 30 min. to the laboratory, where larvae were removed from the cells with a gentle stream of water and collected into 1 mm mesh cloth. Larvae were lightly shaken dry and 10 fifth instars selected by weight and morphology (Rembold et al. 1980; Michelette and Soares 1993). Larvae were pooled in a glass beaker and soaked for 1 min. in 2 ml of 95% *n*-hexane containing 1 μg methyl myristate as an internal standard and 0.05% (w/w) *t*-butyl hydroquinone as an antioxidant. Addition of this antioxidant has been found to prevent significant chemical change of a mixture of fatty acid esters stored at room temperature for 72 wk (Pankiw et al. 2008a). Extracts were filtered through a Buchner funnel to remove particulate matter, and the larvae and glassware were washed further with 2 ml of 95% *n*-hexane, which was added to the extract. Extracts were stored in 7-ml glass, screw-top vials, sealed with aluminum foil and paraffin, and stored for up to 2 wk at -20°C before further processing. South African extracts were shipped by air from Pretoria to College Station, but in other respects were treated identically.

Extracts were concentrated to 1 ml by using a nitrogen stream in a water bath at 55°C and vortexed for 30 sec to wash down any chemicals on the glass. Extracts were fractionated by liquid chromatography using a column of 0.5 g of silica gel (70–230 mesh/60 Å; Sigma-Aldrich, St. Louis, MO, USA) in a Pasteur pipette plugged with a piece of dust-free paper cloth (Kimberly-Clark, Neenah, WI, USA). Before use, columns were rinsed with 10 ml each of 99% dichloromethane and 95% *n*-hexane. Extracts were placed on freshly prepared columns, and two fractions were eluted: the first, containing long and short-chain hydrocarbons, but no esters, with 10 ml of 95% *n*-hexane, and the second, containing the esters, with 10 ml of 99% dichloromethane. The dichloromethane fraction was evaporated to apparent dryness using a nitrogen stream in a water bath at 50°C, and then immediately reconstituted in 1 ml of 95% *n*-hexane and vortexed for 30 sec. This was concentrated to ca 100 μl and transferred to an autosampler vial containing a 250-μl glass insert; the vial previously containing the fraction was rinsed 3 times with 50 μl hexane and the rinse added to the insert. Solvent was removed from the fraction by heating to 50°C, after which the vial was cooled and 20 μl hexane containing 2 μg of n-octadecane (Sigma-Aldrich, St. Louis, MO, USA) added to the fraction as a reference. Fractionated extracts were stored at -20°C for up to 7 d until analysis by gas chromatography, using flame ionization or mass spectrometric detection.



Gas Chromatography Extracts were analyzed with a Hewlett Packard 6890 gas chromatograph (Hewlett-Packard, Palo Alto, CA, USA) equipped with splitless injection, flame ionization detection, a 60 m×0.25 mm ID HP-88 ([88%-cyanopropyl]-methylarylpolysiloxane, Agilent, Santa Clara, CA, USA), column. The inlet temperature was held at 60°C for 0.10 min and then increased to 250°C at 500°C min^{-1}. The column oven temperature was held at 50°C for 2 min, then increased to 170°C at 20°C min^{-}, held for 3 min, then increased to 230°C at 30°C min^{-1}. The carrier gas was hydrogen at a constant flow of 2 ml min^{-1}. Individual fatty acid ester retention times were identified by comparison with >99% pure standards (Sigma-Aldrich, St. Louis, MO, USA). For quantification, standard curves of peak area for each fatty acid ester were constructed. Extract ester quantities were corrected for methodological error by reference to the methyl myristate internal standard.

GC-MS GC-MS analyses were performed on a 6890 GC coupled with a 5975C Inert XL quadrupole mass spectrometer (Agilent, Santa Clara, CA, USA). The GC was equipped with a 30 m×0.25 mm HP- 5MS [(5%-phenyl)-methylpolysiloxane], fused silica capillary column (Agilent, Santa Clara, CA, USA), and a splitless injector using helium as carrier gas at a constant flow of 1.0 ml min^{-1} and an inlet temperature of 300°C. The column temperature was programmed from 150° to 320°C at 20°C min^{-1}. The MS was operated in electron ionization mode (EI) at 70-eV electron energy, using selected ion monitoring (SIM) mode for the following *m/z* (indicative of): 74, 242 (methyl myristate), 74, 270 (methyl palmitate), 88, 284 (ethyl palmitate, 81, 294 (methyl linoleate), 84, 264 (methyl oleate), 79, 292 (methyl linolenate), 74, 298 (methyl stearate), 81, 308 (ethyl linoleate), 98, 310 (ethyl oleate), 79, 306 (ethyl linolenate), 88, 312 (ethyl stearate), and 85, 254 (octadecane).

Comparison of Total Amount of Brood Pheromone Extractable from Larvae of Four Different Populations Quantitated amounts of fatty acid esters were summed to provide a total amount of BP for each sample. Total amounts were transformed to a proportion of mean larval weight (ng BP/g larvae) to account for the expected significant differences between the races ($F_{3,114}$=22.01; P<0.001; data not shown). Total amount of BP/gram of larvae was not normally distributed (Kolmogorov-Smirnov; Z=3.9; df=115; P< 0.001;SPSS 2007) and was therefore transformed by natural log. Total amount was tested by ANOVA for homogeneity of variance (Sokal and Rohlf 1995; SPSS 2007).

Comparison of Brood Pheromone Blends among Four Larval Populations Amount of individual esters was transformed to proportion of total BP, natural log-transformed

and classified by predictive discriminant analysis (Huberty 1994; SPSS 2007). The natural log-transformed ester proportions were normally distributed, meaning that the assumption of multivariate normality was likely met (Huberty 1994). Group covariance matrices were not homogenous as tested by Box's M (M=486.1; $F_{110,15764}$= 3.7, P<0.001; Huberty 1994; SPSS 2007). A linear model was applied despite the potential differences in covariance matrices among larval populations for two reasons: first, Box's M is known to be overly sensitive, and second, the ratio of number of groups (n_g=3) to total samples (p=88) was low (n_g/p=0.03) (as per Huberty 1994). Under these conditions and using external classification through the leave-one-out method, linear discriminant functions perform as well or better than their quadratic counterparts (Huberty 1994). A total of 34 blends from Texas-Africanized colonies, 31 blends from Georgia-European colonies, and 23 blends from South African colonies were analyzed; colonies were sub-sampled 3–6 times. Because colonies are comprised of several patrilines (Tarpy et al. 2004), it was reasonable to include colony-level subsamples to better represent the genetic diversity of the colony. The leave-one-out classification scheme was utilized for external validation, meaning that each data point was categorized based on classification functions generated from all other points (Huberty 1994). Having no *a priori* hypothesis for unequal probabilities of group membership, equal probabilities were used (Huberty 1994). One condition of the discriminant analysis is that members of a group be assigned conclusively to a single category (Huberty 1994). We did not consider this condition true in the case of the Texas-European population, because a possibility existed for Africanized nuclear DNA introgression (Pinto et al. 2005). Therefore, BP blends from the Texas-European larvae were not categorized by the analysis, and rather were classified as ungrouped samples.

Synthetic Pheromone Preparation The synthetic blends of BP derived from Texas-European, Texas-Africanized, and Georgia-European populations were formulated from mean ester percentages obtained using GC and GC/MS, while unpublished percentages of the French blend were personally communicated by Y. Le Conte (Table 1). Synthetic esters were measured by mass and added to an amber glass vial (Grace-Davison, Columbia, MD, USA) with 0.05% of t-butyl hydroquinone (Sigma-Aldrich, St. Louis, MO, USA) added as an antioxidant. The synthetic BP blends were diluted in 95% n-hexane to a concentration of 0.5 μg/μl for application in the bioassays described below.

Pollen Foraging Response of Texas-European Colonies to France and Texas-European Derived Brood Pheromone Blends The pollen foraging bioassay was performed in 12 similarly-sized, Texas-European colonies, installed 1 wk earlier. Each colony was comprised of approximately 1 kg of bees, 1 queen, and few very young larvae (< 2 cm^2). Colonies received 0.6 mg of France or Texas-European derived BP characterized as above or an equal volume of solvent as blank control. This dose was selected through a series of dose-response trials performed prior to experimentation (as per Pankiw and Page 2001). Pheromone was applied on glass plates measuring 14×7 cm. Solvent was allowed to evaporate prior to placement in colonies. A single plate then was hung on metal wire between two frames in the middle of the colony. One hour after placement of glass plates the number of pollen and non-pollen foragers entering colonies was counted for a 5 min period (as per Pankiw et al. 1998). Pollen foragers are distinguishable visually from non-pollen foragers by the pollen pellets on their hind legs. Counts were performed between 08:00–10:00 h. All colonies received all treatments on subsequent days in a random, non-repeating manner. Counts were analyzed by 3×2 *chi-square* contingency table analysis for the effect of pheromone treatment on pollen to non-pollen forager ratio (Sokal and Rohlf 1995; SPSS 2007). Pairwise comparisons were performed using 2x2 *chi-square* contingency table analysis with the Dunn-Šidák method of correcting for possible Type I errors (Sokal and Rohlf 1995).

Pollen Foraging Responses to Texas-Africanized and Georgia-European Derived Brood Pheromone Blends by Texas-Africanized and Georgia-European Colonies The pollen foraging bioassay was performed as described above with 6 Texas-Africanized and 6 Georgia-European colonies each treated with 1.0 mg of the synthetic blend of Texas-Africanized or Georgia-European BP, or an equal volume of solvent control. Texas-Africanized and Georgia-European colony responses to pheromone treatments were statistically analyzed separately.

Modulation of Sucrose Response Thresholds by Texas-Africanized and Georgia-European Derived Brood Pheromone Bblends Frames of pupae collected from 6 Texas-Africanized and 8 Georgia-European colonies were taken to the lab and adults were allowed to emerge for 24 h in an incubator at 30°C, 55% RH. Three plexiglass/wire-mesh cages (1,400 cm^3) each received 300 of either Texas-Africanized or Georgia-European newly emerged bees. Cages were provisioned with 30 ml of 30% sucrose solution and 30 ml of water. Pheromone was applied on 7×7 cm glass plates hung by metal wire in the center of each cage. Each cage received one of three treatments: 1.8 mg of either Texas-Africanized or Georgia-European derived BP (Table 1), or an equivalent volume of solvent control. Solvent was allowed to evaporate prior to inserting

Table 1 Blend formulations of synthetic brood pheromone (%)

Fatty acid ester	European mtDNA			African mtDNA	
	France	Texas, USA	Georgia, USA	Texas, USA	South Africa
Methyl palmitate	3.0	6.9	2.9	4.1	6.0
Ethyl palmitate	3.0	3.9	3.9	4.7	8.8
Methyl stearate	17.0	15.6	6.5	14.9	25.6
Ethyl stearate	7.0	6.4	8.1	10.3	14.5
Methyl oleate	25.0	16.8	20.6	9.0	11.5
Ethyl oleate	8.0	15.4	13.8	15.9	12.9
Methyl linoleate	2.0	2.9	4.2	9.3	4.5
Ethyl linoleate	1.0	5.4	12.1	6.4	4.9

Ethyl linolenate	13.0	12.9	11.0	13.7	8.5

glass plates into cages. Cages were stored in a dark incubator at 30°C, 55% RH. Treatment plates, sucrose, and water were changed daily. Bees were reared thus for 5 d so that they were tested within the first week of adult life (as per Pankiw and Page 2001). Mortality over the course of treatment was less than 15 bees per cage. On the sixth day, a subset of 60 bees was collected from each cage and their sucrose response thresholds were measured using the proboscis extension reflex assay.

Proboscis Extension Reflex Bioassay Honey bees reflexively respond by extending the proboscis when a sufficiently concentrated solution of sucrose is applied to the antennae (Pankiw and Page 2001). The response threshold of an individual may be estimated by the lowest concentration that elicits proboscis extension when bees are presented with an ascending concentration series (Pankiw and Page 2001; Pankiw and Rubink 2002; Pankiw et al. 2002; Pankiw 2003). The proboscis extension reflex bioassay followed previously reported methodologies (Pankiw and Page 2001; Pankiw et al. 2004). Briefly, bees were restrained by thin strips of tape such that their heads and mouthparts moved freely. Bees were allowed 1 h to acclimate to restraint before testing. All bees were tested for proboscis extension to antennal stimulation with water; those responding were allowed to drink water to satiation. Bees then were presented with a logarithmically ascending series of sucrose concentrations sucrose (0.1, 0.3, 1.0, 3.0, 10, and 30%). A single droplet of sucrose concentration was touched to each antenna for <3 sec; ascending concentrations were applied at least 5 min apart. A positive response was recorded if the bee extended her proboscis. Positive responses to sucrose were summed to yield scores that were analyzed by Kruskal-Wallis (Sokal and Rohlf 1995; SPSS 2007). A high score corresponded to high sensitivity or a low response threshold to sucrose and a low score to low sensitivity or a high response threshold to sucrose. Mann-Whitney *U* was performed to assess pairwise differences in sucrose response threshold by treatment using the Dunn-Šidák method as above (Sokal and Rohlf 1995; SPSS 2007).

Results

Comparison of Total Amount of Brood Pheromone Extractable from Larvae of Four Different Populations Total amount of BP extractable from the larval cuticle did not differ among the four honey bee populations ($F_{3,114}$=0.9; P=0.45; SPSS 2007). Mean total extractable amounts were 662±166 ng pheromone/g larvae.

Comparison of Brood Pheromone Blends among Four Larval Populations Two discriminant functions were generated. Means of the functions were different among populations (χ^2=117.5, 20 *df*, P<0.001; SPSS 2007). Squared canonical correlation coefficients showed that function 1 explained 57.2% of the variation among the groups, while function 2 explained 37.2%. Overall, 77% of the samples were correctly classified. That is, 66.7% of the Georgia-European blends categorized correctly, 30% of this group were categorized as Texas-Africanized, and 3.3% as South African. Among the Texas-Africanized blends, 76.5% were correctly categorized, 11.8% were categorized as Georgia-European, and 11.8% as South African. The categorization of South African blends was 91.3% correct, while 4.3% were categorized as Georgia-European and 4.3% as Texas-Africanized. Of the 18 Texas-European blends, 39% were classified as Georgia-European, 33% as Texas-Africanized, and 28% as South African (Fig. 1). Function 1 was the primary discriminator between Texas-Africanized and Georgia-European blends and the South African blends, while function 2 was the primary discriminator

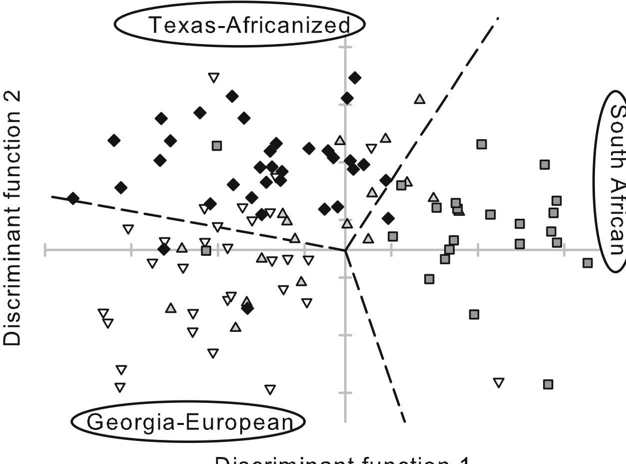

Fig. 1 Scatterplot of the discriminant scores for brood pheromone ester proportions extracted from larvae of colonies of Texas-Africanized and Georgia-European honey bees and South African. Each point represents a single sub-sample. Circled labels indicate the classification of all sub-samples within the territories demarcated by the dashed lines. Georgia-European samples are represented by open, upside-down triangles, Texas-European by grey triangles, Texas-Africanized by black diamonds, and South African samples are represented by dark grey squares

between the Georgia-European and Texas-Africanized blends (Fig. 1).

Plotting the structure matrix coefficients of the transformed ester proportions to the discriminant functions revealed the relative importance of each ester to the classification of the blends (Fig. 2). Vectors were plotted at an angle, the tangent of which was the ratio of function 2 to function 1. The method of calculating the magnitude of the vectors was adapted from Overall and Klett (1972) as the ratio of the standard error of the group means for each ester proportion to the mean standard error of the ester proportions within each group. The ethyl and methyl esters of palmitic (16:0) and stearic (18:0) acids were highly positively correlated to function 1, while methyl linolenate (Me-18:3$\Delta^{9,12,15}$ was highly negatively correlated (Fig. 2). Palmitic and stearic acids are both saturated, while linolenic acid is triple-unsaturated. This means that the South African blends were more likely to exhibit a high proportion of unsaturated fatty acid esters and a relatively low proportion of poly-unsaturated fatty acid esters, particularly methyl linolenate. Both methyl and ethyl linolenate were highly positively correlated with function 2, while methyl oleate (Me-18:1Δ^{9} and ethyl linoleate (Et-18:2 $\Delta^{9,12}$ were highly negatively correlated. Georgia-European blends were more likely to exhibit a higher proportion of methyl oleate and ethyl linoleate, and a lower proportion of the esters of linolenic acid.

Pollen Foraging Response of Texas-European Colonies to France and Texas-European Derived Brood Pheromone Blends Proportion of pollen to non-pollen foragers differed by pheromone treatment (χ^2=64.0, 2 *df*, *P*<0.001; Fig. 3a; SPSS 2007). Pairwise comparisons indicated that all treatments were different from each other, with the greatest ratio of pollen to non-pollen foragers in response to the Texas-European BP blend compared to the French blend (χ^2=15.1, 1 *df*, *P*<0.001) or the solvent control (χ^2=64.2, 1 *df*, *P*< 0.001). Pollen to non-pollen forager ratios in response to the French blend was greater than control (χ^2=22.1, 1 *df*, *P*< 0.001), which was consistent with previous studies (Pankiw et al. 1998; Pankiw and Page 2001; Pankiw 2004a).

Pollen Foraging Responses to Texas-Africanized and Georgia-European Derived Brood Pheromone Blends by Texas-Africanized and Georgia-European Colonies Proportions of pollen to non-pollen foragers also were different by pheromone treatment among Georgia-European colonies (χ^2=121.4, 2 *df*, *P*<0.001; Fig. 3b). Pollen to non-pollen forager ratios were greatest in response to treatment with the Georgia-European derived BP blend compared to either the Texas-Africanized blend (χ^2=3.3, 1 *df*, *P*=0.038) or solvent control (χ^2=109.1, 1 *df*, *P*<0.001). Pollen to non-pollen forager ratios in response to the Texas-Africanized blend was greater than control (χ^2=72.6, 1 *df*, *P*<0.001).

Proportions of pollen to non-pollen foragers differed by treatment among Texas-Africanized colonies (χ^2=59.8,

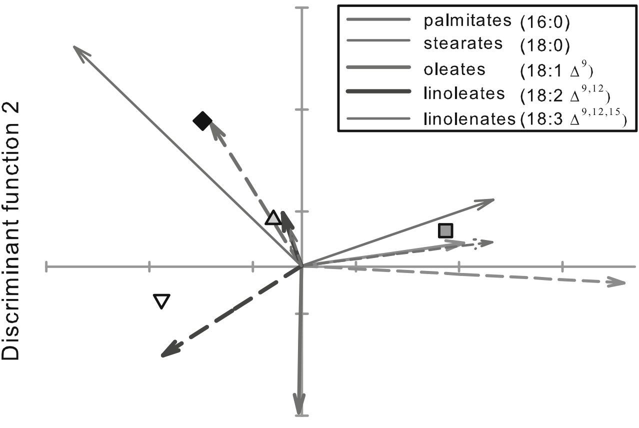

Fig. 2 Strength of the relationship of the proportions of brood pheromone esters to the discriminant functions. Solid lines represent methyl esters and dashed lines ethyl esters of palmitic, stearic, oleic, linoleic, and linolenic acids. Points represent the discriminant score of the group centroid: Georgia-European by an open, upside-down triangle, Texas-European by a grey triangle, Texas-Africanized by a black diamond, and South African by a dark grey square. Vector angles represent the ratio of the correlation of the ester proportion to the discriminant function and magnitudes represent the ratio of between- to within-groups standard error

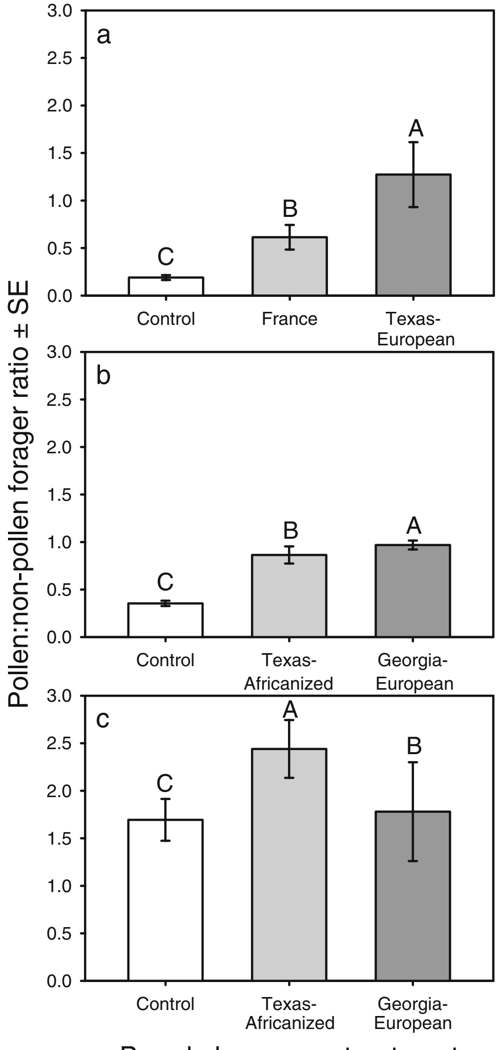

Fig. 3 Pollen to non-pollen forager ratio of **a** Texas-European colonies treated with French or Texas-European derived synthetic brood pheromone blends or solvent control, **b** Georgia-European honey bee colonies in response to Texas-Africanized and Georgia-European synthetic brood pheromone blends, and **c** Texas-Africanized honey bee colonies in response to Texas-Africanized and Georgia-European synthetic brood pheromone blends. Each letter denotes a statistically different subset (*Chi-square*; $P<0.017$)

2 *df*, $P<0.001$; Fig. 3c). Pollen to non-pollen forager ratios were highest in response to the Texas-Africanized blend when compared to the Georgia-European blend ($\chi^2=58.8$, 1 *df*, $P<0.001$) or solvent control ($\chi^2=26.0$, 1 *df*, $P<0.001$). Pollen to non-pollen forager ratios in response to the Georgia-European blend were greater than control ($\chi^2=7.1$, 1 *df*, $P=0.004$).

Modulation of Sucrose Response Thresholds by Texas-Africanized and Georgia-European Derived Brood Pheromone Georgia-European bees exhibited different proboscis extension reflex score distributions between pheromone treatments ($\chi^2=77.2$, 2 *df*, $P<0.001$: Fig. 4a). In Mann-Whitney comparisons, scores were higher when bees were treated with Texas-Africanized blend compared to control, but non-significantly ($Z=-2.3$, $P=0.023$). Scores were lower when bees were treated with Georgia-European blend when compared to control ($Z=-6.5$, $P<0.001$). Georgia-European bees exhibited higher scores when treated with Texas-Africanized derived BP blend compared to those treated with the Georgia-European blend ($Z=-8.3$, $P<0.001$). Proboscis extension reflex scores were not significantly different by pheromone treatment in Texas-Africanized bees ($\chi^2=1.4$, 2 *df*, $P=0.51$; Fig. 4b).

Discussion

Brood pheromone component proportions, blends, were significantly and sufficiently different to correctly classify the population of origin with 77% accuracy. The South African BP blends were characterized by higher proportion of esters of the saturated palmitic and stearic acids, both unsaturated fatty acids. Esters of unsaturated fatty acids oxidize more readily and are therefore more labile than saturated fatty acid esters (Kotz et al. 2006). It is reasonable to hypothesize that the South African blends may be more

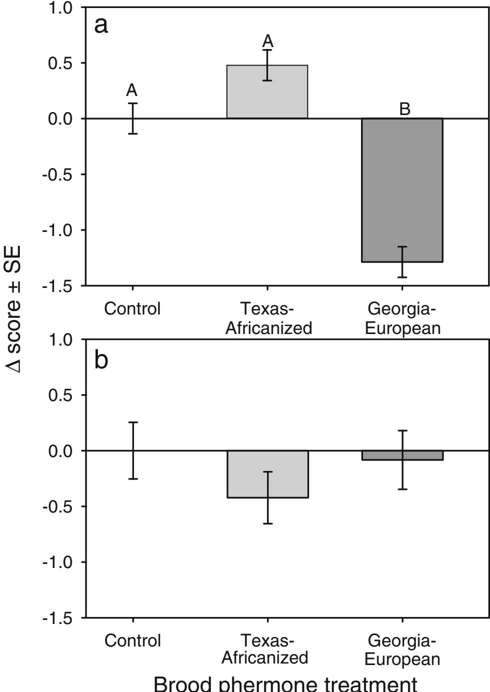

Fig. 4 Proboscis extension reflex scores of **a** Georgia-European or **b** Texas-Africanized honey bees in cages treated with Georgia-European or Texas-Africanized synthetic brood pheromone blends and compared as a mean difference from solvent control treated bees. Letters denote statistically different scores (Mann-Whitney *U*; $P<0.017$)

stable over time relative to the European blends and represent a more persistent pheromone cue. Proportions of methyl oleate were highest in the European blends compared to those extracted from populations with African maternal lineage and suspected Africanized DNA introgression. Methyl oleate has been demonstrated as an attractant for young adult bees in queen retinue bioassays (Keeling et al. 2003). Texas-Africanized blends were characterized by relatively higher proportions of ethyl oleate. Ethyl oleate increases the protein extractable from the hypopharyngeal glands after 14 days when fed to caged bees in the presence of an unmated queen (Mohammedi et al. 1996). Hypopharyngeal glands produce proteinaceous secretions of brood food fed to larvae (Winston 1987). Combined, these differences may be indicative of differential nursing behaviors among the different populations. Interestingly, the Texas BP blends from larvae with European *mt*DNA were evenly categorized among Texas-Africanized, Georgia-European, and South African categories, meaning that these blends may be viewed as intermediate. This result is consistent with our hypothesis of nuclear DNA introgression of African genes in this Texas-European population. Geographic isolation and subsequent selection of naturally and human distributed honey bee races are potential contributory factors that affect pheromone variation. Differential apicultural selection pressures on colonies for pollination or honey production in the USA, France, and South Africa, also may have changed BP blend. Further studies of BP blend variation among single patrilines of larvae will be necessary to determine the genetic and environmental components of this variation.

Contrary to our hypothesis, the Africanized blend did not release a greater proportion of pollen foragers in all colony types; instead, colonies responded with the greatest proportion of pollen foragers when treated with their own synthetic blend of pheromone. Thus, pollen foraging behavior cannot be explained through differences in extractable amounts or blend of BP. In contrast, Pankiw and Rubink (2002) found no race-by-pheromone interaction when testing pollen foraging response to whole hexane extracts of larvae. In our discriminant analysis, Texas-European blends of BP were intermediate between Georgia-European and Texas-Africanized blends. Because Pankiw and Rubink (2002) used Texas-European colonies, it is possible that the differences between Texas-Africanized and Texas-European BP blends were not sufficient to elicit a differential pollen foraging response. As shown previously, (Pankiw and Rubink 2002), Texas-Africanized colonies fielded a higher proportion of pollen foragers relative to Georgia-European colonies. Population differences in pheromone blend and response to blend may be the result of genetic isolation, however, BP blends varied within each population and even within colonies (personal observations). Considering that colonies consist of multiple patrilineal genotypes (Tarpy et al. 2004), forager genotype may interact with pheromone blend to act on response thresholds to BP that regulate division of foraging labor and contribute to intracolony variation in foraging ontogeny and specialization (*reviewed in* Winston 1987). Careful measures of intracolony variation in BP blend and responses of individuals to different blends will be necessary to explore this supposition further.

Modulation of sucrose response thresholds, a primer response, also showed a pheromone blend by population-dependent response interaction. The BP blend derived from Georgia-European colonies significantly decreased sucrose responsiveness in bees of the same population within the first week of adult life vs. the control response. However, Texas-Africanized bees appeared to be insensitive to the modulating effects of BP on sucrose sensitivity regardless of the BP blend environment in which they were reared. This study is the first to measure sucrose response threshold modulation by blends of BP other than the French blend and among individuals with African mitochondrial DNA. Only the Georgia-European blend modulated sucrose responsiveness among bees of USA origin that have a European mitotype in a manner predicted from previous studies (Pankiw and Page 2001; Pankiw et al. 2004). The highly responsive baseline of Africanized bees, consistent with that observed in previous studies (Pankiw and Rubink 2002), may be indicative of a more mature sucrose sensitivity status associated with a faster rate of foraging ontogeny (Pankiw 2003). If BP modulates sucrose responsiveness in pre-foraging Africanized bees, then we predict that modulation should be measurable in bees that are ontogenetically younger than those tested here, given that the French synthetic blend does not modulate USA European ontogenetically mature foragers (Metz and Pankiw unpublished). Brood pheromone modulated sucrose responsiveness is likely a complex interaction of baseline responsiveness, amount, and blend of BP.

This study has shown that BP blend changed among same-stage larvae from different populations. A pheromone comprised of at least 10 compounds presents an enormous challenge to our understanding of how honey bees process mixtures of pheromone compounds. The pattern observed for pollen foraging responsiveness to variation in blends of BP suggests BP may serve as a recognition cue. That is, in each case, there was a positive and significant response to a synthetic blend of BP that was characterized from a source of larvae from the same population as the colony. Pheromone modulated sucrose response threshold did not follow the same pattern, however, primer and releaser responses are not necessarily coordinated but rather uncoupled generating a complex interaction to variation in BP at various levels within a colony.

Abstract Cuticular hydrocarbons (CHCs) are used for chemical communication among nestmates in many ant species, and they may play a role in the discrimination of nestmates and non-nestmates. Using the mandible opening response (MOR) bioassay, we tested the response of the African termite raiding ant, *Pachycondyla analis*, to CHC extracts of nestmates and non-nestmates. The ants were able to distinguish control chemical cues, from nestmate CHCs, and from non-nestmate CHCs, and, based on a CHC recognition threshold, aggression was demonstrated toward non-nestmates. Gas chromatography (GC) and GC-mass spectrometric analyses showed that CHC components of different ant colonies had chain lengths ranging from C_8 to C_{31}, comprising mainly *n*-alkanes, alkenes, and methyl branched alkanes, with the *n*-alkanes occurring in the same proportions among all colonies. The ants were grouped successfully according to their colonies of origin by using discriminant analysis of CHCs. We demonstrate that nestmate recognition occurs in *P. analis*, and that some of the cues involved are evidently alkenes and methyl-branched alkanes.

Introduction

Communication is a common and important phenomenon in all biological organisms. Among social insects, nestmate recognition enables integration within a colony and prevents non-colony members (both conspecifics and heterospecifics) from exploiting the colony's resources (Crozier and Pamilo 1996). The presence of non-nestmates (intruders) usually elicits active defensive behaviors (Hölldobler and Wilson 1990; Vander Meer and Morel 1998). Nestmate recognition in social insects can be adaptive because workers obtain benefits from aiding nestmates and discriminating against non-nestmates provided that the nestmates are more closely related to one another than to members of other conspecific colonies (Hölldobler 1995). The cues involved can be of genetic or environmental origin, and can differ among populations and seasons (Pirk et al. 2001), even in species that form super-colonies like *Formica exsecta* (Katzerke et al. 2006). The primary cues of communication in most insects are chemical in nature (Wyatt 2003) and are perceived by olfaction or contact chemoreception (Breed 1998).

Ants are among the dominant social insects in the world, and they employ complex forms of chemical communication. Over 100 exocrine glands have been described in social insects with more than half of these found in ants (Billen 2004). An array of signals and information on an individual's species, sex, age, caste, status, and relatedness, as well as alarm and trail pheromones are encoded in the secretions from these glands (Howard and Blomquist 2005).

Fielde (1901) advocated that nestmate discrimination signals are encoded in cuticular lipids, particularly those hydrocarbons that coat all insects. Since then, the role of cuticular hydrocarbons (CHCs) has been a subject of much debate, and various studies have attempted to determine

their functions in insect chemical communication. Examples of these roles include recognition at various levels, such as the individual (e.g., D'Ettore and Heinze 2005), nestmate (e.g., Wagner et al. 2000; Akino et al. 2004, Martin et al. 2008a,b), species (e.g., Neems and Butlin 1995; Dapporto 2007), kin (Arnold et al. 1996), and as cues for reproduction and division of labor (e.g., Dietemann et al. 2003; Martin and Drijfhout 2009). Most recently CHCs have been found to be responsible for enforcing altruism in ants (Smith et al. 2009). In adult insects, CHCs are synthesized internally in the oenocytes (Blomquist and Dilwith 1985) and, hence, are under a strong genetic influence reflecting an insect's genetic makeup (Lockey 1991). After synthesis, they are transferred to the cuticle by lipophorin (Schal et al. 2001). CHCs are made up of a homologous series of long, straight-chained saturated alkanes that can be modified by addition of methyl groups or the introduction of double bonds (Jackson and Morgan 1993).

The ant *Pachycondyla analis* (Formicidae: Ponerinae) is a specialized termite predator, which is widely distributed in sub-Saharan Africa (Lévieux 1966). This species, commonly referred to as 'Matabele ants', organizes group raids on termite species that mainly belong to the sub-family Macrotermitinae (Longhurst et al. 1978). There is no information on CHCs of *P. analis*, nor the role they play in nestmate recognition. We recently initiated a comprehensive investigation of the chemical ecology of this ant species, and in the present paper we report the results from a study of CHCs of different colonies of *P. analis* and the role they play in nestmate recognition.

Methods and Materials

Study Species Three colonies of *P. analis* were excavated from Mpala Research Centre (0°17′N, 37°52′E) central Kenya, 250 km north of Nairobi. The colonies were kept in artificial nest boxes (20×20×20 cm) made of aluminium, which were connected to a foraging arena (1.5×1.0 m) made of Perspex. The nests were maintained at 25±1°C, with about 50–60% relative humidity and a 12L: 12D photoperiod. Ants were fed twice daily on live termites (mainly from the subfamily Macrotermitinae) collected around the Duduville campus of *ICIPE* in Nairobi, Kenya.

Extraction of CHCs for Bioassay CHCs from 5 ants per colony were extracted for use as sources of chemical stimuli in bioassays (Guerrieri and d'Ettorre, 2008). Ants previously in contact with their own colony odor were selected for extraction of CHCs. The ants were first killed by placing them on ice for 15 min, and CHCs were extracted by washing them in 500 µl of pentane for 10 min. Solvent was evaporated under a gentle stream of nitrogen, the residue was dissolved in 50 µl of pentane, and stored at −20°C until analysis. Twentyfour extracts were prepared from each of the 3 colonies making a total of 72 extracts. A solvent control (pentane) also was subjected to the same evaporation procedure. An average quantity corresponding to the extract of one ant (10 µl) was applied to the tip of a Pasteur pipette by using a Hamilton syringe. The pipette tip was held downwards until the solvent evaporated from the tip, thus leaving the residue of the extract around the lower and outer part of the pipette.

Mandible Opening Response (MOR) Bioassay Ants were removed from their colonies and transferred to 20 ml glass vials, and immobilized by placing them on ice. They then were harnessed using methods previously described (Guerrieri and d'Ettorre 2008), and were kept undisturbed for 2 hr to recover and habituate to the harness.

Aggression responses were quantified by presenting four different types of stimuli to the test ants from colonies 1, 2, and 3: a) solvent extract only (CTRL); b) extract from colony 1 (C1); c) extract from colony 2 (C2); d) extract from colony 3 (C3). For a test ant, extracts from individuals of its own colony served as nestmate stimuli, while extracts from individuals of other colonies served as non-nestmate stimuli. All ants were tested with all extracts and the control.

In each trial, one stimulus was presented to a harnessed individual ant. A test individual was removed from its resting place and allowed to habituate for 2 min prior to presenting it with the test stimulus. After habituation, its antennae were touched gently for 5 sec with the tip of the stimulating pipette. When the test ant opened its mandibles continuously (i.e., displacing them from the resting position), the behavior was recorded as aggression (score=1). If the individual did not open its mandibles, and instead antennated continuously, the response was recorded as non-aggressive (score=0) following the protocol of Guerrieri and d'Ettorre (2008). After presenting a stimulus, the test ant was returned to its resting place. Stimuli were presented at random to individual ants after an interval of 20 min to allow for the recovery of antennal receptors. From each of the three colonies studied, 24 ants chosen at random were tested with each of the 4 stimuli, thus a total of 72 ants were tested.

Extraction of Cuticular Hydrocarbons (CHCs) for Chemical Analyses Cuticular hydrocarbons were extracted in a way similar to those used for the MOR bioassay, but in this case each ant was extracted in 1 ml of pentane. The solvent was evaporated under a gentle stream of nitrogen, dissolved in 100 µl of pentane, and stored at −20°C until analysis. Twentyfour extracts were prepared from each of the three colonies, making a total of 72 extracts. A pentane control also was subjected to the same evaporation procedure.

Chemical Analyses Gas chromatography (GC) was carried out on an HP 5890 series II GC equipped with a flame ionization detector (FID) and an HP-5 column (30× 0.25 mm ID×0.25 µm film thickness). Nitrogen was used as carrier gas, with a column pressure of 46 psi and injection temperature of 250°C. One µl of sample was injected in the splitless mode, with the oven temperature programmed at 60°C for 5 min to 280°C at 10°C/min, and held at this temperature for 13 min. GC-mass spectrometry (MS) analysis was carried on an Agilent Technologies 7890A GC equipped with an HP-5 MS capillary column (30×0.25 mm ID×0.25 µm film thickness) coupled to 5795C MS. One microliter of each sample was injected in the splitless mode, and helium was used as carrier gas at 1.0 ml min^{-1}. The oven temperature was 35°C for 5 min, increased to 280°C at 10°C min^{-1} and then held at this temperature for 15 min. Spectra were recorded at 70 eV in the electron impact (EI) ionization mode. All the n-alkanes, 2-methylheptadecane, 1-heptadecene, (*Z*)-9-tricosene, and squalene were identified by GC-MS co-injection, and comparison of MS data with those of authentic standards. Other methyl-branched alkanes and alkenes were tentatively identified by using EI diagnostic ions (El-Sayed 2009).

Chemicals *n*-Undecane, *n*-Dodecane, *n*-tridecane, *n*-tetradecane, *n*-pentadecane, *n*-hexadecane, and *n*-heptadecane with the purity of >99% were obtained from Aldrich Chemical Company (Gillingham, Dorset, UK). *n*-Octadecane, *n*-nonadecane, *n*-eicosane, *n*-heneicosane, *n*-docosane, *n*-tricosane, *n*-tetracosane, *n*-pentacosane, *n*-hexacosane, *n*-heptacosane, *n*-nonacosane, and *n*-hentriacontane were provided by Dr. Peter Teal, USDA/ARS-CMAVE, Florida, USA. 1-Heptadecene, (*Z*)-9-tricosene, squalene, and 2-methylheptadecane were provided by Dr. Antony Hooper, Rothamsted Research, Harpenden, UK.

Statistical Analyses Logistic regression was performed on the dichotomous data (1 vs. 0) on the aggressive responses of ants. We tested the differences in aggression response of ants to the solvent control, nestmate and non-nestmate extracts. The levels of aggression between colonies were tested using *Kruskal Wallis* ANOVA. The relative areas of the peaks of the individual compounds in the CHC profile for each ant were standardized to 100%. The standardized peak areas were then transformed following the method proposed by Aitchinson (1986):

$$Z_{ij} = \ln\left[Y_{ij}/g\left(Y_j\right)\right]$$

where Z_{ij} is the standardized peak area i for individual ant j, Yij is the observed peak area i for individual ant j, and g (Yj) is the geometric mean of all peak areas for ant j included in the analyses. We performed a stepwise discriminant function analysis (stepwise DA) on the transformed variables followed by canonical discriminant analysis on the selected peaks to determine whether the colonies could be separated on the basis of their CHC profiles. Pairwise generalized square distances between colonies and classification error rates were also calculated. All statistical analyses were carried out using SAS 9.1.2 statistical software.

Results

MOR Bioassay The number of ants that opened their mandibles when presented with the solvent control was lower compared to an extract (*Wald's* χ^2=58.34, *df*=1, *P*<0.001). There was less mandible opening when ants were presented with a nestmate extract compared to an extract from a non-nestmate (*Wald's* χ^2=101.24, *df*=6, *P*<0.001). In general, the levels of aggression (i.e., MOR) increased

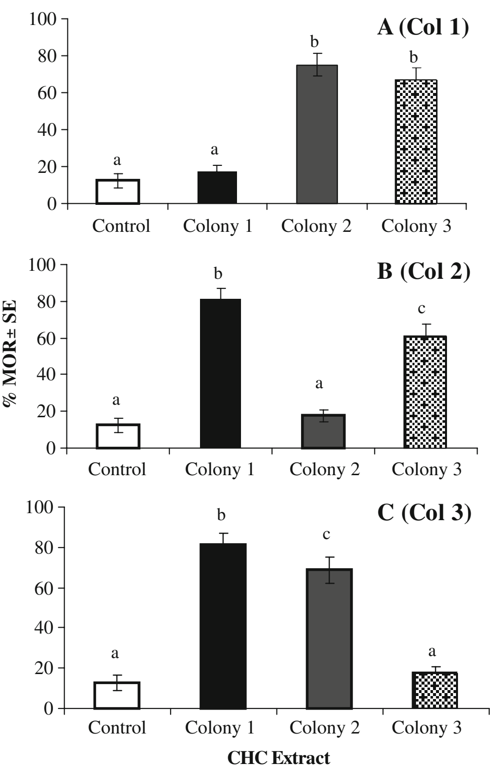

Fig. 1 Mandible opening response (MOR)±SE for, Pachycondyla ants (**A**) from colony 1, (**B**) from colony 2, and (**C**) from colony 3 to the presented extracts. □=Control solvent (pentane), ■=CHC extract from colony 1, ■=CHC extract from colony 2 and = CHC extract from colony 3. Ants responded significantly different to test stimulus and control (*Wald's* χ^2=58.34, *P*<0.001). Response of ants to the extract of nestmate and those of non-nestmate also differed significantly (*Wald's* χ^2=101.24, *df*=6, *P*<0.001). The same letters on bars represent means that are not significantly different

when an ant was presented with a non-nestmate stimulus compared to a nestmate extract or a solvent control (*Wald's* χ^2=132.19, *df*=2, *P*<0.001, Fig. 1). Ants from colony 1 were slightly more aggressive than those from colonies 2 and 3 (Fig. 1), although aggression between colonies was not significantly different (*Kruskal Wallis ANOVA*, χ^2= 5.08, *df*=2, *P*=0.082).

CHC Profiles of P. analis GC-MS analysis revealed that the CHCs of *P. analis* were a complex mixture of alkanes, alkenes, and methyl-branched alkanes ranging from C_8 to C_{31} (Fig. 2, Table 1). The *n*-alkanes, 2-methylheptadecane, 1-heptadecene, (*Z*)-9-tricosene, and squalene had retention times and mass spectra that matched those of authentic standards. The identities of these compounds in the extracts were confirmed further by GC-MS co-injection. Other components in the extracts, including methyl-branched alkanes and alkenes, were identified tentatively from their characteristic mass spectral diagnostic ions (El-Sayed 2009). The major components varied between colonies, with (*Z*)-9-tricosene being present in varying proportions in all the colonies. The proportions of alkanes in the extracts remained constant, while there was variation in the proportions of the alkenes and the methyl-branched alkanes between colonies (Fig. 3).

CHC Differentiation Among Colonies Ants from the different colonies could be distinguished by using the transformed peak areas of the 35 identified compounds (Fig. 2) that differed among the colonies. Using the stepwise DA, 17 variables clustered the ants according to their colonies of origin (*Wilk's* λ=0.0007, *df*=34, 10, *P*< 0.001). Discriminating compounds selected by the stepwise DA were: undecane, 3-methylundecane, 3,6-dimethylundecane, 3,8-dimethyl decane, pentadecane, heptadecane, 3-methylheptadecane, 2,6,10,14-tetramethylpentadecane, octadecane, nonadecane, heneicosane, tricosane, 1-nonadecene, 9-nonadecene, 9-methylnonadecane, squalene, and hentriacontane.

Using the 17 compounds selected by the stepwise DA, ants were grouped into their colony of origin (*Wilk's* λ= 0.0000, *df*=34, 10, *P*<0.001), with function 1 explaining 88.07 % of the variation separating colony 3 from both colonies 1 and 2, and function 2 explaining 11.93 % of the variation further separating colony 3 from 2 and 1 (Fig. 4). All the ants were grouped into their colonies correctly based on their CHC profiles.

Discussion

In this study, we demonstrated the use of a 'yes or no' aggression bioassay by using mandible opening as a measure of aggression between different colonies of *P. analis*. The results show that *P. analis* discriminate between nestmates and non-nestmates, since they were significantly more aggressive toward extracts of non-nestmates. These results

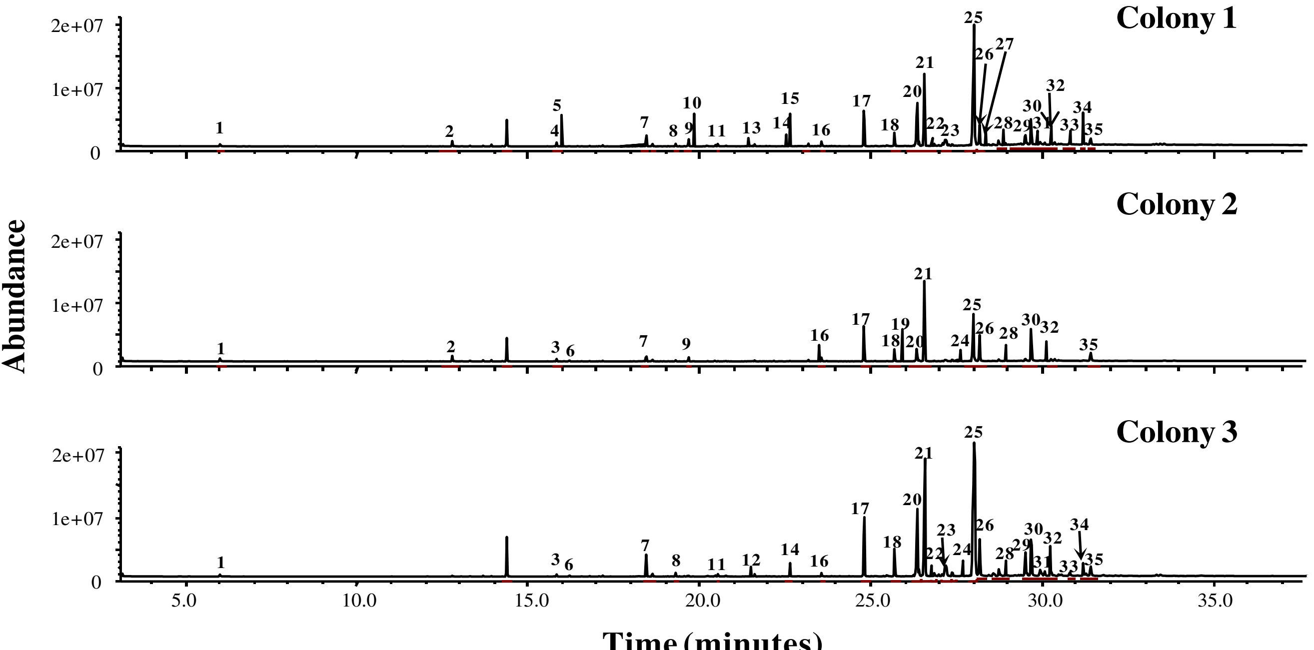

Fig. 2 Total ion chromatograms for the cuticular hydrocarbons of Pachycondyla ants from the colonies studied. Colony 1=CHC extracts from colony 1 ants, Colony 2=CHC extracts from colony 2 ants, Colony 3=CHC extracts from colony 3 ants (see Table 1 for the list of identified compounds)

Table 1 Compounds identified from the cuticular hydrocarbon profiles of *Pachycondyla analis,* along with retention indices and diagnostic ions

No[a]	Compound	RI[b]	Diagnostic EI-MS ions(m/z)
1	*n*-Octane	800	114
2	*n*-Undecane	1100	156
3	5-Methylundecane	1154	43, 57, 71, 85, 99, 112

are in agreement with those previously reported for the invasive Argentine ant (*Linepithema humile*) workers by Vásquez et al. (2008), where they showed evidence that CHCs are used in queen adoption, confirming that the MOR is a sensitive assay that can be used effectively to determine recognition or aggression thresholds in ants. Recognition thresholds usually are based on a template odor that is characteristic of a given colony, with ants deciding to accept or reject an individual when it smells greater than a minimum similarity threshold or below a dissimilarity threshold (Reeve 1989).

Aggression towards nestmates of similar CHC profiles could be due to errors arising while reacting to recognition cues, as shown by Vásquez et al. (2008) in *L. humile,* or due to a lower threshold to avoid false-positive identification. In the present study, the MOR bioassay was used successfully to measure inter-colony aggression at the individual and colony levels in *P. analis*.

We identified 35 different compounds in the CHCs of different *P. analis* colonies. These compounds were mainly alkanes, alkenes, and methyl-branched alkanes, as previously reported for other ant species (Dietemann et al. 2003;

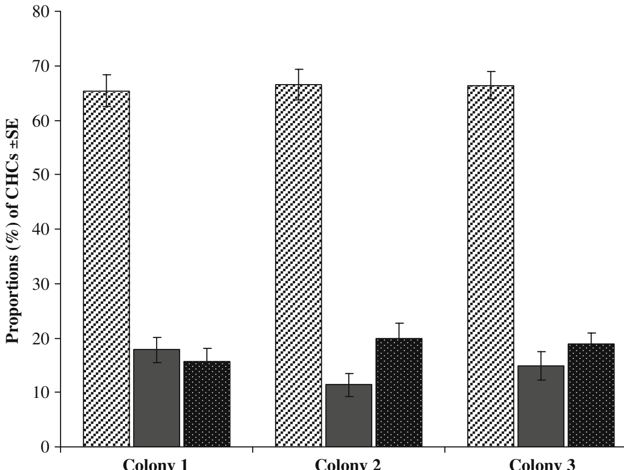

Fig. 3 Proportions±SE of the different groups of hydrocarbons (▨=*n*-Alkanes, ■=Alkenes and ▩=Methyl-branched alkanes) in the cuticular hydrocarbon profiles of *Pachycondyla analis* ants from colony 1, 2 and colony 3 (*error bars* represent mean proportions±SE)

Lucas et al. 2005; Martin et al. 2008b), with (*Z*)-9-tricosene occurring in variable proportions between colonies. In *P. analis, n*-alkanes occurred roughly in the same proportion in all colonies, with the alkenes and methyl-branched alkanes present in different proportions between the colonies, unlike in *Formica japonica* where *n*-alkanes and (*Z*)-9-alkenes varied between colonies (Akino et al. 2004) and in *F. exsecta* where (*Z*)-9-alkenes are colony specific (Martin et al. 2008b). In the genus *Pachycondyla,* species

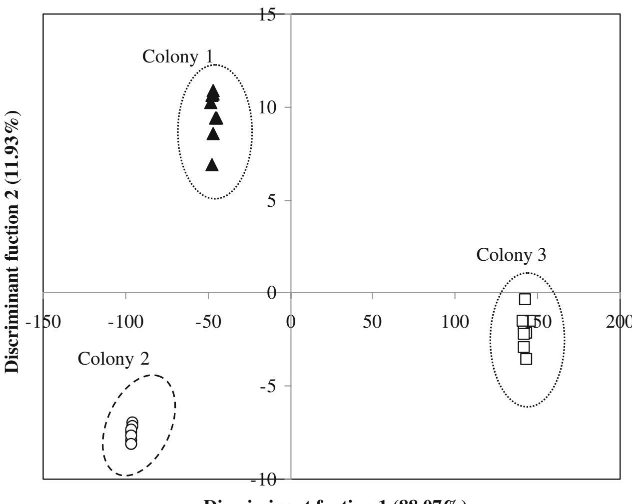

Fig. 4 Discriminant function analysis of ants from the three colonies of *Pachycondyla analis* based on relative proportions of 17 cuticular hydrocarbons determined in stepwise fashion. Colony 1 (*filled triangles*), Colony 2 (*circles*) and Colony 3 (*squares*). Circles around individual points are arbitrarily drawn to denote each colony. All individuals were clearly grouped into their respective colonies based on their CHC profiles

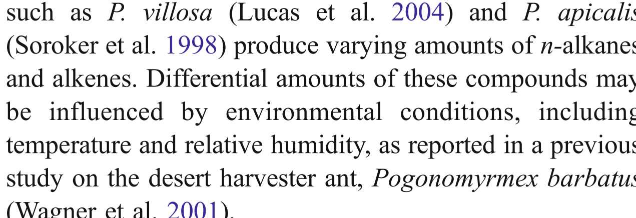

such as *P. villosa* (Lucas et al. 2004) and *P. apicalis* (Soroker et al. 1998) produce varying amounts of *n*-alkanes and alkenes. Differential amounts of these compounds may be influenced by environmental conditions, including temperature and relative humidity, as reported in a previous study on the desert harvester ant, *Pogonomyrmex barbatus* (Wagner et al. 2001).

The alkenes and methyl-branched alkanes in the CHCs could constitute nestmate recognition cues in *P. analis*. (*Z*)-9-Alkene has been reported as a nestmate recognition and aggression cue in *Formica* ants (Akino et al. 2004; Martin et al. 2008a,b), and as a recognition cue in the desert ant, *Cataglyphis niger* (Lahav et al. 2001). Nestmate recognition hydrocarbons identified in this study for *P. analis* might serve two purposes, colony defense (the traditional role of nestmate recognition), and recognition of nestmates when foraging. The roles played by the alkenes and methyl-branched alkanes in nestmate recognition and aggression in *P. analis* need to be further investigated by manipulating the CHC profiles of ants using synthetic compounds to see whether ants respond differently to the manipulated nestmate or non-nestmate CHCs.

The results from the discriminant function analysis show clearly that differences exist in the CHC profiles between colonies of *P. analis*. The implicated compounds (undecane, 3-methylundecane, 3,6-dimethylundecane, 3,8-dimethyldecane, pentadecane, heptadecane, 3-methylheptadecane, 2,6,10,14-tetramethylpentadecane, octadecane, nonadecane, heneicosane, tricosane, 1-nonadecene, 9-nonadecene, 9-methylnonadecane, squalene, and tetratriacontane) can be used effectively to correctly group the ants into their respective colonies. The colony-specific nature of CHCs in *P. analis* is consistent with findings in other ant species (e.g., Lahav et al. 2001; Akino et al. 2004; Lucas et al. 2004; Denis et al. 2006; Martin et al. 2008a,b). We demonstrated that these clear-cut groupings, based on CHC profiles, can explain the degree of aggression between different colonies. Colony 1 was further away from colonies 2 and 3, and exhibited higher aggression toward the latter colonies; likewise, colony 2 and 3 were closer together than colony 1, and were less aggressive toward each other's workers. Thus, these CHC differences could explain the differential acceptance of workers from other colonies competing for the same resources. Intruders or encroachers are usually killed upon encounter (AAY personal observation). By contrast the invasive Argentine ant displays minimal nestmate discrimination and individual non-nestmates are often integrated into an alien colony (Vásquez et al. 2008).

Colony odor recognition cues in ants are phenotypic and are derived either from the environment (diet, nesting sources) or produced endogenously (genetically determined or both) (Vander Meer and Morel 1998); the relative

importance of environmental and genetic differences can vary between populations (Pirk et al. 2001). Whatever the source of CHCs is, it is predicted that each colony will display a uniform odor that constitutes a gestalt. However, in some studies, it has been shown that this is not always the case because different castes within a colony may possess different CHC profiles that code different information within the colony (Dietemann et al. 2003; Martin and Drijfhout, 2009). In the present study, we showed that CHCs in *P. analis* are colony specific. However, a further investigation of workers in a colony based on the roles they play and their body sizes (major vs. minor workers) might reveal differences in the CHCs as is the case in some other ant species.

In summary, the MOR bioassay was used successfully to measure differential responses of *P. analis* workers based on colony of origin. Aggression was found to be associated with colony odor, mainly in the CHCs. As in other ant species, CHCs in *P. analis* comprise three main groups; *n*-alkanes, alkenes, and methyl-branched alkanes. The *n*-alkanes were consistent between colonies, with the alkenes and methyl alkanes serving as possible nestmate recognition cues.

Acknowledgements We thank two anonymous reviewers for their comments, S. P. Kuate and S. Subramanian for comments on an earlier version of the manuscript, Daisy Salifu for statistical advice, and Raphael Erangae for assistance with ants' excavation in the field. Funding for this study was provided in part by the Dutch SII project 2004/09 Activity No. 10799 to *icipe*, DAAD and UP provided a PhD fellowship to AAY and a Claude Leon fellowship to CWWP. The South African National Research Foundation provided support for the work in Pretoria.

RAPID COMMUNICATION

Flight Initiation by Male *Rhodnius prolixus* is Promoted by Female Odors

Claudia A. Zacharias · Gina B. Pontes · Marcelo G. Lorenzo · Gabriel Manrique

Abstract Several triatomine bug species utilize chemical cues for sexual communication. We tested whether female or male *Rhodnius prolixus*, a vector of Chagas disease, produce volatile chemicals that elicit flight responses from conspecifics, and then isolated the source of the chemical. Males confronted with an airstream containing female odors showed a significantly greater take-off frequency compared to a blank airstream or an airstream with male odors. In contrast, females exhibited similar take-off frequencies to male or female odor as to a clean airstream. Occlusion of female metasternal glands with paraffin wax resulted in a significant decrease in male take-off frequency compared to that of intact females. Additionally, excised female metasternal glands elicited a similar take-off frequency from males as did intact females, both significantly greater than the take-off frequency to clean air. These results show that *R. prolixus* females release a pheromone from their metasternal glands that causes upwind flight in conspecific males.

Introduction

Rhodnius prolixus Stål (Hemiptera: Reduviidae: subfamily Triatominae) transmits *Trypanosoma cruzi*, the etiological agent of Chagas disease, in northern South America and parts of Central America. In Latin America, Chagas disease afflicts 15 million people, with roughly a further 90 million at risk from potential transmission.

Triatomines are capable of sustained flight, dispersing over considerable distances (Gringorten and Friend 1979; Schweigmann et al. 1988). Flight is influenced by temperature and nutritional state of the insect (Lehane et al. 1992; Gurevitz et al. 2006). Adults are attracted strongly to light sources (Noireau and Dujardin 2001; Minoli and Lazzari 2006).

It is known that male triatomine bugs are attracted to and aggregate around mating pairs of adults (Baldwin et al. 1971; Manrique and Lazzari 1995). Triatomine bugs have paired Brindley's (BGs) and metasternal glands (MGs) that emit volatile compounds. The compounds emitted from the MGs, in particular, appear to mediate triatomine sexual communication (Crespo and Manrique 2007; Pontes et al. 2008). Pontes et al. (2008) demonstrated that female *R. prolixus* emit MG odors at dusk and in greater quantities than males.

We evaluated whether male or female odor added to an airstream promotes an increase in flight initiation or oriented take-off in adult *R. prolixus*. Also, we demonstrated that the source of the odor responsible for this effect are the female MGs.

Methods and Materials

Rhodnius prolixus were obtained from the Servicio Nacional de Chagas, Argentina, and reared in the laboratory

at 26±1°C, 30–50% RH, 12:12 h L:D, with live hens as a blood meal source. Hens were handled according to the biosafety rules from the Servicio de Higiene y Seguridad, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires. Bugs were sexed before final ecdysis, and the two sexes were kept separately until use. One to 2-months-old virgin adults, starved for 20±5 d, were used in the experiments.

We used a cage constructed of voile fabric (based on Minoli and Lazzari 2006), with a circular acrylic arena (15 cm diam.×5 cm high) hung 1 m above the center of the floor. A vertical wooden rod (1.5 cm diam.×15 cm high), fixed in the center of the arena, functioned as a platform for flight take-off. Bug movement was recorded with an infrared video camera (Videoman, JCC-300, Korea), with an infrared LED light source illuminating the platform. The video monitor was divided into eight 45° sectors, centered on the image of the top of the take-off platform, allowing determination of the angular direction of take-off. A Vaseline® film, applied to the interior surface, allowed only flying insects to leave the arena. A fan fixed inside an 85-cm-long PVC tube (12 cm i.d.) generated an airstream of 12±0.9 cm sec^{-1} (measured with a Testo 405-V1 anemometer, Germany) at the take-off platform. Insects used as odor sources were placed inside mesh-covered, open-ended flasks that permitted airflow. Groups of 20 males or females (four replicates per treatment) were released onto the arena at the start of the scotophase and left for 8 hr. We recorded the number of take-offs and their angular direction.

In the first experiment, we tested the responses of males and females, separately, to: a) clean air, b) air with odors from females, and c) air with odors from males. Ten insects per flask were used in all treatments using insects as odor sources. Next, we occluded the orifices of female glands with paraffin wax (Crespo and Manrique 2007) 24 hr prior to testing the responses of males to the following treatments: a) BG-occluded females, b) MG-occluded females, c) MG- and BG-occluded females, and d) sham females that had wax applied between the prosternum and metasternum that did not occlude the glands. Finally the take-off frequency and orientation of males was also tested to airstreams with: a) excised female MGs (ten glands), b) intact females, and c) control consisting of ten pieces of tissue and cuticle from the coxae of the first legs of females.

Take-off frequency data were analyzed by linear parametric statistics, after normality (P-Plot) and homoscedasticity (Levene's test) were verified. A two-way ANOVA, assuming fixed factors (gender and stimulus type), or a one-way ANOVA was applied, as appropriate. A significant ANOVA was followed by a *post-hoc* comparison (Tukey test). The MGs odor data set did not meet normality assumptions; therefore, data were log-transformed. Take-off frequencies presented in the results section are means (±SEM) from four replicates.

Results and Discussion

Typically, responsive insects climbed the take-off platform, moved their antennae, and took flight. There was a significant interaction (two-way ANOVA, $F_{2,18}$=12.63, P<0.001) between gender and stimulus type, indicating that males and females responded differently to stimuli. Male take-off frequency varied with stimulus (Simple effect, $F_{(2,18)}$= 11.94, P<0.001), with the greatest response being to female odor. There were no significant differences in responses of females to any of the odor treatments (Fig. 1a).

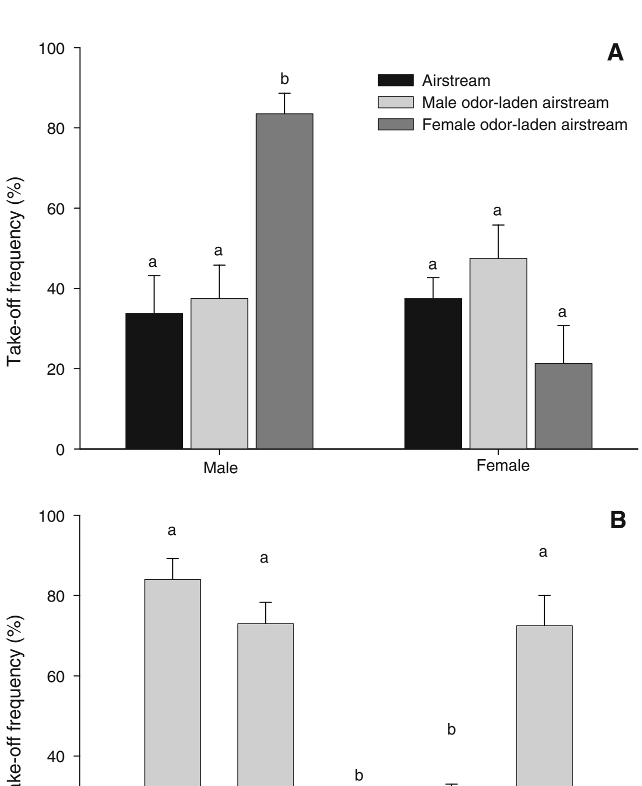

Fig. 1 Take-off frequencies (mean+SEM) of: **a** *Rhodnius prolixus* males or females to airstreams with intact males, intact females or clean air (control), and **b** *R. prolixus* males to various odor-laden airstreams; Intact = intact females, BG = females with Brindley glands occluded with paraffin wax, MG = females with metasternal glands occluded, MG+BG = females with metasternal and Brindley glands occluded, Sham = females that had paraffin applied to the cuticle without occluding any glands. Different letters atop bars denote statistically different means (Tukey, P<0.05). Each treatment consisted of four replicates

In the second experiment, flight frequencies showed a significant (one-way ANOVA, $F_{(4,15)}=19.95$, $P<0.001$) effect of occlusion treatment, with females with occluded MG or MG+BG eliciting significantly lower ($P<0.05$) take-off responses from males than did intact, sham-operated, or BG-occluded, females (these three treatments elicited similar take-off frequencies; Fig. 1b). In the final experiment, male take-off frequency was different depending on treatment (one-way ANOVA, $F_{(2,9)}=13.75$, $P=0.002$). Excised glands elicited a similar take-off frequency as intact females (60±7% vs. 84±5%; $P>0.05$, Tukey test). However, odors from control tissues elicited a lower male take-off frequency compared to odors from intact females (34±7% vs. 84±5%; $P<0.05$) or from excised MGs (34±7% vs. 60±7%; $P<0.05$, Tukey test).

The take-off direction of insects had a non-uniform distribution for all treatments tested. Insects tended to orient toward the direction of the airstream, regardless of odor.

The present work demonstrates that the flight of adult male *R. prolixus* can be triggered by volatile chemical cues released by conspecific females. In contrast, females did not show significant flight responses to male chemical cues. The source of the volatiles that elicit male flight appear to be the MGs of females, because when this gland was occluded with paraffin wax, the flight responses of males decreased significantly. In contrast, occlusion of another gland of females, the BG, or sham operation, did not affect flight responses of males. This sex-specific response suggests that this behavior is part of a mate location mechanism involving a sex pheromone emitted by females (Pontes et al. 2008).

Now that we have established that female *R. prolixus* produce a pheromone that elicits flight from males, chemical identification can proceed. Indeed, the chemical (s) may already have been identified in the study of Pontes et al. (2008). Identification of the pheromone will allow us to determine whether male behavior can be manipulated for controlling vectors of Chagas disease.

Abstract We have developed a simple method for preparing and verifying suitable standards for the acid butanol assay from a readily available source. Phenolics were extracted from fresh apples with methanol, and sugars were removed from the crude extract by treatment with Amberlite resin before fractionating the proanthocyanidins into ethyl acetate. The ethyl acetate fraction was chromatographed on Toyopearl TSK HW-50F to yield about 50 mg of procyanidin dimer and 35 mg of trimer from 1 kg fresh apple fruit. The purity and identity of the standards was easily confirmed by using ESI-MS. In the acid butanol assay, the pure dimer, trimer and purified *Sorghum* procyanidin had similar color yields on a mass basis, and produced about three times more color than purified quebracho tannin. This new standard overcomes problems associated with overestimation of tannin due to use of the unreactive quebracho tannin standard. Use of the new standard will enable accurate comparisons of tannin levels between laboratories and will standardize comparisons between species, thus promoting our understanding of the role of condensed tannins in plants.

Key Words Acid butanol assay · Proanthocyanidin · Procyanidin · Condensed tannin · Polyphenolic

Introduction

Research in chemical ecology relies on accurate methods for quantitative determination of metabolites. Polyphenolics (tannins) comprise one of the most intensively studied classes of secondary products, because they are widely distributed among plants and they have potent bioactivities. One of the most widely employed methods for quantitative analysis of the subclass of polyphenolics known as proanthocyanidins (condensed tannins) is the acid butanol assay (Swain and Hillis 1959) (Fig. 1). The acid butanol assay, in which proanthocyanidins are oxidatively depolymerized to yield colored anthocyanidins that are measured spectrophotometrically, is simple, specific, and reproducible if the optimized reaction conditions described by Porter et al. (1986) are used. Although specific compound analysis by HPLC is attractive for hydrolyzable tannins, HPLC methods for determining individual proanthocyanidins have not been developed adequately (Yarnes et al. 2006). Instead, the acid butanol method is the most widely used assay for selective determination of condensed tannins (Hagerman and Butler 1989; Yu and Dahlgren 2000).

Despite the widespread use of the acid butanol method, there is no generally accepted chemical standard for the assay. Standard curves used to convert absorbance to tannin concentration are generated by using a variety of materials, each with a unique color yield. Lack of a single standard hinders comparison of results between and within labs, and generates confusion about the quantities of tannins found in biological samples (Schofield et al. 2001). Porter et al. (1986) developed the assay by using cyanidin as a standard, but the expense of cyanidin precludes its routine use as a laboratory standard. Catechin, the nominal monomer of the procyanidins, is readily available, but it cannot be used as a

Fig. 1 Reaction of procyanidin dimer (I) with acid butanol to form cyanidin (II) from the extender (*top*) unit and the flavan-3-ol (III) from the terminal (*bottom*) unit. The apple dimer preparation was predominantly epicatechin-(4β->8)-epicatechin (dimer B-2) but contained some epicatechin-(4β->8)-catechin (dimer B-1). Epicatechin, *R*= OH, catechin, *R*= OH

standard because it does not react with acid butanol to yield an anthocyanidin. Quebracho tannin is a commercially available condensed tannin that has been recommended as a standard (Hagerman and Butler 1989). However, purification of the commercial product to remove nontannin materials is labor intensive and has low yield (Nelson et al. 1997; Hagerman 2002). Furthermore, quebracho is a 5-deoxy proanthocyanidin that is resistant to oxidative depolymerization (Schofield et al. 2001), so color yields are low, and tannin contents are typically overestimated (Wolfe et al. 2008), leading to an underestimation of biological potency. *Sorghum* procyanidin is well characterized (Gupta and Haslam 1978) and highly reactive with acid butanol, but it is not available commercially and is tedious to purify (Hagerman and Butler 1980; Hagerman 2002). Furthermore, there is no simple method to verify that the purified product is similar to that produced in other labs from the same plant material.

It has been recommended that the most suitable standard may be a purified proanthocyanidin prepared from the species of interest. The general strategy for purification uses sorption to Sephadex LH20 or similar resins to separate tannin from other phenolics (Mole et al. 1989; Rehill et al. 2006). The tannin that is produced, which contains the particular mixture of the condensed and the hydrolyzable tannins found in the plant, is generally used without further characterization or purification. Variable reactivity of "standards" prepared this way is not surprising given the variation in tannin composition across plant species, season, and environmental conditions. The condensed tannin "standards" prepared in this way from the same species in two different labs, or from different batches of tissue within the same lab, may have significantly different color yields in the acid butanol assay because of differences in the plant source and differences in the methods of purification. Extensive chemical characterization of unique plant standards by each laboratory where they are prepared could overcome these difficulties, but because the tannins produced by these methods are complex mixtures of complex polymeric natural products, characterization is daunting. We propose that adoption of a single, well characterized, chemically defined standard is a simpler solution that can be implemented uniformly in all labs.

Apple fruit is widely available, and comprises abundant proanthocyanidins but not hydrolyzable tannins, thus making it a good potential source for a condensed tannin standard (Guyot et al. 2001; Shoji et al. 2003). HPLC has been used for analytical separation of flavan-3-ol monomers and some small oligomers from apple (Perez-Ilzarbe et al. 1992; Yanagida et al. 2000), but these methods are not modified easily to preparative scale. Yanagida et al. (1999) fractionated apple procyanidins on Toyopearl TSK-gel HW by using a mixture of acetone and 8 M urea as an eluent, but the detection method was complicated, and removal of the urea from the product was laborious. Suitable methods for preparing large quantities of oligomeric proanthocyanidins from apple or other convenient sources have not been published.

Adoption of a single, well characterized standard for the acid butanol assay would improve our understanding of tannins not only in ecological systems, but also in food science, medicine, and nutrition (Hummer and Schreier 2008). With a more uniform basis for reporting tannin content, studies from different laboratories will be more easily compared. The main object of the work described here was to develop a simple method for preparing an acid butanol standard from readily available materials, and to provide simple parameters for validating the standard.

Methods and Materials

Chemicals All solvents were analytical or HPLC grade, and were obtained from Fisher Chemicals (Fair Lawn, NJ, USA), as were trifluoroacetic acid (TFA) and phenylmethane thiol (benzyl mercaptan). Catechin, epicatechin, cyanidin, and delphinidin, and the chromatographic supports Toyopearl HW50F, Sephdex LH 20, and Amberlite XAD7HP were from Sigma Chemical Co. (St. Louis, MO, USA).

Sample Preparation About 1.5 kg fresh Granny Smith apples (*Malus domestica*) were purchased from a local super market (Oxford, OH, USA), to be initially processed in seven batches. About 200 g of the fruit were cut into 1–2 cm cubes, transferred to a 1 l round bottom flask, and refluxed in 800 ml methanol at 70°C for 1.5 h, using a heating mantle to control the temperature and a water jacketed condenser to return the vapor to the pot. The extract was filtered, and the residue was extracted two more times. As the extracts were prepared, they were evaporated under reduced pressure to about one tenth the original volume and combined, yielding a somewhat viscous, sugar-rich extract. The sample (~250 ml) was loaded onto a column (3.8×50 cm) packed with Amberlite XAD7HP resin equilibrated with water, and sugars were eluted with 500 ml deionized water at a flow rate of 3 ml/min. When the eluate was sugar-free, as indicated by lack of reactivity with phenol-sulfuric acid (Dubois et al. 1956), 95% ethanol was used to elute polyphenolics at a flow rate of 2 ml/min. The eluate was periodically checked with the Prussian blue spot test (Hagerman 2002), and when all the phenolics had been eluted (~200 ml), the sample was evaporated under reduced pressure, and the residue was redissolved in about 50 ml water. This extraction process was repeated × 7 to obtain about 350 ml of aqueous sample from the 1.5 kg of fresh fruit. The aqueous sample was partitioned against an equal volume of ethyl acetate × 4, and the ethyl acetate extracts were combined and evaporated under reduced pressure to remove the solvent before redissolving the sample in about 100 ml water and freeze drying to yield about 0.7 g crude phenolics from 1,360 g fresh apple (Table 1).

Column Chromatography About 0.2 g of the freeze dried phenolic fraction was dissolved in 1 ml of methanol and applied onto a Toyopearl HW-50F column (3.0×50 cm) equilibrated with methanol. The column was washed with methanol at 1.5 ml/min, monitoring the eluate at 280 nm to identify fractions to combine. Each pooled fraction was diluted with an equal volume of water and evaporated under reduced pressure to remove the methanol before freeze drying to yield products for further analysis (Fig. 1, Table 1).

Table 1 Yield of fractions obtained by Toyopearl chromatography of crude phenolic extract from apple fruit

Fraction	Yield (mg)
Crude phenolics (ethyl acetate fraction)	704
Toyopearl fractions 1–3	184
Toyopearl fraction 4 (dimers)	51.2
Toyopearl fraction 5 (trimers)	36.8
Toyopearl fraction 6 (trimers, tetramers)	15.2
Toyopearl fraction 7 (tetramers)	24.6
Toyopearl fraction 8 (tetramers)	19.5

Values are typical values for a preparation from 1,360 g fresh apple fruit. Fractions were freeze dried and weighed to determine yields

HPLC Analysis Proanthocyanidin oligomers in each fraction were analyzed by HPLC using an Agilent 1050 system (Santa Clara, CA, USA) equipped with a diode array detector and controlled with Agilent ChemStation software (A.09.03). The system was equipped with two tandem 5 μm Hypersil ODS2 C_{18} cartridge columns (30×2.1 mm) with a guard column of the same materials (Grace Davison, Deerfield IL, USA). Separation was achieved with a gradient of 0.13% TFA in H_2O (A) and 0.1% TFA in acetonitrile (B) at 0.5 ml/min in a 45 min program as follows: 0–10 min, 5% B, 10–15 min, increase to 20% B, 20–25 min, increase to 55% B, 25–35 min, 55% B, 35–40 min decrease to 5% B, 40–45 min, re-equilibrate at 5% B. The samples were filtered through a 0.22 μm cellulose acetate spin filter before injecting 10 μl, and the eluate was monitored at 280 nm.

ESI-MS Analysis Mass spectra were obtained on an Esquire LC ion trap instrument (Bruker Daltonics, Billerica, MA, USA). The electrospray ionization source (ESI) was operated in negative mode. A nominal target mass was set to 1,000 before fine tuning. The capillary, skimmer 1, and trap drive voltages were 3,500, −51.8, and 72.9 V, respectively. The ion charge control was on with a target of 30,000. The 300°C nitrogen dry gas flow rate was 4 l/min, and the nebulization gas pressure was 11 psi. A syringe pump was used to infuse the sample at 10 μl/min. Each data point in the spectrum consisted of an average of eight scans over a mass range of 50–2,000 m/z.

Gel Permeation Chromatography (GPC) GPC was carried out on the Agilent series 1050 HPLC equipped with a Varian PL Gel 5.0 μm MIXED-D, 300×7.5 mm column (Fisher Scientific, Fair Lawn, NJ, USA). An isocratic mobile phase of 1% water in tetrahydrofuran was delivered at 1 ml/min. The samples were dissolved at 1 mg/ml in tetrahydrofuran containing 1% water, and filtered through a 0.22 μm nylon spin filter before injecting 10 μl. The eluent was monitored at 280 nm.

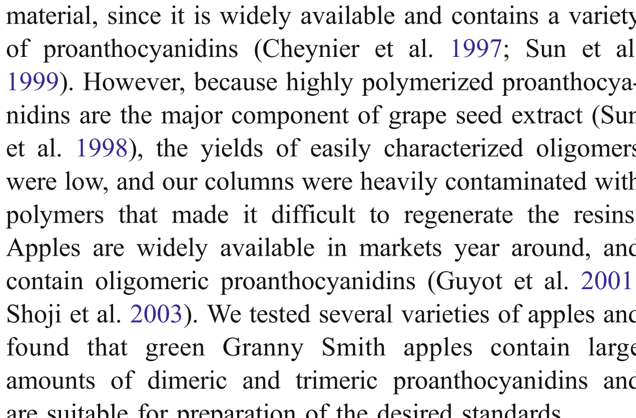
Thiolysis Freeze dried samples were dissolved in methanol at 1 mg/ml and were mixed with an equal volume of thiolysis reagent (5% (v/v) phenylmethanethiol in methanol containing 0.2 M HCl) (Gu et al. 2003). The mixture was heated at 40°C for 30 min, placed in the freezer for 5 min to stop the reaction, and immediately analyzed using an Agilent series 1100 HPLC (Santa Clara, CA, USA) equipped with a diode array detector. Separation was on a 5 µm Agilent Eclipse XDB-C_8 column (4.6 × 150 mm) with a gradient of 0.13% TFA in H_2O (A) and 0.1% TFA in acetonitrile (B) in a 57 min program as follows: 0–3 min, 15% B, 3–8 min, 15–20% B, 8–10 min, 20–25% B, 10–30 min, 25–35% B, 30–34 min, 35–70% B, 34–44 min, 70% B, 44–47 min, 20% B, 47–52 min, 20–15% B, 52–57 min, re-equilibrate with 15% B. Thiolysis products were filtered through a 0.22 µm cellulose acetate spin filter before injecting 10 µl, and monitoring at 220 nm. Products were identified by comparison of elution times to the elution times of catchin and epicatechin obtained commercially, and epicatechin benzylthioether obtained by thiolysis of *Sorghum* procyanidin (Gupta and Haslam 1978). Peak areas were determined using Agilent Chem Station software (A.09.03) and then were converted to moles relative to the flavan-3-ol terminal using standard curves, and the average degree of polymerization (mDP) was calculated from the molar ratio of all the flavan-3-ol units (thioether adducts plus terminal units) to terminal units.

NMR Analysis Samples were dissolved at about 13 mg/ml in 90% H_2O/10% D_2O with DSS as the internal reference for NMR analysis at 500 MHz (proton) or 125 MHz (carbon). The Bruker (Billerica, MA, USA) spectrometer was equipped with a 5 mm probe and temperature was set at 15°C. HSQC was carried out with 128 experiments each with 256 scans and 16 dummy scans.

Acid Butanol Assay Samples were dissolved in methanol at 0.25 mg/ml for reaction with 3.0 ml acid butanol (5% (v/v) hydrochloric acid in n-butanol) and 0.1 ml of ferric ammonium sulfate (2% (m/v) in 2 M HCl) (Hagerman 2002). After 50 min of reaction in a boiling water bath, the samples were cooled, and absorbance was recorded at 550 nm in 1 cm cells, using an Agilent 8453 spectrophotometer (Santa Clara, CA, USA).

Results and Discussion

Starting Material Our goal was to establish a method to isolate a well defined standard for the acid butanol assay from a readily available material. We initially considered using commercial grape seed extract as our starting material, since it is widely available and contains a variety of proanthocyanidins (Cheynier et al. 1997; Sun et al. 1999). However, because highly polymerized proanthocyanidins are the major component of grape seed extract (Sun et al. 1998), the yields of easily characterized oligomers were low, and our columns were heavily contaminated with polymers that made it difficult to regenerate the resins. Apples are widely available in markets year around, and contain oligomeric proanthocyanidins (Guyot et al. 2001; Shoji et al. 2003). We tested several varieties of apples and found that green Granny Smith apples contain large amounts of dimeric and trimeric proanthocyanidins and are suitable for preparation of the desired standards.



Isolation and Characterization of Dimers and Trimers We exhaustively extracted the phenolics from diced apples with methanol, and removed sugars by a rapid, simple treatment with Amberlite resin. Methanol was removed from the phenolic extract, and smaller phenolics including oligomeric proanthocyanidins were selectively extracted with ethyl acetate and separated on Toyopearl into eight fractions (Fig. 2, Table 1). Reversed phase (RP)-HPLC and mass spectrometry (MS) indicated that fractions 1, 2, and 3 contained small phenolics but not procyanidins (data not shown).

RP-HPLC revealed that fraction 4 contained two major components with retention times of 4.21 min and 12.6 min (Fig. 3), but ESI-MS indicated that the fraction comprised compounds with a common molecular mass and fragmentation pattern (Fig. 4a), suggesting a pair of isomers. The molecular ion $[M-H]^-$ at *m/z* 577 is consistent with procyanidin dimer(s) while the *m/z* 289 peak is consistent with interflavan bond breakage to yield the monomer (epi) catechin. The fragment at m/z 425 corresponds to loss of 152 upon C ring cleavage of the terminal unit (Zeeb et al.

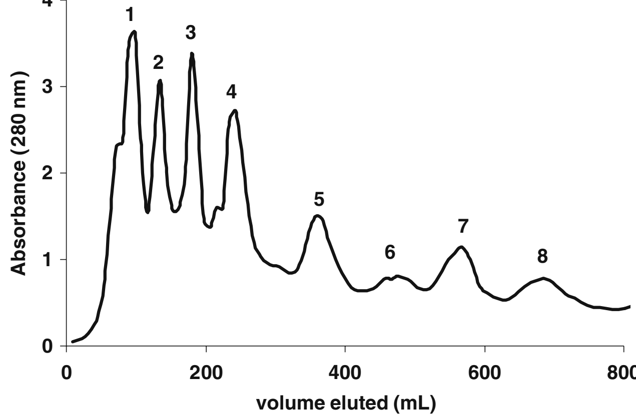


Fig. 2 The ethyl acetate soluble fraction of the apple extract was chromatographed on Toyopearl TSK-HW50 (F) using methanol at 1.5 ml/min as the eluent, and monitoring at 280 nm. The eluate was pooled as indicated to give 8 fractions for further characterization

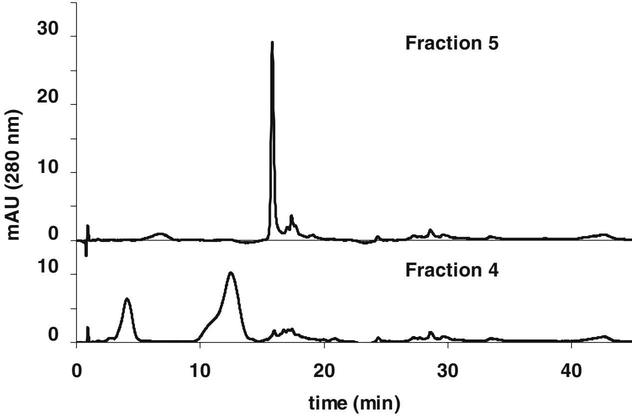

Fig. 3 Fractions 4 (*bottom panel*) and 5 (*top panel*) from the Toyopearl chromatography were analyzed by C-18 RP-HPLC using a gradient of water to acetonitrile with trifluoroacetic acid modification. The eluent was monitored at 280 nm to detect phenolics, which included procyanidin dimers B-1 and B-2 (fraction 4) and trimers (fraction 5)

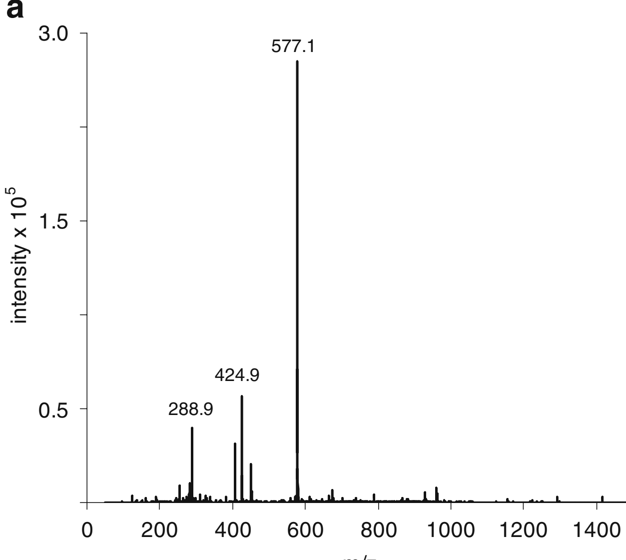
2000). The major signals in the 2D NMR were consistent with dimer B-2 (Table 2) although weaker signals suggested that the sample also contained dimer B-1 (Tarascou et al 2006). The products of thiolysis of fraction 4 were catechin (6.34 min), epicatechin (7.84 min), and epicatechin benzylthioether (31.4 min) in molar ratios of 0.3:0.7:1.4, respectively. The mean degree of polymerization based on thiolysis was 2.4, consistent with the MS determination. We concluded that fraction 4 comprises two procyanidin dimers, B-1 (epicatechin-(4β->8)-catechin) and B-2 (epicatechin-(4β->8)-epicatechin) (Fig. 1). About 50 mg of this mixture of dimers were obtained from about 1 kg of fresh apple (Table 1). Based on RP-HPLC, NMR signal strength, and thiolysis products we estimated that about 70–80% of the dimer was B-2, similar to previous reports for apple procyanidins (Guyot et al. 2001). We recommend that the ESI-MS is a simple, reproducible way to confirm the identity of this fraction. For individuals without access to MS instrumentation, many commercial facilities (e.g., http://www.ccic.ohio-state.edu/MS/) will perform this analysis for a fee.

RP-HPLC indicated that fraction 5 was homogeneous (retention time 15.8 min, Fig. 3), as did ESI-MS (Fig. 4b). The molecular ion $[M-H]^-$ at *m/z* 865 indicated that the fraction contains procyanidin trimer(s), and fragments corresponding to dimer (m/z 577), monomer (*m/z* 288) and typical fragmentation of the C ring on the terminal unit to yield *m/z* 425 confirm that conclusion. The major products resulting from the thiolysis of fraction 5 were quite similar to those for fraction 4. The release of two terminal units, catechin and epicatechin, and one extension unit, epicatechin, in the molar ratio 0.2:0.8:2.6 indicated that fraction 5 was comprised of a mixture of two trimers, epicatechin$_2$-catechin and epicatechin$_2$-epicatechin, with a mean degree of polymerization of 3.6. As expected for higher oligomers, the NMR spectra were broadened for the trimer. Because we did not attempt to purify the various isomers to purity, exact structural assignments cannot be made, but the major peaks in the 2-D NMR (Table 2) correspond to the peaks assigned for trimer C-1 (epicatechin$_2$-epicatechin) and its isomer epicatechin$_2$-catechin (Shoji et al. 2003). About 35 mg of the mixture of trimers were obtained from 1 kg of fresh apple (Table 1). It is likely that trimer C-1 is the major component from this Toyopearl fraction, as in other examinations of apple procyanidins (Guyot et al. 2001), and the identity of this fraction was confirmed easily by ESI-MS.



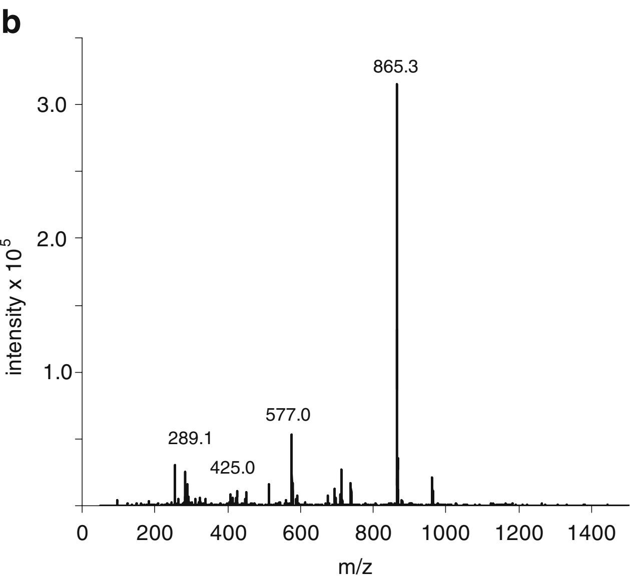


Fig. 4 ESI-MS of fraction 4 (**a**) and 5 (**b**) from the Toyopearl chromatography. The molecular ion in a (*m/z* 577.1) is characteristic of procyanidin dimers, and in b (*m/z* 865.3) is trimers

Table 2 ^{1}H and ^{13}C NMR data for authentic B-2[1], dimer (fraction 4) and trimer (fraction 5) from apple

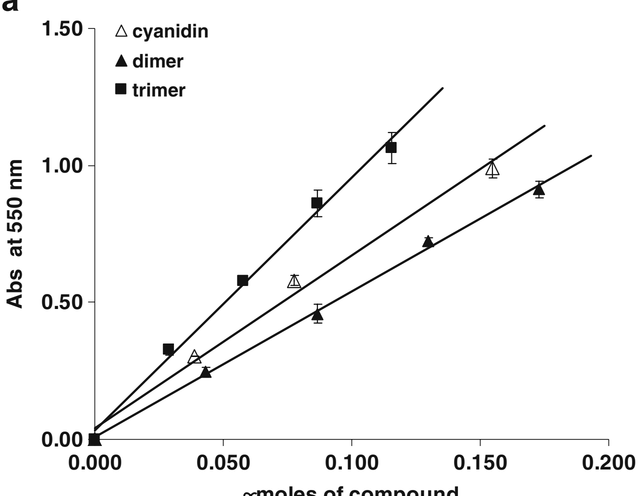
Position	B-2 [1]H	B-2 [13]C	Toyopearl fraction 4 [1]H	Toyopearl fraction 4 [13]C	Toyopearl fraction 5 [1]H	Toyopearl fraction 5 [13]C
2 extender	5.42	78.1	5.27	77.8	4.86	80.52
3 extender	4.06	74.6	4.02	73.9	4.09	74.1
4 extender	4.47	38.7	4.40	38.0	4.60	38.3
2 terminal	4.32	81.3	4.33	81.0	5.28	78.4
3 terminal	4.02	68.4	4.02	73.9	4.32	68.1
4 terminal	2.86	31.1	2.81	30.4	2.87	30.6

[1] Data for the compact conformer of authentic B-2 from Tarascou et al. 2006

HPLC and ESI-MS indicated that fraction 6 was a mixture of procyanidin trimers and tetramers, fractions 7 was procyanidin tetramers, fraction 8 was a mixture of tetramers and pentamers, and fraction 9 (not shown in Fig. 2) was a procyanidin pentamer. The tetramers and pentamers were not fully characterized, but the molecular size homogeneity of fractions 4, 5, 7, and 9 was confirmed by GPC. Each fraction eluted as a single peak with a characteristic retention time (catechin, 8.33 min; Fractions 4, 5, 7, and 9, t_R=8.11, 7.99, 7.91, and 7.87 min, respectively). The retention times were tightly correlated with the assigned molecular masses (mol mass=9E+14$e^{-3.46x}$, where x is retention time in min; R^2=0.996). Although high molecular weight procyanidins have been found in some varieties of apple (Guyot et al. 2001), none were detected in the extracts of Granny Smith apples. As a consequence the chromatographic supports were reconditioned easily for reuse in subsequent purifications, a major advantage for a preparative method.

Acid Butanol Assay In the acid butanol assay, the inter-flavan bond of proanthocyanidins is oxidatively cleaved to yield extender units as the colored anthocyanidin, and terminal units as the flavan-3-ol (Porter et al. 1986) (Fig. 1). Although each anthocyanidin (cyanidin, delphinidin, etc.) has a unique λ_{max}, the absorbance peak is broad, and all the anthocyanidins absorb strongly at 550 nm, with molar extinction coefficients in the acid butanol reagent of 24,500 M^{-1} cm^{-1} and 21,200 M^{-1} cm^{-1} for cyanidin (Fig. 5a) and delphinidin (data not shown), respectively. Thus, standardizing the assay with a well defined compound that yields only cyanidin will give reasonable results even for mixed proanthocyanidins.

The dimers and trimers that we isolated from apple are very reactive in the acid butanol assay. The molar yield of cyanidin from dimer was 84% of the expected yield, and from the trimer was 73% (Fig. 5a), similar to the yields from a variety of oligomers reported by Porter et al. (1986). On a mass basis, the color yield of dimer or trimer was 70–80% that from the well-known polymeric procyanidin from *Sorghum*, and 2.5–3 times higher than the color yield from



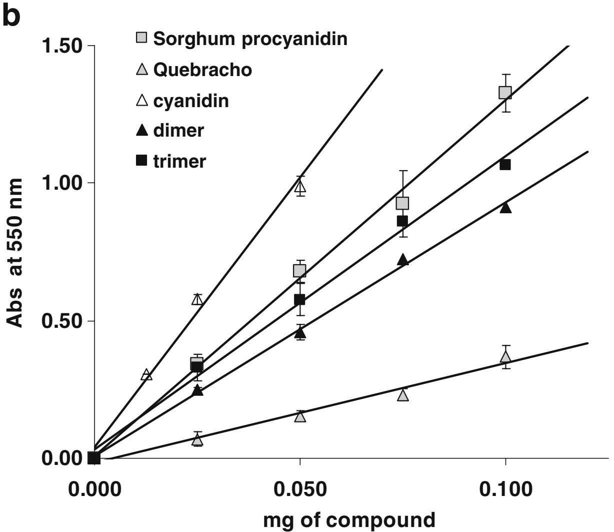


Fig. 5 Acid butanol assay. The absorbance is shown as a function of μmoles of compound (**a**) or mass of compound (**b**) for the purified apple dimer and trimer. The color yield is compared to that of cyanidin, Sorghum procyanidin, and purified Quebracho tannin. Each point is the mean of three determinations, and the error bars show standard deviation. The lines are fit by linear regression, and for every line the R^2 value is >0.99

purified quebracho tannin (Fig. 5b). Because the apple dimer and trimer react with high color yield, similar to the proanthocyanidins found in many common plants, these standards will provide realistic estimates of tannin levels for a wide variety of plants. The problems of gross overestimation of tannin content typically encountered when using quebracho tannin as a standard (Wolfe et al. 2008) will not be encountered with the apple standards.

We recommend that proanthocyanidin concentrations be reported as mass % equivalents of procyanidin dimer. In a recent study of *Ficus* tannins, we reported a range of 0.15 to 6.40% dry matter of proanthocyanidin, using the acid butanol assay standardized with our *Sorghum* procyanidin standard (Kendrick et al. 2009). If we had used the apple dimer, we would have reported values from 0.21 to 8.96% dry matter procyanidin dimer equivalents. The ranking and relative amounts of tannin in the species examined are the same whether the *Sorghum* standard or the dimer standard is used to calculate the tannin level. The important feature of reporting based on the apple dimer is that using that standard, our data could be reliably reproduced for these samples, and compared directly to data from other samples, by any other laboratory. The values calculated with the *Sorghum* tannin standards can be reproduced only by an individual who has access to this particular batch of our *Sorghum* tannin standard, since for complex polymeric tannin mixtures there is no convenient way to confirm that one preparation is identical to another. Since the apple dimer and trimer are defined chemical compounds, inter-laboratory comparisons of acid butanol analysis based on these standards will be more meaningful than comparisons based on poorly defined, polymeric standards such as quebracho or tannins isolated from a specific plant of interest.

In some cases, more biologically meaningful data might be obtained by using a standard purified from a plant of interest. For example, *Acacia* tannins are primarily 3-deoxyproanthocyanidins, which have low color yields in the acid butanol assay (Ishida et al. 2005). The apple procyanidin dimer would provide an unrealistic overestimation of tannin in this case, and the best standard would be one isolated from *Acacia*. In those cases, the apple procyanidin dimer would provide a very useful external reference for characterizing the reactivity of the purified *Acacia* proanthocyanidin for inter-study comparisons.

In summary, we found that the dimer and trimer from fresh apple are suitable standards for the acid butanol assay. Our fractionation and isolation procedure is fast, inexpensive, and yields pure dimeric and trimeric fractions whose identity is easily confirmed by ESI-MS. We believe that wide adoption of these standards will improve the quality of data reporting quantities of proanthocyanidins in a variety of plant tissues.

Acknowledgments We are grateful to Dr. Ian Peat for help with the ESI-MS analysis. Dynamics of the Volatile Defense of Winter "Dormant" Balsam Poplar (*Populus balsamifera*)

Thomas P. Clausen · Janice Chen · John P. Bryant · Frederick D. Provenza · Juan Villalba

Abstract 6-Hydroxycylohex-2-en-1-one (6-HCH) has been reported as a major chemical defense of the winter-dormant internodes of balsam poplar (*Populus balsamifera*) against feeding by herbivores such as the snowshoe hare (*Lepus americanus*). We report that the concentration of 6-HCH in the fall internodes is triggered by a single hard frost, and then undergoes an exponential decline through volatilization over the winter that results in barely detectable quantities by early spring. We conclude that the role of 6-HCH in the defense of mature balsam poplar is more complex than simply acting as a toxin. Rather, 6-HCH's role as a defensive agent must evolve over the course of the winter from being a co-toxin to a cue for a conditioned flavor aversion (CFA) to finally having no role by late spring.

Introduction

The role of chemical defenses in the consumption of winter-dormant *Populus balsamifera* (balsam poplar) by hares has been studied for over two decades (Bryant 1981a, b; Sinclair and Smith 1984; Mattes et al. 1987; Jogia et al. 1989; Reichardt et al. 1990; Clausen et al. 1992; Schmitz et al. 1992). When eating the twigs of either the juvenile or mature ontogenetic phase of poplar, hares eat the woody internodes and reject the highly resinous foliar buds (see Online video clip). Internodes of the mature phase are moderately palatable, while juvenile internodes are unpalatable. Here, we were concerned with the chemical defense of internodes of the mature phase.

Three volatile and potentially toxic shikimates {Fig. 1; salicaldehyde, 6-hydroxycyclohex-2-en-1-one (6-HCH), 1,2-cyclohexadione; Mattes et al. 1987} have been implicated as internode defenses against snowshoe hares (Reichardt et al. 1990). In the case of mature poplar, 6-HCH has been implicated as the primary secondary metabolite that regulates internode consumption (Mattes et al. 1987). In this paper, we consider the possibility that chemical defense of the internodes of the mature phase may change over winter because of the volatility of 6-HCH. Since it is unlikely that 6-HCH is produced throughout the winter, it follows that volatilization would deplete the 6-HCH pool and complicate its role in defense.

The chemistry of the poplar internode shikimates involves complex dynamics (Fig. 2). Phenolic glycosides such as salicortin undergo enzymatic conversion to toxic

Fig. 1 Known volatile defensive secondary metabolites of *Populus balsamifera*. Taken from Mattes et al. 1987 and Jogia et al. 1989

derivatives such as optically active 6-HCH and corrosive cyclohexadione upon tissue damage (Fig. 2; Mattes et al. 1987; Reichardt et al. 1988; Ruuhola et al. 2003). Both esterase and β-glucosidase activity lead to these transformations although, in our previous studies, *in vitro* β-glucosidase treatment of salicortin also leads to a potentially toxic benzyl substituted analog of 6-HCH along with enzyme deactivation (Clausen et al. 1990; Jianjun et al. 1998). The facile conversion of 6-HCH to the toxins phenol under acidic conditions and catechol under basic/oxidative conditions (Clausen et al. 1989; Miyoshi et al. 2001; Ruuhola et al. 2003) is consistent with a toxic mode of action of both 6-HCH and its immediate precursor, salicortin. In addition, substances such as benzyl gentisate, which is enzymatically generated from a biogenetically related glycoside, trichocarpin, affects internode consumption (Mattes et al. 1987). The enzymatic transformations of salicortin and trichocarpin are complete within minutes of tissue damage, similar to what must occur when an internode is masticated by a hare.

The importance of salicortin and related glycosides such as tremulacin in deterring foraging has been widely reported (Lindroth et al. 1988; Reichardt et al. 1988, 1990; Kelly and Curry 1991; Julkunen-Tiitto et al. 1994; Hemming and Lindroth 2000; Haruta et al. 2001; Miyoshi et al. 2001; Ruuhola et al. 2001; Kleiner et al. 2003). Many of these studies have stressed the facile conversion of salicortin to toxic phenol or catechol via 6-HCH as the driving mechanism. In addition, the importance of free 6-HCH in deterring hare selection of mature balsam poplar internodes was shown clearly by Reichardt et al. (1990).

There remain two different hypotheses regarding the mechanisms for why hares are deterred by free 6-HCH

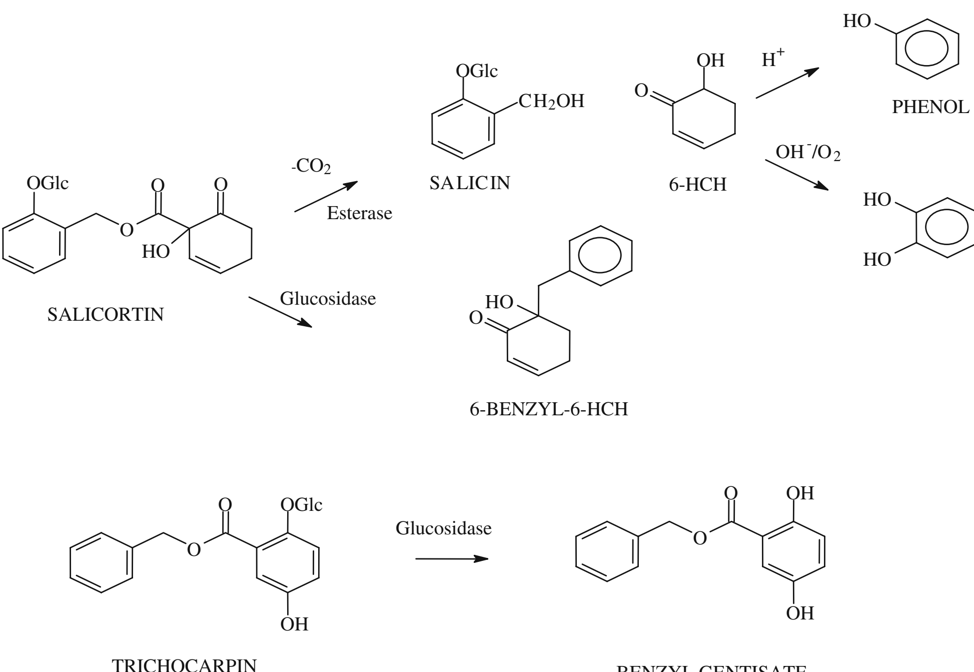

Fig. 2 Facile transformations reported for *Populus balsamifera's* internode secondary metabolites

found in mature balsam poplar internodes. The first is based on the toxicity of 6-HCH, but would be valid only if its concentrations in the plant were above toxic thresholds of ingestion. The other is based on free 6-HCH acting as a warning to hares regarding the presence of additional 6-HCH-producing toxins in the plant. This latter hypothesis is attractive given Tahvanainen et al.'s (1985) observation that hares choose salicaceae browse low in phenol glycosides based on olfactory and not taste stimuli; 6-HCH is volatile and hence has an odor, while its phenol glycoside precursors such as salicortin are not volatile or odiferous.

Both of these mechanisms, however, have an inherent weakness. Over the winter-dormant season, it is unlikely that 6-HCH lost through volatilization will be replenished through metabolic processes. If the concentration of 6-HCH decreases as the winter progresses, then either the toxicity of the browse must decrease (hypothesis 1) or hares must continually adjust their perception of warning signals (hypothesis 2). Thus, further understanding the dynamics of the hare-mature poplar internode browsing system first requires answering the question posed in this study: Does the concentration of mature poplar internode 6-HCH decline over the winter?

Methods and Materials

Starting in late October in 1996, this study focused on the chemistry of mature balsam poplar internodes through mid-January for two consecutive years. About every 1–4 d over the course of the study, a mature (3–4 m tall) poplar tree was selected haphazardly from a stand growing on the University of Alaska Fairbanks campus. A voucher specimen (Clausen 2) has been deposited at the University of Alaska, Fairbanks Museum. Current season growth twigs (diam<4 mm) were collected randomly and immediately processed upon return to the laboratory. Buds were removed, and about 1 g of internode was accurately weighed and extracted for 24 hr in 10 ml MeOH (VWR HPLC grade) containing 0.1% 1-hexadecanol (internal standard; Aldrich-Sigma) at −20°C. Samples were filtered, diluted with MeOH, and analyzed by GC/MS (1 µl splitless injection) using a 5% phenyl dimethyl siloxane (0.25 µm thickness) column (30 m×0.25 mm; Alltech). The following parameters were used. Gas (He) flow rate=1 ml/min; injector and detector temperatures of 275°C and 300°C, respectively; oven temperature program: 50°C for 6 min, then raised to 85°C at 4°C/min, held at 85°C for 2 min, and then ramped to 275°C at 20°C/min to recondition the column. Synthetic 6-HCH from an earlier study (Mattes et al. 1987) was used to determine the retention time of 6-HCH to be 10.5 min.

Results

We did not detect 6-HCH in mature poplar internodes until the first hard frost of the fall at which time 6-HCH internode concentrations were estimated to be about 1% (dry wt). During the 1996/1997 dormant season, its concentrations then exponentially declined (r^2=0.8) to about 0.01% by mid January (Fig. 3). A similar trend was observed over the 1997/1998 dormant season (r^2=0.59; Fig. 3).

Discussion

The volatile phenolic glycoside derivative 6-HCH is absent in poplar in summer presumably because of autotoxicity, as leaf biomass is rapidly killed by contact with 6-HCH (Clausen unpublished). Our observation of a spike in the concentration of 6-HCH after the first hard frost, while possibly coincidental, is not surprising given that freeze-

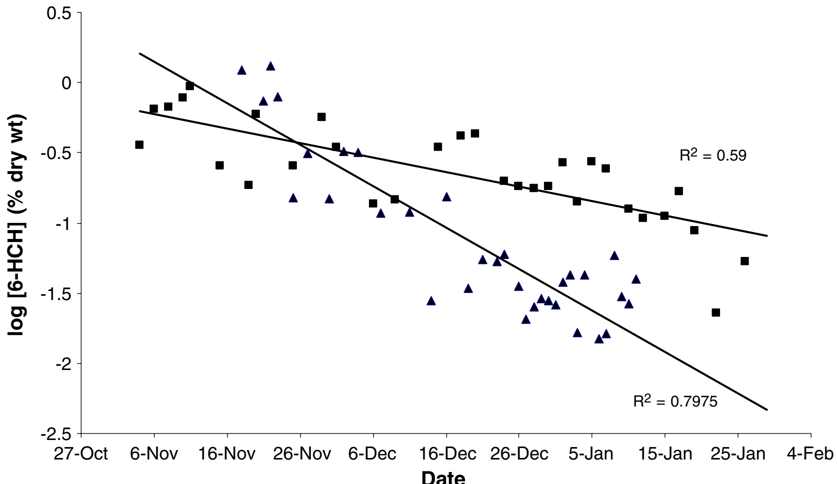

Fig. 3 A logarithmic plot of 6-HCH concentrations in *Populus balsamifera* internodes through the early half of the dormant season of years 1996/1997 (triangles) and 1997/1998 (squares)

thawing of plant material containing salicortin results in its rapid enzymatic breakdown to 6-HCH (Julkunen-Tiitto and Tahvanainen 1989; Orians 1995; Lindroth and Koss 1996; Julkunen-Tiitto and Sorsa 2001).

While our reported early winter concentrations of 6-HCH, as well as the 1.4% reported by Reichardt et al. (1990), may have toxic consequences for browsing hares, the mid-winter amounts found in late January probably have fallen below a toxic threshold. By late January 1997, for instance, the concentration of 6-HCH in mature internodes is projected to be less that 0.01%. Thus, if 6-HCH is to remain an effective antibrowsing defense over the entire winter it must be part of a Conditioned Flavor Aversion (CFA; *vide infra*). CFA involving volatiles such as 6-HCH have been documented in other woody plant–mammals interactions (e.g., Provenza 1996; Lawler et al. 1999; Provenza et al. 2000; Moore et al. 2004, 2005). It is conceivable that even at near zero concentrations free 6-HCH could warn hares of the possibility of phenolic glycoside poisoning following internode consumption. However, such a volatile-containing CFA defense is unlikely as the winter progresses far beyond January. Near Fairbanks, Alaska there are about 80 days of winter after January, and over these 80 days, the 6-HCH concentration will continue to decline towards the zero level found in summer growth. In addition, we would expect hare use of twigs to increase as free 6-HCH concentrations decline if the consequence (toxicity) is linked closely with the volatile cue (free 6-HCH).

Toxic compounds like 6-HCH or salicortin with a generalized defensive function have the potential to deter herbivory through the ability of mammalian herbivores to integrate food cues (e.g., taste, odor, texture) with the food's postingestive consequences (e.g., secondary compounds) (Provenza 1995, 1996). This cue-postingestive feedback interplay enables herbivores to regulate intake of foods that contain secondary compounds in amounts that do not cause toxicity. Strong food aversions occur when a physiochemical agent causes nausea after a food (secondary compound) has been consumed in excess (Provenza et al. 1990). CFA, thus, results from the stimulation of the emetic system of the midbrain and brain stem (Mitchelson 1992). After ingesting a food containing a toxin, afferent impulses to the central nervous system (CNS) cause nausea, which in turn causes the animal to decrease intake of food as a function of the dose of the toxin ingested (du Toit et al. 1991). Consistent with this mechanism, antiemetic drugs, which decrease the stimulation of the emetic system, attenuate food aversions in mammals (Provenza et al. 1994; Lawler et al. 1998). Animals respond strongly to taste in CFA, as afferents for taste converge directly with afferents from throughout viscera in the brain stem (Provenza 1995), but they also respond strongly to other food cues such as odor. Indeed, taste potentiates odor during food ingestion, and it is the tremendous plasticity in the sense of olfaction and its linkages in the brain with the amygdala and the hippocampus that enables animals to learn and remember quite subtle discriminations among vastly diverse food flavors (Provenza 1995, 1996).

Herbivores associate novel odors with aversive post-ingestive consequences from a toxin associated with odor inhalation (Provenza et al. 2000). Thus, odors are important cues in conditioned food aversions, though the odor need not be the cause of the aversion, merely a signal consistently associated with the toxicant in the plant (Lawler et al. 1999; Provenza et al. 2000). For instance, marsupials develop CFA to high concentrations of volatile terpenes because their flavor (cue) is consistently associated with the negative postingestive consequences of ingesting formylated phlor-oglucinol compounds, which are toxic (Lawler et al. 1998, 1999). Thus, 6-HCH may act as a cue and as a trigger for stimulating the emetic system (and conditioning an aversion) when concentrations in the plant are high. 6-HCH also may serve as a cue that causes avoidance, if the aversion is strong enough, even when concentrations in the plant decline over time, as herbivores generalize aversions based on familiar flavor cues (Launchbaugh and Provenza 1993).

The results of Reichardt et al. (1990), which show 6-HCH plays a dominant role in hare utilization of mature balsam popular internodes, and our study that demands 6-HCH play a diminishing role as winter progresses until it fades away completely by early to late spring, are in stark contrast. It is apparent that the role of "free" 6-HCH in the internodes is dynamic and must evolve from being a co-toxin (along with salicortin) early in the dormant season, to perhaps becoming a warning signal for other toxins, to eventually having no consequence as summer approaches.

The evidence is persuasive that snowshoe hares regulate use of mature balsam poplar through a feedback mechanism that prevents toxicity, and that salicortin (along with perhaps trichocarpin) is the primary toxin. Depending on the temperature (Pease et al. 1979), the mass of fresh browse required for hare survival in winter is between 300–400 g/hare/day (Bookhout 1965). Yet, when captive snowshoe hares are fed only internodes of mature poplar growing near Fairbanks, they limit intake of internode biomass to about 100–150 g fresh mass (Bookhout 1965), which is well below their need for survival. Tannins can be ruled out as the cause for lower intake, as they are absent in balsam poplar twigs (Reichardt et al. 1990). Similarly, 6-HCH can be ruled out in the late winter as our study shows its concentrations approach zero. The secondary metabolites of buds, while complex and in abundant amounts, are absent in the internodes (Clausen et al. 1992), which hares selectively consume (see Online video clip). The only other secondary metabolites present in

significant quantities in mature balsam poplar internodes are salicortin and trichocarpin (Reichardt et al. 1990; Clausen et al. 1992). As stated, salicortin is a labile compound that is rapidly converted to toxic 6-HCH through tissue maceration and conditions typically found in the gut (Mattes et al. 1987). In addition, numerous studies show experimentally that salicortin and its benzoyl derivative, tremulacin, have toxic consequences to invertebrate herbivores (Lindroth et al. 1988; Kelly and Curry 1991; Julkunen-Tiitto et al. 1994; Ayres et al. 1997). Finally, hares (Tahvanainen et al. 1985) and moose (Stolter et al. 2009) prefer willows with low concentrations of phenol glycosides.

There is circumstantial evidence that 6-HCH can be associated with a conditioned flavor aversion for hares browsing poplar. The secondary chemistries of many willow species are similar to that of balsam poplar (salicortin is a common major phenol glycoside), and hares appear to use olfaction to select food low in phenolic glycosides (Tahvanainen et al. 1985). Other evidence comes from a study by Schmitz et al. (1992) wherein a nearly two-fold increased consumption of balsam poplar by free-ranging hares was accomplished by drying fresh-clipped twigs at 30°C for 48 hr, thus reducing twig water content by 33% and decreasing the wet-mass ratio from 1.72 to 1.40±0.06. Drying browse sufficient to reduce twig water content would also greatly reduce the concentrations of a low molecular weight volatile such as 6-HCH, which would contribute to the increase in intake of poplar twigs by hares observed in their study.

Based on our findings, we propose that following a hard frost, 6-HCH reaches high concentrations (>1% dry weight) that form part of a toxic basis for herbivore selection of browse. However, as the winter-dormant season progresses, the concentration of 6-HCH drops below a toxic threshold (where it acts as a warning signal) and eventually approaches the zero concentration found during the growing season (that has negligible effect on hare browsing). If and how the changing concentration and shifting role of 6-HCH affects the consumption of mature balsam poplar internodes by snowshoe hares goes beyond the goals and experimental design of this study. In light of our results and discussion, there is a need for future studies to establish if hare usage of balsam poplar significantly changes over the dormant season and to establish the roles of 6-HCH as a CFA factor and that of balsam poplar's major phenolic glycosides (salicortin and trichocarpin).

Plant Volatiles Influence Electrophysiological and Behavioral Responses of *Lygus hesperus*

Livy Williams III · Jacquelyn L. Blackmer · Cesar Rodriguez-Saona · Su Zhu

Received: 25 November 2009 / Revised: 19 February 2010 / Accepted: 14 March 2010 / Published online: 20 April 2010
© US Government 2010

Abstract Previous laboratory studies have shown that the mirid *Lygus hesperus* is attracted to volatiles emitted from alfalfa; feeding damage increases the amounts of several of these volatiles, and visual cues can enhance attraction further. The present study tested single plant volatiles in electrophysiological and behavioral trials with *L. hesperus*. Electroantennogram (EAG) analyses indicated that antennae responded to most plant volatiles included in the test, and that when gender differences were observed, males usually were more responsive than females. Antennal responses to the alcohols (*(E)*-3-hexenol*, (Z)*-3-hexenol, 1-hexanol), the acetate *(E)*-2-hexenyl acetate, and the aldehyde *(E)*-2-hexenal were among the strongest. Moderate responses were observed for *(E)*-β-ocimene, *(E,E)*-α-farnesene, (±)-linalool, and methyl salicylate. A dose dependent response was not observed for several terpenes (β-myrcene, β-caryophyllene, (+)-limonene, or both (*R*)-(+)- and (*S*)-(−)-α-pinenes). EAG responses, however, were not always consistent with behavioral assays. In Y-tube bioassays, males did not exhibit a positive behavioral response to any of the compounds tested. Instead, males were repelled by (*E*)-2-hexenyl acetate, (±)-linalool, *(E,E)*-α-farnesene, and methyl salicylate. In contrast, female *L. hesperus* moved upwind towards *(R)*-(+)-α-pinene, *(E)*-β-ocimene, and *(E,E)*-α-farnesene, and showed a negative response towards (*Z*)-3-hexen-1-ol, *(S)*-(−)-α-pinene, and methyl salicylate. This study emphasizes the use of multiple approaches to better understand host plant finding in the generalist herbivore *L. hesperus*.

Introduction

Plant chemistry plays an important role in the mediation of arthropod behavior (Bernays and Chapman 1994). In particular, plant odors help guide insects to food sources (Byers et al. 1985; Blight et al. 1995; Stensmyr et al. 2001; Dobson 2006), oviposition sites (Showler 2001; Broad et al. 2008), and often that work in concert with insect-derived odors to facilitate mate finding (Dickens 1989; Landolt and Phillips 1997; van Tol et al. 2004; Frati et al. 2009). Furthermore, herbivory usually alters the blend of volatiles emitted by plants (Dicke and van Loon 2003; Tumlinson and Engelberth 2008), thereby providing additional information to insects about the potential suitability of the plant for colonization (De Moraes et al. 2001; Meiners et al.

2005; Choh et al. 2008). The central role of plant volatiles in insect life history has been exploited to manipulate the behavior of economically important species in monitoring and management programs (Smart et al. 1996; Piñero and Prokopy 2003; De Camelo et al. 2007; Martel et al. 2007). Several monophagous and oligophagous species have shown behavioral responses to single plant compounds (Leskey et al. 2001; Coracini et al. 2004; Meagher and Landolt 2008), suggesting that this approach deserves consideration when biologically-based pest control strategies are being developed.

Lygus hesperus Knight (Heteroptera: Miridae) is an important pest of cotton and other crops in western North America (Leigh et al. 1988; Wheeler 2001), and improved understanding of *Lygus*—plant interactions might lead to sustainable crop protection strategies. Studies have demonstrated that *L. hesperus* perceives and responds to plant odors, and that composition of plant odor is altered after damage by this insect. Rodriguez-Saona et al. (2002) showed that feeding and oviposition by *L. hesperus* females induced emission of significant amounts of volatiles from cotton, and the level of emission was positively associated with the number of eggs laid on a plant. Damage to alfalfa by *L. hesperus* increased emissions of several compounds found in the headspace of undamaged plants, and led to production and emission of additional compounds not emitted by undamaged plants (Blackmer et al. 2004). Fifth instar and adult female *L. hesperus* were attracted to volatiles emitted from undamaged alfalfa and from alfalfa infested by onspecifics (Blackmer et al. 2004) This response was enhanced by the presence of a green light-emitting diode (Blackmer and Cañas 2005). Williams et al. (2005) reported that feeding by virgin females of *L. hesperus* induced 2.6-fold higher emission of cotton volatiles than feeding by mated females, and treatment of maize plants with *L. hesperus* salivary gland extracts and artificial mechanical injury resulted in 2.7-fold higher emission of volatiles than artificial mechanical injury alone.

The neurological basis for reception of odors by heteropterans is not well understood, in part because these insects are difficult subjects for electrophysiological studies relative to other groups, such as Lepidoptera (but see Chinta et al. 1994; Groot et al. 1999). The goal of the present study was to evaluate the response of *L. hesperus* adults to individual plant odors by using electrophysiological (electroantennogram, EAG) and behavioral studies in the laboratory. Our specific questions were: 1) Do antennae of female and male *L. hesperus* respond differentially to plant volatiles?, 2) Does *L. hesperus* respond to individual plant volatiles in a behavioral assay?, and 3) Does the insect's electrophysiological response reflect its behavioral response to plant volatiles?

Methods and Materials

Insect Rearing and Maintenance Lygus hesperus nymphs and adults were collected from alfalfa fields located at The University of Arizona-Maricopa Agricultural Center, Maricopa, AZ, USA. To maintain genetic diversity, feral individuals were added to the colony 3–4 times per year. Green beans, carrots, pink bollworm eggs (*Pectinophora gossypiella* [Saunders]) and 10% sucrose solution were provided as food to adults and nymphs. Artificial diet packets, as described by Debolt (1982), were included as part of the feeding regime. Green beans and agar-filled parafilm packets served as oviposition substrates. Diet and oviposition substrates were replaced every other day, and oviposition substrates were placed in paper cartons (8.5× 12.5 cm) where the center of each lid was replaced with nylon organdy to allow air circulation. Newly emerged first instars were transferred to fresh paper cartons and provided with the diet mix indicated above. Containers were maintained in an incubator until adults began to emerge, at which time they were placed in mesh-covered plastic rearing containers (28 cm^3) and held at 26±1°C, 30±10% RH, and 14:10h L:D photoperiod until behavioral bioassays were conducted (7–17-d-old adults). Insects to be used in electroantennography trials were shipped to the laboratory (USDA-ARS Southern Insect Management Research Unit, Stoneville, MS, USA) in paper cartons with green beans. These bugs were transferred to Plexiglass cages (26×26× 20-cm) and held with green beans at 25±1°C, 60–85% RH, and 14:10h L:D photoperiod until experimentation (10–14-d-old adults).

Electroantennography Test Chemicals Fifteen compounds included in this study (Table 1) were tested individually as olfactory stimuli. Plant volatiles comprising green leaf volatiles, monoterpenes, and other groups were chosen based on previous studies that demonstrate their emission from undamaged and insect-infested plants (Takabayashi et al. 1994; Loughrin et al. 1995; Röse et al. 1996; Paré and Tumlinson 1998; Rodriguez-Saona et al. 2002; Blackmer et al. 2004; Williams et al. 2005). For the EAG study, serial dilutions (0.1, 1.0, 10, and 100 μM) of each compound were made with paraffin oil (E. Merck, Darmstadt, Germany). Stimulus applicators were prepared by pipetting 25 μl of a test solution onto a 6 cm by 0.5 cm strip of Whatman no. 1 filter paper (Whatman International Ltd., Maidstone, Kent, UK), after which the filter paper was placed inside a 14.5-cm long glass Pasteur pipette. Fresh stimulus applicators were prepared after 2 h of use. Three controls were used: 1) an empty pipette, 2) a pipette containing 25 μl paraffin oil only on filter paper, and 3) a pipette containing 25 μl 100 μM octanal in paraffin oil on filter paper (octanal standard).

Electroantennography: Dose Dependent Response The electroantennography apparatus (Syntech Ltd., Hilversum, The Netherlands) was linked to a desktop computer (with IDAC-02 data acquisition interface board) on which recording, storing, and quantifying EAG responses were performed. The recording and indifferent electrodes were silver wires enclosed in drawn glass capillary tubes filled with phosphate buffered saline (NaCl, 4 g; Na_2HPO_4, 0.57 g; KH_2PO_4, 0.1 g; KCl, 0.1 g in 500 ml distilled water; pH 7.4). Antennal preparations were made by cutting off the head with a scalpel and mounting it on the indifferent electrode. Care was taken not to damage the antennae or mouthparts. Both antennae remained intact, and the recording electrode was placed on the tip of one randomly chosen antenna. The antennal preparation was bathed continuously by a stream of charcoal-filtered and humidified air at a flow rate of 1 l/min. Air temperature and relative humidity was measured ca. 15 cm from the antennal preparation (overall ranges for all trials: 18.4–25.6°C, 15–56% RH).

EAG recording began 6 min after the antennal preparation was set up. At this time, the following test protocol was used for each recording trial. The controls were tested in the following order (1, 2, 3, 2), after which six randomly chosen chemical treatments were tested. For each chemical, order of delivery of the four doses was random. Delivery of controls (2, 3, 2) was made after each four-dose-series of a chemical treatment. The same chemical was tested at the beginning and end of each recording trial, allowing correction for decrease of antennal response over the course of the trial. After the final chemical treatment for each recording, controls were presented in the following order (2, 3, 2, 1). Presentation of controls throughout the recording session permitted standardization of antennal responses, and correction for antennal fatigue. Test compounds and controls were applied (0.5 sec pulse) at 30 sec intervals separated by a purge of filtered and humidified air via an aluminum tube ca. 5 mm from the antenna. EAGs were measured as maximum amplitude of depolarization

(mV). Each chemical was tested on ≥20 individuals of each gender.

Olfactometry Bioassays were conducted in a, glass Y-tube olfactometer (40 mm diam by 36-cm long) that had a 50° inside angle (Blackmer et al. 2004). Incoming air was filtered through activated charcoal and humidified with doubly distilled, deionized water. The filtered air was split between two 2-l holding chambers; one chamber served as a control (clean air) and the other held the test material. From each holding chamber, air passed into the respective arms of the Y-tube, and then through a fine-meshed nylon organdy screen before entering the main tube of the olfactometer. Airflow through the system was maintained at 4.0 l/min (=3.2 m/min inside the tube) by an inline flowmeter (Gilmont Instr., Barnant Co., Barrington, IL, USA). A smoke test demonstrated laminar airflow throughout the olfactometer. Modifications of the Y-tube setup allowed us to examine the insect's response to both synthetic volatile compounds and a plant visual cue. A light emitting diode (Green LED, NSPG520S, Nichia America Corp., Mountville, PA, USA) was used to simulate a visual plant cue. The light emitted a narrow wavelength in the range of 565±10 nm, and power was supplied by a universal adapter that provided 6 V DC. An LED was inserted behind the organdy screen at the far upwind end of one arm of the Y-tube setup and was flush with the side wall of the tube to eliminate turbulence in the air flow. A 60-cm long, wide-spectrum fluorescent lamp (GE, F20T12-PL/AQ) was positioned 22 cm above the arms of the Y-tube. Before each trial, light intensity over each arm was measured with a light meter (ExTech Instr. Model 401025, Zefon International, St. Petersburg, FL, USA), and the tube was adjusted until intensity was the same in both arms. Light intensity averaged 686.5±3.5 (mean ± S.E.) lux. The Y-tube setup was surrounded by a 50×70×60-cm wooden enclosure painted flat black, and the holding chambers containing the treatments were placed outside the enclosure.

Bioassays A 'trial' refers to all of the behavioral assays conducted each day. Approximately 30–60 min before a trial was initiated, 7 to 17-d-old adult *L. hesperus* were placed into individual tubes as described previously (Blackmer et al. 2004; Blackmer and Cañas 2005). In each day's trials, 20–30 insects were bioassayed. One adult was placed inside the tube, and the end where the bulb tip had been removed was sealed with a cork. Tubes containing bugs were then placed into a separate holding container, so they would not be exposed to test odors before their release. Male and female bugs were included in each trial. For each individual, a clean Y-tube was used. Previous experiments (Blackmer et al. 2004) showed that the responses of experienced and 'naïve' (insects reared in the same manner as the present study) *L. hesperus* to plant volatiles were similar, thus only naïve individuals were used in the present study. Also, Blackmer and Cañas (2005) demonstrated previously that visual and volatile cues in combination resulted in the strongest upwind response by *L. hesperus*. Therefore, in the present study, all synthetic compounds were tested in combination with the LED. At the beginning of each individual assay, the cork was removed from the release tube, and the open end was placed at the downwind end of the Y-tube. Each insect was given 5 min to respond to the treatment, and a choice for the left or right arm of the olfactometer was recorded when the insect walked 1 cm beyond the Y-junction. The following measurements were recorded for all individuals: time required for bug to exit the release tube, percentage exiting release tube, response time to first choice, percentage walking upwind and selecting an arm of the Y-tube, and percentage that went 'all the way' (ATW) to the end of the Y-tube (i.e., exhibited a complete response). Temperature and RH in the olfactometer were maintained at 25.6±0.1°C and 29.9±0.9%, respectively.

Assays were continued until a minimum of 40 individuals made a choice between arms. This sometimes required the testing of more than 100 individuals for each chemical treatment. Bioassays were conducted between 10.00–18.00 h, and the same treatment usually was run on consecutive days until it was completed. Y-tube trials were setup with treatments of a synthetic plant volatile in combination with the green LED cue vs. a humidified blank air control without an LED cue. Additional trials were setup with a humidified blank air control with the green LED vs. a humidified blank air control without an LED cue. Trials that used the LED in the absence of synthetic volatile compounds were included to facilitate comparison of the response to the visual cue only vs. visual plus volatile cues. Sixteen volatiles were tested, which included the following undiluted synthetic compounds: six green leaf volatiles (GLVs), seven monoterpenes, two sesquiterpenes, and methyl salicylate (Table 1). The volume (6 μl) used was selected based on preliminary observations of the insect's upwind response to the test compounds. Higher volumes were used for (+)-limonene, (*E*)-β-ocimene, and (±)-linalool to mimic the pattern of emissions from *Lygus*-induced cotton (Rodriguez-Saona et al. 2002) and alfalfa (Blackmer et al. 2004) (compare Table 1).

Relationship Between Volatile Emission Rates and Lygus Response Although the same amounts were used for most volatiles in our experiments, their emission rates may vary depending on volatility. Thus, a study was conducted to determine the release rates of individual compounds used in olfactometer and EAG assays. For this, a known amount of each volatile compound was applied to a filter paper strip following the methods described above. Filter papers were

placed under a hood for 5 min. Each filter paper then was placed separately inside a 20 ml (internal volume) glass vial for volatile collections. The lid of the vial had two openings, one of these fitted an adsorbent trap containing 30 mg of Super-Q (Analytical Research Systems, Inc., Gainesville, FL, USA), while the other fitted a Pasteur pipette containing ca. 1 g of activated charcoal (Alltech, Deerfield, IL, USA) to clean the incoming air. Volatiles from inside the vials were collected in traps at a constant rate of 2 ml/min, measured with the aid of a flow meter (Watchman II, Kontes Glass Co., Vineland, NJ, USA) connected to a 12 V vacuum pump (Sensidyne, Clearwater, FL, USA). Volatiles were sampled for 5 min under standard laboratory conditions. For each synthetic volatile, the emission rate was recorded from 3 independent replicates. Because the emission rates were measured in closed, small glass vials (20 ml), they may not necessarily reflect the emission rates encountered by insects in the main tube of the olfactometer. The same may be true for EAG assays.

The volatiles trapped in Super-Q adsorbent were eluted using 150 µl dichloromethane, and 400 ng of *n*-octane were added as an internal standard. One µl of each sample was injected onto a Hewlett Packard 6890 gas chromatograph equipped with an HP-1 column (10 m×0.53 mm×2.65 µm; Agilent Technologies, Palo Alto, CA, USA), using a splitless mode with helium as the carrier gas, and a temperature program of 40°C for 1 min, increased gradually at 14°C/min to 180°C (held for 2 min), then at 40°C/min to 200°C (for 2 min), and finally to 220°C (for 5 min). The amount of each volatile compound was calculated in relation to the area of the internal standard.

Data Analyses Maximum EAG responses were control-adjusted with the paraffin oil only control, and expressed as proportional responses relative to the octanal standard. These data then were square root-transformed ($0.5(\sqrt{x} + \sqrt{x+1})$) (Zar 1996), and analysis of variance, PROC MIXED (SAS Institute 2003), was used to compare maximum EAG deflection between gender and plant volatile concentrations. Regression analysis was also used to assess the influence of gender and plant volatile treatment on EAG amplitude (PROC REG and PROC MIXED) (SAS Institute 2003). Due to heteroscedasticity over concentrations, a weighted regression (reciprocal of the variance) was calculated.

For behavioral trials, the null hypothesis that *L. hesperus* showed no preference for either olfactometer arm (a response of 50:50) was analyzed with a Chi-square goodness of fit test after correcting for continuity with Yates' correction factor (Zar 1996). Occasionally, an insect would move back and forth between arms of the Y-tube and when this happened the final choice was considered to be the arm the insect spent the most time in. When the insect went all the way (ATW) to the end of the tube, this was considered to be the final choice and was recorded as 'complete response'. Time required for male and female bugs to exit the release tube, percentage of bugs exiting the release tube, percentage walking upwind into an arm, response time to first choice, and percentage walking upwind to the end of an arm (ATW) for controls vs. treatments were compared by two-way ANOVAs (SigmaStat Software version 3.5). For each gender, time spent in each arm of the arena, number of individuals walking upwind into an arm, and ATW responses between volatile treatments+LED and control+LED were compared by Pearson's goodness of fit Chi-square test for independent samples. Percent data were transformed by the arcsine function, and exit time and time to first choice data by the logarithmic function when needed to meet the requirements of normality and homogeneity of variance before analyses. Means and standard errors were calculated for volatile release data.

A Pearson correlation analysis was conducted to determine if the effects of plant volatiles on *L. hesperus* EAG and behavioral responses were due to the amount of chemical used. First, we correlated emission rates with EAG responses for the highest concentration tested (100 µM) for all compounds. Another analysis was conducted to correlate emission rates with the percent response to each compound in behavioral assays (percentage walking upwind into an arm). Analyses were performed for males and females separately.

Voucher specimens of *L. hesperus* are deposited in the National Entomological Collection, National Museum of Natural History, Smithsonian Institution, Washington, D.C.

Results

Electroantennography Dose-Dependent Responses Average EAG responses by males were greater than by females (F=4.86; df=1, 54.3; P=0.032) (Fig. 1). This difference in EAG response was observed for 1-hexanol at 1 µM (F=2.48; df=1, 1344; P=0.013), for *(Z)*-3-hexenol and *(E)*-3-hexenol at 100 µM (F=3.36 and 3.18, respectively; df=1, 1316 and 1329, respectively; P<0.001 and P=0.002, respectively), for *(Z)*-3-hexenyl acetate at 10 µM (F=2.96; df=1, 1362; P=0.003), and for *(E)*-2-hexenyl acetate at 10 and 100 µM (F=3.89 and 5.55, respectively; df=1, 1315; P<0.001). In contrast, EAG response by females was greater than by males for methyl salicylate at 100 µM (F=2.63; df=1, 1295; P<0.009) (Fig. 1).

Regression analysis of the impact of gender and host plant volatiles on antennal response indicated a linear response between antennal sensitivity (y) and plant volatile concentration (log10×) (Table 2). Contrasts of slopes between the

◀ **Fig. 1** EAG dose response curves of *Lygus hesperus* to 15 synthetic plant volatiles. EAG amplitudes (mean ± SE) are control-adjusted and presented as relative responses to the standard, 100 µM octanal. Each compound was tested on ≥20 individuals of each gender; concentrations (0.1, 1.0, 10, and 100 µM) of each compound in paraffin oil. Significant differences between genders are noted by asterisks (*P= 0.05−0.01, **P=0.01−0.001, ***P<0.001). P values correspond to ANOVA

genders revealed greater (P<0.05) slopes for males for 3 of the 15 plant volatiles (Table 2). Ranked in order of P values (most to least significant), the three significant compounds were: *(E)*-3-hexenol < *(E)*-2-hexenyl acetate < *(Z)*-3-hexenol (Table 2). For methyl salicylate, the slope for females was marginally greater than for males (P=0.056) (Table 2).

Olfactometer Bioassays Females remained longer in their release tube than did males (F=13.31; df=1, 31; P<0.001; 37.1±2.1 vs. 24.8±1.8 sec), but the percentage of females and males exiting the release tubes was not significantly different (F=3.32; df=1, 31; P=0.080; 88.3±1.5 vs. 93.0± 1.6%). Of the individuals that exited the release tube, significantly more males than females progressed upwind to the Y-junction (F=9.11; df=1, 31; P=0.005; 83.6±1.7 vs. 76.0±1.7%), and males were faster than females in making a choice between arms (F=17.15; df=1, 31; P<0.001; 76.6± 3.4 vs. 104.0±3.3 sec). A similar percentage of females and males walked ATW to the end of the Y-tube, regardless of treatment (F=2.33; df=1, 25; P=0.113; 23.7±1.9 vs. 19.8± 1.2% for treatment and F=1.92; df=1, 27; P=0.218; 28.5± 1.4 vs. 18.8±1.0% for control, respectively). There was no difference in ATW response between treatment+LED vs. control+LED (t=1.12; df=1, 62; P=0.268; 21.8±1.2 vs. 23.6±1.2%).

In terms of response to the treatments vs. controls, females exhibited significant (P<0.05) movement upwind into the volatile+LED arm when *R)*-(+)-α-pinene, *(E)*-β-ocimene, or *(E,E)*-α-farnesene was tested (Fig. 2a). Females exhibited significant (P<0.05) movement upwind into the control +LED arm when *(Z)*-3-hexenol, *(S)*-(−)-α-pinene, or methyl salicylate was offered in the volatile+LED arm (Fig. 2a). Significant ATW response by females was observed to control+LED when 1-hexanol and β-myrcene was tested (Fig. 2a). Males exhibited significant movement upwind into control+LED arm when offering *(E)*-2-hexenyl acetate, (±)-linalool, *(E,E)*-α-farnesene, or methyl salicylate in the volatile+LED arm (Fig. 2b). Significant ATW response by males was observed to control+LED when methyl salicylate was used in the volatile+LED arm (Fig. 2b).

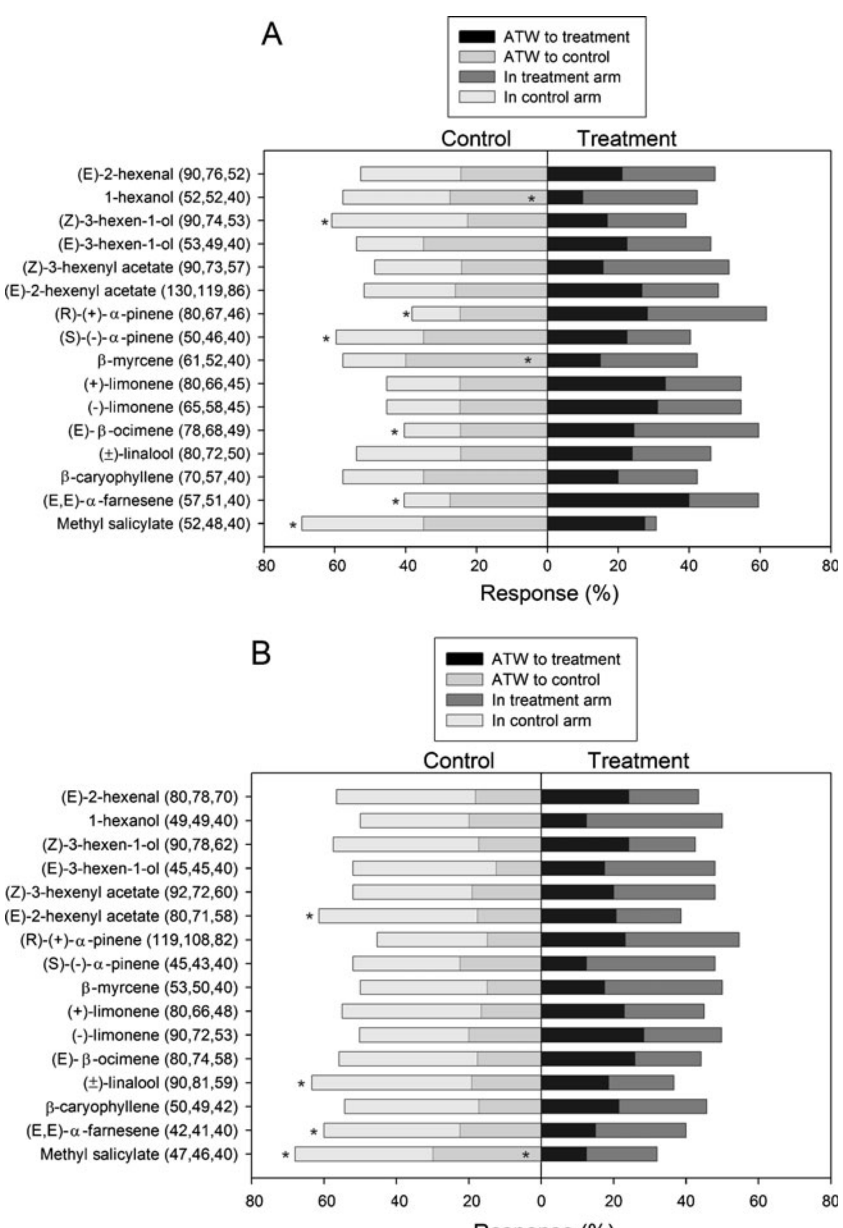

Fig. 2 Behavioral response by female (**a**) and male (**b**) *Lygus hesperus* adults to synthetic plant volatiles + green light-emitting diode (LED) and blank air control + green LED. Asterisk *inside* a column denotes significant difference ($P<0.05$) in locomotion ATW ('all the way') to the end of a Y-tube arm; asterisk *outside* a column denotes significant difference ($P<0.05$) in individuals walking upwind into a Y-tube arm (Pearson's goodness of fit *Chi-square* test for independent samples). Numbers in parentheses indicate total number of insects released, number of insects that exited release tube, and number of insects that moved upwind, respectively

Relationship Between Volatile Emission Rates and Lygus Response Emission rates of plant volatiles in EAG experiments varied from 1.5 ng/min for β-caryophyllene to 41.3 ng/min for (*R*)-(+)-α-pinene (Table 1). Female EAG responses were negatively correlated with emission rates (Pearson correlation = −0.545; P=0.036), indicating that *Lygus* female antennae exhibited stronger responses to highly volatile compounds (e.g., GLVs and monoterpenes). Although the trend was the same for males, the correlation between emission rates and EAG responses in male *L. hesperus* was not significant (Pearson correlation=−0.3; P= 0.278). Emission rates for the behavioral study were several orders of magnitude higher than for the EAG study and varied from 0.4 μg/min for (*E*,*E*)-α-farnesene to 556.3 μg/min for (+)-limonene (Table 1). There was, however, no correlation between emission rates and behavioral responses (percentage walking upwind into an arm) for males (Pearson correlation = 0.054; P=0.849) or

females (Pearson correlation = 0.25; *P*=0.368), indicating that the response of *L. hesperus* to a volatile in our Y-tube experiments was independent of the volatile's emission rate.

Discussion

This study is the first to document the EAG and behavioral responses of *L. hesperus* to host plant volatiles. EAG analyses clearly revealed that *L. hesperus* perceived the compounds tested. Although male antennae were generally more responsive than female antennae, both genders responded to most plant volatiles. For green leaf volatiles, alcohols generally elicited stronger responses by both genders than did the aldehyde or acetates. A strong response to plant alcohols also was reported for *L. lineolaris* by Chinta et al. (1994), although differences between genders were only observed for *(E)*-2-hexenal, where female responses were greater. In the present study, *L. hesperus* showed no gender effect to *(E)*-2-hexenal, but male response was greater than female for *(E)*-3-hexenol, *(Z)*-3-hexenol, and *(E)*-2-hexenyl acetate. However, *L. lineolaris* showed no gender differences in response to *(E)*-2-hexenyl acetate (Chinta et al. 1994). Another mirid, *Lygocoris pabulinus* (L.), also showed no gender differences for *(E)*-2-hexenyl acetate or *(Z)*-3-hexenyl acetate, but female antennae showed greater EAG response to 1-hexanol than did male antennae (Groot et al. 1999).

Previous studies with other mirids have shown that their EAG response to most monoterpenes is relatively low compared to other chemical groups, but when gender differences occur, females usually are more responsive than males (Chinta et al. 1994; Groot et al. 1999). Our results with *L. hesperus* are consistent with these studies in that *L. hesperus* showed low EAG responses to all the monoterpenes and sesquiterpenes tested; however, no gender differences were found for any of the terpenes. For example, female *L. pabulinus* and *L. lineolaris* antennae were more sensitive to (±)-linalool than were male antennae (Chinta et al. 1994; Groot et al. 1999), although *L. hesperus* showed no gender effect for this monoterpene. *Lygus hesperus* was least responsive to the monoterpenes β-myrcene, β-caryophyllene, (+)-limonene, and both enantiomers of α-pinene. Gender differences for methyl salicylate were observed for both *L. hesperus* (in the present study) and *L. pabulinus* (Groot et al. 1999); female antennae were more sensitive than male antennae in both cases. EAG responses to *(E)*-β-ocimene, *(E,E)*-α-farnesene, and methyl salicylate were moderate relative to GLVs, and had similar dose—response curves, except for farnesene, which had a somewhat elliptical shape. Both genders of *Lygus rugulipennis* Poppius showed EAG responses to several GLVs (*(Z)*-3-hexenol, 1-hexanol, and *(Z)*-3-hexenyl acetate) emitted by healthy plants, and to methyl salicylate and β-caryophyllene emitted by *Lygus*-damaged plants (Frati et al. 2009).

In Y-tube behavioral assays of ATW movement and number of bugs in the treatment arm, 13 of the 64 comparisons (of behavioral response, gender, and volatile combinations) were significant. When considering these 13 comparisons, the bugs showed movement toward the treatment only in three of them. These were for female bugs tested with *(R)*-(+)-α-pinene, *(E)*-β-ocimene, and *(E,E)*-α-farnesene for number of individuals in the treatment arm. The results are consistent with our previous studies that show that female *L. hesperus* are attracted to plant odors (Blackmer et al. 2004; Blackmer and Cañas 2005). Blackmer et al. (2004) showed that female *L. hesperus* are attracted strongly to flowering alfalfa with feeding damage and vegetative alfalfa with conspecifics. They also found that vegetative alfalfa damaged by conspecifics (nymphs and adults) emits large quantities of *(E)*-β-ocimene and *(E,E)*-α-farnesene, while flowering alfalfa damaged by adults emits large quantities of *(E)*-β-ocimene. Thus, ours and previous findings indicate that *(E)*-β-ocimene and *(E,E)*-α-farnesene may play key roles in the attraction of female *L. hesperus* to host plants. The role of *(R)*-(+)-α-pinene is less clear because this compound was emitted in low quantities both constitutively and after *Lygus* feeding damage in alfalfa (Blackmer et al. 2004). In the 10 remaining significant comparisons, more bugs were found in the control arm, thus suggesting repellency. Males either did not respond to plant volatiles or were repelled by them, e.g., by (*E*)-2-hexenyl acetate, (±)-linalool, *(E,E)*-α-farnesene, and methyl salicylate. This also is consistent with previous studies that show that males *L. hesperus* are repelled by volatiles from vegetative and flowering alfalfa (Blackmer et al. 2004). Our results unlikely are due simply to the amount of compound used in the behavioral experiments but instead to the way the insect perceives each volatile because emission rates were not correlated with the insect's response. Likewise, *L. rugulipennis* females generally were more responsive than males to host plant and conspecific odors in a wind tunnel and vertical open Y-track olfactometer (Frati et al. 2008). Although we refer to the bugs used in this study as 'naïve', they were, in fact, reared on hosts (green beans and carrots) that might have produced volatiles to which the bugs became conditioned prior to the olfactometer trials. Although Blackmer et al. (2004) demonstrated no difference in *L. hesperus* behavior between experienced and 'naïve' bugs, it is not known if *L. hesperus* held without food prior to the trials would have behaved differently from bugs used in the present study. However, because *L. hesperus* usually is found on host plants where it can feed, it is likely that behavioral

responses exhibited by the bugs in our study are representative of those exhibited under field conditions.

Results of the behavioral study did not always reflect the results of the EAG measurements. For example, EAG response to (*S*)-(−)-α-pinene was weak for both genders, but a strong behavioral response to this monoterpene was observed for both male and female bugs. Conversely, both genders responded strongly to 1-hexanol in EAG trials, but neither gender exhibited a behavioral response to this chemical. Finally, male antennae responded more strongly to *(E)*-2-hexenyl acetate than did female antennae, but females exhibited a behavioral response to this chemical, whereas males did not. In general, although males showed stronger responses than females, both *L. hesperus* genders showed strong EAG responses to the highly volatile GLVs, whereas behavioral responses to plant volatiles varied widely between genders and among different chemical classes, and, thus, was uncorrelated to the volatiles' emission rates. Inconsistencies between electrophysiological and behavioral results are not uncommon (Mayer et al. 1984; Suckling et al. 1996; Wee et al. 2008), and illustrate the importance of using multiple research approaches. Here, we provide three possible explanations for these discrepancies. First, in the present study we tested only single plant compounds. It is likely that more than one plant volatile is needed to elicit a behavioral response in *L. hesperus*. For instance, although male *L. hesperus* has a stronger EAG response than females to the plant alcohols and acetates, its behavioral response towards these compounds may depend on their concentration in the presence of other host plant odors. Second, the present study used only EAG recording to compare with behavioral studies. Electrophysiological studies that use the single-cell technique may show more correspondence with behavioral trials than EAG recordings, which measure the summation of responses by all neurons on the antenna (Anderson et al. 1993; Bjostad 1998). Finally, our current understanding of host plant finding by *Lygus* suggests that several distinct steps, involving long-range and close-range orientation, are involved. Thus, behavioral studies may require a variety of approaches that use different arenas in the lab (e.g., Y-tube olfactometers for walking, and wind tunnels for flight) and field to understand the hierarchical nature of orientation behaviors. Inconsistencies between EAG and behavioral trials notwithstanding, our results draw attention to important points in *Lygus*—plant interactions. Attraction was observed in *L. hesperus* females towards several constitutive and inducible plant volatiles. These chemical cues may help females locate plants that are suitable hosts for feeding, oviposition, and feeding of offspring (Groot et al. 1999; Innocenzi et al. 2004, 2005; Frati et al. 2008). In comparison, repellency was observed commonly in *L. hesperus* males in response to several plant volatiles. Males may use these volatiles to avoid plants that harbor potential competing males (e.g., Pallini et al. 1997), or attract greater numbers of natural enemies (e.g., Turlings et al. 1990; De Moraes et al. 1998).

Recently, there has been increased awareness of the importance of multimodal cues in host-finding by insects. While our results showed that single compounds can be used to attract *L. hesperus* in Y-tubes, both visual and volatile information is important in the orientation behaviors of this insect, and probably need to be incorporated into any trapping system to maximize trap catch. In fact, the addition of a plant visual cue (green LED) in combination with plant volatile cues enhanced the upwind responses of both female and male *L. hesperus* (Blackmer et al. 2004; Blackmer and Cañas 2005). In the future, electrophysiological studies that use single-cell recordings coupled with GC might identify additional compounds detected by *L. hesperus*. Also, further bioassays that use blends of synthetic plant volatiles with experimentally altered ratios and concentrations, and volatile blends emitted by plants and concomitant collection of the volatiles for GC-MS, might give a clearer picture of the relationship between plant volatiles and *L. hesperus* behavior.

Abstract The indirect defense mechanisms of plants comprise the production of herbivore-induced plant volatiles that can attract natural enemies of plant attackers. One of the often emitted compounds after herbivory is methyl salicylate (MeSA). Here, we studied the importance of this caterpillar-induced compound in the attraction of the parasitoid wasp *Diadegma semiclausum* by using a mutant Arabidopsis line. *Pieris rapae* infested *AtBSMT1-KO* mutant Arabidopsis plants, compromised in the biosynthesis of MeSA, were more attractive to parasitoids than infested wild-type plants. This suggests that the presence of MeSA has negative effects on parasitoid host-finding behavior when exposed to wild-type production of herbivore-induced Arabidopsis volatiles. Furthermore, in line with this, we recorded a positive correlation between MeSA dose and repellence of *D. semiclausum* when supplementing the headspace of caterpillar-infested *AtBSMT1-KO* plants with synthetic MeSA.

Introduction

Plants effectively combat herbivorous insects through direct and indirect defenses (Kessler and Baldwin 2002). Direct defense comprises the production and storage of metabolites that negatively influence herbivore performance (Wittstock and Gershenzon 2002). In contrast, indirect defense encompasses the production of metabolites that benefit the natural enemies of herbivores (Dicke et al. 1999; Wäckers et al. 2001; Halitschke et al. 2008; Kost and Heil 2008). Natural enemies such as parasitoids use herbivore-induced plant volatiles (HIPVs) to locate their herbivore host and thereby indirectly aid plants in their combat against herbivorous insects. HIPVs are complex blends of compounds and mainly comprise green leaf volatiles (GLV) (C6 aldehydes, alcohols, and derivatives), terpenoids, and phenolics (Paré and Tumlinson 1997; Dicke 1999b). Green leaf volatiles originate from linolenic and linoleic acid, which are released particularly when cells are damaged (Bate and Rothstein 1998). Terpenoids are synthesized via the mevalonic acid (MVA) or methylerythritol phosphate (MEP) pathway (Dudareva et al. 2006; Gershenzon and Dudareva 2007). Finally, aromatic compounds, such as

methyl salicylate (MeSA) and indole, are formed via the shikimic acid pathway (Paré and Tumlinson 1997). The induced volatile production is orchestrated by at least three main signal-transduction pathways: the jasmonic acid (JA), salicylic acid (SA), and ethylene (ET) pathways (Dicke and Van Poecke 2002; Kessler and Baldwin 2002). These pathways can be induced differentially by different herbivore species (Heidel and Baldwin 2004; De Vos et al. 2005; Schmidt et al. 2005), leading to the emission of a volatile blend that is specific for an herbivore species (Vet and Dicke 1992; Ozawa et al. 2000; Walling 2000; Leitner et al. 2005). These herbivore-specific volatile blends can provide foraging natural enemies of herbivores, such as predators and parasitoid wasps, with detectable and reliable information to locate their prey or host respectively (Dicke et al. 1990; Turlings et al. 1991; Vet and Dicke 1992; Du et al. 1998; Dicke 1999a).

Variation in attraction of carnivorous arthropods towards host or non-host infested plants is ascribed mainly to the presence and relative abundance of attractive compounds within the HIPV blend (D'Alessandro et al. 2009). An intriguing question is which components of the complex HIPV blend affect parasitoid attraction most. This will be different for different parasitoid species. Up to now, several approaches have been applied to study the relative importance of certain HIPVs in the attraction of carnivorous arthropods, e.g., by offering synthetic compounds alone or in mixtures, inducing certain subsets of the HIPV blend with elicitors, or manipulating signal-transduction or biosynthetic pathways through a molecular genetic approach (for review see D'Alessandro and Turlings 2006; Snoeren et al. 2007; Schroeder and Hilker 2008). One HIPV component for which biological relevance for carnivorous arthropod attraction has been addressed is methyl salicylate (MeSA) (De Boer and Dicke 2004; De Boer et al. 2004; James and Price 2004; Zhu and Park 2005; Ishiwari et al. 2007). This methyl ester of the plant hormone salicylic acid (SA) has been reported in the HIPV blends emitted by several plant species, e.g., lima bean (Dicke et al. 1990), tomato (Ament et al. 2004), cabbage (Geervliet 1997; Poelman et al. 2009), and Arabidopsis (Van Poecke et al. 2001; Chen et al. 2003; Snoeren et al. 2009). Its role in the attraction of carnivorous arthropods has been addressed by investigating the response towards synthetic MeSA in field (James and Price 2004; Zhu and Park 2005) and in laboratory studies (Dicke et al. 1990; De Boer and Dicke 2004; De Boer et al. 2004; Ishiwari et al. 2007). However, so far, no studies have addressed the effects of the absence of MeSA from an otherwise complete HIPV blend on the behavior of carnivorous arthropods.

In this study, we focused on the function of MeSA within the HIPV blend through a molecular ecological approach that involves the elimination of MeSA. MeSA is synthesized by SA carboxyl methyltransferase (SAMT), a member of the SABATH methyl transferase family, to which jasmonic acid, indole-acetic acid and cinnamic/*p*-coumaric acid methyltransferases also belong (Seo et al. 2001; Chen et al. 2003; Zubieta et al. 2003; Kapteyn et al. 2007). Related enzymes that methylate benzoic acid (BA) to give MeBA also have been reported (Murfitt et al. 2000). Some SABATH enzymes can methylate both SA and BA with roughly equal efficiencies, and have been designated as Benzoic Acid and Salicylic Acid Methyl Transferases (BSMTs). One such example is the *Arabidopsis thaliana* gene designated *BSMT1* (Chen et al. 2003).

While SAMT or BSMT enzymes have been identified in a number of plant species, including fairy fans (*Clarkia breweri*), snapdragon (*Antirrhinum majus*), petunia (*Petunia hybrida*), Arabidopsis, and jasmine (*Stephanotis floribunda*), we selected Arabidopsis for further work on the physiological significance of MeSA emission because of the availability of molecular genetic tools and because this species is a valuable stepping stone towards other brassicaceous plants for studying the role of HIPVs in plant–insect interactions (Snoeren et al. 2007). We addressed the role of MeSA in the foraging behavior of the parasitoid wasp *Diadegma semiclausum* Hellén (Hymenoptera, Ichneumonidae) that attacks caterpillars feeding on brassicaceous plants including Arabidopsis. Caterpillar feeding is known to induce MeSA in Arabidopsis (Van Poecke et al. 2001; Chen et al. 2003; Snoeren et al. 2009). We used wild-type Arabidopsis plants and a knock-out mutant that does not have a functional BSMT and, thus, no MeSA biosynthesis. We addressed the effects of the mutation on parasitoid- and herbivore behavior, and on headspace composition.

Methods and Materials

Plants and Insect Material An Arabidopsis line with an insertion in the *AtBSMT1* gene was obtained from the Torrey Mesa Institute collection, and the position of the insertion was verified by sequencing (Fig. 1, see also supporting information Fig. S1). Arabidopsis seeds (*A. thaliana* wild-type Columbia (Col-0) and *AtBSMT1-KO* in a Col-0 background) were germinated in sandy Arabidopsis soil (Lentse potgrond BV, Lent, Netherlands), and cultivated in a growth chamber at 21±2°C, 50 to 60% relative humidity (RH), and 8:16 hr, L:D photoperiod with 80 to 110 μmol m^{-2} sec^{-1} PPFD. The soil was heated to 90°C for at least 2 hr prior to sowing of the plants. Two-wk-old seedlings were transferred to plastic containers (5 cm diam) filled with the same soil type. Plants were watered twice a week. To prevent infestation by root-feeding sciarid flies, the soil was treated weekly with the entomopathogenic nematode *Steinernema feltiae* (Koppert Biological Systems,

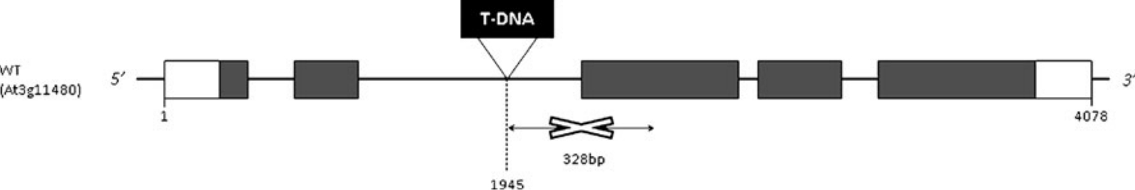

Fig. 1 Illustration of the *AtBSMT* T-DNA mutant (GARLIC_776_B10 Line) from The Torrey Mesa Institute's T-DNA insertion mutant collection. The exons are indicated as grey boxes and nucleotide numbers are given below. The position of the approximately 200-nt T-DNA insertion, as well as a deletion of 328-nt extending downstream from the right border of the T-DNA element and including the end part of intron 2 and the beginning part of exon 3 also are shown. Both insertion and deletion were determined by sequencing. Furthermore, we determined that transcripts from the mutant gene were still produced in the plant, and the processed mRNA had a similar size to that of the wild type (WT) mRNA. However, when the mutant transcript was amplified by RT-PCR and sequenced, it was seen that in the absence of the original 3′ end of intron 2, a new 3′ splice site was used within the remains of exon 3. This led to a protein that is much shorter and does not have SAMT activity (See also Fig. S1)

Berkel en Rodenrijs, the Netherlands). Fully grown vegetative plants were used for the experiments, i.e., at 6–8 wk after sowing.

The small cabbage white butterfly, *Pieris rapae* L. (Lepidoptera, Pieridae), was reared on Brussels sprouts plants (*Brassica oleracea* var. gemmifera, cv Cyrus) in a growth chamber (16:8 hr, L:D; 20±2°C and 70% RH) as described in detail in Fatouros et al. (2005).

The parasitoid wasp *D. semiclausum* was reared on *Plutella xylostella* on Brussels sprouts in a climatized room (16:8 hr, L:D; 20±2°C and 70% RH). Emerging wasps were provided *ad libitum* with water and honey, and are referred to as 'naïve' wasps, as they had received neither exposure to plant material, nor obtained an oviposition experience. This parasitoid is known to be attracted to the volatiles emitted by *P. rapae*-infested Arabidopsis Col-0 plants (Loivamäki et al. 2008).

Plant Treatments Plants were infested by equally distributing 20 first-instar *P. rapae* larvae per plant over the fully expanded leaves. Uninfested plants that otherwise received a treatment similar to the infested plants were used as controls. In all experiments, plants from both genotypes that required an infestation were treated 24 hr before the experiments and kept in a climate room (21±2°C, 50–60% RH; 8:16 hr, L:D photoperiod, and 80–110 μmol m^{-2} sec^{-1} PPFD).

Y-tube Olfactometer Behavioral Assays The effects of HIPVs from wild-type Arabidopsis Col-0 and transgenic *AtBSMT1-KO* plants on parasitoid behavior were tested in a closed-system Y-tube olfactometer as described by Bukovinszky et al. (2005). In short, filtered air was led through activated charcoal and split into two air streams (4 L min^{-1}) that were led through five-liter glass vessels containing the odor sources consisting on each experimental day of 4 plants each with the feeding caterpillars. The olfactometer was illuminated with 4 high-frequency fluorescent tubes (Philips 840, 36 W) from above at an intensity of 60±5 μmol m^{-2} sec^{-1} PPFD. All experiments were conducted in a climatized room (20±2°C).

Naïve, 3–7-d-old female *D. semiclausum* were transferred individually from the cage into the Y-tube olfactometer on a plant leaf; this was done by using alternately a Col-0 or *AtBSMT1-KO* leaf, that had been infested previously by *P. rapae* and from which the caterpillars and their products had been removed carefully. This procedure increases the general behavioral response of the parasitoids to plant cues but does not induce a shift of preference (Kaiser and Carde 1992; Bleeker et al. 2006; Smid 2006). Upon release in the olfactometer, parasitoid behavior and parasitoid choice for one of the two odor sources was observed and scored as described in detail by Bukovinszky et al. (2005). Parasitoids that did not explore one of the two arms of the olfactometer within 5 min or that did not make a final choice within 10 min after release were considered as non-responding individuals, and were excluded from preference analysis. After every 5 parasitoids tested, the odor sources were interchanged to compensate for any unforeseen asymmetry in the set-up.

Experiment 1. Effect of AtBSMT Knock-out on Parasitoid Attraction to Caterpillar-infested Plants To assess the role of MeSA as a cue for parasitoids *in planta*, we compared parasitoid behavior in response to an HIPV blend that lacked MeSA vs. a complete HIPV blend that included MeSA. Caterpillar-infested mutant *AtBSMT1-KO* and wild-type Col-0 plants were offered as odor sources in the olfactometer to *D. semiclausum*.

Experiment 2. Supplementing Headspace of Caterpillar-infested AtBSMT1-KO Plants with Synthetic MeSA To investigate further the role of MeSA, we supplemented the HIPV blend of *AtBSMT1-KO* plants by adding synthetic MeSA (Merck, 99% pure). The supplemented HIPV blend from these *AtBSMT1-KO* plants was tested against the emitted HIPV blend from *AtBSMT1-KO* or Col-0 plants. To determine if parasitoid behavior to MeSA was dose

dependent, different doses of MeSA (0.2 μg, 2 μg, 20 μg, 200 μg) were added downwind to the earlier infested *AtBSMT1-KO* plants. MeSA was diluted in n-hexane (Sigma-Aldrich, 95%). In all experiments, 0.1 ml of the MeSA solution was applied on filter paper (15 cm^2) and positioned in the last section of the olfactometer arm. A piece of filter paper with 0.1 ml hexane was placed at a similar position in the other arm as a control. The solvent was allowed to evaporate for 30 to 60 sec, after which a parasitoid was introduced into the olfactometer. New filter papers with MeSA or hexane were used for each parasitoid tested in the olfactometer.

Caterpillar-feeding Areas of consumed leaf-tissue were assessed for the caterpillar-infested Col-0 and *AtBSMT1-KO* plants that were used in experiment 1. Immediately after finishing an olfactometer bioassay, individual leaves were taped on paper and scanned with a Hewlett-Packard scan jet 3570c. Original leaf shapes were reconstructed by using Paint.NET v3.30, Microsoft Corporation. Quantification of consumed leaf-tissue area was performed using Winfolia pro 2006a, Regent instruments (Québec, Canada).

Headspace Collection And Volatile Analysis Dynamic headspace sampling was carried out in a climate room (20±2°C, 70% RH; 8:16 hr, L:D photoperiod and 90 to 110 μmol photons m^{-2} sec^{-1} PPFD). Twenty-four h before sampling, the pots were removed, roots and soil were carefully wrapped in aluminum foil, and 4 plants were placed together in a 2.5 L glass jar. The glass jars then were covered with insect-proof gauze. Just before trapping, the gauze was removed and the jars were closed with a Viton-lined glass lid having an inlet and outlet. Inlet air was filtered by passing through tubes filled with 200 mg Tenax TA (20/35 mesh; Grace-Alltech, Deerfield, MI, USA). Air was sucked out of the jar with 100 ml min^{-1} by passing through a tube filled with 200 mg Tenax TA. Headspace volatiles from different treatments were collected for a period of 3.5 hr. Fresh weights of all rosettes were determined immediately after the experiments. On each experimental day, headspace samples for two or three replicates of each treatment were collected simultaneously.

Headspace samples were analyzed with a Thermo TraceGC Ultra (Thermo Fisher Scientific, Waltham, MA, USA) connected to a Thermo TraceDSQ (Thermo Fisher Scientific, Waltham, MA, USA) quadrupole mass spectrometer. Before desorption of the volatiles, the Tenax cartridges were dry-purged with helium at 30 ml min^{-1} for 20 min at ambient temperature to remove moisture. Samples were desorbed from the cartridges by using a thermal desorption system at 250°C for 3 min (Model Ultra Markes Llantrisant, UK) with a helium flow at 30 ml min^{-1}. Analytes were focused at 0°C on an electronically-cooled sorbent trap filled with Tenax and Carbograph (Unity™, Markes International LTD, Llantrisant, UK) and were then transferred in splitless mode to the analytical column (Rtx-5 ms, 30 m, 0.25 mm i.d., 1.0 μm film thickness, Restek, Bellefonte, PA, USA) by rapid heating of the cold trap to 250°C. The GC was held at an initial temperature of 40°C for 3.5 min, followed by a linear thermal gradient of 10°C min^{-1} to 280°C, and held for 2.5 min with a column flow of 1 ml min^{-1}. The column effluent was ionized by electron impact ionization at 70 eV. Mass spectra were acquired by scanning from 45–400 m/z with a scan rate of 3 scans sec^{-1}.

Compounds were identified by using the deconvolution software AMDIS (version 2.64, NIST, USA) in combination with NIST 98 and Wiley 7th edition spectral libraries and by comparing their retention indices with those from the literature (Adams 1995). For quantification, characteristic quantifier ions were selected for each compound of interest. MetAlign software (PRI-Rikilt, Wageningen, the Netherlands) was used to remove baseline noise, to align the peaks of all chromatograms of the samples, and to integrate peak areas of quantifier ions. The peak areas of all compounds were corrected for the fresh weight of the leaf rosettes.

Statistical Analysis

Y-tube Olfactometer Behavioral Assays Parasitoid preference for infested *AtBSMT1-KO* vs. infested Col-0 plants (i.e., experiment 1) were analyzed statistically by using a *Chi-square* test, with the null-hypothesis that parasitoids did not have a preference for any of the two odor sources. Second, we analyzed whether the parasitoids exhibited a MeSA-dose-dependent response when the HIPV blend from *AtBSMT1-KO* plants was supplemented with synthetic MeSA (i.e., experiment 2). We constructed an overall generalized linear model (GLM) including MeSA dose as a covariate, the tested genotype combination as a fixed factor, and the interaction of the terms. As the null-hypothesis, we defined that addition of MeSA did not affect attraction of parasitoids. Total number of parasitoids that preferred infested *AtBSMT1-KO* plants with the supplemented MeSA over the control (infested Col-0 or *AtBSMT1-KO*) plants was taken as response variate. Total numbers of parasitoids that made a choice per day were used as the binomial total, which were fixed on 10 except for a single case where 9 wasps responded, and we used a logit-link function. We used a *Chi-square* test, with the aforementioned null-hypothesis, to test for a significant preference of each tested MeSA dose per genotype combination. Parasitoids that did not make a choice were not included in the test.

Third, we investigated the effects of MeSA dose on the proportion of parasitoids that made a choice in the olfactometer experiments. We used the same overall GLM

model as described above, only now with number of non-responding parasitoids as the response variate (SPSS 15.0, Chicago, IL, USA).

A Mann-Whitney-*U* test was used to test whether the consumed leaf area of Col-0 and *AtBSMT1-KO* plants (experiment 1) was different (SPSS 15.0, Chicago, IL, USA).

Headspace Collection The fresh weight of the corrected peak area for a volatile compound quantifier ion was log10 transformed, and for each HIPV, the following mixed model was used to screen for HIPV compound differentiation per genotype: $\log 10(V_{ijk}) \sim G_i + T_j + G{:}T_{ij} + R_k + \varepsilon_{ijk}$, where V=area of quantifier ions per gram fresh weight; G=genotype; T=treatment; R=replicate; ε=residual; i=1,2; j=1,2; and k=1,…,5. Both G and T were used as fixed effects and R as a random effect. Subsequently, two-tailed *t*-tests followed by a Benjamini and Hochberg false discovery rate (BH-FDR) multiple comparison correction were conducted per compound for the genotypes [significance: $q<0.05$; Benjamini and Hochberg 1995].

Results

Headspace Volatile Analysis To evaluate the effects of the BSMT knock-out mutation, we analyzed the headspace of uninfested and *P. rapae*-infested plants of wild-type Col-0 and *AtBSMT1-KO* mutant plants. For the analysis, we selected compounds in the HIPV blend that are known to influence the behavior of carnivorous arthropods, e.g., methyl salicylate, hydrocarbon alcohols, and terpenoids, and compounds predicted to be affected by the KO mutation, i.e. methyl salicylate and methyl benzoate (MeBA) (Fig. 2) (Turlings and Fritzsche 1999; Dicke et al. 1990; Chen et al. 2003; De Boer et al. 2004; Shimoda et al. 2005).

Infested Col-0 and *AtBSMT1-KO* plants differed significantly in the emission of MeSA, ethyl salicylate (EtSA) and MeBA ($q<0.001$); these compounds were induced in Col-0 but not in *AtBSMT1-KO*. The Y-axis represents a ^{10}log scale. Thus, the headspace analysis for infested *AtBSMT1-KO* and infested Col-0 showed that the production of MeBA (No. 10), MeSA (No. 12), and ethyl salicylate (EtSA, No. 13) was hampered. These compounds are emitted from *AtBSMT1-KO* at 14, 59, and 17 times lower emission rates, respectively (Fig. 2).

Several other compounds—1-pentanol, linalool, indole, (*E,E*)-α-farnesene, and (*E,E*)-4,8,12–trimethyltrideca-1,3,7,11–tetraene (TMTT)—similarly were induced in infested Col-0 and *AtBSMT1-KO* plants when compared to uninfested plants. The green leaf volatile (*Z*)-3-hexen-1-ol was induced significantly in only the mutant ($q=0.005$) but not in the wild-type. Uninfested Col-0 and *AtBSMT1-KO* plants did not differ in the emission of volatiles, except for TMTT, which was emitted in somewhat larger amounts by uninfested Col-0 plants than by uninfested *AtBSMT1-KO* plants ($q=0.011$). Finally, uninfested Col-0 plants emitted more 1-octen-3-ol and 1-nonanol than infested plants (Fig. 2).

Y-Tube Olfactometer Behavioral Assays

Experiment 1. Effect of AtBSMT Knock-out on Parasitoid Attraction to Caterpillar-infested Plants Diadegma semiclausum females are attracted to the headspace of *P. rapae*-infested Arabidopsis Col-0 plants (Loivamäki et al. 2008) in which MeSA is an induced volatile compound (Van Poecke et al. 2001). To investigate whether changes in this headspace, as a result of a knock-out mutation in the *AtBSMT1* gene, affected parasitoid attraction, we investigated the behavioral responses of *D. semiclausum* towards plant volatiles induced by *P. rapae* herbivory in a Y-tube olfactometer. Females of *D. semiclausum* preferred the volatiles emitted by herbivore-infested *AtBSMT1-KO* plants over those emitted by infested Col-0 plants ($P<0.05$; Fig. 3a).

The amount of leaf-tissue consumed by the caterpillars did not differ between Col-0 and *AtBSMT1-KO* plants (mean ± SE: Col-0 10.41±0.91 mm^2, *AtBSMT1-KO* 10.88±0.80 mm^2; Mann Whitney *U* test: $U=259.00$; $P=0.90$, $N=23$). Thus, the difference in attraction cannot be explained by a difference in the amount of feeding by the caterpillars.

Experiment 2. Supplementing Headspace of Caterpillar-infested AtBSMT1-KO Plants with Synthetic MeSA To assess whether the absence of MeSA in the HIPV blend can explain the effect on parasitoid behavior, the volatile blend of infested *AtBSMT1-KO* plants was supplemented by adding synthetic MeSA downwind of the plant. Different MeSA doses were used to test for dose-dependent effects of MeSA presence. The addition of MeSA eliminated the preference for the knock-out plants, as seen in experiment 1, and with increasing MeSA dose this effect was stronger. Parasitoid preference was not influenced by the different genotype combinations, but solely by the MeSA dose used (GLM: genotype combination $P=0.167$, MeSA dose $P<0.001$, $R^2=0.28$). Analysis of parasitoid choices for each tested MeSA dose within a tested genotype combination demonstrated that parasitoid preferences slightly varied among the MeSA doses used. Yet, for both genotype combinations tested, *AtBSMT1-KO* HIPV complementation with 0.2 µg MeSA did not result in discrimination between the two odor sources and a complementation with 200 µg MeSA resulted in significant preference for the odor without supplemented MeSA (Fig. 3b, c). When parasitoids were offered a choice between volatiles from infested *AtBSMT1-KO* plants supplemented with 2 or 20 µg MeSA vs. infested Col-0 HIPVs,

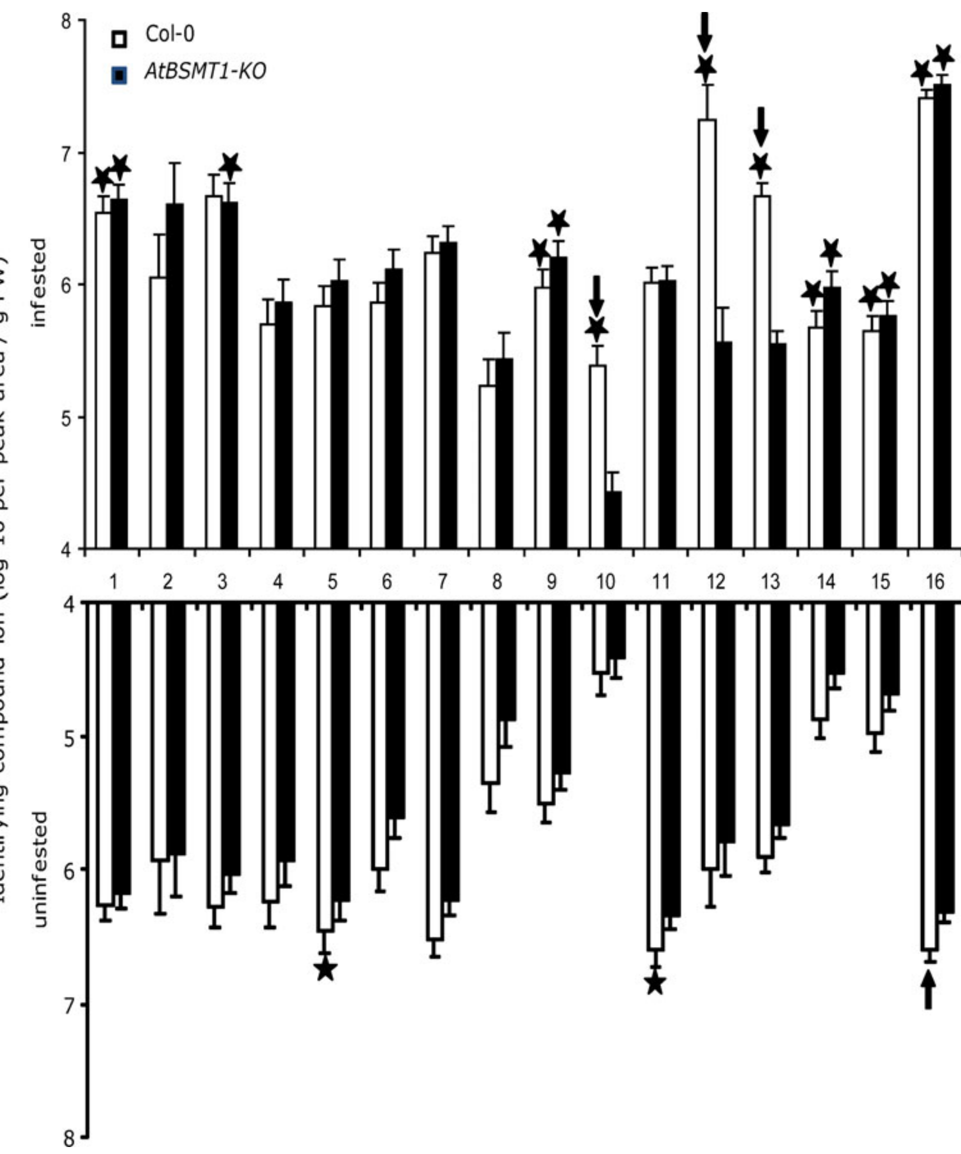

Fig. 2 Emission of volatile compounds of Col-0 wild-type and *AtBSMT-KO* Arabidopsis plants, either uninfested or infested with 20 *Pieris rapae* caterpillars, expressed as peak area (arbitrary units; mean ± SE; N=5) for the identifying ion per g FW. Compounds: 1=1-pentanol (*m/z* 70); 2= (*Z*)-2-penten-1-ol (*m/z* 57); 3= (*Z*)-3-hexen-1-ol (*m/z* 67); 4= α-pinene (*m/z* 93); 5= 1-octen-3-ol (*m/z* 57); 6= ß-myrcene (m/z 93); 7= (*Z*)-3-hexen-1-ol acetate (*m/z* 67); 8= (*E*)-ß-ocimene (*m/z* 93); 9= linalool (*m/z* 93); 10= methyl benzoate (*m/z* 136) 11= 1-nonanol (*m/z* 56); 12= methyl salicylate (*m/z* 120); 13= ethyl salicylate (*m/z* 120); 14= indole (*m/z* 117); 15= (*E*,*E*)-α-farnesene (*m/z* 93); 16= (*E*,*E*)-4,8,12-trimethyltrideca-1,3,7,11-tetraene (TMTT) (*m/z* 69). Bars marked with * indicate a treatment for a genotype significantly emitting more volatiles than its opposite uninfested or infested genotype. Bars marked with arrows represent compounds emitted in significantly different amounts by the two genotypes

they preferred the latter. In contrast, no discrimination between odors from infested *AtBSMT1-KO* plants supplemented with 2 or 20 µg MeSA vs. infested *AtBSMT1-KO* plants was observed.

The addition of MeSA negatively influenced the proportion of parasitoids that made a choice for one of the two odor sources. Analysis of the number of wasps that did not make a choice for one of the two odor sources, showed no effect of the offered genotype combination, but only an effect of the MeSA dose used (GLM: genotype combination P=0.75, MeSA dose P=0.010, R^2=0.15).

Discussion

Variation in the attraction of carnivorous arthropods to HIPVs often is ascribed to the relative contribution of attractive compounds within the complex herbivore-induced blend (Van Den Boom et al. 2004; D'Alessandro et al. 2006, 2009). Plant species can differ in the relative emission rates of individual attractive compounds in response to feeding by distinct herbivores. The commonly induced attractive compounds comprise green leaf volatiles (GLV), terpenoids, phenyl propanoids, and benzenoids. Several studies already have shown *in planta* the importance of some GLV and terpenoids in attracting carnivorous arthropods (Kappers et al. 2005; Schnee et al. 2006; Shiojiri et al. 2006). Yet, empirical evidence for the quantitative importance of single compounds in the total HIPV blend of infested plants is still rare (but see De Boer and Dicke 2004). The parasitoid *D. semiclausum* is attracted to the headspace of *P. rapae*-infested Col-0 plants (Loivamäki et al. 2008), in which MeSA is an induced volatile (Van Poecke et al. 2001). Here, we studied the effect of MeSA on preference for volatile blends in the parasitoid *D. semiclausum*.

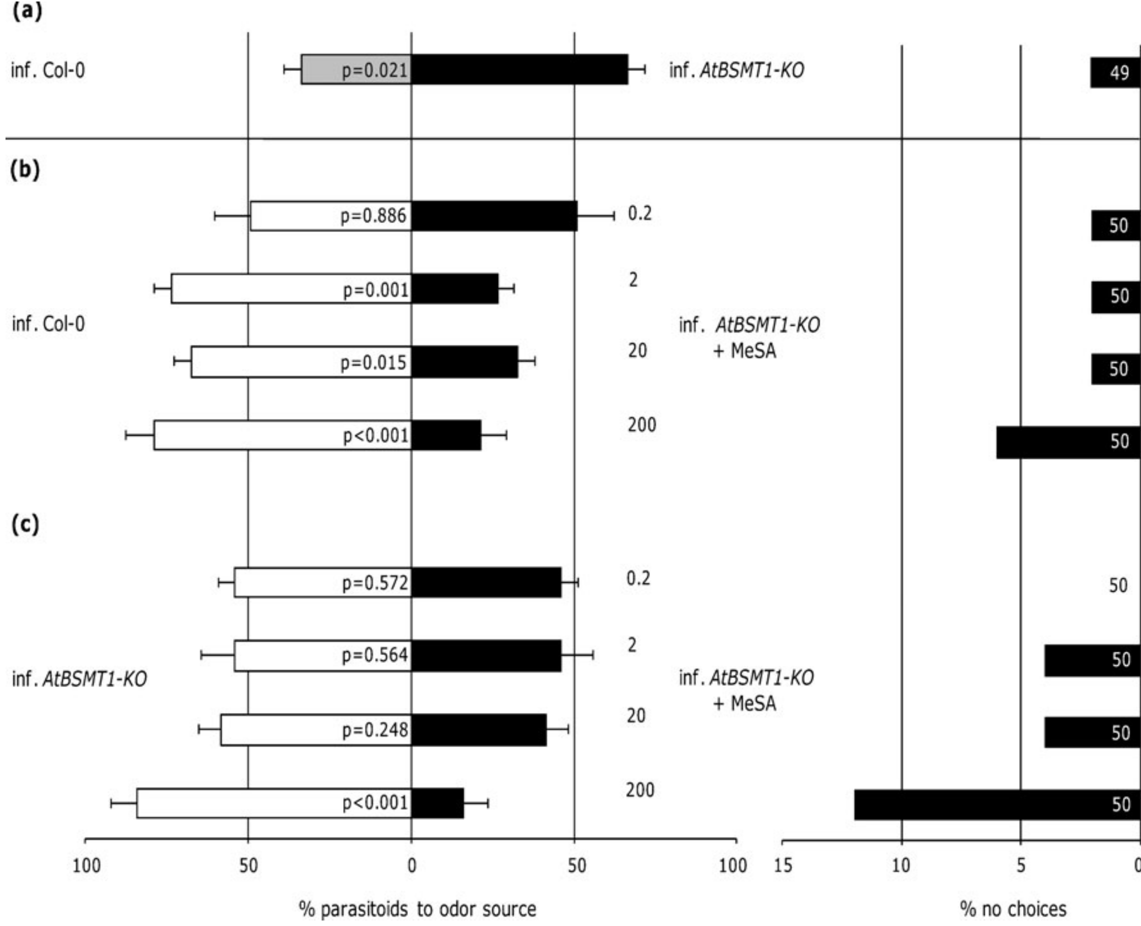

Fig. 3 Behavioral responses of naïve *Diadegma semiclausum* females to volatiles of two sets of *Arabidopsis thaliana* plants (Col-0 vs. *AtBSMT1-KO*), as assessed in the Y-tube olfactometer. All plants were infested (inf.) with 20 *Pieris rapae* caterpillars and in some cases the headspace was supplemented with synthetic methyl salicylate (MeSA), added downwind from the plants. Added MeSA-doses (µg) are indicated to the right of the bars in the left bar plot. Each bar represents the percentage of choices for each of the two odor sources as determined in five replicate experiments; on each replicate day 10 parasitoids were tested per odor source (X^2 test, *P* values). Error bars indicate SE. Generalized linear model analysis for experiments B and C, demonstrated that MeSA dosage ($P<0.001$) and not the offered genotype ($P=0.167$) explained parasitoid behavior. Parasitoid MeSA dosage responses between two tested genotype combinations did not differ ($P=0.270$). The right bar plots indicate the percentage of no choice in each experiment; total number of tested parasitoids are given in these bars

The newly-available Arabidopsis knock-out mutant for benzoic acid and salicylic acid carboxyl methyltransferase (*AtBSMT1-KO*) (Fig. 1, Fig. S1), allowed us to study *in planta* the ecological effects of an HIPV mixture lacking wild type levels of MeSA. Our data show clearly that caterpillar-infested *AtBSMT1-KO* plants attract more parasitoids than infested wild-type Col-0 plants (see Fig. 3a). Thus, although the total HIPV blend from wildtype plants strongly attracts *D. semiclausum* parasitoids (Loivamäki et al. 2008), a genotype that does not emit MeSA in response to caterpillar infestation is even more attractive to the parasitoids. These data indicate that MeSA does not contribute to the attraction of naïve *D. semiclausum* females but instead results in a reduced attractiveness.

This negative effect of MeSA on *D. semiclausum* attraction was not anticipated, as MeSA is commonly induced after herbivory in many plant species, e.g., in lima bean (Dicke et al. 1990), Brussels sprouts (Geervliet 1997; Bukovinszky et al. 2005), tomato (Ament et al. 2004), and Arabidopsis (Van Poecke et al. 2001; Chen et al. 2003). Moreover, the salicylic acid-deficient Arabidopsis mutant *NahG* is less attractive to *Cotesia rubecula* parasitoids upon infestation by *P. rapae,* which suggests an attractive role of MeSA for this parasitoid species (Van Poecke and Dicke 2002). Furthermore, synthetic MeSA has also been demonstrated to attract other carnivore species, such as predatory mites, lacewings, and mirid bugs (Dicke et al. 1990; De Boer and Dicke 2004; James and Price 2004).

However, in our approach we tested the role of MeSA within the total HIPV-blend, by using *AtBSMT1-KO* plants with a hampered MeSA production. By additionally testing the response of the wasps to an HIPV blend from *AtBSMT1-KO* plants that we had supplemented with synthetic MeSA against HIPVs from Col-0 plants and *AtBSMT1-KO* plants, we demonstrated that MeSA acts as a repellent to naïve *D. semiclausum*. Moreover, the repellent effect of MeSA was dose-dependent, and this was reflected in the response level of the parasitoids, as fewer wasps move upwind to make a choice between odor sources with higher MeSA-doses. Additionally, the KO-mutation did not affect the feeding rate of the caterpillars. Thus, the change in volatile emission and parasitoid attraction cannot be attributed to effects of the KO-mutation. The data show that this compound plays a role in the observed repellent effects.

A few other studies also have recorded repellent effects of HIPV compounds to carnivores. For example, an HIPV fraction of maize, containing (*Z*)-3-hexen-1-ol acetate, linalool, and (3*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) was found attractive compared to other tested fractions of the HIPV blend of maize to the parasitoid *Cotesia marginiventris* (Turlings and Fritzsche 1999). For the same plant-herbivore system, naïve *Microplitis rufiventris* parasitoids preferred HIPV blends lacking the induced compound indole (D'Alessandro et al. 2006). Compounds that are repellent also may affect or override the attractiveness of other compounds in the headspace. Isoprenoids have, for example, been found to interfere with host-finding, as demonstrated for transgenic Arabidopsis plants emitting isoprene (Loivamäki et al. 2008). Therefore, to determine whether a hampered enzyme activity for SAMT and BAMT affected the headspace composition in other respects, we also analyzed the headspace of infested knock-out mutant and wild-type plants. We observed that the headspace of caterpillar-infested Col-0 and *AtBSMT1-KO* plants differed only in the emission of MeSA, MeBA, and EtSA. Yet, all other investigated HIPVs were emitted at similar rates by these infested plants (Fig. 2). The emission rates of the compounds whose rates were affected, were up to 60 times lower for *AtBSMT1-KO* plants compared to wild-type plants (Fig. 2). This agrees with the reported activity of the enzyme encoded by the *BSMT1* gene (Chen et al. 2003). The very low emission of MeSA that remains may be ascribed to activity of another SABATH enzyme that shows low levels of activity towards SA and BA (Chen et al. 2003). Eliminating a functional *BSMT1* gene also decreased the emission rate of EtSA. EtSA has been recorded in several plants (Hamilton-Kemp et al. 1988; Scutareanu et al. 1997; Deng et al. 2004) and is perceived by insect chemoreceptors (Ramachandran et al. 1990; Reinecke et al. 2002). Whether MeBA and EtSA also affect the attraction of *D. semiclausum* wasps remains to be investigated.

We investigated the role of MeSA by eliminating it from the total HIPV blend rather than by investigating its role as an isolated compound or as an addition to an artificial blend (see e.g., De Boer and Dicke 2004). We thus demonstrated that it has a repellent effect on the behavior of naïve *D. semiclausum* parasitoids. This finding provides another view on the fitness effects of individual components of herbivore-induced plant volatile blends that do not lure naïve carnivores but rather repel them. An alternative function of HIPV emitted compounds can be to repel herbivores (Dicke 1986; Bernasconi et al. 1998; Kessler and Baldwin 2001; Bruce et al. 2008; Piesik et al. 2008), which also has been demonstrated for MeSA (Hardie et al. 1994; James and Price 2004; Prinsloo et al. 2007; Ulland et al. 2008). MeSA may activate disease resistance and the expression of defense related genes in neighboring plants and in healthy tissue of infected plants (Shulaev et al. 1997). Therefore, the emission of MeSA also could benefit the plant through protecting it at herbivory-derived wounds against infectious pathogens, as has been reported for several GLVs (Brown et al. 1995; Shiojiri et al. 2006). In addition, evidence has accumulated for a plant–plant signaling role for MeSA (Ozawa et al. 2000; James and Price 2004), as well as indications for a priming effect of MeSA on plant defense (Turlings and Ton 2006).

A few studies indicate that parasitoids can learn to respond to individual compounds following a learning experience with an odor mixture (Meiners et al. 2003). This suggests that an innate response of *D. semiclausum* to avoid MeSA-emitting plants could potentially turn into attraction after a learning experience in the presence of a host.

In summary, our study provides evidence for an HIPV component that makes a plant less attractive to a carnivorous insect. This should be seen in the context of the different selection pressures on a plant's emission of volatiles in a multitrophic context. Understanding these selection pressures will provide insight into the role of induced volatiles in the biology of plants (Dicke and Baldwin 2010).

Acknowledgements The authors thank Leo Koopman, Frans van Aggelen, and André Gidding for culturing the insects, Iris Kappers for help with volatile analysis and fruitful discussions, Carola Ros for assistance with the behavioral assays, and Remco van Poecke for statistical assistance regarding volatile data. We thank Harro Bouwmeester for technical support at Plant Research International, and the Netherlands Organization for Scientific Research (NWO/ALW) for a VICI grant (865.03.002; T.A.L.S. and M.D.).

