Orchid (or euglossine) bees constitute a diverse lineage of Neotropical insect pollinators (Ramírez, 2009; Ramírez et al., 2010) that are best known for their fragrance-collecting behavior (Darwin, 1862; Dressler, 1968; Dodson et al., 1969). Male bees collect volatile compounds from multiple floral and non-floral sources that they use subsequently during courtship display (Dressler, 1982; Eltz et al., 2005b). Males of all species of orchid bees (~200) have enlarged hind-tibial organs in which they deposit perfumes that consist primarily of terpenoids and aromatic compounds (Williams and Whitten, 1983; Eltz et al., 1999; Zimmermann et al., 2009a). Male orchid bees land on the surface of fragrance sources and secrete large quantities of long-chain lipids from cephalic labial glands that dissolve the volatile compounds to be collected (Whitten et al., 1989; Eltz et al., 2007). Although it has not been confirmed directly via behavioral experiments, it is likely that perfume chemistry enables females to choose mates and/or discriminate non-specific males (Eltz et al., 1999, 2003, 2005a; Bembé, 2004; Zimmermann et al., 2006). In a recent study, Zimmermann et al. (2009a) analyzed the chemical composition of the fragrances acquired by male orchid bees from 15 closely related sympatric species in the genus *Euglossa* from central Panama. They showed that related lineages of bees accumulate species-specific fragrance blends that have differentiated rapidly during lineage diversification, potentially in response to strong selection against hybridization or mating interference between species. Previous studies also have shown that perfume variation tends to be lower within lineages than between lineages (Eltz et al., 1999, 2005a, 2008; Zimmermann et al., 2006), even when individuals co-occur in the same habitat (Eltz et al., 2005a, 2008). However, the extent of intraspecific perfume variation across geographic regions and genetic gradients has not yet been examined.

Male orchid bees may accidentally accumulate a considerable diversity of inactive (noisy) compounds during the process of perfume collection (Eltz et al., 2005a), as they often collect volatiles from multiple sources, even at local scales (Pemberton and Wheeler, 2006). In addition, variation in the availability and abundance of specific chemicals among habitats may result in disparate fragrance phenotypes (Eltz et al., 2005a). Thus, orchid bees must deal with environmentally induced variability while maintaining a reliable chemical communication system. What proportion of fragrance compounds is biologically active, and thus required for mating? Do conspecific male orchid bees collect similar compounds across disparate habitats? Can different chemical compounds serve homologous functions in distant populations? We designed a comprehensive analysis of fragrance variation within and between interbreeding populations of a single species, *Euglossa* aff. *viridissima*, to answer some of these questions. In particular, we focused on elucidating phenotypic change in the perfumes of *E.* aff. *viridissima* upon the invasion of a novel environment.

The green orchid bee *Euglossa viridissima* is distributed throughout lowland dry forests in northern Mesoamerica (Hinojosa-Diaz et al., 2009), ranging in distribution from southern Costa Rica to Northern Mexico (Fig. 1). Previous taxonomic treatments recognized *E. viridissima* as a single distinct species (e.g., Roubik and Hanson, 2004). However, a recent study of populations from the Yucatan peninsula (Mexico) showed instead that this lineage consists of two cryptic sister species (Eltz et al., 2008). The most prominent morphological difference between the two lineages is in the number of teeth on the mandible of males: two or three dentitions. Additionally, whereas males with three dentitions (hereafter *E.* aff. *viridissima*) collect large quantities of the compound 2-hydroxy-6-nona-1,3-dienyl-benzaldehyde (abbreviated HNDB), males with two dentitions (*E. viridissima*) lack HNDB in their perfumes (Eltz et al., 2008). A detailed systematic analysis of these lineages based on morphology, chemistry, and genetic data is in preparation (Eltz et al., unpublished).

As early as 2003, bees of *E.* aff. *viridissima* were introduced accidentally and naturalized in southeastern United States (Skov and Wiley, 2005). Since then, vigorous populations have become established throughout most of the southern coastal peninsula of Florida (Pemberton and Liu, 2008; Liu and Pemberton, 2009; Pemberton and Ramírez, personal observation). A chemical analysis of the perfumes of naturalized bees from Florida showed that male bees collect multiple fragrance compounds from several plant species, including native, naturalized, and horticultural plants (Pemberton and Wheeler, 2006). However, the composition of these fragrances has not been compared with that of native *E.* aff. *viridissima* populations.

In the present study, we analyzed the chemical composition of the fragrances acquired by *E.* aff. *viridissima* across its native range in Mesoamerica and its introduced range in Florida (U.S.). We estimated the magnitude of

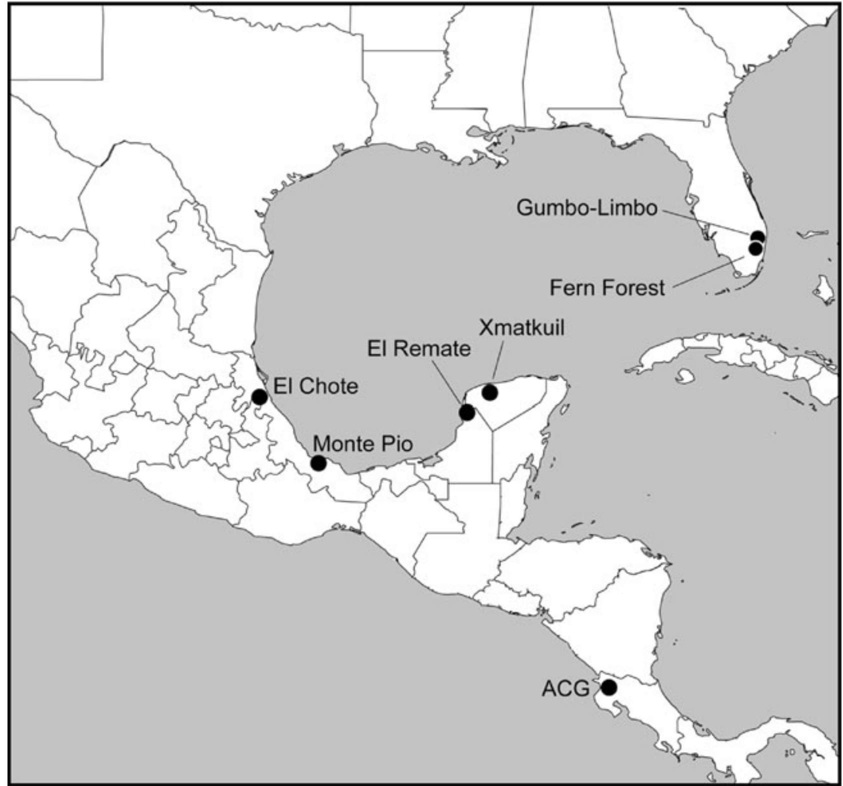

Fig. 1 Map of Mesoamerica and southern United States indicating sampling localities where male *Euglossa* aff. *viridissima* were collected. Native range populations in Mesoamerica were El Chote, Monte Pio, El Remate, Xmatkuil and ACG. Naturalized populations in the United States were Gumbo-Limbo and Fern Forest

intraspecific geographical variation in fragrance composition and identified volatile compounds that vary within and between bee populations. In addition, because the recent introduction of *E.* aff. *viridissima* to the United States may have resulted in both a genetic bottleneck and a habitat shift, we asked whether changes in perfume chemistry have accompanied the naturalization of this lineage of bees.

Methods and Materials

Sampling A total of 114 male orchid bees belonging to the *Euglossa* aff. *viridissima* lineage were collected from five localities across the native range in Costa Rica and Mexico, and two localities in the introduced range in the U.S. (Florida) in 2008 and 2009 (Fig. 1; Supplementary Material Appendix 1). Male bees were lured with synthetic chemical baits consisting of squares of blotter paper impregnated with *p*-dimethoxybenzene, methyl cinnamate, or eugenol (Sigma-Aldrich, St. Louis, MO, USA; Eltz et al., 2008). The impregnated paper squares were suspended 1.5 m aboveground and covered with screen mesh to prevent male bees from accessing the bait. Baiting stations were monitored every 15 min from 9AM until 1PM. Males were captured with hand nets and kept in the shade inside screen cages until subsequent dissection, typically conducted the same day.

Florida populations were sampled at two natural area preserves. Fern Forest (Broward County) is primarily a tropical hardwood forest grading into freshwater cypress swamp and upland pine habitats. Gumbo-Limbo Nature Center (Palm Beach County) is located on a barrier island with a tropical hardwood forest and mangroves. Mesoamerican populations were sampled from various habitats, including secondary seasonally dry tropical forest (ACG), secondary seasonally dry scrubland (Xmatkuil), farmland surrounded by stretches of tropical perennial forest (El Chote), settlement adjacent to tropical perennial forest (Monte Pio), and coastal mangroves (El Remate).

Fragrance Extraction and Chemical Analysis Male bees were cold-anaesthetized either on ice or inside a freezer (−20°C) for 5 min immediately prior to dissection. Right hind tibiae were removed with clean dissecting scissors and deposited in 2 ml screw-cap autosampler vials (Agilent Technologies, Santa Clara, CA, USA), which contained 500 µl of hexane to extract the fragrances. To distinguish between exogenous volatiles and endogenous male-produced lipids, acetates, and straight-chain hydrocarbon compounds, labial glands were dissected, extracted, and analyzed from a subset of individuals (N=43) using the same protocol described above. All compounds present in both leg extracts and labial glands were excluded from the analysis (Fig. 2). Extracted samples were stored at −20°C

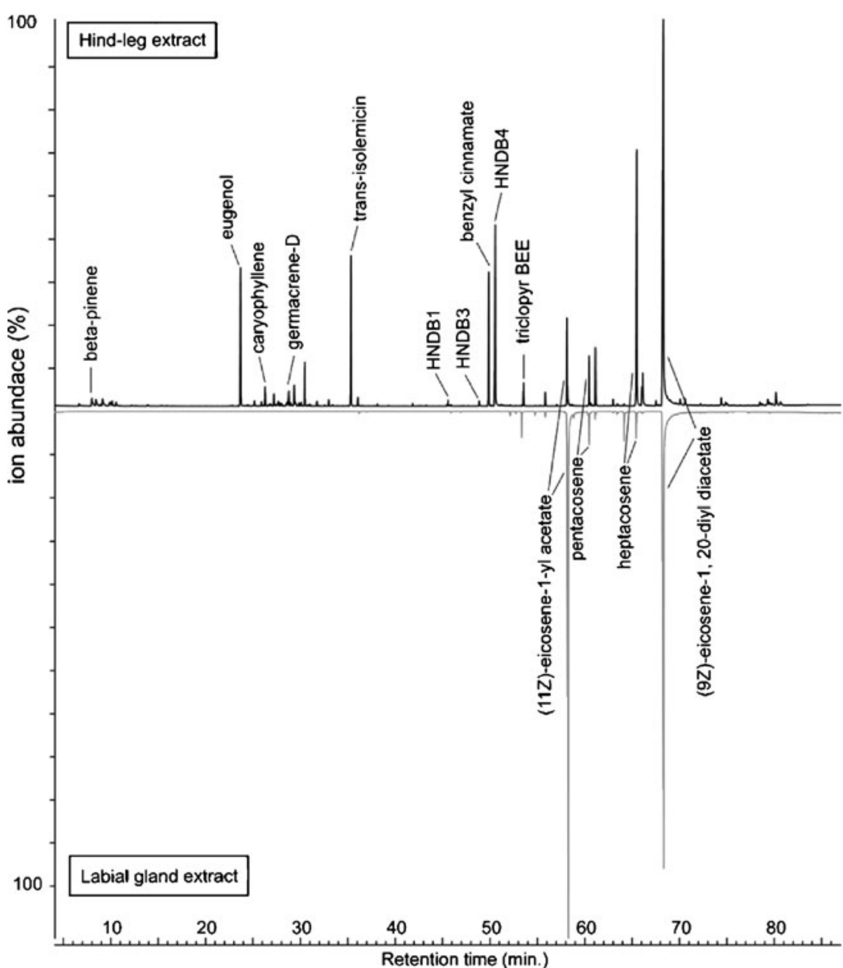

Fig. 2 Overlaid total ion current chromatograms corresponding to hind-leg (black) and labial gland (grey) extracts from the same individual bee. Compounds present in both hind legs and labial glands were considered endogenous in origin and thus were excluded from the analysis. The Y axis indicates ion abundance

until subsequent GC/MS analysis. Voucher specimens of all samples were either pinned or deposited in 200 proof ethanol.

Gas Chromatography/Mass Spectrometry (GC/MS) was conducted at the Department of Environmental Sciences, Policy and Management at the University of California Berkeley, using a 7890A Agilent GC coupled with a 5975C Agilent Mass Selective Detector (Agilent Technologies, Santa Clara, CA, USA). The GC was fitted with a 30 m long, 0.25 mm internal diam, non-polar Agilent HP-5MS capillary column (cat. # 19091S-433). Sample aliquots of 1 µl were injected by using an Agilent 7683B automatic injector operated in splitless mode. The oven temperature was programmed from 60 to 300°C at 3°C/min, using helium as carrier gas with a constant flow rate set to 0.7 ml/min. Mass Selective Detector (MSD) scanning parameters ranged from 50 to 550 amu, with a sampling rate of 2.91 scans/sec and a threshold detection of 150 counts.

Chemical analyses revealed the presence of triclopyr 2-butoxyethyl ester (hereafter triclopyr BEE), in Florida populations only. Triclopyr BEE is the active ingredient of a variety of commercial herbicides. To determine whether male *E.* aff. *viridissima* were actively attracted to this compound, we performed attraction bioassays with both captive and wild bees. Captive bees were nest-trapped in Florida (August 2009) and reared at UC Berkeley in an insectary facility maintained at 25°C, 40–60% humidity, and kept under a 12/12 h light/dark cycle. Male bees were not exposed to any fragrances prior to the bioassay, in which we presented male bees with hind leg extracts that contained large quantities of triclopyr BEE and as little as possible of other volatile compounds. We applied 100 µl of the hexane extract to clean blotter paper squares placed inside a flight cage where the bees were reared. As an experimental control, we presented male bees with labial gland extracts from the same individuals for which fragrance extracts were selected in the experimental treatment. The number of bees displaying fragrance gathering behavior within the first 2 min was recorded.

In addition, to test whether male *E.* aff. *viridissima* from native-range populations also were attracted to triclopyr BEE, we purified this compound from leg extracts using a preparative GC system similar to that of Nojima et al. (2008). A megabore DB-5 capillary column (30 m,

0.53 mm ID, 0.5 um film thickness) was used to separate compounds in an HP 5890 II gas chromatograph (50 to 300°C at 10°/min). Injection was on column, with a 30 m retention gap preceding the actual analytical column. The peak of triclopyr BEE was captured by using a 40 cm piece column trap (HP-1, 0.53 ID) that was connected to the preparative outlet at the time of elution. The substance retained in the trap was washed out with *n*-hexane. Repeated runs yielded approximately 75 μg of purified triclopyr BEE diluted in 1 ml of *n*-hexane. Subsequently, we presented male *E.* aff. *viridissima* with purified extracts of triclopyr BEE. The bioassay was conducted in a disturbed dry forest near Xmatkuil (Merida, Mexico) during the morning of 14 March, 2010. We applied 200 μl of isolated triclopyr BEE in *n*-hexane (~15 μg) to filter paper (Whatman 1, 2 cm) pinned to a small tree at breast height. In the vicinity (>4 m away), we also exposed two *p*-dimethoxybenzene baits, which were visited by dozens of male *E.* aff. *viridissima* during the same morning. Bees that landed on the triclopyr BEE filter paper were observed briefly to verify volatile collection.

Compound Characterization We used the software Chemstation *vE.02.00* (Agilent Technologies) to register chromatogram peaks and save their corresponding spectra in user-built mass-spectral libraries (Ramírez and Eltz, unpublished) which we use to cross-reference additional chromatograms. Libraries were recursively updated as new compounds were found. We further characterized individual compounds by comparing spectra against several published libraries (Adams, 2001; pal600K, Palisade Corporation, USA). Authentic standards of monoterpene and sesquiterpene compounds (Sigma-Aldrich, St. Louis, MO, USA), injected and analyzed under the same conditions and instrument described above (UC Berkeley), were also used to corroborate compound identities (Table 1). Uncharacterized compounds were named based on retention times and EI-mass spectrum ions (Table 1). Automatic peak integration was conducted using the RTE integrator in the software Chemstation *vE.02.00* (Agilent Technologies) set to a minimum-area detection threshold equivalent to 0.5% of the area of the largest peak.

Statistical Methods We built a square matrix containing the absolute quantities (total ion currents) for each compound, containing all samples from all localities. Total ion currents were transformed to relative amounts (percentage) per individual. We compared individual chemical profiles within and between populations via non-metric Multidimensional Scaling (MDS), an ordination technique where a predetermined number of axes of variation are chosen, and non-metric distances are fitted to those dimensions. Because ordination via MDS makes few assumptions about the nature of the data, any distance measure can be applied. We calculated a triangular distance matrix between samples (individuals) using the Bray-Curtis index of dissimilarity, which has the advantage of being insensitive to compounds jointly absent in sample pairs (i.e., pairwise dissimilarities are fixed). We computed 2- and 3-dimensional MDS plots (50 iterations per run) using the software package *ecodist v1.2.2* (written in R). We ran each analysis 10 times; convergence between solutions was visually inspected. To assess statistically whether orchid bee fragrances exhibit greater dissimilarity between populations than within populations, we conducted an Analysis of Similarity (ANOSIM) test, implemented in the software package *vegan v1.15-4* (written in R). Additional descriptive statistics, tests, and plots were produced using R basic packages, freely available at www.cran.r-project.org. We estimated the relative contribution of individual compounds to the observed ordinal dissimilarities using the Similarity Percentage (SIMPER) method, implemented in the software package *primer v6* (Clarke and Gorley, 2006). All MDS calculations were verified using the software *primer*.

Results

We registered a total of 333 compounds in hind leg extracts of 114 males sampled from seven populations (Fig. 1). By comparing the chemical profiles of hind leg extracts against those from labial glands (Fig. 2) we determined that 41 compounds were produced in the bees' labial glands (endogenous origin), and included straight chain hydrocarbons, acetates, diacetates, and alcohols (Supplementary Material Appendix 2). The remaining 292 compounds are thus exogenous in origin, and included monoterpenes, sequiterpenes, bicyclic sesquiterpenes, triterpenes, and other compounds (Table 1). The per-capita number of exogenous compounds across all populations ranged from 1 to 65 chemicals (average 21.50±12.66) with marginally similar means in all seven populations (ANOVA F=3.2118, P=0.075). On average, male bees from Fern Forest (U.S.) exhibited the lowest number of compounds per capita (15.83±10.08), whereas El Remate (Mexico) exhibited the highest number (29.23±6.24; Fig. 3). When the two U.S. populations were combined, they had significantly fewer compounds per individual (17.46±10.78) than all Mesoamerican populations combined (24.14±13.17; ANOVA F= 8.0419, P=0.005).

Our non-metric Multidimensional Scaling (MDS) analysis included exogenous compounds only. When all volatile compounds in the data matrix were included (coded by relative abundances), a strong clustering by population was found (Fig. 4a). This observation was corroborated by the

Table 1 Most common exogenous fragrance compounds collected by male *Euglossa* aff. *viridissima* ranked by their incidence (%) across populations

[a] Similarity Percentage (SIMPER) was used to calculate the relative contribution of each compound to the observed dissimilarity between US and Mesoamerican populations. Values >1% are indicated in bold

ANOSIM results, which indicated that fragrance dissimilarity within populations was lower than among populations ($R=0.433$, $P<0.001$). We found a similar pattern when we excluded the two compounds with the highest contribution to the dissimilarity between U.S. and Mesoamerica (Fig. 4b; see SIMPER analysis below), namely HNDB4 (one of four stereoisomers) and triclopyr BEE. Likewise, MDS ordinations based only on the 50 compounds with the

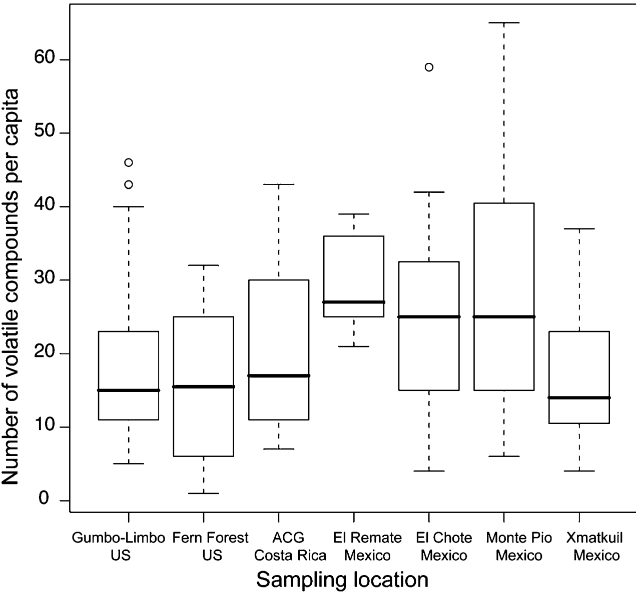

Fig. 3 Boxplots of the number of volatile exogenous compounds per capita in fragrances of male *Euglossa* aff. *viridissima* in native and introduced populations

highest incidence ranks across all populations (Fig. 4c), and the entire dataset transformed into discrete binary (presence/absence) characters (Fig. 4d), also supported a strong differentiation between all populations. In addition, regardless of which data partition we used, we found that introduced (U.S.) and native (Mesoamerica) populations were strongly differentiated (Fig. 4; ANOSIM populations not pooled: R=0.483, P<0.001). To explore the possibility that per-capita compound diversity (number of compounds) affected population differences, we overlaid a bubble-plot on an MDS ordination (based on all fragrance data) with circle diameters proportional to the number of compounds per capita (Fig. 5). Although mean per capita fragrance richness was marginally different among populations (Fig. 3), populations did not appear to cluster based on fragrance diversity alone (Fig. 5).

Our SIMPER analysis revealed that five compounds jointly contributed to >50% of the observed chemical dissimilarity between populations from U.S. and Mesoamerica (Table 1). These included HNDB4 (19.04%), triclopyr BEE (17.37%), eugenol (8.54%), benzyl cinnamate (3.48%), and beta-ocimene (3.41%). With the exception of triclopyr BEE, which was present only in U.S.

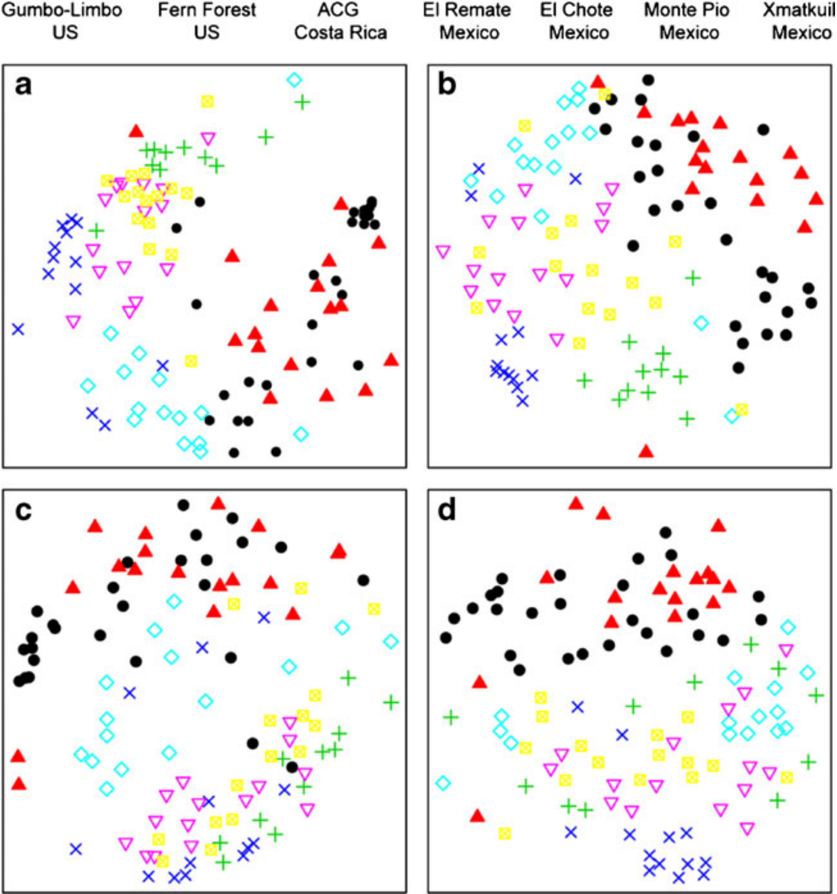

Fig. 4 Non-metric multidimensional scaling (nMDS) plots based on the chemical composition of exogenous compounds present in hind legs of male *Euglossa* aff. *viridissima*. Ordination plots were computed based on **a** all volatile compounds, **b** all volatile compounds except the two most dissimilar between U.S. and Mesoamerican populations (i.e., HNDB4, triclopyr BEE), **c** the 50 compounds with highest incidence across all populations, and **d** all volatile compounds coded as binary characters (presence/absence). Filled circles and triangles correspond to individuals from naturalized populations

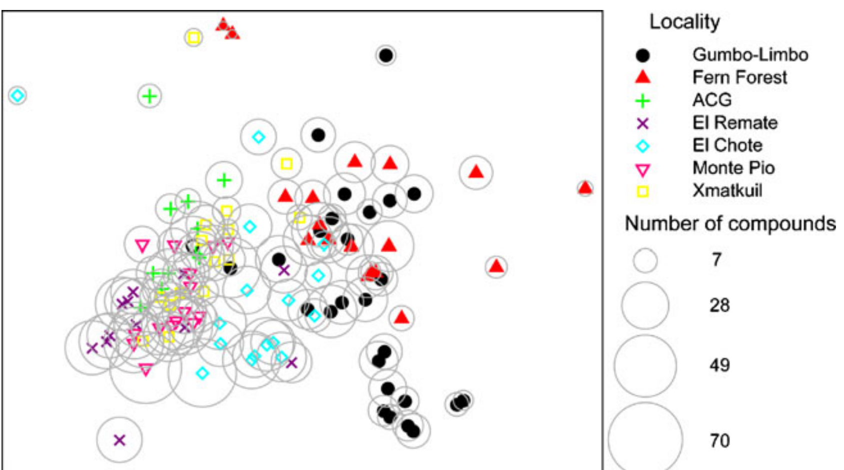

Fig. 5 Bubble plot overlaid on an MDS ordination based on all exogenous fragrance compounds. Circle diameters correspond to the number of volatile exogenous compounds present in the fragrances of each individual. Analyses were performed using the software *primer* (Clarke and Gorley 2006). Filled circles and triangles correspond to individuals from naturalized populations

populations, these compounds exhibited high incidence values across all populations (Table 1). The SIMPER analysis also revealed that of the ten most dissimilar compounds between U.S. and Mesoamerica, eight were present in both population sets (Table 1; Fig. 6 except panels f, j). Of these, six were present in more individuals and had greater relative quantities in Mesoamerican than in U.S. populations (Fig. 6a,c,d,e,g,h). The two remaining compounds (eugenol and caryophyllene) were present in more individuals and had greater relative amounts in U.S. than Mesoamerican populations (Fig. 6b,i). Triclopyr BEE and benzyl benzoate were present only in U.S. and Mesoamerica, respectively (Fig. 6f,j). Triclopyr BEE contributed up to 69% of total fragrance composition in U.S. bees, and it was detected in 63% of individuals (N= 43). Benzyl benzoate contributed up to 17.84% of the fragrance composition in individual bees, and it was detected in 18% of Mesoamerican individuals (N=71).

We also conducted a SIMPER analysis among all seven populations. In 15 of the 21 possible pairwise comparisons, five compounds jointly explained >50% of the observed fragrance dissimilarity (Supplementary Material Appendix 3). In all but two pairwise comparisons, El Remate (Mexico) v. ACG (Costa Rica) and El Remate v. Monte Pio (Mexico), the compounds HNDB4 and eugenol ranked among the top five compounds with highest dissimilarity between populations (Supplementary Material Appendix 3). Sesquiterpene compounds, followed by monoterpenes, contributed the most to the observed dissimilarity between populations (Table 1; Online Appendix 3). Although diverse, triterpenes contributed little or nothing to population structuring.

As described earlier for *E.* aff. *viridissima* (Eltz et al., 2008), four stereoisomers of the compound HNDB were found in male perfumes (Supplementary Material Fig. 1). The compound HNDB4 was by far the most abundant stereoisomer in the majority of populations, except in El Remate (Mexico). The fragrances of all individuals in El Remate had greater relative amounts of the stereoisomers HNDB1, HNDB2, and HNDB3 than all other populations. In some cases, other stereoisomers were more abundant than HNDB4 itself (Supplmentary material Fig. 1). Because our spectral searches against published libraries did not return any significant matches for triclopyr BEE, the identification of this compound was conducted by comparison against analytical standards provided by Dow Agro-Sciences (Indianapolis, IN, US). Both the retention time and EI-spectrum of the analytical standard of triclopyr 2-butoxyethyl ester (triclopyr BEE) perfectly matched peaks in our samples (Fig. 7). Male *E.* aff. *viridissima* were observed displaying fragrance collecting behavior on areas where the herbicide Garlon had been applied in Fern Forest (Pemberton, Pers. Obs.). Triclopyr BEE is one of three available active ingredients present in commercially available herbicides (including Garlon) used for broadleaf weed control. The other active ingredients are triclopyr acid and triclopyr triethylamine salt (TEA).

In our laboratory bioassay, we presented 20 male bees with three hexane leg extracts containing large amounts of triclopyr BEE and trace amounts of other volatile compounds. Within the first two minutes of exposure, six, five, and six individual bees exhibited obvious collecting behavior in the three trials, respectively. Controls (labial lipid extracts) did not elicit fragrance-collecting behavior in any of the trials.

Our bioassay using purified aliquots of triclopyr BEE with native bee populations in the field revealed that male *E.* aff. *viridissima* are attracted to, and collect, this volatile compound. A total of five male *E.* aff. *viridissima* approached the filter paper with triclopyr BEE, landed on it, and performed typical collection behavior. Other males circled the filter paper but did not land on it.

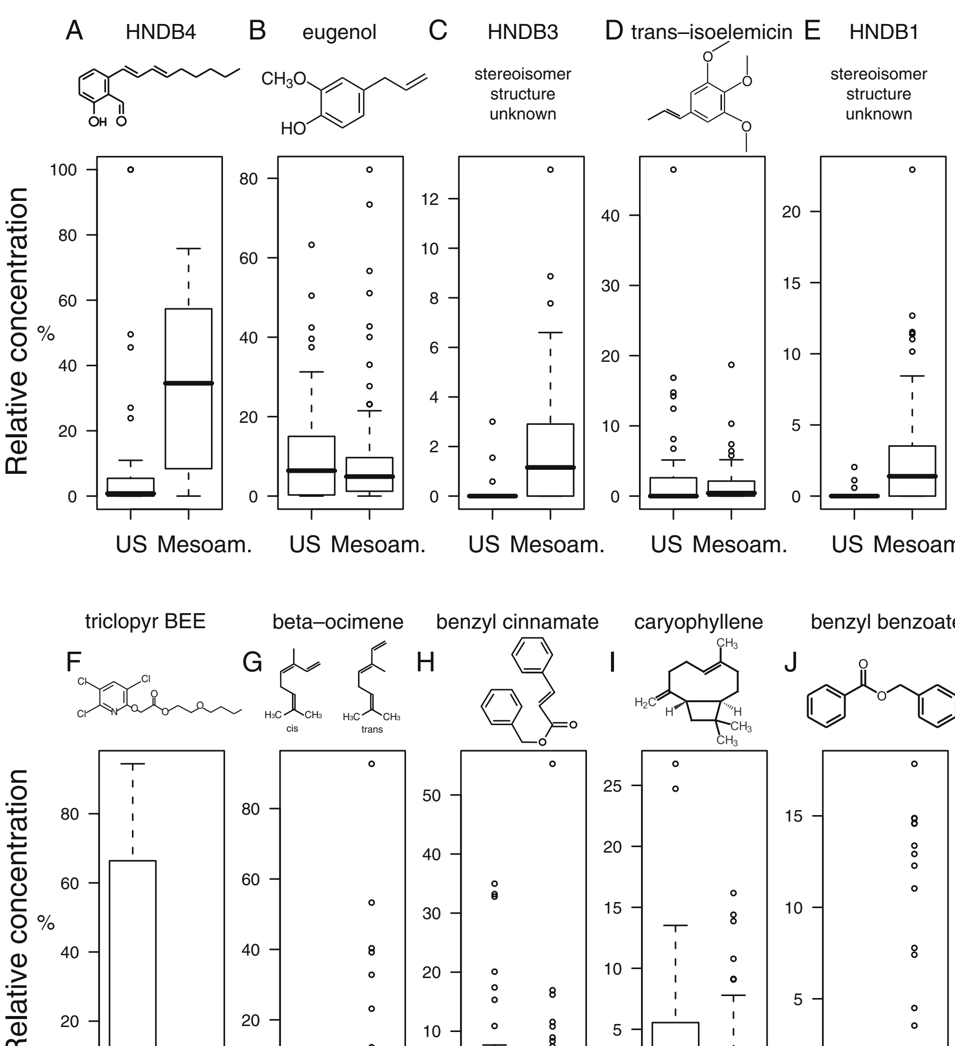

Fig. 6 Boxplots of per-capita relative concentration (relative amount of each compound over all compounds) of ten chemicals detected in bees sampled from native (Mesoamerica) and naturalized (U.S.) populations. These ten compounds had the greatest contributions to dissimilarity between native and naturalized populations

Discussion

Euglossine bees acquire species-specific fragrance bouquets from a great diversity of floral and non-floral sources (Williams, 1982; Whitten et al., 1993; Ramírez et al., 2002; Pemberton and Wheeler, 2006; Zimmermann et al., 2009a). As a result, individual perfume phenotypes may not be attributable to single sources, but instead, emerge from multiple visits to numerous hosts (Eltz et al., 2005a; Pemberton and Wheeler, 2006). Although sympatric species of orchid bees, and particularly closely related lineages (Eltz et al., 1999; Zimmermann et al., 2006, 2009a), exhibit divergent perfume phenotypes, it has been unclear to what extent fragrances vary across geographic regions within lineages. Our results indicate that male *E.* aff. *viridissima* maintain most of the individual compounds of their fragrance phenotypes across distant populations in disparate habitats, but a few major (abundant) compounds can be present or absent from perfume bouquets. Moreover, since populations of *E.* aff. *viridissima* in Florida have been stable for at least seven years, our data suggest that the observed phenotypic changes have negligible effects on population viability. This observation is congruent with the previous report that male *Euglossa tridentata* and *E. erythrochlora* sampled in Isla del Caño, an island 17 km off the coast of Costa Rica, collect substantially fewer compounds per capita than in mainland populations (Eltz et al., 2005a, Pers. Obs.).

The remarkable qualitative consistency we found in fragrance phenotypes is at odds with the considerable habitat variability among the seven sites sampled, but supports the hypothesis that orchid bee perfume preferences are under strong selection (Zimmermann et al., 2009a). The differences in perfume composition that we observed between native and naturalized populations could be

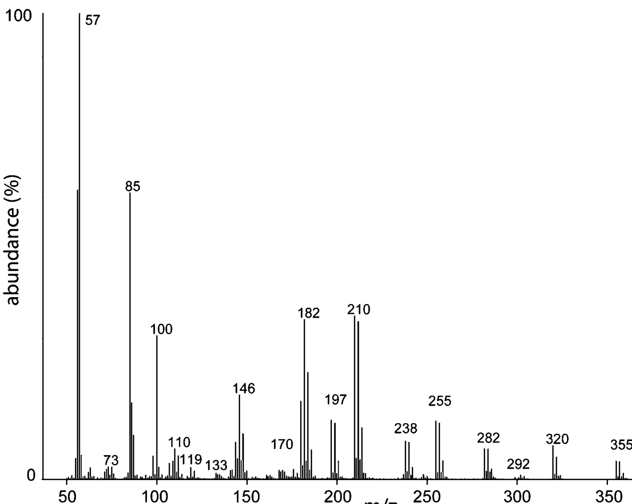

Fig. 7 Mass spectrum of triclopyr 2-butoxyethyl ester, a prevalent compound found in leg extracts of males from naturalized populations of *Euglossa* aff. *viridissima* in Florida (U.S.) and absent in native (Mesoamerican) populations

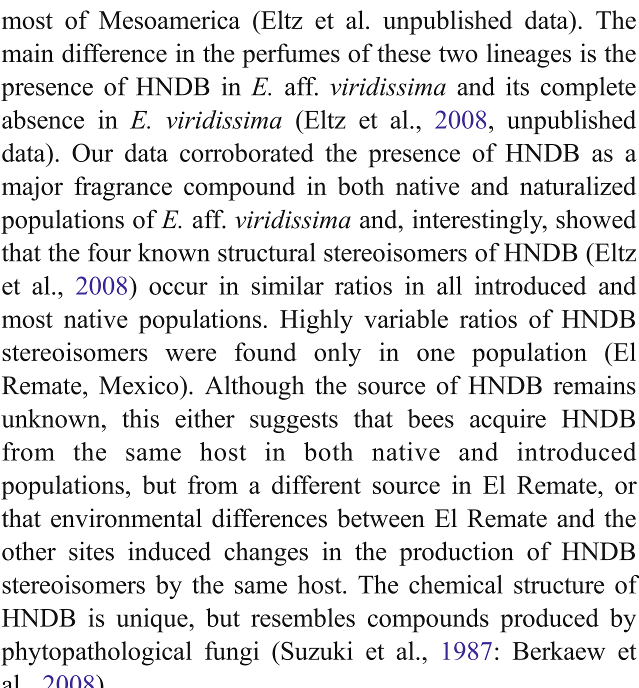
attributed to environmental factors, to differences in chemical preference between populations, or to both. Several factors may influence intraspecific fragrance variation. First, species turnover (beta diversity) of fragrance hosts across habitats may force phenotypic changes via chemical abundance and availability. In fact, a recent survey of volatile compounds present in resins of Amazonian trees revealed not only a vast diversity of monoterpenes and sesquiterpenes, but also pronounced chemical turnover across tree species from different habitats (Courtois et al., 2009). Second, strong female preference for certain fragrance phenotypes may restrict the amount of perfume phenotypic plasticity. Although direct evidence for female choice of fragrance phenotypes is still missing for orchid bees, perfume phenotypes are likely to be under strong sexual selection (Zimmermann et al., 2009a, b). Hence, it is also conceivable that, at evolutionary timescales, new male fragrance phenotypes may emerge through novel female preferences for perfumes that indicate mate genotypic quality or simply exploit a sensory bias (Andersson, 1994).

Genetic data indicate that naturalized populations of *E.* aff. *viridissima* have gone through a severe population bottleneck (Zimmermann et al. unpublished data), and therefore it is possible that population differences in perfume phenotypes have an underlying genetic basis. Rapid evolutionary change in pheromone phenotypes has been demonstrated in several species of insects (Lofstedt, 1993; Takanashi et al., 2005; Groot et al., 2009), and could be tested in orchid bees via common garden experiments.

The orchid bee lineage *E.* aff. *viridissima* is broadly sympatric with its sister taxon (*E. viridissima*) throughout



most of Mesoamerica (Eltz et al. unpublished data). The main difference in the perfumes of these two lineages is the presence of HNDB in *E.* aff. *viridissima* and its complete absence in *E. viridissima* (Eltz et al., 2008, unpublished data). Our data corroborated the presence of HNDB as a major fragrance compound in both native and naturalized populations of *E.* aff. *viridissima* and, interestingly, showed that the four known structural stereoisomers of HNDB (Eltz et al., 2008) occur in similar ratios in all introduced and most native populations. Highly variable ratios of HNDB stereoisomers were found only in one population (El Remate, Mexico). Although the source of HNDB remains unknown, this either suggests that bees acquire HNDB from the same host in both native and introduced populations, but from a different source in El Remate, or that environmental differences between El Remate and the other sites induced changes in the production of HNDB stereoisomers by the same host. The chemical structure of HNDB is unique, but resembles compounds produced by phytopathological fungi (Suzuki et al., 1987: Berkaew et al., 2008).

The presence of large quantities of triclopyr BEE in leg extracts of naturalized bee populations, together with our field and laboratory bioassays, demonstrates that male bees are attracted to and actively collect this herbicide active ingredient. Indeed, previous studies have shown that males of the orchid bee *Eufriesea purpurata* from Brazil collect large quantities of the synthetic pesticide DDT (Roberts et al., 1982; Walter and Roberts, 2007). Although we did not detect triclopyr BEE in leg extracts from native populations, male bees from Mesoamerica clearly were attracted to this compound. This result suggests that a pre-existing sensory bias, rather than rapid adaptation among introduced populations, may explain the collection of organohalogen synthetic chemicals by male orchid bees. Both behavioral and neurophysiological approaches are needed to elucidate the sensory basis of this unusual behavior.

Our results illustrate that male *E.* aff. *viridissima* collect a broad diversity of molecules in native and introduced populations. As shown previously for orchid bees (e.g., Williams and Whitten, 1983; Eltz et al., 1999, 2005a; Zimmermann et al., 2009a), fragrance bouquets were composed mainly of monoterpenes, bicyclic sesquiterpenes, and aromates. We found that perfume compounds that differed the most in abundance among populations also tended to be common to all populations. This was the case for several monoterpene, sesquiterpene, and aromate compounds. For example, whereas eugenol and HNDB were present in >73% of the sampled individuals and contributed significantly to population dissimilarity, most rare compounds contributed little to population dissimilarity. We confirmed this pattern by plotting the contribution to the

dissimilarity between U.S. and Mesoamerica as a function of compound average abundance (data not shown).

Despite contributing little to overall population differences, rare compounds were diverse in our dataset. For instance, we detected numerous triterpenes in fragrances of *E.* aff. *viridissima*, but most of them were present in few individuals and in low concentrations. Because triterpenes exhibit high molecular weights (>400), and thus may not volatilize at ambient temperature, they may constitute poor airborne signaling molecules. We speculate that orchid bees actually collect triterpenes accidentally since they are common components of tree resins (e.g., Burseraceae), which are known to contain numerous volatile compounds (De La Cruz-Cañizares et al., 2005; Courtois et al., 2009). Hence, most of the compounds that were abundant in our dataset, such as sesquiterpenes, monoterpenes, and aromates, contributed the most to population differences, and also are likely to constitute the main courtship signaling molecules in orchid bees.

In summary, the preference for most fragrance compounds acquired by orchid bees appears to be under strong selection. Evidence for this comes from the fact that male bees managed to collect similar compounds across disparate habitats ranging from tropical rain forests to tropical dry forests, to mangroves, to disturbed habitats. However, we also found evidence for pronounced quantitative and qualitative changes across geographic (and possibly genetic) gradients. Previous studies have suggested that saltational changes in fragrance preferences may constitute an important mechanism of evolution of perfume phenotypes as well as speciation in orchid bees (Eltz et al., 2008; Zimmermann et al., 2009a). Because mutations that affect the olfactory system of orchid bees can induce the acquisition or loss of specific chemicals, perfume phenotypes have the potential to evolve fast enough to facilitate lineage differentiation (Eltz et al., 2008; Jackson, 2008; Zimmermann et al., 2009a). Our analysis highlights the opportunistic capacity that orchid bees have to incorporate novel compounds in their perfumes, as illustrated by the gain and loss of several compounds in naturalized populations. Whether population-level changes in perfume phenotypes have underlying genetic components, and are thus subject to selection, should be a fruitful area of future research.

Acknowledgements We thank Rachel Taylor and Anthony Boughton for assistance during fieldwork in Florida. We thank the staff members from the USDA-Agricultural Research Service's Invasive Plant Research Laboratory for providing assistance and allowing access to facilities, and Javier Quezada-Euan and the staff members of the Department of Apiculture at UADY, Mexico, for their long-term cooperation. We thank Roger Blanco and Maria Chavarría for help with collection permits in the Area de Conservación Guanacaste (Costa Rica). Elena Ormeño kindly provided the internal standards used in compound verification; Dong-Hwan Choe provided assistance in the identification of triclopyr BEE. We thank Jenny Jacobs for comments on an earlier version of the manuscript. This research was partly supported by USDA grant NRI-CGP-2008-35302-04680 to NDT.

Abstract Salivary glucose oxidase (GOX) has been reported in a few insect species where it plays a role in protection against infectious disease. Our recent research has focused on the role of this salivary enzyme in the noctuid *Helicoverpa zea*, where it functions as an effector to suppress the induced defenses of the host plant *Nicotiana tabacum*. In this study, we examined the labial gland GOX activities in 23 families of Lepidoptera (85 species) and two families of plant-feeding Hymenoptera (three species). We analyzed the relationship between host breadth and GOX activities, and we found a significant relationship, where highly polyphagous species were more likely to possess relatively high levels of GOX compared to species with more limited host range. We also examined the effect of diet on GOX activity and found that the host plant had a significant effect on enzyme activity. The significance of these findings is discussed in relation to caterpillar host breadth.

Introduction

Caterpillar saliva and regurgitant (=oral secretions) contain chemical cues that may be recognized by plants, thus providing the basis for eliciting unique plant responses to herbivory (Felton and Eichenseer, 1999; Musser et al., 2002; Felton, 2008). Whereas regurgitant arises from the digestive system, caterpillars secrete saliva from their labial and mandibular glands (Felton and Eichenseer, 1999; Felton, 2008; Peiffer and Felton, 2009). Saliva is purported to aid in antimicrobial defense (Liu et al., 2004; Musser et al., 2005b), digestion (Lenz et al., 1991), detoxification (Ahmad and Hopkins, 1993; Mathews et al., 1997), and suppression of host plant defenses (Musser et al., 2002, 2005a). Additional functions may be revealed when proteomic and transcriptomic studies are conducted with lepidopteran salivary glands. This approach has proved successful in identifying key components of saliva from other arthropods (Valenzuela et al., 2003; Harmel et al., 2008).

We reported a salivary glucose oxidase (GOX) from the labial and mandibular glands of *Helicoverpa zea* (Eichenseer et al., 1999), and proposed several functions for the enzyme including mediation of plant defenses. In some cases, GOX may contribute to the initial oxidative burst of H_2O_2 observed in leaves damaged by herbivores

(Bi and Felton, 1995; Bi et al., 1997a; Orozco-Cardenas and Ryan, 1999; Musser et al., 2006). GOX belongs to the family of GMC-oxidoreductases (Iida et al., 2007) and catalyzes the following reaction:

$$\mathrm{D-glucose} + O_2 \rightarrow H_2O_2 + \mathrm{D-gluconic\ acid}.$$

The rapid increase in reactive oxygen species, such as H_2O_2, serves as an initial signal that leads to the production of proteins and other natural products that are involved in induced resistance to herbivores and/or pathogens (Orozco-Cardenas et al., 2001).

GOX has been reported sporadically in other insect species including honey bees (Iida et al., 2007). The highest GOX activity in *H. zea* was found in labial glands of actively feeding larvae (1.2 μmol/min/mg protein or 2.1 nmol/min/labial gland) (Eichenseer et al., 1999). This is among the highest activities recorded for any insect, although only a few caterpillar species (Zong and Wang, 2004; Merkx-Jacques and Bede, 2005; Bede et al., 2006; Babic et al., 2008; Yong-Hong et al., 2008), honey bees (Yang and Cox-Foster, 2005), and one grasshopper species have been assayed for GOX activity (Candy, 1979). While GOX is commonly thought of as an enzyme produced by fungi (Wong et al., 2008), these findings suggest that caterpillars are a rich and novel source of GOX. We currently, however, do not have any evidence for how widespread the enzyme is among Lepidoptera.

Following our early report of GOX in caterpillar saliva (Eichenseer et al., 1999), subsequent studies have revealed that caterpillar saliva functions in suppressing both direct and indirect plant defenses (Musser et al., 2002, 2005a; Zong and Wang, 2004; Bede et al., 2006; Delphia et al., 2006; Weech et al., 2008; Diezel et al., 2009). In several cases, GOX is implicated as the primary salivary effector responsible for suppression (Musser et al., 2002; Zong and Wang, 2004; Bede et al., 2006). GOX may suppress defensive responses by eliciting a salicylic acid burst, which then attenuates jasmonate (JA) and ethylene levels (Felton and Eichenseer, 1999; Musser et al., 2005a; Diezel et al., 2009). The accumulation of salicylic acid may antagonize JA-mediated herbivore defenses in some instances (Bi et al., 1997c; Felton et al., 1999; Stout et al., 1999). JA and/or ethylene (Howe and Jander, 2008; Ankala et al., 2009) regulate many of the induced defenses targeted against chewing herbivores. Moreover, GOX may mask the eliciting action of fatty acid conjugates, such as volicitin on JA and ethylene signaling (Diezel et al., 2009).

To date, GOX suppression of host defenses has been reported from generalist or polyphagous caterpillars—those species feeding on host plants from multiple plant families. We hypothesize that the high expression of salivary GOX may be a strategy used by polyphagous species to evade the inducible plant defenses of their hosts. Due to the potentially broad importance of this enzyme to caterpillar fitness, we conducted this study to: 1) survey for GOX among different caterpillar species; 2) determine if GOX activity is associated with any particular life history traits such as host breadth; and 3) explore how the diet contributes to variation in GOX activities.

Methods and Materials

Source of Insects and Dissection Caterpillars were collected from various host plants in Fayetteville, AR, USA and surrounding areas, or were provided to us from various sources. Table 1 indicates whether insects were from laboratory colonies or were collected from a particular host plant species. Caterpillars were reared on plant material or artificial diet until the last instar, or when were large enough to dissect easily. Some caterpillars were reared from eggs. In all cases, caterpillars were kept at 25°C with a 16:8 h L:D photoperiod. Prior to dissection, healthy, actively feeding caterpillars were anesthetized by crushed ice and water. Entire labial glands were removed from dissected caterpillars with forceps and placed into 1.5 ml microcentrifuge tubes containing phosphate-buffered saline (pH 7.0, 2.7 mM KCl, 137 mM NaCl, 1.5 mM KH_2PO_4, and 8 mM $Na_2HPO_4 \times 7H_2O$) and 1 μM phenylmethylsulfonylfluoride (PMSF) protease inhibitor, and were frozen at −20°C for no more than 3 mo. Previous results with *H. zea* labial glands indicated no significant loss in activity occurred within this period. Depending on the size of the species, samples contained from one to 20 pairs of labial glands from actively feeding larvae, indicated by midguts full of food. Voucher specimens were retained for identification and deposited in the University of Arkansas Arthropod Museum. Unidentifiable larvae were reared to adulthood and then identified. We consulted multiple sources for larval and adult identification (Peterson, 1962; Covell, 1984; Scott, 1986; Stehr, 1987; Wagner, 2005; Powell and Opler, 2009). These references also were consulted to determine diet breadths. For ease of reference, we use the nomenclature of Stehr (1987). In the cases where we had significant representation of species from a given super-family (i.e., Noctuiodea and Papillionoidea), distribution of GOX activities was presented graphically to illustrate relationships to phylogeny.

Artificial Diet A wheat germ meridic diet (Broadway and Duffey, 1986) was used for all experiments not utilizing foliage. Diet ingredients were purchased from BioServ (Frenchtown, NJ, USA). Soy protein concentrate was the source of protein. This regular feeding diet contained 2.1%

dextrose (D-glucose) on a wet weight basis and 36% D-glucose on a dry weight basis. In one experiment, L-glucose was substituted for D-glucose, and in another experiment sucrose or amylose was added in place of dextrose. In both these experiments, three samples of 5 pairs of glands from 2-d-old fifth instars were collected.

Enzyme Assay and Protein Determinations We measured GOX activities as described (Eichenseer et al., 1999). The assay measures the rate of dianisidine oxidation by H_2O_2 produced by GOX. Oxidized dianisidine was measured with a SLM Aminco (Rochester, NY, USA) 3000 diode array spectrophotometer with rate analysis software at 460 nm, using an extinction coefficient of 8.3 $mM^{-1} cm^{-1}$ for 3 min. Ten µl of labial gland homogenate were added to a reaction mixture containing 0.21 mM dianisidine-HCl in 0.1 M phosphate buffer at pH 7.0 (vigorously stirred before adding to cuvettes), 0.14 mmol D-glucose, and 21 U

horseradish peroxidase to make a final volume of 1.56 ml. The amount of protein in each sample was determined by using bovine serum albumin as a standard (Bradford, 1976). Three GOX and protein determinations were made for each sample. By storing a known number of labial glands in a constant volume of saline, we could calculate the relative GOX activity from specific activities. A minimum of three samples containing glands were tested for each species unless otherwise noted.

Glucose Oxidase and Host Specialization To determine if there was a relationship between host specialization and GOX activities, we grouped species into six median GOX activity categories (0–10, 11–50, 51–99, 100–200, 201–400, and >400 nmol/min/mg protein). We tested if there was a significant trend of GOX activity with polyphagous caterpillars (defined here as greater than 10 recorded host genera in more than three plant families) to have higher GOX than oligophagous caterpillars (recorded hosts from one or two host plant families or a narrow range of plant genera) using the Wilcoxon rank sum test.

Diet and Variation in Glucose Oxidase Activities Foliage for experiments with *H. zea*, *H. virescens*, and *M. sexta* were cut from plants grown in pots filled with Terra-Lite®Redi-Earth®Peat-Lite® Mix (Scotts-Sierra Horticultural Products, Marysville, OH, USA) in a greenhouse with temperatures set at 27°C (range 23°–31°), under high pressure sodium lights (100 W) and a 15-h photophase. Pots were watered regularly and supplied with Peters (Scotts-Sierra Horticultural products) fertilizer (N-P-K = 20:20:20) weekly. Pre-flowering plants were selected for all assays. For tobacco plants, leaves were collected from plants between the rosette and bolting stage but before plants produced flowers. In each experiment below, at least three samples of 5 larvae were collected unless noted otherwise.

Neonate *H. zea* larvae were placed on foliage of ‘Hutcheson’ soybeans (*Glycine max*), ‘DeltaPine 50’ cotton (*Gossypium hirsutum*, Delta Pine and Land, Scott, MS), ‘Ozark Pink’ tomato (*Lycopersicum esculentum*), Carolina geranium (*Geranium carolinianum*) grown from field-collected seeds and the soy-protein based artificial diet. Larvae reared on the foliage were placed into 30 ml plastic cups filled with approximately 5 ml solidified agar to provide moisture. Fresh leaves/leaflets were provided every other day. The date when the larva molted to the last instar was recorded and one day later, the glands were dissected and stored for subsequent GOX assays.

For *Manduca sexta* larvae, two populations were assayed: a colony from Carolina Biological Supply (Burlington, NC, USA) and larvae originating from adults reared and collected near Fayetteville, AR, USA. The larvae originating from Carolina Biological were reared on the soy-protein based diet, ‘Ozark Pink’ tomato leaflets, ‘Xanthi-nc’ tobacco (*Nicotiana tabacum*) and *Nicotiana attenuata* grown from seeds collected near Flournoy, CA, USA. Larvae collected from the Arkansas population were reared on ‘Ozark Pink’ tomato foliage, ‘Xanthi-nc’ tobacco, and *Physalis heterophylla* (grown from field-collected seeds) foliage. All caterpillars were reared on their foliage treatments from neonates and dissected as actively feeding fifth instars, 2–3 d after molting. Each of 5 samples per diet treatment consisted of one pair of glands.

For *H. virescens*, larvae were obtained from the University of Arkansas insect rearing facility and reared on the soy protein-based artificial diet, ‘Xanthi-nc’ tobacco leaves, and a transgenic tobacco expressing a bacterial salicylate hydroxylase gene, *nahG*. The hydroxylase metabolizes salicylic acid and compromises the systemic acquired resistance response to various phytopathogens (Felton et al., 1999). More details on the tobacco plants selected are described elsewhere (Bi et al., 1997b; Felton et al., 1999). Two-day old fifth instars were dissected for labial glands.

An outbreak of fall webworm, *Hyphantria cunea*, in Fayetteville, AR enabled us to test how different tree species could affect caterpillar GOX activities. Larvae were collected from webs that were defoliating mulberry, *Morus alba* (Moracaeae), sweetgum, *Liquidambar styraciflua* (Hammalidaceae), persimmon, *Diospyros virginiana* (Ebenaceae), and black walnut, *Juglans nigra* (Juglandaceae) trees. Three samples containing glands from 5 to 7 larvae were collected from one web nest collected off 3 (2 for sweetgum) separate trees. The larvae were all actively feeding (midguts full with leaf material) late instars. Insects were dissected no more than 5 d after collection.

Summary statistics, one-way, two-way analyses of variance, and non-parametric statistics were calculated using JMP 4.0 software (SAS institute, Cary, NC, USA). To understand sources of variation of GOX activities in *H. cunea,* the main effects of tree species, nest, sample, and their interactions were tested with two-way analysis of variance. Significant differences between tree species were tested with Tukey’s HSD test. The remaining experiments designed to understand how diet influences caterpillar GOX activities were tested by one-way analysis of variance, with diet and sample tested as significant sources of variation. If diet was a significant source of variation, Tukey’s HSD test was used to separate means between the dietary treatments.

Results

Glucose Oxidase Variation Among Caterpillar Species Eighty-five species of Lepidoptera in 23 families were examined for GOX activity, as well as three species of

phytophagous Hymenoptera (Table 1). Most caterpillars were leaf feeders, with a few species representing more specialized feeding habits (e.g., *Galleria, Macronoctua, Cadra*). Differences between families were apparent, especially and even between some subfamilies of Noctuidae (Fig. 1). For example, all the Notodontids assayed had detectable GOX activities compared to the variation detected in some of the Noctuid subfamilies (e.g., compare Noctuinae with Heliothinae). With the exception of *P. interragationis*, the Papillionoidea tended to have low GOX activities (Fig. 2). Little activity was found in the labial glands of phytophagous Hymenopterans (Table 1).

GOX activities were distributed unevenly among species of caterpillars (Fig. 3). More than half of the species surveyed possessed GOX activities of less than 50 nmol/min/mg, while 18% had high GOX activities greater than 200 nmol/min/mg, and the activities of the remaining 29% ranged between 51 and 200 nmol/min/mg (Fig. 3).

There was a statistically significant trend for polyphagous caterpillars to have higher GOX than oligophagous

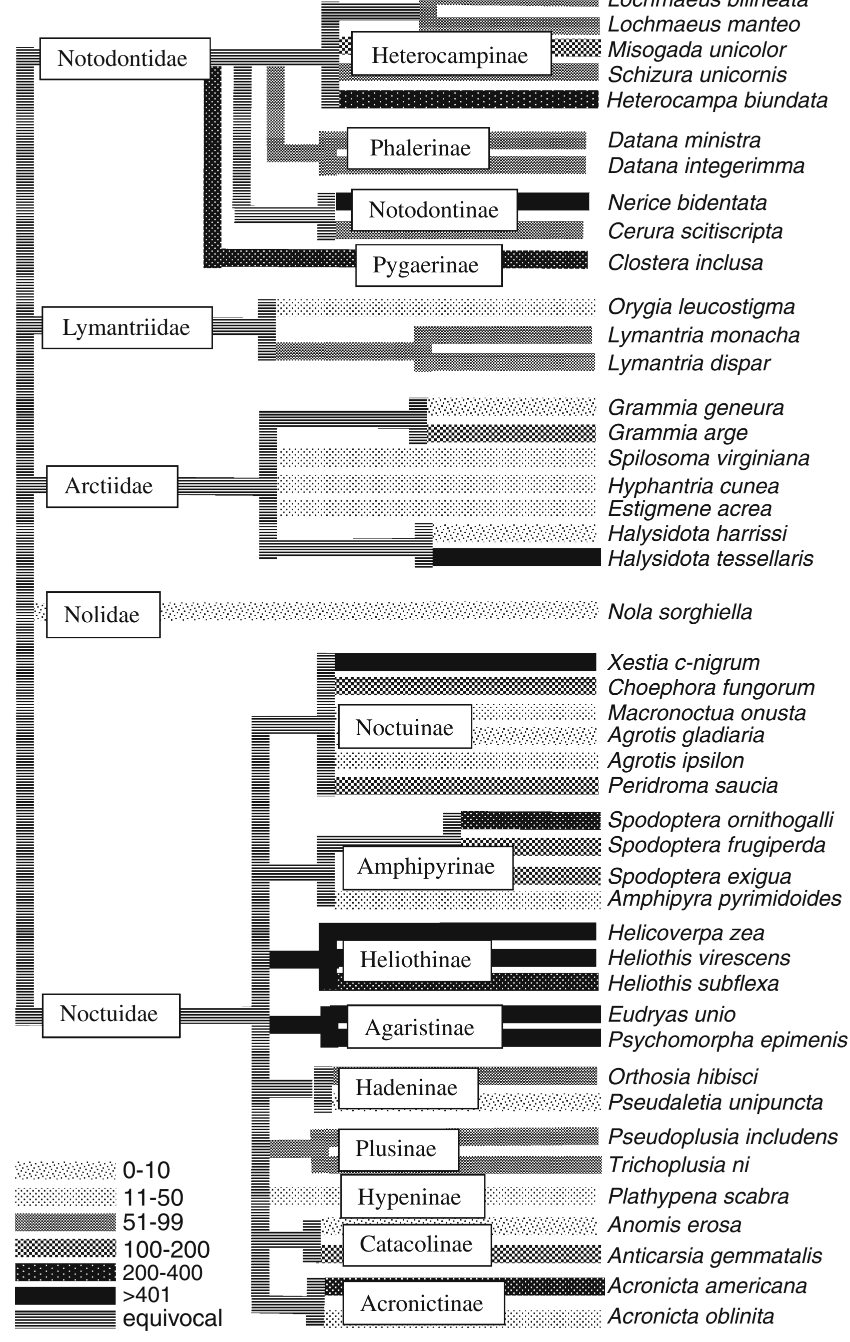

Fig. 1 Distribution of median labial gland glucose oxidase activities based on Noctuoidea phylogeny. Different line patterns represent classes of GOX activities delineated in Fig. 3. Equivocal data indicates uncertainty about the ancestral state of glucose oxidase activity for each taxon. Families and subfamily names are labeled

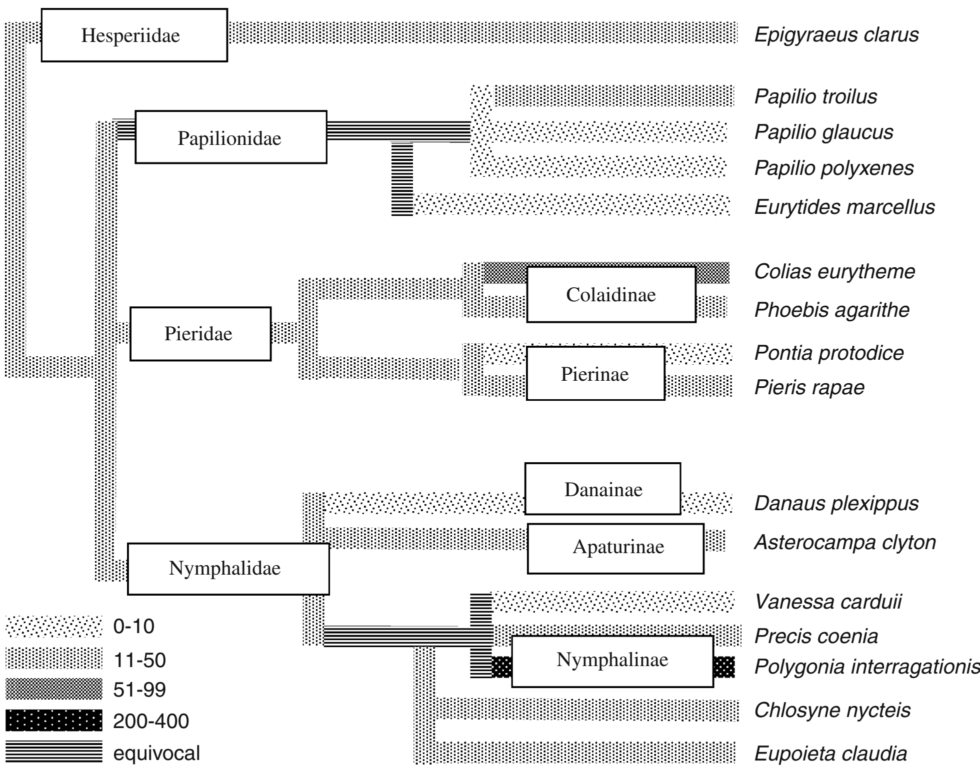

Fig. 2 Distribution of median labial gland glucose oxidase activities based on Papillionoidea phylogeny. Different line patterns represent classes of GOX activities delineated in Fig. 3. Equivocal data indicates uncertainty about the ancestral state of glucose oxidase activity for each taxon. Families and subfamily names are labeled

caterpillars (Wilcoxon rank sum test, $Z=-2.98$, $P=0.003$) (Fig. 4). Sixty-two % of the oligophagous caterpillar species (median activity = 25.4) had GOX activities of less than 50 nmol/min/mg protein, whereas 53% of the polyphagous species (median activity = 107.7) had activities greater than 100 nmol/min/mg. Forty-seven % of the oligophagous species and 53% of the polyphagous species were collected from woody species, but no trend for high or low GOX activities was found for caterpillars collected from woody or herbaceous host plants. A comparison of GOX activities among species collected from the same or closely related host plants or diets also did not reveal any pattern. For example, caterpillars reared on artificial diet had activities that ranged from 0.2 nmol/min/mg (*Manduca sexta*) to the highest activity of 2,680 nmol/min/mg (*H. zea*).

Glucose Oxidase Variation Among Caterpillars Fed Foliage from Different Hosts *Hyphantria cunea* collected on different tree species from four different plant families had seven-fold variation in GOX activities. Caterpillars collected on mulberry, *Morus alba*, and persimmon, *Diospyros virginiana,* had significantly higher activities ($P<0.05$) than caterpillars fed sweet gum, *Liquidambar styraciflua,* and black walnut*, Juglans nigra* foliage (Fig. 5). Two-way analysis of variance detected no significant differences between nests collected from of each

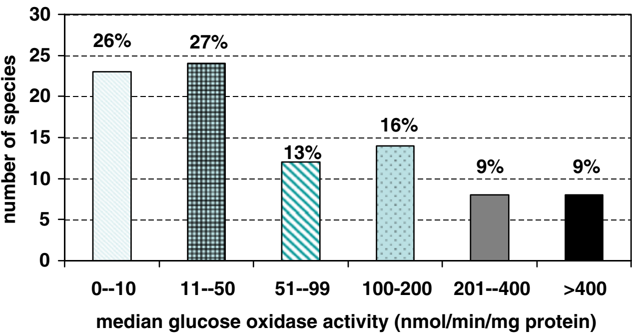

Fig. 3 Distribution of median glucose oxidase activities among caterpillar species. Activities were grouped into six categories (0–10, 11–50, 51–99, 100–200, 201–400, >400). Percentage of species is shown above each bar

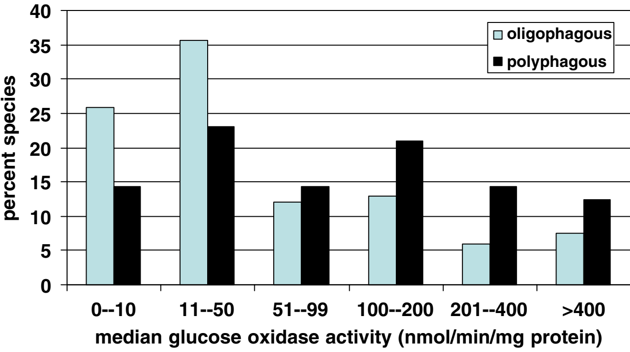

Fig. 4 Distribution of median glucose oxidase activities among polyphagous (≥3 host plant families) and oligophagous families (<3 host plant families). Activities were grouped into six categories (0–10, 11–50, 51–99, 100–200, 201–400, >400)

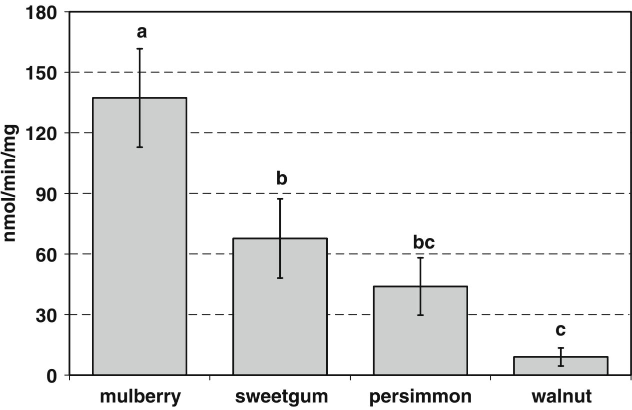

Fig. 5 Glucose oxidase activities of *Hyphantrea cunea* labial glands collected from four different tree species. Bars with different letters are significantly different (Tukey's HSD $P<0.05$)

tree species ($F=0.60$, $P=0.45$, $df=2$) but there was significant variation caused by the tree species ($F=8.02$, $P<0.005$, $df=3$) and a significant tree × nest interaction ($F=3.72$, $P=0.03$, $df=6$). The GOX activities in *Manduca sexta* (Carolina colony) were not affected by the various solanaceous hosts tested, but when compared to larvae fed an artificial diet, GOX activities were somewhat higher than those larvae fed foliage (Fig. 6a). *Manduca sexta* collected near Fayetteville, AR however, had significantly higher GOX activities than the laboratory colony (Fig. 6b). *Helicoverpa zea* also showed significant variation in GOX activities when reared on different diets (Fig. 7). Larvae feeding on cotton and soybean showed lower activity than diet-fed or geranium-fed larvae. Larval *H. virescens* fed tobacco showed lower activity than diet-fed, but there was no statistical difference between larvae on wild-type or nahG tobacco (Fig. 8).

Glucose Oxidase Variation in Artificial Diets Supplemented with Different Ingredients The stereochemistry of dietary glucose did not significantly affect GOX activities. Both D- and L-glucose rations resulted in similar GOX activities in the labial glands of 2-day old sixth instar *H. zea* (Fig. 9a). In the same experiment, when no supplemental glucose was added to the diet, lower GOX activities were measured in the labial glands (Fig. 9a). Adding the disaccharides amylose and sucrose to test diets resulted in GOX activities less than when larvae were fed 2% glucose (Fig. 9b).

Discussion

While GOX has been studied extensively in certain fungi such as *Aspergillus niger* (Wong et al., 2008), GOX has been identified sporadically in insects such as the honey bee *Apis mellifera* (Iida et al., 2007; Li et al., 2008), the aphid *Myzus persicae* (Harmel et al., 2008), lepidopterans including *Helicoverpa zea* (Eichenseer et al., 1999), *Helicoverpa armigera* (Zong and Wang, 2004), *Helicoverpa assulta* (Zong and Wang, 2004), *Spodoptera exigua* (Babic et al., 2008), *Mamestra configurata* (Merkx-Jacques and Bede, 2004), and the grasshopper *Schistocerca americana* (Candy, 1979). This current study is the most comprehensive survey of GOX yet conducted in insects, and greatly extends the number of species that possess quantifiable salivary GOX activities.

Interspecific comparisons were confounded by different diets and the specific time during development when glands were dissected; nevertheless, we believe that species differences do exist. For example, in the heliothine caterpillars significant variation exists among the three species assayed, as they were 1) reared on the same artificial diet, and 2) the glands were collected at similar points during larval development, two days into the last stadium. In another comparison, four noctuid species (*P. scabra*, *A. gemmatalis*, *H. zea*, and *P. includens*) collected on soybeans in the same field late in the growing season within several days of each other also showed at least 10-fold differences in GOX activities.

Because of its multifunctional roles in immunity (Eichenseer et al., 1999; Musser et al., 2005b; Yang and Cox-Foster, 2005), suppression of host defenses, and detoxification, it is not surprising that our findings indicate that GOX is widespread among caterpillar species. However, there were at least three orders of magnitude range in the activities of GOX in the labial glands of caterpillars. This variability is due to interspecific and intraspecific variation in activity. The host plant contributes to significant variation in GOX activities. In some cases, GOX activity was much lower when larvae feed on artificial diet (Merkx-Jacques and Bede, 2005; Yong-Hong et al., 2008), but in the case of *H. zea*, we found that although the particular species of host plant affects activity, there is still substantial activity compared to artificial diet-fed larvae (Peiffer and Felton, 2005). The nutritional or phytochemical factors that may contribute to GOX differences observed in larvae feeding on various host plants are not known. In studies with artificial diets or leaf supplementation, both protein and carbohydrate levels appear to be important in regulating GOX activity. Dietary protein was positively correlated with GOX activity in *S. exigua* (Babic et al., 2008). In *Helicoverpa armigera*, carbohydrates, including sucrose and glucose, were found to increase GOX activities, whereas several plant phenolics such as chlorogenic acid, rutin, and quercetin had no effect (Yong-Hong et al., 2008). In our studies, we have found that dietary glucose similarly affects GOX activities, but that labial GOX activity remains high even during starvation regimes (data not shown). It appears that development has a greater influence on variation than the presence or absence of diet. The host plant or diet not only affects the GOX synthesis within the glands, it also affects the secretion onto the plant surface (Peiffer and Felton, 2005). Consequently, the amount of GOX activity measured in the labial glands does not necessarily indicate how much a given caterpillar species may deposit on the plant surface. At present, we do not know if this variation in GOX synthesis and secretion plays an adaptive role in fitness on respective host plants or if it is merely a consequence of dietary factors and developmental stage.

We observed not only the wide occurrence of GOX among caterpillar species, but also its association with dietary host plant breadth. The majority of herbivorous insects are host specialists, and the mechanisms contributing to host specialization have been comparatively well-studied (Bernays and Graham, 1988; Futuyma and Moreno, 1988; Dyer, 1995). Unfortunately, our understanding of the behavioral/physiological traits that facilitate the expansion of host-range in polyphagous herbivores are, by comparison, poorly understood. Traits such as broad substrate specificity of detoxification enzymes (Mao et al.,

2007), canal cutting behaviors to deactivate defensive plant canals (Dussourd, 2009), and avoidance or suppression of induced defenses (Agrawal, 2000) have been studied as potential mechanisms underpinning host expansion. Our finding that GOX activities are generally higher in polyphagous species suggests a potential mechanism that could contribute to host-range expansion in caterpillar species. Karban and Agrawal (2002) argued that phenotypic plastic traits often are employed by generalist herbivores to maximize their fitness in variable environments. There is now ample data indicating that GOX is subject to considerable phenotypic plasticity due to diet. The relationship of GOX activity and host plant breadth warrants further research.

It is unknown if the effect of GOX on suppression of host-induced defenses is a widespread phenomenon or if it may be restricted to a limited number of host plant species. Nevertheless, GOX suppression of jasmonate-regulated, induced defenses is becoming increasingly recognized as more plant-insect systems are investigated (Musser et al., 2002; Zong and Wang, 2004; Bede et al., 2006; Delphia et al., 2006; Weech et al., 2008). To date, GOX is the one component of caterpillar saliva that has been identified in the suppression of these defenses (Musser et al., 2002; Zong and Wang, 2004; Bede et al., 2006; Diezel et al., 2009).

In addition to suppressing induced defenses, the breadth of potential GOX actions that can circumvent plant defenses is striking. For instance, fungal GOX inhibits the activity of several tomato oxidative enzymes (e.g., polyphenol oxidase, peroxidase, and lipoxygenase) (Begliomini et al., 1995), all of which have been implicated in defense against lepidopteran larvae (Felton et al., 1989, 1994; Felton and Duffey, 1991; Bi and Felton, 1995; Bi et al., 1997a). Because insect GOX has similar substrate specificity and catalytic activity compared to the fungal enzyme, it is not surprising that *H. zea* salivary GOX also inhibits these enzymes (unpublished data). GOX is a potent O_2 scavenger (Wong et al., 2008), and its enzymatic product, gluconic acid, is known to scavenge free radicals (Kataria et al., 1997) and inhibit polyphenol oxidases (Lopez-Caballero et al., 2006). In the presence of low O_2 levels, GOX enzymes may utilize quinone substrates as electron acceptors, thus functioning as a quinone reductase (Leskovac et al., 2005). This may be particularly significant when saliva is ingested in the nearly anaerobic guts of some lepidopteran larvae (Johnson and Barbehenn, 2000). We have found that GOX is stable in the digestive tract of *H. zea* (Eichenseer et al., 1999) and even retains activity in the feces (unpublished data). Consequently, GOX may be a factor in mitigating the oxidation of ingested plant compounds/nutrients formed at the plant-insect interface and throughout the digestive system.

Further molecular characterization of GOX and the analysis of the salivary proteome of *H. zea* is underway in our laboratory. We anticipate that the roles of caterpillar saliva in circumventing plant defense, detoxifying plant products, and providing immunity to disease will be greater appreciated as additional salivary proteins are characterized from *H. zea* and other lepidoptera. Our findings to date, suggest that GOX may be one factor contributing to the expansion of host range among lepidopteran species.

Abstract We examined the effects of the flavonoids pinocembrin and quercetin on the feeding behavior, survival, and development of the Cucurbitaceae pest *Epilachna paenulata* (Coleoptera: Coccinellidae). In no-choice experiments, 48 hr-consumption of *Cucurbita maxima* Duch. leaves treated with pinocembrin at 1, 5, and 50 μg/cm^2 was less than one third of that for leaves treated with 0.1 μg/cm^2 of pinocembrin or untreated leaves. Larvae stopped feeding after 9 days of high doses of pinocembrin (5 and 50 μg/cm^2), and larval weight and survival were negatively affected by pinocembrin at 1–50 μg/cm^2. Delayed mortality in comparison to food-deprived larvae suggests that the mechanism of action for pinocembrin is chronic intoxication, rather than simple starvation from antifeedant effects. In contrast, leaf consumption and larval weight were not significantly affected by quercetin (at 0.1, 1, 5, and 50 μg/cm^2) while mortality rates were only slightly increased. The response of *E. paenulata* larvae in a choice-test to combinations of pinocembrin at antifeedant doses (5 and 50 μg/cm^2) and quercetin at phagostimulant doses (0.01 and 0.1 μg/cm^2) indicated that the feeding deterrent activity of the former completely overshadowed the stimulant activity of the latter. These results demonstrate the different responses of one insect species to two widely distributed plant flavonoids. Pinocembrin strongly affected survival of *E. paenulata* while quercetin had only a weak effect without major consequences on the insect life-cycle.

Key Words Flavonoids · Pinocembrin · Quercetin · *Epilachna paenulata* · Antifeedant · *Coleoptera coccinellidae*

Introduction

Flavonoids are widely distributed in the plant kingdom and are involved in various aspects of plant interactions with other organisms. Increasing evidence suggests a role of flavonoids in plant defenses by contributing to disease resistance and protection against insect herbivory (Harborne and Williams, 2000; Treutter, 2006). The role of flavonoids in insect-plant interactions is complex, with some compounds apparently involved in host recognition, while others may deter or stimulate either feeding or oviposition (Simmonds, 2001).

Recently, we reported (Diaz Napal et al., 2009) on the differential effects of two flavonoids that are widely distributed in nature, pinocembrin (**1**), a flavanone which is found in conifers and Asteraceae species (Dillon and Mabry, 1977; Tewtrakul et al., 2003; Adelmann et al., 2007; Lin et al., 2007), and quercetin (**2**), a ubiquitous, abundant and intensively studied flavonol (Harnly et al., 2006; Harwood et al., 2007) (Fig. 1). When choice-tested at

different doses on *Epilachna paenulata*, **1** demonstrated a clear antifeedant activity, whereas **2** elicited variable behavioral responses (phagostimulant or antifeedant) in the same insect species, depending on the dosage (Diaz Napal et al., 2009). *Epilachna paenulata* (Germar) (Coleoptera: Coccinellidae) is a folivorous South American pest of the Cucurbitaceae species (Camarano et al., 2009), which we have used extensively as a model insect for natural insecticide activity studies (Carpinella et al., 2002, 2003; Maggi et al., 2005; Palacios et al., 2007).

We asked whether the antifeedant (**1** and **2**) and phagostimulant (**2**) effects have consequences on the survival of insects. In order to answer these questions we carried out a comparative study on the effects of these compounds on feeding behavior and survival of *E. paenulata*.

Behavioral experiments have shown that insect responses to a particular compound can be modulated by the presence of other compounds (Simmonds, 2001, 2003). We examined how insects react to the simultaneous presence of both compounds. The system *E. paenulata*-Cucurbitaceae, in which the insect is sensitive to both compounds, and neither compound is found in the plant, provides a neutral study system.

Methods and Materials

General Experimental Procedures and Apparatus ^{1}H (200 MHz) and ^{13}C (50 MHz) NMR spectra were recorded on a Bruker NMR with a Bruker AC 200 console (Bruker, Germany). Tetramethylsilane (TMS) was used as the internal reference (δ 0.00) for ^{1}H and ^{13}C NMR spectra measured in DMSO-d_6. Electron impact mass spectra (EI-MS) were obtained at 70 eV by GC–MS on a Hewlett–Packard 5970 Series mass spectrometer interfaced with a Hewlett–Packard 5890 gas chromatograph (Hewlett-Packard, Santa Clara, CA, USA) fitted with an HP-5MS, 15 m×0.25 mm i.d. column. The temperature was increased from 100 to 200°C at 10°C/min. The optical rotation angle was measured in a JASCO DIP-370 spectropolarimeter (JASCO Co., Tokyo, Japan).

Fig. 1 Chemical structures of pinocembrin (**1**) and quercetin. (**2**)

Chemicals and Chromatographic Media Pinocembrin, used as a reference sample, quercetin, used in the bioassays, and SiO_2 for column chromatography were purchased from Sigma Chemical Co. Inc. (St. Louis, MO, USA). Analytical TLC was performed on silica gel 60 F_{254} Merck plates (Darmstadt, Germany). All other solvents were purchased from Merck (Darmstadt, Germany) and Fisher Scientific (Jersey City, NJ, USA).

Isolation of Pinocembrin **1** was isolated from aerial parts of *Flourensia oolepis* S.F. Blake (Asteraceae) as reported previously (Diaz Napal et al., 2009). In brief, air-dried aerial parts of *F. oolepis* (97 g) were extracted with ethanol for 24 hr at room temperature. After solvent removal under reduced pressure, the extract (1.8 g) was fractionated by silica gel column chromatography until a crystalline solid was isolated (258 mg, 1.14% yield with respect to plant material) and identified as pinocembrin by ^{1}H NMR, ^{13}C NMR and MS.

Pinocembrin (**1**): white powder; mp 194–195°C; $[\alpha]_D^{20}$= −22.81 (*c* 0.86, EtOH); EI-MS: *m/z* (relative intensity, %) 256 (100 M^+) , 179 (82), 152 (67), 124(52), 96 (31), 69 (34); ^{1}H NMR (DMSO-d_6), 20.7°C, δ 2.77 (1H, dd, *J*=17.2, 3.2 Hz, H-3a), 3.06 (1H, dd, *J*=12.8, 17.2 Hz, H-3b), 5.44 (1H, dd, *J*=3.2, 12.8 Hz, H-2), 5.52 (1H, d, *J*=2.2 Hz, H-6), 6.01 (1H, d, *J*=2.2 Hz, H-8), 7.41 (5H, m, H-2′-6′); ^{13}C NMR 25°C, δ 40.45 (C-3), 80.17 (C-2), 95.94 (C-8), 96.84 (C-6), 102.69 (C-10), 127.47 (C-2′/6′), 129.39 (C-4′) 129.46 (C-3′/5′), 139.59 (C-1′), 163.59 (C-9), 164.41 (C-5), 167.62 (C-7), 196.75 (C-4). The spectral data were identical to previously published data of **1** (Bick et al., 1972; Neacsu et al., 2007; Adelmann et al., 2007).

Insects Epilachna paenulata larvae were obtained from a laboratory colony, reared on a natural diet of *Cucurbita maxima* Duch. leaves and maintained in a growth chamber at 24±1°C and 70–75% relative humidity, with a photoperiod of 16/8 hr light-dark cycle, and periodically renewed with field specimens (Maggi et al., 2005).

Leaf Treatments For all bioassays, cotyledon leaves of *C. maxima* seedlings were treated with acetone, which was allowed to evaporate before the insect trial began. The compounds were dissolved at sufficient concentration to achieve the desired doses, ranging from 0.01 to 50 μg/cm^2, in a single 10 μl aliquot. Control leaves were treated with pure acetone. The compounds were applied, and acetone was allowed to evaporate before starting the assay.

Feeding Choice Assay The antifeedant experiments were carried out by the leaf-disk choice test (Carpinella et al., 2002). The dosages applied for **1** and **2** were 1, 5 and 50 and 0.1 and 0.01 μg/cm^2, respectively. Two cotyledon leaves

from a *C. maxima* seedling were placed in a Petri dish; a glass disk with two 1 cm^2 diam holes was placed on top. A third-instar *E. paenulata* was placed equidistant from both a treated (with 10 µl of test solution) and an untreated (10 µl of acetone, solvent control) leaf disk and was allowed to feed for 24 hr. Ten replicates were run for each binary combination tested. Relative amounts (recorded in percentages from 0 to 100) of the treated and untreated substrate area eaten in each test were estimated visually by dividing the food area into imaginary quarters. A feeding index (FI%) was calculated as $[(C-T)/(C+T)] \times 100$ (e.g., Mazoir et al., 2008), where T and C represent consumption on treated and untreated foods, respectively. Effective dose 50 (ED_{50}) values for **1** were determined from the FI% data, using Probit analysis.

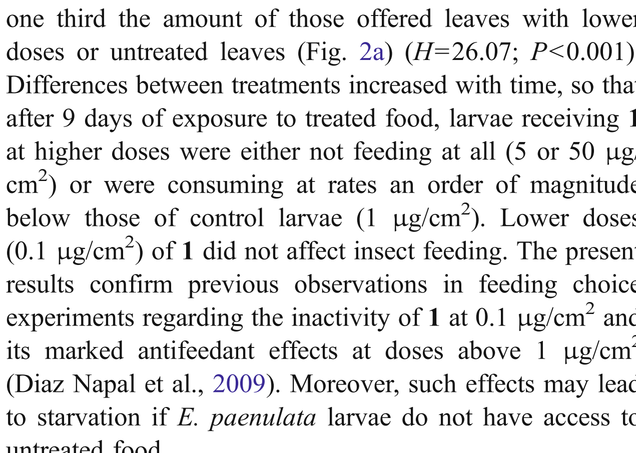
No-choice Feeding Assay One *E. paenulata* larva (first instar) was placed in a Petri dish containing *C. maxima* leaves that had been treated with acetone solutions of either pure **1** or pure **2,** at dosages of 0.1, 1, 5, or 50 µg/cm^2. Leaves were replaced every 24 hr. Ten replicates were used for each treatment. Leaf consumption and body weight were recorded every 24 hr and 48 hr, respectively (Carpinella et al., 2003).

Mortality Assay A group of 10 larvae of *E. paenulata* (first instar) was fed continuously with leaves treated either with 0.1, 1, 5, and 50 µg/cm^2 of pure **1**, pure **2** or acetone (control). A similar set of larvae was not fed at all and acted as food-deprived controls. Three replicates were performed for each treatment. Mortality was recorded every 24 hr. From mortality data, lethal dose 50 (LD_{50}) and lethal time 50 (LT_{50}) values for **1** and **2** were determined by Probit analysis. LD_{50} and LT_{50} were calculated at doses or times at which **1** provoked mortality values below as well as above 50%, thus enabling the Probit calculation.

Statistical Analysis Data did not conform to requirements of normal distribution and homocedasticity, therefore non-parametric tests were used. Results from choice tests were analyzed by the Wilcoxon Signed Rank Test. For each compound, results from no-choice tests on average larval body weight, accumulated consumption values, and average mortality rates at each date, were compared among concentrations by the Kruskal Wallis non-parametric analysis of variance, followed by the Dunn test. Statistical analyses were performed using the SPSS statistical package. Differences were considered significant at $P \leq 0.05$.

Results and Discussion

After 48 hr of exposure to leaves treated with **1** at 1, 5, or 50 µg/cm^2, larvae of *E. paenulata* had consumed less than



one third the amount of those offered leaves with lower doses or untreated leaves (Fig. 2a) ($H=26.07$; $P<0.001$). Differences between treatments increased with time, so that after 9 days of exposure to treated food, larvae receiving **1** at higher doses were either not feeding at all (5 or 50 µg/cm^2) or were consuming at rates an order of magnitude below those of control larvae (1 µg/cm^2). Lower doses (0.1 µg/cm^2) of **1** did not affect insect feeding. The present results confirm previous observations in feeding choice experiments regarding the inactivity of **1** at 0.1 µg/cm^2 and its marked antifeedant effects at doses above 1 µg/cm^2 (Diaz Napal et al., 2009). Moreover, such effects may lead to starvation if *E. paenulata* larvae do not have access to untreated food.

In contrast, the food consumption by larvae fed with **2** did not differ significantly from that of the controls at any dosage or at any time during the experiment (Fig. 3a). In the 12-day experiment, larvae faced with leaves treated with 0.1, 1, 5, and 50 µg/cm^2 of **2** ate as much food as the controls ($H=6.50$; $P=0.066$). Thus, neither the antifeedant nor the dose-dependent phagostimulant activity previously

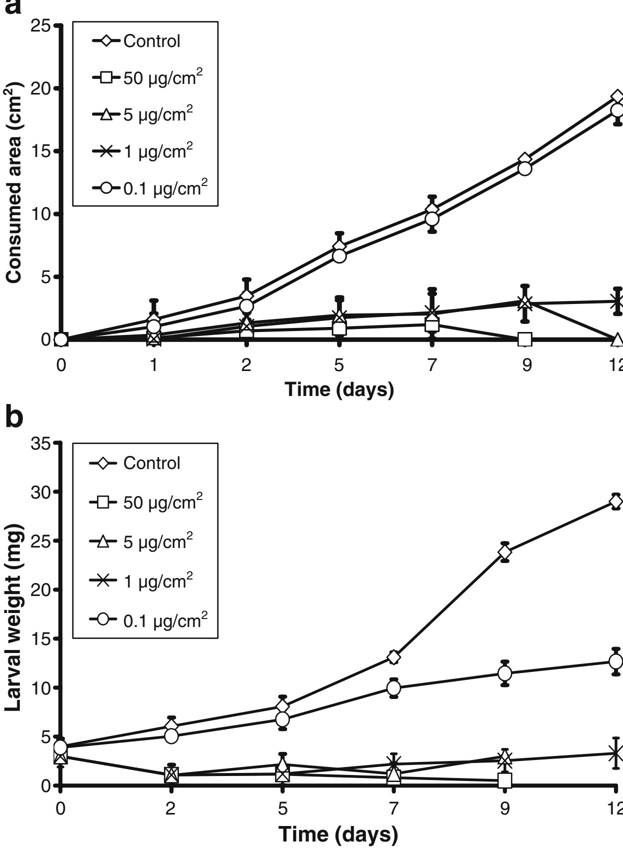


Fig. 2 Average leaf area consumed (**a**) and average body weight (**b**) of *Epilachna paenulata* larvae fed on leaves treated with **1** in no-choice assay. Error bars show standard deviation, where error is not shown it is smaller than the symbol

observed in choice assays with **2** (Diaz Napal et al., 2009), were detected in this system where insects could not switch to untreated food. These results confirm the necessity of comparing different methodologies when studying insect response to plant allelochemicals (Stuart and Polavarapu, 1998).

Larval weight data (Fig. 2b) demonstrated that whereas control larvae body weight steadily increased, larvae treated with **1** at 1 μg/cm^2 or higher doses either did not gain weight or lost weight. From 48 hr onward, significant differences in body weight (H=38.62; P<0.001) were observed between control larvae and those receiving food treated with **1** at doses of 1 μg/cm^2 or higher. After 7 days of receiving food treated with 5 or 50 μg/cm^2 of **1**, larvae had lost about half their original weight (Fig. 2b). Larvae fed on leaves treated with 0.1 μg/cm^2 of **1** gained some weight, but less weight (H=4.20; P<0.001) than control larvae starting at day 9. Compound **2** did not affect the body weight of *E. paenulata* larvae (Fig. 3b) (H=5.51; P=0.2379).

Treatment of leaves with **1** increased larval mortality (Fig. 4a), particularly at the highest dose (50 μg/cm^2), which induced 100% mortality after 12 days. At lower doses of **1**, mortality reached between 20 and 60%. After 5 days of receiving treated food, mortality rates were significantly higher than those observed in the controls (H=30.20; P<0.001) for all concentrations higher than 0.1 μg/cm^2. Food-deprived larvae did not survive longer than 5 days. These results indicate that the presence of **1** on the food of *E. paenulata* larvae strongly affected their survival through feeding inhibition, consistent with the well-established role of flavonoids in the defense of plants against herbivory (Harborne and Williams, 2000).

Larvae offered food treated with **2** at any of the doses tested died at the same rate as the controls (P>0.05) (Fig. 4b). All treatments were significantly different (P< 0.001) from the food-deprived group. According to these results, **1** strongly affected survival of *E. paenulata* larvae, whereas **2** had no major effects on the insect life-cycle.

The LD_{50} of **1** at 124 hr was 18.4 (6.0–56.6) μg/cm^2. A comparison of this value with those reported for the same insect for meliartenin (LD_{50}=0.76 μg/cm^2) and azadirachtin (LD_{50}=1.24 μg/cm^2) (Carpinella et al., 2003), indicates that pinocembrin is 24 and 15 times less active than those compounds, respectively. In molar units, LD_{50} for pinocembrin (70 nmol/cm^2) was 50 and 41 times higher than the

Table 1 Lethal time (LT_{50}) for compound **1** and for food-deprived control in larvae of *Epilachna paenulata* in no-choice feeding assay

Dosage (μg/cm^2)	LT_{50}[a] in days (values and 95% confidence interval)	
	1	Food-deprived larvae
50	5 (4.73–5.87)	
5	8 (6.47–9.47)	
1	10 (8.10–11.85)	
		4 (3.07–4.23)

[a] LT_{50} is the time required to obtain 50% mortality

value for meliartenin (1.4 nmol/cm^2) and azadirachtin (1.7 nmol/cm^2), respectively.

Insects consuming leaves treated with **1** died later than food-deprived larvae, suggesting that the mechanism of activity for **1** is chronic intoxication rather than simple starvation (Defagó et al., 2009). Lethal times 50 (LT_{50}) for **1** (Table 1) were 5, 8, and 10 days for 50, 5 and 1 μg/cm^2, respectively. The LT_{50} for food-deprived larvae was 4 days. Comparing the LT_{50} at 1 μg/cm^2 with the values obtained for meliartenin and azadirachtin on the same insect (Carpinella et al., 2003), **1** acted approximately 4 and 2 times more slowly than meliartenin and azadirachtin, respectively.

It was not possible to calculate LD_{50} and LT_{50} for **2,** since mortality rates did not reach 50% at any point of the experiment (Fig. 4b).

Responses to plant secondary metabolites often play a crucial role in the feeding behavior of herbivore insects. Such responses result from the integration of information provided by taste and olfactory cells (van Loon, 1990) as well as from other extrinsic and intrinsic factors operating on and in the insect (Bernays and Chapman, 2001). Responses of chemical receptors to a specific stimulus may be modified by the presence of other plant constituents, so it may be impossible to predict the response to complex stimuli on the basis of single compound responses (Schoonhoven and van Loon, 2002). Combinations of **1** and **2** were assayed in a choice test, at doses at which **2** was expected to act as phagostimulant and **1** as an antifeedant. Choice assays of these mixtures with *E. paenulata* revealed that the ED_{50} of **1** was approximately the same when offered with or without **2** (Table 2). This insect recognized **1** as a feeding deterrent, and this effect was not modified by the presence of **2** at phagostimulant levels. Increased concentration of a deterrent compound can not only increase activity of the deterrent-sensitive cells, but may also suppress the activity of cells responding to phagostimulants (Bernays and Chapman, 2000), and therefore, negative inputs may dominate insect response to feeding stimulation (Chapman, 2003).

It is not possible to predict the effect of different flavonoids on insects from structural features of the compounds, although empirical evidence suggests that the structure can be important (Simmonds, 2001). According to Morimoto et al. (2000), hydroxyl groups at any position favor antifeedant activity against *Spodoptera litura*, but this

[a] Feeding index for pinocembrin, calculated as $(FI\%) = [(C - T)/(C + T)] \times 100$, values are means of 10 replicates. Significant differences between consumption on treated and control leaves (Wilcoxon signed rank test *$P<0.05$, **$P<0.01$)

idea was not supported by our results since **2** has three more hydroxyl groups than **1**. A further complication arises from the variability in the responses of different insects to the same flavonoid (Simmonds, 2001, 2003). Our results support this observation and suggest that such effects might also depend on compound dosage. The growth of the corn borer *Ostrinia nubilalis* Hubner was reduced by 10 mg/g of **1** added to an artificial diet (Abou-Zaid et al., 1993). In contrast, **1** was reported as attractant and phagostimulant to *Scolytus mediterraneus* (Levy et al., 1974). Insect response to **2** varies greatly. This flavonoid may act as a phagostimulant for some insects, may be either a phagostimulant or a deterrent depending on the concentration tested for other insects (Lattanzio et al., 2000; Green et al., 2003; Simmonds, 2003), and may be inactive in other cases (Morimoto et al., 2000).

In summary, we have shown that compound **1** inhibited feeding and negatively affected survival of the cucurbit insect pest *E. paenulata*. We also found that **1** masked the phagostimulant effects of **2** in a choice test. According to the present results, **1** is less active than other well-known antifeedants such as azadirachtin or meliartenin, but its availability in a variety of plant species and its molecular simplicity, which could allow inexpensive chemical synthesis, suggest that **1** could be applied as an feeding deterrent or could be a target for plant improvement programs to increase natural crop resistance to herbivory.

Abstract Glucosinolates are a diverse group of defensive secondary metabolites that is characteristic of the Brassicales. *Arabidopsis thaliana* (L.) Heynh. (Brassicaceae) lines with mutations that greatly reduce abundance of indole glucosinolates (*cyp79B2 cyp79B3*), aliphatic glucosinolates (*myb28 myb29*), or both (*cyp79B2 cyp79B3 myb28 myb29*) make it possible to test the *in vivo* defensive function of these two major glucosinolate classes. In experiments with Lepidoptera that are not crucifer-feeding specialists, aliphatic and indole glucosinolates had an additive effect on *Spodoptera exigua* (Hübner) (Lepidoptera: Noctuidae) larval growth, whereas *Trichoplusia ni* (Hübner) (Lepidoptera: Noctuidae) and *Manduca sexta* (L.) (Lepidoptera: Sphingidae) were affected only by the absence of aliphatic glucosinolates. In the case of two crucifer-feeding specialists, *Pieris rapae* (L.) (Lepidoptera: Pieridae) and *Plutella xylostella* (L.) (Lepidoptera: Plutellidae), there were no major changes in larval performance due to decreased aliphatic and/or indole glucosinolate content. Nevertheless, choice tests show that aliphatic and indole glucosinolates act in an additive manner to promote larval feeding of both species and *P. rapae* oviposition. Together, these results support the hypothesis that a diversity of glucosinolates is required to limit the growth of multiple insect herbivores.

Introduction

The glucosinolate-myrosinase system is a characteristic defense of the Brassicaceae and related plant families (Halkier and Gershenzon, 2006). In the absence of herbivore attack, glucosinolates, β-thioglucoside-*N*-hydroxyiminosulfates with diverse, amino acid-derived side chains, are stored separately from the activating enzyme, myrosinase (β-thioglucoside glucohydrolase, EC 3.2.1.147). Tissue disruption during herbivory brings glucosinolates into contact with myrosinase, resulting in release of the glucose moiety and formation of biologically active breakdown products, including nitriles, isothiocyanates, thiocyanates, oxazolidine-2-thiones, and epithionitriles (Wittstock and Burow, 2010).

More than 120 different glucosinolate side chains have been identified (Fahey et al., 2001), and about forty of these are found in natural isolates of the model plant *Arabidopsis thaliana* (L.) Heynh. (Brassicaceae) (Kliebenstein et al., 2001; Reichelt et al., 2002). The metabolic diversity of glucosinolates, combined with variation in the breakdown pathways (Wittstock and Burow, 2010), likely results in several hundred defensive metabolites that can be formed during herbivory. Genetic modification of the glucosinolate breakdown pathway shows that qualitative changes affect herbivore resistance (Jander et al., 2001; Lambrix et al., 2001; Burow et al., 2006). Less is known about the specific defensive function of different glucosinolate classes, e.g., those derived from tryptophan, methionine, or phenylalanine. Increased production of both tryptophan-derived (indole) and methionine-derived (aliphatic) glucosinolates through overexpression of the MYB51 and MYB28 transcription factors, respectively, reduced herbivory by *Spodoptera exigua* (Hübner) (Lepidoptera: Noctuidae) on *A. thaliana* (Gigolashvili et al., 2007a, b). Both total glucosinolate content and, more specifically, methylsulfinylalkylglucosinolate levels were negatively correlated with *S. exigua* weight gain (Mewis et al., 2005; Rohr et al., 2006). The related *Spodoptera littoralis* (Boisduval) (Lepidoptera: Noctuidae) showed improved growth in the absence of indole glucosinolates (Schlaeppi et al., 2008). Similarly, reduced aliphatic glucosinolate content increased the growth of the generalist lepidopteran herbivore *Mamestra brassicae* (L) (Lepidoptera: Noctuidae) (Beekwilder et al., 2008).

Some crucifer-specialist insects, including *Pieris rapae* (L.) (Lepidoptera: Pieridae) and *Plutella xylostella* (L.) (Lepidoptera: Plutellidae), not only circumvent the release of toxic breakdown products from glucosinolates (Ratzka et al., 2002; Wittstock et al., 2004) but also co-opt these defensive metabolites as attractive signals. Glucosinolates elicit specific responses in maxillary chemoreceptors and stimulate feeding in both *P. rapae* and *P. xylostella* larvae (Verschaffelt, 1910; Thorsteinson, 1953; Van Loon et al., 2002; Miles et al., 2005). Among ten glucosinolates with side chains derived from tryptophan, methionine, or phenylalanine, indol-3-ylmethylglucosinolate was identified as the strongest oviposition stimulant for *P. rapae* oviposition *in vitro* (Renwick et al., 1992; Städler et al., 1995). Although most experiments show that glucosinolates have positive effects on *P. xylostella* feeding and oviposition (Sarfraz et al., 2006), individual glucosinolates that were increased in transgenic lines did not have unequivocal effects (Sarosh et al., 2010), and 3-butenylglucosinolate levels in *A. thaliana* field studies were negatively correlated with female adult weight (Bidart-Bouzat et al., 2005).

In many *A. thaliana* accessions, the side chains of the most abundant foliar glucosinolates are derived from methionine or tryptophan (Wittstock and Halkier, 2002). Whereas plants with knockout mutations of both *CYP79B2* and *CYP79B3*, two cytochrome P450s that lead to the production of indole-3-acetaldoxime, are blocked in the production of indole glucosinolates (Zhao et al., 2002), double mutants of the *MYB28* and *MYB29* transcription factors have very low levels of aliphatic glucosinolates (Sønderby et al., 2007; Beekwilder et al., 2008). Quadruple mutants (*cyp79B2 cyp79B3 myb28 myb29*) are nearly devoid of both major classes of foliar glucosinolates found in *A. thaliana* Columbia-0 (Col-0; Sun et al., 2009). Together, these mutant lines provide a unique opportunity to investigate the relative *in vivo* function of aliphatic and indole glucosinolates in plant defense against different herbivores.

Methods and Materials

Plants and Growth Conditions *A. thaliana* Col-0 wildtype seeds were obtained from the Arabidopsis Biological Resource Center (ABRC, www.arabidopsis.org). The *cyp79B2 cyp79B3* mutant (Zhao et al., 2002) was kindly supplied by J. Celenza (Boston University, Boston, MA, USA). Creation of *myb28 myb29* and *cyp79B2 cyp79B3 myb28 myb29* mutants has been described previously (Sønderby et al., 2007; Sun et al., 2009). All mutations are in the Col-0 genetic background.

A. thaliana plants for *S. exigua, T. ni, P. xylostella,* and *Manduca sexta* (L.) (Lepidoptera: Sphingidae) experiments were grown in a Conviron (Winnipeg, Canada) chamber in 12×12 cm pots using Cornell Mix [by weight 56% Peatmoss, 35% Vermiculite, 4% Lime, 4% Osmocoat slow-release fertilizer (Scotts, Marysville, OH, USA), and 1% Unimix (Peters, Allentown, PA, USA)] at 23°C, 60% relative humidity, with a light intensity of 180 $\mu mol\, m^{-2} s^{-1}$ photosynthetic photon flux density and a 16:8 h light:dark photocycle. *Arabidopsis thaliana* for *P. rapae* experiments were grown on soil composed of 80% potting soil (Compo, Münster, Germany), 10% sand, 10% Perligran (Knauf Perlite, Dortmund, Germany), and Triabon (Compo, Münster, Germany) and Sierrablen (Scotts, Heerlen, The Netherlands) as fertilizer at 22°C, 60–70% relative humidity, 300 $\mu mol\, m^{-2} s^{-1}$ photosynthetic photon flux density, and a 10:14 h light:dark photocycle.

Insects and Growth Conditions *P. xylostella, T. ni,* and *S. exigua* eggs were purchased from Benzon Research (Carlisle, PA, USA). *M. sexta* eggs were kindly supplied by M. del Campo (Cornell University) and J. Beal (Boyce Thompson Institute). *P. xylostella* for feeding choice experiments were reared in paper cups (0.5 L, International Paper, Memphis, TN, USA) on artificial diet (Southland Products, Lake Village, AK, USA) at 23°C. *P. rapae* were

maintained on Brussels sprouts (*Brassica oleracea var. gemmifera*) in a chamber at 24°C, 65% relative humidity and a 16:8 h light:dark photocycle.

Larval Feeding no Choice Tests Lepidopteran eggs (*T. ni, M. sexta,* and *S. exigua*, and *P. xylostella*) were hatched at 23°C in paper cups (0.5 l, International Paper, Memphis, TN, USA) with a moist paper towel (C-fold white, Kimberly-Clark, Dallas, TX, USA). Individual neonate larvae were placed onto paired 18-d-old mutant and wildtype plants growing together in the same pot, and each individual plant was covered with a mesh cup. Larvae were harvested at 9 d (*T. ni*), 8 d (*M. sexta*), or 10 d (*S. exigua*). The length of the experiment for each species was chosen based on the differing intrinsic growth and feeding rates of the larvae. In each case, even the largest larvae had not consumed the entire *A. thaliana* plant at the end of the experiment. *Plutella xylostella* were harvested at pupation (8–10 d). Larvae and pupae were frozen on dry ice and were lyophilized overnight (~12 h), and weighed. Each experiment was conducted two to four times, giving similar results.

For *P. rapae* larval growth experiments, one neonate larva was placed in a pot containing one 6-wk-old *A. thaliana* Col-0 wildtype or mutant plant, respectively, covered with a perforated plastic bag and placed at 24°C and 65% relative humidity. The weight of the larvae was recorded after 10 d of feeding. For *P. rapae* pupation experiments, groups of ten neonate larvae were placed in a pot containing four 6-wk-old *A. thaliana* Col-0 wildtype or mutant plants, respectively, covered with a perforated plastic bag and placed at 24°C and 65% relative humidity. Additional food plants were provided on demand. Each experiment was run twice independently.

Larval Feeding Choice Tests For *P. xylostella* choice tests, leaves of similar age and size were harvested from paired 20-d-old mutant and wildtype *A. thaliana* plants growing together in the same pot. Leaf areas were scanned, and paired leaves were placed in Petri dishes (9 cm diam, ThermoFisher, Waltham, MA, USA), with their petioles embedded in 0.8% Phytagar (Invitrogen, Carlsbad, CA, USA). Larvae for experiments were raised for 3 d on artificial diet. A single larva was placed with each leaf pair and, after 3 d, leaves were collected and scanned again. Leaf area consumed was calculated using ImageJ (Rasband, 1997–2007). Leaf plug choice experiments were conducted in a similar manner. A single 3-d-old larva was placed in a Petri dish (4.5 cm diam, Thermo-Fisher, Waltham, MA, USA) with paired equal-sized leaf disks of each genotype (0.6 cm^2) on moist filter paper. After 24 h, leaves were scanned and leaf areas were calculated with ImageJ (Rasband, 1997–2007). Intact leaf and leaf plug experiments were conducted twice independently.

For *P. rapae* feeding choice tests, one third-instar *P. rapae* larva was allowed to feed on a pot containing two 6-wk-old plants of two *A. thaliana* lines that were being compared. After 24 h, the plant rosettes were harvested and scanned using a desktop scanner. The removed leaf area was completed and calculated with ImageJ (Rasband, 1997–2007). These experiments were conducted twice independently.

Oviposition Choice Tests For *P. rapae* oviposition experiments, adults were kept without plants for 6 d after eclosion to ensure mating and maximize egg production. A single *P. rapae* female then was introduced to a 39×28×28 cm plastic box containing two 7-wk-old plants, each from a different plant genotype. After 24 h, the eggs laid per plant were counted. These experiments were conducted twice independently.

Glucosinolate Analysis Glucosinolate extraction and HPLC analysis of desulphoglucosinolates was performed as previously described (Kliebenstein et al., 2001; Burow et al., 2006; Hansen et al., 2007), using half rosettes of 6-wk-old plants.

Data Analysis Statistical analyses were conducted with JMP (SAS Institute, Cary, NC, USA) and SigmaStat 3.1 (Systat Software, San José, CA, USA).

Results

Under the growth conditions used for insect experiments, *cyp79B2 cyp79B3* mutants contain little or no indole glucosinolates, *myb28 myb29* mutants have greatly decreased aliphatic glucosinolates, and *cyp79B2 cyp79B3 myb28 myb29* quadruple mutants are deficient in both indole and aliphatic glucosinolates (Table 1; Sun et al., 2009). To determine the relative effects of indole and aliphatic glucosinolate decreases on non-crucifer-specialist Lepidoptera, neonate *S. exigua*, *M. sexta,* and *T. ni* were caged on individual mutant and wildtype Col-0 *A. thaliana* plants. *Spodoptera exigua* larval weight was increased (Fig. 1a) on both *cyp79B2 cyp79B3* and *myb28 myb29* mutants compared to wildtype Col-0. An additive effect was observed in that the larvae grew better on the *cyp79B2 cyp79B3 myb28 myb29* quadruple mutant than on either of the double mutants (Fig. 1a). In contrast, *M. sexta* and *T. ni* weight gain was increased relative to controls only on lines deficient in aliphatic glucosinolates (*myb28 myb29* and the quadruple mutant; Fig. 1b, c). Although the effect was not

quantified, smaller larvae of all three species consumed visibly less plant material than larger ones.

Exogenous addition of glucosinolates is known to result in feeding stimulation for *P. xylostella* (Verschaffelt, 1910; Thorsteinson, 1953; Van Loon et al., 2002). However, we did not observe significant differences in pupal dry weight (Fig. 2a) or time to pupation (Fig. 2b) for *P. xylostella* larvae feeding on mutant and wildtype *A. thaliana.* Although choice tests with intact leaves did not show significant feeding preferences (Fig. 2c), larvae consumed significantly

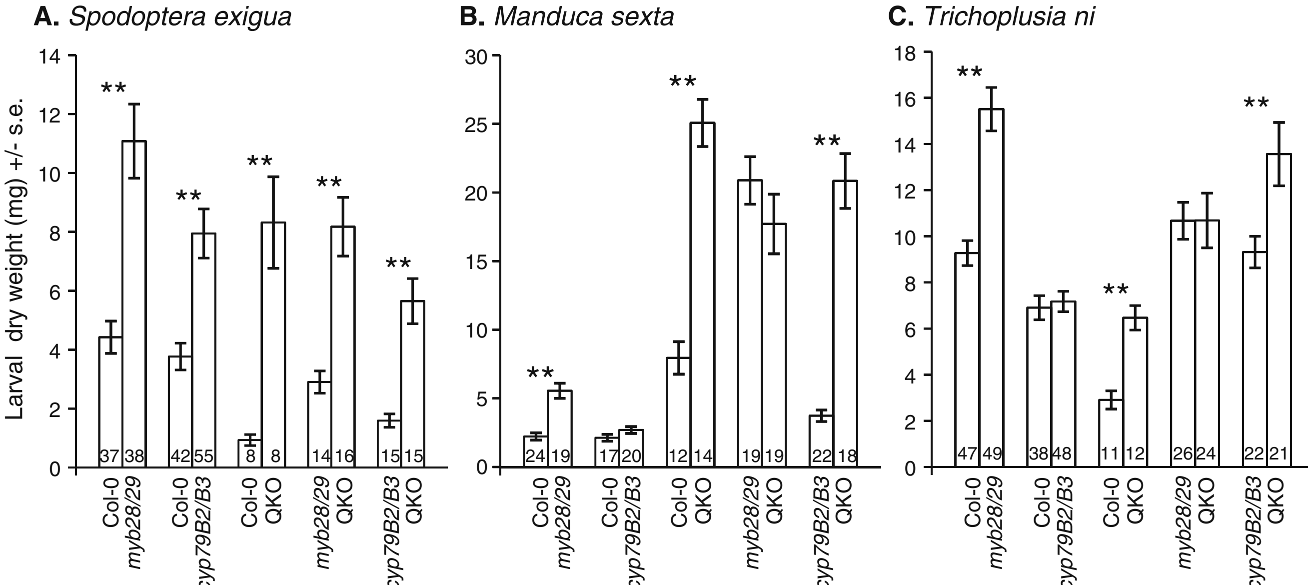

Fig. 1 Dry weight of non-crucifer-specialist Lepidoptera feeding on *Arabidopsis thaliana* Col-0 wildtype and mutants deficient in aliphatic glucosinolates (*myb28/29*), indole glucosinolates (*cyp79B2/B3*), or both (QKO, quadruple knockout) in no-choice tests. **a** *Spodoptera exigua* after 10 d **b** *Manduca sexta* after 8 d **c** *Trichoplusia ni* after 9 d. Additional replicates of these experiments showed similar results

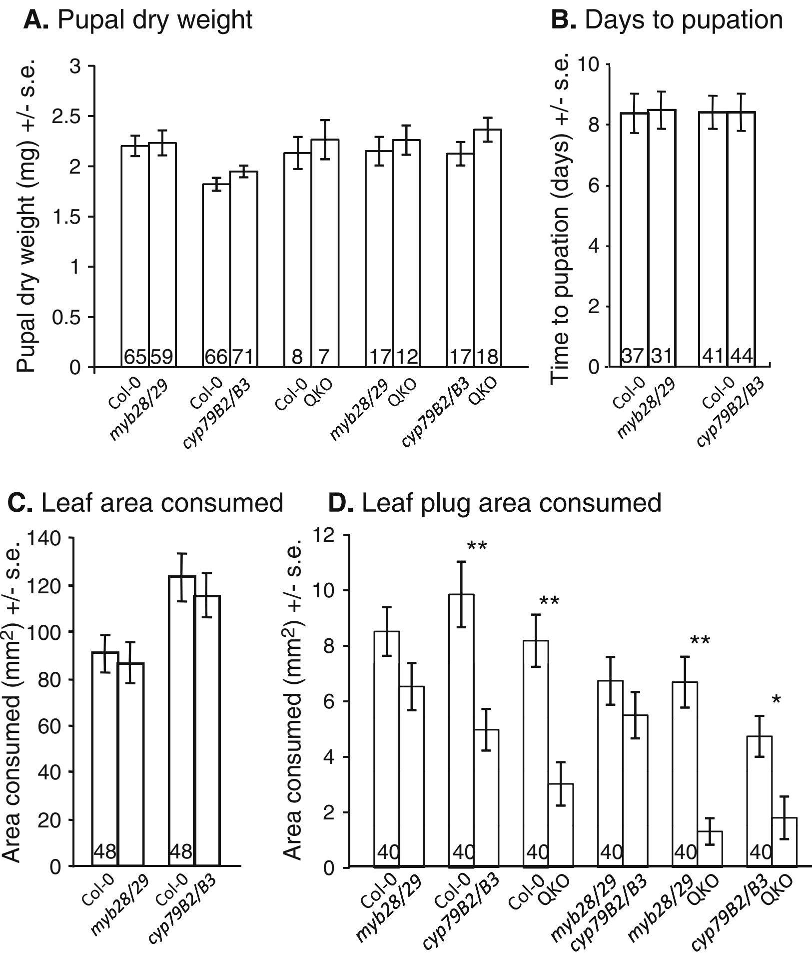

Fig. 2 Growth and feeding of *Plutella xylostella* on *Arabidopsis thaliana* Col-0 wildtype and mutants deficient in aliphatic glucosinolates (*myb28/29*), indole glucosinolates (*cyp79B2/B3*), or both (QKO, quadruple knockout). **a** Dry weight of pupae from larvae grown on whole plants in no-choice tests. **b** Age of larvae at pupation in no-choice tests. **c** Area consumed in detached-leaf choice tests. **d** Area consumed in leaf plug choice tests. All comparisons are with pairs of genotypes grown at the same time in the same flats. Bars are mean +/− standard error. Numbers in the bars represent sample sizes. *$P<0.01$, **$P<0.001$, pair-wise comparisons with Mann-Whitney *U-tests* (A–C) or Wilcoxon signed rank tests (D)

less material from the quadruple knockout mutant than the other genotypes in leaf plug choice tests (Fig. 2d).

When *P. rapae*, another crucifer-feeding specialist, fed on *A. thaliana* deficient in aliphatic and/or indole glucosinolates, there was no effect on larval weight compared to larvae feeding on wildtype plants. Only slight effects were seen in *P. rapae* pupation, with pupae being slightly heavier on *cyp79B2 cyp79B3* mutants (Fig. 3a) and a little longer time to pupation on *myb28 myb29* mutants (Fig. 3c). In contrast, larval choice tests show that Col-0 tissue is highly preferred over all other genotypes in choice tests (Fig. 3d). Experiments comparing double and quadruple mutants show that aliphatic and indole glucosinolates have an additive effect in stimulating larval feeding (Fig. 3d). Direct comparison of the *cyp79B2 cyp79B3* and *myb28 myb29* mutants also show that indole glucosinolates are more important than aliphatic glucosinolates in attracting *P. rapae* feeding.

Choice tests were conducted to determine the relative importance of aliphatic and indole glucosinolates for eliciting *P. rapae* oviposition on intact *A. thaliana.* In these experiments, reduction in aliphatic or indole glucosinolates individually did not affect oviposition in comparisons to wildtype Col-0 ($P>0.05$; Fig. 4). However, the quadruple knockout mutant received fewer eggs when compared to Col-0 wildtype, *myb28 myb20*, or *cyp79B2 cyp79B3* plants (Fig. 4), suggesting that there are additive effects of the aliphatic and indole glucosinolate classes in eliciting *P. rapae* oviposition.

Discussion

The experiments described here support the hypothesis that the glucosinolate diversity found in *A. thaliana* and other crucifers is necessary to limit growth of multiple insect herbivores. Consistent with the negative effects of glucosinolate overproduction (Gigolashvili et al., 2007a, b), decreases in indole and aliphatic glucosinolates cause additive increases in larval growth of the generalist *S. exigua* (Fig. 1a). In contrast, two other non-crucifer specialists, *M. sexta* and *T. ni*, are sensitive only to changes

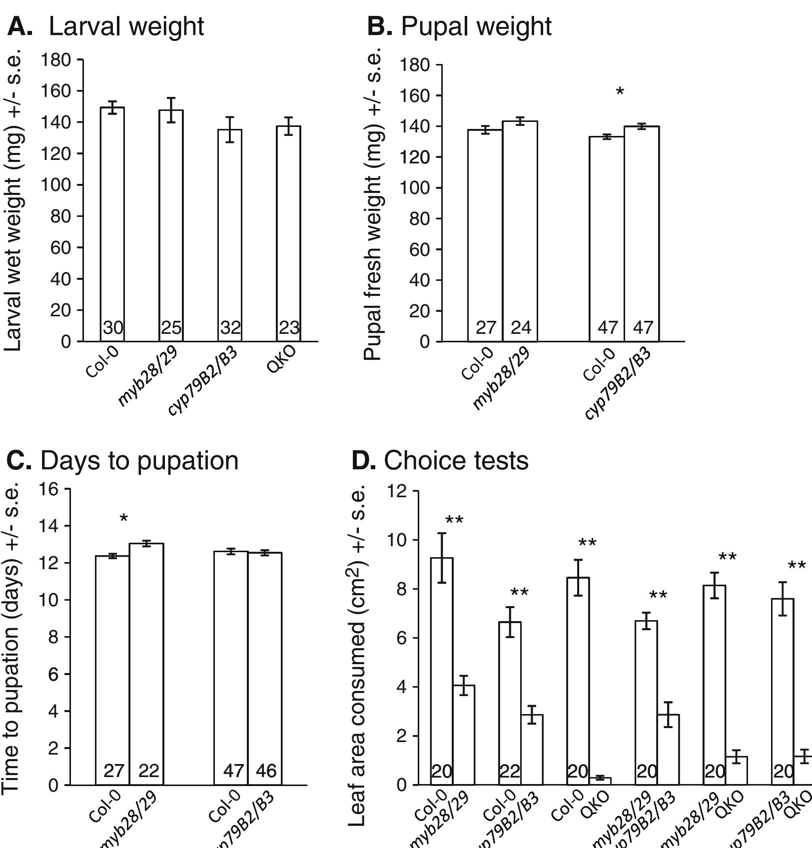

Fig. 3 *Pieris rapae* larval feeding on *Arabidopsis thaliana* Col-0 wildtype and mutants deficient in aliphatic glucosinolates (*myb28/29*), indole glucosinolates (*cyp79B2/B3*), or both (QKO, quadruple knockout) in no-choice (A–C) and dual choice tests (D). **a** Larval weight at day 10 in no-choice tests (no significant differences by ANOVA). **b** Pupal fresh weight. **c** Age of larvae at pupation in no-choice tests. **d** Leaf area consumed in dual choice tests. All data are mean +/− standard error. Numbers in the bars represent sample sizes. **P*<0.01, ***P*<0.001, unpaired Student's *t-tests* (B) or Mann-Whitney *U-tests* (C, D). Shown are data from single experiments that have been repeated with similar results except in B where the difference between Col-0 and *cyp79B2/B3* was not significant in a second experiment

in aliphatic glucosinolate content and are unaffected by the presence or absence of indole glucosinolates (Fig. 1b, c). Conversely, other research shows that indole glucosinolates are particularly important for *A. thaliana* defense against generalist aphids (Kim and Jander, 2007; Kim et al., 2008; De Vos and Jander, 2009; Pfalz et al., 2009). Therefore, *A. thaliana* plants in nature would require both aliphatic and indole glucosinolates for improved protection against a range of different herbivore species. Loss of either glucosinolate class would allow some generalist herbivores to feed more readily (Fig. 5).

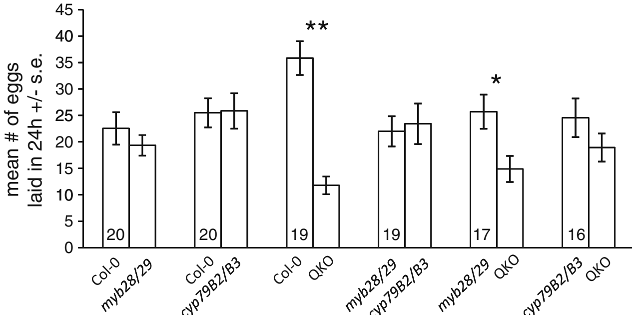

Fig. 4 *Pieris rapae* oviposition on whole *Arabidopsis thaliana* plants in 24-h choice tests comparing Col-0 wildtype and mutants deficient in aliphatic glucosinolates (*myb28/29*), indole glucosinolates (*cyp79B2/B3*), or both (QKO, quadruple knockout). All data are mean +/− standard error. Numbers in the bars represent sample sizes. **P*<0.05, ***P*<0.001, Mann-Whitney *U-test*. Shown are data from a single experiment. Repetition of this experiment showed the same oviposition trends and analysis of the combined data sets showed a significant reduction in oviposition on the QKO relative to Col-0, *myb28/29,* and *cyp79B2/B3*

It is possible that the observed differences in larval growth (Fig. 1) result from variation in plant responses to the three herbivores. However, other experiments have shown similar *A. thaliana* transcriptional responses to different Lepidoptera (Reymond et al., 2004). Additionally, compared to the effects of *myb28 myb29* and *cyp79B2 cyp79B3*, herbivore-induced glucosinolate changes in *A. thaliana* are not large, generally less than two-fold increases in total glucosinolate content (Schlaeppi et al., 2008). Although the *myb28 myb29* and *cyp79B2 cyp79B3* mutations almost completely eliminate aliphatic and indole glucosinolates, respectively, we cannot rule out the possibility that other, as yet uninvestigated *A. thaliana* defense mechanisms also influence the outcome of these experiments. For instance, the MYB28 and MYB29 transcription factors may regulate other pathways that play a role in insect defense, and additional indole compounds are metabolically downstream from CYP79B2 and CYP79B3 (Zhao et al., 2002). CYP79B2 and CYP79B3 are also

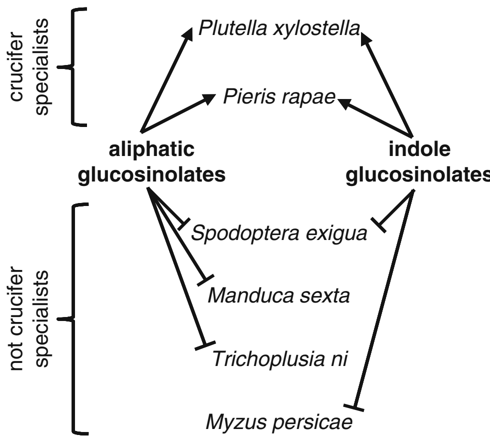

Fig. 5 Indole and aliphatic glucosinolates have differential effects on two crucifer-specialist insect herbivores and four non-specialist herbivores. As indicated by the arrows, both aliphatic and indole glucosinolates act as feeding stimulants for *Pieris rapae* and *Plutella xylostella*. However, growth of these crucifer-feeding specialists is largely unaffected by glucosinolate content. As indicated by the bars, growth of insects that are not crucifer-feeding specialists is reduced in the presence of glucosinolates. Specifically, *Manduca sexta* and *Trichoplusia ni* are affected primarily by aliphatic glucosinolates, *Myzus persicae* (green peach aphid) is affected primarily by indole glucosinolates (Kim et al., 2008), and the two glucosinolate classes have additive effects on *Spodoptera exigua*

required for the biosynthesis of camalexin (Glawischnig et al., 2004). However, unlike glucosinolates, production of this indole phytoalexin is not induced much by the jasmonate-mediated defense pathway, nor is it known to affect insect feeding (Brader et al., 2001; Pegadaraju et al., 2005).

So far, the actual toxic or antifeedant effects of glucosinolate breakdown products on insect herbivores have not yet been identified. However, the observed differences in glucosinolate sensitivity among insects with similar feeding styles (Fig. 1) may provide an inroad into such research. The three tested Lepidoptera might differ in their target site sensitivity, taste receptors, or detoxification mechanisms. However, given that *M. sexta* does not normally consume crucifers, it is unlikely to have specific detoxification enzymes for glucosinolates or their breakdown products.

Consistent with experiments showing that glucosinolates are *P. xylostella* feeding stimulants *in vitro* (Thorsteinson, 1953; Van Loon et al., 2002), aliphatic and indole glucosinolates have additive effects in a leaf plug choice experiments (Fig. 2d). However, in experiments with detached leaves, larvae show no preference when comparing Col-0 and plants lacking either indole or aliphatic glucosinolates (Fig. 2c). One notable difference between the two experiments is the exposed cut leaf surface of the leaf plugs, which might cause the release of volatile glucosinolate-derived stimuli that attract *P. xylostella* larvae. Despite the feeding preferences, even the quadruple knockout mutant did not affect pupal size nor time to pupation (Fig. 2a, b). Glucosinolates are not an absolute requirement for food acceptance, as *P. xylostella* can be raised over several generations on artificial diets or *P. sativum* (sweet pea; Gupta and Thorsteinson, 1960), which do not contain glucosinolates.

Consistent with their efficient glucosinolate detoxification mechanisms (Wittstock et al., 2004), *P. rapae* growth was not affected much by variation in glucosinolate content (Fig. 3). Nevertheless, *P. rapae* exhibited slightly higher pupal weight (Fig. 3b) and later pupation (Fig. 3c) on *cyp79B2 cyp79B3* and *myb28 myb29* mutant lines, respectively. Slower development in nature could be deleterious because larvae would be exposed to predators for a longer period of time, and pupal size has been associated with egg production and overall adult fitness in Lepidoptera (del Campo et al., 2005). Even though the observed glucosinolate effects on the development of individual larvae in this laboratory experiment are quite small (Figs. 3b and c), such fitness changes could lead to more dramatic effects over several generation in a natural setting.

Similar to *P. xylostella* (Fig. 2d), aliphatic and indole glucosinolates have additive effects in stimulating *P. rapae* larvae to feed on *A. thaliana* plants (Fig. 3d). In other research, larvae grew more rapidly on wildtype *A. thaliana* than on *tgg1 tgg2* myrosinase-deficient mutants (Barth and Jander, 2006). Since these myrosinase mutations do not alter glucosinolate content, breakdown products, rather than intact glucosinolates may be the primary *P. rapae* feeding stimulants. *Arabidopsis thaliana* mutants defective in both myrosinase and glucosinolate production could be used to determine whether this is the case. Alternatively, glucosinolate breakdown to simple nitriles upon ingestion (Wittstock et al., 2004) may promote growth due to the release of sulfate and likely elemental sulfur that may be valuable for nutrition.

Although in prior research (De Vos et al., 2008), *P. rapae* laid fewer eggs on *cyp79B2 cyp79B3* mutants compared to wildtype plants, this was not the case in the current experiments (Fig. 4). These dissimilar results have several possible causes: (i) different growth conditions of the *A. thaliana* plants could affect oviposition; (ii) there may be strain-specific differences in the *P. rapae* that were studied; and (iii) different diets consumed by larvae could affect the oviposition preferences of adult butterflies in these experiments. Decreased oviposition on the quadruple knockout line compared to the *myb28 myb29* mutant (Fig. 4) suggests that the role of indole glucosinolates as oviposition stimulants may depend on the relative abundance of aliphatic glucosinolates or their breakdown products. Similarly, aliphatic glucosinolates were important for stimulating *P. xylostella* oviposition on intact *A.*

thaliana plants only in the absence of indole glucosinolates (Sun et al., 2009).

The importance of *A. thaliana* glucosinolate diversity for defense against herbivores in nature remains relatively uninvestigated. (but see Mauricio, 1998; Mauricio and Rausher, 1997; Bidart-Bouzat and Kliebenstein, 2008) Taken together, our results of *in vivo* experiments with *A. thaliana* mutants show that producing more than one class of glucosinolates is advantageous for limiting the growth of generalist herbivores, which are not universally sensitive to all glucosinolate classes (Fig. 5). At the same time, both aliphatic and indole glucosinolates make the plant more susceptible to attack by specialist herbivores. Therefore, a diversity of glucosinolates, as well as tight regulation of their biosynthesis and breakdown, is likely necessary for *A. thaliana* to survive and adapt in a complex natural environment with both specialist and generalist herbivores.

Acknowledgements This research was funded by the VKR-Research Centre for Pro-Active Plants (Villum Kahn Rasmussen's foundation) to B.A.H., and National Science Foundation award #IOS-0718733 to G.J. We thank M. del Campo and J. Beal for providing *M. sexta* eggs, L. Meihls for assisting with *P. xylostella* experiments, and L. Heise for helping to maintain the *P. rapae* culture.

Abstract Sorgoleone, found in the root exudates of sorghum [(*Sorghum bicolor* (L.) Moench], has been a subject of continued research. Sorgoleone production in grain sorghum roots was investigated under different growth conditions. Methanol was the most effective solvent for extracting sorgoleone from grain sorghum roots. Sorgoleone production is high in young developing plants. The maximum concentration (μg mg^{-1} root dry weight) was produced in 5-d-old seedlings; beyond this age, production declined. However, considering both root weight and sorgoleone content per seedling, 10-d-old seedlings had the highest total amounts (μg). Compared with the control, sorgoleone content increased 6.1, 8.6, and 14.2 times when sorghum seeds were treated with auxins, Hoagland solution, and a combination of auxins and Hoagland solution, respectively. Among the innate immunity response elicitors, cellulose (an elicitor of plant origin) stimulated higher sorgoleone production than the others, and it produced 6.2 times more sorgoleone than the control. Combined treatment of sorghum seeds with half strength Hoagland solution and 5 μg ml^{-1} of IBA significantly increased both root growth and sorgoleone content in sorghum seedlings.

Introduction

The allelopathic effect of sorghum was first noticed in crops grown in rotation with sorghum (Breazeale, 1924) and later supported by several studies (Putnam et al., 1983; Forney et al., 1985; Einhellig and Rasmussen, 1989). Several workers have examined the chemical composition of root exudates of sorghum (Guenzi et al., 1967; Lehle and Putnam, 1983; Alsaadawi et al., 1986; Panasiuk et al. 1986). Netzly and Butler (1986) isolated hydrophobic *p*-benzoquinones from grain sorghum roots exudates, which were ultimately identified and named sorgoleone (Netzly et al., 1988). The root hairs of sorghum produce an oily exudate containing the lipid benzoquinone sorgoleone (2-hydroxy-5-methoxy-3-[(8′*Z*, 11′*Z*)-8′, 11′, 14′-pentadecatriene]-*p*-benzoquinone), which is a potent allelochemical (Netzly and Butler, 1986; Inderjit and Duke, 2003). Sorgoleone and its 1 4-hydroquinone form together account for ~50% of the oily exudates from sorghum root hairs (Erickson et al., 2001; Dayan et al., 2009). The remaining percentage consists primarily of alkyl resorcinol analogs, along with small amounts of several sorgoleone congeners that vary in the substitutions in the aromatic ring (Fate and Lynn, 1996; Rimando et al., 1998; Kagan et al., 2003). All these variants of sorgoleone appear to contribute to the overall allelopathic potential of sorghum (Kagan et al., 2003; Rimando et al., 2003). Sorgoleone is phytotoxic to broadleaf and grass weeds at concentrations as low as 10 μM in hydroponic assays (Einhellig and Souza, 1992; Nimbal et al., 1996), and broadleaf weed species are more susceptible than grass

weed species (Uddin et al., 2009). Sorgoleone exerts both pre-emergence and post-emergence effects on different weeds (Czarnota et al., 2001; Weston and Czarnota, 2001).

Factors that affect root hair production and sorgoleone biosynthesis are not well understood. However, sorgoleone biosynthesis is linked intrinsically to the presence of living root hairs (Czarnota et al., 2001; Yang et al., 2004). Furthermore, root hair production is inhibited by excess water (Hess et al., 1992; Yang et al., 2004; Dayan et al., 2007). Sorgoleone levels are sensitive to light; they decreased by nearly 50% upon exposure to blue light (470 nm) and by 23% upon exposure to red light (670 nm) (Dayan, 2006). Sorgoleone levels increase in plants treated with a crude extract of velvetleaf (*Abutilon theophrasti* Medik.) root (Dayan, 2006).

Although the cellular localization and the biosynthetic steps involved in sorgoleone production have been determined (Dayan et al., 2003; Pan et al., 2007; Baerson et al., 2008), limited information is available regarding the factors that affect its biosynthesis. Therefore, this research was conducted to determine the factors that enhance both root growth and sorgoleone content in sorghum roots. Such knowledge may be used to develop a bioherbicide.

Methods and Materials

Plant Material and Growth Conditions Seeds of sorghum (cultivar Chalsusu) were collected from the College of Agriculture & Life Sciences, Gangwon National University, Korea. They were treated with benomyl (a fungicide used for seed disinfection) for 4 h and then rinsed several times in distilled water. For most experiments, 25 seeds along with the treatment material were placed in sterile Petri dishes (100×40 mm) on the surface of sterile Whatman #1 filter paper (diam, 90 mm). The dishes then were placed in a growth chamber at 30°C under standard cool-white fluorescent tubes with a flux rate of 550 μmol s^{-1} m^{-2} and a 16-h photoperiod for 3 wk. However, the seedlings were allowed to grow for 40 d for the experiment to determine the age of maximum seedling growth. Each experiment had four replications and was repeated two to three times.

Extraction Procedure and Sorgoleone Analysis by HPLC Sorgoleone was extracted according to the procedures described by Netzly and Butler (1986); Netzly et al. (1988), and Czarnota et al. (2003a), except that methanol was used as a solvent instead of methylene chloride. Seedling roots were excised and immersed in methanol (1:20 w/v) for 30 sec to extract. The crude extract was filtered and evaporated under vacuum. The dried extract was dissolved in methanol (1 mg ml^{-1}), and the solution was filtered through a poly filter (pore size, 0.45 μm). The filtrate was diluted 4-fold with methanol prior to HPLC analysis. HPLC quantification of sorgoleone was performed using the Futecs NS-4000 HPLC systems (Futecs Co. Ltd.,Daejeon, Korea) with a C_{18} column (250× 4.6 mm, particle size 5 μm; RStech, Daejeon, Korea). The mobile phase was 75% acetonitrile + 25% acidified water. Water was acidified with glacial acetic acid (97.5:2.5 v/v). Sorgoleone was detected at 280 nm with a Waters tunable absorbance detector after injection of 20 μl of the methanol solubilized crude extract sample. The column flow rate was 1 ml min^{-1} with a 40 min total run time for each sample. All samples were run in triplicate. The amount of sorgoleone was calculated on the basis of a standard curve obtained from a purified sample. The sorgoleone standard was provided by Franck Dayan, United States Department of Agriculture-Agricultural Research Service (USDA-ARS), Natural Products Utilization Research Unit.

Optimization of Sorgoleone Extraction Different organic solvents were used, namely methanol, methylene chloride, chloroform, ethanol, butanol, ethyl acetate, hexane, and water, were used to extract sorgoleone from 5-d-old sorghum seedling roots to determine the best solvent for obtaining maximum amounts. The extraction procedure was the same as described above.

Age of Seedling for Maximum Root Growth To determine the optimum age of seedlings for measuring maximum root growth and sorgoleone content, eight sets of Petri dishes (100×40 mm) with four replications were arranged to grow sorghum seedlings. In each dish, 25 seeds were grown. At each 5-d interval, one set of Petri dishes (four dishes) was removed from the growth chamber for measuring root

Table 1 Effect of different organic solvents on sorgoleone extraction from sorghum roots

Organic solvent	Amount of sorgoleone (μg mg^{-1} RDW[a])
Methanol	40.1 a[b]
Methylene chloride	15.7 b
Chloroform	14.0 b
Ethanol	9.8 c
Butanol	0 d
Ethyl acetate	0 d
Hexane	0 d

30	9.6 a	11.9 e	113.9 de
35	9.1 a	11.0 e	100.0 e
40	7.6 b	9.2 f	70.3 f

[a] *RDW* Root dry weight

[b] Mean values (for RDW, mean of 4 replicates with an average of ten seedlings for each replicate; for sorgoleone, mean of four replicates with three samples from each replicate) indicated by the same letter in a column do not differ significantly at 5% level (Tukey's studentized range test)

growth and sorgoleone content, until 40 d after seeding. Water was applied during the entire experimental period.

Auxin Treatment To determine the effect of auxins on root growth and sorgoleone content in roots, three different auxins, namely, indole-3-acetic acid (IAA), indole-3-butyric acid (IBA), and 1-naphthaleneaceti acid (NAA) were tested at different concentrations (0 μg ml^{-1}, 0.1 μg ml^{-1}, 0.5 μg ml^{-1}, 0.75 μg ml^{-1}, 1, 5 μg ml^{-1}, 10 μg ml^{-1}, 25 μg ml^{-1}, and 50 μg ml^{-1}).

Hoagland Solution Treatment Seedlings were grown in Petri dishes as described above, in different strengths Hoagland solution. After seed placement in the dishes, three strengths, i.e., quarter, half, and full Hoagland solution (Hoagland and Arnon, 1950) were applied at three different time points during growth (0 d, 4 d, and 8 d).

Combined Treatment with Auxins and Hoagland Solution Seedlings were grown in Petri dishes in combined solutions of auxins and Hoagland solution (50:50 v/v). Seeds were applied with, quarter, half, or full strengths Hoagland solution along with the optimal concentrations of IAA (1 μg ml^{-1}), IBA (5 μg ml^{-1}), and NAA (1 μg ml^{-1}).

Effect of Elicitors To evaluate the effect of elicitors on growth and sorgoleone content, two elicitors of plant origin (pectin and cellulose) and two of microorganism origin (chitin and chitosan) were tested at different concentrations (0 μg ml^{-1}, 0.1 μg ml^{-1}, 0.5 μg ml^{-1}, 0.75 μg ml^{-1}, 1 μg ml^{-1}, 5 μg ml^{-1}, 10 μg ml^{-1}, and 100 μg ml^{-1}).

[c] Mean values (for RDW, mean of four replicates with an average of ten seedlings for each replicate; for sorgoleone, mean of four replicates with three samples from each replicate) indicated by the same letter in a column do not differ significantly at 5% level (Tukey's studentized range test)

Another experiment was performed using the optimal concentration of each elicitor (chitin, pectin, and cellulose: 1 μg ml^{-1}; chitosan: 5 μg ml^{-1}) applied at 0 d, 3 d, 6 d, and 9 d after seed placement in Petri dish. Distilled water was used before elicitor treatment. Thereafter, seedlings were allowed to grow for 3 wk.

Statistical Analysis All data were analyzed using the SAS 9.1 Software (released in 2006; SAS Institute Inc., Cary, NC, USA). Analysis of variance was performed for each compound concentration, and mean differences were calculated using Tukey's studentized range test. Standard deviations were also provided to indicate the variations associated with the particular mean values.

Results

Optimization of Sorgoleone Extraction The highest amount of sorgoleone was extracted with methanol, followed by methylene chloride and chloroform (Table 1). The amount

IAA Indole-3-acetic acid, *IBA* Indole-3-butyric acid, *NAA* 1-naphthaleneacetic acid

[a] RDW: Root dry weight

[b] Mean values(for RDW, mean of four replicates with an average of ten seedlings for each replicate; for sorgoleone, mean of four replicates with three samples from each replicate) indicated by the same letter in a column do not differ significantly at 5% level (Tukey's studentized range test)

of sorgoleone in methanol was 2.6 and 2.9 times higher than that in methylene chloride and chloroform, respectively. No sorgoleone was detected upon extraction with butanol, ethyl acetate, hexane, or water.

Change in Sorgoleone Content with Seedling Age Root weight increased with seedling age for up to 30 d, but sorgoleone production decreased with age. Sorgoleone concentration was 40.1 μg mg^{-1} and 30.1 μg mg^{-1} root dry weight (RDW) in 5-and 10-d-old seedlings, respectively (Table 2). The RDW was 4.0 mg and 5.9 mg in 5-and 10-d-old seedling, respectively, and it increased up to 9.6 mg at 30 d. Although sorgoleone concentration decreased with seedling age, root weight increased with time; thus, the total amount of sorgoleone was highest in 10-d-old seedlings. The trend of increase in root growth persisted for up to 30 d, after which root growth declined.

Effect of Auxins on Sorgoleone Production Root growth and sorgoleone content varied widely with different concentrations of auxins (Figs. 1, 2). Considerable RDW and amounts of sorgoleone were observed at auxin concentrations of 0.1–5 μg ml^{-1}, after which both RDW and sorgoleone content decreased drastically. The maximum root growth and sorgoleone were observed by treatment with IBA at 5 μg ml^{-1}, followed by treatment with IAA and NAA at 1 μg ml^{-1}. Compared with the control, 5 μg ml^{-1} IBA, 1 μg ml^{-1} IAA, and 1 μg ml^{-1} NAA produced 6.1, 4.6, and 3.8 times more sorgoleone, respectively.

Effect of Hoagland Solution on Sorgoleone Production Root dry weight was higher when Hoagland solution was applied at 0 d than when the solution was applied at 4 or 8 d after seed placement (delayed application), for all strengths (Table 3). Sorgoleone content showed the same trend as RDW, except when full strength solution was applied. It decreased with delay in the application of both quarter- and half-strength. In the case of the application of full-strength Hoagland solution, sorgoleone content increased with delayed application. Half-strength solution produced maximum root growth and sorgoleone content. Compared with the control, total sorgoleone content and root biomass were 8.6 and 1.7 times higher when half-strength solution was applied at 0 d. Treatment of sorghum seeds with half-strength at 0 d produced 2.8 and 2.2 times more sorgoleone based on RDW, than treatments with full-strength and quarter-strength solution, respectively.

Combined Effect of Auxins and Hoagland Solution on Sorgoleone Production Different strengths of Hoagland solution along with the most optimal concentrations of IAA (1 μg ml^{-1}), IBA (5 μg ml^{-1}), and NAA (1 μg ml^{-1}) were applied to sorghum seeds to increase sorgoleone production. Combined treatment dramatically increased root growth and sorgoleone production (Table 4). In particular, combined application of 5 μg ml^{-1} IBA with half-strength Hoagland solution produced 14.2 times more sorgoleone than the control. Further, this combination increased sorgoleone content by 1.6 and 1.5 times as compared with the combination of half-strength Hoagland

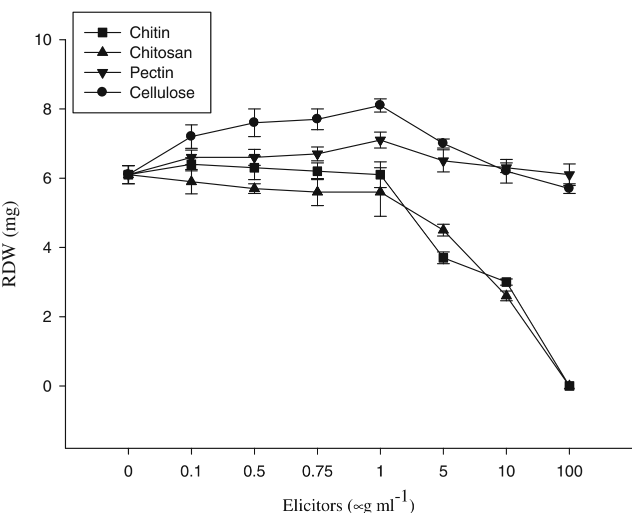

Fig. 3 Effect of elicitors on root growth of sorghum seedlings. Values are presented as mean (SD) (each point is the mean of four replicates with an average of ten seedlings for each replicate). SD: Standard deviation

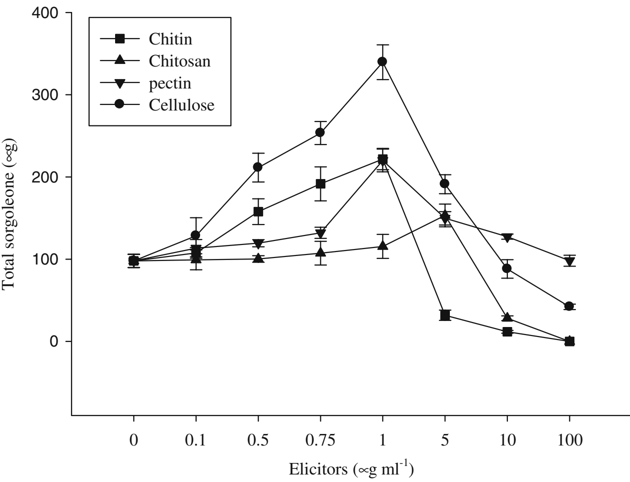

Fig. 4 Effect of different concentrations of elicitors on sorgoleone production in sorghum roots. Values are presented as mean (SD) (each point is the mean of four replicates with three samples from each replicate). SD: Standard deviation

solution with 1 μg ml^{-1} NAA and 1 μg ml^{-1} IAA, respectively.

Effect of Elicitors on Root Growth and Sorgoleone Production Four elicitors—2 of microorganism origin (chitin and chitosan) and 2 of plant origin (pectin and cellulose)—were applied at different concentrations to sorghum seeds. Chitin, pectin and cellulose produced more sorgoleone at 1 μg ml^{-1} than at other concentrations (Figs. 3, 4), while chitosan produced a higher amount at 5 μg ml^{-1} than at other concentrations. With the increase in the concentration of elicitors, sorgoleone content decreased drastically, and in the case of chitin and chitosan, the plants did not survive even at 100 μg ml^{-1} (Fig. 3). Cellulose, an elicitor of plant origin produced the highest root biomass and sorgoleone content at 1 μg ml^{-1}, followed by chitin at 1 μg ml^{-1}. Compared with the control, cellulose at 1 μg ml^{-1} produced 3.5 and 1.3 times more sorgoleone and root biomass, respectively.

Effect of Elicitors, Applied at Different Time Points During Growth, on Sorgoleone Production After seed placement, the optimal concentrations of different elicitors were applied at different time points during growth. Sorghum roots contained more sorgoleone when an elicitor was applied a few days later than when applied in the initial days of growth (Table 5). The highest amount of sorgoleone was obtained when cellulose was applied 6 d after seed placement, followed by chitin, chitosan, and pectin. Compared with the control, cellulose, chitin, chitosan, and pectin produced 6.2, 4.2, 3.3, and 3.2 times more sorgoleone, respectively.

Discussion

Methylene chloride is the most commonly used solvent (Netzly and Butler, 1986; Netzly et al., 1988; Czarnota et al., 2001; Yang et al., 2004) to extract sorgoleone from roots, although chloroform also has been used (Dayan, 2006). In this study, methanol proved to be the best solvent and extracted the maximum amount of sorgoleone, followed by methylene chloride and chloroform. Methanol extracted 2.6 times more sorgoleone than methylene chloride (Table 1).

While root weight increased, sorgoleone production decreased with the age of seedlings. Considering both root weight and sorgoleone content, 10-d-old seedlings were the best, producing the maximum amount of sorgoleone. The trend of increase in root growth persisted until 30 d after which the root growth decreased since the seedlings were

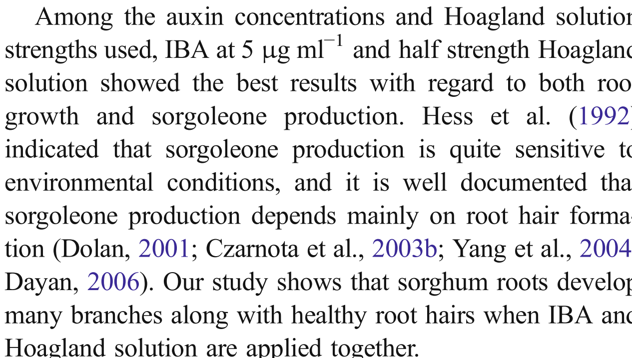
[b] RDW: Root dry weight

[c] Mean values (for RDW, mean of four replicates with an average of ten seedlings for each replicate; for sorgoleone, mean of four replicates with three samples from each replicate) indicated by the same letter in a column do not differ significantly at 5% level (Tukey's studentized range test)

grown under hypoxic conditions. Hypoxic conditions did not impede root growth until 30 d but growth decreased thereafter; this finding was consistent with that of Yang et al. (2004) that sorghum root development is reduced under hypoxic conditions.

In our study, auxins exerted a positive effect on both root growth and sorgoleone production. Auxins govern many biological processes in plants, such as cell enlargement and division, differentiation of vascular tissue, apical dominance, root initiation, and signaling (Teale et al., 2006). Studies conducted using differentiated tissues to investigate the biochemical relationship between exogenous and endogenous auxin levels have provided interesting findings regarding root-derived biologically active compounds. Researchers investigating the physiological role of exogenously applied auxins in root growth and secondary metabolite production have established that signaling molecules can affect plant tissue stability and secondary product accumulation either individually or through interactions with phytohormones. With regard to the effects of auxins on secondary metabolite production, Bais et al. (2001) noted that high levels of exogenous auxins, specifically IAA and NAA, in the presence of low cytokinin levels, decrease the ability of root cultures of *Cichorium. intybus* to produce coumarin. Lin et al. (2003) showed that coniferin content in *Linum flavum* is increased significantly in the presence of auxins. However, Arroo et al. (1995) showed that IAA addition inhibits secondary metabolite accumulation in the hairy roots of *Tagetes patula*. In contrast, addition of either IBA or NAA stimulates ajmalicine and ajmaline production in *Rauvolfia micrantha* hairy root cultures in a hormone-free medium (Sudha et al., 2003), whereas Rhodes et al. (1994) observed a decrease in nicotine content in the hairy roots of *Nicotiana rustica* when the roots were supplied with auxins together with cytokinins. Luczkiewicz et al. (2002) discovered that the production of the sesquiterpene lactone pulchelin E is enhanced in hairy roots of *Rudbeckia hirta*, compared with that in callus and suspensions cultures, in the presence of auxins.

Czarnota et al. (2003b) confirmed that sorghum root hairs are physiologically active with a complex network of smooth endoplasmic reticulum and possibly Golgi bodies. Small globules of cytoplasmic exudates also were observed to deposit an oily material between the cell wall and the plasma membrane near the root hair tips. Our study confirms that sorgoleone production is related directly to the development of sorghum root hairs. Our positive results from using different auxins for enhanced sorgoleone production, suggests that sorghum roots benefit from developing more sorgoleone-rich root hairs. Sorgoleone production also was stimulated by Hoagland solution treatment, suggesting that sorghum roots benefit from Hoagland solution to develop healthy and vigorous roots.



Among the auxin concentrations and Hoagland solution strengths used, IBA at 5 μg ml^{-1} and half strength Hoagland solution showed the best results with regard to both root growth and sorgoleone production. Hess et al. (1992) indicated that sorgoleone production is quite sensitive to environmental conditions, and it is well documented that sorgoleone production depends mainly on root hair formation (Dolan, 2001; Czarnota et al., 2003b; Yang et al., 2004; Dayan, 2006). Our study shows that sorghum roots develop many branches along with healthy root hairs when IBA and Hoagland solution are applied together.

Stimulation of secondary metabolites by elicitation is one of the few strategies that currently is finding commercial application. Elicitors, compounds of biotic or abiotic origin, upon contact with the cells of higher plants trigger increased production of pigments, flavones, phytoalexins, and other defense related compounds (Flores and Curtis, 1992; Sim et al., 1994; Bhagyalakshmi and Bopanna, 1998; Singh, 1999). Sorgoleone production may be affected by pathogenic infections. It has antifungal properties (Suzuki et al., 1998). Initiation of sorgoleone biosynthesis by eliciting plant defense mechanisms have yielded varying results. Cellulose at 1 μg ml^{-1} significantly increased sorgoleone production, followed by chitin at 1 μg ml^{-1} (Table 5). Treatment with chitin, which is known to induce the expression of systemic acquired resistance (SAR) genes (Hahn, 1996; Zhang et al., 2002), exerted a significant effect on sorgoleone production. Treatment with chitosan and pectin also increased production. Moreover, Savitha et al. (2006) observed a positive effect of different biotic and abiotic elicitors on the production of betalain in the hairy root cultures of *Beta vulgari.*

In summary, sorgoleone production is constitutive to the physiology of mature root hairs of sorghum. Great differences in sorgoleone levels are observed during the early stages of seedling development, and sorgoleone biosynthesis is positively affected by most of the stimuli used in this study. In particular, sorghum seeds treated with half strength Hoagland solution and 5 μg ml^{-1} of IBA significantly increase root growth and sorgoleone content in grain sorghum roots.

Acknowledgments We express our gratitude to Dr. Franck E. Dayan for providing the sorgoleone standard. This Study was supported by Technology Development Program for Agriculture, Ministry of Agriculture, Forestry and Foods, Republic of Korea.

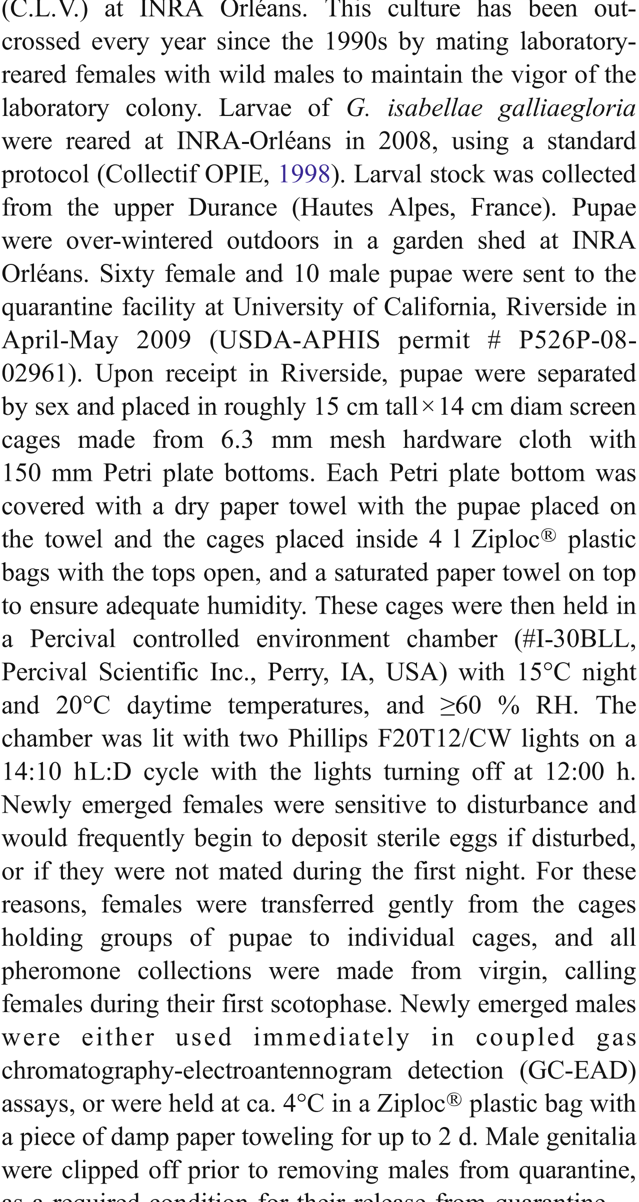
patterns, and restricted geographical distribution, it has become a symbol for several entomological and conservation organizations. It is univoltine, and adults fly at dusk from March to July in pine forests in the eastern part of Spain and the French Alps (Ylla Ullastre, 1997). *Graellsia isabellae* is protected by the Habitats Directive (the European Community initiative for an ecological network of special protected areas, known as "Natura 2000"), Bern Convention, Red Book of Lepidoptera, and Spanish and French red lists (Ministerio de Medio Ambiente, 2006; Ministère de l'Écologie et du Développement Durable, 2008). Despite this protective legislation, the latest Red list of the IUCN considered *G. isabellae* as "data deficient" in terms of its current range and population density (IUCN, 2007). The natural history and ecology of *G. isabellae* has been studied (Ylla Ullastre, 1997, Chefaoui and Lobo, 2007, 2008, Vila et al., 2009), but conservation genetic studies have just started (Vila et al., 2010), and the current distribution and conservation status of the species needs to be updated because new populations have been discovered well beyond the previously known limits of its range (Ibáñez Gázquez et al., 2008).

Previous attempts at identifying the sex pheromone of *G. isabellae* were not successful, due in part to the very small amount of pheromone produced by the insects, and exacerbated by the relatively small number of individuals that were available for analysis of the pheromone gland contents (Zagatti and Malosse, 1998). A mass rearing program produced 245 females, but the amount of pheromone in a composite extract of the dissected glands from those females still proved to be below the threshold for detection by coupled gas chromatography-mass spectrometry (GC-MS). One fragment of information obtained from these efforts was that the antennae of male moths were extremely responsive to C_{16} aldehydes (Zagatti and Malosse, 1998), indicating that the pheromone was probably an aldehyde similar to those reported from some other saturniid species (Witzgall et al., 2004, El-Sayed, 2009).

As part of a larger effort to more effectively assess population sizes and delineate the range of *G. isabellae*, we describe here the identification and synthesis of the female-produced sex attractant pheromone of this insect. The results of preliminary field trials with the pheromone have shown that it is highly attractive to male moths from a number of widely separated populations, suggesting that pheromone-based methods will be effective for detection and sampling of this protected species, and will allow detailed assessments of its conservation status.

Methods and Materials

Insects Pupae of *G. isabellae galliaegloria* Oberthür were obtained from a culture maintained by one of the authors (C.L.V.) at INRA Orléans. This culture has been outcrossed every year since the 1990s by mating laboratory-reared females with wild males to maintain the vigor of the laboratory colony. Larvae of *G. isabellae galliaegloria* were reared at INRA-Orléans in 2008, using a standard protocol (Collectif OPIE, 1998). Larval stock was collected from the upper Durance (Hautes Alpes, France). Pupae were over-wintered outdoors in a garden shed at INRA Orléans. Sixty female and 10 male pupae were sent to the quarantine facility at University of California, Riverside in April-May 2009 (USDA-APHIS permit # P526P-08-02961). Upon receipt in Riverside, pupae were separated by sex and placed in roughly 15 cm tall × 14 cm diam screen cages made from 6.3 mm mesh hardware cloth with 150 mm Petri plate bottoms. Each Petri plate bottom was covered with a dry paper towel with the pupae placed on the towel and the cages placed inside 4 l Ziploc® plastic bags with the tops open, and a saturated paper towel on top to ensure adequate humidity. These cages were then held in a Percival controlled environment chamber (#I-30BLL, Percival Scientific Inc., Perry, IA, USA) with 15°C night and 20°C daytime temperatures, and ≥60 % RH. The chamber was lit with two Phillips F20T12/CW lights on a 14:10 hL:D cycle with the lights turning off at 12:00 h. Newly emerged females were sensitive to disturbance and would frequently begin to deposit sterile eggs if disturbed, or if they were not mated during the first night. For these reasons, females were transferred gently from the cages holding groups of pupae to individual cages, and all pheromone collections were made from virgin, calling females during their first scotophase. Newly emerged males were either used immediately in coupled gas chromatography-electroantennogram detection (GC-EAD) assays, or were held at ca. 4°C in a Ziploc® plastic bag with a piece of damp paper toweling for up to 2 d. Male genitalia were clipped off prior to removing males from quarantine, as a required condition for their release from quarantine.



Solid Phase Micro-Extraction (SPME) Sampling of Sex Pheromone Glands Crude extracts of pheromone were prepared from calling females by wipe sampling of extruded glands with 100 µm PDMS SPME fibers (Supelco, Bellefonte, PA, USA). Females were held in a controlled environment chamber under the same conditions as those for emergence (see above). Approximately 1–2 h after the start of scotophase, calling females were removed from the chamber into the darkened room. The SPME device was taped to the bench top so that both hands could be used to manipulate the insect, and approximately 5–7 mm of the SPME fiber was extruded. A microscope light source controlled with a rheostat was used to illuminate the fiber, and a small flashlight with red film covering the lens was used to confirm that females were indeed calling

immediately prior to pheromone collection. Thus, a female was grasped firmly by the abdomen, with gentle pressure towards the tip of the abdomen to evert the sex pheromone gland (the scale-free segment just anterior to the ovipositor). Once exposed, this area of the abdomen was wiped gently over the SPME fiber, with all surfaces being wiped at least twice. Females then were placed individually into glassine envelopes and held in a refrigerator because they would usually begin to oviposit after this procedure. The loaded SPME fiber was analyzed by GC-EAD or GC-MS.

Solvent Extraction of Sex Pheromone Glands Two composite solvent extracts of abdomen tips of calling females were made by removing glands and rinsing them in pentane. For the first composite extract, all 6 females were extracted on the same day, whereas the second extract from 7 females was made over a 4 d period, again using females during their first scotophase. Sex pheromone glands were removed approximately 1.5–2 h into the scotophase by gently forcing eversion of the sex pheromone gland, clamping the abdomen just anterior to the gland with forceps to maintain the pressure in the gland, then slicing the gland off with a razor blade such that the gland remained inflated in the forceps. The gland then was rinsed with gentle agitation in ca. 1 ml of clean pentane for 30 sec. These extracts were analyzed by coupled GC-EAD without concentration, and by GC-MS after concentration under a gentle stream of nitrogen.

GC-EAD and GC-MS Analyses GC-EAD analyses were performed using DB-5 and DB-Wax columns (both 30 m× 0.25 mm i.d., 0.25 µm film; J&W Scientific, Folsom CA, USA). Helium was used for both the carrier and makeup gas. Temperature programs were 100°C for 1 min, 10°C per min to 275°C for DB-5 and 250°C for DB-Wax, hold for 60 min. SPME injections were made by desorbing the fiber in splitless mode for 60 sec prior to starting the run (injector temperature 250ºC). Solvent extracts (1 µl aliquots) were analyzed in splitless mode. The effluent from the columns was split using an 'X' cross, with half of the sample going to the FID detector and the other half to the EAD. The portion directed to the EAD was diluted in a humidified air stream prior to exposure to the antenna. Males used in GC-EAD analyses were removed from quarantine after the genitalia had been removed, allowed to warm to room temperature, and then a single antenna was removed by pulling it off at the scape. The terminal rami were removed with a razor blade, and the tip was excised to ensure good contact with the saline solution (7.5 g NaCl, 0.21 g $CaCl_2$, 0.35 g KCl, and 0.20 g $NaHCO_3$ in 1 l Milli-Q purified water) in the glass electrodes, which were fitted with an internal gold wire for connection to the amplifier. A single antennal preparation was used for as many as four runs. Kovat's indices were calculated for unknowns and standards relative to blends of straight-chain hydrocarbons.

Syntheses of Authentic Standards The syntheses of mixtures of (4*E*/*Z*, 6*E*,11*E*)- and (4*E*/*Z*,6*E*,11*Z*)-hexadecatrienals are described in the supporting online information.

Tetrahydrofuran was purified by distillation from sodium-benzophenone ketyl under argon. Unless otherwise specified, solutions of crude products were dried over anhydrous Na_2SO_4 and concentrated by rotary evaporation under reduced pressure. Crude products were purified by flash or vacuum flash chromatography on 230–400 mesh silica gel. ^{1}H- and ^{13}C-NMR spectra were recorded on a Varian INOVA-400 spectrometer (Palo Alto, CA, USA) (400 and 100.5 MHz, respectively), as $CDCl_3$ solutions unless otherwise stated. Solvent extracts of reaction mixtures were dried over anhydrous Na_2SO_4 and concentrated by rotary evaporation under reduced pressure. Integer resolution mass spectra were obtained with a Hewlett-Packard (HP) 6890 GC (Avondale PA) interfaced to an HP 5973 mass selective detector, in EI mode (70 eV) with helium carrier gas. The GC was equipped with a DB5-MS column (25 m×0.20 mm ID×0.25 µ film).

4-Nonyn-1-ol (**3**) A solution of THP-protected 4-pentyn-1-ol **1** (5.04 g, 30 mmol) and 25 mg triphenylmethane as an indicator in 50 ml THF was cooled to 0ºC, and treated dropwise with n-BuLi (2.56 M in hexanes, ~12.5 ml) until the solution began to turn orange-red, indicative of excess *n*-BuLi. The solution was stirred 20 min, the ice bath was removed, and butyl iodide (6.44 g, 35 mmol) was added by syringe over 5 min. The solution was refluxed 44 h under Ar, then quenched by pouring into cold 1 M NH_4Cl. The mixture was extracted with hexane, and the hexane layer was washed with saturated brine, then dried and concentrated. The residue was purified by Kugelrohr distillation (oven temp ~105ºC, 0.05 mm Hg), yielding the protected alkynol **2** as a colorless oil (5.6 g, 83%). The product was dissolved in 20 ml MeOH, 0.25 g of *para*-toluenesulphonic acid (PTSA) was added, and the solution was stirred overnight at room temperature. The solution then was poured into 100 ml of 0.5 M aqueous NaOH, and the mixture was extracted 3 times with hexane. The combined hexane extracts were washed with brine, dried, and concentrated. The residue was purified by Kugelrohr distillation, taking off a preliminary fraction containing THP-protected MeOH (bp<40ºC at 1 mm Hg), followed by distillation of the remaining 4-nonyn-1-ol **3** (3.13 g, 94%; oven temp<100ºC at 1 mm Hg). ^{1}H NMR: δ 3.76 (t, 2H, J=6.2 Hz), 2.26–2.31 (tt, 2H, J=7.2, 2.4 Hz), 2.12–2.17 (m, 2H), 1.74 (overlapped tt, 2H, J~7, 7 Hz), 1.67 (br. s, OH), 1.35–1.5 (m, 4H), 0.91 (t, 3H, J=7.2 Hz). ^{13}C NMR: δ 13.8, 15.7, 18.6, 22.2, 31.3, 31.8, 62.3, 79.4, 81.3 ppm.

The ^{13}C spectrum matched that previously reported (Poleschner and Heidenreich, 1995).

(4Z)-Nonen-1-ol (**4**) A 1 M solution of $NaBH_4$ was prepared by dissolving 0.4 g $NaBH_4$ in a mixture of 9.5 ml EtOH and 0.5 ml 2 M aqueous NaOH, and the slightly cloudy solution was filtered. In a separate flask, a solution of $NiOAc_2$•4 H_2O (1.0 g, 4 mmol) was prepared in 50 ml of degassed 95% EtOH under Ar, giving a clear green solution. A balloon of hydrogen gas was attached to the flask, the Ar line was removed, and with vigorous stirring, 1 ml of the $NaBH_4$ solution (1 mmol) was added dropwise, producing a black suspension with the evolution of H_2. The mixture was stirred 10 min, then 0.8 ml of ethylenediamine was added. After stirring an additional 10 min, 4-nonyn-1-ol **3** (2.90 g, 21.4 mmol) was added by syringe. The mixture was stirred until all the starting material had been consumed (3 h), then flushed with Ar, and filtered with suction through a pad of Celite®, rinsing well with EtOH. The violet-colored solution was concentrated to ~10 ml, then poured into 100 ml 1 M HCl and extracted 3 times with hexane. The combined hexane layers were washed with saturated aqueous $NaHCO_3$ and brine, then dried and concentrated. The residue was purified by Kugelrohr distillation (oven temp to 75ºC, 0.5 mm Hg), yielding (4*Z*)-nonen-1-ol **4** (2.76 g, 91%) as a colorless oil. ^1H NMR: δ 5.39 (m, 2H), 3.66 (t, 2H, J=6.4 Hz), 2.13 (m, 2H), 2.06 (m, 2H), 1.64 (overlapped dt, 2H, J~6.5 Hz), 1.49 (br. s, OH), 1.28–1.36 (m, 4H), 0.90 (t, 3H, J=7.2 Hz). ^{13}C NMR: δ 14.2, 22.5, 23.8, 27.1, 32.1, 32.9, 62.9, 129.0, 121.0 ppm. The ^1H NMR data agreed with that previously reported (Joshi et al., 1984).

(4Z)-1-Bromononene (5) Methanesulphonyl chloride (1.89 g, 16.5 mmol) was added dropwise to a solution of (4*Z*)-nonen-1-ol **4** (2.13 g, 15 mmol) and Et_3N (2.02 g, 20 mmol) in 50 ml CH_2Cl_2 at 0ºC. The resulting slurry was stirred at 0ºC for 2.5 h, then poured into ice-water. The organic layer was separated and washed with 1 M HCl, saturated aqueous $NaHCO_3$, and brine, then dried and concentrated. The residue was taken up in 40 ml acetone, LiBr (3.9 g, 45 mmol) was added, and the mixture was stirred at 50ºC overnight, by which time all the mesylate had been consumed. The slurry was cooled and poured into 250 ml water, and the product was extracted with hexane. The hexane layer was washed with brine, dried, and concentrated, and the residue was purified by Kugelrohr distillation (oven temp ≤75ºC at 5.5 mm Hg), yielding the bromide **5** (2.76 g, 74%) as a colorless oil. ^1H NMR: δ 5.45 (dtt, 1H, J=10.2, 7.2, 1.4 Hz), 5.31 (dtt, 1H, J= 10.8, 7.6, 1.6 Hz), 3.42 (t, 2H, J=6.6 Hz), 2.20 (m, 2H), 2.06 (m, 2H), 1.92 (overlapped tt, 2H, J~7 Hz), 1.31–1.37 (m, 4H), 0.91 (t, 3H, J=6.8 Hz). ^{13}C NMR: δ 14.2, 22.5, 25.9, 27.2, 32.1, 32.9, 33.6, 127.6, 132.0 ppm. The ^1H and ^{13}C NMR data were in agreement with those previously reported (Ducoux et al., 1992).

(6Z)-Undecen-1-yne (**6**) A dry flask under Ar was loaded with lithium acetylide-ethylenediamine complex (0.92 g, 10 mmol), and dry DMSO (10 ml) and NaI (150 mg, 1 mmol) were added, followed by dropwise addition of (4*Z*)-1-bromononene **5** (1.44 g, 7 mmol). The mixture was stirred 1 h at room temperature, then quenched by pouring into 100 ml water. The mixture was extracted twice with hexane, and the combined hexane layers were washed with brine, dried, and concentrated. The residue was purified by Kugelrohr distillation (oven temp ~80ºC, 12 mm Hg), giving 0.87 g (83%) of (6*Z*)-undecen-1-yne **6** as a colorless oil. ^1H NMR: δ 5.42 (dtt, 1H, J=10.8, 7.2, 1.2 Hz), 5.33 (dtt, 1H, J=10.8, 7.2, 1.2 Hz), 2.20 (td, 2H, J=7.0, 2.4 Hz), 2.16 (overlapped td, 2H, J~7.2 Hz), 2.05 (m, 2H), 1.96 (t, 1H, J=2.4 Hz), 1.59 (overlapped tt, 2H, J~7.4 Hz), 1.34 (m, 2H), 0.91 (t, 3H, J=7.0 Hz). ^{13}C NMR: δ 14.2, 18.1, 22.5, 26.4, 27.1, 28.7, 32.1, 68.4, 84.7, 128.5, 131.3 ppm. The ^1H and ^{13}C NMR spectra agreed with those previously reported (Asao et al., 2005).

(4E,6E,11Z)-Hexadecatrien-1-ol (**11**) A dry flask was charged with bis(cyclopentadienyl)-zirconium hydridochloride (1.2 g, 4.65 mmol; Alfa Aesar, Ward Hill MA, USA) and flushed thoroughly with Ar. The flask was cooled in an ice-bath, THF was added, and the slurry was stirred 15 min, followed by dropwise addition of (6*Z*)-undecen-1-yne **6** (0.60 g, 4 mmol). The mixture was shielded from light, and stirred at 0ºC for 20 min, then warmed to room temperature and stirred for 3.5 h. The resulting solution was then cooled to 0ºC again, and a solution of iodine (1.07 g, 4.2 mmol) in 5 ml THF was added dropwise until the brown color of excess iodine persisted. The solution was stirred at 0ºC for 45 min, then warmed to room temperature and quenched by pouring into 50 ml of 2 M sodium thiosulphate solution. Hexane (100 ml) was added, and the slurry was mixed thoroughly, then filtered with suction through a pad of Celite®. The organic layer was separated and washed sequentially with sodium thiosulphate solution and brine, then dried and concentrated. The residue was purified by vacuum flash chromatography on silica gel, eluting with pentane. The purified (1*Z*,6*Z*)-1-iodoundecadiene **7**, contaminated with (6*Z*)-1,6-undecadiene (from reduction instead of iodination of the zirconium intermediate), was concentrated and used immediately in the next step. ^1H NMR: δ 6.52 (dt, 1H, J= 14.4, 7.2 Hz), 5.99 (dt, 1H, J=14.4, 1.4 Hz), 5.36 (m, 2H), 1.99–2.1 (m, 6H), 1.46 (overlapped tt, 2H, J~7.4 Hz), 1.30–1.37 (m, 4H), 0.91 (t, 3H, J=7.2 Hz).

A dry flask was charged with bis(cyclopentadienyl) zirconium hydridochloride (1.7 g, 6.6 mmol) and evacuated

and refilled with Ar 5 times. The flask was cooled to~ −15ºC in an ice-salt bath, and 7.5 ml of dry CH_2Cl_2 were added. The mixture was stirred 15 min, then *t*-butyldimethylsilyl-protected 4-pentyn-1-ol **8** (1.19 g, 6 mmol) was added dropwise. The mixture was stirred 30 min, warmed to 0ºC and stirred 30 min, then warmed to room temperature and stirred 30 min. The solvent then was removed under vacuum, and the alkenylzirconium intermediate **9** was taken up in 15 ml THF. A solution of anhydrous $ZnCl_2$ (0.94 g, 7 mmol) in 10 ml THF was added, and the solution was cooled to −78ºC and degassed under vacuum, then warmed to 0ºC, followed by addition of a solution of (1*Z*,6*Z*)-1-iodoundecadiene **7** (0.83 g, ~3 mmol) and tetrakis(triphenylphosphine)palladium in 10 ml THF. The mixture was stirred for 1 h, warmed to room temperature, and stirred until the iodide had been completed consumed (~2 h). The reaction was quenched by pouring into 50 ml saturated NH_4Cl, and the resulting mixture was extracted twice with hexane. The combined hexane extracts were washed with brine, and treated with anhydrous Na_2SO_4 and decolorizing charcoal for 1 h with stirring. The mixture was filtered with suction through a pad of Celite®, then concentrated. The residue was purified by vacuum flash chromatography on silica gel, eluting with 5% EtOAc in hexane. The purified product **10** was concentrated, and the residue was stirred in a mixture of 6 ml THF, 6 ml AcOH, and 3 ml H_2O at room temperature overnight to hydrolyze the silyl protecting group. The mixture then was poured into 100 ml water and extracted with 75 ml hexane. The hexane layer was washed sequentially with saturated aqueous $NaHCO_3$ and brine, dried, and concentrated. The residue was purified by vacuum flash chromatography, eluting with 15% EtOAc in hexane, yielding (4*E*,6*E*,11*Z*)-hexadecatrien-1-ol **11** (0.57 g, 80%, 96% isomerically pure by GC). Attempted recrystallization from hexane at −20ºC was not successful, and so the product was Kugelrohr distilled (0.55 g, 78%; bp~110ºC, 0.1 mm Hg) to remove traces of silica gel. ^{1}H NMR: δ 6.04 (m, 2H), 5.58 (m, 2H), 5.36 (m, 2H), 3.67 (t, 2H, J=6.8 Hz), 2.16 (m, 2H), 2.0–2.1 (m, 6H), 1.67 (overlapped tt, 2H, J~7 Hz), 1.4–1.48 (m, 2H), 1.29–1.36 (m, 4H), 0.90 (t, 3H, J=7 Hz). ^{13}C NMR: δ 14.2, 22.6, 26.9, 27.1, 29.1, 29.6, 32.2, 32.3, 32.5, 62.7, 129.6, 130.5 (2C), 131.2, 131.4, 132.8 ppm. The spectra agreed with those previously reported (Tomida and Fuse, 1993).

(4E,6E,11Z)-Hexadecatrienal (**12**) Oxalyl chloride (0.13 ml, 1.5 mmol) was added by syringe to 3 ml of dry CH_2Cl_2 cooled under Ar to −78ºC in a dry-ice acetone bath. A solution of dry dimethylsulfoxide in CH_2Cl_2 (0.225 ml, 3.36 mmol in 1 ml) was added dropwise over 15 min. The mixture was stirred 20 min, then (4*E*,6*E*,11*Z*)-hexadecatrien-1-ol **11** (0.236 g, 1 mmol) in 1 ml of CH_2Cl_2 was added over 5 min, and the mixture was slowly warmed to~ −45ºC over 30 min, and stirred at that temperature for 30 min. The mixture was cooled to −78ºC again, 1 ml of Et_3N was added dropwise, and the resulting mixture was slowly warmed to room temperature over ~1 h. The mixture then was poured into ice-water and extracted with hexane. The hexane layer was washed successively with saturated $NaHCO_3$ and brine, then applied directly to a column of silica gel (20 ml), eluting the column with 10% EtOAc in hexane. Fractions containing the aldehyde were combined and purified further by Kugelrohr distillation, yielding the aldehyde as a pale yellow liquid (171 mg, 73%). The aldehyde was diluted immediately with hexane to a 5% solution, ~5 mg BHT were added as stabilizer, and the solution was sealed in brown glass ampoules flushed with nitrogen to minimize degradation. NMR spectra were run in deuteroacetone to minimize problems with acid-catalyzed trimerization of the long-chain aldehyde that might result from traces of DCl in the typical NMR solvent, $CDCl_3$. ^{1}H NMR (deuteroacetone): δ 9.71 (t, 3H, J=1.6 Hz), 5.95–6.08 (m, 2H), 5.53–5.62 (m, 2H), 5.29–5.39 (m, 2H), 2.51 (br. t, 2H, J~6.8 Hz), 2.34 (br. quart., 2H, J ~ 6.9 Hz), 2.0–2.1 (m, 6H, partially obscured by deuteroacetone peak), 1.38–1.45 (m, 2H), 1.24–1.34 (m, 4H), 0.87 (t, 3H, J=7.2 Hz). ^{13}C NMR: δ 13.56, 22.28, 25.06, 26.59, 26.85, 31.99, 32.04, 43.10, 129.47, 130.17 (2C), 130.73, 131.52, 132.69, 201.63 ppm. One carbon signal appeared to be obscured by the deuteroacetone signals from 28.6–29.7 ppm. The NMR spectra were in general agreement with those previously reported in $CDCl_3$ solvent (Tomida and Fuse, 1993). MS (EI, 70 EV): 234 (M^+, 2), 216 (1), 190 (7), 177 (6), 163 (7), 159 (9), 150 (23), 134 (38), 121 (38), 119 (47), 107 (26), 95 (51), 93 (53), 91 (48), 81 (59), 79 (100), 67 (86), 55 (55), 41 (57).

Field Trials

Lures were prepared at INRA Orléans from 11-mm red rubber septum lures (Wheaton Scientific, Millville, NJ, USA) loaded with heptane solutions (100 µl, 1 mg/ml) of the synthesized pheromone that had been shipped by courier to INRA from UC Riverside. Loaded septa were placed in a 20-ml glass vial and kept in a freezer or an ice-chest when not in use. Five different experiments were set up to test the efficiency of the lures and compare the attraction of male moths to pheromone lures, light traps, or calling females:

Experiment 1

Lures were tested on 19 May 2009 in the Spanish Pyrenees (San Juan de la Pena, Huesca province, 42.51675°N, 0.69056°W, 1100 m above sea level [a.s.l.]). Two

pheromone-treated or untreated control septa were placed in one mesh cage [16 cm H×32 cmW×16 cm D]. In total, 4 control and 4 treatment cages (a total of 16 septa) were suspended from branches of *Pinus sylvestris,* one of the moth's main host plants, ~0.5 m above ground. Cages were spaced approximately 2 m apart, and were monitored from 21:30 till 23:00 (males mostly fly at dusk). The temperature ranged from 25.4°C at the beginning of the experiment to 11.4°C at the end. Responding males were collected with a net, tissues were sampled non-lethally for DNA analyses, as part of a conservation genetics study, and adults were then released (Vila et al., 2010).

At the same time, we set up a light trap consisting of a night collecting sheet (Bioquip, CA, USA) with a 175 W mercury vapor light mounted on a tripod on one side of the sheet. The light trap was placed 280 m away from the lures (42.51824°N, 0.69341°W, 952 ma.s.l.).

Experiment 2

On 20 May 2009, lures were tested in the Spanish Central Sierra of Guadarrama (Dehesas de Cercedilla 40.76768°N, 4.07006°W, 1375 ma.s.l.). The experimental design was the same as described above, but temperature ranged from 21.9°C to 15.5°C. At the same time, we set up a light trap and 2 calling females (2 d old) in one cage one km away from the lures (40.75798°N, 4.07148°W, 1300 ma.s.l.).

Experiment 3

On 27 and 28 May 2009, lures were tested in the Swiss Alps (Schallberg, Canton du Valais, 46° 29.594′N, 8° 02.581′E, 1364 ma.s.l.). A single pheromone treated septum was nailed to the trunk of a *P. sylvestris* tree 1.5 m above the ground. We placed a total of 7 unmated females a few days old in 5 cages at approximately 15 m from the lure. The experiment started at 21:30 and finished at 23:00. On May 27, temperature was 11ºC when the experiment started and 4ºC at the end. On May 28, temperature was 11ºC at the beginning, and 6ºC when the experiment was terminated.

Experiment 4

On 3 June 2009, we set up lures at the Spanish Natural Park of Puebla de San Miguel (Valencia province, 40.04325°N, 1.06284°W, 1717 ma.s.l.). A single pheromone treated septum was nailed to the trunk of a *P. sylvestris* tree, 1.5 m from the ground. We set a light trap (one 175 W lamp) approximately 140 m from the lure. We monitored both lures and light trap from 21:30 till 23:00. Males were collected with a net, tissues were non-lethally sampled for DNA analyses, and adults were then released.

Experiment 5

On 11 June 2009, we nailed two pheromone treated septa to two pine trees 800 m apart, in the same area as experiment 4 (40.07914°N 1.10293°W and 40.07209°N 1.10473°W). In addition, we set a sticky trap baited with an untreated septum (control), nailed to a pine trunk on the same pine tree used for experiment 4. We simultaneously placed the lures and the control 1.5 m above the ground at 21:30. Different observers monitored the septa until 23:00.

Results

Identification of the Pheromone Analyses of SPME wipe samples and solvent extracts of dissected pheromone glands by GC-EAD showed that only a single trace component in the extracts elicited responses from antennae of male moths (Fig. 1). This compound had a Kovats index (KI) of 1861 on a relatively nonpolar DB-5 column, and 2383 on a polar DB-WAX column. In GC-MS analyses, the active component showed a small molecular ion at *m/z* 234 (1% of base peak), and a base peak at *m/z* 79, for a possible molecular formula of $C_{16}H_{26}O$, consistent with a C_{16} trienal. Comparison of its KI values with those of model compounds suggested that the compound might contain a conjugated diene and an isolated carbon-carbon double bond. Specifically, the KI of the model compound (6*E*,11*Z*)-hexadecadienal was 80 KI units less than that of the unknown on the DB-5 column, suggesting that at least one of the double bonds was conjugated either with another carbon-carbon double bond or with the aldehyde. Furthermore, the KI values of the model compound (5*Z*,7*Z*,11*Z*)-

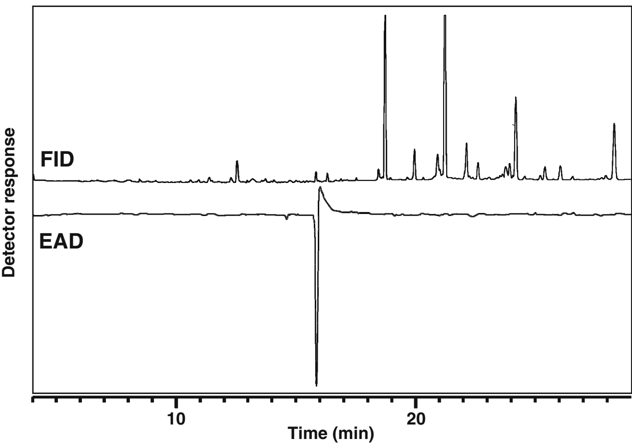


Fig. 1 Coupled gas chromatography-electroantennogram analysis of a SPME wipe sample of everted pheromone gland of a female *Graellsia isabellae*. Top trace is the GC trace; bottom, inverted trace is the response from the male moth antenna. DB-5 column, 100ºC/1 min, 10ºC/min to 275ºC for 60 min

hexadecatrienal (1855 on DB-5 and 2383 on DB-WAX) were similar to those of the unknown, providing support for a C_{16} trienal with a conjugated diene structure. An attempt to determine the position of the diene by derivatization with MTAD failed due to the limited amount of pheromone gland extract available, and the trace amount of pheromone in the extracts. Furthermore, the much stronger responses of antennae of male moths to model compounds with aldehyde vs. alcohol functional groups provided corroborating evidence for the presence of a C_{16} trienal rather than the corresponding tetraenol that would be required by the molecular weight of *m/z* 234.

From the limited number of pheromones known from moths in the same subfamily (Saturniinae), two species (*Antheraea polyphemus* and *A. pernyi*) had been shown to produce (6*E*,11*Z*)-hexadecadienal as a pheromone component (Kochansky et al., 1975, Bestmann et al., 1987, respectively), and a third species, the Ailanthus silkmoth *Samia cynthia ricini*, produced (4*E*,6*E*,11*Z*)-hexadecatrienal (Bestmann et al., 1989). Thus, with no other hard information as to the positions and geometries of the double bonds in the unknown, we synthesized four of the eight possible isomers of this compound. The retention indices of three of these four isomers on the DB-5 column did not match that of the unknown, excluding them from further consideration (KI values: 4*E*,6*E*,11*E*: 1840; 4*Z*,6*E*,11*E*, 1871; 4*Z*,6*E*,11*Z*, 1837). However, the retention time of synthetic (4*E*,6*E*,11*Z*)-hexadecatrienal exactly matched that of the unknown on both the DB-5 and the DB-WAX columns, and the mass spectra of the synthetic and natural compounds were also a good match, providing a tentative identification of the pheromone as (4*E*,6*E*,11*Z*)-hexadecatrienal. Further confirmation of this identification was obtained from field bioassays (see below).

Synthesis of (4E,6E,11Z)-hexadecatrienal Four of the eight possible isomers of 4,6,11-hexadecatrienal were synthesized as isomeric pairs, using Wittig reactions to assemble the conjugated diene structures (see Supplementary Online Information). Having determined that the (4*E*,6*E*,11*Z*)-isomer matched the insect-produced compound in all respects, we then developed a route to that specific isomer (Fig. 2). A key starting material, 4-nonyn-1-ol, was not commercially available, and so it was assembled by alkylation of THP-protected 4-pentyn-1-ol with butyl iodide (83%) (Buck and Chong, 2001). After deprotection (94%), the resulting alkynol **3** was stereoselectively reduced to (*Z*)-4-nonen-1-ol with P-2 nickel and hydrogen, and then converted to (*Z*)-4-nonenyl bromide **5** by treatment with methanesulphonyl chloride and pyridine followed by LiBr in acetone (67% over 2 steps). Reaction of bromide 5 with lithium acetylide-ethylene diamine complex in DMSO (Sonnet and Heath, 1980) then produced enyne **6** (83%). Treatment with bis (dicyclopentadienyl)zirconium hydridochloride followed by iodine (Zeng et al. 2004) stereospecifically gave the key (*E*)-vinyl iodide **7**. A second application of hydridozirconation to *t*-butyldimethylsilyl-protected 4-pentyn-1-ol **8** gave the alkenylzirconium intermediate **9**. This was converted *in situ* to the corresponding zinc organometallic, and palladium-catalyzed coupling of this intermediate with iodide **9** completed the assembly of the *E*,*E*-conjugated diene system (Ribe et al., 2000). Removal of the alcohol's *t*-butyldimethylsilyl protecting group in aqueous acid gave trienol **11** in 78% yield from enyne **6**. Swern oxidation of alcohol **11** completed the synthesis, and after purification, the resulting aldehyde was immediately diluted in hexane and sealed in brown ampoules to minimize degradation.

Fig. 2 Stereoselective synthesis of (4*E*,6*E*,11*Z*)-hexadecatrienal

Field Bioassays

Experiment 1

A total of 20 males were attracted to the treatment cages, whereas no males were attracted to cages containing untreated control septa. Cages with pheromone-treated septa attracted males from 21:48 till 22:30. No males were attracted with the light trap.

Experiment 2

A total of 11 males were attracted by the treated lures. No males were attracted by the controls, by the light trap, or by caged calling females.

Experiment 3

During the course of this experiment conducted over two successive evenings, no males flew towards the caged females; all males observed flew rapidly to the pheromone lures. On May 27, we collected 10 males (between 21:36 and 22:30), all of which were marked by writing a number in the upper-side right forewing, then released at 23:00. On May 28, we collected 34 males, seven of which were recaptures from the previous evening. The first male (non-recaptured) arrived only one min after setting out the pheromone lure.

Experiment 4

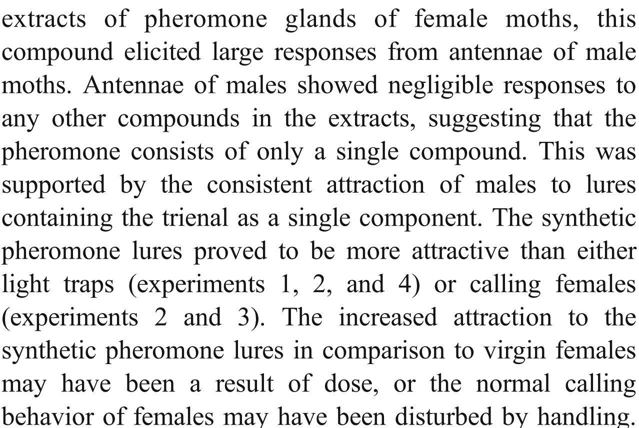
We collected 48 males attracted by the pheromone lure, whereas only one male was attracted by the light trap. Males showed no hesitation in approaching the lure, indicating that the single component was both necessary and sufficient to obtain attraction.

Experiment 5

Four males were attracted by the lure set at site 40.07209°N 1.10473°W, and seventeen males were attracted to the lure deployed at site 40.07914°N 1.10293°W. Interestingly, individuals flew off after a few minutes. No males came to the control lure.

Discussion

As suggested by the strong EAG responses elicited by aldehyde standards in preliminary work by Zagatti and Malosse (1998), the pheromone of *G. isabellae* proved to be a triunsaturated aldehyde, (4*E*,6*E*,11*Z*)-hexadecatrienal. In GC-EAD analyses of SPME wipe samples or solvent extracts of pheromone glands of female moths, this compound elicited large responses from antennae of male moths. Antennae of males showed negligible responses to any other compounds in the extracts, suggesting that the pheromone consists of only a single compound. This was supported by the consistent attraction of males to lures containing the trienal as a single component. The synthetic pheromone lures proved to be more attractive than either light traps (experiments 1, 2, and 4) or calling females (experiments 2 and 3). The increased attraction to the synthetic pheromone lures in comparison to virgin females may have been a result of dose, or the normal calling behavior of females may have been disturbed by handling.



We often observed the first male/s flying readily to the lures a few minutes (1–5) after deploying the septa. In experiments where the septa were nailed to the trunk of a tree, males stayed on the septum itself most of the time, or walked and flew close by or on the tree trunk before flying off a few minutes later. The fact that males that were initially attracted to lures abandoned their search for a female and flew off after a few minutes suggests that other, short-range signals such as contact sex pheromones may be required in order to elicit the full sequence of mating behaviors and/or that males that cannot quickly find the pheromone source (i.e., a female) allocate further efforts to searching for a more accessible mate.

(4*E*,6*E*,11*Z*)-Hexadecatrienal had been previously reported as a pheromone component for another saturniid species, the Ailanthus silkmoth *Samia cynthia ricini* (Bestmann et al., 1989), and the related dienal, (6*E*,11*Z*)-hexadecadienal had been found in other members of the family (*Antherea polyphemus*, Kochansky et al., 1975; *Antherea pernyi* Bestmann et al., 1987). Although (4*E*,6*E*,11*Z*)-hexadecatrienal had been synthesized previously, all reported syntheses used reactions with low stereoselectivity, such as Wittig reactions (Bestmann et al., 1989, Tomida and Fuse, 1993) or Claisen orthoester rearrangements (Singh et al., 1992). Thus, we developed an improved synthesis based on zirconium and zinc organometallics, with a key step being the palladium-catalyzed coupling reaction between alkenylzirconium intermediate **9** and vinyl iodide **7**. In our hands, this proved to be highly stereoselective, giving the desired product in 96% isomeric purity.

Although the pheromone was identified from females belonging to subspecies *G. isabellae galliaegloria* (French Alps), the synthesized pheromone attracted males from a total of three subspecies: *G. isabella paradisea* Marten (experiment 1: Central Spanish Pyrenees), *G. i. isabellae* Graells (experiment 2: Sierra Guadarrama; experiments 4&5: Valencia), and *G. i. galliaegloria* (experiment 3: Swiss Alps).

Previous to this work, field surveys for this species had been carried out using light traps and calling female moths. The identification and testing of the pheromone described

here has demonstrated how the pheromone can be used to dramatically increase the sensitivity of survey methods while simultaneously decreasing the time and effort required to carry out surveys. Having the pheromone in hand will allow us to survey areas where the species is potentially present (Chefaoui and Lobo, 2007, 2008), demonstrate absence with far greater certainty than previously possible, and identify isolated populations of potentially high conservation value.

The success of this project also has shown that problems associated with working with the pheromones of rare or endangered lepidopteran species are manageable, for several reasons. First, the extensive literature on lepidopteran pheromones allows predictions as to likely pheromone structures based on the taxonomic placement of species. Second, with care, it is possible to collect pheromone samples by SPME wipe sampling with no damage to calling females, so that the females can be used subsequently in captive breeding programs. Alternatively, if it is necessary to make solvent extracts of pheromone glands, the sensitivity of current analytical instruments requires that only a few females be sacrificed. Third, field surveys can be carried out with observers or video cameras simply watching pheromone lures, with no insects being caught, so surveys should have minimal impact on moth populations. If responding males are indeed caught with nets, if done carefully, the males sustain minimal damage, as evidenced by our being able to use males captured in this way for mark-recapture studies. For all these reasons, the identification and use of pheromones would seem to be a practical and efficient method of detecting and monitoring rare and endangered species.

Acknowledgments We thank Francis Goussard, David Lees, Enrique Murria, Joaquin Baixeras, Guillermo Fernández, Piedad Lincango, and José Sevilla for assistance in the field. We thank Raimondas Mozuraitis for his work and comments on previous attempts to identify the pheromone using SPME. Abstract We have identified cuticular pheromones that sustain the integrity of the six *Drosophila paulistorum* semispecies. Hexane extracts of male and female cuticles were separated on a silica gel column and analyzed using gas chromatography/mass spectrometry. Both sexes of each of the six semispecies have the same fifteen major cuticular components, all hydrocarbons ranging from C31 to C37. However, all males have four additional ester compounds. Bioassay observations showed that this four-component ester complex imparts a strong anti-aphrodisiac effect on intra-semispecific mating behavior, thus confirming its pheromonal role. The three major ester components are methyl (Z)-9-tetradecenoate ($C_{15}H_{28}O_2$), 11-docosenyl acetate ($C_{24}H_{46}O_2$), and 19-triacontenyl acetate ($C_{32}H_{62}O_2$). The fourth ester is a di-unsaturated acetate with molecular formula $C_{32}H_{60}O_2$, but the positions of unsaturation have not been determined. Bioassays indicate that the male-specific complex of the transitional semispecies, the relict ancestor, imparts anti-aphrodisiac effects on the other semispecies as well, but effectiveness decreases with phylogenetic distances. Across the six semispecies, the male-specific compounds are the same, but vary quantitatively. Apparently, the quantitative differences among these incipient species act efficiently to preclude hybridization in nature. Because *Drosophila paulistorum* is a cluster of incipient species, this opportunity to observe pheromonal influences on speciation is unique.

Key Words *Drosophila paulistorum* · Male pheromone · Cuticular hydrocarbon · Methyl (Z)-9-tetradecenoate · 11-docosenyl acetate · 19-triacontenyl acetate

Introduction

Extensive literature exists concerning the biology of the *Drosophila paulistorum* superspecies (Ehrman, 1965; Ehrman and Powell, 1982), because this complex represents unique evolutionary material caught in *statu nascendi* (Dobzhansky and Spassky, 1959). *Drosophila paulistorum* is a species complex consisting of six semispecies, native to South and Central America. These units do not interbreed in nature, where they are partially separated by their geographical distribution, as their names imply: Andean-Brazilian (AB), Amazonian (AM), Centroamerican (CA), Interior (IN), Orinocan (OR), and Transitional (TR). The TR semispecies is thought to be the relict ancestral one, and is confined to Colombia. The semispecies are morphologically indistinguishable, but can be identified by allozymes, chromosomes, courtship behaviors, and hybridization only in the laboratory. The phylogenetic order of the six semispecies is: TR, IN, CA, OR, AB, AM, as proposed by Gleason et al. (1998) based upon gene sequencing. The semispecies coexist sympatrically over parts of their different geographic distributions in nature, and many degrees of social isolation among them have been detected. In addition to geographical isolation, there are three intrinsic isolating mechanisms: sexual isolation, hybrid inviability, and hybrid male sterility owing to the presence of endosymbiotic microbes (Ehrman et al., 1995). Sexual isolation is the most important of all three, and operates efficiently in nature. Here, we concentrated on the chemicals that foster intra-semispecific, fertile matings via contact/olfactory discrimi-

nation afforded by pheromonal compounds found on insect cuticles.

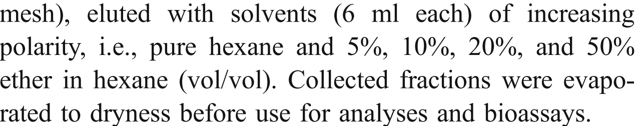
In our earlier brief communication concerning *D. paulistorum* cuticular compounds (Chao et al., 2001), we noted the presence of two male-specific cuticular compounds, methyl (Z)-9-tetradecenoate ($C_{15}H_{28}O_2$) and 11-docosenyl acetate ($C_{24}H_{46}O_2$), and their anti-aphrodisiac properties. These male-specific pheromonal compounds increase in quantity as flies age, and this increase is greatest between the ages 2 days to 3 days, the age of sexual maturity. Kim et al. (2004) studied the influences of social experience on the production of two major cuticular compounds by *D. paulistorum* males, 11-docosenyl acetate, one of the male-specific compounds, and 2-methyltriacontane, a compound common in both male and female species, concluding that socially-isolated flies possessed higher quantities of both compounds compared to communally raised ones. Neither of the above two articles reported the detailed chemical structure characterization of cuticular compounds. More recently, using different GC conditions, we discovered two additional male-specific components, as well as several clusters of higher molecular weight hydrocarbons, which were not revealed in the two earlier studies. In this paper we report the chemical characterizations and quantitative comparisons of these male-specific components, as well as their effects on inter- (sterile) and intra- (fertile) semispecific mating behavior. We also tentatively identify the cuticular hydrocarbons common to both males and females.