Response of a Generalist Herbivore *Trichoplusia ni* to Jasmonate-Mediated Induced Defense in Tomato

Ian M. Scott · Jennifer S. Thaler · Jeffrey G. Scott

Abstract The up-regulation of plant defense-related toxins or metabolic enzyme binding proteins often leads to a negative effect on herbivorous insects. These negative effects can manifest themselves at three points: changes in food ingestion, post-ingestive-changes, and post-digestive changes. Many studies have related the decrease in herbivore growth and/or survival with expression of chemicals that interfere with post-digestive effects such as the anti-nutritive effects of protease inhibitors. Nevertheless, it is unclear whether such compounds impact herbivores via earlier ingestive processes. We addressed this question by using a jasmonate-deficient mutant (Def-1), a jasmonate-overexpressor mutant (Prosystemin or Prosys), and wild-type tomato in three trials with 5th instar *Trichoplusia ni*. Decreases in relative growth rate (RGR) confirmed that *T. ni* fed on the Prosys plants developed poorly compared to those feeding on Def-1 plants (larvae on wild-types were intermediate). Preingestive and postingestive processes contributed to this effect. Total food ingested and the consumptive index were 25% lower on Prosys plants compared to Def-1 plants. Post-ingestive processes, measured by approximate digestibility, were 62% greater on Prosy plants**.** Post-digestive efficiency measured by conversion of ingested and digested food (ECI and ECD) decreased on Prosys plants two-fold compared to Def-1 plants. This post-digestive interference correlated well with the 2-fold decrease in activity of digestive enzymes, serine proteases, in Prosys-fed *T. ni* compared to those on Def-1 plants. No difference in detoxifying enzyme activity was detected.

Key Words Jasmonic acid · Induced plant response · Tomato · *Trichoplusia ni* · Prosystemin · Def-1 mutant · Nutritional index · Serine protease · Detoxification enzyme

Introduction

The induced responses in plants to herbivore and pathogen attack are well documented and often have strong negative consequences for herbivore survivorship, growth and reproduction (Green and Ryan 1972; Karban and Myers 1989; Farmer and Ryan 1992; Stout and Duffey 1996). The negative effects of plant responses can be based on lower nutritional value or more direct toxicity (Duffey and Stout 1996; Barbehenn et al. 2007). In the latter case, a toxic effect would be caused by direct interference with midgut processes or normal life processes (Duffey and Stout 1996). In the former case, many herbivores compensate for sub-optimal nutritional value by increasing food consumption or switching to an alternative food (pre-ingestive effects), altering utilization of the food (post-ingestive effects) or increasing the efficiency of conversion of digested food to solid body matter (post-digestive effects) (Hägele and Rowell-Rahier 1999). Reduced efficiency can be divided further into either: 1) an anti-digestive effect caused by a reduction in the enzymatic conversion of ingested food; or 2) an anti-nutritive effect that reduces the physical availability or chemical composition of the food. An example of an anti-digestive effect is when protease inhibitors (PIs) from the plant reduce the protease activity

in the insect gut, thus affecting the metabolism rate of proteins and the availability of amino acids (Chen et al. 2005). An example of an anti-nutritive effect occurs when polyphenol oxidases (PPOs) cause irreversible covalent modification of amino acids and plant proteins by quinines or quinine-generated reactive oxygen species (Mahanil et al. 2008).

The defense pathway regulated by jasmonic acid (JA) is known to be one of the plant's most important lines of defense against insect herbivores (Farmer and Ryan 1992; Lightner et al. 1993; McGurl et al. 1994; Howe et al. 1996). This pathway influences many different properties in Solanaceous plants, including the formation of defense proteins (PIs), oxidative enzymes (PPO), glandular trichome density, small compounds such as alkaloids (glycoalkaloids in potato and nicotine in tobacco), and volatiles (mono- and sesquiterpenes in tomato). These compounds are known to be inducible (Ryan 2000; Thaler et al. 2002; Boughton et al. 2005; Halitschke and Baldwin 2005; Wasternack 2007). Tomato leaves contain α-tomatine, chlorogenic acid, and rutin shown to be toxic to *Heliothis zea* at foliage concentrations (Elliger et al. 1981), but it has not been determined whether these are induced through the JA pathway. Because of this, plants with an activated jasmonate pathway may vary both in nutritive content as well as levels of toxins. Nutritional quality of the plant may be altered by either changes in the amount of nutrients present or in the presence of compounds that reduce the digestibility of nutrients by the insect. While it has been shown that herbivores feeding on plants with an induced jasmonate response often have severely reduced performance, it has not been investigated to what extent these negative effects on herbivores are due to decreased nutritional availability or increased toxicity.

Modeling the function of JA has been facilitated through the use of tomato mutants or genetic manipulation of wild-type plants to alter the JA biosynthetic pathway. Jasmonate-deficient (Def-1) tomato mutants have an altered octadecanoid pathway converting linolenic acid to JA resulting in a 3-fold lower induction of JA 90 min after wounding compared to wild-type (WT) plants (Howe et al. 1996). As a result, there is a 10-to >25-fold lower accumulation of wound-inducible proteinase inhibitors (PI) in the Def-1 wounded leaves compared to WT plants. The expression of a PI-II related gene, cathepsin D inhibitor (CDI), in Def-1 plants is also less than 10% of those in WT plants (Li et al. 2002). Mortality of *Spodoptera exigua* that fed on Def-1 plants was 30% less, and larval mass of survivors was double that of larvae that fed on WT tomatoes (Thaler et al. 2002). In a second transgenic tomato line (Prosys), prosystemin is over-expressed through the use of a promoter leading to the constitutive overproduction of JA, leading to an overproduction of the defense proteins, PPO (Howe and Ryan 1999), and PIs (McGurl et al. 1994), including arginase and threonine deaminase (Chen et al. 2005). In unwounded Prosys leaves, the typical levels of PI-I, PI-II, and PPO are 14.7x, 19.1x, and 69x greater than in the unwounded WT leaves, respectively (Howe and Ryan 1999). As a result, when thrips and spider mites fed on prosystemin-overexpressing tomatoes, there is reduced damage to the plant and decreased herbivore fecundity compared to WTs (Li et al. 2002). Compared to a wild-type tomato, a Prosys mutant that overexpresses arginase had dramatically higher leaf arginase activity, reduced *Manduca sexta* larval weight gain and leaf consumption, and the level of Arg in the *M. sexta* midgut was reduced significantly (Chen et al. 2005). Jasmonate-induced levels of PIs and PPO work in combination to either modify the dietary protein or bind and inhibit digestive enzymes in the caterpillar midgut, respectively (Chen et al. 2005).

In the present study, the cabbage looper *Trichoplusia ni* (Hbn.) (Noctuidae), an insect with a large range of host plants, was used to investigate the digestive and physiological response to variable JA expression in tomato. The tomato mutants Def-1 and Prosys provide excellent models for unraveling whether the JA-induced defenses act pre-ingestive, post-ingestive, or post-digestive. The objectives of this study were to examine the difference in digestive and physiological responses of *T. ni* that are indicative of: 1) consumption and digestibility of plant nutrients (e.g., leaf area consumed, mass gain, frass production, and nutritional indices); and 2) insensitivity to plant proteins via gut serine proteases, and detoxification by gut monooxygenases, esterases, and transferases. The expectations were that tomato plants expressing higher levels of JA will: 1) have increased levels of anti-digestive and anti-nutritive compounds that will lead to significant differences in the insect's post-digestive nutritional indices; and 2) have increased concentrations of toxic allelochemicals that will lead to significantly greater detoxifying enzymes in the insect.

Methods and Materials

Plant and Insect Material Jasmonic acid deficient (Def-1), wild-type (var. Castlemart) and prosystemin over-expressing 35S::Prosystemin (Prosys) mutant tomatoes were obtained from Gregg Howe, Michigan State University. Def-1 plants were backcrossed 5 times to the Castlemart variety and were homozygous for a mutation within the jasmonate pathway leading to lower JA production (Howe et al. 1996) and a reduced ability to induce proteinase inhibitor I and II (Lightner et al. 1993). The Prosys transgenic tomatoes were developed through an agrobacterium-mediated transformation of var. Better Boy (McGurl et al. 1994), and, as a

consequence, accumulate high levels of wound response proteins in the absence of wounding (Howe and Ryan 1999). Seeds for the Prosys plants were collected from a homozygous line backcrossed to var. Castlemart (Li et al. 2002). All tomato plants were grown in 4″ diam pots with Metromix potting soil in the greenhouse from seed. Plants were used when they were between 4 and 5 wk in age.

Cabbage looper *Trichoplusia ni* larvae were obtained from Benzon Research (Carlisle, PA, USA). Larvae were reared on multispecies diet (Southland Products, Lake Village AR, USA) until the 5th instar. All larvae used in trials were mid 5th instar. Larvae were reared at 26-28°C, 16:8 hr L:D.

Tomato—T. ni Greenhouse Trials Three greenhouse tomato trials were conducted between October 2006 and January 2007. The plants were grown in the greenhouse at 27°C under natural light conditions with supplemental lighting until 22:00 hr. Fertilizer (21:5:20 N:P:K, 150 ppm N) was added weekly to the pots. Fifty Def-1, WT, and Prosys plants without prior herbivore damage were selected for use in the trials. The third leaf from the top was selected for the insect feeding trial. Outlines of the first five leaflets from the leaf were obtained from each plant by using an underlying sheet of white paper and an overlying acetate sheet. A clear plastic clip cage (approx. 5 cm diam.) then was attached to the first or terminal leaflet of the leaf. When all leaflets were traced, a 6–8 hr-starved, pre-weighed *T. ni* larva was placed in each clip cage. After 5–6 hr, the clip cage was moved to an adjacent leaflet on the same leaf, and this was repeated up to three more times over a 24 hr period. The cage was moved depending on the degree of damage per leaflet. If the leaflet was largely or completely consumed by the larva, the cage was moved. If <50% of the leaf area was removed, the cage was not moved. At the end of the trial, the remaining leaf tissue was scanned (Canoscan, Canon, Burlington NJ, USA) and compared to a scan of the leaflet tracing in order to calculate the actual leaf area consumed. Each time a cage was moved the frass produced by the insect was collected.

After 24 hr, all larvae were removed from the cages and held in cups on ice. In the laboratory, the final fresh mass of each larva was measured. Ten of the 50 larvae were randomly selected for measurement of dry mass, the remainder were divided into three groups for enzyme assays. To determine dry mass, larvae were removed from the ice, starved at room temperature for 1–2 hr, weighed, and then frozen at −20°C. Later these larvae were dried at 65°C for 3 d and reweighed. Larvae used in the enzyme assays were placed on ice, and the midgut was removed by dissection as described below. Calculation of the dry mass of the tomato leaflet area consumed was based on dry mass of discs cut from 10–15 leaflets per variety with a #10 cork borer and dried for 3 d at 65°C. These leaf discs were cut from 10 plants, and the disc was cut from the base or the widest part of the leaflet. The surface area damaged on each leaflet was converted to dry mass based on the mean mass per disc for each tomato variety. Initial dry mass of the insects was calculated by multiplying the initial fresh mass by the ratio of the mean final dry mass : fresh mass. Frass collected from individual insects was dried at 65°C for 3 d and weighed.

Nutritional Analysis The nutritional indices calculated for the *T. ni*—fed tomato mutants and wild-type were as follows: relative growth rate (RGR), consumption index (CI), approximate digestibility (AD), efficiency of conversion of digested food (ECD), and efficiency of ingested food (ECI). The indices were calculated according to the Waldbauer method as described in Slansky and Scriber (1985) and Rayapuram and Baldwin (2006). CI [(leaf ingested)/(larval mass gain x number of days)] provides a measure of the total amount of leaf consumed relative to the body mass gained during the 1 day feeding period. Increases in CI have been associated with compensation by nutritionally limited insects. AD [(leaf mass ingested—frass mass)/(leaf mass ingested)] is the difference between the amount of food consumed and the amount of frass produced per unit food consumed. This provides a measure of the efficiency of digestion of the ingested food. ECD [(larval mass gain)/(leaf mass ingested—frass mass)] and ECI [(larval mass gain)/(leaf mass ingested)] provide a measure of the efficiency of conversion of absorbed food and ingested food, respectively. The latter 2 indices measure the mass increment of the insect relative to the amount of food absorbed and eaten, respectively. Lower ECI and ECD indicate that insects are not getting essential macronutrients, whereas a change in AD reflects different mechanisms occurring after ingestion, but prior to digestion. RGR (growth attained per unit of body mass per unit of time) is the product of the relative consumption rate (RCR=mg consumed per mg gained per day) and nutritional indices (RGR=RCR x ECI) (Schoonhoven et al. 2005).

Total Serine Protease Activity Individual *T. ni* midguts were dissected on ice, and the whole midgut was placed in a preweighed cryovial with 100 µl of MilliQ water and reweighed. Samples then were frozen at−80°C until the protease assay was performed. The frozen whole midguts were thawed on ice, transferred to a 1.5 ml centrifuge tube, and additional distilled water was added, based on the midgut mass in order to have a 10% midgut solution. The midgut then was processed using a disposable pellet mixer (VWR) with pestle to fit the 1.5 ml microtube. The 10% homogenate was used to measure total serine protease

activity for 10 individual *T. ni* larvae per tomato variety per trial. Total midgut serine protease activity was quantified with azocasein (Sigma) substrate using a method adapted from Hegedus et al. (2003) (P. Wang, personal communication). The midgut homogenate (20 µl) was added to 150 µl of 1% azocasein solution in pH 11 glycine-sodium hydroxide (0.05 M). All samples were incubated at 28°C for 15 min. TCA (10%) was added (170 µl) and incubated for 1 h at room temperature. The sample was centrifuged at 13,000 RPM for 10 min, and the supernatant was collected. Sodium hydroxide (1 M) was added (340 µl), and the absorbance was read at 495 nm with a Beckman spectrophotometer (Li et al. 2004). Total midgut protease activity is calculated by subtracting the azocasein blank absorbance from the azocasein sample absorbance divided by the incubation time in min multiplied by 1000 ([(Abs $_{(sample)}$—Abs $_{(blank)}$]/min * 1000). The units are tryptic activity (mU) per min of incubation per mg insect body weight (mU/min/mg bw). Leaf homogenate from each of the tomato types also was assessed for protease activity using the above method to ensure that no background protease activity was present due to plant material present in the midguts.

Previous studies have shown that adaptation by insects to protease inhibitors (PIs) in their diet involves increases in the amount of PI-insensitive proteases (Broadway 1995; Jongsma and Bolter 1997). One method of examining the difference in the profile of proteases in the midgut is to apply a protease inhibitor with specific activity. Bowman-Birk soybean protease inhibitor (BBI) (Sigma) was selected as it targets trypsin and chymotrypsin proteases, the principal serine proteases in lepidopterans (Abdeen et al. 2005; Chougule et al. 2008). In order to test the hypothesis that *T. ni* larvae adjust to increasing levels of JA-induced defenses by up-regulating insensitive proteases, differences in the remaining amount of serine protease activity was measured between BBI-incubated midgut homogenates taken from *T. ni* that fed on the three tomato mutants in trial 1 relative to the homogenates incubated without BBI. The midgut homogenates of the treated *T. ni* were incubated for 15 min with BBI over a range of concentrations (0.1, 0.5, 1, 2, and 8 mg/ml) that showed a linear inhibition of protease activity with azocasein substrate with increasing inhibitor concentration until saturation was approached. Total serine protease activity was measured as described above, and the percent inhibition caused by the BBI incubation was determined.

Cytochrome P450/b$_5$ Assay Microsomes were prepared from the dissected midguts of 20 *T. ni* larvae fed on the wild-type and two tomato mutants. The midguts were dissected on ice and rinsed in Rinaldini's saline. The 20 midguts were combined and homogenized in 20 ml 0.1 M sodium phosphate homogenizing buffer (pH 7.5) (Lee and Scott 1989). Homogenates were centrifuged at 10,000 RPM for 20 min, the supernatant was transferred to a 30 ml centrifuge tube and centrifuged at 100,000 RPM for 1 h. The microsome pellet was homogenized in a resuspension buffer (pH 7.5) (Lee and Scott 1989) and frozen at−80°C until the assay was performed. Cytochrome P450 and b$_5$ were determined following the methods described for house fly (Lee and Scott 1989). Microsome protein was determined by the Bradford (1976) method.

Glutathione S-transferase Assay Individual *T. ni* midguts were dissected on ice, rinsed in Rinaldini's saline, and homogenized in 500 µl of sodium phosphate buffer (pH 7.5). Ten individuals per treatment from each of the three trials were analyzed. A disposable pellet mixer was used to grind the midgut-buffer mixture. After homogenizing the midgut, a further 500 µl of buffer were added so that the final preparation was one midgut per 1 ml buffer. Samples were centrifuged at 10,000 RPM, and the supernatant was transferred to 1.5 ml vials. Samples were kept frozen at−80°C until both the glutathione *S*-transferase (GST) and esterase assays were conducted. The substrates, 150 mM 1-chloro-2,4-dinitrobenzene (CDNB) (Sigma) (1 µl), and 150 mM 1,2-dichloro-4-nitrobenzene (DCNB) (Sigma) (1 µl) were used with 15 mM reduced glutathione prepared in pH 7.0 potassium phosphate buffer (50 µl) and homogenate (25 µl). The methods were adapted from Baker et al. (1998) where three replicates were prepared for each midgut sample on a 96 well plate on ice. Readings at 340 nm were taken every 30 sec for 10 min at 25°C using a microplate reader (Thermo Fisher Scientific, Waltham MA, USA). The initial and final readings used for GST activity were at 3 and 8 min (5 min interval) after the initiation of the plate readings. Blank wells were prepared by replacing the homogenate with pH 7.0 buffer. Ten individuals per treatment from each of the three trials were analysed. Protein concentration was determined by the Bradford (1976) method.

Esterase Assay Midgut supernatants were used for the determination of esterase activity. The esterase substrates used were α-and β-naphthyl acetate (NA) and 4-methylumbelliferyl acetate (4-MUA), and a microplate assay was adapted from the methods described by Baker et al. (1998). For the α-and β-NA assays, supernatant was diluted 1:100 with pH 7.0 buffer. Into each plate well we added: 110 µl of buffer, 50 µl of either 4 mM α-or β-NA dissolved in acetone, and 40 µl of diluted sample. After 15 min at 25°C, a stop reagent, 25 µl of 0.8% Diazo Blue in 3.4% SDS was added, followed by a further 10 min wait before measuring the activity at 595 nm (α-NA) or 490 nm

(β-NA). Each plate was set up with triplicate wells of samples, standards with either α-naphthol or β-naphthol (4–40 μM) in buffer and blank wells (buffer only). Esterase activity with all three substrates was standardized to protein concentration.

Statistical Analyses ANCOVA was used to analyze each of the nutritional indices to avoid problems with the statistical analysis of ratios (Raubenheimer and Simpson 1992) (Proc GLM SAS ver 9.1). In all cases, the independent variables are plant type and trial. For RGR, final mass is the dependent variable and initial mass is the covariate. For CI, plant mass consumed is the dependent variable, and initial mass is the covariate. For AD, the plant mass consumed minus the frass mass produced is the dependent variable, and the mass consumed is the covariate. For ECD, the larval mass gain is the dependent variable, and amount consumed minus the frass produced is the covariate. For ECI, the larval mass gain is the dependent variable, and the amount consumed is the covariate. In the case of AD, ECI, and ECD, the interaction between the plant-type and the covariate was tested. Two-way ANOVA was used to analyze the biomarkers (protease, cytochrome P450, cytochrome b_5, esterase, and GST activity) for the three separate trials. Results were combined and analyzed, and the difference between the treatments was compared among and between the trials. Comparison of treatment means used Tukeys (SAS ver.9.1, SAS Institute, Cary NC, USA). Data were log + 1 transformed, and the normality and homogeneity of all data sets were confirmed (SAS ver.9.1). The effects of the sbBBI treatment on protease activity were ARC Sine (Squareroot) transformed and analyzed using one-way ANOVA (SAS ver. 9.1).

Results

Insect Relative Growth Rate, Leaf Area Consumption, Frass Production, and Nutritional Indices Plant-type had a large effect on caterpillar performance with a significantly lower relative growth rate (RGR) when comparing larvae on Prosys plants to those on Def-1 and WT plants (Fig. 1a). *Trichoplusia ni* caterpillars ate 27–31% less on Prosys plants compared to the Def-1 and WT plants (Table 1). The consumptive index (CI) decreased by 25% when larvae fed on Prosys plants and were compared to those on Def-1 plants; larvae feeding on WT plants showed a CI similar to those feeding on Prosys plants (Fig. 1a).

Post-ingestive efficiency, measured as approximate digestibility (AD), was 62% less on Def-1 plants and 34% less on wild type plants compared to Prosys plants. The caterpillars on Def-1 plants ate more, but also produced more frass (Table 1).

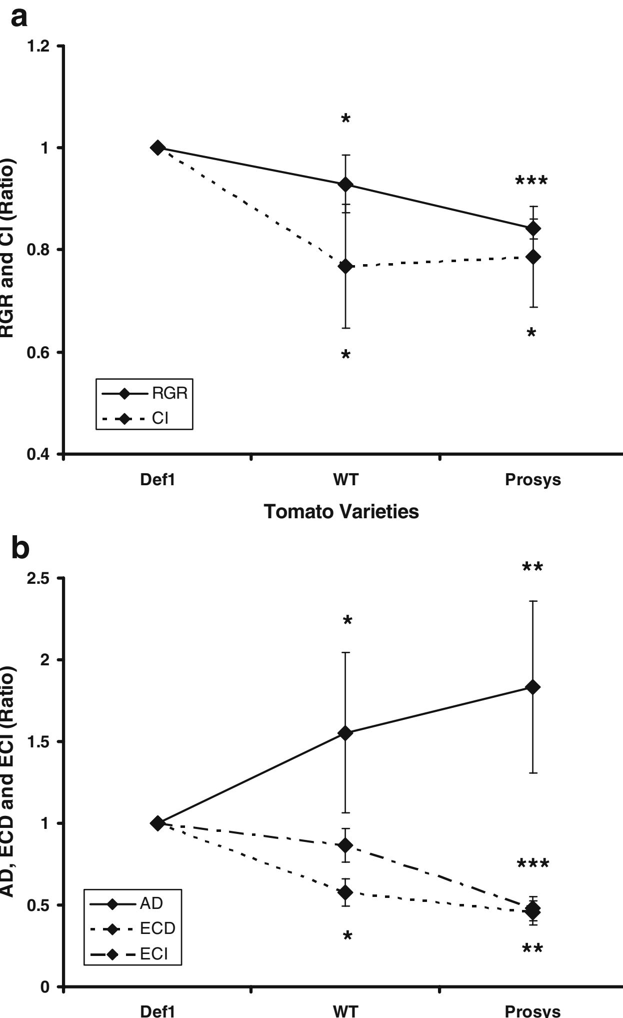

Fig. 1 Mean ratio (± S.E.) for Def-1:Def-1, WT:Def-1 and Prosys: Def-1 of the following: **a** relative growth rate (RGR) and consumption index (CI); and **b** approximate digestibility (AD), efficiency of conversion of digested food (ECD), and efficiency of conversion of ingested food (ECI) for *Trichoplusia ni* feeding for 24 hr on three tomato mutants. RGR, CI, AD, ECD, and ECI ratios marked with either a *, ** or *** indicates that there was a significant difference (*LS Means*, *ANCOVA*, $P<0.05$) between the Def-1 and WT or Def-1 and Prosys mutants in 1, 2, or all of the 3 trials, respectively. $N=27$ (Def-1); 28 (WT) and 28 (Prosys)

In contrast, post-digestive measures of efficiency of food conversion (ECD and ECI) were 2-fold higher for caterpillars fed on Def-1 plants compared to those feeding on WT or Prosys plants (Fig. 1b). The nutritional indices of caterpillars feeding on WT plants were typically intermediate to those of larvae feeding on Prosys and Def-1 plants. (Table 2).

Total Serine Protease Activity Total serine proteases were highest in *T. ni* feeding on the Def-1 plants, intermediate on WT, and lowest on the Prosys plants (One way ANOVA:

Table 1 Mean total dry mass of tomato leaf consumed and dried frass produced by *Trichoplusia ni* feeding for 24 hr on Def-1, wild-type (WT) and Prosys tomato mutants

Plant	Leaf mass[a] mg (S.E.)	Ratio[b] (S.E.)	Frass mass mg (S.E.)	Ratio (S.E.)
Def-1[c]	15.23 (1.34)[A]	1	10.34 (0.49)[A]	1
WT[d]	9.7 (0.65)[A]	0.69 (0.16)	7.14 (0.46)[A]	0.74 (0.14)
Prosys[e]	10.36 (0.78)[A]	0.73 (0.14)	6.17 (0.49)[B]	0.62 (0.13)

[a] Mean (± S.E.) leaf and frass dry mass values having same upper case letter are not significantly different (*two way ANOVA*: $F_{8,69}$=5.57 and $F_{8,69}$=13.62, respectively; *Tukey's P*>0.05).

[b] Mean ratio (± S.E.) for Def-1:Def-1, WT:Def-1 and Prosys:Def-1 are provided for leaf and frass mass.

[c] *N*=27.

[d] *N*=28.

[e] *N*=28.

$F_{8,72}$=13.73; Tukey's P<0.05, Fig. 2). The serine protease activity in leaf samples of all tomato types was 5% or less of the midgut protease activity for larvae feeding on either plant type (data not shown), and therefore cannot be responsible for the observed results.

The estimated value of IC_{50} for Bowman-Birk Inhibitor (BBI) on the midgut total serine protease activity was 2 mg/ml for the insects feeding on WT plants. Saturation of the BBI inhibitor occurred at 8 mg/ml and before 50% inhibition of the Prosys-treated protease midgut activity was reached. At the WT-fed *T. ni* BBI IC_{50} concentration, the level of inhibition was 44% and 31% for the Def-1 and Prosys *T. ni*, respectively (Fig. 3). At this concentration there was greater inhibition of the total serine protease activity in the WT vs. the Prosys *T. ni* midguts (One way ANOVA: $F_{14,30}$=12.86; Tukey's P<0.05). Since BBI is a protease-specific inhibitor, this result indicates that *T. ni* larvae might modify BBI-insensitive proteases to adapt to increasing PI levels in the Prosys plants.

Detoxification Enzyme Activity The total P450 and cytochrome b_5 levels in *T. ni* larvae were unaffected by feeding on the different mutant tomato plants (One way ANOVA: $F_{8,15}$=7.45 and $F_{8,14}$=4.06, respectively; Tukey's P>0.05). No significant differences in the CDNB GST or DCNB GST activity were observed for *T. ni* feeding on the three tomato mutants (One way ANOVA: $F_{8,171}$=61.95 and $F_{8,183}$=5.88, respectively; Tukey's P>0.05).

In general, the *T. ni* 4-methylumbelliferyl acetate esterase, α-and β-naphthyl acetate activity were not affected by plant type (One way ANOVA: $F_{8,180}$= 274.06, $F_{8,195}$=124.49 and $F_{8,243}$=69.21, respectively; Tukey's P>0.05). However, activities of all three larval esterases were significantly higher (Tukey's P<0.05) on the Prosys plants compared to esterase activities of larvae on the other two tomato plants in one of the trials (a different trial for each esterase).

Discussion

Although effects of plant defenses were detected at all stages of caterpillar feeding, they appeared most strongly at the post-digestive stage. Overall caterpillar performance was greater on the Def-1 plants as seen in the significantly higher relative growth rate compared to larvae on WT and Prosys plants. This was due in part to an approximately 30% greater consumption on the Def-1 plants. The consumption index (CI) was lower on Prosys compared to the Def-1 plants, but no different from the wild type plants.

A post-ingestive measure of efficiency, approximate digestability (AD), was greater for *T. ni* that fed on Prosys compared to those on Def-1 plants. This may be a result of the reduced fecal output, likely due to a lowering of the food conversion rate in the midgut of the caterpillars feeding on Prosys plants. The increase in AD may compensate partially for the 2-to 3-fold decrease in efficiency of conversion of both digested (ECD) and ingested food (ECI). These results are comparable with a 3 d trial where *T. ni* larvae fed on Def-1, Prosys, and wild-type tomato plants (unpublished results, J. Thaler). The RGR and ECD for Prosys-fed *T. ni* were much less than the Def-1-fed *T. ni* after 3 d compared to 1 d of feeding, but the relative ECI between the two mutants was the same for the two feeding periods.

Insect larvae often compensate for detrimental digestive effects of their food plants by increasing the approximate digestibility (AD). However, over an 11 d trial, *M. sexta* larvae showed greater leaf consumption and ECD on the LOX3 silenced transgenic *Nicotiana attenuata* (Solanaceae) plants than on WT plants, but AD was no different (Rayapuram and Baldwin 2006). These results are similar in that both *M. sexta* and *T. ni* increase leaf consumption and increase digestibility on jasmonate-deficient plants. However, our study found lowered AD values in larvae feeding on Def-1 and WT plants compared to Prosys plants,

[a] The degrees of freedom, *F* and *P* values are adjusted for the covariate.

[b] The covariate by Plant type interaction for AD and ECI was significant ($P<0.05$), but not for ECD ($P>0.05$)

whereas the *M. sexta* study did not detect any difference in AD in dependence of the food plant. This difference between *T. ni* and *M. sexta* responses to plant types could be due to different jasmonate-regulated traits in tobacco compared to tomato or to differences in the generalist feeder *T. ni* and the specialist feeder, *M. sexta*. In addition, trial length influences the effect of plant type on larval performance and digestion parameters. We observed also that lengthening the feeding period from 1 to 3 d for *T. ni* on tomato WT, Def-1 and Prosys mutants resulted in

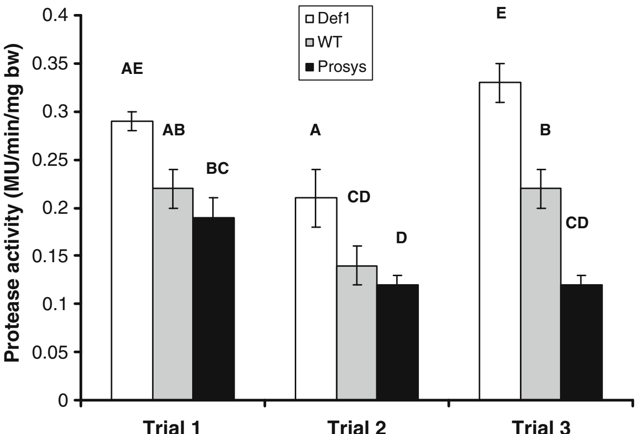

Fig. 2 Serine protease tryptic activity (mU) per min of incubation per mg insect body weight (mU/min/mg bw) in 5th instar *Trichoplusia ni* larvae 24 hr after feeding on three tomato JA mutants in three separate trials. Bars with different shading and the same upper case letter indicate no significant difference between mutants in each trial (two-*way ANOVA*, $P>0.05$). Bars with the same shading and the same upper case letter indicate no significant difference in protease activity for the same mutant between trials (two-*way ANOVA*, $P>0.05$). $N=28$ (Trial 1); 25 (Trial 2), and 28 (Trial 3)

significantly reduced growth and ECD on the Prosys plants, but no difference in AD was detected (unpublished results, J. Thaler).

Further support for the importance of post-digestive stage interference is the reduced serine protease activity in Prosys-fed *T. ni*, compared to those fed on Def-1 plants. There is an inverse relationship between the *T. ni* midgut serine protease levels after 24 hr feeding and the reported levels of defense proteins and enzymes in induced Def-1, WT, and Prosys plants (Howe et al. 1996; Howe and Ryan

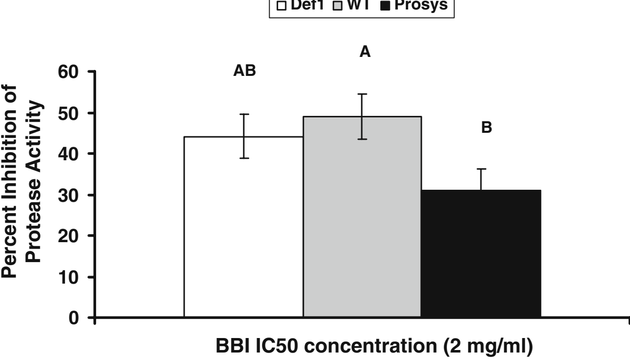

Fig. 3 Percent inhibition of serine protease activity in 5th instar *Trichoplusia ni* larvae after midgut homogenates were incubated with Soybean Bowman-Birk Inhibitor (BBI). Bars with different shading and the same upper case letter indicate no significant difference between mutants (*one way ANOVA*, $P>0.05$). $N=3$ midgut samples per plant type

1999; Li et al. 2002). An inverse correlation between the level of foliar PI activity and larval growth has been observed similarly with both *T. ni* fed on cabbage and *S. exigua* fed on tomato (Broadway et al. 1986; Broadway and Colvin 1992). Prosys plants have constitutively greater levels of PIs, PPO, and other compounds well-characterized by many researchers, so the reduction of serine protease levels in the *T. ni* midguts is just one measurable response that confirms a direct effect of plant nutrients on the insect metabolism. Insects other than the cabbage looper, such as the tomato hornworm, may be more successful herbivores on plants that express higher JA-inducible defenses through their greater ability to compensate for reduced protease levels.

A small compensation for post-digestive interference was detected through the use of the soybean Bowman-Birk inhibitor (BBI) in the present study. To our knowledge this is the first study to examine the effect of BBI on *T. ni* serine protease activity post-feeding on plants expressing a range of PI activity. According to Chougule et al. (2008), BBI has dual specificity towards tryptic and chymotryptic activities. Although the relative amount of trypsin-chymotrypsin activity inhibited by BBI was less in the midguts of the *T. ni* feeding on the Prosys tomatoes, the serine protease activity was reduced to a greater degree than in the midgut of *T. ni* fed on the other two tomato plants. Since we did not isolate the trypsin-like enzymes from *T. ni* that fed on the three tomato mutants, we cannot confirm an increase in the relative proportion of resistant trypsin-like enzymes in the midgut of *T. ni* that fed on the Prosys plants. However, the lower proportion of trypsin-chymotrypsin activity reduced by BBI in the Prosys-fed *T. ni* does agree with the results of a study by Broadway (1995) where *T. ni* fed a diet with cabbage proteinase inhibitors had increased levels of activity from enzymes that were less susceptible to inhibition.

Up-regulation of other proteases may require more than 24 hr, and thus may not be detectable in the WT-fed *T. ni* samples. An increase in the level of proteases with a lower affinity for BBI or the presence of other classes of proteolytic enzymes was thought to be the reason for the lower BBI-inhibitory activity in *Heliothis obsolete* feeding on hemizygote transgenic tomato plants compared to control plants (Abdeen et al. 2005). Those authors suggested that the 1.6-fold increase in BBI-insensitive digestive proteases in *H. obsolete* was a compensation for the partial loss of activity caused by the presence of the introduced serine protease inhibitors in the transgenic tomatoes. The differences between the two studies suggests that BBI may have an effect on a different range of trypsin proteases present in *T. ni* compared to *H. obsolete*, some of which might be up-regulated in response to induced tomato PI levels. Another possibility may be that the protein substrate casein does not reflect quantitatively the activity of the PI-insensitive proteases (Jongsma and Bolter 1997).

Among the many JA-pathway inducible compounds, PPO has a direct effect on digestive processes in insects by decreasing the availability of essential amino acids in the insect gut, considered to be an anti-nutritive effect (Barbehenn et al. 2007). This is different from the effect produced by PIs, since a reduction in protease activity is considered an anti-digestive effect. Despite these differences, tomato mutants that overexpress PPO had a similar negative effect on insect growth, consumption rate, ECD, and ECI (Mahanil et al. 2008) observed in the present study.

A toxic effect or combined mechanism of action that negatively impacts the post-digestive processes cannot be ruled out. However, there was no difference in the levels of cytochrome P450/b_5 and GST, and only small, inconsistent increases in esterase activity in the *T. ni* that fed on the Prosys tomatoes. Induction of insect monooxygenases by phenolic compounds such as indoles and flavones has been described by Yu (1984). However, for both a specialist and a generalist insect fed on transgenic tobacco lines, no correlation between foliar levels of phenolics (chlorgenic acid, rutin, and total flavonoids) and larval growth and survival was noted (Bi et al. 1997). Chlorogenic acid, rutin, and α-tomatine are phenolics found at toxic levels in tomato leaves (Elliger et al. 1981), but detoxification enzyme levels have, to our knowledge, never been measured after insect exposure to these compounds. In selected plant systems, induced monooxygenase or glutathione levels can play a role in the insect response to plant toxins, for example induced GST activity as a generalized detoxification response to plant allelochemicals (Yu 1982, 1984; Wadleigh and Yu 1987; Francis et al. 2005). In the present study, there was no affect on the levels of cytochrome P450/b_5 or glutathione transferases associated with feeding on the three tomato mutants. This confirms the importance of proteins as an induced defense in tomato, rather than alkaloids, in order to reduce herbivory.

We conclude that pre and post-ingestive processes work together to reduce insect growth on plants with high levels of jasmonate regulated defenses. JA-mediated plant responses directly impact midgut protein digestion at least in part through increased defense proteins (PIs) and oxidative enzymes (PPO). In this study, the reduction in serine proteases and the ability of the insect to absorb nutrients for growth was decreased significantly in defended plants, as exemplified by the lower efficiency of conversion of absorbed and ingested food on Prosys-fed versus Def-1-fed *T. ni*. Based upon what we know of the post-digestive stage, a reduction in ECI and ECD indicates that the insect is not able to obtain the necessary essential

macronutrients for growth. In the present case, we have empirical evidence that suggests an anti-digestive effect is occurring since there is a reduction in the protease activity in the insect gut. However, evidence from prior studies with the Prosys mutant details the significantly greater production of PPO relative to the wild-type, a factor that has an anti-nutritive effect. One of the two expectations of this study was met: post-digestive processes were significantly affected by JA-induced defenses due to both anti-digestive and anti-nutritive activity, whereas the toxic affect from tomato allelochemicals did not produce a measured response in the insect.

Abstract Cucumber plants (*Cucumis sativus* L.) respond to spider–mite (*Tetranychus urticae*) damage with the release of specific volatiles that are exploited by predatory mites, the natural enemies of the spider mites, to locate their prey. The production of volatiles also can be induced by exposing plants to the plant hormone jasmonic acid. We analyzed volatile emissions from 15 cucumber accessions upon herbivory by spider mites and upon exposure to jasmonic acid using gas chromatography—mass spectrometry. Upon induction, cucumber plants emitted over 24 different compounds, and the blend of induced volatiles consisted predominantly of terpenoids. The total amount of volatiles was higher in plants treated with jasmonic acid than in those infested with spider mites, with (*E*)-4,8-dimethyl-1,3,7-nonatriene, (*E,E*)-α-farnesene, and (*E*)-β-ocimene as the most abundant compounds in all accessions in both treatments. Significant variation among the accessions was found for the 24 major volatile compounds. The accessions differed strongly in total amount of volatiles emitted, and displayed very different odor profiles. Principal component analysis performed on the relative quantities of particular compounds within the blend revealed clusters of highly correlated volatiles, which is suggestive of common metabolic pathways. A number of cucumber accessions also were tested for their attractiveness to *Phytoseiulus persimilis*, a specialist predator of spider mites. Differences in the attraction of predatory mites by the various accessions correlated to differences in the individual chemical profiles of these accessions. The presence of genetic variation in induced plant volatile emission in cucumber shows that it is possible to breed for cucumber varieties that are more attractive to predatory mites and other biological control agents.

Introduction

Cucumis sativus L. is grown in nearly all temperate regions and is one of the ten most widely cultivated vegetable species, ranking fourth after tomato, onion, and cabbage (Tatlioglu 1993). Cucumber is indigenous to India, and its domestication started there approximately 3,000 years ago, followed by spreading into Western Asia and then southern Europe. In cucumber breeding programs, genotypes are selected for improved performance in specific environments (greenhouse, field, single, or multiple harvest), as well as for intended use (processing, fresh market), consumer preference (fruit shape and quality), pest and diseases

resistance, abiotic stress tolerance, and high fruit yield. It has been observed that the genetic base of commercial cucumber germplasm is not very broad (Staub and Meglic 1993). Despite the agricultural and biological importance of cucurbits, knowledge of their genetics and genome currently is limited (Huang et al. 2009). Moreover, the historical reservoirs of genetic variation in cucumber, such as India (primary center), Burma, and Southern China (secondary center), are subject to genetic erosion (Tatlioglu 1993). So far, plant breeders have hardly selected for crop characteristics that influence the success of biological control (but see Van Lenteren and De Ponti 1990) even though it is obvious that for successful biological control it is important that biological control agents also can find the herbivores, at low densities (Dicke 1999).

Plants respond to herbivore feeding with the production of volatiles that natural enemies use as cues to locate the herbivores. This phenomenon has been observed in various tritrophic systems and is an important mechanism by which plants defend themselves against herbivorous insects (e.g., Dicke and Van Loon 2000; Arimura et al. 2005; Dudareva et al. 2006; D'Alessandro and Turlings 2006; Mumm and Hilker 2006; Hilker and Meiners 2010). Induced defenses allow plants to be cost-effective and also to diminish the risk that herbivores will adapt to plant defenses (Heil 2008; Steppuhn and Baldwin 2008). Plants exhibit variation in these traits, which comprises both intra-individual phenotypic plasticity and genetic polymorphisms among individuals and populations. The plasticity of inducible defense allows individual plants to adapt to changing environments (Agrawal 2001). Polymorphism in traits for resistance against herbivory may result from varying selection pressures among populations.

Herbivory Induced Plant Volatile (HIPV) blends vary considerably both in quantity and quality with plant species or plant varieties (Krips et al. 2001; Hoballah et al. 2002; Degen et al. 2004; Van den Boom et al. 2004; Bukovinszky et al. 2005; Lou et al. 2006). This may result in differences in the degree of attraction of natural enemies of the herbivores (Krips et al. 2001; Hoballah et al. 2002; Bukovinszky et al. 2005; Lou et al. 2006). Knowledge of which of the induced volatiles have ecological significance may aid eventually the development of methods to enhance the attractiveness of crop varieties to beneficial arthropods. Typical plant volatiles that are induced by herbivory are green leaf volatiles: C6-alcohols, -aldehydes and -acetates; phenylpropanoids such as methyl salicylate; and various monoterpenes and sesquiterpenes, as well as two homoterpenes: (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) (Arimura et al. 2005; Dudareva et al. 2006). Green leaf volatiles are fatty acid derivatives that result from the lipoxygenase pathway (D'Auria et al. 2007). Terpenoids are synthesized either via the cytosolic mevalonate (MVA) pathway or via the methylerythritol 4-phosphate (MEP) pathway in the plastids (Aharoni et al. 2005; Rodríguez-Concepción 2006).

The objectives of this study were to explore the variation among cucumber accessions with respect to herbivory-induced volatile emission and to determine to what extent differences in volatile profiles affect the attraction of predatory mites. We compared the volatile emission of various cucumber accessions in response to spider-mite (*Tetranychus urticae*) infestation and jasmonic acid treatment, as well as the attractiveness of a number of these accessions to the predatory mite *Phytoseiulus persimilis*.

To take differences in direct defense into account, e.g., due to differences in cucurbitacin C content (Balkema-Boomstra et al. 2003), jasmonic acid was used to standardize the level of induction, as the production of many induced volatiles is mediated by the jasmonic acid signalling (Dicke et al. 1999; Gols et al. 1999; Degenhardt and Lincoln 2006; Ozawa et al. 2008). Previous work demonstrated that spider–mite infestation and jasmonic acid both induce similar components in the volatile blend of cucumber, albeit in different amounts and at a different time scale (Bouwmeester et al. 1999; Mercke et al. 2004).

Methods and Materials

Plants, Herbivores and Predators Cucumber (*Cucumis sativus*) seeds were obtained from the Centre for Genetic Resources, the Netherlands (CGN), which is part of Wageningen University and Research Centre. As there is little to no information about genetic variation in relation to induced volatiles in cucumber, seven accessions were chosen as representative of various places of origin. In addition, eight cucumber F1-hybrids from commercial breeders were chosen. Seeds were sown and grown at 22–23°C, 60–70% relative humidity, and 16 hr of light per day in a greenhouse at Wageningen University, The Netherlands. SON-T lamps were used to supply extra light when the natural light intensity decreased below 250 μmol m^{-2} sec^{-1}. Plants used for experiments were 3–4-wk-old and had four or five fully expanded leaves.

Two-spotted spider mites, *Tetranychus urticae* Koch, were reared on lima bean plants (*Phaseolus lunatus*) in a greenhouse at 24±4°C, 60±20% relative humidity and a 16:8 hr, L:D photoperiod. For spider mite-infestation, approximately 50 adult female spider mites were evenly distributed on the adaxial side of fully expanded leaves with a fine brush.

Predatory mites, *Phytoseiulus persimilis* Athias-Henriot, were reared on spider mite-infested lima bean leaves to exclude that predator behavior could be influenced by exposure to cues emitted from one specific cucumber accession above others (Dicke et al. 1990b; Takabayashi

and Dicke 1992). Predators were reared in a growth chamber at 23±1°C, 60±10% RH and continuous light. Before experiments, females were starved individually in 1.5 ml microcentrifuge tubes for 3±0.5 hr at 23±1°C.

Application of Jasmonic Acid Plants were sprayed with a 0.5 mM (±)-JA solution (Sigma–Aldrich, St. Louis, MO, USA) with 0.01% Tween-20 using an aerosol spray bottle until completely wet (ca 5 ml per plant). Mock treated plants were sprayed with water containing 0.01% Tween-20. JA-sprayed plants were separated from control and spider–mite infested plants in a different greenhouse compartment but under the same environmental conditions.

Collection and Analysis of Induced Cucumber Volatiles To allow valid comparison of the composition and quantities of the volatiles, headspace samples were collected from all accessions at the same time during the photoperiod. As there were several experiments in different periods of the year, the variety 'Hybrid C' was used as a reference in all experiments. Individual plants were enclosed in glass cuvettes (2.5 l) with a viton-lined lid equipped with an inlet and an outlet and placed in a climate room at 21±1°C and a light intensity of 120 µmol m^{-2} sec^{-1}. A vacuum pump was used to draw air through the glass cuvette at approximately 100 ml min^{-1} with the incoming air being purified through a cartridge containing 200 mg of Tenax TA (20/35-mesh, Alltech). At the outlet, the volatiles emitted by the plants were trapped on a similar cartridge. For quantification of the volatiles released, carvone and benzyl acetate in hexane were added as internal standards in a T-shaped glass liner placed between the cuvette and the Tenax outlet. For spider–mite infested plants, 600 ng of each compound were added to the cuvette, whereas in case of JA-treated plants, 6 ng were added. Volatiles were sampled for 3 hr. Volatiles from at most 11 accessions were collected simultaneously, and five replicate samples were collected for each accession over time (Hybrid C 12 times). To check for background volatiles, released by e.g., materials used, volatiles from empty jars were trapped as well. The amounts of the 24 dominating compounds were quantified in area units under the curve, and were corrected using the response factors of each compound towards the internal standard closest in retention time. For compounds for which we did not have a standard, we estimated the amounts emitted based on the average response factor of compounds between RI 850 and 1,000 (for compounds d, e, and f); on the response factor of (*E*)-β-ocimene (for compound k), or on the average response factor of homo- and sesquiterpenes q, t, w, and x (for compounds r, u, and v).

Gas Chromatography—Mass Spectrometry Headspace samples of cucumber plants were analyzed on a Hewlett–Packard GC-MS or on a Trace GC Ultra™ (Thermo Electron Corporation, Austin,TX, USA) equipped with a Trace DSQ quadrupole mass spectrometer (Thermo Electron Corporation, Austin,TX, USA). For this, Tenax cartridges either were eluted using 3×1 ml of re-distilled pentane : diethyl ether (4:1) or released from Tenax traps using a thermal desorption cold trap setup (TDS; UNITY™, Markes international LTD, UK). After elution, samples were concentrated to about 30 µl, of which 2 µl were analyzed by GC-MS using a gas chromatograph (5,890 series II, Hewlett–Packard) equipped with a 30-m× 0.25-mm i.d., 0.25-µm film thickness column (5MS, Hewlett–Packard) and a mass-selective detector (model 5972A, Hewlett–Packard). The GC was programmed at an initial temperature of 45°C for 1 min, with a ramp of 10°C min^{-1} to 220°C, and final time of 5 min. The injection port (splitless mode), interface, and MS source temperatures were 250°C, 290°C, and 180°C, respectively, and the He inlet pressure was controlled with an electronic pressure control to achieve a constant column flow of 1.0 ml min^{-1}. The ionization potential was set at 70 eV, and scanning was performed from 30 to 250 amu.

Tenax cartridges analyzed on the Trace GC were first dry-purged with helium at 100 ml min^{-1} for 10 min at ambient temperature to remove any water. Volatiles were released from Tenax traps using a thermal desorption cold trap setup by heating at 250°C for 3 min, with a He flow of 30 ml/min. Desorbed volatiles then were transferred to an electronically-cooled focusing trap at −10°C within the TDS. Volatiles were injected in splitless mode into the analytical column (Restek, RTX 5MS, 30 m 0.25 mm i.d., 1.0 µm *df*) by heating the cold trap to 300°C. The GC was held at the initial temperature of 40°C for 3.5 min followed by a linear thermal gradient of 10°C/min to 280°C, and held for 2.5 min with a He flow of approximately 1 ml/min. The column was coupled directly to the ion source of the DSQ quadrupole mass spectrometer, which was operated in the 70 eV EI ionization mode and scanned from mass 45 to 400 amu. An auto sampler was used for the automatic desorption of the Tenax traps (UltrA™, Markes international Ltd, UK). The TC-20 Multi-tube conditioning unit (Markes International Ltd, UK) was used for cleaning the cartridges in between the measurements by heating them to 310°C for 40 min under a He flow. Compounds were identified by comparing the mass spectra with the Wiley and NIST mass spectral libraries and by comparing retention indices with Adams (1995). Headspace samples of plants exposed to spider–mite infestation in a time-series experiment were analyzed on the HP-GC-MS, whereas for the experiment where the headspace from JA-treated plants were compared to the headspace of spider–mite infestations was analyzed by thermodesorption GC-MS.

Olfactometer Set-up and Predatory Mite Bioassay To compare the responses of predatory mites to the induced volatiles of a selection of accessions we used a closed Y-tube olfactometer as previously described (Takabayashi and Dicke 1992; Bukovinszky et al. 2005). Odor sources consisted of a single plant with 4–5 leaves that were infested with 50 spider mites 1 wk prior to the experiment or induced with JA 24 hr prior to the experiment. Experiments compared plants of different accessions that both were infested with spider mites or that were both induced with JA. For each accession, induced plants also were tested against non-induced plants. Individual female predators were released on an iron wire in the basal tube, and their behavior was observed for a maximum of 5 min. The connections of the odor sources to the arms of the olfactometer were interchanged after testing a series of five predators. A choice was recorded when the finish line, halfway up one of the olfactometer arms, was reached within this period. Otherwise it was recorded as no-choice. Each predator was used only once. Per experimental day, 20 predators were tested for each odor combination, and each experiment was repeated on 3–5 different days.

Statistical Analysis Not all volatiles were detected in every replicate of every accession. To be able to determine ratios among accessions and allow log-transformation of data, we added 1,000 area units to all data points, representing the lowest recorded non-zero value. A number of volatiles were not included in the data analysis because they occurred in one or two accessions only, with an abundance of less than 0.1% of the total volatile production.

Peak areas of all compounds were corrected for fresh weight of the leaves. Per compound, the *Student's t-test* was used to determine whether the compound was induced significantly by herbivory. Experiments were conducted over a period of 2 yr. To correct for the inevitable variation in the absolute amounts of individual volatiles, emissions are given as least-squares means as calculated by two-factor ANOVA, with experimental period as the second factor.

Standard Pearson correlation coefficients were determined among individual accessions for each volatile and a *Student's t-test* was used to determine the significance of these correlations. Cluster and correlation analysis also were performed using Genemaths (Applied Maths, Sint-Martens-Latem, Belgium). Principal component analysis (PCA) involves a mathematical procedure that transforms a number of possibly correlated variables into a smaller number of uncorrelated variables called principal components. PCA gives complementary information to ranking lists based on correlation coefficients to specific volatiles. The significance level for correlations was set at $P<0.05$. To comply with ANOVA assumptions, all volatile emission data were log-transformed and normalized (mean of complete data-set set to zero) by dividing by the average volatile emission rate calculated from all experiments.

The choices of predatory mites between odor sources in the Y-tube olfatometer were analyzed with two-sided binominal tests to determine whether the distribution of the predators' choice was significantly different from 50:50. Predators that did not make a choice were excluded from the statistical analysis.

Results

The headspace of cucumber plants induced by spider–mite feeding or treatment with JA consisted of a maximum 24 volatile compounds that collectively represented more than 98% of the total emission of cucumber leaf volatiles (Table 1). Most of these compounds were not detected in the headspace of non-induced plants, except for nonanal, decanal, limonene, (*E*)-2-hexenal, and (*Z*)-3-hexenyl acetate, which were present also in trace amounts in non-induced plants. Methyl jasmonate and jasmone sometimes were detected in the headspace of JA-treated plants, but not in the headspace of mite-damaged plants. Because these two compounds likely are a direct consequence of the JA treatment, they were not included in the statistical analyses.

No visual damage was observed after JA-treatment, whereas spider–mite damage led to a decrease of about 8–14% of the chlorophyll content during a 7-d-period of feeding (data not shown). Feeding damage was sufficient to cause an increase in the total amount of volatiles from day 1 onwards (Fig. 1). Progressing infestation of the mites increased volatile release with time (Fig. 1). JA-application resulted in the release of volatiles from treated leaves within 2 hr and was maximal after 2–3 d (Table 2). The total emission of volatiles varied strongly among the various accessions, ranging from about 80 ng per plant to over 6 μg per plant (Table 2). After 3 d, the volatile emission rate diminished (data not shown).

Mite feeding and JA application both increased the emission of many compounds. By far, the most abundant compounds in plants induced either by *T. urticae* infestation or by JA treatment were DMNT, (*E*)-β-ocimene, (*E,E*)-α-farnesene, and (*Z*)-3-hexenyl acetate (Fig. 2). However, there is a large range of variation among accessions for all compounds (Table 1, Fig. 2). The majority of induced compounds were terpenoids: about 75% of the total volatile blend, consisting of six monoterpenoids [α-phellandrene, thujene, (*Z*)-β-ocimene, (*E*)-β-ocimene, limonene, linalool], two homoterpenes [DMNT, TMTT], and five sesquiterpenoids [(*E*)-β-caryophyllene, (*E,E*)-α-farnesene, and three unknown sesquiterpenoids]. The remaining compounds were an aldehyde, two alcohols, three acetate

esters, one nitrogen-containing aromatic compound, and two oximes. Most of these were released into the headspace within hours after the application of JA or within 1 d after spider–mite feeding started.

Experiments were performed during a 2-yr-period, and thus we have to deal with large absolute differences in volatile release. We, therefore, first analyzed volatile release of accessions for the relative contributions of individual compounds and found that these were rather constant over different experiments. Thus, the relative amount of e.g., (*E*)-β-ocimene varied between 35% and 40% in Hybrid T, 15–25% in CGN20890 and 9–16% in Hybrid C, and for DMNT, 25–32%, 4–8%, and 28–33%, respectively. Furthermore, (*E*)-β-caryophyllene never was detected in headspace samples of Hybrid C and CGN20890, but it was detected in all samples of Hybrid T (1.5–5%). We, therefore, decided to use the data on the relative amounts from the different experiments within one multivariate analysis.

PCA is used in statistics to extract the main relationships in data of high dimensionality. The first axis of the PCA accounted for 42% of the total variation recorded in JA-induced plants. It was positively correlated with the quantity of all compounds that was included as a factor in the analyses and hence separated the accessions according to the total volatile emission. Therefore, we focused rather on the proportions of the compounds in the blend, as this may lead to a better distinction between different accessions. The second axis of the PCA accounted for 17% of the total variation recorded in JA-induced plants (Fig. 3). This component was correlated positively to the proportion of DMNT in the induced blend and roughly separated the European hybrids from the Asian and African landraces (Fig. 3). Indeed, European hybrids ranged from 11% to

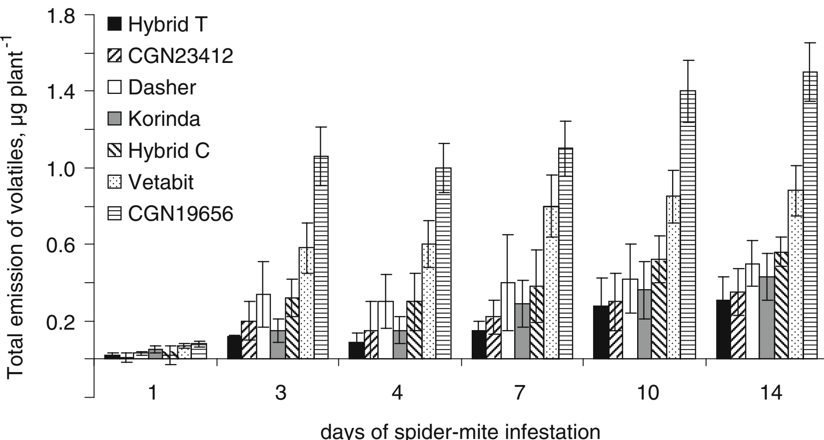

Fig. 1 Total amount of volatile compounds, i.e. the sum of 24 volatile compounds, Mean±SE emitted by 3-wk-old *Cucumis sativus* plants of seven different accessions in response to spider–mite feeding during 14 d. From *left* to *right*: accessions Hybrid T, CGN23412, Dasher, Korinda, Hybrid C, Vetabit and CGN19656. Headspaces were sampled on day 1, 3, 4, 7, 10 and 14 after infestation

56% DMNT in the volatile blend, whereas the accessions from Asia and Africa emitted only 15% to less than 1% of DMNT. The high proportion of DMNT in the European hybrids is correlated to a relatively low proportion of (*E*)-β-ocimene and (*E,E*)-α-farnesene in the volatile blends (Figs. 2, 3, Table 1).

A volatile-volatile matrix based on Pearsons correlation shows clusters of compounds whose proportions in the blend were correlated (positively): (*E*)-β-ocimene, (*E,E*)-α-farnesene, and an unknown sesquiterpenoid one (mutual Pearson correlations of >0.93) cluster strongly together (Fig. 4). A second cluster was formed by limonene, thujene, and α-phellandrene (mutual Pearson correlations >0.80) (Fig. 4). These three volatiles also clustered in the loading plot of the PCA (Fig. 3).

Responses of Predatory Mites We tested the preferences of the predatory mite *Phytoseiulus persimilis* for the volatile blends of a selection of accessions of spider-mite infested and JA-treated plants in a Y-tube olfactometer. Two hybrids were selected that had either a low (hybrid T) or a high volatile emission rate (hybrid C). Furthermore, three landraces were selected, among them the lowest (CGN19821) and the highest (CGN19656) emitter of all accessions used in this study. For all selected accessions, the predatory mites significantly preferred volatiles induced by spider mites or jasmonic acid to blends of non-induced plants (data not shown). Accessions CGN23412, Hybrid C, and Hybrid T were infested with 50 spider mites on each plant and tested against each other 7 d after the onset of infestation. Preferences of predatory mites could be ranked

Fig. 2 Relative contribution of individual volatile compounds to the total volatile blend of different *Cucumis sativus* accessions 2 d after treatment with JA (0.5 mM; 15 accessions) or after 7 d of spider–mite infestation (Sp, seven accessions)

from CGN23412 > Hybrid C > Hybrid T ($P<0.01$; Fig. 5). Although Hybrid C had the highest total release of volatiles (Fig. 1), this did not result in the strongest attraction of predatory mites. The individual volatiles of the mite-infested plants could be ranked according to their attractiveness to predatory mites. This ranking was correlated positively with the relative amounts of (*E*)-2-hexenal, (*E*)-β-ocimene, (*E*)-β-caryophyllene, and (*E,E*)-α-farnesene in the volatile blend (Fig. 5b).

In a parallel experiment, a selection of accessions were treated with JA and used in the Y-tube olfactometer at different times after the onset of the treatment (Fig. 6). Predatory mites preferred the volatiles released by JA-treated CGN19656 above those of Hybrid C, Hybrid T, or CGN19821. The preference was maximal 2–3 d after JA application and diminished afterwards (Fig. 6). As CGN19656 was by far the highest emitter of volatiles (Table 1), this preference is correlated strongly with the

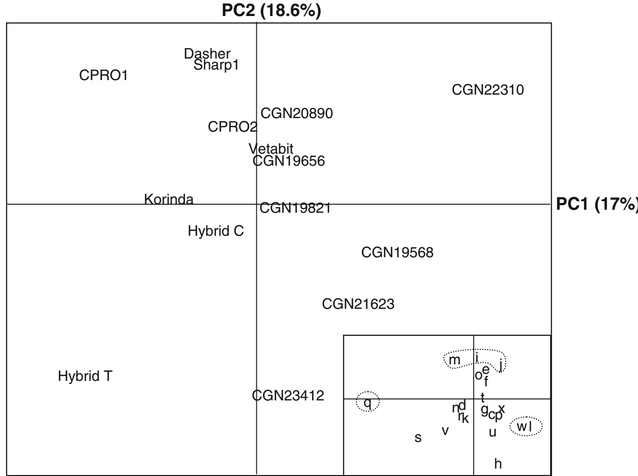

Fig. 3 Principal component analysis based on Pearson's correlations: the second principal component PC2 versus the third principal component PC3 of JA-induced volatiles in cucumber. *Inset* shows the loading plot, *letters* indicate individual volatile compounds, as explained in Table 2. *Dotted circles* indicate those volatiles that are discussed in the text

absolute amount of induced volatiles. Therefore, it is valuable to study the difference between e.g., Hybrid T and CGN19821, that both emit low amounts of volatiles (Table 2). In this case, volatiles released by CGN19821 were significantly more attractive to predatory mites 2 and 3 d after JA application (Fig. 6). CGN19821 had significantly higher proportions of 3-methyl-butanal-*O*-methyloxime, (*E*)-β-ocimene, and (*E*)-β-caryophyllene in its blend, whereas the blend of Hybrid T was relatively rich in (*Z*)-3-hexenyl acetate and DMNT (Fig. 2). The blend of Hybrid C also was more attractive than that of Hybrid T on day 3 (Fig. 6). Hybrid C is relatively rich in (*E,E*)-α-farnesene and TMTT, and low in (*Z*)-3-hexenyl acetate as compared to the blend of Hybrid T (Fig. 2).

Discussion

Varietal or genotypic differences in herbivore-induced plant volatiles have been studied primarily in cultivars of agricultural crops, including cotton (Loughrin et al. 1995),

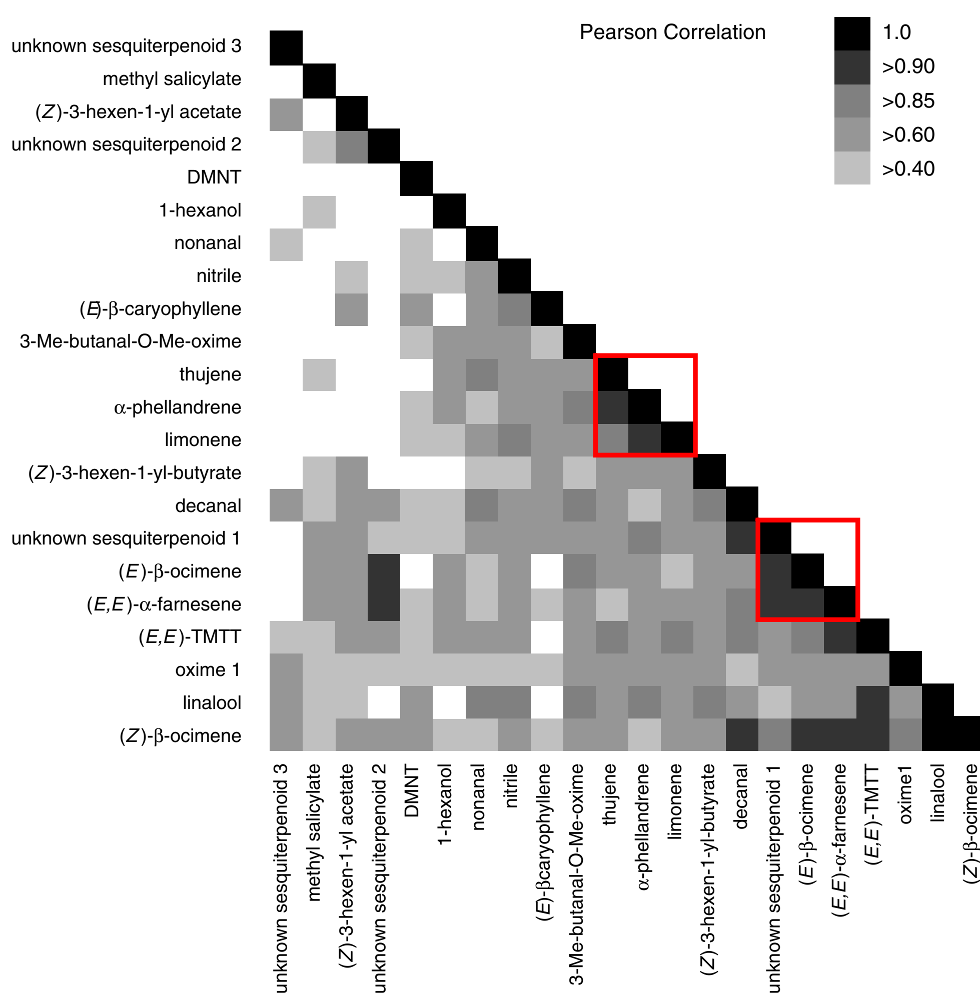

Fig. 4 Volatile—volatile correlation matrix of the 24 compounds emitted by JA-treated cucumber plants. Correlations between volatiles are shown in *gray scale*: the darker the gray color, the higher the percentage of similarity between metabolite expression patterns. *Lined boxes* show those clusters that are discussed in the text

gerbera (Krips et al. 2001), pear (Scutareanu et al. 2003), maize (Hoballah et al. 2004), carrot (Nissinen et al. 2005), rice (Lou et al. 2006), and cruciferous crops (Bukovinszky et al. 2005). In a study that used 31 maize hybrid lines, for example, about 70-fold variation in the quantity of volatiles emitted was found (Degen et al. 2004). The significance of such variation in volatile production among different accessions with respect to the attraction of natural enemies can be evaluated only by behavioral bioassays. For some natural enemies, differential attraction to the odors of

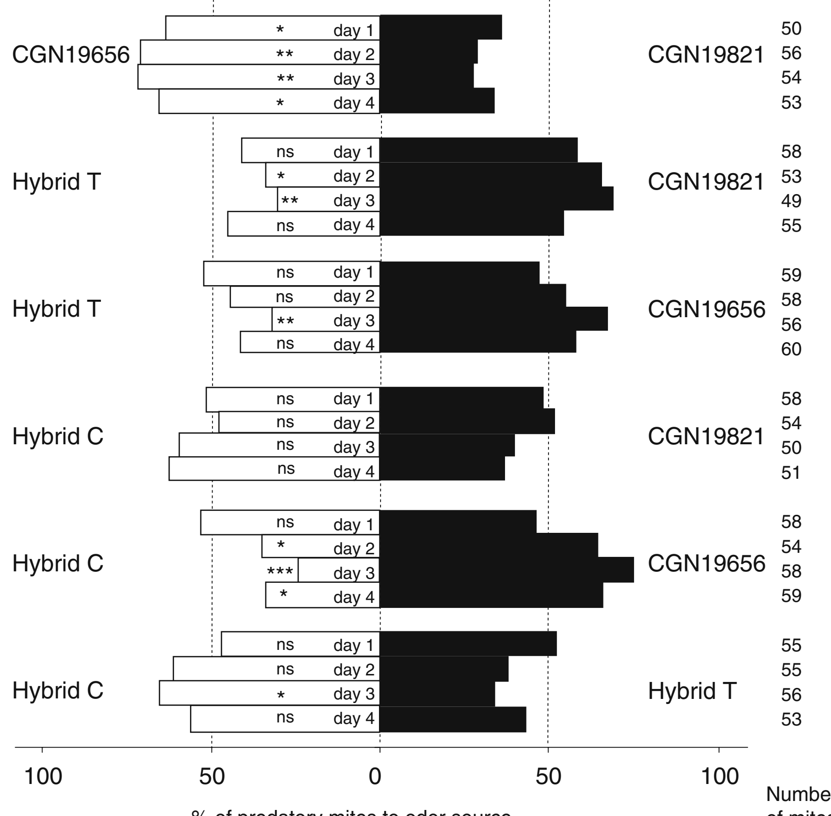

Fig. 6 Relative preferences of *Phytoseiulus persimilis* for headspace of three different *Cucumis sativus* accessions sprayed with 0.5 mM jasmonic acid. Bioassays were conducted three times during 4 d following JA treatment (day 1, 2, 3, 4 since JA treatment, as indicated in the *bars*). *Asterisks* indicate level of significance, as tested with a two-sided binomial test: *ns*, not significant, $*P<0.05$, $**P<0.01$, $***P<0.001$. Numbers of mites are those mites that made a choice for one of either odor sources

particular accessions has been demonstrated (Krips et al. 2001; Hoballah et al. 2002; Bukovinszky et al. 2005). Here, we showed that differences in induced volatile profiles also exist among cucumber accessions and have consequences for predator attraction.

Uninduced cucumber plants released less than 3% of the volatiles emitted by induced plants with (*E*)-2-hexenal and (Z)-3-hexenyl acetate as predominant compounds (Table 2). There were no pronounced differences in the composition of the volatiles collected from undamaged leaves of the European F1-hybrids and landraces from Asia and Africa. The release of these compounds is caused probably by minor damage due to handling of the plants.

The release of induced volatiles varied from 80 ng to over 6 µg per plant after JA application. *Tetranychus urticae* infestation did not cause a similar increase in volatile production, likely because feeding damage is progressing relatively slowly with the development of the mite population, and the plant can adapt to the changing situation, whereas JA application quickly activates the whole signalling cascade to a maximum within 2–3 d. JA application was used to standardize the level of induction and, therefore, is a more accurate induction treatment to investigate potential differences in induced volatile production among various accessions.

A total of 24 compounds, representing approximately 98% of the trapped volatiles, were identified. The majority of the volatile blend consisted of terpene hydrocarbons, with the most abundant components being the monoterpene (*E*)-β-ocimene and the homoterpene (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) Also, the sesquiterpene (*E,E*)-α-farnesene and another homoterpene (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) were among the most abundant volatiles in the released blend. The homoterpenes DMNT and TMTT result from oxidative degradation of the sesquiterpenoid nerolidol and the diterpenoid geranyllinalool, respectively (Gäbler et al. 1991). Although both nerolidol and geranyllinalool are volatile, we detected only nerolidol occasionally in the volatile blend of some of the accessions used, indicating an efficient conversion of the alcohols into the homoterpenes. In other species, like e.g., maize and rice, nerolidol has been found in the herbivory-induced blend, but always together with the degradation product DMNT (Degen et al. 2004; Lou et al. 2006). Besides nerolidol, the only other terpene alcohol detected was linalool, which was found in six accessions. In induced volatile blends of many plant species, linalool is the only terpene alcohol, although in Norway spruce α-terpineol, camphenilol, and borneol also were found (Martin et al. 2003).

Compared to previous studies (Dicke et al. 1990a; Bouwmeester et al. 1999; Mercke et al. 2004), we detected a number of new herbivory-induced volatiles: 2-hexanal, linalool, methyl salicylate, β-caryophyllene, α-phellandrene, thujene, and three unknown sesquiterpenoids in some of the accessions. These differences may be due to treatment differences. Herbivore- or elicitor-induced volatile release varies with time and treatment, applied amount of elicitor (Halitschke et al. 2000), and the herbivore damage level (Gouinguene et al. 2003). In our study, spider–mite infestation and JA treatment led to qualitative as well as quantitative differences in the volatile profile (Fig. 2). The volatile components released by the accessions used due to spider–mite infestation also were detected in the blend of JA-treated plants, although in most of the accessions JA-treatment led to the emission of a larger number of compounds than were emitted in response to spider–mite feeding (Fig. 2). Exceptions are (*Z*)-3-hexen-1-yl butyrate and an unknown sequiterpenoid, which were found in the headspace of spider–mite infested plants of accessions Dasher and Korinda, respectively, but not in the blends of JA-treated plants of these accessions. Apparently, spider mites are not capable of triggering the whole induced volatile potential that cucumber plants have, and JA application resulted in a more 'JA-specific volatile response' that does not mimic exactly the herbivore-induced volatile blend. Herbivore damage likely influences alternative defense pathways that control volatile emission (De Boer and Dicke 2004). Herbivores with piercing-sucking mouthparts may induce more salicylic acid (SA)-mediated defense genes compared to chewing herbivores (Leitner et al. 2005; Zhang et al. 2009). The SA and JA signal-transduction pathways may interact (Pieterse et al. 2009) and lead to different induced volatiles blends

By using PCA based on Pearson correlations on least square means of absolute amounts, the accessions investigated were separated principally on the basis of total volatile emission. Therefore, we focused on the proportions of the compounds in the blend, as this may lead to a better distinction between accessions. The accessions used are not genetically characterized, but quite randomly selected. Nonetheless, our PCA data show a clear difference between European F1-hybrids and the landraces from Asia and Africa, mostly distinguished by the proportions of DMNT, (*E*)-β-ocimene, and (*E,E*)-α-farnesene in the odor blend (Fig. 3). Our results show that, at least for this limited selection of accessions, the European F1 hybrids have lost the capacity to produce large amounts of (*E*)-β-ocimene and (*E,E*)-α-farnesene. As a 'chemical signature' is determined by relative amounts, the consequence is that the induced blends of European hybrids are characterized by a relatively higher proportion of DMNT.

Several compounds identified in cucumber volatile blends could be clustered by using a Pearson correlation matrix. With the exception of (*E*)-β-ocimene, the principal volatile emitted in ten accessions, the emission rates of the

non-alcohol monoterpenes, limonene, α-phellandrene, and thujene were mutually correlated, suggesting that these three monoterpenes may be formed by a single enzyme that is induced upon herbivory. Indeed, several multiproduct synthases have been cloned, e.g., from maize (Köllner et al. 2004), Arabidopsis (Tholl et al. 2005), and *Medicago truncatula* (Arimura et al. 2008). Multi-product terpene synthases significantly contribute to the plasticity of blends and are increasingly found in plants, especially in the context of herbivory (Köllner et al. 2004; Tholl et al. 2005; Arimura et al. 2008). Interestingly, the monoterpene (*E*)-β-ocimene does not correlate with the other monoterpenes, but it is correlated positively with the sesquiterpene (*E,E*) α-farnesene, and another unknown sesquiterpene (Pearson coefficient=0.97). This matches well with previously published data that show that the (*E,E*)-α-farnesene synthase cloned from spider mite-induced cucumber plants also catalyzes the formation of (*E*)-β-ocimene from geranyl diphosphate (Mercke et al. 2004). Furthermore, the (*E,E*)-α-farnesene synthase also produced sesquiterpene in enzymatic assays with a similar RI as 'unknown sesquiterpenoid one' detected in this study. This gene possesses a plastid targeting peptide and hence is likely to produce (*E*)-β-ocimene when activated/induced by herbivory. Indeed, in time course studies, (*E*)-β-ocimene is among the first volatiles released by cucumber (Bouwmeester et al. 1999; Mercke et al. 2004). When herbivory progresses, other volatile compounds are released, amongst them (*E,E*)-α-farnesene. These results suggest then farnesyl diphosphate becomes available in the plastids. To date, increasing evidence is accumulating that the plastidial MEP pathway also may significantly contribute to cytosolic sesquiterpene biosynthesis by allowing IPP to be shuttled between cell compartments (Bick and Lange 2003). Aharoni et al. (2003) suggest that FPP is available in the plastids, based on the observation that transgenic *Arabidopsis* plants harboring a heterologous sesquiterpene synthase from strawberry emit low amounts of the sesquiterpene (*E*)-nerolidol. The exact mechanism remains to be elucidated.

Jasmonic-acid-induced volatiles of accessions CGN19656 and CGN19821 were significantly preferred by *P. persimilis* predatory mites over those of Hybrid T and Hybrid C. As CGN19656 is by far the highest emitter of volatiles, it is not unexpected that this landrace is highly attractive. In contrast, CGN19821 is a landrace that releases low amounts of volatiles, but its blend attracts more predators than the JA-induced blend of Hybrid T, and is equally attractive to the blend of Hybrid C, both of which had an almost 2-fold (Hybrid T) to 9-fold (Hybrid C) higher release of volatiles (Table 1). The relative contributions of 3-methyl-butanal-*O*-methyloxime, β-caryophyllene, and (*E*)-β-ocimene to the 'chemical signature' of the induced blend were significantly higher in CGN19821 than in Hybrid C and Hybrid T (Fig. 2), and this could correlate with its higher degree of predator attraction. In contrast, the proportions of the green leaf volatiles (*Z*)-3-hexen-1-ol, 1-hexanol, and (*Z*)-3-hexen-1-yl butyrate were lower in CGN19821 than in the other two accessions.

Preferences of predatory mites also were studied after spider–mite infestation in cucumber accessions CGN23412, Hybrid T, and Hybrid C. The ranking order of attractiveness in accessions infested with spider mites correlated with the relative proportion of (*E*)-2-hexenal, (*E*)-β-ocimene, (*E*)-β-caryophellene, and (*E,E*)-α-farnesene. Similarly, Loughrin et al. (1995) found that differences in volatile production of cotton cultivars were based mainly on differences in the production of terpenes. Moreover, Krips et al. (2001) concluded that the lower attractiveness of *P. persimilis* to certain gerbera cultivars correlated with the relatively lower emission rates of (*E*)-β-ocimene and linalool in the total volatile blend of these less attractive cultivars. Our study indicates that in cucumber (*E*)-β-ocimene and (*E*)-β-caryophyllene play an important role in the attraction of predatory mites. Previously, it has been shown that *P. persimilis* and other predatory mites are attracted to linalool, methyl salicylate, (*E*)-β-ocimene, DMNT, and (*E*)-nerolidol, when offered individually (Dicke et al. 1990b; De Boer et al. 2004; Kappers et al. 2005). From our data, it seems that the proportion of DMNT within the total blend is not very important for the attraction of *P. persimilis* to induced cucumber volatiles: accessions Hybrid T and Hybrid C, both with relatively high proportions of DMNT, were less attractive in comparison to CGN19656 and CGN19821. However, transgenic *Arabidopsis* plants expressing a nerolidol synthase gene from strawberry (Kappers et al. 2005) emit more DMNT and were significantly more attractive to predatory mites. Additionally, Mumm et al. (2008) found less attraction of parasitoid wasps *Diadegma semiclausum* when *Arabidopsis* plants were treated with fosmidomycin, which specifically inhibits 1-deoxy-d-xylulose 5-phosphate reductoisomerase (DXPR), a key enzyme in the methylerythritol 4-phosphate (MEP) pathway, located in the plastids. However, other terpenoid compounds also were reduced in this study, which limits the conclusion concerning DMNT. Another example of an individual compound that affects the attraction of natural enemies is (*E*)-α-bergamotene that increased *Manduca sexta* egg predation rates on *Nicotiana attenuata* by the generalist predator *Geocoris pallens* (Kessler and Baldwin 2001). Most of these studies used single compounds or mixtures, ignoring the fact that background odors of plants may have a large impact on the 'chemical signature' (Schroeder and Hilker 2008).

The relative production of (*Z*)-3-hexen-1-yl-acetate was higher in Hybrid T than in other accessions. (*Z*)-3-Hexen-1-yl-acetate was found to be neither attractive nor

repellent for *P. persimilis* (Dicke et al. 1990b). Van Wijk et al. (2008) also did not find a response of predatory mites towards this compound. Takabayashi et al. (1994) found indications that two oximes might be repellent to *P. persimilis*. In our study, the relatively high proportion of 3-methyl-butanal-*O*-methyloxime in accession CGN19821 was not found to prevent predatory mites from choosing this accession when tested against accessions with lower production of oxime. Interestingly, 3-methyl-butanal-*O*-methyloxime has been reported to be induced by *Pythium aphanidermatum* infestation of cucumber plants as well (Jansen et al. 2007), thus suggesting a common defense signalling pathway for these two different types of biotic stress.

In summary, this study demonstrates a large range of quantitative as well as qualitative variation for herbivory induced volatile emission by different cucumber accessions. Behavioral studies with predatory mites *P. persimilis* show that these differences have a profound effect on the attraction of a natural enemy of spider mites. We currently are addressing the effects of differentially attractive accessions on predatory mites under greenhouse conditions to exploit the genetic variation for the realization of sustainable horticulture with a reduced use of pesticides.

Modifications of the Chemical Profile of Hosts after Parasitism Allow Parasitoid Females to Assess the Time Elapsed Since the First Attack

Abstract In solitary parasitoids, only one adult can emerge from a given host. In some of these species, when several eggs are laid on the same host, supernumerary individuals are eliminated by lethal larval fights. In the solitary parasitoid *Anisopteromalus calandrae*, the probability of a second larva winning the fight depends on the time elapsed since the first oviposition. The older the first egg is at the moment a second egg is laid, the less chance the second egg has of winning the competition. As a consequence, females of this species lay their eggs preferentially on recently parasitized hosts rather than on hosts parasitized by an egg about to hatch. *Anisopteromalus calandrae* females parasitize bruchid larvae located in cowpea seeds. In a series of choice test experiments using an artificial seed system, we demonstrated that the cue that allows parasitoid females to differentiate between hosts parasitized for different lengths of time comes from the host and not from the artificial seed or the previously laid egg. This cue is perceived at short range, indicating that the chemicals involved are probably partly volatile. Interestingly, although parasitism stops host development, cuticular profiles continue to evolve, but in a different way from those of unparasitized hosts. This difference in the host's cuticular profile after parasitism, therefore, probably underlies the parasitoid female's discrimination.

Introduction

Parasitoid females have to localize hosts to lay their eggs. This localization often is mediated by semiochemicals that can have different origins, such as volatiles released by plants when attacked by herbivores, chemical markers left by host females when they oviposit, or host sex or aggregative pheromones (for a review see Hilker and McNeil 2008). For example, the aphid parasitoid *Aphidius ervi* (Hymenoptera: Braconidae) is attracted by volatiles emitted by the blackcurrant when attacked by aphids (Birkett et al. 2000). Similarly, the Pteromalid wasps *Dinarmus basalis* and *Anisopteromalus calandrae* can localize their bruchid larvae hosts in cowpea seeds due to chemical markers deposited by the bruchid females after oviposition (Kumazaki et al. 2000; Onodera et al. 2002).

After locating their hosts, females have to select which host to parasitize. Indeed, all hosts are not of equal quality, and one of the important parameters influencing this quality is the host's parasitized status. Hosts that have been parasitized already have a lower quality than those that are unparasitized because of the competition among larvae resulting from several clutches laid on the same host (Godfray 1994). In some solitary parasitoids, when several eggs are laid in or on the same host, larvae fight until only one remains. Only one adult thus can emerge from a given host in these species (Hubbard et al. 1987). Parasitoid females generally are able to discriminate between these two categories of hosts (Gauthier et al. 1996; Weber et al. 1996; Darrouzet et al. 2007; Lebreton et al. 2009a). These discrimination capacities may be based on perception of different chemical markers deposited by the first parasitoid during parasitization (Völkl and Mackauer 1990; Jaloux et al. 2005; Stelinski et al. 2007) as well as on alarm

pheromones produced by the host itself after having been stung the first time (Outreman et al. 2001). In other species, host discrimination can be based on the interaction of several protagonists. In the ectoparasitoid *D. basalis* for example, the cue is located on the host, but a transfer of molecules from the parasitoid egg to the host is needed over an extended period (Gauthier and Monge 1999).

It would appear disadvantageous for a parasitoid female to lay several eggs on the same host or to lay eggs on already parasitized hosts. This behavior, called superparasitism, has, however, been demonstrated to be adaptive under certain circumstances, particularly when unparasitized hosts are scarce or distances between oviposition patches are long (van Alphen and Visser 1990). When females are confronted with several parasitized hosts, the survival probability of their offspring can vary from one host to another depending on different factors. Among these, the time elapsed between the two ovipositions is one of the more important (Visser et al. 1992; van Baaren and Nénon 1996; Goubault et al. 2003; Lebreton et al. 2009a); the older the first egg, the less chance the second egg has of surviving, because the previously laid egg hatches first and the larva kills the second egg before it can hatch (Godfray 1994). In a previous study with the solitary ectoparasitoid *Anisopteromalus calandrae*, we demonstrated that survival probability of a second egg decreases strongly when the time interval between two ovipositions increases (Lebreton et al. 2009a). On the other hand, two eggs laid at the same time have about the same probability of winning the competition, while the survival probability of the second egg decreases to 15% when it is laid shortly before the hatching of the first egg. As a consequence, females lay their eggs preferentially on recently parasitized hosts rather than on those parasitized by an egg about to hatch (Lebreton et al. 2009a).

The present study aimed to identify the cue responsible for this discrimination capacity. *Anisopteromalus calandrae* females parasitize bruchid larvae contained in cowpea seeds. When a female encounters a seed containing a host, she taps the seed surface with her antennae to locate the exact position of the host, and then she inserts her ovipositor into the seed in order to probe the host. The cue perceived by females thus could come from a quantitative or qualitative change in an external marker deposited by the first female after oviposition. It also could be due to an internal marker that originates from the host in response to the first sting, which could evolve with time, or from modifications to the egg itself that probably take place during its development. In some species, consecutive cues of different origins inform females about the parasitized status of a host (Islam and Copland 2000; Outreman et al. 2001). Perception of one or more of these cues can inform parasitoid females of the time elapsed since the first parasitism. However, to our knowledge, the few studies that have dealt with this discrimination capacity have never focused on the chemical signals involved.

In the present study, we aimed to investigate whether the cue perceived by females and involved in discrimination between hosts parasitized for different lengths of time originates from the seed, the host, or the egg. For this purpose, by using an artificial seed system, we performed a series of choice tests, in which we presented females with either parasitized seeds, previously laid eggs, or parasitized hosts. After locating the cue, we investigated which compounds could be involved by using gas chromatography and mass spectrometry.

Methods and Materials

Insect Rearing Anisopteromalus calandrae were reared in the laboratory on larvae and pupae of the bruchid *Callosobruchus maculatus* (Coleoptera: Bruchidae). Both *C. maculatus* and *A. calandrae* originated from Ivory Coast (collected in 2000) and were mass-reared under conditions close to that of their area of origin: 12 hr light at 29°C, 12 hr dark at 22°C, and 65% r.h.

Behavioral Analysis To obtain parasitized hosts, we used an artificial seed system consisting of gelatine capsules (1.5 cm long x 0.6 cm diam) containing a bruchid larva (Gauthier and Monge 1999; Darrouzet et al. 2003). The bruchid L4 larvae were placed inside the capsules after removal from seeds by dissection and selection by size. Five capsules were proposed to a group of 5 virgin females during a 2 hr period in a climatic chamber (29°C, 65% r.h.). Because Hymenopteran parasitoids reproduce by arrhenotokous parthenogenesis, virgin females were able to lay only male eggs, which avoids a bias due to the sex of the eggs during the choice test. At the end of the exposure period, eggs on parasitized hosts were located with a dissecting microscope, and parasitized artificial seeds were selected for choice tests.

Choice tests consisted of two artificial seeds each containing one host, one which had been parasitized for 2 hr (recently parasitized capsule, P 2 hr) and the other for 28 hr (parasitized by an egg about to hatch, P 28 hr), placed in a Petri dish (3.5 cm diam x 1 cm high) (Lebreton et al. 2009a). The two capsules were separated by 0.5 cm. To determine whether the cue perceived by females was located on the capsule, on the egg, or on the host, three choice tests were performed, each offering a different part of the artificial seed system to the females. In test 1, capsules were presented that had contained hosts previously parasitized for 2 hr and 28 hr, but now contained an unparasitized host. In test 2, 2- and 28-h-old eggs were

offered in a clean capsule, on an unparasitized host. Finally, in test 3, hosts parasitized for 2 and 28 hr, from which eggs had been removed, were offered in clean capsules.

In a previous study, we demonstrated that mated females distinguish between 2 and 28 hr parasitized artificial seeds (Lebreton et al. 2009a). In the present study, to avoid a bias due to the mating status of females, mated females also carried out these choice tests. The whole oviposition sequence was observed (first capsule visited, capsule with oviposition). The tests ended as soon as females laid an egg but lasted no more than 2 hr to avoid the first egg hatching during the test. After the test, females were removed from the Petri dish. The first capsules visited and the selected capsules were noted. Statistical analyses were performed with a χ^2*-test*.

Chemical Analysis of the Hosts' Cuticular Profile We quantified and identified the chemical compounds present on the host cuticle. For this purpose, samples from one bruchid larva were extracted in 10 µl of pentane, to which 2 µl of an internal standard (C20) were added for 1 min. Samples were analyzed with a Perkin-Elmer Autosystem XL GC (Perkin-Elmer, Wellesley, MA, USA) equipped with a flame ionization detector (FID) and interfaced with Turbochrom workstation software. Each sample was dried to 2 µl. These 2 µl then were injected into the GC-FID injector heated to 220°C in splitless mode, and analyzed by using a BP1 capillary column, which was temperature programmed from 50°C (2 min hold) to 310°C at 7°C/min with a final hold of 10 min. Five categories of host were analyzed: larvae parasitized for 2 hr (P 2 hr, N=6) or 28 hr (P 28 hr, N=14) and unparasitized larvae stored in the same conditions as 2 hr (UnP 2 hr, N=9) or 28 hr parasitized hosts (UnP 28 hr, N=9). As some unparasitized larvae develop to a pre-pupa stage after 28 hr, unparasitized pre-pupae (UnP Pre-pupae, N=6) also were analyzed. The components were identified by GC-MS analysis, performed using a Hewlett-Packard 5890 GC system coupled to a 5989A MS, controlled by HP chemstation software. Hydrocarbons were identified tentatively by their mass spectra (Lockey 1988; Blomquist 2010) and corroborated by their ECL indices. Individual samples and pools of 2 hr and 28 hr parasitized hosts were injected into the GC/MS injector following the same procedure as described above. To analyze whether there was a difference in the cuticular profile of the different categories of host, we performed a discriminant analysis based on the relative amount of the 30 major peaks.

Bioassays with Chemical Extracts from the Host To confirm that compounds observed in GC-MS were responsible for the parasitoid females' capacity to perceive the time elapsed since the first oviposition, we performed another series of choice tests. In these, mated females (N=42) were presented with two capsules, each containing an unparasitized host on which an extract of parasitized hosts had been deposited. These extracts were obtained by immersing 100 hosts parasitized for 2 hr or 28 hr in 200 µl of pentane for one min. Then, 2 µl of each extract (2 or 28 hr; amount corresponding to one host) were deposited on an unparasitized host previously rinsed in pentane to remove its own chemical compounds. After rinsing, we checked that hosts were still alive. One host of each category (with the 2 hr or 28 hr parasitized extract) was used for the choice tests, which took place in a climatic chamber as described above. The first capsule visited and the one selected for oviposition were noted. The proportion of each category of capsules visited first and those on which females oviposited then was calculated. Statistical analyses were performed with a χ^2*-test*. All statistical analyses were performed using Statistica 6.0 software (Statsoft, Inc.).

Results

Behavioral Analysis In tests 1 and 2, parasitoid females first visited each category of capsules equally (test 1, χ^2 = 0.03, df = 1, P=0.87; test 2, χ^2 = 0.61, df = 1, P=0.43) and laid the same number of eggs in each category of capsules (Fig. 1; test 1, χ^2 = 1.58, df = 1, P=0.21; test 2, χ^2 = 0.03, df = 1, P=0.85). In test 3, most females (69.2%) first visited the capsules containing the 2 hr parasitized host rather than the 28 hr parasitized host (χ^2 = 7.69, df = 1, P=0.006). Moreover, most (72.7%) selected the 2 hr parasitized hosts to lay their eggs (Fig. 1; χ^2 = 6.82, df = 1, P=0.009).

Chemical Analysis of the Hosts' Cuticular Profile The GC-MS analysis showed 44 major peaks (Fig. 2) and 71 identified components (Table 1) on hosts. These included a series of n-alkanes and methyl-branched alkanes (C_{25}-C_{35}; Table 1). The same compounds were found on each category of host but in different proportions (Table 1).

The discriminant analysis revealed a difference between UnP Pre-pupae and UnP Larvae (UnP 2 hr: F=3.53, df = 30.1, P=0.020; UnP 28 hr: F=3.35, df = 30.1, P=0.023), but no statistical differences were found between the two categories of UnP Larvae (F=1.21, df = 30.1, P=0.39; Fig. 3). P 2 hr were not different from UnP 2 hr (F=1.28, df = 30.1, P=0.30), whereas P 28 hr were different from P 2 hr (F=3.64, df = 30.1, P=0.018) and had a tendency to diverge from UnP 28 hr (F=2.39, df = 30.1, P=0.073; Fig. 3). P 28 hr also were different from UnP Pre-pupae (F=3.12, df = 30.1, P=0.031; Fig. 3).

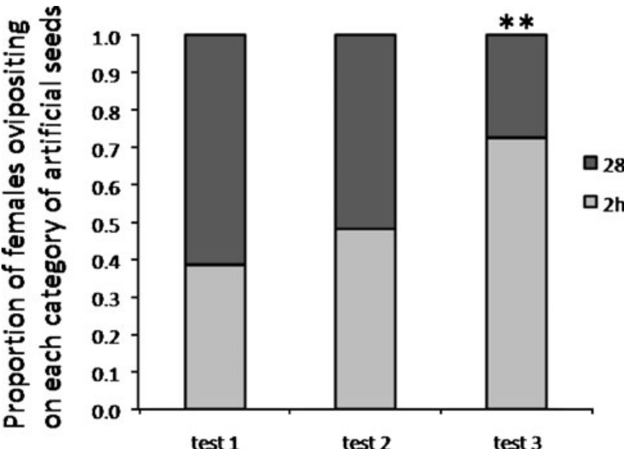

Fig. 1 Proportion of *Anisopteromalus calandrae* females selecting each category of artificial seed on which to lay their eggs (2 hr or 28 hr parasitized) when confronted with each test condition: capsules that previously contained parasitized hosts, but which were presented with an unparasitized host inside for the test (test 1), eggs on an unparasitized host in a clean capsule (test 2), and parasitized hosts on which eggs had previously been removed, in a clean capsule (test 3). Marks show significant differences between proportions observed and a random distribution of 50:50 ** $P<0.01$

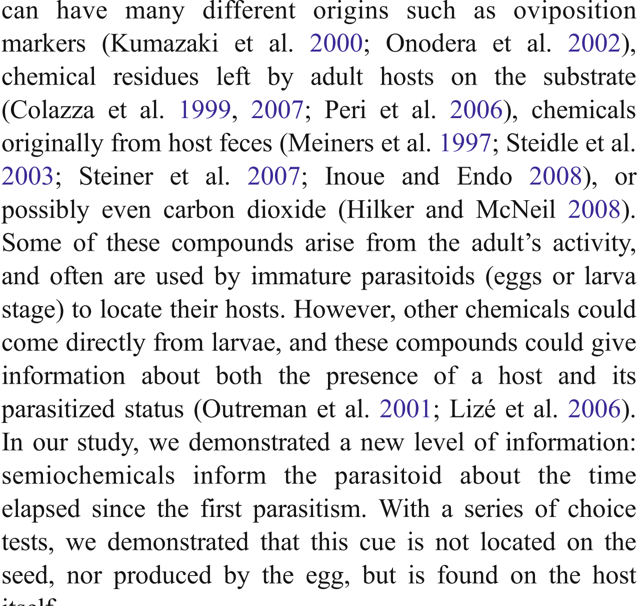
UnP Larvae and P 2 hr could be distinguished from P 28 hr and UnP Pre-pupae on the basis of the first discriminant variable and were characterized by the occurrence of n-C_{28} (peak 15) and n-C_{29} (peak 22). In contrast, P 28 hr and UnP Pre-pupae were characterized by a higher proportion of 3-MeC_{25} (peak 2), n-C_{26} (peak 3), MeC_{27} (peaks 10, 11, 12, 14), DiMeC_{27} (peaks 13, 14), MeC_{28} (peaks 17, 19, 21), and MeC_{29} (peaks 23, 24). The P 28 hr and UnP Pre-pupae differed in the second discriminant variable. P 28 hr were characterized by the occurrence of 3-MeC_{28} (peak 21), MeC_{29} (peak 23), 9,13-DiMeC_{29} (peak 25), and MeC_{31} (peak 32), whereas UnP Pre-pupae were more particularly characterized by the presence of n-C_{26} (peak 3), an unidentified compound (peak 35), and 3,9,13-TriMe-C_{31}.

Bioassays with Cchemical Extracts from Hosts Most females (70.7%) visited the capsule containing the 2 hr parasitized extract first ($\chi^2 = 7.04$, $df = 1$, $P=0.008$). Ovipositing females tended to lay more eggs on these hosts (64.3% vs. 35.7% on hosts with the 28 hr parasitized extract), but the difference was not significant ($\chi^2 = 2.29$, $df = 1$, $P=0.13$).

Discussion

Semio-chemicals are known to play a crucial role in host localization in parasitoids (Afsheen et al. 2008). Host cues



can have many different origins such as oviposition markers (Kumazaki et al. 2000; Onodera et al. 2002), chemical residues left by adult hosts on the substrate (Colazza et al. 1999, 2007; Peri et al. 2006), chemicals originally from host feces (Meiners et al. 1997; Steidle et al. 2003; Steiner et al. 2007; Inoue and Endo 2008), or possibly even carbon dioxide (Hilker and McNeil 2008). Some of these compounds arise from the adult's activity, and often are used by immature parasitoids (eggs or larva stage) to locate their hosts. However, other chemicals could come directly from larvae, and these compounds could give information about both the presence of a host and its parasitized status (Outreman et al. 2001; Lizé et al. 2006). In our study, we demonstrated a new level of information: semiochemicals inform the parasitoid about the time elapsed since the first parasitism. With a series of choice tests, we demonstrated that this cue is not located on the seed, nor produced by the egg, but is found on the host itself.

Our behavioral results show that most of the tested females visited the capsule containing the 2 hr parasitized host first (test 3, 70%), thus indicating that compounds involved in this discrimination capacity are detected not by direct contact but from a short distance. In fact, when females were introduced in the choice test, they came within a few millimetres of the capsules with their antennae but without touching them before finally making their choice (Lebreton, personal observation).

When females were confronted with only the chemical compounds (experimentally deposited on an unparasitized host), they also more often visited the host exhibiting the "most recently parasitized" profile first. However, although they tended to lay their eggs on these hosts, this choice was not as marked as for actually parasitized hosts (Lebreton et al. 2009a). This result suggests that several cues could in fact be necessary for a female to assess host quality accurately. During the first parasitism, *A. calandrae* females also paralyze their hosts by injecting venom (Lebreton et al. 2009b). In the present experiment (bioassays of chemical extracts from hosts), hosts were unparasitized and therefore not paralyzed. It is possible that initially females perceive hosts as "recently parasitized", but on coming closer detect that they are not in fact parasitized because they are not paralyzed.

In a previous study, Outreman et al. (2001) showed that an alarm pheromone produced by aphids after being parasitized allows parasitoid females to determine whether a host is already parasitized or not. They correlated an antennal rejection of the parasitized host with the presence of the pheromone in the hours following the first parasitism. As the pheromone disappeared, the antennal rejection was replaced by a sting rejection. This result indicates that several cues can give the same information.

Fig. 2 Gas chromatogram of the cuticular pentane extract of hosts parasitized for 2 hr (**a**) and 28 hr (**b**). IS = internal standard. Peak numbers correspond to those listed in Table 1

In our study, the difference in the cuticular profile of hosts was visible mainly after 28 hr. It is thus possible that this cue does not inform parasitoids about the parasitized status of hosts just after parasitism, whereas other cues, such as oviposition markers deposited by parasitoids, give this information for shorter periods. When *A. calandrae* females oviposit on unparasitized hosts, generally they deposit a substance with their ovipositors after laying (Lebreton, personal observation). Moreover, when confronted with parasitized capsules (test 1), females tend to select 28 hr parasitized capsules slightly more, even if this difference is not statistically significant from a random choice. This observation may support the hypothesis of an oviposition marker that is more detectable shortly after its deposit. Oviposition markers generally are produced in the Dufour gland. In *A. calandrae*, the Dufour gland contains a mixture of *n*-alkanes (C_{30} to C_{39})(Howard and Baker 2003). Such marking-pheromones commonly are used by parasitoids to inform competitors about previous ovipositions and thus avoid competition (Hoffmeister 2000; Rosi et al. 2001; Stelinski et al. 2007). They also seem to be used by females to discriminate between hosts parasitized by themselves and those parasitized by other parasitoids (van Dijken et al. 1992). More recently, it also has been shown

Table 1 Tentatively identified cuticular hydrocarbons present on the host cuticle, with their relative amount for each host category

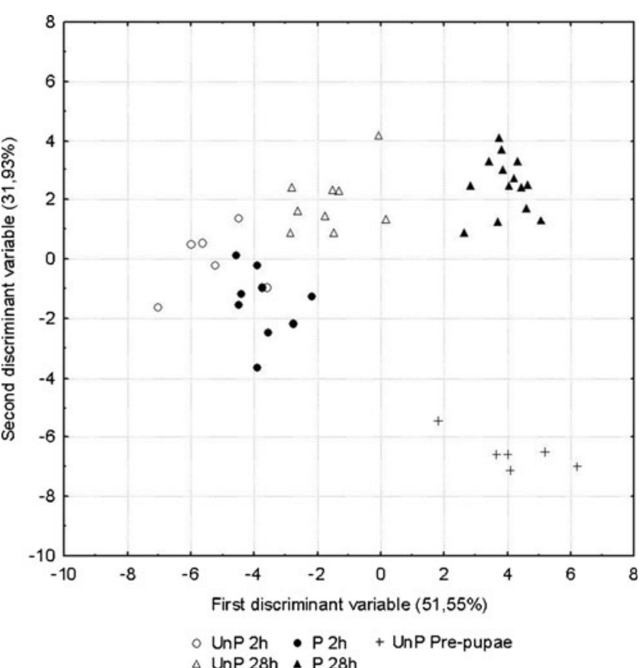

Fig. 3 Discriminant analysis based on the relative amount of the 30 major peaks of the cuticular profile of the different host categories (L4 larvae parasitized for 2 hr (P 2 hr) or 28 hr (P 28 hr), unparasitized L4 larvae stored under the same conditions as 2 hr (UnP 2 hr) and 28 hr (UnP 28 hr) parasitized hosts, and unparasitized pre-pupae (UnP Pre-pupae))

that oviposition markers deposited by larval parasitoids can be perceived by adult hosts, and thus avoid laying their eggs on unsuitable substrate (Stelinski et al. 2009).

Our results show differences in the cuticular profiles of the hosts analyzed. First, the profiles of the unparasitized hosts depend on their developmental stage, with larvae and pre-pupae exhibiting different profiles. The profile of parasitized hosts also changes with time, with hosts parasitized for 2 hr and 28 hr showing different profiles. However, it evolves differently in unparasitized hosts. Although unparasitized pre-pupae and 28 hr parasitized host profiles were similar in terms of the first discriminant variable, they diverged from each other in regard to the second discriminant variable. This result suggests that parasitism affects the evolution of the host profile. The compounds identified (a series of linear and methyl alkanes) were in accordance with those previously identified by Howard (2001). Although these consist of heavy long-chain hydrocarbons (C_{25} to C_{35}), and generally are considered as being detected through direct contact, in our choice test experiments, parasitoid females were able to detect the time elapsed since the first oviposition at a short distance (a few millimetres), i.e., outside the capsule. Nevertheless, considering the high temperature in our experimental procedure (29°C, the mean temperature of the area of origin of these species), some of these

compounds may be semi-volatile. A previous study demonstrated that cuticular hydrocarbons from C_{25} to C_{27} can be volatile and perceived at a distance at 25°C (Saïd et al. 2005). It is possible that only the lighter components play a role in this discrimination. This hypothesis is in accordance with our results, which show that the major difference between 2 hr and 28 hr parasitized hosts is related to these compounds (more particularly from C_{25} to C_{29}). This remains to be tested. Another possibility is the spontaneous oxidation of heavy cuticular lipids to volatile aldehydes or alcohols, as previously observed in other insect species (Bartlelt and Jones 1983; Bartlelt et al. 2002). However, the compounds involved in the discrimination observed in our experiment were pentane-soluble (obtained by immersing bruchids in a pentane solution), and only alkanes were found in these pentane extracts. Further studies are necessary to determine precisely which compounds are involved in this discrimination. The use of selected fractions of the hosts cuticular profiles or the use of blends of synthetic compounds would give us some indications. Moreover, by using olfactometry experiments, we would be able to differentiate between an attractant and an arrestment effect of these compounds. It also would be possible to know whether the profile of 2 hr parasitized hosts could be attractive for parasitoid females or whether that of hosts parasitized for 28 hr could be repellent.

Our results also raise an interesting question about the action of parasitoid venom on host physiology. When females inject their venom into hosts, the latter are paralyzed and their development is stopped. Their cuticular profile, however, continues to evolve. This indicates that some elements of host physiology still operate after venom injection. However, the evolution of the cuticular profile of a parasitized host is perceptibly different from that of an unparasitized host. The parasitoid venom thus appears to disturb the metabolism of hydrocarbons, interfering either with their production or with their dynamic release at the cuticle level. In a previous study, we observed that parasitism disturbs lipid metabolism by decreasing the amount of total lipids present in the host haemolymph (Lebreton et al. 2009b). Studies with other species also have demonstrated that modifications in the composition of the host haemolymph occur after venom injection (Rivers and Denlinger 1995; Nakamatsu and Tanaka 2003). However, in most of these species, the amount of lipids increases after parasitism, probably due to the lysis of fat body cells by the components of the venom (Nakamatsu and Tanaka 2004). The opposite result found in our study suggests other mechanisms. This result raises new questions about the affect of parasitism on a host's lipid metabolism. Identifying the components of venom could shed light on the way parasitoid venom acts on the host physiology.

RAPID COMMUNICATION

Nosema spp. Infection Alters Pheromone Production in Honey Bees (*Apis mellifera*)

Abstract Pheromones in social insects play a key role in the regulation of group homoeostasis. It is well-established that parasites can modify hormone signaling of their host, but less is known about the effect of parasites on pheromone signaling in insect societies. We, thus, tested in honey bees (*Apis mellifera*) the effect of the widespread parasite *Nosema* spp. on the production of ethyl oleate (EO), the only identified primer pheromone in honey bee workers. Since environmental stressors like pesticides also can weaken honey bees, we also analyzed the effect of imidacloprid, a neonicotinoid widely used in agriculture, on EO production. We show that, contrary to imidacloprid, *Nosema* spp. significantly altered EO production. In addition, the level of *Nosema* infection was correlated positively with the level of EO production. Since EO is involved in the regulation of division of labor among workers, our result suggests that the changes in EO signaling induced by parasitism have the potential to disturb the colony homoeostasis.

Introduction

Analogous to the hormones that control the organism homoeostasis, pheromones in social insects play a key role in the regulation of group homoeostasis. However, homoeostasis of both organisms and insect societies can be threatened by parasite infection. For example, in mammals there is evidence that parasites can modify the endocrine system of the host to favor their development and reproduction (Escobedo et al. 2005). In honey bees, the cuticular hydrocarbon profile involved in social recognition can be altered by an activation of the immune system (Richard et al. 2008) or parasitization by the mite *Varroa destructor* (Salvy et al. 2001). However, it is not known whether, analogous to the modification of hormone signaling in the organism, parasites can affect pheromone signaling in insect societies.

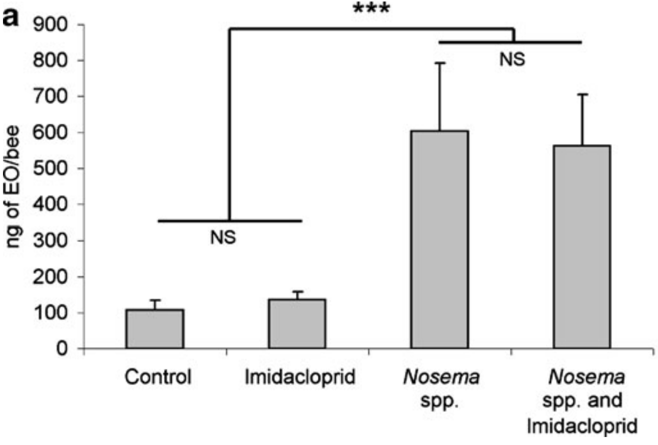
To answer this question, we asked whether the microsporidia *Nosema* spp., potentially involved in worldwide honey bee losses (Higes et al. 2008), could affect the production of pheromone in workers. We analyzed the production of the only indentified primer pheromone in workers: ethyl oleate (EO), which regulates worker behavioral maturation (i.e., inhibits the transition from inside-nest tasks performed by young bees (nurse) to foraging tasks performed by old bees (forager)) (Leoncini et al. 2004). The focus was on primer pheromones because they are essential to the regulation of social behaviors and colony homeostasis. Therefore, a modification in their production could affect the whole colony organization and endanger its survival. Since survival of honey bees can be

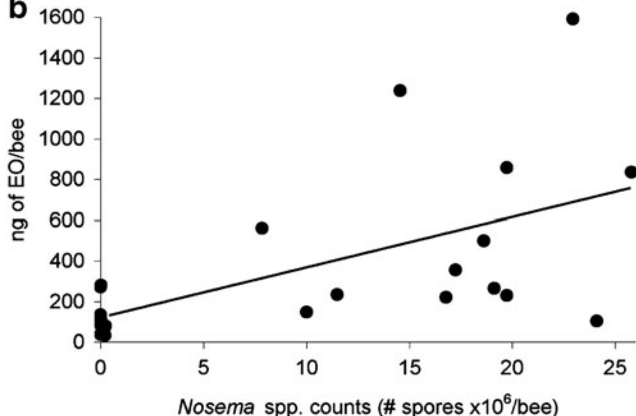
threatened by other stressors, such as pesticides, we also tested the effects of a neonicotinoid (imidacloprid) widely used in agriculture on EO production. Pesticides are known to disrupt pheromone perception, but they also can affect their production (Desneux et al. 2007).

Methods and Materials

Nosema infection and imidacloprid exposure This experiment was part of a larger study described in detail by Alaux et al. (2010). Briefly, in order to test the effect of *Nosema* infection and/or imidacloprid exposure, 1-d-old bees were reared in cages and split into four experimental groups: control groups, groups infected with *Nosema*, groups exposed to imidacloprid, and groups both infected with *Nosema* and exposed to imidacloprid. For each experimental group, 3 colonies were used, with 2 cage replicates for each colony (N=120 bees per cage). For the *Nosema* infection, bees were fed individually at the beginning of the experiment with a sugar solution containing 200,000 spores (Alaux et al. 2010). Spores were isolated previously from infected colonies as in Higes et al. (2007), and genetic analysis showed that our bees were infected with both *N. apis* and *N. ceranae* (see Alaux et al. 2010). For the pesticide exposure, caged bees were chronically exposed 10 h per day to imidacloprid by ingesting a sugar solution containing 7 μg/kg of imidacloprid (a concentration encountered in the environment) (see Alaux et al. 2010). The solution was replaced each day. After 10 d, bees were collected and stored at−20°C in order to measure the level of EO and *Nosema* infection.

EO Quantification Pools of 5 bees were analyzed. Whole-body extracts were prepared in 1.9 ml of iso-hexane with the addition of 100 μl of two internal standard solutions at 10 ng/μl (arachidic acid methyl ester, and methyl heptadecanoate, Sigma-Aldrich, France). Samples were crushed with a glass rod for 2 min at 0°C and centrifuged for 20 min at 4°C (2,500 g). The supernatant was collected and applied to a silica column (silica gel 60, particle size 40–63 m, 230–400 mesh). The first fraction was eluted in 3 ml of a solvent mixture (98.5% iso-hexane, 1.5% diethyl ether). The second fraction containing the EO was eluted in 3 ml of a second solvent mixture (94% iso-hexane, 6% diethyl ether). One ml of this fraction was concentrated to 10 μl under a nitrogen stream, and 1 μl was injected into a fast gas chromatograph (2014, Shimadzu, Japan) equipped with a split-splitless inlet, a flame ionization detector, and a capillary column Omegawax 100 (10 m x 0.10 mm, 0.10 μm film thickness). Samples were injected in split mode. Hydrogen was used as carrier gas with a column flow of 0.52 ml/min. Oven temperature was set at 90°C for 1 min, raised to 195°C at 40°C min^{-1}, stabilized for





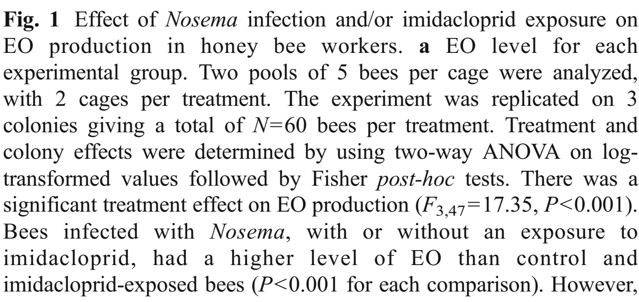


Fig. 1 Effect of *Nosema* infection and/or imidacloprid exposure on EO production in honey bee workers. **a** EO level for each experimental group. Two pools of 5 bees per cage were analyzed, with 2 cages per treatment. The experiment was replicated on 3 colonies giving a total of N=60 bees per treatment. Treatment and colony effects were determined by using two-way ANOVA on log-transformed values followed by Fisher *post-hoc* tests. There was a significant treatment effect on EO production ($F_{3,47}$=17.35, P<0.001). Bees infected with *Nosema*, with or without an exposure to imidacloprid, had a higher level of EO than control and imidacloprid-exposed bees (P<0.001 for each comparison). However, imidacloprid did not affect EO production (control vs. imidacloprid-exposed bees: P=0.81; or *Nosema*-infected bees vs. *Nosema*-infected and imidacloprid-exposed bees: P=0.14). There also was a significant effect of colony origin ($F_{2,47}$=4.59, P=0.017), but no significant interaction with the treatments was found ($F_{6,95}$=0.88, P=0.52) thus demonstrating a consistent effect of the treatments. Data show mean ± SE. *** and NS denote significant (P<0.001) and non-significant differences between treatments, respectively. **b** Relation between EO production and the level of *Nosema* infection. There was a significant positive correlation between the quantity of EO produced and the number of *Nosema* spores infecting bees (r=0.58, P<0.005, N=24)

3 min, then augmented to 210°C at 1°C min^{-1}, stabilized again for 2 min, then increased to 270°C at 40°C min^{-1} and held at 270°C for 3 min. Identification and quantification of EO was based on retention times of EO synthetic compound (Sigma-Aldrich, France) and by comparison of internal standard area, respectively, using a gas chromatography solution program (Shimadzu, Japan). The EO confirmation was done by a mass spectrometer (CP2010, Shimadzu, Japan) operated in the electron impact mode at 70 eV with continuous scans (every 0.2 sec) from a mass to charge ratio (m/z) of 70–400.

Nosema spore counting Since *Nosema* is an intestinal parasite, the honey bee intestinal tract was dissected and macerated in distilled water as in Higes et al. (2007). The spore concentration from the suspension then was determined by using a haemocytometer.

Results and Discussion

Nosema infection caused a significant increase in EO production compared to non-infected groups (Fig. 1a), thus demonstrating that pheromone production can be modified by environmental stressors. However, EO production in imidacloprid-exposed bees did not differ significantly from non-exposed bees (Fig. 1a). Neonicotinoids target the nicotinic acetylcholine receptors and thus can affect neural function (Decourtye et al. 2004), but here no effect was found on pheromone production. Studies with different pesticides are needed to determine whether this absence of modification that we observed is a general phenomenon.

One would expect that *Nosema* infection induces a cost to pheromone production. Contrary to this expectation, parasitized bees produced more EO than healthy ones. Since, EO is present at higher levels in foragers compared to nurses (Leoncini et al. 2004), and because *Nosema* causes a precocious onset of foraging (Wang and Moeller 1970), the EO increase might reflect a forager profile of infected bees compared to control bees. However, further investigation tended to show that the EO increase is not just a consequence of a forager profile. First, the level of EO in parasitized bees was 6 times higher than healthy bees, which is greater than the difference naturally found between nurses (young bees) and foragers (old bees) (100±19 ng EO/nurse, N=60 and 213±25 ng EO/forager, N=120, unpublished data from N=3 colonies, A. Maisonnasse). Second, there was a positive and significant relationship between EO level and the number of *Nosema* spores per bee (Fig. 1b), showing that the EO increase is not an all-or-nothing response but is linked to the level of *Nosema* infection.

Even if the earlier onset of foraging could be a bee response that decreases the *Nosema* load within the hive, the higher EO level in infected bees has the potential to disturb colony organization. The abnormally high level of EO could mislead the colony on the actual number of foragers and delay the onset of foraging in non-infected nurses. It is not known, however, how infected bees who accelerate their behavioral maturation would react to the high inhibitory effects of EO. On the other hand, since *Nosema* infection decreases worker lifespan (Higes et al. 2007), a loss of EO in the colony also can be expected and to accelerate nurse maturation. Field studies are needed to determine the actual response of the colony and whether a failure in pheromone communication induced by parasitism or disease could lead to the colony collapse.

To our knowledge, this is the first demonstration that parasites can modify pheromone production in insect societies. Therefore, our finding indicates that pathogens, besides their effect at the individual level, also can cause damage at the social level.

Changes of Sex Pheromone Communication Systems Associated with Tebufenozide and Abamectin Resistance in Diamondback Moth, *Plutella xylostella* (L.)

Zhen Xu · Guang-Chun Cao · Shuang-Lin Dong

Received: 7 September 2009 / Revised: 1 March 2010 / Accepted: 30 March 2010 / Published online: 21 April 2010

Abstract Many insect pests have evolved resistance to insecticides. Along with this evolution, the sex pheromone communication system of insects also may change, and subsequently reproductive isolation may occur between resistant and susceptible populations. In this study of the diamondback moth, we found that resistant females (especially Abamectin resistant females) produced less sex pheromone and displayed a lower level of calling behavior. Resistant males showed higher EAG responsiveness to the sex pheromone mixture of females, and responded to a broader range of ratios between the two major components compared to the responses of susceptible moths. In addition, wind tunnel experiments indicated that changes associated with insecticide resistance in the Abamectin resistant strain (Aba-R) significantly reduced female attractiveness to susceptible males. Furthermore, mating choice experiments confirmed that non-random mating occurred between the two different strains. Aba-R females with an abnormal pheromone production and blend ratio exhibited significantly lower mating percentages with males from either their own strain or other strains, which corroborates the results obtained by the wind tunnel experiments. The implications of this non-random mating for insect speciation and insecticide resistance management are discussed.

Introduction

The sex pheromone communication system plays a vital role in insect mating and reproduction. This system, particularly in moths, is highly complex and species-specific (Roelofs and Comeau 1969; Lanier and Wood 1975; Costa et al. 1997). Therefore, it often is considered as a powerful force for reproductive isolation and, thus, speciation (Cardé and Baker 1984). Some studies with closely related species have shown that reproductive isolation under natural conditions is the result of differences in sex pheromone systems, as these species can hybridize when confined in the laboratory (Gadenne et al. 1997; Huang et al. 2002; Tabata and Ishikawa 2005; Laurent et al. 2007). Traditionally, sex pheromone communication systems in moths have been assumed to involve strong stabilizing selection on emitters and receivers, and such stabilizing pressure would allow only small, incremental changes in pheromone systems over time (Paterson 1980). However, more recent investigations have revealed that many environmental factors can cause notable changes in these systems (Krokos et al. 2002; Svensson et al. 2002; Bashir et al. 2003; Jun et al. 2003; Yang and Du 2003; Pelozuelo et al. 2004; Nosil et al. 2007; Robbins et al. 2008), and assortative mating can occur between different strains of the same insect species with different pheromone components or different ratios among components (Zhu et al. 1997; Pelozuelo et al. 2004).

Human activity now is a great evolutionary force, and has greatly facilitated the evolution of pesticide resistance in insects (Palumbi 2008). Many studies have focused on

the monitoring, management, and mechanism of pesticide resistance. However, few have addressed changes in sex pheromone communication associated with insecticide resistance (Delpuech et al. 1998, 1999, 2001; Delisle and Vincent 2002; Wei and Du 2004). Considering the importance of insect sex pheromone communication systems in reproductive isolation, studies of changes between pesticide resistant and susceptible insects should provide insight into the process of speciation. In addition, sex pheromones, as selective and environmentally friendly pest means of control, have been used successfully to control some important insect pests including diamondback moth (DBM), *Plutella xylostella* (L.) by trapping-and-killing or mating disruption (Chisholm et al. 1983; Schroeder et al. 2000). If there are changes in an insect sex pheromone communication system associated with insecticide resistance, sex pheromone formulations may require modification for the best control efficiency, and strategies for insecticide resistance management based on gene dilution between susceptible and resistant individuals also may require a re-evaluation.

The diamondback moth (DBM) is a worldwide pest, mainly of cruciferous vegetable and rapeseed crops. It also is the first crop pest in the world to develop resistance to DDT and *Bacillus thuringiensis* (Lingappa and Kulkarni 2004), and has developed resistance to most classes of pesticides. Tebufenozide and Abamectin are two insecticides widely used to control DBM. Tebufenozide was first developed by Rohm and Haas Co. as an agonist of 20-hydroxyecdysone, and kills insects by initiating premature molting (Wing 1988; Wing et al. 1988). Abamectin is a bacterial (*Streptomyces avermitilis*) based toxin that acts on the GABA receptor/chloride ionophore complex and glutamate-gated chloride channel (Clark et al. 1995; Rugg et al. 2005). Resistance of DBM to Tebufenozide has been reported in laboratory selected strains, and to Abamectin in field populations (Cao and Han 2006; Qian et al. 2008). In this study, we report the differences in the DBM sex pheromone communication system associated with Tebufenozide and Abamectin resistance, and a pronounced non-random mating between resistant and susceptible strains.

Methods and Materials

Insects Three strains of *P. xylostella* were used. The susceptible strain (S) was a laboratory strain provided by the Wuhan Insect Virus Research Institute. Previously, a Tebufenozide resistant strain (74-fold) was developed in our laboratory by selection with Tebufenozide for 17 generations during a 37 generation period from the S strain, which carried a cross resistance to Abamectin of 36-fold (Cao and Han 2006). From this strain, Tebufenozide and Abamectin resistances were selected further, respectively, with one of the two insecticides for another 20 generations to obtain the two resistant strains used in this study. The resistance level to Tebufenozide (Teb-R strain) was 141-fold, and to Abamectin (Aba-R strain) was 304-fold, calculated as the LC_{50} ratios between the resistant and susceptible strains. The two resistant strains were maintained in the laboratory by continuous exposure to 3 ppm Abamectin and 2,000 ppm Tebufenozide, respectively. Moth larvae of all strains were reared routinely with vermiculite-cultured radish (*Raphanus sativus*) seedlings under conditions of 25°C, 70–80% RH and a 14:10 hL:D photoperiod. Males and females were separated at the fourth-instar stage based on morphological differences. Pupae were transferred to a dark room, and eclosed moths were fed with 10% honey solution.

Insecticides and Chemicals Tebufenozide (20% suspension concentrate) and Abamectin (0.05% wettable powder) were provided by Dow AgroSciences and Nanjing Baofeng Chemical Co., Ltd., respectively. Two pheromone components Z11-16:Ald and Z11-16:Ac were provided by Professor Du at the Institute of Plant Physiology & Ecology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences. The purity of these two chemicals was determined to be >95% by gas chromatograph (GC) analysis.

Calling Behavior Observation A 2-d-old virgin female moth was introduced into a transparent glass cylindrical container (3.5 cm diam×10 cm height), and placed in an environmentally controlled room (25±1°C, 70–80% RH, and a 14:10 hL:D photoperiod). Calling behaviors were observed by eye under dim incandescent red backlighting at 0.5 hr intervals throughout the day (24 hr). Each female was noted as either calling or not calling. There were three replications for each strain and 10 females per replication.

Electroantennogram Recordings EAG values were recorded by using a previous method (Yang et al. 2009). The binary mixture of Z11-16:Ald and Z11-16:Ac (1:1) were prepared in hexane at different concentrations (1, 10, 100, and 1,000 ng/µl) to test for a dose-response relationship, and in different ratios between Z11-16:Ald and Z11-16:Ac (9:1, 3:7, 5:5, 7:3, 1:9) to test the ratio-response relationship of male moths. One µl of test solution was deposited on a filter paper strip (2.5×1 cm), the solvent was allowed to evaporate for 1 min, then the paper strip was inserted into a Pasteur pipette placed perpendicularly through a hole in a matalline tube with an airflow of 4 ml/s. Stimulations were achieved by directing a puff of air (4 ml/s) through the pipette with a timer-controlled solenoid valve. Control stimulations were performed by

using a pipette with a paper strip treated with pure hexane. Measurements were repeated on 10 individuals of each strain using newly prepared paper strips for each individual. Male moths from the three strains were tested in random order.

Gas Chromatography Analysis Ovipositors and the associated sex pheromone glands were dissected from 2-d-old virgin female moths during the peak calling period, i.e., 1–3 hr after the initiation of scotophase (D1-D3 h). Each gland was soaked for 2 hr in 5 µl redistilled hexane containing an internal standard (11:Ac; 11.3 ng/µl) to extract pheromone components. Twenty replicates (glands) were made for each of the three strains.

To determinate the amounts of Z11-16:Ald and Z11-16:Ac, 2 µl of the 5 µl extract were injected into a GC (GC-14B, Shimadzu, Kyoto, Japan) equipped with a flame ionization detector (FID), a split/splitless injector, and a fused silica capillary column (SPB-50, 30 m× 0.25 mm ID, 0.25 µm film thinckness, Supelco, USA) in splitless mode. Nitrogen was used as carrier gas. The oven temperature was maintained at 100°C for 2 min and then programmed at 10°C/min to 250°C. The injector and FID temperatures were set at 200°C and 270°C, respectively. The quantity of each component was calculated based on the peak area, and calibrated by comparing it with that of the internal standard 11:Ac.

Wind Tunnel Bioassay The methods used in the wind tunnel experiments were similar to those of Lelito et al. (2008). Behavioral responses of males to calling females were observed in a Plexiglas wind tunnel (60 cm high, 90 cm wide, 230 cm long). For all tests, wind tunnel conditions were 3 lux red light, 25±2°C, 60–80% RH with 0.3 m/sec wind speed.

Just before the onset of the scotophase, 2-d-old virgin male moths were transferred individually into test tubes (2.5 cm diam×10 cm height), which were labeled with the strain name. All test tubes then were placed in the darkened room that housed the wind tunnel. At the same time, females of each strain were placed into seperate metal screen cages (4 cm diam×6 cm height) in an adjacent fume hood to prevent the males from being exposed to pheromone prior to testing. One calling female that served as the pheromone source was transferred into a metal screen cage (4 cm diam×10 cm height) and placed in the middle of the wind tunnel (equidistant from the two lateral sides of the tunnel) on a steel screen platform 30 cm high and 150 cm from the release point of male moths. The female was allowed to acclimate for up to 10 min for calling behavior to resume. After that, males were introduced individually into the wind tunnel by using a cylindrical one-end-opened screen cage (release cage, 4 cm diam×8 cm height). The release cage was placed into the tunnel with the open end facing the calling female on a steel screen platform 28 cm high. Each male was given up to 2 min to respond, and was scored for the following behavioral categories: no flight, taking flight, locked on plume, half the distance to source, 10 cm from source, and source contact. Each male was tested once.

To measure the females' attractiveness, 20 male moths were tested for each strain in each replication, with 3 replications for the experiment (total of 60 males for each strain). In each replication, the male individuals from 3 strains were tested randomly (in no particular order) to avoid bias due to female attractiveness and male responsiveness. The female (lure source) was replaced when she was no longer visibly calling. Tests were conducted between D1 to D3 h.

Mating Choice Measurement To elucidate further the effects of insecticide resistance-associated changes in the sex pheromone communication system, mating choice experiments were conducted. Six inter-strain combinations of the 3 strains were tested in a mating cage (35×35× 35 cm). Two-d-old virgin moths were used in this experiment. Ten males and 20 females of each strain were introduced into a cage to provide enough females among which to choose. Males and females of different strains were marked on their wings with different colored inks. The ink marking was tested prior to the study and found not to influence moth mating behaviors. Observations were made at 30 min intervals throughout the 10-h scotophase. Mated moths were removed after recording to avoid repeat mating. Five replicates (cages) were performed for each inter-strain combination.

Statistics Data were analyzed with a one-way analysis of variance, $P<0.05$. Fisher's least significant difference test was used for multiple comparisons among treatments in all experiments. All values were mean±SE unless otherwise designated.

Results

Calling Behavior of Females The periodicities of female calling behavior of the two resistant strains were similar to that of the S strain (Fig. 1). For all three strains, high percentages of individuals started calling as soon as the photophase ended. The highest calling percentages were displayed at 0.5 hr into scotophase (D0.5 hr) for S and Aba-R, and at D1.0 hr for Teb-R. Females of all 3 strains maintained the highest calling percentages for about one hour, and then the calling percentages gradually declined. However, the calling percentages at each time-point were

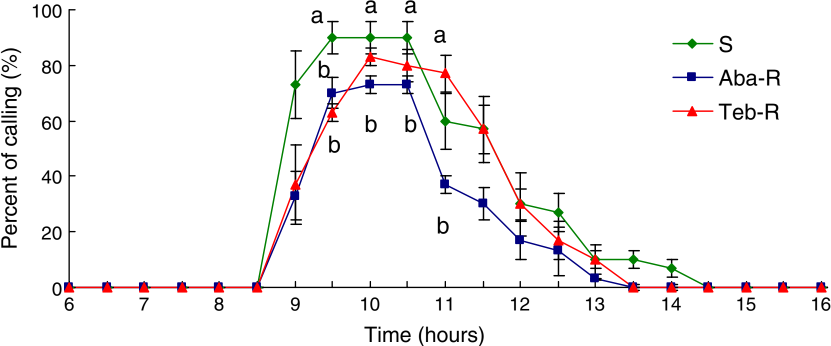

Fig. 1 Calling percentages by S, Teb-R and Aba-R strain females during a 24 hr period. Scotophase was from the 9th to 19th hour. The data series in each time point marked with different letters are significantly different at the 5% level using Fisher's least significant difference test

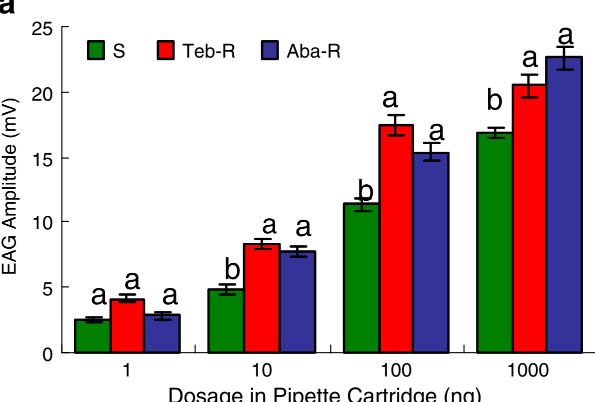
much different among the 3 strains. Compared with the S strain, calling percentages of Aba-R females were consistently lower at each point in time, and significant differences were observed during calling peak time (D0.5h-D2h). This was different for Teb-R females, where the calling percentages were lower than those of S females before D1.5h, but similar to that of S females afterwards. Both Aba-R and Teb-R resistant strains stopped calling at D5.0h, one hour earlier than the S strain, which stopped at D6.0h. For all three strains, no calling behavior was observed in photophase.

EAG Response of Males The dose-response bioassay showed that the 1:1 binary pheromone mixture elicited significantly higher EAG responses in male moths of both resistant strains compared with those of the S strain at all, except the lowest (1 ng), dosages (Fig. 2a). However, no significant difference in EAG responses was observed between the two resistant strains at all dosages tested. Similar results were obtained for pheromone mixtures (100 ng) of differing Z11-16:Ald/Z11-16:Ac ratios. Both resistant strains displayed higher EAG responses compared to the S strain at all five ratios tested (Fig. 2b).

Among different ratios of the binary mixtures, the 5:5 mixture elicited the highest EAG responses in males of all three strains. In addition, the EAG differences between resistant and susceptible males were much greater for ratios of 3:7 and 1:9 than for those of 9:1 and 7:3 (Fig. 2b).

GC Analysis of Female Sex Pheromone Titers The S strain females produced higher amounts of Z11-16:Ald than Aba-R and Teb-R females, and S strain females also produced significantly more Z11-16:Ac than Teb-R females (Table 1). In addition, significantly more Z11-16:Ald was found in the Teb-R strain than in the Aba-R strain females. The ratio of Z11-16:Ald/Z11-16:Ac in S females was 4.57:5.43, similar to that of Teb-R females (4.31:5.69), but much different from that of Aba-R females (1.59:8.41).

Wind Tunnel Bioassay The S strain males exhibited similar behavioral responses to the S and Teb-R strain females with respect to response percentages of all behavioral categories (Table 2). However, these response percentages exhibited by S strain males were reduced significantly when Aba-R strain females were used as the lure source. In other words, Aba-R females, in comparison with S and Teb-R females, were significantly less attractive to S males. For males of Teb-R or Aba-R strains, there were generally no significant



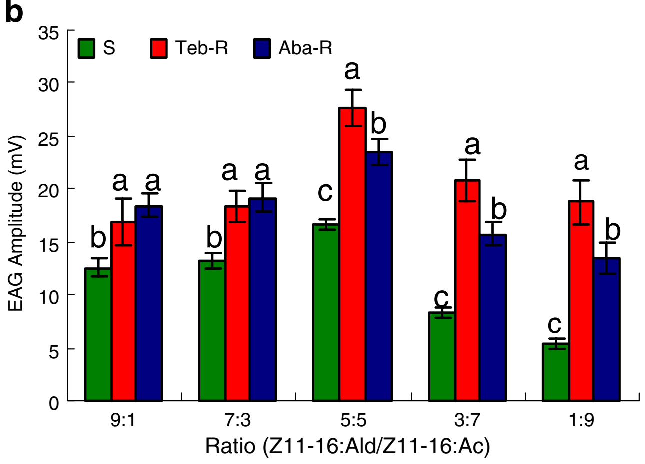


Fig. 2 EAG responses of S, Teb-R and Aba-R strain males to a 1:1 binary female sex pheromone mixture (Z11-16:Ald/Z11-16:Ac) at different doses (**a**), and at the same dose (100 ng) but different ratios (**b**), N=10. The data series at the same dose in panel A or of the same ratio in panel B marked with different letters are significantly different at the 5% level using Fisher's least significant difference test

Table 1 Mean titers (ng±SE) and blend ratios of Z11-16:Ald/Z11-16:Ac in females of three DBM strains (N=20)

Insect strain	Z11-16:Ald	Z11-16:Ac	Sum	Z11-16:Ald/Z11-16:Ac
Aba-R	2.17±1.14 c	11.60±0.85 ab	13.69±0.86 c	1.59:8.41
Teb-R	8.65±0.51 b	11.16±0.75 b	20.09±1.17 b	4.31:5.69
S	11.29±0.65 a	13.43±0.68 a	24.72±1.16 a	4.57:5.43

The data within each column followed by the same letters are not significantly different at the level of 5% using Fisher's least significant difference test

differences in behavioral response to calling females of the different strains. So, females of the 3 strains were of the same attractiveness to males of the 2 resistant strains. There was no significant difference in male responsiveness among different males when an S strain female or a Teb-R strain female was used as the lure. However, when an Aba-R train female was used as lure, the responses of the S strain males were significantly different from that of resistant males. Males of the two resistant strains showed significantly higher response percentages than S males in all five behavioral categories (Fig. 3). There was no difference between Teb-R and Aba-R strain males in their response percentages.

Mating Choice Experiment Observations showed that two types of non-random mating existed in the three two-strain combinations (Fig.4). One was assortative mating, and the other was designated as preferential mating. In the S+Teb-R combination, assortative mating was found, with males of the two strains mating preferentially with the females from the same strain. The number of mated pairs in which both females and males were from the S strain (S♂×S♀) was the highest, significantly higher than those of the other 3 types of mated pairs (S♂+Teb-R♀, Teb-R♂+S♀, and Teb-R♂+Teb-R♀). The number of mated pairs for Teb-R♂+Teb-R♀ was the second highest, and the number for S♂+Teb-R♀ was the lowest. In contrast, in the other two combinations, preferential mating was found. In the S+Aba-R combination, both the S and Aba-R strain males displayed a significant mating preference for S strain females (Fig. 4b). In the Aba-R+Teb-R combination, Teb-R females were mated more than Aba-R females, regardless of the strain origin of the male (Fig. 4c).

Discussion

Sex pheromone communication systems may be a major force that drives moth speciation by causing behavioral reproductive isolation via assortative meeting and mating of conspecific individuals (Linn et al. 2007). In this study, we found differences in sex pheromone communication between susceptible and two insecticide resistant strains of DBM, and we showed that the differences led to an assortative or preferential mating between different strains. The results are important, both for understanding speciation mechanisms potentially caused by changes in sex pheromone communication, and for effective management of insecticide resistance in insect pests.

We found that the titers of sex pheromones in females of the two resistant strains were reduced significantly compared to females of the susceptible strain. This is consistent with the results obtained with Azinphosmethyl susceptible and resistant *Choristoneura rosaceana* (Harris) (Delisle and Vincent 2002; Trimble et al. 2004), and Pyrethroid susceptible and resistant *Heliothis virescence* females (Campanhola et al. 1991). More importantly, the ratio of the two main components of the sex pheromone produced by Aba-R strain females was, surprisingly, shifted to 1.59 :

Table 2 Behavioral responses of males to females in the wind tunnel study (%±SE)

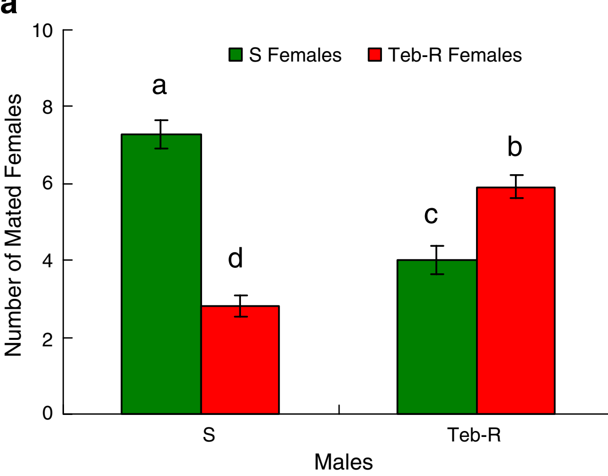
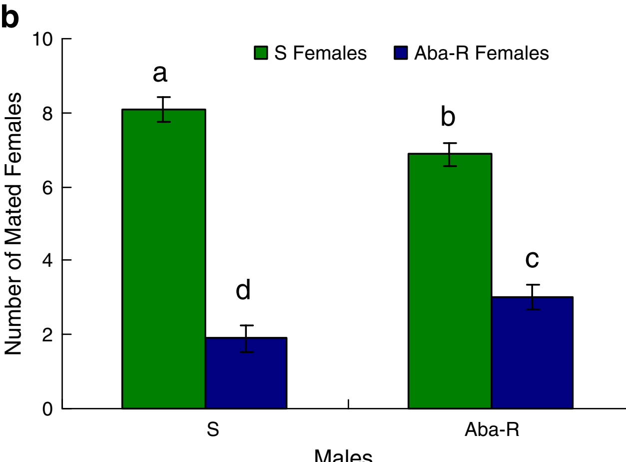
8.41 from 4.57:5.43 in susceptible females. This shift of blend ratio, together with the reduction of pheromone production, led to a lower competitiveness of Aba-R females in luring males. Aba-R females elicited significantly lower behavioral responses of S strain males when compared with S strain females in the wind tunnel experiment. Similarly, Aba-R females were less preferred for mating by S males, and even by males of the same strain, in the mating choice experiment. In contrast, S females and Teb-R males mated significantly less than Teb-R females and Teb-R males, although S females and S males mated significantly more than Teb-R females and S males. These results suggest that blend ratios are more important for mating success than are absolute titers of each pheromone component.

Another interesting result of our study is that insecticide-resistant males showed increased EAG responses to the sex pheromone. To our knowledge, this is the first report of resistant males exhibiting hypersensitivity to sex pheromones, although similar hypersensitivity effects have been reported in male *Grapholita molesta* treated with sublethal Octopamine (Linn and Roelofs 1986), male *Trichogramma brassicae* treated with Chlorpyrifos (Delpuech et al. 1998), and male *Spodoptera litura* treated with Endosulfan (Wei and Du 2004). Males of the two resistant strains also showed a wider response range in the ratios between the two major pheromone components; resistant males displayed higher EAG response to the ratios of 3:7 and 1:9. In the wind tunnel tests, resistant males showed similar behavioral responses to both Aba-R females with the pheromone ratio of 1.59:8.41 and to S females with a ratio of 4.57:5.43. It is reasonable to believe that Aba-R strain males were selected to respond to a wider range of blend ratios as the female pheromone ratio changed. However, the males of Teb-R strain also responded to a wider range of blend ratios with no change in pheromone ratio of the females. Such similar changes in male response (both in blend ratio and sensitivity) of the two resistant strains may be due to similar insecticide resistant mechanisms, although the two insecticides used for selection have different modes of action. For example, enhancement of cytochrome P450 monooxygenase activity was reported recently as one mechanism of resistance against Abamectin and Tebufenozide in DBM (Qian et al. 2008).

Notably, there was a discrepancy between the results of the wind tunnel and the mating choice experiments. Neither Aba-R nor Teb-R strain males displayed significantly different responsiveness to Aba-R and Teb-R strain females in wind tunnel tests, but, in mating choice experiments, Aba-R females were less frequently mated than were Teb-R females to Teb-R males or even to Aba-R males. This possibly is due to two factors. One is that in the mating choice experiment, there may be interactions between sexes and strains, while in wind tunnel tests just one factor (strain) may be operational. Another possible explanation is that the two experiments focused to some extent on different aspects of mating behavior. Wind tunnel tests of female attractiveness focused on a relatively long distance effect, while the mating choice tests were more focused on recognition between the two sexes and female attractiveness at closer range.

In the two DBM resistant strains, there may be a partial compensation of the sex pheromone communication between the two sexes, i.e., females released less amounts and varied ratios of sex pheromone while males responded to female sex pheromone with higher sensitivity and at a wider ratio range. This phenomenon also has been found in *Trichogramma brassicae* treated with $LD_{0.1}$ Deltamethrin (Delpuech et al. 2001). Such compensation in resistant strains is consistent with the "asymmetric tracking" model for the evolution of sex pheromone communication systems (Phelan 1992, 1997), in which the sex pheromone of females has been modified, and some males are able to track the changes. The model of asymmetric tracking involves two stages. In the first, males can be attracted to unusual females while still retaining their responsiveness to the ancestral pheromone blend. The second stage is characterized by the occurrence of assortative mating





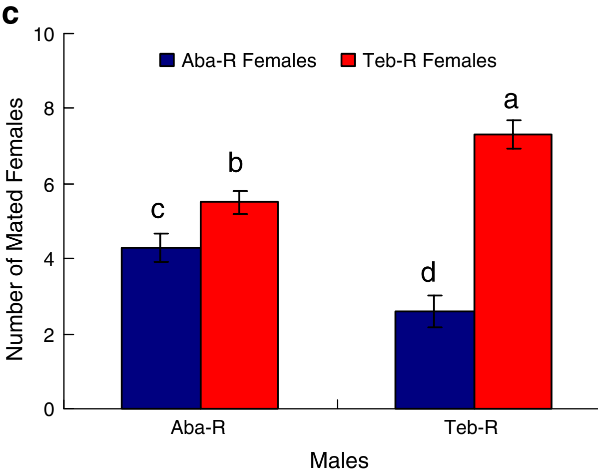


Fig. 4 Number (mean±SE) of females that mated with males of different strains. **a** S+Teb-R combination; **b** S+Aba-R combination; **c** Aba-R+Teb-R combination. *Error bars* with different letters are significantly different from each other at the 5% level by the Fisher's least significant difference test

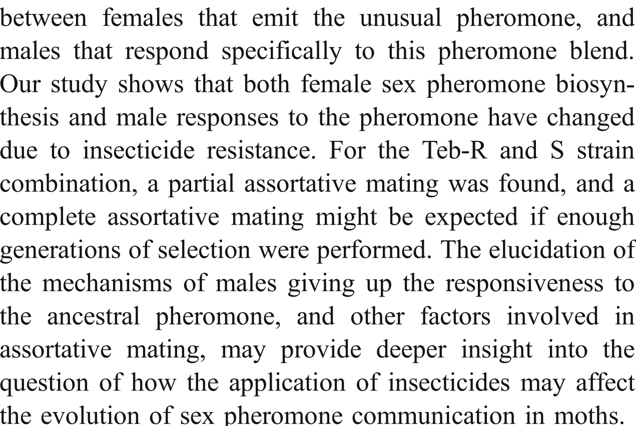

between females that emit the unusual pheromone, and males that respond specifically to this pheromone blend. Our study shows that both female sex pheromone biosynthesis and male responses to the pheromone have changed due to insecticide resistance. For the Teb-R and S strain combination, a partial assortative mating was found, and a complete assortative mating might be expected if enough generations of selection were performed. The elucidation of the mechanisms of males giving up the responsiveness to the ancestral pheromone, and other factors involved in assortative mating, may provide deeper insight into the question of how the application of insecticides may affect the evolution of sex pheromone communication in moths.

Changes in sex pheromone communication associated with insecticide resistance are of significance to the gene dilution-based insecticide resistance prevention and management strategy. Given that the insecticide resistance is recessive (Liang et al. 2003), our present study suggests that the change of the sex pheromone system in the Aba-R strain would have a positive effect on resistance management, as the mating frequency of S females was much higher than that of R females, and the mated pairs of R male and R female were less than one fourth (the proportion when R and S individuals mate randomly). Thus, the changes in the sex pheromone system would be favorable for the management of Abamectin resistance. However, in the case of the Teb-R strain, the effect would be neutral, because the number of mated pairs of R female and male was approximately one fourth, although the total number of mated S females (either with S male or R male) was higher than that of R females. Another implication of our study for pest resistance management is the possibility of using a pheromone lure that is more attractive to resistant males than is the lure for non-resistant individuals. As our wind tunnel experiment revealed, Aba-R resistant females displayed a significantly higher attractiveness to both Aba-R and Teb-R males than to S males. Therefore, use of lures with the blend ratio of the Aba-R female could trap more resistant males in the fields.

Although the two resistant strains with considerably different blend ratios (1.59:8.41 in the Aba-R strain and 4.57:5.43 in the Teb-R strain) were selected from the same S strain, the possibility that the change in sex pheromone is a result of random effects due to genetic bottlenecks can not be excluded. To confirm that the changes truly are due to insecticide resistance, one method might be to develop several new resistant strains from susceptible strains with considerable genetic difference, and check the reproducibility of this effect. Alternatively, insight could be obtained by exploring the resistance mechanisms to the insecticides. For example, Abamectin acts on the GABA receptor/ chloride ionophore complex and glutamate-gated chloride channel (Clark et al. 1995; Rugg et al. 2005). Any variation

associated with insecticide resistance that involves these targets should affect the neurophysiological activity of olfactory receptor neurons, and thus affect a male's response to sex pheromone and a female's pheromone biosynthesis in direct and/or indirect ways. Currently, the resistant mechanisms of the two resistant strains are not completely understood. Enhancement of cytochrome P450 monooxygenase activity was reported recently as one mechanism of resistance against both insecticides in DBM (Qian et al. 2008). This may contribute to the reduction of sex pheromone titers in resistant females, as a metabolic resistance mechanism often is thought to reduce the overall fitness of insects (Roush and McKenzie 1987). A complete understanding of insecticide resistant mechanisms will be helpful in the exploration of how insecticide resistance-associated changes affect the DBM sex pheromone system.

Abstract The sex pheromone of the navel orangeworm, *Amyelois transitella* (Walker) (Lepidoptera: Pyralidae), consists of two different types of components, one type including (11*Z*,13*Z*)-11,13-hexadecadienal (11*Z*,13*Z*-16:Ald) with a terminal functional group containing oxygen, similar to the majority of moth pheromones reported, and another type including the unusual long-chain pentaenes, (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-3,6,9,12,15-tricosapentaene (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H) and (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-3,6,9,12,15-pentacosapentaene (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H). After decapitation of females, the titer of 11*Z*,13*Z*-16:Ald in the pheromone gland decreased significantly, whereas the titer of the pentaenes remained unchanged. Injection of a pheromone biosynthesis activating peptide (PBAN) into the abdomens of decapitated females restored the titer of 11*Z*,13*Z*-16:Ald and even increased it above that in intact females, whereas the titer of the pentaenes in the pheromone gland was not affected by PBAN injection. In addition to common fatty acids, two likely precursors of 11*Z*,13*Z*-16:Ald, i.e., (*Z*)-11-hexadecenoic and (11Z,13Z)-11,13-hexadecadienoic acid, as well as traces of (*Z*)-6-hexadecenoic acid, were found in gland extracts. In addition, pheromone gland lipids contained (5*Z*,8*Z*,11*Z*,14*Z*,17*Z*)-5,8,11,14,17-icosapentaenoic acid, which also was found in extracts of the rest of the abdomen. Deuterium-labeled fatty acids, (16,16,16-D_3)-hexadecanoic acid and (*Z*)-[13,13,14,14,15,15,16,16,16-D_9]-11-hexadecenoic acid, were incorporated into 11*Z*,13*Z*-16:Ald after topical application to the sex pheromone gland coupled with abdominal injection of PBAN. Deuterium label was incorporated into the C_{23} and C_{25} pentaenes after injection of (9*Z*,12*Z*,15*Z*)-[17,17,18,18,18-D_5]-9,12,15-octadecatrienoic acid into 1–2 d old female pupae. These labeling results, in conjunction with the composition of fatty acid intermediates found in pheromone gland extracts, support different pathways leading to the two pheromone components. 11*Z*,13*Z*-16:Ald is probably produced in the pheromone gland by Δ11 desaturation of palmitic acid to 11*Z*-16:Acid followed by a second desaturation to form 11*Z*,13*Z*-16:Acid and subsequent reduction and oxidation. The production of 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H and 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H may take place outside the pheromone gland, and appears to start from linolenic acid, which is elongated and desaturated to form (5*Z*,8*Z*,11*Z*,14*Z*,17*Z*)-5,8,11,14,17-icosapentaenoic acid, followed by two or three further elongation steps and finally reductive decarboxylation.

Key Words Sex pheromone · Biosynthesis · *Amyelois transitella* · Linolenic acid · (5*Z*,8*Z*,11*Z*,14*Z*,17*Z*)-5,8,11,14,17-icosapentaenoic acid · (3*Z*, 6*Z*, 9*Z*, 12*Z*, 15*Z*)-3,6,9,12,15-tricosapentaene · (11*Z*,13*Z*)-11,13-hexadecadienal · Bifunctional Δ11 desaturase · PBAN · Pyralidae

Introduction

Unsaturated C_{10}–C_{18} straight chain alcohols, aldehydes, and acetates have been designated as "Type I" sex

pheromones of lepidopteran insects, and the majority of the known lepidopteran pheromones fall into this class (Ando et al. 2004). In contrast, a number of species in the families Geometridae, Arctiidae, Lymantriidae, and Noctuidae use polyunsaturated C_{17}–C_{23} straight chain hydrocarbons and the corresponding mono- and diepoxide derivatives as pheromone components, classed as "Type II" sex pheromones because of their distinct differences from the Type I group (Millar 2000; Ando et al. 2004).

The Type I alcohol, aldehyde, and acetate components are biosynthesized *de novo* from fatty acid precursors by a series of desaturation, chain elongation, and chain shortening steps that produce pheromone components with specific chain lengths, double bond positions, and double bond geometries. The structures are completed by the adjustment of the terminal functional group by reduction, oxidation, or tranesterification to provide alcohols, aldehydes, or acetates, respectively (Jurenka and Roelofs 1993; reviewed in Tillman et al. 1999). The evidence to date suggests that all of these transformations are carried out in the pheromone gland.

The biosynthesis of Type II pheromones also has been studied, and from reports of pheromone biosynthesis in the Lymantriidae (Kasang et al. 1979), Arctiidae (Rule and Roelofs 1989), and Geometridae (reviewed in Ando et al. 2008), it is clear that there are significant differences between the biosynthetic pathways leading to the two types of pheromones. These include differences in the biosynthetic sites, the substrates, the enzymes involved, and the endocrine regulation of biosynthesis. In distinct contrast to the site of production of Type I pheromones, it is likely that the polyunsaturated hydrocarbons that constitute Type II pheromones are produced in oenocyte cells by chain extension of diet-derived linoleic or linolenic acids, culminating in reductive decarboxylation to remove the terminal functional group (Rule and Roelofs 1989; reviewed in Ando et al. 2008). The final steps are slightly different for odd- vs. even-numbered carbon skeletons. The former probably result from 0–3 cycles of 2-carbon unit chain extension of linoleic or linolenic precursors and subsequent removal of one carbon by reductive decarboxylation to give an odd-numbered chain. In contrast, recent evidence suggests that even-numbered chains probably are produced by the same series of 2-carbon chain extension steps, then α-oxidation and loss of one carbon, followed by loss of a second carbon as CO or CO_2 by an oxidative mechanism (Goller et al. 2007). In some cases, further desaturation also occurs somewhere in the pathway to produce compounds such as the tetraene hydrocarbon pheromones of the arctiid moth *Utetheisa ornatrix* (Linnaeus) (Choi et al. 2007) and the geometrid moth *Operophtera brumata* (L.) (Zhao and Löfstedt, unpublished data). The newly formed polyene skeletons then are transported through the hemolymph by lipophorin carriers from the oenocytes to the pheromone gland (Wei et al. 2004; Matsuoka et al. 2006). The polyene hydrocarbons are emitted from the pheromone gland unchanged, or are further transformed by one or more epoxidation steps to produce unsaturated epoxide pheromone components for release (Miyamoto et al. 1999; Jurenka et al. 2003; Wei et al. 2003; Fan et al. 2004; Wei et al. 2004; Matsuoka et al. 2006).

The endocrine regulation of Type II pheromone biosynthesis also is markedly different from that of Type I pheromones. According to studies published to date, pheromone biosynthesis activating neuropeptides (PBANs) are not involved in the production of unsaturated hydrocarbon pheromone components in the arctiid moth *U. ornatrix* (Choi et al. 2007) or the geometrid moth *Ascotis selenaria cretacea* (Butler) (Wei et al. 2004), but they are involved in the epoxidation of these hydrocarbons in the pheromone gland, for those species that use epoxide pheromones alone or in combination with unsaturated hydrocarbons (e.g., the lymantriid moth *Lymantria dispar* L. (Jurenka et al. 2003) and the geometrid moth *A. selenaria cretacea* B. (Ando et al. 1997; Wei et al. 2004)).

For many years, it was presumed that a particular lepidopteran species produced either Type I or Type II pheromones, but not both. However, examples of species whose pheromone blends contain compounds of both types recently have been found in two moth families. For example, the pheromone blend of the crambid moth *Neoleucinodes elegantalis* consists of (*E*)-11-hexadecen-1-ol and (3Z,6Z,9Z)-3,6,9-tricosatriene (3Z,6Z,9Z-23:H) (Cabrera et al. 2001), whereas another crambid species, *Deanolis sublimbalis*, uses a blend consisting of (*Z*)-11-hexadecenal and 3Z,6Z,9Z-23:H (Gibb et al. 2007). Within the pyralid moth family, several examples are known, including the meal moth, *Pyralis farinalis* (L.) [(11*Z*,13*Z*)-11,13-hexadecadienal (11*Z*,13*Z*-16:Ald) (Landolt and Curtis 1982) + 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H; Leal et al. 2005; Kuenen et al. 2010], the navel orangeworm, *Amyelois transitella* (Walker) [11*Z*,13*Z*-16:Ald (Coffelt et al. 1979) + 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H; Leal et al. 2005; Millar et al. 2005; Kuenen et al. 2010], and the fir coneworm moth, *Dioryctria abietivorella* (Grote) [(9*Z*,11*E*)-9,11-tetradecadienyl acetate (9*Z*,11*E*-14:OAc) + 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H; Millar et al. 2005]. Several other *Dioryctria* species also appear to have analogous pheromone blends containing both Type I and Type II components (Miller et al., 2010a, b; Löfstedt et al. unpub. data).

The biosynthesis of the blends of Type I and Type II pheromone components in such species has not yet been studied. On the basis of previous pheromone biosynthesis studies, the aldehyde and pentaene pheromone components found in *A. transitella* pheromone glands probably arise from two independent biosynthetic pathways. The conjugated diene aldehyde, 11*Z*,13*Z*-16:Ald, may be produced

from palmitic acid in the pheromone gland, by pathways analogous to those for other conjugated diene Type I pheromones. For example, production of 11*Z*,13*Z*-16:Acid, a precursor to the conjugated pheromone in the pine processionary moth, *Thaumetopoea pityocampa* (Denis and Schiffermüller), involves a bifunctional Δ11 desaturase (Quero et al. 1997; Abad et al. 2007). By analogy to other systems, it seems likely that the two long-chain pentaenes, 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H and 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H, are synthesized in oenocyte cells via chain elongation, desaturation, and decarboxylation of diet-derived linolenic acid or other unsaturated fatty acid precursors, and transported to the gland through the hemolymph (Schal et al. 1998a, b; Jurenka and Subchev 2000; Matsuoka et al. 2006). It also is noteworthy that the above polyenes differ in structure by only one two-carbon unit, suggesting that the polyene motif that is common to both components may be synthesized first, followed by chain length adjustment in the later steps of the biosynthesis.

Thus, the objectives of the work reported here were to study the biosynthesis of the polyene hydrocarbon components and the diene aldehyde pheromone component present in the navel orangeworm pheromone gland, and to gain a better understanding of the mechanisms by which the biosynthesis of these two distinct types of pheromone components are regulated in *A. transitella*, including examining the possible role of PBAN.

Methods and Materials

Insects The *A. transitella* moths used in this study were obtained from the Department of Entomology, University of California, Riverside, CA, USA. The larvae were fed on a wheat germ diet as previously described (Coffelt et al. 1978; Girling and Cardé 2006), and kept in 4 liter glass jars in controlled environment chambers with 17:7 L:D, 25± 1°C and 65% relative humidity. Newly emerged adult females were collected daily and held in single-sex cohorts fed with a 10% honey solution. One- to 2-d old female pupae and adults were used throughout this study. Pupae were sexed by the morphological differences in their external genitalia.

Chemicals PBAN (*Helicoverpa zea* pheromone biosynthesis-activating neuropeptide) was purchased from Bachem (Weil am Rhein, Germany). Methyl (9*Z*,12*Z*,15*Z*,18*Z*,21*Z*)-9,12,15,18,21-tetracosapentaenoate and (16,16,16-D_3)-hexadecanoic acid (D_3-16:Acid) were purchased from Larodan Fine Chemicals, Malmö, Sweden. The synthesis of (*Z*)-[13,13,14,14,15,15,16,16,16-D_9]-11-hexadecenoic acid (D_9-11*Z*-16:Acid) was described in Löfstedt et al. (1994), and (9*Z*,12*Z*,15*Z*)-[9,10,12,13,15,16-D_6]-9,12,15-octadecatrienoic acid (D_6-linolenic acid), (9*Z*,12*Z*,15*Z*)-[17,17,18,18,18-D_5]-9,12,15-octadecatrienoic acid (D_5-linolenic acid), and (11*Z*,14*Z*,17*Z*)-[8,8,9,9-D_4]-icosatrienoic acid (D_4-icosatrienoic acid) were obtained from R. Adlof as gifts. 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H and 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H were synthesized as described by Millar et al. (2005), and 11Z,13*Z*-16:Ald and 11Z,13*Z*-16:OH were synthesized as described in Kuenen et al. (2010).

(*Z*)- and (*E*)-6-Hexadecenol (6*Z*-16:OH and 6*E*-16:OH) from our laboratory collection of pheromone components were used to prepare the reference standards needed to identify the double bond configuration of methyl 6-hexadecenoate in the insect extracts. Thus, 2 mg of 6*Z*-16:OH or 6*E*-16:OH were dissolved in 1 ml of dimethylformamide (DMF) in a 4 ml screw-cap vial, 100 mg of pyridinium dichromate were added, and the mixture was stirred overnight at room temperature. Then 1 ml of diethyl ether was added, and the mixture was vortexed briefly to precipitate the chromium salts. Distilled water was added, and the ether layer was then collected, washed twice with distilled water to remove traces of DMF, dried over anhydrous sodium sulfate, and evaporated to dryness. Methyl esters were produced by acid-catalyzed esterification (MeOH/HCl at 80°C for 1 h).

A reference standard of methyl (11*Z*,13*Z*)-11,13-hexadecadienoate (11*Z*,13*Z*-16:Me) also was prepared from 11*Z*,13*Z*-16:Acid by acid-catalyzed esterification.

Extraction of Insect Tissues The pheromone glands of female *A. transitella*, a broad, chevron-shaped structure located on the ventrolateral surface of the intersegmental membrane between abdominal scleromata VIII and IX (Srinivasan et al. 1986), were dissected from cohorts of individual 1- to 2-d-old intact virgin female moths in both the photophase (1 h before lights off) and scotophase (6 h after lights off). Each gland was extracted for 30 min in 10 μl of hexane containing 1 ng of (3*Z*,6*Z*,9*Z*)-3,6,9-henicosatriene (3*Z*,6*Z*,9*Z*-21:H) as internal standard. After removing the pheromone glands, the hemolymph, the abdominal cuticle, and the whole abdomen (i.e., cuticle, hemolymph, and abdominal tissues) were extracted separately. For extraction of the hemolymph, ca. 10 μl of modified Weever's saline (21 mM KCl, 12 mM NaCl, 3 mM $CaCl_2$, 18 mM $MgCl_2$, 170 mM glucose, 5 mM PIPES, 9 mM KOH, adjusted to pH 6.6; Carrow et al. 1981) were injected first into the abdomen, and then the mixture of hemolymph and saline was transferred into a glass vial insert by syringe. Methanol (ca. 30–40 μl per 3–4 female equivalents of hemolymph) was added, and the mixture was extracted × 3 with 10 μl hexane containing 0.1 ng/μl of internal standard (3*Z*,6*Z*,9*Z*-21:H).

The abdominal cuticle was extracted as previously described (Jurenka et al. 2003), first removing the majority of the scales on the abdomen by application of a gentle

vacuum and then removing the abdomen at the junction of the thorax. The abdomen was cut laterally and pinned open. The ovaries were removed along with the majority of the remaining fat body and organs, leaving mostly epidermal tissue attached to the cuticle. The cuticle was rinsed first with 30 µl methanol and then extracted by vortexing 3× with 100 µl hexane containing 0.1 ng/µl 3*Z*,6*Z*,9*Z*-21:H internal standard, 10 min each time. After extraction, the hexane layers were combined into a new glass tube. The external abdominal cuticle also was extracted in this study by successively dipping five intact female abdomens into 100 µl hexane, with 5 sec dipping per individual. The hexane extract then was concentrated to approximately 10 µl for GC-MS analysis.

To extract the hydrocarbons from the whole abdomen with only the pheromone gland removed, the abdominal tissues were immersed in 100 µl methanol in a 2 ml vial and disrupted with a probe sonicator for a few seconds. The resulting homogenate was extracted by sequential vortexing 3× with 100 µl hexane containing 0.1 ng/µl 3*Z*,6*Z*,9*Z*-21:H internal standard. The hemolymph, cuticle, and abdomen tissue homogenate extracts were dried with anhydrous sodium sulfate and purified by passage through a 7× 0.2 cm column of 100-200 mesh Florisil. Approximately 30-40 µl of a crude hexane extract were added to the column, and hydrocarbons were eluted with 1 ml hexane.

Base Methanolysis and Methylthiolation After the first extraction with hexane, the remaining glandular and abdominal tissues were extracted further for fatty acyl moieties. Thus, the glandular tissue was extracted with 20 µl chloroform:methanol (2:1 *v*:*v*) in a glass vial insert for 24 h at room temperature, then the tissue was removed and the extract was concentrated under a stream of nitrogen. The residue was subjected to base methanolysis to convert fatty acyl moieties to the corresponding methyl esters as described by Bjostad and Roelofs (1984). First, 20 µl of 0.5 M KOH in methanol were added, and the vial insert was placed inside a 4 ml screw-cap vial that was heated for 1 h at 40°C. After cooling, 20 µl of 0.5 M HCl in methanol were added to neutralize the alkali, and the mixture was extracted 3× with 20 µl hexane. The combined hexane layers were washed twice with 30 µl distilled water, then dried over anhydrous sodium sulfate.

The residue from extraction of the abdominal tissue with hexane, in 100 µl methanol, was re-extracted with 200 µl chloroform for 24 h at room temperature. The chloroform/methanol extract was transferred to a new 2 ml vial and concentrated under a stream of nitrogen, then subjected to methanolysis by addition of 200 µl of 0.5 M KOH in methanol and warming to 40°C for 1 h. After cooling, 200 µl of 0.5 M HCl in methanol were added, and the mixture was extracted 3× with 200 µl hexane, vortexing for 10 min each time. The hexane layers were combined and washed 2× with 200 µl distilled water, and dried over anhydrous sodium sulphate. The resulting solutions of fatty acid methyl esters were analyzed by GC-MS as described below. The double bond positions of monounsaturated methyl esters were determined by GC-MS analysis of their dimethyldisulfide (DMDS) adducts (Buser et al. 1983; Dunkelblum et al. 1985). DMDS derivatizations were carried out by adding 50 µl DMDS and 10 µl of 5% (by weight) I_2 in diethyl ether to 20 µl of the solution of methylated fatty acids extracted from the pheromone glands, or 50 µl of the methylated fatty acids extracted from the abdomen tissues. Each reaction was stirred in a 2 ml screw-cap vial overnight at 40°C, then 200 µl of hexane were added, and the mixture was washed with 50 µl 5% aqueous sodium thiosulfate. The organic layer then was dried over anhydrous sodium sulfate and evaporated to dryness. The product was taken up in hexane for analysis.

In addition, an extract of artificial diet (1 g diet in 1 ml chloroform/methanol for 24 h) was used to analyze fatty acids from the diet.

Effect of PBAN on Pheromone Production Unmated female moths (0–24-h-old) were decapitated at the end of the photophase and kept individually in small plastic containers. A piece of wet filter paper was placed inside each container to maintain high humidity so that the decapitated animals would not desiccate. After 24 h, 10 pmol PBAN in 4 µl of Weever's saline were injected into the abdomen of each decapitated female. Equal volumes of Weever's saline were injected into decapitated animals as controls. The pheromone glands of treated and control insects were dissected 2 h later, and each gland was extracted with 10 µl hexane containing 0.1 ng (*Z*)-12-tetradecenyl acetate and 0.2 ng (1,3*Z*,6*Z*,9*Z*)-3,6,9-nonadecatetraene as internal standards.

Labeling Experiment The proposed pheromone precursors, D_3-16:Acid, D_9-11*Z*-16:Acid, D_6-linolenic acid, D_5-linolenic acid, and D_4-11*Z*,14*Z*,17*Z*-20:Acid were used to probe the aldehyde and pentaenes biosynthetic pathways. D_3-16:Acid, D_9-11*Z*-16:Acid, and D_6-linolenic acid were dissolved in dimethylsulfoxide (DMSO) at a concentration of 12.5 µg/µl and topically applied to the extruded pheromone gland (0.2 µl of DMSO solution; 2.5 µg/gland) of PBAN-injected decapitated female adults. D_5-linolenic acid and D_4-11*Z*,14*Z*,17*Z*-20:Acid dissolved in DMSO also were topically applied to pheromone glands of the control group of intact female adults that had not been injected with PBAN. After a 2 h incubation, pheromone glands were dissected and extracted as described above.

For injection of the possible pheromone precursors, D_5-linolenic acid and D_4-11*Z*,14*Z*,17*Z*-20:Acid were dissolved

in vegetable oil (75% rapeseed and 25% sunflower oil, ICA, Sweden.) and injected into the abdomens of 1- to 2-d-old female pupae (1 µl of 100 µg/µl solution per female). After adult emergence, at the 6th h of the scotophase, the pheromone gland was removed from 2-d-old females and extracted with 10 µl hexane containing 0.1 ng/µl 3*Z*,6*Z*,9*Z*-21:H as internal standard. After removal of the pheromone gland, the remaining abdominal tissue including the scales was extracted 3× with 100 µl hexane containing 0.1 ng/µl 3*Z*,6*Z*,9*Z*-21:H as internal standard as described above. D_4-11*Z*,14*Z*,17*Z*-20:Acid dissolved in vegetable oil also was injected into 2-d-old female adults at the 2nd h in the scotophase, and the pheromone gland and remaining abdominal tissue were subsequently extracted at the 6th h in the scotophase, followed by the same protocol.

Coupled Gas Chromatography-Mass Spectrometry The aldehyde and pentaene components in pheromone gland extracts, the corresponding deuterium labeled compounds and precursors, and the fatty acid methyl esters derived from methanolysis of tissue and diet extracts were analyzed with a Hewlett-Packard (Palo Alto CA, USA) 5972 mass selective detector coupled to an HP 5890 series II GC equipped with a capillary column (HP-1MS or InnoWax (SGE, Austin, TX, USA), both 30 m×0.25 mm i.d.). The HP-1MS column was programmed from 80°C at 10°C/min to 220°C, hold for 3 min, then to 250°C at 4°C/min, hold for 5 min, and finally to 280°C at 20°C/min, hold for 5 min. The InnoWax column was programmed from 80°C at 10°C/min to 200°C, then to 230°C at 1°C/min, with a final hold for 20 min at 230°C.

Selected ion monitoring (SIM) was used to monitor the pheromone compounds and the incorporation of labeled precursors. The following characteristic ions were chosen for the aldehyde and the hydrocarbons: when each of D_3-16:Acid and D_9-11*Z*-16:Acid was applied, the molecular ion at *m/z* 236 was chosen for 11*Z*,13*Z*-16:Ald, with *m/z* 239 and 243 being used to monitor the corresponding D_3-11*Z*,13*Z*-16:Ald and D_7-11*Z*,13*Z*-16:Ald, respectively. When D_6-linolenic acid was applied to probe the pentaenes biosynthetic pathway, the diagnostic ions at *m/z* 108 and 178 were used to monitor unlabeled 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H, and *m/z* 108 and 206 were used to monitor unlabeled 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H, whereas *m/z* 112 (108 + 4) and *m/z* 178 or 206 were used to monitor labeled 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H or 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H, respectively. Specifically, the ions at *m/z* 178 and 206 remain unchanged in the labeled pentaenes because they arise from cleavages from the nondeuterated end of the chains (Millar et al. 2005). When D_5-linolenic acid was applied, *m/z* 113 (108 + 5) and *m/z* 178 or 206 were used to monitor labeled 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H and 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H, respectively; and when D_4-*Z*11,*Z*14,*Z*17-20:Acid was used, *m/z* 108 and *m/z* 180 (178+2) were chosen for monitoring labeled 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H.

Results

Regulation of Pheromone Production The amount of 11*Z*,13*Z*-16:Ald in pheromone gland extracts from decapitated females 24 h after decapitation and 2 h after injection of saline was barely detectable (0.02±0.02 ng) and was significantly lower than the titer in intact control females (0.25±0.27 ng, P=0.016, N=10) (Fig. 1). However, 2 h after injection of PBAN into the abdomens of decapitated females, the pheromone gland titer of 11*Z*,13*Z*-16:Ald increased to 1.6±1.2 ng (N=9), significantly higher than the titer in either decapitated, saline-injected control females (P<0.001) or intact females (P=0.001). By contrast, the titers of 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H and 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H were not affected by PBAN; the levels of each compound found in glands from normal, decapitated PBAN-injected, or decapitated saline-injected control females were not significantly different (Fig. 1).

The two long-chain pentaenes were found in hexane extracts from various tissues including the pheromone gland, the abdominal cuticle, the abdominal tissue, and the hemolymph of 1- to 2-d-old virgin females (Table 1). The titers of each of the two pentaenes in the pheromone gland and abdominal tissue extracts did not differ significantly between the photophase and scotophase (Table 1). There was no evidence for either of the pentaenes on external cuticular surfaces; extracts prepared by quickly dipping intact adult insects in solvent contained no detectable amounts of the pentaenes.

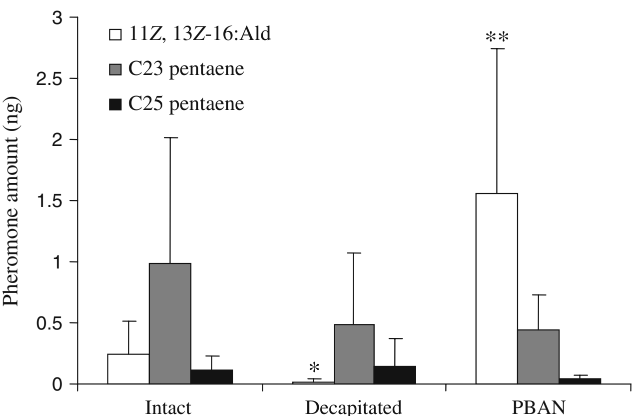

Fig. 1 Titers of 11*Z*,13*Z*-16:Ald, 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H, and 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H in pheromone gland extracts from *Amyelois transitella* intact females, decapitated females injected with saline, and decapitated females injected with 10 pmol PBAN in saline (PBAN). For each column color, significant differences between means were determined by Student's *t*-tests ("*": P<0.05; "**": P<0.01)

Table 1 Titer (ng) of C_{23} and C_{25} pentaenes in various tissues of 1–2 day old virgin female navel orangeworm moths[a]

3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H	0.03±0.01	0.07±0.05	10±6	18±11	2.0±1.7	0.71±0.12

[a] Individual 1- to 2-d-old intact virgin female moths (or in the case of hemolymph, samples of four females) were extracted during the last hour of photophase or the 6th hour of scotophase, respectively. The titer of each polyene (mean ± SD) was determined by GC-MS in selected ion monitoring mode using the base peak (*m/z* 79) for quantification versus 3*Z*,6*Z*,9*Z*-21:H as internal standard. Student's *t*-tests showed no significant differences at the 5% level between photophase and scotophase extracted polyenes in the pheromone gland or whole abdominal tissue

[b] Abdomen = the whole abdomen with the pheromone gland removed, homogenized and extracted

[c] Abdominal cuticle = the abdominal cuticle with the pheromone gland, hemolymph, fat body, and other tissues removed

[d] Hemolymph = the mixture of hemolymph and saline extracted from the abdomen, after injection of 10 µl Weever's saline per female

Fatty Acid Composition in Abdominal Tissue and Pheromone Gland In addition to saturated and unsaturated fatty acid methyl esters such as methyl tetradecanoate (14:Me, related abbreviations are used hereafter for analogous fatty acid methyl esters), 15:Me, 16:Me, 9*Z*-16:Me, 17:Me, 18:Me, 9*Z*-18:Me, 9*Z*,12*Z*-18:Me, and 9*Z*,12*Z*,15*Z*-18:Me, the methanolized abdominal tissue and pheromone gland extracts contained the methyl esters of some longer chain saturated and unsaturated fatty acids, including 20:Me, 22:Me, 24:Me, 5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-20:Me, as well as traces of

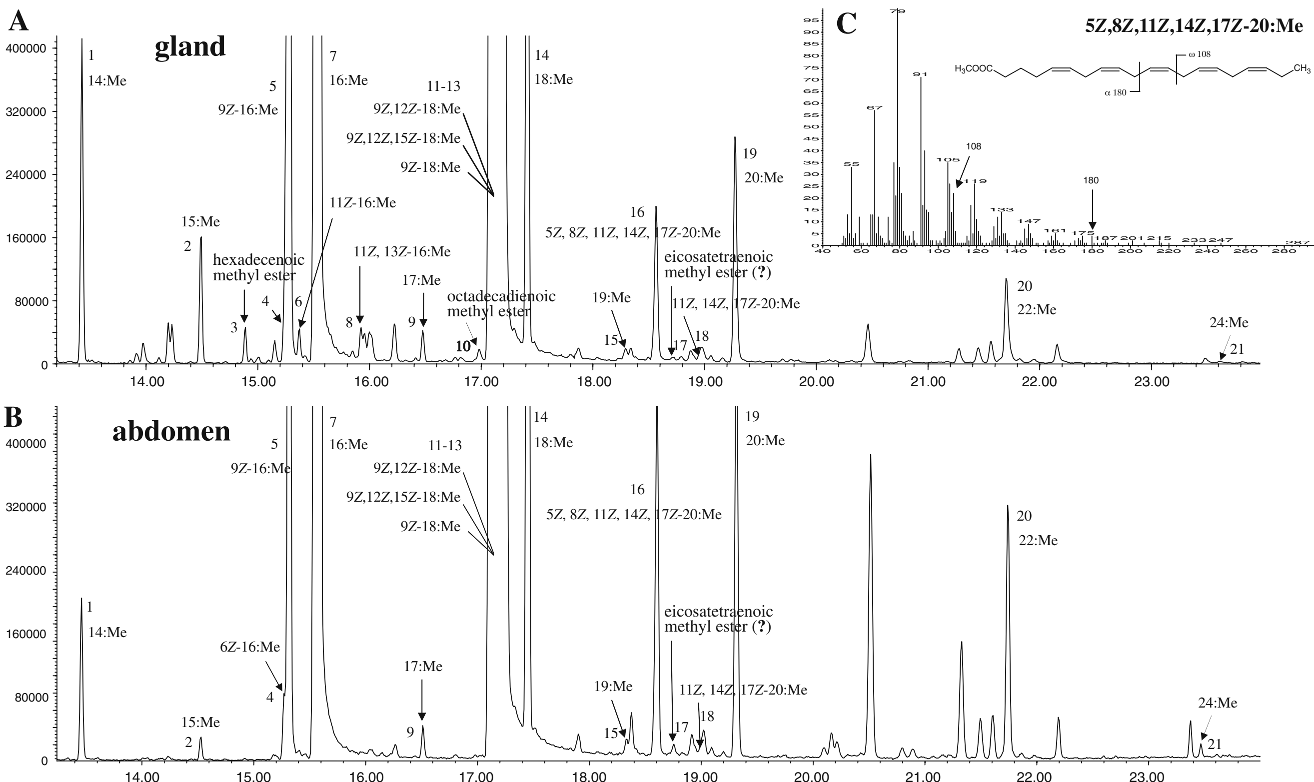

Fig. 2 Total ion chromatograms of the fatty acid compositions (as the methyl esters) of representative pheromone gland (**a**) and abdominal tissue (**b**) extracts (HP-1MS capillary column). Fatty acid methyl esters are coded with a number indicating chain length, followed by a number indicating the number of double bonds, with the positions and geometries given if known. Peak numbers correspond to those listed in Table 2. The omega ion at *m/z* 108, diagnostic for a 3,6,9-triene motif, and the alpha ion at *m/z* 180, diagnostic for a 5,8,11-triene motif counting from the other end of the chain are indicated in the mass spectrum of the C20:5 acid methyl ester (**c**). The weak molecular ion at *m/z* 316 was not detected in full scan mode, but it was detected in the more sensitive selected ion monitoring mode, at a same retention time as the two diagnostic ions at *m/z* 79 and 108

two compounds tentatively identified as 11*Z*,14*Z*,17*Z*-20: Me and a C20:4 methyl ester (Fig. 2, Table 2). In particular, the mass spectrum of 5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-20:Me contained diagnostic ions at *m/z* 108 and *m/z* 180 from the characteristic cleavages and rearrangements of a fatty acid methyl ester with a 5,8,11,14,17 pentaene system (Fellenberg et al. 1987), as well as *m/z* 74 from McLafferty rearrangement of the methyl ester. The molecular ion (*m/z* 316) was not detected in full scan, but it was found in the more sensitive selected ion monitoring mode. Furthermore, this acid must be produced by the insect because it was not found in extracts of the diet used to rear the insects. 11*Z*,14*Z*,17*Z*-20: Acid also was tentatively identified on the basis of its matching retention time with that of an authentic standard, the characteristic base peak at *m/z* 79, and the diagnostic fragment at *m/z* 108 from the same cleavage and rearrangement as shown in Fig. 2c for 5*Z*,8*Z*,11*Z*,14*Z*, 17*Z*-20:Acid.

In extracts of the pheromone gland, the aldehyde pheromone intermediates 11*Z*-16:Me and 11*Z*,13*Z*-16:Me were found, along with traces of a nonconjugated doubly unsaturated C_{18} fatty acid that was not completely identified (peak 6, peak 8, peak10, Fig. 2a). These three compounds were not found in the abdominal tissue extracts.

Table 2 Fatty acid methyl esters detected in the pheromone gland and abdomen of female navel orangeworm

[a] Numbers refer to gas chromatographic peaks in Fig. 2

[b] Amounts are reported relative to that of methyl palmitate, the most abundant component

[c] Abdomen = the whole abdomen with the pheromone gland removed, homogenized and extracted

[d] Full scan mass spectrum

[e] Retention time match on both the HP1-MS and InnoWax columns

[f] DMDS derivative confirmation of double bond location and configuration

[g] The double bond position was not determined

[h] 6*Z*-16:Me in pheromone gland extract was well separated from 9*Z*-16:Me on the InnoWax column, but the two compounds were not resolved on the HP-1MS column. However, the same compounds in the abdomen extracts were separated on both columns. The double bond position of 6*Z*-16:Me was confirmed by DMDS analysis and the configuration was confirmed by comparing the mass spectrum and retention time of both the methyl ester and the corresponding DMDS adduct with those of the reference 6*Z*-16 and 6*E*-16 isomers

[i] Present in trace amount

Another unusual monoenoic C16 fatty acid methyl ester was found in the gland and abdomen extracts after DMDS derivatization of the methyl esters fraction. Specifically, a C16 DMDS adduct was found with a molecular ion at *m/z* 362 (6%) and diagnostic fragment ions at *m/z* 175 (42%) and 187 (81%), corresponding to the DMDS derivative of Δ6-16:Me. By comparing the mass spectrum and gas chromatographic retention times of the methyl ester and its DMDS adduct with those of authentic 6*Z*-16: Me and 6*E*-16:Me and their DMDS adducts, the natural Δ6-16 component was shown to be the 6*Z*-16:Me isomer (Fig. 3).

Labeling Experiment Results Topical application of D_3-16: Acid and D_9-11*Z*-16:Acid to the pheromone gland of PBAN-injected decapitated females resulted in incorporation of the labeled precursors into 11*Z*,13*Z*-16:Ald, with a labeled to unlabelled compounds ratio of 2.7±2.0 % (N=4) and 44±23% (N=6), respectively (Fig. 4a and b). These results demonstrated that both of these acids likely are biosynthetic precursors to 11*Z*,13*Z*-16:Ald, and that 11*Z*, 13*Z*-16:Ald synthesis occurs in the pheromone gland.

When D_5-linolenic acid was injected into 1-to 2-d-old female pupae, the labeled precursor was incorporated into both the C_{23} and C_{25} pentaenes (Fig. 5), with a labeled to

Double bond positions were identified from the diagnostic ions from cleavage of the C-C bond between the two carbons bearing methylthiol groups: Δ6-16, 175/187/362; Δ9-16, 217/145/362; Δ11-16, 245/117/362. **c** Confirmation of the "*cis*" configuration in the insect-produced Δ6-16 monounsaturated fatty acid methyl ester by comparison of the chromatographic retention times of the DMDS adducts, using the diagnostic ions at *m/z* 175 and 187. *a*: Δ6-16:Me DMDS adduct in insect abdomen extract; *b*: authentic 6*Z*-16:Me DMDS adduct; c: authentic 6*E*-16:Me DMDS adduct. **d** Full scan mass spectrum of the Δ6-16 monounsaturated fatty acid methyl ester DMDS adduct from insect abdomen extract (*a*) and authentic 6*Z*-16:Me DMDS adduct (*b*)

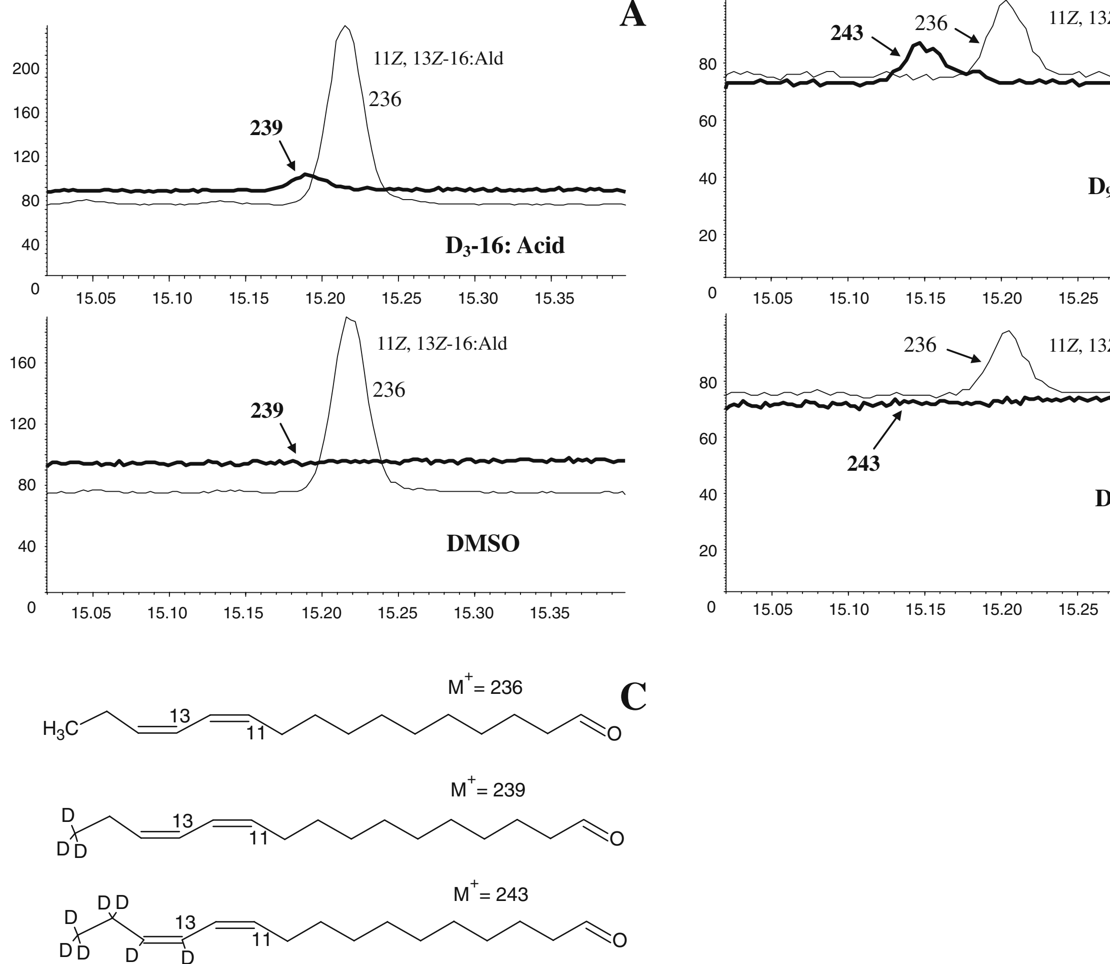

Fig. 4 Selected ion monitoring chromatograms showing incorporation of labeled fatty acid precursors into 11*Z*,13*Z*-16:Ald, using ions 239 and 243 to monitor D_3-11*Z*,13*Z*-16:Ald and D_7-11*Z*,13*Z*-16:Ald, respectively. **a** Deuterium label incorporation into D_3-11*Z*,13*Z*-16:Ald after topical application of D_3-16:Acid in DMSO onto the pheromone gland; **b** Deuterium label incorporation into D_7-11*Z*,13*Z*-16:Ald after topical application of D_9-11*Z*-16:Acid in DMSO onto the pheromone gland; **c** diagnostic ions for unlabeled 11*Z*,13*Z*-16:Ald, D_3-labeled 11*Z*,13*Z*-16:Ald and D_7-labeled 11*Z*,13*Z*-16:Ald

unlabeled compounds ratio of 4.9±0.6% for C_{23} pentaene in the pheromone gland extracts, a 4.0±1.2% ratio in C_{23} pentaene extracted from the abdominal tissues (N=3), and a 3.6±0.2% ratio (N=3) in C_{25} pentaene extracted from abdominal tissues. Because of the small amount of native C_{25} pentaene in the pheromone gland, among the labeled samples only one provided clear evidence for incorporation of label (6.0%). These results demonstrated that linolenic acid is a precursor for both of the pentaene components, but they do not reveal where the biosynthesis of the pentaenes occurs. However, topical application of D_6-linolenic acid to the pheromone gland coupled with PBAN injection, or topical application of D_5-linolenic acid onto the pheromone gland without PBAN injection resulted in no detectable incorporation of label into either of the pentaenes. This suggests that the pentaenes are not synthesized in the pheromone gland, and consequently, that they must be synthesized elsewhere in the abdomen and transported to the pheromone gland for release.

Topical application of D_4-11*Z*,14*Z*,17*Z*-20:Acid onto the pheromone gland of intact females without PBAN injection or injection of D_4-11*Z*,14*Z*,17*Z*-20:Acid into the abdomens of either pupae or adults also did not result in detectable label incorporation into the pentaenes, indicating that this acid probably is not a precursor to the pheromone.

Discussion

This is the first example of a lepidopteran insect in which both of the biosynthetic pathways leading to Type I and Type II moth pheromone components, respectively, have been demonstrated. The general steps of the pathways are parallel to those found in moths which use only one or the

Fig. 5 Selected ion monitoring chromatograms showing incorporation of labeled fatty acid precursors into 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H and 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H after abdominal injection of D_5-linolenic acid into 1–2 d old pupae. **a** Deuterium label incorporation into D_5-3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H; **b** Deuterium label incorporation into D_5-3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H; **c** Ions 108 and 178, and ions 108 and 206 were used to monitor unlabeled 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H and 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H, respectively. Ions 113 and ion 178 were used to monitor D_5-3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-23:H, and ions 113 and 206 were used to monitor D_5-3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H. Because of the small amounts of both native and labeled 3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H, the 206 ion was not detected in labeled D_5-3*Z*,6*Z*,9*Z*,12*Z*,15*Z*-25:H

other pathway, with our results suggesting that navel orangeworm females synthesize 11*Z*,13*Z*-16:Ald from palmitic acid in the pheromone gland. In contrast, the two pentaenes apparently originate from linolenic acid. The fact that the two pentaenes were found in extracts of the pheromone gland, the abdominal tissue, the abdominal cuticle, and the hemolymph of female navel orangeworm moths (Table 1) are consistent with the hypothesis that the pentaenes are synthesized outside the pheromone gland, possibly in oenocyte cells, and then transferred to the gland through the hemolymph by carrier proteins, as has been shown in other lepidopteran species that produce Type II pheromone components (Jurenka et al. 2003; Wei et al. 2003; Matsuoka et al. 2006; Choi et al. 2007).

As expected, the production of 11*Z*,13*Z*-16:Ald in pheromone glands of decapitated females was increased significantly by PBAN injection, whereas the titer of the pentaenes in the gland extracts was not affected by PBAN injection. In addition, the titers of both pentaenes in the gland extracts were the same regardless of whether the glands were extracted during the photophase or the scotophase (Table 1). Thus, PBAN does not appear to be involved in the production of the pentaenes, similar to what was found with the production of polyenes in the geometrid moth *A. selenaria cretacea* (Wei et al. 2004) and the arctiid moth *U. ornatrix* (Choi et al. 2007), and the titer of the pentaenes does not fluctuate with the light-dark cycle.

The fatty acid composition of extracts of pheromone glands and abdominal tissues, coupled with the results showing incorporation of labeled precursors, suggest two distinctly different biosynthetic pathways for the aldehyde and the pentaenes (Figs. 6 and 7). In the pheromone gland, the fatty acid compositions found in the extracts suggested that saturated C_{16} palmitic acid may be a key substrate, being first desaturated at the 11 position to form 11*Z*-16: Acid. A second desaturation, possibly mediated by a bifunctional desaturase such as the one known from *T. pityocampa* (Quero et al. 1997; Abad et al. 2007) then may

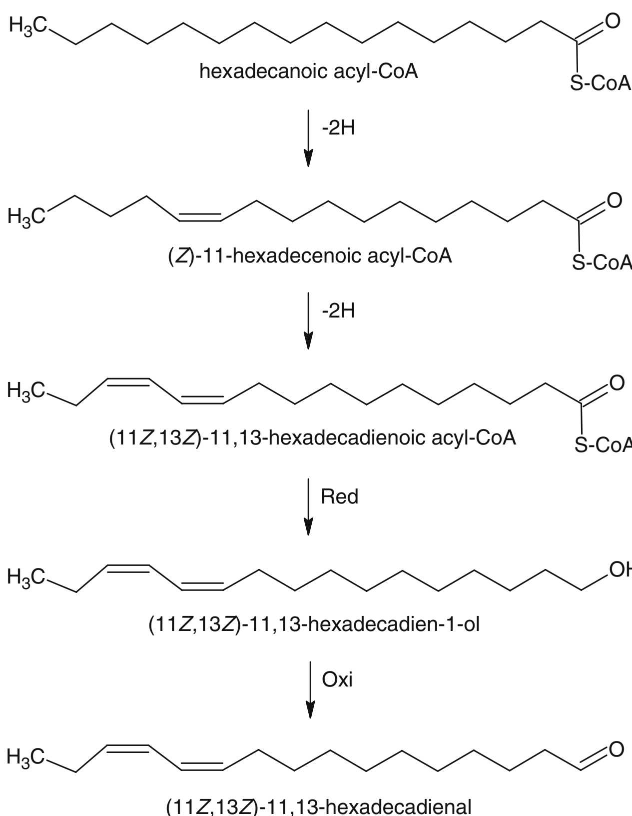

Fig. 6 Proposed biosynthetic pathway for the Type I 11*Z*,13*Z*-16:Ald sex pheromone component produced by female *Amyelois transitella*. "–2H" represents desaturation to form a double bond, "*Red*" indicates functional group reduction and "*Oxi*" indicates terminal oxidation

form 11*Z*,13*Z*-16:Acid, which is subsequently reduced to the corresponding alcohol and finally oxidized to the aldehyde (Fig. 6). The incorporation of deuterium label from saturated D_3-16:Acid and monoenoic D_9-11*Z*-16:Acid precursors into 11*Z*,13*Z*-16:Ald is in agreement with this proposed biosynthetic pathway.

In contrast, our results suggest that the biosynthesis of the two long-chain pentaenes must take place in a markedly different fashion, beginning with different precursors, and likely occurring at a site outside the pheromone gland. The incorporation of deuterium label from labeled linolenic acid into the two pentaenes confirms that linolenic acid can serve as a precursor to these compounds. Furthermore, (5Z,8Z,11Z,14Z,17Z)-icosapentaenoic acid, a likely later-stage intermediate in the biosyntheses of the pentaene hydrocarbons, was found in both abdominal tissue and pheromone gland extracts. Two or three 2-carbon chain extensions of this icosapentaenoic acid would provide the homologous tetracosapentaenoic and hexacosapentaenoic acids, respectively, which would yield the C_{23} and C_{25} pentaene hydrocarbons after decarboxylation. These data suggest that the icosapentaenoic acid with all the double bonds in place is a key intermediate in the biosynthesis of the pentaene hydrocarbons. The fact that we could detect no trace of the corresponding C_{22}, C_{24}, or C_{26} homologs suggests that this intermediate then undergoes a series of chain extensions and the final decarboxylation with all of the intermediates being continuously bound to the relevant enzymes, so that none of them are available as free entities that would have shown up in the analysis (Fig. 7).

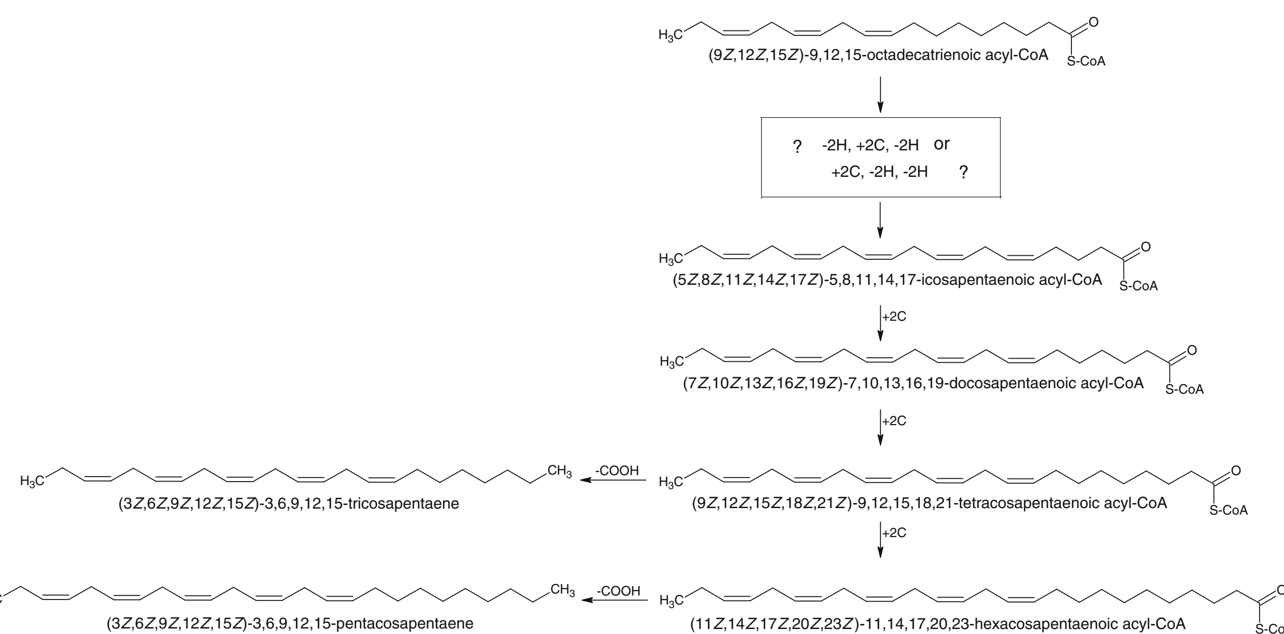

Fig. 7 Proposed biosynthetic pathway for the Type II pentaene sex pheromone components produced by female *Amyelois transitella*. "–2H" represents desaturation to form a double bond, "+2C" represents one cycle of chain elongation by two carbons, "–COOH" means decarboxylation

The presence of (5Z,8Z,11Z,14Z,17Z)-icosapentaenoic acid in the pheromone gland tissue was unexpected, given that most of the total pentaene titer was found in the abdominal tissues (Table 1). However, this acid actually may have been present in the gland extracts only as the result of contamination of the pheromone gland preparations with abdominal tissues, i.e., it is difficult to dissect out pheromone glands that are completely free of surrounding tissues.

Prior studies in other organisms from a broad array of taxa, such as plants, algae, and mammals, suggested a conserved "Δ6 pathway", i.e., the Δ6 desaturation of linolenic acid followed by elongation to produce 8*Z*,11*Z*,14*Z*,17*Z*-icosatetraenoic acid, which is further desaturated at the Δ5 position to produce the icosapentaenoic acid (Napier 2007). In the zebrafish, a bifunctional Δ6/Δ5 desaturase has been identified (Hastings et al. 2001), providing a precedent for this proposed pathway. In the present study, small amounts of the unusual (*Z*)-6-hexadecenoic acid were found in the pheromone gland and the abdomen extracts, which implies that the navel orangeworm may have a corresponding Δ6 desaturase. The fact that labeled 11*Z*,14*Z*,17*Z*-icosatrienoic acid was not incorporated into the pentaenes also suggests that at least the fourth double bond is introduced before elongation of the 18-carbon chain.

The shift from Type I to Type II pheromone components represents a major evolutionary transition that involves a new site of production, a mechanism for transport and selective uptake of polyunsaturated hydrocarbons into the pheromone gland before release, as well as for the evolution of corresponding receptors in male moths, with matching specificity for the detection of the novel pheromone components. It is difficult to envisage all these changes taking place simultaneously, and it is surprising that there are not more reports of species with mixed/intermediate pheromone systems in, for instance, Geometroidea and Noctuoidea, because these two moth superfamilies have many species that possess either Type I or Type II pheromones. The majority of the species for which mixed pheromones have been reported instead belong to the Pyraloidea, from which no cases of pure Type II (hydrocarbon-type) pheromones have been described (Witzgall et al. 2004; El-Sayed 2008). This suggests that the detailed mechanisms and sites of hydrocarbon biosynthesis may differ between the Geometroidea and Noctuoidea on one hand and the Pyraloidea on the other.

Once the hydrocarbon compounds started being exported to and taken up by the pheromone gland, this opened up the possibility for the modification of these compounds by the gland before release. The production of the epoxide derivatives of polyunsaturated hydrocarbons used by some species in the Geometroidea and Noctuoidea should, thus, represent a more advanced character state. Continued radiation then resulted in epoxidation at different positions, yielding one or the other, or in some cases both of the two possible enantiomers of each epoxide, thus allowing a variety of different semiochemicals to be made from a common precursor.

In vitro molecular cloning and functional analysis of the genes for the specific desaturase, elongase, and decarboxylase enzymes postulated in the biosynthesis of the hydrocarbon pheromone components would be helpful in explaining the entire pathway. Likewise, studies of tissue specific expression and *in situ* hybridization could clarify where the different reactions actually take place.

Abstract Previous work has shown that male sorghum plant bugs, *Stenotus rubrovittatus* (Matsumura) (Heteroptera: Miridae), are more attracted to young virgin females than to old virgin females and are not attracted to mated females. Therefore, we examined the effects of age and mating status on female sex pheromone levels. The pheromone components, hexyl butyrate, (*E*)-hex-2-en-1-yl butyrate, and (*E*)-4-oxohex-2-enal, were collected from females in two different ways. First, the compounds were extracted from whole bodies of each female and quantified by gas chromatography-mass spectrometry (GC-MS). Pheromone levels extracted from virgin female bodies decreased with age. In females that had just mated, pheromone levels did not differ from those of virgin females, and pheromone levels in mated females remained relatively constant up to 15 d after mating. This absence of change in pheromone levels extracted from whole bodies of mated females is not congruent with previous reports of lack of male attraction to these females. In a second method for pheromone recovery (adsorption on a PDMS-coated stir bar), GC-MS analysis showed that mated females released lower amounts of pheromone components compared to those emitted by virgin females of the same age (4 d). As was the case with whole body extracts, young virgin females (3 d) released higher amounts of pheromone components than did old virgin females (8 d). The results suggest that male response in *S. rubrovittatus* is dictated more by the quantities of pheromone components released into the volatile headspace by females than by the quantities present in the body.

Key Words Adsorbent · Age · Gas chromatography-mass spectrometry · Mating · Miridae · Polydimethylsiloxane (PDMS)-coated stir bar · Sex pheromone · *Stenotus rubrovittatus*, Heteroptera

Introduction

Females of many insect species produce sex pheromones that attract conspecific males. However, female sex pheromone levels vary with age (Raina et al. 1986; Babilis and Mazomenos 1992; Tang et al. 1992; Delisle and Royer 1994; del Mazo-Cancino et al. 2004) and decline after mating (Raina et al. 1986; Giebultowicz et al. 1991; Ramaswamy and Cohen 1992; Babilis and Mazomenos 1992; Tang et al. 1992; del Mazo-Cancino et al. 2004). Accordingly, male responses to females should change with female age and mating status (Shu et al. 1998; Fukuyama et al. 2007; McClure et al. 2007).

In the sorghum plant bug, *Stenotus rubrovittatus* Matsumura (Heteroptera: Miridae), males are attracted to females (Okutani-Akamatsu et al. 2007). Males of *S. rubrovittatus* are caught in traps baited with young virgin females more frequently than in traps baited with old virgin females, and are rarely caught in traps baited with mated females (Okutani-Akamatsu et al. 2007). Therefore, we hypothesized that young virgin females have higher levels of sex pheromones than old virgin females and that virgin females have higher levels than mated females of the same age. In

S. rubrovittatus, hexyl butyrate, (*E*)-hex-2-en-1-yl butyrate, and (*E*)-4-oxohex-2-enal have been identified as sex pheromone components (Yasuda et al. 2008). In this study, we examined the effects of age and mating status on female sex pheromone levels and discuss relationships between female sex pheromones and male responses to females in *S. rubrovittatus*.

Methods and Materials

Insects Adult *S. rubrovittatus* were collected from gramineous fields in the National Agricultural Research Center, Tsukuba, Japan (36°01′ N, 140°06′ E), on May 26, and June 2, 2008 and were permitted to lay eggs on millet, *Setaria italica*, seedlings at 25°C under conditions of 16:8h, L:D (light phase, 6:00–22:00; hereafter called "laboratory conditions"). Newly hatched nymphs were transferred onto wheat, *Triticum aestivum*, seedlings and kept under laboratory conditions. In this way, *S. rubrovittatus* was reared for several generations under laboratory conditions. Fifth-instar nymphs were isolated in vials (50 ml), each containing five wheat seedlings. Each vial was covered with a sheet of gauze to prevent the nymphs from escaping. The cultures of *S. rubrovittatus* were checked for adults every morning. Emerged adults were used for the following experiments.

Effects of Age and Mating on Female Sex Pheromone Levels—Whole Body Samples To determine whether age and mating affect female sex pheromone levels, 297 virgin females and 158 unmated males (3 d after emergence) were collected from the culture. Each female was placed in a glass vial (50 ml) with five wheat seedlings. Each vial was covered with a sheet of gauze. Then, one male was introduced at 10:00 a.m. into each of 158 vials to mate with the female; the rest of the vials (N=139) contained females that were not allowed to mate (= virgin females). We observed each male-female pair for 1 hr to determine whether they mated. A total of 124 females mated with the male during the 1-hr observation period (mated females, N=124). After mating, males were removed from vials. The 34 females that did not mate within 1 hr were excluded from this experiment. The females were kept for 0, 1, 3, 5, 10, or 15 d (i.e., 3, 4, 6, 8, 13, or 18 d after emergence) under laboratory conditions. The wheat seedlings were replaced every 5 d.

To extract sex pheromone components from female bodies, one female was dipped in 1 ml of hexane with heptadecane (10 μg) for 5 min at room temperature. Heptadecane was used as an internal standard to calculate relative values of each component. Then, the extract was transferred into a glass vial (2 ml) and stored at −20°C until gas chromatography-mass spectrometry (GC-MS) analyses were performed. All extractions were conducted between 11:00 a.m. and 12:00 p.m.

Do Females Release Sex Pheromones? The experimental setup (Fig. 1) for trapping female sex pheromone components from the volatile headspace consisted of a glass tube with a side arm and black screw caps with Teflon®-faced rubber liners. A stir bar coated with polydimethylsiloxane (Twister™, GERSTEL GmbH & Co. KG, Germany, film thickness 1 mm, length 10 mm) was used as an adsorbent (Bicchi et al. 2005) to collect the compounds released from females. To compare relative levels of sex pheromone released by virgin females with those released by mated females, 24 virgin females and 20 mated females (4 d after emergence) were introduced separately into the experimental setup between 2:00 p.m. and 3:00 p.m. and were kept for 1 d under laboratory conditions. Then, the stir bars were removed from each of the experimental chambers. Relative levels of sex pheromone released were also compared between young (3-d-old, N=23) and old (8-d-old, N=23) virgin females. Their sex pheromone components also were collected by using the procedure described above.

To extract sex pheromone components from the stir bars, each stir bar was soaked in 1 ml of hexane with heptadecane (5 μg) as an internal standard. The bars were stirred while soaking on a magnetic stirrer for 30 min at room temperature. The extract was transferred into a glass vial (12 ml). Then, the stir bar was soaked again in 1 ml of hexane and stirred for another 30 min. The second extract was added to the glass vial containing the first extract. The extract was evaporated at 30°C until the volume was reduced to approximately 1 ml. The concentrate was

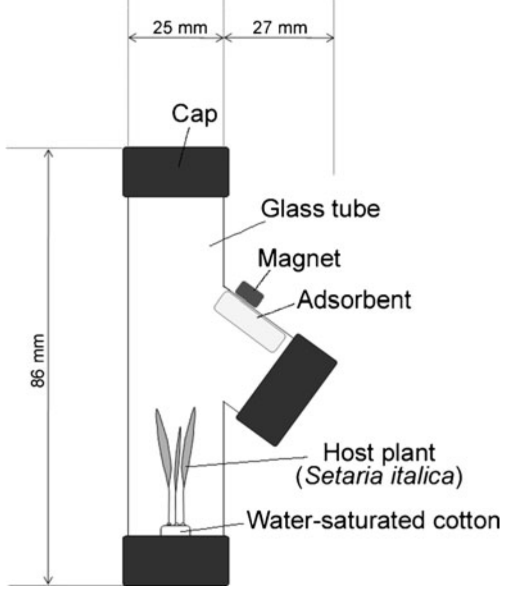

Fig. 1 Experimental setup to collect sex pheromone components released from female *Stenotus rubrovittatus*

transferred into a glass vial (2 ml) and stored at −20°C until GC-MS analyses were performed.

Chemicals Hexyl butyrate (>98.0% chemical purity) and (*E*)-hex-2-en-1-yl butyrate (>95.0%) were purchased from Tokyo Chemical Industry Co., Ltd., Japan. (*E*)-4-Oxohex-2-enal (96.9%) was obtained from the Shin-Etsu Chemical Co. Ltd, Japan.

GC-MS Analysis To determine the quantity of sex pheromone components in each female, GC-MS analysis was performed on an Agilent 6890N GC with an HP-INNOWax column (30 m length×0.25 mm internal diam×0.25 μm film thickness) by splitless injection combined with an Agilent 5975 Network Mass Selective Detector. Mass spectrometric data were acquired by continually alternating between full scanning (range: *m/z* 35–350) and selected ion monitoring (SIM) modes. The quantitative and reference ions for SIM were *m/z* 240 and 99 for heptadecane, *m/z* 129 and 89 for hexyl butyrate, *m/z* 170 and 100 for (*E*)-hex-2-en-1-yl butyrate, and *m/z* 112 and 83 for (*E*)-4-oxohex-2-enal, respectively. Injection temperature was 230°C. Helium was used as carrier gas, and the flow rate was constant at 1.0 ml/min. The initial GC oven temperature was 50°C (2 min hold), increased to 240°C at 10°C/min, and then held for 5 min. The quantity of each sex pheromone component was estimated by using standard linear calibration curves obtained from authentic samples of hexyl butyrate, (*E*)-hex-2-en-1-yl butyrate, and (*E*)-4-oxohex-2-enal, analyzed together with the internal standard heptadecane (Supplemental Data Fig. 1). The absence of co-eluting compounds that might confound the analysis of each analyte and the standard was confirmed by examining mass spectra of each component in the analysis (Supplemental Data Fig. 2). This method has also been used to quantify pheromone components from another plant bug (Byers 2006).

Statistical Analysis To test for effects of age and mating status on total female sex pheromone levels, the quantities of the three sex pheromone components were summed. For the first experiment (whole body extraction), the data were analyzed by two-way analysis of variance (ANOVA) using age and mating as independent variables (Sokal and Rohlf 1995). When an interaction effect between effects of mating and age was significant at the 0.05 level, the data were reanalyzed within each group of females by one-way ANOVA with a Bonferroni correction to test for effects of age on female sex pheromone content (Bonferroni-corrected significance level, 0.025). Then, when the effect of age was significant at the 0.025 level, a Tukey-Kramer honestly significant difference (HSD) test with a Bonferroni correction was used to compare treatments within each group of females (Bonferroni-corrected significance level, 0.025). For the second experiment (headspace analysis), amounts of the female sex pheromone components adsorbed on the stir bars were compared between female groups by one-way ANOVA. JMP version 7.0.1 (SAS Institute 2007) was used for these analyses.

Table 1 Two-way ANOVA table from the test of the effects of age and mating on sex pheromone levels in female *Stenotus rubrovittatus*

Factor	*df*	Mean squares	*F*	*P*
Mating	1	1180.924	97.055	<0.001
Age	5	43.752	3.596	0.004
Mating × age	5	76.978	6.327	<0.001
Residual	224	12.168		

Table 2 Secondary data analysis of the effect of age on sex pheromone levels of *Stenotus rubrovittatus*, separated by mating status (one-way ANOVA)

Factor	*df*	Mean squares	*F*	*P*
Virgin female				
Age	1	72.881	9.209	<0.001
Residual	113	7.914		
Mated female				
Age	1	47.528	2.881	0.018
Residual	111	16.498		

Results

Effects of Age and Mating on Female Sex Pheromone Levels—Whole Body Samples Both age and mating affected sex pheromone levels extracted from female bodies (Table 1). Furthermore, a significant interaction effect was detected, indicating that the effects of age differed between virgin and mated female treatment groups. Hence, the effect of age on sex pheromone levels was tested within each group of females separately. As a consequence, age affected female sex pheromone levels within virgin as well as mated female treatment groups (Table 2). In virgin females (Fig. 2a), female sex pheromone level decreased with age. In contrast, sex pheromone levels in mated females (Fig. 2b) (mated 3 d after emergence), did not differ from those of virgin females at the 3-d time point ($F_{1,38}$=0.08, P=0.722; Fig. 2a, b). Subsequently, however, mated females (Fig. 2b) maintained sex pheromone components at a constant level.

Do Females Release Sex Pheromone? Although (*E*)-4-oxohex-2-enal was not detected from any of the females,

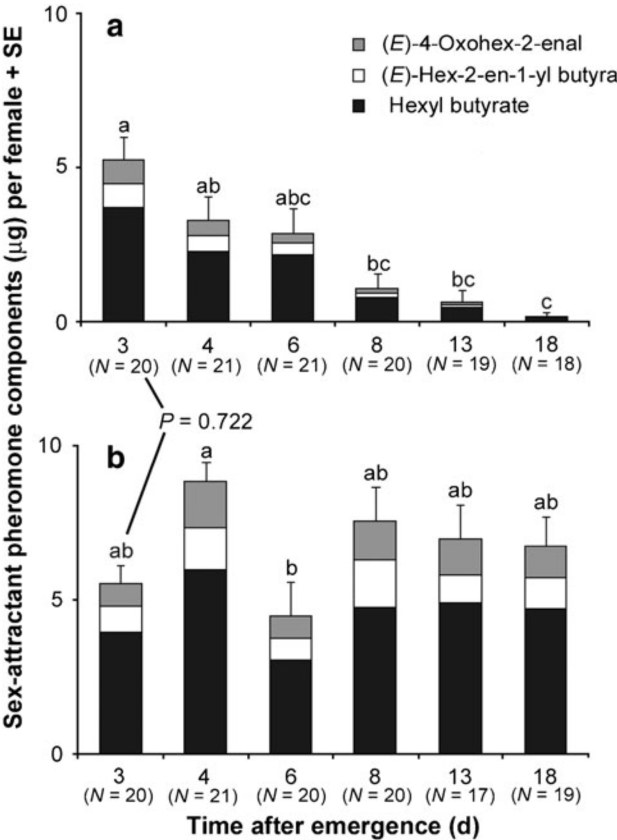

Fig. 2 Changes in the sex pheromone levels extracted from whole bodies of (**a**) virgin female *Stenotus rubrovittatus* and (**b**) mated females. *Letters* indicate significant differences between differently-aged females in each group (Tukey-Kramer HSD test with Bonferroni correction, α=0.025)

other sex pheromone components were detected from both virgin and mated females (Fig. 3). Adsorbed sex pheromone levels were higher in virgin females than in mated females ($F_{1,42}$=12.39, P=0.001; Fig. 3a). On the other hand, adsorbed amounts of sex pheromone components were higher in young virgin females than in old virgin females ($F_{1,44}$=7.313, P<0.01; Fig. 3b).

Discussion

Sex pheromone levels of *S. rubrovittatus* females were altered by both aging and mating. However, the results differed from our predictions in that virgin females have higher levels than mated females of the same age. We first determined the quantity of sex pheromone components of *S. rubrovittatus* females and found that sex pheromone levels decreased with age in virgin females, whereas mated females maintained higher levels. Males of *S. rubrovittatus* are more frequently attracted to young virgin females than to old virgin females and are rarely attracted to mated females (Okutani-Akamatsu et al. 2007). However, the changes in sex pheromone levels in mated female were not congruent with the reported changes in the male response to females. Hence, we determined the quantities of sex pheromone components released from *S. rubrovittatus* females using adsorbents. Adsorbed sex component levels were higher in virgin females than in mated females, although (*E*)-4-oxohex-2-enal was not detected from any of the females. Adsorbents do not always adsorb all of the compounds present in the air. The adsorbed amount of (*E*)-4-oxohex-2-enal might have been too low to detect. However, the amounts of the other compounds adsorbed within a given time should be comparable. Therefore, the result suggests that virgin females release greater amounts of sex pheromones than do mated females. Furthermore, adsorbed sex pheromone levels were higher for young virgin females than for old virgin females, suggesting that young virgins release more amounts of sex pheromones than do old virgins. From these results, it is likely that the levels of sex pheromones released from females affect the response of *S. rubrovittatus* males. Males of *S. rubrovittatus* would be attracted to females that release large amounts of sex pheromone components.

Generally, virgin females have sex pheromones, whereas mated females no longer produce them (Raina et al. 1986; Giebultowicz et al. 1991; Ramaswamy and Cohen 1992;

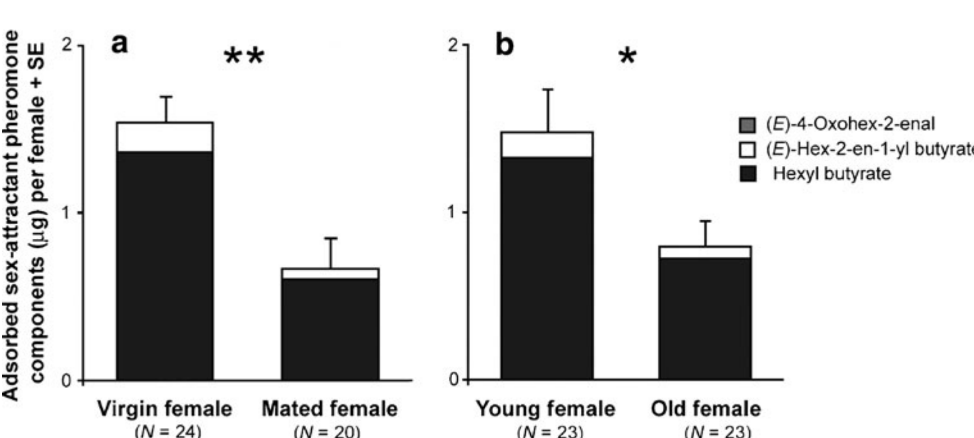

Fig. 3 Comparison of adsorbed sex pheromone levels between (**a**) virgin female *Stenotus rubrovittatus* and mated females of the same age and (**b**) young (3 d) virgin females and old (8 d) virgin females. * P<0.01, **P<0.005 (ANOVA)

Babilis and Mazomenos 1992; Tang et al. 1992; del Mazo-Cancino et al. 2004). In *S. rubrovittatus*, however, the amount of sex pheromone components did not decline after mating. Although it is possible for mated females to have increases in sex pheromone components when remating (Shu et al. 1998), mated *S. rubrovittatus* females normally do not re-mate (Okutani-Akamatsu et al. 2009; Kitsunezuka et al. unpublished data). The sex pheromone components of *S. rubrovittatus* might have other functions in mated females, but this remains to be studied.

Acknowledgments We thank Dr. T. Watanabe of National Agricultural Research Center (NARC) for suggestions and encouragement, Dr. T. Mitsunaga of NARC for advice on statistical analyses, and two anonymous reviewers for their valuable comments. This study was partly supported by a Grant-in-Aid for Research Projects Utilizing Advanced Technologies in Agriculture, Forestry and Fisheries from the Ministry of Agriculture, Forestry, and Fisheries of Japan.

Abstract Rabdosin B, an *ent*-kaurene diterpenoid purified from the air-dried aerial parts of *Isodon japonica* (Burm.f) Hara var. *galaucocalyx* (maxin) Hara, showed a biphasic, dose-dependent effect on root growth and a strong inhibitory effect on root hair development in lettuce seedlings (*Lactuca sativa* L.). Lower concentrations of rabdosin B (20–80 μM) significantly promoted root growth, but its higher levels at 120–200 μM, by contrast, had inhibitory effects. Additionally, all tested concentrations (10–40 μM) inhibited root hair development of seedlings in a dose-dependent manner. Further investigations on the underlying mechanism revealed that the promotion effect of rabdosin B at the lower concentrations resulted from increasing the cell length in the mature region and enhancing the mitotic activity of meristematic cells in seedlings' root tips. In contrast, rabdosin B at higher concentrations inhibited root growth by affecting both cell length in the mature region and division of meristematic cells. Comet assay and cell cycle analysis demonstrated that the decrease of mitotic activity of root meristematic cells was due to DNA damage induced cell cycle retardation of the G_2 phase and S phase at different times.

Introduction

As the largest group of secondary metabolites in plants, terpenes show a wide spectrum of biological activities including allelopathic potential (Calera et al. 1995; Skaltsa et al. 2000; Cangiano et al. 2002; Macías et al. 2002). Numerous mono- and sesquiterpenes have been identified as allelochemicals and their modes of action have been investigated (Muller 1966; Rice 1984; Duke and Oliva 2002; Macías et al. 2004, 2007; Morimoto and Komai 2005; Nishida et al. 2005; Cantrell et al. 2007). However, there are fewer reports concerning the phytotoxic properties of diterpenoids (Macías et al. 1999, 2000). A clerodane diterpene, isolated from *Viguiera tucumanensis*, inhibited both germination and root growth of *Sorghum halepense* and *Chenopodium album* (Vaccarini et al. 1999). A series of diterpenes, primarily *ent*-labdane derivatives from *Potomageton natans* and *Ruppia maritime*, have been found to have toxicity to a number of animals and the alga *Selenastrum capricornornutum* (DellaGreca et al. 2004). The natural diterpenes from *Croton ciliatoglanduliferus* Ort. inhibit photophosphorylation, electron transport, and the partial reactions of both photosystems in spinach thylakoids (Morales-Flores et al. 2007). Macías et al. (2008) reported that helikauranoside A, a new *ent*-kaurane glycosylated diterpenoid isolated from the aerial parts of *Helianthus annuus* L., might be related to the allelopathic behavior shown by this species.

Isodon (formally *Rabdosia*) is a cosmopolitan and important genus of the Labiatae (Lamiaceae) family. *Ent*-kaurene diterpenoids are the main constituent in this genus

and are especially abundant in fresh branches and leaves (Sun et al. 2001). To date, over 400 *ent*-kaurene diterpenoids have been isolated from these plants and been reported to have antibacterial, anti-inflammatory, and antitumor activities (Sun et al. 2001). However, whether these chemical components mediate interactions in natural surroundings is still unknown. Rabdosin B (Fig. 1), a diterpenoid belonging to 6, 7-seco-*ent*-kaurene spirolactone type, was isolated as the most abundant compound from the aerial parts of *Isodon japonica* (Burm.f) Hara var. *galaucocalyx* (maxin) Hara obtained from Gansu, China (Liu et al. 2006). The phytotoxic effect and action modes of this diterpenoid have not yet been reported.

Seeding growth bioassays are a primary tool for determining phytotoxic activity (Inderjit and Dakshini 1995; Szabo 2000), and they may detect potential phytotoxic effects under controlled laboratory conditions (Reigosa and Pazos-Malvido 2007). The growth-limiting effects of various kinds of stress have been related to their effects on the regulation of elongation and cell division (Burssens et al. 2000; West et al. 2004; Peres et al. 2007). Hence, in our study, the elongation of cells in the mature region and the cell division of meristematic cells were both used to evaluate the effects of rabdosin B on root growth. We also used flow cytometry with cell synchronization (Blanco Fernández et al. 2001), together with the conventional determinations of the mitotic index to study the effects of rabdosin B on the cell cycle of root meristematic cells. Additionally, to elucidate further the mechanism of its phytotoxic effects, the extent of DNA damage induced by rabdosin B in roots was checked by using the comet assay or single cell gel electrophoresis (SCGE) assay (Gichner and Plewa 1998; Angelis et al. 1999; Tice et al. 2000), since it has been reported that cell cycle progression can be delayed in response to DNA stress (Cools and De Veylder 2008). The root hair is an extension of the root epidermis and is particularly important due to its many roles within the soil rhizosphere (Bertin et al. 2003). Hence, inhibition of root hair development also was used to evaluate the phytotoxicity of rabdosin B.

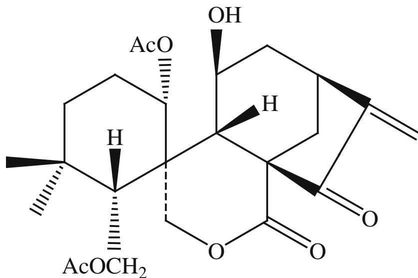

Fig. 1 Chemical structure of rabdosin B, an *ent*-kaurene diterpenoid isolated from the species of *Isodon*

The specific objectives of this study were: (1) to test the effects of rabdosin B on root growth and on root hair development of lettuce seedlings; (2) to establish a link among radicle growth, altered cell cycle, and the extent of DNA damage to reveal the action modes of rabdosin B.

Methods and Materials

Plant Materials and Chemicals Lettuce seeds (*Lactuca sativa* L. cv. Taiyuan) were obtained from Dadi Seed Service (Lanzhou, China). Rabdosin B was isolated previously in our laboratory from *Isodon japonica* (Burm. f) Hara var. *galaucocalyx* (maxin) Hara (Liu et al. 2006). Hydroxyurea (HU) and RNase A were purchased from BBI, USA. Propidium iodide, ethidium bromide (EtBr), normal melting point (NMP) and low melting point (LMP) agarose, were purchased from AMRESCO Inc. (Solon, OH, USA). All other general laboratory reagents were obtained from Sango Biological Engineering Technology and Service Co., Ltd. (Shanghai, China).

Culture Conditions and Treatments Lettuce seeds were rinsed in tap water for 5 min, followed by rinsing × three in distilled water. About 500 seeds were placed into Petri dishes (15 cm diam) that contained two sheets of qualitative filter paper soaked with 13 ml distilled water. They were allowed to germinate for 48 h at 22°C and a photoperiod of 16:8 h L:D. Twelve uniform 2-d-old seedlings were transferred onto 6 cm Petri dishes containing filter paper moistened with different concentrations of treatment solutions (4 ml) and incubated under the same conditions.

Rabdosin B was dissolved in methanol and diluted to the desired concentrations with distilled water. The amount of methanol was uniform for each treatment and never exceeded 1%—i.e., below a level where root growth and root hair development were affected (data not shown).

Measurement of Net Growth Rates (NGR) Seedlings were cultivated as described above. After germination, 12 seedlings per 6 cm Petri dishes were incubated for 48 h. Net growth rates (NGR) were measured to evaluate the influence of rabdosin B on root growth according to the method of Pan et al. (2001). Seminal root lengths of the seedlings in each treatment were measured before and after treatment. NGR was calculated as follows: (final length—initial length)/initial length. Three parallel dishes were examined per treatment, and the experiment was repeated three times.

Measurement of Cell Sizes For determination of cell size, root tips (8 mm long) were excised from 2-d-old seedlings after treatment, fixed in an ethanol/acetic acid (9:1) solution overnight, followed by washing in 90%, 70%, 50%, and

30% ethanol, sequentially. Root tips were cleared with a chloral hydrate/glycerol/water solution (8:1:2, w/v/v) as described by Yadegari et al. (1994). Cells were observed under an optical microscope (Nikon Eclipse E 400) equipped with an ocular micrometer. Cells at the root-hair-forming region of the roots were chosen to determine the mature cell size. The length and width of 20 mature cells were measured from each root, with six roots used per treatment. Three independent experiments were carried out, giving the same statistically significant results.

Measurement of Mitotic Index Squash techniques were modified from Akinboro and Bakare (2007). Briefly, primary roots of lettuce seedlings after treated with rabdosin B were fixed in freshly prepared ethanol-acetic acid (3:1, v/v) for 24 h, then transferred into 70% ethanol and stored at 4°C until use. Roots were hydrolyzed for 8–10 min with 1 M HCl at 60°C followed by rinsing in distilled water (three to four times). Root tips (1 mm) were excised, stained with carbol fuchsin for 10–15 min, and the meristems were squashed under a coverslip to separate the cells. Three slides were prepared for each treatment, and at least 1,000 cells were examined randomly under a Nikon Eclipse E 400 optical microscope to determine the mitotic index, which was calculated as the number of dividing cells per 1,000 observed cells. Three replicate slides were examined per treatment, and the experiment was repeated three times.

Cell Cycle Analysis The cell cycle was analyzed according to the method of Sánchez-Moreiras et al. (2008) with a few modifications. In the present work, cell cycle of lettuce root meristems was synchronized by using the inhibitor hydroxyurea (HU), which reversibly halted the cell cycle in the G_1 and early S phase by inhibiting ribonucleotide reductase, and hence the production of deoxyribonucleotides (Doležěl et al. 1999).

Seedlings with roots 1 mm to 2 mm long were obtained by germinating seeds in the dark for 28 h on moistened filter paper at 22°C. Then, these seedlings were transferred, 50 per dish, to Petri dishes 7.5 cm diam containing filter paper moistened with 5 ml of 2.5 mM HU (pH 6.0). After 6 h incubation in dark at 25°C, seedlings were cleansed of HU by washing × three in distilled water (pH 6.0) to remove the inhibitor (Coba de la Peña and Sánchez-Moreiras 2001). Seedlings then were transferred to 7.5 cm Petri dishes containing filter papers moistened with 5 ml of either distilled water supplemented with methanol (pH 6.0, controls) or rabdosin B solution at a concentration of 200 μM (pH 6.0), and then incubated in the dark at 25°C. Samples were taken every 3 h and were processed as described below.

The apical root meristem (2±0.5 mm long) of each seedling was removed and chopped with a fresh razor blade on clean Petri dishes containing 600 μl Galbraith's nuclear buffer (45 mM $MgCl_2$, 30 mM sodium citrate, 20 mM MOPS, 0.1% Triton X-100; pH 7.0), supplemented with 100% Tween-20 (8 μl in 3 ml buffer), 100% β-mercaptoethanol (7 μl in 1 ml buffer), and RNase A (100 μg/ml). The obtained suspension was filtered twice through 30 μm mesh stainless-steel cell filters, and the filtrate (450 μl) was collected in Eppendorf tubes. Immediately, the nuclei suspension was centrifuged at 100×*g* for 5 min, and the supernatant was decanted and the nuclei pellet resuspended in 200 μl chopping buffer. After resuspension, the solution was stained with propidium iodide (5 μg/ml) for 5–8 min at room temperature before cell DNA contents were evaluated by Epics XL-4 flow cytometry (BECKMAN-Coulter, USA) using a Coulter Elite apparatus with a 488 nm excitation laser. For each sample, at least 10,000 nuclei were analyzed. Histogram profiles were calculated from DNA content histograms using Cellquest software (version 2).

Comet Assay Isolation of nuclei from root tips and comet assay were performed following the method described by Gichner et al. (2004, 2008) with slight modifications. After incubated for 24 h and 48 h, 80-seedlings of each treatment were used for the nuclei isolation and comet assay. The apical 2±0.5 mm long root tip of each seedling was removed and placed in a Petri dish kept on ice and spread with 250 μl of cold 400 mM Tris buffer (pH 7.5). Using a fresh razor blade, the root tips were gently sliced. The plate was kept tilted in the ice so that the isolated root nuclei would be collected in the buffer. Immediately, the obtained suspension was filtered twice through 30 μm mesh stainless-steel cell filters, and the filtrate (200 μl) was collected in Eppendorf tubes. All operations were conducted under dim or yellow light.

The frosted microscope slides were coated with 0.5% normal melting point (NMP) agarose prepared with water at 50°C, dried overnight at room temperature, and kept dry in slide boxes until use. Nuclear suspension (50 μl) and 1% low melting point (LMP) agarose (50 μl) prepared with phosphate-buffered saline were added at 40°C onto each slide. The nuclei and the LMP agarose were mixed gently by repeated pipetting with a cut micropipet tip, and a coverslip was placed on the mixture. The slides were kept at 4°C for 15 min for the gel agarose to solidify. After removing the cover glass, slides were placed in a horizontal gel-electrophoresis tank containing freshly prepared cold electrophoresis buffer (1 mM Na_2EDTA and 300 mM NaOH, pH>13). The nuclei were incubated for 15 min to allow the DNA to unwind prior to electrophoresis at 0.74 V/cm (25 V, 300 mA) for 25 min at 4°C. After electrophoresis, slides were rinsed × three with 400 mM Tris buffer, pH 7.5, stained with 80 μl EtBr (20 μg/ml) for

5 min, dipped in ice-cold water to remove the excessive stain, and covered with a coverslip. Nuclei were analyzed under a fluorescence microscope with an excitation filter of BP 546/10 nm and a barrier filter of 590 nm.

Digital images were captured and analyzed using CASP image-analysis program (Końca et al. 2003). Twenty-five randomly chosen nuclei were analyzed for each slide. Three slides were evaluated per treatment, and each treatment was repeated three times. From the repeated experiments, the averaged median percentage of tail DNA (% tail DNA) and Olive tail moment [OTM, the product of the distance between the gravity centers of the DNA head and the DNA tail ($LX_{Gravity}$) and percent tail DNA ($Tail_{DNA}$), OTM= $LX_{Gravity} \times Tail_{DNA}$, Liu et al. 2004] were used to measure DNA damage for each treatment group.

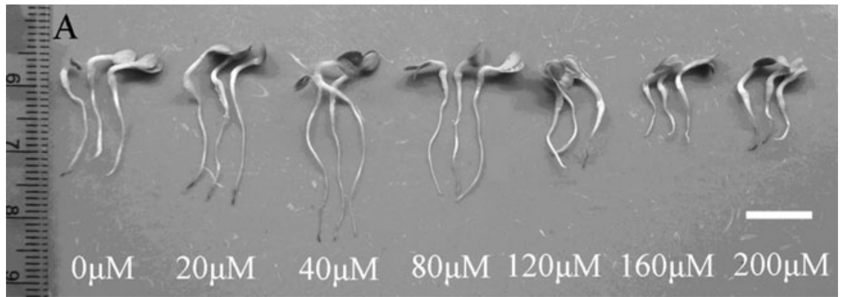
Measurements of Root Hairs Root hairs were evaluated with slight modifications of the method of Yang et al. (2004). Seedlings (ten) were randomly selected from each treatment. A 1 cm root segment was excised from 0.5 cm behind the root tip, fixed in 70% ethanol, placed onto a microscope slide, and covered by a glass cover for microscopic observation. The length and number of root hairs present in certain regions (424 μm root segment) were measured (×3) from the ends and the middle of root segments with an ocular micrometer. Measurements for each treatment were determined from the ten root segments, and mean values were calculated. The experiment was repeated three times.

Statistical Analysis All data are presented as means±SD. Data were subjected to analysis of variance (ANOVA) with significant differences among means identified by LSD multiple range tests using SPSS 11.5. Differences were considered significant at $P<0.05$. To verify the relationship between pairs of data (root NGR/cells length; root NGR/mitotic index; mitotic index/prophase index) at the same rabdosin B concentrations, linear regression analysis was performed, and the coefficient of regression (r) and its level of significance (P) was determined.

Results

Effects of Rabdosin B on Seedling Growth The roots of lettuce seedlings responded to different concentrations of rabdosin B in a dose-dependent, biphasic manner (Fig. 2a). Lower levels of rabdosin B (20–80 μM) significantly promoted the root growth, and the root NGR reached a maximum at 40 μM. Inhibitory effects were observed at high concentrations of rabdosin B (120–200 μM). At all concentrations above 120 μM, the NGR of seedlings decreased, but the NGR of 160 μM and 200 μM rabdosin B treated seedlings remained, respectively, at about 42% and 43% of the control, which displayed a similar level of inhibition (Fig. 2b).

Effects of Rabdosin B on Elongation of Root Cells To evaluate the impact of rabdosin B on cell elongation, we measured the size of mature cells at the root-hair-forming regions of lettuce roots. Rabdosin B affected the cell length in a pattern that was similar to the NGR (Fig. 3). Regression analysis revealed a positive correlation between NGR and cell length ($r=0.992$, $P<0.001$). Lower levels of rabdosin B (20–80 μM) significantly increased the cell length, but



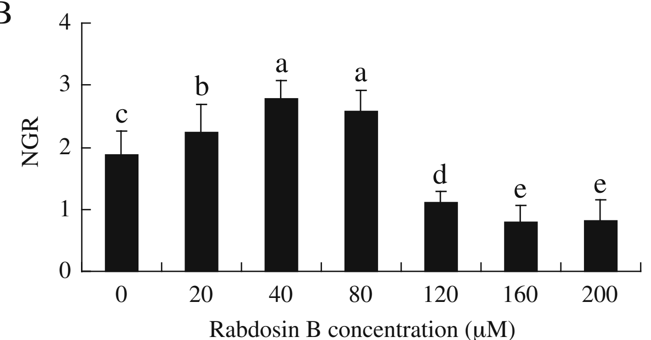


Fig. 2 Effect of rabdosin B on *Lactuca sativa* seedling growth. **a** Effects of increasing concentrations of rabdosin B on the root growth of lettuce seedlings 48 h after treatment. **b** Root NGR in lettuce seedlings calculated after 48 h of treatment. Different letters indicate significant differences at $P<0.05$. *Bars* indicate SD. *Bar*=1 cm

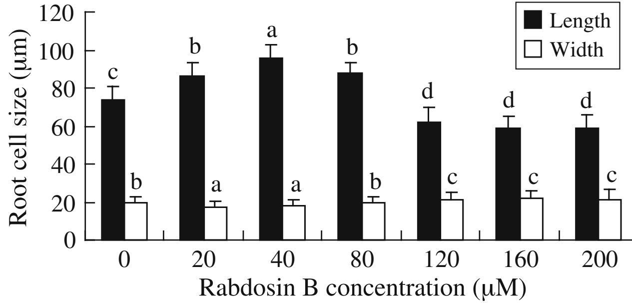

Fig. 3 Effect of rabdosin B on the mature cell sizes (length and width) in lettuce roots 48 h after treatment. Each datum represents average value from 120 cells. Different letters indicate significant differences at $P<0.05$. *Bars* indicate SD

decreased the cell width except at 80 μM. In contrast, after treatment with higher levels of rabdosin B (120–200 μM), the cell length was reduced significantly, but the cell width was increased (Fig. 3).

Effects of Rabdosin B on Mitotic Activity Different concentrations of rabdosin B affected the mitotic index in a pattern that was similar to the NGR ($r=0.989$, $P<0.001$) (Fig. 4a). The mitotic index for root tip cells treated with lower levels of rabdosin B (20–80 μM) significantly increased compared with the control, but at the higher concentrations 120–200 μM, by contrast, the mitotic index decreased. In addition, rabdosin B affected the relative proportion of the various stages of mitosis in meristematic cells with different stages showing different sensitivity to rabdosin B (Fig. 4b). The number of meristematic cells in prophase was analogous to the mitotic index ($r=0.994$, $P<0.001$). However, the percentage of the other phases did not change significantly compared to the control.

Cell Cycle Analysis To determine whether the reduction of prophase treated with 200 μM rabdosin B involved cell cycle changes at some earlier stages, we examined cell cycle phase distribution of the root tip cells by flow cytometry. The inhibitor hydroxyurea (HU) was used to increase the number of mitotic cells and to prove a clear effect of rabdosin B on the cell cycle.

Figure 5a shows DNA content histograms of non-rabdosin B and rabdosin B-treated root tips. The proportion of cells in the S phase of rabdosin B-treated root tips was similar to that of control 3 h after removal of HU, but cells in the G_2 phase were double that of the control. However, at 6 h, the proportion of control cells in phase S was 14.7%, and that of rabdosin B-treated cells was 23.2% (Fig. 5a), while G_2 phase of the treatment group was triple that of the control. Over the next 6 h, the S population of control cells fell steadily to a much lower level between *5.2%* and 6.5%, but the fall in the rabdosin B-treated S phase population was much less pronounced. Instead, the G_2 phase population was similar to that of the control. Cell cycle progression was so slow in rabdosin B treated meristems that the number of cells in S phase was triple that of control meristems after 9 h and 12 h treatments. Figure 5b shows that the S-phase proportion of control cells significantly decreased from 3 h to 12 h, concurrent with a gradually increased G_2-phase proportion. However, after treatment with 200 μM rabdosin B, S-phase and G_2-phase proportions remained at a relative stable level. These results indicate that the root tip cells treated with 200 μM rabdosin B were first arrested in G_2 phase from 3 h to 6 h, and then the cells were arrested in S phase from 9 h to 12 h.

Since flow cytometry could not measure mitotic events, we measured the mitotic index at the same time that the cell cycle was analyzed (3–12 h after removal of HU). Figure 5c showed that the mitotic index of control root tips was only 13‰ 3 h after removal of HU, peaked sharply at 99‰ at 6 h, and by 9 h returned again to 58‰. The mitotic index peak of rabdosin B-treated root tips was lower (75‰), later (at 9 h) and broader (6–12 h).

DNA Damage in Root Nuclei Using Comet Assay To elucidate whether the cell cycle arrest of root tips involved DNA damage, DNA strand breaks were assessed by comet

difference in either % tail DNA or OTM at the lower levels of rabdosin B (20–80 μM) (Fig. 7).

When the cells were treated with rabdosin B (120–200 μM) for 48 h, both % tail DNA and OTM increased in a dose-dependent manner, and they nearly reached 77.5±8.0% and 54.7±13.7 pixels, respectively, as shown in Fig. 7. After treatment with lower levels of rabdosin B (20–80 μM) for 48 h, although the % tail DNA were significantly higher compared with the control, the values were very low, and raised only from 9.1±6.1% to 10.2±5.2%. Moreover, there was no significant difference in OTM values.

Effect of Rabdosin B on Root Hair Development Root hair development in lettuce seedlings (length and density) was significantly inhibited by rabdosin B after treatment for

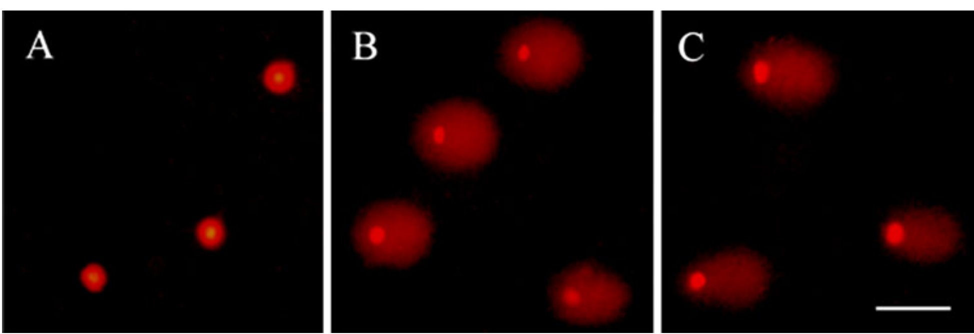

Fig. 6 Comet character showing tails of different length induced by rabdosin B in nuclei of lettuce root cells for a period of 24 h in order to determine the dose response for DNA damage: control (**a**), treated with rabdosin B 120 μM (**b**) and 200 μM (**c**). *Bar*=50 μm

48 h (Fig. 8). The diterpenoid decreased the average root hair length and root hair density in a dose-dependent manner at the concentrations between 10–40 μM, with a larger effect on root hair length than on root hair density (Fig. 9). Only a few bulges were observed on root surfaces when rabdosin B concentrations were raised to 40 μM (Fig. 8).

Discussion

In this study, both significant promotion and inhibition of root growth in lettuce seedlings were observed at the different concentrations of rabdosin B (20–200 μM). Root hair development also was inhibited significantly by rabdosin B in a dose-dependent manner at all of the tested concentrations (10–40 μM). Plant roots, as the first plant organ in contact with the soil, serve a multitude of functions in the plant including anchorage, provision of nutrients and water, and production of exudates with growth regulatory properties (Bertin et al. 2003). Root hairs are tubular outgrowths on the root surface that play an important role in increasing the root's ability to capture nutrients (Forde and Lorenzo 2001). Based on our study, we hypothesize that the abundant *ent*-kaurene diterpenoid might play a critical role in mediating ecological interactions between *Isodon* and other plant species in nature.

Root growth arises from the proliferation of meristematic cells followed by cell expansion that results in root elongation. Lettuce seedlings treated with higher levels of rabdosin B experienced a reduction in root NGR that is strongly correlated with both the changes of cell sizes in the mature region and the decrease of the mitotic index of root meristematic cells. Additionally, the number of meristematic cells in prophase was correlated with the mitotic index, while the percentages of other phases were less affected. Hence, we hypothesized that it depends on the general mechanism that arrests the cell cycle at earlier stages. To test this directly, we performed flow cytometry with nuclei derived from the root tips of seedlings. Flow cytometry analyses showed a significant retardation of the cell cycle in rabdosin B-treated meristems with selective activity at G_2/M and S/G_2 checkpoints. These data are consistent with the supposition that 200 μM

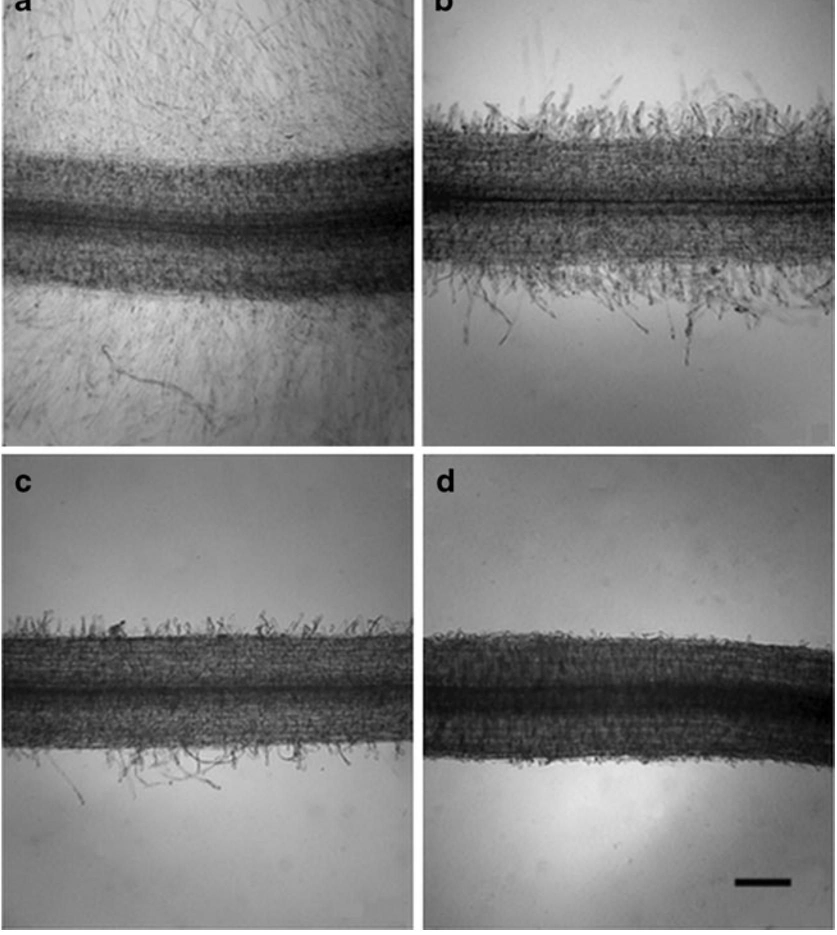

Fig. 8 Light micrographs of lettuce roots showing the inhibitory effects of rabdosin B on root hair development 48 h after treatment. **a** Control; **b**–**d** treatments with 10 μM, 20 μM, and 40 μM rabdosin B, respectively. *Bar*=200 μm

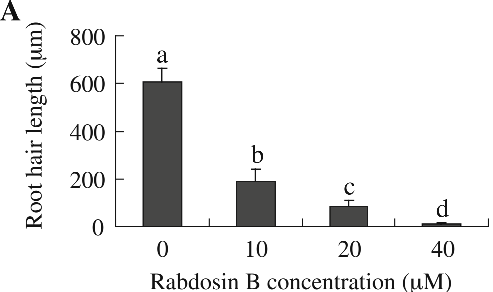

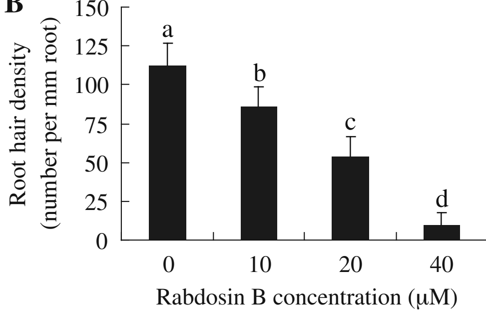

Fig. 9 Influence of rabdosin B on root hair development in lettuce seedlings 48 h after treatment. Root hair development was evaluated by average root hair length (**a**) and root hair density (**b**). Different letters indicate significant differences at $P<0.05$. *Bars* indicate SD

rabdosin B treated root tips experience a cell cycle arrest in the measure G_2 and S phase at different times. The mitotic index results, measured at the same time that the cell cycle was measured (3–12 h after removal of HU),confirmed the flow cytometry results.

Upon induction of DNA damage or after alteration of intracellular redox homeostasis, the cell cycle slows down at the G_1/S and G_2/M transition points (Den Boer and Murray 2000). Hefner et al. (2006) reported that DNA damage-induced cell cycle checkpoints could be initiated in cells of the meristematic organs (root and shoot tip) of irradiated *Arabidopsis* seedlings. In our study, we used the comet assay to determine whether rabdosin B could induce DNA damage in the root tips of lettuce seedlings, and to elucidate the mechanism of the cell cycle arrest. It was shown clearly that higher concentrations of rabdosin B induced a time- and dose-dependent increase in DNA damage in the form of % tail DNA and OTM when compared with control. We confirmed that the DNA damage of root tips could lead to cell cycle retardation. When DNA damage takes place in meristems, plants apparently have evolved DNA stress checkpoint mechanisms that arrest the cell cycle and activate the DNA repair machinery to preserve the genome (Cools and De Veylder. 2008). Cell cycle arrest as a consequence of the retardation of DNA replication and the delay of the start of mitosis also has been associated with an inhibition of the activity of cyclin-dependent kinases, cell cycle gene expression, and a concomitant activation of stress genes (Reichheld et al. 1999; De Veylder et al. 2007; Peres et al. 2007). When DNA stress checkpoints are activated, the induction of DNA-repair genes and the inactivation of genes required for mitosis switch on. This signaling cascade after biotic or abiotic stress affects plant metabolism and "stimulates cell cycle checkpoints, resulting impaired G_1 to S transition, a slowing down of DNA replication, and a delayed entry into mitosis" (Peres et al. 2007).

Our study confirmed that DNA damage-induced cell cycle arrest was initiated in lettuce root tips after treatment with higher concentrations of rabdosin B (200 μM). Interestingly, the roots responded to rabdosin B concentrations in a biphasic way. Concentrations of rabdosin B lower than 80 μM showed a stimulatory effect on root growth, and rabdosin B (20–80 μM) increased the cell length but reduced the cell width, while the mitotic index for root tip cells treated with rabdosin B (20–80 μM) increased compared to the control. An increase in the number of cells in prophase followed a pattern that was similar to the mitotic index. Thus, we conclude that 20–80 μM rabdosin B promotes the root growth in lettuce seedlings by affecting both cell size and cell division.

Examples of hormesis (the stimulation effect of a toxin at low doses) with natural phytotoxins have been reported with single compounds (e.g., gramine and hordenine, benzoxazolin- 2(3*H*)-one, and allyl isothiocyanate), plant extracts (e.g., *Triticum aestivum* L.), and root exudates (e.g., *T. aestivum* and *Triticum spelta* L.) (An et al. 1993; Belz et al. 2005, 2007). Belz (2008) reported that hormetic effects might occur in a natural setting if doses released are low, and they should be regarded as a potential low dose component of plant/plant interference. Research will be needed in order to understand the ecological conditions necessary for hormesis and the potential impacts of low dose stimulation by the diterpenoid.

Parker et al. (2000) reported that root hairs contribute as much as 77% to the total root surface area in cultivated crops, being the major point of contact between plants and the rhizosphere. Our results indicate that rabdosin B strongly inhibits root hair development in a dose-dependent manner. Ethylene plays a role in root hair initiation and elongation (Dolan 2001; Yang et al. 2004; Dugardeyn and Van Der Straeten 2008). Our previous study proposed that leukamenin E (a C-20-non-oxygenated-*ent*-kaurene diterpenoid) might act as a potential ethylene action antagonist in the inhibition of lettuce root hair development (Ding et al. 2008). Therefore, we hypothesize that rabdosin B inhibits root hair development similar to that of leukamenin E through this mechanism of action, as a potential ethylene action antagonist. More studies are needed to confirm this hypothesis.

In summary, this study demonstrated the dual stimulatory and inhibitory effects of rabdosin B on root growth and inhibitory effects on root hair development in lettuce

seedlings, and has provided some possible explanatory mechanisms for this action.

Abstract Reproductive division of labor in advanced eusocial honey bees and stingless bees is based on the ability of totipotent female larvae to develop into either workers or queens. In nearly all species, caste is determined by larval nutrition. However, the mechanism that triggers queen development in *Melipona* bees is still unresolved. Several hypotheses have been proposed, ranging from the proximate (a genetic determination of caste development) to the ultimate (a model in which larvae have complete control over their own caste fate). Here, we showed that the addition of geraniol, the main compound in labial gland secretions of nurse workers, to the larval food significantly increases the number of larvae that develop into queens. Interestingly, the proportion of queens in treated brood exactly matched the value (25%) predicted by the two-locus, two-allele model of genetic queen determination, in which only females that are heterozygous at both loci are capable of developing into queens. We conclude that labial gland secretions, added to the food of some cells by nurse bees, trigger queen development, provided that the larvae are genetically predisposed towards this developmental pathway. In *Melipona beecheii,* geraniol acts as a primer pheromone representing the first caste determination substance identified to date.

Introduction

Female larvae of the eusocial honey bees (Hymenoptera: Apidae: Apini) and stingless bees (Hymenoptera: Apidae: Meliponini) may develop into either an adult queen or a worker. In the vast majority of species, queens are reared in special cells, which are larger than worker cells, and receive more food, which is sometimes of special quality (de Wilde and Beetsma 1982; Wheeler 1986; Hartfelder et al. 2006). Thus, the caste fate of the larvae in these species is determined trophically, which means that an individual's nutritional history triggers endocrine signals, which are caste-specific modulations of juvenile hormone and ecdysteroid titers (Hartfelder and Emlen 2005; Hartfelder et al. 2006) that mediate the subsequent patterns of developmental differentiation (Wheeler 1986). However, queen production in bees of the genus *Melipona* is unique among social bees because brood cells that produce queens and workers are indistinguishable, and all larvae feed on similar amounts of food (Sakagami 1982). Furthermore, *Melipona* queens are reared in significant numbers all year round (Kerr 1948; Darchen and Delage-Darchen 1975; Moo-Valle et al. 2001; Sommeijer et al. 2003; Wenseleers et al. 2004; Morais et al.

2006). To explain the observation that up to 25% of female larvae in *Melipona* nests develop into queens, Kerr proposed a mechanistic, proximate model of genetic caste determination, based on two unlinked loci, each with two alleles, in which only double heterozygous females could develop into queens (Kerr 1948, 1950a, b) (the original assumption of 3 loci for some species was later dismissed; Kerr 1969). Since male bees are haploid, their gametes must have an equal set of alleles at each locus. Therefore, the female progeny of a single mated queen, which are produced from fertilized diploid eggs, separate into 25% queens that are heterozygous at both loci, and 75% workers that are homozygous at one or both loci (Kerr 1948, 1950a, b). However, usually the proportion of queens in *Melipona* broods is lower than 25% (Kerr 1948; Darchen and Delage-Darchen 1975; Moo-Valle et al. 2001; Sommeijer et al. 2003; Wenseleers et al. 2004; Morais et al. 2006). Thus, it was proposed that female larvae that are genetically queens also can develop into workers under sub-optimal food conditions (Kerr et al. 1966; Kerr 1969; Maciel-Silva and Kerr 1991; Velthuis and Sommeijer 1991). A different set of studies, based on theoretical considerations on caste conflict and colony kin structure, viewed the large numbers of queens in *Melipona* as support for the model of self determination of caste fate in social insects (Bourke and Ratnieks 1999; Ratnieks 2001; Wenseleers et al. 2003, 2004; Wenseleers and Ratnieks 2004). According to this evolutionary or ultimate model, a female larva that develops in a normal sized, mass provisioned brood cell has the ability to control her own caste fate (Bourke and Ratnieks 1999; Ratnieks and Helanterä 2009). Thus, when resources are equally available, she could become a queen instead of a worker, thus becoming the reproductive dominant rather than an altruistic worker rearing sisters. One of the assumptions of this model is that all larvae not only feed on the same amount of food, but also on food of the same quality. However, this assumption overlooks existing experimental evidence, which demonstrates that caste fate can be influenced by quantitative, and possibly qualitative, differences in nutrition (Kerr et al. 1966; Kerr 1969; Darchen and Delage-Darchen 1975; Maciel-Silva and Kerr 1991). Nevertheless, specific nutrients that influence the developmental pathway of a female *Melipona* larva have not been described.

In recent chemical analyses involving the species *Melipona beecheii*, we found striking similarities between the pattern of volatiles from labial gland secretions of nurse workers and that of the rectal waste of emerging queens (Jarau, unpublished data). This suggests, that nurse workers may specifically add labial gland secretions to the food provision of certain brood cells, thus inducing the development of queens. In the present study, we tested this hypothesis through structure elucidation of volatiles of labial gland secretions, as well as bioassays, in which synthetic samples of the identified compound were added to the food provisions of developing larvae.

Methods and Material

Study Site and Bee Colonies We used two colonies of *Melipona beecheii* BENNETT, 1831 (Hymenoptera: Apidae: Meliponini) that were kept in a dark room at the Center for Tropical Bee Research (CINAT) of the National University of Costa Rica in Heredia, Costa Rica (9°58′22″N, 84°07′45″W). The nests were connected to the outside via plastic tubes leading through the wall of the building. Colony 1 was used for the collection of bees for chemical analyses (March and April 2007), whereas colony 2 was used for the food manipulation bioassays (March to May 2009). All manipulations in the nests were done under red light without disturbance of the bees.

Chemical Analyses We extracted labial glands of workers that were engaged in the construction and provisioning of brood cells (nurse bees) as well as the hind gut (rectum) of both newly emerged queens and workers. To prepare the extracts, an individual was killed by freezing, the respective body part dissected under a stereo microscope and left in 200 μl pentane for 24 hr at room temperature. The volume of each extract was reduced to 30 μl, and an internal standard (n-undecane) was added to allow quantification of the compounds.

For quantitative analyses, we used a Hewlett Packard HP 5890 gas chromatograph (Series II, Palo Alto, CA, USA) equipped with a DB-5MS capillary column (30 m× 0.25 mm i.d., 0.25 μm film thickness, J & W Scientific, Folsom, CA, USA) and a flame ionization detector (FID), with hydrogen as carrier gas (2 ml/min constant linear flow rate). Injection of 1 μl extract (per sample) was done in the splitless mode with an initial temperature of 50°C. After 1 min, the splitter was opened and the temperature increased by 10°C/min until the oven reached 310°C. The final temperature was held for another 23 min.

For qualitative analyses, the samples were analyzed by using a combined Fisons Instruments GC 8000 series / MD 800 mass spectrometer (carrier gas: helium; column: DB-5MS, 30 m×0.25 mm i.d., 0.25 μm film thickness, J & W Scientific; electron impact: 70 eV). The temperature was initially 60°C for 5 min, then increased by 10°C/min to 300°C and held at this temperature for 30 min. Identification of compounds was based on comparisons of mass spectra with literature data (McLafferty and Stauffer 1989), and with mass spectra and retention times of authentic reference substances. Non-commercial esters were synthesized from the corresponding acid chlorides and alcohols

according to standard procedures. Mass spectra and NMR-data were in accordance with expected data (Francke et al. 2000).

Bioassays To test the effect of geraniol on larval development, we added 10 μg of geraniol (Sigma-Aldrich®) to the larval food provision of recently sealed brood cells by puncturing each treatment cell with a fine needle and injecting 0.01 μl (=10 μg; equivalent to the labial gland contents of 3–4 nurse bees) of geraniol using a 0.5 μl gastight® syringe (Hamilton, Switzerland). The larvae in the treated brood cells were left to develop in their normal environment within the nest for 7–8 wk. We then opened the treatment cells (N=158) and untreated control cells (N=212) from the same colony in order to determine the caste of each pupa. We compared the observed distribution of queens and workers in treated and untreated cells using a 2×2 *chi-square* analysis of contingency table. A Yates correction was applied to adjust the *chi-square* value.

Results

Chemical Analyses Chemical analyses revealed that the main component in labial gland secretions of nurse workers of *Melipona beecheii* was (E)-3,7-dimethyl-2,6-octadien-1-ol, also known as geraniol (2.7±0.9 μg, N=6). Geraniol also was found in rectal extracts collected from newly emerged queens (3.8±1.2 μg, N=6), but was absent from extracts collected from newly emerged workers (N=12; Fig. 1).

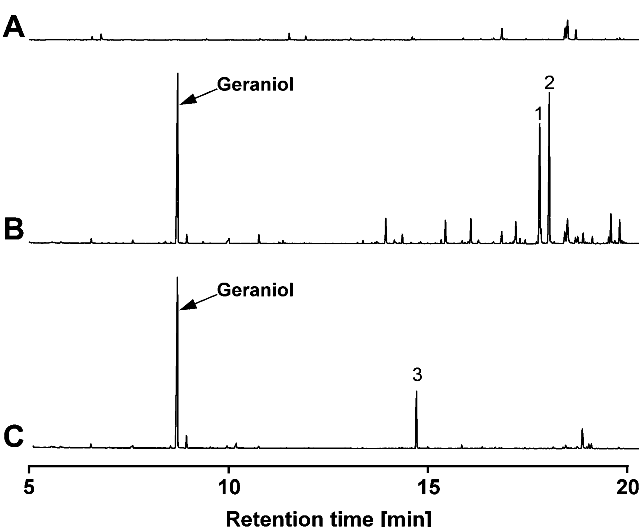

Fig. 1 Gas chromatograms of extracts from the rectum of a newly emerged *Melipona* worker (**A**) or a newly emerged virgin queen (**B**) and from the labial glands of a nurse bee (**C**). Peak height is a measure of abundance (flame ionization detector, A–C same scale). Additional compounds: *1*, (Z)-9-octadecenol; *2*, 1-octadecanol; *3*, geranyl hexanoate

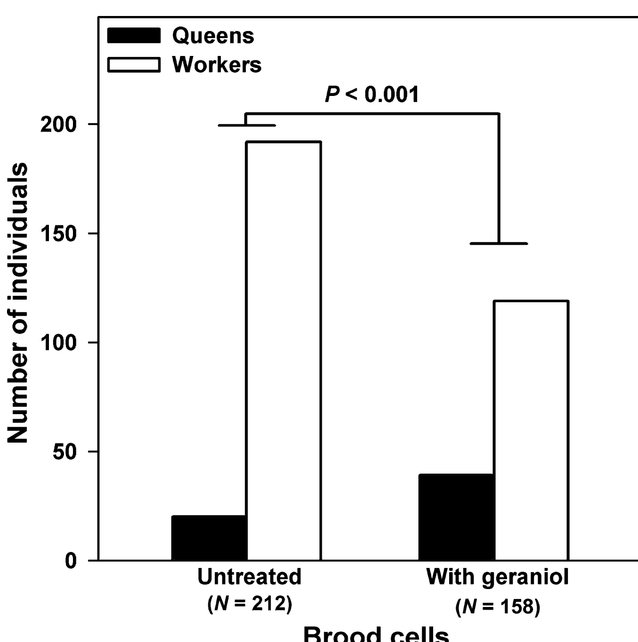

Fig. 2 Distribution of *Melipona* queens and workers among untreated brood and among brood that developed in cells to which 10 μg geraniol were added to the larval provision. 2×2 *Chi-square* analysis of contingency table, Yates correction, df=1, χ^2=14.590

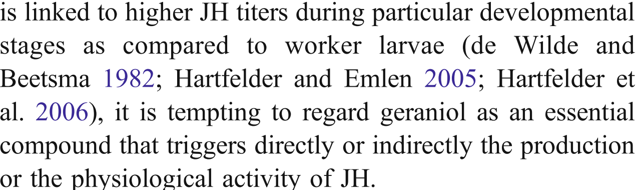
Bioassays The holes in the cells made by injection of geraniol were closed by workers after the treatment, which demonstrates that they were accepted as normal brood cells. Naturally provisioned brood cells contained 116.6±9.4 mg (mean ± SD; N=14) of food. Thus, the addition of 10 μg of geraniol is far below the naturally occurring variation in food amount. We, therefore, assume that any observed effect of geraniol on larval development was caused by the qualitative rather than the quantitative alteration of the food. To test the effect of geraniol on larval development we compared the numbers of queens and workers in brood cells in which 10 μg of synthetic geraniol were added to the larval food provision, with the respective numbers in untreated brood cells from the same colony. The addition of geraniol to the larval food caused significantly more larvae to develop into queens as compared to untreated brood (geraniol: 39 queens, 119 workers; untreated: 20 queens, 192 workers; 2×2 *chi-square* analysis of contingency table, Yates corrected χ^2=14.590, df=1, P<0.001; Fig. 2). Furthermore, the proportion of larvae that developed into queens in geraniol treated brood cells perfectly matched the value (25%) predicted by Kerr's two-locus, two-allele model of genetic caste determination, whereas in untreated cells only 9% of the larvae developed into queens.

Discussion

The mechanism that triggers queen development in bees of the genus *Melipona* has remained unresolved to this day despite more than half a century of research and debate. In the present study, we identified geraniol, the main compound in labial gland secretions of nurse workers, as an exogenous caste determination factor in *M. beecheii*. The finding that in our bioassays 25% of the female brood in geraniol treated cells developed into queens corroborates the two-locus, two-allele model of genetic caste determination in *Melipona* proposed by Kerr (see Introduction). We, therefore, conclude that caste fate in *Melipona* is controlled both genetically and by a factor associated with larval provision: Female larvae that are genetically predisposed towards being queens only will follow this developmental pathway if they received sufficient amounts of a caste determining compound, which, in the case of *M. beecheii*, is geraniol. From the observation that the proportion of queens among larvae in *Melipona* nests is typically less than 25% (Kerr 1948; Darchen and Delage-Darchen 1975; Moo-Valle et al. 2001; Sommeijer et al. 2003; Wenseleers et al. 2004; Morais et al. 2006), we conclude that the concentration of geraniol usually is below this critical threshold in the majority of cells in nature. This indicates that nurse bees only add labial gland secretions to the normal provision (pollen, carbohydrates, hypopharyngeal gland secretions; Velthuis and Sommeijer 1991) in selected brood cells (we are currently investigating the distribution of geraniol among naturally provisioned brood cells). Thus, adult *Melipona* workers, which have little power to control the caste fate of developing larvae by limiting the *quantity* of their food, may exert suppression of queen development by limiting the access to a specific *qualitative* food factor—the primer pheromone geraniol. As a consequence, our results refute the assumption that *Melipona* larvae completely control their own caste fate (Bourke and Ratnieks 1999; Ratnieks 2001; Wenseleers et al. 2003; Wenseleers and Ratnieks 2004; Ratnieks and Helanterä 2009).

The high abundance of young queens in *Melipona* and, thus, the colony-level costs that are associated with the production of excess queens (Wenseleers and Ratnieks 2004), may well be a constraint imposed by its unique mechanism of caste determination. To answer this, detailed knowledge about the exact proximate mechanism by which geraniol acts at the molecular level is needed. It may function directly on gene regulation by triggering the expression of new genes or the repression of others (e.g., Schlichting and Pigliucci 1995; Nijhout 1999; West-Eberhard 2003). Geraniol may represent an essential precursor of a terpenoid compound exhibiting hormonal activity, such as juvenile hormone (JH), or, possibly, geranyl esters. Since queen development in eusocial bees



is linked to higher JH titers during particular developmental stages as compared to worker larvae (de Wilde and Beetsma 1982; Hartfelder and Emlen 2005; Hartfelder et al. 2006), it is tempting to regard geraniol as an essential compound that triggers directly or indirectly the production or the physiological activity of JH.

The impact of exogenous agents, including nutrition, on the development of an organism is well documented for a large variety of species (Gilbert and Epel 2009). However, to the best of our knowledge, geraniol is the first caste determination substance identified as a physiologically active signal for queen development from the larval food of a social insect. Moreover, geraniol is the only primer pheromone, as defined by Nordlund (1981), identified from an insect other than the honey bee (Le Conte and Hefetz 2008)—almost 50 years after the identification of 9-oxo-(*E*)-2-decenoic acid, the queen substance primer pheromone of honey bees (Butler et al. 1962). The impact of geraniol on an individual's physiology sheds new light on the versatility of this compound and its derivatives, which are generally regarded as typical releaser pheromones. It should be noted that a second major compound in the labial gland secretions of nurse bees of *Melipona beecheii* is geranyl hexanoate (Fig. 1), which also is widespread among solitary and other eusocial bees (Bergström 2008). Whether geranyl hexanoate represents a lipophilic storage form of geraniol, or shows physiological activities on its own, awaits further investigation.

Acknowledgements We thank Robert Hodgkison for linguistic help and Robert Paxton for his valuable comments on an earlier version of this paper. The study was supported by DFG grant JA 1715/1 and by funds made available by the *Facultad de Ciencias de la Tierra y el Mar* of the National University of Costa Rica trough an invitation of SJ as Visiting Professor.

Abstract The pine sawyer beetle, *Monochamus galloprovincialis*, is a pest of pine trees in Europe and North Africa. Previously considered a secondary pest of stressed and dying trees, it is now receiving considerable attention as a vector of the pine wood nematode, *Bursaphelenchus xylophilus*, the causal agent of a lethal wilting disease in susceptible species of pines. Adult beetles are attracted to traps baited with a kairomone blend consisting of a host volatile, α-pinene, and two bark beetle pheromone components, ipsenol and 2-methyl-3-buten-2-ol. More recently it has been shown that mature male *M. galloprovincialis* produce a pheromone that attracts mature females in a laboratory bioassay. Here, volatiles were collected from mature male and female *M. galloprovincialis*, and a compound produced specifically by mature males was identified as 2-undecyloxy-1-ethanol from its gas chromatographic retention times, its mass spectrum, and by comparison with synthetic standards. The naturally-derived and synthetic compounds elicited electroantennographic responses from both females and males. Sealed polyethylene vials and polyethylene sachets were shown to be effective dispensers with zero-order release, the latter giving a higher release rate than the former. In two field tests, multiple-funnel traps baited with synthetic 2-undecyloxy-1-ethanol caught both female and male *M. galloprovincialis*, with higher catches at the higher release rate. This compound also synergized the attractiveness of the kairomone blend, the combined mixture catching 80–140% more beetles than the sum of the catches to each bait separately and luring up to two beetles/trap/d in a moderate-density population. We conclude that 2-undecyloxy-1-ethanol is a male-produced aggregation pheromone of *M. galloprovincialis*. This is the first example of a sex-specific compound in the cerambycid subfamily Lamiinae with significant behavioral activity in the field at a range sufficient to make it a useful trap bait. The possible roles of this pheromone in the chemical ecology of *M. galloprovincialis* and its potential use in pine wilt disease management are discussed.

Introduction

Woodboring beetles of the genus *Monochamus* Dejean (Coleoptera: Cerambycidae) comprise a group of species in which the larvae usually colonize woody plants that are dead, dying, or severely stressed. As such they can be considered secondary pests included in the stressed or dead

host species categories described by Hanks (1999). Economic damage produced by these species is due to timber degradation caused by larvae boring into the sapwood and heartwood (McIntosh et al. 2001; Evans et al. 2004). In rare cases, species of *Monochamus* are known to oviposit in and kill standing coniferous trees following forest disturbances (Gandhi et al. 2007). However, woodborers in the genus *Monochamus* are of particular importance since the adults are vectors of the pine wood nematode, *Bursaphelenchus xylophilus* (Steiner et Buhrer) Nickle, the causal agent of pine wilt disease. The pine wood nematode is native to North America and causes a lethal wilting in susceptible species of pines (Wingfield et al. 1982). Nematodes typically are introduced into healthy trees during maturation feeding of adults on the pine shoots (Mamiya and Enda 1972), but nematode transmission also occurs when females oviposit into dying or dead trees. *Bursaphelenchus xylophilus* was introduced into Japan around 1905, later spreading to southeastern China in 1982, Taiwan in 1983, and Korea in 1988, causing widespread mortality and severe losses in pine forests of these Asian countries (Shing 2008; Zhao 2008).

The pine sawyer, *Monochamus galloprovincialis* (Olivier) (Coleoptera: Cerambycidae), is a woodboring insect distributed in Europe and North Africa. It mainly colonizes *Pinus* species, but also will colonize several species of *Abies* and *Picea*. Eggs are deposited in niches chewed within the bark. Larvae bore under the bark, feed in the phloem tissue, later mine into the sapwood, and finally into the heartwood to complete their development and pupate in characteristic pupal cells (Bense 1995). Young adults feed on the bark of pine shoots in the crown of healthy trees for sexual maturation. In southern Europe, it completes its life cycle in 1 year (Vives 2000; Naves et al. 2008), but it may require 2 years in northern latitudes (Tomminen 1993). This longhorn beetle previously was considered a secondary forest pest, but it is now receiving increased attention following the recent introduction of pine wood nematode into Portugal. This disease is killing *Pinus pinaster* Aiton (Mota et al. 1999), and *M. galloprovincialis* has been confirmed as the vector of the disease in this area (Sousa et al. 2001).

Among the Cerambycidae, the genus *Monochamus* has been one of the more well-studied groups from the perspective of its chemical ecology; kairomonal attractants and repellents and oviposition stimulants have been reported for several species, but no pheromones have been isolated and identified (Allison et al. 2004). Both males and females of *M. galloprovincialis* are attracted by blends of pine volatiles and compounds used as pheromone components by *Ips* species bark beetles (Pajares et al. 2004; Francardi et al. 2009), and a kairomonal lure composed of α-pinene, ipsenol, and 2-methyl-3-buten-2-ol has been developed for use in monitoring operations (Ibeas et al. 2007). Presumably, both sexes are brought together on the host plant by these kairomones, and this is followed by copulation and oviposition. Ibeas et al. (2008) described the mating behavior of *M. galloprovincialis* in the laboratory and proposed a chemically-mediated sex recognition by males through the contact of the female elytra with the labial and/or maxillary palpi of the mouthparts. Later, the role of female cuticular compounds in mate recognition was demonstrated, and significant differences between the global hydrocarbon profiles of males and females were found, indicating that females have a contact pheromone on their cuticle that stimulates male copulatory behavior (Ibeas et al. 2009).

Ibeas et al. (2008) also showed that mature female *M. galloprovincialis* were strongly attracted to mature males feeding on pine shoots in an olfactometer. Mature females also were attracted to mature males in the absence of pine shoots, but less strongly. Mature females were not attracted to immature males, and immature females were not attracted to mature or immature males. Males were not significantly attracted by males or females.

The olfactometer data suggested that mature male *M. galloprovincialis* produce a pheromone that attracts mature females. The work reported here was undertaken to isolate and identify this pheromone and to test its attractiveness in the field to male and female *M. galloprovincialis* alone and with the kairomone lures described earlier. Traps baited with the latter are already in use for monitoring the pest, and if the pheromone increases their attractiveness, then the sensitivity of the traps would be enhanced and control by mass trapping might be feasible.

Methods and Materials

Insect Material Insects were allowed to emerge from infested logs of *Pinus halepensis* Miller, *P. pinaster*, and *P. sylvestris* L. collected in the field and brought into the laboratory in Spain. They then were sexed and sent by courier to the UK in individual tubes. They arrived within 2 d and were maintained on shoots of *P. halepensis* in an insectary with 12L:12D cycle (0700–1900 h L: 1900–0700 h D), at temperatures of 25°C and 20°C, respectively, and at ambient humidity. Initially, freshly-emerged beetles were sent from Spain and used immediately. Subsequently, beetles were allowed to feed on pine shoots for 2 wk in Spain before shipment to the UK. These correspond to immature and mature beetles, respectively (Ibeas et al. 2008).

Collection of Volatiles For collection of volatiles, beetles and/or pine shoots were held in a silanized flange flask

(1 l). Air was drawn in through a charcoal filter (10 cm× 2 cm; 10–18 mesh; Fisher Scientific, Loughborough, Leicestershire, UK) at 2 l/min, and volatiles were trapped on Porapak Q (50–80 mesh; 200 mg; Supelco, Gillingham, Dorset, UK) packed between glass wool plugs in a Pasteur pipette (i.d. 4 mm). The Porapak Q was cleaned previously by Soxhlet extraction with chloroform for 8 h, and filters were washed well with dichloromethane before use. Trapped volatiles were eluted from the filter with dichloromethane (3×0.5 ml) and used directly for analyses. Separate flasks were used for male and female beetles, and each flask was fitted with two collection filters attached to pumps with electronic timers arranged to collect volatiles emitted during the light and dark periods on separate filters.

Gas Chromatography (GC) and GC Coupled to Mass Spectrometry (GC-MS) Collections of volatiles were analyzed by GC with flame ionization detection (FID) on an HP6850 instrument (Agilent Technologies, Stockport, Cheshire, UK) fitted with a split/splitless injector and fused silica capillary column (30 m×0.32 mm i.d.×0.25 μm film thickness) coated with polar SupelcoWax10 (Supelco, Gillingham, Dorset, UK). Carrier gas was helium (2.4 ml/min), and the oven temperature was held at 60°C for 2 min then programmed at 10°C/min to 250°C. Injection was splitless at 200°C. Peaks were quantified by comparing peak areas with an internal standard of 1-undecanol (1 μg).

Collections of volatiles also were analyzed by GC-MS on an HP6890 GC coupled directly to an HP5973 MS (Agilent Technologies) operated in EI mode. The capillary column (30 m×0.25 mm i.d.×0.25 μm film thickness) was coated with SupelcoWax10 or non-polar SPB5 (Supelco). Injection was splitless (220°C); the carrier gas was helium (1 ml/min); and the oven temperature was held at 50°C for 2 min then programmed at 6°C/min to 250°C.

GC retention times were converted to Retention Indices (RI) by comparison with the retention times for *n*-alkanes (Zellner et al. 2008). Compounds were identified by comparison of their mass spectra with those in the spectral library (NIST 05 Mass Spectral Library; Agilent Technologies) and subsequent comparison of mass spectra and GC retention times with those of synthetic standards.

GC Coupled to Electroantennographic (EAG) Recording For GC-EAG analyses, an HP6890 instrument was fitted with fused silica capillary columns coated with both polar and non-polar phases as above except that column i.d. was 0.32 mm. The ends of the two columns were connected to a short piece of deactivated fused silica tubing with a glass, push-fit Y-piece. The outlet from this then was split by means of a similar Y-piece connected to the flame ionization detector and to a silanized, glass T-piece (arms 5 cm, i.d. 4 mm), with similar lengths of deactivated fused silica tubing. One arm of the T-piece was connected to a device delivering nitrogen (200 ml/min) in a 3-sec pulse at 17-sec intervals. The third arm of the T-piece passed through the GC oven wall to the insect EAG preparation (Cork et al. 1990).

EAG recording was carried out with a portable device (INR-02; Syntech, Hilversum, The Netherlands) consisting of integrated electrode holders, micromanipulators, and an amplifier. Electrodes were silver wires fitted with glass electrodes pulled to a fine point with an electrode puller and containing saline solution (0.1 M potassium chloride with 1% polyvinylpyrrolidine to reduce evaporation). An antenna was excised at the base and suspended between the glass electrodes, which were cut so that they just accommodated the ends of the antenna. The signal was amplified × 500 and the amplifier was connected to the GC as a detector device. Data were processed with EZChrom Elite v3.0 (Agilent Technologies).

Microacetylation An aliquot (200 μl) of a collection of volatiles from mature male *M. galloprovincialis* in dichloromethane was blown down carefully just to dryness with charcoal-filtered nitrogen. Pyridine (10 μl) and acetic anhydride (10 μl) were added, and the mixture stood at room temperature overnight. The mixture was dissolved in hexane (200 μl) and extracted × 3 with water (100 μl) before drying with a little magnesium sulfate and analyzing by GC-MS.

Synthetic Chemicals Nuclear magnetic resonance (NMR) spectra were recorded in $CDCl_3$ on a JEOL EX270 machine at 270 MHz for ^1H and 67.8 MHz for ^{13}C. Infrared (IR) spectra were recorded as thin films with a Perkin Elmer 298 grating spectrophotometer (Perkin Elmer, Beaconsfield, Buckinghamshire, UK).

2-Undecyloxy-1-ethanol (I, Fig.1) was synthesized by adding an oil dispersion of sodium hydride (60%; 2.8 g, 70 mM) portionwise to a stirred solution of ethanediol (6.2 g, 100 mM) in dry dimethylformamide (70 ml) at room temperature over 30 min. The suspension then was heated at 60°C for 30 min until effervescence had ceased. After cooling to room temperature, 1-bromoundecane (11.8 g, 50 mM) was added dropwise. The mixture was stirred for 2 h at room temperature, then for 2 h at 60°C after which time GC analysis showed all the 1-bromoundecane had reacted. The mixture was cooled and quenched carefully with half-saturated brine (100 ml). After adding 20% diethylether in petroleum ether (150 ml), the mixture was extracted × 3 with half-saturated brine (100 ml). The aqueous extracts were re-extracted with 20% diethylether in petroleum ether (150 ml), and the combined organic extracts were dried with magnesium sulfate and filtered through silica gel (10 g). Analysis by GC showed the product and 1,2-diundecyloxyethane in 57:43 ratio. After removal of solvents

Fig. 1 Structures of male-specific compounds from *Monochamus galloprovincialis* (I), *Anoplophora glabripennis* (II) and (III) (Zhang et al. 2002), and *M. leuconotus* (IV) (Hall et al. 2006b)

on a rotary evaporator, the residue (13.5 g) was distilled to give the product b.p. 125°C/0.04 mm Hg (5.8 g, 54%). IR (film): ν 3440 cm^{-1}; ^{1}H NMR: δ 0.88 (t, J=6.2 Hz, 3H), 1.26 (br, 16H), 1.59 (quin, J=6.8, 2H), 2.21 (s, 1H), 3.47 (t, J=6.6 Hz, 2H), 3.53 (t, J=4.6 Hz, 2H), 3.73 (t, J=4.6 Hz, 2H); ^{13}C NMR: δ 14.13, 22.71, 26.14, 29.35, 29.51, 29.63 (m), 29.69, 31.93, 45.55, 61.90, 71.46, 71.69 MS: m/z (%) 41 (40), 43 (65), 45 (41), 55 (41), 57 (100), 63 (28), 69 (20), 71 (43), 75 (10), 82 (10), 83 (21), 85 (34), 97 (24), 99 (10), 111 (8), 126 (8), 154 (4), 185 (2).

4-Heptyloxy-1-butanol (II, Fig. 1) and 4-heptyloxy-butyraldehyde (III, Fig. 1), male-specific compounds from the Asian longhorned beetle, *Anoplophora glabripennis* (Motschulsky), were synthesized as described by Zhang et al. (2002).

2-(4-Heptyloxy-1-butyloxy)-1-ethanol (IV, Fig. 1), a male-specific compound from the coffee stemborer, *Monochamus leuconotus* (Pascoe), was synthesized from II (Fig. 1) after conversion to the corresponding bromide with phosphorus tribromide in diethylether and reaction with ethanediol as for I (Fig. 1) (Hall et al. 2006b).

Release Rates of Pheromone from Dispensers Release rates of 2-undecyloxy-1-ethanol (I, Fig. 1) from closed polyethylene vials and polyethylene sachets were determined in the laboratory. The compound (41 mg) was impregnated onto a cellulose cigarette filter (15×6 mm; Swan, High Wycombe, Buckinghamshire, UK) inserted into the vial (22×8×1.5 mm thick; Just Plastics Ltd., London, UK) or polyethylene sachet (2.5 cm×2.5 cm×120 μm thick) made from heat-sealed, layflat tubing (International Pheromone Systems Ltd., Wirral, UK). Dispensers were maintained in a laboratory windtunnel (27°C, 8 km/h windspeed), and release rates were determined gravimetrically over 41 d. Data were recorded from only two replicates for each release device as release from these dispensers is known to be uniform (Hall et al. 2006a).

Field Tests Two trapping experiments (Table 1) were carried out in a mature forest of *P. halepensis* at Sierra Espuña (Murcia) National Park, southeastern Spain (37º 57′ N, 1º 24′W). Pine trees were healthy, and breeding material for the pine sawyer was not particularly abundant. Thus, the population of *M. galloprovincialis* in the area was assumed to be at a moderate level. In Experiment 1, we tested the responses of the beetles to the synthetic pheromone alone, to the standard kairomone lure of α-pinene, ipsenol (2-methyl-6-methylene-7-octen-4-ol), and 2-methyl-3-buten-2-ol (Pajares et al. 2004; Ibeas et al. 2007) and to combinations of the two. We also investigated the flight response elicited by verbenone to determine whether this compound could replace α-pinene in the kairomonal mixture, as suggested by Ibeas et al. (2007). In Experiment 2, we replaced the bark beetle pheromone component ipsenol in the kairomone mixtures with ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol).

Dispensers for bark beetle semiochemicals and host compounds were as described previously by Pajares et al. (2004) and Ibeas et al. (2007). Thus, racemic ipsenol, racemic ipsdienol, 2-methyl-3-buten-2-ol, and ~80%-(–)-

verbenone were dispensed from separate bubble-cap or pouch dispensers (Phero Tech Inc. Delta, BC, Canada; now Contech Enterprises) with release rates (and active ingredient loads) quoted by the manufacturer as 0.40 mg/d (40 mg, bubble cap, at 25°C), 0.20 mg/d (40 mg, bubble cap, at 25°C), 11–65 mg/d (3.3 mg, pouch, at 20°C and 30°C), and 2–15 mg/d (790 mg, bubble cap, at 20°C and 30°C), respectively. Racemic α-pinene was dispensed from polyethylene tubing (300 cm long × 11 mm diam; Esencias Catalá, Gandia, Valencia, Spain) at 2.1 g/d as measured gravimetrically at 27°–30°C. The pheromone was dispensed from polyethylene vials (low release rate) or polyethylene sachets (high release rate) as described above except that the loading was 82 mg.

Traps were 12-unit, multiple funnel traps (115 cm long; Phero Tech Inc.) suspended from ropes between trees with the top funnel 1.8 m above ground. The collecting cups were provided with a small piece of DDVP (dimethyl 2,2-dichlorovinyl phosphate) insecticide strip (Econex S. L., Murcia, Spain) to kill trapped beetles. Both experiments were deployed in seven randomized complete blocks. Traps were at least 100 m apart and nearest blocks were 700 m apart. Experiments 1 and 2 were conducted from 3 July to 7 August 2008 and from 7 August to 26 September 2008, respectively. Traps were emptied every 7–10 d and *M. galloprovincialis* in the trap catches were identified and separated by sex (Vives 2000).

Previous experience has shown that *M. galloprovincialis* are not caught in unbaited traps (Pajares, unpublished; Francardi et al. 2009). Thus, no unbaited controls were included in the experiments in order to avoid having treatments with zero mean and variance (Reeve and Strom 2004). Even so, in both experiments, no beetles were caught in traps baited with verbenone. These were excluded from analysis, and the remaining data were square-root transformed to meet the assumptions of normality and homoscedasticity, as confirmed by quantile-quantile plots, and subjected to analysis of variance (ANOVA) by using a generalized linear model for randomized complete blocks (SAS System software, SAS Institute Inc. 1999–2000). Treatment mean catches were compared by Least Significant Difference (LSD) Fisher tests (α=0.05). In addition, normalized data from treatments with lowest catches were subjected to one sample *t*-tests to test for departure of treatment true means from zero.

Results

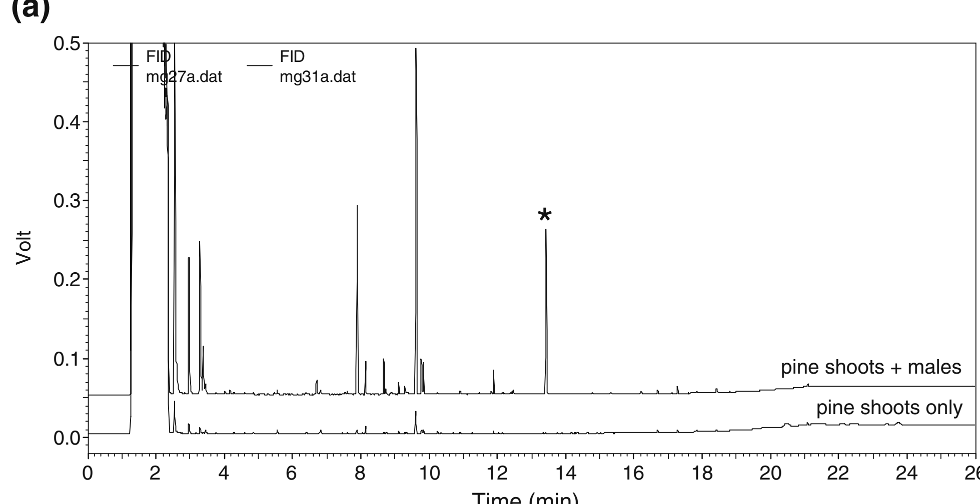
Pheromone Identification Initially, volatiles were collected from freshly-emerged, immature adult *M. galloprovincialis*. Collections were made from two to three males or females separately, with and without shoots of *P. halepensis*, and from shoots of *P. halepensis* only. Collections were made from 0–24 h and 24–72 h after introduction of beetles, and volatiles emitted during the light and dark periods were collected separately. All samples were replicated twice. Analysis of these collections by GC-FID showed no obvious differences between collections from males and females.

Subsequent collections were made from mature beetles that had fed for at least 2 wk on pine shoots. Volatiles were collected from pine shoots only for 24 h, and then one to three beetles added. After addition of beetles much larger amounts of volatiles were collected from the pine shoots, presumably due to the feeding of the beetles (Fig. 2). The main compounds in the extracts were identified (GC-MS) as α- and β-pinene, myrcene, limonene, methyl benzoate, methyl salicylate, α- and β-caryophyllene, and α-farnesene.

An additional compound was observed only in collections from the pine shoots with mature male beetles (Fig. 2). GC retention data for this compound are shown in Table 2 and the EI mass spectrum in Fig. 3a). A library search on the mass spectrum gave 2-hexyloxy-1-ethanol as one of the best fits, albeit with a fit of only 38%. However, the mass spectrum showed several of the ions as doublets two mass units apart, as reported by Zhang et al. (2002) in the mass spectrum of the two *A. glabripennis* male-specific compounds (II and III, Fig. 1). We also observed this phenomenon in the mass spectrum of a male-specific compound (IV, Fig. 1) from *M. leuconotus* (Hall et al. 2006b).

The difference between the RI's on polar and non-polar GC phases (Table 2) showed that the compound from male *M. galloprovincialis* was much less polar than the diether alcohol from *M. leuconotus* (IV, Fig. 1) and closer in polarity to the monoether alcohol (II, Fig. 1). The presence of an alcohol function was confirmed by acetylation (Table 2, Fig. 3b). The difference in RI on the non-polar column between that for the compound from *M. galloprovincialis* and the alcohol from *A. glabripennis* (II, Fig. 1) suggested the former had two carbons more than the latter.

The mass spectrum of the compound from male *M. galloprovincialis* (Fig. 3a) showed an unusual ion at *m/z* 63 corresponding to protonated ethane diol ($HOCH_2$-$CH_2OH_2^+$). The ion at *m/z* 154 could be due to (C_9H_{19}-$CH=CH_2)^+$ formed by elimination of an ether group from a $C_{11}H_{23}$- moiety. A McLafferty-type arrangement of the same moiety would give $C_7H_{15}CH=CH_2^+$ at *m/z* 126. The ion at *m/z* 185 then would correspond to loss of -CH_2-OH from a molecular weight of 216 by cleavage α-β to the ether. Thus, 2-undecyloxy-1-ethanol (I, Fig. 1) was considered a possible structure. This was synthesized from 1-bromoundecane and ethanediol and found to have identical GC retention times (Table 2) and mass spectrum (Fig. 3c) to those for the compound from mature male *M. galloprovincialis*.



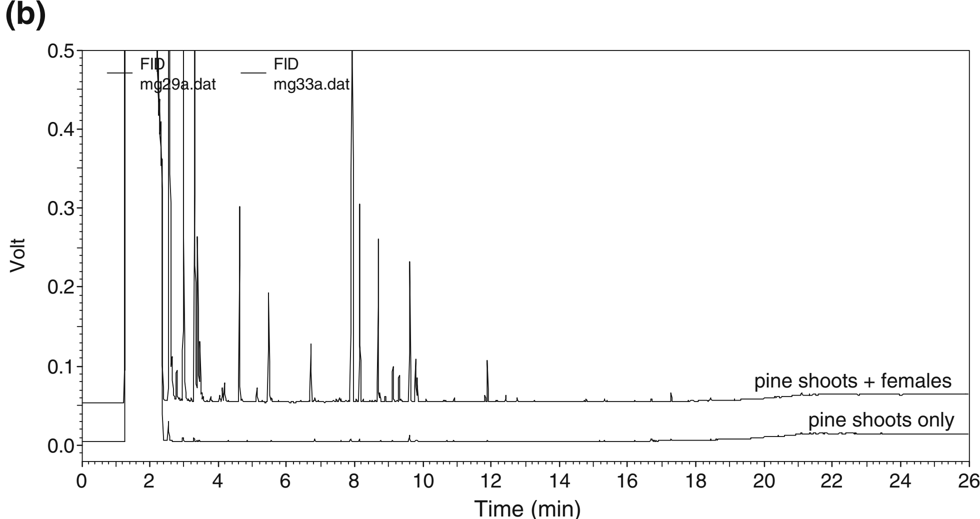


Fig. 2 GC-FID analyses of volatile collections from *Monochamus galloprovincialis* during light period: (**a**) analyses of collection from pine shoots only (24 h; lower trace) and after adding 1 mature male *M. galloprovincialis* (48 h; upper trace); (**b**) analyses of collection from pine shoots only (24 h; lower trace) and after adding two mature female *M. galloprovincialis* (48 h; upper trace). Male-specific compound marked with *

Compound I (Fig. 1) was detected in collections made from mature males during both light and dark periods, although the amount collected during the dark period was approximately half that collected during the light period. The two collections with the most compound I contained approximately 10 µg from two males during a single 12 h light period and approximately 30 µg from one male over two successive light periods. If production were uniform throughout the light period, these figures are equivalent to approximately 0.4 µg/h/male and 1.3 µg/h/male, respectively.

GC-EAG Recording Analyses of collections of volatiles from male and female *M. galloprovincialis* showed a significant and consistent EAG response from antennae of both female (Fig. 4a) and male beetles (Fig. 5a) to the male-specific compound (I, Fig. 1) in volatiles from mature males. No responses to volatiles from the pine were

recorded in these analyses even though α-pinene at least is a known kairomone (Pajares et al. 2004; Ibeas et al. 2007) and has been shown to elicit an EAG response from *M. galloprovincialis* (Álvarez, unpublished). Presumably, the antennal receptors are less sensitive to the kairomones than to the pheromones, and the concentrations of the former were too low in these analyses. Synthetic 2-undecyloxy-1-ethanol (I, Fig. 1) also elicited an EAG response from the antennae of female (Fig. 4b) and, to a lesser extent, male (Fig. 5b) beetles. In these analyses, the EAG responses from the antennae of female beetles seemed to be generally higher than those from the antennae of male beetles. Although the sensitivities of individual preparations were not normalized with a reference standard, the absolute responses above blank to 14 ng injected (7 ng to the antenna) of the natural male-specific compound were 1.85± 0.15 mV (± S.E., N=3) and 0.83±0.32 mV (± S.E., N=3) from females and males, respectively. The responses to 10 ng injected of synthetic I were 1.51±0.15 mV (± S.E., N=9) and 0.66±0.09 mV (± S.E., N=5), respectively. These differences were significantly different by a simple t test (P=0.001 for the natural compound; P=0.023 for the synthetic).

In unreplicated tests, cutting the tip of the antenna before inserting into the recording electrode did not seem to affect the magnitude of the response recorded. The antenna also seemed to be uniformly responsive along its length.

Release Rates of Pheromone from Dispensers Release of synthetic 2-undecyloxy-1-ethanol (I, Fig. 1) from polyethylene sachet dispensers was uniform over the period of measurement of 41 d (Fig. 6). Release from the polythene vials did not start for approximately 5 d, while the compound diffused through the walls but was uniform after about 10 d (Fig. 6). Rates at 27°C and 8 km/h windspeed were 0.16 mg/d (± 0.005 mg/d for the two replicates) for the vial and 0.74 mg/d (± 0.013 mg/d for the two replicates) for the sachet, equivalent to 67 μg/h and 330 μg/h, respectively. Thus, with initial loadings of 82 mg, even the sachets would be expected to last for at least 3 mo under these conditions.

Field Tests In Experiment 1, carried out during 5 wk in the first half of the summer, we tested the responses by both sexes of *M. galloprovincialis* to the synthetic pheromone at two release rates alone or in combination with the standard kairomone lure and to four variations of the kairomone lure designed to investigate the effect of α-pinene and verbenone (Fig. 7). This experiment confirmed that the kairomone mixture of ipsenol, 2-methyl-3-buten-2-ol, and α-pinene is attractive to *M. galloprovincialis*, catching up to one beetle/trap/d. Responses of females were 17–34% lower when α-pinene was either removed or replaced by verbenone in the kairomone mixture, although the differences were not significant. Catches of males were approximately half those of females, but the males responded similarly to the kairomone mixtures with the response significantly reduced by 40% if α-pinene was excluded. Traps baited with verbenone alone captured no beetles during the experiment, and this compound had no significant effect on attractiveness to females or males when added to the kairomone standard.

The male-produced compound, 2-undecyloxy-1-ethanol, attracted both female and male *M. galloprovincialis* (Fig. 7). The high-release dispensers trapped three times more females than the low-release baits, and this difference was significant. Catches of female *M. galloprovincialis* in traps baited with the low and high-release dispensers were significantly different from zero (t-test, P=0.009; P<0.001, respectively), whereas only the high-release dispensers resulted in catches of males significantly different from zero (t-test, P=0.004).

Although traps baited with the high-release dispensers caught two to three times fewer female *M. galloprovincialis* and three to six times fewer males than were caught in traps baited with the kairomone standard, there was a synergism between the pheromone and the kairomones (Fig. 7). The numbers of female *M. galloprovincialis* attracted by the combinations were more than 80% higher than the sum of the catches obtained by the separate components; the numbers of males attracted were 65–75% higher. As a result, the proportion of the sexes trapped by the pheromone-plus-kairomone mixture was less biased to the females (1:2 male:female) than with the pheromone alone (1:3.5). Also, the dose-response effect found to the pheromone alone was not so apparent when it was combined with the kairomone. Catches with the high-release dispensers were only 13% more than catches from the low-release dispensers, and this difference was not significant. The combinations of the pheromone and the standard kairomone bait trapped means of 64.8 and 73.6 beetles/trap over 35 d for low- and high-release pheromone dispensers, respectively, i.e., approximately two *M. galloprovincialis* beetles per trap each day.

Experiment 2 was carried out in the same site for 7 wk during the second half of the beetle flight period and evaluated similar blends to those used in the first experiment except that ipsenol was replaced by ipsdienol (Fig. 8). The four kairomone blends were significantly attractive relative to a zero trap catch, but numbers of beetles trapped were 50–75% lower than those trapped by the analogous blends in the first experiment, and removal of α-pinene did not reduce catches. As in Experiment 1, traps baited with verbenone alone caught no beetles.

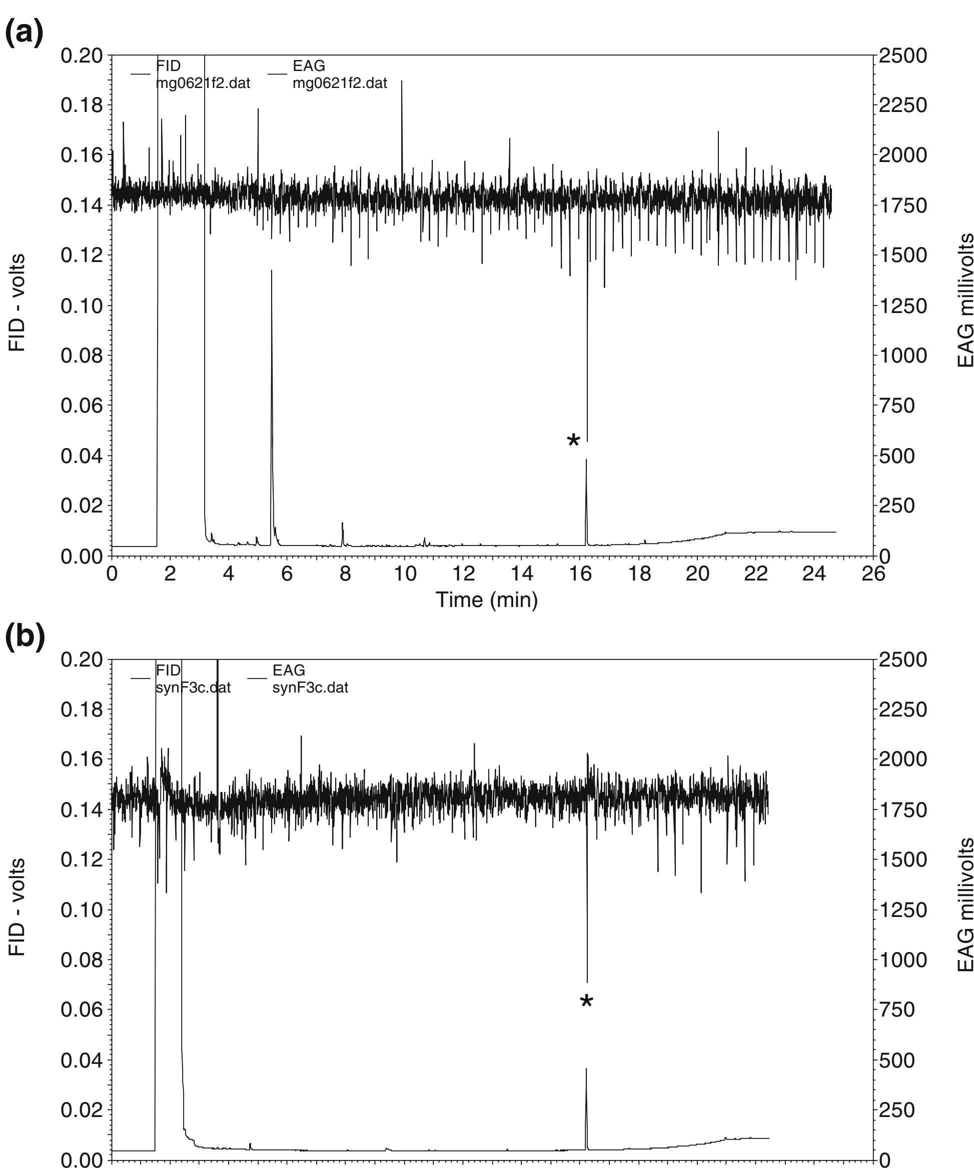

Fig. 4 Linked GC-EAG analyses with EAG recording from female *Monochamus galloprovincialis* antenna: **a** volatiles from mature males and **b** synthetic 2-undecyloxy-1-ethanol (I) (10 ng injected; EAG responses marked with *)

As observed in the first half of the season, *M. galloprovincialis* females were significantly attracted to traps baited with 2-undecyloxy-1-ethanol alone in a dose-response pattern (Fig. 8). Catches with the high-release lures were higher than those with the four kairomonal lures containing ipsdienol, significantly so for two of them. Catches of males were approximately 63% of the catches of females, a proportion much higher than during the first part of flight, when male catches were 30% of female catches.

The synergistic effect of the kairomones and the pheromone on attraction of *M. galloprovincialis* was even greater than in the first experiment. Catches of females were 175% higher and of males 125% higher than the sum of the catches with the pheromone and kairomones separately when the low-release pheromone dispensers were added to the kairomone mixture of ipsdienol and 2-methyl-3-buten-2-ol. Catches of both sexes were 155% higher when the high-release pheromone lures were added. Overall, the kairomone-pheromone mixtures trapped means of 31 and 58 beetles/trap during the 49 d of the experiment for low- and high-release pheromone lures, respectively, i.e., approximately one *M. galloprovincialis* beetle per trap each day.

Discussion

2-Undecyloxy-1-ethanol has been shown to be produced by mature, adult male *M.galloprovincialis* feeding on pine.

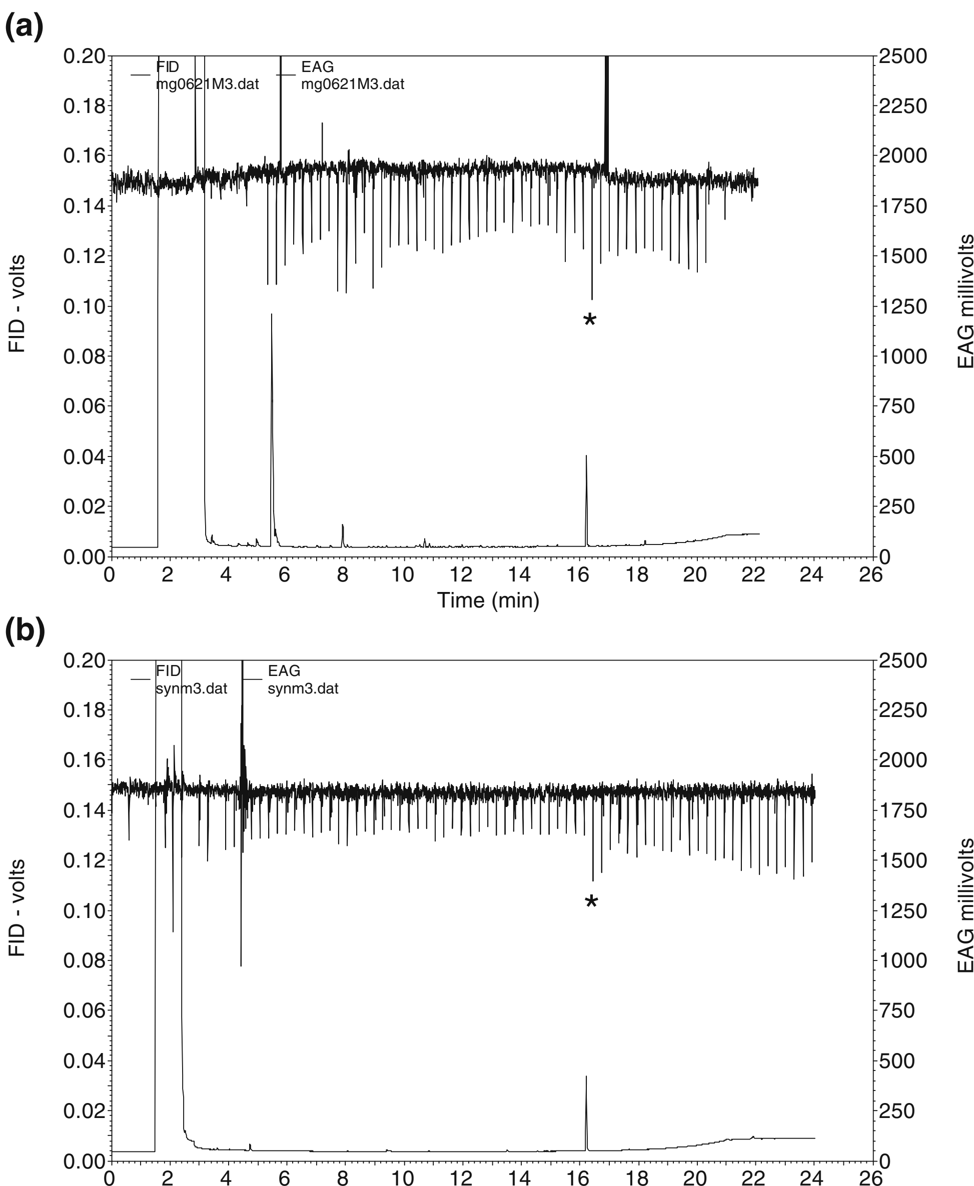

Fig. 5 Linked GC-EAG analyses with EAG recording from male *Monochamus galloprovincialis* antenna: **a** volatiles from mature males and **b** synthetic 2-undecyloxy-1-ethanol (I) (10 ng injected; EAG responses marked with *)

This compound elicits EAG responses from the antennae of both males and females, is attractive to females and males in the field, and enhances the attractiveness of traps baited with blends of pine volatiles and bark beetle pheromone components. We conclude that 2-undecyloxy-1-ethanol is a male-produced aggregation pheromone of *M. galloprovincialis*. These results are partially in agreement with those of Ibeas et al. (2008), who reported that reproductively mature females were consistently attracted to plumes containing odors from mature males in a Y-tube olfactometer. However, these authors did not observe significant attraction of males to the odors from males. This may have been due to the overall lower levels of response by males or to the differences in experimental procedure between the laboratory and field bioassays.

Ethers have been identified as male-specific volatiles in two other species of cerambycids of the subfamily Lamiinae: compounds II and III (Fig. 1) by *A. glabripennis* (Zhang et al. 2002) and IV (Fig. 1) by *M. leuconotus* (Hall et al. 2006b). The structures of these clearly are related (Fig. 1) and quite different from the hydroxyketones and dihydroxy compounds that have been found frequently as male-specific compounds in species from other subfamilies, particularly the Cerambycinae (e.g., Hanks et al. 2007). More recently, other structural types have been identified as pheromones in cerambycids, including the Lamiinae. Males of *Megacyllene caryae* (Cerambycinae) produce several monoterpenes as well as 2,3-hexanediols (Lacey et al. 2008); males of *Rosalia funebris* (Cerambycinae) produce (*Z*)-3-decenyl (*E*)-2-hexenoate (Ray et al. 2009); males of

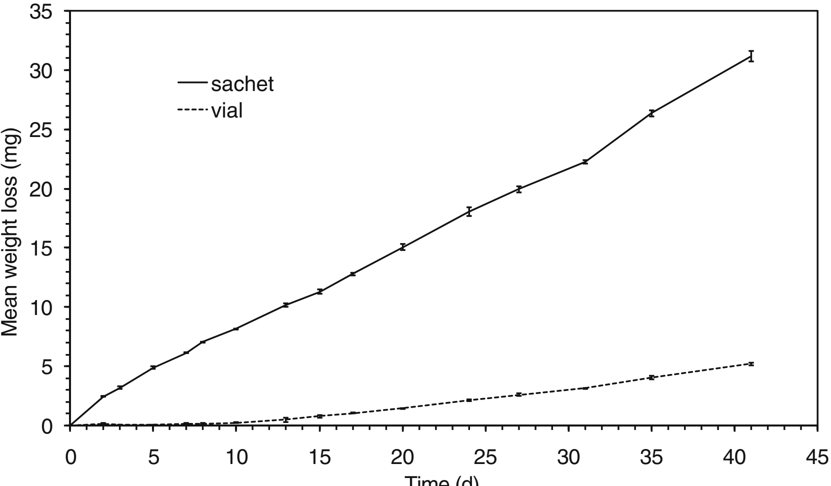

Fig. 6 Release of 2-undecyloxy-1-ethanol from polyethylene vials and sachets maintained in a wind tunnel at 27°C and 8 km/h wind-speed as measured gravimetrically (N=2 for each release device; bars show the range between the two measurements)

Tetropium fuscum (Spondylidinae) produce two homomonoterpenoids (Silk et al. 2007); females of *Prionus californicus* (Prioninae) produce 3,5-dimethyldodecanoic acid, which attracts males (Rodstein et al. 2009); and males of *Hedypathes betulinus* (Lamiinae) produce three homomonoterpenoids (Vidal et al. 2008; Fonseca and Zarbin 2009).

Long-range sex pheromones have not been found in the Lamiinae so far. Hanks (1999) suggested that long-range pheromones might be expected in species where the adults do not feed. Species in the Lamiinae generally feed as adults, and it is thought the adults are brought together on the host plant that is often weakened or stressed. The sexes then locate each other by visual stimuli as well as short-range and contact pheromones. Observations on the reproductive behavior of *M. alternatus* showed evidence of short-range attraction of females by male-emitted volatiles (Fauziah et al. 1987; Kim et al. 1992). Also,

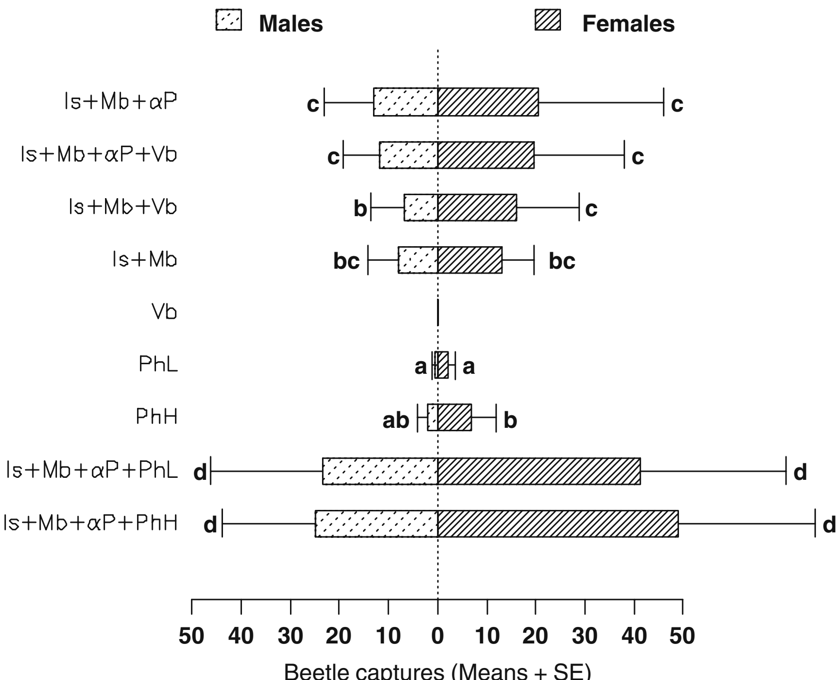

Fig. 7 Catches of *Monochamus galloprovincialis* during Experiment 1 in Sierra Espuña, Murcia, Spain, from 11 July to 7 August 2008 in semiochemical-baited multiple-funnel traps. Compounds are: αP = α-pinene; Is = ipsenol; Mb = 2-methyl-3-buten-2-ol; Vb = Verbenone; PhH and PhL = pheromone at high and low release rates, respectively. For each sex, bars followed by the same letter are not significantly different after ANOVA on data omitting zero catches with verbenone and square-root transformed followed by LSD test (α=0.05); for males F=15.20, df=7,42, P<0.001, N=7; females F=17.98, df=7,42, P<0.001, N=7. Actual means and standard errors are shown in the histogram. Differences among treatment means were assessed after ANOVA on transformed data, which removed variability among replicates

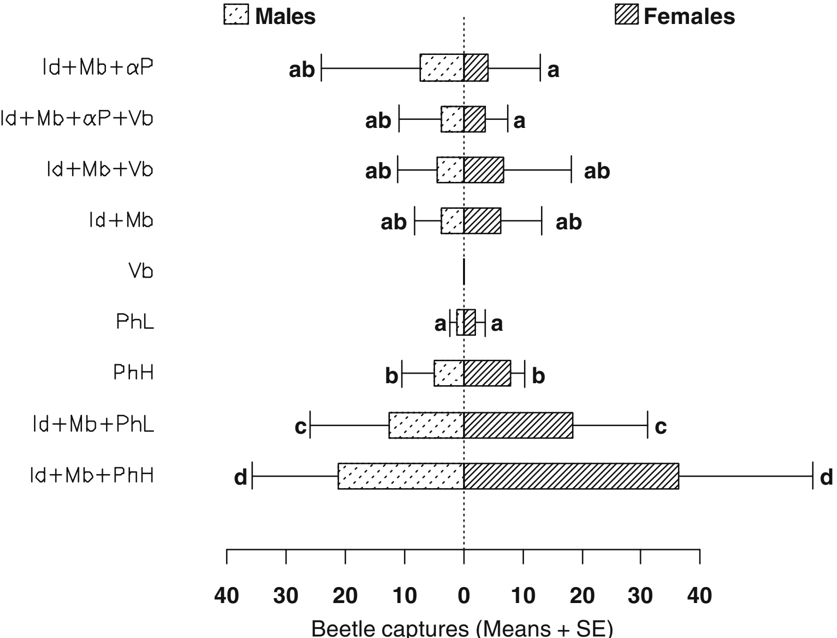

Fig. 8 Catches of *Monochamus galloprovincialis* during Experiment 2 in Sierra Espuña, Murcia, Spain, from 7 August to 26 September 2008 in semiochemical-baited multiple-funnel traps. Compounds are: αP = α-pinene; Id = ipsdienol; Mb = 2-methyl-3-buten-2-ol; Vb = Verbenone; PhH and PhL = pheromone at high and low release rates, respectively. For each sex, bars followed by the same letter are not significantly different after ANOVA on data omitting zero catches with verbenone and square-root transformed followed by LSD test (α=0.05); for males F=9.6, df=7,42, P<0.001, N=7; females F=17.92, df=7,42, P<0.001, N=7. Actual means and standard errors are shown in the histogram. Differences among treatment means were assessed after ANOVA on transformed data, which removed variability among replicates

Fukaya et al. (2004, 2005) reported that olfactory and visual cues mediated short-distance orientation in *A. malasiaca*, presenting clear evidence that males were able to recognize females at close range without direct physical contact, and that olfactory cues were essential and visual cues synergistic for mate location by males. In *Steirastoma breve*, the odors emitted by males elicited strong EAG responses in the females and also attracted females in a two-choice olfactometer (Liendo et al. 2005). Lu et al. (2007) stated explicitly that long-range pheromones are not involved in mate location by *Glenea cantor*.

Among the Lamiinae, the two male-specific compounds (II and III, Fig. 1) identified by Zhang et al. (2002) in volatiles from male *A. glabripennis* elicited EAG responses from the antennae of both sexes of the beetle. A blend of these compounds was significantly attractive to *A. glabripennis* adult females in laboratory olfactometer tests at one critical loading, but attempts to use these compounds as lures for traps in the field have been less successful (Nehme et al. 2009). The male-specific compound detected in volatiles from *M. leuconotus* (IV, Fig. 1) by Hall et al. (2006b) also elicited EAG responses from the antennae of both sexes, but no behavioral function for this compound alone or in combination with host plant volatiles has yet been established despite extensive olfactometer and field trapping studies (Hall and Kutywayo, unpublished).

The range of action of the pheromone in *M. galloprovincialis* is unknown, but the field trapping results indicate that it is attractive over more than the few centimeters reported for the pheromones of other species of the Lamiinae described above and suggest that it might well be active over much more than within-tree distances. Thus, 2-undecyloxy-1-ethanol is the first example in the Lamiinae of a sex-specific compound having a significant behavioral activity in the field at a range sufficient to make it a useful lure for trapping beetles. Several chemical signals appear to be involved in the reproductive behavior of *M. galloprovincialis*. Long-range host selection is driven by a kairomonal response to host volatiles and bark beetle semiochemicals that brings together both sexes to larval host trees (Pajares et al. 2004, Ibeas et al. 2007), and this now seems to be synergized by the male-produced aggregation pheromone. The latter also may play a role in attracting females at relatively short range, as in the Y-tube bioassays reported by Ibeas et al. (2008), and even in recognition of males by females. Finally, the chemically-mediated reproductive behavior of *M. galloprovincialis* is completed when males recognize mates by contact chemoreception of female cuticular compounds (Ibeas et al. 2009).

The field trapping experiments described here confirmed the kairomonal response by *M. galloprovincialis* to lures containing ipsenol, 2-methyl-3-buten-2-ol, and α-

pinene (Pajares et al. 2004; Ibeas et al. 2007; Francardi et al. 2009). Attempts to simplify or improve the response to this mixture by removing the host volatile or replacing it with verbenone showed that the host monoterpene should be included in any operative kairomonal lure to maximize attraction. In field Experiment 2, when ipsenol was replaced by ipsdienol, catches with the four kairomone blends were lower than in the first experiment. It is unlikely that this was due to lower populations later in the season, as catches with the pheromone and mixtures of kairomones and pheromone generally were higher than in the first experiment. The results are consistent with a lower attractiveness of the blends with ipsdienol than those with ipsenol, as reported by Pajares et al. (2004) and Ibeas et al. (2007), but changes in relative responses to kairomones and pheromone during the season cannot be excluded and need to be investigated. The responses to the kairomones ended somewhat earlier than to the pheromone, as only the baits containing the pheromone attracted beetles in mid-late September in Experiment 2 (data not shown). The difference in release rate of the two bark beetle pheromone components (ipsenol was 2× greater than ipsdienol) also may have contributed to the difference in trap catch.

The synergy between the kairomones and pheromone resulted in trap catches of both sexes to the combined mixture increasing by almost 80% in Experiment 1 and by 140% in Experiment 2, compared to the sum of the catches to each bait separately. The kairomone-pheromone combination thus provides a more powerful attractant for *M. galloprovincialis*, able to lure as many as two beetles/trap/d in a moderate population. Only two release rates of the pheromone were evaluated here (67 μg/h and 330 μg/h). Although these were significantly higher than the rate of release of the pheromone by male *M. galloprovincialis* (up to 1.3 μg/h), there was some evidence for a positive dose-response effect of the pheromone, and higher release rates might increase catches even further.

This result allows us to revise the potential of trapping in the management of *M. galloprovincialis*. Traps baited with host attractants have been useful for monitoring *Monochamus* species in Asia and Portugal, and also have been evaluated for control of beetle populations, although the latter trials were reported to be unsuccessful in Japan (Nakamura 2008; Rodrigues 2008). Previous experiments have demonstrated that the response by *M. galloprovincialis* to host monoterpenes alone is very low (Pajares et al. 2004; Ibeas et al. 2007), but we have shown that it is increased by almost two orders of magnitude when bark beetle semiochemicals and the male pheromone also are released. Ipsenol, 2-methyl-3-buten-2-ol, and α-pinene are well-established compounds, currently used for operational monitoring of bark beetles and other xylophagous insects (e.g., Francardi et al. 2009). 2-Undecyloxy-1-ethanol is relatively easy to synthesize and can be conveniently dispensed from polyethylene vials or sachets for long periods in the field. This bait should be useful in management of pine wilt disease, not only for monitoring of the insect vectors and of the nematodes they carry, but also possibly for effective control of the beetle by mass trapping in outbreak situations.

Attractiveness of a Four-component Pheromone Blend to Male Navel Orangeworm Moths

Abstract The attractiveness to male navel orangeworm moth, *Amyelois transitella*, of various combinations of a four-component pheromone blend was measured in wind-tunnel bioassays. Upwind flight along the pheromone plume and landing on the odor source required the simultaneous presence of two components, (11*Z*,13*Z*)-hexadecadienal and (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-tricosapentaene, and the addition of either (11*Z*,13*Z*)-hexadecadien-1-ol or (11*Z*,13*E*)-hexadecadien-1-ol. A mixture of all four components produced the highest levels of rapid source location and source contact. In wind-tunnel assays, males did not seem to distinguish among a wide range of ratios of any of the three components added to (11*Z*,13*Z*)-hexadecadienal. Dosages of 10 and 100 ng of the 4-component blend produced higher levels of source location than dosages of 1 and 1,000 ng.

Introduction

The navel orangeworm, *Amyelois transitella* (Walker) (Lepidoptera: Pyralidae), is a major pest of the multibillion dollar almond, pistachio, and walnut crops in California. The sex pheromone produced by the female navel orangeworm moth was characterized originally as a single component, (11*Z*,13*Z*)-hexadecadienal (Z11,Z13-16:Ald) (Coffelt et al. 1979a). Although this compound stimulated male activation, wing fanning, and upwind movement in laboratory bioassays (Coffelt et al. 1979b), its activity as an attractant for field traps was inconsistent, and it was only weakly attractive when compared to virgin female moths (e.g., Kuenen et al. 2001, 2010). In recent studies, a number of additional compounds have been identified from pheromone gland extracts (Leal et al. 2005; Kuenen et al. 2010), including analogs of Z11,Z13-16:Ald, such as (11*Z*,13*E*)-hexadecadienal (Z11,E13-16:Ald), (11*E*,13*Z*)-hexadecadienal (E11,Z13-16:Ald), (11*Z*,13*Z*)-hexadecadien-1-ol (Z11,Z13-16:OH), (11*Z*,13*Z*)-hexadecadien-1-yl acetate (Z11,Z13-16:Ac), hexadecanal (16:Ald), (*Z*)-11-hexadecenal (Z11-16:Ald), (*Z*)-13-hexadecenal (Z13-16:Ald), ethyl hexadecanoate (16:COOEt, ethyl palmitate), and ethyl (11*Z*,13*Z*)-hexadecadienoate (Z11,Z13-16:COOEt). Two unusual polyunsaturated hydrocarbons, (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-tricosapentaene (C_{23} pentaene) and (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-pentacosapentaene (C_{25} pentaene), also were found in gland extracts. The first group of compounds is typical of the so-called Type I lepidopteran pheromones, that is, compounds with C_{10} to C_{18} straight chains terminating in alcohol, aldehyde, or ester functions. In contrast, the two pentaenes belong to the Type II lepidopteran pheromones, characterized by polyunsaturated hydrocarbons and related epoxides and ketones, with C_{17} to ~C_{25} carbon chain lengths (Ando et al. 2004). Thus, this insect is one of the first examples of a

moth species that might use a combination of both Type I and Type II compounds in its pheromone blend. In field trials, Leal et al. (2005) demonstrated that blends of five of these components, in combination with Z11,Z13-16:Ald, were attractive to male moths, but they did not report further attempts to refine the blend. Thus, it remained unclear as to which specific compounds were necessary and sufficient to constitute an attractive blend. More rigorous attempts to delineate the true blend by using a combination of wind tunnel and field bioassays spanning several field seasons, provided evidence that the pheromone blend is composed of at least four components, Z11,Z13-16:Ald, Z11,Z13-16:OH, (11*Z*,13*E*)-hexadecadien-1-ol (Z11,E13-16:OH), and C_{23} pentaene (Kuenen et al. 2010). Furthermore, Kuenen et al. (2010) found no evidence that other components found in gland extracts, Z11,E13-16:Ald, E11,Z13-16:Ald, Z11,Z13-16:Ac, Z11-16:Ald, 16:Ald, hexadecan-1-ol, and C_{25} pentaene, were components of the pheromone blend.

The aim of the work reported here was to delineate and define the optimal attractive pheromone blend of the navel orangeworm. Our specific objectives were to conduct wind tunnel bioassays to assess: 1. Attraction of male moths to the major component, Z11,Z13-16:Ald, plus one, two, or three of the additional minor components that had been implicated in previous studies; 2. attraction to various blends in which the proportion of a single component was varied systematically while holding the ratio of the other components fixed; 3. the effect of adding other compounds, identified in pheromone gland extracts, to an optimized blend of 4 components; 4. the effect of dose of the pheromone blend on responses of male *A. transitella*.

Methods and Materials

Insects Our colony of *A. transitella* was established with eggs obtained from the USDA, Agricultural Research Service, Parlier, CA, USA, from a colony founded from individuals collected in 2001 from walnuts in Fresno County, CA, USA. Larvae were reared in 3.8-l jars on a red flaky wheat diet (Coffelt et al. 1979a). Cultures were maintained at 26°C, with a photoperiod of 16:8L:D and 50–60% relative humidity. Approximately 80 last instar males were removed daily from the colony and placed in 180-ml plastic cups (20 per cup). These larvae were held in a controlled temperature cabinet separated from the rearing colony, under a reversed photoperiod, 14:10L:D regime at 25°C. Males that emerged each day were transferred to a 30×30×30 cm plastic screen cage, where they were held with access to 10% sucrose solution. All individuals used in bioassays were 2–4-d-old.

Wind-tunnel Bioassays A wind tunnel (1 m wide×1 m high×3 m long), described in Justus et al. (2002), was used for all experiments. Because male *A. transitella* often ascend 15 cm or more after take-off in a pheromone plume, the 1 m height of this tunnel was essential for the bioassay. The wind speed was set to 50–60 cm s^{-1} by regulating two variable-speed fans, one on the tunnel input and the other on the exhaust. The wind speed was verified with a Barnant Tri-Sense (Cole-Parmer 37000-61) anemometer. All air flowing through the tunnel was exhausted from the building. The tunnel's floor was covered with white fabric, and red paper circles, 5.4 cm diam., set randomly (30 per m^2) on the floor in a non-overlapping pattern to provide non-directional visual cues. All experiments were conducted at 24–26°C with a relative humidity of 50–60%. Two lateral banks of 25-W, clear red (Philips Colortone R) and 25-W tungsten lights, on each side of the room, illuminated the ceiling and were set with a rheostat to provide a diffuse light of 7–10 lux in the wind tunnel. A Sanyo VCB-3512T monochrome CCD camera (shutter speed, 1/100 sec), with a 75 mm lens, was mounted at the side of the wind tunnel to record male behavior at the pheromone source (see below).

All experiments were conducted during the last 3 hr of scotophase, the period when female *A. transitella* call and mate (Coffelt et al. 1979b). Test males were brought into the assay room and transferred individually into a small wire mesh cylindrical (3 cm diam.×5 cm high) cage, with one end open and the other closed. Males were acclimated to the conditions of the assay room for 60–180 min. before being tested. To test male responsiveness to a pheromone/odor source, a cage was placed, closed-end facing upwind, on a wire-mesh stand set 21 cm above the tunnel floor and 160 cm downwind of the pheromone source. Once a male began wing fanning, the cage was rotated 180°, thereby allowing him to initiate upwind flight. Test males were used once and discarded.

The following were noted:

Percentage taking flight: proportion of males initiating wing fanning that take flight within 1 min. of the cage being placed on the stand in the pheromone plume.

Latency of taking flight: time from cage being placed on stand in pheromone plume until the initiation of flight.

Percentage of source contact: proportion of males locking onto the plume that landed on the pheromone source.

Latency of source contact: time from initiation of flight to landing on the pheromone source.

Duration of source contact: time of continuous contact with the source after landing. All males walked and wing fanned while in contact with the source. If a male

flew off the source and then re-contacted it (a relatively rare occurrence), we did not consider time spent in a subsequent landing in our measurement of duration of source contact. Observations were terminated after 2 min. of continuous source contact.

Odor Sources All compounds used were synthesized as described in detail in Kuenen et al. (2010). Stock solutions (1 mg/ml in heptane) were formulated from compounds that were re-purified (see Kuenen et al. 2010) immediately before making up the solutions, and had the following purities (known impurities): Z11,Z13-16:Ald, >98% pure (~0.6% Z11,E13-16:Ald and ~0.6% E11,Z13-16:Ald); Z11, Z13-16:OH, >98% chemically and isomerically pure; C_{23} pentaene, >99% pure; Z11,E13-16:OH, >96% pure. Working solutions were prepared by dilution of stock solutions in hexane. Point sources of odor were created by applying 20 µl of a hexane solution of a particular blend to a 1-cm diam. filter paper disk (Whatman #1) mounted on a #3 insect pin. The solvent was allowed to evaporate for 3 min. before the paper disks were placed in glass vials until used (within 2 hr). The filter paper disk was pinned vertically into the eraser of a pencil, 22 cm above the tunnel floor. Each source was placed 100 cm from the upwind end of the tunnel and used for no longer than 20 min.

Statistical Analyses In each experiment, a treatment was blocked daily as a group of five males; within the block, five males were tested consecutively. The order in which treatments were tested was randomized. All treatments were tested on each test day. The proportions of individuals initiating flight or contacting the lure were analyzed for differences by treatment using a *G*-test in SAS 9.1 (SAS Institute 2004). Results from asymptotic and exact tests were the same in all instances. Results of the exact test were reported because effective sample sizes for moths making contact with the lure in some instances were small. Time to initiation of flight, time to lure contact, and the duration of contact, were compared by treatment using Minitab's Regression with Life Data in Minitab 14 (Minitab Statistical Software 2004). The data for each of the above variables were determined to fit a lognormal distribution adequately ($P>0.94$). Treatments with $N<10$ were excluded from analyses, but their means and standard deviations are reported.

Results

Our first experiment tested the effects of addition of one, two, or all three, of these compounds added to Z11,Z13-16:Ald (Fig. 1) in the 100:100:5:15 ratio used by Kuenen et al. (2010). Z11,Z13-16:Ald, as a single component, elicited some activation and flight initiation (59%), but no oriented upwind flight along the plume; no moths reached the

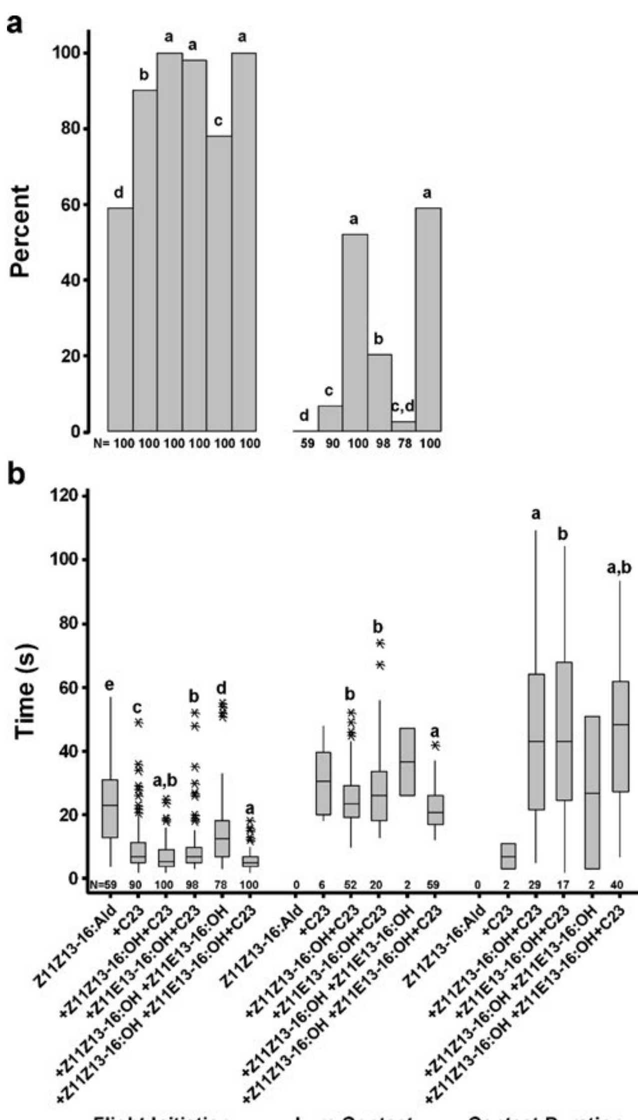

Fig. 1 Flight responses of male *Amyelois transitella* to various pheromone blends containing (11*Z*,13*Z*)-hexadecadienal (Z11Z13-16:Ald; in all blends), (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-tricosapentaene (C23), (11*Z*,13*Z*)-hexadecadien-1-ol (Z11Z13-16:OH), or (11*Z*,13*E*)-hexadecadien-1-ol (Z11E13-16:OH). **a** Percentage of males that initiated flight within 60 sec of exposure to lure, and percentage of males that contacted a lure. N indicates the number of males tested for each response. **b** Time to flight initiation (censored at 60 sec), time to lure contact, and contact duration (censored at 120 sec). Boxes indicate 25th and 75th percentiles, bars inside boxes are medians, whiskers denote the range, and asterisks represent outliers. Z11Z13-16:Ald , Z11Z13-16:Ald + C23 and Z11Z13-16:Ald + Z11Z13-16:OH + Z11E13-16:OH were not included in the analysis of time to contact and contact duration because of inadequate sample sizes. N indicates the number of males tested for each response. Different letters above columns or boxes [in (a) or (b)] indicate significant ($P<0.05$) differences

source. Addition of C_{23} pentaene to Z11,Z13-16:Ald increased the proportion of moths initiating flight, and reduced the mean latency to flight, but the percentage of moths contacting the source was still low (6.7%). Similarly, the blend of Z11,Z13-16:Ald + Z11,Z13-16:OH + Z11,E13-16:OH resulted in greater flight initiation and a shorter mean latency to flight than recorded to Z11,Z13-16:Ald alone but, again, there were few source contacts (2.6%). Addition of either Z11,Z13-16:OH or Z11,E13-16:OH, or both, to the blend of Z11,Z13-16:Ald and C_{23} pentaene, resulted in high levels of flight initiation (98–100%), and short mean latencies (7.3–9.6 sec).

The 4-component mixture evoked the most rapid initiation of flight, followed by the two 3-component mixtures containing C_{23} pentaene, the mixture containing Z11,Z13-16:Ald and C_{23} pentaene, and the remainder of the treatments (Fig. 1). The time of source location followed the same trends seen in percentages of source location. There were 3 treatments that had sufficient numbers of males locating the source that permitted an analysis of latencies of source location (Fig. 1). The 4-component mixture evoked the most rapid source location, followed by the two 3-component mixtures containing C_{23} pentaene. The duration of source contact was longest for the 4-component blend and the Z11,Z13-16:Ald, Z11,Z13-16:OH, and C_{23} pentaene blend, and somewhat shorter for the mixture of Z11,Z13-16:Ald, Z11,E13-16:OH, and C_{23} pentaene.

Taken together, these comparisons demonstrate that a high proportion of source location required Z11,Z13-16:Ald, C_{23} pentaene, and either Z11,Z13-16:OH or Z11,E13-16:OH, or both. Although the 3-component blend of Z11,Z13-16:Ald, Z11,Z13-16:OH, and C_{23} pentaene was statistically indistinguishable from the full 4-component blend for percentage of moths locating the pheromone source, the 4-component blend evoked significantly more rapid flight to the source, supporting the role of Z11,E13-16:OH as a component of the optimal blend. In a follow-up wind tunnel test, aimed at verifying the role of Z11,E13-16:OH and comparing the same series of blend components, the proportion of moths contacting the lure was highest (all 3 treatments differed at $P<0.05$, Hantel-Haenszel-Cochran test) for the 4-component mixture (80.0%), over the Z11,Z13-16:Ald, Z11,Z13-16:OH and C_{23} pentaene blend (56.7%), and the Z11,Z13-16:Ald, Z11,E13-16:OH and C23 pentaene mixture (21.7%), confirming that all 4 compounds are involved in eliciting the full behavioral response.

The second experiment tested the effects of adding different proportions of C_{23} pentaene to a base blend, consisting of Z11,Z13-16:Ald, Z11,Z13-16:OH, and Z11,E13-16:OH (100:100:5). Although the C_{23} pentaene was required for source location, males were remarkably insensitive to the percentage (from 1.5 to 150% of Z11,Z13-16:Ald) of this compound in the 4-component blend (Fig. 2). Based on these results, in further tests we used a 100:15 ratio of Z11,Z13-16:Ald to C_{23} pentaene, equivalent to the optimum ratio used in bioassays of Kuenen et al. (2010).

In the third experiment, the proportion of Z11,Z13-16:OH was varied while holding the ratio of Z11,Z13-16:Ald, C_{23} pentaene, and Z11,E13-16:OH constant (100:15:5). Four-component blends, that varied greatly in the proportion of Z11,Z13-16:OH, elicited similar levels of attraction

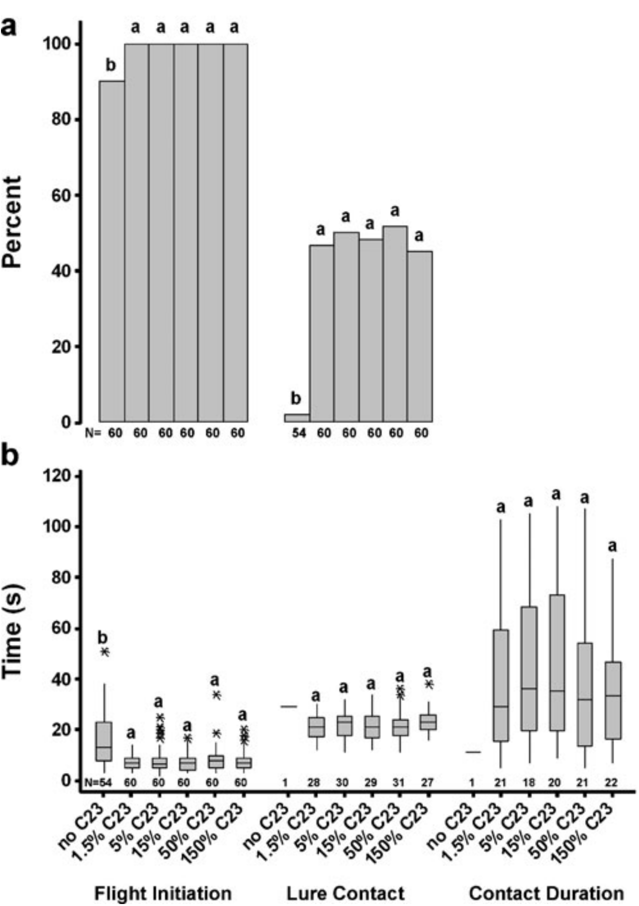

Fig. 2 Flight responses of male *Amyelois transitella* to pheromone blends with different amounts of (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-tricosapentaene (C23). All treatments contain (11*Z*,13*Z*)-hexadecadienal (10 ng), (11*Z*,13*Z*)-hexadecadien-1-ol, and (11*Z*,13*E*)-hexadecadien-1-ol in a 100:100:5 ratio. The percentage of C23 is relative to the amount of (11*Z*,13*Z*)-hexadecadienal. **a** Percentage of males that initiated flight within 60 sec of exposure to lure, and percentage of males that contacted a lure. N indicates the number of males tested for each response. **b** Time to flight initiation (censored at 60 sec), time to lure contact, and contact duration (censored at 120 sec). Boxes indicate 25th and 75th percentiles, bars inside boxes are medians, whiskers denote the range, and asterisks represent outliers. The treatment lacking C23 was not included in the analysis of time to contact and contact duration due to inadequate sample size. N indicates the number of males exhibiting a response. Different letters above columns or boxes [in (a) or (b)] indicate significant ($P<0.05$) differences

and source contact by males; ratios of Z11,Z13-16:OH to Z11,Z13-16:Ald of 30:100 to 300:100 were statistically indistinguishable for all metrics (Fig. 3). Thus, for subsequent experiments, we used the intermediate ratio of 100:100 Z11,Z13-16:Ald to Z11,Z13-16:OH.

Varying the proportion of Z11,E13-16:OH, while holding the ratio of the three other components constant (Z11,Z13-16:Ald to Z11,Z13-16:OH to C_{23} pentaene, 100:100:15), also had little effect on male responses (Fig. 4). Percent source contact increased with inclusion of Z11,E13-16:OH in the blend, but all other metrics were not affected significantly by the presence or absence of this component.

A dose-response comparison using 1, 10, 100, and 1,000 ng, all with the 4-component blend at the optimized ratio, showed that the 10-ng dose elicited the best overall response when comparing across all metrics (Fig. 5). The 100-ng dose resulted in a similar percentage of source contacts, but moths took longer to reach the source and

remained in contact with the source for less time than for the 10 ng dose. Both the 1-ng and the 1,000-ng doses resulted in markedly less source contact, longer latencies for source location, and shorter times in contact with the source, than were observed with the 10-ng dose.

The final experiment tested the effects of adding four other compounds that had been identified in pheromone gland extracts [(3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-pentacosapentaene, ethyl hexadecanoate, Z11,Z13-16:COOEt, and Z11,Z13-16:Ac (Leal et al. 2005; Kuenen et al. 2010), to the optimized 4-component blend. None of these compounds, added to the 4-component blend in the proportions reported by Leal et al. (2005), significantly affected any measure of attraction (flight latency, proportion contacting the source, time to lure contact, or duration of lure contact) compared to the responses to the 4-component blend (data shown in supplementary material).

Discussion

The *A. transitella* pheromone was characterized initially as Z11,Z13-16:Ald by Coffelt et al. (1979a), but this component alone has proven to be minimally attractive in field tests over the last two decades (J.G.M. unpublished data). A number of possible additional components of the *A. transitella* pheromone were described by Leal et al. (2005), but this study did not define the subset of compounds (and their optimal ratio) that was both necessary and sufficient to obtain high attraction. Iterative refinement of the active blend did not prove trivial, requiring several years of wind tunnel and field trials (Kuenen et al. 2010). The present study has expanded on these previous reports by examining the roles of the various compounds in mediating the sequential steps in attraction to the source.

The wind-tunnel assay allowed assessment of the effects of a wide range of component combinations and ratios on sequential stages of the male moths' flight responses, from activation of quiescent moths, to initiation of flight, flight upwind along the pheromone plume, landing on the pheromone source, and time spent in contact with the odor source. As in past work with wind tunnel assays (e.g., Linn et al. 1988; Zhu et al. 1999; Trimble and Marshall 2008), the most diagnostic measure of attraction was the proportion of males reaching and contacting a point source of odor. However, in the present study, several other metrics, including latencies of response and lure contact, were consistent with the proportion of lure contact. The duration of lure contact was less discriminatory among treatments: once males landed on an odor source, they spent many seconds wing fanning and walking on the source, even if the blend was not as attractive as other blends.

The data from our study reinforced the work of Kuenen et al. (2010), by verifying that C_{23} pentaene and Z11,Z13-16:OH are components of the pheromone blend. Z11,E13-16:OH had a less marked effect on the attraction of male moths to blends than C_{23} pentaene or Z11,Z13-16:OH, but still demonstrably affected the overall suite of behaviors.

One of the unexpected results from our studies was the general lack of sensitivity to component ratios by male *A. transitella*, especially given the importance of a precise component ratio in attraction of other moth species (reviewed in Cardé and Haynes 2004). This is likely because production of consistent blend ratios by females is more difficult when components have major structural

differences (Roelofs and Cardé 1977). Furthermore, probably because C_{23} pentaene is biosynthesized in oenocytes and then transported to the pheromone gland (Wang et al. 2010), whereas the other fatty acid-derived components are biosynthesized *de novo* in the gland, it is possible that the blend emitted by females may change during a calling bout as the available C_{23} pentaene becomes depleted.

Male *A. transitella* were sensitive to the dose of pheromone, with attraction being maximal to 10 ng and dropping to higher doses. This peak of response might be indicative of male response being linked to an optimum dose of pheromone, as has been noted with *Grapholita molesta* (Baker and Cardé 1979) and other moth species. Alternatively, the drop in attraction with increasing dose may be the result of small percentages of antagonistic impurities in the synthetic pheromone, which reached the threshold value required to affect the behavior of males, as the overall pheromone dose increased.

Our results, in combination with the data reported by Kuenen et al. (2010), suggest that other minor components found in gland extracts, including (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-pentacosapentaene, ethyl hexadecanoate, ethyl (11*Z*,13*Z*)-hexadecadienoate, and (11*Z*,13*Z*)-hexadecadienyl acetate (Leal et al. 2005; Kuenen et al. 2010), play no role in attraction of male *A. transitella*. However, the latter compound antagonizes attraction of a sympatric species, the meal moth *Pyralis farinalis* L. (Leal et al. 2005; Kuenen et al. 2010) that also uses both Z11,Z13-16:Ald and C_{23} pentaene as components of its pheromone blend. Thus, this compound, and possibly some of the other minor components, may function as behavioral antagonists mediating interspecific interactions.

This characterization of attractive blends for *A. transitella* will help advance the development of field lures for surveillance and population monitoring of this important pest. However, the optimal blends described in this study are not yet ready for operational use, because there are lingering problems with longevity of lures in the field. In particular, Kuenen et al. (2010) reported that pheromone lures decreased dramatically in activity within a day of being deployed, for a variety of lure types that incorporated both an antioxidant and an ultraviolet light stabilizer in their formulations. This suggests that male *A. transitella* are extremely sensitive to degradation of one or more of the components of the blend under field conditions. We have not noted analogous decreases in activity of test solutions in our wind tunnel trials carried out under low-light conditions. This suggests that photooxidation processes occurring in sunlight may be responsible for the rapid loss of activity of field lures.

Past work on mating disruption of *A. transitella* has centered mainly on the use of widely spaced (5 per ha^{-1}) "puffers", which dispensed metered doses of technical grade Z11,Z13-16:Ald in aerosol puffs at set intervals (Shorey and Gerber 1996). This disruptant system has been reported to be effective in suppressing male attraction to traps baited with virgin females and in reducing damage levels in almonds and pistachios (Higbee and Burks 2008), likely acting via the mechanism of "sensory impairment." Use of the complete blend might increase efficacy of disruption, however, especially if the pheromone were formulated with point sources that were attractive (Minks and Cardé 1988; Cardé and Minks 1995; Cardé 2007).

Acknowledgments We thank Tedros Berhane and Sima Raoufian for rearing the insects. Brad Higbee provided valuable insights into the behavior of the navel orangeworm. This project was supported by the Almond Board of California and the California Pistachio Commission.

Abstract In field tests in Europe, traps baited with a blend of isoamyl alcohol, acetic acid, and isobutanol (compounds previously found attractive to a number of noctuids in North America) caught the following noctuid moths: *Agrotis segetum* Schiff., *Agrotis crassa* Hbn., *Agrotis exclamationis* L., *Amathes (Xestia) c-nigrum* L., *Apatele rumicis* L., *Amphipyra pyramidea* L., *Dipterygia scabriuscula* L., *Discestra trifolii* Hfn., *Euxoa aquilina* Schiff., *Euclidia glyphica* L., *Mamestra brassicae* L., *Mamestra oleracea* L., *Mamestra suasa* Schiff., *Mythimna albipuncta* Den. & Schiff., *Mythimna l-album* L., *Noctua pronuba* L., and *Trachea atriplicis* L. A substantial percentage of the catch of each species of moths was females. The presence of isobutanol in the mixture was important for catching *A. rumicis, D. trifolii*, and *E. glyphica*. The addition of 3-methyl-1-pentanol to the ternary mixture did not increase trap captures of any of the moths. Traps baited with the floral attractant phenylacetaldehyde alone caught several species of noctuid moths. However, when phenylacetaldehyde was added to the isoamyl-alcohol ternary blend, no increases in catches of any of the species, relative to the ternary blend or phenyacetaldehyde alone, were observed, with catches of most species being depressed. Comparing the noctuid species attracted to the phenylacetaldehyde- and isoamyl alcohol-based lures showed that phenylacetaldehyde attracted predominantly Plusiinae and Melicleptriinae spp., while isoamyl alcohol-based lures attracted species mostly from the Noctuinae or Hadeninae subfamilies.

Introduction

The Noctuidae is one of the largest and most important families of Lepidoptera, both by total number of species and by economic importance of agricultural pests. The detection and monitoring of flight activity of adult males of many pest noctuid species is performed routinely by using traps baited with sex pheromone. Such sex pheromone-baited traps have proven to be highly sensitive and selective, but they have the inherent weakness for pest control of attracting only male moths. Traps catching female moths would potentially provide more valuable information for pest control decisions. Isoamyl alcohol (3-methyl-1-butanol) or 3-methyl-1-pentanol (naturally occurring in fermenting molasses), in combination with acetic acid, has been found to attract females of several noctuid pests in North America (Landolt 2000; Landolt and Alfaro 2001; Landolt and Highbee 2002). The related isobutanol (2-methyl-1-propanol), in combination with acetic acid, also is known to attract yellowjacket spp. (Hymenoptera, Vespidae) (Landolt 1998; Landolt et al. 1999, 2000). Furthermore, phenylacetaldehyde is a well-known floral

compound that attracts both sexes of several noctuid species, as well as other Lepidoptera (e.g., Creighton et al. 1973; Cantelo and Jacobson 1979).

The principal objective of this study was to test the above compounds for ability to attract European noctuid species, with a particular application as female attractants in pest control programs. Also, we aimed to determine whether there were any synergistic interactions, in attraction to noctuid species, between the various alcohols/acid, produced by fermenting molasses and the floral attractant phenylacetaldehyde.

Methods and Materials

Traps The standard CSALOMON® VARL + funnel traps, produced by the Plant Protection Institute, HAS (Budapest, Hungary) (Tóth et al. 2000, 2002; Subchev et al. 2003) were used. This trap consists of an opaque plastic funnel (top opening, 13 cm o.d., funnel-hole diam., 3 cm, height of funnel, 16 cm), with a 20 × 20 cm flat, plastic roof, and a transparent plastic round container (ca 1 l, held in place by a rubber band). Photos of the trap can be viewed at <www.julia-nki.hu/traps>. The lure was suspended from the middle of the roof and positioned slightly above the level of the upper edge of the large funnel opening. A small piece (1 × 1 cm) of household anti-moth strip (Chemotox®, Sara Lee, Temana Intl. Ltd, Slough, UK; active ingredient 15% dichlorvos) was placed in the container to kill captured insects.

Baits Isoamyl alcohol, isobutanol (2-methyl-1-propanol), 3-methyl-1-pentanol, phenylacetaldehyde, and acetic acid were obtained from Sigma-Aldrich Kft. (Budapest, Hungary) and were stated by the suppliers to be >95% pure. The compounds were loaded onto a 1-cm piece of dental roll (Celluron®, Paul Hartmann Ag. Heidenheim, Germany), and placed inside a polyethylene bag (ca 1.0 × 1.5 cm; 0.02 mm-thick polyethylene foil). The lure dispensers were heat sealed and attached to 8 × 1 cm plastic strips for easy handling when assembling the traps. Lures were wrapped singly in pieces of aluminum foil and stored at −18°C until used. One or three lures were used in the traps to test for effect of lure concentration. Lures in traps were changed at 2–3 wk intervals, as previous experience with similar lures showed that they may lose activity after this period (Tóth et al. 2002).

Trapping Tests were conducted at several sites in Hungary. Traps were suspended at a height of ca 1.0–1.5 m. One replicate of each treatment was incorporated into a block, so that treatments were 8–10 m apart, and blocks were 30–50 m apart.

Experiment 1 was a preliminary, unreplicated test, run at Debrecen, Hajdú-Bihar County, May 3–October 18, 2001. Treatments included binary blends of isoamyl alcohol with acetic acid, isobutanol with acetic acid, and the ternary mixture of all three compounds. Each compound was loaded at 200 mg.

Experiment 2 studied the addition of 10, 30, and 100 mg of isobutanol to the binary isoamyl alcohol: acetic acid mixture (1:1, 100 mg each). Unbaited traps were included as a control. Site: Debrecen, July 1–October 10, 2003, with 4 blocks of traps.

Experiment 3 checked the addition of 3-methyl-1-pentanol (200 mg) to the ternary isoamyl alcohol + acetic acid mixture + isobutanol (1:1:1, 200 mg each) mixture. Unbaited traps were used as a control. Site: Debrecen, July 1–October 10, 2002, with 4 blocks of traps.

Experiment 4 compared the activity of the ternary isoamyl alcohol + acetic acid + isobutanol mixture (1:1:1, 200 mg each) against phenylacetaldehyde (200 mg). Unbaited traps were used as a control. Site: Túrkeve, Jász-Nagykun-Szolnok county, May 2–September 22, 2003, with 5 blocks of traps.

Experiments 5–6 compared the activities of the ternary isoamyl alcohol + acetic acid + isobutanol mixture (1:1:1, 200 mg each), phenylacetaldehyde (200 mg), or the combination of the two baits inside one trap. Unbaited traps were included in the tests as a control. Both tests were run with 5 blocks of traps, Experiment 5: Csenger, Szabolcs-Szatmár County, May 14–September 20, 2004; Experiment 6: Debrecen, May 11–October 11, 2004.

Experiments 7–8 compared the activity of the ternary isoamyl alcohol + acetic acid + isobutanol female-targeted lure (1:1:1, 200 mg each) with that of the respective sex pheromone baits for *Agrotis segetum* Schiff., *Mamestra brassicae* L. and *M. oleracea* L. Pheromone baits used were commercially available lures (Plant Protection Institute, HAS, Budapest, Hungary) Both tests were run with 3 blocks of traps. Experiment 7: Tiszavasvári, Hajdú-Bihar County, May 13–September 25, 2002; Experiment 8: Hajdúnánás, Hajdú-Bihar County, May 14–June 11, 2002.

Statistics The catches (number of insects caught / trap / inspection) from field trapping tests were transformed by $(x+0.5)^{1/2}$ (Tukey 1949, 1955) and analyzed by ANOVA. When the ANOVA showed a significant effect, treatment means were separated by a Games-Howell Test (Games and Howell 1976; Jaccard et al. 1984). In experiments in which one of the treatments caught no insects, the Bonferroni-Dunn test (Dunn 1961) was used to check whether mean catches in other treatments were significantly different from zero or not. All statistical procedures were conducted using the software packages StatView® v4.01 and SuperANOVA® v1.11 (Abacus Concepts, Inc., Berkeley, CA, USA).

Results

In a preliminary test (Experiment 1), substantial numbers of nine noctuid spp. (data not shown, but see Tables 1 and 2 for typical species caught) were caught in traps containing isoamyl alcohol plus acetic acid or the ternary combination with isobutanol. The combination of isobutanol + acetic acid caught few moths. Thus, further experiments concentrated on the isoamyl alcohol/acetic acid mixture. Percentages of females in the traps ranged from 10 to 100%.

Addition of increasing amounts of isobutanol to the isoamyl alcohol + acetic acid blend (Experiment 2), had little effect on catches of *Agrotis exclamationis* L., *Agrotis segetum* Schiff., *Agrotis crassa* Hbn., *Amathes (Xestia) c-nigrum* L., *Euxoa aquilina* Schiff, *Mamestra brassicae* L., *Mamestra oleracea* L., *Mamestra suasa* Schiff., and *Noctua pronuba* L., relative to traps baited with the binary mixture of isoamyl alcohol + acetic acid (Table 1). However, for *Apatele rumicis* L., *Discestra trifolii* Hufn., and *Euclidia glyphica* L., increasing amounts of isobutanol resulted in increased catches (Table 1). Traps baited with the binary mixture of isoamyl alcohol + acetic acid caught significantly more moths for the majority of species than did unbaited traps (Table 1). Again, sizeable percentages of the catches were females, ranging from 18% (for *A. exclamationis*) to 58% (for *M. brassicae*).

The addition of 3-methyl-1-pentanol to the ternary isoamyl alcohol + acetic acid + isobutanol mixture (Experiment 3), had no effect on trap catches of *A. exclamationis, A. segetum, Am. c-nigrum, D. trifolii, M. brassicae, M. oleracea, Mythimna albipuncta* (Denis & Schiff) *Mythimna. l-album* L., *N. pronuba*, or *Trachea atriplicis* L., but resulted in a decreased catch of *Dipterygia scabriuscula* L, relative to catches in traps baited with the ternary blend (Table 2). Traps with the ternary mixture caught significantly more moths of all species than did unbaited traps. The percentages of female moths caught in these traps ranged from 39% (*A. segetum*) to 75% (*M. oleracea*).

Traps baited with the ternary isoamyl alcohol + acetic acid + isobutanol mixture caught significantly more *A. exclamationis, A. segetum, Amphipyra pyramidea* L., *Apatele rumicis* L., *Am. c-nigrum, M. brassicae, M. oleracea*, and *M. suasa* moths than did traps baited with phenylactaldehyde or unbaited controls (Experiment 4**;** Fig. 1). In contrast, traps baited with phenylacetaldehyde caught more moths of *Autographa gamma* L., *Helicoverpa*

Table 1 Mean catches of noctuid moths in field tests in traps baited with mixtures of isoamyl alcohol, acetic acid, and differing amounts of isobutanol, and unbaited (**Experiment 2**). Means with same letter within a given species are not significantly different (*P*=0.05; ANOVA, followed by Games-Howell or Bonferroni-Dunn *post-hoc*)

armigera Hn., *Macdunnoughia confusa* Steph., and *Meristris trigrammica* Hufn. than did traps baited with the ternary mixture or the unbaited controls. *E. glyphica* moths were caught in similar numbers in traps baited with either phenylacetaldehyde or the ternary blend, but catches were significantly higher than those in unbaited traps only for traps baited with 3 dispensers of the ternary mixture. Traps with 3 dispensers of the ternary mixture showed a general tendency of catching more than those with a single dispenser for all species, but the difference was significant only for *A. exclamationis* (Fig. 1). The effect of increased catches with increased number of dispensers was similar for traps baited with phenylacetaldehyde, with only a significant difference for *M. confusa* catches. Female percentages in traps with the ternary mixture ranged from 45% (*E. exclamationis*) to 65% (*M. brassicae*), while in those with phenylacetaldehyde from 11% (*Me. trigrammica*) to 57% (*H. armigera*) (Fig. 1).

In Experiments 5 and 6, traps with both the ternary mixture and phenylacetaldehyde caught significantly fewer moths of *A. exclamationis, A. segetum, Am. c-nigrum, M. brassicae, M. oleracea*, and *M. suasa* than did those baited with only the ternary mixture (Fig. 2). Traps with both phenylacetaldehyde and the ternary mixture also tended to

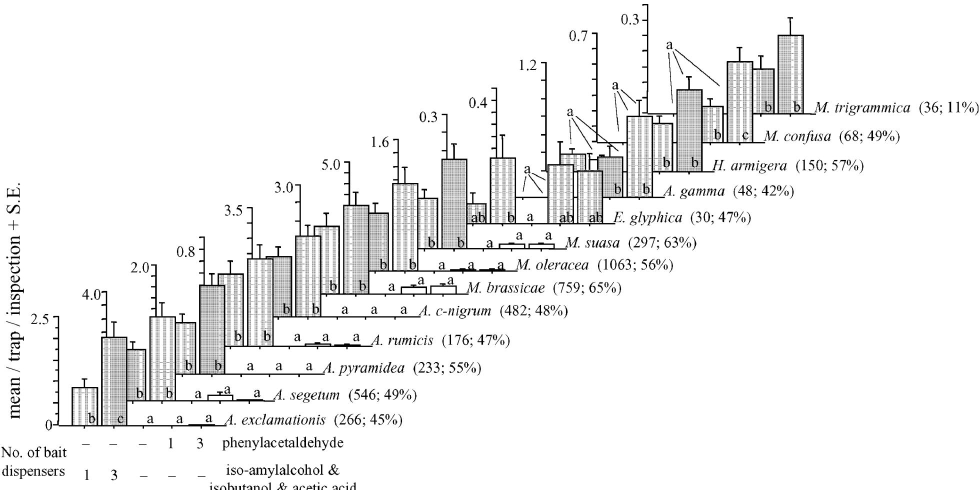

Fig. 1 Mean catches of various noctuid species in field tests in traps baited with one or three dispensers of, a ternary isoamyl alcohol + acetic acid + isobutanol lure, a phenylacetaldehyde lure, or unbaited (Experiment 4). Columns with the same letter within a given species are not significantly different (P<0.05; ANOVA, followed by Games-Howell or Bonferroni-Dunn *post-hoc* tests). Numbers in parentheses after the species show total number of moths caught and % of females in the catch. Species caught were: *Agrotis exclamationis, A. segetum, Amathes c-nigrum, Amphipyra pyramidea, Apatele rumicis, Autographa gamma, Euclidia glyphica, Heliothis armigera, Mamestra brassicae, M. oleracea, M. suasa, Meristris trigrammica*, and *Macdunnoughia confusa*. L

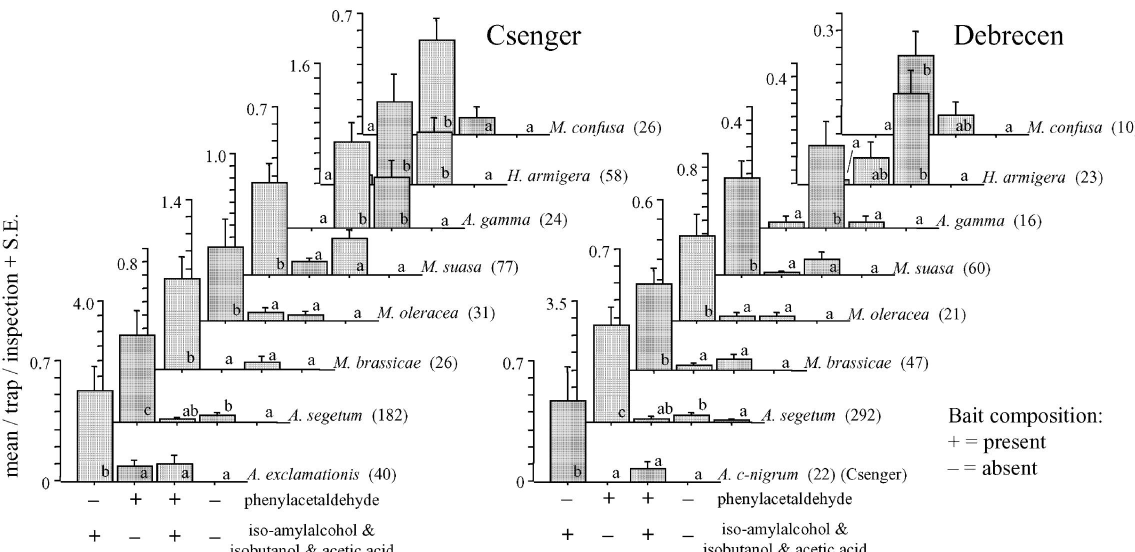

Fig. 2 Mean catches of noctuids in field tests in traps baited with a ternary isoamyl alcohol + acetic acid + isobutanol lure, a phenylacetaldehyde lure, the two types of lures together, or unbaited, at Csenger (Experiment 5) and Debrecen (Experiment 6). Columns with same letter within a given species are not not significantly different ($P<0.05$; ANOVA, followed by Games-Howell or Bonferroni-Dunn *post-hoc* tests). Numbers in parentheses after the species show total number of moths caught. Species caught were: *Agrotis exclamationis, A. segetum*, *Amathes c-nigrum, Autographa gamma*, *Heliothis armigera*, *Mamestra brassicae, M. oleracea*, *M. suasa,* and *Macdunnoughia confusa*

catch fewer moths of *Au. gamma* and *M. confusa* than did traps with phenylacetaldehyde alone, but the difference was significant in only one out of two tests for each species (respectively, Debrecen and Csenger). Traps with phenylacetaldehyde alone or with both types of baits caught similar numbers of *H. armigera*.

In Experiments 7 and 8, the respective sex pheromone-baited traps caught significantly more males of *A. segetum, M. brassicae*, and *M. oleracea* (although the pheromone data were lost for this species in Experiment 7) than did traps baited with the ternary blend of isoamyl-alcohol + acetic acid + isobutanol (which caught ca 5-7%, 25–26%, and 20% of the total amount in the pheromone traps for the respective species). Traps baited with the ternary mixture generally caught more moths of both sexes than did unbaited traps (Table 3).

Discussion

In the present experiments, the blend of isoamyl alcohol, acetic acid, and isobutanol was attractive to male and female moths of 16 species of European noctuids. Previously, isoamyl alcohol, or 3-methyl-1-pentanol, with acetic acid had been shown to attract a North American population of *Am. c-nigrum* (Landolt 2000; Landolt and Alfaro 2001). In this study, we confirmed the attraction of a European population of *Am. c-nigrum* to isoamyl alcohol plus acetic acid. Isoamyl alcohol and acetic acid in a binary mixture was attractive to 13 of the noctuid species, while the presence of isobutanol was important for catching the three additional spp. The addition of 3-methyl-1-pentanol to this ternary mixture did not increase captures of any of these moths. Importantly, the ternary blend attracted a significant proportion of female moths of all the species.

In a study of the species of North American Lepidoptera captured in traps baited with isoamyl alcohol plus acetic acid, Landolt and Hammond (2001) recorded specimens belonging to ca 60 species, 90% of which were Noctuidae. Combined with our European results, this shows that isoamyl alcohol plus acetic acid are probably widely exploited as attractants to food in Noctuidae. The presence of acetic acid and short-chain alcohols generally is attributed to a fermentation process, and may indicate the presence of a carbohydrate source for feeding (Landolt et al. 1999, 2007; Landolt 2000).

We also demonstrated attraction of four noctuid species to phenylacetaldehyde. Phenylacetaldehyde is a floral scent constituent of many flowers (Knudsen et al. 1993), and is known as an attractant of several species of Lepidoptera (e.g., Creighton et al. 1973; Cantelo and Jacobson 1979). Our study confirmed the previously reported attraction of *H. armigera* to this compound (Pawar et al. 1983) or blends containing this compound (Bruce and Cork 2001; Bruce et al. 2002). To our knowledge, the attraction of the other species (*Me. trigrammica*, *M. confusa*, *Au. gamma*) to phenylacetaldehyde has not been reported previously, although the closely related plusiines, *Autographa californica* Speyer and *Trichoplusia ni* Hbn., respond to lures containing this compound (Landolt et al. 2001, 2006).

Table 3 Mean catches of *Agrotis segetum*, *Mamestra brassicae,* and *Mamestra oleracea* in field tests in traps baited with a ternary isoamyl alcohol + acetic acid + isobutanol lure, or the respective pheromone lures (**Experiments 5–6**). Means with same letter within a given species are not significantly different (P=0.05; ANOVA, followed by Games-Howell or Bonferroni-Dunn *post-hoc*)

not av. not available, as several of the traps from this treatment were missing

The species caught in greatest numbers in the study of Landolt and Hammond (2001) in North America belonged to the subfamilies Amphipyrinae, Hadeninae, and Noctuinae. Similarly, the majority of species caught in our study in traps baited with isoamyl alcohol-based lures also belonged to these subfamilies. In contrast, the moths caught in traps baited with phenylacetaldehyde belonged to the subfamilies Plusiinae (2 spp.), Melicleptriinae (1 sp.) and Amphipyrinae (1 sp.). The different subfamily distribution of species that respond to isoamyl alcohol- and phenylacetaldehyde-based lures may reflect general differences in feeding habits of the respective noctuids. It has long been known to moth collectors that *Autographa* (Plusiinae) and *Helicoverpa* (Melicleptriinae) spp. frequent and feed on flowers, while *Agrotis* (Noctuinae) or *Mamestra* (Hadeninae) spp. do not (e.g., Abafi-Aigner 1907; Balachowsky 1972). Interestingly, we found traps containing both isoamyl alcohol- and phenylacetaldehyde-based baits tended to catch fewer moths than traps with the respective single baits. The reason for this negative interactive effect of the two types of compounds is unknown.

Among the species captured in the present study, *Au. gamma*, *A. segetum, A. crassa, A. exclamationis, Am. c-nigrum, D. trifolii, E. aquilina, H. armigera, M. brassicae, M. oleracea, M. suasa,* and *N. pronuba* are regarded as agricultural pests, with, *Au. gamma, A. segetum, H. armigera, M. brassicae,* and *M. oleracea* among the most important economic noctuid pests in Europe (e.g., Balachowsky 1972; Mészáros 1993). In experiments (7 and 8) that compared the isoamyl alcohol-based lures against pheromone lures, relatively high percentages (20–25% of catches in the respective pheromone traps) of *M. brassicae* and *M. oleracea* moths were caught in traps baited with isoamyl alcohol-based lures. Therefore, for these species, especially with further optimization of lures, these isoamyl alcohol-based attractants could become a useful tool. For instance, they could be used to attract both females and males in a lure and kill strategy, thus lowering both the adult moth population as well as the potential offspring of the female. A previous study that used phenylacetaldehyde and a sucrose-methomyl toxicant yielded promising results with mortality of 61% (females) and 44% (males) of released *T. ni* moths (Landolt et al. 1991). However, for *A. segetum* trapped in Experiments 7 and 8, very low percentages of moths (only 5–7% of the numbers in pheromone traps) were caught in traps baited with the isoamyl alcohol-based lures, suggesting that these lures may not be suitable for practical usage for this species.

In summary, isoamyl alcohol-based lures show promise as male and female noctuid moth attractants. A characteristic of the lures tested in this present study is that they attract a number of species, and thus are more general attractants than species-specific sex pheromones. Use of such a single lure would allow several important pests to be trapped in an agricultural system, thereby minimizing monitoring efforts. However, this lack of specificity also can be a disadvantage in that non-target, or even rare and endangered species of moths could be caught. The advantages and disadvantages of the use of such a method should, therefore, be evaluated according to the actual scenario.

Acknowledgements The present research was partially supported by grant NKFP 4/012/2004 OM of the Hungarian Ministry of Education and OTKA grant K 81494. Thanks are due to G Szöcs and Zs. Kárpati for useful discussions and technical assistance in the initial phases of this project.

Abstract The fruit fly, *Drosophila melanogaster* Meigen (Diptera: Drosophilidae), is a model for how animals sense, discriminate, and respond to chemical signals. However, with *D. melanogaster* our knowledge of the behavioral activity of olfactory receptor ligands has relied largely on close-range attraction, rather than on long-range orientation behavior. We developed a flight assay to relate chemosensory perception to behavior. Headspace volatiles from vinegar attracted 62% of assayed flies during a 15-min experimental period. Flies responded irrespective of age, sex, and mating state, provided they had been starved. To identify behaviorally relevant chemicals from vinegar, we compared the responses to vinegar and synthetic chemicals. Stimuli were applied by a piezoelectric sprayer at known and constant release rates. Re-vaporized methanol extracts of Super Q-trapped vinegar volatiles attracted as many flies as vinegar. The main volatile component of vinegar, acetic acid, elicited significant attraction as a single compound. Two other vinegar volatiles, 2-phenyl ethanol and acetoin, produced a synergistic effect when added to acetic acid. Geosmin, a microbiological off-flavor, diminished attraction to vinegar. This wind tunnel assay based on a conspicuous and unambiguous behavioral response provides the necessary resolution for the investigation of physiologically and ecologically relevant odors and will become an essential tool for the functional analysis of the *D. melanogaster* olfactory system.

Key Words Acetic acid · *Drosophila melanogaster* · Flight behavior · Fruit fly · Geosmin · Long-range attraction · Olfactory system · Vinegar fly · Wind tunnel

Introduction

What triggers take-off and upwind flight behavior in an insect? Two types of flight initiation are distinguished in the fruit fly, *Drosophila melanogaster* Meigen (Diptera: Drosophilidae): A fast escape in response to threatening visual stimuli and a slow voluntary take-off based on the assessment of a stimulus that reflects the internal physiological state of the animal (Trimarchi and Schneiderman 1995; Allen et al. 2006; Card and Dickinson 2008). Olfactory cues elicit premeditated flights. Following take-off, the odor signal mediates upwind oriented flight and guides the insect towards the source (Budick and Dickinson 2006; Chow and Frye 2008).

The molecular, genetic, and neurosensory knowledge available from *D. melanogaster* provides the most complete picture of an olfactory system, from odorant receptor genes to neuroanatomy and central processing of the olfactory input (Couto et al. 2005; Benton et al. 2007; Jefferis et al. 2007; Dickson 2008). A current challenge is to expand further our view to include also odor-mediated behavior, which would complete the entire integration pathway from ligand-binding to motor output. A distinct behavior, such as the voluntary initiation of odor-mediated flight, is an opportunity to investigate how *D. melanogaster* processes

chemical signals that evoke the behavior of flying into the scented wind.

Towards this goal, we need to improve our knowledge of the behavioral effect of olfactory receptor ligands in *D. melanogaster*. This relies largely on screening of compounds by extracellular recordings and imaging of the input of olfactory receptor neurons into the antennal lobe. The response of *D. melanogaster* to odors is usually studied in trapping or oviposition assays, using small containers, in spite of common long-range orientation to odor sources in nature. Small dimensions, the lack of an air-flow, and long test duration have led to an elevated response to suboptimal stimuli and have limited the discriminative power and sensitivity of such experiments (Vosshall and Stocker 2007). In addition, the chemicals used as olfactory stimuli in current molecular and neurophysiological studies of the *D. melanogaster* olfactory system do not necessarily match the stimuli used by flies for location of food sources and oviposition sites.

Wind tunnels have been employed to investigate odor-mediated upwind flight behavior in *D. melanogaster* (Budick and Dickinson 2006), but have, with the exception of the pheromone compound *cis*-vaccenyl acetate (Bartelt et al. 1985), not been used to identify behavior-modifying chemicals. We report the use of a wind tunnel to study long-range attraction in relation to odor quality and the internal physiological state of the flies. After measuring fly attraction to vinegar and some of its key chemical components, we investigated the effect of fly age, sex, mating state, and starvation on flight response. The results demonstrate that a flight tunnel is a sensitive instrument for the analysis of odor-mediated behavior in *D. melanogaster*.

Methods and Materials

Insects An Oregon R strain of the fruit fly, *D. melanogaster*, was reared on a standard sugar-yeast-cornmeal diet at room temperature (19–22°C) and under a 8:16 hr L:D photoperiod. Newly eclosed flies were removed from the larval diet daily. Adult flies either were transferred and kept in 30-ml plexiglass vials on fresh diet, or were starved up to 3 d on a humidified piece of cotton wool. Thus, the adults were exposed to the larval diet for a limited period (several hours) after eclosion. For tests with mated males or females, newly emerged test flies were kept together with an excess ratio (ca. 1.5:1) of older virgin flies (ca. 1 wk old) of the opposite sex. Flies were anesthetized with CO_2, and the sexes were separated 24 hr before the experiment. For tests with unmated insects, the sexes of newly emerged flies were separated up to 3 hr after eclosion. Exposure to CO_2 did not exceed 5 min, and preparatory control experiments (data not shown) as well as our subsequent flight assays (e.g., Fig. 2b) did not indicate an adverse effect of anesthetization on fly behavior. The flies were tested during the last 3 hr of the photophase.

Headspace Collection, Chemical Analysis, and Chemicals Volatiles were collected from ca. 70 ml balsamic vinegar (Aceto balsamico di Modena, Urtekram, Denmark, aged at least 3 yr) by blowing charcoal-filtered air (0.9 l/min) with an aquarium pump through the vinegar in a 1-l gas wash bottle, exiting through a Super Q trap at the gas outlet. The volatile trap was a 4×40-mm glass tube containing 35 mg Super Q (80/100 mesh; Alltech, Deerfield, IL, USA) held between glass wool plugs (Tasin et al. 2006). Before use, the trap was rinsed with 3 ml of methanol (redistilled >99.9% purity, Merck, Darmstadt, Germany) and *n*-hexane (redistilled >99.9% purity; Labscan, Malmö, Sweden). After 30 min of collecting vinegar headspace volaitles, compounds were eluted with 0.3 ml of redistilled methanol. These samples were analyzed on a gas chromatograph coupled to a mass spectrometer (GC-MS; 6890 GC and 5,975 MS, Agilent Technologies Inc., Santa Clara, CA, USA). The gas chromatograph was equipped with a DB-Wax or an HP-5MS fused silica capillary column (30 m×0.25 mm× 0.25 µm film thickness; J&W Scientific, Folsom, CA, USA or Agilent Technologies). The amounts of acetic acid, 2-phenyl ethanol, acetoin, and ethyl acetate in the samples were quantified in comparison with synthetic standards (Sigma-Aldrich, Stockholm, Sweden). Ethyl acetate and ethanol were quantified in a headspace collection eluted with pentane. The methanol Super Q extracts were re-vaporized in the wind tunnel by the piezoelectric sprayer (see below).

Wind Tunnel Most of our flight assays were conducted in a wind tunnel, which was built of glass and had a flight section of 30×30×100 cm. The airstream in the tunnel (0.25 m/s) was produced by a fan (Fischbach GmbH, Neunkirchen, Germany), which blew air into the tunnel through an array of four activated charcoal cylinders (14.5 cm diam.×32.5 cm long; Camfil, Trosa, Sweden). A 30×30×30 cm compartment at the upwind end of the tunnel held the piezoelectric sprayer (see below) and was separated from the flight section by a polyamide mesh (pore size 0.5×0.5 mm; Sintab, Oxie, Sweden). The downwind end of the tunnel was closed by the same mesh. The tunnel was lit diffusely from above, and light intensity inside the wind tunnel was 13 lux. Temperature ranged from 19°C to 22°C; relative humidity from 35% to 50%.

The speed of the airstream was selected based on preliminary tests of the response of the flies. Significantly more flies (2-d-old, starved for 2 d) flew to the standard stimulus vinegar at 0.25 m/s (62±10% attraction) and 0.15 m/s (54±9% attraction) than at a lower speed of 0.05 m/s (40±11%; ANOVA, $F=6.20$, $df=14$, $P<0.05$).

Odor Delivery Charcoal-filtered air was blown through the wash bottle with balsamic vinegar (similar as described above but without an air filter) or distilled water (MilliQ, Millipore, Bedford, MA, USA), into a teflon tube (0.5 cm diam.), leading to an attached Pasteur pipette. The pipette was facing downward into a wide-mouth 225-ml glass jar (38 mm diam.). The air stream containing the stimulus (e.g., volatiles of authentic vinegar or distilled water) emanated as a wide plume from the opening of the jar, in the center of the upwind end of the tunnel. The shape of the odor plume was verified with titanium oxide. Flies were scored when landing at the tip of the pipette, at the top edge of the jar, or inside the jar. All glassware was heated to 375°C for 8 hr before use.

Headspace samples and solutions of synthetic compounds were released from a piezoelectric sprayer. A microinjection pump (CMA Microdialysis AB, Solna, Sweden) delivered the solutions at a rate of 10 µl/min from a 1-ml syringe, through teflon tubing, to a 25-µl glass capillary tube with an elongated tip. A piezo-ceramic disc (Valvo, Hamburg, Germany) vibrated the glass capillary at ca. 200 kHz, and thus produced an aerosol that evaporated from the tip of the capillary (El-Sayed et al. 1999). The capillary was placed at the vertical midline, 20 cm from the floor, at the upwind end of the tunnel. The dimension of a hexane plume was measured at the downwind end of the tunnel with a photoionization detector (ppbRAE Plus, Scantec, Sävedalen, Sweden). The plume was approximately in the center of the tunnel, and its cross-section was oval, with a vertical axis of ca. 12 cm and a horizontal axis of ca. 7 cm. The piezoelectric sprayer ensured application of odor solutions at a constant rate and known chemical purity. A glass cylinder (60×95 mm diam.) covered with a metal mesh (pore size 2 mm) shielded the vibrating capillary from flies and mechanical damage. When the sprayer was used to deliver the stimuli for the flight assay, flies were scored when landing at the metal mesh.

Initially, four solvents (Table 1) were assayed in the wind tunnel to help to choose an appropriate solvent that would be efficient to elute and dissolve volatile organic compounds without attracting fruit flies by itself. Distilled water (MilliQ) and the redistilled organic solvents methanol, hexane, and heptane (redistilled >99.9% purity, Labscan) were delivered at 10 µl/min (Table 1). Flies were not attracted to the non-polar solvents hexane and heptane, but these were not suitable for dissolving acetic acid, which is the major headspace component of vinegar. Methanol was a suitable solvent for acetic acid and other vinegar compounds, and was used in subsequent tests.

Table 1 Upwind flight and landing of *Drosophila melanogaster* in a wind tunnel in response to solvents delivered from a piezoelectric sprayer

Solvent (10µl/min)	Flies landing at source[a] (% ±SD)[b]
Water	6±9 a
Methanol	4±2 a
Hexane	0 a
Heptane	0 a

[a] Flies were 2-d-old and starved

[b] Percentages (N=5 batches of 20 flies) followed by different letters indicate significant differences (Tukey's test following ANOVA; F=2.12, df=19, P=0.138)

Trapping Study of Diel Flight Period in the Laboratory A trap was made of a 225-ml capped glass jar filled with 25 ml of a 0.1% Triton X-100 (Tamro Medlab AB, Mölndal, Sweden) solution in distilled water. It contained a 30-ml plastic vial that was filled with the bait, balsamic vinegar (the same as used in the wind tunnel assay and chemical analyses) or a macerated banana-water mixture. Distilled water was the control. A plastic lid holding a cut pipette tip allowed the odor to emanate and provided a trap entry for the flies. Traps were placed in plastic trays filled with water. Five replicates of three different trap lures were randomly distributed in the laboratory. Seventy 1- to 3-d-old flies were released into the wind tunnel room (N=3), 4 hr after onset of the photophase, under a 8:16 hr L:D photoperiod. The traps were checked every 2 hr during the photoperiod.

Test Protocol and Statistical Analyses For wind tunnel assays, batches of 18–24 flies were allowed to walk or fly into a 225-ml glass jar (12 cm high) that was then closed with a screw cap and covered with tin foil. The jar was exposed to the odor plume at the downwind end of the tunnel. A plug closing a 10-mm hole in the middle of the screw cap was removed to allow the flies to exit. The test period was 15 min. Variances of the mean attraction (N=5) were checked for homogeneity (F test or Bartlett's test) and analyzed statistically by a t-test or Tukey's test following an analysis of variance (ANOVA). For the trapping study in the laboratory differences between the two baits and differences between sexes were analyzed by a t-test.