Methods and Materials

Fly Strains For full descriptions of origins and maintenance of all *Drosophila paulistorum* strains, see Ehrman and Powell (1982) and references therein.

Cuticular Compound Extraction Three-day-old, sexually mature male and female virgin flies were examined. In a typical experiment, approximately 100 3-d-old virgin flies per sex were killed by freezing at −70°C. These were later thawed to room temperature, dried on filter papers, and then placed in vials. After 1 ml hexane (HPLC grade) was added, the vial was left standing for 5 min, mixed on a Vortex mixer for 2 min, and left standing for another 5 min before hexane wash was removed. The extraction process was repeated. Combined hexane washes were filtered, stored, evaporated to 0.50 ml, and quantitatively transferred to 1-ml conical vials with Teflon-lined screw caps. These extracts were evaporated to dryness under nitrogen.

Column Chromatography Separation Extract samples were reconstituted in 0.50 ml hexane, applied to a 15×1 cm mini-glass column packed with silica gel (Merck, 60–200 mesh), eluted with solvents (6 ml each) of increasing polarity, i.e., pure hexane and 5%, 10%, 20%, and 50% ether in hexane (vol/vol). Collected fractions were evaporated to dryness before use for analyses and bioassays.



Chemical Derivatization In order to locate positions of C=C bonds, dimethyl disulfide (DMDS; 99.0 + %, Aldrich) derivatives of cuticular compounds were synthesized (Buser et al., 1983; Carlson et al., 1989). Experiments were carried out on the hexane fraction and the 5% ether/hexane fraction. Each pre-dried fraction was dissolved first in 100 μl hexane and then treated with 0.2 ml DMDS and 0.10 ml of iodine/diethyl ether solution (60 mg/ml). The reaction mixture was left standing with mixing at room temperature for 24 h. Hexane (4 ml) was added to the mixture, followed by 0.2 ml sodium thiosulfate aqueous solution (10%), reducing the remaining iodine. The organic layer was evaporated to dryness under nitrogen.

Gas Chromatography/Mass Spectrometry (GC/MS) Analyses Dried samples containing whole extracts or column chromatography fractions from approximately 100 flies were reconstituted in 5 μl hexane immediately before analyses. Electron impact (EI) analyses of fly extracts were carried out on an HP 5890A/5971A GC/MS instrument (Hewlett Packard Corporation, Palo Alto, CA, USA equipped with a 30 m× 0.25 mm×0.25 μm AT-1 column (non-polar), programmed between 150°C and 320°C at 6°C/min, and held at 320°C for 10 min. Injection port temperature was 275°C. Peak areas were calculated using an "auto-integrate" method provided by HP ChemStation software.

Dimethyl disulfide derivatization reaction mixtures were analyzed on a Varian Saturn 2200 ion trap mass spectrometer/ 3800 gas chromatograph instrument; GC conditions were identical to those used with the HP instrument; ion trap temperature was 200°C.

Positive CH_4 chemical ionization (CI) experiments were carried out on an HP 5890/5988A, equipped with a 30 m× 0.25 mm×0.25 μm DB-1 column (non-polar), programmed from 50°C (1 min) to 320°C at 6°C/min.

Mating Observations Bioassay of male cuticular extracts involved direct mating observations. All details concerning our bioassay experimental protocols have been itemized by Ehrman (1965, 1975), and reviewed and adjudicated by Knoppien (1985). Briefly: All replicas were conducted mornings at room temperature in daylight facing north. Beforehand, virgin flies, unexposed to anything male, were aged 2 d to 3 d after light ether anesthetization during which they were sexed (there are no sex differences in abdominal banding in this superspecies), and half were marked via minute distal wing clips (used as control in bioassays). Such marked abrasions have tested neutral

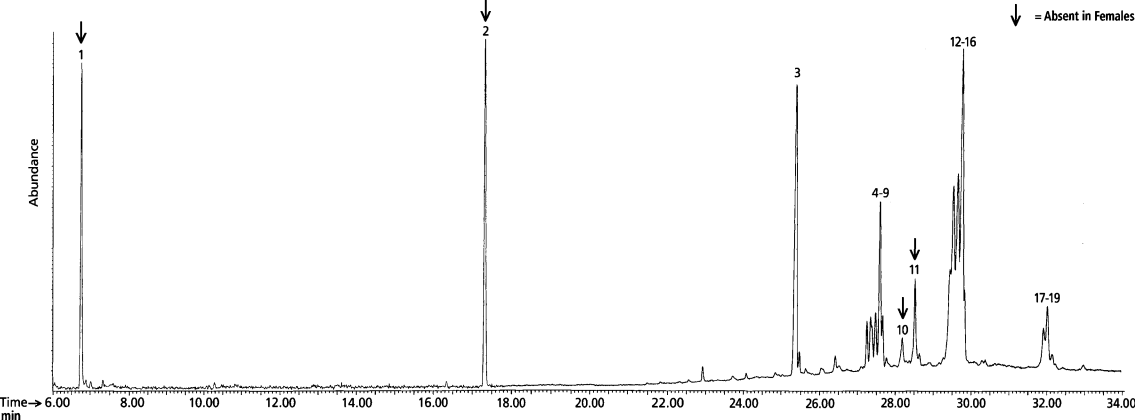


Fig. 1 Gas chromatogram of hexane cuticular extract from 3-day-old Centroamerican (CA) males. Compounds 1, 2, 10 and 11 are not found in females

regarding behavioral influences (Leonard and Ehrman, 1983) in this superspecies.

Samples of the hexane extract or column chromatographic fractions obtained from 20 flies were dissolved in 20 μl of hexane and applied to strips of filter paper that were allowed to stand until the solvent completely evaporated. Twenty virgin females, without repeated anesthetization at any time, walked on the solvent-free filter paper impregnated with samples for 30 sec. Exposed females then were placed, with no further anesthetization, in a glass mating chamber (Elens and Wattiaux, 1964; Ehrman, 1965) together with 20 unexposed, clean females (wings clipped to facilitate identification), plus 40 males. A four-power hand lens was employed to score the following until all flies copulated in approximately 30–40 min: the time (from beginning of observations) each mating takes place; its sequence among other copulae that occur; where in the chamber the mating pair is located (for this purpose a grid constitutes the floor); the kind of female involved; and the kind of male involved. Each copulation lasts approximately 17 min, and females mate only once in these arenas. Recording location of copula, even upside down, prevented scoring a copula more than once. Only the first 20 matings became part of our data, scored as mating preferences, because after the first half of all 40 possible matings, male flies try to mate with any fly still available of any sex indiscriminately (Ehrman and Kim, 1998). (Note that any single male can mate more than once, likely within the second half of all matings. Females never mate more than once under these experimental conditions, nor apparently in nature, as noted by Richmond and Ehrman, 1974.)

Results

Cuticular hexane extracts from male flies of all six semispecies (TR, IN, CA, OR, AB, AM) have the same set of nineteen major compounds, with small variations in intensity patterns between different semispecies (Fig. 1). Samples of males and females, however, have clear differences; i.e., peaks 1, 2, 10, and 11 are absent in all females. Both males and females shared the same remaining fifteen compounds, and each corresponding compound has the same retention time and mass spectrum. Male-specific compounds responsible for peaks 1, 2, 10, and 11 are the focus of this study.

Column Chromatography Fractions of the Male Cuticular Extracts Silica gel column chromatography fractions collected were analyzed by GC/MS. The non-polar hexane fraction gave GC peaks 3, 4–9, and 12–19 (Fig. 1); the slightly polar 5% ether-in-hexane fraction gave only peaks 1, 2, 10, and 11 (GC data not shown). The more polar

Table 1 Numbers of intraspecific matings observed between virgin females (n=20) previously exposed to TR male cuticular compounds and males

	TR × TR	IN × IN	CA × CA	OR × OR	AB × AB	AM × AM
Whole extract	3.0±1.1	5.3±1.0	6.0±3.6	6.0±1.4	6.6±0.3	10.6±2.6
Hexane fraction	10.2±1.2	10.5±1.1	9.5±1.2	10.0±1.0	10.1±1.4	9.8±0.5
5% Ether fraction	2.6±2.0	1.6±1.3	4.6±1.7	4.6±1.2	4.0±0.2	6.6±1.2

Observations were made of 40 males plus 20 untreated females and 20 treated females. A score of ten corresponds to a neutral (no mating preference) response. See Ehrman (1975) for further details and about statistics

fractions (>10% ether) only gave trace amounts of components corresponding to some of the very weak, unlabeled compounds in Fig. 1. A similar study of extracts of females exhibited only compounds found in the hexane fraction of males. Males and females, therefore, share the same set of non-polar compounds; male-specific compounds, on the other hand, are all slightly polar.

Effects of Male Cuticular Extracts on Intraspecific Mating Behaviors Direct mating observations were carried out to determine the sex pheromonal roles of the compounds present in various fractions from silica gel column separation. Results from the AM semispecies are presented here. This experimental design was planned to determine whether the presence of these compounds on virgin females significantly reduced male courtship. Numbers of copulae were recorded for unexposed, clean virgin females vs. virgin females exposed to the whole extract or column chromatographic fractions. A hexane blank also was included in this survey. Number of matings (average ± standard deviation) for the initial halves of the first 20 females exposed to matings were 10.0±1.0, 3.0±1.1, 9.3±2.2, 2.2±1.0, 12.4±2.7, and 11.3±1.5 for the hexane blank, whole extract, hexane fraction, 5%, 10%, and combined 20–50% ether in hexane fractions, respectively. The numbers represent the average of 5 replicas. Hexane blanks elicited a neutral response (number of matings=10) as anticipated. Only the whole extract (number of matings=3.0±1.1) and the 5% ether-in-hexane fraction (number of matings=2.2±1.0) had a "negative" effect on subsequent mating behavior. All others were inactive or neutral in courtship, and all fractions and controls were statistically tested vs. expectations of random mating, which did not occur when biologically-active, anti-aphrodisiacal fractions were surveyed. The mixture found in the 5% ether-in-hexane fraction has an anti-aphrodisiac mating effect.

Bioassay Results of Male TR Cuticular Extract on Mating Behavior of All D. paulistorum Semispecies Following the same bioassay experimental design outlined above, whole extracts and column chromatographic fractions of the male ancestral TR cuticular compounds were tested on all six semispecies. For each semispecies, twenty females were exposed to extracts from twenty male TR (an average of 1 fly-equivalent exposure per female fly), and the mating behaviors of these exposed females vs. twenty clean females were recorded. Only the first twenty matings were tabulated as indicators of mate preferences. Results listed in Table 1 itemize averaged numbers of intraspecific matings of three replicas. The TR hexane fraction, containing a mixture of non-polar compounds, resulted in approximately random matings, a neutral response, for all. The 5% ether fraction elicited a strong anti-aphrodisiac effect, with AM matings affected minimally. The effect of whole extracts resembles that of the 5% ether fraction, though slightly weaker.

Percent Distribution Comparison of the Male-Specific Compounds Across the Six Semispecies Using integrated areas under each GC peak of the whole extract, percent distributions of the four male-specific compounds for each species were calculated. Table 2 summarizes the results showing the quantitative variation of the male-specific pheromonal components across the six semispecies. Values were calculated from three samples of 100 flies each.

Structural Characterization of Male-Specific Compounds EI-MS of the four male-specific compounds (GC peaks 1, 2, 10, 11) share the general characteristics of straight, long chain hydrocarbons with gradually diminishing ion intensities spaced 14 atomic units (au) (CH_2) apart. Definitive assignment of the molecular ion $[M]^+$ was difficult based on EI data alone because of the lack of the $[M]^+$ peak intensity. Molecular weight (MW), therefore, was deduced from the strong $[M+1]^+$ ion of the compound's positive CH_4-CI-MS. Positions of the C=C bonds were determined via MS analyses of the DMDS (CH_3S-SCH_3, MW 94) derivatives. For compounds containing one C=C, DMDS adds across the C=C bond of the compound RCH = CHR', giving the addition product $R(SCH_3)CH$–$CH(SCH_3)R'$ which is 94 au heavier than the underivatized compound. Cleavage of the CH−CH bond results in two diagnostic MS ions due to $[R(SCH_3)CH]^+$ and $[CH(SCH_3)R']^+$ fragments (Carlson et al., 1989). Table 3 summarizes the analysis results.

Compound 1 was identified as methyl (Z)-9-tetradecenoate. EI-MS and CI-MS of compound 1 are shown in Fig. 2a and b, respectively. The strong EI ion at *m/z* 74

Table 3 Structural information of the male-specific compounds and important MS peaks

Peak no.	EI- MS m/z (abundance[a])	CI –MS m/z(abundance[a])	Molecular formula	Compound
1	74 (83), 240 (6.2)	209 (78), 241(100), 269 (25)	$C_{15}H_{28}O_2$	(Z)-methyl 9-tetradecenoate
2	61(18), 306 (15)	61(32),305(28),367(25),395(8.4)	$C_{24}H_{46}O_2$	11-docosenyl acetate

11	61 (16), 418 (19), 478 (1.1)	61(6.2), 417(29), 479(17)	$C_{32}H_{62}O_2$	19-triacontenyl acetate

[a] Abundance is relative to the base peak (100%)

indicates a methyl ester (McLafferty and Turecek, 1993). The weak EI *m/z* 240 $[M]^+$ ion has a strong CI counterpart at *m/z* 241 $[M+1]^+$, confirming a MW of 240. The *m/z* 209 $[M-31(CH_3O)]^+$ ion is present in both EI and CI. The *m/z* 269 $[M+(C_2H_5)]^+$ CI ion together with the *m/z* 166 [M-74] EI ion further supports the assigned MW (Harrison, 1992). EI-MS of the DMDS adduct gave a molecular ion at a *m/z* 334, $[334-47(SCH_3)]^+$ ion at 287 and a $[334-94(SCH_3-SCH_3)]^+$ ion at 240. Two diagnostic ions at *m/z* 117 $[CH(SCH_3)(CH_2)_3CH_3]^+$ and *m/z* 217 $[CH_3OOC(CH_2)_7(SCH_3)CH)]^+$ point to C-9 as the location of the C=C bond. An increase of retention time from 6.69 min of the compound to 15.33 min for the DMDS adduct is consistent with the increase of 94 au, under our GC conditions.

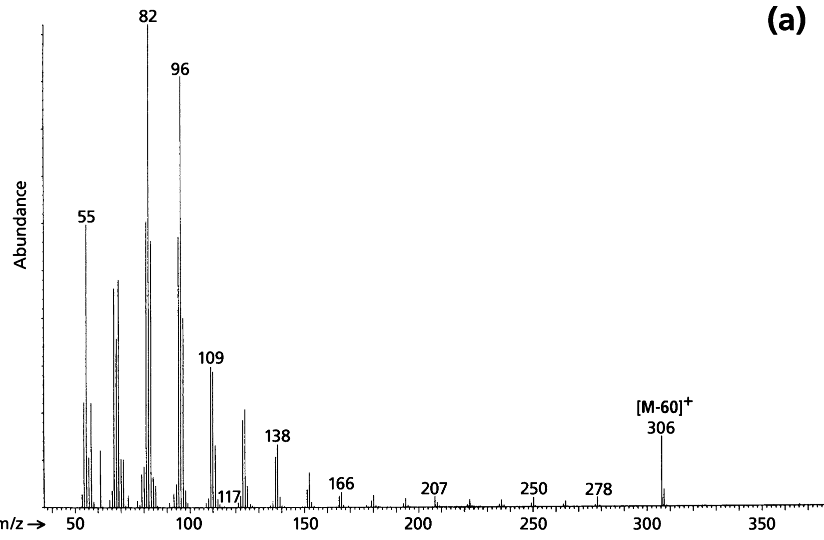

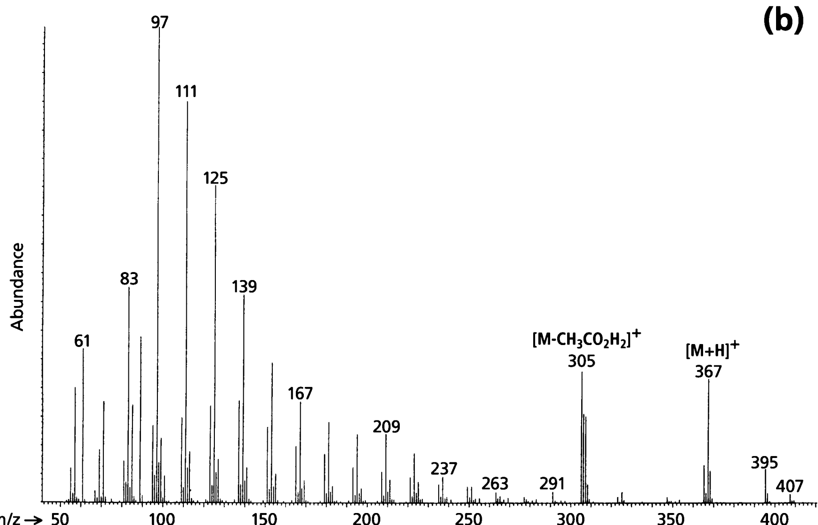

Fig. 3 Mass spectra of GC compound peak 2. 11-Docosenyl acetate ($C_{24}H_{46}O_{2,}$ MW 366). **a** Electron impact MS. A strong $[M\text{-}60)]^+$ (*m/z* 306) ion. Molecular ion (*m/z* 366) absent. **b** Methane chemical ionization MS. $[M+H]^+$ ion at *m/z* 367, $[M\text{-}61]^+$ at *m/z* 305, and $[M+H+28]^+$ at *m/z* 395

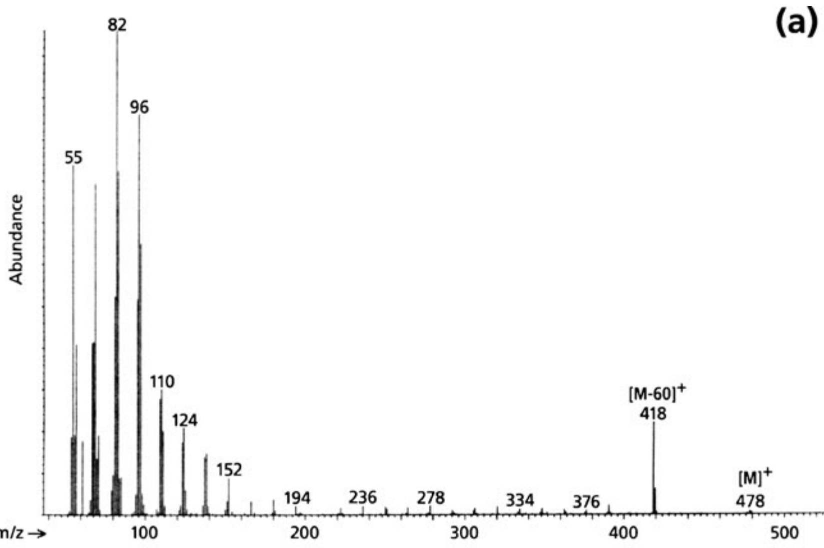
Structural identification including the "Z" configuration of the double bond was confirmed by GC-MS data of the synthetic methyl (Z)-9-tetradecenoate standard ($C_{15}H_{28}O_2$, MW 240), purchased from Sigma-Aldrich, Inc. (St. Louis, MO, USA).

The compound responsible for GC peak 2 is the most abundant of the four male-specific compounds (Chao et al., 2001; Kim et al., 2004). Both EI-MS and CI-MS (Fig. 3) gave the characteristic *m/z* 61 ion for acetate due to the protonated $CH_3CO_2H_2^+$ species (Harrison, 1992). Although the EI (Fig. 3a) had a strong *m/z* 306 ion, based on our CI data, this is not due to the molecular ion; rather it is due to the $[M\text{-}60]^+$ fragment after the neutral loss of an acetic acid (MW 60) moiety. The CI data indicated a 366 MW. Strong CI (Fig. 3) ions at *m/z* 367, 305, and 395, can be assigned to $[M+H]_,^+$ $[M\text{-}CH_3CO_2H_2\ ]^+$, and $[M+C_2H_5]^+$. Based on the overall smooth varying MS intensity pattern, chain branching is not indicated. Its DMDS derivative yielded EI-MS molecular ion $[M]^+$ at *m/z* 460 plus the two diagnostic ions at *m/z* 201 and 259, corresponding to DMDS addition at the C-11 position. Compound 2 is therefore 11-docosenyl acetate ($C_{24}H_{46}O_{2,}$ MW 460). Its stereochemistry is not yet determined.

Compound 11 is due to 19-triacontenyl acetate ($C_{32}H_{62}O_2$, MW 478). Its EI-MS (Fig. 4a) had a weak molecular ion at *m/z* 478 and an intense $[M\text{-}60(C_2H_3O_2)]^+$ ion at 418. Its CI-MS (Fig. 4b) had a prominent ion at *m/z* 479, $[M+H]^+$, giving a MW of 478. Again, both CI and EI had the characteristic *m/z* 61 ion for acetate. The EI-MS of its DMDS adduct exhibited an $[M+H]^+$ ion at *m/z* 573, $[M+H\text{-}SCH_3]^+$ at 526, two diagnostic ions at *m/z* 201 and 372, and an ion at *m/z* 312 (372- 60), indicating a C=C (unknown stereochemistry) at the C19 position in the underivatized acetate.

We were not able to fully characterize the compound responsible for GC peak 10. Its EI-MS (Fig. 5) has a weak



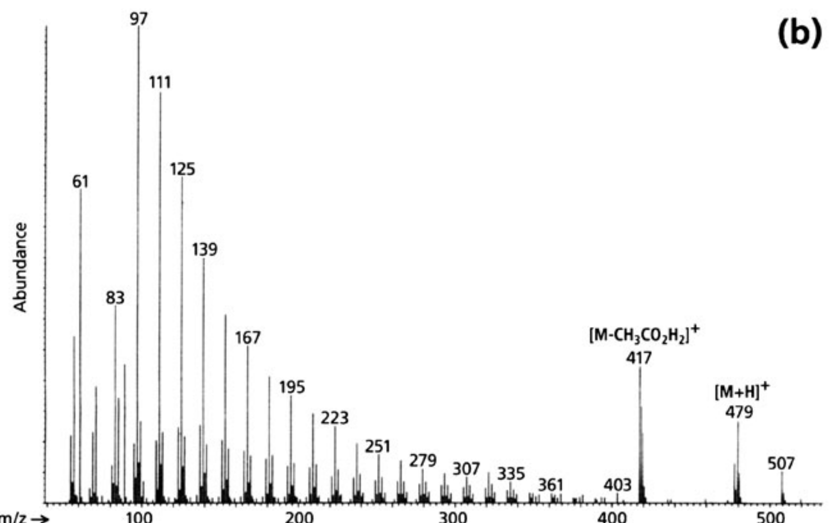


Fig. 4 Mass spectra of GC compound peak 11. 19-Triacontenyl acetate ($C_{32}H_{62}O_2$, MW 478). **a** Electron impact MS. Molecular ion at *m/z* 478, and an intense $[M\text{-}60]^+$ peak at 418. **b** Methane chemical ionization MS. Prominent ions at *m/z* 479 ($[M+H]^+$), *m/z* 417 ($[M\text{-}61]^+$), and *m/z* 507 ($[M+H+28]^+$)

$[M]^+$ ion at *m/z* 476, an *m/z* 61 ion for acetate; its CI has a 475 $[M\text{-}H]^+$ ion and a 415 $[M\text{-}61]^+$ ion. Therefore, this compound is a di-unsaturated acetate ($C_{32}H_{60}O_2$, MW 476). GC-MS analysis of the DMDS derivatization reaction product did not give GC peaks that can be attributed to the DMDS adduct of this fourth component, despite numerous efforts.

Structural Information about the Non-polar Hydrocarbons Both male and female extracts yielded hydrocarbons (GC peaks 3–9 and 12–19 in Fig. 1) in the hexane fraction eluted from the silica gel column. Although their exact chemical structures are not central to this investigation, they warrant preliminary reporting here.

As we have noted previously, Kim et al. (2004) studied the effect of rearing conditions on the quantity of the compound responsible for GC peak 3. Here, we present the MS data analyses for this peak. Its EI-MS (Fig. 6) gave a molecular ion at *m/z* 436. Branch point at C-2 is indicated since the smooth decline of MS peak abundance is disrupted by ions at *m/z* 421 $[M\text{-}CH_3]^+$ and 393 $[M\text{-}C_3H_7]^+$ due to elimination of a terminal methyl group and an isopropyl group, respectively. Its CI-MS (not shown) has ions at *m/z* 435 $[M\text{-}H]^+$, 421 $[M\text{-}CH_3]^+$, and 407 $[M\text{-}C_2H_5]^+$, consistent with the EI data. This compound is tentatively identified as 2-methyltriacontane ($C_{31}H_{64}$), the only saturated hydrocarbon of all 19 cuticular compounds detected.

The rest of the compounds occur by GC in three clusters of peaks (peaks 4–9, 12–16, and 17–19; Fig. 1). Each cluster consists of several slightly overlapping peaks. Figure 7 shows the gas chromatograms of AM and OR females in this region. Although both sexes of all six semispecies gave the similar pattern of three clusters, the detailed quantitative variations differed as illustrated in Fig. 7. Mass spectra of peaks in this region all have the

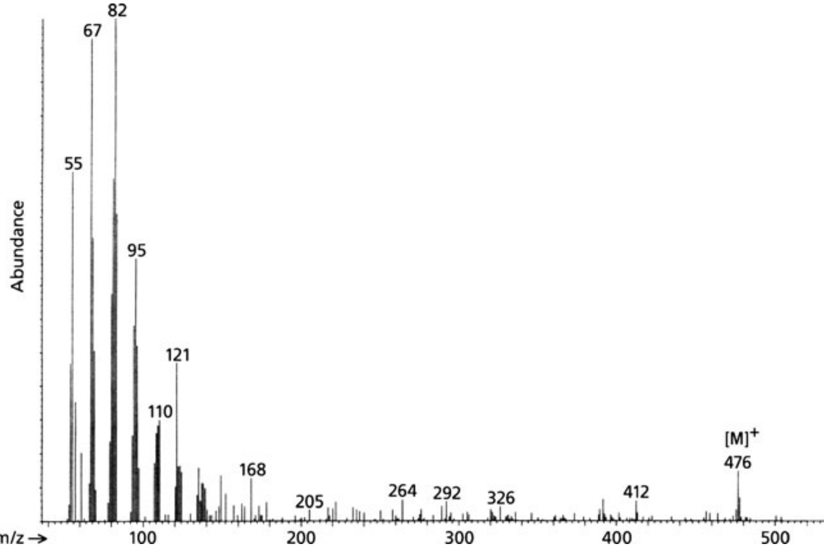

Fig. 5 Electron impact MS of GC compound peak 10. A di-unsaturated acetate with formula $C_{32}H_{60}O_2$ and MW 476

characteristic fragmentation pattern of a long chain linear hydrocarbon. Each weak EI-MS molecular ion $[M]^+$ has a corresponding strong CI ion at *m/z* M-1. Compounds 4 and 5, both with molecular ions at *m/z* 462, are likely due to two positional isomers of a $C_{33}H_{66}$ monoene. Similarly, compounds 6–9 all have molecular ions at *m/z* 460, probably due to four positional isomers of $C_{33}H_{64}$. Compounds 12–16, an overlapping cluster of 5 discernable peaks, share the same EI- and CI-MS. An intense CI-MS ion at *m/z* 487 $[M\text{-}H]^+$, and the corresponding EI-MS ion at *m/z* 488, suggest isomers of $C_{35}H_{68}$ (MW 488). Finally, the last cluster of at least three overlapping peaks, numbered 17–19, based on their MS data, can be assigned to isomers of $C_{37}H_{72}$ (MW 516). In conclusion, cuticular compounds common to both males and females, though not fully characterized, are odd-carbon hydrocarbons, including one terminally branched alkane, 2-methyl triacontane ($C_{31}H_{64}$), plus isomers of unsaturated hydrocarbons $C_{33}H_{66}$, $C_{33}H_{64}$, $C_{35}H_{68}$, and $C_{37}H_{72}$.

Discussion

Cuticular lipid profiles of all six *D. paulistorum* semi-species were found to be similar. Males and females share the same 15 major hydrocarbons. Males possess four additional compounds, all long-chain esters: one methyl ester, methyl (Z)-9-tetradecenoate ($C_{15}H_{28}O_2$); and three acetates—$C_{24}H_{46}O_2$ (11-docosenyl acetate), $C_{32}H_{60}O_2$ (an unsaturated acetate), and $C_{32}H_{62}O_2$ (19-triacontenyl acetate). These three acetates have not been confirmed against their authentic compounds, and organic syntheses are currently underway. Bioassays of the various chromatographic fractions confirmed the pheromonal role of the

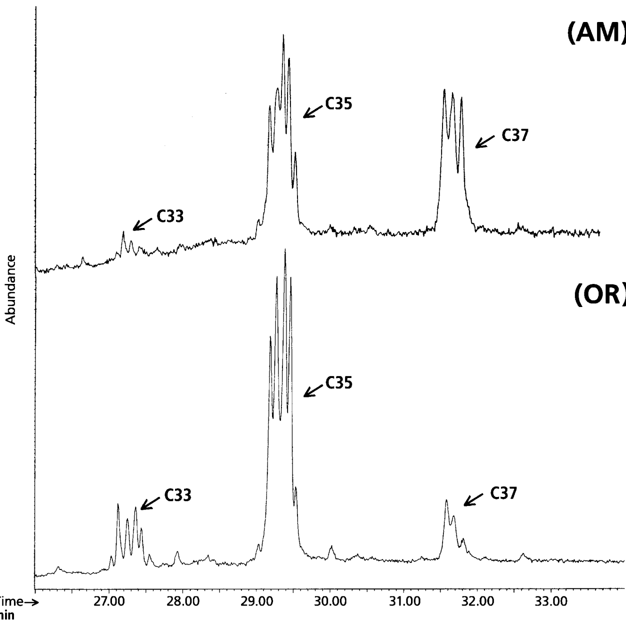

Fig. 7 Gas chromatograms of Amazonian (AM) and Orinocan (OR) females, showing only the region where all unsaturated hydrocarbons, C33 (peaks 4–9), C35 (peaks 12–16) and C37 (peaks 17–19), are eluted

male ester mixture. Preliminary structural data on the fifteen hydrocarbons, ranging from C31 to C37, are reported, but detailed analyses will be the topic of future studies.

Our findings bear close resemblance to the literature on the most studied drosophilid, *D. melanogaster*. For example, in *D. melanogaster*, almost identical chemical compositions of cuticular hydrocarbons were found among members of individual populations, and quantitative variations have been noted between geographic populations (Jallon and Penchine, 1989). It is known that contact during mating may result in mutual exchanges of cuticular hydrocarbons from one sex to the other, subsequently decreasing the attractiveness of both males and females to members of the other sex (Ferveur, 1996). In *D. melanogaster*, a male pheromone compound, (*Z*)-vaccenyl acetate, was found to inhibit mating behavior (Jallon, 1984). More recently, by observing the mating behavior of decapitated flies and by disrupting a single *D. melanogaster* gene, Marcillac et al. (2005) were able to partition production and discrimination of cuticular hydrocarbons functioning as sex pheromones, reflecting *desat1* locus pleiotropy. In *D. paulistorum*, we found a four-component ester blendthat elicited strong anti-aphrodisiac effects on mating behavior. These male-specific pheromones from different semispecies differ only quantitatively, suggesting that both chemical identities as well as quantitative proportions are critical factors that determine effects on mating behaviors.

Gleason et al. (1998), based on gene sequencing, have proposed the phylogenetic order of the six semispecies as: TR (the relict ancestor), IN, CA, OR, AB, AM. These researchers also proposed that because of geographic separation from siblings, Amazonian is approaching the status of a distinct species. Our bioassay results regarding male TR cuticular extracts on mating behaviors of all other semispecies demonstrated that the TR male pheromones impart anti-aphrodisiac effects on the other five semispecies too, but the effect decreases as phylogenetic distances of each semispecies from TR increases. AM, the one most remote from TR, is least affected. This suggests that the male-produced pheromone is at least partially responsible for reproductive isolation by preventing inter-semispecific mating and, therefore, production of sterile offspring. Ehrman et al. (1995) have observed that hybrids of the different semispecies have never been reported in nature, nor has a trapped sperm-storing gravid female ever borne alien sperm. This is so even in regions of geographic sympatry, demonstrating the startling efficiency of pheromones as sensory cues.

Acknowledgments Chemical ionization mass spectra were obtained at the Mass Spectrometry Facility at American Health Foundation, NY. We also thank Dr. Frank Bellevue of SUNY Purchase for help with the DMDS chemical derivatization experiments. This research was partly funded by a Merck/AAAS USRP Award, Research and Science Visions Preparation Program supported by NSF Grant DUE 0524965, the Purchase College Faculty Support Fund, and Purchase College Natural Sciences Student Research Awards. One of the authors, D.B., was a participant in the Research and Science Visions Preparation Program at Purchase College, summer 2006.

sweep out comparatively large areas as they patrol tree trunks and other substrates for females, so that they can locate mates efficiently (Hanks et al., 1996; Hanks, 1999). To our knowledge, contact pheromones have not yet been identified for beetles in the more ancestral subfamilies that lack elongate antennae, including the Prioninae, Parandrinae, and Aseminae (*sensu* Monné and Hovore, 2005). Although males of the prionine, *Prionus californicus* Motschulsky, recognize females via contact chemoreception (Cervantes et al., 2006; Barbour et al., 2007), the compounds that mediate mate recognition have not yet been identified. A greater understanding of the use of contact pheromones in ancestral subfamilies will lend insight into the evolution of mating systems in the Cerambycidae.

Mallodon dasystomus, the hardwood stump borer, is a widely distributed prionine that is native to the southern U.S. The elongate robust adults range in length from 23–47 mm and vary in color from reddish brown to black (Solomon, 1995). Females oviposit near the base of their hosts at sites where the wood is exposed, such as at wounds or areas of previous infestation. Larvae feed in the boles of trees, typically complete their development in 3–4 yr, and emerge as adults from May through July leaving large ovoid emergence holes in the bark (Linsley, 1962; Solomon, 1995). Preferred hosts *of M. dasystomus* include sugarberry, hackberry, oak, sycamore, hickory, willow, boxelder, sweetgum, and in some instances, conifers (Solomon, 1995; Yanega, 1996).

In this study, we explored the chemically-mediated mating behavior of *M. dasystomus*, and tested the hypothesis that males recognize females by contact chemoreception. We characterized the mating behavior of males, and report the identification and synthesis of the bioactive components. Additionally, we sampled cuticular hydrocarbons of males and females using both whole-body solvent extraction and solid phase microextraction (SPME). SPME is a solventless sampling technique that was used in conjunction with solvent extraction to identify the contact pheromones of the cerambycine species *Megacyllene robiniae* (Förster) (Ginzel et al., 2003b), *Megacyllene caryae* (Gahan) (Ginzel et al., 2006), and *Neoclytus acuminatus acuminatus* (F.) (Lacey et al., 2008). Wipe-sampling yields hydrocarbon profiles that are quantitatively different from whole-body solvent extraction (Ginzel et al., 2006). For example, the contact pheromone of *M. caryae,* (*Z*)-9-nonacosene, comprised ~16% of the total hydrocarbons in the hexane extracts of females, but represented ~34–36% of the hydrocarbons in SPME wipe samples of the elytra (Ginzel et al., 2006). These findings suggest that SPME samples more accurately represent those compounds that are accessible to the antennae of males and can be used to predict hydrocarbons that may act as contact pheromones. In this study we also test the hypothesis that contact pheromones are more abundant on the surface of the wax layer and are present in greater abundance in SPME samples when compared to whole-body extracts.

Methods and Materials

Source of Beetles Beetles used in experiments were reared from infested willow and sweetgum at the USDA Forest Service Center for Bottomland Hardwoods Research, Stoneville, MS, from late May to early August 2007 through 2009. As adult beetles emerged, they were shipped to Purdue University, West Lafayette, IN (USDA—APHIS permit No. P526P-09-01631). Upon arrival, beetles were housed individually in cylindrical cages of aluminum window screen (300 cm^3) with 9-cm glass Petri dishes covering top and bottom, and provided feeder vials of 10% sucrose solution (glass vial with a cotton dental roll; Patterson Dental Supply, South Edina, MN, USA). Beetles were kept in an environmental chamber (Mod. No. 1-30BLL, Percival Scientific, Boone IN, USA) on a 16 L –29°C:8D – 25°C cycle that was 12 hr out of phase with natural daylight, and maintained at 80% humidity. Reared beetles may have mated before they were individually caged. Beetles were isolated in these cages for at least 24 hr before being used in bioassays. Beetles used in bioassays were vigorous and active, and were used no more than once per day.

Characterization of Mating Behavior To characterize the mate recognition behavior of *M. dasystomus* in the laboratory, we observed individual males paired with individual females in Petri dish arenas (9 cm diam × 2 cm tall) lined with filter paper (No. 1, Whatman, Maidstone, England). Observations were made in the dark under a red light and ambient laboratory conditions for a minimum of 2 min or until beetles mated. The behaviors of 17 pairs of female and male beetles in these arenas were recorded digitally using a Sony Handy-Cam, model DCR-SR42. All Petri dishes were cleaned, washed with acetone, and air dried between trials. We analyzed videotapes to determine whether one sex displayed directed movement toward the other, a behavior consistent with the use of either vision or volatile pheromones as mate location signals. We also observed whether males responded to females only after contacting them with their antennae, behavior that would suggest the use of contact pheromones.

Role of Contact Chemoreception To illustrate that male *M. dasystomus* recognize females via a contact pheromone, we used the following bioassay adapted from Ginzel *et al.* (2003b).

1. *Freeze-killed female.* An individual female was freeze-killed (−4°C for 20 min), allowed to warm to room temperature (~15 min), and presented to a vigorous male in a Petri dish arena to demonstrate that mate recognition signals were intact. The male was allowed to attempt to mate the female, but separated before copulation occurred.
2. *Solvent-extracted female carcass.* Non-polar compounds were removed from the dead female by immersing her in two successive 10-ml aliquots of analytical grade hexane for 5 min each. The aliquots then were combined and concentrated to 3 ml under nitrogen. The solvent-washed female was presented to the male to test whether he displayed mating behavior. Lack of a response by the male was taken as evidence that chemical recognition signals had been removed.
3. *Reconstituted female.* To test the bioactivity of the extract, we gradually pipetted 0.1 female equivalent (FE) of extract back onto the female carcass, coating the body with the extract. The solvent then was allowed to evaporate, and the reconstituted female was presented again to the same male to confirm that the recognition signal had been restored. If the male did not respond, we incrementally added 0.1 FE to the female, up to a maximum of 1 FE, and retested the female against the same male.

We conducted this videotaped bioassay with six dead females each paired with three different males ($N=18$). Once a male touched a female with his antennae, a clear progression of behavioral steps lead to copulation (arrestment of male, body alignment with female, mounting, and copulation; see Results for details). A trial was scored as a "response" if the male, after making antennal contact with the female, displayed any of these behavioral steps. Bioassays were conducted in glass Petri dish arenas (see above), and numbers of males responding to reconstituted females were compared with those responding to freeze-killed females with a Fisher's exact test (Sokal and Rohlf, 1995).

Identification of Cuticular Hydrocarbons We sampled cuticular components of five female beetles by wiping the length of a SPME fiber (100 µm, polydimethylsiloxane; Supelco Inc., Cat. No. 57300-U, Bellefonte, PA, USA) across the elytra ten times, rotating the fiber between wipes. Samples were analyzed at Purdue University by coupled gas chromatography-mass spectrometry (GC-MS) with electron impact ionization (EI, 70 eV) using a Hewlett-Packard (HP) 6890N gas chromatograph (Hewlett-Packard, Sunnyvale, CA, USA) equipped with a DB-5 capillary column (30 m×0.25 mm×0.25 µm film, J&W Scientific, Folsom, CA, USA) in splitless mode, and interfaced to an HP 5973 mass selective detector (MSD), with helium as the carrier gas. The SPME fiber was thermally desorbed in the heated GC injection port for 1 min and the oven temperature was held at 50°C for 1 min and then ramped at $10°C\,min^{-1}$ to 280°C, with a hold at 280°C for 20 min. Injector and transfer line temperatures were 250°C.

Five female beetles and five males also were sampled by whole-body hexane extraction, allowing us to compare the hydrocarbon profiles of males and females, and the profiles of females produced by the two sampling methods. The cuticular chemicals were extracted from individual freeze-killed beetles by immersing each in two 10-ml aliquots of hexane for 5 min. The aliquots were combined and concentrated to 3 ml under nitrogen. Extracts were analyzed initially at Purdue University by coupled GC-MS as described above. The percentage that each peak contributed to the total hydrocarbons was calculated by integrating the areas under peaks of all hydrocarbons that were consistently present in the total ion chromatograms (Chemstation, Version D.05.01; Hewlett Packard Corp.). Quantitative data presented in Table 1 and Figs. 1 and 2 were produced by these analyses. Differences in mean relative abundance of compounds that comprise the contact pheromone (area under peak/total area of all peaks) between whole-body hexane extraction and SPME of females were compared by analysis of variance (StatSoft, Inc., 2005).

Compounds in whole-body extracts were identified at the University of California, Riverside by GC-MS using the same model of GC-MS instrument and the same type of column as described above. The column was programmed from 100°C for 1 min, $10°C\,min^{-1}$ to 280°C, with a final hold for 20 min at this temperature. Injector and transfer line temperatures were 280°C. Linear and branched chain hydrocarbons were identified by comparing their retention times and mass spectra with those of standards, or by interpretation of the mass spectra in combination with Kovats retention indices. Retention times of methylalkanes relative to straight-chain compounds, and characteristic mass spectral fragments (M^+ ions in combination with diagnostic fragments from cleavage on either side of branch points) can be used to completely and unequivocally identify saturated hydrocarbons found in insect cuticular extracts, as described in detail by Nelson (1993), Nelson and Blomquist (1995), and Carlson et al. (1998).

Synthesis of 2-Methylhexacosane and 2-Methyloctacosane Solvents were Optima grade (Fisher Scientific, Pittsburgh, PA, USA). Tetrahydrofuran (THF) was distilled from sodium/benzophenone ketyl under Ar. Reactions with air- or water-sensitive reagents were carried out in oven-dried glassware under Ar. ^{1}H- and ^{13}C-NMR spectra were recorded on a Varian INOVA-400 (400 and 100.5 MHz,

[a] Percent of total hydrocarbons represents means for five individuals. ND, not detected, SPME, solid-phase microextraction

[b] Peaks are numbered in order of elution from a DB-5 capillary column (see Methods and Materials) and correspond to those in Fig. 1

[c] Molecular ions in bold were observed. Molecular ions in normal font were not observed but could be inferred from the diagnostic ions

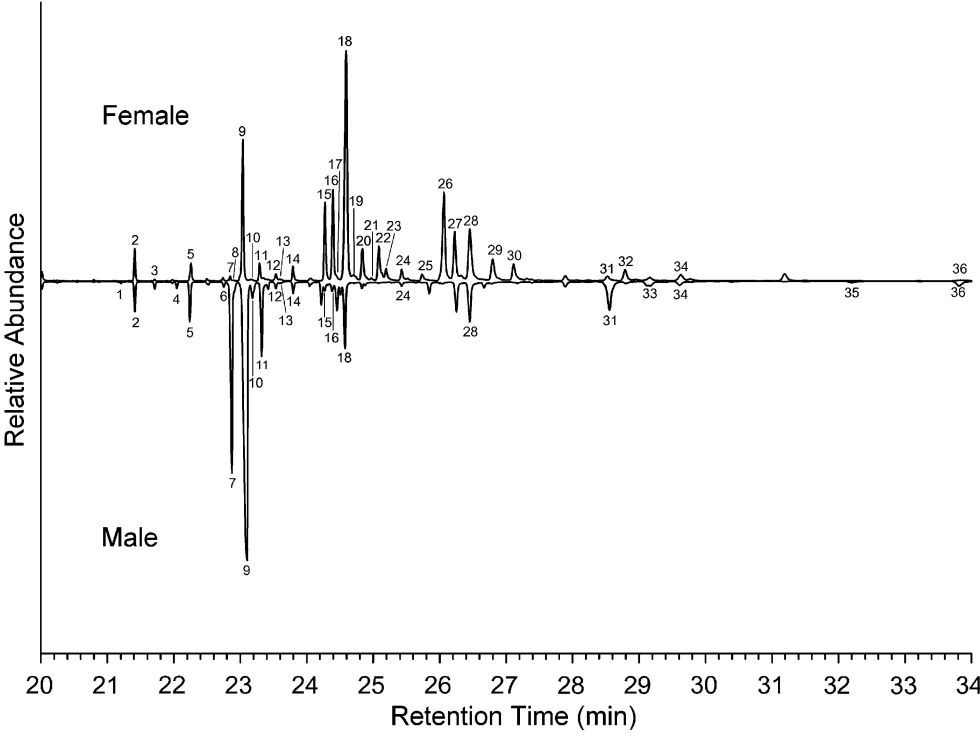

Fig. 1 Representative chromatograms of solvent extracts of female (*top*) and male (*bottom*, *inverted*) *Mallodon dasystomus*

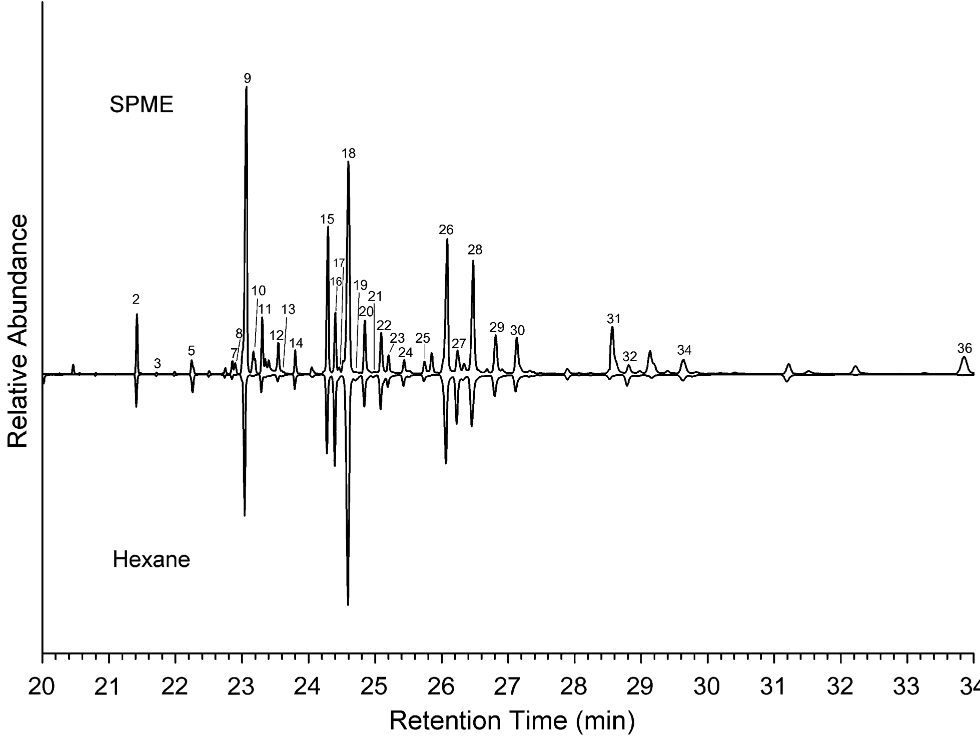

Fig. 2 Representative chromatograms of SPME (*top*) and solvent extracts (*bottom*, *inverted*) of female *Mallodon dasystomus* cuticular hydrocarbons

respectively) spectrometer (Palo Alto, CA, USA), as $CDCl_3$ solutions. ^{1}H NMR chemical shifts are expressed in ppm relative to residual $CHCl_3$ (7.27 ppm) and ^{13}C NMR chemical shifts are reported relative to $CDCl_3$ (77.16 ppm). Unless otherwise stated, solvent extracts of reaction mixtures were dried by treatment with anhydrous Na_2SO_4 and concentrated by rotary evaporation under reduced pressure. Crude products were purified by vacuum flash chromatography (VFC) on silica gel (230–400 mesh; Fisher Scientific). Integer resolution mass spectra were obtained with a Hewlett-Packard (HP) 6890 GC (Avondale, PA, USA) interfaced to an HP 5973 mass selective detector, in EI mode (70 eV) with helium carrier gas. The GC was equipped with a DB5-MS column (25 m×0.20 mm ID×0.25 µm film, J&W Scientific, Folsom, CA, USA). Electrospray ionization exact mass data were obtained with an Agilent 6210 LCTOF instrument, introducing the sample via flow injection into a stream of 95% MeOH and 5% water (0.1% formic acid). The vaporizer and gas temperatures in the ESI interface were 200°C. Fragmenter voltage was 125 V. The instrument was operated in the multisource mode. GC-MS exact mass data were obtained on a Waters GCT Premier instrument operated in EI mode (70 eV) with ion source temperature 200°C and injector temperature 240°C. The GC was programmed from 50°C for 1 min, then 10°C min^{-1} to 300°C, using a DB-5 column as described above.

Synthesis of 2-methylhexacosane

12-(Tetrahydropyran-2-yloxy)-dodecan-1-ol **(2)** This compound was made by a modification of the method of Nishiguchi et al. (2000). Thus, 1,12-dodecanediol **1** (50.0 g, 247 mmol) was dissolved in a mixture of hexane (580 ml), dihydropyran (62.40 g, 741 mmol) and dimethylsulfoxide (21 ml). The mixture was stirred vigorously at 50–55°C while a solution of HCl (0.2 M, 49 ml) was slowly added, and the resulting mixture was stirred 14 h. After cooling, the aqueous phase was separated and extracted with hexane (3×50 ml). The combined organic layers were washed with saturated aqueous $NaHCO_3$ (3×50 ml) and brine (2×100 ml), dried, and concentrated. The crude product was purified by vacuum flash chromatography (VFC) on silica gel affording 57.10 g (81%) of the pure mono-protected product **2** (plus 15.4 g ~55% pure by GC). ^{1}H NMR: δ 1.20–1.40 (m, 16H), 1.46–1.64 (m, 8H), 1.66–1.75 (m, 1H), 1.76–1.88 (m, 1H), 3.37 (dt, 1H, J=6.8 and 9.6 Hz), 3.45–3.54 (m, 1H), 3.62 (t, 2H, J=6.8 Hz), 3.72 (dt, 1H, J=6.8 and 9.6 Hz), 3.82–3.90 (m, 1H), 4.56 (dd, 1H, J= 2.5 and 4.3 Hz). ^{13}C NMR: δ 19.92, 25.72, 25.96, 26.45, 29.65, 29.70, 29.78, 29.79 (3C), 29.81, 29.97, 31.00, 62.58, 63.28, 67.93, 99.09. MS: m/z 285 (M-1, 1), 201 (1), 125 (1), 111 (3), 101 (27, 85 (100), 69 (17), 55 (35), 41 (33).

12-(Tetrahydropyran-2-yloxy)-dodecyl-1-p-toluenesulfonate **(3)** Tosyl chloride (40.92 g, 215 mmol) was added in small portions over 2 hr to a solution of 12-(tetrahydropyran-2-yloxy)-dodecan-1-ol **2** (55.90 g, 195 mmol) in dry pyridine (30.86 g, 390 mmol) and chloroform (390 ml), while stirring at 0°C. The reaction was allowed to warm to room temperature, stirred for 1 d, and then *N,N*-dimethylamino-pyridine (0.10 g) was added. After stirring 2 d, the mixture was concentrated under vacuum. The residue was taken up in ethyl ether (300 ml), and the solution was thoroughly washed with aqueous HCl (10%) (50 ml), saturated aqueous $NaHCO_3$ (2×50 ml), and brine (2×100 ml), then dried and concentrated. The resulting oil was purified by VFC (hexane: ethyl acetate, 9:1) giving the tosylate **3** as a white solid (64.31 g, 74.8% yield). ^{1}H NMR: δ 1.18–1.40 (m, 16H), 1.46–1.65 (m, 8H), 1.66–1.75 (m, 1H), 1.77–1.88 (m, 1H), 2.44 (s, 3H), 3.37 (dt, 1H, J=6.6 and 9.6 Hz), 3.46–3.53 (m, 1H), 3.62 (t, 2H, J=6.8 Hz), 3.72 (dt, 1H, J=6.8 and 9.6 Hz), 3.83–3.90 (m, 1H), 4.56 (dd, 1H, J=2.5 and 4.3 Hz), 7.31–7.35 (m, 2H), 7.76–7.80 (m, 2H). ^{13}C NMR: δ 19.95, 21.87, 25.54, 25.73, 26.46, 29.03, 29.15, 29.60, 29.70 (2C), 29.76, 29.78, 29.98, 31.02, 62.61, 67.92, 70.94, 99.12, 128.12 (2C), 130.02 (2C), 133.45, 144.83. HRMS (ESI): calc. m/z=463.2489 $(M+Na)^+$; found: m/z=463.2486.

15-Methyl-1-(tetrahydropyran-2-yloxy)-hexadecane **(4)** A solution of 1-bromo-3-methylbutane (5.14 g, 34.0 mmol) in dry THF (15 ml) was added dropwise (ca 3 hr) to a suspension of Mg turnings (1.24 g, 51 mmol) in dry THF (19 ml) at room temperature under Ar. After 5 hr, the resulting Grignard reagent solution was diluted with dry THF (30 ml) and added dropwise at –60°C to a previously prepared solution of tosylate **4** (5.00 g, 11.3 mmol) in dry THF (85 ml) under Ar, followed by addition of a solution of Li_2CuCl_4 in THF (0.1 M, 5.7 ml, 0.57 mmol; Aldrich Chemical Co., Milwaukee, WI, USA). The mixture was warmed to room temperature over 2 hr and stirred overnight. The reaction was quenched with saturated aqueous NH_4Cl (50 ml), then extracted with ethyl acetate (4×30 ml). The organic layer was washed with saturated aqueous $NaHCO_3$ (50 ml) and brine (50 ml), dried, and concentrated. The residue was purified by VFC (hexane: ethyl acetate, 95:5) affording compound **4** (3.65 g) in 94.5% yield. ^{1}H NMR: δ 0.85 (d, 6H, J=6.6 Hz), 1.10–1.20 (m, 2H), 1.20–1.40 (m, 21H), 1.44–1.62 (m, 8H), 1.66–1.75 (m, 1H), 1.78–1.88 (m, 1H), 3.37 (dt, 1H, J=6.8 and 9.6 Hz), 3.45–3.53 (m, 1H), 3.72 (dt, 1H, J=6.8 and 9.6 Hz), 3.83–3.91 (m, 1H), 4.57 (dd, 1H, J=2.7 and 4.3 Hz). ^{13}C NMR: δ 19.92, 22.88 (2C), 25.73, 26.47, 27.65, 28.19, 29.72, 29.83, 29.84, 29.89, 29.91, 29.92 (2C), 29.95, 29.99, 30.17, 31.01, 39.28, 62.55, 67.92, 99.06. MS: m/z 339 (M – H, 1), 267 (1), 115 (2), 101 (7), 85 (100), 71 (10), 57 (25), 43 (31) 41 (25).

15-Methylhexadecan-1-ol **(5)** *p*-Toluenesulphonic acid (100 mg) was added to a solution of 15-methyl-1-(tetrahydropyran-2-yloxy)-hexadecane **4** (3.60 g, 10.6 mmol) in methanol (20 ml) and the mixture was stirred at room temperature overnight. Most of the methanol was removed under reduced pressure, water (20 ml) was added to the residue, and the mixture was extracted with hexane (3× 20 ml). The combined organic layers were washed with saturated aqueous $NaHCO_3$ and brine, dried, and concentrated. The residue was purified by VFC (hexane: ethyl acetate, 95:5) affording alcohol **5** (2.53 g) in 93.2% yield. ^{1}H NMR: δ 0.85 (d, 6H, *J*=6.6 Hz), 1.10–1.20 (m, 2H), 1.20–1.40 (m, 22H), 1.51 (non, 1H, *J*=6.6 Hz) 1.53–1.60 (m, 2H), 3.63 (t, 2H, *J*=6.7 Hz). ^{13}C NMR: δ 22.89 (2C), 25.96, 27.65, 28.20, 29.66, 29.83, 29.85, 28.89, 29.91, 29.92 (2C), 29.96, 30.18, 33.04, 39.29, 63.33. MS: *m/z* 238 (M – 18, 1), 223 (1), 210 (3), 182 (3), 168 (1), 153 (2), 140 (2), 125 (8), 111 (21), 97 (36), 83 (55), 71 (26), 57 (96), 43 (100) 41 (87).

1-Iodo-15-methylhexadecane **(6)** Iodine (1.34 g, 5.3 mmol) was added in small portions to a mixture of 15-methylhexadecan-1-ol **5** (0.90 g, 3.5 mmol), triphenylphosphine (1.38 g, 5.3 mmol), and imidazole (0.36 g, 5.3 mmol) in ethyl ether-acetonitrile (3:1–12 ml), and the resulting slurry was stirred at room temperature for 1 hr. The mixture then was diluted with ethyl ether (50 ml), washed with saturated aqueous $NaHCO_3$ and brine, dried, and concentrated. The residue was purified by VFC (hexane) affording 1-iodo-15-methylhexadecane **6** (1.21 g) in 94.1% yield. ^{1}H NMR: δ 0.86 (d, 6H, *J*=6.6 Hz), 1.10–1.20 (m, 2H), 1.20–1.34 (m, 20H), 1.34–1.44 (m, 2H), 1.51 (non, 1H, *J*=6.6 Hz), 1.77–1.86 (m, 2H), 3.18 (t, 2H, *J*=7.0 Hz). ^{13}C NMR: δ 7.56, 22.90 (2C), 27.66, 28.20, 28.79, 29.66, 29.79, 29.85, 29.89, 29.92, 29.93, 29.96, 30.18, 30.75, 33.82, 39.30. MS: *m/z* 239 (M – I, 5), 183 (2), 169 (3), 155 (6), 141 (4), 127 (6), 113 (8), 99 (14), 85 (43, 71 (63, 57 (100), 43 (80).

25-Methylhexacos-9-yne **(8)** *n*-BuLi (1.6 M in hexanes, 4.30 ml, 6.9 mmol) was added dropwise to a solution of 1-decyne **7** (0.91 g, 6.6 mmol) in dry THF (7.0 ml) under Ar at –10°C, and the mixture was stirred for 2 hr, forming a suspension. Dry THF (6 ml) and DMPU (3.36 g, 26 mmol) were added, the mixture was stirred for 1 hr at 0°C, then recooled to –10°C, and a solution of 1-iodo-15-methylhexadecane **6** (1.20 g, 3.3 mmol) in dry THF (2.0 ml) was added dropwise. The reaction was quenched with saturated aqueous NH_4Cl (10 ml) and extracted with hexanes (4× 10 ml). The combined organic layers were washed with saturated aqueous $NaHCO_3$ and brine, dried, and concentrated. The residue was purified by VFC (hexane), affording alkyne **8** contaminated with excess 1-decyne **7**. The impure product was used directly in the next step. ^{1}H NMR: δ 0.86 (d, 6H, *J*=6.6 Hz), 0.88 (t, 3H, *J*=7.0 Hz), 1.15–1.19 (m, 2H), 1.22–1.31 (m, 27H), 1.31–1.42 (m, 4H), 1.42–1.56 (m, 4H), 2.10–2.17 (m, 4H). ^{13}C NMR: δ 14.33, 18.99, 22.89, 27.65, 28.19, 29.10, 29.37, 29.40, 29.46, 29.80, 29.87, 29.91, 29.93, 29.96, 30.18, 32.08, 39.29, 77.55, 80.47. MS: *m/z* 376 (M^+, 12), 281 (3), 193 (8), 152 (7), 137 (18), 124 (24), 109 (36), 95 (70), 81 (100), 67 (92), 43 (98), 41 (68). HRMS (ESI): calc. *m/z*=375.3985 $(M\text{-}H)^+$; found: *m/z*=375.3991.

2-Methylhexacosane **(9)** A mixture of 25-methylhexacos-9-yne **8** (+ 1-decyne, 0.90 g) and 5% Pd/C (0.090 g,) in hexane (15 ml) was stirred at room temperature under hydrogen for 16 hr. The mixture was filtered through Celite, and the filtrate was concentrated. The resulting mixture of hydrocarbons was subjected to Kugelrohr distillation (oven temp to 140°C, 0.05 mm Hg) to remove decane, affording 0.75 g (60% over 2 steps) of pure 2-methylhexacosane **9**. ^{1}H NMR: δ 0.86 (d, 6H, *J*=6.8 Hz), 0.88 (t, 3H, *J*=6.8 Hz), 1.11–1.18 (m, 2H), 1.20–1.34 (m, 44H), 1.45–1.57 (m, 1H). ^{13}C NMR: δ 14.35, 22.89, 27.66, 28.20, 29.59, 29.89, 29.93, 29.96, 30.18, 32.16, 39.29. MS: *m/z* 380 (M^+, 1), 365 (3), 337 (16), 239 (3), 225 (2), 211 (3), 197 (4), 183 (4), 169 (5), 155 (6), 141 (8), 127 (9), 113 (12), 99 (19), 85 (42), 71 (63), 57 (100), 43 (93).

Synthesis of 2-methyloctacosane

2-Methyltetradec-5-yne **(11)** *n*-BuLi (2.88 M, 35 ml, 100 mmol) was added dropwise under Ar to a solution of 1-decyne **7** (13.8 g, 100 mmol) in 200 ml THF cooled in a dry ice-acetone bath. The resulting slurry was warmed to room temperature, and NaI (1.5 g, 10 mmol) and 1-bromo-3-methylbutane **10** (14.3 g, 95 mmol) were added. The resulting mixture was refluxed under Ar for 40 hr, then cooled and quenched with saturated aqueous NH_4Cl. The mixture was extracted with hexane, and the organic layer was washed with brine, dried, and concentrated. The residue was Kugelrohr distilled, collecting a forerun (oven temp <50°C, 0.1 mm Hg) consisting mostly of unreacted 1-decyne **7**. The desired product **11** then was collected in a clean bulb (15.33 g, oven temp 70–80°C, 0.1 mm Hg) in 73% overall yield (86% based on recovered 1-decyne). ^{1}H NMR: δ 0.89 (t, 3H, *J*= 6.8 Hz), 0.89 (d, 6H, *J*=6.8 Hz), 1.25–1.35 (m, 10H), 1.35–1.52 (m, 4H), 1.63–1.72 (m, 1H), 2.12–2.22 (m, 4H). ^{13}C NMR: δ 14.30, 16.95, 18.95, 22.39, 22.86, 27.37, 29.05, 29.32, 29.36, 29.41, 32.04, 38.37, 80.30, 80.40. MS: *m/z* 208 (M^+, 1), 193 (18), 166 (1), 152 (2), 137 (3), 123 (7), 109 (26), 95 (100), 81 (76), 69 (26), 67 (46), 55 (36), 43 (23). HRMS (ESI): calc. *m/z*=208.2186 (M^+); found: *m/z*=208.2193.

13-Methyltetradec-1-yne **(12)** A dry 1 liter 3-neck flask was flushed with Ar and charged with 225 ml dry 1,3-diaminopropane, followed by Li wire (3.2 g, 460 mmol). The mixture was stirred 1 hr at room temperature during which time the Li partially dissolved to give a blue solution. The mixture was heated to 70°C, and stirred for 2 hr, by which time all the Li had dissolved and the blue solution changed to a white suspension. The mixture was cooled to room temperature, and potassium *t*-butoxide (33 g, 295 mmol) was added in one portion with stirring, giving a yellow suspension. After stirring 30 min, 2-methyltetradec-5-yne **11** (15.2 g, 73 mmol) was added over 10 min, and the mixture became warm and turned red-brown. The progress of the isomerization was followed by GC, and after ~1 hr, there was no further change. The mixture was poured into 1 L of a slurry of crushed ice and water, and the mixture was extracted with hexane (3× 250 ml). The combined hexane extracts were washed with water and brine, dried, concentrated, and purified by Kugelrohr distillation (forerun, oven temp <60°C at 0.5 mm Hg; product, oven temp≤100°C, 0.2 mm Hg), yielding 12.76 g of alkyne **12** (83%). ^{1}H NMR: δ 0.87 (d, 6H, J=6.8 Hz), 1.11–1.18 (m, 2H), 1.22–1.34 (m, 12H), 1.35–1.44 (m, 2H), 1.47–1.57 (m, 3H), 1.94 (t, 1H, J= 2.5 Hz), 2.19 (td, 2H, J=7.0, 2.5 Hz). ^{13}C NMR: δ 18.6, 22.9 (2C), 27.6, 28.2, 28.7, 29.0, 29.3, 29.7, 29.8, 29.9, 30.1, 39.2, 68.2, 85.0. MS: *m/z* 193 (M$^+$-15, trace), 179 (trace), 137 (1), 123 (4), 109 (18), 95 (48), 81 (100), 69 (36), 67 (64), 57 (33), 55 (48), 43 (59). HRMS (ESI): calc. *m/z*=207.2107 (M-H)$^+$; found: *m/z*=207.2103.

2-Methyloctacos-13-yne **(14)** A solution of tetradecanol (2.14 g, 10 mmol) and pyridine (0.85 g, 10.5 mmol) in CH_2Cl_2 was cooled to <-10°C in an ice-salt bath, and triflic anhydride (2.2 ml, 13 mmol) was added dropwise. The resulting solution was slowly warmed to room temperature, by which time all the starting alcohol had been consumed. The solution was diluted with 100 ml hexane, and filtered through a 2 cm pad of Celite. The colorless filtrate was concentrated and pumped under vacuum for a few minutes to remove traces of solvent, then the crude triflate **13** was taken up in 10 ml THF and used immediately.

In a separate flask, a solution of 13-methyltetradec-1-yne **12** (2.6 g, 12.5 mmol) in 25 ml THF under Ar was cooled in an ice bath and n-BuLi (2.8 M, 4.8 ml, 13.4 mmol) was added dropwise. After stirring for 15 min, the mixture was cooled to –20°C, the solution of freshly prepared triflate was added dropwise, and the resulting slurry was slowly warmed to room temperature and then stirred for 4 hr. The mixture was quenched with ice water and extracted with hexane. After washing with brine, the hexane solution was dried and concentrated, and the residue was purified by VFC (hexane), followed by Kugelrohr distillation (oven temp up to 100°C, 0.2 mm Hg) to remove low-boiling impurities. The pot residue consisting of essentially pure alkyne **14** was used directly in the next step. ^{1}H NMR: δ 0.84–0.91 (m, 9H), 1.12–1.41 (m, 43H), 2.15 (m, 4H). ^{13}C NMR: δ 14.31, 18.56, 22.86, 27.62, 28.17, 29.07, 29.38, 29.56, 29.78, 29.89, 30.14, 31.79, 32.13, 39.26, 80.44. MS: *m/z* 404 (M$^+$,6), 292 (1), 291 (1), 278 (5), 277 (5), 264 (5), 263 (5), 236 (3), 221 (8), 207 (11), 194 (7), 180 (4), 166 (4), 151 (8), 137 (19), 123 (33), 109 (54), 97 (55), 96 (89), 95 (97), 83 (60), 82 (91), 81 (100), 69 (46), 67 (65), 57 (38), 55 (43), 43 (47). HRMS (ESI): calc. *m/z*=403.4298 (M-H)$^+$; found: *m/z*= 403.4291.

2-Methyloctacosane **(15)** Alkyne **14** was taken up in 50 ml hexane, and 5% Pd on activated charcoal (0.5 g) was added. The flask was fitted with a balloon filled with H_2, and the headspace was flushed with H_2 before sealing and stirring under H_2 until hydrogenation was complete (3 hr). The resulting mixture was filtered through a pad of Celite, rinsing with 20 ml hexane, and the combined filtrate (~70 ml) was cooled overnight at –20°C. The resulting white crystals were filtered with suction in a cold room, yielding 1.38 g of 2-methyloctacosane **15** (>99.5% pure), and 2 g of impure product from the remaining liquor after concentration. ^{1}H NMR: δ 0.86 (d, 6H, J=6.8 Hz), 0.88 (t, 3H, J=6.8 Hz), 1.11–1.18 (m, 2H), 1.20–1.32 (m, 48H), 1.45–1.57 (m, 1H). ^{13}C NMR: δ 14.33, 22.86, 27.64, 28.17, 29.58, 29.90, 30.17, 32.13, 39.29. MS: *m/z* 408 (M$^+$,1), 393 (9), 365 (30), 351 (2), 337 (2), 323 (3), 309 (3), 295 (4), 281 (4), 267 (4), 253 (5), 239 (5), 225 (6), 211 (7), 197 (8), 183 (8), 169 (10), 155 (12), 141 (15), 127 (19), 113 (25), 99 (36), 85 (77), 71 (88), 57 (100), 43 (55).

Bioassays of Hydrocarbon Standards We tested the bioactivity of female-specific compounds in bioassays similar to those described above. The bioactivity of standards of 2Me-C_{26} and 2Me-C_{28} were tested individually and in combination at 1 FE doses in ratios similar to those of SPME samples (28 and 43 ug, respectively). Compounds were quantified by comparing their peak areas in total ion chromatograms with those of an external standard (*n*-docosane). Numbers of males responding to treatments were compared with those responding to freeze-killed females using a Fisher's exact test (Sokal and Rohlf, 1995). Bioassays were conducted in the dark under a red light between 12.00 and 17.00 hr during late June through July, 2009. The remaining female specific compounds were not synthesized and tested because these two synthetic compounds elicited a response in males equal to that of freeze-killed females (see Results).

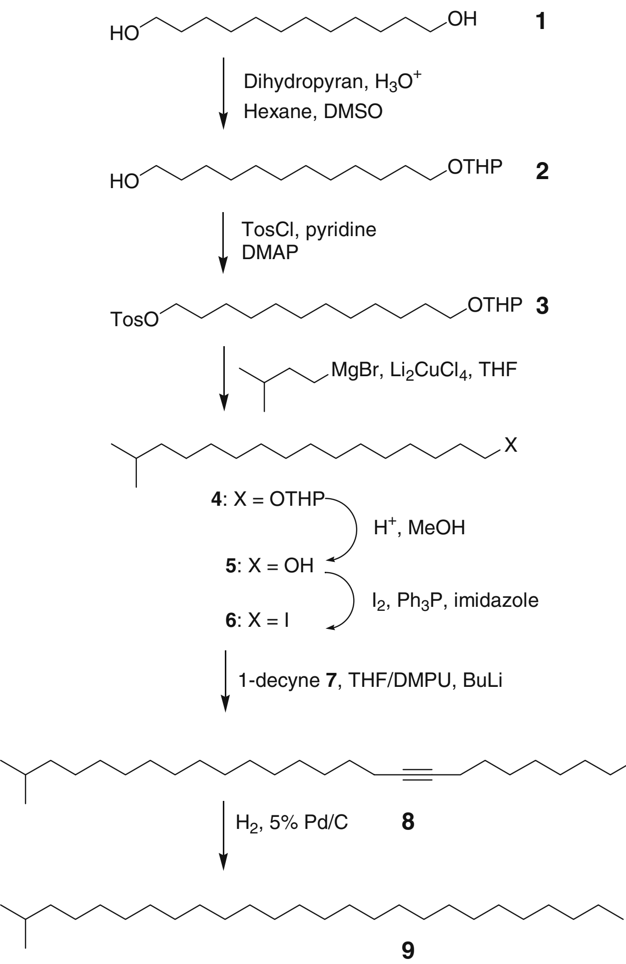

Fig. 3 Synthesis of 2-methylhexacosane

Results

Characterization of Mating Behavior Once a male touched a female with his antennae ($N=17$), a clear progression of cumulative behavioral steps led to copulation: Step 1) male stopped walking and antennated the female; Step 2) the male aligned his body with the female; Step 3) the male mounted the female; Step 4) the male bent his abdomen to connect his genitalia to those of the female. Out of 17 males tested, 15 responded to live females with the full range of behavioral steps after making antennal contact. The remaining two males either ignored the female or responded aggressively (e.g., head raised, biting female's elytra and/or legs) upon encountering the female. In preliminary assays, males were also paired with other males ($N=10$) and, after brief antennal contact, responded aggressively to each other (e.g., biting and kicking) and made no attempt to mate.

Role of Contact Chemoreception All males that were tested displayed a Step 4 behavioral response to freeze-killed females, confirming that signals mediating mate recognition were intact and behavioral signals were not important in mate recognition. None of the males responded to the solvent-washed females, demonstrating that the compounds that mediate mate recognition had been removed by solvent extractions. Of the 18 males tested, 16 displayed Step 4 behavior toward female carcasses to which solvent extracts had been reapplied (response not different from response to freeze-killed females; Fisher's exact test, $F=14.06$, $P>0.05$). Males displayed mating behavior to female carcasses after application of an average (±SE) of 0.15±0.03 FE of crude extract. Two males did not display any mating behaviors to females reconstituted with as much as 0.9 FE of crude extract.

Identification of Cuticular Hydrocarbons Thirty-one compounds were identified in hexane extracts of females, including a series of straight chain compounds from C_{23} to C_{29}. Thirteen compounds were essentially specific to females (Table 1, Fig. 1). Although there were many qualitative differences between hydrocarbon profiles of extracts of females and males, those of females contained two dominant compounds (2Me-C_{26} and 2Me-C_{28}) that were virtually absent in extracts of males. Of these two compounds, the relative abundance of 2Me-C_{26} in SPME wipe samples increased by 65% over solvent extracts (peak 15; Table 1, Fig. 2, means for two sampling methods significantly different, ANOVA: $F_{(1,8)}=10.28$, $P=0.01$),

Compound(s)	No. of males tested	Percent of males responding per step in behavioral sequence[a]			
		Step 1	Step 2	Step 3	Step 4[b]
2Me-C_{26}	21	90 (100)	71 (100)	52 (100)	38 (86)*
2Me-C_{28}	24	96 (100)	79 (100)	67 (100)	58 (100)**
2Me-C_{26}+2Me-C_{28}	27	100 (100)	100 (100)	100 (100)	81 (100)

[a] Response of males to treatments *versus* controls (values in parentheses) were tested with Fisher's exact test (*$P<0.05$, **$P<0.001$)

[b] Numbers of males reaching behavioral step 4 were compared to the response to controls (H_o=no difference in bioactivity between treatment and freeze-killed female)

suggesting that it may be an important component of the contact pheromone. Other less abundant, female-specific compounds included: a C_{25} diene, 11-methyl- and 13-methyl-C_{27}, 11,15-dimethyl-C_{27}, 12-methyl-, 13-methyl-, and 14-methyl-C_{28}, 11-methyl-, 13-methyl-, and 15-methyl-C_{29}, and 13,17-dimethyl-C_{29} (Table 1, Fig. 1). Most of the compounds present in the solvent extracts also were present in the SPME samples of females.

Synthesis of 2Me-C_{26} and 2Me-C_{28} Two different routes for making 2-methylalkanes were explored. In the first (Fig. 3), 1,12-dodecanediol **1** was mono-protected with 3,4-dihydropyran (DHP) to give **2** in 81% isolated yield (Nishiguchi et al., 2000), and the remaining hydroxyl group then was converted to the tosylate **3** (75%). Coupling of tosylate **3** with 3-methylbutyl magnesium bromide with Li_2CuCl_4 catalysis installed the methyl branch, giving 15-methyl-1-(tetrahydropyran-2-yloxy)-hexadecane **4** (95%), which was deprotected in acidic MeOH to give 15-methyl-hexadecan-1-ol **5**. The alcohol was converted to iodide **6** in 94% yield (Corey et al., 1983), giving a synthon that could be converted to any desired long-chain 2-methylalkane. Thus, treatment of 1-decyne **7** in DMPU/THF with *n*-butyllithium followed by addition of iodide **6** gave crude 25-methylhexadec-9-yne **8** contaminated with unreacted 1-decyne. This mixture was reduced with H_2 and 5% Pd/C catalyst, giving 2-methylhexacosane **9** in 60% isolated yield over 2 steps after purification.

2-Methyloctacosane was made by a shorter route (Fig. 4). Thus, reaction of 1-bromo-3-methylbutane **10** with 1-decynyllithium in refluxing THF with NaI catalysis (Buck and Chong, 2001) gave 2-methyltetradec-5-yne **11** in 73% yield (86% based on recovered starting material). Isomerization of the alkyne to the terminal position with the acetylene zipper reaction (Abrams and Shaw, 1988) then gave 13-methyltetradec-1-yne **12**, an alternate synthon for synthesis of a variety of long-chain 2-methylalkanes. Deprotonation of 13-methyltetradec-1-yne **12** with butyllithium followed by reaction with the triflate **13** derived from tetradecan-1-ol in THF gave 2-methyloctacos-13-yne **14** in good yield (Wang and Zhang, 2007), which was then hydrogenated with H_2 and 5% Pd/C catalyst to give the desired 2-methyloctacosane **15**. This route was shorter and more efficient overall than the route used to make 2-methylhexacosane.

Bioassays of Hydrocarbon Standards In bioassays, 2Me-C_{26} and 2Me-C_{28} as individual components elicited some mating responses in males (Step 4 behavior). However, males responded at a rate similar to that elicited by freeze-killed females only when the two compounds were presented as a blend (Table 2).

Discussion

Our results support the hypothesis that male *M. dasystomus* recognize females by a cuticular contact pheromone blend. Males attempted to mate with females only after contacting them with their antennae. In bioassays with freeze-killed females, all males displayed a full progression of mating behaviors and attempted to connect the genitalia, excluding behavioral signals as a component of mate recognition. Additionally, no males attempted to mate with a solvent washed female, suggesting that the mate recognition signals had been removed by the solvent, and that visual signals were not involved. When paired with extracted female carcasses that had been treated with the cuticular extract, 15 of 17 males attempted to mate only after making antennal contact, providing further evidence for an extractable contact pheromone.

Because of the marked differences in the profiles of cuticular lipids between the sexes, our strategy for identifying the contact pheromone components was to synthesize and test the bioactivity of female specific compounds, starting with the most abundant. This approach was effective in the identification of the contact pheromones of *Xylotrechus colonus* F. (Ginzel et al., 2003a) and,

more recently, *N. a. acuminatus* (Lacey et al., 2008). The first two compounds that were synthesized (2Me-C_{26} and 2Me-C_{28}) comprised over 17% of the total hydrocarbons in the cuticular extracts of females. Moreover, there was a significant increase in the proportion of 2Me-C_{26} in the SPME samples when compared to the whole-body hexane extracts, suggesting that it may be an important component of the contact pheromone.

Male *M. dasystomus* responded to both 2Me-C_{26} and 2Me-C_{28} alone in bioassays. However, a blend of the two compounds elicited the greatest response in males, and the response was similar to that of the crude extract, suggesting that these compounds together are the most important components of the contact pheromone. Other cerambycids also have contact pheromones that are multicomponent blends. For example, the contact pheromone of *X. colonus* is comprised of at least three compounds: *n*-C_{25}, 9Me-C_{25}, and 3Me-C_{25} (Ginzel et al., 2003a). Moreover, male *N. a. acuminatus* recognize mates by the presence of 7Me-C_{27}, with two additional branched compounds, 9Me-C_{27} and 7Me-C_{25}, acting as synergists (Lacey et al., 2008). These multi-component blends often are composed of compounds that are homologues, as is the case here with 2Me-C_{26} and 2Me-C_{28}. However, to our knowledge, these compounds are the first 2-methylalkanes and even-chain length hydrocarbons to be identified as contact pheromones in the Cerambycidae. Nevertheless, both 2Me-C_{26} and 2Me-C_{28} are part of the wax layer of other cerambycid species, suggesting that some hydrocarbons may be common to the family. For example, 2Me-C_{26} was found in the cuticular hydrocarbons of male and female *N. a. acuminatus* (Lacey et al., 2008), both sexes of *M. robiniae* (Ginzel et al., 2003b), and in the wax layer of female *M. caryae* (Ginzel et al., 2006). Interestingly, 2Me-C_{28} is more abundant in the wax layer of male than female *M. robiniae* (Ginzel et al., 2003b), whereas it is more abundant in the cuticular hydrocarbons of female than male *M. caryae* (Ginzel et al., 2006).

The solvent extracts of female *M. dasystomus* contained 13 compounds that were essentially absent or greatly reduced in extracts of males. Similar sexual differences were noted in the cuticular lipid profiles of *M. robiniae* and *X. colonus*, in which the compounds constituting the contact pheromones were not completely absent from extracts of males, but were greatly reduced in abundance when compared to extracts of females (Ginzel et al., 2003a, 2006). Here, the differences in the relative amounts of the *M. dasystomus* contact pheromone components, 2Me-C_{26} and 2Me-C_{28}, were obvious, with these two compounds being co-dominant in the hydrocarbon profiles of females. Furthermore, 2Me-C_{26} was significantly more abundant in SPME wipe samples than in hexane extracts of female cuticular hydrocarbons, supporting our previous observations that contact pheromones are present in greater abundance in SPME samples when compared to whole-body extracts. SPME may more accurately represent the compounds that are accessible to the male antennae on the surface of the wax layer, and provide a clearer representation of those hydrocarbons that act as contact pheromones.

During this study, we also observed females displaying behaviors associated with long-range pheromone production. These "calling" behaviors included lowering the head, raising the abdomen, and extending the ovipositor, often in a rhythmic pumping motion. While "calling", one female everted a clear cylindrical, fluid-filled sac from her ovipositor. Female *Prionus californicus* release a powerful sex pheromone from a similar structure (Cervantes et al., 2006; Rodstein et al., 2009). In fact, the calling behaviors of female *M. dasystomus* are almost identical to those of *P. californicus* (Barbour et al., 2006), and similar to other species of insects in which females produce volatile pheromones (e.g., Burkholder et al., 1974; Hammack and Burkholder, 1981). In the subfamily Cerambycinae, the scanty available evidence suggests that mate location might involve three sequential behavioral steps: 1) both sexes are independently attracted to volatiles emanating from the larval host plant; 2) once on the host, males attract both sexes from some distance with aggregation pheromones; and 3) having recruited conspecifics, males recognize females by contact pheromones (Ginzel and Hanks, 2005). In contrast, beetles in the subfamily Prioninae may rely exclusively on sex pheromones to bring the sexes together (Barbour et al., 2006; Cervantes et al., 2006; Rodstein et al., 2009), and then, once in close proximity, the final steps of mate recognition may be mediated by contact pheromones. Although this is the first contact pheromone identified from a cerambycid beetle in the subfamily Prioninae, we anticipate that the use of contact pheromones will be widespread in this subfamily (e.g., Barbour et al., 2007), as it is in many other insect groups.

Acknowledgments We thank Corey Wilkins and Aaron Lancaster for assistance rearing the beetles and Jonathan Larson for assistance in conducting bioassays. We appreciate funding support from Purdue University Department of Entomology, the USDA Forest Service (agreement no. 08-JV-11330127-076), and the U.S. Fish and Wildlife Service (Lower Mississippi Valley Joint Venture, Agreement no. 06-IA-11330127-189, managed by Bill Uihlein), and Southeast Region (Agreement no. 07-IA-11330127-171, managed by Janet Ertel). We are grateful to the following individuals and their institutions for permission to work on their lands and logistical support collecting beetles: Ralph Pearce, Delta National Forest; Martin Blaney, David Luker, and Andy VanHorn, Arkansas Game and Fish Commission; Rodney Wishard, Mike Staten, and Gene Holland, Anderson-Tully Company; David Linden, Yazoo National Wildlife Refuge and Becky Rosamond, Dahomey National Wildlife Refuge. This work was in partial fulfillment of an MS degree for A. E. S. from Purdue University.

successful mating. Although the process of mate selection is conserved by the necessity to perceive and locate a suitable mate, pheromonal signals tend to be highly divergent across species (Johansson and Jones, 2007).

Callosobruchus species (Coleoptera: Chrysomelidae: Bruchinae) are serious pests of stored pulses, cowpeas, pigeonpeas, and other legumes (Rees, 1996, 2004), and are found worldwide, particularly in Eurasia. During mating, two types of sex pheromones are used sequentially. First, a sex attractant pheromone released by the female attracts the male from a distance. Second, a contact sex pheromone causes the male to extrude his genital organ for copulation at close range (Tanaka et al., 1981). Generally, sex attractant pheromones are volatile, whereas contact sex pheromones have low volatility and act as contact or gustatory stimuli (Birch, 1974). The contact sex pheromones have been characterized from *Callosobruchus chinensis* (L.) and *C. maculatus* (F.) as a mixture of monoterpene dicarboxylic acids and some hydrocarbons (Tanaka et al., 1981, 1982; Nojima et al., 2007). However, comparisons of cross-copulatory activity (i.e., interspecific copulatory activity) among four congeneric species revealed that both beetles lacked the ability to discriminate their conspecific and/or heterospecific partners (Shimomura et al., 2010). Meanwhile, we found that male *C. analis* (F.) exhibited copulatory behavior only in response to conspecific females among the four species, and we clarified the presence of a contact sex pheromone in this species (Shimomura et al., 2010). *Callosobruchus analis* is distributed widely in tropical Asia and Africa (Tuda et al., 2005).

Although the sex attractant pheromone of *C. analis* was determined to be a short chain, methyl branched fatty acid (Cork et al., 1991), the contact sex pheromone has not been investigated chemically. In this research, we characterized the contact sex pheromone of *C. analis*, and we discuss the specificity of mate recognition in this species among congeneric species based on the contact sex pheromone.

Methods and Materials

Insects A laboratory-maintained colony was used in this research. The beetles were reared on *Vigna angularis* in a dark incubator at 28°C with ambient humidity. Newly emerged adults from beans were separated immediately by sex. Female beetles that were to be presented to test males were freeze-killed and kept in a freezer (−30°C) until they were used, and males were kept separately in a glass vial (15 mm diam, 35 mm high) and conditioned for 1 d at 27°C with ambient humidity in a dark incubator.

Pheromone Collection Each set of 300–400 virgin females was kept in a glass container (90 mm diam, 100 mm high) for 14–20 d with corrugated filter paper shelters (90 mm diam, Advantec No. 2; Toyo Roshi Kaisha, Tokyo, Japan) to collect cuticular substances rubbed on the filter paper. The filter paper shelters were collected from the containers, cut finely, and Soxhlet-extracted with ether for 24 h. The insides of the glass containers were rinsed with ether, which was combined with the filter papers. The extracts were dried with anhydrous Na_2SO_4, and after filtration, the solvent was evaporated under reduced pressure. The extracts were kept at −30°C until use.

Purification of Pheromone Compounds

Acid-Base Partition The crude pheromone extract was fractionated into basic, acidic, and neutral fractions. The extract was dissolved in 30 ml ether and extracted twice with 20 ml of 0.5 M HCl. The acidic, aqueous layer was alkalized with 5 M NaOH and extracted twice with 20 ml of ether to recover the basic compounds, and this ether layer was washed with brine and dried with anhydrous Na_2SO_4. Acidic compounds were extracted from the original ether layer twice with 20 ml of 0.5 M NaOH. The alkaline aqueous layer was acidified with 5 M HCl and extracted twice with 20 ml of ether to recover the acidic compounds, and this ether layer was washed with brine and dried with anhydrous Na_2SO_4. The remaining ether layer, from which basic and acidic compounds had been extracted, and which contained neutral compounds, was washed with brine and dried by anhydrous Na_2SO_4. After filtration, each fraction was concentrated under reduced pressure.

Column Chromatography The acidic compounds were redissolved in ether and concentrated to dryness with 200 mg of silica gel (Wakogel C-200, Wako Pure Chemical Industries, Osaka, Japan) in a rotary evaporator. The silica gel was applied to the top of a prewetted 500 mg silica gel column. The acidic compounds were eluted sequentially with 7 ml each of hexane, 20% EtOAc in hexane, 50% EtOAc in hexane, EtOAc, 50% EtOAc in methanol, methanol and 0.1% TFA in methanol. The neutral compounds were redissolved in ether and concentrated to dryness with 700 mg of silica gel (Wakogel C-200) in a rotary evaporator. The silica gel was applied to the top of a prewetted 1.5 g silica gel column. The neutral compounds were eluted sequentially with 20 ml each of hexane, 5% ether in hexane, 10% ether in hexane, 20% ether in hexane, 50% ether in hexane, and ether. The basic compounds were not subjected to column chromatography because they had no behavioral activity in the copulation assay (see "Results").

High Performance Liquid Chromatography (HPLC) The active fraction was further purified by normal phase HPLC with LC-10A (Shimadzu, Kyoto, Japan), equipped with a

silica gel column (Inertsil SIL-100A, 3 μm, 4.6 mm× 250 mm, GL Science, Tokyo, Japan) and eluted with 5% 2-propanol in hexane (1 ml/min). The effluent was monitored with a photodiode array detector SPD-M10Avp (Shimadzu) and collected (10 ml/fraction). The active fraction was purified again on the same column; eluted with 2% 2-propanol in hexane (1 ml/min); and the effluent was collected (5 ml/fraction).

Methyl Esterification An aliquot of the active acidic fraction was added to a 50-μl V-shaped vial (Nichiden-Rika Glass, Hyogo, Japan). A volume of 10 μl of sample was mixed with 5 μl methanol and 5 μl of 10% trimethylsilyldiazomethane in hexane solution (Tokyo Kasei, Tokyo, Japan). The mixture was left at room temperature for 30 min, then subjected to analysis by gas chromatography-mass spectrometry (GC-MS).

GC-MS Analysis GC-MS analysis was carried out with a Shimadzu GC 17A instrument equipped with a DB-5 or DB-23 capillary column (30 m×0.25 mm i.d., 0.25 μm film thickness; J&W Scientific, Folsom, CA, USA), coupled to a Shimadzu QP-5000 quadrupole MS in EI mode (70 eV). Helium was used as the carrier gas at a head pressure of 100 kPa and a flow rate of 1.6 ml/min. Oven temperature was set initially at 60°C for 3 min and increased at a rate of 10°C/min to 280°C for the DB-5 column and 220°C for the DB-23, and held for 10 min. The injector and interface temperatures were set at 250°C and 280°C, respectively.

Determination of Stereoisomeric Compositions of Active Compounds The stereoisomeric compositions of the active compounds were determined by using the Ohrui-Akasaka method (Akasaka et al., 1997, 1998; Akasaka and Ohrui, 1999; Yajima et al., 2006, 2007a). An aliquot of the active fraction was dissolved in MeCN:toluene=1:1. (*R*)- or (*S*)-2-(2,3-anthracenedicarboximide)-1-propanol (2A1P-OH, excess amount); 2-(3-dimethylaminopropyl)-1-ethylcarbodiimide hydrochloride (EDC, excess amount); and 4-*N*,*N*-dimethylaminopyridine (DMAP, excess amount) were added successively. The mixture was stirred at room temperature overnight. An aliquot then was loaded onto a silica gel TLC plate (10×10 cm, silicagel 60 F254, Art-5744, Merck, Lindenplatz, Haar, Germany) and developed with hexane:EtOAc=2:1. The target spot, detected by fluorescence, was collected and eluted with EtOAc. After evaporation of the solvent with an N_2 stream, the residue was dissolved in methanol and purified by 2D-HPLC. The HPLC conditions were as follows: 1) first column, Develosil ODS-HG-3 (4.6×150 mm, Nomura Chemical, Aichi, Japan); flow rate, 0.4 ml/min; mobile phase, methanol; column temperature, 0°C; and second column, Develosil ODS-A-3 (4.6×150 mm, Nomura Chemical); flow rate, 0.4 ml/min; mobile phase, methanol:MeCN:THF=2:2:1; and column temperature, −37°C. Fluorescence intensity was monitored at 462 nm (excitation at 298 nm) by using a FP-920 fluorescence detector (Jasco, Tokyo, Japan) to detect the desired compound.

Chemicals Four stereoisomers of 2,6-dimethyloctane-1,8-dioic acid (**1**) were synthesized as described in Nakai et al. (2005). (2*S*,6*R*)-**1** consisted of 83.8% d.e. and >99% e.e.; (2*S*,6*S*)-**1** consisted of 89.4% d.e. and >99% e.e.; (2*R*,6*R*)-**1** consisted of 90.4% d.e. and >99% e.e.; and (2*R*,6*S*)-**1** consisted of 95.8% d.e. and >87.1% e.e.. (*R*)-Callosobruchusic acid, (2*E*,7*R*)-3,7-dimethyl-2-octene-1,8-dioic acid, was synthesized as described in Yajima et al. (2007a) and consisted of >90% e.e.

Synthesis of (S)-Callosobruchusic Acid Column chromatography was performed with Wakogel C-200 (Wako). NMR spectra were recorded on a JNM-ECA400 (JEOL, Tokyo, Japan) (400 MHz for ^{1}H and 100 MHz for ^{13}C). Chemical shifts were expressed in ppm relative to the residual solvent peak. IR spectra were recorded on an IR-4100 spectrometer (Jasco) and are reported in terms of frequency of absorption (cm^{-1}). Optical rotation was measured on a P-2100 polarimeter (Jasco). Elemental compositions were analyzed on a Microcorder JM10 (J-Science, Kyoto, Japan).

(4S,2'E,6'E)-3-[6'-Methyl-8'-(tert-butyldimethylsilyloxy)-2,6-octadienoyl]-4-phenylmethyl-1,3-oxazolidin-2-one (**5**) A mixture of **3** (500 mg, 2.06 mmol) and (*S*)-**4** (1.20 g, 2.70 mmol) was dissolved in benzene (15 ml). The mixture was stirred for 12 h at 80°C and the solvent was evaporated. The residue was purified by SiO_2 column chromatography (hexane/EtOAc=10:1) to afford **5** (855 mg, 93%) as a colorless oil. $[\alpha]_D^{23}$=+42.5 (*c*=0.92, $CHCl_3$). IR (film): ν=1783, 1684, 1635 cm^{-1} (C=O). ^{1}H NMR (400 MHz, $CDCl_3$): δ=0.06 (s, 6H), 0.90 (s, 9H), 1.65 (s, 3H), 2.20 (t, *J*=7.7 Hz, 2H), 2.43 (dt, *J*=7.9, 7.7 Hz, 2H), 2.79 (dd, *J*=9.5, 13.5 Hz, 1H), 3.33 (dd, *J*=3.1, 13.5 Hz, 1H), 4.19 (m, 4H), 4.73 (m, 1H), 5.35 (m, 1H), 7.15–7.37 (m, 6H).

(4S,6'E)-3-[6'-Methyl-8'-(tert-butyldimethylsilyloxy)-6-octenoyl]-4-phenylmethyl-1,3-oxazolidin-2-one (**6**) To a stirred and cooled (−78°C) solution of **5** (758 mg, 1.71 mmol) in dry THF (10 ml) was added a solution of lithium tri-*sec*-butylborohydride (1.0 M in THF, 3.42 ml, 3.42 mmol) under Ar. After stirring for 3 d, the mixture was poured into saturated NH_4Cl aq. The aqueous phase was extracted with ether. The combined extracts were washed with water and saturated NH_4Cl aq., and dried with Na_2SO_4. The organic layer was concentrated under reduced pressure. The residue was purified by SiO_2 column

chromatography (hexane/EtOAc=10:1) to afford **6** (590 mg, 77%) as a colorless oil. $[\alpha]_D^{22}$=+26.2 (*c*=1.38, $CHCl_3$). IR (film): ν=1784, 1697 cm^{-1} (C=O). ^1H NMR (400 MHz, $CDCl_3$): δ=0.06 (s, 6H), 0.90 (s, 9H), 1.46–1.70 (m, 4H), 1.62 (s, 3H), 2.05 (t, *J*=7.6 Hz, 2H), 2.77 (dd, *J*=9.5, 13.5 Hz, 1H), 2.94 (m, 2H), 3.33 (dd, *J*=3.1, 13.5 Hz, 1H), 4.18 (m, 4H), 4.67 (m, 1H), 5.32 (t, *J*=6.3 Hz, 1H), 7.15–7.37 (m, 5H).

(4S,2'S,6'E)-3-[2',6'-Dimethyl-8'-(tert-butyldimethylsilyloxy)-6-octenoyl]-4-phenylmethyl-1,3-oxazolidin-2-one (**7**) To a stirred and cooled (−78°C) solution of **6** (590 mg, 1.33 mmol) in dry THF (5 ml) was added a solution of sodium bistrimethylsilylamide (1.0 M in THF, 1.59 ml, 1.59 mmol) under Ar. After stirring for 30 min, methyl iodide (248 µl, 3.98 mmol) was added to the mixture. The mixture was stirred for 12 h at the same temperature and then the reaction mixture was poured into saturated NH_4Cl aq. The aqueous phase was extracted with ether. The combined extracts were washed with water and brine, and dried with Na_2SO_4. The organic layer was concentrated under reduced pressure. The residue was purified by SiO_2 column chromatography (hexane/EtOAc=10:1) to afford **7** (95 mg, 16%) as a colorless oil. $[\alpha]_D^{26}$=+53.7 (*c*=0.26, $CHCl_3$). IR (film): ν=1784, 1698 cm^{-1} (C=O). ^1H NMR (400 MHz, $CDCl_3$): δ=0.06 (s, 6H), 0.90 (s, 9H), 1.22 (d, *J*=6.7 Hz, 3H), 1.30–1.45 (m, 3H), 1.58 (s, 3H), 1.72 (m, 1H), 2.00 (t, *J*=7.4 Hz, 2H), 2.76 (dd, *J*=9.5, 13.5 Hz, 1H), 3.26 (dd, *J*=3.1, 13.5 Hz, 1H), 3.71 (sxt, 1H, *J*=6.7 Hz, 1H), 4.18 (m, 4H), 4.68 (m, 1H), 5.29 (dt, *J*=1.1, 6.3 Hz, 1H), 7.15–7.37 (m, 5H).

(4S,2'S,6'E)-3-[8'-Hydroxy-2',6'-dimethyl-6-octenoyl]-4-phenylmethyl-1,3-oxazolidin-2-one (**8**) To a stirred solution of **7** (90 mg, 0.20 mmol) in THF (0.8 ml) was added a mixture of solution of tetrabutylammonium fluoride (1.0 M in THF, 4.90 ml, 4.90 mmol) and acetic acid (290 mg, 4.90 mmol). After stirring for 4 h, the mixture was poured into water. The aqueous phase was extracted with EtOAc. The combined extracts were successively washed with saturated NH_4Cl aq., saturated $NaHCO_3$ aq. and brine, and dried with Na_2SO_4. The organic layer was concentrated under reduced pressure. The residue was purified by SiO_2 column chromatography (hexane/EtOAc=2:1) to afford **8** (56 mg, 82%) as a colorless oil. $[\alpha]_D^{26}$=+62.6 (*c*=0.33, $CHCl_3$). IR (film): ν=3428 cm^{-1} (O–H), 1770, 1697 cm^{-1} (C=O). ^1H NMR (400 MHz, $CDCl_3$): δ=1.23 (d, *J*=6.7 Hz, 3H), 1.30–1.50 (m, 3H), 1.66 (s, 3H), 1.74 (m, 1H), 2.00 (t, *J*=7.4 Hz, 2H), 2.76 (dd, *J*=9.5, 13.5 Hz, 1H), 3.26 (dd, *J*=3.1, 13.5 Hz, 1H), 3.71 (sxt, 1H, *J*=6.7 Hz, 1H), 4.14–4.23 (m, 4H), 4.68 (m, 1H), 5.41 (dt, *J*=1.1, 6.3 Hz, 1H), 7.15–7.37 (m, 5H).

(2E,7S)-Callosobruchusic acid (**2**) To a stirred solution of **8** (52 mg, 0.15 mmol) in CH_2Cl_2 (1 ml) was successively added $NaHCO_3$ (76 mg) and Dess-Martin periodinane (Dess and Martin, 1983) (180 mg, 0.45 mmol) at 0°C. After stirring for 30 min, the reaction was quenched by the addition of a saturated $NaHCO_3$ solution. The aqueous phase was extracted with CH_2Cl_2, and the organic extract was washed with brine and dried with Na_2SO_4. After concentrating under reduced pressure, the residue was dissolved in a mixture of *t*-BuOH (1 ml) and 2-methyl-2-butene (0.4 ml). The mixture then was cooled to 0°C, and a solution of 20% NaH_2PO_4 solution (0.5 ml) and $NaClO_2$ (140 mg, 1.50 mmol) was added. The solution was stirred for 1 h and then poured into water. The aqueous phase was extracted with EtOAc, and the organic extract was washed with brine, dried with Na_2SO_4. The organic layer was concentrated under reduced pressure. The residue was dissolved in THF (1 ml) and water (0.5 ml). To the solution was added solid LiOH (10 mg, 0.40 mmol). After stirring for 30 min, the mixture was poured into water. The aqueous phase was extracted with CH_2Cl_2. The aqueous phase was acidified with 6 N HCl and extracted with EtOAc. The organic extract was washed with brine and dried with Na_2SO_4. The organic layer was concentrated under reduced pressure. The residue was purified by SiO_2 column chromatography (hexane/EtOAc=1:5) to afford **2** (2 mg, 7% in three steps) as a colorless solid. $[\alpha]_D^{27}$=+10.1 (*c*=0.10, $CHCl_3$). ^1H NMR (400 MHz, $CDCl_3$): δ=1.22 (d, *J*=6.7 Hz, 3H), 1.45 (m, 1H), 1.54 (quint, *J*=7.5 Hz, 2H), 1.68 (m, 1H), 2.15 (s, 3H), 2.17 (m, 2H), 2.48 (sep, *J*=6.7 Hz, 1H), 5.69 (s, 1H). The physical properties were in good accord with previous report (Nanda and Scott, 2004).

*Determination of the Enantiomeric Purity of the Synthetic (S)-**2*** (*R*)- and (*S*)-2A1P-O bis-ester of (*S*)-**2** were prepared as described above and were analyzed by HPLC. The HPLC conditions were as follows. Column; Develosil ODS-A-3 (4.6 mm i.d.×150 mm, Nomura Chemical), mobile phase; MeOH:MeCN:THF=2:2:1, temp; −40°C, flow rate; 0.4 ml/min. Detection was carried out by monitoring fluorescence intensity at 460 nm (excitation at 362 nm) by using a FP-920 fluorescence detector (Jasco). The retention times of the (*R*)-2A1P-O bis-ester of (*S*)-**2** and (*S*)-2A1P-O bis-ester of (*S*)-**2** were 64.1 min and 77.0 min, respectively.

Behavioral Bioassay Males in vials were removed from the incubator and acclimated to conditions in an assay room for 1 h before the copulation assay. The assay was performed at 27°C in the light.

(1) Female dummy: Freeze-killed females were warmed to room temperature and washed sequentially with ether, methanol, and ether to remove the substances of the cuticular surface. After the solvent had evaporated,

the solvent-washed female was stabbed in the abdomen with insect pins and presented to the male in the vial to see if the male displayed his genital organ.

(2) Glass rod dummy: The tip of a glass rod (2 mm i.d., 100 mm length) was rounded by flame on a gas burner and abraded with sandpaper to imitate the female's body.

Five microliters of the extracts or synthetic compounds dissolved in ether were applied to each dummy with a micro syringe. After the solvent had evaporated, the dummy was presented to the male in the vial. Copulatory activity was evaluated by observing whether males tried to copulate and display their genital organ for at least 2 min in each assay. Each male and each female dummy was tested only once. The sample dose was adjusted in terms of female equivalents (feq; note that feq calculations were based on filter paper extracts, not on female whole-body extracts). The numbers of males that extruded their genital organs to the treated or solvent control were compared with a Fisher's exact probability test. Multiple comparisons for male copulatory activity were performed by Fisher's exact probability test followed by a series of sequential Bonferroni-corrections ($P<0.05$) (Rice, 1989).

Results

Purification and Identification of Acidic Pheromone Compounds Female contact sex pheromone was extracted from the filter papers taken from female containers. The yield of crude extract from approximately 2,100 females was 201.8 mg. The crude extract elicited strong copulatory behavior as previously reported (Shimomura et al., 2010); all male beetles tested attempted to copulate with female dummies treated with 0.5 feq crude extract. When the crude extract was fractionated into acidic, neutral, and basic fractions, only the acidic fraction elicited strong copulatory behavior that matched the behavioral response elicited by the crude extract (100%). The acidic fraction was purified by silica gel column chromatography, and seven fractions were obtained. When each fraction was assayed, only the 50% EtOAc in hexane fraction (Fr. 3) elicited strong copulatory behavior (80%; Fig. 1). This fraction was further purified by normal phase HPLC, and copulatory behavior was elicited by the 0–10 min fraction eluted with 5% isopropanol in hexane (95%; Fig. 1). The active fraction was purified further by normal phase HPLC, and copulatory behavior was elicited with the 5–10 min fraction eluted with 2% isopropanol in hexane (90%; Fig. 1). The yield of the fraction was 300 µg. The small portion of acidic compounds in this active fraction were derivatized to methyl esters and subjected to GC-MS analysis.

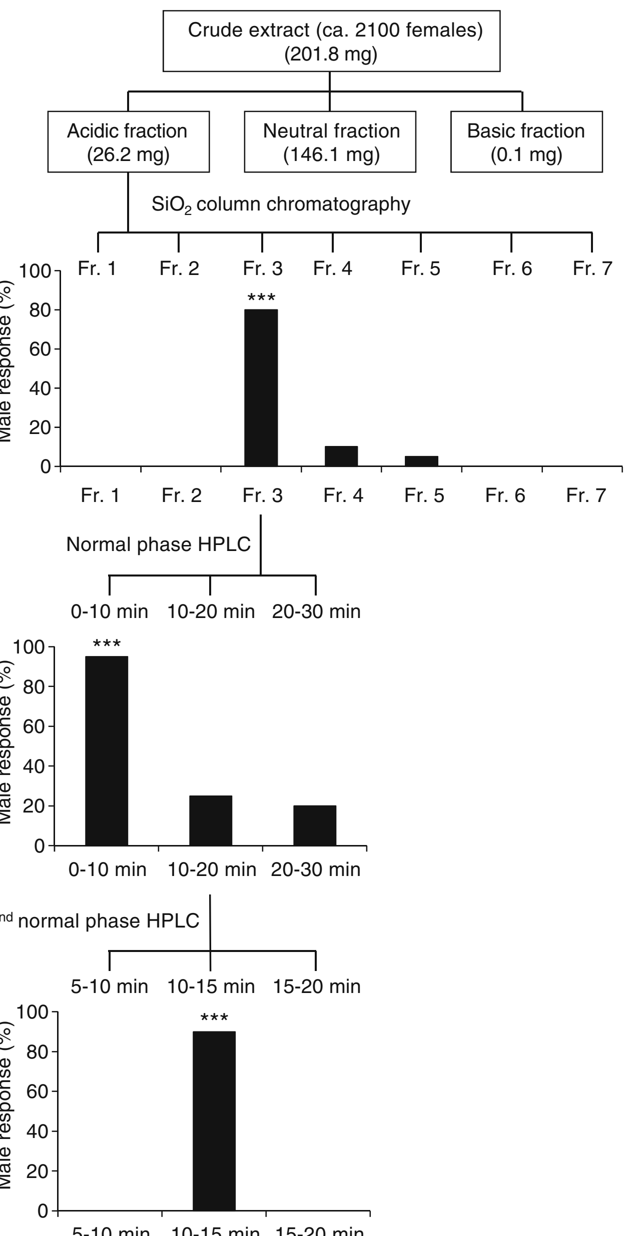

Fig. 1 Fractionation procedure for crude extract collected from female *Callosobruchus analis* by filter paper method and male copulation responses to female dummies applied with each fraction. Twenty males were tested for each fraction. All fractions were tested at 0.5 female equivalents. *Asterisks* above bars indicate significant differences between test fraction and negative control (solvent alone) (Fisher's exact probability test, ***; $P<0.001$)

GC-MS analysis detected two compounds in the active fraction, compound **1** and **2** (Fig. 2a). The mass spectrum of compound **1** was similar to that of a dimethyl ester of 2,6-dimethyloctane-1,8-dioic acid, the contact sex pheromone of *C. maculatus* (Nojima et al., 2007) (Fig. 2b). The mass spectrum of compound **2** was also similar to that of a dimethyl ester of (*E*)-3,7-dimethyl-2-octene-1,8-dioic acid, the contact sex pheromone of *C. chinensis* (Tanaka et al.,

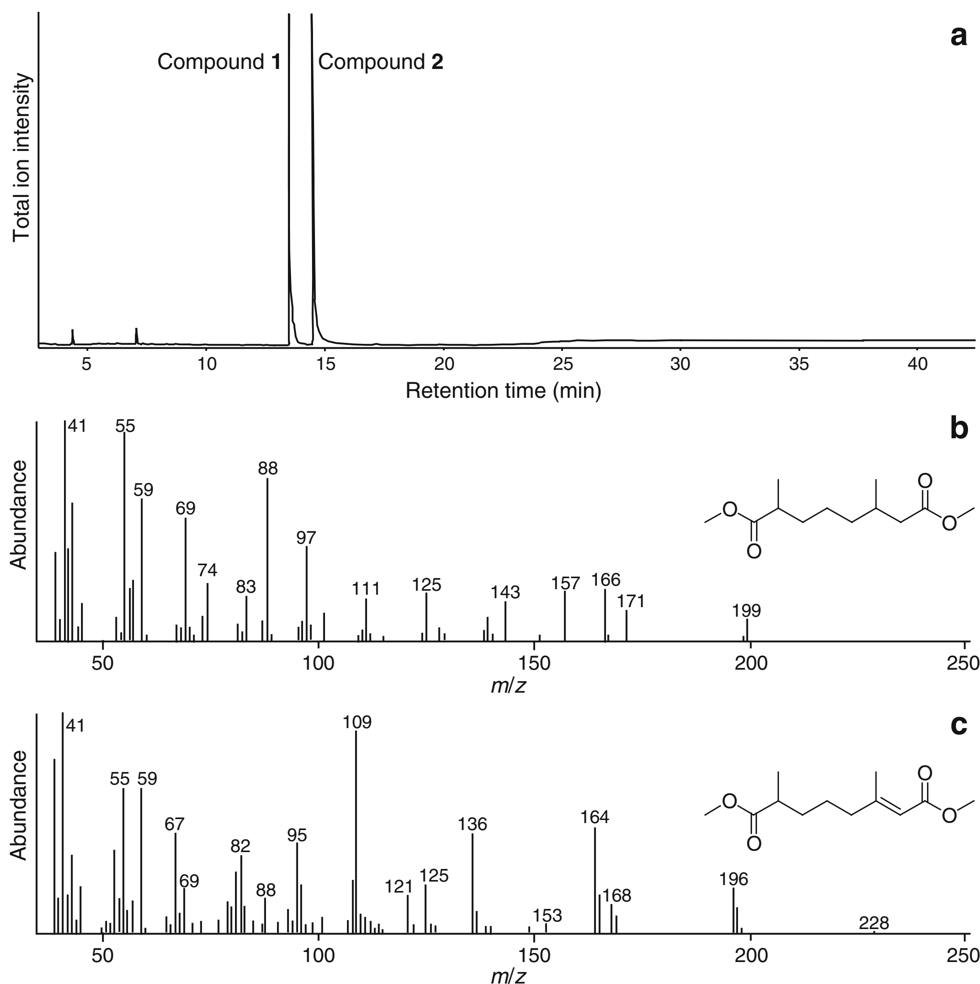

Fig. 2 GC-MS spectra of the active fraction from the original acidic fraction from female *Callosobruchus analis*. Total ion chromatogram of the active fraction (**a**). EI-mass spectra of methyl esterfied natural compound **1** identified as 2,6-dimethyloctane-1,8-dioic acid (**b**) and natural compound **2** identified as 3,7-dimethyl-2-octene-1,8-dioic acid (**c**)

1981) (Fig. 2c), in which the differences in the relative abundance of fragment ions are due to the different electron voltages used each study. The mass spectra and retention times of the two compounds on two different columns matched those of synthetic standards.

Determination of the Chemical Composition 2A1P-O derivatives of synthetic standards were analyzed by 2D-HPLC. During the first column analysis, all stereoisomers of 2A1P-O derivatives of synthetic compound **1** and **2** were eluted in fraction 14.7–19.5 min. This fraction was injected directly onto the second column by on-column injection with a six-way bulb system to avoid incorporation of impurities on the second column. All stereoisomers of (*S*)-2A1P-O derivatives of synthetic compound **1** and **2** were separated clearly by the second column (Fig. 3a). Likewise, the (*S*)- and (*R*)-2A1P-O derivatives of the active acid fraction were analyzed by 2D-HPLC. The (*S*)-2A1P-O derivatives of the active acid fraction were separated into a series of peaks (Fig. 3b). In this chromatogram, peaks 2 and 6 eluted with retention times indicative of (*S*)-2A1P-O derivatives of (*S*)-**2** and (2*S*,6*R*)-**1**, respectively (Fig. 3b). Subsequent analysis of (*R*)-2A1P-O derivatives of the active acid fraction revealed a series of peaks and that the retention times of each enantiomer were inverted with respect to each other (Fig. 3c). The retention times of peaks 1 and 3 were consistent with those of (*S*)-2A1P-O derivatives of (*S*)-**2** and (2*S*,6*R*)-**1**, respectively (Fig. 3c). The peak area ratios were almost identical; peak 2:peak 6= 63.3:36.7 for [(*S*)-2A1P-O derivatives] and peak 1:peak 3= 64.5:35.5 for [(*R*)- 2A1P-O derivatives]. The other peaks did not match the retention time for (*S*)- and (*R*)-2A1P-O derivatives. Thus, the chemical composition was determined as (2*S*,6*R*)-**1**:(*S*)-**2**=1.8:1. The amounts of compounds (2*S*,6*R*)-**1** and (*S*)-**2** in the active fraction from the filter paper extract were quantified as 92 and 51 ng/female, respectively.

Synthesis of Callosobruchusic Acid Although several asymmetric syntheses of callosobruchusic acid (**2**) have been reported (Mori et al., 1983; Gramatica et al., 1985; Giersch and Schulte-Elte, 1990; Abo and Mori, 1993; Yu et al., 2002; Nanda and Scott, 2004), we developed a new asymmetric synthesis of **2** to obtain an optically pure

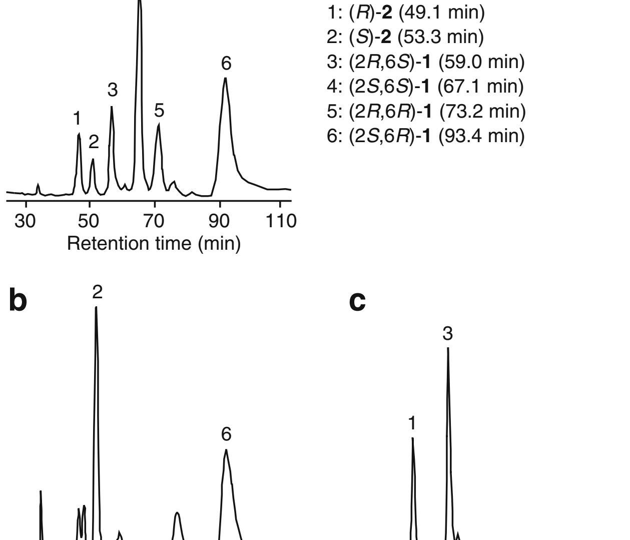

Fig. 3 2D-HPLC chromatograms of (*S*)-2-(2,3-anthracenedicarboximide)-1-propanyl (2A1P-O) derivatives of synthetic standards (**a**), (*S*)-2A1P-O derivatives of active fraction (**b**) and (*R*)-2A1P-O derivatives of active fraction (**c**)

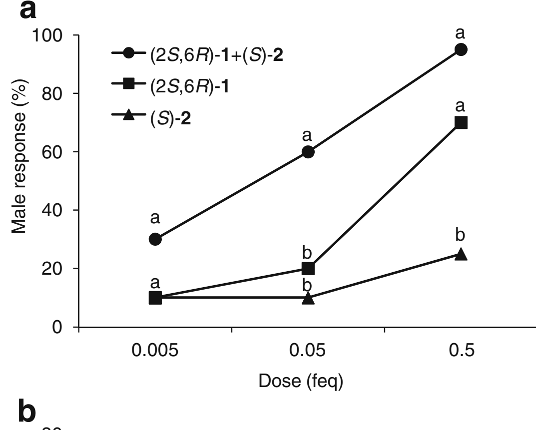
sample of (*S*)-**2** (Scheme 1). The synthesis is based on the strategy for the synthesis of 2,6-dimethyl-1,8-octane-dioic acid, the contact sex pheromone of *C. maculatus* (Nakai et al., 2005). The known aldehyde **3** (Imamura et al., 2004) was coupled with (*S*)-**4** (Evans and Weber, 1987; Nemoto et al., 1995) by the Wittig reaction. The resulting conjugate double bond of **5** was chemoselectively reduced by lithium tri-*sec*-butylborohydride (L-Selectride) to give **6**. The diastereoselective alkylation (Evans et al., 1982) of **6** with methyl iodide in the presence of sodium bistrimethylsilylamide (NaHMDS) afforded **7**. Although the chemical yield was very low, ^{1}H NMR analysis suggested that **7** was stereochemically pure. The *t*-butyldimethylsilyl (TBS) group of **7** was removed under mild conditions to prevent the epimerization of the chiral center (Yajima et al., 2008) to give **8**. Finally, the hydroxyl group of **8** was oxidized under mild conditions (Yajima et al., 2007b), and the chiral auxiliary group was carefully removed by LiOH to give the desired (*S*)-**2**. The enantiomeric purity of synthetic (*S*)-**2** was determined according to the reported procedure (Yajima et al., 2007a). HPLC analyses of (*R*)- and (*S*)-2A1P-O bis-esters of (*S*)-**2** produced a single peak, indicating that synthetic (*S*)-**2** is optically pure (>99% e.e.).

Behavioral Assay: 1. Female Dummy The pheromonal activity of both synthetic stereoisomers was confirmed in copulatory assays by using female dummies. The mixture of the natural ratio of (2*S*,6*R*)-**1** and (*S*)-**2** resulted in dose-dependent copulatory activity, and 95% of tested males exhibited copulation responses at 0.5 feq (Fig. 4a). In a single compound assay of (2*S*,6*R*)-**1**, 70% of males exhibited copulatory responses to this stimulus at 0.5 feq, but only 20% of males exhibited copulatory responses at 0.05 feq (Fig. 4a). In a single compound assay of (*S*)-**2**, only 25% of males exhibited copulation responses at 0.5 feq (Fig. 4a).

We next compared the stereochemistry-activity relationship for **1** at 0.5 feq. A small percentage of males exhibited copulatory behavior with (2*S*,6*S*)-**1** (25%), and a small, but significant percentage of males responded to (2*R*,6*R*)-**1** (40%). No copulatory behavior was observed with (2*R*,6*S*)-**1** (Fig. 4b). Only 15% of males exhibited copulation behavior with the mixture of (2*S*,6*R*)-**1** and (2*R*,6*S*)-**1** (Fig. 4b)

Behavioral Assay: 2. Glass Rod Dummy Male *C. analis* exhibited a significant copulatory response to a glass rod applied with 0.5 feq of crude extract or 0.5 feq of the synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2** plus 0.5 feq of the neutral fraction. No copulatory behavior was observed

Scheme 1 Synthesis of callosobruchusic acid. *a* (*S*)-**4**, benzene (93%); *b* L-Selectride, THF (77%); *c* NaHMDS, MeI, THF (16%); *d* TBAF, acetic acid, THF (82%); *e* Dess-Martin periodinane, $NaHCO_3$, CH_2Cl_2; $NaClO_2$, 2-methyl-2-butene, NaH_2PO_4, *t*-BuOH, H_2O; LiOH, THF, H_2O (7%)



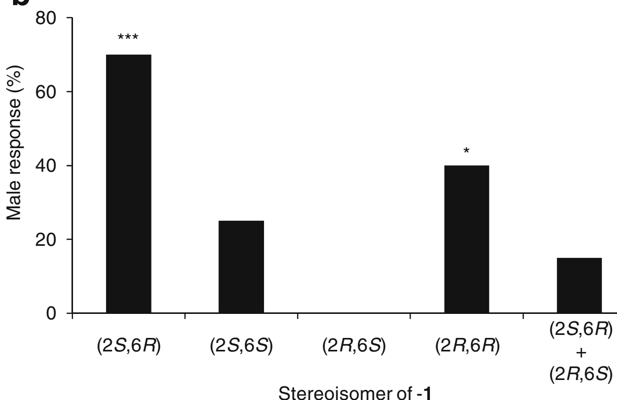


Fig. 4 Copulatory response of male *Callosobruchus analis* to female dummies applied with synthetic compounds. **a** Dose-behavioral assay of (2*S*,6*R*)-2,6-dimethyloctane-1,8-dioic acid (**1**) and (2*E*,7*S*)-3,7-dimethyl-2-octene-1,8-dioic acid (**2**). The ratio of mixture (2*S*,6*R*)-**1**+(*S*)-**2** was applied at the natural ratio of (2*S*,6*R*)-**1**:(*S*)-**2**=1.8:1 (see "Results" section). Twenty males were tested at each dose. *Different letters* within the same dose indicate significant differences (Fisher's exact probability test followed by a sequential Bonferroni test: $P<0.05$). **b** Stereoisomer-behavioral assay of **1**. All assays were tested at 0.5 female equivalents. Twenty males were tested for each isomer. *Asterisks* above bars indicate significant differences between test fraction and control (solvent applied) (Fisher's exact probability test, *; $P<0.05$, ***; $P<0.001$)

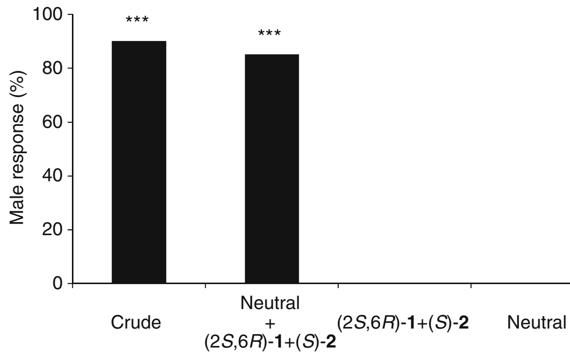
when the rod was applied with 0.5 feq of the synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2** or with 0.5 feq of the neutral fraction (Fig. 5). The neutral fraction was purified further into six fractions by column chromatography, and each fraction or combination of fractions was assayed with 0.5 feq of the synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2**. The combined hydrocarbon fraction (hexane elute fraction: Fr. 1) with 5% ether elute fraction (Fr. 2) plus 0.5 feq of the synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2** exhibited comparable copulation activity to those of the original neutral fraction plus 0.5 feq of the synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2** (Fig. 5). However, marginal activity was elicited from hydrocarbon fraction (Fr. 1) plus 0.5 feq of the synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2** or 5% ether fraction (Fr. 2) plus 0.5 feq synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2** (Fig. 5).

Discussion

Previously, *C. analis* has been shown to use a contact sex pheromone in its mating system, and, based on cross-copulatory analysis, this contact sex pheromone might be species specific (Shimomura et al., 2010). The extracts collected directly from whole bodies of female *C. maculatus* did not elicit copulatory activity from males, possibly due to the large quantities of chemicals and the sticky nature of the extracts (Nojima et al., 2007). Meanwhile, the extracts collected by the filter paper method from the containers that had housed female *C. maculatus* and *C. chinensis* elicited copulation activity from male *C. maculatus* and *C. chinensis*, respectively (Tanaka et al., 1981; Nojima et al., 2007). Therefore, we used the same male copulatory behavior in an assay to guide our fractionation procedure. Because male *C. analis* did not show copulatory behavior against females of *C. maculatus* and *C. chinensis* (Shimomura et al., 2010), we, at first, hypothesized that *C. analis* might use a different kind of compound as the contact sex pheromone from that of



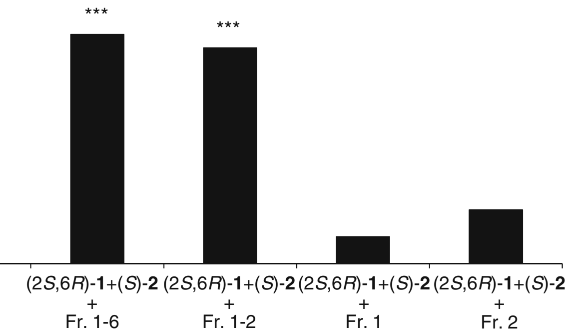


Fig. 5 Copulatory response of male *Callosobruchus analis* to glass rod dummies applied with test samples. Twenty males were tested for each sample. Each fraction and/or compound was combined so that the total mass reflected 0.5 female equivalents. *Asterisks* above bars indicate significant differences between test sample and control (solvent applied) (Fisher's exact probability test, ***; $P<0.001$)

C. maculatus and *C. chinensis*. However, GC-MS analysis of the purified active fraction revealed two compounds: 2,6-dimethyloctane-1,8-dioic acid (**1**), previously reported as a contact sex pheromone of *C. maculatus* (Nojima et al., 2007), and callosobruchusic acid, (*E*)-3,7-dimethyl-2-octene-1,8-dioic acid (**2**), which was reported as a contact sex pheromone of *C. chinensis* (Tanaka et al., 1981, 1982).

In insect pheromonal communication, it is clear that bioactivity frequently may depend on chirality (reviewed in Mori, 2007). Therefore, we expected that the chirality of the two compounds was related to the species-specific copulation activity of male *C. analis*. Since the stereoisomeric compositions of the *C. maculatus* contact sex pheromone, 2,6-dimethyloctane-1,8-dioic acid (**1**), and the *C. chinensis* contact sex pheromone, (*E*)-3,7-dimethyl-2-octene-1,8-dioic acid (**2**), were determined by the 2D-HPLC-Ohrui-Akasaka method as (2*R*,6*S*):(2*S*,6*R*):(2*S*,6*S*):(2*R*,6*R*)=43:38:18:trace for *C. maculatus* (Yajima et al., 2006), and (*R*):(*S*)=3.3–3.4:1 for *C. chinensis* (Yajima et al., 2007a), we applied the same methodology in this case. As a result, the chemical composition was determined as (2*S*,6*R*)-**1**:(*S*)-**2**=1.8:1, which meant that both compounds were stereochemically pure, unlike the case of *C. maculatus* and *C. chinensis*. The copulation assay with synthetic compounds clarified the role of both compounds. The synthetic mixture showed the same copulatory activity as the crude extract. However, (2*S*,6*R*)-**1** alone exhibited significantly less activity than the synthetic mixture at 0.05 feq, and (*S*)-**2** alone exhibited marginal activity, even at 0.5 feq. Therefore, we confirmed that (2*S*,6*R*)-**1** functions as a main compound, and (*S*)-**2** acts as an additive compound; both compounds were needed for full copulatory activity.

While female *C. maculatus* uses **1** as the contact sex pheromone, male *C. analis* did not exhibit copulation behavior with female *C. maculatus* in a cross-copulation experiment (Shimomura et al., 2010). To clarify this inconsistency, we compared the stereochemistry-activity relationship by using four stereoisomers of **1**. Intriguingly, the males exhibited weak copulation behavior to (2*R*,6*R*)-**1** and (2*S*,6*S*)-**1**, namely diastereomers of the natural isomer, but no males exhibited copulation behavior to the (2*R*,6*S*)-**1**, enantiomer of the natural isomer. In the contact sex pheromone of *C. maculatus*, (2*R*,6*S*)-**1** is the most abundant stereoisomer on the cuticular surface (Yajima et al., 2006). Therefore, we next combined (2*S*,6*R*)-**1** with (2*R*,6*S*)-**1**. The pheromonal activity of (2*S*,6*R*)-**1** was masked clearly by the (2*R*,6*S*)-**1** enantiomer. These results revealed partial evidence of mate recognition specificity of male *C. analis*.

There are many examples where contact sex pheromones are active even when applied on artificial objects (e.g., gelatin capsules, plastic vials, glass rods, or stainless steel spatulas) (see Tanaka et al., 1981; Fukaya and Honda, 1992; Zhang et al., 2003; Sugeno et al., 2006). Since males of *C. chinensis* and *C. maculatus* also exhibited copulation behavior to a glass rod treated with contact sex pheromone compounds (Tanaka et al., 1981; Nojima et al., 2007), we attempted to use the glass rod as a dummy for *C. analis*. As expected, male *C. analis* exhibited significant copulation behavior with the glass rod applied with 0.5 feq of crude extract. However, unlike in the case of the female dummy, no males exhibited copulation behavior to the glass rod applied with 0.5 feq of the synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2**. As for the copulation activity of male *C. maculatus*, the glass rod applied only with the neutral fraction collected from the females by the filter collection method elicited copulation activity, albeit weakly (Nojima et al., 2007). In the case of *C. analis*, no copulation behavior was observed to the glass rod applied only with the female neutral fraction. Cuticular hydrocarbons acted as a synergist for the contact sex pheromone of *C. chinensis* and *C. maculatus* (Tanaka et al., 1981; Nojima et al., 2007). Therefore, we combined 0.5 feq of the synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2** with the neutral fraction, and copulation activity was similar to that of the crude extract. Although, in the case of *C. chinensis* and *C. maculatus*, the hexane eluted fraction (containing some hydrocarbons) of the neutral fraction was enough for the synergistic effect (Tanaka et al., 1981; Nojima et al., 2007), in the case of *C. analis*, marginal activity was exhibited when 0.5 feq of the synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2** was combined with the hexane eluted fraction of the neutral fraction. Meanwhile, the copulation activity elicited by 0.5 feq of the synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2** combined with the hexane eluted fraction and 5% ether fraction of the neutral fraction was similar to that of the crude extract. Marginal activity was exhibited with 0.5 feq synthetic mixture of (2*S*,6*R*)-**1** and (*S*)-**2** combined with the 5% ether fraction of the neutral fraction. We, therefore, suggest that there may be another synergist for *C. analis*, and male *C. analis* may discriminate the female with a multi cue system, but further work is needed.

There have been few reports on stereoisomeric composition and/or the stereochemistry-activity relationship regarding contact sex pheromones. The German cockroach, *Blattella germanica*, for example, uses 3,11-dimethylnonacosan-2-one as the major component of contact sex pheromones (reviewed in Gemeno and Schal, 2004). The stereochemistry of this dimethylketone was confirmed as (3*S*,11*S*) (Mori et al., 1981; Nishida and Fukami, 1983), and the four stereoisomers were active individually (Nishida and Fukami, 1983; Eliyahu et al., 2004). In the comparative analysis of stereochemistry-activity relationship for *C. maculatus*, although the natural stereoisomeric ratio was the most active, each stereoisomer was active individually (Yajima et al., 2006). As for *C. chinensis*, each enantiomer also was active.

(*R*)-**2** was half as active as (*S*)-**2** (Mori et al., 1983). Meanwhile, in the case of *C. analis*, the enantiomer of the natural pheromone exhibited no copulation activity and masked the activity of the natural isomer. There are numerous examples of enantiomeric antagonistic effects in sex attractant pheromones. Indeed, in closely related and sympatric species, each species is suppressed by addition of the enantiomer produced by the other species, as a system of premating, reproductive isolation (Millar, 2000). The distributions, host plants, and habitats of *Callosobruchus* species overlap considerably, and the sympatric population of these three beetles also has been reported (Haines, 1989; Tuda et al., 2005). We, therefore, suggest that rigorous mate recognition of *C. analis*, including antagonistic effects, might have arisen during species differentiation.

The present study is the third example of a contact sex pheromone in *Callosobruchus* seed beetles. In all three cases, monoterpene dicarboxylic acids were used as the main compounds. Compounds **1** and **2** had been identified previously from the urine of some mammals treated with squalene synthase inhibitor (Bostedor et al., 1997). Furthermore, it was determined that these compounds were derived from farnesol, and the biosynthetic pathway was proposed (Bostedor et al., 1997). Similar biosynthesis could be occurring in the contact sex pheromones of *Callosobruchus* species, but this remains to be clarified.

Acknowledgments We thank Dr. Yukihiko Toquenaga (University of Tsukuba) for providing *C. analis*. We are also thankful to Associate Editor Steven J. Seybold for his help on previous drafts of this manuscript.

ovaries. In this study, we measured the 9-ODA content of normal and laying workers, and tested whether 9-ODA elicits attacks against laying workers.

Methods and Materials

Measurement of 9-ODA Content of Mandibular Pheromone

Bees were sampled randomly until 6 workers showing no ovarian activation on dissection were obtained from each colony. After this, all queens were removed from the colonies. Two weeks later, workers bees were sampled again until 6 workers were obtained with fully developed ovaries. The heads of the two types of bees were stored in 200 µl dichloromethane for 2 month at −15°C.

The extracts were evaporated to dryness under nitrogen, and the residues were re-dissolved in 20 µl of an internal standard, octanoic acid and tetradecane in dichloromethane, and 20 µl of bis-trimethylsilyltrifluoroacetamide. Extracts were injected splitlessly into a Hewlett Packard 6890 gas chromatograph, equipped with a 25×0.32 mm i.d., methyl silicone column, programmed from 60°C (held for 1 min) to 110°C at 50°C.min^{-1}, then to 220°C at 3°C.min^{-1}. Helium, at 1 ml.min^{-1} was the carrier gas. The compound 9-ODA was identified, based on comparison of retention time with that of an authentic standard, and quantified in relation to the internal standards.

Observation of Workers' Responses to 9-ODA

Experiments were conducted at Yunnan Agricultural University, Kunming, China. Twenty worker bees from each of three queenright and queenless colonies of *Apis cerana* were anesthetized with CO_2 and marked. They were divided into equal groups: one treated with 10 µg 1% w/w 9-ODA, similar to the quantity produced by a laying worker, another with 10 µg 200% w/w 9-ODA, similar to that produced by a queen (Tan et al., 2009), and the third (control) treated with 10 µg distilled water. When the anesthetized workers recovered, they were returned to their hives on a single frame and monitored for 3 min with digital video cameras, one on each side of the frame, to record any aggressive behaviour.

Statistical Analyses Independent *t*-tests compared the amounts of 9-ODA between queenright *A. cerana* workers and queenless laying workers. *Chi-square* tests were used to compare the aggression behavior directed to treated workers, between test and control groups, and between queenright and dequeened colonies. Count data were used in the *chi-square* calculations.

Results

Mean 9-ODA content in extracts of *A. cerana* workers was different (t_4=4.8, P<0.009) between queenright [0.014± 0.005 µg (SD)] and queenless [0.096 µg±0.029 (SD)] colonies. In queenright colonies, within 3 min after workers treated with 9-ODA (either 0.1 µg or 0.2 mg/bee) were released, greater percentages $(0.1\mu g : \chi^2_1 = 25.5,\ P < 0.001; 0.2mg : \chi^2_1 = 38.6, P < 0.001)$ of treated workers were attacked compared to the control groups (Table 1). In queenless colonies, greater percentages $(0.1\mu g : \chi^2_1 = 18.3, P < 0.001; 0.2mg : \chi^2_1 = 21.8, P < 0.001)$ of treated workers also were attacked after release, compared to the control groups (Table 1). However, overall, there were fewer attacks against treated workers in queenless colonies than in queenright colonies. This effect was significant for treatment with 0.2 mg of 9-ODA ($\chi^2_1 = 12.3, P = 0.001$), but not quite significant for treatment with 0.1 µg ($\chi^2_1 = 3.4, P = 0.067$). In both queenright and queenless colonies, workers were

Table 1 Number of treated *Apis cerana* workers attacked by nestmates (Mean±SD%), (N=10 workers per colony, 3 colonies)

		Control	Test	Control	Test
0.1 µg	1	0	6	0	4
	2	1	6	0	4
	3	1	9	0	6
	Total	2 (6.7±5.8%)[c]	21 (70.0±17.3%)[a]	0 (0.0±0.0%)[c]	14 (46.6±11.5%)[a]
0.2 mg	1	1	9	0	5
	2	1	9	0	5
	3	2	10	0	6
	Total	4 (13.3±5.8%)[c]	28 (93.3±5.8%)[b]	0 (0.0±0.0%)[c]	16 (53.3±5.8%)[a]

[a] Mean percentages within one column or one row followed by a different letter are significantly different

more sensitive to the higher dose of 9-ODA. The difference was significant for the queenright colonies but not significant for queenless colonies $\left(\text{queenright}: \chi_1^2 = 5.5, P = 0.019;\ \text{queenless}: \chi_1^2 = 0.3, P = 0.606\right)$ (Table 1).

Discussion

Within a week of being dequeened, some 40% of workers in an *A. cerana* colony have activated ovaries (Tan et al., 2009). We found that pheromonal changes corresponded with this ovarian activation, with the mandibular gland extract of a laying worker containing approximately seven times as much 9-ODA as a worker without activated ovaries.

In our behavioral tests, we showed that other workers attacked workers with a queen-like 9-ODA bouquet, suggesting that detection of these pseudoqueens is mediated by the pheromonal cue (Hepburn, 1992). Although laying workers increased their 9-ODA content, it was still considerably less than that produced by queens. In *A. mellifera*, such a difference in mandibular gland content is sufficient for laying workers to be perceived as such by their nestmates and be attacked (Plettner et al., 1995).

Interestingly, more workers treated with 9-ODA were attacked in queenright colonies than in queenless ones. This effect may, in part, be due to greater numbers of attacking bees lacking ovarian activation in queenright colonies than in queenless ones (Tan et al., 2009). However, it also may be due to an increased tolerance of laying workers in queenless colonies over that in queenright colonies, perhaps mediated by prior 9-ODA levels in the respective colony types.

Acknowledgements Financial support was granted by the Xishuangbanna Tropical Botanical Garden, Chinese Academy of Science and the National Agricultural Production Systematic Fund (nyncytx-43-kxj13) to Ken Tan. We thank the Institut für Bienenkunde, Oberursel, Germany for the gift of 9-ODA and Professor Crewe, from the University of Pretoria, for the use of GCs.

Test run in Uppland, Sweden, Aug. 6–Sept. 11, 1991

[a] Means followed by the same letter are not significantly different ($P<0.05$), according to ANOVA on log(catch + 1) transformed data followed by Tukey's test ($N=5$)

main attractant (Wassgren et al., 1992; Anderbrant et al., 1995; Bergström et al., 1995), suggesting that the length of the carbon chain is an essential characteristic of the pheromone for a given species. On the other hand, these two, and several other *Neodiprion* species, also are attracted to two or more compounds in which the acetate group of the main pheromone compound has been replaced with other acyl moieties (Anderbrant et al., 1992a, 1997, 2005; Anderbrant, 1999).

The most widespread diprionid species, *N. sertifer*, has a well characterized sex pheromone, with the acetate [**(*SSS*) Ac**] (Table 1) or propionate [**(*SSS*)Pr**] of (2*S*,3*S*,7*S*)-3,7-dimethyl-2-pentadecanol (diprionol) as the main component. The (2*S*,3*R*,7*R*)-isomer of the acetate [**(*SRR*)Ac**] can act as a synergist to these major components in certain geographic areas, as an antagonist in other areas, and can have no effect when added in other areas (Tai et al., 1990; Anderbrant et al., 1992b, 2000). The (2*S*,3*R*,7*S*)-isomer of the acetate [**(*SRS*) Ac**] is able to replace the synergistic function of **(*SRR*)Ac** in Siberia and the antagonistic function in Europe, although, in the latter case, it has to be in much larger relative amounts (Anderbrant et al., 1992b, 2000).

To evaluate whether simpler molecules could mimic pheromonal activity, Tai et al. (1992) synthesized the diprionol acetate analogs, (2*S*,3*S*)-3-methyl-2-pentadecanol acetate [**(*SS*–)Ac**] and (2*S*,3*S*)-3-methyl-2-pentadecanol acetate [**(*SR*–)Ac**] (Table 1). These analogs lacked the methyl group in the 7-position (the hyphen in our compound acronyms indicates a missing methyl group relative to diprionol, see Table 1). Field tests in Japan showed that the analogs were active to *N. sertifer* males. To evoke the same response as the natural pheromone compound, however, the analogs had to be applied in an amount approximately 50 times greater.

In order to get a more complete picture of what molecular elements are important for pheromonal activity in this species, we investigated the effect of the two analogs tested by Tai et al. (1992), as well as of analogs lacking the methyl group at the 3-position, (2*S*,7*S*)-7-methyl-2-pentadecanol acetate [**(*S*–*S*)Ac**], or the first methyl group of the carbon chain, (2*S*,6*S*)-2,6-dimethyl-1-tetradecanol acetate [**(–*SS*)Ac**, Table 1]. Field trials were performed both in Sweden and in Japan. In addition, we tested whether

N. sertifer males were attracted to esters other than acetate and propionate, of the major pheromone component, as has been found for *D. pini* (Anderbrant et al., 2005).

Methods and Materials

Chemicals used were of high chemical and stereogenic purities, and were synthesized according to Högberg et al. (1990), Hedenström et al. (1992), Tai et al. (1990, 1992), and Hedenström et al. (2002). Purity details and abbreviations of compounds used below are given in Table 1. Two of the compounds were produced both in the Japanese and one of the Swedish laboratories (MSU), and the batches are labeled J or S, respectively, at the end of the chemical acronym. Chemicals were dissolved in *n*-hexane or *n*-heptane before being applied to dispensers.

Field experiments were conducted in young Scots pine, *Pinus sylvestris* L., plantations in the provinces of Uppland (in 1991), Östergötland (in 1993 and 1995) and Skåne (in 1997), situated in the east and south of Sweden. Additional experiments were carried out in young Japanese red pine, *Pinus densiflora* Siebold. & Zucc., stands in Hyogo and Osaka prefectures, southern Honshu, central Japan (in 1995 and 1997). Lund-I sticky traps (Anderbrant et al., 1989) were used with the chemicals released from dental cotton rolls (Celluron No. 2, Paul Hartmann S.A., France). This dispenser shows a relative decrease in release rate of diprionol acetate that is independent of load (Anderbrant et al., 1992a), thus releasing roughly constant ratios of

[b] Trap lost.

compounds over time if the compounds tested are similar. For instance, the release rate is about 10% of the original load after 2 d at 20°C and 1 m.s^{-1} wind speed, and 1% after 10 d, for dispensers loaded with 6, 60, or 600 µg diprionol acetate (Anderbrant et al., 1992a). Traps were placed at least 30 m apart, at about 2 m above ground, in pine trees. To reduce positional effects, traps were moved to a new random position after each check, in most tests.

In 1991 the activities of the **(*SS*–)Ac**, **(*S*–*S*)Ac** and **(–*SS*)Ac** analogs were compared with **(*SSS*)Ac** using one dose only. In test 1, each compound was tested alone, while in test 2 the analogs were combined with **(*SSS*)Ac** to evaluate possible synergistic or antagonistic effects. In 1993 (test 3), three different doses of each analog were used to make a comparison with the results in Japan of Tai et al. (1992) possible. In 1995, the effects of addition of **(*SR*–)Ac,** **(*SRR*)Ac**, or **(*SRS*)Ac** analogs to **(*SSS*)Ac** were tested (tests 4 and 5]. Tests 6–9 (in 1995 and 1997) investigated whether higher doses of the analogs, **(*SS*–)Ac** (of either Swedish or Japanese origin) and **(*SR*–)Ac**, could be used as substitutes for **(*SSS*)Ac** and **(*SRR*)Ac**. In 1997 (test 10), the attraction to four different esters of diprionol was compared. To compensate for the different release rates of the different esters, the amount of the propionate applied on the dispenser was doubled, while the amounts of the *iso*-butyrate and butyrate were quadrupled, compared to that of the acetate (c.f., Anderbrant et al., 2005).

Results

When tested in 1991 and 1993, none of the three analogs [**(*SS*–)Ac**, **(*S*–*S*)Ac**, and **(–*SS*)Ac**] alone caught significant numbers of *N. sertifer* males in Sweden, despite the presence of a relatively large population, as judged by the catch in the trap loaded with **(*SSS*)Ac** (test 1, Table 2). Further, addition of any of these analogs to **(*SSS*)Ac** did not yield increased catches of *N. sertifer*, relative to traps baited with **(*SSS*)Ac** alone (test 2, Table 3). The lack of activity of the analogs, in Sweden, was confirmed in test 3, in which doses up to 100 times that of **(*SSS*)Ac** were tested (Table 4). Only few individuals were caught in the analog-baited

One trap set up at two sites, Östergötland, Aug. 28–Nov. 8, 1997.

[a] Trap positions rotated one and two times, respectively, but only total catches are reported.

traps, regardless of dose, not different from that of the unbaited trap; catches in traps baited with **(*SSS*)Ac** were much greater. However, in Japan, the **(*SS*–)Ac** analog, particularly of Japanese origin, attracted significant numbers of males (relative to the control) when tested in amounts 10 times higher than that used for **(*SSS*)Ac**-baited traps (tests 7 and 9, Tables 5 and 6). The **(*SS*–)AcJ** also was attractive to Swedish *N. sertifer* males (tests 6 and 8, Tables 7 and 8). In Trial II of test 6, the catch in traps baited with **(*SS*–)AcJ** was not different from the catch in traps baited with **(*SSS*)Ac** (albeit at one tenth the dose). However, in Trial I, the catch of *N. sertifer* in traps baited with **(*SS*–)AcJ** was less (but still higher than in control traps) than in traps baited with **(*SSS*)Ac**.

In Sweden, addition of the analogs **(*SRR*)Ac**, **(*SRS*)Ac**, or **(*SR*–)Ac** to **(*SSS*)Ac** resulted in a decrease in catch, relative to that in traps baited with **(*SSS*)Ac** alone (tests 4 and 5, Tables 9 and 10). At the same dose (1.0 μg) of analog, the antagonistic effect was significant for **(*SRR*)Ac** and **(*SR*–)Ac**, but not for **(*SRS*)Ac** (test 5, Table 10). In Japan, however, addition of **(*SR*–)Ac** to other attractive compounds [but not to **(*SSS*)Ac**, which was not tested] had no effect on trap capture (test 7, Table 5).

When the different esters of diprionol were tested in Sweden in 1997, **(*SSS*)Ac** and **(*SSS*)Pr** were attractive to *N. sertifer*, but **(*SSS*)*i*Bu** and **(*SSS*)Bu** were not (test 10, Table 11). At the higher dose (to compensate for lower volatility), **(*SSS*)Pr**-baited traps caught a greater number of *N. sertifer* than traps baited with **(*SSS*)Ac**; in contrast, catches in traps baited with the higher doses of **(*SSS*)*i*Bu** and **(*SSS*)Bu** were not different from the blank.

Discussion

Based on the results presented here, and earlier studies (Tai et al., 1990, 1992; Anderbrant et al., 1992b, 2000), Swedish and Japanese populations of *N. sertifer* differ from each other in several ways with respect to response of males to pheromone and related compounds. In both countries, the

Test run in Östergötland, Sweden, Sept.14–Oct. 7, 1995.

[a] Means followed by the same letter are not significantly different ($P<0.05$), according to ANOVA on log(catch + 1) transformed data followed by Tukey's test ($N=3$).

(2*S*,3*S*,7*S*)-isomer of acetate or propionate esters of diprionol are the only compounds that, in relatively low doses, attract males by themselves. However, the isomer **(*SRR*)Ac** is strongly antagonistic [when added to **(*SSS*)Ac**] in Sweden, but is apparently without effect in Japan [this study; Anderbrant et al. (2000)]. Earlier field tests in Japan indicated a small synergistic effect of **(*SRR*)Ac** over a wide range of **(*SRR*)Ac**/**(*SSS*)Ac** ratios (Tai et al., 1990, 1992).

In Sweden none of the three analogs, **(–*SS*)Ac**, **(*S*–*S*)Ac**, or **(*SS*–)Ac**, elicited catches of males when used in traps by themselves, and, further did not did not affect the catches of males when added to **(*SSS*)Ac**. This suggests that the analogs did not bind effectively to the antennal receptors tuned to **(*SSS*)Ac** (Hansson et al., 1991). In Japan, however, **(*SS*-)Ac**, in amounts 10–20 times higher than that of **(*SSS*)Ac**, caught male *N. sertifer* in traps (tests 7 and 9, Tables 5 and 6). Unfortunately, no unbaited traps were used in these two trials, but the other two analogs, **(*S*–*S*)Ac** and **(–*SS*)Ac**, caught lower numbers. The weak, but distinct, activity of **(*SS*–)Ac** in Japan is in accordance with results obtained by Tai et al. (1992). They used 100 times more of this analog, compared with **(*SSS*)Ac**, to get similar catches. When the amount of compound used is so much greater, as it is in some of these tests, there is an increased risk of other contaminants or isomers influencing male responses. However, in this case it is unlikely, as the amount of contaminating **(*SSS*)Ac** acetate had to be very low and would not explain the attraction to **(*SS*–)Ac** in Japan (Table 1). We speculate that ***SSS***-tuned receptors differ between Japanese and European populations, with receptors of Japanese *N. sertifer* males binding relatively effectively to analogs lacking the methyl group in the 7-position, but receptors of Swedish males requiring this structural feature for effective binding. This is supported also by the lack of effect of addition of the three analogs to **(*SSS*)Ac** in test 2 (Table 3); i.e., the analogs do not seem to

Table 11 Catch of male *Neodiprion sertifer* in traps baited with different esters of (2*S*,3*S*,7*S*)-3,7-dimethyl-2-pentadecanol [(***SSS***)ester] 1997 (Test 10)

Test run in Skåne, Sweden, Sept. 2–30 (Trial I) and Sept. 2–24 (Trial II).

[a] Means within a trial followed by the same letter are not significantly different ($P<0.05$) according to ANOVA on log(catch + 1) transformed data followed by Tukey's test (Trial I and II $N=5$).

bind at all to the receptors of *N. sertifer* males of Swedish origin.

An earlier investigation in Japan showed that the attraction to **(*SS*–)Ac** was synergized by addition of **(*SR*–)Ac** over a wide range of ratios (Tai et al., 1992). However, catches were small, and no repositioning of traps was carried out in these trials. No such effect of **(*SR*–)Ac** was found in the present investigation (test 7, Table 5). In fact, in Sweden **(*SR*–)Ac** showed antagonistic activity. These results are consistent with the response to **(*SRR*)Ac** in the two countries, and maybe explained by **(*SR*–)Ac** binding to the same receptor as does **(*SRR*)Ac**. Further, test 5, and to some extent test 4, showed that **(*SR*–)Ac** is a stronger antagonist than **(*SRS*)Ac** (Tables 9 and 10), suggesting that the presence of the methyl group at carbon 7 in an *R*-configuration is problematic for a receptor tuned to a *S*-methyl configuration at this position.

While the presence of a methyl group at each of the three stereogenic carbons apparently is essential to evoke an adequate response from males, the functional group on carbon 2 appears less critical; **(*SSS*)Ac** and **(*SSS*)Pr** are similarly active, both electrophysiologically and behaviorally (this study; Hansson et al., 1991; Anderbrant et al., 1992a, 2000). *Diprion pini* shows an even broader tolerance to different esters, with the acetate, propionate, and *iso*-butyrate esters of (2*S*,3*R*,7*R*)-3,7-dimethyl-2-tridecanol being attractive (Bergström et al., 1995; Anderbrant et al., 2005). It is interesting to note that the *S*-configuration at carbon 2 is important, and apparently conserved, within the Diprionidae (only one investigated species, *Gilpinia pallida*, employs a compound with 2*R* configuration, see Hedenström et al., 2006).

However, the terminal end (i.e., farthest away from the functional group) of the molecule is essential for the attractive effects. For *N. sertifer*, homologs of **(*SSS*)Ac** with one or two carbons less, or one carbon more, in the chain are completely inactive in the field (Wassgren et al., 1992). These homologs actually were found in small quantities in female extracts and also induced antennal responses during gas chromatography—electroantennographic detection recordings (Wassgren et al., 1992). Also *D. pini*, which has a main pheromone component with (2*S*,3*R*,7*R*)-configuration, showed electrophysiological, but not behavioral, responses to esters of (2*S*,3*S*,7*S*)-diprionol and its homologs (Anderbrant et al., 1995). Whether these homologs stimulate the same receptor as the pheromone or other receptors is unknown.

Neither *N. sertifer* nor *D. pini* has been subjected to a thorough investigation of single sensillum recordings in response to the various analogs/homologs. One obstacle to such a study is that the main pheromone component in both species stimulates several neurons with different amplitudes (Hansson et al., 1991; Anderbrant et al., 1995), making reliable quantifications difficult. Detailed molecular structure-electrophysiological response studies have been undertaken for other systems. For instance, recordings of 42 analogs of (*Z*)-5-decenyl acetate, a pheromone component of the turnip moth, *Agrotis segetum*, were subjected to quantitative structure-activity modeling (Norinder et al., 1997 and references therein).

In sawflies, the combination of a complex, chiral pheromone molecule and a need for high stereogenic purity has stimulated the search for active analogs that are easier to synthesize for practical use. The results presented in this study indicate that it might be difficult to find such an analog. Instead, a more practical solution may be a simpler synthetic approach that produces mixtures containing the actual pheromone along with inactive stereoisomers (Hedenström et al., 2002). Successful population monitoring with such a mixture has been performed for *Diprion jingyuanensis* Xiao et Zhang in China (Zhang et al., 2005).

Acknowledgments We thank Eva Annerfeldt, Erling Jirle, Rolf Wedding, and Fredrik Östrand for technical assistance. Financial support was provided by The Swedish Council for Forestry and Agricultural Research, The Swedish Natural Science Research Council, The Bank of Sweden Tercentenary Foundation, and Carl Tryggers Stiftelse för Vetenskaplig Forskning. We also are grateful for financial support from EU (Objective 1 the region of South Forest Counties) and Länsstyrelsen i Västernorrlands län.

2007), and Omura et al. (2002a) found that *Niponia nodulosa* Verhoeff, a cryptodesmid polydesmidan, secretes 1-octen-3-ol and geosmin. Cyanogenesis was not detected in either case. Such findings led to the assumption that cyanogenesis is not universal among polydesmidan millipedes.

Duffey et al. (1977) and Omura et al. (2002b) found that the chemical content of the defensive secretion varied considerably among twelve xystodesmid millipedes, and that the variable chemical composition might be used chemotaxonomically to distinguish some members of this group.

In this study, we investigated three sympatric species: *Polydesmus complanatus* (L.) (distributed in central, eastern, northern, and southeastern Europe), *Brachydesmus (Stylobrachydesmus) avalae* Ćurčić & Makarov (endemic to Serbia), and *Brachydesmus* (*Stylobrachydesmus) dadayi* Verhoeff (distributed in Bulgaria, Hungary, Serbia, and Slovakia) (all Polydesmidae). The objectives were: 1) to determine and identify the chemical components of the defensive secretions from three European polydesmids; 2) to test for possible intergeneric and interspecific variation of the chemical constituents, especially in closely related forms; and 3) to confirm the consistency of cyanogenesis in the members of the Polydesmidae.

Methods and Materials

Collection and Handling of Millipedes Individuals of *P. complanatus*, *B. avalae*, and *B. dadayi* were collected in the autumn (September–November 2009) at Mt. Avala, near Belgrade. Millipedes were stored in plastic boxes with a layer of partly decomposed litter and kept in the laboratory for a few days at 10°C in the dark. Humidity in the boxes was kept high by spraying water on the litter every day.

Dissection and Anatomical Description of Glands Defense glands are not present on each pleurotergite in the three polydesmids: in *P. complanatus* they are present on somites 5, 7, 9, 10, 12, 13, and 15–19, and in both *Brachydesmus* species on somites 5, 7, 9, 10, 12, 13, and 15–18. In these pleurotergites, the defense glands are located on lateral sides on both paranotal expansions. Five specimens of each of these polydesmid species were cold anaesthetized, and the defensive glands were excised from the pleurotergites. Each gland was placed carefully on a slide and examined under the microscope (Axioskop 40, Carl Zeiss; magnification 400×).

Chemical Extraction For the collection of secretions, ten females and ten males of each of the three species were extracted in hexane (0.5 ml) for 10 min. To eliminate the effects of composition-altering oxidation and degradation of compounds, a portion of the extracts was subjected to gas chromatography-mass spectrometric (GC-MS) analysis immediately after preparation.

Chemical Analyses Analyses were performed on an Agilent 7890A GC system equipped with a 5975C inert XL EI/CI MSD and a FID detector connected by capillary flow technology through a 2-way splitter with make-up gas. An HP-5 MS capillary column (Agilent Technologies, Santa Clara, CA, USA, 25 mm i.d., 30 m length, 0.25 μm film thickness) was used. Samples were injected in splitless mode. The injection volume was 1 μl, and the injector temperature was 250°C. The carrier gas (He) flow rate was 1.1 ml/min, whereas the column temperature was programmed linearly in a range of 60–310°C at a rate of 10°C/min with initial 2-min and final 8-min holds. The transfer line temperature was 280°C. The FID detector temperature was 300°C. EI mass spectra (70 eV) were acquired in *m/z* range of 35–550, and the ion source temperature was 230°C.

A library search and mass spectral deconvolution and extraction were performed by using NIST AMDIS (Automated Mass Spectral Deconvolution and Identification System) software, ver. 2.64. We used retention index (RI) calibration data analysis parameters at a 'strong' level with a 10% penalty for compounds without an RI. The retention indices were determined experimentally by the method of van Den Dool and Kratz (1963). This method is based on the retention times of *n*-alkanes, which were injected after the sample under the same chromatographic conditions. The search was performed against our own library containing 4,951 spectra, and the commercially available NIST05 Willey07 library containing approximately 500,000 spectra (identifications supported by data in Table 1 and Supplemental Data Figs. 1 and 2).

Percentages (relative) of the identified compounds were computed from the corresponding GC-FID peak areas.

Detection of Hydrogen Cyanide Hydrogen cyanide secreted from live millipedes was examined qualitatively by using filter paper that had previously been impregnated with a saturated solution of picric acid and was air-dried. After the filter paper was sprayed with 5% sodium bicarbonate, and without drying, a live millipede was placed onto the paper and squeezed forcefully (five specimens of each species). If the millipede secretions contained hydrogen cyanide, the color of the portion of the paper stained by the secretions gradually turned orange (Noguchi et al., 1997).

Results

Eight compounds were identified in the *n*-hexane whole-body extracts of the three polydesmid species (Table 1,

Table 1 Chemical composition of the defensive secretions in three polydesmid millipede species analyzed by GC-FID and GC-MS

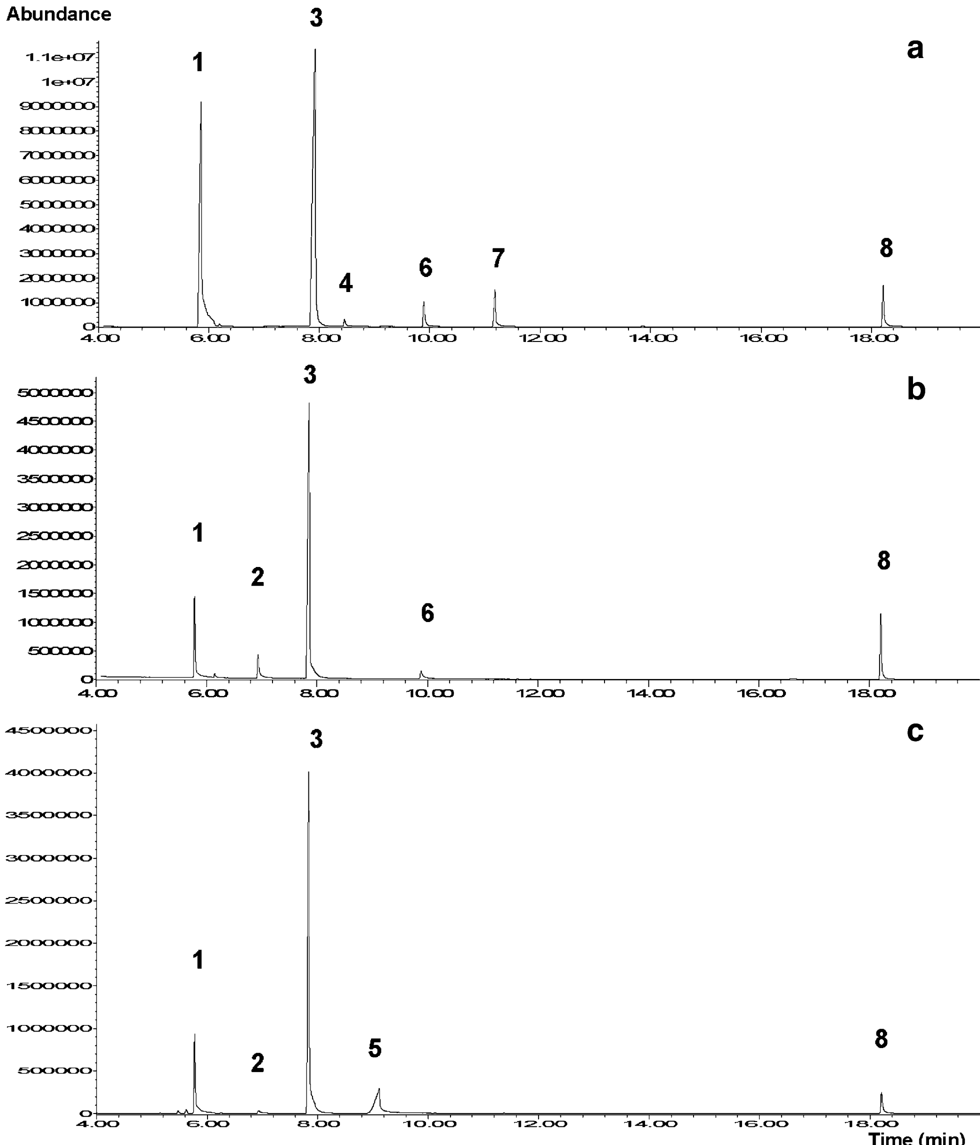

Fig. 1 Total ion chromatograms of the hexane whole-body extract from adult millipedes, *Polydesmus complanatus* (**a**), *Brachydesmus* (*St.) dadayi* (**b**), and *Brachydesmus (St.) avalae* (**c**). Peak 1: benzaldehyde; peak 2: benzyl alcohol; peak 3: benzoylnitrile; peak 4: benzyl methyl ketone; peak 5: benzoic acid; peak 6: benzyl ethyl ketone; peak 7: mandelonitrile; and peak 8: mandelonitrile benzoate

Supplemental Data Table 1 and Supplemental Data Figs. 1 and 2). The extracts showed different GC-MS patterns (Table 1 and Fig. 1). The extract of *P. complanatus* contained six compounds (Fig. 1a). The major components were benzoylnitrile and benzaldehyde; the minor components were mandelonitrile, benzyl ethyl ketone, mandelonitrile benzoate, and benzyl methyl ketone. The extract of *B. dadayi* contained only five compounds (Fig. 1b). The major component was benzoylnitrile; the minor components were benzaldehyde, mandelonitrile benzoate, benzyl alcohol, and benzyl ethyl ketone. The extract of *B. avalae* had six compounds (Fig. 1c). The major component was benzoylnitrile; the minor ones were benzoic acid, benzaldehyde, mandelonitrile benzoate, benzyl alcohol, and a trace amount of benzyl ethyl ketone. In all species, we confirmed the presence of hydrogen cyanide. No significant difference in the amounts of the components was observed between the sexes in the three analyzed species.

Discussion

In all three polydesmids that we analyzed, benzoylnitrile was a major component of the whole body extract. The second major component was benzaldehyde, which, along with hydrogen cyanide, is known as the most common defensive substance in various millipedes. A review of the literature shows that benzyl ethyl ketone, benzyl methyl ketone, and benzyl alcohol were detected for the first time from representatives of the order Polydesmida.

The dissection of glands in the three polydesmids showed that they have a typical structure, consisting of an inner elongated compartment or reservoir and a smaller compartment or vestibule. In *P. complanatus*, the reservoir stores mandelonitrile, whereas the vestibule contains an enzyme that catalyzes the breakdown of mandelonitrile into hydrogen cyanide and benzaldehyde (Hopkin and Read, 1992). Because we did not confirm the presence of mandelonitrile in both *Brachydesmus* species, we hypothesize that mandelonitrile benzoate is a cyanogenic precursor in these two species.

There is a controversy about the taxonomic position of the genera *Polydesmus* and *Brachydesmus*. Namely, these genera are differentiated mainly according to the number of pleurotergites (19 pleurotergites in *Brachydesmus* species vs. 20 in *Polydesmus* species), but in many forms of both genera, pleurotergites and gonopods show similar structure. Strasser (1971) speculated about the validity of the genus *Brachydesmus*, and even about some species with 19 pleurotergites from the genus *Polydesmus* [(e.g., *Polydesmus gradjensis* (Jawlowski) or *Polydesmus jugoslavicus* (Jawlowski)]. Hoffman (1979) treated *Brachydesmus* as a subgenus of the genus *Polydesmus*. However, Enghoff and Kime (2005) retained full generic status for both groups. The present study clarified the differences in chemical composition of the defensive secretions in these two polydesmid genera. Mandelonitrile was detected only in *P. complanatus*. On the other hand, benzyl alcohol was detected only in the *Brachydesmus* species. The presence of benzyl alcohol and absence of mandelonitrile may be a chemogeneric characteristic of *Brachydesmus* relative to *Polydesmus*. This difference supports the validity of the genus *Brachydesmus*.

Additionally, we demonstrated intrageneric variation in the chemical composition of whole-body extracts in the *Brachydesmus*, including the presence of benzoic acid only in *B. avalae* (Table 1). As another example of intrageneric variation, Casnati et al. (1963) and Eisner et al. (1975) showed that *P. collaris collaris* and *P. vicinus* produced HCN, benzaldehyde, mandelonitrile benzoate, and mandelonitrile. In contrast we have shown that whole-body extracts of *P. complanatus* contain benzoylnitrile, benzyl methyl ketone, and benzyl ethyl ketone, which were absent in *P. collaris collaris* and *P. vicinus* (Table 1). In most previous analyses of the Polydesmidae, only the major chemical components of the millipede exudates were identified (Casnati et al., 1963; Eisner et al., 1975; Duffey et al., 1977; Conner et al., 1977). Our study demonstrates that most differences among the polydesmid defensive secretions are found among the minor components, and that the chemical patterns in the defensive fluids may be useful in chemotaxonomy.

Shear et al. (2007) noted that the families of Xystodesmidae and Gomphodesmidae are cyanogenic and also produce benzoylnitrile (=benzoyl cyanide), which is not found in other families. However, Conner et al. (1977) found benzoylnitrile in the defense secretion of *Pseudopolydesmus serratus* (Polydesmidae). Thus, we confirmed the presence of benzoylnitrile in representatives of the family Polydesmidae.

The primary function of defensive secretion in the polydesmids is protection against potential predators (Duffey et al., 1977; Hopkin and Read, 1992; Omura et al., 2002a). Duffey et al. (1977) found that benzoylnitrile, the most abundant component, possesses anaesthetizing properties for potential predators, especially ants, which are abundant in the habitat from which we collected all of our specimens. A secondary function of the defensive secretion may be antimicrobial and antifungal. The three species that we analyzed are likely exposed to microbial attack. *Polydesmus complanatus* is a stratobiont, restricted mainly to litter and the uppermost soil layers. Both representatives of the genus *Brachydesmus* are minute geobionts, which inhabit deeper soil layers. Roncardi et al. (1985) found that the mixture of benzaldehyde, benzoic acid, benzoylnitrile, and mandelonitrile benzoate in some

xystodesmid millipedes was a more effective spore germination inhibitor than any individual compound. Furthermore, they noted that the antifungal function of the defensive secretion mixture could be a factor in preventing invasion of the cyanogenic gland and contamination of the millipede with microorganisms. Our results showed that the extracts of *P. complanatus* and *B. dadayi* contained benzaldehyde and mandelonitrile benzoate, whereas the extracts of *B. avalae* contained benzaldehyde, benzoic acid, and mandelonitrile benzoate. Mixed with other detected compounds, the defensive secretion in the species that we analyzed likely has a protective function for the cyanogenic glands, as well as the cuticle.

Our results confirm cyanogenesis in the family Polydesmidae. Benzyl ethyl ketone, benzyl methyl ketone, and benzyl alcohol were detected for the first time in the order Polydesmida. The specificity in the chemical composition of defensive secretions might serve as criteria for the chemotaxonomy in polydesmid species. Further studies are necessary in order to clarify differences in chemical composition in additional polydesmid representatives.

Acknowledgments We thank Steven Seybold (USA) and two anonymous reviewers, whose comments greatly improved the manuscript. This study was supported by the Ministry of Science and Technological Development of Serbia (Grants Nos. 143053 and 142053).

Glycine and GABA in the digestive juice of privet-specialist insects

exceeded 50 mM (Konno et al. 1997). An injection experiment with ^{15}N-labeled glycine showed that glycine is actively transported from hemolymph to the midgut lumen against the concentration gradient in *B. wallichii* (Konno et al. 2001), suggesting that the glycine secreted in digestive juice has physiological functions. Glycine completely inhibited the lysine-decreasing activity of privet leaf extract and enzymatically activated oleuropein in *in vitro* experiments (Konno et al. 1997, 1998). Further, our recent experiments also showed that glycine functions as adaptation *in vivo*. When the non-specialist caterpillars, i.e., the Eri silkworm, *Samia ricini,* were fed privet leaves coated with free glycine, both the decrease in lysine concentration of the midgut contents and the retardation of growth observed in larvae fed privet leaves were completely prevented, and the larvae grew successfully (Konno et al. 2009). These results indicate that glycine secretion in the digestive juice of several privet specialists is an adaptive trait against the oleuropein-based chemical defense of privet trees. Further, as a chemical model that might explain this phenomenon, we hypothesized that amino residues in glycine inhibit the lysine-decreasing activity by competing with the amino residue in the side chain of lysine for oleuropein (Konno et al. 1999, 2009) (Fig. 1).

In the present study, we attempted to address several remaining questions. First, we wanted to examine the generality of glycine secretion among privet-feeding insects. Second, we were interested in knowing whether or not glycine is the only amino acid or chemical that can function as an adaptation against the privet defense and that has been adopted by privet specialists for that purpose. Our chemical model predicted that not only glycine, but also other amino acids containing amino residues could function in the adaptation to the privet defense. To address the first and second points, we extended the survey to investigate the presence of glycine or other amino acids in the digestive juice of additional lepidopteran species, both privet feeders and non-feeders, and also some hymenopteran species. We found that most privet specialists, whether Lepidoptera or Hymenoptera, have glycine or other amino acids such as

GABA in their digestive juice. The third question was what structure in amino acids is important for inhibiting the privet activity. Fourth, we asked whether the concentrations of amino acids found in the digestive juice were sufficient to inhibit the lysine-decreasing activity. These last two points were analyzed and clarified by *in vitro* experiments. We speculate on the evolutionary processes and characteristics of these convergent adaptive traits in privet specialists, and how the cost of adaptation may have affected the coevolutionary process between the privet tree and its specialists.

Methods and Materials

Insects The Eri silkworm, *Samia ricini*, and the true silkworm, *Bombyx mori* are maintained in our institute as experimental insects. Larvae of all other lepidopteran and hymenopteran species used in the present study were collected from wild populations in Tsukuba, Ibaraki, Japan (36°N, 136°E). These species are listed in Table 1.

Analysis of Amino Acids in the Digestive Juice and Midgut Lumen To examine whether the glycine secretion observed in the larvae of several privet-specialist lepidopteran species is a general trait found in all privet-feeding insect species, we analyzed the digestive juice of larvae of 42 herbivorous lepidopteran and hymenopteran species. The digestive juices (N=3–10) were collected from the last instar larvae fed their host plants at 3 d after the last ecdysis as described previously (Konno et al. 1996, 1997). In short, larvae were starved for 1 d prior to the collection in order to decrease contamination of leaf material. Then, an electric shock was administered to the larvae, and the vomited digestive juice was collected. The fact that the larvae of most species vomited a large amount of fluid compared to their body sizes (e.g., an Eri silkworm with 5 g weight vomited more than 1 ml of fluid) suggests that the vomited fluid came from the midgut. Further, the glycine concentration in vomited digestive juice and that in samples collected from the anterior parts of midgut lumen by dissection showed good agreement both in *Bombyx mori* (8.98 mM and 5.72 mM in vomited digestive juice and sample collected from midgut lumen, respectively) (Konno et al. 1996) and in *Brahmaea wallichii* (50.05 mM and 52.94 mM, respectively) (Konno et al. 1997, 2001). These facts indicate that the digestive juice collected using the electric shock method well represents the condition of digestive juice in the midgut lumen or what is called midgut fluid. The collected digestive juice was analyzed by an auto amino acid analyzer (Model L5000; Hitachi, Tokyo) based on HPLC and the ninhydrin reaction. The digestive juice of *Artopoetes pryeri*, a privet-specialist that did not have glycine nor 19 other protein amino acids in its digestive juice, but had an unidentified ninhydrin-positive compound, was further analyzed by ^{1}H and ^{13}C -NMR. For this analysis, digestive juice was collected from 50 larvae by dissection. The ninhydrin-positive peak in the digestive juice was purified by HPLC, and ^{1}H and ^{13}C-NMR spectra were measured.

Analysis of the Lysine-decreasing Activity of Privet Leaves and Inhibitory Activity of Amino Acids, Amines and Ammonium Ion The analyses were performed as described previously (Konno et al. 1997, 1998, 1999). In short, the lysine-decreasing activity of the privet leaves was reproduced *in vitro* by mixing together an oleuropein-containing fraction free of activating enzymes, and an activating enzyme-containing fraction free of oleuropein, both of which were prepared from privet leaves and lacked any lysine-decreasing activity alone. The oleuropein-containing solution was prepared by homogenizing steamed privet leaves (100°C, 4 min) with 5 volumes of water and collecting the supernatant by centrifugation. The solution contained approximately 0.6% oleuropein. The activating enzyme-containing solution was prepared from fresh privet leaves by collecting an organelle fraction by differential centrifugation. Analyses were performed in 750 µl of sodium phosphate buffer solution (pH 7.0) that contained 1% ovalbumin, 500 µl of oleuropein-containing solution prepared from 100 mg of steamed privet leaves, 100 µl of enzyme-containing fraction prepared from 80 mg of privet leaves, and the indicated amounts of amino acids, amines, or ammonium ion. These conditions were determined in order to simulate roughly the conditions in the midgut lumen of caterpillars feeding on privet leaves. This assumes that fresh leaf material contains 25% of dry matter, that the dry leaf matter contains 20% of protein, and that fresh leaf material is diluted by five volumes of digestive juice in the midgut lumen. Reactions were performed at 25°C for 2 h, and stopped by the addition of 6 M HCl. After the reactions, the ovalbumin was hydrolyzed in 6 M HCl at 110°C for 22 h. The lysine content in hydrolyzed ovalbumin was analyzed by the same auto amino acid analyzer described above.

Results

Occurrence of High Concentrations of Glycine in the Digestive Juice of Privet-Specialist Lepidopteran and Hymenopteran Larvae We found very high concentrations of glycine in many of the privet-feeding species (Table 1). The average concentration of glycine for 11 privet-feeding species was 40.396 mM, and was significantly higher than that for 32 non-privet-feeding species (2.198 mM) (Mann-

The values of concentrations not otherwise indicated are the concentrations of glycine

GABA and β-alanine were not detected in the species unless the concentrations of these amino acids were otherwise indicated in the parentheses

The values for each species are an avarage from 3–10 individuals

[a] The data for this species was taken from Konno et al. (1997)

Whitney's U-test, P=0.002). Six out of eleven privet-feeding species showed glycine concentrations higher than 15 mM, and 7 out of 11 showed glycine concentrations higher than 10 mM. In *Dolbina tancrei* (Sphingidae), *Brahmaea wallichii* (Brahmaeidae), and *Naxa seriaria* (Geometridae), the concentrations were around 50 mM (0.4%), and in *Inurois fletcheri* (Geometridae) the concentrations reached 88 mM (0.7%). Further, in the privet-specialist sawfly, *Macrophya timida* (Hymenoptera), the glycine concentration reached 164 mM (1.2 %) (Table 1). In *Brahmaea wallichii*, a glycine-specific secretory mechanism has been identified in the midgut (Konno et al. 2001). In contrast, none of the 32 non-privet-feeding species showed a glycine concentration higher than 15 mM, and more than half of the species eventually had no glycine in their digestive juices (Table 1).

GABA and β-Alanine in the Digestive Juice of Some Privet Specialists Among the 11 privet-feeding species examined, 4 species did not have glycine in their digestive juice; these 4 species included *Artopoetes pryeri* (Papilionoidae), *Crainophora fasciata* (Noctuidae), *Amphipyra monolitha* (Noctuidae), and *Spilosoma imparilis* (Arctiidae) (Table 1). We further analyzed the digestive juice of the larvae of a Lycaenidae butterfly, *Artopoetes pryeri* (Fig. 2a), for amino acids other than glycine. GABA (γ-amino butyric acid), an amino acid known as a neurotransmitter (Waagepetersen et al. 1999), was present in high concentration (60.812± 40.992 mM, N=10) (Fig. 2b, c, d, e) instead of free glycine, while the concentrations of other free amino acids were low. The unexpected presence of GABA was confirmed further by ^{1}H-NMR analyses (Fig. 2c, d). The spectra of the purified ninhydrin-positive compound were as follows. For ^{1}H-NMR(400 MHz, D_2O):δ 1.80 (2H, quint, J=7.4 Hz), 2.20 (2H, t, J=7.4), 2.91 (2H, t, J=7.6). For ^{13}C-NMR (100 MHz, D_2O): δ 23.77, 34.51, 39.40, 181.63. These spectra were identical to those of the pure GABA standard. Further, in the digestive juice of two other privet-feeding species, *Crainophora fasciata* (Noctuidae) and *Amphipyra monolitha* (Noctuidae), 9.851 mM and 34.757 mM of β-alanine was observed, respectively. In total, 10 of 11 privet species retained high concentrations of either glycine, β-alanine, or GABA, with the only exception being *Spilosoma imparilis* (Arctiinae). The average concentrations of the most abundant amino acids in the digestive juices were significantly higher in privet-feeding species (49.553 mM) than in non-feeding species (4.217 mM) (Mann-Whitney U-test, P<0.001) (Table 1). No detectable GABA, β-alanine, and only a trace amount (less than 2 mM) of glycine were observed in the water extract of privet leaves extracted with five volumes of water. This observation together with our previous observation on active secretion of glycine in the digestive juice in *Bramaea wallichii* (Konno et al. 2001) indicated that high concentrations of glycine, GABA, and β-alanine found in the digestive juice of prevet specialists is derived from insects rather than from privet leaves.

Comparison of the Abilities of Amino Acids, Amines, and Ammonium Ion to Inhibit Lysine-decreasing Activity To examine whether the glycine in the digestive juice has an adaptive role at the concentrations found in the digestive juice of privet specialists, we performed an *in vitro* experiment in which protein (ovalbumin) was mixed with oleuropein activated by enzymes in the presence of glycine, thus imitating the conditions in the midgut lumen of privet specialists. The lysine content of treated protein was analyzed (Fig. 3a). Untreated ovalbumin contained 2.962±0.075 (μmol / 10 mg ovalbumin) of lysine, and in the ovalbumin treated by enzymatically activated ovalbumin without the

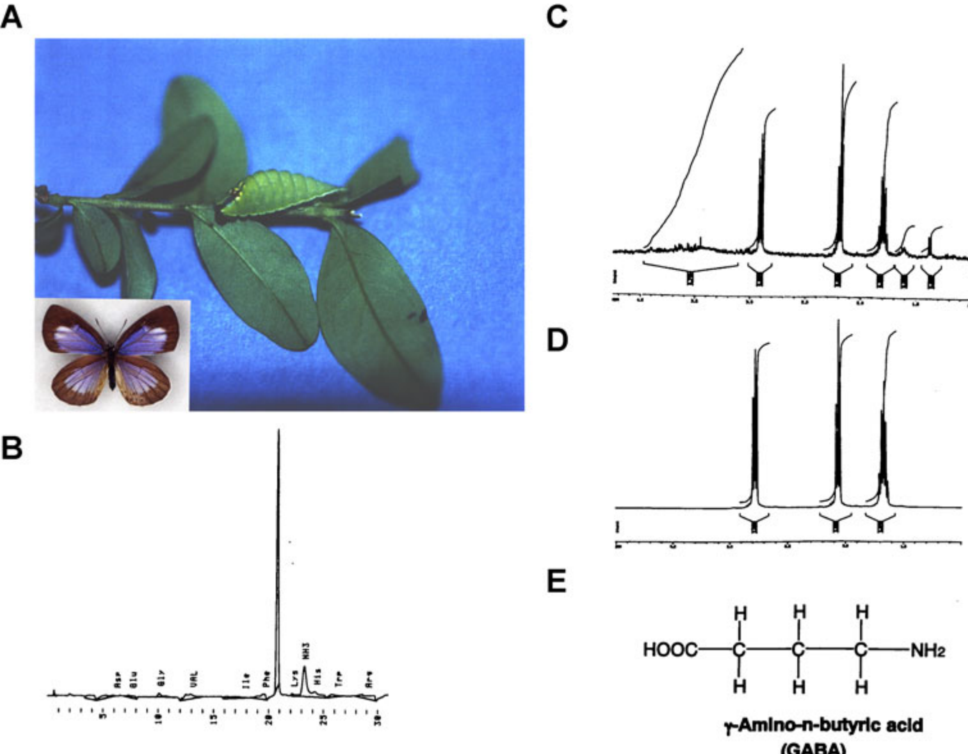

Fig. 2 A high concentration of GABA (γ-amino butyric acid) found in the digestive juice of larvae of a Lycaenidae butterfly, *Artopoetes pryeri*. **a** A larva and an adult (bottom left) of *A. pryeri*. **b** A ninhydrine-positive peak in the digestive juice of larvae of *A. pryeri* detected using an auto amino acid analyzer. **c** The ^{1}H-NMR spectrum of the chromatographically purified ninhydrine-positive peak in the digestive juice. **d** The ^{1}H-NMR spectrum of pure GABA. **e** The molecular structure of GABA

addition of glycine, the lysine content decreased to 0.619±0.102 (μmol / 10 mg ovalbumin). When ovalbumin was treated in the presence of 13.3 mM and 26.6 mM of glycine, the lysine contents in protein were 2.414±0.151 and 2.557±0.086 (μmol / 10 mg ovalbumin), respectively, and the lysine decrease was inhibited. The *in vitro* results that 13.3–26.6 mM glycine inhibited the lysine-decreasing activity suggest that the amount of glycine found in privet-feeding insects (15 mM–150 mM) would prevent the lysine-decreasing activity of the privet leaves and its adverse effects also *in vivo*. In fact, our recent *in vivo* results showed that the presence of 30 mM of glycine in the midgut lumen due to concomitant administration of glycine during the oral administration of privet leaves prevented the loss of lysine and significantly improved the growth performances of the non-specialist Eri silkworms, *Samia ricini* (Konno et al. 2009).

GABA also inhibited the lysine-decreasing activity as effectively as glycine (Fig. 3a). When ovalbumin was treated by enzymatically activated oleuropein in the presence of 13.3 mM and 26.6 mM of GABA, the resulting lysine contents were 2.286±0.019 and 2.576±0.109 (μmol / 10 mg ovalbumin), respectively, thus indicating that the GABA found in digestive juice has an adaptive role. β-Alanine also efficiently inhibited the lysine-decreasing activity of oleuropein (Fig. 3a).

Since glycine, GABA, and β-alanine are amino acids, and since glutaraldehyde and iridoid aglycones, which are similar to glutaraldehyde, have been reported to bind to amino residues of free amino acids and to the side chain of lysine in protein (Richards and Knowles 1968; Kawahara et al. 1992; Touyama et al. 1994; Bianco et al. 1999a, b), we hypothesized that the amino residues in glycine, GABA, and β-alanine inhibit the lysine-decreasing activity by competing with the amino residue in the side chain of lysine for oleuropein (Fig. 1). To examine this possibility, we analyzed the inhibitory activity of amino acids, amines, ammonium ion, and related compounds (Fig. 3a, b). Alanine, propyl amine, ammonium acetate, ammonium chloride, GABA, glycine, and β-alanine showed inhibitory activity, while sodium acetate and urea, which do not have amine properties (such as basicity), did not inhibit the lysine-decreasing activity. These results indicated the relevance of our hypothesis (Fig. 1). However, the inhibitory activity differed significantly among the amino acids and amine-related compounds tested. While glycine, GABA, and β-alanine inhibited lysine-decreasing activity almost completely at lower concentrations (13.3 mM–26.6 mM) and propylamine also showed strong inhibition, alanine and ammonium ion did not inhibit the activity completely even at concentrations 5 times higher (53.3 mM–133.3 mM) (Fig. 3a, b). These results can be attributed to the similarity in structure among glycine, β-alanine, GABA, and propylamine, all of which have amino residues at the ends of the molecules, vs. alanine (as well as all other protein forming amino acids except lysine) which does not. Its amino residue is half hidden by other parts (i.e., side chains) of the molecule. Thus, the amino acids that

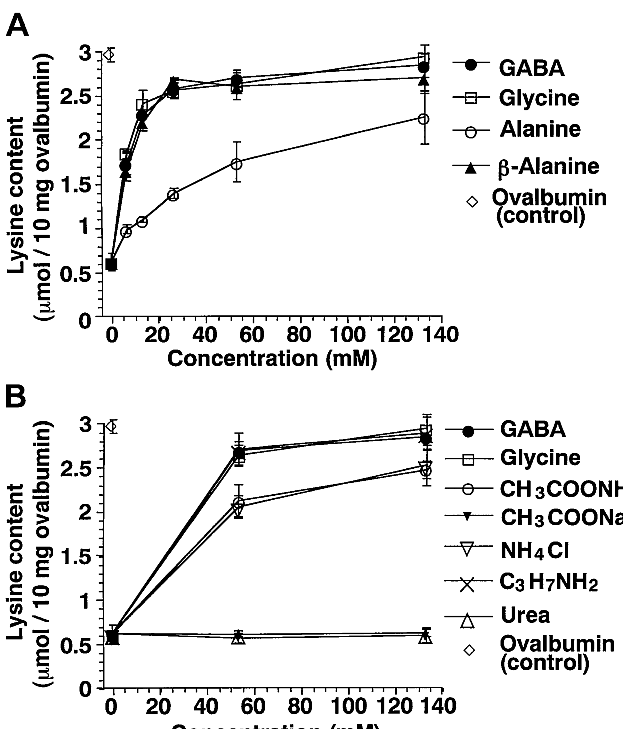

Fig. 3 Inhibitory effects of glycine, GABA, and other amino acids, amines, and ammonium ion on the lysine-decreasing activity of privet leaves. Untreated ovalbumin contains approximately 3 μmol lysine per 10 mg ovalbumin. When ovalbumin was exposed to the lysine-decreasing activity of the privet leaves, the lysine decreased to approximately 0.6 μmol per 10 mg ovalbumin. The indicated amounts of amino acids, amines, and ammonium ion were added in the treatment, and the amounts of lysine in treated ovalbumin were measured (average±SD, N=3)

have been adopted by privet specialists worked most effectively.

Discussion

In this study, we found that a number of phylogenetically distinct privet-feeding insects have convergently developed similar molecular strategies based on the same chemical principle, namely the secretion of amino acids such as glycine, GABA, and β-alanine as a neutralizer, in order to feed on the privet tree defended by an iridoid glycoside, oleuropein. To our knowledge, this is the first study to identify a biological role of animal-derived GABA in plant-herbivore interactions, and also the first to establish a biological role of animal-derived GABA that does not involve neurons, such as a role in neurotransmission or neurodevelopment (Waagepetersen et al. 1999).

In this study, we found that 7 of 11 privet specialists secrete glycine, that 10 of 11 privet specialists secrete glycine, GABA, or β-alanine, and that the concentrations of these amino acids are significantly higher in privet specialists than non-privet specialists. Further, our biochemical analyses showed that these amino acids inhibit the decrease in lysine caused by oleuropein *in vitro* (Fig. 3), and that glycine inhibits the decrease in lysine and improves the non-specialists' performance *in vivo* (Konno et al. 2009). All these findings indicate that amino acid secretion in the digestive juice is a general and efficient adaptive trait of privet-specialists against the privet defense based on oleuropein, the iridoid glycoside in its leaves.

The present experiments are the first to elucidate a physiological mechanism of insect adaptation to an iridoid glycoside-based defense, which is found widely in plants (Bowers 1991). It is an interesting question whether similar adaptive mechanisms exist in the specialist herbivores of iridoid-defended plants other than privet trees. Glutaraldehyde-like alkylators (di-aldehyde) are not only produced by the activation of iridoids by β-glucosidase (Konno et al. 1999), but also by the activation of caulerpenyne by esterase activity in an invasive sea green algae, *Caulerpa taxifolia* (Jung and Ponert 2001). In both cases, they exert lysine-decreasing activity *in vitro* (Konno et al. 1999; Weissflog et al. 2008), although the structures of the precursors, oleuropein and caulerpenyne, are very different. It would be interesting to examine whether caulerpenyne also functions in the defense of the sea algae and whether amino acid secretion also exists in the digestive juices of specialist feeders of the sea algae as an adaptation in the marine ecosystem.

It is clear that the iridoid-based defense of privet trees can be classified as an anti-nutritive plant defense in which essential amino acids of nutritive proteins are targeted and destroyed by the plant itself (Felton and Gatehouse 1996; Zhu-Salzman et al. 2008), similar to the defenses that involve phenolics and tannins (Felton et al. 1989; Felton and Gatehouse 1996), proteinase inhibitors (Felton and Gatehouse 1996; Lawrence and Koundal 2002), and arginase and threonine deaminase (Chen et al. 2005). Despite the importance of such anti-nutritive plant defenses, adaptive mechanisms against them have been established only in limited cases, such as the excretion of tannin-binding proline-rich protein in mammalian saliva that defend against tannin (Shimada 2006), the production of catalase against peroxidase-activated phenolics (Felton and Duffey 1991), or the induction of insensitive proteinase against proteinase inhibitor (Broadway 1995). Our study on this molecular adaptive mechanism of privet specialists against the iridoid-based anti-nutritive defense of privet trees contributes a unique example of insect adaptation to an anti-nutritive defense.

Figure 1 presents our latest chemical model of the privet-privet specialist relationship based on our present and previous studies (Konno et al. 1997, 1998, 1999, 2009). The model suggests that one amino residue in a molecule of

an amino acid is required to prevent the loss of one molecule of lysine in dietary protein. The model also predicts that not only glycine but also all other amino acids and molecules with amino residues could prevent lysine loss and protein denaturation. Our experiments (Fig. 3) showed that the prediction holds, and the results imply that any amino acid is a potential neutralizer of the protein-denaturing / lysine-decreasing activities exhibited by privet leaves.

However, the amino acid found in the digestive juices of the privet specialists we examined was glycine in many cases, β-alanine in two cases, and GABA in a single case; no other amino acids were found in the juices from privet specialists. This pattern could be explained only if we assume the costs incurred by a privet specialist in adapting to a chemical defense of the privet tree. It is clear that, in adapting to the privet tree chemical defense, herbivores incur adaptive costs by adopting an amino acid secretion strategy, since it is necessary to consume one amino residue of some molecule to save one molecule of lysine, an essential and valuable amino acid. The cost of adaptation must be less than the benefit it provides. For this reason, the amino acids used and consumed by herbivores must be non-essential amino acids, such as glycine, or derivatives thereof that insects can synthesize by themselves, such as GABA and β-alanine, which can be easily produced from glutamate and aspartate, respectively. For the same reason, the amino acids used by privet specialists must have sufficient neutralizing effects at low concentrations. We observed that glycine, GABA, and β-alanine are five times more effective than alanine (Fig. 3a). The digestive juices of many privet-specialist species contain 40–160 mM of GABA or glycine (0.3–1.2% for glycine). These concentrations are probably necessary and sufficient for these specialists. If they need to substitute glycine, β-alanine, or GABA with alanine, it is estimated that 200–800 mM (1.8–8.9%) of alanine would be necessary. However, the cost to secrete such high concentrations of alanine (the cost of alanine itself and the cost to transport a large amount of alanine across the midgut) would be quite high. Further, such a high concentration (8%) of alanine would be harmful because of high osmotic pressure, and also 8% alanine is close to saturation (the solubility of alanine to water at 25°C is 121 g/l, 12.1%), and this could make secretion difficult. Therefore, glycine, β-alanine, and GABA seem to be the only amino acids that are at once economical and efficient, and for which the benefits of production exceed the costs.

The evolution to amino acid secretion seems to have occurred at least four times convergently, once for Lepidoptera with GABA, once for Lepidoptera with β-alanine, and at least once each, but probably more, in Lepidoptera and Hymenoptera with glycine. The secretion of glycine has evolved more frequently and is distributed more widely among insects than the secretion of β-alanine or GABA (Table 1). This pattern also could be explained from the standpoint of the cost of adaptation, since β-alanine and GABA are likely to be costlier than glycine because of the cost of carbon. All our results suggest that in privet /privet-specialist systems, herbivores incur costs in adaptation and evolve into these adaptive traits only if benefits exceed costs. The trait with the cheapest cost of adaptation is selected for. Due to the lack of empirical observations, it has not been clear whether herbivores incur adaptive costs in adapting to plants with chemical defenses (Gould 1988; Futuyma and Keese 1992; Agrawal 2000). The present study provides empirical observations of the cost of adaptation.

Our results show a rare example of physiological adaptation to a quantitative defense (Lambers et al. 1998) (that is, a defense with compounds, such as phenolics and tannins, that reduce digestibility and exist in large quantities). In the evolution of a quantitative defense, it seems reasonable to suppose the existence of “quantitative” types of coevolutionary arms races. These may include corresponding escalations of the amounts of defense and adaptive substances and/or mechanisms in plants and herbivores, respectively, that may finally reach an equilibrium condition after the extinction and/or exclusion of less well adapted species, and decrease in the population of herbivores on the plant species. In the evolution of the privet-privet specialist relationship, it is possible that such “quantitative” types of coevolutionary arms races coexisted with the classical “qualitative” types of coevolutionary arms races, which include upgrading of and innovations in the defense chemicals and adaptive mechanisms, as has been reported in the coevolution of coumarin-containing plants such as Umbelliferae and herbivores feeding on them (Berenbaum 1978, 1991). Indeed, most qualitative defenses have a quantitative (dose-dependent) aspect. Oleuropein, which has a much stronger lysine-decreasing activity than other iridoids (Konno et al. 1999) would be a “second-generation” or “upgraded” iridoid that may have evolved from less active iridoids through a “qualitative” type of coevolutionary arms race. In contrast, the surprisingly high concentration of oleuropein in privet leaves (ca. 3% of leaf wet weight, 55 mM) (Konno et al. 1998) and of glycine (164.8 mM, 1.24%) and GABA (60.8 mM, 0.63%) in the digestive juice of specialist insects may have resulted from a “quantitative” type of coevolutionary arms race to destroy (strategy of plant) and/or save (strategy of herbivores) ca. 5 mM (Konno et al. 2009) of lysine in the gut lumen, since lysine is crucial for herbivores.

Acknowledgements We thank Prof. Keiichi Honda in Hiroshima University for invaluable suggestions, and Mrs. Mayumi Hazeyama for rearing insects. hypothesis (Gauld et al., 1992, 1994), which posits that tropical parasitoids are not more diverse because sequestering hosts are more toxic and thus less available to parasitoids. Indirect support for this component of the nasty host hypothesis comes from studies that show a negative relationship between levels of sequestered host defensive compounds and parasitoid success (Campbell and Duffey, 1979; McDougall et al., 1988; Sime, 2002; Nieminen et al., 2003; Singer and Stireman, 2003; Lampert et al., 2008).

We used larvae of the catalpa sphinx, *Ceratomia catalpae* Boisduval (Lepidoptera: Sphingidae), and its parasitoid, *Cotesia congregata* Say (Hymenoptera: Braconidae), to test some assumptions of the nasty host hypothesis. The catalpa sphinx specializes on species of *Catalpa* (Bignoniaceae) (Baerg, 1935; Bowers, 2003), which contain the iridoid glycosides catalpol and catalposide (Nayar and Fraenkel, 1963; von Poser et al., 2000), terpenoids that are unpalatable to a range of generalist herbivores (Bowers, 1991). However, these compounds are used as feeding stimulants by catalpa sphinx larvae (Nayar and Fraenkel, 1963), which also sequester them for their own chemical defense (Bowers and Puttick, 1986; Bowers, 2003). Catalpa sphinx larvae hydrolyze catalposide to catalpol before sequestration, and caterpillar catalpol concentrations (5–20% total dry weight) can be several times higher than catalpa leaf iridoid concentrations (2–5% dry weight) (Bowers and Puttick, 1986; Bowers, 2003). Most of the iridoid glycosides are stored in the hemolymph, which contains approximately 50% dry weight catalpol (Bowers, 2003). Further, larvae regurgitate onto potential predators to repel them, and this regurgitant contains iridoid glycosides (Bowers, 2003).

The gregarious koinobiont parasitoid, *Cotesia congregata*, is the major parasitoid of catalpa sphinx larvae in the Eastern U.S. (Baerg, 1935; Ness, 2003a, b). *Cotesia congregata* generally are restricted to larvae of Sphingidae as hosts; however, Krombein et al. (1979) list only 15 sphingid species as hosts and also list *Trichoplusia ni* (Noctuidae) as a host. In laboratory experiments, *Hyles lineata* (Sphingidae) also was shown to be a permissive host, *Pachysphinx occidentalis* was a refractory host, showing complete encapsulation, and *Sphinx vashti* was considered semi-permissive, showing some encapsulation (Harwood et al., 1998). In another experiment, *T. ni* was a semi-permissive host (Beckage and Tan, 2002). *Cotesia congregata* attacks its hosts during the 2nd through the 4th instars by rapidly injecting eggs. Larvae develop in the hemocoel, bathed in and eating hemolymph, over approximately 2 weeks, then exit through the host cuticle, and pupate inside silken cocoons attached to the host. *Cotesia congregata* successfully parasitize catalpa sphinx larvae despite catalpol sequestration by this host.

The effects of sequestered iridoid glycosides on predators are well documented. Checkerspot butterflies that sequester these compounds induce vomiting in birds that eat them (Bowers, 1980, 1981), and invertebrate predators will reject or perform poorly when offered caterpillars sequestering iridoid glycosides (de la Fuente et al., 1994/1995; Dyer and Bowers, 1996; Camara, 1997; Strohmeyer et al., 1998; Theodoratus and Bowers, 1999; Rayor and Munson, 2002). There is mixed evidence that sequestered iridoids harm parasitoids. The specialist braconid, *Cotesia melitaearum,* grew faster when developing in caterpillar hosts (*Melitaea cinxia*, Nymphalidae) with higher levels of iridoid glycosides, and development of the generalist ichneumonid, *Hyposoter horticula,* was not affected by levels of iridoid glycosides in the host (Harvey et al., 2005). In contrast, a field survey found that *M. cinxia* feeding on *Plantago lanceolata* (Plantaginaceae) plants that were low in iridoids were more likely to be parasitized than larvae feeding on high iridoid glycoside containing plants (Nieminen et al., 2003).

In this study, we tested one assumption of the nasty host hypothesis by examining the effects of catalpol sequestration by catalpa sphinx larvae on the performance of its parasitoid *Cotesia congregata*. We examined the leaf chemistry of several populations of catalpa trees across the Eastern United States, and tested for correlations with sequestered iridoids in catalpa sphinx larvae from those populations. We then determined whether different levels of average sequestration at a site were related to differences in parasitism success and performance of *C. congregata*. In this system, one assumption based on the nasty host hypothesis is that increased catalpol sequestration is associated with decreased parasitoid success.

Methods and Materials

Collections Sixty-seven separate sites with *Catalpa bignonioides* were located and surveyed throughout the Eastern U.S., ranging from Southern New Jersey to Western North Carolina, from 14–19 August, 2007. Most stands were individuals or small groups of trees in residential or public lots. Six of the stands were attacked by catalpa sphinx larvae, and catalpa sphinx larvae parasitized by *Cotesia congregata* (as determined by the presence of emerged cocoons) were found at all locations except for Cape May Co., New Jersey (Table 1).

Each population was sampled according to the following protocol. All catalpa sphinx larvae within reach (~2.8 m) were removed from trees along with the leaves upon which they fed. Larvae were a combination of 3rd, 4th, and 5th instars (~20%, 64%, and 16%, respectively) during these collections. Leaves and larvae were placed in 1 l plastic Ziploc® boxes and stored in a cooler until they could be processed in the laboratory at the University of Colorado, Boulder. Additional catalpa sphinx larvae were shipped in late August from a

collection made at the Clemson University Experimental Forest (Pickens Co., South Carolina).

Plant and Insect Chemistry Upon arrival in Colorado, a subset of five to ten unparasitized larvae from each population were starved for 8 h, weighed, and frozen at −80°C for chemical analysis with gas chromatography [extraction protocol and instrument setup followed those described previously by Bowers (2003)]. The remaining larvae were removed from leaves, placed in a growth chamber set to 25°C with a 16:8 h, L:D photoperiod, and maintained on washed *C. bignonioides* leaves collected from the University of Colorado campus until either pupation or parasitoid emergence. The damaged leaves on which caterpillars had been collected were washed with distilled water to remove caterpillar frass, pooled by population, oven-dried at 50°C, then ground into a fine powder for chemical analysis. Leaves from the Pickens Co., South Carolina, population arrived almost entirely eaten and were not included in the chemical analysis. We extracted iridoids from a 50 mg subsample of the leaf powder from each population and quantified catalpol and catalposide. Iridoid extraction methods and instrument setup were the same for leaves and caterpillars.