Results

Attraction to Vinegar and Synthetic Vinegar Compounds in the Wind Tunnel Starved, 2-d-old flies were strongly attracted to volatiles of authentic vinegar emanating from the wash bottle (50% of the test flies reached the source after 9.0±2.8 min, and overall attraction was 62±10% within the 15-min experimental period, Fig. 1c). The

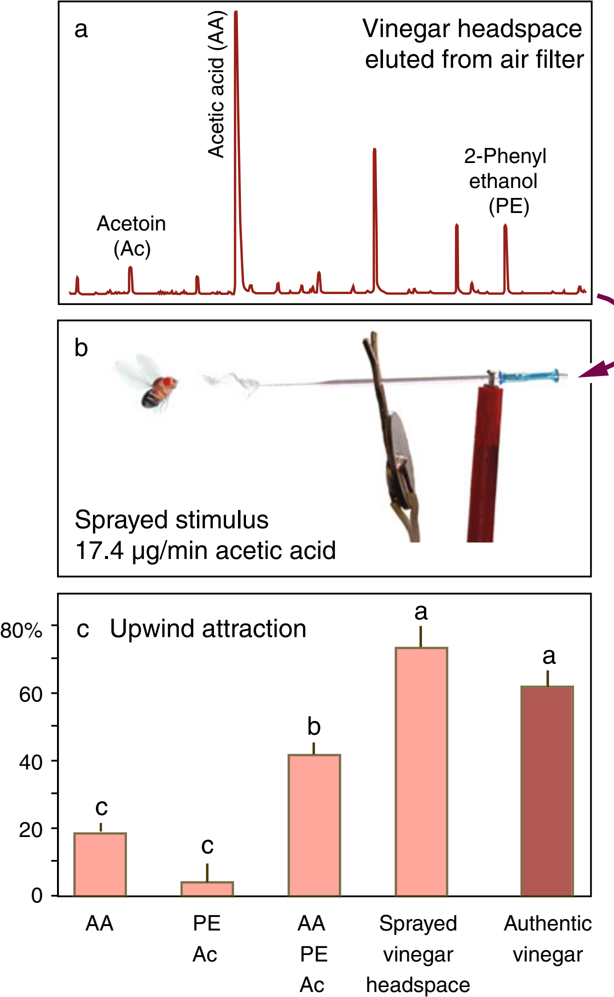

Fig. 1 Attraction of 2-d-old starved *Drosophila melanogaster* adults in a wind tunnel to GC-MS analyzed (**a**) and defined odor samples that were released from a glass capillary attached to a piezo-ceramic disk (piezoelectric sprayer) (**b**). The release rates of acetic acid (AA), the main vinegar compound (17.4 µg/min), ethyl acetate (0.103 µg/min), acetoin (Ac; 0.58 µg/min), and 2-phenyl ethanol (PE; 1.22 µg/min) in the sprayed treatment and in the synthetic blends mimicked the release rates from authentic vinegar. Flies were attracted to sprayed synthetic vinegar compounds, sprayed methanol extract of Super Q-trapped vinegar volatiles, and to authentic vinegar from a wash bottle (**c**). *Different lowercase letters* in (**c**) indicate significant differences according to ANOVA followed by Tukey's test (N=5 batches of 20 flies; F=50.61; df=24, P<0.001; *error bars* show standard deviation of the mean)

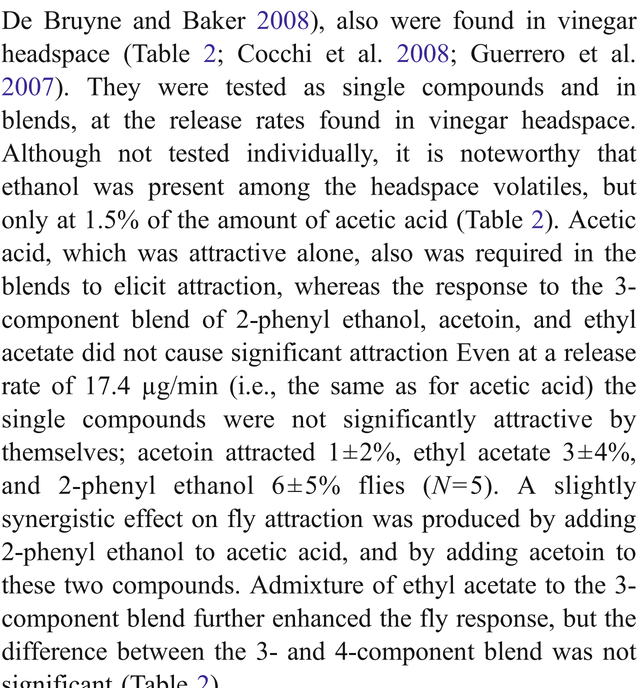
quantitative assessment of vinegar headspace volatiles revealed that acetic acid was the most abundant compound (Fig. 1a). It was released from the wash bottle at 17.4 µg/min (GC-MS). Re-vaporized (sprayed) methanol extract of vinegar volatiles collected on Super Q, releasing acetic acid at the same rate, attracted 74 ±14% flies (Fig. 1c).

Three known ligands of *D. melanogaster* olfactory receptor neurons, acetoin, ethyl acetate, and 2-phenyl ethanol (Stensmyr et al. 2003; Hallem and Carlson 2006; De Bruyne and Baker 2008), also were found in vinegar headspace (Table 2; Cocchi et al. 2008; Guerrero et al. 2007). They were tested as single compounds and in blends, at the release rates found in vinegar headspace. Although not tested individually, it is noteworthy that ethanol was present among the headspace volatiles, but only at 1.5% of the amount of acetic acid (Table 2). Acetic acid, which was attractive alone, also was required in the blends to elicit attraction, whereas the response to the 3-component blend of 2-phenyl ethanol, acetoin, and ethyl acetate did not cause significant attraction Even at a release rate of 17.4 µg/min (i.e., the same as for acetic acid) the single compounds were not significantly attractive by themselves; acetoin attracted 1±2%, ethyl acetate 3±4%, and 2-phenyl ethanol 6±5% flies (N=5). A slightly synergistic effect on fly attraction was produced by adding 2-phenyl ethanol to acetic acid, and by adding acetoin to these two compounds. Admixture of ethyl acetate to the 3-component blend further enhanced the fly response, but the difference between the 3- and 4-component blend was not significant (Table 2).



Threshold Concentration of Orientation to Vinegar in the Wind Tunnel A dose-response test showed that re-vaporized methanol extracts of Super Q-trapped vinegar volatiles elicited significant attraction at release rates ranging over three orders of magnitude (Table 3). The release rate of acetic acid from vinegar was 17.4 µg/min as measured from Super Q traps, but flies were still attracted to a 1,000-fold diluted headspace collection that released as little as 17.4 ng/min acetic acid. This agrees with the significant attraction to a 1,000-fold dilution of vinegar in water. In contrast, the response to a 1:10 dilution of acetic acid alone was not different from the response to the blank, thus corroborating the synergistic effect of the other vinegar compounds (Tables 2 and 3).

Antagonistic Effect of an Off-flavor on Attraction to Vinegar in the Wind Tunnel During preliminary trapping tests with the banana–water mixture (see below), we regularly observed a decrease in attraction when the bait was growing moldy. Geosmin, an off-flavor produced by mold fungi, had an antagonistic effect on attraction to vinegar. Methanol extracts of trapped vinegar volatiles containing geosmin in a ratio of 1:10 (w/w) relative to acetic acid, sprayed at release rates of 0.174 and 0.0174 µg/min acetic acid, attracted fewer flies (18±12% and 17±10%, respectively) than trapped vinegar volatiles without geosmin (51 and 42% attraction, respectively; Table 3) (t-test, t=3.30 and 3.28, df=8, P<0.05).

Effect of Age, Starvation, Sex, and Mating Status on Response of D. melanogaster in the Wind Tunnel The

[a] Percentages in bold-faced font (N=5 batches of 20 flies) are significantly different from the blank (t-test; P<0.005). Sprayed methanol extract of Super Q-trapped vinegar volatiles were diluted further with methanol to obtain known amounts of acetic acid. Bubbled vinegar from a wash bottle was diluted in water; standard vinegar headspace contained acetic acid at 17.4 µg/min

[b] *nt* not tested

response of fed flies to authentic vinegar, disregarding age, was not significantly different from a blank test with water (Fig. 2a). Starvation for one day significantly increased the rate of upwind attraction of 1-d-old flies to the vinegar. Attraction of older, 2- to 6-d-old flies peaked when they were deprived of food for 2 d. During the 24 hr period after eclosion, few flies were attracted (1.6%, data not shown). With flies of 1 d and older, age did not have a significant effect on upwind attraction (Fig. 2a). These tests were done with mixed batches of females and males, of unknown mating status. In order to verify a possible effect of sex and mating, virgin or mated flies were separated by sex either immediately after eclosion (virgin test flies) or 1 d before the experiment (mated test flies). Neither sex nor mating status had a significant effect on attraction (Tukey's test following ANOVA, F=1.54, df=24, P=0.23) (Fig. 2b).

Trapping Study of Diel Flight Period in the Laboratory After *D. melanogaster* were released from their food vials, traps baited with vinegar or banana–water mixture captured 15% of the flies during the remaining 4 hr of the photoperiod. On the following day, 39% and 62% of the remaining flies were captured, during the first and second half of the photophase, respectively. Significantly more flies were attracted to vinegar (76% and 72% of the trapped males and females) than to the banana–water mixture (t-test, t=3.72, df=10, P<0.005). The ratio between trapped males and females was not different (t-test, t=1.71, df=4, P=0.16). Most flies were trapped during the photophase, only 6% of the flies were caught during the scotophase.

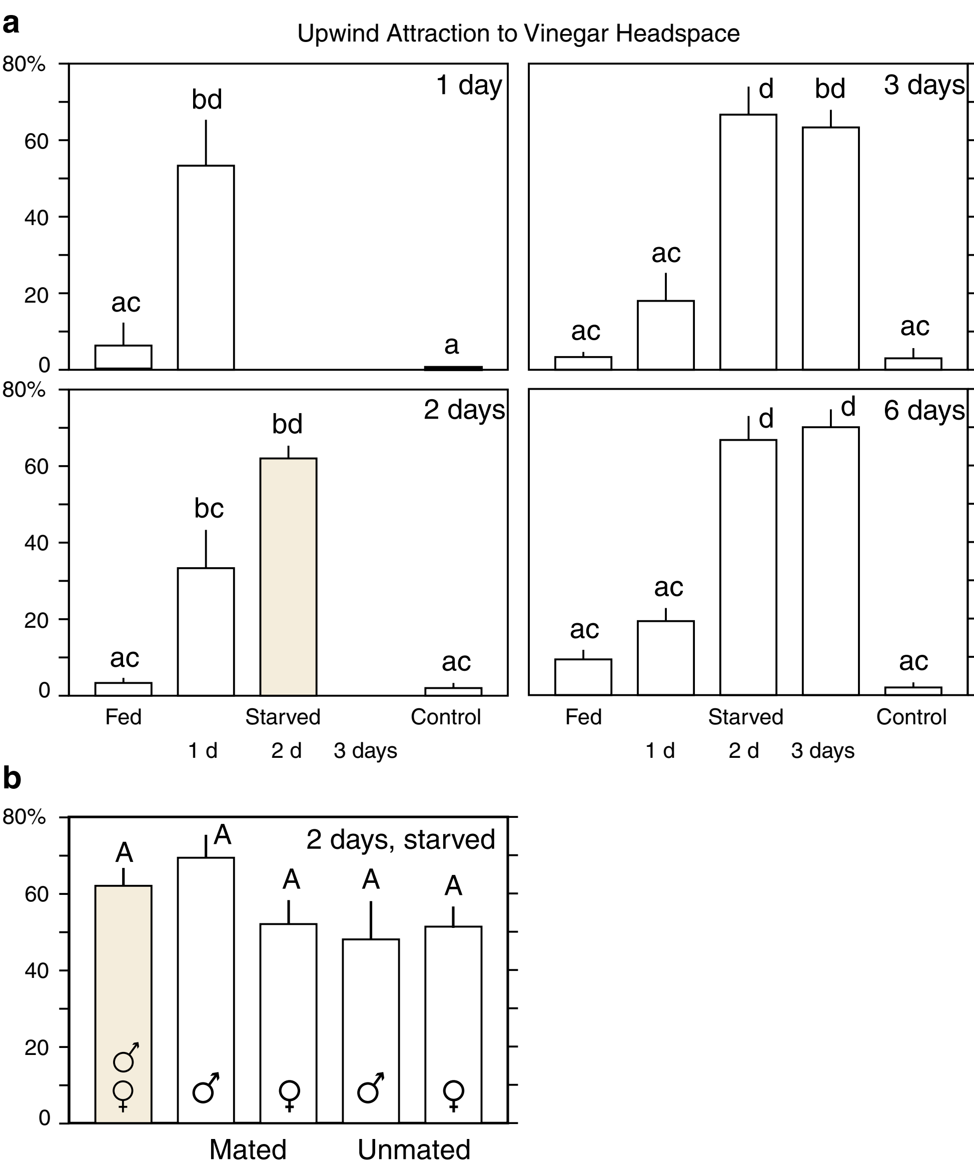

Fig. 2 Attraction of *Drosophila melanogaster* adults in a wind tunnel to vinegar headspace volatiles. **a** Mean percentage of 18–24 flies (N=5) flying upwind and landing at the outlet of an air stream passing a wash bottle with vinegar. Flies, which were tested between 1 d and 6 d after eclosion, were fed, or starved for 1–3 d. For each age, water was tested as control on flies of similar starvation time as those flies showing the highest attraction to vinegar. Tests were done with a mixture of males and females of unknown mating status. The shaded bar indicates conditions chosen as standard for the other wind tunnel experiments of the study. Bars with different letters are significantly different (ANOVA followed by Tukey's test; F=20.62; df=84, P<0.05; error bars show standard deviation of the mean). **b** Attraction of 2-d-old, 2-d-starved males and females, sexes unseparated (shaded as shown in panel **a**), and sexes separated before and after mating (ANOVA followed by Tukey's test; F=1.54, df=24, P=0.23)

Discussion

Flies and other insects rely on odors to detect food and mates. Perception of odors has been studied thoroughly in *D. melanogaster*, particularly by extracellular recordings from olfactory neurons (De Bruyne et al. 2001; Stensmyr et al. 2003; Hallem and Carlson 2006). These neurons generate excitation patterns that are transmitted to higher brain centers where a behavioral response is created (Jefferis et al. 2007; Schlief and Wilson 2007; Shang et al. 2007; Root et al. 2008). A current challenge with *D. melanogaster* is to relate chemosensory perception and coding to the natural behavior of long-range attraction to odors.

Airborne odor typically is encountered in intermittent bursts (Baker et al. 1998), and the generation of an appropriate behavioral response requires instantaneous assessment of its quality. Since long-range displacement costs energy and involves risks, it is vital to evaluate odor quality downwind from the source. Wind tunnel assays monitor the conspicuous outcome of this sensory evaluation, i.e., upwind flight orientation behavior, which is elicited within short time intervals after perception of relevant signals. We have established a sensitive and discriminative flight tunnel assay that facilitates the identification of behaviorally relevant odors, thus providing a link between the neurophysiology, behavioral physiology, and chemical ecology of *D. melanogaster.*

Balsamic vinegar is a robust stimulus for studying the fly's odor-mediated upwind flight attraction. Following chemical analysis, we applied the wind tunnel assay to reduce the chemical complexity of the vinegar headspace (Zeppa et al. 2002; Guerrero et al. 2007; Cocchi et al. 2008) to a simple blend of volatiles that produced nearly the same

attractive response as vinegar. Acetic acid, the main component of vinegar headspace, attracted flies as a single compound. Adding 2-phenyl ethanol and acetoin had a synergistic effect (Fig. 1, Table 2). This agrees with recent findings that the complex odor of apple cider vinegar activates several olfactory glomeruli in the antennal lobe; only two glomeruli (and consequently few odor components) are required for close-range attraction in *D. melanogaster* (Semmelhack and Wang 2009).

Overripe mango, which is another powerful attractant for *D. melanogaster*, also releases acetic acid and 2-phenyl ethanol. A blend of these two compounds with ethanol is an attractive trap lure for *D. melanogaster* (Zhu et al. 2003), and addition of ethanol to the 3- and 4-component synthetic blends that we tested in our study might complement the attraction found for the complete vinegar bouquet. Thus, the role of ethanol in the long-range attractant for *D. melanogaster* merits additional study.

Attraction to acetic acid is not unique to *D. melanogaster*. Noctuid moths attracted to fermenting sweet baits also respond to acetic acid (Landolt 2000). 2-Phenyl ethanol is, like acetic acid, a yeast product; it is also found in insect-pollinated plants and known to attract many insect species from different taxa (Andersson et al. 2002; El-Sayed 2009).

Sensitivity to acetic acid is expressed in *D. melanogaster* adults and larvae (Hoffmann and Parsons 1984; Cobb 1999; Ruebenbauer et al. 2008; Joseph et al. 2009), supporting the idea that this compound is of ecological relevance. Acetic acid probably serves as a cue for the presence of fermenting fruit and other substrates used as food or oviposition sites. Interestingly, Joseph et al. (2009) recently demonstrated gustatory-mediated attraction vs. olfactory-mediated positional repulsion in response to egg-laying substrates containing acetic acid, under close-range conditions. Under long-range conditions, acetic acid plays an essential role in upwind flight attraction (Table 2), which we assume is relayed through olfactory neurons. Despite its strong behavioral effect, it is yet unclear how *D. melanogaster* perceives and processes acetic acid. In comparison, olfactory neurons expressing receptors for 2-phenyl ethanol, acetoin, and ethyl acetate, and their associated glomeruli in the antennal lobe are already known (Fishilevich and Vosshall 2005; Hallem and Carlson 2006; De Bruyne and Baker 2008; Asahina et al. 2009).

Semmelhack and Wang (2009) showed that activity in the glomeruli DM1 and VA2 is associated with close-range attraction of *D. melanogaster* to vinegar. The vinegar compounds ethyl acetate and acetoin are the strongest known stimuli for these two glomeruli (De Bruyne and Baker 2008). Ethyl acetate and acetoin may be sufficient for close range attraction and oviposition (Ruebenbauer et al. 2008; Semmelhack and Wang 2009), but a blend of these compounds did not induce upwind flight attraction in the absence of other vinegar volatiles (Table 2). It will be rewarding to study the representation of defined blends of synthetic compounds in comparison with complex authentic odors such as vinegar.

The threshold concentration for initiation of upwind flight reflected odor quality. *Drosophila melanogaster* responded to the odor of vinegar even at a 1,000-fold dilution, or a release rate of 17.4 ng/min of the main compound acetic acid. In comparison, attraction to a 10-fold dilution of acetic acid alone was not significant (Table 3). Admixture of further vinegar volatiles to acetic acid had a synergistic effect on attraction (Table 2), while admixture of geosmin, an off-flavor produced by micro-organisms such as mold fungi (La Guerche et al. 2006), produced an opposite, antagonistic effect on attraction to vinegar.

The stimulus application method is a keystone element of wind tunnel bioassays. The piezoelectric sprayer (El-Sayed et al. 1999) enables the release of chemicals at a known constant rate and purity. It enables the parallel chemical and behavioral analysis of headspace collections of natural odour sources, as a starting point for tests with synthetic chemicals. The comparison of fly attraction to authentic and re-vaporized headspace corroborates the validity of the spray application procedure (Fig. 1).

The piezoelectric sprayer disperses solutions of synthetic and authentic chemicals in solvent. Methanol, which did not elicit a significant response from *D. melanogaster* (Table 1), is a good choice for a solvent in this spray system. It is easily vaporized and dissolves polar- and to some extent, non-polar compounds. Our results on the response to methanol agree with a study by Hoffmann and Parsons (1984) that showed no attraction of *D. melanogaster* and three other species of *Drosophila* to methanol. Comparison between authentic vinegar- and sprayed methanol extracts of Super Q-trapped volatiles did not show an impact by methanol (Fig. 1c). Interestingly, tests on higher dilutions (1:100 and 1:1,000) indicated a stronger attraction to the methanol extracts (diluted in methanol) than to the authentic vinegar (diluted in distilled water) (Table 3). This suggests a possible synergistic activity of methanol to stimuli tested at threshold concentrations, and the effect of methanol in the context of other components of the attractant bears further investigation. It is, however, unclear if this effect was due to the solvent or due to the different odor application methods.

Water is a straightforward solvent for vinegar, however dilutions in water cannot be analyzed by gas chromatography. It is noteworthy that a few flies responded to distilled water, although attraction was not significantly different from blank (Table 1). Water has been reported earlier to be critically important for attraction to traps baited with synthetic fruit odors (Zhu et al. 2003). *Drosophila*

melanogaster sense water with gustatory receptor neurons on the proboscis that projects into a specific region of the suboesophagal ganglion, and with hygrosensory neurons located on the antennae that projects into the antennal mechanosensory centre (Fischler et al. 2007; Liu et al. 2007; Inoshita and Tanimura 2008). It is remarkable that stimuli from outside the antennal lobe, i.e., the olfactory center, generate or contribute to an upwind flight response in *D. melanogaster*.

The response of *D. melanogaster* to vinegar was modulated by hunger, whereas sex and age did not have an effect (Fig. 2). The olfactory system is under circadian clock control (Tanoue et al. 2008). Sexual activity peaks during the night (Fujii et al. 2007), but flies respond to food during the day. Starvation had a decisive effect on attraction to vinegar, in both sexes, irrespective of mating status. Upwind flight of hungry flies to the odor of vinegar demonstrates that odor cues are processed with respect to the physiological state of the fly to generate an appropriate behavioral response. In the case of a hungry fly, this response is expressed as a voluntary take off and the initiation of flight towards the odor source.

We conclude that our wind tunnel assay and the piezoelectric delivery system enables the measurement of a conspicuous and unambiguous behavioral response. The measurement of this response provides the necessary resolution for the investigation of physiologically and ecologically relevant odors and will become an essential tool for the functional analysis of the *D. melanogaster* olfactory system.

Acknowledgments This study was supported by the Linnaeus initiative "Insect Chemical Ecology, Ethology and Evolution" IC-E3 (Formas, SLU). We thank Teun Dekker and Mattias Larsson for helpful comments and discussions. Jörgen Lantz constructed the wind tunnel.

Abstract Dietary carotenoids are important pigments, antioxidants, and immune-stimulants for birds. Despite recent interest in carotenoids in bird ecology, we know surprisingly little about the carotenoid content of invertebrates consumed by birds. We compared carotenoid (lutein, β-carotene, and total) concentrations in invertebrates brought to nestlings by two insectivorous passerines, the great tit, *Parus major* and the pied flycatcher, *Ficedula hypoleuca*. We also compared carotenoid levels between environments that were either polluted by heavy metals or were not polluted, because the carotenoid-based plumage color of *P. major* nestlings is affected by environmental pollution. Lepidopterans were the most carotenoid-rich food items and contained the largest proportion of lutein. There were no differences in carotenoid concentrations in the food items of the two bird species but *P. major* nestlings obtained more carotenoids from their invertebrate diet than *F. hypoleuca* nestlings because the *P. major* diet had a higher proportion of lepidopteran larvae. In polluted areas, *P. major* nestlings consumed lower levels of dietary carotenoids than in unpolluted areas because of temporal differences in caterpillar abundance between polluted and unpolluted sites. Our study suggests that pollution-related difference in nestling plumage color in *P. major* is related to varying dietary proportion of lutein-rich food items rather than pollution-related variation in insect carotenoid levels.

Introduction

Carotenoid pigments have been studied intensively in avian ecology during the last decade (Hill and McGraw 2006). Besides their important role in visual signaling, plant-derived carotenoids have essential physiological functions as antioxidants, immunostimulants, and pro-vitamins in birds (Surai et al. 2001). Birds acquire all of their carotenoids through their diet (Goodwin 1986; Brush 1990). For example, some herbivorous invertebrates that are rich in plant-derived carotenoids are important sources of carotenoids for insectivorous birds, such as the great tit, *Parus major* (Partali et al. 1985; Slagsvold and Lifjeld 1985; Tummeleht et al. 2006; Isaksson and Andersson 2007; Eeva et al. 2008). While carotenoid concentrations have been documented for one important food item, herbivorous caterpillars (Partali et al. 1985; Isaksson and Andersson 2007; Sillanpää et al. 2008), there is little information on other important invertebrate groups. A better understand of dietary carotenoids will elucidate the sources of variation in carotenoid levels in wild birds.

We compared carotenoid (lutein, β-carotene, unidentified carotenoids, and total) concentrations in dietary invertebrates for two insectivorous passerines, the great tit and the pied flycatcher, *Ficedula hypoleuca*. To get the most relevant information about the bird's diet, we collected the food items that birds brought to their nestlings. Sampling invertebrates collected by birds ensures that we are sampling just those species that are important for birds during breeding. Furthermore, with this sampling procedure we could estimate the mass proportions of the

main invertebrate groups in the diets of birds, which enabled us to calculate species-specific dietary carotenoid profiles. Because plasma carotenoid levels and plumage color of *P. major* are related to environmental pollution (Eeva et al. 1998, 2009), we collected data at two separate sites, one polluted by heavy metals and the other a relatively unpolluted reference site.

Methods and Materials

Study Site The data were collected from 12 study sites in the summers 2000 and 2002, in the pollution gradient of a copper smelter in the town Harjavalta (61°20′ N, 22°10′ E), SW Finland. Elevated heavy metal concentrations occur in soil, vegetation, insects, and birds in the polluted area (Kiikkilä 2003), and metal contents decrease exponentially with increasing distance to the smelter, approaching background levels at sites further than 5 km from the smelter (Jussila and Jormalainen 1991). A more detailed description of the study area and the pollution gradient has been given in Eeva et al. (1997). Six study sites in the proximity (<2 km) of the pollution source and six more distant (>5 km) sites were established with 40–50 nest boxes at each site.

Food Samples We collected food samples (N=338 individual food items) from *F. hypoleuca* and *P. major* parents feeding their nestlings at the age of 6–11 or 8–13 d, respectively. Since *P. major* nestlings hatched, on average, 16 d earlier than *F. hypoleuca*, the sampling of invertebrates also took place about 16 d later in the latter species. Birds were captured with a shutter trap at the entrance hole of a nest-box. A piece of plastic transparency above the begging nestlings prevented parents from giving the food items to nestlings. When an adult bird entered the nest-box we took the food item. Maximum duration of disturbance per brood was 20 min. Invertebrates were identified and classified into eight groups as follows: spiders (Aranae), beetles (Coleoptera), ants (Formicidae), adult moths, and butterflies (Lepidoptera), lepidopteran caterpillars, sawfly caterpillars (Symphyta), cockroaches (Ectobiidae), and other invertebrates (including Diptera, adult Hymenoptera, Isopoda, Lithobiidae, Myriapoda, and Gastropoda). Food items were weighed (mg) and preserved at −20°C in the dark until analysis. Sampling was conducted following the Finnish guidelines for ethical treatment of vertebrate experimental subjects.

Carotenoid Analyses For carotenoid analyses, 1–9 individuals from the same taxonomic group were put together, freeze-dried, and ground into fine powder. The total number of samples was 63 from *F. hypoleuca* diets and 23 from *P. major* diets. The powder (15 mg) was extracted three times in dark at 10°C with 400 µl of acetone, and the residue was then washed with 100 µl of acetone. The combined acetone extract (1300 µl) was concentrated for 50 min with an Eppendorf concentrator and was freeze-dried. The freeze-dried residue was dissolved in 300 µl of acetone, and 60 µl were injected into the HPLC system. The carotenoid composition was analyzed at 450 nm using a YMC C-30 column (250× 4 mm, i.d., 5 µm). β-carotene was quantified as β-carotene equivalents and the other carotenoids as lutein equivalents, using commercial lutein and β-carotene as standards (Extrasynthese, France). In some of the samples, the concentrations were below the detection limit (0.5 µg/g) and were replaced with a value of $0.5/\sqrt{2}$ in the statistical analyses (Hornung and Reed 1990).

Although the degradation of carotenoids is relatively slow at −20°, it is likely that some degradation occurred during the relatively long sample storage (7–9 yr). The first-order degradation kinetics of total carotenoids in wheat flour at −20° is described by the rate equation $\ln C = \ln C_0 - kt$; C = concentration, k = reaction rate constant, 0.15×10^{-3} day^{-1}, t = time in days (Hidalgo and Brandolini 2008). From that rate equation, we estimate that when we analyzed our samples they contained 61–68% of the original carotenoid concentration. The exact degradation rate is unknown since it may depend on the matrix (Hidalgo and Brandolini 2008). Therefore, absolute concentrations found in this study cannot be compared directly with levels found in fresh invertebrates. The main interest in our study, however, was to compare relative concentrations among different invertebrate groups.

Statistical Analyses We analyzed carotenoid concentrations (lutein, β-carotene, unidentified carotenoids, and total carotenoids) with separate generalized linear models with a negative binomial error distribution and log link function by using the GLIMMIX procedure of SAS 9.1 (SAS Institute 2003). The independent factors in the models were: bird species, year, area (polluted vs. unpolluted), and invertebrate group. Due to the small number of samples in most invertebrate groups, we did not consider the interactions between the main effects. Statistical interpretation of the group-differences was based on the 95% confidence intervals of the means. For example, if the 95% confidence intervals of means overlap half the length of one arm, this corresponds approximately to statistical significance at p= 0.05 (Cumming 2009).

Results

Carotenoid concentrations in different invertebrate groups are shown in Table 1. There were no statistically significant

Table 1 Mean concentrations (μg/g, d.w.) of lutein, β-carotenoid, unidentified carotenoids, and total carotenoids in invertebrate groups normally consumed by *Parus major* and *Ficedula hypoleuca* nestlings in polluted and unpolluted areas

Group	n	Lutein mean (±SE)	β-carotenoid mean (±SE)	Unidentified mean (±SE)	Total mean (±SE)
Aranae	9	1.7 (±0.27)	1.2 (±0.17)	3.3 (±0.82)	6.1 (±1.3)

differences in mean concentrations of carotenoids in dietary invertebrates consumed by the two bird species, nor between years or study areas (for lutein, β-carotene, unidentified carotenoids, and total: P>0.05 in all cases). Invertebrate groups, however, differed significantly in their mean carotenoid concentrations (Table 1). The highest lutein, β-carotene, and total carotenoid concentrations were found in lepidopterans (Fig. 1). Moderate total concentrations were found in Coleoptera, Symphyta, and Aranae (Fig. 1). Ants, cockroaches, and the group "other" invertebrates showed the lowest total concentrations (Fig. 1). The proportion of lutein from total carotenoids was highest in lepidopterans (mean±SE proportions calculated over individual samples: 56±4.9% for caterpillars; 40±6.5% for adults). The proportion of β-carotene was highest in cockroaches (44±18.9%), and the proportion of unidentified carotenoids was highest in beetles (45±7.4%) and spiders (44±6.7%).

Although there were no differences in the concentration of carotenoids in food items used by the two bird species, the birds used different invertebrate groups in different proportions (Table 2). For example, in the unpolluted area, the biomass-based proportion of carotenoid-rich lepidopteran larvae in diet was 3.4 times higher in *P. major* than in *F. hypoleuca* (Table 2). We calculated the carotenoid profile for the nestling diet of each species, taking the varying dietary proportions of different invertebrate classes into account (Fig. 2). *Parus major* nestlings received 1.4 and 5.7 times more carotenoids than *F. hypoleuca* nestlings in the polluted and unpolluted areas, respectively (Fig. 2). This

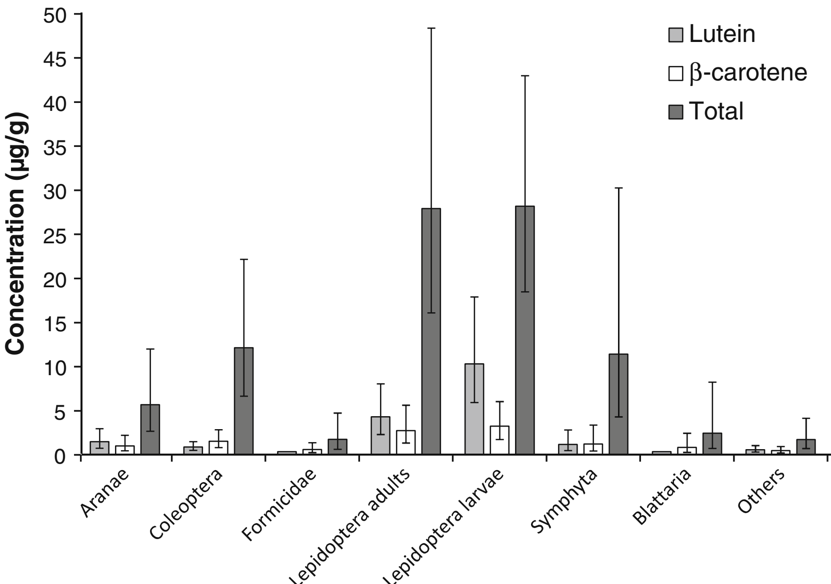

Fig. 1 Mean concentrations (μg/g, d.w.) of lutein, β-carotenoid, and total amount of carotenoids in invertebrate groups consumed by *Parus major* and *Ficedula hypoleuca* nestlings. Values are model based expected marginal means backtransformed from a log-scale. Error bars indicate the 95% confidence interval. N=86

Table 2 Proportions (% of total fresh mass) of invertebrate groups in the diet of *Parus major* and *Ficedula hypoleuca* nestlings in polluted and unpolluted areas

Group	*P. major*		*F. hypoleuca*	
	Polluted	Unpolluted	Polluted	Unpolluted
Aranae	8.1	3.9	2.5	10.8

Calculated from total biomass of collected food items (*P. major*: *N*=121; *F. hypoleuca*: *N*=217)

was due primarily to the much higher proportion of lepidopteran larvae in diet of *P. major* (Table 2). In *P. major*, dietary carotenoid content was lower in the polluted area, while in *F. hypoleuca* it was higher in the polluted area (Fig. 2). For both polluted and unpolluted areas the proportion of dietary lutein was somewhat higher in *P. major* (48%) than in *F. hypoleuca* (37%).

Discussion

Carotenoid concentrations differed among the main invertebrate food groups in the nestling diets of *P. major* and *F. hypoleuca*. Lepidopterans were the most carotenoid-rich food items, with lepidopteran caterpillars (e.g., *Operophtera brumata*, *Epirrita autumnata*) containing the largest amount of lutein on a mass and proportional basis. Relatively high carotenoid concentrations also were found in adult Lepidoptera (e.g., *Bupalus piniarius, Thera obeliscata*), which are an important source of carotenoids especially for *F. hypoleuca*. Beetles, sawfly larvae, and spiders contained moderate total carotenoid concentrations, but with a much lower proportion of lutein than in lepidopterans. Some invertebrate groups that were important in the diet of *F. hypoleuca*, such as ants and cockroaches, had relatively low carotenoid concentrations.

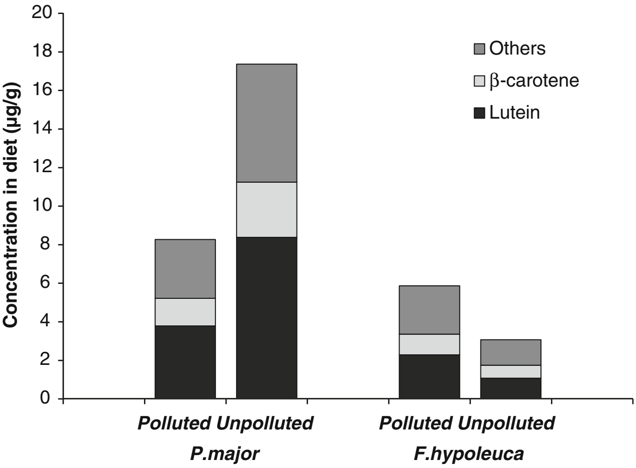

Fig. 2 Concentrations of lutein, β-carotenoid and other carotenoids in the invertebrate diet of *Parus major* and *Ficedula hypoleuca* nestlings. The values take account the concentration in each invertebrate group (Table 1) and the proportion of each group in the diet (Table 2)

The levels of carotenoids in the insects in our study, were lower than previously published values. Sillanpää et al. (2008) found lutein concentrations of 80–90 µg/g (d.w.) in a sample of autumnal moth (*Epirrita autumnata*) larvae, while in our sample the average caterpillar lutein concentrations was only 14 µg/g (d.w.). Isaksson and Andersson (2007) reported lutein concentrations of 16–26 µg/g (w.w.) in lepidopteran caterpillars, equivalent to 123–200 µg/g (d.w.) assuming that caterpillar water content is 87% (Sillanpää et al. 2009). Lutein concentration of sawfly larvae was 15–18 µg/g (d.w.) in a study of Sillanpää et al. (2008), while it was 3 µg/g (d.w.) in our sample. The relatively large differences most likely are due to degradation of carotenoids during the relatively long storage of our samples (see Methods). However, the rather diverse species composition in our samples also may partly explain these differences. For example, lepidopteran caterpillars include species of Geometridae, Noctuidae, Arctiidae, Lasiocapidae, and Nymphalidae, and there is likely variation in carotenoid concentrations among the species within this group (Isaksson and Andersson 2007).

The carotenoid profiles of the invertebrates normally consumed by *P. major* and *F. hypoleuca* nestlings were diverse. In all, 34% of total carotenoids was lutein, 21% β-carotene, and 46% unidentified carotenoids. The large number of species in our samples suggest that the unidentified carotenoids may include numerous compounds. For example, astaxanthin and lycopene are important carotenoids in insects, and likely are represented in our samples (Goodwin 1986). Carotenoid profiles of our samples also varied within the same insect group, possibly due to highly variable species composition. For example,

within Coleoptera, the highest carotenoid concentrations (up to 98 μg/g) occurred in samples containing only ladybirds (Coccinellidae). *Coccinella septempunctata*, which was the primary ladybird species in our sample, has a very diverse carotenoid profile (Britton et al. 1977). These unpalatable beetles, which are especially numerous in the polluted area, frequently were observed in the nestling diet of *F. hypoleuca,* while *P. major* seems to avoid them (Eeva et al. 2005).

Invertebrate carotenoid profiles differ from plasma carotenoid profiles of *P. major* and *F. hypoleuca* nestlings. In plasma, lutein is the dominant carotenoid, comprising up to 57% (*F. hypoleuca*) and 75% (*P. major*) of the total carotenoids (Biard et al. 2006; T. Eeva, unpublished data). Birds absorb different carotenoids disproportionally, and xanthophylls (like lutein) generally are absorbed relatively efficiently (Goodwin 1986; Surai et al. 2001; McGraw 2005). Xanthophylls also are the primary carotenoids in the integument coloration of many bird species, including *P. major* (McGraw 2006; Eeva et al. 2008). Many bird species can modify dietary carotenoids chemically, but in *P. major* the main feather pigments (lutein and zeaxanthin) are transported from food to feathers without modification (Brush 1990; McGraw 2006).

We found no significant differences in carotenoid concentrations of food items collected by the two bird species. This is not surprising since the diets of *P. major* and *F. hypoleuca* include some of the same species (Cramp and Perrins 1993; Eeva et al. 2005). Furthermore, due to a large variation in concentrations among samples and relatively small sample size (especially in *P. major*), our analysis could not have detected small differences in carotenoid concentrations. The normal diet of *P. major* nestlings, however, contains considerably more carotenoids than the diet of *F. hypoleuca* because *P. major* consumes a much larger proportion of carotenoid-rich lepidopterans (Eeva et al. 2005). In agreement with our study, Sillanpää et al. (2008) showed that there was no pollution-related difference in concentrations of lutein and β-carotene in caterpillars of one important dietary lepidopteran species, the autumnal moth (*Epirrita autumnata*).

Temporal differences in caterpillar abundance between polluted and unpolluted sites are an important determinant of dietary carotenoid concentration and carotenoid intake in our study species (Eeva et al. 2005; Sillanpää et al. 2009). Heavy metal rich food is known to retard growth and increase mortality of herbivorous insect larvae (Heliövaara and Väisänen 1990; Martens and Boyd 1994; Ruohomäki et al. 1996). At least in some years, the peak abundance of lepidopteran caterpillars occurs later in the polluted area (Sillanpää et al. 2009). As a consequence, the diet of *P. major* nestlings in the polluted sites contains lesser amounts of carotenoids than the diet in the unpolluted area. In contrast, the nestlings of later-breeding *F. hypoleuca* may consume more carotenoids in the polluted area than their conspecifics in the unpolluted area.

Carotenoid concentrations differ markedly among the main invertebrate taxa in the diet of *P. major* nestlings. Lepidopterans are the most carotenoid-rich food items, and contain a high proportion of lutein. Dietary variation in carotenoid levels may have important consequences for bird species that use carotenoid pigments for their feather coloration. Lutein is the most important feather color pigment in *P. major*, the pale yellow coloration of *P. major* nestlings in a polluted area is a manifestation of low dietary carotenoid levels (Eeva et al. 1998). Our study suggests that this difference in nestling plumage color is due to varying dietary proportion of lutein-rich food items rather than due to pollution-related variation in insect carotenoid levels.

Acknowledgements We thank Jorma Nurmi, Mari Ryömä, and Janne Riihimäki for participating in field work, and Terhi Sundman for help in carotenoid analyses. Anssi Teräs, Antti Haarto, Seppo Koponen, Veikko Rinne, Kai Ruohomäki, Ilari Sääksjärvi, and Jouni Sorvari identified the invertebrate samples. Eric Le Tortorec revised the English in the manuscript. Predator Avoidance by Phytophagous Mites is Affected by the Presence of Herbivores in a Neighboring Patch

Yasuyuki Choh · Junji Takabayashi

Abstract When predators invade a leaf patch inhabited by herbivores, the herbivores disperse to a neighboring predator-free leaf patch, thus escaping from the predators. However, the neighboring patch might already be used by con- or heterospecific herbivores. We used laboratory bioassays to examine whether perception of odor from con- or heterospecific competitors on a neighbored lima bean leaf patch influences dispersal behavior of the herbivorous mite *Tetranychus urticae* when attacked by predatory mites *Phytoseiulus persimilis*. The dispersal rates of *T. urticae* that perceived odors from leaf patches infested by conspecifics or cowpea aphids (*Aphis craccivora*) did not differ from the control (the dispersal rate of *T. urticae* that perceived odor from uninfested leaf patches). By contrast, the dispersal rate of *T. urticae* was reduced when they perceived odors from leaf patches that were currently or had previously been infested by larvae of the common cutworm (*Spodoptera litura*). Previous herbivory by *S. litura* larvae induced resistance in leaf patches to *T. urticae* as indicated by the reduced number of eggs laid by *T. urticae*. Our results are discussed with respect to the feeding behavior of the tested competitors of *T. urticae* and the impact of the plant and arthropod community on the dispersal behavior of these mites.

Introduction

Herbivorous arthropods are known to leave the host plant that they are currently infesting in the presence of their predators (Loose and Dawidowicz 1994; Tikkanen et al. 1996; Nilsson and Bengtsson 2004; Kunert et al. 2005; Choh and Takabayashi 2007). The leaving prey may evaluate a new host plant nearby before and/or after leaving the host plant. Our previous study showed that the suitability of new host plants affects the dispersal behavior of an herbivorous mite (*Tetranychus urticae*) (Choh and Takabayashi 2007). However, even if the neighboring new host plant is acceptable to them, the plant may already be inhabited by conspecific and/or heterospecific herbivore species. Since herbivore-infested plants can change their defensive levels against herbivores depending on the herbivore species (Karban and Baldwin 1997; Ohgushi 2005; Schaller 2008), differences in whether a plant is infested by con- or heterospecific herbivores will affect the suitability of the plant. Thus, the presence of other herbivore individuals on a neighboring host plant would also affect the dispersal behavior of herbivores in response to the invasion of predators.

Many herbivore species are reported to use plant odors as a cue for host plant selection (Visser 1986; Bernays and Chapman 1994; Dicke 2000). Furthermore, herbivores may respond to odors from plants infested by conspecifcs and heterospecifics as cues to the quality of host plants (Dicke 1986; Loughrin et al. 1995: Bolter et al. 1997; Pallini et al. 1997; De Moraes et al. 2001; Horiuchi et al. 2003; Meiners et al. 2005). For example, *T. urticae* mites avoid odors from cucumber plants infested with the western flower thrips (*Frankliniella occidentalis*), which is not only a competitor, but also an intraguild predator (Pallini et al. 1997). We showed previously that *T. urticae* respond to odors from

neighboring patches that result in leaving or staying on the current predator-invaded patch or not (Choh and Takabayashi 2007).

Based on our previous study, we hypothesized that herbivores change their dispersal behavior for predator avoidance in response to odors from host plants infested by other herbivores. To test this hypothesis, we used lima beans, a herbivorous mite (*T. urticae*), and a predatory mite (*Phytoseiulus persimilis*). As heterospecific competitors, common cutworm (*Spodoptera litura*) and cowpea aphid (*Aphis craccivora*) were used. We examined the dispersal of *T. urticae* from the current leaf patch invaded by predators to a clean leaf patch when they perceived odors from a neighboring leaf patch with conspecific or heterospecific competitors. Furthermore, we tested whether herbivore-induced leaf volatiles were involved in the dispersal changes. The oviposition of *T. urticae* on a leaf patch that had been infested previously by heterospecific competitors was measured also to evaluate plant resistance induced by competitors.

Methods and Materials

Plants and Arthropods Lima bean plants (*Phaseolus lunatus* cv. Sieva) were grown in soil in a greenhouse at 25±2°C, 60–70% relative humidity (RH), and a photoperiod of 16 L-8hD. We used plants at 10–15 d post-germination.

Herbivorous spider mites (*T. urticae*) were obtained from the Laboratory of Ecological Information (Graduate School of Agriculture, Kyoto University) in 2002, and reared on lima beans in an incubator (25±2°C, 60–70% RH, 16 L-8hD).

Cowpea aphids (*Aphis craccivora*) were collected from a crop field at the Center for Ecological Research in Otsu, Shiga, Japan in May 2007. The insects were reared on broad bean plants (*Vicia faba*) in an incubator (20±2°C, 60–70% RH, and a photoperiod of 16 L-8hD).

Common cutworms (*Spodoptera litura*) were obtained from a culture maintained at the National Institute of Agrobiological Sciences in Tsukuba, Ibaraki, Japan in 2006. The insects were reared on an artificial diet (Insecta LF; Nihon Nousan Kogyo Ltd., Yokohama, Japan) in an incubator (25±2°C, 50–70% RH, and a photoperiod of 16 L-8hD).

Predatory mites (*P. persimilis*) were purchased from Koppert BV (Berkel and Rodenrijs, The Netherlands). They were reared on detached lima bean leaves, heavily infested with *T. urticae*, in an incubator (25±2°C, 60–70% RH, 16 L-8hD). Fresh *T. urticae*-infested leaves were added every other day.

All experiments were conducted in a climate controlled room (25±2°C, 60–70% RH, 16 L-8hD).

Wind Tunnel Experiments: Dispersal Behavior of T. urticae General A 3.5×2.5 cm intact leaf patch was cut from a primary leaf of a lima bean plant (hereafter, current patch), and placed on water-saturated cotton wool in a Petri dish (15 cm diam., 1 cm height). Then, a 3.5×2.0 cm intact leaf patch (hereafter, alternative patch) also was cut from another primary leaf of the same plant, and was placed in the same Petri dish, 5 cm away from the current patch. Thirty randomly selected adult female *T. urticae* were placed on the current patch and were allowed to lay eggs for 24 hr. We then connected the current patch and the alternative patch with a Parafilm bridge (5 cm length, 0.5 cm width) and placed ten adult female *P. persimilis* on the current patch. As *P. persimilis* prefer the eggs of *T. urticae* to the adults (Blackwood et al. 2001), we assumed that the introduced predatory mites were arrested on the current patch by the presence of prey eggs that had been laid 24 hr before the introduction.

We studied the question whether odors from patches with conspecific and heterospecific competitors affect dispersal behavior of the herbivorous mites from the current patch to an uninfested alternative patch. A patch with competitors was prepared of a 3.5×3.5 cm leaf from a primary leaf of a lima bean plant; the patch was placed on water-saturated cotton wool in another Petri dish (15 cm diam.). We placed either ten female adult *A. craccivora*, or 3 2nd–3rd instars of *S. litura*, or 30 female adult *T. urticae* on a leaf patch, and kept it for 24 hr. We used such leaf patches as the odor source patches.

Dispersal Movement Upwind of Odor Source (= Leaf Patch with Con- and Heterospecific Competitors) The set-up was placed in a wind tunnel (air flow: 10 cm/s, size: 40×40×80 cm), with the three leaf discs being positioned in the following order: the odor source patch with the competitors was placed upwind, the current patch was placed downwind, and the alternative clean patch was placed between the current patch and the odor source patch. In this way, *T. urticae* perceived odors from the odor source patch with competitors when dispersing upwind from the current patch to the alternative patch. The number of *T. urticae* that dispersed to an alternative patch and the number of *T. urticae* killed by predators on each current patch were counted 24 hr after the introduction of the three patches into the wind tunnel. We repeated the above experiments 40 times per treatment (Fig. 1a).

Dispersal Movement Downwind of Odor Source (= Leaf Patch with Heterospecific Competitors) For control, the experiment described above was modified by changing the position of patches in the wind tunnel. The odor source

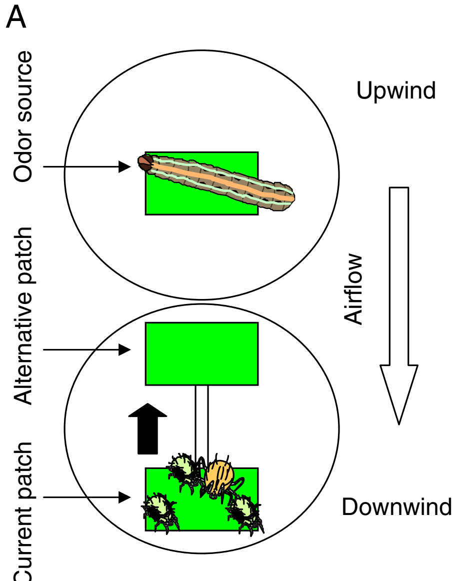

Fig. 1 Set-up for wind tunnel experiments. The current patch and alternative leaf patch were connected by a "bridge" made of Parafilm. The black arrow indicates the direction in which dispersal from a current patch to an alternative patch was possible. *White arrow*: direction of airflow. *Small mites*: symbol for herbivorous *Tetranychus urticae*; *large mite*: symbol for predatory *Phytoseiulus persimilis*; larva on odor source patch: symbol for competitors located on odor source patch: tested competitors for set-up A where dispersal was possible upwind of the odor source: *T. urticae*, *Spodoptera litura*, and *Aphis craccivora*; for set-up B where dispersal was possible downwind of the odor source: only *S. litura*

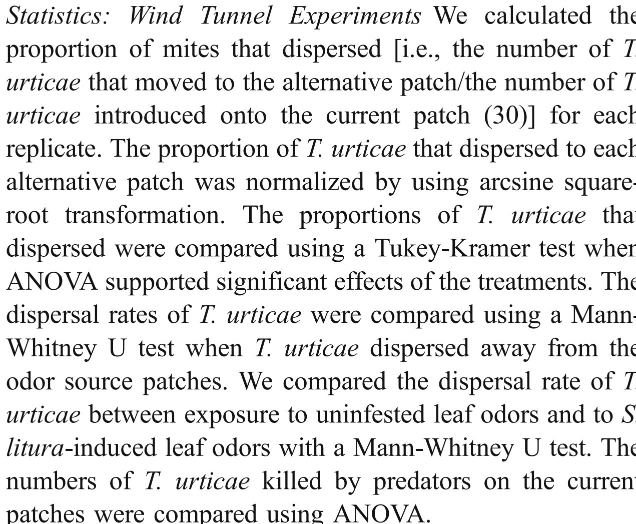
patch with competitors was placed upwind, the alternative (uninfested) patch was placed downwind, and the current patch was placed between the alternative patch and the odor source patch. Thus, mites moved downwind of the odor source patch when dispersing to the alternative patch. We used as odor source patch only those infested with *S. litura*. The number of *T. urticae* on each alternative patch was counted 24 hr after the introduction of the three patches into the wind tunnel. We repeated the above experiments 18 times per treatment (Fig. 1b).

Dispersal Movement Upwind of Odor Source (= Leaf Patch that Has Previously Been Infested with Heterospecific Competitors) To test whether leaf odors induced by herbivory affect the dispersal of *T. urticae*, we conducted experiments similar to those described above, but using an odor source leaf patch that had been infested previously by three 2nd–3rd instars of *S. litura* for 24 hr and, for control, an uninfested odor source leaf patch. Prior to the experiments, the associated products of herbivores (i.e., feces and exuviae of larvae) were removed. These patches were placed into the wind tunnel in the following order: the odor source patch upwind, the current patch downwind, and the alternative clean patch between the odor source and the current patch. The number of *T. urticae* on each alternative patch was counted 24 hr after the introduction of the three patches into the wind tunnel. We repeated the above experiments 18 times per treatment (Fig. 1a).



Statistics: Wind Tunnel Experiments We calculated the proportion of mites that dispersed [i.e., the number of *T. urticae* that moved to the alternative patch/the number of *T. urticae* introduced onto the current patch (30)] for each replicate. The proportion of *T. urticae* that dispersed to each alternative patch was normalized by using arcsine square-root transformation. The proportions of *T. urticae* that dispersed were compared using a Tukey-Kramer test when ANOVA supported significant effects of the treatments. The dispersal rates of *T. urticae* were compared using a Mann-Whitney U test when *T. urticae* dispersed away from the odor source patches. We compared the dispersal rate of *T. urticae* between exposure to uninfested leaf odors and to *S. litura*-induced leaf odors with a Mann-Whitney U test. The numbers of *T. urticae* killed by predators on the current patches were compared using ANOVA.

Competitor-Induced Plant Resistance to T. Urticae When competitors have fed previously on a new leaf patch, the leaf may show induced resistance against *T. urticae*. To test this possibility, we made a 5×5 cm leaf patch from a primary leaf of a lima bean plant, and put it on water-saturated cotton wool in a Petri dish (9 cm diam, 1.4 cm high). Ten female adult *A. craccivora*, or three 2nd–3rd instars of *S. litura*, or 30 female adult *T. urticae* were placed on the leaf patch. To keep a part of a leaf uninfested, the herbivores were enclosed in a cage (4 cm diam., 0.5 cm high) which was covered with nylon gauze. All herbivore

individuals and eggs of *T. urticae* were removed from the leaf disc 24 hr after the introduction. As a control, no herbivorous arthropods were kept in the cage on the leaf patch. Subsequently, a female adult *T. urticae* that had been randomly selected from the culture was placed on the uninfested part of the leaf patch, and the number of eggs laid by the mite during the following 3 d was measured. We repeated the experiment 24 times. The numbers of *T. urticae*-eggs were compared with a Tukey-Kramer test among treatments when ANOVA supported significant effects of the treatments.

Results

Wind Tunnel Experiments Dispersal Movement Upwind of Odor Source (= Leaf Patch with Con- and Heterospecific Competitors) Dispersal behavior of *T. urticae* towards a clean, uninfested patch differed when mites were exposed to odor source patches with different herbivore species ($F_{3, 156}$=3.635, P<0.014, ANOVA). When *T. urticae* perceived odors from the odor source patch with *S. litura*, the dispersal rate was lower than when they perceived odors from the odor source patches with no herbivores or with *A. craccivora* (P<0.05, Tukey-Kramer test; Fig. 2). Although the dispersal rate of mites exposed to odors from the patch with *S. litura* tended to be lower than that the one of mites exposed to odors from the patch with *T. urticae*, the difference was not significant (P>0.05, Tukey-Kramer test; Fig. 2). There were no significant differences in the number of *T. urticae* killed by predators on the current patch among the four treatments ($F_{3, 156}$=1.377, P=0.252, ANOVA; Fig. 3) (Fig. 1a).

Dispersal Movement Downwind of Odor Source (= Leaf Patch with Heterospecific Competitors) When *T. urticae* dispersed to an uninfested patch away from the odor source patch infested with *S. litura*, the dispersal rate did not differ from the one of mites dispersing to an uninfested patch away from a control patch without competitors (leaf patches with *S. litura*; 0.24±0.051, uninfested control leaf patches; 0.25±0.042, Mann-Whitney *U* test, U=76, P=0.66) (Fig. 1b).

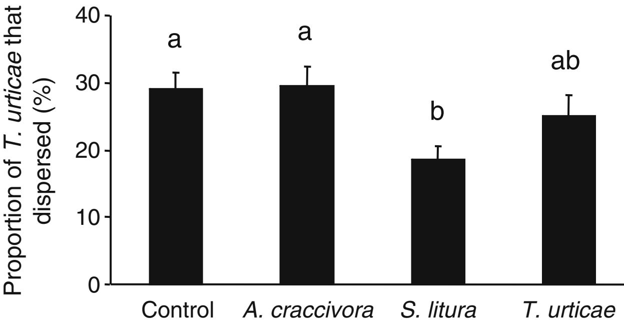


Fig. 2 The proportion (mean+SE) of *Tetranychus urticae* female adults that dispersed from the current patch to the alternative patch when competitors were on the odor source patches. The *letters* above each bar indicate significant differences among treatments by the Tukey-Kramer test (P<0.05)

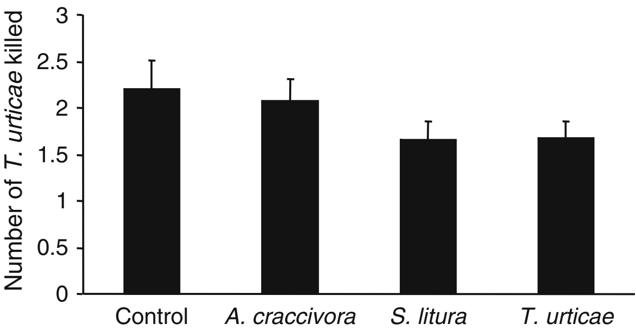

Fig. 3 The number (mean+SE) of *Tetranychus urticae* female adults killed by *Phytoseiulus persimilis* on the current patch when they dispersed from the current patch to an alternative patch next to an odor source patch with competitors

Dispersal Movement Upwind of Odor Source (= Leaf Patch that Has Previously Been Infested with Heterospecific Competitors) When *T. urticae* was exposed to odors from a patch that had been infested previously by *S. litura*, the dispersal rate to a clean patch was lower compared to the rate when exposed to odors from an uninfested leaf patch (*S. litura*-induced leaf odors; 0.12 ± 0.023, uninfested leaf odors; 0.26±0.041, Mann-Whitney *U* test, U=76, P=0.011, (Fig. 1a).

Competitor-Induced Plant Resistance to T. Urticae Oviposition activity of *T. urticae* differed on the leaf patches with previous herbivory by *S. litura, A. craccivora, T. Urtica*, and an untreated control ($F_{3, 92}$=2.896, P<0.039, ANOVA). When *T. urticae* was placed on a leaf patch with previous herbivory by *S. litura*, the oviposition rate was lower than on an uninfested leaf patch (P<0.05, Tukey-Kramer test; Fig. 4). Although the oviposition rate on a leaf patch with previous herbivory by *S. litura* tended to be lower than that on leaf patches with previous herbivory by conspecifics and by *A. craccivora*, there were no significant differences between them (P>0.05, Tukey-Kramer test; Fig. 4).

Discussion

Tetranychus urticae disperses from a patch with predators to an uninfested patch for predator avoidance (Choh and

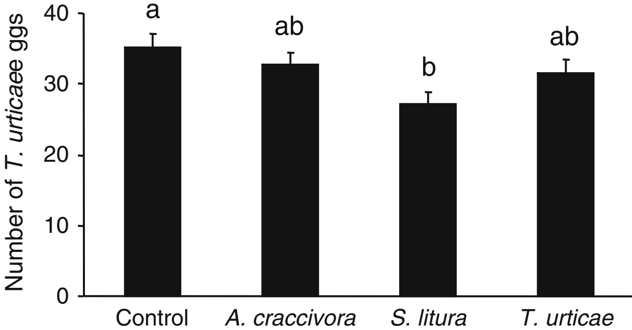

Fig. 4 The number (mean+SE) of eggs laid by *Tetranychus urticae* female adults on the leaf patches that had previously been infested by competitors. The *letters* above each bar indicate significant differences among treatments by the Tukey-Kramer test ($P<0.05$)

Takabayashi 2007). When *T. urticae* perceived odors from an odor source patch with *S. litura*, it showed reduced dispersal compared to when exposed to odors from the control patch (no herbivores). As the mortality of *T. urticae* killed by predators on the current leaf patch was the same irrespective of herbivore species on the odor source leaf patches, the reduced dispersal was not due to a difference in the mortality of adult *T. urticae* killed by the predators.

In contrast to the dispersal of mites exposed to odors from patches with *S. litura*, their dispersal did not change when exposed to odors from patches with conspecifics or *A. craccivora*. These results suggest that *T. urticae* distinguishes herbivore species on the odor source patches by using volatile infochemicals. Odors from *S. litura* larvae themselves, from feces of the larvae, and from the leaf patch are potential cues of the volatile infochemicals that affect the dispersal of *T. urticae*. When lima bean plants are infested by herbivores of different species, they emit different blends of volatile compounds, which can be specific to the herbivore species (Ozawa et al. 2000). In fact, *T. urticae* also showed reduced dispersal when exposed to leaf volatiles from an odor source patch that had been infested previously by *S. litura*. *T. urticae* might change its dispersal in response to such differences in the volatiles. The leaf area consumed by *S. litura* was larger than that consumed by the other two herbivore species. In addition, the feeding mode of *S. litura* (chewing) differs from that of *T. urticae* and *A. craccivora* (sucking). Such differences might partly explain the volatile emission from herbivore-infested lima bean leaves, and the different responses of spider mites to these volatiles. Turlings et al. (1998) reported that herbivores with different feeding modes (caterpillar: *Spodoptera littoralis*, stemborer; *Ostrinia nubilalis*, and aphid *Rhopalosiphum maidis*) could trigger distinctly different quantities of volatiles in plants. It also has been reported that volatiles from lima bean leaves infested by *S. exigua* differ from those from *T. urticae*-infested lima bean leaves (Ozawa et al. 2000). Further study is needed to test how volatile emission from herbivore-infested leaves differs among the three herbivore species that we used in this study.

The intensity and effects of herbivore-induced plant resistance depend on the herbivore species (Agrawal 2000; Agrawal and Karban 2000; van Zandt and Agrawal 2004). We found reduced oviposition of *T. urticae* on the leaf patches that had been infested previously by *S. litura*, suggesting that feeding of *S. litura* induced resistance to *T. urticae* in lima bean leaves. It remains unanswered which defensive traits (e.g., physical or chemical traits) are involved in the *S. litura*-induced resistance to *T. urticae*. It also has been reported that some herbivores induce susceptibility to other herbivores after previous feeding on plants (Underwood 1998; Agrawal 2000; Karban and Agrawal 2002; Rotem and Agrawal 2003). Thus, when prey disperses to a patch with competitors, the effects of the previous feeding of the competitors on the dispersed prey would depend on the combination of herbivore and plant species.

Herbivorous arthropods are known to select and/or distribute on host plants according to herbivore-induced changes in plants (Gilbert et al. 2001; Rostás and Hilker 2002; Kessler et al. 2004; Carroll et al. 2006; Delphia et al. 2007; Viswanathan et al. 2008). For example, several studies have shown that herbivores use volatiles from herbivore-infested plants to find new host plants (Rostás and Hilker 2002; Carroll et al. 2006; Delphia et al. 2007). In this study, dispersing *T. urticae* avoided the leaf patches with *S. litura* with induced resistance against *T. urticae* by using leaf odors. When *T. urticae* leaves the current patch invaded by predators, the resistance of neighboring leaves infested by competitors might be a factor that affects the behavior.

Predators might induce not only antipredator behavior in prey but also nonconsumptive effects on prey that would not result in death (Peacor and Werner 2000; Schmitz et al. 2004; Pangle and Peacor 2006; Werner and Peacor 2006). There have been many demonstrations that nonconsumptive predator effects on prey affect communities through a trait-mediated indirect interaction (see Werner and Peacor 2003; Schmitz et al. 2004; Peckarsky et al. 2008). However, it still is not well understood how communities affect predator-prey interactions. We showed here that the dispersal behavior of prey to escape from predators was affected by the presence of competitors on neighboring patches. In addition, other organisms (e.g., plants, predators, parasites, symbionts) in the neighboring patches might also affect the antipredator responses of prey. Predator avoidance by prey is a key component that determines predator-prey dynamics. We suggest that predator-prey dynamics are not independent of the community, and that theory and experiments should focus on the effects of community on predator-prey interactions.

Abstract Females of the solitary endoparasitoid *Cotesia vestalis* respond to a blend of volatile organic compounds (VOCs) released from plants infested with larvae of their host, the diamondback moth (*Plutella xylostella*), which is an important pest insect of cruciferous plants. We investigated the flight response of female parasitoids to the cruciferous plant *Brassica rapa*, using two-choice tests under laboratory conditions. The parasitoids were more attracted to plants that had been infested for at least 6 hr by the host larvae compared to intact plants, but they did not distinguish between plants infested for only 3 hr and intact plants. Although parasitoids preferred plants 1 and 2 days after herbivory (formerly infested plants) over intact plants they also preferred plants that had been infested for 24 hr over formerly infested plants. This suggests that parasitoids can distinguish between the VOC profiles of currently and formerly infested plants. We screened for differences in VOC emissions among the treatments and found that levels of benzyl cyanide and dimethyl trisulfide significantly decreased after removal of the host larvae, whereas terpenoids and their related compounds continued to be released at high levels. Benzyl cyanide and dimethyl trisulfide attracted parasitoids in a dose-dependent manner, whereas the other compounds were not attractive. These results suggest that nitrile and sulfide compounds temporarily released from plants under attack by host larvae are potentially more effective attractants for this parasitoid than other VOCs that are continuously released by host-damaged plants.

Key Words Herbivore-induced plant volatiles · Indirect defense · Tritrophic interaction · *Brassica rapa* · *Plutella xylostella* · *Cotesia vestalis*

Introduction

Many plant species release specific blends of volatile organic compounds (VOCs) in response to attack by herbivores. The release of VOCs induced by herbivory can attract natural enemies of herbivores and may guide parasitoids or predators to their hosts or prey (Turlings et al. 1990; Takabayashi and Dicke 1996). Chemical information of this nature has attracted considerable attention as an indirect defense of plants against herbivorous insects mediated by their natural enemies at a higher level in a tritrophic interaction system (Karban and Baldwin 1997; Sabelis et al. 2007). However, the plant defense may not be constant, since the composition of plant VOCs can vary both in quality and in quantity, depending on various biotic and abiotic factors, and these changes can affect the attractiveness of the plants to natural enemies of the herbivores (Takabayashi et al. 1994; Maeda et al. 2000; Gouinguené and Turlings 2002).

The profile of VOCs also can change during the course of herbivory (Loughrin et al. 1994; Turlings et al. 1998; Scascighini et al. 2005). Diurnal cycles in the release of VOCs are related to the attraction of natural enemies of herbivores or to deterrence of herbivores (Loughrin et al. 1994; De Moraes et al. 2001; Shiojiri et al. 2006a), and the importance of the effects of light in a diurnal cycle have been reported (Gouinguené and Turlings 2002). However, there is a little information on changes in VOCs of infested plants during and after herbivory, particularly from the perspective of potential differences in plant-insect interactions between the two phases (Mattiacci et al. 2001; Hoballah and Turlings 2005). In natural ecosystems, herbivores may not stay on a single plant, but may move among plants, be eliminated by other predators (Shiojiri and Takabayashi 2005), or pupate and become unsuitable targets for parasitoids to oviposit. Thus, parasitoids may be able to distinguish between plants currently being attacked (hereafter, “infested plants”) and plants that were formerly attacked by herbivores (hereafter, “formerly infested plants”). By focusing on the difference in compositions of VOCs released from infested and formerly infested plants, we may be able to identify effective attractants for parasitoids.

In Japan, *Brassica* plants (Capparales: Brassicaceae) are grown during the spring, close enough together for adjacent plants to touch. A tritrophic system forms among the plant species, herbivorous insects, and their parasitoids. Caterpillars of the diamondback moth, *Plutella xylostella* L. (Lepidoptera: Yponomeutidae), are oligophagous on cruciferous plants. The specialist parasitoid wasp *Cotesia vestalis* (Haliday) [= *C. plutellae* (Kurdjumov)] (Hymenoptera: Braconidae) oviposits on *P. xylostella* larvae. The female parasitoids are attracted to crucifers infested by *P. xylostella* larvae through a specific blend of VOCs (Shiojiri et al. 2000) and lay a single egg per host.

Under laboratory conditions, infested cruciferous plants attract various parasitoids by emitting specific blends of VOCs (Mattiacci et al. 1994; Shiojiri et al. 2000; Van Poecke et al. 2001), and the mechanisms for the induction, regulation, and biosynthesis of those VOCs have been characterized (Mattiacci et al. 1995; Van Poecke and Dicke 2002; Shiojiri et al. 2006b; D’Auria et al. 2007; Herde et al. 2008). However, it is unclear which VOC components attract *C. vestalis*. In the present study, we screened for potential parasitoid attractants, by investigating the flight response of female parasitoids to plants that had been infested by their host larvae, *P. xylostella*, for different durations (infested plants), and their response to plants at various times after herbivory (formerly infested plants). We then analyzed the headspace volatiles released from infested and formerly infested plants to establish the time course of changes in the relative amounts of plant VOCs after the start of herbivory and after removal of the larvae, and tested synthetic versions of VOCs to evaluate their effectiveness as attractants for parasitoids.

Methods and Materials

Plants and Insects Japanese mustard spinach, *Brassica rapa* L. var. *perviridis* (Capparales: Brassicaceae), was cultivated in a greenhouse (25±3°C, 60±10% relative humidity (RH), 16L:8D photoperiod). Five plants were reared in a plastic pot (90 mm diam, 70 mm depth) for 4–5 wk, and were used for both insect rearing and flight preference tests. Diamondback moths, *P. xylostella*, originally collected from fields in Ayabe, Kyoto Prefecture, Japan, in 2001, were mass-reared on potted plants in a climate-controlled room (25±3°C, 60±10% RH, 16L:8D photoperiod). Eggs were collected every day, and hatched larvae were reared on cut plants in small cages (width 25 cm, depth 15 cm, height 10 cm). The solitary parasitoids *C. vestalis*, which parasitize mainly *P. xylostella* larvae, were obtained from their hosts collected in the same fields and were reared on *P. xylostella*-infested plants under the same conditions as their hosts. For use in the two-choice test, wasp cocoons were collected from the stock culture, and newly emerged adults were maintained with 50% aqueous honey in acryl cages (width 35 cm, depth 25 cm, height 30 cm) separately from the host-infested plants until the experiments.

Flight Response of Parasitoids to Host-infested Plants and to Synthetic Compounds The flight response of *C. vestalis* females was assessed by using a two-choice test in an acrylic chamber (width 35 cm, depth 25 cm, height 30 cm, 3,000 lux) in a climate-controlled room (25±3°C, 60±10% RH) (Shiojiri et al. 2000). Infested plants were prepared by allowing 15 third-instar *P. xylostella* to feed on potted plants of *B. rapa* for 3, 6, and 24 hr (hereafter, 3, 6, and 24 hr-infested plants, respectively; Fig. 1). The infestation began at 12:00 am, during the middle of the light phase of the photoperiod. Formerly infested plants were prepared by removing the host larvae from 24 hr-infested plants and then by using the plants for experiments 48 and 72 hr after the start of the infestation (1 and 2d-after plants, respectively; Fig. 1). In every treatment, we used almost the same size larvae, showing similar feeding activity, and the areas of damage caused by the larvae were identical for a given 24 hr-infested plant and the 1d-after and 2d-after versions of that plant. Intact plants were prepared as controls, without any treatment. To produce a two-choice test design, one potted plant from a given treatment was placed ca. 10 cm from a plant that had been subjected to a different treatment inside the acrylic chamber, with the leaves not overlapping.

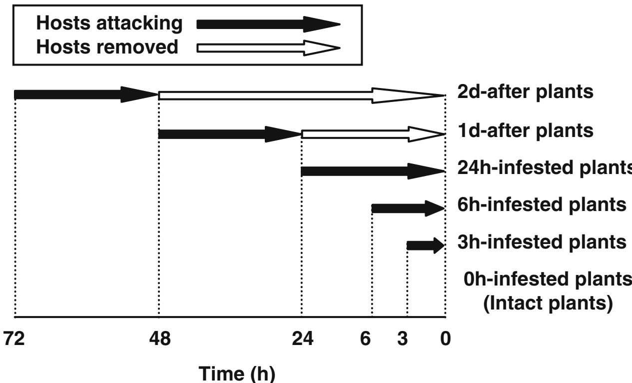

Fig. 1 Experimental time line for infestation of *Plutella xylostella.* Data were collected at various times following infestation (0, 3, 6, and 24 hr-infested plants) and following removal of larvae (1 and 2d-after plants)

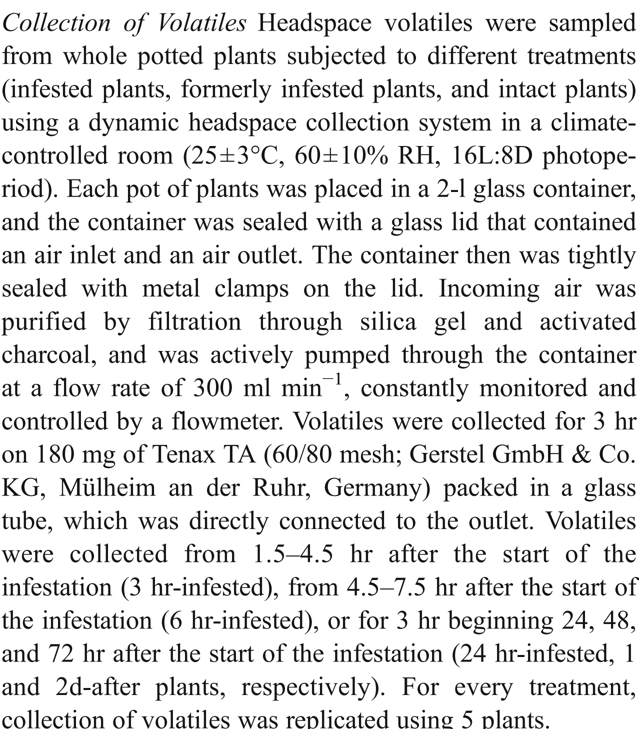
At the start of each trial, a group of 10 female parasitoids was released from glass tubes (25 mm diam, 120 mm height) at a position centered between the two pots. After hovering between the two potted plants inside the chamber, the females landed on one of the plants. The total numbers of first landings on each potted plant by the parasitoids were counted for 30 min. After landing, parasitoids were carefully removed from the chamber with an insect aspirator. A few females that did not land on any potted plants within 30 min were recorded as no-choice subjects. At the end of each test, the test chamber was wiped with 70% ethanol aq., and the inside air was flushed out with a fan to avoid potential contamination by volatiles. Another group of 10 parasitoids was tested on the same day, with the positions of the plants subjected to different treatments switched to counteract any potential positional effects. These data were pooled as a single replicate. Three replications were carried out on different days. Individual insects (60 parasitoids in all) were used only once.

To test the flight response of parasitoids to compounds that were identified from infested plants and formerly infested plants (as described in the next section), we used triethyl citrate (Wako Pure Chemical industries, Ltd., Osaka, Japan) as a solvent and prepared 1–100 mg/l solutions of the test compounds. Each solution (200 μl) was applied to two square pieces of filter paper (20× 20 mm, Advantec No. 1, Japan) that were placed together on a cover glass (24×24 mm, Matsunami No. 1, Japan), which was then placed in the pot beside the intact plants. As a control, solvent only (200 μl) was applied to filter papers on the cover glass and placed beside intact plants. The preference of the parasitoids for intact plants presented together with the synthetic compounds vs. control plants was tested in the acrylic chamber. The amount of each compound in the headspace of the plants was checked and compared with the amount in the headspace of infested plants.



Collection of Volatiles Headspace volatiles were sampled from whole potted plants subjected to different treatments (infested plants, formerly infested plants, and intact plants) using a dynamic headspace collection system in a climate-controlled room (25±3°C, 60±10% RH, 16L:8D photoperiod). Each pot of plants was placed in a 2-l glass container, and the container was sealed with a glass lid that contained an air inlet and an air outlet. The container then was tightly sealed with metal clamps on the lid. Incoming air was purified by filtration through silica gel and activated charcoal, and was actively pumped through the container at a flow rate of 300 ml min^{-1}, constantly monitored and controlled by a flowmeter. Volatiles were collected for 3 hr on 180 mg of Tenax TA (60/80 mesh; Gerstel GmbH & Co. KG, Mülheim an der Ruhr, Germany) packed in a glass tube, which was directly connected to the outlet. Volatiles were collected from 1.5–4.5 hr after the start of the infestation (3 hr-infested), from 4.5–7.5 hr after the start of the infestation (6 hr-infested), or for 3 hr beginning 24, 48, and 72 hr after the start of the infestation (24 hr-infested, 1 and 2d-after plants, respectively). For every treatment, collection of volatiles was replicated using 5 plants.

Chemical Analysis of Headspace Volatiles The headspace volatiles collected in the Tenax tubes were analyzed using a gas chromatography-mass spectrometry (GC-MS) system consisting of an Agilent 6890N gas chromatograph (Agilent Technologies, Inc., Palo Alto, CA, USA) coupled with an Agilent 5973N quadrupole mass selective detector. The collected volatiles were desorbed from the Tenax in a Thermodesorption System (Gerster, Inc.) by heating the tube from 20°C (1 min hold) to 200°C (4 min hold) at a rate of 60°C min^{-1}. The released volatile compounds were carried through a transfer line (250°C) to a Cold Injection System (Gerster, Inc.) and cryofocused at −100°C (30 sec hold). They then were heated at a rate of 12°C min^{-1} to 260°C (5 min hold) and injected by a splitless mode into an analytical capillary column (HP-5MS, 30 m×0.25 mm i.d., 0.25 μm film thickness; Agilent Technologies Inc.). Helium was used as carrier gas at a flow rate of 1.2 ml min^{-1}. The GC oven was programmed to start at 40°C (9 min hold) and then to rise at a rate of 10°C min^{-1} to 280°C (5 min hold). The column effluents were ionized by electron impact ionization (70 eV) with an ion source temperature of 250°C and monitored in the mass selective mode with a scan range from 35 to 350 m/z. Volatile compounds were identified tentatively by comparing their mass spectra with those in the Wiley Library database and further confirmed by comparing retention times and mass spectra to commercially available authentic standards (Wako Pure Chemical Industries, Ltd., Osaka, Japan and Tokyo Chemical Industry Co., Ltd., Tokyo, Japan). (*E*)-*β*-Ocimene was synthesized from (*Z*)-*β*-ocimene (available as mixture of ocimene

isomers; SAFC Supply Solutions, St. Louis, MO, USA) by isomerizing the *cis* to the *trans* configuration (Sgoutas and Kummerow 1967).

Statistics In the flight response test, significant differences between the numbers of wasps that landed on either of the two potted plants and the null hypothesis of an expected ratio of 0.5:0.5 were analyzed by using a replicated *G*-test to account for suspected heterogeneities among the replications (Sokal and Rohlf 1995). To compare the relative amounts of each volatile compound released from the plants after different treatments, the total ion peak area of each compound detected by GC-MS analysis was calculated by integration. We applied one-way analysis of variance (ANOVA), followed by Tukey's HSD test, to the results of the chemical analysis. When necessary, data were normalized using logarithmic transformation [ln $(10x + 1)$] to meet the assumptions for ANOVA. These analyses were performed using JMP software (version 7.0.1, SAS Institute Inc., Cary, NC, USA).

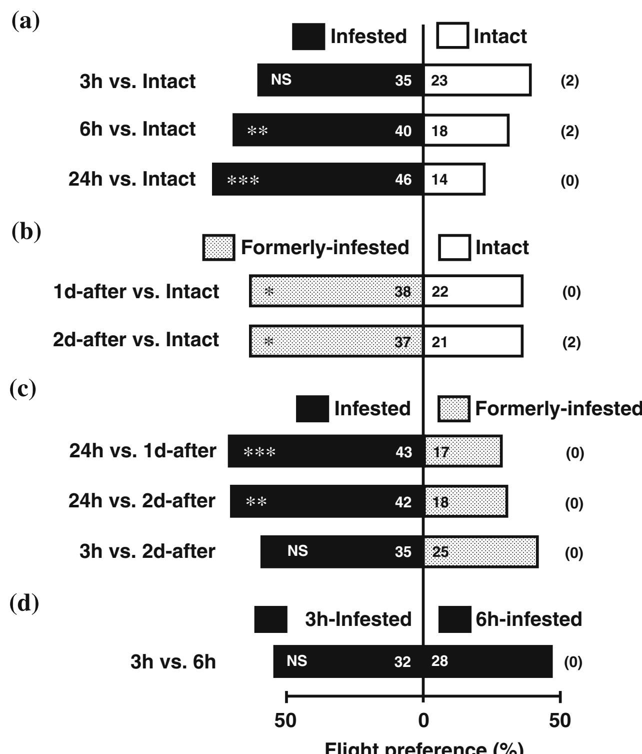


Fig. 2 Flight preferences (%) of female parasitoids *Cotesia vestalis* (N=60) among intact plants (open bars), *Plutella xylostella* larvae-infested plants (3, 6, and 24 hr: filled bars) and formerly infested plants (1 and 2d-after: dotted bars). Numbers in bars indicate the number of parasitoids that landed on each plant. Numbers in parentheses indicate parasitoids that did not choose any plants. Asterisks mean significant differences within each preference test set (replicated *G*-test; *: P<0.05, **: P<0.01, ***: P<0.001, NS = no significance)

Results

Flight Response of Parasitoids to Infested and Formerly Infested Plants Female parasitoids preferred 6 and 24 hr-infested plants over intact plants in the two-choice test (Fig. 2a) but 3 hr -infested plants were not distinguished from intact plants (Fig. 2a) or from 6 hr-infested plants (Fig. 2d). Female parasitoids also preferred 1 and 2d-after plants over intact plants, respectively (Fig. 2b). When offered both 24 hr-infested plants and formerly infested plants (1 or 2d-after) at the same time, parasitoids preferred the 24 hr-infested plants (Fig. 2c). When offered 3 hr-infested plants and 2d-after plants in the two-choice test, parasitoids showed no significant preference (Fig. 2c). There was no significant heterogeneity among replicates in any tested sets (replicated *G*-test, df=2, P>0.05 for each G_h), suggesting good reproducibility of the two-choice test.

Volatiles Released from Infested and Formerly Infested Plants Profiles of VOCs released by infested plants, formerly infested plants, and intact plants were quantitatively but not qualitatively different. In the headspace of these plants, 11 major compounds were identified by GC-MS analysis, and other unidentified minor compounds were ignored. Various alkanes and aldehydes with lengths of C9 to C24 were ignored as impurities, since they were also detected from the blank headspace. Ten compounds were identified by using authentic standards, and junipene was tentatively identified although an authentic standard was not available. The compounds included the nitrile, benzyl cyanide (Fig. 3); the sulfur-containing compounds, aryl isothiocyanate and dimethyl trisulfide (Fig. 3); the monoterpenes, myrcene, limonene, (E)-β-ocimene, and α-pinene (Fig. 4); the sesquiterpenes, (E,E)-α-farnesene and junipene (Fig. 4); and the terpenoid related ketones, 6-methyl-5-hepten-2-one and 6,10-dimethyl-5,9-undecadien-2-one (Fig. 4).

The relative amounts of benzyl cyanide (ANOVA, MS=1.885, df=5, F=27.415, P<0.001) and dimethyl trisulfide (MS=0.923, df=5, F=22.998, P<0.001) in the headspace increased after the start of the infestation (Fig. 3). The relative amounts of the four monoterpenes (myrcene, MS=0.148, df=5, F=4.662, P=0.004; limonene, MS=0.314, df=5, F=8.494, P<0.001; (E)-β-ocimene, MS=0.369, df=5, F=9.901, P<0.001; α-pinene, MS=1.144 df=5, F=9.385, P<0.001; Fig. 4), and one sesquiterpene [(E,E)-α-farnesene, MS=0.372, df=5, F=5.134, P=0.0024; Fig. 4] increased following infestation. However, no significant differences were observed in the relative amounts of the remaining compounds, aryl isothiocyanate (MS=0.401, df=5, F=2.189, P=0.089; Fig. 3), junipene (MS=0.069, df=5,

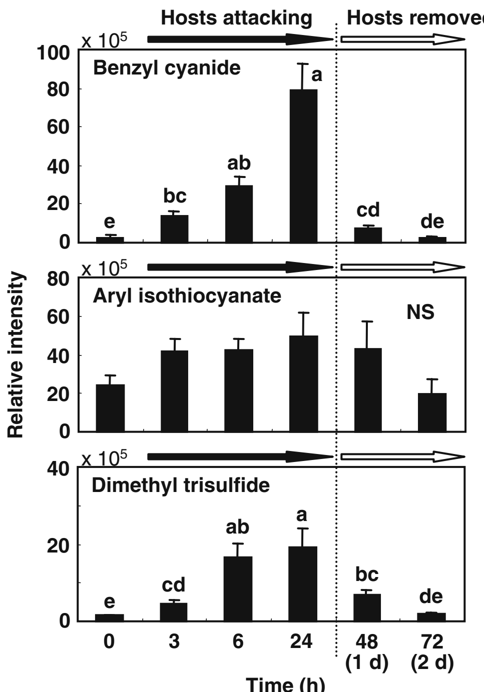

Fig. 3 Time-course indicating relative amounts of a nitrile and sulfur-containing compounds detected by GC-MS analysis of the headspace volatiles released from intact plants (0 hr), *Plutella xylostella* larvae-infested plants (3, 6, and 24 hr) and formerly infested plants (1 and 2d-after) (N=5). Different small letters mean significant differences in relative amounts of each compound (ANOVA followed by Tukey's HSD test; P<0.05, NS = no significance)

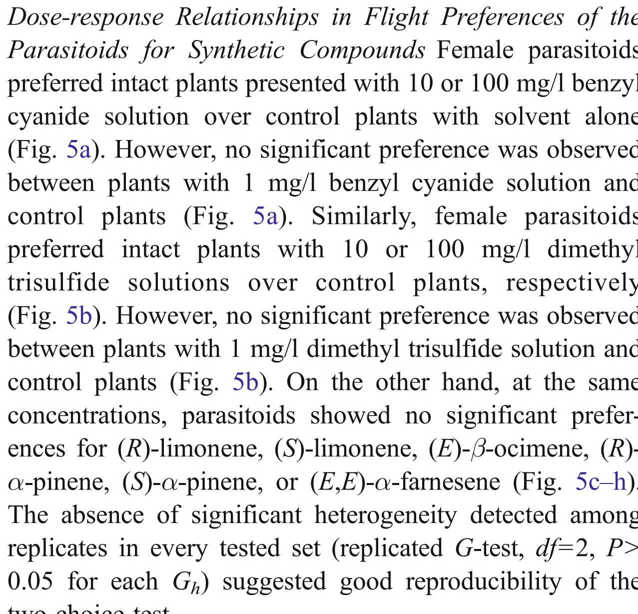
F=1.968, P=0.120; Fig. 4), 6-methyl-5-hepten-2-one (MS=0.281, df=5, F=1.354, P=0.276; Fig. 4), and 6,10-dimethyl-5,9-undecadien-2-one (MS=0.133, df=5, F= 1.118, P=0.377; Fig. 4).

The compounds with significant differences during the time-course measurements were analyzed further by using a pairwise test. In particular, benzyl cyanide, dimethyl trisulfide, (E)-β-ocimene, and α-pinene were induced as soon as 3 hr after the start of the infestation (Figs. 3 and 4). Limonene and (E,E)-α-farnesene were not induced until 24 hr after infestation (Fig. 4). After removal of the larvae, benzyl cyanide and dimethyl trisulfide decreased rapidly, and the amounts of both compounds released from 1 and 2d-after plants were smaller than those released from 24 hr-infested plants (Fig. 3). The relative amounts of the two compounds from 1d-after plants were larger than those from intact plants (Fig. 3), but the amounts in 2d-after plants did not differ significantly from intact plants (Fig. 3). In contrast, most terpenoids were released from the plants at significantly higher levels than from intact plants after the larvae had been removed (Fig. 4), and the amounts of limonene, (E)-β-ocimene, α-pinene, and (E,E)-α-farnesene released from 1 and 2d-after plants were not significantly different from those of 24 hr-infested plants (Fig. 4).



Dose-response Relationships in Flight Preferences of the Parasitoids for Synthetic Compounds Female parasitoids preferred intact plants presented with 10 or 100 mg/l benzyl cyanide solution over control plants with solvent alone (Fig. 5a). However, no significant preference was observed between plants with 1 mg/l benzyl cyanide solution and control plants (Fig. 5a). Similarly, female parasitoids preferred intact plants with 10 or 100 mg/l dimethyl trisulfide solutions over control plants, respectively (Fig. 5b). However, no significant preference was observed between plants with 1 mg/l dimethyl trisulfide solution and control plants (Fig. 5b). On the other hand, at the same concentrations, parasitoids showed no significant preferences for (R)-limonene, (S)-limonene, (E)-β-ocimene, (R)-α-pinene, (S)-α-pinene, or (E,E)-α-farnesene (Fig. 5c–h). The absence of significant heterogeneity detected among replicates in every tested set (replicated G-test, df=2, P> 0.05 for each G_h) suggested good reproducibility of the two-choice test.

The highest levels of benzyl cyanide (3.68±0.59 ng) and dimethyl trisulfide (0.50±0.16 ng) were released by 24 hr-infested plants. When intact plants were treated with 10 mg/l benzyl cyanide, levels in the headspace were approximately three-fold higher than the levels from 24 hr-infested plants. Even higher levels were detected with benzyl cyanide applied at 100 mg/l. When dimethyl trisulfide was applied at concentrations of 10 and 100 mg/l, 200–500 times the amount released from 24 hr-infested plants were detected in the headspace. The tested concentrations of other synthetic VOCs were similar to the amounts released by the infested plants detected in the headspace.

Discussion

Female *C. vestalis* parasitoids showed a significant preference for *B. rapa* plants that had been infested for 24 hr with larvae of their host herbivores, *P. xylostella*, over formerly infested plants from which the larvae had been removed (Fig. 2c). GC-MS analysis revealed that benzyl cyanide and dimethyl trisulfide were released at significantly higher levels from 24 hr-infested plants than from formerly infested plants (Fig. 3). These results suggest that the two compounds released from 24 hr-infested plants are potentially better attractants for parasitoids than the other VOCs released from formerly infested plants.

We further tested synthetic versions of benzyl cyanide and dimethyl trisulfide as strong candidates for parasitoid attraction, and found that intact plants presented together with the single compounds attracted parasitoids in a dose-dependent manner (Fig. 5a,b), in contrast to the other compounds found in the headspace (Fig. 5c–h). When

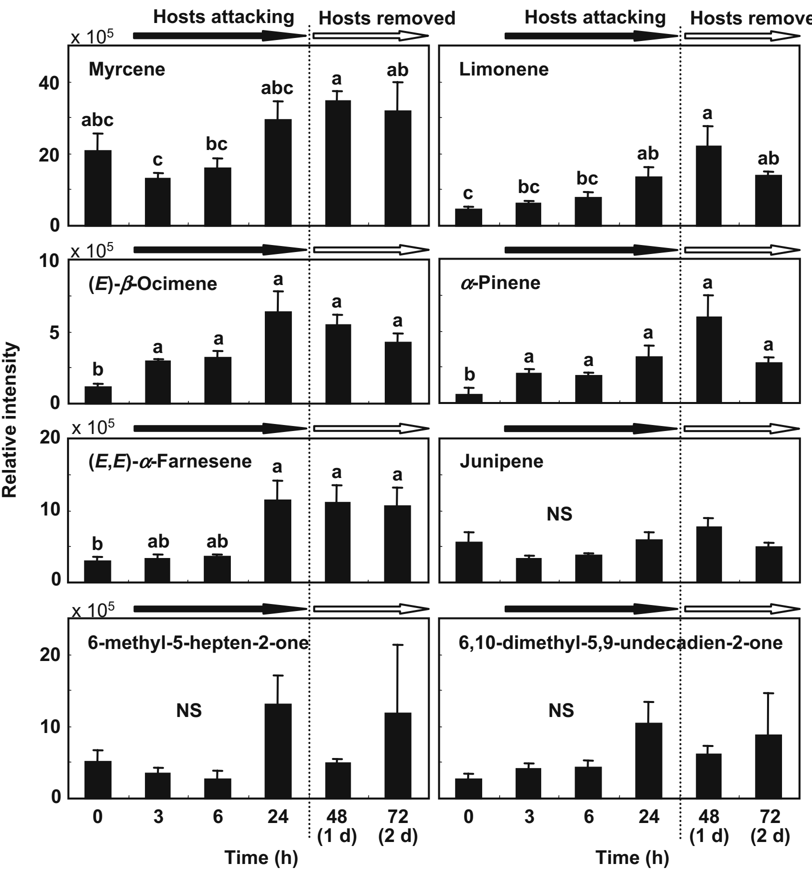


Fig. 4 Time-course indicating relative amounts of terpenoids detected by GC-MS analysis of the headspace volatiles released from intact plants (0 hr), *Plutella. xylostella* larvae-infested plants (3, 6, and 24 hr) and formerly infested plants (1 and 2d-after) (N=5). Different small letters mean significant differences in relative amounts of each compound (ANOVA followed by Tukey's HSD test; $P<$ 0.05, NS = no significance)

benzyl cyanide was applied to intact plants at the most attractive concentration (10 mg/l; Fig. 5a), its concentration in the headspace was only a few-fold higher than the concentration detected in the headspace of 24 hr-infested plants. On the other hand, when dimethyl trisulfide was applied at the attractive concentrations (10 and 100 mg/l; Fig. 5b), its concentration in the headspace was far larger than the concentration released from 24 hr-infested plants. These results suggest that although either compound can act as a parasitoid attractant, benzyl cyanide is most likely to be responsible for parasitoid discrimination between 24 hr-infested plants and formerly infested plants. Dimethyl trisulfide may have little effect at the levels normally released by these plants.

Significant differences in the amounts of VOCs detected by chemical analysis may not always result in significant preferences by parasitoids. For example, significantly larger amounts of benzyl cyanide were analytically detected from 3 hr-infested plants than from 2d-after plants (Fig. 3), but no significant preference was shown by parasitoids between these plants (Fig. 2c). Differences in the amounts of VOCs are necessary for parasitoids to discriminate between plants, but small differences sometimes may not be enough to be perceived by parasitoids with their limited sensitivity to VOCs.

Female parasitoids preferred 6 or 24 hr-infested plants over intact plants (Fig. 2a). There was also a slight, but not significant, trend in the preference for 3 hr-infested plants over intact plants. This trend is supported by the observation that parasitoids did not discriminate between 3 and 6 hr-infested plants (Fig. 2d). GC-MS analysis revealed that the emission of some VOCs was induced within a few hours of the initial damage by larvae. Together with benzyl cyanide and dimethyl trisulfide, (E)-β-ocimene and α-pinene were significantly increased in 3, 6, and 24 hr-infested plants (Fig. 4). (E)-β-Ocimene and α-pinene were not attractive to parasitoids at the tested concentrations (Fig. 5e–g), which are similar to the levels these compounds released by the infested plants. Benzyl cyanide may be the main compound that attracts parasitoids to infested plants, and dimethyl trisulfide may be of less importance. However, the relative attractiveness for parasitoids of mixtures of terpenoids with benzyl cyanide and dimethyl trisulfide has not been tested, but may be important in light of the potential ability of the parasitoids to use associative learning about VOCs (Turlings et al. 1993; Vet et al. 1995).

Formerly infested plants, which no longer had larvae, were still preferred by the parasitoids over intact plants (Fig. 2b). It appears that the plants kept releasing VOCs that attracted the parasitoids for 2 d after herbivory had

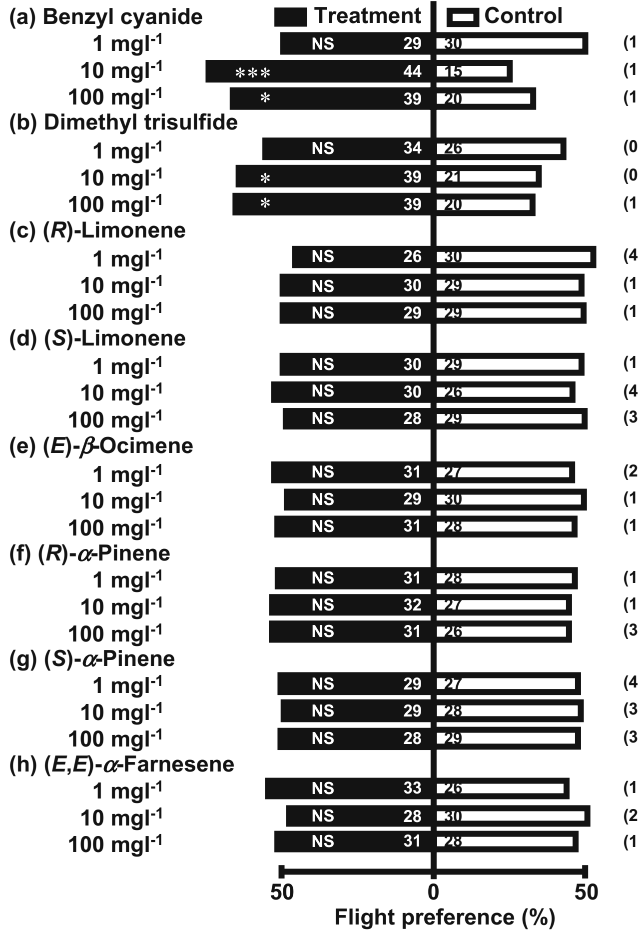

Fig. 5 Flight preferences (%) of female parasitoids *Cotesia vestalis* (N=60) between intact plants presented together with different concentrations of synthetic compounds (filled bars) and control plants (open bars). Numbers in bars indicate the number of parasitoids that landed on each plant. Numbers in parentheses indicate parasitoids that did not choose any plants. Asterisks mean significant differences within each preference test set (replicated G-test; *: $P<0.05$, ***: $P<0.001$, NS = no significance)

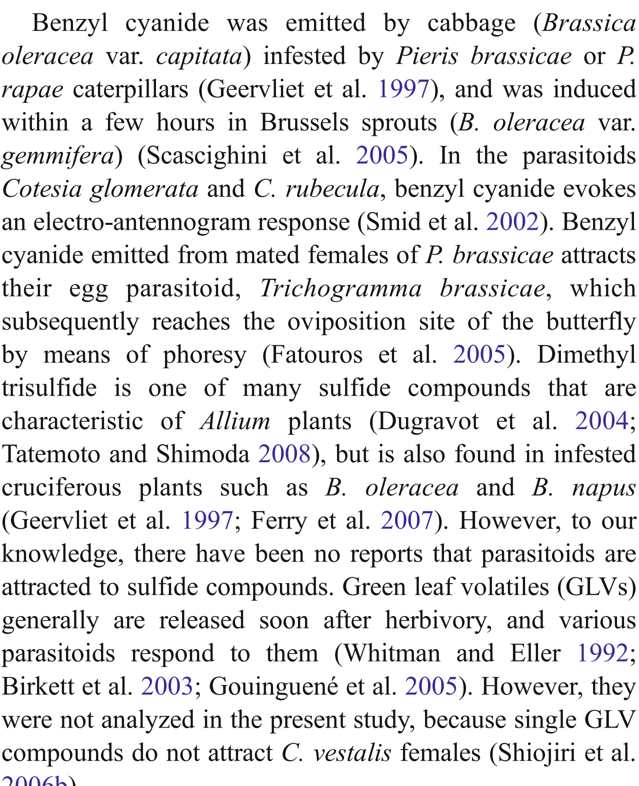
stopped. Benzyl cyanide and dimethyl trisulfide cannot explain the observed preferences, since the two compounds decreased rapidly after removal of the larvae (Fig. 3). On the other hand, terpenoids were emitted from formerly infested plants at significantly higher levels than from intact plants (Fig. 4). Ibrahim et al. (2005) reported that *C. vestalis* preferred intact cabbages plus synthetic (*R*)-(+)-limonene to control cabbages, depending on the cabbage subspecies. In this study, intact plants plus individual synthetic terpenoids, including (*R*)-(+)-limonene, did not attract parasitoids significantly (Fig. 5c–h). These results imply that a certain blend of VOCs, especially of terpenoid compounds, was responsible for the preference for formerly infested plants over intact ones. There was also another possibility that the hosts themselves and visual cues, such as damage holes, might have affected the preference for infested and formerly infested plants over intact plants.



Benzyl cyanide was emitted by cabbage (*Brassica oleracea* var. *capitata*) infested by *Pieris brassicae* or *P. rapae* caterpillars (Geervliet et al. 1997), and was induced within a few hours in Brussels sprouts (*B. oleracea* var. *gemmifera*) (Scascighini et al. 2005). In the parasitoids *Cotesia glomerata* and *C. rubecula*, benzyl cyanide evokes an electro-antennogram response (Smid et al. 2002). Benzyl cyanide emitted from mated females of *P. brassicae* attracts their egg parasitoid, *Trichogramma brassicae*, which subsequently reaches the oviposition site of the butterfly by means of phoresy (Fatouros et al. 2005). Dimethyl trisulfide is one of many sulfide compounds that are characteristic of *Allium* plants (Dugravot et al. 2004; Tatemoto and Shimoda 2008), but is also found in infested cruciferous plants such as *B. oleracea* and *B. napus* (Geervliet et al. 1997; Ferry et al. 2007). However, to our knowledge, there have been no reports that parasitoids are attracted to sulfide compounds. Green leaf volatiles (GLVs) generally are released soon after herbivory, and various parasitoids respond to them (Whitman and Eller 1992; Birkett et al. 2003; Gouinguené et al. 2005). However, they were not analyzed in the present study, because single GLV compounds do not attract *C. vestalis* females (Shiojiri et al. 2006b).

It is reasonable for parasitoids to use benzyl cyanide as a host-searching cue, since it is common in cruciferous plants as a breakdown product of glucosinolates through a rapid reaction catalyzed by myrosinase at damaged sites (Wittstock and Halkier 2002). Benzyl cyanide was not detected in feces of *P. xylostella* larvae, which can disarm consumed glucosinolates by means of glucosinolate sulfatase (Ratzka et al. 2002). Nonetheless, female parasitoids could detect benzyl cyanide released from damaged plant tissue. In addition, benzyl cyanide could be systemically inducible, like terpenoids and GLVs, through the jasmonic acid (JA) pathway as suggested for other *Brassica* species (Bruinsma et al. 2009). Further physiological studies are needed to investigate JA-dependent induction of benzyl cyanide and dimethyl trisulfide in *B. rapa*.

In the present study, we clarified the attractants for parasitoids by screening for candidates based on the relative amounts of VOCs released from plants currently under attack and from plants that were attacked in the past. Further comparative studies to identify the VOCs that attract foraging parasitoids to various plant species are necessary, to effectively use VOCs for biological control. Further studies could also reveal details of the chemical basis for the tritrophic systems that are formed in ecological processes.

Acknowledgements We are grateful to Kimiko Kanbe and Yumiko Togashi (NARC) for their help in rearing insects and cultivating plants used in the experiments. This study was partly supported by a Grant-

in-Aid for Young Scientists (B) [No. 21710241 for SK] and by a Grant-in-Aid for Scientific Research (B) [No. 19380188 for TS] from the Japan Society for the Promotion of Science (JSPS).

Abstract Feeding by herbivorous insects may change photosynthetic activity of host plants. We studied how feeding and oviposition by herbivorous stink bugs, *Murgantia histrionica* and *Nezara viridula* (Heteroptera: Pentatomidae), affect photosynthetic parameters of *Brassica oleracea* (savoy cabbage) and *Phaseolus vulgaris* (French bean). First, we measured photosynthetic gas exchange, chlorophyll fluorescence imaging, and emission of induced volatile organic compounds (VOC) immediately after feeding and during a post-feeding period. Photosynthesis decreased rapidly and substantially in *B. oleracea* and *P. vulgaris* infested by feeding bugs. Stomatal conductance did not decrease proportionally with photosynthesis; instead, inhibition of photosynthesis likely was due to a reduced diffusion of CO_2 in the mesophyll. We also measured the impact of oviposition *per se* and oviposition associated with feeding on photosynthetic parameters. A surprisingly large inhibition of photosynthesis was detected in cabbage leaves in response to oviposition by *M. histrionica*, even when oviposition was not associated with feeding activity. High resolution chlorophyll fluorescence imaging revealed that the damage to photochemistry caused by feeding and oviposition was restricted to the attacked areas. By contrast, the photochemical yield increased temporarily in the unaffected areas of the attacked leaves, indicating the onset of a compensatory response. Measurement of volatile organic compounds (VOC) revealed that feeding-damaged plants did not emit detectable amounts of VOC, indicating cellular damage (methanol and green leaf volatiles). However, feeding by *M. histrionica* induced emission of mono- and sesquiterpenes in savoy cabbage leaves. The different time-course of the induction of these two classes of terpenes may reflect the induction of two different biosynthetic pathways and indicate different roles of these terpenoids in tritrophic interactions.

Introduction

Infestation by insects can trigger complex physiological responses in plants (Nabity *et al.* 2009). In particular, the

impact of herbivorous insects on photosynthesis is variable. Different insect feeding habits (*e.g.*, chewing, piercing-sucking) contribute to this variability (Welter 1989; Peterson and Higley 2001). Where photosynthetic tissue is lost during insect feeding, both an increase (Welter 1989) and a decrease (Zangerl *et al*. 2002) of photosynthesis of the remaining leaf tissue may be observed. Water balance in the remaining tissue also may be altered after tissue loss by caterpillar feeding (Zangerl *et al*. 2002; Aldea *et al*. 2006). When no loss of photosynthetic tissues occurs (*e.g*., when piercing-sucking insects attack a plant), photosynthetic damage often is less apparent. In these cases, measurements of gas exchange (CO_2 uptake and H_2O release) have been used to show a reduction in photosynthetic rates (Burd and Elliott 1996; Haile *et al*. 1999; Macedo *et al*. 2003).

The effects of insect oviposition have received less attention than the direct impact of insect feeding activity on photosynthesis. Schröder *et al*. (2005) reported that net photosynthetic rate, electron transport rate (J_{max}), and maximum rate of Rubisco activity (V_{cmax}) of pine needles laden with eggs of an herbivorous sawfly were lower than in egg-free control plants that were not attacked. Egg deposition by herbivorous sawflies is associated with wounding of a plant since sawflies "saw" with their ovipositor into plant tissue and lay eggs into this ovipositional wound. To date, it is still unknown how insect oviposition that is not associated with ovipositional plant wounding affects photosynthesis. Furthermore, it is unknown how the combination of oviposition and feeding damage affects photosynthesis (Hilker *et al*. 2002).

In addition to gas exchange, chlorophyll fluorescence provides a powerful, non-invasive tool for investigating the effects of various stresses on the component processes of photosynthesis (Baker *et al*. 2001). One of the key parameters provided by chlorophyll fluorescence is the quantum yield of photosystem II in light-adapted leaves (Φ_{PSII}). This parameter is related to the rate of carbon fixation (Genty *et al*. 1989), and it may be used to calculate the photosynthetic electron transport rate driving photosynthesis and photorespiration (Di Marco *et al*. 1990). Damage to the photochemistry of photosynthesis also is revealed by measurements of the quantum yield in dark-adapted leaves (the ratio between variable and maximal fluorescence, F_v/F_m) and by the amount of photochemical energy lost as heat (the non-photochemical quenching of fluorescence, NPQ) (Genty and Harbinson 1996). The development of imaging fluorescence has further improved the suitability of this technique to assess damage to the photosynthetic apparatus (Baker *et al.* 2001). Imaging fluorescence indicates the topography of damage and may detect systemic damage, *i.e*., damage to parts that are not affected directly by the stressor (Chaerle *et al*. 2007). Herbivore damage to foliage frequently initiates changes in the primary photosynthetic reactions. For instance, fluorescence imaging showed that feeding by larvae of *Trichoplusia ni* (Hübner) (Lepidoptera: Noctuidae) led to reduction of Φ_{PSII} and the rate of CO_2 uptake in host plants (Zangerl *et al*. 2002; Tang *et al*. 2006).

Another indicator of damage in plants is the emission of volatile organic compounds (VOC). Several studies have shown that insects can induce or change the spectrum of volatiles emitted by plants (Karban and Baldwin 1997; Dicke and Hilker 2003). Some VOC are emitted upon damage to membranes (*e.g*., six-carbon (C6) VOC produced by lipoxygenation of membranes, often referred to as LOX compounds) or cell walls (methanol) (Loreto *et al*. 2006). Other VOC are emitted as part of sophisticated defensive strategies that have evolved and defend plants against herbivores, either directly (deterring the attack) or indirectly (*e.g*., allowing communication with predators or parasitoids of the herbivores) (Dicke and Hilker 2003). Induction of volatiles occurs locally at the site of oviposition and systemically at leaf lamina adjacent to the oviposition site (Meiners and Hilker 2000; Colazza *et al*. 2004a; Conti *et al*. 2006; Hilker and Meiners 2006).

In this study we examined how feeding, oviposition, and both feeding and oviposition by the stink bugs *Murgantia histrionica* (Hahn) and *Nezara viridula* (L.) (Heteroptera Pentatomidae) affect photosynthetic processes in two herbaceous plants, savoy cabbage, *Brassica oleracea* L., and French bean, *Phaseolus vulgaris* L., respectively. We chose these stink bugs because of their different feeding habits on host plant leaves. Preliminary observations showed that *M. histrionica* adults adopt a lacerate-and-flush feeding mode (*sensu* Miles 1972). This involves heavy damage to the mesophyll tissue due to mechanical cell laceration and extra-oral digestion by salivary enzymes (Miles 1972; Hory 2000). Conversely, *N. viridula* adults prefer to feed on leaf veins with a stylet-sheath feeding mode (*sensu* Miles 1972), destroying only a few cells and causing minimal mechanical damage (Miles 1972; Hory 2000). In contrast to their feeding modes, oviposition behavior of the two pentatomids is similar. Neither species cuts or otherwise physically damages the host substrate during oviposition; the eggs are laid in clusters on the leaf surface. Eggs are glued together and adhere to the leaf surface by a sticky oviduct secretion (Bin *et al*. 1993; Colazza *et al*. 2004b). Since oviposition habits do not differ between the pentatomid species, experiments on the effects of oviposition alone or in combination with feeding were conducted only with *M. histrionica* ovipositing on *B. oleracea.*

The influences of feeding and oviposition activities on plant leaves were investigated by measuring leaf gas exchange and by chlorophyll fluorescence imaging. The latter approach enabled us to visualize and quantify spatial variation in the components of the photosynthetic process. The emission of VOC also was measured to determine

whether VOC can provide an early indicator of damage to the photosynthetic apparatus. Furthermore, our measurements elucidated the time-course of induction of volatile molecules that may have antioxidant action (Vickers *et al*. 2009) and that may be involved in indirect defense against biotic stressors (Dicke *et al*. 2009).

Methods and Materials

Plants and Insects

Two plant—herbivore systems were used: savoy cabbage (*Brassica oleracea*), a host plant of *Murgantia histrionica*; and French bean (*Phaseolus vulgaris*), a host plant of *Nezara viridula*.

Seeds of *B. oleracea* var. sabauda (cv. Salto, kindly provided by Royal Sluis Brand) were placed individually in pots filled with peat. Seven days later, seedlings were transplanted into plastic pots filled with a mixture of inert substrates, agriperlite (BPB Vic; Agrimport, Italy) and vermiculite (Sopram, Italy). Plants were kept in a greenhouse under controlled conditions (25±3°C, 50–60% RH, 12:12 L:D), watered daily, and fertilized with a solution of Flory 9 Hydro (N-P-K 15-7-22) (Planta Regenstauf), sequestrene (NK 3–15 containing Fe EDDHA, Syngenta) and urea (Hydro Agri Italia Milano) (1 l solution: 1 g Flory 9, 0.04 g sequestrene and 0.1 g urea). All experiments were conduced with 4–5-wk-old plants with 5–6 fully expanded leaves.

Seeds of French bean plants (*P. vulgaris*, cv Lingua di Fuoco) were placed individually in plastic pots filled with fertilized commercial soil (Trflor - HOCHMOOR) and grown in a greenhouse under controlled conditions (25±3°C, 50–60% RH, 12:12 L:D). Plants were watered regularly to pot capacity and fertilized once per week with full-strength Hoagland's solution. Ten-d-old plants with 3–4 fully expanded leaves of the central plant portion of savoy cabbage and French bean were used for the experiments.

Murgantia histrionica originally was collected from cabbage in the area of Beltsville, MD, USA, in the year 2000 and maintained under quarantine conditions in a growth chamber (25±1°C, 60±5% RH, 16:8 L:D) at the entomology laboratory of the University of Perugia, Italy. The colony of *M. histrionica* was reared in plastic cages and fed on cabbage as described by Conti *et al*. (2004).

Nezara viridula adults were collected in Central Italy, and the colony was reared under laboratory conditions (25±1°C, 60±5% RH, 16:8 L:D) in a plastic cage where it was fed on sunflower seeds, seasonal fresh vegetables, and water as described by Colazza *et al*. (1999).

Mated *M. histrionica* and *N. viridula* females of the same age (10-14-d-old) were used for plant treatments.

Plant Treatment

Plants were treated by exposing single leaves to single insect females, placed on the lower surface inside a suitable "clip cage" (3.8 cm diam; 1 cm high; modified Petri dish with the rim covered by a small sponge ring). One insect per cage and two cages per plant were kept under controlled environmental conditions (25±1°C, 60±5% RH). After 8 h, the cages with insects were removed, and measurements were started.

Savoy cabbage plants were subjected to the following treatments with *M. histrionica*: a) feeding punctures, b) combination of feeding punctures and oviposition, and c) oviposition only. Gravid *M. histrionica* with excised stylets were used to obtain plants with egg masses uninjured by adult feeding activity. To excise the stylets, mated females in the pre-ovipositional state were immobilized at −4°C for ~4 min, and their stylets were drawn from the labium with an entomological pin (no. 000) and half their length amputated with precision micro-scissors under a stereomicroscope (Zeiss® Stemi SV8) illuminated by optical fiber illumination (Intralux® 5000). French bean plants were exposed to *N. viridula* to assess the impact of feeding activity only.

Measurements of gas exchange, chlorophyll fluorescence, and VOC emissions were carried out before insects started to feed (control), immediately after insect removal (time 0), and 24, 48, and 72 h after insect removal. The effect of oviposition and of the combination of feeding and oviposition was assessed 24 h after removing the insect, *i.e*., 24–32 h after oviposition. All experiments were replicated on five different plants.

Visible Injury

Evidence of insect feeding was recorded 0 and 48 h after insect removal. For observation and documentation, we used a stereomicroscope (Wild® M420) equipped with a high resolution digital camera (SIS® ColorView 12).

Gas Exchange Analyses

Gas exchange was measured in the upper lamina, using the LI-6400 Portable Photosynthesis System (Li-Cor, Lincoln, NE, USA). A portion (6 cm^2) of the leaf area on which the insect was allowed to feed and/or oviposit was clamped in a gas-exchange cuvette and exposed to a 0.44 L min^{-1} flow of synthetic air, contaminant-free and made by mixing N_2 (80%), O_2 (20%) and 400 ppm CO_2. The relative humidity within the chamber was controlled at 45–55%. Measurements were done at a photosynthetically active radiation (PAR) of 400 μmol $m^{-2}s^{-1}$ and a cuvette temperature of 25°C. Photosynthesis (A), transpiration (T), and stomatal

conductance (g_s) were calculated using the LI-6400 software from the difference between CO_2 and H_2O concentration at the cuvette inlet and outlet. Water use efficiency (WUE) was calculated as WUE = A/T. To measure VOC emissions the outlet of the cuvette was disconnected from the LI-6400 system, and the flow was diverted into a silcosteel cartridge packed with 200 mg of Tenax (Agilent, Cernusco sul Naviglio, Italy). A volume of 30 L of air was pumped through the trap at a rate of 150 mL min^{-1}. The cartridge was analyzed immediately by GC-MS (see below).

Chlorophyll Fluorescence Imaging

Chlorophyll fluorescence imaging was used as an effective indicator of invisible injury to the leaf caused by the treatments, in particular, damage to the photochemical leaf apparatus. Fluorescence images generally were taken from upper leaf part; however, in the oviposition treatment, images also were taken from the lower leaf part to better visualize the effect of eggs deposited on that leaf side (see *e.g.* Fig. 5). Images of chlorophyll fluorescence were obtained using the MINI-Imaging-PAM Chlorophyll Fluorometer (Walz, Effelrich, Germany). The MINI-Imaging-PAM employs blue LEDs, with a wavelength peak at 450 nm, for pulse modulated measuring light, continuous actinic illumination, and saturation pulse. The fluorescence signal emitted by leaves was collected by a charge-coupled device (CCD) camera with a resolution of 640×480 pixels (exposed leaf area 3×1.6 cm). Pixel value images of the fluorescence parameters were displayed with the help of a false color code ranging from black (0.000) through red, yellow, green, blue, to pink (1.000 = end scale). Leaves were dark adapted for 15 min prior to determination of minimal (F_0) and maximal (F_m) chlorophyll fluorescence. These measurements were used to calculate the maximum quantum yield of PSII photochemistry ($F_v/F_m = (F_m–F_0)/F_m$). Leaves then were exposed to actinic, moderate light intensity (371 µmol $m^{-2}s^{-1}$) and, after a steady-state fluorescence (F_s) was reached, a saturating pulse was applied to determine the maximum fluorescence (F'_m). Chlorophyll fluorescence images taken from illuminated leaves were used to calculate the operating photochemical efficiency of PSII ($\Phi_{PSII} = (F'_m–F_s)/F'_m$; Genty *et al.* 1989). Non-photochemical quenching (NPQ), which reflects thermal dissipation of excess light energy, then was calculated from $NPQ = (F_m–F'_m)/F_m$ (Bilger and Björkman 1991).

Gas Chromatography-Mass Spectrometry (GC-MS) Analyses

GC-MS analyses were performed with an Agilent 6850 gas chromatograph coupled to an Agilent 5975C Mass Selective Detector (Agilent Technologies, Wilmington, DE, USA). The GC was supplied with a thermal desorber UNITY (Markes International Limited). The GC was equipped with a splitless injector and an HP-5MS capillary column (30 m in length, 250 µm i.d. and 0.25 µm film thickness). The column oven temperature was kept at 40°C for the first 5 min, then increased by 5°C min^{-1} to 250°C, and maintained at 250°C for 2 min. Helium was used as carrier gas. The concentration of each volatile was calculated by comparison with the peak area of a gaseous standard. The GC-MS was calibrated weekly using cylinders with standard mixtures of the main isoprenoids emitted by plants at an average concentration of 60 ppb (Rivoira, Milan, Italy). Compound identification was made by using the NIST library provided with the GC/MS ChemStation software (Agilent). GC peak retention time was substantiated by analysis of parent ions and main fragments of the spectra.

Statistical Analyses

Data shown represent the means ± s.e. of measurements of five different plants. Means were analyzed by ANOVA and statistically separated by Tukey's test. Means significantly different at the 95% confidence level ($P<0.05$) are shown by different letters. The package GraphPad InStat version 3.10 for Windows was used (GraphPad Software, San Diego, CA, USA, www.graphpad.com). ANOVA *P* and *F* values, and degrees of freedom are given in figure legends. Chlorophyll fluorescence images are shown as single measurements that are representative of the mean effect of the treatment.

Results

Visible Injury

Feeding by *M. histrionica* caused visible injury to cabbage leaves. This damage was evident soon after insect removal (Fig. 1a) and did not develop further after 48 h (Fig. 1b). When examined with the stereomicroscope, the injury caused appeared as sub-circular discolored lesions that were more evident in the upper than in the lower leaf lamina. These lesions were formed by conglomerates of radial stripes starting from the central stylet puncture sites (Fig. 1c). In the lower leaf lamina, the stylet punctures were visible as black spots (Fig. 1d) with a protruding salivary sheath (flange) (Fig. 1d insert). No damage was dectectable by stereomicroscopic studies of French bean leaf lamina 0–48 h after feeding by *N. viridula*.

Gas Exchange Analyses

The effect of *M. histrionica* feeding and egg deposition on photosynthesis, stomatal conductance, transpiration, and

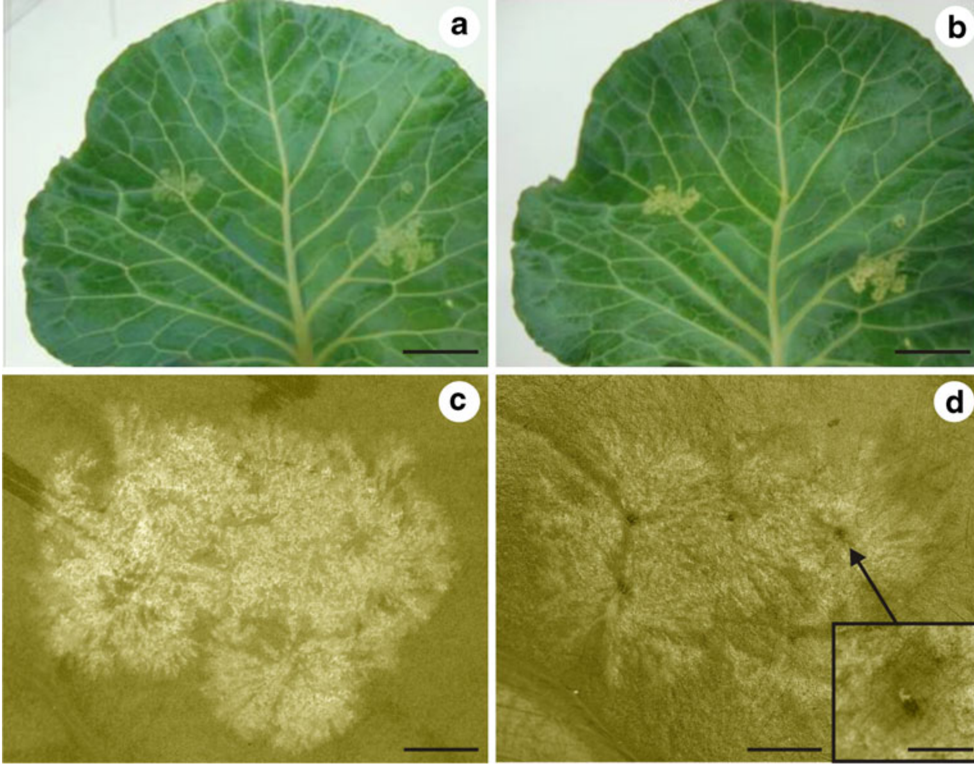

Fig. 1 Damage caused by feeding *Murgantia histrionica* adults on savoy cabbage leaves. **a** Feeding damage immediately after insect removal (time = 0 h) (scale bar = 1 cm); **b** Feeding damage 48 h after insect removal (scale bar = 1 cm); **c** Magnification of feeding damage on upper leaf lamina (time = 0 h) (scale bar = 1 mm); **d** Magnification of feeding damage on lower leaf lamina at time = 0 h (scale bar = 1 mm), inset: external salivary sheath material (flange) (scale bar = 0.5 mm) (time = 0 h)

WUE of cabbage leaves is shown in Fig. 2. Insect feeding reduced photosynthesis activity to 50% of the control leaf immediately after feeding (0 h, Fig. 2a), whereas stomatal conductance and transpiration rate were not significantly affected at this stage (Fig. 2b, c). During the post-feeding period, photosynthesis remained considerably lower than in controls, and stomatal conductance and transpiration decreased significantly reaching the lowest value 72 h after feeding. The WUE reflected the large inhibition of photosynthesis after insect feeding, decreasing dramatically immediately after feeding and slowly but incompletely recovering during the following 72 h (Fig. 2d). Photosynthesis also was measured in leaves that were offered to the insects but on which the insects did not feed. In this case, no inhibition of photosynthesis was observed (data not shown).

Oviposition by *M. histrionica* on cabbage leaves significantly reduced photosynthesis, stomatal conductance, and WUE with respect to controls (Fig. 2, hatched bars). The combination of oviposition and feeding damage resulted in the strongest negative effect in all gas exchange parameters (Fig. 2a-c, cross-hatched bars). However, as a consequence of the simultaneous and sharp decrease of photosynthesis and transpiration, WUE in these leaves remained unchanged (Fig. 2d).

Photosynthesis of bean leaves was affected strongly by *N. viridula* feeding (Fig. 3a). During the post-feeding period, photosynthesis of treated leaves recovered to some extent but remained significantly lower than in controls. Stomatal conductance and transpiration rate were slightly but not significantly reduced immediately after feeding (Fig. 3b, c). However, a statistically significant inhibition of these two parameters was found 24 and 48 h after feeding. The WUE was strongly reduced immediately after feeding, and slowly recovered during the post-feeding period (Fig. 3d). After 72 h, the WUE value was slightly lower than in control leaves but not statistically different.

Chlorophyll Fluorescence Imaging

Leaf damage inflicted by stink bug feeding was separated into light and severe symptoms by using chlorophyll fluorescence images (Fig. 4a), and in particular the F_v/F_m parameter. This is a conserved parameter in non-stressed leaves in which F_v/F_m values between 0.70–0.80 are recorded (Bjorkman and Demmig 1987). Decreases in F_v/F_m are a clear indicator of damage to the photosynthetic apparatus, which is often unrecoverable when the F_v/F_m drops to very low values (Maxwell and Johnson 2000). In our experiments, an F_v/F_m of 0.73 ± 0.005 (N=5) was recorded in control leaves and in areas of the test leaves that were distant from areas attacked by the insects of both plant species. Areas in which the F_v/F_m ratio was in the range of 0.50 to 0.70 were defined as 'light damage', and areas where the ratio F_v/F_m was less than 0.50 were defined as 'severe damage'. Immediately after feeding, the severe damage caused by *M. histrionica* was about 15% of the total damage, but this fraction increased slightly within 48 h after feeding (Fig. 4b). This increase was due not to a

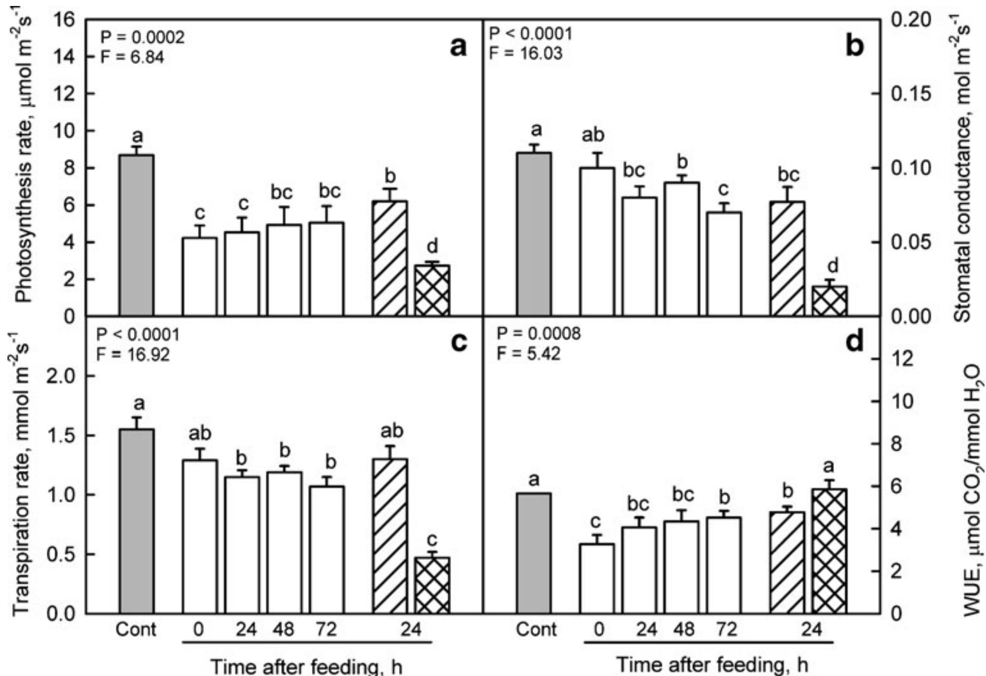

Fig. 2 Photosynthesis rate **a**, stomatal conductance **b**, transpiration rate **c**, and water use efficiency (WUE) **d** of savoy cabbage leaves after an 8 h long exposure to *Murgantia histrionica* adults. Bars represent control leaves (Cont, grey bars), leaves after feeding (white bars), leaves after oviposition (hatched bar), and leaves after oviposition and feeding (cross- hatched bar). Post-feeding measurements were carried out after 0, 24, 48, and 72 h, whereas in the cases of oviposition, and feeding and oviposition, measurements were carried out after 24 h only. Mean values ± s.e. (N=5) are given. Different letters indicate significant (P<0.05) differences as evaluated by ANOVA and Tukey's test. ANOVA degrees of freedom are the same for each plot: treatments (between columns) = 6, residuals (within columns) = 28

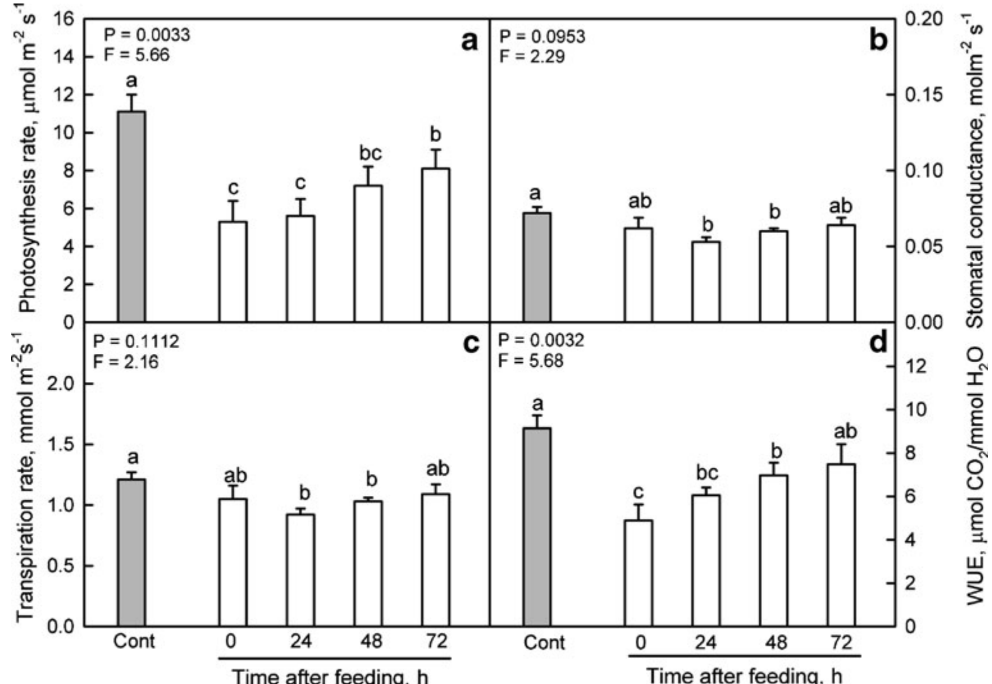

Fig. 3 Photosynthesis rate **a**, stomatal conductance **b**, transpiration rate **c** and water use efficiency (WUE) **d** of French bean leaves after an 8 h long exposure to *Nezara viridula* adults. Bars represent control leaves (Cont, grey bars) and of leaves after feeding (white bars). Post-feeding measurements were carried out after 0, 24, 48, and 72 h. Mean values ± s.e. (N=5) are given. Different letters indicate significant (P< 0.05) differences as evaluated by ANOVA and Tukey's test. ANOVA degrees of freedom are the same for each plot: treatments (between columns) = 4, residuals (within columns) = 20

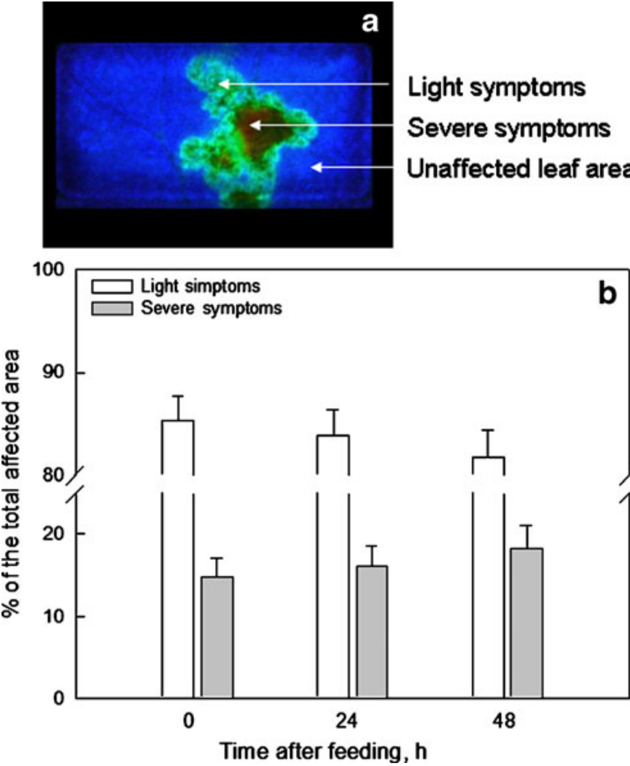

Fig. 4 Savoy cabbage leaves injured by feeding activity of *Murgantia histrionica* adults. **a** Chlorophyll fluorescence image of an attacked area. Light symptoms are defined those of areas in which the ratio F_v/F_m was in the range of 0.70 to 0.50 (green areas in our false color scale), whereas severe symptoms identify the areas in which the ratio F_v/F_m was less than 0.50, compared to the values in unaffected leaf area (0.73±0.005). **b** percentage of total feeding damage with light and severe symptoms 0, 24, or 48 h after feeding. Mean values ± s.e. (N=5) are given. Separation of means over time by ANOVA did not indicate significant differences

progressive enlargement of the damaged area but to the reduction of F_v/F_m in areas that showed only light symptoms immediately after the feeding.

Feeding damage on cabbage leaves caused by *M. histrionica* also was clearly visible by fluorescence emission measurements (Fig. 5c–h). In this case, fluorescence was used to investigate whether the damage spread beyond the areas that were visibly injured over time. There were no negative effects of herbivores on fluorescence parameters in the areas of leaves classified as unaffected (Fig. 6); by contrast, photochemical efficiency of PSII (Φ_{PSII}) of these areas slightly increased after feeding (Fig. 6c, white bars). In the leaf areas with symptoms of injury, F_v/F_m and Φ_{PSII} were reduced, particularly when the symptoms were severe (Fig. 6a, c, black bars). Interestingly, the expected increase of NPQ that generally accompanies the reduction of photochemical efficiency and the consequent dissipation of the photochemical energy (see *e.g.*, Fig. 6b, black bars) was not observed; NPQ even was reduced in the areas affected by severe symptoms.

Chlorophyll fluorescence also was measured in the cabbage leaves on which *M. histrionica* laid eggs but did not feed (Fig. 5i, j) and in leaves with both oviposition and feeding damage (Fig. 5k, l). The values of F_v/F_m of the areas surrounding the eggs were not affected significantly (Fig. 6a, hatched bar), but NPQ and Φ_{PSII} were reduced in these leaves (Fig. 6b, c, hatched bars). Again, as for gas-exchange measurements, the most negative effect was found in the leaves with co-occurring feeding damage and egg deposition, where the chlorophyll fluorescence parameters were reduced significantly (Fig. 6, cross-hatched bars).

Chlorophyll fluorescence images of French bean leaves attacked by feeding *N. viridula* are shown in Fig. 7, and quantitative fluorescence data are shown in Fig. 8. Despite the absence of visible damage induced by the feeding of this insect, the values of F_v/F_m and Φ_{PSII} were reduced

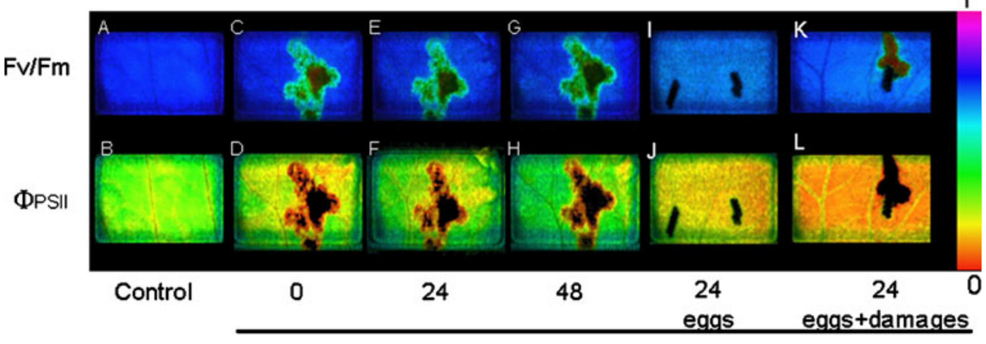

Fig. 5 Fluorescence images of savoy cabbage leaves after feeding (C–H), oviposition (I–J) and feeding and oviposition (K, L) by *Murgantia histrionica* adults. The panels show false color images of maximum photosynthetic efficiency (F_v/F_m, top) and PSII operating efficiency (Φ_{PSII}, bottom) of a control leaf (A, B) and a leaf exposed to insect (C–L). The images were taken 0 h (C–D), 24 h (E–F; I–J; K–L) and 48 h (G–H) after an 8 h long exposure to a single insect

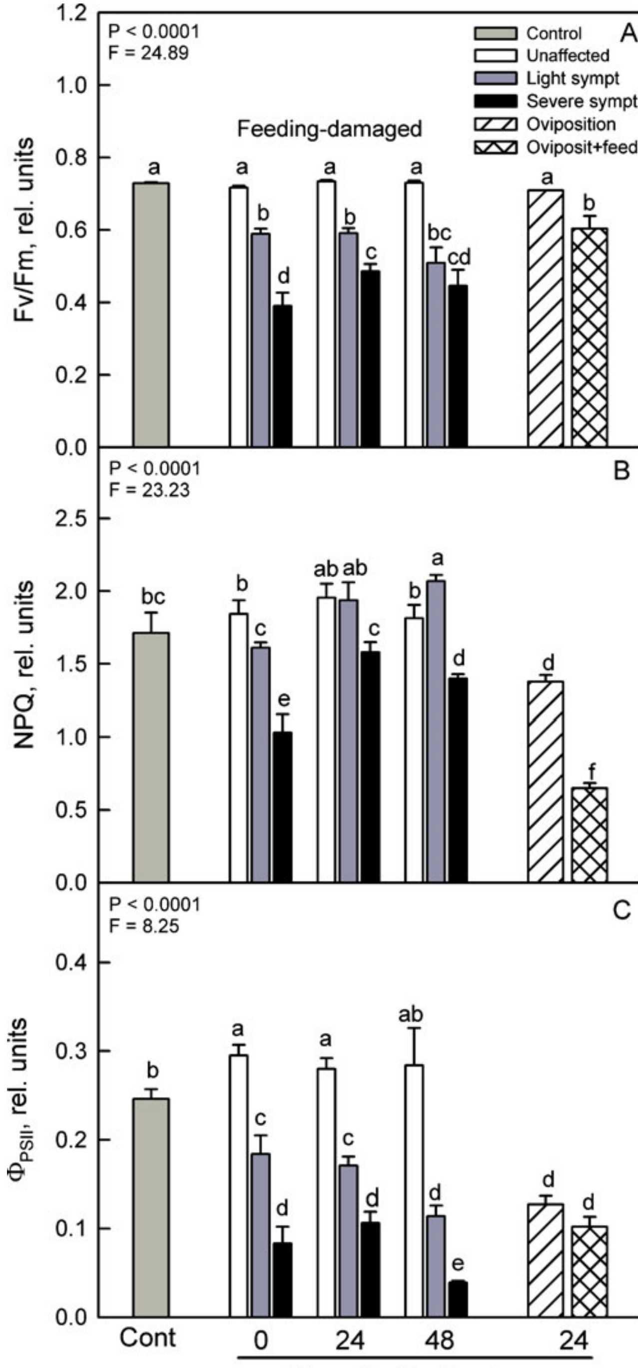
Fig. 6 Effect of *Murgantia histrionica* on chlorophyll fluorescence parameters of savoy cabbage leaves: maximum quantum yield of PSII in dark adapted leaves **a**, non-photochemical quenching **b**, and quantum efficiency of PSII in light adapted leaves **c**, in cabbage leaves. Measurements were performed 0, 24, and 48 h after feeding, and 24 h after oviposition or oviposition and feeding. Bars represent control leaves (Cont, grey bar), and leaves after feeding (color-coded bars), oviposition (hatched bar), and oviposition and feeding (cross-hatched bar). Chlorophyll fluorescence parameters were measured in leaf parts characterized with different types of injury after feeding: white—unaffected area, dark grey—light symptoms, black—severe symptoms. Mean values ± s.e. (N=5) are given. Different letters indicate significant (P<0.05) differences as evaluated by ANOVA and Tukey's test. ANOVA degrees of freedom are the same for each plot: treatments (between columns) = 10, residuals (within columns) = 48



significantly (Fig. 8a, c), and NPQ was enhanced significantly (Fig. 8b) 24 h after feeding, with respect to control leaves. The damage revealed by the fluorescence parameters was transient, as all indicators returned to pre-stress levels within 72 h after feeding.

Gas Chromatography-Mass Spectrometry (GC-MS) Analyses

VOC emissions were undetectable in control plants of cabbage and bean (Fig. 9). VOC emissions that indicate cellular damage (methanol and green leaf volatiles generated by membrane lipoxygenation) also were undetectable in both plant-insect associations. However, feeding by *M. histrionica* induced emission of monoterpenes and sesquiterpenes, among which β-phellandrene, sabinene, eucalyptol, and β-caryophyllene were the most abundant. The induction of jasmonates (methyl jasmonate, jasmonoyl-serin, jasmonoyl-leucine) also was observed, but only immediately after *M. histrionica* feeding. The time course analysis also identified significant differences among the emitted VOC. In particular, β-caryophyllene only appeared 24 h after feeding, whereas the emission of the other terpenes was observed immediately after feeding and remained high for at least 72 h after feeding. These induced terpenes were not detected in French bean leaves after feeding by *N. viridula*.

Discussion

Plant injury caused by insects with piercing-sucking mouthparts often is less evident than damage caused by chewing insects. The latter directly reduce the photosynthetic leaf lamina and induce emission of LOX that indicate damage to cell membranes (Hatanaka 1993). As a compensatory response, the remaining part of the lamina that is not attacked may present higher photosynthesis (Welter 1989). However, chlorophyll fluorescence imaging reveals that the injury caused by chewing herbivores often extends beyond the removal of the lamina, affecting adjacent tissues (Zangerl *et al*. 2002).

Piercing-sucking herbivores may feed on sap of xylem, phloem, or other plant cells. Their feeding site and the amount of tissue damage may vary considerably (Walling 2000). Visible damage often is absent when feeding is limited to a few hours (Guerrieri and Digilio 2008). Damage to photosynthesis also is expected to be lower in piercing-sucking than in chewing herbivores (Hare and Elle 2002). Photosynthesis injuries do not develop when cotton

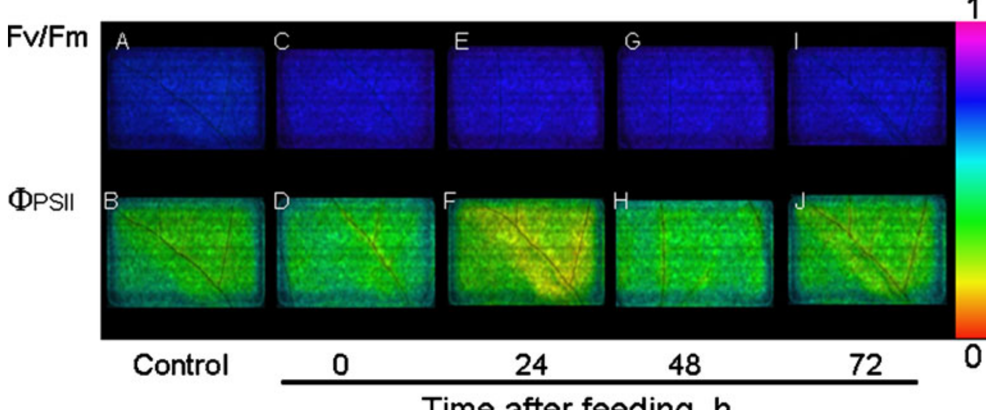


Fig. 7 Fluorescence images of French bean leaves after *Nezara viridula* feeding. The panels show false color images of maximum photosynthetic efficiency (F_v/F_m, top) and PSII operating efficiency (Φ_{PSII}, bottom) of control leaves (A, B) and of leaves exposed to insect feeding (C–J). The images were taken immediately (= 0 h) after removal of the insect (C–D), and 24 h (E–F), 48 h (G–H) and 72 h (I–J) after insect feeding

leaves are attacked by aphids for few hours (Gomez *et al*. 2006), but occur after herbivores attack a plant for several days (Reddall *et al*. 2004).

The damage caused on cabbage leaves by *M. histrionica* adults was visible immediately, whereas that provoked by *N. viridula* was not. However, both gas exchange and chlorophyll fluorescence imaging revealed substantial damage to the photosynthetic apparatus caused by both insect species. The reduction of photosynthesis following an 8-h feeding-period by a single insect was more rapid and greater than the reduction of transpiration and stomatal conductance. An increase of transpiration was observed in sugar maple seedlings attacked by thrips (Kolb *et al*. 1991). This increase was attributed to the larger conductance of gases both at stomatal and cuticular level caused by the insect punctures, and explained an unexpected increase of photosynthesis in damaged leaves (Kolb *et al*. 1991). In our experiments, however, the negative impact of insect feeding damage on photosynthesis seems to be independent of the effect on water relations. Consequently, a strong reduction of the WUE was observed immediately after feeding. WUE recovered slowly over 72 h post feeding.

Chlorophyll fluorescence imaging was used to clarify i) whether *N. viridula* feeding induced damage to the photochemistry of photosynthesis of French bean leaves, which might explain the rapid reduction of CO_2 gas exchange; and ii) whether injuries induced by both *N. viridula* and *M. histrionica* extended beyond the areas on which they actually fed, as observed for chewing insects (Zangerl *et al*. 2002). The large transient inhibition of photochemical efficiency of PSII (Fig. 8c) confirmed the substantial reduction of photosynthesis caused by *N. viridula* feeding. The limited and transient damage to the maximal quantum yield of PSII caused by *N. viridula* (Fig. 8a) indicated no permanent damage of the photochemistry. This is similar to the situation observed during photoinhibition (Powles and Björkman 1982). In *Nicotiana attenuata* feeding-damaged by *Tupiocoris notatus*, expression of genes that encode proteins involved in photosynthetic processes is up-regulated, potentially mitigating damage to photosynthesis caused by the piercing-sucking insect (Voelckel and Baldwin 2003). We observed a more complete recovery of fluorescence than of photosynthetic gas exchange after a 72-h recovery (Figs. 8c and 3a). Thus, photosynthesis is not permanently impaired by *N. viridula*, and the electron transport driving photorespiration compensates for the lower electron transport driving photosynthesis. This, in turn, suggests a lower CO_2 concentration in the chloroplasts after *N. viridula* feeding. Thus, the transient impairment of photosynthesis in *N. viridula*-fed leaves likely is caused by larger resistances to CO_2 diffusion in the mesophyll (Evans and Loreto 2000).

Murgantia histrionica caused visible and permanent damage to the leaf lamina in cabbage. As for *N. viridula*, the photosynthetic damage occurred rapidly, whereas transpiration and stomatal conductance declined more slowly; consequently, a fast reduction of WUE was observed. Because areas of *M. histrionica*-fed leaves were injured permanently, recovery of photosynthesis was incomplete. Chlorophyll fluorescence imaging allowed us to distinguish between damage with severe and light symptoms, and to follow the development of damage over 72 h after feeding. A permanent impairment of photosynthetic photochemistry was recorded in all damaged areas (see Fig. 6a, dark grey and black bars). Non-photochemical quenching of fluorescence increases when the light energy is dissipated non-radiatively and is not used for photochemistry (Bilger and Bjorkman 1991). However, in areas that suffered severe injuries, NPQ actually was reduced (Fig. 6b). This indicated permanent damage to the photochemical apparatus and inefficient dissipation of energy. Interestingly, the Φ_{PSII} of lightly and severely damaged areas did not recover during the post-feeding period, and in fact decreased over the 72 h after feeding (Fig. 6c). The recovery of photosynthesis (Fig. 2a) therefore was driven by an improved performance of the unaffected areas (Fig. 6c, white bars). This finding supports the observation that the attack of a plant by herbivores may

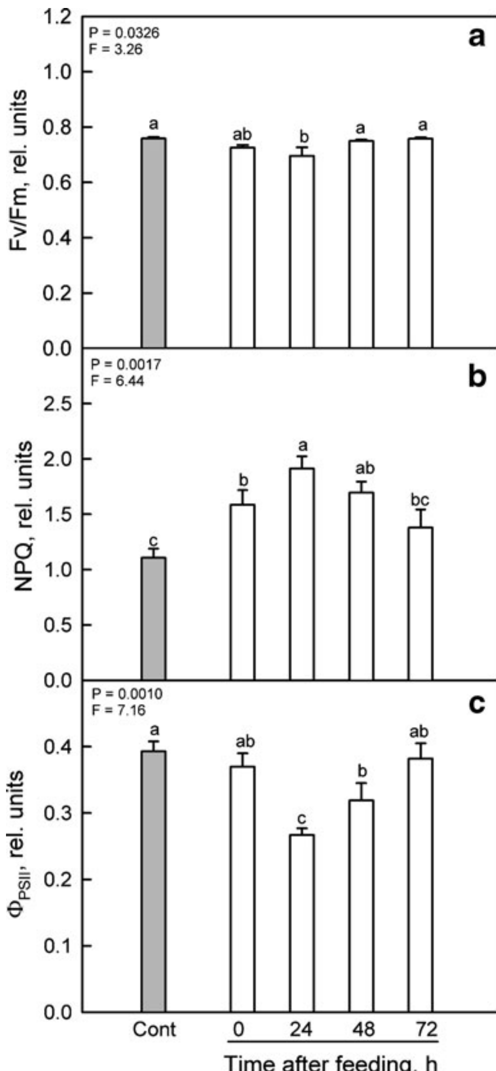

Fig. 8 Effect of feeding by *Nezara viridula* on chlorophyll fluorescence parameters of French bean leaves: maximum quantum yield of PSII in dark adapted leaves **a**, non-photochemical quenching **b**, and quantum efficiency of PSII in light adapted leaves **c**. Measurements were performed in control leaves (Cont, gray bars) and 0, 24, 48, and 72 h after feeding (white bars). Mean values ± s.e. (N=5) are given. Different letters indicate significant (P<0.05) differences as evaluated by ANOVA and Tukey's test. ANOVA degrees of freedom are the same for each plot: treatments (between columns) = 4, residuals (within columns) = 20

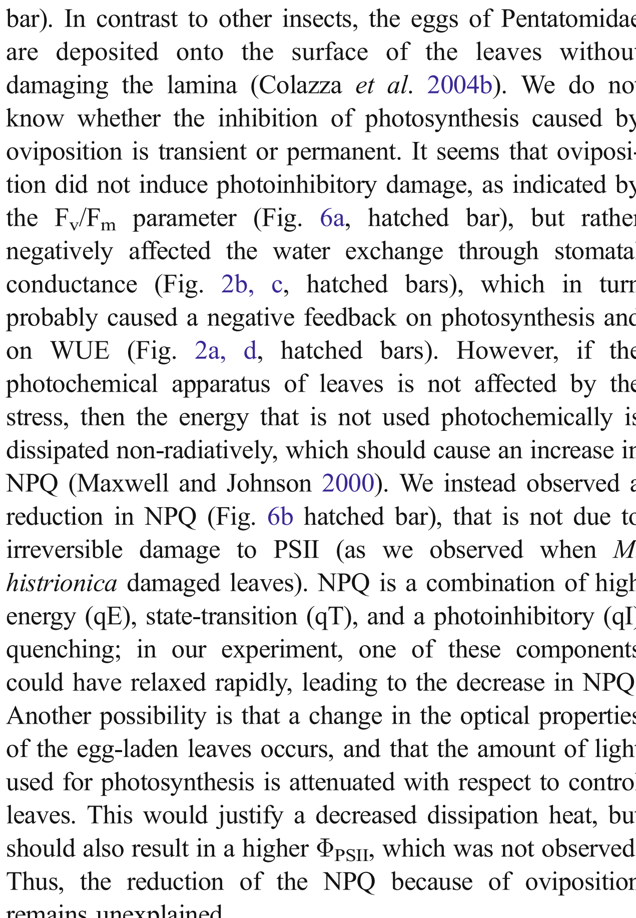
stimulate compensatory responses in parts of the leaf that are not directly affected (Voelckel and Baldwin 2003). This is not always observed. For instance, in cotton leaves infested by spider mites, stomatal conductance was reduced but photosynthetic performance was not affected (Schmidt *et al*. 2009).

Oviposition by *M. histrionica* inhibited photosynthesis. This is expected when oviposition is associated with nearby mechanical damage (Fig. 2a, cross-hatched bar). Surprisingly, however, photosynthesis also was inhibited when oviposition only (without feeding damage) occurred (Fig. 2a, hatched



bar). In contrast to other insects, the eggs of Pentatomidae are deposited onto the surface of the leaves without damaging the lamina (Colazza *et al*. 2004b). We do not know whether the inhibition of photosynthesis caused by oviposition is transient or permanent. It seems that oviposition did not induce photoinhibitory damage, as indicated by the F_v/F_m parameter (Fig. 6a, hatched bar), but rather negatively affected the water exchange through stomatal conductance (Fig. 2b, c, hatched bars), which in turn probably caused a negative feedback on photosynthesis and on WUE (Fig. 2a, d, hatched bars). However, if the photochemical apparatus of leaves is not affected by the stress, then the energy that is not used photochemically is dissipated non-radiatively, which should cause an increase in NPQ (Maxwell and Johnson 2000). We instead observed a reduction in NPQ (Fig. 6b hatched bar), that is not due to irreversible damage to PSII (as we observed when *M. histrionica* damaged leaves). NPQ is a combination of high energy (qE), state-transition (qT), and a photoinhibitory (qI) quenching; in our experiment, one of these components could have relaxed rapidly, leading to the decrease in NPQ. Another possibility is that a change in the optical properties of the egg-laden leaves occurs, and that the amount of light used for photosynthesis is attenuated with respect to control leaves. This would justify a decreased dissipation heat, but should also result in a higher Φ_{PSII}, which was not observed. Thus, the reduction of the NPQ because of oviposition remains unexplained.

Emission of induced VOC is a well-known response to biotic and abiotic stresses (Dicke and Baldwin 2010; Loreto and Schnitzler 2010). Some VOC are induced by physical damage. In particular, methanol emission results from cell

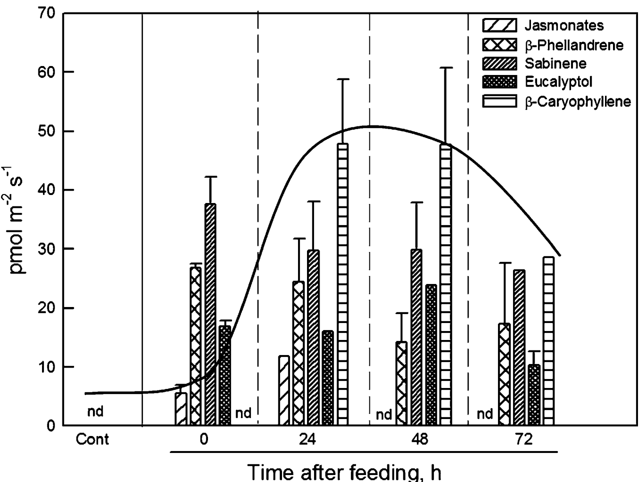


Fig. 9 Effect of feeding by *Murgantia histrionica* on the composition of induced volatile organic compounds (VOC) released from savoy cabbage plants. Measurements were carried out in control plants (Cont), and 0, 24, 48, and 72 h after feeding. Means ± s.e. (N=5) are given. The third-order best fit of β-caryophyllene emission was generated by Sigmastat

wall damage, and a family of C6 compounds results from degradation of cellular membranes (Loreto *et al*. 2006). Colazza *et al*. (2004a) and Williams *et al*. (2005) observed minimal emissions of these stress-induced compounds in leaves attacked by *N. viridula,* and they concluded that the damage caused by feeding was minor. Similarly, we also did not find detectable emissions of these compounds in leaves of *P. vulgaris* damaged by feeding *N. viridula*. Other classes of compounds are induced by biotic stresses and may serve to allow plant communication with predaceous or parasitic insects that feed on herbivores or their eggs (Dicke and Hilker 2003). For instance, *N. viridula* feeding on French beans induced an increase of the emissions of the monoterpene linalool, of the C16 homosesquiterpene (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, and of the C11 homomonoterpene 4,8-dimethyl-1,3(*E*),7-nonatriene (Colazza *et al*. 2004a). Feeding injury of maize by *N. viridula* females also induced emissions of linalool; the sesquiterpenes (*E*)-β-caryophyllene, α-trans-bergamotene, and (*E,E*)-β-farnesene; and the homoterpene (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Williams *et al*. 2005). Induced sesquiterpenes seem to act as olfactory cues that attract enemies of herbivores during tritrophic interactions (Schnee *et al*. 2006). In this study, we report the induction of several monoterpenes and sesquiterpenes, but only when cabbage leaves were attacked by feeding *M. histrionica*; in contrast to previous studies, we did not observe induction of volatiles when *N. viridula* fed upon *P. vulgaris.* It is likely that the feeding damage caused by *N. viridula* in our study was too small to induce biosynthesis and emission of defensive VOC. Alternatively, it is possible that VOC emission is absent or very low in some cultivars of French bean. This may reflect artificial or natural selection that limits carbon loss to improve productivity.

The profile of emitted compounds following the attack of *M. histrionica* confirms the observation that the lacerate-and-flush feeding mode induces classes of compounds that are more similar to those induced by chewing insects, rather than those induced by piercing-sucking insects that feed on phloem (Williams *et al*. 2005). In our study, the compound with the highest emission rate was the sesquiterpene (*E*)-β-caryophyllene. It was not observed until 24 h after feeding, as previously reported by Conti *et al*. (2008). We suggest that this delay, relative to other volatiles that are emitted immediately after feeding, reflects delayed induction, and that the maximal putative ecological activity of (*E*)-β-caryophyllene occurs 24–48 h after insect feeding.

Monoterpenes were induced more rapidly than sesquiterpenes, and their emission was sustained over the 72 h of our investigation (Fig. 9). This is more consistent with the very rapid time-course of induction that generally has been observed for insect-induced volatiles (Paré and Tumlinson 1997). Monoterpenes and sesquiterpenes are formed from two different biochemical pathways (Loreto and Schnitzler 2010). Flux through the monoterpene pathway is closely linked with photosynthesis, whereas the sesquiterpene pathway is not. Thus, the time course of the appearance of these compounds in our experiments may indicate a different rate of induction of the two pathways. This may be related to different functions for the two classes of volatiles. Unknown VOC, produced by plants attacked by *M. histrionica* (Conti *et al*. 2008), and terpenoids induced by *N. viridula* (Colazza *et al*. 2004a) act as attractants for the parasitoids *Trissolcus brochymenae* Ashmead (Conti *et al.* 2006) and *T. basalis* Wollaston (Hymenoptera: Scelionidae), respectively, which parasitize the eggs of the attacking pentatomids (Colazza *et al*. 2004b).

Finally, we note that jasmonate and its derivatives also were detected, but only immediately after the end of feeding. Jasmonates are important signaling molecules involved in a range of physiological responses; in particular, they are produced in response to plant wounding during insect attack (Browse and Howe 2008) and may trigger a range of physiological responses such as the induction of proteinase inhibitors and pathogen defense genes (Glazebrook 2005). In line with this physiological function, we observed very rapid induction of jasmonates in response to the attack of piercing-sucking insects.

Acknowledgments This work was supported by the project of the Italian Ministry of Education, University and Research (MIUR) 2007 “Enhancing foraging behaviour of insect egg parasitoids: the role of the volatile organic compounds and the epicuticular layers of the plants”. The authors are thankful to Dr. Claudia Vickers for critically reviewing the paper.

Nitrogen Deficiency Affects Bottom-Up Cascade Without Disrupting Indirect Plant Defense

Abstract Nitrogen (N) is an important macronutrient for plants and insects alike, and the availability of this critical element may considerably modify bottom-up effects in tritrophic systems. By using hydroponically cultured *Glycine max*, we investigated the impact of N deficiency on plant growth, photosynthetic efficiency, primary metabolism, and herbivore-induced volatile (VOC) emission. Cascading effects of N deficiency on higher trophic levels were assessed by measuring the performances of the herbivore *Spodoptera frugiperda* and its parasitoid *Cotesia marginiventris*. In addition, we studied the volatile-guided foraging behavior of *C. marginiventris* to explore whether nutrient stress affects the plant's indirect defense. Our results show that photosynthetic efficiency, leaf N, and soluble protein content were significantly reduced in N deficient plants whereas root biomass was increased. Nitrogen starved plants emitted the same range of herbivore-induced VOCs as control plants, but quantitative changes occurred in the release of the main compound and two other volatiles. Herbivore growth and the performance of parasitoids developing inside the affected hosts were attenuated when caterpillars fed on N deficient plants. The behavioral response of *C. marginiventris* to induced VOCs from N deficient hosts, however, remained unaffected. In summary, N stress had strong bottom-up effects over three trophic levels, but the plant's indirect defense remained intact.

Introduction

In terrestrial ecosystems, nitrogen (N) is an important macronutrient for plants. Due to soil properties, N availability can be patchy and may vary even on a small scale (Keddy 2007). Plants show plastic responses to N deficiency by profoundly reprogramming N and carbon (C) metabolism (Lou and Baldwin 2004; Scheible et al. 2004). In an effort to acquire the missing nutrients more efficiently, plants resort to altered biomass allocation between shoot and root and enhanced root branching. Deficiency also leads to sugar and starch accumulation in leaves, and exerts negative feedback on photosynthesis. Eventually, impeded uptake will lead to reduced leaf N content and a higher C/N ratio (Hermans et al. 2006).

Ecologically, a shift towards more C and less N can cause significant changes in bottom-up interactions between primary producers and subsequent trophic levels. Plant N content may affect either herbivore development directly (Scriber 1977; Fischer and Fiedler 2000; Berner et al. 2005; Coley et al. 2006), or deficiency effects can cascade up to higher trophic levels, thus altering top-down influences. Soil conditions may indirectly alter the abundance or performance of parasitoids and predators. For instance, ladybird beetles (*Aiolocaria hexaspilota*) feeding on willow leaf beetles (*Plagiodera versicolora*) had a higher adult mass and shorter developmental time when their prey was reared on leaves with high N content (Kagata et al. 2005).

A plant's nutritional quality is determined not only by the amounts of primary compounds such as proteins or carbohy-

drates but also by the levels of secondary metabolites. Both factors are intertwined as N availability may affect the synthesis of constitutive and induced defensive secondary compounds. Depending on the metabolites and plant species in question, N availability may lead to changing levels of secondary compounds (e.g., Dudt and Shure 1994; Stout et al. 1998; Hemming and Lindroth 1999; Cipollini et al. 2002; Lou and Baldwin 2004; Chen et al. 2008a).

As a response to feeding or egg deposition by herbivores, plants release volatile organic compounds (VOC), which comprise mainly fatty acid derivatives, terpenoids, phenyl propanoids, and benzenoids. Within the ecosystem, these metabolites can have multiple functions, but primarily they are known as signals that guide natural enemies to their herbivorous prey or host (Holopainen 2004; Heil 2008; Dicke 2009). The production and release of VOCs may vary considerably depending on the plant's nutritional status. Maize seedlings, for example, show decreased emissions of induced plant VOCs when N-P-K fertilization was reduced (Gouinguené and Turlings 2002). Manipulating N availability alone, however, resulted in enhanced levels of induced VOCs in maize (Schmelz et al. 2003) and cotton (Chen et al. 2008a) but not in *Nicotiana attenuata* at low levels of N (Lou and Baldwin 2004). Concentrations of the phytohormone jasmonic acid (JA) correlated negatively with N availability and positively with VOC induction, thus, it was suggested that changes in JA provide a mechanism to regulate the magnitude of plant defense responses (Chen et al. 2008a).

A blend of VOCs that varies in the composition or quantity of its components due to abiotic factors may constitute a signal with altered information content and may potentially modify the host finding behavior of natural enemies (Turlings and Wäckers 2004; Rostás and Turlings 2008). Several studies have explored the effects of abiotic factors, such as light (Maeda et al. 2000; Gouinguené and Turlings 2002), humidity (Gouinguené and Turlings 2002), carbon dioxide (Vuorinen et al. 2004b), UV radiation (Winter and Rostás 2008; Blande et al. 2009), ozone (Vuorinen et al. 2004a), or nutrient supply (Gouinguené and Turlings 2002) on VOC induction. Only some of these also have tested whether altered VOC blends affect parasitoid or predator attraction (Maeda et al. 2000; Vuorinen et al. 2004a, b; Winter and Rostás 2008; Blande et al. 2009). However, behavioral experiments are necessary to understand whether a given abiotic factor has the potential to disrupt the facultative mutualism between plants and natural enemies. Changes in the release rate of certain compounds do not automatically translate into differential host searching behavior (Rostás et al. 2006), while stronger or weaker attraction may not always be reflected by detectable changes in the measured VOCs of an induced plant (Gouinguené et al. 2005; Rostás and Turlings 2008; D'Alessandro et al. 2009).

Soybean plants (*Glycine max*) demand high amounts of N, and a large proportion of it is acquired from N-fixing rhizobacteria. This makes soybean generally less dependent on soil N, but nevertheless, deficiency may occur in patches where appropriate symbionts are lacking or whenever plants and bacteria fail to establish good root nodulation. Unfavorable environmental conditions or fungicide application has been shown to reduce strongly root nodulation and thus nitrogen acquisition (Roth 2009; Zilli et al. 2009).

Here, we addressed the question, whether N deficiency would result in significant bottom-up effects in a tritrophic system consisting of soybean, the herbivore *Spodoptera frugiperda,* and its larval parasitoid *Cotesia marginiventris.* In addition to direct effects on the growth, development, survival, and longevity of plants and insects, we focused on the impact of low N availability on the quantity and quality of herbivore induced plant VOC and the attractiveness of the blends for host searching parasitoids.

Methods and Materials

Plant and Insect Material Soybean seeds (*Glycine max* (L) Merr. cv. London) were obtained from Saatbau Linz (Leonding, Austria). Seedlings were grown in plastic trays (30×20×4.5 cm, Wiesauplast, Wiesau, Germany) containing silica sand for 14–16 d and then subjected to N treatments. Further rearing conditions of plants and insects are described in Winter and Rostás (2008).

Nitrogen Treatments After 14–16 d, plants (V 1 stage, McWilliams et al. 1999) were removed carefully from the sand, and roots were rinsed with deionized water. All seedlings then were transferred to black plastic containers (30.5×20.3×13.3 cm, Rotilabo® Drehstapelwanne, Carl Roth, Karlsruhe, Germany) containing 5.6 l of hydroponic solution, aerated with a membrane pump. Fifteen plants were grown in each container with a distance of 7 cm between each individual. The hydroponic solution was exchanged every 3–4 d. To maintain appropriate salt concentrations and pH of the solution, electric conductivity (EC) and pH were regularly controlled with a combined pH/EC tester (Combo 2, Carl Roth, Karlsruhe, Germany). EC was adjusted to 2.2 mS, pH was kept at 5.9–6.1.

Plants were exposed for 5 d to a modified Hoagland solution (Hoagland and Arnon 1938). For plants growing in nitrogen deficient solution (–N treatment), KNO_3 was replaced with K_2SO_4 (Carl Roth, Karlsruhe, Germany), and $Ca(NO_3)_2$ with $CaCl_2$ (AppliChem, Darmstadt, Germany) in equivalent concentrations.

Effects of Nitrogen Deficiency on Plant Growth and Physiology The effect of N deficiency on growth and

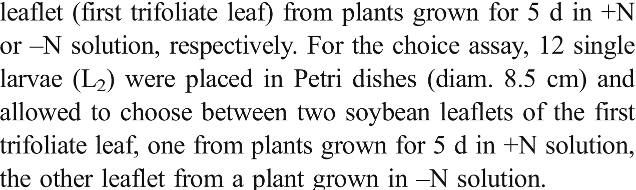
physiology of soybean was assessed by exposing plants to the respective N treatments for 5 d. Then, shoots and roots of six plants per treatment were freeze-dried for 48 h and weighed to calculate shoot-to-root-ratios. Eight plants per treatment grown in the same cohort were used to determine C/N-ratios and concentrations of soluble proteins in the leaves. For this, leaf discs were cut out with a cork borer (diam 17.8 mm) from unifoliate leaves, freeze-dried, weighed, and ground. Half of the material was used to analyze total C and N content by quantitative decomposition of substances by oxidative combustion (CHN-O-Rapid, Heraeus, Hanau, Germany). The other half was extracted 3 × with 500 µl deionized water. Extracts were combined, and soluble protein content was determined with Bradford reagent (Sigma-Aldrich, Seelze, Germany) using bovine serum albumin (1.4 mg ml^{-1} in water) as standard. Samples were arranged in a 96 well plate, and absorbance was measured with a photometer (Multiskan EX, Thermo Labsystems, Vantaa, Finland) at 595 nm.

To assess the effects of N limitation on the photosynthetic efficiency of soybean, the adaxial leaf side of the first trifoliate leaf of 5 plants per treatment was examined with a PAM-2000 fluorometer (Walz Mess–u. Regeltechnik, Effeltrich, Germany). Maximum photochemical yield of photosystem II (PSII) was measured in dark-adapted leaves as the ratio of variable (Fv) to maximal (F_M) chlorophyll fluorescence at room temperature with Fv/F_M = (F_M - F_0)/F_M (Schreiber et al. 1986). Minimum fluorescence (F_0) was excited at 655 nm and 600 Hz modulation frequency, and maximum fluorescence (F_M) was measured with 100 kHz modulation frequency. The F_M was elicited by saturating pulses of 0.8 s duration from a built-in halogen lamp.

Plant-Mediated Effects of Nitrogen Deficiency on Herbivore Growth, Developmental Time, Survival and Feeding Behavior An herbivore performance test was conducted to assess the effects of plant N limitation. Fifty neonate larvae of *Spodoptera frugiperda* were weighed and kept individually in Petri dishes (diam. 8.5 cm) with moistened filter paper in a climate chamber as described above. They were fed *ad libitum* with fresh cut leaflets of the first trifoliate soybean leaves from plants kept for 5 d in +N or –N solution. Each plant was harvested only once. Weight increases of larvae were measured between day 5 and 6 (L_2) and day 10 and 11 (L_3). In addition, pupal and adult weights, as well as developmental times were recorded.

Two feeding trials were performed to see whether larvae (L_2) compensated for potentially lower food quality due to N limitation by ingesting larger quantities of leaf tissue (no-choice assay), or by choosing food with potentially higher quality (choice assay).

For the no-choice assay, 15 single larvae (L_2) were placed in Petri dishes (diam. 8.5 cm) and fed with one soybean



leaflet (first trifoliate leaf) from plants grown for 5 d in +N or –N solution, respectively. For the choice assay, 12 single larvae (L_2) were placed in Petri dishes (diam. 8.5 cm) and allowed to choose between two soybean leaflets of the first trifoliate leaf, one from plants grown for 5 d in +N solution, the other leaflet from a plant grown in –N solution.

After 24 h, leaf consumption was measured by scanning the leaves and calculating the removed areas as described in Rostás et al. (2006).

For C/N analyses, another cohort of 8 neonate larvae was treated as described for the performance test. After 6 and 15 d, respectively, the larvae were starved for 1 hr, frozen, freeze dried, and ground. Total C and N content was analysed as described above.

Herbivore-Mediated Effects of Plant Nitrogen Deficiency on Parasitoid Growth, Developmental Time and Longevity The developmental time, growth, and longevity of the parasitoid *Cotesia marginiventris* developing inside *S. frugiperda* was measured to assess host-mediated effects of plant N limitation. Three-day old *S. frugiperda* larvae were fed with freshly cut soybean leaves of the respective N treatment for 2 d. The larvae then were offered in six groups of 5 to a 4–6 d old mated *C. marginiventris* female in a Petri dish (diam. 5.5 cm). After parasitism of 15 larvae per treatment was observed, caterpillars were kept separately in Petri dishes (diam. 8.5 cm) with moist filter paper and fed *ad libitum* with freshly cut leaves from +N or –N plants. Food was exchanged at least every 2nd day. Emerging parasitoid cocoons were transferred to individual Petri dishes (diam. 5.5 cm) with dry filter paper. Eclosed parasitoids were provided with water only. Developmental time, pupal weight at 24 hr post emergence, and longevity of the adult parasitoids were recorded.

Plant-Mediated Nitrogen Effects on VOC Emission and Parasitoid Behavior The effects of N limitation on the emission of herbivore-induced volatiles and consequently on the behavior of the parasitoid was investigated in a six-arm-olfactometer (for details see Turlings et al. 2004). Soybean plants exposed for five days were placed individually into the cup of an odor source vessel of the six-arm-olfactometer and provided with approximately 50 ml of the accordant hydroponic solution. The cup was covered with two semicircular polycarbonate plugs that had an opening in the center to hold the plant in an upright position and to prevent larvae from falling into the solution. Twenty-five *S. frugiperda* larvae (L_2) were placed on each plant and were allowed to feed overnight (approx. 16 hr). On the following day, volatile collections and behavioral assays were carried out simultaneously from 9:00 AM till 12:00 AM. Ten fluorescent lamps (PAR inside odor source vessels: 130 µmol photons m^{-2} sec^{-1} at 30 cm distance from

lamps) were switched on 3 hr before testing the wasps. Odor source vessels containing a plant that had received either +N or –N treatment were placed vis-à-vis in the olfactometer. The other four vessels remained empty as controls. After connecting the vessels to the air delivery and the olfactometer, the air stream was allowed to stabilize for 10 min. The flow rate was 1.2 l min^{-1} for incoming air and 0.6 l min^{-1} for air going out to the behavioral arena or the volatile traps, respectively.

Mated 3–5 d old females of *C. marginiventris* were used in the behavioral assays. Wasps had no oviposition experience prior to the experiment. All wasps were tested in groups of 6, as they do not interfere with each other's choices (Turlings et al. 2004). After 30 min, the choices made by the parasitoids were recorded, and the group was replaced by a new one. Five groups of wasps were tested on the same day. One day with 5 releases was considered as one replicate. Six replicate days were carried out with a new pair of plants and new wasps each day. Volatiles emanating from soybeans were collected with SuperQ traps as described previously (Rostás and Eggert 2008). After each experimental day, the glass and teflon parts of the olfactometer were cleaned with deionized water and rinsed with ethanol (v/v 70%), acetone, and hexane. After evaporation of the solvents, all glass parts were placed in an oven at 200°C for 1 hr.

Trapped volatiles were eluted with 150 µl methylene chloride. Two internal standards (*n*-octane and nonyl acetate, Sigma-Aldrich, Taufkirchen, Germany, 400 ng each in 20 µl methylene chloride), were added, and the samples were stored at −80°C. The qualitative and quantitative volatile composition of each sample was analyzed on an Agilent Technologies 6890N Network GC System coupled with a 5973 Network Mass Selective Detector. Three µl of each sample were injected with an automated injection system in pulsed splitless mode. The column was an Agilent 19091-s933 HP-1 capillary column (length 30 m, diam 0.25 mm, film thickness 0.25 µm). The oven was held at 35°C for 3 min and then increased with 8°C min^{-1} to a final temperature of 230°C that was held for 10 min. Helium (1.5 ml min^{-1}) was used as carrier gas. Compounds were identified using MSD ChemStation (Agilent Technologies) software with the Wiley 275 mass spectrum library and by using the software MassFinder3/Terpenoids library (Hochmuth Scientific Software, Hamburg, Germany). Identities were confirmed further by co-injection of authentic standards (Sigma-Aldrich, Taufkirchen, Germany). Quantification was obtained by comparing the area of the compounds to the areas of the internal standards.

Statistical Analyses Plant parameters were analyzed with a Mann-Whitney-*U*-test. Values of plant C/N ratios and soluble protein contents were Bonferroni corrected prior to the analyses. Performance parameters of *S. frugiperda* and *C. marginiventris* were compared with ANCOVA using initial weight of *S. frugiperda* as covariable and measured performance parameters as variables. Herbivore mortality was analyzed with a χ^2-test.

Plant photosynthetic efficiency, larval feeding in the no-choice assay, larval C/N ratios, and differences in VOC compositions were analyzed with Student's *t*-tests for independent samples. Only VOCs occurring in at least 50% of all samples were analyzed statistically. Larval feeding in the choice assay was assessed with a *t*-test for dependent samples. The analyses were conducted using the STATISTICA 7.1 software package (StatSoft, Tulsa, OK, USA).

For the six-arm-olfactometer, the entity computing a repetition in the statistical analysis corresponds to the response of a group of 6 wasps released, which was shown to follow a multinomial distribution (Ricard and Davison 2007). As the data did not conform to simple variance assumptions implied in using the multinomial distribution, we used quasilikelihood functions to compensate for the overdispersion of parasitoids within the olfactometer. The model was fitted by maximum quasi-likelihood estimation in the software package R (http://www.R-project.org), and its adequacy was assessed through likelihood ratio statistics and examination of residuals (Turlings et al. 2004).

Results

Effects of Nitrogen Limitation on Plant Morphology and Physiology Plants exposed to –N conditions for 5 d showed a significantly decreased shoot-to-root ratio due to increased root biomass (dry weight) compared to +N exposed plants (Table 1). In leaves of –N plants, the amounts of soluble proteins were reduced significantly whereas the C/N ratio was increased due to a lower N content (Table 1). Maximum photochemical efficiency of PS II, measured as F_V/F_M, was reduced significantly in –N compared to +N treated plants (Table 1).

Plant-Mediated Nitrogen Effects on Herbivore Growth, Developmental Time, Survival, and Behavior Herbivore larvae fed with leaves from N deficient plants gained significantly less biomass during their development, which resulted in significantly lower pupal and adult weights (Table 2). The C/N ratios in these larvae were reduced compared to larvae fed with +N treated plants. However, developmental time (Table 2), as well as larval mortality (χ^2 test, χ^2=0.08, *df*=1, *P*>0.5) and successful adult emergence (χ^2 test, χ^2=0.35, *df*=1, *P*>0.5), were not influenced by plant N limitation. In choice and no-choice tests, the

larvae did not consume significantly more leaf tissue from –N treated than from +N treated plants (Fig. 1).

Plant-Mediated Nitrogen Effects on Parasitoid Growth, Developmental Time, and Longevity Individuals of *C. marginiventris* reared in caterpillars of *S. frugiperda*, which in turn were fed with leaves from –N treated soybeans, had significantly lower pupal weights. Developmental time and longevity did not differ between wasps reared in herbivore larvae fed with +N or –N treated leaves (Table 3).

Plant-Mediated Nitrogen Effects on VOC Emission and Parasitoid Behavior In both N treatments, only trace amounts of (*E,E*)-α-farnesene could be detected from undamaged soybean plants. In contrast, plants damaged by *S. frugiperda* larvae released 22 different compounds of which 18 were identified (Fig. 2). The main constituents were (*E,E*)-α-farnesene (20% and 41% of total emission for +N and –N plants, respectively) and indole (24% and 12% of total emission for +N and –N plants, respectively) when emission was corrected for plant fresh weight. While the same compounds were emitted by +N and –N treated soybean plants, three substances were released in significantly different amounts. The release rates of the sesquiterpenes β-bergamotene and (*E,E*)-α-farnesene were approx. five times (t=−2.51. df=10, P<0.05) and three times (t=−2.64. df=18, P<0.05) higher in –N plants than in +N plants. In contrast, a 50% decrease was observed in the emission of (*Z*)-3-hexenyl-α-methylbutyrate (t=2.30. df= 10, P<0.05). All other volatiles were released in similar amounts. The statistical values given here refer to emission rates corrected for plant fresh weight, but the same pattern was obtained for uncorrected values (Student's-*t*-test). Differences in the quantities of the three volatiles did not cause a significant shift in overall emission.

Naïve females of *C. marginiventris* were highly attracted by the herbivore-induced volatiles of both +N and –N-treated plants when compared to clean air. But wasps had no preference for either one of the offered plant odors (log-linear- model, P>0.05, N=6, Fig. 3).

Discussion

Deficiency in N severely affected the morphology and physiology of soybeans. In our study, plants lacking N increased their root biomass while shoot biomass remained

unchanged (Table 1). Shifting the root-shoot-ratio is a well known response to low N availability and is considered to be an adaptation to suboptimal substrates which allows plants to more efficiently absorb nitrate from the soil (Schopfer and Brennicke 2005; Hill et al. 2006). It has been proposed that changes in phytohormonal balances in conjunction with sugar signals orchestrate cell division and differentiation, thus leading to optimized root morphology (Hermans et al. 2006).

We found that shortage in N supply negatively affected photosynthesis as indicated by the reduced maximum photochemical efficiency of PSII (Table 1). These results corroborate several studies that have used chlorophyll fluorescence to monitor the responses to N deprivation (Lu and Zhang 2000; Kumagai et al. 2007). Deficiency downregulates open PS II reaction centers and leads to increased light induced non-photochemical quenching and enhanced susceptibility to photoinhibition (Lu and Zhang 2000). A lack in chlorophyll content and ribulose-1, 5-bisphosphate-carboxylase/-oxygenase (RuBisCo), the most abundant protein in plants, is likely to also have contributed to a decline in photosynthesis. Chlorophyll and RuBisCo were not measured specifically, but leaves of soybeans exposed to N stress had lower leaf N levels, contained less protein (Table 1), and were lighter in color.

Negative effects on the leaf's N and protein content correlated with poor growth of *S. frugiperda* larvae. Caterpillars fed with –N leaves gained less weight during their development and had reduced pupal and adult weights compared to larvae reared on +N leaves (Table 2). Similar results were reported from *Spodoptera exigua* developing on N deficient cotton (Chen et al. 2008b) or larvae of other Lepidoptera feeding on several host plants (Coley et al. 2006). However, studies exist where the correlation between food N content and herbivore growth is less consistent, implying that N is a limiting nutrient for larval development, but not the only one (Tabashnik 1982). Clancy (1992) hypothesized that host plant N determines the amount of food ingested and thus affects the amount of other nutrients incorporated, resulting in an altered growth

rate and survival rates of the herbivore caused by a deficiency of other nutrients than N.

Interestingly, despite poorer growth on –N leaves, *S. frugiperda* larvae did not prefer the superior food when both types of leaves were offered in a dual-choice assay, nor did they show any compensational feeding in a no-choice setup (Fig. 1). This contrasts with findings reported by Chen et al.(2008b) and Merkx-Jacques et al.(2008) who found that *S. exigua* larvae opted for leaves of high N content or a protein-biased diet, respectively. The incongruent feeding behavior of the two species may reflect their different feeding preferences. Larvae of *S. exigua*, for instance, are known to prefer leaves while *S. frugiperda* may often change to fruiting structures when available.

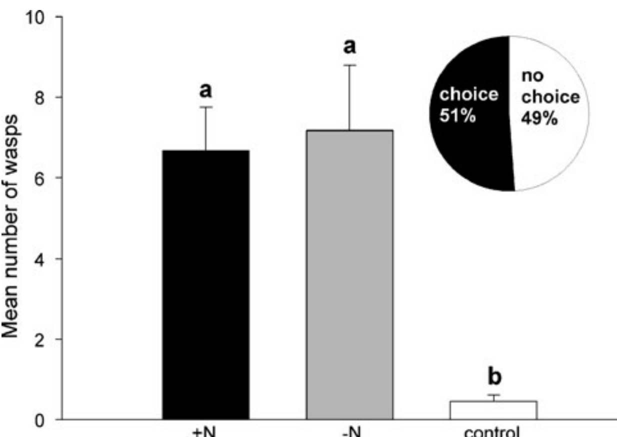

Fig. 3 Response of naïve *Cotesia marginiventris* to herbivore induced volatiles of soybean. Plants were reared in either full (+N) or nitrogen deficient (–N) Hoagland solution. Control was clean air; total numbers of wasps choosing one of the four control arms were divided by four. Bars represent mean (+SE) numbers of wasps making a choice in the olfactometer. Different letters indicate statistically significant differences (Log-linear model fitted to quasipoisson distribution; $N=6$ independent experiments with 30 wasps each). Pie chart shows mean percentage of wasps making a choice

The impact of N deficiency on the first trophic level was transmitted indirectly to the third trophic level as the growth of *C. marginiventris* also was affected. Parasitoids had significantly lower pupal and adult weights when their hosts had fed on N-deprived soybean leaves (Table 3). Pupal weight often is correlated with fecundity and consequently with fitness (Bourchier 1991). Thus, females of *C. marginiventris* that hatch from poor hosts may be expected to produce fewer eggs and have fewer offspring. Plant quality is crucial for the performance and fertility of parasitoids in many cases (Campan and Benrey 2004; Setamou et al. 2005; Caron et al. 2008; Sarfraz et al. 2008). *Cotesia flavipes* had a higher mean progeny size on its host *Chilo partellus,* when this was reared on cultivated compared to wild gramineous plants (Setamou et al. 2005). Eventually, the effect of poor plant quality on parasitoid fitness depends on the species' life history. Gregarious, koinobiont parasitoids, for instance, should be affected more strongly than solitary parasitoids when choosing poor hosts. They spend a considerable amount of time in examining their hosts and will lay their eggs in one or relatively few individuals (Brodeur and Boivin 2004). In contrast, females of the generalist, solitary endoparasitoid *C. marginiventris* allocate their offspring to many caterpillars by feeding on different host plants and thus reducing the fitness costs imposed by parasitizing an inferior host. Nevertheless, fitness costs could be substantial if a larger patch is affected by N deficiency and if wasps forage exclusively within this patch.

The host foraging behavior of parasitoid wasps is influenced by herbivore-induced plant VOCs, which are used as signals to locate those particular plants that are infested by herbivores. Soybeans grown in N deficient hydroponic solution emitted the same spectrum of herbivore-induced VOCs as fertilized plants. However, quantitative changes were found for some VOCs. Low N availability led to more than three times higher emission rates of the main compound (*E,E*)-α-farnesene, and significantly increased the release of the sesquiterpene β-bergamotene. Emission of the green leaf volatile (*Z*)-3-hexenyl-α-methylbutyrate, however, was significantly reduced (Fig. 2). Despite these changes, total amounts of VOCs were not affected by N deficiency.

Increased levels of constitutive mono- and sesquiterpenes have been found in N limited *Heterotheca subaxillaris* (Mihaliak and Lincoln 1985). Looking at induced VOCs, higher levels were found also in N deficient, hydroponically cultivated maize, and in soil-grown cotton. In both plants, the accumulation of the phytohormone jasmonic acid (JA), an important factor in the signaling cascade leading to volatile biosynthesis, correlated negatively with N (Schmelz et al. 2003; Chen et al. 2008a). It has been argued that N starved plants produce greater induced defense responses because N deficiency commonly leads to higher levels of leaf sugars and starch. This larger pool of nonstructural carbohydrates may be used for enhanced VOC biosynthesis (Schmelz et al. 2003).

Females of *Cotesia* spp. have been reported to respond in a dose-dependent manner to the total blend of herbivore-induced VOCs (NgiSong et al. 1996; Turlings et al. 2004). With the main compound (*E,E*)-α-farnesene being emitted in higher amounts by N deficient soybeans, a preference for this odor could have been expected. Naïve *C. marginiventris* females, however, did not differentiate between the blends of stressed and fertilized plants (Fig. 3). Our results thus confirm observations by Chen et al. (2008a) from cage experiments with cotton plants. The authors found that *C. marginiventris* parasitized the same numbers of caterpillars irrespective of the plants' N levels and concluded that the parasitoids did not differentiate between the herbivore induced VOC blends.

Several reasons for this behavior are conceivable. First, the VOCs that were emitted in higher quantities were not the relevant key compounds that induce wasp attraction. This notion is supported by an elegant experiment using transgenic *Arabidopsis thaliana* that overexpressed the maize terpene synthase gene TPS10. In this study, Schnee et al. (2006) demonstrated that several sesquiterpenes, among them (*E*)-β-farnesene or (*E*)-α-bergamotene, were not attractive to naïve *C. marginiventris*. Moreover, the wasps responded only if they had experienced these compounds during oviposition. Further evidence comes from studies that tested specific fractions of the induced odor blend. D'Alessandro and Turlings (2005) confirmed that a blend lacking most sesquiterpenes was as attractive to naïve and experienced *C. marginiventris* as the full mix. The same holds true for a blend that lacked VOCs from the shikimic acid pathway, while on the other hand, wasps responded strongly to unknown compounds in quantities that were too low to be detected (D'Alessandro et al. 2006, 2009; Rostás and Turlings 2008). In fact, our knowledge on which VOCs innately trigger attraction in parasitoids is fairly rudimentary and needs further testing. Moreover, in nature, such cues are rarely isolated but always occur within the context of background odor, that may mask or enhance the odors of the target plant (Mumm and Hilker 2005; Schroeder and Hilker 2008).

In summary, N deprivation had a strong negative impact on the whole tritrophic system, attenuating the performance of soybean plants, herbivorous caterpillars, and the parasitoid larvae that developed inside *S. frugiperda*. Despite such adverse effects on the plant's physiology and some alterations in VOC emission, the signal that indicates the presence of potential hosts obviously remained unchanged as the wasps' host searching behavior was not affected. These results suggest that the induced indirect defense against herbivores remains stable and effective even under low N conditions. On the parasitoid's side, reduced fitness due to low N availability cannot be ruled out, but might be negligible if only few plants within a patch are affected. From the plant's perspective and from a biocontrol point of view, this should be beneficial as abiotic stress in this case does not promote higher susceptibility to another biotic stress factor.

A Biochemical Interpretation of Terpene Chemotypes in *Melaleuca alternifolia*

Andras Keszei · Yasmin Hassan · William J. Foley

Received: 19 November 2009 / Revised: 24 March 2010 / Accepted: 29 April 2010 / Published online: 29 May 2010

Abstract The variation of foliar monoterpenes in the Australian Tea Tree (*Melaleuca alternifolia*) has been of significant interest both to the essential oil industry as well as to ecologists. The majority of studies on leaf chemistry have been aimed directly towards obtaining oil of higher quality or quantity. In the current study, we aimed to understand how molecular mechanisms contribute to the chemical variability of this species, based on chemical analysis of the leaf oils from a biochemical perspective. Correlations between monoterpenes across the species as well as within chemotypes show strong, persistent patterns, which enable us to establish groups based on possible common biosynthetic origins. We found that three distinct enzymes corresponding to these groups: a sabinene-hydrate synthase, a 1,8-cineole synthase, and a terpinolene synthase may be sufficient to explain all six chemotypes in *M. alternifolia*.

Key Words *Melaleuca alternifolia* · Australian Tea Tree · Chemotypes · Terpene synthase (TPS) · Terpinen-4-ol · Cineole · Terpinolene · Barycentric plot · Viridiflorene · Aromadendrene · Calamenene

Introduction

Identification of the genes that underlie phenotypic traits provides a crucial link to understanding evolutionary processes, such as adaptive evolution and genetic drift, since genetic variation forms the basis for selection and evolution. Understanding how genetic information is related to phenotypic variation of ecologically important traits presents a major challenge in evolutionary biology. It requires first the identification of those traits, their mode of expression, and finally, information of the key genes involved. Since it is hard to meet all these criteria, the relationship between genes, phenotypes and ecological function has only been achieved in a few cases in natural populations.

Distinct intra-specific chemical variation in foliar terpenes can occur in natural populations (Vernet et al. 1986) and is widespread in many Australian plants of the family Myrtaceae (Keszei et al. 2008). *Melaleuca alternifolia* is a Myrtaceous tree that shows chemotypic variation of foliar terpenes throughout its range (Butcher et al. 1994). The chemotype rich in terpinen-4-ol is widely used medicinally (Cox et al. 2001; Hammer et al. 2006), and therefore, a lot of research in the species has been restricted to the one chemotype. The presence of chemotypes in Tea-Tree indicates that the foliar leaf oil traits may be the result of adaptation to complex biotic interactions, as those found to influence chemical variability in thyme (Linhart and Thompson 1999; Linhart et al. 2005). To gain a similar understanding of the well-studied system that Australian Tea-Tree represents, we need to focus on leaf oil in light of its variability and biosynthetic origin, and not as a raw product.

Melaleuca alternifolia contains foliar oils that are a complex mixture of mono- and sesquiterpenes (Brophy et al. 1989). Terpene synthases are responsible for the direct production of the majority of the terpenes found in essential oils. They are capable of producing single or multiple compounds from the same prenyl-diphosphate substrate (Degenhardt et al. 2009). Examining correlations between groups of terpenes and working under the assumption that

strong positive correlation indicates a common biogenetic origin, Zavarin (1970) predicted the presence of a single terpene synthase in *Picea* that catalyzes the formation of sabinene, terpinolene, and γ-terpinene in a set ratio. An enzyme was isolated later that encodes a terpene synthase that showed the predicted catalytic profile (Gijzen et al. 1991). Qualitative variation in plant terpenes likely is due to variation in terpene synthase genes, and may be deduced from identifying the correlations among compounds that potentially have the same biosynthetic origin.

In *M. alternifolia*, previous work has established chemotypes based on variation in the concentration of 1,8-cineole, terpinen-4-ol, and terpinolene (Butcher et al. 1992). *Melaleuca alternifolia* is restricted to coastal flood plains of north-eastern New South Wales (NSW) with neighboring populations in the 'granite belt' in southeast Queensland, Australia. The geographic distribution of the three major monoterpenes reveals terpinen-4-ol in the majority in populations in the center of the natural range, while terpinolene dominates in the northwest, and 1,8-cineole in the south. Butcher et al. (1994) have shown that this corresponds to co-occurrence with the sister species *M. linariifolia* in the south and *M. trichostachya* in the north of NSW. *Melaleuca linariifolia* also is characterized by having both terpinen-4-ol and 1,8-cineole rich chemotypes, while *M. trichostachya* has terpinolene and 1,8-cineole rich chemotypes. It has been proposed that the respective *M. alternifolia* chemotypes may be a result of past hybridization. However, it also is possible that the convergence of chemical traits is due to similar patterns of herbivore pressure where the species geographically co-occur.

The purpose of the current work was to identify correlations and chemical patterns that allow us to predict the biosynthetic origin of chemotypic variation in *M. alternifolia* terpenes. This in turn will facilitate a search for the molecular components involved, and ultimately an understanding of the forces and mechanisms that have brought about and maintain chemical variation in Australian Tea-Tree.

Methods and Materials

Population Sampling Mature leaf material (ca. 20 g wet mass) was collected from 20 mature trees at eight sites and 15 from a ninth site across the species' natural geographic range (Table 1). However, populations from the far south of the range (Port Macquarie) were excluded, because they have been proposed to be hybrids with southern lineages of *M. linariifolia* (Butcher et al. 1995). We chose trees that were at least 100 m apart to avoid collecting from related trees (Rossetto et al. 1999), and the location of each tree was recorded. Samples were refrigerated at 4°C within 2 hr of collection. The extraction of leaf oils was completed on the day of collection in order to minimize the possibility of evaporation and oxidative degradation.

Table 1 Frequency of chemotypes sampled at each site across the natural geographic range of *Melaleuca alternifolia*

Extraction and Analysis of Terpenes Mature leaf material was separated from stems, weighed, and placed in 10 ml of ethanol (Baker et al. 2000) containing 0.25 $g \cdot l^{-1}$ of *n*-tridecane as an internal standard. The samples were left in ethanol for 7 d to complete extraction. A further 4 g leaf material from each tree were oven-dried at 60°C and weighed to calculate oil concentration on a dry weight basis.

Gas chromatography was carried out on an Agilent 6890 GC using an Alltech AT-35 (35% phenyl, 65% dimethylpolyoxylane) column (Alltech, Wilmington, DE, USA). The column was 60 m long (internal diam. 0.25 mm) with a stationary phase film thickness of 0.25 μm. Helium was used as carrier gas. The ethanol extract was filtered through a 0.45 μm filter, and 1 μl was injected at 250°C at a 1:25 split ratio. The temperature program was as follows: 100°C for 5 min, ramping to 200°C at 20°C·min^{-1}, followed by a ramp to 250°C at 5°C·min^{-1}, and held at 250°C for 4 min. The total elution time was 25 min. The components of the solvent extract were detected by using an FID and an Agilent 5973 Mass Spectrometer dual setup through an SGE MS/FID splitter. Several peaks were identified tentatively by comparisons to authentic standards (α-pinene, β-pinene, β-myrcene, β-phellandrene, terpinen-4-ol, 1,8-cineole, α-terpineol, β-caryophyllene, kindly made available by Mike Lacey and Thomas Wallenius, CSIRO Canberra). The remaining peaks were identified by comparison to mass spectra and retention times of compounds published using the same AT35 chromatographic column and run parameters (Southwell and Lowe

1999; Russell and Southwell 2002). Quantities of compounds were calculated by recording peak areas of the FID trace in MSD Chemstation Data Analysis (Agilent Technologies, Deerfield, IL, USA) and relating them to the internal standard (tridecane) and leaf dry weight.

Statistical Analysis We separated monoterpene and sesquiterpene data, as the two chemical groups are biosynthetically distinct, and are influenced by separate genetic factors (Keszei et al. 2008). Initially, we used principal components analysis to identify chemotypes as had been done previously (Butcher et al. 1994). However, this method did not unambiguously separate some of the published chemotypes that were based on polymodal and disjunct distributions of major oil components (data not shown). Consequently, we calculated Pearson's correlation coefficients on the entire sample set based on the absolute concentrations of terpenes to eliminate false negative correlations potentially introduced when data on terpene proportions are used. The individual components were divided into groups based on the correlations, and the proportion of each of these groups was plotted on a ternary barymetric plot. To predict the effect of individual biosynthetic genes, we re-calculated Pearson's correlation coefficients within each of the resulting clusters to obtain chemical groups characteristic of individual chemotypes.

Results

GC-MS analyses of ethanolic extracts of mature leaf material of *M. alternifolia* revealed the presence of 47 compounds comprising 20 monoterpenes and 27 sesquiterpenes. Significant variation in leaf oil concentration was found both between sites and among chemotypes. The lowest foliar oil concentration recorded was of a tree of chemotype 3 from Bald Rock Creek, Queensland (10 $mg \cdot g^{-1}$ dry matter (DM)), whereas the highest yielding was of an individual of chemotype 5 at Wooli Road, NSW, with a foliar oil concentration of 141 $mg \cdot g^{-1}$ DM. The distribution of oil yield shows a normal distribution throughout the species, and this pattern persists when examined at the level of individual chemotypes (data not shown).

Monoterpenes Monoterpenes are the dominant components of *M. alternifolia* leaf oil, and comprised between 9 and 128 $mg \cdot g^{-1}$ of dry leaf weight. Sesquiterpene content ranges between 0.8 $mg \cdot g^{-1}$ and 14 $mg \cdot g^{-1}$ or between 5 and 21% of the total leaf oils. Concentrations of mono- and sesquiterpene concentrations are positively correlated with each other. The ratio of monoterpenes to sesquiterpenes is continuous and polymodal, with a major mode at 62%, one at 80%, and one at 86%. The three major monoterpenes: terpinen-4-ol, 1,8-cineole, and terpinolene show well defined, discontinuous concentration ranges from which it is possible to assign all but one of the sampled individuals to known chemotypes.

Pearson's correlation values among concentrations of all of the monoterpenes within the full sample set established three groups showing strong intercorrelations ($r>0.8$): **Group A**: α-thujene, α-terpinene, γ-terpinene, terpinen-4-ol, **Group B**: α-pinene, β-pinene, myrcene, limonene, 1,8-cineole, α-terpineol, and **Group C**: α-phellandrene, terpinolene, linalool.

Common biosynthetic intermediates (Fig. 1) suggest that these three main groups may be the products of three distinct terpene synthases. Concentrations of *(Z)*-piperitol, *p*-cymene, β-phellandrene, sabinene, and *(Z)*-sabinene hydrate did not show strong ($r<0.8$) correlations to any other group, however, they showed the strongest correlation to group A. As each of these compounds readily undergoes post-biosynthetic conversion or is the product of such a process (Bohlmann et al. 1999; Keszei et al. 2008), their concentration may not directly reflect enzymatic activity. As such, the lack of a strong positive correlation need not rule out biosynthetic relatedness. Provided that there was either a strong statistical correlation or evidence of a common biosynthetic origin, monoterpenes were assigned to one of the three groups. The variation in the proportions of these three groups relative to the total monoterpene pool is discontinuous, and clearly resolves all chemotypes (Fig. 2).

The leaf oil of one individual from Bald Rock Creek, Queensland, showed 1,8-cineole and terpinolene as the major components. However, the ratio between the two compounds did not fit any of the established chemotypes. Furthermore, the ternary plot resolved the individual as a distinct separate group.

Looking at the contributions of the three independent biochemical groups in Fig. 2, it is evident that out of the seven chemotypes, chemotypes 1, 2, and 5 represent cardinal chemotypes dominated by a single compound, and chemotypes 3, 4, and 6 fall between these as intermediates. In the ternary plot, only chemotype 5 is plotted on an apex, while chemotype 1 shows significant contributions from both Groups B and C, and chemotype 2 shows significant contributions from Groups A and B. This can be explained by two processes: the major monoterpene synthases in chemotypes 1 and 2 may also synthesize compounds characteristic of the other major biosynthetic groups. In this case, compounds belonging to separate groups will show strong correlations in the cardinal chemotypes. It also is possible that the monoterpene profile of these chemotypes is determined by more than one active terpene synthase. If this were the case, we would expect the

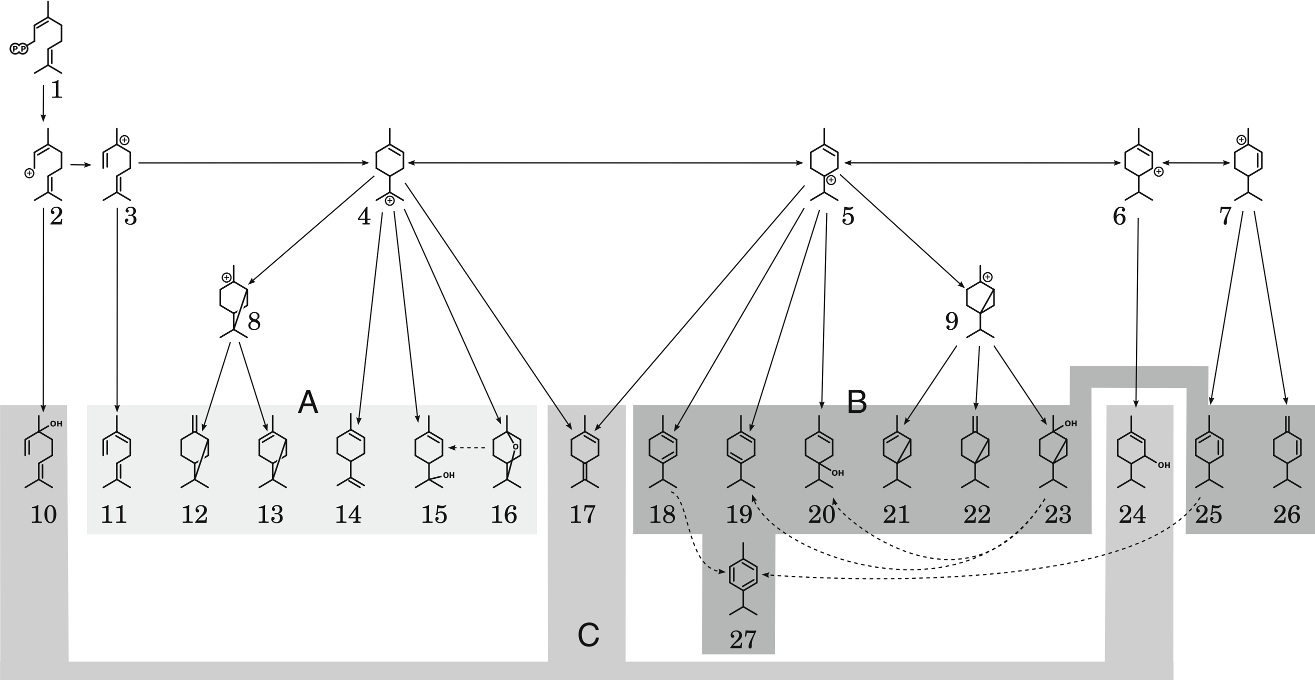

Fig. 1 Biosynthetic relationships between monoterpenes found in *Melaleuca alternifolia*. The products of the three proposed terpene synthases are indicated by shaded boxes. 1: geranyl diphosphate, 2: linalyl carbocation, 3: geranyl carbocation, 4: α-terpinyl carbocation, 5: terpinenyl carbocation, 6: piperitenyl carbocation, 7: phellandryl carbocation, 8: pinyl carbocation, 9: sabinyl carbocation, 10: linalool, 11: myrcene, 12: β-pinene, 13: α-pinene, 14: limonene, 15: α-terpineol, 16: 1,8-cineole, 17: terpinolene, 18: α-terpinene, 19: γ-terpinene, 20: terpinen-4-ol, 21: α-thujene, 22: sabinene, 23: sabinene hydrate, 24: piperitol, 25: α-phellandrene, 26: β-phellandrene, 27: *p*-cymene

correlation matrices to separate monoterpenes of different biosynthetic origins into separate groups.

To test these possibilities, Pearson's correlation coefficients were calculated between concentrations of each of the monoterpenes in the cardinal chemotypes, and compared to the overall pattern. Table 2 shows the resulting correlation matrices. The correlations between monoterpenes in the individual chemotypes illustrate the likely products of the distinct enzymes (Table 3).

In chemotype 1, dominated by terpinen-4-ol, two groups emerge: Group 1A: α-thujene, a-terpinene, γ-terpinene, terpinolene, terpinen-4-ol, *(Z)*-piperitol; and Group 1B: limonene, 1,8-cineole. Concentrations of myrcene, α-pinene, β-pinene, α-terpineol, α-phellandrene, and β-phellandrene show significant correlation to compounds in both groups, but they show somewhat stronger correlation to Group 1A. Concentration of linalool, *p*-cymene, sabinene and sabinene hydrate show no significant correlations to other compounds.

In the terpinolene dominated chemotype 2, two strong groups can be distinguished: Group 2C: α-thujene, α-phellandrene, α-pinene, α-terpinene, γ-terpinene, terpinolene, linalool; Group 2B: α-pinene, myrcene, limonene, β-phellandrene, 1,8-cineole, α-terpineol, γ-terpinene, terpinen-4-ol. Concentrations of β-pinene, *p*-cymene, sabinene, and sabinene hydrate show no significant correlation to other compounds.

In chemotype 5, dominated by 1,8-cineole, only a single distinct group could be identified: Group 5B: α-pinene, β-pinene, myrcene, a-phellandrene, limonene, β-phellandrene, 1,8-cineole, α-terpineol, terpinen-4-ol.

Sesquiterpenes Sesquiterpenes have always been considered minor and therefore insignificant components of the leaf oils of all *M. alternifolia* samples. However, we found that their contribution to some of the oils was as high as 20% of the total oil, which is higher than that of the main monoterpene groups in some chemotypes.

Calculation of the Pearson correlation coefficients among the concentrations of the sesquiterpenes (Table 3) showed strong correlations. The sesquiterpenes β-gurjunene, unknown peaks at 12.85 min, 12.95 min, and 13.59 min, α-elemene, unknown peak at 13.76 min, calamenene, unknown peak at 15.11 min, β-eudesmol showed discontinuous distributions. Interestingly, none of the sesquiterpenes with discontinuous distributions correlated with each other. Based on Pearson's correlation coefficients of $r>0.8$, we established the following groups; Group D: elixene, bicyclogermacrene; Group E: guaiene, α-gurjunene, aromadendrene, unknown peak at 13.59 min,

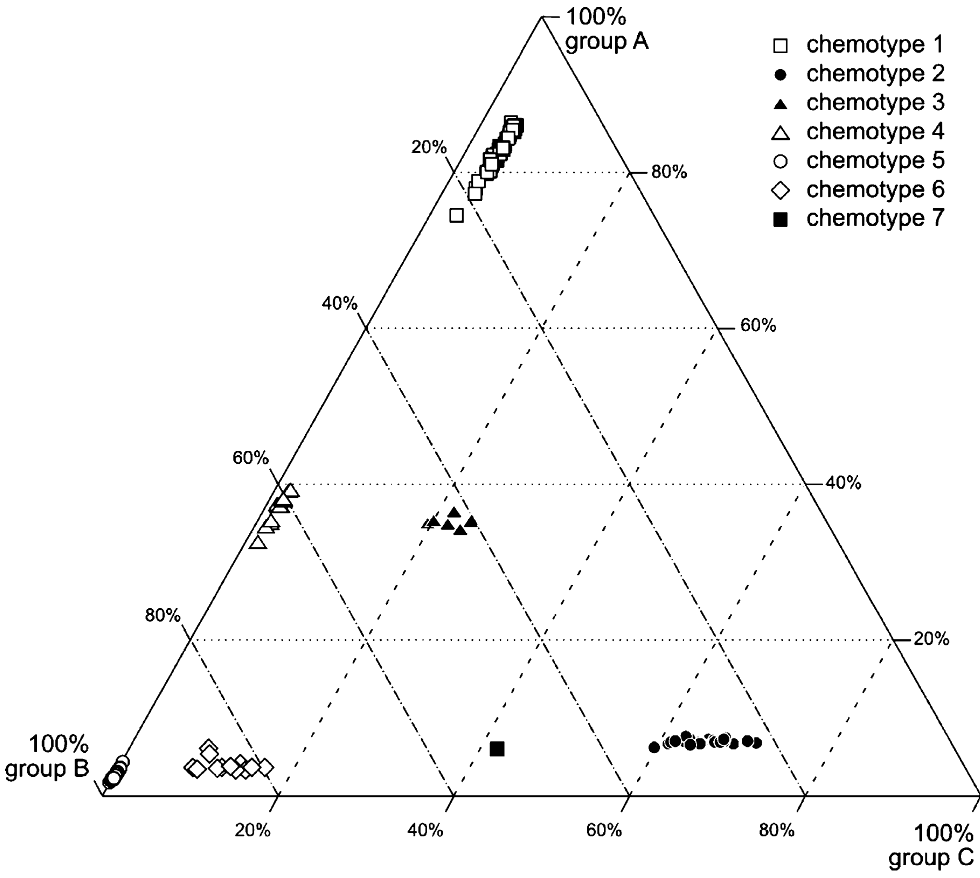

Fig. 2 A ternary barycentric plot showing the contributions of the three biochemical groups of compounds (as shown in Fig. 1) to the monoterpene fraction of the leaf oil profile of *Melaleuca alternifolia*. All six chemotypes are resolved and show discontinuous distributions. The intermediate chemotypes (3,4 and 6) are positioned between the cardinal chemotypes (1,2 and 5), which confirms a codominant relationship between the genetic components involved

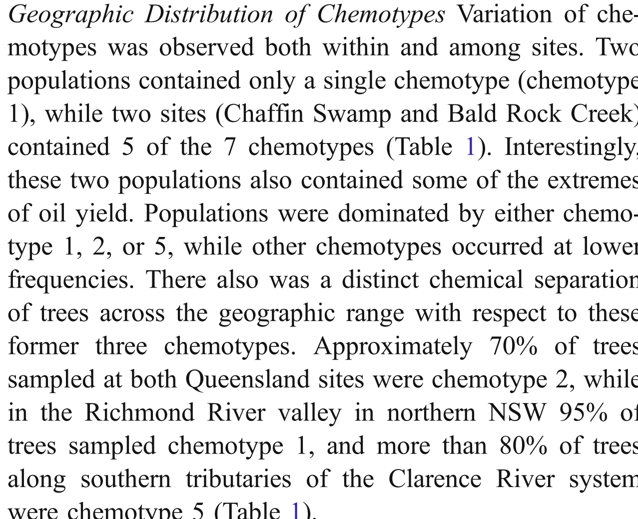
allo-aromadendrene, viridiflorene, globulol, viridiflorol, isoaromadendrene epoxid e, unknown peak at 15.11 min, β-gurjunene; Group F: α-elemene, γ-muurolene; Group G: 13.79 min, δ-cadinene, β-cadinene, γ-cadinene, cubenol, (also showed strong correlation to α-gurjunene and γ-muurolene). None of the other sesquiterpenes showed significant correlation to any other compounds.

The two strongest sesquiterpene patterns that reflect the monoterpene chemotype were the ratio between aromadendrene and viridiflorene (Fig. 3), and the presence/absence of calamenene, shown together with another sesquiterpene that showed discontinuous but independent distribution: β-eudesmol. Chemotype 2 shows a viridiflorene to aromadendrene ratio different from all other chemotypes, although correlation between the two compounds is high ($r>0.8$) in all chemotypes. Calamenene content also is indicative of chemotype 2. Of the cardinal chemotypes, chemotype 2 is the only one that showed no calamenene content in any of the individuals sampled (Fig. 3). None of the other chemotypes was correlated with any of the sesquiterpene patterns, and no more sesquiterpene patterns were found to be correlated with monoterpene chemotypes. The correlations among sesquiterpene concentrations generally were lower than among monoterpenes. However, this may be a result of their lower concentrations leading to lower measurement accuracy.



Geographic Distribution of Chemotypes Variation of chemotypes was observed both within and among sites. Two populations contained only a single chemotype (chemotype 1), while two sites (Chaffin Swamp and Bald Rock Creek) contained 5 of the 7 chemotypes (Table 1). Interestingly, these two populations also contained some of the extremes of oil yield. Populations were dominated by either chemotype 1, 2, or 5, while other chemotypes occurred at lower frequencies. There also was a distinct chemical separation of trees across the geographic range with respect to these former three chemotypes. Approximately 70% of trees sampled at both Queensland sites were chemotype 2, while in the Richmond River valley in northern NSW 95% of trees sampled chemotype 1, and more than 80% of trees along southern tributaries of the Clarence River system were chemotype 5 (Table 1).

Discussion

Monoterpene Chemotypes We identified six chemotypes in this study, all of which had been described previously (Butcher et al. 1994), and an individual tree that did not group with any of the recognized chemotypes. We grouped the monoterpenes on the basis of their likely biosynthetic

Monoterpenes (bottom) and sesquiterpenes (top). Values above 0.7, 0.8, and 0.9 are emphasized using incremental shading. Strong positive correlations (>0.7) between monoterpenes correspond to grouping based on common carbocation intermediates as shown in Fig. 1

origins (Fig. 1) and calculated intercorrelations between them. Here we discuss the possible underlying biochemical factors that lead to these distinct patterns.

The two likely processes are based on different types of catalytic action. First, each terpene may be produced by a single, specific enzyme, and certain terpenes may co-occur as a result of genetic linkage (Wilderman et al. 2004). Alternatively, terpenes in each group may be products of the same reaction by a single enzyme (Wise et al. 1998). It is more common for a single terpene synthase to produce multiple products than a single product exclusively, and therefore, we expect that the latter explanation is the most likely. Support for this proposal comes from functional assays of terpene synthase enzymes in other species. Heterologous expression and functional characterisation of 1,8-cineole synthase from *Arabidopsis thaliana* (Chen et al. 2004) and *Salvia officinalis* (Wise et al. 1998) show that those enzymes catalyze not only the formation of 1,8-cineole, but also of limonene, myrcene, α-and β-pinene, and α-terpineol as by-products, and that the ratios of products are constant characteristics of these enzymes. These compounds also are the major contributors to the Group B terpenes of *M. alternifolia*.

A single enzyme can also synthesise one product, which can subsequently be modified into multiple products by other processes. In particular, the Group A terpenes in *M. alternifolia* may result from re-arrangement of unstable *cis*-sabinene hydrate. In *Origanum majorana*, sabinene synthase also produces sabinene hydrate, which is rearranged after steam distillation to give terpinen-4-ol, α- and γ-terpinene, and terpinolene (Fischer et al. 1987). Young leaves of chemotype 1 in *M. alternifolia* are rich in *cis*-sabinene hydrate (41%) (Russell and Southwell 2002), and these also are known to undergo temperature-catalysed transformation to the aforementioned products during hydrodistillation (Brophy et al. 1989). It also has been shown that *cis*-sabinene hydrate can undergo a non-enzymatic acid solvolysis *in vivo* as the leaf ages (Southwell and Stiff 1990; Cornwell et al. 1995), resulting in Group A monoterpenes in the mature leaf of *M. alternifolia*. This reaction would be expected to contain terpinolene as a by-product, and in chemotype 1 individuals, there is indeed a strong positive correlation between concentrations of terpinen-4-ol and terpinolene.

In chemotypes 2, 3, 6, and 7, however, terpinolene most likely is synthesized by a separate terpinolene synthase. In *M. alternifolia*, the concentration of terpinolene is positively

Table 3 Pearson's pairwise correlation coefficients between individual monoterpene concentrations shown for only the three cardinal chemotypes of *Melaleuca alternifolia*

Values above 0.8 and 0.9 are emphasized using incremental shading. The compounds with the highest levels of correlation in these groups are expected to be the products of a common terpene synthase

correlated with those of linalool and α-phellandrene, and together they comprise Group C terpenes. However, when just focusing on chemotype 2 individuals, it can be seen that α-terpinene, γ-terpinene, α-phellandrene, and β-phellandrene also show strong correlation with terpinolene. These compounds, therefore, may be synthesized by more than one of the enzymes that define the terpene composition of Tea Tree oil.

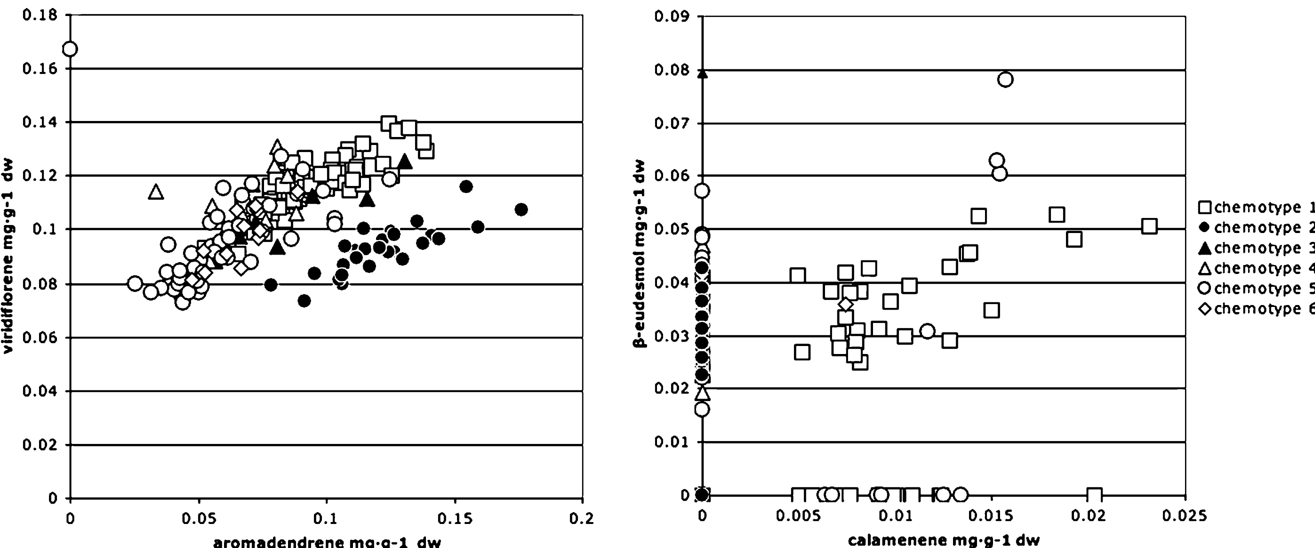

Fig. 3 Correlations of concentrations of the sesquiterpenes viridiflorene and aromadendrende, as well as of β-eudesmol and calamenene with respect to chemotypes

Three studies that examined the expression of terpinolene synthases show different products (Wise et al. 1998; Bohlmann et al. 1999; Huber et al. 2005). This suggests that terpinolene can be produced from different carbocation intermediates, and that it is not unusual that the monoterpene components positively correlated to terpinolene in *M. alternifolia* do not match the profile of any currently known terpinolene synthase.

Three groups of monoterpenes describe the majority of variation in Australian Tea Tree. Pairwise correlation of concentrations of individual monoterpenes as a proportion of total monoterpenes shows that almost all monoterpenes show strong correlation to one of the major groups. The lowest correlation to any single group is shown by *p*-cymene. However, it has been shown that this compound may be an oxidation product that can be derived from multiple monoterpenes (Brophy et al. 1989), and its concentration may depend more on extrinsic factors that affect *in vivo* oxidation, rather than on individual enzymatic processes.

Sesquiterpene Chemotypes This is the first study to examine sesquiterpene patterns in *M. alternifolia*, and it is clear from the analyses that there are strong correlations among concentrations of individual compounds. Viridiflorene and aromadendrene showed two distinctly different ratios, and the higher viridiflorene ratio was exclusive to chemotype 2. As both share the same viridiflorane structure, it leads us to expect two aromadendrene synthase variants, both responsible for synthesizing the same suite of compounds in slightly different, but nevertheless characteristic ratios. The only other pattern linked to a monoterpene chemotype was the concentration of calamenene, which was consistently absent from all chemotype 2 individuals. As calamenene has two less hydrogens ($C_{15}H_{22}$) than would result from the cyclization and dephosphorylation of FPP ($C_{15}H_{24}(P_2O_7H_3)$), it is likely that its synthesis is linked to the presence of a reductase from the P450 superfamily of enzymes, as in mint monoterpene biosynthesis (Bertea et al. 2001). Compared to monoterpenes, there were many more compounds that were not correlated to other constituents, and our sampling probably missed some combinations. It is interesting to note, however, that the only variation linked to monoterpene variation was found in chemotype 2. None of the other sesquiterpenes showing discontinuous distributions was correlated to other monoterpene chemotypes. This suggests that formation of sesquiterpenes is independent of the monoterpene chemotype in Tea Tree, and that the correlation in chemotype 2 may be at a molecular level.

Biochemical Origin of the Chemotypes We propose that three major enzymes are responsible for the three major chemotypes. These are (i) sabinene hydrate synthase that produces the Group A compounds, (ii) 1,8-cineole synthase that yields Group B compounds, and (iii) a terpinolene synthase responsible for group C products. The barycentric plot showing the individual contributions suggests that in chemotypes 1 and 2, a separate 1,8-cineole synthase also may be contributing to the oil profile. Chemotype 3 demonstrates that all three enzymes may be present at once; therefore, in a diploid organism such as *M. alternifolia*, at least two loci need to be involved in coding for the foliar monoterpene synthases that determine chemotype.

The effect of the proposed individual terpene synthases appears to be codominant. This is supported by the intermediate position of chemotypes 3, and 4, and 6

compared to 1, 2, and 5 as shown in Fig. 2. While chemotypes 3 and 4 fall exactly halfway between the contributing cardinal chemotypes, indicating equal contribution from all sides, chemotypes 6 and 7 are not as straightforward. In chemotype 6, the contribution of the group B and group C compounds is 3:1 and 2:1. This may indicate that: (i) our hypothetical 1,8-cineole synthase utilizes GDP as a substrate more efficiently than does terpinolene synthase, or that (ii) the two genes have a cumulative effect, where product proportions are determined by the number of alleles present of each synthase. In the case of multiple copy gene families such as terpene synthases, duplication often is the mechanism behind the increase in the number of genes contributing to the same process. Among duplicated genes, the process of gene conversion can occur whereby similar sequences recombine with each other regardless of actual chromosomal topology, whereby in effect a sharing of alleles will occur across loci. In such a scenario, the 3:1 contribution may be explained by two loci sharing alleles.

The distribution of chemotypes across the natural range further supports the idea that chemotypes 3, 4, 6, and 7 are likely intermediate chemotypes, particularly because, unlike chemotypes 1, 2, and 5, neither our nor previous studies (Homer et al. 2000) have found them to occur in monochemotypic populations. Furthermore, if they are intermediates, then they should be found in populations that contain the contributing cardinal chemotypes. In one population, Dilkoon Creek, which occurs between the two chemically distinct regions of NSW, 35% of trees recorded were chemotype 4. Chemotypes 1 and 5 also are present in this population. These are the two chemotypes that were used in a controlled cross experiment that reinforced the intermediate nature of chemotype 4 (Shelton et al. 2002). Finally, chemotypes 3, 6, and 7 that contain group C compounds occur mostly in Queensland populations, where chemotype 2 is dominant.

Butcher et al. (1994) have raised the possibility of chemotypes 2 and 5 being the results of introgression from sister species *M. linariifolia* and *M. trichostachya*. In the case of *M. linariifolia*, chemical analyses have been devised that are able to separate the two species based on the ratio of *cis*- and *trans*-sabinene hydrate (Southwell and Stiff 1990). This shows that even though the two species apparently share similar chemotypes, the final chemistries are obtained via enzymatically different routes. This separation does, however, depend only on differences between Group A compounds, and without at least a thorough analysis of the corresponding group B dominated chemotypes, it is hard to reach any conclusive answer. On the other hand, chemotype 2 of *M. alternifolia* is very similar to a corresponding chemotype of *M. trichostachya* (Brophy and Doran 1996). Furthermore, not only does chemotype 2 differ from all others in its monoterpene composition, but it also displays further differences in two independent sesquiterpene traits. In other plants, genes for terpene biosynthesis often co-locate on the chromosomes, and if this is also true in *Melaleuca*, the consistent co-variation of these traits indicate that chemotype 2 is not just the result of variation of a single gene, but of multiple linked loci.

In summary, the examination of purely chemical data from *M. alternifolia* from a biochemical point of view has enabled us to make much deeper conclusions about the origins of the different chemotypes. By using biochemical knowledge with the power of statistically analyzing a large number of samples, it has been possible to develop a set of hypotheses about the nature of terpene synthases that are contributing to natural variation. Ultimately, this provides a framework for uncovering the individual molecular processes and identifying the actual genes that contribute to the maintenance of such remarkable chemical variation of an industrially, medicinally, and ecologically important species.

Abstract A high molecular weight humic fraction (>3,500 Da) was characterized chemically by DRIFT and ^{1}H NMR spectroscopy, and was applied to *Zea mays* L. plants to evaluate its effect on phenylpropanoid metabolism. The activity and gene expression of phenylalanine (tyrosine) ammonia-lyase (PAL/TAL), and the concentrations of phenolics and their amino acid precursors phenylalanine and tyrosine were assayed. Maximum induction of PAL/TAL activity and expression was obtained when the concentration of added humic substance was 1 mg C/l hydroponic solution. Phenylalanine and tyrosine significantly decreased (−16% and −22%, respectively), and phenolic compounds increased in treated plants. The effects of the humic substance could be ascribed partly to indoleacetic acid (27 nmol/mg C) in the humic fraction. Our results suggest that this humic fraction induces changes in phenylpropanoid metabolism. This is the first study that shows a relationship between humic substances and the phenylpropanoid pathway.

Introduction

Humic substances (HS) are ubiquitous constituents of environmental organic matter that are responsible for many complex chemical reactions in soil (Stevenson 1994). The general term "humic substances" includes fractions that are identified on the basis of their molecular size and solubility in alkali and acids, and that build up in soil during the microbial degradation of organic matter (Stevenson 1994). These degradation products may be modified further through reactions such as polymerization, condensation, and oxidation to produce complex substances that differ in molecular weight from a few hundred up to several million Daltons (Stevenson 1994).

It is believed that humic substances in solution are a set of relatively small molecules, which are loosely bound by intermolecular hydrophobic interactions (Piccolo 2002). HS have a high apparent molecular weight, but can be reversibly disrupted by treatment with low concentrations of mono-, di-, and tricarboxylic acids. The amphiphilic properties of organic acids in root exudates can dissociate HS into low and high molecular weight fractions (Piccolo 2002; Nardi et al. 2005; Canellas et al. 2008). Bioactive molecules such as indoleacetic acid may be released from the HS upon dissociation of the parent material (Nardi et al. 2009).

Humified organic matter stimulates plant growth and improves the yields of agricultural crops (Canellas et al. 2002; Eyheraguibel et al. 2008). High molecular weight HS

also can act as root growth promoters via auxin-mediated pathways (Trevisan et al. 2009). HS may have practical applications in agriculture as a source of new organic-mineral fertilizers and as inhibitors of plant stress (Cavani et al. 2006; Kaufmann et al. 2007; Schiavon et al. 2008).

HS induce carbon and nitrogen metabolism by increasing the activity of the enzymes of glycolysis, the Krebs cycle, and N assimilation (Quaggiotti et al. 2004; Muscolo et al. 2007). However, there is no information on the interactions between HS and secondary metabolism. Among secondary metabolites, phenolic compounds (e.g., flavonoids and phenylpropanoids) provide protection to plants against a range of biotic and abiotic stresses (Dixon and Paiva 1995). Phenylalanine (tyrosine) ammonia-lyase (PAL/TAL; EC 4.3.1.5) catalyzes the first committed step in the biosynthesis of phenolics by converting phenylalanine to *trans*-cinnamic acid and tyrosine to *p*-coumaric acid. Phenylalanine usually is the preferred substrate, but the monocot enzyme can use both phenylalanine and tyrosine (Rösler et al. 1997; Andersen et al. 2007).

Since HS stimulate C and N metabolism (Quaggiotti et al. 2004; Nardi et al. 2007), and these in turn cross-talk with phenylpropanoid metabolism, we hypothesized that HS might also directly or indirectly activate PAL and consequently alter phenolic levels. To test this hypothesis, high molecular weight HS derived from earthworm feces were supplied to maize plants growing in hydroponic solution, and the effects on phenylpropanoid metabolism were analyzed in terms of PAL/TAL activity, gene expression, content of amino acids and phenolic compounds.

Methods and Materials

Earthworm Culture Conditions The feces of *Nicodrilus* (=*Allolobophora* (Eisen) = *Aporrectodea* (Oerley)) *caliginosus* (Savigny) and *Allolobophora rosea* (Savigny) were collected in September for 3 yr from the surface of uncultivated couchgrass (*Agropyron repens* L.) fields at the College of Agriculture farm (University of Padova). The soil was classified as Calcaric Cambisol (FAO-ISSDS 1999). After collection, the feces were immediately air-dried.

Extraction of HS Feces (20 g) were extracted with 0.1 N KOH (200 ml). The extract was dialyzed against distilled water with a 14 kDa molecular weight cut-off Visking membrane (Medicell, UK) (Muscolo et al. 2007), desalted with ion exchange Amberlite IR-120 (H^+ form) (Stevenson 1994), adjusted to pH 2.1 with glacial acetic acid, and dialyzed against distilled water with a 3,500 Da molecular weight cut-off Spectra/Por® 3 tubing (Spectrum, Gardena, CA, USA). The dialyzed solution was vacuum distilled to remove acetic acid, reduced in volume to about 50 ml, and freeze-dried. From 20 g of feces, 0.76 g of humic carbon was obtained. C, H, N, and S were determined with an elemental analyzer (Thermo Electron model EA 1110 Waltham, MA, USA). Oxygen was calculated by difference, and the ash content was determined by incineration at 700°C (Stevenson 1994). The concentration of COOH groups was determined by potentiometric titration with a VIT 90 AutoTitrator (Radiometer, Copenhagen, DK) using first derivative method to analyze the data. All determinations were performed in triplicate.

^1H NMR Spectra were recorded with a Bruker ACF 250 spectrometer (Bruker, Karslruhe, Germany) with 40 mg/ml samples of HS in D_2O and a 5-mm multinuclear probe. Spectra were accumulated with 16 K data point, one pulse sequence, 40° pulse angle, 3 s relaxation delay, and a sweep width of 2.5 kHz. To obtain a satisfactory signal to noise ratio 1000–2000 scans were needed. Gated irradiation was applied between acquisitions to pre-saturate the residual water peak. Chemical shifts were measured from sodium 3-trimethylsilyl-propionate-2,2,3,3-d_4 (TSP).

DRIFT Spectra were recorded with a Bruker TENSOR series FT-IR Spectrophotometer (Ettlingen, Germany) equipped with an apparatus for diffuse reflectance (Spectra-Tech. Inc., Stamford, CT, USA). The spectra were collected from 4000 to 400 cm^{-1} and averaged over 100 scans at a resolution 4 cm^{-1} and converted into Kubelka-Munk units. KBr powder (Aldrich Chemical Co. Milwaukee, WI, USA) was used for the background reference. Analyses of spectral data were performed with Grams/386 spectral software (Galactic Industries, Salem, NH, USA). Spectral sections from 1850 to 600 cm^{-1} were baseline-corrected to an absorbance value of 0.00 at 1850 cm^{-1}. The 2nd derivatives of the IR spectra were used for wave-number determination of overlapped bands.

Indoleacetic Acid (IAA) Determination IAA was determined by using an enzyme linked immuno-sorbent assay (ELISA) standardized with methylated IAA (Phytodetek-IAA, Sigma, St. Louis, MO, USA). The ELISA test utilized a monoclonal antibody to IAA and was sensitive in the range of 0.05–100 picomoles. The tracer and standard solutions were prepared following the manufacturer's instructions, and the absorbances were read at 405 nm with a Biorad microplate reader (Hercules, CA, USA). Samples containing HS at 150–750 µg C/ml were analyzed in duplicate.

Plants Maize seeds (*Zea mays* L. var. DK 585) were soaked for one night in distilled running water and germinated for 60 h in the dark at 25°C on filter paper wet with 1 mM $CaSO_4$. Seedlings were grown for 14 d in hydroponic conditions using a Hoagland no. 2 modified solution (Hoagland and Arnon 1950) with the following composition (µM): KH_2PO_4 (40), $Ca(NO_3)_2$ (200), KNO_3 (200), $MgSO_4$ (200),

FeNaEDTA (10), H_3BO_3 (4.6), $CuCl_2$ (0.036), $MnCl_2$ (0.9), $ZnCl_2$ (0.09), NaMoO (0.01). Plantlets were grown in a climate chamber with a 14:10 h, L:D cycle, air temperature of 27/21°C, relative humidity of 70/85%, and at a photon flux density (PFD) of 280 mol/m^2/s. When plants were 12 d old, they were treated for 48 h with concentrations of HS equivalent to 0, 0.5, 1, or 2 mg C/l in the hydroponic solution. Leaves of 20 control or treated seedlings were harvested, frozen in liquid nitrogen, and stored at −80°C for gene expression analysis. For enzyme activity, amino acid, phenolic, and flavonoid measurements, fresh tissue from 20 plants per treatment was used. For fresh weight measurements, 10 plants per treatment were collected and weighed. The experiment was replicated five times.

Glutamine Synthetase Assay Glutamine synthetase (EC 6.3.1.2) was extracted by crushing 1 g leaf tissue in 3 ml of ice-cold buffer containing 100 mM Hepes-NaOH pH 7.5, 5 mM $MgCl_2$, 1 mM dithiothreitol, and 0.10 g polyvinylpyrrolidone. After filtering through two layers of muslin, and centrifuging at 20,000x*g* for 15 min, 150 μl of extract were added to 600 μl pH 7 buffer containing 90 mM imidazole-HCl, 60 mM hydroxylamine, 20 mM Na_2HAsO_4, 3 mM $MnCl_2$, 0.4 mM ADP, and 120 mM glutamine. The mixture was incubated 15 min at 37°C and then stopped by adding 250 μl of a mixture of equal parts 10% (w/v) $FeCl_3$ in 0.2 M HCl, 24% (w/v) trichloroacetic acid (TCA), and 50% (w/v) HCl. The γ-glutamyl hydroxamate was determined at 540 nm (Cánovas et al. 1991), and activity was expressed as μmol product/g fresh weight/min.

PEP-carboxylase Assay PEPC (EC 4.1.1.31) was extracted by homogenizing 1 g leaf tissue in 10 ml ice-cold buffer (pH 8.2) containing 0.1 M Tris-HCl, 1 M Na_2EDTA, 10% glycerol, 5 mM β-mercaptoethanol, and 0.10 g polyvinylpyrrolidone. After the extract was filtered through 2 layers of muslin and centrifuged at 4°C for 20 min at 17,000x*g*, the PEPC reaction was started by adding PEP to bring the final concentration to 2 mM in the crude extract. The oxidation of NADH was monitored at 340 nm at 30°C (Schweizer and Erismann 1985). The activity was expressed as μmol NAD^+/g fresh weight/min.

Phenylalanine (Tyrosine) Ammonia-lyase Assay PAL/TAL (EC 4.3.1.5) was extracted by homogenizing 1 g leaf tissue in 5 ml ice cold 100 mM potassium-phosphate buffer (pH 8.0) containing 1.4 mM 2-mercaptoethanol and 0.10 g polyvinylpyrrolidone. After centrifuging at 4°C for 15 min at 15,000x*g*, the supernatant was chromatographed on Sephadex G-25 equilibrated with the same buffer. Total protein was measured using the Bradford method (Bradford 1976). A mixture of 0.4 ml of 100 mM Tris–HCl buffer (pH 8.8), 0.2 ml of 40 mM phenylalanine, and 0.2 ml of enzyme extract was incubated for 30 min at 37°C and stopped with 0.2 ml 25% TCA (Mori et al. 2001). Phenylalanine was added to the control after incubation and the addition of the acid. After centrifuging 15 min at 4°C at 10,000x*g*, the absorbance of the supernatant was measured at 280 nm relative to the control. TAL activity was assayed at 40°C by monitoring *p*-coumaric acid formation at 310 nm in the same buffers containing 1.9 mM L-tyrosine (Rösler et al. 1997). PAL and TAL activities were expressed as nmol product/mg protein/min.

Semi-quantitative RT-PCR Total RNA was extracted from frozen leaves as described in Quaggiotti et al. (2004) using the Nucleon Phytopure kit (Amersham-Pharmacia, UK). The RNA was analyzed spectrophotometrically (A_{280}/A_{260}), and electrophoresis (1% agarose gel) was used to verify intact nucleic acid. RNA was treated with 10 U of Dnase RQ1 (Promega, Milano, Italy) per 50 μg RNA at 37°C for 30 min. Five μg of RNA from each treatment were used in the reverse transcriptase reaction, using 200 U of ImProm-II™ Reverse Transcriptase (Promega, Milano, Italy) and oligodT as primers in 20 μl reaction mixtures. Mixtures were incubated at 37°C for 60 min, 70°C for 5 min, and 4°C for 5 min to stop the RT reaction.

RT-PCR experiments were performed with specific primers (forward: 5′-CGCATCAACACCCTCCTC-3′; reverse: 5′-GATGTAGGAGAGCGGGACCA-3′) to evaluate the expression level of PAL (*ZmPAL1*: GenBank Accession number L77912). For all PCR reactions, 1 μl of the cDNA was used in a 20 μl reaction mixture with 2 μl of a 0.025 U/μl Taq-polymerase (Amersham-Pharmacia-Biotech, Piscataway, NJ, USA). Between 14 and 30 cycles were tested to determine the optimal number of cycles, corresponding to the exponential phase in the amplification for each gene. Each PCR cycle consisted of: 3 min initial denaturation at 95°C, 30 s denaturation at 95°C, 30 s annealing at 61°C, 30 s extension at 72°C, 7 min final extension at 72°C.

The constitutively expressed actin gene (GenBank Accession number J0128) was used as an internal control to normalize the obtained gene expression results. The primers were: forward: 5′-TGTTTCGCCTGAAGATCAC CCTGTG-3′; reverse: 5′-TGAACCTTTCTGACCCAAT GGTGATGA-3′.

PCR products were separated by electrophoresis in a 1.5% agarose gel, stained with ethidium bromide and analyzed with the ImageJ program (ImageJ 1.23 J, Wayne Rasband, National Institute of Health). To confirm the expression analysis results, PCR reactions were carried out on cDNAs obtained from two different RNA extractions from two independent experiments, and were repeated at least 4 times for each cDNA.

PCR products obtained from the gene expression analysis were sequenced to verify specific amplification of

each gene. DNA was eluted from the agarose gel with the QIAquick Gel Extraction-Kit Protocol (QIAGEN, Valencia, CA, USA) kit. Gene sequencing was carried out at the BMC Genomics at Padova University, using the ABIPRISM original Rhodamine Terminator kit (PE Biosystems, Branchburg, NJ, USA) and specific and universal primers. Gene sequences were compared with Blastx and Blastn (NCBI, http://www.ncbi.nlm.nih.gov/entrez/query.fcgi).

Amino Acid Content Amino acids were extracted according to Maggioni and Renosto (1980). Qualitative and quantitative determinations were carried out with a Beckman Amino Acid Analyzer (Model 118 CL La Brea, CA, USA) using amino acid standards Type H (Pierce-Thermo-Fisher Scientific, Rockford, IL, USA).

Extraction and Measurement of Soluble Phenolics and Flavonoids Leaves were crushed with 3 ml methanol per g leaf. After 30 min on ice, the samples were centrifuged for 30 min at 4°C at 5,000x*g*, and the supernatants were stored at −20°C until use. Phenolics were measured by the Folin method (Arnaldos et al. 2001) standardized with gallic acid. Flavonoids were extracted from 1 g leaves with 50 ml of acidified methanol solution and stored at 4°C for 16 h before recording absorbance at 300 nm. Flavonoids were expressed as gallic acid equivalents (Meenakshi et al. 2009).

Statistical Analysis All data were the means of five replicates, and the standard deviations did not exceed 5%. Results were processed statistically with the Student-Newman-Keuls test ($P \leq 0.05$) (Sokal and Rohlf 1969).

Results

HS Characterization The elemental analysis of HS indicated that the sample had a low H/C ratio (Table 1), which is typical of highly condensed aromatic rings (Visser 1983). The HS contained 27±0.72 nmol of IAA per mg C.

The ^{1}H NMR spectrum was divided into three main regions: aromatic hydrogens from 6.0 to 8.0 ppm; hydrogens attached to oxygen groups in carbon a (defined as sugar-like) from 4.2 to 3.0 ppm, and aliphatic hydrogens from 3.0 to 0.5 ppm (Fig. 1). HS had a poorly resolved aromatic proton region and an intense and broad region attributed to sugar-like and polyether components. Other broad and intense resonances at 0.83 ppm and 1.3 ppm were due to the protons of terminal methyl groups of methylene chains, respectively (Fan 1996). Two further intense resonances appeared at 2.9 ppm and 3.40 ppm and were assigned to protons in α CH_3 of acetoacetate and ether aliphatics, respectively (Fan 1996). These groups presumably were bound chemically to the HS macrostructure (Muscolo et al. 2007).

The DRIFT spectrum was characterized by broad and overlapped bands (Fig. 2), which were sharpened and resolved by recording in the second derivative mode (Fig. 2). The amide I (1660 cm^{-1}) and amide II (1540 cm^{-1}) bands were resolved clearly. The intense band at 1726 cm^{-1} was assigned to the C = O stretching mode of COOH groups (Niemeyer et al. 1992). The bands at 1459 and 1418 cm^{-1} were due to CH_2 bending and COO^- symmetric stretching modes, respectively. Strong negative peaks were near 1164, 1078, 1033, 983, and 893 cm^{-1} in the secondary derivative mode. They were attributed mainly to C-O stretching of carbohydrates (Stevenson 1994), as well as to C-C stretching motions of aliphatic groups and in-plane C-H bending of aromatic rings. The band characteristic of aromatic rings was found at 1514 cm^{-1}, while that at 1230 cm^{-1} was due to C-O stretching vibrations in phenols and carboxyl groups.

Plant Growth, Enzyme Activities and Amino Acid Content HS significantly increased plant fresh weight up to the concentration of 1 mg C/l (+115%, $P \leq 0.05$). However, plants treated with HS at 2 mg C/l had a fresh weight (+109%, $P \leq 0.05$) similar to that of plants treated with HS at 0.5 mg C/l (+110%, $P \leq 0.05$).

Application of HS to maize seedlings significantly increased the activity of GS and PEPC (Table 2). Doses up to 1 mg C/l HS increased the content of some amino acids (glutamate, aspartate, serine, proline, glycine, methionine) in the leaves (Table 3). When HS was applied at 2 mg C/l, the content of amino acids decreased, except for aspartic acid, threonine, and alanine (Table 3). Phenylalanine and tyrosine, the amino acid precursors of the phenylpropanoids, decreased in plants treated with HS at 1 mg C/l, while they were unchanged (phenylalanine) or higher (tyrosine) in presence of HS at 0.5 and 2 mg C/l (Table 3). Alanine, valine, and leucine levels changed in a pattern similar to that noted for tyrosine.

Table 1 Composition characteristics of (C, H, N, O, S) the high molecular weight humic fraction (HS). Sulfur was not detected

	C	H	N	O	C/N	Ash	Total acidity meq/g	IAA[a] nmol
HS	52.3±0.1	5.1±0.4	2.2±0.3	40.4±0.2	23.7	0.53±0.05	4.6±0.5	27±0.72

[a] Indoleacetic acid (IAA) in 1 mg C high molecular weight humic fraction (HS)

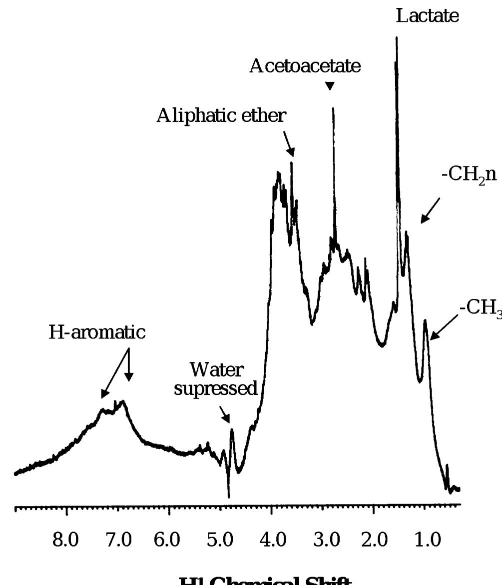

Fig. 1 ^{1}H NMR spectrum of humic fraction extracted from earthworm feces in D_2O. The spectrum shows an aromatic H region (6.0–8.0 ppm) poorly resolved, a broad region (4.2–3.0 ppm) attributed to sugar-like components, polyether materials or methoxy groups, and an intense aliphatic region (3.0–0.5 ppm)

PAL/TAL Gene Expression and Activity, Content of Phenolic Compounds

There was increased accumulation of *ZmPAL1* transcripts in HS-treated plants compared to controls (Fig. 3). In particular, the maximum level of mRNA was observed when plants were supplied with HS at 1 mg C/l (+337%). The activity of PAL/TAL also was significantly higher in maize seedlings treated with HS than the control, and the maximum increase in PAL (+40%) and TAL (+538%) activities was observed when plants were treated with HS at 1 mg C/l (Table 4). Although TAL activity was stimulated by HS more than PAL, the specific activity of PAL was higher under all conditions.

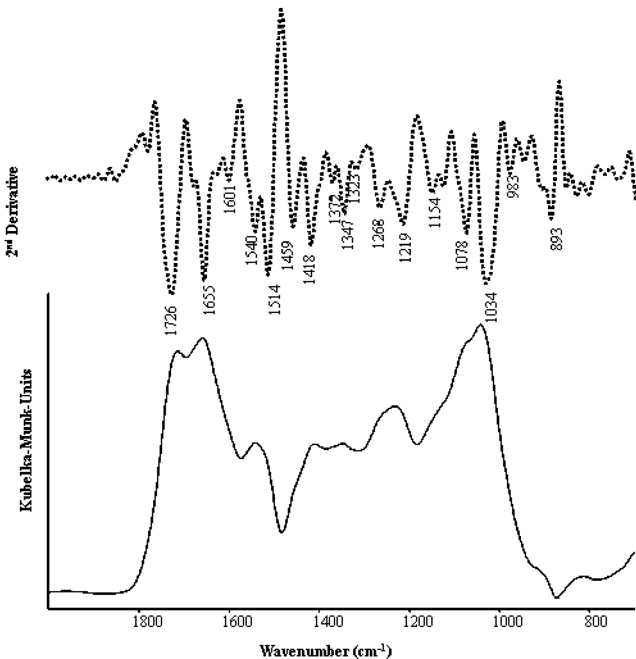

Fig. 2 DRIFT spectrum (*lower line*) of humic substances extracted from earthworm feces. 2nd derivative spectrum (*upper line*) improved the resolution of overlapped and hidden bands in the investigated spectral region

Consistent with the enhancement of PAL expression and activity, the content of total phenolic acids and flavonoids increased following HS treatment, and the maximum values (+45% and +24%, respectively) were measured with HS at 1 mg C/l (Table 4).

Discussion

Despite the considerable amount of physiological and biochemical data on effects of soil HS and earthworm-derived HS on plant growth (Nardi et al. 2009), the effects of HS on secondary metabolism have not been investigated previously.

The earthworm-derived HS used here had a low H/C ratio, which Van Krevelen's diagram suggests is typical of highly condensed aromatic rings (Visser 1983). The presence of hydrophobic domains, such as hydrocarbon chains and aromatic rings, suggested that this fraction was similar to other high molecular weight HS (Muscolo et al. 2007), although it contained less IAA than some preparations of high molecular weight HS (Trevisan et al. 2009). There were physiologically relevant concentrations of IAA in the HS doses applied to maize seedlings in these experiments. How IAA is associated with HS is not well understood. Nevertheless, the high concentration of organic acids released by roots into the rhizosphere may modulate the IAA bioavailability from HS (Nardi et al. 2005). Moreover, HS extracted with acetic acid has a more flexible conformation than bulk humic matter (Nardi et al. 2005;

Table 2 Glutamine synthetase (GS) (μmol/g f.w./ min) and PEP-Carboxylase (PEPC) (μmol NAD^+/g f.w./min) activities in *Zea mays* leaves. Plants were treated for 48 h with high molecular weight humic substances (HS) at the indicated concentrations

[b] Values in the same row followed by the same letter are not statistically different at $P<0.05$ as per the Student–Newman–Keuls test

Canellas et al. 2008). Thus, the activity of the HS used here likely was related to its chemical composition and molecular conformation in addition to its molecular weight (Canellas et al. 2010).

The high molecular weight HS stimulated phenylpropanoid metabolism, as confirmed by the induction of PAL and TAL enzyme activities and expression, and the increased accumulation of some phenolics.

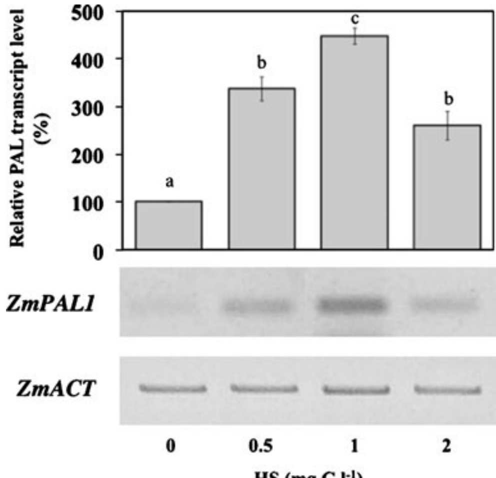

Fig. 3 Gene expression (mRNA level) and relative transcript accumulation of *ZmPAL1* in leaves of *Z. mays* plants grown for 12 d in Hoagland modified complete nutrient solution and treated for 2 d with HS at 0 (control), 0.5, 1, or 2 mg C/l. Transcript amounts were determined using the semiquantitative PCR method in the linear range, and *ZmACT* was used as internal control. The accumulation of the gene transcript was normalized relative to *ZmACT* transcript and expressed relative to the control (100%). Values are shown on bars. Different letters on bars indicate significant differences between treatments ($P<0.05$, ±SD)

HS may have promoted plant growth through the induction of carbon and nitrogen metabolism. PEPC and GS activities were increased, and glutamate and aspartate accumulated in a HS-concentration-dependent manner. The decrease of both phenylalanine and tyrosine in the HS-treated plants (1 mg C/l) may be attributed to consumption of these two amino acids for the synthesis of phenylpropanoids.

Consistent with these findings, PAL/TAL was induced by HS, with maximum activity in plants dosed with HS equivalent to 1 mg C/l. The induction of PAL was noted at the level of gene expression, similar to other studies in which phenylpropanoid synthesis has been enhanced at the transcriptional level by fungal elicitors and hormones (Shinya et al. 2007; Lewis et al. 2008). Flavonoid synthesis,

Table 4 Phenylalanine ammonia-lyase (PAL), tyrosine ammonia-lyase (TAL) activities, total phenolic acid and flavonoid content in *Zea mays* leaves. Plants were treated for 48 h with high molecular weight humic substances (HS) at the indicated concentrations[a]

in particular, is induced by auxins through transcriptional activation (Lewis et al. 2008). In addition, a relationship between flavonoid accumulation and auxin transport has been reported (Buer and Muday 2004; Peer and Murphy 2007). Given that HS contains IAA and exhibits auxin-like activity (Zandonadi et al. 2007; Canellas et al. 2010), the stimulation of phenylpropanoid metabolism likely occured through auxin-mediated signal transduction. High molecular weight HS does not to enter the symplast, but it remains in the apoplast bound to the cell wall where it act as an exogenous signal molecule. As a result, HS is able to induce auxin-like responses including stomata opening (Russell et al. 2006) and lateral root formation (Trevisan et al. 2009). Since HS is poorly characterized, it is possible that its effects on phenylpropanoid metabolism could be ascribed to co-purified fungal elicitors and/or other signalling molecules (hormones, organic acids, peptides, and fatty acids) (Le Floch et al. 2003; Kim et al. 2007). Chemical moieties characteristic of HS, including alcohol, phenol, and carboxyl groups, also could stimulate changes in plant metabolism (Nardi et al. 2009; Zancani et al. 2009).

In summary, the present work shows that application of high molecular weight HS to hydroponically grown maize seedlings changed secondary metabolism associated with the synthesis of phenolic compounds. The stimulatory effects of HS on plant secondary metabolism provide an innovative approach to exploring plant responses to stress.

Acknowledgements This work was partially supported by a grant from the University of Padova (ex 60%, 2008) awarded to Prof. Serenella Nardi. We are grateful to Dr. Andrea Ertani and Dr. Sara Trevisan for their helpful assistance. The authors would like to thank Professor Ann E. Hagerman for her precious help in the improvement of the manuscript.

Specialist Leaf Beetle Larvae Use Volatiles from Willow Leaves Infested by Conspecifics for Reaggregation in a Tree

Abstract Young, gregariously living larvae of the willow leaf beetles *Plagiodera versicolora* are known to exhibit characteristic aggregation-dispersion-reaggregation behavior and local fidelity to a host tree. In this study, we investigated whether plant volatiles induced by feeding *P. versicolora* larvae were involved in the reaggregation behavior. Under laboratory conditions, we conducted dual-choice bioassays and found that the first and second instars discriminated between volatiles from leaves infested by larvae and volatiles from uninfested leaves. The discriminative behavior was dependent on both the time leaves were infested and the age of discriminating larvae. First and second instars preferred odor from 1-d-infested leaves to odor from uninfested leaves, whereas third instars (solitary stage) did not discriminate between these volatile blends. Odor from 2-d-infested leaves was preferred to odor from 1-d-infested leaves by first instars, whereas odor from leaves infested for 3 d was not attractive to these very young larvae. Neither was odor of leaves infested for 1 d and then left uninfested for 1 or 2 d attractive to young larvae. The data suggest that the first and second instars use volatiles from a leaf newly infested by conspecific larvae as one of the reaggregation cues. We detected several herbivore-induced compounds in the headspace of the attractive leaves. Among those, a mixture of synthetic (*E*)-β-ocimene, (*Z*)-β-ocimene, *allo*-ocimene, and linalool was found to attract the larvae.

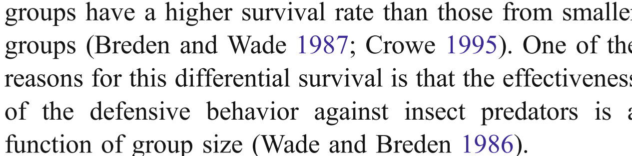
Introduction

Volatile and non-volatile chemicals of food plants play multiple roles in insect—plant interactions (Schoonhoven et al. 2005). Studies on the response of herbivorous arthropods to plant volatiles have focused mainly on adult herbivores finding a host plant for their oviposition. Uninfested leaves emit a blend of volatiles that can be exploited by adult herbivores as information indicating the presence of a host plant (e.g., Bernays and Chapman 1994; Dicke and van Loon 2000; Yoneya et al. 2009a). Foraging adult herbivores also use volatiles from infested plants for host search; some of these odors act as attractants (Bolter et al. 1997; Dicke and van Loon 2000; Kalberer et al. 2001; Horiuchi et al. 2003) and some as repellents (Dicke 1986; Dicke and van Loon 2000; De Moraes et al. 2001; Kessler and Baldwin 2001; Horiuchi et al. 2003; Heil 2004; Yoneya et al. 2009a), thus preventing colonization of food resources that are infested by the same or different herbivore species.

In contrast to arthropods at the adult stage, herbivorous arthropod larvae are rather sedentary, although they may move among host food plants in search of suitable resources. Herbivorous larvae also have been demonstrated to use volatiles from host plants in their foraging behavior (e.g., Huang and Mack 2002; Carroll et al. 2006, 2008; Castrejon et al. 2006; Shiojiri et al. 2006). In dual-choice



tests, saltmarch caterpillar (*Estigmene acrea*) larvae showed a clear preference for volatiles from soybean leaves over those from maize and tomato leaves (Castrejon et al. 2006). By using Y-tube olfactometer bioassays, Carroll et al. (2006) examined the orientation responses of sixth instar fall armyworms (*Spodoptera frugiperda*) to odors from herbivore-damaged and undamaged maize seedlings. The sixth instars preferred odors from damaged maize seedlings to those from undamaged seedlings. Shiojiri et al. (2006) reported that armyworm (*Mythimna separata*) larvae used hostplant volatiles to determine their feeding and hiding behavior. It should be noted that the aforementioned studies focused on generalist herbivores at their larval stages. In contrast, little is known regarding the olfactory responses of the larval stages of specialist herbivores to plant volatiles, particularly those induced by herbivores (but see, Landolt et al. 2000).

Host plant location by leaf beetles (Chrysomelidae) is mediated by cues from both uninfested and infested host plants; furthermore, several leaf beetle species rely on aggregation pheromones (Fernandez and Hilker 2007, and references therein). Most of these studies on chrysomelid host plant location focus on behavior of adults. Knowledge on the chemical cues that are relevant for colonization of host plants by chrysomelid larvae is scarce, even though chrysomelid larvae frequently may move between plants (Bach 1993). For example, the green leaf volatile (*Z*)-3-hexen-1-ol associated with vertical structures has been shown to attract larvae of *Cassida denticollis* (Müller and Hilker 2000). Another example that studied the impact of non-volatile host plant compounds on chrysomelid larval host plant colonization showed that variation in content of phenol glycosides may affect distribution of the willow leaf beetle *Phratora vitellinae,* whereas larval distribution of *Plagiodera versicolora* is not affected (Rowell-Rahier et al. 1987). While larvae of *P. vitellinae* use plant phenolglycosides as precursors for the biosynthesis of their defensive secretion (mainly salicylaldehyde), *P. versicolora* larvae do not use these phenolglycosides for the production of the major compounds of their defensive secretions (mainly cyclopentanoid monoterpenes) (Pasteels et al. 1984).

Plagiodera versicolora is a specialist herbivore that feeds exclusively on Salicaceae species (Hood 1940). The larvae hatch from clutches of 15–25 eggs that are laid on the underside of leaves, and the hatched larvae exhibit gregarious behavior while feeding on leaves (Wade 1994). This gregariousness is typical of the first and second instars (Wade and Breden 1986). Crowe (1995) found that larvae remain aggregated on the natal leaf for 1–5 d. Thereafter, they move singly from the natal leaf to other leaves, and reaggregate on a new leaf within a few hours of dispersal (Wade and Breden 1986; Crowe 1995). Young larvae benefit from reaggregation since individuals from larger groups have a higher survival rate than those from smaller groups (Breden and Wade 1987; Crowe 1995). One of the reasons for this differential survival is that the effectiveness of the defensive behavior against insect predators is a function of group size (Wade and Breden 1986).

Crowe (1995) studied the factors involved in this reaggregation behavior. Although *P. versicolora* larvae respond positively to the presence of conspecific larvae (Crowe 1995), the mechanisms underlying the break-up of the initial aggregation, subsequent dispersion, and reaggregation at a new feeding site on a leaf remain to be elucidated. In the field, we have observed that reaggregated groups consist of both the first and second instars of different egg clutches (Yoneya, unpublished data). Thus, the members of a reaggregated group may not always be from the same egg clutch. We hypothesized that one of the factors promoting settlement, site selection, and subsequent reaggregation on a new willow leaf by dispersing first and second instars is the volatiles emitted from a leaf infested by conspecifics of the dispersing instars. We conducted a combination of dual-choice bioassay and chemical analyses to test whether larvae responded to leaves with different histories of infestation.

Methods and Materials

Insects Adult *P. versicolora* were collected in the field from April to October 2005–2008. Every year, we established a new colony. The colony was maintained in a climate-controlled chamber (25±3°C, 50–70% RH, L18:D6). Larvae from one clutch of eggs (approximately 20) were stored in a plastic cup (diam. 13 cm; height 10 cm), the lid of which was pierced with 50–60 holes (diam. 1–2 mm) to permit air exchange. We offered the beetles fresh field-collected uninfested *Salix eriocarpa* leaves (10 leaves at a time) every 2–3 d until beetles had reached sexual maturity. When beetles were provisioned with fresh leaves, they were placed into a new cup.

Plants We cut a total of 130 shoots (1 or 2 yr-old; length 18 cm) from *S. eriocarpa* trees growing on the floodplain of the Yasu River in Shiga Prefecture, Japan, in early May and mid-August 2004. The shoots were individually potted in humus (using pots that were 15 cm in diam. and 13 cm high) and maintained in a greenhouse (25±3°C, L18:D6) for 2 mo. When the newly emerged plant shoots were approximately 20 cm high, we used them in the bioassay.

For the preparation of infested leaves, we placed two second instar *P. versicolora* on each of five leaves of a potted *S. eriocarpa* plant grown in a greenhouse. We did not place larvae on the first or second leaves from the shoot tip, as eggs in the field generally are found on leaves near

the center of a branch (King et al. 1998). An adjacent uninfested leaf (i.e., a leaf of the same age and the same length, ca. 10 cm) on the same branch was used as the control. Both the infested and uninfested leaves were detached with a razor blade and gently washed with water to remove feces and other associated products. Those leaves were used for experiments within 30 min. after the detachment, and were not used for more than 2 hr.

Dual-choice Bioassay An infested and an uninfested leaf of the same size (length ca. 10 cm) were collected from the same branch by cutting with a razor blade. The leaves were washed gently with water to remove feces and other associated products, and placed immediately on moist paper (8×4 cm) in a Petri dish (diam. 14 cm; height 2.5 cm; Fig. 1). In order to exclude possible visual effects, we covered the infested part with a piece of nylon gauze. We also placed a piece of nylon gauze on an uninfested leaf. A piece of Parafilm was placed so as to bridge the 2 leaves (Fig. 1), with the size of the Parafilm changed according to the larval instar being tested (first instar: 2× 0.4 cm; second instar: 3×0.5 cm; third instar: 5×0.6 cm). A *P. versicolora* larva was placed in the middle of the Parafilm bridge; when it reached one of the two leaves, we recorded this as a choice. When a larva chose neither leaf after 1 hr, we classified it as a no-choice individual. We excluded no-choice individuals from statistical analyses. Each experiment was replicated three to four times on different days. Odor source leaves were used once for each replicate. Individual larvae were used only once. The data were subjected to a binomial test. In order to compare the different data sets, we used Fisher's exact probability test.

The following experiments were conducted:

1. Effects of larvae of different developmental stages. In the field, larvae aggregate during the first and second instars. Thus, we tested the response of first, second, and third instars to a leaf infested by second instars for 1 d and compared this response with the response to an uninfested leaf. In this experiment, a combination of odor sources was offered to larvae of three developmental stages in each replicate.
2. Effects of the duration of infestation. Raupp and Denno (1984) reported that leaves that had been infested by larvae for 3 d no longer provided suitable resources. Thus, we tested whether the first instars responded to volatiles from a leaf that had already been infested by second instars for 2 or 3 d.
3. Effects of the duration of attractive qualities after the termination of the damage. In the field, we did not observe larvae aggregating in a previously infested site that currently lacked larvae (Yoneya, personal observation). We prepared a leaf that had been infested by second instars for 1 d and then left uninfested for 1 or 2 d (previously infested leaf). We tested the response of first instars given a choice between a previously-infested leaf and uninfested leaf.
4. Identification of odor compounds from infested leaves that were attractive to larvae. On the basis of the results of the chemical analyses, we tested the response of first instars to volatile compounds whose amounts were significantly higher in the headspace of attractive infested leaves than in that of uninfested leaves. Hexane was used as the solvent. A hexane solution of test compounds was impregnated into a piece of filter paper (1×3 cm). After evaporation of the solvent, a piece of filter paper with test compounds was placed on one of the two uninfested leaves in a Petri dish. As a control, solvent-impregnated filter paper was placed on the other leaf. The preference of first instars between an uninfested leaf supplemented with the test compounds and an uninfested control leaf was observed. To perform the bioassays, an ocimene and linalool mixture (IFF Chemicals, Florida, U.S.A.) was used. By GC-MS analyses, the mixture was shown to contain (*E*)-*β*-ocimene (74.6% of total ion intensity), (*Z*)-*β*-ocimene (7.2%), *allo*-ocimene (10.8%), and linalool (7.4%). A piece of filter paper (0.5 cm^2) was impregnated with 1 / μl hexane solution of the mixture (100 ng/μl). The amounts of (*E*)-*β*-ocimene emitted from the filter paper (0.1±0.01; peak area of GC/MS normalized with the internal standard: see below) was adjusted to be roughly the same as that emitted from a 1-d-infested leaf during 1 h (0.20±0.02; peak area of GC/MS normalized with the internal standard: see below).

Chemical Analysis of Volatiles from Willow Leaves We compared the headspace volatiles of leaves infested by *P. versicolora* larvae with those of uninfested leaves. We conducted the chemical analyses of volatiles only when the volatiles attracted the larvae. Infested and uninfested leaves were newly prepared for chemical analyses. The preparation of infested and uninfested leaves was the same as those used for the bioassays.

We used 10 uninfested or infested leaves (0.9–1.5 g) detached from 2 infested plants with a razor blade in each sample. The cut-edge of the detached leaf petiole was covered with a piece of moist cotton wool to prevent desiccation. We collected the volatiles in a climate-controlled room (25±2°C). As an internal standard, we used a piece of filter paper impregnated with 1 µl of a hexane solution of tridecane (0.5 µg/µl). We placed the leaves and filter paper in a glass bottle (2 L) fitted with 2 nozzles. One nozzle was connected to an air cylinder and

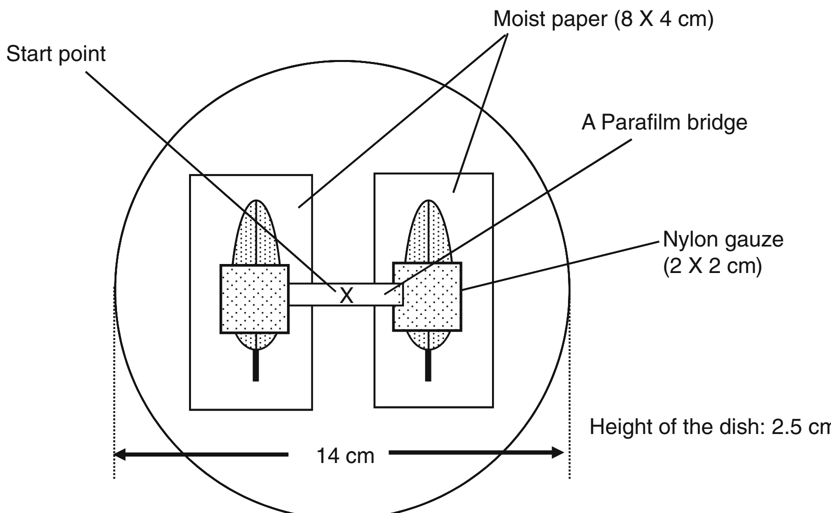


Fig. 1 The bioassay arena used to investigate choices between an infested leaf and an uninfested leaf (each ca. 10 cm long) on moist paper (8 cm×4 cm). We connected the 2 leaves with a Parafilm bridge. The size of the Parafilm bridge varied according to the developmental stage of the tested larvae (first instar: 2×0.4 cm; second instar 3×0.5 cm; third instar: 5×0.6 cm)

the other nozzle to a glass tube packed with Tenax TA adsorbent (GL: Tenax TA 20/35, 100 mg; I.D., 3 mm; length, 160 mm). Air from the cylinder was drawn into the glass bottle, and volatile compounds from the headspace of the bottle were collected on the Tenax TA for 1.5 hr at a flow rate of 100 ml/min.

The collected volatile compounds were analyzed with a gas chromatograph-mass spectrometer (GC-MS) [GC: Hewlett Packard 6890 gas chromatograph (GC) equipped with an HP-5MS capillary column (length, 30 m; I.D., 0.25 mm; film thickness, 0.25 µm); MS: Hewlett Packard 5973 mass selective detector (70 eV) equipped with a thermal desorption cold-trap injector (TCT: CP4010; Chrompack, The Netherlands)]. Headspace volatiles collected on Tenax-TA were released from the adsorbent by heating in the TCT at 220°C for 8 min with He gas flow (1 ml/min). The desorbed compounds were collected in the TCT cold trap unit (SIL5CB-coated fused silica capillary) at−130°C. Flash heating of the cold trap unit induced a sharp injection of the compounds into the capillary column of the GC connected to the unit. The GC oven temperature was programmed to increase from 40°C (5-min hold) to 280°C at 15°C/min. The headspace volatiles were tentatively identified by comparing their mass spectra with those of the Wiley databases (Wiley7N and Wiley275), and the database of National Institute of Advanced Industrial Science and Technology (SDBS compounds and spectral search.) (http://riodb01.ibase.aist.go.jp/sdbs/cgi-bin/direct_frame_top.cgi). Further, we compared their retention times with those of authentic compounds (Wako Chemicals, Osaka, Japan, and IFF Chemicals, Florida, U.S.A.). The compounds for which no authentic compounds were available were regarded as tentatively identified with more than 90% of spectra matching with the databases. We normalized the ion intensity of each peak to a "peak area" by dividing the intensity by the ion intensity of the internal standard and the mass (g) of fresh leaves. We compared the peak area of each compound between infested and uninfested leaves on the same plant using the Mann-Whitney *U* test. Chemical analyses were repeated four times for each odor source except for uninfested leaves detached from 2-d-infested plants (N=3).

Results

Both first and second instars preferred a leaf infested by second instars for 1 d to an uninfested leaf (binomial test for larvae of both instars, P<0.01) (Fig. 2). In contrast, third instars showed no preference between the two leaf types (binomial test, P=0.855) (Fig. 2). In the remaining experiments, we used first instars, as the responses of the first and the second instars were not significantly different (Fig. 2; Fisher's exact probability test, P>0.05).

The first instars preferred volatiles from leaves previously infested by second instars for 2 d to uninfested leaf volatiles (binomial test, P=0.015) (Fig. 3a). The first instars showed no preference between an uninfested leaf and a leaf infested by second instars for 3 d (binomial test, P=0.322) (Fig. 3a). The two preference data in Figure 3a were not significantly different (P=0.41, Fisher's exact probability test). First instars showed no preference between an uninfested leaf and a leaf that had been infested by second instar larvae for 1 d and then left uninfested for 1 or 2 d (binomial test, P=0.585, P=0.315, respectively) (Fig. 3b).

We recorded 26 and 29 volatile compounds in the headspace of leaves infested for 1 and 2 d, respectively (Table 1). The tentative identifications of (*E*)-2,6-dimethyl-1,3,5,7-octatetraene, α-copaene, β-gurjinene, (*E*)-β-caryophyllene, β-cubebene, germacrene D, (*syn*)- or (*anti*)- 2-methylbutanal oxime, (*syn*)- or (*anti*)-3-methylbutanal oxime, 2-

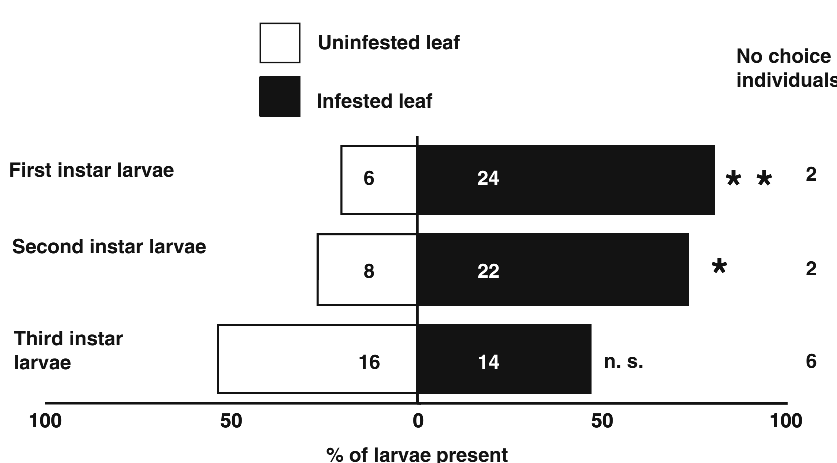

Fig. 2 Olfactory responses of the first, second, and third instar *Plagiodera versicolora* larvae to uninfested vs. 1-d-infested leaves. NS: no significant difference, * :0.01<P<0.05, ** :0.001<P<0.01 (binomial test). Numbers in bars indicate the number of larvae that responded to volatiles

methylbutanenitrile, and 3-methylbutanenitrile were based only on the Wiley databases and on "SDBS compounds and spectral search." The major compounds were (*Z*)-3-hexen-1-ol, (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, (*E*)-4-8-dimethyl-1,3,7-nonatriene and (*E,E*)-α-farnesene. The compounds that were present in significantly higher amounts in the headspace of 1- and 2-d-infested leaves than in the respective controls were benzyl alcohol, 2-hydroxybenzaldehyde, (*E*)-β-ocimene, linalool, (*E*)-4,8-dimethyl-1,3,7-nonatriene, *allo*-ocimene, (*E*)-2,6-dimethyl-1,3,5,7-octatetraene, α-copaene, germacrene D, (*E,E*)-α-farnesene, and δ-cadinene (Table 1). These were considered as candidate compounds that attracted the larvae.

To test the possible involvement of herbivore-induced volatiles in the attraction of the larvae, we focused on the response of larvae to (*E*)-β-ocimene, as this compound was one of the major induced compounds in the headspace of 1- and 2-d-infested leaves. To perform the bioassays, a mixture of ocimene and linalool, which contained two further candidates (*allo*-ocimene and linalool) in addition to (*E*)-β-ocimene, was used. (*Z*)-β-Ocimene, which was present at a significantly higher level in 1-d-infested leaves than in uninfested leaves, was also in the mixture (see Methods and Materials). Thus, we judged that the ocimene and linalool mixture could be used to test whether the larvae used *P. versicolora*-induced *S. eriocarpa* volatiles for their reaggregation. First instars preferred an uninfested leaf supplemented with the mixture to an uninfested control leaf (binomial test, P=0.022) (Fig. 3c).

Discussion

In our experiments, larvae as well as their associated products (feces, visible secretions, etc.) were removed from leaves. Volatile compounds of larval secretion origin reported in previous studies (e.g., Rowell-Rahier and Pasteels 1986) were not detected in the headspace of larvae-infested willow leaves. Thus, the volatiles that were recorded in the headspace of *S. eriocarpa* plants infested by *P. versicolora* larvae, but not or in trace amounts in that of uninfested plants in this study, were considered to be *P. versicolora* larvae-induced plant volatiles.

The positive responses of first and second instars and the neutral response of third instars (non-aggregation stage) to the 1-d-infested leaf volatiles, compared with their responses to uninfested leaf volatiles, suggest that herbivore-induced leaf volatiles are involved in the reaggregation behavior of the first and the second instars on a tree in the field (Wade and Breden 1986; Crowe 1995). In fact, we did not observe third instars in the field in aggregated *P. versicolora* groups consisting of first and second instars. Crowe (1995) reported that trails made with the secretions of larvae, including feces, and certain leaf-surface chemicals were used by the larvae as cues to follow, suggesting that some contact chemicals are also involved in the reaggregation process.

We found that the first instars preferred volatiles from uninfested leaves supplemented with a synthetic ocimene and linalool mixture that contained three induced volatiles other than (*E*)-β-ocimene. These herbivore-induced volatiles might play a role in evoking the aggregation response of the first instars. Herbivore-induced ocimene and/or linalool are reported to be involved in interactions between plants and carnivorous arthropods (e.g., Dicke et al. 1990; Du et al. 1998; Ishiwari et al. 2007). The adult willow leaf beetle *Phratora vulgatissima* is known to show moderate electrophysiological responses to ocimene released from willow leaves (Fernandez et al. 2007). It remains to be investigated which compound(s) in the mixture attract the larvae. Further, whether the mixture of the same and different concentrations also affects the behavior of the first, and the second instars, but not that of the third instars, remains to be answered. Brilli et al. (2009) reported that constitutive and herbivore-induced monoterpenes emitted from leaves of hybrid popular attracted *Chrysomela populi* beetles.

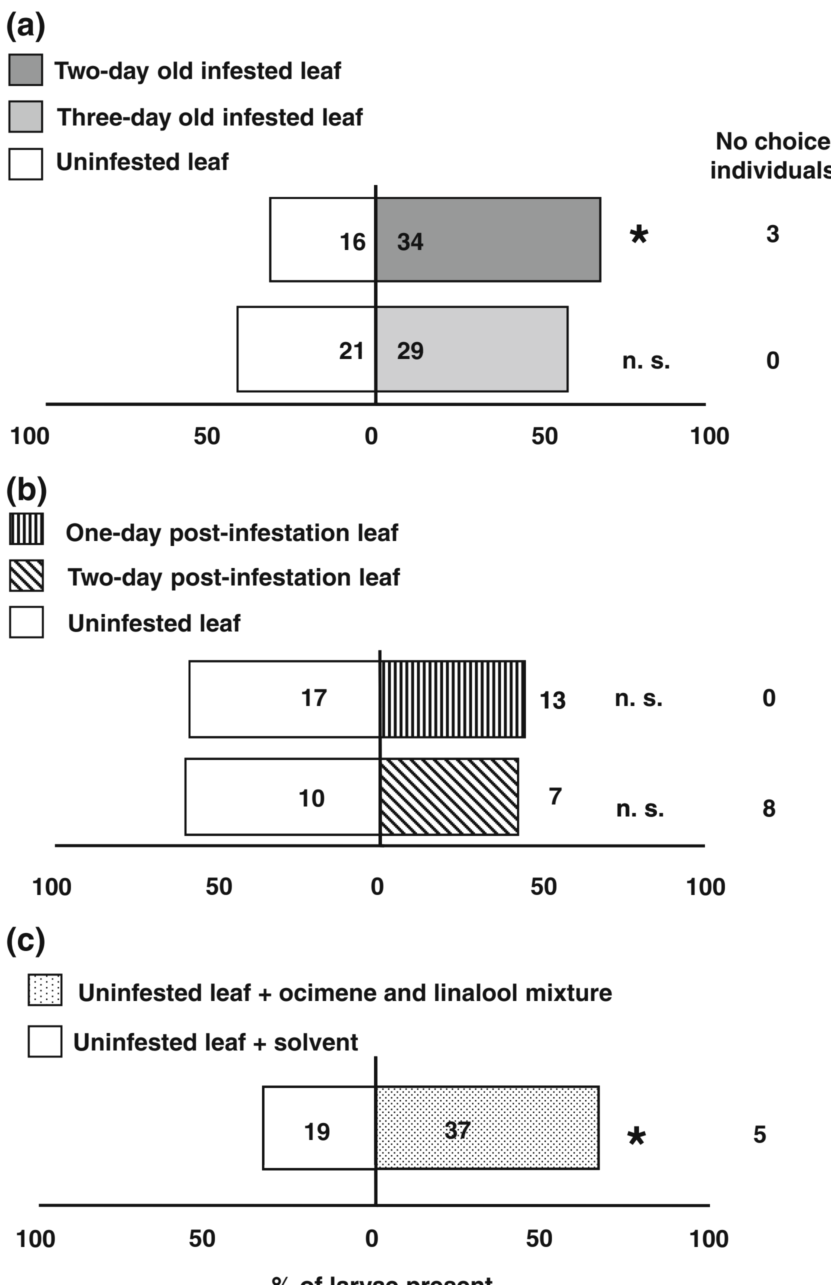

Fig. 3 Olfactory response of first instar *Plagiodera versicolora* larvae to differently treated leaves. NS: no significant difference, * :0.01<P<0.05 (binomial test). Numbers in bars indicate the number of larvae that responded to volatiles. (**a**) Comparisons of uninfested leaves vs. 2-d-infested leaves, and uninfested leaves vs. 3-d-infested leaves. (**b**) Comparison of uninfested leaves vs. 1-d-infested leaves 1 day after the removal of larvae, and uninfested leaves vs. 1-d-infested leaves 2 days after the removal of larvae. (**c**) Comparison of uninfested leaves supplemented with 1 µl hexane vs. leaves supplemented with a hexane solution of 100 ng/µl ocimene and linalool mixture

The first instars showed a preference for 2-d-infested leaves over uninfested leaves, and an equal preference for 3-d-infested leaves and uninfested leaves compared with uninfested leaves. This finding was in accordance with a previous study showing that the quality of the 3-d-infested leaves was not suitable for the larvae within aggregation stages (Raupp and Denno 1984). The volatiles may indicate the suitability to the larvae. Likewise, the first instars showed no preference for previously infested leaves. As the gregarious behavior of early instars is an important life history strategy in terms of defense against predators (Breden and Wade 1987), these differing responses would facilitate their reaggregation at a site where conspecific larvae of the aggregation stage had settled and started feeding. The chemical profiles of herbivore-induced volatiles would be highly dependent on the duration of damage and the time since last damage (Turlings et al. 1990; Maeda and Takabayashi 2001; Arimura et al. 2004, 2008; Hoballah and Turlings 2005). For example, corn seedlings release large amounts of volatile terpenes in response to damage caused by *Spodoptera exigua* larvae (Turlings et al. 1990). They were detected even after the removal of the larvae.

Green leaf volatiles [(*Z*)-3-hexenal, (*E*)-2-hexenal, and (*Z*)-3-hexenol] are detected when larvae are actively damaging the plants. In contrast, some volatile terpenes [α-*trans*-bergamotene, (*E*)-β-farnesene, and (*E*)-nerolidol] are detected several hours after the removal of the larvae. Arimura et al. (2004) studied the temporal patterns of systemic emission of germacrene D in poplar plants infested by forest tent caterpillars. After removal of the caterpillars, emission was reduced during the next 24 hr. The dependence of leaf odor attractiveness on the duration of infestation found in our study with *P. versicolora* larvae might be explained by differential time course emissions of *P. versicolora* larvae-induced volatiles in *S. eriocarpa*.

Yoneya et al. (2009b) reported that 17 compounds were detected in the headspace of infested plants, and four compounds in that of the uninfested plants. By contrast, in the present study, 1-d-infested leaves emitted 26 compounds and uninfested leaves emitted 13 compounds. Yoneya et al. (2009b) used a whole plant as the odor source, while this study used detached leaves as the odor source for chemical analyses, because the dual choice tests were conducted with detached leaves. These data indicate that due to the stress of detachment, the leaves emitted a larger number of volatiles than whole plants. Schmelz et al. (2001) previously reported that detached corn leaves released substantially different amounts of induced volatiles than uninfested ones.

Several studies show that herbivore-induced plant volatiles may have multifunctional effects in ecosystems, such as attracting carnivorous natural enemies of infesting

herbivores, avoiding/attracting conspecific/heterospecific herbivores, and mediating plant-plant communications (Arimura et al. 2009). We recently reported that ladybird (*Aiolocaria hexaspilota*) adults showed no preference for *S. eriocarpa* infested by leaf beetle adults (non-prey) over uninfested plants, but moved more often to the willow plants infested by leaf beetle larvae (prey) than to uninfested plants (Yoneya et al. 2009b). Furthermore, adult *P. versicolora* (either satiated or starved) are attracted to uninfested *S. eriocarpa* leaf volatiles, while only starved female *P. versicolora* are attracted to adult-infested *S. eriocarpa* volatiles in their foraging (Yoneya et al. 2009a). Here, *P. versicolora* larvae-induced volatiles are shown to affect the behavior of conspecific larvae as well. Thus, the volatiles from the larva- and adult-infested willow plants have multiple specific functions in the field. Such volatiles would play important roles in the infochemical networks of a willow community.

Abstract Plants infested with herbivores release specific volatile compounds that are known to recruit natural enemies. The response of natural enemies to these volatiles may be either learned or genetically determined. We asked whether there is genetic variation in the response of the predatory mite *Phytoseiulus persimilis* to methyl salicylate (MeSa). MeSa is a volatile compound consistently produced by plants being attacked by the two-spotted spider mite, the prey of *P. persimilis*. We predicted that predators express genetically determined responses during long-distance migration where previously learned associations may have less value. Additionally, we asked whether these responses depend on odors from uninfested plants as a background to MeSa. To infer a genetic basis, we analyzed the variation in response to MeSa among iso-female lines of *P. persimilis* by using choice-tests that involved either (1) MeSa presented as a single compound or (2) MeSa with background-odor from uninfested lima bean plants. These tests were conducted for starved and satiated predators, i.e., two physiological states, one that approximates migration and another that mimics local patch exploration. We found variation among iso-female lines in the responses to MeSa, thus showing genetic variation for this behavior. The variation was more pronounced in the starved predators, thus indicating that *P. persimilis* relies on innate preferences when migrating. Background volatiles of uninfested plants changed the predators' responses to MeSa in a manner that depended on physiological state and iso-female line. Thus, it is possible to select for context-dependent behavioral responses of natural enemies to plant volatiles.

Key Words *Phytoseiulus persimilis* · Methyl salicylate · I-tube olfactometer · Preference · Genetic variation · Context dependence

Introduction

Predatory arthropods are known to respond to herbivore-induced plant volatile chemicals (Dicke and Van Loon 2000; Sabelis et al. 2007). This phenomenon prompted the hypothesis that first and third trophic levels "conspire" against the second: the infested plants attract the natural enemies that can reduce or eliminate herbivore pressure, whereas the predators acquire information on the location of its prey (Dicke and Sabelis 1988; Dicke and Van Loon 2000; Kessler and Baldwin 2001, but see Allison and Hare 2009). However, for such a system to evolve and function, a number of conditions have to be fulfilled (Van der Meijden and Klinkhamer 2000; Janssen et al. 2002). Among them, it requires that the predators evolve behavioral responses to plant-produced volatiles induced by herbivore feeding. These responses may rely on predators learning to associate herbivore-induced plant volatiles with the presence of prey. Alternatively, predators evolved genetically determined preferences for plant volatiles induced by herbivorous prey, if in the past generations predators innately responding to such volatiles (i.e., prior to any experience) had higher fitness than those that did not show such behavior. Fitness benefit would be obtained because these volatiles were reliably coupled with the presence of prey. Therefore, we expect genetic bases for predator responses to these plant volatiles that are induced

by the feeding of prey, irrespective of the species of infested plant.

We investigated whether there is genetic variation in the response of the predatory mite *Phytoseiulus persimilis* (Athias-Henriot) to a selected herbivore-induced plant volatile, methyl salycilate (MeSa). MeSa is one of the volatile compounds consistently induced by feeding of the two-spotted spider mite (*Tetranychus urticae* Koch)—the prey of *P. persimilis*—on a variety of plant species (van den Boom et al. 2004). Empirical studies showed that it plays a key role in predator attraction to the volatile blends induced by the spider mite (de Boer and Dicke 2004a; de Boer et al. 2004; van Wijk et al. 2008; Ament et al. 2010). A genetic basis for the responses of *P. persimilis* to blends of volatile compounds has been demonstrated in two studies on selection for responses of satiated predators to the complete blend of volatiles released by spider-mite infested lima bean (Margolies et al. 1997; Jia et al. 2002). However, innate preferences for the full volatile blend of infested bean may be the result of the underlying innate response to a single compound shared by the blends of many plant species infested by the spider mite—a condition that is fulfilled by MeSa. In this study, we applied an analysis using iso-female lines (David et al. 2005) to detect genetic variation in response to MeSa among *P. persimilis* lines. A significant difference in the olfactory responses among iso-female lines indicates a genetic basis for this trait, provided that systematic environmental influences are controlled for.

The odor of uninfested plants is a permanent feature of the volatile signal under natural settings. Therefore, we hypothesized that the background odors of uninfested lima bean may affect the predator's perception of MeSa and the strength of response to MeSa. Lima bean leaves heavily infested with spider mites also were used for culturing of the predator population used in this experiment. Therefore, any pre-conditioning of the predator to the odors experienced in the culture would be to the volatile blend of infested lima bean that is quantitatively different from the blend of uninfested bean (e.g., Dicke et al. 1990). Hence we expected that an enhanced predator response to MeSa presented with the background odors of uninfested lima bean would be a result of altered perception to MeSa when presented within a context rather then due to predator pre-conditioning to specific volatiles. Mechanically damaged plants produce increased amounts of a distinct group of volatiles called green leaf volatiles (GLVs), which are also emitted by intact plants in smaller amounts (Hatanaka 1993; Matsui et al. 2000; van den Boom et al. 2004). Thus, we term the background odors provided by the punched leaf discs used in this experiment as GLVs.

Genetically determined responses to herbivore-induced plant volatiles are particularly relevant, and subject to natural selection, in situations where predators cannot yet have learned the association between the presence of specific volatiles and prey. The predatory mite *P. persimilis* may experience such situations during the migratory phase that follows the exploitation of the previous colony of prey. These phases of the predator life history can be approximated by manipulating the predator's hunger level because food conditions provide the proximate cue for the onset of migratory behavior (Sabelis and Afman 1994). Satiation prevails during foraging in dense colonies of spider mites, and starvation induces take-off to aerial dispersal, followed by exploration of the new landing site (Sabelis and van de Baan 1983; Sabelis et al. 1984; Sabelis and van der Meer 1986; Sabelis and van der Weel 1993; Sabelis and Afman 1994; Pels and Sabelis 1999). During the migratory phase, the predators encounter an environment characterized by plant volatiles most likely to be different from those experienced before; the previously learned associations of specific volatiles may be of little value in locating the prey. Therefore, we hypothesized that the innate responses to MeSa depend on the context of the test (satiated vs. starved predators).

We determined the responses of a total of 18 iso-female lines of *P. persimilis* in the olfactory tests where predators were presented with the choice of 1) MeSa in clean air vs. clean air, or 2) MeSa in the background of GLVs vs. GLVs. These tests were performed using either satiated or starved predators. Variable olfactory responses to MeSa among the iso-female lines would indicate genetic variation for this trait in the population under study. In particular, we predicted that this variation would be more pronounced in starved predators, and we asked to what extent this variation depends on the presence of volatiles of uninfested plants in the background.

Methods and Materials

Predatory Mites The base population of *P. persimilis* was maintained in the laboratory (25°C, 70% humidity, and 16:8, L:D conditions) on a diet of two-spotted spider mites (*T. urticae*) on detached leaves of lima bean plants. The culture originated from a sample of predators collected in 2002 at different locations throughout Sicily (Partinico, Scopella, Trappeto, Terrasini, Siculiana, Laghetto, Menfi, Trabia, Alcamo), where they are probably endemic (De Moraes et al. 2004). Iso-female lines were obtained by randomly selecting a number of females from the base population, which from then on were kept separately in Petri dishes. Typically in haplodiploid arthropods such lines are obtained through mating between the virgin female and her sons (oedipal mating). However, *P. persimilis*, just as probably the whole family Phytoseiidae, is pseudo-arrhenotokous, i.e., sons and daughters arise from fertilized

eggs, and male zygotes become haploid due to paternal genome inactivation and elimination during embryogenesis (Helle et al. 1978; Nelson-Rees et al. 1980). Hence, mating is a prerequisite for producing eggs destined to become females, as well as males. For this reason, we selected already mated females, and propagation of the lines occurred through brother-sister mating. There were 18 lines established, which were allowed to propagate for 7 wk before the onset of the olfactory tests (for at least 5 generations). All lines were reared in the same climate room (under conditions as described for the base population) to minimize any effect of environment on predatory behavior. Incidental mixing among the lines was prevented by maintaining each line in a separate rearing enclosed in a plastic container with a small opening covered with gauze (mesh width=0.07 mm, average adult predator size= 0.5 mm, average predator egg size=0.2 mm, small enough to prevent immi- and emigration) to allow for airflow. Additionally, each of these containers was surrounded by its own water barrier. Individual iso-female lines were labelled with numbers (1–18) for identification.

Tests of Olfactory Preference Behavioral responses of predators to MeSa were tested in a so-called I-tube: a single straight glass tube (length 20 cm, 0.5 cm diam) with a small opening (2 mm) in the middle to introduce the predatory mites (Fig. 1). This olfactometer was provided with a trap at the end of either arm of the I-tube to collect predators. Opposite the entrance hole, another opening (0.5 cm diam) was present that was gauze-covered and served as an air-outlet. At the ends of the I-tube, there were plastic trap vials (30 mm diam, height 55 mm), which in turn were connected to jars that either contained a capillary with MeSa or not. The traps were designed as an easy-to-enter-yet-difficult-to-exit vial, and were provided with a water source (wet cotton wool). After purification by activated carbon filters, the air was flowing at 20 l/h through the jars, the vials, and then the arms of the glass tube, leaving the system through the opening in the middle of the I-tube. At release in the middle of the I-tube, a mite found itself in air streams coming from right and left, i.e., one with MeSa and the other without. Subsequently, it could move left or right in the I-tube and ultimately entered one of the trap vials or remained in the I-tube. After release of the test animals, the entrance hole was sealed with Parafilm®. Pilot experiments showed that the I-tube olfactometer produced results consistent with our knowledge of the responses of *P. persimilis* to the full blend of herbivore-induced plant volatiles (Van Wijk, unpublished data).

Per replicate experiment, a total of 25 adult females were released (except for a few cases where numbers were less than 25, yet larger than 20) sequentially. Visual cues play no role in predator orientation, as the predator is blind and orients itself by a means of chemical cues. A previous study that used a Y-tube set-up showed that there is no effect of possible residues, deposited along the path taken by an individual, on the choices of the subsequent individuals (Sabelis and van de Baan 1983). After 25 min, the number of mites in each of the two trap vials was counted. The number that remained in the I-tube, was scored as "no choice". For each consecutive replicate of a line, a new clean I-tube was used, and the side of the arm containing air with MeSa was inter-changed to exclude any unforeseen asymmetries in the experimental set-up. Per line per treatment, roughly 120 mites were tested in 4–8 replicate experiments (in one case, three replicates were performed).

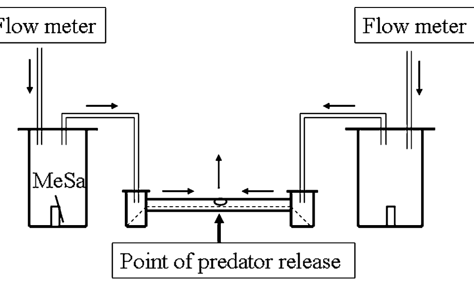

Fig. 1 Experimental set-up of the I-tube olfactometer. The diagram depicts a horizontal tube (the glass I-tube) with two openings, where the bigger one serves as an air-outlet. The *thick vertical arrow* below the I-tube indicates the location of the small opening—the point of release of the predators. The *broken line* indicates a thin capillary inside the glass tube to provide structure, on each side ending in a metal pin leading down into the trap vial. The trap vials were connected with plastic tubes to jars that either contain a capillary with MeSa or not. The remaining *arrows* indicate the direction of air-flow. Above the set-up there was a source of dispersed light (not shown)

Synthetic MeSa (Sigma-Aldrich Fluka, pure; assay ≥99%) was offered undiluted in a small capillary (9 µl, 0.60 mm diam, Omnilabo) placed in one of the jars connected to the I-tube (Fig. 1). The air flow was led through the set-up at least 2 h before the start of the test. The MeSa evaporation rate was ±30 µg/h. This evaporation rate was chosen based on preliminary experiments to find a concentration to which the base population exhibited a neutral (50:50) response. Such a set-up allows detection of either increased or decreased responses of the iso-female lines to MeSa with reference to the response of the base population. It is difficult to compare this evaporation rate with previous studies that attempted to measure the dose-response relations, because these assessments were based on filter paper as a substrate (de Boer and Dicke 2004b; van Wijk et al. 2008). Unlike filter paper, capillaries generate a constant evaporation rate. It is also difficult to compare this evaporation rate with evaporation from infested Lima bean plants, because there are hardly any data available. The only data we are aware of is 0.4–0.8 µg/h estimated by de Boer and Dicke (2004b) from data in Dicke et al. 1999, evaporated from 10 leaves after 3 d of infestation

by 50 adult female spider mites per leaf with a flow rate of 30 l/h. It is unclear at what distance from the plant this concentration was measured, and also how such concentrations of MeSa changed over the time of infestation.

Experimental Design We assessed olfactory preferences of 18 iso-female lines by subjecting satiated and starved adult female predators to two types of olfactory tests that involved choices between either (1) MeSa in clean vs. clean air, or (2) MeSa with a background of green leaf volatiles (GLVs) vs. green leaf volatiles (GLVs). The background odors of GLVs were provided by discs (1.5 cm diam) punched from the leaves of 2-wk-old, uninfested Lima bean plants (var. *Phaseolus lunatus*, Big Lima). New leaf discs were punched for each test from fresh primary leaves, and placed inside the plastic trap vials of the I-tube—one disc in each of the vials—on a ball of wet cotton wool. Airflow was allowed to pass through the I-tube for an additional 15 min before the start of the olfactory test to allow the GLVs to reach the middle of the I-tube. The responses of the satiated predators were determined by testing females taken straight from the culture where they were kept in a well fed state. Starved predators were obtained by food-deprivation for 24 h prior to the olfactory tests. During the period of food deprivation, mites were kept in a closed Eppendorf vial placed in a climate box at 18°C, with water provided via a strip of wet filter paper.

The total of 18 olfactory tests performed daily on each of the 18 lines was about the maximal number feasible under the experimental protocol. The main aim of this study was to sample a large number of iso-female lines. Therefore, we preferred to test as many lines as possible per day, at the expense of obtaining simultaneous replicates for each line. To minimize effects of the time of day on predatory responses, we randomized the order of testing of the 18 lines each day. The number of replicates varied between four and six per hunger level for each olfactory test (i.e., tests with or without GLVs context). Tests were performed within a period of 5 wk.

Statistical Analysis We aimed to determine (1) whether there is a genetic component in predator response to MeSa, and (2) whether this behavior is dependent on the nutritional status or the environmental context provided by the volatiles of uninfested plants in the background. To address the first question we constructed a mixed-effects model that included the iso-female line effect as the random effect; hence, the response variable (i.e., a single data point) was the mean response per replicate per line based on the numbers of individuals that made a choice (hence, excluding the no-choice individuals). In this analysis, we tested whether the amount of variation explained by the random effect of iso-female line is different from zero. The variation due to iso-female line is a measure of the total amount of variation among tested lines that is due to variation in their genes, provided that the differences among the lines arising from heterogeneity in rearing conditions can be excluded (David et al. 2005). It reflects broad-sense heritability that comprises the additive genetic variation as well as the non-additive effects of dominance and epistasis. The amount of this variation was estimated by using restricted-maximum likelihood method of the SPlus 6.2 software (Pinheiro and Bates 2000; Venables and Ripley 2002), which adjusted for the fixed effects of hunger level (satiated or starved) and GLVs context (MeSa presented alone or MeSa in the background of GLVs). Additionally, we tested whether the responses of the lines changed within the period of testing such that there was a decreasing or increasing trend. To this end we also tested the covariate representing the number of days elapsed from the onset of testing the first replicate of a line within a treatment. A significant covariate would indicate that environmental effects, consistent in time, contribute to the differences among the lines. A non-significant covariate, on the other hand, would indicate that no effect of consistent differences among the rearing environment of the lines was detected, thus strengthening the argument that the variation among the lines reflects genetic differences. The number of days elapsed since the onset of testing encompassed a period of 1–2 wk. Thus, it may have encompassed the responses of more than one generation of predators (Sabelis 1981). A non-significant covariate would be consistent with a positive correlation between mean values in different generations (a result that supports a genetic basis for preference within iso-female lines, David et al. 2005), although the design of this study did not address this correlation explicitly. The diagnostics plots showed that the assumptions of the mixed effect model were satisfied (the random variables were normally distribution with mean zero and independent for different groups, and the within-group errors were independent and normally distributed with a mean of zero), hence, the response variable was not transformed.

To address the second question we tested for the situation where different genotypes respond to MeSa differently, dependent on predator satiation level or volatile presentation (as reflected in two- and three-way interactions between the line effect and the experimental factors). Therefore, in the second part of the analysis, we also analyzed the probability of an individual choosing MeSa in relation to three explanatory variables: iso-female line (18 lines), hunger level (satiated or starved), and GLVs context (MeSa presented alone or MeSa in the background of GLVs) by fitting a logistic regression model with logit link function and binomial error variance in SPlus 6.2 for Windows. The response variable in this analysis was the

response of an individual predator. The relevance of the explanatory variables was assessed based on the comparison of values of deviance and Akaike's Information Criterion for the models that included combinations of one or more of the three explanatory variables (Agresti 1990; Quinn and Keough 2002). We further tested the fit of the regression model with respect to given explanatory variable by comparing this model with an appropriate reduced model (i.e., a model that contains all terms of the complete model but the explanatory variable tested) by using the log-likelihood ratio test (Agresti 1990). Additionally, we analyzed the effect of the three explanatory variables on the probability of an individual making a choice (i.e., the probability of individual entering any trap vial in the I-tube).

Results

The first part of this section presents the analysis of the variation detected among the iso-female lines. The second part deals with the analysis of the probability of predators choosing MeSa using the factors iso-female line, hunger level, and GLVs context. Finally, we discuss the probability of predators making a choice (i.e., the probability of choosing either arm).

Variation among Lines The variation explained by the iso-female line was different from zero (P=0.02, Table 1), thus supporting the hypothesis that there is a genetic component in predator responses to MeSa. It is a measure of the total amount of variation among the tested iso-female lines that is due to genetic variation, provided that the differences among the lines due to heterogeneity in rearing conditions are negligible. We detected no systematic change in the average responses of the lines within the period of testing (P=0.56, Table 1). This result supports the conclusion that the observed differences among the lines were not due to systematic differences among the rearing environment of the lines, but rather reflect genetic variation.

In this analysis, the effect of hunger level was significant, but not the GLVs provided as context. However, inspection of the data (Fig. 2; in each panel the ordering of lines from low to high response results in a different sequence of lines) indicates that there is variation in the responses of different lines dependent on the level of these two factors. This interaction was explored further in the second part of the analysis.

Probability of Choosing MeSa We used the logistic regression method to analyze the probability of predators choosing MeSa in relation to the factors: iso-female line, hunger level, and GLVs as context. Comparison of deviance and AIC values throughout all models (that included combinations of one or more of the three effects) revealed that iso-female line, hunger level, and GLVs as context, all affected the probability that a predator would choose MeSa (log-likelihood ratio test, P_{line}<0.001, P_{hunger}<0.001, P_{GLVs}=0.02). Figure 2 shows the variation among iso-female lines in the proportion of individuals choosing MeSa, categorized by hunger level, when MeSa is presented alone and when it is presented with the background of GLVs. Visual inspection of these figures indicates an interaction between iso-female line, hunger level, and GLVs as context. Therefore, we also compared the deviances and AIC values of the models that included the effects as well as their interaction terms. The final model that best described predator responses included the interaction between the iso-female line and the two fixed effects (log-likelihood ratio tests; $P_{line\ x\ hunger}$<0.001, $P_{line\ x\ GLVs}$<0.001, $P_{hunger\ x\ GLVs}$=0.41, $P_{line\ x\ hunger\ x\ GLVs}$<0.001). Figure 3 exemplifies the three-way interaction by presenting the responses of some of the iso-female lines.

Probability of Making a Choice We constructed a logistic regression model describing the probability that a predator

Table 1 Mixed-effects model of predator responses to MeSa; iso-female line was the random effect and the fixed effects included the hunger level (2 levels: satiated, starved) and GLVs context (2 levels: MeSa presented alone, MeSa in the background of GLVs). The number of days from the onset of testing the line within a given treatment was added as covariate. The significance of fixed effects, their interaction and the significance of the random effect (i.e., the hypothesis that the variance of random effect ≠ 0) was tested using the likelihood ratio tests (Pinheiro and Bates 2000; Venables and Ripley 2002)

Effect		Likelihood ratio (df_1, df_2)	P value	Variance
Random	Iso-female line	5.25 (7, 6)	0.02	0.003
	Residual			0.05
Fixed	Hunger level	6.75 (6, 5)	0.009	
	GLVs context	0.05 (6, 5)	0.81	
	Days from onset of testing	0.34 (6, 5)	0.56	
Interaction	Hunger level: GLVs context	0.03 (7, 6)	0.86	

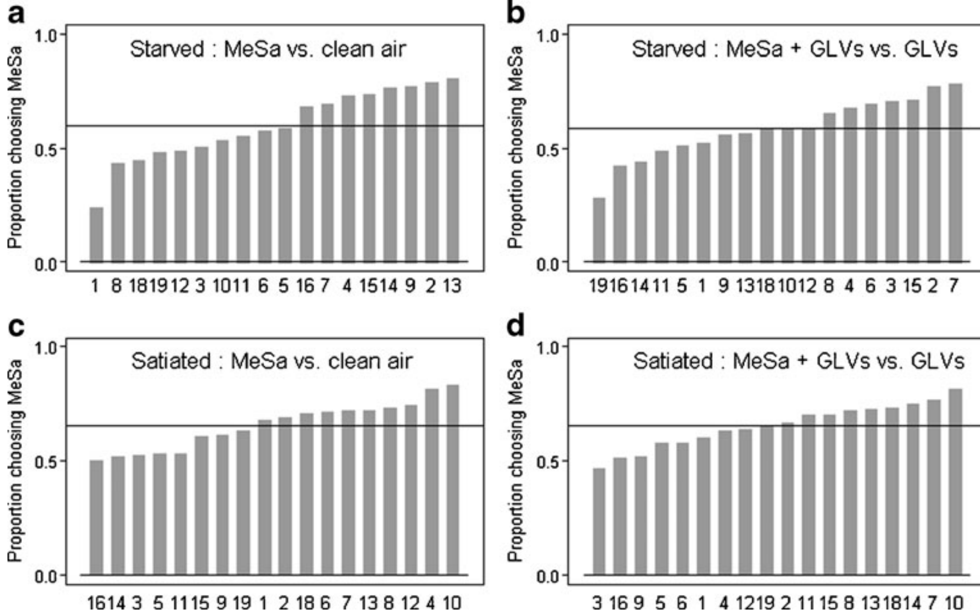

Fig. 2 The responses of eighteen iso-female lines of *Phytoseiulus persimilis* by starved predators in the tests (**a**) MeSa plus clean air vs. clean air, (**b**) MeSa plus the background of GLVs vs. GLVs, and by satiated predators in the tests (**c**) MeSa plus clean air vs. clean air, (**d**) MeSa plus the background of GLVs vs. GLVs. The bars show the proportion of individuals choosing the arm containing MeSa (y-axis) calculated for each line (x-axis). The *horizontal lines* indicate the average responses obtained by pooling replicates over all iso-female lines within each of the experimental treatments. Note that in each panel the ordering of lines from low to high response results in a different sequence of lines, e.g., line 10 is on the right in (**c**) and (**d**) but on the left in (**a**) and in the middle in (**b**)

will make a choice in the olfaction test (i.e., it will choose either arm). The full model (i.e., line + test + hunger) explained the responses better than the null model (log-likelihood ratio, $P<0.001$). All main effects were individually significant ($P_{\text{line}}<0.001$, $P_{\text{test}}<0.001$, $P_{\text{hunger}}=0.03$, see Fig. 4).

Discussion

We asked whether there is genetic variation in responses of *P. persimilis* to the plant volatile MeSa in a field-collected population. To this end we employed the iso-female line technique where the variation among iso-female lines is

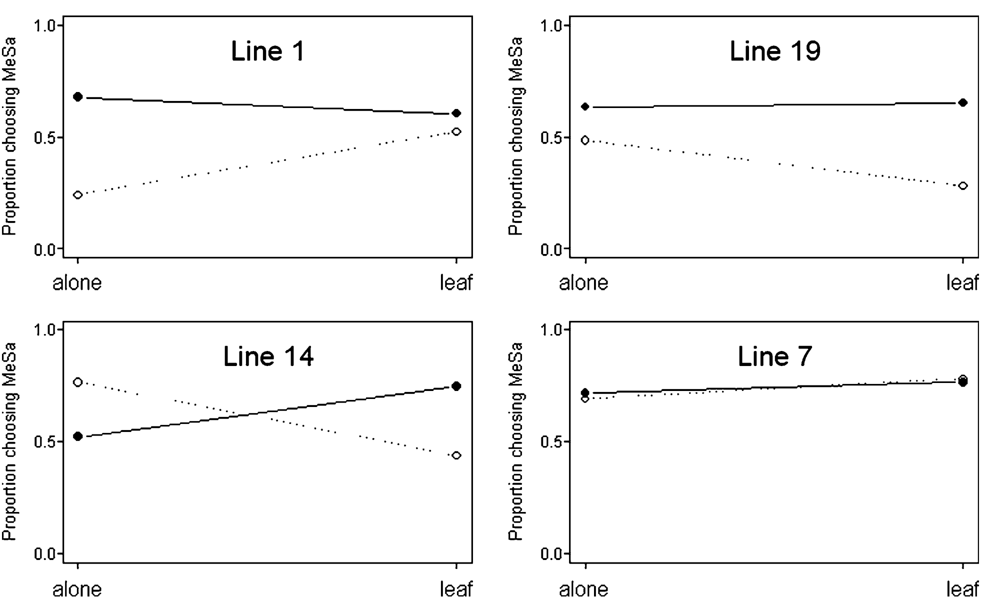

Fig. 3 Illustration of the interaction between iso-female line, hunger level and GLVs context in selected iso-female lines; the graphs present the mean proportions of individuals choosing MeSa (values on the y-axis) categorized by the factors. *Open circles* connected by *dashed line* refer to the responses of the starved predators, *closed squares* connected by *solid line* to the responses of the satiated predators, and the x-axis presents the categorization with respect to GLVs context

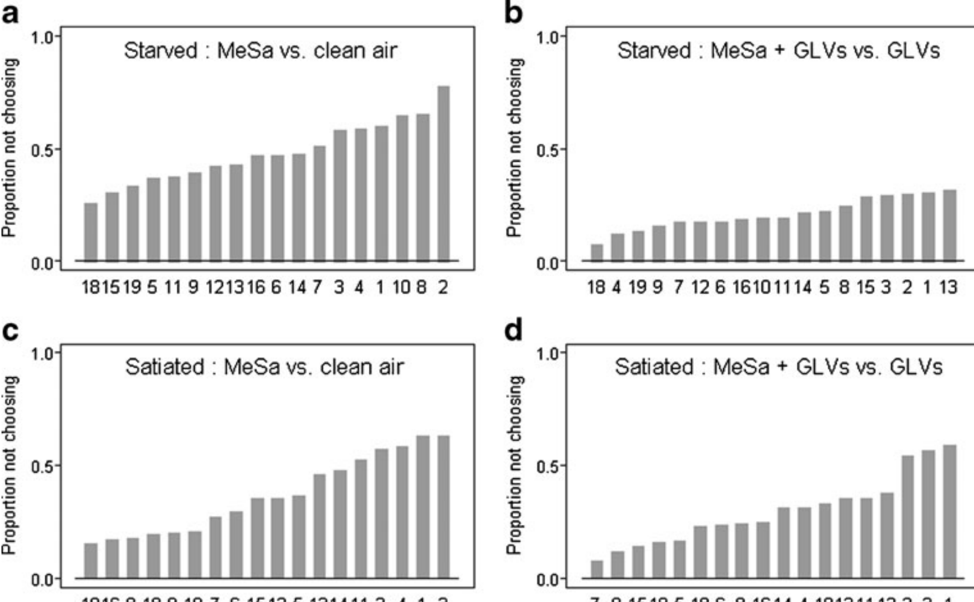

Fig. 4 Variation in the mean proportion of no-choice individuals (y-axis) in the 18 iso-female lines (x-axis) of *Phytoseiulus persimilis* categorized by hunger level and GLVs context. No-choice individuals are those that remained in the glass tube for the duration of the test, i.e. did not make a choice. The panels present the proportions observed for starved predators in the tests (**a**) MeSa plus clean air vs. clean air, (**b**) MeSa plus the background of GLVs vs. GLVs, and for satiated predators in tests (**c**) MeSa plus clean air vs. clean air, (**d**) MeSa plus the background of GLVs vs. GLVs

interpreted as the variance due to differences in their genes provided the heterogeneity among the rearing environments does not systematically influence the behavior of individual lines. We showed that the variation in predator responses to MeSa explained by the iso-female line was significantly different from zero. From this result, we infer that the studied population harbors genetic variation in olfactory responses to MeSa. There is more variation among the lines when the predators are starved, yet variation is also present in satiated mites. However, it is only when predators are starved that we observe the full range of responses ranging from avoidance to preference. This pattern occurs when predators have a choice of both MeSa presented alone and MeSa against a background of GLVs.

Using the variances quantified from the mixed-effects model for response to MeSa (see Statistical Analysis) we were able to obtain an estimate of broad-sense heritability defined as $H^2 = \frac{\sigma^2_{line}}{\sigma^2_{line}+\sigma^2_{residual}} = 0.05$, where $\sigma^2_{residual}$ is the remaining amount of unexplained variation that represents the environmental variance (Table 1). The value of estimated broad-sense heritability is relatively small and comparable with most values of narrow-sense heritability of fitness traits (Houle 1992; Visscher et al. 2008; Tien et al. 2009). Moreover, our results indicate that any estimate of heritability may be deflated due to large values of residual, i.e., unexplained, variance detected in this study (Table 1). The residual variance represents the environmental variance, and its magnitude indicates heterogeneity in other uncontrolled factors, such as predator age, and correlated with it the amount of experience.

To date, studies that have measured the attractiveness of MeSa (or other herbivore-induced plant volatiles) to natural enemies have not controlled for genetic background (e.g., de Boer and Dicke 2004b; van Wijk et al. 2008). However our results show that predator populations may be genetically variable for the tested responses, and that the behavior of various genotypes may influence the average response measured at the population level. Thus, the average population response may be characterized by a weak attraction or no clear preference if genotypes of extreme innate preferences are tested together and their responses pooled. To illustrate this, we calculated the proportions of individuals choosing MeSa by pooling the replicates over all iso-female lines for each of the experimental treatments. These values (shown in Fig. 2 as horizontal lines) may be treated as estimates of the responses to MeSa measured at the level of the base population from which the lines originated, under the assumption that different iso-female lines (i.e., genotypes) are represented. Indeed, there is little difference among the experimental treatments.

The inclusion of GLVs in the background of MeSa presentation does not, at first glance, appear to change the overall result that a wider range of responses is expressed by starved predators (compare Fig. 2a, c and Fig. 2b, d). However, closer inspection reveals that the addition of the

background of GLVs does change the behavior of individual lines. We observed a whole range of patterns in the responses of the lines that exemplify a significant three-way interaction between iso-female line, hunger level, and GLVs as background (except for line 5 that shows indifferent responses in all tests without exception). In particular, there are iso-female lines characterized by an extreme response to MeSa if the predators are starved and the choice-test involves MeSa in the background of GLVs, whereas their responses in all the other treatments are indifferent (lines 19 and 3). The example of these lines may indicate that testing the responses of starved predators to MeSa presented in the background of GLVs are essential conditions for eliciting an innate response of the predators. However, there are also lines characterized by extreme responses to MeSa if the predators are starved and the choice-test involves MeSa presented alone (e.g., lines 1 and 9), and predator responses in all the other treatments are indifferent. The example of these lines may thus indicate that the adding of GLVs as a background to MeSa confounds the predator's perception of this volatile. The remaining iso-female lines show yet other patterns of interaction among the factors iso-female line, hunger level, and GLVs as background (see Fig. 3 for examples).

We conclude therefore that the responses of *P. persimilis* to MeSa are context-dependent in that they depend on the genetically determined preference of the tested individuals (i.e., their genotypes) as well as on the environmental context in which the volatile is presented. Further research is needed to understand how a biologically relevant single compound cue is perceived and interpreted when presented in a mixture (van Wijk 2007; Shröder and Hilker 2008), a more realistic situation in nature. In our study, the addition of a background odor of GLVs increased the proportion of individuals making a choice in olfaction tests (Fig. 4). Thus, we conclude that GLVs affected the predator's perception of MeSa. This effect of GLVs on the willingness to choose varied among individual lines (which indicates a genetic basis also in this aspect of behavior).

Given the genetic basis in the responses to MeSa in this population collected from the field, we conclude that there is opportunity for an evolutionary response on the part of the predators to using MeSa as a plant signal indicating prey presence. The distribution of prey is patchy and unpredictable under natural conditions. Hence, it is expected that *P. persimilis* undergoes long-lasting food deprivation during dispersal (Sabelis and Afman 1994). Our findings may indicate stronger reliance of the predator on genetic predispositions during this migratory phase in which the predator alternates passive aerial dispersal and local exploration for prey patches. Thus, natural selection may be more efficient in shaping the olfactory responses when the predators are starved and therefore probably migrating.

Our results show that the responses of *P. persimilis* to plant volatiles are far from simple. Even in the case of a single plant volatile, we observed genetic variation expressed in a context-dependent manner. Iso-female lines created from a field-collected base population showed responses to MeSa ranging from preference to avoidance (although the latter response was much less common). The variation is still present in the population and conflicts with the prediction that preference for environments associated with the presence of MeSa has fitness benefits (i.e. helps locate the prey) and should therefore prevail. This raises the question of the mechanism that maintains the observed genetic variation in the field; the question could be addressed with selection experiments for olfactory responses to single volatile compounds and mixtures. Our results suggest that such experiments will be more successful if conducted on starved predators.

Changes in Monoterpene Emission Rates of *Quercus ilex* Infested by Aphids Tended by Native or Invasive *Lasius* Ant Species

Carolina I. Paris · Joan Llusia · Josep Peñuelas

Abstract The emission of volatile organic compounds (VOCs) depends on temperature and light. Other factors such as insect herbivory also may modify VOC emission. In particular, aphid feeding promotes the release of new compounds and changes the composition of plant volatile blends. Given that some aphids are tended by ants, we investigated whether ants change the emission of VOCs indirectly through attendance on aphids. The effect of *Lachnus roboris* aphids and two different tending ant species on terpene emission rates of 4-year-old holm oak (*Quercus ilex*) saplings was investigated during a field experiment. There were five treatments: saplings alone (T1), saplings infested with *L. roboris* aphids (T2), saplings infested with aphids tended by the local ant *Lasius grandis* (T3), those tended by small colonies of the invasive ant *Lasius neglectus* (T4), and those tended by large colonies of the same invasive ant species (T5). The infestation by *L. roboris* elicited the emission of Δ^3-carene and increased the emission of myrcene and γ-terpinene. Terpene emissions were modified depending on the tending ant species. Attendance by the local ant *L. grandis* increased α and β-pinene and sabinene. Attendance by the invasive ant *L. neglectus* only decreased significantly the emission of myrcene, one of the major compounds of the *Q. ilex* blend. Aphid abundance decreased with time for all treatments, but there was no difference in aphid abundance among treatments. Total terpene emission rates were not correlated with aphid abundance. These results highlight that aphids and tending ants may change terpene emission rates, depending on the ant species.

Introduction

Plants emit a broad spectrum of volatile organic compounds (VOCs), mainly isoprene and monoterpenes, which have multiple protective and signaling functions (Peñuelas and Llusia 2004), including defensive and alellopathic roles. For example, they act as herbicides and may inhibit seed germination, cytochromic respiration, and growth of annual plants (Peñuelas et al. 1996). Under certain conditions, i.e., abiotic stress or herbivore attack, new volatiles may be produced *de novo* or released

from storage organs (Kesselmeier and Staudt 1999). These induced emissions have received increasing attention since the first studies that showed emission in response to herbivore attack (Dicke and Sabelis 1988). Some compounds of the emitted blend act as deterrents of the herbivore or as signals to attract predators or parasitoids that protect the plant against insects.

Holm oak (*Quercus ilex* L.) is a widespread tree of the Mediterranean basin, and it is a major source of VOCs (Staudt et al. 2001). In contrast to many deciduous oak species that emit large amounts of isoprene, *Q. ilex* emits huge amounts of monoterpenes, although it has no specific VOC storing organs (Staudt and Seufert 1995), and there is no storage pool of VOCs in the leaves or bark (Pasqua et al. 2001). The compositional fingerprint of the emissions is controlled mainly by genetics (Staudt et al. 2003). However, the synthesis and emission of these VOCs are modulated continuously by environmental factors such as light, temperature (Staudt and Bertin 1998; Llusia and Peñuelas 1999) and severe drought (Llusia and Peñuelas 1998), or by biological factors such as herbivore attacks (Staudt and Lhoutellier 2007). Identifying those biotic factors that promote changes of VOC emissions from holm oak is crucial for Mediterranean ecosystems because the monoterpenes released play a key role both in the biology of the community and in the formation of oxidants and secondary aerosols in the troposphere (Kesselmeier and Staudt 1999; Peñuelas and Staudt 2010). This has consequences for air quality and visibility, and even for the climate on a regional scale (Peñuelas and Llusia 2003).

In Spain there are many aphids that feed on *Q. ilex* (Nieto-Nafría and Mier-Durante 1998), in particular *Lachnus roboris* L., which is an obligate myrmecophilous aphid (Michel 1942; Sudd and Sudd 1985), and is tended by several ant species that collect honeydew as food (Paris and Espadaler 2009). Honeydew, a sugar solution excreted by aphids while feeding on sap plants, is the main food of several ant species (Carroll and Janzen 1973). Through aphid attendance, ants may exert indirect effects on plants, such as a decrease in seed production (Rico-Gray and Castro 1996), plant herbivory (Suzuki et al. 2004), and pollination (Lach 2007). The degree of these indirect effects varies among native ants, primarily as a result of differences among species in aggressiveness, territoriality, colony density, worker abundance, and the strength and persistence of the interactions between particular ant species (Styrsky and Eubanks 2007). In the case of invasive ants, it is assumed that the indirect effect on plants through aphid attendance may increase in magnitude because invasive ants frequently cause local hemipteran outbreaks (Styrsky and Eubanks 2007). The aggressive behavior and unicolonial structure of invasive ants may achieve higher colony densities and worker abundance compared with those of native ants (Passera 1994). As a consequence, native ants are displaced, and honeydew sources are dominated by tending invasive ants (Holway et al. 2002). In response to ant attendance, aphids may increase sap feeding (Buckley 1987; but see Yao and Akimoto 2001) as well as the frequency of honeydew excretion, and they may change the sugar composition of honeydew (Fischer et al. 2002). Previous studies have shown that *L. roboris* excretes more drops of honeydew per minute when tended by the invasive ant *Lasius neglectus* than when tended by the native ant *Lasius grandis* (Paris and Espadaler 2009). This apparently is related to the higher intensity of attention shown by this invasive ant (Paris and Espadaler 2009).

As a consequence of aphids feeding on plants, VOC emissions may change and new compounds may appear (Du et al. 1998; Powell et al. 1998). Considering the direct effect of ants on aphid feeding and the indirect effect on plants, we hypothesized that the composition of the VOC blend of *Q. ilex* changes when the aphid *L. roboris* is tended by the invasive rather than the native *Lasius* ant species. Given that the effect of invasive ants on other components of the ecosystem is in part related to their abundance (Holway et al. 2002), we investigated whether the VOCs emitted by holm oak change according to the size of the *L. neglectus* colony.

We hypothesized that VOCs emitted by holm oaks would change qualitatively and quantitatively (i) according to the presence of the aphid *L. roboris*, (ii) depending on which ant species tended the aphids (invasive *L. neglectus* or native *L. grandis*), and (iii) depending on the size of the invasive ant colony. In this study, we aimed: a) to test these three hypotheses and to discover whether such changes occurred; b) to identify the compounds whose emission rates changed when holm oaks became infested with aphids; and c) to determine the compounds linked to ant attendance. We sampled volatiles emitted by holm oak saplings alone or infested with *Lachnus roboris* that were tended or not tended by *L. grandis* or *L. neglectus*.

Methods and Materials

Study Site

This experiment was performed at a field close to the Center of Ecological Research and Forestry Applications (CREAF) at the Autonomous University of Barcelona (41° 30′ N, 2° 6′ E). We used 4-yr-old saplings of *Quercus ilex* (mean±SE diameter, 13.08±0.62 mm) placed in 10-L pots the previous year that were filled with a mixture of commercial humus and a sandy soil (1:1). We used this mixture because previous work showed that in commercial humus alone, ant digging promotes rapid loss of water and consequent drying of the plant.

Ant and Aphid Colonies

At the beginning of June, when new inseminated queens of *L. neglectus* were particularly easy to find under flat rocks and leaf litter, we sampled several queens and workers from an invaded area of the University campus. Fertilized queens are easy to identify because they are huge compared with workers and because they lack wings. Young queens are adopted by workers (Espadaler and Rey 2001). The queens began to lay eggs in the first few days after their capture (Paris, pers. observ.). Given that *L. neglectus* is a polygynic ant species (Boomsma et al. 1990), we placed three queens in each nest to ensure that the colony remained polygynic. In a preliminary experiment, we placed 30, 65, and 150 workers plus 3 queens in artificial nests. We realized that in small colonies of *L. neglectus* the queens were decapitated, but this did not occur in colonies with 150 workers. Therefore, we tried 30 workers per queen and found that with this proportion the colony grew. Finally, we decided to place three queens with 90 or 210 workers, to simulate small and large colonies, respectively. Newly inseminated queens of the native ant *L. grandis* were collected in June of the previous year during a nuptial flight in the campus. Recently landed queens were sampled immediately and brought to the laboratory to rear colonies for the planned experiment. One queen of the native ant *L. grandis* was placed in each nest because this is a monogynic ant species.

Until the experiment started, ants were kept in artificial nests consisting of 3.77 cm^3 (7.5×0.8 cm) nesting tubes, one-third filled with water, plugged with cotton wool, and covered with aluminium foil. The tubes were placed inside plastic boxes (17.7×11.2×3.5 cm) which were set in a growth chamber adjusted to a photoperiod and temperature regime that simulated the ongoing season. We fed the ants *ad libitum* with an artificial diet, according to Bhatkar and Whitcomb (1970), and with Tenebrionidae larvae that had been killed previously by freezing.

In the middle of June, we sampled *L. roboris* aphids, larvae and adults from holm oaks in invaded and control areas. The aphids were pooled and distributed evenly among saplings. We placed 10.5±1.1 (mean±SE aphids per sapling) aphids on saplings 2 d before transferring the artificial ant nests to the pots. Previous work to develop the general design of this experiment showed that after 4–9 days only between 12.5 and 20% of the aphid colonies (a colony = more than five individuals) survived without attention from ants. The ants were starved for 48 hr before transferring the artificial ant nests to the pots. The artificial nest was placed on the soil of the pot without the aluminium paper, to motivate the ants to move into the soil. At that moment, we checked how many queens were still inside the artificial nest. The colonies of the invasive ant began to move immediately, while the colonies of the native ant began to move 3 to 5 hr after placing the tube on the soil. After one day, all the colonies had moved into the soil. During the experiment, Tenebrionidae larvae were provided to avoid aphid predation by the ants. We placed on the soil, close to the sapling trunk, a glass with a freshly killed larva on it. The ants tended the aphids for 1 wk prior to the first measurements of VOCs.

The number of aphids added to each sapling was chosen as a trade-off among several variables: mean aphid abundance per tree, the percentage of infested twigs and mean ant activity per tree that had been estimated under natural conditions on mature holm oaks (oaks that produce acorns), and the size and age of the saplings. Previous data showed that at the University campus, *L. roboris* were scarce on holm oaks colonized by the native or by the invasive ant species (mean aphid abundance per tree ±SE, *L. grandis*: 28.54±11.92, *L. neglectus*: 59.43±16.90; % of infested twigs ±SE, *L. grandis*: 1.37±0.63%, *L. neglectus*: 2.75±0.91%) (Paris and Espadaler 2009). If we had extrapolated these estimations to the saplings used for this experiment, which had a mean of 16 twigs per sapling, only three aphids should have been added to each sapling. This aphid abundance would not have provided enough honeydew for ant colonies and would probably not have exerted any effect on VOC emissions from the holm oak.

On other hand, the aphid abundance should be related to the size of the ant colonies. Larger colonies than those used for this experiment may need a greater supply of honeydew, which would require more aphids. We considered that a 4-yr-old *Q. ilex* sapling would not be able to carry more than 20 aphids without becoming stressed by aphid feeding.

Experimental Design

Five treatments with 4 saplings per treatment were used: sapling alone (T1); sapling + aphids (T2); sapling + aphids + *L. grandis* (native ant) colony (T3); sapling + aphids + *L. neglectus* (invasive ant) colony of 90 workers (small colony) (T4); and sapling + aphids + *L. neglectus* colony of 210 workers (large colony) (T5). T1 represented the situation of basal emissions of VOCs (without any biotic stress). T2 simulated an aphid infestation without ant attendance, to determine which VOCs are elicited by aphid feeding alone (first hypothesis). To investigate the effect of the attendance of different ant species (second hypothesis), we established T3, T4, and T5. The number of *L. neglectus* workers in T4 and T5 was altered to test the effect of colony size (third hypothesis). The morphological traits (height, trunk diameter, dry weight, number and area of leaves) of the saplings did not differ among treatments (Kruskall Wallis, $P>0.324$).

Each pot was placed in a plastic box (49×29×25 cm) filled with the same soil mixture as that used for the pots. The plastic boxes were surrounded by two barriers of non-

toxic sticky resin (Tanglefoot®, Tanglefoot Company, MI, USA) to prevent ants escaping and other ant species entering. This device worked as a buffer area, which developed a gradient of humidity, from the pot, where we watered the plant, to the plastic box. This gradient of humidity was necessary to allow the ants to establish in an environment with sufficient humidity according to their preferences.

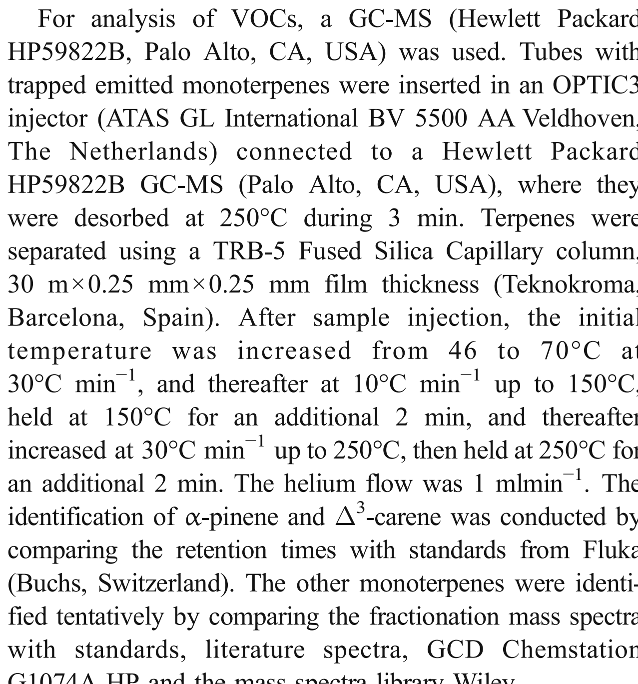
VOC Sampling and Analysis

Before sampling VOCs, we counted the number of aphids. We sampled VOCs 1 wk after the ants had begun to tend the aphids. During the daily sampling protocol, we sampled VOCs from the empty chamber to test whether adsorption occurred on the enclosure walls of the chamber. Given that soil may act as a source or sink for VOCs (Asensio et al. 2007), we sampled VOCs from extra boxes filled with soil but without plants or roots (termed soil boxes). The values obtained from soil boxes represent the blank for the system, so they were subtracted from the measured plant VOC emissions. The plants and soil boxes were watered the evening before sampling of VOCs.

Five saplings, belonging to different treatments, were sampled for VOC emissions each day on 4 different days between 9:30 and 14.00 hr. VOCs were sampled from the soil boxes at 3 different times during the morning: at the beginning of the daily sampling, after 2 samplings of holm oak VOCs had been made, and at the end of the daily sampling.

Sampling of VOC emissions was conducted by enclosing the sapling in a cylindrical dynamic chamber made of Tedlar, which was mounted in a cylindrical aluminium frame (65 cm high, 35 cm diam) and had a volume of 62.5 L. After the cylindrical chamber had been installed on each tree, we waited 10 min before sampling the VOCs. Inside the chamber was a fan that homogenized the air. The air entering and leaving the chamber passed through respective glass tubes (11.5 cm long and 0.4 cm internal diam) filled with Carbotrap C (300 mg), Carbotrap B (200 mg) and Carbosieve S-III (125 mg) adsorbents from Supelco (Bellefonte, PA, USA), which were separated by plugs of quartz wool. These tubes were conditioned previously for 20 min at 350°C with a stream of purified helium.

In order to obtain comparable results, the emission rates were expressed on a leaf dry weight basis. The sampling time was 10 min, and the flow was adjusted to 500 ml min^{-1}. The glass tubes (with trapped VOCs) were stored in a portable refrigerator at 4°C, and taken to the adjacent laboratory. At the laboratory, the glass tubes were stored at−30°C before analysis, for no longer than 48 hr.



For analysis of VOCs, a GC-MS (Hewlett Packard HP59822B, Palo Alto, CA, USA) was used. Tubes with trapped emitted monoterpenes were inserted in an OPTIC3 injector (ATAS GL International BV 5500 AA Veldhoven, The Netherlands) connected to a Hewlett Packard HP59822B GC-MS (Palo Alto, CA, USA), where they were desorbed at 250°C during 3 min. Terpenes were separated using a TRB-5 Fused Silica Capillary column, 30 m×0.25 mm×0.25 mm film thickness (Teknokroma, Barcelona, Spain). After sample injection, the initial temperature was increased from 46 to 70°C at 30°C min^{-1}, and thereafter at 10°C min^{-1} up to 150°C, held at 150°C for an additional 2 min, and thereafter increased at 30°C min^{-1} up to 250°C, then held at 250°C for an additional 2 min. The helium flow was 1 mlmin^{-1}. The identification of α-pinene and Δ^3-carene was conducted by comparing the retention times with standards from Fluka (Buchs, Switzerland). The other monoterpenes were identified tentatively by comparing the fractionation mass spectra with standards, literature spectra, GCD Chemstation G1074A HP and the mass spectra library Wiley.

Frequent calibration (once every 3 analyses) with external standards (α-pinene, Δ^3-carene, *p*-cymene, limonene) was used during the quantification. The detection limit was about 0.6 ng. The calibration curves were always highly significant ($r^2 > 0.99$). At the end of the experiment, the leaves were harvested from all the saplings to determine the dry weight after drying at 70°C in a ventilated oven until the weight was constant. Monoterpene emission rates were calculated as the difference between the amount of each compound emitted in samples from plants and the amount emitted from soil boxes without the plant (blank). The VOC emissions were expressed as μg per g of dry weight of leaves per hour.

Statistical Analysis

We applied Mann-Whitney and Kruskall-Wallis procedures because the data did not fit a normal distribution. To test the first hypothesis, we compared the VOC emissions of holm oaks alone (T1) against the emissions of saplings whose aphids were not tended (T2) by using the Mann-Whitney procedure. Given that the colony size of the invasive ant *L. neglectus* (T4 vs. T5, third hypothesis) did not produce differences in any emitted VOCs (Mann-Whitney, $P>0.2$), these treatments were combined. To test the effect of different tending ant species on VOC emissions (T2 vs. T3 vs. T4+T5, second hypothesis) we used the Kruskall-Wallis test. Two tailed exact *P* values are reported. When significant values arose, we performed the nonparametric Dunn's test for multiple comparisons, according to the process proposed by Zar (1996). Finally, aphid abundance was compared among treatments and by day using the

Kruskall-Wallis procedure and correlated with the total emission of VOCs using the Spearman procedure. All analyses were conducted using STATISTICA 6.0 for Windows (StatSoft, Inc. Tulsa, OK, USA, 1996).

Results

One day after placing the artificial nests on soil pots, all ant colonies had moved into the soil and begun to tend aphids. Total emissions from the holm oak increased 1.31-fold when aphids were present (range 0.62–2.13 $\mu g.g^{-1}.h^{-1}$) while the attendance by *L. grandis* and *L. neglectus* increased the total emissions 5- and 1.19-fold, respectively (*L. grandis* range: 3.60–5.06 $\mu g. g^{-1}.h^{-1}$; *L. neglectus* range: 0.27–2.19 $\mu g.g^{-1}.h^{-1}$). In all treatments, α- and β-pinene, myrcene, and sabinene comprised the main compounds of the *Q. ilex* blend (Fig. 1). Δ^3-Carene, a minor compound, was not emitted by uninfested saplings and was produced only by infested plants, independent of whether the aphids were tended or not (Fig. 2). The emission of myrcene and γ-terpinene increased significantly when holm oak saplings were infested with *L. roboris* (Mann-Whitney, T1 vs. T2, $U_{4,\ 4}$=0, P<0.03 for both components) (Fig. 2).

The terpene emissions of holm oak saplings changed according to the tending ant species (Table 1). In particular, α- and β-pinene, camphene, sabinene and Δ^3-carene increased when aphids were tended by the native ant *L. grandis* compared with unattended aphids or those tended by the invasive ant *L. neglectus* (except camphene and Δ^3-carene) (Kruskall-Wallis, α- and β-pinene: $H_{2,\ 16}$=8.74, P<0.01; sabinene: $H_{2,\ 16}$=8.49, P<0.01, camphene: $H_{2,\ 16}$= 7.65, P<0.02; Δ^3-carene: $H_{2,\ 16}$=7.50, P<0.02; Dunn's test $Q_{0.05,\ 3}$=2.39) (Table 1). The attention of the invasive ant decreased the emission of myrcene (Kruskall-Wallis, $H_{2,\ 16}$= 11.31, P<0.003) but no changes were detected for the other compounds (Table 1).

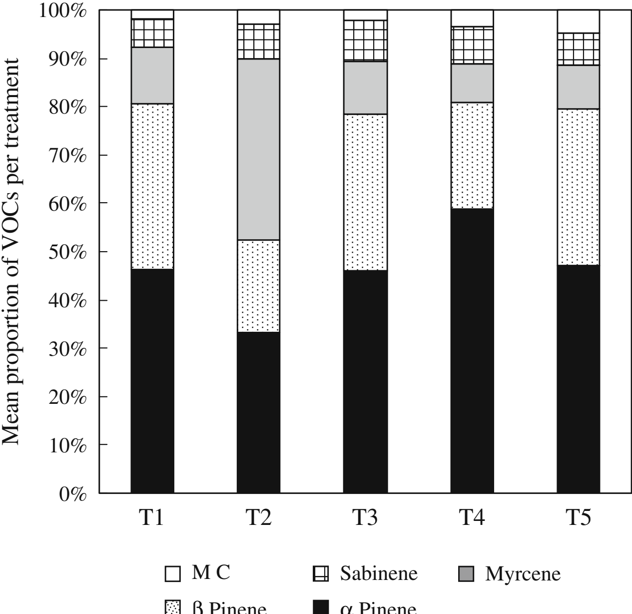


Fig. 1 Proportion of terpenes emitted by *Quercus ilex* saplings alone (T1), from saplings infested with *Lachnus roboris* aphids (T2), saplings with aphids tended by the native ant *Lasius grandis* (T3) or tended by the invasive ant *Lasius neglectus* from small colonies (T4) or from larger colonies (T5). MC: minor compounds (less than 1.5 % of total emission). They were γ-terpinene, terpilone, α-thujene, Δ^3-carene, Camphene and α-terpine

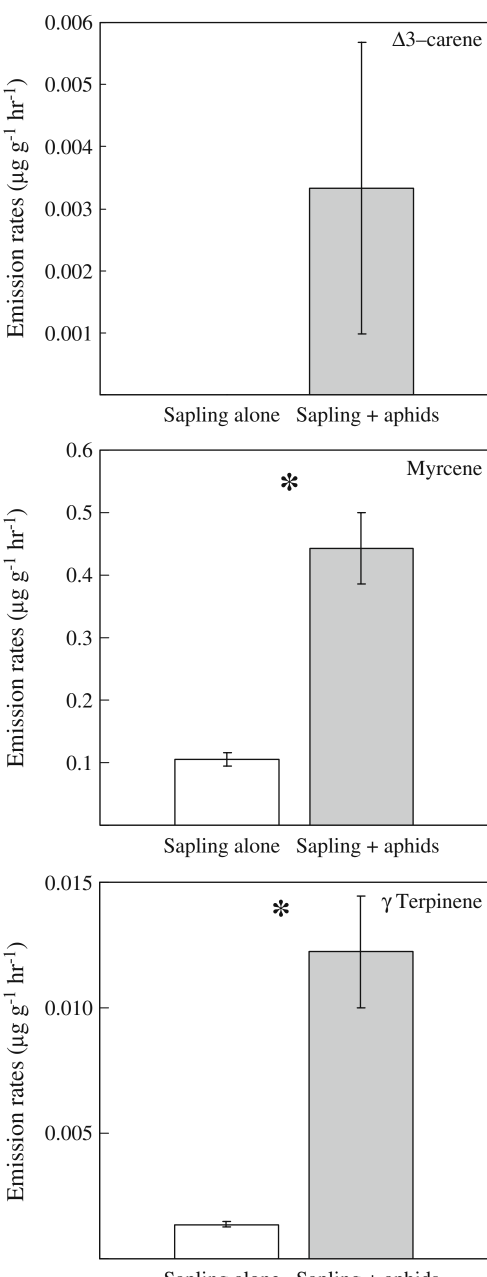

Fig. 2 Mean and standard error of volatile organic compounds emitted at different rates by *Quercus ilex* saplings alone (T1) or infested with *Lachnus roboris* aphids (T2). Asterisk shows statistical significance between treatments according to Mann Whitney's test (P<0.05)

Table 1 Means and standard error (μg. $g^{-1}.h^{-1}$) of main compounds emitted by *Quercus ilex* saplings (N=4 for T2 and T3 and N=8 for T4+T5) infested with not tended aphids (T2) or infested with aphids tended by the native ant *Lasius grandis* (T3) or by the invasive ant *Lasius neglectus* (T4 and T5 coupled). Different letters indicate statistical differences of non parametrical comparisons treatments (Dunn's test, P<0.05)

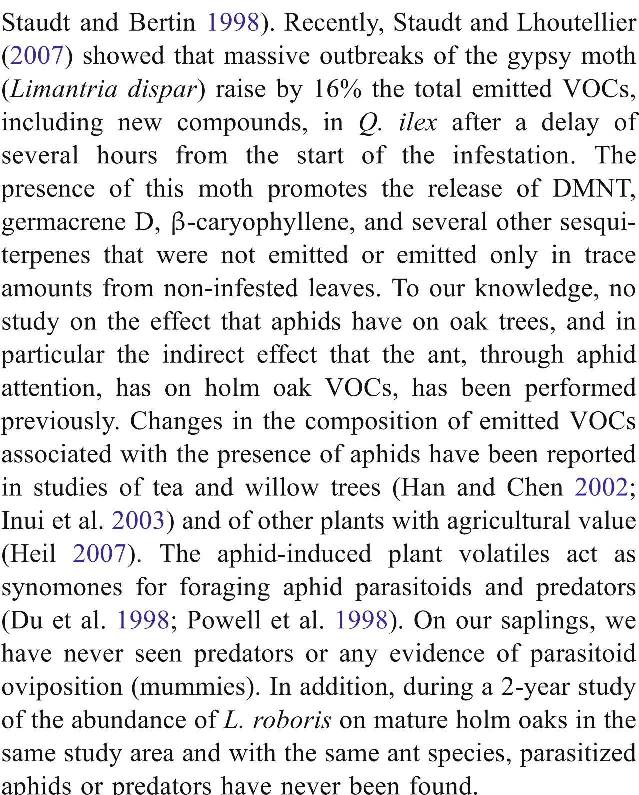
The abundance of aphids decreased with time for all infested saplings (mean aphids per day ±SE, day 1: 10.5±1.1, day 2: 17.8±0.9, day 3: 6.5±1.0, day 4: 3.3±0.7) ($H_{2,\ 16}$= 11.59, P<0.01), but aphid abundance did not differ among treatments (mean aphids per treatment ±SE, T2: 13±4.2; T3: 9.4±1.6; T4+T5: 11.9±1.4; $H_{2,\ 16}$=0.02, P<0.99). No correlation was found between aphid abundance and total emitted VOCs (r_s=−0.01, P<0.9, N=12).

Discussion

The infestation by *L. roboris* elicited the emission of Δ^3-carene and increased significantly the emissions of myrcene and γ-terpinene. The most important biogenic volatile organic compounds (BVOCs) produced by terrestrial plants are isoprene and monoterpenes, such as those mentioned above (Karl et al. 2009). In the Mediterranean basin there are several plants that emit isoprenoids, particularly those of the *Quercus* genus (Owen et al. 2002). Among them is the holm oak (*Quercus ilex*), which despite lacking storage organs is a strong emitter of monoterpenes in comparison with other *Quercus* spp. that emit mainly isoprene (Kesselmeier and Staudt 1999). The blend produced by holm oak has been studied mainly in relation to its modulation by abiotic factors (temperature, light, drought, different CO_2 concentrations) (Staudt and Bertin 1998; Llusia and Peñuelas 1999; Rapparini et al. 2004; Peñuelas and Staudt 2010). In accordance with previous reports of holm oak terpene emissions, we found that the blend produced by holm oak saplings was composed mainly of α- and β-pinene, sabinene and myrcene (Street et al. 1997;



Staudt and Bertin 1998). Recently, Staudt and Lhoutellier (2007) showed that massive outbreaks of the gypsy moth (*Limantria dispar*) raise by 16% the total emitted VOCs, including new compounds, in *Q. ilex* after a delay of several hours from the start of the infestation. The presence of this moth promotes the release of DMNT, germacrene D, β-caryophyllene, and several other sesquiterpenes that were not emitted or emitted only in trace amounts from non-infested leaves. To our knowledge, no study on the effect that aphids have on oak trees, and in particular the indirect effect that the ant, through aphid attention, has on holm oak VOCs, has been performed previously. Changes in the composition of emitted VOCs associated with the presence of aphids have been reported in studies of tea and willow trees (Han and Chen 2002; Inui et al. 2003) and of other plants with agricultural value (Heil 2007). The aphid-induced plant volatiles act as synomones for foraging aphid parasitoids and predators (Du et al. 1998; Powell et al. 1998). On our saplings, we have never seen predators or any evidence of parasitoid oviposition (mummies). In addition, during a 2-year study of the abundance of *L. roboris* on mature holm oaks in the same study area and with the same ant species, parasitized aphids or predators have never been found.

The volatiles induced by insect damage depend on the feeding habits (Delphia et al. 2007) and on the density of herbivores (Dicke et al. 1993; Tumlinson et al. 1993). In general, phloem feeders induce lower emissions of plant volatiles compared with chewing insects, even under high levels of plant infestation (Staudt and Lhoutellier 2007). Aphids are all phloem feeders, and their feeding behavior comprises two phases. The first is the probing phase, during which the aphid inserts its stylet and tests sap quality, and the second is the ingestion phase, during which the aphid regulates sap intake using its cybarial pump (Miles 1987). During probing, the stylet of the aphid transiently punctures epidermal, mesophyll, and parenchyma cells. For the most part, however, aphids penetrate plant tissues via a primarily intercellular route, and their impact on plants is thought to be largely due to removal of photosynthesis products and injection of saliva (Goggin 2007). After identifying a suitable plant and locating on the plant, aphids begin to ingest sap from the sieve tube (Miles 1987). The ability to prevent sieve tube plugging is an important adaptation that allows aphids to remain at a single feeding site for hours at a time (Goggin 2007). Despite the low level of cell damage that aphids produce when inserting their stylets between cells (Goggin 2007), some aphid species may trigger large responses in plant volatiles shortly before starting to feed. The plant response induced by aphids usually appears with a delay of several hours after infestation (El-Aouni et al. 2007) and may cause systemic production of volatiles for up 24 hrs after the aphids have been removed from the

plant (Guerrieri et al. 1996). Du et al. (1998) found that 6-methyl-5-hepten-2-one, linalool, geranic acid, and (E)-β-farnesene appeared during the first day after *Acyrthosiphon pisum* infestation of broad bean plants and increased in concentration with increasing duration of aphid feeding. These facts highlight an immediate plant response that is amplified with time and does not stop immediately.

In our study, we began to sample VOCs 1 week after aphids began to feed on *Q. ilex* saplings. This suggests that we probably sampled VOCs when the response of the saplings was amplified. Moreover, the response of the saplings may have continued, because aphid abundance decreased with time in all treatments, but no correlation between aphid abundance and total emitted VOCs was found. The decrease in the number of aphids could be due to ant predation, despite the fact that ants were provided with freshly killed Tenebrionidae to prevent aphid predation. On holm oak, the main prey of *L. grandis* and *L. neglectus* are Psocoptera (33.8% and 31.1% of total predated insects, respectively) and the untended aphid *Hoplocallis picta* (35.4% and 37.8% of total predated insects, respectively) (Paris and Espadaler 2009). *Lachnus roboris* represents only 1.5% and 2.5% of total predated insects for *L. grandis* and *L. neglectus*, respectively (Paris, unpublished data). We have never seen ants carrying aphids to the nest but, as mentioned, both ant species prey on *L. roboris* so we cannot completely discount aphid predation.

As stated above, our results showed that feeding by *L. roboris* induced the emission of Δ^3-carene and increased the emission of myrcene and γ-terpinene. It has already been reported that mature holm oaks release Δ^3-carene in very low quantities (1.9–8.3% of total emissions depending on the month) (Street et al. 1997), but previous studies did not report whether or not the sampled holm oaks were infested by aphids because this trait was not related to the aims of those studies. The reported temporal variations of Δ^3-carene emissions in these studies coincided with the population dynamics of *Lachnus roboris* on holm oaks (Street et al. 1997), which shows a main peak abundance at the end of spring or beginning of summer and a secondary peak abundance at the beginning of autumn (Paris and Espadaler 2009). This leads us to think that the sampled mature holm oaks could have been infested by aphids.

Why Different Species of Tending Ants Resulted in Different Emissions

Our results also showed that the attendance of ants may change the VOC emissions of plants, and that their effect is dependent on the ant species. When the local ant *L. grandis* was present, α- and β-pinene, sabinene, camphene, and Δ^3-carene increased significantly compared with the emissions of saplings with untended aphids. On the other hand, attention from the invasive ant *L. neglectus* decreased only the emission of myrcene, one of the main VOCs emitted by holm oak. However, when the effect of *L. neglectus* colony size was tested, no difference was found in BVOC emissions. We suspect that this finding could be explained by the adjustment that *L. roboris* can make to its rates of feeding and excretion when tended by different ant species. According to electrical penetration graphs obtained during feeding, aphids are able to regulate the ingestion of sap (Tjallingii 1995). Once a plant is accepted as a suitable source, the total time of penetration of sieve elements is the same with or without the presence of tending ants (Rauch et al. 2002). The total duration of penetration is composed of two waveforms: E1 (salivation) and E2 (ingestion of sap). Rauch et al. (2002) suggested that it is the duration of ingestion of sap that aphids change when they are tended. However, these authors were unable to distinguish between E1 and E2 waveforms but suggested that an increase in sap ingestion may occur as honeydew excretion increases when ants tend aphids. Therefore, *L. roboris* probably adjusted its feeding rate, not necessarily by increasing it but by modifying its frequency and the opening time for the cybarial pumping of sap. In addition, aphids are able to regulate the number of drops excreted per minute and the mean volume of honeydew drops, depending on whether or not they are tended. It has been demonstrated that when aphids are tended by ants, they increase the number of drops per minute but decrease the volume of drops (Yao and Akimoto 2001). This evidence shows that aphids apparently maintain a constant excretion rate (drops* $hour^{-1}$ * $aphid^{-1}$ per drop volume) regardless of whether tended or not. The excretion frequency (drops* $hour^{-1}$ * $aphid^{-1}$) was significantly higher when *L. roboris* was tended by the invasive ant (Paris and Espadaler 2009). However, we cannot determine whether or not the volume of the drops changes when aphids become tended by the invasive or by the native ant. Therefore, we cannot be totally sure whether the rate of honeydew excretion changes. However, some kind of regulation of excretion rate should have occurred because the frequency (drops per minute) changed. This change in the frequency of excretion of *L. roboris* could reflect an adjustment of aphid feeding when tended by *L. neglectus* instead of *L. grandis*, which may affect the VOC emissions of the plant.

Ants and Aphids as Sources of VOCs

Volatiles are involved in ant social behaviors such as recruitment, foraging, alarm, caste and nestmate recognition (Hölldobler and Wilson 1990), as well as in their interactions with other species. On the other hand, aphids emit volatiles in association with crowding, dispersion, alarm, and sexual attraction (Pickett et al. 1992). As a

result, in our experiment both insects may have been sources of BVOCs. We searched each compound detected in this study in the literature and in Pherobase, a web-based library of BVOCs elicited from plants and insects (http://www.pherobase.com/). Terpenes can be emitted in large amounts by aphids as a component of the alarm blend (Francis et al. 2005). In a study of the volatile compounds emitted by 23 different aphid species, myrcene, α- and β-pinene, camphene, and γ-terpinene were emitted by several aphid species after crushing but not during their feeding on plants (Francis et al. 2005). Total emission of the main component of the alarm pheromone in the pea aphid (*Acyrthosiphon pisum*), when attacked by predators, averages 16.33±1.54 ng per aphid and ranges from 1.18 to 48.85 ng per aphid (Schwartzberg et al. 2008).

Concerning ants, α- and β-pinene, sabinene and camphene have been detected as components of the alarm blend in the ants *Crematogaser laboriosa*, *Pristomyrmex pungens* (except myrcene), *Lasius niger* (except camphene), *Technomyrmex albipes* (except camphene and β-pinene), and *Tetramorium caespitum* (except camphene and β-pinene) (Hayashi and Komae 1980). However, these authors gave information about the proportion of each compound represented in the blend and not the absolute values. Janssen et al. (1997) found that β-pinene occurs only in picogram quantities at foraging trails of *P. pungens* and is a major component of monoterpene secretions from the poison gland of this species. In leaf cutting ants, when a foraging trail is made by dribbling volatile trail pheromone, only 40 pg/μl–0.4 ng/μl is necessary to trigger trail-following activity (Riley et al. 1974). At high concentrations (4 μg/μl), the ants are repelled from the trail (Riley et al. 1974). In ants of *Tetramorium* sp., the Dufour's gland (a gland that produces several volatiles) may contain between 30 and 70 ng of a chemical blend per worker (Hölldobler and Wilson 1990). In workers of *Pogonomyrmex badius*, the main alarm pheromone is stored in quantities of 0.2–34 μg in the mandibular gland reservoir (Hölldobler and Wilson 1990). These examples highlight that the emission of VOCs by aphids and ants occurs at a level three or four orders of magnitude below those detected in this study, although ants can store high quantity of VOCs. Concerning Δ^3-carene, there is no evidence that this component has been secreted by ants or by aphids.

Should Aphids and Tending Ants be Considered as a New Driving Factor for Monoterpene Emissions in BVOC Inventories of the Mediterranean Region?

To answer this question we should consider the seasonality of monoterpene emissions by *Q. ilex*, the abundance of trees infested with aphids and the amount of honeydew collection by ants, whether these factors overlap in time, and the intensity of ant-aphid mutualism. In Europe, forests cover 40.4% of the vegetated surface and are the major source of monoterpene emissions (Karl et al. 2009). Monoterpene emissions arise in summer, and the main contribution comes from forests of the Boreal and Mediterranean regions where *Pinus* spp. and *Q. ilex* are the main emitters as a result of the area they cover (Karl et al. 2009). According to Köble and Seufert (2002), *Q. ilex* contributes 2.1% to the forested area and is the first tree species of newly synthesized monoterpene emissions (standard emissions factor of 43 μg $g^{-1}h^{-1}$). Monoterpenes are emitted mainly by *Q. ilex* during the summer, especially in July and August, owing to the light and temperature dependence of their production (Staudt and Bertin 1998) and the seasonality shown in the monoterpene synthase activity of *Q. ilex* (Fischbach et al. 2002). At fragments of mixed forest colonized by *L. neglectus* or by local ants, the number of trees colonized by ants peaks in June or July depending on the year (Paris 2007). Honeydew collection per holm oak, by *L. neglectus* and *L. grandis*, follows the same temporal variation (Paris and Espadaler 2009). This evidence suggests that the period of maximum monoterpene emission from forests, the number of trees infested with aphids, and honeydew collection by ants overlap in time. At forest stand level, it is the intensity of aphid infestation, i.e., the area covered by infested trees and the abundance of different tending ant species that could change the rate of monoterperne emission for the purposes of the BVOC inventories. In Spain, *L. roboris* seems to be a rare aphid (Paris and Espadaler 2009) that does not exceed a level of 10% of infested trees at stand level (Melia et al. 1993), in contrast to the situation in temperate forests, where this aphid species is more frequent (Sudd and Sudd 1985). However, *Lasius* spp. and other tending ant species tend many aphid species on different tree species, especially *Pinus pinaster* and *P. halepensis*, two monoterpene emitters that are broadly distributed in the Mediterranean region (Karl et al. 2009). Thus, monoterpene emission by other tree species apart from *Q. ilex* could be modified also by tending ants.

Monoterpenes play different roles in the troposphere and for plants. In the troposphere, monoterpenes can contribute to the formation of O_3 from a series of reactions with NOx emitted from anthropogenic and natural sources, and to the formation of secondary organic aerosols as a result of the gas/particle partitioning of their reaction products (Karl et al. 2009). At the plant surfaces, as well as in the mesophyll monoterpenes quench O_3 that protects the plant against oxidative stress (Holopainen 2004), and protects the plant against higher temperatures (Copolovici et al. 2005). Taking into account the facts that the invasive ant *L. neglectus* decreased total monoterpene emissions by 76% in comparison with *L. grandis*, that this invasive ant is

expanding its range in Europe (Espadaler et al. 2007), and that it is displacing native ants we suggest that massive aphid outbreaks in areas where this invasive ant occurs should be considered when modelling the emission of VOCs. A rapid way to include this information in inventories will be to estimate the proportion of trees colonized only by *L. neglectus*. Moreover, it will be necessary to know how monoterpene emission changes in other tree species colonized by *L. neglectus*, in particular other *Quercus* and *Pinus* spp., which are the main monoterpene emitters in the Mediterranean region (Karl et al. 2009).

In summary, the results of this study highlight that the amount of various terpenes emitted by holm oaks can increase or decrease (depending on the compound), or new compounds can be released, according to the presence of aphids and the identity of the tending ant species. However, the range of ant colony sizes tested here had no effect on terpene emission rates. We discard the possibility that changes in α- and β-pinene, sabinene, and camphene emissions were caused by emissions from ants or aphids because of the scale at which these insects emit VOCs. Therefore, from an ecological perspective, the altered monoterpene composition of the *Q. ilex* blend associated with the feeding of aphids and tending ants may affect the protection that monoterpenes exert against episodes of high O_3 and temperatures during the Mediterranean summer (Pinto et al. 2007).

Cucumber Volatile Blend Attractive to Female Melon Fly, *Bactrocera cucurbitae* (Coquillett)

Matthew Samuel Siderhurst · Eric B. Jang

Received: 19 February 2010 / Revised: 7 May 2010 / Accepted: 19 May 2010 / Published online: 5 June 2010
© US Government 2010

Abstract The melon fly, *Bactrocera cucurbitae* (Coquillett), is a serious crop pest throughout the Asia Pacific subcontinent and Southeast Asia, causing damage to tree fruits, cucurbits, and related crops. Attractants for female melon flies are of particular interest as they could be used in control tactics to reduce pest levels. Previous work has shown that freshly sliced cucumbers are attractive to female melon flies, but the compounds responsible for this attraction were not identified. The objective of the present study was to create a synthetic lure for female *B. cucurbitae* based on its close association with Cucurbitaceae. Coupled gas chromatography-electroantennogram detection (GC-EAD) analysis of fresh and aged puréed cucumbers identified 31 compounds that were detected by females. Compounds that elicited EAD responses initially were screened as single components in glass McPhail traps in outdoor rotating olfactometer experiments. Four criteria were used to select compounds for testing in blends: a) strength of EAD response elicited; b) amount of compound present; c) relative attractiveness of a single compound; and d) compound novelty to Cucurbitaceae. Several synthetic blends attracted significant numbers of females in outdoor rotating olfactometer experiments; a nine-component blend (lure #7) was the most attractive. Field captures of female *B. cucurbitae* in traps baited with lure #7 were twice those in traps baited with Solulys protein bait. Besides having a female-biased attraction, this lure may have several advantages over protein baits: it can be used with a dry trap, is long lasting, and it captured low numbers of non-target species. Possible applications of this lure include trapping (for detection and/or monitoring/delimitation) and control/eradication (e.g., mass trapping, attract-and-kill, or as an attractant for existing protein insecticide bait sprays such as GF-120).

Key Words Melon fly · Gas chromatography-electroantennogram detection · Kairomone · Female attractant · Tephritidae · Cucumber · Volatiles · Bioassay · *Bactrocera cucurbitae*

Introduction

The melon fly, *Bactrocera cucurbitae* (Coquillett), is a serious pest of tropical agricultural crops, causing damage to at least 81 host species (Dhillon et al. 2005). Infestations are particularly high in cucurbit crops, in which fruit losses can range from 30 to 100% (Dhillon et al. 2005). The melon fly was the first (in 1895) of four tephritid fruit flies to invade Hawai'i. Melon fly, the Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann), and the oriental fruit fly, *Bactrocera dorsalis* (Hendel), cause up to an estimated 15 million USD/year in direct costs to Hawaiian agriculture (Nakahara 1977), and 300 million USD/year in lost markets (Miller et al. 1992). Melon fly also is considered a major quarantine pest for subtropical agricultural states, such as California, Florida, and Texas, which deploy grid trapping for early detection of this pest.

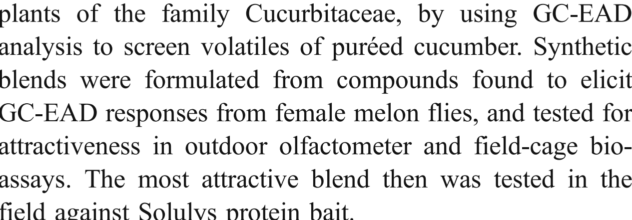
Plant semiochemicals are critical to fruit fly behaviors, such as host finding and oviposition, and have been studied

as sources of attractants for detection and control (Jang and Light 1996; Light and Jang 1996). While several attractants for males currently are known (raspberry ketone and its derivatives cuelure and melolure), chemicals that attract females are limited to food-type attractants, such as fermenting sugars, hydrolyzed protein, and yeast (Jang and Light 1996). Unfortunately, these liquid lures lack potency, have limited field life, are difficult to handle, and attract non-target species. Non-food-based female attractants are a promising, if elusive, goal for control programs, given that such attractants have the potential to kill individual females and prevent future offspring (Jacobson et al. 1971; Jang and Light 1996; Light and Jang 1996). The most promising sources for female attractants are plant materials, such as host fruits and leaves. Host fruits are of particular interest since some tephritid females prefer host fruit volatiles when searching for oviposition sites (Jang and Light 1996; Light and Jang 1996). However, isolation and identification of attractant compound(s) from fruits often is difficult, as the fruit odors can be complex blends of chemicals, which may change composition during fruit ripening. Additionally, it is possible that polyphagous fruit flies, such as the melon fly, detect and/or respond to a wider array of chemical cues than do oligophagous fruit flies, such as the apple maggot, *Rhagoletis pomonella* (Walsh) (Siderhurst and Jang 2006).

Rapid screening of multiple compounds of interest and/or analysis of complex blends has been facilitated by coupled gas chromatography-electroantennogram detection (GC-EAD) systems, which have been successfully used to identify fruit fly attractants from several plant sources (Cosse et al. 1995; Zhang et al. 1999; Nojima et al. 2003a, b; Malo et al. 2005; Siderhurst and Jang 2006; Alagarmalai et al. 2009). Identification of electroantennogram-active fruit volatiles for *R. pomonella* has led to the development of agriculturally useful control lures (Zhang et al. 1999; Stenliski and Liburd 2002). Attractive plant-host volatiles also have been identified without use of electrophysiology by gas chromatography-mass spectrometry (GC-MS) and behavioral bioassays (Nigg et al. 1994; Hwang et al. 2002; Massa et al. 2008).

Melon fly has a strong host association with a variety of cucurbits, and its attraction to cucumber, zucchini, bitter melon, kabocha, cantaloupe, and ivy gourd has been investigated (Miller et al. 2004; Piñero et al. 2006). Freshly sliced cucumber is especially attractive (Miller et al. 2004; Piñero et al. 2006), and has been utilized to investigate melon fly behavior in field situations (Prokopy et al. 2003, 2004). Additionally, farmers in Hawai'i have used fresh-sliced or mashed cucumber for many years to attract and control female melon fly.

The objective of the present study was to find a female attractant for melon fly, based on its close association with



plants of the family Cucurbitaceae, by using GC-EAD analysis to screen volatiles of puréed cucumber. Synthetic blends were formulated from compounds found to elicit GC-EAD responses from female melon flies, and tested for attractiveness in outdoor olfactometer and field-cage bioassays. The most attractive blend then was tested in the field against Solulys protein bait.

Methods and Materials

Insects Adult flies used in bioassays were obtained as pupae from the mass-rearing unit at the USDA ARS Pacific Basin Agricultural Research Center, Mass-Rearing Facility in Honolulu, Hawai'i. Larvae were reared on a standard wheat, sugar, yeast diet (Tanaka et al. 1969). Pupae were shipped by air to Hilo, HI, where they were placed into 30× 30×30 cm aluminum screen cages, containing sugar, water, and hydrolyzed protein. Flies were held at 24°C, 60–80% relative humidity, and 12 L:12D photoperiod until use. Prior to testing, flies were immobilized at 5°C, separated into groups of either 50 males or females, and then held at room temperature (24°C) for at least 1 h before use. Flies were approximately 9–11 d old when tested and presumed to be mated (>95% of females from mixed cages are mated by d 7; Jang et al. 1997).

Fruits Cucumber fruit (variety unknown) was purchased from local supermarkets and stored no longer than 1 wk at 4°C before use.

Volatile Sampling Headspace sampling from fresh, 1-, 3-, and 5-d-old puréed cucumber slurries was conducted using Porapak Q absorbent (50/80 mesh; Alltech, Deerfield, IL, USA). The absorbent (1 g) was packed between glass wool in a Pasteur pipet, preconditioned at 70°C for 16 h, washed with dichloromethane, and then dried under carbon-filtered nitrogen. Individual, intact cucumbers (~200 g) were puréed and immediately transferred to a 4-l, round-bottom aeration chamber for aging (at 28°C) and volatiles collection. Carbon-filtered nitrogen (1 l. min^{-1}) was used to sweep volatiles from the chamber through the collection pipet for 1 h. Collections from cucumber slurries were made immediately following maceration (fresh), and at 1-, 3-, and 5-day intervals. No air flow was passed through the aeration chamber during the aging periods. Volatiles were eluted from the absorbents with 1 ml of dichloromethane, concentrated under a purified nitrogen stream and stored at −8°C until analysis.

Headspace collections also were made with three different solid phase microextraction (SPME) fibers: polydimethylsiloxane (PDMS; film thickness 100 µm; Supelco Inc., Bellefonte, PA, USA), polyacrylate (PA; film thick-

ness 85 μm), and carbowax/divinylbenzene (CW/DVB; film thickness 70 μm). SPME collections were conducted to assess whether additional cucumber volatiles, not collected by Porapak Q, elicited EAD responses from melon fly antennae. SPME fibers were conditioned before use in a GC injector (250°C) for 30 min. Puréed cucumber (~100 g) immediately was transferred after blending to a 500-ml clear, straight-sided jar, with a screw-top lid fitted with a Teflon liner. Collections from cucumber slurries were made immediately following maceration (fresh), and at 1-, 3-, and 5-day intervals. No air flow was passed through the aeration chamber during the aging periods. The SPME needle was inserted through a small hole in the lid, and the fiber was exposed for 1–24 h to absorb volatiles. SPME fiber exposure time was varied to ensure detection of minor volatile components. The fiber was inserted into the GC injection port to desorb volatiles.

Instrumentation Electroantennogram responses to cucumber volatiles were recorded using an Agilent Technologies (Palo Alto, CA, USA) 6890 GC coupled to a Syntech (Hilversum, The Netherlands) EAD system. The GC was equipped with an HP-5 column (30 m×0.32 mm ID 0.25 μm film thickness), with hydrogen as carrier (2.3 ml. min^{-1}) and makeup (added before the splitter, at 10 ml. min^{-1}) gas. A Graphpack-3D/2 flow splitter was attached to the end of the column, and the effluent was split 1:1 between the flame ionization detector (FID) and the EAD (via a 250°C transfer line). The injector, in splitless mode, and FID were held at 250°C and 275°C, respectively. The oven temperature program began at 80°C (held for 1 min), then was increased at 10°C.min^{-1} to 240°C, and held for 13 min. Whole female fly heads were removed with forceps and secured with electrode gel (Spectra 360, Parker Laboratories, Inc., Fairfield, NJ, USA) between the electrodes of a Syntech EAG probe antenna holder. Antennal preparations were discarded after one or two runs. Humidified air (400 ml.min^{-1}) was used as a carrier for effluent from the EAD transfer line to the antennal preparation. The signals generated by the EAD and FID were passed through a Syntech NL 1200 high-impedance amplifier and analyzed by using Syntech GC-EAD2000 software version 2.5. For Porapak Q collections, four runs with high signal:noise ratios were conducted to determine consistent EAD responses for each treatment. Peaks eliciting EAD responses in at least 3 of the runs were subjected to identification by GC-MS. SPME collections were not replicated more than twice per fiber type or collection time, with peaks with reproducible EAD responses subjected to identification by GC-MS.

GC-MS analysis was performed on an Agilent 6890N GC interfaced with a Hewlett-Packard 5973 Mass Selective Detector. The GC was equipped with an HP-5MS column (30 m×0.25 mm ID 0.25 μm film thickness), which was temperature programmed from 60 to 300°C at 10°C.min^{-1} following a 1 min. delay. The injector temperature was 250°C, and helium was the carrier gas (1.1 ml.min^{-1}.). Compounds from cucumber were identified on the basis of their retention times and mass spectra (NIST98 mass spectral database) and in comparison with authentic standards.

Chemicals Chemicals were purchased from Sigma-Aldrich (Saint Louis, MO, USA). Compound purities were >98% based on GC-FID analysis. In all bioassay and field experiments, compounds were presented neat in 1- or 5-μl glass capillary tubes, either as single components in capillaries or as groupings of capillaries with each component in a separate capillary. Compounds used in lure compositions were selected according to three parameters: they must have evoked reproducible and relatively high amplitude EAD responses, their relative amounts in cucumber volatiles (determined by GC-FID), and their relative attractiveness (trap captures) in olfactometer bioassays using single compounds.

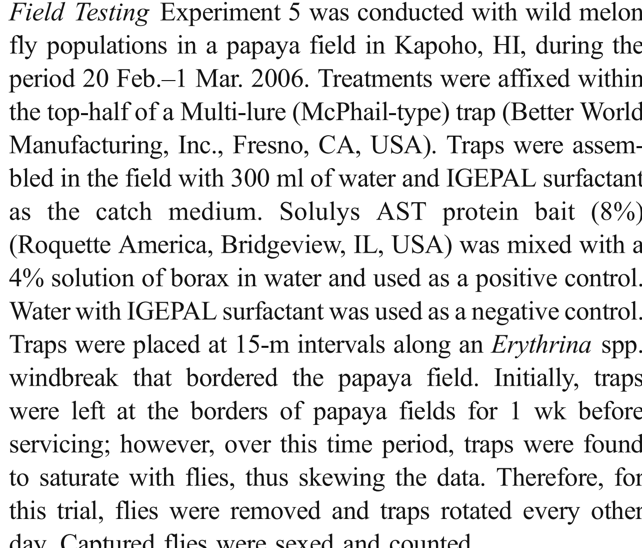
Bioassays An outdoor multiple-trap rotating olfactometer was used to evaluate the attractiveness of single compounds and blends of cucumber volatiles to melon flies. The outdoor olfactometer consisted of a 3×3×2.5 m rectangular wooden-framed screen cage (Jang et al. 1997), used to compare different treatments in competitive tests. A rotating hub with 10 arms, each ca 62 cm long, was hung from the center of the cage, ca 1.8 m from the floor. The arms of the motorized hub unit revolved at 1.5 rpm. Treatments were prepared by affixing, with tape, glass capillaries containing synthetic compounds within small invaginated glass McPhail traps. The bottoms of these traps were filled with 30 ml of water containing 2 drops of the nonionic surfactant IGEPAL (Sigma-Aldrich). Traps were assigned randomly to hub arms. Approximately 500 flies of each sex were placed in the outdoor cage and left for approximately 4 h (initiated 09:00–10:00; terminated 13:00–14:00). Tests were conducted under ambient outside conditions (usually 23–28°C) under natural (indirect) light. Tests never were conducted on days when rain was persistent and heavy. At the end of each test, flies were removed from the traps, and counted by sex. Between replicates, capillaries were removed from the traps, and the traps washed in hot soapy water. Each experiment was replicated four times.

Experiment 1 evaluated the attractiveness of individual chemicals from cucumber volatiles to melon flies. Five or six treatment traps, containing 1-μl capillaries, and a control were assigned randomly to hub arms and run together as a replicate group. To standardize for different

ambient conditions (e.g., temperature, humidity, light levels, etc.), the number of flies caught by the negative control (water plus surfactant only) was subtracted from all other trap catches.

Experiments 2 and 3 tested melon fly attraction to blends of six nine-carbon aldehydes or alcohols. The structurally similar (*Z*)-6-nonenal (*Z*6-9:al), (*E*,*Z*)-2,6-nonadienal (*E*2*Z*6-9:al), (*E*)-2-nonenal (*E*2-9:al), and (*Z*)-6-nonen-1-ol (*Z*6-9:1-ol) were among the most abundant chemicals collected on Porapak Q, while nonanal (9:al) and 1-nonanol (9:1-ol) were apparent in SPME collections, and both elicited EAD responses from female melon flies. Experiment 2 tested two blends of all six compounds: four compounds (*Z*6-9:al, *Z*6-9:1-ol, 9:al, 9:1-ol) emitted from 1-μl capillaries and two compounds (*E*2*Z*6-9:al, *E*2-9:al) from 5-μl capillaries (lure #1), and all six from 5-μl capillaries (lure #2), along with a control. Experiment 3 was a subtraction bioassay based on lure #1. In addition to lure #1, four blends (lures #3–6) with various compounds missing were tested.

Experiment 4 tested melon fly attraction to lures containing an expanded set of compounds, all shown to elicit both high EAD and behavioral responses from *B. cucurbitae*. Given the preference of *B. cucurbitae* for freshly sliced cucumber (Miller et al. 2004; Piñero et al. 2006), chemicals released from fresh cucumber were selected over those from aged cucumber. Lure #7 was based on lure #3 plus five additional compounds: 1-octen-3-ol (1-8:3-ol), acetic acid (AA), hexanal (6:al), (*E*)-2-octenal (*E*2-8:al), and 1-hexanol (6:1-ol). Lure #8 was based on lure #3 plus 2 additional compounds, 1-8:3-ol and AA. Lure #9 was composed of *Z*6-9:al, *Z*6-9:1-ol, 1-8:3-ol, and AA.



Field Testing Experiment 5 was conducted with wild melon fly populations in a papaya field in Kapoho, HI, during the period 20 Feb.–1 Mar. 2006. Treatments were affixed within the top-half of a Multi-lure (McPhail-type) trap (Better World Manufacturing, Inc., Fresno, CA, USA). Traps were assembled in the field with 300 ml of water and IGEPAL surfactant as the catch medium. Solulys AST protein bait (8%) (Roquette America, Bridgeview, IL, USA) was mixed with a 4% solution of borax in water and used as a positive control. Water with IGEPAL surfactant was used as a negative control. Traps were placed at 15-m intervals along an *Erythrina* spp. windbreak that bordered the papaya field. Initially, traps were left at the borders of papaya fields for 1 wk before servicing; however, over this time period, traps were found to saturate with flies, thus skewing the data. Therefore, for this trial, flies were removed and traps rotated every other day. Captured flies were sexed and counted.

Data Analysis Results were analyzed by ANOVA, and means compared using Tukey's HSD studentized range test (Proc GLM, SAS 2000). Trap catches from Experiments 4 and 5 were transformed by $\sqrt{X+0.5}$ to normalize the distribution and stabilize variance, before statistical analysis.

Results

GC-EAD analysis of headspace volatiles from puréed cucumber revealed 31 compounds that elicited consistent electroantennogram responses from *B. cucurbitae* females (Fig. 1, Tables 1, 2). GC-MS analysis, along with

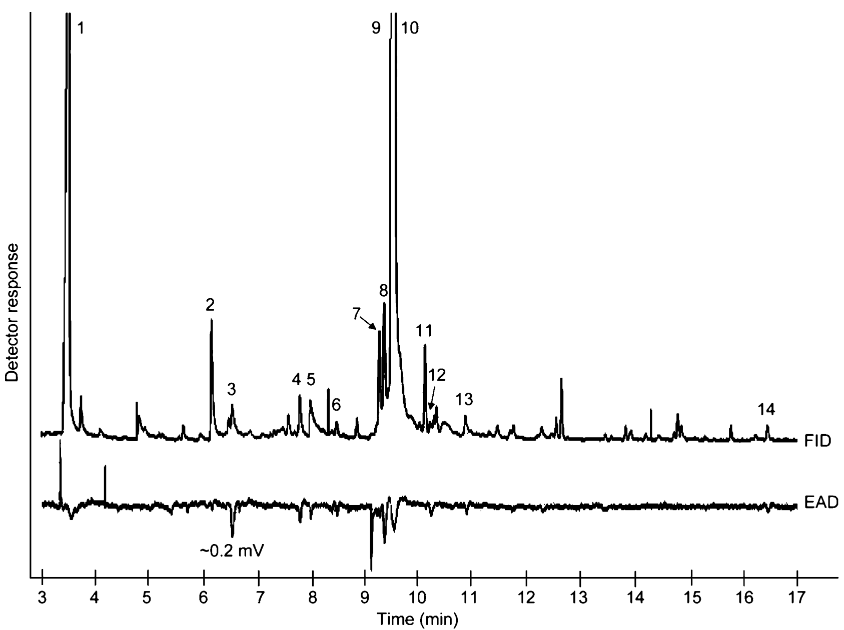


Fig. 1 Coupled gas chromatograph (flame ionization detection; *FID*) and electroantennogram detection (*EAD*) run of volatiles from 3-d-old puréed cucumber, using female *Batrocera cucurbitae*. Volatile collections were made using a SPME CW/DVB fiber. *1* = acetic acid; *2* = (*E*)-2-heptenal; *3* = 1-octen-3-ol; *4* = (*E*)-2-octenal; *5* = (*E*)-2-octen-1-ol; *6* = nonanal; *7* = (*E*,*Z*)-2,6-nonadienal; *8* = (*E*)-2-nonenal; *9* = (*E*,*Z*)-2,6-nonadien-1-ol; *10* = (*Z*)-6-nonen-1-ol; *11* = decanal; *12* = (*E*,*E*)-2,4-nonadienal; *13* = (*E*)-2-decenal; *14* = unknown 4

comparison with authentic standards, was used to identify these compounds, with the exception of 3,5-octadien-2-one, which was only tentatively identified by mass spectral pattern, and four compounds that could not be identified. Of the 31 compounds, twenty-five were present in the Porapak Q collections, while SPME sampling revealed an additional six compounds. There was a high level of overlap between the collection methods, with 13 of the EAD-active compounds detected in both. Given the small number of SPME replications, and variations between collections, we did not quantify differences between the fibers. Volatiles collected by Porapak Q were not quantified but relative abundances were used as a rough guide for lure formulation. For the purpose of this comparison FID detector response to all compounds was assumed to be equal.

Headspace collections from fresh cucumber consisted predominantly of *E*2*Z*6-9:al and *E*2-9:al, while the most abundant components of aged samples were *Z*6-9:1-ol, 6:1-ol, and AA. The number of EAD responses observed was roughly constant among the different-age cucumber preparations, although, as noted, the amounts of collected material varied greatly (Tables 1, 2). The chemicals, 1-8:3-ol, *E*2-9:al, and 6:ol elicited the largest EAD responses

[a] Absolute configurations not determined

[b] Compounds eliciting EAD responses from other tephritids are indicated by species (*Anastrepha ludens* = *Al, Batrocera dorsalis = Bd, Ceratitis capitata = Cc, Rhagoletis pomonella = Rp) (Light and Jang 1987; Light et al. 1988; Jang et al. 1989; Lee et al. 1998; Nojima et al. 2003a; Malo et al. 2005)*

when the data from all different-age cucumber preparations were averaged (Table 1). However, strict comparison of EAD responses among several partially co-eluting compounds is complicated by the fact that the EAD voltage did not return to baseline before the antenna was stimulated by the next peak (e.g., Fig. 1, *Z*6-9:al, *E*2*Z*6-9:al, *E*2-9:al, and *Z*6-9:1-ol).

Experiment 1 showed a wide variation in single compound attractancy in the outdoor olfactometer bioassay (Table 3),with 1-8:3-ol and *Z*6-9:al being the most attractive. In general, more females than males were caught, although the bias to an individual compound did not exceed a ratio of 2:1 (females: males).

In Experiment 2, only the mean number of female flies caught to lure #1 was greater than the mean number of flies caught in the control (ANOVA: $F=7.017$, $df=5$, $P=0.001$). Both lures #1 and #2 caught female and male flies in a roughly 2:1 ratio (Fig. 2).

In the third experiment (Experiment 3), female melon fly catches to lure #3 were greater than to all other catches (ANOVA: $F=15.441$, $df=11$, $P<0.001$; Fig. 3). The number of males caught by this lure was the only other catch significantly greater than that of the control. The compounds 9:al and 9:1-ol appeared to have an antagonistic effect on attractiveness, as their removal (i.e., lure #1 compared to lure #3) led to increased trap captures. In contrast, the removal of *Z*6-9:1-ol (i.e., lure 6) from lure 3 resulted in decreased fly attraction. Neither of the binary blends tested (lure #4 = *E*2*Z*6-9:al plus *E*2-9:al; lure #5 = *Z*6-9:al plus *Z*6-9:1-ol) was attractive.

In the experiment (Experiment 4) testing additional EAD-active compounds, female melon fly catches to lure #7 were greater than all other catches (ANOVA: $F=8.444$, $df=7$, $P<0.001$; Fig. 4). This increase indicates that one, or more, of 6:al, *E*2-8:al and 6:1-ol are critical lure components in the attraction of females to lure #7.

Wild female melon fly catches in a papaya field (Experiment 5) were greater (ANOVA: $F=27.367$, $df=5$, $P<0.001$) to lure #7 than to the other lures tested (Fig. 5). Male melon fly catches to lure #7 were not significantly greater than male catches to Solulys, but both were greater than catches in the negative control. Lure #7 also appeared to be highly species specific with traps baited with this lure containing only ca 1% *B. dorsalis*, the other major *Bactrocera* sp. abundant in the papaya fields. In comparison, Solulys-baited traps captured ca 10% *B. dorsalis*. The only non-target insects regularly found in traps baited with lure #7 were species of Ceratopogonidae, Phoridae, Gryllidae and Tettigoniidae.

Concurrent with experiment 5, there were also Cuelure traps in an adjoining field, and catches from those traps are shown for rough comparison (Fig. 5). Strict comparison with the Cuelure catches is not possible as the Cuelure treatments used a different trap type (a bucket trap instead of a Multilure trap) and kill agent (volatile pesticide instead of water); however, it is interesting to note that female

[a] Relative to control. Trap catches reflect the number of flies caught minus the number of flies caught in the negative control

catches to lure #7 are roughly comparable to male catches using Cuelure in its standard trap.

Discussion

Thirty-one compounds, among the volatiles collected from puréed cucumber, elicited consistent electroantennogram responses from melon fly females in GC-EAD runs. The identified compounds were mostly alcohols and aldehydes, many of which are commonly produced by fruits and flowers of various plants. A number of the compounds [e.g., AA, 6:al, (*E*)-2-hexenal (*E*2-6:al), 6:1-ol, 1-8:3-ol, (*E*)-2-octen-1-ol, linalool, and methyl geranate] that elicited EAD responses from female melon flies also are known to stimulate responses in other fruit fly species, such as *Anastrepha ludens* (Malo et al. 2005), *B. dorsalis* (Light and Jang 1987; Lee et al. 1998), *C. capitata* (Light et al. 1988; Jang et al. 1989) and *R.. pomonella* (Nojima et al. 2003a). Another group among these 31 compounds, are the six- and nine-carbon alcohols and aldehydes not previously shown to elicit electrophysiological responses from tephritids. These oxygenated compounds are produced by the enzymatic breakdown of linolenic and linoleic acids, initiated by plant-issue damage, via the lipoxygenase (LOX) pathway (Hornostaj and Robinson 1999; Feussner

and Wasternack 2002), and have been found previously in both fresh and fermented cucumbers (Kemp et al. 1974; Zhou and McFeeters 1998). The predominant volatile isolated from fresh blended cucumber is *E*2*Z*6-9:al, which is also the most important compound in producing the characteristic cucumber smell perceived by humans (Forss et al. 1962; Schieberle et al. 1990). Interestingly, several LOX pathway derivatives, or close analogs, have been

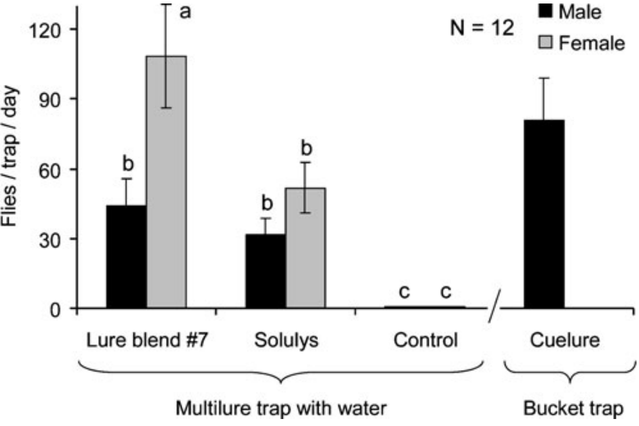

Fig. 5 Numbers (mean/trap ± SE) of wild *Batrocera cucurbitae* caught in traps in a papaya field in Kapoho, HI (Experiment 5) baited with the best synthetic cucumber blend (Lure #7) or Solulys protein bait. Different letters represent significant differences ($P<0.05$) between the mean numbers of flies caught (ANOVA, followed by Tukey's HSD). Cuelure trap captures from an adjoining field, cannot be compared with the other catches, but are shown for rough comparison

implicated previously in melon fly attraction. One of these, (*E*)-6-nonenyl acetate, attracts female melon flies (Jacobson et al. 1971) as well as stimulates oviposition (Keiser et al. 1973). Other compounds, including (*Z*)-3-hexen-1-ol and *E*2-6:al, are prominent in extracts of bittermelon, *Momordica charantia* L., and attract *B. cucurbitae* (Binder et al. 1989).