Leaf iridoid glycoside amounts (mg) were divided by the weight of the extracted sample to obtain a percentage dry weight of catalpol and catalposide for each population. Because leaf samples were pooled, we could not statistically compare the iridoid glycoside concentrations of leaves among populations. To estimate caterpillar iridoid glycoside concentrations on a dry weight basis, we used a conversion factor (D.W./F.W.= 0.1193, r^2>0.98) obtained from a separate set of 30 starved 4th and 5th-instar *Manduca sexta* larvae that were killed, weighed, dried, and weighed again. We applied this conversion factor to the wet weight of the catalpa sphinx larvae to calculate larval dry weight to allow direct comparisons with leaf iridoid concentrations, We did not have sufficient numbers of catalpa sphinx larvae to obtain fresh-dry weight conversions from this species. Larval catalpol concentration was compared among six populations using analysis of variance (ANOVA) (SPSS version 9.0). Populations were treated as a random factor. We then used linear regression to determine whether sequestered iridoids were dependent on leaf chemistry.

Parasitism by Cotesia congregata *and Caterpillar Sequestration-Parasitoid Relationships*. When *C. congregata* cocoons appeared on the remaining larvae, larvae were isolated in individual plastic cups to allow parasitoid adults to develop. Any adult *C. congregata* were anesthetized and removed, while any hyperparasitoids of *C. congregata* were killed and preserved for voucher specimens. After all *C. congregata* and their hyperparasitoids had emerged, catalpa sphinx larvae were killed by freezing and then dissected to examine them for the presence of parasitoid larvae. Any cocoons that did not yield adults were dissected to identify the occupant (*C. congregata* or hyperparasitoid). We added the total number of dead *C. congregata* larvae inside catalpa sphinx hosts to the number of cocoons to calculate total parasitoid clutch size, and divided the number of *Cotesia* cocoons by total clutch size to determine the proportion that survived until pupation. Average total clutch size and arcsine-square root transformed mortality were compared among populations, treating population as a random factor, using 1-way ANOVA. Parasitism level was calculated as the number of parasitized catalpa sphinx divided by the total number of larvae collected at each site and compared among populations using a χ^2 test.

Results

Insect Collections and Parasitoid Success We collected over 500 individual catalpa sphinx larvae from seven populations. Trees typically were heavily attacked by dozens to hundreds of larvae, often to the point of defoliation. Approximately one-third of the larvae collected were parasitized by *C. congregata*, which were absent only at the Cape May Co., New Jersey site.

Levels of parasitism by *C. congregata* varied five-fold among populations, ranging from 15% to 80% (χ^2= 182.51, P<0.001) (Fig. 1). The average total parasitoid clutch size (adults + larvae dead inside catalpa sphinx host) among all sites was 24.52±1.69 individuals per

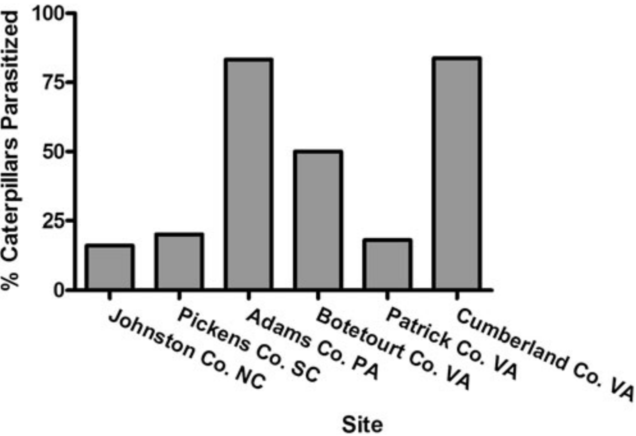

Fig. 1 *Cotesia congregata* parasitism levels for six populations of catalpa sphinx larvae (*Ceratomia catalpae*)

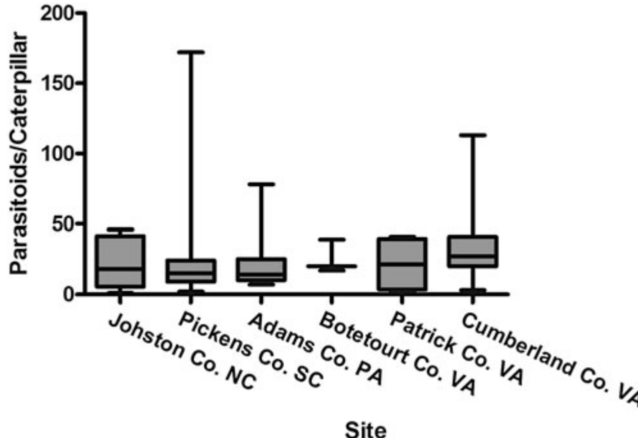

Fig. 2 Comparison of *Cotesia congregata* total clutch size among populations. *Lines* within boxes represent medians, *box* margins represent 25th and 75th percentiles, and *whiskers* represent the extreme low and high values

brood with a median of 21, which did not differ significantly among the surveyed populations ($F_{5,164}$= 1.79, P=0.12) (Fig. 2). Clutch size varied widely from 1 to 172. Only 11 broods contained over 100 individuals. Within-brood survivorship was over 90% for all populations, and it varied significantly among populations ($F_{5,164}$=3.33, P=0.007). This result was driven by the results from the Cumberland Co., Virginia, population (the only population to have catalpa sphinx larvae that contained over ten dead parasitoid larvae); if this population is excluded from analysis, parasitoid survivorship to pupation did not significantly vary among the other populations ($F_{4,82}$=1.35, P=0.26).

Hyperparasitoids were found only in *C. congregata* from parasitized catalpa sphinx larvae collected from the Adams Co., Pennsylvania, and Cumberland Co., Virginia sites. At least one hyperparasitoid individual emerged from 16% of *Cotesia* broods from the Adams Co. population and 6% of those from the Cumberland Co. population. Hyperparasitoid species included those that attacked larval stages [e.g., *Mesochorus* sp. (Ichneumonidae) (Baur and Yeargan, 1994)] and pupal stages (e.g., *Hypopteromalus* (Pteromalidae) (Gaines and Kok, 1999) of *Cotesia*.

Plant and Caterpillar Chemistry Iridoid glycoside concentrations in catalpa leaves varied over 3-fold, ranging from 3–10% dry weight depending on the population (Fig. 3). Leaves contained much higher concentrations of catalposide than its precursor catalpol (Fig. 3). Caterpillar iridoid glycoside concentrations also varied among populations ($F_{5,29}$=5.63, P=0.001), ranging from 6.5% to 22.5% dry weight catalpol (mean: 13.04%±0.87). Larvae from populations with higher concentrations of leaf iridoids tended to sequester higher concentrations of catalpol, although this was only marginally significant (r^2=0.20, P=0.09; caterpillar catalpol = 0.55*leaf iridoids + 8.63) (Fig. 4a).

Caterpillar Chemistry and Parasitoid Fitness Responses - There was a weak positive but not significant relationship between sequestration and total clutch size of *C. congregata* in each population (r^2=0.04, P=0.09) (Fig. 4b). Within-brood survivorship was over 90% for all broods and decreased as caterpillar sequestration increased (r^2= 0.29, P=0.03), when all broods were considered (Fig. 4c). Again, this relationship was driven by results from the Cumberland Co., Virginia population. If this population is excluded, there is no negative relationship between brood survivorship and sequestration (r^2=0.85, P= 0.07).

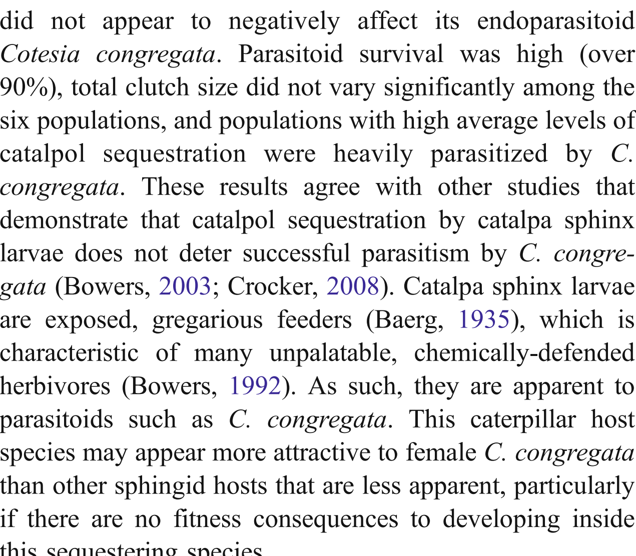
Discussion

The nasty host hypothesis assumes a deleterious effect of host sequestered plant toxins on insect parasitoids (Gauld et al., 1992, 1994). Catalpa sphinx catalpol sequestration



did not appear to negatively affect its endoparasitoid *Cotesia congregata*. Parasitoid survival was high (over 90%), total clutch size did not vary significantly among the six populations, and populations with high average levels of catalpol sequestration were heavily parasitized by *C. congregata*. These results agree with other studies that demonstrate that catalpol sequestration by catalpa sphinx larvae does not deter successful parasitism by *C. congregata* (Bowers, 2003; Crocker, 2008). Catalpa sphinx larvae are exposed, gregarious feeders (Baerg, 1935), which is characteristic of many unpalatable, chemically-defended herbivores (Bowers, 1992). As such, they are apparent to parasitoids such as *C. congregata*. This caterpillar host species may appear more attractive to female *C. congregata* than other sphingid hosts that are less apparent, particularly if there are no fitness consequences to developing inside this sequestering species.

Our data do not support the component of the nasty host hypothesis that posits that chemically defended hosts are unsuitable to parasitoids (Gauld et al., 1992, 1994). Instead, parasitism levels and clutch size tended to increase in populations of caterpillars that were more chemically defended. There was an overall decrease in larval *C. congregata* survival as average caterpillar chemistry increased; however, the significance of this effect was heavily influenced by seven out of 83 parasitoid broods collected from a single population. Parasitoid survival was not negatively affected by chemistry if these broods, which were the only broods out of almost 200 with 10 or more dead larvae, were not considered.

A potential explanation for our results is that sequestering herbivores are “safe havens” for developing endoparasitoids (Dyer and Gentry, 1999; Gentry and Dyer, 2002; Smilanich et al., 2009). According to this hypothesis, parasitoids that develop inside chemically defended hosts receive fitness benefits in that they are protected from their own natural enemies, including hyperparasitoids and predators of the host. This hypothesis is supported by studies in which parasitoids perform better when reared from more toxic individuals of a single host species (Zvereva and Rank, 2003; Harvey et al., 2005). Large scale surveys of parasitoid incidence have shown that chemically defended insects typically have high levels of parasitism in the field (Cornell and Hawkins, 1995; Gentry and Dyer, 2002).

Sequestering catalpa sphinx larvae provide a safe haven for developing *C. congregata* parasitoids if these sequestering caterpillar hosts are protected from natural enemies such as caterpillar predators and hyperparasitoids of *C. congregata*. The importance of catalpol sequestration as a predator deterrent for both catalpa sphinx and emerged *C. congregata* pupae remains unknown. Catalpol is a deterrent to ants (Dyer, 1995; Dyer and Bowers, 1996), as well as to

a variety of other predators (de la Fuente et al., 1994/1995; Theodoratus and Bowers, 1999; Rayor and Munson, 2002). Ants are major antagonists of catalpa sphinx larvae in the Eastern US and can repel larvae from entire trees (Ness, 2003a, b). Ants may act as an important selective agent for catalpol sequestration, and high catalpol levels may allow catalpa sphinx larvae to avoid ant harassment.

The presence of hyperparasitoids would suggest catalpa sphinx larvae may not be completely safe havens for primary parasitoids. Hyperparasitoids successfully developed from *C. congregata* cocoons in two different populations. Catalpol is sequestered by *C. congregata* (Bowers, 2003). It is currently unknown whether hyperparasitoid development is adversely affected by catalpol sequestered by *C. congregata*, and how such fourth trophic level effects might very among different hyperparasitoid taxa. In another study, *Mesochorus* sp. (Ichneumonidae) (*Mesochorus* was the most common hyperparasitoid genus reared in this study) adults contained small amounts of catalpol when reared from parasitoids of sequestering checkerspot caterpillars, thus indicating that hyperparasitoids do consume catalpol (Reudler Talsma, 2007). If hyperparasitoids are unaffected by the relatively low levels of iridoid glycosides sequestered by *C. congregata,* then the warningly colored catalpa sphinx larvae could provide a strong visual cue for hyperparasitoid host location.

Although our results did not reveal any strong negative relationships between caterpillar chemical defense and parasitoid success, future study is needed to determine whether catalpol might be intrinsically toxic to developing *C. congregata* larvae or any other parasitoid species. Catalpol acts as a feeding deterrent to non-adapted insects (Bowers and Puttick, 1988), and *C. congregata* larvae may lack catalpol-sensitive gustatory receptors. However, there are also post-consumption toxic effects of catalpol on several herbivore species (Bowers and Puttick, 1988, 1989). Catalpol exposure and consumption may have more subtle effects on *C. congregata,* such as prolonged development time; measuring this was not possible with host larvae parasitized in the field.

Further study is necessary to determine the ecological importance of the safe haven hypothesis. In particular, field studies that closely examine the palatability of chemically defended host species to generalist predators are needed to evaluate whether their parasitoids are less prone to attack by predators. In addition, the potential of hyperparasitism deterrence by developing inside chemically defended hosts deserves consideration. Controlled lab experiments that manipulate dietary catalpol and catalpol sequestration of parasitized catalpa sphinx larvae would provide further evidence that *C. congregata* are not negatively affected by catalpol sequestration. Finally, the role of chemical defense in determining parasitoid host choice deserves future study. The safe haven hypothesis predicts that parasitoids may prefer unpalatable hosts, and this preference for chemically defended hosts would provide strong support for the adaptive use of hosts unpalatable to natural enemies.

Acknowledgements We thank Karen Kester and Vanessa Crocker, Department of Biology, Virginia Commonwealth University; Richard Olsen, USDA-ARS, Washington DC, and the U.S. National Arboretum; and Clyde Sorenson, Department of Entomology, NC State University for advice on catalpa sphinx locations and Laura McLoud for shipping caterpillars from Clemson, SC. Ellen Brown of the Reynolds Homestead Historical Site, Ernest and Fred Tyson, and David Pace permitted collections on private property. Richard Olsen, Carolina Quintero, Susan Whitehead, and two anonymous reviewers provided useful comments on the manuscript. This study was funded by NSF grant DEB 0614883 to MDB and LAD.

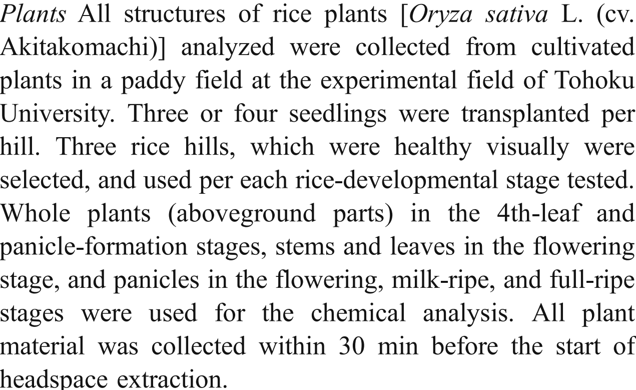
generation hatches and disperses to dominant gramineous weeds such as *P. annua* in the spring (Higuchi et al., 2001; Kikuchi and Kobayashi, 2003). Initially, they reproduce mainly on gramineous weeds such as *P. annua* and *L. multiflorum*. The invasion of adults into rice paddy fields gradually increases with the heading of the rice and rapidly increases with flowering (Okuyama, 1974; Hachiya, 1999; Ishimoto, 2004). Afterwards, the invasion ceases abruptly. In autumn, the bugs disperse to gramineous weeds such as *D. ciliaris*, where they lay diapausing eggs (Higuchi et al., 2001). However, the connection between the invasion of the bugs into the paddy fields and the flowering of the rice has been unclear for many years.

Many phytophagous insects, including mirid bugs, use host plant odors as olfactory cues to find hosts (Visser, 1986; Groot et al., 2003; Blackmer et al., 2004; Hori, 1999; Hori et al., 2006). In previous studies, we investigated the behavioral responses of rice leaf bugs to rice plant odors with a linear track olfactometer. The attractiveness of plants to bugs differed with the rice growth stage and with the part of the plant. Although *T. caelestialium* adults were attracted to the odors of whole rice plants in the panicle-formation stage and to panicles in the flowering stage, they were not attracted to other structures tested (Niiyama et al., 2007). In addition, the host odor preferences of the bugs changed between rice plants and gramineous weeds according to the developmental stage of the rice (Fujii et al., 2010). Bugs tended to prefer flowering rice panicles to gramineous weeds, whereas they preferred gramineous weeds to rice plants before the rice flowering stage. After the flowering stage, they showed no preference between rice plants and weeds. Therefore, we hypothesized that the volatile compounds released by rice change during development, and that flowering rice panicles emit compounds attractive to the bugs. In this study, we analyzed rice plant volatiles from various developmental stages, and we investigated the attractiveness of a characteristic compound emitted from flowering panicles.

Methods and Materials

Insects Rice leaf bugs were collected from a field of Italian ryegrass (*Lolium multiflorum*) and a grassland in experimental fields of the Agricultural Experiment Stations of Akita Prefecture and Tohoku University, Japan. The bugs were maintained on seedlings of wheat (*Triticum aestivum* L.) in an acrylic cage at 25±1°C, and were kept under a reversed photoperiod (8D:16L). The olfactory response of the rice leaf bug is not strongly influenced by mating experience or adult age (Niiyama et al., 2007). Therefore, 2- to 10-d-old adult mated males and females were used for all trials.



Plants All structures of rice plants [*Oryza sativa* L. (cv. Akitakomachi)] analyzed were collected from cultivated plants in a paddy field at the experimental field of Tohoku University. Three or four seedlings were transplanted per hill. Three rice hills, which were healthy visually were selected, and used per each rice-developmental stage tested. Whole plants (aboveground parts) in the 4th-leaf and panicle-formation stages, stems and leaves in the flowering stage, and panicles in the flowering, milk-ripe, and full-ripe stages were used for the chemical analysis. All plant material was collected within 30 min before the start of headspace extraction.

Standard Chemicals β-Caryophyllene (purity: >90.0%), (−)-limonene, α-humulene, and farnesene were purchased from Tokyo Kasei Kogyo Co. Ltd. (Tokyo, Japan). 2-Heptanone, 3-octanone, 6-methyl-5-heptene-2-one, (*Z*)-3-hexenyl acetate, methyl benzoate, linalool, methyl salicylate, *n*-dodecene, *n*-dodecane, *n*-decanal, *n*-tridecene, *n*-undecanal, *n*-undecanol, and geranyl acetone were purchased from Wako Pure Chemical Ind. Ltd. (Osaka, Japan). (*Z*)-3-Hexenol, α-copaene, and (*Z*)-thujopsene were purchased from Sigma-Aldrich Co. (St. Louis, Mo., USA). (*Z*)-3-Hexenal was supplied by Zeon Co. (Tokyo, Japan). β-Elemene was supplied by Nippon Terpene Chemicals Inc. (Kobe, Hyogo, Japan).

Extraction of Headspace Components Headspace components of rice plants were extracted with solid-phase microextraction (SPME) and analyzed by gas chromatography-mass spectrometry (GC-MS). Headspace components were analyzed three times. Each replication was done with a new set of plant materials from different rice hills. Fresh plant material (5 g) from a rice hill was gently curled and/or folded, and placed into a sample vial (40 ml) with a Mininert® valve (As One Corp., Osaka, Japan). Headspace of the plant materials in the vials was extracted via SPME (100 μm polydimethylsiloxane; Supelco, Bellefonte, PA, USA) at 22±1°C for 30 min.

Chemical Analysis by GC-MS Headspace components extracted with SPME were subjected immediately to GC-MS. They were identified by comparing gas chromatograph (GC) retention times and mass spectra with those of the authentic standards. Compounds that were not commercially available were identified with a National Institute of Standards and Technology (NIST) mass spectral database and a mass spectral data book by Adams (2001). GC-MS was conducted with a Shimadzu GCMS-QP2010 equipped with a DB-5MS column (30 m×0.25 mm inner diam, 0.25 μm film thickness, J&W). Mass data were analyzed by a Shimadzu GCMS Solution with a NIST mass spectral database. Helium was used as carrier gas at a column head pressure of 100 kPa. The GC was set for

splitless injection (splitter opened after 1 min). The temperature program of the column oven was as follows: isotherm for 5 min at 35°C, 4°C/min gradient to 200°C, 30°C/min gradient to 300°C, and isotherm for 10 min at 300°C. The injector and detector temperatures were 220°C and 250°C, respectively.

Bioassay The attractiveness of β-caryophyllene was evaluated with a linear track olfactometer modified from an original design (Sakuma and Fukami, 1985; Hori, 1998). It was made of transparent acrylic tubing and steel rods. The rods formed a T-junction at the point where the airstreams carrying the treatment and control airflows met from two side arms in the olfactometer. At the T-junction, the bugs chose the direction in which to proceed. A rubber septum (Precision Seal®, white, for 7-mm outer diam glass tubing, Sigma-Aldrich Co., St. Louis, Mo., USA) impregnated with 100 μl of a hexane solution of β-caryophyllene [concentrations (*v/v*%): 0.0001, 0.001, 0.01, 0.1, or 10%] was placed on the treatment side, whereas a septum impregnated with only hexane was placed on the control side. An airflow filtered through activated charcoal was sucked out by pump at a rate of 1.0 l/min regulated by an airflow meter. Ten bugs were placed in a pot installed at the base of the central vertical tube of the olfactometer. It was difficult to observe the orientation behavior of bugs under the light conditions because bugs were strongly influenced by light. We had previously confirmed that bugs fed similarly in the dark and under lights. Therefore, all bioassays were conducted in a dark room kept at 25±1°C to remove the influence of light. The numbers of bugs in the traps of the treatment and control sides were counted 2 hr after the start of the assay. In preliminary tests, approximately equal numbers of bugs entered each side trap when both side chambers were empty. Each comparison was replicated 12 times, and the treatment and control sides were alternated after half of the replications had been completed. The bugs were used once only.

Quantification of β-Caryophyllene Emitted from Rice Plants Quantities of β-caryophyllene emitted from rice plants were calculated by GC-MS as described above. The peak area of the total ion chromatogram of β-caryophyllene was measured, and the concentration was calculated using a calibration curve. The calibration curve was obtained from the peak area of an authentic standard of β-caryophyllene emitted from a rubber septum treated with it. The rubber septum treated with 100 μl of a hexane solution of β-caryophyllene was placed into a sample vial (40 ml) with a Mininert® valve, and its headspace was extracted by SPME (100 μm polydimethylsiloxane) at 22±1°C for 30 min. From the calculation result, it was shown that the concentration of β-caryophyllene in the headspace of flowering rice panicles (5 g) was equivalent to that of a rubber septum treated with 100 μl of 0.0012% β-caryophyllene.

Statistical Analysis The numbers of bugs in the traps of the treatment and control groups were analyzed by a Wilcoxon matched-pairs signed-ranks test. The attractiveness of β-caryophyllene to the bug was estimated by an excess proportion index (*EPI*) according to the formula:

$$EPI = (nt - nc)/(nt + nc),$$

where *nt* and *nc* represent the total number of bugs in the treatment and control traps, respectively (Sakuma and Fukami, 1985). Differences in relative contents of each volatile compound among different rice developmental stages and plant parts were analyzed by a Games-Howell test.

Results

Volatile Components of Rice Plants The volatile composition of rice plants changed according to developmental stage (Table 1). In addition, the volatile compositions of plants in the flowering stage differed between the panicles and the stems and leaves. The relative content of geranyl acetone was high in all rice plant structures analyzed. However, the relative geranyl acetone contents of whole plants in the panicle-formation stage and flowering panicles were relatively lower than those of the others, showing significant differences from that of milk-ripe panicles. Relative content of green leaf volatiles (GLVs) was relatively high in whole plants in the fourth-leaf stage (relative level of (*Z*)-3-hexenol was high, although a significant difference was not obtained) and in panicles in the full-ripe stage (relative levels of (*Z*)-3-hexenal and (*Z*)-3-hexenol were high, although, again, significant differences were not obtained), whereas relative GLV levels in the other rice plant structures were low. In contrast, relative terpene amounts emitted from whole plants in the panicle-formation stage, and from panicles and stems and leaves in the flowering stage were higher than those of the other rice plant structures. However, terpene composition of stems and leaves in the flowering stage was different from those of whole plants in the panicle-formation stage and panicles in the flowering stage: the relative level of linalool was higher, although a significant difference was not obtained. In addition, the relative level of β-caryophyllene was lower. The composition of terpenes was similar between whole plants in the panicle-formation stage and panicles in the flowering stage (in both cases, the relative levels of β-caryophyllene and β-elemene were high). The relative β-caryophyllene content in flowering panicles was significantly higher than those of other rice structures except for whole plants

[e] ND = not detected

in the panicle-formation stage. The relative β-elemene content of whole plants in the panicle-formation stage was significantly higher than those of other rice structures except for both plant parts in the flowering stage. In milk-ripe panicles, relative terpene content was decreased, and in full-ripe panicles, terpenes were not detected at all. Statistical analysis showed that relative contents of 2-heptanone, 3-octanone, n-dodecane, n-decanal, and (*Z*)-thujopsene in flowering panicles also were high among rice structures tested. In flowering panicles, the relative tridecene content also was higher than in other rice structures, although, again, a significant difference was not

obtained. In whole plants in the panicle-formation stage, the relative α-farnesene content was significantly higher than those of the other rice structures.

Amounts of β-Caryophyllene Emitted from Rice Plants Amounts of β-caryophyllene from whole plants in the fourth-leaf stage, whole plants in the panicle-formation stage, flowering panicles, and stems and leaves in the flowering stage were equivalent to those from a rubber septum treated with 100 μl of hexane solutions of β-caryophyllene at concentrations of 0.0012, 0.0031, 0.0012, and 0.0015%, respectively. β-Caryophyllene was not detected from the headspaces of the panicles in the milk-ripe and full-ripe stages.

Behavioral Response of the Rice Leaf Bug to Authentic β-Caryophyllene Standard The behavioral response of the rice leaf bug to β-caryophyllene is shown in Fig. 1. Adult females were significantly attracted to β-caryophyllene at a concentration of 0.001% (T=7, Z=2.089, P=0.037). However, females were significantly repelled by β-caryophyllene at a high concentration, such as 10% (T=5, Z=2.0732, P=0.038). In contrast, adult males were neither attracted nor repelled by β-caryophyllene at any concentration tested.

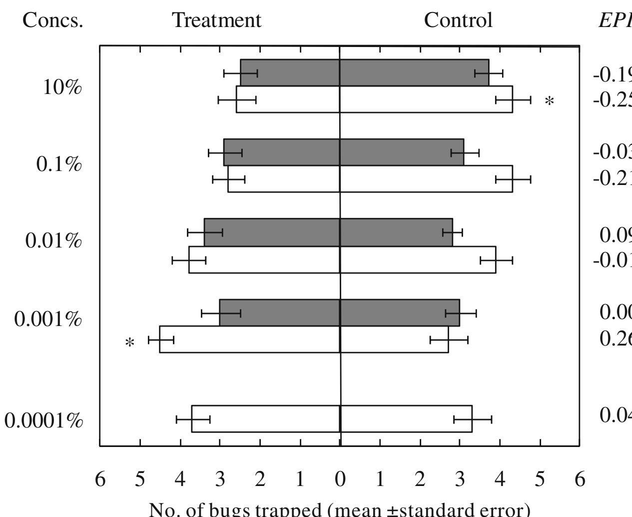

Fig. 1 Behavioral response of the adult rice leaf bug to β-caryophyllene. Gray bars: males; white bars: females. $EPI = (nt - nc)/(nt + nc)$, where nt and nc are the total number of bugs in the treatment and control traps, respectively. Significant difference: * P<0.05 in Wilcoxon matched-pairs signed-rank test (N=12)

Discussion

The invasion of rice leaf bugs into rice paddy fields gradually increases with the heading of rice, and rapidly increases with flowering (Hachiya, 1999; Ishimoto, 2004). In previous studies, we demonstrated that the attractiveness of rice plant odor to bugs differed with the rice developmental stage and the part of the plant (Niiyama et al., 2007). Bugs were attracted to whole plants in the panicle-formation stage and to panicles in the flowering stage. In addition, the preference of the bugs for either rice plant odors or gramineous weed odors changed according to the stage of development (Fujii et al., 2010). Bugs tended to prefer rice plants in the flowering stage to gramineous weeds but preferred gramineous weeds to rice plants in the vegetative stage. Bugs showed no preference between rice plants and gramineous weeds after the milk-ripe stage of the rice. In the present study, rice plant odors contained ubiquitously occurring plant volatiles; the quantitative composition of the volatile blends released differed among the developmental stages or plant parts; Therefore, it is thought that the amounts of active compounds and the ratio of volatile compounds are what is important for the plant's attractiveness to the bugs.

In whole plants in the panicle-formation stage and panicles in the flowering stage, the relative levels of sesquiterpenes—especially, β-caryophyllene—were higher than those in the other rice plant structures. β-Caryophyllene was not detected in the headspace of panicles in the milk-ripe nor full-ripe stages. In the olfactometer test, *T. caelestialium* females were attracted to β-caryophyllene at a concentration of 0.001%. These results suggest that β-caryophyllene is one of the attractants in the rice plant odor that acts as a key compound in the bugs' invasion into paddy fields. However, β-caryophyllene also was detectable in the odor of whole plants in the fourth-leaf stage and in stems and leaves in the flowering stage, which did not exhibit attractiveness to the bugs. Furthermore, the amounts of β-caryophyllene emitted from these rice plant structures were similar (i.e., amounts from whole plants in the fourth-leaf stage, whole plants in the panicle-formation stage, flowering panicles, and stems and leaves in the flowering stage were equivalent to those from a rubber septum treated with β-caryophyllene at concentrations of 0.0012, 0.0031, 0.0012, and 0.0015%, respectively). Thus, it appears that it is the relative content of β-caryophyllene and also the composition of the other compounds that are important for the attractiveness. Volatiles from whole plants in the fourth-leaf stage or from stems and leaves in the flowering stage, may contain compounds that mask the attractiveness of β-caryophyllene and/or compounds that repel the bugs. Rice leaf bugs were attracted only to 0.001% β-caryophyllene and not to the other concentrations tested. This result suggests that amount of β-caryophyllene—as well as the relative content of β-caryophyllene and composition of the other compounds—is important for attractiveness.

The attractiveness of β-caryophyllene to female bugs at a concentration of 0.001% was lower than that of flowering

rice panicle odor (*EPI* by β-caryophyllene: 0.26 [present study]; *EPI* by flowering panicles: 0.48 [previous study by Niiyama et al., 2007]). In some insect species, it has been reported that several host plant volatiles act synergistically as attractants (Nojima et al., 2003; Tasin et al., 2007). Other volatiles of flowering panicles likely act synergistically with β-caryophyllene.

Adult male bugs were not attracted to any tested concentration of β-caryophyllene. In our previous study, although males tended to be attracted to panicles in the flowering stage, this attraction was not significant (Niiyama et al., 2007). The difference in olfactory response to β-caryophyllene between females and males may be one of the causes of the difference in response to flowering rice panicles. However, males are attracted to the odor of whole plants in the panicle-formation stage, as are females (Niiyama et al., 2007). It is thought that rice odor must contain compounds other than β-caryophyllene that are related to male attraction.

Although β-caryophyllene is distributed widely among plant species (e.g., Weissbecker et al., 2000; Asaro et al., 2004; Bertoli et al., 2004; Deng et al., 2004), it has been demonstrated that this compound is used by several insect species as an olfactory cue for host finding. For example, the damson-hop aphid *Phorodon humuli* (Schrank) (Campbell et al., 1993), the western corn rootworm beetle *Diabrotica virgifera virgifera* LeConte (Hammack, 2001), the grapevine moth *Lobesia botrana* Den et Schiff. (Tasin et al., 2006), the boll weevil *Anthonornus grandis* Boheman (Minyard et al., 1969), and the Colorado potato beetle *Leptinotarsa decemlineata* (Say) (Khalilova et al., 1998) use this sesquiterpene for host plant location.

Similar to the rice leaf bug, many species of stink bugs cause pecky rice (e.g., Harper et al., 1993; Jahn et al., 2004; Takeuchi et al., 2004) and invade paddy fields after the heading of rice (Nakasuji, 1973; Rashid et al., 2006). Flowering rice panicle odor also may be attractive to other species of rice-ear bugs and may cause their invasions into paddy fields. Hori (2009) has demonstrated that the sorghum plant bug *Stenotus rubrovittatus* (Matsumura) also is attracted to flowering rice panicle odor. The rice bug *Leptocorisa chinensis* Dallas too is attracted to rice plants with flowering panicles (Kainoh et al., 1980). We suspect that β-caryophyllene may play the role of an olfactory cue in finding the suitable developmental stage of rice plants for other species of rice-ear bug as well.

In this study, we analyzed volatile components of cut plant parts that had shown attraction of bugs in our previous studies (Niiyama et al., 2007; Fujii et al., 2010). We extracted volatile constituents efficiently from plants of various developmental stages by SPME. In addition, we compared volatiles between panicles and stems and leaves by using cut plant parts. However, cut plant odors may differ from intact plant odors (e.g., Lou et al., 2005). Therefore, it will be necessary to investigate the volatiles released from intact plants.

Our findings suggest that β-caryophyllene is just one of the attractants in flowering rice panicle odor, which causes the invasion of rice leaf bugs into paddy fields. Because, the attractiveness of β-caryophyllene was lower than that of flowering rice panicle odor, and because there were several other compounds whose relative levels in whole plants in the panicle formation stage and/or panicles in the flowering stage also were higher than those in the other rice plant structures, it is necessary to investigate how these other compounds relate to the attractiveness of flowering rice panicle odor. Attractants released from flowering rice panicles may make it possible to establish new control methods for the bug, including traps.

elicit specific VOCs that attract belowground natural enemies to the roots (Rasmann et al., 2005). Both aboveground and belowground emitted VOCs can act as indirect defenses, attracting natural enemies that eventually kill the herbivore. Aboveground and belowground induced responses, however, are not mutually independent. For example, signaling hormones induced in one compartment may be transported throughout the plant and trigger systemic responses in the undamaged plant parts as well (Bezemer and van Dam, 2005). Recent studies show that root herbivory alters VOC profiles induced by aboveground herbivores feeding on the same plant, which affects the preference of aboveground parasitic wasps searching for aboveground feeding hosts (Rasmann and Turlings, 2007; Soler et al., 2007). These examples illustrate the importance of belowground induced responses for aboveground multitrophic interactions associated with plants.

When VOC blends contain relatively few compounds or when belowground feeding causes a general repression of VOC emissions—as is the case for maize (Rasmann and Turlings, 2007)—the differences between aboveground and belowground induced plants are relatively easily identified. However, in plant species such as *Nicotiana attenuata* and several Brassicaceous species, which emit complex VOC profiles that contain several hundreds of different individual compounds belonging to various biosynthetic groups, pinpointing shifts in VOC blends is more challenging (van Dam and Poppy, 2008; Bruinsma et al., 2009; Gaquerel et al., 2009). The analytical challenge in detecting shifts in these VOC blends goes beyond detecting a single 'responsible' compound. VOCs, like all metabolites, are produced via intricate biosynthetic networks in which the production of various compounds is interrelated. Another complicating factor is that damage by belowground or aboveground herbivores may cause several VOCs in the profile to change in different directions (Soler et al., 2007; Bruinsma et al., 2009). As 'pure chemicals are rare in nature' and 'real odors are mixtures of volatiles' (Bargmann, 2006), it is seldom that single VOCs are associated with the complete behavioral response of an organism; it is more likely that multiple compounds in the plant-emitted VOC blends serve as cues. Moreover, different compounds in the blend may elicit similar responses, and a single compound may elicit only a behavioral response when offered in the proper background of other plant VOCs (Mumm and Hilker, 2005). Under such conditions, a comprehensive and system-wide approach is needed to identify the biosynthetic shifts that occur in these complex blends, especially when the aim is to correlate multiple changes in VOC blends to binary parasitoid preference tests. Traditional statistical approaches, such as series of ANOVAs on each individual compound, do not provide this comprehensive overview. Therefore, novel bioinformatic approaches based on multivariate data analysis are required to characterize these complex VOC data sets, and link the outcome to ecological data such as preference tests (van Dam and Poppy, 2008).

Multivariate approaches have been used widely in plant metabolomics studies. Only recently are they more commonly implemented for the (unsupervised) analysis of large VOC data sets (Leitner et al., 2008; van Dam and Poppy, 2008; Bruinsma et al., 2009; Gaquerel et al., 2009). Multivariate analyses are tailored to deal with complex data sets that contain variables that are correlated. Interrelated variables are also common to VOC data sets, because they contain groups of VOCs derived from communal biosynthetic pathways, and even from single enzymes producing a range of products (e.g., terpene biosynthetic enzymes; Schnee et al., 2006; Tholl, 2006). Hence, multivariate analyses are more appropriate to extract the biologically relevant information from VOC blends than multiple single ANOVAs, which ignore these internal correlations. Last but not least, multivariate analyses provide a better understanding of the system because they summarize the variation of potentially hundreds of compounds in a limited number of—typically two or three—factors. These consist of 'scores' that are indicative for the compositional difference of VOC blends for each subject (plant), while the relative importance of each VOC in a factor is quantified by model 'loadings' (Jansen et al., 2010). Scores and loadings can be plotted in two-dimensional figures that provide attractive visual support for whether and how different VOC profiles differ from each other.

Two types of multivariate models can be distinguished based on their objective: unsupervised models, of which Principal Component Analysis (PCA) is most widely used, describe all information in the data as well as possible. Different origins of the information (e.g., experimentally induced or stochastic variation) are not distinguished. Supervised methods, on the other hand, focus on *a priori* defined differences between plants, corresponding to treatments imposed by the experiment. Supervised models therefore are more appropriate to distinguish differences between VOC blends emitted by plants that are experimentally induced (Jansen et al., 2010). Partial Least Squares-Discriminant Analysis (PLSDA) is the method that is most widely used to this end in metabolomic analyses (Barker and Rayens, 2003). This model consists of a 'prediction' of whether each plant was treated or not, and quantifies the importance of each VOC in the separation between treatment groups. This latter quantification is referred to as a Discriminant Function. PLSDA is often applied to dichotomous problems, for example, to compare induced with control plants. However, choice tests in biological experiments often are more complex than that and require

multiple comparisons between treatment groups. This can be solved by defining ‘protected contrasts’ between more than two groups based on experimentally or biologically relevant combinations of the treatments, as is often employed in analysis of variance models (Sokal and Rohlf, 1995). We employed such protected contrasts in our PLSDA model to explicitly correlate consistent shifts in the VOC profiles due to root or shoot induction with the host plant choices of parasitic wasps.

Here, we present a case study to illustrate how the novel combination of PLSDA with protected contrasts can identify biological relevant shifts in complex VOC blends. The aim of the analysis is: 1) to identify shifts in VOC blends elicited by shoot feeding herbivores on feral cabbages (*Brassica oleracea*) that were previously induced at the roots or the shoots; and 2) to link these shifts to parasitoid preference data in a statistically sound and visually attractive fashion. For the initial induction of the cabbage plants, we used jasmonic acid (JA), an endogenous plant hormone that is part of the signaling cascade induced by chewing insects and biotrophic leaf pathogens (De Vos et al., 2005). External JA application triggers various herbivore-induced responses in *Brassica* spp. including VOC emissions that attract natural enemies to the plant (Loivamäki et al., 2004). Here, we induced the cabbage plants either via the roots or on the shoots. The use of JA as the initial inducer has the advantage that both roots and shoots can be induced quantitatively and in a similar fashion, which is not achievable when using real insect herbivores. For our case study, this experimental advantage was prioritized over the fact that external JA application does not exactly mimic herbivore induced VOC in cabbages (Bruinsma et al., 2009). Three days after JA treatment, we placed ten *Pieris brassicae* or ten *P. rapae* caterpillars on the leaves of each plant to analyze the effects on JA pretreatment on aboveground VOCs induced by natural herbivore damage. Both caterpillar species are known to induce the production of similar groups of VOCs in various cabbage species, but differ in the amount of damage they do (Geervliet et al., 1997; Smid et al., 2002). Plants with caterpillars were presented in pairs or triplets to female *Cotesia glomerata*, a gregarious parasitoid wasp that frequently parasitizes both *Pieris* species in the field (Brodeur and Vet, 1995; Geervliet et al., 2000). Similarly treated plants with caterpillars were used to collect the dynamic headspace of control, root JA-induced and shoot JA-induced plants on direct thermodesorption traps. After GC-MS analyses of the VOC profiles, we used the experimental design plus the hierarchical preferences of the parasitoids to develop a PLSDA model combined with contrast analyses to reveal which shifts in the VOC blends may explain the wasps' behavior.

Methods and Materials

Plant Growth and Induction Feral *Brassica oleracea* L. (Brassicacea) seeds from a batch that was originally collected from several individuals in a wild population near Heteren (see van Dam et al., 2004) and propagated for one generation in the communal garden at the NIOO (open pollination), were germinated on glass beads. After 1 week, the seedlings were transferred to 1.3 l pots filled with a sand-peat mixture. Plants were watered with tap water as needed. When plants had six true leaves, they were assigned to the following treatment groups: shoot jasmonic acid induction (SJA); root JA induction (RJA); or control (CON). Plants in the SJA group received 500 μg jasmonic acid (JA; Sigma, St Louis, IL, USA) in a 0.1% Triton X-100 solution on the oldest two leaves, and the RJA group received 500 μg JA in 10 ml 0.1% Triton solution injected in the soil near the roots. CON plants and untreated organs of the JA-induced plants were treated with similar volumes of acidic solution (pH=3.7 with HCl; 0.1% Triton) to control for acid induced responses (see van Dam et al., 2004 for a detailed description of the procedure). This amount of JA has been shown to increase leaf glucosinolates 3–7 day after application (Qiu et al., 2009). The control plants received a solution with a similar pH to control for induction effects due to the acidity of the JA solution.

Parasitoid Choice Tests Pieris brassicae L. (Lepidoptera; Pieridae; large white) and *P. rapae* L. (Lepidoptera; Pieridae; small white) caterpillars were obtained from a culture maintained on *B. oleracea* cv. *gemmifera* var. Cyrus at the Laboratory of Entomology, Wageningen University, The Netherlands. Three days after the JA treatments, 10 first instar larvae per plant were placed on two untreated leaves. The larvae were allowed to feed for at least 3 h before plants were used in the choice experiment. *Cotesia glomerata* (Hymenoptera; Braconidae) wasps were obtained from parasitized *P. brassicae* larvae reared as above. After emergence from the cocoons, adult wasps were kept in a communal cage with access to honey and water. After 3–6 day, female wasps were isolated from the culture and given a single oviposition experience with a first instar caterpillar presented on a paint brush (Smid et al., 2007). The experienced wasps then were introduced singly via a sliding observation window into a cage (100×70×70 cm) covered with fine mesh gauze on three sides and the roof. Two plants with caterpillars were placed 30–40 cm apart in the back of the cage. When there were three plants, they were placed in a triangular configuration (30 cm apart). Wasps were released individually on the bottom of the cage equidistant to all plants. Per set of plants, 10–15 female wasps were tested for their preference. After five tests, the

positions of the plants were swapped. Individual plants were used for one set only. The preference observations were performed over several days. On each day, at least one replicate of each possible treatment combination was included to control for day-effects. A positive choice was scored as the first landing of the wasp on a plant, after which the wasp was removed immediately. Individual wasps were used only once for a preference test. The preference data were analyzed with replicated G-tests (Sokal and Rohlf, 1995). Within each comparison, each set of plants and the 10–15 females that chose between them, were considered as one replicate in the G-test.

Volatile Trapping and GC-MS Analysis A separate group of plants was treated as above with JA. Three days later, CON, SJA, and RJA groups all received 10 caterpillars on two untreated leaves. The plants were transferred individually to 17 l glass bell jars (41 cm high, 24.5 cm diam) placed on a stainless steel bottom plate in a controlled climate cabinet (21°C, 70% r.h.). At the top, the jars were supplied constantly with pressurized air (200 ml/min; Hoekloos, Rotterdam, The Netherlands) cleaned over a Zero Air generator to remove hydrocarbons (Parker Hannifin Corp, Tewksbury, MA, USA). Volatiles were collected by pulling headspace air over a steel trap filled with 150 mg Tenax TA and 150 mg Carbopack B (Markes International Ltd., Llantrisant, UK) with a vacuum pump. Traps were mounted at shoot level to an outlet on the side of the jar. Flow rates over the traps were set to 100 ml/min using mass flow regulators (Sho rateTM, Brooks Instrument, Hatfield, PA, USA). After 45–60 min, traps were removed, capped, and stored at 4°C till analysis. Four jars with individual mass flow regulators were sampled in parallel. Six to seven full series of 4 plants and two background VOC profiles from an empty jar were sampled between 9:00 and 17:00 h. Thus, we sampled the following numbers of individual plants in each experiment: P. brassicae experiment 15 CON, 14 SJA, 15 RJA, and 6 untreated plants without caterpillars for background trapping; P. rapae experiment: 13 CON, 13 SJA, 13 RJA, and 12 untreated plants without caterpillars.

VOCs were desorbed from the traps using an automated thermodesorption unit (model Unity, Markes International Ltd., Llantrisant, UK) at 200°C for 12 min (He flow 30 ml/min) and focused on an internal Tenax cold trap (−10°C). After 1 min of dry purging, trapped VOCs were introduced into the GC-MS (model Trace, ThermoFinnigan, Austin, TX, USA) by heating the cold trap for 3 min to 270°C. Split ratio was set to 1:4, and the column used was a 30 m× 0.32 mm ID RTX-5 Silms, film thickness 0.33 μm (Restek, Bellefonte, PA, USA). Temperature program: from 40°C to 95°C at 3°C/min, then to 165°C at 2°C/min, and finally to 250°C at 15°C/min. The VOCs were detected by the MS operating at 70 eV in EI mode. Mass spectra were acquired in full scan mode (33–300 AMU, 0.4 scan/sec). Compounds were identified by their mass spectra using deconvolution software (AMDIS) in combination with NIST 2005 (National Institute of Standards and Technology, USA, http://www.nist.gov) and Wiley 7th edition spectral libraries. Additionally, mass spectra (minimum match factor=85/100) and linear retention indices (LRI, window set to +/−2) of chromatographic peaks were compared with values reported in the literature (Adams, 2007), based on which we compiled a database of over 13.000 literature LRI entries from studies using similar phases as the RTX-5 column (5% phenyl equivalent polysilphenylene-siloxane). Additionally, we obtained reference spectra from several authentic standards (farnesene, limonene, methyljasmonate, methylsalicylate, dimethyldisulfide, dimethyltrisulfide, octanal, nonanal, decanal, cis-3-hexen-1-ol, 2-phenylethylalcohol, indole, benzylcyanide, and phenylethylisothiocyanate; Sigma- Aldrich, St. Louis, Il, USA). The integrated signals generated by the AMDIS software from the MS-chromatograms were used for comparison among the treatments. Peak areas in each sample were divided by the total volume in ml that was sampled over the trap to correct for differences in sampling volume between experiments.

Multivariate Data Analysis of VOC Data Only those VOCs with a peak area larger than the background and found in more than 50% of the samples of either treatment group were selected for multivariate analysis. Thus, in the P. brassicae experiment 116 compounds, and in the P. rapae experiment 136 compounds were statistically analyzed. Prior to analysis, the P. rapae data were transformed as log (x+1) and for both caterpillar spp. the data were unit-variance scaled. We analyzed two contrasts that were of interest: the difference between all JA-treated and control plants (CON vs. (SJA+RJA)), and between RJA and SJA plants. These two ‘protected contrasts’ were modeled using two separate Partial Least Squares Discriminant Analysis (PLSDA) models per caterpillar species (Barker and Rayens, 2003). The first contrast describes the general effect of JA application, regardless of where the JA was applied, by contrasting the VOC profiles emitted by plants in the control group against those emitted by both JA-treated groups (CON vs. (RJA-SJA), lower horizontal axes in Fig. 2a, b). This axis thus indicates which VOCs explain the preference of parasitic wasps for JA-induced plants in general. The second contrast was that between the SJA and RJA plants, thus revealing which VOCs are responsible for the parasitoids’ preference for shoot induced plants. For validation purposes, 1000 models with randomly permuted class labels were fitted alongside every model. The number of latent variables required for both models was determined using cross-validation (Geladi and Kowalski, 1986). To rule

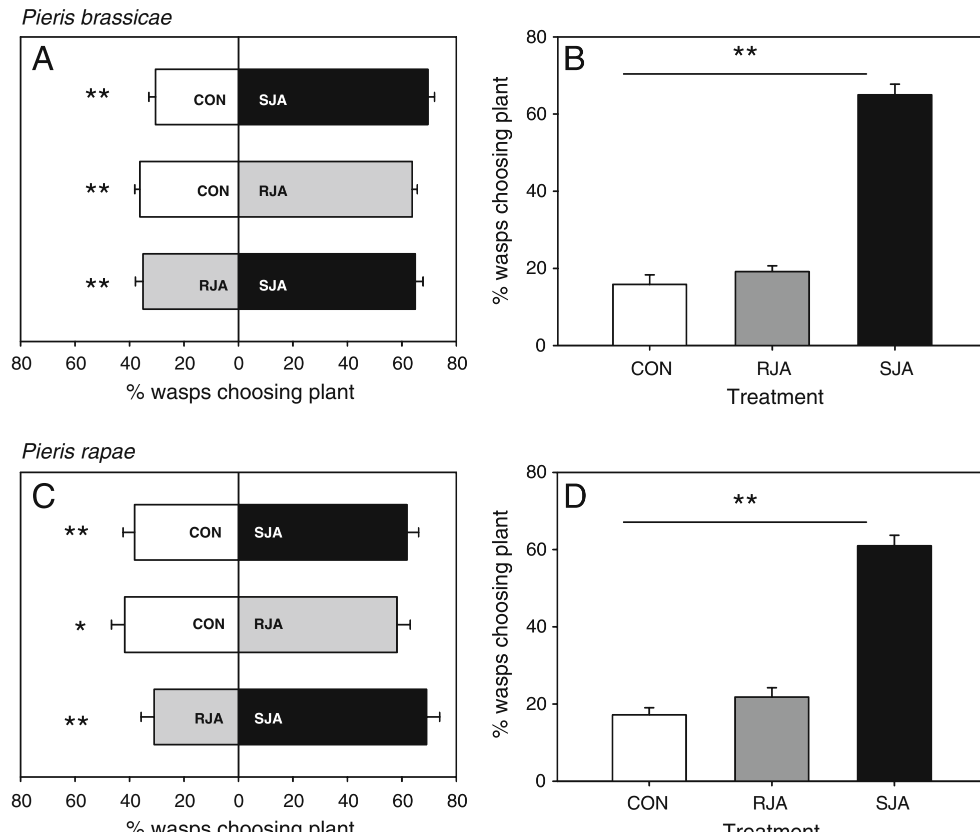

Fig. 1 Preference of *Cotesia glomerata* wasps expressed as the percentage of wasps preferring the plant (±s.e.m. calculated over 8–18 replicate test runs of 10–15 females per run). **a** and **c** Dual-choice tests between plants treated with jasmonic acid (JA) to the roots (RJA), to the shoots (SJA) or with acidic water (CON) 3 d before 10 Pieris brassicae (**a**) or 10 Pieris rapae (**c**) larvae were added. *Asterisks* denote a significant difference in preference between the two plants (* P Gp<0.01, ** P Gp<0.001, see Table 1. **b** and **d)** Triple choice tests between CON, RJA and SJA plants. *Asterisks* denote an overall significance in preference between the three plants (** P Gp<0.001)

out model over-fit, the predictive capacity of each model from the cross-validation was compared to that of permuted models of equal complexity. The permutation test also was used to determine the likelihood of each VOC being involved in the modeled contrasts: this is done by comparing the value of the discriminant function for each VOC to those of the same VOC in the discriminant functions of the randomly permuted data sets (which form a 'null distribution'). This comparison can be translated into a *P*-value for each VOC in each contrast.

Results

In dual choice tests, 5-day old *Cotesia glomerata* females always preferred JA-induced plants over control plants, regardless of where the JA was applied or the *Pieris* species that was used (Fig. 1a, c; Table 1). However, when given the choice, wasps consistently and significantly preferred SJA plants over RJA plants, irrespective of the caterpillar species that was feeding on the leaves (Fig. 1a,c). This strong and significant preference for SJA plants also was evident when plants from the three different treatment groups were presented simultaneously to the wasps (Fig. 1b, d).

In both VOC analyses, the first discriminant axis represents the contrast between the control and both the RJA and SJA plants (Fig. 2a, b, horizontal axes). The importance of each VOC in this contrast is represented by the horizontal position of the compound, and its significance for each contrast is indicated by both point labels. This showed that the increased emission of monoterpenes is shared by RJA and SJA plants (compounds 6–15 in Fig. 2a, b, and Table 2), which contributed highly to the separation of both JA-treated groups from the CON group. The induction of monoterpene emissions by JA-application was consistent for both *Pieris* species (Fig. 3). One VOC decreased after JA application: in the *P. brassicae* experiment, the emissions of dimethyldisulfide (DMDS) were lower in JA-treated plants (compound 5 in Fig. 2a). Significant decreases in DMDS emissions in JA-induced plants were not observed in the *P. rapae* experiment.

Interestingly, we found a clear contrast in VOC profiles between root and shoot JA-induced plants (RJA vs. SJA; vertical axes in Fig. 2). Shoot JA application strongly induced the emission of several sesquiterpenes (compounds number 16–18, 20–23) and a homoterpene (number 19), whereas root induction did not result in elevated emissions of these compounds (Table 2; Fig. 2a, B; Fig. 4a, b). Again, this pattern was similar for both herbivore experiments and was also observed for unidentified sesquiterpenes (Table 2,

CON control

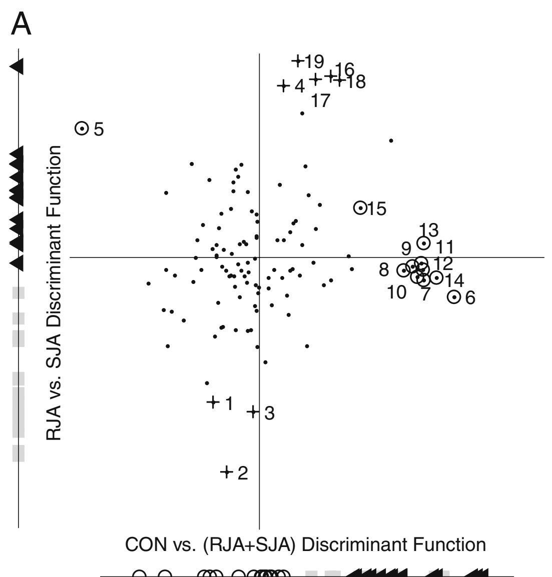
SJA shoot jasmonic acid induction

RJA root jasmonic acid induction

Fig. 4b). The levels of a few compounds were lower after shoot than after root JA treatment; in the *P. brassicae* experiment, several aldehydes (compounds 1–3), and in the *P. rapae* experiment, 2,4-pentadione (compound 24), were more pronounced in control and root induced than in shoot induced plants (Table 2, Fig. 2a, b). In contrast to the differences in terpene emissions, these effects were observed for only one of the *Pieris* species.

Discussion

Based on the results of our combined PLSDA–protected contrast analysis, we could easily identify which VOCs are associated with parasitoid preference. In all choice experiments, *C. glomerata* females strongly preferred aboveground JA-induced plants that had the highest emissions of sesqui- and homoterpenes, even when neighboring belowground induced plants showed equally increased monoterpene levels. This indicates that sesquiterpenes are more attractive cues for this parasitoid species than monoterpenes are. This does not preclude that monoterpenes themselves are attractive as well, but our results show that their attractiveness was context-dependent. The emission of various VOCs from other biosynthetic classes changed after JA application as well, but only the shifts in terpene emissions were consistent for both experiments. Several other studies have shown that plants with enhanced levels of monoterpenes or sesquiterpenes/homoterpenes are more attractive to *C. glomerata* females (van Poecke et al., 2001;



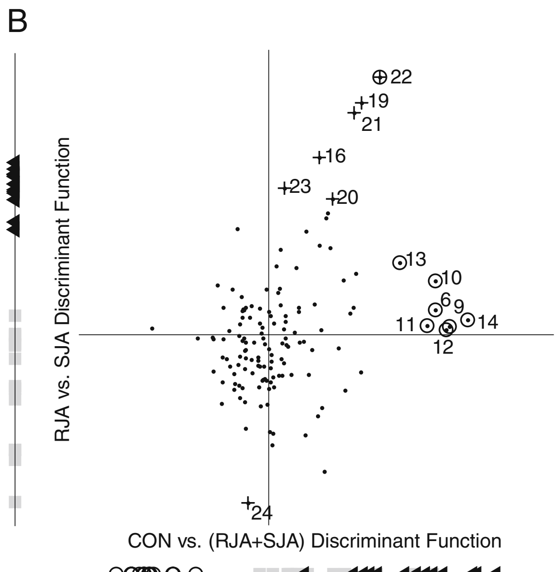


Fig. 2 Two-dimensional PLS-Discriminant fingerprints for VOCs emitted by *Brassica oleracea* plants with **a**. 10 *Pieris brassicae* larvae or **b** 10 *P. rapae* larvae. The separation of individual plants on each discriminant function are given on the *left vertical* (RJA vs. SJA) and *lower horizontal* (CON vs. (RJA+SJA)) *axes* in each figure. Open circles=control plants, grey squares=root-induced (RJA) plants; black riangles=shoot-induced (SJA) plants. The two-dimensional plots in the middle show the contribution of each VOC to the separation. The position of each point is determined by its importance for the contrasts. The numbered VOCs (see Table 1) contributed significantly to the separation of treatment groups (encircled: (CON vs. (RJA+SJA)), crosses: for (RJA vs. SJA). Statistical significance was determined by testing the discriminant function value of a VOC against a null distribution of 1000 models on randomly permuted treatment group assignments ($P<0.05$)

a. The table contains only those volatile organic compounds (VOCs) that were found to significantly contribute to the separation of the treatment groups. The numbers in the first column refer to the numbers in the contrast plot in Fig. 2a and b. Compounds indicated with a * were identified by comparison of pure standards, the other compounds were identified based on MS reference manuals (Adams, 2007), NIST 2005, Wiley 7th Ed. MS library, and our own MS and LRI literature library. All plants had 10 *Pieris brassicae* or 10 *P. rapae* caterpillars feeding on their shoots at the time of VOC collection. b. RI=retention index on the GC-MS; column RTX5-MS. One monoterpene and five sesquiterpenes could not be sufficiently identified based on their RI value and mass spectrum using our criteria, and were given sequential numbers. c. indicates whether this compound had been reported earlier in various *Brassica* species (B, based on references Bruinsma et al., 2009; Geervliet et al., 1997; Gols et al., 2008; Soler et al., 2007) or *Arabidopsis* (A, based on reference Rohloff and Bones, 2005). d.The P-values were determined by testing the discriminant function value of a VOC against a null distribution of 1000 models on randomly permuted treatment group assignments. Values in bold are $P<0.05$

Mumm et al., 2008). The strength of our approach, however, lies in the fact that we could readily contrast the relative importance of these two terpene classes within the VOC blend and could directly relate differences in VOCs between JA-treatments to parasitoid choice behavior. Our analysis, however, cannot reveal whether one, several, or all of the terpenes together are responsible for the observed preferences. This could be assessed experimentally by presenting isolated compounds—in combination with the appropriate background odors—to parasitoids in choice tests, or by using plants that are genetically modified with terpene synthase genes (Kessler and Baldwin, 2001; Ibrahim et al., 2005; Kappers et al., 2005; Mumm and Hilker, 2005). The latter approach has shown that single terpene synthases generally yield mixtures of similar terpenes within a class (Kappers et al., 2005; Schnee et al., 2006; Tholl, 2006). This is consistent with the induction patterns we saw in our experiments, in which several members of a biosynthetic class responded uniformly to the induction treatments. The absence of a strong selection on terpene synthases to produce a single product, underscores our assumption that plant VOC cues likely consist of 'bouquets' of different VOCs, and that it is the quality of the blend rather than the quantity of a single compound that determines the behavioral response (van Poecke et al., 2001).

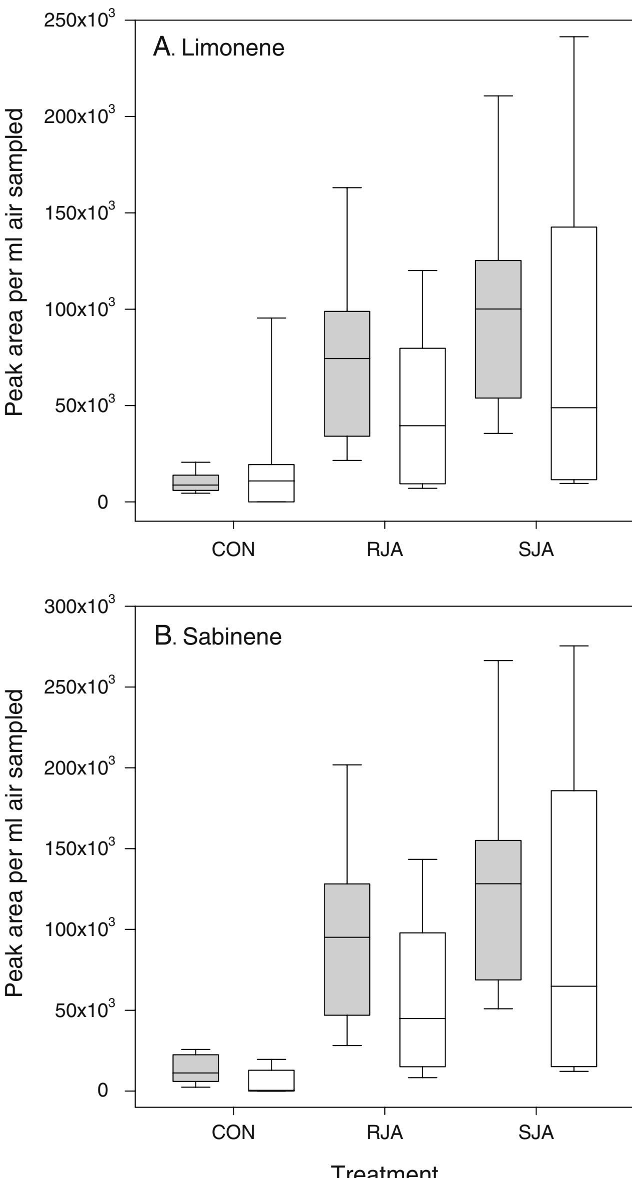

Fig. 3 Box plots showing the median value, the 25th percentile, and 75th percentile of the peak area per ml sampled air for **a** limonene, and **b** sabinene. *Grey bars*: values in Pieris brassicae experiment, *white bars*: values in P. rapae experiment. CON=control plants, RJA=root jasmonic acid (JA) induced plants, SJA=shoot JA induced plants. The *error bars above* and *below the box* indicate the 90th and 10th percentile

As expected, JA application only partly mimicked herbivore-induced responses. Similar to the induced responses caused by root herbivore damage, only shoot induction with JA significantly increased the emission of sesqui- and homoterpenes, whereas root herbivory and root JA application did not (Soler et al., 2007). JA application to the roots, however, did not increase the emissions of sulfides, such as DMDS, which have been found to be induced by cabbage root fly larvae. These sulfides also are of biological relevance, but they play a dual role. It has been suggested that *C. glomareta* wasps use these as cues to avoid root infested plants (Soler et al., 2005), whereas soil dwelling beetle predators of root fly larvae, and parasitoids of *Plutella xylostella*, another leaf feeding cabbage specialist, may use DMDS as a positive cue to locate their host or prey (Ferry et al., 2007; Kugimiya et al., 2010). As JA application did not increase the emission of sulfide compounds in root induced plants, we could not asses the ecological role of this compound in our set-up. For *C.*

glomerata, it is of ecological and evolutionary relevance to assess the difference between root and shoot-infested plants, as root-infested plants yield hosts of inferior quality or her offspring. Wasps emerging from caterpillars on root-infested plants attain lower body masses, which eventually results in a lower fitness (Soler et al., 2005). In an earlier study, we found that parasitoid fitness parameters were reduced significantly on shoot JA-induced plants (Qiu et al., 2009). Yet, we found that shoot JA-induced plants were strongly preferred by female wasps. The discrepancy between parasitoid performance and preference may be explained partly by the fact that JA-induction does not provide the full complement of volatile cues that this parasitoid needs to locate the most suitable hosts.

There is ample evidence that female *C. glomerata* wasps have the ability to detect terpenes and various plant odors with their antennae and can learn to prefer different odors when rewarded (Vet et al., 1995; Smid et al., 2002, 2007). Much less is known about how parasitoids perceive and integrate compositional shifts in complex VOC mixtures, and how they learn to respond to these changes within complex odor plumes (but see Vet and Groenewold, 1990). Learning more about sources of variation in plant odor signals is important for our understanding of the evolution of plant-parasitoid interactions and the role of VOC therein (Vet, 1999; Allison and Hare, 2009; Schuman et al., 2009). The signal-to-noise ratio of the odor profiles determines the reliability of the information, and this may influence the way parasitoids respond to plant cues, innately or through learning. *Vice versa*, the way parasitoids perceive and learn to distinguish between plant VOCs may influence the evolution of plant VOC emissions with regards to the quantitative and qualitative composition of the odor blend in response to herbivore damage (Vet, 1999; Allison and Hare, 2009). Our study demonstrates that parasitoids are able to specifically detect enhanced emissions of sesqui- and homoterpenes against a background of equally increased monoterpene emissions in JA-induced plants. This suggests that the presence of especially sesqui- and homoterpenes in the VOC mixtures may serve as a reliable cue that signals the presence of shoot induction by actively feeding herbivores on a plant that is free from root herbivores.

Unexpectedly, our results also reveal that the terpene synthases of the cytosolic mevalonate (MVA) pathway, leading to the synthesis of sesqui- and homoterpenes (Degenhardt and Gershenzon, 2000; Hopke et al., 1994; Tholl, 2006), are induced by shoot JA application only. In contrast, the biosynthesis of monoterpenes via the methyl-erythritol phosphate (MEP) pathway, which is located in the plastid, is equally elicited by root and shoot JA application. It has been known longer that terpene and sesquiterpene synthases are induced by internal as well as external JA (Ozawa et al., 2000; Tholl, 2006). However, it was hitherto unknown that terpene synthases belonging to these two major biosynthetic pathways may respond differently to JA application, solely depending on where the JA was applied on the plant. It is unlikely that the differential induction of mono- and sesquiterpenes is merely a matter of signal dilution in root induced plants. First, monoterpene emissions were equally enhanced in root and shoot JA-induced plants. Moreover, similar regulatory differences have been found for the induction of glucosinolates, which serve as direct defense compounds in Brassicaceae (Hopkins et al., 2009). Shoot JA induction increased the levels of indole glucosinolates that are derived from tryptophan, whereas root induction triggered the production of the aliphatic glucosinolates (van Dam et al., 2004; Jansen et al., 2009). The latter are produced from methionine via a different biosynthetic and regulatory pathway. Taken together, these results imply that root induced responses are regulated fundamentally different from responses triggered by shoot herbivory. This may provide plants with the option to optimize their inducible defense responses in natural environments where both root and shoot herbivores may interact with the plant (Bezemer and van Dam, 2005). Eventually, the differential expression of both direct and indirect induced defenses after root and shoot herbivory may have profound effects on the performance of above-ground herbivores and parasitoids associated with plants (Masters et al., 2001; Soler et al., 2005; Qiu et al., 2009). In addition to population-based variation in the sensitivity to induction hormones (Schuman et al., 2009), root induction may be yet another level of variation that determines differences in induced VOC profiles between plants.

Here, we have shown how novel bioinformatic analyses successfully bridge the gap between ecologically relevant observations and JA-induced changes in VOC blends. Our supervised PLSDA coupled to protected contrast analysis provided strong statistical support as well as visually appealing information on shifts in chemically complex VOC profiles. It enabled us to assess the relative importance of shifts in different VOC blends and directly link these to the behavior of higher trophic levels associated with these plants. This could not have been achieved with a conventional discriminant analysis that focused only on how each treatment group differed from all other groups. We expect that this method can be applied easily to similar experiments with real herbivores, which may yield novel information regarding the relative importance of specific (groups) of VOCs that are differentially induced by aboveground and belowground induction. The results also show that multivariate analyses do not only provide answers to experimental questions, but also may provide additional insight and generate novel, testable hypotheses about the internal regulation and coordination of above-

ground and belowground induced responses in plants. Bioinformatic analyses, thus, are an invaluable tool to 'see the woods from the trees' that should be applied more frequently to analyze plant VOC blends and other complex chemical data sets.

Acknowledgements The authors thank C.E. Raaijmakers and G. Disveld at NIOO-KNAW for assistance, L. Koopman, A. Gidding of the laboratory of Entomology Wageningen University for providing *Pieris* eggs, and S. Schaper, NIOO-KNAW for setting up the first sets of parasitoid observations. J. Harvey, NIOO-KNAW, provided valuable comments on an earlier version of this manuscript. NM van Dam thanks the Netherlands Organization for Scientific Research (NWO) for funding her work with a VIDI grant, no. 864-02-001, and B-L Qiu was granted by the China Scholarship Programs no. [2006]3036.

and soil fertility (Dixon and Paiva, 1995; Lillo et al., 2008). A number of ecological theories have been formulated to model the plant carbon allocation to phenolic secondary metabolites. The carbon-nutrient balance hypothesis postulates that in nitrogen-limited plants secondary metabolism is directed towards carbon-rich metabolites, such as phenylpropanoids (Coley et al., 1985). That hypothesis and other related theories consider modulation of the synthesis of phenolic secondary metabolites to be an indirect effect of nutrient deficiency, which limits the plants' ability for growth (Tuomi et al., 1990; Jones and Hartley, 1999). Many earlier studies either supported or contradicted this hypothesis, which now appears to be over-simplified. Recent studies have shown that carbon and nitrogen metabolisms are linked by a sophisticated regulatory network (Matt et al., 2002; Fritz et al., 2006). Factors that affect photosynthesis, such as low light intensity can, via a decrease in primary metabolites, provoke a decrease in phenylpropanoids under normal nutrient conditions (Matt et al., 2002). Alternatively, the concentrations of foliar phenolics, particularly flavonoids, may be regulated by a need for photoprotection that depends on the amount of light in excess of the capacity of the photosynthetic enzymes for utilizing light (Close and McArthur, 2002).

The environmental growing conditions in Finland differ considerably from south to north, ranging from southern boreal to northern boreal and subarctic climatic vegetation zones. Consequently, the quality and quantity of phenolics are expected to differ among bilberry leaves growing in different parts of the country. Previous studies have shown that the phenolic content in juniper (*Juniperus communis*) and birch (*Betula pubescens*) leaves increases with latitude (Stark et al., 2008; Martz et al., 2009). However, although the effect of altitude and/or latitude on AC content of bilberry fruit has been previously shown (Lätti et al., 2008; Rieger et al., 2008), no data are available about changes of phenolic composition in bilberry leaves along large geographical gradients. In addition to the latitudinal gradient, the synthesis of phenolics in bilberry leaves may change along the successional stages of the forest. Furthermore, a change in phenolics as leaves develop has been demonstrated previously (Jaakola et al., 2004).

The aim of the present study was to determine the variations in the soluble phenolics in bilberry leaves following leaf development and along environmental gradients. We investigated changes in the biosynthesis and composition of phenolics during development of bilberry leaves collected from plants naturally growing in three sites in northern boreal latitudes (forest, clear cut, and fell). In addition, we conducted a study at 116 sites along a large geographical gradient ranging from south to north boreal latitudes, analyzing the soluble phenolic composition and antioxidant capacity of mature bilberry leaves. Our hypotheses were that: (i) the biosynthesis of leaf-soluble phenolics vary along with leaf development in different growing conditions, and (ii) more environmentally stressful growing conditions such as those found towards higher latitudes promote higher concentrations of leaf-soluble phenolics.

Methods and Material

Study Sites and Collection of Plant Material

Experiment I To investigate changes in composition and biosynthesis of bilberry (*Vaccinium myrtillus* L.) leaf phenolics during leaf development in northern boreal environments, leaves were collected from naturally growing plants on 12 June, 27 June, 17 July, and 5 September 2006 in the Rovaniemi area in northern Finland. Three sites were selected: a clear cut area, (C), which was logged in 2000, an old successional Norway spruce (*Picea abies*) forest (F), only about 50 m from C (66°21′N 26°21′E, 70 m a.s.l.), and a higher altitude fell (T) (Vennivaara, 66°32′N 25°36′ E, 229 m a.s.l.). The fell contained characteristic high-altitude vegetation with sparsely growing old-growth Scots pine (*Pinus sylvestris*) trees. Five plants separated by a minimum of 3 m were selected each time, transported to the laboratory in an icebox, and the leaves were detached immediately, sorted, frozen in liquid nitrogen, and stored at −80°C until phenolic and RNA were extracted. Healthy individuals representing the average development stage at the sampling site were selected.

Experiment II To investigate variation in composition of the leaf phenolics along environmental gradients, samples were collected at 116 study sites that belong to the National Forest Inventory (NFI) network in Finland. The latitudes of these sites range from 59º49′ N to 70°04′ N (about 400 km north of the Arctic Circle). With an average of 143 m, altitudes in Finland generally are low. However, increases in latitude coincide with increases in altitude, and in the northern latitudes, even a small shift in altitude can have great significance for growing conditions. The geobotanical zones range from south boreal forests in the south of Finland to north boreal and subarctic conditions in the northernmost parts. We utilized sites selected for the BioSoil project (Finnish Forest Research Institute), which included

626 sites all belonging to the NFI site network. For this study, we first selected sites with minimum bilberry coverage of 10% in the ground vegetation, and then used a systematic selection that ensured even distribution of sites in different parts of the country. In the north, every second BioSoil site with bilberry coverage of at least 10% was selected, but in the south, every third site was selected. The NFI sites belong to several different forest development classes that correspond to successional stages of the forest. To ensure that the role of latitude or altitude is not influenced by differences in the age structure of sites, we chose only development classes from advanced thinning to mature stands (classes 3–6 in NFI classification), and excluded open clear cuts and forests with young seedlings (mean height of seedlings <1.3 m, classes 0–2 in NFI classification). Phenolic content and composition did not differ among the rest of the forest development classes (classes 3–6) ($P>0.05$, not shown), and thus we did not include the forest class in testing for the effects of latitude and altitude. Correlations between the concentrations of phenolics in bilberry leaves and other site characteristics in NFI site database or the soil nutrient concentrations analyzed in connection with the BioSoil project will later provide further opportunities to investigate correlations between leaf quality and growth conditions, and will be published elsewhere.

Latitudes and altitudes of the selected sites ranged from 60º00′ N to 69°60′ N and from 20 m to 370 m, respectively (Fig. 1a). The predominant tree species most commonly was Norway spruce (*Picea abies*), but in the north, Scots pine (*Pinus sylvestris*) and mountain birch (*Betula pubescens* ssp. *czerepanovii*) also were common. At each site, a composite sample of 20 young and healthy shoots cut from 20 individual phenotypes was collected randomly to exclude from our results the role of genetic variation among bilberry individuals. The sampling period extended from 3 July 2006 to 30 August 2006 (Fig. 1b). For practical travelling reasons, samples collected in Experiment II were not frozen in liquid nitrogen as in Experiment I, but rather were stored in paper bags after harvesting and sent to the laboratory where the branches were weighed and dried at 40°C for 48 h. Leaves then were detached, milled, and stored in sealed plastic bags in the dark at 4°C until extraction of soluble phenolics.

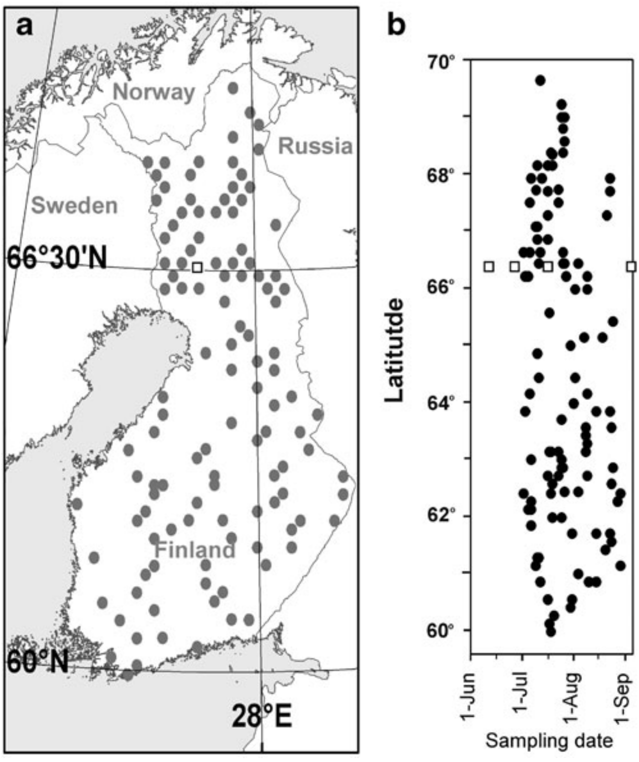

Fig. 1 Location of Experiment II sampling plots in Finland (**a**) and distribution of the sampling during the summer 2006 (**b**). Sampling plots for Experiment I are also indicated by *open squares*

Chemical Analysis of Leaves In this study, the term “phenolics” refers to soluble phenolics only, since cell-wall bound phenolics were not extracted. Leaf pigments and phenolics from dried leaves were extracted by incubating and shaking 1 g of milled leaves in 10 ml of acidic water (0.1% HCl) for 1 h in the dark at 4°C. After gross filtration over filter paper, samples were centrifuged for 10 min at 3,000*g,* and the supernatants were stored at −20°C until analysis. Control extractions showed a similar composition after longer extraction or extraction in boiling water for 5 min. Frozen leaf samples from Experiment I were ground in liquid nitrogen and extracted once with 10 volumes of acidified methanol /water (*v*/*v*) (0.1% HCl) by shaking for 1 h at 4°C in the dark. After centrifugation, the supernatant was transferred into glass tubes and stored at −20°C until analysis.

Due to the large number of samples in Experiment II, a fast and reliable analysis protocol was adopted. Acid hydrolysis of crude leaf extracts (incubation in 2 N HCl for 1 h at 80°C, see below) leads to the production of ACs from PAs, caffeic acid from CGAs, *p*-coumaric acid and other HCA derivatives, and

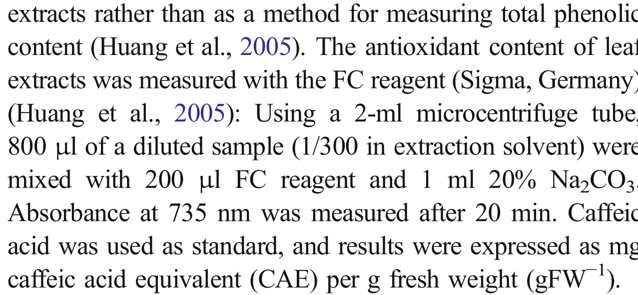
flavonols from flavonol glycosides. HPLC analysis of the samples from Experiment I (N=60) before and after acid hydrolysis allowed us to compare both methods for quantification of phenolics. Statistically significant linear correlations were found between quantification results obtained with or without acid hydrolysis, especially for the percentage of CGAs, HCA derivatives (*p*-coumaric and cinnamic acid derivatives other than caffeic and ferulic acids), flavonols and PAs (R^2=0.714, 0.961, 0.839, and 0.955, respectively). The total amount of phenolics (sum of quantified compounds) measured before and after acid hydrolysis was, however, about 50% lower after hydrolysis (not shown), but both values remained significantly proportional (R^2=0.369, F=36.34, P<0.001). The use of fresh and dry material, different extraction solvents and the inability to quantify catechins from hydrolyzed extracts due to technical reasons may partly explain this difference. Consequently, acid hydrolysis of crude extracts followed by HPLC analysis was adopted as a general protocol for comparison of the samples from Experiment II.

Phenolic composition of hydrolyzed and unhydrolyzed plant extracts was established by HPLC using a Spherisorb ODS II column (4.6×250 mm, particle size 5 µm) and precolumn (Waters, Milford, MA, USA). Samples were eluted from the column by a solvent gradient consisting of Solvent A [0.1% (*v*/*v*) H_3PO_4] and Solvent B [100% MeOH] as previously described (Keski-Saari and Julkunen-Tiitto, 2003). Peaks were identified according to their retention times, UV spectra, and by using HPLC/MS (Keski-Saari and Julkunen-Tiitto, 2003). Quantification was carried out with a UV/visible diode-array detector (Waters PDA 996) at 320 nm for all peaks except catechin, which was determined at 280 nm. The following phenolics were used as references for quantification: CGA (for non-hydrolyzed extracts), caffeic acid (for hydrolyzed extracts), *p*-coumaric acid for all other HCAs, (+)-catechin, hyperin (for non-hydrolyzed extracts), and quercetin (for hydrolyzed extracts) for all flavonol glycosides. Chlorogenic acid (CGA) (3-O-caffeoylquinic acid), caffeic acid, *p*-coumaric acid, (+)-catechin, and hyperin were obtained from Sigma (Germany). Quercetin was purchased from Aldrich (Germany).

Monomeric anthocyanin (AC) content was measured using the differential pH method with cyanidin-3-O-glucoside (BioChemika, Germany) as reference (Lee et al., 2005).

Proanthocyanidins (PAs) were analyzed after their conversion to ACs by incubation of the extracts in 2 N HCl for 1 h at 80°C under conditions optimized for bilberry extracts (Zhang et al., 2004). After cooling, the solution was neutralized by the addition of NaOH, centrifuged, and 20 µl were analyzed by HPLC as described above, with detection at 535 nm using cyanidin-3-O-glucoside as standard.

The Folin-Ciocalteu (FC) reaction can be interpreted as a method for estimating the antioxidant capacity of food or plant



extracts rather than as a method for measuring total phenolic content (Huang et al., 2005). The antioxidant content of leaf extracts was measured with the FC reagent (Sigma, Germany) (Huang et al., 2005): Using a 2-ml microcentrifuge tube, 800 µl of a diluted sample (1/300 in extraction solvent) were mixed with 200 µl FC reagent and 1 ml 20% Na_2CO_3. Absorbance at 735 nm was measured after 20 min. Caffeic acid was used as standard, and results were expressed as mg caffeic acid equivalent (CAE) per g fresh weight (gFW^{-1}).

Radical scavenging activity (RSA) of the samples was measured by using the free radical 2,2-diphenyl-1-picrylhydrazyl (DPPH, Sigma, Germany). Five µl of a diluted sample extract (1/10 in 50% aqueous methanol), representing 50 µg of dried leaves, were mixed with 1 ml of 0.25 mM DPPH at 20°C. Absorbance at 517 nm was measured immediately (A_0) and after 15 min (A_{15}) and 30 min. Decrease in absorbance was still linear after 15 min of reaction time but a plateau usually was reached at 30 min, so that the value measured at 15 min (A_{15}) was used to calculate RSA. RSA was expressed as the percentage of quenched DPPH after 15 min of reaction time, and was calculated by using the equation: $RSA\,(\%) = ((A_0 - A_{15})/A_0)*100$. Under these experimental conditions, 1.38 µg ascorbic acid were necessary to obtain an activity of 20%.

RNA Extraction and Gene Expression Analysis To complement leaf phenolic composition data from Experiment I, we analyzed the steady state expression of selected genes of the flavonoid pathway. Total RNAs were isolated as described previously (Jaakola et al., 2001) and reverse transcribed to cDNA with Superscript III reverse transcriptase (Invitrogen, Carlsbad, CA, USA). Quality of the isolated RNA was verified by measuring the absorbance spectrum with a NanoDrop N-1000 spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA) and by electrophoresis in a 1% (*w*/*v*) ethidium bromide-stained agarose gel. The transcript accumulation of bilberry flavonoid biosynthetic genes chalcone synthase (CHS; AY123765), dihydroflavonol 4-reductase (DFR; AY123767), anthocyanidin synthase (ANS; AY123768), and anthocyanidin reductase (ANR; FJ666338) was detected using a LightCycler® SYBR Green I Master qPCR kit (Roche Molecular Biochemicals, Germany). Quantitative real-time PCR analyses were performed with a LightCycler 480 instrument and software (Roche Molecular Biochemicals, Germany). PCR conditions were as follows: initial denaturation at 95°C for 10 min, followed by 45 cycles at 95°C for 10 sec (ramp rate 4.4°C/sec), 60°C for 20 sec (ramp rate 2.2°C/sec) and 72°C for 10 sec (ramp rate 4.4°C/sec). The melting curve was measured at 95°C for 0.5 sec (ramp rate 4.4°C/sec), 57°C for 15 sec (ramp rate 2.2°C/sec), and 98°C for 0 sec (ramp rate 0.11°C/sec). The primers 5′-CCAAGGCCATCAAGGAATG-3′ and 5′-TGATACATCATGAGTCGCTTCAC-3′ were used for amplifying CHS,

5′-GAAGTGATCAAGCCGACGAT-3′ and ATCCAAG TCGCTCCAGTTGT-3′ for DFR, 5′- TCTTCTAC GAGGGCAAATGG-3′ and 5′-ACAGCCCATGAAATC CTGAC-3′ for ANS, and 5-GCTGGTGTTTCT CCCACAAT-3′ and 5′-CAGGCAACACCTTACCAACA-3′ for amplifying ANR. Quantification of PCR products was performed using glyceraldehyde-3-phosphate dehydrogenase (GAPDH; AY123769, primers 5′-CAAACTGTCTTGCCC CACTT-3′ and 5′-CAGGCAACACCTTACCAACA-3′) as a control gene. Results were calculated with the LightCycler®480 (Roche) software (release 1.5.0 SP1), using the calibrator-normalized PCR efficiency-corrected method (technical Note No. LC 13/2001, Roche Applied Science). Specificities of PCR products were verified by melting curve analysis.

Soil Carbon and Nitrogen Analysis We analyzed soil nutrient status from sites of Experiment I in the Rovaniemi area. At each site, we sampled 6 soil cores extending through the whole humus layer (max. 5 cm depth). Soil was dried (60°C, 48 h), milled, and analyzed by CHN-analyzer (CHN-1000 Elemental Analyzer, LECO Corporation, MI) in an accredited laboratory (Finnish Forest Research Institute, Central Laboratory Services). Carbon (C) and nitrogen (N) contents (% of dry weight) were measured.

Statistical Analyses SPSS 15.0 (SPSS, Inc., Chicago, IL, USA) for Windows was used for statistical analysis. Normality of variables was checked before performing the statistical analysis described below. To investigate differences among the three sites (no replication) and the sampling time effect (four time points) in Experiment I, one-way ANOVA followed by pair-wise comparisons using Tukey's HSD test were made. For Experiment II, regression analyses were done to measure the coefficient of determination R^2 and ANOVA F and P values between the variables and latitude, altitude, and sampling date. In order to determine which factor (latitude, altitude, or latitude and altitude) was most significant in predicting the variables, information-theoretical approach and Aikaike's Information Criterion (AIC) were used (Burnham and Anderson, 2002). This approach is used commonly in observational studies such as in the present experiment to determine which model best fits the data.

Results

Soluble Phenolic Composition of Mature Leaves Bilberry leaves were mature in mid-July, so only samples collected on 17 July 2006 in Experiment I are described in this section. At that time, fruits were purple at T and C sites but still green at F site. The level of phenolics in mature leaves varied considerably (from 30.16 to 80.03 mg gFW^{-1}) between sites, but the same compounds were detected throughout the summer, and only the relative proportions of the different compounds changed (data not shown). In every sample, the most abundant compounds were CGAs (Table 1), including caffeoylquinic acid comprising about 85% of the CGAs and a methyl-chlorogenic acid derivative accounting for less than 15%. The second most abundant class, flavonol glycosides (Table 1) included mainly quercetin derivatives such as quercetin-glucuronide, hyperin, quercetin-arabinoside, but also contained kaempferol-glucuronide and two myricetin derivatives. Other compounds present in lower proportions were catechins (3 peaks), HCAs comprised of over 90% *p*-coumaric acid derivatives, and PAs (including procyanidins and prodelphinidins). In mid-July, ACs (two cyanidin glycosides) were detected only in samples collected at C and T sites. High standard deviations calculated over all the samples collected in mid-July (N=15) can be explained by the different growing conditions, as described below.

Table 1 Soluble phenolic content and composition of mature bilberry leaves collected on 17 July 2006 in the Rovaniemi area

Compound	$mggFW^{-1}$ [a]	(%) [b]
Sol. phenolics	55.39±16.61	(100)
CGAs	29.85±7.29	(55.5)
Flavonol glycosides	17.52±8.74	(29.6)
Catechins	3.91±0.73	(7.4)
HCAs	3.40±0.87	(6.3)
PAs	0.69±0.42	(1.1)
ACs	0.016±0.022	(0.02)

[a] Values are mean values ± SD (N=15)

[b] % of the total soluble phenolics

The average RSA of the leaf extracts estimated by using the DPPH method was 21.43±7.46% (N=15) in mid-July. The amount of antioxidants estimated by the FC method was 28.19±7.91 mg CAE gFW^{-1} in the same period.

Effect of Environment and Foliar Development on Phenolic Composition Although in every site the total phenolic levels were similar in young leaves, at the end of the growing season compound levels were lower in the forest (F) than in the clear cut (C) or fell (T) sites (Fig. 2a). F samples had a significantly higher water content (F=10.52, P=0.002) than the T and C samples (57.60±2.41, 52.05±0.32, and 54.29±2.28% H_2O in F, C, and T samples, respectively) but the differences were not big enough to explain the differences measured in phenolic composition between the samples. The C and T samples had similar compositions (Fig. 2b–g) with the total phenolic content slightly increasing during leaf development. HCAs strongly decreased during early leaf development stages, CGAs remained relatively stable in all stages, while the flavonol glycoside content increased rapidly until the mature stage in mid-July. The flavonol content, however, did

Fig. 2 Concentrations ($mg g FW^{-1}$) of total phenolics (**a**), HCAs (hydroxycinnamic acids) (**b**), CGAs (chlorogenic acid derivatives) (**c**), flavonol glycosides (**d**), catechins (**e**), PAs (proanthocyanidins) (**f**), ACs (anthocyanins) (**g**), RSA (radical scavenging activity) (**h**), and antioxidants (Folin-Ciocalteu values) (**i**) in bilberry leaves collected in the Rovaniemi area in summer 2006 in three different sites (Experiment I). On the same sampling date, samples statistically different from the others at $P=0.05$ are indicated by a star. Values are means ± SD ($N=5$). *F* forest; *C* clear cut; *T* fell

not significantly change in mature leaves from mid-July to early September ($F=1.29$, $P=0.289$, and $F=2.170$, $P=0.179$ for C and T sites, respectively). The PA content showed a similar trend to flavonol glycosides. Phenolic content of F samples was not only lower but its composition was different from that of the C and T samples. F leaves were characterized by lower contents in CGAs, flavonols, and PAs compared to C and T leaves. Moreover, CGA content decreased, whereas flavonol content did not significantly increase during leaf development ($F=0.755$, $P=0.536$). The proportion of kaempferol glucuronide remained stable during all stages in all samples but interestingly, it was always significantly higher in F compared to C and T samples (21.96±6.66, 10.13±2.27, and 10.12±3.16% of all flavonol glycosides in F, C, and T samples, respectively, all sampling times included). The AC amount measured in F leaves also was lower than in C and T leaves, but was not statistically different due to high individual variation (93.79±89.31, 193.38±107.7, and 284.18±262.48 $\mu g\ gFW^{-1}$ in F, C, and T samples, respectively).

Expression of the key genes of the flavonoid pathway was studied in the C, F, and T leaves using quantitative RT-

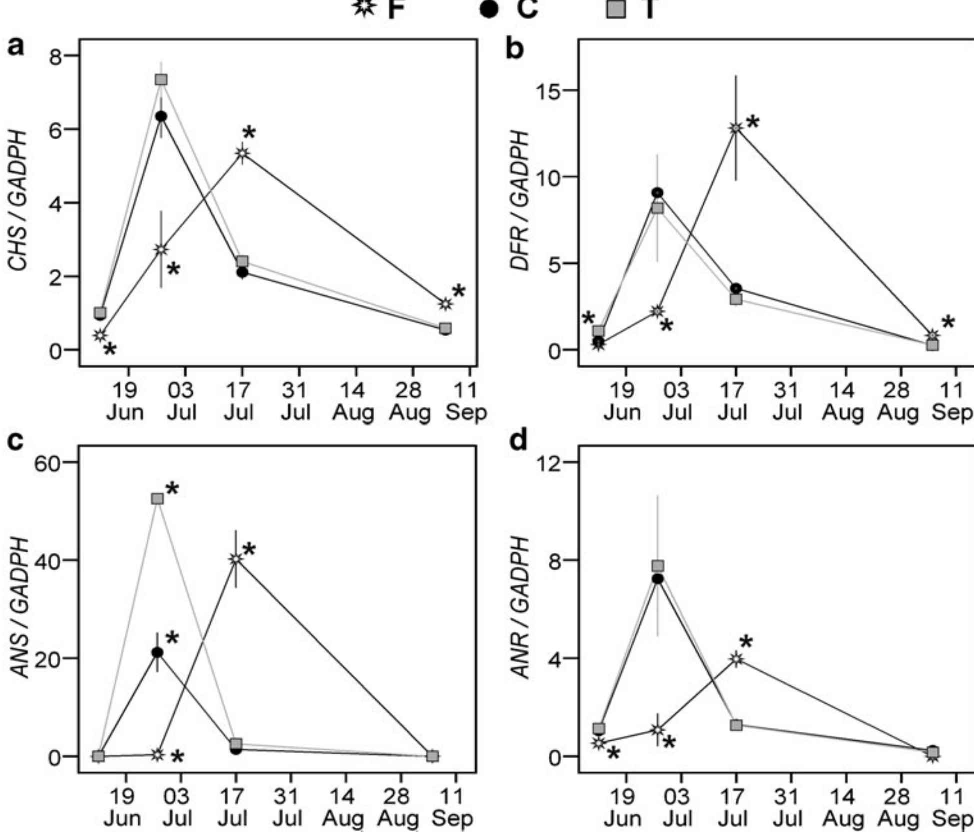


Fig. 3 Expression analysis of the *CHS* (**a**), *DFR* (**b**), *ANS* (**c**), and *ANR* (**d**) genes in bilberry leaves growing in the Rovaniemi area in different sites (Experiment I) in summer 2006 using qPCR. *GADPH* gene expression was used as reference. On the same sampling date, samples statistically different from the others at $P=0.05$ are indicated by a *star*. Values are means ± SD ($N=3$–5). *F* forest; *C* clear cut; *T* fell

PCR. Whatever the site, the expression level of the selected genes was similar in young (12 June) and old leaves (5 September) (Fig. 3). Differences, however, were observed in the developmental profile of transcript accumulation in C and T compared to F samples. At the end of June, the expression of flavonoid synthesis genes was several-fold higher in leaves growing in open areas (T and C samples) compared to forest leaves (F), which was consistent with the accumulation of the phenolics (Fig. 2).

The RSA activity measured with the DPPH test increased three-fold from young leaves to old leaves in F and C sites, but activity was always higher in the C compared to the F samples (Fig. 2h). A significantly higher activity was measured in T compared to C and F samples in young leaves in early June, but similar values were measured in early September in all samples. A similar developmental pattern was observed for the antioxidants quantified by using the FC method: they increased in all samples during foliar development, with similar values in T and C samples and significantly lower values in F samples from the end of June onwards (Fig. 2i). When analyzing correlations between biochemical parameters and RSA activity or FC values (antioxidant content), it appeared that the content of PA was the parameter most strongly correlated with RSA activity and FC values (R^2= 0.753 and 0.909, respectively). Strong linear relationships also were found with catechin content (R^2=0.747 (RSA) and 0.715 (FC)) and flavonols (R^2=0.473 (RSA) and 0.677 (FC)), but less with total phenolics (R^2=0.224 (RSA) and 0.426 (FC)). Thus, antioxidant capacity was best explained by PA and flavonols but not total phenolics.

To establish whether the nutrient status of the study sites was correlated with the concentration of leaf phenolics, soil samples collected in the C, F, and T sites were analyzed for carbon and nitrogen content. Results showed that among the three sites, the T site had the lowest nitrogen availability (high carbon/nitrogen ratio) (Table 2). Similar values were observed for the C and F sites which are separated by only 50 m, but the highest N availability was measured at the C site, which was logged in 2000.

Effect of Latitude and Altitude on Phenolics Experiment I showed that most of the changes in bilberry leaf composition occurred in early development stages before mid-July. We, therefore, tested the effect of maturation on leaf properties in Experiment II by linear regressions between biochemical

Table 2 Soil nutrient status in bilberry collecting sites in Rovaniemi area

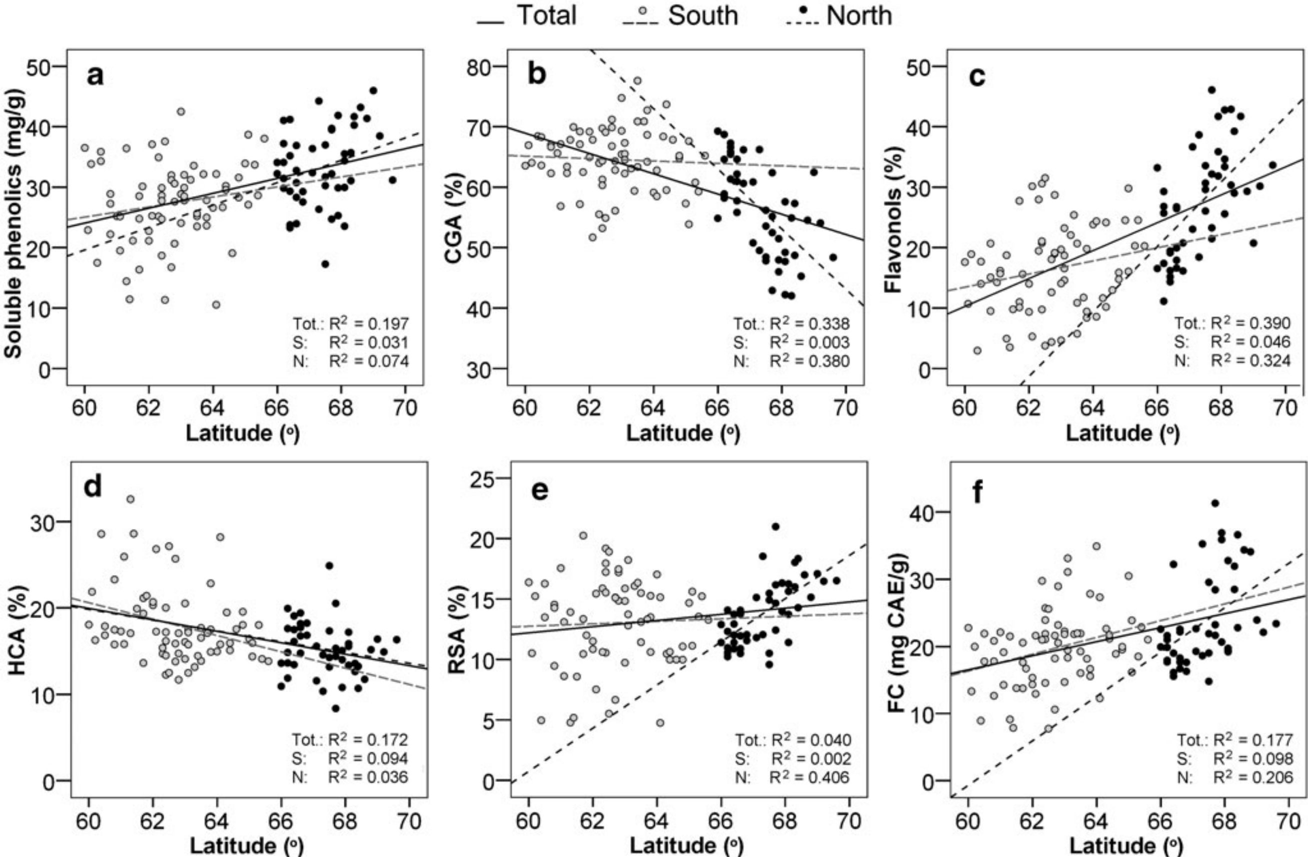

Fig. 4 Effect of latitude on the content of phenolics (mg per g dry weight (mg gDW^{-1})) (**a**), the proportion of CGAs (chlorogenic acid derivatives) (**b**), flavonols (**c**), HCAs (hydroxycinnamic acids) (**d**), the RSA (radical scavenging activity) (**e**), and the Folin-Ciocalteu values (**f**) in bilberry leaves. The total population (N=116) was divided into two sub-populations based on the latitude: the South (N=70, latitudes <66°N) and the North (N=46, latitudes >66°N) populations. Linear regression lines and coefficients of determination R^2 are indicated in each panel for each population. *Tot*. Total population, *S* Southern population, *N* Northern population

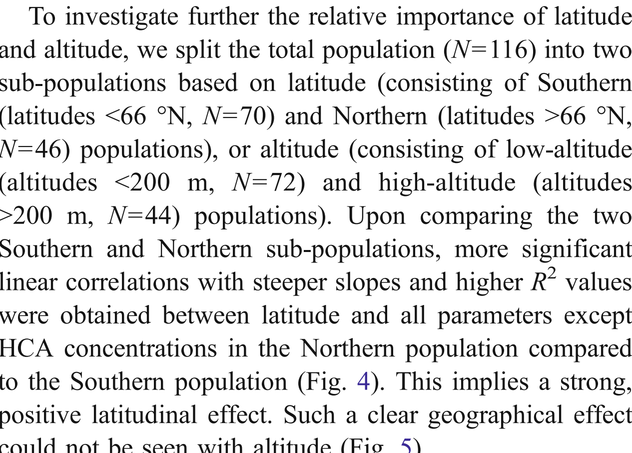
parameters and the date of sampling. There was a significant relationship between the date of sampling (P<0.001) with the proportion of ACs (R^2=0.212) but with only a minor effect and little consequences on leaf composition due to the low abundance of ACs in bilberry leaves (0.02±0.04% in hydrolyzed leaf extracts, N=116). There were no significant relationships between the date of sampling and the total phenolic content, the proportion of CGAs, flavonols, HCAs and PAs, the RSA activity, or the FC values (P=0.382, 0.076, 0.707, 0.005, 0.004, 0.008 and 0.031, respectively).

The northern parts of Finland are characterized by higher altitudes, and significant changes in the leaf composition were measured with increasing latitude and/or altitude (Figs. 4 and 5). Since latitude and altitude are closely correlated (R^2=0.465, F=106.68, P<0.001), we applied the Information Theoretic approach with Aikaike's Information Criterion (AIC) values to determine which model, latitude, altitude, or latitude and altitude, best fit the variation in leaf phenolics. The models that included both latitude and altitude were best in explaining the contents of all analyzed parameters (Table 3).



To investigate further the relative importance of latitude and altitude, we split the total population (N=116) into two sub-populations based on latitude (consisting of Southern (latitudes <66 °N, N=70) and Northern (latitudes >66 °N, N=46) populations), or altitude (consisting of low-altitude (altitudes <200 m, N=72) and high-altitude (altitudes >200 m, N=44) populations). Upon comparing the two Southern and Northern sub-populations, more significant linear correlations with steeper slopes and higher R^2 values were obtained between latitude and all parameters except HCA concentrations in the Northern population compared to the Southern population (Fig. 4). This implies a strong, positive latitudinal effect. Such a clear geographical effect could not be seen with altitude (Fig. 5).

Antioxidant capacities were higher at higher latitudes and altitudes (Figs. 4 and 5, Table 3). No analysis of linear correlations between RSA or FC values with the different leaf parameters were completed because phenolic content and composition were measured only after acid hydrolysis had occurred (such data could be used only for sample comparison, see Methods and Material).

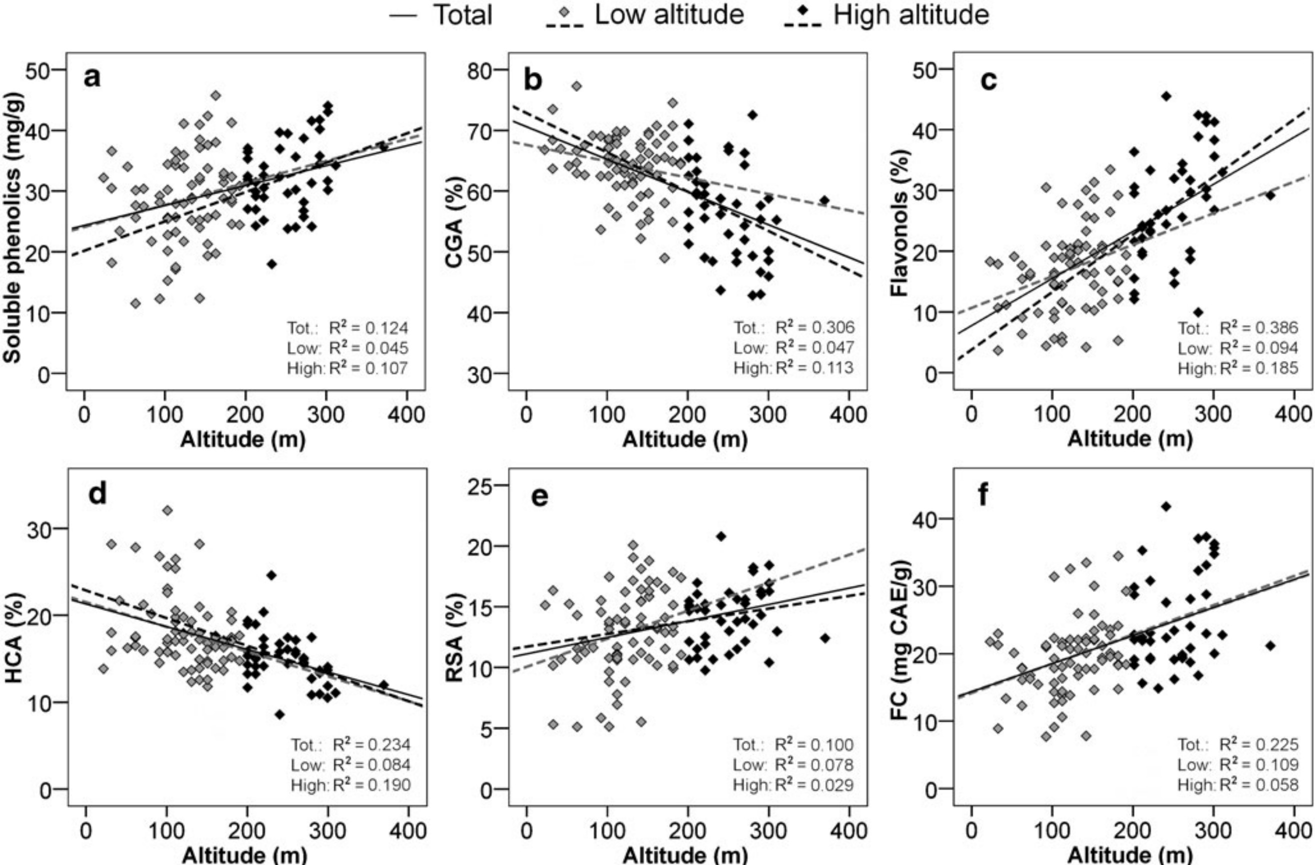


Fig. 5 Effect of altitude on the content of phenolics (mg gDW^{-1}) (**a**), the proportion of CGAs (chlorogenic acid derivatives) (**b**), flavonols (**c**), HCAs (hydroxycinnamic acids) (**d**), the RSA (radical scavenging activity) (**e**), and the Folin-Ciocalteu values (**f**) in bilberry leaves. The total population (N=116) was divided into two sub-populations based on the altitude: the low-altitude (N=72, altitudes <200 m) and the high-altitude (N=44, altitudes >200 m) populations. Linear regression lines and coefficients of determination R^2 are indicated in each panel for each population. *Tot*. Total population, *Low* low-altitude population, *High* high altitude population

Discussion

Bilberry leaf composition measured in this study is in agreement with other previously published reports (Witzell et al., 2003; Jaakola et al., 2004; Riihinen et al., 2008), with CGAs and flavonol glycosides as the most abundant compounds. Flavonol glycosides included quercetin and kaempferol as previously reported (Fraisse et al., 1996; Jaakola et al., 2004; Harris et al., 2007), and also myricetin derivatives. Catechins, HCAs (mainly *p*-coumaric derivatives), PAs, and ACs were minor components.

Although only three sites were studied in Experiment I without replication, clear differences in the leaf phenolic composition were measured among the sites. Similar

Table 3 Models Akaike's Information Criterion (AIC) and R^2 values of the different biochemical parameters of bilberry leaf and the geographical factors (latitude and altitude)

Compounds	Latitude		Altitude		Latitude + Altitude	
	AIC value	R^2	AIC value	R^2	AIC value	R^2

composition and developmental variations were measured in leaves collected in open areas under high light conditions (clear cut (C) and fell (T) leaves), with most importantly, a high increase in flavonols during early stages of leaf development. Leaves that developed in the low-light forest environment (F) displayed lower phenolic content and a different composition from C and T leaves, with particularly lower amounts of flavonols and PAs. Expression analysis for key genes of the flavonoid pathway suggested that the synthesis of flavonol and PAs was delayed in F leaves compared to C and T leaves. The proportion of kaempferol derivatives in flavonols also was higher in F compared to C and T leaves, in accordance with an earlier study in which an increased quercetin:kaempferol ratio was detected in bilberry leaves growing under direct sun exposure (Jaakola et al., 2004). In all types of leaves, composition did not significantly change in mature leaves after mid-July.

Light induces expression of flavonoid pathway genes (Hartmann et al., 2005; Matus et al., 2009), but nitrogen and temperature also can affect this pathway (Witzell and Shevtsova, 2004; Lillo et al., 2008; Usadel et al., 2008). Clear cutting sometimes can increase soil temperatures and enhance soil nitrogen availability through changes in nutrient release rates from litter and soil organic matter (Palviainen et al., 2005; Thiel and Perakis, 2009). Concentrations of leaf phenolics generally are higher in nutrient-poor than in nutrient-rich soils (Close and McArthur, 2002; Witzell and Shevtsova, 2004), but we observed the lowest soil carbon/nitrogen ratio (highest nitrogen availability) in the C site, which also showed the highest concentration of leaf phenolics. Thus, the variation in concentration of leaf phenolics among the three sites did not seem to correlate with soil nitrogen availability.

A previous study showed that production of phenolics was higher in upper bilberry leaves exposed to direct sunlight than in lower shaded ones (Jaakola et al., 2004). Our results are in agreement with this result, but we were able to show here that the genes involved in flavonoid synthesis are highly expressed in shade leaves as well but with a different timing. Similar maximum relative levels of gene expression were measured in leaves growing under different conditions, but surprisingly the accumulation of the corresponding phenolics remained lower in old F leaves. However, steady-state expression levels of key genes of the flavonoid pathway do not measure the actual enzymatic activity. The less favorable growing conditions in August compared to July at such latitudes might prevent full enzymatic activity and thus inhibit efficient synthesis of secondary compounds.

On the basis of our results, higher light intensity seemed to be a more important factor regulating the concentration of phenolics than the soil nutrient status, but this needs to be verified with investigations that use replicated study sites. Light has been proposed previously as having a stronger effect than soil nutrient availability on the production of flavonols in bilberry leaves (Witzell and Shevtsova, 2004).

The antioxidant capacity of bilberry leaves, measured with the DPPH or the FC method, increased during development, with higher capacities measured in C and T leaves compared to F leaves. PAs appeared to have an important role in the antioxidant capacity, which is in line with previous results (Määttä-Riihinen et al., 2005).

We also conducted an investigation on bilberry leaf phenolic composition along a large environmental gradient (60º00′ N to 69°60′ N with altitudes ranging from 20 to 370 m) (Experiment II). In line with our hypothesis, we found an increase in leaf phenolics with increasing latitude. By selecting similar forest successional stages that had similar light conditions, we excluded the role of forest development stage from the trends along the environmental gradients. Furthermore, in samples collected from July to the end of August, there was no effect of sampling date on the composition of the mature bilberry leaves. The data are consistent with the results from the analysis of mature leaves presented above (Experiment I). The northern parts of Finland are characterized by higher altitudes, with altitude closely correlated with latitude; we, therefore, also tested whether latitude, altitude, or latitude + altitude is the most powerful determinant of phenolic content and composition of bilberry leaves. Statistical analyses showed that all phenolic groups were best correlated with a model that included both latitude and altitude. These results are in line with previous work on bilberry fruits, in which ACs are a major component and where latitude and altitude were shown to affect their content (Lätti et al., 2008; Rieger et al., 2008).

The higher content of secondary metabolites found in bilberry leaves in the subarctic and north boreal sites, as compared to the south boreal sites, may reflect the adaptation of bilberry to northern growing conditions. The northernmost sampling sites in this study correspond to a subarctic environment, where plants are continuously subjected to several abiotic stresses, such as frequent frost spells, almost continuous light during the growing season, and nutrient-poor soils. Higher altitudes, especially in combination with northern latitudes, also contribute to severe growing conditions with low mean temperatures and high light intensity due to a discontinuous tree canopy. All of these factors, especially higher ultraviolet B radiation, affect secondary metabolic pathways (Dixon and Paiva, 1995; Witzell and Shevtsova, 2004; Lillo et al., 2008; Usadel et al., 2008). High need for photoprotection in the north can be explained by the fact that photo-oxidative stress induced by light intensity may be increased at low temperatures, because of the limiting effect

of temperature on photosynthesis (Close and Mcarthur , 2002). Flavonoids prevent photo-oxidative damage that could result from excess light in relation to the photosynthetic capacity (Close and Mcarthur, 2002). In boreal forests, the overstory trees form an effective shade for understory vegetation. The density of the tree canopy is higher in the southern than in the northern boreal areas for the same forest developmental class (e.g., Salemaa et al., 2008), so need for flavonoids and other photoprotective compounds would be greatest at high latitudes.

Our results demonstrate the importance of the geographical patterns of latitude and altitude on the chemical quality of bilberry leaves, which underlines the importance of light conditions on the concentration of flavonoids in plants. These findings support the idea that synthesis of polyphenolic secondary compounds are means of active adaptation to environmental stresses, rather than an indirect effect of nutrient deficiency that limits the plant growth.

In summary, our results show that foliar development and abiotic stresses characterizing the growing sites have significant effects on quantitative and qualitative composition of phenolics in bilberry leaves. The leaves of plants growing in high-light intensity sites, higher latitudes, and/or higher altitudes have over a two-fold higher concentration of total phenolics compared to plants growing in lower altitudes and low-light intensity sites. This may have implications for potential allelopathic effects of bilberry on tree seed germination and root growth (Jäderlund et al., 1996; Mallik and Pelissier, 2000), on food intake and digestibility of bilberry leaves (Duncan and Poppi, 2008) and to the harvesting of bilberry leaves by the health-promoting natural product industry (Mäkitalo et al., 2006).

Acknowledgments The authors thank K. Mikkola for providing background information for site selection, R. Nielsen and M. Weissman for technical help, and J. Hyvönen for statistical advices. We are indebted to everyone involved in the sampling that was done in connection with the BioSoil project (Finnish Forest Research Institute). This work was supported by the European Commission, Regional Development Fund (project "Mette" number 70025/05), the Lapland Regional Fund of the Finnish Cultural Foundation (to F. M.), the Kone Foundation, Finland (to F. M.), and the Academy of Finland (grant no 09141 to L. J.).

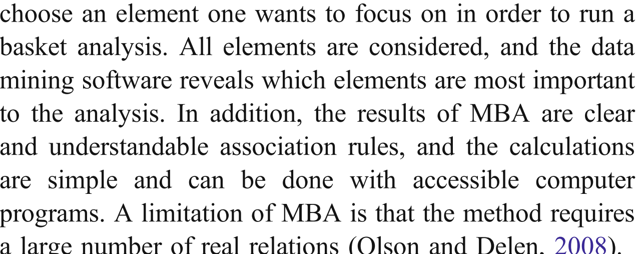
often have been used to monitor general atmospheric pollution levels on a regional scale, and substrate-plant relationships are important to differentiate between geogenic and anthropogenic element sources (Reimann and de Caritat, 2000).

Instruments currently used to investigate these problems usually are conventional statistical methods such as multivariate analysis of variance (MANOVA), factorial MANOVA, analysis of covariance (ANCOVA), regression analysis, and principal component and classification analysis (PCCA). There is, however, a need to find new statistical tools for environmental analysis that determine relations hidden in a set of data and present them as simple association rules. Innovative statistical methods are helpful to identify ecological trends and changes in response to environmental change (Samecka-Cymerman et al., 2007; Ferguson et al., 2008).

This research evaluated Market Basket Analysis (MBA), a novel data mining technique, for testing ecological and biogeochemical hypotheses. Until now, this technique has been used only to study the habits of shoppers in supermarkets and the contents of their shopping trolleys. MBA is a modelling technique based upon the theory that if a certain group of items is bought, this makes it more (or less) likely that another group of items also will be purchased. MBA is, thus, a technique that discovers relationships among pairs of products purchased together. This technique, however, also can be applied to other research areas to determine relations hidden in a set of data and present them as simple association rules (Agrawal et al., 1993; Agrawal and Srikant, 1994; Han et al., 2001; Witten and Frank, 2005). Association rule mining was first introduced by Agrawal et al. (1993), who were inspired by MBA and designed a framework for extracting rules from a set of transactions related to items bought by customers. They also proposed the *a priori* algorithm that discovers large (frequent) item sets. Since then, many advances have been introduced to handle various data types and structures (Messaoud et al., 2008).

MBA analysis is an intuitive application of association rules, striving to analyze customer buying patterns by finding associations between items that customers put into their baskets. Each customer's basket is represented as a Boolean vector, denoting which items are purchased. The vectors are analyzed to find which products are frequently bought together (by different customers), i.e., associated with each other (Cios et al., 2007). These co-occurrences are represented in the form of association rules: LHS⟹RHS where the left-hand side (LHS; Body) implies the right-hand side (RHS; Head).

MBA offers advantages over classical pattern recognition techniques such as PCCA or other types of data mining. MBA is undirected, and it is not necessary to



choose an element one wants to focus on in order to run a basket analysis. All elements are considered, and the data mining software reveals which elements are most important to the analysis. In addition, the results of MBA are clear and understandable association rules, and the calculations are simple and can be done with accessible computer programs. A limitation of MBA is that the method requires a large number of real relations (Olson and Delen, 2008).

We applied this statistical tool to determine relations hidden in a set of ecological data and to present them as simple association rules, assuming that the results obtained would be clear and simpler to interpret. The value of the method was tested by determining the chemical composition of the fern *Athyrium distentifolium*, sampled from sites with different types of bedrock in the Tatra mountains. This fern was selected because it grows abundantly in the Tatra mountains and accumulates elevated levels of metals when growing on serpentine and metalliferous soils (Cornara et al., 2007).

The Tatra mountains and the adjacent lowlands along the Polish–Slovak border form part of a Biosphere Reserve, created in 1993 in the context of the UNESCO MAB program. This area is a strictly protected region in the country (Bytnerowicz et al., 2003). It is practically free from local pollution and, thus, useful for investigations into relations between the bedrock and the chemical element contents of plants. *Athyrium distentifolium* grows in the Tatra mountains on lithosoils with a shallow layer of organic material, in sites characterized by different types of substrates: granites, gneisses, limestones, dolomites, and sandstones (Bac-Moszaszwili et al., 1979). The first two substrates in particular usually contain elevated levels of certain elements (Kabata-Pendias, 2001), and form special conditions for plant growth. The distribution of *A. distentifolium* offered an opportunity to compare the elemental composition of this species on different types of parent rock, in order to evaluate whether the concentrations of chemical elements in a plant correlate with parent rock geochemistry (Reimann and de Caritat, 2000; Neff et al., 2006). The aim of the present study was to use MBA as well as PCCA to investigate the influence of bedrock on concentrations of a number of elements in *A. distentifolium*, and to compare the results obtained with the two different techniques. We investigated the hypothesis that different types of rock would influence the concentrations of elements in this fern.

Methods and Materials

Fern Sampling A total of 118 sampling sites in the Tatra mountains were selected, on different substrates. Thirty sites were situated on limestones and dolomites (later

combined as limestones), 18 were selected on quartz sandstones, and 70 on granites and gneisses (later combined as granites). At each site, five *A. distentifolium* samples were collected within a 25×25 m area. Each sample consisted of a mixture of three subsamples of fronds. As required by the rules set by the Environmental Monitoring and Data Group (Markert et al., 1996) and the European Heavy Metal Survey (Harmens et al., 2004), the collected ferns had not been exposed directly to canopy throughfall, as they were collected in open areas.

Chemical Analyses Before analysis, plant material was washed for a few seconds in distilled water and dried at 50°C to constant weight. Fern samples were ground and homogenized in a laboratory mill. Samples (300 mg dry weight, in triplicate) were digested with nitric acid (ultra pure, 65%) and perchloric acid (ultra pure, 70%) in a microwave oven (MARS5 CEN Corporation). After dilution to 50 ml, the plant digests were analyzed for Fe, Mg, Mn, and Zn by using Flame Atomic Absorption Spectrophotometry and for Cd, Cr, Cu, Ni, and Pb by using Furnace Atomic Absorption Spectrophotometry (AVANTA PM GBC Scientific Equipment). Ca, Na, and K were determined with a flame photometer (PFP7 JENWAY Ltd.). All elements were determined against standards (Atomic Absorption Standard Solution, Sigma Chemical Co), and blanks were prepared in the same way as samples. Blanks and standards contained the same matrix as samples. All results for plants were calculated on a dry weight basis.

The recovery rates of elements (percentages with SD) were as follow: Ca (98±3), Cd (96±5), Cr (101±4), Cu (98±3), Fe (98±2), K (98±3), Mg (97±3), Mn (102±2), Na (100±3), Ni (95±5), Pb (94±5), and Zn (103±3). The standard reference material consisted of bush branches and leaves (DC73348, LGC).

Statistical Analyses Differences between sampling sites in terms of concentrations of elements in ferns were evaluated by ANOVA on log-transformed data to obtain a normal distribution of features according to Zar (1999). The normality of the analyzed features was checked by means of *Shapiro-Wilk's W* test, and the homogeneity of variances was checked by means of *Bartlett's test* (Sokal and Rohlf, 1994; Zar, 1999). Sampling sites were divided into three groups according to the type of substrate. Sampling sites in group one consisted of granites and gneisses, those in group two of limestones and dolomites, and those in group three of sandstones. We grouped granites and gneisses together as both are more acid types of primary rock, while limestones and dolomites were grouped together as basic types of rock (Kabata-Pendias, 2001).

A *post-hoc LSD test* (Zar, 1999) was used to compare the concentrations of elements in ferns in groups 1, 2, and 3.

Market Basket Analysis MBA was used to classify the ferns by means of association techniques in terms of the concentrations of elements in the plants, in order to identify groups that tend to occur together within the sampling sites and to identify relationships between them (Witten and Frank, 2005; Han and Kamber, 2006).

The *a priori* algorithm is a popular and efficient algorithm for deriving association rules from large data sets, based on some user-defined "threshold" values. An association is an expression of the form: Body –>Head (Support, Confidence). The confidence value denotes the conditional probability of the Head of the association rule, given the Body of the association rule. The support value is computed as the joint probability (relative frequency of co-occurrence) of the Body and the Head of each association rule. Rules originating from the same item set have identical support but can have different confidence values (Agrawal et al., 1993; Agrawal and Srikant, 1994; Han et al., 2001; Witten and Frank, 2005; Nisbet et al., 2009). The *Lift* (also called improvement factor) describes the predictive power of a rule. It shows how much better a rule is at predicting the result than just assuming the result in the first place. The Lift is the ratio of the density of the target after application of the left-hand of the Body and Head rule to the density of the target in the population. In other words, it is the ratio of the records that support the entire rule to the number that would be expected, assuming that there is no relationship between the items. A Lift greater than 1 (100%) means that the resulting rule is better at predicting the result than guessing whether the resultant item is present, based on individual item frequencies. The higher the Lift of a rule, the better its predictive power (Berry and Linoff, 2004; Banek et al., 2006). For the purpose of MBA, we divided the concentrations of each element in the plants into quartile groups. Each group was arbitrarily categorized as follows: very low (values between minimum and Quartile 1), low (values between Quartile 1 and Quartile 2), high (values between Quartile 2 and Quartile 3), and very high (values between Quartile 3 and maximum).

Principal Component and Classification Analysis Principal component analysis (PCA) often is used in ecology to reduce the data and stabilize subsequent statistical analyses (Vaughan and Ormerod, 2005). PCCA previously has been applied in environmental sciences (Deng et al., 2007; Otto et al., 2008). PCCA is based on PCA and offers a practical and clear classification of a set of data for a number of objects (Legendre and Legendre, 1998). We established

whether relations between ferns growing on particular types of substrate and their elemental concentrations derived from PCCA would also be found by MBA. Thus, we could evaluate whether MBA also can be applied in ecology and environmental protection research.

All calculations were performed with Statistica version 8.0 (StatSoft Inc. 2008).

Results and Discussion

The concentrations of the chemical elements in ferns from three substrate types in the Tatra mountains (Table 1) differed significantly (ANOVA, $P=0.05$). *Athyrium distentifolium* from limestones contained the highest concentrations of Ca and Mg (*post hoc* LSD test, $P<0.05$), while ferns from granites contained the highest concentrations of Cd and Pb, and those from sandstones contained the highest concentrations of Cr (*post hoc* LSD test, $P<0.05$). The results for granites and limestones are in agreement with data published by Kabata-Pendias (2001), while Reimann et al. (2007) also found increased levels of Cr in plants from sandstones.

MBA was used to classify the ferns in terms of concentrations of elements and associations with substrate type (Table 2). The higher the Lift of a rule, the greater its predictive power (Banek et al., 2006). Based on the Lift values, we can conclude that the relation “If Body then Head” was more likely to occur in limestones (Lift 367–432%) and sandstones (Lift 419%) than in granites (Lift 158–174%). This information (Table 2) leads to the conclusion that ferns from limestones contained very low concentrations of Cd, Fe, Mn, and Pb, and very high concentrations of Ca and Mg (confidence 85–100%). Ferns from granites contained high concentrations of Mn, and very high concentrations of Cd and Pb (confidence 82–91%). Ferns from sandstones contained a very high level of Cr (confidence 100%).

The PCCA ordination of the sampling sites (Fig. 1) shows that the first principal component discriminated between ferns growing on limestones (positive scores) and those growing on granites (negative scores). The ferns growing on sandstones had negative scores for the second principal component.

Projection of the variables onto the factor plane indicated that factor 1 was positively related to Ca and Mg and negatively related to Cd, Pb, and Mn, while factor 2 was negatively related to Cr. Ferns growing on limestones were differentiated by the value of factor 1, which related positively to Ca and Mg. Ferns growing on granites also were differentiated by the value of factor 1, which was negatively related to Cd, Pb, and Mn. Ferns growing on

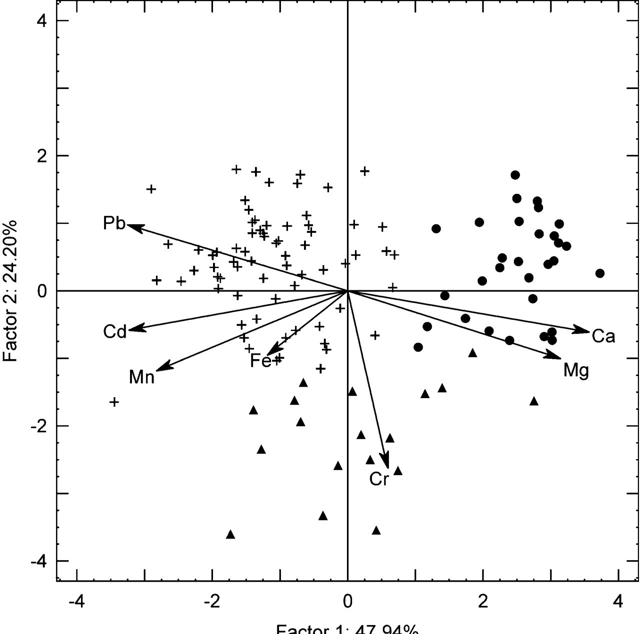

Fig. 1 Ordination of the 132 sampling sites by *PCCA* based on concentrations of elements in *Athyrium distentifolium* and projection of the concentrations of metals in ferns onto the factor plane; ▲ = granites, + = limestones, ● = sandstones

sandstones were differentiated by the value of factor 2, which was negatively related to Cr.

Ordination with PCCA resulted in a classification of the ferns from the Tatra mountains which was similar to that obtained by MBA (Table 3). Both analyses yielded the same elements that distinguished ferns growing on the same type of parent rock. MBA delivered more information on the relations between concentrations of elements in the ferns and the type of bedrock than PCCA, because MBA revealed not only the dominant elements (as PCCA did) but also elements with lower concentrations in ferns, in relation to a particular substrate. The highest concentrations of Ca and Mg were found in ferns on limestones, while the highest concentrations of Cd, Mn, and Pb were found in ferns on granites, and the highest concentration of Cr was found in ferns on sandstones. The lowest concentrations of Cd, Fe, Mn, and Pb were found in ferns on limestones (Table 3).

MBA is an undirected method, which does not require choosing specific items and finding their associations with other items, and also can reveal associations that may not have been expected by the investigator. In addition, data for this analysis are allowed to have certain characteristics, such as very large numbers of records, sparseness, and heterogeneity (Orson and Delen 2008). MBA as a data mining method was designed for the analysis of large data sets, thus making it useful for the data sets created by ecologists (McIntosh et al., 2007). We showed that MBA is a useful method for analyzing bioaccumulation of elements in plants and relations between plants and their environment. MBA possibly could discover associations and correlations among items in large data sets collected on a national or even larger scale. A disadvantage may be the necessity to group data before analysis, as was done in our investigation.

Saliva consists of macromolecular compounds and small organic substances, including volatile organic compounds (VOCs), but the composition and functions of VOCs are not as well defined as some macromolecules. Saliva includes antibacterial, anti-viral, and antifungal proteins, such as lysozyme, lactoferrin, peroxidases, carbonic anhydrase, cystatins (cysteine proteinase inhibitors), and secretory immunoglobulin A. Antimicrobial peptides, histidine-rich histatins, and β-defensins, also are found in saliva from inflammation sites (Marcotte and Lavoie, 1998; Dodds et al., 2005). The von Ebner gland protein (VEGh), a member of the lipocalin family, represents one of the several saliva components that also are present ubiquitously in other body secretions (e.g., tears and semen). Lysozyme, also found in saliva, is present in other body fluids such as blood and sweat (Nieuw Amerongen and Veerman, 2002). Digestion-aiding salivary enzymes, such as α-amylase and a human-specific, hydrophobic lipase, participate in the first step of food digestion in the oral cavity (Marcotte and Lavoie, 1998; Isenman et al., 1999). Saliva also contains glycosylated (mucin-type) proteins that are responsible for the viscous gel-like properties of saliva (Wu et al., 1994). The small organic molecules previously described in saliva include hormones, amino acids, peptides (Marcotte and Lavoie, 1998), and nitric oxide (Benjamin et al., 1994; Palmerini et al., 2003).

More than 300 bacterial species have been found in the oral cavity, which also contribute to saliva chemical composition through secretion of their metabolic by-products (Scannapieco, 1994; Marcotte and Lavoie, 1998). Analysis of the sulfur-containing volatile compounds in breath has been reported in the investigation of sources for malodors in the oral cavity, and anaerobic bacterial activity contribute particularly to malodorous breath (Ochiai et al., 2001; Rodríguez et al., 2002; van den Velde et al., 2007). Small organic compounds of environmental origin may be transported into the saliva via the digestive tract, through the lungs (Kostelc et al., 1981; Amorim and Cardeal, 2007), or via transdermal absorption through the skin into the blood stream, followed by filtration into saliva (Jimbo, 1983; Jiang et al., 1996; Cross et al., 1997; Chatelain et al., 2003).

Several papers report comparative measurements in plasma and saliva for single organic compounds such as steroid hormones or their metabolites at relatively high concentrations (Hill et al., 2001; Jönsson et al., 2003; Contrerars et al., 2004; Kumar et al., 2005; Higarshi et al., 2007). Additionally, drug metabolite measurements in pharmacokinetic (Matin et al., 1974; Guo et al., 2007) and forensic studies (Lo Muzio et al., 2005; Gognard et al., 2006) have been reported in saliva. Samyn et al. (2007) recently reviewed various analytical procedures when using oral fluids in drug abuse investigations. However, there are relatively few reports on the endogenous volatile compounds in saliva. Lochner et al. (1986) report finding 39 compounds after solvent extraction and derivatization followed by gas chromatography-mass spectrometry (GC-MS). This approach is relatively tedious and, therefore, not suitable for a large number of analyses. Sastry et al. (1980) have reviewed different analytical methods for measuring VOCs in the salivary headspace by gas chromatography. However, these approaches are not applicable for a large number of analyses. Ligor (2009) recently reviewed preconcentration methods used in breath analysis, including solid-phase microextraction (SPME) methods.

In a previous study, we described the VOC profiles found on human skin (Soini et al., 2006; Penn et al., 2007), and in the present work we examined the VOCs in saliva samples from the same large group of subjects living in the Austrian Alps (Penn et al., 2007). As a prelude to systematic studies of a human population, it was necessary to develop a reliable analytical procedure for the large number of samples. We describe here an efficient and precise quantitative method for screening the native volatile compounds present at low levels in human saliva. We used a novel static stir bar sorptive extraction step followed by chemical analysis by GC-MS. The data from a large number of volatile compound profiles in human saliva and skin were evaluated by using a previously described chemometric pattern recognition technique (Dixon et al., 2006, 2007; Penn et al., 2007; Xu et al., 2007). The analytical method may have further potential in physiological, metabolic, pharmacokinetic, environmental, and forensic applications that require high analytical throughput and high sensitivity in analyzing various volatile compound levels in human saliva.

Methods and Materials

Sample Collection Saliva samples were collected in a non-stimulated fashion from 175 healthy volunteers within a geographically distinct area in a village in the Austrian Alps (Penn et al., 2007). Subjects did not have any dietary restrictions. Their food intake was documented in a questionnaire, and they were instructed to rinse their mouths with water before saliva collection, without brushing their teeth or using any mouthwashes. After 5 min of the water rinse, about 3 ml of saliva per person were accumulated in a plastic container by spitting. Samples were frozen at −20°C until analyses.

Reagents and Materials All analytical standard compounds were purchased from Sigma-Aldrich/ Fluka Chemical Company (Milwaukee, WI, USA) or TCI America (Portland, OR, USA). Stir bars (Twister™, 10 mm, 0.5 mm film

thickness, 24-μl polydimethylsiloxane (PDMS) volume) used for sample collection were provided by Gerstel GmbH (Mülheim an der Ruhr, Germany). The stir bars were conditioned prior to and between individual runs in the TC-2 tube conditioner (Gerstel GmbH) at 300°C under a purified stream of helium. Saliva samples (0.5 ml) were placed in 10-ml headspace vials (Gerstel) with screw caps equipped with high purity silicon/PFTE septa (Gerstel). Samples were diluted with 2.0 ml of high-purity water (OmniSolv®, EM Science, Gibbstown, NJ, USA). As an internal standard, 8 ng 7-tridecanone (Aldrich) were added in 5 μl of methanol (Baker Analyzed, Mallinckrodt Baker, Inc., Phillisburg, NJ, USA) to each vial, followed by the addition of a preconditioned stir bar into the liquid phase. The vials were closed and were subsequently incubated at 40°C for 3 h in an oven. The sampling bars were not stirred, but rather equilibrated in the vials in a static mode. After sampling, stir bars were rinsed with high-purity water (OmniSolv®), dried with paper tissue, and placed in thermal desorption autosampler device (TDSA) tubes for the analysis. After the analysis, TDSA tubes were washed with 50% OmniSolv® acetonitrile (EMD Chemicals, Darmstadt, Germany) in water containing 0.1% trifluoro-acetic acid (99%, Aldrich Chemical Company, Milwaukee, WI, USA), followed by a rinse with high-purity Omni-Solv® water and acetone (EMD Chemicals), and dried in the oven at 85°C for 60 min.

Analytical Instruments The GC equipment consisted of an Agilent 6890N gas chromatograph connected to the 5973i MSD mass selective detector (Agilent Technologies, Inc., Wilmington, DE, USA). Positive electron ionization (EI) mode at 70 eV was used with the scanning rate of 4.51 scans/sec over the mass range of 35–350 amu. The MSD transfer line temperature was set at 280°C. The ion source and quadrupole temperatures were set at 230°C and 150°C, respectively. Samples were thermally desorbed in a TDSA automated system (Gerstel), followed by injection into the column with a cooled injection assembly, CIS-4. The TDSA was operated in splitless mode. The TDSA temperature program for desorption was 20°C (hold for 0.5 min), then a 60°C/min ramp to 250°C (final hold of 3 min). Temperature of the transfer line was set at 280°C. The CIS-4 was cooled with liquid nitrogen to −80°C. After desorption and cryotrapping, CIS-4 was heated at 12°C/sec to 280°C, with the hold time of 10 min. The CIS-4 inlet was operated in the solvent vent mode, a vent pressure of 14 psi, a vent flow of 50 ml/min, and a purge flow of 50 ml/min. Compounds in the samples were separated on a DB-5MS [20 m × 0.18 mm, i.d., 0.18 μm film thickness] capillary column from Agilent (J&W Scientific, Folsom, CA, USA). The temperature program in the GC operation was 50°C for 1 min, then increased to 160°C at a rate of 5°C/min, followed by the second ramp at a rate of 3°C/min to 200°C (hold time: 10 min). The carrier gas head pressure was 14 psi (flow rate, 0.7 ml/min at constant flow mode and under retention time-locking conditions).

Data Analysis Saliva and skin volatile compound data were combined and evaluated with a newly developed chemometric pattern recognition method as described in Dixon et al. (2006); Penn et al. (2007); and Xu et al. (2007).

Method Development and Optimization All volunteers for the initial optimization study provided informed consent to participate in this study (05-9661), as approved by the Indiana University Bloomington Institutional Review Board. Saliva samples from healthy donors (by their own recognition) first were pooled and 0.5 ml aliquots were used for method development. The highly viscous sample matrix appeared to retain small organic volatile compounds, effectively competing with the PDMS material used in sorptive extraction. We learned this when stir bar extraction with stirring in the aqueous phase resulted in low recoveries and a high variation in the peak areas (40–50% relative standard deviation, RSD). Similar results were obtained by using a conventional headspace approach (Soini et al., 2005) with the stir bars. When the saliva samples and stir bars were set in the extraction vials at elevated temperatures for 1 hr without stirring (35 and 40°C), the recoveries increased, but peak area variability still exceeded 20% (RSD). At 40°C, extraction times of 1, 2, 3, and 4 hr revealed that peak areas reached the maximum plateau with a 3-h extraction time (data not shown), whereas the reproducibility of peak areas was less than 5% (RSD, N=4) for most of the compounds.

Results

Reproducibility Chromatographic analysis of seven selected salivary components in a pooled sample showed relatively good within-day reproducibility (Table 1). An internal standard was not added to the aliquots of pooled saliva. The long-term reproducibility of the method is reflected in the consistent variability (RSD=14.7%) in integrated peak area of the internal standard during an analysis of 175 samples (Fig. 1).

Characterization of Volatile Organic Compounds (VOCs) in Saliva In our previous report of the axillary skin VOCs for the same subject group, we found 373 repeatedly appearing compounds on the skin among about 5,000 VOCs for the 196 subjects (Penn et al., 2007). The chemometric data evaluation of the 175 salivary VOC profiles [consisting typically of

[b] Tentative identification

100–300 peaks (Dixon et al., 2006; Penn et al., 2007)], revealed that 166 of the 373 compounds from the constant axillary sweat compound group (i.e., 44.5%) also were found in saliva. We identified or tentatively identified 90 saliva VOCs (Table 2) among the 166 compounds that were found in common to saliva and skin (Penn et al., 2007). Thus, among the compounds in common, 76 remain unidentified. There was a substantial profile variability of total ion chromatograms (TIC) among the individual saliva samples (Fig. 2). All lactones, and amides (100%) and nearly all carboxylic acids (89%) and aldehydes (83%) found in the group of constant compounds on skin also were present in saliva. Smaller overlap was found for ketones (60%), ethers (50%), hydrocarbons (47%), esters (44%), alcohols and phenols (42%), and amines (12%). No androgen steroids were found in saliva, possibly due to the low detection limits.

Discussion

Individual variability observed among the salivary VOC profiles likely is due to several variables, including personal habits such as diet, environment, and genetics. Interestingly, almost half of the repeatedly appearing 373 VOCs on the skin found in the previous study (Penn et al., 2007) also were found in saliva. This suggests that these compounds could be endogenous. Because of the many possible entry routes for VOCs into the salivary flow, elucidation of their origin and route of entry is likely to be a difficult and complex task. For example, small organic compounds, such as pharmaceuticals, can move from blood to saliva via passive transcellular diffusion, ultrafiltration, or active transport mechanisms. Lipophilicity and molecular weight of the compounds of interest are among properties that influence the blood-saliva transfer rate (Höld et al., 1995). Targeted metabolic experiments containing a particular compound could verify some of the hypothesized excretion routes into saliva through the body and clarify which compounds are exogenous (externally transferred) or endogenous (internally transferred) in origin.

Salivary VOC composition could be an excellent indicator of environmental and occupational chemical exposure through transdermal absorption, inhalation through lungs, or via food intake. Environmental exposure to phthalates has been well documented in different body fluids. Multifunctional phthalate compounds can originate from soaps, shampoos, cosmetics, plastics, paints, and pesticide formulations. Their metabolites have been found

[a] Tentative identification

in human urine (Silva et al., 2004a), breast milk (Calafat et al., 2004), amniotic fluid (Silva et al., 2004b), serum (Kato et al., 2003), and saliva (Silva et al., 2005). In general, salivary sampling is a less invasive alternative compared to serum collection for many biomedical applications (Cook, 2002; Gröschl and Rauh, 2006; Chiappin et al., 2007).

Certain limitations may pertain in sampling for sufficient volumes of saliva from infants, geriatric subjects, or subjects with certain physiological states that cause reduced saliva production (Granger et al., 2007). Saliva collection methods also may influence sample composition and induce interference to the analytical methods. Stimulated (e.g., by chewing gum) vs. non-stimulated saliva flow, or use of certain devices such as cotton balls or swabs placed in mouth can influence the final composition of the saliva (Gröschl and Rauh, 2006; Schipper et al., 2007). In this study, a non-stimulated saliva collection approach was chosen because stimulating agents and polymer-containing collection devices could introduce further contaminants in the analysis of the innate salivary VOC analysis.

In summary, the static stir bar extraction method for analyzing small organic compounds in saliva provided a sensitive and precise analytical approach for a large variety of compounds with different functional groups. The long-term reproducibility of the method allowed the analysis of a large number of samples in a high-throughput fashion. In this study, there was a large number of volatile compounds identified in saliva from a group of 175 subjects that were in common with components in previously analyzed sweat samples from the same subject group. This suggests that saliva presents a systemic body fluid that is potentially suitable for monitoring small organic compounds in physiological, metabolomic, pharmacokinetic, forensic, and toxicological studies.

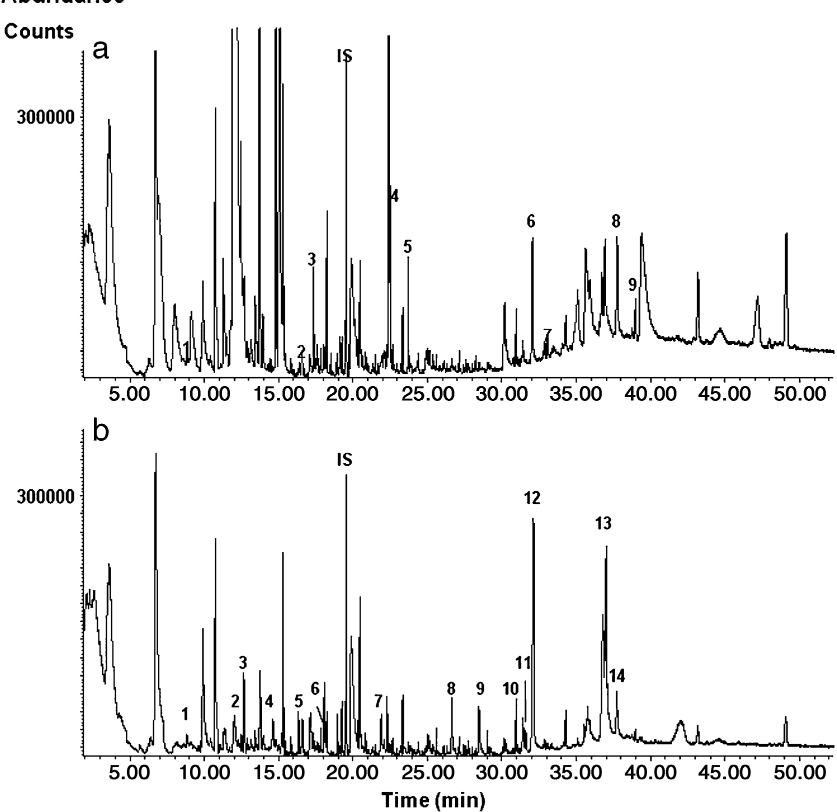

Fig. 2 Representative GC-MS total ion chromatograms of salivary VOC profiles from two subjects from different families: **a**: a female, and **b**: a male. Analytical conditions are described in the text. Numbers and names for selected compounds are **a**: 1=acetophenone, 2=eugenol, 3=β-caryophyllene, 4=hexadecane, 5=methyldihydro-*cis*-jasmonate, 6=hexadecanoic acid, 7=ethyl hexadecanoate, 8=oleic acid, 9=docosane and **b**: 1=acetophenone, 2=γ-heptanolactone, 3=decanal, 4=nonanoic acid, 5=nicotine, 6=tetradecane, 7=dodecanoic acid, 8=tetradecanoic acid, 9=caffeine, 10=methylhexadecanoate, 11=9-hexadecenoic acid, 12=hexadecanoic acid, 13=oleic acid, 14=octadecanoic acid. Introduction

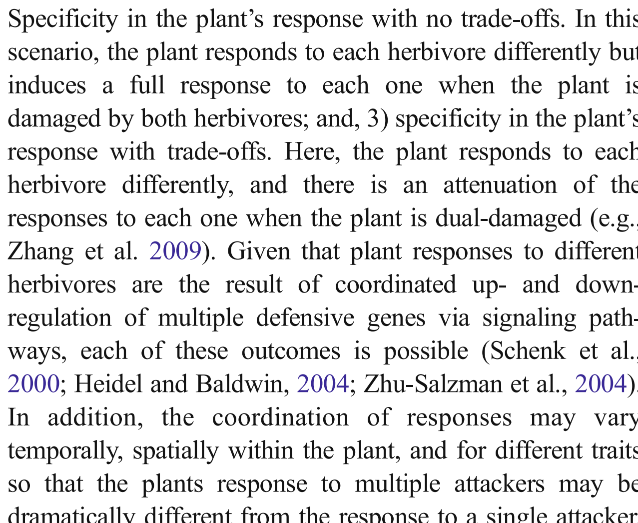
Plants frequently are attacked by more than one herbivore species at the same time (e.g., Strauss, 1991; Vos et al., 2001; Hufbauer and Root, 2002). Specific plant responses can be related to feeding by insects from different feeding guilds (Walling, 2000), and can manifest themselves at different levels of biological integration, including transcriptional, biochemical, and organismal levels. Feeding by chewing caterpillars causes severe damage to plant tissues, most often accompanied by severe tissue loss. In addition, elicitors of plant defenses, including various fatty acid-amino acid conjugates, have been isolated from caterpillar regurgitant (Alborn et al., 1997; Pohnert et al., 1999; Halitschke et al., 2001). Mechanical wounding and elicitors in the caterpillar's oral secretions activate the jasmonate pathway, leading to the production of jasmonic acid (JA) and induction of defenses against many challengers (Farmer and Ryan, 1992; Karban and Baldwin, 1997; McCloud and Baldwin, 1997; Ohnmeiss et al., 1997; Moura and Ryan, 2001).

Compared to chewing caterpillars, phloem feeders cause limited tissue damage (Walling, 2000). Phloem-feeding insects, such as whiteflies and aphids, frequently activate the salicylic acid (SA) signaling pathway (Kempema et al., 2007; Zarate et al., 2007), and can manipulate resources within a plant by acting as sinks, causing increased translocation of nutrients to the attacked tissue (Walling, 2008). In addition, aphids secrete various, potentially signaling hydrolytic enzymes into the phloem during feeding including pectinases, glucosidases, peroxidases, and lipases (Miles, 1999; Mutti et al., 2008; De Vos and Jander, 2009). Aphids can not only alter localized expression of genes associated with the SA-dependent pathway, like pathogenesis-related (PR) proteins (Moran and Thompson, 2001; Martinez de Ilarduya et al., 2003; Zhu-Salzman et al., 2004), but also JA-dependent genes, such as proteinase inhibitors (PI) (Martinez de Ilarduya et al., 2003; Voelckel et al., 2004). Aphid-dependent regulation of gene expression also can act systemically on JA- and SA-associated genes (Martinez de Ilarduya et al., 2003; Heidel and Baldwin, 2004; Voelckel et al., 2004), as well as on several housekeeping genes (Divol et al., 2005). However, some studies have not found significant systemic induction of PI (Heidel and Baldwin, 2004) or PR proteins (Divol et al., 2005) by aphids.

How plants cope with multiple co-occurring species of herbivores can be critical in insect-plant interactions (Shiojiri et al., 2001; Vos et al., 2001; Rodriguez-Saona et al., 2003, 2005; Dicke et al., 2009; Zhang et al., 2009). Plant responses to attack by multiple species of herbivores may result in three possible outcomes: 1) an additive response due to a lack of response specificity to different herbivores; 2)



Specificity in the plant's response with no trade-offs. In this scenario, the plant responds to each herbivore differently but induces a full response to each one when the plant is damaged by both herbivores; and, 3) specificity in the plant's response with trade-offs. Here, the plant responds to each herbivore differently, and there is an attenuation of the responses to each one when the plant is dual-damaged (e.g., Zhang et al. 2009). Given that plant responses to different herbivores are the result of coordinated up- and down-regulation of multiple defensive genes via signaling pathways, each of these outcomes is possible (Schenk et al., 2000; Heidel and Baldwin, 2004; Zhu-Salzman et al., 2004). In addition, the coordination of responses may vary temporally, spatially within the plant, and for different traits so that the plants response to multiple attackers may be dramatically different from the response to a single attacker.

Trade-offs in plant response can occur when different defense pathways are induced simultaneously, and there is increasing evidence that specifically the SA and JA signaling pathways can mutually affect each other. For instance, SA suppresses JA-dependent defense gene expression, either through inhibiting JA synthesis or its action (Doares et al., 1995). Similarly, induction of the JA pathway often inhibits the induction of the SA pathway (Stout et al., 1998; Preston et al., 1999; Felton et al., 1999; Paul et al., 2000; Thaler et al., 2002; Mur et al., 2006). Stout et al. (1998) showed that the negative effects of methyl jasmonate, a volatile derivative of JA, on beet armyworm caterpillar growth were eliminated by exposure of treated plants to SA. These trade-offs can occur as a result of simultaneous attack by herbivores and pathogens, and potentially when attacked by herbivores with different feeding habits (Stout et al., 2006). For example, growth rates of beet armyworm caterpillars increased when feeding on tomato plants previously fed upon by potato aphids compared to control plants (Stout et al., 1998).

In tomatoes (*Solanum lycopersicum* Mill.), caterpillars and aphids induce different plant responses. The beet armyworm, *Spodoptera exigua* (Hübner), induces the production of a variety of plant defenses including PIs (Broadway et al., 1986) via the jasmonate-signaling pathway (Thaler et al., 2002). In contrast, Fidantsef et al. (1999) found that feeding by the potato aphid *Macrosiphum euphorbiae* (Thomas) and the green peach aphid *Myzus persicae* Sulzer on tomato plants induces local expression of lipoxygenase and PR protein P4, but does not induce PI II. In a previous study, we investigated how single attack or attack by both beet armyworm caterpillars and potato aphids influence the adult preference and caterpillar performance of beet armyworm and its parasitoid *Cotesia marginiventris* (Cresson) in tomato plants (Rodriguez-Saona et al., 2005). We demonstrated that caterpillars and aphids induce different levels of plant resistance, but also

that dual-damaged plants were phenotypically distinct from plants damaged by either herbivore alone. For example, relative to undamaged plants, oviposition by moths was lower on caterpillar-damaged plants and higher on aphid-damaged plants compared to undamaged controls. Plants damaged by both herbivores, however, received equal oviposition as control plants. The widespread evidence across systems that aphids induce the salicylate pathway (e.g., Martinez de Ilarduya et al., 2003; Zhu-Salzman et al., 2004) suggests that aphid feeding may compromise resistance to caterpillars. Thus, we hypothesized that the plant's defensive response to caterpillars was weakened when aphids also fed on the plant.

In this study, we tested this hypothesis by employing an approach that integrates gene expression (microarray analysis and quantitative real-time PCR (qRT-PCR)) and biochemical measures (leaf carbon: nitrogen, protein quantification, and PI activity) with insect performance assays. Consistent with our hypotheses, we find a high level of attenuation and suppression of genes in dual-damaged plants compared to those that are damaged by a single herbivore.

Methods and Materials

Plants and Insect Colonies

Seeds of tomato plants (*S. lycopersicum* var. Castlemart) were planted in 500 mL pots filled with soil mix and 5–10 pellets of Nutricote (13-13-13 N-P-K). Plants were grown in a greenhouse between January and July under natural light supplemented with 400-W sodium halide lamps, watered daily, and fertilized weekly with a 15-20-15 N-P-K fertilizer. Plants, 25−27 d after planting, with two fully expanded leaves were used for experiments.

Two generalist insect herbivores were used to damage the tomato plants: the beet armyworm (*S. exigua*) and the potato aphid (*M. euphorbiae*). Beet armyworm caterpillars were obtained from the USDA Laboratory, Stoneville, MS, USA, and reared on an artificial diet (Southland Products, Lake Village, AR, USA) at room temperature (25°C). Potato aphids were collected in Southern Ontario from tomato plants and maintained on tomato plants in an environmental chamber (23°C, 14:10 L:D, and 60% relative humidity).

Experimental Treatments

Treatment procedures followed those described in Rodriguez-Saona et al. (2005). Plants (N=128) were randomly assigned to one of the following four treatments: (1) undamaged (control) plants; (2) plants damaged by 40 adult aphids on leaf 1; (3) plants damaged by one 3rd instar *S. exigua* caterpillar on leaf 2; and (4) simultaneous attack by both herbivores as in treatments 2 and 3. Leaves were numbered from the bottom of the plant, with the oldest leaf designated as "leaf 1." Please note: i) leaves 1 and 2 are strongly connected to leaf 3, but both leaves are only weakly connected to each other (Stout et al., 1996; Rodriguez-Saona et al., 2005); ii) the location of feeding, i.e., whether aphids or caterpillars fed on leaf 1 or 2, had no effect on the way leaf 3 responded to damage by these two herbivores (Rodriguez-Saona et al., 2005); and iii) there was no difference in the amount of leaf damage in the caterpillar only and dual damage treatments (Rodriguez-Saona et al., 2005). Both herbivores were confined to leaves 1 and 2 using spun polyester sleeves (35 cm wide×45 cm long) (Rockingham Opportunities Corporation, Reidsville, NC, USA). Control plants had sleeves but no herbivores.

Immediately after placing the insects on the plants, plants were transferred to a growth chamber (23°C, 14:10 h L:D, and 60% relative humidity, and a light intensity of 430 μmol/m^2/sec) for 5 d, a duration sufficient to induce systemic plant defenses (Rodriguez-Saona et al., 2005). After 5 d, plants had at least 4 fully-expanded leaves. Individual leaflets from leaf 3 of each plant (N=6, 8, 8, and 10 per treatment for trials 1, 2, 3, and 4, respectively) then were excised and used for either carbon and nitrogen analysis, total protein analysis, PI analysis, or gene expression analysis with cDNA tomato microarrays and quantitative RT-PCR. Leaflets from the same position of leaf 3 were used for each analysis. In addition, a leaflet from leaf 4 from each plant was used to conduct performance assays; similar to leaf 3, leaf 4 shares vascular connections with leaves 1 and 2 (Orians et al., 2000; C.R-S. unpublished data). The entire experiment was replicated 4 times (except for protein and PI which were replicated three times). Because aphids and caterpillars were placed on leaves 1 or 2 and the molecular, biochemical, and organismal measures were done on leaves 3 and 4, all the effects and interactions reported herein are systemic.

Gene Expression

Leaflets from leaf 3, taken from 5 different plants of the same treatment, were combined for each replicate (N=4 per treatment) and flash-frozen in liquid nitrogen for gene expression analyses. Tomato microarray chips (TOM 1 array) were purchased from the Boyce Thompson Institute (http://ted.bti.cornell.edu). The microarray target preparation and hybridization methods followed Dr. David Galbraith's (University of Arizona) protocols located at websites: http://www.maizearray.org/ and http://ag.arizona.edu/~dgalbrai/, and the instructions are paraphrased below.

Purification of tRNA and mRNA

Total RNA was extracted with Trizol reagent (Invitrogen, Carlsbad, CA, USA) from 5 g of powdered tomato leaf tissue for each treatment following the manufacturer's procedures. mRNA was purified from the total RNA samples using the Oligo (dT) Dynabead approach (Dynal Biotech, Inc., Lake Success, NY, USA) according to the manufacturer's protocol. We purified a minimum of 3 μg of mRNA in 4 rounds of purification of the total RNA through Oligo (dT) Dynabeads. Purified mRNA was stored at –70°C.

Direct Labeling of mRNA

Three μg of mRNA from each sample were reverse transcribed with Superscript II (Invitrogen) to produce one of two fluorescence-labeled targets, Cy3-dUTP or Cy5-dUTP (1 mM) (Amersham Biosciences, Piscataway, NJ, USA). Labeled cDNA was purified with Microcon YM30 columns (Millipore, Billerica, MA, USA). As an additional control, we included a dye-swap reversal for each treatment.

Hybridization of the Labeled cDNA to the Microarray Slides

The Cy3- and Cy5-labeled cDNA targets were denatured and subsequently hybridized onto preheated cDNA tomato microarray slides for 10 h at 60°C. The slides were washed according to the microarray hybridization protocol and dried prior to being scanned. A loop design was used for the hybridization scheme such that each sample was hybridized with every other as well as dye reversals for each of the samples. Eight true biological replicates of each treatment, including dye-swaps, were hybridized onto the microarrays. Ultimately, 6, 6, 7, and 3 samples of undamaged, aphid-damaged, caterpillar-damaged, and dual-damaged plants, respectively, were represented by the successful hybridizations.

Microarray Scanning and Analyses

The dry slides were scanned with a Gene Pix 4100 A (Axon Molecular Devices, Union City, CA, USA) at Western Illinois University. The laser intensity of the microarray scanner was set by the manufacturer. The photomultiplier detector was set such that the overall intensities of the scanned features for the two scanned images on a single microarray slide were close to equal. In addition, the detector was set at the highest level while maintaining the overall intensity below saturation. The scanned images were further normalized using the ratio of medians following the procedures outlined in the Acuity® 4.0 software (Axon Molecular Devices).

Each microarray slide was scaled to the slide with the highest signal intensity using Microsoft Excel. We ln-transformed the data and used the Acuity® 4.0 software to perform a one-way ANOVA for Multiple Groups, and then a 2-tailed *t-test* after testing the variance for each gene. The statistical cut-off used to assay significant genes was a *P*-value of ≤0.05 and at least a two-fold change in expression. The raw data are available in Table S1 (Supplemental Material). Genes that were statistically significant were organized further by hierarchal clustering using Acuity® 4.0 software. Genes were classified into biologically significant groups by using information about their known or expected function obtained though several search engines, gene databases, and protein databases. These protein databases included UniProt—Swiss-Prot Protein Knowledgebase (http://ca.expasy.org/sprot/) through The ExPASy (Expert Protein Analysis System) proteomics server of the Swiss Institute of Bioinformatics (SIB). We also searched the Entrez Gene through the National Center for Biotechnology Information at http://www.ncbi.nlm.nih.gov, which provided Gene References Into Function (GeneRIFs).

Quantitative Real-time PCR (qRT-PCR)

To validate the microarray results, we conducted qRT-PCR for the following herbivore defense-related genes: arginase, wound-induced PI II CEV 157, threonine deaminase, wound-induced PI I and II, lipoxygenase, and polyphenol oxidase D and F. Total RNA isolated during the RNA purification procedure described above was treated with TURBO DNase (Ambion, TX, USA) to remove any remaining DNA. DNase was inactivated and removed, and RNA was further purified by the RNeasy RNA cleanup MinElute columns (Qiagen, Hilden, Germany) according to the manufacturer's recommendations. RNA quantity was analyzed photospectrometrically, and RNA integrity was determined with RNA 6000 Nano Chips run on an Agilent 2100 Bioanalyzer (Agilent, Waldbronn, Germany). Subsequently, 400 ng of DNA-free total RNA were converted into single-stranded cDNA by using a mix of random and Oligo-dT primers according to the ABgene protocol (ABgene, Epsom, UK). Gene-specific primers were designed with the Primer3 software (http://frodo.wi.mit.edu/primer3) on the basis of sequences obtained for the genes of interest and 4 potential housekeeping genes (RPS18A, actin, beta-tubulin, eIF4A-2) to serve as the endogenous control ('normalizer'). qRT-PCR was done in optical 96-well plates on a MX3000P Real-Time PCR Detection System (Stratagene, La Jolla, CA, USA) using the Absolute™ QPCR SYBR® green Mix (ABgene) to monitor double-stranded DNA synthesis in combination with ROX as a passive reference dye included in the PCR master mix. A dissociation curve analysis was performed

for all primer/probe pairs, and all experimental samples yielded a single sharp peak at the amplicon's melting temperature. Furthermore, we tested the four housekeeping genes as invariant endogenous controls in the assay to correct for sample-to-sample variation in qRT-PCR efficiency and errors in sample quantitation, and found that both actin and eIF4A-2 performed best as endogenous controls ('normalizer'). The dynamic range of a given primer/probe system and its normalizer was examined by running triplicate reactions of five different RNA concentrations. Since the target and normalizer had similar dynamic ranges, the comparative quantitation method (ΔΔCt) was used, and data were transformed to absolute values with $2^{-\Delta\Delta Ct}$ for obtaining fold changes between treatments.

In addition, 5 stress-related genes (dehydrin, ethylene precursor 1-aminocyclopropane-1-carboxylate oxidase, allene oxide cyclase, peroxidase, and acidic endochitinase) and 3 pathogenesis-related genes (glutathione S-transferase, PR4, and PR-1A1) were validated by qRT-PCR. The same protocol described above was used, except that 400 ng of total RNA were converted into single-stranded cDNA by using a mix of random and Oligo-dT primers following the Verso™ SYBR® Green 2-Step qRT-PCR Low Rox Kit protocol (Thermo Fisher Scientific, Rockford, IL, USA). Then qRT-PCR was done in optical 96-well plates on a StepOnePlus Real-Time PCR System (Applied Biosystems, Foster City, CA, USA). Quantification was performed on three biological replicates for each treatment.

Relative fold changes for each gene were compared to the aphid treatment, which was set to one. qRT-PCR fold change (relative to controls) was analyzed by using a one-way ANOVA with JMP (Sall and Lehman, 1996), followed by a Fisher's Least Significant Difference (LSD) test to assess separation of fold differences.

Carbon and Nitrogen

Leaflets for total leaf carbon and nitrogen analyses were oven-dried at 60°C for 48 h. Carbon and nitrogen concentrations were measured with 5 mg of dried ground leaf material by micro-combustion in an Elemental Combustion System 4010, CHNS-O analyzer (Costech Analytical Technologies, Valencia, CA, USA).

Total Protein

To determine total protein content, we followed methods modified from Jones et al. (1989). Buffer-soluble protein was extracted by homogenizing weighed leaf samples in 0.5 ml of 0.1 M NaOH (pH 11.8). The samples were vortexed for 3 sec and incubated at room temperature for 30 min. After incubation, samples were vortexed again and centrifuged at 11,000 rpm for 10 min at room temperature. Five µl of supernatant were mixed with 250 µl of Bradford reagent (Coomassie brilliant blue) in a cuvette, and the absorbance was measured at 595 nm. Total protein (mg of protein per gram of tissue sample) was calculated using a standard of bovine serum albumin in 0.1 M NaOH.

Proteinase Inhibitors

We measured the plant's ability to inhibit the hydrolysis of the artificial substrate azocasein by commercial trypsin in our four treatments. The procedure followed methods described in Rodriguez-Saona et al. (2005). Samples were ground in Tris HCl (pH 7.8) extraction buffer (3 µl/mg fresh weight), vortexed for 3 min, and centrifuged at 11,000 rpm for 10 min at 10°C. Sixty µl of the supernatant were added to 20 µl of Tris buffer, 50 µl of 2% azocasein in Tris buffer, and 20 µl of a 0.001 M HCl solution containing 200 ng of trypsin. A set of controls with no sample also was prepared for each sample using an identical procedure and adjusting the total volume with the Tris buffer. After incubation for 20 min at 28°C, 100 µl of trichloroacetate (100% w/v) were added to denature the substrate and stop the reaction. Samples then were centrifuged for 10 min at 8,000 rpm. One hundred µl of 1 M NaOH were added to 100 µl of the supernatant from each sample, and absorbance was measured at 450 nm. The activity of trypsin inhibitor is reported as one minus the percent ratio of sample to control absorbance (Orians et al., 2000).

Performance Assays

No-choice bioassays were conducted to test whether prior damage by aphids, caterpillars, or both herbivores differentially affected the performance of beet armyworm caterpillars compared to undamaged plants. Neonates were placed individually in 90-mm Petri dishes lined with moist filter paper and allowed to feed for 5 d on leaflets from one of the four treatments described above. All leaflets were excised from leaf 4. Petri dishes were kept at room temperature. Each trial had a total of 10 caterpillars per treatment ($N=40$) and was repeated 4 times. On day 5, all live caterpillars were weighed and mortality was recorded.

Statistical Analyses of Biochemical and Organismal Assays

The effects of aphids, caterpillars, and trial, and their interactions, on total leaf carbon:nitrogen ratio, total protein, PI activity, and caterpillar mass were analyzed using ANOVA (Systat 1998; SPSS Science, Chicago, IL, USA). *Post-hoc* pair-wise comparisons between treatments were performed using LSD tests. Percent data were arcsin-square root transformed and caterpillar mass were ln-

transformed prior to analysis to meet assumptions of normality and homogeneity of variance. Mortality data were analyzed using *G*-tests.

Results and Discussion

Gene Expression: Specificity of Induction

Specificity in the tomato responses to aphids and caterpillars at the transcriptomic level was detectable, and is represented in the microarray analysis where beet armyworm caterpillars induced the systemic expression of different genes than potato aphids (Fig. 1; Table 1). Herbivory systemically up- or down-regulated approx. 2% of the genes on the Cornell array (277 out of 13440) (Table S1). Eighty percent of the genes (222 out of 277) were up- or down-regulated by only one of the herbivores, confirming substantial specificity of the plant responses. Aphid feeding changed expression of 2.8 times more genes compared to caterpillar feeding (239 vs. 85, respectively) (Fig. 1). Ninety-three genes were up-regulated by aphid feeding, while 56 genes were up-regulated by caterpillar feeding compared to controls; twenty-five of these genes were up-regulated by both aphids and caterpillars (Fig. 1). One hundred and forty six genes were down-regulated by aphids, while 29 genes were down-regulated by caterpillars compared to controls; twenty-two of these genes were down-regulated by both herbivores (Fig. 1). Dual-damage induced changes in 11 genes; 8 of them were also induced by caterpillars alone, while the other 3 genes were induced by both caterpillars and aphids when feeding alone, and the expression of none of these genes was enhanced compared to when damaged by a single herbivore (Table 1).

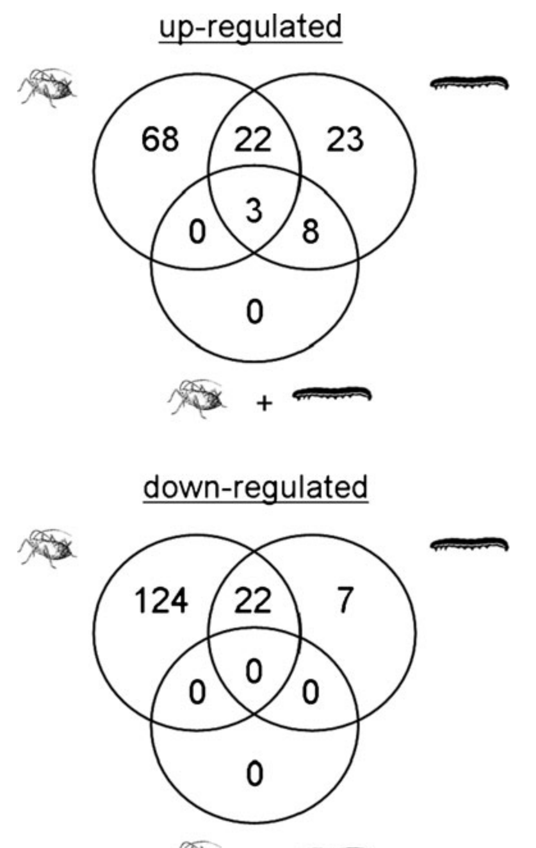


Fig. 1 Venn diagrams of the numbers of overlapping and non-overlapping transcriptional responses of tomato genes up-and down-regulated by aphids, caterpillars, or aphids and caterpillars. Numbers are up- or down-regulated genes that met our combined criteria of a minimum of 2-fold change in gene expression and a significant ANOVA (*P* values≤0.05)

Of all of the genes assayed, the most strongly systemically induced by herbivory were those related to herbivore defense, but gene expression was altered in many functional categories (Table 1). Seven herbivore defense-related genes were systemically induced by caterpillar feeding >10-fold greater than controls; including genes encoding for polyphenol oxidases, threonine deaminase, and an array of different protease inhibitors (Table 1A). These defense genes often are associated with the JA pathway (Fidantsef et al., 1999). In contrast, aphid feeding increased expression of fewer herbivore defense-related genes and to a much lesser extent than following caterpillar feeding (<6-fold induction).

Induction of pathogenesis-related proteins such as PR-1A1 and glutathione S-transferase was not specific to aphids (Table 1B). Similarly, salicylic acid methyltransferase that catalyzes the formation of methyl salicylate, the volatile derivative of SA, was induced by both herbivores (Table 1C). The lack of specificity in plant responses to aphid and caterpillar feeding in this category is surprising given previous results that aphids, but not caterpillars, are strong inducers of salicylate pathway-regulated genes (Walling, 2000). It is possible, however, for caterpillars to induce the SA pathway as shown for *S. exigua* caterpillars feeding on tobacco plants (Diezel et al., 2009). It is also possible for genes in the pathogen defense category to be regulated by JA (Li et al., 2004). An example is the translation-inhibitor protein that was strongly up-regulated by caterpillar feeding (Table 1B). Another possibility is that some of the SA pathway genes might have been missed because they may have been induced locally or soon after herbivore infestation.

Our findings are similar to a study by De Vos et al., (2005) who reported that the aphid *M. persicae* induces more *Arabidopsis* genes than the caterpillar *Pieris rapae* (L.), and a study in tobacco by Voelckel et al. (2004) that found that the magnitude of induction by *Myzus nicotianae* Blackman aphids was smaller than by the caterpillar *Manduca sexta* L.; although more genes were induced by

Table 1 Relative ratios of selected genes up- or down-regulated by aphid, caterpillar, and dual herbivory on tomato plants compared to non-wounded plants. For each gene, ratios with different letters indicate significant differences among treatments ($P \leq 0.05$)

caterpillars in the later study than by aphids. A higher number of genes were systemically down-regulated by potato aphid feeding than up-regulated in our study (146 vs. 93; Fig. 1). This is consistent with De Vos et al. (2005) who found a total of 1349 being down-regulated and 832 up-regulated by *M. persicae*. Although we did not find genes expressed only in the dual-damage treatment, we found a different pattern of gene expression in this treatment compared to aphid- and caterpillar-damage treatments (Fig. 2). In fact, our cluster analysis shows greater similarities in gene expression between dual-damaged and control plants than to those damaged by only aphids or caterpillars. Voelckel and Baldwin (2004) also found specificity in gene expression of tobacco plants singly or simultaneously attacked by a piercing-sucking mirid bug and the chewing caterpillar, *M. sexta*. In plants damaged by both herbivores simultaneously, they found a distinct transcriptional pattern from either herbivore alone. In

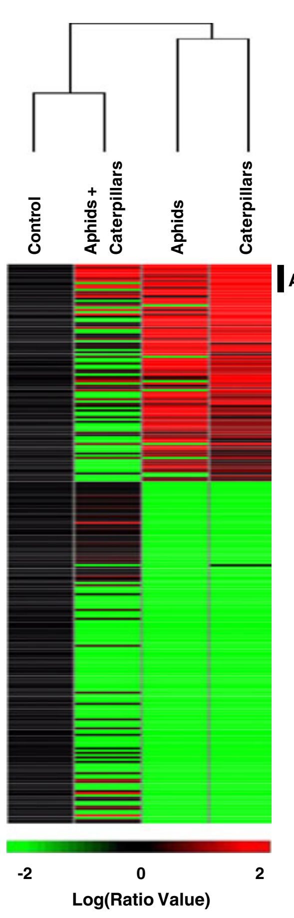

Fig. 2 Cluster analysis of the tomato genes up- and down-regulated in response to feeding by aphids, caterpillars, or aphids and caterpillars. The dendrogram on top of the cluster illustrates the relationship among the four treatments. Ratio values are calculated between herbivore-infested and non-infested control plants (set to 1). Genes up-regulated by treatment appear in red (positive log-ratio values), while those that were down-regulated appear in green (negative log-ratio values). Each row in the column corresponds to a single gene, and a color scale is presented below the figure. Letter A indicates a cluster of many of the plant defense genes associated with Table 1A

Tomato plants were damaged by aphids, by caterpillars, or by both aphids and caterpillars. All of the qRT-PCR values are normalized to the aphid treatment (set to 1). Bars indicate means±SE. Different letters represent statistically significant differences between treatments ($P \leq 0.05$). $N=3$

contrast to our finding, however, Voelckel and Baldwin's study found only specificity after the first day of feeding, not in later days, whereas our study shows specificity five days after attack. These two studies thus show distinct genetic outcomes for the integration of specific plant responses when damaged by multiple herbivores.

Gene Expression: Bi-Directional Trade-offs

Suppression of systemic gene expression in the dual-damage treatment, where expression is changed to levels no longer different from controls, was found in 58% of the genes up- or down-regulated by one herbivore (135 out of 222), indicating a high degree of trade-offs in the expression of specific responses (Table 1). These trade-offs were reciprocal and occurred across functional categories. Caterpillar feeding suppressed up- or down-regulation of 66% (127 out of 192) aphid regulated genes, whereas aphid feeding only prevented up- or down- regulation of 8 out of 30 (27%) of the genes regulated by caterpillar feeding (Table 1). The expression of 12 caterpillar-induced genes was confirmed by qRT-PCR (Fig. 3a–l). Of these 12 genes, 5 showed attenuated expression in the dual damage treatment (i.e., expression in the dual-damage treatment was less than in the caterpillar-only treatment but more than in the aphid-only treatment), while 7 showed suppression (i.e., expression in the dual-damage treatment was different from the caterpillar-only treatment but not from the aphid-only treatment).

The pattern of attenuation of expression falls into two categories: 1) in some cases, aphids had no effect on the genes independently (e.g., threonine deaminase), but reduced the response of those genes to caterpillar damage (Tables 1 and 2) more remarkably, some genes (e.g., proteinase inhibitor gene I—SGN-U143556) that are strongly up-regulated by caterpillar feeding, and weakly induced by aphid feeding, the expression in dual-damaged plants was still reduced compared to the caterpillar-only treatment (Table 1). The same was true for some genes that showed aphid-dependent regulation: caterpillar alone had no effect (e.g., MAP kinase; Table 1), but attenuated the down-regulation of these genes to aphid damage in the dual attack and some genes that were strongly down-regulated by aphid feeding and weakly suppressed by caterpillar feeding (e.g., lipase; Table 1), still were attenuated in the dual-damage treatment compared to the aphid only treatment.

Thus, although aphids may minimize the magnitude of induction of plant responses by causing little cellular damage and avoiding detection, they also reduce the plant's ability to induce the responses to caterpillar feeding. This is consistent with the "decoy hypothesis," which states that by inducing the salicylate pathway aphids can suppress the jasmonate pathway defenses to their own benefit (Zhu-Salzman et al., 2004; Thompson and Goggin, 2006; Zarate et al., 2007). Our evidence shows that aphid feeding can suppress or attenuate induction of many jasmonate pathway-regulated genes, but we do not have evidence that this occurs due to induction of the salicylate pathway as the pathogen defense-related genes were induced similarly in caterpillar and aphid treatments (Table 1B; Fig. 3n–p). The genes in our "pathogen defense-related" category may or may not be regulated by the salicylate pathway. However, based on the microarray data even the two genes known to be salicylate-regulated PR proteins 1 and 1A1 were only weakly up-regulated by aphids (Table 1B), while qRT-PCR analyses detected no differences in PR protein induction

between single and dual damaged treatments (Fig. 3o–p). In addition, we found attenuation of genes in many categories, not just those involved in defense (Table 1C–D). However it is achieved, attenuation of the jasmonate pathway expression may benefit the caterpillars and aphids, as both have lower performance on tomato plants treated with JA (Thaler et al., 2001; Cooper and Goggin, 2005).

Gene Expression: Lack of Specificity

There was an overlap of gene regulation in the case of 44 genes (out of the 277 genes influenced by herbivory), where both aphids and caterpillars, when feeding alone, up-regulated or down-regulated the systemic expression of the same genes (22 and 22 genes, respectively). Interestingly, however, for all 44 genes that lacked specificity the expression of these genes in the dual-damage treatment was not different from the controls. These included herbivore defense related genes (e.g., wound-inducible carboxypeptidase), photosynthesis related genes (e.g., triose phosphate chloroplast precursor), and signaling related genes (e.g., 1-aminocyclopropane-1- carboxylate oxidase homolog) (Table 1). For example, aphids and caterpillars down-regulated several genes associated with photosynthesis when feeding alone but not when feeding together on the same plant (Table 1C). A possible explanation for this scenario is that almost no gene is inducible only by a single transcription factor or signaling pathway. If two insects that induce different signaling pathways/transcription factors feed simultaneously on a plant, then these pathways/factors might interfere with each other. This could result in negative feedback or inhibition leading to a zero sum transcription of the respective subset of genes.

Ultimately the translation of these genetic changes to impacts on herbivores is what is critical, and such data from our system are discussed below.

Chemistry and Bioassays: Foliar Chemicals

Interactions between plant responses to caterpillar and aphid feeding impacted plant nutritional quality, as shown by the significant aphid×caterpillar effects on C/N and protein (Table 2). Aphid feeding decreased the C/N ratio in systemic leaves while caterpillar feeding had no effect (Fig. 4a). When both herbivores fed on the plant, however, the C/N ratio was equal to the control treatment, indicating that caterpillar feeding affected the plant's response to aphids. This effect is consistent with aphids manipulating the nutritional content of plants for their own benefit by increasing the proportion of nitrogen in leaves (e.g., Flynn et al., 2006), which is critical considering that leaf nitrogen is often a limiting resource for herbivorous insects (Mattson, 1980). This likely explains our previous finding that caterpillar consumption (in the first 7 days of development) increases on aphid-damaged plants compared to control plants, and also that the amount of caterpillar consumption on caterpillar-damaged plants was not affected by aphids (Rodriguez-Saona et al., 2005). Stout et al., (1998) also reported increased growth rates of beet armyworm caterpillars on tomato plants previously damaged by aphids compared to undamaged plants. Aphid and caterpillar feeding alone had no effect on the amount of protein in systemic leaves. However, both herbivores feeding on the plant reduced the amount of protein compared to aphid-damaged plants (Fig. 4b).

Our data show that caterpillars induced systemically high PI enzymatic activity, but this was not affected by aphids. Caterpillar-damaged plants had three times higher PI enzyme activity compared to control plants (Fig. 4c; Table 2), while aphids had no effect on PI activity, even though they did weakly induce PI gene expression (see results above). This is consistent with Stout et al. (1998) who found that local feeding by *Helicoverpa zea* (Boddie) increased PI activity, whereas feeding by potato aphids had no effect. However, the presence of aphids did not affect the PI activity induced in response to caterpillar damage even though our transcriptomic data indicated that aphid feeding strongly interfered with PI gene expression. Thus, although the results of the current study indicate that aphid feeding could both weakly induce expression of several PI genes and cause attenuation of PI genes induced by caterpillars, neither of these effects on gene expression led to a change in PI activity. Gene expression may not translate directly to protein activity due to a level of

Fig. 4 Effects of damage singly by aphids or caterpillars or simultaneous damage by aphids and caterpillars on amounts of carbon/nitrogen (C/N) ratio (**a**), protein (**b**), and proteinase inhibitors (**c**), as well as on *Spodoptera exigua* caterpillar mass (**d**) and mortality (**e**). transcript above which no more protein is made, post-transcriptional regulation, or interactions between gene products. Alternatively, the PI assay used simply may not be sensitive enough. In fact, in our previous study (Rodriguez-Saona et al., 2005) PI activity was about 20% lower in the dual-damage treatment than in the caterpillar only treatment, although this difference was not significant and not observed in the present study.

Chemistry and Bioassays: Caterpillar Performance

Prior caterpillar feeding decreased the mass of bioassay caterpillars by 54% (Fig. 4d) and increased caterpillar mortality by 28% (Fig. 4e). Bioassay caterpillars were 46% heavier and had 5% lower mortality on aphid-damaged plants compared to control plants, but these differences were not significant (Fig. 4d–e; G=0.27, P=0.6). Caterpillar performance on dual-damaged plants was similar to that on caterpillar-damaged plants (Table 2).

Therefore, caterpillar damage had a strong negative effect on subsequent caterpillar growth and survivorship, whereas aphid damage had only a weak and non-significant effect on caterpillar performance, and we found no attenuation of resistance in dual-damaged plants. These bioassays reveal the complicated relationship between gene expression, biochemical activity, and impacts on herbivores. In a previous paper (Rodriguez-Saona et al., 2005), we demonstrated that aphid feeding does influence compo-

nents of *S. exigua*'s ecology. For example, moth host acceptance was substantially lower on caterpillar-damaged plants, higher on aphid-damaged plants, and intermediate on dual-damaged plants. This finding is concordant with gene expression results from the current study and others that find conflict between some JA and SA regulated genes and synergisms between others (Schenk et al., 2000; Bodenhausen and Reymond, 2007). In our previous study, we further concluded that beet armyworm moth preference correlates with caterpillar performance only when plants were damaged by a single herbivore (aphids or caterpillars), but not in the dual-damaged treatment (Rodriguez-Saona et al., 2005). Insect preference and performance often are not correlated in part because different plant traits influence these aspects of herbivore biology (e.g., Prudic et al., 2005). Thus, some components of the plant's response to caterpillars that are influenced by aphids have impacts on other herbivores. Because interactions with multiple herbivores on the same plant are common under more natural conditions (Strauss, 1991; Hufbauer and Root, 2002) and because aphid densities are often reported to be very high in the field (Dixon, 1977), it is likely that under these conditions the interference by aphids in direct plant defenses against chewing herbivores can be even stronger than observed in our experiments.

In summary, we employed a combination of molecular, biochemical, and organismal approaches to investigate the interactions between tomato plants, the beet armyworm caterpillar, and the potato aphid. At the molecular level, both attacking insects influenced each other. At the biochemical level, the presence of aphids was too weak to change the PI activity (caterpillar-induced proteins), but the presence of caterpillars did alter the aphid influence on C/N ratios. Finally, at the organismal level, aphids did not overwrite the negative effects of caterpillars on the caterpillar's performance. However, our previous study (Rodriguez-Saona et al., 2005) shows that aphids do overwrite the repellency effects of caterpillars on the moth's oviposition preference.

When comparing across all three biological levels of organization, our data produced consistent results when considering each herbivore separately: caterpillars induced high expression of several JA-regulated defensive genes, resulting in high PI activity and reduced caterpillar performance, whereas aphids induced weak expression of only a few defensive genes associated with the JA pathway and did not induce PI activity or affect herbivore performance; but not when considering them together: when plants were attacked simultaneously by caterpillars and aphids, strong interactions exhibited at the molecular level translated into interactive effects on some chemicals, i.e., C/N ratio, but not PI activity, and some components of host suitability for herbivores, i.e., adult preference, but not caterpillar performance. Taken together, our study shows that caterpillar performance on plants could not be explained simply by the levels of defenses but by their balance with the nutritional content as a result of single or multiple herbivory. This study is a reminder that predictions by global gene expression studies need further verification across different levels of biological integration. Future studies will explore the mechanisms for attenuation in the dual treatment, characterize the transcriptional responses of JA and SA signaling genes in a time course experiment, and investigate aphid performance on single- and dual-damaged plants.

Acknowledgements We thank Deborah Tam, Joseph Sherman, Joshua Lighton, and Spencer Williams for laboratory assistance, and Robert Holdcraft for help with figures and tables. We appreciate comments from Anurag Agrawal, Stuart Campbell, Jin-ho Kang, Dan Kliebenstein, Scott McArt, Martin de Vos, Caroline von Dahl, and anonymous reviewers. Funding was provided by the National Science Foundation Plant Genome Research Initiative (No. 0820367 to ROM and SMH), the National Research Initiative of the USDA Cooperative State Research, Education and Extension Service (No. 2004-01540 to ROM and SMH, and 2006-35302-17431 to JST), the USDA Cooperative State Research, Education and Extension Service Special Grant (No. 2006-34155-17118 to CRS), and the Western Illinois University research council for partial funding of this project.

opment (Creelman and Mullet, 1997; Wasternack and Parthier, 1997; Feussner and Wasternack, 2002), drought stress (Moons et al., 1997), accumulation of storage proteins (Beardmore et al., 2000) and leaf senescence (He et al., 2002) although the latter effect is controversial (see Seltmann et al., 2010). Jasmonates are especially well known for their roles played in defense against tissue damage, pathogen infection, and herbivory (van Kleunen et al., 2004; Arnold and Schultz, 2002; Howe, 2004; Babst et al., 2005; Truman et al., 2007), and serving as local and systemic signal molecules (Zhang and Baldwin, 1997; Stratmann, 2003; Ferrieri et al., 2005; Thorpe et al., 2007). They promote the transcriptional modification of numerous genes (Jung et al., 2007) that can impact whole-plant resource allocation of both nitrogen- and carbon-containing substrates (Meuriot et al., 2004; Babst et al., 2005; Gómez et al., 2010), as well as manifest in responses at cellular levels (Creelman and Mullet, 1997; Rickauer et al., 1997; Xie et al., 1998; Reymond and Farmer, 1998; Weber, 2002; Cheong et al., 2002; Farmer et al., 2003; Pauwels et al., 2008).

Such responses can manifest in the up-regulation of specialized biochemical pathways that have evolved as defenses against abiotic and biotic stressors (Osbourn, 1996; Farmer et al., 2003; Zhao et al., 2005). For example, the pathway of phenolic acid metabolism in plants requires the initial steps of general phenylpropanoid metabolism providing precursors for the synthesis of lignin, tannins, flavonoids, and other phenolics that serve to build physical barriers and/or reserves of alleochemicals in plant defense (Arnold and Schultz, 2002). It is well known that JAs will elevate the activity of key enzymes, including phenylalanine ammonia-lyase (Hudgins et al., 2004; Bower et al., 2005) and caffeoyl CoA *O*-methyltransferase (Lee et al., 1997), that promote the deamination of phenylalanine, the primary substrate of this pathway, as well as catalyze the *O*-methylation of key intermediates leading to increased lignification (Lee et al., 1997; Caño-Delgado et al., 2003; Hudgins et al., 2004).

Upstream from the phenylpropanoid pathway, the biosynthesis of aromatic compounds proceeds via the seven-step shikimate pathway to a branch point intermediate chorismate (Kloosterman et al., 2003). Chorismate subsequently is converted to three aromatic amino acids, tryptophan, tyrosine, and phenylalanine, as well as other aromatic compounds, via specific terminal pathways. This process is coupled tightly via metabolite feedback control mechanisms (see dashed lines in Fig. 1) impacting a subset of three key regulatory enzymes in the pathway: 3-deoxy-D-arabino-heptulosonate 7-phosphate (DAHP) synthase, chorismate mutase, and prephenate dehydratase (Bickel and Schultz, 1979; Herrmann and Weaver, 1999). Yet, little is known about the regulation of the shikimate pathway in concert with downstream phenolic metabolism.

Current "omics" research on plant defense responses has provided many new insights into induced plant responses and when coupled with physiological and biochemical studies at the whole plant level, can be illuminating. For example, Naoumkina et al. (2007), using cell cultures from *Medicago truncatula,* observed a 24 h delay in transcriptional modification of the early metabolic steps of the phenylpropanoid pathway after MeJA treatment, but a rapid (within hours) increase in medicarpin, an isoflavonoid produced from this pathway. This highlights that transcriptional up-regulation is not necessarily coupled with biochemical up-regulation.

Understanding the latent manifestations of highly integrated and interactive response networks can be difficult (Meuriot et al., 2004; Jung et al., 2007; Pauwels et al., 2008). In a recent prospectus, Schwachtje and Baldwin (2008) suggest that a key link in the defense network is reprogramming of primary metabolism, where such metabolites may themselves serve as signals that subsequently activate downstream pathways. Thus, primary metabolites may serve dual roles as signal and substrate for downstream secondary metabolism.

Here, we report on the use of the short-lived radioisotope, carbon-11 ($t_{½}$ 20.4 min) as $^{11}CO_2$ to measure in *Nicotiana tabacum* the partitioning of new carbon into metabolite pools of photosynthate, as well as into metabolites of the shikimate pathway. The use of carbon-11 for studying the partitioning of new carbon into metabolic pools enabled us to retest the same plant over short periods of time. These studies would be difficult to carry out if not impossible by using carbon-14 or carbon-13, as the metabolic pools would become enriched with tracer preventing a clear delineation between new and old carbon utilization. Furthermore, the use ^{11}C at true tracer concentrations placed us in a unique position to explore the effects MeJA had on [^{11}C]photosynthate pools unimpaired by the feedback control mechanisms described above. Most particularly, we were able to explore how such effects filtered down to regulation of the shikimate pathway and its coordination with up-regulation the phenylpropanoid pathway.

Here, we hypothesized that MeJA would cause rapid changes in [^{11}C]photosynthate pools, thus favoring increased partitioning of new carbon into amino acids. Furthermore, we hypothesized that MeJA would impart selective control over the shikimate pathway, thus giving rise to different partitioning of new carbon into its metabolites. We showed for the first time that defense induction, triggered by application of MeJA, can manifest in selective reprogramming of new carbon utilization in the shikimate pathway. As importantly, we show that metabolic reprogramming can be transient matching key transcript expression patterns.

Fig. 1 Shikimate pathway showing known metabolite feedback loops (dashed lines) that can affect metabolic regulation. This pathway is controlled by three key regulatory enzymes: 3-deoxy-D-arabino-heptulosonate 7-phosphate synthase, chorismate mutase, and prephenate dehydratase. Metabolite feedback loops truncate at specific branch points within the pathway and are designated by+or—for promotion or inhibition (as adapted from Bickel and Schultz, 1979; Herrmann and Weaver, 1999)

Methods and Materials

General Approach In the studies described, we devised a protocol for measuring the effects of our treatment on the partitioning of recent carbon (as ^{11}C) and unlabeled endogenous carbon (as ^{12}C), into key metabolite pools. Specifically we dosed leaf-3 (counting down from the apex) of an intact plant with $^{11}CO_2$ tracer, and then 4 h or 15 h after treatment, we administered a second dose tracer to leaf-4 of the same plant. A 2 d study cycle (Fig. 2) shows the coordination in time between baseline and retest tracer administrations with MeJA treatment and the plant's light/dark cycle. The present study also required extraction of small amounts of tissue from the plant through leaf excision at its petiole. Prior to beginning our MeJA studies, we performed a proof-of-concept study to confirm that leaf excision would not induce metabolic reprogramming. At 4 and 15 h post leaf-3 excision, the [^{11}C]photosynthate composition was unchanged between leaf-3 and leaf-4 as was the ^{11}C amino acid profiles for tyrosine, phenylalanine, and tryptophan (data not shown). In summary, we found that cleanly excising a study leaf from the plant at its petiole does not induce changes in the metabolites of interest within the remaining tissues. With this knowledge, we designed an experimental protocol for testing same plants by using separate doses of ^{11}C before and after treatment.

Plant Material Tobacco plants (*Nicotiana tabacum* L. cv Samsun) were grown from seed in commercial potting mix

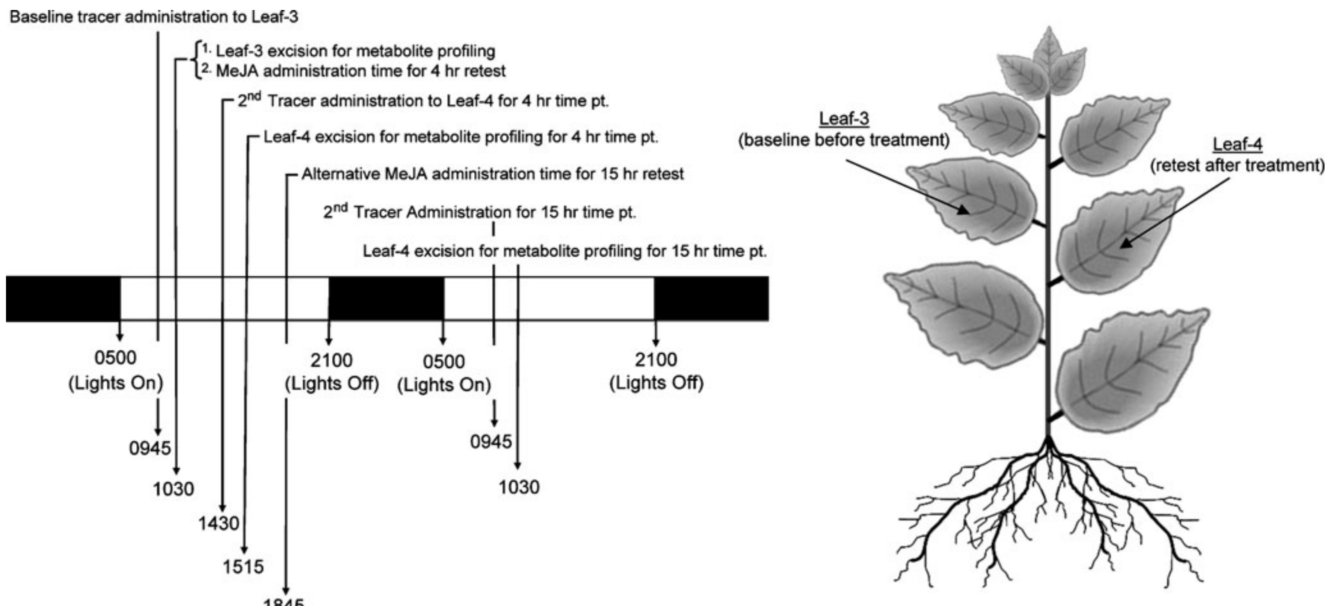

Fig. 2 Two-day study cycle of plants (*Nicotiana tabacum*) subjected to either a 4 h or 15 h metabolite profiling. Changes in metabolite profiles at either time point were always compared back to baseline responses from the same plant. Baseline ^{11}C tracer administration was always at 09.45 h Leaf excision for tissue extraction always occurred 45 min after tracer administration. Note that the 4 or 15 hr metabolite profiling time points dictated the time of day when control or MeJA treatments were applied to the study plant. Treatments were always applied during the light cycle

with a slow release fertilizer (Osmocote) under metal-halide lamps at 24°C with a 16/8 h-350 umol m^{-2}sec^{-1} photoperiod, and were used for experiments at their 7-leaf stage of development.

Radiotracer Production $^{11}CO_2$ was produced *via* the ^{14}N (p,α)^{11}C nuclear transformation (Ferrieri and Wolf, 1983) from 50 ml volume high-purity nitrogen gas target using 17 MeV protons from the TR-19 (Ebco Industries Ltd, Richmond, BC, Canada) cyclotron at Brookhaven National Laboratory, and captured on molecular sieve (4Å) (full details in Ferrieri et al., 2005).

Radiotracer Administration The $^{11}CO_2$ that was trapped on the molecular sieve was desorbed and quickly released into an air stream at 400 ml min^{-1} as a discrete pulse for labeling a leaf in a 5×10 cm lighted cell (920 umol m^{-2}sec^{-1}) (Ferrieri et al., 2005). A PIN diode radiation detector (Bioscan Inc., Washington DC, USA) affixed to the bottom of the cell enabled continuous measurement of radioactivity levels within the cell. The difference between the amount of radioactivity registered in the pulse height, and residual radioactivity after the pulse had passed through the cell was a reflection of leaf tracer fixation. This value was used to normalize measurements to the same amount of carbon-11. In past studies (Ferrieri et al., 2005), we were able to correlate these measurements in radioactivity with direct changes in the CO_2 concentration entering and exiting the leaf cell by using infrared gas exchange, IRGA (Li-Cor model 6162).

We administered ^{11}C to leaf-3 and leaf-4 in series, before, and after treatment. Leaf designation was determined by counting down from the apex, with leaf-1 designated as the first leaf that was expanded to 50% of its full capacity.

Tissue Extraction and Derivatization Thirty minutes after the tracer was administered, the study leaf was cleanly excised at its petiole. The 5×10 cm area exposed to $^{11}CO_2$ was cut away from the remaining leaf tissue, weighed, and flash frozen in liquid nitrogen (LN_2). Using a mortar and pestle, the frozen tissue was ground to a fine particulate, and extracted in 3 ml of methanol (50% v/v in DI water) for 10 min at 90°C. The extract was separated by pipette and filtered through a 0.22 μM filter (Millipore Inc., Billerica, MA, USA). The total volume of the extract was measured and 150 μl aliquot delivered into a 2 ml brown-glass vial (Fisher Scientific, Inc., Pittsburgh, PA, USA). An equal volume of *o*-phthalaldehyde amino acid derivatizing reagent (OPA) containing 0.1% (v/v) mercaptoethanol and 0.1% (v/v) sodium hypochlorite (Sigma Life Science, St. Louis, MI, USA) was delivered into the same vial. The mixture was vortexed and then allowed to react at ambient temperature for 3 min. Primary amino acids are readily converted into UV absorbing iso-indole derivatives by OPA enabling their separation with reversed-phase high-performance liquid chromatography and quantification (Chow et al., 1987). While the OPA method has been

successfully used for measuring amino acids in purified plant extract, some have questioned how effective the method is for unpurified extracts (Martin et al., 1982). To confirm the validity of this method, we tested several amino acid standards in pure methanol/water (50% v/v), and in a methanol/water solution containing unpurified tissue extract, and subjected each sample to OPA reaction. Using the chromatography method described in the next section, we observed the same UV response from standards (within 5% standard error) in both types of formulations.

Analysis of Amino Acids A 50 μl volume of the derivatized mixture was injected onto a reversed-phased analytical HPLC column (Phenomenex, Torrance, CA, USA: Ultramex™ C_{18}, 10 μ particle size, 250×4.6 mm i.d.) using a pre-column gradient mixer (Isco, Lincoln, NE, USA) and a mobile phase comprised of A (DI water), B (0.01 M NaH_2PO_4-buffered at pH 6.8 using trifluoroacetic acid), and C (methanol). At injection, the mobile phase (1.5 ml min^{-1}) was sustained at 75% A: 25% B for 5 min and then programmed to attain 20% B: 80% C by 30 min. The mass levels of the amino acid derivatives were measured with a variable wavelength UV detector (Sonntek Inc., Upper Saddle River, NJ, USA) at 340 nm. The outlet of the UV mass detector was connected in series to a NaI gamma radiation detector (Ortec Inc, Oak Ridge TN, USA) that enabled direct measurement of the amount of radioactivity associated with each substrate eluting the column. Analog outputs from both the mass and radiation detectors were fed to a chromatography data acquisition station (SRI Instruments, Torrance, CA, USA) where integrated peak areas were measured from both inputs.