Our bioassay approach allowed us to identify which of these 31 compounds were required for eliciting male and female melon fly attraction. After first screening single compounds in a rotating olfactometer trap (Experiment 1), six nine-carbon LOX pathway derivatives were tested further in blend combinations. Catches in these trials (Experiments 2 and 3), showed that a blend of *E*2*Z*6-9:al, *E*2-9:al, *Z*6-9:al, and *Z*6-9:1-ol was attractive to melon fly, while addition of 9:al and 9:1-ol to this blend had behavioral antagonistic effects. In a further trial (Experiment 4), several additional compounds were tested, with the blend (lure #7) containing five additional (to the previous four) compounds proving to be the most attractive to female flies. This nine-component blend was attractive to melon flies when tested in papaya fields, catching more female flies than Solulys protein bait traps. Although our approach has proven successful in identifying an attractive lure, further refinement of components and blend ratios, perhaps employing the mixture principles and response surface methodology recently described by Lapointe et al. (2008), could produce a more effective attractant for female melon flies.

Our success in producing a synthetic lure for female melon fly holds promise for future applications in trapping for detection (new infestations/biosecurity) or monitoring (for treatment timing), and in control or eradication (e.g., mass trapping, attract-and-kill, an attractant added to existing protein insecticide bait sprays such as GF-120) programs. The ability of the lure to attract females is advantageous over other attractants (such as Cuelure) that only attract males, because removal of females should have a more significant impact on a pest population. That catches of females to the lure in the field trial were roughly similar to catches of males in Cuelure-baited traps, not withstanding differences between the respective fields and trap types, was encouraging. However, more rigorous comparison between the two lures will be needed to establish their relative attractancy, and their impact on pest populations.

Apart from female-biased attraction, synthetic cucumber lures, such as our nine-component lure #7, have the potential to improve the ease of use of traps for catching female melon flies. Current lures that attract females are limited to food-type attractants, which often lack potency, have limited field life, are difficult to handle, and attract non-target species. Synthetic cucumber lures have the potential to be longer lasting (after formulation into a

matrix), may be adaptable to use with a dry trap, and from our limited study, appear to capture fewer non-target species than food-type attractants.

Abstract Attraction of the mosquitoes *Aedes aegypti* and *Ae*. *albopictus* to plant infusions was evaluated by using a modified sticky-screen bioassay that improved the resolution of mosquito responses to odorants. Under bioassay conditions, solid-phase microextraction-gas chromatographic analyses of the volatile marker chemical indole showed that odorants diffused from bioassay cups, forming a concentration gradient. Infusions were prepared by separately fermenting senescent leaves of eight plant species in well water. Plant infusions were evaluated over an 8-fold range of leaf biomass and/or a 28 d fermentation period. The responses of gravid females of both mosquito species varied with the plant species and biomass of plant materials used to make infusions, and with the length of the fermentation period. Infusions made from senescent bamboo (*Arundinaria gigantea*) and white oak (*Quercus alba*) leaves were significantly attractive to both mosquitoes. In general, infusions prepared by using low biomass of plant material over a 7–14 d fermentation period were most attractive to *Ae*. *aegypti*. In contrast, *Ae*. *albopictus* was attracted to infusions made using a wider range of plant biomass and over a longer fermentation period. Both mosquito species were more attracted to a non-sterile white oak leaf infusion than to white oak leaf infusion that was prepared using sterilized plant material and water, thus suggesting a role for microbial activity in the production of odorants that mediate the oviposition response of gravid mosquitoes.

Introduction

Aedes aegypti L. and *Ae*. *albopictus* (Skuse) are the principal vectors of dengue and dengue hemorrhagic fever viruses on a global basis (Gubler 2002). Immature stages of both mosquito species inhabit human-made containers placed in residential landscapes. Gravid females lay eggs in water-filled containers. The oviposition behavior of these mosquitoes is mediated by visual, olfactory, tactile, or chemo-tactile cues associated with their container habitats (Bentley and Day 1989; Millar et al. 1992; Navarro et al. 2003; Ponnusamy et al. 2008). Chemical cues that mediate oviposition behavior originate from organic infusions in containers as metabolic products of microbial origin (Benzon and Apperson 1988; Isoe and Millar 1995; Sumba et al. 2004; Sant'Ana et al. 2006; Ponnusamy et al. 2008, 2010).

A variety of plant species and plant-associated materials have been used to produce organic infusions for investigating the oviposition behavior of mosquitoes or for monitoring oviposition activity in the field. Infusions made from a variety of grasses (Reiter et al. 1991; Chadee et al. 1993; Rawlins et al. 1998; Polson et al. 2002; Sant'Ana et al. 2006) and from oak leaves (*Quercus* spp.) (Szumlas et al. 1996; Trexler et al. 1998) have been used in oviposition

traps (ovitraps) for monitoring the egg-laying activity of container-inhabiting *Aedes* mosquitoes in the field. Other organic materials, such as sod and pelletized plant-based animal feeds, have been fermented to create infusions that were attractive to gravid *Aedes* (Lampman and Novak 1996a; Ritchie 2001) and *Culex* mosquitoes (Lampman and Novak 1996b). Gravid females of other mosquitoes, such as *Culex nigripalpus* (Theobald) (Ritchie 1984), *Cx. quinquefasciatus* (Say) (Isoe et al. 1995b; Mboera et al. 2000), and *Cx. tarsalis* Coq. (Isoe and Millar 1995) are attracted to hay and grass infusions. Ovitraps baited with organic infusions have been used to monitor arbovirus vectors during disease outbreaks or to collect mosquitoes for arbovirus testing (Tsai et al. 1989; Savage et al. 1993; Nasci et al. 2002; Polson et al. 2002).

Notably, there are no standard methods for producing infusions. Tightly closed plastic garbage bags (Reiter et al. 1991; Chadee et al. 1993; Trexler et al. 1998), fiberglass tubs (Isoe et al. 1995a), open containers (Rawlins et al. 1998), and closed plastic containers (Sant'Ana et al. 2006) have been used to make infusions from plant materials. Moreover, the attractiveness of infusions to gravid mosquitoes changes over the fermentation time (Isoe et al. 1995b; Sant'Ana et al. 2006; Ponnusamy et al. 2010) and with the species and amounts of plant materials fermented (Ponnusamy et al. 2010). Maw (1970) concluded that these changes were because of variations in bacterial activity, and Reiter (1986) recommended that infusions should be prepared by a standard protocol because rapid changes in the microbial population and chemical composition could change the attractiveness of infusions with time.

There also appears to be a lack of standard methods of evaluating and interpreting the biological activity of organic infusions. Most commonly, infusions are evaluated based on the numbers of eggs laid in containers holding test and control media. However, this measure represents an endpoint of the biological activity of various cues, and it fails to separate the effects of attractants and contact chemo-stimulants on the oviposition response (Benzon and Apperson 1988; Isoe et al. 1995a).

The objectives of our research were to: (1) refine a sticky-screen bioassay used previously (Trexler et al. 1998) for measuring the attraction of *Aedes* mosquitoes to plant infusions; (2) compare several methods of preparing infusions that were attractive to gravid *Ae. aegypti* and *Ae. albopictus*; (3) validate that females can be guided within our 2-choice bioassay cages by an odor gradient emanating from the cup holding plant infusion; (4) evaluate effects of plant species, plant biomass, and fermentation time of infusions on the responses of gravid mosquitoes; and (5) determine the significance of microbial activity to the production of attractive infusions.

Methods and Materials

Origin and Maintenance of Mosquito Colonies Aedes aegypti and *Ae. albopictus* colonies were established from eggs collected in New Orleans, LA, USA in 2003. At 6–8 month intervals, adults were added to each mosquito colony to sustain genetic diversity. Larvae of both species were reared as described by Trexler et al. (2003). Mosquito colonies were maintained in separate insectaries at ~28°C, ~75% RH, and a photoperiod of 14:10, L:D, including two twilight periods (60 min each). Eggs for maintenance of mosquito colonies were obtained from females that were blood-fed on a human forearm. Gravid females for oviposition bioassays were produced by feeding 7–14-d-old females on a human forearm 4–5 d prior to the setup of an experiment. The protocol for feeding was in compliance with IRB Guidelines of North Carolina State University.

Preparation of Plant Infusions We hypothesized that production of odorants that attract gravid mosquitoes would be influenced by many factors, including the type and amount of fermented organic material, the amount of headspace available, and duration of the fermentation. Initially, the ratio of plant biomass to well water (33.6 g per 4 L = 1X infusion) described by Trexler et al. (1998) was used to make white oak leaf (WOL) infusion in black plastic trash can liners (14 µm thickness, No. 386014, Central Polybag, Corp., Linden, NJ, USA). We compared three fermentation methods in which: (1) the plastic bag was left open; (2) the plastic bag was tightly sealed with no headspace above the infusion; or (3) the bag was tightly sealed, but ballooned to create a headspace above the infusion equal to approximately 50% of the capacity of the bag. Methods 1 and 3 were intended to achieve aerobic decomposition, while method 2 was intended to accomplish facultative anaerobic fermentation of plant materials. After 1, 2, and 4 week fermentation periods, each type of infusion was tested for attractive odorants against gravid *Ae. aegypti* in a sticky-screen bioassay (Trexler et al. 1998) modified as decribed below.

The potential chemical reactivity of the plastic trash bags was of concern. Therefore, we used Teflon bags (TFM Modified PTFE homopolymer inert bag, No. P-00021-2, 63.5 µm thickness, Big Science, Inc., Huntersville, NC, USA) as an alternative container for producing plant infusions. Infusions were made in tightly clamped Teflon bags, leaving a headspace equivalent to ~50% of the bag volume for the entire fermentation period. Plant infusions were prepared by using senescent leaves of bamboo (*Arundinaria gigantea*), white oak (*Quercus alba*), live oak (*Quercus virginiana*), pecan (*Carya illinoensis*), hackberry (*Celtis occidentalis*), red maple (*Acer rubrum*),

redtop panicgrass (*Panicum rigidulum*), and harvested Bermuda grass (*Cynodon dactylon*) that were obtained from multiple sites in Raleigh, NC and New Orleans, LA. For each plant infusion, there were 6–8 replicate bioassays per trial with three trials completed on different dates.

Optimization of Sticky-screen Attractant Bioassay In preliminary experiments, the original and a modification of the sticky-screen bioassay method of Trexler et al. (1998) were evaluated using white oak leaf (WOL) (*Quercus alba*) infusion (Trexler et al. 1998) and gravid *Ae. aegypti* and *Ae. albopictus*. The original method involved placing a screen coated with insect glue (Tanglefoot®, Tangle Foot Co., Grand Rapids, MI, USA) directly on top of the bioassay cup (120 ml, polypropylene, No.13-711-57, Fisher Scientific) that was spray-painted flat black on the exterior. Gravid females attracted to volatiles and attempting to enter the test cup were trapped on the sticky-screen. However, some females were routinely found free in the cage, indicating that the capture efficiency of this design needed improvement. Therefore, we modified the sticky-screen method by placing the screen approximately 4.2 cm below the cup rim on top of a clear polycarbonate ring (4.2 cm diam.×3.2 cm high) that was cut from a fluorescent tube lamp guard (No. 1743564, Copper Lighting, Peachtree City, GA, USA); this ring held the sticky-screen just above the surface of the water. In each bioassay, two black cups (test and control) were placed randomly in diagonal corners of a reach-in cage (30×30×30 cm, Lucite® CP acrylic, Lucite International, Inc.) fitted with a stockinette sleeve (No. 081620, Albahealth LLC, Rockwood, TN, USA). Cages were placed on shelves in a room where environmental conditions were the same as in the insectary. Ten gravid females were transferred into each cage, and after a 24 or 48 hr bioassay, females trapped on each sticky screen were counted. For the original or modified bioassay, there were 6 replicate cages per trial with three to four trials completed on different dates.

Reach-in Cage Bioassay of Plant Infusions The modified sticky screen bioassay described above proved to be superior to the conventional method for evaluating plant infusions in reach-in cages. Consequently, the modified method was used to bioassay plant infusions. In setting up a bioassay, the contents of the Teflon bag were mixed vigorously prior to removing infusion. The plant infusions were diluted to 50% with well water before the test cup was filled (30 ml) and well water (30 ml) was placed in the control cup. The 1X Bermuda hay infusion was evaluated undiluted (100% infusion) and diluted to 50% and 10% with well water.

Evaluation of Odorant Diffusion Patterns To examine diffusion patterns of odorants in bioassay cages, indole was used as a marker chemical to quantify volatiles in and around a bioassay cage. Specifically, we were interested in measuring the concentrations of indole inside the bioassay cage at various distances from the test cup and above the cage at two time points: immediately after setting up the bioassay (0 hr) and 24 hr later (24 hr). Two cups, a test cup, and a control cup were placed diagonally at the corners inside a standard bioassay cage. The test cup contained 30 ml of distilled water to which 90 μl of a 10 μg/μl indole (CAS No. 120-72-9, Sigma Aldrich Co) solution in dichloromethane were added. The control cup contained 30 ml of distilled water. The headspace was sampled simultaneously at various positions inside and outside the bioassay cage with solid phase microextraction (SPME) (DVB/CAR/PDMS, Supelco) for 10 min. Prior to placement, SPME fibers were conditioned at 250°C for 20 min in a gas chromatograph (GC) inlet (Agilent) purged with helium. Volatiles were captured at five positions inside the bioassay cage (at the surface of the sticky screen inside the test cup, in the middle at the lip of the test cup, 10 cm above the test cup, in the middle of the cage, and at the surface of the sticky screen inside the control cup) and at one position outside the cage, 1 cm above the center of the cage. These experiments were replicated three times.

Indole captured on SPME fibers at both time points (0 hr and 24 hr) was analyzed by using an Agilent 7890A GC with a flame ionization detector (FID), equipped with a DB-5 (30 m×0.25 mm×0.25 μm) column (J&W Scientific) and a 2-m deactivated guard column (Alltech) using helium as a carrier gas. The injector and the detector were kept at 260°C and 280°C, respectively. The oven was held at 45°C for 1 min, then heated to 180°C at 10°C/min, and finally heated at 20°C/min to 280°C and held at the final temperature for 5 min. Samples were injected splitless with an inlet purge time of 0.75 min. Quantification of samples was based on external calibration using a dilution series of indole in the range of 0.1–100 ng of compound injected in the GC.

Comparison of Sterile and Non-sterile Infusions We evaluated the attraction of gravid females to non-sterile and sterile WOL infusions based on the hypothesis that non-sterile infusions would be significantly more attractive to gravid mosquitoes. In behavioral assays, we compared 2-week old WOL (0.5X) infusion (4.2 g leaves/L water) that was produced using sterilized oak leaves and well water (autoclaved for 45 min at 120°C) against unsterilized infusion (unsterilized leaves and well water). After autoclaving, well water (1 L) and WOL (4.2 g) were combined in sterile glass jars (2 L) fitted with threaded plastic lids. Similarly, non-sterile infusion was produced in sterile jars but with leaves and water that were not sterilized. Jars were held at 28°C for 2 weeks before infusions were tested in

modified sticky-screen bioassays. Test cups filled with sterile WOL infusion (30 ml, 50% dilution) were evaluated against control cups containing non-sterile WOL infusion (30 ml, 50% dilution). After a 48-hr bioassay, females trapped on screens in test and control cups in each cage were counted separately.

Walk-in Cage Bioassay of Plant Infusions Based on results from small cage experiments, 1-wk-old bamboo leaf (BL) (1X) and 2-wk-old WOL (0.5X) infusions were evaluated against gravid *Ae. aegypti* and *Ae. albopictus* in a two-choice sticky screen bioassay in a walk-in cage (4×4×2 m height) (Lumite, Inc., Gainesville, GA, USA) that was set up indoors using a wooden frame. Environmental conditions in the walk-in cage were variable, with mean daily temperature and humidity ranging from 24–27°C and 66–83%, respectively. Humidity was provided by a household humidifier (Cool-Moisture Humidifier, No. 564B, Kaz Inc., Southborough, MA, USA). A light regimen of 14:10, L:D was used with the photophase provided by 4 twin bulb (35 W) fluorescent fixtures placed at each corner of the cage. At the beginning and end of the dark period, partial light (1 hr) was provided by an incandescent bulb (25 W) placed in the center of the cage. To reduce penetration of external light into the cage, it was covered with white cotton bed sheets, which were then covered with black plastic sheeting.

Each infusion was evaluated four times on separate dates. With each replicate trial, the positions of treatment and control containers were exchanged. Number 10 tin cans (17 cm high×15 cm diam., 4 L nominal) painted black inside and out with Rustoleum® were used as bioassay containers. Infusion was added to one can, and the same volume of well water was added to the control can. The volume of infusion was 0.5 L or 1.23 L, either undiluted 1x infusion (100% infusion) or 1X infusion diluted with an equal volume of well water (50% infusion). Sticky screens (15 cm diam.) then were placed on top of clear polypropylene cups (7.5 cm high×6 cm diam.) inside each can approximately 15 cm from the lip. At approximately noon, the test and a control container were placed 1 m apart in the middle of the cage, and 30 gravid mosquitoes were released in the cage. After 24 hr, the bioassay was terminated and females trapped on each screen were counted.

Statistical Analyses The Oviposition Activity Index (OAI), described by Kramer and Mulla (1979), was used to evaluate the response of gravid mosquitoes to plant infusions. The OAI standardizes the data by converting the number of females trapped on the sticky screen in the test cup to a proportion after correcting for the number of females trapped on the screen in the control cup. The OAI ranges from −1 to +1, with 0 indicating neutral response. Within each experiment, an OAI was calculated for each replicate as follows:

$$\mathrm{OAI} = \frac{N_t - N_c}{N_t + N_c},$$

where N_t is the number of females trapped on the screen in the test container and N_c is the number of females trapped on the screen in the control container. The SAS procedure PROC UNIVARIATE (SAS for Windows ver. 9.1, SAS Institute, Cary, NC, USA) was used to generate an approximate t statistic which was used to test the hypothesis that the mean OAI for each treatment is significantly greater (attraction) or less (repulsion) than 0 at $\alpha \leq 0.05$.

Results

Optimized Sticky-screen Bioassay Modifying the sticky-screen bioassay by placing the glue-coated screen inside the cup increased the number of gravid females trapped in the test cup containing WOL infusion (Fig. 1). Additionally, fewer free females remained in cages in which the sticky-screen was placed inside of the bioassay cup than in cages with the screen on top of the bioassay cup (Fig. 1).

Fermentation Methods for Plant Infusions Generally, 7-d-old WOL infusions were less attractive to gravid *Aedes* than 14- and 28-d-old infusions (Fig. 2). For both mosquito species, infusions prepared in closed bags with a headspace above the infusion elicited consistently higher responses from gravid females than infusions prepared in open bags or closed bags without a headspace (Fig. 2).

Evaluation of Odorant Diffusion Patterns Under "still air" bioassay conditions, the amount of indole detected using 10 min of headspace sampling with SPME was highest at the position nearest to its source and declined toward the center of the cage as well as upward (Table 1). Only trace amounts of indole were detected in the center of the cage, in the control cup, and above the cage. The pattern was the same at the two time points indicating that the bioassay arrangement maintained an odor gradient for at least 24 hr.

Response to Plant Infusions: White Oak In general, the number of gravid *Ae. aegypti* and *Ae. albopictus* caught on the sticky screen decreased as leaf biomass increased, but this effect was more pronounced for *Ae. aegypti* (Fig. 3). Gravid *Ae. aegypti* were attracted to low biomass infusions (0.5X=4.2 g leaves/L well water) across the entire 28-d fermentation period. The highest OAI (0.42) was achieved with 0.5X biomass infusions after 14 days of fermentation. In contrast, with the exception of the first week, *Ae. aegypti*

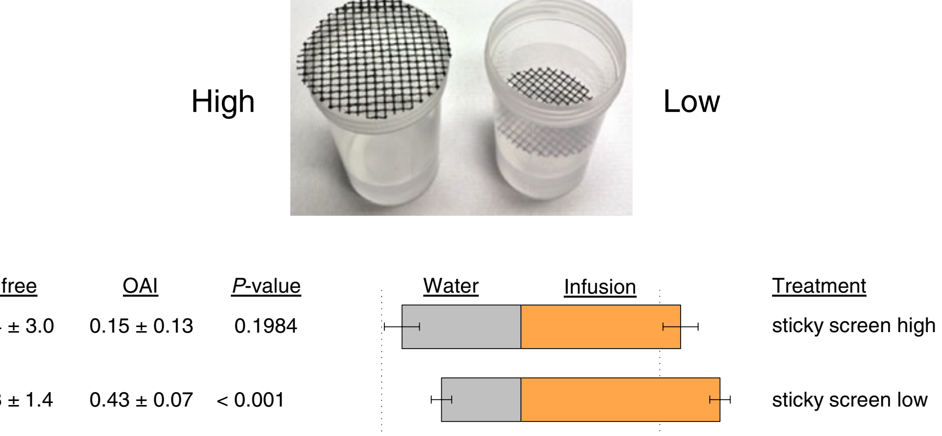

Fig. 1 High and low placement of glue-coated screens in bioassay cups used in modified and original sticky-screen bioassay, respectively. Clear cups are shown here to demonstrate the placement of the screens, but for bioassays the cups were spray-painted flat black on the exterior. Sticky-screen bioassay results for 0.5X (4.2 g leaves/L water) white oak leaf infusion showing higher capture of *Aedes aegypti* in the modified assay. There were six replicate cages per trial and three trials completed on different dates for both the modified and original bioassays

females were repelled by high biomass (4X) infusions over the 28 day fermentation period (Fig. 3).

In comparison, *Ae. albopictus* was attracted to WOL infusions over a broader range of leaf biomass and fermentation times (Fig. 3). The highest mean OAI for *Ae. albopictus* was achieved using 0.5X biomass infusions after 14 and 28 days of fermentation, but the 1X biomass infusions also elicited responses from *Ae. albopictus* across

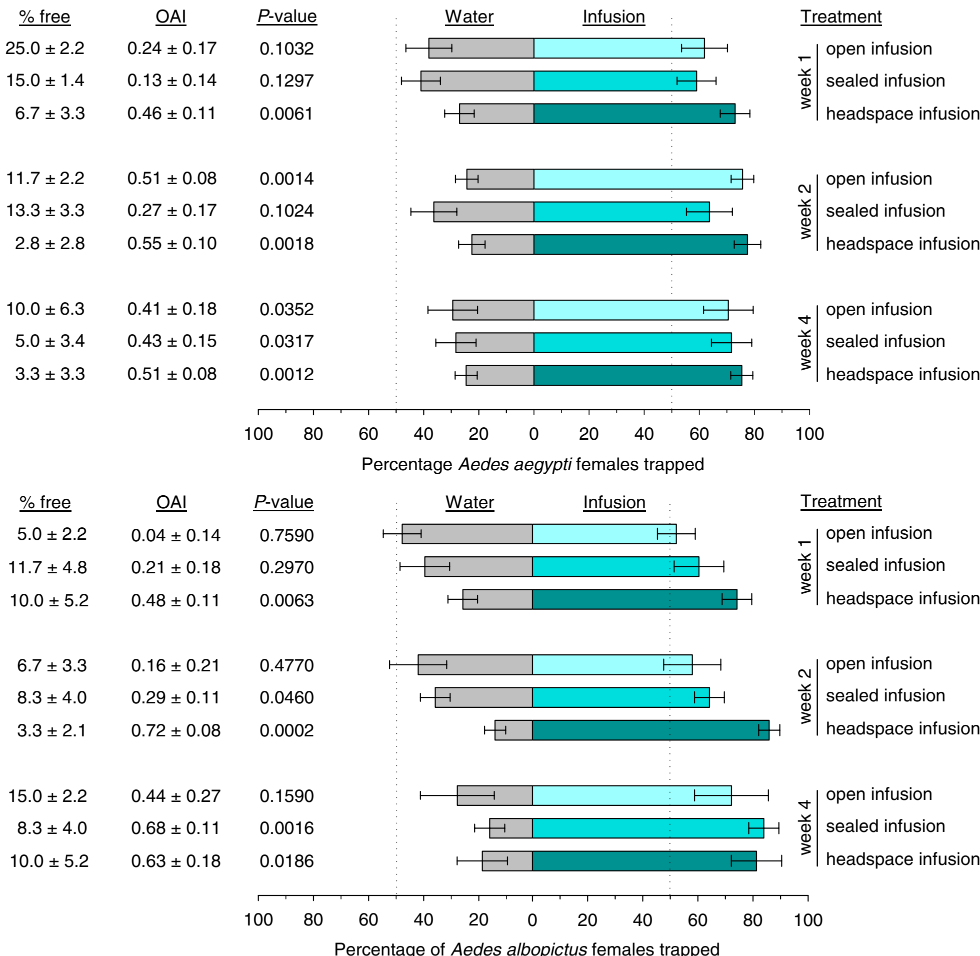

Fig. 2 Evaluation of fermentation procedures and infusion age on attraction of gravid *Aedes aegypti* and *Ae. albopictus* to 0.5X (4.2 g leaves/L water) white oak leaf infusion. There were six replicate bioassay cages per infusion age within each fermentation procedure

Table 1 Amount of indole detected in 10-min SPME collections inside and above the bioassay cage

Sampling position	Amount of indole (ng)			
	0hr		24hr	
	Mean[a]	SE	Mean[a]	SE
Test cup, at the screen	1.27	0.67	0.91	0.26
Test cup, at cup lip	0.43	0.16	0.49	0.14
Test cup, 10 cm above	0.12	0.01	0.20	0.07

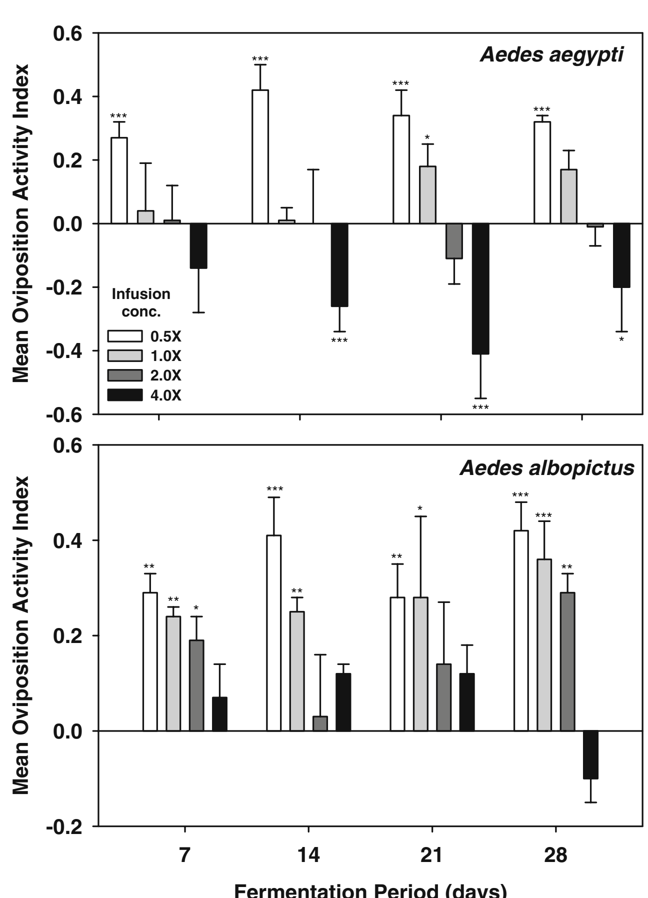

Fig. 3 Effects of leaf biomass and fermentation duration on attraction of gravid mosquitoes to white oak leaf infusions. For each infusion age, there were six replicate cages per trial and three trials completed on different dates. Student's *t*-test of the hypothesis that mean OAI for each treatment is significantly greater (attraction) or less (repulsion) than 0. ***$P \leq 0.001$, **$0.01 \leq P > 0.001$, *$0.05 \leq P > 0.01$. 1X infusion = 8.4 g leaves per L water

28 days of fermentation. *Aedes albopictus* was not significantly attracted to 4X biomass infusion (Fig. 3).

Bamboo The largest response from both mosquito species to 1X biomass infusions was to bamboo infusion that had been fermented for 7 days (Fig. 4). Attraction of *Ae. aegypti* decreased with longer fermentations. The responses of gravid *Ae. aegypti* were significantly greater than 0 after 7, 14, or 28 days of fermentation; however, the OAI was not significantly different from 0 after 21 days of fermentation ($P=0.288$). *Aedes albopictus* females were attracted to 1X biomass infusion at each bioassay interval over the 28-d time course of fermentation (Fig. 4).

Hackberry Aedes aegypti was attracted to a 1X biomass infusion made from hackberry tree leaves only at the 28 day time point (Fig. 5). For other fermentation time points, mean OAI values were <0.15 and not significantly different from zero ($P>0.05$). In contrast, *Ae. albopictus* responded to 1X biomass infusion at each bioassay interval in the 28 day fermentation period (Fig. 5) and responded most strongly to infusion that had been fermented for 14 days (Fig. 5).

Bermuda Hay In general, *Ae. aegypti* exhibited repellent or neutral responses to 1X Bermuda hay infusions and two dilutions of this infusion, regardless of the age of the infusion (Fig. 6). In contrast, *Ae. albopictus* was attracted to all dilutions and ages of Bermuda hay infusion, except for the undiluted infusion after 14 days of fermentation (Fig. 6).

Live Oak, Red Maple, Pecan, and Panicgrass A live oak infusion at 1X biomass was not attractive to *Ae. aegypti* or *Ae. albopictus* in any of the bioassays completed during the

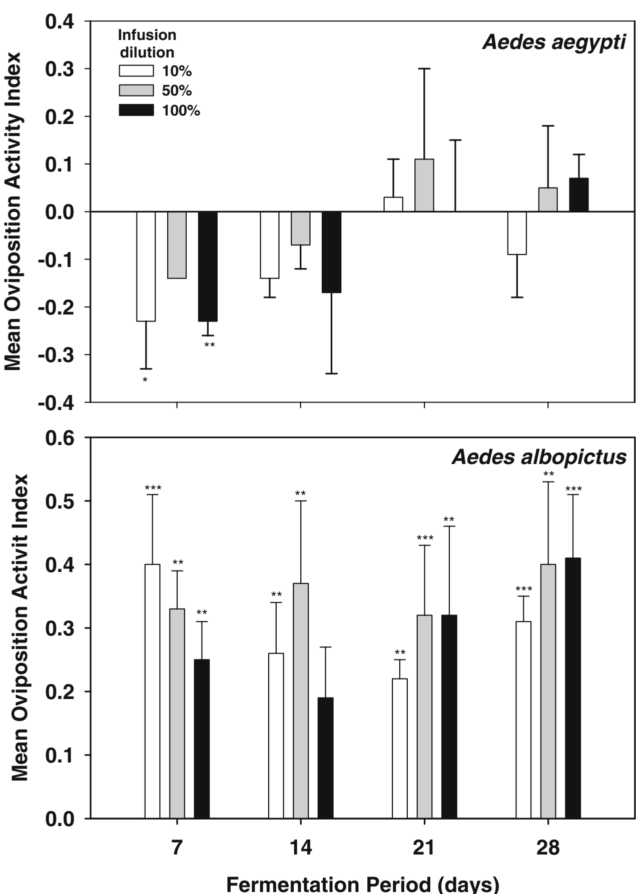

Fig. 6 Effects of infusion concentration and fermentation duration on attraction of gravid mosquitoes to 1X Bermuda hay infusion. Student's *t*-test of the hypothesis that mean OAI for each treatment is significantly greater (attraction) or less (repulsion) than 0. $***P \leq 0.001$, $**0.01 \leq P > 0.001$, $*0.05 \leq P > 0.01$. 1X infusion = 8.4 g leaves per L water

28 day period of fermentation. For both species, mean OAI values were ≤ 0.15 and not significantly different from zero ($P > 0.05$). Similarly, OAI values derived from responses of both mosquito species to 1X biomass infusions prepared from red maple leaves, pecan leaves, and panicgrass were not significantly different from zero.

Responses to Non-sterile and Sterile WOL Infusions Non-sterile WOL infusion was significantly more attractive to *Ae. aegypti* and *Ae. albopictus* than was sterile infusion (Table 2). The mean OAI for both mosquito species was highly significant, reflecting the high level of attraction of these mosquitoes to the non-sterile infusions and the possible role of microbial fermentation (Table 2).

Walk-in Cage Boassays Of the plant infusions that were tested, BL and WOL infusions elicited the strongest oviposition responses and were further evaluated in walk-in cage bioassays. Both mosquito species exhibited signif-

Table 2 Response of gravid mosquitoes to non-sterile and sterile white oak leaf infusions in sticky-screen bioassays

Species	Mean total no. females (SE) captured per trial[a]		Mean OAI[b] (SE)	$P \geq \|t\|$[c]
	Non-sterile infusion	Sterile infusion		
Aedes aegypti	41.6 (1.6)	16.3 (0.4)	0.43 (0.05)	< 0.001
Aedes albopictus	45.6 (0.4)	13.0 (0.4)	0.55 (0.03)	< 0.001

icant, albeit variable, responses to the dilutions and volumes of both plant infusions (Table 3). The responses of *Ae. aegypti* generally were more consistent to undiluted infusions of both plant species. *Aedes albopictus* was highly attracted to undiluted infusions of both plant species, but exhibited the strongest response to BL infusion (Table 3).

Discussion

Our investigation is the first comprehensive analysis of methods used to produce and optimize organic infusions for production of oviposition attractants for *Ae. aegypti* and *Ae. albopictus*. With indole as a marker odorant, we determined that volatiles from test containers placed inside bioassay cages would provide females with differential cues to guide them to attractive infusions. In contrast to our present research with WOL infusion, Trexler et al. (1998) reported that WOL infusions mediated oviposition of *Ae. triseriatus* (Say) and *Ae. albopictus* through contact with nonvolatile arrestants or oviposition stimulants rather than through odorants. However, we found that lowering the sticky screen deeper into the bioassay cup significantly increased the ability of females to differentiate between treatments, presumably by creating more headspace or through a yet unknown interaction of olfactory and visual cues at close-range as the female enters the infusion container.

The importance of microbial metabolic activity in breaking down organic matter and producing semiochemicals that mediate the oviposition responses was suggested by the lack of significant attraction of *Ae. aegypti* and *Ae. albopictus* to a sterile WOL infusion. However, it should be noted that the leaves used to construct the sterile WOL infusion were autoclaved. It is possible that high temperature would have affected the chemistry of the resulting infusion, altering the response of gravid mosquitoes by chemical changes rather than biological changes. Recently, however, we showed that microbe-associated contact chemical cues in the infusion elicited *Ae. aegypti* females to oviposit more when microbes were present than when they were filtered out (Ponnusamy et al. 2008). Similarly, *Culex* laid fewer eggs in response to Bermuda grass infusion that had been filtered to remove microorganisms (Isoe and Millar 1995).

Table 3 Effects of volume and dilution on attraction of gravid *Aedes* mosquitoes to bamboo leaf (1X) and white oak leaf (0.5X) infusions in walk-in cages using the sticky-screen bioassay procedure. Infusions were prepared as 1X (8.4 g/L well water) or 0.5X (4.2 g/L well water) infusions, and were used either at 100% or after dilution with an equal volume of well water (50%)

Infusion	Volume (ml)	Dilution (%)	Mean Oviposition Activity Index (± SE)[a]			
			Ae. aegypti	$P > \|t\|$[b]	*Ae. albopictus*	$P > \|t\|$[b]
Bamboo leaf	500	50	−0.12 (0.13)	0.4287	0.44 (0.09)	0.0159
		100	0.34 (0.01)	< 0.001	0.72 (0.13)	0.0125
	1230	50	0.36 (0.09)	0.0310	0.63 (0.14)	0.0193
		100	0.35 (0.11)	0.0557	0.50 (0.13)	0.0305
White oak leaf	500	50	0.47 (0.08)	0.0116	0.08 (0.11)	0.5486
		100	0.32 (0.13)	0.0869	0.56 (0.04)	< 0.001
	1230	50	0.22 (0.04)	0.0125	0.16 (0.06)	0.0718
		100	0.41 (0.10)	0.0276	0.32 (0.15)	0.1151

[a] OAI (Oviposition Activity Index) is the mean of four trials

[b] Student's *t* test of the hypothesis that mean OAI for each treatment is significantly greater (attraction) or less (repulsion) than 0

The importance of microbial metabolism is also suggested by our finding that infusions prepared in closed Teflon bags with some headspace were more attractive to gravid mosquitoes than infusions produced in open bags or closed bags without headspace. In closed bags with headspace, microbial breakdown of organic materials likely occurred through facultative anaerobic fermentation. Similarly, Sant'Ana et al. (2006) found that fermentation of *Panicum maximum* grass in a sealed plastic container produced infusions that were more active in eliciting an oviposition response from *Aedes* (*Stegomyia*) mosquitoes than infusions prepared in an open container.

Even under uniform fermentation conditions, there were large batch-to-batch variations in the response of gravid mosquitoes to some infusions. We attribute this variation to differences in the quality and amounts of attractive odorants released from infusions. Since we used senescent plant materials that were collected from the ground to make infusions, it is likely there were differences in the leaf condition as well as differences in the species composition of the microbial community associated with plant materials. Significant variation in the abundance and species composition of microbial populations is known to occur on the surfaces of leaves from the same trees (Brunel et al. 1994; Yang et al. 2001; Lambais et al. 2006). Such differences would be expected to result in variations in microbial populations in our experimental plant infusions and in corresponding differences in the amounts and kinds of odorants that were produced. Notably, infusions made from live oak, red maple, pecan, and panicgrass leaves were not attractive to *Ae*. *aegypti* or *Ae*. *albopictus*. These results reinforce the critical importance of the plant species used to produce infusions. The implication of our findings is that plant infusions can be an inconsistent source of attractive odorants, and that each batch of infusion should be evaluated to verify that it is behaviorally active before it is used in the field. Ideally development of a mosquito monitoring or surveillance system would involve controlled release of specific chemically defined oviposition cues.

In sticky-screen bioassays in reach-in cages, infusions were differentially attractive to each mosquito species depending on the plant species, biomass used and length of fermentation period. In general, *Ae*. *aegypti* exhibited higher attraction to low biomass infusions produced over short fermentation times from just a few plant species. In contrast, *Ae*. *albopictus* was attracted to infusions that were produced using a broader range of plants species, biomass, and fermentation periods. For example, *Ae*. *aegypti* was either repelled or exhibited a neutral response to infusions made from Bermuda hay, while *Ae*. *albopictus* was significantly attracted to Bermuda hay infusions regardless of the age of the infusion. Walk-in bioassay cage results were concordant with results of reach-in cages. In walk-in cage bioassays, both mosquito species were significantly attracted to WOL and BL infusions. Generally, *Ae*. *aegypti* was attracted to diluted and low volume infusions. Surprisingly, *Ae*. *albopictus* was attracted to 1X WOL infusion over a narrower range of infusion volumes compared to *Ae*. *aegypti*.

In previous investigations, infusions made by fermenting a variety of grass and hay species have been reported to be active towards gravid *Ae*. *aegypti* in laboratory and field bioassays (Reiter et al. 1991; Chadee et al. 1993; Rawlins et al. 1998; Polson et al. 2002; Sant'Ana et al. 2006). In these investigations, the response of mosquitoes was evaluated by using an end point; the numbers of eggs deposited in test containers holding infusions compared to control containers holding water. Higher numbers of eggs deposited in test containers was interpreted to indicate that more gravid mosquitoes were attracted to the test infusion. With an olfactometer, Hazard et al. (1967) showed that gravid *Ae*. *aegypti* were not attracted to any of the volatile chemicals released from alfalfa hay infusion. However, the hay infusion contained nonvolatile chemicals that arrested females at the surface of the water and stimulated them to oviposit. Similar negative results of olfactometer experiments involving hay infusion were reported by Allan and Kline (1995) for gravid *Ae*. *aegypti*. Isoe et al. (1995a) and Isoe and Millar (1995), in bioassays of gravid *Culex* mosquitoes, cautioned against using the numbers of eggs deposited as an endpoint for assessing attraction to plant infusions. They emphasized that differentiating oviposition responses mediated by olfactory attractants from nonvolatile oviposition stimulants cannot be done simply by counting eggs. Thus, the increased oviposition previously reported for *Ae*. *aegypti* in response to hay and grass infusions likely resulted from nonvolatile chemicals that arrested gravid females at the surface of the water and stimulated them to lay eggs, rather than from odorants that attracted gravid females from a distance. The intent of our study was to evaluate olfactory-mediated responses of gravid females to volatiles from plant infusions. It should be noted that attraction of gravid females to odorants that emanate from a plant infusion might not result in increased oviposition because volatile chemicals that attract females may not necessarily function also as oviposition stimulants. However, some species of cultivable bacteria in bamboo leaf infusion produce metabolites that attract gravid females and also stimulate them to lay eggs. With bioassay-guided fractionation of bacterial extracts, carboxylic acids and methyl esters associated with 14 species of bacteria cultured from bamboo leaf infusion were shown to be potent oviposition stimulants (Ponnusamy et al. 2008). A mix of these same 14 species of bacteria produces odorants that are highly attractive to gravid *Ae*. *aegypti* (Ponnusamy et al. 2010).

Optimally attractive infusions for *Ae*. *aegypti* and *Ae*. *albopictus* required fermentation periods of different

lengths depending on the plant species. Similar results were reported by Isoe et al. (1995b) for response of *Culex quinquefasciatus* and *Cx*. *tarsalis* to Bermuda grass infusion. *Culex quinquefasciatus* continued to respond significantly to Bermuda grass infusions that were fermented over a longer period of time compared to *Cx*. *tarsalis*, which preferred infusions that were fermented over a shorter period. Sant'Ana et al. (2006) found that *Aedes* (*Stegomyia*) mosquitoes exhibited the highest oviposition responses to 15–20-d-old infusions produced from the grass *Panicum maximum*. On average, ovitraps containing younger or older infusions received lower numbers of eggs. Ponnusamy et al. (2010) showed that the attraction of gravid *Ae*. *aegypti* and *Ae*. *albopictus* to WOL and BL infusions was significantly associated with changes in the abundance and diversity of bacterial species, which in turn was affected by plant species, leaf biomass and fermentation time.

Currently, we are characterizing the attraction and egg-laying response of gravid *Ae*. *aegypti* and *Ae*. *albopictus* to individual bacterial species cultured from BL and WOL infusions and characterizing semiochemicals that mediate attraction and oviposition. An understanding of the bioactivity of bacterial species may explain why *Ae*. *aegypti* and *Ae*. *albopictus* are differentially attracted to the two types of infusions. Pickett et al. (2010) emphasized the importance of investigating the chemical ecology of disease vectors with the aim of developing efficient tools for surveillance and control. In this regard, the optimized infusions, specific bioactive microbes isolated from them, and specific compounds that attract and stimulate females to oviposit can be used in mosquito and virus surveillance, mass trapping, and other intervention approaches to reduce the human burden of *Aedes*-transmitted arboviral diseases.

Abstract The antitermite (termiticidal and antifeedant) activity of *Protium javanicum* Burm. f. extract was investigated. The ethyl acetate fraction was active. Scopoletin (**1**), quercetin, and stigmasterol were isolated by bioassay-guided fractionation. Scopoletin had the highest activity among the three compounds. In order to investigate the structure-activity relationship (SAR) of the methoxy and hydroxy groups at the C-6 and C-7 positions of the coumarin skeleton, we synthesized several coumarin derivatives whose chemical structures are similar to scopoletin. Scopoletin exhibited the strongest termiticidal activity among the 10 compounds tested, followed by 6-methoxycoumarin (**3**), 6-hydroxycoumarin (**7**), and umbelliferone (**8**). All compounds except coumarin (**9**) showed antifeedant activity.

Key Words *Protium javanicum* Burm. f. · *Coptotermes formosanus* Shiraki · Scopoletin · 6-Methoxycoumarin 6-Hydroxycoumarin · Umbelliferone · SAR

Introduction

Termites pose a serious threat to both the plant kingdom and buildings. There are over 2,800 described species with about 185 considered to be pests. They cause considerable damage to annual and perennial crops and the wooden parts in buildings, especially in the semi-arid and sub-humid tropics (Verma et al. 2009). Among the many species, *Coptotermes formosanus* Shiraki is the subterranean termite responsible for major destruction of wooden materials in countries such as Japan, and Taiwan, and the southern parts of the United States. For this reason, *Coptotermes formosanus* Shiraki has been bioassayed in many research studies (Chang and Cheng 2002; Zhu et al. 2003; Cheng et al. 2007; Katsumata et al. 2007; Mozaina et al. 2008).

Synthetic chemicals currently are used to control termites. However, synthetic termiticides have a negative impact on the global environment, including causing health hazards to humans. To avoid these impacts, naturally occurring compounds that are bio-active against termites are being identified. A number of diverse compounds derived from termite-resistant wood species have been reported to be toxic to termites: these include the abietane-type diterpene, 6,7-dehydroroyleanone, from *Taxodium distichum* (Kusumoto et al. 2009); abietane diterpenes, plumbagin, isodiospyrin, and microphyllone, from *Diospyros sylvatica* (Ganapaty et al. 2004); naphthoquinone, 7-methyljuglone, from *Diospyros virginiana* L. (Carter et al. 1978); and iridoid glycoside, loganin, from *Guettarda speciosa* L. (Yaga and Kinjo 1985).

Protium javanicum Burm. f. (Burceracea) is known locally as "*kayu bawang*" and "*kayu pahit*" in Bengkulu-Indonesia. Kayu bawang has been utilized as a building material in desks, ground sills, and exterior walls because of its biological durability. Species of the genus *Protium*

comprise an attractive commercial botanical source of aromatic compounds. In folk medicine, gum and oleoresins from *Protium* species, among other medicinal applications, are used for preparing tonics, stimulants, and anti-inflammatory agents; treating ulcers (Rüdiger et al. 2007); and treating headaches, eyelid inflammation, and rheumatic pains (Deharo et al. 2001). The resin also is often burned to illuminate houses in the forest and repel undesirable insects (Rüdiger et al. 2007).

Chemical investigation of *Protium* species has led to the identification of steroids, triterpenes, coumarins, lignans, and other derivatives. Propacin and sitosterol have been found in wood of *P. opacum* (Zoghbi et al. 1981), and cleomiscosin, along with *p*-coumaric ethyl ester, fraxetin, scopoletin, and lupeol, has been isolated from the stems and bark of *P. heptapyllum* (Almeida et al. 2002).

Thus far, to the best of our knowledge, no phytochemical investigation has been reported on *P. javanicum*. In this study, we isolated compounds from *P. javanicum* by bioassay-guided fractionation, and investigated their anti-termite activities against *C. formosanus*. In addition, we examined the antitermite activities of scopoletin and coumarin derivatives whose chemical structures are similar to scopoletin to evaluate the effect of chemical structure on the antitermite properties.

Methods and Materials

General Experimental Procedures ^{1}H and ^{13}C-NMR spectra were recorded on a JOEL ECA 600 spectrometer with tetramethylsilane (TMS) as an internal standard. MS spectra were recorded using a JOEL JMS-700/GI mass spectrometer. Column chromatography (CC) was performed on a neutral silica gel (Silica Gel 60 N, spherical, neutral, 40–50 μm) (KANTO Chemical Co., Inc.). Melting points were determined on a Yanagimoto micro melting-point apparatus. Compounds **2**, **3**, **4**, **5**, and **6** were synthesized in our laboratory according to previously described methods (Crosby and Berthold 1962; Castillo et al. 1986). Compound **7** was purchased from Sigma-Aldrich. Compounds **8**, **9**, and **10** were purchased from Tokyo Chemical Industry Co., Ltd.

Plant Material The leaves of *P. javanicum* were collected from Bengkulu Utara, Indonesia. Identification of the plant material was performed by the Herbarium of Andalas University, where voucher specimens are deposited.

Extraction and Isolation of Antitermite Compounds Fresh leaves of *P. javanicum* (10 kg) were macerated at room temperature in methanol (3×30 L). The mixture was subsequently filtered and concentrated *in vacuo* to yield a methanol extract (614 g). This extract was suspended in water and partitioned successively with *n*-hexane, EtOAc, and *n*-BuOH to yield *n*-hexane (69 g), EtOAc (118 g), *n*-BuOH (56 g), and water (290 g) fractions, respectively. Each stage of the isolation process and all column fractions were monitored for antitermite activity. The ethyl acetate fraction contained the highest activity among all fractions as assessed by the no-choice feeding test.

A portion of the ethyl acetate fraction (69 g) was subjected to silica gel column chromatography with *n*-hexane-EtOAc, EtOAc-acetone, and acetone-MeOH step-wise (100:0 to 0:100) to obtain 12 fractions (E1–E12), which were combined for TLC analysis. Fractions E3, E9, and E10 were the most active. Stigmasterol colorless crystals (19.9 mg) were purified from fraction E3 by re-crystallization with *n*-hexane, mp. 147–148°C, EI-MS m/z (rel. int. %): 412 (M^+, 80), the ^{1}H-NMR and ^{13}C-NMR spectra were in good agreement with reported data (Farines et al. 1981; Akihisa et al. 1987). Fraction E9 (1.46 g) was subjected to CC on silica gel, eluted with *n*-hexane-EtOAc, and EtOAc-acetone (100:0 to 0:100) to obtain 6 sub fractions (E9a–E9f). Sub fraction E9d was subjected further to flash CC on silica gel, eluting with $CHCl_3$-MeOH mixtures of increasing polarity (100:0 to 0:100), affording quercetin as a yellow amorphous powder (10.2 mg). Compound **1**, a pale yellow crystal (23.1 mg), was isolated from fraction E10 (2.58 g). CC on silica gel was performed on fraction E10, which was eluted with *n*-hexane-EtOAc (100:0 to 0:100), and then EtOAc-acetone (100:0 to 0:100) to give 5 sub-fractions (E10a–E10e). Flash CC on silica gel was performed subsequently on sub-fraction E10b, which was eluted with *n*-hexane-$CHCl_3$ (100:0 to 0:100). This, in turn, was followed by re-crystallization with chloroform. The structure of **1** was confirmed by ^{1}H and ^{13}C-NMR; DEPT, COSY, HMBC, HMQC, and MS; and by comparing the data with the literature (Steck and Mazurek 1972; Barberá et al. 1986b; Razdan et al. 1987). Scopoletin (**1**), quercetin, and stigmasterol were reported previously in *P. heptapyllum* (Almeida et al. 2002; Rüdiger et al. 2007), but this is the first time they have been isolated from *P. javanicum*.

Quercetin Yellow amorphous powder, mp. >300°C; ^{1}H-NMR δ (Acetone-d_6): 6.27 (1H, d, *J*=2.0 Hz, H-6), 6.53 (1H, d, *J*=2.0 Hz, H-8), 6.99 (1H, d, *J*=8.2 Hz, H-5′), 7.70 (1H, dd, *J*=8.58 and 2.8 Hz, H-6′), 7.83 (1H, d, *J*=2.8 Hz, H-2′), 12.16 (1H, s, OH-5); ^{13}C-NMR δ (CD_3OD): 94.5 (C-8), 99.3 (C-6), 104.6 (C-10), 116.1 (C-2′), 116.3 (C-5′), 121.7 (C-6′), 124.2 (C-1′), 137.3 (C-3), 146.3 (C-3′), 148.1 (C-2), 148.8 (C-4′), 158.3 (C-9), 162.6 (C-5), 165.6 (C-7), 177.4 (C-4). The melting point, as well as the ^{1}H and ^{13}C-NMR data were in agreement with reported data (Barberá et

al. 1986a; Fossen et al. 1998; Tatsis et al. 2007; Luo et al. 2009).

Compound **1** *(Scopoletin)* Pale yellow crystals, mp. 181–182°C; ^{1}H-NMR δ (CD_3OD): 3.91 (3H, s, CH_3), 6.20 (1H, d, J=9.6 Hz, H-3), 6.77 (1H, s, H-8), 7.11 (1H, s, H-5), 7.85 (1H, d, J=9.6 Hz, H-4); ^{13}C-NMR δ (CD_3OD): 56.8 (OCH_3), 104.0 (C-8), 110.0 (C-5),112.56 (C-10), 112.62 (C-3), 146.1 (C-4), 147.1 (C-6), 151.4 (C-9), 152.9 (C-7), 164.0 (C-2). FAB-MS m/z: 193 $[M+H]^+$ (matrix: mixture of dithiothreitol and dithioerytritol 3:1).

Synthesis Procedure and Spectral Data of Coumarin Derivatives 2,5-Dihydroxyanisole (**a1**, 1.5 g, 11 mmol) and ethyl 3,3-diethoxypropionate (2.44 g, 13 mmol) were dissolved in liquid phosphoric acid (5 ml) in a small flask and heated at 100°C for 2 h. The mixture was poured over 25 g of crushed ice; the precipitate was recovered by filtration and washed with cold water. The solid product was subjected to CC on silica gel with the eluent $CHCl_3$-EtOAc (8:2) to give isoscopoletin (**2**). Compounds **3**, **4**, and **5** were synthesized in similar manner with the exception that 4-methoxyphenol (**a2**), 3-methoxyphenol (**a3**), and 3,4-dimethoxyphenol (**a4**), respectively, were used instead of **a1** (Scheme 1).

Compound **2** *(Isoscopoletin)* Pale yellow needles, mp. 183–184°C (96% yield); ^{1}H-NMR δ ($CDCl_3$:CD_3OD=4:1): 3.96 (3H, s, CH_3), 6.27 (1H, d, J=9.6 Hz, H-3), 6.85 (1H, s, H-8), 6.94 (1H, s, H-5), 7.65 (1H, d, J=9.6 Hz, H-4); ^{13}C-NMR δ ($CDCl_3$:CD_3OD=4:1): 56.2 (OCH_3), 99.5 (C-8), 111.4 (C-5), 112.1 (C-10), 113.1 (C-3), 143.4 (C-6), 144.0 (C-4), 149.1 (C-9), 151.3 (C-7), 162.4 (C-2); EI-MS m/z (rel. int. %): 192 (M^+, 60), 177 (13), 164 (50), 149 (80), 122 (25), 118 (100).

Compound **3** *(6-Methoxycoumarin)* Colorless crystals, mp. 95–96°C (58% yield); ^{1}H-NMR δ ($CDCl_3$): 3.85 (3H, s, CH_3), 6.43 (1H, d, J=9.6 Hz, H-3), 6.92 (1H, d, J=2.8 Hz, H-5), 7.11 (1H, dd, J=9.3 and 2.8 Hz, H-7), 7.27 (1H, d, J=8.9 Hz, H-8), 7.66 (1H, d, J=9.6 Hz, H-4); ^{13}C-NMR δ ($CDCl_3$): 56.0 (OCH_3), 110.1 (C-5), 117.2 (C-3), 118.0 (C-8), 119.3 (C-10), 119.6 (C-7), 143.3 (C-4), 148.6 (C-9), 156.2 (C-6), 161.1 (C-2); FAB-MS m/z: 177 $[M+H^+]$ (matrix: mixture of dithiothreitol and dithioerytritol 3:1).

Scheme 1 Synthesis of coumarin derivatives (**2**–**5**)

Compound **4** *(Herniarin)* Colorless crystals, mp. 115°C (88% yield); ^{1}H-NMR δ ($CDCl_3$): 3.88 (3H, s, CH_3), 6.25 (1H, d, J=9.6 Hz, H-3), 6.81 (1H, d, J=2.8 Hz, H-8), 6.85 (1H, dd, J=8.6 and 2.8 Hz, H-6), 7.38 (1H, d, J=8.2 Hz, H-5), 7.64 (1H, d, J=9.7 Hz, H-4); ^{13}C-NMR δ ($CDCl_3$): 55.9 (OCH_3), 101.0 (C-8), 112.65 (C-10), 112.68 (C-6), 113.2 (C-3), 128.9 (C-5), 143.5 (C-4), 156.0 (C-9), 161.3 (C-2), 163.0 (C-7); EI-MS m/z (rel. int. %): 176 (M^+, 95), 148 (100), 133 (60), 119 (35), 105 (16).

Compound **5** *(Scoparone)* Yellow needles, mp. 122–123°C (59% yield); ^{1}H-NMR δ ($CDCl_3$): 3.92 (3H, s, CH_3), 3.95 (3H, s, CH_3), 6.28 (1H, d, J=9.6 Hz, H-3), 6.83 (1H, s, H-8), 6.87 (1H, s, H-5), 7.64 (1H, d, J=9.6 Hz, H-4); ^{13}C-NMR δ ($CDCl_3$): 56.4 (OCH_3), 100.0 (C-8), 108.1 (C-5), 111.5 (C-10), 113.5 (C-3), 143.4 (C-4), 146.4 (C-6), 150.0 (C-9), 152.9 (C-7), 161.4 (C-2); EI-MS m/z (rel. int. %): 206 (M^+, 100).

Compound **6** *(Ayapin)* Compound **6** was obtained from esculetin (**10**) (Castillo et al. 1986). Briefly, the reaction of **10** (232 mg, 1.3 mmol) with diiodomethane (0.21 ml, 2.6 mmol) in the presence of sodium hydride (62.5 mg, 2.6 mmol) in hexamethylphosphoric triamide (4 ml) at room temperature to afford **6** (59% yield) as colorless crystals, mp. 199.5°C; ^{1}H-NMR δ ($CDCl_3$): 6.07 (2H, s), 6.28 (1H, d, J=9.6 Hz, H-3), 6.82 (1H, s, H-8), 6.83 (1H, s, H-5), 7.58 (1H, d, J=9.6 Hz, H-4); ^{13}C-NMR δ ($CDCl_3$): 98.4 (C-8), 102.4 (CH_2), 105.0 (C-5), 112.7 (C-10), 113.4 (C-3), 143.5 (C-4), 144.9 (C-6), 151.27 (C-9), 151.29 (C-7), 161.2 (C-2); EI-MS m/z (rel. int. %): 190 (M^+, 100), 162 (73), 161 (43), 113 (37).

The structure of compounds (**2**–**6**) were elucidated and confirmed by ^{1}H and ^{13}C-NMR, MS, and by subsequent comparisons with reference data from the available literature (Duddeck and Kaiser 1982; Tsukamoto et al. 1984; Afek et al. 1986; Debenedetti et al. 1998; Maes et al. 2005).

Termites Workers and soldiers of *C. formosanus* Shiraki were obtained from a laboratory colony maintained at 28°C ± 2 and >85% Relative Humidity (RH) at the Deterioration Organisms Laboratory of the Research Institute for Sustainable Humanosphere (RISH), Kyoto University, Japan.

Termiticidal and Antifeedant Tests A no-choice test was employed for evaluating termiticidal and antifeedant activities (Watanabe et al. 2005). Test samples [(10 mg for every fraction from the leaves of *P. javanicum* extract, 0.5 mg for isolated compounds, and 5 μmol for compound **1**, and the coumarin derivatives (**2**–**10**)] were dissolved in 0.05 ml acetone. The resulting solution was applied to paper discs (1.5 mm thick 8 mm diam, Advantec, Tokyo, Japan), and the paper discs were dried overnight in a vacuum

desiccator. Subsequently, each disc was placed onto a plastic spacer in an acrylic resin cylinder with a plaster bottom (80 mm diam × 60 mm height), and thirty-three active termites (30 workers and 3 soldiers) were added to each cylinder. The cylinders were placed on a cotton sheet in a plastic tray and kept in a dark incubator at 28°C ± 1 and 80% ± 5 RH for 2 wk. The number of dead termites was counted daily. The mass loss of the paper disc was measured at the end of the test. Paper discs treated with acetone only were used as a negative control. Three replications were performed for each sample. Termite mortality (%) and mass loss of the paper disc (%) were calculated using the following equations:

$$Termite\,Mortality(\%) = \frac{Number\ of\ Dead\ Termites}{Total\ Number\ of\ Test\ Termites} \times 100\%$$

$$Mass\,Loss(\%) = \frac{Vacuum\ Dried\ Weight\ Before\ Test - Vacuum\ Dried\ Weight\ After\ Test}{Vacuum\ Dried\ Weight\ Before\ Test} \times 100\%$$

Statistical Analysis Tukey's multiple comparison test was used to evaluate differences in percent mortality and mass loss in antitermite activities. Results with $P<0.05$ were considered significant. Calculations were performed using statistical software (Stats Direct, UK).

Results and Discussion

Antitermite Activities of Protium javanicum Fractions Against Coptotermes formosanus Shiraki We evaluated the termiticidal and antifeedant activities of *n*-hexane, EtOAc, *n*-BuOH, and water fractions of *P. javanicum* leaves methanol extract. Among all fractions, the ethyl acetate fraction showed the highest activity against *C. formosanus*, when tested initially at 10 mg/0.05 ml acetone in the no-choice feeding test. After 14 days, 42.4% of termites given the ethyl acetate fraction died on average. This percentage was significantly different from that of the control at the $P<0.05$ level (Tukey's multiple comparison test). Moreover, when testing antifeedant activity, the average mass loss of the paper disc treated with the ethyl acetate fraction reduced five-fold as compared to the control (Table 1).

Table 1 Antitermite activities of *Protium javanicum* fractions against *Coptotermes formosanus* Shiraki[a]

Fraction	Mortality of termite (%)	Mass loss of paper disc (%)
n-Hexane	26.3±9.7a,b	0.6±0.3b
EtOAc	42.4±8.0a	8.5±9.8b
BuOH	15.1±0b,c	10.9±8.9b
H_2O	12.1±5.2b,c	12.7±4.3b
Control	1.0±1.8c	41.6±3.1a

[a] Data are given as mean ± standard deviation of triplicate tests (N=3). Numbers followed by different letters (a–c) are significantly different at the level of $P<0.05$ according to Tukey's multiple comparison test

Antitermite Activities of Isolated Compounds The isolation of scopoletin (**1**) together with quercetin and stigmasterol from the ethyl acetate fraction was achieved by CC followed by re-crystallization with chloroform, and we then evaluated the antitermite activities, the results of which are summarized in Figs. 1 and 2. Average termite mortality of scopoletin (**1**) (55.6%) was higher than those of control, quercetin (15.2%), and stigmasterol (2.0%) after 14 days' exposure at the $P<0.05$ level (Tukey's multiple comparison test) (Table 2). The termites least consumed the paper disc treated with scopoletin (**1**), with the mass loss of the disc (avg. 9.7%) being significantly different from the control (avg. 47.6%), quercetin (avg. 32.4%), and stigmasterol (avg. 41.2%). These results show that scopoletin (**1**) has the highest activity among the 3 compounds.

Structure-Activity Relationship (SAR) of Scopoletin and Coumarin Derivatives to Antitermite (Termiticidal and

Antifeedant) Activities By comparing the activity of latifolin and its derivatives, it has been suggested previously that the phenolic hydroxyl group at the C-5 position of the A ring is responsible for a compound's antitermite activities (mortality and mass loss) (Sekine et al. 2009). The effect of stilbene glucosides and their related compounds on termite feeding behavior also has been investigated, with piceid exhibiting the highest feeding-deterrent effect followed by isorhapontin and astringin. An increase in the termite mortality rate also has been reported for isorhapontigenin when the compound is methylated (Shibutani et al. 2004). The antifeedant activity of some flavonoids was influenced by the position of hydroxyl groups (Ohmura et al. 2000). Several of the monomethoxycoumarins (5-alkoxycoumarins and their derivatives) have been reported as having nematicidal activity. Among these, 5-ethoxycoumarin showed the highest activity against the phytopathogenic nematode, *Bursaphelenchus xylophilus* (Takaishi et al. 2008). On the other hand, coumarin and its derivatives are isolated chiefly from higher plants, especially the Rutaceae family, and exhibit various biological and pharmacological activities, such as anti-bacterial, anti-oxidant, anticoagulant, anti-inflammatory, rodenticidal, and analgesic properties (Murray et al. 1982). Until now, however, studies on the SAR of coumarin derivatives to termiticidal activity have not been performed.

In this study, for scopoletin (**1**), our interest focused on the modification of the position of the methoxy and hydroxy groups at C-6 and C-7, respectively, of the coumarin skeleton. In order to investigate the structure-activity relationship (SAR), we synthesized several coumarin derivatives whose chemical structures are similar to scopoletin (compounds **2**, **3**, **4**, **5**, and **6**) in good yields and four compounds were purchased (compounds **7**, **8**, **9**, and **10**). Finally we collected 10 compounds (Fig. 3) and tested them for antitermite (termiticidal and antifeedant) activities.

The daily termite mortality against *C. formosanus* with scopoletin (**1**) and coumarin derivatives (**2**–**10**) was determined for 2 weeks. The results are summarized in Fig. 4. Compound **1** showed the highest mortality (avg. 59.6%), while the mortality of compound **2** (avg. 11.1%) decreased five-fold compared to compound **1**. Compound **3**, bearing a substituent OCH_3 at the C-6 position, showed 46.5% mortality on average. Compound **7**, bearing an OH group at the C-6 position, showed an average mortality of 45.5%. Compound **8**, bearing a substituent OH group at the C-7 position, killed 36.4% of termites on average. Other compounds had lower activities and exhibited different patterns of mortality change. The mortality of compound **1** showed a steady increase for 2 weeks, while the mortality

6-Hydroxycoumarin (**7**)	45.5±9.1a,b	4.8±1.4c,d
Umbelliferone (**8**)	36.4±5.2b,c	21.0±9.3b
Coumarin (**9**)	12.1±0d,e	47.7±10.6a
Esculetin (**10**)	11.1±1.7d,e	18.4±2.9b,c
Control	0.0±0e	57.5±1.7a

[a] Data are given as mean ± standard deviation of triplicate tests (N=3). Numbers followed by different letters (a–c) are significantly different at the level of $P<0.05$ according to Tukey's multiple comparison test

1) Scopoletin **2**) Isoscopoletin **3**) 6-Methoxycoumarin **4**) Herniarin **5**) Scoparone

6) Ayapin **7**) 6-Hydroxycoumarin **8**) Umbelliferone **9**) Coumarin **10**) Esculetin

Fig. 3 Chemical structure of scopoletin (**1**) and coumarin derivatives (**2**–**10**)

started to increase sharply after 5 days for compounds **3** and **7**, and after 7 days for compound **8**. In addition, termiticidal activity was retarded in compounds **2**, **4**, **6**, **9**, and **10**, and the mortality of compound **5** increased slightly after 12 days. The results of statistical analyses of the mortalities of compound **1** and of the coumarin derivatives are shown in Table 2.

Exposure of termites to the treated paper discs for 14 days resulted in the following average mass losses for compound **1** and the coumarin derivatives (**2**–**10**): 2.0%, 21.7%, 4.7%, 3.5%, 8.3%, 19.4%, 4.8%, 21.0%, 47.7%, and 18.4%, respectively (Fig. 5). Compound **1** elicited the lowest loss, showing a significantly greater reduction in feeding activity compared to the control and nine other compounds (Tukey's multiple comparison test) (**2**–**10**). The average mass losses for paper discs treated with compounds **2**–**8**, or **10** were lower than that of the control (avg. 57.5%). Compound **9**, unsubstituted at the C-6 and C-7 positions of the coumarin skeleton, showed no significant difference from control, exhibiting the lowest antifeedant activity with a higher average mass loss than those of other compounds (Table 2). Among the compounds active for termite mortality (**1**, **3**, **7**, and **8**), the average mass loss for compound **1** (2.0%) was lowest, followed by losses for compounds **3** (4.7%) and **7** (4.8%). Interestingly, compound **4** did not show any mortality in particular, although the average mass loss (3.5%) was lower than those for **3** and **7**.

In summary, we isolated scopoletin (**1**), quercetin, and stigmasterol from the ethyl acetate fraction of *P. javanicum* Burm. f. leaf extract by bioassay-guided fractionation. We evaluated the antitermite activities of scopoletin (**1**), quercetin, and stigmasterol against *C. formosanus* Shiraki and found that scopoletin (**1**) showed the highest activity among the three compounds. In order to investigate the SAR of the methoxy and hydroxy groups at the C-6 and C-7 positions of the coumarin skeleton, respectively, we synthesized several coumarin derivatives whose chemical structures are similar to scopoletin. The comparison of termite mortalities for compound **1** and coumarin derivatives (**2**–**10**) suggested that compound **1** showed the strongest termiticidal activity among the 10 compounds tested, followed by **3**, **7**, and **8**, in that order (Fig. 4). The other compounds showed weak activity. Further, all compounds except compound **9** showed antifeedant activity (Fig. 5). These results suggest that scopoletin and other coumarin derivatives whose chemical

Abstract Different folivorous marsupials select their food from different subgenera of *Eucalyptus*, but the choices cannot be explained by known antifeedants, such as formylated phloroglucinol compounds or tannins, or by nutritional quality. Eucalypts contain a wide variety of plant secondary metabolites so it is difficult to use traditional methods to identify the chemicals that determine food selection. Therefore, we used a metabolomic approach in which we employed ^{1}H nuclear magnetic resonance spectroscopy to compare chemical structures of representatives from the two subgenera and to identify chemicals that consistently differ between them. We found that dichloromethane extracts of leaves from most species in the subgenus *Eucalyptus* differ from those in *Symphyomyrtus* by the presence of free flavanones, having no substitution in Ring B. Although flavanoids are known to deter feeding by certain insects, their effects on marsupials have not been established and must be tested with controlled feeding studies.

Introduction

Plants contain a wide array of chemicals and nutrients that influence how animals respond to them. Although ecologists have long understood the value or liability of general classes of compounds, such as "tannins" or "terpenes" (Swihart et al. 2009), they are just beginning to recognize how specific compounds or particular molecular structures influence how animals choose their diets. Without this knowledge of structure and function, it is impossible to evaluate ideas about dietary constraints on an herbivore's life history, habitat selection, fitness, competition, and coevolution. Although this applies to all herbivores, it is particularly acute in studies of larger mammalian herbivores. It is widely believed that differential responses to secondary compounds allow mammalian herbivores to partition the available resource to reduce interspecific competition (Marsh et al. 2003a). Without detailed chemical knowledge, these ideas cannot be assessed and incorporated into conservation and monitoring programs.

Several factors make it difficult to understand interactions between animals and plants. The first is the complexity of the chemical profile in plants. Related to this is the need to consider intraspecific as well as temporal and spatial variation in chemical makeup. This variation makes it hard to design specific assays for compounds that might be active. Bioassay guided fractionation has been used successfully to identify specific antifeedant compounds in arctic plants (Reichardt et al. 1985; Bryant et al. 1989) and in Australian eucalypts (Pass et al. 1998). In

this procedure, compounds are isolated progressively from a plant and fed to animals to identify the compound of interest. Among other problems, this approach requires great effort to fractionate large volumes of extracts to use in long-term feeding tests with mammals.

McIlwee et al. (2001) suggested that spectra of plants obtained with near infrared reflectance spectroscopy (NIRS) could be related to how much animals eat of those plants. In this way, NIRS could be used to predict feeding in vertebrate browsers independent of a detailed understanding of the underlying chemistry. While that approach has been useful in eucalypts (Foley et al. 1998; Wallis and Foley 2003), NIRS is not suitable for deciphering the underlying chemistry that contributes to differences in the NIR spectra of plants. Nonetheless, spectroscopic approaches are attractive because they give a more comprehensive view of plant chemistry than do assays of broad classes of compounds. In contrast to NIRS, ^{1}H nuclear magnetic resonance spectroscopy (^{1}H NMR) is a spectroscopic approach that can provide structural information about the underlying chemical differences between groups of plants. In this paper, we evaluate the use of ^{1}H NMR spectroscopy combined with principal components analysis (PCA) of the spectra to identify significant chemical differences between subgenera of *Eucalyptus* that support known differences in feeding behavior.

Within *Eucalyptus* there are distinct differences among the subgenera in the extent to which marsupial (and insect) herbivores use the foliage as food. In particular, the two largest subgenera, *Symphyomyrtus* (common name symphyomyrtles) and *Eucalyptus* (common name monocalypts) are used differentially by marsupial browsers. Koalas (*Phascolarctos cinereus*) and common brushtail possums (*Trichosurus vulpecula*) feed predominately on foliage from species in the *Symphyomyrtus*, whereas common ringtail possums (*Pseudocheirus peregrinus*) and greater gliders (*Petauroides volans*) eat leaves mostly from the subgenus *Eucalyptus* (Moore et al. 2004a).

The aversion of ringtail possums to symphyomyrtles is due to their sensitivity to the nauseating effects of formylated phloroglucinol compounds (FPCs) such as sideroxylonal-A (Fig. 1, structure **1**) (Moore et al. 2004b). These compounds are absent from the monocalypts but variably present in the symphyomyrtles, which explains diet selection by koalas and brushtail possums in both the laboratory and the field (Wallis et al. 2002; Scrivener et al. 2004; Moore and Foley 2005) as follows. Both species feed mainly from symphyomyrtles but select leaves to limit their ingestion of FPCs. In contrast, captive brushtail possums eat very little monocalypt foliage but they eat much more when the foliage is coated with the tannin-blocking agent, polyethylene glycol (PEG), while PEG

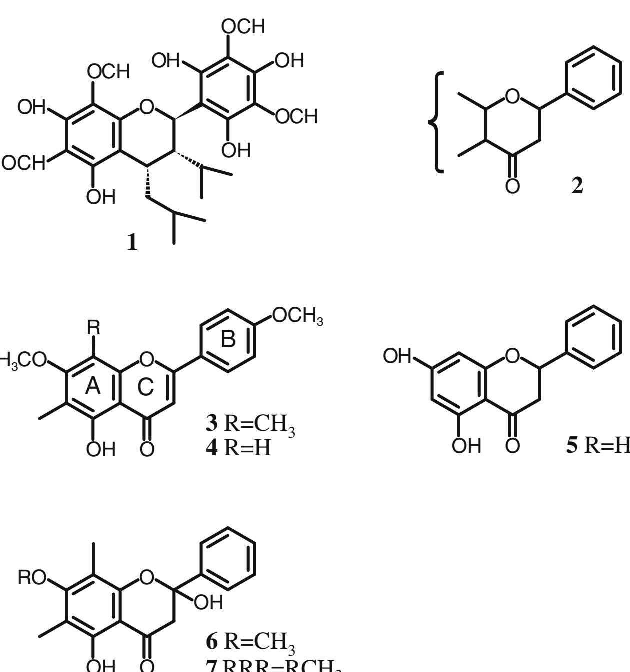

Fig. 1 The structures and partial structures of compounds referred to in the text. **1** sideroxylonal-A; **2** proposed partial structure of a compound in the extract of *E. agglomerata*; **3** eucalyptin; **4** demethyleucalyptin; **5** pinocembrin; **6** and **7** novel 2-hydroxyflavanone structures from *E. rossii*

has no effect on feeding by the common ringtail possum (Marsh et al. 2003b). In mixed stands of eucalypt trees, representatives from both major subgenera tend to co-dominate (Pryor 1959). Thus, by specializing on the PSMs produced by a particular eucalypt subgenus, different folivores could inhabit the same tracts of forest without competing for food (Marsh et al. 2003a). Along with hyrax (Hoeck 1975) and bamboo lemurs (Tan 1999; Yamashita et al. 2009), this is one of the few clear examples of dietary partitioning by vertebrates. If we could identify the factors in monocalypts that deter feeding by the koala and common brushtail possum or the mechanism by which the common ringtail possum processes the monocalypt compounds, then we would have a better understanding of niche partitioning by sympatric vertebrate herbivores.

In this research, we compared extracts from the leaves of a wide variety of monocalypt and symphyomyrtle species. We hypothesized that, unlike the symphyomyrtles, the monocalypts contain specific compounds that are unpalatable to koalas and brushtail possums, and that ^{1}H NMR spectra could reveal these compounds. We added additional control to the study by including several *E. melliodora* (*Symphyomyrtus*) with varying concentrations of sideroxylonals, expecting those with low concentrations of sideroxylonals to group closer to the monocalypts than do those with higher concentrations.

Methods and Materials

Preliminary Collection We did an initial study of a small number of species growing around Canberra, ACT, Australia, to see if ^{1}H NMR spectroscopy would detect consistent differences between the eucalypt subgenera and, if so, would identify the types of compounds that contribute to the differences. By beginning with a small number of species, we could also examine intraspecific variance. Leaf samples were collected from mid-canopy from five individuals of each of the following species: *E. agglomerata, E. dives, E. elata, E. macrorhynca,* and *E. rossii* (monocalypts); *E. globulus ssp bicostata, E. mannifera*, and *E. polyanthemos* (symphyomyrtles). We also collected leaves from 10 individuals, known to vary in FPC concentration, of another symphyomyrtle, *E. melliodora*. Leaves were frozen upon collection and later freeze dried but left unground.

Large-scale Collection The preliminary study gave promising results so we undertook a larger study of a diversity of taxa from *Eucalyptus* and *Symphyomyrtus*. In this way, we could determine whether there are consistent chemical differences between the subgenera. All leaf samples were collected during a single field trip to the Currency Creek Arboretum 80 km south of Adelaide in South Australia in April 2006. The collection included 83 symphyomyrtles (11 of 15 sections that did not include species in the monotypic *Racemus*, *Similares,* or *Pumilio,* or any of the six species in *Platysperma*) and 31 monocalypts (10 of 11 sections that excluded the monotypic *Nebulosa*). A small branch from mid-canopy height of each shrub or tree was cut, and from it about 60 g of mature leaf were stripped, sealed in a plastic bag, and placed in a portable freezer. Upon returning to Canberra, the leaves immediately were freeze dried and ground to pass a 1 mm sieve by using a Cyclotec 1093 Mill (Tecator, Sweden). The resulting powder was stored in the dark in clear plastic 50 ml specimen containers.

Extraction For the preliminary study, we crushed 2.00± 0.05 of leaves into a conical flask, added 40±1 ml of AR grade dichloromethane (DCM), stoppered the flask, and extracted the sample for 48 hr. The solvent was decanted into a round-bottomed flask through a sintered glass funnel fitted with a Whatman No. 41 filter paper and rotary-evaporated at 40°C. The resulting material was redissolved in a small amount of DCM, transferred to a glass vial, dried under a stream of air for 48 hr, and freeze–dried.

For the large-scale collection, we weighed 2.00±0.01 g of dry ground leaves into a conical flask, containing 40± 1 ml DCM. After 5 min of sonication, the extraction was continued for 23 hr with occasional stirring. The solvent was decanted into a round-bottomed flask through a sintered glass funnel fitted with a Whatman No. 41 filter paper, and the leaf residue was re-extracted for about 1 hr in 10 ml DCM. The extract was filtered, added to the first extract, and the solvent was removed by rotary evaporation at 40°C. The resulting crude material was transferred quantitatively with five aliquots of DCM (2 ml each) to a pre-weighed glass vial. We then dried the extracts under a gentle stream of N_2 for about 24 hr, freeze–dried them to remove any remaining solvent, and reweighed them to give the amount of extract per g of dry leaf.

NMR Spectroscopy ^{1}H NMR spectra were measured using a Bruker Avance 750 spectrometer (Bruker Daltonics Inc., Billerica, MA, USA) with a 5 mm TXI XYZ ^{1}H -^{13}C -^{15}N probe, operating at 749.66 MHz (^{1}H). Crude leaf extracts were dissolved in $CDCl_3$ at a concentration of 10 mg/ 750 µl. Spectra were recorded at 298 K and referenced to the residual $CHCl_3$ signal (δ7.26), and chemical shifts are expressed in ppm downfield from TMS. The following parameters were used for ^{1}H spectra: (pulse program:zg) 9.014 KHz spectral width, 64 K data points, 32 scans, 90° pulse (8.0 µs), 1 sec recycle delay. No exponential line broadening was applied prior to Fourier transformation. The 2D-NMR spectra were measured using either a Bruker Avance 750 spectrometer, operating at 749.66 MHz (^{1}H) and 188.52 MHz (^{13}C) with conditions as described above and using the following parameters: COSY: (pulse program: cosydfph) 4 K × 760 data points, 8 scans; HSQC: (pulse program: hsqcetgpsi2) 2 K × 512 data points, 24 scans; HMBC: (pulse program: hmbcgplpndqf) 4 K × 512 data points, 24 scans, or a Bruker Avance 300 spectrometer with a 5 mm BBIz probe, operating at 300.13 MHz (^{1}H) and 75.47 MHz (^{13}C) using the following parameters: COSY: (pulse program: cosygpmftp) 1 K × 512 data points, 4 scans; HSQC: (pulse program: invieagssi) 1500 × 512 data points, 16 scans; HMBC: (pulse program: inv4gplplrnd) 1500 × 512 data points, 32 scans.

Statistical Analysis Spectra were binned and Principal Component Analysis (PCA) was done using the Bruker Amix software package (version 3.6.8). Spectra were binned from 10.6 to 0 ppm, excluding the regions from 7.3 to 7.2 and 1.3 to 1.2 ppm, with a bin width of 0.1 ppm or from 10.6 to 7.3 ppm with a bin width of 0.05 ppm. Bins were scaled relative to the largest bin. A number of principal components sufficient to explain at least 95% of the variance were calculated (typically 6–12 principal components).

Large-scale Extraction of E. rossii (monocalypt) and Fractionation of the Dichloromethane Extract Freeze–dried intact leaves (260 g) were extracted by soaking (twice) for 24 hr with petroleum spirit (bp 60–70°C, about

1.5 l per extraction) at room temperature, followed by two extractions with redistilled DCM under the same conditions. The two DCM extracts were combined to yield, after rotary evaporation, a green gum (4.6 g, *ca* 2% of dry leaf mass). On redissolving the extract in DCM, a small quantity of a white, DCM-insoluble residue remained in the flask. This material was identified as ursolic acid by 2D-NMR spectroscopy and confirmed by comparison of NMR and melting point data with literature values. The soluble portion of the extract was subjected to flash column chromatography on silica gel (Merck Keiselgel 60, 40–63 μm, 100 g). Elution with DCM yielded a fraction containing crude 2,5-dihydroxy-7-methoxy-6,8-dimethylflavanone (35 mg), while further elution with 10% ethyl acetate/DCM yielded a fraction from which yellow crystals of 2,5,7-trihydroxy-6,8-dimethylflavanone (10 mg) were obtained.

Results

Preliminary Collection A large broad singlet peak at δ1.29, from lipid and/or wax components dominated the ^{1}H NMR spectra of the DCM extracts of the leaves of all species. As this peak was common to both subgenera, it was considered unlikely to be associated with antifeedant properties and it was omitted from the spectra prior to PCA to avoid its effect masking the contribution from minor constituents. The scores plot from the PCA reasonably separates the subgenera along the Principal Component 2 (PC2) axis (Fig. 2a), the major loadings being 1.05 (i.e., 1.10–1.00 ppm in the negative direction, correlating to the symphyomyrtle species) and 1.35 (positive, monocalypts) (Fig. 2b). Both of these bins may contain lipid methylene (δ1.35) and methyl (δ1.05) resonances, particularly those of unsaturated lipids, and so they were considered to be poor potential indicators of chemical differences between the subgenera. Further analyses showed that optimum separation occurred only when the regions of the ^{1}H NMR spectra between δ 10.6 and 7.3 ppm were included in the analysis (Fig. 3a). Here, PC1 produces a tight grouping of monocalypt species, with the exception of *E. elata* and two individuals of *E. macrorhynca*. Although these individuals have a similar score in PC1, they are separated from the remaining monocalypts in PC2. The symphyomyrtles also show a tight grouping with the exception of four out of five of the individuals of *E. melliodora* known to have a low FPC content (Fig. 3a). The major loadings in the positive direction (*Symphyomyrtus*) of PC1 were 10.13 (10.15–10.10 ppm) and 10.23, due to the aldehyde proton resonances of FPCs (Fig. 3b), while the monocalypts were typified by loadings at 7.48 and 7.43 (Fig. 3b).

The region between δ7.5 and δ7.3 of most of the monocalypt ^{1}H NMR spectra revealed a pattern of one doublet and two triplets, with integrals of 2, 2, and 1, respectively (Fig. 4), typical of a monosubstituted aromatic ring. There were two exceptions: the spectra from *E. rossii*, in which the doublet signal was further downfield (δ7.71), and those of *E. elata*, which had no such resonances (Fig. 4). These signals were absent from the spectra of the symphyomyrtle species, as typified by *E. globulus* (Fig. 4), which suggests that monocalypt species differ from symphyomyrtle species by the presence of a phenolic compound bearing a monosubstituted ring. However, the small differences between species in the chemical shifts of these resonances suggest that the monocalypts share a class

of compounds having similar structures, rather than a specific compound.

To gain more information about the structure of these phenolic compounds, 2D-NMR spectra were run on one sample of the DCM extract of *E. agglomerata*. The COSY, HSQC, and HMBC spectra confirmed that the three resonances, at δ7.47, 7.44, and 7.38, were due to a monosubstituted aromatic ring. However, apparent splitting of the peaks at δ7.44 and 7.38 suggested that these signals were due to at least two sets of overlapping resonances. The HMBC spectrum allowed the assignment of the quaternary carbon of the aromatic ring (at δ138.8) and revealed a connection from that resonance to another three proton coupling system (again overlapping pairs of almost equal intensity) consisting of resonances at δ5.42, a doublet of doublets (dd) (J 13.2 and 3.2 Hz, overlapped with a similar resonance at δ5.40), δ3.05 (dd, J 13.2 and 17.0 Hz, overlapped with δ3.02) and δ2.85 (dd, J 3.2 and 17.0 Hz, overlapped with δ2.845). Those resonances were coupled further to a carbon resonance at δ196.1. This evidence leads to the partial structure (Fig. 1, structure **2**) and suggests that the major phenolic constituents of the extract were a mixture of two flavanone compounds in approximately equal proportions, both having no substitution on Ring B and differing only in their substitution in Ring A. The complexity of the HMBC spectrum, due to overlap of some aromatic resonances and the presence of many similar minor constituents, prevented the full elucidation of the Ring A substitution patterns of these compounds. However, the ^{1}H NMR data were largely compatible with a mixture of two compounds having Ring A substitution patterns analogous to those of the commonly occurring flavones (ring-C unsaturated analogues of flavanones), eucalyptin (Fig. 1, structure **3**) and demethyleucalyptin (Fig. 1, structure **4**), although there were some discrepancies between the ^{1}H chemical shifts (and those of connected carbons found from the HMBC) for these compounds and those reported for the corresponding flavanone analogues (Diaz et al. 1987; Hsieh et al. 1998; Mayer 1990).

In summary, PCA analyses performed only on the ^{1}H NMR spectra identified the region between 7.5 and 7.3 ppm as being the major point of difference between species of the two subgenera. Inspection of 1H NMR spectra reveals

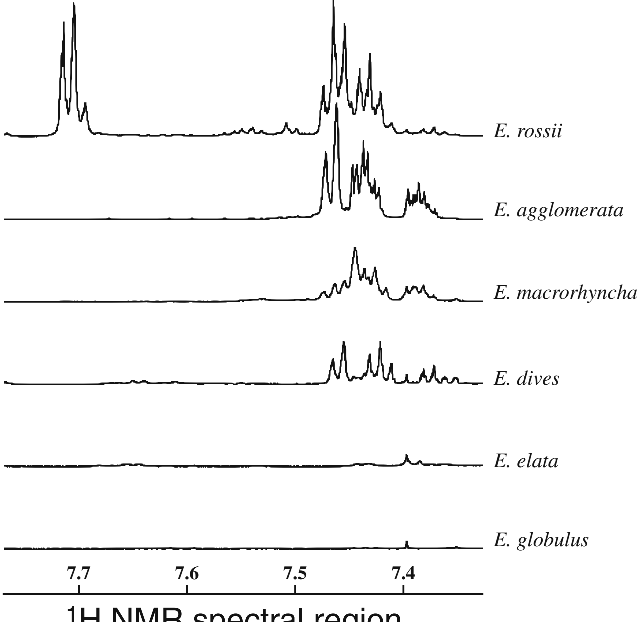

Fig. 4 The region of the ^{1}H NMR spectra of dichloromethane extracts of eucalypt leaves between δ 7.75 and δ 7.35. All are monocalypts except *E. globulus*, which gives a trace typical of *Symphyomyrtus.* One monocalypt, *E. elata*, tends to group away from other monocalypts

that the resonances present in this region can be attributed to a monosubstituted aromatic ring, while the 2D NMR data prove that the monosubstituted aromatic ring is the B ring of a flavanone. However, even within single species, a complex mixture of compounds with varying A-ring substitution patterns occurs. The exact nature of these substituents remains uncertain until the compounds are isolated from a larger collection of the plant material. That said, structures similar to that of the widely occurring unsubstituted B-ring flavanone, pinocembrin (Fig. 1, structure 5) seem likely.

Large-scale Collection A PCA of the ^{1}H NMR data of extracts from the large scale collection of 83 symphyomyrtle and 31 monocalypt species produced results (Fig. 5a) similar to those obtained for the preliminary collection. Again, the monocalypts largely group together with major loadings at 7.48 and 7.43 ppm (Fig. 5b). This suggests that there are consistent chemical differences between the leaves of species from these two major eucalypt subgenera.

A few symphyomyrtle species group close to the monocalypts in the PCA (Fig. 5). Inspection of their ^{1}H NMR spectra reveals that this is due to a combination of two features. First, they show very small or no resonances corresponding to FPCs (e.g., *E. nitens*), similar to our observations in the preliminary experiment for *E. melliodora* with low concentrations of the FPC, sideroxylonal (Fig. 3a). Second, the symphyomyrtles that grouped close to the monocalypts show one or more peaks in the region from δ 7.5–7.4. However, the chemical shift and multiplicity of these resonances suggest that they are not due to unsubstituted B-ring flavanones. In some cases, the resonance was a doublet, with a coupling partner at lower field (ca. δ 7.8–7.7) suggesting a 4′-substituted flavone, such as eucalyptin (Fig. 1, structure 3) or related compounds. In contrast, the spectra of three species, *E. dundasii*, *E. salubris,* and *E. pleurocorys*, had resonances with multiplicity typical of a monosubstituted aromatic system (i.e., a one proton triplet, a two proton triplet, and a two proton doublet) with chemical shifts of δ 7.55, 7.44, and 8.04, respectively, but the latter shift suggests a flavone with an unsubstituted B-ring rather than a flavanone derivative. The presence of a resonance at δ 6.6 in the spectra of these species, perhaps due to H-3, supports this suggestion. Another species of interest is *E. grandis*, which also has resonances in its spectrum due to a monosubstituted aromatic ring. However, in this case the shifts (δ7.30 (2H, t), 7.26 (2H, d) and 7.21 (1H, t) are not compatible with those of the B-ring of a flavone or a flavanone. Leaves of *E. grandis* contain the β-triketones, flavesone, leptospermone, and isoleptospermone (Boland et al. 1991), and it seems likely that these aromatic resonances may be due to the aromatic analogue, grandiflorone, which has not been

Some species are labelled as follows: (*Eucalyptus*) 1—*E. dives*; 2—*E. brevistylis*; 3—*E. staeri*; 4—*E. buprestium*; 5—*E. marginata*; 6—*E. lacrimans;* 7—*E. moorei*; 8—*E. amydalina;* 9—*E. elata;* 10—*E. laevopinea;* (*Symphyomyrtus*) 11—*E. nitens*; 12—*E. dundasii*; 13—*E. salubris*; 14—*E. caleyi*; 15—*E. brunnea*; 16—*E. angustissima*; 17—*E. dawsonii;* 18—*E. pleurocorys;* 19—*E. grandis*. **b** Loadings plot

reported previously in eucalypts. The only ^{1}H NMR data reported for grandiflorone was at 60 MHz (Hellyer and Pinhey 1966), at which frequency the aromatic protons are unresolved, but the shift of δ 7.22 agrees reasonably well with those found at 750 MHz in this work.

Of the outlying monocalypts, two species, *E. amygdalina* and *E. moorei*, contained substantial quantities of unsubstituted B-ring flavanones, but a large score in PC2 separated them from most monocalypts. The loadings responsible for this score were at 7.83 and 7.87 ppm due to eucalyptin and 8-demethyleucalyptin (confirmed by comparison of the ^{1}H NMR spectra of these species with literature data) (Sarker et al. 2001). Horn and Lamberton

(1963) found these flavones in both monocalypt and symphyomyrtle species, while we found NMR evidence of many further occurrences in both sub-genera, thus suggesting that they have no chemotaxonomic significance. The other outlying monocalypt species (*E. brevistylis*, *E. buprestium*, *E. dives*, *E. elata*, *E. lacrimans, E. laevopinea, E. marginata,* and *E. staeri*) contained no unsubstituted B-ring flavanones.

The literature provides some support for our observation that flavanones with unsubstituted B-rings occur in monocalypts but not in symphyomyrtles. A wide variety of flavonoids have been isolated from symphyomyrtle species, including C-methylated flavones, C-methylated flavonols and flavonols (Wollenweber and Kohorst 1981; Conde et al. 1997). In contrast, the unsubstituted B-ring flavanones pinocembrin, alpinetin, and O,O-dimethylpinocembrin, have been reported only in the monocalypt *E. sieberi* (Bick et al. 1972). A reanalysis of negative ion ESIMS data published by Eschler et al. (2000) revealed that the spectra of all the monocalypt species contained an ion at m/z 255, which plausibly could be the $M\text{-}H^+$ ion of pinocembrin. The m/z 255 ion was present in substantially lower relative abundance in the two species *E. andrewsii* and *E. haemastoma*.

Large-scale Extraction of E. rossii and Fractionation of the DCM Extract We attempted to isolate and characterize the compounds responsible for the major aromatic resonances observed in the ^{1}H NMR spectrum of the leaf extract of *E. rossii* leaves. The appeal of the species was that its ^{1}H NMR spectrum suggested the presence of a flavonoid with an unsubstituted B-ring that differed in the aromatic region from that of most other monocalypt species. The DCM extract yielded two compounds tentatively assigned as novel 2-hydroxyflavanones (Fig. 1, structures **6** and **7**). The structural elucidation of these compounds will be reported elsewhere.

Discussion

We demonstrated that a broad metabolomic approach using ^{1}H NMR spectra of the DCM extracts of leaves can detect consistent chemical differences between the two major eucalypt subgenera. In particular, monocalypt leaf extracts contain flavanones having an unsubstituted B-ring, typified by resonances in the region from δ 7.4–7.3, while species of symphyomyrtle do not contain this class of compounds. In contrast, the symphyomytles have unique signals in the vicinity of 10 ppm that correspond to FPCs. These differences provide a correlative explanation for why brushtail possums refrain from eating monocalypt foliage (Marsh et al. 2003a). Furthermore, these differences help explain dietary niche partitioning in marsupial folivores and provide clues about the evolutionary relationships between eucalypts and the animals that eat them. As pointed out previously, most eucalypt forests contain mixed stands with representatives from both major subgenera tending to co-dominate (Pryor 1959). This, together with the high intraspecific chemical variation in eucalypts (Moore et al. 2004b) that is largely under genetic control (Andrew et al. 2007), creates a patchy landscape for folivores with likely effects on the ecosystem (Whitham et al. 2008).

While we have no direct evidence that unsubstituted B-ring flavanones are responsible for the feeding behavior of brushtail possums, many flavonoids have been reported to deter feeding by insects (Treutter 2006). The reported isolation of free flavonoids from eucalypt epicuticular wax may support an antifeedant role for these compounds (Wollenweber and Kohorst 1981). Furthermore, flavonoids with an unsubstituted B-ring differ, both in biological activity and chemical reactivity, from flavonoids with mono or di-substitution in Ring B (Pannala et al. 2001; Jia et al. 2003). Thus, such compounds may have antifeedant activity that differs from that of other flavonoids, which are more widely distributed across the eucalypt genera. These results suggest two worthwhile directions for feeding studies. It would be reasonable to compare feeding by brushtail possums offered monocalypt species that have unsubstituted B-ring flavonoids to those few species that do not have these compounds (*E. brevistylis*, *E. buprestium*, *E. dives*, *E. elata*, *E. lacrimans, E. laevopinea, E. marginata,* and *E. staeri*). In addition, we suggest a comparison of feeding by possums offered artificial diets containing isolated pinocembrin (an unsubstituted B-ring flavanone, Fig. 1, structure 5) to those offered diets containing flavonoids with B-ring substitution.

We acknowledge that monocalypts may contain compounds with feeding deterrent activity that were not extracted with DCM and were thus not detected in our study. Indeed, more polar compounds including flavonoid glycosides and proanthocyanidins (condensed tannins) are well known to have antifeedant activity (Marsh et al. 2003b) but would not be present in a DCM extract. On the other hand, the exclusive production of unsubstituted B-ring flavanones by monocalypts, revealed in this research, indicates that these species are capable of biosynthetic pathways unavailable to symphyomyrtles. Such processes may produce unique flavonoid glycosides and proanthocyanidins, as these compounds share common biosynthetic precursors with flavanones (Veitch and Grayer 2008). This prompts a similar study using methanol extracts to determine whether the more polar metabolites of these subgenera show similar differentiation to that seen in DCM extracts.

A key message of this paper is the value of spectral approaches and metabolomics for elucidating ecological problems. The literature contains numerous examples in which the study design was based on the assumption that a particular nutrient, especially nitrogen, was limiting. One advantage of spectral approaches is that they require no preconceived ideas about chemical or nutrient composition, but provide a holistic view of the material. Approaches such as NIRS have been used to discriminate groups, such as leaf samples from different species or with differing susceptibility to herbivory, but this method is of limited value for deciphering the underlying chemistry. The better method is broad metabolite profiling, in which one aims to identify as many metabolites as possible in a single extract to provide the biochemical phenotype of the organism (Allwood et al. 2008). One of the preferred methods, gas chromatography-mass spectrometry, can be used routinely to determine the concentrations of 300–500 polar and non-polar metabolites per sample (Lisec et al. 2006). Its disadvantages include the need for compounds to be in mass spectral libraries (i.e., known compounds), the need to derivatize non-volatile compounds, and the need for a calibration system to account for differences in detection sensitivity among compounds. Therefore, GC-MS is not suitable for poorly understood systems, such as *Eucalyptus*. In contrast, ^{1}H NMR spectroscopy offers several benefits (Nicholson et al. 1998): 1) samples require minimal treatment; 2) detection is universal, since virtually all organic compounds give ^{1}H NMR signals; 3) resonance intensity is directly proportional to the concentration of compound; 4) the bins responsible for the major loadings in the PCA provide structural information about compounds.

Acknowledgments We wish to thank Cora Shiroyama for help in collecting the samples, Lynnette Lambert for assistance with ^{1}H NMR spectroscopy and Professor Eckhard Wollenweber for valuable discussions and a generous gift of reference samples. Andras Keszei helped with the figures. The comments of three anonymous reviewers led to marked improvements in the manuscript.

Abstract We investigated whether Mediterranean goats use salivary tannin-binding proteins to cope with tannin-rich forages by determining the affinity of salivary or parotid gland proteins for tannic acid or quebracho tannin. Mixed saliva, sampled from the oral cavity, or parotid gland contents were compared to the intermediate affinity protein bovine serum albumin with a competitive binding assay. Goats that consume tannin-rich browse (Damascus) and goats that tend to avoid tannins (Mamber) were sequentially fed high (*Pistacia lentiscus* L.), low (vetch hay), or zero (wheat hay) tannin forages. Affinity of salivary proteins for tannins did not differ between goat breeds and did not respond to presence or absence of tannins in the diet. Proteins in mixed saliva had slightly higher affinity for tannins than those in parotid saliva, but neither source contained proteins with higher affinity for tannins than bovine serum albumin. Similarly, 3 months of browsing in a tannin-rich environment had little effect on the affinity of salivary proteins for tannin in adult goats of either breed. We sampled mixed saliva from young kids before they consumed forage and after 3 months of foraging in a tannin-rich environment. Before foraging, the saliva of Mamber kids had higher affinity for tannic acid (but not quebracho tannin) than the saliva of Damascus kids, but there was no difference after 3 months of exposure to tannin-rich browse, and the affinity of the proteins was always similar to the affinity of bovine serum albumin. Our results suggest there is not a major role for salivary tannin-binding proteins in goats. Different tendencies of goat breeds to consume tannin-rich browse does not appear be related to differences in salivary tannin-binding proteins.

Key Words Defense mechanism against tannins · Tannin-binding capacity · Parotid · Lentisk · *Pistacia lentiscus*

Introduction

Although dietary tannins may have some positive effects (Mueller-Harvey 2006), the ingestion of large amounts of tannins by most herbivores is associated with reduced feed intake and digestibility, and decreased availability of a wide array of nutrients, the most important of which is protein. Condensed tannins can be excreted via the feces, but some are metabolized and excreted as urinary metabolites; hydrolyzable tannins can be partially absorbed, and some of them can be toxic (Mueller-Harvey 2006). Domestic ruminants employ a variety of behavioral mechanisms to cope with dietary tannins, such as avoidance (sheep; Titus et al. 2000), modified meal patterns (cattle; Landau et al. 2000), and foraging selectivity that maintains dietary tannins all year-long in a narrow range of concentration (goats; Kababya et al. 1998) that may be beneficial (Mueller-Harvey

2006). In addition, herbivores may use associations between classes of PSMs to reciprocally neutralize their deleterious effects (Lyman et al. 2008; Mote et al. 2008). Physiological adaptations also exist, encompassing tannin-resistant rumen flora (Odenyo et al. 1999), improved liver capacity to detoxify tannins (Dearing et al. 2005), and the secretion of tannin-binding salivary proteins (TBSPs; Shimada 2006). TBSPs have a binding affinity for tannins that is 5–80 times that of bovine serum albumin (BSA).

Mehansho et al. (1983) discovered that in rats, parotid TBSPs are induced by tannin ingestion. Subsequently TBSPs in saliva have been reported for many species of rodents (mouse, root vole), lagomorphs (rabbit, mountain hare, North American pika), ungulates (moose, musk ox, mule deer, roe deer, fallow deer), perissodactyls (white, Indian and black rhinoceroses), and primates (man, macaque) (Shimada 2006). The feeding niche theory states that herbivores that consume more browse are more likely to secrete TBSPs (Shimada 2006). Notable exceptions include a variety of marsupials, which are browsers but do not secrete TBSPs (Shimada 2006), and the Indian rhinoceros, a grazer with saliva that has similar or higher affinity for tannins than that of the black rhinoceros, a browser (Clauss et al. 2005). In arid areas, where nitrogen is the first limiting nutrient, animals face a trade-off between the cost of secreting proteins in their saliva and the benefit of preventing protein depletion by tannins.

Since tannin-rich browse is a major component of goat diets in Mediterranean shrublands (Landau et al. 2002), one would expect them to produce TBSPs. Distel and Provenza (1991) did not find TBSPs in the saliva sampled from the oral cavity of goats and Lamy et al. (2008) did not find TBSPs in sheep and goat parotid saliva. Austin et al. (1989) did not identify TBSPs in cattle and the tannin-binding capacity of salivary proteins for tannins did not differ between cows fed high- or low-tannin diets (Makkar and Becker 1998).

The overall objective of our study was to evaluate the affinity of saliva from domestic goats (*Capra hircus*) kept in a tannin-rich environment for tannin. Our specific objectives were: a) to test if salivary proteins have a higher affinity for tannin than that of BSA; b) to compare the affinity for tannins of parotid versus mixed saliva; c) to test if short- and long-term exposure to dietary tannins stimulates salivary affinity for tannins; and d) to test the "feeding niche" theory by comparing the affinity for tannins of saliva from two goat breeds that differ in their propensity to ingest tannin-rich browse.

Methods and Materials

Animals Adult and kid goats were selected from the experimental flock at Ramat HaNadiv, located at the southern tip of the Carmel Ridge, Israel (32°33′ N, 34°57′ E). All procedures were monitored by the Israel Council on Animal Care Guidelines (ICACG 1994).

The region is characterized by an average yearly rainfall of 600 mm, and a rainy season of 180 d, from October to April. The ecosystem is a disturbed Mediterranean shrubland (garrigue) featuring steep, rocky slopes with scarce patches of shallow soil. The vegetation is dominated by low trees (mainly *Phillyrea latifolia* L.) and tall shrubs, mainly lentisk *(Pistacia lentiscus* L.) and *Calicotome villosa* Poir. Link, that can contribute over 60% of the plant matter ingested by goats (Landau et al. 2005; Glasser et al. 2008).

Experiment 1 The response of goats to short-term tannin exposure was compared in two breeds with contrasting tendencies to consume tannin-rich lentisk: Damascus (high) and Mamber (low) (Glasser 2009). Four yearling female goats of each breed were selected at random, weighed and kept in separate 3×3 m dirt floor pens. Average (± SE) animal weight was 29.5±0.28 kg for the Mamber goats and 41.0±0.81 kg for the Damascus goats. After a 14 d period of adaptation to the pens, the feeding trial comprised four 10 d periods during which goats were fed a base ration of 350 g d^{-1} of a commercial concentrate feed (Ambar, Hadera, Israel) and an *ad libitum* allowance of a forage that changed between periods in crude protein (CP) and tannin content (expressed as Polyethylene glycol-binding-tannins, Landau et al. 2004). The forages were as follows: Period 1—vetch hay with high protein and low tannin content (15.8% and 1.5% of DM (dry matter), respectively); Period 2—freshly clipped foliage of lentisk with low protein and high tannin content (7.8% and 19.3% of DM, respectively); Period 3—vetch hay as in Period 1; Period 4—wheat hay with medium protein and no tannin (11.7% and 0% of DM, respectively) (Table 1).

At the end of each feeding period, saliva samples were extracted from the oral cavity ("mixed") and from the parotid gland, and blood was sampled from the jugular vein. Serum from the blood samples was stored at −20°C until it was analyzed for urea, which was used to estimate the effect of lentisk tannins on protein metabolism (Silanikove et al. 1996a).

Experiment 2 The response of goats to long-term tannin exposure was compared in Damascus and Mamber goats. Mixed saliva samples were collected from nine female kids of each breed at 3 months of age, before the animals had any foraging experience, and again after the animals had 3 months of foraging experience in tannin-rich brushland. To further assess the effect of long-term foraging in tannin-rich brushland, mixed saliva was collected from four adult goats of each breed.

Period 2	–	–	630	530	–	–
Period 3	710	700	–	–	–	–
Period 4	–	–	–	–	580	380

Saliva Collection Saliva was sampled from the oral cavity in the morning, before the goats or kids were fed, in order to minimize food contamination. A sponge was tied to the animal's mouth for 15 min and then squeezed above a 50 ml tube. The saliva samples were then frozen (−20°C) until analysis.

Extraction of parotid saliva requires anesthesia. The procedure was conducted in the morning, before the goats were fed, to avoid regurgitation and aspiration of rumen contents during unconsciousness. The goats were sedated intravenously by xylazine (Phoenix Pharm Distributors, Oakland, New Zealand; 0.03 mg kg^{-1}) and anaesthetized intravenously by a 1:2 v/v mixture of Ketamine (Clorake-tam1000; Vetoquinal, Lore, France) and Diazepam (Assival, Teva, Petah Tiqwa, Israel). A fine catheter (Angiocath 16-gauge, Becton Dickinson Infusion Therapy Systems Sandy, UT) was inserted, with the help of a guide wire, into the parotid duct, which opens in the inner cheek in front of the 3rd maxillary premolar tooth. Saliva was then aspirated with a syringe while gently massaging the gland, and collected into capped tubes. After removal of the catheter, the goats were given yohimbine (Procomil; Phoenix Pharm Distributors, Oakland, New Zealand) intravenously to counteract the sedative effect of xylazine. The saliva samples were frozen (−20°C) until analysis.

Saliva was prepared for analysis according to Fickel et al. (1998) with minor modification. Saliva was centrifuged at 3,000×g for 5 min at 4°C to remove particulate matter and desalted by dialysis against deionized water for 24 h at 4°C using membrane with a 3 kDa molecular weight cut-off (GeBA, Kfar Hanagid, Israel). Protein concentration was determined in triplicate using the bicinchoninic acid (BCA) method of Smith et al. (1985) with BSA (Thermo Fisher Scientific Inc., Rockford, IL, USA) as a standard. Samples containing less than 100 µg protein ml^{-1} were concentrated by ultrafiltration using 3 kDa molecular weight cut-off membranes (Centricon tubes, Millipore, Bilerica, MA, USA), and more concentrated samples were diluted, so that salivary protein was in a range between 100 and 120 µg protein ml^{-1}.

Affinity for Tannins Affinity for tannins was estimated as described by Fickel et al. (1999) with minor modifications (Fig. 1). The assay is based on the inhibition of trypsin by tannins and reversal of inhibition when tannin-binding proteins such as TPSP are present. N-α-benzoyl-DL-arginine-p-nitroanilide, which is cleaved by trypsin to the chormophore p-nitroaniline, was used as the substrate, since it is not a protein and does not interact with tannins. Our main modification was to dissolve the substrate in dimethyl sulfoxide (DMSO) to increase enzyme efficiency (OD_{405} of the positive control was 1.8 times greater with DMSO than with water as solvent); to increase sensitivity (OD_{405} of the negative control with DMSO as solvent was 0.80 of that with water); to enhance the affinity of BSA; and to improve substrate solubility.

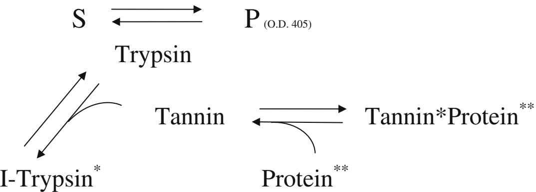

Fig. 1 The tannin-binding assay based on the inhibition of trypsin by tannins and reversal of inhibition by tannin-binding proteins. S = Substrate (Nα-benzoyl-DL-arginine-p-nitroanilide), P = Product, I-Trypsin = Inactivated trypsin, Protein = BSA or Salivary proteins

The assay was done in 96-well plates, with three wells for each control or test sample. Each well was filled with 100 µl pre-incubation mix consisting of: 90 mM Tris-HCl (pH 8.2), 18 µM $CaCl_2$, 100 µg ml^{-1} trypsin, 25 µg ml^{-1} tannic acid (Sigma, Rehovot, Israel) or 50 µg ml^{-1} quebracho extract (Trask Chemical, Marietta, GA, USA) containing 42% PEG-binding tannins (Landau et al. 2004). BSA or protein-standardized saliva (20 µg ml^{-1}) was added, the reactions were pre-incubated for 15 min at room temperature, and substrate was added. After 20 min at 37°C, the reactions were stopped by adding 50 µl of acetic acid, and optical density was read at 405 nm (OD_{405}) with a plate-reader (Lucy 2, Anthos, Imola, Italy). The four controls for each reaction were: Background, all components without trypsin; Positive control, substrate, trypsin, and buffer, without tannin or test protein; Negative control, with trypsin, tannin, and buffer, without test protein; BSA control, with trypsin, tannin, buffer, and BSA, a protein that has moderate affinity for tannin.

Three ratios were used to evaluate the affinity of saliva samples for tannins. Comp max, OD_{405} sample / OD_{405} positive control, is equal to 1.0 when the salivary protein completely scavenges the tannin, and is less than 1.0 when the salivary protein partially protects trypsin. Comp min, OD_{405} sample / OD_{405} negative control, is equal to 1.0 when the salivary protein does not interact with tannin, and is greater than 1.0 when the salivary protein binds tannin. Comp BSA, OD_{405} sample / OD_{405} BSA, is equal to 1.0 when the salivary protein and BSA have the same affinity for tannin, and is greater than 1.0 when the salivary protein has higher affinity for tannin than BSA. Therefore, the value of Comp BSA is a meaningful estimate, which allows categorization of salivary proteins as tannin-binding proteins or proteins with no special affinity for tannin as defined by Shimada (2006).

Statistics In experiment 1, urea serum concentration was analyzed by ANOVA using the GLM procedure of SAS (SAS 1989). Terms in the repeated measures analysis were goat breed and diet as main effects, their interaction, goat within breed as error term, and period as the repeated measure. In the statistical analysis of the tannin binding assay, the ELISA plate effect was significant in both experiments 1 and 2, as noted before by Fickel et al. (1999). Therefore, before data from different plates were combined (Exp.1), we ascertained that OD_{405} values for positive and negative controls, and for BSA did not differ between plates. In experiment 1, analyses of tannin-binding were made separately for tannic acid and quebracho extract using a repeated measures analysis with goat breed, diet, and saliva type as main effects, their interactions, goat within breed as error term, and period as the repeated measure. Statistical separation of means used the studentized Tukey-Kramer range test (SAS 1989). Also, all measurements of tannin-binding from experiment 1 were combined (eight goats, four periods, N=32) and Student's paired t-tests were used to compare the affinity for tannins of parotid and mixed saliva.

In experiment 2, backgrounds for titer plates differed, therefore only effects measured on one micro-titer plate could be analyzed, and the number of wells limited the complexity of analyses for kids (N=9 for each breed). Thus, the effects of grazing experience and breed were analyzed separately, without interaction. Paired t-tests were used to evaluate the effects of kid grazing experience and breed on the affinity for tannins of saliva proteins, and a one-way ANOVA was used to compare kids to mature goats.

Results

Experiment 1 Goats were not deterred by tannins in lentisk foliage (Table 1). Intake was similar for periods 1 (vetch) and 2 (lentisk) in Damascus goats, and a small decrease was noted in Mamber goats. However, protein status, as assessed from blood urea concentration, was markedly affected by diets during these periods: blood urea concentrations were lowest (P<0.001; Fig. 2) with lentisk foliage and highest with vetch hay. In period 4 (wheat hay), intake decreased more in Mamber goats than in Damascus goats (Table 1), and blood urea concentrations in both were intermediate (Fig. 2). Damascus goats had higher (P<0.05) blood urea concentration than Mamber goats in period 3 (vetch), but not in the other periods, resulting in a significant breed × diet interaction (P<0.05).

Protein concentration was higher (P<0.001) in mixed saliva than in parotid saliva (332±32 and 145±19 µg ml^{-1}, respectively). For mixed saliva, but not parotid saliva, the concentration of protein after dialysis was affected by diet

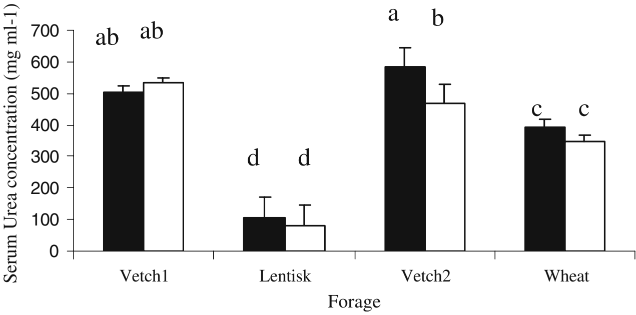

Fig. 2 Blood serum concentration of urea (mg l^{-1}) in Damascus (*black bars*) and Mamber (*white bars*) goats fed sequentially diets with vetch hay, lentisk foliage, vetch hay, and wheat hay (*bars*, means; *error bars*, standard error; N=4). Means with the same letters do not differ at P<0.05 (Adjusted Tukey-Kramer multiple range test)

($P<0.05$) or breed ($P<0.05$), but not their interaction (Table 2). Mixed saliva protein concentration was higher for Mamber goats than for Damascus goats (485±71 and 268±50 μg ml^{-1}, respectively, $P<0.05$) and feeding wheat hay to Mamber goats resulted in the highest salivary protein concentration in experiment 1.

The paired comparison of Comp min, Comp max, and Comp BSA data of experiment 1 by paired *t*-tests showed that the affinity of mixed saliva was higher for both quebracho and tannic acid than the affinity of parotid saliva (Table 3).

The ANOVA models for Comp min and Comp max were not significant. The only significant ($P<0.05$) ANOVA model was for Comp BSA, in which saliva source significantly affected tannin-binding ($P<0.01$), but diets and breeds did not. In other words, neither goat breed nor diet affected Comp min, Comp max, or Comp BSA. Therefore, the values shown in Table 3 are averages of all goats and dietary treatments by saliva and tannin type. The average Comp max values for quebracho and for tannic acid indicated a low level of protection of trypsin from tannin by saliva protein (Table 3).

The average Comp BSA values for quebracho tannin indicated that salivary protein had a lower affinity for quebracho than BSA (Table 3). The corresponding values for tannic acid indicated that salivary protein had affinity for tannins similar to BSA. Therefore, salivary proteins did not belong to the family of TBSPs, which have an affinity for tannins 5−80 times higher than that of BSA.

Experiment 2 Three months of exposure to a tannin-rich foraging environment by goat kids with no prior foraging experience only affected Comp min measured with quebracho. A small increase was noted for Mamber kids after exposure to tannin-rich pasture (Table 4).

Before grazing, the saliva of Mamber kids had higher Comp min values, when measured with tannic acid, than the saliva of Damacus kids ($P<0.01$; Table 5) but that difference faded ($P>0.08$) after adaptation to grazing.

Table 2 Protein concentration (μg ml^{-1}) of mixed saliva in Damascus and Mamber goats in the four consecutive periods of experiment 1 (means±SE)

	Damascus	Mamber
Period 1 (vetch hay)	316±143 ^{b}	493±29 ^{ab}
Period 2 (lentisk foliage)	173±37 ^{b}	279±32 ^{b}
Period 3 (vetch hay)	289±27 ^{b}	393±56 ^{ab}
Period 4 (wheat hay)	296±137 ^{b}	775±127 ^{a}

Means with the same superscripts do not differ at $P<0.05$ (Tukey-Kramer adjusted multiple range test); Main effects: breeds, Mamber> Damascus, $P<0.05$; Diets, Vetch and wheat hay>lentisk, $P<0.05$; Breed × Diet, $P=0.14$

Table 3 Comparison of Comp min, Comp max, and Comp BSA, between mixed and parotid saliva in experiment 1 (means±SE)

	Parotid saliva	Mixed saliva
Quebracho extract		
1.24±0.03 ^{b}	1.32±0.03 ^{a}	Comp min
0.40±0.01 ^{b}	0.43±0.01 ^{a}	Comp max
0.80±0.02 ^{b}	0.85±0.02 ^{a}	Comp BSA
Tannic acid		
1.36±0.03 ^{b}	1.47±0.03 ^{a}	Comp min
0.27±0.007 ^{b}	0.29±0.005 ^{a}	Comp max
1.00±0.03 ^{b}	1.08±0.03 ^{a}	Comp BSA

Row-wise, means with different superscripts differ at $P<0.01$ (paired *t*-tests)

There were no differences between breeds in measurements of salivary affinity for tannins when quebracho was used in the assay.

When we compared the six-month-old kids to the adults of both breeds (Fig. 3), the breed × age interaction was significant ($P<0.05$), the effect of age was highly significant ($P<0.001$), but breed was not significant. Comp min with tannic acid tended to be greater for adults than for kids (($P=0.06$) in Damascus goats, but not Mamber goats (Fig. 3).

Discussion

The sharp decrease in serum urea following ingestion of lentisk foliage (Fig. 2) agrees with the increased fecal excretion of proteins and decreased N retention reported before for animals ingesting lentisk (Silanikove et al. 1996b; Decandia et al. 2000). This suggests that lentisk foliage was a suitable choice of forage for our investigation of salivary tannin-binding proteins.

Here, we present three arguments against a prominent role of salivary tannin-binding as a defense against dietary tannins in goats: a. the lack of a tannin-induced increase in

Table 4 The effect of 3 months grazing experience on the affinity of mixed saliva for quebracho tannin and tannic acid, measured as Comp min, in Damascus and Mamber kids: means±standard error; $N=9$

salivary tannin-binding (experiment 1); b. the similar affinity for tannins of parotid and mixed saliva (experiment 1); and c. the similar affinity for tannins of saliva protein and BSA (experiments 1 and 2).

The goats used in experiment 1 were habituated by many months of earlier exposure to tannin foliage while in pasture. In addition, they consumed lentisk for 10 days before saliva collection. Therefore, if short-term exposure to tannins induces the secretion of TBSPs, the transition from vetch hay (period 1) to lentisk foliage (period 2) should have resulted in an increased affinity of the goat saliva for tannins. Likewise, the reverse transition (lentisk in period 2 to vetch in period 3) should have decreased this affinity. Neither the increase nor the decrease occurred. Also, in experiment 2, there was no effect of 3 months exposure of naïve Damascus kids to a tannin-rich environment. In Mamber kids, there was a modest effect that was significant for Comp min only (Table 4). This casts a serious doubt on the ability of dietary tannins to induce salivary tannin-binding in goats, similar to the results for cattle (Makkar and Becker 1998) and sheep (Austin et al. 1989).

In rodents, tannin ingestion can induce parotid hypertrophy and production of TBSPs in the parotid (Bennick 2002; Gho et al. 2006). In roe deer, the affinity of mixed saliva for tannin is only 50% (tannic acid) to 65% (quebracho) of that of parotid saliva (Fickel et al. 1998). In contrast, our study showed that mixed saliva had higher affinity for tannins than parotid saliva (Table 3). We regard limited tannin-binding by parotid saliva as evidence that salivary protein is not a line of defense against dietary tannins in goats.

The affinity of mixed saliva and parotid saliva for tannin was approximately equal to that of BSA in experiment 1 of the present study (Table 3); and was less than that of BSA in experiment 2. In comparison, TBSPs have affinity for tannins 5–80 times higher than that of BSA (Shimada 2006). This constitutes a third argument against the role of salivary tannin-binding as a defense against tannins in goats.

It is widely believed that because grazers such as cattle and sheep consume diets virtually free of tannins, they do not produce TBSPs (Austin et al. 1989). According to the "niche theory", goats, which include a significant amount of tannin-rich browse in their diets (Kababya et al. 1998; Landau et al. 2002), should produce salivary tannin-binding proteins. In particular, Damascus goats, which behave more as "browsers" than Mamber goats (Glasser 2009), should produce more TBSPs. Our data showed that the tendency to consume tannin-rich browse was not reflected in higher salivary tannin-binding capacity in either young animals (Table 5) or in adults (Fig. 3). This is in agreement with Lamy et al. (2008), who reported considerable similarity in SDS-PAGE profiles between sheep and goat parotid salivary proteins, and who did not identify proline-rich proteins (a category of TBSPs) in either type of saliva.

Tannic acid and quebracho tannins are models of hydrolyzable and condensed tannins and thus have limitations (Rautio et al. 2007). Commercial preparations of tannic acid may contain simple galloylglucoses or even gallic acid (the hydrolysis product of gallotannins) in addition to true "tannins". Lentisk foliage contains monogalloyl glucose and gallic acid (Romani et al. 2002), suggesting tannic acid is not a bad model for phenolics in this plant. Quebracho is a profisetinidin condensed tannin that is structurally and functionally different from the procyanidin typically contained in Northern hemisphere plants, including those found in Mediterranean environments (Rautio et al. 2007). In other words, both tannin preparations tested here, but in particular quebracho, may have contained tannin chemical structures that were not encountered in the diets consumed by goats in experiments 1 (lentisk foliage) and 2 (Mediterranean brushland).

It is possible that the salivary proteins of goats bind only to specific tannins, and not to tannic acid or quebracho, which were tested here. TBSPs in moose (*Alces alces* L.) and beaver (*Castor canadensis* Kuhl) bind specifically to linear condensed tannins that are common in their diets, and not to others, while in black bear (*Ursus americanus* Pal.), an omnivore, TBSPs have affinity for a great variety of

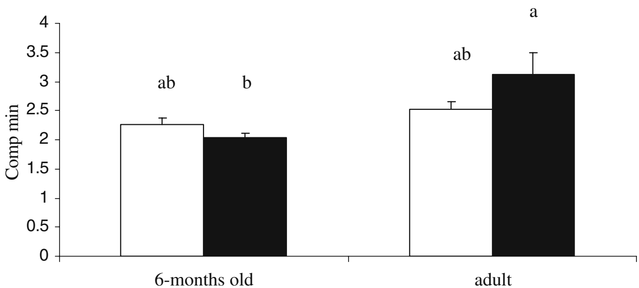

Fig. 3 Affinity of saliva for tannic acid measured as Comp min. Saliva from Damascus (*black bars*) and Mamber (*white bars*) kids (N=9) or adult goats (N=4). *Bars*, means; *error bars*, standard errors; means with the same letters do not differ at P<0.05 (Adjusted Tukey-Kramer multiple range test)

tannins (Hagerman and Robbins 1993). Goats are opportunistic feeders that are exposed to a wide array of tannins in a variety of habitats. Under free ranging conditions, Damascus and Mamber goats may forage on more than twenty tanniferous plants throughout the year (Glasser et al. 2008), each of them containing a great variety of tannins and other phenolics. For instance, thirteen different galloyl derivatives, flavonoid glycosides, and anthocyanins, have been identified in lentisk foliage (Romani et al. 2002). Because goats consume such a wide variety of tannins, we would not expect their TBSPs, if any, to be specific to a narrow range of tannin structures, but this hypothesis needs further research. Indeed, where TBSPs exist, for example in roe deer (*Capreolus capreolus* L.), tannin-binding by salivary proteins can be demonstrated by using both quebracho and tannic acid as tannin sources (Fickel et al. 1998), even though roe deer select diets with low amounts of tannic acid but reject quebracho tannin, when given a choice (Clauss et al. 2003).

Our study confirms the claim of Shimada (2006) that the ingestion of tannins in browse does not necessarily imply that salivary tannin-binding is a mechanism used to counteract their deleterious effects. In summary, explanations for the resilience of Mediterranean goats to lentisk tannins must involve other mechanisms such as microbial adaptations in the distal parts of the gastro-intestinal tract or detoxification in the liver

Abstract The fire ant, *Solenopsis invicta* (Hymenoptera: Formicidae), is considered one of the most aggressive and invasive species in the world. Toxic bait systems are used widely for control, but they also affect non-target ant species and cannot be used in sensitive ecosystems such as organic farms and national parks. The fire ant uses recruitment pheromones to organize the retrieval of large food resources back to the colony, with *Z,E*-α-farnesene responsible for the orientation of workers along trails. We prepared *Z,E*-α-farnesene, (91% purity) from extracted *E,E*-α-farnesene and demonstrated disruption of worker trail orientation after presentation of an oversupply of this compound from filter paper point sources (30 µg). Trails were established between queen-right colony cells and food sources in plastic tubs. Trail-following behavior was recorded by overhead webcam, and ants were digitized before and after presentation of the treatment, using two software approaches. The linear regression statistic, r^2 was calculated. Ants initially showed high linear trail integrity (r^2=0.75). Within seconds of presentation of the *Z,E*-α-farnesene treatment, the trailing ants showed little or no further evidence of trail following behavior in the vicinity of the pheromone source. These results show that trailing fire ants become disorientated in the presence of large amounts of *Z,E*-α-farnesene. Disrupting fire ant recruitment to resources may have a negative effect on colony size or other effects yet to be determined. This phenomenon was demonstrated recently for the Argentine ant, where trails were disrupted for two weeks by using their formulated trail pheromone, *Z*-9-hexadecenal. Further research is needed to establish the long term effects and control potential for trail disruption in *S. invicta*.

Key Words Red imported fire ant · Ant · Trail pheromone · Trail disruption · Invasive species · *Z,E*-α-farnesene · *Solenopsis invicta*

Introduction

In the early 1960s, Wright proposed that synthetic sex pheromone could disrupt mating of moths (Wright 1964). The feasibility of this was soon demonstrated (Gaston et al. 1967). Since then, the identification of sex pheromones of many moth species has been achieved along with the development of successful direct pest control options based on pheromones and other attractants (El-Sayed 2010; Witzgall et al. 2010). Despite the discovery and characterization of ant trail pheromones over the past several decades (Tumlinson et al. 1971; El-Sayed 2010), surprisingly little examination of these compounds has been undertaken for pest management. Research on the potential for using odorants in this way has targeted the control of leaf cutting ants (Robinson and Cherrett 1978) and the red imported fire ant (Vander Meer 1983, 1996), but the current paradigm remains largely confined to improving the performance of toxic baits (e.g., Rust et al. 2004).

New application technologies that deliver pheromones against invasive pest ants could help reduce our reliance on

the use of insecticides for ant pest control in sensitive ecosystems or where insecticides are undesirable. Trail pheromone disruption that affects recruitment is an example of a novel tactic for ant pest management. The Argentine ant (*Linepithema humile*) trail pheromone, *Z*-9-hexadecenal (Cavill et al. 1979), is being examined for disruption of trails by using either polyethylene tubing dispensers (Tatsuki et al. 2005; Tanaka et al. 2009) or widely dispersed point sources of pheromone (Suckling et al. 2008, 2010). This compound also is a moth pheromone (El-Sayed 2010). Tubing dispensers showed some disruption of traffic rates on the ground or tree trunks, when placed on bamboo at a 50 cm height above the ground (Tatsuki et al. 2005). The mechanism of disruption of trailing behavior observed for individuals at close range before and after exposure involved changes in walking track angles (Suckling et al. 2008). This single component was shown at a laboratory scale to be capable of disorienting trail following workers when presented in greater than physiologically normal quantities (Suckling et al. 2008). Measurement of trail disruption was achieved by assessing trail linearity as measured by the square of the linear correlation coefficient (r^2) (Suckling et al. 2008). The disruption concept was extended successfully to the field by using widely-dispersed wax-covered sand laden with the pheromone (Suckling et al. 2008) and formulated as sprayable microencapsulated particles (Suckling et al. 2010). Treatment achieved up to 90% disruption of visible Argentine ant trails for two weeks in 400 m^2 plots under hot and windy conditions in Hawaii's Volcanoes National Park (Suckling et al. 2010). Foraging to baits also was significantly reduced. These interesting developments suggest that this approach could have applicability to other invasive pest ant species, if impacts on nests can be demonstrated.

The Red Imported Fire Ant, *Solenopsis invicta*, is one of the 100 worst invasive alien species in the world (Lowe et al. 2000). Imported fire ants infest more than 330 million acres in 13 southern tier US states and Puerto Rico and are spreading northward (USDA APHIS 2009). This invasive ant is estimated to be responsible for almost $7 billion annually in damage repair, medical care, and control costs. The affected economic sectors are broad ranging and include households, electric service and communications, agriculture, schools, and recreation areas (Lard et al. 2006). In the last decade, *S. invicta* has changed from an invasive pest ant in the United States to a global problem, with infestations occurring in New Zealand (now eradicated, Christian 2009), Australia (Henshaw et al. 2005), Mexico (Sánchez-Peña et al. 2005), Taiwan (Chen et al. 2006), China (Zhang et al. 2007), and many Caribbean Island countries (Davis et al. 2001). The monogyne social form of *S. invicta* in the USA has population densities up to 100 colonies/ha and, at 250 thousand workers per colony, the resource demands are great.

Toxic ant baits have been developed and refined over the past decades in response to a need for fire ant control over large areas with minimal amounts of toxicant (Williams et al. 2001). Toxic baits are more environmentally friendly in that they introduce significantly less insecticide into the environment than mound drenches. However, fire ant baits also have a negative effect on non-target ant species that could otherwise slow fire ant reinfestation rate by feeding upon newly mated fire ant queens (Nichols and Sites 1991). More environmentally-friendly control methods are needed for management and, under certain circumstances, eradication of this invasive ant. Disruption of the critical recruitment process potentially could decrease colony resources and concomitantly population densities, and/or induce colonies to move.

Ants exhibit a wide variety of recruitment and orientation methods by using pheromones that direct worker movement between the colony and food sources or during colony migration. Similarly, the glandular sources and the chemistry of recruitment pheromones is diverse (Vander Meer and Alonso 1998). The Dufour's gland of fire ant workers is the source of its recruitment pheromone, which has been divided into three behavioral categories: orientation induction (Vander Meer et al. 1990), attraction (Vander Meer et al. 1988), and orientation (Vander Meer et al. 1981). Orientation induction requires essentially all Dufour's gland components, and acts to increase the sensitivity of workers to the orientation part of the pheromone. Two components, *Z,E*-α-farnesene and a bicyclic homosesquiterpene-diene, homoeudesmandiene, but not a tricyclic homosesquiterpene monoene as previously suggested (Vander Meer et al. 1988), account for 100% of the attractive element of the recruitment pheromone. *Z,E*-α-Farnesene accounts for 100% of the orientation (movement of worker ants back and forth along a trail) part of the recruitment process. The ants are sensitive to *Z,E*-α-farnesene trails as low as fg/cm levels. Laboratory trials were the first step in assessment of the potential for developing trail pheromone disruption against the Argentine ant (Suckling et al. 2008), before more expensive field trials (Suckling et al. 2010). Since behavioral responses to synthetic chemically-based disruption are concentration-dependent, we considered that it was sufficient to record statistical significance with the phenomenon in the laboratory as a first step before formulation development. This paper focuses on demonstration of the potential for trail pheromone disruption of red imported fire ants by using *Z,E*-α-farnesene, the recruitment orientation pheromone.

Methods and Materials

Chemicals and Synthesis A mixture of Z,E-α-farnesene (91% purity) and *E,E*-α-farnesene (9%) was synthesized

and maintained in a petroleum ether (115 mg/ml) stock solution until use. The preparation of *E,E*-α-farnesene from 60 kg of cv. Granny Smith apples (*Malus domestica* × *M. sylvestris*) was done following Murray (1969). The 60 kg of apples were divided into 5×12 kg batches that were washed, adding the apples in portions in 2 L of petroleum ether (boiling range 35–60°C). The apples were stirred for approximately 1 min then transferred into another 1.5 L of solvent where the stirring process was repeated. The solvent from the combined extracts of all the apples was removed *in vacuo* to give 36.2 g of a waxy solid. The solid was analyzed by TLC (10% EtOAC, 90% petroleum ether), which indicated the presence of *E,E*-α-farnesene by comparison with an authentic standard. The waxy solid was then dissolved in 400 ml petroleum ether (boiling range 35-60°C) and refrigerated overnight at 0°C. Solids were removed by filtration and discarded. The solvent extracts then were divided into two equal portions, and to each portion urea (130 g) was added. The material was refrigerated again overnight at 0°C. Solids were removed by filtration, and the solvent removed *in vacuo*. The crude product thus formed was purified by column chromatography using 5% EtOAc / 95% petroleum ether as eluant. The appropriate fractions were collected and repurified under the same conditions. The product (1.05 g), verified by ^{1}H-NMR (Spicer 1994), was collected as a colorless oil.

Following the procedure of Ramaiah et al. (1995), photo-isomerization of *E,E*-α-farnesene to *Z,E*-α-farnesene entailed dissolving *E,E* -α-farnesene (385 mg, 1.88 mmol) in benzene (12 ml), and dividing the solution into 4×3 ml portions that were put into 4 quartz spectrophotomer cells (1×1×4 cm). A drop of acetophenone was added to each of the samples. The solutions were sealed with a plastic lid and then photo-irradiated at 254 nm using a Hoefer UVC 500 UV Crosslinker. After 4 h, the photo-isomerization had reached approximately 40% conversion, and further irradiation had no effect. The solvent then was removed *in vacuo*, the crude material was redissolved in diethyl ether (10 ml), and tetracyanoethylene was added in small portions (50 mg at a time) until monitoring by GC-MS indicated that most of the unwanted *E,E* isomer had been consumed. It was not possible to remove all of the *E,E* isomer by addition of further tetracyanoethylene. The solvent was removed *in vacuo*, and the product was purified by column chromatography using petroleum ether as eluant. The product was obtained as a colorless solution, which was a mixture of *Z,E:E,E* isomers in the proportion 91:9 as determined by GC-MS, with a final yield of 115 mg.

Insects Queen-right colonies of *S. invicta* were collected in the field or started from field-collected newly-mated queens and maintained by standard methods (Banks et al. 1981). Prior to experiments, a colony cell (15 cm Petri dishes with a central hole in the lid and a layer of moistened Castone® in the bottom) was placed at one end of a white plastic tub (50×37 cm and 12 cm deep) that had the inner sides coated with Fluon® (Asahi Glass Co. Tokyo) to prevent escapes. Each colony cell was allowed to rest for at least 16 h before experiments. The ants were starved, but had continual access to water. Trail formation was achieved by placing one thawed house cricket (*Acheta domesticus*) and an absorbent cotton ball (Johnson and Johnson) dampened with 10% sugar water at the opposite end of the tub from the colony cell. Trials began once the trail had formed, with workers visibly trailing back and forth.

Video Recording A Logitech webcam (640×480 pixels, Notebook Pro, Logitech, Freemont, CA, USA) supported by retort stand was used to record a vertical view of fire ant workers trailing to and from a food source. Filming generated Audio Video Interleave (avi) files at a rate of 15 frames/s onto a laptop computer (actual screen size 10×12 cm at 480×640 pixels) to record fire ant walking tracks, with the method developed on Argentine ants (Suckling et al. 2008).

Experiment 1 Point source trail disruption was tested by placing treated (30 µg *Z,E*-α farnesene in 10 µl petroleum ether) or control filter paper (10 µl petroleum ether) within ca. 1 cm of an established trail. The treatment and control solutions were applied to filter paper squares (Whatman No. 1, 1 cm^{2}) by gas tight syringe and allowed to evaporate for ca. 1 min in a fume hood before use. The fume hood was left switched on for the entire experiment to remove any excess pheromone from the laboratory. Furthermore, control papers were tested before treated papers to reduce the likelihood of pheromone contamination. The experiment was repeated four times (*N*=4 colonies). Movies were recorded for 1 min before, and 1 min after, paper squares were placed within 1 cm of an existing trail.

Experiment 2 This experiment aimed to test the effect of trail disruption at two concentrations (solvent control plus 30 or 300 µg *Z,E*-α farnesene), and was repeated four times (*N*=4 colonies), using the same methods as above. Movies were recorded for 1 min before, and up to 10 min after paper squares were placed within 1 cm of an existing trail.

Statistical Analysis Two software approaches were used for track analysis, by instantaneous and continuous tracking. The instantaneous position of individual ants was recorded using MaxTraq v1.92 trial edition (Innovision Systems, Lapeer, MI, USA) (Suckling et al. 2008). The x-y positions of all the ants present were recorded from individual frames at 5 s intervals, as this was sufficient time for the ants to leave the video frame under control conditions, rendering

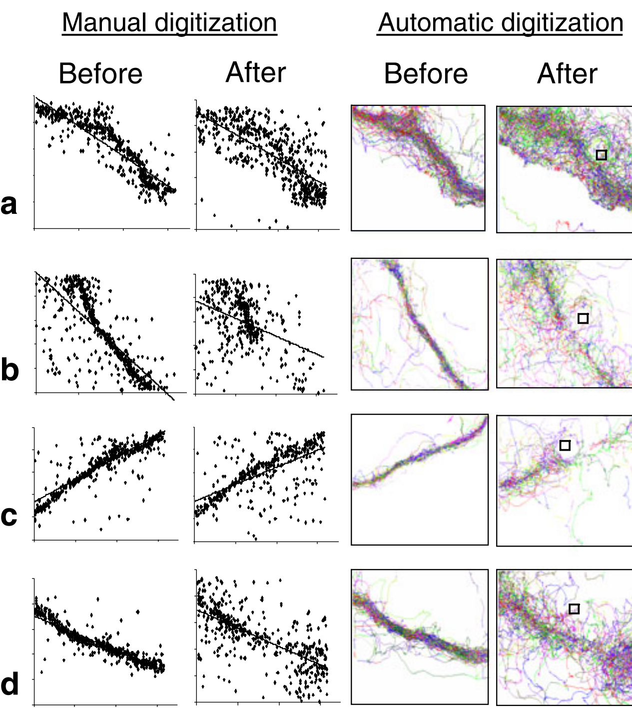

Fig. 1 Superimposed positions of red imported fire ants, *Solenopsis invicta*, in four replicate trails (**a**–**d**), with either manual digitization (left two columns) sampled instantaneously at 5 s intervals from 1 min before and 1 min after treatment, or continuously using automatic digitization (right two columns). The small square shows approximate placing near the ant trail of 1 cm filter paper loaded with 30 µg *Z,E*-α-farnesene. Trail integrity (r^2, calculated from manual digitizations) dropped from the minute before to the minute after in each replicate (**a**: r^2=0.77–0.49, **b**: r^2=0.58–0.16; **c**: r^2=0.72–0.40; **d**: r^2=0.81–0.45)

the individual samples independent. Digitizing required one mouse click per ant, but it was possible to capture the position of every ant in the frame (a labor intensive process), which enabled the determination of the linearity of trails in each frame, by calculation of r^2.

However, it was realized that this could be replaced with an approach that sub-sampled the movements of multiple individual ants, frame by frame, for differences with the preceding reference frame.

Thus, continuous analyses of the majority of ants walking (up to 25 individuals per frame) were conducted after processing, by using novel software that was developed in house with HALCON/C languages interface (MvTech Software GmbH, Munich, Germany, 2009) for the Microsoft Windows operating system. The Multiple Individual Tracking Software enables the implementation of high-speed video tracking systems capable of accurately tracking multiple objects (2–25 insects), at high speeds (>60 frames/sec). It allows for offline processing of digitally recorded videos as well as real-time processing of images from fast video streams (where the video stream does not require storage except as a text file). Identification of the target is based on both the morphological features, and its temporal speed in successive images. It utilizes a subtraction algorithm to construct tracks for each target insect. The target of the previous image is matched with the target of the current image, creating unique motion estimation for each moving object. During this process, any target estimation errors, such as when insects occlude and split, are detected and corrected. Tracking is activated once an insect enters the camera field of view. The insect is detected immediately by the change in the detection modules. While tracking insects, the tracking module keeps looking for new insects entering the field of view. The digitized images recorded per frame as X,Y coordinates for each insect were stored as a text file on the hard disk. Another program, written in Borland Delphi (version 7; Borland Software Corporation, Austin, TX, USA), was used to visualize the tracks and to export the images of resulting tracks as bitmap files. In addition, this program was used to analyze and evaluate the tracks and to calculate movement parameters.

Results

Ant trails showed clear visual evidence of a trail disruption effect well within a minute of exposure to 30 µg *Z,E*-α-

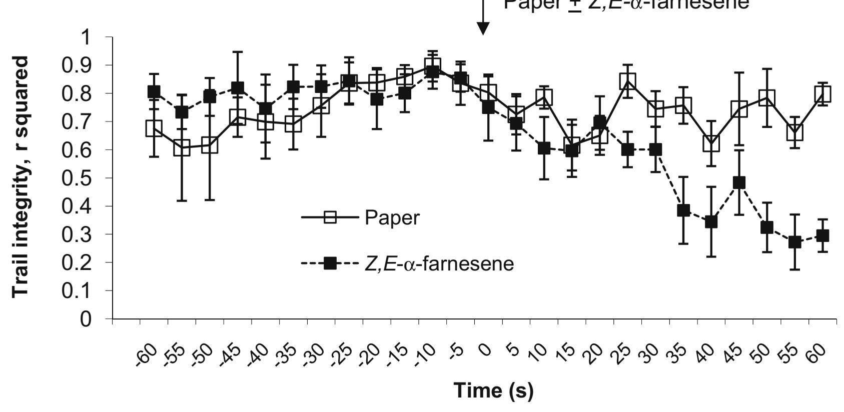

Fig. 2 Red imported fire ant, *Solenopsis invicta,* trail integrity (mean±SEM), r^2, sampled at 5 sec intervals for 1 min before and after introduction of 30 µg *Z,E*-α-farnesene (statistical significance is presented in Table 1)

farnesene presented as a point source on filter paper (supplementary material, downloadable movie of trail disruption and software). Two methods extracted similar behavioral effects. The width of the trail was broadened visibly in the minute after treatment, and the effect was quantified using the trail integrity statistic r^2 (Suckling et al. 2008) derived from locations of ants sampled every 5 sec for a minute before or after presentation of treated paper (Fig. 1). The software using continuous recording of the actual trails of ants showed a similar effect, but in more detail. Random movement away from the previous trail was more evident.

Obvious trails, with significant r^2 values, were evident only before treatment, and after treatment only with solvent controls (Fig. 2). With the trail pheromone treatment, the ants were less able to follow the trail they had sensed moments before, and this was demonstrated by the reduction of the r^2 value after treatment (Fig. 2). The mean (±SEM) values before treatment (r^2=0.75±0.03) were reduced after treatment (r^2=0.48±0.03), compared to the controls that did not change (before r^2=0.75±0.03; after r^2=0.73±0.02). The two-way analysis of variance showed a significant effect from pheromone treatment and time (before and after treatment), as well as an interaction between these variables (Table 1) because of declining trail integrity over time (Fig. 2). A short delay occurred after treatment before the trail showed evidence of disruption as diffusion occurred, so assessment in the first minute is a conservative measure of an effect.

The effect of increasing disruption over time and with an increased concentration of the pheromone is evident in the next experiment (Fig. 3), displayed using the Multiple Individual Track System. When post-treatment recordings of longer duration are examined, the trails show increasing evidence of disruption over time. In the case of experiments with 300 µg loadings of *Z,E*-α-farnesene on filter paper (Fig. 3), the trails appear to literally melt away over time as diffusion spreads the oversupply of trail pheromone over existing trails.

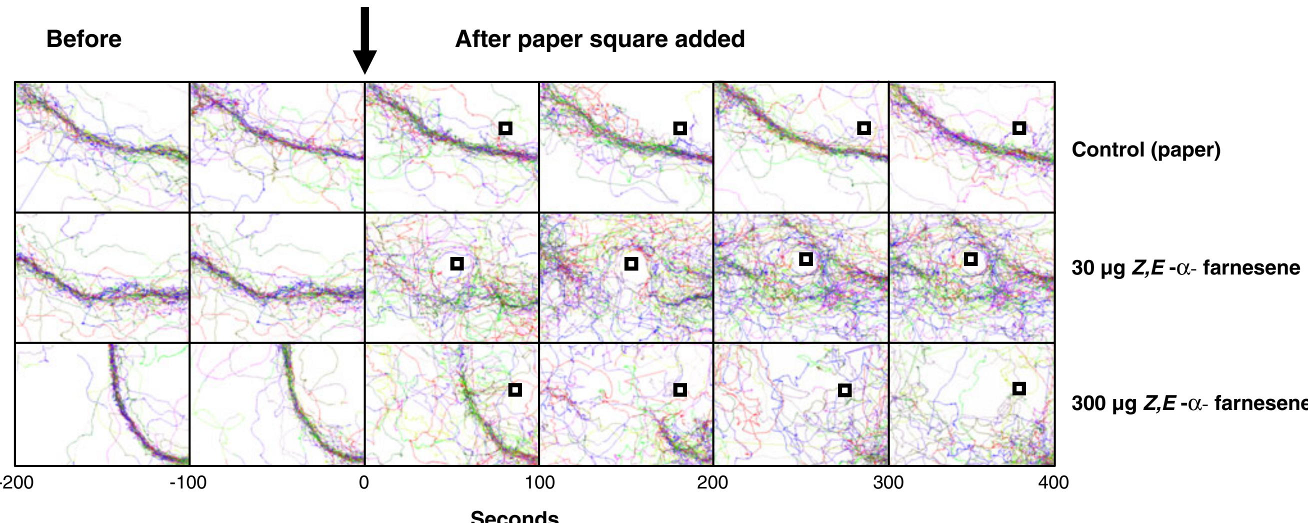

Fig. 3 Trail formation in red imported fire ant, *Solenopsis invicta,* before treatment (-200-0 s) and at 0–400 s after trail disruption, from the addition of an oversupply of trail pheromone *Z,E*-α-farnesene (solvent control, 30 or 300 µg on 1 cm² of filter paper). Walking tracks of ants were recorded by webcam and analyzed by Multiple Individual Tracking Software, written in-house

Discussion

We have demonstrated for the first time that the trail-following behavior of *S. invicta* can be disrupted by an oversupply of the trail pheromone, *Z,E*-α-farnesene. This is the first step in a new line of enquiry against this pest species. The precedent case of trail pheromone disruption in one other species (Argentine ant) has advanced to a formulation lasting up to two weeks in the field under windy conditions, and field tests over several months in a combination treatment with toxic baits as part of the Japanese eradication program at the port of Yokohama (S. Tatsuki pers. comm.). A single point source can be used for demonstration of disruption of the nearest trails (Tatsuki et al. 2005; Suckling et al. 2008), although demonstration of sustained nest level effects is needed (Suckling et al. 2010). The potential to use trail disruption as a management tool or in some circumstances, eradication, against fire ants is a worthy goal, but will require suitable technology to release *Z,E*-α-farnesene or other compounds at an effective rate and cost.

The analysis of ant trail movies into statistical parameters such as r^2 for trail integrity sampled at regular intervals (Suckling et al. 2008) enabled a new approach to measuring the impact of disrupting trailing behavior. The bioassay uses a statistical definition of trail following (r^2), and trail disruption is defined when this statistic becomes insignificant. This offers a number of advantages, including an objective statistical basis and lack of bias as to what constitutes a trail, disrupted or otherwise. However, it is labor intensive. In contrast, the development of software that automatically performs the digitization of multiple individuals and tracks their movements without requiring mouse clicks offers greater digitization speed. These advanced functions expedite recording and analysis of insect behavior, and have enabled our experiments to investigate trail behavior from many individuals quickly.

Trail pheromone disruption of *Solenopsis invicta* warrants further examination, but any eventual use would rely on appropriate technology for delivery of the necessary concentrations, as well as an understanding of the biological implications, if any, of reducing the efficiency and potentially information and energy (food) content of workers returning to the nest. The chemical instability and likely cost of the trail pheromone compounds could prove to be an insurmountable problem to achieving this, although further research may overcome these barriers, particularly since plant-based production via synthase has been established (Green et al. 2007). If this is the case, there could be various ways of using the phenomenon of trail disruption, depending on how well it works and what effect it has on the insects over time. There are also other related ant species which use this compound (Barlin et al. 1976; El-Sayed 2010). It is potentially useful in integrated pest management, for example in combination with poison baits, possibly before baiting treatment to improve bait removal to the nest after starvation, or after insect densities have been lowered by baiting. Trail disruption could prove to be useful in the event of detection of new incursions of this species, for example to island nations (Davis et al. 2001; Henshaw et al. 2005; Chen et al. 2006; Christian 2009), where the prospects of eradication may be greater.

Certainly, there is a high risk of failure in establishing an entirely new pest management tactic against ants based on trail pheromones, but there is also a great reward for success if they can be successfully developed and deployed for these pests. The very low eco-toxicological hazard of these compounds presented in such a low quantity means that they could become acceptable tools for use in sensitive environments, and wherever conventional pesticides are undesirable. We have shown that a trail pheromone compound can locally disrupt *S. invicta* trails, and other active compounds should also be investigated for their potential effects. Trail pheromone disruption against this species will require the development of sustained release formulations to determine if the approach can be made practical in the field.

Deciphering the Chemical Basis of Nestmate Recognition

Abstract Social insects maintain colony cohesion by recognizing and, if necessary, discriminating against conspecifics that are not part of the colony. This recognition ability is encoded by a complex mixture of cuticular hydrocarbons (CHCs), although it is largely unclear how social insects interpret such a multifaceted signal. CHC profiles often contain several series of homologous hydrocarbons, possessing the same methyl branch position but differing in chain length (e.g., 15-methyl-pentatriacontane, 15-methyl-heptatriacontane, 15-methyl-nonatriacontane). Recent studies have revealed that within species these homologs can occur in correlated concentrations. In such cases, single compounds may convey the same information as the homologs. In this study, we used behavioral bioassays to explore how social insects perceive and interpret different hydrocarbons. We tested the aggressive response of Argentine ants, *Linepithema humile*, toward nest-mate CHC profiles that were augmented with one of eight synthetic hydrocarbons that differed in branch position, chain length, or both. We found that Argentine ants showed similar levels of aggression toward nest-mate CHC profiles augmented with compounds that had the same branch position but differed in chain length. Conversely, Argentine ants displayed different levels of aggression toward nest-mate CHC profiles augmented with compounds that had different branch positions but the same chain length. While this was true in almost all cases, one CHC we tested elicited a greater aggressive response than its homologs. Interestingly, this was the only compound that did not occur naturally in correlated concentrations with its homologs in CHC profiles. Combined, these data suggest that CHCs of a homologous series elicit the same aggressive response because they convey the same information, rather than Argentine ants being unable to discriminate between different homologs. This study contributes to our understanding of the chemical basis of nestmate recognition by showing that, similar to spoken language, the chemical language of social insects contains "synonyms," chemicals that differ in structure, but not meaning.

Key Words Nest-mate recognition · Cuticular hydrocarbons · Argentine ants · *Linepithema humile*

Introduction

Recognition of group members is considered a key innovation in the evolution of sociality, as the direct and indirect fitness benefits of social living can be gained only if altruistic behaviors are directed toward the appropriate recipients. Some of the fundamental contributions to our understanding of social evolution, and the underlying social recognition systems, have come from research on social insects. Social insects have evolved a highly sophisticated recognition system that allows individuals to identify a non-colony mate among large numbers of colony mates. These insects are able to achieve such precise discrimination with a single sweep of the antenna across the cuticle of another

individual. The cues used for nest-mate recognition are typically hydrocarbons on the exoskeleton of workers (Thomas et al. 1999; Wagner et al. 2000; Torres et al. 2007). These cuticular hydrocarbons (CHCs) usually are a complex mixture of alkanes, alkenes, and methyl-branched alkanes (Martin and Drijfhout 2009b). The number of CHCs that have been recorded for an ant species ranges from as few as 8, in *Formica exsecta* (Martin and Drijfhout 2009b), to as many as 110, in *Myrmica incompleta* (Elmes et al. 2002). In total, almost 1,000 different CHCs have been described for ants (Martin and Drijfhout 2009b). CHC profiles usually are colony specific, with colonies having different relative concentrations of compounds (Nielsen et al. 1999; Tentschert et al. 2002; van Wilgenburg et al. 2006; Foitzik et al. 2007; Martin et al. 2008a; Brandt et al. 2009). Studies have shown that there is a positive relationship between the level of aggression among colonies and their differences in CHC profiles (Suarez et al. 2002; Zweden et al. 2009). Moreover, behavioral studies have shown that workers often act aggressively toward dummies or workers that have been treated with CHCs of non-colony mates (Thomas et al. 1999; Wagner et al. 2000; Akino et al. 2004; Ozaki et al. 2005; Torres et al. 2007; Martin et al. 2008a). However, little is known about the mechanisms that allow individual social insects to discriminate between the complex cocktails of chemicals emitted by members of their own colony versus those of other colonies.

The primary function of CHCs is to prevent water loss, with not all CHCs functioning for recognition (Hadley 1984; Singer 1998). For example, it appears that methyl-branched alkanes and alkenes, but not *n*-alkanes, are used as nest-mate recognition cues (Bonavita-Cougourdan et al. 1987; Dani et al. 2005; Lucas et al. 2005; Martin et al. 2008b; but see Greene and Gordon 2007). Additionally, some cues may be used for intra-colony recognition. Workers performing different tasks may have different CHC profiles (Kaib et al. 2000; Wagner et al. 2001; Martin and Drijfhout 2009c), and can detect and respond to these intra-colony differences (Greene and Gordon 2003). Finally, not all compounds within a profile may function independently as recognition cues. A recent study of *Formica* ants and *Vespa* hornets has shown that CHC profiles are a mixture of correlated and non-correlated compounds (Martin et al. 2008a; Martin and Drijfhout 2009b). Within a CHC profile, many of the hydrocarbons are structurally related, being part of a homologous series, in which all members possess the same methyl group or double bond, with a backbone that varies in length by two carbons [e.g., 15-methyl-pentatriacontane (15-MeC35), 15-methyl-heptatriacontane (15-MeC37), 15-methyl-nonatriacontane (15-MeC39)]. The relative amounts of compounds within a homologous series often are constant, both within colonies (Martin et al. 2008a; Martin and Drijfhout 2009b) and species (Martin and Drijfhout 2009b). Consequently, a single compound may provide the same information as its homologs.

It also is possible that social insects may not be able to distinguish between structurally related chemicals. Several studies of honey bees have shown that workers are able to discriminate compounds that differ in functional group better than those that differ in carbon chain length, especially when the latter differ by only a few carbons (Vareschi 1971; Getz and Smith 1990; Chaline et al. 2005; Guerrieri et al. 2005). Taken together, these finding suggest that the chemical basis of nest-mate recognition may be simpler than it appears, and that specific features of a few key hydrocarbons may allow social insects to identify colony mates. If so, we would predict that homologous CHCs that are correlated in abundance, and thus contain redundant information, should elicit similar behavioral responses.

The aim of this study was to investigate the aggressive response to homologous CHCs by using the Argentine ant, *Linepithema humile*, as a model species. The Argentine ant, native to South America, is an introduced and invasive species in many temperate regions of the world (Suarez et al. 2001; Tsutsui and Case 2001). Although native populations display intraspecific (inter-colonial) aggression across spatial scales, ranging from tens to hundreds of meters (Suarez et al. 1999; Tsutsui et al. 2000; Pedersen et al. 2006), introduced populations are characterized by the formation of much larger supercolonies, up to several thousand kilometers long (Suarez et al. 1999; Tsutsui et al. 2000; Giraud et al. 2002; Corin et al. 2007; Bjorkman-Chiswell et al. 2008; Sunamura et al. 2009). This unicolonial structure is one of the keys to the success of introduced populations (Holway et al. 1998).

We showed previously that Argentine ants can perceive and respond aggressively to colony mates treated with a single hydrocarbon, and the intensity of the response varies from colony to colony (Brandt et al. 2009). We also showed that Argentine ants show a higher aggressive response when several different hydrocarbons are applied simultaneously. In this study, we tested whether compounds within a homologous series elicit correlated nest-mate recognition responses. For this, we conducted a series of field-based bioassays, in which we compared the behavioral response of workers to hydrocarbon extracts augmented with one each of eight synthetic hydrocarbons that were either homologs or non-homologs of each other. In addition, we investigated the relationships among these compounds in CHC profiles within and among 14 Argentine ant colonies.

Methods and Materials

For the behavioral assays, we used Argentine ants from three supercolonies in California: Berkeley (B), Lake

Hodges (LH), and Cottonwood (CW). These supercolonies are behaviorally and genetically distinct from each other (Tsutsui et al. 2000, 2003). To test whether the hydrocarbons of a homologous series triggered similar responses, we tested the behavior of workers to filter papers treated with hydrocarbon extracts of colony mates, augmented with one of eight synthetic HCs (see hydrocarbon synthesis and behavioral assays below). We tested two homologous pairs of methyl-branched alkanes [15-MeC35 and 15-MeC37; 17-methyl-pentatriacontane (17-MeC35) and 17-methyl-heptatriacontane (17-MeC37)], and one methyl-branched alkane with a different methyl branch position [19-methyl-heptatriacontane (19-MeC37]. We also tested three homologous tri-methyl alkanes [5,3,17-trimethyl-tritriacontane (5,13,17-triMeC33), 5,13,17-trimethyl-pentatriacontane (5,13,17-triMeC35), and 5,13,17-trimethyl-heptatriacontane (5,13,17-triMeC37)]. All behavioral assays were conducted in the field. For controls, we tested the behavioral response of Argentine ant workers to filter papers treated with CHCs of their own colony mates (negative control) or of workers from a foreign colony (positive control).

Synthesis of Monomethyl Hydrocarbon Nestmate Recognition Cues We synthesized the mono-methyl hydrocarbons **1–5** [15-MeC35 (**1**), 17-MeC35 (**2**), 15-MeC37 (**3**), 17-MeC37 (**4**), and 19-MeC37 (**5**)] according to the schemes in Figs. 1 and 2 (see Table 1 for yields). 2-Ketone precursors **6a–b** were reacted with α-Grignard reagents **7a–c** of desired length to produce 3° alcohols **8a–d**, which were separated from hydrocarbon byproducts by silica column chromatography. Dehydration of **8a–d** with catalytic TsOH created mixtures of isomers of alkenes **9a–d**, which were purified by a second silica column. The alkenes **9a–d** were subsequently hydrogenated with catalytic Pd/C under hydrogen (1 atm) to yield the desired mono-methyl hydrocarbons **1–4**.

We began synthesis of the symmetrical hydrocarbon **5** by the double addition of an α-C18-Grignard reagent **7a** to ethyl acetate (**10**) to form 3° alcohol **8e**. Dehydration of **8e** with catalytic TsOH produced a mixture of isomers **9e.** Both products **8e** and **9e** were purified by silica gel chromatography from hydrocarbon byproducts. The alkene **9e** was hydrogenated with catalytic Pd/C under hydrogen to yield hydrocarbon **5**.

Products (and purity) were characterized by NMR and gas chromatography-mass spectrometry (GC-MS). NMR was not particularly useful to confirm the exact structures, since there were so many similar carbons and protons in the compounds. The alcohol products **8a–e** appeared as a single peak on GC, and the diagnostic ion as M^+-H_2O in the mass spectrum. The alkene products **9a–e** appeared as two peaks on GC, with the M^+ ion diagnostic in the mass spectrum and a ^{1}H NMR multiplet at ~5 ppm corresponding to the expected alkene protons. We observed the final products **1**–**5** as single peaks in the GC with $(M\text{-}Me)^+$ as one of the main fragments in the mass spectrum. A $(M\text{-}Me)^+$ peak is a common fragment of saturated linear hydrocarbons. Other main diagnostic mass spectral fragments arose from fragmentation at the tertiary carbon. The ^{1}H NMR spectrum, although not diagnostic, supported the structure of the final products.

Synthesis of Tri-methyl Hydrocarbon Nestmate Recognition Cues We synthesized the tri-methyl compounds **11**, **12,** and **13** [5,13,17-triMeC33 (**11**), 5,13,17-triMeC35 (**12**), and 5,13,17-triMeC37 (**13**)] by sequential Grignard reactions (Figs. 3, 4). Treatment of 8-bromooctanoic acid (**14**) with two equivalents of methyl lithium provided methyl ketone **15**, which was converted to ketal **16** with TsOH and ethylene glycol. Grignard reagent, derived from bromo ketal **16**, was added to 2-hexanone (**17**) to produce tertiary alcohol **18**. Alcohol **18** was dehydrated with TsOH and, following a H_2O work up, gave the deprotected methyl ketone **19**. Addition of the Grignard reagent, derived from protected ketal **20** to ketone **19**, produced alcohol **21**. The 5,13,17-trimethyl core **22** was produced following dehydration, and subsequent deprotection of alcohol **21**. To eliminate the possibility of cyclization, the intermediate **22**

Me–C(=O)–OEt (**10**) —(BrMg—R, THF; **7a** $R = (CH_2)_{17}Me$)→ R–C(Me)(OH)–R (**8e**) —(TsOH, benzene)→ **9e** —(Pd/C, Et_2O)→ **5**

Table 1 Summary of reaction yields for mono-methyl hydrocarbons. For identity reactants see Fig. 1

Product	Reactants	8 a–d (%)	9 a–d (%)	Product (%)
15-methyl-pentatriacontane	6a+7b	61	89	89
17-methyl-pentatriacontane	6b+7a	66	65	87
15-methyl-heptatriacontane	6a+7c	84	91	97
17-methyl-heptatriacontane	6b+7b	87	91	93
19-methyl-heptatriacontane	10+7a+7a	38	47	89

was reacted with Wittig reagent **23a–c** to form triene **24a–c**. The hydrogenation of **24a–c**, with Pd/C H_2 at elevated pressure, produced the saturated alkanes **11**–**13**. The structures of hydrocarbons **11**–**13** were confirmed by the fragmentation patterns of the mass spectra. The tri-methyl compounds produced were a mixture of the chiral forms.

Preparation of Filter Paper To prepare the treatment solution for the filter papers used in the behavioral assays, we extracted the CHCs of ca 8000 frozen, field-collected workers by immersing the ants in n-hexane for 10 min. Hydrocarbons were separated from polar surface lipids by running samples through a Pasteur pipette filled with silica gel. The eluate was divided into 10 aliquots, the solvent evaporated, and the extract reconstituted in 267 µl hexane. To each of the vials we added either 218 µl of a synthetic hydrocarbon (1 mg/ml hexane) or 218 µl of hexane (control). The amount of synthetic hydrocarbon solution used was a 2–7-fold increase of that in the CHC profile (Brandt et al, unpublished data). Next, we added 9 µl of treatment (about 15 ant equivalents) or control solution to each filter paper (6 x 4 mm, with three slits). We allowed the hexane to evaporate, and stored the filter papers in the freezer (−20°C) until used in the behavioral assays.

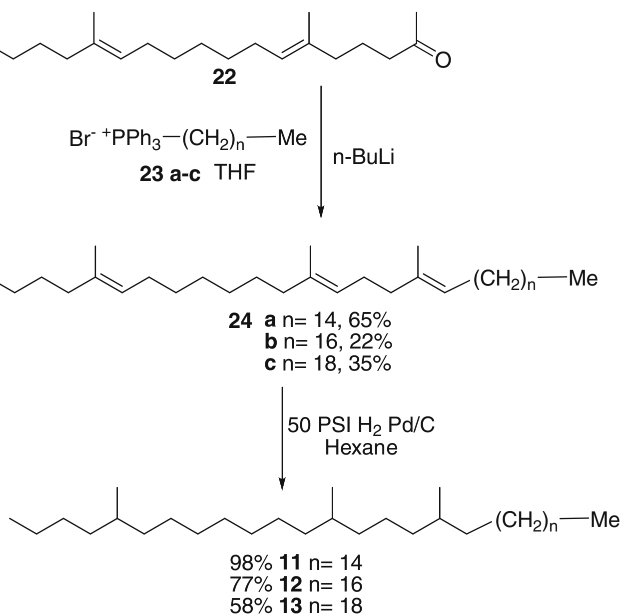

Fig. 4 Synthesis of hydrocarbons 5,13,17-trimethyl tritriacontane (**11**), 5,13,17-trimethyl pentatriacontane (**12**) and 5,13,17-trimethyl heptatriacontane (**13**)

Behavioral Assays Seven Argentine ant workers were collected from a foraging trail, and their responses to a filter paper treatment recorded for 3 min. in a 35 mm, Fluon-coated Petri dish. We scored behavioral assays as either aggressive (flaring of mandibles, biting or grabbing of the filter paper) or non-aggressive. We repeated this 45 times for each treatment, and tested 10 treatments, for colonies LH and LP, and nine treatments for colony CW (a total of 1,305 trials). All behavioral assays were conducted blind with regard to the treatment.

Statistical analyses were carried out using Genstat (version 6). We used generalized linear mixed models (GLMM), with the presence or absence of aggression as the

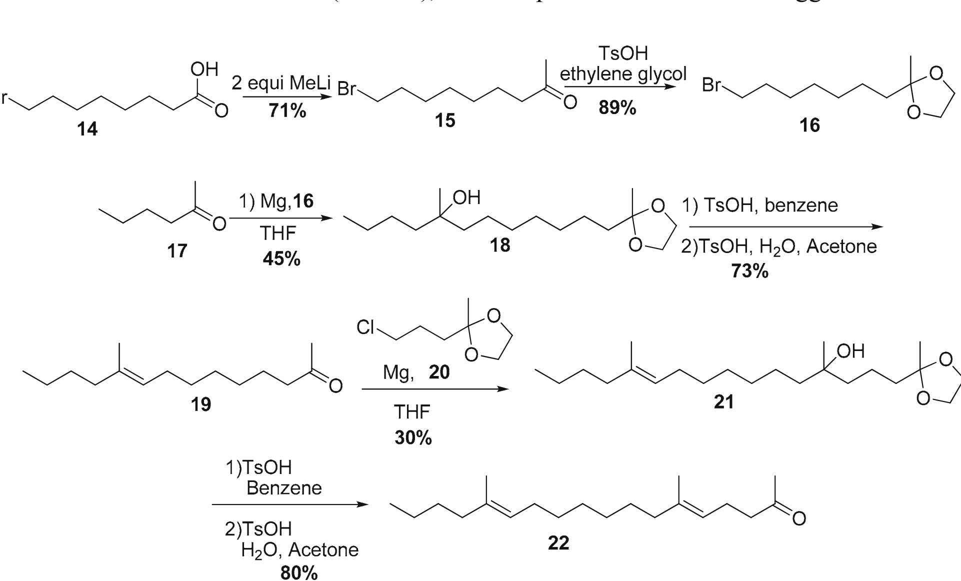

Fig. 3 Synthesis of the 5,13,17-trimethyl core compounds (**22**)

response variable and colony identity as a random factor, to accommodate repeated measures of each colony.

Chemical Analysis Cuticular lipids, from at least 12 workers from each colony, were extracted by immersing an individual ant in 45 μl of hexane for 10 min, and the individual's CHC profile analyzed by GC–MS. For quantification, 1 μl of each sample was injected splitless (temperature 250°C) into an Agilent 7890 GC equipped with an HP5-MS capillary column (30 m×250 mm× 0.25 μm, Agilent Technologies). Helium, at 1 $ml.min^{-1}$, was the carrier gas, and the column oven was programmed at 80°C, for 2 min., then to 270°C at $20°C.min^{-1}$, then to 310°C at $3°C.min^{-1}$. Electron impact mass spectra were obtained with an ionization voltage of 70 eV and a source temperature set to 250°C. Chromatograms were integrated using the program ACD SpecManager (version 10.0, Advanced Chemistry Development), and relative proportions of each peak area, to that of the total sample, were calculated. Selected ion monitoring was used to record m/z 99, 113, and 127. Full mass spectra of all the peaks in the cuticular extracts from a pool of 50 ants of each colony also were recorded, enabling characterization of the compounds based on diagnostic ions and Kovat's indices.

Inter- and intra-colony ratios (relative amounts) of the compounds used in the behavioral assays were based on quantitative analyses of individuals of 14 colonies, three of which were used in our study and the others published in Brandt et al (2009). To avoid pseudo-replication we included colonies only that are chemically and genetically distinct from each other. Data were analysed using SPSS 12.0.

Methyl-branched hydrocarbons with the same carbon-chain backbone often co-elute on a non-polar column as a single peak. While others have determined the ratios of the different hydrocarbons within a given peak by the ratios of the respective diagnostic ions (Martin et al. 2008a), this method failed to provide consistent results in our study. Therefore, we correlated relative amounts of whole peaks (i.e., all the co-eluting compounds) with other whole peaks.

Results

Synthetic Hydrocarbon Experiment In general, workers frequently were more aggressive ($F_{1,1164}$=14.68, P<0.001) to filter papers augmented with a single synthetic hydrocarbon than to filter papers treated only with nest mate hydrocarbons (negative control), but were less frequently aggressive ($F_{1,1164}$=5.76, P=0.017) to filter papers augmented with synthetic hydrocarbons than to filter papers treated with non-colony mate hydrocarbons (i.e., positive control; Fig. 5). Workers showed similar frequencies of aggression to each of the compounds in the respective pairs of homologous monomethyl hydrocarbons (i.e., to 15-MeC35 and 15-MeC37, and to 17-MeC35 and 17-MeC37). The location of the methyl branch of a monomethyl alkane had an effect on the frequency of aggression of workers, but carbon chain did not (Fig. 5; branch position, $F_{2,621}$=11.60, P<0.001, chain length $F_{1,621}$=1.49, P=0.222). In contrast, workers showed different frequencies of aggression to filter papers treated with the three homologous trimethyl hydrocarbons; workers were more often aggressive to filter papers treated with 5,13,17-triMeC33 than to those treated with 5,13,17-triMeC35 or 5,13,17-triMeC37. For these compounds, there was an effect of chain length ($F_{2,402}$=4.18, P=0.016).

Relationship Among Compounds Monomethyl C35 and C37 peaks were correlated both across and within colonies (Fig. 6, Table 2). Similarly, 5,13,17-triMeC35 was highly correlated with 5,13,17-triMeC37 across, but to a lesser extent within, colonies (Fig. 6, Table 2). There was a weaker correlation between the 5,13,17-triMeC33 and the 5,13,17-triMeC35 peaks both across and within colonies. The 5,13,17-triMeC33 and the 5,13,17-triMeC37 peaks were not correlated across or within colonies (Fig. 6, Table 2).

Discussion

The recognition code of social insects generally is embedded in a complex mixture of chemicals. This study provides a significant step forward in the understanding of the

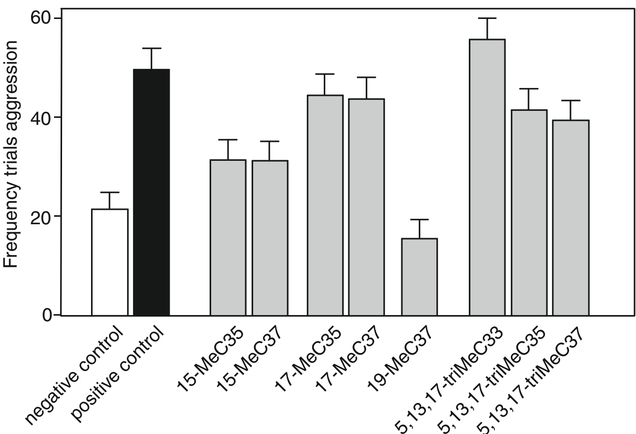

Fig. 5 Mean frequencies of aggression (±SE) exhibited by *Linepithema humile* workers across colonies to filter papers treated with cuticular hydrocarbons of the same colony augmented with a synthetic hydrocarbon (*grey bars*) and filter paper controls (*black* = cuticular hydrocarbons of a foreign colony only, and *white* = cuticular hydrocarbons of the same colony only). 13-methyl-pentatriacontane (13-MeC35), 15-methyl-pentatriacontane (15-MeC35), 17-methyl-pentatriacontane (17-MeC35), 13-methyl-heptatriacontane (13-MeC37), 15-methyl-heptatriacontane (15-MeC37), 17-methyl-heptatriacontane (17-MeC37), 5,3,17-trimethyl-tritriacontane (5,13,17-triMeC33), 5,13,17-trimethyl-pentatriacontane (5,13,17-triMeC35), and 5,13,17-trimethyl-heptatriacontane (5,13,17-triMeC37)

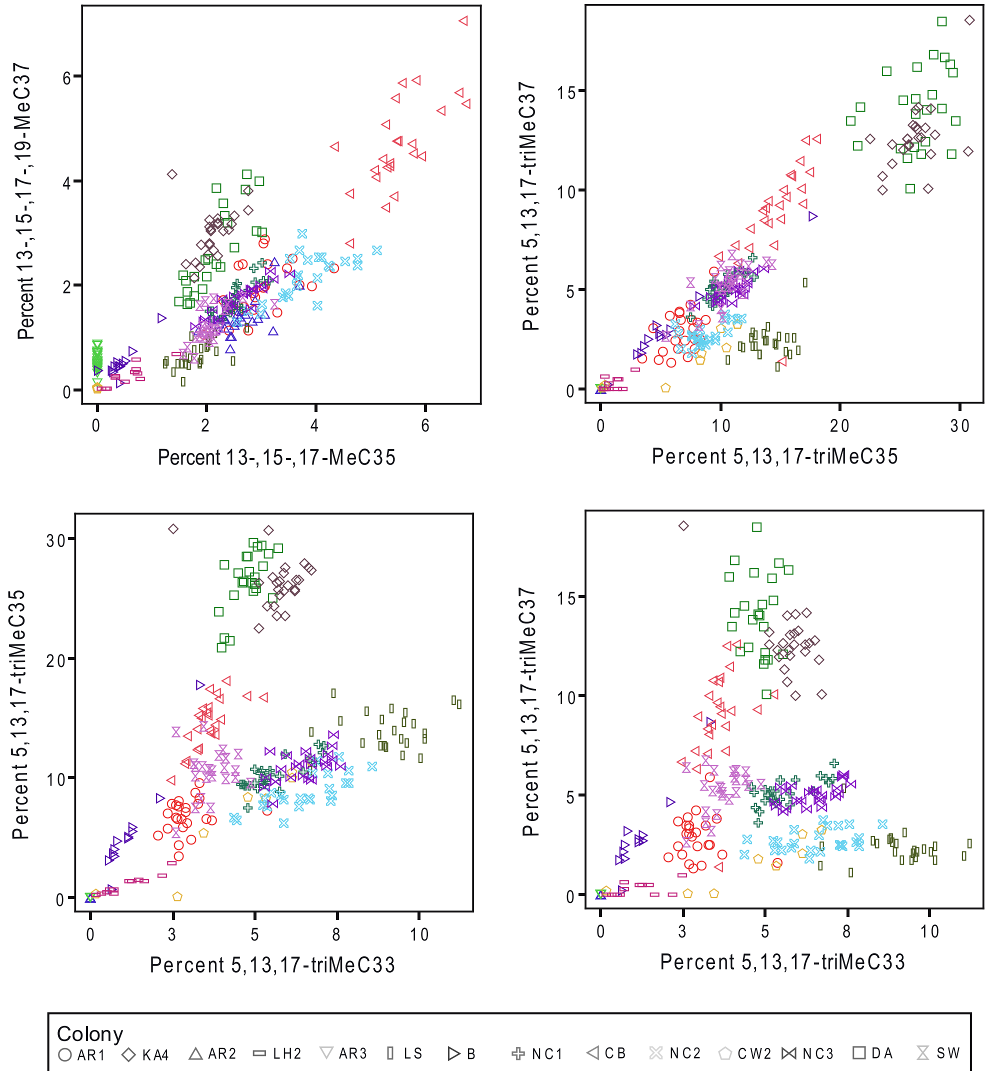

Fig. 6 Correlations between relative proportions of hydrocarbon peaks (consisting of co-eluting compounds) within cuticular hydrocarbon profiles of *Linepithema humile*. Distinct supercolonies are encoded for individuals within the same supercolony. Sampling locations and abbreviations for supercolonies are described in the methods and in Brandt et al. (2009). 13-,15-,17-MeC35 = total of 13-methyl-pentatriacontane, 15-methyl-pentatriacontane, and 17-methyl-pentatriacontane; 13-,15-,17-MeC37 = total of 13-methyl-heptatriacontane, 15-methyl-heptatriacontane, and 17-methyl-heptatriacontane; 5,13,17-triMeC33 = 5,3,17-trimethyl-tritriacontane; 5,13,17-triMeC35 = 5,13,17-trimethyl-pentatriacontane; 5,13,17-triMeC37 = 5,13,17-trimethyl-heptatriacontane

chemical basis of nest mate recognition by suggesting that, similar to spoken language, the chemical language of social insects contains "synonyms": chemicals that differ in structure, but are interpreted as being equivalent.

In general, Argentine ants showed similar levels of aggression to nest-mate CHC profiles augmented with compounds that differed in chain length but with the same methyl-branch position. There are at least two possible explanations for this. First, ants may not be able to discriminate among roughly similar homologs. It has been shown that honey bees often generalize odors with the same functional group, and that the ability to discriminate among compounds decreases with decreasing differences in chain length and increasing chain length (Vareschi 1971; Guerrieri et al. 2005). We tested compounds of very long carbon-chain length (33, 35, and 37), differing only by two or four carbons. Thus, it is possible that Argentine ants respond similarly to these homologs because they perceive them as

Table 2 Correlations (r^2) between relative amounts of hydrocarbons present in the cuticular hydrocarbon profile of *Linepithema humile*

Compounds[a]	Between colonies	Within colonies +/− s.d.
13-,15-,17-MeC35 vs. 13-,15-,17-,19-MeC37	r^2=0.863, P<0.001	r^2=0.71 +/− 0.16
5,13,17-triMeC35 vs. 5,13,17-triMeC37	r^2=0.943, P<0.001	r^2=0.63 +/− 0.20
5,13,17-triMeC33 vs. 5,13,17-triMeC37	r^2=0.375, P=0.187	r^2=0.30 +/− 0.48

[a] 13-methyl-pentatriacontane (13-MeC35), 15-methyl-pentatriacontane (15-MeC35), 17-methyl-pentatriacontane (17-MeC35), 13-methyl-heptatriacontane (13-MeC37), 15-methyl-heptatriacontane (15-MeC37), 17-methyl-heptatriacontane (17-MeC37), 5,3,17-trimethyl-tritriacontane (5,13,17-triMeC33), 5,13,17-trimethyl-pentatriacontane (5,13,17-triMeC35), and 5,13,17-trimethyl-heptatriacontane (5,13,17-triMeC37)

the same compound. Alternatively, homologous CHCs may elicit the same aggressive response because they convey the same information. The data from our and other studies (Martin et al. 2008a; Martin and Drijfhout 2009b) show that homologs often occur in concentrations correlated within the CHC profile; colonies or individuals that produce relatively high or low concentrations of one compound also produce relatively high or low concentrations of a homolog. Increasing the concentration of one compound within the CHC profile may thus change the profile to a degree similar to increasing the concentration of the homolog. Although the exact biosynthetic mechanisms that regulate the number and position of methyl branches are unknown (Howard and Blomquist 2005), it has been suggested that amounts of homologous CHCs are correlated because they share a biosynthetic pathway (Martin and Drijfhout 2009b). However, we found that the relative amount of one of the compounds did not correlate with the amounts of its homologs; the amount of 5,13,17-triMeC33 was only weakly correlated with homologous 5,13,17-triMeC35, and not at all with 5,13,17-triMeC37. Interestingly, this lack of correlation was matched by responses to these compounds; workers were more frequently aggressive to nest-mate CHC profiles augmented with 5,13,17-triMeC33 than to those augmented with 5,13,17-triMeC35 or 5,13,17-triMeC37. Thus, it appears that the amounts of some homologous CHCs are not strictly related biosynthetically, and that Argentine ants are able to distinguish between certain homologs of similar carbon length.

In spite of this, our data show that individual compounds within a profile do not necessarily function as independent recognition cues, but rather that groups of homologs may do so. Consequently, the diversity of recognition cues likely may be far smaller than the number of CHCs in a profile. Studies on colony-cue recognition by social insects typically perform statistical tests, such as discriminate and principal component analysis, using all the CHCs in a profile as variables (Nielsen et al. 1999; Tentschert et al. 2002; van Wilgenburg et al. 2006; Foitzik et al. 2007). Our findings, as well as those of other studies (Martin and Drijfhout 2009a), indicate that it may be more appropriate to treat highly correlated compounds as a single variable. Moreover, when testing the function of individual CHCs in colony recognition, specificity of response may be elucidated more readily by testing non-homologous CHCs.

The evolution of complex signals, such as CHC profiles, can be driven by the value of providing additional and more reliable information. However, signal evolution is expected to be constrained by the interaction of physiological factors and the chemoreception system. Ants may not have evolved additional pathways that allow for variation in concentration among homologous CHCs because they either cannot detect or generate this type of variation.

Abstract Mate finding in many spider species is mediated, at least in part, by chemical cues. Although few have been characterized, most spider sex pheromones seem to be associated with the silk threads of adult females, attracting and/or triggering sexual behaviors in males. *Schizocosa malitiosa* (Araneae: Lycosidae) is a wolf spider common in dry environments in Southern Uruguay. Here, we report evidence for the occurrence of a female sex pheromone in the silk of virgin *S. malitiosa* females. The pheromone elicits typical courtship displays by conspecific males (palpal drumming and leg shaking), when it is applied to an artificial substrate. We also showed that this pheromone is quickly inactivated under field conditions, possibly due to the effect of dew, and that it is readily extracted from the silk by water, which renders the silk threads inactive. Preliminary chemical analyses by mass spectrometry suggest that the pheromone is a low molecular weight, highly oxygenated polar compound, present in a high concentration only in older virgin females. Quick inactivation in the field of the pheromone would allow males to discriminate between recent and old cues, thus facilitating mate searching and sexual meeting, by preventing males from following old cues for wandering females that could be distant in space and/or time.

Introduction

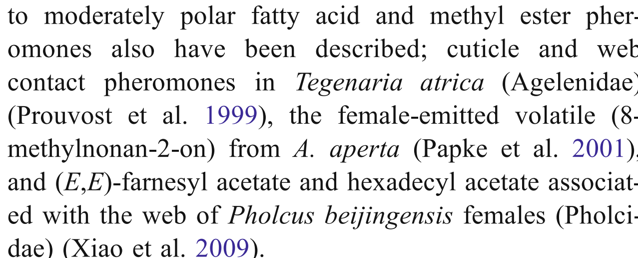
Sex pheromones are widespread chemical substances involved in sexual communication, sex recognition, and species-specific recognition (Wyatt 2003). In spiders, knowledge of their action is limited mainly to inferences from behavioral observation (Gaskett 2007). There is evidence for volatile pheromones in spiders (Olive 1982; Riechert and Singer 1995; Searcy et al. 1999; Gaskett et al. 2004; Aisenberg et al. 2010), and one such pheromone has been characterized chemically in *Agenelopsis aperta* (Agelenidae) (Papke et al. 2001). However, most studies involve sex pheromones associated with the web or draglines released by the females during locomotion (Tietjen and Rovner 1982; Schulz 2004; Huber 2005; Gaskett 2007). There also is indirect evidence for the occurrence of sex pheromones, mainly descriptions of courtship behaviors observed when males are placed on a substrate previously exposed to a conspecific female (Hegdekar and Dondale 1969; Tietjen

1977, 1979; Rypstra et al. 2003; Roberts and Uetz 2005; Baruffaldi and Costa 2010). Other properties of the female silk threads, however, such as the mechanical or physical characteristics of its surface, may provide males with information about the species identity and/or female mating status, thus eliciting sexual behavior (Anderson and Morse 2001; Schulz 2004; Annes and Morse 2006).

To establish the presence of a sex pheromone associated with silk threads, and exclude the possibility of tactile cues, one must: 1) show that males sexually respond to untreated silk threads in the absence of a female; 2) extract the chemical signal from the silk thread; 3) show that activity is lost from washed silk threads; and 4) recover male sexual response once the solvent from an extract is evaporated from an inactive substrate (Schulz 2004). Some researchers have obtained clear responses when they expose male spiders to female silk extracts (Roberts and Uetz 2004; Stoltz et al. 2007; Perampaladas et al. 2008), and often the loss of a male response when female silk threads are washed with solvent has been reported (Hegdekar and Dondale 1969; Dondale and Hegdekar 1973; Lizotte and Rovner 1989). Solvent treatment of the silk, however, may alter a variety of its physicochemical surface properties, which may in turn affect the response of males (Schulz 1999; Shao and Vollrath 1999).

Extraction of a chemical signal from its natural support, the silk thread, and the recovery of its attractive properties from the extract is not only a good indicator of the presence of a pheromone, but also may provide hints about the chemical characteristics of the semiochemical. The solvent, for example, provides information about the polarity of the pheromone (Schulz 2004). Similarly, the persistence of the biological activity of a pheromone once it has been extracted may be studied as a function of time, and this may correlate with structural features that affect the stability of the compound in a specific solvent. When the solvent is water, experimental data on the persistence of the pheromone may bear ecological and adaptive significance. Information about the persistence of chemical signals under natural conditions provides fundamental data for understanding how males respond to such cues over time in the field, and for deducing the sexual strategies involved in mate location for males and females.

Solvents used for extraction of spider pheromones from silk have varied from polar (water, methanol, ethanol) to medium or non-polar (ether, hexane). Most studies have reported polar solvents as more suitable (Gaskett 2007), and in fact the two characterized contact pheromones associated with female web threads from the linyphiid, *Linyphia tringularis* (Schulz and Toft 1993), and the ctenid, *Cupiennius salei* (Papke et al. 2000), are both polar compounds bearing free hydroxyl and carboxyl groups, and therefore readily soluble in methanol or water. Nonetheless, non-polar to moderately polar fatty acid and methyl ester pheromones also have been described; cuticle and web contact pheromones in *Tegenaria atrica* (Agelenidae) (Prouvost et al. 1999), the female-emitted volatile (8-methylnonan-2-on) from *A. aperta* (Papke et al. 2001), and (*E*,*E*)-farnesyl acetate and hexadecyl acetate associated with the web of *Pholcus beijingensis* females (Pholcidae) (Xiao et al. 2009).



Schizocosa malitiosa (Araneae: Lycosidae) is a wandering wolf spider that occurs at high densities on the Southern coasts of Uruguay. Females are frequent throughout the year, showing a biannual life cycle, whereas males mainly reach adulthood in autumn, then search for females (Costa 1991). Male density decreases during winter and remains low thereafter, suggesting mortality is high at the end of the winter. Mate attraction is accomplished by the presence of silk from a female, which elicits male searching behavior (slow locomotory movements contacting the substrate with the palpal cymbium), as well as courtship displays (Costa 1975; Costa and González 1986). Courtship in *S. malitiosa* includes visual (foreleg shaking), vibratory (palpal drumming), and tactile (touching and mounting attempts) signals (Costa 1975). Males can assess the reproductive status of females by putative contact semiochemicals on their silk (Baruffaldi and Costa 2010). Aisenberg and Costa (2005) showed that mated females of *S. malitiosa* are partially reluctant to remate. González and Costa (2008) found that this reluctance is acquired immediately after mating, and persists for at least 1 month under laboratory conditions. In experiments with silk from females of different ages, mating status, and egg-sac occurrence, males displayed the most intense courtship towards silk threads of older virgin females (20–40 days after last molt) (Baruffaldi and Costa 2010).

Here, we report evidence of the presence of a female sex pheromone in the silk threads of *Schizocosa malitiosa*, including a preliminary structural study based on mass spectrometry of female silk extracts. In addition, we report a study of pheromone persistence under laboratory and field conditions.

Methods and Materials

Spider Collection and Maintenance Seventy sub-adult females and 130 sub-adult males of *S. malitiosa* were collected in Marindia (34° 46′ 49.9″ S, 55° 49′ 34.1″ W), Canelones, Uruguay, from March to August of 2007 and 2008. They were individually housed in plastic Petri dishes (9.0×5 cm), each with a moistened cotton ball. Spiders were fed *ad libitum* with *Tenebrio molitor* larvae (Coleoptera: Tenebrionidae). To accelerate their development, sub-adults were kept in a warmed room (24.2±1.0°C; mean±SD; range: 21–27°C) until they molted into adults. Molting was

checked daily, and maturity was determined by observing male and female genitalia under a dissecting microscope. Adults were maintained at room temperature (20.1±4.2°C, range: 11–26°C). Males were used for experiments 7 d after their molting to adulthood, and were randomly assigned to a treatment. Females were used 20 d after molting, as previous results indicated that the silk threads of older females elicited higher male sexual response (Baruffaldi and Costa 2010). Voucher specimens were deposited in the arachnological collection of Facultad de Ciencias, Universidad de la República, Montevideo, Uruguay.

Silk Collection Silk for the pheromone persistence and solvent-extraction experiments was obtained from 20 individual virgin females placed in cylindrical plastic containers (9 cm diam × 5 cm height). The substrate was a cardboard disc (9 cm diam) covered with gauze; four wooden toothpicks were affixed vertically onto the cardboard, forming a square. Two centimeters were left between the toothpicks and the container wall, so as to allow females to entangle their silk around the toothpick bases. After 48 h, the spiders were removed, and the gauze (with the silk) was lifted off the toothpicks.

Silk for chemical analysis and for testing the activity of pheromone extracts was obtained similarly, but cardboard and gauze were not used as substrate; instead, the toothpicks were replaced by glass capillary tubes (2 mm diam) affixed vertically to the base of the dish. The silk was collected by spinning a capillary tube so as to wind the silk threads at the tip. The capillary was broken immediately into a V-shaped vial, and the silk was immersed in 0.1 ml of distilled water for 3 h to extract pheromone.

Pheromone Persistence To investigate persistence of the chemical signal, gauze with silk from females was kept under laboratory and outdoor conditions, and the response of males (see below) to silk from both treatments was evaluated through time. Gauze left outdoors was pinned onto discs of expanded polystyrene, and covered with a screened cage (2 cm mesh). Silk left under laboratory conditions was placed on an open plastic Petri dish.

Solvent Extraction of Pheromone Silk from virgin females first was tested for activity with a male (palpal drumming and leg shaking, see below), then extracted with solvent, and finally re-tested with a different male after air drying the gauze. Gauze was extracted in a glass Petri dish with 3×10 ml of solvent, each for 10 min. Hexane, methanol, and distilled water were used as solvents to investigate pheromone solubility.

Activity of Extracts To show unambiguously that the response of males was triggered by a chemical signal, silk extracts were evaporated onto clean gauze, and the sexual response of males was evaluated (see below). Only water extracts were used, given that water-extracted gauze from the previous experiment was clearly inactive, indicating that water was the most efficient solvent for extraction. A piece of clean gauze was placed on a glass plate, which was marked at the bottom for pinpointing the location of the pheromone. The silk extract (0.1 ml) from an individual female was added to the gauze on top of the mark, and the water was left to evaporate.

Male Behavioral Responses The measured sexual responses of males to the silk and the extract from virgin females were palpal drumming and leg shaking. Palpal drumming is characterized by bouts of rapid oscillations of the palps while contacting the substrate with the tips. Leg shaking also entails bouts of rapid up-and-down oscillations of the two extended forelegs. Data recorded were: a) the occurrence (presence/absence) of palpal drumming and leg shaking during each trial, and b) the frequency of the male behavior when it occurred, i.e., the number bouts of drumming and the number of leg shakes performed during a 5-min period.

In the pheromone persistence and solvent extraction experiments, the gauze with silk was placed in the bottom of a plastic Petri dish (9 cm diam), and a cylindrical cage (10 cm diam, 8 cm height) was placed upside down around the dish to enclose one male spider. This cage had a 3-cm round hole near the base through which the male was introduced by using a cylindrical tube (2.8 cm diam, 10 cm length). The tests were performed under laboratory conditions during the daytime. The behavior of the male was recorded continuously for 5 min. For the persistence trials, if two consecutives males did not show any sexual response, the silk was considered unattractive.

For the solvent-extraction trials, in order to restrict movement of the male and to ensure that he would walk over the pheromone extract, two glass cylinders were placed concentrically on the gauze (10 and 8 cm diam, 16 and 8 cm height, respectively), so as to leave the pheromone extract between both cylinders. The male then was released within this circular corridor, and his behavior was recorded. The same procedure was carried out with 20 independent samples of extract, using 0.1 ml of distilled water as control. Half of the males were tested with the pheromone extract first and the control second (24 h in between), and the other half was tested in the reverse order.