Compounds were identified by their elution times and correlated to those of authentic standards. Changes in endogenous substrate concentrations were correlated by correcting each chromatogram for the gram fresh weight of tissue that was used for a particular extraction. Samples also were corrected for analytical dilutions. Changes in radioactive substrate levels were normalized to a standard amount of ^{11}C tracer that was administered to a particular leaf. Radioactivity data was decay corrected back to a common time point owing to the extremely short half-life of ^{11}C (20.4 min). An additional 50 μl aliquot was taken in order to assay for total [^{11}C]photosynthate radioactivity in each tissue extract. This measurement was carried out using a separate static gamma counter. The efficiencies of both the flow and static gamma counters were calibrated against standards.

We note that although a full profile of [^{11}C]amino acids was measured, that data went beyond the scope of the present work and are not reported here. However, we pooled all observed radioactive amino acids and reported their total distribution relative to the soluble [^{11}C]photosynthate fraction.

Analysis of Radioactive Soluble Sugars A 50 μl volume of the methanol:water extract was injected onto a reversed-phased analytical HPLC column (Phenomenex, Torrance, CA, USA: Luna™ NH_2, 5 μm particle size, 250×4.6 mm i.d.). At injection, the mobile phase (1.5 mlmin^{-1}) was sustained at 80% acetonitrile: 20% water. Elution profiles of soluble sugars were matched against standards using a refractive index (RI) detector (Sonntek Inc., Upper Saddle River, NJ, USA). For radioactive extract analysis, the outlet of the RI detector was connected in series to a NaI gamma radiation detector (Ortec Inc, Oak Ridge TN, USA) that enabled direct measurement of the amount of radioactivity associated with each substrate eluting the column. Analog outputs from both the mass and radiation detectors were fed to a chromatography data acquisition station (SRI Instruments, Torrance, CA, USA) where integrated peak areas were measured from both inputs. The same corrections were made, as described above, for sample size and radioactive decay of the tracer. For the purpose of this work, all radioactive sugars were pooled and related back to their total distribution relative to the soluble [^{11}C]photosynthate fraction.

Measurement of Endogenous Cinnamic Acid Levels PAL catalyzes the formation of *trans*-cinnamic acid from phenylalanine. Therefore, measurement of endogenous cinnamic acid levels as a function of time after treatment should give us insight into the coordination between downstream phenolic metabolism and the shikimate pathway. In parallel studies, leaves were dried for 24 h in an oven at 70°C, weighed to obtain a dry mass, and extracted in tetrahydrofuran (Sigma Life Science, St. Louis, MI, USA) for 3 h at 25°C according to the procedure of Budi-Muljono et al. (1998). Gas chromatography analysis was performed on aliquots of tissue extract using a non-polar fused-silica column (30 m×0.53 mm i.d.) coated with methyl silicone gum (HP-1: Hewlett Packard Co. Rockville, MD, USA) at a film thickness of 2.65 μm. The gas chromatograph (Hewlett Packard 5890 Series II) was equipped with a flame ionization detector operated at a temperature of 300°C. The other instrument conditions were as follows: injector temperature, 230°C; carrier gas-helium; carrier gas inlet pressure, 100 kPa; oven temperature, 50–250°C at 10°Cmin^{-1}. Analyses were performed using the splitless injection mode. Data was acquired using a Vision IV chromatography station (Scientific Systems, Inc., State College, PA, USA). *Trans*-cinnamic acid was identified based on its elution time matched against that from an authentic sample. Peaks were integrated and correlated to a mass amount using a calibrated detector mass response curve.

Treatments Plants were sprayed uniformly with either DI water (as a control) or a 500 μM solution of MeJA in DI water immediately following excision of leaf-3 to acquire the baseline measurement of metabolic partitioning of tracer. Because MeJA was shown to distribute rapidly throughout the plant, we opted to treat the entire above-ground foliar tissue (Thorpe et al., 2007). After treatment, plants were housed individually in a positive air flow holding box illuminated using auxiliary halogen lights (300 $\mu mol m^{-2} sec^{-1}$). This ensured that interplant communication via plant volatile emissions would not compromise retest responses in study plants. Plants then were retested using leaf-4, and a second dose of ^{11}C tracer, at 4 or 15 h after treatment (Fig. 2).

Statistical Analysis One of the advantages of using short-lived radioisotopes is that they do not accumulate in the plant, and so retests can be performed over time and after treatment allowing the same plant to be used as its own control. All data derived from matched plant studies (baseline/post-treatment) and were presented as change in response relative to baseline values. As pointed out earlier, by using the same plant in a test-retest protocol, rather than averaging values across individual plants at baseline (untreated) and post-treatment (treated), we obtained a smaller standard error. Comparisons were made in the change of the ^{12}C and ^{11}C profiles from baseline levels to post-treated levels of control and MeJA treated plants using ANOVA single-variate analysis.

Results

The effects of MeJA on primary plant metabolism were evident from the changes seen in the [^{11}C]photosynthate composition (Fig. 3) 4 and 15 h after treatment. In unstressed plants (N=4), the typical [^{11}C]photosynthate comprised 90.2±2.0% soluble sugars, 3.0±0.6% amino acids and 6.8±2.1% of other labeled substrates that were not accountable in our sugar and amino acid analyses. Control treatments (N=5) had no effect on this distribution. However, MeJA (N=4) caused a significant decrease in the [^{11}C]sugar fraction to 83.7±2.3% (P=0.041) by 4 h post-treatment relative to controls with a commensurate increase in the [^{11}C]amino acid fraction to 6.3±0.9% (P=0.039) and an increase in the other [^{11}C]labeled substrate fraction to 10.0±2.5% (P=0.046). This trend was more significant by 15 h post-treatment using MeJA with the [^{11}C]sugar fraction decreasing to 59.4±6.6% (P<0.001), the [^{11}C] amino acid fraction increasing to 27.6±3.1% (P<0.001), and the [^{11}C]other fraction increasing to 13.0±7.5% (P=0.054). Alhough tissues were extracted just 30 min after tracer administration, leaf export of selected components comprising the [^{11}C]photosynthate mix might have altered its composition in the study leaf. However, we note that leaf export of [^{11}C]photosynthate by this time point was unchanged by MeJA treatment: 19.1±5.1% of fixed ^{11}C in untreated leaves and 19.6±2.8% 15 h after MeJA treatment (Gómez, unpublished).

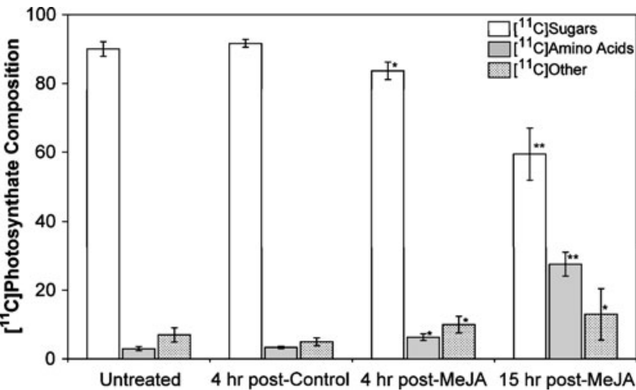

Fig. 3 Effect of treatments of *Nicotiana tabacum* at 4 h (control, N=5; MeJA, N=4) and 15 h (MeJA, N=4) on the partitioning of new carbon as ^{11}C into soluble sugar, amino acid and unknown substrate fractions of [^{11}C]photosynthate. Error bars denote standard deviations on means. Data bars denoted by * and ** indicate that change in ^{11}C-partitioning into metabolic pools from the untreated state to the control or MeJA treated states was significant at the 5% and 1% confidence levels, respectively, according to the ANOVA single variate analysis

Over the same timeline ^{11}C-partitioning into tyrosine (Fig. 4a) was only slightly elevated by MeJA at 4 h post-treatment though significantly (P=0.28) relative to controls. For phenylalanine (Fig. 4b) and tryptophan (Fig. 4c), ^{11}C-partitioning into these amino acids was much more responsive to MeJA with each showing a 12-fold elevation relative to baseline levels. These changes were significantly different from those of control treatments (P<0.001 and P=0.017, respectively). Interestingly, no change in the ^{12}C profiles of these compounds was noted during this time course. By 15 h, the elevated partitioning of ^{11}C into phenylalanine and tyrosine returned to baseline levels, and were not significantly different from those of controls. [^{11}C] Tryptophan levels, however, continued to grow in magnitude reaching a 30-fold elevation relative to baseline levels (P<0.001). Again, no change was noted in the ^{12}C profiles of these metabolites by 15 h post-treatment. Like others (e.g., Zangerl, 2003), we observed that MeJA reduced leaf level photosynthetic activity by 40% (by 15 h post-treatment) although this result was only marginally significant (P=0.075).

Finally, our studies assessed changes in endogenous cinnamic acid levels over the same timeline of treatment. PAL catalyzes the conversion of phenylalanine to *trans*-cinnamic acid which serves as a substrate for subsequent

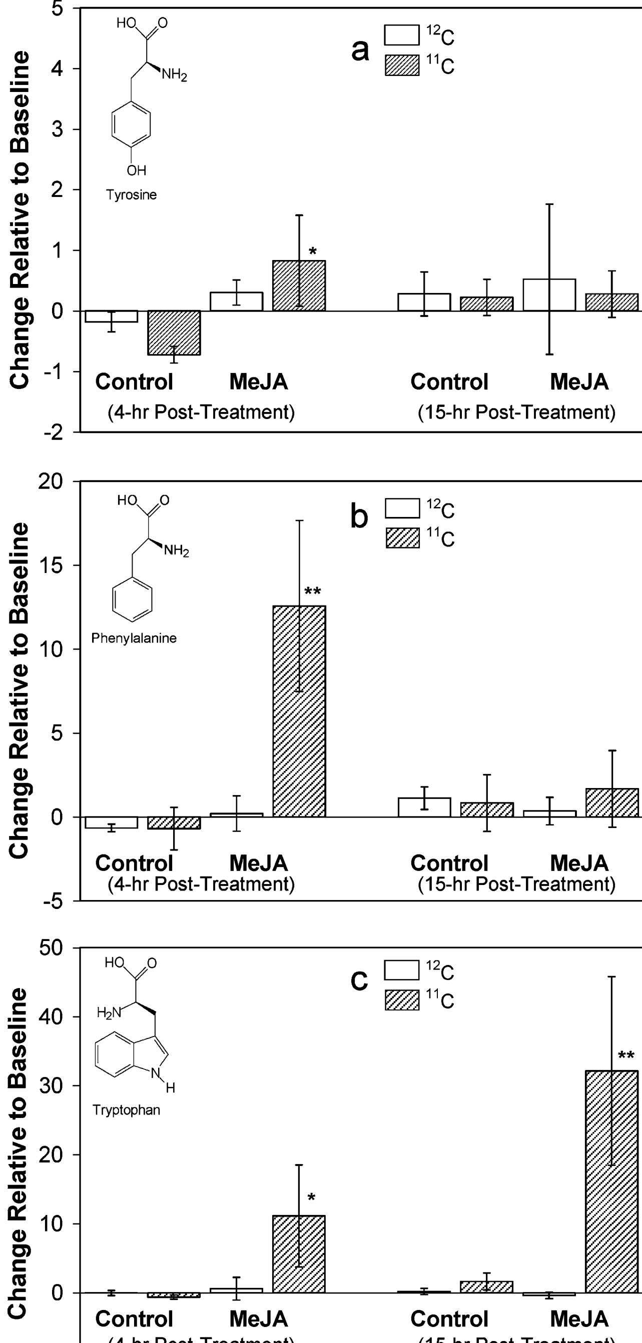

Fig. 4 Effect of treatments of *Nicotiana tabacum* at 4 h (Control, N= 4; MeJA, N=4) and 15 h (Control, N=4; MeJA, N=3) on the metabolic partitioning of ^{12}C and ^{11}C into the shikimate pathway involving biosynthesis of tyrosine (Fig. 4a), phenylalanine (Fig. 4b), and tryptophan (Fig. 4c) amino acids. Results presented as the change in ^{12}C and ^{11}C levels within individual compounds relative to their baseline values (untreated). Error bars denote standard deviations on means. Data bars denoted by * and ** indicate that the change in ^{11}C-partitioning into specific aromatic amino acids from the untreated state to the control or MeJA treated states was significant at the 5% and 1% confidence levels, respectively, according to the ANOVA single variate analysis

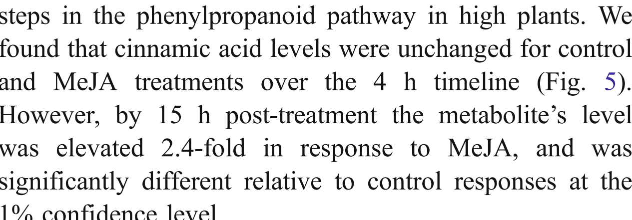

steps in the phenylpropanoid pathway in high plants. We found that cinnamic acid levels were unchanged for control and MeJA treatments over the 4 h timeline (Fig. 5). However, by 15 h post-treatment the metabolite's level was elevated 2.4-fold in response to MeJA, and was significantly different relative to control responses at the 1% confidence level.

Discussion

While compensatory photosynthesis is considered an important physiological response of plants (McNaughton, 1983; Crawley, 1983; Rosenthal and Kotanen, 1994; Strauss and Agrawal, 1999), it generally is restricted to re-growth tissue, and is not a universal response (Zangerl et al., 1997). A reduction in the available carbon resources through suppression of photosynthetic activity might reduce the endogenous pools of amino acids since there would simply be fewer carbon skeletons available. The fact that we see no change in the size of the endogenous aromatic amino pools, even though metabolic partitioning of new carbon (as ^{11}C) into these pools is seen to increase, may be a reflection of the balance between carbon input, metabolic reprogramming, and even resource re-allocation (i.e., physical transport from source tissues). Indeed, partitioning of new carbon (as ^{11}C) away from soluble sugars and into amino acids is evident with 27.6% of the [^{11}C]photosynthate comprising amino acids by 15 h post-treatment with MeJA. Given the short-lived nature of the isotope, we doubt that the increased [^{11}C]amino acid fraction after MeJA treatment is due to increased protein turnover. Furthermore, other studies by us have shown that MeJA will increase radioactive ^{13}N ($t_{½}$ 9.97 min) utilization as amino acids, as well as increase leaf export of these substrates (Gómez et al., 2010). Even so, there are many conditions (e.g., pathogen attack) that will reduce photo-

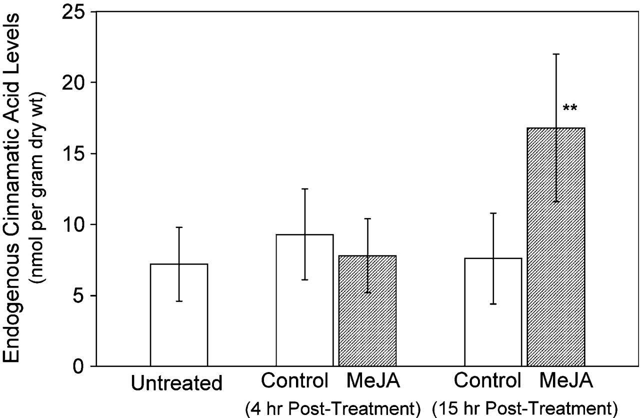

Fig. 5 Effect of control (N=4) and MeJA (N=4) treatments at 4 and 15 hr on endogenous levels of *trans*-cinnamic acid in tissue extract

synthesis, but will increase levels of soluble sugars and amino acids due to the higher energy demands of the plant during stress (Baena-González, 2010). Future studies will explore how the balance of carbon and nitrogen is maintained during early stress induction.

Most importantly, our results suggest that defense induction triggered by MeJA manifests in the reprogramming of only new carbon and not of existing carbon stores. This observation correlates with observations made by Arnold and Schultz (2002) that new carbon is incorporated into tannins during defense induction. It remains unclear why existing carbon stores were not utilized to up-regulate the phenylpropanoid pathway. This could reflect the fact that remobilization of existing carbon stores is a slower process and was not detected during the short timeline of this present study. We note that analyses of jasmonate-responsive genes in *Arabidopsis* (Jung et al., 2007) reveals a complex profile of both up-regulated and down-regulated transcripts differing in expression patterns over time for up to 24 h after MeJA treatment. In future studies, we need to explore whether longer time points give further insight into plant responsiveness to MeJA and its ability to utilize available carbon (both old and new) in defense.

Interestingly, 4 h after MeJA treatment, the level of [^{11}C] phenylalanine was transiently increased, but quickly returned to baseline levels by 15 h after treatment. As the first step in phenolic metabolism, this is a crucial biochemical reaction supporting both plant development and plant defense. Such behavior might be reasonable in light of findings by Jung et al. (2007) showing that MeJA will transiently induce transcript accumulation of numerous genes in *Arabidopsis* (e.g., At5g67300 associated with a MYB transcription factor in signal transduction). We note that many MYB transcription factors play essential roles in regulating phenolic metabolism during defense induction (Stracke et al., 2007; Malone et al., 2009). Furthermore, phenylalanine itself has been shown to promote PAL activity in *Cryptomeria* and *Perilla* cell suspension cultures (Ishikura et al., 1986), as did JA up-regulate transcripts associated with the phenylalanine ammonia lyase isoform 1 in *Populus nigra L*. (Babst et al., 2009). Indeed, we observed increased endogenous levels of cinnamic acid, but only 15 h after MeJA treatment, thus highlighting the need for studies that explore the coordination between the expression profiles of genes and relevant metabolism. Finally, we note that JA will up-regulate transcripts associated with DAHP synthase in *Populus* (Babst et al., 2009), as will wounding increase DAHP activity promoting increased carbon turnover within the shikimate pathway (Dyer et al., 1989). Our observation of increased partitioning of new carbon into [^{11}C]phenylalanine and other metabolites of the shikimate pathway may be a reflection of direct action of the phytohormone on DAHP and possibly other branch-point enzymes of that pathway. Future studies using transformed plants should provide additional insight here.

Like phenylalanine, a similar transient behavior was observed in the metabolic partitioning of ^{11}C into tyrosine, although not as large. Since phenylalanine and tyrosine derive from the same branch point (prephenate-to-arogenate) within the shikimate pathway, it seems reasonable that they exhibit similar transitory behavior.

Finally, MeJA treatment rapidly increases ^{11}C-partitioning into tryptophan, which continues to increase over a 15 h window after treatment. We note that tryptophan promotes chorismate mutase in the shikimate pathway, which may affect carbon partitioning from chorismate to tyrosine and phenylalanine (Bickel and Schultz, 1979). However, the endogenous concentrations of aromatic amino acids were unchanged over the timeline of our studies. Therefore, we rule out the possibility that feedback loops, that either promote or inhibit amino acid biosynthesis are likely responsible for the changes in ^{11}C-partitioning that we observed.

Tryptophan plays a major role in plant metabolism as the primary precursor in the biosynthesis of indole-3-acetic acid (IAA), a growth regulator that is part of the auxin family, key hormones that regulate growth and development (Doerner, 2008). Jung et al. (2007) reported a group of genes that were induced 1-2 h after MeJA treatment, reaching a maximum accumulation by 8 h and diminishing after 24 h. These middle-stage expression genes included those for transcription factors as well as tryptophan synthase subunits and the JR2 gene linked to IAA-Ala hydrolase. Therefore, it seems reasonable that ^{11}C-partitoning into tryptophan would remain elevated over the timeline of our study.

In summary, the use of ^{11}C as described in this paper offers unique opportunities to explore rapid temporal changes in new carbon metabolism. As we have demonstrated, studies of this nature can provide insight into how plants use their new carbon resources in response to stress.

(2008) suggested that autumn colors could signal tree quality to myrmecophilous specialist aphids, which attract aphid-tending ants that defend the trees from other herbivores. Another indirect defense hypothesis (Holopainen, 2008) states that green foliage, e.g., in *Alnus* before leaf fall, can continue to produce herbivore-induced plant volatiles and maintain volatile-based indirect plant defenses against aphids until leaf abscission, but in yellowing foliage indirect defenses become weaker, thus creating an enemy-free space for specialist aphids. This hypothesis is based on the fact that herbivore-damaged plants attract the natural enemies of the herbivorous insect by releasing herbivore-induced plant volatiles (Turlings et al., 1990; Kessler and Baldwin, 2001; Kappers et al., 2005; Mäntylä et al., 2008; Dicke and Baldwin, 2010; Holopainen and Gershenzon, 2010). The induction of the terpene volatiles, however, in particular is strongly photosynthesis dependent (Arimura et al., 2008). During leaf maturation and the start of senescence, photosynthesis declines and expression of photosynthesis- and carbon fixation-related genes decrease (Kontunen-Soppela et al., 2010). Furthermore, phenolic compounds, which are responsible for the leaf autumn coloration (Wilkinson et al., 2002), are formed through the shikimate pathway and have phosphoenolpyruvate (PEP) as a fundamental precursor. Isoprene and monoterpenes, produced through the chloroplastic MEP pathway, share this precursor (Rosenstiel et al., 2003; Magel et al., 2006). Under limited substrate conditions in autumn, PEP might be preferentially allocated to form phenolic compounds instead of isoprenoids (Fares et al., 2010). Therefore, in deciduous trees, a reduced proportion of photosynthesis-related VOCs could be expected during the advance of senescence and leaf coloration. Moreover, this should lead to nearly total loss of MEP dependent compounds after abscission, as these compounds are not released from storage pools (Ghirardo et al., 2010) as in needle litter of terpene-storing conifers (Kainulainen and Holopainen, 2002; Isidorov et al., 2010).

Ougham et al. (2005) proposed that biochemical reactions related to autumn color development and leaf senescence may affect volatiles released from plant leaves. They expected that peak emission of volatiles would coincide with the phase when the leaf was yellow or red but still alive, and that insect herbivores may respond to these volatiles, rather than to bright colors. Indeed, some plant species emit the sesquiterpene (*E*)-β-farnesene, which is the major component of the aphid alarm pheromone. Transgenic *Arabidopsis* plants that over-express (*E*)-β-farnesene synthase and emit (*E*)-β-farnesene are repellent to aphids and arrest aphid parasitoids; the olfactory (*E*)-β-farnesene cues override the yellow visual cues that normally are strongly attractive to *Myzus persicae* aphids (Beale et al., 2006). Blande et al., (2010) found that aphid feeding upon green foliage of *Betula pendula* and *Alnus glutinosa* induces emissions of methyl salicylate (MeSA) in both tree species, and intensity of emission is dependent on the duration of feeding. MeSA is known to act as both an aphid repellent in spring (Glinwood and Pettersson, 2000a) and an attractant of autumn migrants (Pope et al., 2007), but also an attractor of foraging predators and parasitoids (Zhu and Park, 2005; Pareja et al., 2009).

Many volatile organic compounds (VOCs), particularly terpenes (Gershenzon, 1994; Loreto and Schnitzler, 2010) are costly (in glucose units) to produce, and as much as 10% of fixed carbon could be released to the atmosphere as volatiles (Penuelas and Llusia, 2003). Given the high cost, we tested a hypothesis that disintegration of chloroplasts and chlorophyll during autumn senescence may reduce the plant's ability to produce defensive VOCs.

Using a population of cloned *Betula pendula* that started autumn senescence in a field site, we addressed three specific questions. First, are the emissions of costly, photosynthesis-related terpenes and other herbivore-inducible VOCs lower in senescing (e.g., Bruggemann and Schnitzler, 2001) foliage than in green foliage? Second, are there emissions of specific aphid-repelling volatile compounds during the most active nutrient translocation period in yellowing leaves? Finally, does disintegration of chloroplasts and other cell organelles (Keskitalo et al., 2005) in the last stage of senescence lead to elevated emission of green leaf volatiles (GLVs), which could help aphids to avoid abscising leaves?

Methods and Materials

Plant Material Ten 1-yr-old micropropagated silver birch (*Betula pendula* Roth) saplings, originating from naturally regenerated birch forest (mixed *B. pendula* and *B. pubescens*) in Punkaharju (southeastern Finland; 61°48′ N, 29° 18′ E), were selected randomly. The potted saplings were grown at the Ruohoniemi experimental field at the Kuopio Campus Research Garden of the University of Eastern Finland (UEF) (62°13′ N, 27°13′ E, 80 m asl) in central Finland from May 2007 onwards (described e.g., in Blande et al., 2007 and Karnosky et al., 2007). Our surveys indicated that birch aphids did not appear on the saplings in this field site in summer and autumn 2007. Each sapling was healthy with green leaves, and no signs of senescence were visible prior to the start of the experiment (September 17) when they were brought from the field site to growth chambers. Some of the neighboring saplings already had distinctive foliage yellowing and were rejected during tree selection. However, we assumed that the autumn senescence process also had begun in our saplings, as the autumn senescence process, once initiated by environmental fac-

tors, seems to be a tightly controlled developmental program that is not significantly altered further by environmental factors (Keskitalo et al., 2005). The proportion of yellowing leaves in each sapling was monitored during the experiment. A leaf was considered yellow if one third or more of the leaf area was showing symptoms of yellowing. The proportion of green and yellow leaves was calculated on this basis.

All saplings were kept in two growth chambers under controlled conditions, which were based on the last 10 year mid-September weather and light conditions at the Ruohoniemi efield. The growth chambers were programmed with the following conditions; minimum temperature 8°C at 5:00, maximum 12°C from 15:00 to 17:00, relative humidity from 75% to 95%. Lights were on from 7:00 to 18:00, and the maximum light intensity (c.a. 350 $\mu mols^{-2}m^{-2}$) was maintained from 13:00 to 15:00 for 2 hr.

Collection of Volatiles from Shoots and Litter Emissions were collected four times from the main shoot of 9 saplings on September 18–19 (d 1), 21–22 (d 3), 24–25 (d 6), and 27–28 (d 9), 2007, until the fall of leaves began. After abscission, VOC emissions from the fresh litter were collected. Each shoot was enclosed in a pre-cleaned (oven-heated 120°C, 1 hr) multi-purpose polyethylene terephthalate (PET) cooking bag, (vol. 3 l, Look, Terinex Ltd., UK) (Ibrahim et al., 2010). The bags were fastened carefully to the shoot bark with gardening wire with care taken not to damage any foliage. One of the two outermost bag corners was cut and an air inlet tube inserted. Clean charcoal-filtered, and MnO_2 scrubbed air was pumped through Teflon tubing and into the bag at 400 ml/min to flush the system, and then reduced to 230 $ml min^{-1}$. The remaining bag corner was cut, and a stainless steel tube containing approximately 150 mg of Tenax TA-adsorbent (Supelco, mesh 60/80) was inserted and fastened into the opening. Air was pulled through the Tenax tube by battery-operated sampling pumps (Rietschle Thomas, Puchheim, Germany). The air flow through the Tenax tube was set to 200 ml min–1 with an M-5 bubble flowmeter (A.P. Buck, Orlando, FL, USA). Samples were collected between 9:00 and 15:00. After leaf abscission, emissions from leaf-free branches were sampled to detect possible bark emissions. Due to easy fall of leaves during the abscission phase, we sampled freshly abscised leaves to better evaluate emissions of the last stage. The newly generated litter was collected from these 5 saplings and stored separately in 5 pre-heated (1 h at 120°C to remove any adhered plant VOC from surfaces) and cooled 1.5 l glass containers in growth chambers. VOC emissions were sampled from these containers at +22°C by a similar method 6 day after the last sampling of foliar BVOCs. Each glass container held an average of 40 leaves. After VOC sampling, the leaves were dried in an oven at a temperature of 70°C until the dry weight was constant.

The VOC samples were analyzed with a gas chromatograph-mass spectrometer (Hewlett-Packard GC 6890, MSD 5973). Trapped compounds were desorbed with a thermal desorption unit (Perkin-Elmer ATD400 Automatic Thermal Desorption system) at 250°C for 10 min, cryofocused at −30°C, and injected onto an HP-5 capillary column (50 m×0.2 mm i.d.×0.5 μm film thickness, Hewlett-Packard) with helium as carrier gas. The temperature program was as follows: 40°C 1 min, 5°C min-1 to 210°C, 20°C min-1 to 250°C, 250°C 8 min. Compounds were identified and quantified by comparing the mass spectra to those of pure standards (one external standard mixture for terpenes and one for GLVs) and to spectra in the Wiley library (Vuorinen et al., 2004). Our terpene standard included pure compounds: α-pinene, sabinene, β-pinene, myrcene, (*E*)-β-ocimene, limonene, 1,8–cineole (eucalyptol), 1-chloro octan, γ-terpinene linalool, (*E)*-DMNT, alloocimene, α-copaene, longifolene, *trans*-β-farnesene, aromadendrene, α-humulene, δ-cadinene, and caryophyllene oxide. The GLV standard included: *cis*-3-hexen-1-ol, *trans*-2-hexenal, 1-hexanol, 1-octen-3-ol, *cis*-3-hexenyl acetate, 1-chloro octan, nonanal, *cis*-3-hexenyl butyrate, methyl salicylate, *cis*-3-hexenyl isovalerate, and *cis*-3-hexenyl tiglate. All compounds were purchased from Sigma-Aldrich (parent company of Sigma, Aldrich, Fluka and Supelco) except sabinene from CHEMOS GmbH, *trans*-β-farnesene and *cis*-3-hexenyl isovalerate from Bedoukian Research Inc. DMNT was synthesized in-house from commercial citral using methyltriphenylphosphonium bromide and butyl lithium (Ibrahim et al., 2008).

Data Analysis The quantities of emitted compounds in the headspace of plants and litter leaves were calculated in nanograms per g dry weight per h. Emission rates for each sample were compared with one-way ANOVA or non-parametric Kendall's W Test if data did not follow a normal distribution. The proportion of yellowing leaves was tested with Dunnet's test. A principal component analysis (PCA) (SIMCA-P 11.5.0.0, Umetrics AB, Umeå, Sweden) was used to divide the VOCs on the basis of the composition and ordination of the saplings for each sampling date (eigenvalues over 1 were extracted, and the original data compressed to two principal components PC1 and PC2).

Results

The proportion of green leaves in foliage was significantly affected ($F_{3,27}$=14.27, P<0.001) during the monitoring period with the proportion significantly lower on days 6

and 9 (Dunnet's test) than on the first day (Table 1). There were trends for total terpene emissions to decrease and total green leaf volatiles (GLVs) to increase (Fig. 1), but only total GLV emissions differed significantly among days ($F_{3,26}$=4,46, P=0.012) being higher on day 6 than on day 1. The emissions of the common photosynthesis-related monoterpenes (1,8-cineole, α-pinene, β-myrcene, β-pinene, limonene, and sabinene) were low during the yellowing process, and did not differ among the days (Table 1). Inducible terpenes, monoterpenes (*E*)-β-ocimene and linalool, the homoterpene (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), and the sesquiterpene α-copaene, were emitted only from saplings with green foliage. The inducible aromatic compound, methyl salicylate (MeSA), was emitted by green foliage and by one sapling already showing yellowing symptoms, but not from leaves in the later phases of senescence. MeSa emissions differed significantly (W=0.543, P=0.043) (nonparametric Kendall's W Test) among days. The GLVs *cis*-3-hexenol and *cis*-3-hexenyl acetate were emitted in minor amounts (17% of total emission) from green foliage. These compounds also were emitted from yellowing leaves and became more common volatiles just before leaf abscission. Principal component analysis (Fig. 2) showed that the emission of *cis*-3-hexen-1-ol was linked mostly to leaf senescence, and the emission was correlated positively with proportion of senescing leaves (r=0.682, P<0.01, N=30). The ratio of *cis*-3-hexen-1-ol to *cis*-3-hexenyl acetate concentrations in emissions changed from 0.8 in green and yellowing foliage to 4.0 just before abscission, and it increased to 100 after leaf abscission, as *cis*-3-hexenyl acetate was not detectable in fresh litter samples.

No volatile emissions were detected from the leafless shoots. Analysis of VOC emissions from abscised leaves in fresh leaf litter indicated that GLV compounds constituted more than 75% of the emission of birch leaves at the early decomposition stage (Fig. 3). Some emissions of monoterpenes and MeSa were detected, but the dominating photosynthesis related monoterpene α-pinene was not detected, while linalool, β-myrcene, and limonene were detected.

Discussion

VOC Emissions during Senescence There were sequential changes in the emission profiles during senescence of birch foliage, and principal component analysis was able to characterize and group the saplings separately on day 1 and 9 on the basis of the emission composition during the yellowing process. Inducible terpenes and photosynthesis-related monoterpenes were typical of green foliage emission profiles, and GLVs typical of senescing foliage. Our first hypothesis that a reduced proportion of costly photosynthesis-related VOCs will be emitted by senescing foliage is supported by our results, which show that VOCs known to be induced by herbivores (Vuorinen et al., 2007; Blande et al., 2010) or abiotic stress (Ibrahim et al., 2010) like DMNT, linalool, and (*E*)-β-ocimene are emitted by green leaves, but not by mostly yellow foliage. These

Table 1 Mean (±S.E.) proportion of green leaves in foliage of *Betula pendula* saplings and emissions of volatile compounds (ng g^{-1} DW h^{-1}±S.E.) for four sampling dates during the leaf yellowing process. (*N*=9)

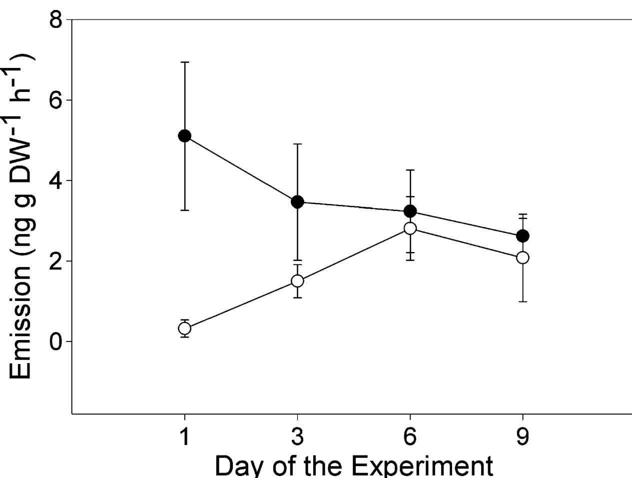

Fig. 1 Trend of total terpene (solid symbols, ●) and total GLV (open symbols, ○) emissions (mean±S.E.) from yellowing birch saplings *(N*= 9) over four sampling dates during the monitoring period (days 1—9) of leaf color change

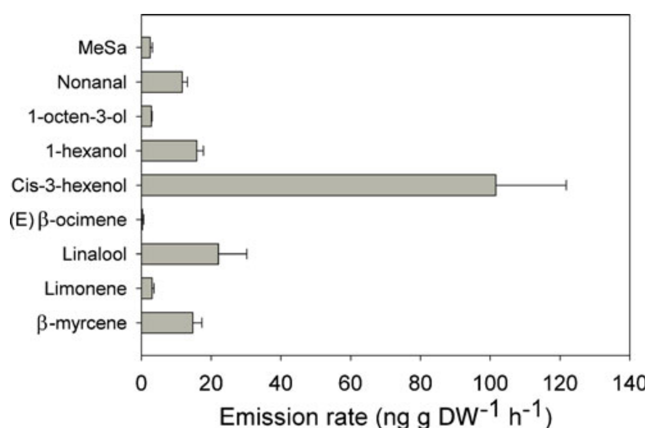

Fig. 3 VOC emissions (mean±S.E.) from fresh *Betula pendula* leaf litter. Sampling of volatiles at +22°C was conducted following 5 days incubation in growth chambers after leaf fall. *(N*=5)

inducible compounds can be found in small amounts (emission rates below 50 ngg^{-1} DW h^{-1}), in the emissions of actively growing intact *B. pendula* saplings (Vuorinen et al., 2005). Fungal pathogen infection, however, may increase (*E*)-β-ocimene emission by 30-fold, and chewing herbivore feeding increase the emission of these compounds by more than 10-fold (Vuorinen et al., 2007). We did not find the sesquiterpene (*E,E*)-α-farnesene in the emission profile, although during summer it is emitted abundantly by many *B. pendula* genotypes (Vuorinen et al., 2005, 2007; Ibrahim et al., 2010) and is a typical herbivore-induced VOC in several plant species (e.g., Blande et al., 2007; Pinto et al., 2007). However, α-pinene and β-pinene—light and photosynthesis-related monoterpenes (Hakola et al., 2001; Loreto et al., 2004)—were emitted from leaves in the last stage of senescence, which is against our hypothesis. Explanation for this could be that there were still 20% greenish leaves on the same shoot among senescent leaves, and these may be responsible for monoterpene emissions when analyzing emissions on a shoot or branch basis. Alternatively, α-pinene and β-pinene may have still unknown functions relating to degeneration of photosynthesis.

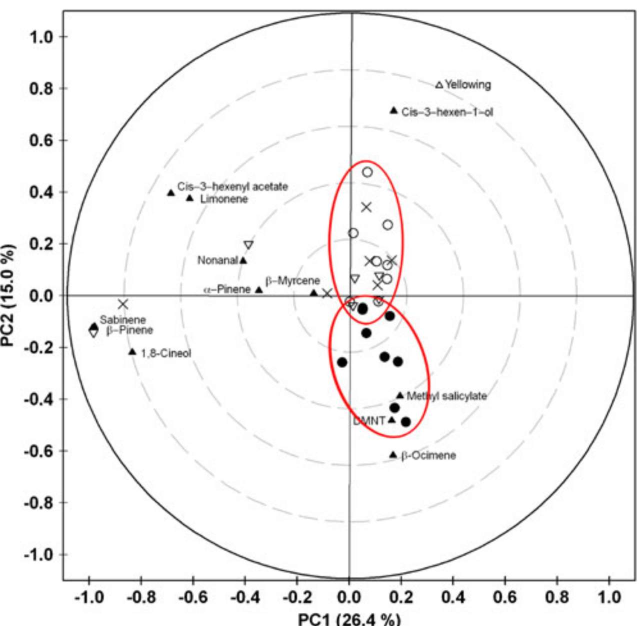

Fig. 2 A principal component bi-plot, showing the variation of volatile organic compound (VOC) composition and ordination of the *Betula pendula* saplings for each sampling date (day 1, 3, 6 and 9), on the basis of foliar VOC emission profile (1–4). Sapling symbols: ●=day 1, ▽= day 3, X=day 6, and o=day 9. Compounds are marked with the symbol ▲ and the symbol △ marks the proportion of yellow leaves

Against our second hypothesis, we did not find emission of the sesquiterpene (*E*)-β-farnesene—a known aphid alarm pheromone released by some plant species in nature (Beale et al., 2006)—or any other aphid repellent volatile that might have been expected according to the co-evolution hypothesis (Hamilton and Brown, 2001). MeSa is an aphid-induced compound in *B. pendula* (Blande et al., 2010); it is less reactive than most of the terpenes in the atmosphere, and emissions are induced even by abiotic factors such as ozone (Pinto et al., 2007). It is known to repel certain migrating aphids in spring (Glinwood and Petersson, 2000a), but mostly it is an attractant of autumn migrants (Pope et al., 2007). The cessation of MeSA emissions from leaves starting to change color together with the color signals could inform aphids of nutrient remobilization in leaves.

In accordance with our third expectation, GLVs dominated the VOC profile in the later stages of senescence, particularly in abscised leaves. GLVs commonly are emitted from mechanically damaged plant material (Fall et al., 1999; Vuorinen et al., 2005; D'Auria et al., 2007;),

including plant material damaged by chewing and piercing herbivores (Pinto et al., 2007). Some GLVs, for example *cis*-3-hexen-1-ol, can increase the predation rate of generalist predators (Kessler and Baldwin, 2001). Our saplings did not have any direct herbivore or mechanical damage, and the emissions of GLVs were rather low. Emissions of hexenol, hexanal, *cis*-3-hexen-1-ol, and *trans*-2-hexenal have been found to be associated with the senescence of grass crops (Karl et al., 2005). Physical stress leading to senescence strongly affects emission rates of GLVs (Fall et al., 1999). Our results suggest that these compounds might be related to the disintegration of cell organelles and dying cells (Keskitalo et al., 2005) during formation of necrotic leaf spots a few days before abscission. The dominance of *cis*-3-hexen-1-ol and concomitant decrease of *cis*-3-hexenyl acetate in leaf emissions in the last phase of senescence could be the olfactory cue, which female aphids might rely on to avoid falling from foliage with abscising leaves (Glinwood and Petersson, 2000b).

VOC Emissions after Leaf Fall The most common photosynthesis-related monoterpene (α-pinene) was not emitted from the fresh birch litter, which indicates that the emission of this highly volatile compound depends on photosynthesizing leaves in deciduous species that do not store monoterpenes. However, some other monoterpenes like β-myrcene, linalool, and (*E*)-β-ocimene were found in litter emissions. This could be due partly to emissions from aqueous and lipid phase stores (Noe et al., 2006) in abscised leaves due to limited volatility in cold autumn conditions. Furthermore, as the litter leaves were incubated for a few days in the same container, emissions per unit of leaf dry mass are not quantitatively comparable to foliage emissions due to possible adsorption and desorption of compounds onto the container surfaces (Schaub et al., 2010) and loss of leaf weight due to decomposition. The condensation and accumulation of terpenes on leaf and container surfaces could be an explanation for the appearance of linalool in litter samples, although it was detectable only in green foliage of saplings.

The dominance of GLV compounds in the VOC emission profile of fresh litter, and particularly the compound *cis*-3-hexen-1-ol, was most obvious and could be a result of the increasing proportion of necrotic leaf tissues during microbial decomposition. High concentrations of GLVs have been found in the forest atmosphere in autumn when senescing and litter leaves thaw after freezing spells of weather and emit GLVs (Karl et al., 2001). Fall et al. (1999) demonstrated with aspen, beech, and clover that after leaf detachment, emissions of GLVs were not dependent on light, and emissions were enhanced greatly as detached leaves dried out. Our results show that GLVs dominate in the emissions from senescing leaves and fresh leaf litter, although leaves did not undergo thawing or drying. Substantial *cis*-3-hexen-1-ol and *cis*-3-hexenyl acetate emissions from birch foliage and birch litter in autumn could have significant atmospheric and ecological impacts, as both compounds participate strongly in secondary organic aerosol formation in reactions with tropospheric ozone (Pinto et al., 2007; Hamilton et al., 2009) and hydroxyl radicals (Hamilton et al., 2009).

VOCs and the Coevolutionary Theory of Autumn Colors Handicap signals are strategic signals that indicate that an individual has possession of a great deal of some resources for costly investments (Zahavi, 1975). If the signal is not costly, then other individuals might mimic strong defense and thus diminish signal reliability (Hamilton and Brown, 2001). Green foliage is known to have high light use efficiency and photosynthetic capacity (Evain et al., 2004). There is a strong coupling of photosynthesis and phytogenic VOC emissions (Penuelas and Lusia, 2003), and among other functions these compounds are effective cues for predators and parasitoids toward herbivore-attacked plants (Holopainen, 2008; Dicke and Baldwin, 2010; Holopainen and Gershenzon, 2010). Our results indicate that particularly costly terpenes (Gershenzon, 1994; Loreto and Schnitzler, 2010) are diminished in volatile emission of yellowing birch leaves. This observation suggests that green foliage is capable of facilitating induced indirect defense based on volatile terpenes. It should be tested in behavioral experiments whether the color-changing senescing leaves are able to produce sufficiently volatile terpenes as odor signals for natural enemies of aphids and other herbivorous insects. Further research also should elucidate whether increasing GLV emissions from senescing foliage distinguishes herbivore-damaged leaves from undamaged leaves and whether carnivores can respond to this difference. Behavioral tests could give support for the hypothesis (Holopainen, 2008) that honest signals of herbivore damage for natural enemies of herbivorous insects are produced only by green foliage, and hence senescing foliage could provide an enemy-free space for aphids.

2008; Himanen et al., 2009). Accumulated plant VOCs may volatilize into the atmosphere, depending on their concentration and physiochemical properties (Niinemets et al., 2004). Some VOCs, such as sesquiterpenes, may have allelopathic effects on neighboring plants (Fischer et al., 1989; Macías et al., 1996; Abdelgaleil and Hashinaga, 2007; Abdelgaleil et al., 2009; Wang et al., 2009).

Mikania micrantha H.B.K. (Compositae), a fast-growing vine species, is one of the world's most aggressive weeds. The plant originated from South and Central America (Maffei et al., 1999), and has led to serious ecological problems in Southeast Asia and the Pacific region (Zhang et al., 2004). In Southern China, *M. micrantha* has caused serious damage to crops and forests (Zhang et al., 2004; Wang et al., 2009). In natural ecosystems, rapid invasion of *M. micrantha* during recent years is correlated with extinction of native species (Lee and Klasing, 2004). Beside the efficient take-up of water and nutrients, *M. micrantha* releases phytotoxic compounds that inhibit germination and growth of neighboring plants (Cock et al., 2000; Ismail and Chong, 2002; Shao et al., 2005; Ni et al., 2006). Several studies indicate that allelopathy may be a phenomenon that increases fitness of invasive plants (Callaway and Aschehoug, 2000; Inderjit and Duke, 2003; Gómez-Aparicio and Canham, 2008). In general, allelopathy is more common under extreme environmental conditions, where water, light, or nutrients are limited (Anaya, 1999; Valladares et al., 2007). A similar stress situation might be true in the case of elevated CO_2 concentration.

β-Caryophyllene synthase catalyses the conversion of farnesyl diphosphate to β-caryophyllene, a common sesquiterpene of essential oils of many plants (Cai et al., 2002). β-Caryophyllene inhibits seedling growth of *Brassica campestris* and *Raphanus sativus* (Wang et al., 2009). Kil et al. (2000) reported that β-caryophyllene is a component of the essential oil of *Artemisia lavandulaefolia*, which suppresses seedling growth of *Achyranthes japonica* (Miq.). Overexpression of the sesquiterpene synthase gene namely Os*TPS3* [(*E*)-β-caryophyllene synthase)] in rice plants increases the production of the compound after methyl jasmonate (MeJA) treatment, and MeJA-treated transgenic rice plants attract more parasitoid wasps of *Anagrus nilaparvatae* than the wild-type (Cheng et al., 2007). These studies suggest that the β-caryophyllene synthase and β-caryophyllene may play a role in the indirect defense of plants.

We hypothesized that increasing atmospheric CO_2 concentrations may change allelochemical production and allelopathic potential of the invasive alien plant *M. micrantha*, which, in turn, may affect its interactions with native plants by affecting their germination and seedling growth.

Methods and Materials

Plant Materials Plants of *M. micrantha* H.B.K. (1.5 m high) were collected from a natural population in Qi Ao Island, Zhuhai (N 21°48′, E 113°3′) and maintained in a greenhouse in Guangzhou (N 23°8′, E 113°17′). They were cut into 10 cm pieces and transplanted into plastic pots (20 cm diam; 25 cm high) and allowed to climb on 1.5 m bamboo stakes. Uniform seedlings (about 1.2 m high) were selected and planted in 12 pots (one plant per pot). Transplanted pots were transferred into growth chambers at 350 or 750 ppm CO_2 concentration with 10 hr daylight 12 000 lx at 25°C; 14 hr night at 15°C and 80% relative humidity. Plants were watered with diluted Hoagland solution (25% *v*/*v*) and randomized twice a week to avoid internal chamber effects. Seeds of *R. sativus*, *B. campestris,* and *Lactuca sativa* were purchased from Guangzhou Seed Company (Guangzhou, China), and seeds of *M. micrantha* were collected from Qi Ao Island, Zhuhai. β-Caryophyllene (>98.5% purity) was purchased from Sigma-Aldrich Chemie GmbH (D-89555 Steinheim, Germany).

SSH Library Construction Suppression subtractive hybridization (SSH) was used to generate a cDNA library (Diatchenko et al., 1996). Briefly, 30-d-old *M. micrantha* plants grown at 350 ppm CO_2 were exposed to 750 ppm CO_2 for 6 d, or left at 350 ppm CO_2. Total RNA then was isolated from the 5th and 6th leaves (counted basipetally from the apex) using the standard guanidine thiocyanate method (Chomczynski and Sacchi, 2006). Double strand cDNA was synthesized using the SMART™ cDNA amplification Kit (Clontech). A subtracted cDNA library was constructed using the PCR-Select cDNA Subtraction Kit (Clontech). PCR products were purified using the QIAquick PCR purification kit (Qiagen) and ligated into the pGEM-T easy vector (Promega). The constructs were transformed into *E. coli* Top10 (Invitrogen). Positive clones were verified by PCR using T7 and SP6 primers and sequenced with an ABI 3730 sequencer (Applied Biosystems, Inc.). All obtained sequences were compared with DNA databases using the BLASTX sequence comparison software (Altschul et al., 1997) at the NCBI website (http://www.ncbi.nlm.nih.-gov/BLAST). An identified expressed sequence tag (EST) named WGJ87 (658 bp) showed high level of sequence similarity (e^{-35}) to a characterized β-caryophyllene synthase gene from *Artemisia annua* (accession number AAL79181) (Cai et al., 2002), and this inspired us to do further analysis.

Real-time Quantitative PCR Real-time PCR was performed with RNA isolated from *M. micrantha* leaves to confirm activation of β-caryophyllene synthase expression in response to increased CO_2 concentration. Twelve pots of

M. micrantha (1.2 m high) were transferred into the growth chambers at 350 or 750 ppm CO_2 for up to 12 d. The 5th and 6th leaves of each plant from three pots were harvested at 3, 6, 9, and 12 d. Total RNA was isolated from the harvested leaves and quantified based on the absorbance at 260 nm. The integrity of RNA was checked with agarose gel electrophoresis. The RNA (1 μg) was treated first with DNase I (Invitrogen) to remove any genomic DNA contamination. The RNA then was reverse transcribed using oligo (dT) primer and ThermoScript RT-PCR System (Invitrogen) according to the manufacturer's instructions.

Real-time PCR was performed on the ABI PRISM 7000 sequence detection system (Applied Biosystems) in a volume of 20 μl containing 0.2 μM of each primer, 10 μl of 2×SYBR Green I (Roche) and 1 μl of the cDNA temple. The PCR cycling conditions were: 95°C for 1 min, 40 cycles of 95°C for 15 sec, 55°C for 15 sec, 72°C for 45 sec, and 85°C for 20 sec for signal collection in each cycle. To assess the specificity of the PCR amplification, a melt-curve analysis was performed at the end of the reaction by increasing temperature from 55 to 99°C and held for 5 sec at every increment of 1°C, and a single peak was observed.

The PCR primers were WGJ87F1 (5′-TAAGAAGGAG CAAGAAAGAGTGC-3′) and WFG87R1 (5′-CTC TTTGATGTCTTCTTCCACTTC-3′) for β-caryophyllene synthase, and WGJ60 (5′-GATTCCACCAGACCAG CAAAGG-3′) WGJ61 (5′-CACCACGAAGACGAAGCA CAAG-3′) for ubiquitin. The primers were designed from the sequenced ESTs, and the ubiquitin gene was chosen as internal standard. Real-time PCR reactions were performed in triplicate. Analysis of relative gene expression data was performed with the $2^{-\Delta\Delta CT}$ method (Livak and Schmittgen, 2001) using *M. micrantha* plants exposed to 350 ppm CO_2 as a reference.

GC-MS and GC Analysis Twelve pots of *M. micrantha* grown at 350 ppm CO_2 for 30 d were exposed to 750 ppm for 3, 6, 9, and 12 d. Control plants were left at 350 ppm CO_2. The 5th and 6th leaves of each plant were harvested at 9:30 in the morning 3, 6, 9, and 12 d after exposure. For analysis of the volatiles sesquiterpenes, 500 mg fresh leaves were ground in liquid N_2. After addition of 5 g Na_2SO_4, the powder was enclosed in a 22-ml glass tube, and the 65-μm solid-phase microextraction (SPME) PDMS-DVB fiber (Supelco, Bellefonte, PA, USA) was inserted into the tube to collect volatiles at 80°C for 25 min. The SPME fiber was injected into a GC-MS system for analysis. For quantification, 11.3 ng of β-caryophyllene was added as an internal standard in one of the control samples.

GC-MS analysis of volatile sesquiterpenes was performed with a Finnigan Voyager using a BPX5 column (25 m×0.22 mm×0.25 μm), He (1 $ml\,min^{-1}$ gas flow rate), a splitless injection temperature 220°C, a quadrupole-type mass selective detector with a transfer line temperature 230°C, a source temperature 200°C, an ionization potential 70 eV, and a scan range 35 to 450 amu. The initial temperature was 60°C. After 3 min, the temperature was increased to 120°C (gradient of $10°C\,min^{-1}$); the temperature was then further increased to reach 180°C (gradient of $5°C\,min^{-1}$) and finally to 250°C (gradient of $25°C\,min^{-1}$). Individual sesquiterpenes were tentatively identified by a peak matching library search that used authentic standards and NIST (National Institute of Standard and Technology) and Wiley libraries.

Changes of the β-caryophyllene were analyzed by GC-FID using an HP-5MS column (30 m×0.25 mm×0.25 μm), N_2 (1 $ml\,min^{-1}$ gas flow rate) as carrier. Two ml headspace samples were analyzed using the parameters described above.

Bioassay of β-Caryophyllene Seeds of *R. sativus*, *B. campestris*, *L. sativa,* and *M. micrantha* were surface-sterilized with 0.5% $KMnO_4$ for 10 min and then washed × 3 with sterile distilled water. β-Caryophyllene was dissolved in ethyl acetate, and different volumes of this solution were added to filter paper in glass containers (6× 6×10 cm) to get 0.375, 3, and 24 $mg\,L^{-1}$ concentrations. After complete evaporation of ethyl acetate, 20 seeds of each target plant and 5 ml distilled water were placed in each glass container (Wang et al., 2009). Plants were grown in growth chambers at 350 or 750 ppm CO_2 (at 25±1°C with10 hr light, 14 hr dark and 80% relative humidity). Germination rate (3 d for *R. sativus* and *B. campestris*; 7 d for *L. sativa* and *M. micrantha*), root length, and shoot height of seedlings were recorded from each filter paper at the time of harvest (9 d for *R. sativus* and *B. campestris*; 16 d for *L. sativa* and *M. micrantha*). The magnitude of inhibition or stimulation in bioassay was used as the response index (*RI*) as per Williamson and Richardson (1988):

$$\mathrm{RI} = 1 - \mathrm{C}/\mathrm{T}(\mathrm{T} \geq \mathrm{C})$$
$$\text{or } \mathrm{RI} = \mathrm{T}/\mathrm{C} - 1(\mathrm{T} < \mathrm{C})$$

Where, C is control and T is treatment value. The absolute value of *RI* represents the phytotoxic effect. Value of $RI>0$ is considered stimulatory, while <0 is considered inhibitory.

Statistical Analysis Phytotoxicity of β-caryophyllene expressed as *RI* index was analyzed using one-way ANOVA followed by the Duncan's multiple range tests. Relative expression level of β-caryophyllene synthase gene and relative abundance of β-caryophyllene in *M. micrantha* leaves were analyzed using two-way ANOVA followed by the Duncan's *post hoc* tests using the SPSS 13.0 software package (SPSS, Inc., Chicago, IL, USA).

Results

Induction of β-Caryophyllene Synthase Real-time PCR analysis showed that elevated CO_2 significantly increased the transcript levels of β-caryophyllene synthase in the leaves of *M. micrantha* (Fig. 1). Transcript levels were increased 9.07, 18.95, 16.55, and 27.68 fold after the plants were exposed to 750 ppm CO_2 for 3, 6, 9, and 12 d, respectively. However, the gene did not significantly change its expression level when plants were grown in the chamber with CO_2 at 350 ppm.

Levels of β-Caryophyllene GC analysis indicated differences in the emission of β-caryophyllene between *M. micrantha* plants exposed to 750 ppm CO_2 and those kept at 350 ppm CO_2 (Fig. 2). Control plants grown at 350 ppm CO_2 did not significantly change during the experiment (12 d). However, plants at 750 ppm CO_2 varied in emission of β-caryophyllene during the experiment time. Maximum emission was found in plants exposed to 750 ppm CO_2 for 9 d. *M. micrantha* leaves in all plants exposed to 750 ppm CO_2 had significantly higher levels of β-caryophyllene than those exposed to 350 ppm CO_2 (Fig. 2).

Phytotoxicity of β-Caryophyllene β-Caryophyllene inhibited seed germination, root and shoot growth of *B. campestris*, *R. sativus*, *L. sativa,* and *M. micrantha*. The response indices (*RI*) of *B. campestris* grown under 350 ppm CO_2 were −0.08, −0.15, and −0.18 for the seed germination, root and shoot growth, respectively (Table 1). Root growth of *R. sativus*, *L. sativa* and *M. micrantha* was more sensitive than shoot growth. β-Caryophyllene at 24 mg L^{-1} significantly inhibited the seed germination and seedling growth of all four tested plant species (Table 1).

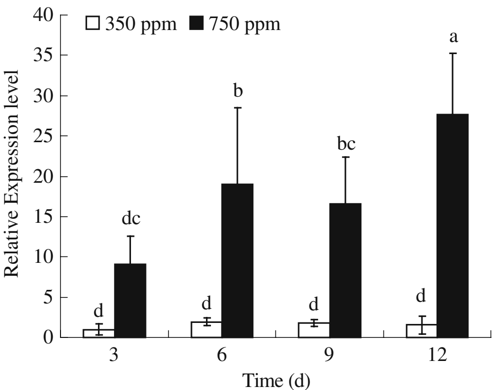

Fig. 1 Relative expression level of β-caryophyllene synthase gene in *Mikania micrantha* leaves as analyzed by real-time PCR. Plants were grown at 350 ppm CO_2 or 750 ppm CO_2 for the indicated period. Three replicates were used for treatment. Each bar represents means± SD. Different letters above the bars indicate significant differences ($P<0.05$) according to Duncan's multiple range tests. Two-way ANOVA: time effect, F=3.82, df=3, $P<0.05$ (P=0.031); the concentration of CO_2 effect, F=66.62, df=1, $P<0.001$; time×the concentration of CO_2 interaction, F=3.41, df=3, $P<0.05$ (P=0.043)

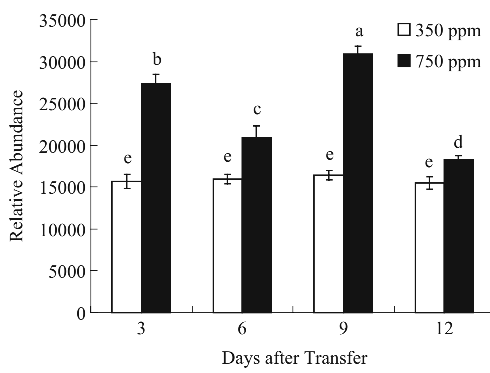

Fig. 2 Relative abundance of β-caryophyllene emission from *Mikania micrantha* leaves analyzed by GC. Plants were grown at 350 ppm CO_2 or 750 ppm CO_2 for the indicated period. Three replicates were used for treatment. Each bar represents means±SD. Different letters above the bars indicate significant differences ($P<0.05$) according to Duncan's multiple range tests Two-way ANOVA: time effect, F=69.88, df=3, $P<0.001$; the concentration of CO_2 effect, F=542.86, df=1, $P<0.001$; time×the concentration of CO_2 interaction, F=57.18, df=3, $P<0.001$

To determine the effects of elevated CO_2 on the phytotoxicity of β-caryophyllene, the seeds of the four plants were treated with β-caryophyllene in a similar way and then exposed to chambers with different CO_2 concentrations (350 and 750 ppm). β-Caryophyllene at a concentration of 24 mgL^{-1} inhibited root growth of *B. campestris*, *R. sativus*, *L. sativa,* and *M. micrantha* by 37, 38, 24, and 24% (corresponsive *RI*=−0.37, −0.38, −0.24, and −0.24), respectively, when CO_2 concentration was 350 ppm (Table 1). At elevated CO_2 concentration (750 ppm) β-caryophyllene at 24 mgL^{-1} inhibited root growth of *B. campestris*, *R. sativus*, *L. sativa,* and *M. micrantha* by 45, 58, 34, and 28% (corresponsive *RI*=−0.45, −0.58, −0.34, and −0.28), respectively (Table 1). Elevated CO_2 concentration enhanced the allelopathic potential of β-caryophyllene on all test species. Similar trends were observed with respect to seed germination and shoot growth of all the target plants.

Discussion

We identified a β-caryophyllene synthase gene sequence (GenBank FJ767894) in *M. micrantha.* Real-time PCR analysis showed that elevated CO_2 significantly increased the transcript levels of the β-caryophyllene synthase gene in the course of the experiment (Fig. 1). GC analysis confirmed that plants of *M. micrantha* did not significantly change their emission of β-caryophyllene when they were grown in the chamber with CO_2 at 350 ppm. However, plants exposed to 750 ppm CO_2 significantly increased the

Table 1 Effect of β-caryophyllene on seed germination and seedling growth expressed as Response Indices (*RI*) of four plants under 350 and 750 ppm CO_2. All data are presented as means±SD. Each value is the mean of three replicates. Different letters in the same row indicate significant differences ($P<0.05$) according to Duncan's multiple range test

emission of β-caryophyllene and reached the maximum level at 9 d after the exposure (Fig. 2). β-Caryophyllene emission capacity may depend on many factors, such as the rate of its synthesis, the rate of its conversion to other sesquiterpenes, and the rate of emission as volatile compounds from intact tissue. Our data showed clearly that elevated CO_2 concentration induced the expression of the β-caryophyllene synthase gene and increased the emission of β-caryophyllene in *M. micrantha*. These findings support our hypothesis that emission of VOCs from plants is particularly sensitive to changes of environmental factors such as CO_2. Leaves of *Quercus ilex* also increase volatile emission of monoterpenes at elevated CO_2 levels (Staudt et al., 2001). Elevated CO_2 typically has both physiological and biochemical effects on VOC emissions (Rosenstiel et al., 2003; Niinemets et al., 2004).

Allelochemicals play a role in mediating interspecific interactions (Dicke et al., 1990; Legrand et al., 2003; Duke, 2007). Terpenoids, a diverse group of secondary compounds, have a variety of ecological functions, including allelopathy (Gershenzon and Croteau, 1993; Sharkey and Singsaas, 1995). Allelopathy is a phenomenon whereby various plants enhance competitiveness and fitness (Singh et al., 2003; Kegge and Pierik 2010). The allelopathic potential of a given plant may vary in different habitats. Environmental stresses such as light, or nutrient or water deficiency may enhance allelopathic potential of plants (Anaya, 1999). β-Caryophyllene, a well-known volatile sesquiterpene with allelopathic potential, has been reported previously to inhibit development of seedlings of various plant species (Kil et al., 2000; Wang et al., 2009). A previously characterized β-caryophyllene synthase gene of *A. annua* also was induced previously by a fungal elicitor, suggesting a role for β-caryophyllene in plant defense (Cai et al., 2002). Emission rates of β-caryophyllene from orange trees (*Citrus sinensis* (L.) OSBECK, var. *Navel* and *Navel Late*) vary with light intensity and temperature (Hansen and Seufert, 2003). Here, at elevated CO_2 levels (750 ppm), phytotoxic effects of β-caryophyllene were enhanced on all tested plants, especially on *R. sativus*. Hence, CO_2 concentrations not only affected the emission of β-caryophyllene from *M. micrantha* leaves (Fig. 2), but also increased its phytotoxicity (Table 1). In other words, an increase in CO_2 concentrations may have multiple effects on plant-plant interactions.

Many studies suggest that climate changes may affect structure and function of ecological systems (Walther, 2003; Jump and Penuelas, 2005). Temperature changes in the subtropical north Indian plains seem to influence biosynthesis of essential oil constituents in *A. annua* (Bagchi et al., 2003). It has been suggested that rising atmospheric CO_2 concentrations increase abundance, biomass, and fitness of vines that may interfere with regeneration and diversity of forest ecosystems (Sasek and Strain, 1991; Granados and Körner, 2002; Zotz et al., 2006; Song et al., 2009). Increasing CO_2 concentration has been suggested previously as a factor that could facilitate exotic plant invasion (Song et al., 2009). Our experiment was conducted over 12 days. In nature, however, an increase in

CO_2 concentration is likely to occur over a long period of time for which the plant may even acquire adaptation. Recently, Klironomos et al. (2005) reported on the over estimation of plant responses in experiments that use abrupt increase of CO_2 concentration. Although 100 years (predicted time for doubling of CO_2 concentration) is a short time (in evolutionary terms) for acquiring such an adaptation, there is some evidence, however, that shows microevolution occurring in plants over short periods of time (Collins and Bell, 2004; Ward and Kelly, 2004). Based on such reports and our findings, we postulate that a future increase in atmospheric CO_2 levels may alter allelopathic potential of the invasive vine *M. micrantha*. Future studies are, of course, required to determine how the release of volatile allelochemicals and CO_2 concentrations will affect invasion of *M. micrantha* in Southern China.

Acknowledgements We thank Prof. Azim Mallik for linguistic corrections and help with the introduction and discussion of the paper. Three anonymous reviewers provided valuable suggestions to improve the manuscript. reliable indicators of their presence to parasitoids, but the detectability of these cues is low. On the other hand, stimuli emitted by the food plants of their herbivorous hosts are more detectable because they are emitted in larger amounts, but they do not necessarily indicate the presence of the herbivores (Vet and Dicke, 1992). In order to cope with this problem, parasitoids may combine stimuli from both their hosts and host food plants (Turlings et al., 1991a, 1993; Vet and Dicke, 1992; Dicke, 1999a, b; Fatouros et al., 2005; Tamò et al., 2006). Natural enemies, such as insect parasitoids, use infochemicals from host plants to locate the habitat of their hosts (Vinson, 1976; Dicke and Sabelis, 1988; Turlings et al., 1990; Vet and Dicke, 1992; Dicke, 1999b; Mumm and Hilker, 2006; Schnee et al., 2006; Heil, 2008). Natural enemies are able to discriminate between blends of volatiles produced by mechanically damaged and herbivore-damaged plants (Eller et al., 1988; Turlings et al., 1991b; Vet and Dicke, 1992; Dicke, 1999a). In addition to herbivore-induced plant volatiles, several other factors also may affect host searching behavior of a parasitoid, such as visual and vibrational stimuli from the host or host plant, the presence of competitors or natural enemies, previous oviposition experiences (learning), and physiological state of the parasitoid (Lawrence, 1981; Wardle, 1990; Wardle and Borden, 1990; Wäckers and Lewis, 1994; Casas et al., 1998; Dicke, 1999b; Dicke and Grostal, 2001).

The success of biological control agents in many projects has been attributed in particular to high host searching efficiency (Neuenschwander and Ajuonu, 1995; Ngi-Song and Overholt, 1997; de Moraes et al., 1999; Neuenschwander, 2001). For instance, the superiority of *Apoanagyrus (Epidinocarsis) lopezi* De Santis over *Apoanagyrus diversicornis* Howard (which is more fecund than *A. lopezi*) was attributed to its higher capacity to locate and parasitize young host instars at low densities (Neuenschwander, 2001). Similarly, *Cardiochiles nigriceps* Viereck displayed a higher host searching capacity, and consequently detected and parasitized more larvae of *Heliothis virescens* (Fabricius) compared to *Microplitis croceipes* Cresson (de Moraes et al., 1999).

Apanteles taragamae Viereck, the parasitoid that was used in the present study, is a solitary larval endoparasitoid of the legume pod borer *Maruca vitrata* Fabricius (Lepidoptera: Crambidae). It parasitized on average 63% of *M. vitrata* larvae on *Sesbania cannabina* (Retz) Pers. (Huang et al., 2003). The wasp also can transmit the multi-nucleopolyhedrovirus *Mavi*MNPV to larvae of *M. vitrata* (M. Tamò, personal communication).

Maruca vitrata is one of the key insect pests of cowpea, causing up to 80% of yield loss (Nampala et al., 2002). Damage by *M. vitrata* to grain legumes is made by its larvae (Taylor, 1978). Larvae feed on flower buds, flowers, and pods of cowpea (Taylor, 1978; Sharma, 1998). Infestation of flowers was found to be higher than that of flower buds and pods (Sharma, 1998). Larvae of this crambid also were reported to damage leaves of some wild leguminous plants, such as the peabush, *S. cannabina* (Huang et al., 2003).

An attempt to exert biological control of this insect pest is made through the importation of *A. taragamae* from Taiwan into Benin by the International Institute of Tropical Agriculture (IITA). The potential of the wasp as biological control agent is being evaluated.

In this study, we assessed the role of volatiles produced by *M. vitrata* larvae and two host plants, cowpea and peabush, in the host selection process by the parasitoid wasp *A. taragamae* by using a Y-tube olfactometer. Cowpea is the main cultivated host plant of *M. vitrata* in Benin whereas peabush is the host plant on which the parasitoid was collected in Taiwan.

Methods and Materials

Plant materials Seeds of the local cowpea variety Kpodji-guêguê and of peabush were sown in potted soil. Pots were placed in a greenhouse at 28±1°C, and 76±6% relative humidity (means ± SD). Plants were watered every 3 days during the experimental period. Experiments started at the onset of flowering. Flowers or stem portions were collected from cowpea (*Vigna unguiculata)* or peabush (*Sesbania cannabina)* plants to prepare the different odor sources used in the olfactometer tests.

Insect Materials

Mass rearing of Maruca vitrata Pupae of *M. vitrata* were obtained from a stock culture at the field station of the International Institute of Tropical Agriculture (IITA) in Benin. They were placed in open Petri dishes that were incubated in wooden cages (44×45×58 cm) with sleeves, having sides of fine screen and a glass top, and kept at 27.0±0.6°C and 60.9±4.6% relative humidity (means ± SD). Adults emerged inside the cages and were fed by using cotton fibers moistened with 10% glucose solution. Four-d-old female moths were transferred in groups of four or five individuals to transparent cylindrical plastic cups (3 cm diam.×3.5 cm high) and kept for 24 h to allow for oviposition, which occurred on the inner surface of the cups. Ovipositing females were fed with small pieces of filter paper moistened with 10% glucose solution, which were replaced every 24 h. Cups carrying eggs were kept under the same experimental conditions until the larvae hatched. Larvae were transferred to large cylindrical plastic containers (9 cm diam.×12 cm high) provided with artificial diet prepared according to Jackai and Raulston

(1988), and developed through five instars until pupation. The artificial diet contained 4 l water; 59.2 g Agar-agar; 400 g cowpea grain flour; 127.2 g wheat or maize germ flour; 60 g Wesson salt; 44.4 g sorbic acid; 6.3 g methyl p-hydroxy-benzoate; 25 g ascorbic acid; 50 ml acetic acid; 6 ml formaldehyde; 11 g aureomicin; 22 g potassium hydroxide; 29.6 ml choline chloride; and 30 ml vitamin B mixture (Jackai and Raulston, 1988). Pupae were collected and placed in cages. All larvae used in the experiments were obtained from the mass production.

Mass rearing of Apanteles taragamae Cocoons of *A. taragamae* were obtained from the stock culture at the IITA station in Benin that originated from parasitoids collected on *S. cannabina* infested by *M. vitrata* at the World Vegetable Center (AVRDC) in Taiwan. Emerged adults were kept in plastic cylindrical cups (4.5 cm diam.× 5 cm high). A hole (2 cm diam.) punched in the lid of the cups was covered with fine mesh. Adults of *A. taragamae* were fed with honey streaked on the fine mesh of the lid. To allow mated female wasps to parasitize hosts, they were offered, during 24 h, 2-d-old larvae of *M. vitrata* in a small cylindrical cup (3 cm diam.×3.5 cm high) containing a piece of artificial diet. The exposed larvae were reared until cocoon stage. Cocoons were collected and placed in cylindrical cups (4.5 cm diam.×5 cm high). Mass production of wasps took place in a climate chamber with a temperature of 25.3±0.5°C (mean ± SD) and a relative humidity of 78.9±5.6% (mean ± SD). Female wasps used for the different choice tests were obtained from this mass rearing.

Maruca vitrata Multi-Nucleopolyhedrovirus (MaviMNPV) *Maruca vitrata* multi-nucleopolyhedrovirus *(Mavi*MNPV) is a baculovirus isolated from infected larvae of *M. vitrata* on peabush in Taiwan (Lee et al., 2007; Chen et al., 2008). Infected larvae were sluggish, pinkish, and ceased feeding 3–4 day after virus exposure. When dead, larvae were found hanging from the top of the plant with the prolegs attached to the host plant. The virus attacks all larval stages with a high susceptibility of early instars (first and second stages). *Mavi*MNPV potentially could be used as a component in an Integrated Pest Management Programme against *M. vitrata* (Lee et al., 2007). It has been introduced to the IITA-Benin laboratory from AVRDC for experimental purposes.

Oviposition-experienced female wasps Emerged adult female parasitoids were kept together with males for 48 h in cylindrical plastic cups (4.5 cm diam. × 5 cm high) to allow mating. They were fed with honey. Mated females gained oviposition experience by parasitizing two 2-d-old *M. vitrata* larvae in cylindrical plastic cups (3 cm diam. × 3.5 cm high), 30 min prior to the olfactometer tests. The host larvae had been reared on artificial diet. These oviposition-experienced parasitoid females had not received contact with the odor sources used in the present study.

Odor-experienced female wasps Two-d-old mated female parasitoids were kept together with uninfested cowpea flowers for 24 h in cylindrical plastic containers (9 cm diam×12 cm high) where they were fed with honey streaked on the mesh cover of containers. Thirty min prior to the olfactometer test, they were allowed to parasitize 2-d-old larvae feeding on cowpea flowers. Odor-experienced females were used only to test for their response to the volatiles from uninfested cowpea flowers against clean air.

Dynamic olfactometer set-up The response of *A. taragamae* females to volatiles produced by cowpea, peabush flowers, and host larvae was investigated by using a glass Y-tube olfactometer similar to that used by Gnanvossou et al. (2003). Clean airflow was divided in two, and each subflow passed through one of the two odor sources connected to the arms of the glass Y-tube olfactometer. The windspeed in the olfactometer was controlled at 4 l/min.

Bioassay procedure Naïve mated females of *A. taragamae* (without oviposition experience) and oviposition-experienced wasps alternatingly were introduced individually at the entry of the Y-shaped glass tube. Their movement was observed for maximally 10 min. A test began when the wasp started to move. Female wasps remaining motionless for more than 5 min at the release point were discarded from the analysis. Parasitoid wasps that did not reach the end of the olfactometer arm were considered as non-responding wasps. After testing two naïve and two oviposition-experienced female parasitoids, the positions of the odor sources were exchanged to correct for any unforeseen asymmetry in the experimental set-up. Odor sources were renewed after testing eight naïve and eight experienced female wasps. A total of 16–20 naïve and oviposition-experienced female wasps were tested daily, and 60–70 naïve and oviposition-experienced females were tested in total for each choice situation. All female wasps used in this study were 3-d-old.

Bioassays on the response of naïve and oviposition-experienced female wasps to volatiles produced by cowpea flowers The influence of volatiles produced by cowpea flowers on the host selection behavior of both naïve and oviposition-experienced females of *A. taragamae* was investigated by testing the following odor combinations: a) 4 uninfested flowers vs. clean air; b) 4 caterpillar-infested flowers from which larvae were removed prior to the

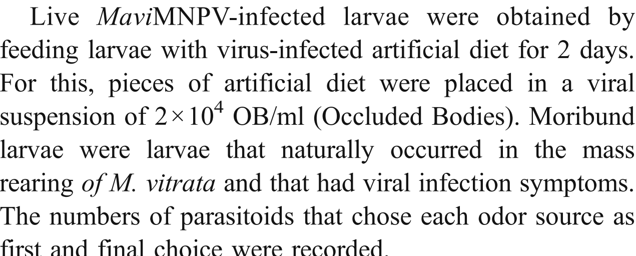
experiment vs. clean air; c) 4 caterpillar-infested flowers from which larvae and their feces were removed prior to the experiment vs. clean air; d) 4 mechanically damaged flowers vs. clean air; e) 4 uninfested vs. 4 caterpillar-infested flowers from which larvae were removed prior to the experiment; f) 4 uninfested vs. 4 mechanically damaged flowers; g) 4 caterpillar-infested flowers from which larvae and feces were removed prior to the experiment vs. 4 uninfested flowers; h) 4 caterpillar-infested flowers from which larvae were removed prior to the experiment vs. 4 mechanically damaged flowers.

Infested cowpea flowers consisted of racemes carrying 4 flowers, infested with 10 1-d-old larvae of *M. vitrata* for 24 h. Before the infestation, racemes were placed in water-filled cylindrical plastic vials (4.5 cm diam × 11.5 cm high) sealed with parafilm to keep racemes fresh and hydrated. Larvae were removed 15 min prior to using the flowers in an olfactometer experiment. Flowers were mechanically damaged 15 min prior to the experiment by three scratched lines onto flowers by using a clean needle.

Bioassays assessing the influence of previous contact with cowpea and peabush plants on the host searching behavior of A. taragamae The influence of an odor experience on the behavioral response to uninfested flowers was studied by using odor-experienced female wasps for odor combination (a) (clean air vs. uninfested cowpea flowers).

As the wasp strain in use was collected originally on peabush plants, the effect of leaves and flowers of this plant on the host searching behavior of the wasp was evaluated by using both naïve and oviposition-experienced females. The *M. vitrata* larvae cause damage to peabush mostly by destroying leaves (Huang et al., 2003). However, flowers of this leguminous shrub also may be damaged. Both naïve and oviposition-experienced female wasps were used to test the following odor combination: i) Uninfested stem portions carrying 4 leaves and 4 flowers of *S. cannabina* vs. clean air.

Bioassays on the effect of volatiles from host larvae on the host searching behavior of A. taragamae The effect of volatiles produced by *M. vitrata* larvae on the host selection behavior of *A. taragamae* was assessed by using healthy, moribund, and live *Mavi*MNPV-infected larvae. Virus-infection had occurred during the mass rearing of *A. taragamae*. Our objective was to assess whether the wasps, being capable of transmitting the baculovirus, avoid infected larvae. Both naïve and oviposition-experienced female wasps were used to test the following odor combinations: j) 10 healthy larvae vs. clean air; k) 10 moribund *Mavi*MNPV-infected larvae vs. clean air; l) 10 healthy larvae vs. 10 moribund *Mavi*MNPV-infected larvae; m) 10 *Mavi*MNPV-infected larvae vs. clean air; n) 10 *Mavi*MNPV-infected larvae vs. 10 healthy larvae.



Live *Mavi*MNPV-infected larvae were obtained by feeding larvae with virus-infected artificial diet for 2 days. For this, pieces of artificial diet were placed in a viral suspension of 2×10^4 OB/ml (Occluded Bodies). Moribund larvae were larvae that naturally occurred in the mass rearing *of M. vitrata* and that had viral infection symptoms. The numbers of parasitoids that chose each odor source as first and final choice were recorded.

Statistical analysis Analysis of data on the number of parasitoids per odor source was performed by using binomial tests with the null hypothesis that the distribution of the wasps over the two arms of the olfactometer was 50:50. Differences between naïve and experienced females wasps were tested with a 2×2 contingency table analysis based on *Chi-square*. Non-responding wasps were recorded but not included in the statistical analysis.

Results

Influence of volatiles from cowpea flowers on the host searching behavior of A. taragamae In all experiments, the responses of the naïve and the oviposition-experienced wasps were not significantly different (contingency table tests, $P > 0.05$). Therefore, we combined the data for naïve and oviposition-experienced wasps.

Females of *A. taragamae* were significantly attracted to volatiles from *M. vitrata*-infested cowpea flowers from which larvae had been removed prior to the experiment, when tested against clean air or uninfested flowers (Fig. 1). Similar results were obtained when the wasps were offered infested flowers from which larvae and feces had been removed prior to the experiment, against clean air or uninfested flowers. The parasitoids did not discriminate between volatiles from uninfested flowers and clean air, between volatiles from mechanically damaged flowers and clean air, or between volatiles from mechanically damaged and uninfested flowers (Fig. 1). Female wasps did discriminate between volatiles from *M. vitrata*-infested flowers and mechanically damaged flowers (Fig. 1).

Response to volatiles produced by uninfested peabush and cowpea flowers Volatiles from stem portions carrying uninfested leaves and flowers of the peabush *S. cannabina* attracted *A. taragamae* females when tested against clean air (Fig. 2). When wasps were given an odor experience, uninfested cowpea flowers were preferred over clean air (Fig. 3), while without the odor experience there was no effect of volatiles from uninfested flowers on parasitoid attraction (Fig. 1).

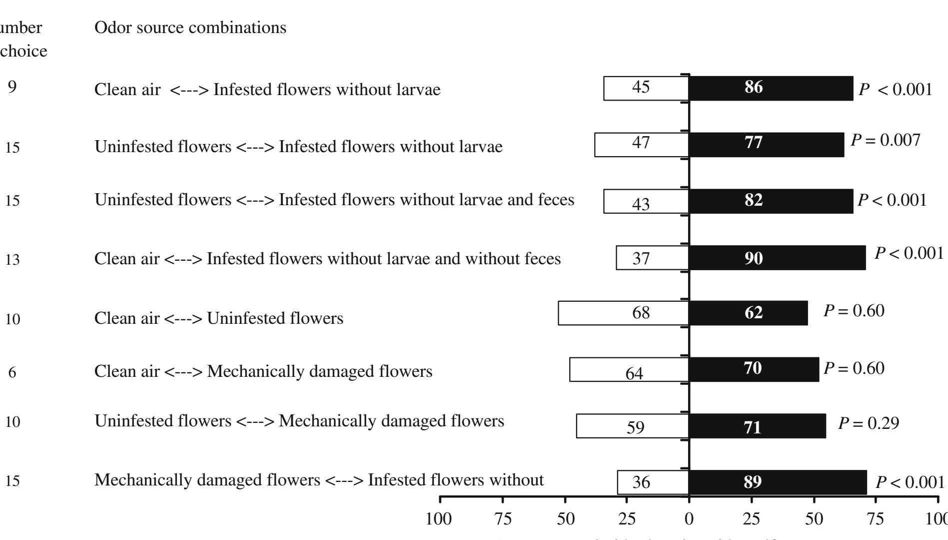


Fig. 1 Behavioral response of *Apanteles taragamae* females offered choices between volatiles from cowpea flowers, that were either uninfested, mechanically damaged, or infested with *Maruca vitrata*, and clean air in a Y-tube olfactometer. *Numbers in bars* represent the total number of parasitoids that chose the olfactometer arm. *P*-values given to the right of the bars are for the two-tailed binomial test

Response to volatiles from host larvae Females of *A. taragamae* displayed a preference for volatiles produced by healthy *M. vitrata* larvae when tested against clean air (Fig. 4). Wasps did not show any preference for volatiles from moribund *Mavi*MNPV-infected larvae over clean air, and they preferred volatiles emitted by healthy larvae over volatiles from moribund *Mavi*MNPV-infected larvae. The parasitoid females did discriminate volatiles from live *Mavi*MNPV-infected larvae against clean air (Fig. 4), but no preference was displayed when they were given a choice between volatiles from healthy larvae and live *Mavi*MNPV-infected larvae.

Discussion

Results from this study show the importance of *M. vitrata*-induced floral volatiles produced by cowpea in the host selection process of *A. taragamae*. Female wasps were attracted by volatiles emitted by *M. vitrata*-infested cowpea flowers from which the larvae had been removed. The parasitoids were not attracted to uninfested cowpea flowers, but this changed when they had received an odor experience. Indeed, long-range volatiles produced by undamaged or herbivore-damaged plants are known to attract natural enemies of herbivorous insects, thus increasing their efficiency in locating their hosts' habitat (Dicke and Sabelis, 1988; Turlings et al., 1990; Vet and Dicke, 1992; Ngi-Song et al., 1996; Du et al., 1998; Dicke, 1999b; Shimoda et al. 2005; Moayeri et al., 2007; Dicke and Baldwin, 2010). In most cases, studies have addressed the volatiles that are produced by leaves. In our study, however, volatiles were emitted by the previously infested flowers. Floral volatiles are known primarily as attractants for pollinators (Jervis et al., 1993; Pichersky and Gershenzon, 2002). However, herbivorous insects that feed or oviposit on flowers have been reported to rely on cues from flowers to locate their hosts (Ekesi et al., 1998; Jönsson et al., 2005; Andrews et al., 2007), and parasitoids may also use floral volatiles to locate a food source (nectar) (Wäckers, 2004). However, to our knowledge only one other study has shown that herbivore-damaged flowers emit volatiles that attract a parasitoid enemy of florivorous herbivores (Jönsson and Anderson, 2008). It will be interesting to investigate how volatiles from herbivore-infested flowers affect the behavior

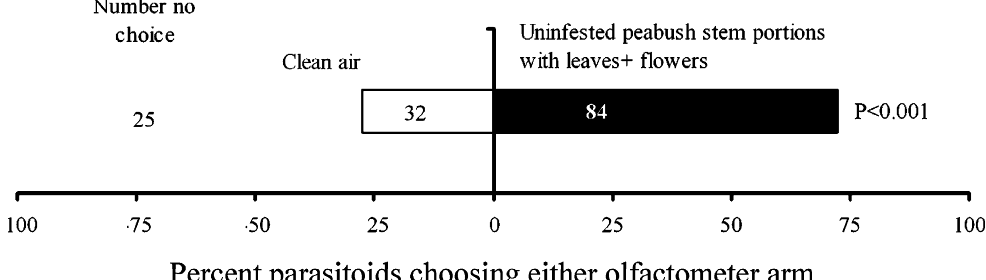

Fig. 2 Behavioral response of *Apanteles taragamae* females to uninfested leaves and flowers of peabush in a Y-tube olfactometer. *Numbers in bars* represent the total number of parasitoids that chose olfactometer arm. *P*-value given to the right of bars is for the two-tailed binomial test

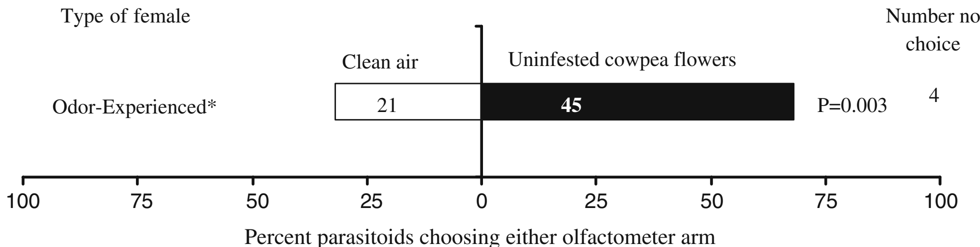

Fig. 3 Behavioral response of odor-experienced females of *Apanteles taragamae* to uninfested cowpea flowers in a Y-tube olfactometer. *Numbers in bars* represent the total number of parasitoids that chose olfactometer arm. *P*-value given to the right of bars is for the two-tailed binomial test. *: Odor-experienced female wasps are females that that had parasitized two 2-d-old larvae reared in the presence of host-infested cowpea flowers, 30 min prior to the olfactometer test

of pollinators. After all, herbivore-infested flowers are likely to be an inferior food source to pollinators.

The attraction of *A. taragamae* to uninfested peabush leaves and flowers may be a reflection of a genetic trait related to searching in peabush fields. Indeed, the current wasp species was imported from Taiwan, where it was collected from *M. vitrata* larvae feeding on peabush leaves. Volatiles from uninfested plants have been reported to be long-range attractants in some other parasitoid species (Elzen et al., 1983; Ding et al., 1989; Ngi-Song et al., 1996). Thus, *Cotesia flavipes* Cameron, originally collected in maize showed a preference for uninfested maize plants over sorghum in a dual choice olfactometer experiment (Ngi-Song et al., 1996). Likewise, the endogenous parasitoid *C. sesamiae* (Cameron) preferred volatiles produced by uninfested sorghum plants over those from maize. Indeed, both sorghum and *C. sesamiae* originate from Africa and share the same environment. The braconid *Macrocentrus grandii* Goidanish, a larval parasitoid of the European corn borer, *Ostrinia nubilalis* (Hubner), was attracted to uninfested maize plants (Ding et al., 1989). However, herbivore-infested plants were found to be more attractive than uninfested plants (Turlings et al., 1991a; Du et al., 1998; Vet et al., 1998; Dicke, 1999b).

In the host habitat, short-range stimuli from the host itself are reliable indicators of its presence, but they usually are not well detectable (Vet and Dicke, 1992). Our study shows that the parasitoid wasp *A. taragamae* was significantly attracted to volatiles emitted by *M. vitrata* larvae. An oviposition experience through the parasitization of larvae fed with artificial diet did not affect the parasitoid's response to host larval volatiles. The use of kairomones by parasitoids for host location has been reported in many parasitoid species (Afsheen et al., 2008). The braconid parasitoid *Microplitis. croceipes* was attracted to odors of *Heliothis virescens* (Fabricius) larvae (Elzen et al., 1987; Röse et al., 1997). Similarly, the bruchid larval parasitoid *Eupelmus vuilleti* (Crw) was reported to respond to volatiles from *Bruchidius atrolineatus* (Pic) larvae (Cortesero and Monge, 1994). However, usually herbivore-induced plant volatiles are more attractive to parasitoids than herbivore-produced volatiles (Turlings et al., 1991a; Steinberg et al., 1992).

Herbivore-associated organisms such as microbes also may be a source of chemical information to parasitoids

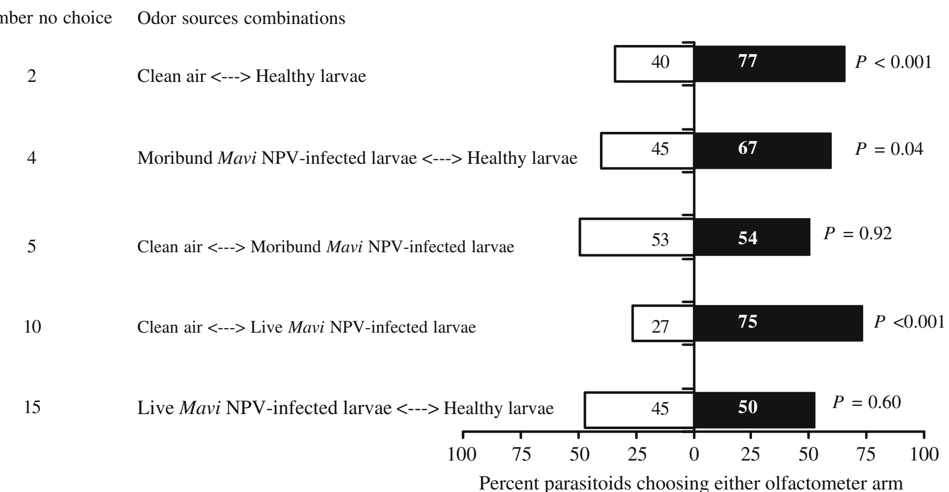

Fig. 4 Behavioral response of *Apanteles taragamae* females offered choices between volatiles from healthy *Maruca vitrata* larvae, moribund or live *Mavi*MNPV-infected larvae, and clean air in a Y-tube olfactometer. *Numbers in bars* represent the total number of parasitoids that chose olfactometer arm. *P*-values given to the right of bars are for the two-tailed binomial test

during host location (Vet and Dicke, 1992). *Apanteles taragamae* has been found to be a vector for the transmission of *Mavi*MNPV to larvae of *M. vitrata* and could acquire and transmit the virus over several generations (M. Tamò, personal communication). In this study, females of *A. taragamae* were attracted to *Mavi*MNPV-infected live larvae, but not to moribund larvae (Fig. 4). The wasps did not discriminate between volatiles from healthy and *Mavi*MNPV-infected live larvae, but they preferred the volatiles from healthy larvae over those from moribund larvae. Apparently, the viral infection only affected larvae attractiveness in a late stage of infection. The virus disease symptoms appear about 3–4 day after infection of the *M. vitrata* larvae (Lee et al., 2007). Our observations are similar to those reported for the parasitoid *Biosteres longicaudatus* Ashmead, which was unable to locate immobilized or dead hosts (Lawrence, 1981).

*Mavi*MNPV, like other baculoviruses, which are host-destroying viruses, is likely to affect negatively the development of *A. taragamae,* and it needs more attention for its management. Parasitoids and insect pathogens often are involved in scramble competition for host resources in dually infected and parasitized hosts. In such cases, some parasitoid species develop a strategy to enhance their developmental rate (Escribano et al., 2000). The temperature seemed to influence *Mavi*MNPV symptoms development in parasitized larvae. At 29°C, *A. taragamae* pupated on average 6 d after parasitization, and this limited the detrimental effect of the virus infection (Dannon et al. unpublished data). Interactions between the wasp and *Mavi*MNPV need to be investigated further to evaluate the effects of the virus on the parasitoid and to identify factors that avoid or limit the detrimental effect on the wasp reproduction.

In summary, this study shows that floral volatiles produced by *M. vitrata*-infested cowpeas flowers attracted *A. taragamae* females. Uninfested leaves and flowers of peabush also attracted the parasitoid. In contrast, the wasp was attracted to uninfested cowpea flower only after an odor experience. Olfactory cues from *M. vitrata* larvae also were used by the wasp in its host selection process. Further research should assess the influence of other key host plants of *M. vitrata,* such as *Pterocarpus santalinoides* L'herit ex DC.*,* and *Lonchocarpus sericeus* (Poir) H.B.K. on the host selection behavior of *A. taragamae.*

the sex ratio of the progeny becomes important (Godfray, 1994). Both gregarious and solitary species can superparasitize hosts, but, in solitary parasitoids, the presence of supernumerary juveniles results in competition for survival and the death of all but one. This competition has been defined as a lethal larval combat (Ueno, 1997), physiological suppression (Vinson and Hegazi, 1998), or scramble competition (Mayhew and Hardy, 1998). Solitary parasitoids must, therefore, lay their eggs on unparasitized hosts to increase the chances of survival of their progeny. However, while the expected fitness gain per host is lower when females superparasitize, superparasitism by solitary species can be an adaptive behavior in certain circumstances (van Alphen and Nell, 1982), e.g., when the number of unparasitized hosts is small or when travel time between patches is long (van Alphen and Visser, 1990). Such behavior is adaptive only if the second egg laid on an already parasitized host can "win" the competition with the first immature (Lebreton et al., 2009).

Eupelmus vuilleti (Crw.) (Hymenoptera: Eupelmidae) is a solitary ectoparasitoid of the larvae of *Callosobruchus maculatus* Fabr. (Coleoptera: Bruchidae) in the tropical zones of West Africa. Females perceive various types of information from seeds that contain their hosts, thus enabling them to change their oviposition behavior. They can discriminate between unparasitized and parasitized hosts, preferring to lay eggs on unparasitized hosts, thus changing their offspring sex ratio (Darrouzet et al., 2007, 2008). They also can discriminate unparasitized hosts from hosts parasitized by a different wasp species, *Dinarmus basalis*: this discriminative capacity seems to be due to chemical cues that probably originate from the Dufour's gland, and that were deposited by previous ovipositing females (Jaloux et al., 2005). After oviposition by *E. vuilleti* females, hydrocarbons also are found on seeds (Darrouzet, personal observation) and can be perceived by other conspecific females, which could, in turn, alter their responses. However, in this species, the nature and origin of cues perceived by conspecifics are still unknown.

This study determined whether cuticular hydrocarbons deposited artificially on seeds are perceived by *E. vuilleti* females, and whether these females change their oviposition accordingly. Specifically, (1) we tested whether the CHC profiles from males and females are different, and (2) we presented seeds labeled with CHCs from males or females to ovipositing females.

Methods and Materials

Rearing Conditions Bruchid *Callosobruchus maculatus* (F.) (Coleoptera, Bruchidae) and wasp *Eupelmus vuilleti* samples were taken from populations that have been established in the laboratory since 1997, and which originated from Burkina Faso (West Africa). They were mass-reared in a climate-controlled chamber under conditions close to those at their place of origin: 12 hr light at 33°C, 12 hr dark at 23°C and 70% r.h.

Preparation of Reproductive Patches A circle of six equidistant gelatine capsules, each containing one *C. maculatus* L_4 larva, was fixed in an arena (diam=8 cm, height=2.5 cm; henceforth called a reproductive patch, Fig. 1). Each bruchid fourth instar (L_4) was placed inside the capsule after being removed from its seed by dissection and selected by weight (9.12±0.20 mg). The gelatine capsules mimic the bruchid pupal chamber in the seed and enable oviposition by *E. vuilleti* females (Darrouzet et al., 2003). Two different areas within the patch were prepared to provide aggregates of hosts with different properties (Darrouzet et al., 2007). Three adjacent capsules were labeled with cuticular hydrocarbons (CHCs) from males or females (L capsules), and the other three adjacent capsules remained unlabeled (unL capsules). CHCs from the abdomen of parasitoids were transferred onto the cap of the capsules by rubbing the individuals for 10 sec. Each capsule was labeled by using a single individual that was put to sleep at 4°C before rubbing. Control patches were prepared with six unlabeled capsules.

Sample Preparation and Chromatographic Procedures Cuticular hydrocarbons were extracted in conical vials with 1 ml dichloromethane (Sigma Aldrich) from males (3 replicates of 10 males), females (6 replicates of 10 females), CHC labeled capsules (50 upper part of capsules; i.e., the part in contact with the ovipositing parasitoid females), and from unlabeled capsules (50). After mixing for 1 min, the insects or capsules were removed, and the extracts were dried to 2 µl and analyzed by gas chromatography. Samples first were analyzed using a Perkin-Elmer Autosystem XL GC (Perkin-Elmer, Wellesley, MA, USA) with a flame ionization detector (FID)

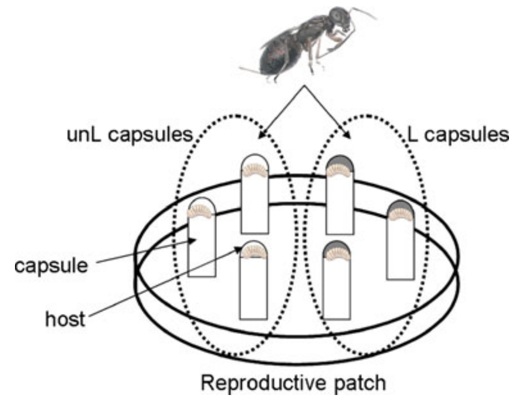

Fig. 1 Diagram of a reproductive patch

and Turbochrom software. Samples were injected into the GC-FID injector at 220°C in splitless mode and analyzed by using a BP1 capillary column (25 m, ID 0.32 mm), which was temperature programmed from 150°C (2 min) to 300°C (10 min) at 5°C/min.

The components then were identified by GC-MS analysis by using a Hewlett-Packard 5890 GC system coupled to a 5989A MS, controlled by HP ChemStation software. Pools of males (30 individuals) and females (60 individuals) were injected into the GC-MS injector using the procedure described above. Hydrocarbons were identified by their mass spectra corroborated by their ECL indices (for review see Lockey, 1988; Blomquist, 2010), using the M^+ of diagnostic ions and the $M\text{-}15^+$ when visible to confirm their methylbranch numbers (Nelson, 1993).

Oviposition of Mated Females To obtain mated females, 2-h-old virgin females were mated with a 24-h-old virgin male. Two patches containing unlabeled (unL) and labeled (L) capsules were offered daily (2 exposure periods of 4 hr) to each mated female (24 individuals, 13 females with L capsules labeled with CHCs from males, and 11 females with L capsules labeled with CHCs from females). Oviposition was performed in the climate-controlled chamber. At the end of each period, the positions of each egg laid in each capsule were noted. After each period, old capsules were replaced by new ones. To determine the sex of eggs laid by mated females, at the end of each period, each egg laid on a capsule was transferred to a different host and deposited in a different cell on a Plexiglas sheet closed by a Plexiglas cover-slide until the emergence of the adult parasitoids (Darrouzet et al., 2003). On emergence, the sex ratio was measured as the proportion of females emerging from the cells on the Plexiglas sheets (i.e., the secondary sex ratio).

Results were compared with mated (19) females ovipositing in the same experimental conditions in reproductive patches containing a circle of six unlabeled capsules.

Statistical Analyses Data were tested for normal distribution and homogeneity of variance (*Levene test*) and then were analyzed by using a *Mann-Whitney's U-test* for unpaired samples, a *Wilcoxon test* for paired samples, and a *Student's t-test*. The sex ratios of eggs laid in parasitism and superparasitism were compared by using a standard χ^2*-test*. All statistical analyses were performed with Statistica 6.0 software (Statsoft, Inc.).

Results

Analyses of CHCs from Males and Females The GC-FID analyses distinguished 38 peaks in females and 24 in males, ranging in chain length from 26 to 37 carbon atoms (Fig. 2). These peaks were found also on labeled capsules (results not shown). The GC-MS analyses identified 95 different molecules in the CHC profiles from females but only 64 in males (Table 1). CHCs profiles from males contained fewer methylated compounds than those from females (see Table 1).

Oviposition of Females Within Control Patches (Unlabeled Capsules) Comparison of two random areas of three adjacent capsules showed that females had the same oviposition activity for the number of parasitized hosts (*Student t test*: t=0.44, df=18, P=0.67) (Fig. 3a), eggs laid (*Student t test*: t=0.30, df=18, P=0.77) (Fig. 3b), and self-superparasitized hosts (*Wilcoxon test*: Z=1.32, P=0.19) (Fig. 3c).

Oviposition of Females Within Patches when Capsules L Were Labeled with Female CHCs Ovipositing females parasitized more hosts and laid more eggs in unL capsules than in L capsules (*Wilcoxon test*: Z=2.28, P=0.023 and Z=2.03, P=0.043, respectively) (Figs. 3a and b). However, they self-superparasitized the same number of hosts in unL and L capsules (*Student t test*: t=1.63, df=22, P=0.12) (Fig. 3c). These females had the same oviposition activity in unL capsules as females ovipositing in three random adjacent capsules in control patches (number of eggs laid, *Student t test*: t=0.023, df=29, P=0.98; number of parasitized hosts: t=0.72, df=27, P=0.47; number of self-superparasitized hosts: t=0.54, df=29, P=0.59) (Figs. 3b, a, and c, respectively). However, they laid fewer eggs in L capsules than females ovipositing in three random adjacent capsules in control patches (*Mann-Whitney U test*: U=47.5, P=0.05) (Fig. 3b), and parasitized fewer hosts (*Mann-Whitney U test*: U=49.5, P=0.05) (Fig. 3a). But they self-superparasitized the same number of hosts (*Student t test*: t=0.21, df=29, P=0.83) (Fig. 3c).

Oviposition of Females Within Patches When Capsules L Were Labeled with Male CHCs Females had the same oviposition activity in unL and L capsules (parasitized hosts: *Student t test*: t=0.16, df=12, P=0.88; eggs laid: t=0.12, df=12, P=0.90; self-superparasitized hosts: *Wilcoxon test*: Z=0.25, P=0.80) (Figs. 3a, b, and c, respectively). Females parasitized the same number of hosts in unL or L capsules as females ovipositing in three random adjacent capsules in control patches (unL capsules, *Student t test*: t=−1.85, df=30, P=0.074; L capsules: t=−1.88, df=30, P=0.069), laid the same number of eggs (unL capsules: t=−1.12, df=30, P=0.268; L capsules: t=−1.38, df=30, P=0.176), and self-superparasitized the same number of hosts (unL capsules, *Mann-Whitney U test*: U=168.5, P=0.074; L capsules: U=121.5, P=0.95).

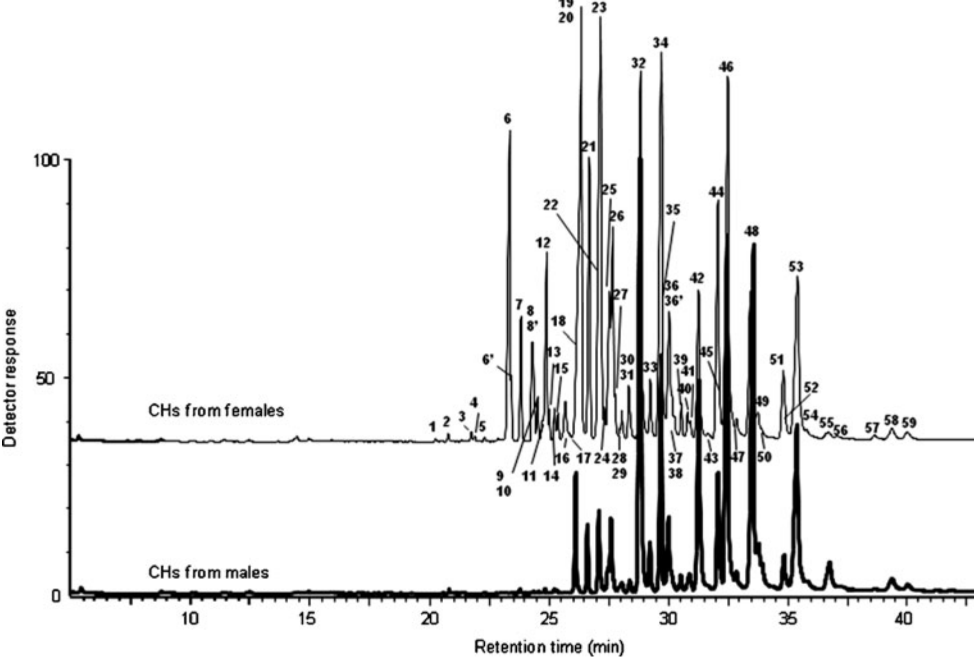

Fig. 2 GC-FID chromatogram of cuticular hydrocarbon profiles from *Eupelmus vuilleti* males and females

Oviposition of Females Between Separate Patches Females had the same oviposition behavior for patches containing L capsules labeled with male CHCs as females ovipositing in control patches (mean number ± SE of eggs laid: 33.23±1.42 vs. 29.84±1.58; *Student t test*: t=2.19, df=31, P=0.15; self-superparasitized hosts: 1.9±0.31 vs. 2.71±0.48; *Mann-Whitney U test*: U=160, P=0.157). When patches containing L capsules were labeled with female CHCs, females also had the same oviposition behavior in those patch as females in control patches (mean number ± SE of eggs laid: 25.83±1.17; *Student t test*: t=3.17, df=30, P=0.08; self-superparasitized hosts: 3.44±0.6; *Student t test*: t=0.86, df=25, P=0.36). However, females laid fewer eggs in the patch when L capsules were labeled with female rather than male CHCs (*Student t test*: t=15.90, df=24, P<0.001). Also, they self-superparasitized more hosts (*Student t test*: t=6.05, df=19, P=0.02).

Sex Ratio of Progeny When two capsule areas were compared within patches, we showed that females produced the same offspring sex ratio (proportion of females) in unL and L capsules, whatever the sexual origin of the CHCs deposited on L capsules (female CHCs: SR=0.68 in unL capsules vs. 0.62 in L capsules χ^2=1.07, df=1, P=0.30; male CHCs: SR=0.79 vs. 0.71, χ^2=2.38, df=1, P=0.12). Females within control patches also produced the same offspring sex ratio in two random areas (SR=0.65 vs. 0.62, χ^2=0.24, df=1, P=0.62).

Offspring sex ratios (L + unL capsules) were female biased, i.e., SR=0.66 for females ovipositing in patches containing L capsules labeled with female CHCs (χ^2=21.74, df=1, P< 0.001), 0.75 for females ovipositing in patches containing L capsules labeled with male CHCs (χ^2=68.00, df=1, P< 0.001), and 0.64 for females ovipositing in control patches (χ^2=28.31, df=1, P<0.001). However, females laid more daughters in patches containing L capsules labeled with male CHCs than in control patches or patches containing L capsules labeled with female CHCs (χ^2=9.52, df=1, P= 0.002 and χ^2=5.02, df=1, P=0.025, respectively) (Fig. 4).

Discussion

Eupelmus vuilleti females had different ovipositing activities depending on whether or not the seeds were labeled previously with CHCs. This adaptive oviposition shows that *E. vuilleti* females can detect these compounds present on seeds, and that their oviposition behavior is modified by the sexual origin of these CHCs. The presence of CHCs from other females modified egg distribution on hosts, whereas the male CHC label affected only the sex ratio of the progeny. These results demonstrate that parasitoid females can use (i) chemical residues present in the environment (such as CHCs deposited on seeds) and (ii) the sexual origin of such compounds to change their oviposition behavior.

In *E. vuilleti* species, males and females have different CHC profiles. CHCs from females contain certain mono- and dimethyl-branched compounds, which are absent from males. This shows a sexual dimorphism in the profiles. Although the functional significance of this sexual dimorphism in *E. vuilleti* remains to be tested, it may be significant, as is the case in some insects such as the cricket *Teleogryllus oceanicus* (Thomas and Simmons,

Table 1 Identification (using GC-MS) and relative amounts (% of total, using GC-FID) of the cuticular hydrocarbons from *Eupelmus vuilleti* males and females. A "/" separates carbon atom numbers when compounds have a methyl group that may be placed at either of these positions and cannot be discriminated using GC-MS

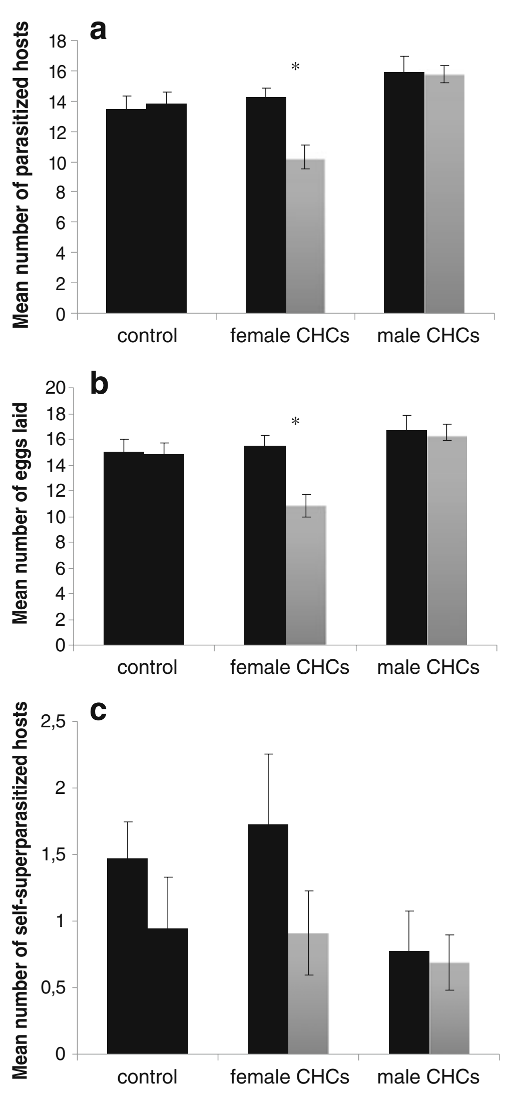

Fig. 3 Mean number and standard error of parasitized hosts (**a**), eggs laid (**b**) and self-superparasitized hosts (**c**) by *Eupelmus vuilleti* females ovipositing in unlabeled (unL) or labeled (L) capsules. *$P<0.05$

2008) or various species of Drosophila (Cobb and Jallon, 1990). If the chemical composition of CHCs is used as a contact pheromonal signal for mate choice, sexual selection may drive differentiation of these compounds. Various studies of several species of insects have demonstrated such differentiation (Howard and Blomquist, 2005; see appendix in Thomas and Simmons, 2008; Ferveur and Cobb, 2010). Particular compounds produced by only one sex can stimulate the sexual behavior of the other, or a specific sex ratio among hydrocarbons that are present in the two genders can influence mate choice (Ginzel et al., 2003). It also has been shown that some selected traits related to mate choice need maturation delay to be effective. This delay also may involve CHC profiles, as the differences among these compounds are more marked between sexes when insects are older (Chenoweth and Blows, 2005). The CHCs profiles of *E. vuilleti* were not analyzed according to age in this study. This trait may not be of great importance in this species, however, as adults are sexually mature when they emerge (Darrouzet, personal observation).

Many insects deposit chemical residues on different substrates, and these traces can provide intraspecific and/or

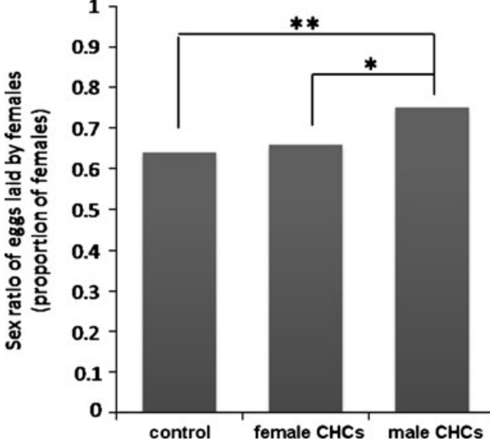

Fig. 4 Sex ratio of eggs laid by *Eupelmus vuilleti* females confronted with only unlabeled capsules (control), capsules labeled by female CHCs or male CHCs. *$P<0.05$; **$P<0.01$

interspecific cues that modify the behavior of receiving individuals. Marking pheromones are used by many parasitoid species, thus avoiding the laying of their eggs in hosts that have already been parasitized and that are less useful for the larval development of their offspring (Godfray, 1994; Nufio and Papaj, 2001). In a previous study, Darrouzet et al. (2007) showed that *E. vuilleti* females discriminated parasitized from unparasitized hosts. Under the same experimental conditions, the parasitized status of hosts was mimicked by labeling seeds containing unparasitized hosts with female CHCs. Females showed the same differences in oviposition strategy (in the location of eggs laid) when they were in the presence of either unlabeled or female CHC labeled seeds (in this study) as in the presence of both unparasitized and parasitized hosts (see Darrouzet et al., 2007). They laid more eggs on unparasitized hosts (unlabeled seeds in this study) than on parasitized hosts (labeled seeds). This mimicry was not obtained with seeds labeled with male CHCs. Hydrocarbons, thus, may be the chemical information used by ovipositing females to discriminate unparasitized from parasitized hosts. Jaloux et al. (2005) observed that *E. vuilleti* females used such compounds, deposited by *Dinarmus basalis* females after laying eggs, to superparasitize their hosts. In this interspecific competition, *E. vuilleti* females laid more eggs in superparasitism than in parasitism. The glandular secretion deposited by *D. basalis* females originates from the Dufours' gland.

Cuticular and Dufour's gland secretions may result in identical activity because of the similarity in hydrocarbon composition. However, there are differences in the relative concentrations between cuticular and Dufour's gland hydrocarbons, as is the case in *E. vuilleti* (Darrouzet, personal observation). This similarity seems to be a widespread phenomenon in insects as described, for example, in bumblebees (Oldham et al., 1994), polistes wasps (Dani et al., 1996), honeybees (*Apis mellifera*: Gozansky et al., 1997), and some parasitoid wasps (*Cephalonomia tarsalis*, *C. waterstoni*, *Anisopteromalus calandrae* and *Pteromalus cerealellae*: Howard and Baker, 2003; *Dinarmus basalis*: Jaloux et al., 2005).

Eupelmus vuilleti females drill the seeds with their ovipositor and oviposit on the bruchid larvae *C. maculatus,* which develop in seeds of a legume, the cowpea *Vigna unguiculata* (Walp.). The bruchid and its parasitoid emerge in granaries after the cowpea seeds have been harvested and reproduce in this storage environment. Several generations of *C. maculatus* and *E. vuilleti* develop in granaries throughout the dry season. *Eupelmus vuilleti*, therefore, lives in an environment where several types of seed are stored. Under these conditions, females exploring the surface of the seeds looking for bruchid hosts to oviposite, or males searching for females with whom to copulate, could touch seeds and thus deposit CHCs because of crowding. These chemical residues could then be perceived and used by conspecifics to identify the gender of individuals. The perception of female CHCs on a seed that contains a host could inform a conspecific female that the host may already be parasitized and the perception of male CHCs could indicate that the host is unparasitized. The lengths of the CHCs identified in this study range from 24 to 37 carbon atoms, which is similar to that found in other parasitoid species (Howard and Baker, 2003). Given their long chains, these compounds mainly are non-volatile and are, therefore, probably detectable for some time after being deposited. As female CHCs prevent other females from laying their eggs on the same hosts, they probably are perceptible for at least a period that will prevent the first individual laid from being affected adversely as a result of a second oviposition (Roitberg and Mangel, 1988). It is not known how long such a marker can last. Moreover, the way in which *E. vuilleti* deposits CHCs in a seed store still has to be determined. However, chemical residues may remain on a substrate as described in previous studies, and thus indirectly associated with the host (Borges et al., 2003; Conti et al., 2004). The footprint may consist of non-volatile lipids, secreted by specialized glands, identical to those found on the cuticle (Nakashima et al., 2004), or CHCs present in the wax layer of the cuticle (Colazza et al., 2007). The egg parasitoid species *Trissolcus basalis* uses the CHCs on the cuticle of their hosts (the stink bug *Nezara viridula*) as contact kairomones to discriminate gender (Colazza et al., 2007). Additionally, Müller and Riederer (2005) showed that compounds from a phytophagous insect could be adsorbed on a plant surface and be used as host-finding kairomones for parasitoids.

In Hymenoptera parasitoids, females have a haplodiploid genetic system for allocating the sex of their progeny, where males develop from unfertilized eggs and females from fertilized eggs (Godfray, 1994). This sex allocation can be modulated by various factors such as the number of conspecific females in the reproductive patch (Hamilton, 1967) or the presence of already parasitized hosts (Darrouzet et al., 2008). Although a single female is expected to lay the minimum number of sons able to mate with all their sisters, when the competition level increases (with more females or more already parasitized hosts), the same female would benefit by producing a higher proportion of sons in order to mate with both her own daughters and those of other females. This is predicted by Hamilton's local mate competition (LMC) theory (Hamilton, 1967). Moreover, additional information also could help the female to adjust her progeny allocation for already parasitized hosts, such as the sex of the juvenile in or on the host (Lebreton et al., 2010), its age (Lebreton et al., 2009), or its species (Gauthier et al., 1999). *Eupelmus vuilleti* females can alter their offspring sex ratio as predicted by the LMC theory. The

sex ratio changes in response to the presence of conspecific females and/or already parasitized hosts (Darrouzet et al., 2003, 2007, 2008).

Little attention has been paid to the role of males in influencing sex allocation, although males can influence female sex allocation in a number of ways in haplodiploid organisms (Henter, 2004). Males may change their fertilization ability by producing sperm unable to fertilize eggs: mated females thus would produce more unfertilized eggs, i.e., sons. A second possibility is that males could transfer sperm to females during mating, but that incompatibility between paternal and maternal genomes could lead to the death of daughters. Males also may actively search for mates and then influence female sex allocation because they only transfer their genes to the next generation when the females lay fertilized eggs, i.e., daughters.

Finally, according to the constrained model (Godfray, 1990), when the proportion of virgin females increases in the population, mated females should produce a higher proportion of daughters, thus compensating for the number of sons produced by these "constrained" females. However, mated females would benefit by detecting the proportion of virgin females present. This estimation could be performed on the basis of the encounter rate of courting males in the environment (Ode et al., 1997). Under our experimental conditions, there were no males. However, females produced more daughters when they perceived male odor on seeds. This suggests that males may influence female sex allocation by depositing their odor in the environment.

In summary, this study supports the idea that, in *E. vuilleti*, females adjust their oviposition behavior according to the sexual origin of cuticular traces left by conspecifics on seeds. When they detect traces of other females, they lay fewer eggs on these seeds but when they perceive traces of males, they produce more daughters. This result highlights the importance of the precise nature of the chemicals present in the environment on strategy adjustments.

Acknowledgments We would like to thank two anonymous reviewers for providing useful comments on the manuscript.

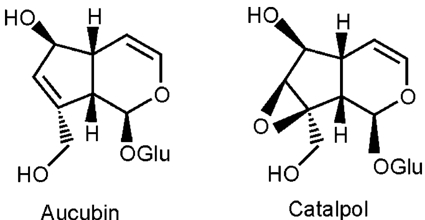

Fig. 1 Chemical structures of aucubin and catalpol

10–12% dry weight in leaves, although amounts can vary with leaf and plant age and among individuals (Bowers and Stamp, 1993); 2. *P. major*, which produces only aucubin in relatively low amounts of 0.5–2.0% in leaves (Barton and Bowers, 2006); or 3. both. *Junonia coenia* Hübner (Nymphalidae) is a specialist on iridoid glycoside producing plants, and larvae can sequester high amounts of iridoid glycosides, which render them unpalatable (Theodoratus and Bowers, 1999). *Estigmene acrea* (Drury) (Arctiidae) is a conspicuous grazing generalist (Bernays et al., 2004) that preliminary analyses suggested can sequester iridoids (Bowers, 2009), while *Spilosoma congrua* (Walker) (Arctiidae) is a cryptic, grazing generalist that can also sequester iridoids (Bowers and Stamp, 1997). All these species feed on both *Plantago* species.

Methods and Materials

Freshly hatched larvae were reared in groups of 10 until the third instar, when they were placed individually into 100 mm Petri dishes for the remainder of the trial. Larvae were reared upon one of four leaf diets: freshly excised leaves of *P. major*, *P. lanceolata*, *P. major* until the antepenultimate instar then changed to *P. lanceolata*, or *P. lanceolata* until the antepenultimate instar then changed to *P. major*. Leaves of a mixture of ages were collected daily from many individual plants in stands around Boulder, CO, USA. Leaves were of various ages, and no attempt was made to collect leaves from particular plants or of a certain age. Iridoid glycoside concentrations of leaves were not measured. Larvae were frozen at −80°C immediately upon reaching the final instar. Sample sizes ranged from 8–10 individuals/diet, except for *E. acrea* reared on *P. major* followed by *P. lanceolata*, where mortality was high and only 2 larvae were available. Larvae were prepared for analysis and iridoid glycosides [derivatized using Tri-sil Z (Pierce Chemical Company)] quantified by gas chromatography (methods in Bowers and Stamp, 1997). Fresh to dry weight conversions were obtained from separate sets of caterpillars, and all results are reported on a dry weight basis. Bonferroni-adjusted 1-way analyses of variance (ANOVA) were performed for each species, comparing the percent dry weight of total iridoid glycosides (analyzed as the arc-sine transformed proportion) and the proportion of catalpol (arc-sine transformed) sequestered among diets. Tukey's HSD post-hoc tests were applied where appropriate.

Results

Junonia coenia larvae sequestered the greatest concentration of iridoids, while *E. acrea* sequestered the lowest concentration, and *S. congrua* was intermediate (Fig. 2). All three species sequestered both aucubin and catalpol when both were available, although the relative proportion of the two compounds varied among both diets and species. Catalpol has not been reported in *P. major* (Barton and Bowers, 2006 and references therein), and thus, none was found in the larvae reared solely on this plant, so these larvae were not included in analyses of catalpol sequestration.

Estigmene acrea was a poor sequesterer and was particularly inefficient at sequestering catalpol, which could not be compared statistically (Fig. 2). Diet did not influence

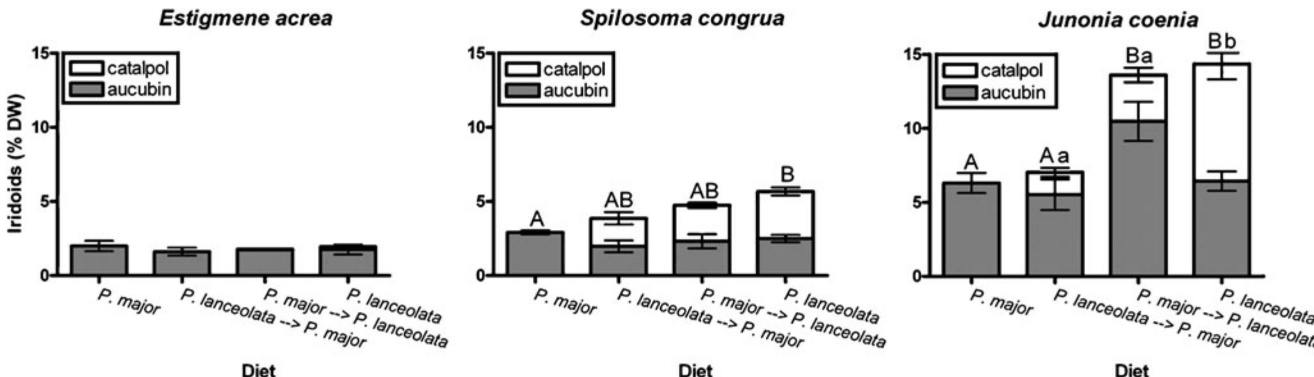

Fig. 2 Average (±1 SEM) iridoid glycoside sequestration of three caterpillar species varying in degree of specialization. *Uppercase letters* indicate significantly ($P<0.05$) different total iridoid glycoside means according to Tukey's Honestly Significant Difference post-hoc tests, while *lowercase letters* indicate significant differences in the proportion of catalpol

E. acrea sequestration ($F_{3,26}$=0.26, P=0.85). *Spilosoma congrua* was particularly effective at sequestering catalpol. Catalpol made up the majority of the sequestered iridoids and proportion of catalpol was not influenced by diet ($F_{2,21}$=0.71, P=0.50); however, diet did influence total iridoid sequestration ($F_{3,30}$=8.18, P<0.001) (Fig. 2). Diet influenced both the proportion of catalpol ($F_{2,23}$= 82.68, P<0.001) and total iridoids ($F_{3,31}$=5.80, P=0.003) sequestered by *J. coenia* (Fig. 1).

Discussion

The three species differed substantially in their sequestration ability. *Junonia coenia*, a specialist on iridoid glycoside containing plants, sequestered the highest amounts. The amount of total iridoid glycosides was almost three times higher when these larvae were fed solely *P. lanceolata* than when they were fed *P. major*. Feeding experiments with wolf spiders showed that such a difference renders *P. lanceolata*-reared *J. coenia* less palatable than those reared on *P. major* (Theodoratus and Bowers, 1999). In addition, however, catalpol appears to be a more toxic iridoid than aucubin (Puttick and Bowers, 1988), which may also contribute to this difference in palatability. *Spilosoma congrua* sequestered about one third the levels of iridoids sequestered by *J. coenia*. Of three *Spilosoma* species tested, *S. congrua* was the only species with the ability to sequester iridoid glycosides; its congeners, *S. virginica* and *S. latipennis* were unable to sequester iridoids (Bowers and Stamp, 1997). Interestingly, although *E. acrea* was able to sequester aucubin in about the same amounts as *S. congrua*, it was poor at sequestering catalpol. *Estigmene acrea* thus was particularly effective at breaking down or eliminating catalpol.

In both *S. congrua* and *J. coenia*, diet had a strong effect on the amount of iridoids sequestered. Since most food is eaten and most iridoids are ingested in the later instars, the host plant fed on during the later instars most affected the chemical content of the caterpillars. This was most apparent in *J. coenia*, in which feeding on *P. lanceolata* in the later instars doubled the amount of sequestered iridoids compared to larvae fed only *P. major* or *P. lanceolata* followed by *P. major*. Indeed, larvae fed *P. lanceolata* after *P. major* had levels of total iridoid glycosides almost as high as larvae reared exclusively on *P. lanceolata* (Fig. 2). However, feeding exclusively on *P. lanceolata* resulted in much higher levels of catalpol being sequestered compared to larvae fed on *P. major* followed by *P. lanceolata*. Although less dramatic, similar results were found for *S. congrua*. These results emphasize the importance of host plant choice in later instars, as that affects sequestration and consequent protection against natural enemies.

Both arctiid species in this study graze among several plant species, including species that vary widely in secondary chemistry (Bernays et al., 2004). Depending on the plant species consumed, these caterpillars can sequester quite different profiles of secondary compounds, and potentially vary dramatically in their palatability to natural enemies. Furthermore, *E. acrea* can sequester a quite different group of compounds, pyrrolizidine alkaloids, and retain these compounds through to the adult stage in amounts as high as approximately 4% dry weight (Hartmann et al., 2005). Thus, larvae of *E. acrea* are better at sequestering pyrrolizidine alkaloids than iridoids. However, given the polyphagous feeding behavior of this species, it could encounter both pyrrolizidine alkaloid and iridoid glycoside containing hostplants and could sequester both kinds of compounds.

In summary, this study provides the first quantification of sequestration of iridoid glycosides by *E. acrea*, and showed that only low levels are sequestered and that catalpol is inefficiently sequestered, if at all. Second, we showed that host plant species affects sequestration of iridoids in *S. congrua* and *J. coenia*, but not *E. acrea*. Third, the variation in sequestration among diets was greatest for *J. coenia*, the species sequestering the highest amounts and concentrations of iridoid glycosides. Overall, our results show that although plant defense compounds may be sequestered by both generalist and specialist insects, the amounts that different species contain and the efficiency with which those compounds are sequestered may vary considerably.

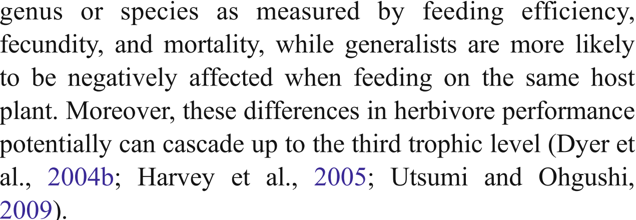
apparent lack of defensive properties for a variety of plant secondary compounds that have no antiherbivore function when tested separately from complex natural mixtures (Harborne, 1988; Ayres et al., 1997).

Quantification of the tritrophic effects of plant defenses has been the focus of many studies in chemical ecology. The bottom-up or "green desert" model suggests that plant defenses work directly to limit herbivore populations, which in turn limits natural enemy populations (White, 1978; Abe and Higashi, 1991). Plant defenses also have been found to mediate top-down forces by attracting natural enemies to herbivores (Vet and Dicke, 1992; De Moraes et al., 1998; Turlings and Wackers, 2004) or by decreasing herbivore resistance to parasitoids (Zvereva and Rank, 2003; Bukovinszky et al., 2009; Lampert and Bowers, 2010). In the latter example, sequestered toxins negatively affect a caterpillar's immune response by reducing its ability to encapsulate and kill parasitoid eggs, thus rendering them more vulnerable to successful attacks (Haviola et al., 2007; Smilanich et al., 2009). On the other hand, plant defenses can have detrimental effects on natural enemies. Herbivore sequestered plant defenses can provide resistance by being toxic or deterrent to natural enemies (Campbell and Duffey, 1981; Barbosa et al., 1986; Dyer, 1995; Ode, 2006; Singer et al., 2009). Parasitoid performance often is linked to the host herbivore performance, such that negative effects of plant chemistry on the herbivore are associated with negative effects on the parasitoid (Harvey et al., 2005; Soler et al., 2005; Gols et al., 2008). These deleterious effects of plant defenses on parasitoids, combined with higher toxicity and diversity of plant defenses in the tropics, are suggested to explain why there is no latitudinal diversity gradient for parasitic hymenoptera ("nasty" host hypothesis, Gauld et al., 1992).

While the effects of plant chemistry on the third trophic level vary among study systems, one strong bitrophic pattern is that there are marked differences in the response of specialist herbivores, which are adapted to specific host plant chemistry, and generalist herbivores, which are adapted to compounds from many different host plants but have a comparatively weaker response to specific defenses. Most studies that compare the effects of chemistry on specialists versus generalists have focused on single compounds (Bowers and Puttick, 1989; Van Dam et al., 1995; Wasano et al., 2009) or a broadly measured mixture of compounds (e.g., total phenolics, Bi et al., 1997, also see Coley et al., 2005) as opposed to examining synergy. However, there is growing evidence that synergistic defenses also affect specialist and generalist differently (Hagele and Rowell-Rahier, 2000; Dyer et al., 2003). Whether or not the defensive compounds are acting synergistically, specialists tend to be better adapted to the variety of secondary metabolites within a single host plant genus or species as measured by feeding efficiency, fecundity, and mortality, while generalists are more likely to be negatively affected when feeding on the same host plant. Moreover, these differences in herbivore performance potentially can cascade up to the third trophic level (Dyer et al., 2004b; Harvey et al., 2005; Utsumi and Ohgushi, 2009).



In this paper, we examine how synergistic imide and amide chemical defenses found in *Piper* spp. (Piperaceae), known collectively as *Piper* amides, affect specialist and generalist herbivores. We specifically test the hypotheses that: (1) *Piper* amides act synergistically to negatively affect herbivore growth and survivorship; (2) synergistic effects vary between specialist and generalist herbivores; and (3) there are negative synergistic effects on a specialist herbivore's resistance to parasitoids. To test these hypotheses we performed a series of experiments that examined the performance of specialist and generalist lepidopteran larvae on *Piper* amides found in two species of *Piper*—*P. cenocladum* and *P. imperiale.*

Methods and Materials

Piper The genus *Piper* is diverse with high intraspecific diversity of secondary metabolites, including the *Piper* amides (reviewed by Parmar et al., 1997; Kato and Furlan, 2007). These compounds contain a phenyl moiety with a variable length carbon side chain (typically with at least one unsaturation) ending in a carbonyl carbon. The nitrogen containing portion of the amide is derived from piperidine, pyrrole, or an isobutyl group, and may contain an unsaturation, an epoxide, or a carbonyl group. *Piper cenocladum* and *P. imperiale* are two species of particular interest due to their high densities in forest understories, high diversity of consumers, and previously recorded synergy among some of the *Piper* amides present in the leaves (Dyer et al., 2004b; Fincher et al., 2008).

Piper imperiale is a large shrub or small tree found in the lowland tropical wet forest of Costa Rica and is morphologically and ecologically similar to *P. cenocladum* (Burger, 1971). It contains three imides: 5′-desmethoxydihydropiplartine (an analog of piplartine found in *P. cenocladum*), piplaroxide (an epoxide derivative of 5′-desmethoxydihydropiplartine), and an alkene (Fincher et al., 2008); these compounds deter arthropods (Fincher et al., 2008). *Piper imperiale* also contains at least five different sesquiterpenes, and their role as a plant defense has not yet been determined (Fincher et al., 2008). Several facultative ant species have been found inhabiting *P. imperiale*. However, these plants do not produce food rewards for the ants, and it is unknown if the plants benefit from the presence of ants.

Piper cenocladum is a tall understory plant with large, long-lived leaves and is common in the lowland wet forests of Costa Rica (Burger, 1971). This shrub is defended by a combination of *Piper* amides and a mutualism with *Pheidole bicornis* Forel ants. Plants uninhabited by ants increase amide production by at least a factor of three (Dodson et al., 2000; Dyer et al., 2001). *Piper cenocladum* contains two imides and an amide at high concentrations (total amide content can be as high as 3.8% dry weight): 4′-desmethylpiplartine (0.18% dry weight with an ant colony and 0.45% without ants), piplartine (0.14% with ants and 0.58% without ants), and cenocladamide (0.09% with ants and 0.33% without ants, Dodson et al., 2000). Other experiments have demonstrated that these *Piper* amides deter arthropods and act synergistically against some herbivores (Dyer et al., 2003, 2004b).

Herbivores The species-rich genus, *Eois* (Geometridae), is specialized on the genus *Piper,* with *Eois* species specializing on an average of two *Piper* species (Connahs et al., 2009). *Eois nympha* feeds on both *P. cenocladum* and *P. imperiale* (Dyer and Gentry, 2002). In Costa Rica, *Eois* are parasitized at a rate of 23.4% by a combination of wasps (Braconidae and Ichneumonidae) and flies (Tachinidae) (Connahs et al., 2009). *Spodoptera frugiperda* (Noctuidae) is a *Piper* naïve generalist herbivore native to tropical regions of the western hemisphere and is a major crop pest in several regions of North America. Eggs were purchased from Agripest, North Carolina, USA and a lab colony was maintained at Tulane University.

Experiments The synergistic effects of *Piper* amides from *P. cenocladum* and *P. imperiale* were examined on specialist and generalist caterpillars. For experiments with *P. imperiale* imides, we used both a specialist and a generalist caterpillar, and for experiments with *P. cenocladum* amides, we used only the specialist. In each experiment, larvae were fed diets containing different concentrations of single amides or a combination of amides. The amides were synthesized in the laboratory at Mesa State College (Richards et al., 2001). Amide concentrations for experimental diets were chosen based on concentrations found in *Piper* leaves, and were calculated as the % dry weight of the leaf disk or artificial diet. These experiments were labor and material (field-collected larvae and synthetic amides) intensive. Thus, it was difficult to conduct them at the same time and with identical methods.

Piper imperiale Imides Before initiating experiments, we quantified the imide concentrations in fully expanded new leaves of 39 individual *P. imperiale* shrubs, using methods previously described by Dodson et al. (2000). Leaves were collected at 39 different sites, spread evenly across the forest at La Selva Biological Station, Heredia province, Costa Rica. The *P. imperiale* leaves contained 0.13% (±0.021 SE) dry weight total imides. Dry weight of individual imides was distributed as follows: 0.006% (±0.001 SE) alkene, 0.12% (±0.021 SE) piplaroxide, and 0.003% (±0.001 SE) 5′-desmethoxydihydropiplartine. We performed leaf disk bioassays on the specialist, *E. nympha*, at La Selva (Dec 2007–Feb 2008), using concentrations similar to these natural concentrations (but slightly lower). We collected early instar (1–2) larvae of *E. nympha* from the field, and randomly assigned them to petri dishes with 9 cm diam disks of fresh *P. imperiale* leaf cuttings. Before adding the caterpillars, we pipetted 1 ml of methanol solution containing amides onto the underside of each leaf disk, covering the entire surface, and allowed the methanol to evaporate. Control diets included methanol only. Imide concentrations added to the leaf disks were alkene (0.001, 0.003, 0.01, 0.05% dry weight), 5′-desmethoxydihydropiplartine (0.001, 0.003, 0.01, 0.05% dry weight), piplaroxide (0.001, 0.01, 0.1, 0.2%), and mixtures which were equal parts of each compound with total imide dry weights of 0.003, 0.06, 0.12, and 0.3% (0.001, 0.02, 0.04, 0.1% of each compound). These added imides supplemented existing leaf defensive chemistry. We placed six individuals on each diet concentration and recorded the survival; for caterpillars that reached pupation, we recorded pupal mass, which is a good measure of potential fecundity (Tammaru et al., 1996; Thiery and Moreau, 2005; Hazarika et al., 2007).

In a second synergy experiment with *P. imperiale* imides, we used newly hatched caterpillars from a *S. frugiperda* lab colony. The control diet consisted of 35 g powdered Fall Armyworm Diet (Southland Products, Inc. Lake Village, AR, USA) mixed with 201 ml distilled water and 1.5 ml linseed oil. For experimental diets, a single compound or a combination of compounds was added to the powdered control diet as follows, alkene: 0.001, 0.006, 0.01, 0.1%, 5′-desmethoxydihydropiplartine: 0.001, 0.003, 0.01, 0.1%, piplaroxide: 0.001, 0.12, 0.25, 0.5%, and mixtures that were equal parts of each compound with total imide dry weights of 0.003, 0.15, 0.3, and 0.9% (0.001, 0.05, 0.1, 0.3% of each compound). Each treatment started with 310 larvae and culled to 300 at Day 3 to have the same starting number across treatments. Survival was recorded daily from days 9–40 and again on days 43, 45 and 53. We used Day 53 as a cutoff since over 95% of the larvae had pupated by then (those that were still alive were assumed to make it to pupation). Due to high mortality on the mixed diets, we were unable to compare pupal mass for this treatment.

Piper cenocladum Amides We performed similar leaf disk bioassays of *E. nympha* with amides from *P. cenocladum.*

Diet treatments consisted of cenocladamide, piplartine, 4′-desmethylpiplartine and equal part mixtures. Added concentrations varied from 0.01 to 0.8% dry weight, with 7–9 different concentrations per diet. Fresh leaves were collected from plants with ants in the field that had a mean total amide dry weight of 0.41% (±0.02 SE), while concentrations without ants was 1.36% (±0.02 SE)(Dodson et al., 2000). Thus, the amide concentrations added were likely within the natural range of the plant. Caterpillars had been naturally exposed to parasitoids in the field prior to collection, and since they were randomly assigned treatments in the lab, we assumed equal parasitism frequency before placement on diets. Therefore, differences in mortality caused by the emergence of a parasitoid are due to post-treatment differences in the development of the immature parasitoid, which may be correlated with the immune response as well as nutritional indices (Smilanich et al., 2009). During the fourth instar, we measured weight gain, average weight, food consumed, and frass produced. Using dry weight conversions, we calculated relative growth rate (GR = larval dry weight gain / average larval dry weight during interval) and approximate digestibility (AD = (dry weight of food consumed−dry weight of frass) / dry weight of food consume) (Waldbauer, 1968). In summary, the response variables for this experiment were: survival, pupal mass, parasitoid related mortality, GR, and AD.

Analysis For both experiments, we used linear and logistic regressions to estimate the effects of diet concentration on pupal weights, survivorship, and parasitism rates. We further examined the relationships between *P. cenocladum* amide concentrations and *E. nympha* pupal mass and parasitism frequency with path analysis (Proc CALIS, SAS Institute Inc., NC, USA). Based on previous path models (Smilanich et al., 2009), we chose simple models *a priori* in which amide concentration had direct and indirect (via GR and AD) effects on pupal mass and parasitism frequency. Path analyses were conducted for all diets (three single amide diets and one mixed diet) and models yielding goodness of fit *chi-squares* with *P*-values greater than 0.05 were considered a good fit to the data.

An interaction index (α) is usually calculated in standard synergy studies (Tallarida, 2000). It is calculated as, $\alpha = Z/\sum(f_i A_i)$. Where f_i represents the fraction of a compound in the mixed diet and A_i is the concentration of that compound necessary to achieve a certain level of response when tested individually; Z is the concentration of the mixture of compounds necessary to achieve a certain level of response. Values of α significantly less than one demonstrate a synergy. However, our data were inappropriate for these calculations because in all experiments there were single amides that did not significantly affect the response variables, making it impossible to determine A_i. Thus, any increase in effect resulting from including these ineffective compounds was considered evidence of synergy.

Results

Piper imperiale Imides Piper imides had a synergistic effect on *E. nympha* pupal mass, but not on survival. The mixed imide diets reduced pupal mass (r^2=0.95, $F_{1,3}$= 38.77, P<0.05, Fig. 1). However, there was no significant relationship between change in pupal mass and piplaroxide (r^2=0.72, $F_{1,3}$=5.11, P=0.15) or 5′-desmethoxydihydropiplartine (r^2=0.70, $F_{1,3}$=4.66, P=0.16) concentrations. The alkene appeared to have a positive effect on *E. nympha*, since increasing the concentrations of alkene caused increases in pupal mass (r^2=0.99, P<0.01, $F_{1,3}$=219.93). There were no significant associations between *Piper* amide concentration and survival for any single or mixed diets (logistic regression, P>0.05). Mean survivorships were 100% for the control, 96% for the alkene diet, 92% for the 5′-desmethoxydihydropiplartine diet, 75% for the piplaroxide diet, and 75% for the mixture diet.

Piper imides had a synergistic effect on *S. frugiperda* survival. All concentrations of 5′-desmethoxydihydropiplartine produced results similar to the control (Fig. 2). The highest concentration piplaroxide diet (0.5% dry wt) and all concentrations of alkene caused reduced larvae survival. In contrast, larvae experienced 100% mortality on all mixed diets.

Piper cenocladum Amides Piper amides of *P. cenoncladum* had synergistic effects on the survival of *E. nympha.* While there was no relationship between individual *Piper* amide concentrations and *E. nympha* survival (logistic regression, piplartine failed goodness-of-fit test, 4′-desmethylpiplartine χ^2=4.44, *df*=1, P<0.05, β=−15.31±8.25, *Wald*=3.44, *df*=1, P>0.05, cenocladamide χ^2=0.59, *df*=1, P>0.05), a mixture of all three amides significantly affected survivorship (χ^2=25.50, *df*=1, P<0.001, β=−4.62±1.07, *Wald*=18.691, *df*=1, P<0.001). Mean survivorship for control, piplartine, cenocladamide, 4′-desmethylpiplartine, and mix diets were 83, 85, 89, 81 and 33%, respectively.

There was a significant treatment effect on parasitoid success (ANOVA, $F_{4,\ 138}$=6.78, P<0.01, Fig. 3). The mixture was the only treatment associated with an increased parasitism frequency (Logistic regression, χ^2=12.64, *df*=1, P<0.001, β=3.47±1.10, *Wald*=9.91, *df*=1, P<0.01). No larvae died of parasitism on piplartine or control diets, and there was no relationship between cenocladamide and parasitism, and 4′-desmethylpiplartine and parasitism (cenocladamide χ^2=0.01, *df*=1, P>0.05, 4′-desmethylpiplartine

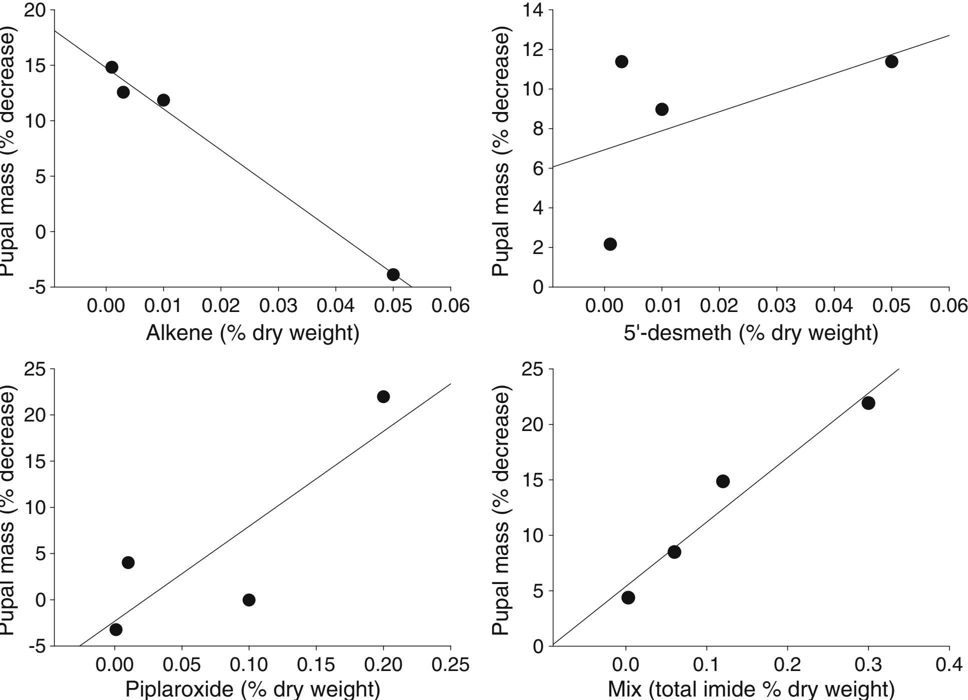


Fig. 1 Percent decrease in pupal mass of *Eois nympha* from control when reared on *Piper imperiale* leaf disks with alkene, 5′-desmethoxydihydropiplartine (5′-desmeth), piplaroxide and a mixture of all three imides added

χ^2=5.43, *df*=1, $P<0.05$, β=21.87±11.32, *Wald*=3.73, *df*=1, $P>0.05$). The parasitoid frequency path model demonstrated that mixed *Piper* amide concentration had a greater direct positive effect on parasitoid success than any single amide treatment (Fig. 4). Parasitoid success also was negatively affected via GR and AD, but there were no significant effect of amide treatments on GR and AD (Fig. 4).

There were negative effects of 4′-desmethylpiplartine and mixed amide concentrations on pupal mass of *E. nympha* (4′-desmethylpiplartine diet, r^2=0.36, $P<0.05$, $F_{1,11}$=6.18, mixed diet r^2=0.76, $P<0.001$, $F_{1,10}$=31.64), but pupal mass did not change with piplartine and cenocladamide concentrations (r^2=0.001, r^2=0.09, respectively, $P>0.05$). The pupal mass path model showed that

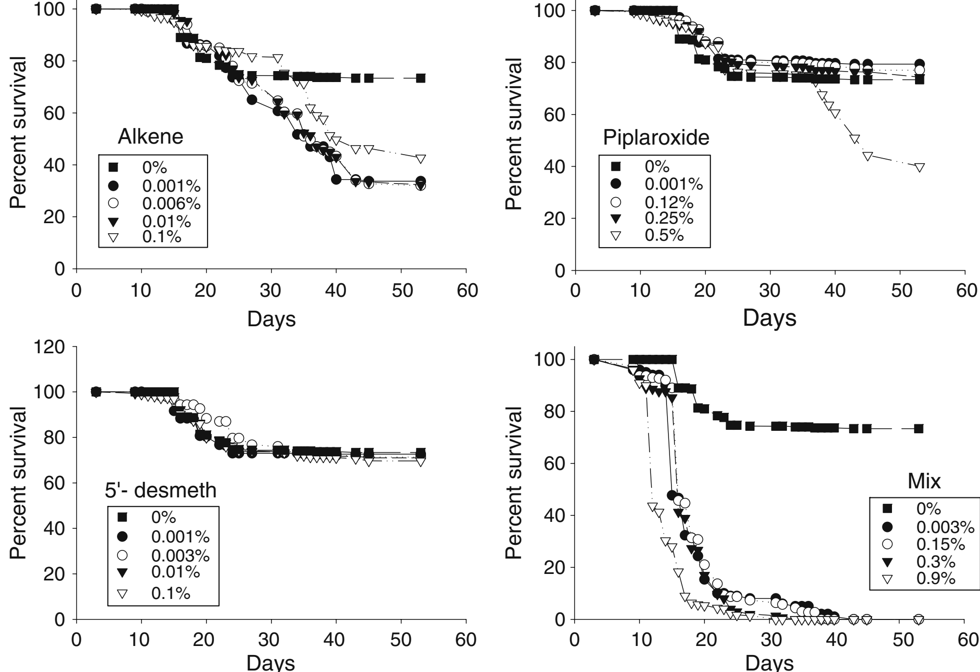

Fig. 2 Percent survival of *Spodoptera frugiperda* feeding on artificial diets with alkene, 5′-desmethoxydihydropiplartine (5′-desmeth), piplaroxide and a mixture of all three imides. Mix concentrations indicate the total imide concentrations

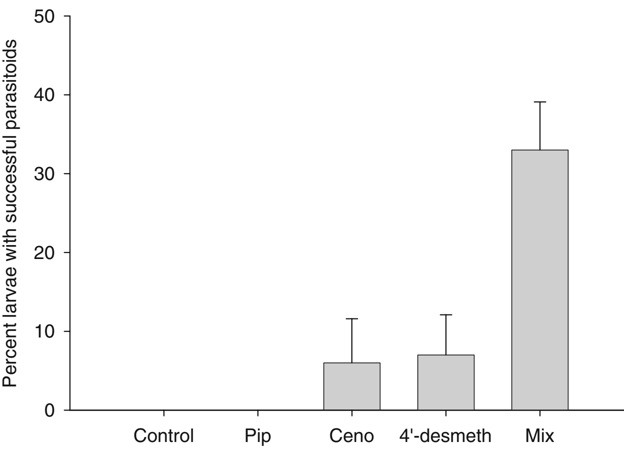

Fig. 3 Percentage of *Eois nympha* with successful parasitoids when reared on *Piper cenocladum* leaf disks containing methanol without amides (control, $N=12$) or with piplartine (Pip, $N=26$), cenocladamide (Ceno, $N=18$), 4′-desmethylpiplartine (4′-desmeth, $N=27$) and a mixture of the three amides ($N=60$) added. The mixture had significantly higher parasitoid success (*LSD*, $P<0.01$)

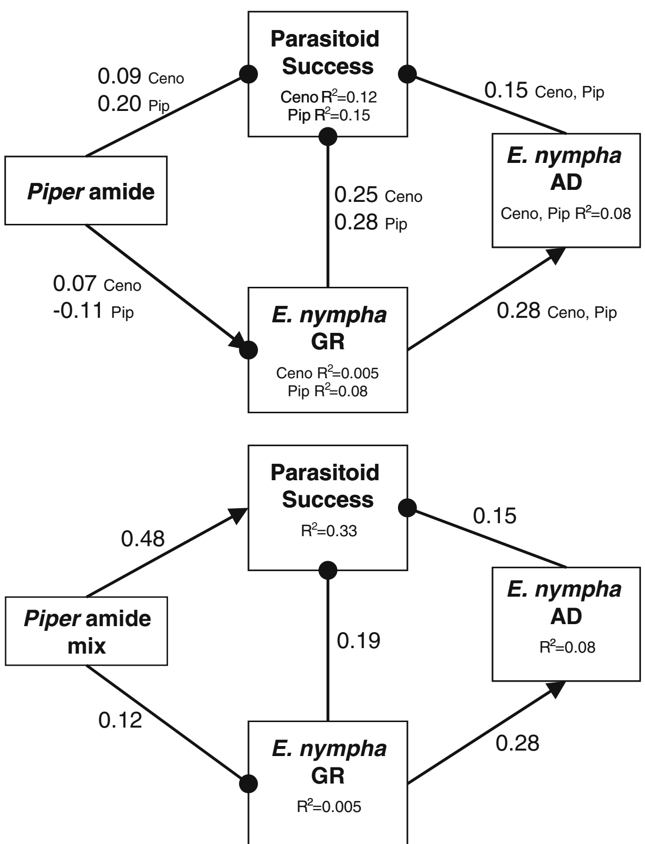

Fig. 4 Effects of *Piper* amides on parasitoid success in *Eois nympha* larvae reared on leaf disks with *Piper cenocladum* amides added (Parasitoid Frequency Model). Positive effects between variables are indicated by an arrow and negative effects are indicated by a bullet. Relationship strengths are indicated by the standardized path coefficient. R^2 values indicate the total variance explained in the model. The top diagrams the relationships for larvae on single amide treatments. 4′-desmethylpiplartine is not represented due to the lack of fit of the model ($\chi^2=41.84$, $df=1$, $P<0.001$). The model was a good fit for cenocladamide (Ceno, $\chi^2=0.22$, $df=1$, $P=0.64$) and piplartine (Pip, $\chi^2=0.17$, $df=1$, $P=0.81$). The bottom diagrams the relationships for larvae on the mixed amide treatment ($\chi^2=0.04$, $df=1$, $P=0.84$)

the mixed *Piper* amide treatment had the greatest direct negative effect on pupal mass compared to any of the single amide treatments (Fig. 5), and there was an indirect effect of amides on pupal mass via GR and AD. Again this relationship was strongest for the mixed treatment (Fig. 5).

Discussion

Piper amides synergistically affected both generalist and specialist herbivores via different mechanisms. Similar to a previous study with *P. cenocladum* amides (Dyer et al., 2003) and studies with other compounds (e.g., Roslin and Salminen, 2008), the mixture of amides in *P. imperiale* had dramatic toxic effects on survivorship of the naïve generalist *Spodoptera* caterpillars, while the negative effects on the specialist *Eois* caterpillars were more subtle. For *Eois*, increasing *Piper* amides caused increased parasitoid success and lower pupal mass, and this effect was more than doubled in response to increasing mixtures of amides as opposed to individual amides.

The synergistic effects of *Piper* amides on parasitism have interesting tritrophic implications. The traditional view of plant chemical defenses usually focuses on sequestration of toxins that confer a defensive benefit to the herbivore (Brower, 1984; Singer et al., 2009). However, our results are consistent with other recent studies that have shown an indirect positive effect of plant chemical defenses on parasitoids via disrupting the caterpillar immune response (Haviola et al., 2007; Smilanich et al., 2009). Since *Eois* species sequester *Piper* amides (Dyer et al., 2004a), the mechanisms for affecting parasitism include a direct negative effect on hemocytes responsible for the immune response or an indirect effect via decreasing overall herbivore vigor. Since the feeding efficiency measurements were not affected by ingestion of *Piper* amides, it is more likely that the increases in parasitism were due to direct toxicity of amides to immune cells. We did not directly measure the immune response, thus, there may be alternative explanations for these results, and further investigation is warranted. Interestingly, this *Piper*-*Eois*-parasitoid system is not consistent with the assumption of the “nasty” host hypothesis that herbivore sequestered plant defenses reduce host suitability for parasitoids (Gauld et al., 1992). We found the opposite; parasitoids were more successful in herbivores on more toxic mixed diets, which is consistent with previous studies that demonstrate that specialist parasitoids are less susceptible to changes in host

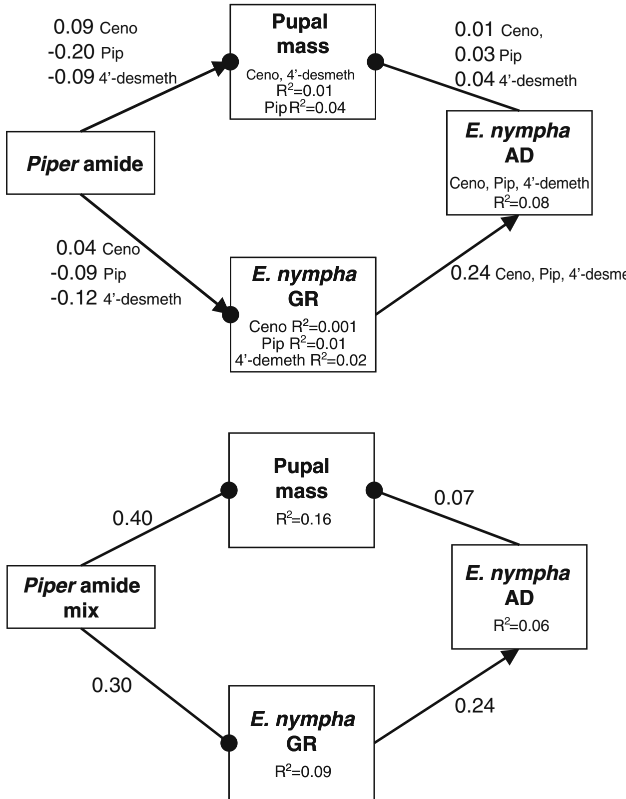

Fig. 5 Effects of *Piper* amides on pupal mass in *Eois nympha* larvae reared on leaf disks with *Piper cenocladum* amides added (Pupal Mass Model). For diagram description refer to Fig. 4. Model fit: Cenocladamide (Ceno) χ^2=2.23, *df*=2, *P*=0.33, Piplartine (Pip) χ^2=0.73,*df*=2, *P*=0.69, 4′-desmethylpiplartine (4′-desmeth) χ^2=3.52,*df*=2, *P*=0.17, Mix χ^2=0.15, *df*=2, *P*=0.93

chemistry than generalists (Gunasena et al., 1990; Barbosa et al., 1991; Harvey et al., 2003, 2005).

Results from the *P. cenocladum* experiments demonstrate that the effectiveness of different natural enemies is context dependent (Bronstein, 1994; Heil et al., 2002; McKey et al., 2005). The control leaves, which were collected from plants containing ants, had low amide concentration (Dodson et al., 2000; Dyer et al., 2001), high survival, and no parasitoid related mortality. Thus, when ants are present, they should be the main source of mortality and primary mechanism of *Eois* control. In comparison, the mixed amide leaves, which had concentrations similar to those found in plants without ants present (Dodson et al., 2000; Dyer et al., 2001), had high mortality from parasitoids. These two strategies of biotic and chemical plant defense may differ in their overall effectiveness and costs to the plants. For instance, producing high concentrations of amides may be costly to *P. cenocladum*, but the ecological cost of herbivory is lessened due to lower generalist herbivory and high mortality from parasitism on specialist herbivores. The same trade-off between physiological and ecological costs applies to *P. cenocladum* individuals that house ants, which produce low concentrations of amides while maintaining high levels of costly lipid and protein rich food bodies for the ants (Dyer et al., 2004b); in this case, it is the ants that maintain low levels of generalist and specialist herbivory (Letourneau et al., 2004). In contrast, *P. imperiale* does not have ant mutualists and suffers higher levels of herbivory by generalists and specialists (Fincher et al., 2008), even though relatively low levels of amides are necessary for synergistic defense against generalist caterpillars (a 0.9% mixture caused 100% mortality in 31 days) compared to *P. cenocladum* (a 1.34% mixture of *P. cenocladum* amides caused 100% mortality in 54 days, Dyer et al. 2003).

In summary, we found that *Piper* amides in two species of *Piper* have negative synergistic effects on specialist and generalist herbivores. *Piper* amides were highly toxic and acted as a strong bottom-up force on generalist herbivores, while specialists were indirectly affected by positive synergistic effects of amides on parasitoids, which can be an important top-down force in herbivore regulation. When considering these responses of generalist and specialist herbivores to synergistic plant defenses, some interesting questions arise: Did synergistic compounds evolve in response to specialist herbivores that circumvented the toxicity of individual defenses? What are the physiological mechanisms that result in effective defensive synergy of secondary metabolites? In our experiments, specialists were able to circumvent the toxicity and developmental effects of diets spiked with single amides via unknown physiological mechanisms, but were strongly affected by synergistic mixes via effects on parasitoid development. Because the fresh leaf disks already contained *Piper* amides, all treatments in the specialist experiments were to some degree mixed diets. This means that in response to selective pressures from herbivores, an increase in the concentration of a single amide would have little adaptive value. In contrast, a small increase in several *Piper* amides would result in significantly reduced pressure from *Eois* populations, through decreased pupal mass, fecundity, parasitoid resistance, and survival. Similar results in other plant-insect systems would have interesting implications for tritrophic theories of coevolution and specialization (e.g., Singer and Stireman, 2005).

Acknowledgments This study was funded by NSF grants DEB-0344250 and CHE-0718732, as well as grants from Earthwatch Institute and the University of Nevada Reno. We thank the owners of El Bejuco and La Tirimbina, the Costa Rica National Parks, and the Organization for Tropical Studies (OTS) for use of their facilities. Excellent technical assistance was provided by Earthwatch volunteers and H. Garcia Lopez. We are grateful to the chemical ecology and tropical entomology laboratory group at Tulane University and Jeff Harvey for insights and assistance that improved this manuscript.

established extraction and identification technique widely used to analyze organic compounds in different matrices (Chai et al., 1993; Chai and Pawliszyn, 1995; Xiong et al., 2004; Ouyang and Pawliszyn, 2006; Bocchini et al., 2009). Recently Yassaa and Williams (2007) published a study dealing with the sampling of monoterpenoid compounds from *P. sylvestris* by SPME. An example of SPME/GC/MS analysis of volatile compounds *in vivo* is provided by Asaro et al. (2004) who studied the role of volatiles associated with preferred and non preferred hosts of *Rhyacionia frustrana* (Comstock) pest.

Here, we investigated the differential attractiveness of volatile compounds produced by three pine species on *N. sertifer* females. A SPME/GC/MS method for the qualitative and quantitative determination of volatiles from *P. sylvestris, P. nigra*, and *P. pinea* was set up. Our specific aim was to study the olfactory response by the sawflies to pine volatile compounds that were found to be characteristic for an attractive species (*P. sylvestris*) and a non-attractive species (*P. pinea*).

Methods and Materials

SPME/GC/MS Two different SPME fibres, 75 μm Carboxen™–PDMS and 70 μm Carbowax/Divinylbenzene (CW/DVB), specified by Supelco (Supelco, Milan, Italy) as suitable for sampling volatiles and semivolatile compounds, respectively, were tested. The SPME fiber, after sampling, was desorbed (10 min, 280°C) inside the injector of a Varian 3400 Gas Chromatograph (Varian, Walnut Creek, CA, USA) connected to a Varian Saturn 2000 Ion Trap Mass Spectrometer. The chromatographic capillary column was a DB-5MS J&W (30 m×0.25 mm I.D., 0.25 μm film thickness). The chromatographic elution was temperature programmed as follows: 50°C for 10 min, then from 50°C to 225°C at a rate of 5°C/min. The overall analysis time was 45 min. Mass spectra were acquired in the range *m/z* 40–450, at a rate of one scan per sec. Chromatographic peaks were identified by means of an automatic search of the NIST library of mass spectra and compared with mass spectra of terpenoid compounds reported in the literature (Adams, 2007). Standard compounds, namely α-pinene, β-pinene, myrcene, and limonene were purchased from Sigma-Aldrich (Sigma-Aldrich, Milan, Italy); δ-3-carene was purchased from Carl Roth (Carl Roth GmbH, Karlsruhe, Germany). Standard compounds were used to confirm compound identification and to carry out the bioassays.

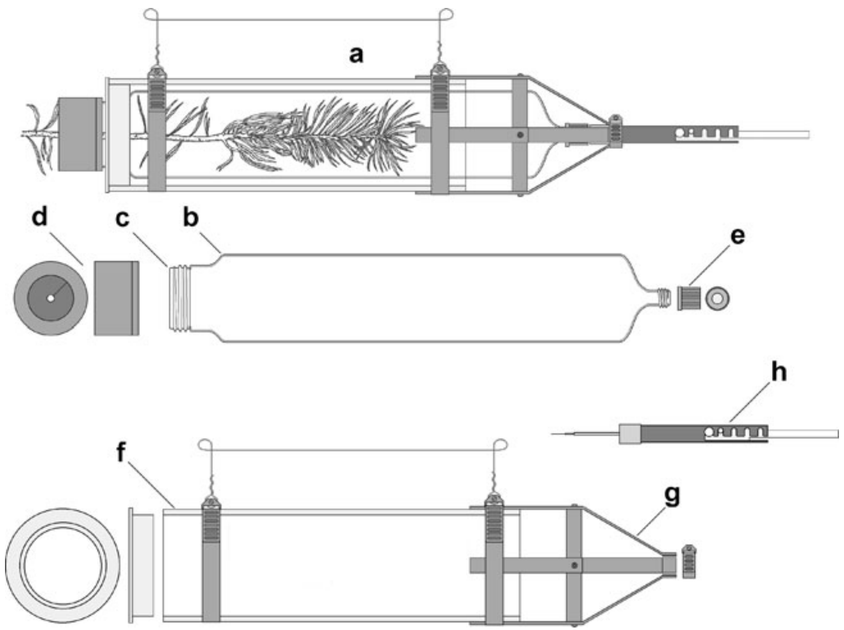

Fig. 2 Sampling structure used for the *in vivo* SPME sampling (**a**). The container was a glass cylinder with an internal volume of 1.2 l (**b**) and, at one end, an opening large enough to allow the branch to be placed inside it (**c**). The opening was fitted with a screw cap sealed with rubber/Teflon, (**d**) and can be tightly closed around the branch itself. At the other end of the glass cylinder, another opening was fitted with a hole screw cap (**e**) and was used for SPME sampling operations. The glass cylinder was housed inside a PMMA (polymetyl methacrylate) cylinder (285×90 mm) (**f**) provided with a metallic structure (**g**) in order to maintain the SPME holder (**h**) in a stable position during sampling operation

Method Set-Up A laboratory test was carried out in order to determine which of the two fibers (Carboxen–PDMS and CW/DVB) was more suitable for sampling volatiles emitted by pine needles. Known amounts of *P. nigra* needles were put inside a 40 ml vial sealed with screw caps with a PTFE septum. The two fibers were exposed to the headspace for 15, 30, and 60 min at ambient temperature and then desorbed. The sum of the areas of all the chromatographic peaks was calculated. For each sampling time, the calculated area was higher for the experiments carried out with the Carboxen–PDMS fiber. Due to this result, all successive experiments were performed using a Carboxen–PDMS fiber.

Sampling time is a critical step to be optimized in an SPME method. For this reason, sampling time vs. total area experiment was performed. The tested sampling periods were 5, 15, 30, and 60 min; a sampling time of 60 min was considered sufficient to allow a representative absorption of the volatiles.

Replicate analyses of volatiles (4 samples of needles for each pine species) from *P. pinea*, *P. nigra*, and *P. sylvestris* were performed. Relative standard deviations ranged from values as low as 10% for limonene in *P. pinea* samples to more than 100% for less abundant compounds.

Despite the high variability of results, a discriminant analysis allowed the identification of limonene as the compound that can successfully discriminate between *P. pinea* and the other pine species. In Fig. 1, a box-and-whisker plot for limonene (area percentage) as determined in the three pine species is shown.

In Vivo Laboratory Experiment An *in vivo* laboratory experiment was performed by using a Carboxen–PDMS fiber with a sampling time of 60 min. To better control absorption conditions, a container which can house a whole tree branch was custom-made (Fig. 2). The cylinder was suspended from the tree in such way as to maintain natural branch bearing.

Before starting the *in situ* sampling, an experiment was performed comparing the summed areas of the chromatographic peaks at 60 and 120 min for *P. sylvestris in vivo* sampling and 60 min long sampling of *P. sylvestris* needles under the same conditions described in the "method set-up" section. Data showed that the *in vivo* conditions required longer sampling times in order to reach a satisfactorily high amount of adsorbed volatiles. This was probably due to the higher volume of the glass branch container with respect to the amount of pine leaves present inside it. A sampling time of 120 min was considered sufficient to give a good representation of the volatile composition of living plants.

In Situ Sampling Experiments To test the analytical sampling system *in situ* and *in vivo*, a pinewood in Piedimonte (about 550 m above sea level, Province of Forlì-Cesena, Italy), 1.9 ha large and mainly formed by 20–30 yr-old *P. domestica*, *P. sylvestris*, and *P. nigra* trees, was used.

Sampling experiments were carried out on the last 10 d of November (mean temperature 15°C; mean illuminance 28.57 klx), in the afternoon (3–5 p.m.). This period of the year was chosen because it corresponds with the peak of flight period of *N. sertifer*, which in temperate regions, starts at the end of September and the beginning of October (Baronio et al., 1997). *In situ* sampling was performed on 3 different days by using 9 SPME fibers. Each day 3 samples for each pine species were collected. A total of 27 samples from different trees were collected. After sampling, SPME fibers were stored at −80°C and later analyzed by GC/MS.

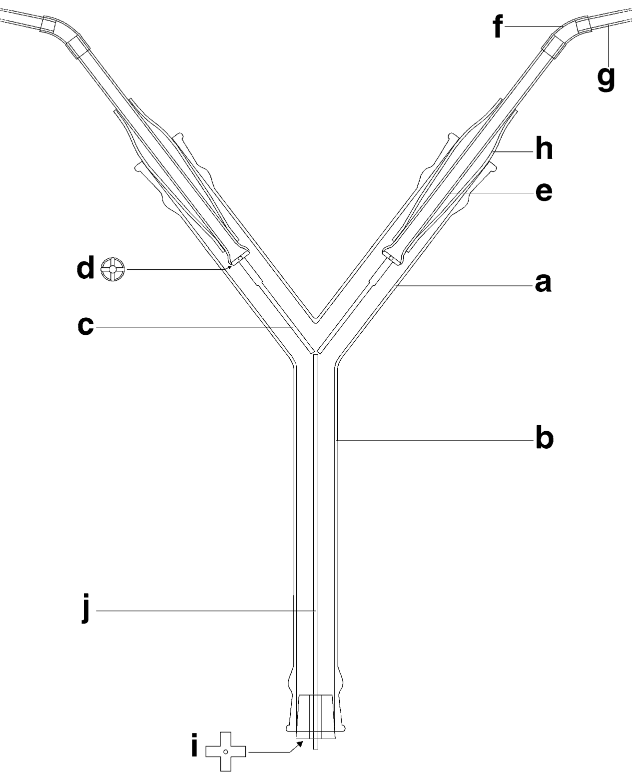

Fig. 3 The modified Y-tube olfactometer used in bioassays. The Y-tube had a diameter of 30 mm and a thickness of 2 mm; the two arms were 185 mm long, forming a 75° angle (**a**). The stem was 250 mm long (**b**). In each arm, a 40 mm long frosted glass stick with a thickness of 3 mm (**c**) was connected by a cross-shaped glass weld (**d**), to a glass tube 230 mm long and 10 mm large (**e**). These glass tubes were connected by 30 mm polyethylene tubes (**f**) with two PTFE (polytetrafluorethylene) tubes (**g**) and inserted into a spindle-like glass tube (**h**) which was fitted at the upper side of the two arms to maintain the frosted glass stick at the centre of the arms and parallel to them, leading to a contact of the glass sticks. A silicon rubber plug (**i**), placed at the base of the stem, was equipped of another frosted glass stick (**j**) with a thickness of 3 mm. The silicon rubber plug had a cross shape which allowed the air flow from the olfactometer

Bioassays—Insects We tested the olfactory response of *N. sertifer* females to pine volatiles in laboratory olfactometer bioassays. The sawflies were taken from a lab-rearing obtained from a population collected in two pine stands located in Piedimonte and Vessa (Forlì-Cesena province). Larvae were reared in plastic boxes (28×18×12 cm) kept at 20°C, 70% r. h., and 12 hr photophase, and were fed with *P. sylvestris* branches taken from the woodland. Female cocoons were sexed and stored inside Petri dishes until emergence. Female individuals chosen for the olfactometer test were 5–10 d-old virgin specimens. In this species, oviposition starts on average on the 5th day after cocoon emergence (Baldassari et al., 2003).

Bioassays—Olfactometer A modified Y-tube glass olfactometer was used. A glass "railroad" was inserted into the Y-tube, in a similar way to the wire "railroad" used in the Y-tube modified by Sabelis and Van de Baan (1983) (Fig. 3). The whole olfactometer was suspended from a wood board covered with white cardboard. The wood board was connected with a metallic hinge to another horizontal board; in this way the olfactometer could be angled from the vertical to the horizontal position.

A mechanical pump was used to force air flows inside the olfactometer's two upper arms. The air stream was humidified by passing through water, and filtered by using a carbon filter. Two flow-meters kept air flows to 2 l per min. Air was forced through two 100 ml Büchner flasks, one of which (odor chamber) was spiked with a known amount of the compounds to be tested. Each Büchner flask was connected via the two PTFE tubes to the two upper arms of the olfactometer.

By introducing CO_2 smoke inside the upper arms of the apparatus, we tested whether the two separate air flows mixed. No mixing was observed. We observed that *N. sertifer* female individuals could move easily and climb inside the olfactometer that was set in an upright position. Laboratory walls were painted white, and windows were closed during experiments. An halogen lamp was fixed to the ceiling, producing a light intensity of 1,000 lx at the crossing of the olfactometer arms.

Neodiprion sertifer females were tested singly by placing them inside the vertical shaft of the olfactometer on a platform made of brass mesh on the top of silicon plug. Each individual was tested once. If the individual did not reach the Y shape junction position within 5 min, the behavior was classified as "no choice". If the individual reached one of the two Y arms of the olfactometer within 5 min, this behavior was classified as "first choice". A "final choice" was assigned to individuals that reached the top of the chosen arm after more than 3 min. In the other cases, a "no choice" behavior was considered.

In order to add to the scent chamber an amount of volatile compound that mimics the plant release, the amounts of limonene and myrcene were quantified by the standard addition method. The apparatus used for *in vivo* laboratory experiments was utilized to quantify volatiles released from a branch of *P. sylvestris*. Briefly, known amounts of the compound to be quantified were added to the glass cylinder containing the branch (20 to 25 cm long), and the areas obtained after SPME/GC/MS analysis were plotted vs. the added amounts of standard. The calculated regression curve was used to determine the amount of compound initially present inside the glass cylinder. The

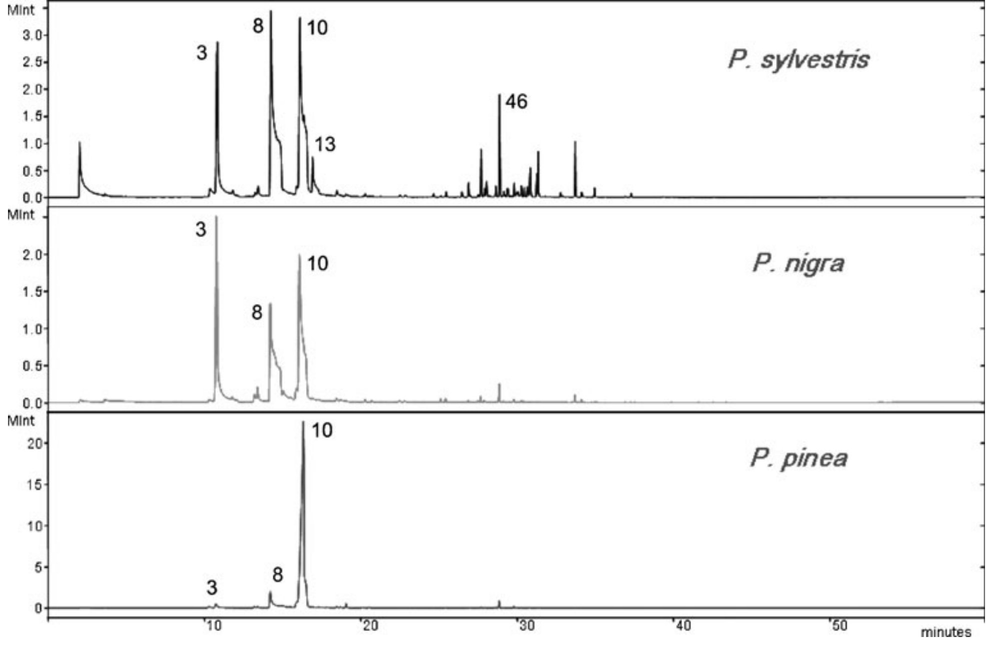

Fig. 4 SPME/GC/MS chromatograms of volatiles emitted from the three different *Pinus* species. Numbers as in Table 1 (3: α-pinene, 8: δ-3-carene + myrcene, 10: limonene, 13: terpinolene and 46: (Z)-caryophyllene)

obtained amounts of limonene and myrcene were in the range 1–2 μg/l. The volatile compounds were deposited in the scent chamber in excess with respect to the concentration measured in the glass cylinder in order to let a small fraction of it evaporate in the air flow, thus maintaining a constant concentration of the volatile compound during the experiment.

The scent chamber was regenerated after 30 min of testing, and observations were resumed after 5 min. After having tested the behavior of 10 individuals, the instrument was rotated 180° in order to avoid any position bias (Koschier et al., 2000). Olfactometer glass walls were washed with dichloromethane before each variation in concentration and before changing the tested chemical compound.

Statistical Analysis A discriminant analysis was used to ordinate the compositions of volatile blends of the three pine species. After GC/MS analysis, peak areas were measured in each chromatogram, and area percentage was calculated for the identified compounds. These values were subjected to a discriminant analysis using the software STATISTICA (RELEASE 5.1) (STATSOFT INC, 1995).

For statistical analysis of the olfactometer data, a *chi-square* test was used to statistically compare differences in choice between clean air and air spiked with the volatile

Table 1 Compounds identified in the chromatograms of volatiles sampled from *Pinus pinea*, *P. nigra* and *P. sylvestris* trees

N.	Retention time (scan)	Compound	N.	Retention time (scan)	Compound
1	622	Tricyclene	34	1,521	Phenyl ethyl acetate

Table 2 Mean relative (%) total peak areas and standard deviations (SD) of the most abundant compounds in the headspace of three pine species (*in vivo* sampling, 9 samples for each *Pinus* species)

Compounds	*P. nigra*		*P. pinea*		*P. sylvestris*	
	Mean	SD	Mean	SD	Mean	SD
α-pinene	44.97	44	19.39	132	16.49	82
β-pinene	4.43	63	3.57	113	1.35	126
Myrcene	10.68	82	4.73	72	39.83	45
Limonene	18.30	64	66.12	48	23.40	54

Table 3 Discriminant analysis results showing the standardized coefficients of the variables, indicating the compounds which have more weight in separating the three groups

Compounds	Root 1	Root 2	
Myrcene	2.11	1.02	$P<0.001$
δ-Cadinene	1.63	0.54	$P<0.001$
Limonene	0.24	2.42	$P<0.001$
trans-Verbenol	−0.76	−0.80	$P<0.001$
β-Pinene	0.36	1.72	$P<0.001$
α-Pinene	0.65	1.01	$P=0.055$

compound to be tested. The null hypothesis was that the percentages of individuals choosing the spiked air and the pure air flows were 50%, respectively.

Results

In Situ Sampling Experiments—SPME/GC/MS Representative chromatograms obtained by analyzing the volatile fraction of the three pine species *P. pinea*, *P. sylvestris*, and *P. nigra* are shown in Fig. 4. A total of 66 chromatographic peaks were identified by GC/MS (Table 1). The most abundant compounds, in terms of absolute areas of the chromatographic peaks, were α- and β-pinene, myrcene, and limonene. Their relative amounts in the headspace of the three pine species are reported in Table 2 (areas of each identified compound are expressed as relative percentages).

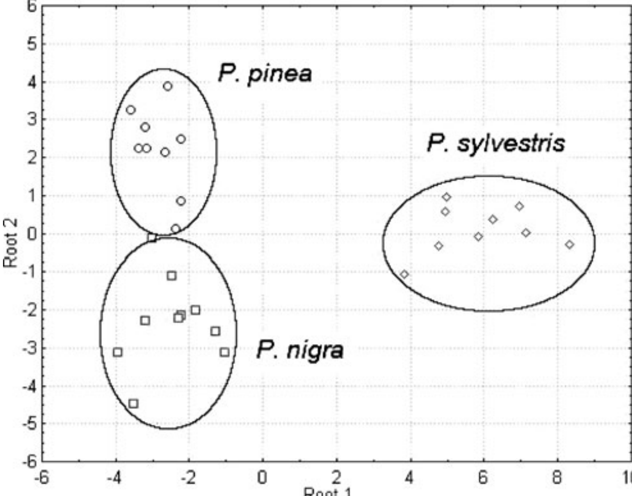

Fig. 5 Discriminant analysis applied to chromatographic data, showing significant differences in the composition of volatile blends emitted from three *Pinus* species. Each *symbol* represents an *in vivo* sampling experiment. The graph was generated applying root coefficients showed in Table 3

A discriminant analysis was applied to the quantitative GC/MS data, and the first two discriminant functions (i.e., root 1 and root 2) showed a clear ordination of the data into three groups (Fig. 5), each corresponding to a pine species. *Pinus pinea* can be differentiated from *P. sylvestris* and *P. nigra* mainly by limonene and myrcene, as evinced from the values of the standardized coefficients (Table 3). In particular, the first discriminant function shows the highest contribution for myrcene, while the second function is affected mainly by limonene. Limonene was the main component of the *P. pinea* volatile fraction. The mean percentage of the limonene peak area represents 66% of the *P. pinea* volatile blend composition, whereas the peak area of this compound accounts for 18% and 23% of all detected volatile components in *P. nigra* and *P. sylvestris*, respectively. Since the odor of *P. pinea* is characterized by its high relative amounts of limonene, we assumed that this terpenoid protects *P. pinea* trees from *N. sertifer* attacks. The highest mean percentage peak area of myrcene was found in *P. sylvestris*; the discriminant analysis revealed that *P. sylvestris* can be separated statistically from the two other species by this volatile compound.

Table 4 Olfactory responses by *Neodiprion sertifer* females (final choice) to limonene (1 µl and 2 µl added to the odor chamber) vs. air and to myrcene (1 µl) vs. air

Compound tested		Control		Statistics[a]	
N	%	*N*	%	χ^2	*P*
Limonene 1 µl		Air			
41	87.23	6	12.77	24.6	<0.001
Limonene 2 µl		Air			
14	31.11	31	68.89	3.67	=0.055
Myrcene 1 µl		Air			
26	57.78	19	42.22	0.20	=0.658

[a] Comparison was made by *Chi-square* test. Yates correction was used to calculate χ^2 values (*d.f.*=1)

Bioassays According to the results obtained by GC/MS, the appropriate volatile compounds to be used in the bioassay were limonene (1 µl and 2 µl added to the odor chamber) and myrcene (1 µl added to the odor chamber). Females' reactions were investigated by recording the reactions of 50 and 48 specimens, respectively.

Olfactometric reactions of female individuals to volatiles are shown in Table 4. Females showed a high percentage of choice. In particular, in the three experiments the percentages of choice were 94, 92, and 96% in the bioassay with 1 µl of limonene, 2 µl of limonene, and 1 µl of myrcene, respectively. *Neodiprion sertifer* females were attracted significantly by the lowest amount of limonene (1 µl in the odor chamber): a statistically significant percentage of individuals (87.23%) chose the arm of the olfactometer leading towards the limonene spiked odor chamber ($P < 0.01$, χ^2 test). This behavior changed when the amount of limonene added to the odor chamber was increased from 1 to 2 µl; in this second condition, most individuals (68.89%) chose the non-spiked odor chamber. Myrcene (1 µl) attracted *N. sertifer* females only in 57.78% of cases, showing no attractive pattern ($p > 0.05$, χ^2 test).

Discussion

Previous studies have shown that the sawfly *N. sertifer* avoids ovipositing on *P. pinea*, whereas *P. sylvestris* and *P. pinea* are accepted for oviposition. We suggest that the high amounts of limonene released by *P. pinea* may contribute to the avoidance of this tree since (a) high amounts of limonene were shown here to repel *N. sertifer* females, and (b) only *P. pinea* released high relative amounts of limonene, whereas no such high limonene emission was found in the two other species. While limonene was repellent at high doses, low amounts attracted the sawflies. This behavior has not been documented previously for *N. sertifer* although it has been detected in other insects living on coniferous trees. For example, α-pinene is repellent to many insects but it may be attractive to the same insects at lower concentration (Annila and Hiltunen, 1977).

It is remarkable that egg deposition of *N. sertifer* occurs in autumn when the limonene content in *P. pinea* needle is higher than earlier in the year (Tiberi et al., 1999). The pattern of *N. sertifer* females selecting *P. sylvestris* and *P. nigra* trees for laying eggs is similar to that of the pine processionary moth *Thaumetopoea pityocampa* which lays a limited number of eggs on *P. pinea*, but prefers *P. sylvestris* and *P. nigra* (Tiberi et al., 1999). Future studies need to investigate whether avoidance of *P. pinea* by this moth is mediated by the same volatiles as in *N. sertifer*.

forest trees, where their abundance and diversity are greatest (Arnold et al., 2001).

The interaction between endophytes and their hosts varies from mutualistic to parasitic, depending on species, physiological state, chemistry of the host plant, environmental stress, and other abiotic conditions (Espinosa-García et al., 1993; Gilbert and Strong, 2007). These fungi may impact survival and fitness of plants in all terrestrial ecosystems, and may play a significant role in plant biogeography, evolution, and community structure (Rodríguez et al., 2009).

The secondary metabolites produced by endophytes or their infected hosts could be chemical defenses against herbivores, pathogens, or competitors (Schulz and Boyle, 2005; Strobel, 2006; Herre et al., 2007). *In vitro* competition experiments show that endophytic fungi inhibit the growth of other endophytic fungi (Espinosa-García et al., 1993) and phytopathogens (Yue et al., 2000; Arnold et al., 2003). Endophytes in the tissues of living plants are relatively unstudied as potential sources of novel natural products. These compounds offer an enormous potential for the discovery of new agrochemicals and drugs of natural origin (Tan and Zou, 2001; Schulz et al., 2002).

Muscodor has been isolated as an endophyte from tropical trees and vines in Central America, Australia, and Thailand. Four species of *Muscodor* are known: *M. albus* from small limbs of *Cinnamomum zeylanicum* in Honduras and *Myristica fragrans* in Thailand (Worapong et al., 2001; Sopalun et al., 2003); *M. roseus* from two monsoonal rainforest tree species, *Grevillea pteridifolia* and *Erythophelum chlorostachys* in Northern Australia (Worapong et al., 2002); *M. vitigenus* from *Paullinia paullinioides*, a liana growing in the understory of the rainforests of the Peruvian Amazon (Daisy et al., 2002a); and *M. crispans* from *Ananas ananassoides*, a wild pineapple in the Bolivian Amazon Basin (Mitchell et al., 2008). Based on morphological and DNA sequence analyses, González et al. (2009) found that *M. yucatanensis* is a new species. Colonies of this fungus are whitish and produce a strong musty odor when grown on potato dextrose agar (PDA). They grow slowly and do not produce reproductive structures. *Muscodor* species produce a mixture of toxic volatile organic compounds (VOCs) that are lethal to a wide variety of plant and human pathogens. The mixture of VOCs consisted primarily of alcohols, acids, esters, ketones, and lipids, including 3-methyl butyl acetate (isoamyl acetate), which was the most active compound (Ezra et al., 2004a,b; Strobel, 2006).

This paper describes part of a long-term project on the chemical ecology of endophytic fungi and their possible role in plant defense mechanisms (González et al., 2007; Macías-Rubalcava et al., 2008). We investigated the allelochemical potential of the endophytic fungus *Muscodor yucatanensis* and cataloged the compounds it produces *in vitro*.

We performed bioassays to test the toxicity of VOCs and organic extracts of the mycelium and culture medium. We assessed the effects of the extracts on the growth of other endophytic fungi from El Eden plant species, on some important phytopathogens, and on dicotyledonous and monocotyledonous plants. We also evaluated the chemical composition of the VOCs mixture and of the organic extracts from mycelium and culture medium.

Methods and Materials

Fungal Material *M. yucatanenis* was isolated from surface sterilized segments of healthy leaves of *Bursera simaruba* (Burseraceae) ('chacah' or 'palo mulato') collected at the Ecological Reserve El Eden, Quintana Roo, Mexico in September 2004. A specimen of the plant was deposited in the University of California, Riverside Herbarium (G.P. Schultz & R. Palestina # 1092/UCR 110695). The fungus was cryogenically preserved in liquid nitrogen vapor 10% glycerol, and was deposited in the fungal collection of Herbario Nacional de México (MEXU), UNAM, accession number MEXU 25511.

Effects of VOCs Bioassays were performed using six endophytic fungi isolated from *B. simaruba* and other surrounding plants in the El Eden Ecological Reserve: *Colletotrichum* sp., *Phomopsis* sp., and *Guignardia mangifera* (isolated from the leaves of *Callicarpa acuminata*); the unknown isolate 120 and *M. yucatanensis* (isolated from *Bursera simaruba* leaves); and *Xylaria* sp. (isolated from *Pteridium aquilinum* leaves). As a complement to bioassays that used these endophytic fungi, we also tested VOCs on phytopathogenic microorganisms: fungi *Fusarium oxysporum, Alternaria solani,* and *Rhizoctonia* sp., and fungoids *Phytophthora parasitica* and *P. capsici.*

Bioassays were performed under sterile conditions using divided Petri dishes (9 cm) with two compartments containing PDA medium. The plastic walls dividing the plate prevented the diffusion of any soluble compounds produced by *M. yucatanensis* to the second compartment but did allow free exchange of VOCs. Due to the very slow growth of *M. yucatanensis* on PDA medium, an inoculum of it was placed in one of the compartments of the dish and grown at 25–27°C and a photoperiod of 12:12h fluorescent light (Octron 4100 K, Ecologic, 32 W) for 10 d before the bioassay. The inoculum from a test species was then placed in the other compartment of the dish, which was then wrapped with two layers of plastic wrap and incubated as above. Growth of the test organisms was assessed after different times of incubation, depending on individual growth rate. *Phytophthora capsici*, *P. parasitica*, *Colletotrichum* sp., *Phomopsis* sp., and *Rhizoctonia* sp. were examined after 3 d; *A. solani* and *F.*

oxysporum after 4 d, and *G. mangifera*, isolate 120, *Xylaria* sp. and *M. yucatanensis* after 10 d. The average of two perpendicular diameter measurements for each mycelium was recorded at the end of the bioassays and compared with the respective controls (Macías-Rubalcava et al., 2008). Experiments were performed following a complete randomized design with four replications per treatment.

Recovery of test fungi that were severely inhibited by *Muscodor* VOCs was evaluated by transferring an agar plug of the test microorganism to a new Petri dish with fresh PDA and incubating under the same conditions. Recovery was evaluated by measuring mycelial diameter as described above and comparing results with controls.

Phytotoxicity of the VOCs was tested on roots of two dicots, amaranth (*Amaranthus hypochondriacus*; Amaranthaceae) and tomato (*Lycopersicon esculentum* var. Pomodoro; Solanaceae), and one monocot, barnyard grass (*Echinochloa crus-galli*; Poaceae). We selected these test plants because we needed plants that have rapid, homogenous, high frequency germination, and because seeds of tropical plants including *B. simaruba* germinate poorly. Amaranth seeds were purchased at a local market at Tulyehualco, Mexico, D. F., tomato seeds in Semillas Berentsen, Celaya, Guanajuato, Mexico, and barnyard grass seeds were collected from plants growing in the greenhouse of Instituto de Ecología (UNAM).

The bioassays were performed with divided Petri dishes containing PDA and inoculated with *M. yucatanensis* in one compartment. The endophyte was grown at 28°C for different times (0, 3, 5, 10, 15, 20, 30, and 50 days) before introducing seeds into the other compartment that contained 1% water agar. At each time, 10 test seeds were sown and dishes were wrapped with two layers of plastic wrap and placed in a germination cabinet in the dark at 27°C. Root lengths of test plants were measured after 24 hr (amaranth), 48 hr (barnyard grass), or 72 hr (tomato) of exposure to *Muscodor* VOCs. Root lengths were compared to controls that did not have the *M. yucatanensis* inoculum. Experiments were performed following a complete randomized design with four replications per treatment.

We evaluated recovery of seeds and seedlings that were severely inhibited by *Muscodor* VOCs. Inhibited seeds and seedlings were removed from the divided Petri dishes and placed in new Petri dishes with fresh 1% water agar, and incubated as before. Root lengths were measured after 24 and 48 hr, and compared with their respective controls.

Organic Extracts of Culture Medium and Mycelium Fungi release some secondary metabolites into the environment while retaining others in the mycelium. *M. yucatanensis* was cultured in 18 Erlenmeyer flasks (1,000 ml), each containing 500 ml of potato dextrose broth (PDB). Each flask was inoculated with three agar plugs taken from a stock culture of *M. yucatanensis* on PDA, and was incubated with constant agitation on an orbital shaker at 150 rpm for 6 wk at 25–27°C and a photoperiod of 12:12 hr (fluorescent light).

At the end of the fermentation process, culture medium in each flask was separated from the mycelium by filtration. Culture medium (9 L) was extracted × 3 with 9 L of dichloromethane (CH_2Cl_2) and then × 3 with 9 L of ethyl acetate (EtOAc). The combined organic phases were filtered over anhydrous Na_2SO_4 and concentrated *in vacuo* to give 306.9 mg of a yellowish resinous product. The mycelium was extracted with CH_2Cl_2 and EtOAc (3×2 L). The combined mycelium extracts were evaporated to yield 2.73 g of a yellowish resinous product.

Organic extracts of the culture medium and mycelium were tested with the same eleven test microorganisms used in the bioassays described above. Both extracts were evaluated at 125, 250, 500, and 1,000 μg/ml in sterile PDA, added before the agar had solidified in 6-cm Petri dishes. The positive control was the commercial fungicide Prozycar® (carbendazim: methyl benzimidazol-2-yl-carbamate) added to agar at 200 μg/ml. This concentration of Prozycar completely inhibited test microorganisms in a preliminary bioassay. Unamended PDA was used as negative control. An inoculum (5 mm^2 agar plug) of each test microorganism was placed on the amended agar in a Petri dish and incubated in darkness at 27°C. The average of two perpendicular measurements of the mycelium was recorded after 3, 4, and 10 d of incubation depending on the growth rate of the test microorganism. The experiment used a complete randomized design with four replications per treatment.

A Petri dish bioassay was used to evaluate the effect of the organic extracts (culture medium and mycelium) on the root length of amaranth, tomato, and barnyard grass. Each extract was evaluated at 50, 125, 250, and 500 μg/ml by adding the extract to 1% water agar before the agar had solidified. Unamended water agar was used as negative control, and agar with 1,000 μg/ml of Rival® (Glyphosate: N-(phosphonomethyl) glycine) as positive control. This level of Glyphosate completely inhibited root growth in the test plants in a preliminary bioassay. Ten seeds of each test plant were sown directly on agar in 6 cm Petri dishes and incubated in the dark at 27°C. Root lengths were measured 24 hr after treatment for amaranth, 48 hr for barnyard grass, and 72 hr for tomato. The experiment used a complete randomized design with four replications per treatment.

Qualitative Analysis of VOCs M. yucatanensis mycelium was grown on PDA for 10 d in 15 ml SPME vials. A Solid Phase Micro Extraction (SPME) syringe was placed through a small hole drilled in the side of the vial through a Teflon septum and exposed to the vapor phase for 60 min. The SPME syringe (DVB–PDMS–Carboxen 50/30, Supelco Bornen, Belgium) was conditioned before use for 40 min at 250°C. After exposure to the VOCs, the syringe was inserted into the split (1:50 ratio) injection port of a gas

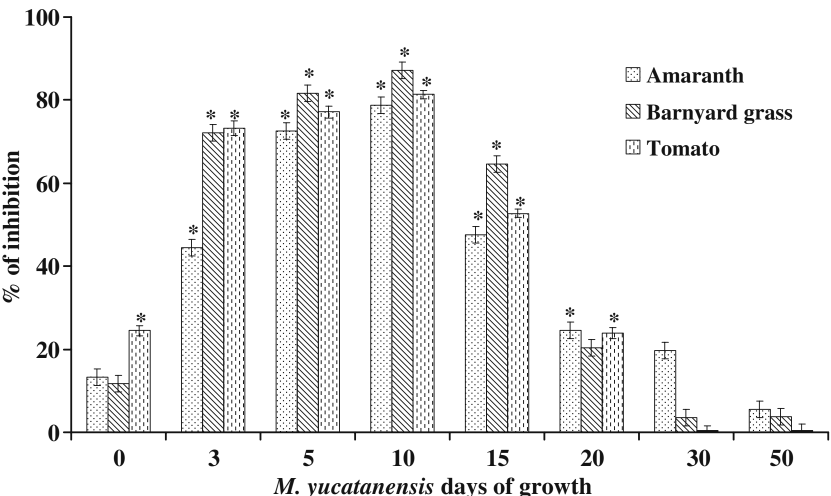

Fig. 1 Phytoinhibitory activity of VOCs produced by *Muscodor yucatanensis* after different periods of growth. The root lengths of amaranth, tomato, and barnyard grass seedlings were determined after 24 hr of exposure to VOCs (Amaranth): 48 hr of exposure (barnyard grass); or 72 hr of exposure (tomato). Vertical bars represent SD, $N=4$; $^{*}P<0.05$

chromatograph (GC) (Agilent 6890N) interfaced to a LECO time of flight mass spectrometer (MS-TOF) operating at unit resolution with electron ionization (EI) operating at 200°C . Separation on a 10 m × 0.18 mm I.D. DB5 J&W capillary column with a film thickness of 0.18 micron used the following temperature program: 40°C for 0.5 min, followed by 280°C for 2.5 min at 70°C/min. The carrier gas was ultra high purity helium at 1 ml/min. A 3 min injection time was used to introduce the sample into the GC. The MS was scanned at a rate of 10 scans/s over a mass range of 30–450 Da. Data acquisition and data processing were performed with the LECO ChromaTOF software system. We established that the SPME syringe effectively trapped fungal volatiles in preliminary tests. To evaluate background compounds, comparable analyses were conducted on vials containing only PDA, and the data were subtracted from the unknowns.

M. yucatanensis VOCs were identified by retention index (RI). Linear retention indices were calculated for all volatile constituents using a homologous series of *n*-alkanes with the parameters described above. Chemical identification was confirmed by comparison of mass spectra with the NIST database (National Institute of Standards and Technology).

Qualitative Analysis of the Organic Extracts Extracts were dissolved in CH_2Cl_2, and one μl of each extract was directly injected into the gas chromatograph equipped and operated as

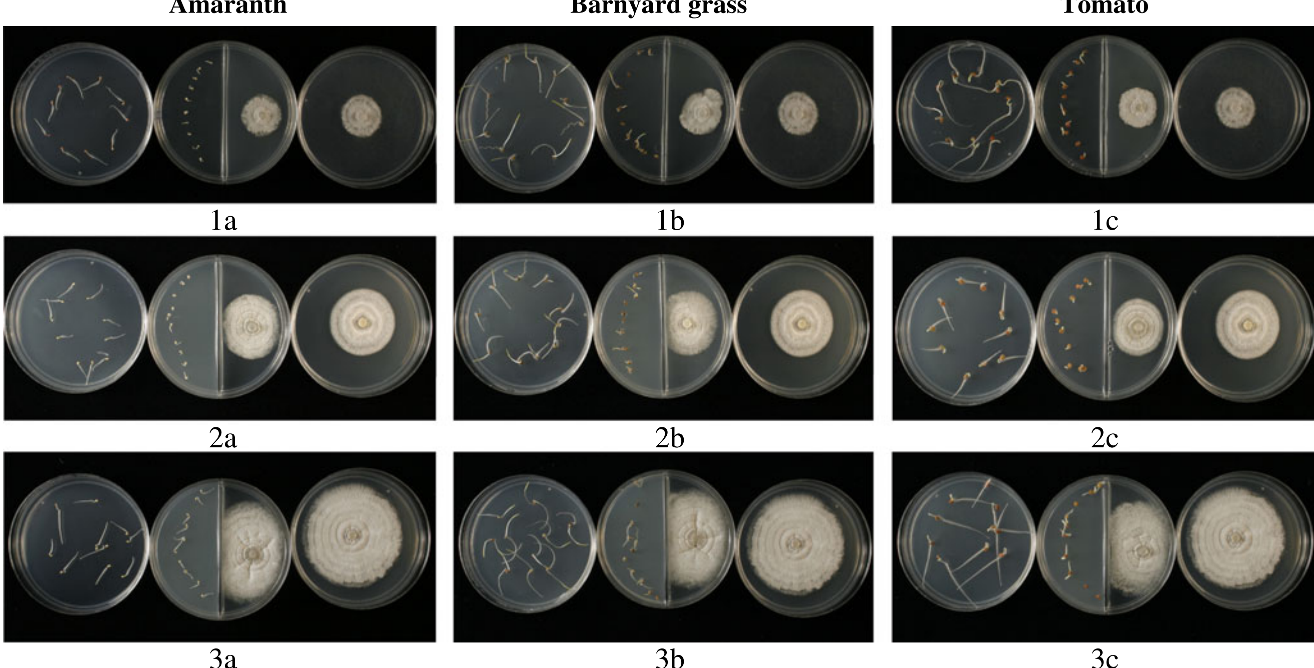

Fig. 2 Phytoinhibitory activity of VOCs from *Muscodor yucatanensis* grown for 5 (1), 10 (2), and 15 (3) days on the root length of amaranth (1a, 2a, and 3a), barnyard grass (1b, 2b, and 3b) and tomato (1c, 2c, and 3c)

Table 1 Percent recovery of the root length of amaranth, tomato and barnyard grass at 24 hr and 48 hr, after exposure to *Muscodor yucatanensis* VOCs

Muscodor yucatanensis days of growth	% of recovery[a]					
	Amaranth		Tomato		Barnyard grass	
	24 hr	48 hr	24 hr	48 hr	24 hr	48 hr
0	78.6	87.3	72.3	92.9	65.3	81.2

20	20.2	67.3	17.3	75.3	14.6	69.5
30	22.3	70.2	98.6	100	100	100
50	87.5	97.6	90.3	98.3	100	100

[a] Percent of root length recovery compared with the respective control

described above, but with the column temperature programmed as follows: 40°C for 1 min, followed by 280°C for 5 min at 20°C/min. The injector was set at 250°C with a 1:50 split ratio and solvent delay of 100 sec. The MS was scanned at a rate of 10 spectra/s over a mass range of 33–600 Da. Background was established with an extract of PDA.

Components were identified by comparison of their RI, determined relative to the retention times (RT) of a series of n-alkanes with linear interpolation on the HP-5 MS capillary column. They were also confirmed by comparison of their mass spectra using the NIST database. The relative amounts of individual components of the organic extracts were expressed as percentages of the peak area relative to the total peak area.

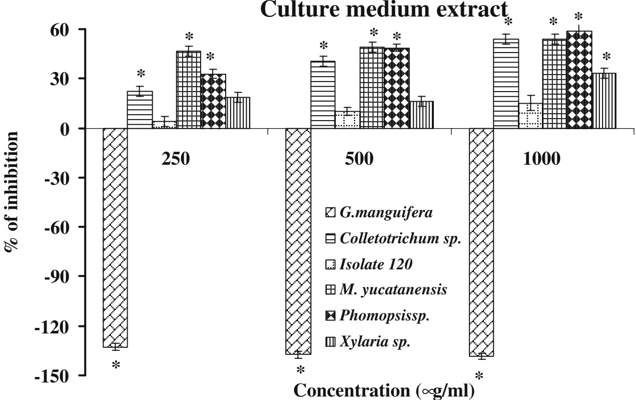
Statistical Analysis Bioassay data were analyzed by ANOVA and Tukey's tests (Mead et al., 2002) using Statistica 6.0. IC_{50} (50% inhibitory concentration) values for organic extracts were calculated by probit analysis (Zar, 2007) based on the average growth diameter of the mycelium and root length with SPSS 15.0 software. Data are represented as mean ± standard deviation (SD). A *P* value less than or equal to 0.05 was used to identify significant differences from controls.

Results

Effect of VOCs VOCs were lethal to the endophytes *Colletotrichum* sp., *Phomopsis* sp., and *Guignardia mangiferae*, and to the phytopathogens *Phythophthora capsici*, *P. parasitica, Rhizoctonia* sp., and *Alternaria solani. Fusarium oxysporum* remained alive and recovered 86 % of its growth after exposure to VOCs. The three endophytic fungi were not significantly inhibited by these VOCs: isolate 120 was inhibited only slightly (3.3 %), *M. yucatanensis* was not inhibited (0 %), and *Xylaria* was non-significantly stimulated (18 %).

The phytoinhibitory activity of VOCs increased proportionally from the first day of *Muscodor* growth, and was most inhibitory after 10 d of endophyte growth (Fig. 1). However, phytotoxic activity decreased significantly from 15 to 50 d. Figure 2 is a qualitative example of phytotoxic activity after 5, 10, and 15 d of *Muscodor* growth. Roots of the most affected plants darkened before dying.

The recovery of germinating seeds after exposure to VOCs is shown in Table 1. VOCs produced by mycelium that was 3–15-d-old were very inhibitory to the three test plants. However, the roots of seedlings exposed to VOCs



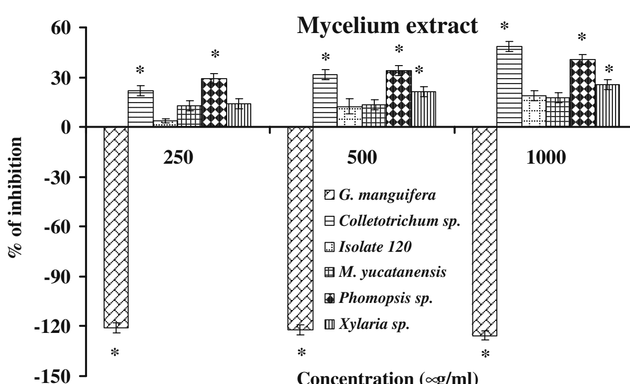


Fig. 3 Inhibitory activity of the culture medium and mycelium organic extracts from *Muscodor yucatanensis* against six endophytic fungi. Vertical bars represent SD, *N*=4; *$P<0.05$

from 1–3-d-old mycelia or 20–50-d-old mycelia recovered 1 to 2 d after exposure.

Effects of Organic Extracts Figure 3 shows significant dose-dependent fungal growth inhibition caused by both extracts of *M. yucatanensis* on almost all test endophytic fungi. *Colletotrichum* sp. and *Phomopsis* sp. were significantly inhibited by both extracts at all concentrations. The culture medium extract from *M. yucatanensis* caused a significant reduction in its own growth at all concentrations. In contrast, the mycelium extract did not significantly inhibit the growth of *M. yucatanensis*. *Xylaria* sp. was inhibited only by the highest concentration of either extract. IC_{50} values for the culture medium extract on the radial growth of *Colletotrichum* sp. was 794 μg/ml; for *M. yucatanensis,* 591 μg/ml ; and for *Phomopsis* sp., 631 μg/ml. IC_{50} for the mycelium extract for all endophytic fungi was >1,000 μg/ml.

G. mangifera was significantly stimulated by both extracts at all concentrations tested (Fig. 3). We estimated that the concentration required to stimulate a 50% increase in radial growth (SC_{50}) for *G. mangifera* was 94 μg/ml for the culture medium extract and 104 μg/ml for the mycelium extract.

The effects of the culture medium and the mycelium extracts on the radial growth of phytopathogenic microorganisms are shown in Fig. 4. In general, extracts were inhibitory only at 500 and 1,000 μg/ml, and the IC_{50} values for almost all phytopathogens were >1,000 μg/ml.

Both extracts inhibited root growth of the three test plants in a concentration-dependent manner (Fig. 5). The culture medium extract was more phytotoxic. The IC_{50} values of the culture medium extract were 112 μg/ml for tomato, 132 μg/ml for amaranth, and 435 μg/ml for barnyard grass. The crude culture medium extract was more active than Glyphosate which had IC_{50} values of 33 μg/ml for tomato, 234 μg/ml for amaranth, and 114 μg/ml for barnyard grass. All IC_{50} values for mycelium extract were >500 μg/ml.

Chemical Composition The main volatile secondary metabolites produced by a 10-d-old *M. yucatanensis* culture comprised 38 compounds that were identified by GC/MS (Table 2). The culture medium extract contained 32 compounds, while the mycelium extract consisted of 23 compounds (Tables 3, 4). In general, the compounds present in

both extracts are alcohols, esters, and ketones of saturated and unsaturated compounds, as well as benzene derivatives.

Discussion

Muscodor yucatanensis, like other *Muscodor* species (Ezra et al., 2004a,b; Strobel, 2006), produces a mixture of volatile compounds (VOCs) when cultured under *in vitro* conditions. These VOCs are selectively toxic to other endophytic and phytopathogenic fungi, and to plant roots. Strobel et al. (2001) found that VOCs of *M. albus* isolates had low inhibitory effects against fungi and bacteria. However, when these authors tested *M. albus* VOCs as a mixture they observed that they acted synergistically and killed a broad range of fungi and bacteria.

[b] Compounds presents in the culture medium and mycelium organic extract of *Muscodor yucatanensis*. Compounds found in the control PDB broth are not included in this table

M. yucatanensis VOCs emitted by 3–15-d-old fungus significantly inhibited germination and root elongation of the three test plants. Many damaged seeds and seedlings could recover from inhibition if they had been exposed to VOCs from fungi that had been cultured 1–3 d, or more than 15 d. The loss of toxicity in older cultures may be due to depletion of nutrients from the culture medium, which may result in a change in VOCs production. Ezra et al. (2004b) investigated the VOCs emission profile of *M. albus* from 14 to 19 d growth and found that concentration of volatiles increased continuously, reflecting the increased growth of the fungus. After day 19, *M. albus* VOCs production declined, probably because of the depletion of carbohydrates in PDA.

Our bioassays with VOCs showed that, in general, they were lethal to endophytic and phytopathogenic fungi. However, the VOCs were not inhibitory to *M. yucatanensis* or to the endophytes *Xylaria* sp. or isolate 120, or to the phytopathogen *F. oxysporum*. Only five compounds that have been reported previously in other *Muscodor* species were found in the *M. yucatanensis* VOCs: octane; 2-methyl butyl acetate; 2-pentyl furan; caryophyllene, and aromadendrene (Atmosukarto et al., 2005; Strobel, 2006; Strobel et al., 2007). We did not find naphthalene in the VOC mixture of *M. yucatanensis*, but we found some derivatives of naphthalene. These compounds were reported in *M. albus*, *M. roseus,* and *M. vitigenus* (Strobel et al., 2001; Daisy et al., 2002b; Ezra et

[a] Compounds presents in the culture medium and mycelium organic extract of *Muscodor yucatanensis*

al., 2004a). The VOCs bioactivity suggested that *M. yucatanensis* plays an important mutualistic role by augmenting host defensive responses against pathogens and/or competitors and also provides defense against some of its own competitors.

The present study is the first to identify the chemical constituents of organic extracts from the *in vitro* culture medium and mycelium of a species of *Muscodor* and to report their *in vitro* bioactivity on the growth of other endophytic and phytopathogenic fungi and plants.

M. yucatanensis was not inhibited by the mycelial organic extract. However, its growth was inhibited 50% or more by the culture medium extract, apparently an autotoxic response.

The highly significant growth stimulation of *G. mangifera* by three concentrations of mycelial extract tested was unexpected. Rodrigues et al. (2004) estimated that *Guignardia* isolates were among the endophytes most frequently isolated from tropical woody plant species of Brazil. These authors thought that *Guignardia* species does not regularly co-evolve with hosts but instead 'jumps' to unrelated hosts. This species is polyphagous and occurs on many different and often unrelated plant species. We do not know if *Guignardia* grows more rapidly *in vivo* when it infects host plant tissues already infected with *Muscodor*. Further studies that target this potential interaction could provide insight into fungal community dynamics and competitive and facilitative strategies.

The culture medium extract of *M. yucatanensis* was toxic to roots of test plants at higher concentrations than the mycelial extract. The culture medium had 23 compounds. Both extracts share 12 allelochemicals including benzene derivatives, phenolic compounds, cyclopentadienes, esters, lactones, alkanes, aldehydes, and carboxylic acids. It is possible that the most abundant compounds present in the culture medium extract are responsible for its strong allelochemical potential. This may provide a defense mechanism for *M. yucatanensis* against other endophyte competitors, as well as against some competitors and phytopathogens of *B. simaruba*. Given that both extracts of *M. yucatanensis* stimulate growth of *Guignardia mangifera,* there may be some metabolites that enhance symbiotic relationships with other endophytic fungi.

We have limited understanding of the mechanisms that regulate the integrated functions responsible for the success of endophyte-plant relationships. The ecological functions of the thousands of endophytic fungi associated with tropical plants are currently understudied. Dry tropical forests in Yucatan

Peninsula, and natural protected areas such as the Ecological Reserve of El Eden, Quintana Roo in Mexico, are sources of biological resources that consist of diverse macro and micro-organisms. Further studies of endophytic relationships in plant communities will contribute to an increased knowledge of the biodiversity of microorganisms associated with plants, the allelochemicals they produce that gives them an aggregate value, and the tangled web of biotic and abiotic interactions they exhibit.

Acknowledgements This work was supported by grants IN230107 DGAPA-UNAM and CONACyT 81017. We thank Dr. Arturo Gómez-Pompa for support to work in El Eden Ecological Reserve, and to Biol. Juan Castillo for help in the field work. We also thank to Dra. Olga Gómez from Instituto de Fitosanidad, Colegio de Postgraduados, Montecillo, Estado de México for the donation of plant-pathogenic microorganisms used in the bioassays; and Biol. Carmen Loyola for valuable help with photos of results on phytoinhibitory activity of VOCs from *Muscodor yucatanensis*, and María Teresa Caudillo from Instituto de Ecología, UNAM for support with the bioassays.

Zar, J. H. 2007. Biostatistical Analysis. 5th ed. Prentice Hall, Upper Saddle River, New Jersey.

antennal scape and foreleg femur than do females. After sexing, males and females were placed in separate plastic boxes (7.5×8.5 cm) and fed green maté branches. Insects were maintained at 25±2°C at 60±5% RH, under a 12:12 hrL/D photoperiod. The mating history of field-captured beetles was unknown.

Pheromone Collection and Analysis Groups of either 4 males or 4 females were placed in an all-glass aeration chamber, and the released volatiles were trapped on Super Q columns (200 mg; Alltech, Deerfield, IL, USA) as previously reported (Zarbin et al., 2003). Samples were collected continuously over 15 day by using a humidified and charcoal-filtered airstream (1 $l.min^{-1}$). Volatiles from each aeration were eluted from the Super Q columns with distilled hexane, with the adsorbent traps changed after 10 collections. Extracts were concentrated to 400 µl (one insect equivalent per 100 µl) using argon (Zarbin et al., 1999; Zarbin, 2001).

In order to investigate the effect of host plant on release of pheromone, beetle volatiles were collected as described above for 24 h over 3 day, either in the presence or absence of a small branch of host plant (N=3 per treatment). The same procedure was performed to determine the diel rhythm of volatile release from males during the photophase and scotophase and, subsequently, every 2 hr of the photophase (over 3 day; N=3 males per treatment). Plant volatiles were also collected from 67 g of green maté branches. Branches were placed in all-glass aeration chambers, and volatiles were collected over 24 hr. After elution from traps, the collections were concentrated (10 g of green maté branches/100 µl) under argon (Zarbin et al., 1999; Zarbin, 2001). Data were analyzed by ANOVA, followed by a Tukey *post-hoc* test using BioEstat 3.0 software (Ayres et al., 2003).

Extracts were analyzed by gas chromatography-mass spectrometry (GC–MS) using a Shimadzu gas chromatograph (model 17A) coupled to a Shimadzu QP5050A electron ionization mass detector. The GC was operated in the splitless mode, and was equipped with a DB-5 (30 m×0.25 m×0.25 µm) or a DB-Wax (30 m×0.25 m×0.25 µm) capillary column (both Agilent Technologies, Santa Clara, CA, USA). The column oven was maintained at 50°C for 3 min, and then increased to 250°C at 7°C.min^{-1} to 250°C. The concentration of the major chemical component from the sex-specific volatiles was determined by using an external standard curve (1, 10, 100, 500, 1,000, 1,500, and 2,000 ppm) based on tridecane.

Synthesis ^{1}H- and ^{13}C-NMR spectra were recorded using a Bruker ARX-200 spectrometer (200 and 50 MHz, respectively) in a $CDCl_3$ solution. Chemical shifts are expressed in ppm relative to $CDCl_3$ (7.27 and 77.23 ppm for ^{1}H and ^{13}C NMR, respectively). The infrared (IR) spectra were measured as films using a Bomem B100 spectrometer. Crude products were purified by flash or vacuum flash chromatography on silica gel (230–400 mesh). (*E*)-6,10-Dimethyl-5,9-undecadien-2-one (geranylacetone) **(A)** is commercially available (Fluka® 99.5% *E* isomer; Sigma-Aldrich, Milwaukee, WI, USA, 60/40 *E*/*Z* isomers). (*E*)-6,10-Dimethyl-5,9-undecadien-2-ol **(B)** and (*E*)-6,10-dimethyl-5,9-undecadien-2-yl acetate **(C)** were synthesized as described in Fig. 1.

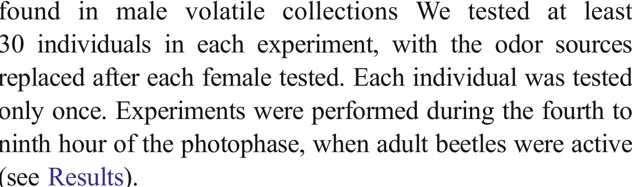
Synthesis of (E)-6,10-dimethyl-5,9-undecadien-2-ol (B) A dry THF solution (5 ml) of ketone **A** (Fluka®, 99.5%) (1 g, 5.1 mmol) was added slowly to a suspension of $LiAlH_4$ (0.290 g, 7.7 mmol) in THF (15 ml) at 0°C. The mixture was stirred for 5 hr at room temperature, then cooled to 0°C, hydrolyzed with $NaOH_{(aq)}$ (15%; 5 ml), and extracted several times with diethyl ether. The combined ether extracts were washed with water, dried over Na_2SO_4, and concentrated. The crude product was purified by flash chromatography (hexane/ethyl acetate, 8/2), yielding alcohol **B** (0.909 g, 90% yield). ^{1}H NMR (200 MHz, $CDCl_3$): δ 1.19 (d, 3H, J=6.16 Hz), 1.44–1.52 (m, 3H), 1.60 (s, 3H), 1.62 (s, 3H), 1.68 (s, 1H), 1.92–2.14 (m, 6H), 3.73–3.87 (m, 1H), 5.02–5.21 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 16.0, 17.7, 23.5, 24.4, 25.7, 26.6, 39.2, 39.7, 68.0, 123.9, 124.3, 131.4, 135.7. IR (ν Max, cm^{-1}): 824, 1082, 1127, 1377, 1447, 2853, 2915, 2966, 3349.

Synthesis of (E)-6,10-dimethyl-5,9-undecadien-2-yl acetate (C) An excess of acetic anhydride (0.5 ml, 5 mmol) and pyridine (0.5 ml) was added to alcohol **B** (0.800 g, 4.0 mmol) in dichloromethane (15 ml). The solution was stirred for 12 hr, diluted with dichloromethane (20 ml), and then washed with $HCl_{(aq)}$ (10%). The organic layer was

Fig. 1 Racemic synthesis of (*E*)-6,10-dimethyl-5,9-undecadien-2-ol (**b**) and (*E*)-6,10-dimethyl-5,9-undecadien-2-yl acetate (**c**) from (*E*)-6,10-dimethyl-5,9-undecadien-2-one (**a**)

washed with saturated $NaHCO_3$ solution before the dichloromethane solution was separated, dried over Na_2SO_4, and concentrated. After flash chromatography (hexane/ethyl acetate, 9/1), the acetate **C** was obtained at 85% yield (0.784 g). ^{1}H NMR (200 MHz, $CDCl_3$): δ 1.22 (d, 3H, J=6.26 Hz), 1.50–1.65 (m, 8H), 1.68 (s, 3H), 1.94–2.10 (m, 9H), 4.79–4.98 (m, 1H), 5.03–5.17 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 15.9, 17.7, 20.0, 21.4, 23.9, 25.7, 26.7, 36.0, 39.7, 70.7, 123.4, 124.3, 131.4, 135.7, 170.8. IR (ν Max, cm^{-1}): 1018, 1058, 1127, 1240, 1371, 1439, 1736, 2853, 2921, 2971.

Laboratory Bioassay of Synthetic Pheromone Female *H. betulinus* responses to synthetic pheromone racemic mixtures were tested in a binary choice Y-tube olfactometer, using humidified, charcoal-filtered air at 4 $l.min^{-1}$. The olfactometer consisted of a Y-shaped glass tube (4×40 cm) with two 20-cm arms. Hydrochloric acid and ammonium hydroxide were mixed to confirm the plume distribution of odor sources throughout the system (Baker and Linn, 1984). Odor sources were placed at the base of one arm of the olfactometer, and consisted of a 2×2 cm piece of filter paper loaded with synthetic pheromone, plant volatiles, or hexane (control). A single female beetle was placed at the base of the main olfactometer tube, and its behavior was observed for 20 min. A female that walked upwind and made contact, within 20 min., with a filter paper containing either the treatment or control odor source was recorded as a positive or negative response, respectively. Females that did not contact either the treatment or control odor source were excluded from the statistical analysis. The Y-tube was cleaned with alcohol and left to dry for 5 min after testing 4 females. The positions of the olfactometer arms were reversed upon changing the odor sources. A preliminary study showed that there was no difference in the responses of males or females in the olfactometer when both of the arms were blank, indicating a lack of positional effect of the experimental setup. Nine experiments testing female responses were performed: 1) to 10 μl of the plant volatiles extract; 2) to 5 μg (5 μl of a solution of 1 μg/μl hexane) of synthetic major pheromone component; 3) to 8 μg of synthetic major component; 4) to 5 μg of synthetic major component plus 10 μl of the plant volatiles collection; 5) to 8 μg of synthetic major component plus 10 μl of the plant volatiles collection; 6) to ternary mixture **I** (5 μg **C**: 0.43 μg **A**: 0.038 μg **B**); 7 to ternary mixture **II** (8 μg **C**: 0.69 μg **A**: 0.06 μg **B**); 8) to ternary mixture **I** plus 10 μl of the plant volatiles collection; and 9) to ternary mixture **II** plus 10 μl of the plant volatiles collection. The ternary mixture ratio [91.4:7.9:0.70 of racemic (E)-6,10-dimethyl-5,9-undecadien-2-yl acetate, (E)-6,10-dimethyl-5,9-undecadien-2-one and (E)-6,10-dimethyl-5,9-undecadien-2-ol, respectively] that was used in the experiment was similar to that



found in male volatile collections We tested at least 30 individuals in each experiment, with the odor sources replaced after each female tested. Each individual was tested only once. Experiments were performed during the fourth to ninth hour of the photophase, when adult beetles were active (see Results).

Data were analyzed by the Chi-squared test using BioEstat 3.0 software (Ayres et al., 2003).

Results

The chromatographic profile of volatiles from male and female *H. betulinus* showed three male-specific compounds, **A**, **B**, and **C**, with the following retention times (Rts) and Kovat's Indices (KIs) on the DB-5 column: **A**: Rt=16.65 min., KI=1,448; **B**: Rt=16.72 min, KI=1,454; **C**: Rt=18.84 min, KI=1,573. The ratio between these components was calculated as 7.9:0.7:91.4, respectively, based on the area of the GC peaks (Fig. 2). The mass spectrum of compound **A** was simple, with a base peak at *m/z* 43, a fragment at *m/z* 69, and a molecular ion of 194 Da (Fig. 3a). When this spectrum was compared to the NIST library, it was evident that the compound might be (E)-6,10-dimethyl-5,9-undecadien-2-one (geranylacetone) or its 5*Z* isomer (nerylacetone). Compound (**A**) was identified as geranylacetone by co-injection of the crude extract with geranyl- and nerylacetone standards on the two GC columns. Identification was based on the similarity of retention times and fragmentation pattern.

Compound **B** had a similar retention time as component **A**. The mass spectrum (Fig. 3b) showed a molecular ion of *m/z* 196, a base peak at *m/z* 41, and other fragments at *m/z* 69 (90%) and 153 (34%), suggesting that **B** may be related to geranylacetone with hydrogenation at the carbon 5, or the corresponding alcohol, geranylacetol. Reduction of compound **A** with $LiAlH_4$ (Zarbin et al., 1998) yielded an alcohol with the same retention time and mass spectrum as compound **B**, confirming its chemical structure as (E)-6,10-dimethyl-5,9-undecadien-2-ol. In a previous study, this alcohol was identified as the primary component of the male-produced sex pheromone of the longhorn beetles, *Tetropium fuscum* and *Tetropium cinnamopterum*, members of the Spondylidinae subfamily, and was named fuscumol (Silk et al., 2007).

The mass spectrum of component **C** showed a base peak at *m/z* 109, fragments at *m/z* 43 (60%), *m/z* 69 (51%), and had a molecular weight of 238 Da (Fig. 3c). The molecular weight of component **C** was 42 Da greater than component **B**, and the retention time more than 2 min longer. These differences, in addition to the appearance of a fragment at *m/z* 43, suggested the presence of an acetyl group. This was

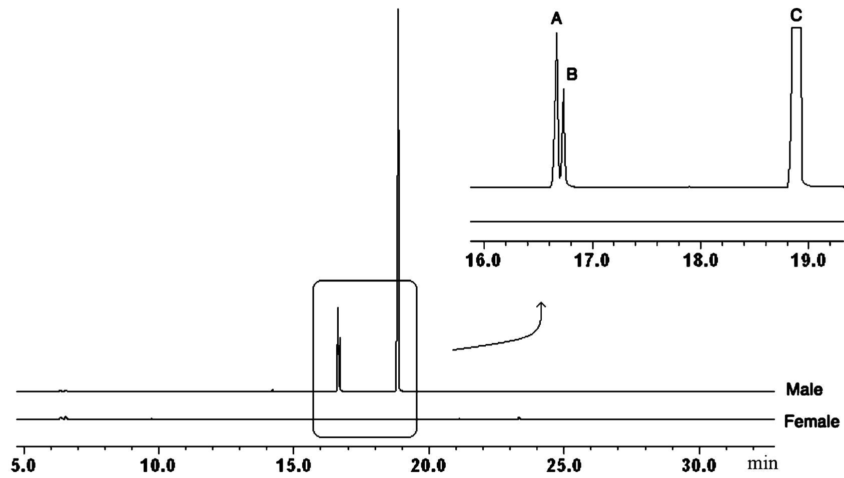


Fig. 2 Gas chromatographic analyses of volatiles obtained from male and female *Hedypathes betulinus*. The three male-specific compounds are (*E*)-6,10-dimethyl-5,9-undecadien-2-one (**a**), (*E*)-6,10-dimethyl-5,9-undecadien-2-ol (**b**), and (*E*)-6,10-dimethyl-5,9-undecadien-2-yl acetate (**c**)

also supported by the appearance of a fragment at *m/z* 178, resulting from the loss of acetic acid (M^+ - 60). Acetylation of alcohol **B** by acetic anhydride and pyridine (Leal et al., 1999) resulted in an ester with a fragmentation pattern and retention time that perfectly matched that of compound **C**. Thus, the major compound was identified as (*E*)-6,10-dimethyl-5,9-undecadien-2-yl acetate (fuscumol acetate).

The production of (*E*)-6,10-dimethyl-5,9-undecadien-2-yl acetate **C** was dependent on the presence of host plant. Beetles that fed on green maté released more total volatiles (344.2±86.5 μg/insect/day) than beetles that did not feed on green maté (0.53±0.35 μg/insect/day) ($F_{1,4}$=157.02, P< 0.05) (Fig. 4a). The release of pheromone components occurred during the photophase rather than the scotophase ($F_{1,4}$=14.93, P<0.05) (Fig. 4b), with maximum release occurring between 4 and 6 hr after the onset of the photophase (Fig. 4c). Six hours after the onset of the photophase, the amount of pheromone released decreased ($F_{5,12}$=94.08, P<0.001), from that of peak release, to an amount similar to that at the start of the photophase (Fig. 4c).

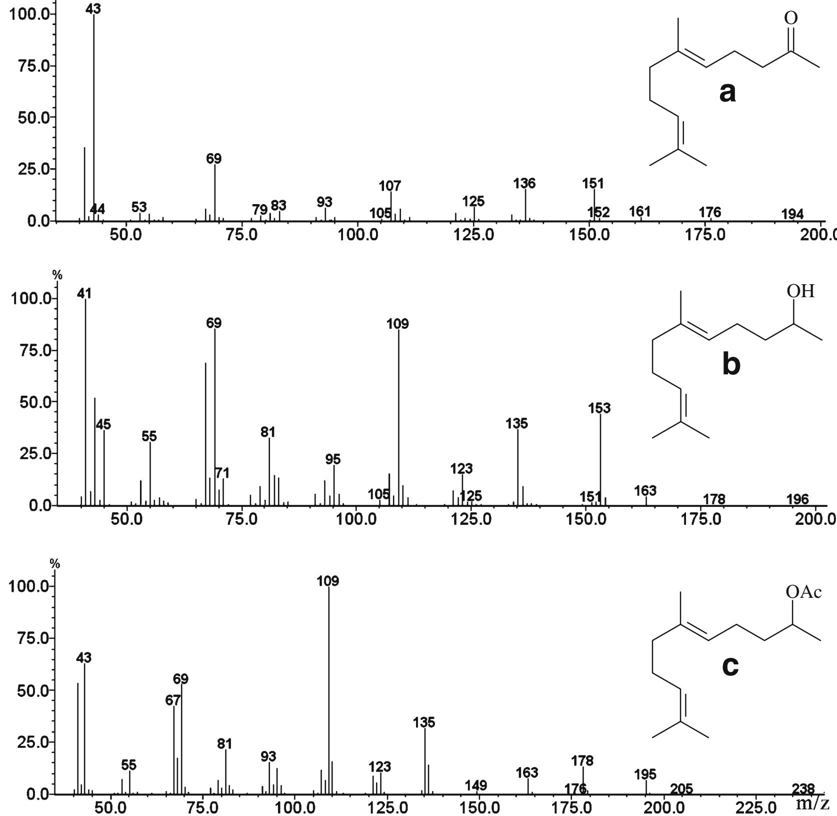

Fig. 3 Mass spectra of compounds **a** [(*E*)-6,10-dimethyl-5,9-undecadien-2-one], **b** [(*E*)-6,10-dimethyl-5,9-undecadien-2-ol], and **c** [(*E*)-6,10-dimethyl-5,9-undecadien-2-yl acetate]

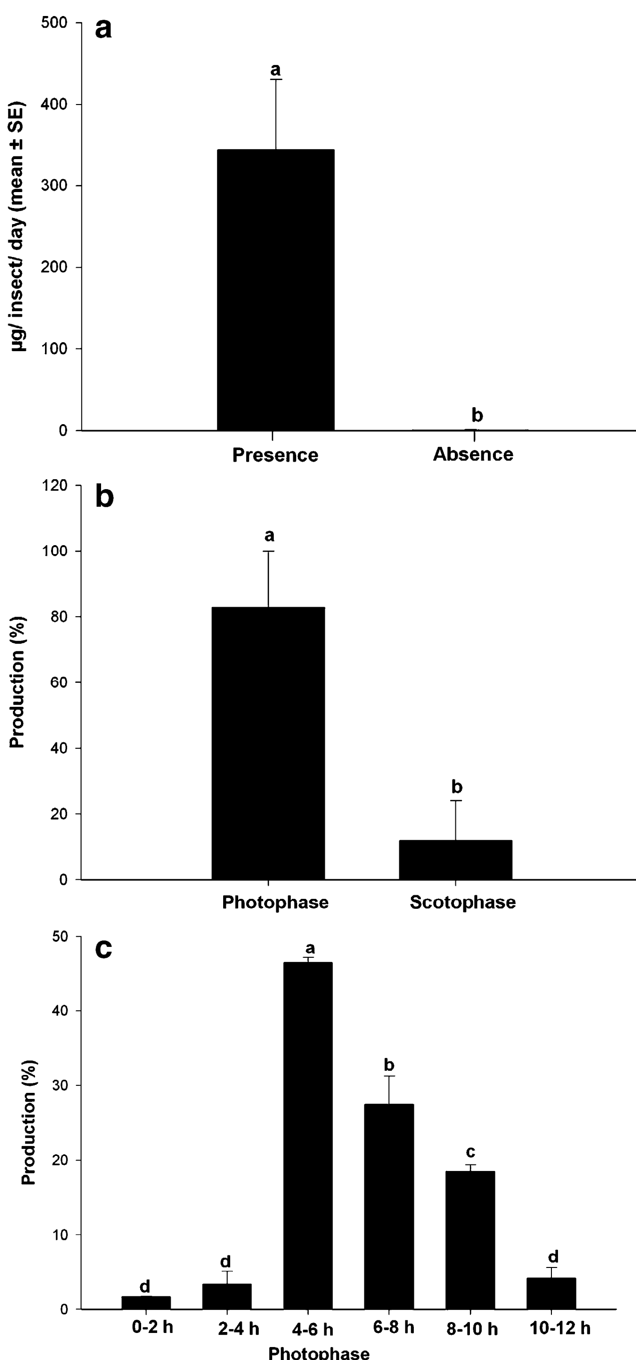

Fig. 4 Comparison of the amounts of the major component **C** [(*E*)-6,10-dimethyl-5,9-undecadien-2-yl acetate] collected from aeration of *Hedypathes betulinus* males: **a** in the presence and absence of green maté branches; **b** between the photophase and scotophase; **c** among different times of the 12 hr of the photophase. Mean values followed by the same letter are not significantly different (ANOVA followed by a Tukey post-hoc test; *N*=3)

Female *H. betulinus* responses to the various treatments are shown in Tables 1 and 2. The major component alone at 5 µg (χ^2=0.034; *df*=1; *P*>0.05) and 8 µg (χ^2=0.143; *df*=1; *P*>0.05), and the ternary mixture **I** alone (χ^2=0.29; *df*=1; *P*>0.05) were not attractive to females (Table 1). However,

ternary mixture **II** was attractive when compared with the control (χ^2=5.452; *df*=1; *P*< 0.05).

Although plant volatiles alone were not attractive to females (X^2=0.133; *df*=1; *P*= 0.715), addition of these volatiles to the various pheromone component mixtures increased attraction. A greater number of females were attracted to the combination of host plant volatiles and component **C** at both doses tested, 5 µg (χ^2=7.53; *df*=1; *P*= 0.006) and 8 µg (χ^2=11.64; *df*=1; *P*< 0.001). Similarly, both doses of ternary mixture **I** (χ^2=5.828; *df*=1; *P*=0.015) and **II** (χ^2=9.783; *df*=1; *P*=0.001), as well as major component **C,** were attractive when combined with host-plant volatiles (Table 2).

Discussion

We identified the male-produced pheromone of *H. betulinus* as a mixture of three compounds: (*E*)-6,10-dimethyl-5,9-undecadien-2-yl acetate (major), (*E*)-6,10-dimethyl-5,9-undecadien-2-one (geranylacetone), and (*E*)-6,10-dimethyl-5,9-undecadien-2-ol. Within the sub-family Lamiinae, a male-produced volatile pheromone that attracts both sexes (i.e., an aggregation pheromone) has been identified previously for *Anoplophora glabripennis* (Zhang et al., 2002; Nehme et al., 2009). In field tests, addition of host-plant volatiles to this aggregation pheromone increased attraction of *A. glabripennis*, particularly for virgin females (Nehme et al., 2010). Evidence for a male-produced contact sex pheromone has been reported for *Steirastoma breve* (Liendo et al., 2005) and *Monochamus galloprovincialis* (Ibeas et al., 2008), while *A. glabripennis* females produce a contact recognition pheromone (Zhang et al., 2003). Our bioassay data indicated that the male-produced pheromone of *H. betulinus* is a sex pheromone, as conspecific males were not attracted to the pheromone. Thus, this is probably the first volatile sex pheromone identified from this subfamily. However, this needs to be confirmed in rigorous field tests by testing different ratios and concentrations of the compounds.

The male-produced compounds we identified in *H. betulinus* are different from male-produced sex or aggregation pheromones of other cerambycid species in the subfamily Cerambycinae (Allison et al., 2004; reviewed by Ray et al., 2006; Hanks et al., 2007; Lacey et al., 2008). The pheromones of most of these species typically are compounds with short chain (6–10 carbon) α-hydroxyl ketones or (α, β)-diols (Hanks et al., 2007; Lacey et al., 2008), although two exceptions are the male-produced aggregation pheromone of *Phymatodes lecontei* [(*R*)-2-methylbutan-1-ol] (Hanks et al., 2007), and a component of the sex pheromone of *Hylotrupes bajulus* (1-butanol) (Reddy et al., 2005). The pheromone components of *H. betulinus* also are different

determining that none of these compounds was attractive individually. Volatiles collected from male *Rosalia funebris* contained a major male-specific compound, (*Z*)-3-decenyl (*E*)-2-hexenoate, and several minor compounds (Ray et al., 2009). Despite the attraction, in the field, of both sexes of *R. funebris* to lures baited with synthetic (*Z*)-3-decenyl (*E*)-2-hexenoate, the authors suggested that the minor components may form part of the natural pheromone, and that traps baited with a more complete blend could attract more beetles.

Our results demonstrated that addition of host-plant volatiles to the pheromone enhanced attraction to females (Table 2). Host plant volatiles often enhance an insect's response to sex pheromones, and this effect may result in true synergism; a response to the pheromone and plant volatile mixture that is greater than the sum of responses to the individual components (Reddy and Guerrero, 2004). Increased pheromone attraction due to the presence of host odors occurs in several insect groups, such as moths (Dickens et al., 1990, 1993; Reddy and Guerrero, 2000; Deng et al., 2004; Yang et al., 2004), beetles (Phillips et al., 1984; Byers et al., 1990; Nakamuta et al., 1997; Zhang and Schlyter, 2003), and flies (Landolt et al., 1992). In the Cerambycidae, host odor and pheromone synergism has been documented in *Anaglyptus subfasciatus* (Nakamuta et al., 1997), *Tetropium fuscum* and *T. cinnamopterum* (Silk et al., 2007), and *A. glabripennis* (Nehme et al., 2010). Only in *A. glabripennis* are adults attracted to plant volatiles alone, and in that case, this effect is more apparent for males than females (Nehme et al., 2010).

Studies of numerous cerambycid species suggest that conspecific location in these species is mediated first by attraction to host-plant volatiles and subsequently to pheromones (Hanks, 1999; Allison et al., 2004). Ginzel and Hanks (2005) hypothesized that cerambycine mate location and recognition results from three sequential behaviors: (1) both sexes are independently attracted to larval hosts by plant volatiles; (2) males attract females at short-range with pheromones; and (3) males recognize females by contact pheromones. In our study, female *H. betulinus* were not attracted to host-plant volatiles alone, indicating that mate location involves only stages 2 and 3, consistent with previous observations of the mating behavior of this species (Fonseca and Zarbin, 2009).

In summary, we have identified the sex pheromone of *H. betulinus* and described the temporal pattern of pheromone release. Future studies will determine the stereochemistry of components **B** and **C**, the biosynthesis and site of production of the components, as well as the activity of the pheromone and host-plant volatiles in the field.

Acknowledgments We thank VIER farm for providing access to their fields for insect collection. This research was supported by the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq, Brazil) and Instituto Nacional de Ciências e Tecnologia de Semioquímicos na Agricultura. We also thank Dr. Jeffrey R. Aldrich (USDA-ARS, Beltsville, MD/USA) for revising the draft version of the manuscript.

probably through the presence of a female-specific pheromone component. Upon contact or near contact, the male either retreats or mounts dorsally. He is especially likely to retreat if she has already mated (King et al., 2005); and retreats appear to be related to females that release an antiaphrodisiac when a male approaches, rather than from physical aggression from the female (King and Dickenson, 2008a). If a male mounts the female, he then continues to court her by vibrating his entire body on her. Fanning, mounting, and vibrating by a male do not require any active solicitation by the female, i.e., even dead females elicit such behaviors.

Pheromone components involved in mating behavior in other pteromalid species include pheromones used in attracting a mate and eliciting male courtship behaviors (Ruther et al., 2000). Among insects generally, female-produced pheromones are more common and better known (Keeling et al., 2004); however, in the parasitoid wasp *Nasonia vitripennis* Walker (Hymenoptera: Pteromalidae), some male pheromones are known to affect a female's response to the male (e.g., Ruther et al., 2007). It is not uncommon for male and female parasitoids to have many of the same pheromones but in different quantities (Keeling et al., 2004; Ruther and Steiner, 2008), and this is true of *N. vitripennis* (Steiner et al., 2006). Prior to this study, no pheromone components of *S. endius* were known for either males or females. We report the identification of a pheromone component in *S. endius* that is very different from that reported for other pteromalids.

Methods and Materials

Spalangia endius *Colony* The *S. endius* were from a colony established from wasps collected in 1996 from Zephyr Hills, FL, USA and maintained by using pupae of a natural host, the house fly, *Musca domestica* L. (Diptera: Muscidae). Hosts were produced following techniques described in King (1988), but we used wood shavings in place of vermiculite as the rearing substrate. Parasitized hosts were isolated individually in glass test tubes prior to emergence of the wasp in order to obtain female virgin wasps. Virgin males were obtained from separate colonies parasitized by virgin females.

Semiochemical extraction and gas chromatography-mass spectrometry analyses Gas chromatography-mass spectrometry (GC-MS) was used to compare semiochemical extracts from males and females to determine if sex-specific compounds were detectable. The semiochemical extracts from males and females were obtained by two different methods, solvent extraction of whole insects and solid phase micro extraction (SPME). A third method (Super-Q trapping of volatiles) was used to prepare extracts from females alone. The purpose of solvent extractions was to remove all soluble compounds from the wasp's exoskeleton, whereas SPME was used specifically to collect emitted volatiles. For each solvent extraction, 10 wasps were killed by freezing at −17°C, transferred to a microtube, and extracted in dichloromethane (30 min, 60 µl). Extract volume was reduced to 20 µl under a gentle stream of nitrogen. For SPME, collections were made by exposing the fiber [65 µm polydimethylsiloxane/divinylbenzene blend (Supelco Inc., Bellefonte, PA, USA)] for 20 min to the static headspace of a 1.5 ml vial with a Teflon-lined septum (National Scientific, Rockwood, TX, USA) containing 10 insects.

Headspace volatiles were collected from females by using Super-Q porous polymer traps (Alltech Associates, Deerfield, IL, USA). This technique permitted a larger quantity of volatiles to be collected than the SPME method. For the trap collection of the volatiles, a Magnetek Universal Ser. 41ZF vacuum pump was used to pull the headspace of a 125 ml side-arm flask through 5-mm-diam. glass tubing that contained a 5 to 8-mm plug of Super-Q porous polymer. The Super-Q was held in place by a fine stainless steel screen (fused into trap glass wall) and glass wool. A variable number of 0-d-old females were placed in the flask. Females were replaced with new females every 2 d. Volatiles from a total of 200 females were collected over a 2-mo period. The flask opening was plugged with a cork with a hole, which was filled with glass wool to allow the free inflow of air. To recover the collected volatiles, the Super-Q traps were rinsed weekly with dichloromethane (2 ml). This was concentrated to 400 µl or 2 µl/ female equivalent. No food or water was fed to the insects during the collection period.

All three types of extracts were analyzed by a Hewlett Packard 5973 mass selective detector, interfaced with a Hewlett Packard 6890 GC (Agilent Technologies Inc., Santa Clara, CA, USA). A split/splitless inlet was used in splitless mode with either a 15-m DB-1 (0.25 mm i.d., 0.1 µm film thickness) or a 30-m DB-5MS (0.25 mm i.d., 1.0 µm film thickness) capillary column (J & W, Agilent Technologies Inc., Santa Clara, CA, USA). Carrier gas was He set at constant pressure (6 psi), and injector temperature was set at 280°C. The oven temperature started at 50°C for 1 min and increased to 280°C at a rate of 10°C/min.

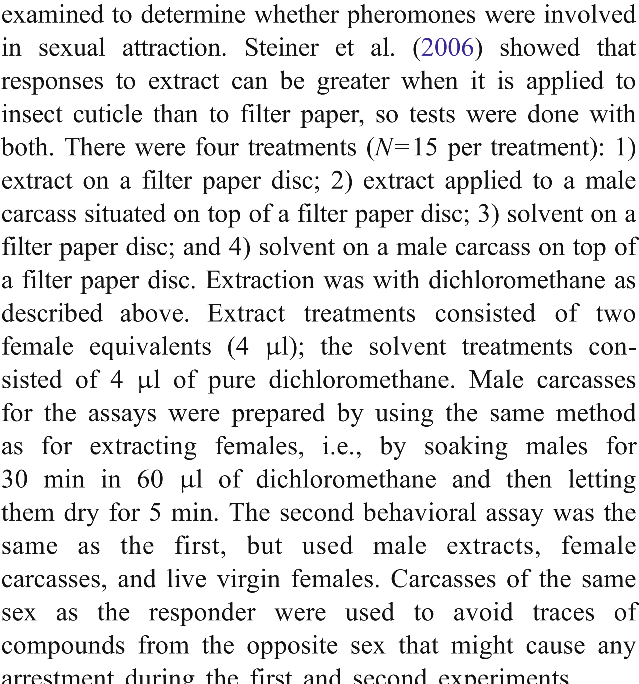
GC-Electroantennographic Detection (GC-EAD) analysis Male antennal responses to female-specific compounds from the SPME and Super-Q extracts were examined to determine how sensitively the female-specific compounds were detected. GC-EAD connections were made by inserting the base of an excised male antenna into a saline-filled Ag/AgCl glass pipet grounding electrode.

The suspended male antenna was maneuvered by a micromanipulator, into a stream of purified, humidified air (20 ml/sec) that emerged from a 20-cm-long L-shaped glass tube (7 mm i.d.) that ended 1 cm from the antenna. A second glass pipet Ag/AgCl-recording probe (Syntech, Hilversum, The Netherlands), fitted onto a second micromanipulator, was placed in contact with the distal cut end of the antenna. Stimuli were introduced into the air stream from the GC effluent (split between FID and EAD, GC-EAD interface temperature set at 280°C) through a hole in the glass tube positioned 10 cm from the antenna. The GC-EAD responses were amplified (500×) with an AC/ DC UN-6 amplifier (Syntech). Acquisition and analysis of the responses were performed by a computer equipped with an analog to digital conversion board (IDAC, Syntech) running GC-EAD software (Syntech). The GC was a Hewlett Packard 6890 GC (Agilent Technologies Inc.). A split/splitless inlet was used in splitless mode with 15-m DB-1 (0.25 mm i.d., 0.1 μm film thickness) capillary column (J & W, Agilent Technologies Inc.). Carrier gas was He set at a flow rate of 24 cm/sec, and injector temperature was set at 250°C. The oven temperature started at 50°C for 1 min and increased to 150°C at a rate of 10°C/min, followed by 30°C/min to 280°C.

Chemicals Methyl 4-methylsalicylate was purchased from Frinton (Vineland, NJ, USA). Methyl 3- and methyl 5-methylsalicylate were purchased from Aldrich (St. Louis, MO, USA). Methyl 6-methylsalicylate was synthesized from ethyl 6-methylsalicylate (APIN, Abingdon, Oxon) according to Castracani et al. (2003), except that the reaction ran for 5 hr. Reaction completion was checked by GC-MS.

Bioassays All behavioral assays were conducted in a small blue plastic dish (1.5 cm diam, 1 cm high) filled three quarters with dry sand and covered by a glass cover slip. A wasp was tapped from its glass tube into the dish. The dish contained a single treatment or control on filter paper (6 mm diam. Whatman No. 1), which was centered on top of the sand. Arrestment time of a test wasp was recorded for 5 min (adapted from Steiner et al., 2006). Arrestment time was the time that the wasp spent with a body part touching the filter paper (or carcass in the first experiment). No wasp was tested more than once, and all were between 0 and 1-d-old. Prior to data analyses, arrestment times were log transformed to improve normality and homoscedasticity. Log-transformed arrestment times were compared among treatments by using analyses of variance (ANOVA) or independent *t*-tests.

Response to extracts of the opposite sex In the first behavioral assay, male responses to female extract were



examined to determine whether pheromones were involved in sexual attraction. Steiner et al. (2006) showed that responses to extract can be greater when it is applied to insect cuticle than to filter paper, so tests were done with both. There were four treatments (N=15 per treatment): 1) extract on a filter paper disc; 2) extract applied to a male carcass situated on top of a filter paper disc; 3) solvent on a filter paper disc; and 4) solvent on a male carcass on top of a filter paper disc. Extraction was with dichloromethane as described above. Extract treatments consisted of two female equivalents (4 μl); the solvent treatments consisted of 4 μl of pure dichloromethane. Male carcasses for the assays were prepared by using the same method as for extracting females, i.e., by soaking males for 30 min in 60 μl of dichloromethane and then letting them dry for 5 min. The second behavioral assay was the same as the first, but used male extracts, female carcasses, and live virgin females. Carcasses of the same sex as the responder were used to avoid traces of compounds from the opposite sex that might cause any arrestment during the first and second experiments.

Responses to fractionated female-specific compounds The third bioassay experiment compared male behavioral responses to fractions containing one of the female-specific compounds or their combination. First, a female extract was obtained by soaking 150 females in 900 μl of dichloromethane for 30 min. Ninety female equivalents of the extract were blown dry under nitrogen and resuspended in 200 μl hexane prior to column chromatography on silica gel. The column was made with 5 cm of silica gel (70–230 mesh) in a Pasteur pipette with glass wool blocking the tapered part of the pipette. The female extract was loaded on the silica column, and three fractions were collected. Elution solvents were hexane, 1:1 diethyl ether: hexane, and diethyl ether (2 ml of each, in that order). The fractions were analyzed by GC-MS. One female-specific compound (previously identified as **A**) was present in the 1:1 diethyl ether/hexane fraction, and the second compound (previously identified as **B**) was found in the diethyl ether fraction. These two fractions were blown dry under nitrogen and resuspended in dichloromethane prior to behavioral analysis. The experiment compared the male behavioral responses to four treatments: 1:1 diethyl ether:hexane fraction (**A**), diethyl ether fraction (**B**), 1:1 blend of the two fractions (**A**+**B**), and solvent (dichloromethane) control (N=15 males each). Each treatment consisted of two female equivalents (4 μl) applied to a 6 mm piece of filter paper. The solvent control was applied in the same volume.

Response to methyl methylsalicylate isomers The fourth behavioral assay compared the male behavioral responses to authentic standards of four methyl methylsalicylate positional

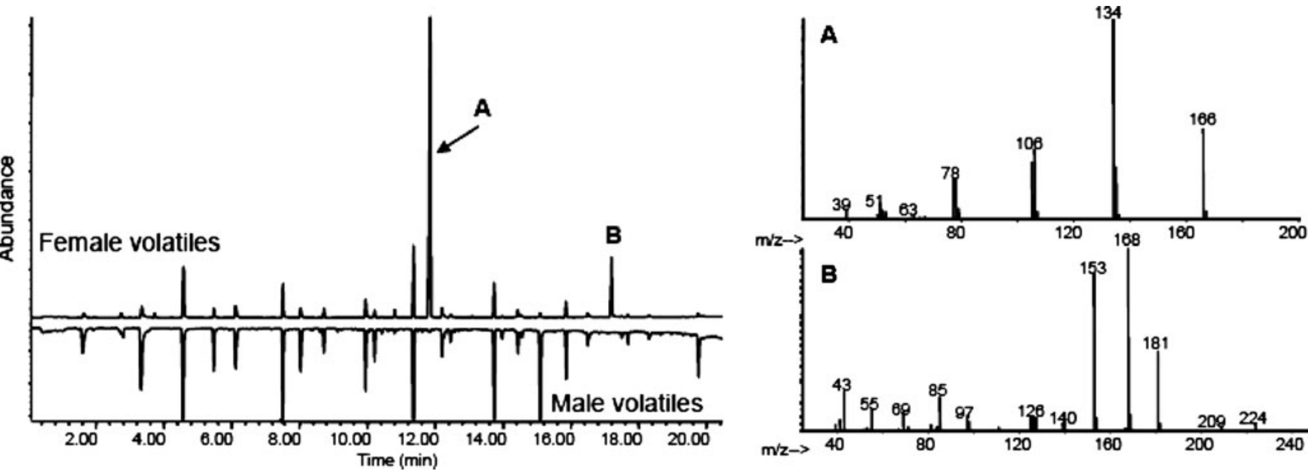


Fig. 1 Comparison of total ion chromatograms of SPME samples from male and female *Spalangia endius*. This illustrates the two female-specific compounds, **A** and **B**, and their mass spectra

isomers vs. vacuum-collected female volatiles. The two female-specific compounds were present in the vacuum collected volatiles. All methyl methylsalicylate isomers were applied at two female equivalents (about 300 ng). An arrestment time bioassay of virgin males was completed by using six different treatments, methyl 3-methylsalicylate, methyl 4-methylsalicylate, methyl 5-methylsalicylate, and methyl 6-methylsalicylate, along with vacuum-collected female volatiles (two equivalents), and a solvent control, all in 4 µl of dichloromethane. The temperature and relative humidity during these four behavioral experiments ranged from 21 to 24°C and 35% to 55%, respectively.

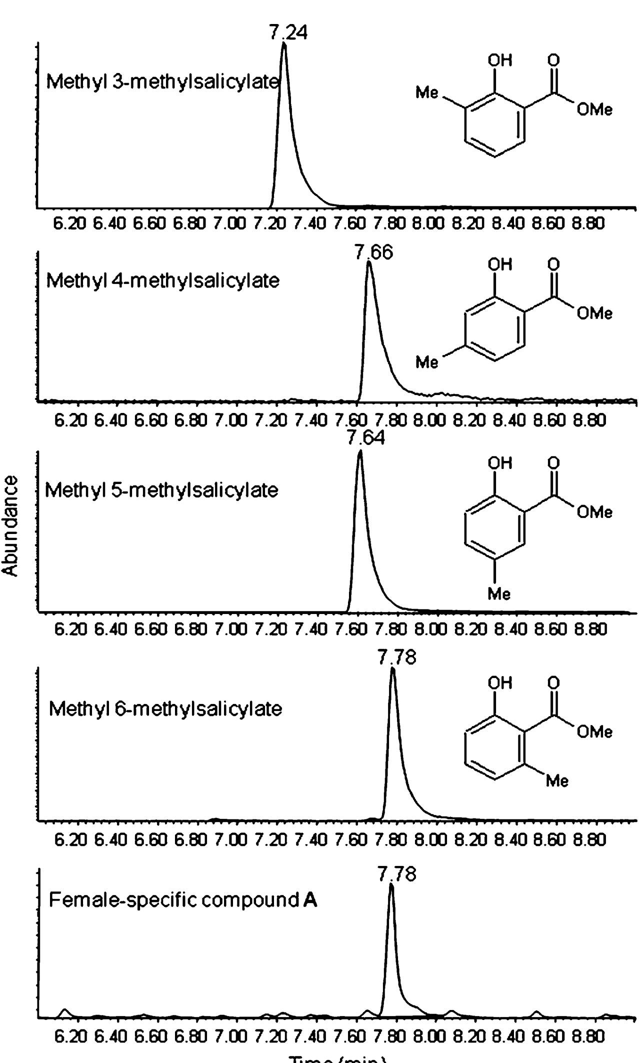

Fig. 2 Comparison of total ion chromatograms of authentic standards of four possible isomers of methyl methylsalicylate and female-specific *Spalangia endius* compound **A** (retention times from analysis on DB1 capillary column)

Results

Gas chromatography-mass spectrometry analyses Comparison of SPME collection (N=4) from adult *S. endius* males and females revealed two female-specific peaks (**A** and **B** in Fig. 1). The most abundant, **A,** was also present in all Super-Q collections (N=8); but only trace amounts of **B** could be detected in these collections. The two peaks were always detected in female body washes (N=5) in a 98:2 ratio, respectively. These two compounds were never detected in male volatiles collections or body extracts. The mass spectrum of compound **A** (Fig. 1) suggested an isomer of methyl methylsalicylate; no MS library (Wiley 1995) match was found for compound **B** (Fig. 1). Compounds **A** and **B** eluted from the silica column in 1:1 diethyl ether:hexane and diethyl ether, respectively, suggesting that both compounds are oxygenated.

The library mass spectra of the four possible isomers of methyl methylsalicylate were similar; thus authentic standards were acquired for all four for comparison to the natural product. The standard isomers all were separable by GC.

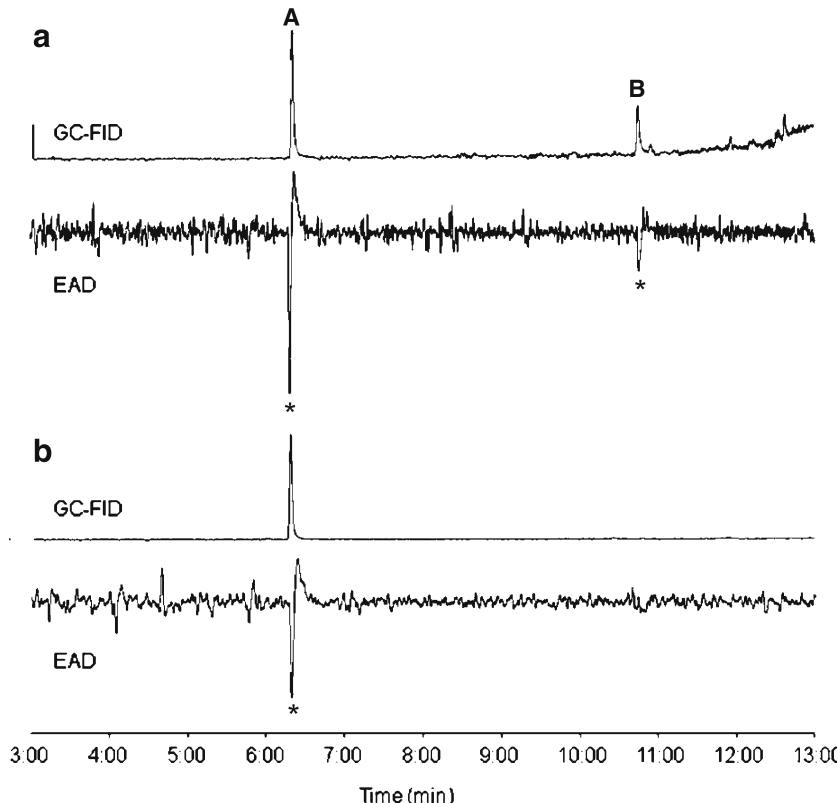

Fig. 3 Antennal response of male *Spalangia endius* to **a**) female-specific compounds **A** and **B** from the SPME sample and **b**) synthetic methyl 6-methylsalicylate; * indicates a positive response

Only methyl 6-methylsalicylate had an identical GC retention time and mass spectrum compared to compound **A** (Fig. 2).

Gas chromatography-Electroantennographic Detection (GC-EAD) analysis The GC/EAD analysis showed that male antennae (N=5) responded to the two female-specific compounds (Fig. 3 top), and that the male antennal response to natural **A** was identical in GC retention time compared to the response to synthetic methyl 6-methylsalicylate (Fig. 3 bottom).

Response to extracts of the opposite sex A 2-way ANOVA of arrestment time by extract (extract, solvent) and carcass (present, absent) was done for males and females separately. For males, there was no significant interaction between extract and carcass (F=0.09, df=1, 56, P=0.77), meaning the effect of each does not depend on the other. There were significant individual effects for both extract and carcass (F=45.79, df=1, 56, P=<0.001; F=21.62, df=1, 56, P=<0.001, respectively). Male arrestment was increased by the extract as can be seen by comparing solvent to extract and by comparing carcass with solvent to carcass with extract (Table 1). Male arrestment also was increased by the carcass being present, as can be seen by comparing extract alone to carcass with extract and solvent alone to carcass with solvent. For females, there were no significant effects of extract, carcass, or the interaction between them (F=0.31, df=1, 56, P=0.58; F=0.52, df=1, 56, P=0.47; F=1.66, df=1, 56, P=0.20). Thus, females did not appear to arrest to extract or carcass.

Responses to fractionated female-specific compounds A 2-way ANOVA of arrestment time by fraction-containing-**A** (present, absent) and fraction-containing-**B** (present, absent) was performed (Table 2). There was no significant interaction (F=0.013, df=1, 56, P=0.91) and no significant effect

Table 1 Arrestment times of *Spalangia endius* males and females to solvent and to extract of the opposite sex, with or without a carcass of same sex present[a]

	Solvent	Extract	Solvent with carcass	Extract with carcass
Male	0.29±0.09 (0–1.00)	0.97±0.14 (0–1.63)	0.75±0.10 (0–1.20)	1.49±0.06 (0–1.87)
Female	0.61±0.12 (0–1.26)	0.83±0.12 (0–1.53)	0.85±0.13 (0–1.59)	0.77±0.10 (0–1.18)

[a] Table entries are log-transformed mean ± s.e. (minimum–maximum), in log sec, N=15 per treatment per sex

Table 2 Arrestment times of *Spalangia endius* males and number of males that fanned to column fractions containing methyl 6-methylsalicylate and/or unknown compound and to solvent control[a]

Fraction content	Arrestment time	# Males that fanned
Solvent[b]	0.71±0.11 (0–1.49)	0
Methyl 6-methylsalicylate (A)	1.24±0.12 (0.30–2.19)	4
Mixture (A+B)	1.19±0.14 (0–2.39)	2
Unknown compound (B)	0.69±0.09 (0–1.40)	0

[a] Table entries are log-transformed mean±s.e. (minimum–maximum), in log sec, N=15 per treatment

[b] Dichloromethane

of the fraction containing **B** (F=0.071, df=1, 56, P=0.79), but there was a significant effect of the fraction containing **A** (F=20.09, df=1, 56, P<0.001). Thus, this experiment showed that relative to solvent control, males arrest to the fraction containing the **A** compound, but not to the fraction containing the **B** compound, and that the response to one fraction is not affected by the presence of the other fraction. Males periodically fanned during trials that included the **A** containing fraction.

Response to methyl methylsalicylate isomers To preserve statistical power, planned comparisons were used (Ruxton and Beauchamp, 2008). The first comparison of arrestment times in the bioassay (Table 3) was between the female-specific volatiles and methyl 6-methylsalicylate. Arrestment times did not differ (t=0.061, df=28, P=0.95), and so their times were combined into group 1. The next comparison was among the other three synthetic isomers (methyl 3-methylsalicylate, methyl 4-methylsalicylate, methyl 5-methylsalicylate), which did not differ either (F=0.57, df=2, 42, P=0.57); so the isomers' arrestment times were grouped and became group 2. Groups 1 and 2 then were compared, which showed that arrestment time was greater for female-specific volatiles and methyl 6-methylsalicylate than for other isomers (t=3.76, df=73, P<0.001; untransformed means: 20.27±8.01 s vs. 4.07±0.71 s, respectively). The last comparison was group 2 and the solvent control, which showed that males do not arrest significantly to the methyl 3, methyl 4, and methyl 5 isomers (t=0.87, df=58, P=0.39). Although males did not significantly arrest unless methyl 6-methylsalicylate was present, occasional courtship-fanning to methyl 6-methylsalicylate and other isomers was seen.

Table 3 Arrestment times of *Spalangia endius* males and number of males that fanned to isomers of methyl methylsalicylate, as well as to solvent and to volatiles of females[a]

Isomer or control	Arrestment time	# Males that fanned
Solvent[b]	0.61±0.10 (0–1.36)	0
3	0.44±0.11 (0–1.18)	1
4	0.47±0.12 (0–1.23)	3
5	0.60±0.11 (0–1.28)	2
6	0.95±0.12 (0–1.84)	5
Volatiles	0.93±0.17 (0–2.38)	1

Discussion

The study showed that female *S. endius* emitted two female-specific compounds, methyl 6-methylsalicylate and an unidentified second compound. The analyses of the extracts and the male behavioral results are consistent with the idea that methyl 6-methylsalicylate functions as a female-emitted pheromone component. Both female-specific compounds were biologically active when analyzed by GC-EAD. However, males arrested only to the silica fraction containing methyl 6-methylsalicylate and to the same degree as they arrested to the complete natural blend. In other words, the silica fraction with the unidentified material did not arrest males and did not increase arrestment to the silica fraction containing methyl 6-methylsalicylate.

The exact roles of methyl 6-methylsalicylate and the unidentified compound in intersexual interactions in *S. endius* remain to be determined. This study evaluated only male arrestment responses; it is possible that these two female-specific compounds, individually or as a blend, have long-range behavioral effects. Methyl 6-methylsalicylate might be described as a sex pheromone component because males fanned to the compound periodically, and fanning is seen only during male attraction to females (King et al., 2005; King, 2006). However, why only some males fanned is unclear. Given that males arrested to it, the compound might also be important in eliciting or maintaining the courtship

that males perform once mounted, as an attraction pheromone, or both.

Methyl 6-methylsalicylate has been identified before in some ants (e.g., Torres et al., 2001; Schönrogge et al., 2008) and some beetles (Moore and Brown, 1979; Gnanasunderam et al., 1984). It has never been identified before in the Pteromalidae or from any other wasps or bees. Although methyl 6-methylsalicylate has been identified from more than 20 species of ants, its function is known for only a fraction of them. It acts as a sex pheromone in *Polyergus breviceps* and *P. rufescens* (Greenberg et al., 2004; Castracani et al., 2005); a trail pheromone in *Tetramorium impurum* and *Mayriella overbecki* (Morgan and Ollett, 1987; Kohl et al., 2000); and as an alarm pheromone in *Gnamptogenys pleurodon* (Duffield and Blum, 1975). Sometimes methyl 6-methylsalicylate is mixed with other compounds to elicit a response, such as in *P. breviceps* and *P. rufescens* (Greenberg et al., 2004; Castracani et al., 2008); or it is the only compound needed to elicit a sexual response, such as in *P. rufescens* (Castracani et al., 2005). In *Camponotus* spp., *Bothroponera soror*, *P. breviceps, P. rufescens,* and *G. pleurodon*, methyl 6-methysalicylate comes from the mandibles (Brand et al., 1973; Longhurst et al., 1980; Blum et al., 1987; Greenberg et al., 2004; Castracani et al., 2005). In *T. impurum* and *M. overbecki*, methyl 6-methylsalicylate is found in the poison gland (Morgan and Ollett, 1987; Kohl et al., 2000). The location of methyl 6-methylsalicylate in *S. endius* currently is unknown, though preliminary experiments suggest it may be distributed over the entire cuticle.

Acknowledgments We thank D. Klumpp for use of his laboratory and V. Ryzhov, J. Miller, and N. Blackstone for feedback on the manuscript.

that approach dispensers. We recently have determined that the behavioral mechanism responsible for disruption of peachtree borer, *Synanthedon exitiosa* Say (Lepidoptera: Sesiidae) in orchards treated with polyethylene tube dispensers is competitive attraction (Teixeira et al., 2010). Here, our objective was to characterize the timing and duration of peachtree borer approaches to dispensers placed in orchards singly or at high density.

Another non-competitive behavioral mechanism proposed for mating disruption is the advancement of the male's diel rhythm of response, which causes the temporal decoupling of male and female flight (Cardé and Minks, 1995). According to this hypothesis, males perceive the pheromone permeated in a crop area, and begin flying much earlier than when females initiate calling, thereby decreasing male response when females release pheromone. There are no definitive tests that substantiate the importance of this mechanism, perhaps because in disrupted areas it is necessary to monitor a relatively large number of dispensers to obtain a sufficient number of data points for a robust analysis (Cardé et al., 1998). The use of field-deployed digital cameras and digital video recorders (DVR) to continuously monitor moths approaching dispensers can circumvent this difficulty, as multiple dispensers can be monitored simultaneously, and video can be examined later at a convenient timing. In this study, we used cameras and DVRs to record approaches by peachtree borer to a polyethylene tube dispenser placed singly in an orchard, and to 12 dispensers deployed in another orchard as part of a mating disruption trial.

The Sesiidae are unusual among moth families that use long-range sex pheromones in that they mimic Hymenoptera, both in appearance and flight behavior, and are primarily diurnal. Diel activity periods preferred by most species are the morning hours or late afternoon, usually not the hottest midday hours. (Eichlin and Duckworth, 1988). Peachtree borer originally infested several species of wild *Prunus* native in the eastern and central U.S., but became a pest of peaches, sweet cherries, and tart cherries when these were introduced into its range (Snow, 1990). Peachtree borer larvae feed on the phloem and vascular cambium of the lower trunk and roots. Along with stressing the tree and providing entryways for microbial diseases, borer feeding may girdle and kill young trees. Peachtree borer has only one generation per year, and the adult flight lasts most of the summer, peaking in August in Michigan. Volatiles emanating from the gum of infested trees, conspecific cocoons, and frass stimulate oviposition by female peachtree borer (Gentry and Wells, 1982; Derksen et al., 2007). The long seasonal period of activity and the sheltered feeding habit of borer larvae make these pests difficult to control with conventional insecticides.

Since the identification of (*Z,Z*)-3,13-octadecadienyl acetate as the pheromone of peachtree borer (Tumlinson et al., 1974), a number of studies have documented successful disruption of peachtree borer orientation to pheromone-baited traps, as well as reduction in pest density, through the use of synthetic sources of pheromone (McLaughlin et al., 1976; Snow, 1990). However, mating disruption to control peachtree borer has not been adopted widely, in part, because of pheromone cost and the labor involved in deploying dispensers. Characterization of moth interactions with synthetic pheromone dispensers may help maximize the efficacy of disruption and decrease costs. It also may help guide the development of other pheromone-based means of control, such as mass trapping and attract-and-kill.

Methods and Materials

Field Plots Isomale-Dual™ pheromone dispensers (Shin-Etsu Chemical Co. Ltd., Tokyo, Japan) were placed on 12 May 2009 in peach orchards (*Prunus persica* (L.) Batsch) located in Coloma, southwest Michigan, as part of a mating disruption trial. This dispenser is registered for mating disruption of peachtree borer and lesser peachtree borer *S. pictipes* (Grote & Robinson), and contains 33.3 mg of (*Z,Z*) and of (*E,Z*)-3,13-octadecadienyl acetates. The dispensers were deployed at 371 per hectare (150 per acre) in a 1.6 ha (4.0 ac) plot. On 11 July, one dispenser was removed from this plot and placed singly near the center of another 0.9 ha (2.3 ac) peach plot in the same farm located ~250 m west of the original plot. A standard red rubber septum lure (Trécé, Adair, OK, USA) containing a proprietary blend of the sex pheromone that consisted mostly of *(Z,Z)*-3,13-octadecadienyl acetate also was placed in the plot. Both orchards were planted with a mixture of peach cultivars approximately 10 years old, and known to be heavily infested with peachtree borer. Standard insecticide and fungicide sprays were conducted by the grower. No insecticide treatments were specifically directed toward peachtree borer.

Video Recordings Video recordings were conducted using a field-deployed DVR (model QH25DVR, QSee, Anaheim, CA, USA) powered by a 12 V Deka marine-type battery (DC31DT, Lyon Station, PA, USA). Power supply to the DVR was controlled by a 12 V DC timer. One DVR and two digital cameras (model QOCDC, QSee, Anaheim, CA, USA) were used in the orchard with the single dispenser and the lure. In the other orchard where dispensers had previously been deployed, 12 dispensers were monitored using three DVRs and four sets of cameras per DVR. The recording arena consisted of a 60×90 cm white corrugated plastic platform that provided a high-contrast background (Fig. 1). Dispensers and lures were placed hanging from a 15 cm wire placed on the center of the platform. The platform was located on the tree row, 120 cm from the ground. The single dispenser and the lure were placed 32 m

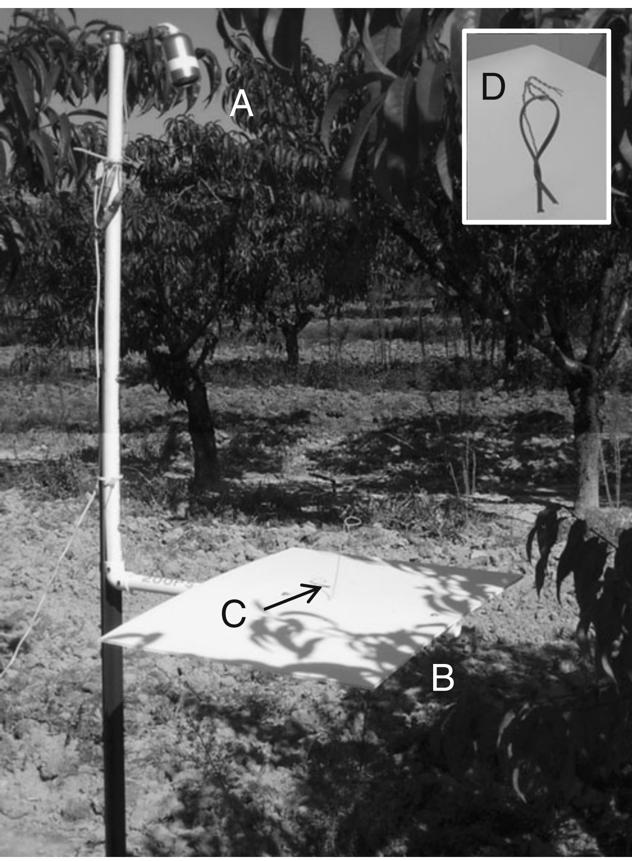

Fig. 1 Peachtree borer approach recording setup. **a** Camera mounted on a PVC pole attached to a metal pole. **b** Corrugated plastic platform. **c** Location of wire stand to hang the dispenser. **d** Detail of wire stand and dispenser

apart in the same row. In the other orchard, the platforms for each four camera set were 10 m apart. The dispenser in the platform was taken from the nearest tree so that the dispenser density in the area remained constant. Dispensers had been placed in 3 out of every four peach trees in the plot. The three sets of four cameras were placed in a transect across the plot, each set in the same row so that camera cables did not interfere with the passage of farm machinery between the rows. Recordings started on 11 July and ended on 18 August, and consisted of four 5 d to 6 d consecutive periods separated by 2 d to 3 d when the batteries were recharged. Recordings were made from 10:00 to 16:00 h. The same dispensers and lure were used throughout the study.

Video Analysis Video recordings were transferred from the DVR to a computer for visual evaluation. Preliminary observation of a sample of video records indicated that most approaches to the dispensers occurred in August, coinciding with the peak flight of peachtree borer in the area. The recording period from 13 to 18 August yielded the high number of approaches necessary for a robust statistical analysis. Therefore, we decided to use this period for detailed analysis of moth approaches to the dispensers. Focusing on a single week of data also allowed us to avoid variability due to changing environmental conditions over extended periods of time. Detailed scoring consisted of recording the time when a dispenser or lure was approached by a moth. An approach was defined as a period of time when a moth was observed casting while moving towards the dispenser, or remaining in sustained flight facing the dispenser. Events where moths were seen flying by but did not interact with the dispenser were not considered approaches. In the rare occasions when more than one moth was present, individual moths were tracked separately. Lesser peachtree borer and several other sesiid moths that approached the dispensers were excluded. The same observer scored all the approaches. The timing of approaches was determined based on the time stamp of the video recordings. When moths approached dispensers for less than 1 sec, the approach time was considered to be 1 sec. The duration of longer approaches was rounded up to the nearest second. The average approach timing (time of end plus time of beginning)/2 was calculated for each approach.

Statistical Analyses The average and standard deviation of approach timings was calculated for each observation date, and with data pooled by single dispenser, high-density dispensers, or lure treatment. The residuals of analysis of variance conducted on approach timing data were not normally distributed. Therefore, the non-parametric Kruskal-Wallis test as implemented in PROC NPAR1WAY of SAS (SAS Institute 2001) was used to determine differences in approach timing among treatments. Differences among treatments were determined by date, with daily approach timings, and with approach data over the entire period pooled by treatment. Approach timing data also were compared pooled by date to determine differences among dates. A frequency histogram was constructed using mean approach timing data pooled by treatment with bins consisting of 15 min time intervals during the diel flight period.

A frequency histogram of approach durations for each treatment, with bins consisting of 1 sec duration intervals, showed differences in the shape of the underlying frequency distributions. These differences strongly biased statistical tests towards the occurrence of significant differences among treatments. To avoid this bias, we characterized differences among treatments using the frequency histogram. In addition, we used PROC UNIVARIATE of SAS to calculate the median and interquartile range (IQR) for daily approach durations by treatment, and approach durations pooled by treatment over the entire period.

Trends in approach duration along the diel flight period were investigated using regression analysis by date and treatment, and with data pooled by date and by treatment, using PROC REG of SAS.

Results

Recordings during the period from 13 to 18 August were scored in detail, with the exception of 17 August when rainfall during the flight period almost completely stopped moths from approaching pheromone sources. The total number of moth approaches recorded during the 5-day period were 226, 175, and 292 to single dispenser, high-density dispensers, and lure, respectively. One of the cameras trained on a dispenser placed at high density malfunctioned during the whole period, and so the dataset corresponds to 11 dispensers only.

Approach Timing The mean approach timing (h:min:sec±SD) of peachtree borer to single dispenser, high-density dispensers, and lure was 11:33:12 ± 00:46:43, 11:43:52 ±00:45:58, and 11:41:21 ± 00:45:54 AM (Table 1). There were significant differences among approach timings to single dispenser, high-density dispenser, and lure when data were pooled by treatment (χ^2=8.7; *df*=2, *P*=0.01) and by date (χ^2=150.1; *df*=4, *P*<0.001). There were significant differences among treatments with daily data on 16 and 18 August (χ^2=6.1; *df*=2, *P*=0.05 and χ^2=7.9; *df*=2, *P*=0.01, respectively), but not on 13, 14, and 15 August (χ^2=0.8; *df*=2, *P*=0.64, χ^2=0.4; *df*=2, *P*=0.82, and χ^2=0.69; *df*=2, *P*=0.71, respectively). On 16 August, the earliest approach timing was recorded with the single dispenser, while on 18 August the earliest approaches were with the lure. The frequency histogram of approach timings recorded during the study period (Fig. 2) shows that approaches started between 10:15 and 10:30 AM and ended between 14:30 and 14:45. With all treatments, the highest percentage of approaches was recorded between 11:30 and 11:45 AM.

Approach Duration The frequency histogram of approach durations over the 5 days of this study showed distinct distributions among treatments (Fig. 3). Approaches to dispensers placed at high density were shorter than with the single dispenser or the lure, with over 50% of the approaches lasting less than 1 sec. In addition, few long approaches were recorded with dispensers placed at high density. The distribution of approaches to the single dispenser and lure were similar but a higher frequency of longer approaches was recorded with the lure. The relative rank of median approach durations was constant when analyzed per day (Table 2) with shorter approaches to dispensers placed at high density, then intermediate approach durations to the single dispenser, and the longest approaches recorded with the lure. With approach data pooled by treatment, the median was 1 (less than 1 sec) and IQR was 1 to 2 with dispensers placed at high density, indicating that 75% of approaches lasted less than 2 sec. With the single dispenser, the median was 3 sec and IQR was 2–4 sec, while with the lure the median was 4 sec and IQR was 2–5 sec.

There were no significant trends in approach duration vs. time of day with data pooled by treatment or date, or when data were analyzed separately by treatment and date (linear regression, *P*>0.05).

Discussion

Peachtree borer males in an orchard treated with a high density of pheromone dispensers for mating disruption did not approach the dispensers earlier than males in an orchard with a single dispenser. Therefore, this study does not support the hypothesis that one of the mechanisms of mating disruption is the advancement of male flight and the resulting loss of synchrony of male and female diel flight period caused by ambient permeation with artificial pheromone. Although there were statistical differences among the periods of approach to the single dispenser, high-density dispensers, or the lure when the 5 day data were pooled, treatments were not significantly different in three of the 5 days. On the dates when there were statistical differences among treatments, the relative timing of the approach period among treatments was not consistent. Considering that there was day-to-day variation in the relative timing of approach, and that differences among pooled treatment averages (~10 min) were much smaller than the standard deviation of treatment means (~45 min),

we do not attribute biological significance to the differences among treatments. Video recordings suggest that day-to-day variation in the approach period was related to environmental conditions like cloudiness and wind speed. Peachtree borer approached artificial sources of pheromone mostly between 11:00 and 12:30 AM EST in Michigan, in mid August, which is similar to 11:00–12:00 AM CST determined by Greenfield and Karandinos (1979) in southwest Wisconsin, in late July.

In contrast to the timing of the approaches, placement of the dispensers singly or at high density had a consistent effect on the duration of the approaches. Most approaches to dispensers placed at high density lasted less than 1 sec, while approaches to single dispenser were longer, and approaches to the lure were the longest. This relative rank of approach duration was consistent on all days of the study. Therefore, we conclude that dispenser density affects the duration of male peachtree borer approaches to the dispensers. The release rate and/or pheromone blend composition also may affect the duration of the approach, as suggested by the difference between the single dispenser and lure. Peachtree borer males initiate mating while hovering near the female, and do not alight until coupling with the female by using their genital claspers (Slingerland, 1899; Barry and Nielsen, 1984). Possibly as a consequence of this specific behavior, most approaches to the dispensers or lure were relatively short. Nevertheless, several males spent a relatively long period of time hovering near the dispenser or lure, and some attempted mating by striking them with the tips of their abdomens. The frequency distribution of approaches to dispensers by three tortricid species observed by Stelinski et al. (2004) in non-disrupted plots was similar to that of peachtree borer, although approaches tended to be longer: most obliquebanded leafroller *Choristoneura rosaceana* (Walker) remained near the dispenser for less than 10 sec, and the majority of Oriental fruit moth *Grapholita molesta* (Busck) and redbanded leafroller *Argyrotaenia velutinana* (Walker) remained for less than 20 sec.

We hypothesize that differences in the duration of approaches to dispensers singly or at high density are related

to competition among dispensers, or to changes in the behavior of moths exposed to dispensers at high density. Regarding the first hypothesis, we previously have determined that disruption of peachtree borer is mediated by competitive attraction (Teixeira et al., 2010). In the competitive-attraction equation (Miller et al., 2010), which relates male catch in a monitoring trap to the presence of competing pheromone sources like dispensers and females, the *findability* terms express the attraction potential of the different pheromone sources, measured as the proportion of moths that find an attractant source. The *retentiveness* terms measure the proportion of time that moths spend approaching a pheromone source and recovering the ability to follow another plume afterwards, in relation to the moth active sexual life time. The *retentiveness* term is deemed to be constant across dispenser densities, but our direct measurements show that, at least near the dispenser, the approach duration is not constant. It may be that competition among dispensers is expressed not only by the proportion of moths that find one attractant, but also by how much time moths spend interacting with each dispenser at a given density. Observations of moths suggest that competition among dispensers may be expressed behaviorally, as when moths find one dispenser but immediately shift to following a pheromone plume emanating from a nearby dispenser, which is more likely to happen as dispenser density increases.

Regarding the hypothesis that moth behavior changes as a result of exposure to dispensers at high density, shorter approach duration may be a symptom of the behavioral mechanism of disruption that changes from competitive-attraction to a non-competitive mechanism as dispenser density increases. When disruption is caused by non-competitive mechanisms, such as camouflage, sensory inhibition away from the dispenser, or sensory imbalance, moths do not approach the dispensers. It is possible that there is a continuum from competitive attraction to a non-competitive behavioral mechanism with increasing dispenser density. For example, male codling moth *Cydia pomonella* (L.) (Lepidoptera: Tortricidae) responded to wax droplets in a manner consistent with competitive attraction at low density, but appeared to have become desensitized when wax droplet density was increased greatly (Miller et al., 2006b). The high density that we used, 371 dispensers per hectare, is much lower than that used with codling moth, but peachtree borer is extremely responsive to its pheromone (Tumlinson et al., 1974).

It is also possible that after multiple approaches to a dispenser, moths associate short-range visual or other cues from the dispenser with reduced probability of mating, and consequently reduce their effort near a dispenser. In a plot treated with high dispenser density, it is likely that a moth interacts multiple times with dispensers in the same day. Behavioral habituation, as opposed to physiological consequences of exposure to pheromone, may explain why approaches to dispensers at high density are shorter but moths still approach the dispensers.

With respect to the consequences for mating disruption of peachtree borer, shorter approach time with high dispenser density indicates decreased dispenser retentiveness. We measured only the duration of approaches near the dispenser, not the duration of the whole period when a moth is following the plume, or the recovery period following the approach. In addition, the overall impact of changes in retention time depends on the number of approaches to the dispensers that each moth makes, which is currently unknown. However, if moth inactivation from exposure to a high dose of pheromone near the dispenser is dependent on the duration of the exposure, then a small reduction in the duration of the approach may have a disproportionate impact on retention time because moths will recover faster. Our results suggest that there is a decrease in the disruptive activity of each dispenser with increasing dispenser density which, so long as the underlying moth behavioral mechanism remains competitive attraction, will lead to a higher number of moths caught in monitoring traps than expected as a function of dispenser density. Another and potentially more important consequence for mating disruption is that approaches to lures in monitoring traps placed in orchards with high dispenser density may also be shorter than when moths are placed in non-disrupted orchards. As a consequence, trap catch could be lower in disrupted blocks because of decreased trap efficiency and not because moths cannot find the trap. It

remains to be determined whether pheromone permeation affects the behavior of male moths that find females.

Fig. 1 Approximate distribution of *Ostrinia nubilalis.* The European corn borer has been observed in most Eurasia as well as North Africa and North America. Because of a certain degree of confusion concerning the taxonomic status of *O. scapulalis* and *O. nubilalis* (Frolov et al., 2007) the Eastern limit of the distribution may be underestimated

clasper response (Klun, 1968). This observation provided a reliable bioassay for the presence of pheromone in extracts of female corn borers. The sex pheromone produced by female ECB was extracted for the first time in 1968 from 10,000 females (Klun, 1968). The active sex pheromone was isolated as a single component that could elicit male response. The male sex stimulant was identified as (*Z*)-11-tetradecenyl acetate (Z11-14:OAc) (Klun and Brindley, 1970), a compound that since has been found to be part of the pheromone blend of more than 300 moth species (El-Sayed, 2010). Synthetic Z11-14:OAc was shown to possess biological properties identical to the natural pheromone in a close-range bioassay (Klun and Brindley, 1970). In the first field trials, the presence of the geometrical isomer (*E*)-11-tetradecenyl acetate (E11-14:OAc) was found to have a negative impact on trap catches (Klun and Robinson, 1971). However, contradictory results were reported from other field sites where males were specifically attracted to E11-14:OAc, Z11-14:OAc attracting comparatively few males in these locations (Roelofs et al., 1972). The hypothesis advanced then was that the distinct catches would correspond to different strains of corn borer that employed a different pheromone system (Roelofs et al., 1972). The pheromone polymorphism of the ECB had just been discovered.

When geometrically pure isomers could be synthesized and made available for field assays, previous conclusions regarding ECB pheromone communication could be revisited and modified. Male ECB were, indeed, weakly attracted to pure Z11-14:OAc (Klun et al., 1973). The addition of a small fraction of pure E11-14:OAc, however, dramatically increased trap captures, and the requirement of the E isomer for optimum attraction became obvious from field tests (Klun et al., 1973). Ultimately, the composition of female abdominal tips was scrutinized to identify pheromone components of the two behavioral strains, and females were found to produce either 97:3 Z/E11-14:OAc or 1:99 Z/E11-14:OAc (Kochansky et al., 1975). Tetradecyl acetate (14:OAc) also was found in gland extracts but had no effect on attraction (Kochansky et al., 1975). Similarly, trace amounts of (*Z*)-11-hexadecenyl acetate (Z11-16:OAc) were detected in extracts from E-strain females, but this compound was without noticeable behavioral effects (Peña et al., 1988).

Reproductive Isolation Between the Strains

It was shown through analyses of the sex pheromone of female moths that two strains of corn borer exist. The occurrence in nature of Z and E pheromonal phenotypes of the ECB was established through an extensive survey conducted in the mid-1970’s. In this survey, males at different geographic sites were found to respond to opposite isomeric blends of 11-14:OAc (Klun and Cooperators, 1975). Studies also revealed that the most prevalent ECB pheromonal phenotype in nature is the 97:3 Z/E11-14:OAc; the E strain having a more restricted distribution in Europe and North America probably because it may lack certain adaptive features possessed by Z strain individuals (Klun and Cooperators, 1975; Anglade and Stockel, 1984). This would explain the limited part of North America that was effectively colonized by the E strain, essentially close to the sites of introduction. Apart from the pheromone, there seem

to be no fixed differences between types, nor are there any morphological characters that permit differentiation.

In regions where sympatric populations of the Z and E strains were detected, males responding to a 1:1 blend occasionally were captured, and it was suggested that these males could be hybrid individuals produced from crosses between the two pheromonal types (Klun and Cooperators, 1975; Cardé et al., 1978). An alternative explanation may lie in a broader window of response in certain populations caused by genetic variability within these populations; these males would be a mixture of individuals that respond predominantly to Z or E blend (Klun and Cooperators, 1975; Cardé et al., 1978). Nevertheless, viable hybrids can be obtained under laboratory conditions (Liebherr and Roelofs, 1975), and interbreeding of opposite pheromonal types is not unlikely because aggregation of males and females of both strains occurs in similar grassy habitats (Showers et al., 1976; Dalecky et al., 2006). The inter-strain crosses, when successfully completed, give progeny showing heterosis, with the portion of individuals surviving each life stage being significantly higher (Liebherr and Roelofs, 1975). Similarly, F2 sibling crosses show 100% viable matings, and females do not exhibit a reduced fecundity (Liebherr and Roelofs, 1975). However, the hybrid crosses that occur under confined conditions are much less frequent than intra-strain crosses, and laboratory choice tests suggest that a degree of premating reproductive isolation exists between the two strains (Liebherr and Roelofs, 1975). A plausible explanation would be that a large proportion of the males are inhibited from attempting mating by the detection of the incorrect sex pheromone isomer ratio (Liebherr and Roelofs, 1975). Since an increase in the amount of the respective minor component eliminates male attraction, it was hypothesized that this presumably would cause reproductive isolation in the field and, therefore, support separate species status for the two strains (Kochansky et al., 1975).

Because of the relative rarity of inter-strain matings under laboratory conditions, it might be expected that such matings would be even rarer in nature. In addition, the few hybrids produced may not be able to mate at all (Liebherr and Roelofs, 1975). Analysis of the Δ11-tetradecenyl acetate isomeric composition of wild female moths indicated that sympatric pheromonal types mate assortatively with only a low level of hybridization detected (Klun and Maini, 1979; Roelofs et al., 1985; Klun and Huettel, 1988). Evidence that the Z and E pheromone strains of *O. nubilalis* are not freely interbreeding in areas of coexistence first came from allozyme data (Cardé et al., 1978). Although small, the genetic divergence detected between the Z and E strains is suggestive of ongoing speciation, and justifies that the strains could be considered as semispecies (populations that have acquired some attributes of species rank for which the speciation process is partially complete) or sibling species (Cardé et al., 1978). This was confirmed by a subsequent study that involved 30 loci corresponding to regulatory and non-regulatory enzymes in which the values of genetic distance obtained were indicative of taxa at the beginning of divergence (Cianchi et al., 1980). Areas in North America are secondary contact zones of recent origin where introgression could occur, though at a low level (Cardé et al., 1978).

The behavioral response of hybrid males was characterized to define precisely the response profile of hybrid males, which is crucial to understanding the interaction between sympatric Z and E individuals. Glover et al. (1991) reported that many hybrid males from reciprocal crosses failed to complete the behavioral sequence to locate a female, regardless of the blend they were exposed to. In addition, the few males that responded did not exhibit a preference for any particular blend but, rather, were attracted to a broad range of blends (Glover et al., 1991). Given that most hybrid males do not respond to any blend, and that the remaining ones are not tuned to any particular blend, F1 hybridization should be seen as a transient stage with a limited possibility of creating recurrent gene flow between the strains. However, the actual fate of hybrid individuals in the field remains obscure.

Pheromone Biosynthesis and Its Regulation

The pheromone components, E11-14:OAc and Z11-14:OAc, are produced through the fatty acid cycle. Palmitic acid is shortened to a 14-carbon intermediate through one cycle of β-oxidation. Desaturation then is accomplished by a Δ11-desaturase to give the (*E*)- and (*Z*)-11-tetradecenoyl precursors, which are subsequently reduced and acetylated to form the pheromone compounds (Roelofs et al., 1987) (Fig. 2). In both strains, the Δ11-desaturase produces the same ratio of the (*E*)- and (*Z*)-11-tetradecenoyl intermediates (Roelofs et al., 1987; Wolf and Roelofs, 1987). The enzyme has been characterized and expressed in a heterologous system, thus confirming its capacity to produce both geometric isomers of Δ11-tetradecenoyl from myristic acid (Roelofs et al., 2002). *In vivo* experiments that involve the use of labeled precursors have helped to determine that substrate selectivity occurs during the reduction step (formation of fatty alcohol from the acyl precursors); no selectivity of the acetylation step was noticed (Jurenka and Roelofs, 1989; Zhu et al., 1996b).

As in other moth species, the presence of lipid droplets in the pheromone gland cells has been reported in the ECB (Ma and Roelofs, 2002). These lipid droplets consist of triacylglycerols, the main pool of non-membrane lipids (Ma and Roelofs, 2002). Fatty acyl pheromone analogues, (*Z*)-

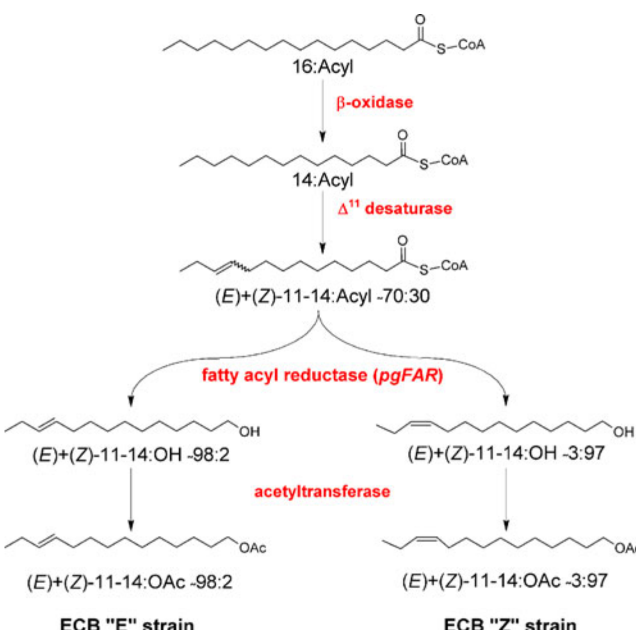

Fig. 2 Biosynthetic pathway towards the female *Ostrinia nubilalis* pheromone. *De novo* biosynthesis of (*Z*)- and (*E*)-11-tetradecenyl acetates starts from palmitoyl-CoA. One cycle of β-oxidation generates myristoyl-CoA, which is a substrate for a fatty acyl Δ11 desaturase. The (*E*)- and (*Z*)-11-tetradecenoyl moieties produced are converted into the corresponding alcohols by a fatty acyl reductase *pgFAR*. Finally, an acetyltransferase catalyzes the conversion of the fatty alcohol precursors into acetates

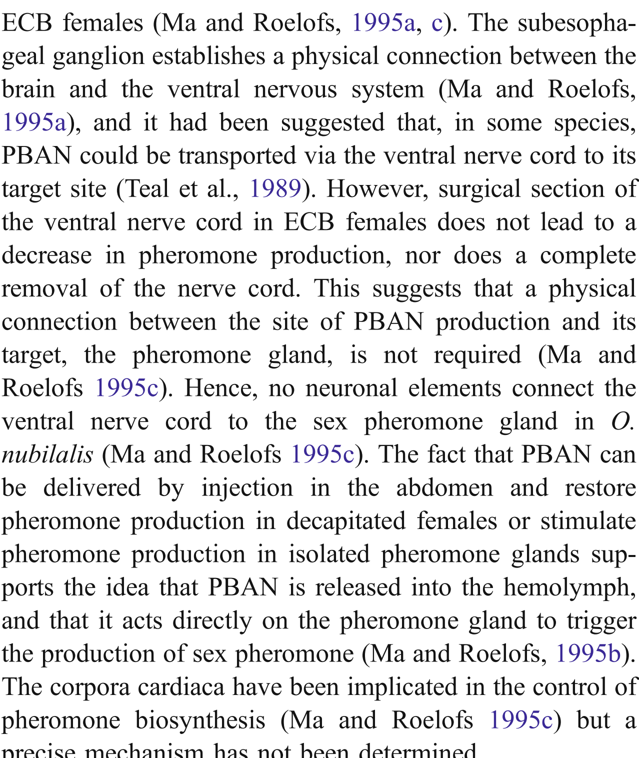
and (*E*)-11-tetradecenoate, are found predominantly in the triacylglycerols (Foster, 2004). The physiological role of these lipid deposits in the sex pheromone biosynthesis is two-fold. First, they seem to function as a sink for excess fatty acyl precursors, especially the direct precursor of the minor component (Foster, 2004). Second, they may be a source for the biosynthesis of pheromone, especially of tetradecanoate (14:Acyl), precluding the necessity for *de novo* biosynthesis of this acid during the period of pheromone production (Foster, 2004).

The sex pheromone production in female corn borers exhibits a cyclic pattern throughout the photoperiod, with a peak during the scotophase, and a valley with no pheromone during the photophase (Foster, 2004). The pattern changes slightly as females age, with the peak observed towards the end of the scotophase in young females, an apparent constant titer during the scotophase in 2 to 3-day-old females, and a peak in the early scotophase in older females (Foster, 2004; Kárpáti et al., 2007). This pattern apparently correlates with the mating activity as observed under laboratory conditions (Kárpáti et al., 2007). Pheromone biosynthesis is regulated by the neuropeptide pheromone biosynthesis activating neuropeptide (PBAN) (Raina and Klun, 1984; Raina et al., 1989; Ma and Roelofs, 1995b). PBAN is produced in three discrete sets of neurosecretory cells in the subesophageal ganglion of adult



ECB females (Ma and Roelofs, 1995a, c). The subesophageal ganglion establishes a physical connection between the brain and the ventral nervous system (Ma and Roelofs, 1995a), and it had been suggested that, in some species, PBAN could be transported via the ventral nerve cord to its target site (Teal et al., 1989). However, surgical section of the ventral nerve cord in ECB females does not lead to a decrease in pheromone production, nor does a complete removal of the nerve cord. This suggests that a physical connection between the site of PBAN production and its target, the pheromone gland, is not required (Ma and Roelofs 1995c). Hence, no neuronal elements connect the ventral nerve cord to the sex pheromone gland in *O. nubilalis* (Ma and Roelofs 1995c). The fact that PBAN can be delivered by injection in the abdomen and restore pheromone production in decapitated females or stimulate pheromone production in isolated pheromone glands supports the idea that PBAN is released into the hemolymph, and that it acts directly on the pheromone gland to trigger the production of sex pheromone (Ma and Roelofs, 1995b). The corpora cardiaca have been implicated in the control of pheromone biosynthesis (Ma and Roelofs 1995c) but a precise mechanism has not been determined.

PBAN interacts with a G protein-coupled receptor (Choi et al., 2003) and promotes the opening of ion channels leading to an influx of extracellular calcium ion into the ECB pheromone gland cells (Ma and Roelofs, 1995b). The increase of cytosolic calcium leads to the activation of secondary messengers such as cAMP that in turn activate kinases and/or phosphatases, which stimulate the pheromone biosynthesis pathway (Rafaeli, 2009). From investigations conducted in different moth species, it has been shown that various enzymatic steps are under the influence of PBAN, from the control of fatty acid synthesis to the metabolism of fatty acid precursors (Tillman et al., 1999). In *O. nubilalis*, PBAN affects pheromone biosynthesis during the reduction step, that is the conversion of (*Z*)- and (*E*)-11-tetadecenoyl precursors into the corresponding alcohols (Eltahlawy et al., 2007).

Genetic Basis of Pheromone Polymorphism

The finding that viable hybrids could be obtained when crossing the two pheromone strains has made possible a full series of investigations aimed at unraveling the genetic basis of polymorphism in the corn borer communication system, notably the genetics that regulates the geometric composition of the sex pheromone.

Hybrid females from reciprocal crosses have an isomeric complement that approximates 65:35 E/Z, which is intermediate from that of either of the parent strains (Klun and Maini, 1979). The difference in female pheromone production is

controlled primarily by one autosomal locus with two alleles under Mendelian inheritance (Klun and Maini, 1979; Roelofs et al., 1987). Recently, a genetic map based on crosses between the two strains confirmed that the pheromone production trait is encoded by a single autosomal locus (Dopman et al., 2004).

The E/Z ratio produced by females from two successive backcrosses is variable to a higher degree than predicted (Löfstedt et al., 1989). This additional variation in the blend of pheromone components could not be explained directly under the basic "1-locus-2-alleles" model and it was, therefore, considered that independently segregating modifier genes that affect the exact ratio produced by heterozygous females could be present in some populations (Löfstedt et al., 1989; Zhu et al., 1996a). It has been proposed that the basic model can be extended based on the idea that there are two variant alleles in the Z strain for the major pheromone production locus, while the E strain carries one allele at this locus (Zhu et al., 1996a). The genetic variation noticed in the Z strain could result from another locus than the major production locus itself, although the data available so far suggest that, if it exists, this locus would be in linkage disequilibrium with the major production locus (Zhu et al., 1996a).

The autosomal gene in question has been proposed to encode for a factor that affects the specificity of the final reduction step, because a specific change in this critical step would produce various pheromone blends of acetate components (Roelofs et al., 1987; Zhu et al., 1996a, b). Indeed, the last reduction step is certainly decisive for the determination of the final pheromone ratio since both parental strains, and F1 females possess a similar ratio of geometric isomers of the unsaturated 14-carbon intermediates (Roelofs et al., 1987). *In vivo* labeling experiments were used to demonstrate that the reductase system differs between the two strains (Zhu et al., 1996b). Recent molecular investigations have confirmed the existence of two fatty acyl reductase alleles with strain-specific substrate specificities (Lassance et al., 2010). A genetic mapping approach was used to confirm the link between the genotype at the fatty acyl reductase *pgFAR* locus and the phenotype for pheromone production (Lassance et al., 2010). The variation unraveled by Zhu et al. (1996a) can be interpreted as the consequence of polymorphism existing within each strain at the *pgFAR* locus. Future experiments should aim at determining the level of variation existing for the *pgFAR* gene in natural populations of ECB.

Location of Production Site

In the adult female *O. nubilalis*, nine abdominal segments can be distinguished; seven of them are covered with scales, whereas the remaining terminal segments form the ovipositor that normally remains telescoped within the preceding segments (Ma and Roelofs, 2002). When describing the isolation of the sex pheromone, Klun (1968) reported that it could be isolated from the fused 9th and 10th abdominal segments. Furthermore, the sex pheromone was localized on the surface of the ovipositor, which is characteristic of many moth species (Klun and Maini, 1979). Details on the ECB sex pheromone gland ultrastructure revealed that the gland is formed by a single layer of hypertrophied epidermal cells that are located in the dorsal fraction of the intersegmental membrane between the 8th and 9th/10th segments, thus forming a half-ring gland (Ma and Roelofs, 2002).

The cells that form the gland have some characteristic features such as the presence of numerous mitochondria, the presence of lipid droplets both in the cells and the overlying cuticle, apical plasma membrane foldings, and smooth endoplasmic reticulum (Ma and Roelofs, 2002). Gas chromatographic analysis has confirmed the presence of both the pheromone components and their immediate fatty acyl precursors in the dorsal intersegmental membrane (Ma and Roelofs, 2002). *In situ* hybridizations using the Δ11-desaturase as probe were performed in the sister species *O. scapulalis*, and revealed that the enzyme producing the fatty acyl precursors is expressed only in the dorsal part of the terminal abdominal segments. The molecular observations thus corroborate the biochemical results (Fukuzawa et al., 2006). Similar results are to be expected for *O. nubilalis.*

Male Behavioral Response to the Pheromone

In nature, the females release sex pheromone that attracts potential mates from a distance. The detection of pheromone by males results in a well-defined stereotypic behavioral sequence composed of successive steps: orientation towards the pheromone source, upwind flight, and location of the odor source (Glover et al., 1987). In the close vicinity of the pheromone source, males of *O. nubilalis* respond by taking part in a characteristic precopulatory courtship display (Klun, 1968).

As mentioned earlier, the identification of the sex pheromone was tightly linked to the understanding of the associated male behavioral response. Precopulatory behavior was used in a close-range bioassay to demonstrate the activity of Z11-14:OAc in the Z strain (Klun, 1968). This behavioral response could be elicited in the complete absence of the minor component of the pheromone (Webster and Cardé, 1984), suggesting that this behavior does not require a complete pheromone blend to be elicited or that the close-range bioassay used did not allow for a

determination of the behavioral function of the minor component. However, the results of both field-trapping and flight tunnel studies have shown the importance of the natural pheromone blend compared to the use of the single major component for orientation, upwind flight, and source location (Klun et al., 1973; Klun and Cooperators, 1975; Glover et al., 1987). Indeed, when males were flown to a series of pheromone sources that varied in the percentage of the minor isomer, very few insects completed the sequence of behaviors when none of the minor component was applied (Glover et al., 1987; Linn et al., 1997). The flight tunnel assay is very discriminating because males must fly upwind to the chemical source for a reasonable distance (1 m to 2 m in general), and show close-range behaviors that include landing close to the source and displaying. This type of bioassay established that the males show limited to no attraction to the blend of the opposite strain (Glover et al., 1987, 1990) (Fig. 3).

In a close-range bioassay, Z, E, and F1 hybrid males responded more intensively to the isomeric blend that corresponds to sibling females (Klun and Maini, 1979). However, in each male type, some males also responded to other isomeric combinations, with E males being the least specific in their response preferences (Klun and Maini, 1979). Among field-captured individuals, some males showed a broad response window, and exhibited a response to isomer ratios well outside that produced by their respective females (Klun and Huettel, 1988). The behavioral response of males was evaluated in wind tunnel assays, and revealed the ability of males to discriminate blend quality during flight. Typically, ECB males display increased specificity with successive steps in the flight sequence (Linn et al., 1997). Males of the two strains, as well as their hybrids, exhibited different levels of specificity for ratios: Z males were quite discriminating with fewer insects performing a full behavioral sequence when exposed to blends other than the Z blend (Roelofs et al., 1987; Glover et al., 1990; Linn et al., 1997). On the other hand, E males had a broader window of response, with some rare males even being attracted to the blend produced by Z females, which may indicate that E males are less canalized in their behavioral response compared to Z males (Roelofs et al., 1987; Glover et al., 1990; Linn et al., 1997) (Fig. 3). The variability reported for some males may help explain how individuals belonging to different pheromonal types can closely interact, thus leading to interbreeding in the field. As a rule of thumb, the peaks of male response (corresponding to source contact in the flight tunnel) are centered on the natural female-produced ratio (Linn et al., 1997). Hybrid males exhibit high levels of upwind flight and source contact to a wide range of E:Z ratios (Fig. 4) indicating that, unlike their parents, they are not tuned to a specific ratio; they are, however, characterized by a relative lack of response to any dose of the 99:1 ratio typically attractive to E males (Roelofs et al., 1987; Linn et al., 1997). Interestingly, an appreciable number of hybrid males (10%) can exhibit source contact with sources mimicking a 98:2 ratio (Linn et al., 1997).

The survey conducted by Klun and his collaborators in the 1970's indicates that the sex-attraction response specificities of populations of males vary somewhat from generation to generation and from one geographic location to another (Klun and Cooperators, 1975). In addition to the established pheromone polymorphism, populations may differ in their voltinism, the number of generation per year, with univoltine and bivoltine populations having been reported (Roelofs et al., 1985). In the U. S., Z strain populations can be either uni- or bivoltine, whereas the E strain is bivoltine (Roelofs et al., 1985). The two Z populations have different sensitivities for responding to the ratio of the minor component, with bivoltine Z borers requiring less E isomer to complete the behavioral sequence (Glover et al., 1987). The temporal and spatial heterogeneity of male responses can be seen as an expression of intraspecific genetic variability within the populations and strains. However, because of the somewhat broad window of response exhibited by males, pheromone traps cannot be used to accurately estimate hybridization level or assign the

pheromone-response genotype of captured males (Glover et al., 1990), and future surveys should include the use of appropriate molecular markers.

Behavioral Antagonists

Some compounds, when added to the sex pheromone blend can, dramatically affect its attractiveness. Such a molecule is said to be an antagonist. Here, I will not consider responses to chemical analogues of the sex pheromones, although studies devoted to explore this issue have been conducted; only naturally occurring compounds produced by species more or less related to the ECB are considered.

The isomer of the ECB pheromone components (*Z*)-9-tetradecenyl acetate (Z9-14:OAc) is the most studied ECB behavioral antagonist. This compound is part of the pheromone used by two other extant species from the genus, namely *O. zealis* and *O. zaguliaevi* (Huang et al., 1998; Ishikawa et al., 1999a, b). Indeed, the ECB most likely evolved from an ancestral species that used a blend of Z9-14:OAc and Z/E11-14:OAc as pheromone components (Ishikawa et al., 1999b). Early data showed clearly that the addition of Z9-14:OAc reduced the attraction of ECB males to their sex pheromone blend (Klun and Robinson, 1972; Struble et al., 1987; Glover et al., 1989). Electrophysiological recordings suggested that males possess receptors that respond to Z9-14:OAc (Struble et al., 1987). It was first hypothesized that behavioral antagonists such as Z9-14:OAc would interact with the same chemoreception sites as the pheromone components (Nagai et al., 1977). However, single sensillum recordings demonstrated the existence of a specific detection channel in both E and Z strains for Z9-14:OAc (Hansson et al., 1987). The recent identification of an olfactory receptor from *O. scapulalis* that is primarily tuned to E11-14:OAc but inhibited by Z9-14:OAc opens the possibility for a direct action of the antagonist in distorting the firing rates of olfactory receptor neurons (ORN) expressing olfactory receptors (OR) that respond to the pheromone components (Miura et al., 2010). The antagonists may interfere through two distinct mechanisms: via the antagonist pathway itself, or via interferences with the agonist pathway. It is noteworthy that the behavioral antagonism-related ORN sometimes can respond to an agonist component, a phenomenon reported for the Asian corn borer, *O. furnacalis* (Takanashi et al., 2006; Domingue et al., 2007a). Investigations of the genetics of male response to pheromone components have revealed that the spike amplitude of cells that respond specifically to Z9-14:OAc do not appear linked to the factor that determines the development of Z and E11-14:OAc-responding ORNs (Cossé et al., 1995).

Other compounds have been reported for their antagonism of ECB pheromone, with the addition of as little as 1% in the pheromone blend leading to antagonism: (*E*)-9-tetradecenyl acetate (E9-14:OAc), (*E*)-and (*Z*)-9-dodecenyl acetate (E9-12:OAc and Z9-12:OAc, respectively) (Klun and Robinson, 1972; Klun et al., 1979; Struble et al., 1987; Glover et al., 1989), as well as (*Z*)-11-hexadecenal (Z11-16:Ald) (Gemeno et al., 2006; Linn et al., 2007a). These compounds have not been found as part of the pheromone blend of any *Ostrinia* species (Ishikawa et al., 1999b). As they have been found in other moth species, one could hypothesize that they have evolved under the private channel hypothesis, thus lowering the probability of cross attraction and, therefore, preventing male mistakes (Löfstedt, 1993; Cardé and Haynes, 2004). On the other hand, the antagonistic activity of some of these compounds may have no adaptive origin (no selective pressure for the emergence of the antagonism), but may be purely coincidental; these molecules may be able to interact with the

olfactory receptors implicated in the antagonist pathway because of their structural similarity to Z9-14:OAc (Linn et al., 2007a).

Smelling the Pheromone: The Male Olfactory System

The demonstration that the antennae of the ECB male are involved in the sex pheromone response came from a study by Klun in the late 1960's (Klun, 1968). This was consistent with observations reported earlier that established the antennae as the primary interface of olfactory reception in moths, and insects in general (Schneider, 1957, 1962). The antennae in both sexes are filiform, with about sixty flagellomeres, but the basal diameter of the antenna in the male is larger than in the female (Hallberg et al., 1994). The response resulting from the detection of a recognized odorant can be measured as an action potential, and electroantennograms (EAG) represent recordings of the summed electrical potentials being sent to the brain by ORNs for which odor stimulants elicit a response (Schneider, 1962, 1969; Mayer et al., 1984). The action potentials are transmitted so as to increase the response in the proximal direction only (Nagai, 1981). Typically, EAG potentials are visualized as negative change in the background potential.

The morphology of the antenna has been described, highlighting particular features of the antenna of male corn borers (Hallberg et al., 1994). Along the filiform antenna of corn borer males, the olfactory sensilla occupy the ventral surface, the dorsal surface being covered by scales (Cornford et al., 1973; Hallberg et al., 1994). Different sensillum types have been characterized, with the sensilla trichodea representing the most abundant type of sensillum found on the antenna (Hallberg et al., 1994). It was noticed that the highest EAG response was obtained when the ventral side of the antenna faced the air stream conveying the pheromonal stimulus (Nagai et al., 1977). This suggested that the sensilla housing olfactory receptor neurons sensitive to Z and E11-14:OAc are localized mainly on the scale-free ventral part of the male antenna and could, therefore, be the sensilla trichodea, given that these are more numerous on male antenna as opposed to female antenna (Cornford et al., 1973). Electrophysiological recordings from single sensilla trichodea indicated that the olfactory receptor neurons that respond to pheromone are housed within this type of sensilla (Hansson et al., 1987). In total, three subtypes of sensilla trichodea have been described on the ECB antenna: one longer type that is innervated by three sensory cells (trichodea A), and two shorter types innervated by two or one single sensory cell (trichodea B and C, respectively) (Hallberg et al., 1994). Note that in the female, only trichoid sensilla with two or three cells have been observed, and the trichoid sensilla appear shorter in females than in males (Hallberg et al., 1994). It was shown that the EAG response to the pheromone components is proportional to the length of the antenna that is stimulated, indicating that olfactory receptor neurons tuned to pheromone components occur regularly throughout the entire antenna (Nagai, 1981). Similarly, the fact that the ratio between the response to E and Z11-14:OAc remained constant, regardless of the length stimulated, suggested that the olfactory receptor neurons that respond to the major and minor pheromone components are distributed evenly along the antenna (Nagai, 1981). Therefore, the number of sensilla trichodea was predicted to be uniform per unit of surface area; this was confirmed by direct measurements (Nagai, 1981). Interestingly, the distribution of the various subtypes of sensilla trichodea along the antenna is uneven. The type A (three cells) is the most common type in the basal part, whereas in the distal part the majority of the sensilla are of the type B (two cells). In contrast, the type C sensilla (one cell) has an even distribution, and constitutes a large proportion of the sensilla present towards the tip of the antenna (Hallberg et al., 1994). The adaptive significance of this particular arrangement remains to be clarified.

Nagai et al. (1977) attempted to establish a link between antennal response recorded by EAG and the behavioral response of male exposed to the female sex pheromone by comparing the electrophysiological responses to Z and E11-14:OAc of Z and E strain males as well as to hybrid individuals. For individuals of the Z strain, Z11-14:OAc always gave a significantly larger EAG response than E11-14:OAc. Although the amplitude of the antennal response decreased throughout the lifespan of the preparation, the response E/Z ratio varied little over time; the E isomer eliciting a response about 70% of that elicited by identical amount of the Z isomer. On the other hand, no difference in the EAG response to the geometrical isomers could be detected when testing individuals of the E strain. Hybrids from reciprocal crosses were intermediate in their responses, although they appeared closer to the E strain males. However, other authors have reported that the E strain individuals have a stronger EAG response to E11-14:OAc than to Z11-14:OAc, making possible a distinction between the strains via EAG recordings (Linn et al., 1999). The amount used to stimulate the antenna during these tests appears critical, and this is certainly a factor that needs to be considered with particular attention.

Single sensillum recordings have revealed important differences between the subtypes of sensilla trichodea, and demonstrated that the strains are highly distinguishable in their electrophysiological responses (Hansson et al., 1987; Hallberg et al., 1994). In type A, one cell responds to the major pheromone component, the second cell to the minor

component, and the third to the behavioral antagonist. Type B sensilla houses cells that respond to the pheromone components only, whereas the single cell present in type C sensilla responds to either the major pheromone component or the behavioral antagonist (Hallberg et al., 1994). Typically, extracellular recordings of male antenna exhibit high-amplitude spike responses from an olfactory cell responding to the major pheromone component, and a low-amplitude spike from an olfactory cell responding to the minor component (Hansson et al., 1987; Hallberg et al., 1994). Furthermore, there is a positive correlation between the spike amplitude and the spike frequency of olfactory receptor neurons (Cossé et al., 1995). The existence of a correlation between spike size produced by stimulated pheromone-responding olfactory receptor neurons and the diameter of the neurons' dendrites has been demonstrated by morphometric measurements (Hansson et al., 1994). Thus, spikes with large amplitude are produced by receptor neurons that are larger than the receptor neurons that elicit spikes of small amplitude. One possibility is that a larger dendrite diameter may be facilitating the presence of more receptor sites specific for the pheromone component to which the olfactory receptor neuron is tuned; the consequence being a higher sensitivity to that component and an action potential of higher amplitude (Hansson et al., 1994; Cossé et al., 1995). Similarly, the outer dendritic segments taper distally in the sensillum (Hallberg et al., 1994). This gradual narrowing of the dendrite diameter towards the tip theoretically optimizes the charge transfer to the dendritic root while minimizing the dendrite volume (Cuntz et al., 2007).

The response profiles obtained from electrophysiological recordings of male corn borer antenna, as well as those for other species, suggested that the main pheromone component always elicits response from OR neurons displaying large spike amplitude, and that the behavioral response may be influenced by the spike amplitude and frequency evoked when these cells are stimulated. However, the results reported by Cossé et al. (1995) indicate that the behavioral response is not necessarily elicited by the component that evokes responses from the large spike amplitude neuron in olfactory sensilla because F2 hybrid males possessing Z-like antennae from an electrophysiological viewpoint responded behaviorally to the E blend. To test whether or not the antennal phenotype is a controlling factor in pheromone blend discrimination, Linn et al. (1999) used an antennal transplant technique to produce individuals with mixed phenotypes for antennal and behavioral responses. Their results were in agreement with the study of Cossé et al. (1995), and suggested that the sex pheromone preference of males is independent of the make-up of the peripheral sensilla and is, therefore, determined at a higher level. However, because the actual projection pattern of the ORNs is unknown, no firm conclusion can be drawn.

The investigations conducted to identify the female sex pheromone of the ECB have revealed also that the olfactory system of the male is organized such that it can detect small variations in the geometric composition of the attractant, and that each strain responds optimally to different geometrical proportions of Δ11-tetradecenyl acetate (Klun et al., 1973). Although the major sex pheromone component is Z or E11-14:OAc, the insect is obviously exquisitely sensitive to small amounts of the opposite isomer (Klun et al., 1973). No increase in EAG response was found when antennal preparations were stimulated with mixtures at the ratios found to be best in field trials (Nagai et al., 1977). Single sensillum responses from olfactory sensilla on the male antenna clearly indicated that the two pheromone-components are detected by different specialized receptors (Hansson et al., 1987; Löfstedt et al., 1989). Also, electrophysiological recordings from single sensilla indicated that, irrespective of the strains, all males have sensory cells sensitive to both pheromone compounds (Hansson et al., 1987). Taken together, these results can be interpreted as further indication that the pheromonal signal is integrated at a higher echelon than the peripheral level. The central nervous system input from the cells appears to be differentially interpreted to give the various phenotypic behavioral responses observed (Roelofs et al., 1987).

Understanding the central nervous processing is necessary when trying to link the processes that occur at the periphery with behavioral responses. Sex pheromone receptor neurons project into the antennal lobe, the first-order olfactory brain area, through the antennal nerve (Hansson, 1995). The antennal lobe comprises a number of glomeruli in which synaptic contacts are made between receptor neurons, projection neurons, and interneurons (Hansson, 1995). Each receptor neuron arborizes in a single glomerulus within the antennal lobe (Anton et al., 1997). Based on three-dimensional reconstructions that allow high resolution of the antennal lobe neuroanatomy, the number of glomeruli in the antennal lobe of Z strain male and female individuals was estimated to be approximately 66 and 64, respectively (Karpati et al., 2008). Located at the entrance of the antennal nerve of male moths, a few enlarged glomeruli dedicated to the reception of pheromonal information constitute the macroglomerular complex (MGC). The number of glomeruli that form the MGC compartments is variable between species and can be an indicator of the number of sex pheromone components, as well as pheromone antagonists detected by highly specialized olfactory receptor neurons. In *O. nubilalis*, the MGC of both E and Z strain males consists of three enlarged glomeruli (Anton et al., 1997; Karpati et al., 2008). Two

large highly convoluted and interdigitated glomeruli of variable shape and dimension receive information from E11 or Z11-14:OAc-responding ORNs, and the third glomerulus, located posteriorly to the two others, is dedicated to Z9-14:OAc, a behavioral antagonist (Anton et al., 1997; Karpati et al., 2008).

The two strains are indistinguishable on the basis of the neuroanatomy of their MGC: in both strains, ORNs that respond to the major pheromone component arborize in the largest medial glomerulus of the MGC, whereas the minor pheromone component-specific ORNs arborize in a smaller lateral glomerulus (Karpati et al., 2008). Olfactory output is made by projection neurons that have dendritic branches in the MGC and axons projecting through the inner antennocerebral tract to the calyces of the mushroom bodies and the lateral protocerebrum (Hansson, 1995; Anton et al., 1997). In the ECB, neurons are classified according to the component eliciting response at the lowest level of abundance, namely E or Z. E+Z-blend neurons respond equally to the same levels of Z and E isomers and mixtures of the two isomers (Anton et al., 1997). Recordings and staining of projection neurons responding to E or Z11-14:OAc show that they arborize only in the E or Z11-14:OAc-specific compartment of the MGC, respectively (Karpati et al., 2008). Similarly, projection neurons that exhibit a larger sensitivity to a blend rather than to either of the pheromone component alone arborize in both pheromone-sensitive MGC glomeruli (Karpati et al., 2008). Finally, neurons described in Anton et al. (1997) as generalist are most likely local interneurons arborizing in most if not all glomeruli (Karpati et al., 2008). Interestingly, the type of blend neurons that discriminate strain-specific blends is apparently consistent with the behavioral profile of each type of male (Anton et al., 1997). This might explain, in part, the ability of insects to discriminate behaviorally between the pheromone ratios of the different strains (Anton et al., 1997). However, it is still unclear whether these neurons are essential in the behavioral response that follows detection of different ratios of pheromone components (Karpati et al., 2008). Irrespective of their type, the antennal lobe neurons differ in their absolute sensitivity (Anton et al., 1997). It is worth mentioning that both receptor and antennal lobe neurons respond to both pheromone isomers when stimulated at high concentrations, while specific responses of the neurons are observed only at lower concentrations (Anton et al., 1997). Therefore, it is important to bear in mind that the pheromone concentrations and ratios used in electrophysiological experiments should be within the natural range that males may encounter.

The males of both pheromone strains and reciprocal hybrids exhibit the same neuron types, but the abundance of these types differs between the types of males, which indicates the existence of strain-specific characteristics at the antennal lobe level (Anton et al., 1997). The two strains have an identical MGC morphology accompanied by a reversed functional topology, with both olfactory receptor neurons and projection neurons displaying opposite innervation patterns (Karpati et al., 2008). Karpati et al. (2008) proposed that the occurrence of an interchange of olfactory receptors between pheromone receptor neurons within the same sensillum would explain the finding of a reversed functional topology, while olfactory receptor neuron and projection neuron arborization patterns in the MGC remained unchanged. The pheromone receptor neurons would always arborize to the same location in the MGC but the ORs expressed within the membrane of their dendrites would be tuned to a different pheromone component, thus leading to an opposite behavioral response. One may argue that such a receptor swap occurs when antennae are transplanted from one strain to the other, such as reported by Linn et al. (1999), who observed maintenance of the behavioral response of the implanted strain, which is not according to the prediction. However, because of a lack of information concerning the neuroanatomy of individuals that undergo antennal transplantation and, in particular, how the axonal targeting of olfactory receptor neurons is influenced, no definitive conclusion can be drawn from this type of experiment. Further studies are required to elucidate what factors determine the type of receptor expressed in a particular olfactory receptor neuron, and the arborization path followed by the sensory axon of that olfactory receptor neuron. Recently, a series of ORs responding to pheromone components has been identified in the ECB (Wanner et al., 2010). ORs appear to be narrowly and broadly tuned, with some responding nonspecifically to (*E*) and (*Z*)-11- or -12-tetradecenyl acetate, as found in *O. scapulalis* (Miura et al., 2010; Wanner et al., 2010); the latter E and Z12-14:OAc constitute the pheromone components of a close relative of the ECB, the Asian corn borer *O. furnacalis* (Ishikawa et al., 1999b). Previous electrophysiological recordings of ORNs indicated that ECB males possess ORNs responsive to E and Z12-14:OAc, and that these ORNs are, indeed, the same large- and small-spiking ORNs responsive to the ECB pheromone components (Domingue et al., 2006, 2007b). Some rare ECB males may be attracted to the Asian corn borer blend (Linn et al., 2003, 2007b); this alteration in the normal behavior might be caused by a firing ratio of ORNs responsive to E and Z12-14:OAc close to the ratio observed in response to the attractive ECB blend (Domingue et al., 2007b).

Many advances have been made during the last 30 years, and we have a much better understanding of

the ECB male olfactory system. Nevertheless, the precise mechanism leading to blend discrimination remains unknown. Most studies have used neurophysiological approaches, and the molecular bases of pheromone detection in ECB are yet to be unraveled. For example, the actual diversity of ORs in ECB, and what factors determine on which sensory dendrites they are expressed, remain essentially unexplored.

Genetics of Male Response

As the genetics underlying ECB sex pheromone differences was investigated, the heredity of male sexual response preferences toward specific mixtures of Δ11-tetradecenyl acetate was also scrutinized. Two types of response are distinguishable: the physiological response at the level of male antennae, and the behavioral response of males.

Electrophysiological recordings from single olfactory sensilla on male antenna showed that the reaction patterns of males from the two strains are distinguishable (Hansson et al., 1987; Roelofs et al., 1987). Males from the first filial generation were characterized as intermediate by displaying two types of olfactory cells that gave similar spike amplitudes to the E and Z isomers (Hansson et al., 1987). The inheritance of the response profiles is determined by a single autosomal gene with two alleles (Hansson et al., 1987; Roelofs et al., 1987). Because the locus controlling female pheromone production also was found to be autosomal, the possible linkage of the two loci or the existence of a single locus that determines both phenotypes came to be questioned. Evidence showed that even if the inheritance of pheromone production and the electrophysiological response of pheromone receptor cells are most often coupled in a complementary fashion, so that production and response are coordinated, their coordination can be uncoupled in matings among individuals of opposite types (Klun and Huettel, 1988). The experiments conducted by Löfstedt et al. (1989) demonstrated unambiguously the absence of a close linkage between the autosomal genes that determine the sex pheromone production and the organization of olfactory receptors in *O. nubilalis*. That was the first time where the degree of genetic linkage between characteristics of the sender and responder in a pheromone communication system had been investigated.

In terms of behavioral response profile, the F1-generation hybrid males from reciprocal crosses exhibited similar response profiles with about 50% of the males being attracted to different ratios of geometrical isomers (97:3, 65:35, 50:50, 35:65 Z/E), with the noticeable exception of the 1:99 Z/E blend that seldom attracted males (Roelofs et al., 1987; Glover et al., 1990; Linn et al., 1997). The remaining 50% of the F1 progeny do not respond to any blend (Roelofs et al., 1987; Glover et al., 1990). In Lepidoptera, males are the homogametic sex, usually denoted ZZ, and the females are the heterogametic sex, denoted ZW. The observation that paternal backcrosses to Z or E strains gave individuals with response profiles similar to that of the pure Z or E parent males indicated that the inheritance of the behavioral response is determined by a major sex-linked factor (Roelofs et al., 1987). It is not known if this major factor consists of a single gene or whether it consists of a set of closely linked genes. The demonstration that male behavioral response is determined by a locus present on the sex chromosome was made by using triose phosphate isomerase (TPI) an allozyme marker for the Z chromosome (Glover et al., 1990). A perfect match between the phenotype at TPI and the response profile of males indicated a complete linkage of the TPI locus and the locus controlling response to sex pheromone, thus confirming the sex linkage of male behavior (Glover et al., 1990). There was evidence for little recombination between the allozyme marker locus and the male behavior locus (Glover et al., 1990). It is worth mentioning that the phenotype at TPI may not always differ between populations of the E and Z strains, as reported by Cianchi et al. (1980). Genetic mapping of male response showed that TPI and the locus responsible for the difference in male behavioral response are not tightly linked, and a factor other than response to pheromone may maintain the linkage disequilibrium between TPI and response (Dopman et al., 2004, 2005).

Since the locus controlling male behavioral response is sex-linked, and the locus determining male electrophysiological response is autosomal, it appears evident that these loci are not linked and may segregate independently. For this reason, certain crosses between the E and Z strains should produce unusual males that respond behaviorally to one blend despite possessing antennae that respond electrophysiologically to the opposite blend. A study was undertaken to examine whether or not these unusual males possessing the wrong antennae can perform a complete behavioral sequence in a wind tunnel experiment. Males were produced through F2 crosses between the two races and the analysis of the spike amplitudes obtained with recordings of E-behavioral responders revealed that some males with Z-like antennae can fly to the E pheromone source (Cossé et al., 1995). This provided further support for the idea that the sex-linked factor associated with behavioral response affects the way an incoming signal from the antenna is processed in the central nervous system of male moths. The sex-linked factor that controls the behavioral response profile of males may, therefore, influence the architecture of the antennal lobe. The pattern

of neuron types found in the antennal lobes of hybrid or pure strain males coincide to some extent with the behavioral profile (Anton et al., 1997). Unfortunately, the limited number of recordings made did not allow the authors to draw any firm conclusion, despite striking coincidence. A study that focuses on males obtained from paternal backcrosses (EZxZ and ZExE), which should possess to a large extent only Z- or E-blend neurons, should give a clue regarding the link between discrimination of different ratios of pheromone components at the level of the antennal lobe and the behavioral response profiles of males, thus providing a physiological basis for the differences in behavior. The finding that the functional topology of the MGC in Z and E strain males is reversed (Karpati et al., 2008) indicates that further research is still required.

Given that the loci for sex pheromone production, male electrophysiological response, and male behavioral response are on different pairs of chromosomes, the response and the signal are not expected to be physically linked in this pheromone system.

Evidence for A Male-Produced Pheromone

Laboratory tests conducted under confined conditions have indicated that the two ECB strains are not freely interbreeding, which may result from the action of a chemical governing sexual behavior at close range (Liebherr and Roelofs, 1975; Pélozuelo et al., 2007). The detection of the incorrect substance may inhibit a large proportion of the females from accepting the mating overture (Liebherr and Roelofs, 1975). Males possess on both sides of the claspers and at the intersection between the 7th and 8th sternites two tufts of differentiated scales called hairpencils. The first clear evidence for the existence of a male pheromone in the ECB came from the observation that males deprived of their hairpencils have a decreased mating success (Royer and McNeil, 1993).Recently, the pheromone from hairpencils was demonstrated to play an crucial role in female choice, and was identified in the Z strain as a mixture of 16-carbon acetates, namely (*Z*)-9-hexadecenyl acetate, (*Z*)-11-hexadecenyl acetate, (*Z*)-14-hexadecenyl acetate, and hexadecanyl acetate (Lassance and Löfstedt, 2009). The bouquet produced by males of the E strain was found to be of similar composition but lacked (*Z*)-11-hexadecenyl acetate in most individuals (Lassance and Löfstedt, 2009). The behavioral significance of this difference in composition remains to be firmly demonstrated.

Males produce compounds that are structurally similar to those used by females, and both sexes appear to rely on the same genes to produce their pheromones. This finding raises interesting questions concerning the coevolution of the two traits, and especially for the coevolution of the two detection systems.

Concluding Comments

One of the purposes of investigating the European corn borer chemical ecology was to provide new tools to monitor and control the pest. Trapping systems that rely on synthetic sex pheromone have been used to catch the attracted males and monitor adult activity (Pélozuelo and Frérot, 2007). However, the information gathered from such pheromone-baited traps may be taken with circumspection as it is still unclear how well moth phenology correlates with trapping data and, while only males are captured, their mating status is unknown (McNeil, 1992; Pélozuelo and Frérot, 2007). The obvious potential of semiochemicals should not be questioned, but increasing our knowledge of the factors that influence their efficacy and how to interpret what we observe is necessary.

One line of ECB research that has not been sufficiently pursued is host plant selection by females. Whereas the ECB owes its name to the use of maize as a host, the insect can thrive on more than 200 plants species (Caffrey and Worthley, 1927). Little is known about what criteria determine the suitability of a host, in particular, what are the cues that make a host attractive to gravid females. The two pheromone strains may differ in their host preference, as exemplified by studies conducted in Canada, the U. S., and France (McLeod, 1981; Straub et al., 1986; Eckenrode and Webb, 1989; Bontemps et al., 2003; Thomas et al., 2003; Pelozuelo et al., 2004). The use of transgenic maize that express *Bacillus thuringiensis* toxin, and the associated strategies that prevent the emergence of resistance, require a better knowledge of the host range actually used by ECB in the field. Is *O. nubilalis* a truly opportunistic polyphagous species, or is it a mosaic of host-plant races hidden under the same name?

The two strains of *O. nubilalis* are sufficiently isolated to be considered as sibling species but still compatible enough from a genetic point of view to produce fertile offspring. As such, the ECB has become a model to study the evolution of sex pheromone communication (Smadja and Butlin, 2009). A series of studies have elucidated the genetic bases of the polymorphism observed in this sex pheromone communication system. While the gene responsible for the differences in female-produced sex pheromone has been characterized, those involved in the differences in male behavior and antennal responses are still unidentified. The two pheromone strains of *O. nubilalis* constitute a unique system to investigate how speciation affects different parts of the genome.

The apparent simplicity of the ECB communication system, as it turns out, has ample hiden complexity, and, as some who spent some years investigating the ECB chemical ecology say, "the more answers we obtain with the ECB, the more questions we get in return". The recent identification of the male-produced pheromone, a trait acting as a reproductive barrier between the strains, opens a new dimension of ECB research. Fascinating discoveries may be just around the corner, and corn borers probably have many more secrets to reveal.

Acknowledgements I thank Christer Löfstedt, Charles Linn Jr, and two anonymous reviewers for their comments on a previous version of the manuscript, and Christer Löfstedt for his support.

mass spectrometric analysis of ink supernatant indicated high levels of epinephrine in ink stripped from the intact ink sacs of dead specimens (Fig. 1). Since there were no previous reports of significant levels of epinephrine in cephalopod ink, we concluded that the finding was either a significant novel discovery or an artifact resulting from contamination by autolysis or the sampling method.

Catecholamines, such as dopamine, nor-epinephrine, and 5-hydroxytryptamine were documented from the nervous tissue of cephalopods as far back as 1971 (Juorio, 1971). Subsequently, epinephrine has been found in the haemolymph of the curled octopus *Eledone cirrhosa* (Lacoste et al., 2001) and also reported from other tissues such as nerves in trace amounts (Springer et al., 2005).

Consequently, the observation of an epinephrine spike in the ink of *S. australis* was of interest. The possibility was raised that epinephrine in its ink may have evolved as an allelochemical against vertebrate predators with respiratory surfaces exposed to sea water.

Of the other non-melanin components of cephalopod ink, the presence of the enzyme tyrosinase commonly is reported (e.g., Prota et al., 1981; Derby, 2007) and was suggested as the component responsible for anti-tumour activity in mammalian cells (Takaya et al., 1994; Naraoka et al., 2000). However, the physiological or behavioral significance of ejecting tyrosinase into sea water in response to a predator or as a signal of alarm to conspecifics is difficult to explain.

Along with DOPA, dopamine, and taurine, the presence of proteins in cephalopod ink is widely accepted. For example, Linh Tran et al. (2006) emphasised the claim that melanins *in vivo* are strongly bound to a protein host and that sample preparation frequently removes the protein, leaving subsequent studies to focus on the chromophore alone. Similarly, Meredith et al. (2006) suggested that the term melanin should 'encompass both the chromophore and the associated protein'. The presence of proteins within the eumelanin structure also has been suggested by Meng and Kaxiras (2008).

Two major obstacles have stood in the way of describing fully the chemical structure of the melanin complex. It has a monotonous absorbance pattern in the visible and near UV part of the spectrum. It is insoluble in all useful solvents, and thus, it defies structural analysis (Linh Tran et al., 2006).

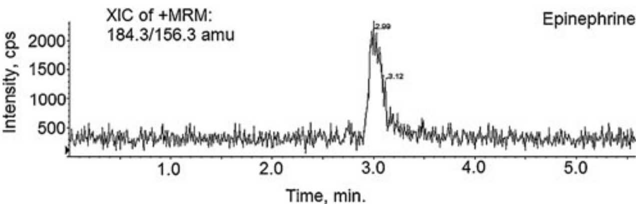

Fig. 1 Chromatogram of epinephrine in diluted ink from the ink sac of *Sepioteuthis australis*

Our initial discovery of a spike of epinephrine, along with a question about the biological justification for ejecting tyrosinase with ink led to this investigation. The aim was, therefore, to measure the levels of epinephrine and protein in the ink of *S. australis* specimens. Because of a suspicion that the epinephrine in our initial sample may have been an artifact, we undertook to compare the ink recovered by methods that minimized the chance of contamination from ink sac tissues (Syringed ink from freshly caught specimens), with that recovered by more traditional procedures (Stripping Method).

Histological studies of the ink sac were performed, along with comparative analyses of ink sampled from *S. australis* by each procedure.

Methods and Materials

Histological Structure of the Ink Sac The ink sacs of five *S. australis* were dissected from freshly-caught specimens and fixed in buffered formalin. They were infiltrated subsequently with paraffin wax, and a series of transverse and longitudinal histological sections was cut and stained with haematoxylin and eosin. Sections were viewed under the microscope, and representative views were photographed for analysis.

Ink Sampling Ink samples from specimens of *S. australis* were collected for comparison by two different methods:

> *Syringed Ink Method*. Squid were caught along the South Australian coast, placed 'live' on a bed of ice, and anaesthetized with a $MgCl_2$ spray (Messenger et al., 1985) before being killed by decapitation across the edge of the mantle (i.e., posterior to the pleuro-visceral ganglion) to avoid stimulation of ink release. The mantle cavity was opened immediately along its ventral surface, and the proximal end of the ink sac was freed from the surrounding tissue. The duct end of the ink sac was cut off with sharp scissors and held open with forceps before the ink was carefully drawn from the distal lumen with a 1 ml syringe fitted with a yellow (200 μl) automatic pipette tip. The sample then was transferred to an Eppendorf tube, taking care not to touch the outside surface of the syringe onto the lip of the tube. Samples were held on ice until they were stored at −80°C.
>
> Attempts to run this difficult collection protocol rendered only 6 ink samples with a sufficient volume of uncontaminated ink from approximately 30 squid caught. Many squid had emptied their ink sacs prior to

sampling attempts, or it proved impossible to introduce the tip of the syringe into the ink sac without contamination from external fluids. Problems also arose from the tendency of the pipette tip to adhere to the inside of the sac unless the fluid was drawn up very slowly. However, sufficient material was removed from stored material near the duct of the ink sac for analysis, representing uncontaminated ink. Of course, the nature of the ink could change once it was ejected into sea water, but that was not the focus of this study.

Milked Ink Method. Fresh squid were purchased within a day of being caught and held on ice (not frozen) by arrangement with Valente Seafoods, Adelaide, Australia. Dead animals were taken to the laboratory on ice, and the ink was extracted as soon as possible by the following method. The mantle cavity was opened along its ventral surface and the entire ink sac dissected out. The duct end was cut off and held over an Eppendorf collection tube while the ink was 'milked' by running forceps down its length, taking care not to introduce external fluids. Samples then were held on ice until stored at −80°C.

These samples represent ink contaminated with exudates from cells after autolysis, contents of the ink gland chambers, and possibly materials from the external surface of the ink sac.

Determination of Epinephrine, DOPA, Dopamine, and Taurine HPLC grade acetonitrile was obtained from Biolab (Australia). DL-DOPA, DL-dopamine, taurine, epinephrine/adrenaline, and ammonium acetate were purchased from Sigma-Aldrich (Australia). Water was purified for HPLC analysis by using a Milli-RQ ultrapure Water System (Millipore, USA).

Ink sampled by either method (about 50 mg) was vortex mixed with water, centrifuged, and the supernatants diluted 10 times with water. These unwashed samples were analyzed directly. Additional samples were washed repeatedly with water to remove soluble material, and the recovered melanin was suspended in 10 volumes of water and stirred for 2 hr at ambient temperature. The extract was centrifuged, and aliquots of the supernatants were transferred to autosampler vials for analysis.

The analytical equipment consisted of a solvent delivery system comprising two Shimadzu LC-10ADVP pumps used isocratically, a DGU-14A degasser, and SIL-HTC auto sampler (Shimadzu, Japan) held at 10°C. The HPLC system interfaced with a triple stage quadruple mass spectrometer (API 3000, Applied Biosystems, Canada) via an electrospray source. Instrument control, data acquisition, and data analysis were performed with Analyst software V1.4.1 (Applied Biosystems). For each analyte, MRM transitions were optimized in the positive mode by infusing the relevant reference compound; DOPA 298.3→152.3, dopamine 154.3→137.3, epinephrine 184.3→166.3, norepinephrine 170.3→152.3, and taurine 126.0→108.0. A Hilic C18 column (3×50 mm, Phenomenex) equipped with a matched guard was used with a mobile phase consisting of 30% acetonitrile and 10 mM aqueous ammonium acetate, delivered at a flow rate of 0.2 ml/min. The injection volume was 10 µl. Reference solutions were prepared fresh on the day.

Determining Protein in Ink Supernatants Mushroom tyrosinase, L-3, 4-Dihydroxyphenylalanine (L-DOPA), bovine pancreatic trypsin, subtilisin A, and pepsin were obtained from Sigma (St. Louis, MO, USA). SDS-PAGE was performed by using ready-made (NuPAGE) 4–12% (1.5 mm thick) SDS-acrylamide gels, MOPS-SDS running buffer, and SDS sample buffer. These were all obtained from Invitrogen Pty Ltd. Agarose was obtained from Amersham Biosciences Pty Ltd. All other chemicals used were of analytical grade.

To 300 µl of the ink sample, 100 µl of 50 mM Tris–HCl pH 8.0 was added. The mixture was vortexed at maximum speed for 30 sec and allowed to stand overnight at 4° C. The mixture was vortexed again for 30 sec and centrifuged at 13,000 rcf for 10 min. Fifty µl of the ink supernatant was mixed with SDS-PAGE sample buffer and incubated at 70° C for 10 min (all samples were non-reduced so that the tertiary structure of the proteins was preserved). Ten µl of the ink-SDS buffer incubate was loaded onto an SDS-acrylamide gel plate. The gel was run in a 1:20 dilution of MOPS running buffer made from a concentrated stock buffer solution. The gel was stained with a 0.1% (w/v) coomassie brilliant blue R-250 solution and de-stained in an acetic acid-water–methanol mixture (1:5:5).

Determining Electrophoretic Mobility of Proteins Present The method of Madaras et al. (2005) was used. Proteins in this method separate out on the basis of net protein electric charge, and the separation is not dependent on protein size. Electrophoresis was done by using a sodium barbitone buffer pH 8.6 where all the proteins that migrate towards the positive electrode possess a net negative charge. One µl of the Tris–HCl ink extract was loaded into an agarose gel plate sample well. Electrophoresis was performed by using 50 mM sodium barbitone buffer (pH 8.6, at ~2 Vcm^2). The gel was stained as described for SDS acrylamide gels. The stained protein bands were evaluated by the Gel-Pro Analyzer (Media Cybernetics USA) computer imaging software.

Enzyme Digestion of the Melanin Fraction Although no proteins could be detected in the Syringed Ink supernatant,

the possibility remained that some proteins were covalently linked to the melanin surface and were not detected in the supernatant or a melanin emulsion. To investigate this possibility, a series of experiments was performed using proteolytic enzymes to see whether proteins could be digested from the melanin. For this experiment, six ink samples from each group (Syringed or Milked Ink) were pooled (~600 µl) and washed repeatedly using un-buffered 0.15 M NaCl. The ink was suspended in the solution, vortexed at maximum speed for 30 sec, centrifuged at 13,000 rcf for 5 min, and the supernatant discarded. This process was repeated x 5. The washing process was designed to remove any freely soluble proteins present in the melanin ink leaving only the melanin particles.

The washed ink pellet was divided into two aliquots, and two different enzyme digests were prepared: one using 200 µl pepsin (0.05 mg/ml final concentration) at pH 1.0 in 0.1 M HCl, and the other using 200 µl trypsin (0.03 mg/ml) and subtilisin A (0.02 mg/ml final concentration) at pH 7.5 in tris-buffered saline pH 8.0. The washed melanin precipitate and enzyme mixtures were incubated at 37ºC for 4 h with occasional mixing. The digests then were centrifuged at 13,000 rcf for 10 min and examined for the presence of proteins by SDS-PAGE as described above.

As a positive control to demonstrate enzyme digestion, human albumin was used at 0.5 mg/ml concentration. The proteolytic enzyme concentrations and the conditions for the digestion of albumin were the same as those used for the melanin.

*Tyrosinase Assay T*yrosinase activity was assayed by the dopachrome method (Fling et al., 1963) as follows. The standard reaction mixture contained the substrate (5 mML-DOPA) in 0.1 M sodium phosphate buffer (pH 6.8), and 10 µl of the ink supernatant (as described above) were added to 990 µl of the L-DOPA substrate. The reaction took place in a micro cuvette with a path length of 1 cm, and the absorbance at 475 nm was monitored continuously for 10 min with a spectrophotometer (Shimadzu UV-1601) at 25º C. One unit of tyrosinase was defined as the amount of enzyme required to oxidize 1 µmol of L-DOPA per min under the above conditions, and calculated by using the molar extinction coefficient of dopachrome (3600 M−1 cm−1). For a positive control tyrosinase enzyme (mushroom> 1000 unit/mg) was used.

Results

Investigating the Histological Structure of the Ink Sac Histological sections revealed a mass of glandular tissue at the base of the ink sac, which sometimes extended over half way along the length of the lumen (Fig. 2). This mass seemed to comprise a series of compartments and ducts that increased in size as they matured and moved further into the lumen of the sac. The large spaces further away from the basal layer were filled with ink.

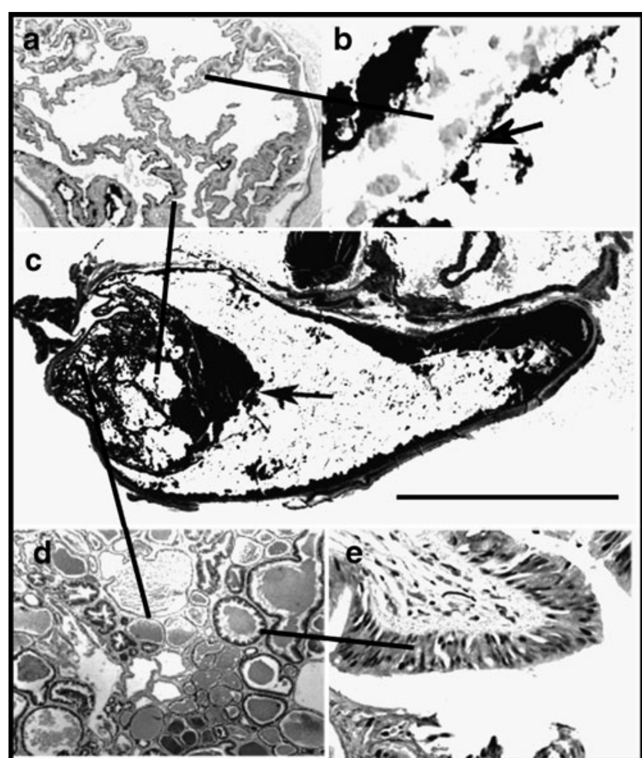

Fig. 2 Histological sections of the ink sac of *Sepioteuthis australis*. Legend: **c** Longitudinal section of whole ink sac (*arrow* indicates basal glandular area); Scale bar 10mm; **a** Melanin-producing reticulated tissue; **b** Melanin Granules in cells; **d** Mixed tissue (follicles and mucous ducts?) at the base of the gland; **e** Mucus-producing epithelium

Three distinct histological elements were found within the glandular tissue: apparently enclosed follicles that contained light-staining material (Fig. 2d); ducts lined with mucus-secreting cells (Fig. 2e); and reticulated epithelial layers with melanin granules visible in the cytoplasm of cells (Figs. 2a and b). It was not possible, without detailed serial-sectioning, to positively determine whether the glandular tissue was either comprised of closed follicles or tubular glandular epithelium, or a combination of both (Fig. 2).

Determination of the Presence of Epinephrine, DOPA, Dopamine, and Taurine After centrifugation of the diluted Milked Ink, substantial amounts of DOPA and taurine were recorded consistently (mid to high ppb range). Since the initial viscosity of the collected ink samples ranged from liquid to paste for different specimens, and analysis was performed directly after dilution, no attempts were made to quantitate the catecholamines. Dopamine was present to a lesser extent, but varied depending on the individual

samples. In some ink isolates, significant amounts (low ppb range) of epinephrine and nor-epinephrine were found (Fig. 1). These levels fluctuated among ink samples, and often no trace of either analyte was found in ink samples from different animals.

The same observations were made when melanin was separated from the supernatant. Suspensions of melanin, purified to different extents, were allowed to stir for 2 hr. After centrifugation and analysis of the supernatants, the presence of all the previously mentioned compounds was evident. Interestingly, dopamine was released into solution at a much slower rate than DOPA.

By contrast, supernatant from Syringed Ink showed no measurable traces of epinephrine or nor-epinephrine. This result matched that found for the protein content of Syringed Ink. However, DOPA, dopamine, and taurine were detected consistently in all ink supernatants, or were found to desorb from separated melanin, regardless of the method used to collect the original ink (Fig. 3).

Determining the Presence of Protein in Ink Supernatants Figure 4 shows the non-reduced SDS-PAGE of Milked and Syringed ink samples. No proteins were found in the Syringed Ink extracted from 'live' animals, while the Milked Ink samples yielded strong indications of protein. The purpose of the SDS surfactant was to mobilize all proteins according to size by negating charge. From the result, it was concluded that the protein present fell into a narrow mass range, or was mainly a single component.

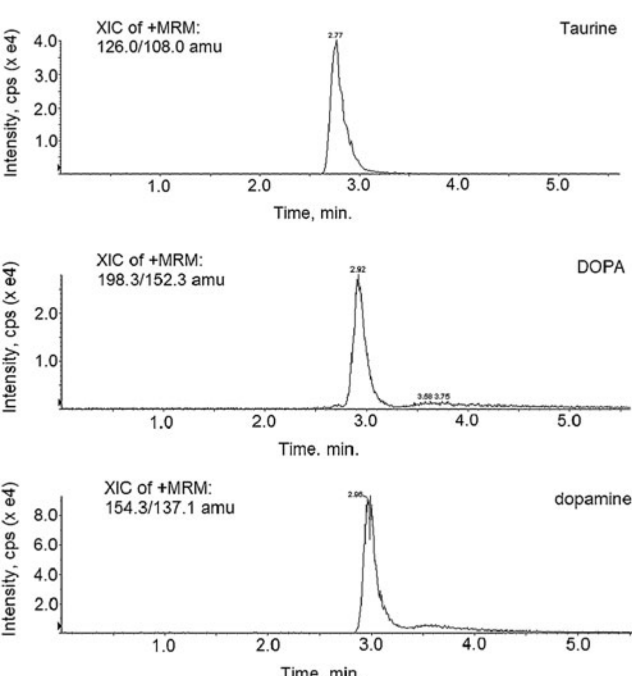

Fig. 3 Chromatograms of taurine, dopa and dopamine in ink collected by the Syringed method. The individual molecular ion→fragment mass transitions are shown separately and the scale varied according to each specific sample

Determining the Electrophoretic Mobility of the Proteins Present in Ink Sample Supernatants Figure 5 shows the agarose gel electrophoresis and protein scan on the pooled ink supernatants for which protein bands previously had been detected by SDS-PAGE (Fig. 4). Proteins in this method separated out on the basis of the net protein electric charge, and the separation was not dependent on the protein size. There was only one major protein band visible. This result, in conjunction with the SDS-PAGE result, once again indicated that the major protein in the ink found in these samples was composed largely of one high molecular weight protein that carried a net negative charge at pH 8.6.

Enzyme Digestion of the Melanin Fraction of Ink to Release Bound Proteins Figure 6 shows the results of the protein digestion experiments on the washed ink melanin. No protein could be detected when the melanin was obtained from Syringed Ink. However, protein was detected in both the pepsin and trypsin-subtilisin digested melanin collected by the Milked Ink Method. This most likely is due to precipitated and denatured protein that could not be removed by the washing process. Once exposed to the enzymes, soluble protein-peptides were released. The positive control experiment showed that both pepsin and trypsin-subtilisin completely digested albumin during the 4 hr incubation, and that the enzymes themselves are not detectable on the SDS-PAGE gel at the concentration used in the digestion experiment (Fig. 7).

Tyrosinase Assay on the Ink Samples Table 1 shows the residual tyrosinase activity in the Syringed Ink samples compared with the Milked Ink samples. While none of the Syringed Ink samples showed tyrosinase activity, the Milked Ink showed values comparable to the positive control that used commercial tyrosinase.

Discussion

The study of cephalopod ink involves several approaches. First, there is the biological approach, which seeks to understand the significance of inking behavior for the biology of a species. This may include an interest in the production of: 'smoke screens' and pseudomorphs (Bush and Robison, 2007), allelochemicals (Lucerno et al., 1994), or alarm signals to conspecifics (Wood et al., 2008). Recent elegant work has shown it to be a combination of these factors (Wood et al., 2010). The approach taken in the current study is, therefore, interested primarily in the nature of the ink as it would be ejected from the ink sac *in vivo*.

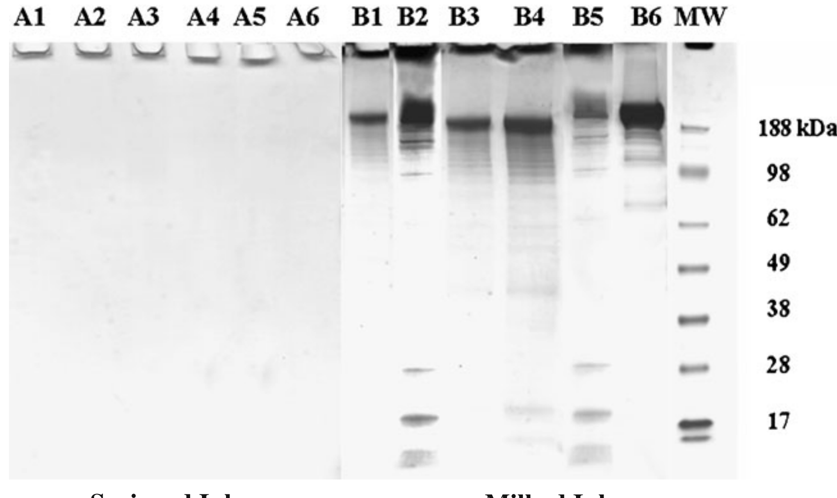

Fig. 4 Shows the non-reduced SDS-PAGE on ink samples; A1 to A6 were independent Syringed Ink samples from 6 different animals and B1 to B6 were independent Milked Ink samples from 6 different animals. MW is the molecular weight standards used

A second approach focuses on the cellular biochemical mechanisms of melanin synthesis where the intra- and extra-cellular location of enzymes and substrates is of interest (such as in melanosomes, etc.) (e.g., Palumbo et al., 1997; Palumbo, 2003). A third approach has no particular interest in cephalopod biology or melanin synthesis. Rather, its focus is on the utility of the ink for culinary or therapeutic purposes (Russo et al., 2003; Lei et al., 2007). Finally, the ink of cephalopods often is used in studies that attempt to determine the structure of melanin itself (Linh Tran et al., 2006; Meredith et al., 2006: Meng and Kaxiras, 2008).

However, despite the variety of perspectives taken in the study of cephalopod ink, no real attention has been given to the definition of its actual provenance. Because of the paucity of information about cephalopod ink sac structure and histology, no distinction seems to have been made between material located within the glandular chambers of the ink sac and that stored in the ink sac lumen and ready for ejection.

The results of experiments conducted on the ink of *S. australis* indicated that there was no epinephrine or protein naturally present in the supernatant of ink carefully syringed from the duct end of the ink sac in freshly-killed animals (Syringed Ink). By contrast, there were proteins (and possibly epinephrine) in samples milked from the ink sacs of dead specimens.

The SDS-PAGE experiment showed that all the protein present fell within a narrow mass range, while agarose gel

The enzymes alone are not detectable (at the concentration used in the digestion experiment), "8" molecular weight standards

electrophoresis, which separates proteins based on net electric charge, also indicated a single protein having an overall negative charge. Further analysis indicated that a single large molecular weight protein predominated in the non-melanin fraction of Milked Ink. Ink samples that contained this protein had strong tyrosinase enzyme activity.

In pursuit of proteins which may have been bound to the melanin fraction of the ink, and hence not evident in electrophoresis experiments, we performed digestion experiments to liberate such tightly bound species. No indication was found of the presence of bound proteins in the Syringed Ink samples. Hence, there was no detectable protein, either bound or free, in the ink carefully syringed from the duct area of the ink sac of freshly-killed *S. australis* specimens. In the case of Milked Ink, the presence of a protein that exhibited tyrosinase activity was most likely due to contamination from the rupture of glandular tissue at the base of the ink sac.

For comparison with other cephalopod studies, we analyzed ink supernatants for the presence of DOPA, dopamine, taurine, epinephrine, and nor-epinephrine. While traces of epinephrine and nor-epinephrine were recorded from Milked Ink samples, none was found in Syringed Ink collected from 'live' animals. On the other hand, in agreement with published reports (e.g., Lucerno et al., 1994), DOPA, dopamine, and taurine were consistently present in all ink samples analyzed, although in varying amounts. Exact quantification was not pursued, as the moisture content of the original ink samples varied from liquid to a paste consistency.

When seeking an explanation for our results, we searched for information on the gross histological structure of other cephalopod ink sacs and were surprised to find just a single published paper (Wang et al., 2008). This indicated the presence of a glandular mass at the base of the ink sac of the cuttlefish, *Sepiella maindroni*. Wang et al. (2008) described the basal secretory tissue as being highly branched, extending into the basal lumen of the ink sac and containing blood vessels, most of which were capillaries.

By comparing the histological structure of the ink sac of *S. australis* with that of *S. maindroni* (Wang et al., 2008), it was possible to note an important structural difference. The glandular tissue in *S. australis*, rather than being entirely dendritic and exposed to the ink sac lumen, as described for *S. maindroni,* seemed also to consist of a number of compartments, separate from the lumen (Fig. 2).

Using the structure of the *S. australis* ink sac as a guide, we propose that the ink along with its cargo of allelochemicals is synthesized in the basal mixed-glandular compartments and then released into the lumen of the sac for storage, perhaps by a break in the thin inactive compartmental walls. Indications are that the mucus component of ink may be synthesized in separate tubular structures.

We suggest it is this essentially protein-free material that is expelled by the animal for defensive and signalling purposes. Further, from this work, it is possible to suggest that tyrosinase activity in the ink of *S. australis* is present only when the basal glandular tissue is damaged, either during the sampling procedure or by autolysis after death.

A complicating factor may arise from the similarity between tyrosinase and haemocyanin, which is reputed to display tyrosinase-like activity (Schoot Uiterkamp and Mason, 1973; Jaenicke and Decker, 2004). Reported tyrosinase activity of cephalopod ink may be due to the

Table 1 Residual tyrosinase activity in the ink samples a1 to a6 (syringed) and b1 to b6 (milked), compared with mushroom tyrosinase (10 μg)

Samples	Tyrosinase activity (units)	Samples	Tyrosinase activity (units)
A1	0	B1	16
A2	0	B2	30
A3	0	B3	23
A4	0	B4	27
A5	0	B5	15
A6	0	B6	55
		tyrosinase enzyme	36

One unit of tyrosinase was defined as the amount of enzyme required to oxidize 1 μmol of L-DOPA per min under the assay conditions (see "Methods"), which was calculated using the molar extinction coefficient of dopachrome (3600 M^{-1} cm^{-1})

presence of hemocyanin, which has been included in samples by the rupturing of vessels in the ink gland.

While other studies have consistently documented the presence of proteins in the ink of cephalopod species (Prota et al., 1981; Takaya et al., 1994; Naraoka et al., 2000; Derby, 2007), we have been unable to detect free proteins or those associated with the melanin itself in Syringed Ink from *S.australis*.

There are at least three possible explanations. First, there may be significant differences among cephalopod taxa with regard to ink secretion and composition. Second, sampling procedures to date may have ruptured glandular cells, thus releasing proteins with tyrosinase activity. Third, there may be well-hidden (buried) proteins deep within the melanin superstructure that are not accessible to proteolysis. The latter alternative seems unlikely in view of recent findings by Meredith et al. (2006) showing that melanin consists of layers of pi-stacked 5,6-dihydroxyindole-2-carboxylic acid and 5,6-dihydroxyindole oligomer sheets.

Regarding the presence of DOPA, dopamine, and taurine in the ink supernatant, there is clear consistency with the findings of others who have studied different cephalopod species (Lucerno et al., 1994; Fiore et al., 2004). Our recordings of epinephrine and nor-epinephrine in some samples of ink preserved from dead animals can almost certainly be ascribed to contamination either from autolysis of cells after death or from damage while stripping of well-vascularised glandular tissue.

In order to understand the role of chemicals associated with the ink of *S. australis* there is a need for further work such as that of Gilly and colleagues (Gilly and Lucero, 1992; Lucerno et al., 1994) as well as that of Wood et al. (2010) on the effects of cephalopod ink allelochemicals on conspecifics and other marine organisms. A good example of such investigations on another mollusc taxon is that conducted by Derby and associates using the ink of *Aplysia* (e.g., Derby, 2007; Derby et al., 2007).

It is the various approaches and extraction methods for studying the ink of cephalopods that leads to confusion. The term 'ink' then is ambiguous. In some cases, it is regarded as the product of an ink sac being homogenized in a Waring blender (e.g., Naraoka et al., 2000). In others, it is the contents of an ink sac being removed after careful dissection (Liu and Simon, 2003; Fiore et al., 2004). Finally, it may be the dark material with its accompanying allelochemicals that may be ejected by many cephalopods when under threat or stress, as for *S. australis* in this study.

Acknowledgements We thank all those who accompanied us on squid fishing expeditions. Andrew Beck and Shaun O'Sullivan produced high quality sections of ink sac tissue. Miguel De Barros Lopez gave us invaluable advice and guidance. The School of Pharmacy and Medical Sciences, through Allan Evans, gave us material support and encouragement without which we could not have conducted this work.

Gross et al., 2010). Since its establishment in the 1980s, it has become the dominant ladybird in much of the USA and Canada (Koch and Galvan, 2008). One decade later, it was introduced into Europe and has now colonized 13 European countries (Brown et al., 2008).

One important characteristic of the harlequin ladybird is its high resistance to pathogens and predators. It was shown recently that adult *H. axyridis* were less susceptible to the entomopathogenic fungus, *Beauveria bassiana*, than the native European species, *Adalia bipunctata* and *Coccinella septempunctata* (Roy et al., 2008). *Harmonia axyridis* also was not a suitable host for the reproduction of various entomopathogenic nematodes (Shapiro-Ilan and Cottrell, 2005). Further, lower levels of parasitism by the wasp *Dinocampus coccinellae* were reported for *H. axyridis* compared to *C. septempunctata* (Koyama and Majerus, 2008).

In the immune system of insects, antimicrobial peptides are synthesized *de novo* following an infection (Boman and Hultmark, 1987). In recent years, due to the growing resistance of microbes to antibiotics, a number of studies have focused on the presence and effectiveness of antimicrobial peptides in insect hemolymph. Several of these peptides have been isolated and sequenced (Bulet and Stöcklin, 2005). Most studies involved model insects like *Drosophila melanogaster* and *Galleria mellonella* (Schmid-Hempel, 2005; Brown et al., 2009), but little is known about the disease resistance of Coleoptera, especially coccinellid beetles (Bulet et al., 1991; Gross et al., 2008).

In order to understand the rapid spread of *H. axyridis*, we evaluated several potential mechanisms that underlie the observed disease resistance of this species. As the survival of juvenile stages is one key factor for the successful establishment of invasive populations (Marco et al., 2002), we compared the antimicrobial efficacy of larvae and adults in *C. septempunctata* and *H. axyridis*. Antimicrobial defense of leaf beetles can be exerted either by the innate immune system or by volatile fumigants (Gross et al., 2008; Gross and Schmidtberg, 2009). Thus, we tested the hemolymph as well as several volatile components emitted by *H. axyridis* for antimicrobial potential. Furthermore, we investigated the mode of action of antimicrobial activities by determination of the minimal inhibitory activities (MIC) and activity measurement of key-enzymes of hemolymph obtained from live and frozen beetles.

Methods and Materials

Insects For establishing a laboratory rearing culture of *Harmonia axyridis* (Coleoptera: Coccinellidae), adults were collected in October 2008 in the surroundings of Dossenheim, Germany and reared permanently under controlled conditions in a climate chamber (24°C day, 19°C night, 60% humidity, 16:8 hr/L:D) at the Julius Kühn Institute, Dossenheim. Insects were kept in rearing cages (40×30×30 cm) and fed a diet of pea aphids (*Acyrthosiphon pisum*) reared on beans (*Vicia faba*), pollen (Ullmann, Erlensee, Germany), and water *ad libitum*. Eggs from *Coccinella septempunctata* (Coleoptera: Coccinellidae) were purchased (Katz Biotech, Baruth, Germany), and the beetles reared permanently under the same conditions. For all experiments, we used laboratory reared beetles (larvae and adults).

Microorganisms Bacillus subtilis, B. thuringiensis subsp. *tenebrionis* (strain 10 BI 256–82, isolated from *Tenebrio molitor* (Coleoptera: Tenebrionidae), Krieg et al., 1984), and *Micrococcus luteus*, were chosen as Gram-positive bacteria, and *Escherichia coli* (K12/D31) was used as Gram-negative organism. The yeast *Saccharomyces cerevisiae* (DSM 70499) was tested as an example for fungi (Gross et al., 1998, 2002). All organisms were obtained from the strain collection at the Julius Kühn Institute, Dossenheim. Bacteria were cultivated on Standard 1 agar plates (Roth, Germany) at 28°C (*Bacillus* and *Micrococcus*) or 37°C (*E. coli*), and the yeast on Sabouraud agar (Roth, Germany) at 28°C.

Agar Diffusion Assay

Insect Treatments Fourth instars and adults of both ladybird species were injected with 0.5 µl of sterile water or a dense (~10^{10} cells/ml) heat-inactivated (65°C, 60 min) suspension of *E. coli* with a microapplicator (Burkard, Germany) laterally into the abdomen 24 hr prior to hemolymph collection. A third group of larvae and adults served as untreated control.

Hemolymph Collection Hemolymph was collected from fourth instars or adults. Twenty-four hours after treatment, insects were pressed gently between two glass slides until they released their hemolymph by reflex bleeding from the joint between tibia and femur and elytral edges (adults), or setae (larvae). When this treatment was insufficient, a middle leg was cut with micro-scissors. The emanating hemolymph was absorbed directly from one individual insect onto small disks of sterile filter paper (3 mm diam). No distinction between males and females was made for either adults or larvae. Samples on paper disks were applied directly onto agar plates that contained the microorganisms and their respective growth media. Numbers of replications for treatments of adults were $N>9$, for treatments of larvae $N=12$. Untreated sterile filter paper disks were used as controls.

Bacteria For detection of hemolymph activity or synthetic compounds against bacteria, test plates were prepared as described by Gross et al. (1998, 2002).

Yeast Antifungal activity was determined with an inhibition zone assay against live *S. cerevisiae* according to Gross et al. (1998). The yeast was grown for 24 hr at 37°C in 100 ml of Sabouraud broth (Roth). Inhibition zone assays were performed on Sabouraud agar (Roth). After sterilization, the medium was mixed with 2 ml of yeast suspension from the submerged culture. Each Petri dish was filled with 5 ml of the inoculated medium.

Headspace The antimicrobial activity of eleven synthetic volatile organic compounds (VOCs) known from the headspace of adult *H. axyridis* (Cai et al., 2007) were tested against three model microorganisms (*E. coli, M. luteus, S. cerevisiae*) as described above: benzaldehyde (Aldrich), phenol (Roth), (+)-α-pinene (Fluka), (−)-α-pinene (Fluka), n-heptane (Merck), n-octane (Merck), n-nonane (Merck), toluol (Roth), R-(+)-limonene (Aldrich), 2-butanone (Fluka), 2-pentanone (Fluka). Two μl of undiluted VOCs were pipetted into a hole (3 mm diam) punched previously into the agar. Each test was replicated ten times.

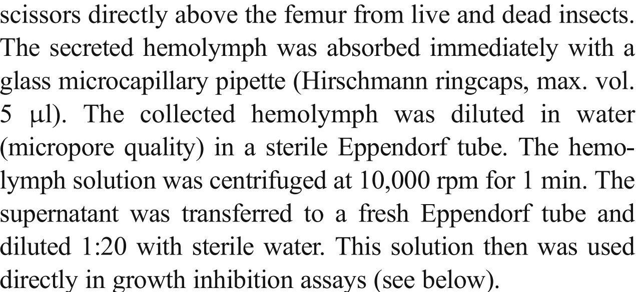
Evaluation of Antibacterial and Antifungal Activity After application of the hemolymph samples, Petri dishes were kept at 37°C for 24 hr. Diameters of inhibition zones caused by the samples through radial diffusion into the agar were measured after 24 hr. Series of similar inhibition zone tests were conducted using different concentrations of the antibiotic gentamicin (Serva) for all bacteria or nystatin (Serva) for yeast. The straight calibration lines obtained were used to calculate the antimicrobial activity in μg/ml of the respective antibiotic.

Activity Determination for Key Enzymes

Measuring of Enzyme Activity Muramidase (lysozyme-like) activity against cell walls of Gram-positive bacteria was measured by using the lytic zone assay with freeze-dried *M. luteus* (Sigma, Deisenhofen, Germany) as described previously (Gross et al., 2002). Some of the hemolymph samples caused clear zones in the turbid agar by dissolving the bacterial cell walls. Diameters of these lytic zones were measured after 24 hr of incubation at 37°C. Units/ml lysozyme were calculated using dilutions of chicken lysozyme (Sigma).

Determination of the Minimal Inhibitory Concentration (MIC)

Hemolymph Collection Hemolymph was collected from unchallenged adult beetles. The number of replications for each test group was >5. One hind leg was cut with micro-



scissors directly above the femur from live and dead insects. The secreted hemolymph was absorbed immediately with a glass microcapillary pipette (Hirschmann ringcaps, max. vol. 5 μl). The collected hemolymph was diluted in water (micropore quality) in a sterile Eppendorf tube. The hemolymph solution was centrifuged at 10,000 rpm for 1 min. The supernatant was transferred to a fresh Eppendorf tube and diluted 1:20 with sterile water. This solution then was used directly in growth inhibition assays (see below).

Assays to Determine the Minimal Inhibitory Concentration (MIC) of the Hemolymph The antimicrobial activity of hemolymph from live and dead beetles was evaluated with broth microdilution assays. Bacteria and yeast were grown overnight in liquid media with shaking at 28°C. Prior to experiments an inoculum of bacteria was transferred to liquid Mueller Hinton Broth (MHB) (Fluka), while the yeast strain was cultivated in Sabouraud Dextrose Broth (Roth). Microbial growth was monitored as absorbance of the overnight cultures at 600 nm. Aliquots were removed and plated on the respective nutrient agar in order to determine the numbers of CFU at 28°C. The optical density (OD) of each culture was determined, and cultures were diluted to a final concentration of 10^6 CFU. Ninety-six well flat bottom microtiter plates (Sarstedt) were used in the inhibition assays. The cultures were serially diluted. Forty μl hemolymph solution at a concentration of 5 μl/ml medium were pipetted into the first well and then 1:2 diluted with each of the following pipetting steps until the 12th well in each row. In each assay, the inhibitory effect of hemolymph from live and dead beetles was compared for the organism tested. Gentamicin at a concentration of 50 μg/ml was used as positive reference. In the first well, 20 μg/ml gentamicin were applied and 1:2 diluted until the 12th well. For MIC tests with *S. cerevisiae*, 50 μg nystatin per ml dimethylsulfoxid (DMSO) were used as reference. Aliquots of 100 μl of the bacterial and fungal cultures were added to each well. All microorganisms were tested separately. All tests were repeated five times with three rows from the same hemolymph pool each time. Microtiter plates were incubated in a shaker for 22 hr at 28°C. Antimicrobial activity was assessed by visually detecting turbidity in the wells. Growth inhibition was verified with a spectrophotometer at 600 nm (Microplate reader Floustar Omega, BMG Labtech). Data were collected with the software Omega 1.10 (BMG Labtech) and analyzed (Mars 1.11, BMG Labtech). The MIC was defined as the lowest concentration of the hemolymph or the antibiotic that inhibited all visually detectable microbial growth.

Statistical Analysis Differences in the antimicrobial activity of hemolymph from adults and larvae of the two ladybird species *C. septempunctata* and *H. axyridis*, as well as their

lysozyme-like activity were analyzed by Mann-Whitney *U* tests (Sachs, 1992). All statistical tests were performed with Statistica 5.5 software (StatSoft, 1999).

Results

Antimicrobial Activity The hemolymph of both adults and larvae of *C. septempunctata* showed a weak activity against Gram-positive bacteria (*M. luteus*), nearly no activity against Gram-negative bacteria (*E. coli*), and no activity against yeast (*S. cerevisiae*) (Table 1). While injection of sterile water increased the antibacterial activity in adults, only the injection of a dense bacterial suspension induced an increase in activity against Gram-negative *E. coli* in larvae. The activity against Gram-positive *M. luteus* increased slightly in larval hemolymph after water injection, but increased significantly when dead bacteria were injected ($P<0.05$, Mann-Whitney *U* test). In contrast, the hemolymph of *H. axyridis* strongly inhibited the growth of both bacteria and yeast (Table 1). Inhibition was strongest against *E. coli*, followed by *M. luteus*, and lowest against yeast. Compared to *C. septempunctata*, the antibacterial activity in *H. axyridis* hemolymph was between 640 (Gram-positive bacteria) and up to 16,000 times (Gram-negative bacteria) higher. These results were obtained irrespective of whether the ladybirds had been untreated or immune challenged ($P>0.05$, Mann-Whitney *U* test). The activity against yeast decreased after injection of water or an inactivated bacteria suspension into larvae, and after injection of bacteria in adults compared to untreated control ($P>0.05$, Mann-Whitney *U* test).

Minimal Inhibitory Concentration (MIC) The hemolymph of live *H. axyridis* inhibited the growth of yeast and all three bacteria tested. Inhibition was strongest for *E. coli* and *S. cerevisiae*, followed by *B. subtilis*, and lowest for *B. thuringiensis* subsp. *tenebrionis*. This species also was least susceptible to gentamicin (Table 2). After freezing the beetles at −20°C for a period of 13 to 66 days prior to hemolymph collection, the inhibitory activity decreased significantly, but the same susceptibility pattern was observed (Table 2). The concentration of gentamicin necessary to fully inhibit growth of *E. coli* was 0.2 µg/ml. The amount of hemolymph from live beetles (0.16 µl/ml) necessary for similar growth inhibition of *E. coli* was about four times lower than the hemolymph amount necessary to fully inhibit *B. subtilis* (0.63 µl/ml), and 2.5 µl/ml were necessary to inhibit the growth of *B. t. tenebrionis* (Table 2). The inhibitory effect of hemolymph from frozen beetles was eight times lower for *E. coli*, eight times lower for *B. subtilis*, and 2 times lower for *B. t. tenebrionis* compared to hemolymph from live beetles. The concentration of antifungal nystatin necessary to obtain complete growth inhibition of yeast was 3.13 µg/ml. A similar growth inhibition was observed by adding 0.16 µl hemolymph from live beetles to the medium. Its antifungal activity was four times higher compared to hemolymph from frozen beetles (Table 2).

Enzyme Activity Enzyme activity in the hemolymph of *H. axyridis* was higher than in *C. septempunctata* (Fig. 1a, b). In larvae of both species, hemolymph activity was higher than in adults. We observed an increase in the lysozyme-like activity in treated larvae (water, bacteria) compared to untreated larvae within both species (Mann-Whitney *U* test, $N=12$, $P<0.001$). There was no statistically significant difference between untreated and treated adults within either species ($P>0.05$, Mann-Whitney *U* test). Differences between treatments were not statistically significant ($P>0.05$, Mann-Whitney *U* test).

Table 1 Mean values and standard deviations of antimicrobial activity of hemolymph of two ladybird species *Coccinella septempunctata* and *Harmonia axyridis* in µg/ml antibiotic equivalent (gentamycin: *Escherichia coli* and *Micrococcus luteus*; nystatin: *Saccharomyces cerevisiae*) analyzed by agar diffusion assay

Nystatin	–	–	–	3.13

The number of replications for each group is >5

Headspace Three out of eleven tested VOCs known from the headspace of *H. axyridis* (phenol, (+)-α-pinene, benzaldehyde) inhibited the growth of bacteria, *E. coli* and *M. luteus*, as well as the yeast (Fig. 2). The other VOCs tested showed no inhibitory effects.

Discussion

The hemolymph from unchallenged *H. axyridis* strongly inhibited the growth of all tested microorganisms. By contrast, the hemolymph from unchallenged *C. septempunctata* showed no inhibitory effects against the same microorganisms. After injection of water or inactivated bacteria, the antibacterial activity in the hemolymph of *C. septempunctata* adults and larvae increased significantly. It is striking that neither treatment challenged the immune system of *H. axyridis*, but at the same time decreased the antifungal activity in its hemolymph. To date no other study has reported similar findings. This leads us to suggest a possible interference in the induction of different immune pathways. It was reported earlier (Lemaitre et al., 1997) that insects might respond to different challenges and, thus, adapt their disease resistance accordingly while

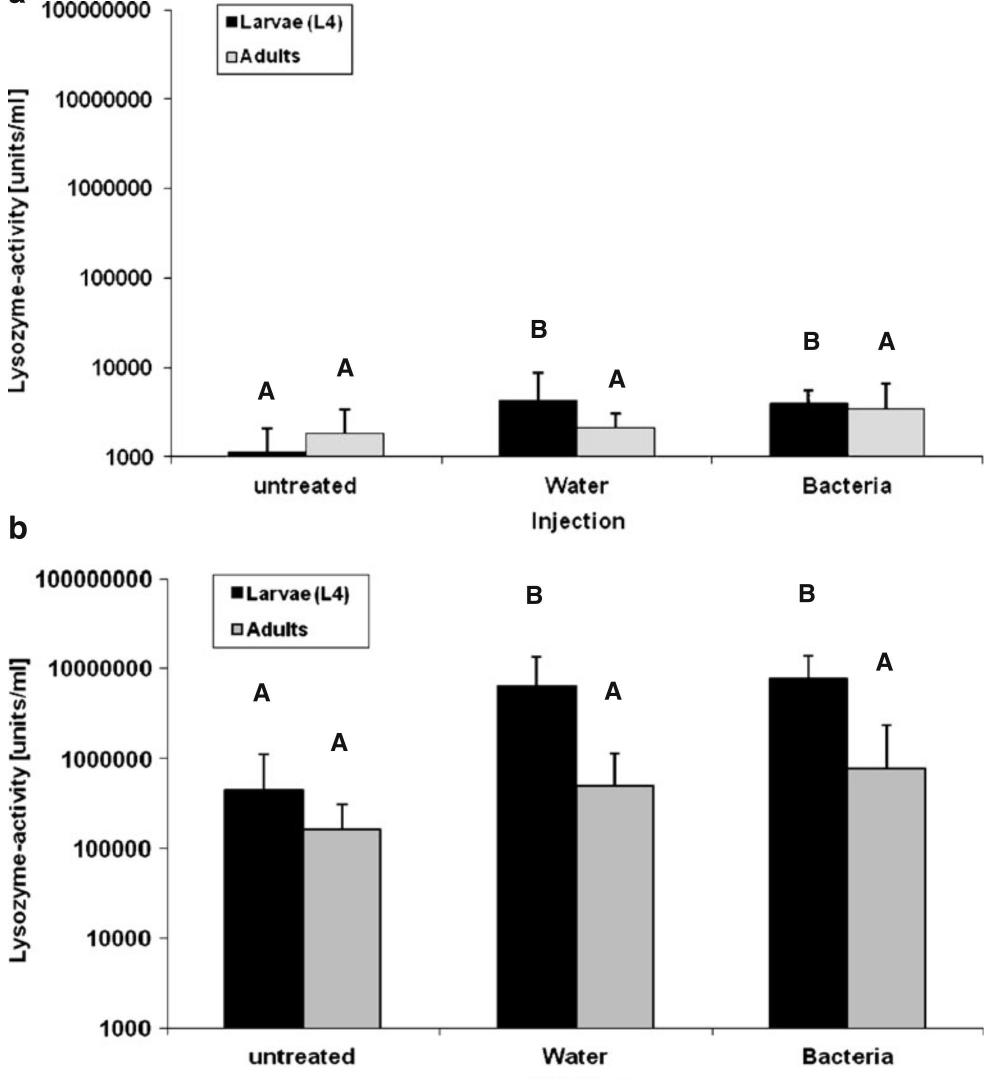

Fig. 1 Lysozyme activity [units/ml] of the hemolymph of ladybird beetles. **a**: *Coccinella septempunctata*. **b**: *Harmonia axyridis*. While there is no statistically significant difference between the three treatments of adults of both species (*grey bars*), there is an increase in the lysozyme-like activity in treated larvae (water, bacteria) compared to untreated larvae within both species (*black bars*; Mann-Whitney *U* test, N=12, P< 0.001)

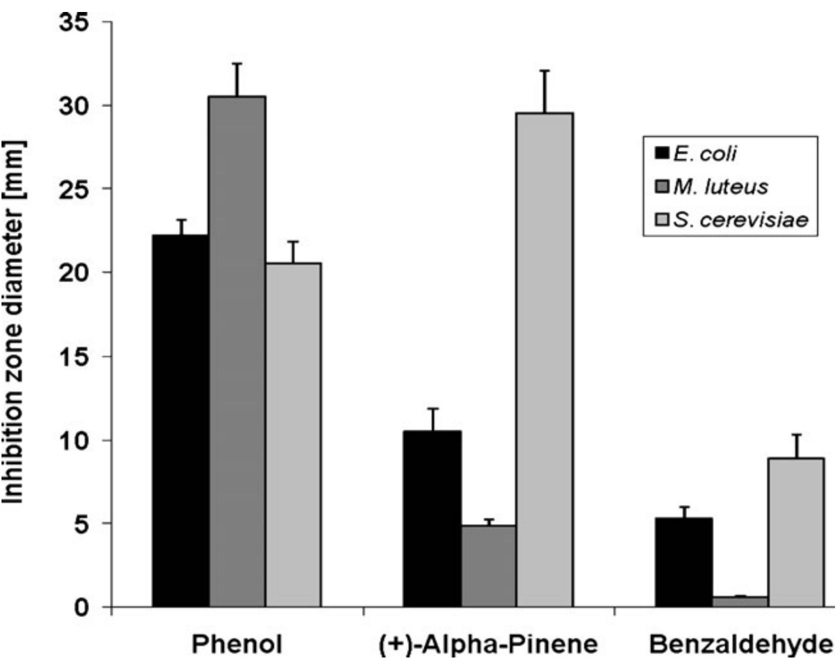

Fig. 2 Growth inhibition of bacteria (*Escherichia coli, Micrococcus luteus*) and yeast (*Saccharomyces cerevisiae*) by synthetic VOCs (phenol, (+)-α-pinene, benzaldehyde) present in the headspace of *Harmonia axyridis*. *Bars* represent mean and standard deviation of inhibition zone diameters (mm, N=10)

minimizing the resources necessary for this defensive response.

Lysozyme activity against *M. luteus* was more than hundredfold higher in the harlequin ladybird when compared to *C. septempunctata*. Induction increased the lytic activity in both larvae but not in adults of either species (Fig. 1). The higher activity of this enzyme might assure increased survival rates of larvae in the populations of the invasive *H. axyridis* compared to *C. septempunctata*. Furthermore, adults of *H. axyridis* additionally produce 38 volatile organic compounds (VOCs) (Cai et al., 2007). Three of them, phenol, (+)-α-pinene, and benzaldehyde, inhibited the growth of both bacteria and yeast in our assays. Additionally, a synergistic amplification of antimicrobial active VOCs is possible. These compounds may engulf the insects with an antimicrobial cloud. This phenomenon was recently reported for leaf beetles (Gross et al., 2008; Gross and Schmidtberg, 2009). Such a mechanism could be important, especially during overwintering, as *H. axyridis* forms aggregations consisting of hundreds of individuals in cavities under rocks or plants. Further studies will be necessary to test this hypothesis.

The MIC assays showed, that hemolymph of untreated adult *H. axyridis* inhibited the growth of Gram-negative *E. coli* and *S. cerevisiae* more strongly than the growth of Gram-positive bacteria (*B. subtilis* and *B. t. tenebrionis*). Moreover, the hemolymph from live beetles was significantly more efficient than hemolymph from frozen beetles against all organisms tested. We observed a difference in the susceptibility of *S. cerevisiae* between these two assays. The yeast was more susceptible to hemolymph in the liquid medium MIC assays compared to agar diffusion assays. This could be due to a better contact of the active compounds in the fluid than on the agar.

Antimicrobial peptides (AMP) effective against Gram-negative organisms known from invertebrates generally are produced after recognition of foreign compounds. They are, thus, considered induced defenses. We observed the contrary in *H. axyridis*; the hemolymph of unchallenged beetles caused in agar diffusion assays and MIC tests strong inhibition of microbial growth. This finding suggests high concentrations of constitutive antimicrobial compounds present in hemolymph. Inducible AMPs have been isolated from several insect orders, but few studies have been conducted with Coleoptera (Bulet et al., 1991). The chemical nature of the antimicrobial compounds in the hemolymph of *H. axyridis* is not yet known. The costs of maintaining a highly efficient immune system have been related to an inferior tolerance of starvation and desiccation in parasitoid resistant *Drosophila* (Hoang, 2001). Few data are available on stress tolerance of *H. axyridis* (Agarwala et al., 2008) and nothing is known how stress affects its immune system. We currently are conducting studies to evaluate various stress factors and their effects on the antimicrobial defense of *H. axyridis*.

Interestingly, in microtiter plate assays, we observed that the hemolymph of *H. axyridis* partially lost its activity after freezing live beetles at −20°C prior to hemolymph extraction. This effect was strongest against Gram-positive bacteria (*Bacillus subtilis, B. thuringiensis*) and weaker against Gram-negative *E. coli* and yeast (Table 2). A destruction of the antimicrobial compound due to the death

of the beetles is unlikely because the freezing of live beetles should stop immediately any destructive physiological processes. In an earlier study, it was suggested that low temperatures may change the qualitative and quantitative composition of antimicrobial peptides in insect hemolymph (Stephen and Johnson, 1962). The observed changes were, however, variable between species and age groups of the tested cockroaches. Duration of freezing had no effect on protein composition. Stephen and Johnson (1962) found qualitative changes of hemolymph proteins more pronounced for weak clot producing cockroach species. The hemolymph of multicolored lady beetles produces such clots only very slowly upon secretion (pers. observ.). Corresponding to Stephen's observations, protein stability is not assured after freezing and thawing of hemolymph samples. The reduction of the antimicrobial efficacy observed in our studies might be due to thawing of the frozen beetles prior to hemolymph collection. To our knowledge, no other studies have reported a similar loss of the inhibitory effect, since neither hemolymph from live nor from dead insects has been evaluated. Further assays on the kinetic of microorganism growth are necessary to verify the bactericidal/fungicidal or merely growth inhibitory effect of the hemolymph observed in our assays.

Gram-negative *E. coli* and the yeast *S. cerevisiae* were more susceptible to the antimicrobial substances in the hemolymph of adult *H. axyridis* than the two Gram-positive *Bacillus* species. In contrast, the third Gram-positive species tested, *M. luteus*, also was strongly inhibited. It has been reported that *M. luteus* is highly sensitive to chicken lysozyme (Altincicek et al., 2008). The high lysozyme activity in the hemolymph of *H. axyridis* compared to *C. septempunctata* may explain the strong inhibition of bacteria by both adult and larval hemolymph. It is not surprising that higher concentrations of antimicrobial compounds were necessary to inhibit the growth of insect pathogenic *B. t. tenebrionis*. This strain has been isolated from a beetle (*Tenebrio molitor*) and is mainly infective for beetles (Krieg et al., 1984). Recently, it was reported that the antimicrobial peptide rhinocerosin isolated from the coconut rhinoceros beetle is more active against Gram-positive bacteria with a MIC value of 1.0 µg/ml (Yang et al., 1998). A study on two different synthetic antimicrobial peptides found a wide variation in MIC values of 128 µg/ml, 16 µg/ml, and 4 µg/ml against *E. coli* (Kamysz and Turecka, 2005). For *H. axyridis*, it is not yet known whether antimicrobial proteins or other factors (review in Boman and Hultmark, 1987) are responsible for the observed microbial growth inhibition.

The differences in the antifungal activity between the two ladybird species tested are notable. Whereas the hemolymph from untreated adult *C. septempunctata* had no antifungal activity, the inhibitory activity of hemolymph from adult *H. axyridis* beetles corresponded to 100–1,000 µg/ml of the antimycotic nystatin. Little is known about the antifungal activity of insect hemolymph, probably because of a low search effort for antifungal proteins (Bulet and Stöcklin, 2005). Few studies, however, have reported strong growth inhibition of fungi by inducible insect hemolymph compounds (Lamberty et al., 1999), and defensins and cecropins are known for their antibacterial but also antifungal activities (Vilcinskas and Gross, 2005). Hence, our study is the first to report antifungal activity in an unchallenged beetle species. The presence and rapid response of the constitutive defenses in *H. axyridis* might be another factor that could help explain the competitive superiority of this exotic species when compared to native ladybird beetles.

In the present study, we did not differentiate between sexes or morphs with different elytral colors. Recent preliminary data suggest no differences in disease resistance between female and male *H. axyridis* (Gross, unpubl. data). Further studies of variations in hemolymph activity in different life stages, sexes, and morphs are necessary to understand its importance for the competitive success of *H. axyridis* (Fedorka et al., 2004).

Most studies have focused on behavioral differences between *H. axyridis* and native ladybirds in Europe (Soares and Serpa, 2007; Brown et al., 2008), Canada (Labrie et al., 2006), the USA (Yasuda et al., 2004) and Japan (Ware and Majerus, 2008). Larger size and physically better defended larval stages contribute to higher survival rates (Snyder et al., 2004) and to superiority in aggressive encounters with other ladybird species (Pell et al., 2008). Cannibalism and intraguild predation have been observed even when aphid prey is abundant (Pell et al., 2008). In Canada, *H. axyridis* has a shorter development time for younger larval stages than indigenous ladybird species (Labrie et al., 2006). Furthermore, *H. axyridis* adults are rarely preyed upon (Pell et al., 2008), and under laboratory conditions, adult beetles are rejected by the predatory hemipteran, *Podisus maculiventris* (Houg-Goldstein et al., 1996; DeClercq et al., 2003). Cottrell and Shapiro-Illan (2003, 2008) found that *H. axyridis* is more resistant to various *B. bassiana* strains when compared to highly susceptible native coccinellids. Roy et al. (2008) showed for three species of ladybirds that much higher concentrations of *Beauveria bassiana* conidia were required to artificially infect *H. axyridis*.

In summary, the observed disease resistance against antagonistic microorganisms is one more fitness parameter that contributes to the enormous capacity of *H. axyridis* to exploit new habitats and to out-compete other coccinellid species. The importance of disease resistance for life history traits and population dynamics of *H. axyridis* under different climatic and geographic conditions awaits further studies.

Acknowledgements We thank Svenja Hoferer, Jürgen Just, Vanessa Lessle, Kira Schneider, and Sabine Wetzel for excellent technical assistance. The authors thank Eva Gross for linguistic improvements and two anonymous reviewers for helpful comments on an earlier version of the manuscript.

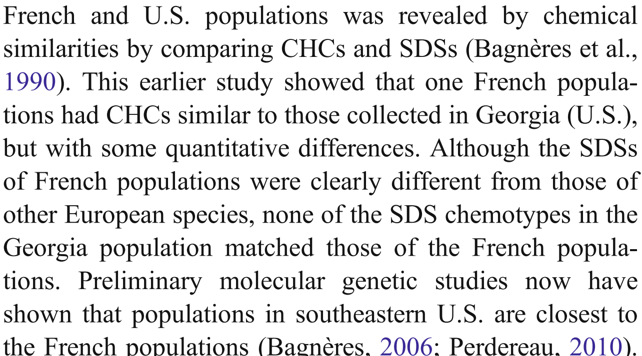
shown that environmental factors such as food, temperature, and social environment can affect the composition of CHC profiles (Florane et al., 2004; Dronnet et al., 2006). Although the processes underlying the production of chemical signatures are not well understood, analysis of these signatures has proved to be effective for termite classification. Qualitative differences in hydrocarbons can discriminate between species, whereas quantitative differences can discriminate between populations and colonies (Haverty et al., 1997; Page et al., 2002; Bagnères and Wicker-Thomas, 2010). Analysis of CHCs among Rhinotermitidae has helped to clarify the taxonomy of the Asian *Reticulitermes* (Takematsu and Yamaoka, 1999); the Australian *Heterotermes* and *Coptotermes* (Watson et al., 1989; Brown et al., 1990); the American *Coptotermes* and *Reticulitermes* (Bagnères et al., 1990; Haverty et al., 1991, 1996, 1997, 2000); and the European *Reticulitermes* (Clément et al., 2001).

In the Rhinotermitidae and Termitidae, soldiers have a frontal gland that secretes defensive compounds. These soldier defensive secretions (SDSs) are believed to play a role in defending colonies against predators and competitors (Zalkow et al., 1981), and they also may play a role in the production of primer pheromones in *Reticulitermes* (Henderson, 1998; Tarver et al., 2009). SDSs can be composed of alkanes, aldehydes, ketones, and terpenes, as well as more complex compounds (Quintana et al., 2003; Piskorski et al., 2007). They have often been studied in combination with CHC profiles as their composition differs geographically and among taxa (Bagnères et al., 1990), and they can be useful for identifying species (Bagnères et al., 1990; Haverty et al., 1996; Nelson et al., 2001, 2008; Clément et al., 2001; Piskorski et al., 2009).

The use of chemical compounds for taxonomy (chemotaxonomy) has been widely used and proved valuable in numerous termite species, particularly *Reticulitermes*. However, less attention has been paid to chemical variation within species, in particular with respect to invasive species (Haverty et al., 1990). This study analyzed both CHCs and SDSs within native and introduced populations of *Reticulitermes flavipes* (Kollar). In the United States, this termite is known as the eastern subterranean termite, but it has been introduced and established in other countries such as Canada, Chile, and Uruguay, as well as France and Germany (Clément et al., 2001; Austin et al., 2002, 2005; Su et al., 2006). For a long time, the introduced populations of France were considered as a European species, *Reticulitermes santonensis* (Feytaud, 1924). They are now considered to be introduced populations of *R. flavipes* on the basis of the homology of several mitochondrial and nuclear DNA sequences (Clément et al., 2001; Jenkins et al., 2001; Austin et al., 2002, 2005; Ye et al., 2004; Su et al., 2006), although the first correspondence between



French and U.S. populations was revealed by chemical similarities by comparing CHCs and SDSs (Bagnères et al., 1990). This earlier study showed that one French populations had CHCs similar to those collected in Georgia (U.S.), but with some quantitative differences. Although the SDSs of French populations were clearly different from those of other European species, none of the SDS chemotypes in the Georgia population matched those of the French populations. Preliminary molecular genetic studies now have shown that populations in southeastern U.S. are closest to the French populations (Bagnères, 2006; Perdereau, 2010).

This study determined and analyzed both CHCs and SDSs from three introduced populations in France and six native populations in the southern U.S. The main aims were (1) to determine whether an analysis of the chemical variation permits the discrimination of geographical populations and localities, and (2) to evaluate the degree of chemical similarity and variability among native and introduced populations.

Methods and Materials

Field Collection and Sampling In the U.S., samples were collected in Florida and Louisiana as it has been suggested that populations in France may have originated from these areas (Bagnères, 2006; Perdereau, 2010). In Florida, 3 populations were collected from 12 collection points, 3 in the Blackwater River State Forest, 3 in the Wakulla State Forest, and 6 in the Osceola National Forest (Fig. 1). In Louisiana, 3 populations were collected from 16 collection points, 6 in New Orleans, 6 in Jean Lafitte National Historical Park and Preserve, and 4 in Baton Rouge (Fig. 1). In France, 3 introduced populations were taken from 43 collection points: 20 in the Forêt de Saint Trojan in the south of the Ile d'Oléron (Charente Maritime), 20 in the Forêt d'Olonnes (Vendée), and 3 in Tours (Indre et Loire) (Fig. 1). Termites from these 9 populations were collected from 2006 to 2009. To draw comparisons on a similar scale, the distance between each population did not exceed 200 km, and transects within each population were less than 2 km, except for the populations in Oléron and Olonnes, which were on a larger scale (4 km). Samples from the 9 populations studied were collected from wood fragments or tree stumps at the 9 localities. At least 20 workers were taken from each collection point. For these 71 samples, the species was determined by morphological and chemical identification for the French populations and DNA analysis for the U.S. populations as described previously (Clément et al., 2001; Austin et al., 2002).

Analyses of Cuticular Hydrocarbons Twenty workers per collection point (71 in total with 12 from Florida, 16 from

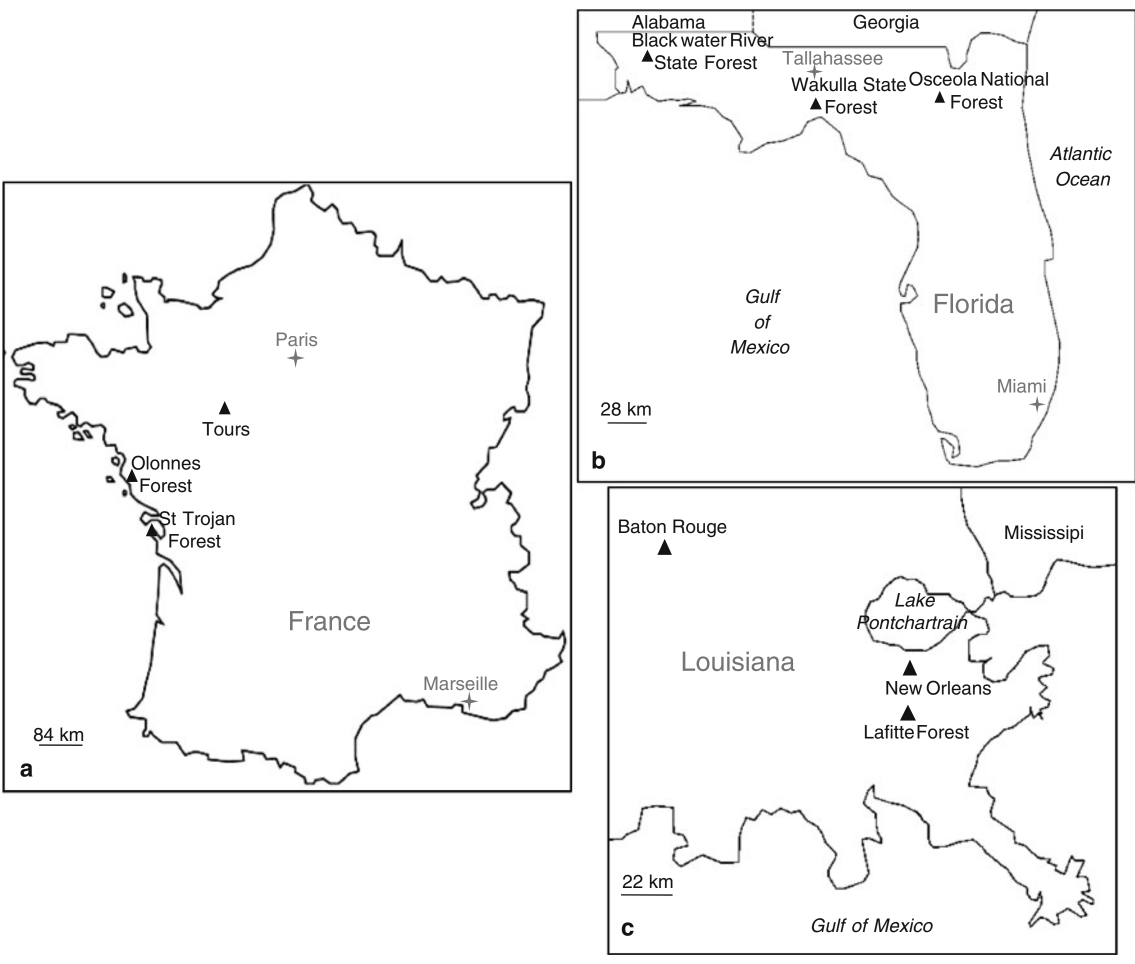


Fig. 1 Locations of *Reticulitermes flavipes* populations in (**a**) France, (**b**) Florida, and (**c**) Louisiana

Louisiana and 43 from France) were pooled for chemical extraction. The CHCs in each pool were extracted by rinsing individuals in a non-polar solvent (hexane in the U. S. and pentane in France) for 5 min, and then samples were dried for transport and stored at −20°C until analysis (1 month at the latest). Before injection, extracts were re-dissolved in 200 µl of pentane with 10 µl of 10^{-7} g/ml of *n*-eicosane (*n*-C20) as an internal standard. Samples (2 µl) were analyzed by GC with a Delsi Nermag DN 200, flame ionization detection (FID) (Alpha MOS, Toulouse, France), and a fused silica capillary column CP Sil 5 (WCOT) (Varian Inc., Palo Alto, CA, USA) (i.d. 0.25 mm×25 m×0.12 µm). The injection mode was splitless (15 sec), and the carrier gas was helium at a linear flow rate of 1.5 cm/sec. The temperature was programmed from 70°C to 150°C at 30°C/min and held at 150°C for 5 min, and then raised to 320°C at 5°C/min. Compound identification was based on previously reported analyses of CHCs with GC-MS (Howard et al., 1978; Bagnères et al., 1990), and checked by us by injecting 2 µl of pooled sample of each population in a GC-MS (Hewlett Packard 5890 GC (Agilent Technologies, Santa Clara, CA, USA) coupled to a Hewlett Packard quadrupole 5889A MS (Agilent Technologies) in electron impact mode (70 eV)) with the same column and temperature program as noted above for GC-FID, with an interface temperature of 250°C. Eighteen main CHCs present in all individuals were selected for analysis: 9-tricosene (*e1*), x-tricosene (*e2*), *n*-tricosane (*a3*), 11-methyltricosane (*m4*), 4/2-methyltricosane (*m7*), 9-tetracosene (*e8*), 3-methyltricosane (*m9*), *n*-tetracosane (*a11*), 11-methyltetracosane (*m12*), 5-methyltetracosane (*m14*), 4/2-methyltetracosane (*m16*), 9-pentacosene (*e17*), pentacosadiene (*n18*), *n*-pentacosane (*a19*), 11+13-methyl pentacosane (*m21*), 7,9-pentacosadiene (*n25*), 4/2-methylpentacosane (*m26*), and 3-methylpentacosane (*m29*). The areas under these 18 peaks were integrated by using Galaxie v.1.8.508.1 (Varian), and the relative proportions of each peak were calculated as described by Bagnères et al. (1990). Discriminant analyses were performed by using Rgui v.2.10.1. to determine whether pre-defined groups (i.e., the 3 localities and the 9 populations) could be discriminated on

the basis of their chemical profiles. This confirmed that the groups corresponded to the classification of the collection points. The same software was used to carry out principal component analysis (PCA) to determine the chemical relationship among the collection points.