Mass Spectrometry A MicroTof-Q mass spectrometer (Burker Daltonics, Billerica, MA, USA) was employed for accurate mass measurements of metabolites. The MS was operated in negative-ion electrospray mode, and was calibrated on the experimental day using Tunemix (Burker Daltonics, Billerica, MA, USA) for a low mass range. The

electrospray source conditions were as follow: endplate off-set voltage −500 V, capillary voltage −4500 V, nebulizer 0.4 bar, dry gas flow 4.0 L/min, dry gas temperature 180°C.

Full-scan TOF MS spectra were acquired for the measurement of accurate mass of ions.

Tandem mass spectrometry analysis was performed in an Esquire 6000 Ion Trap (Bruker Daltonics, Billerica, MA, USA) operated in a negative ion electrospray mode, with endplate off set voltage −500 V, capillary voltage −4000 V, nebulizer 10 psi, dry gas flow 4.0 L/min, and dry gas temperature 300°C. Aqueous silk extracts from adult males, mated females, and virgin females were diluted with methanol (1:1), and analyzed by direct injection.

Statistical Analyses The PAST package (Hammer et al. 2003) for statistical analyses was used. Non-parametric statistics were used throughout; specific tests employed are given in the results section.

Results

Pheromone Persistence The silk under outdoor conditions remained active for 3.2±1.3 d (mean±SD, range 1–5, N=20), while indoors the activity lasted for 18.7±5.4 d (range 8–28, N=20). The percent of males responding with either drumming or leg shaking decreased sharply for silk left outdoors, while more than 50 % of the males courted silk even after 15 d of indoor exposure (Fig. 1). Moreover, when comparing the occurrence of each male's sexual behavior on a daily basis, we found that both leg shaking and palpal drumming occurred in higher ratios toward indoor-treated silk after 3 and 4 days, respectively (Table 1). Similarly, the frequencies of bouts of palpal drumming and leg shaking were significantly lower as soon as 2 days after the silk was exposed outdoors (Table 1).

Solvent Extraction Before the solvent treatments, most males displayed both sexual behaviors, with no statistical differences among treatment groups (Cochan-Q test, P>0.9; Fig. 2). After silk extraction with methanol and water, we found a reduction in male sexual response (McNemar test, P<0.001 for both behavior/solvent combinations), whereas no difference was observed for either behavior after hexane extraction (McNemar test, P>0.20) (Fig. 2). When comparing male sexual responses after methanol and water extraction, the water-extracted silk elicited less leg shaking (χ^2=10.13, P<0.003), while palpal drumming was not statistically different between either solvent treatment (χ^2=3.13, P>0.05) (Fig. 2).

Hexane treatment of the silk did not affect the frequencies of palpal drumming nor leg shaking, while both polar solvents decreased the frequencies of the courtship displays (Fig. 3).

Activity of Extracts Fifteen males responded to the pheromone extracts while only one showed courtship behavior in the control trails (N=20 for each treatment). The majority of males that responded to the extract (8 out 15) displayed both courtship behaviors (Fig. 2). Both leg shaking and palpal drumming were more frequent in tests with aqueous extracts of silk from females than from the control (McNemar test, P<0.001)

Single males that showed leg shaking with the water control performed a single up-and-down movement. The response to the silk extract was more typical, although the number of bouts of palpal drumming and the frequency of leg shaking was significantly lower than that for the untreated silk of females (Mann-Whitney test, U=26.4, P<0.01 for palpal drumming; U=6, P<0.001 for leg shaking) (Fig. 3).

Mass Spectrometry While all samples were extremely dilute, and showed a variety of background ions in their mass spectra, we found differences in the mass spectra of

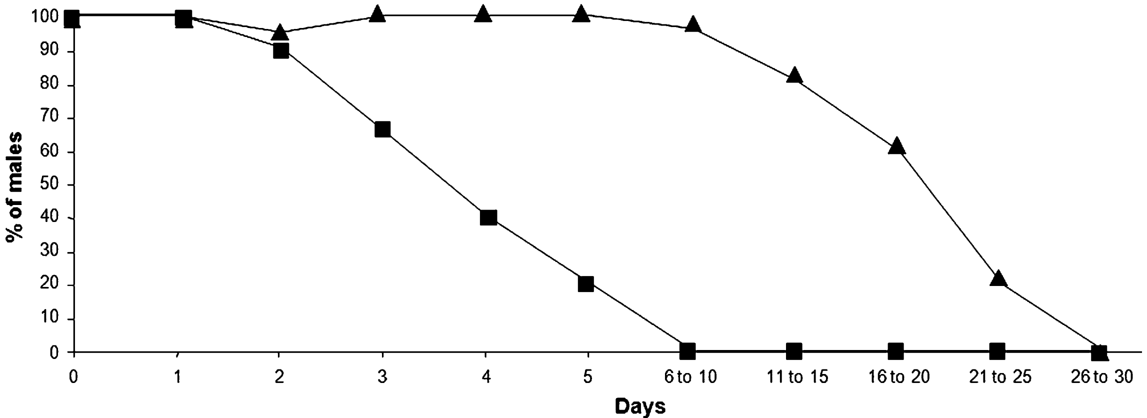


Fig. 1 Percent of *Schizocosa malitiosa* males displaying courtship behavior toward female silk kept under indoor (▲) or outdoor (■) conditions. The persistence of the chemical cue was significantly longer indoors (Mann-Whitney test; U=0, P<0.001)

Table 1 Male *Schizocosa malitiosa* sexual responses to silk exposed to outdoor/indoor conditions. Data are shown for the period during which both silk types were active (*N*=20 for each day/treatment combination)

Days	Palpal drumming				Leg shaking			
	Outdoor		Indoor		Outdoor		Indoor

* $P<0.01$ or ** $P<0.001$ for the occurrence of the male response (χ^2 test between indoor/outdoor treated silk).

† $P<0.05$ or †† $P<0.01$ for the number of bouts or shakes in the male response (Mann-Withney test between indoor/outdoor treated silk)

‡ Not statistically tested because less than 5 males responded to the outdoor-treated silk.

silk extracts of males and mated females (Fig. 4 a, b) from those of virgin females (Fig. 4 c, d). In the latter, two ions at *m/z* 205 and 111 were present in all (12) samples analyzed from different individuals in older virgin females, and in newly-molted females (Fig. 4 c, d, respectively). These ions were absent from mass spectra of silk extract from males, and present only in low amounts in mass spectra of silk extracts from mated females. HR-MS of these ions gave the exact masses of 205.0354 and 111.0084, which suggest the formulae $C_7H_9O_7$ and $C_5H_3O_3$, respectively (calculated: 205.0348 and 111.0082). Further, MS-MS analyses showed the *m/z* 111 ion to be a fragment of the *m/z* 205 ion, and the same analysis showed that the *m/z* 205 ion fragmented to give *m/z* 173 and 143 ions. While no HR-MS was obtained from *m/z* 173, due to low intensity, *m/z* 143 appears to have a molecular formula of $C_6H_7O_4$ (calculated: 143.0344; found: 143.0350). Insufficient data are available, at this point, to postulate a possible chemical structure for biological evaluation.

Discussion

In species with wandering females who are laying down silk impregnated with pheromone (Rovner 1968; Tietjen 1977;

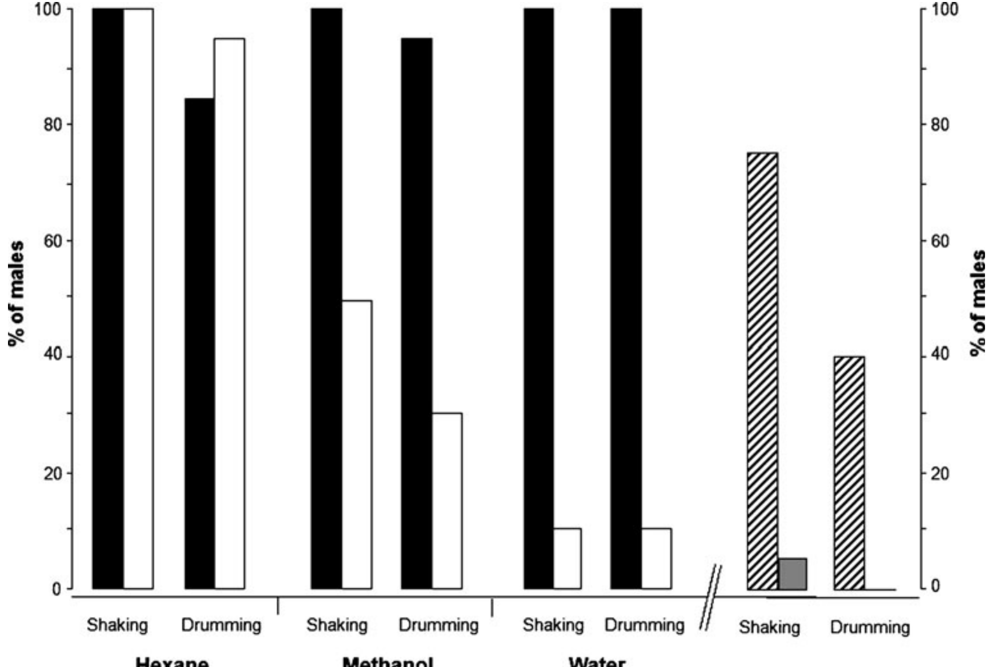

Fig. 2 Left: percent of *Schizocosa malitiosa* males responding to female silk before (*solid bars*) and after (*white bars*) solvent extraction. Right: percent of males responding to gauze treated with female silk water extract (*stripped bars*) or water control (gray bars)

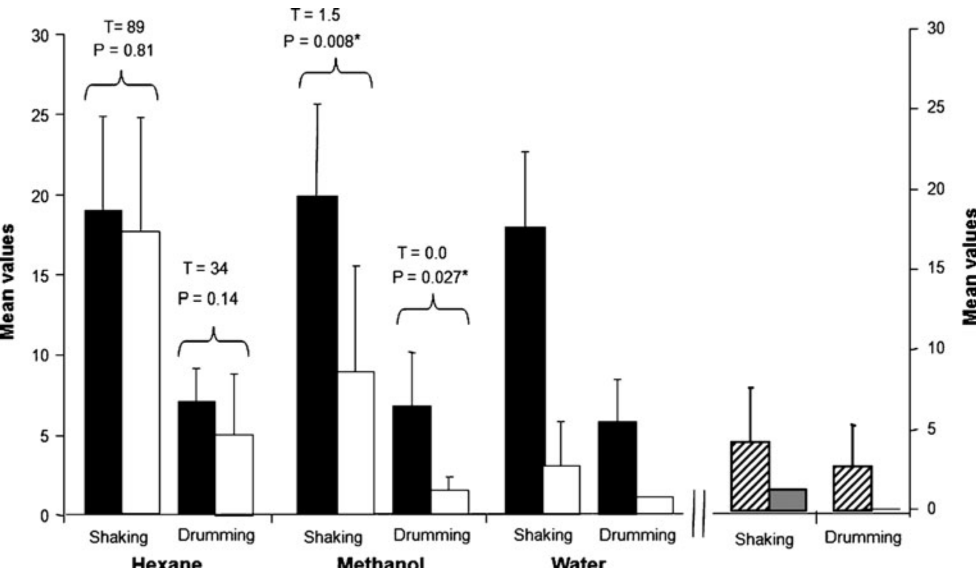

Fig. 3 Left: frequencies of leg shakes and palpal drumming bouts by *Schizocosa malitiosa* males before (*solid bars*) and after (*white bars*) solvent treatment of the silk (differences after extraction were tested with the Wilcoxon test; the effect of water extraction was not tested due to the low number of males that responded). Right: frequencies of leg shakes and palpal drumming bouts to gauze treated with female silk water extract (*stripped bars*) or water control (*gray bars*)

Tietjen and Rovner 1980; Lizotte and Rovner 1989), both conspecific males and the signaling female would benefit by quick degradation of the pheromone. The indication from active chemical signals that a female is nearby may facilitate the sexual meeting process and generate a higher mate encounter rate (Hegdekar and Dondale 1969). If the chemical cue in the silk lasts very long, males would increase their own predatory risks by spending energy and time unsuccessfully courting and following old silk remains of females that are distant in space and/or time (Andersson and Iwasa 1996).

In the silk left outdoors, the loss of attraction was due possibly to combined action of environmental factors such as sunlight, wind, and dew. Indeed, we found that both rain (Baruffaldi, unpublished data) and water extraction of the silk efficiently eliminated its attractiveness, which is consistent with the likely role of dew in our experimental results. The slower, although noticeable, decrease of attractiveness of the silk thread left indoors, suggests that the pheromone is chemically unstable or slowly evaporating, independently of such environmental factors. This observation is in agreement with previous results from Lizotte and Rovner (1989), who reported a decrease in the stimulatory efficacy produced by 1-day-old silk threads of the wolf spiders *Lycosa longitarsis* and *Lycosa tristani*.

As far as we know, no previous study has experimentally tested spider pheromone persistence under field conditions. An understanding of the reproductive strategies of male and female wolf spiders, specifically related to their wandering behavior, may benefit from these studies. Dondale and Hegdekar (1973) observed that silk from females of the wolf spider, *Pardosa lapidicina*, quickly lost the ability to attract males after it was washed with water or sprayed with water mist. These authors suggested that rain and/or dew could affect the persistence of chemical cues associated with the silk threads. Our findings support this notion, and specifically provide evidence for the important function of dew in modulating the activity of pheromone from *S. malitiosa* females. Rain is sporadic in Uruguay, but dew is common in late autumn and early winter, coinciding with the sexual period of this species (Costa 1991).

The treatment of silk threads with different solvents indicates that the active female-specific compound is polar, and, given the pheromone solubility in water and methanol, one may conclude that it is a highly polar molecule. All described female spider sex pheromones associated with silk are derivatives of short chain carboxylic acids, with free hydroxyl and carboxylic groups (Schulz 2004). Water-washed silk of females frequently released palpal investigation by males after leg contact, but elicited no sexual displays, suggesting that silk threads represent tactile unspecific stimuli that orient male perception, while the final cue is sensed after chemical examination with the palps. Male courtship responses when water extracts of silk from females were applied to clean gauze, indicates the presence of a water-soluble pheromone that triggers male sexual behavior.

The polarity of the sex pheromone in spiders may be related to characteristics of their habitat. Spiders that inhabit dry environments can develop water-labile compounds, whereas those associated with wet environments, such as the pisaurid, *Dolomedes triton*, and some lycosids, use water-resistant polar compounds (Roland and Rovner 1983; Lizotte and Rovner 1989). In this vein, *S. malitiosa* inhabits various terrestrial dry environments, being frequent in those modified by human action (Costa 1991), and appears to produce a water-labile polar sex pheromone.

Several related studies have reported male searching behavior and/or duration of male movement as an indication of the presence/absence of female cues, in particular when

Fig. 4 HR-MS spectra of aqueous silk extract of a *Schizocosa malitiosa* male (**a**), mated (**b**) and virgin females (old: **c**; newly molted: **d**). The two ions highlighted in **c** and **d** were observed consistently in silk extracts from 12 individual virgin females

the males were exposed to low intense stimuli such as extracts (Roberts and Uetz 2004; Stoltz et al. 2007; Perampaladas et al. 2008). In this study we did not include such data, since it is an ambiguous parameter in *S. malitiosa*, observed not only in the presence of female cues, but also when males are exposed to silk threads of adult males or juvenile individuals (Baruffaldi and Costa 2010). Instead, we obtained unambiguous differences by registering typical sexual behaviors such as leg shaking or palpal drumming.

The present mass spectral data provide a basis for speculation as to the pheromone structure. *M/z* 205 may be the ion M–H, which would result in a molecular formula of $C_7H_{10}O_7$ for the pheromone; this would be a highly oxygenated compound with three double bond equivalents, and possibly bearing at least one free carboxylic group. However, the loss of 32 mass units from *m/z* 205 in the MS-MS study suggests that it may be a methanol adduct of *m/z* 173, and this may also be the case with *m/z* 143 and 111, whose molecular formulae differ by CH_4O. The fragmentation of either parent ion to give the major *m/z* 111 suggests a labile compound, which is consistent with our results in the persistence experiments.

The ion at m/z 111 was the most abundant in all old virgin females, which are most attractive for males. In contrast, silk threads from newly-molted virgin and mated females, which trigger only low rates of palpal drumming and leg shaking (Baruffaldi and Costa 2010), showed low intensity of the m/z 111 in their water extracts, suggesting that this ion is, indeed, related to the chemical communication system. Interestingly, the low, but still detectable, occurrence of the putative pheromone in the silk of newly-molted virgin and mated females agrees with the hypothesis proposed by Baruffaldi and Costa (2010) that the release of chemical cues and sexual receptivity are not synchronous in these females, suggesting slow chemical and quick behavioral changes.

The final chemical characterization of *S. malitiosa* sex pheromone will be challenging due to the small amount in which it is found on the silk, and its apparent instability in water. A large sample will be needed for ^{1}H-NMR studies which, along with the mass spectral data, should provide the additional information required for absolute identification.

Acknowledgements The authors wish to thank the Comisión Sectorial de Investigación Científica (CSIC, UdelaR), Comisión Académica de Posgrado (CAP, UdelaR) and PEDECIBA for financial support to LB, and Ms. Natalia Berta for technical assistance in mass spectrometry. We thank Emily MacLeod and two anonymous reviewers for comments and suggestions that improved the manuscript. We also thank Anita Aisenberg, Macarena Gonzáles and Carlos Toscano for their help in the collection of spiders. Mass spectrometry facilities at Polo Tecnologico-FQ were supported by UE Grant Proyecto Enlaces-UE URY 2003-5906.

Abstract Adults of the sorghum chafer, *Pachnoda interrupta* Olivier (Coleoptera: Scarabaeidae: Cetoniinae), form aggregations during the mating period in July, but also in October. The beetles aggregate on food sources, e.g., *Acacia* spp. trees or sorghum with ripe seeds, to feed and mate. During the mating season, field trapping experiments with live beetles as bait demonstrated attraction of males to unmated females, but not to mated females or males, indicating the presence of a female-emitted sex pheromone. Unmated females combined with banana (food source) attracted significantly more males and females than did unmated females alone. Other combinations of beetles with banana were not more attractive than banana alone. Thus, aggregation behavior appears to be guided by a combination of pheromone and host volatiles. Females and males were extracted with hexane during the mating period, and the extracts were compared by using GC-MS. In a field trapping experiment, 19 compounds found only in females were tested, both singly and in a mixture. Traps baited with one of the female-associated compounds, phenylacetaldehyde, caught significantly more beetles than any other treatment. However, the sex ratio of beetles caught in these traps did not differ from that of control traps, and it is possible that other components may be involved in the sex pheromone signal. Furthermore, traps baited with a mixture of all 19 compounds attracted significantly fewer beetles than did phenylacetaldehyde alone.

Introduction

The sorghum chafer, *Pachnoda interrupta* Olivier (Coleoptera: Scarabaeidae: Cetoniinae), is present in semi-arid parts of Africa subject to strong seasonal variation in rainfall and temperature, mainly in the Sahel and Sudan ecoregions (Schmutterer 1969; Grunshaw 1992; Jago 1995; Sastawa and Lale 2000), but also parts of Ethiopia (Hiwot 2000). As

a reflection of the climatic conditions, the growth and abundance of plants is highly seasonal in these regions (White 1983), especially with regard to fruits and flowers, on which the polyphagous adults of *P. interrupta* feed (Clark and Crowe 1978; Grunshaw 1992; Hiwot 2000). During the dry period, which lasts approximately from November to May, adult *P. interrupta* estivate in the soil under trees and bushes (Wolde-Hawariat et al. 2007). After the short rains in June, adult beetles emerge to feed and mate, often forming dense aggregations on food sources, e.g., flowering *Acacia* spp. The mating season ends with the onset of the rainy season, when the females oviposit in the topsoil. The larvae develop in the soil, feeding on plant litter, and pupate towards the end of the rains, in August (Seneshaw and Mulugeta 2002). New adults emerge in September–October and feed intensively before going into estivation.

During the September–October feeding period, the sorghum chafer can be a devastating pest on sorghum, *Sorghum bicolor* (L.) Moench (Poaceae), causing mean yield loss of up to 70% in severely affected areas of Ethiopia (Yitbarek and Hiwot 2000). Efficient control methods are not available, but farmers trap adults with simple containers baited with fruit (Ministry of Agriculture and Ethiopian Agricultural Research Organization 1999). Traps baited with a combination of food (e.g., fruit) and pheromones have proved to be efficient for control of several beetle species that are pests on commercial crops (Alpizar et al. 2002; Oehlschlager et al. 2002). Field observations of mating and aggregation in adult *P. interrupta* led us to suspect that a pheromone could be involved in these behaviors. We performed field experiments and chemical analyses to investigate whether this was the case. The identification of pheromone compound(s) used in mating or aggregation could enable the development of highly attractive lures that could be employed in mass trapping of this pest.

Methods and Materials

General Methods in Field Experiments In all field experiments, Japanese beetle traps (Trécé, Palo Alto, CA, USA) were suspended from wooden poles ca. 3 m above ground. Except where otherwise noted, a randomized complete block design (N=10) was used, with 10 m between traps and at least 50 m between blocks. Traps were emptied and lures replaced each morning.

Field Activity Patterns of Males and Females Field experiments that investigated the activity patterns of male and female adults during the mating season were carried out in unused farmland with sparse vegetation near the village of Embuay Bad in Ethiopia (09°48′N, 40°00′E), 265 km northeast of Addis Ababa, 1206 m above sea level, 28 June–13 July 2008. Mean daily trap catch was used as an indicator for field activity. For these experiments, traps were baited with half a banana that was mashed and put in the collection chamber of the trap, where captured beetles could access it. This bait has been shown previously to be highly attractive to *P. interrupta* (Ministry of Agriculture and Ethiopian Agricultural Research Organization 1999; Hiwot 2000; Wolde-Hawariat et al. 2007). Traps were placed throughout the site, with a minimum distance of 50 m between them. For logistical reasons, we were not able to deploy 10 traps as originally planned throughout the active period (N=2 for 28 June and 3 July, N=4 for 29 June–2 July, N=10 for 4–9 July, and N=5 for 11–13 July). Data were not collected on 10 July.

Pheromone Communication in the Field Field experiments that investigated pheromone communication and host interactions were carried out at Rasa (09°55′N, 40°05′E), located 255 km northeast of Addis Ababa, Ethiopia. Experiments were performed 11–16 July and 7–13 October, 2005, in a grazing area characterized by scattered *Acacia* spp. trees. Live beetles and/or three 1 cm thick banana slices were placed in fine mesh metal net cages that were fitted into the top of the vanes of the traps. For treatments where beetles of one sex were used as part of the bait, 5 adults were placed in the mesh cage, whereas for treatments with both males and females as bait, 5 beetles of each sex were used. For experiments conducted during the mating period (July), beetles that were used as bait were excavated from estivation sites in Rasa during May, before mating had commenced. The beetles used in October were collected in the field during July. Beetles were separated according to sex and kept at the Department of Biology at Addis Ababa University, Ethiopia, under natural light and temperatures ranging between 20 and 25°C, and fed banana *ad libitum* until used in experiments. Unbaited traps were included as a negative control.

Identification of Compounds For investigation of female-specific compounds during the mating season, male and female beetles were excavated from estivation sites in the field, near Rasa, during May 2007, and were kept as described above. As mating takes place after the beetles emerge in June–July, in the early part of the rainy period, the beetles excavated were thus assumed to be unmated. As no distinct calling behavior was observed, beetles were selected for extraction by putting a male and female together in a box between 10 am and 2 pm, when beetles have been observed previously to mate (unpublished). When the males started clasping the females for mating, they were separated and put in 50 ml Erlenmeyer flasks.

Once 10 beetles had been added to a flask, redistilled hexane (HPLC grade, Tamro MedLab AB, Gothenburg, Sweden) was added, with just enough hexane to cover the beetles (approximately 5 ml). After 5 min with light agitation, the solvent was removed and stored for gas chromatography-mass spectrometry (GC-MS) analysis. These extracts were called "first extracts." Next, a similar amount of solvent was added to the beetles and left to stand overnight. The solvent was removed and labeled "second extract." Whole-body extractions as well as extractions of body parts [abdominal tip (outermost 3 mm), abdomen without the tip, and all body parts except abdomen] were performed.

GC-MS was used to compare extracts from males and females, and extracts from the different body parts. Analyses were carried out on an HP 6890 Series GC System connected to an HP 5973 Mass Selective Detector (Hewlett-Packard Company, Wilmington, DE, USA) fitted with a BPX5 fused-silica capillary column (25 m× 0.22 mm i.d., 0.25 µm film thickness, SGE Inc., Melbourne, Australia). A volume of 1 µl was injected in splitless mode (60 sec valve time), and inlet pressure was 77.1 kPa. The GC was programmed as follows: 5 min at 50°C, then with 5°C/min to 320°C, with helium as a carrier gas at a flow rate of 1 ml/min. The transfer line was set to 300°C. Identification of compounds was performed by comparison of mass spectra and gas chromatographic retention indices with those of synthetic reference compounds. Compounds were regarded as female specific when they occurred repeatedly in females and were absent or present in much lower doses in males. A semi-quantitative analysis of extract components was conducted by adding pure nonanal as an internal standard. No response factors were determined.

Field Testing of Female-Specific Compounds Compounds found by GC-MS to be specific to females during the mating season were tested in the field. Synthetic compounds (for purity and CAS number, see Table 1) were purchased (Sigma-

[b] 200 mg of 33% solution in tetrahydrofuran.

[c] All single compounds (including optical isomers) present in individual dispensers put together in a plastic container

Aldrich Sweden AB, Stockholm, Sweden). Emission rates for dispensers were tested in a cylindrical wind tunnel (1 m long, 60 cm diam, 0.25 m/sec air flow, 25°C) in Alnarp, Sweden. Dispensers were replaced in the field each morning, just before the active period of adult *P. interrupta*, which are day-active (Grunshaw 1992), and release rates were calculated for the first 8 hr. Dispensers were weighed after loading, and then weighed again after 1, 2, 4, 6, and 8 hr in the wind tunnel. For comparison, we determined the release rates in this wind tunnel for plant compound lures that had been shown previously to be attractive in the field (Wolde-Hawariat et al. 2007). These were found to have a release rate of 0.5–1 mg/h during the 8 hr measurement period. Based on this analysis, we chose combinations of dose and dispenser for the female compounds that ensured a similar emission rate for each compound.

The least volatile compounds were put on cotton rolls (no. 2 dental cotton roll, Demedis GmbH, Langen, Germany) without any further modification ("cotton roll," Table 1). For more volatile compounds, cotton rolls were pushed into 4 ml glass vials (45×14.7 mm, clear, Skandinaviska GeneTec AB, Västra Frölunda, Sweden) until the cotton was level with the rim of the opening of the vial ("cotton roll in vial," Table 1). Cotton rolls were placed in vials before test compounds were applied. For the most volatile compounds, a cotton roll was put inside a vial closed with a cap (black, closed top, 13 mm, Skandinaviska GeneTec AB). A hole (2 mm diam) was made in the cap, and the cotton roll was placed so that it was in direct contact with the cap when it was screwed tightly to the vial. Two variants were made of this dispenser: 1) one for the most volatile compounds, where the chemical was applied towards the edge of the vial ("capped vial, distal application," Tables 1 and 2) one for compounds that were less volatile, where the chemical was applied just underneath the hole in the cap ("capped vial, centered application," Table 1). All compounds were applied neat, apart from indole and benzoic acid (solid at room temperature), which were dissolved in tetrahydrofuran (99+% by GC, Sigma-Aldrich Sweden AB) at a concentration of 33%.

Each compound was tested singly and in a mixture. In the mixture, all compounds were applied to individual dispensers, placed together in a round plastic container (diam 68 mm, height 30 mm, Semadeni, Ostermundingen, Switzerland) and secured with metal wire. For comparison, treatments also were included with live unmated male and female *P. interrupta* in wire mesh cages as bait. Beetles that were used as bait were excavated from estivation sites near Rasa in May 2008, separated by sex, and kept at the Department of Biology of Addis Ababa University as described above. Experiments were performed 10–12 July, 2008, at Embuay Bad (see above). The experimental design followed the general procedure outlined above, with two exceptions: $N=5$ was used and treatments were moved one position within blocks daily before replacing the dispensers, to decrease the influence of position effects. The tests were

[b] The estimated amounts per individual were determined from the second extracts of female abdominal tips without an analysis of the response factors of the authentic standards on the GC-MS instrument. The presence or absence in first and second extracts from females is indicated by + or −. These compounds were not present in first or second extracts from males

[c] Enantiomeric composition not determined

conducted when the male bias in sex ratio of beetles caught by positive control traps got less pronounced, during the last 3 d of the active season in July 2008 (see also "Results", field activity patterns of male and female beetles).

Statistical Analyses For the statistical evaluation of data from the field experiments, cumulative trap catch over the field testing period was used. Male and female responses were treated separately. Treatments with a mean trap catch of females or males below 1 were excluded (no treatment had a mean trap catch below 1 for one sex, while having a mean trap catch above 1 for the other sex). For the remaining treatments, trap catch was $\log_{10}$-transformed before analysis with a General Linear Model (GLM), with treatment (type of lure) as a fixed effect, and block as a random effect (Minitab 14 for Windows). If there were significant effects in the GLM procedure, we compared treatment means by using a *Tukey's post hoc* test. Within each experiment, sex ratios of treatments (excluding those with a mean trap catch below 1) were compared to those of a positive control by using 95% binomial confidence intervals (Newcombe 1998), with the Bonferroni correction for multiple comparisons. The significance level used in all tests was $\alpha = 0.05$. For all experiments, data are presented in graphs as back-transformed means, with error bars denoting the standard error of the mean.

Results

Field Activity Patterns of Males and Females Male *P. interrupta* showed higher flight activity for most of the period during the mating season (Fig. 1); female flight was delayed. During the first 8 d of the trapping period, the mean trap catch was moderate (the highest mean daily catch was 29 beetles per trap), and there was a strong male bias in catch (>90%). From July 7, beetle activity increased, but the proportion of females remained low. Female activity drastically increased on 12 July, making the sex ratio approximately even. With the onset of heavy rains (13 July 2008), the beetles ceased flying and were not observed mating or feeding on hosts.

Pheromone Communication in the Field During the mating period in July, traps baited with unmated females caught a significantly higher proportion of males than the positive control traps (baited with mashed banana in the collection chamber; Figs. 2 and 3). The sex ratio caught by other treatments did not differ significantly from the positive control. Few beetles (1 or less of each sex) were attracted to

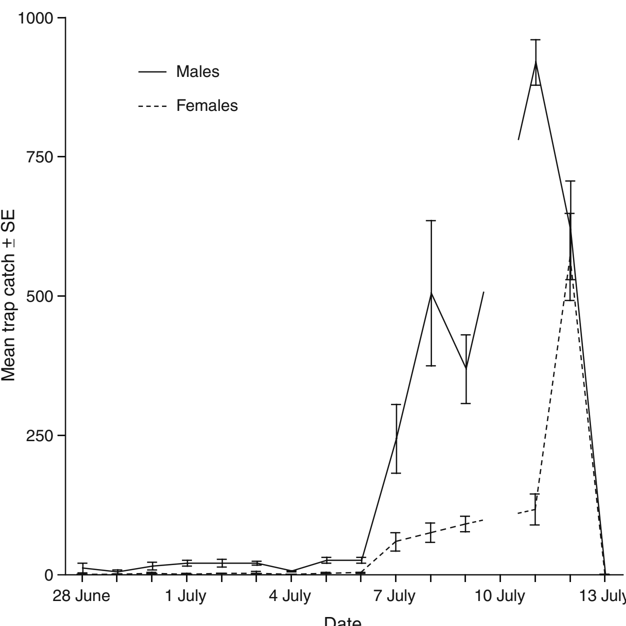

Fig. 1 Flight responses (trap catches) of male (solid line) and female (dashed line) *Pachnoda interrupta* to mashed banana, 28 June to 13 July 2008, Embuay Bad, Ethiopia. Error bars show standard error of the mean, and sample sizes were N=2 (28 June, 3 July), N=4 (29 June–2 July), N=10 (4–9 July), and N=5 (11–13 July). The break in the line denotes that no trap catch data were collected on 10 July

traps baited with males, males together with females, or unbaited traps (negative control). Unmated females combined with food (3 1 cm-thick slices of banana) caught significantly more males than any other treatment, but also attracted females to the extent that the sex ratio did not differ significantly from that of the positive control traps. Traps baited with males and food or both sexes and food did not catch significantly more than traps baited with banana slices alone. In October, the newly emerged adults were not attracted to traps baited with beetles alone, neither to males, females, nor both sexes together (Fig. 4). Traps baited with combinations of beetles and food, however, were significantly more attractive than traps baited with food alone. The highest catch was obtained in traps baited with both sexes and food, followed by traps baited with males and food.

Identification of Female-specific Compounds Extracts obtained during the mating season from male and female beetles were dominated by hydrocarbons and fatty acids, typical constituents of the insect cuticle and fat body. Small amounts of more volatile compounds also were identified (Fig. 5). The monoterpenes α-pinene, β-pinene, *p*-cymene, and limonene as well as geranylacetone were present in female first extracts from all parts of the body, but were absent in male extracts. The female second extracts also contained these compounds, and 14 additional female-

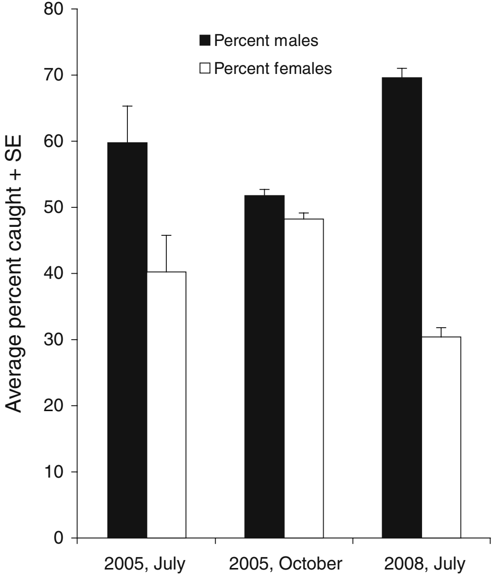

Fig. 2 Percentage male and female *Pachnoda interrupta* in positive control traps baited with mashed banana July 2005, October 2005, and July 2008 showing the differing sex ratios

specific compounds, which were identified in extracts from the abdominal tip (Table 2). The identified compounds were short chain carboxylic acids, esters, aromatic compounds, and aldehydes. Indole, propyl acetate, and 2-methylpropyl acetate were found in the largest estimated quantities.

Field Testing of Female Compounds The female-specific compounds were tested in the field. Two enantiomers of α-pinene, one enantiomer of β-pinene, and two enantiomers of limonene were included (Table 1), since the enantiomeric composition of these compounds in the natural product was unclear. The peak corresponding to 2-methylpropyl acetate was not clearly identified at the time of field testing, and this compound was not included. Traps baited with phenylacetaldehyde caught dramatically more beetles than all other treatments (Fig. 6), catching a mean of 1191 beetles per trap, compared to a mean of 64 beetles per trap for hexanoic acid, the second most attractive compound. The mixture of all compounds caught significantly less than did phenylacetaldehyde alone, whereas no treatment caught significantly less than unbaited traps or traps baited with solvent alone (negative controls). Sex ratios were male-biased for all treatments and did not differ significantly among treatments and the positive control (traps baited with mashed banana).

Discussion

Field trapping with live beetles as bait showed that during the mating period, unmated female *P. interrupta* were particularly attractive to males (Fig. 3), indicating that a female-emitted sex pheromone is present. However, females also were attracted, albeit to a far lower degree than males. With scarabs, the attraction of both sexes to a female-produced pheromone also has been observed in the Japanese beetle, *Popillia japonica* Newman (Potter and Held 2002), and opportunistic attraction of same-sex individuals to sex pheromones has been implied as a mechanism in the formation of aggregations in bark beetles (Schlyter and Birgersson 1999). The reason for the lack of male-biased attraction to unmated females in a later field study (Fig. 6) is unknown, but, as the mating period is brief, a possible explanation could be that the beetles had either passed or not yet reached mating maturity.

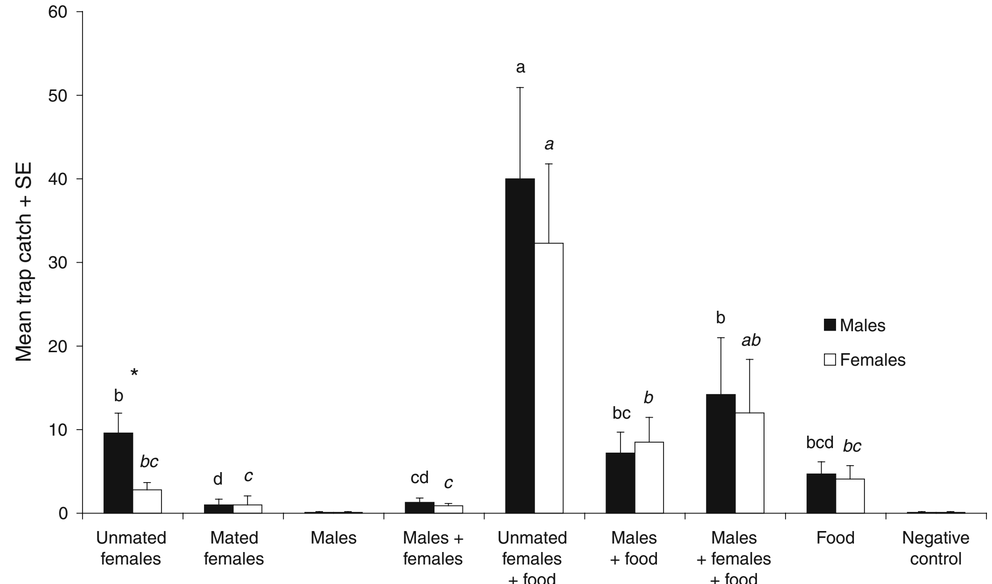

Fig. 3 Flight responses (trap catches) of both sexes of *Pachnoda interrupta* to various combinations of beetles and food (banana), 11–16 July 2005, Rasa, Ethiopia. Subgroups (males-normal font; females-italicized font) denoted by different letters are significantly different (α=0.05, Tukey's b on transformed data). Error bars show standard error of the mean and sample size was N=10. Treatments marked by asterisks differed significantly from the positive control (Fig. 2) in sex ratio. Data from treatments with a mean trap catch below 1 were not included in the statistical analysis

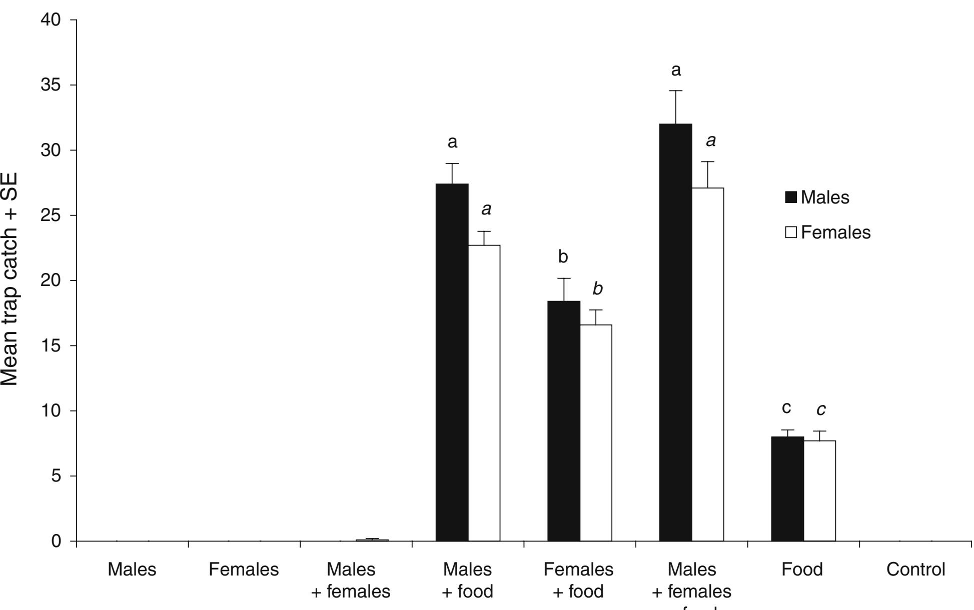

Fig. 4 Flight responses (trap catches) of both sexes of *Pachnoda interrupta* to various combinations of beetles and food (banana), 7–13 October 2005, Rasa, Ethiopia. Subgroups (males-normal font; females-italicized font) denoted by different letters are significantly different (α=0.05, Tukey's b on transformed data). Error bars show standard error of the mean and sample size was N=10. No treatments differed significantly from the positive control (Fig. 2) in sex ratio. Data from treatments with a mean trap catch below 1 were not included in the statistical analysis

In June–July, *P. interrupta* form large aggregations on *Acacia* spp. trees where they feed and mate, and the most obvious underlying reasons for the observed female attraction are facilitation of food and mate finding, as has been suggested for other insect species (Thornhill and Alcock 1983). The aggregations have been observed to increase in frequency and size later in the mating season. This could be linked to the observed delay in female flight activity (Fig. 1), since the aggregations are likely to be caused by an interaction between the female pheromone signaling system and the host, as evidenced by the strong attraction of both sexes to unmated females combined with food (banana) (Fig. 3). In other insects, increased attraction has been observed to combinations of pheromones with volatiles from hosts used for feeding (Klein et al. 1981; Seybold et al. 2006), oviposition (Dickens et al. 1993), or both (Bartelt et al. 1985), and shifts in sex ratio of attracted conspecifics when unmated females are combined with food volatiles have been observed in *P. japonica* (Klein et al. 1981) and the diamondback moth, *Plutella xylostella* (L.) (Reddy and Guerrero 2000). Access to food also could increase pheromone emission by females (McNeil and Delisle 1989), and aggregations might be influenced by pheromone release rate as well as the presence of host volatiles.

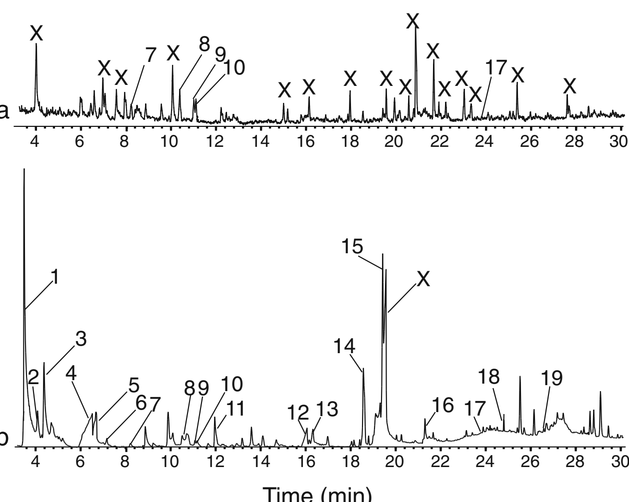

Fig. 5 Enlarged part of gas chromatograms of hexane extract of the abdominal tip of female *Pachnoda interrupta* during the mating season. **a** First extraction. **b** Second extraction. 1. Propyl acetate; 2.1-Methylpropyl acetate; 3. 2-Methylpropyl acetate; 4. 3-Methylbutyric acid; 5. 2-Methylbutyric acid; 6. Hexanoic acid; 7. α-Pinene; 8. β-Pinene; 9. *p*-Cymene; 10. Limonene; 11. Phenyacetaldehyde; 12. Benzoic acid; 13. Octanoic acid; 14. (*E*)-2-Decenal; 15. Indole; 16. (*E*)-2-Undecenal; 17. Geranylacetone; 18. (2*E*,4*E*)-2,4-Dodecadienal; and 19. 4-Dodecanolide (numbers as in Table 2). The symbol X indicates artifacts comprising silicone derivatives from the column and hydrocarbon impurities from the solvent

Insects also may alter the profile of volatile compounds emitted by their hosts by feeding damage or by inoculation with microorganisms (Zagatti et al. 1997; Macías-Sámano et al. 1998; Wertheim et al. 2002). In scarabs, adults feeding on plant hosts have been shown to induce emission of volatiles that facilitate aggregation (Harari et al. 1994), as well as mating behavior (Ruther et al. 2002). However, as we did not observe an increase in attraction during the mating season when we combined food with males, or with both sexes together (Fig. 3), it is unlikely that the synergy in attraction to unmated females with food during the mating season is due to a change in the volatile profile emitted by the food. During October, adult beetles are active above ground for 1–2 wk and feed (but do not mate) before going into estivation. Accordingly, unmated females

Fig. 6 Flight responses (trap catches) of both sexes of *Pachnoda interrupta* to various potential female-associated semiochemicals, 10–12 July 2008. Subgroups (males-normal font; females-italicized font) denoted by different letters are significantly different (α=0.05, Tukey's b on transformed data). Error bars show the standard error of the mean and the sample size was *N*=5. No treatments differed significantly from the positive control (Fig. 2) in sex ratio

were not attractive to males during this period (Fig. 4), whereas a combination of either or both sexes with food increased attraction above that to food alone. Possible mechanisms behind this increase in attraction are changes to the volatile profile of the host by feeding or inoculation with microorganisms, which however would contrast with the seeming lack of importance of such changes during the mating season.

Field testing of synthetic female-unique compounds established that phenylacetaldehyde (PAA), a common constituent of flower volatiles (reviewed in Knudsen et al. 2006), was highly attractive to males (Fig. 6). We hypothesize that PAA is a female-produced pheromone component for *P. interrupta,* but this will need to be proved through biochemical labeling or other approaches. No pheromones have been described for scarab species of the subfamily Cetoniinae, but other scarab species exhibit considerable diversity in pheromone semiochemistry, and several small aromatic compounds have been identified as pheromone components (e.g., phenol, anisole, and methyl benzoate) (reviewed in Leal 1998). On the other hand, some scarab attractants have been found in flowers (Knudsen et al. 2006), and the use of plant volatiles, including PAA (Honda 1980; Bellas and Hölldobler 1985), as attractants with pheromones has been observed in several insects (Boch and Shearer 1962; Baker 1989; Eller et al. 1994; Hassanali et al. 2005; Bartelt et al. 2009; Kim et al. 2009).

In agreement with the results of the field experiments where unmated females attracted both sexes, female *P. interrupta* also were attracted to PAA (Fig. 6). The strong attraction of both sexes to traps baited with PAA might in part be a dose effect, as suggested above concerning aggregations. We estimated that the release rate of PAA was 0.5–1 mg/h from the field lures. Although individual females only contained an estimated 0.2 ng of PAA, during the mating season, *P. interrupta* form aggregations with thousands of adults, and the effective emission of PAA from one of these aggregations may be quite high. High release rates of semiochemicals have been shown to be

necessary for attraction in the Coleoptera, e.g., to pheromone components in *Ips typographus* (L.) (Schlyter et al. 1987) or to host attractant monoterpenes in many other bark beetles (reviewed in Seybold et al. 2006). Furthermore, the involvement of additional components in the pheromone communication system of *P. interrupta* cannot be ruled out, and the inclusion of such compounds might enhance the specificity of the signal, and lower the threshold for response (Linn et al. 1986). Practical limitations forced us to forego extensive field testing of blends, and a treatment including all identified female-unique compounds proved to be less attractive than the treatment with PAA alone (Fig. 6).

The high level of attraction to the putative pheromone compound PAA is promising for future application. Both sexes are attracted, and traps catch adults, which is the life stage causing damage in this system. Trapping has proven efficient for control in other pest species where adults are the damaging stage (reviewed by Witzgall et al. 2010). PAA could be combined with previously identified host-related attractants, such as 2,3-butanediol (Bengtsson et al. 2009), eugenol, and methyl salicylate (Wolde-Hawariat et al. 2007) for evaluation of synergistic effects, and to further improve the attractiveness of lures. Such lures could be powerful instruments for monitoring, but also for mass trapping of *P. interrupta*.

Acknowledgments We thank the Plant Protection and Regulatory Department of the Ministry of Agriculture and Rural Development of Ethiopia for providing traps for the field trapping experiment. This work was financed mainly by a grant from the Swedish International Development Agency (Sida/SAREC) for which the authors are grateful. In addition, Swedish support was supplied by the IC-E^3 Linnaeus program. The authors are also grateful for financial support provided by the Ethiopian Institute of Agricultural Research, especially the secretariat for the Agricultural Research Fund. Generous stipends from the Lars Hiertas Minne and Ångpanneföreningen Trusts helped finance the field experiments in this study. The authors would also like to thank Dr. Mattias C. Larsson for valuable comments on the manuscript.

Sex Pheromone of the Spanish Population of the Beet Armyworm *Spodoptera exigua*

Patricia Acín · Gloria Rosell · Angel Guerrero · Carmen Quero

Received: 19 February 2010 / Revised: 20 April 2010 / Accepted: 4 June 2010 / Published online: 24 June 2010
© Springer Science+Business Media, LLC 2010

Abstract The pheromone composition of the Spanish population of the beet armyworm (BAW), *Spodoptera exigua* (Lepidoptera: Noctuidae), was identified. Analysis of female gland extracts showed the presence of compounds *Z*9,*E*12–14:Ac (**1**), *Z*9–14:Ac (**2**), *Z*11–16:Ac (**3**), *Z*9,*E*12–14:OH (**4**), *Z*9–14:OH (**5**), and *Z*11–16:OH (**6**) in a ratio of 26:11:1:22:31:9. The amount of compound per gland ranged from 2.08 ng for **5** to 0.09 ng for **3**. However, analysis of female volatiles by SPME revealed only the presence of compounds, **1**, **2, 3,** and **5** in a 34:40:4:22 ratio. In electroantennogram assays, compound **1** elicited the highest response, and the C14 acetates evoked higher electrophysiological responses than the corresponding alcohols or C16 isomers. In a wind tunnel, no behavioral difference was observed between formulations based on the gland extracts and female volatiles. In both cases, males responded as when virgin females were used as the attractant source. Compound **1** alone elicited upwind flight by males, but required the presence of compound **5** in a 80:20 to 40:60 ratio for full activity. Ternary mixtures of **1**, **5** and the minor components did not improve the performance of the **1**+**5** blend in a 60:40 ratio. In the field, the mixture **1**+**5**+**3** in a 56:37:7 ratio was the most attractive formulation, and is expected to be useful in future pest control strategies.

Introduction

The beet armyworm (BAW), *Spodoptera exigua* (Hübner) (Lepidoptera: Noctuidae), is a polyphagous pest widely distributed in Africa, Asia, Australia, North America, and southern Europe that attacks numerous crops and ornamental plants in the field and greenhouses. In southern Spain, the damage caused by this moth has increased considerably, particularly in greenhouses, possibly due to pesticide resistance. One alternative proposed to control this pest has been the use of a synthetic pheromone as a specific and environmentally-friendly management tool. The pheromone composition of BAW has been studied by numerous researchers, but with a great disparity among all existing data. Initial studies on pheromone gland extracts from American strains identified (*Z*,*E*)-9,12-tetradecadienyl acetate (*Z*9,*E*12–14:Ac, compound **1**) as a pheromone compound, but the low efficiency of this acetate in field tests led to a reinvestigation of the pheromone complex (Brady and Ganyard 1972). Whereas Persoons et al. (1981) found compound **1**, (*Z*,*Z*)-9,12-tetradecadienyl acetate (*Z*9,*Z*12–14:Ac), (*Z*)-11-tetradecenyl acetate (*Z*11–14:Ac), (*Z*)-9-tetradecenyl acetate (*Z*9–14:Ac, compound **2**) and tetradecyl acetate (14:Ac) in pheromone gland extracts, Tumlinson et al. (1981, 1990) reported the

presence of compounds **1**, *Z*9,*Z*12–14:Ac, **2**, (*Z*)-11-hexadecenyl acetate (*Z*11–16:Ac, compound **3**) and (*Z*)-9-tetradecenol (*Z*9–14:OH, compound **5**) in a 40:48:6:2:4 ratio in volatile collections. By contrast, Rogers and Underhill (1981) established that the blend **1**+**5** in 1:10 ratio was highly attractive to males whereas Mitchell et al. (1983) found the mixture **1**+**5** in 10:1 ratio to be the most attractive. Analysis of the strains present in other countries has also shown a disparity in pheromone composition. Thus, in Taiwan Cheng et al. (1985) proved that the latter blend also was highly effective but, in Japan, Mochizuki et al. (1994) reported a pheromone blend composed of compounds **1**, **2**, (*Z*,*E*)-9,12-tetradecadienol (*Z*9,*E*12–14:OH, compound **4**), and **5** in a 98:60:86:100 ratio. In China, the pheromone composition of the insect was reported to be a mixture of these chemicals but in a 47:18:17:18 ratio (Dong and Du 2002). Therefore, it was not a surprise to discover that different commercial formulations of the pheromone were not sufficiently attractive in southern Spain to monitor and control the BAW in greenhouses. Consequently, the pheromone blend of the Spanish population was investigated.

Methods and Materials

Insects S. exigua moths were reared on an artificial diet based on wheat (T. Cabello, personal communication). The initial larvae were sent by T. Cabello (University of Almería, Spain), allowed to pupate, and sexed. The pupae then were placed in plastic containers until emergence and maintained on a reversed 16:8 L:D cycle at 24±1°C and 60% RH. The emerged adults were separated from pupae every day and fed with cotton balls soaked with a 10% sugar solution.

Chemicals Compound **1** was obtained from Sigma-Aldrich (St Louis, MO, USA), compound **2** from Acros-Organics (Geel, Belgium), and compounds **3, 4, 5,** and **6** were provided by SEDQ, S.A. (Barcelona, Spain). All compounds were >95% pure by GC or GC-MS analysis. Dimethyl disulfide was purchased from Sigma-Aldrich Química (Madrid, Spain). The solvents used (hexane, ether) were of analytical quality.

Pheromone Extracts Before proceeding to the gland excision, virgin females of different ages were observed to determine the moment of maximum calling activity. Groups of 10 virgin females were placed in plastic boxes under a red lamp in the dark, and their behavior was monitored every 30 min. During the calling period, the pheromone glands were excised and immersed in hexane. After 1 h of extraction, the supernatant was collected and stored at −80°C. A total of 28 extracts of 2–8 glands per extract were studied.

Volatiles Collection Five virgin females were selected and placed for 16 h (overnight) in a 40 ml vial (29×81 mm) containing a polydimethylsiloxane fiber (100 µm) for solid phase microextraction (SPME) (Matich et al. 1996). The fiber was inserted into the injection port of a GC-MS system for 5 min for analysis. A total of eight volatile collections were performed.

Derivatization with Dimethyl Disulfide (DMDS) Location of the double bonds in the monounsaturated compounds of the pheromone gland extracts was determined by DMDS derivatization, as previously described (Buser et al. 1983). Briefly, the pheromone gland extract (ca. 20 female equivalent) in 100 µl hexane was reacted with 100 µl DMDS and 5 µl iodine solution (60 mg/ml in ether) at 40°C for 24 h. The mixture was cooled, diluted with 200 µl hexane, and the iodine was removed by treatment with 100 µl of 5% aq. soln. of $Na_2S_2O_3$. The organic phase was concentrated to ca. 10 µl and kept at −80°C until GC-MS analysis.

Chemical Analysis Gland extracts and synthetic compounds were analyzed on a Fisons GC 8000 series coupled to a MD 800 mass spectrometer (ThermoFisher Scientific, Madrid, Spain) using helium (1 ml/min) as the carrier gas. The column used for analysis was a 30 m×0.25 mm i.d.×0.25 µm HP-5MS fused silica capillary column (Agilent Technologies, Madrid, Spain) under the following chromatographic conditions: injection at 70°C for 1 min, then program of 5°C/min up to 120°C, and 3°C/min up to 300°C, which was maintained for a further 10 min. Electron impact mass spectra were recorded at 70 eV in the range of m/z 40–400. The extracts were carefully concentrated to 1–2 µl, and then the entire extract was injected in splitless mode. For SPME analysis, a 30 m×0.25 mm i.d.×0.25 µm SPB-20 column (Supelco, Bellefonte, PA, USA) was used under the following conditions: injection at 100°C for 1 min, then program of 10°C/min up to 120°C, 3°C/min up to 250°C, and 5°C/min up to 260°C, which was kept for a further 10 min. Injections were made in splitless mode, and the mass range was also 40–400.

Electroantennogram (EAG) Assays and Coupled GC-EAD The EAG apparatus was commercially available from Syntech (Hilversum, The Netherlands). In brief, male antennae were excised, cut on both ends, and fixed to both electrodes with conducting gel Spectra 360 (Parker Lab. Inc., Hellendoorn, The Netherlands). A flow of humidified pure air (1000 ml/min) was directed continuously over the male antenna through the main branch of a glass tube (7 cm long×5 mm diam). Test stimulations were carried out by

giving puffs of air (300 ml/min) for 100 ms through a Pasteur pipette with the aid of a stimulus controller CS-01 (Syntech). The pipette contained a small piece of filter paper (1.5 cm diam) on which the gland extracts or the synthetic compounds **1–6** (10, 100, and 1000 ng diluted in hexane) had been deposited. The solvent was allowed to evaporate before the tests. Test compounds were applied at intervals of 60 sec on 10 antennae, and three times on each antenna. The antennae of at least 10 insects were used for the experiments. Control puffs with a piece of paper containing only solvent (hexane) were also intercalated between two consecutive stimuli to determine the baseline depolarization of the antennae. The signals were amplified (100 ×) and filtered (DC to 1 kHz) with an IDAC-2 interface (Syntech), digitized on a PC, and analyzed with the EAG Pro program. Depolarization means were compared for significance using analysis of variance (ANOVA) followed by LSD tests ($P<0.05$).

To establish the optimum conditions for performing the EAG experiments, the activity of different aged males (1–4 d-old) at different times of the photoperiod (3rd, 5th, 7th, and 8th h into the scotophase), 1 h before the onset of the scotophase and 1–2 h at the beginning of the photophase, was studied.

GC-EAD analysis was carried out on the pheromone glands of virgin females to which Hez-PBAN (pheromone biosynthesis-activating-neuropeptide, 50 pmol) had been applied 45 min before excision. Hexane extracts of the glands were analyzed on a Focus GC (Thermo Instruments, Barcelona, Spain) equipped with an FID detector, a split/splitless injector, and a second make up gas (nitrogen). Helium was the carrier gas (1–2 ml/min), and the column was a 30 m×0.25 mm i.d.×0.25 μm HP-5 fused silica capillary column (Agilent Technologies, Madrid, Spain). The effluent from the column was split 50:50, and branches to the FID and EAD were from a deactivated fused silica capillary column (35 cm long×0.25 mm i.d.). The transfer tube to the EAG preparation was heated to 230°C, and the GC conditions were the same as for the GC-MS.

Wind Tunnel Assays Assays were conducted in a glass tunnel of 180×50×50 cm as previously described (Quero et al. 1995). The wind was pushed through the tunnel by a 30 cm diam fan at 20 cm/s. The tunnel was illuminated with two red light fluorescent tubes dimmed to 1 lux. The temperature was maintained at 25±2°C, and the relative humidity was 43±10%. BAW males were acclimatized to the experimental conditions of the tunnel for 30 min, and individually released into the tunnel between the 6th and the 8th h of the scotophase. Before the tests, the insects were placed on filter paper in a Petri dish, then introduced into the tunnel at a height of 20 cm and a distance of 125 cm from the emission source. After a 30 sec acclimatization period, the behavior of the males was recorded for 5 min. For each responding insect, the following four types of behavior were recorded: taking flight; halfway: oriented upwind flight and arrival to the middle of the tunnel; final: arrival to the proximity of the lure; and contact: landing and contact with the source. In each treatment, a minimum of 40 virgin males of 1–3 d-old were used, and each insect was tested only once. The attractant source consisted of filter paper loaded with 1 μg of the most active EAG component (compound **1**) plus the corresponding amount of the other components to test the desired formulation. For statistical analyses, a χ^2 homogeneity test ($P<0.05$) was performed for every treatment.

Field Trials Field tests were conducted in greenhouses at two locations (Campo de Cartagena and Lorca) in the province of Murcia (southern Spain) from 6 July to 13 October 2006. In 2008, two more trials were conducted in the same province at the locations of Torre Pacheco from 1 July to 14 November, and Mazarrón from 21 July to 11 November. All tests were implemented by Kenogard, S.A. Three formulations were tested in 2006: F1: compounds **1+5** (91:9 ratio, 182 μg of **1**+18 μg of **5**); F2: compounds **1+5+3** (87:2.5:10.5 ratio, 174 μg of **1**+5 μg of **5**+21 μg of **3**); and F3: compounds **1+5+2+4** (31:31:16:22 ratio, 62 μg of **1**+ 62 μg of **5**, +32 μg of **2**+44 μg of **4**), along with a commercial formulation (C1=Pherocon® BAW, Trécé, Adair, OK, USA) (two replicates per formulation in each location). In 2008, five formulations were assayed: the same F2 as above; F4: **1+5** (60:40 ratio, 174 μg of **1**+116 μg of **5**); F5: **1+5** (80:20 ratio, 174 μg of **1**+43.5 μg of **5**); F6: **1+5+2** (35:23:42 ratio, 174 μg of **1**+116 μg of **5**+209 μg of **2**); and F7: **1+5+3** (56:37:7 ratio, 174 μg of **1**+116 μg of **5**+23 μg of **3**), along with two different commercial lures: C1 as above, and C2 (Econex, Econex S.L., Murcia, Spain) (two replicates per formulation in each location). The synthetic chemicals were dissolved in hexane, and the required amounts were deposited onto red rubber septa (Aldrich, Milwaukee, WI, USA). Delta traps containing the septa were suspended at a height of 120–150 cm, and the distance between traps was about 10–15 m. The number of males caught per trap was recorded every week, the traps were emptied, and the septa were replaced every 3 wk. For statistical analyses, the number of moths captured per trap was converted to $\sqrt{(x+0.5)}$ and subjected to ANOVA followed by LSD test ($P<0.05$).

Results

Pheromone Composition Females of all ages showed a maximum calling behavior during the last 3 h of the

scotophase (data not shown). Thus, young females (1st–3rd scotophase) started to call 6 h after the onset of the scotophase, with the number of calling females gradually increasing until the end of the dark period. Females of 3rd–5th scotophase reached peak calling activity during the 6–7 h into the scotophase.

Analysis of the pheromone glands excised at the maximum calling period showed the presence of the previously identified compounds **1**–**5** by their GC retention times on polar and non-polar columns, and mass spectra in comparison with those of authentic samples (Fig. 1). In addition, *Z*11–16:OH (**6**) also was detected in very low amounts (0.58 ng/gland).

To confirm the presence of this previously unidentified compound in any of the BAW strains studied, DMDS derivatization of the extract produced an adduct with a molecular ion of *m/z* (%) 334 (16) and diagnostic ions at *m/z* 117 (72) and 217 (100). The molecular ion corresponded to the addition of DMDS to one double bond and the other ions were assigned to fragments $[CH_3(CH_2)_3CH(SCH_3)^+]$ and $[(CH_3S)CH(CH_2)_{10}OH]^+$, confirming the structure of the new product. The presence of compounds **2**, **3,** and **5** was also verified by DMDS adducts. The final composition of the extract was a mixture of compounds **1**–**6** in a 26:11:1:22:31:9 ratio, and the amount of compound per gland ranged from 2.08 ng for **5** to 0.09 ng for **3** (Fig. 2). However, analysis of female volatiles using the SPME technique revealed only the presence of compounds **1**, **2**, **3**, and **5** in a 34:40:4:22 ratio (Fig. 2).

GC-EAD analysis of PBAN-treated pheromone gland extracts confirmed the presence of compounds **1, 2, 4, 5,** and **6** but in a different ratio from those found in non-treated glands (Fig. 3). Compound **1** elicited the highest response followed by the 14-carbon compounds **2, 4,** and **5**. Compound **6,** in turn, induced a very small EAG depolarization.

EAG Assays Males of 1st–2nd scotophase elicited higher electrophysiological responses (2.0 mV on average) than older males (1.6 mV of 2nd–3rd scotophase, 1.5 mV of 3rd–4th scotophase) (data not shown). In addition, males displayed increasing EAG responses with time, reaching a maximum at the end of the scotophase (values rose from 1.6 to 2.2 mV, and dropped to 1.6 mV after the scotophase). When the pheromone compounds **1–6** were tested at several doses (10, 100, and 1000 ng), the highest responses were displayed by compound **1** (Fig. 4). Depolarizations induced by compounds **2–6** were dose-dependent, with the responses induced by the C16 compounds being lowest (Fig. 4). The relative activity of the compounds followed the order **1** > **4** ≅ **2** > **5 > 3** ≅ **6**.

Wind Tunnel Assays Blends of synthetic compounds in a ratio similar to that found in gland extracts and volatile collections elicited similar responses by males as did five calling females (data not shown). No significant differences were observed at any stage of the courtship sequence, although the number of contacts elicited by virgin females was slightly higher (63%) than the formulations of gland extracts (43%) and volatiles (51%).

When tested alone, compound **1** evoked a remarkable long-range attraction (71% of males reached the proximity

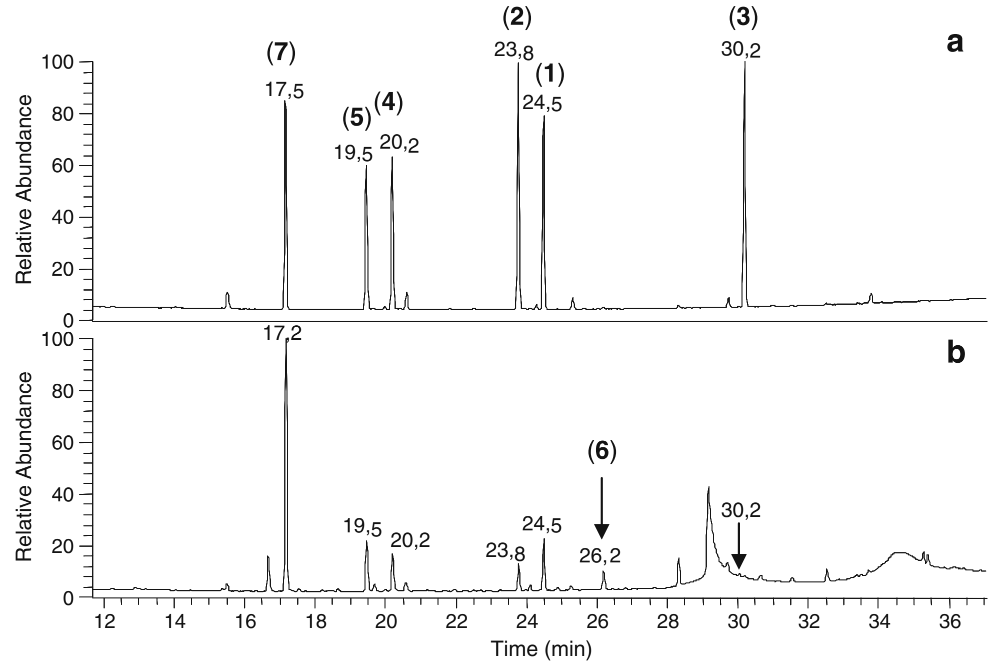

Fig. 1 Gas chromatography (GC) analyses of **a** blend of synthetic compounds **1-5** and internal standard (**7**), **b** gland extract of four *Spodoptera exigua* females. Identities of compounds are as follows: *Z*9,*E*12–14:Ac (**1**), *Z*9–14:Ac (**2**), *Z*11–16:Ac (**3**), *Z*9,*E*12–14:OH (**4**), *Z*9–14:OH (**5**) and 12:Ac (IS, **7**). Compound in **b** at retention time 26.2 min corresponds to *Z*11–16:OH (**6**) as shown independently by GC-MS analysis of the DMDS adduct

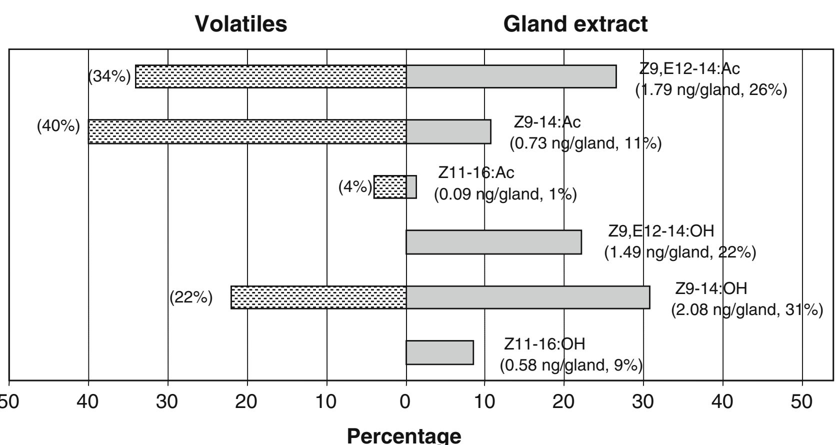

Fig. 2 Pheromone composition of *Spodoptera exigua* found in gland extracts during the calling period (*N*=28 extracts of 2–8 female glands), and volatiles from females (*N*=8 of 5 virgin females) by SPME. Percentage and estimated mean amounts of compounds are in parenthesis

of the lure) but no insect landed at the source (Fig. 5). Binary mixtures of **1** with compounds **2**, **3,** and **5** also induced upwind flight on males, but only blend A (**1**+**5** in a 60:40 ratio) induced males to significantly contact the source (71%). Other **1**+**5** binary mixtures ranging from 80:20 to 40:60 did not significantly differ in activity in comparison to the 60:40 blend, but higher relative amounts of **5,** such as 20:80 or 0:100 of the **1**+**5** blend dramatically affected the number of males arriving in the vicinity of the source (data not shown).

Binary blends of **1** with **2** or **3** induced close approach to the source in 45–55% of males but none of them made contact (Fig. 5). When both **2** and **3** were added to blend A, in the same proportion as in female volatiles, the resulting blends D (**1**+**5**+**2** in 35:23:42 ratio) and E (**1**+**5**+**3** in 56:37:7 ratio) also elicited the complete behavioral sequence in males. The slightly lower number of insects contacting the source in comparison to blend A was not significant (Fig. 5). Lowering the relative amount of compound **5** to 2.5% in the **1**+**5**+**3** blend (formulation F) resulted in a clearly less active formulation.

When compounds **4** and **6** were added to blend A, they evoked dissimilar effects. Compound **4** had no effect on the number of males contacting the source when added to blend A at two different doses (blend A+10% of **4**: 68% contacts, blend A+50% of **4**: 66% contacts). In contrast, the presence of compound **6** markedly decreased the number of males flying upwind and contacting the source (blend A: 71% of contacts, blend A+10% of **6:** 52%, blend A+50% of **6:** 40%) (Fig. 6).

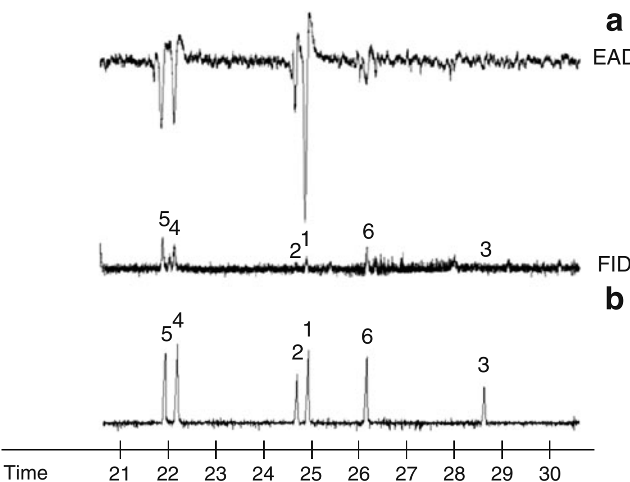

Fig. 3 **a** GC-EAD response of a *Spodoptera exigua* antenna from a male to a PBAN-treated pheromone extract. **b** GC of a mixture of synthetic compounds *Z*9,*E*12–14:Ac (**1**), *Z*9–14:Ac (**2**), *Z*11–16:Ac (**3**), *Z*9,*E*12–14:OH (**4**), *Z*9–14:OH (**5**), *Z*11-16:OH (**6**) (100 ng each)

Field Assays In the 2006 trials, a mixture of compounds **1**+**5** in a 91:9 ratio (formulation F1, Fig. 7) (Mitchell et al. 1983) resulted in a remarkably attractive lure (95.5±15.5 and 51±21 males per trap in each field). When compound **3** was added to this mixture to produce a similar composition to the one described by Tumlinson et al. (1990), the resulting formulation F2 attracted more males than F1, but the difference was significant in only one of the fields tested (149±55 males/trap caught in F2 vs. 51±21 in F1). By contrast, the mixture **1**+**5**+**2**+**4** in a 31:31:16:22 ratio (formulation F3), an initial pheromone composition found in gland extracts, displayed attractant activity similar to that of F1 (Fig. 7). In one field, all new formulations were superior to the commercial lure C1, whereas in the other field only F2 was more effective.

In 2008, formulation F7 (**1**+**5**+**3** in a 56:37:7 ratio) was the most attractive in the two fields (489±8 males/trap caught in field A and 620±95 in field B), being significantly more efficient than F2, F4, and F6 (Fig. 8).

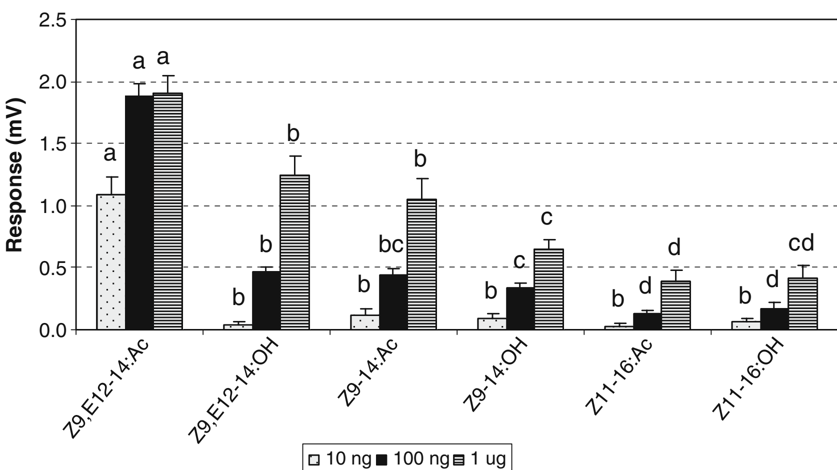

Fig. 4 EAG responses of antennae from male *Spodoptera exigua* (N=10) to different doses of compounds *Z*9,*E*12–14:Ac (**1**), *Z*9–14:Ac (**2**), *Z*11–16:Ac (**3**), *Z*9,*E*12–14:OH (**4**), *Z*9–14:OH (**5**), and *Z*11–16:OH (**6**) identified in female gland extracts. Bars (± SE) with the same letters within the same dose are not significantly different (ANOVA, LSD test, P<0.05)

F7 was also superior to the two commercial lures C1 and C2 in field B and to C1 in field A. By contrast, F6 was the least active formulation (Fig. 8).

Discussion

The sex pheromone of the Spanish population of the BAW, determined from female gland extracts, has been identified as a mixture of compounds **1–6** in a 26:11:1:22:31:9 ratio, although volatiles emitted by virgin females lack the presence of alcohols *Z*9,*E*12–14:OH (**4**) and *Z*11–16:OH (**6**). This is not surprising because it is known that the composition of the pheromone gland and volatiles released by females may differ remarkably (Cross et al. 1976; Hill et al. 1975). The composition of female volatiles was similar to that found by Tumlinson et al. (1990) with the exception of *Z*9,*Z*12–14:Ac, which was absent in our extracts. The relative differences in both strains could be due to the different origin of the strains or the different extraction methods used: volatile collections followed by entrainment on charcoal by the American team and SPME analysis of female effluvia in this work. The diene alcohol **4** was moderately EAG-active and had a neutral effect on male behavior. However, in the Japanese population, this chemical stimulated the receptor cells tuned to alcohol **5** (Mochizuki et al. 1993). Moreover, combining alcohol **4** with the corresponding acetate **1** resulted in an efficient formulation in the field (Rogers and Underhill 1981; Mochizuki et al. 1994). Alcohol **6**, in turn, was practically inactive by EAG, but inhibited the responses of males when mixed with the highly active formulation, **1+5** (60:40). Its presence in gland extracts suggests that it is likely a biosynthetic precursor of the corresponding *Z*11–16:Ac (**3**) (Bjostad et al. 1987). However, to our knowledge, no biosynthetic studies of the pheromone have been undertaken to prove this assumption.

In wind tunnel studies, the combination **1+5** in a 60:40 ratio (blend A) was the most active among all the binary and ternary mixtures tested, but this proportion is not critical because similar levels of activity were achieved by

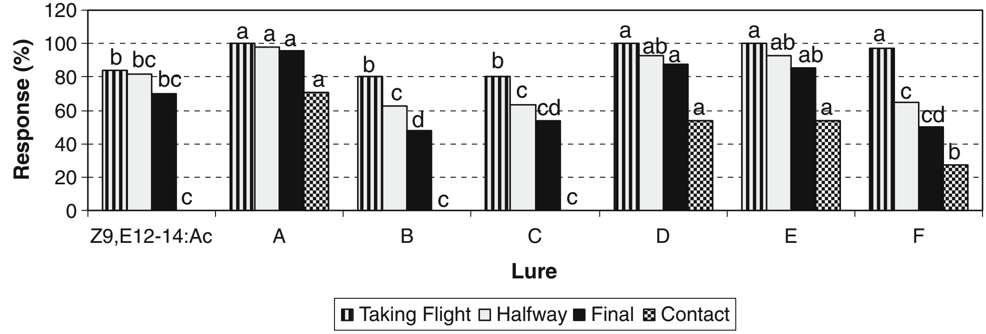

Fig. 5 Percentage of response of *Spodoptera exigua* males (N=40–48) in wind tunnel to 1 µg of *Z*9,*E*12–14:Ac (**1**) and to blends A: **1+5** (60:40), B: **1+2** (46:54), C: **1+3** (90:10), D: **1+5+2** (35:23:42), E: **1+5+3** (56:37:7), F: **1+5+3** (87:2.5:10.5). Bars with the same letters within the same behavior are not significantly different (*Chi square* test of homogeneity, P<0.05)

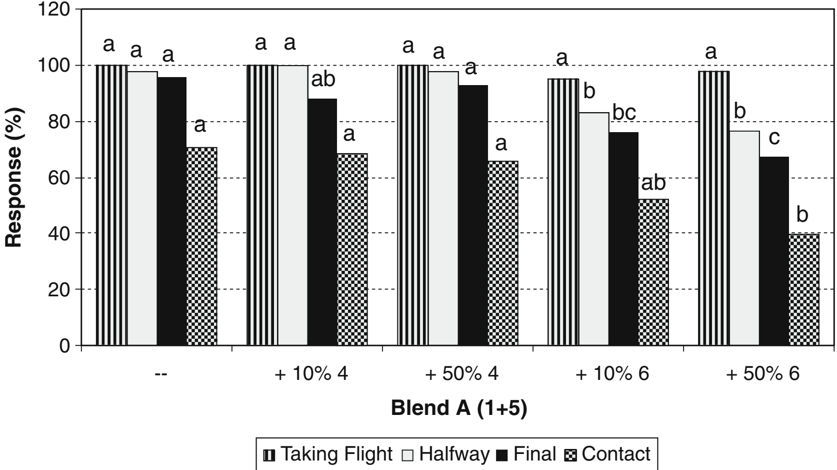

Fig. 6 Percentage of response of *Spodoptera exigua* males (N=41–69) in wind tunnel to blend A (**1**+**5**, 60:40) and mixtures with compounds **4** and **6** in different ratios (**1**: *Z*9,*E*12–14:Ac, **4**: *Z*9,*E*12–14:OH **5**: *Z*9–14:OH, **6**: *Z*11–16:OH). Bars with the same letters within the same behavior are not significantly different (*Chi square* test of homogeneity, P<0.05)

blends 80:20 to 40:60. This result is consistent with the relative amounts of both compounds found in gland extracts and female volatiles. Both chemicals have been found to be tuned to two different receptor neurons in male-specific sensilla trichodea (Dickens et al. 1993; Mochizuki et al. 1993), and, in the field, this formulation in a 10:1 ratio was reported to be active in Florida (Mitchell et al. 1983), Taiwan (Cheng et al. 1985), and in a 70:30 ratio in Japan (Wakamura 1987).

In field tests, initially we compared the most effective formulations found by Mitchell et al. (1983) (F1) and Tumlinson et al. (1990) (F2) with one commercially

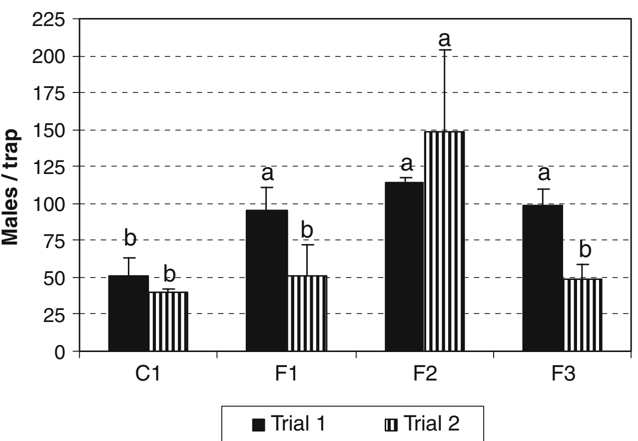

Fig. 7 Mean number of catches (± SE) of *Spodoptera exigua* males in traps baited with various pheromone formulations in two different fields in 2006: C1 (commercial bait), F1: **1**+**5** (91:9), F2: **1**+**5**+**3** (87:2.5:10.5), F3: **1**+**5**+**2**+**4** (31:31:16:22) (**1**: *Z*9,*E*12–14:Ac, **2**: *Z*9–14:Ac, **3**: *Z*11–16:Ac, **4**: *Z*9,*E*12–14:OH, **5**: *Z*9–14:OH). Bars with the same letter within the same trial are not significantly different (ANOVA, LSD test, P<0.05)

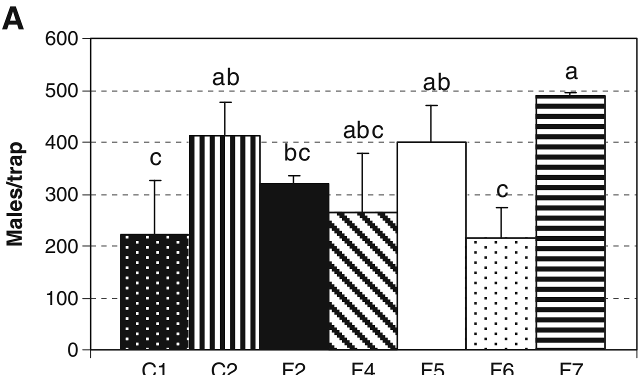

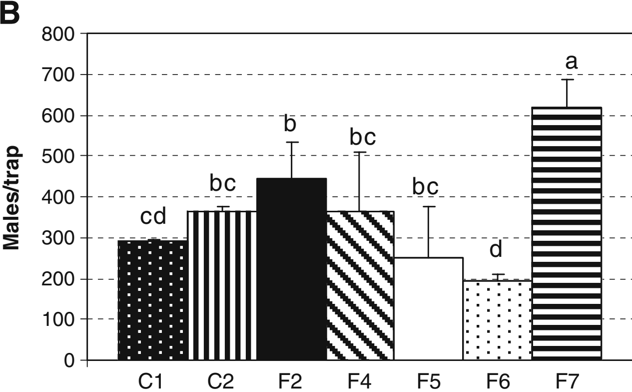

Fig. 8 Mean number (± SE) of *Spodoptera exigua* males caught in traps baited with various pheromone formulations in two different fields (A,B) in 2008: C1, C2 (commercial baits), F2: **1+5+3** (87:2.5:10.5), F4: **1+5** (60:40), F5: **1+5** (80:20), F6: **1+5+2** (35:23:42), F7: **1+5+3** (56:37:7) (**1**: *Z*9, *E*12–14:Ac, **2**: *Z*9–14:Ac, **3**: *Z*11–16:Ac, **4**: *Z*9,*E*12–14:OH, **5**: *Z*9–14:OH). Bars with the same letter within the same trial are not significantly different (ANOVA, LSD test, P<0.05)

available (C1), along with a new formulation (F3) of similar composition to the pheromone gland extract lacking compounds **3** and **6**. In the first trial, all formulations were significantly more attractive than the C1, although without a significant difference among them. In the second trial, F2 was the most efficient formulation. Based on these results, a new set of experiments was designed in 2008 to further improve formulation F2. Thus, addition of compound **3** (7%) to formulation F4 (blend A above) resulted in a more efficient blend (F7), not only in comparison to its parent F4 but also to F2. In fact, F7 was the most attractive formulation found for BAW males. Our results show that in the Spanish population the presence of the minor component **3** appears to be important for the development of new attractant formulations to catch BAW males.

Compound **2**, the major component of the pheromone released by females, deserves some comments. First, this compound was only moderately active on male antennae, activity similar to that of diene alcohol **4**, a component absent in female volatiles. Second, in a wind tunnel, compound **2** decreased the attractant activity of the major component **1**, and that of the highly active blend A as well. Third, in the field, addition of **2** to formulation F4 resulted in a less efficient lure, the resulting formulation F6 being the least efficient of all tested. These data are in agreement with those of Tumlinson et al. (1990) in which compound **2**, also the major component released by American BAW females, also reduced the number of catches when it was incorporated into the lure. It is surprising that this compound emitted by females as a major component reduces the attraction of conspecific males in the laboratory and in the field. Does the female use this compound to modulate the activity of the key components **1** and **5** under some specific but yet unknown conditions? It was also unexpected that occasionally compound **2** elicited in males spikes from neurons sensitive to the major compound **1** (Dickens et al. 1993), with the threshold of the cells responding to acetate **2** being ca. 1000 times higher than that of the cells responding to acetate **1** (Mochizuki et al. 1993). These data do not correspond to the relatively high emission of compound **2** by females relative to compounds **1** and **5**, the two components from which receptor cells have so far been identified (Mochizuki and Shibuya 1991; Mochizuki et al. 1993) (see above). These data indicate that more research is needed to clarify the role of compound **2** in the chemical communication system of the BAW.

In summary, we have identified the pheromone composition of the Spanish population of the BAW, and found that extracts of female glands exhibit a remarkably different composition relative to volatiles emitted by females. Electrophysiological and behavioral activity of the pheromone components, and mixtures thereof, have resulted in a new highly active formulation (F7) for the Spanish BAW population, which should be useful in future IPM strategies.

Acknowledgements We gratefully acknowledge T. Cabello (University of Almería) for providing us with BAW larvae for rearing and useful advice, P. Fuchs (Kenogard, S.A.) for conducting the field tests, and SEDQ S.A. for providing us with compounds **3–6**. We are also indebted to MICINN for an I3P fellowship to P. Acín and a Ramón y Cajal contract to C.Q. Financial support was provided by CICYT (project AGL 2006-13489-C02-01/AGR).

Abstract General odorant-binding proteins (GOBPs) of moths are postulated to be involved in the reception of semiochemicals other than sex pheromones, the so-called "general odorants." We have expressed two GOBPs, AtraGOBP1 and AtraGOBP2, which were previously isolated from the antennae of the navel orangeworm, *Amyelois transitella*. Surprisingly, these two proteins did not bind compounds that are known to attract adult moths, particularly females. The proper folding and functionality of the recombinant proteins was inferred from circular dichroism analysis and demonstration that both GOBPs bound nonanal in a pH-dependent manner. EAG experiments demonstrated that female attractants (1-phenylethanol, propionic acid phenyl ester, and isobutyric acid phenyl ester) are detected with high sensitivity by the antennae of day-0 to day-4 adult females, with response declining in older moths. The same age-dependence was shown for male antennae responding to constituents of the sex pheromone. Interestingly, AtraGOBP2 bound the major constituent of the sex pheromone, Z11Z13-16Ald, with affinity comparable to that shown by a pheromone-binding protein, AtraPBP1. The related alcohol bound to AtraPBP1 with higher affinity than to AtraGOBP2. AtraGOBP1 bound both ligands with low but nearly the same affinity.

Key Words *Amyelois transitella* · AtraGOBP1 · AtraGOBP2 · AtraPBP1 · Circular dichroism · Electroantennogram recording · Female attractants · General odorant-binding proteins · Protein expression

Introduction

There is growing evidence in the literature suggesting that odorant-binding proteins (OBPs) are involved in the early events of odorant reception in insects. OBPs were first isolated from moth antennae (Vogt and Riddiford 1981), but they have now been identified from insects in all orders hitherto investigated [for a recent example, see (Gong et al. 2009a)]. RNA interference experiments in the southern house mosquito, *Culex quinquefasciatus* (Pelletier et al. 2010), and the malaria mosquito, *Anopheles gambiae* (Biessmann et al. 2010), showed that reduction in OBP expression leads to lower sensitivity for the detection of specific odorants, whereas a model has been proposed for the fruit fly, *Drosophila melanogaster*, in which an OBP, LUSH, activates the receptor while bound to a pheromone ligand (Laughlin et al. 2008). In contrast, moth pheromone receptors are activated directly by ligands, as demonstrated by expressing receptors in a heterologous system devoid of OBPs and stimulating with pheromones (Nakagawa et al. 2005). Previously, we demonstrated that an OBP from the silkworm moth, *Bombyx mori*, BmorPBP1, enhances sensitivity when the moth receptor BmorOR1 is expressed in the empty neuron system of the fruit fly (Syed et al. 2006).

The existence of at least two groups of OBPs became apparent when the first ones were isolated from moth species. Pheromone-binding proteins (PBPs), postulated to be functionally involved in pheromone reception, are enriched or expressed only in male antennae, and show poor conserved sequences between species (Vogt et al. 1991). In contrast, some highly conserved antennal proteins show expression in both males and females, thus suggesting that they are involved in the reception of "general" odorants (i.e., odorants other than pheromones) and, consequently,

they were dubbed general-odorant binding proteins (GOBPs) (Vogt et al. 1991). Immunocytochemical studies have further substantiated this hypothesis. PBPs have been expressed in the pheromone-detecting, long trichoid sensilla in the male antennae of the silkworm moth, *B. mori*, and the wild silkworm moth, *Antheraea polyphemus* (Steinbrecht et al. 1995). In contrast, GOBPs have been shown to be expressed in basiconic sensilla, which are sensitive to plant-derived compounds and other "general" odorants (Steinbrecht et al. 1995). Exceptionally, a GOBP from *Mamestra brassicae*, MbraGOBP2, has been expressed in long trichoid sensilla and has high affinity for a behavioral antagonist detected by neurons housed in these sensilla (Jacquin-Joly et al. 2000). Additionally, it has been shown that a female pheromone constituent of *A. polyphemus* binds to a GOBP expressed in male and female antenna (Ziegelberger 1995). In contrast to PBPs from *B. mori*, BmorGOBP2 was recently shown to bind bombykol, but not bombykal, thus suggesting a possible role in pheromone reception (Zhou et al. 2009).

Recently, we isolated and cloned the cDNAs that encode various olfactory proteins from the navel orangeworm, *Amyelois transitella* (Walker) (Lepidoptera: Pyralidae), a major pest of almonds, pistachios, and walnuts (Leal et al. 2009). Considering that two proteins, AtraGOBP1 and AtraGOBP2, were enriched in female antennae, we hypothesized that they may be involved in the reception of female attractants. Here, we report that recombinant AtraGOBP1 and AtraGOBP2 did not bind semiochemicals known to attract adult moths, particularly females, i.e., 1-phenylethanol, propionic acid phenyl ester (hereafter referred to as PAPE = phenyl propionate), and isobutyric acid phenyl ester (hereafter referred to as IBAPE = phenyl 2-methylpropionate) (Price et al. 1967), but rather showed higher affinity to nonanal, a component of the head space volatile from almonds (Beck et al. 2009). Electroantennogram (EAG) studies showed that all these semiochemicals are detected by the antennae, so reception of female attractants may involve other yet unknown OBPs. Interestingly, both AtraGOBP1 and AtraGOBP2 bound to and discriminate two constituents of the *A. transitella* sex pheromone (Leal et al. 2005b), suggesting a possible role in pheromone reception.

Methods and Materials

Protein Expression and Purification Each cDNA fragment was amplified by PCR with gene-specific primers and *PfuUltra* HotStart DNA polymerase (Stratagene, La Jolla, CA, USA) as *Taq* DNA polymerase, gel-purified by using QIAquick Gel Extraction Kit (Qiagen, Valencia, CA, USA), and subcloned into the recognition site of *Eco* RV in pBluescript SK (+) (Stratagene) as previously described (Leal et al. 2009). Each insert DNA was used as template for PCR-based insertion of recognition sites of restriction enzymes. The following primers were designed for the PCR: 5-KpnI-AtraGOBP1, 5′-CCGGGGTACCCGAC GTGGCCGTCATGAAGG-3′; 3-BamHI-AtraGOBP1, 5′-GCGCGGATCCTTATGTCTCGGCCTCCATGA-3′; 5-HaeIII-AtraGOBP2, 5′-TTTGCGGCCAGTGCTGAGG TGATGAGCCAT-3′; 3-XhoI-AtraGOBP2, 5′-CCGCTCGAGTCAATATTTCTCCATGACTG-3′. After incubation at 95°C for 2 min, we initiated forty cycles of stepwise PCR with the following amplification program (95°C for 30 sec, 40°C for 30 sec, and 72°C for 1 min). One microgram of pET-22b(+) plasmid DNA (Novagen, Gibbstown, NJ, USA) was double-digested with *Msc* I and *Bam* HI or *Xho* I (New England Biolabs, Ipswich, MA, USA), and gel-purified.

For preparation of pET-22b-AtraGOBP1, 1 μg of the PCR product amplified by 5-KpnI-AtraGOBP1 and 3-BamHI-AtraGOBP1 was treated with *Kpn* I (New England Biolabs) and subsequently re-purified by QIAquick PCR Purification Kit (Qiagen). Purified DNA was treated with T4 DNA polymerase (New England Biolabs) at 12°C for 20 min to remove 5′-protruding single strand DNA fragment. After re-purification of DNA by QIAquick PCR Purification Kit (Qiagen), DNA was digested with *Bam* HI. Five hundred bp of DNA fragment were gel-purified and ligated into pET-22b (+) digested previously. Construction of the vector was confirmed by sequencing.

For construction of pET-22b-AtraGOBP2, the PCR product amplified by 5-HaeIII-AtraGOBP2 and 3-XhoI-AtraGOBP2 was purified by QIAquick PCR purification kit and double-digested with *Hae* III and *Xho* I. The treated DNA fragment was gel-purified and ligated into pET-22b (+) vector as described above.

Expression was performed in LB medium with transformed BL21(DE3) cells (Novagen) following a previously reported protocol (Leal et al. 2009). Proteins in the periplasmic fraction were extracted with 10 mM Tris·HCl (pH 8) by using three cycles of freeze-and-thaw and centrifuging at 16,000×*g* to remove debris. The supernatant was collected and loaded on HiPrep DEAE FF column (GE Healthcare Biosciences, Piscataway, NJ, USA). Unless stated otherwise, all separations by ion-exchange chromatography were done with a linear gradient of 0–500 mM NaCl in 10 mM Tris·HCl (pH 8). Fractions containing the target proteins were further purified on HiPrep Q FF column (GE Healthcare Biosciences) and, subsequently, on Mono Q 10/100 GL column (GE Healthcare Biosciences). These fractions containing target proteins were concentrated by centrifuging in Centriprep YM-10 (Millipore, Billerica, MA, USA) at 3000 × *g* until sample volume was less than 5 ml. Then, the sample was loaded on HiLoad 26/60

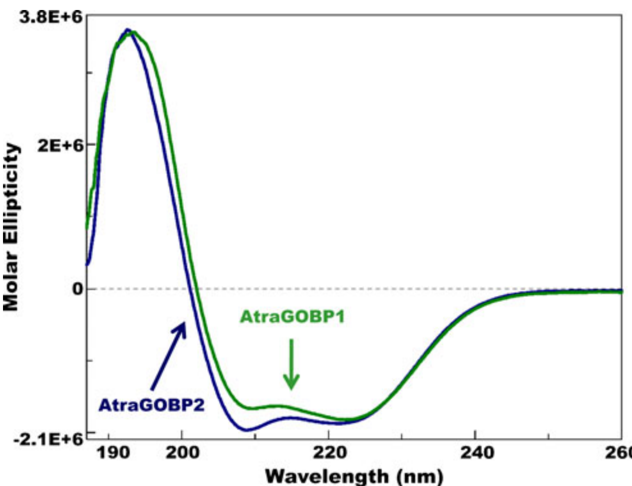

Fig. 1 Far-UV-CD spectra of two general-odorant binding proteins from the navel orangeworm, *Amyelois transitella*. AtraGOBP1, green trace; AtraGOBP2, blue trace. Note the lowest minima for AtraGOBP2 and AtraGOBP1 appeared at 209 nm and 223 nm, respectively

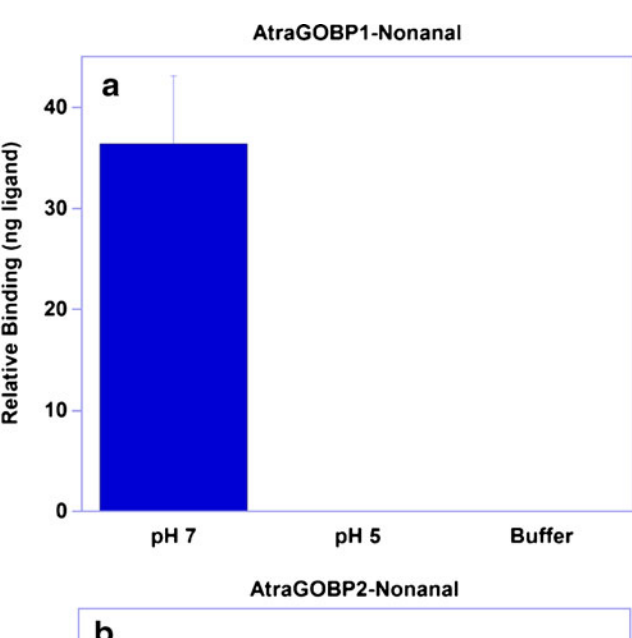
Superdex-75pg gel-filtration column (GE Healthcare Biosciences) preequilibrated with 150 mM NaCl and 20 mM Tris·HCl (pH 8). Fractions were analyzed by SDS-PAGE and LC-MS. LC-ESI-MS was performed with a LCMS-2010 (Shimadzu, Kyoto, Japan). HPLC separations were done on Zorbax 300SB-C8 Narrow Bore column (100×2.1 mm; 5 µm; Agilent Technologies, Palo Alto, CA, USA) with a gradient of water and acetonitrile plus 2% acetic acid as a modifier. The detector was operated with the nebulizer gas flow at 1.0 l/min and the curved desolvation line and heat block at 250°C. Fractions containing traces of nontarget proteins were purified further by Mono-Q column with a shallower gradient buffer. Highly purified protein fractions were concentrated by Centriprep YM-10, desalted on HiPrep 26/10 desalting column (GE Healthcare Biosciences) with water as mobile phase, analyzed by LC-ESI/MS, lyophilized, and stored at −80°C until use. The concentrations of AtraGOBPs were measured by UV radiation at 280 nm in 20 mM sodium phosphate (pH 6.5) and 6M guanidine HCl by using the theoretical extinction coefficients calculated with expasy software (http://us.expasy.org/tools/protparam.html). AtraPBP1 was prepared as previously reported (Leal et al. 2009). Circular dichroism (CD) spectra were recorded by using a J-810 spectropolarimeter (Jasco, Easton, MD, USA) with 0.2 mg/ml AtraGOBPs in either 20 mM ammonium acetate, pH 7 or 20 mM sodium acetate, pH 5.

Binding Assays Binding was measured by incubating AtraGOBPs or AtraPBP1 with test ligands, separating unbound and bound protein, extracting ligand from the latter sample, and analyzing by gas chromatography, according to a previously reported "cold binding assay" (Leal et al. 2005a). After lowering pH to release the ligand, bound protein fractions were extracted and analyzed by gas chromatography with flame ionization detection (GC-FID) for quantification and by GC-mass spectrometry (GC-MS) for confirmation of ligand identity. GC-FID and GC-MS were performed with a 6890 series GC and a 5973 Network Mass Selective Detector (Agilent Technologies), respectively. Both instruments were equipped with the same type of capillary column (HP-5MS, 25 m×0.25 mm; 0.25 µm; Agilent Technologies) operated under the same temperature program. For female attractants of low molecular weight, the oven was operated at 50°C for 1 min, increased to 180°C at a rate of 10°C/min, and held at the final temperature for 5 min, whereas for pheromones the



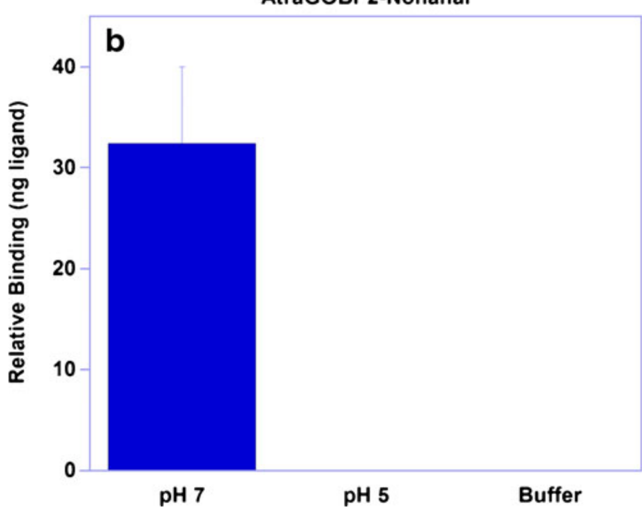


Fig. 2 Binding of nonanal to *Amyelois transitella* AtraGOBPs. This aldehyde showed high affinity to AtraGOBP1 (**a**) and AtraGOBP2 (**b**) at high pH, but no affinity at low pH. No traces of the ligand were detected in the buffer at pH 7. Histogram bars represent mean+SEM (*N*=5)

temperature program began at 70°C for 1 min, increased to 250°C at a rate of 10°C/min, and held at the final temperature for 10 min. Additionally, binding was measured by a competitive binding assay with *N*-phenyl-1-naphthylamine (NPN) as a fluorescent reporter (Ban et al. 2002). Fluorescence spectra were recorded on a Shimadzu RF-5301 PC spectrofluorometer.

Insects Details of *A. transitella* rearing have been previously described (Parra-Pedrazzoli and Leal 2006). Briefly, larvae were raised on roasted pistachio in growth chambers (Percival Scientific, Perry, IA, USA) under 28±2°C temperature, 75±10% relative humidity (RH), and a 16:8h (light:dark) photo regime. Emerging moths were collected daily, separated by sex, and transferred to plastic boxes (12×12×5 cm; 669 ml lunchbox, TakeAlong containers, Rubbermaid, Fairlawn, OH, USA) provided with up to ten layers of water soaked paper towels (Thirsty Ultra Absorbent, 27.9×27.9 cm; Safeway, Phoenix, AZ, USA). Box covers were perforated to allow air circulation. This arrangement provided ~100% RH.

Electroantennogram (EAG) Recordings We developed a method wherein an adult moth is restrained in a pipette tip (200 µl, USA Scientific Inc., Ocala, FL, USA) that was cut from the top to have a large (ca. 2 mm) tip diameter. The moth was pushed gently through the base of the pipette tip with a humidified tissue paper stub until the antennae and part of the head protruded from the tip. The head was immobilized with a non-drying clay (Claytoon™, Van Aken International, CA, USA) leaving a small part of one eye and two antenna exposed. The pipette tip holding the

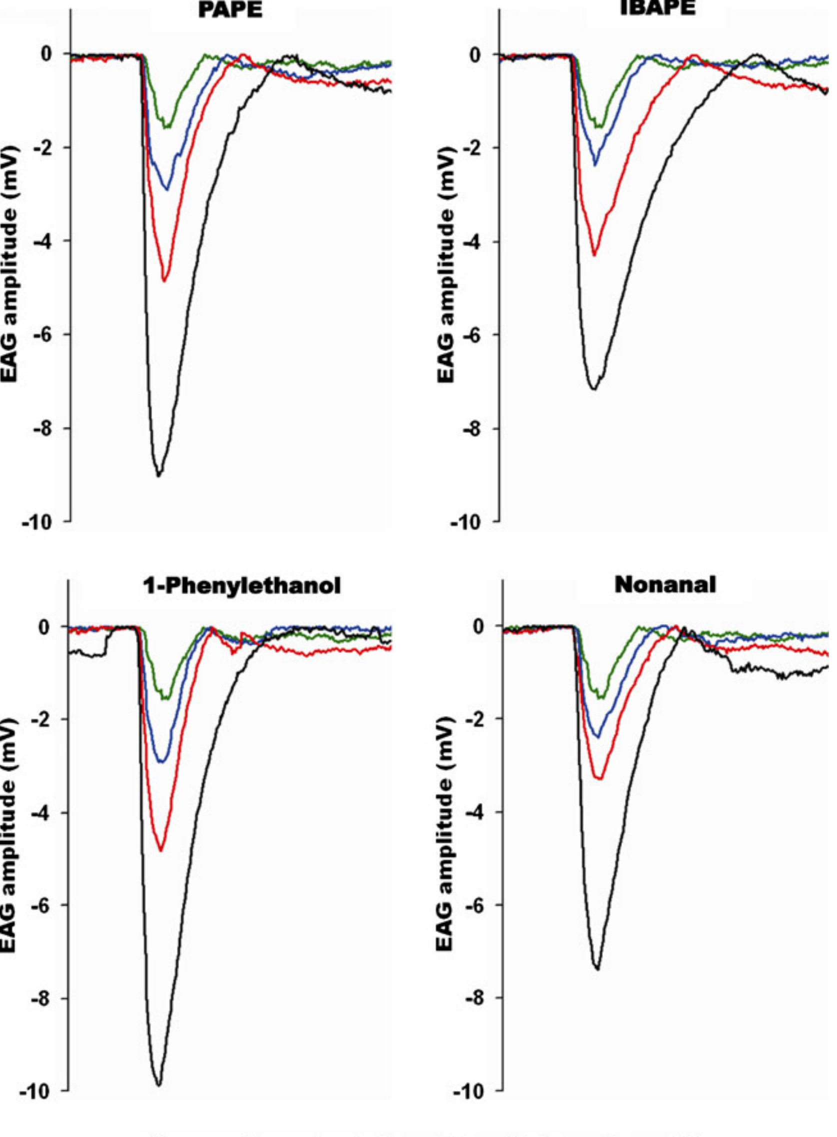

Fig. 3 EAG traces recorded from antennae of live female *Amyelois transitella* in response to PAPE, IBAPE, 1-phenylethanol, and nonanal. All traces from top to bottom show the responses to control, and increasing doses of the test compounds (from 0.1 to 10 µg/µl source dose)

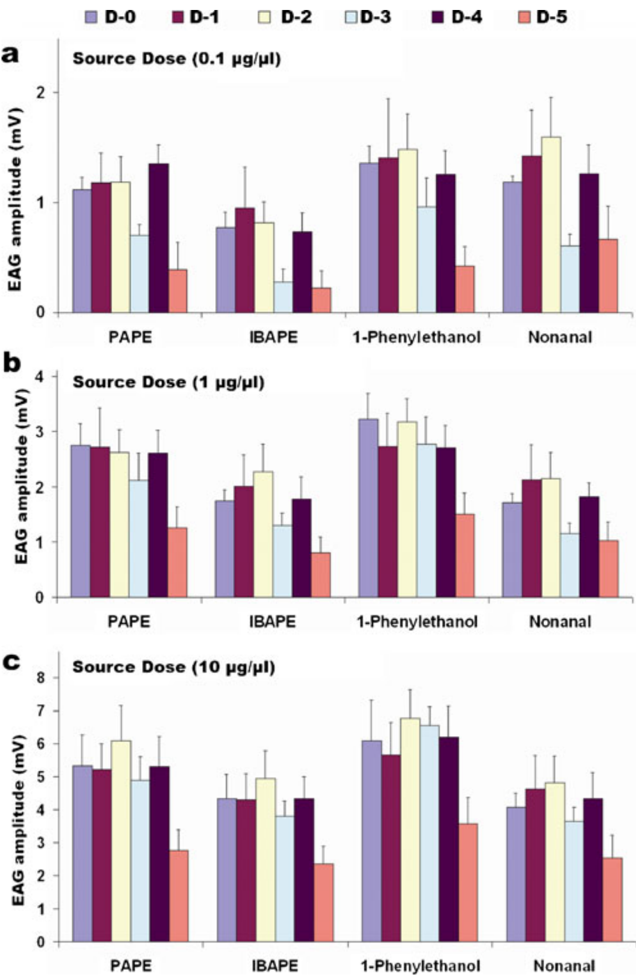

Fig. 4 Age-dependent responses of female *Amyelois transitella* antennae to attractants and nonanal. Responses displayed in (**a**), (**b**), and (**c**) were recorded with 0.1, 1, and 10 µg/µl source dose, respectively. Histogram bars represent mean+SEM (N=10)

restrained moth was placed on a platform of the EAG Micromanipulator MP-12 (Syntech, Kirchzarten, Germany) between the two electrode holders. A saline filled electrode impaled the exposed area of the eye under the microscope (Leica MZ75) that served as reference while the recording electrode contacted the two antennae whose distal segments were excised. Indifferent and recording electrodes were filled with 0.1M KCl solution with 0.5% polyvinylpyrrolidone. The EAG signals were amplified, monitored, and analyzed with software EAG 2000 (Syntech). The preparation was held in a humidified air stream delivered by the Syntech stimulus controller (CS-55 model; Syntech) at 26 ml/sec to which a stimulus pulse of 4 ml/s was added for 500 ms. Signals were recorded for 10 s**ec**, starting 2 sec before the onset of the stimulus pulse. The antennal preparation was stimulated with a 500 ms pulse during which ca. 2 ml of the purified air from a 5 ml polypropylene syringe containing the stimulus were added into the main air stream. Throughout this study, charcoal-filtered atmospheric air was used for the main airflow and stimulus delivery. To prevent changes in airflow during stimulation, a compensatory charcoal-filtered airflow of 2 ml/sec was delivered via another solenoid valve through a blank syringe into the glass tube, and at the same distance from the preparation. Following high responses, a gap of at least 1 min was allowed between stimulations.

Chemical Stimuli Nonanal and 1-phenylethanol (both >90% pure) were from Fluka (St. Louis, MO, USA). Propionic acid phenyl ester (PAPE) and isobutyric acid phenyl ester (IBAPE) (both >95% pure) were purchased from Tokyo Chemical Industry (Portland, OR, USA). (*Z,Z*)-11,13-Hexadecadienal (Z11Z13-16Ald), (*Z,Z*)-11,13-hexadecadienol (Z11Z13-16OH), and (*Z,Z,Z,Z,Z*)-3,6,9,12,15-tricosapentaene (Z3Z6Z9Z12Z15-23Hy) were

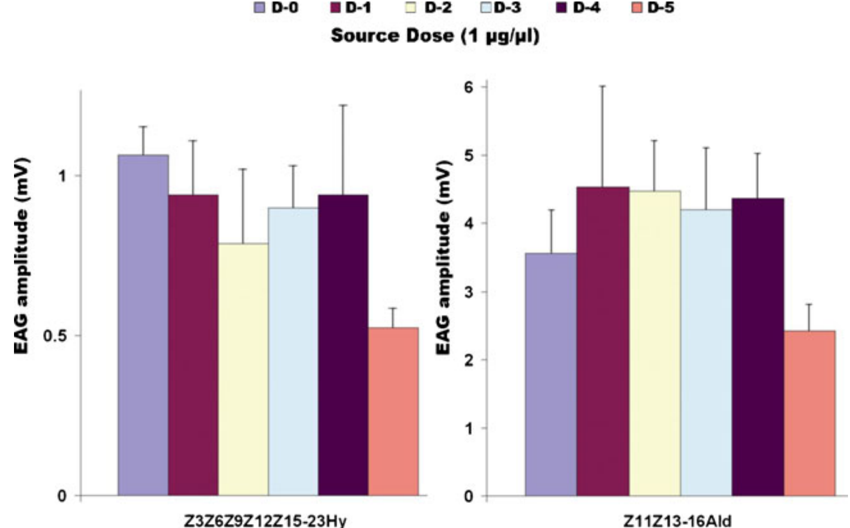

Fig. 5 Age-dependent responses of male *Amyelois transitella* antennae to the major constituent of the sex pheromone, Z11Z13-16Ald, and a key secondary constituent, Z3Z6Z9Z12Z15-23Hy. Histogram bars represent mean+SEM (N=10)

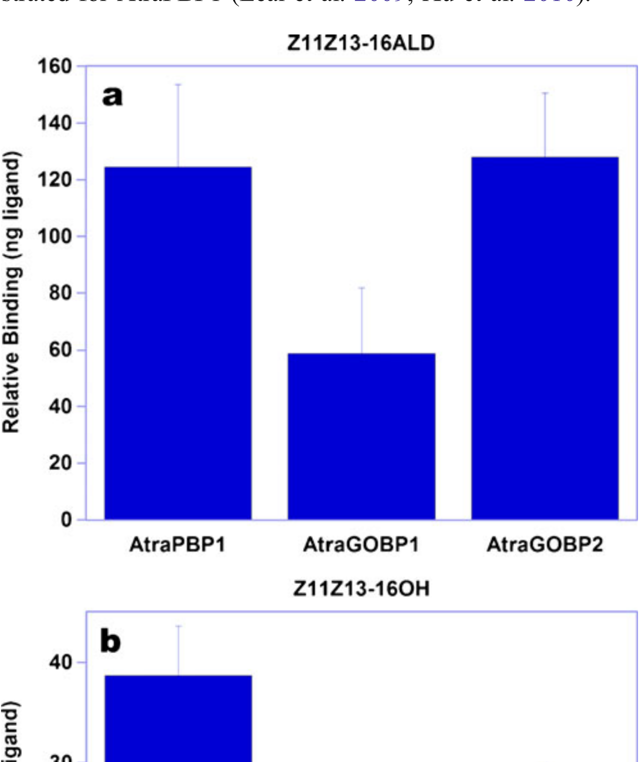
obtained from Bedoukian Research Inc. (Danbury, CT, USA). All chemicals were diluted, w/v, with hexane distilled in an all-glass apparatus to make a stock solution of 10 µg/µl, and decadic dilutions were made. An aliquot (10 µl) of a stimulus solution was loaded onto a filter paper strip (8×40 mm), hexane was evaporated by gently shaking for 10 sec under a fumehood, and the strip was placed in a 5 ml polypropylene syringe from which various volumes were ejected. Hexane alone and an empty syringe served as negative controls.

Results and Discussion

By using a previously developed protocol for functional expression of OBPs (Wojtasek and Leal 1999), we generated recombinant samples of AtraGOBP1 and AtraGOBP2 of high purity (>98%, by LC-MS). LC-ESI-MS analysis of AtraGOBP1 gave a molecular mass of 16,897 Da consistent with the calculated molecular mass of 16,903 Da (Leal et al. 2009) given the formation of three disulfide bridges (expected 16,897 Da). Deconvolution of the mass spectrum from AtraGOBP2 gave a molecular mass of 16,161 Da in close agreement with the calculated molecular mass of 16,166 Da (Leal et al. 2009) considering the formation of three disulfide linkages (expected, 16,160 Da). Far-ultraviolet (UV)-circular dichroism (CD) spectra from both proteins resembled that of the pheromone-binding protein AtraPBP1 (Leal et al. 2009), with maximum at ca. 193 nm and two minima at 209 nm and 223 nm (Fig. 1). Therefore, both AtraGOBP1 and AtraGOBP2 are α-helical-rich proteins, which is a common feature of moth OBPs (Wojtasek and Leal 1999). The spectra from AtraGOBP1 and AtraGOBP2 differed slightly in the maximum and in the intensity of the first of the two minima (Fig. 1).

Because gene expression analysis suggested that AtraGOBP1 and AtraGOBP2 are highly expressed in female antennae (Leal et al. 2009), we hypothesized that these proteins might be involved in the reception of attractants. We then tested by a cold binding assay (Leal et al. 2005a) whether AtraGOBP1 and/or AtraGOBP2 would bind semiochemicals like PAPE, IBAPE, and 1-phenylethanol, which are commonly referred to as female attractants (Price et al. 1967). Surprisingly, none of these ligands bound to the test proteins, but high background levels occurred even when these ligands were incubated with a buffer solution (devoid of protein), precluding an unambiguous conclusion. We then tested competitive binding by fluorescence by using a NPN reporter (Ban et al. 2002). None of the tested ligands displaced NPN, thus confirming that PAPE, IBAPE, and 1-phenylethanol do not bind to AtraGOBP1 or AtraGOBP2. To confirm that the recombinant proteins were functional, we searched the literature for other possible test compounds. Evidence that a GOBP from the Asiatic rice borer, *Chilo suppressalis* (Walker) (Lepidoptera: Crambidae), has high affinity for aldehydes (Gong et al. 2009b) led us to test nonanal, which has been identified in the headspace volatiles from almonds and demonstrated to stimulate antennae of female *A. transitella* in EAG studies (Beck et al. 2009). Nonanal bound with high affinity to both AtraGOBP1 (Fig. 2a) and AtraGOBP2 (Fig. 2b) at high pH. The fact that no binding was detected at low pH (Fig. 2) suggests that both AtraGOBP1 and AtraGOBP2 undergo pH-mediated conformational changes, as previously demonstrated for AtraPBP1 (Leal et al. 2009; Xu et al. 2010).



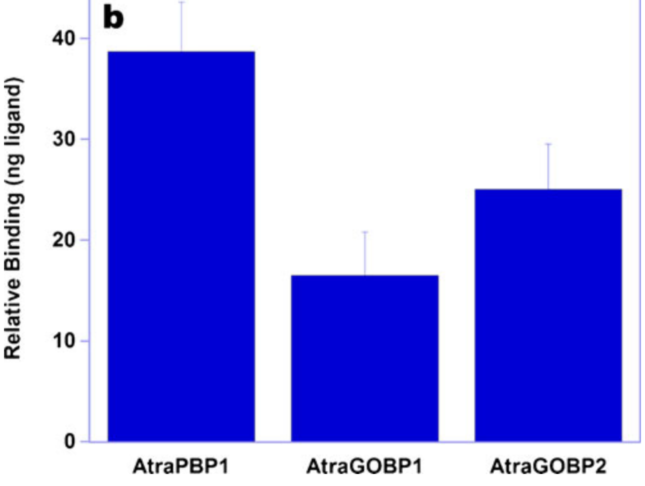


Fig. 6 Binding of the aldehyde and alcohol constituents of the *Amyelois transitella* sex pheromone system to male and female olfactory proteins. **a** test ligand, Z11Z13-16Ald and **b** test ligand, Z11Z13-16OH. The high affinity of the aldehyde to AtraPBP1 and AtraGOBP2 is comparable (**a**), whereas the alcohol showed higher affinity for AtraPBP1 than AtraGOBP2. AtraGOBP1 bound both aldehyde and alcohol with low but comparable affinity. Histogram bars represent mean+SEM (N=5)

The observation that both AtraGOBP1 and AtraGOBP2 were functional but do not bind known female attractants (Price et al. 1967) prompted us to test whether PAPE, IBAPE, and 1-phenylethanol indeed are detected by female antennae. EAG recordings from live moths showed that female antennae responded to these attractants as well as to nonanal in a dose-dependent manner (Fig. 3). With immobilized female moths we were able to record EAG response as high as 10 mV at the highest dose tested (Fig. 3). During these measurements, we noticed a small change in EAG responses with the age of the test moth. Therefore, we determined the effect of age on EAG response to female attractants. Regardless of the dose (0.1, 1, or 10 μg/μl source dose) and the compound tested, female antennal responses decreased significantly at day-5 (Fig. 4). At lower doses, we noticed a reduced response from day-3 moths in a few cases, but the fact that the responses of day-4 moths were always higher and that these discrepancies were not observed at a higher dose (10 μg/μl source dose) suggests the variations at day-3 with lower doses are not physiologically significant.

We then compared the age dependence on EAG responses of male antennae by stimulating with constituents of the *A. transitella* sex pheromone system (Leal et al. 2005b). With both the major component of the female-produced sex pheromone, Z11Z13-16Ald, and another key component, Z3Z6Z9Z12Z15-23Hy, we observed a similar trend (Fig. 5). EAG responses to these pheromones recorded from male moth antennae were almost unchanged from day-0 to day-4, with a significant decrease in day-5, thus mirroring female response to female attractants. Overall EAG responses to Z11Z13-16Ald were (≈4x) higher than those to Z3Z6Z9Z12Z15-Hy at the same concentration, in part because of the lower volatility of the hydrocarbon compared to the smaller aldehyde. Male and female antennae responded with comparable intensity to Z11Z13-16Ald and 1-phenylethanol, respectively, tested at the same dose (compare Figs. 4b and 5).

Finally, we tested whether AtraGOBP1 and/or AtraGOBP2 would bind and discriminate the aldehyde and alcohol constituents of the *A. transitella* sex pheromone as reported from a GOBP from *B. mori* (Zhou et al. 2009). Both AtraGOBP1 and AtraGOBP2 bound Z11Z13-16Ald and Z11Z13-16OH in a pH-dependent manner, i.e., high affinity at high pH and significantly lower (virtually no) binding affinity at low pH. Interestingly, AtraGOBP2 bound to the main constituent of the sex pheromone with affinity equivalent to that of AtraPBP1 (Fig. 6a). The secondary constituent, Z11Z13-16OH, bound to AtraGOBP2 with smaller apparent affinity than to AtraPBP1 (Fig. 6b). On the other hand, AtraGOBP1 bound both Z11Z13-16Ald and Z11Z13-16OH, but with lower affinity than that observed for both AtraGOBP2 and AtraPBP1 (Fig. 6).

Taken together, these data suggest that reception of PAPE, IBAPE, and 1-phenylethanol might involve other OBPs than AtraGOBP1 and AtraGOBP2. Since we employed a protein-based approach for the isolation and cloning of olfactory proteins, we were able to identify only proteins expressed at high levels. Therefore, we cannot exclude that other OBPs are involved in the reception of these female attractants in *A. transitella*. The genome of *B. mori*, for example, showed a much higher OBP diversity than previously envisioned from isolated OBPs (Gong et al. 2009a). As indicated by EAG data, these attractants are indeed perceived by female antennae, but their transport to the receptors is not likely to be mediated by either AtraGOBP1 or AtraGOBP2. Interestingly, these proteins bound constituents of the sex pheromone, with the affinity of AtraGOBP2 to the main component being comparable to that of a pheromone-binding protein, AtraPBP1. Given the previous examples of GOBPs binding pheromone components in *A. polyphemus* and *B. mori* (Ziegelberger 1995; Zhou et al. 2009) and our data, it is tempting to suggest that these AtraGOBPs, particularly AtraGOBP2, are involved in pheromone reception. The larger number of pheromone constituents (Leal et al. 2005b) compared to the number of known PBPs (Leal et al. 2009) and the affinity of GOBPs for pheromones favor this hypothesis. However, evidence for the expression of GOBPs in pheromone-detecting sensilla and how reducing their expression by RNA interference (Pelletier et al. 2010) may affect pheromone reception remain exciting topics for future research.

Acknowledgments We are grateful to Bedoukian Research Inc. for providing samples of the constituents of the navel orangeworm sex pheromone; to Dr. Julien Pelletier for helpful comments on the manuscript; and to Dr. Brad Higbee (Paramount Farming) for providing moths and pistachios to reinvigorate and maintain our laboratory colony. Z.L. wishes to thank Professor Baozhen Hua (Northwest A & F University, China) for his guidance during his Ph. D. studies. This work was supported in part by USDA-AFRI Grant 2009-05278, by the Almond Board of California, and by the California Pistachio Research Board. Z.L. (Northwest A & F University, China) was supported by the Scholarship Council of China to conduct part of his Ph.D. studies in Davis and D.M.V. (Universidade Federal do Paraná, Curitiba, Brazil) received an undergraduate scholarship from Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) under a FIPSE-CAPES sponsored U.S.-Brazil Higher Education Consortium Program.

RAPID COMMUNICATION

Odorant Receptor from the Southern House Mosquito Narrowly Tuned to the Oviposition Attractant Skatole

David T. Hughes · Julien Pelletier · Charles W. Luetje · Walter S. Leal

Received: 3 June 2010 / Revised: 22 June 2010 / Accepted: 25 June 2010 / Published online: 11 July 2010

Abstract Oviposition attractants are environmental cues that allow *Culex* gravid female mosquitoes to locate suitable sites for egg-laying and, therefore, may be exploited for environmentally friendly strategies for controlling mosquito populations. Naturally occurring skatole has been identified as an oviposition attractant for the Southern House mosquito, *Culex quinquefasciatus.* Previously, we identified in *Cx. quinquefasciatus* female antennae an olfactory receptor neuron (ORN) highly sensitive to skatole and an odorant-binding protein involved in the detection of this semiochemical. Here, we describe the characterization of an odorant receptor (OR), CquiOR10, which is narrowly tuned to skatole when expressed in the *Xenopus* oocyte system. Odorant-induced response profiles generated by heterologously expressed CquiOR10 suggest that this OR is expressed in the mosquito ORN sensitive to skatole. However, geranylacetone, which stimulates the antennal ORN, was not detected by CquiOR10-expressing oocytes, thus raising interesting questions about reception of oviposition attractants in mosquitoes.

Introduction

Culex mosquitoes are vectors of pathogens including the human filarial nematode, *Wuchereria bancrofti*, and encephalitis-causing viruses, such as St. Louis, Japanese, Venezuela equine, Western equine encephalitis, and West Nile virus (Nasci and Miller, 1996).[1] Given the resistance of *Culex* populations to modern insecticides, alternative methods of controls are sorely needed. Larval development is a particularly vulnerable phase in the life cycle of *Culex* mosquitoes, as eggs are laid in rafts from which hundreds of larvae emerge in confined areas—thus facilitating management. Gravid females rely on environmental oviposition attractants to locate oviposition sites. Skatole, a natural product found in animal excreta and also a product of fermentation of organic material, has been identified as an oviposition attractant for the Southern House mosquito, *Culex quinquefasciatus* (Millar et al., 1992). Field studies have demonstrated that traps baited with optimal doses of skatole collected significantly more eggs (Mboera et al., 2000) and gravid females (Leal et al., 2008) than control traps, thus suggesting that in combination with a biological agent, *Bacillus thuringiensis* var. *israelensis* (Barbosa et al., 2010) oviposition attractants may be used in "attract-and-kill" strategies. Chemical ecology and olfaction are the pillars of these semiochemical-based, environmentally friendly strategies. Therefore, identification of olfactory proteins involved in the reception of these semiochemicals may open the door for development of better oviposition attractants. Recently, we demonstrated by RNA interference that an odorant-binding protein (OBP) from *Cx. quinquefasciatus*, CquiOBP1, is involved directly in the

[1] We apologize for not being able to cite all the relevant literature due to reference limitations of rapid communication format.

reception of skatole and other oviposition attractants (Pelletier et al., 2010a). We also have characterized an odorant receptor (OR) from this mosquito species, CquiOR2, which is highly sensitive to indole and moderately sensitive to skatole (Pelletier et al., 2010b). Here, we characterize CquiOR10 and show this OR to be highly sensitive and narrowly tuned to skatole.

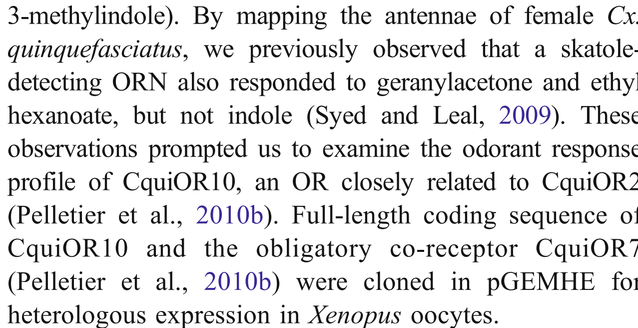
Methods and Materials

Expression of CquiOR10 in the Xenopus Oocyte System Oocytes were prepared as previously described (Pelletier et al., 2010b). CquiOR10 and CquiOR7, initially cloned into pBlueScript (Pelletier et al., 2010b), were transferred to pGEMHE for use as templates for synthesis of capped cRNA by using mMessage mMachine kits (Ambion). Twenty-five ng of cRNA encoding each OR subunit were injected into Stage V–VI Xenopus oocytes. Oocytes were incubated at 18°C in Barth's saline (in mM: 88 NaCl, 1 KCl, 2.4 NaHCO3, 0.3 CaNO3, 0.41 CaCl2, 0.82 MgSO4, 15 HEPES, pH 7.6, and 100 μg/ml amikacin) for 2–5 d prior to electrophysiological recording.

Electrophysiology and Data Analysis Odorant-induced currents were recorded under two-electrode voltage clamp from oocytes expressing ORs, by using an automated parallel electrophysiology system (OpusXpress 6000A; Molecular Devices). Oocytes were perfused with ND96 (in mM: 96 NaCl, 2 KCl, 1 CaCl2, 1 MgCl2, 5 HEPES, pH 7.5). Odorants were diluted in ND96 and applied for 20 sec at a flow rate of 1.65 ml/min with extensive washing in ND96 (5–20 min at 4.6 ml/min) between applications. Current responses approached a plateau during the 20 sec application (Pelletier et al., 2010b). Micropipettes were filled with 3 M KCl and had resistances of 0.2–2.0 MΩ. The holding potential was −70 mV. Current responses were filtered (4-pole, Bessel, low pass) at 20 Hz (−3 db), sampled at 100 Hz, and were captured and stored with OpusXpress 1.1 software (Molecular Devices). Initial analysis of electrophysiological data was done with Clampfit 9.1 software (Molecular Devices). Curve fitting of concentration-response data was done with Prism 4 (Graphpad).

Results and Discussion

In our search for molecular targets that may be used in a reverse chemical ecology approach for the development of better oviposition attractants (Leal et al., 2008), we recently have mined the genome of *Cx. quinquefasciatus* and identified an OR sensitive to indole, CquiOR2, which also responded to methylindoles, including skatole (IUPAC name,



3-methylindole). By mapping the antennae of female *Cx. quinquefasciatus*, we previously observed that a skatole-detecting ORN also responded to geranylacetone and ethyl hexanoate, but not indole (Syed and Leal, 2009). These observations prompted us to examine the odorant response profile of CquiOR10, an OR closely related to CquiOR2 (Pelletier et al., 2010b). Full-length coding sequence of CquiOR10 and the obligatory co-receptor CquiOR7 (Pelletier et al., 2010b) were cloned in pGEMHE for heterologous expression in *Xenopus* oocytes.

To identify the best ligand for this receptor, oocytes expressing CquiOR10 + CquiOR7 were screened first with a panel of odorants (Fig. 1a), each applied for 20 sec at a concentration of 10 μM with extensive washing between applications. Skatole (3-methylindole) elicited the largest current responses, but the receptor also responded with lower sensitivity to indole, other methylindoles, and 2-methylphenol. Interestingly, CquiOR10 was unresponsive to many compounds in the test panel of 23 odorants, including other oviposition attractants such as trimethylamine, nonanal, and the mosquito oviposition pheromone (MOP) (Leal et al., 2008).

Next, we performed concentration-response analyses for skatole and two other ligands, indole and 2-methylphenol, which were identified as the best ligands among the indoles and phenols, respectively, for the related receptor CquiOR2 (Pelletier et al., 2010b). Skatole was the most potent of these compounds, activating the CquiOR10 + CquiOR7 receptor with an EC_{50} of 90 nM. Indole and 2-methylphenol were less potent, activating CquiOR10 + CquiOR7 with EC_{50} values of 2.4 μM and 41 μM, respectively. Interestingly, indole and 2-methylphenol also displayed lower efficacy (maximal response) than skatole (40±2% and 69±3% of skatole, respectively). In addition, the response threshold for skatole was two to three orders of magnitude higher than that observed for indole and 2-methylphenol (Fig. 1b, c). Thus, we found that heterologously expressed CquiOR10 is highly sensitive and narrowly tuned to the oviposition attractant skatole.

In female antennae of the Southern House mosquito, skatole is detected by a small-spike-amplitude ORN housed in A1 sensilla (Syed and Leal, 2009), which is also sensitive to a lower degree to geranylacetone and ethyl hexanoate, but does not respond to indole or 2-methylphenol [see Figs. S5, S6, supporting information in (Syed and Leal, 2009)]. In the *Xenopus* oocyte system, CquiOR10 was unresponsive to geranylacetone. Although expression of ORs in heterologous systems, such as the *Xenopus* oocyte system, is an invaluable tool for de-orphanizing and characterizing receptors, it does not completely mimic the insect olfactory system. Typically, these systems are devoid of OBPs, odorant-degrading enzymes, sensory neuron membrane proteins, and other

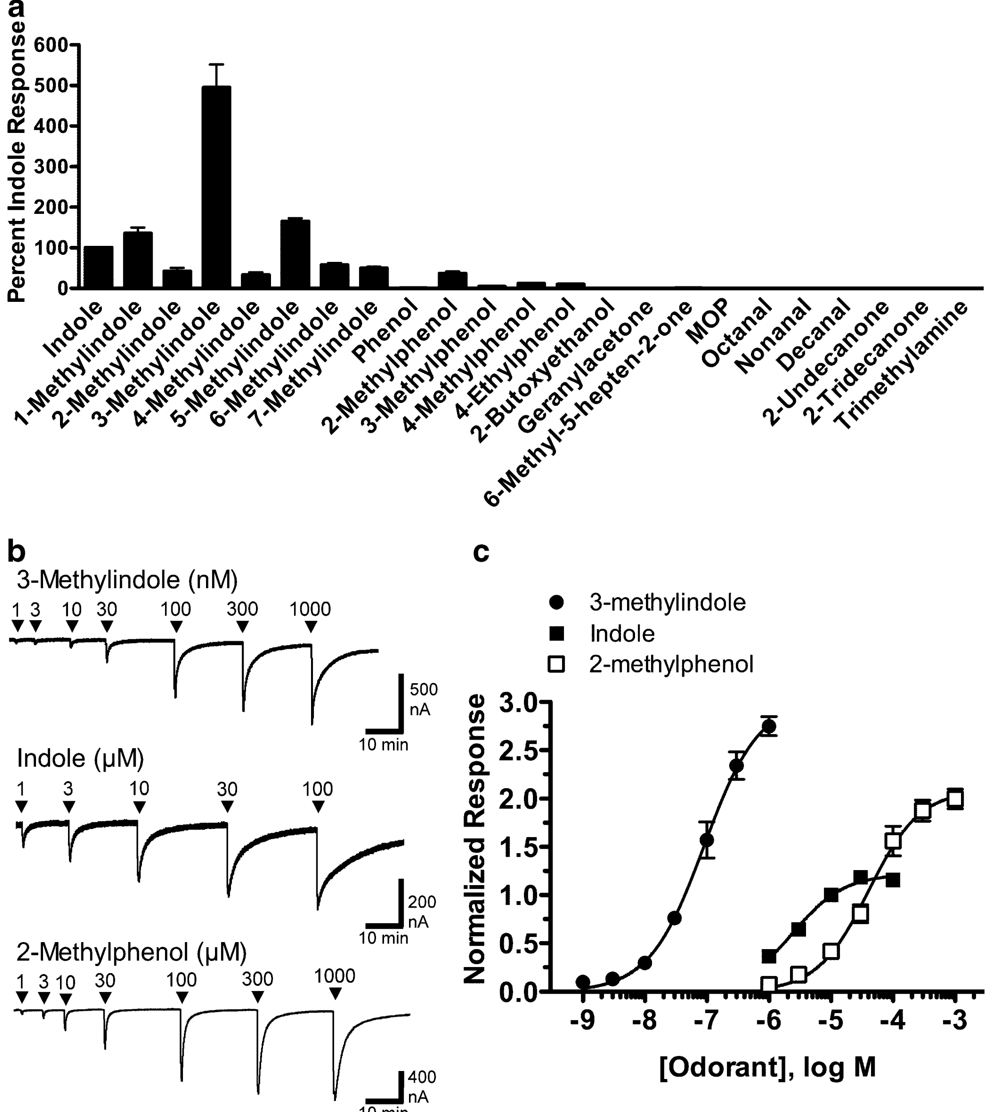


Fig. 1 Odorant receptor CquiOR10 is highly sensitive to skatole (3-methylindole). **a** Oocytes expressing CquiOR10 + CquiOR7 were challenged with a panel of odorant compounds. Each odorant was applied at a concentration of 10 μM for 20 sec with 10 min washes between applications. All responses are normalized to the response of the same oocyte to 10 μM indole (mean ± SEM, N=4–5). **b** Oocytes expressing CquiOR10 + CquiOR7 were challenged with a range of concentrations of 3-methylindole (*top trace*), indole (*middle trace*) or 2-methylphenol (*bottom trace*). Each odorant was applied for 20 sec with 5–20 min washes between applications. Note different scales: from top to bottom 500, 200 and 400 nA. **c** Oocytes expressing CquiOR10 + CquiOR7 were challenged with a range of concentrations of 3-methylindole, indole, and 2-methylphenol. Responses were normalized to the response of each oocyte to 10 μM indole and are presented as mean ± sem (N=3–5 for each odorant tested). Data were fit to the equation: $I = I_{max}/(1 + (EC_{50}/X)^n)$ where I represents the current response at a given concentration of odorant (X), I_{max} is the maximal response, EC_{50} is the concentration of odorant yielding a half maximal response, and n is the apparent Hill coefficient. Derived values are: 3-methylindole, EC_{50}=90±17 nM, N=1.0±0.1; indole, EC_{50}=2.4±0.3 μM, N=1.1±0.2; 2-methylphenol, EC_{50}=41±7 μM, N=1.0±0.1

olfactory proteins that may play a part in the selectivity and sensitivity of the olfactory system. Thus, it is conceivable that heterologously expressed CquiOR10 and the receptor in its native environment differ in the detection of geranylacetone because the former is devoid of OBPs. However, one cannot rule out the possibility that a separate ORN responding to geranylacetone has the same spike amplitude as the skatole-detecting ORN (Syed and Leal, 2009), thus rendering them indistinguishable by single unit recordings. Alternatively, the same small-spike neuron sensitive to skatole may express another OR along with CquiOR10. In marked contrast to the mammalian olfactory system, co-expression of ORs has been documented in *Drosophila melanogaster*. Co-expression of CquiOR10 and another OR would not be entirely surprising given the number of putative odorant receptors in the Southern House

mosquito genome (Pelletier et al., 2010b) and the number of ORNs in their sensory system (Syed and Leal, 2007, 2008). Future research aimed at testing these three hypotheses might lead to deeper understanding of odorant reception in mosquitoes.

Binding Specificity of Recombinant Odorant-Binding Protein Isoforms is Driven by Phosphorylation

Abstract Native porcine odorant-binding protein (OBP) bears eleven sites of phosphorylation, which are not always occupied in the molecular population, suggesting that different isoforms could co-exist in animal tissues. As phosphorylation is a dynamic process resulting in temporary conformational changes that regulate the function of target proteins, we investigated the possibility that OBP isoforms could display different binding affinities to biologically relevant ligands. The availability of recombinant proteins is of particular interest for the study of protein/ligand structure-function relationships, but prokaryotic expression systems do not perform eukaryotic post-translational modifications. To investigate the role of phosphorylation in the binding capacities of OBP isoforms, we produced recombinant porcine OBP in two eukaryotic systems, the yeast, *Pichia pastoris*, and the mammalian CHO cell line. Isoforms were separated by anion exchange HPLC, and their phosphorylation sites were mapped by MALDI-TOF mass spectrometry and compared to those of the native protein. Binding experiments with ligands of biological relevance in the pig, *Sus scrofa*, were performed by fluorescence spectroscopy on two isoforms of recombinant OBP expressed in the yeast. The two isoforms, differing only by their phosphorylation pattern, displayed different binding properties, suggesting that binding specificity is driven by phosphorylation.

Introduction

The pheromonal system in mammals is considered to be sensitive and specific (Tirindelli et al. 2009), requiring specific interactions between the molecular elements involved at every step of the detection and integration pathways (Brennan and Kendrick 2006). The first level of specificity is ensured by the nature of the pheromone itself: Its composition is stable within a species, both quantitatively and qualitatively. Integration of the signal from its reception by sensory organs to the data processing by the brain is highly specific (Brennan and Kendrick 2006). The olfactory receptors are also specific. They have only a small tolerance for changes in size or branching of ligand analogs (Buck 2004; Kato and Touhara 2009).

One step where the specificity is not clear is at the peripheral level of pheromone reception, in particular the

role of odorant-binding proteins (OBP) in olfactory transduction. These soluble proteins are secreted by specialized glands in the vicinity of olfactory neurons and function at least as vehicles of odors and pheromone component molecules, but a more specific role in their binding was suggested when they were discovered (Pelosi et al. 1982). Arguing against the specificity of OBP is their low diversity in each animal species, and their broad binding spectrum to molecules of different chemical structures (Pelosi 1996, 2001). In the last decade, structural studies [X-ray crystallography (Spinelli et al. 1998; Vincent et al. 2000), fluorescence spectroscopy (Paolini et al. 1999), and isothermal calorimetry (Burova et al. 1999)] were conducted on model OBPs (bovine, porcine), which were obtained by purification of the major form from nasal tissue. Alternatively, recombinant proteins were produced in high yields by overexpression in organisms such as bacteria and yeast (Parisi et al. 2005; Wei et al. 2008; Nagnan-Le Meillour et al. 2009a). These cells, however, display different metabolic pathways from mammalian cells, and the corresponding recombinant proteins do not always resemble their native counterparts. In particular, post-translational modifications (PTM) such as disulfide bridge formation, glycosylation, or phosphorylation, if present, can differ strongly from that obtained in mammalian cells (Narhi et al. 1991; Daly and Hearn 2005).

There is growing evidence that OBPs are involved in the first step of odorant discrimination by 1) enhancing receptor sensitivity and specificity (Ko and Park 2008; Vidic et al. 2008; Ko et al. 2010), and/or 2) selectively binding odorant molecules of various chemical structure by sub-types differing in their primary sequence (Loëbel et al. 1998; Briand et al. 2000; Tcatchoff et al. 2006). In addition, we demonstrated recently that a dynamic mechanism involving PTM could be responsible for OBP diversity and specificity (Le Danvic et al. 2009; Nagnan-Le Meillour et al. 2009b). Indeed, porcine OBP can be posttranslationally modified by phosphorylation, and we suggested that this PTM could generate a diversity of OBP isoforms with specific binding properties (Nagnan-Le Meillour et al. 2009b). PTM is known to regulate signalling pathways, and phosphorylation could be a mechanism of regulation of OBP specificity towards odorant ligands. To investigate further the binding specificity of potential phosphorylated isoforms, we undertook the production of recombinant OBP in two different eukaryotic systems, the yeast, *Pichia pastoris*, which successfully expresses high yields of secreted OBP, and a mammalian cell line, CHO (Chinese Hamster Ovary), the metabolic pathways of which could be close to those of pig, *Sus scrofa*, glandular cells. Our goal was to validate the use of recombinant proteins to study further the role of phosphorylation in OBP binding to pheromone components. We purified OBP isoforms by anion-exchange HPLC and we mapped their phosphorylation sites, which were compared with those previously characterized in the native form of OBP (Nagnan-Le Meillour et al. 2009b). Binding experiments with ligands of biological relevance to *S. scrofa* (male and female pheromones) were conducted by a fluorescent probe displacement assay on two isoforms of recombinant OBP expressed in the yeast. The two isoforms, differing only by their phosphorylation pattern, displayed different binding properties, suggesting that this binding specificity is indeed driven by phosphorylation.

Methods and Materials

Expression of Recombinant OBP in Yeast (OBP-Pichia) The recombinant porcine odorant binding protein (OBP) was expressed in the methylotrophic yeast, *Pichia pastoris* (GS 115 strain) and purified as previously described (Nagnan-Le Meillour et al. 2009a). After a ten-fold concentration (Vivaspin 20, 3000 MWCO, Sartorius, Palaiseau, France) and extensive dialysis against water, the culture supernatant was dried under vacuum (Eppendorf, Le Pecq, France) and stored at −20°C before purification.

Expression of Recombinant OBP in CHO cells (OBP-CHO) The cDNA sequence encoding OBP (GenBank accession number AF436848) was amplified by PCR from the *OBP/pPIC3.5K* plasmid used for expression in yeast, with the following primers: sense 5′-**CACC**ATGAAGAGTCTGCTGCTGAGT-3′ and antisense 5′-TCACTTGGCAGGACAGTCATCTCT-3′. The sense primer contains the CACC bases (in bold) allowing directional cloning into the *pcDNA™3.1D/V5-His-TOPO®* vector of the pcDNA™3.1 Directional TOPO Expression kit (Invitrogen, Paisley, UK), followed by codons of the natural signal peptide of the protein (underlined). PCR amplification was carried out on a Thermal Cycler (Mastercycler Gradient, Eppendorf) with 100 ng of cDNA template in a solution containing 1.25 U of Hot Start Proofreading DNA polymerase (Accu Prime™ *Pfx*, Invitrogen), 0.3 µM of each PCR primer, and 1 X of DNA polymerase manufacturer's buffer containing dNTP in a final volume of 50 µl. The reaction cycles were performed as follows: 95°C for 2 min, followed by 35 cycles of 15 sec at 95°C, 30 sec at 60°C, and 1 min at 68°C. The single PCR product obtained was ligated into the *pcDNA3.1d* expression vector according to the manufacturer's instructions. The plasmid DNA was amplified into One Shot® Top10 chemically competent cells (Invitrogen). After purification (QIAprep Spin Miniprep kit, QIAGEN, Courtaboeuf, France), the *OBP/pcDNA™3.1D* plasmid was sequenced in both senses (Genoscreen, Lille, France).

CHO-K1 cells (Chinese Hamster Ovary, clone K1) were grown in Dulbecco's Modified Eagle's Medium (DMEM F-12, Gibco BRL, Invitrogen) containing 10% non supplemented fetal bovine serum (FBS, Perbio, Thermo Fischer Scientific, Courtaboeuf, France) in a 5% (*v*:*v*) CO_2 atmosphere at 37°C. Cells were transfected with 3 µg of *OBP/pcDNA™3.1D* at a 50% confluence by using ExGen500 (Euromedex, Souffelweyersheim, France) in culture dishes. The supernatant medium was collected 48 hr after transfection.

Protein Purification Purification of recombinant proteins was achieved by high-resolution anion exchange liquid chromatography on a DIONEX HPLC device (Voisins-le-Bretonneux, France). Proteins were separated on a PROPAC PA1 column (4×250 mm), in 50 mM Tris/HCl, pH 6.0 (buffer A), by using a linear gradient of 0–1 M NaCl at a flow rate of 0.8 ml/min. Typically, samples of 500 µl in buffer A were injected, and resulting fractions were collected and extensively dialyzed against MilliQ water. OBP isoforms were identified in HPLC fractions by Western blot with anti-OBP antibodies (Nagnan-Le Meillour et al. 2009b). Their identity was confirmed by peptide mapping, followed by MALDI-TOF mass spectrometry as already described (Nagnan-Le Meillour et al. 2009b). A part of the recombinant OBP-Pichia was purified by FPLC (Nagnan-Le Meillour et al. 2009a), which does not separate the different isoforms (total OBP-Pichia). Recombinant proteins were quantified with the Micro BCA Protein Assay kit (PIERCE, Thermo Fischer Scientific).

Immunodetection of Phosphorylations with Specific Antibodies HPLC fractions (OBP-Pichia and OBP-CHO) and total OBP-Pichia were suspended in sample buffer, to be separated by SDS-PAGE (Nagnan-Le Meillour et al. 2009a). An aliquot of crude nasal tissue extract (Nagnan-Le Meillour et al. 2009b) was added as a migration control of OBP, together with molecular weight markers (Precision Plus Protein All Blue, Bio-Rad, Marnes-la-Coquette, France). Western blots with specific antibodies directed against phosphoserine, phosphotyrosine, and phosphothreonine (Invitrogen, Paysley, UK) were performed exactly as described in Nagnan-Le Meillour et al. (2009b). Detection of signal was carried out with an ECL Plus Western Blotting Detection kit (GE Healthcare, Orsay, France).

Mapping Phosphorylation Sites in Recombinant OBPs The sites of phosphorylation in recombinant OBP isoforms and total OBP-Pichia were determined by the BEMAD (Beta-Elimination followed by Michael Addition of DTT) method followed by MALDI-TOF MS analysis, fully described for total native OBP from pig nasal tissue in Nagnan-Le Meillour et al. (2009b). Briefly, total proteins and isoforms purified by HPLC were separated by SDS-PAGE and stained with Coomassie blue R solution. Band slices were treated with trypsin (T) and/or chymotrypsin (CT) without alkylation and reduction to generate specific peptides. Peptides then were incubated with alkaline phosphatase to remove phosphate groups prior to the linkage of DTT (dithiothreitol, Sigma-Aldrich, La Verpillière, France) by Michael addition. After a step of enrichment of DTT-modified peptides by using thiol columns, peptides were eluted directly into the matrix (α-cyano-4-hydroxycinnamic acid, Sigma-Aldrich, La Verpillière, France) with 25 and 50% acetonitrile (Nagnan-Le Meillour et al. 2009b), and analyzed by MALDI-TOF MS. The theoretical masses of DTT-modified peptides were calculated from the OBP peptide map (NP_998961) by using the peptide-mass software at www://expasy.org/tools/peptide-mass.html.

Position of the Phosphate Groups in the Three-dimensional Structure of Porcine OBP Phosphate groups were added to the residues that could undergo phosphorylation in the OBP sequence. We used the complete set of atomic coordinates available for the non-phosphorylated OBP (PDB identifier 1E02) obtained after addition of the first eight N-terminal and the Lys158 C-terminal residues to the crystal structure obtained by Vincent et al. (2000) according to the method described in a previous work (Nagnan-Le Meillour et al. 2009a). We used the CHARMM program (McKerell et al. 1998) with the possibility of adding phosphated pre-residues, and by using a homemade program, the related Cartesian coordinates for the phosphate groups (mono-anionic) could be determined easily. Images were created with the MacPyMOL™ software.

Binding Assay Studies using Fluorescence Spectroscopy Androstenone (3-keto-5α-16-androstene), androstenol (3α-hydroxy-5α-androst-16-ene), testosterone (17β-hydroxy-3-oxo-4-androstene), palmitic acid (hexadecanoic acid), myristic acid (tetradecanoic acid), and AMA (1-aminoanthracene) were purchased from Sigma-Aldrich (La Verpillière, France).

UV-visible spectra were recorded on a double beam spectrometer (Cary-100 Varian, Les Ullis, France) with a cell of 0.5 cm path length. The protein concentration was calculated by UV-visible spectroscopy, by using the molar extinction coefficient of 11740/M•cm for OBP (calculated by the software "ProtParam tool" at www.expasy.org) at the maximum of absorption (280 nm). Fluorescence measurements were performed on a Fluoromax-3 (Jobin-Yvon, Longjumeau, France) spectrofluorimeter at 22°C with semi-micro quartz cell (0.5 cm light-path) with reflecting window. The steady-state fluorescence spectra were recorded at 0.5 nm intervals with an integration time of 1 sec. The solution absorbance was <0.1 at the excitation

wavelength, to avoid inner filter effects. The fluorescent probe AMA was dissolved in 100% ethanol as 1 mM stock solution. For protein titration, aliquots of AMA were successively added to the protein at 2.5 µM in 50 mM Tris buffer (pH 7.8), and emission spectra were acquired after a 15 min equilibration period. All solutions were excited at 295 nm, which corresponds to the protein absorption band, where the absorption of the Trp16 residue is much higher than that of tyrosines (Lakowitz 1999). Emission spectra were recorded without Glan-Thompson polarizers in the excitation and detection channels. The excitation and emission bandwidths were set to 3 nm. The spectra were recorded 3 times and averaged to increase the signal-to-noise ratio. Before data analysis, the spectra were normalized by taking the Raman line of water as reference. In order to obtain real intensities of the emission bands of free AMA and probe in interaction in the OBP pocket, a spectral decomposition of the fluorescence spectra was achieved with the LabSpec 5.21 software (Jobin Yvon). This decomposition was carried out after a conversion of the spectra into wave numbers.

The dissociation constant ($K_{d\text{-}AMA}$) of the OBP-AMA complex was calculated from the binding curve by fitting the experimental data with the use of the computer program Origin 7.5 (OriginLab Corporation, Northampton, MA, USA). The affinity of the five ligands was measured in competitive binding assays, using AMA as the fluorescent probe at a 3.75 µM concentration, whereas the competitor ligand concentration varied from 0 to 15 µM. The spectra were recorded 15 min after the ligand addition, and the competition was monitored by following the fluorescence intensity decrease of the band of AMA bound to the protein. The apparent K_d values of the ligand-protein systems were calculated according to $K_d = [IC_{50}]/(1 + [AMA])/K_{d-AMA}$ where $[IC_{50}]$ is the competitor concentration that yields a fluorescence decay of 50% of the protein-AMA complex.

Results and Discussion

Isoform Purification and Identification As phosphorylation could confer different global charges to isoforms, we used strong anion exchange chromatography with a linear gradient of NaCl for their purification. Isoforms of OBP-Pichia and OBP-CHO were obtained by HPLC purification (Fig. 1). The eluted fractions were collected manually and were extensively dialyzed against water. Fractions were dried under vacuum and suspended in sample buffer to be analyzed by SDS-PAGE (Fig. 2a) and by western blot with anti-OBP antibodies (Fig. 2b). For OBP-Pichia, four peaks (Fig. 1a) were immunodetected with anti-OBP antibodies (Fig. 2b), but only two (peak 2 = OBP-Pichia-iso2 and peak 3 = OBP-Pichia-iso3) were in sufficient quantity (135 µg per run) to perform further analysis. They were eluted at 0.31 M and 0.32 M NaCl respectively that reflects slightly different charges.

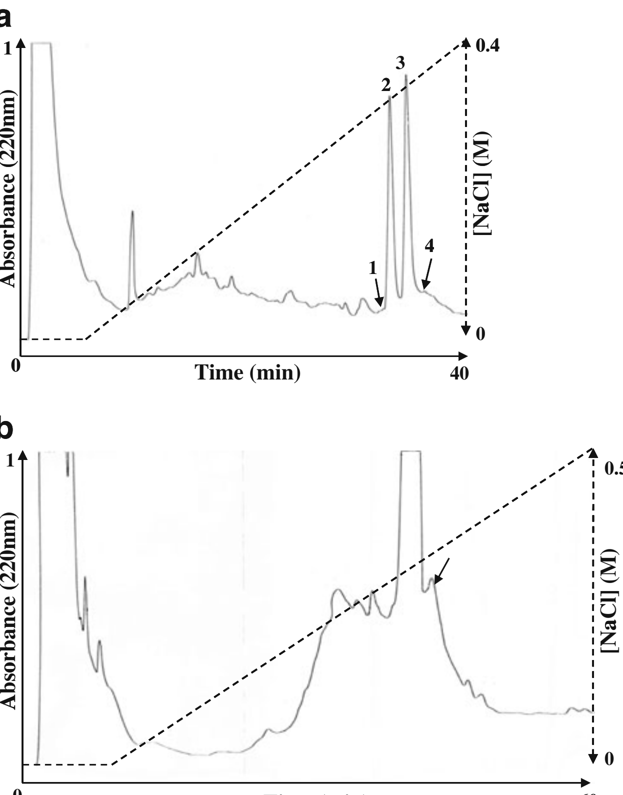

Fig. 1 Purification of recombinant *Sus scrofa* OBP isoforms by anion exchange HPLC. *Dotted lines* represent the linear gradient of NaCl. **a** Chromatogram of OBP-Pichia purification (peaks 1 to 4 contain protein immunoreactive to anti-OBP antibodies). **b** Chromatogram of OBP-CHO purification (the *arrow* indicates the protein that is immunoreactive to anti-OBP antibodies)

The purification of OBP-CHO allowed separating the protein from other elements of the DMEM medium (in particular BSA in large amounts in FBS), but only one peak eluted at 0.26 M NaCl was immunopositive to anti-OBP antibodies (Figs. 1b and 2b).

Peptide mapping analysis was performed on OBP-Pichia isoforms from SDS-PAGE gel (identical to the one in Fig. 2a), giving 70% of peptide recovery for OBP-Pichia-iso2 and 90% for OBP-Pichia-iso3 (data not shown). In comparison, the percentages were 80% for OBP-native and total OBP-Pichia (Nagnan-Le Meillour et al. 2009a). In both cases, the 1–15 peptide of theoretical mass 1711.7810 Da was retrieved, indicating that the signal peptide was properly removed through the secretion pathway, as it was previously observed for OBP-native and total OBP-Pichia (Nagnan-Le Meillour et al. 2009a). As the quantity of purified OBP-CHO isoform was scarce, the identity of the protein was confirmed by BEMAD,

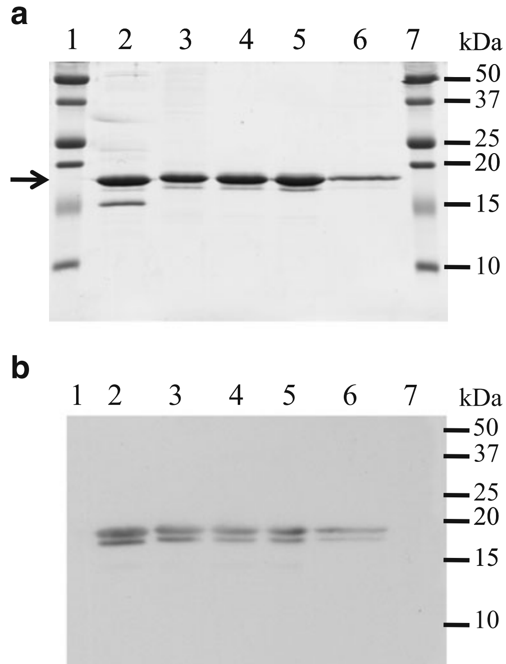

Fig. 2 Identification of recombinant *Sus scrofa* OBP isoforms. **a** SDS-PAGE, Coomassie blue staining. **b** Western blot with anti-OBP antibodies (1:20,000 dilution, ECL Plus detection, 15 sec exposure). (1 and 7) Molecular weight markers (BioRad), (2) crude extract of nasal mucus, (3) total OBP-Pichia, (4) OBP-Pichia-iso2, (5) OBP-Pichia-iso3, (6) OBP-CHO. Note that molecular weight markers are not labeled with specific antibodies (wells 1 and 7)

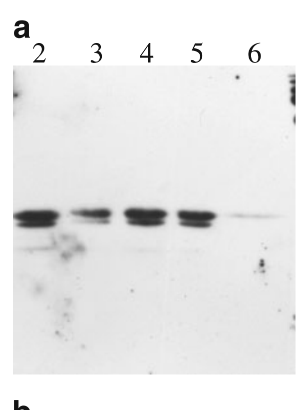
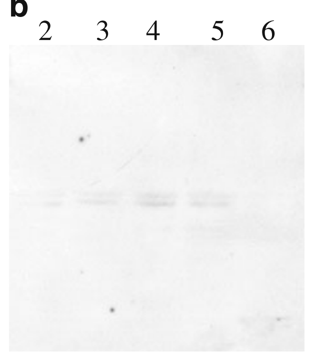
which gives information on both amino acid sequence and phosphorylation sites with a single sample.

Immunodetection of Phosphorylation Aliquots containing the same quantity of proteins as above were analyzed by western blot with specific antibodies raised against the three types of phosphorylation. A strong immunoreactivity of all recombinant proteins was observed with the anti-phosphoserine antibody (Fig. 3a, wells 3 to 6), identical to the one of native OBP (Fig. 3a, well 2). In contrast, the signal was weak with anti-phosphotyrosine antibody (Fig. 3b), and no signal was obtained with antiphospho-threonine antibody (Fig. 3c). These results are consistent with those already obtained with native OBP and could reflect the high number of modified serines compared to the two other residues (Nagnan-Le Meillour et al. 2009b).

Mapping of Phosphorylation Sites DTT addition confers a tag of defined molecular mass to peptides bearing phosphate groups: 136.2 Da for one DTT, 272.4 Da for 2 DTT and 408.6 Da for 3 DTT. The measured masses of peptides obtained after BEMAD treatment were compared to the theoretical list of potential DTT-modified peptides calculated from the OBP protein sequence (NP_998961). The BEMAD results are given in Table 1 for OBP-Pichia, Table 2 for OBP-CHO, Table 3 for OBP-Pichia-iso2, and Table 4 for OBP-Pichia-iso3. The spectra obtained for OBP-Pichia-iso2 and OBP-Pichia-iso3 are provided in Supplementary data. It should be noted that some peptides, unmodified by DTT also were found in the spectra (italicized in Tables), despite the use of thiol columns to enrich the samples in DTT-modified peptides. This was reported previously for the native protein (Nagnan-Le Meillour et al. 2009b) and reflects the fact that each phosphorylated isoform could be in minor quantity compared to non-phosphorylated forms. As phosphorylation is a dynamic process, only a small fraction of the pool of a protein is phosphorylated at a given time as a result of a stimulus. The consequence also is that phosphoproteins are heterogeneous and exist in several phosphorylated forms. Indeed, several forms of one peptide were observed for each recombinant protein or isoform.





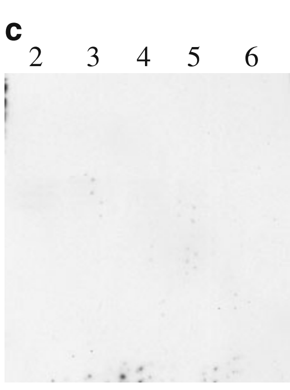


Fig. 3 Immunodetection of *Sus scrofa* phosphorylated OBP isoforms. **a** anti-phosphoserine antibodies (1:500 dilution). **b** anti-phosphotyrosine antibodies (1:2,000 dilution). **c** anti-phosphothreonine antibodies (1:500 dilution). Treatments in wells are as described in Fig. 2. Secondary antibodies at 1:40,000 dilution (rabbit IgG, HRP linked whole antibodies, GE Healthcare). ECL Plus detection, 1 min exposure. Molecular weight markers are not labeled with specific antibodies (wells 1 and 7)

The results obtained for the total recombinant OBPs were compared to those obtained for the native protein in the same experimental conditions (Nagnan-Le Meillour et al. 2009b; Table 5). Ser13, Ser41, Ser49, and Ser57 are phosphorylated in the three proteins (OBP-native, OBP-Pichia and OBP-CHO). The phosphorylation of Ser23, Ser24, Tyr52, Ser67, Thr71, Tyr82 is common to the OBP-native and OBP-Pichia, while Ser91, Tyr92, Ser94, Thr96, Ser101, Thr112, and Thr115 are possibly phosphorylated in the recombinant OBP-Pichia and OBP-CHO, but never in the native OBP. These special features shared by recombinant proteins could indicate differences between the phosphorylation processes in the three eukaryotic cells.

The OBP-CHO isoform is less affected globally by phosphorylation (Tables 2 and 5). This could mean that the protein is indeed less phosphorylated in CHO cells, or that the quantity of recombinant OBP-CHO is too small to provide a representative phosphorylation pattern of the protein through the single isoform that could be obtained by purification, even after a ten-fold concentration of the culture supernatant. Other isoforms could exist but in too small quantity to be detected and analyzed. Whatever the case, it was not possible to perform binding assays with such small quantities, and we did not consider further the recombinant OBP from CHO in this work.

Despite the combined use of T and CT to obtain the best assignment of phosphorylation sites, some ambiguous positions remained, in particular in peptides 89–98 and 99–114 from OBP-Pichia (Table 1), and in peptide 89–114 from OBP-CHO (Table 2). For example, three DTT are linked to the peptide 89–98 bearing 4 potential phosphorylation sites (Ser91, Tyr92, Ser94, Thr96), and peptide 99–114 bears only one DTT, but 2 sites could be phosphorylated, Ser 101 and Thr112. Besides these ambiguities in the sites location, several masses observed for one given peptide suggest the presence of more heterogeneity: peptide 112–120 of total OBP-Pichia (Table 1) could be phosphorylated on either Thr112 or Thr115 (mass 1069.7437 Da for one DTT), or on both amino acids (mass 1221.9386 Da for 2 DTT). In OBP-Pichia-iso2, this peptide is modified by only one DTT (mass of 1085.4845 Da, Table 3), so that either Thr112 or Thr115 is phosphorylated. In OBP-Pichia-iso3, the same peptide bears 2 DTT, indicating that both residues are phosphorylated. The presence of several forms of different peptides increases the number of possible combinations that could be estimated as 114 for total OBP-Pichia, 15 for OBP-Pichia-iso2, and 44 for OBP-Pichia-iso3 (data not shown). Obviously, all these isoforms do not exist, but the presence of the same peptides with different phosphorylation status suggests a much higher

number of isoforms than the two obtained by HPLC purification. Indeed, it is visible in SDS-PAGE (Fig. 2a) that each protein is composed of two bands, even after strong anion exchange purification. This means that each OBP-Pichia isoform should be purified further by a second different HPLC system.

Ligand Binding Monitored by Fluorescence Spectroscopy Recombinant proteins obtained by expression in CHO cells were in too small quantities to perform ligand binding studies, despite adaptation of the method of fluorescence spectroscopy to the use of purified isoforms. We, thus, measured the affinity of the two isoforms expressed in the yeast (OBP-Pichia-iso2 and OBP-Pichia-iso3) for five selected ligands, all of biological relevance in the porcine species (androstenol, androstenone, testosterone, palmitic acid, and myristic acid). The two isoforms were first titrated with the fluorescent probe, AMA, and displayed comparable affinity to total OBP-Pichia. However, OBP-Pichia-iso3 presents a slightly better affinity for AMA than OBP-Pichia-iso2. The $K_{d\text{-}AMA}$ were estimated to 0.56±0.04 μM, 0.46±0.03 μM and 0.55±0.04 μM, for OBP-Pichia-iso2, OBP-Pichia-iso3 and total OBP-Pichia (Nagnan-Le Meillour et al. 2009a), respectively. Competitive binding experiments then were carried out with proteins saturated with 3.75 μM AMA. The displacement curves are reported in Fig. 4 and the calculated binding constants are listed in Table 6. Recombinant OBPs from *P. pastoris*, isoforms or total protein, did not bind testosterone. This result was expected from the in-gel binding assay with native OBP that did not bind testosterone (Le Danvic et al. 2009), which is the natural ligand of VEG (Von Ebner's Gland protein), another protein of the nasal mucus. Whatever the ligand, OBP-Pichia-iso2 displayed

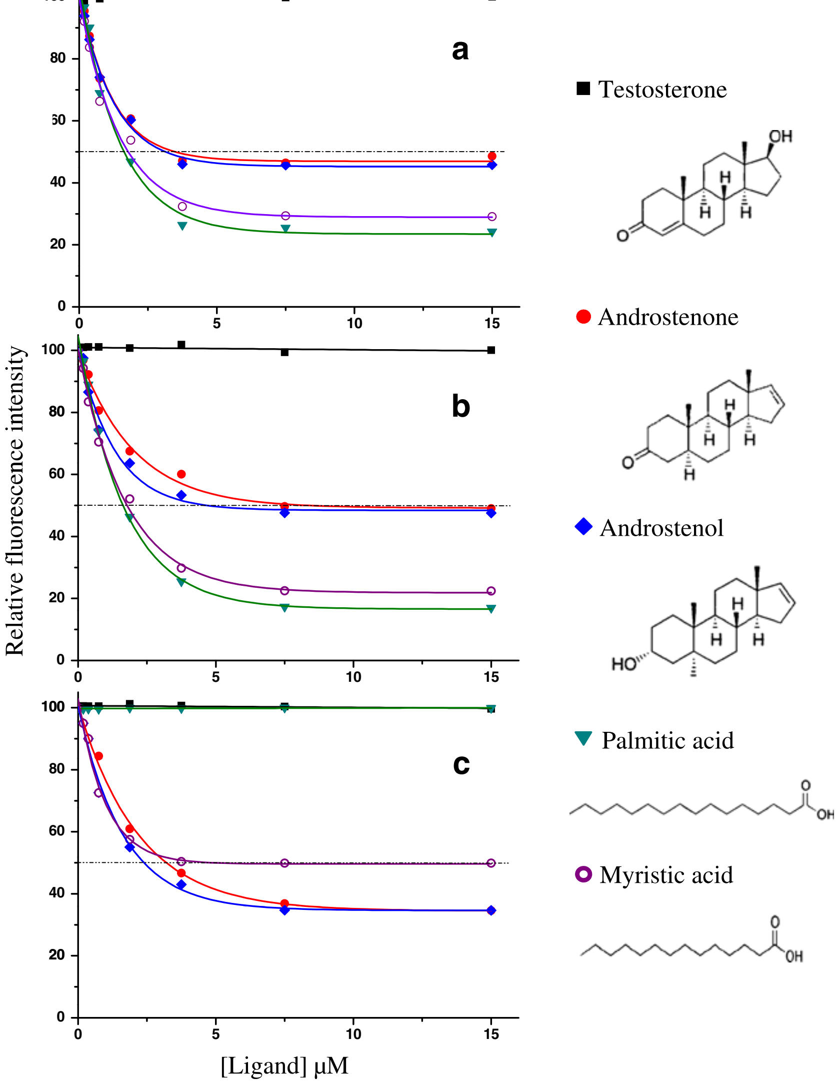

Fig. 4 Competitive binding assays of five selected ligands of biological relevance to recombinant *Sus scrofa* OBPs expressed by the yeast. Proteins were assayed at 2.5 μM and saturated with 3.75 μM of the fluorescent probe 1-AMA. Competitors were added at increasing concentration from 0 to 15 μM. **a** Total OBP-Pichia; **b** OBP-Pichia-iso2; and **c** OBP-Pichia-iso3

Table 6 Values of $[IC_{50}]$ and calculated dissociation constants relative to the binding of ligands (testosterone, androstenone, androstenol, palmitic acid and myristic acid) to total *Sus scrofa* OBP-Pichia, OBP-Pichia-iso2 and OBP-Pichia-iso3

Ligand	Total OBP-Pichia		OBP-Pichia-iso2		OBP-Pichia-iso3	
	IC_{50} (μM)	Kd (μM)	IC_{50} (μM)	Kd (μM)	IC_{50} (μM)	Kd (μM)
Testosterone	–	–	–	–	–	–
Androstenone	3.5	0.5	7.7	1.0	3.2	0.3
Androstenol	3.2	0.4	4.5	0.6	2.4	0.2
Palmitic acid	2.1	0.3	1.6	0.2	–	–
Myristic acid	2.2	0.3	1.8	0.2	4.3	0.5

the same behavior as total OBP-Pichia; that could be explained by the fact that it is the closest to total OBP-Pichia, in terms of phosphorylation. However, when compared to total OBP-Pichia, OBP-Pichia-iso2 presents a lesser affinity for androstenone and androstenol and a higher affinity towards the two fatty acids studied.

OBP-Pichia-iso3 presents very different behaviors according to the ligand. It has a high affinity for the pig sex steroids (androstenone: $K_d = 0.3$ and androstenol $K_d = 0.2$) but less affinity for myristic acid ($K_d = 0.5$), and it displays no binding to palmitic acid, these two fatty acids differing only in the chain length, C_{14} and C_{16}, respectively. This isoform seems to be more likely tuned to steroids. This binding specificity could be relied on the absence of Thr136, Ser23, Ser24, Ser49, and Ser91 to Ser101, and the phosphorylation of the three residues Thr77, Tyr78, and Tyr82 (Table 5). It is surprising to note the important difference of affinity between the two OBP isoforms for palmitic acid, which is illustrated by the spectral data (Fig. 5). A marked decrease in the fluorescence intensity of

Fig. 5 Fluorescence spectra set for the competitive binding assay. **a** OBP-pichia-iso2-AMA/palmitic acid; **b** OBP-pichia-iso3-AMA/palmitic acid; **c** OBP-pichia-iso2-AMA/ androstenone; and **d** OBP-pichia-iso3-AMA/androstenone. [protein] = 2.5 μM, [AMA] = 3.75 μM, and [ligand] from 0 to 15 μM (excitation wavelength: 295 nm). *Arrows* indicate the fluorescence decrease according to increasing ligand concentration

the AMA band (484 nm) is observed with successive additions of palmitic acid for OBP-Pichia-iso2 (Fig. 5a) while this ligand does not compete with AMA bound to OBP-Pichia-iso3 (Fig. 5b). This behavior is reversed to a lesser extent for androstenone where the fluorescence decrease of the probe is more pronounced for OBP-Pichia-iso3 (Fig. 5c) than for OBP-Pichia-iso2 (Fig. 5d). It also may be observed on spectra set of Fig. 5, normalized with the water Raman line (328 nm), that the protein fluorescence band (342 nm) is not affected by the substitution of AMA by ligands. Thus, the two isoforms selectivity are quite complementary, OBP-Pichia-iso2 presents a good affinity for fatty acids (components of the female appeasing pheromone, Guiraudie et al. 2003), while OBP-Pichia-iso3 has marked affinity for the male sex steroids (Katkov et al. 1972).

Location of Phosphate Groups on the 3-D Structure of Porcine OBP The phosphate groups were added to the OBP three-dimensional structure to visualize their position and predict their possible involvement into OBP-ligand interactions. As a starting point, the phosphorylated native OBP was constructed (Fig. 6a), as it bears residues that are always phosphorylated in the recombinant proteins (Table 5), except Thr122, non-phosphorylated in *Pichia* proteins. Phe35 was added, as we have shown that this residue participates in the reorientation of the ligand towards the exit of the protein (Nagnan-Le Meillour et al. 2009a), together with Tyr 82 that has a key-role in the binding and release processes (Golebiowski et al. 2006, 2007; Nagnan-Le Meillour et al. 2009a). In Fig. 6, these two residues are in the open position, for a better view of the binding pocket. In the closed position, they display hydrophobic interactions, certainly reinforced by negative charges of the phosphate group born by Tyr82. Ser 23 could have interactions with ligands, as its side chain and phosphate group point to the internal cavity. Side chains and phosphates of the other phosphorylated residues clearly are positioned outside the binding pocket, pointing out to the surface of the protein. Interestingly, most of these residues are located on β-strands determined by X-ray crystallography (Spinelli et al. 1998): Ser23, Ser24 on β1, Ser41 in β2, Tyr52 and Ser57 in β3, and Ser67 in β4. Ser13 is located on the N-terminal flexible part, Ser49 on the loop between β2 and β3, and Thr122 on the loop near the α-helix.

In a second step, we highlighted on the 3-D structure the differences in phosphorylation patterns of the two *Pichia* isoforms studied for their binding properties (Fig. 6b, c). Contrary to the mapping of phosphorylation sites of native OBP, several ambiguities remained in the location of these sites in the two *Pichia* isoforms. We made the choice to represent all the possibly phosphorylated residues for each isoform. For OBP-Pichia-iso2 (Fig. 6b), either Thr77, or Tyr78, or Tyr82 is phosphorylated, but phosphate groups were added on the three because they have different positions in the structure: Thr77 is out of the binding pocket, Tyr78 is in the bottom of the binding pocket, and Tyr82 lines the gate. The alternative phosphorylation of these residues could influence strongly the binding, in particular if Tyr82 is not phosphorylated. These residues are phosphorylated in OBP-Pichia-iso3 (Fig. 6c), while Ser23, Ser24, and Ser49 are not. In addition, among Ser91, Tyr92, Ser94, Thr96, and Ser101, only one is phosphorylated in OBP-Pichia-iso3, but they are all represented with a phosphate group on the structure (Fig. 6c). They are located

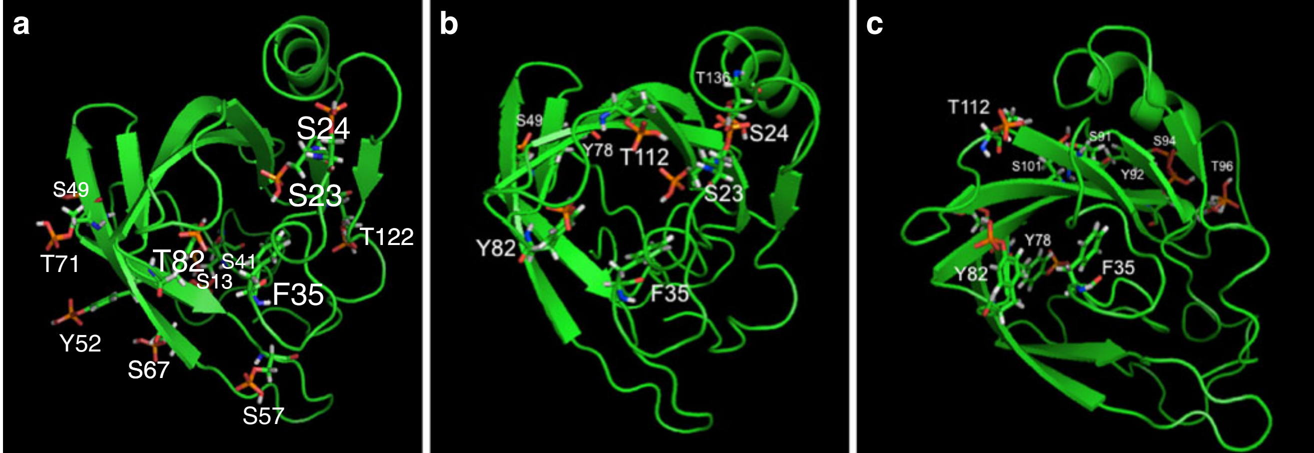

Fig. 6 Three-dimensional representation of phosphorylated porcine OBP. Images were generated from the modified PDB file (1E02) with MacPyMOL. The OBP backbone is represented as a ribbon (*green*). The side chains of the selected residues and their phosphates (*orange*) are in stick representation. The identities of the residues are indicated (*white*). The protein is oriented with the face displaying the binding pocket. **a** Native OBP; **b** OBP-Pichia-iso2; and **c** OBP-Pichia-iso3

at the protein surface, so their involvement in the binding with ligand is less probable. Phosphate groups located at the protein surface could more likely be involved in OBP-OBP and/or OBP-receptor interactions. Moreover, the binding selectivity could result from different positions of the ligand in the binding cavity, constrained by changes in the structure upon phosphorylation/dephosphorylation of both internal and external residues. The location of phosphates in the structure helps to visualize the results, but docking experiments and molecular dynamics studies will be required to understand the electrostatic interactions that they could establish with the ligands.

In summary, OBP is secreted by Bowman's gland into the extracellular mucus lining the nasal cavity of *S. scrofa*. This secreted protein is not supposed to undergo phosphorylation in the rough endoplasmic reticulum compartment, as kinases and phosphatases are localized in the cytoplasm of the cell. However, there is evidence for the presence of ecto-enzymes at the cell surface in a variety of cell types, in particular ecto-kinases and ecto-phosphatases that have a potential role in intercellular regulation and reception and transduction of external stimuli (Nath et al. 2008). Our study indicates that the phosphorylation of secreted proteins is a mechanism that is common to yeast and mammalian cells. As phosphorylation is a dynamic mechanism, the results observed reflect the phosphorylation pattern of OBP at a given time, corresponding to a given physiological status of the cell (Mann et al. 2002). Differences in phosphorylation patterns of OBP produced by the three types of cells could arise from different ratio in the kinases (e.g., more Ser/Thr kinase in *Pichia* than in other cells), or from different responses to culture conditions (or the physiological state for the secreting cells). Taking into account the heterogeneity of recombinant proteins from different cells, an exhaustive study of ligand binding capacities now will be conducted with isoforms purified from pig nasal tissue. Fortunately, the large amount of OBP produced by an animal (5–15 mg) will allow structure function-relationship studies on native proteins.

In this perspective, the present ligand binding studies already have a biological meaning. Even though the two *Pichia* isoforms differ slightly from native isoforms, they display properties of binding to pheromonal ligands that are physiologically relevant. The ligands used in this study are pheromone components in the pig species. The two fatty acids are part of a maternal pheromone that has an appeasing effect on piglets (McGlone and Anderson 2002). Androstenol and androstenone are secreted by the sub maxillary glands into male saliva (Katkov et al. 1972), but only androstenone has been identified as a pheromone component that facilitates expression of both attraction to the male and a receptive mating stance in estrous females (Dorries et al. 1995). For adult females, androstenone is a sex pheromone, but for piglets, the perception of androstenone reduces agonistic behaviors and is considered as a submissive pheromone (McGlone 1985; McGlone and Morrow 1988). Testosterone, the natural ligand of VEG (a pheromone binding protein) (Le Danvic et al. 2009), is never bound by any of the OBP isoforms. Conversely, both OBP isoforms bind a closely related steroid, androstenone, differing from testosterone by a single alcohol. Our results lead us to conclude that OBP is not a passive carrier of odorant or pheromonal molecules. Rather, OBP is a pool of isoforms with different binding properties, capable of distinguishing between two fatty acids differing by 2 CH_2 or between two steroids differing by an alcohol, ensuring a fine coding of molecules with a high significance in the mating or the maintaining of hierarchy inside the porcine species.

Abstract Female moths of *Lyclene dharma dharma* (Arctiidae, Lithosiinae) produce three sex pheromone components (**I**–**III**), for which we assigned the following novel chemical structures; 6-methyl-2-octadecanone (**1**) for **I**, 14-methyl-2-octadecanone (**2**) for **II**, and 6,14-dimethyl-2-octadecanone (**3**) for **III**. In the Iriomote Islands where the insects were collected, a lure including racemic **1** and **2** attracted the male moths without mixing **3**. In this study for further confirmation of the plane structures, the positional isomers with a methyl branch at the 4-, 5-, 7-, 13-, or 15-position (**4**–**8**, respectively) were synthesized. The GC-MS analyses revealed that natural components **I** and **II** were best fitted with those of **1** and **2**, respectively, among the methyl-2-octadecanones examined, indicating the usefulness of this analytical instrument and authentic standards for the determination of the positions of methyl branches. In field trapping tests, **4**–**8** could not substitute for **1** or **2**, nor did these compounds inhibit the active binary lure of **1** and **2**, indicating that the males strictly recognized the 2-ketones with a methyl branch at the 6- or 14-positions. Next, the absolute configurations of **I** and **II** were determined by HPLC with a normal-phased chiral column (Chiralpak AD-H), which could separate the enantiomers of both **1** and **2**. The chiral HPLC analysis of a crude pheromone extract indicated that the females exclusively produced (*S*)**-1** and (*S*)**-2**. Furthermore, a field evaluation of each enantiomer revealed that (*S*)**-1** and (*S*)**-2** were bioactive but (*R*)**-1** and (*R*)**-2** were not.

Introduction

To date, lepidopteran sex pheromones have been identified from more than 600 species (El-Sayed 2009; Ando 2010). These pheromones mainly are composed of unsaturated C_{10}–C_{18} fatty alcohols and their derivatives (Type I) and C_{17}–C_{23} unbranched polyenyl hydrocarbons and their epoxides (Type II) (Ando et al. 2004). The Type II pheromones have been identified from 17 species in the family of Arctiidae, but no pheromones of species in the arctiid subfamily Lithosiinae have been reported. Larvae of the lithosiine species, which feed mainly on lichen in a forest, are not agricultural pests, but contribute to the ecosystem of the forest. Recently, we found novel pheromone components (**I**–**III**) from females of a lichen moth,

Lyclene dharma dharma Moore (Arctiidae, Lithosiinae), and their chemical structures were assigned as follows: 6-methyl-2-octadecanone (**1**) for **I**, 14-methyl-2-octadecanone (**2**) for **II**, and 6,14-dimethyl-2-octadecanone (**3**) for **III** (Yamamoto et al. 2007). The assignment was accomplished mainly by GC-MS analyses of the pheromone extract before and after the Wolff-Kishner reduction, which converted the ketones to methyl-branched hydrocarbons. In addition to the analyses, an optically inactive sample of each component was synthesized (Do et al. 2009; Taguri et al. 2010). The GC-MS data of the synthetic **1**–**3** coincided with those of the natural components, and the male moths were attracted by a mixture of **1** and **2** in the field, whereas the biological activity of **3** was unclear (Do et al. 2009). While these experiments suggested the accuracy of our structure assignments, at least for **I** and **II**, we were also interested in obtaining GC-MS data and data on the biological activity of structural analogs of **1** and **2** as this information would further confirm the structural assignments. This identification is the first case of the methyl-branched 2-ketones produced by Lithosiinae species. They are the first such compounds reported for moths and, thus, chemical data of the compounds in this group is limited. Since Lithosiinae includes a large number of species, it is expected that some species utilize other methyl-branched ketones as a pheromone. For these reasons, we synthesized positional isomers of **1** and **2** as follows: 4-methyl-, 5-methyl-, 7-methyl-, 13-methyl-, and 15-methyl-2-octadecanones (**4**–**8**, respectively). The GC-MS data were compared to those of the natural components **I** and **II**, and the male attraction activities were evaluated in the field, along with 6-methyl-2-nonadecanone (**9**). The stereochemistry of the natural pheromone components had not been studied previously. Furthermore, although males had been caught in traps with racemic synthetic compounds (Do et al. 2009), the complete structures of the components produced by females, including their absolute configurations, remained to be determined. Therefore, we analyzed the *L. d. dharma* pheromone by utilizing chiral chromatography, and tested responses of males to the chiral compounds in field tests by using each of the synthetic enantiomers of **1** and **2** (Mori 2009).

Methods and Materials

Instuments ^{1}H and ^{13}C NMR spectra were recorded by a Jeol Delta 2 Fourier transform spectrometer (JEOL Ltd., Tokyo, Japan) at 399.8 and 100.5 MHz, respectively, for $CDCl_3$ solutions containing TMS as an internal standard. GC-MS was conducted in EI mode (70 eV) with an HP5973 mass spectrometer system (Hewlett-Packard) equipped with a split/splitless injector and a DB-23 column (0.25 mm ID×30 m, 0.25 µm film, J & W Scientific, Folsom, CA, USA). The column temperature program was 50°C for 2 min, 10°C/min to 160°C, and 4°C/min to 220°C. The carrier gas was helium. HPLC employed a system composed of a pump (PU-980, Jasco), a refractive index (RI) detector (RI-98SCOPE, Labo System, Tokyo, Japan), and an integrator (807-IT, Jasco). Resolution of the enantiomers was accomplished with a chiral column (Chiralpak AD-H, 4.6 mm ID×25 cm; Daicel Chemical Industry, Osaka, Japan), which was eluted with 0.05% 2-propanol in hexane at a flow rate of 0.5 ml/min.

Chemicals The syntheses of optically inactive **1**–**3** were reported previously (Yamamoto et al. 2007; Do et al. 2009; Taguri et al. 2010). Those optically active compounds (97% ee) were synthesized by a different route (Mori 2009). Other positional isomers, **4**–**8**, were prepared by the following procedures (see Fig. 1). NMR data of synthetic intermediates are shown in supplements. 6-Methyl-2-nonadecanone (**9**) was synthesized by the same route as **1** (Yamamoto et al. 2007) by using dodecylmagnesium bromide instead of undecylmagnesium bromide.

*4-Methyl-2-octadecanone (**4**, Scheme I)* By Swern oxidation, 1-pentadecanol (**10**) was converted to pentadecanal, which was coupled with methyllithium to yield 2-hexadecanol (**11**). The alcohol (**11**) was converted to tosylate by the treatment of tosyl chloride, and the tosylate was coupled with allylmagnesium chloride by employing the Schlosser's copper-catalyzed Grignard reaction (Fouquet and Schlosser 1974) to yield 4-methyl-1-octadecene (**12**). The 2-ketone (**4**) was obtained by Wacker oxidation of **11** (Tsuji 1984; Taguri et al. 2010). ^{1}H NMR δ: 0.88 (3H, t, J=6.8 Hz), 0.89 (3H, d, J=6.6 Hz), ~1.3 (26H, m), 1.98 (1H, m), 2.13 (3H, s), 2.21 (1H, dd, J=15.7, 8.1 Hz), 2.41 (1H, dd, J=15.7, 5.7 Hz).

*5-Methyl-2-octadecanone (**5**, Scheme II)* A phosphonium salt was prepared from 1-bromotridecane and triphenylphosphine (PPh_3) and converted to an ylide by treatment with butyllithium. 5-Hexen-2-one (**13**) was coupled with the ylide to synthesize a 1:1 mixture of (Z)- and (E)-5-methyl-1,5-octadecadiene (**14**). A selective reaction at the terminal double bond of **14** by Wacker oxidation produced 5-methyl-5-octadecen-2-one (**15**), which was reduced by catalytic hydrogenation to yield 5-methyl-2-octadecanone (**5**). ^{1}H NMR δ: 0.86 (3H, d, J=6.2 Hz), 0.88 (3H, t, J=6.6 Hz), ~1.3 (24H, m), ~1.4 (2H, m), ~1.60 (1H, m), 2.14 (3H, s), 2.42 (2H, m).

*7-Methyl-2-octadecanone (**6**, Scheme III)* 5-Hexen-1-ol (**16**) was converted to iodide (**17**) by reaction with a mixture of I_2, PPh_3, and imidazole. The phosphonium salt, which was prepared from **17** and PPh_3, was treated with $NaN(SiMe_3)_2$ to obtain an ylide, and then a 1:1 mixture of

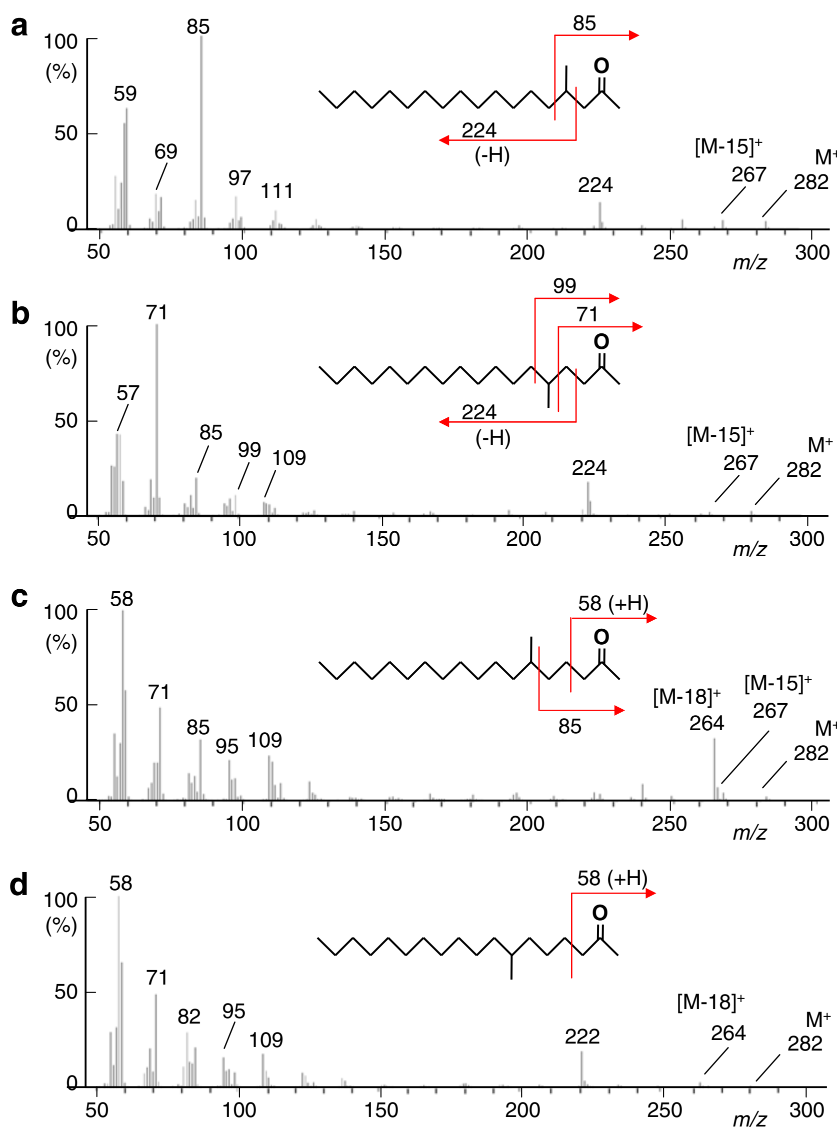

Fig. 2 Mass spectra of synthetic 2-ketones: a, 4-methyl-2-octadecanone (**4**); b, 5-methyl-2-octadecanone (**5**); c, 6-methyl-2-octadecanone (**1**); and d, 7-methyl-2-octadecanone (**6**)

(*Z*)- and (*E*)-7-methyl-1,6-octadecadiene (**18**) was synthesized by Wittig coupling with the ylide and 2-tridecanone. Wacker oxidation at the terminal double bond of **18** produced 7-methyl-6-octadecen-2-one (**19**), which was reduced by catalytic hydrogenation to yield 7-methyl-2-octadecanone (**6**). ^{1}H NMR δ: 0.83 (3H, d, *J*=6.5 Hz), 0.88 (3H, t, *J*=6.7 Hz), ~1.1 (2H, m), ~1.3 (23H, m), ~1.55 (2H, m), 2.13 (3H, s), 2.42 (2H, t, *J*=7.4 Hz).