The dissimilarity of hydrocarbon profiles among workers from different collection points was quantified by modifying Nei's standard genetic distance (Nei, 1987) as previously described (Queller, 1993; Dronnet et al., 2006) and by using Euclidean distances. The Nei and Euclidean distances were based on the relative amounts of chemical compounds. For each distance, dissimilarity matrices were constructed for all possible pairs of collection points from the mean relative areas of the CHC peaks at different levels: within each population, among populations within each locality (France, Florida, and Louisiana) and among each pair of localities (France/Florida, France/Louisiana, and Florida/Louisiana). Nei and Euclidean distances vary between 0 and 1; 0 indicates that the chemical profiles are identical, whereas 1 indicates that there are no shared compounds. Non-parametric Kruskal-Wallis tests were used for multiple independent comparisons of populations, localities, and groups of localities. Dunn's multiple comparison tests were carried out to define the specific difference between cuticular compound variations at each level of comparison by using XLSTAT v.2009.3.1.

Analyses of Soldier Defensive Secretions Defensive compounds were extracted from 50 soldiers (13 from France, 17 from Florida, and 20 from Louisiana). Because SDSs are volatile compounds, a special method was used for extraction and transport. Each extraction was performed by plunging one soldier into 20 µl of solvent (pentane or hexane) in a conical glass insert for 2 min. Each extract then was transferred to a Transferpettor (BRAND GMBH+ CO KG, Wertheim, Germany) cap (4×0.2 cm), one end of which was previously sealed. The other end of the glass cap was rapidly flame-sealed to avoid the evaporation of SDSs during transport to the laboratory. Two internal standards were used to check the extraction: one was added to the empty cap before extraction (*n*-octadecane) and the second was added just before injection (humulene). Two µl of each extract were analyzed by GC-MS with the instrumentation described above. The temperature program ran from 40°C to 200°C at 5°C/min and then increased at a rate of 8°C/min to 320°C with helium as carrier gas at a linear flow rate of 1.5 cm/sec. The chemotype of each sample then was determined according to the presence or absence of peaks on the GC traces. When present, determination of compounds was confirmed by comparing their retention times and mass spectra with data from previous studies on U.S. and French *R. flavipes* soldiers (Zalkow et al., 1981; Bagnères et al., 1990; Nelson et al., 2001).

Results

Proportions of Cuticular Hydrocarbons in French and American Populations The relative proportion of each cuticular hydrocarbon was determined for the 71 collection points. No qualitative difference was apparent in the CHC components of workers. All profiles had the same 18 hydrocarbons that had previously been found in *R. flavipes/ R. santonensis* (Bagnères et al., 1990) (Fig. 2). However, there were quantitative variations among the collection points.

Discriminant analysis revealed that the relative proportions of a large number of cuticular hydrocarbons discriminated both populations and localities. No single component could be used to separate the nine populations and the three localities, as nearly the whole of the chemical signature (72–83% of the peaks) was needed. The first discriminant analysis performed on relative amounts of the 18 peaks of each collection point discriminated the nine populations significantly. Of these, the relative proportions of 15 compounds (i.e., *e2*, *a3*, *m4*, *m7*, *e8*, *m9*, *a11*, *m12*, *m14*, *n18*, *a19*, *m21*, *n25*, *m26,* and *m29*) varied significantly among populations (*Wilks'* $\lambda<0.05$, $F=12.25$, $df=120, 354$, $P<0.001$). The two first principal axes accounted for 76.89% of the overall variance between groups (the first axis accounted for 46.14% and the second for 30.74%). A large percentage (97.18%) of the collection points were classified correctly in the original groups, with only two collection points of the Oléron population assigned to the Olonnes population. The second discriminant analysis performed on the 3 localities distinguished France, Florida, and Louisiana significantly (Fig. 3). Discriminant analysis selected 13 peaks (i.e.,. *e1*, *e2*, *a3*, *e8*, *m9*, *a11*, *m12*, *m14*, *e17*, *n18*, *a19*, *n25,* and *m29*), grouping all collection points within the assigned localities (*Wilks'* $\lambda<0.05$, $F=37.77$, $df=24, 114$, $P<0.001$). The two first axes accounted for 100% of the chemical variation between groups, with 70.27% of the variation explained by the first axis and 29.73% by the second axis. A large percentage (98.59%) of the collection points was correctly assigned to the original locality group, with only one collection point in Louisiana being grouped with the French colonies.

Principal component analysis based on cuticular hydrocarbon profiles of worker samples revealed that the first two principal components accounted for 41% of the total chemical variation (Fig. 4). The first axis accounted for most of the variation (25%) among Florida and Louisiana populations. The second axis accounted for 16% of the variation, distinguishing the Florida populations from the others. Principal component analysis showed that proportions of CHCs in French populations appeared closer to the three Louisiana populations than the three Florida populations. Chemical variations within and between populations

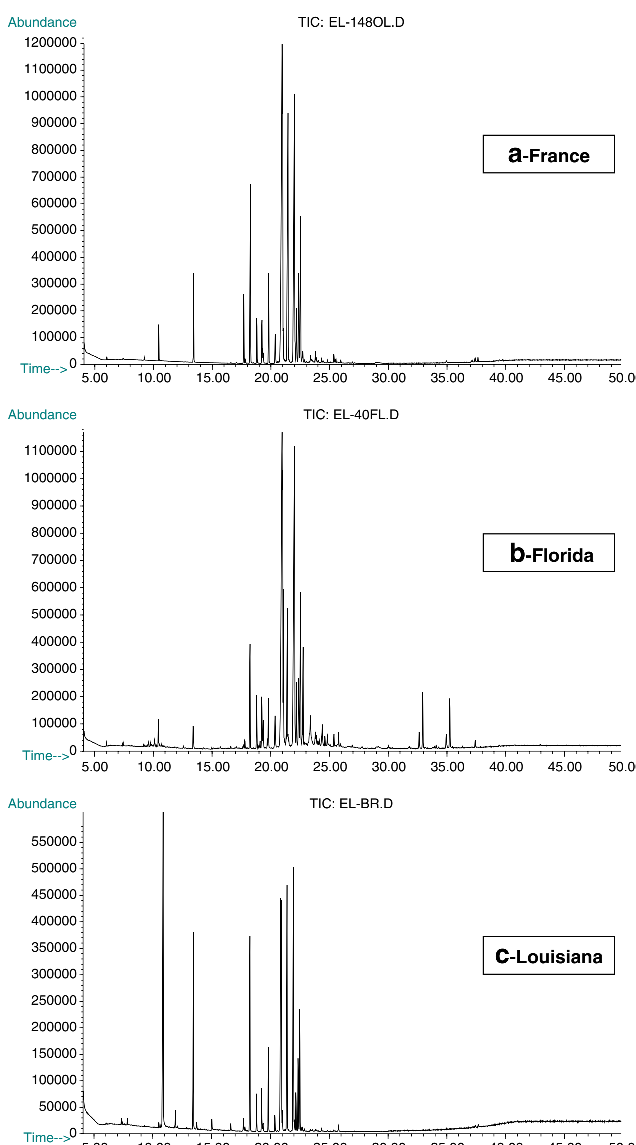

Fig. 2 Total ion chromatograms of GC-MS analysis of cuticular hydrocarbon extracts from populations of *Reticulitermes flavipes* from (**a**) France, (**b**) Florida, and (**c**) Louisiana. (the 2 first peaks between 10 to 14 min are the 2 internal standards)

in France appeared lower than in Florida and Louisiana. Although the French populations in St Trojan and Olonnes covered a greater geographical area than the American populations, their chemical profiles were less variable.

Chemical Dissimilarity Distances The chemical dissimilarity distances (Euclidean and Nei) within populations, between populations within localities, and between pairs of localities were calculated (Table 1). Non-parametric tests used to compare the chemical dissimilarity distances showed similar results for the Euclidean and Nei distances. The chemical distance within each population (Table 1) was similar for all the populations except for the Olonnes population which had a low variability in the CHC composition (Kruskal-Wallis test, $P<0.001$; Dunn's procedures for Olonnes-Oléron, $P<0.001$; Olonnes-Osceola, $P<0.001$; Olonnes-Black River, $P<0.05$; Olonnes-Wakulla, $P<0.05$; Olonnes-New Orleans, $P<0.001$; Olonnes-Lafitte, $P<0.001$), although it was similar to the chemical distances within the Tours and Baton Rouge populations. The chemical dissimilarity distances, both Euclidean and Nei distances, among populations within localities were significant (Table 1). The chemical distances between French populations were significantly less than those observed between populations in Florida and Louisiana (Kruskal-Wallis test, $P<0.001$; Dunn's procedures for France-Florida, $P<0.001$, France-Louisiana, $P<0.001$). Similarly, the chemical distances among the Louisiana populations were smaller than those observed among the Florida populations (Kruskal-Wallis test, $P<0.001$; Dunn's procedure, $P<0.001$). The chemical distance between localities (Table 1) showed that the distance between French and Louisiana was not significantly different from that between the French and Florida localities (Kruskal-Wallis test, $P<0.001$, Dunn's procedure, $P>0.05$). The chemical distance between the Florida and Louisiana localities was significantly greater than those between the French and Florida localities and the French and Louisiana localities (Kruskal-Wallis test, $P<0.001$, Dunn's procedures for Florida/Louisiana vs. France/Florida, $P<0.001$; Florida/Louisiana vs. France/Louisiana, $P<0.001$).

Soldier Defensive Secretions Six isoprenoid compounds were identified from the SDS extracts: α-pinene, β-pinene, limonene, γ-cadinene, cadinene aldehyde, and geranyl linalool. These compounds were the same as those found previously by Zalkow et al. (1981), Bagnères et al. (1990) and Nelson et al. (2001). Qualitative analyses of the SDSs on the basis of the presence/absence of peaks revealed 6 chemotypes, three of which were different from those found by Bagnères et al. (1990) (Table 2, chemotypes a, e, and f). γ-Cadinene, cadinene aldehyde, and geranyl linalool were present or absent in the various chemotypes, but the monoterpenes α-pinene, β-pinene, and limonene always were present. Two of the chemotypes were found in the French populations, one of which had already been reported (Bagnères et al., 1990; Quintana et al., 2003) with the monoterpenes and the geranyl linalool (Table 2 chemotype b), and the second, the most common in our samples, not previously reported, was composed only of monoterpenes (Table 2 chemotype a). Two chemotypes were observed in Florida and four in Louisiana. One chemotype (chemotype a) was common to France and Louisiana, but none was common to France and Florida.

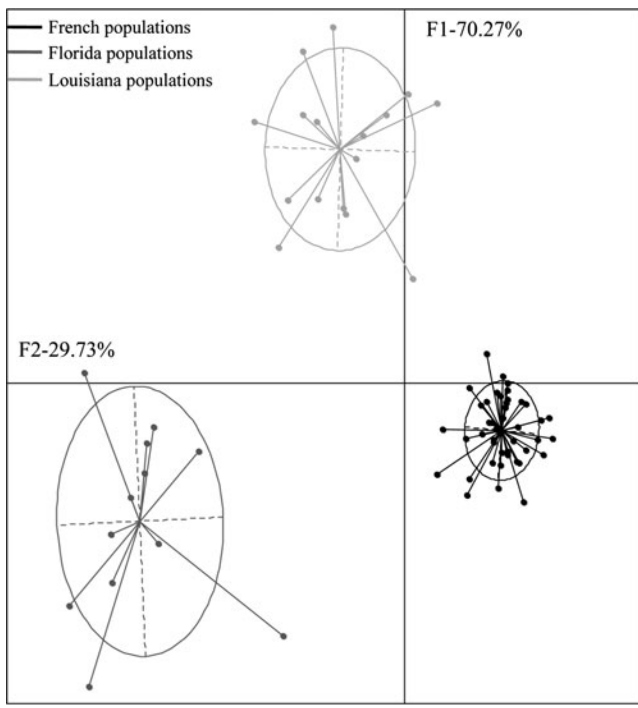

Fig. 3 Chemical differentiation of relative proportions of cuticular hydrocarbons of *Reticulitermes flavipes* among three localities (France, Florida, and Louisiana) on the two first axes of the discriminant analysis. Axes I and II account for 100% (70.27% and 29.73% respectively) of the total variation among localities

Discussion

This study showed that CHCs provide a useful marker for discriminating termite populations, since the results made it possible to discriminate localities and populations within *R. flavipes*. CHC proportions appear to be useful markers for distinguishing the various populations by determining the similarity within each geographical scale.

One major finding was the unexpected chemical homogeneity observed within introduced populations relative to the chemical variation within native populations. Even though chemical distances within populations were not significantly lower in France than in the U.S., the PCA revealed less divergence among the profiles for each collection point for the introduced populations than for the populations in Florida and Louisiana. This result is all the more significant as the comparison was drawn by using a similar geographical scale within populations, except for two French populations, which had a wider area. The use of two different solvents (i.e., hexane and pentane) cannot explain this variation, primarily because the polarities of the two solvents are similar if not identical. Furthermore, the dried samples all were dissolved a second time in pentane before GC analysis. Finally, if these solvents would have caused significant quantitative differences, then these should have been detected by the PCA. The U.S. populations would have been differentiated from the French populations, and the differences between Florida and Louisiana would have been less apparent.

The remarkable hydrocarbon homogeneity observed within the introduced populations of *R. flavipes* compared to the native populations has previously been detected in other introduced social insects. Recent research had revealed a similar change in CHC profiles within introduced ants, *L. humile* (Brandt et al., 2009) and *W. auropunctata* (Errard et al., 2005). These two studies showed that the CHC profiles of ants from native

[a] Different letters inside the parentheses indicate significant differences among groups (Kruskal-Wallis and Dunn *Post-Hoc* Tests).

populations were diverse, whereas the profiles of ants from various localities in introduced populations were uniform. This suggests that the introduction event into a new environment may be the cause of the reduced chemical variability of introduced populations. It is possible that, similarly to the introduced ant hypotheses, the reduced variability of recognition cues observed in introduced populations of *R. flavipes* is due to a reduction of genetic diversity through a genetic bottleneck (Tsutsui et al., 2000) or a selective process for the less common alleles of recognition (Giraud et al., 2002).

In all cases, the chemical homogeneity occurring in introduced populations of *R. flavipes* could explain two particular characteristics of the social organization in its French range. The first characteristic is the absence of aggression between colonies, which has been observed among all French populations of *R. flavipes* (Clément and Bagnères, 1998). Cuticular hydrocarbons generally are considered to have an important role in conspecific and colony member recognition (Clément and Bagnères, 1998; Blomquist and Bagnères, 2010). Thus, a low variability of chemical signature within introduced populations of *R. flavipes* could induce the recognition of non-nestmates as nestmates, thereby reducing intraspecific aggression. The second characteristic is the significant level of merging between separate colonies that has been found within one of the introduced French populations of *R. flavipes* studied (the Oléron population) (Perdereau et al., 2010). One of

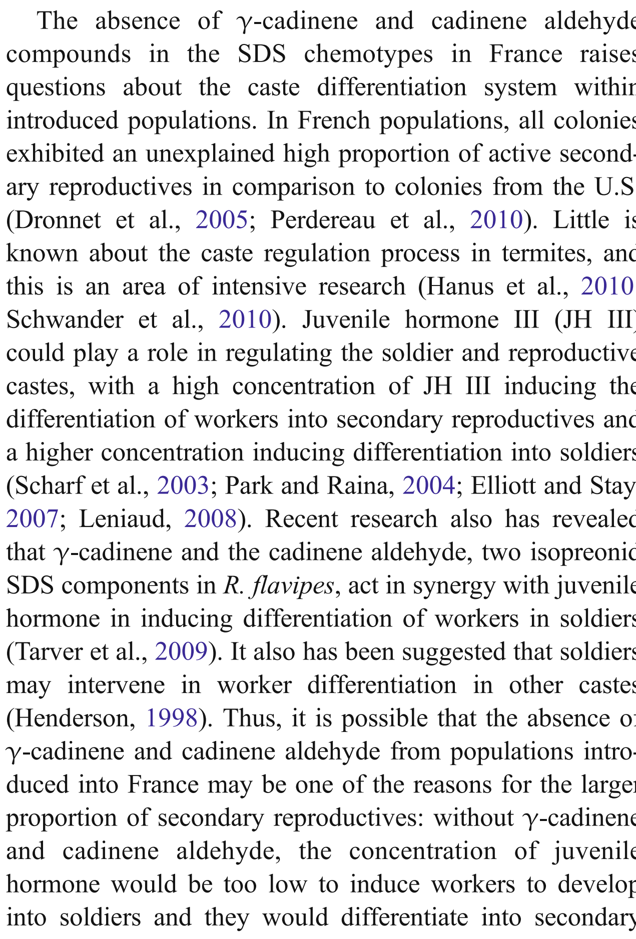
Table 2 Comparison of *Reticulitermes flavipes* soldier defensive secretion phenotypes by locality

Localities	Number of soldiers	Defensive secretion components					
		α-pinene	β-pinene	limonene	γ-cadinene	cadinene aldehyde	geranyl linalool
France							
Chemotype a	10	X	X	X	_	_	_
Chemotype b	3	X	X	X	_	_	X
Florida							
Chemotype c	15	X	X	X	X	X	_
Chemotype d	2	X	X	X	X	X	X
Louisiana							
Chemotype a	11	X	X	X	_	_	_
Chemotype c	6	X	X	X	X	X	_
Chemotype e	2	X	X	X	X	_	_
Chemotype f	1	X	X	X	_	X	_

the characteristics that appear essential for colony fusion is the absence of intraspecific aggression among individuals of the two parental colonies. The CHC homogeneity in introduced populations of *R. flavipes* could explain the lack of intraspecific aggression and, indirectly, the high rate of colony fusion within these introduced populations, as has been recently proposed for the Argentine ant, *Linepithema humile* (Vasquez et al., 2009).

This study also revealed that CHC profiles differed significantly among U.S. populations, whereas the three French populations exhibited similar CHC profiles. One possible explanation for this general pattern is that the three French populations all derived from a single original source population. This hypothesis is supported by several phylogeographic studies performed on *Reticulitermes* species, which showed that discrimination based on CHC profiles often is consistent with discrimination based on DNA markers (Jenkins et al., 2000; Clément et al., 2001; Copren et al., 2005; Austin et al., 2007). Another explanation that cannot be excluded is that the new habitat in France may have more consistent ecological factors, which may be the reason for the homogenous CHC profiles in all French populations of *R. flavipes*. Although studies have revealed that food, temperature, and social environment can affect the composition of CHC profiles (Florane et al., 2004; Dronnet et al., 2006), this second hypothesis is unlikely to explain the results obtained over this large geographic scale. Phylogeographic studies are needed to determine whether the French populations were founded from one or a few North American source population(s).

Concerning the source of the three introduced populations, results based on both CHC profiles and SDS chemotypes suggest that the French populations analyzed may have originated from Louisiana rather than from Florida. Principal component analysis showed that the CHC profiles of the three populations of Louisiana were closer to the chemical profiles of the three French populations than those in Florida. The analyses of SDSs showed, for the first time, a similar chemotype in the native and introduced ranges. This chemotype, not previously reported, is composed only of monoterpenes and is found in both France and Louisiana. The hypothesis that French populations came from Louisiana is also plausible from a historical point of view. During the 17th and 18th centuries, Louisiana was part of “New France” and New Orleans was the main trading port. Populations of *R. flavipes* may have been arrived in France on boats carrying agricultural and forestry products. In support of this, the first invasion of termites into France was reported in two major ports (Rochefort and La Rochelle) that were involved in international trade (Bobe-Moreau, 1843; Quatrefages, 1853).



The absence of γ-cadinene and cadinene aldehyde compounds in the SDS chemotypes in France raises questions about the caste differentiation system within introduced populations. In French populations, all colonies exhibited an unexplained high proportion of active secondary reproductives in comparison to colonies from the U.S. (Dronnet et al., 2005; Perdereau et al., 2010). Little is known about the caste regulation process in termites, and this is an area of intensive research (Hanus et al., 2010; Schwander et al., 2010). Juvenile hormone III (JH III) could play a role in regulating the soldier and reproductive castes, with a high concentration of JH III inducing the differentiation of workers into secondary reproductives and a higher concentration inducing differentiation into soldiers (Scharf et al., 2003; Park and Raina, 2004; Elliott and Stay, 2007; Leniaud, 2008). Recent research also has revealed that γ-cadinene and the cadinene aldehyde, two isopreonid SDS components in *R. flavipes*, act in synergy with juvenile hormone in inducing differentiation of workers in soldiers (Tarver et al., 2009). It also has been suggested that soldiers may intervene in worker differentiation in other castes (Henderson, 1998). Thus, it is possible that the absence of γ-cadinene and cadinene aldehyde from populations introduced into France may be one of the reasons for the larger proportion of secondary reproductives: without γ-cadinene and cadinene aldehyde, the concentration of juvenile hormone would be too low to induce workers to develop into soldiers and they would differentiate into secondary reproductives instead.

This study illustrates that hydrocarbon analysis is effective at discriminating populations of a *Reticulitermes* species. The CHC profiles reveal the possible origin of *R. flavipes* populations introduced into France and the history and routes of invasion. The homogeneity of the cuticular hydrocarbon profiles observed within introduced populations seems to be related to particular biological characteristics of introduced populations. Further studies should be carried out into the relationship between CHC variations and intraspecific aggression.

Acknowledgments We thank Simon Dupont for help in collecting samples of *R. flavipes* in France, Ed Vargo, and Claudia Husseneder for help in collecting samples in Louisiana (U.S.), Michael Scharf and Nan-Yao Su’s team for collecting samples in Florida (U.S.), and Tony Tebby for editing the manuscript. We thank Sylvain Guyot for his help in Rgui analyses. This work is part of the Ph.D. thesis of E. Perdereau.

Drywood termites are cryptic, seldom leaving obvious or visible external signs of their presence in wood. A commonly used sign for determining the presence of drywood termites is the occurrence of fecal pellets, ejected through a “kick-out hole” in the external surface of wood from the internal galleries (Ebeling, 1975). These pellets often are found as conical piles or are scattered on horizontal surfaces below infested wood. These hexagonally sided pellets are diagnostic for drywood termites, and can be used to distinguish damage from that by other wood-destroying insects (Ebeling, 1975; Moore, 1992).

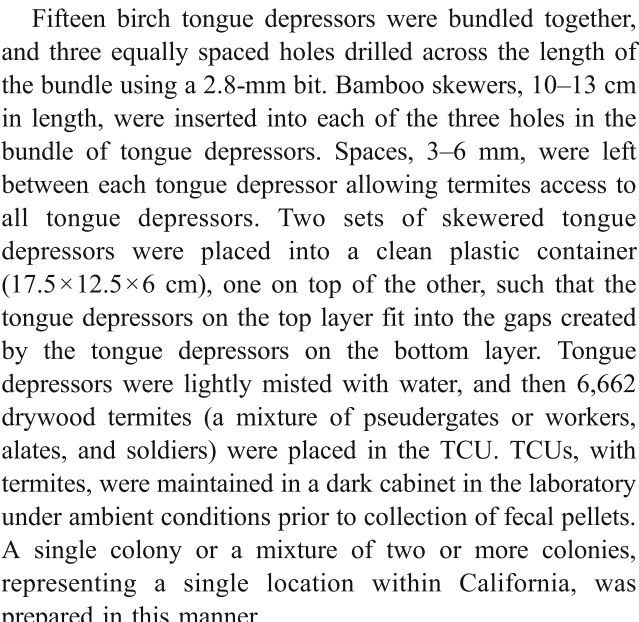
Grace and Yamamoto (2009) demonstrated the relationship between the cellulose and lignin content of the food utilized by small groups of *C. brevis* and *Incisitermes immigrans* (Light), and the quantity of fecal pellets produced over time. They also discussed the use of the size and number of fecal pellets for estimating both size and age of drywood termite colonies.

Drywood termites excrete feces in the form of hard, even-shaped fecal pellets. These fecal pellets contain the same mixture of hydrocarbons as the insects that produced them, albeit in slightly different proportions (Haverty et al., 2005). Because cuticular hydrocarbons are species specific in termites (Page et al., 2002), pellets can be used to identify the termite species that produced them. Rather than simply signaling the general presence of termites or providing a diagnosis of the species of termite inhabiting the wood, we postulated that these pellets could be chemically characterized so as to determine the status of a colony as active (alive) or inactive (dead).

Here, we report quantification of the hydrocarbons in pellets of *I. minor* aged for up to 1 year after they were produced. We document the changes in proportions of selected hydrocarbons as an indication of the length of time since the pellets were excreted.

Methods and Materials

Collection of Termites and Preparation of Termite Containment Unit Termites, *I. minor*, were removed from one naturally infested board (98.9×13.3×271.8 cm) collected on 19 July 2006 from Lakeview, California, and stored at the University of California Richmond Field Station. The board was cut across the grain into pieces, 5–8 cm thick, and stored at room temperature. A wood chisel was used to separate pieces of wood into smaller pieces, 0.5–1.0 cm thick. Termites were removed from all visible galleries with forceps. All remaining live termites, including soldiers and primary reproductives (alates), were placed in a termite containment unit (TCU). Termites thus collected were likely from a large mixed colony (Booth et al., 2010) or from multiple colonies. We were not able to assign the various galleries in the wood to any particular colony.



Fifteen birch tongue depressors were bundled together, and three equally spaced holes drilled across the length of the bundle using a 2.8-mm bit. Bamboo skewers, 10–13 cm in length, were inserted into each of the three holes in the bundle of tongue depressors. Spaces, 3–6 mm, were left between each tongue depressor allowing termites access to all tongue depressors. Two sets of skewered tongue depressors were placed into a clean plastic container (17.5×12.5×6 cm), one on top of the other, such that the tongue depressors on the top layer fit into the gaps created by the tongue depressors on the bottom layer. Tongue depressors were lightly misted with water, and then 6,662 drywood termites (a mixture of pseudergates or workers, alates, and soldiers) were placed in the TCU. TCUs, with termites, were maintained in a dark cabinet in the laboratory under ambient conditions prior to collection of fecal pellets. A single colony or a mixture of two or more colonies, representing a single location within California, was prepared in this manner.

Pellet Collection and Aging Process After all the TCUs had acclimated to laboratory conditions over several weeks, new holding chambers were prepared. A total of 3,402 live workers were transferred to a new TCU. All wood debris, pellets, dead termites, and damaged tongue depressors were discarded. The termites in the new holding chambers were maintained in the laboratory under ambient conditions for 2 weeks. At the end of this period, all pellets were removed, and sub-samples collected and readied for the aging study. Concurrently, three samples of 20 workers, three samples of 20 alates, and one sample of 20 soldiers were also collected for hydrocarbon analysis. Live termites were placed in a 20-ml scintillation vial and frozen until extraction.

Fecal pellets were separated from debris by sequentially sifting them through successively smaller sieves (Haverty et al., 2005). It was important to avoid contamination of samples with any extrinsic hydrocarbons. Thus, all substances such as hand lotion, lip balm, Parafilm, and waxed paper were kept away from the work area. Gloves were worn when handling pellets, and implements that came in contact with pellets were wiped with a paper towel dampened with absolute ethanol to remove any oils or waxes. Pellets were separated from fine debris by removing individual pellets with forceps or with an aspirator, until a sample weighing approximately 200 mg was obtained.

In developing this protocol we made one estimate and one critical assumption. The estimate was that at least 1,000 pellets were needed for each hydrocarbon analysis (based on preliminary analyses of pellets collected from drywood termites maintained in our laboratory). The critical assumption was based on work conducted by Scheffrahn et al. (1997) using *C. brevis* and *I. snyderi* (Light) from southern Florida. In that study, 40 *I. snyderi*

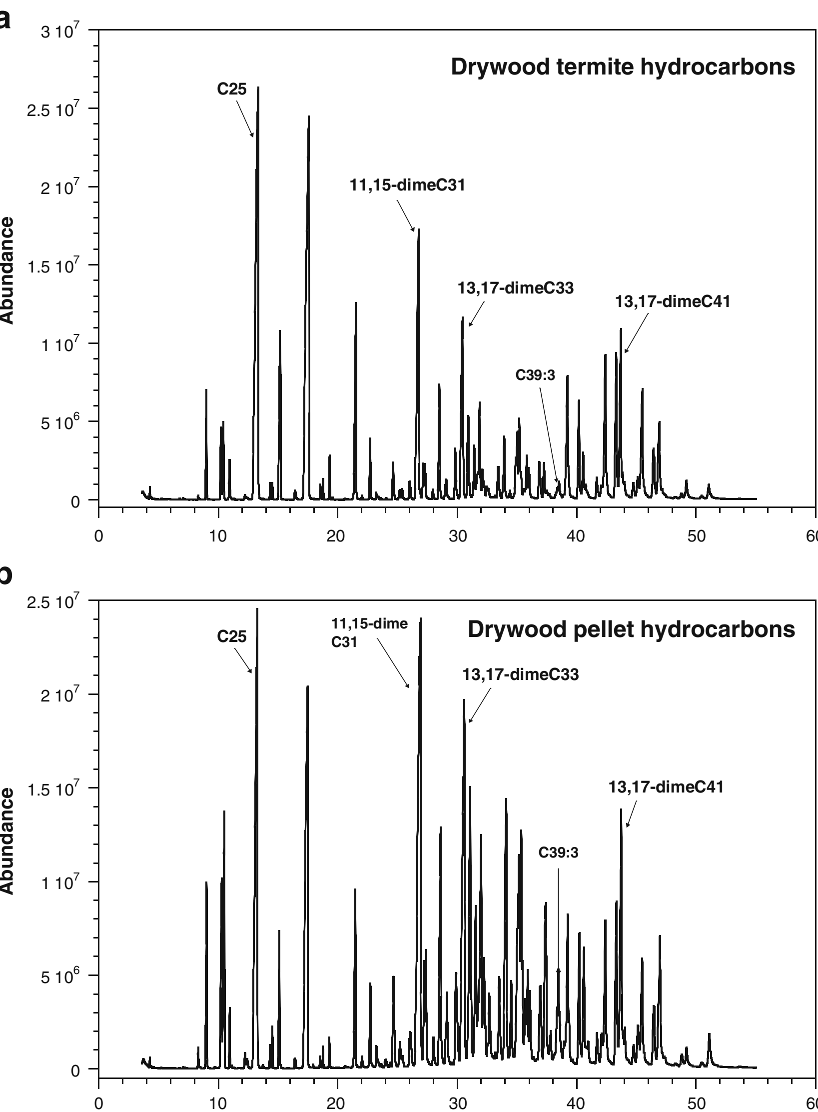


Fig. 1 Total ion chromatogram of cuticular hydrocarbons from **a** workers of *Incisitermes minor* (Hagen) and **b** from fecal pellets from the same collection. Acronyms for hydrocarbons are derived as follows: *X-me* location of methyl groups, the total number of carbons *CXX* in the hydrocarbon component excluding the methyl branch(es), and *CXX:Y* the number of double bonds following a colon

(pseudergates or workers) produced 573 pellets over 4 weeks, slightly less than 150 pellets/wk or about 3.5 pellets/individual/wk. In a study with small groups of *C. brevis* and *I. immigrans*, Grace and Yamamoto (2009) found that these species produced 4.9 to 7.0 pellets/individual/wk. For our study, we assumed that *I. minor* would produce pellets at roughly the same rate and, therefore, we needed about 3,000 to 5,000 individuals in a TCU for this study. We prepared one TCU to collect the requisite quantity of fecal pellets.

Four sub-sampling intervals, each replicated three times, were used: 0, 30, 90, and 365 days from the initial collection date. Sub-samples were stored in clean, 20-ml scintillation vials, sealed with 1.5×1.5 mm mesh screen. Vials were stored in a dark cabinet at the University of California Richmond Field Station at ambient temperature.

Voucher samples of *I. minor* pseudergates or workers and soldiers from this study (fresh, not dried) were preserved in 85% ethanol and deposited in the Essig Museum, University of California at Berkeley (Haverty et al., 2005).

Extraction Procedure and Characterization of Hydrocarbons Hydrocarbons from workers, alates, soldiers, and fecal pellets of *I. minor* were extracted, characterized, and quantified as previously reported (Haverty et al., 2005). Frozen termite samples were thawed and dried at 70°C for approximately 1 h before extraction. Each sub-sample of fecal pellets or termites was placed in a 20-ml scintillation vial, and immersed in 10 ml of *n*-hexane for 10 min. After extraction, hydrocarbons were separated from other compounds through 4 cm of activated Sigma silica gel (70–230 mesh) in

[a] Mean percent (SD) of total hydrocarbon composition. Compounds are listed in elution order

[b] Acronyms for hydrocarbons are derived as follows: location of methyl groups (X-me), the total number of carbons (CXX) in the hydrocarbon component excluding the methyl branch(es), and the number of double bonds following a colon (CXX:Y)

[c] These hydrocarbons were not reported for *I. minor* pseudergates or fecal pellets in Haverty et al. (2005)

[d] An isomeric mixture or two or more compounds co-eluted in this peak

Pasteur pipette mini-columns. The resulting hydrocarbon fractions were evaporated to dryness under a stream of nitrogen and redissolved in 60 •l of *n*-hexane for gas chromatography-mass spectrometry (GC-MS) analysis. A 3-µl aliquot was injected into the GC-MS.

GC-MS analyses were performed on an Agilent 6890 gas chromatograph interfaced with an Agilent 5973 Mass Selective Detector, using Agilent Chemstation data analysis software (G1701CA version C.00.00). The GC-MS was equipped with an HP-1MS, fused silica capillary column (30 m×0.25 mm i.d, 0.25 µm film thickness), and was operated in split mode (split ratio of 30:1), using helium as carrier gas. The column oven was programmed from 200–320°C at 3°C min^{-1}, with a final hold of 11 min. Electron impact (EI) mass spectra were obtained at 70 eV.

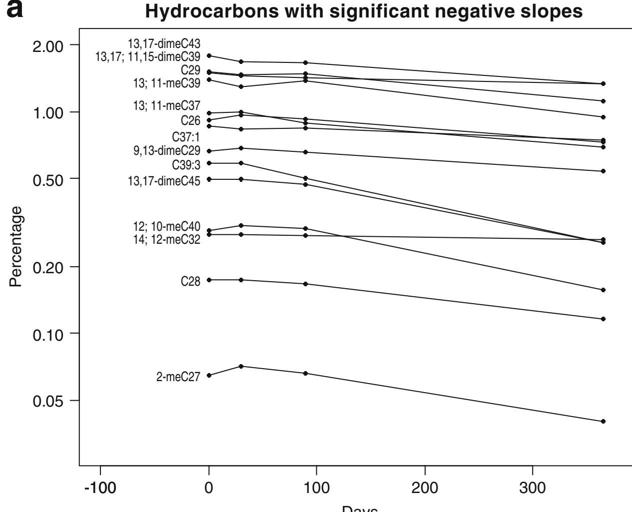
All chemicals of interest were identified by their retention times and mass spectra. Mass spectra of methyl-branched alkanes were interpreted as described by Blomquist et

Table 2 Relative abundance[a] of hydrocarbon classes from pseudergates, alates, soldiers, and fecal pellets of *Incisitermes minor* (Hagen)

Hydrocarbon class	Pseudergates	Alates	Soldiers	Fecal pellets
Normal Alkanes	38.39	23.12	29.77	18.71
Olefins[b]	18.38	21.11	20.31	20.66
Terminally branched methylalkanes	3.90	4.49	5.32	5.19
Internally branched methylalkanes	9.01	7.70	8.88	8.33
Dimethylalkanes	25.24	36.18	29.79	37.40
Trimethylalkanes	5.09	7.40	5.92	9.71

[a] Percent of total hydrocarbon composition

[b] All peaks with co-eluting olefins and saturated compounds are summarized as olefins



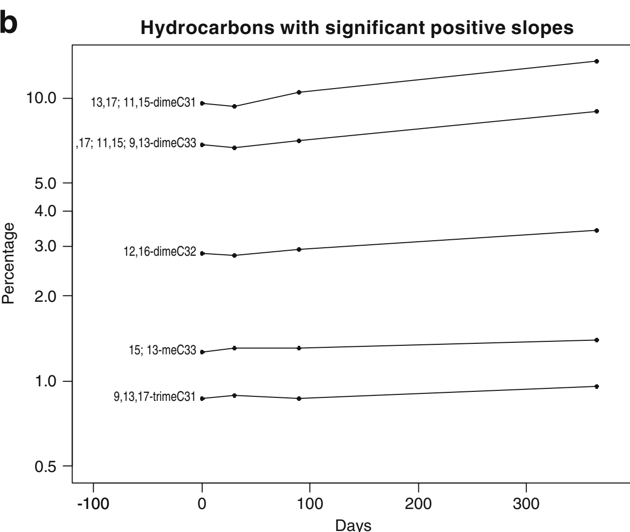


Fig. 2 Changes in percent content of individual hydrocarbons, over time, from fecal pellets of *Incisitermes minor* workers. **a** hydrocarbons with significant (α=0.05) negative slopes, and **b** hydrocarbons with significant positive slopes. Acronyms for hydrocarbons are derived as follows: *X-me* location of methyl groups, the total number of carbons, *CXX* in the hydrocarbon component excluding the methyl branch(es), and *CXX:Y* the number of double bonds following a colon

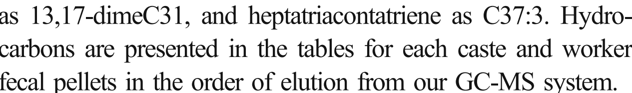
al. (1987) so as to identify methyl branch locations. Mass spectra of di- and trimethylalkanes were interpreted as described by Page et al. (1990) and Pomonis et al. (1978). Olefins were identified by their mass spectra, although double bond positions were not determined (Haverty et al., 2005).

In the text, tables, and figures, we use shorthand nomenclature to identify individual hydrocarbons or mixtures of hydrocarbons. This shorthand uses a descriptor for the location of methyl groups (X-me), the total number of carbons (CXX) in the hydrocarbon component excluding the methyl branch(es), and the number of double bonds following a colon (CXX:Y). Thus, pentacosane is represented as *n*-C25, 11-methylnonacosane as 11-meC29, 13,17-dimethylhentriacontane



as 13,17-dimeC31, and heptatriacontatriene as C37:3. Hydrocarbons are presented in the tables for each caste and worker fecal pellets in the order of elution from our GC-MS system.

Statistical Analysis GC-MS peak (some peaks contained more than one compound or a mixture of positional isomers) areas were converted to percentages of total hydrocarbon fraction, enabling mean (±SD) relative amounts of each hydrocarbon peak for workers and alates, and overall mean (±SD) of each hydrocarbon peak for the fecal pellets, to be calculated.

The percentage of each hydrocarbon peak for pellets of each aging period was transformed to the log of the percentage (dependent variable Y) and regressed against the days of aging (independent variable X). Hydrocarbons with slopes different from 0 (α=0.05) were separated into two groups: those with a significant positive slope and those with a significant negative slope. For each aging period (0, 30, 90, and 365 day), an index of age (I_{age}) was created by subtracting the sum of the percentages of the hydrocarbons with a negative slope over time from the sum of the percentages of the hydrocarbons with a positive slope over time [$I_{age}=\sum(PEAK_{positive})$ minus $\sum(PEAK_{negative})$, for each aging period]. The I_{age} for each aging period then was regressed against the aging period (R Development Core Team, 2004).

Results and Discussion

The cuticular hydrocarbons for *I. minor* pseudergates and fecal pellets were characterized previously (Haverty et al., 2000, 2005). The composition of the hydrocarbon mixture

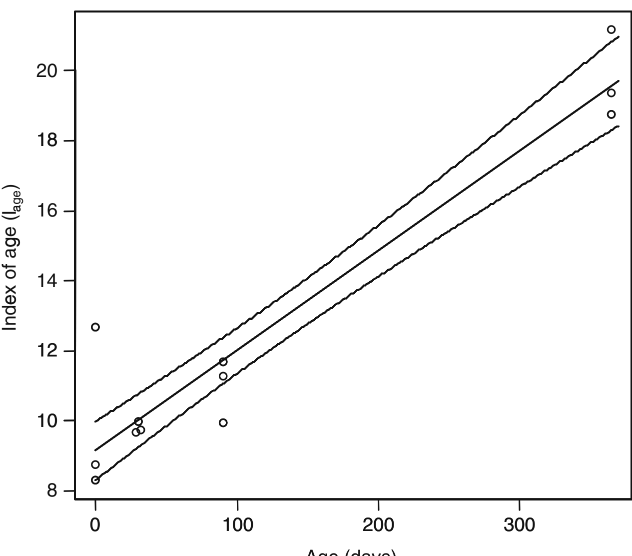


Fig. 3 Fitted line and 95% confidence intervals for a plot of the mean of index of age (I_{age}) against age. Values for 30 day are jittered a small amount so that all three data points can be seen

for this species and the hydrocarbons from their fecal pellets in the present study are displayed in Fig. 1 and summarized in Table 1.

Hydrocarbons from Termites *n*-Alkanes and dimethylalkanes were the predominant classes of hydrocarbons in all castes and in fecal pellets (Table 2), as previously reported by Haverty et al. (2000, 2005). *n*-Alkanes comprised from 23.12% to 38.39%, unsaturated components from 15.21% to 19.03% , terminally branched monomethylalkanes from 3.90% to 5.32%, internally branched monomethylalkanes from 7.70% to 9.01%, and dimethylalkanes from 25.25% to 36.18%, of the total hydrocarbon content. There was also a homologous series of trimethylalkanes, representing 8.26% to 9.48% of the total hydrocarbon content.

The hydrocarbons of *I. minor* characterized in this study included all of the compounds reported by Haverty et al. (2005), as well as 18 additional hydrocarbons (Table 1). These additional hydrocarbons were not abundant, never representing more than 0.85% of the total hydrocarbon (as for the mixture of 12,16-dimeC34 and C35:1 in soldiers) content, and usually much less. The detection of these additional hydrocarbons in this study are likely due to the greater concentration of the extracted hydrocarbons used or, possibly, colony to colony variation.

Hydrocarbons from Termite Fecal Pellets In general, the hydrocarbons from whole-body extracts of *I. minor* were represented in extracts of fecal pellets. As with whole-body extracts of *I. minor*, dimethylalkanes were the predominant class of hydrocarbon, followed by olefins and normal alkanes (Table 2). Only two hydrocarbons (*n*-C30 and 13-meC30; Table 1) were found in termites and not in fecal pellets, but these were present in small quantities, less than 0.1% of the total hydrocarbon content. The lack of these two hydrocarbons in fecal pellets may be a function simply of the concentration of the extracts.

Changes in Hydrocarbons of Fecal Pellets over Time We identified 73 hydrocarbon peaks in fecal pellets of *I. minor* (Table 1). Of these peaks (data from non-significant slopes not reported), 19 of 73 (26%) had a significant change, either positive (five) or negative (14), over time (Fig. 2). This is a much higher number of statistically significant slopes (different from 0), than would be expected by chance alone (5% of 73 peaks is <4 peaks).

The index, I_{age}, for each of the three replications (A, B, and C at 0, 30, 90, and 365 day) was plotted against the associated number of days (Fig. 3). The fitted line, with a 95% confidence interval for the means to show the variability of the replicates, had a high adjusted R^2 (= 0.888) value, suggesting that it might be possible to predict fecal age by the index.

We do not know the basis by which peaks increase or decrease over the 1-year period. In general, those that increased in relative abundance tended to have higher initial relative abundances; i.e., mono-, di-, or tri-methylalkanes with carbon chains of 31, 32, or 33. Those that decreased were represented in five of the six classes of hydrocarbons, ranging from C26 to C45. Only the terminally branched hydrocarbons were not represented in peaks with negative slopes.

The composition of the hydrocarbon mixture of insects is genetically controlled (Toolson and Kuper-Simbrón, 1989; Kaib et al., 1991; Page et al., 1991; Coyne et al., 1994). This composition can be slightly affected by diet and environmental conditions (Hadley, 1977; Espelie et al., 1994; Chapman et al., 1995; Howard, 1998; Woodrow et al., 2000). Haverty et al. (1996) demonstrated significant seasonal variation in quantities of some hydrocarbons of *Coptotermes formosanus* Shiraki from Hawaii; these differences were small and associated with the production of alates. However, the qualitative mix of hydrocarbons has been shown to be stable over decades among species of cone beetles in the genus *Conophthorus* (Page et al., 1990).

The motivation for our study was to devise a method for the evaluation of the success or failure of drywood termite treatments, including fumigation and local application methods. With the recent classification of sulfuryl fluoride (the only fumigant active ingredient registered in California) as a greenhouse gas (Mühle et al., 2009) and the anticipated increase in local treatments, we felt that there would be considerable interest by the industry, regulatory agencies, and consumers for a simple and accurate means to determine whether or not a targeted colony/infestation is still in a structure. Our method, based on changes in hydrocarbon chemistry over time, shows promise to this end. Future research includes: (1) validating these findings for additional species of drywood termites and geographic populations of the same species, (2) validating these findings at different times of the year, and (3) exploring seasonality in pellet production and hydrocarbon quality in pellets.

Acknowledgments We thank Robin Tabuchi, Lynette Yang, Shawn Leighton, and Sara Moore for technical assistance in removing and culturing termites and the tedious work of collecting samples of termite fecal pellets. We extend thanks to the pest management professionals who provided us with the infested wood used to collect the drywood termites. This research was made possible, in part, by contract #084-2856-5 to VRL by the California Structural Pest Control Board, Department of Consumer Affairs, Sacramento, California.

EAD) in order to identify which compounds emitted by *C. arvense* inflorescences are perceived by the fly.

Methods and Materials

Plant Material and Volatile Collection The *Cirsium arvense* plants were from the Ecological Botanical Garden of the University of Bayreuth. *C. arvense* is a dioecious plant. Staminate and pistillate flower heads emit the same scent compounds, although the total amount of scent is higher in staminate flower heads (Theis et al. 2007; Primante and Dötterl unpublished data). The petals of both sexes reflect light mainly in the blue (max. 450 nm) and red range (650–700 nm) (Primante and Dötterl unpublished data). We, therefore, did not discriminate between flower sexes. Flowering branches were cut in the field and placed in water in the laboratory for immediate scent collection. Four to seven flower heads of *C. arvense* were enclosed in a polyester oven bag (Toppits, Germany), and over an 8 h period the emitted volatiles were trapped in an adsorbent tube filled with 20 mg of a 1:1 mixture of Tenax-TA (mesh 60–80, Supelco) and Carbotrap (mesh 20–40, Supelco) (Dötterl et al. 2005). Volatiles were eluted with 60 µl of acetone (SupraSolv, Merck KgaA, Germany) to obtain 6 odor samples for the electrophysiological experiments.

Electrophysiological Experiments and Chemical Analyses Electrophysiological analyses of the floral scent samples were performed with the GC-EAD system as described by Dötterl et al. (2005). Antennae from 23 females and 11 males of *E. balteatus* (one antenna per individual, one run per antenna) were tested between July and August 2008 on our 6 odor samples (3–5 female and 1–5 male antennae per sample). To identify the EAD-active compounds, 1 µl of the scent samples was analyzed on a Varian 3800 gas chromatograph fitted with a 1079 injector and a ZB-5 column (5% phenyl polysiloxane; length, 60 m; inner diam, 0.25 mm; film thickness, 0.25 µm; Phenomenex) and a Varian Saturn 2000 mass spectrometer (Dötterl et al. 2005). Component identification was carried out using the NIST 08 mass spectral database or MassFinder 3, and was confirmed by comparison of mass spectra and retention times with those of authentic standards.

Behavioral Assay To determine the relative importance of olfactory and visual cues for finding flowering *C. arvense* by flies experienced in foraging, we conducted two-choice bioassays in a flight cage at the end of summer 2009.

Pupae of *E. balteatus* were provided by Katz Biotech Ag (Baruth, Germany) and kept in a small gauze tent (60×60×60 cm) at 23°C until hatching. Immediately after the adults hatched, they all were transferred to a flight cage (7.20×3.60×2.20 m) that was set up in a greenhouse. The population of 55 female and 30 male adult flies were fed on fresh flowers of *C. arvense,* but all floral material was removed from the cage at least 12 h before conducting a bioassay.

We performed two two-choice bioassays to assess fly attraction to floral cues: 1) Visual only vs. visual and olfactory cues combined, and 2) Olfactory only vs. visual and olfactory cues combined. In the assays, flies were offered flowering branches (with 30–40 flower heads

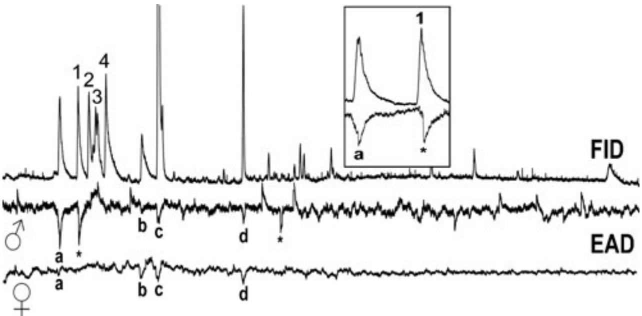

Fig. 1 Examples of coupled gas chromatographic and electroantennographic detection (GC-EAD) of a *Cirsium arvense* inflorescence scent sample using antennae of female and male *Episyrphus balteatus*. a: phenylacetaldehyde; b: (*E*+*Z*)-pyranoid linalool oxide; c: methyl salicylate; d: dimethyl salicylate. The abundant compounds acetophenone (1), (*E*)-furanoid linalool oxide (2), coeluting linalool and methyl benzoate (3) and 2-phenylethanol (4) did not elicit responses. The responses marked with an asterisk are artifacts as shown in the box where we present an enlarged section of the FID and corresponding antennal response of the male. The antennal response did not occur simultaneously with FID peak 1

each) in quartz glass cylinders constructed to present either visual or olfactory cues, or both. The basic cylinder for testing attraction to olfactory and visual cues in combination consisted of a transparent quartz glass cap and body and a sleeve of Macrolon®, which connected and sealed the cap and body. The Macrolon® sleeve had 60 holes (diam 0.2 cm), arranged in three horizontal lines to allow diffusion of floral scents. The cylinders were mounted on a black polyvinyl chloride (PVC) disc (diam 11 cm) that was attached to a square wooden table. A tube coupled the cylinder to a membrane pump (flow 1 $1 min^{-1}$; G12/01EB, Rietschle Thomas, Puchheim, Germany). A modified transparent cylinder without holes and without connection to a pump was used for testing visual attraction only. A cylinder with holes and the pump, but painted black with semi-matte varnish, was used for testing olfactory attraction only.

The two test cylinders were set up 2 m apart for each of the two bioassays. Each test was conducted for 40 min, and 20 min after beginning the test, the position of the cylinders was exchanged. The behavior of the flies was classified as "approaching" when flies hovered in front of the cylinder but did not land, and "landing" when flies contacted the glass cylinder. To assure that an individual fly was counted only once in a specific test, responding flies were captured.

Results and Discussion

In the bioassays, *E. balteatus* preferred a combination of both cue modalities over visual cues but not over olfactory cues. When testing a combination of visual and olfactory cues against visual cues, 24 flies were attracted by the combination of both cues and no flies were attracted by the visual cues (*chi square* observed vs. expected test: χ^2= 24.0; df=1; P<0. 001) (Table 1). When testing a combination of visual and olfactory cues against olfactory cues, both types of cylinders had the same attractiveness (*chi square* observed vs. expected test: χ^2=0.36, df=1; P=0.55) (Table 1). These experiments demonstrate that experienced flies primarily use olfactory cues for seeking *C. arvense* flower heads, whereas visual cues do not play a significant role. We did not determine whether flies would respond to visual cues in the absence of *C. arvense* odors. *C. arvense* flowers reflect light in the blue range of light, and blue was somewhat attractive to *E. balteatus* (Sutherland et al. 1999).

The GC-EAD measurements revealed the candidate molecules responsible for attraction of flies. Four compounds occurring in the scent of *C. arvense* flower heads (Theis et al. 2007), consistently elicited antennal responses, in more than 50% of tested antennae from both female and male flies: phenylacetaldehyde, methyl salicylate, dimethyl salicylate, and pyranoid linalool oxide (Fig. 1). Less consistent responses were found for the two coeluting compounds methyl benzoate, which was not described by Theis et al. (2007), and linalool (47% response rate); and for 2-phenylethanol (41% response rate). Although we did not test the isolated EAD-active compounds for attractiveness, our results, and those of other researchers, led us to hypothesize that at least methyl salicylate and 2-phenylethanol are attractants for *E. balteatus*. These compounds were emitted in abundant amounts from the flower heads used in this study (Fig. 1), and have been described previously as syrphid attractants (Zhu and Park 2005). In a field experiment, they increased the attractiveness of yellow sticky cards (Zhu and Park 2005).

Recently, Majetic et al. (2009) found that augmentation of inflorescences of *Hesperis matronalis* with scent (collected at night from *H. matronalis*) increased visitation by syrphids, whereas the color of this color-polymorphic plant (white vs. purple) did not influence the visitation rate of flies. Their study also showed that syrphid flies respond to floral scent, but they performed the experiments with manipulated inflorescences. Our study demonstrates for the first time that a syrphid fly uses olfactory and not visual cues to find an unmanipulated pollen/nectar host-plant.

Acknowledgments Gregor Aas helped with plant material and provided the greenhouse and Irmgard Schäffler participated in useful discussions. Lynn Amanda Staff, Joseph Woodring, and two anonymous referees gave valuable comments on an earlier version of the manuscript. are instead attracted to the mixture as a whole. Here, we seek to disentangle these alternatives.

In the present study, we investigated the behavioral response of the predatory mite *Phytoseiulus persimilis* to individual volatile compounds and to binary mixtures thereof. This predatory mite feeds on the highly polyphagous two-spotted spider-mite *Tetranychus urticae* (Bolland et al., 1998). The predatory mite relies entirely on olfactory cues to locate distant spider-mite-infested plants (Sabelis and Van der Baan, 1983; Sabelis et al., 1984; Dicke et al., 1990; Dicke and Dijkman, 1992). Different plants produce qualitatively and quantitatively different odor mixtures in response to spider-mite feeding (van den Boom et al., 2004). Consistent with the chemical diversity of the information associated with its prey this predatory mite responds to a wide variety of spider-mite induced plant odor mixtures (van den Boom et al., 2002) and a wide range of structurally different volatile compounds (Dicke et al., 1990; de Boer and Dicke, 2004a, b; Kappers et al., 2005; van Wijk et al., 2008). Discriminating the odor of a spider-mite-infested plant from an uninfested conspecific is a challenging task because many components of both odor mixtures will be present in both. Spider-mite-infested tomato, for example, emits substantial amounts of 19 compounds, 5 of which change significantly in concentration after spider-mite infestation.

Discrimination of the target odor from similar odor sources essentially can be achieved in two ways. Odor perception could be elemental, i.e., the mites perceive and respond to individual components of the mixture. As the components in a mixture are recognized, a component that is an attractant when presented individually is also in a mixture recognized as an attractant. Hence, if odor perception is elemental, the additive effects of all individually recognized attractants and repellents in the mixture will form a likely estimate of the attraction to the mixture. However, in most olfactory systems, the different chemical components of odor mixtures are not detected as independent elements because different odorants of the same mixture may compete for the same receptor site (Oka et al., 2004; Rospars et al., 2008), or because they may affect each other's representation through cross-glomerular circuit interactions in the olfactory system (Kay and Stopfer, 2006; Riffell et al., 2009). Consequently, odor perception becomes synthetic, the individual components of a blend may no longer be recognizable in the mixture, and the mixture is perceived as a distinct odor different from its individual components. This may facilitate the ability to discriminate between mixtures that share many components such as the odor of herbivore-infested plants and uninfested conspecifics. This is because synthetic perception releases the brain from the constraint of representing an odor in the same way, whether it is part of a mixture or not. Hence, correlated olfactory input can be decorrelated in such a way, that the ensemble of neurons encoding one odor, shares little or no overlap with the ensemble of neurons encoding the other. Consequently, when olfaction is strictly synthetic, the response elicited by a specific volatile compound may be entirely different from its contribution to the response elicited by a mixture that it is part of.

The central nervous system of *Phytoseiulus persimili*s consists of just 10.000 cells (van Wijk et al., 2006a). Its glomerular olfactory system is similar to the system found in insects and vertebrates (van Wijk et al., 2006b). The relative simplicity of this mite's olfactory system combined with its reliance on olfaction to locate distant prey makes it an ideal model organism to study how predators utilize the complex and variable source of olfactory information that herbivore- infested plants provide.

The olfactory response elicited by the individual components of an odor mixture serve as the input for three conceptual models that are used to predict the response elicited by the mixture. These model predictions were compared to the observed response elicited by the binary mixture in the predatory mite *P. persimilis*.

(1) One model is additive and therefore tests the assumption that the response elicited by each of the mixture's components contribute equally to the response elicited by the mixture.
(2) In a second model, the response elicited by an odor mixture is equal to the response elicited by the mixture's component that elicits the strongest response. Hence, this model is consistent with the frequently observed phenomenon of overshadowing, i.e., an olfactory system that receives competitive inputs by the different chemical components in the odor mixture. The odor that elicits the strongest response inhibits the perception of or the response to the other components in the mixture.
(3) The third model is intermediate between the other two models. Here, we assume that the response to a mixture is equal to the mean response elicited by its components. Hence, it is assumed that all of the mixture's components contribute equally to the response elicited by the mixture, while the perception of or the response to each component is reduced by the fraction of the total number of components in the mixture.

Because odors occur at different concentrations, we do not only investigate how the different components of odor mixtures affect the response that these mixtures elicit, but also, whether the same mechanism applies at different concentrations of the same odor mixture. This was examined in a separate series of experiments where we asked if a function that describes the response to a binary mixture as a function of the response to its components at

one concentration also describes the response to the same mixture at other concentrations.

Methods and Materials

Plants and Mites Lima been plants (*Phaseolus lunatus*) were grown from seeds in a climate room (22°C, 60% RH, 16:8 LD). After 2 week, these plants were infested with two spotted spider-mites (*Tetranychus urticae* Koch) to establish a culture of this mite. Predatory mites (*Phytoseiulus persimilis* Athias-Henriot) were reared in a climate room (25°C, 60% RH, 16:8 hL:D) on detached, spider-mite-infested Lima bean leaves. The predatory mites received fresh, spider-mite-infested Lima bean leaves every day, and the culture was harvested every day except for the weekend. This frequent harvesting of adult female mites ensured that most mites used in the experiments were one to a few days old after their molt to the adult phase. Predatory mites were obtained originally in 2001 from various locations near the coast of Sicily, Italy. Before choice tests, female predatory mites were kept in Eppendorf tubes and were deprived of water and food for 16–22 hr.

Odor Odors were selected from a panel of pure volatile compounds used to assess the olfactory response of *P. persimilis* (van Wijk et al., 2008). The odors selected for this study ensure that all possible combinations of repellents, attractants, and odors that elicited no response could be made. Most odors were obtained from Fluka with the exception of 2,3-dimethyl pyrazine that was obtained from Aldrich. Octan-1-ol and butan-1-ol were obtained from Sigma, dodecyl acetate from Aldrich, methyl salicylate (MeSA) from Sigma-Aldrich, and β-ocimene (70% *E*- and 30% *Z*- isomers) from R. C. Treat & co. The terpenoids (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) were provided by Dr. W. Boland of the Max Planck Institute for Chemical Ecology, Jena, Germany.

Olfactory Response Tests Choice tests were conducted as described by van Wijk et al. (2008). In short, the response to the odors was assessed by using an experimental arena constructed from a Petri dish (diam 9 cm) positioned upside down. A radial airflow was established by the connection of a vacuum pump (flow 0.42 l/min) to an opening at the center of the bottom (lid) of the Petri dish. Prior to the experiment, groups of about 25 predatory mites were placed in cartridges that could be fitted between the vacuum pump and the experimental arena. For each replicate, the arena was provided with fresh odor sources and a new cartridge with a new group of predatory mites. Each odor was tested in a different set-up. To restrain predatory mites after their choice on each side of the arena, an insect glue barrier divided the arena into two halves except for an opening of 3 cm at the center of the bottom of the arena. This opening allowed mites to move from the cartridge to the side of their choice, and it allowed mites to move from one side to the other. One side contained filter paper (diam. 1 cm) with 0.5 μl of the odor (dissolved in hexane), and the other side contained a control filter paper with 0.5 μl of the solvent (hexane). Odor sources were prepared in a fume hut, and the solvent was allowed to evaporate for 1 min before the odor source was placed in the set-up. Mites were released from the cartridge, and after 3 min the mites at both halves of the choice dish were counted.

Control Experiments To assess whether there is a difference between the measured olfactory preference of *P. persimilis* released in groups and *P. persimilis* released individually, a control experiment was conducted. In this experiment, the olfactory preferences of mites released individually (40 mites) and mites released in groups (six groups each with ca. 20 individuals) were compared. Four different combinations were tested: 1) no odor at both sides of the Petri-dish; 2) a Lima bean leaf discs (1,5 cm) vs. no odor at the control side; 3) a leaf disc at both sides; 4) a spider-mite infested leaf disc (web, eggs and mites removed) vs. an uninfested leaf disc.

Experimental Design and Statistics The preference of nine groups, each consisting of ca. 25 mites was tested for each of the two odors and their binary mixture. The experimental design followed a 3×3 Latin square; the odors (A, B, and the mixture AB) formed one side of the square while the other consisted of the experimental sequence. Hence, each odor was perceived by three groups first, by three groups second, and so on, thereby ensuring that three clusters of three groups of ca. 25 mites received the three odors in three different sequences. All experiments in one Latin square were completed in ca. 75 min. The mites were held ca. 20 min. in Eppendorf tubes between subsequent choice tests.

Assuming individual mites make independent choices, the response to each of the three odors compared to the control was analyzed using the replicated *G*-test for goodness of fit (Sokal and Rohlf, 1995). Differences among choice experiments were determined by analysis of variance (*ANOVA*) of the arcsine square root transformed frequencies of the olfactory preference, followed by Bonferroni *post-hoc* testing. This not only allowed us to test if there was a difference between the responses to the odors, but also if there was an effect of the position in the sequence and whether there was a difference among the experimental sequences as a whole.

The experimental results were compared to three model predictions. These models predict the response that a binary mixture elicits as a function of the response to each of the mixture's components. The first model had the following additive structure:

$$E_{(AB)} = \left(0.5 + \left(O_{(A)} - 0.5\right) + \left(O_{(B)} - 0.5\right)\right)*100\%$$

Here, $E_{(AB)}$ is the expected attraction to the mixture AB in%, and $O_{(A)}$ and $O_{(B)}$ are the observed fractions of mites attracted to odor A and B, respectively. If $E_{(AB)}$ became greater than 100%, it was assumed to be 100%. Under the second model, it was assumed that the response that a mixture elicits was equal to the response elicited by the mixture's component that elicited the strongest response. Hence, there is always a complete overshadowing. Under the third model, the expected response elicited by the binary mixture was predicted to be equal to the mean of the response elicited by its components $\left[\left(E_{(AB)} = \left(\left(O_{(A)+}O_{(B)}\right)/2*100\%\right)\right]$. The observed attraction to the binary mixture was compared to the expected attraction under each of the three models using a X^2 for goodness of fit test.

Binary Mixtures with the Same Component Ratio at Different Concentrations Dose response curves (pure odor, 10, 100, and 1000 times diluted odor in hexane) were generated in a way similar to the experiments described by van Wijk et al. (2008). The response to each concentration of each odor was tested in 6 replicate experiments, each based on ca. 20 predatory mites. Dose response curves for the binary mixtures described here were measured simultaneously with the dose response curves for their components published earlier (Van Wijk et al., 2008).

Results

Control Experiments To examine if *P. persimilis* mites released in groups show the same preference for odors in the experimental set-up as *P. persimilis* released individually, 4 control experiments were conducted. The olfactory responses by *P. persimilis* assayed in groups did not differ from those tested individually (Table 1).

To examine whether the repetitive testing affected the responsiveness of the mites, a meta-analysis was performed on all experiments listed in Table 2. We regressed the responsiveness defined as absolute fraction of mites attracted to each odor minus 0.5, on the position in the experimental sequence. We found that the responsiveness did not vary with the position in the experimental sequence (equation of the regression line: $y = -0.0017x + 0.1244$, r^2=0.0002 with y being the responsiveness and x being the position in the experimental sequence). Additionally, we checked for each experiment whether there were differences among the different experimental sequences and among the positions of odors in the experimental sequence using ANOVA on the arcsine square root transformed frequencies of the olfactory preference followed by Bonferroni post-hoc analysis (Supplemental data Table 1). We did not detect any effect of the sequential testing on the olfactory preference except for experiment 1 (α-humulene and linalool). In this experiment, a significant effect of the position in the experimental sequence was found. This was due to the significant heterogeneity in the response to α-humulene (Table 2). In 9 choice tests (three times as the first, the second, and the third odor in the sequence), significant repellence was measured only once, when the odor was presented as the first odor in the sequence. Significant attraction was measured twice, when the odor was presented as the third odor in the sequence. The other six replicates revealed neither attraction nor repellence.

The Contribution of Each Component to the Mixture's Attractiveness We investigated the response of *P. persimilis* to 25 binary mixtures and to their individual components. Table 2 reports the fraction of mites (9 replicate experiments of ca. 25 mites per mixture) that were attracted to each binary mixture and its components. Table 2 also reports the predicted response under each of the proposed models, i.e., the additive response, the averaged response, and the overshadowing response model.

Based on the response to the mixtures' components, the experimental results can be divided into three groups: (1) experiments in which both components did not elicit a significant choice (G_p^{ns}) (experiment 1 to 7, Table 2); (2) experiments in which one of the components elicited a response (G_p*) whereas the other did not (experiment 8 to 17, Table 2); and (3) experiments in which both components elicited a response (G_p*) (experiment 18 to 25, Table 2). Figure 1 depicts the difference between the observed attraction to each binary mixture and the predicted attraction under each of the models.

In experiment 1 to 7 both components of the mixture elicited no response. Hence, in these experiments, the averaged response model and the overshadowing response model predict no significant attraction to or repellence of the mixture. Likewise, the additive response model predicts no response except when the response that each odor elicits borders significance and has the same direction. This latter case explains the significant difference between the observed absence of a response (G_p^{ns}) for the mixture and the expected response under the additive response model in experiments 2 (octan-1-ol and TMTT) and 5 (farnesol and

dodecyl acetate) (Fig. 1). The significant response to the mixtures (G_p*) in experiment 3 (dodecyl acetate, and 2,3-dimethyl pyrazine) and 6 (hexyl acetate and *cis*-3-hexen-1-ol) was significantly different from the predicted response under all three models. Given the variances among replicates, this does not necessarily imply that the difference among the components and the mixture differ significantly. As the experimental design followed a 3×3 Latin square, differences among odors were determined by analysis of variance (*ANOVA*). In this *ANOVA,* the arcsine square root transformed frequencies of the 27 individual choice experiments were analyzed for significant differences among the response to odors, position in the experimental sequence, and the three groups of different experimental sequences in the experiment. This analysis revealed that there were significant differences between the odors in experiment 6 (F_2=4.33, P<0.05) and in experiment 3 (F_2=18,34, P<0.05). *Post hoc* analysis revealed that the response to the mixture was significantly different from the response to its individual components. Hence, we conclude that in these experiments a mixture of two compounds that individually elicited no response, elicited a response when blended together in a binary mixture.

In experiment 8 to 16, one component of the binary mixture elicited no response whereas the other did. The overshadowing response model predicts that the response to the mixture is equal to the response elicited by the mixture's component that elicited a response. The additive response model predicts a response similar to that. Only the response to the mixture in experiment 8 (α-pinene and *cis*-3-hexen-1-ol) was significantly different from that predicted by the overshadowing response model. Experiments 8, 10 (dodecyl acetate and octan-1-ol) and 16 (linalool and MeSA) revealed a significant difference between the observed and the predicted response under the additive response model. In experiment 16, this appears to result from the fact that the repellence by the mixture was greater than the additive repellence by its components. *ANOVA* and the subsequent *post hoc* analysis revealed that this difference tended to be significant at P=0.07, *d.f.*=6. The reverse is seen in experiments 8 and 10. Here, the mixture elicited no response (G_p^{ns}) whereas one of its components did (G_p*). The *ANOVA* revealed that in both experiments the response to the mixture was not significantly different from the response to its components. Hence, although the responses to the mixture and its components were not significantly different, the replicated *G*-test indicates that the mites made no choice when provided with the mixture, whereas they did when offered one of its components. Moreover, the observed response in experiment 8 was significantly different from both the overshadowed response and the additive response model. In conclusion, in experiments in which only one of the mixtures' components elicited a response, the two models that predict overshadowing for the response to the mixture are most consistent with the observed response. There are, however, several cases where the component that elicited no response contributed to the response elicited by the binary mixture (experiment 8, 10, and 16).

In the last group of experiments, components in each mixture elicited a response. As in the previous groups of experiments, none of the models accurately predicts the response to all binary mixtures in this group. On one side of the spectrum, there are cases of overshadowing by the

component that elicited the strongest response, which was most obvious in experiment 17 (octan-1-ol and 3-octanone) and 20 (MeSA and β-ocimene) but this also applies to experiment 21 (β-ocimene and octan-1-ol), 24 (farnesol + 3-octanone), and 25 (dodecyl acetate and linalool). The additive response model accurately predicts the results obtained in experiment 19 (dodecyl acetate and MeSA), 20, 21, 24, and 25 (dodecyl acetate and linalool). Experiment 18 (MeSA + 3-octanone) revealed a weak additivity, which was significantly different from all three proposed models. There also are cases that are consistent with the additive response model experiment 19, 21, and 22 (benzyl benzoate and farnesol). On the other side of the spectrum, there was clear synergism in experiment 23 (farnesol and 2,3-dimethyl pyrazine), which was significantly different from the predictions under all three proposed models.

Binary Mixtures with the Same Component Ratio at Different Concentrations Here, we examined the hypothesis that a function that describes the attraction to an odor mixture as a function of the attraction to its components at one concentration also applies to other concentrations of the mixture. For example, if a mixture of two compounds is as attractive as the sum of the attractiveness of its components, we asked if this relation holds over a range of concentrations where the two components occur in the same ratio.

Dose response curves for the response to binary mixtures and the response to their components were constructed (Fig. 2). Apart from propionic acid, none of the odors elicited a significant response at the lowest concentration (1000× diluted). Since the individual components hardly elicited a response by the *P. persimilis* at this low concentration (van Wijk et al., 2008), and since the binary mixtures also hardly elicited a response (except for octan-1-ol + decan-1-ol), we only considered the three higher concentrations to test the null hypothesis. The null hypothesis was rejected in five (Fig. 2e to i) out of nine examined dose response curves of binary mixtures and their components.

In two experiments in which the null hypothesis was not rejected, the response elicited by one component overshadowed the response elicited by the other at all concentrations (Fig. 2a and b). Hence, the possibility that α-pinene was not perceived cannot be excluded (Fig. 2b). A mixture of two equally attractive components was not more attractive than either of its components (at all concentrations tested). Figure 2d shows a mixture of two compounds that were neither attractive nor repellent at any concentration. At the two highest concentrations, i.e. pure and 10× dilution, the response to the mixture was not significantly different from the response to its components. At the 100×

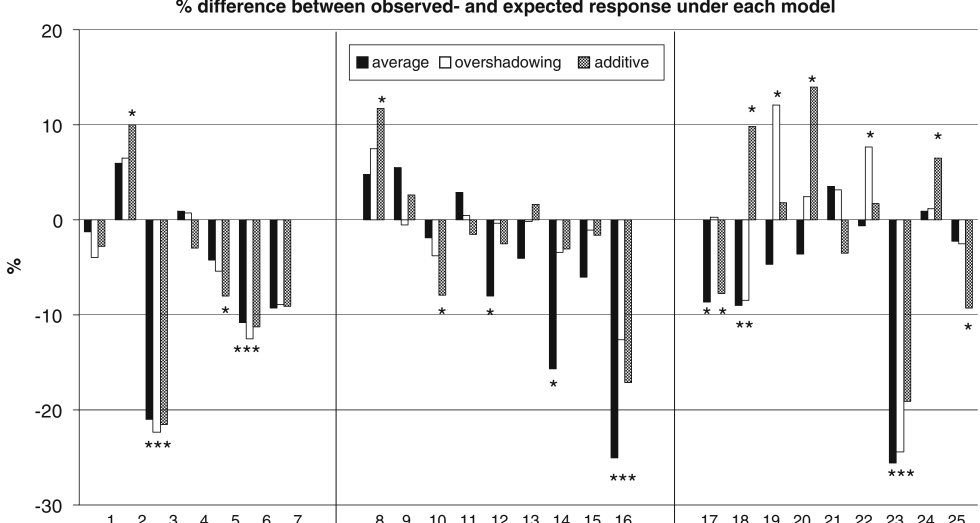

Fig. 1 Behavioral responses by *Phytoseiulus persimilis* to various odors. Below each group of three bars is the reference number of the experiment (also present in Table 2). Depicted is, for each experiment, the difference between the observed attraction (N=225 mites divided over 9 replicate choice tests) and predicted attraction under the averaging, the overshadowing and the additive response model respectively. A * indicates a significant difference ($X^2_{d.f.=1}$ P<0.05) between the observed response and the response under the model. The results are divided in three blocks representing experiments with both components of the mixture not eliciting a response, one component eliciting a response and both components eliciting a response, respectively

dilution, this difference was significant (F_2=4.72, P=0.026), however, the mixture was significantly attractive (G_p*) only at this dilution level while it tended to become significant at the 10× dilution (P (G_p)=0.055). Hence, this is an example where a mixture of two components that elicited no response when presented individually, triggered significant attraction when offered in combination. Although statistical significance for the difference between the mixture and its components was reached only at the 100× dilution, this result does not violate the null hypothesis tested here, as the qualitative contribution of each of the mixture's components to the response of the mites was the same at all concentrations.

The graphs depicted in Fig. 2e to i, all contain at least two points in the dose–response curve that require a different function to describe the attraction to the mixture as a function of the attraction to its components at different odor concentrations. Hence, we conclude that in five out of nine examined dose–response curves of binary mixtures of a constant component ratio, the relative contribution to the behavior elicited by each of the mixture's components varies with the odor concentration. Consistent with the results reported in Table 2 both components of the mixtures used in the dose–response experiments (Fig. 2) also do not appear to contribute equally to the response elicited by the mixtures. Sometimes the response to the mixture is very different from the response to both components. Figure 2e (100× dilution, 2,3-dimethyl pyrazine [(G_p^{ns}, G_h^{ns}), α-terpinene (G_p*, G_h*)]) shows an example of a mixture consisting of a neutral and an attractive compound that together are repellent (G_p*). Figure 2f (10× dilution: propionic acid (G_p*) and octan-1-ol, (G_p*)) shows an example of two attractive compounds that together are repellent (G*).

Discussion

Models based on neurophysiological principles have provided interesting insights in olfaction (Cleland and Linster 2005) and ideally are used to predict the response to odor mixtures. However, the neurophysiology of olfaction in organisms like *P. persimilis* is too poorly understood to construct models of olfactory information processing that incorporate morphological traits and physiological processes. This is why we used phenomenological models to test underlying general principles of information processing as they become apparent from behavioral responses.

The additive response model was based on the assumption that odors presented as individual compounds or as part of mixtures always elicit the same response. This requires that these odors are perceived strictly as elemental objects, and that each recognized object always triggers the same response. The responses to each compound are assumed to sum up to a response towards a mixture of these compounds. In the majority of mixtures studied (13 out of 25), the model prediction was significantly different from the observed results. This is consistent with results of

Fig. 2 The dose response relation of binary mixtures and their components. The experiments were conducted to assess if a function which describes the response of *Phytoseiulus persimilis* to a binary odor mixture as a function of the response to its components at one concentration also describes the response to the mixture at a different concentration. The y-axis represents the attraction of *P. persimilis* to the odor (N=120 mites divided over 6 replicates = 100%), the x-axis represents the four odor concentrations in decreasing sequence (pure, 10×, 100× and 1000× –diluted in hexane). The lowest concentration was omitted from the analysis as the mites hardly responded to the mixture. Above each odor concentration is an abbreviation which qualitatively describes the response to the odor mixture as a function of the response to its components. Abbreviations: ovA/ovB: overshadowing by compound A or B, eq: equal to the mixture's components, me: mean, sy: synergism, op: opposite of its components, at: a mixture of neutral compounds which is attractive, TMTT: (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene

studies in spiny lobsters (Lynn et al., 1994; Derby et al., 1996), beetles (Thiery and Visser, 1986), and humans (Schiet and Cain, 1990; Laing et al., 1994) where the response to odor mixtures also was found to be different from the additive response to their components. We conclude that in the majority of the assessed mixtures, *P. persimilis* does not respond to components in odor mixtures as if each of these components is experienced in isolation.

The overshadowing response model is based on the assumption that a component that elicits the strongest response suppresses the detection of or the response to all other components in the odor mixture. This model was best applicable to the specific situation where only one of the mixture's components elicited a response. If both components elicited a response, it fared much more poorly, however. We conclude that the response to an odor mixture usually does not result from absolute overshadowing by the mixture's component that elicits the strongest response.

In its assumption that all components equally contribute to the response elicited by the mixture, the averaged response model retains a key feature of the elemental perception of odors. On the other hand, the contribution of each of the mixture's components to the elicited response is reduced by a factor equal to the number of other components in the mixture. This latter assumption states clearly that each component of an odor mixture affects the perception of or the response to all other components that are part of the mixture. The predicted response under the overshadowing and the averaged response model were significantly different from the observed response in respectively 8 and 9 out of 25 mixtures examined. We conclude that these two models, which assume that components of odor mixtures affect each other's perception, explain the observed response better than the additive model, which assumes an elemental perception of odor mixtures.

Our results suggest that there is no simple rule that will predict accurately the response of *P. persimilis* to binary mixtures as a function of the response to their components. For the simple binary mixtures tested here, the model that predicts the responses to mixtures best still fails to explain 32% of the observed responses. Although the three selected models together span a large part of the possible response spectrum we found that the observed response was significantly different from all three models in 20% of the mixtures assayed.

If we consider the results of both the experiments that tested model predictions and the dose response experiments, we find almost all possible interactions between the components in odor mixtures. There are examples of overshadowing, averaging, synergies, and even a case of attractive components that became repellent when offered in a mixture. There were components of mixtures that in isolation elicited no response, whereas they clearly affected the response elicited by mixtures they were part of. Furthermore, mixtures of the same two components at a constant concentration ratio gave—in the majority of the dose response curves assessed—rise to different interactions at different concentrations (Fig. 2). We conclude that the effect that different components in mixtures exert on the mite's response varies both with component identity and odor concentration. Consequently, knowledge about the repellence or the attractiveness of a specific odor has a limited predictive or explanatory value if this information is used in the context of the response that odor mixtures elicit in *P. persimilis*.

The response to some mixtures was so different from the response elicited by their components that they were probably perceived as something quite different from their components. Some species appear to perceive binary odor mixtures as elemental objects whereas, depending on the combination of odors in the mixture, binary mixtures appear to possess more synthetic properties in other species. Humans, for example, perceive the components of binary mixtures, while they fail to do so in mixtures with a complexity of three to four components (Laing and Francis, 1989; Livermore and Laing, 1996; Marshall et al., 2006). Binary mixtures appear to possess a varying degree of synthetic properties in other species such as rabbits (Coureaud et al., 2009), rats (Staubli et al., 1987; Linster and Smith, 1999; Wiltrout et al., 2003), and slugs (Hopfield and Gelperin, 1989; Sekiguchi et al., 1999).

Phytoseiulus persimilis is well known to acquire a preference for the odor of spider-mite-infested plants over the odor of uninfested plants. However, more remarkably, this predatory mite also learns to prefer odor from uninfested plants if this is associated with food (Drukker et al., 2000; van Wijk et al., 2008). If, in contrast to the results reported here, olfaction were strictly elemental, the mites could in theory associate each of the detectable components in an odor mixture with the presence of their prey. *Phytoseiulus persimilis* has been reported to acquire a preference for MeSA after it has been given the opportunity to associate MeSA containing plant odors with prey (de Boer and Dicke, 2004a), while other components of food-associated odors do not appear to be associated with prey (van Wijk et al., 2008). Parasitoids and bees also behaviorally generalize their conditioned response from a mixture to a small number of its components, while they do not generalize this response to other detectable components in the mixture (Meiners et al., 2003; Reinhard et al., 2010). Other arthropods may not generalize their response to any of a mixture's components. The black bean aphid is repelled by nine host compounds, while a mixture of these repellents is an attractant (Webster et al., 2010). Similarly, the moth *Manduca sexta* responds only to a full floral odor blend and not to its components (Riffell et al., 2009).

There is evidence that representations of odors become more distinct from their components with increasing mixture complexity and with the degree of similarity of the mixture's components. Measurements of the odor induced activity in second order neurons in the olfactory pathway of zebrafish have revealed that binary mixtures of pure odorants are often dominated by the responses induced by one of the components, while complex mixtures of food extracts that have many components in common are more distinct from their components (Tabor et al., 2004). Rats perceive mixtures of similar compounds as dissimilar from their components, while mixtures of dissimilar compounds are perceived as similar to their components (Wiltrout et al., 2003). In our experiments using simple binary mixtures, the mites responded to some mixtures as if they were odors distinct from their components. With increasing mixture complexity, there are more ways for components of odor mixtures to affect each others perception, thereby facilitating the mixtures distinctness from its components. This may well explain why the predatory mites do not generalize their response from the highly attractive odor of a spider-mite infested plant to most spider-mite induced components (van Wijk et al., 2008).

tomatillo). Both species are difficult to control, and pheromones have been used for monitoring *H. virescens* moth flight and abundance (Chapin et al., 1997; Parajulee et al., 2004).

The chemical composition of *Heliothis* female sex pheromones have been studied in detail (Roelofs et al., 1974; Tumlinson et al., 1975; Klun et al., 1982; Heath et al., 1991). The pheromone glands of female *H. virescens* produce at least seven compounds, not all of which have been shown to affect male behavior (Groot et al., 2009). The pheromone compound with the highest titer is (*Z*)-11-hexadecenal (*Z*11-16:Ald), which together with (*Z*)-9-tetradecenal (*Z*9-14:Ald) must be present to elicit oriented male flight behavior (Vetter and Baker, 1983). (*Z*)-11-hexadecenol (*Z*11-16:OH) also is produced by the pheromone gland of *H. virescens.* This compound inhibits the response of males when they are exposed to relatively high concentrations in a pheromone plume (Vetter and Baker, 1983), but when males are exposed to lower amounts of this alcohol in combination with *Z*11-16:Ald and *Z*9-14:Ald, they are attracted (Ramaswamy et al., 1985; Groot et al., unpublished data). *Heliothis subflexa* females produce all of the above compounds but in different ratios from those produced by *H. virescens* (Sheck et al., 2006). The males of *H. subflexa* must be exposed to Z11-16:Ald, Z11-16:OH, and (*Z*)-9-hexadecenal (Z9-16:Ald) to become attracted. Additionally, *H. subflexa* females produce (*Z*)-11-hexadecenyl acetate (*Z*11-16:OAc) which enhances *H. subflexa* male attraction (Groot et al., 2009) but inhibits responses of male *H. virescens* (Vetter and Baker, 1983).

Both *H. virescens* and *H. subflexa* have a similar set of odorant receptor proteins (HvORs and HsORs) that are preferentially produced in the male antennae (Krieger et al., 2004; Vásquez et al., in press). One of these receptors, HvOR13, has been shown to be the receptor of the major pheromone component *Z*11-16:Ald (Gohl and Krieger, 2006; Grosse-Wilde et al., 2007; Kurtovic et al., 2007; Wang et al., in press), and it is expected that the *H. subflexa* ortholog, *HsOR13*, has the same function. *HvOR15* and *HsOR15* have male antenna-biased expression (Krieger et al., 2004; Vásquez et al., in press), and were considered candidate receptors for the critical component *Z*9-14:Ald in *H. virescens* and *Z*9-16:Ald in *H. subflexa,* respectively (Baker, 2009; Krieger et al., 2009; Gould et al., 2010), but recent work with *H. virescens* indicates that this is unlikely (Wang et al., in press), although it is possible that *HvOR15* could be the receptor of (*Z*)-9-tetradecenoic acid (*Z*9-14:COOH), the oxidation product of *Z*9-14:Ald.

We recently have examined the expression levels of five candidate pheromone receptors in *H. virescens* and *H. subflexa*, including *HvOr13, HsOR13*, *HvOR15*, and *HsOR15*. We found that *HvOR13* and *HsOR1*3 transcript abundance was comparable between *H. virescens* and *H. subflexa* male antennae, while *HvOR15* was expressed at higher levels than *HsOR15* (Vásquez et al., in press). This study supported earlier findings (Krieger et al., 2004) showing that transcript levels of these receptors in *H. virescens* are lower in females than in males. Because all of the antennal material used for these experiments was obtained from 2 h post eclosion adults, we do not know if age and/or physiological state could affect their transcript levels. As moths age, male response to female pheromones in some moth species increases (Gadenne and Anton, 2000; Domingue et al., 2006; Evenden and Gries, 2008), and in others it remains constant (Delorme and Payne, 1984). These behavioral data suggest that pheromone receptor expression may vary with age in some species. In *H. virescens,* older males are more responsive to the female sex pheromone and also mate more frequently than younger males (Shorey et al., 1968), but we lacked data on whether this behavior correlated with increased production of pheromone receptor proteins and corresponding higher transcript levels. We also did not know whether production of pheromone receptor proteins decreases after males mate as might be expected based on the finding that *H. virescens* virgin males are more likely to mate than males that had mated (Klepetka and Gould, 1996).

The goal of this study was to examine the effect of age and mating status on *HvOR13* and *HvOR15* gene expression in *H. virescens*, and *HsOR13* and *HsOR15* gene expression in *H. subflexa*. We compared gene expression levels of each of these *OR* genes between virgin male moths collected at different ages (2 h, 1 d, 2 d, 4 d, and 8-d); and between 4-d-old virgin male moths and 4-d-old male moths that had mated multiple times. We hypothesized that receptor transcript levels would increase as the male moths age and become more likely to mate. We further hypothesized that males that had mated would have decreased receptor protein production via reduced *OR* transcript abundance.

Methods and Materials

Insect Rearing and Sample Collection Heliothis virescens and *H. subflexa* individuals used in this experiment were collected from laboratory colonies maintained at North Carolina State University. The *H. virescens* colony was established in 1988 from eggs collected from tobacco in Yadkin County, North Carolina (Gould et al., 1995). The *H. subflexa* colony was established in 1997 from larvae collected from *Physalis angulata* in Florence and Barnwell Counties, South Carolina (Sheck et al., 2006). Field and large cage experiments indicate that these insect strains have maintained normal mate calling and response behaviors (Groot et al., 2006; Gould et al., unpublished).

For our experiments, two cohorts of each insect species were reared at different time periods so that we would have independent biological samples. For *H. subflexa*, the first and second cohorts were reared in June 2008 and July 2008, respectively. For *H. virescens*, the first and second cohorts were reared in September 2008 and October 2008, respectively. For each cohort, a total of 378 neonate larvae of each species were placed individually into 30 ml plastic cups containing corn/soy meal artificial diet (Burton, 1970). Larvae were reared in these cups until the pupation stage, at which time they were separated by sex. Approximately 120 male pupae from each species were placed in small plastic containers (9 cm diam, 7.5 cm high) covered with cheesecloth with a maximum of 40 pupae per container. Pupae and the eclosed adults were kept in a reversed light cycle (14 L:10 D) at 27°C and 50% RH so that experimental procedures could be conducted during the day.

Male adult eclosion was checked at the start of the scotophase, and then every 2 h for the first 8 h of each scotophase. Each emerging male was placed in a 200 ml cup with a cheesecloth top and was provided with a 10% sugar water solution. This procedure was followed for 3–5 d for each species. Fifty adult males that were less than 2 h old were collected and were assigned in groups of ten to the following age treatments: 8 d, 4 d, 2 d, 1 d, and 2 h. For the 2 h treatment, moths were between 0 and 2-h-old. All age treatments correspond to the time at which antennae dissection was performed after eclosion. In addition, we singly paired ten 2-h-old male moths with virgin females in 200 ml cups and maintained them in this condition until the males were dissected. The antennae of these mated male moths were dissected 4 d after eclosion for comparison to 4-d-old virgin males. Mating was confirmed by successful egg hatch. For each cohort, two pools of 5 pairs of antennae were collected per treatment, and each pool represented a sample (experimental replicate). For each sample, the antennae were dissected and immediately placed in a 1.5 ml RNase free tube on dry ice. The antennae were stored at -80°C until RNA extraction. This rearing and dissection regime gave us two biological samples per treatment, per cohort, per species.

Expression Levels of HvOR13, HsOR13, HvOR15 and HsOR15 in Male Moth Antennae using qRT-PCR RNA was isolated from each pool of 5 pairs of antennae (sample unit) using an RNeasy Plus Mini Kit (Qiagen, Valencia, CA, USA). RNA was quantified using a NanoDrop ND-1000 Spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA). Samples ranged from 0.9 to 3.6 μg total RNA. cDNA was synthesized from 150 ng total RNA using Array Script reverse transcriptase (Ambion, Foster City, CA, USA) in a reaction mix that included random hexamers (Applied Biosystems, Foster City, CA, USA), 10X Array Script buffer (Ambion), RNAseOUT (Invitrogen, Carlsbad, CA, USA), and 10 mM dNTPs (Invitrogen). Primers were designed using PRIMER EXPRESS 2.0 software (Applied Biosystems) to target exons of the *OR* genes (*HvOR13*, *HsOR13, HvOR15 and HsOR15)* and two housekeeping genes (*RL31* and *RPS3*) (Vásquez et al., in press). The housekeeping genes *RL31* and *RPS3* were both used as control genes. The same primers were used for *H. virescens* and *H. subflexa* samples since they amplify highly similar homologous cDNA sequences as verified by qRT-PCR product sequencing and alignment to cDNA sequences (Vásquez et al., in press). The sequences for the primers (5′ to 3′) used are as follows:

qHOR13-F: CTGCAAACGCCACATACGAT
qHOR13-R: CCCTTGAATTTGGTAGTGTAGTCAAA
qHOR15-F: TTCTGGTCAAATGATGCTTGGT
qHOR15-R: TCCCGGCTGAGTAATTGTTATACA
qRPS3-F: GGGACCAGCAAGGCAAGA
qRPS3-R: GGGCTCTGTTACCAGGAT
qRL31- F: CTTACACAAACGGCTTCATGGA
qRL31-R: CTGCGAATTTACGGATTTCCTT

Expression levels of *HvOR13*, *HsOR13*, *HvOR15, HSOR15, RL31,* and *RPS3* were determined using quantitative real-time PCR (qRT-PCR) with an ABI Prism 7900 sequence detector and a 384-well optical reaction plate (Applied Biosystems). Each reaction well had a total volume of 10 μl and contained 2 μl cDNA sample, 5 μl of SYBR Green PCR Master Mix (Applied Biosystems), 1 μl of a 10 μM stock of each primer, and 1 μl of nuclease free water (Invitrogen). The qRT-PCR program was run as follows: 50°C for 2 min, 95°C for 10 min, followed by 40 cycles of denaturation at 95°C for 15 sec, annealing and extension at 60°C for 1 min, followed by 95°C for 15 sec and 60°C for 15 sec. A dissociation curve was used to determine primer specificity. A negative control (cDNA reaction without reverse transcriptase enzyme) was used to check for genomic DNA contamination. Three technical replicates (individual reaction wells) were run for each sample per primer pair. Each sample was run twice on separate plates so that we had two measurements (runs) for the same biological material per cohort and per species. A standard curve was created for each primer set using five serial dilutions of genomic DNA to calculate the relative quantities of RNA levels for each sample. The standard curve method was used for data analysis, thus, for each sample, triplicate wells were averaged and the ratio of the gene of interest to the housekeeping gene was calculated (ABI User Bulletin 2). Note that the *H. sublexa* and *H. virescens* samples were collected and analyzed by qRT-PCR at different times, and thus, this experiment was not intended to provide a direct comparison of expression levels between the two species. For a between species comparison see Vásquez et al. (in press).

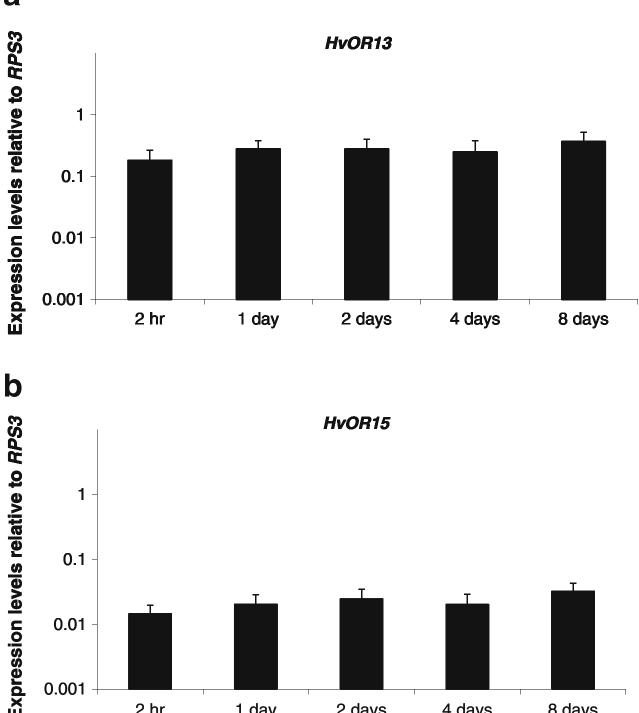

Fig. 1 Odorant receptor gene expression levels in *Heliothis virescens* male antennae across five ages determined by qRT-PCR. Expression levels of **a** *HvOR13* and **b** *HvOR15* were calculated relative to the control gene *RPS3* using the standard curve method. Bars on each column represent standard errors for the mean expression value (*N*= 4). Significant differences in levels of gene expression among treatments are indicated with different alphabetic letters

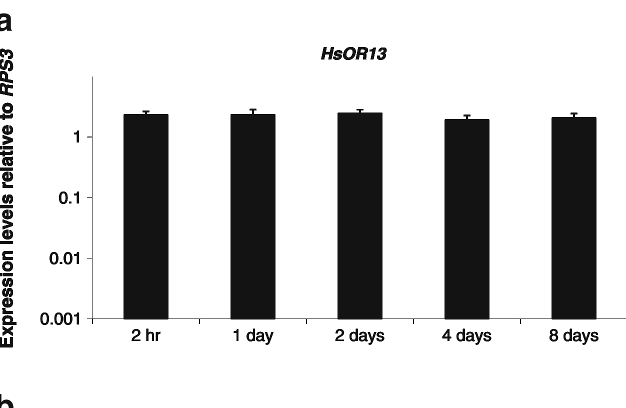

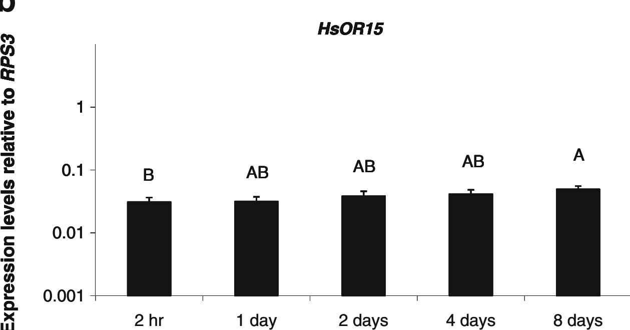

Fig. 2 Odorant receptor gene expression levels in *Heliothis subflexa* male antennae across five ages determined by qRT-PCR. Expression levels of **a** *HsOR13* and **b** *HsOR15* were calculated relative to the control gene *RPS3* using the standard curve method. Bars on each column represent standard errors for the mean expression value (*N*= 4). Significant differences in levels of gene expression among treatments are indicated with different alphabetic letters

Statistical Analyses A mixed model ANOVA was used to analyze gene expression data (log transformed) with gene expression as the response; cohort, age and the interaction treated as fixed effects; and run, run by cohort, run by age and experimental replicate nested within cohort by age treated as random effects. PROC MIXED (SAS, 2004) was used to perform the ANOVA as well as mean comparisons using LSMEANS. Gene expression in antennae of 4-d-old virgin and mated males was compared using *t*-tests.

Results

Housekeeping Genes Two housekeeping genes, *RPS3* and *RL31,* were used in this experiment. *RPS3* expression levels did not differ across *H. virescens* treatments (F=1.2, df=5, 12, P=0.364); or *H. subflexa* treatments (F=2.21, df=5, 4.84, P=0.206). Similarly, *RL31* expression levels were comparable across *H. virescens* treatments (F=2.73, df=5, 12, P=0.071); and *H. subflexa* treatments (F=4.36, df=5, 4.7, P=0.072). Therefore, we present only *HvOR* and *HsOR* expression results standardized to *RPS3* (for *RL31* results, see supplementary material).

Effects of Age Relative RNA quantities of pheromone receptor genes *HvOR13*, *HsOR13*, *HvOR15*, and *HsOR15* in the antennae of *H. virescens* and *H. subflexa* virgin males of five different ages (2 h, 1 d, 2 d, 4 d, 8 d) and 4-d-old mated males were calculated based on a standard curve and normalized to the housekeeping control genes. C_T values estimated for the *OR* and housekeeping genes are reported in Table S1 (Supplementary material). Transcript levels for *HvOR13* in *H. virescens* male antenna were similar (F= 0.72, df=4, 9.64, P=0.599) for all five ages examined (Fig. 1a). *HvOR15* was expressed at comparable levels (F= 0.73, df=4, 10.4, P=0.592) across all age treatments as well (Fig. 1b). In *H. subflexa* male antennae, no significant difference in expression levels of *HsOR13* (F=0.76, df=4, 10.1, P=0.575) was found across all five ages (Fig. 2a). In contrast, *HsOR15* expression levels were 1.6 times higher (F=3.69, df=4, 10.3, P=0.041) in 8-d-old males than those of 2-h-old males (Fig. 2b).

The mean *HvOR13*/*HvOR15* and *HsOR13*/*HsOR15* ratios for the 2 h treatment also were examined. *HvOR13* expression (normalized to *RPS3*) was 12.7 times higher than that of *HvOR15* (t=2.06, df=14, P=0.029), while *HsOR13* expression was 75.2 times higher than that of

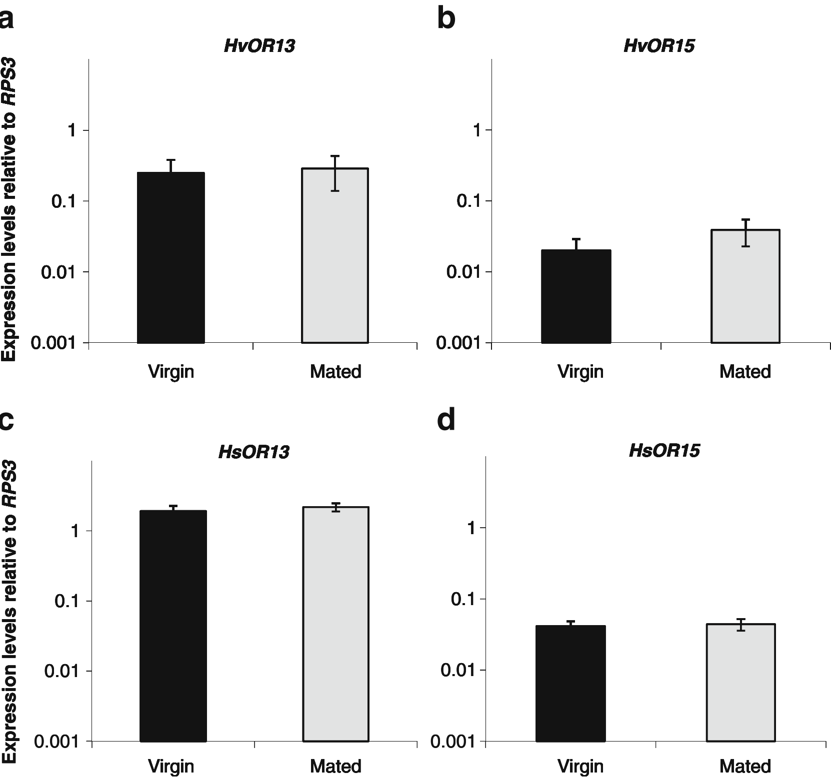

Fig. 3 Odorant receptor gene expression levels in antennae of 4-day-old virgin and mated *Heliothis virescens* and *Heliothis subflexa* males determined by qRT-PCR. Expression levels of **a** *HvOR13*, **b** *HvOR15*, **c** *HsOR13*, and **d** *HsOR15* were calculated relative to the control gene *RPS3* using the standard curve method. Bars on each column represent standard errors for the mean expression value (N=4). Significant differences in levels of gene expression among treatments are indicated with different alphabetic letters

HsOR15 (t=7.01, df=14, P<0.001). These gene expression ratios were approximately three times lower than those found by Vásquez et al. (in press) (*HvOR13*/*HvOR15* = 33.9, *HsOR13*/*HsOR15* = 268.4). These differences may be related to minor technical differences between studies that could affect RNA quantity estimates. However, the *HvOR13*/*HvOR15* ratio is consistently lower than the *HsOR13*/*HsOR15* ratio in both studies, thus, despite the differences in gene expression levels, both studies indicate that *OR13* expression is considerably higher than *OR15* in *H. subflexa* than *H. virescens*.

Effects of Mating Transcript levels of *HvOR13* and *HvOR15* were not significantly different between virgin and mated 4-d-old *H. virescens* male antennae (t=0.20, df=14, P=0.424 and t=1.09, df=14, P=0.147, respectively) (Fig. 3a, b). Likewise, *HsOR13* and *HsOR15* expression levels did not differ (t=0.56, df=14, P=0.292 and t=0.23, df=14, P=0.409, respectively) between virgin and mated 4-d-old *H. subflexa* male antennae (Fig. 3c, d).

Discussion

In biological systems, it is expected that gene expression levels will correlate with physiological and biological needs. For example, Fox et al. (2001) demonstrated that *Anopheles gambiae* females down-regulate one of their odorant receptor genes after taking a blood meal, presumably because these females are switching from searching for blood meals to searching for oviposition sites. Other studies in *A. gambiae*, *Drosophila melanogaster*, and *Caenorhabditis elegans* also have shown a correlation between changes in expression of a specific set of genes and behavioral and physiological responses (e.g., Peckol et al., 2001; Dierick and Greenspan, 2006; Abrantes et al., 2008; Zhou et al., 2009).

Male moths also could be expected to alter expression levels of odorant receptor genes based on their physiological and life history status. However, studies that investigate expression levels of odorant receptor protein genes or odorant binding protein genes in male insects, generally examine males of one post-eclosion age category and mating status, or different pre-eclosion age categories (e.g., Michalak et al., 2007; Xiu and Dong, 2007; Patch et al., 2009). In *H. virescens*, only one study has examined odorant receptor expression in male antennae at different times during pupal development (Krieger et al., 2009). A study that examined expression of one odorant receptor and one pheromone binding protein at nine time points during a 24 h period post eclosion in *Spodoptera littoralis* male antennae (Merlin et al., 2007) found no drastic changes in transcript abundance throughout this period of time. Another study that measured the effects of both age and

mating status in the diamondback moth, *Plutella xylostella* (Zhang et al., 2009), found that both factors affected expression levels of the pheromone binding protein gene, *PxylPBP1*. Transcript levels of this gene in male antennae decreased with time after emergence, and interestingly, 16-h-old mated males had considerably higher gene expression levels than unmated males of the same age. We could not find studies that examined effects of mating status and age over a period of time longer than 24 h on *OR* transcript levels.

Our results show that expression levels of *HvOR13*, *HsOR13,* and *HvOR15* do not change as the male moth ages over a period of eight days. It appears that quantities of *HsOR15* RNA increase slightly as the male *H. subflexa* moth ages, however, further replication is needed to confirm this trend. Mating status had no effect on expression levels of either gene in the two moth species. Our results indirectly suggest that males could be equally attuned to female pheromones regardless of age and previous mating experience. However, investment in pheromone receptor levels could be only a small component in the overall male responsiveness to females as other molecules (e.g., pheromone binding proteins, sensory neuron membrane proteins, pheromone degrading enzymes) may be involved in neuronal activation, or, furthermore, male response could be under central brain control. Another factor to consider is that RNA transcript levels do not always correspond with protein levels (Abreu et al., 2009; Bahrndorff et al., 2009), and this could be the case with pheromone receptor proteins.

Because there are no other studies that investigate changes in expression levels of pheromone receptor genes in male moths of ages beyond 24 h after eclosion or changes due to mating status, we compared our results to findings regarding effects of age and mating status on the actual behavioral response of male moths to pheromones. Some studies of male moths suggest that there is an increase in behavioral response to live females or synthetic female pheromones as virgin males age (Traynier, 1970; Baker and Carde, 1979; Gemeno and Haynes, 2000). Experiments with other species suggest there is an increase then decrease in virgin male response to live females or female pheromones (Kanno and Sato, 1978; Delisle, 1995; da Silva et al., 2006). In *Heliothis virescens*, the response of virgin males to female pheromone blends increases with age (Shorey et al., 1968). These behavioral results would not have been predicted from our findings as *OR* transcript levels in adult male antennae remained constant across time. The behavioral change in these insects could of course be due to changes in other aspects of the peripheral or central nervous system. For example, in a study with male *Agrotis ipsilon*, the corpora allata, which produces juvenile hormone (JH), was removed (Gadenne et al., 1993) and male sexual activity was dramatically lowered. Antennal sensitivity to the main pheromone component was measured in allatectomized and control males, and no statistical difference in the amplitude of the EAG response was found between these two groups. Morevover, JH controls behavioral responsiveness to pheromone by acting on central olfactory neurons (Anton and Gadenne, 1999).

In addition, there are a number of studies that have examined the effect of male moth age on electrophysiological response to female pheromones. The results of these indicate that male electrophysiological response varies across species. For *Ostrinia nubilalis*, based on a cut-sensillum technique, there was an increase in male electrophysiological response to female pheromone as the male moths aged (Domingue et al., 2006). Likewise, *Agrotis ipsilon* intracellular recordings indicated an increase in male electrophysiological response to female pheromone as the male moths aged (Gadenne and Anton, 2000). In contrast, in *Helicoverpa zea*, EAG response to the major pheromone component in the female blend remained constant in 1–3 day old male moths (Delorme and Payne, 1984). In cases where a change in electrophysiological response was found, a change in pheromone receptor gene expression could be involved, but this remains to be determined in the *Heliothis* species we examined. With regard to mating status, a study of *Vitacea polistiformis* showed that EAG responses of males to synthetic female pheromone were four times higher in virgin males than mated male moths (Pearson and Schal, 1999). In *H. virescens,* older males are less likely to mate than younger male moths (Klepetka and Gould, 1996). Thus, both studies suggest that production of pheromone receptor proteins could be higher in virgin male moths, and that mating could lead to a lower *OR* gene expression level. Nevertheless, our results do not support a correlation between mating and down-regulation of the *OR* genes examined.

There clearly is a high degree of variation among species in the effects of male age and mating status on behavioral and electrophysiological response to pheromones, but these results at the behavioral and electrophysiological level have not been linked to studies on expression level of genes involved in male response to pheromones. Our current work and that of Merlin et al. (2007) and Zhang et al. (2009) are a first step in this direction, but before any overall assessment of this relationship can be arrived at there is a need for similar gene expression studies in other moth species over the majority of their life spans.

of (*Z*)-11-hexadecenal and (*Z*)-13-octadecenal, in a 1:1 ratio (Bjostad et al., 1981). This sex pheromone blend is used to monitor populations of this pest in Israel (Anshelevich et al., 1993), and attempts to control the insect by sex pheromone mating disruption also are underway in Israel (Ally R. Harari, personal communication). However, a possible drawback for the successful development of mating disruption of this insect is the instability of the natural pheromone. Aldehydes are unstable under field conditions, suffering from relatively rapid oxidation and polymerization. More stable and behaviorally active structural analogs of aldehyde pheromone components hence are potentially useful in pest management (Ujvary et al., 1993).

In this study, we report the electrophysiological and behavioral responses of *C. gnidiella* males to formate analogs of (*Z*)-11-hexadecenal and (*Z*)-13-octadecenal, namely (*Z*)-9-tetradecenyl formate and (*Z*)-11-hexadecenyl formate, respectively.

Methods and Materials

Insects Cryptoblabes gnidiella larvae were collected from an infested vineyard in Southern Uruguay (Juanicó, Canelones, 34°34′ S, 56°15′ W). The larvae were maintained on post-harvest grape remains, under a 14:10 hr (L:D) photoperiod at 22±1°C and 70–80% relative humidity. Pupae were sexed and maintained separately in cylindrical plastic boxes (12 cm diam., 11.5 cm high) until adult emergence. Adults were fed on a liquid diet, based on honey and sugar, until used in experiments.

Gas Chromatography-electroantennogram Detection (GC-EAD) Studies Analyses were carried out using an HP 5890 Series II Gas Chromatograph with simultaneous flame ionization and electroantennogram detection. The column effluent was split by a fused silica outlet splitter (Alltech Associates, State College, PA, USA), with N_2 makeup (30 ml.min^{-1}) added before the splitter. The outlet column to the EAD was heated to 220°C and passed through a water-cooled condenser tube (1 cm diam.), into a stream of charcoal-filtered and humidified air (300 ml.min^{-1}), to the antennal preparation. The antenna was located 1 cm downstream from the column exit and contacted antenna holders (Syntech, Hilversum, The Netherlands) via electrically conductive gel. The holders were connected to a pre-amplifying probe (10X, Syntech), and the EAD response was further amplified with a high-impedance amplifier (Syntech, Kirchzarten, Germany). The EAD signal finally was fed back to the GC motherboard for digitization and processing. The GC was equipped with an injector in the split mode and an Elite-5 column (Perkin Elmer, Fremont, CA, USA) (30 m × 0.25 mm, 0.25 μm), and operated with a constant carrier gas (H_2) flow of 2 ml.min^{-1}. The temperature program used was 70°C (held for 1 min) to 240°C at 10°C.min^{-1}.

To study the responses of antennae to pheromone components after exposure to formates, 1–3-d-old males (N=10) were placed individually in Petri dishes (9 cm diam.) with 150 holes (each, ca 1 mm diam.) evenly distributed over the base. Another Petri dish base, containing a piece of filter paper (2×2 cm) loaded with 5 μg of the formates (1:1 mixture), was connected to the bottom of the first, allowing the vapor of the formates to enter the upper Petri dish through the holes. The formates were dissolved in *n*-hexane, and the solvent allowed to evaporate before the tests. Males were exposed for 1 hr in the dark, transferred to a clean container, cooled for 5–10 min. before their antennae were excised for GC-EAD studies. The GC-EAD conditions were as described above, except a temperature program of 150°C (held for 1 min) to 240°C at 10°C.min^{-1} was used. The responses of antennae to the pheromone (1:1 mixture, 0.5 mg.ml^{-1}, 0.5 μl, 30:1 injector split ratio) were recorded as the height of the EAD signal, and compared (Mann-Whitney test) to the responses of antennae from control males (N=10) that had been treated under the same conditions without exposure to formates.

Wind Tunnel Experiments Experiments were conducted in a cylindrical acrylic tube (150 cm long × 40 cm diam.) equipped with a controlled suction pump, activated charcoal filters, and a metal screen to smooth the airflow (0.2–0.3 m.s^{-1}). Experiments were carried out at 21–25°C and 70–80% relative humidity. Two hours before the tests, 3–5-d-old virgin males were placed in individual glass tubes (8 cm long × 4.5 cm diam.) with mesh covering both ends. The tests were conducted during the dark period, and the behavioral responses of males were observed and recorded on a digital camera with night-vision technology (Sony DCR-SR45).

Four treatments were evaluated in the wind tunnel tests: **a)** a natural rubber septum containing 50 μg of pheromone (1:1 ratio of components); **b)** a septum loaded with 50 μg of pheromone (1:1 ratio) plus 50 μg of formates (1:1 ratio); **c)** calling virgin females (3–7-d-old); and **d)** calling virgin females along with a septum containing 50 μg of formates (1:1 ratio) placed outside, on top of, the tube enclosing the females. Treatments were hung at the tunnel entrance, inside a glass tube (8 cm long × 4.5 cm diam.; gauze-enclosed for the calling females). For the treatments with virgin females, 1–2 females were placed in the glass tube 2 hr before the experiments; in all replicates, at least one of the females was observed calling throughout the test period. Fifteen individual males were tested to each of the treatments, except (c), in which 20 males were tested.

Tests were run 1–5 hr before the photophase. Each tube containing a male was hung at the end of the tunnel, left

closed for 1 min to allow the odor plume to reach the male, the gauze removed, and the behavior of the male recorded for the next 10 min. The behaviors recorded were, oriented flight (directed toward the source) and source contact. Each male was tested only once. The behavioral data from the various treatments were compared using *Chi-squared* tests.

Field Tests Field trials were performed in an infested commercial vineyard (see insect collection for location), from mid January through early March 2010. Six different ratios of pheromone and formates were tested: 1:0, 0:1, 5:1, 1:1, 1:5, and 1:10. All septa (except 0:1 treatment) were loaded with 1 mg of pheromone (10 µl of a 100 $mg.ml^{-1}$ hexane solution, 1:1 ratio of components), and varying amounts of formates (100 $mg.ml^{-1}$ hexane solution; 1:1 ratio of components). Septa were hung in delta traps (white corrugated plastic; 24×15 cm base × 13.5 cm high), which were placed in vineyard rows (Gewürztraminer variety). Traps were spaced 20 m apart, with treatments randomly distributed in each of four independent blocks, separated by at least 40 m. Once a week, for 6 wk, male captures were checked, treatments within each block rotated, and septa in traps changed. In addition, sticky bases of traps were changed as needed, according to the captures of males. The number of males caught was transformed [$\sqrt{(x + 0.5)}$] for normality, and the data were analyzed by a factorial ANOVA, with blocks and time as independent factors (Statgraphics Plus 5.1). Differences among treatment means were assessed by a Tukey's test ($P \leq 0.05$).

Analytical Procedures Coupled gas chromatography-mass spectrometry (GC-MS) analyses were carried out using a QP-2010 Shimadzu machine, equipped with an OPTIMA-5-MS column (Macherey-Nagel) (30 m × 0.25 mm, 0.25 µm), operated at a constant carrier gas (He) flow of 1 $ml.min^{-1}$. The column oven temperature program was 70°C (held for 1 min), to 300°C at 7°$C.min^{-1}$, the injector temperature was 250°C, and the interface temperature 310°C. Injection (1 µl) was in the split mode. Electron ionization (EI; 70 eV) was used. NMR spectra (^{1}H, ^{13}C, DEPT) were recorded on a Bruker Avance DPX 400 (400 MHz) spectrometer, using $CDCl_3$ as solvent and TMS as internal standard, and are reported in δ values.

Synthesis of Compounds The sex pheromone components, (*Z*)-11-hexadecenal and (*Z*)-13-octadecenal, were obtained by oxidation of the corresponding alcohols with pyridinium chlorochromate (PCC) (1:2.2 molar ratio) in dichloromethane (Corey and Suggs, 1975). The crude product, in dichloromethane, was filtered through silica gel, the solvent evaporated, and the residue purified by flash chromatography (silica gel, hexane-ethyl acetate 9:1) to obtain the pheromone components (97 and 96% pure by GC-MS, respectively). (*Z*)-11-hexadecenal: ^{1}H NMR (400 MHz, $CDCl_3$), δ (ppm): 9.79 (s; 1H, CHO), 5.37 (t, *J*=5.4 Hz, 2H, CH = CH), 2.44 (m, 2H, $H_2C–CH_2O$), 2.05–2.04 (m, 4H), 1.29–1.65 (m, 12H, CH_2), 0.88–0.91 (m, 3H, CH_3). ^{13}C NMR (100 MHz, $CDCl_3$), δ (ppm): 203.2; 129.9; 44.3; 32.4; 32.0; 30.1; 29.8; 29.6; 27.6; 27.3; 23.1: 23.0; 22.7; 14.5. (*Z*)-13-octadecenal: ^{1}H NMR (400 MHz, $CDCl_3$), δ (ppm): 9.77 (s, 1H, CHO), 5.36 (t, J=4.6 Hz, 2H, CH = CH), 2.41–2.45 (m, 2H, $H_2C–CH_2O$), 1.98–2.07 (m, 4H, $H_2C–CH = CH–CH_2$), 1.60–1.67 (m, 2H, CH_2), 1.27–1.33 (m, 16H, CH_2), 0.89–0.93 (m, 3H, CH_3). ^{13}C NMR (100 MHz, $CDCl_3$), δ (ppm): 203.0; 129.8; 42.5; 30.9; 29.5; 27.2; 22.2; 14.6. MS (EI) *m/z* (%): 266 (2); 248 (5); 152 (5); 149 (6); 138 (6); 137 (5); 136 (6); 135 (13); 125 (9); 124 (10); 123 (10); 122 (8); 121 (22); 112 (13); 111 (22); 110 (16); 109 (20); 108 (8); 107 (8); 99 (6); 98 (42); 97 (37); 96 (38); 95 (41); 94 (11); 93 (12); 85 (11); 84 (24); 83 (46); 82 (44); 81 (50); 80 (12); 79 (13); 71 (14); 70 (29); 69 (60); 68 (24); 67 (46); 57 (27); 56 (26); 55 (100); 54 (17); 53 (5); 43 (25); 42 (8); 41 (43).

Both formates were synthesized from the corresponding alcohols, (*Z*)-9-tetradecenol and (*Z*)-11-hexadecenol (Pherobank, The Netherlands). Dicyclohexylcarbodiimide (DCC, 0.38 g, 1.84 mmol) was added to a solution of formic acid (70 µl, 1.84 mmol) in dried dichloromethane (6 ml), before (*Z*)-9-tetradecenol (0.3 g, 1.41 mmol) was added, along with 4-dimethylaminopyridine (DMAP) (catalytic amount). The same procedure was used with (*Z*)-11-hexadecenol (0.3 g, 1.25 mmol), adjusting the amount of reagents to maintain the same molar ratios (Neises and Steglich, 1978). The mixture was stirred for 4 hr under a nitrogen atmosphere at ambient temperature, before the crude product was diluted with dichloromethane (15 ml), filtered, and washed with a saturated solution of NaCl. After evaporation of the solvent, the residue was purified by flash chromatography (silica gel, hexane-ethyl acetate 9:1) to obtain 304 mg of (*Z*)-9-tetradecenyl formate and 302 mg of (*Z*)-11-hexadecenyl formate (90% yield and 99% purity, by GC-MS, for both formates). (*Z*)-9-tetradecenyl formate: ^{1}H NMR (400 MHz, $CDCl_3$), δ (ppm): 8.06 (s, 1H, OCOH); 5.30–5.39 (m, 2H, CH = CH); 4.16 (t, J=6.8 Hz, 2H, CH_2O); 1.99–2.02 (m, 4H, $H_2C–CH = CH–CH_2$); 1.62–1.69 (m, 2H, $H_2C–CH_2O$); 1.26–1.37 (m, 14H, CH_2); 0.89 (t, J=7.0 Hz, 3H, CH_3). ^{13}C NMR (100 MHz, $CDCl_3$), δ (ppm): 161.4; 130.1; 129.9; 64.3; 32.1; 29.8; 29.5; 29.3; 29.3; 28.6; 27.3; 27.1; 25.9;

Results

GC-EAD Studies The sex pheromone analogs, (*Z*)-9-tetradecenyl formate and (*Z*)-11-hexadecenyl formate, elicited EAD responses from *C. gnidiella* male antennae (Fig. 1). Although these responses were not quantified, they were similar in magnitude to those of the pheromone components (Fig. 1). That a single antenna responded successively to an analog and pheromone component, respectively, suggests that the perception of the analog did not severely impair the subsequent responses of the antennal receptors. This is consistent with the results from the experiment in which males were pre-exposed either to formate vapors or control air before EAD responses to the pheromone components were recorded: the magnitude of the EAD responses to either pheromone component was similar regardless of pre-exposure (Fig. 2).

Wind Tunnel Experiments No behavioral responses were observed to the formates alone or the control septum in the wind tunnel (data not shown). Over 85% (13/15) of males showed oriented flight, and 60% (9/15) contacted the odor source when tested to synthetic sex pheromone (Fig. 3a). However, an antagonist effect was observed when males were tested to the mixture of pheromone and formates, with only 6.6% (1/15) of males exhibiting oriented flight and 0% contacting the odor source (Fig. 3a). This effect also was apparent when using calling virgin females. Using calling females alone, 45% (9/20) of males exhibited oriented flight and all of these contacted the source, whereas, when calling females were tested with the formates, no males exhibited oriented flight or contacted the source (Fig. 3b).

Field Tests The field trial was conducted during a period of high population levels of the insect, as evidenced by the captures in the pheromone traps (1:0 treatment; average of 314 males/wk and a total of 1,847 over the 6 wk of the experiment; Fig. 4). When the formates mixture was added to the septa, a dose-dependent decrease in male catches was observed (Fig. 4a). Factorial analysis showed no significant effect among blocks ($F_{3,130}$=0.75; P>0.5), but significant effects of time (sampling week; $F_{5,130}$=18.15; P<0.001) and treatment ($F_{5,130}$=217.68; P<0.001). All pheromone: formate blends captured significantly fewer males than pheromone-baited traps. When septa were loaded with a greater amount of formates than pheromone, only one insect was trapped (in 1:5 blend), even though the total amount of pheromone was the same (1 mg) for all treatments (Fig. 4a). The difference in captures was significant in the first week of the experiment, and this tendency was maintained throughout the whole experimental period (Fig. 4b).

Discussion

Our study demonstrates that the sensory system of *C. gnidiella* males can detect (*Z*)-9-tetradecenyl formate and (*Z*)-11-hexadecenyl formate, possibly due to their structural similarity to the sex pheromone components, (*Z*)-11-hexadecenal and (*Z*)-13-octadecenal, respectively. The structural change between each pheromone component and its corresponding analog is the replacement of a methylene group in the α-position to the carbonyl group of the aldehyde by an oxygen atom, with no change in the relative position of the double bond and chain length with respect to the C = O group. Although this substitution causes strong electronic and structural changes at the terminal (functional group) end of the molecule, other molecular characteristics may not be as strongly affected, and therefore may be recognized at the sensory level. This substitution did not result in the analogs being recognized as pheromone mimics but, rather, as antagonists of male attraction, as evidenced by both wind tunnel and field studies in which the formates were potent inhibitors of responses to synthetic or natural pheromone. It is possible that the antagonistic effect occurs at an integrative level affecting, for example, the perceived proportion of blend components, or at a peripheral level. In *Helicoverpa zea* (Noctuidae), for instance, Grant et al. (1989) showed that both the main sex pheromone component, (*Z*)-11-hexadecenal, and an analog, (*Z*)-9-tetradecenyl formate, elicited responses from the same class of receptor neurons on the male antenna. However, in the absence of further electrophysiological data, we cannot say whether the formates interact

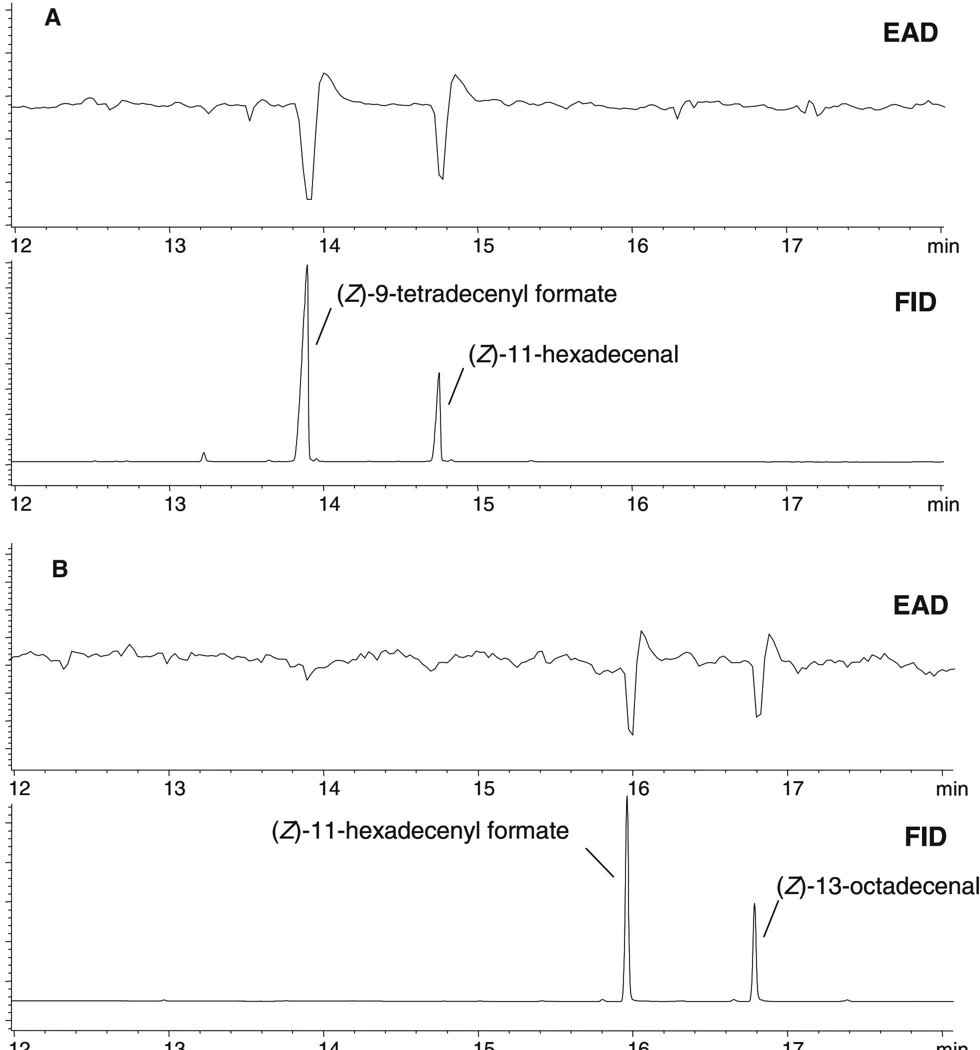

Fig. 1 Gas chromatography-electroantennogram detection responses of *Cryptoblabes gnidiella* male antennae to co-injected pheromone components and their corresponding formate analogs: (**a**) (*Z*)-11-hexadecenal and (*Z*)-9-tetradecenyl formate, and (**b**) (*Z*)-13-octadecenal and (*Z*)-11-hexadecenyl formate. EAD = electroantennogram detector; FID = flame ionization detector

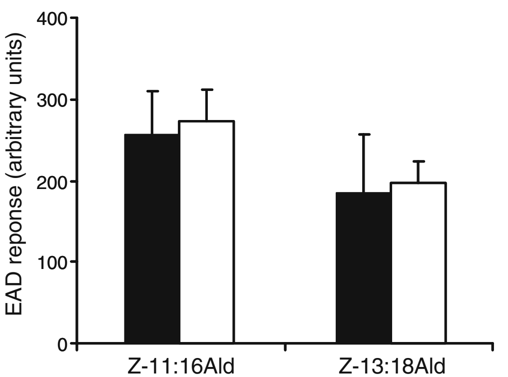

Fig. 2 Electroantennogram detection (EAD) responses of *Cryptoblabes gnidiella* male antennae to sex pheromone components, (*Z*)-11-hexadecenal (Z11-16:Ald) and (*Z*)-13-octadecenal (Z13-18:Ald), after pre-exposure to the vapors of formate pheromone analogs (*open bars*) or control treatment (*black bars*). Responses are expressed as the peak height of the antennal signal (in arbitrary units). N=10 antennae/treatment, excised from different males. Error bars indicate SEM, P>0.3 for both pheromone components (Mann-Whitney test)

with the same or different receptor cells as the pheromone components.

Our data also suggest that the formate analogs do not block the responses of the pheromone receptors to pheromone, with EAD responses from the male antenna being similar for both pheromone components, regardless of pre-exposure to formate. However, it is possible that blocking of the pheromone receptor responses by the analogs could occur with exposure to increased amounts of the formates or a shorter latency between exposure to the formates and the pheromone. A recent study (Giner et al., 2009), using (*E*,*E*)-8,10-dodecadienyl trifluoromethyl ketone, an analog of codlemone, (*E*,*E*)-8,10-dodecadien-1-ol, the sex pheromone of the codling moth, *Cydia pomonella*, found that the electrophysiological responses of antennae of *C. pomonella* males to codlemone were lower for analog-treated males, although only when higher dosages (>50 μg) of the analog were used.

Parapheromones generally are regarded as non-natural compounds, structurally related to natural pheromones, that

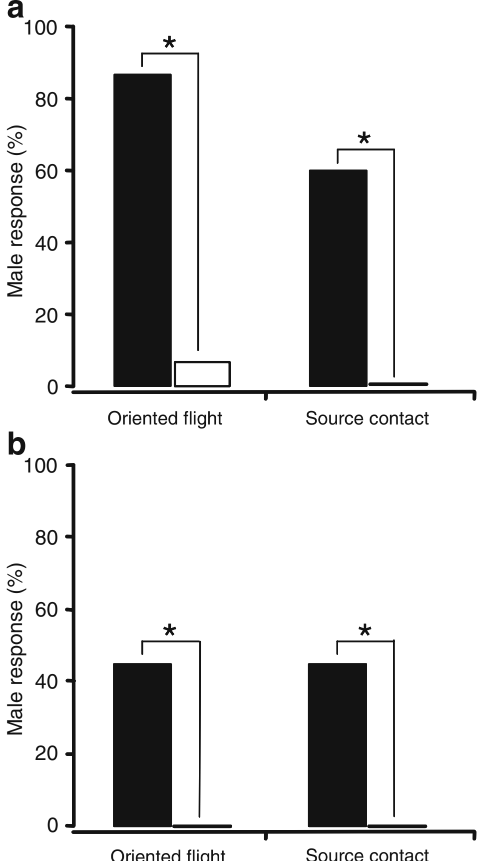

Fig. 3 Behavioral responses (oriented flight, source contact) of male *Cryptoblabes gnidiella* to different odor sources in wind tunnel tests: **a** 50 µg of pheromone (black bars; N=15) or 50 µg pheromone plus 50 µg formates (open bars if different from zero; N=15). **b** Calling virgin females (black bars, N=20) or calling virgin females plus a septum with 50 µg formates (zero males responded, N=15). The asterisks indicate responses of pairs of treatments that are different (χ^2 test; P<0.01)

affect a pheromone-based communication system (Renou and Guerrero, 2000). A large variety of parapheromones has been described and, according to their behavioral effect, are regarded as mimics, synergists, or agonists of the natural pheromone, or as antagonists or inhibitors (Renou and Guerrero, 2000 and references therein). Chemically, these analogs include modifications of the carbon chain or of a polar functional group. Among such compounds, the aldehyde group is replaced by more stable groups, such as formate, methyl, methylene, nitrile, oxime and isothiocyanate, resulting in compounds with either attractant or inhibitory activities (Ujvary et al., 1993).

Formates have been reported as mimics of moth aldehyde pheromones, but, to our knowledge, not conclusively as behavioral antagonists. In *Dichocrocis punctiferalis* (Pyralidae), a 10:1 mixture of (*E*)- and (*Z*)-8-tetradecenyl formate was as attractive as the natural pheromone, a 10:1 blend of (*E*)- and (*Z*)-10-hexadecenal (Mori et al., 1990). Likewise, (*Z,E*)-7,9-11-dodecatrienyl formate, the analog of the major sex pheromone component [(*Z,E*)-9,11,13-tetradecatrienal] of the carob moth, *Ectomyelois ceratoniae* (Pyralidae), was as attractive to males as the natural trienal (Todd et al., 1992). The case of *Heliothis virescens* (Noctuidae) is unclear. Tingle and Mitchell (1978) reported that males of *H. virescens* did not respond to the sex pheromone, a 16:1 blend of (*Z*)-11-hexadecenal and (*Z*)-9-tetradecenal, when it was released simultaneously with the analog (*Z*)-9-tetradecenyl formate. According to these authors, pre-exposure to the formate analog also reduced the behavioral responses of *H. virescens* males to the pheromone. However, another report (Mitchell et al., 1978) showed that a mixture of (*Z*)-9-tetradecenyl formate and (*Z*)-9-tetradecenal in a 16:1 ratio was as attractive as the natural pheromone in field trials.

Parapheromones have potential in integrated pest management strategies, especially when natural pheromones are difficult to synthesize or decompose rapidly under field conditions. While mixtures of pheromone and attraction antagonists have shown promising results in mating disruption

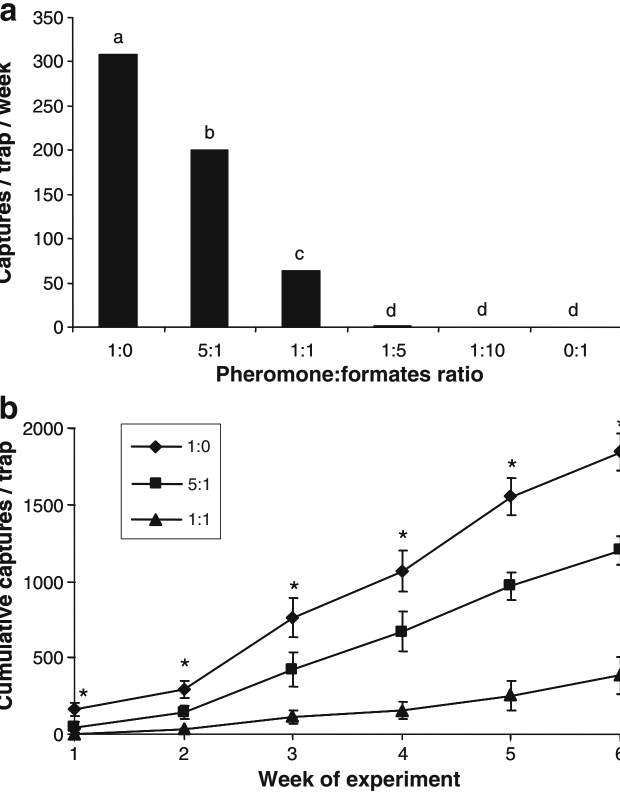

Fig. 4 Catches of *Cryptoblabes gnidiella* males during a 6-week field trial testing different ratios of a synthetic pheromone blend to a two-component blend of formate analogs. **a** Average weekly captures of males. Different letters above bars indicate means that are different (Tukey's test; family error rate <0.05). **b** Cumulative catches of males throughout the trial. Only the 1:0, 5:1, and 1:1 treatments are shown (week 1 = January 27, 2010; error bars indicate standard deviation, * indicates differences among treatments (Tukey's test; family error rate <0.05)

of several species, the potential of parapheromones as mating disruptants has been investigated less (Renou and Guerrero, 2000; Sole et al., 2008). In the case of *C. gnidiella*, there is a strong interest in developing a mating disruption strategy to produce pesticide-free wine with higher market value, especially in regions of the world in which pheromone-based control strategies are already in place for other grapevine pests. We will explore the use of these formate analogs for mating disruption of this pest.

Acknowledgments The authors wish to thank National Agency for Research and Innovation (ANII, Uruguay), PEDECIBA (Uruguay) for financial support to CS, and Juanicó S.A. for allowing us to collect insects and perform experiments in their vineyard. Helpful comments on the manuscript by Pablo Guerenstein and Iris B. Scatoni are also acknowledged.

Three colonies were fed with 30% (w/w) sucrose syrup (hereafter "S-fed"), three fed with the same syrup containing 0.005% (w/w) quercetin (P1-fed), and the others fed the same syrup with 0.01% quercetin (P2-fed). Nectars contain about 0.0005% quercetin (Kenjerić et al., 2007), and honey contains about 2–12 mg phenolics/100 g (Yaoa et al., 2005). Here, we focused on the post-ingestive effect of nectar phenolics on workers and used quercetin concentrations within the typical range for natural honey. Each day, 200 g of test solution and 20 mg of pollen cake (corn pollen moulded into a doughy consistency using a 50% sucrose solution) were supplied to each colony. During the period of the feeding trial, water was available *ad libitum* for the caged colonies. The feeding trial lasted 15 days.

Colony Inspection and Worker Bees' Ovarian Examination Daily inspection of colonies was made twice a day, once in the morning (09:00–11:30) and again in the afternoon (12:00–14:30). At each time, each colony was observed for 10 min to record egg laying by the queen and in-hive worker bee activities such as building cells and tending brood. This procedure provides 'snapshot' data about the reproductive status in each colony.

After colonies were fed for 15 d, more than 300 foraging bees from each colony were captured at the hive entrance. The sampled bees were killed with 70% ethanol, and their ovaries were examined after fixing the insect to a wax board with an insect pin through the thorax. Under a microscope, the 3rd and 4th metasomal segments were separated using two pairs of forceps. The digestive tract was removed to reveal the ovaries. Ovaries were scored as: 0 = ovarioles not visible, 1 = ovarioles clearly visible, or 2 = small eggs or full-size eggs present. For each sample, the bees with each ovarian score were recorded as n_1 (score = 0), n_2 (score = 1), and n_3 (score = 2), and the weighted means of the ovarian scores were calculated as

Table 1 Effect of quercetin in nectar on ovarian development of worker bees

Colony[a]	Number of examined bees	Number of bees with each ovarian score[b]			Weighted mean of ovarian score
		0	1	2	
S-fed	306	176	117	13	0.47
S-fed	309	145	148	16	0.58
S-fed	302	180	115	7	0.43
P1-fed	301	128	162	11	0.61
P1-fed	309	157	137	15	0.54
P1-fed	316	132	171	13	0.62
P2-fed	318	96	183	39	0.82
P2-fed	306	82	183	41	0.89
P2-fed	301	89	177	35	0.82

[a] S-fed, P1-fed and P2-fed represent the colonies fed 30% sucrose syrup, the same syrup containing 0.005 and 0.01% quercetin, respectively.

[b] Ovaries were scored as: *0* ovarioles not visible, *1* ovarioles clearly visible, or *2* small eggs or full-size eggs present.

Fig. 1 Production of queen-like worker bees in colonies of *Apis mellifera* fed with quercetin-laced syrup. The colonies continuously built queen cells throughout the experiment when they were fed with 30% sucrose syrup containing 0.01% quercetin. Queen cells are typically concentrated in the bottom of the brood nest, but colonies fed quercetin-laced syrup built queen cells that were randomly distributed near the center and periphery of the brood nest. In contrast, control colonies fed a diet of pure 30% sucrose syrup with no phenolics did not produce any queen cells during the experiment. *Arrows* indicate the locations of queen cells in the quercetin-treated colonies

$(n_1\times0+n_2\times1+n_3\times2)/(n_1+n_2+n_3)$. The weighted means of the ovarian scores were compared between the S- and P-fed colonies using one-way ANOVA, followed by *post hoc* tests (least significant difference, LSD).

Results and Discussion

After the colonies were fed for 2 to 3 days, 3–11 queen cells emerged in each of the P2-fed colonies (Fig. 1). Some queen cells were torn down by worker bees, but new ones were re-built in the same or in different locations. The queen cells were not positioned in the bottom of the brood, but were randomly distributed throughout the brood nest (Fig. 1). Workers challenged their queens at least two times in each P2-fed colony during the first 3 days of the feeding trail. The S-fed and P1-fed colonies produced no queen cells during the experimental period.

Although workers in each colony were developed from a single mixed brood, experimental colonies had different levels of ovarian development 15 days after starting the feeding trial. In the P2-fed colonies, 12.4% of the worker bees had full-size eggs, and 58.7% had activated ovaries (Table 1). However, only 3.9% of the workers in the S-fed colonies and 4.2% in the P1-fed colonies contained small eggs in their ovarioles, and 41.4% and 50.8% had activated ovaries, respectively (Table 1). Ovarian scores were significantly different among three groups ($F_{2,8}$=25.52, P=0.001). The worker bees had higher ovarian scores in the P2-fed colonies than in the P1-fed and S-fed colonies (LSD, P<0.001 for comparisons between P2-fed and S-fed and between P2-fed and P1-fed). No differences were found between P1-fed and S-fed colonies (P>0.05). Thus, high levels of quercetin caused adult bees to become queen-like.

The excessive numbers of queen cells and well-developed ovarian workers suggested that high concentrations of quercetin in nectar disturbed the pheromonal communication system in honeybee colonies. Quercetin supplementation may affect the production of bee brood and queen pheromones. However, workers began to attack queens and built queen cells only a few days after the trial started. It is unlikely that queens and broods were affected by nectar phenolics during the very early stages of the feeding trial, as they did not directly feed on honey. Another possibility is that nectar phenolics altered worker responses to queen pheromone. The major components of QMP are not volatile, and are transmitted through worker-worker physical contact after workers lick QMP from the queen (Naumann et al., 1991). Worker gustatory receptors are involved in the QMP transmission, that nectar phenolics can modulate bee gustatory responsiveness (Liu et al., 2007; Liu and Liu, 2010). Thus, nectar phenolics such as quercetin might alter bee gustatory response thresholds, disturbing the effective transmission of QMP within a colony.

Although nest homeostasis and bee enzymes can partly detoxify or break down phenolics during the processing of nectar by worker bees (Mao et al., 2009), honey does contain phenolics especially when nectar and pollen were collected during extreme weather (Kenjerić et al., 2007). Extreme weather events are becoming more common due to global climate change (Easterling et al., 2000), suggesting that honeybee populations are at risk of altered social organization due to changes in plant composition in the future.

Acknowledgement We thank Xuewen Zhang for assistance in the feeding trail. We also thank Dr. David Roubik and three anonymous reviewers for comments on earlier version of the manuscript. This work was supported by the National Basic Research Program of China (2007CB411603) and the National Natural Science Foundation of China (30870445).

grazing management. Within this grassland, *C. brevicollis* is distinguished by its strong tussocks with leaves that are rarely defoliated, in contrast to inflorescences and other accompanying plant species. In recent years, cattle farmers have reported the frequent occurrence of teratogenesis, mainly in the form of arthrogryposis, in early pregnant cows grazing in June–July in one of the main common grazings of Picos de Europa (*Puertos de Aliva*). In 2007, this type of teratogenesis occurred in 16% of the cows that were at risk the previous year while grazing in Aliva (Busqué et al., 2008). The scarcity of other known toxic plant species or teratogenic agents in Aliva, and the absence of similar diseases in cows grazing in nearby rangelands where *C. brevicollis* is not present, support the hypothesis of a causal link between the ingestion of this plant and the incidence of teratogenesis. Additionally, the similarity of this syndrome to the one known as Crooked Calf Disease in North America (Panter et al., 2009), where some plant species rich in certain alkaloids at specific phenological stages are ingested by early pregnant cows, strengthens this hypothesis.

The objectives of this study were to identify and quantify the existing alkaloids in the different plant parts (leaves, stems, and inflorescences) of *C. brevicollis*, and to analyze the relationship between phenology and their concentration. This information is fundamental to considering the possibility that this sedge, or certain parts of it, could be a teratogenic agent in grazing cattle, and to elucidating a hypothesis that explains the nature of this type of intoxication.

Methods and Materials

Study Area The valley of Aliva (43°10′24″N, 4°46′24″W) is a communal rangeland of glacier origin located within the Picos de Europa massif in northern Spain. Its grazing area ranges from 1,300 to 2,000 m above sea level (m.a.s.l), comprising a total of 1,500 hectares. Limestone is the predominant rock, and soils are highly permeable, with high levels of organic matter in the top horizon (12–16%) and moderately low pH values (5–6). Vegetation is mainly a mixture of different grassland types—species-rich *Nardus stricta*, *Mesobromion*, subalpine calcareous, and eutrophic grasslands- and *Genista*-*G. legionensis* and *G. occidentalis*—dominated shrubland. *Carex brevicollis* is abundant in the *Mesobromion* grasslands, which account for approximately 50% of the area of Aliva. Most of these plant communities are of conservation interest at the European level (European Commission 2007). In terms of grazing use, Aliva is an early summer rangeland for most livestock herds of the area. Stocking rate at the beginning of June is 1.5 Livestock Units (LU) per hectare, and in mid July 1.0 LU ha^{-1}. By the beginning of August, when available forage is usually very limited, most cattle and horse herds have already left for other nearby common grazing. Cattle are the predominant livestock type, with approximately 60% of the total LU and a total of 62 different herds. Horses (20%), sheep (16%) and goats (1%) also are present. Forage utilization is high in all grassland types (Bedia et al., 2009).

Plant Sampling Plant samples were collected periodically for the determination of alkaloids during the grazing periods of 2007 and 2008 in three zones within the rangeland at contrasted altitudes (1,350, 1,600, and 1,850 m; named Lower, Mid, and Upper zones henceforth). Sampling dates were 2nd June, 14th June, 28th June, 12th July, 27th July and 14th August in 2007, and 2nd June, 18th June, 3rd July, and 18th July in 2008. Sampling was performed at mid-day, collecting separately green leaves and reproductive stems-inflorescences from non-defoliated plants, and frozen to −8°C. Leaves were collected on all dates, but stems-inflorescences were not always present (Table 1). The total number of samples collected in the field was 68, of which 19 corresponded to inflorescences and stems, and 30 to leaves.

Determination of Alkaloids Frozen samples of leaves, stems, and inflorescences were freeze-dried and milled in a ball mill (Retsch, type MM2). Extraction of alkaloids was performed as described in Muzquiz et al. (1993, 1994). Finely ground samples (0.5 g) were homogenized in 5% trichloroacetic acid with an Ultra-Turrax for 1 min. The mixture was centrifuged for 5 min. at 12100 g, and the supernatant was decanted. The procedure was repeated twice. After centrifugation, 1 ml of 10 M NaOH was added to the combined supernatants. Alkaloids then were extracted with dichloromethane (3×5 ml). The dichloromethane extract was evaporated to dryness, and the alkaloids were dissolved in 1 ml of methanol.

For the quantification of alkaloids, a Perkin-Elmer gas chromatograph equipped with a nitrogen-phosphorous detector (NPD) and operated by a Turbochrom workstation was used. The column employed was a SPB-1 (30 m×0.25 mm id), and helium was used as carrier gas. The temperatures of the injector and detector were 240 and 300°C, respectively. The oven temperature was 150°C, increased by 5°C min^{-1} until reaching 235°C, the temperature that was maintained for 23 min.

As standards of brevicolline and brevicarine were not found, and considering that these alkaloids are derivative of harmane (Vember et al., 1967), their quantification was performed using the commercial standard harmaline hydrocloride dihydrate (Sigma). A stock solution of 1 mg harmaline/1 ml methanol was prepared to perform the calibration curve. Different dilutions from 0.1 to 1 mg/ml

Table 1 Concentration of alkaloids (% dry weight) in the samples of inflorescences, stems and leaves of *Carex brevicollis* collected at different dates and zones (lower: 1350; mid: 1600; upper: 1850 m.a.s.l.) in the Alpine Rangeland of Aliva (Picos de Europa National Park, Spain)

n.a.: sample not available due to the phenology of the plant.

produced a linear response with a correlation coefficient greater than 0.99. The amount of total alkaloids was determined as the addition of brevicolline and brevicarine concentrations.

A capillary GC-MS was applied for the identification of the alkaloids. A Perkin-Elmer Autosystem XL gas chromatograph (working with the same column and conditions as above) was coupled with a mass selective detector (Perkin-Elmer Turbomass Gold) that was combined with the Turbomass software for the identification of alkaloids in the samples.

Phenology In 2007, the reproductive phenology of *C. brevicollis* plants was measured in eight locations within Aliva at different altitudes (1,350, 1,450, 1,525, 1,600, 1,700, 1,775, 1,800, and 1,850 m), by using grazing enclosures, and in six consecutive weeks from the beginning of June to mid-July. Three of these locations corresponded to the Lower, Mid, and Upper zones where plant samples also were harvested. Reproductive phenology was quantified according to the state of the female flowers of the sedge by using the following scale: 1) flowers not yet visible, 2) stigmas just visible, 3) stigmas clearly visible and utricules starting to swell, and 4) utricules well developed. Phenological scores between 0 and 1 were assigned at each location and for each weekly measurement according to the proportion of spikes in each of the phenological states defined (e.g., 0 when all the spikes counted were in state 1, and 1 when all the spikes counted were in state 4).

Growing Degree Days (GDD) GDD were calculated for all sampling dates in the eight phenology locations in order to be used as indirect estimators of the reproductive phenol-

ogy of *C. brevicollis*. Their calculation involved integrating estimated average daily temperatures above 5°C from the 1st of April of each year until the measuring dates. Average daily temperatures were estimated from an exhaustive temperature database collected from a nearby valley (Riofrio, 16 km SSE of Aliva), where 12 temperature sensors (©Onset Hobo® Pro v2) were positioned at regular intervals in an altitudinal gradient from 700 to 2,500 m. These sensors were programmed to record hourly average air temperatures. The estimation of GDD involved the following steps. First, regressions of average daily temperature against altitude for each day between 1st April and 15th August of 2007 and 2008 were performed with the Riofrio dataset. Second, daily average temperature-altitude regressions for the Aliva sites were adjusted by relating the predicted daily average temperatures at 1,450 m in Riofrio (R) with the temperature data recorded by an additional sensor of the same type installed in Aliva at that altitude (A): A=1.06R -2.08 (R^2=0.93). Finally, and according to observed differences in Aliva, a daily correction of the average temperature values of +1°C was performed for the Aliva phenology locations with southern or eastern aspects.

The threshold daily average temperature of 5°C when calculating GDD was chosen after testing showed that it offered the best relationship with phenology and the highest values of explained variance in the statistical models performed.

Statistical Analyses We employed linear mixed-effects models to compare the concentration of each alkaloid (response variable) among the different plant parts (fixed effect), considering as random effect the sampling dates in each zone where samples of the three plant parts were collected (Table 1; a total of 19 subjects).

The existence of phenological changes in the concentration of alkaloids of *C. brevicollis* was approached by using the estimated GDD as surrogate for plant reproductive phenology after testing the robustness of their relationship through linear regression for the 2007 data (Fig. 3). GDD then was used as a continuous explanatory variable capable of capturing relevant phenological information from each of the observations collected in the experiment. The use of GDD instead of phenology in the models was justified by the advantages in its measurement and calculation.

The analyses of the concentration of alkaloids (brevicolline, brevicarine, and total alkaloids) in each plant part (inflorescences, leaves, and stems) were performed by constructing analysis of covariance (ANCOVA) models in which GDD was the covariate and Zone (Lower, Mid, and Upper) and Year (2007, 2008) were fixed effects. Starting from the more elaborate models with the three effects and their interactions, simpler models were developed to acquire finally the simplest models without significantly increasing the residual variance. Simplifications consisted mainly of initially removing non-significant interactions, and next removing non-significant main effects not involved in significant interactions. Some models also were simplified and improved by merging some levels within the Zone effect. Models in which the Zone and Year effects were removed were regression models in which GDD captured all the relevant information contained in the fixed effects (this was the case of the models represented in Figs. 4 a, b, c, and 5 c). Models in which some of the fixed effects or their interaction with GDD remained, were represented by different regression lines (models represented in Figs. 5 a and 6 a), as is characteristic of ANCOVA models.

Other ANCOVA models were performed to study the relationships between the concentrations of the two alkaloids in the same plant part (Figs. 4 d and 5 e) or different plant parts (Fig. 7). In these models, one alkaloid was used as response variable and the other as covariate, while Zone and Year again were used initially as fixed effects.

For certain models, some observations (maximum of two) were rejected if that improved significantly the explanatory power of the models. These rejections are mentioned explicitly in the text.

The final models selected in each analysis were diagnosed for their compliance with ANOVA assumptions through the observation of plots of standardized residuals against fitted values to discard heteroscedasticity, and of quantile-quantine normal error plots to check for normal distribution of the residuals. Transformation of the response variable or of the covariate was performed when that improved significantly the distribution of the residuals. All analyses were conducted in the R language and environment for statistical computing (R Development Core Team, 2009).

Results

Determination of Alkaloids The β-carboline alkaloids brevicolline and brevicarine were the major alkaloids present in *C. brevicollis*, showing distinct peaks in all samples analysed (Fig. 1). Their identity was confirmed by the comparison of their mass spectral degradation pattern (Fig. 2) with published results (Mahboobi et al., 1999; Terenteva et al., 1969).

Alkaloids in Different Plant Parts Brevicolline concentrations were significantly different among plant parts (P<0.001), following the order *leaves*>*stems*>*inflorescences* (mean values of 0.54, 0.24, and 0.11, respectively, *SE* of the log transformed values of 0.092 and 36 *df*). In

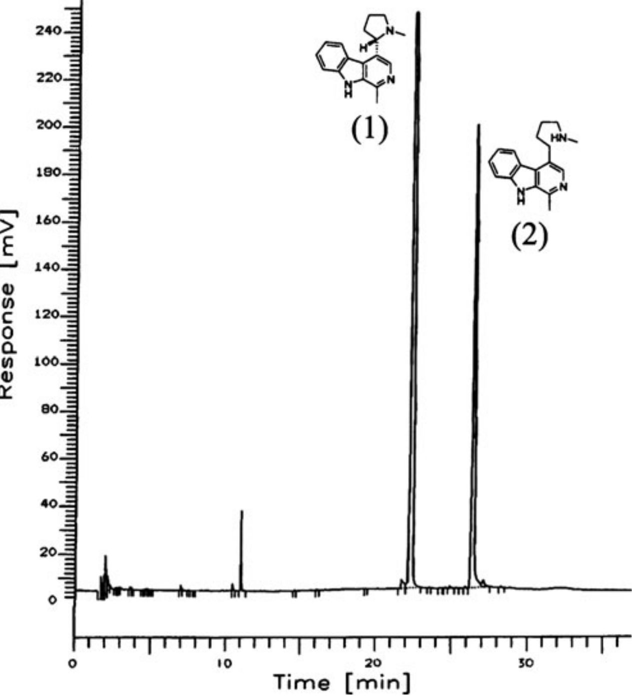

Fig. 1 Chemical structure of the β-carboline alkaloids brevicolline (1) and brevicarine (2) and an example of their profile in leaves of *Carex brevicollis* as obtained by capillary gas-liquid chromatography

the case of brevicarine, concentrations also were different ($P<0.001$), following the inverse order: *inflorescences> stems> leaves* (mean values of 0.16, 0.10, and 0.08, respectively, *SE* the log transformed values of 0.119 and 36 *df*).

Plant Phenology In 2007, GDD was a good predictor of *C. brevicollis* phenology measured by the state of female spikelets (Fig. 3). The regression obtained showed a window of phenological development between 250 and 550 degree days, below which reproductive stems were not yet totally formed, and above which the stems were starting to decay and fruits began to fall off.

Alkaloids in Inflorescences A strong negative logarithmic relationship between the concentration of the existing alkaloids in inflorescences and GDD was found (Fig. 4 a, b, and c). These models were built after rejecting the two observations with the lowest GDD values, as they diverted from the general trend. These outliers were located at values of GDD below those estimated to correspond with flower development (< 250°C; Fig. 3).

For brevicarine (Fig. 4 a), the resultant model was *log(carI)= log(GDD)+ Zone*, where the effect of the

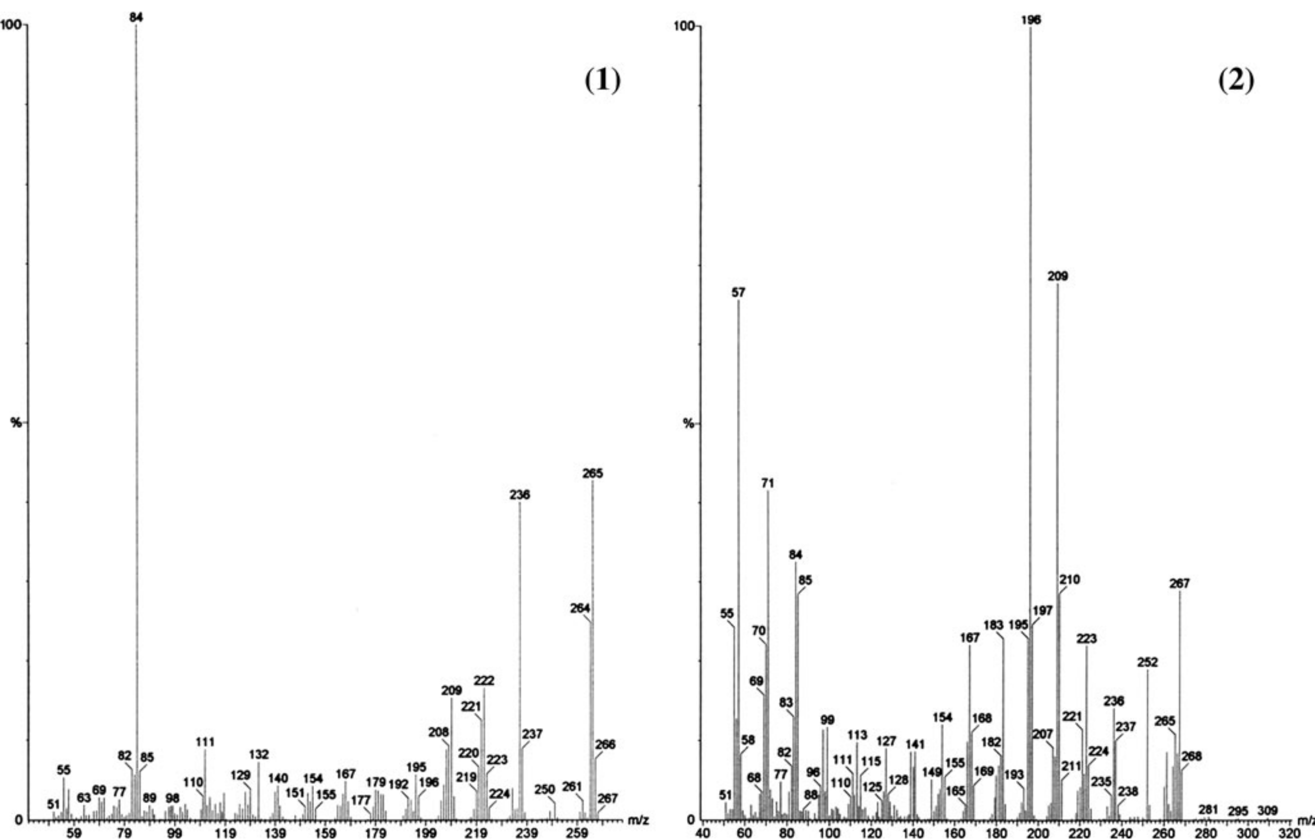

Fig. 2 Mass spectra of the alkaloids brevicolline (1) and brevicarine (2)

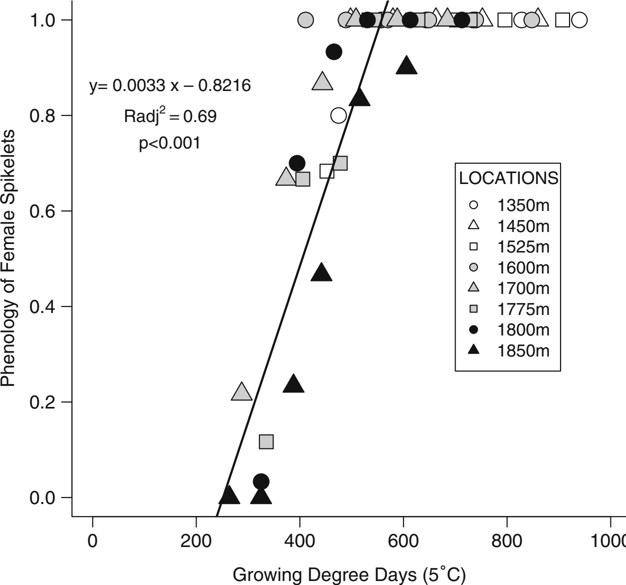

Fig. 3 Relationship between Growing Degree Days with a minimum threshold value of 5°C and an index of phenology of *Carex brevicollis* according to the state of female spikelets (0: all female spikelets with flowers not yet visible; 1: all female spikelets with utricules well developed). Regression performed considering only the observations with phenology values of less than 1

covariate *log(GDD)* was highly significant ($P<0.001$; slope of -1.21 ± 0.248 *SE*), while the *Zone* was not ($P=0.077$; but still kept in the model to reach high explanatory power). A regression model just considering the covariate showed an $R^2_{adj}=0.51$. For brevicolline (Fig. 4 b), the model used was *log(coll)= log(GDD)*. In this case, neither the fixed effects *Zone* and *Year*, nor their interactions, were significant, and could be removed. The covariate *log(GDD)* was highly significant ($P<0.001$; slope of -1.18 ± 0.208 *SE*). Finally, total alkaloids (Fig. 4 c) were fitted to the model *log(alkI)= log(GDD)*. As with brevicolline, neither the fixed effects nor their interactions were significant, and could be removed. The covariate *log (GDD)* was also highly significant ($P<0.001$; slope of -1.12 ± 0.210 *SE*).

A strong positive relationship was also found between the two main existing alkaloids in *C. brevicollis* (Fig. 4 d). In this case, two observations with high brevicarine values were discarded, one that clearly behaved as an outlier and the other because of its potential high influence on the regression. The resulting model was *carI= coli+ Zone*. In this model, the mid and upper zones were grouped together as a single level, as they behaved similarly, and this improved its statistical significance. The slope of the relation between brevicarine and brevicolline was 1.15

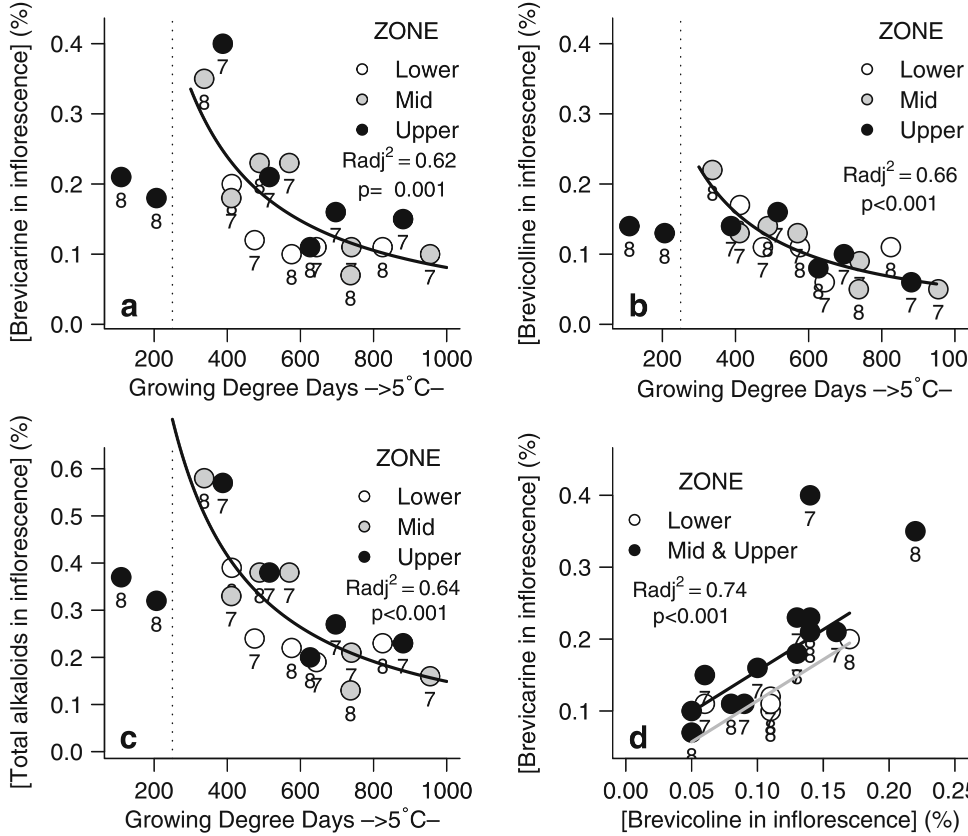

Fig. 4 Alkaloid concentrations in the inflorescences of *Carex brevicollis*. **a** Brevicarine against Growing Degree Days (GDD); **b** Brevicolline against GDD; **c** Total alkaloids against GDD; **d** Relationship between brevicolline and brevicarine. The coefficient of determination and probability in each figure correspond to those of each analysis of covariance. Lines correspond to the regressions between the response variable and the covariate (in 4D the black line refers to the mid and upper zones and the grey line to the lower zone). Labels next to each point indicate year. In figures A, B, and C the observations with GDD below 250, and in figure D the observations with brevicarine greater than 0.3, were not used in the generation of the models

(± 0.176 *SE*), the intercept for the lower zone was 0.00 (± 0.023 *SE*), and that for the mid and upper zones was 0.04 (± 0.014 *SED*) higher. A simple regression model without considering the zone effect reduced the R^2_{adj} to 0.61.

Alkaloids in Leaves Only the concentration of brevicarine showed certain trends related to *GDD*, though always with small absolute values (Fig. 5). The different behavior observed between 2007 and 2008 suggested that different models would be appropriate for each year. In 2007, brevicarine in leaves followed a model of the type *sqrt (carL)= GDD+ Zone*, where the mid and upper zones were grouped together due to their similar behavior (Fig. 5 a). Both *GDD* and *Zone* were highly significant ($P<0.001$). The slope of the regression was $-9.10\times10^{-5}\pm1.81\times10^{-5}$ *SE*, and the difference in intercept values between the lower and mid–upper zones was $+9.40\times10^{-2}\pm1.438\times10^{-2}$ *SED*. In 2008, a quadratic regression best fit the data after considering as an outlier the observation with the highest brevicarine value (Fig. 5 c). The model was *sqrt (carL)= GDD+ GDD²*, showing a minimum value of 0.025% of brevicarine at 703 *GDD*. The intercept was 0.54 ± 0.005 *SE*, the parameter for GDD $-1.09\times10^{-3}\pm2.02\times10^{-4}$ *SE*, and for GDD² $7.77\times10^{-7}\pm1.642\times10^{-7}$ *SE*.

Brevicolline in leaves for each year did not show any defined pattern with *GDD* or *Zone* (Fig. 5 b and d). In 2007, observations were closer to their mean value (0.44 ± 0.020 *SE*; $P<0.001$) than in 2008 (0.63 ± 0.082 *SE*; $P<0.001$). A model considering all observations and the year as the only effect, produced a significant difference between the 2 years (0.20 ± 0.068 *SED*; $P<0.007$). Due to the low brevicarine concentrations in leaves, total alkaloids showed a pattern similar to that of brevicolline.

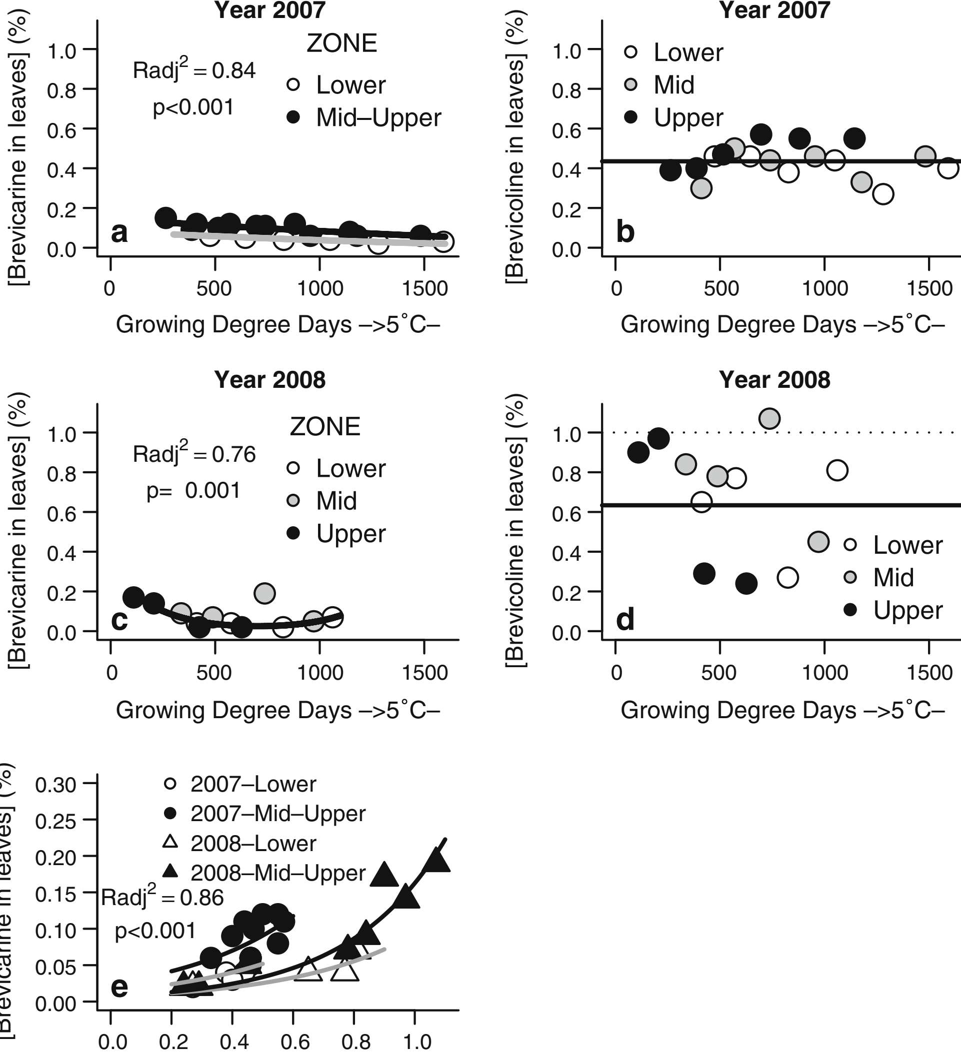

Fig. 5 Alkaloid concentrations in leaves of *Carex brevicollis*. **a** Brevicarine against Growing Degree Days **(**GDD) in 2007; **b** Brevicolline against GDD in 2007; **c** Brevicarine against GDD in 2008; **d** Brevicolline against GDD in 2008. **e** Relationship between brevicolline and brevicarine. The coefficient of determination and probability in each figure correspond to those of each analysis of covariance. Lines correspond to the regressions between the response variable and the covariate GDD (in 5A and 5E the black line refers to the mid and upper zones and the grey line to the lower zone). Observations that were not used in the generation of the models were the one with the highest brevicarine value in figure C, the one with the highest brevicolline value in figure D and two observations not represented in figure E

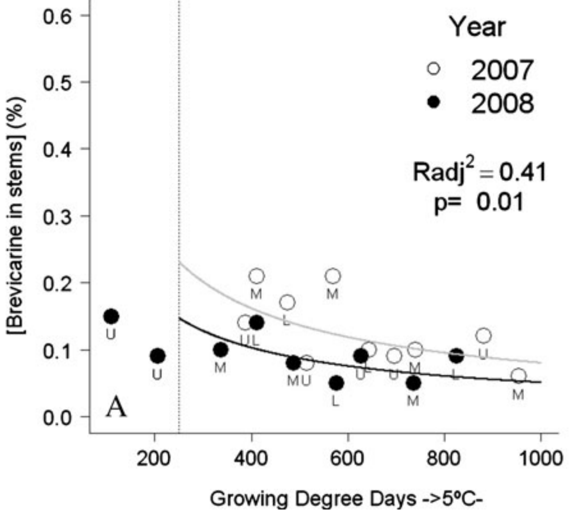

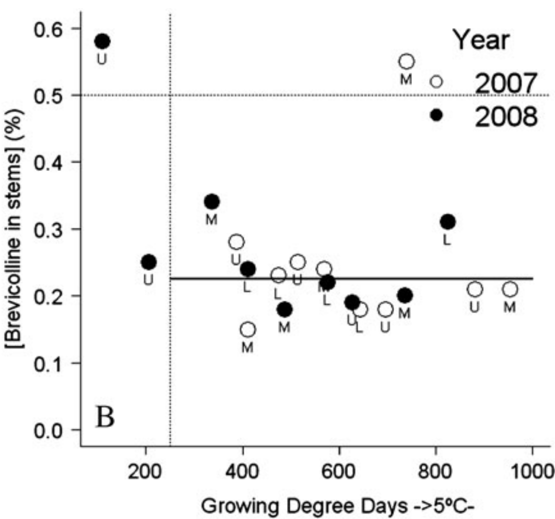

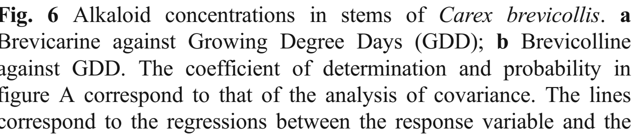

Fig. 6 Alkaloid concentrations in stems of *Carex brevicollis*. **a** Brevicarine against Growing Degree Days (GDD); **b** Brevicolline against GDD. The coefficient of determination and probability in figure A correspond to that of the analysis of covariance. The lines correspond to the regressions between the response variable and the covariate (black for the year 2008, and grey for the year 2007). Labels next to each point indicate site (Lower, Mid, and Upper). The two observations with brevicolline values greater than 0.5 in figure 6B were not considered in the model generation

Finally, a robust model was found that related brevicarine and brevicolline concentrations in leaves (Fig. 5 e): *log (carL)=colL+Year+Zone*. In this model, two observations corresponding to the first sampling date of 2007 in the mid and upper zones were omitted, as they behaved as outliers. In the case of the *Zone*, the mid and upper levels were merged as one in order to gain more explanatory power and parsimony. The three explanatory variables were highly significant ($P<0.001$): the slope for *colL* was 2.59±0.249 *SE*; the difference in the intercept between the lower and rest of zones was 0.56±0.098 *SED*; and the difference in the intercept between 2007 and 2008 was −0.71±0.109 *SED*.

Alkaloids in Stems Brevicarine in stems showed a pattern similar to that of inflorescences, although with lower values, less accentuated decrease with *GDD*, and with a weaker logarithmic relationship (Fig. 6 a). The resulting model was *log(carS)=log(GDD)+Year*. The effect of the covariate *log(GDD)* was significant ($P=0.032$; slope of −0.76±0.276 *SE*), and so was the fixed effect *Year* ($P=0.016$; difference in the intercept between years: −0.45± 0.166 *SED*). A model just considering the covariate was not significant ($P=0.066$).

Brevicolline in stems showed no clear pattern with any of the effects studied (Fig. 6 b). Withdrawing two observations with abnormally high values resulted in the rest of the observations close to a mean value of 0.23± 0.013 *SE*.

Finally, no clear relationship was found between the concentrations of brevicarine and brevicolline in stems (not represented).

Relations Between Alkaloids in Different Plant Parts The proportion of brevicarine to total alkaloids in inflorescences was related to the proportion of brevicolline to total alkaloids in leaves (Fig. 7). The model generated was: *prCarI=prColL+Zone+prColL x Zone*. Lower and Upper zones were grouped together. The significance of the interaction term in both models ($P<0.01$) was due to the different behavior of the Mid zone with respect to the Lower and Upper zones. *Zone* as fixed effect was not significant, and the covariate *prColL* was near the threshold of significance ($P=0.05$). The slope for the linear relationship between the continuous variables and for the Lower–

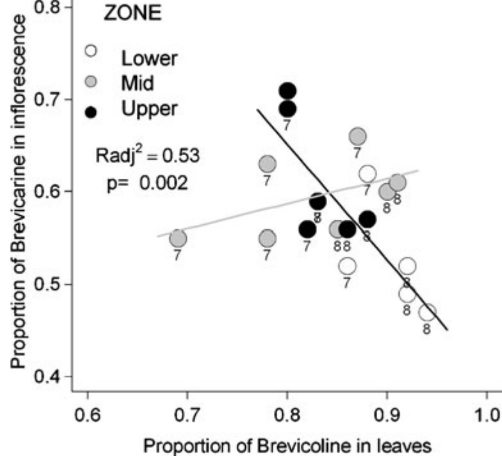

Fig. 7 Relationship between the proportion of total alkaloids in inflorescences being brevicarine and the proportion of total alkaloids in leaves being brevicolline. The black line corresponds to the linear regression for the lower and upper zones, and the grey line for the mid zone

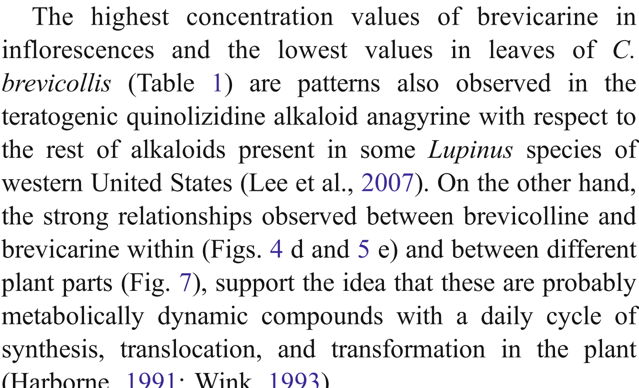
Upper observations was −1.25±0.272 *SE*. The change in slope for the Mid site was 1.52±0.351 *SED*.

Discussion

Flowering phenology of *Carex brevicollis* started early after snowmelt, and was of short duration (Fig. 3). This is characteristic of many sedges of temperate regions (Grime et al., 2007), and also is common in many subalpine and alpine plant species, allowing them to complete seed development before environmental conditions become adverse (Dunne et al., 2003; Inouye et al., 2003). This strategy also is seen in plants subjected to predictable disturbance events, such as strong defoliation by large herbivores during seasonal grazing periods (Pakeman, 2004; de Bello et al., 2005). The observed strong response of flowering phenology to growing degree days also reflects the lack of important additional sources of environmental control of the reproductive phase of *C. brevicollis*, such as water stress, which is frequent in this rangeland later in mid summer.

With respect to the determination of the existing alkaloids in *C. brevicollis*, the results of the mass-spectrometric investigation (Fig. 2) confirmed the existence of brevicolline, a derivative of harmane, with peaks of the molecular ion (M^+ 265) and fragment ions from the pyrrolidine ring. Brevicolline possesses the core nicotine structure (Wagner and Comins, 2006) and the base peak (m/e 84; Fig. 2.1) also is observed in the fragmentation of nicotine (Vember et al., 1967). The presence of brevicarine was supported by the findings of Terenteva et al. (1969), who located its molecular ion in the mass spectrum at m/e 267.

The concentrations of the β-carboline compounds found in *C. brevicollis* in Aliva reaffirm early findings on the presence of brevicolline and brevicarine in leaves of this species (Sharipov et al., 1975). β-Carbolines are a group of pharmacologically interesting and biologically active compounds (Cao et al., 2007). San Emeterio et al. (2008) found that the concentration of brevicolline in plants of *C. brevicollis* was related to the presence of endophytes, arguing that this alkaloid was produced by the plant as a defense against fungal infection. The presence of alkaloids in leaves of certain plant species of grasslands has been considered as a deterrent mechanism against herbivory. This is the case, for example, of *Merendera montana* (Gómez et al., 2003), a plant that frequently shares intensively grazed herbaceous communities with *Carex brevicollis.* With respect to inflorescences, herbivory and selectivity of pollinators also are mediated by the presence of alkaloids in different parts of the flowers and nectar of some herbaceous species (Adler et al., 2001; Adler and Irwin, 2005).



The highest concentration values of brevicarine in inflorescences and the lowest values in leaves of *C. brevicollis* (Table 1) are patterns also observed in the teratogenic quinolizidine alkaloid anagyrine with respect to the rest of alkaloids present in some *Lupinus* species of western United States (Lee et al., 2007). On the other hand, the strong relationships observed between brevicolline and brevicarine within (Figs. 4 d and 5 e) and between different plant parts (Fig. 7), support the idea that these are probably metabolically dynamic compounds with a daily cycle of synthesis, translocation, and transformation in the plant (Harborne, 1991; Wink, 1993).

Growing degree days explained most of the variation in the concentration of alkaloids linked to date and zone in the majority of models developed. The significance of the zone effect in some models, especially in those relating the concentrations of brevicolline and brevicarine within each plant part (Figs. 4 d and 5 e) could be a result of the increase of alkaloids concentration in plant tissues with altitude (Carey and Wink, 1994; Gómez et al., 2003). Year changes in the mean and deviation of brevicolline concentration in leaves (Figs. 5 b and d) also could be attributed to the influence of different environmental factors not explicitly considered in the study (Gay et al., 2007).

The decreasing concentration of brevicolline and brevicarine observed in inflorescences of *C. brevicollis* along its phenological development (Fig. 4) coincided with the pattern observed in other alkaloids from rangeland plant species, such as those of *Delphinium* spp. from western United States (Ralphs et al., 1997), but differed from others, such as anagyrine in *Lupinus leucophyllus*, with highest concentrations at seed maturation (Lee et al., 2007). The lack of a defined phenological pattern of brevicolline and brevicarine concentrations in leaves (Fig 5) also has been reported for other alkaloids in different plant species (Gómez et al., 2003; Lee et al., 2007). In the case of the reproductive stems of *C. brevicollis*, changes in their alkaloid concentrations with phenology were similar to those of inflorescences for brevicarine (Fig. 6 a) and to those of leaves for brevicolline (Fig. 6 b), underlining the main role of the stem in the translocation of these compounds between leaves and inflorescences.

Two factors suggest that the alkaloid brevicarine from the inflorescences of *C. brevicollis* could be the main teratogenic agent in cattle in the rangeland of Aliva. First, we observed frequent defoliation by livestock of inflorescences of this sedge, and at early phenological stages, when the concentration of brevicarine is highest (Fig. 4). In contrast, the ingestion of leaves usually is scarce. Unlike in Aliva, the ingestion of *C. brevicollis* in other rangelands has been related directly to the occurrence of abortions in cows, mares, and ewes (Sandwith and Montserrat, 1968). How-

ever, these abortions occur mainly at the end of summer and autumn (Ruiz de los Mozos et al., 2008), when no inflorescences remain on the plant, and so should be attributed only to the ingestion of leaves, possibly with higher concentrations in brevicolline (Fig. 5) and thus higher abortifacient capacity (Marcu, 1965; Yasnetso and Sizov, 1972). The second factor supporting our hypothesis on the nature of the teratogen in Aliva considers that the type of deformity produced, arthrogryposis, implies that the embryos are susceptible to the action of the teratogenic agent from 1 month of age, when their limbs start to develop (Curran et al., 1986). The data we have gathered on birth dates of deformed calves from cows that previously grazed in Aliva, although yet insufficient to draw definite conclusions, locates the period 30–60 days of gestation of most of these cows between June and July, generally coinciding with the presence of inflorescences of *C. brevicollis* in their home range areas.

The validation of this hypothesis, along with the described strong relationship of brevicarine concentration in inflorescences of *C. brevicollis* with growing degree days (Fig. 4 a), would enable the definition of the seasonal time window with maximum danger of toxicity, depending on the series of daily temperatures from snowmelt to summer and on the spatial distribution of each particular cattle herd within the rangeland. This could provide useful management information for farmers to minimize the risks of teratogenesis.

Acknowledgments This work was financially supported by the Spanish Research Institute for Food and Agriculture Technology (INIA RTA2009-00129) and by the Government of Cantabria (CIFA-INIA agreement CON08-043). The authorities and personnel of the Picos de Europa National Park offered invaluable support during field work. Finally, we wish to thank Guy Beaufoy, Matt Doughty, and two anonymous reviewers for help in improving this manuscript.

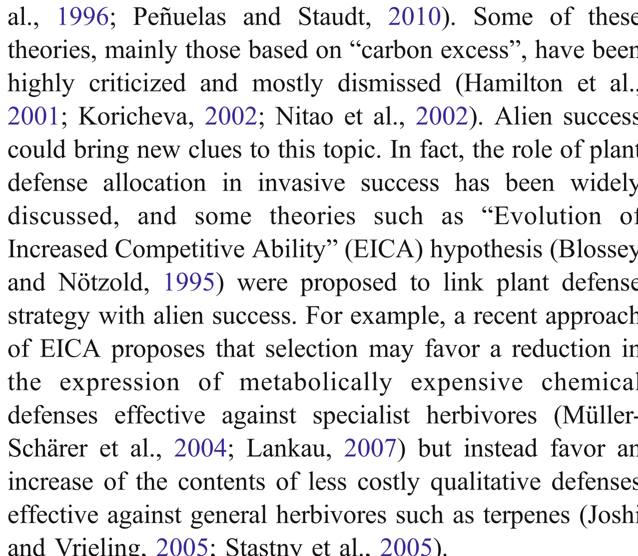
most isolated ecosystem of the Earth (Vitousek and Walker, 1989), are particularly vulnerable to invasions by non-indigenous species (Harrington and Ewel, 1997). Hawaiian native ecosystems and plant species are strongly affected by alien plant species (Mack and D'Antonio, 2003; Hughes and Denslow, 2005; Hughes and Uowolo, 2006). In the Hawaiian Islands, around 861 flowering plant species (47% of total Hawaiian angiosperm flora) are naturalized alien species (Wagner et al., 1999), that have been introduced mainly in the last 200 years (Smith, 1996).

The capacity to produce carbon based secondary compounds (CBSC) such as phenolics, tannins, and terpenes, can be involved in the competition between alien and native plant species by conferring chemical defenses against herbivores, allelochemical defenses against neighboring competing plants (Peñuelas et al., 1996; Peñuelas and Estiarte, 1998; Kursar and Coley, 2003; Mote et al., 2007; Cipollini et al., 2008; Khanh et al., 2008), or/and greater anti stress capacity (Peñuelas and Llusià, 2003, 2004; Filella and Peñuelas, 1999).

Phenolics, including low molecular mass phenolics and condensed polyphenolics such as tannins act by reducing digestibility rather than through direct toxicity (Eichhorn et al., 2007), but many of them also have toxic effects, and may be more toxic for some herbivores than for others (Mole et al., 1990; Cipollini et al., 2008). They are effective mainly against specialist herbivores (Beck and Schoonhoven, 1980; Coley et al., 1985; Bernays and Chapman, 1994; Bennet and Wallsgrove, 1994). Nevertheless, several studies also have demonstrated that they can inhibit the growth of generalist herbivores (Eck et al., 2001; Kouki and Manetas, 2002; Nomura and Itioka, 2002; Albrectsen et al., 2004; Boege and Dirzo, 2004; Kurokawa and Nakashizuka, 2008), although not always (Bi et al., 1997; Goverde et al., 1999; Mutikainen et al., 2000). Terpenes act as deterrents, toxins or modifiers of insect development (Bennet and Wallsgrove, 1994). They are effective against non adapted specialist herbivores (Sorensen et al., 2005), and generalist herbivores (Mihaliak et al., 1987; Landau et al., 1994; Mote et al., 2007). Moreover, terpenoids have many other protective properties such as defense against fungi and pathogens (Gershenzon and Duradeva, 2007), and against abiotic stresses such as high temperature, drought, ozone, or excess radiation (Peñuelas and Llusià, 2003, 2004).

Many hypotheses and theories have been proposed in the last few decades to explain plant defensive strategy against herbivores. They range from theories based on plant capacity to allocate resources in excess of growth demands into defenses, such as a "carbon excess" hypothesis (Bryant et al., 1983; Peñuelas and Estiarte, 1998), to theories with more evolutionary bases (Hamilton et al., 2001) that bypass theories on enhanced terpenoid production as a result of enhanced nutrient availability (Harley et al., 1994; Litvak et



al., 1996; Peñuelas and Staudt, 2010). Some of these theories, mainly those based on "carbon excess", have been highly criticized and mostly dismissed (Hamilton et al., 2001; Koricheva, 2002; Nitao et al., 2002). Alien success could bring new clues to this topic. In fact, the role of plant defense allocation in invasive success has been widely discussed, and some theories such as "Evolution of Increased Competitive Ability" (EICA) hypothesis (Blossey and Nötzold, 1995) were proposed to link plant defense strategy with alien success. For example, a recent approach of EICA proposes that selection may favor a reduction in the expression of metabolically expensive chemical defenses effective against specialist herbivores (Müller-Schärer et al., 2004; Lankau, 2007) but instead favor an increase of the contents of less costly qualitative defenses effective against general herbivores such as terpenes (Joshi and Vrieling, 2005; Stastny et al., 2005).

We aimed to study the link between the plant invasive success in the Oahu (Hawaii) flora and CBSC contents. With this purpose, we conducted an analysis of leaf total phenolic (TP), leaf total tannin (Tta), and leaf total terpene (TT) accumulation in 35 native and 38 alien woody plant species randomly chosen among the most representative current Hawaiian flora in order (i) to compare TT, Tta, and TP contents of native plants with those of alien plants after taking into account the phylogenetic effects, and (ii) to compare also the relationships of TT, Tta, and TP contents with the leaf traits linked to foliar economy and production capacity, such as photosynthetic capacity (Amass), leaf mass per unit area (LMA), and leaf N, P, and K contents. With these investigations, we additionally aimed to test the predictions of some of the CBSC hypotheses such as the "excess carbon" hypotheses (decreased phenolics and tannins in alien nutrient-rich fast-growing species), nutrient-enhanced terpene production, and the modified "competitive ability" hypotheses (increased less costly terpene accumulation against generalist herbivores and decreased more costly phenolic and tannins accumulation against adapted herbivore specialists in alien species).

Methods and Materials

Field Sites

The study was conducted in May 2007 on the island of Oahu (Peñuelas et al., 2010; Sardans et al., 2010), the third largest of the Hawaiian Islands. As typical of larger Hawaiian Islands, the climate is characterized by steep rainfall gradients over short distances (Müller-Dombois and Fosberg, 1998). While precipitation is distributed almost uniformly in lowland and mountain rain forests, lowlands at the leeward side have a pronounced dry summer season.

Due to the oceanic tropical climate, temperature oscillations are small with winters having on average 2–3°C cooler temperatures than summers. As large differences in composition of native and alien vegetation occur in response to rainfall gradients, four sites with distinct precipitation regimes were selected for plant sampling in the leeward lowlands of Oahu and at the leeward side of Koolau mountains (Appendix Table 1) (see details in Peñuelas et al., 2010).

The four key soil types found across the sites rank according to the state of weathering as *oxisols* > *ultisols* > *mollisols* > *inceptisols* (Uehara and Ikawa, 2000; Deenik and McClellan, 2007). More leached *oxisols* and *ultisols* with lower pH are among the soils with lowest fertility, and *Mollisols* exhibit the highest fertility (Uehara and Ikawa, 2000; Deenik and McClellan, 2007). *Inceptisols*, the youngest soils, typically show weak profile development, and exhibit tremendous variability in fertility depending on genesis (Deenik and McClellan, 2007). While the *inceptisols* in rocky soils and mountainous land are of low fertility, the Tantalus series *inceptisols* are of moderate to high fertility. Thus, in our study, the broad soil classes rank according to fertility as *mollisols* > *inceptisols* (Tantalus) > *oxisols* ≅ *ultisols* > *inceptisols* (mountainous soils).

Plant Sampling and Site Climate

For each species, 3 individual plants were sampled. Several twigs per plant were sampled in the morning hours between 8:00–12:00. Species coordinates and sampling altitude were noted for each site, and this information was used to link species locations to specific soil types and derive location-specific climatic data. We used ARCGIS 9.1 to determine long-term average monthly and annual precipitation, and precipitation of the 3 driest months and annual precipitation, and average, maximum and minimum temperatures from high resolution climatic grids (Giambelluca et al., 1986, T. Giambelluca unpublished data) (see details in Peñuelas et al., 2010).

Study Species

Altogether 73 species, randomly sampled in the 4 sites, were studied, 35 native and 38 aliens (Peñuelas et al., 2010). Out of the 73 studied species, 36 were trees, 29 shrubs, 3 woody vines to shrubs, 3 woody vines, one subshrub, and one mistletoe (Sardans et al., 2010) (Appendix Table 2). Once an individual of a given abundant species was randomly selected, then we were looking non-randomly for 2 more individuals of the given species. The event of species selection, however, was random. Also, in drier sites, dominated by a few species, we sampled essentially all woody species.

Species were classified according to site preference as dry, dry-mesic, mesic, dry-wet, mesic-wet, and wet forest species. The invasiveness of species was quantitatively scored by using a four-level scale as 0 (native species), 1 (low invasiveness), 2 (moderate-high), and 3 (very high). These scores were based on Australia/New Zealand weed risk assessment (WRA) system scores (Pheloung et al., 1999) modified to Hawaii and other Pacific Islands (Daehler et al., 2004) that are reported in Pacific Island Ecosystems at Risk (PIER) project online database maintained by U.S. Forest Service's Institute of Pacific Islands Forestry (http://www.hear.org/pier/), and on recent updates on species invasive potential in Oahu (Daehler and Baker, 2006). For species not quantitatively scored in these assessments, species invasiveness was based on authors' observations on species abundance, presence of seedlings, and capacity of vegetative reproduction throughout the leeward ecosystems in Oahu. Although the overall risk score assessment provides 32 scales for the scored species, we used a simplified scoring with 4 ranks to make it more robust.

Chemical Analyses

Total phenolic content (TP) of leaves was determined by the improved Folin-Ciocalteu assay (Singleton and Rossi, 1965; Marigo, 1973). The improvement relative to standard assay was the use of a blank of polyvinylpolypyrrolidone (PVPP). PVPP retains the phenolic compounds avoiding their reaction with Folin-Ciocalteu solution, thereby providing a true blank sample. For extraction of phenols, 15 mg of dried pulverized leaf sample with 10 ml methanol: water (70:30 v/v) extraction solution were incubated for 30 min in an ultrasound bath at 40°C. Thereafter, the mixture was centrifuged for 10 min at 10000 rpm. Two (A and B) aliquots of 1 ml were obtained from each sample and added to a 25 ml volumetric flask. One aliquot (B) was brought to pH 3.5 with 0.1 M HCl and mixed with 0.5 g of PVPP during 10 min. Sixteen ml of distilled water then were added to both samples A and B, and 1 ml of Folin-Ciocalteau reagent to each one of the flasks. After 3 min of incubation at 40°C, 2 ml of a saturated $NaCO_3$ (20%) solution was added to each one of the samples, and distilled water were added until 25 ml. The samples were incubated at 40°C for an additional 20 min, and the absorbances of the samples, A and B were determined at 760 nm using a spectrophotometer Helios Alpha (Thermo Spectronic, Cambridge, UK).

Total soluble tannins (Tta) were extracted from 20 mg of leaf powder with 12 ml of 70% acetone. Tubes containing the sample and the acetone were sonicated three times for 1 min allowing the tubes to cool for 3 min between successive sonications. After centrifugation, the extract was

assayed with the butanol/HCl method (Porter et al., 1986) modified as in (Makkar and Goodchild, 1996). Briefly, 0.5 ml of the extract was mixed with 3 ml butanol-HCl (95:5) and 0.1 ml of ferric reagent (ferric ammonium sulfate in 2 N HCl) and kept in a boiling water bath for 60 min. After cooling the tube, absorbance was measured at 550 nm by spectrophotometer Helios Alpha. Non-heated replicate tubes for each extract were used as anthocyanins blank, and its absorbance was substracted from the absorbance of the heated tubes. The Tta content on a dry weight basis was estimated by using a 1 cm wide cuvette (Porter et al., 1986; Makkar and Goodchild, 1996). Tta analyses were conducted in triplicate.

For terpene analysis, the leaves of each species were crushed in liquid nitrogen with a Teflon pestle in a Teflon tube until a homogeneous powder was obtained. After homogenization, 1 ml of pentane was added before the pulp defrosted. The tubs were maintained at 25°C during 24 h, and after this period a sample of each extract was put into a 300 µl glass vial. Samples were injected automatically into a GC-MS (HP 6800 series 2, Hewlett Packard, Palo Alto, CA, USA) following a split of 0.5:50. Solvent delay was 3 min. The initial temperature of 40°C was immediately increased with a ramp of 30°C$\,$min^{-1} to 60°C. The second ramp rate was 10°C$\,$min^{-1} to 150°C, which was held for 3 min. The third ramp rate was 70°C$\,$min^{-1} to 250°C, which was held for 5 min. The carrier gas was helium at 0.7 ml$\,$min^{-1}. A mass selective detector was used with an electronic impact of 70 ev. The identification of monoterpenes was conducted by GC-MS comparing with standards from Fluka (Buchs, Switzerland), literature spectra, and GCD Chemstation G1074A HP and Willey 7n spectra library. Frequent calibrations (once every 5 analyses) with α-pinene, 3-carene, β-pinene, β-myrcene, *p*-cymene, limonene, sabinene, and α-humulene standards were used for quantification. Terpene calibration curves (N=4 different terpene contents) were always highly significant (r^2>0.99 for the relationships between signal and the amount of terpene standard injected). The most abundant terpenes had similar sensitivity (differences were less than 5%). The quantification of the terpene peaks were conducted using the ion with mass 93 in the fractionation spectrum. The total GC run time was 23 min. All processes were performed in the same way for native and alien species.

Statistical and Phylogenetic Analyses

The program Phylomatic (Webb and Donoghue, 2005) was used to build a phylogenetic tree of the species studied (Fig. 1). Briefly, this program assembles a phylogeny for the species of interest employing a backbone plant megatree based on a variety of sources involving primarily DNA studies. Our phylogenetic hypothesis was based on the conservative megatree, where unresolved nodes were included as soft politomies. We employed programs in the PDAP package (Garland et al., 1993) to transform the phylogenetic tree into a matrix of phylogenetic distances, and assessed whether the studied traits showed significant phylogenetic signal—i.e., the tendency of closely related species to resemble each other due to shared ancestry—employing the randomization procedure in the PHYSIG module developed by Blomberg et al. (2003). This test consists in comparing the variance in phylogenetic independent contrasts observed in the real dataset against a null distribution obtained after the phenotypic data were randomized across the tips of the phylogeny (i.e., breaking any pattern of phylogenetic resemblance between relatives). Phylogenetic signal was considered significant if the variance in contrasts of the real dataset was lower than the variance in 95% of the permuted datasets. To perform comparisons across traits, we employed the k statistic that estimates how much phylogenetic signal is present in the phenotypic data compared against the expectation from a random walk model of phenotypic evolution (Blomberg et al., 2003). If k=1, then the phenotypic trait has exactly the amount of signal expected for the phylogenetic tree employed and a model of evolution of random walk (Brownian motion); k>1 indicates a stronger phylogenetic resemblance than expected; and k<1 the opposite pattern. These analyses were performed to determine if phylogenetic correction was necessary in subsequent regression analyses. We employed generalized linear models (GLM) to analyze how total leaf phenolics, tannins, and terpenes varied as a function of species origin (native or alien) that was included as independent categorical variable.

The sampling altitude (relative to sea level) correlated significantly with the main climate variables of each respective site (total annual precipitation, the precipitation of the three driest months, mean annual temperature, annual mean of the daily minimum temperature, annual mean of the daily maximum temperature, annual mean of the monthly temperature fluctuation, and annual mean of the coldest temperature of each month) (data not shown). Because of this, altitude was used as covariate in all the conducted general linear models in order to take into account the effects that climate could have on the analyzed leaf variables.

To analyze the sources of variation in total phenolic, total tannin, and total terpene contents, we conducted a general linear model (GLM) with site (4 different sample sites), species origin (native and alien), and soil type (5 different soil types) as independent categorical variables, altitude as independent continuous variable, and in the case of variables with phylogenetic fingerprinting, phylogenetic distances also included as continuous independent factor. To conduct these analyses we used Matlab 7.6.0 with REGRESSIONV2 module (Lavin et al., 2008).