*13-Methyl-2-octadecanone (***7***, Scheme IV)* Starting from 1,9-nonanediol (**20**), tetrahydropranyl (THP) ether of 9-bromononan-1-ol (**21**) was prepared by mono-bromination with HBr and protection of the remaining hydroxyl group. The bromide **21** was coupled with allylmagnesium chloride under the copper-catalyzed condition, and 11-dodecen-1-ol (**22**) was obtained after cleavage of the THP ether. Using a similar procedure to that in Scheme III, the alcohol **22** was converted to a 1:1 mixture of (*Z*)- and (*E*)-13-methyl-1,12-octadecadiene (**23**) by iodination and Wittig coupling with 2-heptanone, and 13-methyl-2-octadecanone (**7**) was synthesized by Wacker oxidation and catalytic hydrogenation of the diene **23**. ^{1}H NMR δ: 0.84 (3H, d, *J*=6.5 Hz), 0.88 (3H, t, *J*=6.8 Hz), ~1.1 (2H, m), ~1.3 (23H, m), ~1.55 (2H, m), 2.13 (3H, s), 2.41 (2H, t, *J*=7.5 Hz).

*15-Methyl-2-octadecanone (***8***, Scheme V)* With a similar procedure to that in Scheme IV, 1,10-decanediol (**24**) was introduced to tetrahydropranyl (THP) ether of 10-bromodecan-1-ol (**25**), which was coupled with 3-butenylmagnesium bromide under the copper-catalyzed condition and deprotected to yield 13-tetradecen-1-ol (**26**). The alcohol **26** was converted to a 1:1 mixture of (*Z*)- and (*E*)-15-methyl-1,14-octadecadiene (**27**) by iodination and Wittig coupling with 2-pentanone, and 15-methyl-2-octadeca-

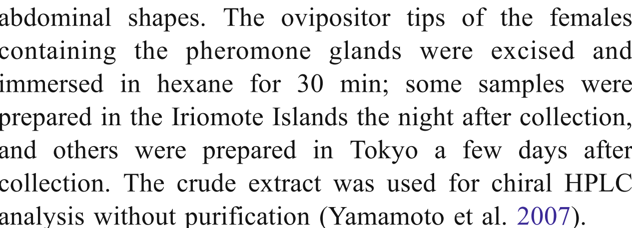
[a] Values within each column followed by a different letter are significantly different at $P<0.05$ by Tukey-Kramer test

none (**8**) was synthesized by Wacker oxidation and catalytic hydrogenation of the diene **27**. ^{1}H NMR δ: 0.84 (3H, d, J=6.5 Hz), 0.87 (3H, t, J=6.8 Hz), ~1.1 (2H, m), ~1.3 (23H, m), ~1.55 (2H, m), 2.13 (3H, s), 2.41 (2H, t, J=7.5 Hz).

Field Trapping of Male Moths The attraction of *L. d. dharma* males by synthetic lures was examined in the Iriomote Islands, located in a subtropical zone (24.29°N, 123.86°E), from 2008 to 2010. Rubber septa (white rubber, OD 8 mm; Sigma-Aldrich, St. Louis, MO, USA) were used as dispensers, and synthetic components (> 97% purities on GC-MS analyses) dissolved in hexane (100 μl) were applied to them. Each lure was placed at the center of a sticky board trap (a 30×27 cm bottom plate with a roof; Sumitomo Chem. Co., Tokyo, Japan), which was set separately from the others by at least 10 m at about 1.5 m above the ground in a mixed forest area including many evergreen brood-leaved trees, such as *Castanopsis sieboldii* and *Ficus variegata*. Three traps were deployed for each synthetic lure, and three control traps with septa treated only with hexane (100 μl) also were tested. The number of captured males was counted at least every 2 weeks.

Pheromone Extract The adults of *L. d. dharma* were collected with a black-light in the Iriomote Islands in 2008 and 2009. The collection was carried out during 17:00–23:00 on several days without strong wind or moonlight. Moths attracted to the black-light were kept singly in a small glass vials, and separated by sex based on their



abdominal shapes. The ovipositor tips of the females containing the pheromone glands were excised and immersed in hexane for 30 min; some samples were prepared in the Iriomote Islands the night after collection, and others were prepared in Tokyo a few days after collection. The crude extract was used for chiral HPLC analysis without purification (Yamamoto et al. 2007).

Results

*Synthesis of Methyl-branched 2-Octadecanones (***4**–**8***)* As shown in Fig. 1, 4-methyl-, 5-methyl-, 6-methyl-, 13-methyl-, and 15-methyl-2-octadecanones (**4**–**8**, positional isomers of **1** and **2**) were prepared by Wacker oxidation of the corresponding methyl-branched olefins, which were synthesized in moderate yields starting from an alcohol (**10**, **16**, **20**, or **24**) or a ketone (**13**). The olefin (**12**) is a monoenyl compound, and others are dienyl compounds. Since the Wacker oxidation preferentially proceeds at a terminal position (Tsuji 1984), the dienes (**14**, **18**, **23**, and **27**) were successfully converted to mono-unsaturated 2-ketones (**15**, **19**, and two other octadecen-2-ones), which were hydrogenated over Pd-C to yield expected saturated 2-ketones (**4**–**8**). Their chemical structures were confirmed by NMR analyses; in particular, the ^{13}C-NMR spectra reflected positions of the keto and branched methyl groups. Table 1 shows the ^{13}C-NMR assignments of **4**–**6** in addition to the published data for **1**. The methyl branch approaches the 2-

keto group from the 7-position of **6** to the 4-position of **4**. Chemical shifts of the methylene carbons between the two groups were strongly affected by their accession, and used to characterize the structures of these positional isomers. The signals of each carbon at a higher position than the methine carbon resonated at almost the same frequency in the four isomers, while the total numbers of the signals of the methylene carbons were different as a matter of course. On the other hand, **7** and **8** possessing the methyl branch at a terminal side showed a signal pattern around the carbonyl group common to **2,** but these three positional isomers could be differentiated by the patterns at the terminal side (see supplemental Table 1).

GC-MS Analysis of Synthetic Methyl-2-octadecanones Figure 2 shows the EI mass spectra of **1** and **4**–**6**. Among these synthetic methyl-2-octadecanones, the mass spectrum of the natural pheromone component **I** (Yamamoto et al. 2007) best coincides with that of **1**. Since ionization dominantly occurred at the 2-keto group, each positional isomer exhibited a distinguishable spectrum. The 6-methyl-2-ketone **1** and the 7-methyl isomer **6** showed the same base peak at *m/z* 58, which was produced by a McLafferty rearrangement, and characteristic ions derived from cleavage around the methyl branches could not be clearly recorded. However, abundant $[M–H_2O]^+$ was characteristically detected from **1**. In the case of 4-methyl isomer **4** and 5-methyl isomer **5**, base peaks were recorded at *m/z* 85 and 71, respectively. These ions are expected to be produced by a cleavage of the bond between the 4- and 5-positions, namely, the β- and γ-positions from the 2-keto group. The *m/z* values are different by fourteen mass units reflecting the positions of their methyl branches. These four isomers showed the following retention times (RTs) on a polar capillary column (DB-23): **1**, 19.61 min; **4**, 19.25 min; **5**, 19.78 min; and **6**, 19.60 min. On the other hand, the mass spectra of **7** and **8** are similar to that of **2**, with a base peak at *m/z* 58 (see supplemental Fig. 1). Detailed examination of the spectra revealed diagnostic ions as follows; $[MeCH(CH_2)_9]^+$ at *m/z* 153 for the 13-methyl isomer **7**, $[MeC(CH_2)_{10}]^+$ at *m/z* 167 for the 14-methyl isomer **2**, and $[MeC(CH_2)_{11}]^+$ at *m/z* 181 for the 15-methyl isomer **8**. These fragment ions might be produced by a two-step procedure. Acetone (*m/z* 58) might be first expelled from the molecule and then the produced alkene might be cleaved, losing the short alkyl chain next to the branching point. While their relative intensities are small (< 3%), these three positional isomers could be differentiated. The mass spectrum of the natural pheromone component **II** (Yamamoto et al. 2007) best coincides with that of **2**. These three isomers showed different RTs on the DB-23 column as follows: **2**, 19.81 min; **7**, 19.72 min; and **8**, 19.94 min.

Field Evaluation of the Synthetic Pheromone Analogs Since lures baited with racemic **1** and **2** in a ratio of 2:1 successfully attracted the *L. d. dharma* males in our previous field tests (Do et al. 2009), the biological activities of the positional isomers **4**–**8** and a long-chain analog **9**

also were examined as racemic mixtures. Table 2 shows the results of the field evaluation of **4**–**6**, which were mixed with **2** in place of **1** or with the binary lure of **1** and **2**. Their binary mixtures with **2** were completely unattractive to male *L. d. dharma* moths, indicating that pheromone analogs **4**–**6** could not substitute for **1**. In the case of the ternary lures, all the mixtures of **1** and **2** with one of the analogs attracted males the same as did the binary lure of **1** and **2**, indicating that no analogs were inhibitory. Table 3 shows results of the field evaluation of **7**–**9**. The octadecanones **7** and **8** were mixed with **1** in place of **2**, and the nonadecanone **9** was mixed with **2** in place of **1**. The positional isomers **7** and **8** could not substitute for **2** nor did they interfere with the **1** and **2** binary lure activity. The C_{19} analog **9** could not replace **1** for the male attraction, and inhibited the activity of the lure with **1** and **2**.

Chiral HPLC Analysis of the Natural Pheromone Each racemic mixture of methylketones, **1** and **2**, showed two peaks. Although the resolution of **2** was not perfect, the two enantiomers of **1** were almost separated completely. The chiral HPLC analysis of optically pure samples showed the following RTs: (*S*)-**1**, 19.2 min; (*R*)-**1**, 17.7 min; (*S*)-**2**, 20.2 min; and (*R*)-**2**, 21.1 min. In the case of dimethylketone **3,** including four stereoisomers, the optically inactive mixture showed one broad peak. Since the sensitivity of the RI detector is low, a small amount of the synthetic and natural methylketones could not be detected. Thus, after their injection onto the chiral HPLC column, the eluted materials were collected every 30 s and analyzed quantitatively by GC-MS. Even if **1** and **2** were included by the same fraction, GC-MS could quantify them separately. Figure 3a and b shows the chiral HPLC analyses of a synthetic pheromone (a mixture of racemic **1** and **2**, 500 ng each), and a pheromone extract (80 female equivalent, FE), respectively. This analysis indicated that two enantiomers of each component were equivalently included in the synthetic sample but (*S*)-**1** and (*S*)-**2** were dominant in the extract. The histogram of Fig. 3b shows that optical purity of the natural 6-methyl component is higher than that of the 14-methyl component.

Tested at a copse in the Iriomote Islands from December 8, 2008 to January 13, 2009, using three traps for each lure. **1** = 6-methyl-2-octadecanone (a racemic mixture), **2** = 14-methyl-2-octadecanone, **3** = 6,14-dimethyl-2-octadecanone (a mixture of four stereoisomers)

[a] Number of Males captured by one trap during one night (mean ± SE). Values within each column followed by a different letter are significantly different at $P<0.05$ by Tukey-Kramer test

Field Evaluation of Optically Active **1**–**3** The biological activities of optically active samples of the pheromone components were evaluated in the field. In the first experiment, each enantiomer of **1** was mixed with **2** and **3**, and male attraction to the combined lure was compared with that of the lure containing racemic **1**. Optically inactive **2** and **3** were used in this test. The lure including (*S*)-**1** captured as many male moths, as did the lure with racemic **1** (Table 4). The lure including (*R*)-**1** attracted some moths, but the total number was about seven times smaller than the lure with (*S*)-**1**, indicating that the males exclusively responded to the (*S*)-isomer and that the (*R*)-isomer did not interfere. Next, each enantiomer of **2** was mixed with optically inactive **1** and **3**, and the activity was compared with that of racemic **2**. The lure including (*S*)-**2** captured as many male moths as did the lure with racemic **2** (Table 5). The activity of the lure with (*R*)-**2** was very weak, also indicating the exclusive male response to the (*S*)-isomer and no disturbance by the (*R*)-isomer. Finally, the influences of (6*S*,14*S*)-**3** and (6*R*,14*R*)-**3** on the male attraction by a mixture of (*S*)-**1** and (*S*)-**2** were examined. The female moths produce three pheromone components, **I**–**III**, in a ratio of 2:1:1, but the role of component **III** was not be clarified in our previous field tests, which used optically inactive **3** as component **III**. Therefore, these three optically active compounds were mixed in a 2:1:1 ratio, and two other ratios, 2:1:3 and 2:1:10. Table 6 shows

Tested at a copse in the Iriomote Islands using three traps for each lure in 2009. **1** = 6-methyl-2-octadecanone, **2** = 14-methyl-2-octadecanone, **3** = 6,14-dimethyl-2-octadecanone

[a] *L. d. dharma* males captured by one trap during one night (mean ± SE). Values within each column followed by a different letter are significantly different at $P<0.05$ by Tukey-Kramer test

the results. Similar to the result of optically inactive **3** (Do et al. 2009), inclusion of (6*S*,14*S*)-**3** or (6*R*,14*R*)-**3** as the third component in a naturally occurring ratio did not affect male attraction to the binary lure of (*S*)-**1** and (*S*)-**2**. However, the number of captured males was significantly reduced when the dose of (6*S*,14*S*)-**3** was increased up to five times that of (*S*)-**1**. This reduction was not brought about by (6*R*,14*R*)-**3**. While this result did not elucidate the function and stereochemistry of **III**, it suggests that males might recognize (6*S*,14*S*)-**3** but not (6*R*,14*R*)-**3**. The former stereoisomer (6*S*,14*S*)-**3** bears two chiral centers, as does the bioactive combination of (*S*)-**1** and (*S*)-**2**.

Discussion

The *L. d. dharma* females produce a novel sex pheromone composed of methyl-branched 2-octadecanones. In this study, the methyl branches at the 6- and 14-positions, which had been determined by comparing the mass spectra of natural components and synthetic candidates **1**–**3**, were supported by GC-MS analyses of several positional isomers (**4**–**8**; Fig. 1). The mass spectra of **4**–**8** were different from those of the natural pheromone components (Yamamoto et al. 2007) to a greater or lesser extent. Methyl-branched hydrocarbons produced diagnostic secondary ions cleaved at a methyl branch (Ando et al. 2004). In the case of methyl-branched ketones, ionization is expected to occur mainly at the keto group, and the intensity of the secondary ions is extremely diminished. However, the mass spectra of 4-, 5-, and 6-methyl 2-ketones, **4**, **5**, and **1**, are quite different because each methyl branch affects the McLafferty rearrangement. While the spectrum of 7-methyl-2-ketone **6** had a pattern similar to that of **1**, **6** showed an abundant fragment ion at *m/z* 222 (18%) and could be differentiated from **1**. The relative intensities of the ion at *m/z* 222 in the spectra of 13-, 14-, and 15-methyl 2-ketones, **7**, **2**, and **8**, were also low (<5%, see supplemental Fig. 1). Unfortunately, a fragmentation pathway reflecting the methyl branch at the 7-position cannot be proposed for the *m/z* 222 ion; thus, diagnostic ions of **6** could be identified only after measurement of the mass spectra of some other positional isomers, especially 8-methyl-2-ketone. The mass spectra of three 2-ketones, which included a methyl branch at the position far from the keto group, were similar, as expected from their structures, but detailed analysis of the spectra identified diagnostic ions which characterized each from the others. These results indicate the usefulness of GC-MS analysis to determine the positions of both the keto group and the methyl branch in methyl-branched ketones.

This is the first identification of a pheromone from the Lithosiinae, a large group in the family Arctiidae, including 78 species inhabiting Japan. Thus, similar compounds might be identified from related species. Several Lithosiinae species, such as *Bizone hamata* and *Nipponasura sanguinea*, have been recorded in the Iriomote Islands; however, traps baited with synthetic 2-ketones attracted no male moths except for *L. d. dharma* in our field tests. While the larvae feeding on lichen contribute to the ecosystem of the forest, information on the ecological aspects of the lithosiine species is limited, and the pheromone could be utilized as a monitoring tool for the adults of *L. d. dharma*.

No branched ketones have been characterized from any other female moths, but 6-methyl-5-hepten-2-one (sulcatone) was found in brushes of a male moth (Aplin and Birch 1970) and wings of a male butterfly (Honda 1980).

Furthermore, structurally related pheromones have been identified from insects in other orders, such as 3,11-dimethyl-2-heptacosanone and its C_{29} derivative in a cockroach, *Blattella germanica* (Nishida et al. 1974; Schal et al. 1990), and 10-methyl-2-tridecanone (Guss et al. 1983) and 6,12-dimethyl-2-pentadecanone (Chuman et al. 1987) in *Diabrotica* spp. beetles.

Pheromone components of *L. d. dharma* include chiral centers and, while chiral GC did not resolve these methyl-branched compounds (Mori 2009), normal-phase HPLC equipped with a chiral column (Chiralpak AD-H) was successful in the enantiomeric separation of **1** and **2**. The chiral HPLC analysis of the pheromone extract revealed that natural mono-methyl components were not optically pure, but females dominantly produced (*S*)-**1** and (*S*)-**2** (Fig. 3). In our pheromone research, the chiral HPLC has been used for the resolution of several epoxy compounds in lepidopteran Type II pheromones (Qin et al. 1997; Yamamoto et al. 1999; Ando et al. 2004), an acetate of secondary alcohol produced by a midge (Hall et al. 2009), and a ketol and a diol produced by a long-horned beetle (Kiyota et al. 2009). This study is the first successful application of chiral HPLC to methyl-branched pheromones, and it is noteworthy that enantiomers of less polar volatiles showed different chromatographic behaviors on a chiral HPLC column. Several sex pheromones with a chiral center at a methyl-branched position have been identified from lepidopteran species, and their stereochemistry has been reported as follows: (*R*)-10-methyldodecyl acetate in *Adoxophyes honma* (Tamaki et al. 1983), (*S*)-14-methyl-1-octadecene in *Leucoptera clerkella* (Sato et al. 1986), (5*S*,9*S*)-5,9-dimethylheptadecane in *L. scitella* (Tóth et al. 1989), (5*R*,11*S*)-5,11-dimethylheptadecane in *Lambdina fiscellaria fiscellaria* (Li et al. 1993a), (*S*)-2,5-dimethylheptadecane in *Lambdina fiscellaria lugubrosa* (Li et al. 1993b), (*S*)-7-methylheptadecane and *meso*-7,11-dimethylheptadecane in *L. athasaria* and *L. pellucidaria* (Duff et al. 2001), and (3*S*,13*R*)-3,13-dimethylheptadecane in *Nepytia freemani* (King et al. 1995). All of the absolute configurations were presumed by bioassays with synthetic stereoisomers, but direct instrumental analyses have never been accomplished. It is important to know whether or not chiral HPLC can be applied to these chiral compounds, particularly, the hydrocarbons produced by Lyonetiidae and Geometridae species. In this study, the absolute configurations of the dimethyl component **III** could not be determined by the chiral HPLC analysis because the separation of four stereoisomers was not achieved. In order to utilize chiral HPLC for a wide range of pheromone studies, the property and applicability of some chiral columns should be examined in detail.

The field evaluation of synthetic methylketones **1**–**9** indicated that the *L. d. dharma* male moths recognized only the 2-ketones with a methyl branch at the 6- or 14-positions on a C_{18} chain. This result corroborated the assignments of **1** and **2** to the pheromone components **I** and **II**. The positional isomers **4**–**8** could not play a role as a substitution of **1** or **2** or as an inhibitor against the binary lure baited with **1** and **2**. These isomers could not compete with the natural pheromone components. Moreover, the field tests with stereoisomers showed that the bioactive enantiomers were (*S*)**-1** and (*S*)**-2**, which were dominant in the pheromone glands. This result confirms the mating communication of *L. d. dharma* triggered by (*S*)-**1** and (*S*)-**2**, and attraction by the mixture of (*S*)-**1** and (*S*)-**2** was not inhibited by the antipodes. While GC-MS data of the synthetic 6,14-dimethy-2-ketone **3** coincided well with that of the natural component **III**, the assignment of the 6,14-dimethyl structure was not confirmed by the biological activity of the four stereoisomers of **3** (Do et al. 2009). As for the optically inactive sample of **3**, field tests with the stereoisomers of **3** did not elucidate a behavioral role for this compound although the pheromone extract included as much **III** as **II**. One possibility is that **III** has some effects, such as a repellent effect, on males of related species. We are analyzing the pheromones of other Lithosiinae species, and expect that the role of **III** will be clarified through those studies.

Acknowledgments We thank Mr. C. Ishigaki of the Tropical Biosphere Research Center for helping with the field tests of synthetic lures.

Abstract *Callosobruchus rhodesianus* (Pic) (Coleoptera: Chrysomelidae: Bruchinae) is a pest of stored legumes through the Afro-tropical region. In laboratory bioassays, males of *C. rhodesianus* were attracted to volatiles collected from virgin females. Collections were purified by various chromatographic techniques, and the biologically active component isolated using gas chromatographic-electroantennographic detection analysis. Gas chromatography-mass spectrometry and NMR analyses suggested that the active compound was 2,3-dihydrohomofarnesal, i.e., 7-ethyl-3,11-dimethyl-6,10-dodecadienal. The structure was confirmed by non-stereoselective and enantioselective total synthesis. Using chiral gas chromatography, the absolute configuration of the natural compound was confirmed as (3*S*,6*E*)-7-ethyl-3,11-dimethyl-6,10-dodecadienal. Y-tube olfactomter assays showed that only the (*S*)-enantiomer attracted males of *C. rhodesianus*. The (*R*)-enantiomer and racemate did not attract males, suggesting that the (*R*)-enantiomer inhibits the activity of the natural compound. In combination with previous reports about sex attractant pheromones of congeners, we suggest that a saltational shift of the pheromone structure arose within the genus *Callosobruchus*.

Key Words *Callosobruchus rhodesianus* · 2,3-Dihydrohomofarnesal · (3*S*,6*E*)-7-Ethyl-3,11-dimethyl-6,10-dodecadienal · GC-EAD · Seed beetle · Sex attractant pheromone · Saltational shift

Introduction

Pheromones are an important component of communication systems of many taxa, especially in insects. The composition of pheromones can be diverse, even in closely related species (Symonds and Elgar, 2008). In insects, closely related species commonly use the same, or similar, compounds as pheromones, with species specificity achieved by using a unique blend in a multi-component pheromone system. This phenomenon has been studied extensively in moths. Closely related taxa often use the same major component, while the pheromones of related species are different, in terms of the minor components of the blend or in ratios of components (specific ratios of *cis*/*trans* and/or enantiomeric, isomers) (Cardé and Haynes, 2004).

There are two ways in which pheromone composition is thought to evolve. The first involves a gradual process of small changes in components, or a change in relative proportions of components over time, such that related species share closely related, or identical, components (Roelofs and Brown, 1982). In the second way, major changes, leading to saltational shifts, generate a new phenotype that is greatly or completely different from the antecedent (Baker, 2002).

Seed beetles of the genus *Callosobruchus* (Coleoptera: Chrysomelidae: Bruchinae) are serious pests of stored pulses, cowpeas, pigeon peas, and other legumes (Rees, 1996, 2004). To date, the genus *Callosobruchus* is comprised of some 20 species (Borowiec, 1987), and is distributed worldwide, particularly across the Old World. Female-produced sex attractant pheromones have been identified from four species: *Callosobruchus analis* (Fabricius) (Cork et al., 1991), *C. maculatus* (Fabricius) (Phillips et al., 1996), *C. subinnotatus* (Pic) (Shu et al., 1999), and *C. chinensis* (L.) (Shimomura et al., 2008). The species, *C. analis*, *C. maculatus*, and *C. subinnotatus* use methyl branched short-chain fatty acids as pheromones (Cork et al., 1991; Phillips et al., 1996; Shu et al., 1999), while *C. chinensis* uses homosesquiterpene aldehydes (Shimomura et al., 2008). In light of this, we initiated a project to clarify two matters: first, whether the structural shifts of the sex attractant pheromone were restricted only to *C. chinensis*, and second, to determine if there is a correlation between pheromone structure and molecular-based phylogenies previously reported (Tuda et al., 2006).

Callosobruchus rhodesianus (Pic) is found mainly in southern Africa, but has spread around the equator where it is sporadically reported (Southgate, 1979; Giga and Smith, 1983). In terms of morphological similarity, *C. rhodesianus* had been regarded as synonymous with *C. chinensis* (e.g., Skaife, 1926). However, Southgate (1958) concluded that they were separate species, based on morphological characteristics of antennae and genitalia. In a comparative study of four *Callosobruchus* species, *C. rhodesianus* was found to be more successful in a greater range of climatic conditions than the other species (Giga and Smith, 1983). Therefore, it was suggested that *C. rhodesianus* had potential to spread further, especially to subtropical regions, although there are no reports of this occurring to date.

Because of its narrow distribution and limited damage to legumes (Booker, 1967), the biology of *C. rhodesianus* rarely has been studied. In this paper, we report the isolation and identification of the female sex attractant pheromone of *C. rhodesianus*, and discuss differences in the pheromone compared to previously identified pheromones of congeners.

Methods and Materials

Insects A laboratory colony of *C. rhodesianus* was used. The beetles were reared on *Vigna angularis* in a dark incubator, at 28°C, in ambient humidity. Newly emerged adults from beans were separated, by sex, until used.

Pheromone Collection Charcoal-filtered air was passed over approximately 1,000–1,500 virgin females, in a group, in a 1-l glass chamber. The headspace volatiles were drawn by an air pump through a glass column (12 mm i.d., 90 mm length) filled with Tenax TA (1.5 g, 80/100 mesh, GL Science, Tokyo, Japan). The airborne collections were made for 10–14 d and eluted from the adsorbent with 10 ml of pentane. The extracts were concentrated in a nitrogen stream in an ice bath and kept in a freezer (−30°C) until use.

Column Chromatography Crude volatile collections were subjected to column chromatography (1 g of silica gel; Wakogel C-200, Wako Pure Chemical Industries, Osaka, Japan). The column was eluted sequentially with 10 ml each of pentane–diethyl ether in ratios of 10:0 (v/v), 9.5:0.5, 9:1, 8:2, 5:5, and 0:10.

High Performance Liquid Chromatography (HPLC) Active fractions were further purified by HPLC using a LC-10A (Shimadzu, Kyoto, Japan) equipped with a silica gel column (Inertsil SIL-100A, 3 μm, 4.6×250 mm, GL Science), and with 3% diethyl ether in pentane (1 ml.min^{-1}) as the mobile phase. The eluent was monitored with a photodiode array detector (SPD-M10Avp, Shimadzu), and fractions were collected every 1 min.

Coupled Gas Chromatographic-Electroantennographic Detection (GC-EAD) Analysis The GC-EAD technique was performed as previously described (Shimomura et al., 2008), using a DB-5 or DB-23 capillary column (30 m× 0.25 mm i.d., 0.25 μm film thickness; J&W scientific, Folsom, CA, USA) for the analyses. Nitrogen was used as the carrier gas at a head pressure of 135 kPa and a flow rate of 2 ml.min^{-1}. Samples were injected in splitless mode, with the purge valve off for 2 min. The oven temperature was set initially at 60°C for 3 min, increased at 10°C.min^{-1} to 220°C (for DB-23) or 280°C (for DB-5), and then held for 10 min. The injector temperature was set at 250°C, and the flame ionization (FID) and EAD outlet temperatures at 280°C. The column eluent was combined with nitrogen make-up gas (30 ml.min^{-1}) and then split 1:1 to the FID and EAD.

Gas Chromatographic-Mass Spectrometric (GC-MS) Analyses Gas chromatography-electron ionization mass spectrometry (GC-EI-MS) was carried out with a Shimadzu GC 17A, equipped with a DB-5 capillary column (30 m× 0.25 mm i.d., 0.25 μm film thickness) and splitless injection, coupled to a Shimadzu QP-5000 quadrupole mass spectrometer in EI mode (70 eV). Helium was the carrier gas, at a head pressure of 100 kPa and a flow rate of 1.6 ml.min^{-1}. The oven temperature was set initially at 60°C for 3 min, increased at 10°C.min^{-1} to 280°C, and held for 10 min. The injector and interface temperatures were set at

250°C and 280°C, respectively. Gas chromatography-chemical ionization mass spectrometry (GC-CI-MS) was performed on a Shimadzu GCMS-QP2010. Iso-butane, at 50 kPa, was used as reagent gas, with the other analytical conditions the same as in the GC-EI-MS analysis.

Preparative Gas Chromatography GC-EAD-active compounds were isolated by a micro-preparative GC system (Nojima et al., 2008), with modification. An HP 5890 series II GC (Palo Alto, CA, USA), equipped with a ZB-1 wide-bore capillary column (30 m×0.53 mm i.d., 1.50 μm film thickness; Phenomenex, Torrance, CA, USA) was operated in splitless mode. Nitrogen was used as carrier gas, at a head pressure of 30 kPa and a flow rate of 5 ml.min^{-1}. The oven temperature was set initially at 60°C for 3 min, increased at 10°C.min^{-1} to 250°C, and held for 10 min. The temperatures of the injection and collection (modified from an injection port) ports were set at 250°C. To collect an active component, a pre-cleaned collection trap, consisting of a 40-cm-long, deactivated wide-bore capillary tube (Agilent, Palo Alto, CA, USA), was connected to the end of the column, with a direct injection glass liner (1 mm Uniliner®, 1 mm ID, 6.3 mm OD×78.5 mm length; Restek, Bellefonte, PA, USA) set on the collection port just prior to the retention time of a target component. A preconditioned cooling sheath (Nojima et al., 2004), containing dry ice, was set on the exposed collection trap. Retention times of active components were checked previously by FID under the same analytical conditions. After sample collection, the sheath was removed and the collection trap pulled out to detach it from the injection liner. The collection trap was set up immediately for NMR sample preparation and eluted with C_6D_6 (99.96%, Merck, Darmstadt, Germany) directly into a 3 mm OD NMR tube (Shigemi, Tokyo, Japan).

NMR Analysis ^{1}H-NMR analysis of isolated active compound was performed on a JNM-ECA 600 spectrometer (JEOL, Tokyo, Japan). Chemical shifts were expressed in ppm relative to the residual solvent signal.

Enantioselective Gas Chromatography An HP 5890 series II GC, equipped with two β-DEX 225 capillary columns [each 30 m (60 m)×0.25 mm i.d., 0.25 μm film thickness; Supelco, Bellefonte, PA, USA], connected with a press fit connector (Agilent), was operated in splitless mode. Helium was used as carrier gas at a head pressure of 200 kPa and a flow rate of 1.2 ml.min^{-1}. The oven temperature was set at 120°C and held for 360 min. The injector temperature was set at 250°C, and the FID temperature at 280°C.

Synthesis NMR spectra (400 MHz for ^{1}H and 100 MHz for ^{13}C) were recorded on a JNM-ECA 400 spectrometer (JEOL). Chemical shifts are expressed in ppm relative to the residual solvent signal. IR spectra were recorded on an IR-4100 spectrometer (Jasco, Tokyo, Japan). Optical rotation was measured on a P-2100 polarimeter (Jasco). Elemental compositions (ECs) were analyzed on a Micro-corder JM10 (J-Science, Kyoto, Japan).

*Synthesis of Stereoisomeric Mixture of 2,3-Dihydrohomofarnesal (**1**)* A mixture of geometrical isomers at C-6 of 2,3-dihydrohomofarnesal (**1**) was prepared from homofarnesal **2** (Shimomura et al., 2008) by chemo-selective reduction of the α,β-unsaturated aldehyde using Stryker's reagent (Brestensky and Stryker, 1989) (Scheme 1).

To a stirred solution of a stereoisomeric mixture of **2** (10 mg, 0.043 mmol) and *tert*-butyldimethylchlorosilane (TBSCl) (16 mg, 0.107 mmol), in dry, deoxygenated benzene (0.5 ml), was added a solution of $[(Ph_3P)CuH]_6$ (50 mg, 0.026 mmol) in dry, deoxygenated benzene (2 ml). The mixture was stirred for 1 h, filtered through a Celite pad, and the filter cake washed with benzene. The combined filtrate and washings were concentrated under reduced pressure. The residue was dissolved in tetrahydrofuran (THF, 0.5 ml) and 70 mM phosphate buffer (pH 7.0, 0.2 ml). To this solution was added 1 M tetrabutylammonium fluoride (TBAF, 120 ml, 120 mmol). The mixture was stirred for 30 min and then poured into water. The aqueous layer was extracted with Et_2O, and the combined organic layers were washed with water and brine. The organic layer was dried with Na_2SO_4 and concentrated under reduced pressure. The residue was purified by SiO_2 column chromatography (hexane/EtOAc=80:1) to afford a stereoisomeric mixture of **1** (7 mg, 70%) as a colorless oil. EI-MS *m/z* (relative intensity): (6*Z*)-**1**: 236 (M^+, 1), 207 (6), 193 (21), 175 (9), 137 (24), 123 (26), 107 (16), 95 (29), 81 (46), 69 (100), 55 (59), 41 (68). EI-MS: (6*E*)-**1**: 236 (M^+, 1), 207 (6), 193 (22), 175 (10), 137 (30), 123 (27), 107 (18), 95 (29), 81 (54), 69 (100), 55 (66), 41 (71).

*Stereoselective Synthesis of 2,3-Dihydrohomofarnesal (**1**)* Both enantiomers of 2,3-dihydrohomofarnesal were synthesized from (*R*)- and (*S*)-citronellol (>97% e.e.) (Scheme 2). Briefly, known **3**, prepared from citronellol (Pichlmair et al., 2006), was epoxidized with *m*-chloroperbenzoic acid, and the resulting epoxide treated with periodic acid to give aldehyde **4**. Addition of Grignard reagent, prepared from 2-bromo-1-butene to **4**, afforded allylic alcohol **5**, which was subjected to Johnson-Claisen rearrangement to provide ester **6**. The geometry of the

Scheme 1 Synthesis of a stereoisomeric mixture of 2,3-dihydrohomofarnesal. **a** TBSCl, $[(Ph_3P)CuH]_6$, benzene, then TBAF, pH 7 phosphate buffer, THF (70%)

Scheme 2 Synthesis of both enantiomers of 2,3-dihydrohomofarnesal. **a** *m*-CPBA, CH_2Cl_2; **b** HIO_4, THF, H_2O (90%); **c** 1-buten-2-yl magnesium bromide, THF (77%); **d** triethyl orthoacetate, propanoic acid, toluene (96%); **e** LAH, Et_2O (95%); **f** PCC, MS4A, CH_2Cl_2 (73%); **g** isopropylidene triphenyl phosphorane, THF (89%); **h** Li, liq. NH_3, THF, EtOH (96%); **i** Dess-Martin periodinane, $NaHCO_3$, CH_2Cl_2 (85%)

resulting double bond was confirmed to be exclusively *E* by ^{1}H NMR analysis of **6**. Ester **6** was converted into the corresponding alcohol **7** by LAH reduction, and oxidation of the resulting alcohol with PCC afforded aldehyde **8**. Wittig condensation of **8** with isopropylidene triphenyl phosphorane (generated from isopropyl triphenylphosphonium iodide and *n*-BuLi) gave **9**, and then the *p*-methoxybenzyl protecting group of **9** was removed under Birch conditions to give alcohol **10**. Finally, oxidation of the hydroxyl group of **10** with Dess-Martin periodinane (Dess and Martin, 1983) afforded (3*S* or *R*,6*E*)-2,3-dihydrohomofarnesal **1**. The details of the syntheses were as follow.

(S)-6-(4-Methoxybenzyloxy)-4-methylheptanal (**4**) To a stirred and cooled (0°C) solution of (*S*)-**3** (469 mg, 1.70 mmol) in CH_2Cl_2 (10 ml) was added *m*-chloroperbenzoic acid (*m*-CPBA) (77%, 528 mg, 3.06 mmol). The mixture was stirred for 1 h and quenched with 1 M NaOH. The aqueous layer was extracted with CH_2Cl_2, and the combined organic layers were washed with water and brine. The organic layer was dried with $MgSO_4$ and concentrated under reduced pressure to give the corresponding epoxide (500 mg). To a stirred and cooled (0°C) solution of the epoxide in THF/water (10:1, 13 ml) was added periodic acid dihydrate (974 mg, 4.27 mmol). The mixture was stirred for 1 h and quenched with saturated aqueous $NaHCO_3$. The aqueous layer was extracted with Et_2O, and the combined organic layers were washed with water and brine. The organic layer was dried with $MgSO_4$, concentrated under reduced pressure, and purified by SiO_2 column chromatography (hexane/EtOAc=30:1) to afford **4** (381 mg, 90%) as a colorless oil. $[\alpha]_D^{25}$=−3.4 (*c*=1.3, $CHCl_3$). IR (film): ν=1,724 cm^{-1} (C = O). ^{1}H NMR (400 MHz, $CDCl_3$): δ=0.89 (d, *J*=6.4 Hz, 3H), 1.44 (m, 2H), 1.65 (m, 3H), 2.43 (m, 2H), 3.49 (m, 2H), 3.80 (s, 3H), 4.41 (d, *J*=11.8 Hz, 1H), 4.43 (d, *J*=11.8 Hz, 1H), 6.88 (d, *J*=8.7 Hz, 2H), 7.25 (d, *J*=8.7 Hz, 2H), 9.76 (s, 1H). ^{13}C NMR (100 MHz, $CDCl_3$): δ=19.2, 28.7, 29.4, 36.4, 41.5, 55.1, 67.8, 72.5, 113.6, 113.7, 129.1, 130.5, 159.0, 202.8. EC calculated for $C_{15}H_{22}O_3$: C, 73.00; H, 8.80. Found: C, 72.86; H, 8.59.

(4RS,7S)-9-(4-Methoxybenzyloxy)-7-methyl-3-methylene-nonan-4-ol (**5**) A Grignard reagent was prepared from 2-bromo-1-butene (466 mg, 3.45 mmol), Mg (91 mg, 3.73 mmol), and a catalytic amount of I_2 in dry THF (6 ml) under Ar atmosphere at 75°C. The resulting solution was added into a stirred and cooled (−78°C) solution of **4** (345 mg, 1.38 mmol) in dry THF (1 ml). The mixture was stirred for 15 h at room temperature and then quenched with saturated aqueous NH_4Cl. The aqueous layer was extracted with Et_2O. The combined organic layers were washed with brine, dried with $MgSO_4$, and concentrated under reduced pressure. The residue was purified by SiO_2 column chromatography (hexane/EtOAc=12:1) to afford **5** (326 mg, 77%) as a colorless oil. $[\alpha]_D^{24}$=−3.9 (*c*=1.0, $CHCl_3$). IR (film): ν=3,427 cm^{-1} (O–H). ^{1}H NMR (400 MHz, $CDCl_3$): δ=0.879 and 0.883 (d, *J*=6.3 Hz, 3H), 1.04 (t, *J*=7.1 Hz, 3H), 1.19–1.65 (m, 8H), 1.99 (m, 1H), 2.08 (m, 1H), 3.47 (m, 2H), 3.80 (s, 3H), 4.04 (t, *J*=6.3 Hz, 1H), 4.41 (d, *J*=12.0 Hz, 1H), 4.42 (d, *J*=12.0 Hz, 1H), 4.83 (s, 1H), 4.99 (m, 1H), 6.87 (d, *J*=8.8 Hz, 2H), 7.25 (d, *J*=8.8 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ=12.2, 15.3, 19.6, 19.7, 23.7, 23.9, 29.8, 29.9, 32.7, 32.78, 32.83, 36.6, 36.7, 55.3, 68.26, 68.28, 72.53, 72.55, 75.8,

76.0, 108.3, 108.5, 113.7, 129.2, 130.7, 153.5, 153.6, 159.1. EC calculated for $C_{19}H_{30}O_3$: C, 74.47; H, 9.87. Found: C, 74.20; H, 9.82.

*(4E,8S)-Ethyl 4-ethyl-10-(4-methoxybenzyloxy)-8-methyl-4-decenoate (***6***)* A mixture of **5** (55 mg, 0.18 mmol) and freshly distilled triethyl orthoacetate (156 mg, 0.96 mmol), with a few drops of propanoic acid in toluene (2 ml), was stirred and heated at reflux under conditions for the distillation of ethanol. Heating was continued for 24 h, followed by concentration of the reaction mixture under reduced pressure. The residue was purified by SiO_2 column chromatography (hexane/EtOAc=30:1) to afford **6** (66 mg, 96%) as a colorless oil. $[\alpha]_D^{23}=-4.0$ (c=1.0, $CHCl_3$). IR (film): ν=1,736 cm^{-1} (C = O). ^{1}H NMR (400 MHz, $CDCl_3$): δ=0.87 (d, J=6.7 Hz, 3H), 0.96 (t, J=7.5 Hz, 3H), 1.10–1.68 (m, 5H), 1.23 (t, J=7.1 Hz, 3H), 1.98 (m, 2H), 2.01 (q, J=6.7 Hz, 2H), 2.31 (m, 2H), 2.38 (m, 2H), 3.46 (m, 2H), 3.80 (s, 3H), 4.12 (q, J=7.5 Hz, 2H), 4.41 (d, J=12.0 Hz, 1H), 4.42 (d, J=12.0 Hz, 1H), 5.08 (t, J=7.1 Hz, 1H), 6.87 (d, J=8.8 Hz, 2H), 7.25 (d, J=8.8 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ=13.2, 14.2, 19.5, 23.1, 25.0, 29.6, 31.5, 33.4, 36.7, 37.4, 55.3, 60.2, 68.4, 72.6, 113.7, 124.9, 129.2, 130.8, 139.1, 159.1, 173.6. EC calculated for $C_{23}H_{36}O_4$: C, 73.37; H, 9.64. Found: C, 73.28; H, 9.37.

*(4E,8S)-4-Ethyl-10-(4-methoxybenzyloxy)-8-methyl-4-decen-1-ol (***7***)* To a stirred and cooled (0°C) suspension of lithium tetrahydridoaluminate (LAH, 93 mg, 2.44 mmol) in dry Et_2O (2 ml) was added a solution of **6** (92 mg, 0.24 mmol) in dry Et_2O (1 ml). The mixture was stirred for 30 min at room temperature. The stirred mixture was cooled to 0°C, and excess reagent destroyed by successive additions of water (0.1 ml), 15% NaOH (0.1 ml) and water (0.3 ml). After stirring for 45 min at room temperature, the mixture was filtered through a Celite pad, and the filter cake was washed with Et_2O. The combined filtrate and washings were concentrated under reduced pressure, and the residue purified by SiO_2 column chromatography (hexane/EtOAc=20:1) to afford **7** (78 mg, 95%) as a colorless oil. $[\alpha]_D^{23}=-2.5$ (c=1.0, $CHCl_3$). IR (film): ν=3,390 cm^{-1} (O–H). ^{1}H NMR (400 MHz, $CDCl_3$): δ=0.88 (d, J=6.3 Hz, 3H), 0.96 (t, J=7.5 Hz, 3H), 1.10–1.69 (m, 8H), 1.92–2.08 (m, 6H), 3.47 (m, 2H), 3.63 (t, J=6.3 Hz, 2H), 3.80 (s, 3H), 4.41 (d, J=12.0 Hz, 1H), 4.42 (d, J=12.0 Hz, 1H), 5.10 (t, J=7.1 Hz, 1H), 6.87 (d, J=8.8 Hz, 2H), 7.25 (d, J=8.8 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ=13.2, 19.5, 22.9, 25.0, 29.6, 31.0, 32.7, 36.7, 37.5, 55.2, 62.8, 68.4, 72.5, 113.7, 124.8, 129.2, 130.7, 140.3, 159.0. EC calculated for $C_{21}H_{34}O_3$: C, 75.41; H, 10.25. Found: C, 75.23; H, 10.42.

*(4E,8S)-4-Ethyl-10-(4-methoxybenzyloxy)-8-methyl-4-decenal (***8***)* To a stirred suspension of pyridinium chlorochromate (PCC, 495 mg, 2.30 mmol) and powdered 4A molecular sieves (MS4A, 250 mg) in CH_2Cl_2 (8 ml) was added a solution of **7** (386 mg, 1.15 mmol) in CH_2Cl_2 (1 ml). The mixture was stirred for 3 h, and then diluted with Et_2O. The mixture was filtered through a Celite pad, and the filter cake was washed with Et_2O. The combined filtrate and washings were concentrated under reduced pressure, and the residue was purified by SiO_2 column chromatography (hexane/EtOAc=30:1) to afford **8** (278 mg, 73%) as a colorless oil. $[\alpha]_D^{21}=-1.7$ (c=0.98, $CHCl_3$). IR (film): ν=1,725 cm^{-1} (C=O). ^{1}H NMR (400 MHz, $CDCl_3$): δ=0.88 (d, J=6.3 Hz, 3H), 0.96 (t, J=7.5 Hz, 3H), 1.00–1.69 (m, 5H), 1.97 (m, 2H), 2.02 (q, J=7.5 Hz, 2H), 2.32 (m, 2H), 2.50 (m, 2H), 3.47 (m, 2H), 3.80 (s, 3H), 4.41 (d, J=12.0 Hz, 1H), 4.42 (d, J=12.0 Hz, 1H), 5.07 (t, J=7.1 Hz, 1H), 6.87 (d, J=8.8 Hz, 2H), 7.25 (d, J=8.8 Hz, 2H), 9.75 (t, J=1.8 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$): δ=13.1, 19.5, 23.2, 25.0, 28.6, 29.6, 36.7, 37.4, 42.3, 55.3, 68.4, 72.6, 113.7, 125.3, 129.2, 130.7, 138.7, 159.1, 202.8. *(3S,6E)-7-Ethyl-3,11-dimethyl-6,10-dodecadienyl 4-methoxybenzyl ether (***9***)* To a stirred suspension of isopropyl triphenylphosphonium iodide (692 mg, 1.90 mmol) in dry THF (10 ml) at −78°C was added dropwise 1.6 M n-BuLi in hexane (890 µl, 1.40 mmol) under Ar atmosphere. After stirring for 30 min at room temperature, the mixture was added dropwise to a solution of **8** (50 mg, 0.15 mmol) in dry THF (1 ml) at −78°C under Ar. After stirring for 1 h, the mixture was poured into water. The aqueous phase was extracted with hexane, and the combined extracts were washed with water, brine, and dried with Na_2SO_4. The organic layer was concentrated under reduced pressure, and the residue was purified by SiO_2 column chromatography (hexane/EtOAc=100:1) to afford **9** (48 mg, 89%) as a colorless oil. $[\alpha]_D^{25}=-4.0$ (c=1.0, $CHCl_3$). ^{1}H NMR (400 MHz, $CDCl_3$): δ=0.88 (d, J=6.3 Hz, 3H), 0.95 (t, J=7.5 Hz, 3H), 1.11–1.62 (m, 5H), 1.60 (s, 3H), 1.68 (s, 3H), 2.01 (m, 8H), 3.47 (m, 2H), 3.80 (s, 3H), 4.41 (d, J=12.0 Hz, 1H), 4.42 (d, J=12.0 Hz, 1H), 5.06 (t, J=7.1 Hz, 1H), 5.10 (m, 1H), 6.87 (d, J=8.8 Hz, 2H), 7.26 (d, J=8.8 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ=13.3, 17.7, 19.6, 23.1, 25.0, 25.7, 27.0, 29.6, 36.5, 36.7, 37.6, 55.3, 68.4, 72.5, 113.7, 124.2, 124.5, 129.2, 130.8, 131.2, 140.7, 159.1. EC calculated for $C_{24}H_{38}O_2$: C, 80.39; H, 10.68. Found: C, 80.44; H, 10.84.

*(3S,6E)-7-Ethyl-3,11-dimethyl-6,10-dodecadien-1-ol (***10***)* Under Ar atmosphere, lithium (19 mg, 2.7 mmol) was added to liquid NH_3 (10 ml) at −78°C. After stirring for 30 min below −40°C, a solution of **9** (48 mg, 0.13 mmol) in THF (20 ml) and ethanol (1.5 ml) was added dropwise. Stirring

was continued for 1.5 h at −40°C and, during this time, lithium (19 mg, 2.7 mmol) was added to the reaction mixture. The reaction was quenched with NH_4Cl. Subsequently, NH_3 was removed by gentle warming, and the residue was diluted with water and extracted with hexane. The combined organic layers were washed with brine and dried with $MgSO_4$. After concentration, the residue was purified by SiO_2 column chromatography (hexane/EtOAc= 30:1) to afford **10** (30 mg, 96%) as a colorless oil. $[\alpha]_D^{23}$= −2.4 (c=0.68, $CHCl_3$). IR (film): ν=3,352 cm^{-1} (O–H). ^1H NMR (400 MHz, $CDCl_3$): δ=0.91 (d, J=6.7 Hz, 3H), 0.96 (t, J=7.5 Hz, 3H), 1.14–1.67 (m, 6H), 1.60 (s, 3H), 1.68 (d, J=0.7 Hz, 3H), 2.03 (m, 8H), 3.68 (m, 2H), 5.06 (t, J= 6.7 Hz, 1H), 5.10 (m, 1H). ^{13}C NMR (100 MHz, $CDCl_3$): δ=13.3, 17.7, 19.6, 23.1, 25.0, 25.7, 26.9, 29.2, 36.5, 37.5, 39.9, 61.2, 124.1, 124.5, 131.3, 140.8. EC calculated for $C_{16}H_{30}O$: C, 80.61; H, 12.68. Found: C, 80.34; H, 12.89.

*(3S,6E)-2,3-Dihydrohomofarnesal (***1***)* To a stirred and cooled (0°C) solution of **10** (19 mg, 0.079 mmol) in CH_2Cl_2 (1 ml) was added $NaHCO_3$ (31 mg) and Dess-Martin periodinane (158 mg, 0.37 mmol). After stirring for 1 h at room temperature, the reaction was quenched with saturated aqueous $NaHCO_3$. The aqueous phase was extracted with Et_2O, and the organic extract was washed with saturated aqueous $NaHCO_3$, water, and brine, and then dried with Na_2SO_4. After concentration, the residue was purified by SiO_2 column chromatography (hexane/ EtOAc=40:1) to afford (S)-**1** (16 mg, 85%) as a colorless oil. $[\alpha]_D^{22}$=−10.0 (c=0.66, $CHCl_3$). IR (film): ν= 2,712 cm^{-1} (C–H), 1728 (C = O). ^1H NMR (400 MHz, C_6D_6): δ=0.78 (d, J=6.3 Hz, 3H), 1.02 (t, J=7.7 Hz, 3H), 1.05–1.27 (m, 2H), 1.62 (s, 3H), 1.74 (s, 3H), 1.75–2.01 (m, 5H), 2.07 (q, J=7.5 Hz, 2H), 2.15 (m, 2H), 2.23 (m, 2H), 5.16 (t, J=7.1 Hz, 1H), 5.29 (m, 1H), 9.40 (t, J= 2.0 Hz, 1H). ^{13}C NMR (100 MHz, C_6D_6): δ=13.4, 17.7, 19.8, 23.4, 25.3, 25.8, 27.3, 27.7, 36.9, 37.4, 50.9, 124.2, 124.9, 131.2, 141.1, 200.8.

*(3R,6E)-2,3-Dihydrohomofarnesal (***1***)* (R)-**1** was prepared from (R)-**3** in the same manner as described above. $[\alpha]_D^{23}$=+9.8 (c=0.55, $CHCl_3$). IR, ^1H and ^{13}C NMR spectra were identical with that of the (S)-isomer.

Behavioral Assays A Y-tube olfactometer (15-mm i.d. glass Y-tube, 70-mm long arms connected to a 100-mm long stem at 120° angle) was used for the behavioral assays. The assays were carried out at 28°C and 60% relative humidity. Newly emerged beetles were kept singly in a glass tube (8-mm i.d.×30-mm long), both ends of which were covered with cotton. Males were acclimated in an assay room overnight. To test the biological activity of crude extracts, fractions of extracts, and synthetic compounds, the test sample was applied to a filter paper disc (6 mm). The disc was inserted in the end of one arm of the olfactometer after the solvent had evaporated, while a control disc (treated with pentane or hexane) was inserted in the end of the other arm. The position of the discs was randomly assigned in every assay. Subsequently, the cotton covers of the glass tube containing the beetle were removed, and the tube introduced into the end of the Y-tube olfactometer. Immediately, a vacuum pump was connected to the stem, and air, filtered through activated charcoal, was drawn through the Y-tube at approximately 200 ml.min^{-1}. Which disc a beetle reached (or not) within 10 min was recorded. Each beetle was tested only once and exchanged every time. Thirty beetles were tested to each treatment. The distribution of beetles in the two arms was subjected to a binomial test, against a test proportion of 0.5, in a two-tailed test (Siegel, 1956). Beetles not reaching either disc were not included in the data sets used in the binominal tests. The number of beetles that reached the discs was compared between fractions using Fisher's exact probability test.

Results

In a preliminary Y-tube olfactometer assay, all males that entered an arm chose the female volatiles over the control (Table 1). GC-EAD analyses of the female volatiles consistently revealed two EAD-active compounds, with retention times of 16.3 min and 17.6 min on DB-5 (Fig. 1). GC-MS analysis of the headspace collection suggested that these compounds were unknown. Therefore, a bulk crude collection (from ca 30,000 virgin females) was made and fractionated by silica gel column chromatography. The presence of active fractions/compounds was monitored by the Y-tube olfactometer assay and GC-EAD, respectively. Only the 5% ether fraction was significantly attractive (16 of 17 males chose the sample disc, P<0.001); both EAD-active compounds were found in this fraction. The fraction

Table 1 Y-tube olfactometer responses of adult male and female *Callosobruchus rhodesianus* to volatiles collected from virgins of each sex

Sample[a]	Target[b]	Sample	Control	No choice	P
Female volatile	Female	2	1	27	ns
	Male	17	0	13	<0.001
Male volatile	Female	1	0	28	ns
	Male	5	0	24	ns

[a] Tested at 1.5 female equivalents

[b] Thirty virgin beetles were tested to each sample

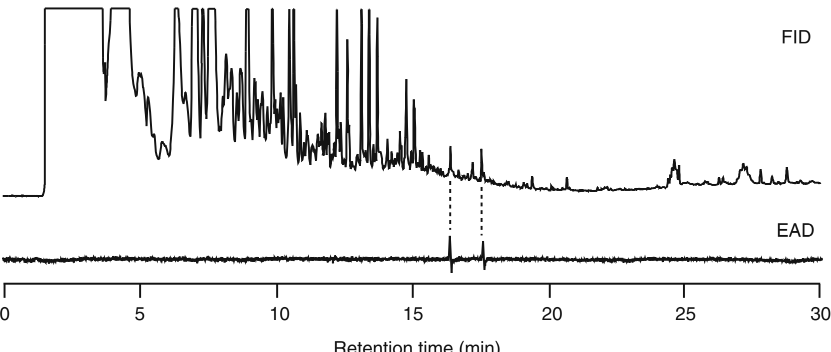

Fig. 1 Coupled gas chromatographic (flame ionization detection; FID)-electroantennographic detection (EAD) analysis of antenna of male *Callosobruchus rhodesianus* to volatile collections from virgin female *C. rhodesianus* (DB-5 column)

was purified further by normal-phase HPLC. The two EAD-active compounds were found in the 8 min to 9 min. (first compound; 16.3 min on DB-5) and 11 min to 12 min. (second compound; 17.6 min on DB-5) fractions. Y-tube olfactometer assays of the two fractions, showed only the second fraction (11 min to 12 min. fraction) to be attractive (13 of 15 males chose the sample disc, $P<0.01$). When both fractions were combined, 16 of 17 males chose the disc treated with the combined fraction (not different from the activity of the second compound fraction alone; Fisher's test; $P=0.588$) over the control. Therefore, we determined only the structure of the second compound. The active HPLC fraction was purified further by preparative GC, and the isolated compound (approximately 25,000 female equivalents, 20 μg/C_6D_6 0.2 ml) was subjected to GC-MS and NMR analyses.

GC-EI-MS analysis of the compound showed a base peak at *m/z* 69 and fragments at *m/z* (% intensity relative to the base peak) 207 (3), 193 (11), 175 (5), 163 (1), 149 (3), 137 (18), 123 (17), 107 (12), 95 (21), 81 (33), 55 (25) and 41 (60) (Fig. 2). The fragmentation pattern was similar to that reported previously for homofarnesal, the female sex attractant pheromone of *C. chinensis* (Shimomura et al., 2008). GC-CI-MS analysis showed characteristic ions at *m/z* 219 $[M + 1\text{-}H_2O]^+$ (100) and 237 $[M + 1]^+$ (14), while no peaks were detected in the high-mass region between *m/z* 238 and 300, indicating a molecular weight of 236. The high-resolution EI-mass spectrum of the compound was consistent with a molecular formula of $C_{16}H_{28}O$ [observed *m/z*: 236.2129 (3% intensity relative to the base peak); calculated *m/z*: 236.2140]. This molecular formula indicated three degrees of unsaturation.

In the ^{1}H-NMR spectrum of the compound, the presence of an aldehyde group adjacent to a methylene group (CHO—CH_2) was evident from a signal at 9.35 ppm (t, 1H, $J=2$ Hz). Two distinct olefinic protons at 5.24 (1H) and 5.11 (1H) ppm were detected. Two methylene groups at allylic positions (CH_2—C═C) were detected at 2.18 (m, 2H) and 2.11 (m,

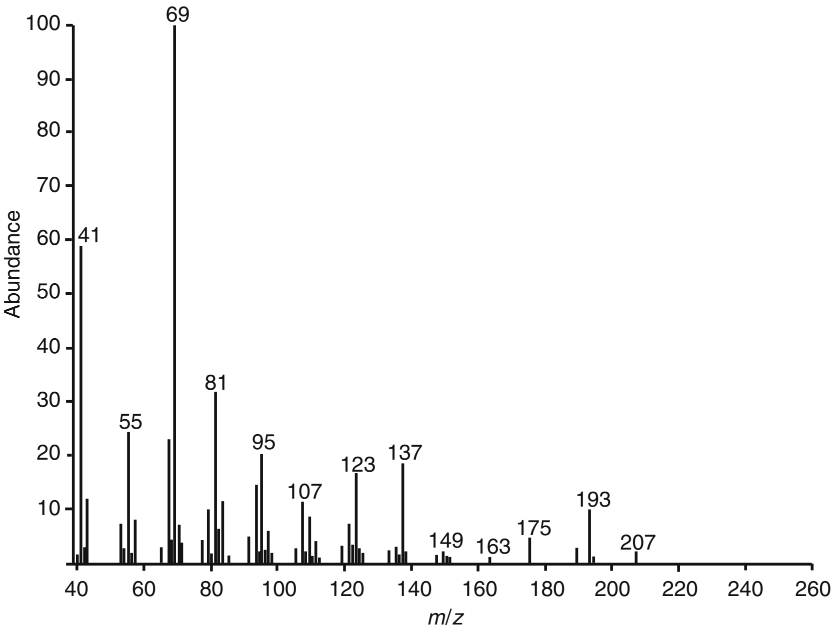

Fig. 2 Electron ionization mass spectrum of the active pheromone compound from female *Callosobruchus rhodesianus*

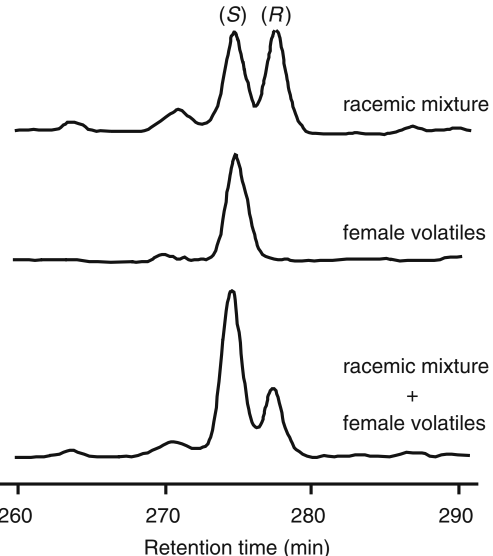

Fig. 3 Chiral gas chromatographic (β-DEX 225) analysis of the active compound from female *Callosobruchus rhodesianus* and synthetic racemic (*E*)-7-ethyl-3,11-dimethyl-6,10-dodecadienal

2H) ppm. Obscure signals also were detected at 1.72–1.96 (5H) ppm, which could be assigned to two methylene groups at another allylic position and an α-position of an aldehyde group, along with one methine group. Three distinct methyl signals were clearly observed: two signals at 1.68 (s, 3H) and 1.57 (s, 3H) ppm, derived from two methyl groups on the double bond (CH_3)—C═C, and one signal adjacent to the methine group (CH_3—CH) at 0.73 ppm (d, 3H, J=6.9 Hz). The presence of one ethyl group on the double bond (CH_3—CH_2—C═C) was evident from signals at 0.97 (t, 3H, J= 7.6 Hz) and 2.02 (q, 2H, J=7.6 Hz) ppm for a terminal methyl and an allylic methylene group, respectively, with an appropriate coupling constant.

These data, plus the similarity of the MS fragmentation pattern with homofarnesal, suggested the compound was a 2,3-dihydrohomofarnesal, i.e., 7-ethyl-3,11-dimethyl-6,10-dodecadienal. GC-EAD analysis of the synthetic mixture of the geometric isomers showed that one of the two geometrical isomers elicited responses in male antennae. The retention times and mass spectrum of the isomer matched that of the natural compound.

2,3-Dihydrohomofarnesal is a homolog of 2,3-dihydrofarnesal (3,7,11-trimethyl-6,10-dodecadienal), in which a C-7 ethyl group is substituted for a methyl group. Given the elution order on GC columns of the two *cis*/*trans* isomers of 2,3-dihydrofarnesal (Bartschat et al., 1997), the compound was proposed to be (*E*)-7-ethyl-3,11-dimethyl-6,10-dodecadienal. Synthetic (*E*)-2,3-dihydrohomofarnesal (see below) had retention times and spectroscopic data identical to the natural compound.

To confirm the absolute configuration of (*E*)-2,3-dihydrohomofarnesal, both enantiomers of (*E*)-2,3-dihydrohomofarnesal were synthesized, and the absolute configuration of natural (*E*)-2,3-dihydrohomofarnesal was investigated by chiral capillary column GC analysis. Natural (*E*)-2,3-dihydrohomofarnesal collected from female *C. rhodesianus* showed only one peak at the same retention time of (*S*)-**1** (Fig. 3).

The pheromonal activity of both synthetic enantiomers was confirmed in Y-tube olfactometer assays. 50% of males were significantly attracted to 10 ng of (3*S*,6*E*)-2,3-dihydrohomofarnesal (Fig. 4). Neither (3*R*,6*E*)-2,3-dihydrohomofarnesal nor the racemate of (*E*)-2,3-dihydrohomofarnesal was more attractive than solvent controls (Fig. 4).

Discussion

In laboratory bioassays, we confirmed that only male *C. rhodesianus* beetles were attracted to odors from live virgin females, suggesting the presence of a female-produced sex attractant pheromone. GC-EAD analysis, using male antennae, of the volatiles of virgin females showed two compounds to be EAD-active. Chromatographic fractionation and bioassay showed only the later-eluting compound to be attractive, and this was identified as (*E*)-2,3-dihydrohomofarnesal. In insect pheromonal communication, bioactivity often depends on chirality (reviewed in Mori, 2007). By using chiral GC analysis, we confirmed

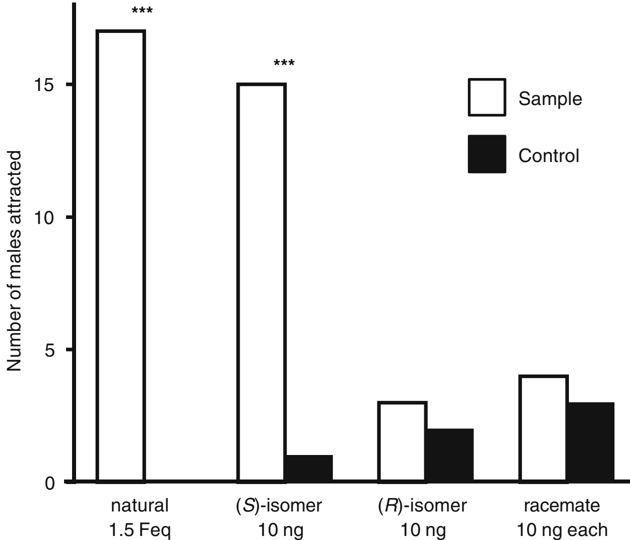

Fig. 4 Y-tube olfactometer responses of male *Callosobruchus rhodesianus* to volatile collections from virgin females, synthetic (3*S*,6*E*)- and (3*R*,6*E*)-7-ethyl-3,11-dimethyl-6,10-dodecadienal, and racemate. Thirty males were tested in each assay. The distribution of males between sample and control in each treatment was subjected to a binominal test (two-tailed test with the test proportion set at 0.5). *Asterisks* above bars indicate significant differences (***; P<0.001) from the test proportion. Males that did not reach either disc were not included in the data analysis. Feq = female equivalent

that female *C. rhodesianus* produced only the (*S*)-enantiomer. The olfactometer assay confirmed that the (*S*)-isomer was attractive to male beetles, whereas the (*R*)-enantiomer or the racemate were not. Thus, (3*S*,6*E*)-2,3-dihydrohomofarnesal is a natural pheromone component of *C. rhodesianus*, and the (*R*)-isomer inhibits its activity.

2,3-Dihydrohomofarnesal is the second example of a homosesquiterpene aldehyde being a sex attractant pheromone in the genus *Callosobruchus*. The first, homofarnesal, (2*Z*,6*E*)- and (2*E*,6*E*)-7-ethyl-3,11-dimethyl-2,6,10-dodecatrienal, was identified in *C. chinensis* (Shimomura et al., 2008). In both pheromone examples, an extra carbon unit is added to the C-7 methyl group of the sesquiterpenoid skeleton. Other homosesquiterpenes have been reported from insects (e.g., juvenile hormone), and these are synthesized *via* the mevalonate pathway from mevalonate and homomevalonate (Morgan, 1999). The pheromone components of *C. rhodesianus* are likely to be biosynthesized *via* a similar pathway, followed by enantioselective reduction of the double bond at position 2-3, but this remains to be clarified.

The genus *Callosobruchus* is comprised of some 20 species (Borowiec, 1987). In this genus, female sex attractant pheromones now have been identified from five species. While the pheromones of *C. rhodesianus* and *C. chinensis* are homosesquiterpene aldehydes, the pheromones of the other species consist of short chain fatty acids, including (*Z*)-3-methyl-2-heptenoic acid for *C. analis* (Cork et al., 1991), a mixture of (*Z*)-3-methyl-2-heptenoic acid and (*E*)-3-methyl-2-heptenoic acid for *C. subinnotatus* (Shu et al., 1999), and a mixture of (*Z*)-3-methyl-2-heptenoic acid, (*E*)-3-methyl-2-heptenoic acid, (*Z*)-3-methyl-3-heptenoic acid, (*E*)-3-methyl-3-heptenoic acid, and 3-methyleneheptanoic acid for *C. maculatus* (Phillips et al., 1996). Although new pheromone compounds can arise by simple, gradual modification of a biosynthetic pathway (Symonds and Elgar, 2008), the very different structures of the homosesquiterpene aldehydes and short-chain fatty acids in the genus *Callosobruchus* suggest more saltational changes in biosynthetic pathway usage for pheromone biosynthesis.

A molecular-based phylogenic study that used mitochondrial DNA of the genus *Callosobruchus* separated it into three distinct clades: one clade containing *C. rhodesianus, C. analis*, *C. subinnotatus*, and *C. maculatus*, designated the *maculatus* clade; a second containing *C. chinensis*, designated the *chinensis* clade; and a third paraphyletic group of species (Tuda et al., 2006). In the *maculatus* clade, *C. rhodesianus* has a different sex attractant pheromone structure from the other species. Moreover, *C. rhodesianus* is phylogenetically distant from *C. chinensis*, yet the sex attractant pheromones of both species are structurally comparable. This is somewhat similar to the biosynthesis of aggregation pheromones of bark beetles in the genera *Dendroctonus* and *Ips*, in which the most closely related species within each genus have the greatest differences in pheromone composition (Symonds and Elgar, 2004), yet in both genera the same mevalonate pathway is used (Seybold et al., 2000). We suggest that both gradual and saltational shifts in pheromone evolution occur in the genus *Callosobruchus.* Biosynthetic studies of these compounds are required to clarify the evolution of pheromones in the genus.

Acknowledgements The authors are grateful to Takasago International Co. for kind gifts of both enantiomers of citronellal. We thank Dr. Takane Fujimori (Tokyo University of Agriculture) for his advice on the structural analysis.

RAPID COMMUNICATION

Sexually Mature Cuttlefish are Attracted to the Eggs of Conspecifics

Abstract Cuttlefish typically are solitary, but form aggregations to spawn. We tested the hypothesis that bioactive factors in the eggs of conspecifics may facilitate the formation of spawning groups of *Sepia officinalis*. Cuttlefish detected odors from cuttlefish eggs, resulting in an increased ventilation rate. Extracts from female ovaries induced the largest increase in ventilation rate, suggesting that this organ could be a potential source of the bioactive chemicals. In y-maze assays, sexually mature, but not subadult, cuttlefish, were attracted to odors of cuttlefish eggs. These data suggest that *Sepia* eggs could be a source of reproductive pheromones.

Key Words Chemoattraction · Reproductive behavior · Spatial orientation · Invertebrate · Mollusk

Introduction

Many species of decapod cephalopods (cuttlefishes, squids) form large, near-shore aggregations for spawning, and lay their eggs in large, communal masses (Hanlon and Messenger 1996). The mechanisms that facilitate this behavior are largely unknown. Cuttlefishes typically are solitary or semi-solitary and semelparous; spawning occurs inshore when they are 1 year old to 2 years old.

Chemical attractants facilitate reproduction in many mollusks (Susswein and Nagle 2004), and cuttlefish are capable of chemoreception over a distance (Budelmann et al. 1997). Here, we tested the hypothesis that *Sepia officinalis* eggs could provide a source of chemoattractants (Zatylny et al. 2000). First, we evaluated whether cuttlefish detect odors from freshly laid eggs, measuring ventilation rate in a bioassay (Boal and Golden 1999). This method has been used previously to show that cuttlefish detect a wide range of odors, including those of food (Boal and Golden 1999). Second, we recorded ventilation responses to eggs laid ~36–48 h previously, and to extracts of female reproductive organs, to determine the potential source(s) of bioactive factor(s). Third, we investigated whether cuttlefish were attracted to egg odors when presented in a simple y-maze.

Methods and Materials

Subjects were first generation *S. officinalis* (National Resource Center for Cephalopods, Galveston, Texas). Sexual maturity was determined behaviorally; sex was confirmed by necropsy. Housing and experimental tanks were interconnected within a 57,000-l marine system of recirculating artificial seawater (ASW; salinity 34±2 ppt, temperature 17.5±1.5°C; Hvorecny et al. 2007).

Ventilation rate Trials were conducted in Plexiglas tanks (38.1×19.6×26.7 cm, 18.5 l) with flow rates of 91±3.8 ml/sec (Boal and Golden 1999). In dye tests, red food coloring almost instantly spread evenly throughout the tank, with no color remaining after ~10 min. Subjects were sub-adults (5–7 mo post-hatching, approx. 9.0–13.0 cm mantle length) for

tests of newly laid eggs. In the remaining trials, these same subjects were sexually mature adults (eight female, six male; 8–10 mo post-hatching).

A single cuttlefish was placed into an experimental tank and allowed to settle (typically 20–30 min). After this, ventilations were counted for 20 sec. in each minute. If the number of ventilations was steady for 5 consecutive min., the sampling period was increased to 30 sec. If the number of ventilations remained steady for a further 5 min., an odor sample was added to the water supply line and ventilations were counted (30 sec/min) for 10 min. Changes in ventilation rate (VR: ventilations/min) were calculated by subtracting the average VR, in the 5-min. period before addition of odor, from peak VR in the 5 min. after addition of odor. Changes in VR among treatments were compared by using a single Friedman two-way analysis of variance by ranks, followed by multiple comparisons tests.

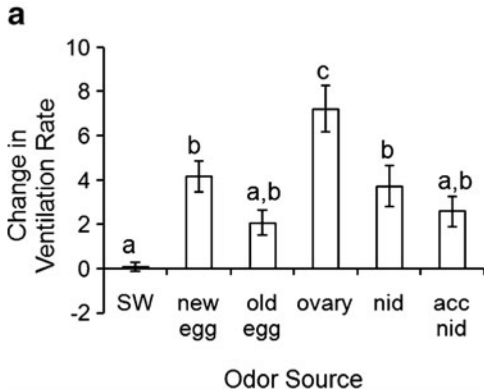
Y-Maze The y-maze base compartment (49×63×20 cm) was connected to two arms (each 24.5×70×20 cm), separated by a 60-degree angle, with a perforated gate between the base and arms (Boal and Marsh 1998). During trials, the sides and top of the maze were covered with dark towels. Cuttlefish were viewed in mirrors beneath the transparent maze floor. Cuttlefish rarely looked down toward the mirrors.

The y-maze was filled to a depth of 15 cm; seawater entered the distal ends of the arms and drained at the opposite end of the maze. During trials, odor solutions were dripped into the seawater inflow (1 drop/sec) using intravenous solution bags. It took 1.5 min (early trials) or 1 min (later trials) for control dye to travel from the inflow to the drain. Trials typically were separated by many hours, and the location (left/right) of odors added to the maze was randomized.

At the trial start, one cuttlefish was placed in the base compartment. After a 30-sec delay, the odor drips were switched on. After a further delay (1.5 min, early trials; 1 min, later trials), behavioral monitoring began. Once the cuttlefish reached the behavioral criteria (see below), an overhead light was switched on and the gate raised, allowing it access to the y-maze arms. A cuttlefish was considered to have made a choice when its entire body entered one maze arm. Two criteria were used to ensure that a cuttlefish was exposed to odors from each maze arm before it gained access to the arms: it had to travel to both sides (left and right) of the base compartment, and then be positioned at least half-way back in the base compartment so that it would not move simply into the nearest maze arm once the gate was raised.

The first group of cuttlefish (N=15; eight females, seven males) was tested at 7- and 9-mo post-hatching; the second group (N=16; six females, ten males) was tested at 11-mo post-hatching. Not all cuttlefish responded by choosing an arm.

Odor preparation Sepia officinalis eggs (fresh <1 h, N=10; old=36–48 h, N=16) and reproductive tract organs from two anesthetized individuals were frozen on dry ice. Eggs (individually), ovaries (30 g, 90 g), nidamental glands (50 g, 46 g), and accessory nidamental glands (3.6 g, 7.0 g) were extracted and purified on C18 Sep-Pak Plus cartridges, as previously described (Buresch et al. 2003). Peptides and proteins were eluted with 5 ml (eggs) or 15 ml (reproductive organs) of 50% acetonitrile/0.1% heptafluorobutyric acid. The eluates (new eggs: 50 ml; old eggs: 80 ml; ovaries: 45 ml or 135 ml; nidamental glands: 60 ml or 75 ml; accessory nidamental glands: 15 ml or 30 ml) were pooled, and divided into 1-ml aliquots (eggs) or ten equal aliquots (organs), and lyophilized.



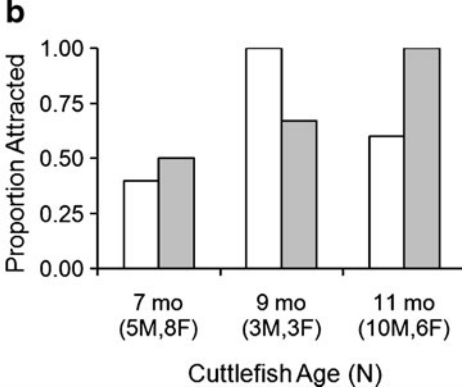


Fig. 1 *Sepia officinalis* responses to various extracts of eggs and reproductive tissue. **a** Ventilation responses (±SEM) to purified extracts of freshly laid eggs (new egg), 36–48 h-old eggs (old egg), ovary, nidamental glands (nid), and accessory nidamental glands (acc nid), or seawater controls (SW). **b** Attraction of males (*open bars*) and females (*shaded bars*), of different ages, to purified extracts of 36–48 h-old eggs. Different letters atop bars indicate means that were significantly different (P<0.05; Friedman analysis of variance by ranks)

In all experiments, fresh ASW was a control. ASW (100 ml) containing a mashed shrimp, then filtered to remove particulates, was the food control. Odor samples were prepared by re-suspending 1 aliquot of gland or egg extract in 15 ml ASW (VR experiments) or 20 ml ASW (attraction experiment). In each trial, 5 ml (VR experiments) or 20 ml (attraction experiment) of the resulting suspension were used.

Results and Discussion

Cuttlefish increased their ventilation rate in response to odors from recently laid eggs, extracts of ovary, and nidamental glands, but not to odors from older eggs or extracts from accessory nidamental glands (Friedman analysis of variance by ranks, $Fr=31.43$, $N=14$, $k=6$, $P<0.001$; Fig. 1a). Responses to extracts of ovaries were significantly greater than responses to all other odors tested, suggesting that the stimulatory chemicals in eggs might originate there.

In the y-maze, more sexually mature cuttlefish were attracted to the arm containing purified extracts of freshly laid eggs than to the arm containing only ASW (16 of 22 attracted, $X^2=4.54$, $df=1$, $P<0.05$; Fig. 1b; c.f., food control, four of 13 attracted; ASW control, 7 to left arm, 6 to right arm), indicating their attraction to odors from eggs. Previously, Zatylny et al. (2000) isolated a peptide from eggs of S. *officinalis* that stimulated contractions of the female genital tract. Although we do not know whether this compound is the same or related to the compound(s) that mediate VR rate and attraction in our study, it is likely that eggs contain a number of bioactive factors (Susswein and Nagle 2004) that stimulate different responses from cuttlefish.

Our results indicate that in *Sepia*, as in *Loligo* (Buresch et al. 2003) and *Aplysia* (Painter et al. 1998), eggs are a source of pheromones that play a role in coordinating essential reproductive behavior.

Lack of Evidence for HLA-Linked Patterns of Odorous Carboxylic Acids Released from Glutamine Conjugates Secreted in the Human Axilla

Abstract Genetic factors within the major histocompatibility locus (MHC) have been shown to influence body odors in mice. MHC-dependent preferences for body odors also have been reported in humans. The axillary glands are a key odor-forming organ in humans, and it is assumed that they provide behaviorally relevant odors. Volatile carboxylic acids are the most diverse class of known axillary odorants, and the pattern of these acids is genetically determined. These acids are released by an N_α-acyl-glutamine-aminoacylase present in skin bacteria. We tested a hypothesis concerning whether or not the inherited individual-specific patterns of odorous acids are strongly influenced by polymorphic genes in the MHC. Axilla secretions were collected in 12 families, comprising 3 to 6 siblings, who had been typed for HLA-A, B, and DRB1 loci. The samples were treated with N_α-acyl-glutamine-aminoacylase, and the methyl esters of the released acids were analyzed with comprehensive two-dimensional gas chromatography (GC × GC) and time-of-flight mass spectrometry (ToF MS). The patterns of the analytes were compared by distance analysis. The distance was lowest between samples taken from the same individual, confirming the presence of donor-specific odor-prints. A much higher distance was observed between siblings, but there were no differences among siblings sharing none, one, or both HLA-A,B,DRB1 haplotypes. By applying principal component analysis, a clear clustering of samples taken from one individual was confirmed, but no clustering was observed for siblings sharing identical HLA-A,B,DRB1 alleles. Thus, the genetically determined pattern of N-acyl-glutamine conjugates of volatile carboxylic acids, secreted in the human axilla, appears not to be determined by genes residing in the HLA complex.

Key Words Human body odor · Odortype · Volatile carboxylic acids · Major histocompatibility locus · Human leucocyte antigen complex · HLA-dependent mate selection · Comprehensive two-dimensional gas chromatography · Time-of-flight mass spectrometry

Abreviations

MHC	Major histocompatibility locus
HLA	human leucocyte antigen
GC	gas chromatography
ToF MS	time-of-flight mass spectrometry
N-AGA	N_α-acyl-glutamine-aminoacylase
PCA	principal component analysis

Introduction

A large body of literature describes the fascinating phenomenon of mice being able to discriminate odors of urine originating from congenic mice that differ solely in their major histocompatibility complex (MHC) loci (Yamaguchi et al., 1981). This MHC-dependent odor discrimination forms the basis of a number of well-established behavioral effects, such as odor-dependent mate selection, in which mice prefer to mate with MHC-dissimilar partners (Yamazaki et al., 1976), and parent-progeny recognition (Yamazaki et al., 2000). MHC-dependent mating preferences also have been reported in a variety of other species, including non-mammals (Reusch et al., 2001; Olsson et al., 2003). MHC-dependent mating preferences may help mice to maximize the frequency of MHC-heterozygotes in their offspring and prevent inbreeding (Penn and Potts, 1999).

The MHC in humans is better known as the HLA-region (Human leucocyte antigen). Studies in which humans evaluated the pleasantness of body odors on worn T-shirts found a preference for body odors of HLA-dissimilar persons (Wedekind et al., 1995; Wedekind and Furi, 1997). Interestingly, in females, this preference was reversed if they used contraceptive pills. Later, Thornhill et al. (2003) found similar effects when men rated female odors, but not when women rated male odors. Santos et al. (2005), on the other hand, found significant correlations between the frequency of shared HLA-alleles and the rating of body odors as 'indifferent' when women rated male odors but not *vice versa*. The preference for odors from HLA-different donors was not confirmed in a recent study (Roberts et al., 2008), although this study found an MHC-correlated shift in pleasantness when women started to use oral contraceptives. Evidence for higher than random MHC-dissimilarity within married couples also comes from a recent genomic study (Chaix et al., 2008). HLA-associated odor choices were reported to be influenced by paternally inherited HLA alleles, with a preference for odors of male donors with more HLA matches to a woman's paternally inherited alleles (Jacob et al., 2002). These studies suggested that in humans, as in mice, individuals may have a distinct body odortype, which is (a) partially genetically determined, and (b) more specifically determined, at least partly, by MHC or MHC-linked alleles, although the actual underlying mechanism is unknown and the chemicals involved have not been identified.

In most of the human studies, worn T-shirts served as an odor source, whereas in mice the odortype was the urine (Yamaguchi et al., 1981). Singer et al. (1997) showed that various carboxylic acids (e.g., phenyl-acetic acid) were important discriminators in mouse urine, as their relative abundances were associated with different MHC-types. They concluded that the body odortype resulted from a 'compound odor' of several acids, with the relative abundance of different acids, rather than presence or absence of specific compounds, generating the odor differences in mice.

Several studies have addressed the chemical nature of human body odorants secreted in the axilla. Early studies found the two odoriferous steroidal pig pheromones, 5α-androst-16-en-3-one and 5α-androst-16-en-3α-ol, in human axillary secretions (Brooksbank et al. 1974; Claus and Alsing 1976). Zeng et al. (1991) reported (*E*)-3-methyl-2-hexenoic acid as a key odor component, along with several other carboxylic acids. In our previous work (Natsch et al., 2006), we identified a series of 26 carboxylic acids in axillary secretions. These molecules are secreted as N_{α}-acyl-glutamine-conjugates, with the free acids released from the conjugates by the enzyme N_{α}-acyl-glutamine-aminoacylase (N-AGA), produced by the commensal skin bacteria inhabiting human axilla (Natsch et al., 2003, 2006). In a recent population study on pairs of monozygotic twins, we showed that the pattern of odorous acids is similar between different sampling days of the same individual, and also similar within pairs of homozygotic twins, but differs between unrelated individuals (Kuhn and Natsch, 2009). Four sulfanyl-alkanols have been reported as further odor components in axillary secretions (Hasegawa et al., 2004; Natsch et al., 2004; Troccaz et al., 2004). These compounds are released from secreted Cys-Gly conjugates by the sequential action of a dipeptidase and a β-lyase, present in the commensal bacteria of the human axilla (Emter and Natsch, 2008).

The studies above were all performed on human 'odorants' that could be perceived by the human nose (i.e., the studies always had a specific focus to identify only odorous compounds, generally determined with a gas chromatograph equipped with a sniff port). Other studies have looked at volatile chemicals on human skin, not discriminating odorous from non-odorous ones. Penn et al. (2007) studied all compounds detectable by gas chromatography (GC) in samples from axilla skin in a large population in the European Alps and identified 373 consistent peaks, based on mass spectrometric (MS) evidence. However it proved difficult to separate endogenous from exogenous volatiles and no information on the odorous nature of the chemicals was given.

Only a few studies have addressed HLA-associated chemosignals in humans, and only with basic analytical methodology. Eggert et al. (1998) used GC to assess volatiles in human urine, and concluded that the patterns were linked to the HLA, without actual identification of the chemicals Savelev et al. (2008) found variation in the levels of 3-methylbutanal on human panelists. No HLA-typing of the panelists was performed, but the bacterial flora from two 3-methylbutanal-emitting panelists was shown to be able to

metabolize a peptide, derived from a HLA-class 1 protein, with a terminal leucine. These data show that leucine-containing peptides are degraded to 3-methylbutanal by the microflora of some panelists, but still give no clear link to a chemical basis of HLA determined odortypes.

Thus, the key published studies on HLA-correlated odor preferences have been performed at a behavioral level and did not identify the chemicals involved. Here, we try to fill this gap by using a targeted analytical approach to address a specific hypothesis: do the genetically determined patterns of Gln-bound odorant carboxylic acids reveal part of an HLA-dependent body-odor type in humans?

Because the HLA complex is a multigenic system, comprising highly polymorphic loci forming an even larger number of different HLA-haplotypes, a general population study is unlikely to find many instances of HLA-identical pairs suitable for a statistically relevant comparison. On the other hand, two siblings from the same family have a 25% chance of being HLA-identical. Therefore, we determined the HLA-A,B,DRB1 haplotypes of 48 individuals in 12 families, and analyzed patterns of carboxylic acids in three repeated samplings with a GCxGC–Time-of-Flight (ToF) MS method. Individuals from the same family identical at none, one, or both of their HLA-haplotypes were studied to elucidate the effect of identity in the HLA complex on the similarity of the carboxylic acid pattern.

Methods and Materials

General All reagents and solvents were purchased from Fluka (Buchs, Switzerland), if not noted otherwise. The synthesis of reference compounds has been described previously (Natsch et al., 2003, 2006).

Subjects and Study Setup Twelve families comprising 3–7 siblings of identical sex were recruited (1 family with 3 individuals; 9 families with four individuals, 1 family with five individuals and 1 family with seven individuals; two individuals decided to withdraw from the study resulting in a total study population of N=48; see supplementary Table S1). Participation was voluntary, with subjects informed in detail about the goals of the study. After they gave their written consent, subjects were compensated for their participation with a voucher (100 Swiss francs). Sweat from each subject was sampled three times on different days (with the exceptions of four panelists sending back only two samples, see Table S1), with at least a 1wk interval between sampling days. The samples from the right and left axilla were pooled for analysis, as our previous analytical study that used identical methods had shown high similarity between right and left samples obtained on the same day (Kuhn and Natsch, 2009). On two sample days, volunteers donated DNA in the form of mouth swabs (Gentra/Qiagen Puregene Buccal cell Core kit A, Qiagen, Hombrechtikon, Switzerland).

DNA Extraction and HLA-Typing For each donor, one DNA-sample was extracted from buccal swabs by the high salt procedure, and a parallel sample was extracted with the Gentra/Qiagen Puregene Buccal cell Core kit A, according to manufacturers instructions (Qiagen, Hombrechtikon, Switzerland). The donors were typed for HLA-A, B (intermediate resolution), and DRB1 (high resolution) by reverse polymerase chain reaction-sequence-specific oligonucleotides (PCR-SSO) hybridization on microbeads (luminex technology), using the LabType reagents (OneLambda, Ingen, Chilly-Mazarin, France) (Rahal et al., 2008). A total of 11 HLA-A, 18 HLA-B, and 19 HLA-DRB1 alleles were identified in this group of donors.

Collection of Axillary Secretions and Treatment with Recombinant N-AGA Axillary secretions of individual donors were sampled on cotton pads fixed in the axilla during 45–60 min of physical exercise, as physical exercise is a reliable method for secretion of significant amounts of odor precursors (Starkenmann et al., 2005; Kuhn and Natsch, 2009). Immediately after collection, individual pads were suspended in 25 ml of 30% EtOH in H_2O to avoid any bacterial metabolism, and sent to the laboratory where they were frozen at -80°C until analysis. Pads were removed from the sampling solution, and the liquid phase was extracted once with 5 ml hexane. The aqueous phase, containing the glutamine conjugates of the carboxylic acids of the left and right axilla sampled from the same day, were pooled and lyophilized for 16 h and re-suspended in 1 ml H_2O. A 0.6 ml sample of this concentrated aqueous extract was amended with the Gln-conjugate 5-amino-2-(2-methylundecanamido)-5-oxopentanoic acid as internal standard (final concentration 0.166 μM). The sample then was treated with 5 μg of the recombinant enzyme N-AGA [produced and purified as described before (Natsch et al., 2003); this is sufficient to ensure complete hydrolysis of Gln-conjugates even if present at a total concentration of >100 mM]. In addition, the two enzymes (5 μg of each) that release sulfanyl-alcohols from Cys-Gly conjugates were added, (Emter and Natsch, 2008). After 4 h incubation at 36°C, 50 μl 1 M HCl and 80 mg NaCl were added, and the sample extracted with 140 μl methyl-*t*-butyl-ether. The organic phase (100 μl) was transferred to a GC vial, 7 μl of a 2 M solution of (trimethylsilyl)-diazomethane and 18 μl of methanol containing 0.025 mM ethyl-caprinate as a second internal standard, were added, and the sample was heated to 40°C for 30 min to form the methyl esters of the enzymatically released acids.

GCxGC-ToF MS Analysis of Axillary Secretions A LECO Pegasus 4D GCxGC-ToF MS system (LECO, St. Joseph, MI, USA) was used, consisting of a 6890 N gas chromatograph equipped with split/splitless injector (Agilent Technologies, Palo Alto, CA, USA), a dual stage, four-jet cryogenic modulator (licensed from Zoex), a second-dimension column oven, and a Pegasus III time-of-flight mass spectrometer (LECO). The analytical method has been described in detail recently (Kuhn and Natsch, 2009). The following modifications, from the previously used method, were applied. Samples were injected in the pulsed splitless mode, with the inlet pulse pressure set to 65.3 psi for 4.6 min. A capillary column of 30 m length×0.25 mm i.d., coated with 0.25 µm of VF-5MS (5% phenyl- 95% dimethyl-polysiloxane), was used for the first-dimension (Varian, Palo Alto, CA, USA), with a temperature program of: 35°C for 5 min, 10°C.min^{-1} to 120°C, 5°C.min^{-1} to 210°C, then 30°C. min^{-1} to 260°C, and held for 8 min. The modulation time was 5 sec. The separate, second-dimension oven was kept at the temperature as the first-dimension oven, but the modulator housing was kept 15°C above the first-dimension oven temperature.

As the sweat samples from different donors, and even from the same donors on different days, varied greatly in concentrations of key analytes, each sample was analyzed first by GC (using flame ionization detection) to determine the level of the methyl-ester of 3-methyl-2-hexenoic acid. This dominant compound is the first to reach the non-linear range of the analytical method if samples are too concentrated. Based on preliminary analysis, the samples were diluted with MTBE/methanol (85/15, v/v), and the injection volume was adjusted (0.2 – 3.0 µl) so that 5-8 ng of this dominant analyte was injected on to the column in all samples. With this approach, data distortion, due to measuring concentrated samples outside of the linear range, was avoided.

The study design required that 9453 sub-peaks be identified, correctly combined, and quantified (137 samples×23 analytes, with an assumed three modulations per ^{1}D peak; 21 endogenous analytes and two internal standards). This was done with the data processing, peak identification, and peak quantification approach described in detail elsewhere (Kuhn and Natsch, 2009), with all the parameters adjusted for the changed column lengths used in this study. The chemical names and structures of the analytes are given Table 1 and supplementary Table S2, respectively. The precision of the GCxGC-MS method was determined by three times injecting the same sample (07C2);

[a] Identification method was either (1) synthetic reference compound injection, (2) library database search, (3) homologues series position on the separation plane and interpretation of its mass spectrum

the relative standard deviation of the peak area for each of the 21 analytes was between 0.1 and 6.0 per cent. Attempts also were made to quantify the sulfanyl-alkanols, but these were below the limit of quantification in the majority of the samples and, thus, were not evaluated further.

Evaluation of Results The consolidated GCxGC-ToF MS analyses resulted in a matrix of 134 samples of sufficient concentration and quality (see supplementary Table S1), with peak areas for 21 endogenous analytes per sample. First, a normalization step (Xu et al., 2007) was performed, as the amount of sweat in the different samples is difficult to control (different intensity of physical exercise, different transfer of sweat from skin to the pad). For each sample, each analyte was divided by the sum of all evaluated analytes, thus normalizing the sum of all evaluated analytes in a sample to 1. The data analysis then was performed with these normalized data.

The distance between two samples was calculated with the normalized Euclidean distance according to Eq. 1:

$$\text{Normalized Euclidean distance} = \sqrt{\sum_{n=1}^{m}\left(\frac{(X_n - Y_n)}{s_n}\right)^2} \quad (1)$$

Where X and Y are the two samples, m is the number of the analytes, X_n and Y_n are the normalized peak areas of analyte n in the two samples, and s_n is the measured standard deviation for the peak n over all samples.

This normalized distance measure corrects for the fact that the different analytes have different relative abundances and different scales (i.e., different *m/z* were used for their integration). Also this distance measure is symmetrical (e.g., distance of sample X to Y is identical to the distance of Y to X). Based on this, a distance matrix with all possible comparisons between individual samples within a particular family was calculated. The distances between samples (a) from the same individual on different days, (b) from two siblings, (c) from two siblings sharing none, (d) siblings sharing one, or (e) siblings sharing two HLA-haplotypes, then were compared. In addition, the distance matrix was transformed to ranks, assigning to each sample a rank based on the distance it has to each of the other samples of the same family. Finally, the averages for each normalized peak area per individual were also calculated. With these averages, the similarity matrix (also according to Eq. 1) was calculated again to compare individuals between families.

Principal component analysis (PCA) was performed based on the correlation matrix using Minitab statistical software (Minitab Inc., version 15.1.1.0., Coventry, UK).

Results

HLA-Typing of the Study Families The segregation of HLA haplotypes within siblings of each family could be inferred based on HLA-A, B, and DRB1 alleles. In 8 families, we were able to define all four possible individual HLA-A, B, DRB1 haplotypes (referred to as a, b, c, and d), whereas in 4 families only 3 haplotypes (a, b, c) were present. In the few instances in which HLA-A or HLA-B typing could not be performed, due to low amplification efficiency, high resolution HLA-DRB1 typing confirmed the distribution of haplotypes. The HLA alleles detected in this study group are all common in Caucasoid populations. Table 2 summarizes the HLA-haplotyping in the study group. In all families, at least two individuals shared both HLA-haplotypes. As expected, the frequency was highest for two siblings being haplo-identical (i.e., sharing 1 haplotype), whereas non-identical comparisons (i.e., with 2 different haplotypes) within families were slightly under-represented in the study population.

Distance Analysis of Odor Samples Within One Family Figure 1 shows a box-plot for the averages of the five distance values over the 12 families. In addition, the rank of each sample relative to others in the same family was calculated (closest = rank 1 or most distant = rank 11 in a family with 12 samples). Table 3 summarizes the averages

Table 2 Study population and segregation of hla haplotypes

	Individual						
Family	A	B	C	D	E	F	G
01	a/b	a/b	a/b	b/c	a/b		
02	a/b	c/d	a/c	a/c			
03	a/b	a/c	a/b	a/b			
04	a/b	a/b	NT	a/c			
05	a/b	b/c	a/d	a/d			
06	a/b	a/c	c/d	c/d			
07	a/b	c/d	a/b				
08	a/b	a/c	b/d	NT	a/c	a/b	c/d
09	a/b	a/c	b/d	a/c			
10	a/b	a/c	a/c	a/c			
11	a/b	a/c	a/c	c/d			
12	a/b	b/c	a/d	a/d			

NT not tested, individual withdrew from study

HLA-A,B,DRB1 haplotypes in each family were designated with the letters a,b,c, and d

For example in family 07, individuals A and C share the same 2 HLA haplotypes (a/b) whereas individual B has inherited 2 different haplotypes (c/d). In each family, haplotypes are formed by different combination of HLA antigens, with the exception of the common haplotype A1,B8,DR3 that was identified in 2 families

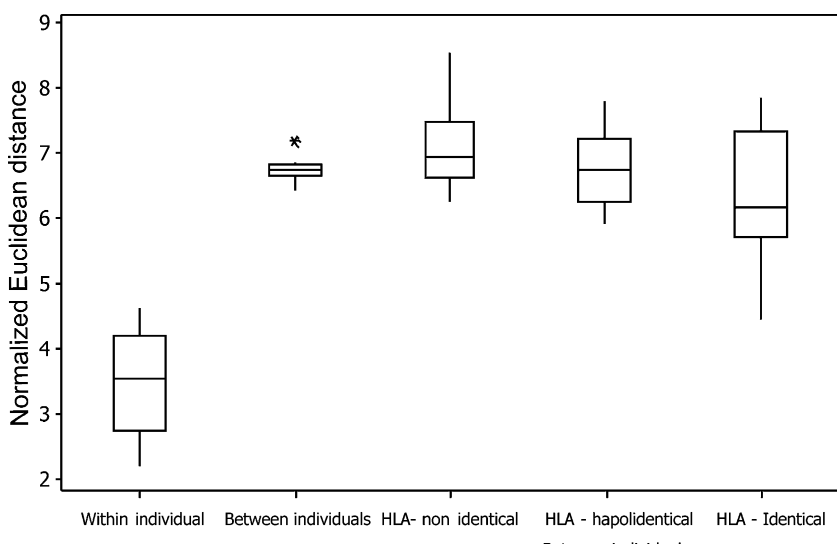

Fig. 1 Distance analysis for the comparisons among individual samples. Within each family the distance matrix between all individual samples was calculated. These distances were separated according to the following: (1) within one subject among samples taken on different sampling days, (2) between subjects in the same family, (3) between samples originating from two siblings sharing none, one or both HLA-alleles. For each family, the average of these comparisons was calculated. The boxplots show the distribution of all these averages in the twelve families

of the ranks for the individual families. Both these evaluations clearly indicate that samples from the same individual are closest to each other; when comparing different individuals within families, the distance is consistently higher. However, the distance of the acid patterns are, on average, similar, regardless of whether the individuals share none, one, or two HLA-haplotypes (Fig. 1). Also, the ranks of the comparisons are only slightly lower for the HLA-identical siblings compared to the haplo-identical or non-identical comparisons (Table 3), thus excluding HLA-linked genes as a key influence on the pattern of odorous acids.

Principal Component Analysis for Individual Families PCA was performed on all individual samples from within one family. The PCA results for four families are shown in Fig. 2 (see Supplementary information Figure S1 for the PCA plots of all 12 families). Inspection of these PCA plots showed no indication that HLA-identical siblings, overall, have an acid pattern that is closer to each other compared with haplo-identical or non-identical pairs. Thus, for example, in Fig. 2a, the three HLA-identical siblings A, C and D span the whole range of PC1 and are equally distant from their haplo-identical brother B. In Fig. 2b, the HLA-identical siblings C and D are at a similar distance to each

Table 3 The average ranks of the comparisons between samples within the twelve families

	Within individual	Between individuals	Between individuals		
			HLA-non identical	HLA-haploidentical	HLA-identical
Family 1	2.7	6.1		6.3	6.0
Family 2	1.5	5.8	5.5	5.8	5.8
Family 3	1.5	6.4		6.6	6.2
Family 4	2.4	5.2		4.6	6.3
Family 5	1.7	6.3	8.4	5.6	5.6
Family 6	1.5	7.0	7.4	7.6	4.3
Family 7	1.5	5.5	5.3		6.0
Family 8	1.6	10.0	10.6	10.1	7.5
Family 9	1.6	6.4	6.0	6.2	7.4
Family 10	2.5	6.8		6.8	6.7
Family 11	2.8	6.7	8.4	6.7	5.1
Family 12	1.8	6.3	5.9	7.4	5.1
AVERAGE	1.9[a]	6.5	7.2	6.7	6.0

[a] The theoretical average rank for samples from the same individual would be 1.5 with 3 samples per individual, if samples from one individual are always closest to each other; the observed average value of 1.9 is quite close to this value

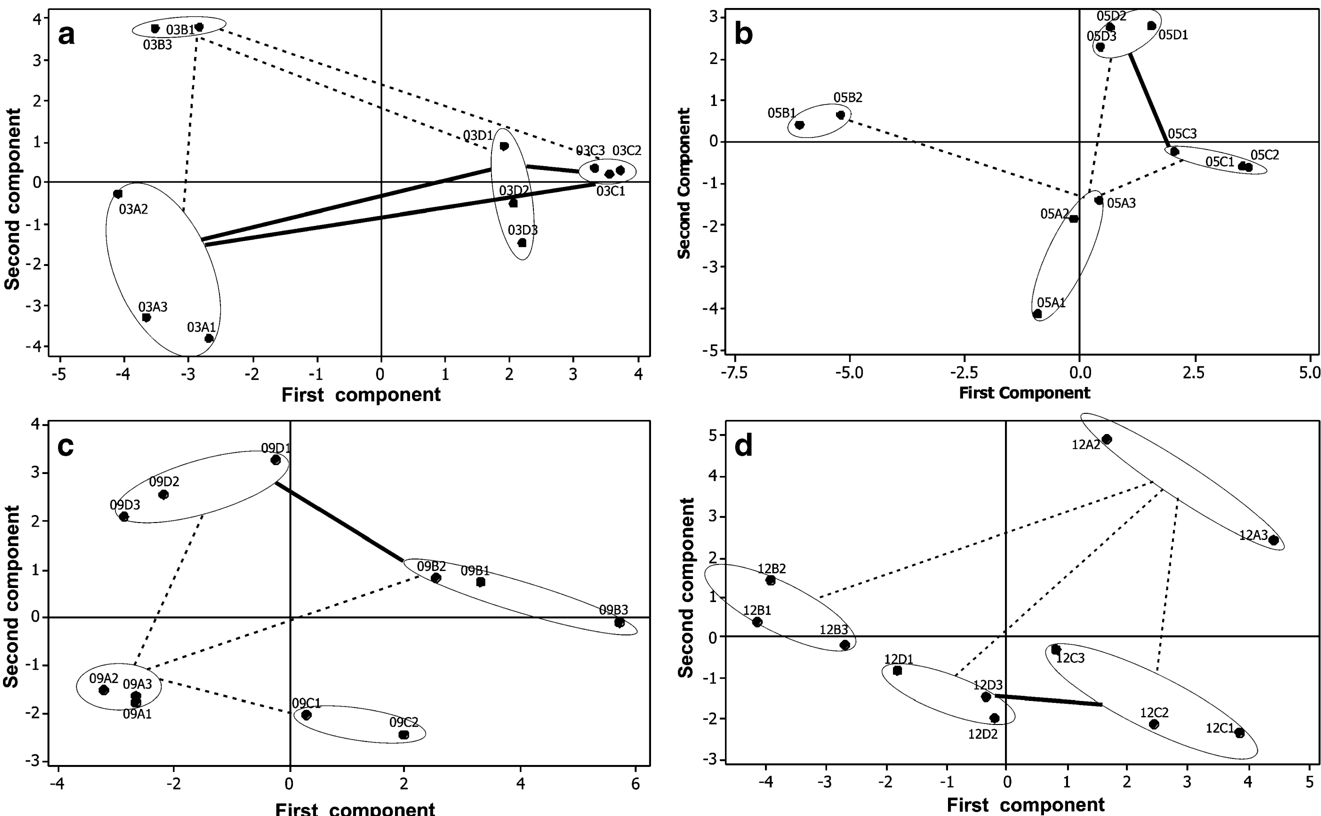

Fig. 2 Principal component analysis based on the correlation matrix of all the samples from families 3 **a**, 5 **b**, 9 **c**, and 12 **d**. The samples from different individuals (marked with capital letters) are connected with a solid line if HLA-identical, with a dotted line if HLA-haploidentical, or not connected if they are HLA-dissimilar at both loci

other, as is their haplo-identical sister A. In Fig. 2c, the non-identical brother C is separated from B at the same distance as is his HLA-identical brother D. The same also is true in Fig. 2d for the HLA-identical pair D and C, being at the same distance as the non-identical pair D and B. For more comparisons see Figure S1.

Analysis of the Average Values for each Individual: Comparing Different Families A final evaluation was made based on average normalized peak areas of each individual in order to look for differences between individuals within one family, compared to differences between individuals from different families. Overall, the average Euclidean distance between individuals from the same family is 5.07, whereas it is slightly higher (5.94) between individuals from different families ($P<0.001$) (data not shown). The average rank for samples from the same family is 17.2 compared to 24.5 for individuals from different families ($P<0.001$; 48 individuals evaluated, ranks go from 1 to 47, with a theoretical average of 24). This indicates that, overall, siblings (sharing on average 50% of the genome) are closer in their odorous acid profile than are unrelated individuals, although the effect is weak.

Discussion

The subject of HLA-linked body odors in humans has received much attention since the seminal paper of Wedekind et al. (1995). This topic mainly has been addressed in behavioral work, with a variety of studies on HLA-typed odor donors and HLA-typed odor sniffers rating the attractiveness of odor samples on T-shirts (Havlicek and Roberts, 2009). So far, no detailed chemical analysis has revealed specific classes of odorous compounds that are linked to HLA-genes or HLA-associated loci. Here, we addressed a specific hypothesis: is the composition of odorous acids, which can be released from glutamine-conjugates secreted in the human axilla, strongly affected by genes in the HLA complex, thus leading to similar odorous acid-patterns in HLA-identical siblings as compared to siblings with differing HLA loci? Our results indicated that HLA-linked genes are not the major determinants for the genetic influence on patterns of these odorous compounds. Both similarity analysis and PCA indicated that these acids form part of a stable odortype of individuals, confirming our earlier results of a twin study (Kuhn and Natsch, 2009), yet the patterns in HLA-identical

siblings were not significantly closer than were the patterns from HLA-disparate odor donors.

We can think of four possible explanations why the HLA-loci appear to influence human body odors, but that this effect is not apparent in the odorous compounds we analyzed. First, our targeted analytical approach may have been focused too narrowly. The odorous carboxylic acids investigated in this study were considered candidate molecules to form part of an HLA-determined odor for several reasons: (a) they are the most diverse group of known human body odorants, and therefore have potential to carry sufficient information to reveal individuality and individual-specific information, (b) their pattern is genetically determined to a significant extent (Kuhn and Natsch, 2009), (c) they are strongly perceived by the human nose at low concentrations (Gautschi et al., 2007), and (d) they are absent in a low-odor population in the Far East (carrying a specific loss-of-function mutation in the transport protein ABCC11; see below), confirming their contribution to human body odor (Martin et al., 2010). Nevertheless, we cannot exclude other groups of compounds as candidates for HLA-determined odorants. One diverse group of compounds in human axillary secretions is the sulfanyl-alkanols (Hasegawa et al., 2004; Natsch et al., 2004; Troccaz et al., 2004). These compounds appear to share the same biosynthetic route as the acids (the most abundant compound, 3-methyl-3-sulfanyl-hexan-1-ol, shares the same unusual carbon skeleton as the two dominant acids; additionally, a similar methylbranching is found in other compounds). Given their potentially similar biosynthesis and physiology, we consider it unlikely that sulfanyl-alkanols specifically, but not the carboxylic acids, are linked to the HLA. Another class of molecules reported from axillary secretions is amino-acid degradation products, such as isovaleric acid, 2-methyl-butyric acid, and iso-butyric acid, and their corresponding aldehydes. Such molecules could be derived from bacterial catabolism of HLA fragments or HLA-bound peptides, as previously suggested (Savelev et al., 2008), which would give a direct functional link to the HLA. As the HLA-proteins are not the main proteins available for non-specific bacterial catabolism in the axilla, and because all these compounds are derived from essential amino acids, it seems unlikely to us that they are key determinants of a genetically determined body odor.

A second reason for a lack of an HLA-influence in our study is the exclusion of the effect of skin micro-flora by our experimental setup. We mimicked the effect of bacterial hydrolysis by addition of an excess of a recombinant enzyme to each sample to ensure complete hydrolysis of the freshly secreted Gln-conjugates in the axillary secretions. Consequently, we effectively measured the 'maximal formation of the carboxylic acids', rather then the levels of acids actually present on axilla, and thus excluded any effect of different bacterial populations on the skin of the subjects, which could be confounded by personal grooming and lifestyle. In mice, addition of the single enzyme pronase to serum liberated the MHC-determined odorants (Yamazaki et al., 1999), although germ-free mice also had MHC-determined odorants in the urine (Yamazaki et al., 1990). If the same were true in humans, microflora would not affect the HLA-determined odortype, and hence our experimental approach would not affect odortype. However, the (yet unproven) 'micro-flora hypothesis' (Penn and Potts, 1998) suggests that MHC-genes influence the composition of the commensal microflora, which, in turn, determine odor, rather than genes in the MHC-locus directly determining odorants or precursors. If this were the case in humans, our approach would miss such effects. However, for the odorous acids we studied, we consider it unlikely to be the case. All these molecules are linked by the same peptide bound to glutamine, and can be released by one single enzyme with broad substrate specificity (Natsch et al., 2006). We consider it unlikely that subtle differences in the specificity of an aminoacylase in different bacterial strains would confer specific odor patterns to individuals.

Third, we cannot be certain that the HLA-linked body odorants are secreted by axillary glands, as has been assumed in the literature (see Havlicek and Roberts, 2009). However, there are several reasons to consider the axilla the most likely source of HLA-related body odors: (a) the onset of axillary odors is triggered by hormonal changes at puberty, suggesting that these odors are linked to sexual behavior and partner selection, (b) in terms of intensity, odors from the axilla are the strongest emitted by human skin, and (c) the axilla is a specific 'scent organ' (Stoddart, 1990), present only in humans, and is thought to have evolved with upright walking to present odors to other humans. Based on the results of the current study, future analytical studies on HLA-dependent odorants should focus on other body regions (e.g., the face or neck) as sources of odors with a relevant biological meaning.

Finally, the HLA-effect on human odors could be inherently weak, and therefore not detected in our approach. A recent study (Roberts et al., 2008) found no significant general preference for MHC-dissimilarity across normal menstrual-cycle women, nor a significant preference for MHC-similarity associated with contraceptive-pill use.

Kwak et al. (2010) recently reviewed why it had also proven difficult to find a chemical basis of MHC-odortypes in mice, and concluded that studies had largely focused on key volatiles associated with the MHC, rather then looking for patterns of odorants. They proposed that only the latter approach may move the field ahead. Yet, our study used this approach and failed to reveal a chemical basis for

human HLA-linked odortypes. Given that axillary odors have been investigated in great detail (Zeng et al. 1991; Gautschi et al., 2007), with different groups confirming or independently finding the same key odorous compounds (Hasegawa et al., 2004; Troccaz et al., 2004; Starkenmann et al., 2005), it seems fairly unlikely that new odorous compounds that are strongly HLA-linked will be found in axillary secretions. We suggest it may be more productive to search for HLA-linked odorants in other skin regions. It has been established recently, that a large fraction of the Asian population lacks axillary odor, and notably the ability to produce the acids investigated in this study, due to a single nucleotide polymorphism (SNP) in the ABCC11 transport protein (Nakano et al., 2009; Martin et al., 2010). In individuals carrying this SNP on both chromosomes, body odors that are not secreted by apocrine glands can be investigated. If a preference for body odors of HLA-dissimilar persons exists in this population, a detailed analysis could find new human odor components, outside of the classical axillary odors, which carry HLA-linked odor information.

Acknowledgments We thank Prof. G. Fráter, Dr. B. Schilling, and Dr. Joachim Schmid for valuable input, W. Stauch and Dr. R. Emter for help with sweat and DNA extraction, S. Tessier for HLA DNA typing, and, last but not least, our special thanks go to all the volunteers for participating in the study.

Family Scents: Developmental Changes in the Perception of Kin Body Odor?

Camille Ferdenzi · Benoist Schaal · S. Craig Roberts

Received: 2 February 2010 / Revised: 24 May 2010 / Accepted: 22 June 2010 / Published online: 20 July 2010
© Springer Science+Business Media, LLC 2010

Abstract There is increasing evidence that human body odors are involved in adaptive behaviors, such as parental attachment in infants or partner choice in adults. The aim of the present study was to investigate changes in body-odor perception around puberty, a period largely ignored for odor-mediated behavioral changes, despite major changes in social needs and in odor emission and perception. Nine families with two children (8 pre-pubertal, aged 7–10, and 10 pubertal, aged 11–18) evaluated body odors of family members and unfamiliar individuals for pleasantness, intensity, and masculinity, and performed a recognition task. The hypothesized emergence of a parent–child mutual aversion for the odor of opposite-sex family members at puberty was not found, contradicting one of the few studies on the topic (Weisfeld et al., J. Exp. Child Psychol. 85:279-295, 2003). However, some developmental changes were observed, including reduced aversion for odor of the same-sex parent, and increased ability of adults, compared to children, to recognize odor of family members. Sex and personality (depressive and aggressive traits) also significantly influenced odor judgments. Further research with larger samples is needed to investigate the poorly explored issue of how olfactory perception of self and family members develops, and how it could correlate with normal reorganizations in social interactions at adolescence.

Introduction

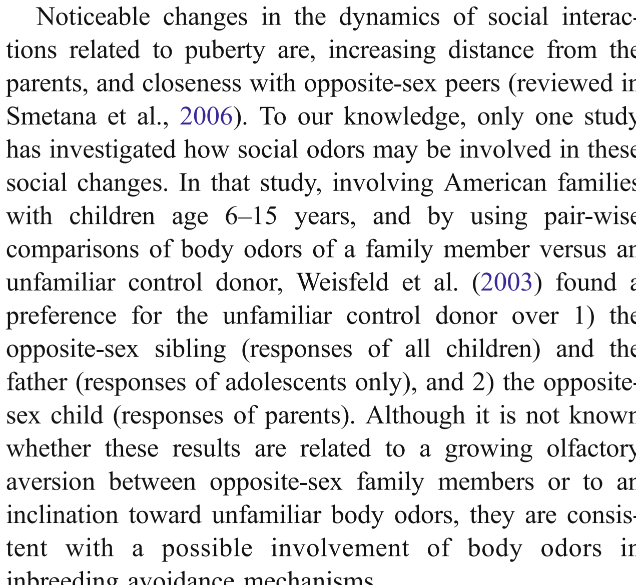
The extent to which human body odors influence interpersonal relationships generates considerable interest in western societies, within the scientific community and the general public. Although the function of social odors is well-documented in other animals (e.g., Brown and Macdonald, 1985; Wyatt, 2005), it has, until recently, been underestimated in humans, a species improperly considered to have a poor sense of smell (see Schaal and Porter, 1991). In the past few decades, however, research interest in the perception of social odors, notably in infant and adult populations, has increased considerably.

Mothers can discriminate the odor of their own child (e.g., Schaal et al., 1980; Kaitz et al., 1987), and infants recognize and prefer the body odor of their mother over that of another woman (e.g., Macfarlane, 1975). This maternal odor appears to guide infants toward the breast and to have a calming effect (Schaal et al., 1980; Doucet et al., 2007). In older children, a preference for maternal odor is present (e.g., Montagner, 1974), and the comforting effect of parental odors is reported by some children (Ferdenzi et al., 2008). Therefore, it has been hypothesized that body

odor is involved in the development of infant–mother attachment (Winberg and Porter, 1998), although such a mechanism still needs to be documented more rigorously. The feeling of security brought by affective bonds with the attachment figure is essential to a child's social and emotional development (Bowlby, 1988). Because familiar parental body odors contribute to create reassurance, they could have a significant contribution to attachment processes.

In adults, research has focused mainly on body-odor perception in the context of sexual-partner choice. Human odors convey information about factors involved in mate choice, such as a woman's fertility state (Singh and Bronstad, 2001), a man's personality (Havlicek et al., 2005), age, sex, and individual identity (Schleidt et al., 1981; Chen and Haviland-Jones, 1999; Olsson et al., 2006), and levels of genetic similarity (reviewed in Havlicek and Roberts, 2009). Disassortative preferences [i.e., oriented toward the odor of people having fewer alleles in common at the major histocompatibility complex (MHC)], have been reported in several studies (e.g., Wedekind et al., 1995; Thornhill et al., 2003; see Havlicek and Roberts, 2009, for a discussion). Such a tendency might have evolved in mammals, thus increasing resistance to pathogens by favoring MHC-heterozygosity in offspring and/or by avoiding general inbreeding (Potts et al., 1991; Penn et al., 2002). As body odors appear to be more genetically than environmentally determined (Roberts et al., 2005), and as there seems to be a familial component to body odor (Porter et al., 1986), it is likely that adult raters prefer odors of individuals who are genetically different, not only from themselves, but also from one or both of their parents (see also, Jacob et al., 2002).

In view of the studies on children and adults, we hypothesized that preference for odors of kin over non-kin change adaptively during development. Specifically, the preference for maternal body odor during infancy and childhood (serving attachment functions) may shift in sexually-mature adults toward a preference for body odors that differ from family odor, thus serving a mate-choice function. There is precedent for the idea that odor preferences can shift according to context. For example, the use of hormonal contraception (mimicking hormonal levels experienced during pregnancy) appears to disrupt adaptive disassortative preferences for a man's body odor (Wedekind et al., 1995) toward individuals who are more genetically similar to themselves (Roberts et al., 2008). This has been interpreted as an adaptive behavioral shift that normally would occur during pregnancy to promote kin interaction and elicit additional offspring care. Similarly, we suggest that olfactory perception of parental odors may shift around puberty because of major changes in reproductive physiology and social consequences (emergent sexual behavior, fluctuation in attachment to parents).



Noticeable changes in the dynamics of social interactions related to puberty are, increasing distance from the parents, and closeness with opposite-sex peers (reviewed in Smetana et al., 2006). To our knowledge, only one study has investigated how social odors may be involved in these social changes. In that study, involving American families with children age 6–15 years, and by using pair-wise comparisons of body odors of a family member versus an unfamiliar control donor, Weisfeld et al. (2003) found a preference for the unfamiliar control donor over 1) the opposite-sex sibling (responses of all children) and the father (responses of adolescents only), and 2) the opposite-sex child (responses of parents). Although it is not known whether these results are related to a growing olfactory aversion between opposite-sex family members or to an inclination toward unfamiliar body odors, they are consistent with a possible involvement of body odors in inbreeding avoidance mechanisms.

The aim of this study was to investigate possible changes in the perception of kin body odor around puberty. Involving entire families, we investigated age-related changes in recognition and pleasantness, intensity, and masculinity evaluations of the body odor of parents, siblings, self, and unfamiliar individuals, as well as the impact of other potentially confounding variables (children's body self-esteem and temperament). To perform an absolute, rather than comparative, approach and to test the existence of aversions, we measured each sample's pleasantness by using rating scales rather than paired comparisons between a familiar and a control odor, such as those used by Weisfeld et al. (2003). We hypothesized that we would find further evidence of a bidirectional aversion (child–parent and parent–child) for the odor of opposite-sex individuals, in pubertal children only.

Materials and Methods

Participants Nine families, each with two children, took part in the experiment. The sample consisted of $N=9$ mothers (age, 39–52 yr), $N=7$ fathers (44–54 yr) and $N=18$ children (8 pre-pubertal, including 6 boys, age 7–10 yr, and 10 pubertal, including 7 boys, age 11–18). The children were reported as related biologically to both tested parents. Families were characterized by relatively high income and education level of the parents (>£50,000/year, degree/diploma), and of Caucasian origin. Age groups were completed following the children's answers to the Pubertal Development Scale (PDS; Petersen et al., 1988), the 7–10-yr-olds being classified almost exclusively in the pre-pubertal/early pubertal stages, and the 11–18-yr-olds in the mid-pubertal/late pubertal/post-pubertal stages. The families were recruited through press releases and word-of-mouth among

University of Liverpool staff. For their participation, they received £20 and a free family ticket to a local botanical garden. The study was approved by the Committee on Research Ethics of the University of Liverpool and complied with the Declaration of Helsinki guidelines on human experimentation.

Odor-Collection Procedure Instructions on how to collect body odors were given both in person (CF) and through use of an illustrated instruction sheet. The participants also received reminders by email shortly before each key step of the 5-day testing period. Participants were provided with 100% cotton t-shirts (Fruit of the Loom Inc., Bowling Green, KY, USA), previously washed with an unscented detergent (Surecare Sensitive™, Robert McBride Ltd, Manchester, UK). The t-shirts were worn for three consecutive nights, simultaneously by all family members. Starting 2 d before wearing the shirts, participants were asked to refrain from drinking alcohol and eating strong foods (e.g., curry, chili and other spices, garlic, onion, pepperoni, blue cheese, cabbage, asparagus; see Roberts et al., 2005). On the evening that odor collection started, before putting the t-shirt on, all participants were required to shower with a non-perfumed soap (Simple™, Accantia Health & Beauty Ltd, Solihull, UK) and were instructed not to use any scented products, such as antiperspirants, deodorants, perfumes, or colognes. Participants also were instructed to avoid sexual intercourse and odor contamination (from partner, cooking, other odorous clothes or pets) during the time they wore the t-shirt. No obvious contamination (by perfume, coffee, or tobacco, for example) was recorded by the experimenter (CF), who smelled every sample once. On the morning of each collection night, participants were instructed to store their t-shirt in a closed and identified zip-lock bag. Parents returned the samples of the whole family to the laboratory on the morning after the third collection night. No major infringement (food, smoking, drinking, etc.) to the instructions was noted, according to the answers of each participant to a questionnaire concerning their behaviors during the testing period. Each t-shirt was cut into four halves (from navel to collar and along the side seams), combined into two samples (front left + back right, and front right + back left), and stored at −80°C for a maximum length of 46 d. This procedure was used to duplicate the number of available samples while limiting possible side-related differences in odor quality (Ferdenzi et al., 2009). Previous studies showed that freezing for this length of time (and longer) does not influence body odor quality (Roberts et al., 2008; Lenochova et al., 2009).

Personality Questionnaires Children completed the Body Esteem Scale for Adolescents and Adults (BESAA; Mendelson et al., 2001), that measures how they feel about their appearance and weight. Both parents evaluated the personality of their children by means of the Early Adolescent Temperament Questionnaire Revised (EATQ-R; Capaldi and Rothbart, 1992; Ellis and Rothbart, 2001). Only four dimensions were considered in the present study, either because they were related with some aspects of social interactions (Affiliation, 6 items; Aggression, 7 items) or because they were shown previously to be influential on odor perception (Depressive Mood, 5 items; Shyness, 5 items; Herberner et al., 1989; Pause et al., 1998).

Evaluation Procedure T-shirt halves were placed in zip-lock plastic bags (30×30 cm) and left at ambient temperature 2.5–3 hr before beginning the session. None of the participants reported nasal congestion or olfactory dysfunction. Participants were instructed to avoid wearing perfume on the testing day, and not to smoke or eat/drink in the 30 min preceding the session.

Perceptual Ratings of Familiar and Unfamiliar Individuals During the first olfactory task, participants rated all samples from the family (including their own t-shirt), the same number of unfamiliar samples, and a blank (unworn t-shirt). That is, 7–9 samples in total, according to whether the father took part or not. Unfamiliar samples were provided by members of other families and matched for sex and approximate age with the samples of the target family (age variation: 0.00±1.61 yr in children, 0.00±3.70 yr in parents). Families were unacquainted with each other. Participants evaluated each sample in a random order, on 9-point scales, for *pleasantness* [ranging from −4 (not pleasant at all) to +4 (very pleasant)], *intensity*, and *masculinity* [ranging from 1 (not intense/masculine at all) to 9 (very intense/masculine)]. They were instructed to take 15-sec breaks between samples. Special care was given to the children to ensure that they understood the rating labels.

Recognition of Familiar vs. Unfamiliar Individuals The second olfactory task was a recognition task involving pairs of odors, i.e., a target sample (from a family member) and the paired control (unfamiliar). As an example, a child smelled his father's odor and the odor from an unknown man of approximately the same age and had to answer the question: "which one belongs to your dad?" Once samples of all family members were evaluated, separated by 15-sec breaks, the same task was repeated twice. In total, 9–12 pairs of samples (according to whether the father took part or not) were evaluated. Across the three repetitions, pairs and members of the pairs were presented in random order, with sample coding altered. The number of correct answers was computed for each target odor (from 0 to 3). To limit fatigue and odor adaptation, the two olfactory tasks were

separated by a break of several minutes and completion of the questionnaire.

Data Analysis Most variables were distributed normally (Kolmogorov-Smirnov tests, α=0.05) but, because of the small size of the sample and the nature of some variables (e.g., recognition scores, with a small number of categories), we used non-parametric statistics.

First, the ability to distinguish the odor of a family member from the odor of an unknown individual was tested with a *Chi-square* goodness-of-fit test. This test compares the observed distribution of participants falling into each score modality (0, 1, 2, or 3 correct answers over the 3 trials) and the distribution expected if participants answered by chance (e.g., 0, 9, 9, and 0 participants in the categories 0, 1, 2, and 3, respectively, if there were 18 participants in total, answering by chance would give 50% correct answers and thus a score of 1 or 2). An odor is recognized when the observed distribution is significantly different from the distribution expected by chance, because of a high number of participants having three correct answers (for example, 0, 3, 4, and 11 participants giving 0, 1, 2, and 3 correct answers, respectively). Note, that a significant difference between the distributions could also be because of a high number of participants having 0 correct answers (for example 11, 4, 3, and 0 participants giving 0, 1, 2, and 3 correct answers, respectively).

To test our main hypothesis, that an aversion for the odor of opposite-sex family members would appear with advancing puberty, we computed the differences between the pleasantness score of the odor of each family member minus the pleasantness score of the unfamiliar odor it was paired with. We used Mann-Whitney *U*-tests to compare pre-pubertal and pubertal children for this variable. As the number of girls was limited in this experiment, because of recruitment difficulties, we did not perform analyses on separate sexes, but considered olfactory evaluations between opposite-sex individuals and between same-sex individuals. Although pooling evaluations of female and male odors could have been problematic, it is acceptable here, as there was no significant difference of pleasantness between the odor of mothers and fathers, unknown adult females and males (Wilcoxon matched pairs tests), and girls and boys (Mann-Whitney *U*-tests on the rating of the mother and the father). Note, that an exploratory analysis of sex differences showed that girls rated the odor of their father (but not the unfamiliar man) as less pleasant than did boys (Mann-Whitney *U*-test, $P<0.05$).

Finally, we tested the influence of personality variables by using a Principal Component Analysis performed on the Kendall tau correlation matrix. For higher intelligibility, only results for recognition and pleasantness were linked to personality dimensions (that is, average of the mother's and the father's evaluation on each personality dimension of the EATQ-R, and children evaluations on the body esteem scale BESAA).

Results

Recognition of Familiar vs. Unfamiliar Individuals

By Children When children were asked to distinguish the odor of self from the odor of an unfamiliar child on three occasions, their answers did not differ from chance levels ($\chi^2(3)=4.44$, $P>0.05$). They also answered at chance levels for the odors of their mother and sibling ($\chi^2(3)=5.00$ and 4.44, respectively, $P>0.05$), but not for their father ($\chi^2(3)=8.29$, $P<0.05$. However, this effect was not from more frequent right answers but from more frequent wrong answers).

By Adults Parents tended to recognize their own smell, compared to the odor of an unfamiliar donor, better than by chance ($\chi^2(3)=7.62$, $P=0.054$). Mothers recognized the odor of their child better than by chance ($\chi^2(3)=11.78$, $P<0.01$), whereas fathers did not ($\chi^2(3)=5.86$, $P>0.05$. Parents also identified the odor of their spouse at above-chance levels ($\chi^2(3)=8.71$, $P<0.05$).

Hedonic Ratings of Familiar vs. Unfamiliar Individuals

By Children Contrary to our expectations, analysis of the pleasantness difference, between the odor of familiar and unfamiliar adults, revealed no significant pubertal age-group difference for the ratings of opposite-sex adults (Fig. 1). However, a marginal difference for the ratings of same-sex adult was found (Mann-Whitney *U*-test, $P=0.074$). Pre-pubertal children preferred the odor of an unfamiliar same-sex adult (parent = -1.33 ± 2.07 vs. unfamiliar = 0.33 ± 3.39) whereas, pubertal children preferred the familiar adult (parent = 0.70 ± 1.95 vs. unfamiliar = -0.50 ± 1.96). No significant difference between pubertal age groups appeared for the intensity and masculinity ratings of the stimuli. Likewise, these groups did not differ for the pleasantness, intensity, or masculinity rating differences between self and an unfamiliar child, and between the sibling and an unfamiliar child.

By Parents The analysis of the pleasantness difference between the odors of own child, vs. an unfamiliar child, revealed no significant difference between pre-pubertal and pubertal odors, either when parents evaluated a child from the opposite sex (pre-pubertal children: own = $-0.14\pm.69$

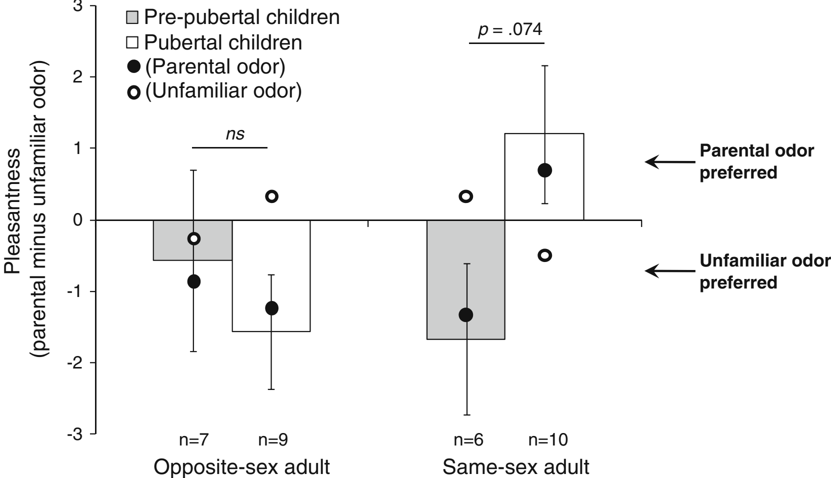


Fig. 1 Ratings by children of the body odors of familiar and unfamiliar adults. The *bars* represent the difference of pleasantness between the odors of familiar and unfamiliar adults (parent minus unfamiliar control adult, matched in sex and age), as a function of the age group of the rater (*grey* = pre-pubertal; *white* = pubertal), and for adults of the opposite and same sex as the rater (Mean ± SEM). A positive difference indicates that parental odor is preferred over unfamiliar odor. Age groups marginally differ (at $P<0.10$) on the rating of the same-sex adult (*ns*=not significant, $P>0.10$). The average ratings are also presented (*black circle*: odor of the parent; *white circle*: odor of the unfamiliar individual)

vs. unfamiliar = 0.29±1.80; pubertal children: own = 0.78± 1.48 vs. unfamiliar = −0.33±2.35) or the same sex as their own (pre-pubertal children: own = 1.33±1.63 vs. unfamiliar = −0.67±2.80; pubertal children: own = 0.00±1.33 vs. unfamiliar = 0.67±1.50). The body odors of children were evaluated positively, on average, and there was no aversion appearing at adolescence for the opposite-sex child (Fig. 2), under the conditions of the study.

Link with Personality Variables The factor analysis on the personality and pleasantness/recognition data are presented in Table 1. Six factors had eigen values higher than 1.00 and were, therefore, considered for interpretation. The first factor, explaining 18% of the variance, is interpretable in terms of the link between the level of the child's depressive mood and his/her ability to recognize the odor of his/her mother. Aggression and body esteem were negatively

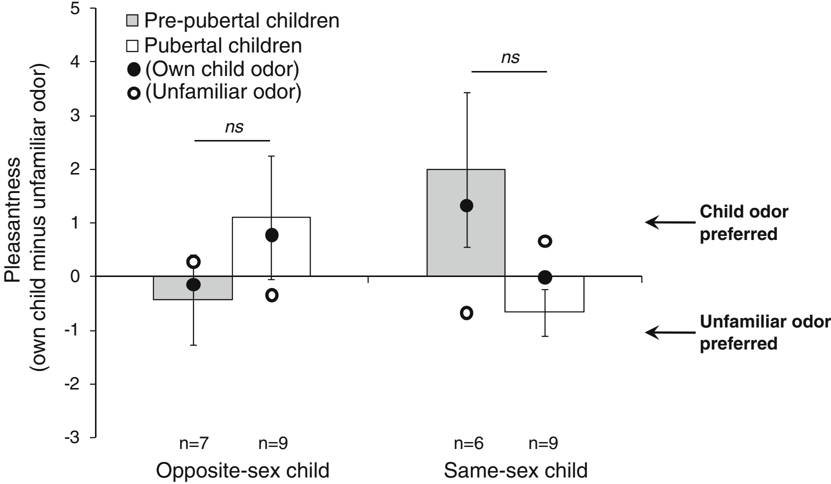

Fig. 2 Ratings by parents of the body odors of familiar and unfamiliar children. The *bars* represent the difference of pleasantness between the odors of familiar and unfamiliar children (own child minus unfamiliar control child, matched in sex and age), as a function of the age group of the rated child (*grey* = pre-pubertal; *white* = pubertal), and for children of the opposite and the same sex as the adult rater (Mean ± SEM). A positive difference indicates that the odor of a parent's child's is preferred over that of an unfamiliar one. Age group differences were not significant (*ns* = not significant, $P>0.10$). The average ratings are presented (*black circle*: odor of the own child; *white circle*: odor of the unfamiliar child)

Table 1 Results of the Principal Component Analysis on the personality variables (Affiliation, Aggression, Depressive Mood and Shyness dimensions of the EATQ-R questionnaire, and the BESAA body esteem score) and the olfactory evaluations of the children (pleasantness and recognition of the odor of self, the mother, the father and the sibling), based on the Kendall tau correlation matrix. Only loadings superior to 0.50 on Factors F1 to F6 are visible

	F1	F2	F3	F4	F5	F6
Depressive Mood	0.66					
Recognition—Mother	0.92					
Pleasantness—Self		0.77				
Pleasantness—Mother		−0.82				
Recognition—Father		0.64	−0.55			
Recognition—Self			0.64			
Recognition—Sibling			−0.81			
Body Esteem				−0.58		
Aggression				−0.50		
Pleasantness—Sibling				0.91		
Pleasantness—Father					0.91	
Affiliation						0.73
Shyness						−0.81
Explained variance	18%	16%	12%	11%	9%	8%
Eigenvalue	2.30	2.05	1.57	1.47	1.22	1.01
Total explained variance	74%					

linked to pleasantness of the sibling's odor, as shown by the fourth factor (11% of the variance). The sixth factor shows that affiliation and shyness are inversely correlated. Finally, and of minor interest to our questions, the second and third factors represent the inverse relationship firstly, between the pleasantness of the odors of self and of mother, and secondly, between the ability to recognize the odor of self from the odor of father and sibling.

Discussion

Developmental Effects The main aim of this study was to investigate the possibility of a pubertal shift in preferences for family body odors, characterized by the development of a mutual aversion between opposite-sex children and parents. The rationale for such a hypothesis is the transition from child–parent attachment to mate-choice necessity, both mechanisms potentially involving body-odor perception and evaluation. Initial results by Weisfeld et al. (2003) suggested such a phenomenon. However, here we did not find any such shift in children or parents. Specifically, no aversion occurred in parents who gave positive ratings of the odors of children. The only developmental difference that we found was a marginally significant effect on children's perception of odor of the same-sex parent. Pre-pubertal children tended to display an aversion for odor of the same-sex parent (the unfamiliar adult was rated more positively), while pubertal children rated the same-sex parent more positively than the unfamiliar adult, with overall ratings less negative than those of pre-pubertal children. As same-sex pairs were mostly boy–father (11 vs. only 5 girl-mother pairs), a possible explanation to this effect could be that perceptions become less negative after puberty, because of a specific reduction in sensitivity to major odorous compounds of male axillary sweat (androstenone and androstadienone: Dorries et al., 1989; Hummel et al., 2005) by boys. Adolescent males' greater tolerance for androstenes, and other unpleasant odorants with less biological significance (Chopra et al., 2008), is believed to be caused by pubertal changes in the levels of gonadal steroids. Our study also revealed that, whereas parents, who might have developed this ability through years of experience, recognized the odors of self, of their child (mothers only), and of their spouse, children (pre-pubertal and pubertal) were unable to recognize their own odor or the odors of other family members. Furthermore, in contrast to the results of another study (Weisfeld et al., 2003), children tended to pick out the odor of the unfamiliar man as being the odor of their father. This intriguing result needs further investigation.

In summary, these results suggest that there may be modifications in social odor perception at adolescence, but that these seem related to general phenomena (e.g., global sensitivity changes, experiential factors) rather than to specific aversions to opposite-sex family members. However, our limited sample size precludes a firm conclusion that such aversions do not exist. Further research with larger samples is needed to test developmental shifts in the perception of familiar body odor on each sex separately.

Sex Differences Although sex could not be taken into account in the present study, because of the small sample of girls, a preliminary analysis revealed that girls rated the odor of their father (but not those of an

unfamiliar adult male) as more unpleasant than boys did. Many studies have documented sex differences in social olfaction and reported a significant advantage for females. Females appear to be more sensitive than males to volatile chemicals present in axillary secretions, namely androstenone and androstadienone, at least from puberty onwards (Dorries et al., 1989; Hummel et al., 2005). Female sensitivity seems to be particularly focused on odors with social significance (Lundström et al., 2006), and even more so during the fertile period of the menstrual cycle (Doty et al., 1981; Grillo et al., 2001; Ferdenzi et al., 2009). In addition, females rely on body odors during social interactions related to partner choice significantly more often than do males (Herz and Inzlicht, 2002; Havlicek et al., 2008). Females also recognize the odor of familiar individuals more readily than do males (Schleidt et al., 1981), which was also true for adults in the present study; mothers significantly recognized the odor of their child, whereas fathers did not. This male–female difference is probably linked to a greater physical proximity between mothers and offspring, particularly in child care (Geary, 1998) and through adolescence (Smetana et al., 2006). Because of this female advantage in social olfaction, and because of differential changes in olfactory sensitivities in adolescent boys and girls (see above), sex is a factor to be considered in future research on the function of social odors during human development.

Personality and Body Odor Perception In the present study, the depressive trait of a child's temperament was positively related to its ability to recognize its mother's odor. Although previous studies found no link between personality and perception of the body-related compound androstadienone (Filsinger et al., 1987), our results corroborate studies that have shown that neuroticism in adults (depression loads heavily on the neuroticism dimension; Eysenck, 1990) is associated with higher olfactory sensitivity and better identification abilities, perhaps because of higher emotional activation (Pause et al., 1998; Chen and Dalton, 2005). Biologically significant odors, such as mother's odor, might thus be more salient to children with depressive tendencies than to others. We also found that the pleasantness of a sibling's odor was negatively linked to personality traits such as aggression. To interpret this particular link, it would be useful to determine if aggression is linked with higher levels of sibling rivalry, which could be linked to more negative evaluation of a sibling's odor. The roles of odors in the interactive behavior of siblings (Porter and Moore, 1981; Weisfeld et al., 2003) has been even less studied than odors in child–parent interactions, and is deserving of greater attention.

Acknowledgments The authors thank all the participants, Kevin Reid (Director of Ness Botanical Garden, Neston, UK) for offering free family tickets to the participants, and two anonymous reviewers for their constructive comments on the manuscript. This research was supported by Fyssen Foundation, Paris.

Host Specific Social Parasites (*Psithyrus*) Indicate Chemical Recognition System in Bumblebees

Abstract Semiochemicals influence many aspects of insect behavior, including interactions between parasites and their hosts. We studied the chemical recognition system of bumblebees (*Bombus*) by examining the cuticular hydrocarbon cues of 14 species, including five species of social parasites, known as cuckoo bees (subgenus *Psithyrus*). We found that bumblebees possess species-specific alkene positional isomer profiles that are stable over large geographical regions and are mimicked by three host-specific cuckoo parasites. In three host-cuckoo associations where mimicry is poor, possibly due to recent host shifts, these cuckoos produce dodecyl acetate a known chemical repellent that allows the cuckoos to invade their host colonies. Our findings indicate cuckoos use two chemical mechanisms, mimicry and repellents, to invade their hosts, and this may reflect different stages of an ongoing dynamic arms race.

Introduction

The first line of defence in an insect society is its sophisticated cuticular hydrocarbon recognition system. Colonies usually can recognize their nest-mates and detect intruders, whom they often attack vigorously. Many social parasites, however, are able to break into the fortresses of their hosts and take advantage of them for extended periods without being harmed. Parasites have evolved some remarkable strategies, such as chemical mimicry (Lenoir et al. 2001) that enable them to evade the colony's recognition system. These adaptations provide a way of studying the chemical recognition systems of social insects.

Recent studies have begun to reveal the groups of hydrocarbons (Greene and Gordon 2007; Martin et al. 2008a) and mechanisms (Ozaki et al. 2005; Martin et al. 2008b) involved in the recognition systems used by social insects. These studies show the importance of looking at relationships within and between groups of hydrocarbons, rather than assuming that all hydrocarbons form part of the signal. By using this new approach, rather than the standard multivariate statistical methods that compare all components simultaneously (Martin and Drijfhout 2009a), we studied the host specific *Psithyrus* cuckoo bees as a tool to search for the bumblebee species recognition system. Hydrocarbons are synthesized in the oenocytes and transported to the cuticle and Dufour's gland where they are secreted. These hydrocarbons are present as a thin oily layer that covers the insects' entire surface and that acts primarily as an anti-desiccation agent. In bumblebees, these hydrocarbons are dominated by *n*-alkanes and alkenes. The alkenes are unusual in that they are rich in (*Z*) positional isomers, which include all positions from 5 to 15 (Lanne et al. 1987; Tengö et al. 1991; Ayasse et al. 1995, 1999). This unique richness is likely to have a functional role, since it

should be costly to maintain biochemical mechanisms to produce a variety of isomers (Morgan 2004), and bees are able to detect and recognize different isomers (Châline et al. 2005; Blažytė-Čereškienė and Būda 2007).

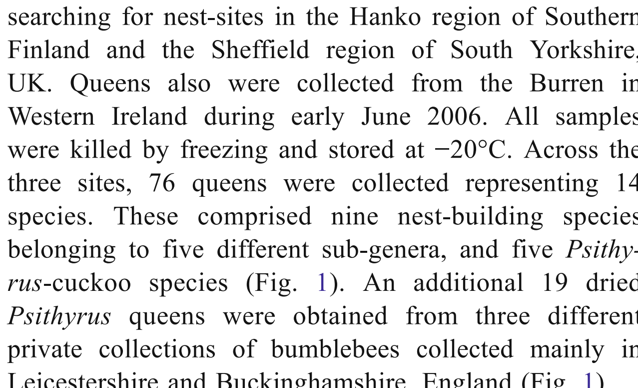
There are over 250 species of bumblebees, *Bombus*, of which 30 have evolved into social parasites known as cuckoo bumblebees (Williams 1998). For simplicity, all cuckoo bumblebees are referred to as *Psithyrus,* although they are now considered a subgenus within *Bombus* (Williams 1998), while all remaining non-parasitic bumblebee species are referred to as *Bombus*. The *Psithyrus* female (queen) invades an established nest of its host bumblebee species and lays eggs that are reared by host workers into new *Psithyrus* sexuals, since all *Psithyrus* species lack a worker caste. Typically, *Psithyrus* females of a given species only parasitize nests of one, or a few, host species (Richards 1927; Reinig 1935; Alford 1975; Fisher 1987; Williams 2008), but their host invasion behavior can be highly variable (Kupper and Schwammberger 1995; Frehn and Schwammberger 2001).

Psithyrus females are well adapted to their parasitic life style, having thicker cuticles, longer stings, tougher inter-segmental membranes, sharper more powerful, mandibles, and a larger venom sac and Dufour's gland than their hosts (Richards 1927; Free and Butler 1959; Alford 1975). These features facilitate the successful usurpation of the host nest (Fisher and Sampson 1992) and are found also in socially parasitic wasps (Edwards 1980) and ants (Tsuneoka and Akino 2009), both distantly related but socially similar taxa. The *Psithyrus* females often visually mimic their host color patterns, especially in Europe (Williams 2008), and employ a variety of chemical mechanisms that facilitate nest invasion. For example, *B. (Ps.) norvegicus* secrete dodecyl acetate from their enlarged Dufour's gland, which repels host workers (Zimma et al. 2003). *Psithyrus* females are thought to locate their host colony by species-specific olfactory cues (Sladen 1912; Fisher 1983), since *Psithyrus* species can distinguish host from non-host species based on their Dufour's gland extract (Fisher et al. 1993).

Free and Butler (1959) suggested that, to aid in nest invasion, *Psithyrus* species may have evolved similar recognition cues to their host species that could explain their high host-specificity. Here, we tested the hypothesis that *Psithyrus* species mimic the chemical profiles of their host species. In addition, we investigated whether the presence of the repellent dodecyl acetate is a general feature of *Psithyrus* bumblebees, since the production of a repellent appears counter-productive for species thought to use chemical mimicry.

Methods and Materials

Sample Collection Between April and June 2007, bumblebee queens were caught while feeding on flowers or



searching for nest-sites in the Hanko region of Southern Finland and the Sheffield region of South Yorkshire, UK. Queens also were collected from the Burren in Western Ireland during early June 2006. All samples were killed by freezing and stored at −20°C. Across the three sites, 76 queens were collected representing 14 species. These comprised nine nest-building species belonging to five different sub-genera, and five *Psithyrus*-cuckoo species (Fig. 1). An additional 19 dried *Psithyrus* queens were obtained from three different private collections of bumblebees collected mainly in Leicestershire and Buckinghamshire, England (Fig. 1).

Chemical Analyses Cuticular hydrocarbon extracts from each bumblebee were prepared by removing one pair of wings and immersing them in a vial containing 80 µl of HPLC grade hexane at room temperature for 15 min. Wings were used in order to minimize potential contamination from glandular secretions. The extracts were evaporated and stored at 5°C. A Dufour's gland extract of each bumblebee (excluding the 19 dried *Psithyrus* samples) also was obtained following the same procedure used for the wings. The Dufour's gland contains only internally produced hydrocarbons. The remaining pairs of wings then were pooled for each species providing a stronger extract that allowed better resolution of the positional isomers after dimethyl disulfide (DMDS) derivatization (see below). The cuticular hydrocarbon extracts from the 19 dried *Psithyrus* samples were obtained by immersing the entire body and wings in a small glass dish containing 1 ml of hexane for 5 min before transferring the hexane to a vial where it was evaporated. This ensured that sufficient extract was available for DMDS derivatization. Just prior to analysis, 30 µl of hexane were added to the vials, and the samples were analyzed on an HP6890 gas chromatograph (GC) equipped with an HP-5MS column (length: 30 m; internal diam: 0.25 mm; film thickness: 0.25 µm) connected to an HP5973 quadrupole mass spectrometer (MS) with 70 eV electron impact ionization. Samples were injected in the splitless mode, and the oven was programmed from 70°C to 200°C at 40°C/min, and then from 200°C to 320°C at 15°C/min, and held for 2 min at 320°C. Helium was used as carrier gas, at a constant flow rate of 1.0 ml/min. Compounds were characterized by the use of standard MS databases, diagnostic ions, and their Kovats indices. Pooled wing extracts, individual body washes, and individual Dufour's gland samples were subject to DMDS derivatization in order to determine the alkene double bond positions (Carlson et al. 1989) and re-analyzed on the GC-MS under the same conditions as the non-derivatizated samples.

Data Analyses The analysis of the three main groups of compounds (acetates, *n*-alkanes, and alkenes) were con-

ducted separately, as there is growing evidence (Châline et al. 2005; Greene and Gordon 2007; Martin and Drijfhout 2009a) that the profile perceived by the insect and that produced by the GC-MS are not congruent. For acetates and *n*-alkanes, peak areas were integrated from the original (i.e., non-derivatized) individual Dufour's gland and wing gas chromatograms. Data were log-transformed in order to meet the assumption of equal variances before conducting *t*-tests in SPSS v14. For the alkenes, the presence of several isomers, often with overlapping retention times, meant accurate integration from the original gas chromatograms was not possible. Therefore, the proportion of each alkene isomer present was calculated from the derivatized sample chromatograms as follows. By using the characteristic ions for each isomer at each chain length, the amounts of these ions were individually integrated using the 'extract ion' function in MSD Chem-Station. This produced a table of ion counts for each isomer at each chain-length for each individual. This was converted to a percentage of the overall count, and any compound (i.e., an isomer at a specific chain length) that represented less than 0.5% was excluded. The percentage of the remaining isomers was re-calculated.

We then investigated whether any patterns existed that connected the positional isomers to chain-length before calculating the proportion of each isomer irrespective of its chain-length for each individual. Initially, the proportion of each isomer was calculated in the normal way, i.e., total (*Z*)-10 = (*Z*)-10C_{23} + (*Z*)-10C_{25} + (*Z*)-10C_{27}. This produced an unusual isomer pattern in *B. hortorum* (see "Results"). However, the apparent anomaly might be explained better from a functional viewpoint since isomers potentially can be read from either end of the molecule. Therefore, we calculated the proportion of each isomer so that only *odd* isomers were present e.g., (*Z*)-13 = (*Z*)-10C_{23} + (*Z*)-12C_{25} + (*Z*)-13C_{27}. This approach is supported by the facts that even positional isomers (e.g., [*Z*]-8 and [*Z*]-10) are a biochemical rarity,

since (*Z*)-9-oleic acid is the key precursor, and in insects Δ desaturases are normally odd-numbered (e.g., 5, 9, 11, and 11) (Byers 2006).

Results

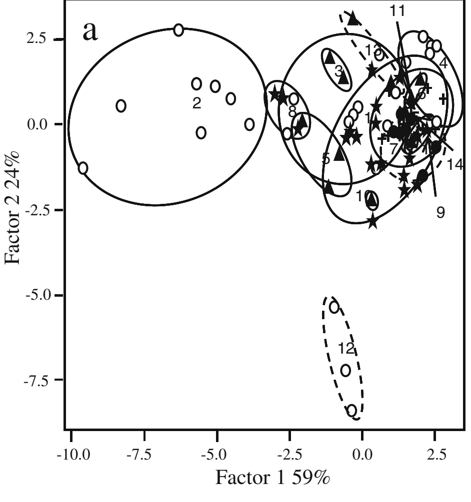
General Findings Figure 2 shows that non-polar compounds extracted from the bumblebee wings and their Dufour's glands are almost exclusively (>99%) composed of *n*-alkanes (C_{21}–C_{31}) and alkenes (various isomers) except in *B. (Ps.) campestris,* in which it is >90% due the presence of methylated compounds that are rare (<1%) in all other species. In addition to the hydrocarbons, dodecyl acetate, a volatile compound, was detected in the Dufour's gland of three of the five *Psithyrus* species (Fig. 2). The hydrocarbon ion counts (*n*-alkanes and alkenes) extracted from the wings (Fig. 2a) and the Dufour's gland (Fig. 2b) are significantly higher among *Psithyrus* than the non-parasitic *Bombus* (wings $P=0.018$, $t=-2.729$ $df=12$; Dufour's gland $P=0.018$, $t=-2.735$ $df=12$).

n-Alkanes For all species, the *n*-alkanes account for 23–54% of the hydrocarbons in the wing extracts and 14–50% of the Dufour's gland extracts (Figs. 2a, b). Comparison of the *n*-alkane profiles shows high variability between individuals. Consequently, no distinct differences between species, and no clear associations between the *n*-alkane profiles of *Psithyrus* and their hosts were apparent in either the wing or the Dufour's gland samples (Supplemental Fig. 1). This is further supported by Discriminant Analysis (DA) in which the *n*-alkanes only separate one of the non-parasitic *Bombus* species, whereas the alkenes separate all of the non-parasitic *Bombus* species (Fig. 3).

Alkenes The alkenes are the most abundant group of compounds detected in the wing, Dufour's gland, and whole body extracts with a wide range of isomers detected, even within the profile of a single species. These include all isomers from (*Z*)-5 to (*Z*)-14. All three *B. hortorum* queens possessed the same rich and highly unusual isomer pattern, with respect to which isomer was prevalent at each chain-length (Fig. 4). However, when double bond positions are viewed differently see ("Methods"), the apparently unusual isomer pattern of *B. hortorum* becomes clear; i.e., the production of mainly the (*Z*)-13 isomer (Fig. 4).

Although we detected odd and even isomers from (*Z*)-5 to (*Z*)-14, our re-interpretation of the results is that odd isomers from (*Z*)-5 to (*Z*)-21 were detected (as shown in subsequent figures). The same overall conclusions are reached, irrespective of the method used to calculate the isomer profiles, but fewer odd isomers are implied.

We were able to separate all of the non-parasitic *Bombus* species by using only the observed variation between species in their alkene isomer profile (Fig. 3). The only exceptions were three samples from the *B. terrestris*-group that all had distinctive isomer profiles (Fig. 5). This chemo-group (*B. terrestris II*) was composed of a Finnish *B. lucorum*, and two *B. terrestris* from Sheffield that were morphologically indistinguishable from their conspecifics.



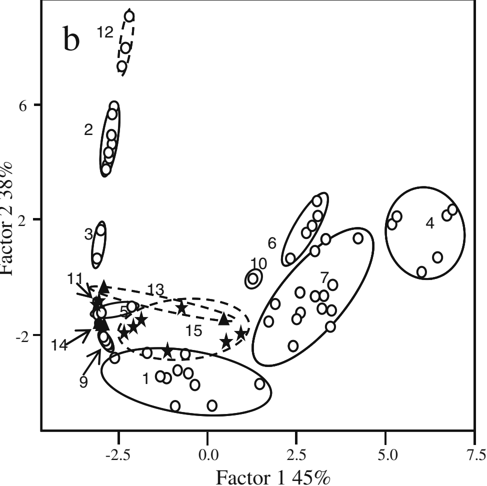


Fig. 3 Comparison of the discriminant analysis using SPSS based on the transformed proportions (for method see Martin and Drijfhout 2009a) for **a** alkanes and **b** alkene isomers from the Dufour's gland of each bumblebee queen. Different symbols are used where ellipses that enclose all individuals of that species overlap. Ellipses for the cuckoo species are dashed. The two factors indicate the amount of variation explained by each discriminate component. The isomer profile of *Bombus hortorum* (No. 8) was so different from all other species that it was removed from the analysis otherwise it was difficult to visualize the data. 1.*B. pascuorum*; 2. *B. lapidarius*; 3. *B. jonellus*; 4. *B. pratorum*; 5.*B. terrestris II*; 6. *B. terrestris*; 7. *B. lucorum*; 8.*B. hortorum*; 9. *B. muscorum*; 10. *B. monticola*; 11. *B. (Ps.) campestris*; 12. *B. (Ps.) rupestris*; 13. *B. (Ps.) sylvestris*;14. *B. (Ps.) vestalis*; 15. *B. (Ps.) bohemicus*

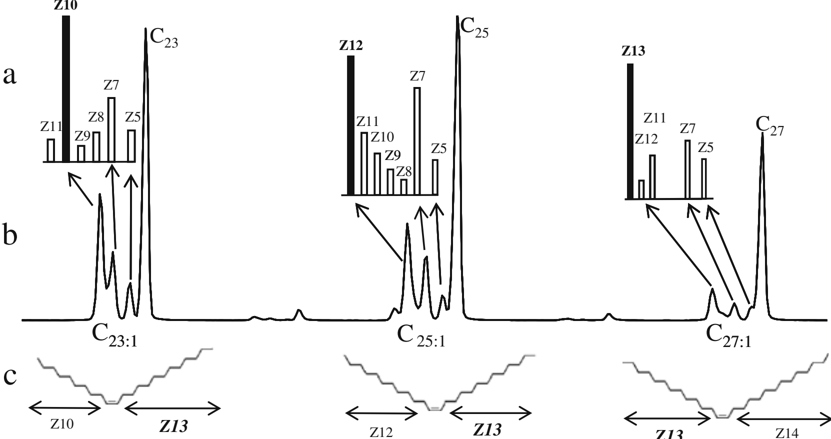

Fig. 4 **b** The gas chromatogram of *Bombus hortorum* showing at each chain length three alkene peaks that contain up to seven different co-eluting isomers and a single *n*-alkane peak. **a** The proportion of each isomer after derivatization that revealed an unusual isomer pattern. **c** However, the most abundant isomer at each chain length (*Z*)-10-$C_{23:1}$, (*Z*)-12-$C_{25:1}$, and (*Z*)-13-$C_{27:1}$ are in fact all (*Z*)-13 if position is determined from either end of the molecule

In two species (*B. pascuorum* and *B. lucorum*), conspecific queens were collected from three different countries (Fig. 1). Despite this, all 11 *B. pascuorum* queens had similar alkene isomer profiles, as shown by the small amount of variation (Fig. 5) and forming a single cluster (Fig. 3b). Although the 15 *B. lucorum* queens also form a single cluster (Fig. 3b), there were small but consistent differences in the isomer profiles between the Sheffield and Finnish populations (Fig. 5).

Mimicry of Hosts' Species Specific Alkene Isomer Patterns by Psithyrus The nine non-parasitic *Bombus* species all had species-specific alkene isomer patterns in their Dufour's gland extracts (Fig. 5) that mirrored their pooled wing extracts (Fig. 5). The (*Z*)-7 and (*Z*)-9 alkene isomer ratios of several *Psithyrus* species showed a remarkable resemblance to those of their hosts (Figs. 5, 6), irrespective of whether wing, entire body, or Dufour's gland extracts were compared (Fig. 5). For example, the (*Z*)-7: (*Z*)-9 ratio is dominated by (*Z*)-9 in both *B. pascuorum* and its cuckoo *B. (Ps.) campestris*, while it is dominated by the (*Z*)-7 isomer in *B. lapidarius* and its cuckoo *B. (Ps.) rupestris*. This chemical similarity between the cuckoos and their hosts is even more remarkable considering that the hosts are spread across four sub-genera (Fig. 1) with greatly differing (*Z*)-7: (*Z*)-9 ratios (Fig. 6). *Bombus (Ps.) vestalis* is a close mimic of a rare chemo-type detected within the *terrestris*-group, while all other *B. terrestris* possess a very different isomer ratio. Furthermore, the match between host and cuckoo in the case of *B. lucorum* and *B. (Ps.) bohemicus* is closer in the UK population than the Finnish population, as the UK *B. (Ps.) bohemicus* queens are the only *Psithyrus* species to produce isomers other than (*Z*)-7 and (*Z*)-9 in any appreciable amounts (Fig. 5).

Presence of Dodecyl Acetate The presence of volatile repellent dodecyl acetate was not detected on any of the wing samples (N=76) (Fig. 2a) nor the Dufour's gland extracts of any non-parasitic *Bombus* species studied (Fig. 2b). However, dodecyl acetate was a major compound detected in the Dufour's gland of all *B. (Ps.) bohemicus* (N=6), *B. (Ps.) sylvestris* (N=3) and *B. (Ps.) vestalis* (N=2) females (Fig. 2b). These are all species that invade hosts with slightly different alkene isomer patterns from their own (Fig. 5). In these species, dodecyl acetate represented an average of 21% of the non-polar compounds extracted from the Dufour's gland. Dodecyl acetate was absent from the Dufour's glands of all *B. (Ps.) campestris* (N=2) and *B. (Ps.) rupestris* (N=3) (Fig. 2b), both species that mimic closely the isomer profiles of their hosts (Fig. 5).

Discussion

This study has revealed an additional level of detail contained within an insect's cuticular hydrocarbon profile that is a potential candidate for encoding the recognition cues used by bumblebees. Among the insects, bumblebees are unusual in the variety of isomers they produce, as shown by this and previous studies (Lanne et al. 1987; Tengö et al. 1991; Ayasse et al. 1995, 1999; Urbanová et al. 2004). The nine non-parasitic *Bombus* species in this study and four additional species (*B. ignitus, B. diversus, B. hypocrita,* and *B. deuteronymus*; authors' unpublished data) all have species-specific alkene isomer patterns. The high isomer diversity and stable species-specific patterns are consistent with a functional role in recognition, which is supported by the mimicry of these isomer profiles by the three corresponding

Fig. 5 Species-specific alkene isomer patterns determined from the pooled wing, Dufour's gland and entire body extracts for 14 bumblebee species. The top two graphs represent the non-parasitic *Bombus* species, while the three lower inverted graphs present the data for the corresponding *Psithyrus*-cuckoo species. Arrows indicate alternative hosts. The error bars represent one SD. No error bars are present for the pooled wing samples as sample sizes are one. The asterisk indicates species that produce the repellent dodecyl acetate

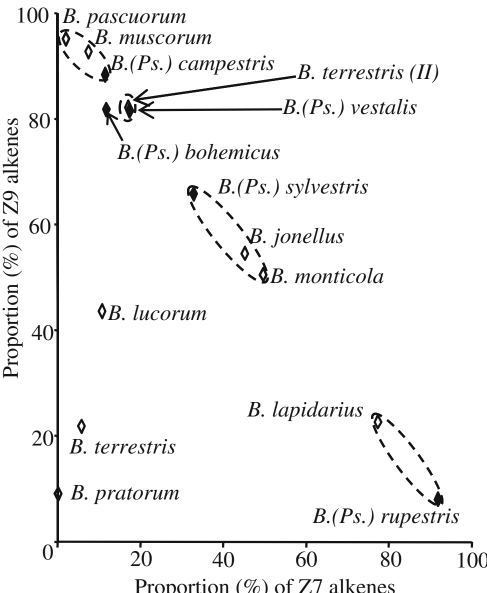

Fig. 6 The matching of a wide range of host (*Z*)-7: (*Z*)-9 alkene isomer profiles occurring across four sub-genera by five *Psithyrus* species that all belong to the same sub-genus (see Fig. 1). The dotted ellipses link the host and cuckoo species

species of social parasite (i.e., cuckoos). In contrast, in those cases where the host and cuckoo isomer profiles do not match, the cuckoos produce a known worker repellent, dodecyl acetate, that represents an alternative strategy for invading colonies. Within each species, the variability of alkene isomers remained small, even where specimens were collected from three countries and had different color forms e.g., *B. pascuorum*. Species-specific alkene isomer profiles found in this study also can be seen in *B. terrestris* collected from Sweden, Israel, and Germany (Tengö et al. 1991) and *B. lapidarius* collected from Sweden (Tengö et al. 1991). This stability of discrimination signals within a species across coarse geographical scales also has been found previously in *Drosophila* flies (Rouault et al. 2001), bark beetles (Symonds and Elgar 2004), and *Formica* ants (Martin et al. 2008c). Conversely the *n*-alkanes show high variability both among individuals within species and among species, resulting in no species-specific profiles. Alkane production is influenced by environmental factors, such as temperature, humidity, and task (Wagner et al. 2001; Martin and Drijfhout 2009b), which may explain this variation.

Hydrocarbons identified in the Dufour's gland of bumblebees also are present on their eggs (Ayasse et al. 1999) as well as on their cuticles (Oldham et al. 1994; Ayasse et al. 1995; this study). This may help "fool" host workers into rearing *Psithyrus* eggs. The recent finding that *Psithyrus* females have retained their ability to produce wax also may help explain their chemical integration into the colony (Sramkova and Ayasse 2008).

The possibility that the cuckoos' profiles have been acquired from either the hosts that raised them or that they will invade is small, because 82 out of the 95 *Psithyrus* females were caught searching for nests rather than being removed from host colonies. As there is a close match between the external (entire body or wing extracts) and internal (Dufour's gland extract) hydrocarbon profiles, *Psithyrus* females may be examples of mimics that biosynthesize their chemical disguise prior to invasion rather than acquire it from their hosts after invasion (Lenoir et al. 2001).

The production of dodecyl acetate by three of the five *Psithyrus* species appears inconsistent, but it is produced only by *Psithyrus* species that fail to closely mimic their host in terms of alkenes. Dodecyl acetate is a known bumblebee worker repellent (Zimma et al. 2003) and represents an alternative way of invading colonies. Limited behavioral observations show that host-cuckoo interactions that involve the two cuckoo species lacking dodecyl acetate (*B. (Ps.) rupestris* and *B. (Ps.) campestris*) are non-aggressive (Hoffer 1888; Sladen 1912; Fisher 1988), whereas aggressive and non-aggressive interactions have been observed against cuckoos that produce dodecyl acetate (Sladen 1912; Van Honk et al. 1981; Küpper and Schwammberger 1995). Similar compounds (e.g., decyl-acetate and decyl butyrate) also are found in the enlarged Dufour's glands of slave-making *Formica* and *Polyergus* ants, where they act as repellents during raids (Regnier and Wilson 1971; Graham et al. 1979; D'Ettorre et al. 2000; Tsuneoka and Akino 2009).

Co-evolution is a dynamic process that may be at different stages for different cuckoo-host associations. For example, *B. pascuorum* and *B. lapidarius* are both common species, and their cuckoos (*B. (Ps.) campestris* and *B. (Ps.) rupestris*) are close color and chemical mimics. *Bombus (Ps.) sylvestris* is a close chemical mimic of *B. jonellus* and *B. monticola,* both uncommon species in Britain, but its other host there is *B. pratorum,* a species with a similar ecology (e.g., early nesting, pollen-stores, small colony size (Sladen 1912)) and that is common and widespread (Williams 2007). This may indicate that *B. (Ps.) sylvestris* has undergone a host shift. This is supported by the facts that *B. (Ps.) sylvestris* produces the worker repellent dodecyl acetate and remains a much closer color mimic of *B. jonellus* than *B. pratorum.* The UK *B. (Ps.) bohemicus* population is unique in its ability to produce other isomers besides (*Z*)-7 and (*Z*)-9 in substantial amounts (Fig. 5). This may result from the cuckoo tracking the profiles of different species within the *lucorum*-complex, and could be evidence of an ongoing "arms race".

The presence of two distinct chemo-types within the *terrestris*-group (Fig. 5) is supported by Pamilo et al. (1984) who also suggested the presence of two sibling species of *B. lucorum* with a wide distribution in

Fennoscandia based on phosphoglucomutase (PGM) gene variation. German laboratory colonies of *B. lucorum* also had isomer profiles similar to our *B. terrestris* II group (Tengö et al. 1991), whereas, field caught *B. terrestris* (around Bonn) have isomers similar to UK *B. terrestris* and *B. lucorum* (Sramkova and Ayasse 2009). The *B. lucorum-terrestris* species complex is poorly resolved taxonomically, and additional morphological, chemical, and genetic data are needed before clear species boundaries can be defined.

The invasion behavior of *Psithyrus* females ranges from highly aggressive to passive (Dronnet et al. 2005), as an invading queen may usurp the host queen (Wilson 1971) or live in peaceful cohabitation with her (Fisher 1987, 1988; Carvell et al. 2008). This might arise from different chemical mechanisms being employed (i.e., mimicry or repellents) by different *Psithyrus* species.

Acknowledgments Thanks go to Matthew Heard of CEH Wallingford, Dave Goulson of Stirling University, and Maggie Frankum of Leicester for providing additional *Psithyrus* queens. Also, thanks to Roger Butlin, Paul Brakefield, and Duncan Jackson of Sheffield University for detailed comments, in addition to the helpful comments by two anonymous referees. Funding was provided by NERC (NE/C512310/1 and NE/F018355/1).

New Types of Flavonol Oligoglycosides Accumulate in the Hemolymph of Birch-Feeding Sawfly Larvae

Matti Antero Vihakas · Lauri Kapari · Juha-Pekka Salminen

Abstract Larvae of nine species of sawflies (*Symphyta*) were fed with the foliage of three birch species, after which the larval hemolymph composition was studied by HPLC–DAD and HPLC–ESI–MS. The hemolymph of sawfly larvae contained high concentrations of flavonol oligoglycosides (tri-, tetra-, penta-, and hexaglycosides) that could not be found in the larval foliar diet. In addition, there were significant between-sawfly species differences in both flavonoid composition and concentration (from 0.6 to 12.3 mg/ml) of the hemolymph. This suggested that the studied species have different biosynthetic activities for the synthesis of flavonoid oligoglycosides. Variation in the foliar diets did not cause differences in the hemolymph composition. Our hypothesis is that sawflies use foliar flavonoid monoglycosides rather than flavonoid aglycones to produce these new types of oligoglycosides. These findings open up new possibilities for understanding the more holistic role of flavonoids in insect biochemistry and complex interactions between plants and herbivores.

Key Words Sawfly larvae · Hemolymph · Flavonol oligoglycosides · Mass spectrometry

Introduction

Flavonoids are a well-known group of phenolic compounds due to their ubiquitous presence in nature and potential health–promoting effects on humans (Iwashina, 2000; Ross and Kasum, 2002). The role of flavonoids in plant-herbivore interactions is complex, as they can function both as feeding stimulants and anti-feedants (Simmonds, 2001, 2003; Cipollini et al., 2008). In addition, some insects have developed methods to utilize flavonoids to increase their fitness. Some butterfly species can e.g., sequester flavonoids into their wing pigments that can help in mate recognition (Geuder et al., 1997; Burghardt et al., 2000).

Earlier studies with birch-feeding insect herbivores have shown that the lipophilic flavonoid aglycones of the epidermal layer of birch leaves act as defensive compounds e.g., against the larvae of autumnal moth (*Epirrita autumnata*) (Lahtinen et al., 2004). However, insects also have developed methods to avoid the harmful effects of these defenses. *Epirrita autumnata* and other birch-feeding insects—such as sawfly larvae—were shown to partially detoxify flavonoid aglycones by glycosylation (Salminen et al., 2004; Lahtinen et al., 2005); addition of a single sugar unit into the lipophilic flavonoid aglycone enables the excretion of the formed water-soluble flavonoid monoglycoside into the feces of larvae. However, not all flavonoid aglycones were glycosylated. Only 22% of the ingested flavonoid aglycones were glycosylated by *E. autumnata* larvae (Salminen et al., 2004), and with sawfly larvae the glycosylation percentages varied from 35 to 44%, depending on the species (Lahtinen et al., 2005). It has remained unclear what the metabolic fate for the remaining portion of ingested flavonoid aglycones is, since only traces were found excreted as such in the feces, and the new fecal monoglycosides did not represent even one half of the ingested amounts of aglycones.

The purpose of this study was to clarify whether any of the missing portions of flavonoid aglycones could be found in larval hemolymph. We had not studied larval hemolymph composition earlier. Therefore we first did some preliminary HPLC-analyses of hemolymph with several species of insect herbivores. We found no flavonoids in the hemolymph of lepidopteran larvae (*E. autumnata* and *Agriopis aurantiaria*), possibly because of the high polyphenol oxidase activities in their hemolymph (Ruuhola and Salminen, unpublished data). On the contrary, hemolymph of sawfly larvae contained high levels of flavonoids. To study this phenomenon further, we collected a diverse set of larvae from nine species of birch-feeding sawflies that grew in the northern part of Finland. Each larval species was fed with the foliage of three birch species. These birches were known to differ in their flavonoid aglycone composition and content (Valkama et al., 2003, 2004). Our hypothesis was that different flavonoid aglycone compositions of the three types of foliar diets would be seen directly as differential flavonoid composition of the hemolymph samples.

Methods and Materials

Insect Bioassay and Collection of the Hemolymph Field experiments were conducted at the Kevo Subarctic Research Station in Utsjoki, northern Finland (69°45'N, 27°00'E). The forest of the study area is dominated by mountain birch (*Betula pubescens* subsp. *Czerepanovi* (Orlova) Hämet-Ahti) that is a tree line forming species in northern Fennoscandia. The larvae used in the experiment originated from a field grown 'laboratory stock' replenished by yearly collections of wild larvae. Each year pairs of adult males and females were enclosed in mesh bags on mountain birch branches, and the hatching larvae were allowed to feed on naturally growing leaves until the end of the last instar. Prepupating larvae were placed in plastic vials containing moist sphagnum moss where the larvae formed cocoon for overwintering. The species selected for the experiment, from the phenologically earliest to the latest, were: *Amauronematus amplus* Konow, *Pristiphora alpestris* Konow, *Nematus viridescens* Cameron, *Nematus brevivalvis* Thomson, *Arge* sp. Schrank, *Nematus pravus* Konow, *Trichiosoma scalesii* Leach, *Nematus viridis* Stephens, and *Dineura pullior* Schmidt. *Arge* sp. belongs to the family Argidae, *Trichiosoma scalesii* to the family Cimbicidae, while the rest are members of the subfamily Nematinae in the family Tenthredinidae.

During the summer of 2004 emerging adult females were allowed to feed on honey water, after which they were enclosed in mesh bags on the branches of haphazardly chosen mountain birch trees. Larvae were allowed to feed in the mesh bags until 2nd–3rd instar, after which the bags were cut down and the larvae were taken into the laboratory. The larvae were divided into three groups to be fed with leaves from either mountain birch, dwarf birch (*Betula nana* L.), or silver birch (*Betula pendula* Roth). We used the same three mountain and silver birch individuals throughout the experiment. Since dwarf birches are so small in size, we used haphazardly chosen tree individuals for feeding until the last 4 d of the experiment when the larvae were fed with leaves from the chosen three experimental trees. Larvae were grown singly in 48 ml plastic vials and fed with new leaves every 3rd d. When the larvae had reached their last instar, they were preserved in liquid nitrogen and transferred to the University of Turku in southern Finland (Table 1). Hemolymph sampling was done by piercing a small hole with a needle into the integument of larva and then gently pressing out a small droplet of hemolymph.

HPLC and MS Analyses Hemolymph was analyzed immediately after its collection by HPLC–DAD without any purification steps. Samples were manually injected (5 or 20 μl) because of the small volumes. The HPLC column was LiChroCART Superspher 100 RP-18 (75×4 mm I.D., 4 μm, Merck, Germany). The HPLC–DAD system (Merck-Hitachi, Tokyo, Japan) consisted of a manual Rheodyne injector, an L-7100 pump, an L-7455 diode array detector, and a D-7000 interface module. Two solvents were used: 0.05 M H_3PO_4 (A) and acetonitrile (B). The elution profile was: 0–3 min, 100% A; 3–20 min, 0–25% B in A (linear gradient); 20–23 min, 25–70% B in A (linear gradient); 23–47 min, column wash and stabilization. The flow rate was 1 ml/min. The UV spectra of hemolymph components were acquired between 195 and 450 nm, and detection wavelength was 341 nm. Additional HPLC–ESI–MS analyses were done by a Perkin-Elmer Sciex API 365 triple quadrupole mass spectrometer (Sciex, Toronto, Canada) that has ion spray interface and Analyst Software 1.1 for data handling. The column used and chromatographic conditions were the same as in Salminen et al. (1999).

Table 1 Insect bioassay information

	Dates for the final feeding day in 2004	Number of larvae per tree species
Amauronematus amplus	5.7.	33
Pristiphora alpestris	7.7.	33
Nematus viridescens	15.7.	33
Nematus brevivalvis	16.7.	33
Arge sp.	28.7.	33
Nematus pravus	10.8.	33
Trichiosoma scalesii	11.8.	18
Nematus viridis	14.8.	33
Dineura pullior	24.8.	39

The mass spectrometer was used in the positive ion mode, and mass spectra were obtained between 100 to 1600 atomic mass units.

Flavonoid Quantification The total flavonoid contents of hemolymph samples were quantified from the HPLC–DAD analyses at 341 nm. First, we detected all such HPLC peaks that had UV spectra characteristic of flavonoids. Then the HPLC peak areas of all the flavonoids were summed up to obtain the total flavonoid content of each sample. Flavonoids were quantified as quercetin equivalents using quercetin (Sigma Chemical Co, St. Louis, MO, USA) as an external standard.

Results

At first, hemolymph samples of nine sawfly species were analyzed by HPLC–DAD. In the HPLC–DAD chromatograms most of the peaks eluted shortly after 12 min, and many of the peaks co-eluted and produced a hump (Fig. 1). The short elution time of peaks suggested that the compounds were hydrophilic and they might contain sugars. The unknown compounds could not be simple flavonoid aglycones or monoglycosides that were known to elute much later in the chromatogram (Ossipov et al., 1995, 1996; Valkama et al., 2003). These data suggested that the unknown compounds might contain at least two sugar units. The UV spectra of the main compounds were characteristic of flavonols (Fig. 1). In flavonol aglycones such as kaempferol, quercetin, and myricetin, the band I UV absorptions vary between 359–370 nm. However, the band I UV absorptions of unknown hemolymph compounds were mainly between 341–349 nm. This kind of hypsochromic shift in band I maxima has been seen associated with the glycosylation of flavonols (Markham and Mabry, 1975).

Hemolymph samples then were analyzed by HPLC–ESI–MS, but there was enough hemolymph material for only seven of the nine sawfly species: *Amauronematus amplus*, *Arge* sp., *Nematus brevivalvis*, *Nematus pravus*, *Nematus viridis*, *Pristiphora alpestris,* and *Trichiosoma scalesii*. Time range 11–19 min in the HPLC-chromatograms was named as a

Fig. 1 HPLC-chromatograms of hemolymph samples of nine sawfly species. Arrows show UV spectra of some the main peaks (obtained between 195–450 nm)

"flavonoid part" of the chromatogram, and mass spectra were first acquired from this area (Fig. 2). Most of the mass spectra from the "flavonoid part" had an ion at *m/z* 303, which fit with the flavonol aglycone quercetin (Kite et al., 2007; Veitch et al., 2008). In addition, a clear pattern of ions could be seen in the mass spectra of different sawfly species: quercetin was followed by ions differing by 162 Da from each other: 465, 627, 789, 951, 1113, and 1275. Value 162 Da indicated a glycosidic bond between quercetin and carbohydrate units (glycohexopyranose e.g., glucose or galactose). The ions 465, 627, 789, 951, 1113, or 1275 could derive from molecular ions ($[M+H]^+$) of flavonol monoglycosides or oligoglycosides, or they could be fragments of these ions. For this reason, each peak in the HPLC chromatograms was analyzed separately for its composition using single ion monitoring. This analysis revealed that all main peaks in the chromatograms belonged to individual flavonol oligoglycosides i.e., compounds where several carbohydrates were attached to a flavonol nucleus. The molecular ion of flavonol oligoglycoside was always preceded by its mass fragments, and each fragment represented a loss of one carbohydrate unit from the original flavonol oligoglycoside structure. The largest oligoglycoside was a quercetin hexaglycoside (*m/z* 1275), but quercetin tri- (*m/z* 789), tetra- (*m/z* 951), and pentaglycosides (*m/z* 1113) also were present (Fig. 3). There were only traces of quercetin mono- (*m/z* 465) and diglycosides (*m/z* 627) in the samples. Interestingly, each sawfly species had its own selection of flavonol oligoglycosides in the hemolymph. Quercetin hexa- and pentaglycosides were found in three sawfly species: *Arge* sp., *Nematus viridis,* and *Nematus brevivalvis,* and the other species contained different compositions of quercetin tri- and tetraglycosides (Table 2).

Many of the mass spectra had ions from the following ion pattern: *m/z* 597, 759, 921 and 1083. These ions were 30 Da less than the quercetin oligoglycoside ions next to them (represented by *m/z* 627, 789, 951, and 1113). This indicated that one of the glycohexopyranosides in quercetin oligoglycosides was replaced by a glycopentofuranoside e.g., arabinose sugar that has a molecular mass 30 Da

Fig. 2 Positive ion mass spectra of an HPLC–ESI–MS run of seven sawfly species. Mass spectra were recorded from the flavonoid part (11–19 min) of the chromatogram

Fig. 3 Positive ion mass spectra of flavonol oligoglycosides in the sawfly hemolymph. A: quercetin triglycoside, B: quercetin tetraglycoside, C: quercetin pentaglycoside, D: quercetin hexaglycoside E: quercetin tetraglycoside with one pentose sugar (*m/z* 921) co-eluting with a quercetin tetraglycoside (*m/z* 951), F: kaempferol pentaglycoside (*m/z* 1097) co-eluting with a quercetin hexaglycoside (*m/z* 1275). Interpretation of the ions: *m/z* 303=quercetin; *m/z* 465=quercetin with one hexose sugar; *m/z* 597=quercetin with one hexose sugar and one pentose sugar; *m/z* 627=quercetin with two hexose sugars; *m/z* 759=quercetin with two hexose sugars and one pentose sugar; *m/z* 773=kaempferol with three hexose sugars; *m/z* 789=quercetin with three hexose sugars; *m/z* 921=quercetin with three hexose sugars and one pentose sugar; *m/z* 935=kaempferol with four hexose sugars; *m/z* 951=quercetin with four hexose sugars; *m/z* 1097=kaempferol with five hexose sugars; *m/z* 1113=quercetin with five hexose sugars; *m/z* 1275=quercetin with six hexose sugars; *m/z* 1577=$[2M+H]^+$ ion of a quercetin triglycoside. A hexose sugar refers to a glycohexopyranoside and a pentose sugar to a glycopentofuranoside

less than glucose or galactose. However, only one of the glycohexopyranosides in flavonol oligoglycosides was replaced by a glycopentofuranoside since there was no mass spectral evidence of flavonol oligoglycosides with two or more glycopentofuranosides. The largest quercetin oligoglycoside with a glycopentofuranoside sugar was a quercetin pentaglycoside in *Nematus brevivalvis* and *Nematus viridis* (*m/z* 1083). This compound had four glycohexopyranosides and one glycopentofuranoside attached to the quercetin backbone (Table 2).

Some of the mass spectra showed yet another ion pattern: *m/z* 287, 449, 611, 773, 935, and 1097. The ions in the pattern were divided from each other by 162 Da. Again, this indicated a glycosidic bond between a flavonoid and a glycohexopyranoside. The peak at *m/z* 287 was interpreted as kaempferol (Veitch et al., 2008), and the following ions represented several glycohexopyranosides attached to the kaempferol nucleus. The largest kaempferol oligoglycoside was a kaempferol pentaglycoside (*m/z* 1097) in *Arge* sp. (Table 2). Kaempferol oligoglycosides always were less common than quercetin oligoglycosides.

During the feeding experiments, each species of sawfly larvae were divided into three groups that were fed with different birch diets (*B. nana*, *B. pendula,* and *B. pubescens* subsp. *Czerepanovi)*. Different birch diets had no significant effect on the hemolymph composition within the same sawfly species (data not shown). This means that, for instance, quercetin triglycosides were always the main metabolites in the hemolymph of *Trichiosoma scalesii* although the larvae had eaten different birch diets. The total flavonoid contents of hemolymph samples were quantified from the HPLC–DAD chromatograms (Fig. 4). Total flavonoid contents varied markedly among different sawfly species (from 0.6 to 12.3 mg/ml). Different birch diets did not have significant effects on the total flavonoid contents within the same sawfly species.

Discussion

Hemolymph of sawfly larvae was found to contain high concentrations of flavonol oligoglycosides. These compounds seem to be *de novo* metabolites i.e., produced by the sawfly larvae themselves since the diet of larvae, birch leaves, are known to contain only flavonol aglycones and monoglygosides (Ossipov et al., 1996; Keinänen and Julkunen-Tiitto, 1998; Lahtinen et al., 2005). Ability to glycosylate flavonoids also has been reported in insects other than sawfly larvae: Larvae of *Epirrita autumnata* detoxify flavonoid aglycones into flavonoid monoglycosides (Salminen et al., 2004); *Dissoteira carolina* grasshoppers glycosylate quercetin (Hopkins and Ahmad, 1991); *Polyommatus icarus* butterflies produce kaempherol 3-*O*-glucoside from dietary kaempherol (Wiesen et al., 1994); and *Bombyx mori* silkworms produce quercetin mono-, di-, and triglucosides that are not originally present in their diet (Tamura et al., 2002; Hirayama et al., 2008). Ferreres et al. (2007) studied the larvae of *Pieris brassicae* L. and found

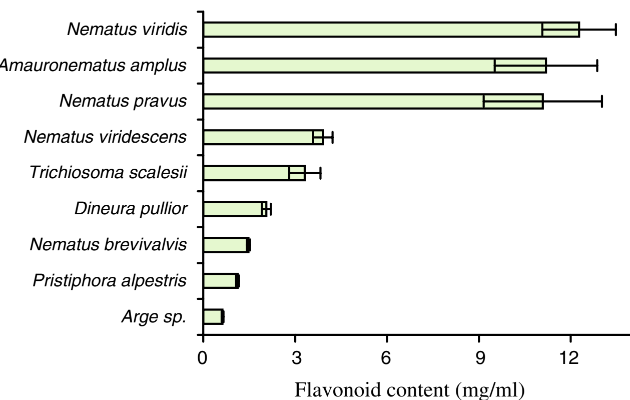

Fig. 4 Total flavonoid contents in the hemolymph of sawfly species. Bars show standard error of the mean

several quercetin and kaempherol derivatives that could be either sequestration or metabolism products of the insect.

This study raises the question of how flavonol oligoglycosides are metabolized by sawfly larvae. The studied birch species (*B. nana, B. pendula, and B. pubescens* subsp. *czerepanovii*) have different compositions and concentrations of epidermal flavonoid aglycones (Valkama et al., 2003, 2004), and our original hypothesis stated that different flavonoid aglycone compositions of foliar diets would be seen as differential flavonoid compositions of the hemolymph samples. It could also be possible that sawfly larvae use these epidermal flavonoid aglycones as a starting material for the flavonol oligoglycoside synthesis. However, our results showed that different birch diets did not have significant effects on the compositions of hemolymph samples or concentrations of flavonol oligoglycosides. Also, no trace of epidermal flavonoid aglycones (except kaempferol in kaempherol oligoglycosides) was found in the hemolymph. The main flavonol aglycone part of flavonol oligoglycosides in the sawfly hemolymph was quercetin but this compound seems to be absent from birch leaf epidermal flavonoid aglycones (Valkama et al., 2003; Lahtinen et al., 2006). These findings oppose the idea that sawfly larvae use epidermal flavonoid aglycones for flavonol oligoglycoside synthesis.

Additionally, this study could not answer our original question about the metabolic fate of birch-derived flavonoid aglycones in sawfly larvae. It seems likely that the larvae use birch leaf flavonol monoglycosides rather than flavonol aglycones for flavonol oligoglycoside synthesis. First, all the birch species in this study contain many vacuolic quercetin monoglycosides (Ossipov et al., 1996; Keinänen and Julkunen-Tiitto, 1998; Graglia et al., 2001; Riipi et al., 2002; Salminen and Lempa, 2002). The concentrations of vacuolic quercetin monoglycosides in birch leaves also are generally higher than the concentrations of other flavonol monoglycosides (kaempherol or myricetin). This would give a partial explanation of why the majority of flavonol oligoglycosides in sawfly hemolymph were quercetin oligoglycosides and why kaempferol oligoglycosides were less common. Birch leaves contain also myricetin monoglycosides, but the hemolymph samples did not show clear evidence of myricetin oligoglycosides. This can mean that the sawfly species of this study may not have the ability to synthesize myricetin oligoglycosides.

The exact structures of flavonol oligoglycosides are unknown. At least one of the sugar units has to be attached directly to a flavonol nucleus, and the remaining sugars will be attached to other hydroxyl groups in flavonol nucleus, or the sugar units may chain to each other. Examples of plant derived flavonol oligoglycosides (e.g., Kite et al., 2007; Taylor et al., 2007; Veitch et al., 2008) give insight about the possible conformations of sawfly flavonol oligoglycosides. To fully solve the structures, one needs to isolate individual flavonol oligoglycosides and determine their structures, e.g., by NMR techniques. However, one sawfly larva contains only a few microliters of hemolymph, and it would require substantial amounts of larval material (several hundreds of individuals) to produce enough hemolymph for the isolation process. With the sparsely populated birch-feeding sawfly larvae, it was beyond the scope of this study to collect such large amounts of hemolymph.

Flavonoid compositions and concentrations within one sawfly species were approximately the same among feeding experiments with different birch species. Small differences could be detected in some of the replicates: e.g., the larvae of *Nematus viridis* with one birch diet contained quercetin hexaglycosides but the same larvae with another birch diet contained only quercetin pentaglycosides. Species to species differences in total flavonoid concentrations and flavonol oligoglycoside compositions were more obvious (Fig. 4. and Table 2). Some sawfly species contained a series of quercetin oligoglycosides up to hexaglycosides, while other species produced only quercetin triglycosides. This suggested that the sawfly species have different biosynthetic abilities to produce flavonol oligoglycosides.

The total flavonoid contents of hemolymph samples were estimated with quercetin as an external standard. However, the use of quercetin as a standard for flavonol oligoglycosides poses a problem. With quercetin, the whole molecule exhibits UV absorption but the situation is different with flavonol oligoglycosides: in this case, only the flavonol part of the molecule shows UV absorption, and the sugar stays “invisible” to UV detection. This is due to different chemical structural properties of sugars and flavonols. The UV-absorbing chromophore of quercetin oligoglycosides is quercetin (302 Da). With quercetin triglycoside (788 Da), for instance, 302/788=38% of molecular mass of the molecule belongs to the UV-absorbing quercetin while 62% of the molecule stays invisible to UV detection. This means that the total flavonoid contents of hemolymph samples (0.6 to 12.3 mg/ml, Fig. 4) are underestimated when only a quercetin standard is used. To get more accurate results one needs an authentic flavonol oligoglycoside standard that is isolated from sawfly larvae. However, it was beyond the scope of this study to collect such large quantities of birch sawfly larvae. Our goal in future studies is to isolate flavonol oligoglycoside standards from larval hemolymph, and these standards will allow us to make more accurate estimations of the flavonol oligoglycoside concentrations in hemolymph samples.

The biological significance of flavonol oligoglycosides for sawfly larvae remains unknown. Glycosylation of flavonoid aglycones has been seen as a detoxification mechanism

for the larvae of *Epirrita autumnata* (autumnal moth) (Salminen et al., 2004). Another study showed that sawfly larvae are capable of glycosylating birch leaf flavonoid aglycones and excreting them as flavonoid monoglycosides into their feces (Lahtinen et al., 2005). A simple hypothesis could propose flavonol oligoglycosides as detoxification products of sawfly metabolism. However, as shown by Salminen et al. (2004), mere flavonoid monoglycosides are hydrophilic enough to be excreted into feces. Why would sawfly larvae need to spend extra sugar units and energy for this oligoglycosylation process? Perhaps flavonol oligoglycosides have some other function for the sawfly larvae. One possibility is that larvae utilize plant secondary chemicals to promote their own defense strategies againts their natural enemies e.g., ants, parasites, or birds. Many Tenthredinidae (Hymenoptera) sawfly species exhibit a defensive strategy termed "easy bleeding", which means the release of hemolymph through the integument as a result of even slight mechanical pressure or disturbance (Müller et al., 2001; Boevé and Schaffner, 2003; Prieto et al., 2007). We have observed easy bleeding in many of our study species too, but the role of flavonoid metabolism in this respect remains hypothetical. The biological role of flavonol oligoglycosides in sawfly hemolymph needs to be examined in more detail in future studies.

Intraspecific Geographic Variation of Fragrances Acquired by Orchid Bees in Native and Introduced Populations

Abstract Male orchid bees collect volatiles, from both floral and non-floral sources, that they expose as pheromone analogues (perfumes) during courtship display. The chemical profile of these perfumes, which includes terpenes and aromatic compounds, is both species-specific and divergent among closely related lineages. Thus, fragrance composition is thought to play an important role in prezygotic reproductive isolation in euglossine bees. However, because orchid bees acquire fragrances entirely from exogenous sources, the chemical composition of male perfumes is prone to variation due to environmental heterogeneity across habitats. We used Gas Chromatography/Mass Spectrometry (GC/MS) to characterize the perfumes of 114 individuals of the green orchid bee (*Euglossa* aff. *viridissima*) sampled from five native populations in Mesoamerica and two naturalized populations in the southeastern United States. We recorded a total of 292 fragrance compounds from hind-leg extracts, and found that overall perfume composition was different for each population. We detected a pronounced chemical dissimilarity between native (Mesoamerica) and naturalized (U.S.) populations that was driven both by proportional differences of common compounds as well as the presence of a few chemicals unique to each population group. Despite these differences, our data also revealed remarkable qualitative consistency in the presence of several major fragrance compounds across distant populations from dissimilar habitats. In addition, we demonstrate that naturalized bees are attracted to and collect large quantities of triclopyr 2-butoxyethyl ester, the active ingredient of several commercially available herbicides. By comparing incidence values and consistency indices across populations, we identify putative functional compounds that may play an important role in courtship signaling in this species of orchid bee.

Introduction

Most insects rely on chemical compounds (pheromones) to identify and attract conspecific mates (Wyatt, 2003). The chemical composition of mating pheromones may range from single molecules to diverse, complex mixtures (Symonds and Elgar, 2004, 2008; Billeter et al., 2009). Because mating pheromones usually consist of species-

specific blends, they often mediate prezygotic reproductive isolation among closely related lineages (Cardé et al., 1977; Roelofs et al., 2002). In insects, mating pheromones are synthesized *de novo* or from sequestered precursors. In either case, both biotic and abiotic factors influence pheromonal chemical composition (Stennett and Etges, 1997; Groot et al., 2009). Hence, an important question is how insect populations that colonize novel environments respond to environmental changes that influence mating pheromones. In addition, to understand the underlying mechanisms of pheromone evolution in insects, we must examine intraspecific phenotypic variation in pheromone chemistry across habitats, geographic regions, and genetic gradients.