We employed the same rationale to analyze potential differences between native and alien species in the ratios of total phenolics, tannins, and terpene contents relative to leaf chemical, physiological and anatomical traits: foliar N and P contents, foliar photosynthetic capacity (A_{mass}), and LMA reported in a previous study of these species (Peñuelas et al., 2010). We also conducted discriminant analyses with pairwise combinations of leaf total phenolics with leaf N and P contents, A_{mass}, and LMA as continuous independent variables and species origin (alien or native) as a grouping variable. As described above, ordinary least squares (OLS) GLM or Phylogenetic general least square (PGLS) GLM analyses were selected depending on the significance of the phylogenetic fingerprinting (see above). We conducted a principal component analysis (PCA) with leaf economics spectrum (LMA, A_{mass}, [N], and [P]) as variables, and then correlated the factor scores (PC1 and PC2) with the leaf contents of phenolics, tannins, and terpenes. We also conducted a PCA with the leaf contents of phenolics, tannins, and terpenes to investigate whether native and alien species were significantly separared by these variables. Thereafter, we used the PC1 and PC2 scores of this PCA to correlate with LMA, A_{mass}, [N], and [P]. To test whether the observed frequency of alien species that accumulated terpenes was equal in the different continents of origin we conducted a *Chi-square* analysis.

An ANOVA test also was conducted to test for different terpene content depending on the continent of origin. We used Matlab 7.6.0 with REGRESSIONV2 module (Lavin et al., 2008) and Statistica 6.0 software (StatSoft, Inc. Tulsa, OK, USA).

Results

Total Leaf Phenolic, Tannin, and Terpene Contents

Appendix Table 3 shows the species values of total phenolics (TP), total tannins (Tta), and total terpenes (TT). They ranged between 8 and 159 $mg g^{-1}$ DW, 1 and 36 $mg g^{-1}$ DW, and 0 and 13 $mg g^{-1}$ DW, respectively (Appendix Table 3). All analyzed species exhibited detectable contents of TP and Tta, whereas only 25 out of the 73 species analyzed had detectable contents of terpenes (Appendix Table 3). Neither TP nor Tta nor TT contents presented significant phylogenetic fingerprinting. Neither soil type nor sampling site had significant effects on leaf total phenolics (TP) (P=0.12 and P=0.62, respectively), total tannins (Tta) (P=0.45 and P=0.74, respectively), or total terpenes (TT) (P=0.31 and P=0.70, respectively).

Terpenes were detected in 13 alien species and in 12 native species. The frequencies observed were not different from the frequencies expected under the hypothesis of equal frequency of leaf terpene accumulation in the different continents of origin (observed X^2=2.12 that was within the range of X^2=7.81 that includes the 95% of the distribution at $d.f$=3). Overall, alien species had higher (135%; P=0.039) leaf TT contents compared with native species, but did not have significantly different total leaf phenolic and tannin contents (Fig. 2). The different levels of species invasiveness had no significant effect on TP and Tta contents either, but TT contents increased with increasing species invasiveness, considering only terpene-containing species (Fig. 2). There were no differences in leaf terpene content among invasive species of different continent origins (one-way ANOVA, P=0.67). The PCA for all the CBSCs did not separate alien from native species (data not shown). Only terpene contents were different between alien and native species (Fig. 2). The CBSC PCA scores did not correlate either with the PCA scores for physiological foliar economic spectrum traits (data not shown).

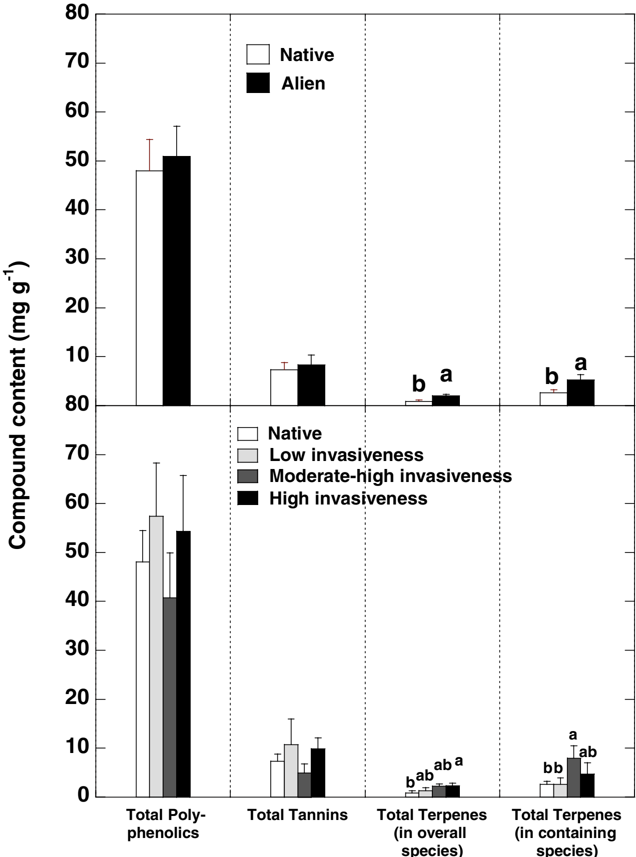

Fig. 2 Total leaf phenolics ($mg g^{-1}$), total leaf tannins ($mg g^{-1}$) and total leaf terpenes ($mg g^{-1}$) in native and alien species, and depending on the invasiveness index. Significant differences (P<0.05) between native and alien species are indicated by different letters.Total terpenes are shown calculated for the overall set of species studied and also only for the species containing terpenes

Relationships with Foliar Nutrient Contents, A_{mass}, and LMA

Appendix Table 3 shows the species values of the TP:N, TP:P, Tta:N, Tta:P, TT:N, and TT:P ratios. The ranges of these ratios among the studied species set were broad, showing great differences among species. The ranges of TP:N and TP:P ratios were 0.4–18.2 $g g^{-1}$ and 2.9–394 $g g^{-1}$, respectively. The ranges of Tta:N and Tta:P ratios were 0.05–3.11 $g g^{-1}$ and 0.8–74.5 $g g^{1}$, respectively. The ranges of TT:N and TT:P ratios were 0–15 $g g^{-1}$ and 0–428 $g g^{-1}$, respectively (Appendix Table 3). None of those ratios exhibited significant phylogenetic fingerprinting.

Despite having higher foliar N content (Peñuelas et al., 2010), aliens had higher leaf TT:N content ratio (80%; P= 0.03) compared with native plants (Fig. 3), reflecting much higher terpene content. No significant effects of sampling site or soil type were observed on the ratios between leaf TT content and leaf economic traits (data not shown).

The ratio between phenolic contents and photosynthetic capacity was 50% lower in alien species compared with native species (P=0.011). There was no other effect of species origin, sampling site, or soil type on the ratios of leaf TP and Tta contents relative to the leaf economic traits (Fig. 4).

In native species, TP was negatively correlated with leaf N, and leaf P contents and A_{mass}. In alien species, TP was

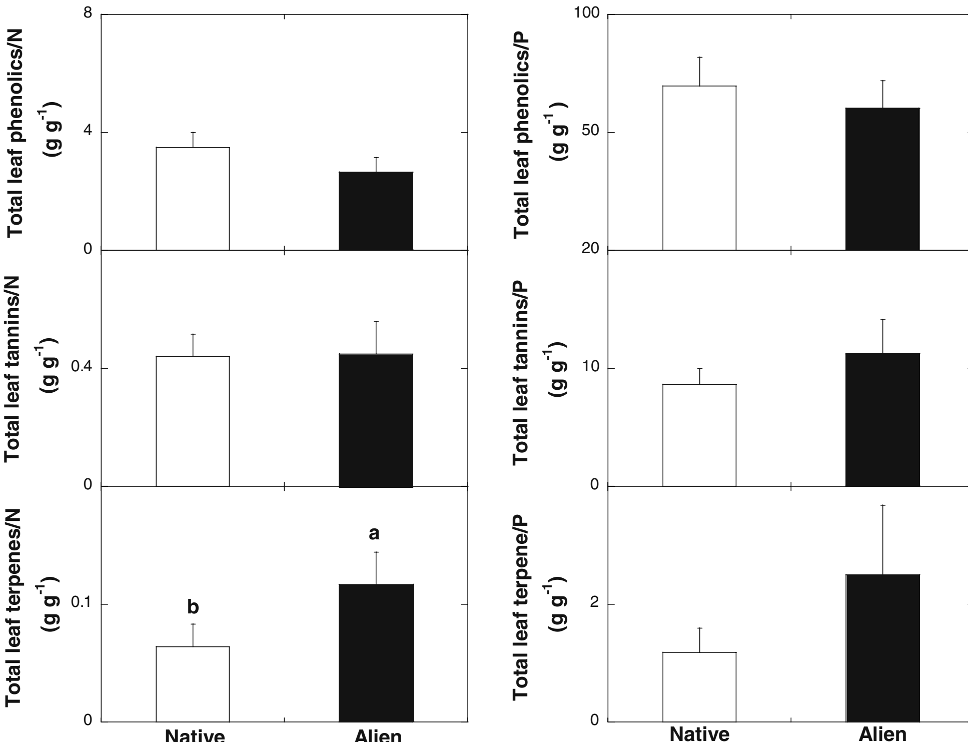

Fig. 3 Ratios of Total leaf phenolics, total leaf tannins and total leaf terpenes relative to leaf N and P contents ($g g^{-1}$). Significant differences ($P<0.05$) between native and alien species are indicated by different letters

significantly correlated only with leaf P content (Fig. 5). In contrast, we did not observe any significant relationships of Tta and TT contents with nutrient contents or with A_{mass} (data not shown).

The discriminant analyses of TP and leaf [N] (Wilk's Lambda=0.85, P=0.003), TP and leaf [P] (Wilk's Lambda= 0.84, P=0.008), and TP and Amax (Wilk's Lambda=0.84, P=0.006) separated alien from native species due to their higher N and P contents and A_{mass}.

Discussion

Alien species had similar total leaf phenolic (TP) and tannin (Tta) contents but higher leaf total terpene (TT) contents than native plants, with no phylogenetic signal in the differences. Moreover, alien species had higher leaf N and P contents, and Amass than native species, and, as a result, alien species had a lower leaf phenolics content/photosynthesis ratio than native species, thus suggesting a lower relative effort on accumulating leaf phenolics. Conversely, the total terpene content relative to N and P contents was larger in alien than in native species. These greater contents of terpenes, providing more qualitative (more dependent on their toxicity than on their quantity) lower cost chemical defenses against generalist herbivores, may counterbalance the lower leaf structural defenses and higher leaf nutritional quality of alien plants. Alien plants thus would be able to deter herbivore attacks using a different strategy of defense. On the other hand, the higher terpene accumulation was independent of the continent of origin of the alien species (Asia, Australia, the Americas, Africa), which indicates that being alien either selects for higher terpene contents post-invasion, or that species with high terpene contents are pre-adapted to invasiveness.

Another possibility to explain these results is that the Hawaiian environment is unusual in some sense that selected for lower terpene levels in the past, and so the real pattern is not that invasive plants have higher terpenes than natives, but Hawaiian plants have lower terpenes that continental species. In that case, the higher terpene levels of the alien species may not have any functional role in invasion, but simply be a result of Hawaiian plants having low concentration of terpenes. With our current knowledge, however, this possibility does not seem likely. Terpene contents have proven not to be determined phylogenetically, at least in this study, suggesting that this capacity is widespread throughout the entire plant taxa spectrum. Certainly, terpenes have been proven to accumulate in response to some climatic stresses (Peñuelas and Llusià, 2003, 2004) but in this regard, the climate conditions of the natural habitats of alien species are similar in most cases to Hawaiian climate. Moreover, the percentage of species that accumulate terpenes was not different between native and aliens showing that the capacity to produce and accumulate terpenes is not different although alien species accumulate greater amounts of terpenes. The number of studies that have conducted a terpene screening in an extensive number

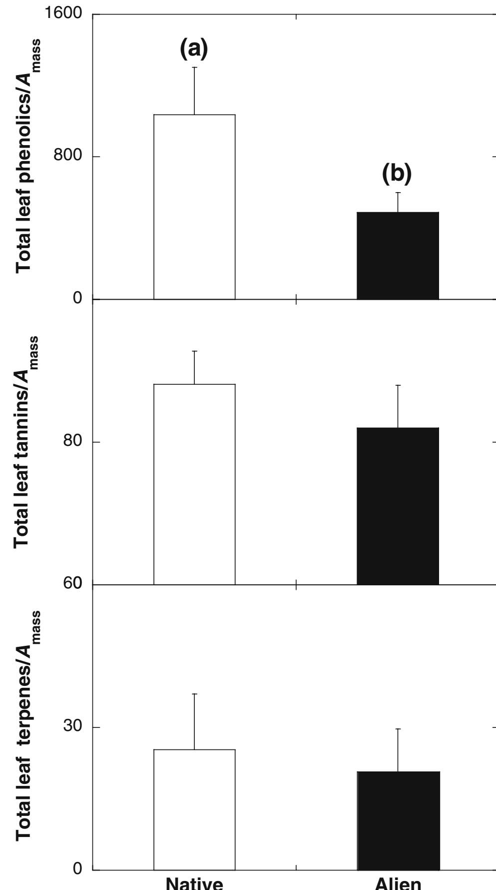

Fig. 4 Total leaf phenolics (mg g^{-1})/A_{mass} (μmols g^{-1} s^{-1}), total tannins (mg g^{-1})/A_{mass} (μmols g^{-1} s^{-1}) and total leaf terpenes (mg g^{-1})/A_{mass} (μmols g^{-1} s^{-1}) ratios. Significant differences (P<0.1) between native and alien species are indicated by different letters between brackets

of species in different regions of the world is, however, scarce, and to clearly discern whether or not terpene accumulation capacity is differently distributed throughout the world is not possible at this moment.

Some recent studies of the changes in chemical defenses in alien populations relative to non-alien populations of the same species have reported that invasive populations evolve a greater resistance to generalist herbivores (e.g., Legar and Forister, 2005). In temperate grassland systems, higher concentrations of toxic secondary compounds also have been found in invaders. The explanation seems to be that these compounds are not only defensive against generalists but also attractive to specialists. Thus, in the native range, the plants are constrained from evolving higher levels due to increased attraction of specialist enemies. In the introduced range where specialist herbivores are absent, the plants can invest more resources to defenses such as terpenes against generalist herbivores (Joshi and Vrieling, 2005). Previous studies also have observed no loss of defenses against generalist herbivores in alien species populations (Leger and Forister 2005; Hull-Sanders et al., 2007). The allocation to lower cost defenses such as terpenes should be more compatible with a low LMA and high photosynthetic capacity (Lankau, 2007). This strategy can be especially successful for alien plants in environmentally rich sites, such as wet tropical environments where higher growth and production provides a greater ability to compete for space occupation and resources uptake. Higher terpene contents are compatible with a fast return strategy of "leaf economics spectrum"

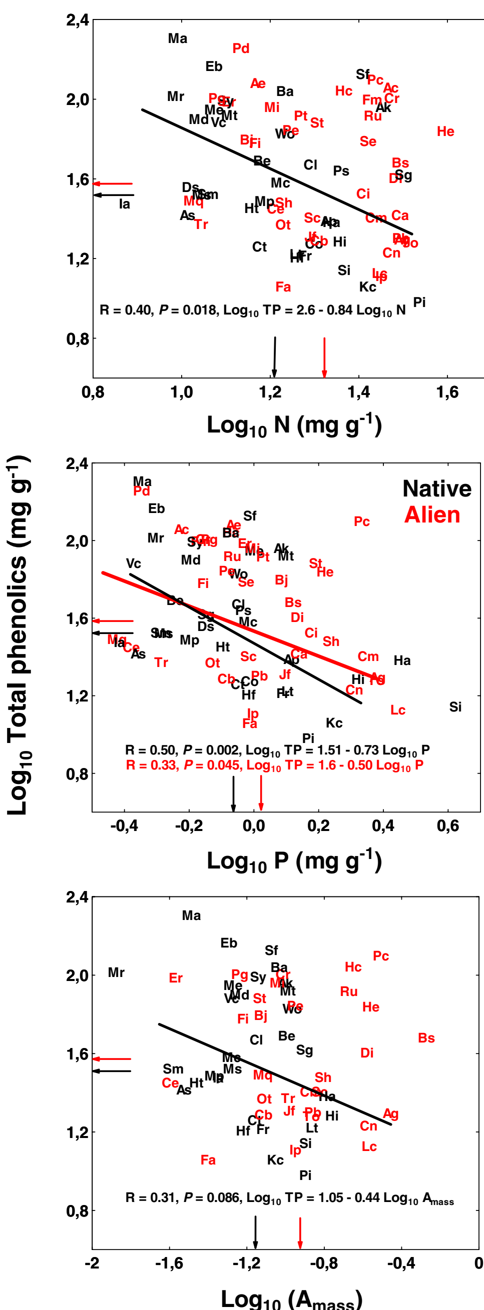

Fig. 5 Relationships between total log$_{10}$ leaf phenolics (mg g^{-1}) and log$_{10}$ leaf N (mg g^{-1}), log$_{10}$ leaf P (mg g^{-1}) contents, and log$_{10}$ A_{mass} (μmols g^{-1} s^{-1})

based on a higher photosynthetic capacity, higher nutrient content, lower LMA, and faster return on investment in foliage (Wright et al., 2004). These traits help to explain the success of invasive plant species (Pattison et al., 1998; Baruch and Goldstein, 1999; Funk and Vitousek, 2007) since they can contribute to faster growth rates for invaders and confer a competitive advantage over native species (Reich et al., 1997; Blumenthal and Hufbauer, 2007). Peñuelas et al., (2010) have observed these faster returns from their investments in nutrients and dry mass in leaves, and these higher contents of most nutrients in these alien species in Oahu (Hawaii).

The higher terpene contents and higher nutrient contents fit better the hypotheses based on higher nutrient availability translating into higher carbon fixation and activity of the enzymes involved in terpene production (Harley et al., 1994; Litvak et al., 1996; Peñuelas and Staudt, 2010) than the hypotheses based on carbon nutrient balance (Bryant et al., 1983; Peñuelas and Estiarte, 1998). The data for native species fits the latter hypotheses but the data for alien species does not. Total phenolic contents were inversely correlated with foliar N and P contents and A_{mass} in the native species, but this did not happen in alien species, except for foliar P content. Phenolics are especially active defenses against specialist herbivores (Coley et al., 1985; Bennet and Wallgrove 1994). Thus, in native plants, the presence of specialist herbivores placed species along a continuous gradient between a high allocation to defense (high phenolics content) and low leaf production capacity (low leaf nutrient content) to a low allocation to defense (low phenolics content) and high allocation to leaf production capacity (high nutrient content). Conversely, aliens with no specialist herbivores did not present this trend. Our results also provided partial support (in aliens) for the hypothesis that leaf phenolic contents would be affected by N and P in different ways because of their different cellular metabolic processes (Wright et al., 2010).

Foliar Tta and TT contents were not related to any of those leaf economic traits in any of both groups of species nor to any of the main nutrients, N or P. Regarding the more evolutive hypotheses, the results partially support the modified EICA-related hypothesis (Joshi and Vrieling, 2005; Stastny et al., 2005), which suggests that alien species have a larger content of low cost defenses such as terpenes against generalist herbivores. These results also demonstrate, however, that aliens had not lost the capacity for formation of high-carbon cost phenolics or tannins.

The different results of alien vs. native comparisons for TT, Tta, and TP contents also suggest a set of different possible physiological, ecological, and evolutionary roles of these different types of CBSC. The higher or lower content of different chemical compounds does not depend only on a defense strategy. Other environmental factors such as temperature or drought could explain changes of secondary metabolites contents such as terpenes since they are also involved in protection mechanisms in the face of abiotic (Peñuelas and Llusià, 2003, 2004; Peñuelas and Munné-Bosch, 2005; Lewis et al., 2006) and biotic (Viiri et al., 2001; Gershenzon and Dudareva 2007) stressors. Volatile terpenes also are involved in plant defense by multitrophic signalling (Dicke and Baldwin, 2010).

In summary, the results show that alien species invest less in structural defenses (they have lower LMA) but more in terpenes, which are low cost chemical defenses, effective at lower contents than other chemical defenses (Mote et al., 2007), and which strongly deter generalist herbivore attacks (Landau et al., 1994; Mote et al., 2007). Thus, the results are partly in accordance with the most recent "Evolution of Increased Competitive Ability" (EICA) hypothesis, which proposes that lower cost defensive compounds are effective in deterring generalist herbivores in the introduced range. However, the results are not in accordance with the expected decreases in other high cost defense components such as TP and Tta. These higher contents of lower cost defenses together with higher nutrient content and growth rates fit well with the fast-growing strategy of the alien species in resource rich areas such as the tropical islands with old weathered soils where the plant invasive success is an emerging phenomenon.

Acknowledgements We thank Theodore Garland Jr. for providing most of the statistical programs used for phylogenetic analyses. This research was supported by the University of Hawaii (G. P. Wilder research funds), and grants from the Spanish Government (CGL2006-04025/BOS, CGL2010-17172 and Consolider-Ingenio Montes CSD2008-00040), the Catalan Government (SGR 2009-458), the Estonian Ministry of Education and Science (grant SF1090065s07), the Spanish National Research council (CSIC-PIF08-006-3), and the Estonian Science Foundation (grant 7645).

[a] averages are based on the number of species sampled and species-specific locations. In statistical analyses, exact species-specific environmental data were used

Table 2 Family, plant growth form, sampling sites in Oahu, Hawaii, characteristic ecological distribution, continent of origin and invasiveness of all studied species

Species[a]	Family	Growth form	Sampling site[b]	Species ecology	Continent of origin	Invasi-veness[c]
Acacia confusa	Fabaceae	Tree	St. Louis Heights	dry-mesic	Asia	3
Acacia koa	Fabaceae	Tree	Wiliwilinui	mesic-wet		0
Ageratina adenophora	Asteraceae	Herb	Tantalus	mesic-wet	Americas	2
Alyxia stellata	Apocynaceae	Vine/Shrub	Wiliwilinui	mesic-wet		0
Antidesma platyphyllum	Euphorbiaceae	Tree	Tantalus	mesic-wet		0
Ardisia elliptica	Myrsinaceae	Shrub	Hahaione Valley	mesic-wet	Asia	3
Bischofia javanica	Euphorbiaceae	Tree	Tantalus	mesic-wet	Asia	2
Bobea elatior	Rubiaceae	Tree	Wiliwilinui	wet		0
Broussaisia arguta	Hydrangeaceae	Shrub	Wiliwilinui	wet		0
Buddleja asiatica	Scrophulariaceae	Shrub	Wiliwilinui	mesic-wet	Asia	2
Carmona retusa	Boraginaceae	Shrub	St. Louis heights	dry-mesic	Asia	1
Casuarina equisetifolia	Casuarinaceae	Tree	St. Louis heights	dry-mesic	Australia	3
Cestrum nocturnum	Solanaceae	Shrub	Tantalus	wet	Americas	3
Cheirodendron trigynum	Araliaceae	Tree	Wiliwilinui	wet		0
Cinnamomum burmannii	Lauraceae	Tree	Tantalus	mesic-wet	Asia	2
Citharexylum caudatum	Verbenaceae	Shrub	Tantalus	mesic-wet	Americas	3
Clermontia oblongifolia	Campanulaceae	Tree	Tantalus	wet		0
Clerodendrum macrostegium	Verbenaceae	Shrub	Tantalus	wet	Asia	1
Coffea arabica	Rubiaceae	Shrub	Tantalus	mesic-wet	Africa/Asia	2
Coprosma longifolia	Rubiaceae	Shrub	Wiliwilinui	mesic-wet		0
Desmodium incanum	Fabaceae	Shrub	Hahaione Valley	dry	Americas	2
Diospyros sandwicensis	Ebenaceae	Tree	Tantalus	dry-mesic		0
Elaeocarpus bifidus	Elaeocarpaceae	Tree	Tantalus and Wiliwilinui	mesic-wet		0
Eucalyptus robusta	Myrtaceae	Tree	St. Louis heights	dry-mesic	Australia	1
Falcataria moluccana	Fabaceae	Tree	St. Louis heights	dry-mesic	Asia	2
Ficus macrophylla	Moraceae	Tree	Hahaione Valley	mesic-wet	Australia	2
Ficus microcarpa	Moraceae	Tree	St. Louis heights	dry-mesic	Asia	3
Freycinetia arborea	Pandanaceae	Vine/Shrub	Tantalus	wet		0
Haematoxylum campechianum	Fabaceae	Tree	St. Louis heights	dry	Americas	2
Hedyotis acuminata	Rubiaceae	Vine/Shrub	Tantalus	mesic-wet		0
Hedyotis fosbergii	Rubiaceae	Shrub	Wiliwilinui	wet		0

Table 2 (continued)

Species[a]	Family	Growth form	Sampling site[b]	Species ecology	Continent of origin	Invasiveness[c]
Hedyotis terminalis	Rubiaceae	Shrub	Wiliwilinui	mesic-wet		0
Heliocarpus americanus	Malvaceae	Tree	Hahaione Valley	dry-mesic	Americas	1
Hibiscus arnottianus	Malvaceae	Tree	Tantalus	wet		0
Ilex anomala	Aquifoliaceae	Shrub	Wiliwilinui	wet		0
Ilex paraguariensis	Aquifoliaceae	Tree	Tantalus	mesic-wet	Americas	1
Jasminum fluminense	Oleaceae	Vine	St. Louis Heights	dry-mesic	Africa	2
Korthalsella complanata	Santalaceae	Mistletoe	Wiliwilinui	wet		0
Labordia tinifolia	Loganiaceae	Shrub	Tantalus	wet		0
Lantana camara	Verbenaceae	Shrub	Hahaione Valley	dry-mesic	Americas	3
Mangifera indica	Anacardiaceae	Tree	Tantalus	mesic-wet	Asia	1
Melaleuca quinquenervia	Myrtaceae	Tree	St. Louis heights	dry-mesic	Australia	2
Melicope clusiifolia	Rutaceae	Shrub	Wiliwilinui	wet		0
Melicope peduncularis	Rutaceae	Shrub	Wiliwilinui	wet		0
Metrosideros macropus	Myrtaceae	Tree	Wiliwilinui	wet		0
Metrosideros polymorpha	Myrtaceae	Tree	Hahaione Valley and Tantalus	mesic-wet		0
Metrosideros rugosa	Myrtaceae	Shrub	Wiliwilinui	wet		0
Metrosideros tremuloides	Myrtaceae	Tree	Tantalus	mesic-wet		0
Myrsine lessertiana	Myrsinaceae	Shrub	Wiliwilinui	wet		0
Myrsine sandwicensis	Myrsinaceae	Shrub	Wiliwilinui	wet		0
Ochna thomasiana	Ochnaceae	Shrub	Hahaione Valley	dry	Africa	1
Passiflora suberosa	Passifloraceae	Vine	Wiliwilinui	dry-mesic	Americas	2
Persea americana	Lauraceae	Tree	Tantalus series	mesic-wet	Americas	1
Pimenta dioica	Myrtaceae	Tree	St. Louis heights	dry	Americas	1
Pisonia umbellifera	Nyctaginaceae	Tree	Tantalus	mesic-wet		0
Pluchea carolinensis	Asteraceae	Shrub	Hahaione Valley	dry-mesic	Americas	2
Pouteria sandwicensis	Sapotaceae	Tree	Tantalus	mesic-wet		0
Psidium cattleianum	Myrtaceae	Tree	Hahaione Valley	mesic-wet	Americas	3
Psidium guajava	Myrtaceae	Tree	Hahaione Valley	dry-mesic	Americas	3
Rubus rosifolius	Rosaceae	Shrub	Wiliwilinui	wet	Americas	2
Santalum freycinetianum	Santalaceae	Tree	Wiliwilinui	dry-mesic		0
Scaevola gaudichaudiana	Goodeniaceae	Shrub	Wiliwilinui	wet		0
Schinus terebinthifolius	Anacardiaceae	Tree	Hahaione Valley	dry-mesic	Americas	3
Senna surattensis	Fabaceae	Tree	St. Louis heights	dry	Asia/Australia	1
Sida fallax	Malvaceae	Shrub	Hahaione Valley	dry-mesic		0
Smilax melastomifolia	Smilacaceae	Vine	Wiliwilinui	mesic-wet		0
Stachytarpheta cayennensis	Verbenaceae	shrub	Hahaione Valley	dry-mesic	Americas	3
Syzygium cumini	Myrtaceae	Tree	Tantalus	mesic-wet	Asia	1
Syzygium sandwicensis	Myrtaceae	Tree	Wiliwilinui	wet		0
Tabebuia rosea	Bignoniaceae	Tree	St. Louis heights	dry-mesic	Americas	1
Trema orientalis	Ulmaceae	Shrub	Hahaione Valley	dry-mesic	Africa/Asia	2
Vaccinium calycinum	Ericaceae	Shrub	Wiliwilinui	wet		0
Wikstroemia oahuensis	Thymelaeaceae	Shrub	Wiliwilinui	mesic-wet		0

[a] Species nomenclature follows ARS/GRIN online database (USDA, ARS, National Genetic Resources Program. *Germplasm Resources Information Network - (GRIN)*, National Germplasm Resources Laboratory, Beltsville, Maryland, http://www.ars-grin.gov/cgi-bin/npgs/html/index.pl) and for Hawaiian native species missing from this database (mainly *Rubiaceae* and *Rutaceae*) species nomenclature follows the Manual of the flowering plants of Hawai'i (Wagner et al., 1999)

[b] Table 1 for the description of the study sites

[c] 0 – native species, 1 – low, 2 – moderate-high, 3 –high invasiveness

Table 3 Foliar contents of total phenolics (TP), total tannins (Tta) and total terpenes (TT) and their respective ratios relative to leaf N and P content for the studied native and alien species

Species[a]	Species code	Origin	Total Phenolics (TP) ($mg g^{-1}$)	Total Tannins (Tta) ($mg g^{-1}$)	Total Terpenes (TT) ($mg g^{-1}$)	TP:N ($g g^{-1}$)	TP:P ($g g^{-1}$)	Tta:N ($g g^{-1}$)	Tta:P ($g g^{-1}$)	TT:N ($g g^{-1}$)	TT:P ($g g^{-1}$)

preserve vegetative growth and reproduction, yet minimize fitness costs to the plant (Koornneef and Pieterse, 2008; Dicke and Baldwin, 2010; Heil, 2010; Mooney et al., 2010). These complex biochemical and physiological responses are dynamic and often result in a local or systemic resistance to further challenge (De Vos et al., 2006; De Vos and Jander, 2009).

Plants deploy defense-signaling pathways regulated by salicylic acid (SA), jasmonic acid (JA), ethylene, and reactive oxygen species (ROS) in response to herbivores and pathogens (Glazebrook, 2005; Walling, 2009). These pathways are interconnected and can act antagonistically, additively, or synergistically (Mur et al., 2006). The convergence of these pathways at key signaling nodes (NPR1, WRKY70, and glutaredoxin) may enable prioritization of the signaling pathways allowing deployment of the most effective local and systemic defenses against an intruder (Koornneef and Pieterse, 2008). In addition, these defense pathways communicate with abscisic acid (ABA), auxin, gibberellic acid, and brassinosteroid signaling pathways to coordinate the magnitude and quality of the defense response activated (López et al., 2008; Spoel and Dong, 2008). There is accumulating evidence for additional defense-signaling pathways that are modulated after herbivore attack; however the identities of these pathways have yet to be revealed (van de Ven et al., 2000; Glazebrook, 2005; De Vos et al., 2006; De Vos and Jander, 2009; Bhattarai et al., 2010).

Plant defense responses to insects in the order Hempitera are distinct, as these insects use their stylets and salivary secretions in disparate manners to recover nutrients from their host plants. For example, mirid bugs, pyrrhocorids, lygaeids, planthoppers, and leafhoppers are destructive, since they lacerate cells, solubilize cell contents, and consume the cellular slurry (Miles, 1999; Walling, 2009). At the cellular level, these Hemiptera can be as damaging as caterpillars or beetles that cut and tear foliage. At the other end of the spectrum are aphids and whiteflies (Tjallingii, 2006; Walling, 2008). Aphids will puncture numerous mesophyll cells in their search for phloem sieve elements, while whiteflies rarely damage cells on their stylet's path to the phloem.

Over 1,555 whitefly species have been described, although most studies have focused on polyphagous whiteflies, such as the *Bemisia tabaci* species complex and *Trialeurodes vaporariorum* (Westwood), that interfere with agricultural and horticultural productivity (De Barro et al., 2005; Martin and Mound, 2007). *Trialeurodes vaporariorum* is a common pest of greenhouses worldwide and fields in temperate climates, while *B. tabaci* (Gennadius) biotype B, also known as *Bemisia argentifolii (*Bellows and Perring), is more widespread, destructive, and invasive (van Lenteren and Noldus, 1990; Inbar and Gerling, 2008). The success of *B. tabaci* biotype B likely is due to a variety of strategies including: ability to adapt to a wide range of plant habitats, broad host range, voracious feeding that may allow it to infest plants with phloem sap of different nutritional values, increased fecundity, breeding strategies that promote invasiveness, and rapid emergence of insecticide-resistant strains (Liu et al., 2007; Inbar and Gerling, 2008; Walling, 2008).

The destructiveness of *B. tabaci* biotype B is correlated with depletion of photosynthates, deposition of large amounts of excreta (honeydew) that supports sooty mold growth, and its ability to vector over 111 virus species (Inbar and Gerling, 2008). In addition, this whitefly causes plant developmental disorders that can contribute to agricultural losses including tomato fruit irregular ripening and the curcurbit leaf-silvering disorder, the characteristic used in the common name of this biotype (the silverleaf whitefly) (Schuster et al., 1990; De Barro and Khan, 2007). Recently, two newly identified biotypes (MS, Ug6) also were shown to cause silvering, thus demonstrating that this trait has been acquired several times (Delatte et al., 2005; Sseruwagi et al., 2005).

Several studies have evaluated the response of crop and model plants to *B. tabaci* feeding. In the model plant *Arabidopsis thaliana* (L. Heynh), *Bemisia tabaci* biotype B causes a profound reprogramming of gene expression (Kempema et al., 2007). *B. tabaci* causes increases in SA-regulated pathogenesis-related (*PR*) protein gene transcripts and decline in JA-regulated defense RNAs in infested leaves (locally) and systemically in apical, non-infested leaves (Zarate et al., 2007). Use of defense-response mutants and transgenic lines that alter the activity of the SA- and JA-regulated defense-signaling pathways (*coi1, npr1, cev1, cim10*, and NahG) and methyl jasmonate (MeJA) treatments show that *B. tabaci* induces decoy defenses (Zarate et al., 2007). The suppressed JA-regulated defense pathway, not the induced SA-regulated defense pathway, controls the resistance traits that retard nymph development.

The role of the JA, SA, and ethylene defense-signaling pathways in regulating the expression of the resistance traits in crop plants that deter *B. tabaci* nymph development is less well characterized. Studies in squash show that plants can discriminate the elicitors/effectors (chemical signals) introduced by two different *B. tabaci* biotypes (van de Ven et al., 2000). *SLW1* (a M20b peptidase-like gene) and *SLW3 (*a leaf-specific β-glucosidase-like gene) RNAs accumulate preferentially in response to *B. tabaci* biotype B feeding but not *B. tabaci* biotype A. Both *SLW1* and *SLW3* appear to be regulated by SA-independent pathways (van de Ven et al., 2000). *SLW1* RNAs accumulate after JA and ethylene treatments, while *SLW3* transcripts do not accumulate in response to known defense signals.

Changes in peroxidase, chitinase, and β-1,3-glucanase activities have been noted after *B. tabaci* infestations of

cassava, squash, and tomato (Jiménez et al., 1995; Mayer et al., 1996; Antony and Palaniswami, 2006). In addition, *B. tabaci* biotype B infestation of *Phaseolus vulgaris* (L.) causes the release of volatiles that are recognized by its parasitoid *Encarsia formosa* (Gahan) (Birkett et al., 2003). However, in cotton, no changes in volatile bouquets were detected (Rodriguez-Saona et al., 2003). The levels of two pathogenesis-related (*PR*) protein gene RNAs (PR69B and P6) are known to accumulate during *B. tabaci* biotype B infestation (Sánchez-Hernández et al., 2006). Furthermore, 244 differentially regulated genes were identified using spotted cDNA arrays after *B. tabaci* infestation of tomato (Estrada-Hernandez et al., 2009).

Given the ability of plants to discriminate between *B. tabaci* biotypes, *Macrosiphum. euphorbiae* (Thomas) biotypes, and *Tetranychus urticae* (Koch) lines (van de Ven et al., 2000; Hebert et al., 2007; Kant et al., 2008), it was of interest to develop a more comprehensive understanding of the changes in plant defense-response gene expression in response to two species of whiteflies with distinctive host ranges and abilities to induce developmental disorders and vector viruses. To this end, the temporal and spatial expression of nine tomato genes that respond to wound/ defense signals, including systemin, JA, ethylene, ABA, and SA, were monitored after feeding by *B. tabaci* biotype B or *T. vaporariorum*. In addition, the roles of wound signals in the tomato-*Bemisia* interaction were investigated using a transgenic tomato line expressing a *LapA1:GUS* (*Leucine aminopepetideA1*:β-glucuronidase) reporter gene construct, which is a sensitive monitor for wounding.

Methods and Materials

Plant Growth, Insect Colonies and Whitefly Infestations Tomato plants (*Solanum lycopersicum cv.* Rutgers and cv. Pto238R) were grown in UC Soil Mix III in a growth chamber at 25°C with a 16/8-h L:D. At planting, soil was supplemented with osmocote. At 4 wk, tomato plants were transferred to insect cages in the greenhouse. Plants were fertilized once per week with Miracle-Gro. Seven-wk-old plants (cv. Rutgers) were used for the temporal and spatial RNA studies. These plants had 15 leaves, and leaves were numbered beginning at the base of the plant. Greenhouse temperatures averaged 29°C (day) and 16°C (night). Silverleaf whitefly [*B. tabaci* (Gennadius) biotype B; also known as *Bemisia argentifolii* (Bellows and Perring)] and greenhouse whitefly [*Trialeurodes vaporariorum* (Westwood)] colonies were raised on *Phaseolus vulgaris* (L.) plants. *Bemisia tabaci* cultures were assayed periodically for isozyme variants to ensure culture purity.

When plants were 7-wk old, the 7th and 8th leaves were encased individually in nylon-mesh bags, and 250 whiteflies adults (200 females and 50 males) were placed inside each bag. Control plants were encased in a similar manner, except no insects were added (bagged control; Control B). A second set of control plants was neither bagged nor infested to assess the impact of bagging on wound- and defense-response gene expression (unbagged control; Control U). After 9 d of feeding, adult whiteflies were removed by aspiration, and the infested tomato leaves (leaves 7 and 8) and apical, non-infested leaves (leaf 9) were harvested directly in liquid nitrogen. In time-course experiments, infested and control leaves were harvested at 0, 1, 3, 5, 7, and 9 d post infestation. Experiments were repeated once and in each experiment each sample was a pool of leaves from three different plants. This infestation protocol resulted in ca. 2,000 nymphs per leaf. Similar nymph densities have been noted in field-grown tomatoes (Gusmão et al., 2006).

Excised shoots from 3- to 4-wk-old tomato (Peto 238R) plants were treated with 10 μM MeJA (24 hr), 100 μM ABA (24 hr), 29 ppm ethylene (24 hr), 1 pmol systemin (12 hr), or 0.1, 0.25 or 0.5 mM salicylic acid (24 hr). Treatments and controls have been described previously (Gu et al., 1996; Chao et al., 1999).

RNA Extractions and RNA Blot Hybridizations Leaves (2.5 g) were ground to a fine powder in liquid N_2. After N_2 evaporation, 5 ml extraction buffer (100 mM LiCl, 100 mM Tris-HCl, pH 8.0, 10 mM EDTA, 1% SDS) at 80°C and 5 ml of water-saturated phenol (80°C) were added. After vortexing for 30 sec, 6 ml chloroform:isoamyl alcohol (24:1) were added. The sample was vortexed for 30 sec and centrifuged at 3,200 × *g* at 4°C for 60 min. The aqueous layer was removed and mixed with one volume of 4 M LiCl. After 1 hr at −80°C, total RNA was recovered by centrifugation at 3,200 × *g* at 4°C for 60 min, washed with 70% EtOH, resuspended in water, and stored at −80°C.

Total RNAs (15 μg) were size fractionated on 1.0% formaldehyde-agarose gels, blotted to nylon membranes (Hybond-N, Amersham, Piscataway, NJ, USA), hybridized with ^{32}P-labeled probes, and washed under conditions of high stringency as described in Pautot et al. (1991). RNA blots for the whitefly infestation experiments were used once to assure maximum sensitivity. RNA blots with defense chemical treatments were reused once. Probes were labeled using [^{32}P]-dCTP (Amersham). Autoradiographic signals were quantitated using a phosphoimager (Molecular Dynamics).

The *PR-1* (P6 protein, pP6), *PR-4* (P2 protein, pPR-P2), *Chi3* (acidic chitinase, pChi3), *Chi9* (basic chitinase, pChi9), *GluB* (basic β-1,3-glucanase, pGluBAS), and *GluAC* (acidic β-1,3-glucanase, pGluAC) cDNA clones were provided by Dr. Pierre de Wit (Wageningen Agricultural University, Wageningen, The Netherlands) (van Kan et al., 1995). The proteinase inhibitor 2 (*pin2;* pT2-47*)* cDNA clone was provided by Dr. C.A. Ryan (Washington

State University, Pullman, WA, USA) (Graham et al., 1985). The *LapA1* partial cDNA clone (pDR57) was previously described (Pautot et al., 1993). There are two genes (*LapA1* and *LapA2*) encoding LAP-A that are 98% identical at the nucleotide level (Gu et al., 1996); transcripts for both genes are detected under the hybridization conditions utilized. The *PAL* gene family in tomato (cv. Craigella) consists of 26 family members (Chang et al., 2008). RNAs for only two *PAL* genes (*PAL1* and *PAL5*) have been detected in tomato (Lee et al., 1992). The *PAL1* RNA is not abundant, whereas the *PAL5* RNA accumulates during development and in response to abiotic and biotic stresses (Chang et al., 2008). The tomato *PAL5* cDNA clone pPal1-16 was 1.6 kb in length and was isolated as a whitefly-induced cDNA by using differential RNA display from cv Rutgers (D.P. Puthoff and L.L. Walling, unpublished results). Partial sequence of this clone showed 97% nucleotide identity with *PAL5* of tomato cv. BonnyBest (Accession P26600) (Lee et al., 1992).

GUS Histochemical and Fluorometric Assays The *LapA1:GUS* line U78 was characterized previously (Chao et al., 1999). Homozygous *LapA1:GUS* or UC82b (wild-type control; WT) tomato plants were planted per 1-gallon pot (2 plants/pot) and grown in the greenhouse in insect cages. At 3 wk, pots were encased in nylon mesh bags, and plants were infested with 100 *B. tabaci* biotype B or served as non-infested controls. After 21 d of infestation, second, third and early fourth instar nymphs were feeding on the abaxial leaf surfaces. At this time, developmentally matched leaves from the control and infested plants were harvested for GUS staining. Leaves from 6-wk-old control (WT) and *LapA1:GUS* plants grown in insect-free cages were wounded by pricking the abaxial surface of leaflets with a straight pin. Pin pricks were administered to reflect the density of feeding whitefly nymphs (10 pricks per cm^2). Six-wk-old control (WT) and *LapA1:GUS* plants were mechanically wounded by crushing of the leaf lamina as previously described Chao et al. (1999). Pin-pricked and crushed leaves, as well as developmentally matched leaves from non-damaged WT (control) and *LapA1:GUS* plants, were harvested 24 hr later. All tissues were stored at −80°C until use.

Extraction and measurement of GUS activity in leaves was according to Jefferson (1987) with the following modifications. Leaves were ground to a fine powder in liquid nitrogen, and 30 mg of tissue were homogenized in GUS extraction buffer (50 mM $NaPO_4$, pH 7.0, 10 mM β-mercaptoethanol, 10 mM EDTA, 0.1% sodium lauryl sarcosine, 0.1% Triton X-100). Extracts (10 µl) were assayed in a 500-µl reaction with GUS assay buffer (2 mM 4-methylumbelliferyl-β-D-glucuronide in GUS Extraction Buffer) with 20% (v/v) methanol to reduce endogenous GUS activity (Kosuge et al., 1990). After 0, 30, and 60 min, 100-µl aliquots were removed and added to 1.9 ml 0.2 M Na_2CO_3. Methlyumbelliferone (MU) concentrations were determined by using a Dyna Quant 200 fluorimeter using MU standards. Each plant extract was assayed in triplicate. Protein concentrations were determined with the bicinchoninic acid (BCA) assay (Pierce, Rockford, IL, USA) using bovine serum albumin standards. Protein samples were pretreated with 0.1 M iodoacetamide in 0.1 mM Tris-HCl (pH 8.0) at 37°C for 20 min prior to the BCA assay to reduce interference caused by β-mercaptoethanol (Hill and Straka, 1988).

For GUS histochemical staining, 3-wk-old, greenhouse-grown *LapA1:GUS* tomato seedlings were infested or wounded. Infested plants were monitored for appearance of first, second, and third instar nymphs. Feeding sites of immature insects in each instar were evaluated on at least three different plants after 20 d of feeding. Infested leaves were harvested and stained for GUS activity (Jefferson, 1987). In brief, tomato leaves were harvested into GUS staining buffer (100 mM $NaPO_4$, 0.5 mM $K_3[Fe(CN_6)]$, 0.5 mM $K_4[Fe(CN_6)]$, 10 mM EDTA, 0.5 mg/ml X-gluc, 0.1% Triton X-100, 20% methanol). X-gluc (5-bromo-4-chloro-3-indoyl β-D-glucuronic acid) was purchased from Research Products International (Mt. Prospect, IL, USA). After vacuum infiltration for 5 min at 20–25 mm Hg, tissue was incubated at 37°C overnight. Tomato leaves were cleared with repeated changes of 95% ethanol and viewed in a dissecting scope. While Arabidopsis gene-trap lines demonstrated that the GUS histochemical assay was working (data not shown), GUS activities were not detected histochemically in infested or wounded *LapA1:GUS* plants. Increasing infiltration times, increasing number of 5-min infiltrations, pretreating leaves by dipping in hexane for 10 sec to 1 min, or performing GUS staining reactions in the presence of 1%–4% DMSO or 0.05%–0.5% Silwet (a wetting agent) did not enhance histochemical detection of GUS activity in the mature *LapA1:GUS* leaves.

Results

Whiteflies Do Not Increase Levels of LapA or pin2 RNAs Whiteflies do not cause extensive damage to plant tissues since their stylets follow an intercellular path to reach phloem sieve elements. Therefore, it was important to determine if (a) the occasional epidermal cell piercing, (b) passage of the whitefly stylet through the leaf cell's extracellular matrix, and (c) the puncturing of phloem elements would be perceived as a wound response in tomato. To this end, the levels of RNAs for two well-studied wound-response genes—leucine aminopeptidase (*LapA)* and proteinase inhibitor 2 *(pin2)*—were used as

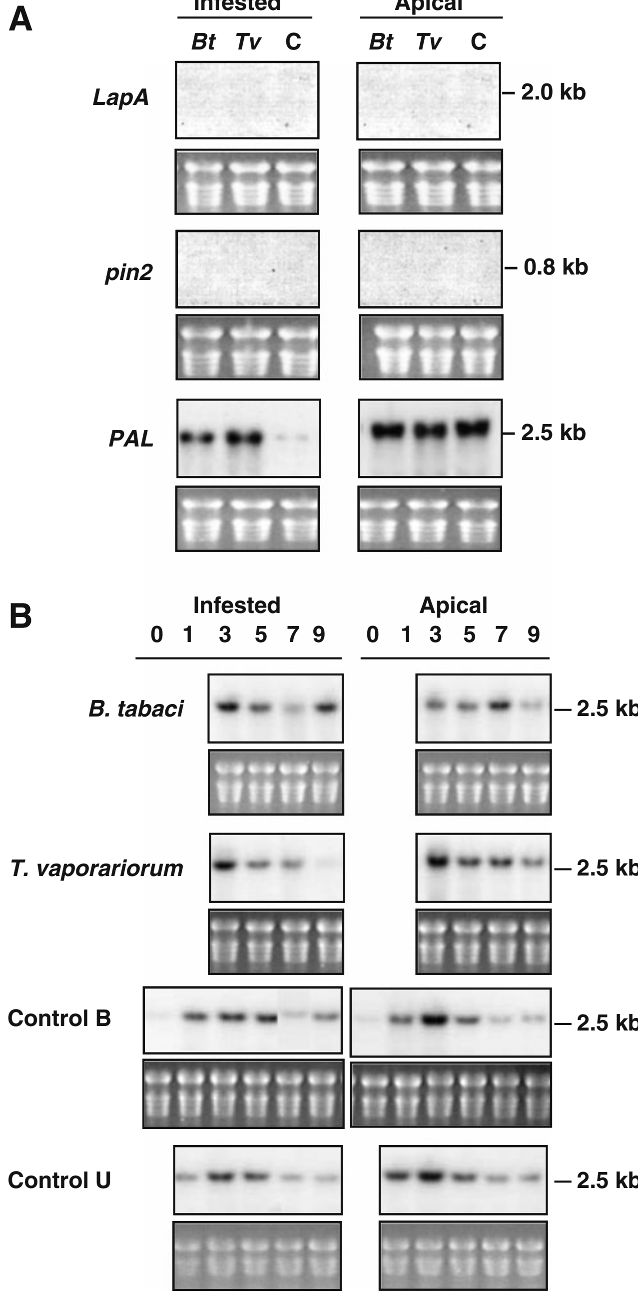

Fig. 1 Changes in *LapA*, *pin2*, and *PAL* gene expression after whitefly feeding. **A** Leaves 7 and 8 of 8-wk-old tomato plants were infested with 250 adult *Besimia tabaci* biotype B (*Bt*) or *Trialeurodes vaporariorum* (*Tv*). Leaves from non-infested control plants (C) were encased in nylon-mesh bags but no insects were added. After 9 d of infestation, adult whiteflies were removed and infested leaves and apical, non-infested leaves (leaf 9) were harvested. Total RNAs isolated and RNA blots (15 μg/lane) were hybridized with ^{32}P-labeled probes for leucine aminopeptidase (*LapA*), proteinase inhibitor 2 (*pin2*), and phenylalanine ammonia lyase (*PAL*). Film exposure times were 3 (*PAL*) or 6 (*LapA*, *pin2*) days. **B** Plants were infested with *B. tabaci* biotype B (*Bt*) or *T. vaporariorum* (*Tv*) as described in Panel **A**. Infested and apical, non-infested leaves were harvested 0, 1, 3, 5, 7, and 9 d after infestation. Leaves from control plants that had leaves 7 and 8 encased in insect bags (Control B) and untreated plants (Control U) were harvested at 0, 1, 3, 5, 7, and 9 d. Total RNA blots were hybridized with a ^{32}P-labeled *PAL* probe. Exposure times were 24 hr. Stained gels visualizing rRNAs are shown as a loading controls. Results from infested leaf 7 and apical leaf 9 are displayed (**A, B**). Infested leaf 8 was also analyzed and results were similar to that of leaf 7 (data not shown)

sentinels to monitor the activation of the tomato wound-signaling pathway.

The 7th and 8th leaves of 8-wk-old tomato plants were enclosed in fine-mesh nylon bags and each leaf was infested with 250 adult whiteflies/leaf (4 females:1 male). To control for possible responses to the inadvertent mechanical damage that occurred during the infestation procedures and plant handling, two sets of controls were included. Some control plants had their leaves encased in nylon bags but insects were not added (Control B). A second set of control plants were not bagged or infested (Control U). The levels of *LapA* and *pin2* RNAs were determined in the infested and apical non-infested leaves at 0, 1, 3, 5, 7, and 9 days after whitefly infestation (Fig. 1A).

Throughout the 9-day infestation, adults fed, mated, and oviposited. During the first 3 days of infestation, only whitefly adults were feeding (500 per plant). During this period, no increases in *LapA* or *pin2* RNAs were detected (data not shown). Between days 3 and 5, eggs began to hatch and first-instar nymphs established feeding sites. The numbers of feeding nymphs increased over the 9-day period. At the time of harvest, there were approximately 2,000 immature insects and 250 adult insects associated with each infested tomato leaf. Most nymphs were in their second and third instars. Despite the large numbers of whitefly nymphs (10 nymphs/cm^2 leaf area), neither the *LapA* nor *pin2* transcripts were detected in the infested leaves at 9 days post infestation (Fig. 1A) or at earlier times (data not shown).

Since many wound-response genes are expressed systemically and local and systemic responses can be distinct, the levels of *LapA* and *pin2* RNAs in apical, non-infested leaves were determined. *LapA* and *pin2* RNAs were not detected in apical leaves from control or infested plants after 9 days (Fig. 1A) or at earlier times (data not shown). This is in sharp contrast to the rapid increase in *LapA* or *pin2* mRNA levels that have been previously reported after mechanical wounding or caterpillar feeding (Pautot et al., 1993; Howe et al., 1996).

Although visual damage is not observed after whitefly feeding, wound-response genes (*LapA* and *pin2*) might be expressed in a subset of leaf cells (i.e., the epidermal cells that were pierced), and RNA signals may be diluted by the majority of non-responding cells. For this reason, it was of interest to determine if wound-response genes were activated in leaf cells immediately surrounding the stylet path or at the whitefly feeding sites. To this end, transgenic tomato plants expressing the wound-activated *LapA1* gene

promoter fused to the β-glucuronidase (GUS) coding region (*LapA1:GUS*) were used in whitefly infestation studies. Due to the exceptional stability of GUS in plant cells, GUS was the reporter gene of choice in these studies. GUS activity can be detected for several days after promoter activation (Weinmann et al., 1994). Three-wk-old *LapA1:GUS* and WT plants were infested with 100 *B. tabaci*. After 21 d of infestation, leaves had second, third, and early fourth-instar nymphs. As positive controls, leaves from developmentally matched plants were wounded by crushing or pin pricking. Both histochemical and fluorometric assays were performed.

Using the GUS histochemical detection method, no GUS activity was detected in controls or, more surprisingly, in wounded or JA-treated samples; however, GUS activities were readily detected using a GUS fluorometric assay (Table 1). The inability to detect GUS staining in older leaves in this study contrasted to previous reports that readily detected GUS histochemically after JA treatments in 7- to 10-day-old

Table 1 Fluorometric analysis of GUS activity in transgenic *LapA1:GUS* tomato plants in response to wounding and whitefly feeding

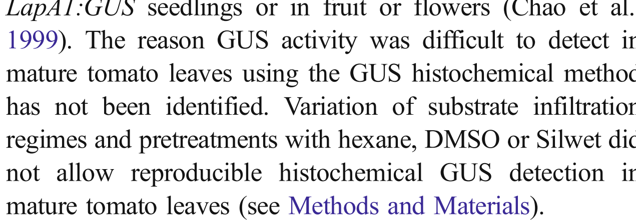
[a] GUS activity in leaf extracts from 6-week-old *LapA1:GUS* control plants (untreated) or *LapA1:GUS* plants infested with *Bemisia tabaci* biotype B (20 d), wounded by leaf lamina crushing (24 hr), or wounded by pricking the leaf with a straight pin (24 hr). GUS activities were measured in triplicate from individual plants and therefore reflect plant-to-plant variation in treatment responses. GUS and protein levels were determined as described in Methods and Materials. One representative experiment is displayed

[b] Overall average for each treatment (+/− standard deviation). Bold numbers are statistically different from the "Untreated" sample determined by a *t*-test (2-tailed, unequal variance, 0.05 level). Numbers designated with an asterisk are significantly different from the "*B. tabaci*" treatment determined by a *t*-test (2-tailed, unequal variance, 0.05 level)



LapA1:GUS seedlings or in fruit or flowers (Chao et al., 1999). The reason GUS activity was difficult to detect in mature tomato leaves using the GUS histochemical method has not been identified. Variation of substrate infiltration regimes and pretreatments with hexane, DMSO or Silwet did not allow reproducible histochemical GUS detection in mature tomato leaves (see Methods and Materials).

For the reasons above, GUS activities in leaf extracts were monitored fluorometrically. These assays showed plant-to-plant variability in GUS activity levels in all treatments and controls; however, trends in GUS activities in the treated and control plants were readily discerned. Control, non-infested *LapA1:GUS* plants had low levels of GUS activity ranging from 195 to 342 pmol 4-MU/min/mg protein (Table 1) similar to that observed by Chao et al. (1999). *Bemisia tabaci* feeding caused no significant changes of GUS activity (Table 1). *LapA1:GUS* leaf lamina that were pin pricked to mimic mechanical damage (similar to that inflicted during feeding by some species of aphids) had higher levels of *LapA* promoter activity (2.6- to 9.7-fold); however, due to plant-to-plant variation, these values were not statistically significant from untreated leaves. Larger and statistically significant increases in *LapA1* promoter activity (7 to 40-fold) were detected after the more severe mechanical wound (leaf crushing; Table 1), which is known to activate *LapA1* (Chao et al., 1999).

PAL is Not a Good Molecular Sentinel for Whitefly Feeding Increases in *PAL* transcripts have been correlated with wounding, pathogen infection and aphid feeding (Lee et al., 1994; Moran and Thompson, 2001). Therefore, the changes in *PAL* RNAs in response to *B. tabaci* and *T. vaporariorum* feeding were monitored from 0 to 9 days after infestation of tomato plants. Analysis of temporal and spatial RNA blot studies showed that *PAL* RNA levels increased transiently (days 1–5) and then declined (days 7–9) in both bagged (Control B) and unbagged (Control U) leaves and in apical leaves of control, non-infested plants (Fig. 1B). These data indicated that the small mechanical stresses that occurred during movement of the plants within the insect cages and not the process of encasing leaves in nylon bags were sufficient to increase *PAL* transcript levels. In some experiments, large increases in *PAL* transcripts were detected in infested leaves after 9 days of feeding by *B. tabaci* or *T. vaporariorum* relative to controls (Fig. 1A). In other experiments, *PAL* RNAs were only slightly elevated after *B. tabaci* feeding relative to controls on day 9 (Fig. 1B). While it appears that tomato *PAL* genes respond to whitefly feeding, *PAL* was not a reliable molecular marker for whitefly feeding responses.

Whiteflies Cause PR RNA Accumulation To determine if tomato *PR* RNAs accumulated after whitefly feeding, the

levels of *GluB* (basic β-1,3-glucanase), *Chi9* (basic chitinase), *PR-1* (P6 protein), *PR-4* (P2 protein), *GluAC* (acidic β-1,3-glucanase), and *Chi3* (acidic chitinase) transcripts were determined at 9 days after *B. tabaci* or *T. vaporariorum* infestation. Overall, similar gene expression patterns were noted after infestations with both species of whiteflies. *GluB*, *Chi9*, and *PR-1* transcripts accumulated to high levels in infested leaves relative to the controls (Fig. 2A). Smaller increases in *PR-4* and *Chi3* RNAs were detected in infested leaves and *GluAC* transcripts were not detected (Fig. 2A).

The levels of *PR* RNAs from infested and control plants were evaluated in infested and apical, non-infested leaves on days 0, 1, 3, 5, 7, and 9 after *B. tabaci* and *T. vaporariorum* infestation. While six *PR* gene RNAs were evaluated in this study (Table 2), only the *GluB* and *PR-1* data are presented here (Fig. 2). *GluB* transcripts were first detected 5 days after infestation with *B. tabaci* and *T. vaporariorum. GluB* RNA levels peaked 7 days post infestation (Fig. 2B). *GluB* RNAs also were detected in the apical, non-infested leaves on day 7. *GluB* transcripts were not detected in the leaves from the two sets of control plants that had either had their leaves encased in insect-proof bags (Control B) or were not manipulated (Control U) (Fig. 2B).

The spatial and temporal patterns of *PR-1* RNA accumulation were more complex. Over the 9-day infestation period, *PR-1* RNA levels were modulated by developmental signals. This conclusion was based on the fact that *PR-1* RNAs were detected at low levels in the non-infested leaves from both controls on days 1–3 and increased between days 5 and 7 (Fig. 2C). In addition, low levels of *PR-1* RNAs were detected in apical leaves on days 5–9, reflecting the younger age of these leaves and the beginning of the *PR-1* developmental program (Fig. 2C). It should be noted that these leaves showed no signs of senescence, and therefore *PR-1* transcript levels could not be attributed to initiation of the senescence program, as has been previously reported (John et al., 1997). Despite this developmental regulation, it was clear that both *B. tabaci* and *T. vaporariorum* feeding enhanced *PR-1* transcript accumulation in infested leaves relative to control plants. Differences in *PR-1* transcript levels in apical leaves from infested or non-infested plants also were observed in this experiment (Fig. 2C). In other replicate experiments, the systemic accumulation of *PR-1* RNAs was not as pronounced (Fig. 2A; data not shown).

Changes in Chi3, Chi9, GluAC, and PAL—Transcripts in Response to Wound and Defense Signals The responses of the tomato *PR* genes encoding the *GluB*, *PR-4*, and *PR-1* to wound and defense signals (i.e., MeJA, systemin, ABA, ethylene, and SA) in the tomato cultivar UC82b were reported previously (Chao et al., 1999) and are summarized in Table 2. To understand the potential defense signals important in the regulation of other tomato defense genes used in this study, the accumulation of transcripts for *Chi3*, *GluAC*, *Chi9*, and *PAL5* was determined after SA, MeJA, systemin, ABA, and ethylene treatments (Fig. 3; Table 2). Like previously characterized *PR* genes (Chao et al., 1999), *GluAC*, *Chi9*, and *Chi3* RNAs did not accumulate in response to systemin or ABA treatments.

Both *Chi9* and *GluB* encode proteins with a vacuolar location (van Kan et al., 1995). *Chi9* transcripts accumulated with a pattern similar to *GluB* RNAs; *Chi9* and *GluB* RNAs were most abundant after MeJA and ethylene treatments (Fig. 3; Chao et al., 1999). The dependence of *GluB*, *Chi9*, and *PR-1* RNA accumulation on ethylene signal transduction also has been supported by the analysis of mutant tomatoes expressing the *Nr* mutation, over-expressing the wild type NR, or down-regulating tomato *ETR* genes (Ciardi et al., 2001). *Chi9* RNA levels also were elevated in control treatments, as previously reported for *GluB* and *PR-1* (Chao et al., 1999). This may be due to a volatile released by control plants that accumulates in the enclosed environments used for the ethylene and MeJA treatments. Notably, *LapA*, *Chi3* and *GluAC* were not modulated by this additional defense signal.

Chi3 and *GluAC* encode apoplastic proteins (van Kan et al., 1995). Similar to the pattern previously reported for *PR4* (Chao et al., 1999), *Chi3* and *GluAC* transcripts were most abundant after ethylene treatments (Fig. 3). Of the three *PR* genes examined in this study, only *Chi3* transcripts accumulated in response to exogenous SA. These data contrast to studies by van Kan et al. (1995) who showed increases in *Chi3* and *GluAC* RNAs after treatment with 1 mM SA. This may be due to the facts that van Kan et al. (1995) used a different tomato cultivar, applied SA to petioles (vs. seedling shoots in this paper), and/or used a higher concentration of SA (1 mM). In the excised seedling assay used here, 1 mM SA caused necrosis in the UC82b cultivar and could not be evaluated (Chao et al., 1999).

Surprisingly little is known about *PAL5* expression after biotic stress in tomato plants (Gorlach et al., 1995). Figure 3 shows that tomato *PAL5* transcripts were detected in all control and treated leaf samples. *PAL5* RNAs increased in response to MeJA (3-fold) and smaller increases (1.4- to 2.0-fold) were seen with ethylene and ABA treatments (Fig. 3). In contrast, *PAL5* RNA levels declined after treatments with 0.1, 0.2 and 0.5 mM SA relative to control.

Discussion

The ability of plants to quickly and accurately perceive their biotic attackers is essential for mounting an effective defense. Plants must identify and respond to the chemical

Fig. 2 Changes in *PR* gene RNA levels in response to whitefly feeding. **A** Tomato plants were infested with *Besimia tabaci* biotype B (*Bt*) or *Trialeurodes vaporariorum* (*Tv*) or served as non-infested controls (C). Control leaves were encased and nylon bags but insects were not added as described in Fig. 1A. Total RNA blots were hybridized with ^{32}P-labeled basic β-1,3-glucanase (*GluB*), basic chitinase (*Chi9*), *PR-1* (P6), *PR-4*, acidic chitinase (*Chi3*), or acidic β -1,3-glucanase (*GluAC*) cDNA probes. Experiments were repeated once and each lane is pooled leaf material from three plants. Film exposure times were: 3 d for *Chi9*, *GluB*, and *PR-4*; 2 d for *PR-1*, 4 days for *Chi3*; 6 d for *GluA*, **B, C** Plants were infested as in Fig. 1B. Infested and apical, non-infested leaves were harvested 0, 3, 5, 7, and 9 d after *B. tabaci* biotype B (*Bt*) or *T. vaporariorum* (*Tv*) infestation. Controls were leaves from bagged but non-infested (Control B) or untreated (Control U) plants. RNA blots were hybridized to each ^{32}P-labeled *PR* gene probe in Panel **A**; only data from the *GluB* (Panel **B**) *or PR-1* (Panel **C**) probes are shown in Panel **B**. Stained gels visualizing rRNAs are shown as a loading control. Film exposures time were 2 d

Table 2 Tomato wound- and defense-response gene expression

Gene	Protein	Relative RNA increases in response to wound and defense signals[a]					
		WF	MeJA	Eth	ABA	SYS	SA
LapA[b]	Leucine aminopeptidase	o	+++	+	+	+++	−
pin2[c]	Proteinase inhibitor II	o	+++	−	+	+++	−
PAL[d]	Phenylalanine ammonia lyase	+/++	+	+	+	o	−
GluB[b]	Basic β-1,3-glucanase	++	+[e]	++[e]	o	−	+
Chi9[d]	Basic chitinase	++	++[e]	+[e]	o	o	o
PR-1[b]	P6 protein (PR-1-like protein)	++	++[e]	+++[e]	o	o	+++
GluAC[d]	Acidic β-1,3-glucanase	o	+	+++	o	−	o
Chi3[d]	Acidic chitinase	+	+	+++	−	o	++
PR-4[b]	P2 protein (win-like protein)	+	o	+++	o	o	o

[a] Fold increase in RNAs relative to control samples was determined by phosphoimager quantitation of RNA blot signals. RNAs that were unchanged or declined relative to control are indicated with a zero (o) or minus symbol (−), respectively. RNAs that increased are indicated with plus symbols: from 1.5 to 3.0 fold (+), 3.1 to 10 fold (++), and greater than 10 fold (+++). Treatments included silverleaf or greenhouse whitefly infestations (WF), 100 μM methyl jasmonate (MeJA), 29 ppm ethylene (Eth), 100 μM abscisic acid (ABA), 1 pmol systemin (Sys), and 0.25 mM salicylic acid (SA)

[b] Defense chemical treatment data are from Chao et al. (1999). Whitefly-response data appear in this paper

[c] The *pin2* probe was hybridized to a RNA blot similar to that shown in Fig. 3 and autoradiographic signals quantitated (data not shown). Whitefly response data appear in this paper

[d] Defense chemical treatment and whitefly-response data appear in this paper

[e] Control samples had elevated levels of these transcripts relative to other genes, therefore increases in these RNA levels may be underestimated. Discussion of these results are in Chao et al. (1999)

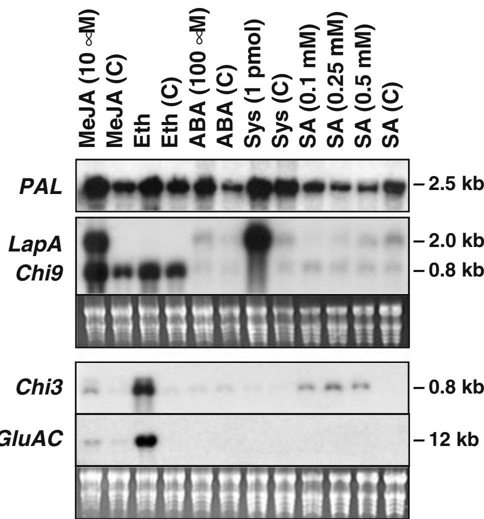


Fig. 3 RNA blot analyses of wound- and defense-response RNAs in tomato plants treated with defense signals. Excised tomato seedlings were treated with 10 μM MeJA, 29 ppm ethylene (Eth), 100 μM ABA, 1.0 pmol systemin (Sys), or 0.1, 0.25, or 0.5 mM SA. For each treatment, the corresponding control is shown (C). Total RNA blots were hybridized to ^{32}P-labeled *PAL*, *LapA*, *Chi9*, *Chi3*, and *GluAC* probes. Transcript sizes are shown in kb and were determined using a RNA marker run in a parallel lane. Stained gels visualizing rRNAs are shown as a loading control. The stained gel for the *PAL5* blot is not shown. Exposure times were 21–23 hr

(effectors) and mechanical signals that accompany pest attack (Felton and Tumlinson, 2008; Howe and Jander, 2008; Walling, 2009; Wu and Baldwin, 2009). Previous studies have indicated that plants can discriminate signals introduced by closely related arthropods, such as whitefly, aphid and spider mite biotypes (van de Ven et al., 2000; Hebert et al., 2007; Kant et al., 2008). For example, squash plants can perceive differences in the signals delivered by *B. tabaci* biotypes A and B. Only biotype B causes the squash leaf silvering disorder and preferentially induces the defense-response genes *SLW1* and *SLW3* (van de Ven et al., 2000). It is presumed that the *B. tabaci* biotype B effectors, which elicit these biotype-specific changes in gene expression and leaf development programs, are of insect or endosymbiont origin and introduced via the rapidly gelling or watery salivas of the whitefly (van de Ven et al., 2000).

For the reasons above, it was of interest to understand if two distinct whitefly species—*B. tabaci* and *T. vaporariorum*—would provoke similar or distinct defense gene expression programs in tomato. While *B. tabaci* and *T. vaporariorum* both have broad host ranges and use similar mechanical strategies to recover nutrients from the phloem, their ability to vector viruses and cause developmental disorders are distinct (Inbar and Gerling, 2008). *Bemisia tabaci* biotype B, but not *T. vaporariorum*, causes the tomato irregular fruit-ripening disorder (Schuster et al., 1990), but neither of these whiteflies induces leaf silvering in tomato. The data presented here showed that *B. tabaci*

and *T. vaporariorum* feeding on tomato leaves induce similar temporal and spatial patterns of defense- and wound-response gene expression. These results indicate that these whiteflies must introduce effectors with similar chemical structure(s) or activities to regulate wound- and defense-response gene expression. Furthermore, these whiteflies must also introduce species-specific effectors to cause the irregular-ripening disorder.

This study used nine tomato wound- and defense-response genes to assess defense responses to *B. tabaci* and *T. vaporariorum*. These genes included two well-characterized wound-response genes (*Pin2* and *LapA*) that are known to be JA-responsive and dependent on the jasmonate receptor JAI1 (COI1) (Chao et al., 1999; Li et al., 2004). *PAL5*, which encodes a rate-limiting enzyme for the shikimate pathway that provides the chemical precursors for phenolic compounds used for cell wall strengthening and as anti-nutritive compounds, also has been studied (Dixon et al., 2002). *PAL5* RNAs accumulate in response to a wide variety of biotic stresses; however, little was known about tomato *PAL5* responses to defense signals (Chang et al., 2008; Guo and Wang, 2009). The studies presented here show that tomato *PAL5* RNAs decreased in response to SA and increase after MeJA, ethylene, and ABA treatments (Table 2). *PAL5* RNA accumulation patterns reported here are consistent with the results of Lee et al. (1994). These investigators reported two *PAL5* RNA forms; the long *PAL5* RNA is detected constitutively, while the short *PAL5* RNA accumulates in response to wounding and pathogen infection.

The third group of tomato genes studied included six *PR* genes (*GluB, Chi9, PR-1, GluAC, Chi3*, and *PR-4)* that respond to pathogen attack (van Kan et al., 1995). Treatments of excised seedlings with MeJA, ABA, SA, systemin, and ethylene indicate that these genes display four basic expression programs (Table 2; Chao et al., 1999). All *PR* genes were ethylene responsive, and their response to exogenous MeJA and/or SA distinguished the *PR* genes further. *GluB, Chi9*, and *PR-1* (P6) transcripts increased in response to exogenous MeJA. However, their regulation was distinctive from *Pin2* and *LapA*, since *GluB*, *Chi9*, and *PR-1* RNAs did not increase in response to exogenous ABA or systemin (Table 2; Chao et al., 1999). Unlike *GluB* and *Chi9, PR-1* RNAs increased after SA treatments (Table 2). In contrast, *Chi3* and *PR-4* transcripts accumulated to low levels and *GluAC* RNAs were barely detected in response to exogenous MeJA; only *Chi3* RNA levels were modulated by SA (Table 2; Chao et al., 1999).

One prevailing theme from the studies presented here is that the tomato response to phloem-feeding whiteflies has a compelling similarity to pathogen infection (van Loon et al., 2006). *PR* RNAs and proteins accumulate after infection with both biotrophic and necotrophic pathogens in tomato including avirulent and virulent *Cladosporium fulvum* (Cooke.) (van Kan et al., 1992), *Fusarium oxysporum* (Schlecht) (Rep et al., 2002), *Phytophthora infestans* (Mont. de Bary) (Christ and Mosinger, 1989), and *Botrytis cinerea* (Pers.) (Benito et al., 1998). Both *B. tabaci* and *T. vaporariorum* infestations resulted in similar patterns of *PR* gene expression. *PR* RNAs were not detected at 1 or 3 days after whitefly infestation, indicating that a total of 500 adult whiteflies per plant (250 adults/leaf × 2 leaves) were insufficient to cause *PR* RNAs to accumulate locally or systemically. Five days after infestation, *GluB, Chi9*, and *PR-1* transcripts became abundant in the whitefly-infested leaves, and *GluB* RNAs accumulated systemically by day 7. *Chi3* and *PR-4* RNAs also increased but were less abundant and *GluAC* RNAs were barely detected after whitefly feeding.

The increases in *PR* RNAs correlated with the time of crawler emergence from eggs and the initiation of nymph feeding. Therefore, it is not clear if adults lacked the salivary effectors to activate *PR* gene expression, or if the changes in *PR* gene expression were dependent on the larger number of insects feeding during days 5–9. It is noteworthy, that *B. tabaci* biotype B leaf silvering of squash plants was thought initially to be a nymph-specific disorder, since as few as three feeding nymphs can cause squash leaf silvering (Costa et al., 1993). Recently, it was shown that large numbers of male *B. tabaci* biotype B infest squash are capable of inducing leaf silvering (De Barro and Khan, 2007). These data suggest that large numbers of adult whiteflies may be needed for tomato or squash plants to perceive whitefly effectors to induce defense genes and developmental disorders, respectively. This may reflect differences in the potency or quantities of effectors in adult whitefly saliva or the amount of time adults spend salivating relative to nymphs.

When the responsiveness of different *PR* genes to whitefly feeding and exogenous hormone treatments were examined collectively, the role of the defense-signaling pathways in the tomato-whitefly interactions could be proposed (Table 2, Fig. 3, Chao et al., 1999). This was based on the presumption that exogenous hormone treatments accurately report the roles of defense hormone signaling pathways after whitefly infestation. It is clear that all six *PR* genes examined in this study were complexly regulated, since these *PR* genes responded to two or more defense-hormones (i.e., MeJA, ethylene, and/or SA). As developed below, it is clear that no one defense hormone can explain *PR* gene regulation after whitefly infestation. Therefore, it is likely that multiple hormones act together to orchestrate this defense response; the possibility of a novel signal transduction pathway involvement cannot be excluded at this time.

It appears unlikely that a rise in ethylene can explain the induction of *PR* genes after whitefly feeding. This

conclusion is based on the facts that all six *PR* RNAs accumulated in response to exogenous ethylene, but *GluAC* RNAs did not accumulate after whitefly feeding. Increases in ethylene and induction of ethylene pathway genes have been noted during aphid infestations of both susceptible and resistant tomato, barley and melon plants (Argañdona et al., 2001; Mantelin et al., 2009; Anstead et al., 2010). In the *M. eurphorbiae*-tomato interaction, the ability to perceive ethylene is important for basal resistance (innate immunity) but not gene-for-gene resistance (Mantelin et al., 2009).

PR RNA levels after whitefly feeding were not correlated with responsiveness to SA, for only three of the five *PR* RNAs that accumulated were SA-regulated. This is a fundamental difference in the regulation of *PR* genes in tomato vs. Arabidopsis. Most *PR* genes in Arabidopsis are SA-regulated and suppressed by whitefly feeding (van Loon et al., 2006; Zarate et al., 2007).

Finally, the *PR* RNAs that were most abundant after whitefly feeding also increased markedly after MeJA treatments. This suggests that the JA-pathway may be activated after whitefly feeding. However, it should be noted that there was not a strict correlation of MeJA and whitefly responsiveness, since *GluAC* RNAs accumulated in response to MeJA treatments but not after whitefly infestation, and *PR-4* was whitefly induced but did not respond to exogenous MeJA. Several other genes induced by whitefly infestation are known to be regulated by MeJA. This includes a whitefly-induced tomato gene (*Wfi1*) that encodes a subunit of the NADPH oxidase (D.P. Puthoff and L.L. Walling, unpublished results) and the squash *SLW1* gene that is preferentially induced by the *B. tabaci* biotype B (van de Ven et al., 2000). These observations in tomato are in marked contrast to the changes in gene expression observed after the *B. tabaci* interactions in Arabidopsis, where SA-regulated *PR* RNAs accumulate and JA-regulated wound/defense response genes are suppressed (Kempema et al., 2007; Zarate et al., 2007). In addition, *B. tabaci* infestations of Lima bean (Zhang et al., 2009) and Arabidopsis (Zarate, Navarre and Walling, unpublished results) cause increases in SA levels; the changes in SA and JA levels after whitefly infestation of tomatoes has not yet been assessed.

While JA-regulated *PR* RNAs are abundant after whitefly feeding, this was not the case for JA-regulated wound-response genes. Two sets of data indicate that heavy infestations (up to 10 insects per cm^2) by *B. tabaci* and *T. vaporariorum* did not activate the wound-signaling pathway in tomato. First, feeding by over 500 *B. tabaci* adults (day 3) and over 2,000 *B. tabaci* nymphs and 500 adults (day 5) per tomato leaf were not sufficient to increase *LapA* or *pin2* transcripts to detectable levels locally or systemically. Second, *B. tabaci* infestation of transgenic *LapA1:GUS* tomato plants showed that the *LapA1* promoter activity was similar in leaves of *B. tabaci*-infested and non-infested control plants. These data suggest that the whitefly stylet's piercing of epidermal cells, movement between cells (which disrupts essential cell-to-cell contacts), puncturing of the sieve elements, and consumption of phloem nutrients were not perceived as sufficient physical or mechanical stresses to activate the tomato JA-dependent wound-response pathway (Walling, 2008).

These data also indicate that tomato responses to whitefly adult and nymph feeding were distinct from responses to tissue-damaging herbivores. Caterpillars, beetles, and cell-content feeding spider mites and thrips all induce JA-regulated wound-response gene expression in tomato (Pautot et al., 1993; Li et al., 2002; Ament et al., 2004). This regulation occurs at the transcriptional level, since *Pin2* and *LapA* promoter:reporter genes are activated by wounding and caterpillar feeding in transgenic tomato, potato, tobacco, silver birch, Arabidopsis, and white spruce (Thornburg et al., 1990; Keinonen-Mettälä et al., 1998; Chao et al., 1999; Godard et al., 2007).

Pin2 genes also are induced in some, but not all, aphid-plant interactions (Thornburg et al., 1990; Fidantsef et al., 1999; de Ilarduya et al., 2003). Consistent with aphids piercing mesophyll cells in their search for a phloem-sieve element, the potato aphid (*M. euphorbiae*) and green peach aphid [*Myzus persicae* (Sulzer)] infestations of tomato plants cause *Pin1* and *Pin2* RNA levels to increase transiently (6–12 hr post infestation), and prior to the accumulation of *PR* RNAs (12–48 hr post infestation) (de Ilarduya et al., 2003). Consistent with this result, *Pin2* RNAs were not detectable 7 days after *M. euphorbiae* feeding (Fidantsef et al., 1999). Interestingly, the *Pin2* promoter was not activated after a non-synchronous aphid infestation of transgenic *Pin2*:CAT tobacco plants in the field (Thornburg et al., 1990).

Whiteflies may avoid activation of wound-responses due to their refined feeding behaviors that avoid puncturing mesophyll cells, which distinguishes feeding by whiteflies from aphids (Tjallingii, 2006; Walling, 2008). It is also possible that chemical constituents of the watery and gelling salivas of whitefly adults and nymphs do not activate the JA-dependent wound signaling pathway. Alternatively, whitefly salivary factors may directly or indirectly antagonize the tomato wound-response pathway. Since whiteflies are known to increase SA levels during infestation of Arabidopsis and Lima beans (Zhang et al., 2009; Zarate, Navarre, and Walling, unpublished results), it is possible that the increases in SA promote the antagonistic cross-talk between the JA- and SA-defenses. Cross-talk, which is known to occur in the *B. tabaci*-Arabidopsis and in other biotic interactions, may suppress the JA-regulated traits that slow nymph development (Thaler et al., 2002;

Zarate et al., 2007; Koornneef et al., 2008). In addition, there is substantial evidence for constituents of hemipteran saliva influencing insect-plant interactions (Miles, 1999; Felton and Tumlinson, 2008; Walling, 2009). Some aphid salivary proteins appear important in chelating calcium to influence wound-induced protein coagulation at stylet punctures of the phloem (Will et al., 2007). Saliva constituents also contribute to aphid fitness, activate/suppress plant gene expression, induce a local resistance to further aphid infestations, and induce infestation symptoms (Lapitan et al., 2007; Mutti et al., 2008; De Vos and Jander, 2009). Some caterpillars and beetles have oral or salivary secretions that antagonize activation of wound-response genes. These interactions include: the corn earworm [*Helicoverpa zea* (Boddie)] with tobacco [(*Nicotiana tabacum* (*L.*)], the beet armyworm [*Spodoptera exigua* (Hübner)] with *Medicago truncatula* (Gaertn), the Colorado potato beetle [*Leptinotarsa decemlineata* (Say)] with tomato, and the small white butterfly larvae [*Pieris rapae* (L.)] with Arabidopsis (Reymond et al., 2000; Musser et al., 2002; Bede et al., 2006; Lawrence et al., 2007).

Avoiding activation of wound-responses may contribute to the success of *B. tabaci* and *T. vaporariorum* on their hosts (Walling, 2008), and this appears to be the case for *B. tabaci* interactions in Arabidopsis (Kempema et al., 2007; Zarate et al., 2007). However, in tomato, the role of JA-regulated defense traits against whiteflies is not as well understood. Sánchez-Hernández et al. (2006) showed that the tomato *spr2* (*suppressor of prosystemin-mediated responses2*) mutant and transgenic line that ectopically expresses Prosystemin (*35S:ProSys*) influences whitefly-tomato interactions. The *spr2* mutant blocks JA biosynthesis and alters volatile emission profiles (Sánchez-Hernández et al., 2006). The *35S:ProSys* line over-expresses the wound peptide precursor Prosystemin and has constitutively activated wound-response genes (McGurl et al., 1994). *Bemisia tabaci* adults prefer to oviposit on *spr2* plants, indicating that JA is essential for the production of volatiles that deter *B. tabaci* acceptance of tomato plants; however, *35S:Prosys* plants did not display the expected reciprocal phenotype (i.e., repellency) (Sánchez-Hernández et al., 2006). When adult eclosion from fourth-instar nymphs was monitored, fewer adults emerged from *35S:Prosys* plants than wild-type or *spr2* plants (Sánchez-Hernández et al., 2006). These data suggest that ectopic expression of the tomato wound-response pathway may impede *B. tabaci* development at the level(s) of nymph settling or development. Therefore, avoiding activation of the wound-response pathway of tomato would be advantageous to whitefly success, as it is in the model plant Arabidopsis (Zarate et al., 2007).

The importance of *PR* gene products in defense against phloem-feeding insects is not understood at the present time. In tomato, the *PR* genes that responded most strongly to whitefly feeding encoded proteins with either a vacuolar (*Chi9* and *GluB*) or an apoplastic (*PR-1*) location (van Kan et al., 1995). Aphid feeding also causes *GluB* and *PR-1* RNAs to increase in tomato (de Ilarduya et al., 2003). Unlike aphids, it is anticipated that whiteflies would have limited contact with the vacuolar *PR* proteins, since their mouthparts rarely pierce mesophyll cells during the search for a feeding site in the phloem. It seems likely that whiteflies would contact the apoplastic proteins, such as *PR-1* protein. The exterior of whitefly mouthparts would have limited physical contact with *PR-1* due to the salivary sheath that encases the flexible whitefly stylet. In contrast, whiteflies may consume minute quantities of apoplastic proteins and chemicals, as they secrete and then ingest, a watery saliva to “taste” the chemical environment of the apoplast (Lei et al., 1998a). It is thought that whiteflies use these gustatory cues as indicators of host-plant suitability and as signals to guide the stylet’s route to the phloem sieve element. Consistent with this is the fact that the tomato resistance gene *Mi-1*, which mediates a modest resistance to whiteflies, appears to influence resistance traits that act prior to phloem feeding (Jiang et al., 2001).

Since whiteflies recover their nutrients from the phloem and occasionally drink water from xylem (Lei et al., 1998b), the phloem and xylem are additional sites for proteins/chemicals that can influence whitefly-plant interactions. For example, some aphid-resistance (*R*) genes control a phloem-localized resistance traits (Kaloshian et al., 1995; Klingler et al., 1998). It is not clear whether the tomato *PR* proteins accumulate in the phloem or xylem after hemipteran feeding, although some *PR* proteins have been reported in xylem sap of *Fusarium oxysporum*-infected tomato plants (Rep et al., 2002). Furthermore, the transcriptome of phloem sap, phloem tissue and vascular-enriched tissue have shown that some stress-related RNAs, including some *PR* RNAs, are detected in the phloem (Le Hir et al., 2008). The role of phloem- or xylem-localized PRs or other phloem-localized proteins that deter aphids (Yoo et al., 2000), on whitefly host acceptance, longevity, fecundity, and nymph development has yet to be tested.

Letter from the Editor-in-Chief

© Springer Science+Business Media, LLC 2010

At a recent meeting of the Editorial Board of the Journal of Chemical Ecology, the decision was made to compile information and guidelines for authors whose chemical ecological papers contain a considerable molecular component. Previously, The Journal published two other sets of guidelines: one for the Identification and Syntheses of Compounds (August 2008—JCE 34:984–986); and another for SPME Techniques (December, 2009—JCE 35:1383).

The following guidelines were prepared by Associate Editor Steven J. Seybold with critical assistance from an *ad hoc* committee of Editorial Board Members and contributors that included Jonathan Gershenzon (Max Planck Institute for Chemical Ecology, Jena), Dezene Huber (University of Northern British Columbia), Patricia Nagnan-Le Meillour (INRA, Université de Lille), Julien Pelletier (University of California, Davis), Erika Plettner and Carlos Castillo (Simon Fraser University), Ada Rafaeli (The Volcani Center, Bet Dagan), Claus Tittiger (University of Nevada), and Linda Walling (University of California, Riverside).

The intent of these new "molecular" guidelines is not to daunt or discourage authors from submitting molecular work. Indeed, much of the information provided here is well-known to molecular contributors. The guidelines in this respect simply bring together useful information that can serve as a quick reference. For others, however, they should be useful for determining appropriateness of content of submission as well as accepted methods of presentation. Researchers should use them as they prepare submissions to The Journal.

John T. Romeo
December, 2010

3', 5'-monophosphate (cAMP), complementary deoxyribonucleic acid (cDNA) (= copy DNA), complementary ribonucleic acid (cRNA) (=copy RNA), cytidine 5'-mono-, di-, or triphosphate (CMP, CDP, or CTP), deoxyadenosine 5'-mono-, di-, or triphosphate (dAMP, dADP, or dATP), deoxycytidine 5'-mono-, di-, or triphosphate (dCMP, dCDP, or dCTP), deoxyguanosine 5'-mono-, di-, or triphosphate (dGMP, dGDP, or dGTP), deoxynucleotide triphosphate (dNTP), deoxyribonucleic acid (DNA), double stranded ribonucleic acid (dsRNA), flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN), guanosine 5'-mono-, di-, or triphosphate (GMP, GDP, or GTP), genomic deoxyribonucleic acid (genomic DNA, gDNA), messenger ribonucleic acid (mRNA), micro ribonucleic acid (miRNA), nicotinamide adenine dinucleotide (NAD, NAD+), nicotinamide adenine dinucleotide phosphate (NADP, NADP+), nicotinamide adenine dinucleotide phosphate, reduced (NADPH), nicotinamide adenine dinucleotide, reduced (NADH), ribonucleic acid (RNA), ribosomal ribonucleic acid (rRNA), short interfering (silencing) ribonucleic acid (siRNA), transfer ribonucleic acid (tRNA), uridine 5'-mono-, di-, or triphosphate (UMP, UDP, or UTP).

3) **Buffers:** 2-[bis(2-hydroxyethyl)amino]ethanesulfonic acid (BES), *N,N'*-bis(2-hydroxyethyl)glycine (Bicine), 2-[bis(hydroxyethyl)amino]-2-(hydroxymethyl)-1-propane-1,3-diol (BisTris), 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonic acid (CHAPS), ethylenediaminetetraacetate (EDTA), ethyleneglycol-bis-(β-aminoethyl ether)-*N,N,N',N'*-tetraacetic acid (EGTA), 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), 2-(*N*-morpholilino)ethanesulfonic acid (MES), 3-(*N*-morpholino)propanesulfonic acid (MOPS), 1,4-piperazinediethanesulfonic acid (PIPES), *N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid (TES), *N*-[tris(hydroxymethyl)methyl]glycine (Tricine), tris(hydroxymethyl)-aminomethane (Tris), tris-buffered saline (TBS).
4) **Related Terms:** base pair (bp), kilobase pair (kb), megabase pair (Mb), nucleotide (nt), Coenzyme A and its derivative (CoA), amplified fragment length polymorphism (AFLP), restriction fragment length polymorphism (RFLP), diethylaminoethyl (DEAE), bovine serum albumin (BSA), GTP-binding protein (G protein), gene of interest (= target gene) (GOI), quantification cycle (in PCR) (C_q).

For terms not present in the lists above, contributors should consult the recommendations of the International Union of Biochemistry and Molecular Biology (http://www.chem.qmul.ac.uk/iubmb/)

B. Abbreviations and Descriptions of Molecular Assays

1) **Gel Electrophoresis Assays**: polyacrylamide gel electrophoresis (PAGE), sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS PAGE), Southern blotting (gel electrophoresis with blotting and detection of DNA, capitalized because it is named after E.M. Southern = DNA blotting), northern blotting (gel electrophoresis with blotting and detection of RNA, not capitalized = RNA blotting), western blotting (gel electrophoresis with blotting and detection of proteins, not capitalized = protein blotting), two-dimensional polyacrylamide gel electrophoresis (2D-electrophoresis, 2-DE, or 2D-PAGE), electrophoretic mobility shift assay (EMSA).
2) **Polymerase Chain Reaction Assays**: polymerase chain reaction (PCR), rapid amplification of cDNA ends (RACE), real-time polymerase chain reaction (real-time PCR or qPCR), reverse transcription polymerase chain reaction (RT-PCR), RNA interference (RNAi).
3) **Microarray Assays**: expressed sequence tag (EST), genome survey sequence (GSS), high-throughput genome sequence (HTGS), sequence-tagged site (STS), tentative unique genes (TUGs).
4) **Protein/Peptide Assays**: dithiothreitol (DTT), electrospray ionization mass spectrometry (ESI-MS), enzyme-linked immunosorbent assay (ELISA), fast-protein liquid chromatography (FPLC), high-performance liquid chromatography (HPLC), immunoglobulin G, M, etc. (IgG, IgM, etc.), isoelectric point (pI), liquid chromatography tandem mass spectrometry (LC MS-MS), matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS), nuclear magnetic resonance (NMR), radioimmunoassay (RIA), tryptic digestion.

III. Presentation of Molecular Biological Content

A. PCR and PCR Primers

In the **Methods and Materials** include sequences of all forward and reverse PCR primers in one table and subdivide the table by the function of the primers. Functions might include generating probes for a northern blot experiment; primers for real-time PCR analysis; genomic or cDNA isolation; 3'- or 5'-RACE; or tissue localization assays. Examples of these tables can be found in: Lu et al. 2007, p. 1360; Xiu and Dong 2007, p. 950; Saltzmann et al. 2008, p. 1404; Li et al. 2008, p. 1594; Xiu et al. 2008, p. 489; Shivaji et al. 2010, p. 182. Primers should be written from 5' to 3', without any space between the abbreviations for the bases.

Provide the quantity of nucleic acid template used in the reaction; the quantities (molar concentrations) of all reagents (primers, dNTPs, and the polymerase); and the reaction volume. Also provide cycling conditions including temperatures and times, number of cycles, as well as the brand and model of the thermocycler and the method of isolation of the PCR products. Optimally, isolated PCR products (or products that have been cloned into plasmids) should be sequenced in both senses (5' to 3' and 3' to 5'), however, sequencing one strand of the product at least twice to confirm the identity of each base is also acceptable. The commercial entity or center responsible for the sequencing should also be indicated in the manuscript.

B. Real-time PCR (qPCR)

For guidelines to proper experimental design, calculation of gene expression, and statistical analysis in real-time PCR experiments, contributors should refer to Bustin et al. (2009) and Rieu and Powers (2009). Bustin et al. (2009) provide a checklist (in their Table 1) of all of the information necessary to consider and include when describing a high-quality real-time PCR experiment for publication. For the Journal, background data on real-time PCR should be included in the supplemental data section. Because real-time PCR is a quantification method highly dependent on the quality of the template (RNA or cDNA) and the efficiency of the amplification (C_q), authors should include tables that show the efficiencies of the amplification reaction for each gene monitored, including the reference gene(s). An example of this can be found in Zhang et al. (2009) (Supplemental Data Tables 1 and 2). R-squared values from the standard curves for genes analyzed by real-time PCR (including the reference gene(s) and the no-treatment controls) should also be included in these tables.

Authors are strongly encouraged to characterize the expression of multiple (typically three) reference genes for these experiments. Authors should determine the stability of the expression of their reference genes under their experimental conditions (validation of the reference genes) and then compare the normalized data from their treatments and provide statistical information on those comparisons that they view as most relevant. The expression of the reference gene should not differ significantly among the tissues, life stages, castes, etc. that are under investigation (based on the same experimental procedures used for the genes of interest). This cannot necessarily be predicted *a priori,* so multiple reference genes should be checked and then the gene that best fits the criterion of "no significant change" should be used as the reference.

C. Genomics

Papers that use genomic, proteomic, or metabolomic approaches to study problems relevant to chemical ecology are appropriate for the Journal, provided that they are focused on chemical ecological themes (Tittiger 2004; Liu et al. 2007; McLean et al. 2007; Lawrence et al. 2008; Leiss et al. 2009). Manuscripts describing studies that utilize these approaches should go beyond cataloging and provide unique insights into regulatory networks, mechanisms, or demonstrations of ecological function.

For guidelines on genomics content, the Journal follows the conventions adopted by the journal *Molecular Endocrinology* and those of the Functional Genomics Data Society (http://www.mged.org/). Authors submitting expression or tiling microarray datasets must clearly identify in the **Methods and Materials** the platform, which includes the name of the vendor or array source, the name of the genechip or array and its version (e.g., Affymetrix Murine Genome U74v2 Set). Authors must thoroughly describe the filtering criteria used to evaluate the raw data and provide references for the statistical methods used to analyze the data. Filtered gene lists provided as supplemental data must be provided as Excel spreadsheets and not PDFs. Specific examples of supplemental data accompanying gene expression profiling manuscripts can be found in Ohlsson Teague et al. (2009); supplemental data available at: (http://mend.endojournals.org/cgi/content/full/me.2008-0387/DC1).

Experiments must be described according to minimum information about a microarray experiment (MIAME) guidelines (Brazma et al. 2001). Papers based on unreplicated gene expression profiling experiments will not be accepted for publication. Supporting experiments (i.e., real-time PCR or RT-PCR) are not a substitute for the biological replications of a genomics gene expression profiling experiment. However, microarray data must be verified by using an independent RNA sample; not with the RNAs used in the microarray experiments. The Journal recommends consultation with a statistician regarding experimental design and data analysis strategies for all gene expression profiling experiments.

Upon acceptance of a paper, authors of microarray datasets are required to have submitted the complete dataset to the Gene Expression Omnibus (GEO) (http://www.ncbi.nlm.nih.gov/geo/), which is the public gene expression archive of National Institute of Biotechnology Information (NCBI); or to ArrayExpress (http://www.ebi.ac.uk/microarray-as/ae/), which is the corresponding database of the European Bioinformatics Institute (EBI). Submission requirements can be found at either website. Datasets can be submitted confidentially to NCBI GEO

prior to publication and held there until the paper is in press or published.

D. Proteomics

For guidelines on proteomics content, the Journal generally follows the conventions adopted by the journal *Molecular and Cellular Proteomics* (http://www.mcponline.org/site/misc/itoa.xhtml or http://www.mcponline.org/site/misc/PhialdelphiaGuidelinesFINALDRAFT.pdf).

When presenting protein identifications based on a single peptide sequence, authors should provide precursor mass, charge, and mass error (Carletti et al., 2008, see Table 1 on p. 809). Papers that use proteomic methods and report molecular structures, whether based on x-ray crystallography, NMR, or computational modeling, will be accepted only after the structural coordinates have been deposited in the Worldwide Protein Data Bank: http://rcsb-deposit.rutgers.edu/ and http://pdbdep.protein.osaka-u.ac.jp/. Whenever possible, peptide sequences should be identified with matching accession numbers (see below).

E. GenBank and other Database Accessions for Manuscripts Reporting New Amino Acid or Nucleotide Sequences

Here, the Journal generally follows the conventions and publication guidelines adopted by *Insect Biochemistry and Molecular Biology* (http://www.elsevier.com/wps/find/journaldescription.cws_home/390/authorinstructions#). The GenBank sequence database is an open access, annotated collection of all publicly available nucleotide sequences and their protein translations. This database is produced at NCBI at the U.S. National Library of Medicine as part of the International Nucleotide Sequence Database Collaboration. The data are organized by accession numbers, which are unique identifiers in bioinformatics allocated to nucleotide and protein sequences to allow tracking of different versions of that sequence record and the associated sequence in GenBank or the Worldwide Protein Data Bank.

The Journal requires that authors deposit any novel nucleic acid sequences described in their paper in the GenBank database (http://www.ncbi.nlm.nih.gov/genbank/ or http://www.ncbi.nlm.nih.gov/WebSub/?tool=genbank) or in the EMBL data library (http://www.ebi.ac.uk/embl/) and report the accession number in the **Methods and Materials** of the manuscript. Deposition of such data should be made at the time of submission. Papers will be accepted only after these data have been deposited in one of these databases. Note that the information provided in the GenBank accessions (nucleotide sequence, deduced protein sequence, etc.) is extensive and often makes the presentation of a DNA sequence and its protein translation unnecessary as a figure in the manuscript.

New amino acid sequences should be deposited in the Worldwide Protein Data Bank: http://rcsb-deposit.rutgers.edu/ and http://pdbdep.protein.osaka-u.ac.jp/.

There are different types of accession numbers in use based on the type of sequence cited, each of which uses a different code. Authors should explicitly mention the *type of accession number together with the actual number*, bearing in mind that an error in a letter or number can result in a dead link in the online version of the article. Please use the following format: accession number type ID: xxxx (e.g., MMDB ID: 12345; PDB ID: 1TUP).

been demonstrated. Liu et al. (2010) reported that GOBPs of the navel orangeworm, *Amyelois transitella* (Walker) (Lepidoptera: Pyralidae), bind with high affinity to the major component of the sex pheromone, (11*Z*, 13*Z*)-16Ald.

In the silkworm, *Bombyx mori* (L.) (Lepidoptera: Bombycidae), 44 genes that encode putative OBPs have been identified from the genome sequence (Gong et al., 2009). The genes that encode pheromone binding protein 1 (BmorPBP1) and general odorant binding protein 2 (BmorGOBP2) are clustered close together on chromosome 19 in the same orientation. They have the same intron insertion sites between codons and splice sites within codons. The transcripts for *BmorPBP1* and *BmorGOBP2* are expressed at an extremely high level in adult antennae compared to other tissues (Zhou et al., 2009). The *Bmor-GOBP2* transcript is higher than *BmorPBP1* in the brains of both sexes (Gong et al., 2009). Immunocytochemical studies showed that both proteins are expressed in the antennae of males and females (Steinbrecht, 1998; Maida et al., 2005).

Pheromones are blends of volatile chemicals that typically are specific to a species, and, for *B. mori,* the pheromone blend comprises bombykol, bombykal, and (10*E*,12*E*)-hexadecadien-1-ol (Kaissling et al., 1978). However, only bombykol is able to induce mating behavior at a physiological concentration, and bombykal acts as an antagonist to bombykol (Kaissling, 2009). BmorPBP1 and its binding to pheromone components has been the subject of intense study in recent years, as a model system for understanding the functions that OBPs may play in insect olfaction *in vivo*. Cells that express BmorPBP1 are closely associated with the cells that express BmorOR-1 and BmorOR-3 in the long trichoid sensilla (Krieger et al*.,* 2005; Nakagawa et al*.,* 2005; Forstner et al., 2006), and co-expression of BmorPBP1 with BmorOR-1 in an ‘empty’ neuron of *Drosophila melanogaster* increased the sensitivity of the receptor to bombykol (Syed et al., 2006). BmorPBP1 also has been shown to mediate a response to bombykol, but not to bombykal in cultured HEK293 cells expressing BmorOR-1 (Grosse-Wilde et al., 2006) and in moth sensilla (Pophof, 2004). Recently, a highly sensitive receptor to bombykol has been identified in *D. melanogaster* (Syed et al., 2010). This raises the question on the selectivity and specificity that olfactory receptors alone contribute in insect olfaction.

Binding of BmorPBP1 to bombykol has been demonstrated by X-ray crystallography (Sandler et al., 2000); NMR structural characterization (Damberger et al., 2000; Horst et al., 2001; Lee et al., 2002); electrospray ionization-mass spectrometry (ESI-MS) (Oldham et al., 2000; Hooper et al., 2009); and other biochemical methods (Wojtasek and Leal 1999; Leal et al., 2005a, b). The binding is both pH and ligand dependent. Thus, at an acidic pH, or in the absence of bombykol, the C-terminus of the PBP forms an α-helix and occupies the ligand binding pocket, and a conformational change, brought about by a change in pH to more acid near the ORs, is thought to be the ligand release mechanism when the BmorPBP1-bombykol complex reaches the ORs (Wojtasek and Leal 1999; Leal et al., 2005a, b). However, there is some evidence that BmorPBP1 can bind to both bombykol and bombykal (Gräter et al., 2006; Zhou et al., 2009). A recent binding study that used a high-throughput ESI-MS analysis showed that BmorPBP1 bound much more strongly to (10*E*,12*Z*)-hexadecadienoic acid and (10,12)-hexadecadiyn-1-ol than to bombykol (Hooper et al., 2009).

BmorGOBP2 is expressed in larval sensilla (Laue, 2000) and in the long trichoid sensilla of female moths (Steinbrecht, 1998; Maida et al., 2005), which respond specifically to linalool and benzoic acid (Kaissling, 2009). However, the binding of BmorGOBP2 to these two plant volatiles has not been elucidated, whereas the binding of BmorGOBP2 to both bombykol and bombykal has been demonstrated. Furthermore, X-ray crystallography has shown that, when bombykol is bound to BmorGOBP2, a different conformation is adopted from that found when bombykol binds to BmorPBP1. In the former, a hydrogen bond is formed with Arg110 rather than with Ser56, as is the case with BmorPBP1. Furthermore, a second hydrogen bond is formed with Glu98, which leads to an overall stronger affinity of BmorGOBP2 for bombykol (Zhou et al., 2009).

Ligand specificity and selectivity, and, in fact, the functional roles of insect OBPs in olfaction, have been challenged consistently, even more so since insect olfactory receptors have been characterized (Krieger et al., 2005). Zhou et al. (2009) showed differential binding of BmorGOBP2 to bombykol and bombykal by X-ray crystallography. In the present study, we provide further evidence of the possible involvement of the BmorGOBP2 gene in moth olfaction by examining the tissue expression patterns throughout the developmental stages of *B. mori*, and through a comparative binding study of recombinant BmorGOBP2 to plant volatiles, as well as to the sex pheromone components. We employed molecular ligand docking to predict the binding interactions of BmorPBP1 and BmorGOBP2 with the ligands. Two synthetic pheromone analogs were found to bind better than the sex pheromone components. Electroantennogram (EAG) recordings from the antennae of male moths were made with the analogs to investigate how the binding data and the molecular docking predictions might relate to biological significance.

Methods and Materials

Real-time PCR Bombyx mori cocoons were provided by Prof. Y. –P. Haung (Institute of Plant Physiology and

Ecology, CAS, China), and adult moths were dissected, immediately after eclosion, into antennae, heads (without antennae), and bodies. Heads and bodies also were collected from 2nd, 3 rd, 4th, and 5th instar larvae. Detailed protocols for total RNA extraction with the RNAqueous kit (Ambion, Huntingdon, UK) and two step real-time PCR on each tissue with the ETROscript kit (Ambion) on an ABI 7500 (Applied Biosystems, Foster City, CA, USA) have been described previously (Zhou et al., 2009). The sequences of *BmorGOBP2* (GenBank No. NP_001037498) and *BmorPBP1* (GenBank No. NP_001037494) were downloaded from NCBI GenBank (http://www.ncbi.nlm.nih.gov/). The *B. mori* reference gene, actin A4 (GenBank No. U49644), was used in each real-time PCR experiment to check loading, reverse transcriptase efficiency, and the integrity of the transcripts. For each tissue, real-time PCR analyses were conducted with two tissue preparations. The reactions were hot-started for 2 min at 95°C, followed by 40 cycles of 95°C for 15 sec, 60°C for 30 sec, and 72°C for 15 sec. The PCR primers (Table 1) were designed with Primer3 (http://frodo.wi.mit.edu/).

Relative tissue expression was quantified as described in Zhou et al. (2009). Briefly, after PCR, Ct values were exported into the LinRegPCR program to correct the amplification efficiencies for each reaction. The relative expression levels (Pfaffl ratio) of each OBP gene to the reference gene then were calculated in each tissue from [(E,obp$^{\Delta Ct,obp}$]/[(E,ref$^{\Delta Ct,ref}$], where E,obp and E,ref are the corrected amplification efficiencies for OBP and the reference gene, respectively. ΔCt,obp is calculated from [Ct,obp of heads or antennae—Ct,obp of body], and ΔCt, ref is calculated from [Ct,ref of heads or antennae—Ct,ref of body]. The results are presented as the mean fold change of two biological samples combined from both male and female tissues.

Protein Expression and Purification of Recombinant OBPs Full-length cDNAs that encode mature BmorGOBP2 and BmorPBP1 were cloned into the bacterial expression vector pET17b (Novagen, Darmstadt, Germany) between the *Nde*I and *Eco*RI restriction sites, and verified by sequencing. Plasmids with the correct inserts were transformed into BL21(DE3)pLysS *E. coli* cells, and protein synthesis was induced at OD_{600} of 0.5–0.8 with IPTG (4 mM) for 3 h. All proteins were found to be expressed as inclusion bodies, and solubilization was performed by denaturation in urea/DTT, renaturation, and extensive dialysis, by using a protocol applied successfully to other OBPs. The recombinant proteins were purified by two rounds of anion-exchange chromatography with a HiPrep 16/40 column (GE Healthcare, Hatfield, UK) filled with DE-52 resin (Whatman, Kent, UK), followed by gel filtration on a Sephacryl S-200 HiPrep 26/60 column (GE Healthcare). A MonoQ column also was used at the final stage of purification. The purified proteins were stored at −20°C in 20 mM Tris-HCl pH 7.4 buffer.

Chemical Synthesis The seven analogs of bombykol, including bombykal, were synthesized in-house at Rothamsted Research. Nuclear magnetic resonance spectroscopy (NMR) and gas chromatography with flame ionization detection (GC-FID) analyses confirmed the structure and purity of the synthesized compounds. ^{1}H- and ^{13}C-NMR spectroscopy were performed by using a Bruker 500 Advance NMR spectrometer with ^{1}H referenced to $CDCl_3$ (7.25 ppm) and ^{13}C to $CDCl_3$ (77.0 ppm). Purified compounds were analyzed on a Hewlett-Packard 5890 Series II gas chromatograph (GC), fitted with a nonpolar HP-1 capillary column (40 m, 0.32 mm i.d., 0.52 µm film thickness), a cool-on-column injector, and a flame ionization detector (FID) (Agilent Technologies, West Lothian, UK). The GC oven temperature was maintained at 40°C for 1 min and then raised by 10°C /min to 200°C, and the carrier gas was nitrogen at 80 cm/sec. Benzoic acid (99%), (±)-linalool (97%), and N-phenyl-1-naphthylamine (NPN) (98%) were purchased from Sigma-Aldrich (Dorset, UK).

Fluorescence Competitive Binding Assay To measure the binding of the fluorescent probe NPN to OBPs, a 2 µM protein solution (1 ml) in 20 mM Tris-HCl, pH 7.4 and 4.5, was titrated with aliquots of 1 mM NPN dissolved in methanol to final concentrations of 0.05–16 µM. The protein/NPN complex was excited at 337 nm, and emission spectra were recorded between 300 and 450 nm on a luminescence spectrometer LS50B (Perkin-Elmer, Cambridge, UK) at 25°C in a right angle configuration with a 1 cm light path quartz cuvette and 5 nm slits for both excitation and emission. The competitive binding of ligands was measured by using NPN (4 µM) as the fluorescent reporter and 0.05–7 µM concentrations of each ligand

Table 1 The PCR primers used in real-time PCR for quantification of transcript levels in the silkworm, *Bombyx mori*

OBP gene	Forward primer (5′-3′)	Reverse primer (5′-3′)
BmorGOBP2	ATCATATGACCGCCGAGGTGATGAGCCACG	GGAATTCTCAGTATTTTTCGATAACTGCTT
BmorPBP1	CAGTGGATGCGTCTCAAGAA	GTCTCATCGGCTCCATGTTT
Actin	CGTTCGTGACATCAAGGAGA	ACAGGTCCTTACGGATGTCG

dissolved in methanol, which gave molar ratios from 0.01 to 1.61 (bombykol:NPN). The total volume of methanol in the protein solution was maintained at 21 µl (2.1%) by adding methanol without ligands. Bound ligand was evaluated from the values of fluorescence intensity assuming that the protein was 100% active, with a stoichiometry of 1:1 protein:ligand at saturation.

Partitioning Binding Assay In the partitioning binding assay (Danty et al., 1999), the protein concentration was calculated from the OD_{280} values and the extinction coefficient of the protein solution assuming all pairs of Cys residues form disulfide bridges. In practice, 20 µl of protein (0.5 mM) in 20 mM Tris buffer (pH 7.4) were added to the 100-µl v-shaped vial (Wheaton Scientific, Millville, NJ, USA), and then 20 µl of hexane containing a mixture of ligands (14 µM each), including bombykol, were layered on top [higher concentrations up to 10 mM of protein were used and similar results obtained (data not shown)]. The two phases were mixed gently, centrifuged at 13,000×*g* for 5 min, and then incubated at room temperature for at least 1 h. After incubation, 2 µl of the top phase containing the ligands were injected into the GC, and the amount of ligand that had gone into the protein phase was determined from the GC trace by using Equations 1 and 2 (below), and through comparison with the results obtained before incubation and without protein.

Each experiment was performed with at least three replicates and repeated at least twice for each sample. The binding of ligands to the OBPs was quantified by GC-FID on an HP Agilent 6890 Series GC system (Hewlett Packard, Wokingham, Berkshire, UK) with a wax column (HP-5MS, 25 m, 0.25 mm i.d., 0.25 µm film thickness; Agilent Technologies) and a cool-on-column injector, and a flame ionization detector (FID). The system was operated under the following temperature program: 100°C for 1 min, increased to 250°C at a rate of 10°C/min, and held at the final temperature for 10 min. The carrier gas was nitrogen at a linear flow rate of 80 cm/sec. The amount of each ligand in the hexane fraction was calculated from the chromatograms by using a single point internal standard (IS). The internal standard used was tridecane (99% chemical purity) (Sigma-Aldrich, Dorset, UK). The first analysis contained a known amount of internal standard and the compounds of interest, and the binding of the ligand was calculated from:

$$\text{Internal Response Factor (IRF)} = [\text{areaIS} \times \text{amountSC}]/[\text{amountIS} \times \text{areaSC}], \quad (1)$$

$$\text{amount of specific compund} = [\text{amountIS} \times \text{IRF}]/\text{areaIS}, \quad (2)$$

Where, IS is the internal standard and SC is the specific compound of interest.

Docking Experimental Procedure Flexible docking of the ligands to BmorPBP1 and BmorGOBP2 was performed by using a genetic search algorithm and a semi-empirical force field of the AutoDock (v.4.2) program (Morris et al., 2009). The crystallographic structures of BmorPBP1 (1DQE) (Sandler et al., 2000) and of BmorGOBP2 (2WC6) (Zhou et al., 2009) were used. Water molecules were removed, and polar hydrogens were added to the proteins and ligands. For the ligands, all torsions were released except the ones around the conjugated double and triple bonds. The default AutoDock force field was applied (Huey et al., 2007). The whole proteins were covered by grid maps with a spacing of 0.374 Å. For the genetic algorithm, default parameters were used starting from random positions and orientation of the ligands. Each ligand was subjected to 100 Lamarkian genetic algorithm runs, with 25×10^6 evaluations in each and with the rest of the parameters set to the default values of the AutoDock GUI, AutoDock Tools. The root mean square deviation (rmsd) tolerance of the resulting docked structures was ≤2 Å. The binding pocket topologies (area and volume) were calculated by using the CASTp server (http://sts.bioengr.uic.edu/castp/calculation.php) (Dunda et al., 2006).

Electrophysiology Insects for electrophysiological studies either were obtained as pupae from Prof. Y. –P. Haung (see above) or purchased from Warwick Insect Technologies (Coventry, UK). Pupae were sexed and kept at 20°C, 16:8 h L:D, until adults emerged. Electroantennogram (EAG) recordings were made by using Ag-AgCl glass electrodes filled with saline solution [composition as in Maddrell (1969), but without glucose]. An antenna of an adult male adult *B. mori* was excised and suspended between the two electrodes. The tip of the terminal process of the antenna was removed to ensure a good contact. Signals were passed through a high impedance amplifier (UN-06, Syntech, Hilversum, The Netherlands) and analyzed by using a customized software package (Syntech).

The stimulus delivery system, which employed a filter paper in a disposable glass Pasteur pipette cartridge, has been described (Wadhams et al., 1982). The stimulus (2 sec duration) was delivered into a purified airstream (1 l/min) flowing continuously over the preparation. Standard solutions (1 mg/ml) of test compounds were applied (10 µl) to filter paper strips, and the solvent was allowed to evaporate (30 sec) before the strip was placed in the cartridge. The control stimulus was hexane (10 µl). Fresh cartridges were prepared immediately prior to each stimulation (N=5).

Responses to control and test solutions were compared for significant differences by using Student's *t*-test.

Results

Expression of Bombyx mori OBPs The levels of transcripts of *BmorGOBP2* and *BmorPBP1* were very low in heads at all larval stages and in adult heads without antennae (Fig. 1). They were very high in the adult antennae, indicating that both genes are highly up-regulated in adult antennae and could be involved in olfaction and detection of semiochemicals. These results are consistent with high levels of the moth proteins found in antennae by Western blot analysis and immunocytochemical labeling experiments (Steinbrecht, 1998; Maida et al., 2005), and also with the developmental profile of OBP *Aaeg-OBP10* mRNA isolated from the intact yellowfever mosquito, *Aedes aegypti* (L.) (Diptera: Culicidae) (Bohbot and Vogt, 2005).

The *B. mori* transcripts also were observed in the earlier stages. We cannot exclude the possibility that two OBPs may have a different function in the larva than in the adult. Larvae are the stage that feeds on plant materials, and they may use this OBP to detect plant volatiles, whereas adults are the stage that reproduces and disperses, and no longer needs to feed. Thus, they may use this OBP to detect pheromone components.

Fluorescence Competitive Binding Assay In the binding assay with BmorGOBP2, attempts to displace NPN by the sex pheromone component bombykol and the plant volatiles [(±)-linalool and benzoic acid] showed that bombykol gave the most displacement, whereas the other two ligands showed much less displacement (Fig. 2). The binding of bombykol to BmorGOBP2 also was pH-dependent, as demonstrated for BmorPBP1 (Leal et al., 2005b), with displacement of NPN greatest at pH 7.5, but displacement of NPN greatly decreased at pH 4.5 over a range of concentrations (Fig. 3).

We next measured the displacement of NPN from recombinant BmorGOBP2 and BmorPBP1 by bombykol and bombykal (Fig. 4). For BmorPBP1, there was no difference in binding between bombykol and bombykal, with the reductions in NPN fluorescence of 41.1±19.4% (N=30) and 34.3±14.2% (N=12), respectively, at 6 μM concentration. Interestingly, BmorGOBP2 showed a similar binding to bombykol as BmorPBP1, but BmorGOBP2 unexpectedly showed a difference in binding of bombykol from bombykal 41.1±15.1% (N=8) and 15.0±3.7% (N=3) (P<0.01, d.f.=10) at 6 μM concentration, respectively. However, the displacement at lower concentrations was low (10–20%). This could be due to non-specific binding and could be affected by other compounds that might bind during protein expression in *E. coli* cells (Oldham et al., 2000).

Partitioning Binding Assays We deployed a partitioning binding assay (Danty et al., 1999) to avoid using the fluorescent probe and the possibility of non-specific displacement. In this assay, the protein in buffer is incubated with a mixture of ligands dissolved in hexane in two phases, (see Methods and Materials), so that each

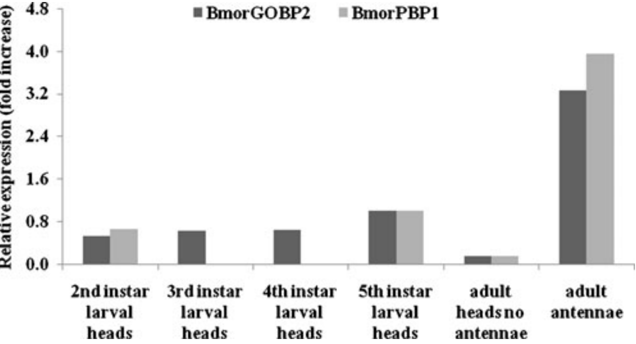

Fig. 1 Transcript levels of *Bombyx mori* OBP genes *BmorPBP1* and *BmorGOBP2*. The transcript levels in adult antennae (mixed sexes) and heads at different larval developmental stages were measured by real-time PCR (see Methods and Materials). The fold-changes are normalized with the actin gene and relative to the transcript level in the body of each stage. The values are the mean of two biological samples and three replicates of each sample

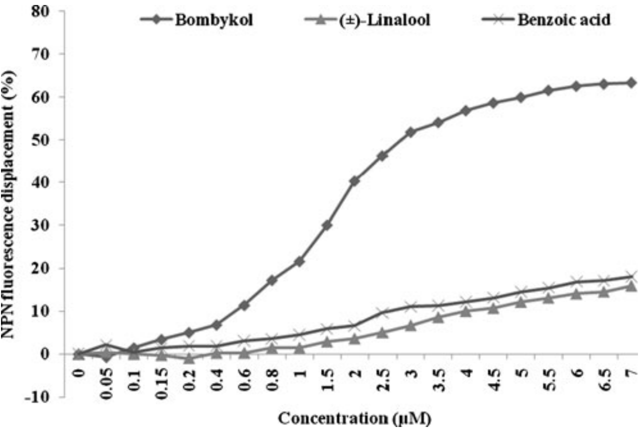

Fig. 2 Fluorescence displacement of N-phenyl-1-naphthylamine (NPN) from *Bombyx mori* BmorGOBP2 by bombykol (♦); benzoic acid (**X**); and (±)-linalool (▲). The protein and NPN were both at 2 μM. The protein/NPN complexes were excited at 337 nm and the fluorescence emission at 395 nm was measured before and upon titration with methanol solutions of the competitors to final concentrations of 0.5–7 μM. The reductions in NPN fluorescence emission at 395 nm were normalized to the NPN fluorescence before titration. The decrease in NPN fluorescence intensity at the emission maximum (395–400 nm), at increasing concentrations of competitors, is presented as (Fligand/Fnpn) with Fligand=the peak fluorescence intensity at a distinct competitor concentration. Fnpn=the peak fluorescence intensity of the OBP/NPN complex

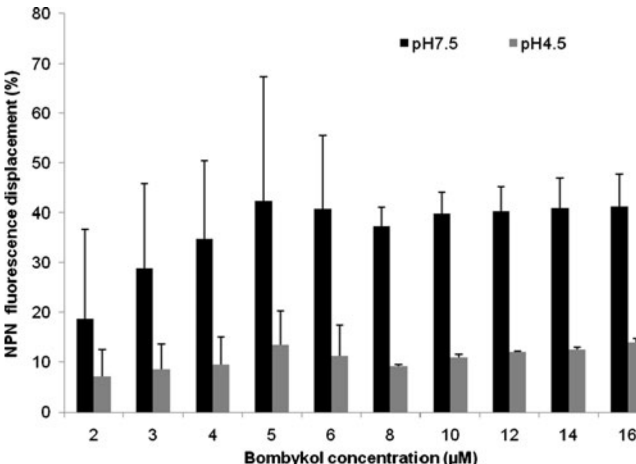

Fig. 3 Fluorescence displacement of NPN (2 μM) by bombykol from *Bombyx mori* BmorGOBP2 (2 μM) at different pHs using a mean of three or four replicates with standard deviations

compound competes for binding. The depletion of the compound from the hexane phase by the protein in the buffer can be measured by GC-FID analysis under equilibrium condition as compared with a control (with no protein). The advantage of this assay is that a mix of ligands (Fig. 5) can be used, and the high concentration of protein in the buffer resembles the high concentration of OBP within the antennal lymph. Both BmorGOBP2 and BmorPBP1 bound to bombykol and most of its analogs, except those with their double bonds replaced by triple bonds (Figs. 6, 7 and 8). Again, there was no difference between the binding of bombykol and bombykal to BmorPBP1, which is consistent with the fluorescence displacement binding results (Fig. 4) and with those of others (Gräter et al., 2006). For BmorGOBP2, bombykol binding was slightly better than bombykal, indicating the effect of changing of the functional group from an alcohol in bombykol to an aldehyde in bombykal to form two hydrogen bonds in BmorGOBP2 (Fig. 7) (Zhou et al., 2009). Interestingly, (10*E*,12*Z*)-hexadecadienyl acetate (**3**) bound best, and (10*E*,12*Z*)-octadecadien-1-ol (**4**) and bombykol (**1**) bound equally well. Moving the position of the double bonds of the pheromone (**6**) reduced the binding to the proteins, and changing from a double bond in bombykol to a triple bond in (10*E*)-hexadecen-12-yn-1-ol (**7**) and (10,12)-hexadecadiyn-1-ol (**8**) further reduced the binding to both BmorGOBP2 and BmorPBP1. Overall, BmorGOBP2 displayed better differential binding to the analogs than did BmorPBP1.

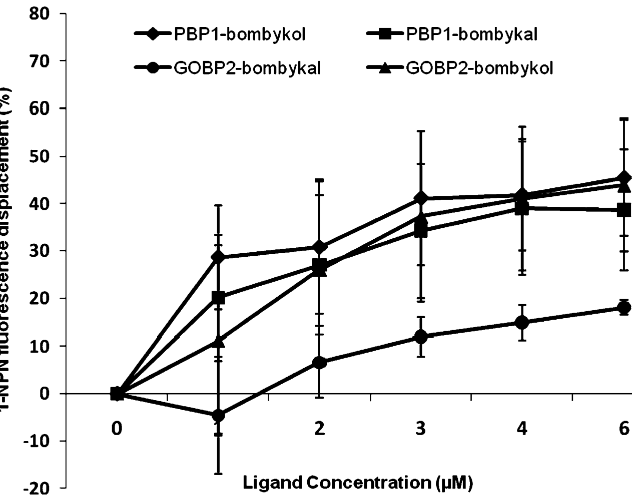

Fig. 4 Displacement of the fluorescent probe NPN by bombykol and bombykal. The protein and NPN were both incubated at a concentration of 2 μM. The OBP/NPN complexes were excited at 337 nm and the fluorescence emission at 395 nm was measured before and upon titration with bombykol or bombykal at a concentration of from 1–6 μM. The reductions in NPN fluorescence emission at 395 nm were normalized to the NPN fluorescence before titration. Each point is the average of at least two replicates (*N*) with the standard error (*N*=30 for BmorPBP1/bombykol, *N*=12 for BmorPBP1/bombykal, *N*=8 for BmorGOBP2/bombykol, *N*=3 for BmorGOBP2/bombkal)

Molecular Docking The previously published X-ray crystallography structures of BmorPBP1 (Sandler et al., 2000) and BmorGOBP2 (Zhou et al., 2009) provide a unique opportunity for molecular modeling and ligand docking. AutoDock 4.2 was used to predict blind docking of bombykol and the analogs to BmorPBP1 (1DQE) and BmorGOBP2 (2WCK), and to estimate the free energy of binding of the protein-ligand complexes. The docking algorithm successfully placed the analogs into the same binding cavity as those of the models obtained from crystal structures. Each ligand was subjected to 100 genetic algorithm runs (see Docking Experimental Procedures in the Methods and Materials). AutoDock performs cluster analysis or “structure binning” based on all-atom mean square deviation (RMSD). The resulting families of docked conformations are ranked in the order of increasing energy (rank 1 is the lowest energy cluster) (Table 2). In very few cases, less populated clusters were observed with lower energy. However, these were not selected as representative of the predicted bound ligand structure as their mean energy difference was 2.5 kcal/mol less than that of the most populated cluster. This is within the range of error of the AutoDock force field (±2.5 kcal/mol). In these cases, the largest cluster was taken as the predicted bound ligand structure (Table 2). Molecular docking showed that in the conformation of bombykol with the lowest binding energy, there are two hydrogen bonds with Glu98 and Arg110 (Fig. 7). The energy minima reached for the BmorGOBP2/ligand complexes are considerably lower than the corresponding ones for BmorPBP1 (Table 2), with most of the lower binding energy conformations having their hydroxyl group oriented towards Arg110 and away from Ser56 without any van der Waals interaction between Ser56 and bombykol (Fig. 7), which is consistent with the crystal

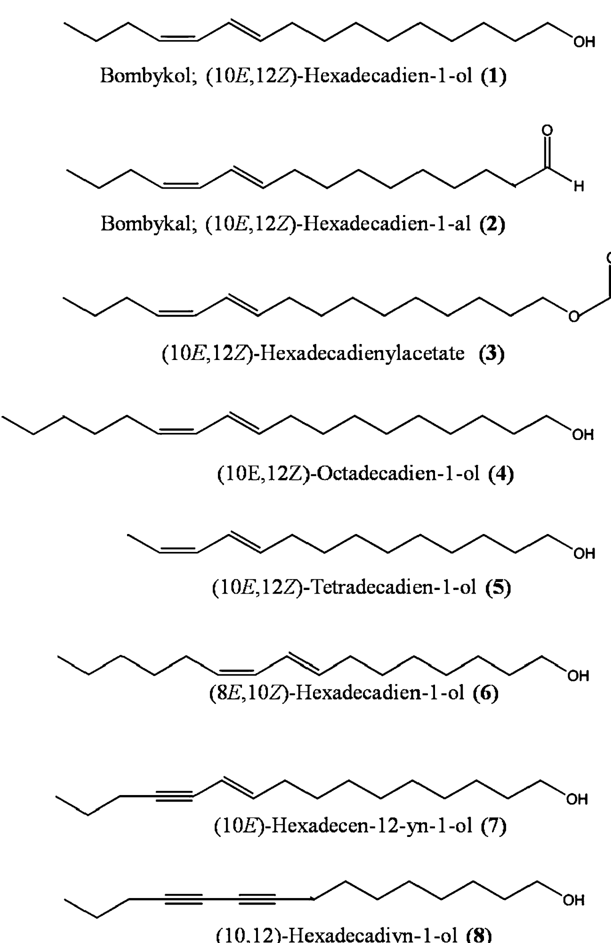

Fig. 5 Structures of the *Bombyx mori* sex pheromone components and their analogs used in this study

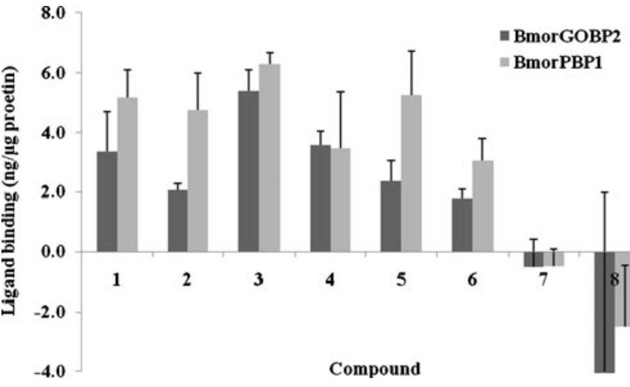

Fig. 6 Binding of bombykol and its analogs to *Bombyx mori* odorant-binding proteins (OBPs). The ligand binding (ng compound per μg protein) was measured with the partitioning binding assay (see Methods and Materials) as the depletion of compound from the top hexane phase into the bottom protein phase relative to that without protein. Each compound is represented with its code as shown in Fig. 5. Each column is the mean of at least three replicates (*N*) and the bar denotes the standard error (*N*=3 for OBP/compound 3, *N*=3 for OBP/compound 4, *N*=7 for OBP/bombykol, *N*=4 for OBP/bombykal, *N*=4 for OBP/compound 5, *N*=4 for OBP/compound 6, *N*=4 for OBP/compound 7, *N*=3 for OBP/compound 8)

structures of BmorGOBP2/ligand complexes (Fig. 8) (Zhou et al., 2009). Furthermore: 1) The docked ligand conformations show tighter clustering (fewer clusters) for BmorGOBP2 than for BmorPBP1. The lowest energy clusters are invariably more populated for all ligands (higher N values) for BmorGOBP2 than for BmorPBP1. This may be explained by a smaller binding cavity in BmorGOBP2 (volume=616.5 Å^3) as compared to that of BmorPBP1 (volume=888.8 Å^3) that may restrict the ligand(s) from attaining multiple conformations within the binding pocket; 2) The ligands rotate more freely in BmorPBP1 than in BmorGOBP2, as shown by greater RMSD differences between the best binding conformers; 3) Both bombykol and bombykal reach the same energy minimum (−7.87) with BmorGOBP2, showing that they have a similar binding affinity. These data provide further evidence and support the binding results (Figs. 2, 4 and 6) in showing that BmorGOBP2 can bind sex pheromones and discriminate between the pheromone analogues better than can BmorPBP1.

The analog (10*E*,12*Z*)-hexadecadienyl acetate (**3**) has a lower E_{min} value (i.e., the free energy of binding of the most favorable conformation within a given cluster). Thus, the analog is predicted to bind better than bombykol or bombykal to both BmorGOBP2 and BmorPBP1, consistent with the results obtained with the partitioning binding assays (Fig. 6) and by the ESI-MS analysis (Hooper et al., 2009). This indicates that the functional group of the analog may interact with Glu98 and Arg110 to form two hydrogen bonds as observed in the crystallographic structures of BmorGOBP2/bombykol (Zhou et al., 2009), and that it, together with bombykol, are better ligands than bombykal. The molecular docking also predicts the lowest binding energy for (10*E*,12*Z*)-octadecadien-1-ol (**4**)/OBP complexes (Table 2).

Electrophysiological Responses Electroantennogram (EAG) recordings showed that bombykol (**1**) and bombykal (**2**) are the most active in triggering an antennal response (Table 3, Fig. 9). (10*E*,12*Z*)-Hexadecadienyl acetate (**3**) and (10*E*,12*Z*)-octadecadien-1-ol (**4**) were shown, for the first time, to elicit significant responses from the male *B. mori* antenna ($P<0.01$ and $P<0.05$, respectively), whereas changing double bonds to triple bonds (**7**) and (**8**) reduced the EAG responses, respectively. This was consistent with the partitioning binding results (Fig. 6), as well as the ligand docking predictions (Table 2). The biological activity thus correlates with the binding data and molecular docking prediction for these compounds. Shortening the length of the alkyl carbon chain by two carbons (**5**) or moving two double bonds (**6**) further reduced the EAG activity as demonstrated by earlier work (Kaissling et al., 1978).

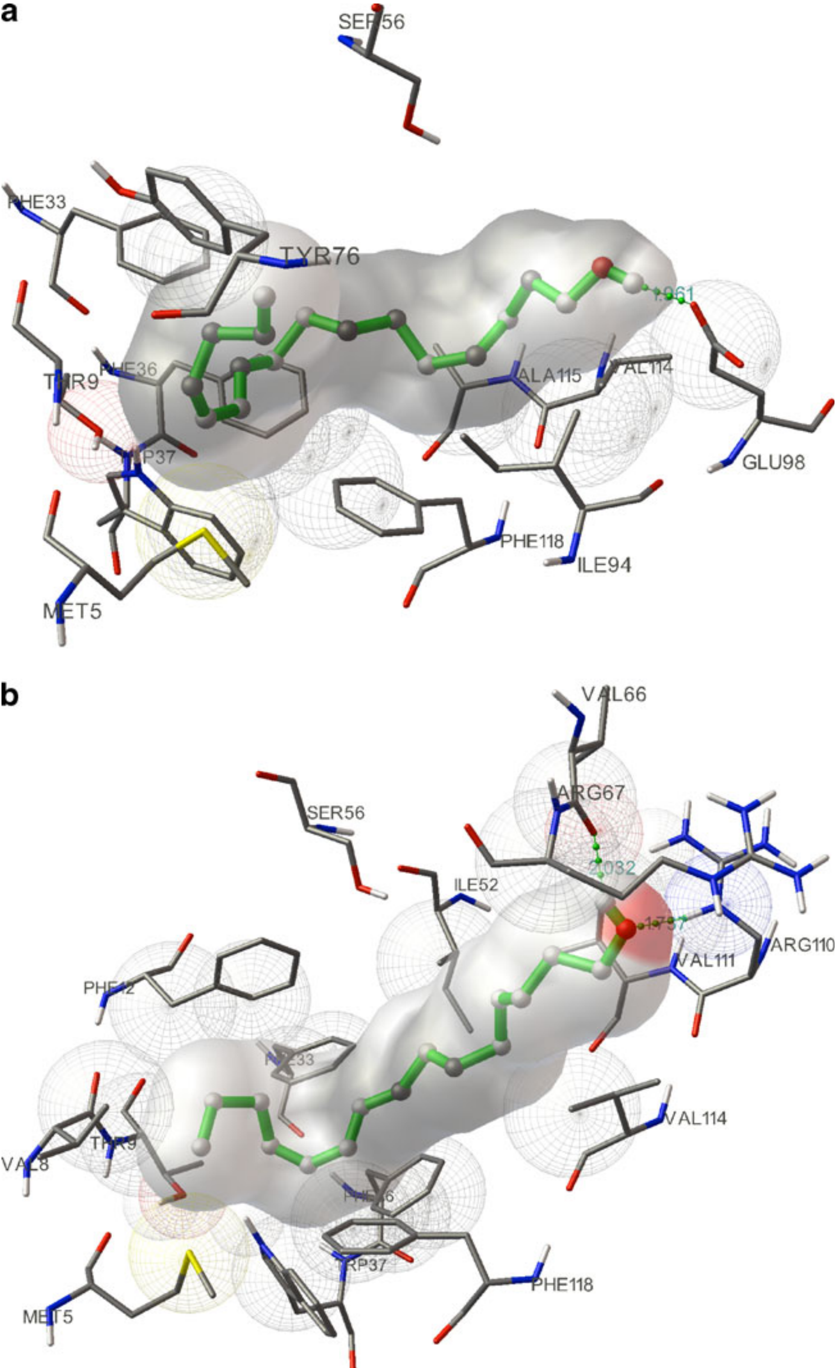

Fig. 7 Molecular contacts of bombykol in the binding pocket of *Bombyx mori* BmorGOBP2 as predicted by molecular docking. The figures were drawn with AutoDockTools (ADT)Python (Sanner, 1999). The spheres and the cloud around the docked bombykol molecule (green stick) are the electrostatic potential (red=oxygen, blue=nitrogen, grey=carbon) for van der Waals (vdWs) contacts and vdW's volume over the whole molecule, respectively. The hydroxyl group of the docked bombykol molecule, with the lowest binding energy, forms hydrogen bonds with Arg110 and Val66 (**a**) and Glu98 (**b**) as in crystal structures. Ser56 forms no vdWs interactions with bombykol

Discussion

Our understanding of the molecular and biochemical mechanisms that mediate chemoreception in insects has been improved greatly by the discovery of olfactory and taste receptor proteins. However, 50 years after the discovery of the first insect sex pheromone from *B. mori*, it is still unclear how such hydrophobic compounds selectively reach the dendrites of sensory neurons *in vivo* across aqueous space to interact with the sensory receptors. The presence of soluble polypeptides in high concentration in the lymph of chemosensilla still poses unanswered questions. More than two decades after their discovery and despite the wealth of structural and biochemical information available, the physiological functions of odorant-binding proteins (OBPs) are still not well understood. It is possible that the combinatorial actions by different OBPs and ORs may provide the foundation for insects to discriminate various odorants (Pophof, 2004; Krieger et al., 2005; Xu et al., 2005; Syed et al., 2006;

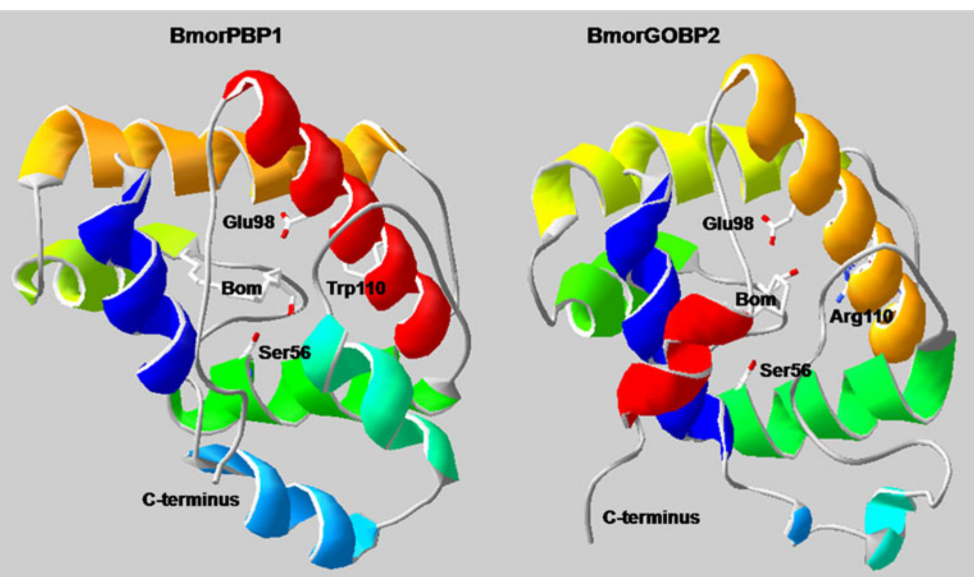

Fig. 8 Three-dimensional structure of *Bombyx mori* BmorPBP1 and BmorGOBP2 bound with the sex pheromone component (10*E*,12*Z*)-hexadecadien-1-ol (stick). The C-termini and the key amino acid residues, which form hydrogen bonds, are labeled. The BmorPBP1 structure 1DQE (Sandler et al., 2000) and BmorGOBP2 structure 2WC6 (Zhou et al., 2009) are downloaded from the protein data bank (http://www.rcsb.org/pdb/home/home.do) and displayed with Swiss-Pdb Viewer 3.7

Laughlin et al., 2008). The transcripts of *BmorGOBP2* and *BmorPBP1* were low in the larval stages, but very high in adult antennae, suggesting a role in adult moth olfaction related to mating and reproduction (adult moths do not feed). When the corresponding recombinant proteins were studied in partitioning binding assays, BmorPBP1 bound to the sex pheromone bombykol as well as its analogs (see also Sandler et al., 2000; Horst et al., 2001; Oldham et al., 2000; Hooper et al., 2009; Zhou et al., 2009). However, there was evidence from the binding assays that BmorGOBP2 can also bind the sex pheromone components bombykol and bombykal (Fig. 6; Gräter et al., 2006; Zhou et al., 2009). It is interesting that both BmorPBP1 and BmorGOBP2 bind to the sex pheromone components, suggesting that the specificity of binding to insect OBPs does not determine the specificity of the receptor neuron response (Kaissling, 2009). This prompted further investigations into the specific binding of BmorGOBP2 to other semiochemical analogs.

Both the fluorescence competition and the partitioning binding assays showed that BmorGOBP2 bound to bombykol more strongly than to bombykal, which is consistent with the results obtained by a cold binding assay (Zhou et al., 2009). The structural evidence indicates that the lack of a hydrogen bond to Glu98 in the BmorGOBP2/bombykal complex may be responsible for this difference (Fig. 8) (Zhou et al., 2009). On the other hand, although BmorGOBP2/ligand complexes have lower energy minimums than BmorPBP1/ligand complexes, the docking experiments failed to provide evidence for the discriminatory binding of

[d] Most populated cluster is Rank 12 comprising of 18 conformations

BmorGOBP2 between bombykol and bombykal (Table 2) as suggested previously (Zhou et al., 2009). It can be argued that BmorPBP1 could have higher affinity for bombykol than bombykal because of the difference in the energy minimum between BmorPBP1/bombykol and BmorPBP1/bombykal complexes (−6.83 kcal/mol vs −6.40 kcal/mol) (Table 2).

The specific expression of BmorGOBP2 in the female sensilla has been demonstrated (Steinbrecht, 1998; Maida et al., 2005), but neither binding to any semiochemicals nor the physiological role of BmorGOBP2 in *B. mori* has been reported. The specific and high up-regulation of the expression of BmorGOBP2 gene in adult antennae suggests that BmorGOBP2 may have a role in the perception of semiochemicals, most likely for plant volatiles. However, our data support the view that BmorGOBP2 can be used preferentially to capture the sex pheromone rather than common plant volatiles such as linalool and benzoic acid. Previous experiments that used an antibody raised against BmorGOBP2 have shown that only a small fraction of sensilla in male antennae contain BmorGOBP2, whereas only few sensilla of female antennae express BmorPBP1 (Steinbrecht, 1998; Maida et al., 2005). The perception of bombykol and bombykal occurs via male receptor neurons within sensilla containing only BmorPBP1. Furthermore, the female receptor neurons innervating the abundant long sensilla trichodea that contain only BmorGOBP2 are very sensitive to linalool and benzoic acid, and never have been found to respond to the pheromones (Kaissling, 2009). These results argue that there is a physiological role of BmorGOBP2 in sex pheromone perception *in vivo*. However, the moth GOBP2 also has been found expressed in male moth antennae (Vogt et al., 1991a) and co-expressed with PBPs (Nardi et al., 2003). The dramatic up-regulation of BmorGOBP2 gene in adult antennae and the binding to sex pheromone components of BmorGOBP2, as reported in this study and others (Gräter et al., 2006), warrant further investigation.

The binding data of BmorGOBP2 also suggest that the protonation of OBPs plays an important role in ligand binding and release, and support the mechanism of pH-dependent release of ligands as demonstrated previously for BmorPBP1 (Wojtasek and Leal 1999; Damberger et al., 2000; Horst et al., 2001; Kowcun et al., 2001; Lee et al., 2002; Leal, 2003) and other insect OBPs. For the honey bee, *Apis mellifera* L. (Hymenoptera: Apidae), PBP AmelASP1, ligand binding is activated at low pH and is dependent on protonation of Asp35, which locks down the C-terminus in a confirmation that closes the active site by a hydrogen bond to the main chain of Val118 (Pesenti et al., 2008). In the predicted BmorPBP1/bombykol structure, the C-terminus blocks the rear entry to the pocket, with Val135 coming within 4Å of bombykol (Sandler et al., 2000; Gräter et al., 2006). However, with BmorGOBP2, the blocking of the rear pocket by the bulge formed by amino acid 33-35 means that the C-terminus cannot sense the ligand directly and plays a role in ligand release (Zhou et al., 2009). The involvement of the C-terminus in BmorGOBP2 binding remains to be determined.

We used synthetic pheromone analogs to test the specificity in ligand binding of the two moth OBPs. (10*E*,12*Z*)-Hexadecadienyl acetate (**3**) showed better binding to BmorGOBP2 than did either bombykol or bombykal in the partitioning binding assay, consistent with the ligand docking experiments (Table 2). The ligand docking experiments also predict that BmorGOBP2 forms more energetically favorable complexes with this analog than does BmorPBP1, and that (10*E*,12*Z*)-octadecadien-1-ol (**4**) should have a good binding to both OBPs as supported by our binding experiments (Fig. 6) and to BmorPBP1 by previous ESI-MS analysis (Hooper et al., 2009). Our binding data for (10*E*,12*Z*)-tetradecadien-1-ol (**5**) is contradictory to the prediction of the docking results, showing good binding to BmorPBP1 and BmorGOBP2 (Fig. 6), but consistent with the poor binding obtained with a cold binding assay (Zhou et al., 2009). Our binding data confirmed the reduced binding of (8*E*,10*Z*)-hexadecadien-1-ol (**6**) compared with the sex pheromones, as measured by the ESI-MS analysis, but contradicted the better binding predicted by ligand docking (Table 2) and the cold binding assay (Zhou et al., 2009). The replacement of double bonds by triple bonds (**7**, **8**) significantly reduced the binding for both OBPs. The

[c] P=significance of difference from hexane control (N=5)

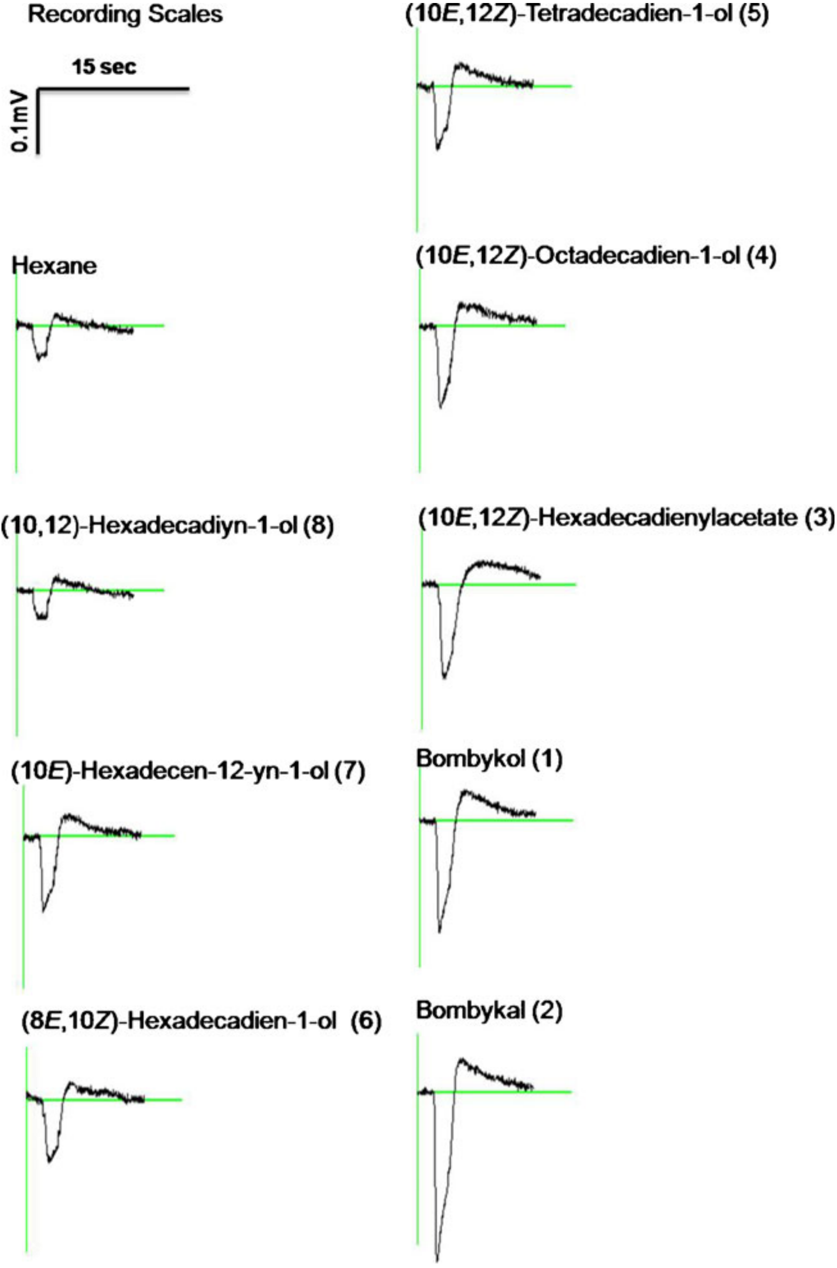

Fig. 9 Electroantennogram (EAG) recordings from male *Bombyx mori* antennae. The stimulus (2 sec duration) was delivered into a purified airstream (1 l/min) flowing c ontinuously over the preparation. The horizontal lines indicate a recording time of 15 sec in each case. Standard solutions (1 mg/ml) of test compounds were applied (10 µl) to filter paper strips and the solvent was allowed to evaporate (30 sec) before the strip was placed in a glass cartridge. The control stimulus was hexane (10 µl). Fresh glass cartridges were prepared immediately prior to each stimulation. Responses to control and test solutions were compared for significant differences by using Student's*t*-test. *N*=5

molecular docking also placed them as less favorable ligands for both OBPs. However, the ESI-MS analysis showed that (10,12)-hexadecadiyn-1-ol (8) bound twice as much as bombykol. In agreement with Hooper et al. (2009), bombykal did not bind to BmorPBP1. The negative values of the binding data to compound (**7**) and (**8**) are unexpected. Other compounds that bound to the OBPs during expression in *E. coli* (Oldham et al., 2000) were displaced by the ligands and measured by GC together with (**7**) and (**8**). Because of these surprising results, a measure of the biological activity was sought by recording overall EAG responses for the sex pheromones as well as the analogs (Table 3, Fig. 9). As expected, the EAG responses were significant for the pheromone components, bombykol (**1**) and bombykal (**2**). The monoyne analogue (**7**) elicited a small EAG response but the diyne analog (**8**) elicited no EAG response. The EAG activity relates well, not only to the results obtained by the partitioning binding assay, which showed significantly increased binding of (10*E*,12*Z*)-hexadecadienyl acetate (**3**) and (10*E*,12*Z*)-octadecadien-1ol (**4**), but also to the ligand docking results (Table 2) and to the ESI-MS analysis (Hooper et al., 2009). Unlike the data from *in vitro* binding and molecular docking, the higher EAG activity of sex pheromone components (**1**) and (**2**) over activity of the analogs (**3**) and (**4**) correlate better with the sexual behavior of adult male moths. Further behavioral studies are needed to

establish any physiological relevance of the analogs (**3**) and (**4**) in moth olfaction. Single sensillum recordings from sensillum types with known protein content could investigate precisely the effects of their binding to protein *in vivo*.

We previously reported the X-ray crystallography structures of BmorGOBP2 complexed with bombykol and four of its analogs that showed that the mode of bombykol binding to BmorGOBP2 differed from that found for BmorPBP1. In the BmorGOBP2 complex, the hydroxyl hydrogen of bombykol forms a hydrogen bond to Arg110, and the hydroxyl group of bombykol also is involved in forming a second hydrogen bond with Glu98, whereas in BmorPBP1, one hydrogen bond is formed with Ser56 (Fig. 8). This could explain why (10*E*,12*Z*)-hexadecadienyl acetate (**3**) appears to bind more strongly to BmorGOBP2 than other analogs. This chemical may be utilizing different molecular interactions when it binds to an OBP, which may influence the conformational properties of the OBP/ligand complex and thus signal transduction. EAG recordings derived from a response of the whole antenna and, at realistic physiological concentrations, as used here, usually correlate with behavior, which could be a positive or negative response. The differences in EAG activities and ligand binding between the sex pheromone components and the analogs necessitate further investigations into the physiological roles of OBPs *in vivo* and interaction between OBPs and sensory receptors. Such research has begun with electrophysiological approaches (Pophof, 2004) and modern molecular technologies such as RNA interference (RNAi) to control OBP gene expression in mosquitoes (Biessmann et al., 2010; Pelletier et al., 2010). Similar studies in crop pests, such as the tobacco hornworm, *Manduca sexta* (L.) (Lepidoptera: Sphingidae), which shares sex pheromone components with *B. mori*, could lead to an alternative pest control strategy by preventing sex pheromone detection, thus reducing moth populations (Zhou et al., 2010).

(Couvillon et al., 2008). This suggested to us that guards might be responding to communication from an alerted nestmate.

A honey bee guard, upon encountering an intruder, frequently bites the intruder and raises her abdomen, extruding her sting. Both behaviors release pheromones (Free, 1987). The mandibular gland secretes a substance, of which 2-heptanone (2H) is important, which likely marks bitten individuals (Boch and Shearer, 1971), while an extruded sting shaft carries alarm pheromones that disperse (Free, 1987). The main component of this sting shaft alarm pheromone is iso-pentyl acetate (IPA); it alerts bees and induces them to sting (Boch et al., 1962). It has been hypothesized that these pheromones may be the mechanism by which guards communicate to other guards that there is an increased probability of intrusion (Couvillon et al., 2008).

We tested the hypothesis that alarm pheromones cause a rapid shift in guards so that they adopt a less permissive acceptance threshold. Such an induced shift should result in an increase in the rejection of both nestmates and non-nestmates, as a non-permissive threshold is less tolerant of differences between cues and colony templates.

Methods and Materials

We used six honey bee colonies of mixed European race, predominantly *Apis mellifera mellifera*, located in an apiary beside our laboratory. Housing and maintenance followed published protocols (Couvillon et al., 2008). Data were collected 12 November–5 December 2008, between 9 a.m. and 4 p.m., when it was warm enough for guarding to occur. Five colonies acted as discriminator hives, and the sixth as a non-nestmate source.

We used a standard behavior-recognition assay by natural entrance guards (Downs and Ratnieks, 2000). Each discriminator hive received one nestmate and one non-nestmate under each of eight chemical treatments (see below). Using forceps, we placed one bee at a time on the entrance platform and observed the guard reaction for 90 sec. An introduction was scored as rejected or accepted (Couvillon et al., 2008). A minimum of 30 min between treatments allowed residual odors to disperse. We made 960 introductions in total.

Chemicals were from Sigma Chemical Co (St Louis, MO, USA). We injected a known quantity into a 30-l plastic bag inflated with air to create the desired concentration, with air pumped from the bag via two plastic tubes to side holes on the entrance platform. Delivery of the air + chemicals (flow rate 1.5 l.min^{-1}) began 10 sec before the introduction of a bee and continued during the 90 sec of observation. Alarm pheromones release responses within seconds in recipients.

It was important to determine appropriate concentrations of treatments. For IPA and 2H, we established a minimum concentration that caused an increase in guard number. IPA induces these responses at lower concentrations than 2H (Boch and Shearer, 1971). Therefore, we tested IPA at 3, 10, and 30 µl per 30 liters of air (Treatments 1–3), and 2H at 10, 30, and 100 µl per 30 l of air (Treatments 4–6). Additionally, we included two controls, pentane (100 µl) and geraniol (100 µl), the latter the active component of honey bee Nasanov attraction pheromone (Boch and Shearer, 1962). These controls were important to test whether bees responded specifically to alarm pheromones or generally to chemicals (either pentane control or a non-alarm pheromone). Treatment sequence was randomized each day.

We used a binary logistic regression (BLR) model to analyze response variable (accept/reject by guard) against factors of day, colony, bee type (nestmate *vs.* non-nestmate), and treatment (1–8), as well as interactions.

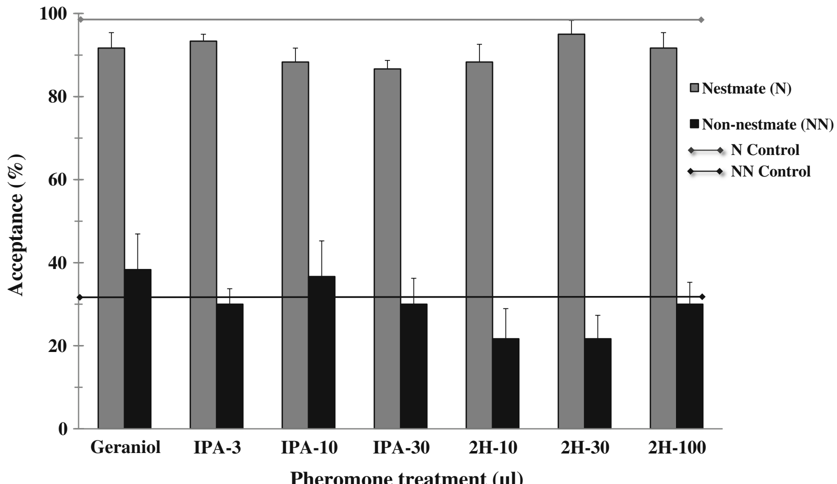

Fig. 1 Effect of chemical treatments on acceptance threshold by guard honey bees toward nestmates and non-nestmates. There was no effect (P=0.46) on guard acceptance threshold for either nestmates or non-nestmates under either iso-pentyl acetate (IPA) or 2-heptanone (2H) at any concentration. Acceptance (%) of nestmates (*grey*) and non-nestmates (*black*) did not differ from pentane control (*grey* and *black* lines, showing 98% nestmate and 32% non-nestmate acceptance, respectively). *Error bars* are S.E.M

Results

Guards discriminated nestmates (92% acceptance) from conspecific non-nestmates (30% acceptance) across all chemical treatments (BLR, Odds Ratio=0.08, P<0.001, Fig. 1). The 62% difference of acceptance demonstrates that normal guarding occurred and confirmed the suitability of the bioassay. There was no significant difference (BLR, P=0.97) in acceptance with (100% nestmate/50% non-nestmate) or without (91% nestmate/33% non-nestmate) the pump. Additionally, there was no significant difference (BLR, Odds Ratio=0.80, P=0.74) in acceptance under pure air (95% nestmate/25% non-nestmate) *vs*. pure air plus pentane control (95% nestmate/20% non-nestmate).

Neither IPA nor 2H affected guards (BLR, Odds Ratio=0.95, P=0.46, Fig. 1). This result indicated that no concentration of either chemical resulted in acceptance threshold shifts. Additionally, there was no effect of geraniol. Day and colony effects were significant (BLR, Day: Odds Ratio=1.116, P=0.004; Colony: Odds Ratio=1.37, P=0.011), so these were retained as factors. Neither is unusual, as it is normal to see day-to-day and inter-hive variation in acceptance (Couvillon et al., 2008, 2009).

There was no significant interaction between bee type and day (BLR, Odds Ratio=0.95, P=0.37), colony (BLR, Odds Ratio=0.84, P=0.23), or treatment (BLR, Odds Ratio=0.97, P=0.74).

Discussion

Our results show no significant effect of either IPA or 2H, which are major components of honey bee alarm pheromones. Therefore, we reject the hypothesis that alarm pheromone is the mechanism that causes rapid shifts in the acceptance threshold of guard honey bees. In rejecting this hypotheses, it is important to consider whether our experimental method may not have detected an effect. One possibility is that we did not administer the chemicals at appropriate levels. However, we performed a preliminary study to determine the minimum amounts of IPA or 2H that cause an increase in guard numbers (Maschwitz, 1964); we used a range of amounts that was lower than and above this threshold. Alternatively, the administered pheromone amounts may have been too high. While initial administration of IPA causes a dose-dependent increase in aggression, IPA amounts above a certain threshold cause guards to become hesitant (Boch and Shearer, 1971). At even our highest amount, we did not observe this change in behavior. Additionally, over the concentration range tested, if guards were non-permissive at low concentrations and hesitant/permissive at higher ones, this would give a higher order model fit for the acceptance threshold data. This was not the case. Therefore, it seems that our concentration range was behaviorally appropriate. Another possibility is that other components of the two alarm pheromones may be the cause of the acceptance threshold change. While we tested only the major alarm compounds, these did trigger the appropriate guarding responses, suggesting they were sufficient. Future work should examine the real-time chemical changes in the headspace that precede shifts in acceptance threshold, by using methods such as APCI-MS (atmospheric pressure chemical ionization-mass spectrometry; Goubault et al., 2006).

We have shown that guard honey bees rapidly respond to increased intrusion by becoming less permissive (Couvillon et al., 2008). The rejection of the alarm pheromone hypothesis strengthens the alternative hypothesis that each guard individually monitors intrusion levels and responds by shifting her threshold towards non-permissiveness following contact with intruders. This hypothesis could be tested by comparing the acceptance thresholds of guards who have and have not experienced increased intrusion before and after the increase.

2009); *Anoplophora glabripennis* (Motschulsky) (Lamiinae), in which the male emits a 1:1 blend of the ethers 4-(*n*-heptyloxy) butanal and 4-(*n*-heptyloxy) butan-1-ol (Zhang et al., 2002); *Monochamus galloprovincialis* (Olivier) (Lamiinae), in which the male emits the ether 2-undecyloxy-1-ethanol (Pajares et al., 2010); and the brown spruce longhorn beetle, *Tetropium fuscum* (F.), and its congener, *Tetropium cinnamopterum* Kirby (Spondylidinae), in which males emit (*E*)-6,10-dimethyl-5,9-undecadien-2-ol (geranyl acetol) (Silk et al., 2007).

Volatile isoprenoids are ubiquitous as semiochemicals in many insect herbivore–plant systems (Hick et al., 1999), but the *Tetropium* pheromone was the first homoterpenoid alcohol found in a cerambycid species. A terpenoid structural motif has also been identified in the subfamily Lamiinae, in the species *Hedypathes betulinus* (Klug) (Fonseca et al., 2010) and *Steirastoma breve* (Sulzer) (C. Liendo, pers. comm.). As the compound was first discovered in *T. fuscum*, Silk et al. (2007) named the pheromone "fuscol". We subsequently learned that this term had already been used to refer to a marine lobane diterpene isolated from the gorgonian, *Eunicea fusca* Duchassaing and Michelotti (Kosugi et al., 1998); hereafter we refer to the *T. fuscum* pheromone component as "fuscumol".

We have been developing tools for survey, detection, and control of *T. fuscum* since its discovery in Halifax, Nova Scotia, Canada in 1999 (Smith and Hurley, 2000). Native to Europe, *T. fuscum* was first discovered in Canada in mature, apparently healthy red spruce, *Picea rubens* Sarg., in Point Pleasant Park, next to a Halifax container port facility (Smith and Hurley, 2000). In Europe, *T. fuscum* breeds primarily in stressed or dying Norway spruce, *Picea abies* (L.) Karst, and is sympatric with *T. castaneum* (L.) (Juutinen, 1955); the latter is not known in North America. In Nova Scotia, *T. fuscum* has been detected in nine counties (Cunningham, 2010), and infests red spruce, white spruce, *P. glauca* (Moench) Voss, black spruce, *P. mariana* (Mill.) B.S.P., and Norway spruce (Smith and Humble, 2000). In its new range, *T. fuscum* overlaps with the transcontinental, Nearctic, *T. cinnamopterum*, which infests dying or recently felled spruce and occasionally pines (Furniss and Carolin, 1980).

Many cerambycids are attracted to host volatiles (Linsley, 1961; Allison et al., 2004). A synthetic "spruce" blend of monoterpenes plus ethanol was attractive to *T. fuscum* and its congeners, *T. cinnamopterum* and *T. castaneum* (Sweeney et al., 2004, 2006). Silk et al. (2007) found that racemic fuscumol was unattractive by itself but, when combined with the spruce blend and ethanol, it synergized capture of males and females of both *T. fuscum* and *T. cinnamopterum* in traps. As fuscumol synergizes attraction of both sexes, it functions as an aggregation pheromone (Wertheim et al., 2005), albeit with a significant bias to females, suggesting that it may also be involved in mating (Silk et al., 2007).

Fuscumol is a secondary alcohol with a chiral center, so two enantiomers, *R*- and *S*-, are possible. Chirality affects behavioral and olfactory responses to pheromones and host volatiles in many insect species (Mori, 2007). In most species, and particularly sex/aggregation pheromone systems studied to date, the pure, naturally occurring pheromone enantiomer is more attractive than the antipode (opposite enantiomer), but the effect of the antipode in racemic blends differs among species: it has no inhibitory effect on response to the active enantiomer in roughly 60% of species studied, but can reduce attraction in other species (Mori, 2007). Presence of the antipode in racemic blends of synthetic sex or aggregation pheromone inhibits attraction of the cerambycid species, *Neoclytus mucronatus mucronatus* (F.) (Lacey et al., 2007), *Hylotrupes bajulus* (L.) (Reddy et al., 2005a), and *Megacyllene caryae* (Gahan) (Lacey et al., 2008).

Our first objective was to determine which enantiomer(s) of fuscumol was produced by male *T. fuscum* and *T. cinnamopterum* and to test whether fuscumol chirality affected antennal response [determined by electroantennography (EAG)] and trap capture of *T. fuscum* and *T. cinnamopterum* in the field; our Canada field experiments were also replicated in Poland in order to test the effect of fuscumol chirality on a different population of *T. fuscum*, as well as *T. castaneum*. Our second objective was to test the relationship between release rate of fuscumol and attraction of *Tetropium* spp., as measured by capture in traps baited with racemic fuscumol and host odors. Our third objective was to compare the relative responses of males and females of each *Tetropium* spp. to fuscumol and host odors, so as to explore the compound's roles in sex attraction and aggregation.

Methods and Materials

Collection of Beetles and Volatiles Adult *T. fuscum* and *T. cinnamopterum* were reared from spruce bolts (35 cm long × 20–40 cm diam.) cut from infested trees in Halifax, Nova Scotia, and incubated at 20–22°C and 45–60% RH in a containment facility at the Atlantic Forestry Centre (AFC) of Natural Resources Canada in Fredericton, New Brunswick. Emergence was checked 5 days each week over 12 weeks. Adults were identified to species (Smith and Humble, 2000), sexed, and stored individually in glass vials at 3–4°C until used.

Volatiles were collected separately from male and female *T. fuscum* and male *T. cinnamopterum* by drawing air through activated charcoal, then through a glass chamber (2.8 cm diam. × 18 cm long) containing 5–6 beetles, and finally through Super-Q® (~200 mg), using a vacuum line

and a flow rate of 250–300 ml.min^{-1}. Two 9 cm diam. circles of Whatman® #5 filter paper were inserted in each glass chamber: one piece lined the inside of the chamber to provide purchase for the beetles, and the other was pleated to separate individuals. Beetles were acclimatized in the room (20–22°C, 40–60% RH, 15:9 (L: D) cycle) for 24 hr prior to volatile collection. Two identical systems were set up so that volatiles could be sampled simultaneously from separated male and female *T. fuscum* or *T. fuscum* and *T. cinnamopterum* males. Each pairing was replicated twice, with different beetles, for a total of 4 samples from *T. fuscum* males, 2 samples from *T. fuscum* females, and 2 samples from *T. cinnamopterum* males. Volatiles were collected for 24–96 hr per replicate. The glass chambers and lines were cleaned between each replicate, and the activated charcoal was replaced every second replicate. Dichloromethane (3×5 ml) was used to rinse the inside of the glass chambers and elute volatiles from the Super-Q®.

Chemical Analyses Extracts and synthetics were analyzed by gas chromatography/mass spectrometry (GC/MS) on a Hewlett-Packard 5890 GC coupled with a 5971 mass selective detector in the electron ionization (EI; 70 eV) mode. The GC was fitted with a SPB-5 capillary column (30 m×0.32 mm×0.25 µm film; Supelco, Bellefonte, PA, USA), and helium used as carrier gas. The splitless injection port was set at 220°C. The column oven temperature was programmed from 70°C (held for 3 min.) to 220°C at 15°C.min^{-1}, and held for 15 min.

NMR (^{1}H and ^{13}C) analysis was carried out on a Varian Inova® 300 MHz spectrometer in $CDCl_3$ with TMS as internal standard. IR spectra were recorded on a Perkin Elmer® 727B IR-spectrometer with KBr disks. Rotations were determined on neat samples or samples dissolved in methylene chloride, on a Perkin Elmer 241 polarimeter, using the 589 sodium D-line.

Electroantennography Extracts and synthetic compounds were tested for antennal stimulation of *T. fuscum* and *T. cinnamopterum* males and females, using a coupled gas chromatograph-electroantennogram detection (GC/EAD) and separate EAG systems. GC/EAD techniques have been described previously (Silk et al., 2007). Briefly, antennae from males and females were excised close to the head and used intact with Spectra®-60 gel (Parker Laboratories Inc., Fairfield, NJ, USA) for electrical contact. A Varian CP-3380 gas chromatograph with a flame ionization detector (FID) was modified for use with a GC/EAD signal-recording device (IDAC-232, Syntech, The Netherlands). The effluent from the capillary column (Supelco DB-5, 30 m×0.30 mm×0.25 µm) was split (50/50) between the FID and the antennal preparation. Injections were in the splitless mode with helium as carrier gas and the splitless injector at 220°C. The column oven was programmed from 60°C (held for 5 min.) to 220°C at 20°C.min^{-1}. Syntech GC/EAD software v.2.6 was used to analyze the data.

EAG responses of male and female *T. fuscum* to puffs of (*R*)-fuscumol, (*S*)-fuscumol, racemic fuscumol, and hexane (control), were recorded. For this, 1 µl of a 10 mg/ml dilution of a compound was placed on a strip of filter paper inside a disposable glass pipette. Each antenna was given a single puff of each treatment (including the hexane control) in random order, with 1 min between each puff. For each insect, a standardized relative response was calculated by dividing the amplitude of response to each treatment by the amplitude of response to the hexane control.

Chemical Syntheses Synthetic (racemic) fuscumol **(1)** (>99% pure; GC/MS) was furnished (Fig. 1) by lithium aluminum hydride (LAH) reduction of commercially available (*E*)-geranyl acetone **(2)** (Aldrich Chemicals, Milwaukee, WI, USA; <0.5% *Z*-isomer), and the structure of the secondary alcohol verified by EI mass spectrum, and ^{1}H and ^{13}C NMR (see Silk et al., 2007).

Enantioselective syntheses of (*S*)- and (*R*)-fuscumol (**3 & 5**, respectively) were first carried out via asymmetric reduction of (*E*)-geranyl acetone **(2)** with diethylaniline-borane (DEANB) and the stereospecific Corey-Bakshi-Shibata (CBS)-reduction catalysts (Salunkhe and Burkhardt, 1997), (*R*)-(+)-2-methyl-CBS-oxazoborolidine and (*S*)-(−)-2-methyl-CBS-oxazoborolidine (as 1M solutions in toluene; Aldrich Chemicals). Briefly, 0.13 ml of the (*R*)- or (*S*)-catalyst at 22°C (0.13 mmol), in 2 ml of toluene, was added to 424 mg (2.6 mmol) of DEANB, followed by 500 mg (*E*)-geranyl acetone (2.58 mmol) **(1)** over 1 hr. Following stirring for an additional hour, the reaction mixture was carefully quenched with MeOH (hydrogen evolution), followed by 5 ml of 1.0N HCl. The organic layer was separated, and the aqueous phase extracted with diethyl ether. The combined organic phases were washed with HCl, water, and brine, and dried over $MgSO_4$.

Fig. 1 Synthesis of racemic fuscumol. *LAH* lithium aluminum hydride

E-geranyl acetone (**2**) → LAH → racemic-fuscumol (**1**)

Second, we carried out a kinetic resolution of racemic (*E*)-fuscumol **(1)** by enantioselective syntheses using immobilized lipases: a thermostable acrylic resin-supported lipase from *Candida antarctica*, Novozyme® 435, and a Celite®-supported porcine pancreatic lipase (ppl) (Amano Pharmaceutical Co., Nagoya, Japan). Briefly, 71.1 mg of immobilized Novozyme 435 enzyme (1 M in toluene; 10,000 units/g, Aldrich Chemicals; Gries et al., 2006) were stirred with 600 mg (3.09 mmol) of racemic alcohol **(1)** and 0.53 ml of an acylating agent, vinyl acetate, (Aldrich Chemicals) in 3 ml of hexane. The mixture was warmed to 40°C, and stirred for 7 days. Progress of the reaction was monitored by TLC; the reaction was found to be complete [by GC/MS after derivatization with (*S*)-acetyl lactyl chloride; see below] after 7 days. The resin was filtered, and the solvent evaporated *in vacuo*. (*S*)-Alcohol **(3)** and (*R*)-acetate **(4)** were separated by flash chromatography using silica gel and diethyl ether/hexane (1:20) as eluent. (*R*)-Fuscumol **(5)** was furnished by hydrolysis of **(4)** with K_2CO_3/MeOH (Fig. 2). Optical purities of the alcohols, both synthetics and insect extracts, were determined by treatment with (*S*)-(−)-2-acetoxy propionyl chloride [(*S*)-acetyl lactyl chloride; pyridine/DMAP catalyzed] (Slessor et al., 1985), which gave baseline resolution of diastereomers by GC/MS on the SPB-5 column. In addition, some separation was effected by chiral β-cyclodextrin column chromatography (Supelco β-DEX™ 120, 30 m×0.25 mm×0.25 μm film) using the same temperature programming as for the SPB-5 column.

We also attempted a reduction of (*E*)-geranyl acetone **(2)** with fermenting Baker's yeast, *Saccharomyces cerevisiae*, (with D-glucose) and with the $NADP^+$-dependent alcohol dehydrogenase from *Thermoanaerobium brockii*.

The absolute configuration of the Novozyme 435 lipase-produced fuscumol was determined as follows. Briefly, treatment of (−)-fuscumol acetate with catalytic OsO_4 and an oxidant gave a mixture of oxidized products (approximately a 1:1 mixture of each double bond oxidation product, as well as some oxidation of both double bonds) that was subjected to oxidative cleavage, using silica-supported $NaIO_4$, yielding three products, one of which was 4-acetoxypentanal, that were easily separated by silica gel chromatography using 10:1 hexanes:ethyl acetate as eluent. This aldehyde was oxidized to give the acid, which was treated with methanolic K_2CO_3 to give the corresponding lactone. Repeating the sequence, starting with the (+)-alcohol, which, after periodate cleavage, gave the hemiacetal, which was oxidized with PCC to give the lactone. Starting with the (−)-acetate (rotation −2.9), (*R*)-(+)-5-methyl-4,5-dihydrofuran-2(3H)-one {$[\alpha]_D$=+7.3 (c=3.7, CH_2Cl_2)} was obtained, whereas starting with (+)-alcohol ($[\alpha]_D$=+2.9), (*S*)-(−)5-methyl-4,5-dihydrofuran-2(3H)-one {$[\alpha]_D$=−6.7 (c=1.0, CH_2Cl_2)} was generated. Given this, (+)-fuscumol has the (*S*) configuration, whereas (−)-fuscumol has the (*R*) configuration. The spectral characteristics and optical rotation values fully agreed with an earlier report (Oritami and Yamashita, 1973). The Novozyme 435 lipase technique was then used to produce (**3**) and (**5**) (Fig. 2) in gram quantities for field testing.

Field Trapping Experiment—Chirality and Host Volatiles The effect of fuscumol chirality and host volatiles on attraction of *Tetropium* spp. was tested in a 4×2 factorial trapping experiment conducted in spruce-dominated forests on McNabs Island, Nova Scotia from 15 May to 27 June 2007, and in Białowieża, Poland, from 30 April to 25 June 2007 (sites described in Sweeney et al., 2006). There were

Fig. 2 Resolution of racemic fucumol, with the lipase Novozyme 435 producing (*S*)- and (*R*)-fuscumol

four levels of pheromone [(*S*)-fuscumol; (*R*)-fuscumol; racemic fuscumol; blank] and two levels of host volatiles (spruce blend + ethanol; blank) for a total of six different lure treatments. Fuscumol was dispensed from a lure, consisting of a 0.2 ml thin-wall, clear, dome-capped polymerase chain reaction (PCR) sample tube (Axygen Scientific Inc., CA, USA) containing ca. 15 mg of synthetic pheromone, with a 1 mm diam. hole drilled in the cap. Release rate of fuscumol was initially 800 μg/d, dropping to about 80 μg/d after 30 days at 23°C (determined by weight loss). Release rates of spruce blend (a blend of monoterpenes, Sweeney et al., 2006) and ethanol were about 2,000 mg/d, and 275 mg/d, respectively. The host volatile lures have a field life of about 90 days at 21–24°C, so were not replaced for the 8-wk duration of the experiment. The fuscumol lures were replaced once, after 4 weeks.

Treatments were replicated 15 times in Nova Scotia and nine times in Poland, using a randomized complete block design with 30 m between traps and blocks. Colossus® traps (ConTech Enterprises, Delta, British Columbia) were used in Nova Scotia and PT Intercept® traps (AlphaScents, Portland, OR, USA) were used in Poland (Sweeney et al., 2006). Each trap was suspended from a rope tied between two conifers, separated by at least 2 m, with the collecting bucket 10–20 cm above the ground. The bucket contained a 50:50 mixture of propylene glycol and deionized water plus 0.5 ml/l of Kodak Photo-Flo® 200 and 12.5 mg/L of Bitrex®. Traps were checked weekly and specimens preserved in 70% ethanol. All *Tetropium* spp. were sexed and identified to species, and voucher specimens retained at AFC, Fredericton, New Brunswick.

Field Trapping Experiment—Release Rate The effect of fuscumol release rate on capture of *Tetropium* spp. was tested in Nova Scotia and Poland using similar methods as described for the chirality experiment. There were five treatments: (1–3) low, medium, and high release rate, of racemic fuscumol (1 mg/d, 4 mg/d, or 32 mg/d, respectively, measured at 20–21°C), each combined with a spruce blend lure (2,000 mg/d) and ethanol lure (275 mg/d); (4) spruce blend and ethanol lures; and (5) unbaited trap. The fuscumol release devices (ConTech Enterprises, Delta, British Columbia) were a bubble cap (1 mg/d), or pouch design (4 mg/d and 32 mg/d) that released racemic fuscumol at a steady rate over roughly 60 days. The experiment was conducted from 27 May to 30 July 2008 on McNabs Island, Nova Scotia with 10 replicates, and from 7 May to 2 July 2008 at Białowieża, Poland, with 11 replicates. At both sites, treatments were laid out in a randomized complete block design.

Data Analysis Data for standardized antennal responses to treatment stimuli were first tested for differences between males and females using *t*-tests on log (y+1) transformed data; if antennal response did not differ between the sexes, data were pooled and analyzed by a repeated measures ANOVA with individual antennal preparations as blocks, and the Ryan-Einot-Gabriel-Welsch multiple range test (SAS Institute 2002–2003).

For trapping bioassays, data for total season catch per trap of each species were transformed by log (y+1) and subjected to ANOVA, using the model: mean catch = block + pheromone + host volatiles + pheromone × host volatiles + error. When there was significant interaction between pheromone and host volatiles, data were subjected to ANOVA using the model: mean catch = block + lure treatment + error. Means were compared using the Ryan-Einot-Gabriel-Welsch multiple range test. Loss of data because of trap disturbance was rare, but if a trap was found disturbed during a weekly check we did not include that week's catch in the season totals for all treatments in the affected block. Residuals from all ANOVAs were tested for significant deviations from normality using the Shapiro-Wilk test (Zar, 1999) in SAS (PROC Univariate) (SAS Institute, 2002–2003); if residuals were non-normal, data were rank transformed and subjected to ANOVA (Friedman's test) (Zar, 1999). We compared the relative responses of different *Tetropium* spp. to the treatments by testing for correlation in catch per trap of *T. fuscum* vs. *T. castaneum* in Poland and *T. fuscum* vs. *T. cinnamopterum* in Nova Scotia; traps that captured neither species were excluded.

Responses of Males vs. Females Separate ANOVAs were run for catch of males and females of each species in field-trapping bioassays. For each species and trapping bioassay, we tested the correlation between catch of males and females across all treatments, excluding traps with zero catch. For each species, the total numbers of males vs. females captured with each lure treatment (as well as all treatments pooled) were tested for significant deviation from 50:50 using chi square goodness-of-fit tests; treatments in which expected counts were <5 were excluded from analysis (Zar, 1999).

Results

Synthesis LAH reduction of (*E*)-geranyl acetone **(2)** gave racemic fuscumol **(1)** in high yield (>99%; Fig. 1) with spectra matching those previously reported (Silk et al., 2007).

Treatment of **(2)** with whole-cell-fermenting Baker's yeast failed to yield any reduced product, but a thermophilic enzyme, an $NADP^+$-dependant alcohol dehydrogenase from *Thermoanaerobium brockii*, did produce a small amount of (*S*)-(+)-fuscumol **(3)** after 7–8 days of reaction

[determined by (*S*)-acetyl lactate formation and GC/MS; ee >90%], but in very low yield (<1%); **(2)** is, therefore, a poor substrate for this enzyme.

Asymmetric reduction of (*E*)-geranyl acetone **(2)** with DEANB and CBS catalysts produced (*S*)-fuscumol **(3)** with the (*R*)-2-methyl-CBS-catalyst and (*R*)-fuscumol **(5)** with the (*S*)-2-methyl-CBS catalyst, at 87% ee and 74% ee, respectively, estimated by formation of the (*S*)-acetyl lactyl diastereomers followed by GC/MS analysis on the SPB-5 column with baseline resolution (Slessor et al., 1985). Both reactions occurred in good yield (>90%).

Enzymatic resolution of racemic fuscumol **(1)** with a ppl lipase produced (*S*)- and (*R*)-fuscumols, but only at ca. 60% ee. However, enzymatic resolution of racemic fuscumol **(1)** with a lipase from *C. antarctica* (Novozyme 435) produced (*S*)- and (*R*)-fuscumols (**3** and **5**, respectively; Fig. 2) with improved chiral (ee >95%) and overall purity (>98%). Spectroscopic data for the Novozyme 435 lipase-produced (*S*)- and (*R*)-fuscumols are reported. ^{1}H and ^{13}C assignments were based on extensive 1-D and 2-D NMR experiments, including 1-D ^{1}H and ^{13}C, DEPT, COESY, HMBC, HMQC, and NOESY. The ^{1}H and ^{13}C NMR chemical shifts are reported in ppm, and multiplicity terms used are: s (singlet), d (doublet), ht (heptet of triplets), st (sextet of triplets), and m (multiplet) (See Fig. 1 for C-numbering scheme).

^{1}H NMR (Fig. 1, $CDCl_3$, 300 MHz): 1.20 (d, *J*=6.1 Hz, C-1H_3), 1.45–1.54 (m, O*H* and C-3H_2), 1.60 (s, C-13H_3), 1.62 (s, C-12H_3), 1.68 (d, *J*=1.1 Hz, C-11H_3), 1.95–2.14 (m, C-4H_2, C-7H_2 and C-8H_2), 3.81 (sextet, *J*=6.2 Hz, C-2*H*), 5.08 (ht, *J*=1.3, 9.3 Hz, C-9*H*), 5.15 (st, *J*=1.3, 7.2 Hz, C-5*H*). ^{13}C NMR ($CDCl_3$, 75 MHz): 16.0 (C-12), 17.7 (C-13), 23.5 (C-1), 24.4 (C-4), 25.7 (C-11), 26.7 (C-8), 39.2 (C-3), 39.7 (C-7), 67.8 (C-2), 124.0 (C-5), 124.3 (C-9), 131.4 (C-10), 135.6 (C-6). IR (neat) cm^{-1}: 3323 (br, s), 2966 (s), 2921 (s), 2856 (m), 1669 (w), 1447 (s), 1375 (s), 1329 (w), 1303 (w), 1172 (w), 1125 (s), 1109 (s), 1083 (m), 1024 (w). $[\alpha]_D^{24}$=+24.9 (neat); = +7.3 (c=2.8; CH_2Cl_2); ee=95% {lit. Madyastha and Gururaja, (1994) (*S*)-fuscumol $[\alpha]_D$=+3.4 (c=5.0, $CHCl_3$)}. (*R*)-*fuscumol:* spectra as per *S*-fuscumol; $[\alpha]_D^{24}$=−24.7 (neat); −6.33 (c=1.4; CH_2Cl_2); ee=95%.

The absolute configuration of the Novozyme 435 lipase-produced fuscumol was initially assigned by comparison of spectra and optical rotation with the product previously published, in which (**3**) was produced by asymmetric reduction of (**2**) with cell-free systems from *Alcaligenes eutrophus* in the presence of $NADP^+$ (Madyastha and Gururaja, 1994). This allowed a tentative assignment of the *dextrorotatory* product (**3**) as having the (*S*)-configuration, with a rigorous confirmation of the absolute configuration of the alcohols by chemical degradation of optically enriched (*S*)- or (*R*)-fuscumol to the known (*S*)-(−)-5-methyl-4, 5-dihydrofuran-2(3H)-one and (*R*)-(+)-5-methyl-4, 5-dihydrofuran-2(3H)-one (Mori, 1975), respectively.

Pheromone Chirality Male-produced fuscumol from both *T. fuscum* and *T. cinnamopterum* was determined to have the (*S*)-stereochemistry by comparing mass chromatograms and spectra of the (*S*)-acetyl lactyl diastereomers from racemic fuscumol (Fig. 3a), male *T. fuscum* (Fig. 3b), male *T. cinnamopterum* (not shown), and (*S*)-(+)-fuscumol (Fig. 3c) produced by the lipase method whose absolute stereochemistry had been determined previously. Direct separation of fuscumol enantiomers using chiral capillary columns (β- or γ-cyclodextrin) was unsatisfactory, with poor resolution of the alcohols.

GC/EAD and EAG Analyses GC/EAD analysis of *T. fuscum* male volatiles collected on Super-Q® showed only one consistent EAD-active peak, with a retention time corresponding to that of fuscumol; male and female antennae were equally responsive.

EAG Analysis Antennal responses (Fig. 4) to (*R*)-fuscumol (*t*=−0.66, *df*=23, *P*=0.51), (*S*)-fuscumol (*t*=−0.3, *df*=23, *P*=0.77), or racemic fuscumol (*t*=0.03, *df*=23, *P*=0.98) did not differ between male and female *T. fuscum*, so data were

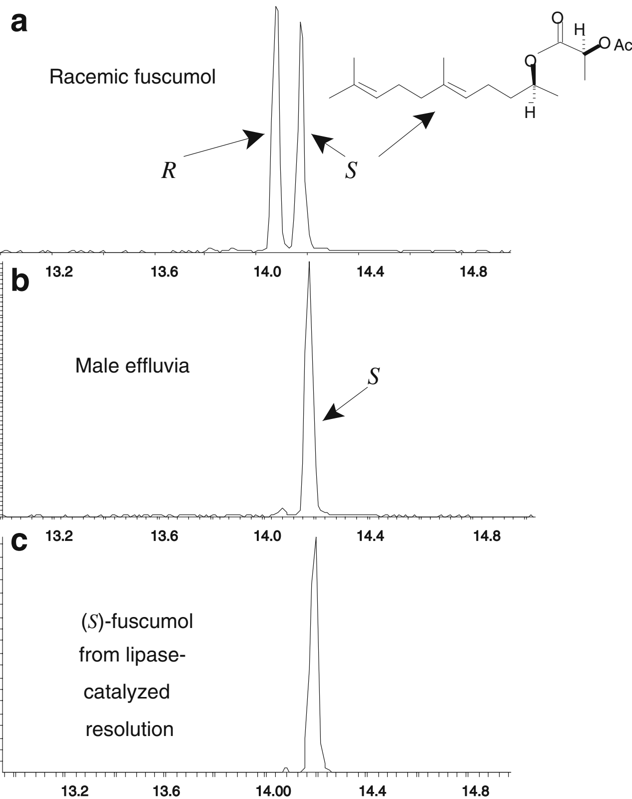

Fig. 3 Resolution of (***S***)-acetyl lactate diastereomers of racemic fuscumol shown by : total ion mass chromatograms of **a** racemic fuscumol diastereomers; **b** (*S*)-acetyl lactyl derivative of male *Tetropium fuscum* effluent, (*S*)-diastereomer, ~ 98% pure with the (*R*)-diastereomer as the earlier eluting peak; **c** (*S*)-(+)-fuscumol/(S)-acetyl lactyl derivative from Novozyme 435 resolution

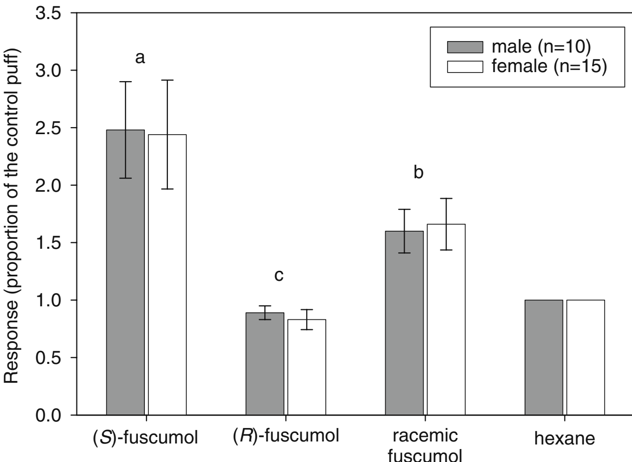

Fig. 4 Electroantennogram responses to the different enantiomers of fuscumol. For each antenna, the magnitude of each response was standardized as a percentage of response to a control (hexane) puff. Bars represent mean response ± SE. Males and females did not differ in response to any treatment (*t*-tests, $P>0.05$). *Different letters above the bars* indicate significantly different mean responses (sexes pooled), as determined by repeated measures ANOVA with REGW test on data transformed by log (y + 1)

pooled and analyzed by repeated measures ANOVA. Standardized antennal response differed among treatments (F= 57.4; df=2, 48; $P<0.001$), with the greatest response to (*S*)-fuscumol, then to the racemate, and (*R*)-fuscumol (Fig. 4).

Field Trapping Experiment—Chirality and Host Volatiles Mean catches of *T. fuscum, T. cinnamopterum*, and *T. castaneum* were affected by the presence of host volatiles (Table 1; Fig. 5a–d). Mean catches of *T. cinnamopterum* (Fig. 5b), *T. fuscum* in Poland (Fig. 5c), and *T. castaneum* in Poland (Fig. 5d) also were affected by fuscumol chirality and the interaction between chirality and host volatiles (Table 1). Host volatiles, therefore, had a strong effect on catches of *Tetropium* spp. to fuscumol. Without the spruce blend and ethanol lures, only pure (*S*)-fuscumol captured more *T. fuscum* (Fig. 5c) and *T. castaneum* (Fig. 5d) than the control, and this occurred in Poland only. In Nova Scotia, fuscumol by itself [pure (*S*)-, pure (*R*)-, or racemic] was not attractive to *T. fuscum* (Fig. 5a) or *T. cinnamopterum* (Fig. 5b). However, adding either (*S*)-fuscumol or racemic fuscumol to traps baited with host volatiles synergized attraction of all three species, increasing catch of *T. fuscum* some 1.7X in Nova Scotia and 6X in Poland, and increasing catch of *T. cinnamopterum* and *T. castaneum* by 5X, and 17X, respectively.

(*S*)-Fuscumol was the active enantiomer in all three *Tetropium* species. Mean catch in traps baited with (*R*)-fuscumol plus host volatiles did not differ from that in traps baited with host volatiles only, and was less than that in traps baited with (*S*)-fuscumol plus host volatiles for all species (Fig. 5). However, presence of the (*R*)-enantiomer did not affect response of beetles to the active (*S*)-enantiomer: mean catch in traps baited with (*S*)-fuscumol or racemic fuscumol did not differ for any *Tetropium* species (Fig. 5).

The catch of *T. castaneum* in traps baited with fuscumol and host volatiles was similar to that of *T. fuscum*, with significant correlations in catch per trap (r=0.79, N=46, $P<0.001$). There was a similar correlation between catches of *T. fuscum* and *T. cinnamopterum* (r=0.49, N= 73, $P<0.001$).

Field Trapping Experiment—Release Rate Addition of fuscumol, at any release rate tested, to traps baited with host volatiles increased catch of *T. fuscum* in Nova Scotia ($F_{4,36}$=18.6, $P<0.001$, Fig. 6a), *T. cinnamopterum* ($F_{4,36}$= 35.1, $P<0.001$, Fig. 6b) and *T. castaneum* ($F_{4,40}$=42.8, $P<$ 0.001, Fig. 6d). In Poland, only the combination of fuscumol at the medium release rate (4 mg/d) plus host volatiles captured more *T. fuscum* ($F_{4,40}$=35.4, $P<0.001$) than did host volatiles alone (Fig. 6c). However, mean catch in traps baited with racemic fuscumol plus host volatiles did not differ among the high, medium, and low release rates of fuscumol for any *Tetropium* species (Fig. 6), in spite of a 32-fold difference in release rate.

The response to fuscumol release rates was similar among *Tetropium* species, with significant correlations in catch per trap between *T. fuscum* and *T. castaneum* in Poland (r=0.46, N=46, P=0.001) and between *T. fuscum* and *T. cinnamopterum* in Nova Scotia (r=0.74, N=46; $P<0.001$).

Responses of Males vs. Females For each *Tetropium* species, males and females responded similarly to the treatments, with the highest catches of both sexes occurring in traps baited with the combination of host volatiles plus either racemic or (*S*)-fuscumol (Figs. 5 and 6). However, catches in these treatments were also often female biased (Tables 2 and 3). In the chirality experiment, catch of females was correlated ($P<0.001$) with that of males for *T. fuscum* (r= 0.90, N=44, Poland; r=0.77, N=70 Nova Scotia), *T. cinnamopterum* (r=0.69, N=49) and *T. castaneum* (r= 0.91, N=42). Results were similar in the release rate experiment, with correlations ($P<0.001$) between numbers of males and females captured of *T. fuscum* (r=0.70, N=43, Poland; r=0.62, N=45, Nova Scotia), *T. cinnamopterum* (r=0.73, N=39) and *T. castaneum* (r=0.88, N=45).

For traps baited with a combination of host volatiles, plus either racemic or (*S*)-fuscumol, the chi square goodness-of-fit tests indicated a bias toward female catch in about half of the cases (Tables 2 and 3). This was most apparent for traps baited with high release rates of racemic fuscumol plus host volatiles, in which catches were female-biased for all three *Tetropium* species (Table 3). In contrast,

Table 1 ANOVA tables showing the effect of pheromone [(*S*)-fuscumol, (*R*)-fuscumol, racemic fuscumol, blank], host volatiles (spruce blend plus ethanol) and their interaction on mean numbers of *Tetropium* spp. (sexes pooled) captured per trap [data transformed by log(y+1)]

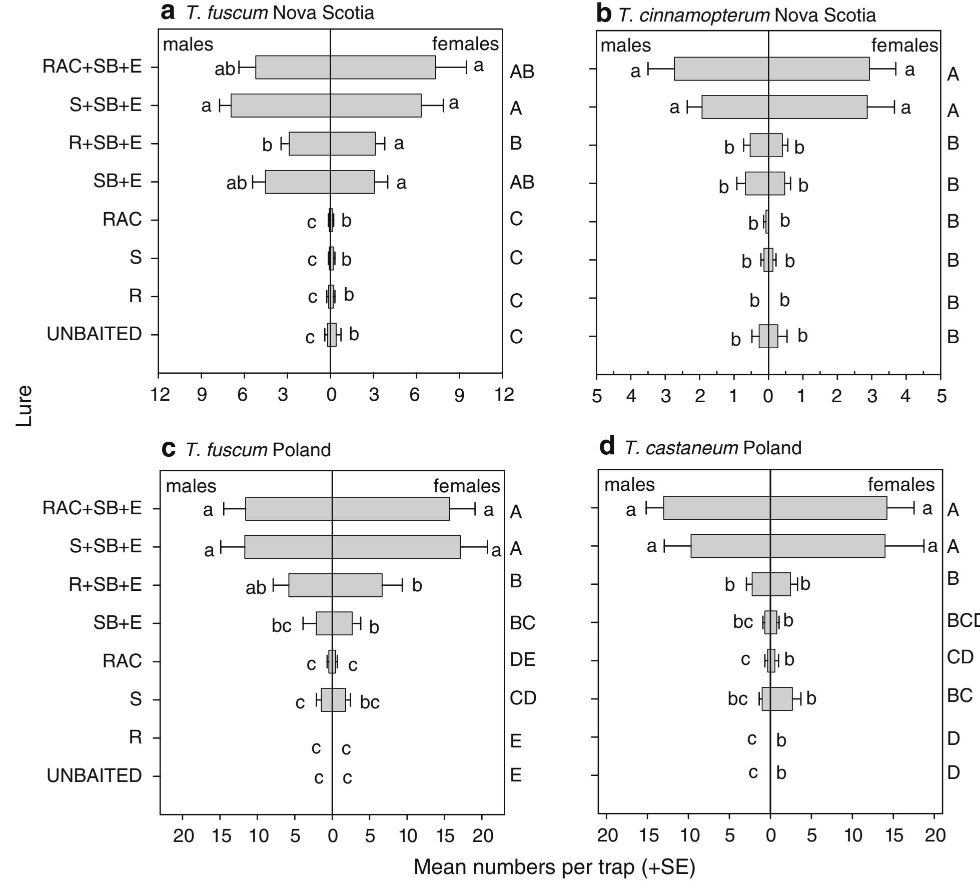

Fig. 5 Effect of fuscumol chirality on mean (+SE) total catch in intercept traps of: **a** *Tetropium fuscum* in Nova Scotia; **b** *T. cinnamopterum* in Nova Scotia; **c** *T. fuscum* in Poland; and **d** *T. castaneum* in Poland, in 2007. Traps were baited with fuscumol [racemic (RAC), S, or R enantiomers], either alone, or with spruce blend and ethanol (SB+E). Traps baited with SB+E only or left unbaited served as controls. *Lowercase letters* indicate significant differences in means within each species and sex; *uppercase letters* indicate significant differences in mean catch (sexes pooled) within species [ANOVA and Ryan-Einot-Gabriel-Welsh test on log(y+1) transformed data; P=0.05]

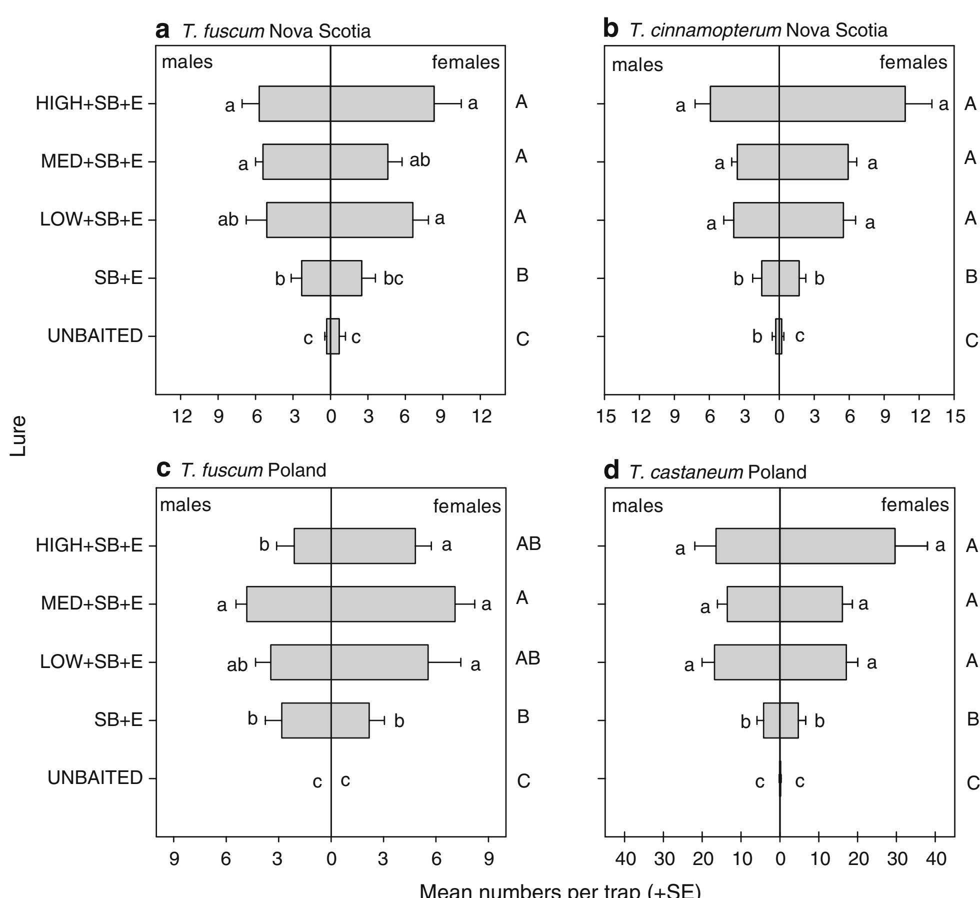

Fig. 6 Effect of racemic fuscumol release rate on mean (+SE) total catch in intercept traps of: **a** *Tetropium fuscum* in Nova Scotia; **b** *T. cinnamopterum* in Nova Scotia; **c** *T. fuscum* in Poland; and **d** *T. castaneum* in Poland, in 2008. Traps were baited with spruce blend and ethanol (SB+E) and fuscumol emitted at 32 mg/d (HIGH), 4 mg/d (MED), or 1 mg/d (LOW). Traps baited with SB+E only or left unbaited served as controls. *Lowercase letters* indicate significant differences within each species and sex; *uppercase letters* indicate significant differences in mean catch (sexes pooled) within species [ANOVA and Ryan-Einot-Gabriel-Welsh test on log(y+1) transformed data; P=0.05]

there was no female bias in traps baited with either host volatiles alone or (*R*)-fuscumol plus host volatiles (Tables 2 and 3). Catch of *T. fuscum* in Nova Scotia was male biased in traps baited with host volatiles alone (Table 2).

Discussion

We demonstrated that (*S*)-fuscumol [(2*S*,5*E*)-6,10-dimethyl-5,9-undecadienol], and not (*R*)-fuscumol, is emitted by males of the longhorn beetle species, *T. fuscum* and *T. cinnamopterum*, and that it synergizes long-range attraction of males and females of both species to host volatiles. Moreover, results from the trapping bioassays in Poland showed that the congener, *T. castaneum*, also is attracted to the combination of (*S*)-fuscumol and host volatiles, suggesting that males of this species also emit (*S*)-fuscumol; this requires chemical confirmation. Presence of the (*R*)-enantiomer did not, however, inhibit attraction of *T. fuscum, T. cinnamopterum*, or *T. castaneum* to the combination of (*S*)-fuscumol and host volatiles. Lack of an inhibitory effect of the antipode on the attractiveness of a natural pheromone enantiomer has been observed in several longhorn beetle species in the subfamily Cerambycinae (Lacey et al., 2004; Hanks et al., 2007).

The trapping bioassays confirm earlier findings (Silk et al., 2007) that fuscumol is only slightly attractive on its own, and that the presence of both host volatiles and fuscumol is necessary for increased and synergized attraction of *T. fuscum* and *T. cinnamopterum*, as well as *T. castaneum.* Synergy in attraction, to a combination of host volatiles and sex or aggregation pheromones, has been observed in other cerambycid species such as *H. bajulus* (Reddy et al., 2005b), *Anoplophora glabripennis* (Motschulsky) (Nehme et al., 2009), and *Monchamus galloprovincialis* (Pajares et al., 2010), as well as in many other phytophagous species in the Coleoptera, Diptera, and Lepidoptera (Landolt and Phillips, 1997).

The low level of attraction of females to fuscumol by itself and the synergistic effect in combination with host volatiles suggests that females should favor male *T. fuscum* that emit fuscumol (i.e., "call") on a suitable host tree. Indeed, we have evidence that *T. fuscum* males are induced to call by the presence of certain host volatiles (Silk et al., 2010). Lemay et al. (2010) observed <10% of *T. fuscum* males calling in clean laboratory Petri-dish bioassays, but

the frequency of calling increased in the presence of other males as well as the host volatiles, (*R*)-(−)-linalool and (3*Z*,6*E*)-α-farnesene (Silk et al., 2010).

The addition of fuscumol to traps baited with host volatiles synergized attraction of both sexes of *T. fuscum*, *T. cinnamopterum*, and *T. castaneum*, confirming that it functions as an aggregation pheromone. The most obvious function of such aggregation is for mating. By attracting females, males obviously increase their chances of finding mates. Responding males may benefit from increased encounters with responding females (Landolt and Phillips, 1997), while responding females may benefit by finding males, especially in low-density populations (Wertheim et al., 2005), as well as suitable hosts that may be scarce (Raffa et al., 1993). Other potential benefits of such aggregation to *T. fuscum* are "swamping" of natural enemies (Wertheim et al., 2005) or helping to overcome tree defenses and thereby increase colonization success, as shown for several Scolytine bark beetle-conifer systems (Borden, 1974). Similar to Scolytine bark beetles, *Tetropium* spp. are associated with ophiostomatoid fungi (Jacobs et al., 2003) and feed entirely in the phloem of

Table 3 Sex ratio of *Tetropium* species captured in traps baited with racemic fuscumol at three different release rates (HI=32 mg/d; MD=4 mg/d; LO=1 mg/d) plus the host volatile lures, spruce blend (SB), and ethanol (E), in Nova Scotia (NS) and Poland (PL) in 2008. Traps baited with host volatiles only and unbaited traps served as controls. *Chi square* tests were run only when expected counts were 5 or greater

freshly felled trees or living trees that are weakened, stressed, or dying (Juutinen, 1955; Schimitschek, 1929). However, the effects of attack density and the role of associated fungi on colonization success of *T. fuscum* are unknown.

Although the combination of fuscumol plus host volatiles attracted both sexes, we observed a significant bias toward female catch for all three *Tetropium* spp. In contrast, catches in traps baited with host volatiles alone were either unbiased or, in one case, male-biased. Juutinen (1955) reported a natural 1:1 sex ratio for *T. fuscum*, and we have observed the same ratio in more than a thousand *T. fuscum* and *T. cinnamopterum* reared from infested spruce bolts (Sweeney et al., unpublished data). Female-biased attraction to male-produced aggregation pheromones has been observed frequently in Scolytine bark beetles, suggesting that male-produced aggregation pheromones may have evolved from initial roles as sex pheromones for female attraction (Raffa et al., 1993).

Positive dose–response relationships, with sex or aggregation pheromones, have been found for many insect species, including the longhorn beetle, *H. bajulus* (Reddy et al., 2005a). In bark beetles and their predators, a positive pheromone dose–response relationship may depend on the presence of host kairomones (Miller et al., 2005). We did not observe a dose–response relationship with fuscumol release rates. However, we found differences in trap catch at different fuscumol release rates: catch of male *T. fuscum* in Poland in host-volatile traps increased only when fuscumol was added at the medium release rate, while fuscumol, added at the high rate to host volatiles, captured all three *Tetropium* spp. with a strong female bias. These results suggest that higher densities (i.e., release rates) of males on host trees would increase the ratio of females to males and consequently the probability of male mating success. Both sexes of *T. fuscum* mate repeatedly (Schimitschek, 1929; Juutinen, 1955), and repeated copulation improves egg fertilization rate (Schimitschek, 1929).

The attraction of three different *Tetropium* spp. to the combination of (*S*)-fuscumol and host volatiles suggests that cross-attraction and aggregation of congeners on host trees may occur in areas of sympatry. *Tetropium fuscum* and *T. castaneum* are sympatric over much of Europe (Juutinen, 1955) and, since the introduction of *T. fuscum* to Canada, this species and *T. cinnamopterum* co-occur in several counties of Nova Scotia. The lack of response to (*R*)-fuscumol, indicates that any pre-mating species-specific

responses that might exist among the three *Tetropium* spp. are not mediated by enantiomer-specific responses to fuscumol. If cross-attraction is not costly, or reproductive isolation is mediated by other mechanisms, then there would be no selection pressure for divergence in pheromones (Symonds and Elgar, 2007). We cannot rule out the possibility that there are additional, as yet undetected, pheromone components emitted by *Tetropium* males that reduce attraction of congeners, however, it is likely that reproductive isolation among *Tetropium* spp. is mediated, at least in part, by close-range mechanisms. As shown for several species of longhorned beetles (Ginzel and Hanks, 2003), there is evidence that males of *T. fuscum* and *T. cinnamopterum* recognize conspecific females (i.e., are elicited to stop, mount, and copulate) by species-specific cuticular hydrocarbons or blends that act as contact pheromones (Silk et al., unpublished).

In summary, we have shown that (*S*)-fuscumol, and not (*R*)-fuscumol, is emitted by males of *T. fuscum* and *T. cinnamopterum*, and this compound synergizes the attraction of *T. fuscum, T. cinnamopterum*, and *T. castaneum* to host volatiles. The presence of the (*R*)-enantiomer in synthetic racemic fuscumol did not inhibit attraction of any of the *Tetropium* spp. These results have practical benefits for trapping surveys of *Tetropium* spp., particularly surveys for early detection of the potential invasive species, *T. fuscum* and *T. castaneum* in North America, because a single trap can target more than one species and racemic fuscumol is easier and cheaper to synthesize than (*S*)-fuscumol. Indeed, synthetic fuscumol has been used in surveys for monitoring the spread of *T. fuscum* in Canada and the United States since 2007, and has enabled detection of the beetle in more than 40 new locations outside of the quarantine zone in Nova Scotia (Cunningham, 2010).

Acknowledgements We thank the Canadian Food Inspection Agency, Natural Resources Canada—Canadian Forest Service (Forest Invasive Alien Species Fund), and (through the auspices of Spray Efficacy Research Group International) Forest Protection Limited (NB), Ontario Ministry of Natural Resources, and the Nova Scotia Ministry of Natural Resources for generous funding and in-kind support. We thank M. Rhainds, D. Pureswaran, G. LeClair, C. Simpson and two anonymous reviewers for helpful comments on an earlier version of this manuscript, H. Mills for help with synthetic chemistry, M. Lavigne for help with graphics, J. Price, N. Brawn, K. Burgess, A. Doane, B. Guscott, N. Harn, S. Laity, W. MacKay, K. O'Leary, A. Papageorgiou, S. Richards, A. Sharpe, D. Seaboyer, K. Sućko, and T. Walsh for technical assistance, L. Hanks, E. Lacey, J. Millar, and A. Ray for advice, and N. Carter, D. Davies, E. Hurley, and T. Scarr for support. Whitten (Givaudan, Switzerland) personal communication], suggesting that it may be a behaviorally active compound that is collected actively by males. This has remained speculative, though, since HHA failed to lure male orchid bees in previous bioassays (M. Whitten and G. Gerlach personal communication; T. Eltz unpublished data.). However, HHA is a chiral compound, and the tested synthetic product was a mix of unknown isomeric composition (R. Kaiser personal communication), leaving room for further investigation. In the present study, we determined the stereochemistry of HHA in tibial extracts of three species of *Euglossa*. Furthermore, we synthesized an optically pure RR-HHA [(6*R*, 10*R*)-6,10,14-trimethylpentadecan-2-one] in addition to a mixture of the four possible optical isomers of HHA. Bioassays were conducted in southern Mexico and Panama to test behavioral attractiveness to male orchid bees.

Methods

Identification and Stereochemistry of 6,10,14-Trimethylpentadecan-2-one in Extracts of Euglossa Species Hexane extracts of pairs of hind legs of individual male *Euglossa imperialis*, *E. allosticta,* and *E. crassipunctata* (one each) were purified on a 500 mg Strata SI-1 Silica Teflon coated solid phase column with stepwise gradient elution using 1–11% ethyl acetate in pentane in steps of 1%. An elution and collection volume of 750 µl for each fraction was used, with twice the volume for fractions 4–6. These fractions, containing the ketone, were combined and evaporated to dryness under a stream of argon at room temperature, and then were redissolved in 1 ml of pentane and washed with 200 µl of 0.2 M KOH. The organic layer was collected and dried with sodium sulfate before it was evaporated to dryness under a stream of argon at room temperature and finally redissolved in 50 µl cyclohexane.

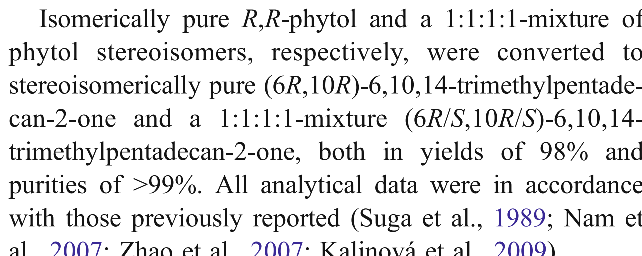
The ketone in the purified extract was reduced to alcohol with lithium aluminum hydride according to standard method, and then was derivatized with (R)-(+)-trans-chrysanthemoyl chloride (Brooks et al., 1973). The diastereomers were analysed with a Hewlett-Packard 6890N gas chromatograph (GC) with a polar Varian factorFOUR VF-23ms column (30 m×0.25 mm i.d., d_f=0.25 µm) and an HP 5973 mass spectrometer (GC-MS) in SIM mode (m/z=123, 124, 153, and 168). The carrier gas (1 ml/min) was helium; 1 µl of the sample was injected splitless, the injector temperature was 250°C, and the aux temperature was 280°C. The column temperature was increased from 50°C by 10°C/min up to 110°C, from 110°C by 0.01°C/min up to 115°C, and from 115°C by 10°C/min up to 230°C.

Identification was made by comparing the retention times and mass spectra of the unknown alcohol derivatives with a reduced and derivatized synthetic reference mixture of all four stereoisomers of 6,10,14-trimethylpentadecan-2-one and also with a derivatized synthetic reference mixture of (2*S*,6*R*,10*R*)- and (2*R*,6*R*,10*R*)-6,10,14-trimethylpentadecan-2-ol. Reduction of the ketone to the alcohol creates a new stereogenic center at the carbon with the formed hydroxyl group, which is disregarded when the stereochemistry of the original ketone is determined. Identification also was made by comparing the GC/infra red (GC/FT-IR) spectrum of the ketone in the extract with that of the synthetic ketone.

Chemicals Commercially available chemicals were used without further purification. Stereoisomerically pure (*R*,*R*)-phytol was purchased from TCI America. Preparative liquid chromatography was performed on normal-phase silica gel (Merck 60, 230–400 mesh, 0.040–0.063 mm, 10–50 g/g of product mixture) employing a gradient technique with an increasing concentration (0–10%) of distilled ethyl acetate in distilled cyclohexane. Progress of the reaction was monitored with thin layer chromatography on silica gel plates (Merck 60, precoated aluminium foil) using ethyl acetate (40%) in cyclohexane as an eluent. Plates were visualized with ultraviolet irradiation and/or by spraying with vanillin in sulfuric acid and heating at 120°C. Purity of the product was checked by GC on a Varian 3300 GC instrument using a capillary column (EC-1, 30 m×0.32 mm i.d, d_f=0.25 µm, with nitrogen as carrier gas and a split ratio of 1:20). The temperature was programmed for 2 min at 100°C followed by 10°C /min up to 300°C. GC-MS analyses were carried out on a Saturn 2000 GC/MS/MS instrument with a Varian 3800 GC instrument, using a capillary column (CP-Sil 5 CB, 30 m×0.32 mm i.d, d_f=0.25 µm, carrier gas helium, column flow = 1 ml/min, split ratio 1:20) and the temperature program described above. GC/FT-IR analysis of the natural and synthetic compounds was carried out on a Thermo Scientific Nicolet 6700 FT-IR spectrophotometer, coupled via an GC/FT-IR interface to an Agilent 7890A GC with a polar Varian factorFOUR VF-23ms column (30 m×0.25 mm i.d., d_f=0.25 µm). The carrier gas (1 ml/min) was helium; 1 µl of the sample was injected splitless, the injector temperature was 250°C, and the transfer line and flow cell temperature were both set at 250°C. The column temperature was increased from 50°C by 10°C/min up to 230°C, and kept at 230°C for 10 min. Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Avance 500 (500 MHz ^{1}H, 125.8 MHz ^{13}C) spectrometer using $CDCl_3$ as solvent and TMS as internal standard.

Oxidizing phytol with $NaIO_4$ and a catalytic amount of $RuCl_3$ (Sasaerila et al., 2003) gave pure (6*R*/*S*,10*R*/*S*)-6,10,14-trimethylpentadecan-2-one in near quantitative yield. Synthesis of (6*R*, 10*R*)-6,10,14-trimethylpentadecan-2-one was performed using the same method from stereoisomerically pure (*R*,*R*)-phytol.

Bioassays The *RR*-HHA and the 1:1:1:1 stereoisomeric mixture of HHA were dissolved at 100 mg/ml in pentane (Uvasol, Merck, Germany). Bioassays were conducted on 2 days in two different forest localities (near Palenque and near Lancanja, Chiapas) in southern Mexico in September 2008, and on 3 days in one forest locality in Central Panama (Barro Colorado Island) in May 2009. Aliquots of 50 µl of test solutions and solvent controls were pipetted onto filter papers (Whatman 1, 2.5 cm) pinned to trees at breast height. Filter papers were observed between 0900 to 1200 and refreshed once or twice during the morning with additional aliquots of 50 µl of test solution or solvent. We routinely exposed other synthetic chemical bait compounds (e.g., 1,8-cineole, methyl salicylate, *p*-dimethoxybenzene) in the vicinity. Those were of much higher absolute concentration than the HHA lures and at least 5 m away from them. Males were only counted as having visited a HHA lure when they had landed on the respective filter paper and performed characteristic volatile collecting behavior.



Isomerically pure *R*,*R*-phytol and a 1:1:1:1-mixture of phytol stereoisomers, respectively, were converted to stereoisomerically pure (6*R*,10*R*)-6,10,14-trimethylpentadecan-2-one and a 1:1:1:1-mixture (6*R*/*S*,10*R*/*S*)-6,10,14-trimethylpentadecan-2-one, both in yields of 98% and purities of >99%. All analytical data were in accordance with those previously reported (Suga et al., 1989; Nam et al., 2007; Zhao et al., 2007; Kalinová et al., 2009).

In bioassays both the (6*R*,10*R*)-6,10,14-trimethylpentadecan-2-one and the stereoisomeric 1:1:1:1-mixture attracted male euglossine bees in southern Mexico and Panama (Table 1), whereas solvent controls were not attractive. Overall, the (6*R*,10*R*)-6,10,14-trimethylpentadecan-2-one attracted more individuals and species than the 1:1:1:1-mix. Generally, the HHA lures attracted relatively few bees in comparison with other synthetic compounds that were exposed at the same time (data not shown). On several occasions, a male *E. imperialis* first was attracted to a 1,8-cineole bait and subsequently visited a HHA filter paper.

Results

HHA in hind leg pouches of male *Euglossa imperialis*, *E. allosticta*, and *E. crassipunctata* is optically pure (6*R*,10*R*)-6,10,14-trimethylpentadecan-2-one, based on comparison with synthetic reference mixtures of known stereoisomeric composition (Figs. 1 and 2).

Discussion

Our analytical results demonstrate that HHA in male *Euglossa* hindleg pouches is (6*R*,10*R*)-6,10,14-trimethylpentadecan-2-one. This is in agreement with HHA being chemically derived from phytol [(2E,7*R*,11*R*)-3,7,11,15-tetramethyl-2-hexadecen-1-ol] from source plants. We further show that (6*R*,10*R*)-6,10,14-trimethylpentadecan-2-

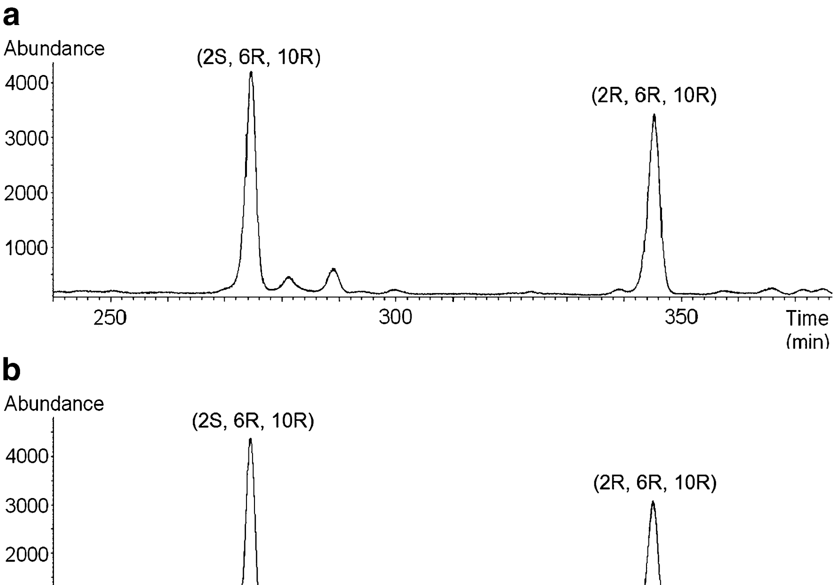


Fig. 1 **a** GC-MS chromatogram of a derivatized synthetic mixture of (2*S*,6*R*,10*R*)- and (2*R*,6*R*,10*R*)-6,10,14-trimethylpentadecan-2-ol. **b** GC-MS chromatogram of a reduced and derivatized extract from *Euglossa crassipunctata*. Two peaks appear due to an extra stereogenic centre created by the reduction of the ketone to alcohol. Extracts from *E. imperialis* and *E. allosticta* show the same result

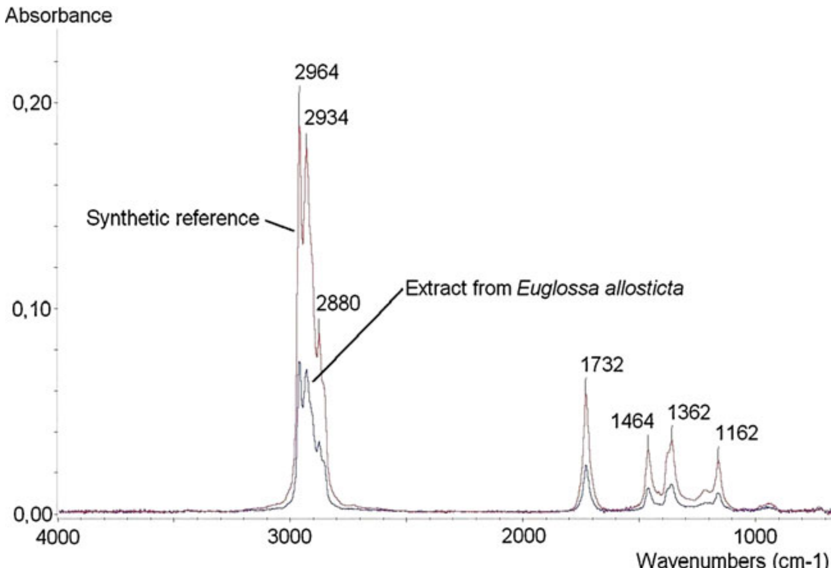

Fig. 2 GC/FT-IR spectra of synthetic (6*R*,10*R*)-6,10,14-trimethylpentadecan-2-one and extract of *Euglossa allosticta*

one is a behaviorally active component for males of at least six species of euglossine bees that actively approached and collected the compound. Probably, extended bioassays would further extend the list of responsive taxa, especially with regard to rarer euglossine species. However, it should be noted also that our bioassays in Panama failed to attract *Euglossa despecta*, a species that has large quantities of HHA in its hindlegs (Zimmermann et al., 2009) and that was common at other chemical baits at the time of the study. Generally, HHA did not attract as many male bees as did some of the traditional synthetic bait compounds such as 1,8-cineole, methyl salicylate, or *p*-dimentoxybenzene. This may in part be explained by the relatively lower concentration of HHA in our bioassays, but probably also by its low volatility. HHA has a molecular weight of 268, whereas the mentioned other attractants have molecular weights around 150. In fact, HHA is the largest natural molecule known to date that attracts male orchid bees in pure form (Williams and Whitten, 1983; Ramírez et al., 2002). Its attractiveness to males, along with the recent discovery of other male-attracting semivolatiles in euglossine fragrances (Eltz et al., 2008; Ramírez et al., 2010), suggests that these larger and less volatile compounds are functionally important in the male signal. On one hand, they might act as a matrix or fixative for more volatile components such as mono- and sesquiterpenes (Eltz et al., 2007). On the other hand, they might represent the characteristic core of the fragrance signal, which is ornamented with more volatile but ubiquitous additives. In other words, the large and heavy components may represent the "base note" of a complex and multi-layered male odor.

Table 1 Number of males of different species of orchid bees visiting filter papers impregnated with either (6*R*,10*R*)-6,10,14-trimethylpentadecan-2-one or a 1:1:1:1-mixture of (6*R*/*S*,10*R*/*S*)-6,10,14-trimethylpentadecane-2-one at equal (overall) concentration. Solvent (pentane) controls attracted no bees at all. Data were pooled across localities/dates for Mexican and Panamanian bioassays

Little is known about the natural source(s) of HHA for male euglossine bees. Among the many floral scents and essential oils analyzed by R. Kaiser (personal communication), HHA is relatively widespread, but occurs normally only as a minor component. Notable exceptions are a small number of euglossophilous orchids, in which HHA is the dominant compound found in the floral headspace (>50% of peak area): *Polycycnis ornata, Kegeliella kupperi*, *Acineta alticola*, and *Soterosanthus shepheardii* (R. Kaiser and M. Whitten personal communication). However, it is doubtful whether any of these orchids would be present in sufficient population densities to represent a significant HHA source for orchid bees. The outstanding abundance of HHA in male fragrances (Zimmermann et al., 2009) suggests rather that HHA sources are highly available, i.e., not orchids. Euglossine-pollinated aroids seem more likely candidates. HHA represented about half of the

volatiles in the headspace of inflorescences of *Anthurium thrinax*, an euglossophilous aroid from French Guyana (Hentrich et al., 2010). Among the male *Euglossa* visiting this plant for fragrance collection, the majority were *Euglossa hemichlora* (Hentrich et al., 2010), a widespread species that also collected HHA in southern Mexico and Panama (Zimmermann et al., 2009, this paper). *Anthurium thrinax* is restricted to the Guianas; other euglossophilous congeners occur in Central America (Dressler, 1968), but their floral scent has not been investigated.

Acknowledgements We are grateful to Falko Fritzsch and Carlos Hernandez Velez for help in the field. TE is supported by the Deutsche Forschungsgemeinschaft (EL 249/4 and 6) and EH, JB, EW and JA are grateful for the financial support from EU (Objective 2 the region of South Forest Counties) and Länsstyrelsen i Västernorrlands län.

attraction is so powerful that the lure has been used in the male annihilation technique to eradicate *B. dorsalis* (e.g., in Okinawa, Japan) (Steiner et al., 1965; Koyama et al., 1984). *Bactrocera dorsalis* males that have fed on ME sequester the metabolite phenylpropanoids, (*E*)-coniferyl alcohol and 2-allyl-4,5-dimethoxyphenol, in their rectal glands, and use them as a sex pheromone attractive to females, as well as for defense against predators (Nishida et al., 1988a; Shelly and Dewire, 1994; Tan and Nishida, 1998; Hee and Tan, 1998; Khoo et al., 2000; Wee and Tan, 2001). Although *B. correcta* males have a strong affinity to ME, nothing is known about the acquisition of ME in the rectal gland nor the ecological significance of the metabolites in this species. Our preliminary analyses of *B. correcta* revealed an entirely different composition of ME metabolites in the rectal gland from those found in *B. dorsalis*. This prompted us to examine rectal volatiles in *B. correcta*, as it may provide a clue for understanding the role of the sex pheromone in promoting reproductive isolation between sympatric populations of these species.

Methods and Materials

Insects Bactrocera correcta were raised on an artificial diet, developed for the Sterile Insect Technique mass rearing program, at 26±2°C and 65–70% RH, under a photoperiod of 12L:12D (light intensity 2000 Lux) at the Irradiation for Agricultural Development Sub-Division Bureau of Agricultural Production Quality Development, Department of Agricultural Extension, Bangkok, Thailand (Orankanok et al., 2007).

Instruments Proton nuclear magnetic resonance (^{1}H-NMR) spectra were measured in $CDCl_3$, with a Bruker Avance 400 FT-NMR, using TMS as an internal standard (J-values are given in Hz; letters s, d, t, m represent singlet, doublet, triplet, and multiplet, respectively). Electron ionization (EI), gas chromatography-mass spectrometry (GC-MS) analyses were performed on an Agilent 5975 inert XL mass spectrometer coupled with an Agilent 6890 gas chromatograph. The GC was fitted with an HP-5MS capillary column (28 m×0.25 mm, 0.25 μm film thickness), which was programmed from 60°C (1 min. holding) to 280°C at 10°C.min^{-1}. Helium was the carrier gas.

Feeding Test and Sample Preparation (1) Laboratory-reared males of *B. correcta* (11-d-old after eclosion, segregated from females) were fed on ME (Aldrich Chemicals Co., Milwaukee, WI, USA), impregnated (10 μl/disc) on small filter paper discs (Advantec, antibiotic test disc, thick, 8-mm diam.), from 15:30–16:00. Adults were then kept in small plastic cages with a sugar-yeast hydrolysate mixture and water. Rectal glands were dissected from males 6 or 24 hr after treatment, and each gland was extracted with ethanol (250 μl). After GC quantification of each individual sample, 10 male rectal gland extracts were combined and chromatographed on a silica gel column (Wako gel C-200, 0.3 g, Wako Pure Chemical Industries, Japan), eluting in sequence with mixtures containing increasing concentration of ethyl acetate in hexane. Major phenylpropanoids, **1** and **2**, were eluted with 25% ethyl acetate in hexane, and purified further by HPLC (YMC-pack SIL, 300×10 mm i.d., S-5 μm), with 66% ethyl acetate in hexane (2.5 ml.min^{-1}) as the mobile phase. The two compounds eluted at retention times of 13.8 and 14.4 min, respectively. (2) In order to examine the propensity to sequester sesquiterpene hydrocarbons by *B. correcta*, laboratory-raised males (15 d after eclosion, segregated from females) were exposed for several minutes to small filter paper discs (same as above) treated with a mixture of ME (1 mg/disc), β-caryophyllene (2 mg/disc), and α-humulene (2 mg/disc). The treated flies were kept with a sugar-yeast hydrolysate mixture for 24 hr and individuals were extracted with ethanol (500 μl). Amounts of compounds in each whole body extract were quantified by GC analysis.

Field Trapping of Male Flies (1) Male *B. correcta* were collected in Bangkok (Wireless Rd, Bangkok 10330, Thailand) on November 24, 2006, using ME traps. Rectal glands were dissected from males, and each gland extracted with ethanol (250 μl). (2) In a similar manner, males of *B. correcta* and *B. dorsalis* were collected in a mixed fruit orchard in Northern Bangkok on November 30, 2007, using ME as a lure (males could not contact the lure). Males were soaked individually in small vials, each with 250 μl ethanol, after identification to species. (3) In order to examine the attractiveness of sesquiterpene hydrocarbons, wild male flies were captured in sticky traps, either with ME (5 mg/rubber septum) or a sesquiterpene mixture (β-caryophyllene + α-humulene, 5 mg each/rubber septum) at a mango orchard (15°21′36″ North; 99°38′15.7″ East) on July 3, 2009, and at a guava orchard (14°07′55.559″ North; 100°48′28.762″ East) in Thailand on July 24 and August 24, 2009. Trapped flies were removed from the sticky board and soaked individually in 250 μl ethanol for species identification and chemical analysis.

Chemicals A geometry-selective Horner-Emmons reaction was employed for syntheses of (*Z*)-3,4-dimethoxycinnamyl alcohol and (*Z*)-coniferyl alcohol. An ylide was prepared from bis(2,2,2-trifluoroethyl)(methoxycarbonylmethyl) phosphonate (Aldrich Chemicals Co.) (3.3 g, 10.3 mmol) and 18-crown-6 (10.9 g, 41.6 mmol), dissolved in THF (50 ml), followed by mixing with 20.0 ml (10.1 mmol,

0.5 M in toluene) of potassium bis(trimethylsilyl)amide [KN(TMS)$_2$] (Aldrich Chemicals Co.) under a N_2 current (−78°C). 3,4-Dimethoxybenzaldehyde (2.0 g, 12.0 mmol, Wako Pure Chemical Industries) dissolved in THF was added to the above with a syringe and stirred for 30 min. After usual work-up and purification by silica gel column chromatography (Wako gel C-200, 10 g, eluting with 20% ethyl acetate in hexane), methyl (*Z*)-3-(3,4-dimethoxyphenyl)-2-propenoate 2.43 g (yield: 91%) was obtained as a solid. The methyl ester (960 mg, 4.32 mmol) was dissolved in anhydrous toluene (20 ml) in a three-necked flask, and DIBAL (40 mmol, 1.0 M in hexane, Wako Pure Chemical Industries) added slowly at 0°C; the reaction mixture was held at this temperature for 1 hr. The ethyl acetate-soluble reaction mixture was eluted with 30% ethyl acetate in hexane from silica gel (Wako C-200, 10 g) to yield 700 mg (yield: 83%, >96% *Z*) of (*Z*)-3,4-dimethoxycinnamyl alcohol as a colorless solid. Likewise, (*Z*)-coniferyl alcohol (>98% *Z*) was obtained as a crystalline mass by reacting the ylide with *O*-acetyl vanillin (prepared by acetylation of vanillin in acetic anhydride-pyridine), followed by reduction with DIBAL in toluene. Authentic samples of sesquiterpenes, (–)-β-caryophyllene (Sigma Chemical Co., St. Louis, MO, USA), and α-humulene and (–)-alloaromadendrene (Fluka Chemie AG, Buchs, Switzerland) were purchased.

Quantification of Rectal Volatiles Ethanolic extracts of rectal glands from *B. correcta* males were quantified using a Hewlett Packard 5890 Series II Plus GC, equipped with a flame ionization detector and an HP-5MS (15 m×0.25 mm i.d, 0.25 μm film thickness) column, and an Agilent 5975 inert/N MSD Chemstation. One microliter of each rectal gland sample from laboratory-raised males fed on methyl eugenol, containing an internal standard (1-hexadecanol; Wako Pure Chemical Industries, Japan), was analyzed by GC. For whole body samples of wild *B. correcta* males, and for laboratory-raised males fed on a mixture of methyl eugenol + β-caryophyllene + α-humulene, 1-pentadecanol (Aldrich Chemicals Co.) was used as an internal standard.

Preparation of a Sesquiterpene Fraction from Wild B. correcta Males Ethanolic extracts of field-trapped *B. correcta* males (9 specimens that contained sesquiterpenes), captured at the Bangkok site (2) on November 30, 2007, were combined, and the solvent was removed *in vacuo* (below 35°C). The residue was dissolved in a small amount of hexane and passed through a short column of silica gel (0.30 g of Wako gel C-200). The fraction eluting with hexane (3 ml) was used to obtain a ^{1}H-NMR spectrum.

Molecular Cloning and Sequence Analysis Total DNA extraction, PCR amplification, and sequence analysis were carried out as described in a companion paper (Tan et al., unpublished). PCR amplifications were performed for the rDNA containing a part of the 16S rRNA gene, the tRNA^{val} gene, and a part of the 12S rRNA gene, in male fly specimens obtained from two different outdoor locations, to compare with those from the laboratory strain (Tan et al., unpublished). The DNA sequence data have been deposited in Genbank under the following accession numbers: (1) AB569585 [Northern Bangkok City (Nov. 30, 2007)], and (2) AB569586 [Guava orchard (14°07′55.559″ North; 100°48′28.762″ East, August 24, 2009)].

Results

Sequestration of ME Metabolites in Rectal Glands Within 24 hr after feeding on ME, two phenylpropanoid volatiles, **1** and **2** (Fig. 1), increased in quantity in male rectal glands. These chemicals were in approximately equal amounts. After isolation of pure **1** and **2** by preparative HPLC, ^{1}H-NMR of both compounds showed a typical cinnamyl olefinic moiety with a coupling constant between H-2 and H-3 of J=11.6 or 11.7 Hz, confirming the geometry to be *Z*. These compounds were identified as (*Z*)-coniferyl alcohol (1, *cis*-4-hydroxy-3-methoxycinnamyl alcohol) and (*Z*)-3,4-dimethoxycinnamyl alcohol from the spectrometric data below and by comparison with the data of the authentic compounds.

(*Z*)-Coniferyl alcohol (**1**). GC relative retention index on HP-5MS: 1682. EI-MS: *m/z* (%): 180 (58, M$^+$), 162 (48), 147 (44), 137 (100), 124 (53), 119 (36), 103 (21), 91 (60), 77 (23), 65 (22). ^{1}H-NMR δ (ppm): 3.90 (3H, s, OCH_3), 4.44 (2H, double d, $J_{1\text{-}2}$=6.5, $J_{1\text{-}3}$=1.6, H-1), 5.63 (1H, s, OH), 5.79 (1H, double t, $J_{2\text{-}3}$=11.7, $J_{2\text{-}1}$=6.5, H-2), 6.52 (1H, d, $J_{3\text{-}2}$=11.7, H-3), 6.74 (1H, double d, $J_{6'\text{-}5'}$=8.1, $J_{6'\text{-}2'}$=1.9, H-6′), 6.77 (1H, d, $J_{2'\text{-}6'}$=1.9, H-2′), 6.89 (1H, d, $J_{6'\text{-}5'}$=8.1, H-5′).

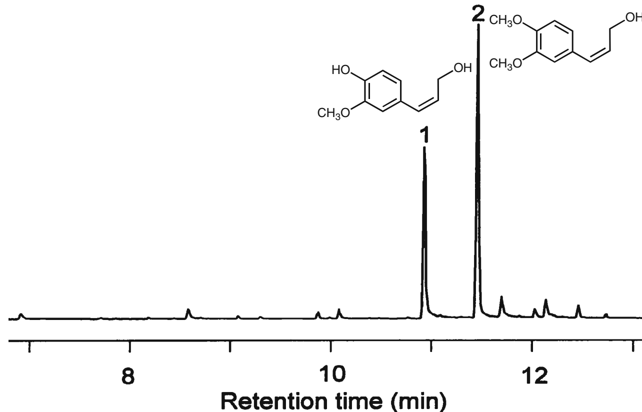

Fig. 1 Gas chromatogram of rectal gland volatiles in *Bactrocera correcta* 24 h after feeding on methyl eugenol [**1**: (*Z*)-coniferyl alcohol, **2**: (*Z*)-3,4-dimethoxycinnamyl alcohol]

(*Z*)-3,4-Dimethoxycinnamyl alcohol (**2**). GC relative retention index on HP-5MS: 1727. EI-MS: *m/z* (%) 194 (66, M^+), 176 (54), 165 (14), 161 (29), 151 (100), 138 (50), 115 (16), 105 (21), 91 (30), 77 (25). ^{1}H-NMR δ (ppm): 3.89 (3H, s, OCH_3), 3.90 (3H, s, OCH_3), 4.45 (2H, double d, $J_{1\text{-}2}$=6.5, $J_{1\text{-}3}$=1.6, H-1), 5.80 (1H, double t, $J_{2\text{-}3}$=11.6, $J_{2\text{-}1}$=6.5, H-2), 6.51 (1H, d, $J_{3\text{-}2}$=11.6, H-3), 6.78 (1H,dd, $J_{6'\text{-}5'}$=9.6, $J_{6'\text{-}2'}$=1.8, H-6′), 6.79 (1H, d, $J_{2'\text{-}6'}$=1.8, H-2′), 6.85 (1H, d, $J_{6'\text{-}5'}$=9.6, H-5′).

No other ME metabolites were detected in significant amounts in the rectal glands, although ME was present in a trace amount in glands 6 hr after treatment. Mean amounts (µg/male ± SD) of **1** and **2**, respectively, after ingestion of ME were 2.66±4.0 and 4.7±8.8, 6 hr after treatment, and 54.9±26.8 and 40.0±14.6, 24 hr after treatment (*N*=10 for each time). Thus, the total amount of **1** + **2** was roughly 10 µg/male, 6 hr after feeding on ME, and had increased to nearly 100 µg/male, 24 hr after feeding on ME.

Volatiles in the Rectal Glands of Wild Flies Whole body extracts of *B. correcta* males, captured at various sites in Thailand using ME-baited traps, were made and analyzed. Among 24 males captured in Bangkok (November 30, 2007), 16 (67%) contained both or either of **1** and/or **2** in varying quantities (Fig. 2). However, 9 of the 24 males (38%) possessed three major compounds, **3**, **4**, and **5**, in much larger quantities than compounds **1** and **2**, accompanied by several other related minor components, all of which exhibited a molecular ion at *m/z* 204, characteristic of sesquiterpene hydrocarbons. Compounds **3**, **4**, and **5** were identified as β-caryophyllene, α-humulene, and alloaromadendrene, respectively (Fig. 3), from the retention indices (on HP-5MS), mass fragmentation patterns, and diagnostic ^{1}H-NMR spectra of the sesquiterpene fraction (hexane eluate on silica gel chromatography) isolated from a whole body extract.

Compound **3** (β-caryophyllene). GC relative retention index on HP-5MS: 1435. EI-MS: *m/z* (%): 204 (5, M^+), 189 (20), 175 (10), 161 (34), 147 (29), 133 (90), 120 (42), 105 (58), 93 (100), 91 (80), 79 (69), 69 (79), 55 (30), 41 (60). ^{1}H-NMR δ (ppm): 0.98 (3H, s) 1.00 (3H, s), 1.61 (3H, s), 4.82 (1H, s), 4.94 (1H, s), 5.30 (1H, m).

Compound **4** (α-humulene). GC relative retention index on HP-5MS: 1470. EI-MS: *m/z* (%): 204 (4, M^+), 189 (3), 161 (3), 147 (15), 121 (28), 107 (16), 93 (100), 80 (32), 55 (9). ^{1}H-NMR δ (ppm): 1.06 (3H, s), 1.43 (3H, s) 1.64 (3H, s), 1.93 (2H, d, *J*=7.1), 2.51 (2H, d, *J*=7.4), 4.87 (1H, t, *J*=8.4), 5.16 (1H, d, *J*=15.9), 5.60 (1H, double t, *J*=15.9 and 7.4).

Compound **5** (alloaromadendrene). GC relative retention index on HP-5MS: 1477. EI-MS: *m/z* (%): 204 (29, M^+), 189 (34), 161 (95), 147 (56), 133 (71), 119 (64), 107 (74), 105 (89), 93 (81), 91 (100), 79 (69), 69 (66), 55 (35), 41 (58). ^{1}H-NMR δ (ppm): 0.25 (1H, double d, *J*=9.4 and 10.8), 0.55 (1H, double double d, *J*=6.2, 9.4, 10.9), 0.94 (3H, d, *J*=6.8), 0.96 (3H, s, H-1), 1.00 (3H, s), 2.67 (1H, q, *J*=8.1), 4.72 (2H, m).

The mean quantities of the three sesquiterpenes in the bodies of the nine males are given in Fig. 4, with total amounts of the three compounds as high as 250 µg/male. However, as shown in Fig. 2, the profiles of sesquiterpenes

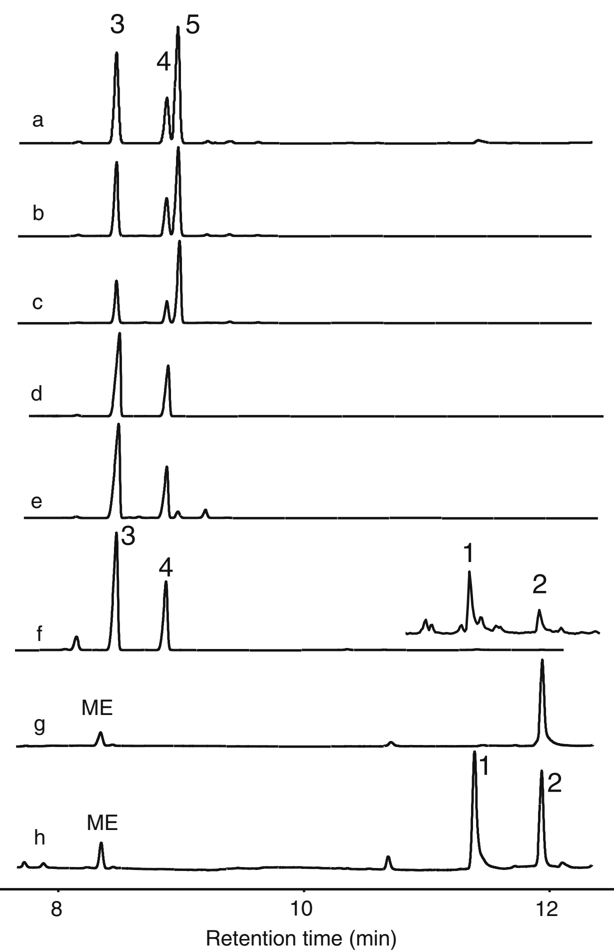

Fig. 2 Gas chromatogram of rectal gland volatiles in individual males (a-h) of *Bactrocera correcta* captured in Bangkok, Thailand (Nov. 30, 2007). All chromatograms show flame ionization detection only, except sample "f", for which mass spectral total ion current detection is also shown because of the trace amounts of compounds **1** and **2**. ME = methyl eugenol. ME-metabolites **1**: (*Z*)-coniferyl alcohol, **2**: (*Z*)-3,4-dimethoxycinnamyl alcohol. Sesquiterpenes **3**: β-caryophyllene, **4**: α-humulene, **5**: alloaromadendrene

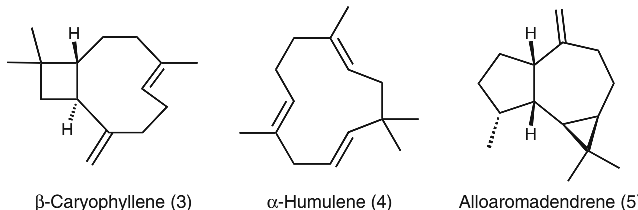

Fig. 3 Sesquiterpene hydrocarbons sequestered in the rectal gland of wild *Bactrocera correcta* males collected in Thailand (relative stereochemistry is shown for compounds **3** and **5**)

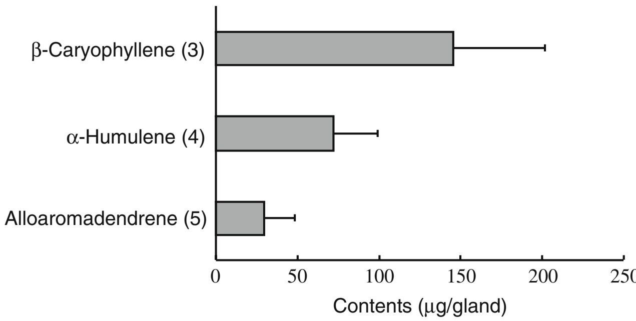

Fig. 4 Mean amounts (±SE) of rectal sesquiterpenoids in 9 *Bactrocera correcta* males captured in Bangkok, Thailand (November 24, 2006)

in each male differed from each other and could be classified roughly into two types: a "β-caryophyllene + α-humulene + alloaromadendrene (**3** + **4** + **5**)" type, in which **5** was frequently the most abundant component (e.g., a-c in Fig. 2), and a "β-caryophyllene + α-humulene (**3** + **4**)" type, in which **3** was greater in quantity (e.g., d-f in Fig. 2). In both types, trace amounts (<1.0 μg/male) of ME-metabolites **1** and **2** were detected. In contrast, some males (e.g., g and h in Fig. 2) possessed large quantities of **1** and/or **2**, but only trace amounts of sesquiterpenes. A small amount of unmetabolized ME was detected in gas chromatograms "g" and "h" (whole body extracts) (Fig. 2).

The above quantifications were carried out using whole body extracts of males. In order to determine the reservoir site of the sesquiterpenes, the rectal gland was dissected from 5 males of *B. correcta* captured in Bangkok (November 24, 2006), and analyzed by GC-MS. All rectal glands possessed ME metabolites **1** and **2** in varying quantities, ranging from 0.1 μg to 10 μg/gland, and sesquiterpenes **3**, **4**, and **5** in much larger quantities (over 250 μg total/gland; mean ± SD/gland: β-caryophyllene (**3**), 134.5±84.5 μg; α-humulene (**4**), 86.6±64.2 μg; alloaromadendrene (**5**), 41.8±42.5 μg; total, 262.1±115.5 μg, N=5].

Incorporation of ME Metabolites and Sesquiterpenes In order to determine a fly's ability for accumulating sesquiterpenes and ME-metabolites, laboratory-raised males of *B. correcta* were fed with a mixture of ME, β-caryophyllene (**3**), and α-humulene (**4**), in a ratio of 1:2:2. Males incorporated the sesquiterpenes (**3** and **4**), together with ME metabolites (**1** and **2**), in an approximate ratio of total ME metabolites: β-caryophyllene: α-humulene of 0.8: 2: 2 (Table 1). No other compounds derived from the sesquiterpenes were detected.

Field Traps with Sesquiterpenes and Rectal Volatile Composition of Wild Males A 1:1 mixture of β-caryophyllene and α-humulene was tested, along with ME-baited traps, in a guava orchard in Thailand (July 24 and August 24, 2009).

Table 1 Phenylpropanoid metabolites and sesquiterpenes in the whole body extracts of *Bactrocera correcta* males fed on a mixture of methyl eugenol, β-caryophyllene (**3**) and α-humulene (**4**) (N=7)

Compound	Content (μg/male) ± SD
(*Z*)-Coniferyl alcohol (**1**)	11.0±3.8
(*Z*)-3,4-Dimethoxycinnamyl alcohol (**2**)	1.3±1.1
β-Caryophyllene (**3**)	31.0±5.4
α-Humulene (**4**)	30.6±9.3

The catch (3) of male *B. correcta* in the sesquiterpene-baited traps was low relative to that (43) in the ME-baited traps. No males of *B. dorsalis* were caught in the sesquiterpene-baited traps, while 9 males of this species were caught in ME-baited traps. The same experiment was conducted in a mango orchard on July 3, 2009, but no *B. correcta* males were trapped, while 15 *B. dorsalis* males were captured only in ME-baited traps.

The whole body extract of individual flies was subjected to GC or GC-MS analysis. Among 19 *B. correcta* males captured alive in the ME-baited traps on July 24 and August 24, 2009, 17 possessed large quantities of compounds exhibiting either "**3** + **4**" or "**3** + **4** + **5**" type patterns; the remaining 2 flies contained only trace, but significant, amounts of "**3** + **4**" or "**3** + **4** + **5**" mixtures. Of two males collected alive in the sesquiterpene-baited traps on August 24, one possessed substantial quantities of compounds **1**, **3**, and **4**, and the other had only trace amounts of the "**3** + **4**" pattern. Among the flies captured in orchards, some males possessed minor components, tentatively identified as β-elemene and germacrene D by retention index values (1402 and 1495, respectively) and MS fragmentation patterns. In contrast, 7 males of *B. dorsalis* captured on July 3 at a mango orchard, and 9 males captured in a guava orchard on July 24 and August 24 possessed no sesquiterpenes.

Morphological and DNA Analyses There were no morphological differences among the 3 groups (i.e., laboratory strain and the two collections of wild flies in Bangkok and the guava orchard) of *B. correcta*. The DNA sequences of *B. correcta* captured in the field-trapping test were analyzed and compared to those from laboratory-raised *B. correcta* and *B. dorsalis* (Tan et al., unpublished). The alignment of rDNA fragments indicated that the 3 groups belonged to the same clade of *B. correcta* species and differed from the distinct clade of *B. dorsalis* (Fig. 5).

Discussion

In laboratory tests, we characterized the production of two phenylpropanoid volatiles, (*Z*)-coniferyl alcohol (**1**) and

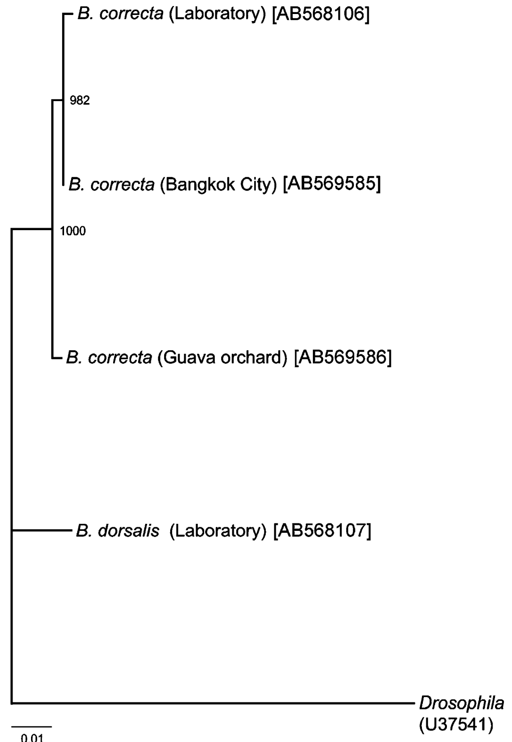

Fig. 5 Phylogenetic relationships resulting from the neighbor-joining analysis of rDNA sequences. The values shown at the nodes of the branches are the confidence levels from 1000 replicate bootstrap samplings. The scale bars indicate the evolutionary distance between the groups. GenBank accession numbers are given for the members reported in this paper together with those from laboratory-raised *B. correcta* (Tan et al., unpublished) and the mitochondrial genes of *Drosophila melanogaster*

(*Z*)-3,4-dimethoxycinnamyl alcohol (**2**), sequestered in the rectal glands of males of *B. correcta* after feeding on ME. The production of these compounds contrasts (Fig. 6) with the situation in *B. dorsalis*, in which (*E*)-coniferyl alcohol (ECF) and 2-allyl-4,5-dimethoxyphenol (DMP) are the two major metabolites (Nishida et al., 1988a), although (Z)-3,4-dimethoxycinnamyl alcohol (**2**) was detected in several specimens of wild *B. dorsalis* as a very minor component (Nishida et al., 1988b). The total quantity of **1** and **2** sequestered in the rectal gland of *B. correcta* is over 100 μg/gland, a quantity similar to that of total ECF and DMP sequestered by male *B. dorsalis* supplied with ME as an intact oil. It has been demonstrated that ME metabolites are transported selectively via hemolymph to the rectal gland after biotransformation of ME in the crop in *B. dorsalis* (Hee and Tan, 2006). Our work suggests that similar, but different, enzymatic processes function in these two sympatric species.

ECF and DMP, sequestered in the rectal gland and subsequently released during courtship as "smoke", act as a sex pheromone that attracts conspecific females in *B. dorsalis* (Nishida and Fukami, 1990; Tan and Nishida, 1996, 1998; Hee and Tan, 1998; Khoo et al., 2000). The function of **1** and **2** in mating of *B. correcta* is unknown. Tests should be conducted to determine their attractiveness to conspecific females as well as their deterrence/non-responsiveness to *B. dorsalis*, and similarly with *B. dorsalis* ME-sequestered metabolites toward *B. correct*a females. The sequestered metabolites in *B. dorsalis* also play a role in defense, deterring or poisoning predatory animals, such as birds, lizards, and spiders (Nishida and Fukami, 1990; Tan and Nishida, 1998; Wee and Tan, 2001, 2005). The amount of sequestered phenylpropanoids in our trapped wild males of both species was often large (>50 μg/body). Thus, a possible allomonal function of these metabolites needs to be investigated.

Further, a large proportion of males in the wild population of *B. correcta* contained large quantities of a series of sesquiterpene hydrocarbons, including β-caryophyllene and α-humulene. As we did not detect these compounds in our laboratory-reared males (raised on an artificial diet during larval and adult stages), this suggested that adults might seek out and sequester these compounds. β-Caryophyllene and α-humulene are common plant volatile constituents, particularly in fruits that are major hosts of these flies, such as mango and guava (Nishimura et al., 1989; Tamura et al., 2000; Sandoval et al., 2007). Our studies confirmed this, with the laboratory-feeding test that demonstrated the ability of *B. correcta* males to sequester these sesquiterpenes, and the field trial that showed that *B. correcta*, but not *B. dorsalis*, males were attracted to a mixture of β-caryophyllene + α-humulene.

Fig. 6 Comparison of methyl eugenol metabolites accumulated in the male rectal gland of *Bactrocera correcta* and *B. dorsalis*

Methyl eugenol (ME)
B. dorsalis
4,5-Dimethoxy-2-allylphenol (DMP) + (*E*)-Conferyl alcohol (ECF)
B. correcta
(*Z*)-Conferyl alcohol (**1**) + (*Z*)-3,4-Dimethoxycinnamyl alcohol (**2**)

The GC-profiles of the major sesquiterpenes found in *B. correcta* males sorted into two distinct types (**3** + **4** + **5** or **3** + **4**), suggesting two distinct sources of these sesquiterpenes (including or excluding alloaromadendrene) that the respective insects had fed on. Both β-caryophyllene and α-humulene have been described as smelling "sweet fruity" to humans (Shivashankara et al., 2006). Ripe guava fruits produce more β-caryophyllene than do immature fruits (Chyau et al., 1992; Soares et al., 2007). Therefore, the rectal gland sesquiterpenes released by males during courtship may convey the presence of ripe fruits to females.

β-Caryophyllene and α-humulene were detected in a male *Bactrocera unimacula* captured on a fruit fly-attracting orchid flower, *Bulbophyllum vinaceum*, which produces ME and other phenylpropanoid volatiles (but not sesquiterpenes), in Borneo (Tan et al., 2006). One of the flies captured (on August 24, 2009) by the sesquiterpene mixture in the guava orchard was identified tentatively as *B. unimacula*. Males of *B. dorsalis* occurring sympatrically with *B. correcta* in Thailand did not seem to accumulate sesquiterpenes **3**, **4** and **5**, suggesting a different role of the rectal sesquiterpenes during intra- and/or inter-specific interactions. Sesquiterpenes are known to be associated with other tephritid fruit fly species. β-Caryophyllene has been reported following aeration of calling males of Mediterranean fruit fly, *Ceratitis capitata*, together with other terpenoids and esters (Gonçalves et al., 2006). Males of Caribbean fruit fly, *Anastrepha suspensa*, release a multi-component volatile pheromone including sesquiterpenes (Nation, 1990). The quantity of sesquiterpenes in *B. correcta* males is extraordinarily high (often over 250 μg/gland), which also suggests a possible role in defense. Further work is needed to clarify the pheromonal and/or allomonal roles of rectal sesquiterpenoids in conjunction with the unique phenylpropanoids (**1** and **2**) in *B. correcta*.

Acknowledgements We thank S. Chinvinijkul, Supaap Pinkeaw, and Akkajit Duangkum of the Department of Agricultural Extension, Bangkok, for their assistance during this investigation. We are also grateful to Dr. Todd E. Shelly (USDA-APHIS, Waimanalo, Hawaii, USA) for reviewing this paper. This work was partly supported by the Grant-in-Aid for Scientific Research from JSPS (No. 19310142) from the Ministry of Education, Culture, Sports, Science and Technology of Japan, and JST in Research for Promoting Technological Seeds.

a deterrent, or an anti-nutritional factor, could be involved in plant part discrimination.

Glucosinolates, amino acid-derived secondary metabolites primarily found in the mustard order Brassicales, are crucial host plant recognition cues for pierid butterflies such as the cabbage whites (*Pieris* sp.) and related species (Renwick and Chew, 1994; Hopkins et al., 2009). Glucosinolate containing plants often contain a mixture of different structures, metaphorically known as the glucosinolate 'profile', which often differ between plant organs (e.g., Agerbirk et al., 2008).

Differential insect behavioral responses and their correlations with variation in individual glucosinolates have been observed (e.g., under field conditions, Rodman and Chew, 1980; Griffiths et al., 2001; Bidart-Bouzat and Kliebenstein, 2008; under laboratory conditions, Huang and Renwick, 1994; Giamoustaris and Mithen, 1995; Li et al., 2000; Gols et al., 2008; de Vos et al., 2008; Sun et al., 2009, but see also Reifenrath et al., 2005; Reifenrath and Städler, 2009; Badenes-Pérez et al., 2010). In one case that involves a monophagous insect and a glucosinolate of unusual proposed structure, host plant preference was linked to presence of a distinct glucosinolate (Larsen et al., 1992). Thus, there may be a chemosensory basis for evolution of host plant or plant part discrimination based on differential sensitivity to individual glucosinolates (Hopkins et al., 2009). Phytophagous butterfly larvae also have sensory organs for various primary metabolites (Schoonhoven et al., 2005), some of which could be correlated to total nitrogen contents of plant parts.

The purpose of this work was to search for evidence for a chemical basis of the assumed plant part preferences of orange tip larvae, and to develop a bioassay for a hypothetic semiochemical responsible for floral parts feeding. We pursued this purpose in two parallel ways: (1) by observation of caterpillar feeding choice on original host plants and after transfer to various positions on *A. petiolata*, and (2) by chemical analysis of plants collected during the period of orange tip larval occurrence.

Methods and Materials

Identification of Plants and Animals Flowering *C. pratensis* and *A. petiolata* were identified in the field from their characteristic morphologies. Eggs of the orange tip butterfly were tentatively identified in the field, and the identity confirmed from comparison of the morphology of the resulting larvae with the same illustrated descriptions as used previously (Agerbirk et al., 2006). Selected larvae were reared to pupation to confirm the identification based on pupal morphology. Photographs of the studied material including egg and the transition from larva to pupa have been published elsewhere (Agerbirk and Jørgensen, 2008). Four pupae produced four female butterflies the following spring, all of which were confirmed to be *A. cardamines* by morphology.

Collection of Plants Plant shoots of flowering plants (*C. pratensis* cut above the rosette and *A. petiolata* cut below a number of fresh leaves) were collected in plastic bags at natural growth sites in May 2008 and transported to the laboratory within a few hours. Unless otherwise noted, all plants and animals were from Lake Utterslev Mose (= locality DK1), Copenhagen, Denmark. *A. petiolata* was collected within 20 m of the lake rim (e.g. 55 42′ 57″ N, 12 30′ 22″ E), while *C. pratensis* was collected at the public lawns ("Gyngemosen") NE of the lake and NW of Highway 16 (e.g. 55 43′ 19″N, 12 29′ 43″E). We also sampled *C. pratensis* floral parts from two other, previously described localities (DK2, DK3) (Agerbirk et al., 2010a). The individual plants DK3a and DK3b were the same as described in that paper and were dried without lyophilization as described in that paper.

Observation of Egg Position and Caterpillar Feeding Behavior Flowering shoots of *C. pratensis* and *A. petiolata* with orange tip eggs or neonate larvae were collected as above and kept in individual, numbered beakers with tap water in the laboratory, and exposed to sunlight through an east facing glass window. If the orange tip egg could be located, the position was registered. Most L1/L2 larvae collected (N=26) were subject to detailed observations on the original host plants. (However, L1/L2 larvae collected on days with experimental manipulation of larval position were used directly in the behavioral experiments, and hence not observed on the original host plants). The position and behavior of each larva, as well as signs of feeding, were observed and noted at least daily between Monday and Friday, and representative specimens were photographed in order to illustrate characteristic feeding patterns. The observations on original host plants typically were carried out for 2–3 d for an individual larva, after which they were moved to fresh plants to be used for experiments. It was not meaningful to standardize the observation period because the material was collected at different stages, including eggs, newly hatched larvae, and slightly older larvae.

One intact *C. pratensis* plant (on the flower of which oviposition by an orange tip was observed the day before), with its root system and approximately 1 l of attached soil+grass, was removed from the locality, and was cultivated in the laboratory during the entire larval development including hatching and pupation (May 7–24). The spontaneous feeding behavior of the resulting larva, which was not manipulated in any way, was observed 5 d a week. When the remains of the host plant had been left, *A. petiolata* was offered for

completion of the 5th instar and pupation (pupal wt. 112 mg), to confirm identification.

Rearing of Larvae for Behavioral Experiments As soon as or before original plants started to deteriorate visibly, larvae were gently transferred (with a moist paint brush) to fresh bolting *A. petiolata* shoots, collected at the locality 0–2 d before, and kept in the laboratory immersed in beakers with tap water. They were exposed to reduced daylight through an east facing window until use. This stock of larvae, supplemented with newly collected larvae of various instars, served as the material for additional behavioral experiments.

Behavioral Experiments For behavioral experiments, *A. petiolata* side branches with a specific morphology and growth stage were used, with leaves immediately next to the lower 1–2 siliques (Fig. 1) and with flowers with fresh petals. As the natural availability of branches with this morphology (including fresh flowers) ceased late in the experimental period, we ended this type of experiment even though additional late instars were available.

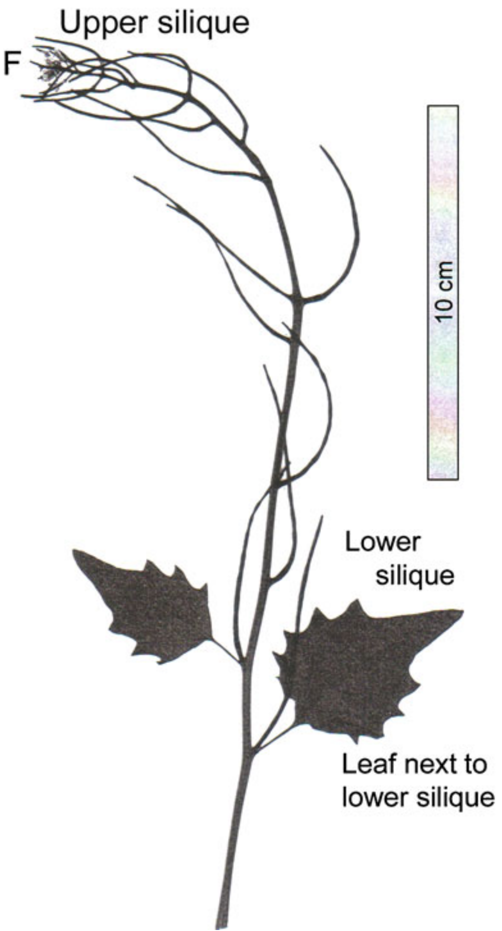

Fig. 1 *Alliaria petiolata* branch with siliques next to cauline leaves, as used for behavioral experiments with orange tip larvae. F=flowers

Two plant part preference experiments were carried out. The purpose of the 'leaf/silique choice experiment' was to test whether an absolute preference for silique feeding could be demonstrated in a choice situation, where both a silique and a leaf were within close proximity to the larva. Larvae of known instar were gently transferred to lower parts of *A. petiolata* branches (one larva per branch in separate beakers), with about half of the larvae of each instar placed on lower siliques and the other half placed on leaves immediately next to lower siliques (Fig. 1). The feeding during the 24 hr experimental period was registered by careful inspection of the branch for feeding traces at the end of 24 hr. Occasional observation of some larvae during the experiment also was carried out in order to qualify the subsequent inspection of the branch for feeding traces. Selected branches with larva and feeding traces were photographed with a background 5×5 mm grid after the experiment, and ingested amounts were estimated by comparison with un-touched leaves.

The purpose of the 'vertical position experiment' was to test whether the vertical position of the larva, either near the plant apex with flowers or at lower levels near the leaves, would influence the subsequent plant part feeding choice of the larva (as suggested by the outcome of the leaf/silique choice experiment). Larvae were placed either on the uppermost silique, near the flowers, or on the lower-most silique, next to a leaf (Fig. 1). Evaluation of the feeding choices was as described for the leaf/silique choice experiment.

Whether or not occurrence of leaf feeding depended on the initial position of the larva was tested by Rice's conditional binomial exact test (Rice, 1988) of 2×2 matrixes with leaf feeding vs. no leaf feeding as a function of larval position. (Fisher's exact test gave the same pattern of significance vs. non-significance). The significance level was set at 5% (two-tailed test), and results for L1-L4 were pooled because there was no indication of differences among these instars. Whether or not flower feeding depended on initial larval position was tested in the same way.

Plant Sampling and Dissection for Chemical Analysis - Plants for chemical analysis were sampled (in parallel to larvae and plants for behavioral experiments) at the main study locality (DK1) in May (2008), which was the oviposition and larval feeding period of orange tip butterflies at the locality. Plants for chemical analysis were dissected and lyophilized immediately after arriving in the laboratory; the time from collection in the field to dissection and lyophilization was 3 hr or less. In dissection for chemical analysis, upper stem was defined as the upper inflorescence (with flowers) and included flower stalks; middle stem was defined as the lower inflorescence (with

siliques) and included silique stalks; and lower stem was defined as the basal part of the stem, from the lowermost silique downwards. Leaves were cauline (stem) leaves, not rosette leaves. Siliques and flowers included only these organs, as the stalks attaching them to the stem were included with stems. For nitrogen analysis of specific plant organs, we aimed at pooling only from the same individual, but in the case of flowers, siliques, and upper stems, the samples in most cases had to be pooled from several individual plants to provide sufficient amounts for the analysis.

Determination and Identification of Glucosinolates Glucosinolates were determined by extraction of lyophilized plant parts in boiling 70% MeOH, binding to anion exchange columns, enzymatic desulfation, elution (in 5×1 ml H_2O) and subsequent HPLC with diode array detection of desulfo derivatives relative to an external standard of sinigrin (**15**) treated similarly in parallel (Agerbirk et al., 2007). The exact HPLC conditions were different for the two plant species: HPLC conditions for *C. pratensis* samples were optimized specifically to achieve separation of all glucosinolates known from this species (Agerbirk et al., 2010a). For *A. petiolata*, a Supelcosil LC-ABZ column, 25 cm× 4.6 mm, 5 µm, was used with flow rate 1 ml/min, and elution by 2 min of H_2O followed by a 48 min linear gradient from 0 to 60% MeOH, a brief wash with MeOH, and equilibration with H_2O. Peak identification by comparison with authentic reference compounds supplemented by LC-MS of selected samples was as previously described (Agerbirk et al., 2010a). Glucosinolate levels in *A. petiolata* were $\log_{10}$-transformed to remedy non-normal distribution of the original data, and subjected to statistical analysis. Due to unexpected occurrence of several chemotypes of *C. pratensis* with qualitative differences among them, the various chemotypes were reported separately, and quantitative statistical tests of glucosinolate levels in this plant were not considered meaningful.

Nitrogen Determination Total nitrogen (and carbon) contents of lyophilized samples from locality DK1 were determined on an elemental analyzer (Carlo Erba model NA 1500, Carlo Erba, Milan, Italy) in the laboratory of Jeffrey Dukes at University of Massachusetts, Boston, MA, USA. Two samples (*A. petiolata* leaves,%N 3.27, and upper stems,%N 5.99) deemed unreliable by the analysis-lab due to abnormal values for associated standards were excluded from the data and calculations. Numbers for %N were converted to proportions (0.00–1.00), which were arcsin transformed to remedy non-normal distribution of the original data.

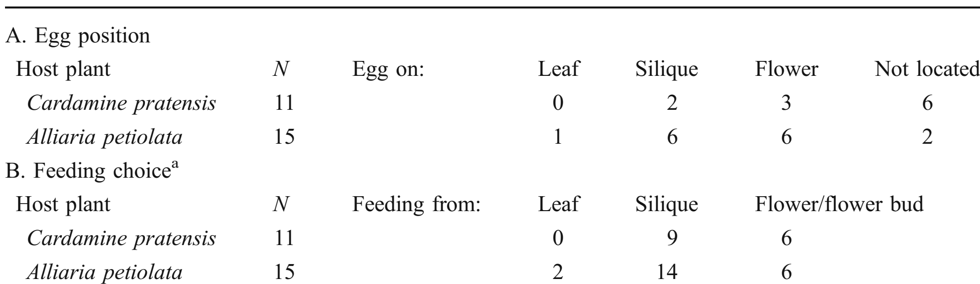
Statistical Analysis of Chemical Data Levene's test was used to confirm that transformed glucosinolate and nitrogen levels met the variance homogeneity assumptions of ANOVA. Differences between nitrogen and glucosinolate levels among plant parts within each species were examined by ANOVA. Where the ANOVA was significant, unplanned multiple comparison among plant parts was made using Scheffé *post-hoc* test with significance level set at 0.05. In one case with $N=1$ for one plant part, this plant part was excluded before ANOVA with *post-hoc* test.

Results

Oviposition Site Almost all eggs or egg shells located on *C. pratensis* or *A. petiolata* were on siliques or flowers, including their basal parts, while a single egg was observed on a leaf close to a silique (Table 1A). Usually, only a single egg or larva was observed per plant, but in some cases two (Fig. 2) or even three orange tip eggs or larvae were present naturally.

Plant Part Choice on Original Host Plants Feeding habits of L1/L2 instars on the original host plants nearly always (88%) included silique feeding. Flower feeding also was frequent (46%), while only few larvae ate leaves at all (Table 1B) (but one fed exclusively on a leaf during the first and the initial part of the 2nd instar). The flower feeding behavior by early instars on *C. pratensis* was quite stereotypic, with the feeding starting from the basal part of the flower (Fig. 2) whether or not the flower was open. Floral parts egg position and feeding by orange tips was obviously dominant for both host plant species, and it was

Table 1 Egg position and feeding choice by orange tip L1/L2 larvae hatched on original host plant shoots



A. Egg position

Fig. 2 Second instar orange tip larvae ("L") feeding on flowers of *Cardamine pratensis*. The entire flower was usually eaten, starting from the outside of basal parts as illustrated ("Feeding damage")

not considered relevant to test statistically whether slight differences between patterns on the two plant species existed. For comparison of plant part distribution with published field data, see "Discussion".

The feeding behaviour of a single larva through all five instars on an intact *C. pratensis* plant complemented the observations. In the first three instars (L1-L3), the larva ate flowers and siliques. The 4th instar (L4) also ate upper stem, and 5th (final) instar (L5) ate the remaining stem except the lower 9 cm (ca. one third) as well as all cauline leaves and part of the rosette leaves.

Leaf/Silique Choice Experiment The probability of leaf feeding was not significantly different for larvae placed initially on a leaf vs. larvae placed initially on a nearby silique (P=0.21). Irrespective of their initial position, larvae frequently ingested leaves as well as siliques (Table 2A). The amounts of leaf ingested were typically substantial i.e., more than the minute test bites seen when another species of insect larvae probed unacceptable *Barbarea vulgaris* plants (Agerbirk et al., 2003). Flower feeding was infrequent for L2-L4 instars in this experiment. Apparently, the frequency of feeding on each plant part was a consequence of a limited mobility within 24 hr, and was sufficient to reach the leaf even when they were placed at the silique and vice-versa, but was generally insufficient to reach the more distant flowers.

A single L5 larva was included in the experiment, but was not included in the pooled results for statistical testing due to its atypical behavior: The individual was placed on the leaf next to the lower silique, from which approximately 3 cm^2 (ca. 1/5 of the entire leaf) was eaten. Rather than eating the remaining leaf or neighboring silique, it moved overnight to the flowers and upper siliques, which were ingested entirely. This observation led us to include as many L5 larvae as available in the vertical position experiment.

Vertical Position Experiment This experiment, in which larvae were placed on either lower or upper siliques, confirmed the importance of larval position inferred above. Young to intermediate instars (L1-L4) placed near leaves exhibited frequent leaf feeding (50%) and no flower feeding, while larvae placed near flowers exhibited frequent flower feeding (45%) and no leaf feeding (Table 2B). The probability of leaf feeding was significantly higher when larvae were placed on lower siliques than when placed on upper siliques (P=0.01). Likewise, the probability of flower feeding was significantly higher when larvae were placed on upper siliques compared to lower siliques (P=0.015). Based on the combined experiments, we concluded that any preference of L1-L4 larvae for floral parts (siliques and flowers) would be too weak to be of practical use in a bioassay for a hypothetic stimulant or deterrent. Indeed,

Table 2 Feeding choice by orange tip larvae during 24 hr after experimental manipulation of larval position

Instar	Placed at	*N*	Feeding from:	Leaf	Silique	Flower/flower bud
A. Leaf/silique choice experiment: larvae placed on either lower *Alliaria petiolata* silique or the leaf immediately next to it						
L2-L4	Lower silique	10		5	7	0
	Leaf at silique	6		5	4	1
L5	Leaf at silique	1		1	1	1[a]
B. Vertical position experiment: larvae placed on either lower *Alliaria petiolata* silique (at leaf) or upper silique (at flowers)						
L1-L4	Silique at leaf	10		5	8	0
	Silique at flowers	11		0	9	5
L5	Silique at leaf	4		1	4	3[a]
	Silique at flowers	3		0	3	3[a]

[a] Ate all flowers as well as flower-supporting part of stem

For statistical evaluation: See text

feeding choice by young and intermediate instars (L1-L4) seemed to be governed mainly by proximity, at least under our laboratory conditions.

Seven available L5 larvae also were included in the vertical position experiment, and all except one (from lower silique) moved to flowers and ingested the entire upper part of the inflorescence within 24 hr, while only a single had eaten from leaves (Table 2B). For this instar, the probability of flower feeding did not depend on the initial position of the larvae ($P=0.94$). Despite the low number of replicates, we interpret this result as a tendency for L5 instars to prefer floral parts.

Glucosinolate Profiles of Leaves and Floral Parts The two main hosts of orange tip butterflies at the DK1 locality, an urban lake habitat in the greater Copenhagen area, appeared to be *A. petiolata* and *C. pratensis*. There was no difference in the kinds of glucosinolates in vegetative or floral parts of *A. petiolata*, but when the levels were compared, there was a significant effect of the plant parts in statistical analysis by ANOVA. Flowers and upper stems contained higher levels of the major glucosinolate sinigrin (**15**) and the phenolic indole glucosinolate **12** (with proportional traces of **10**) relative to leaves (Table 3, Fig. 3).

In the other common host plant at the locality, *C. pratensis*, the mixture of glucosinolates was more complex. Plants from the main locality (DK1) contained three dominant glucosinolates – the phenolic glucosinolate sinalbin (**8**), the *O*-methyl derivative **9,** and the hydroxylated aliphatic glucosinolate **4** – and a number of minor glucosinolates including the indole glucosinolate **10** (Table 4, Fig. 3). The glucosinolate profiles of floral and vegetative parts were similar, with no obvious indications of a particular glucosinolate profile or higher glucosinolate level of floral parts.

As a hypothetic floral parts signature was expected to be of general nature, we included floral parts of the same plant

Table 3 Glucosinolate profiles (μmol/g dry wt., mean (s.d.)) of floral and vegetative parts of *Alliaria petiolata* in May

Plant part	**10**	**12**	**15**	*N*

Statistical significance of differences in major glucosinolates between plant parts were tested by ANOVA ($P<0.001$: ***, $P<0.01$: **, $P<0.05$: *, $P>0.05$: ns, not tested: -). Significant differences in a *post-hoc* Scheffé test ($P<0.05$) are indicated with different letters

species from other localities (DK2, DK3). Floral parts of individual *C. pratensis* plants from these localities showed qualitative differences from both floral parts and leaves at the main locality in terms of glucosinolate profiles. In a plant from locality DK2, *sec*-butylglucosinolate (**3**) rather than the hydroxy derivative **4** was the dominating aliphatic glucosinolate in flowers. At locality DK3, flowers of two individual plants had glucosinolate profiles that deviated even more from those at locality DK1, as the methylated aromatic glucosinolate **9** was nearly absent (Table 4). Plant DK3a accumulated benzylglucosinolate (**7**) and a short chain hydroxylated aliphatic glucosinolate (**2**) in flowers while both **3** and **4** were absent. In contrast, plant DK3b accumulated the non-hydroxylated **3** but not **7**. The distinctive profiles of floral parts from localities DK2 and DK3 were similar to leaf glucosinolate profiles of the same plants reported elsewhere (Agerbirk et al., 2010a).

Nitrogen Levels in Different Plant Parts In *A. petiolata*, total N content was higher in upper stems than in leaves, and there was also a tendency for high N levels in flowers. In the case of *C. pratensis*, however, there was no statistically significant difference in N content among floral parts and leaves (Table 5).

Discussion

An initial purpose of the behavioral experiments was to establish a bioassay for a hypothetic semiochemical (Agerbirk et al., 2003; Miles et al., 2005; Nielsen et al., 2010) responsible for floral parts feeding. Branches of *A. petiolata* (Fig. 1) with adjoining lower siliques and upper leaves (in contrast to the distance between these organs on the main stem), as well as a controlled laboratory environment, were used in an attempt to maximize the sensitivity for any larval preference. However, the larval feeding behavior seemed to be governed mainly by the position of the larvae in laboratory experiments with young and intermediate instar larvae (L1-L4). We believe that the laboratory test situation was relatively similar to the natural situation in terms of physical conditions and plant chemistry because relatively fresh *A. petiolata* branches were used. It can be argued that biochemical changes in the detached *A. petiolata* branches kept in the laboratory may have compromised a semiochemical responsible for plant part preference. Obvious consequences of the laboratory rearing at lower light intensity and significantly less UV light than in the field could be decreases in levels of photosynthetic products or UV induced metabolites with a significant turnover rate. Indeed, a recent experiment used for demonstrating specific movement to flowers of third

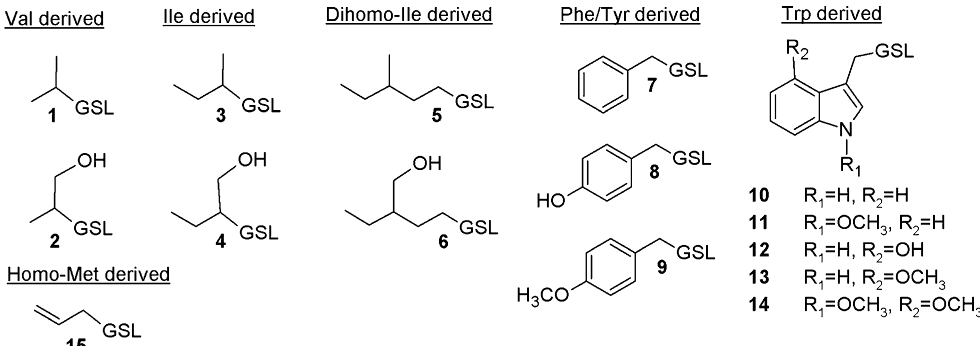

Fig. 3 Glucosinolates detected in *Cardamine pratensis* or *Alliaria petiolata* from the investigated localities, and two glucosinolates (**6** and **14**) known from other accessions of *C. pratensis* but not detected in this investigation. GSL: The constant part of the glucosinolate molecule, C (SGlc)$NOSO_3^-$. Systematic (and common names, if in general use) of the glucosinolates (GSLs) are: **1**, 1-methylethylGSL (isopropylGSL); **2**, 1-(hydroxymethyl)ethylGSL; **3**, 1-methylpropylGSL (*sec*-butylGSL); **4**: 1-(hydroxymethyl)propylGSL; **5**, 3-methylpentylGSL; **6**, 3-(hydroxymethyl)pentylGSL; **7**, benzylGSL (glucotropaeolin); **8**, 4-hydroxybenzylGSL (sinalbin); **9**, 4-methoxybenzylGSL; **10**, indol-3-ylmethylGSL (glucobrassicin, GB); **11**, 1-methoxy**10** (neoGB); **12**, 4-hydroxy**10** (4-hydroxyGB); **13**, 4-methoxy**10** (4-methoxyGB); **14**, 1,4-dimethoxy**10** (1,4-dimethoxyGB), **15**, 2-propenylGSL (sinigrin)

instar *Pieris brassicae* (Smallegange et al., 2007) involved intact plants (in a greenhouse). However, the feeding on detached original host plants kept in the laboratory was almost exclusively from floral parts, suggesting that even if plant biochemistry changed due to the laboratory conditions, the positional effect was sufficient to enable the larvae to behave as in the field. Hence, biochemical changes due to the laboratory conditions are not likely to have influenced the plant part choices of the larvae. In agreement with this argument, the spontaneous behavior of young larvae, when their position had not been manipulated, agreed well with published field observations (Wiklund and Åhrberg, 1978; Courtney, 1981; Dempster, 1997), except that Dempster (1997) described floral feeding to precede silique feeding in general on *C. pratensis*. This slight difference from our observations may depend on local conditions such as relative phenologies of insect and host plant (Wiklund and Friberg, 2009).

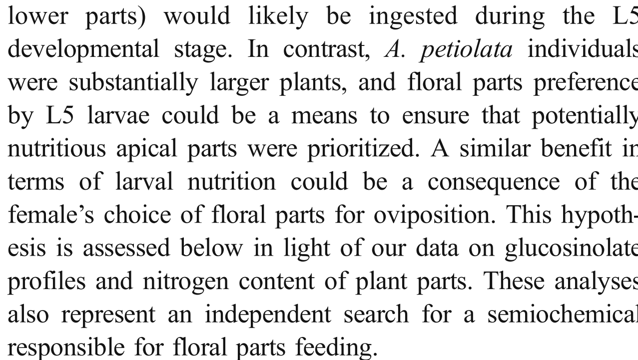
Statistical significance of differences in major glucosinolates between plant parts were tested by ANOVA ($P<0.001$: ***, $P<0.01$: **, $P<0.05$: *, $P>0.05$: ns). Significant differences in a *post-hoc* Scheffé test ($P<0.05$) are indicated with different letters. [a] The level of significance was *** whether or not lower stem was excluded in ANOVA.

The feeding behavior of the single larva followed through all instars on the same plant immediately suggested a biological advantage for flexible feeding behavior. The inflorescence of the *C. pratensis* individual chosen by the female was too small to support full development of the larva if only siliques and flowers were ingested. Larval migration to other plants would be needed if only floral parts were accepted, but such movement to other, perhaps distant plants poses an obvious risk (Wiklund and Åhrberg, 1978; Dempster, 1997). Hence, utilization of vegetative parts would allow larvae to avoid or delay risky migration. Although this observation of a single larva can be dismissed due to lack of replication, we find it of interest and worthy of additional investigation as a complement to the traditional assumption of the existence of leaf avoidance (Wiklund and Åhrberg, 1978). The outcome of our experimental manipulations and the observation of occasional leaf feeding by young larvae on original host plant shoots (Table 1) confirm the observed spontaneous leaf acceptance by orange tip larvae.

The apparent preference for flowers by L5 larvae was reminiscent of a similar behavior reported for *Pieris brassicae* L3 and *Athalia rosae* L4 larvae (Smallegange et al., 2007; Bandeili and Müller, 2010), and suggests that proximity was not the only factor controlling orange tip L5 larval feeding. The most direct advantage of the tendency for feeding from the top would be to avoid accidental cutting of the main plant axis by the vigorously feeding L5 instars, which would lead to loss of the upper parts of the plant. As usual for late instar caterpillars (Theunissen et al., 1985), L5 larvae ingested a tremendous amount of material. In this case it was comparable to the remaining parts (after feeding by previous instars) of the relatively small *C. pratensis.* Thus, a strong plant part preference might have little effect on this plant species, because the majority of the plant (except tough



lower parts) would likely be ingested during the L5 developmental stage. In contrast, *A. petiolata* individuals were substantially larger plants, and floral parts preference by L5 larvae could be a means to ensure that potentially nutritious apical parts were prioritized. A similar benefit in terms of larval nutrition could be a consequence of the female's choice of floral parts for oviposition. This hypothesis is assessed below in light of our data on glucosinolate profiles and nitrogen content of plant parts. These analyses also represent an independent search for a semiochemical responsible for floral parts feeding.

A comparison of the glucosinolate profiles of vegetative and floral parts of two host plant species revealed no consistent floral parts glucosinolate profile. Based on the analyses of the chemically simple *A. petiolata*, a preliminary hypothesis for a hypothetic glucosinolate 'signature' or profile of floral parts could be a higher total level of glucosinolates, or a higher level of indole glucosinolates (**10**–**14**) or perhaps of aromatic (**7**–**14**) or phenolic (**8**+**12**) glucosinolates in general. Based on the literature, a different balance of aromatic vs. aliphatic glucosinolates (van Loon et al., 1992; Huang and Renwick, 1994) or of *O*-methylated vs. non-substituted aromatics (Sun et al., 2009) would be candidate signatures that could possibly be distinguished by insect sensory organs. Based on separately reported analytical chemistry research (Agerbirk et al., 2010a), we obtained reliable glucosinolate profiles of *C. pratensis* floral parts and leaves. However, none of the hypotheses of a floral parts 'signature' was supported when data for three populations of *C. pratensis* were considered. From the data in Table 4, a tendency for higher levels of **10** in floral parts than in leaves is suggested, but levels of **10** were higher in leaves than in floral parts in the individual plants from locality DK2 and 3 (Agerbirk et al., 2010a; unpublished results), so a hypothesis of a role of **10** was not generally supported. Indeed, the difference in glucosinolate profile between the two species and between individuals from different populations of *C. pratensis* appeared to be much greater than any systematic differences between vegetative and floral parts (Table 4). Consequently, there appears to be no basis for using glucosinolate profiles for larval distinction of floral parts from leaves.

A similar glucosinolate profile of flowers and vegetative parts, with a general tendency for higher levels in flowers of undamaged plants, also had been reported from *Arabidopsis thaliana*, *Raphanus sativus*, *Brassica nigra,* and *Sinapis alba* (Brown et al., 2003; Strauss et al., 2004; Smallegange et al., 2007; Bandeili and Müller, 2010). Glucosinolates were constitutively high but generally less inducible in radish flowers compared to leaves, as expected for an organ with high fitness value (Strauss et al., 2004). Our data do not exclude the possibility that floral parts could be deficient in the enzyme myrosinase (which converts glucosinolates to defensive products such as

isothiocyanates), but a recent report demonstrated high levels of myrosinase in floral parts of the crucifer *S. alba* (Bandeili and Müller, 2010), showing that floral parts high in glucosinolates may indeed also be high in myrosinase.

It was a surprise to discover that *C. pratensis* plants from different localities had different glucosinolate profiles; a more extensive investigation of glucosinolate variation in the species is published separately (Agerbirk et al., 2010a). Two subspecies of *C. pratensis* with different chromosome numbers had different probabilities of oviposition by orange tip butterfly females in Sweden (Arvanitis et al., 2007, 2008), but the *C. pratensis* populations at three Danish localities investigated here had identical chromosome numbers (Agerbirk et al., 2010a).

In *A. petiolata*, there was a tendency for higher N contents in upper parts, although the difference from leaves was statistically significant only for upper stems (which were frequently eaten by late instar orange tip larvae). Given the low number of replicates, this result should be interpreted with caution. However, the *A. petiolata* parts high in N were also high in glucosinolates and were both from the plant apex, suggesting that the measured tendency reflects a real biological phenomenon. As nitrogen is considered to be a limiting resource for herbivorous insects (Mattson, 1980), floral parts feeding may thus be a nutritional advantage in the case of feeding on *A. petiolata*. Position-dependent levels of nitrogen and glucosinolates also have been reported by Traw and Feeny (2008) for various leaf-positions of *Brassica nigra* and *B. kaber* (syn. *Sinapis arvensis*). However, in the case of *C. pratensis*, floral parts did not have higher total N than leaves (Table 4). Hence, our data do not support the hypothesis that floral parts feeding in general provide a nutritional advantage for orange tip larvae in terms of N content.

Nutritionally available N can only be approximated by total N if the majority of plant N is in a form available for protein or nucleotide biosynthesis; N in secondary metabolites may not be available for such biosynthesis. Intake of nitrogen in glucosinolates by orange tips and related species is balanced 1:1 by excretion of nitrogen in a nitrile (Agerbirk et al., 2006), a nitrile-derived functional group (Vergara et al., 2006; Agerbirk et al., 2007), or possibly inorganic ammonia from hydrolysis of nitrile groups (Agerbirk et al., 2010b). However, even a high glucosinolate level of 100 μmol/g dry wt. would correspond only to 0.14% N for non-indoles (and 0.28% N for the indoles **10**–**14**), so glucosinolate N was only a low fraction of the total N content of any plant part and total N could be regarded as a proxy of nutritionally available N. This result agreed with another investigation (Traw and Feeny, 2008).

In summary, we found a tendency for floral parts preference for L5 larvae, but no evidence for any L1-L4 larval behavioral preference for floral parts. For a classical example of a floral parts feeding butterfly, it was surprising that the feeding preferences of the larvae were so unspecific compared to the recently discovered within-plant selective foraging by intermediate to late instar *P. brassicae* and *A. rosae* (Smallegange et al., 2007; Bandeili and Müller, 2010). If the tendency of late instars to move to flowers is a real phenomenon, it still is not certain that a chemical signal is involved; we did not, for example, test the effect of positioning the inflorescences up-side down (Bandeili and Müller, 2010). Much of the natural tendency for young orange tip larvae for floral parts feeding can apparently be attributed to the choice of floral parts for oviposition by female butterflies (Wiklund and Åhrberg, 1978). Having established that floral parts are as rich and diverse in glucosinolates as vegetative parts, the wide range of host plants used by orange tip butterflies may imply that there is no basis for selection of a chemically less well defended plant part (Courtney and Chew, 1987). However, flower feeding recently has been demonstrated to lead to faster growth of two species of glucosinolate adapted larvae (Smallegange et al., 2007; Bandeili and Müller, 2010), supporting a hypothesized overall nutritional or micro-environmental benefit of feeding on floral parts.

Alternative explanations for flower oviposition in *Anthocharis* could be phylogenetic conservatism (the entire clade of anthocharines and euchloeines oviposits on floral and fruiting parts), perhaps due to mutual dependency with other behavioral patterns such as the “red egg syndrome” (Shapiro, 1981; Nomakuchi et al., 2001) or an optimized host plant search strategy: exclusive investigation of flowers may save valuable time during the oviposition period or allow the search for nectar source plants (Wiklund and Åhrberg, 1978) and plants for oviposition to be combined. The present demonstration of flexible but position-dependent larval plant part choice, glucosinolate diversity in floral parts and variable but relatively high N levels in floral parts underlines the importance of the positioning of eggs by ovipositing females, and shows that crucifer floral parts may be as diverse and well defended as crucifer foliage.

Acknowledgements We thank two anonymous reviewers for helpful comments and suggestions to an earlier version of the text, Claus T. Ekström and J. Michael Reed for statistical advice, Birgitte B. Rasmussen for skillful glucosinolate analysis, and the laboratory of Jeffrey Dukes for determination of total nitrogen and carbon. This research was financially supported by Torben og Alice Frimodts Fond to NA and the Arabis Fund to FC.

soccata, but populations may survive on wild graminaceous plants when sorghum is not available (Padmaja et al., 2010).

In India, the losses due to *A. soccata* damage have been estimated to reach as high as 90% of grain, and 45% of fodder yield (Sukhani and Jotwani, 1980; Jotwani, 1982). The annual economic losses in sorghum due to this pest have been estimated at US$200 million (ICRISAT, 1992). The pest is especially serious in late-sown crops, but sometimes also appears with early sowing, when the preceding dry season is interrupted by frequent rain showers (Nimbalkar and Bapat, 1987). The levels of infestation may go up to 90–100% under delayed sowing (Hiremath and Renukarya, 1966). Although these are old estimates, similar yield losses occur even today because of the lack of acceptable levels of genetic tolerance/resistance to this insect pest in parental lines, compounded further by cost constraints that limit the use of insecticides by farmers in developing countries.

Odors emanating from crops play a role in the orientation of insect pests towards their host plants and in recognition of these plants as sites for feeding and oviposition (Visser, 1986; Bruce et al., 2005). Thus, knowledge of the volatile compounds emitted by *S. bicolor* and insect responses to them is needed in the study of insect pest-sorghum plant relationships. Field observations of insect trap catches have suggested that *A. soccata* females are attracted to volatiles emitted by shoot fly susceptible seedlings but not resistant seedlings, and it has been shown that trap catch varies according to the growth stage of the plant (Nwanze et al., 1998). However, the semiochemicals involved have not been identified previously. Therefore, the objective of the present study was to identify plant-derived attractants (kairomones) for *A. soccata.*

Methods and Materials

Insect Rearing The culture of *A. soccata* used in the experiments was established with field collected insects from the Directorate of Sorghum Research (Hyderabad, India). *A. soccata* females were released inside wiremesh screened cages (30×30×30 cm) onto 15–20-d-old sorghum seedlings (cultivar DJ 6514) and were provided with 20% sucrose solution on a cotton swab in a Petridish. The sucrose solution was changed daily. They were maintained under controlled conditions (27°C, 70% RH, 12:12 h L:D) in the laboratory on sorghum seedlings.

Plants Seeds of sorghum cultivars 'Swarna' and IS 18551 were planted individually in 7 cm (diam.)×6 cm (deep) plastic pots filled with compost. Plants were grown in a glasshouse under controlled conditions (25°C, 60% RH, 16:8 h L:D). Natural lighting was supplemented with sodium lamps (SON-T 600W) that gave photosynthetically active radiation of approximately 24600 lux at bench height. The seedlings used for experiments were 15–21 d after seedling emergence when they carried fifth leaves and the sixth leaf had just started to show.

Chemicals Authentic chemical standards used in behavioral studies were (*Z*)-3-hexen-1-yl acetate, octanal, methyl salicylate (all 99% purity, Avocado Research Chemicals), (-)-(*E*)-caryophyllene (85% purity, Pfaltz & Bauer inc., Stamford, CT, USA), (-)-α-pinene, (+)-α-pinene (98% purity, Sigma Aldrich, Gillingham, UK), 6-methyl-5-hepten-2-one, decanal (99% purity, Sigma Aldrich), and nonanal (95% purity, Sigma Aldrich).

Air Entrainment of Sorghum Plants Volatiles from the highly susceptible sorghum cultivar 'Swarna' and a resistant control, IS 18551, were collected with equipment that allows sampling of volatiles from live plants (Agelopoulos et al., 1999). Plants were 15–21 d after seedling emergence, the most susceptible growth stage. All equipment viz., glassware and aluminium plates, was washed with Teepol detergent (Herts County Supplies, Herts, UK), rinsed with acetone and distilled water, then dried in an oven at 180°C for 2 h. Porapak Q tubes were eluted with redistilled diethyl ether and heated at 132°C for 2 h under a stream of purified nitrogen to remove contaminants. Plants were enclosed individually in glass vessels (190 mm high×100 mm wide), open at the bottom and closed with a collection port at the top. The bottom was closed with two semicircular aluminium plates that fitted around the stem of the plant and were clipped to a flange on the open end of the glass vessel. One of the aluminium plates was drilled to accommodate an inlet port, and air, purified by passage through an activated charcoal filter, was pumped into the vessel through this (400 ml/min). Volatiles were collected on Porapak Q (50 mg, 60/80 mesh; Supelco, Bellefonte, PA, USA) in a glass tube (5-mm diam; Alltech Associates, Lancashire, UK) inserted into the collection ports on the top of the vessels. Further pumps drew air (300 ml/min) through these tubes. Rates were controlled so that more purified air was pumped in than was drawn out, ensuring that unfiltered air was not drawn into the vessel from outside and obviating the need for a tight seal around the stem, which would have caused damage to the plant. All connections were made with PTFE tubing (Alltech Associates, Lancashire, UK) with brass ferrules and fittings (North London Valve, London, UK) and sealed with PTFE tape (Gibbs & Dandy, Luton, UK). Plants were entrained for 2 d, and the Porapak Q filter was eluted with 0.5 ml of redistilled diethyl ether, providing a solution that contained the isolated volatile compounds. Samples were

stored in vials in a freezer (−20°C) until used for the experiments.

Gas Chromatography Analysis Volatiles were analyzed on a Hewlett-Packard 6890 GC equipped with a cold on-column injector, a flame ionization detector (FID), a non-polar HP-1 bonded-phase fused silica capillary column (50 m×0.32 mm i.d., film thickness 0.52 μm) and a polar DB-WAX column (30 m×0.32 mm i.d., film thickness 0.82 μm). The oven temperature was maintained at 30°C for 1 min, and programmed at 5°C min^{-1} to 150°C, and held for 0.1 min, then 10°C min^{-1} to 230°C. The carrier gas was hydrogen. A 2 μl aliquot of the headspace sample was injected onto a capillary GC column. Quantification was carried out by comparison with 100 ng of external standard using authentic samples of standards.

Stereochemistry of α-pinene and caryophyllene was determined by using an HP5890 GC (Agilent Technologies, UK) equipped with a cool on-column injector and a FID, fitted with a β-cyclodextrin chiral capillary column (30 m× 0.25 mm i.d., 0.25 μm film thickness). The GC oven was maintained at 30°C for 1 min and then raised by 5°C min–1 to 150°C where it was held for 30 min. The carrier gas was hydrogen. A 1-μl aliquot solution that contained equal quantities of both enantiomers of the compounds in redistilled hexane was injected onto the chiral GC to establish that successful separation of enantiomers took place. This was followed by co-injections of the air entrainment sample, first with an authentic standard of one enantiomer and then with the second enantiomer. Peak enhancement with either enantiomer confirmed the presence of that enantiomer in the air entrainment sample.

Coupled Gas Chromatography-Electroantennography (GC-EAG) Electroantennogram (EAG) recordings were made with Ag-AgCl glass microelectrodes filled with Ringer solution (7.55 g l^{-1} sodium chloride, 0.64 g l^{-1} potassium chloride, 0.22 g l^{-1} calcium chloride, 1.73 g l^{-1} magnesium chloride, 0.86 g l^{-1} sodium bicarbonate, 0.61 g l^{-1} sodium orthophosphate). The head of a female *A. soccata*, anaesthetized by chilling, was separated from the body with a microscalpel, and the tip of the arista of one antenna was removed. The indifferent electrode was inserted within the head capsule, and the recording electrode was placed over the cut arista. The coupled GC-EAG system, in which the effluent from the GC column is simultaneously directed to the antennal preparation and the GC detector, has been described previously (Wadhams, 1990). Separation of the volatiles was achieved on a Hewlett-Packard 6890 gas chromatograph equipped with a cold on-column injector and a FID. The column used was 50 m×0.32-mm i.d. HP-1. The oven temperature was maintained at 30°C for 2 min, and then programmed at 15°C min^{-1} to 250°C. The carrier gas was helium. Electroantennogram signals were passed through a high-impedance amplifier (UN-06; Syntech, the Netherlands), and simultaneous recordings of the EAG and FID responses were obtained with specialized software (EAD version 2.3; Syntech, the Netherlands). Ten coupled runs were completed for each sample. FID peaks were considered to be active if they elicited an EAG response in two or more coupled runs.

Coupled Gas Chromatography-Mass Spectrometry (GC-MS) A 2 μl aliquot of the air headspace sample was injected onto a capillary GC (Agilent 6890) directly coupled to a mass spectrometer (Agilent 5973 MSD). Ionization was achieved by electron impact at 70 eV, 250°C. The oven temperature was maintained at 30°C for 5 min and then programmed at 5°C min^{-1} to 250°C. Tentative identifications of compounds that elicited an EAG response were made by comparison of spectra with those of authentic samples in a database (NIST 2005). Tentative identifications were subsequently confirmed by coinjection of the natural headspace sample with authentic standards and showing peak enhancement on two GC columns of different polarity (HP-1 and DB-WAX).

Olfactometer Bioassays A Perspex four-arm olfactometer (Pettersson, 1970) was used to determine behavioral responses of *A. soccata* females to intact *S. bicolor* (var. 'Swarna') plants, and a synthetic volatile blend that comprised all identified compounds that elicited an EAG response at the same concentration (2.64 μg) and ratio as in the headspace sample. The natural ratio was 24.7: 1.0: 0.014: 2.8: 7.8: 3.9: 1.1: 3.3, respectively, for (*Z*)-3-hexen-1-yl acetate, α-pinene, (-)-(*E*)-caryophyllene, methyl salicylate, octanal, decanal, 6-methyl-5-hepten-2-one, and nonanal. Prior to each experiment, all glassware was washed with Teepol, rinsed with acetone and distilled water, and baked in an oven overnight at 160°C. Perspex components were washed with Teepol solution, rinsed with 80% ethanol solution and distilled water, and left to air dry. The olfactometer was fitted with a filter-paper base (Whatman No. 1, 11 cm diam) to provide traction for the walking insect, and was illuminated from above by uniform lighting from two 18W/35 white fluorescent light bulbs screened with greaseproof paper to make it diffuse. It was surrounded by black paper to remove any external visual stimuli. *A. soccata*, obtained from the laboratory culture (3–5-d-old mated females), were transferred individually from the rearing cage into the central chamber of the olfactometer. A single shoot fly was introduced through a hole in the top of the olfactometer. Air was drawn through the central hole at the rate of 400 ml min^{-1}, and subsequently was exhausted from the room. Each shoot fly was given 2 min

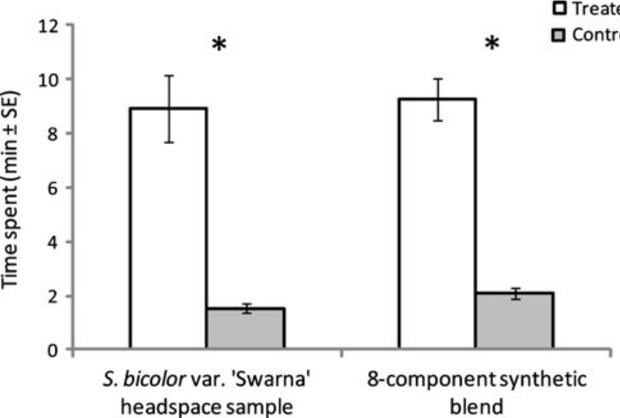

Fig. 1 Behavioral response of female *Atherigona soccata* to sorghum cv. 'Swarna' seedling volatiles in the olfactometer: time spent in treated and control arms (N=10). *Significantly different from control (P<0.01). The 8-component synthetic blend comprised (*Z*)-3-hexen-1-yl acetate, α-pinene, (-)-(*E*)-caryophyllene, methyl salicylate, octanal, decanal, 6-methyl-5-hepten-2-one, and nonanal in a 24.7: 1.0: 0.014: 2.8: 7.8: 3.9: 1.1: 3.3 ratio (2.64 μg total dose on filter paper)

to acclimatize in the olfactometer after which the experiment was run for 16 min for each replicate. The olfactometer was rotated 90° every 2 min to eliminate any directional bias in the room. It was divided into four regions corresponding to each of the four glass arms. Time spent and number of entries into each olfactometer arm was recorded with Olfa software (F. Nazzi, Udine, Italy). Ten replicates were carried out for each odor source tested. For each series of replicates, the mean time spent in treated and control regions were compared using a paired *t*-test (Genstat v. 12).

Initially, responses to headspace samples collected from sorghum seedlings were tested. Ten μl of the headspace sample were placed onto a piece of filter paper, 30 sec were allowed for the solvent to evaporate, and then it was placed in the treated arm. This dose was approximately the amount emitted by one sorghum plant over 1 h. The three control arms contained a piece of filter paper with 10 μl of redistilled diethyl ether. Synthetic compounds that elicited an EAG response were used as treatments in subsequent bioassays. Responses to individual compounds were tested by using 10 μl of 100 ng μl^{-1} solutions formulated in redistilled hexane in the treated arm and 10 μl of redistilled hexane in the control arms. Finally, compounds that elicited a positive behavioral response were formulated as a synthetic blend in redistilled hexane that comprised all the active compounds in the same concentration and ratio as in the headspace sample from which they were identified. A choice test between 10 μl synthetic blend and 10 μl headspace sample was carried out (Webster et al., 2008). These two treatments were assigned randomly to different glass arms in each replicate. The other two arms contained filter paper with 10 μl hexane, and were used as controls. Time spent in each region was recorded for 16 min. Ten replicates were carried out.

Results

Behavioral Responses to Headspace Samples In the olfactometer bioassay, female *A. soccata* spent significantly more time in the treated region of the olfactometer than the controls when a 10 μl aliquot of the *S. bicolor* headspace sample from the shoot fly susceptible cultivar 'Swarna' (growth stage: 15–21 days after emergence) was used (P= 0.001). Flies spent almost six times longer in the treated region of the olfactometer; mean time spent in the treated region (± S.E.) was 8.92 (± 1.22) min, whereas mean time spent in the control regions was 1.54 (± 0.18) min (Fig. 1). However, when volatiles collected from the shoot fly resistant cultivar IS 18551 were tested, attraction did not occur; mean time spent in the treated region was 1.99 (± 0.33) min, whereas mean time spent in the control regions was 4.49 (± 0.11) min.

Identification of Compounds that Elicited an EAG Response Coupled GC-EAG with female *A. soccata* revealed eight compounds eliciting an EAG response in the headspace sample of 'Swarna' (Fig. 2). By using coupled GC-MS and GC peak enhancement on two GC columns of different polarity, these compounds were identified as (*Z*)-3-hexen-

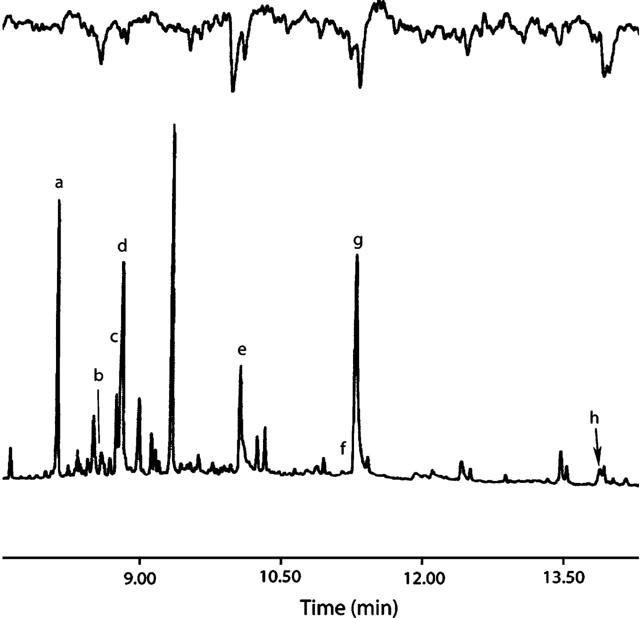

Fig. 2 Representative GC-EAG recording of female *Atherigona soccata* responses to sorghum cv. 'Swarna' seedling volatiles (HP1 column). The FID peaks marked are those that elicited responses in two or more coupled runs: *a* (-)-α-pinene, *b* 6-methyl-5-hepten-2-one, *c* octanal, *d* (*Z*)-3-hexen-1-yl acetate, *e* nonanal, *f* methyl salicylate, *g* decanal, *h* (-)-(*E*)-caryophyllene

Table 1 Compounds electrophysiologically active with *A. soccata* identified in *Sorghum bicolor* cv. 'Swarna' volatiles

Compound	Retention Index (HP-1, non-polar)	Retention Index (DB-WAX, polar)	Concentration (ng μl^{-1})
Green leaf volatiles and other aliphatic compounds			
6-Methyl-5-hepten-2-one	966	1,346	6.7
Octanal	980	1,298	46.3
(Z)-3-Hexen-1-yl acetate	988	1,317	146.0
Nonanal	1,084	1,393	19.4
Decanal	1,186	1,498	22.8
Aromatic compounds			
Methyl salicylate	1,175	1,796	16.3
Terpenoids			
(-)-α-Pinene	934	1,024	5.9
(-)-(*E*)-Caryophyllene	1,432	1,602	0.08

1-yl acetate, α-pinene, (-)-(*E*)-caryophyllene, methyl salicylate, octanal, decanal, 6-methyl-5-hepten-2-one, and nonanal. Chiral GC analyses showed that (-)-α-pinene and (-)-(*E*)-caryophyllene were present in the natural sample. The quantities of the EAG active compounds present in the attractive 'Swarna' headspace sample used in the bioassay are listed in Table 1.

Behavioral Responses to Synthetic Compounds All eight compounds that elicited an EAG response were behaviorally active when presented individually at a standard dose (1 μg on filter paper), with female *A. soccata* spending significantly longer in the treated region of the olfactometer (Table 2). When an eight-component synthetic blend of the EAG active compounds, at the same concentration and ratio as in the natural headspace sample (Table 1), was tested, a similar response to that obtained with the natural sample was observed, with the shoot flies spending more time in the treated region of the olfactometer than the controls ($P=0.001$) (Fig. 1). Furthermore, when this synthetic blend and the natural headspace sample were tested in a choice test, the shoot flies did not show any preference for either of the two treatments ($P=0.951$) (Fig. 3), thus demonstrating that the synthetic blend had activity similar to the natural sample. The total time spent in the two olfactometer treatment arms was greater than the total time spent in the two control arms ($P<0.001$). Further bioassays showed that a reduced component blend, based on a different headspace sample, comprising (*Z*)-3-hexen-1-yl acetate, (-)-α-pinene, and (-)-(*E*)-caryophyllene in the ratio (10.9: 1.0: 0.04) and concentration in that sample (0.42 μg) was highly attractive ($P<0.001$). When presented alone and in a choice test with a natural sample, it elicited a similar level of attraction ($P=0.763$).

Comparison of the Emission of Volatiles Between the Two Sorghum Varieties The shoot fly susceptible cultivar 'Swarna' and the shoot fly resistant control IS 18551 had different volatile profiles (Fig. 4). IS 18551 emitted fewer volatiles than 'Swarna' (overall emission was approx. 16 times less). In addition to the pronounced quantitative variation, we found substantial qualitative variation as IS 18551 did not emit α-pinene, (-)-(*E*)-caryophyllene, methyl salicylate, or octanal.

Table 2 Response of female *Atherigona soccata* to compounds (1 μg on filter paper) tested individually in olfactometer bioassay ($N=10$)

Compound	Treated mean (min)	SE	Control mean (min)	SE	*P* value (*t*-test)
(*Z*)-3-Hexenyl acetate	6.23	(± 0.61)	2.72	(± 0.21)	<0.001
Methyl salicylate	6.09	(± 0.63)	2.81	(± 0.26)	0.002
6-Methyl-5-hepten-2-one	5.05	(± 0.78)	3.18	(± 0.24)	0.048
(-)-α-Pinene	7.64	(± 0.69)	2.57	(± 0.20)	<0.001
Nonanal	5.61	(± 0.64)	3.04	(± 0.27)	0.01
Decanal	5.11	(± 0.44)	3.21	(± 0.21)	0.008
(-)-(*E*)-Caryophyllene	7.93	(± 0.98)	2.29	(± 0.29)	<0.001
Octanal	6.87	(± 0.72)	2.69	(± 0.21)	<0.001

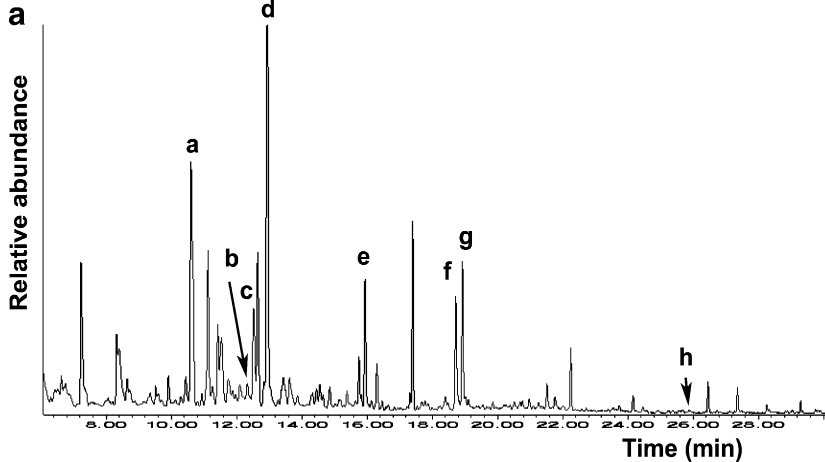
Discussion

Host plant recognition and selection in insects is determined mainly by the ovipositing female since newly emerged larvae often are limited in their dispersal abilities. Choice of a suitable oviposition site is crucial to the survival of progeny. Visual factors such as shape, color, and size are involved in this process, but chemical cues unambiguously play a major, if not decisive, role in host selection (Renwick and Chew, 1994). This study combined GC-EAG detection of active compounds in headspace collections and bioassays of behavioral responses of sorghum shoot fly, *A. soccata*, to these volatiles. Through this dual approach, we were able to identify active compounds in complex headspace blends and confirm that these compounds attracted female *A. soccata*. To the best of our knowledge, this is the first identification of sorghum seedling volatiles functioning as kairomones in attracting *A. soccata* to hosts.

The four-arm olfactometer bioassay (Pettersson, 1970) was chosen because it gives sufficient time for the initial escape responses of insects after release from the holding chamber to wear off. Air was drawn from the center of the arena, which was divided into four discrete odor fields. A significantly longer period of time spent in the treated arm indicated a positive response that required attraction for movement into it, although there may have been an arrestment component to a positive response. *A. soccata*



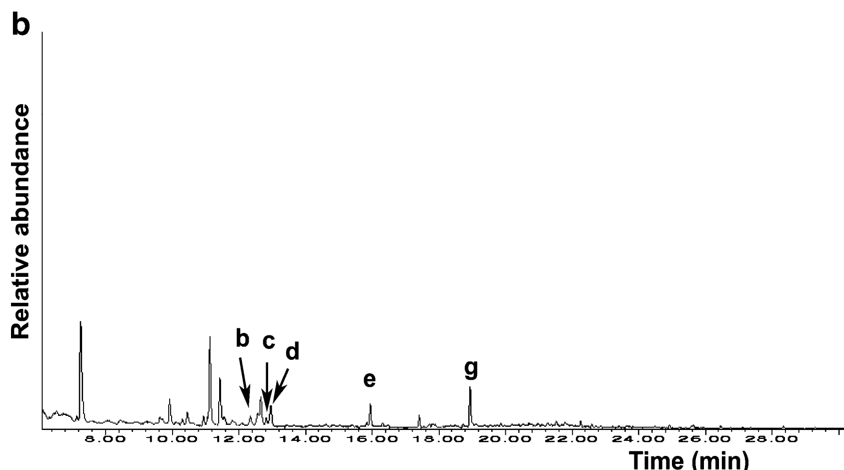


Fig. 4 Gas chromatogram (GC) traces of compounds identified in headspace samples of sorghum seedlings (HP5 column) **A** sorghum cv. 'Swarna'; **B** sorghum cv. IS18551. *a* (-)-α-pinene, *b* 6- methyl-5-hepten-2-one, *c* octanal, *d* (*Z*)- 3-hexen-1-yl acetate, *e* nonanal, *f* methyl salicylate, *g* decanal, *h* (-)-(*E*)-caryophyllene

females were attracted to the volatiles of susceptible sorghum seedlings in an earlier investigation, but the compounds responsible were not identified (Nwanze et al., 1998). In the present study, coupled GC-EAG revealed eight compounds that elicited an EAG response in a headspace sample collected from the susceptible sorghum cultivar, 'Swarna'. A synthetic kairomone blend that comprised all eight compounds in the same concentration and ratio (Table 1) elicited a similar behavioral response to the odor of headspace sample (Fig. 1). Furthermore, the shoot flies did not show any preference for the headspace sample over the synthetic blend when offered the choice, suggesting that the volatile compounds used in host location have been identified (Fig. 3). Laboratory bioassays where compounds are tested against clean air are a simplification of the more complicated situation that occurs in the field, where there are background volatiles emitted from other plants. In field situations, it is likely that blends of compounds are required for host recognition when ubiquitous compounds are used (Bruce et al., 2005; Bruce and Pickett, 2010). In the current study, individual host compounds were attractive, whereas, in other insects, positive behavioral responses are obtained only when a blend of volatiles is used (e.g., Webster et al., 2010).

Three compounds (nonanal, decanal, and (*Z*)-3-hexen-1-yl acetate) have been reported previously in volatiles from 4-wk-old *S. bicolor* (Serena cultivar) seedlings trapped on Tenax TA adsorbent (Lwande and Bentley, 1987), but the response of *A. soccata* to these compounds was not reported. Our study also revealed differences in the absolute quantity of odors emitted, as well as in the qualitative composition between the attractive susceptible cultivar 'Swarna' and a resistant control, IS 18551, which was not attractive. IS 18551 did not emit α-pinene and (-)-(*E*)-caryophyllene, which we found were key compounds responsible for the positive response to 'Swarna' volatiles in the olfactometer, even when released at relatively low rates. Trap crops could be developed by selection of plants that release higher amounts of the attractive compounds. Varietal or genotypic differences in volatile emission have been recorded for other plant species (Loughrin et al., 1995; Halitschke et al., 2000). Studies on different maize varieties revealed intraspecific variation both in quantity and quality of the odors released (Turlings et al., 1998; Gouinguene et al., 2001) within maize cultivated in temperate regions (Degen et al., 2004).

Host plant resistance is one of the most effective and preferred methods of controlling *A. soccata*. Considerable progress has been made in developing techniques to screen for *A. soccata* resistance, identifying the sources of resistance and the mechanisms of resistance. However, efforts to breed *A. soccata* resistant high yielding cultivars have not yet been successful. Thus, there is a need to look into the role of biochemical factors like plant volaties in ovipositional behavior of *A. soccata* as has been done successfully in the related cereal maize (Lupoli et al., 1990). Plant chemistry is probably the most important source of information contributing to the final decision by an insect to oviposit or not and depends on the balance of opposing positive and negative cues evoked by phytochemicals that determine whether a plant is accepted or rejected by a herbivore. Selection of sorghum genotypes that are not preferred for oviposition by *A. soccata* is valuable for the development of *A. soccata* resistant plants. This study, by identifying sorghum volatiles that elicit electrophysiological and positive behavioral responses with *A. soccata*, provides insight into the differential attraction/oviposition between susceptible and resistant genotypes observed in the field. Future work will analyze volatiles of other sorghum cultivars, and assess effects on attraction of *A. soccata* in the field.

However, Ballhorn et al. (2008a) observed higher cyanogenic potential in some cultivars (CV-2116, CV-2357, and CV-2233) than in wild types. Low concentrations of linamarin are found in U.S. varieties such as Fordhook 242 and Henderson also known as butter beans.

Arthropods like some other insects have developed detoxification mechanisms for these compounds. For instance, *Heliconius* butterflies metabolize cyanogenic glycosides found in their *Passiflora* host plants, sequestering some of its metabolic derivates and utilizing nitrogen from the rest (Engler et al., 2000). Larvae of *Acraea horta* (L.) were found to feed selectively on *Kiggelaria Africana* L. plants with high content of cyanogenic glycosides, and accumulate these compounds in the body in all developmental stages (Raubenheimer, 1989). Some zygaenid butterflies require the presence of cyanogenic glycosides in the host plant for normal development. Larvae of the butterfly *Zygaena filipendulae* (L.) (Zygaenoidea) developed at a decelerated rate when feeding on young acyanogenic *Lotus corniculatus* Plenus host plants as compared to those feeding on host plants with accumulated cyanogenic glycosides (Zagrobelny et al. 2007). In some Lepidopterans such as *Heliconius melpomene* (L.) (Papilionoidea) and Zygaenidae, detoxification is accomplished *via* a β-cyanoalanine synthase located in the mitochondria (Zagrobelny et al., 2008). The cherry-oat aphid, *Rhopalosiphum padi* L. (Hemiptera: Aphididae) prefers plants with endogenous β-glucosidase, which is released when the insect punctures and destroys plant tissue (Leszczynski et al., 2003).

The two spotted spider mite, *Tetranichus urticae* (Koch) (Acari: Tetranychidae), feeds on more than 150 different plant species (Jeppson et al., 1975) and has a high acceptability for plants of the Fabaceae family. Agrawal et al. (2002) and Magowski et al. (2003) reported that host plant preference by the two-spotted spider mite was influenced by the presence of natural toxins, and these impacted mite reproductive performance. Negative response to those chemicals can be overcome by conditioning, i.e., increasing acceptability of the host plants to subsequent spider mite generations (Navajas, 1998; Yang et al., 2001). Host plants also induce physiological changes in the mites by activating detoxification enzymes such as general esterases and glutathione S-transferases; this affects the susceptibility of the mites to some pesticides. Increased spider mite tolerance to λ-Cyhalothrin, which contains the cyano functional group, has been observed when mites were reared on lima beans (Yang et al., 2001).

Linamarin is used as a translocation chemical of sugars and nitrogen to the fruit (Frehner et al., 1990). In bean plants, linamarin is stored in the leaf epidermis (Poulton, 1990) instead of leaf mesophyll protoplasts (Frehner and Conn, 1987), which has been reported in other plants. Mites feed on the cell contents of plant epidermis (Boutaleb et al., 2000), which could imply that they ingest significant quantities of linamarin.

Plant chemical defenses against herbivores may negatively affect the fitness of entomophagous natural predators (Ode, 2006). In fact, some herbivorous insects sequester plant chemicals (including cyanogenic glycosides) and use them to defend against predators (Nishida, 2002; Hartmann, 2004). Such compounds also may affect insect predators indirectly by reducing the health of the herbivore prey (Hunter, 2003), or the predator may be affected by the plant compounds indirectly when feeding on their herbivore host or prey (Ode, 2006). Evidence for indirect toxic effects of plant chemicals to parasitoids comes from studies of host-parasitoid interactions. Campbell and Duffey (1979, 1981) described the effects of α-tomatine on the parasitoid *Hyposoter exiguae* (Viereck) parasitizing *Heliothis zea* (Boddie), which were grown on artificial diets that simulated tomato plant contents including α-tomatine. Similarly, Thorpe and Barbosa (1986) and Barbosa et al. (1986, 1991) studied the effects of nicotine on *Cotesia congregata* (Sey) parasitizing *Manduca sexta* L., which were grown on artificial diet that simulated tobacco plant concentrations of nicotine. Increased mortality of the parasitoid occurred at high concentrations of nicotine. There is no evidence for toxic effects of plant chemicals on predatory arthropods, but the fecundity and movement of the predatory mite *P. persimilis* Athias-Henriot is significantly affected by the host plant species used to feed its prey, *T. urticae* (Skirvin and de Courcy Williams, 1999). Because *T. urticae* is capable of infesting many plant species, the use of predatory mites as biological control agents may be impacted by the host plant on which the prey feeds, particularly within the Fabaceae where the content of cyanogenic glycosides is well documented. Additionally, bean plants frequently are used in the mass rearing of Phytoseiid mites because these plants grow fast and are excellent host for *T. urticae*. It is important to determine whether some of these plants may indirectly affect the fitness of the predators and therefore their quality as biological control agents.

Our specific objectives were: (1) to determine the content of linamarin and lotaustralin in lima bean, in *P. lunatus,* primary and terminal trifoliate leaves, in adults and nymphs of *T. urticae* feeding on primary and trifoliate lima bean leaves, and in adult mite predators, *P. persimilis,* feeding on spider mites fed on primary and trifoliate lima bean leaves; and (2) to determine the impact of host plant on fecundity and sex ratio of *T. urticae* and *P. persimilis*.

Methods and Materials

Maintenance of Mite Cultures Colonies of *T. urticae* and *P. persimilis* were established from stocks provided by Syngenta Bioline, Oxnard, CA, USA. Spider mites were

reared on Shell bean, a dark red kidney bean, *Phaseolus vulgaris*, (The wax Co., LLC, Armony, MS, USA), in a greenhouse. The predatory mites were reared in cages by using a variation of the procedure described by Fournier et al. (1985) in an environmentally controlled rearing room.

Maintenance of Plants Bean plants of *P. vulgaris* and *P. lunatus* were grown by using the same method. Plants were grown in 60 long × 20 wide × 20 high cm plastic planters filed with a bottom layer of perlite and a top layer of top soil vermiculite and polyacrylamide mix.

A mixture of 20 g water absolving polymer (cross-linked potassium polyacrilate / polyacrylamide copolymer) (TeraGel®, T-400, The Terawet Corporation, San Diego, CA, USA) and 10 g water soluble fertilizer (All purpose, plant food, Miracle-Gro, Marysville, OH, USA) was added to 2.5 L of tap water. The polymer provided a consistent water balance to the soil mix and reduced water lost. The aqueous solution was left undisturbed for 24 hr to allow TeraGel's polyacrylamide crystals to become completely hydrated. The resulting gel was homogeneously incorporated into a 2:1 potting soil (Moist control, Miracle-Gro Marysville, OH, USA) and vermiculite (Coarse, Sunshine, SunGro Horticulture, Bellevue, WA, USA) mixture with the help of a gardening spatula. The bottom of the planters was filled with 2.5 L of perlite (coarse, Sunshine, SunGro Horticulture, Bellevue, WA, USA) as support and to allow drainage for maintaining a consistent soil moisture. The soil mixture then was added to the planters, and 70 seeds were planted in each. Five g of slow release fertilizer (vegetable and bedding, Osmocote, Marysville, OH, USA) were spread on top of the planted seeds. Planters were irrigated daily with tap water after seed germination.

Leaf Sampling for Chemical Extraction Leaf samples of two different ages were collected from un-infested red and lima bean plants. From lima beans, 21-d-old primary leaves and 5-d-old terminal leaves (trifoliate) and 21-d-old primary leaves from red beans were selectively cut and placed in plastic boxes (35.5×19.6×10.7 cm) for transport to the laboratory. Leaf samples were dried in a vacuum oven at a low temperature of 20°C and a negative pressure of 3.63 kPa (kilopascals) until they were completely dry. Dry leaf samples were placed in plastic Ziploc® bags, labeled, and stored in a refrigerator at minus 16°C until ready for chemical extraction and analysis.

Tetranychus urticae Rearing and Sample Preparation Red bean and lima bean plants were infested with spider mites 10 d after germination. Infestation of the planters was carried out by manually introducing spider mites (from infested red bean leaves) onto 20 bottom leaves from each planter. The infested red bean leaves were placed on top of clean leaves and left there for 8 hr, thus allowing adult mites to migrate to the new leaves. The dry red bean leaves were removed, and the spider mites were allowed to reproduce on the plants of study for 22 d under greenhouse environmental conditions at 26±3°C and 35±10% RH and constant artificial light.

Infested lima bean leaves of the two ages described above and infested primary red bean leaves were collected individually by corresponding group age and placed in 4 L round plastic containers (half full) to which 2 cm diam round holes covered with a 60 µm nylon screen were randomly distributed as a source of ventilation. The boxes were closed with lids, and then were placed into an environment control room at 27±1°C and 50±5% RH for a period of 24 hr. The lids of the containers were gently removed to collect the web with mites, and this web was transferred to a piece of tissue paper with the help of a spatula. The tissue paper pieces with spider mites from the different leaf samples then were placed flat in plastic containers and transferred immediately into a freezer at minus16°C for 15 min to freeze the spider mites. Finally, the paper towel pieces with the frozen mites were gently shaken inside a 100 ml plastic cup to separate the frozen mites from the web. One hundred mg samples of clean frozen mites from each leaf species and type sample were weighed (PB303-S Mettler Toledo, Fisher Sci., Suwanee, GA, USA) into 1.5 ml plastic centrifuge tubes (P. No. FX4264GG, A. Daigger & Co., Inc., Vernon, Hills, IL, USA) and stored at minus16°C until they were analyzed chemically.

Phytoseiulus persimilis Rearing and Sample Preparation The predatory mites were reared using modified Ziploc® screw cover cylindrical 473 ml containers (Ziploc Twist'n Loc, small, round, S.C. Johnson & Son, Inc. Racine, WI, USA) connected from top to bottom to allow vertical movement of the predators between containers as reported by Fournier et al. (1985). Different sets of rearing cages were provided with each leaf type described above, and were infested with spider mites from the greenhouse. Each starting cage was filled with 15 infested leaves placed vertically to allow mite movement. Approximately 100 *P. persimilis* females from the stock colony were introduced into each cage. New cages with infested leaves were attached to the top of the starting cages after 3 d to allow predators to move from old leaves onto new ones. This process was repeated every 3 d for a 3 wk period at 27±2°C, 65±5% RH and 14:10 h (L: D) photoperiod to ensure that more than 2 generations of *P. persimilis* feeding developed on spider mites from each of the 3 leaf types tested (primary and terminal trifoliate lima bean and primary red bean leaves).

Adults of *P. persimilis* were collected from each of the 3 treatments in 120 ml plastic sample containers, connected to the top of each cage series. These containers were transferred to a freezer at −16°C for 15 min to freeze the

predators. One hundred mg samples of clean frozen mites from each leaf species and age sample were weighed (PB303-S Mettler Toledo, Fisher Sci., Suwanee, GA, USA) into the 1.5 ml plastic centrifuge tubes and stored at −16°C until chemical analyzes.

Chemical Analysis The samples consisting of un-infested primary red bean leaves, primary and trifoliate lima bean leaves, *T. urticae* reared on these 3 different leaf types, and *P. persimilis* reared on *T. urticae* from these 3 leaf types were all analyzed for contents of linamarin and lotaustralin by using the same method. Determination of the content of linamarin and lotaustralin was done by high performance liquid chromatography (HPLC) following a modification of the method reported by Stochmal and Oleszek (1994) and Oomah et al. (1992).

Lima Bean Leaves Portions of 1 g of each of the dry leaf samples were placed individually into 20 ml scintillation glass vials (P. No. 3002-1, Fisher Scientific, Suwanee, GA, USA), and 10 ml 70% methanol were added to each vial. The mixture was blended with the use of a tissue tearor (Model 985-370, Biosperr products, Inn, Daigger, Vernon Hills, IL, USA) for 3 min. Vials were closed and placed in a Branson sonic water bath (Model 3210, Fisher Scientific, Suwanee, GA, USA) for 20 min at 25°C. Samples were transferred individually to 25 ml Corex glass centrifuge tubes (P. No. A-34520-25, Cole Palmer, Vernon Hills, IL, USA) and loosely closed with screw lids. The tubes with the samples were centrifuged (Model Br4i, Jouan, Thermo Fisher Scientific, Suwanee, GA, USA) at 8,000 RPM at 10°C for 10 min. The aqueous solution was transferred to clean scintillation glass vials and placed into a vacuum oven at 40°C for 2 hr to remove the methanol. Carbohydrates and other impurities were removed from the water extracts by solid-phase extraction passing them through a pre conditioned C18 Sep-Pak (WAT036905, Waters, Co., Franklin, MA, USA) with 3 ml aliquot 20% methanol. One ml of the water extract was placed on top of the Sep-Pak and pushed slowly into the C18 material with a soft stream of pure nitrogen; then 5 ml of the 20% methanol solution were also gently pushed through into clean 20 ml glass vials with the gentle stream of pure nitrogen. This procedure was repeated for the remaining extracts. Purified eluates were combined and dried in the vacuum oven at 40°C. The concentrated samples were dissolved in 0.450 ml of a methanol:water:phosphoric acid (85:15:0.05) solution, which was the solvent used as mobile phase during HPLC analysis. Before injection, the 0.450 ml sample was filtered throughout a Watman mini-uniprep, 45 μm nylon filter media (Cat. No. UN203NPUNYL, VWR Suwanee, GA, USA) to remove any precipitates.

Tetranychus urticae and Phytoseiulus persimilis One ml of the 70% methanol solution was added to each of the 100 mg frozen samples. The samples were centrifuged (Model No. 5410, Eppendorf, Fisher Scientific, Suwanee, GA, USA) at 14,000 rpm for 10 min; then transfered to the sonic water bath as described above. After sonication, the excess methanol was removed by blowing with a gentle stream of nitrogen, with a glass Pasteur pipette directly into the centrifuge tube. The contents of the tube were transfer to the filtering unit, and 100 μl of the methanol:water: phosphoric acid (85:15:0.05) were added. Finally, each sample was transferred to 12×32 mm glass screw neck, total recovery glass vials (P. No. 186999385c, Waters, Co. Milford, MA, USA) prior to HPLC analyses. Peak identification was done as described above.

The HPLC analysis was done on a Waters Alliance 2690 controller, equipped with a Waters 410 differential refractometer detector, by automatically injecting a 20 μl sample into an Eurospher 100-5, RP18 (Icon, Scientific, Inc., North Potomac, MD, USA) column (P. No. 25VE181ESJ, Knauer, 250 mm× 4.6 mm i.d. and 5 μm particle size) with an integrated pre-column. The column was eluted with an isocratic flow rate of the methanol:water:phosphoric acid (85:15:0.05) at 1 ml per min at room temperature. Data were collected, and peaks were identified against the retention times for linamarin and lotaustralin standards (P. No. L466000 and L471250, respectively, TRC, Inc. Ontario, Canada) dissolved in the methanol: water:phosphoric acid at a known concentration of 1 mg/ml, via Chromeleon V. 6.8 software, (Dionex, Co. Houston, TX, USA) (Fig. 1).

Bioassays To determine the effect of linamarin on *T. urticae*, young adult male and female pairs from the stock culture reared on shell kidney red bean leaves were transferred to un-infested leaves with the aid of a 00 soft bristle brush. These un-infested leaves were either one of 3 types, and one was treated with linamarin: (1) 5-d-old shell red kidney bean primary leaves as control (2) 5-d-old lima bean terminal trifoliate leaves, (3) 21-d-old primary lima bean leaves, and (4) 5-d-old primary leaves of red shell kidney beans sprayed with 200 μl of a 800 ppm solution of linamarin. Each mite pair was encased inside a 50×9 mm tight fit Petri dish (P. No. 351006, Falcon, Fisher Scientific), which also enclosed a portion of the leaf when closed. Each dish had a 5 cm diam window covered with a 60 μm nylon screen in the center of the lid for ventilation. Three of these dishes were placed inside of 100×100×30 mm square clear plastic boxes (P. No. 091-C, Pioneer Packaging, Dixon, KY, USA), and 1 g of the saturated polyacrylamide was added to maintain humidity. The boxes were closed with lids and placed inside an environmental chamber (Model I30VL, Percival, Perry, IA) at 26±1°C, 65±5% RH and 14:10 h (D:L) photoperiod for 8 d. Nine pairs of *T. urticae* per each treatment and control were placed in experimental dishes.

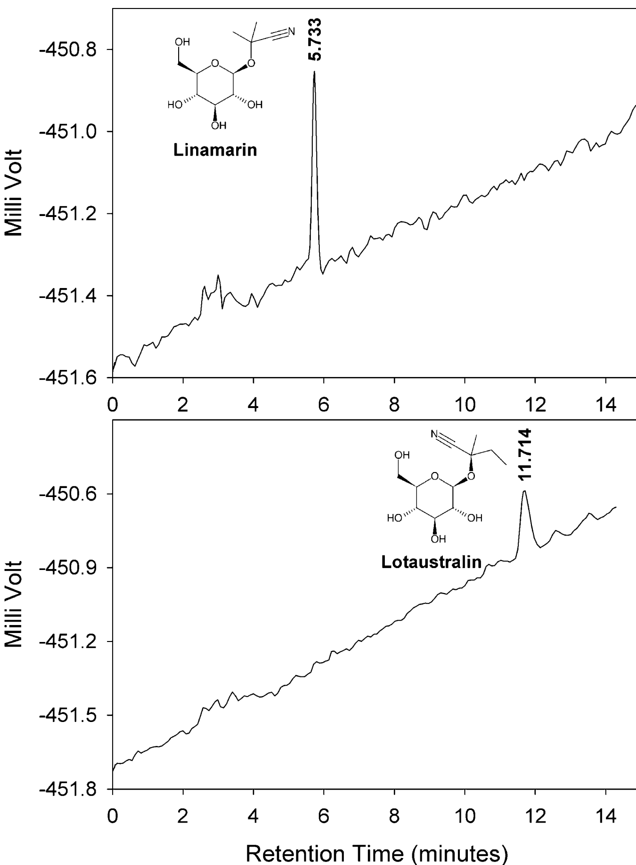

Fig. 1 Output graphs of HPLC data of standard solutions of linamarin and lotaustralin. Linamarin peak appears at 5.7 min and lotaustralin at 11.7 min. Baseline increased with retention time

At the end of the 8 d, period each dish was examined carefully under the stereo microscope to determine adult survival, total progeny including eggs, larvae, and nymphs. The sex of nymphs was determined, and the sex ratio within each dish was calculated as number of females per male (= females / males).

The effect of linamarin on the third trophic level was studied by a modification of the method described above. Pairs of male and female of *P. persimilis* were placed on leaves of the 3 types and were heavily infested with spider mites. These pairs and the corresponding infested leaves were encased in the tight fit Petri dishes as described. Dishes with predator pairs were placed inside boxes and allowed to reproduce for 8 d in an environmental chamber under the same conditions as described above. At the end of the 8 d period, dishes were examined carefully to determine adult survival, and to count total progeny produced including eggs, larvae, and nymphs. Twelve pairs of predators were set for each treatment.

Data Analysis Identification of the sample peaks was done by comparison of their retention times to those of standard solutions of linamarin by using the same procedures. Contents of linamarin and lotaustralin in parts per million (ppm) were calculated by comparing the graphic integration data of the biological samples from the analytical instrument to graphic integration of known concentration of a linamarin standard using MS-Excel 2003.

Data consisting of total progeny and progeny sex ratio in females per male of mite pairs of *T. urticae* and *P. persimilis* were compared among the different leaf type treatments using analysis of variance (ANOVA), and means were compared by the Tukey-Kramer HSD test using JMP statistical software (SAS Institute, 2007). Regression analysis was used to determine the impact of observed linamarin concentrations on the total progeny produced per female, and the progeny sex ratio was expressed as females per male.

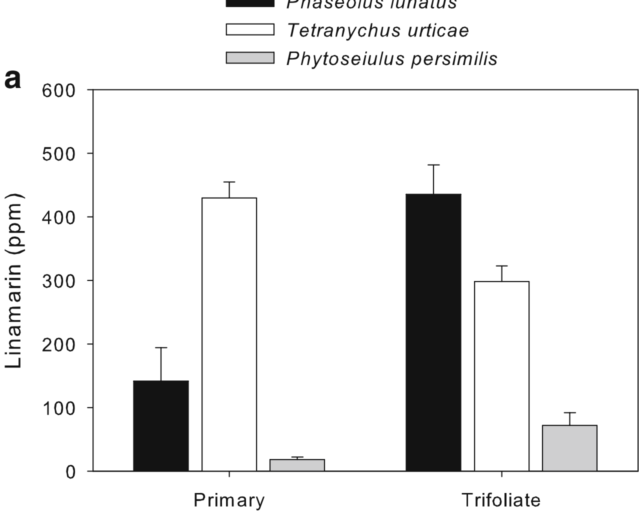
Results

Content of Linamarin and Lotaustralin Linamarin concentrations observed in the tissue of two types of lima bean leaves were not consistent with the concentration at the second trophic level. That is, chemical analyzes revealed that the content of linamarin was higher in terminal trifoliate leaves (435.5 ppm) than in primary leaves (142.1 ppm) of Henderson bush lima beans. However, the content of linamarin was higher in spider mites from primary leaves (429.8 ppm) than in those from terminal trifoliate leaves (298.2 ppm) of lima beans (Fig. 2). Lotaustralin concentrations were detectable only in the primary leaves of lima beans (103.12 ppm) and in the spider mites feeding on them (175.0 ppm). In terminal trifoliate Lima bean leaves and spider mites feeding on them lotaustralin was undetectable (Fig. 2). In addition, linamarin and lotaustralin were not detected in red bean leaves and spider mites feeding on them.

Eggs of spider mites feeding on primary Lima bean leaves had a concentration of linamarin of 26.32 ppm, approximately 6% of the concentration observed in adult mites, and there were no detectable quantities of lotaustralin.

The concentration of linamarin in mite tissue declined at the third trophic level. Predatory mites feeding on prey from terminal trifoliate and primary Lima bean leaves had a mean concentration of 71.9 and 18.42 ppm of linamarin, respectively. Analyses of predatory mite tissue did not detect lotaustralin in any of the samples (Fig. 2).

Effect of Host Plant on Reproduction and Sex Ratio The total progeny produced per female of *T. urticae* was not significantly affected by host plant species, but spider mites feeding on red bean primary leaves sprayed with a



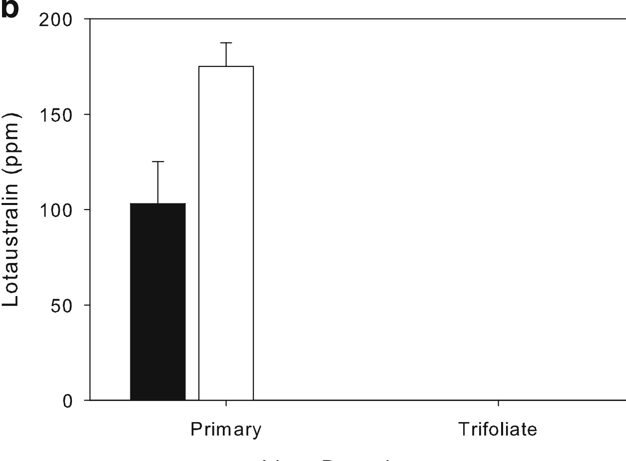


Fig. 2 Content of linamarin (**a**) and lotaustralin (**b**) in parts per million (ppm) in plant, spider mite, and predatory mite tissues of primary and terminal trifoliate leaves of Henderson lima bean plants. Brackets represent standard deviation

linamarin solution produced significantly less progeny than similar un-sprayed leaves (F=7.88; df=3, 36; P<0.001) (Table 1). The female:male sex ratio of the progeny of spider mites feeding on un-sprayed red bean primary leaves was significantly higher than that of mites feeding on both types of lima bean leaves and sprayed red bean leaves (F=12.72; df=3, 34; P<0.001) (Table 1).

Host plant linamarin effects were more noticeable on the predatory mites. Both, number of progeny per female (F=133.41; df=2, 33; P<0.001), and female:male sex ratio (F=24.68; df=2, 31; P<0.001) were significantly different among the 3 host plant leave types tested and were inversely proportional to linamarin content present in the prey tissue (Table 2). Linear regression analysis showed a significant negative impact of prey linamarin content on progeny per female (R^2=0.83; F=169.50; df=1, 34; P<0.001) and progeny female:male sex ratio (R^2=0.55; F=38.83; df=1, 32; P<0.001).

Discussion

Our results showed that the concentration of linamarin was higher in terminal trifoliate leaves than in primary leaves in Henderson lima bean plants. This is consistent with results reported previously by Ballhorn et al. (2008b). However, the concentration of linamarin in spider mites feeding on Henderson lima bean leaves was reversed. Spider mites feeding on primary leaves had a higher concentration of linamarin than mites feeding on terminal trifoliate leaves. One possible explanation for this apparent inconsistency could be the lower nutritional value of primary leaves as compared to young (terminal) trifoliate leaves. Ballhorn et al. (2008b) reported higher concentration of soluble protein in young secondary leaves than in primary leaves of lima beans. Nitrogen in the form of protein is considered to be one of the critical elements in the growth of herbivores (Scriber, 1984; Panda and Khush, 1995). Spider mite fitness has been reported to correlate with host plant nutritional content,

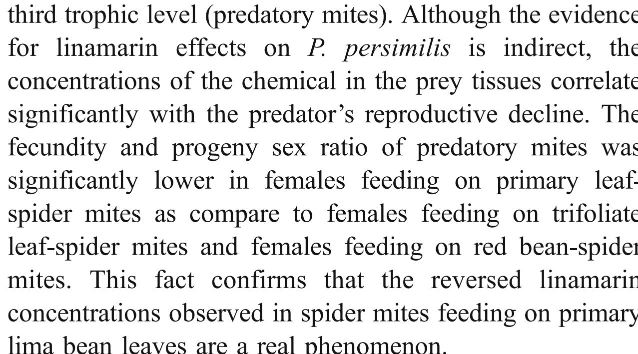
especially nitrogen in the form of protein (Wermelinger et al., 1991). Herbivores have the capacity to compensate for variations in plant nitrogen content by adjusting consumption (Panda and Khush, 1995; Felton, 1996). Spider mites growing on primary leaves must consume more tissue in order to maintain the same growth and reproductive activity, thereby increasing the amount of secondary compounds ingested. In most plants, aging leaves tend to go through changes in chemical composition, decreasing in water and nitrogen content, thereby reducing their nutritional value (Scriber, 1984). The fecundity and intrinsic rate of increase (r_m) of *Mononychellus tanajoa* (Bondar) increased when they were developing in young leaves of cassava plants as opposed to older leaves of these plants (Yaninek et al., 1989). Howeler and Cadavid (1983) reported that old leaves of cassava have reduced nitrogen content. In our study, we found no evidence of reduced fecundity in spider mites feeding on older primary leaves, which suggests that spider mites may be adjusting for the reduced nutritional value of the host leaves.

Fecundity and progeny sex ratio of *T. urticae* females feeding on primary vs. trifoliate lima bean leaves did not show significant differences despite the presence of lotaustralin in primary leaves and its absence in trifoliate leaves and the higher accumulation of linamarin observed in spider mites feeding on primary leaves. Spider mites feeding on red bean primary leaves did not produce more progeny, but, the sex ratio of their progeny was twice as high as that of spider mites feeding on Lima bean leaves. In a study of host plant suitability, Yano et al. (2001) observed that fecundity was not affected in spider mites feeding on unsuitable host; however, fitness of the population was impacted by reduced fertility of males. While female fecundity remained unaffected in lima bean leaves, the reduced sex ratio observed in their progeny could be explained by male infertility.

The sex ratio of spider mite progeny from females feeding on red bean leaves was reduced to the same levels as those observed in females feeding on Lima bean leaves when a solution of 1,000 ppm of linamarin was sprayed on the red bean leaves. The fecundity of female spider mites feeding on red beans was not statistically different from that of females feeding on Lima bean leaves. However, females feeding on linamarin-sprayed red bean leaves produced significantly fewer progeny. The concentration of linamarin in the spray solution was more than twice the levels observed in Lima bean leaves (1,000 vs. 449 and 142 ppm) producing a higher level of linamarin exposure in mites feeding on sprayed red bean leaves. This may be an indication of the existence of a linamarin concentration threshold for biological activity on spider mite females.

The impact of host plant linamarin accumulated at the second trophic level (spider mites) was amplified at the



third trophic level (predatory mites). Although the evidence for linamarin effects on *P. persimilis* is indirect, the concentrations of the chemical in the prey tissues correlate significantly with the predator's reproductive decline. The fecundity and progeny sex ratio of predatory mites was significantly lower in females feeding on primary leaf-spider mites as compare to females feeding on trifoliate leaf-spider mites and females feeding on red bean-spider mites. This fact confirms that the reversed linamarin concentrations observed in spider mites feeding on primary lima bean leaves are a real phenomenon.

Although *P. persimilis* feeds on spider mite eggs, which showed a much lower concentration of linamarin, fecundity and progeny sex ratio were both inversely proportional and negatively correlated to the linamarin concentrations present in the spider mite prey. Adults of *P. persimilis* do not eat eggs exclusively, and apparently these predators were considerably more sensitive to the concentrations of linamarin than *T. urticae*. Arthropod natural enemies, such as predators and parasitoids, often are more susceptible to plant secondary chemicals than herbivores (Ode, 2006). Direct evidence for linamarin impact on the third trophic level requires prey reared on artificial diet with artificial manipulation of linamarin concentrations. These studies will be conducted in the future.

The third trophic level effect of cyanogenic glycosides on *P. persimilis* may have implications for the relative effectiveness of this predator as a biological control agent against *T. urticae* in host plants with a high content of cyanogenic glycosides. The fitness of *P. persimilis* is reduced greatly by the presence of linamarin, while *T. urticae* appears to have significant tolerance to this chemical. The reduction in progeny sex ratio that *T. urticae* experience while feeding on lima bean leaves seems to be a small trade off for the protection that these plant semiochemicals provide against its predator *P. persimilis*. However, our data do not provide evidence for linamarin sequestration in *T. urticae*, as concentrations of this chemical in plant tissue do not correlate with the concentrations accumulated in the mite tissues. Increased linamarin concentrations in mites feeding on primary lima bean leaves can be explained by trophic interactions between herbivore and plant. Linamarin concentration in plant tissues also is an important consideration when choosing a host plant for *in vivo* mass rearing of phytoseiid mites on spider mite prey.

herbivores elicits different quantities and blends of HIPVs than do jasmonates (Bruinsma et al., 2009).

Research on other feeding-induced plant responses often shows substantial seasonal or ontogenetic variation in their magnitude (Stout et al., 1996; Thaler et al., 1996; Karban and Baldwin, 1997). Such findings suggest that these induced responses may be best developed in, and perhaps limited to, relatively young plants or plant tissues (Karban and Myers, 1989).

In contrast to inducible direct defenses, the potential for seasonal variation in HIPV production has received minimal study. In maize (*Zea mays*), HIPV production in seedlings is inducible, but HIPV production in mature leaves apparently is not (Köllner et al., 2004). In soybean (*Glycine max*), feeding by the fall armyworm, *Spodoptera frugiperda*, induced ca. ten times the total HIPVs from leaves of 5-wk-old non-flowering vegetative plants compared to 10-wk-old flowering plants (Rostas and Eggert, 2008).

Although the study of induced HIPVs in cultivated species in the laboratory has logistic advantages, it is difficult to draw strong inferences on the evolution and maintenance of HIPV production in cultivated species because the interacting species often are far removed from their evolutionary context. One natural system in which such limitations can be overcome involves the native, undomesticated plant species, *Datura wrightii* (Solanaceae) and its native herbivores and natural enemies. In the laboratory, young plants of this species produce similar blends of HIPVs either when fed upon by the specialist chrysomelid beetle *Lema daturaphila*, or when treated with MeJA (Hare, 2007).

Unlike most of the rapidly-growing annual species in which HIPV production has been studied, *D. wrightii* has a long growing season in the sage scrub habitats of inland southern California. Seeds germinate in March or April after winter rains, but flowering usually is not initiated until June, after which plants continue to grow while also producing flowers and seed capsules through November. The plant is perennial, and plants may produce new sprouts from the root crown as early as February.

Within southern California populations, *D. wrightii* exhibits two leaf trichome phenotypes, and aspects of the ecology and genetics of the trichome dimorphism have been described elsewhere (van Dam and Hare, 1998; van Dam et al., 1999). The 'velvety' phenotype is densely covered by short, non-glandular trichomes and feels velvety to the touch, whereas the 'sticky' phenotype is less densely covered with glandular trichomes that secrete esters of glucose and aliphatic acids, and these leaves feel sticky to the touch. The trichome phenotype is governed by a single locus and is inherited in a Mendelian fashion; the allele for the sticky phenotype is dominant over that of the velvety phenotype (van Dam et al., 1999). Seedlings, new sprouts produced during the spring, and even new sprouts produced in mid-season after plants have been completely defoliated, all produce leaves that are covered with glandular trichomes (Elle et al., 1999). In all cases, however, the homozygous recessive genotype soon begins to produce leaves with a progressively greater proportion of nonglandular trichomes until differentiation to the velvety phenotype is completed (van Dam et al., 1999).

The herbivore community that attacks *D. wrightii* is relatively simple, being comprised of some five to ten species, depending upon season and location (Elle and Hare, 2000; Hare and Elle, 2002). The most abundant herbivore species overall is *Lema daturaphila*, a folivore whose adult and larval stages impose chronic, season-long herbivory on both trichome phenotypes. On sticky plants, the most abundant herbivore is the mirid bug, *Tupiocoris notatus*. This insect punctures and kills leaf cells while removing their contents. Both species are multivoltine and feed on *D. wrightii* throughout the plant's growing season. Other herbivores usually are less abundant and more limited seasonally in their occurrence (Elle and Hare, 2000).

A number of generalist natural enemies are associated with the herbivores of *D. wrightii*, but the most abundant is the predaceous western big-eyed bug, *Geocoris pallens* (Heteroptera: Lygaeidae). This is one of several generalist predators that is more effective against both *L. daturaphila* and *T. notatus* when the herbivores are on velvety rather than on sticky plants (Gassmann and Hare, 2005). Individual components of the HIPV blends of other plant species are known to attract *G. pallens* (Kessler and Baldwin, 2001; Halitschke et al., 2008), and this suggests that this predator may be attracted to some key compounds within a blend regardless of the blend's overall composition. This predator also inflicts higher mortality on eggs and young larvae of *L. daturaphila* on herbivore-damaged or MeJA-treated *D. wrightii* plants than on undamaged or untreated plants (J. D. Hare, pers. obs.).

In order to understand the potential for *D. wrightii* to release HIPVs that may attract natural enemies of its herbivores, this study analyzed the HIPV production of field-grown *D. wrightii* plants that were damaged by resident herbivore populations. Abundances of *L. daturaphila, T. notatus*¸ and *G. pallens* were monitored to determine how the seasonal production of HIPVs might relate to seasonal abundance patterns of the historically most abundant herbivores and their natural enemy. The goal was to test the null hypothesis of no qualitative or quantitative variation in induced HIPV production during the growing season. If the null hypothesis were rejected, then the variation in HIPV production might be caused either by variation in abiotic factors, such as temperature and relative humidity, that are known to vary over the growing season as well as to affect HIPV production (Gouinguene and Turlings, 2002), or by

ontogenetic changes in plants that are normally correlated with seasonal development. Seasonal variation in HIPV production indeed was observed. Therefore, additional experiments were performed on other plants using MeJA to control more precisely the process of induction to separate the effects of ontogenetic development of plants from seasonal variation in abiotic parameters on qualitative and quantitative variation in HIPV production.

Methods and Materials

Study Site Experiments were carried out in two adjacent fields at the experimental farm of the University of California, Riverside. In one field, plants were attacked naturally by a resident population of herbivores, whereas plants in the other field were induced by MeJA. To control for possible genetic variation in HIPV production, only plants of the highly inducible MVV6 and MVV8 lines (Hare, 2007) were used. All plants were backcross progeny of heterozygote sticky pollen acceptors and their original homozygous recessive velvety pollen parent for four (herbivory plot) or five (MeJA-induced plot) generations.

The collection of volatiles from herbivore-damaged plants, and herbivore and natural enemy abundances were monitored in a 2-yr-old field plot of plants that was maintained in a 'naturalized' condition with minimal weed control and no irrigation after the normal winter rains. Both herbivore and natural enemy populations had become established in this field, and surviving velvety plants were more abundant than sticky plants by the time this experiment was initiated.

For collection of volatiles from plants with better control of the timing and level of induction, a second plot was established 0.1 km away. Given the size of mature plants (1 m in height and 3 m in diam., Hare et al., 2003), it would have been impractical to attempt to induce these experimental plants to the same extent and at the same time with natural herbivory, so precisely-timed applications of MeJA were used instead. The separation of this plot from the herbivore-infested plot aided in keeping this plot free from herbivores and the plants uninduced prior to MeJA application.

For this plot, seeds were planted in a seedling flat on 24 January, 2009, stratified in a cold room (5.6 ° C) for 10 d, then placed in an incubator with alternating day and night temperatures (16:8 L:D, 30°:20 ° C). After 21 d, seedlings were transplanted to 10 cm pots and kept in the greenhouse (15°–30 ° C), with natural illumination extended to 16 h/d with sodium vapor lamps.

There were 10 blocks of 16 plants spaced 2.3 m apart within and between rows, and blocks were separated from each other by 8.4 m of bare ground. The area was treated with a pre-emergence herbicide (Trifluralin at the rate of 668 ml/ha). The plot was furrow-irrigated prior to transplanting for 24 h, then for 8 h 3 days after transplanting, and weekly for 8 h for three wk thereafter. The plants were not irrigated after 21 April, 2009, and no rainfall occurred during the experiment. The absence of any rainfall during the spring and summer is characteristic of the sage scrub habitat in which *D. wrightii* commonly occurs. Seedlings were transplanted to the field prior to differentiation of adult trichome type to facilitate establishment on 31 March, 2009, but this precluded having equal numbers of sticky and velvety plants in each block. After differentiation was complete, the observed frequency of sticky to velvety plants over all blocks was 82 sticky: 78 velvety, not significantly different from an expected 1:1 ratio for these backcross progeny. Plants were treated weekly, except during the weeks when volatiles were collected, with prophylactic applications of acephate (Orthene 97, Valent Chemical Co., Walnut Creek, CA, USA 1.2 g/l) in water to protect them from herbivory. Preliminary experiments showed that acephate alone did not induce HIPVs.

Induction and HIPV Collection in the Field Field procedures utilized aeration chambers, air lines, and traps of the same design as used previously in the laboratory (Hare, 2007). Aeration chambers were made from polyester cooking bags (unprinted 45 × 55 cm bags, Terinex, Bedford, U.K.). HIPVs were adsorbed on traps made of 4.6 mm O.D. glass tubing and filled with 25 mg of Super-Q (Alltech, State College, PA, USA). Air was introduced into the bag through PTFE tubing (4.6 mm O.D.) and was withdrawn from the bags through the traps through PVC tubing (4.6 mm I.D.) downstream of the traps. Air flow was provided by two 12-V portable air pumps (Model # MOA-P125-JH, Gast Manufacturing, Benton Harbor, MI, USA). One pumped air to the bags and the other withdrew it. A 12-V deep-cycle marine battery powered both pumps. A manifold with 16 pairs of flow meters (Aalborg Instruments, Orangeburg, NY, USA) was constructed so that inlet and exhaust flow to and from 16 sampling bags could be precisely and independently regulated at 1.0 l/min for each plant. Inlet air was drawn through a filter of activated charcoal placed between the pump and the manifold. Preliminary studies showed that the charcoal filter was sufficient to remove all ambient HIPVs.

Because the canopies of mid-season plants are comprised of several thousand leaves (Hare et al., 2003), it was not possible to sample HIPV production from the whole plant. An aeration bag was placed over the terminal leaves of a branch and secured with a twist-tie around the stem. The bag enclosed 4–6 full-sized leaves and a similar number of growing leaves. Branches with flowers were not used to avoid confounding floral volatiles with foliar

HIPVs. Volatiles were collected for 90 min. At the termination of the aeration, traps were wrapped in aluminum foil, labeled, returned to the laboratory, and stored at −20° C for extraction later that day. Two groups of 16 plants were aerated each day, usually from 08.30 h until 10.00 h, and from 11.00 h until 12.30 h.

Plants to be treated with MeJA were aerated twice, once prior to MeJA treatment and once afterward. As bags were removed from the aeration prior to MeJA treatment, the twist-ties were reattached to the branch where they sealed the bag to serve as a marker so that precisely the same leaves could be aerated after MeJA treatment. The upper surfaces of all leaves were sprayed with a solution of 8 mM MeJA in 0.1% Tween 20® in water just to run-off after the pretreatment aeration. This rate was chosen because it induced similar quantities of HIPVs as feeding by *L. daturaphila* in laboratory experiments (Hare, 2007). Plants were aerated a second time on the 3rd day following treatment. After post-treatment aeration, the aerated branches were clipped, brought to the laboratory, then all aerated leaves were removed and dried (80ºC for 48 h) to determine dry mass. A preliminary experiment showed that 0.1% Tween 20 alone did not induce HIPVs. After both aerations in a natural state, plants were "rejuvenated" by cutting them back to the root crown and allowing them to resprout and produce new foliage. After a month, plants were once again aerated before and after treatment with MeJA.

Herbivore-damaged plants were aerated only once. Because they were all being damaged, no pre-treatment aeration was possible. For both trichome phenotypes, branches were selected with actively feeding, 2nd or older instars of *L. daturaphila,* but larvae were removed prior to aeration. Sticky plants also were attacked by *T. notatus*, which also were removed prior to aeration. After aeration, the aerated leaves were removed and brought back to the laboratory. The percent defoliation averaged over all aerated leaves was estimated by a trained person before leaves were dried, as above, and the same person made all estimates throughout the experiment.

Five series of aerations were completed at 5wk intervals, starting the week of 27 April, 2009, and concluding the week of 14 September, 2009. Uninduced plants were aerated on Mondays and Tuesdays, herbivore-damaged plants were aerated on Wednesdays, and MeJA-induced plants were aerated on Thursdays and Fridays. All aerations took place under clear skies and full sunlight and were typical of inland southern California in all respects. Data on air temperature, relative humidity, and light intensity, recorded hourly from 09.00 h until 13.00 h, were obtained from records from the California Irrigation Management Information System (CIMIS) weather station located at the UC Riverside experimental farm (supporting information Table S1). A total of 736 aerations were planned over the season, but data from 18 were lost due to random accidents such as leaky or punctured bags, leaving a total of 718 aerations: 561 aerations from MeJA-treated and rejuvenated plants and 157 from plants naturally damaged by herbivores.

Volatiles were eluted from the traps with 150 µl of CH_2Cl_2 containing 4 ng/µl of 1-bromoheptane as an internal standard into autosampler vials with 250 µl glass inserts and sealed with crimp caps and PTFE-lined rubber septa. Samples were analyzed by gas-liquid chromatography largely as described in Hare (2007) except that a shorter column (DB-5, 30 m, 0.25 mm ID, 0.25 µm film thickness, J & W Scientific, Folsom, CA, USA) and an autoinjector (Hewlett-Packard 7673) were used. To confirm identifications, selected samples were analyzed with a Hewlett-Packard 6890 gas chromatograph coupled to a Hewlett-Packard 5973 mass selective detector, and the mass spectra and retention times of compounds were matched with those of authentic standards as described in Hare (2007). Peak quantification in units of $ng{\cdot}g^{-1}$ leaf (dry wt.) h^{-1} was made using Agilent ChemStation® software based on comparison of their peak height with that of the internal standard.

Insect Abundances Insect censuses were taken at 2 wk intervals from 1 May through 25 September, 2009. For each census, up to 16 plants, 8 sticky and 8 velvety, were randomly selected, and a sleeve cage was placed around the base of each plant with the lower drawstring tied around the base of the plant. The cage remained open to allow recolonization of any arthropods that were disturbed by placing the cage around the plant. On the next day, the sleeve cage was quickly drawn around the plant, and the upper drawstring was tied to fully cage the plant, then the plant was cut at the base and returned to the laboratory. Plants were placed in plastic trash bags, and all arthropods were anesthetized with CO_2. Cages were opened, and all insects were removed, counted, and placed in labeled vials with 70% ethyl alcohol. Abundances of *L. daturaphila* and *G. pallens* are reported for each sampling date for both sticky and velvety plants, but abundances of *T. notatus* are reported only for sticky plants because *T. notatus* rarely occurs on velvety plants (Hare and Elle, 2002).

Statistical Analyses Analyses were carried out on total HIPVs, calculated as the sum of all individual HIPVs per plant, followed by multivariate analyses on the HIPV blend because the quantities of individual HIPVs were intercorrelated (van Dam and Poppy, 2008). I used PROC PRINCOMP of SAS (SAS Institute, 2008) to conduct an exploratory Principal Components Analysis (PCA) based upon the covariance matrix of all 718 samples to calculate a smaller number of uncorrelated components that were linear combinations of the original variables and to identify particular components contributing most to the patterns of variation in

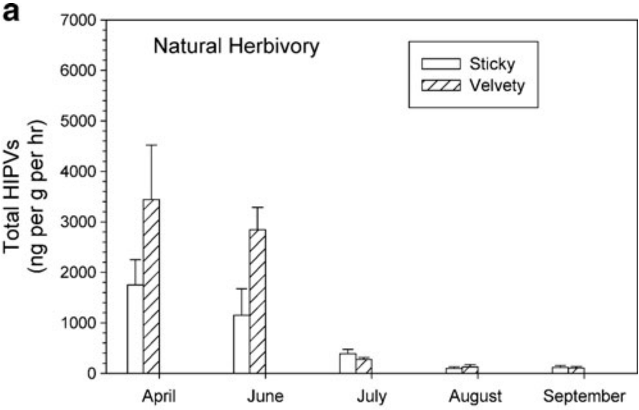
HIPV production. The factor loadings show how much each of the original variables contributes to each new component, and factor scores for the new components were calculated for each original observation. General patterns of variation illustrated by bivariate plots of the factor loadings and means of factor scores were explored further with restricted maximum likelihood (REML) analyses of variance (ANOVA) on the individual HIPVs with greatest factor loadings. Repeated measures ANOVAS using PROC MIXED of SAS were used to compare HIPV production of nonrejuvenated and rejuvenated plants before and after MeJA treatment. These models also included trichome type and aeration date, and all interactions as fixed effects. Where appropriate, two-way interactions were decomposed using the SLICE option of PROC MIXED. REML approaches to ANOVA are more appropriate than conventional approaches (e.g., PROC GLM of SAS) when sample sizes are unequal. In all models, 'block' (e.g., the group of 16 plants) was included as a random factor but was deleted from the final model when not statistically significant. For all HIPV analyses, the $\log_{10}$ (x+1) transformation was used to ensure normality of errors; the x+1 transformation was required because a few plants produced no detectable HIPVs, especially late in the season.

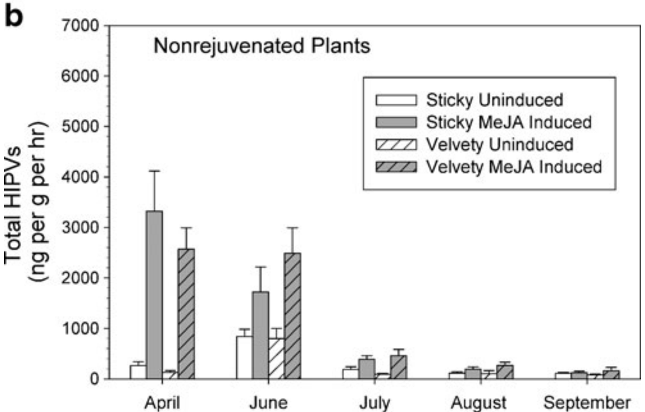
Analysis of covariance (ANCOVA) was used to analyze $\log_{10}$-transformed HIPV production of herbivore-damaged plants. Aeration date, trichome type, and their interaction were included as fixed effects, and percent defoliation was included as a covariate. Insect abundances also were analyzed by restricted maximum likelihood ANOVA after the $\log_{10}$ (x+1) transformation using a model that including sampling date, trichome phenotype, and their interaction as fixed treatment effects.

Results

HIPVs in the Field In general, the group of compounds detected was similar to those reported in a previous laboratory study (Hare, 2007). Abundant compounds included (*E*)-β-ocimene, (*E*)-β-caryophyllene, (*Z*)-3-hexenyl acetate, and (*E*)-4,8,dimethyl-1,3,7 nonatriene (hereafter DMNT). Other components of more limited abundance and occurrence included limonene, linalool, an isomer of bergamotene, α-humulene, β-selinene, nerolidol, and (*E*, *E*)-4,8,12 trimethyl-1,3,7,11 tridecatetraene (hereafter TMTT). In contrast to the laboratory studies, methyl salicylate, (*E, E*)-α-farnesene, and geranyl acetone were detected occasionally from plants aerated in the field. Basic statistics for all compounds are available in supporting information Table S2.

HIPV production by herbivore-damaged plants varied significantly over time (ANCOVA, date effect $F_{4,\ 132}$= 44.04, P<0.001, Fig. 1a). In April, defoliation averaging 7.3% and 8.3% on sticky and velvety plants, respectively, resulted in the production of over 2,500 ng total HIPVs g^{-1} leaf tissue (dry wt.) h^{-1}. In June, defoliation of 4.9 and 10.5% on sticky and velvety plants resulted in the production only about 2,000 ng total HIPVs g^{-1} leaf tissue (dry wt.) h^{-1} (Fig. 1a). Defoliation levels were higher in July, averaging 13.1 and 13.4% on sticky and velvety plants, respectively, but the production of HIPVs dropped to less than 350 ng $\cdot g^{-1}$





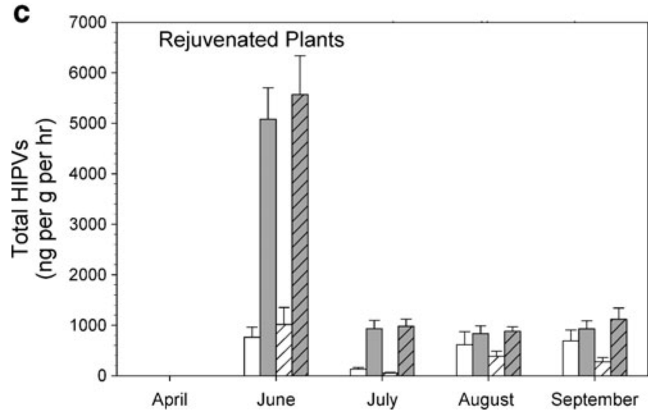


Fig. 1 Total HIPV production in the field for herbivore-damaged *Datura wrightii* plants (**a**), and for nonrejuvenated (**b**) and rejuvenated (**c**) plants before (Uninduced) and after application of MeJA (MeJA Induced). Mean (+ standard errors) production in $ng \cdot g^{-1}$ (dry wt) leaf wt h^{-1} are shown for plants expressing the sticky or velvety trichome phenotype

leaf tissue (dry wt.) h^{-1}. Plants produced only about 110 ng total HIPVs g^{-1} leaf tissue (dry wt.) h^{-1} in August and September in response to herbivory averaging 8.5 and 7.3% on sticky and velvety plants in August and 8.8% and 8.4% in September. There was no linear relationship between percent defoliation and $\log_{10}$ HIPV production overall (P=0.14, Fig. 2), nor was there any heterogeneity of slopes between percent defoliation and total HIPV production within sampling dates (P=0.78). Neither did HIPV production differ significantly between trichome types (P=0.26). In summary, herbivory averaging 7–8% defoliation resulted in the production of nearly 25-fold more HIPVs when inflicted on plants in April than when inflicted in August or September.

MeJA treatment also significantly increased HIPV emission but the amount varied over the season (repeated measures ANOVA, treatment by date interaction $F_{4,\ 149}$= 22.16, P<0.001). In April, plants emitted nearly 2,700 more ng total HIPVs g^{-1} leaf tissue (dry wt.) h^{-1} after MeJA treatment than before treatment, but the difference was cut substantially by June (Fig. 1b). The differences before and after MeJA treatment continued to decline throughout the summer, but were statistically significant from April through August (repeated measures ANOVA, SLICE decomposition of monthly differences, all $F_{1,\ 149}\geq$ 16.32, all P<0.001). The difference in HIPV production before and after MeJA treatment in September was not statistically significant (P=0.45), indicating that MeJA did not induce HIPV production at this time.

All sampled plants successfully resprouted, and the differences in total HIPV production of these rejuvenated plants before and after MeJA treatment always were statistically significant (repeated measures ANOVAs, all $F_{1,\ 120}\geq$19.59, all P<0.001) and ranged from a maximum difference of over 4,000 ng total HIPVs g^{-1} leaf tissue (dry wt.) h^{-1} in the June aeration to a low of 365 ng total HIPVs g^{-1} leaf tissue (dry wt.) h^{-1} in the August aeration (Fig. 1c). Direct comparison of nonrejuvenated and rejuvenated plants showed that rejuvenated plants produced

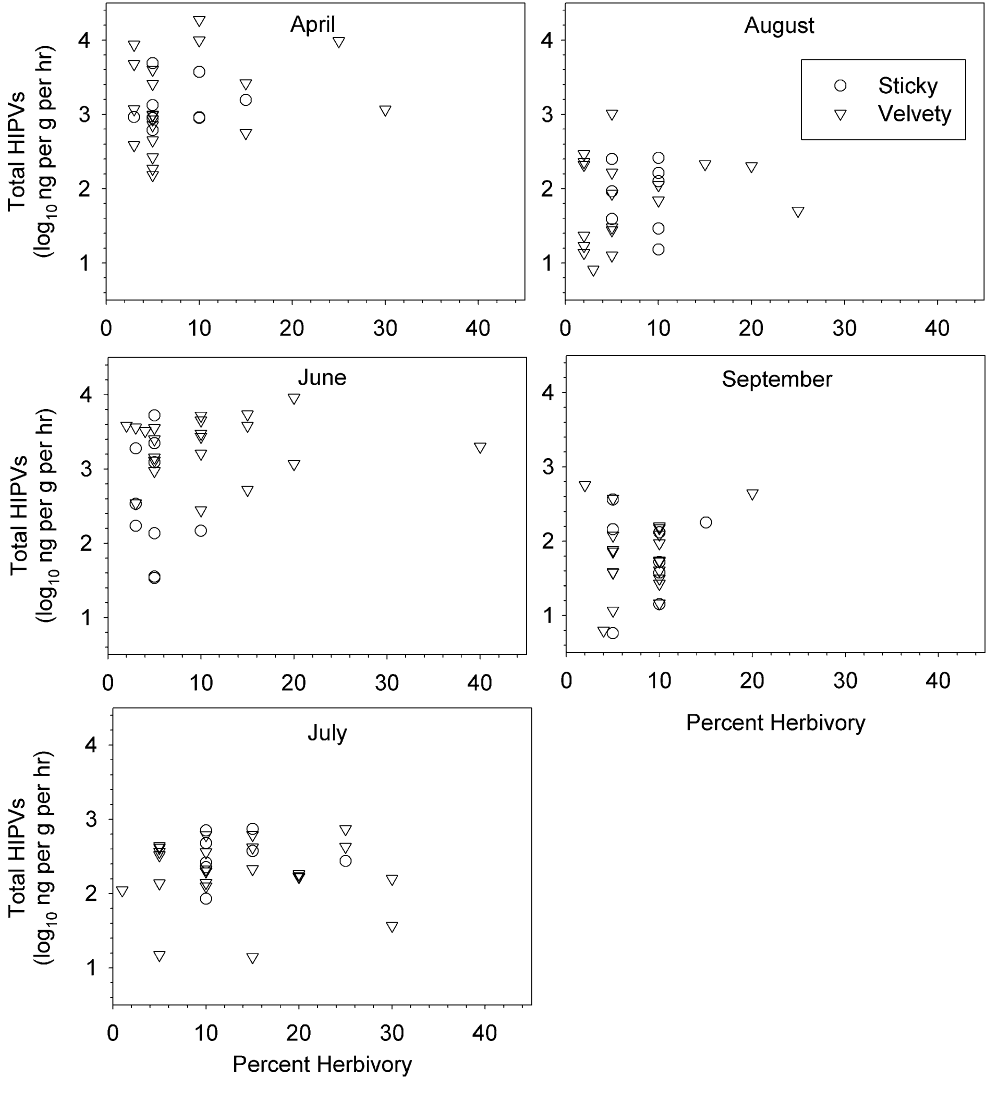

Fig. 2 Relationships between total HIPV production ($\log_{10}$ ng·g^{-1} (dry wt) leaf wt h^{-1}) and percent defoliation of *Datura wrightii* for each monthly aeration for herbivore-damaged plants expressing the sticky (*circles*) or velvety (*triangles*) trichome phenotype

significantly greater quantities of HIPVs after treatment with MeJA, (repeated measures ANOVA rejuvenation effect $F_{1,\ 269}$=61.55, P<0.001), but the differences declined over the season (rejuvenation by date interaction $F_{3,\ 269}$= 9.85, P<0.001, Fig. 1b, c). For neither non-rejuvenated nor rejuvenated plants did total HIPV production vary with trichome phenotype (all P≥0.09).

PCA analysis yielded seven components whose eigenvalues were greater than 1.0, and the first component (PC 1) accounted for 50.3% of the total variance in the data. Principal Components # 2 through 7 accounted for 8.0, 7.1, 6.4, 5.7, 4.8, and 4.2% of the total variance, respectively, for a total of 86.5%. All original variables except nerolidol and TMTT had positive loadings on PC 1, indicating that this component can be interpreted largely as a “general production” factor much like a “general size” factor in morphological studies. The highest factor loadings were for (*E*)-β-ocimene and (*E*)-β-caryophyllene (Fig. 3a), and plants that emitted relatively greater quantities of (*E*)-β-ocimene and (*E*)-β-caryophyllene had relatively higher scores on PC 1.

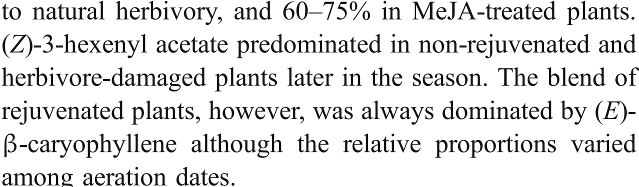
The original variables loaded positively or negatively on PC 2, indicating differences in the composition of the HIPV blends. PC 2 contrasts plants that, among other differences, had higher concentrations of (*Z*)-3-hexenyl acetate and DMNT with plants that produced higher concentration of the sesquiterpenes, α-humulene, or (*E*)-β-caryophyllene (Fig. 3a). The remaining principal components generally contrasted particular compounds of limited occurrence that were not easily interpreted, so detailed analyses were carried out only for PC 1 and PC 2.

Factor scores for PC 1 were greater for MeJA-treated plants or herbivore-damaged plants than uninduced plants to varying amounts, depending upon aeration date, induction method, and rejuvenation treatment (Fig. 3b–e for rejuvenated plants and Fig. 3f–j for nonrejuvenated and herbivore-damaged plants); scores for PC 1 reflected patterns similar to those for total HIPVs (Fig. 1). The changes in factor scores for PC 2 were more variable among aeration dates and treatments. There was relatively little change factor scores for PC 2 before and after MeJA treatment for nonrejuvenated plants in April and rejuvenated plants in June (Fig. 3f, b), indicating

that the blends were greater in concentration but similar in composition after induction. Substantial changes in scores for PC 2 were observed in the post-treatment aerations for rejuvenated plants in July, August, and September (Fig. 3c–e) and for herbivore-damaged plants in April (Fig. 3f). The relatively greater negatives scores for PC 2 post-induction in the rejuvenated plants reflect relatively higher production of (*E*)-β-caryophyllene and other compounds with high negative loadings for PC 2 in rejuvenated plants. The differences in composition of HIPV blends from nonrejuvenated plants before and after induction declined in the later aerations, however, as shown by similar scores for PC2 in July through September (Fig. 3h–j).

The high factor loadings for (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, DMNT, and (*E*)-β-caryophyllene (Fig. 3a) on PC1 and/or PC 2 justified more detailed analyses of these particular compounds. For herbivore-damaged plants, all of these major compounds were produced in significantly higher concentrations in April and June than in July through September (ANOVA; all date effects $P<0.001$, Fig. 4a, d, g, j). For MeJA-treated plants, (*Z*)-3-hexenyl acetate was generally the most abundant HIPV prior to MeJA treatment, but the ability of MeJA to induce higher levels of this compound was inconsistent in both non-rejuvenated and rejuvenated plants over time (repeated measures ANOVA, treatment by date interaction $F_{4,\ 149}=5.32$, $P<0.001$ for non-rejuvenated plants and $F_{3,\ 120}=7.23$, $P<0.001$, for rejuvenated plants, Fig. 4b, c). (*E*)-β-Ocimene and (*E*)-β-caryophyllene were induced consistently by MeJA in rejuvenated plants and relatively young nonrejuvenated plants, but less so in older nonrejuvenated plants [(*E*)-β-ocimene: MeJA treatment by date interaction $F_{4,\ 149}=21.55$, $P<0.001$ for nonrejuvenated plants and $F_{3,\ 120}=8.41$, $P<0.001$ for rejuvenated plants; (*E*)-β-caryophyllene: MeJA treatment by date interaction $F_{4,\ 149}=9.34$, $P<0.001$ for nonrejuvenated plants and $F_{3,\ 120}=13.90$, $P<0.001$ for rejuvenated plants, Fig. 4h, i, k, l]. More variable results were obtained for DMNT (MeJA treatment by date interaction $F_{4,\ 149}=28.09$, $P<0.001$ for non-rejuvenated plants and $F_{3,\ 120}=7.58$ for rejuvenated plants, Fig. 4e, f). Rejuvenated plants produced significantly more quantities of (*E*)-β-ocimene and (*E*)-β-caryophyllene than non-rejuvenated plants (all rejuvenation treatment effects $P>0.003$) although the magnitude of the differences varied over the season (all rejuvenation treatment by date interactions $P<0.004$).

In summary, the composition of the HIPV blends varied over the season as a result of quantitative differences in the induction of different HIPVs at different times. The induced blend of herbivore-damaged and nonrejuvenated plants was dominated by (*E*)-β-caryophyllene in April and June and comprised ca. 44–49% of all HIPVs, depending upon trichome phenotype and sampling date in plants subjected



to natural herbivory, and 60–75% in MeJA-treated plants. (*Z*)-3-hexenyl acetate predominated in non-rejuvenated and herbivore-damaged plants later in the season. The blend of rejuvenated plants, however, was always dominated by (*E*)-β-caryophyllene although the relative proportions varied among aeration dates.

Insect Abundances All sampled plants were infested with *L. daturaphila*, and all sampled sticky plants were infested with *T. notatus* in the first census, and the infestation rate of *L. daturaphila* never dropped below 85%. Similarly, the infestation rate of *T. notatus* never dropped below 67%. The infestation rate of *G. pallens* was more variable, ranging from 0 and 26% of sticky and velvety plants in the first census to between 57–100% of all plants irrespective of trichome phenotype through mid-September. After an initial peak following colonization of plants in the spring, densities of larvae of *L. daturaphila* declined to a range of from 3–35 per plant throughout the remainder of the season (ANOVA, census date effect $F_{10,\ 153}=6.25$, $P<0.001$, Fig. 5a). Abundances did not differ significantly between sticky and velvety phenotypes ($P=0.92$) nor did the census date by time interaction ($P=0.27$). Densities of *T. notatus* increased from ca. 28 per plant at the beginning of the season to over 200 per plant in mid-August, but because of the large variation within censuses, the differences in densities did not differ significantly among censuses ($P=0.21$, Fig. 5b). Densities of *G. pallens* also showed a seasonal peak in the spring but then declined to a range of from 1–5 per plant for the remainder of the season (census date effect $F_{10,\ 153}=7.91$, $P<0.001$, Fig. 5c). Surprisingly, abundances of *G. pallens* were significantly greater on sticky than velvety plants throughout the season (phenotype effect $F_{1,\ 153}=7.97$, $P=0.005$). Observations of egg masses of *L. daturaphila* showed evidence of predation by *G. pallens*, throughout the season, but predation was not quantified.

Discussion

The ability of *D. wrightii* to increase HIPV production in response to natural herbivory and treatment with MeJA is constrained seasonally and by ontogenetic stage. Greater quantities of induced HIPVs were produced by induced plants during the two aerations in the spring, when plants were growing vegetatively and had not yet begun to flower, than in the summer when plants continued to grow vegetatively but also began flowering and fruiting. The ability of plants to emit HIPVs in response to MeJA treatment during the three summer aerations was restored partially by cutting the plants back to ground level and allowing them to produce new foliage from the root crown.

Fig. 4 Production of (*Z*)-3-hexenyl acetate, DMNT, (*E*)-β-ocimene, and (*E*)-β caryophyllene in the field for herbivore-damaged *Datura wrightii* plants, and nonrejuvenated and rejuvenated plants before (Uninduced) and after application of MeJA (MeJA Induced). Mean (+ standard errors) in ng·g^{-1} (dry wt.) leaf hr^{-1} are shown for plants expressing the sticky or velvety trichome phenotype

Although the HIPV production of rejuvenated plants was significantly greater than nonrejuvenated plants during each of the three summer aerations, it always was lower than nonrejuvenated plants in the spring.

The relatively high proportion of (*E*)-β-caryophyllene in young plants is consistent with previous laboratory work with this system (Hare, 2007), and it suggests that this may be one compound that is differentially induced during the

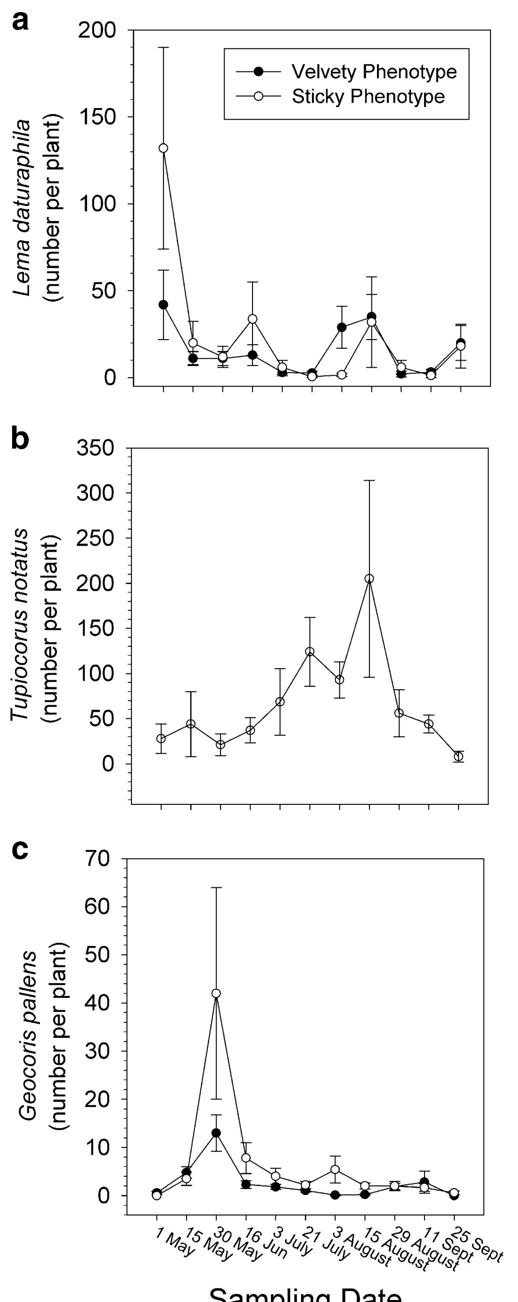


Fig. 5 Densities per plant of motile stages of the herbivores *Lema daturaphila* (**a**), *Tupiocoris notatus* (**b**), and the predator *Geocoris pallens* (**c**) sampled from *Datura wrightii* every 2 weeks. Means (± standard errors) are shown

earlier stages of plant ontogenetic development. Over time, however, the production of (*E*)-β-caryophyllene in older plants declined, leaving the blend of induced HIPVs relatively richer in (*Z*)-3-hexenyl acetate later in the summer.

Because of the potential for seasonal variation in the inducibility of HIPV production in response to natural herbivory, it was important to attempt to separate the effect of seasonally varying factors, such as temperature and humidity, from endogenous aspects of plant development that might have caused induced HIPV production to vary. One approach to separate seasonality from ontogeny might have been to transplant fresh seedlings to the field at different times during the summer (Thaler et al., 1996), but this would have been ecologically unrealistic with regard to natural germination of *D. wrightii,* as well as logistically difficult to establish transplants in the field during the heat of the summer. The observation that plants completely defoliated by herbivores resprout with juvenile foliage and then redifferentiate (Elle et al., 1999) suggested a different, more ecologically relevant approach toward separating seasonal from ontogenetic variation in HIPV production. This approach simply required that mature plants be cut back and allowed to resprout. This manipulation restored HIPV production, but to varying extents depending upon when during the season the plants were cut back. Thus, both seasonal and ontogenetic factors may constrain inducible HIPV responses in *D. wrightii*. The rejuvenated plants also served as a positive control and showed that the lower levels of HIPVs from unrejuvenated plants in the three summer aerations compared to the two spring aeration were not simply the result of any environmental factor that might preclude HIPV collection during the summer.

It is well-established that induced direct defenses are more pronounced in younger plant tissues (Thaler et al., 1996; Karban and Baldwin, 1997; van Dam et al., 2001), but relatively little is known as to the potential age-related variation in inducible HIPV production. In maize, HIPV production of leaves could be induced in 14-d-old seedlings but not in mature leaves (Köllner et al., 2004). HIPV production was an order of magnitude higher in vegetative stages of soybean than in flowering plants (Rostas and Eggert, 2008). This limited evidence, along with the present study, suggests that, as with inducible direct defenses, induced HIPV production may also be maximized in relatively young tissues.

Under natural conditions, *D. wrightii* is embedded in a community of plants, each with their own communities of herbivores and natural enemies. Plants occur in patches that persist for several years (Hare and Elle, 2004). Individual plants within patches quickly become colonized by over-wintering adults of *L. daturaphila*, *T. notatus*, and other herbivores in the early spring, then suffer chronic herbivory throughout the growing season. Plants also are colonized by *G. pallens* and other generalist natural enemies at about the same time (Gassmann and Hare, 2005). Only two species of parasitoid have been recovered from southern California *L. daturaphila* populations, and these are the tachinid fly, *Myiopharus infernalis,* and the chalcid wasp, *Conura delumbis*. The host range of both are poorly known but include, at least, other species of beetles from non-solanaceous plant species (Arnaud, 1978; Burks, 1979).

Both parasitoids also are most abundant in late summer (J. D. Hare, pers. obs., see also Puttler (1966)).

The original goal of this study was to understand the potential for *D. wrightii* to release HIPVs that may attract natural enemies of its herbivores. The temporal pattern of abundance of insects and HIPV production suggests several possibilities. In view of the rapid colonization of plants by both herbivores and natural enemies, it may not be beneficial for *D. wrightii* to produce any "long-range" cues except perhaps in the early spring, when some plants are colonized by herbivores but most are not. Using a modeling approach, Puente et al. (2008a) concluded similarly that "the utility of the volatile cues is consistently greater when a smaller proportion of plants is occupied by herbivores, indicating that their usefulness may be reduced to zero in fields saturated with volatiles," presumably when all plants are finally discovered and damaged by herbivores. On the other hand, if natural enemies can respond quantitatively as well as qualitatively to HIPVs, then plants producing stronger or more desirable cues may benefit over plants that produce weaker cues even when all plants are infested.

A possible explanation that would be consistent with the greater HIPV production by young *D. wrightii* plants is based upon the "optimal defense" theory of defense against herbivores. Optimal defense theory is based upon the premise that the allocation of resources is determined by the net result of the costs of that defense balanced against its benefit in terms of plant fitness (McKey, 1974). One consequence of this is the prediction that defensive traits should be maximally deployed during stages of high risk and/or low tolerance (Boege and Marquis, 2005). Although *L. daturaphila* densities were highest in the spring, those of *T. notatus* were not, and these species have shown different seasonal patterns of abundance in southern California; particularly a secondary peak usually occurred in late September and October in other years (Elle and Hare, 2000; Hare and Elle, 2002). It may be difficult to identify periods of differential risk of herbivory based upon the persistent abundance of these two herbivore species. A more likely application of the optimal defense theory in this system would be based upon ontogenetic variation in tolerance to herbivory. As *D. wrightii* grows, the plants produce a large, fleshy tap root that stores carbohydrate. Possibly, the ability of *D. wrightii* to tolerate herbivory increases with age such that continued allocation to defense, including HIPV production, becomes progressively less beneficial, possibly accounting for the seasonal decline in HIPV production.

Additionally, induced volatiles may be adaptive to *D. wrightii* for reasons other than, or in addition to, mediating herbivore-natural enemy interactions. In other systems, for example, some HIPVs confer resistance against herbivores or pathogens, and others mitigate abiotic stresses (Holopainen, 2004; Penuelas and Llusia, 2004; Dudareva et al., 2006; Gershenzon and Dudareva, 2007). Although no such studies have yet been undertaken in *D. wrightii* to evaluate these possibilities, they cannot be ignored. Such additional roles, of course, would introduce substantial complications into the study of the production of HIPVs by *D. wrightii* and in assessing how and when HIPVs might benefit plant fitness (Dicke and Baldwin, 2010). Finally, it also is possible that HIPV production is merely a genetically correlated consequence of other induced plant responses to herbivore damage and incidental to the interactions between *D. wrightii*'s herbivores and their natural enemies. Nevertheless, current results suggest the testable hypothesis that, by whatever combination of mechanisms, any benefits of HIPV production by *D. wrightii*, as well as any natural selection on *D. wrightii* genotypes that favors different quantities or blends of HIPVs (Hare, 2007), may be confined largely to the early periods of vegetative growth when HIPV production is greatest.

Most research on HIPVs has been performed in the laboratory and on cultivars of domesticated plant species (Dicke and Baldwin, 2010), and this is one of a few studies to investigate the seasonal variation in the production of induced HIPVs of an undomesticated plant species under field conditions. Results generally support previous laboratory studies on *D. wrightii* showing that young, vegetative plants can be induced to produce HIPVs. The laboratory studies, however, were performed only on young plants and were insufficient to capture both the dynamic change in the ability of plants to produce HIPVs over the course of the natural growing season and the changes in the composition of those HIPV blends. That the induced HIPV response of *D. wrightii* is largely confined to ontogenetically young tissues is consistent with studies in other systems showing that other induced plant responses are largely confined to young plants (Karban and Baldwin, 1997; Boege and Marquis, 2005). It is perhaps less obvious that HIPV production in *D. wrightii* is well-matched to the patterns of seasonal abundance of *D. wrightii*'s herbivores and their natural enemies.

Several enzymes located inside and on the surface of plant cells are probably involved in the synthesis of H_2O_2 (Apel and Hirt, 2004). Membrane-bound NADPH oxidase (Levine et al., 1994; Bolwell, 1999), an apoplastic peroxidise (POD) (Bolwell et al., 1995), and peroxisomal xanthine oxidase (XO) (Sandalio et al., 1997) have been implicated in hydrogen peroxide production. Xanthine oxidase produces $O_2^{\bullet -}$, which is converted to H_2O_2 by superoxide dismutase (SOD) (Montalbini, 1992a). The oxidative purine catabolic pathway, which includes XO, is selectively induced in wheat plants infected with *Puccinia recondita* (Montalbini, 1992b). Increases in XO activity found in beans upon infestation with *Uromyces phaseoli* were successfully inhibited by allopurinol treatment, and the resultant hypersensitive cell collapse also was inhibited when infected with pathogens (Montalbini, 1992a).

Moloi and Van der Westhuizen (2006) demonstrated that NADPH-oxidase is involved in the defense response of wheat to the RWA. In this study, we demonstrated the importance of the xanthine/xanthine oxidase system for the induction of resistance to Russian wheat aphid infestation.

Methods and Materials

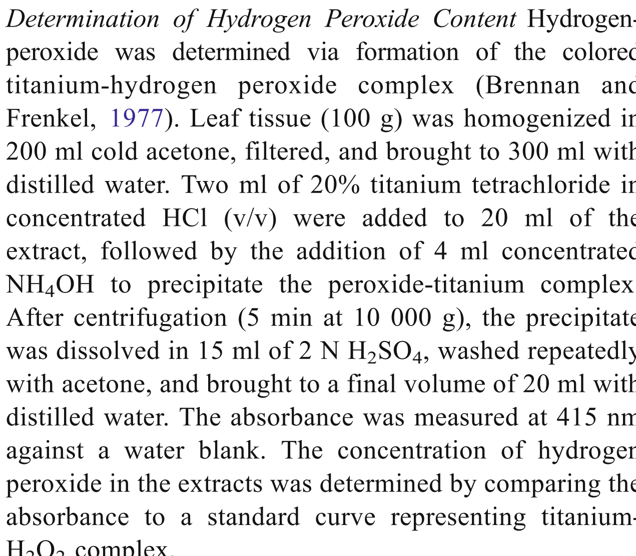
Plant and Aphid Material Wheat (*Triticum aestivum*) plants, resistant (cv. *Tugela DN*) and susceptible (close isogenic cv. *Tugela)* (Du Toit, 1989) to the RWA (biotype SA1) *Diuraphis noxia* (Mordvilko) were grown in a glasshouse at day and night temperatures of 25° C and 21° C respectively.

A colony of RWA was obtained from the Agricultural Research Station in Bethlehem, South Africa. The aphids were maintained on *Tugela* wheat until experimental wheat plants were infested. Plants were infested at the second-leaf growth stage with 25 fourth instar aphids per plant.

All the leaves of the plant were collected at specific time intervals after infestation and immediately frozen in liquid nitrogen. They were then stored at −20° C for subsequent analyses.

Enzyme Extraction Enzymes were extracted by grinding 1 g of frozen leaf tissue with 100 mg acid-washed sand in 10 ml of 100 mM potassium phosphate buffer (pH 7.5) containing 1 mM EDTA and 1% PVP (Rao et al., 1997). After centrifugation (25 000×g, 20 min), the supernatant was used for the enzyme assays.

Protein concentrations were determined with the Biorad Microplate method (Rybutt and Parish, 1982). The assay mixture consisted of 160 µl distilled water, 40 µl BioRad, and 10 µl standard (0.5 µg. μl^{-1} γ-globulin) or sample (Bradford, 1976).



Determination of Hydrogen Peroxide Content Hydrogen-peroxide was determined via formation of the colored titanium-hydrogen peroxide complex (Brennan and Frenkel, 1977). Leaf tissue (100 g) was homogenized in 200 ml cold acetone, filtered, and brought to 300 ml with distilled water. Two ml of 20% titanium tetrachloride in concentrated HCl (v/v) were added to 20 ml of the extract, followed by the addition of 4 ml concentrated NH_4OH to precipitate the peroxide-titanium complex. After centrifugation (5 min at 10 000 g), the precipitate was dissolved in 15 ml of 2 N H_2SO_4, washed repeatedly with acetone, and brought to a final volume of 20 ml with distilled water. The absorbance was measured at 415 nm against a water blank. The concentration of hydrogen peroxide in the extracts was determined by comparing the absorbance to a standard curve representing titanium-H_2O_2 complex.

Determination of Superoxide Dismutase Activity Following the method of Keppler and Novacky (1987), SOD activity was measured by measuring the inhibition of the nitroblue tetrazolium (NBT) reduction. The reaction mixture consisted of 50 mM phosphate buffer (pH 7.8), 13 mM methionine, 75 µM NBT, 2 µM riboflavin, and 50 µl sample. The reaction mixture was irradiated by placing it 30 cm below two fluorescent lamps (2×40 W) for 10 min. A non-irradiated duplicate was used as a control (reference cuvette). After irradiation, the absorbance of the reaction mixture was measured at 560 nm (Hitachi U-2000 double-beam spectrophotometer). In addition, a sample without crude extract was irradiated and used to measure the maximum attainable absorbance at 560 nm. The SOD activity is expressed as log [A560 (with crude extract) mg^{-1}/A560 (without crude extract)] (Keppler and Novacky, 1987).

Determination of Peroxidase Activity The peroxidase assay mixture consisted of 40 mM potassium buffer (pH 5.5), 5 mM guaiacol, and 8.2 mM H_2O_2. The change in absorbance was measured at 470 nm for 180 sec at 30°C (Hitachi U-2000 double-beam spectrophotometer) (Zieslin and Ben-Zaken, 1991).

Determination of Chitinase Activity Chitinase activity was measured according to the method of Wirth and Wolf (1990), with slight modifications. The method is based on the precipitability of carboxymethyl-chitin-remazol brilliant violet 5R (CM-Chitin-RBV) (Loewe Biochemica GmbH) from buffered solutions with HCl.

The reaction mixture for determining chitinase activity consisted of 66.6 mM Na-acetate buffer (pH 5.0), and 100 µl CM-chitin-RBV (2 $mg.ml^{-1}$) and sample. The reaction mixture was incubated at 37°C, and after 30 min

the reaction was stopped by the addition of 100 µl of 2 M HCl. The sample was put on ice for 10 min to allow complete precipitation and subsequently centrifuged at 12 000 g for 7 min. Before measuring the absorbence at 550 nm, the sample was diluted 4× with distilled water (Wirth and Wolf, 1990).

In Vivo Treatment with Allopurinol The effect of allopurinol (4-hydroxypyrazolo(3,4-d)pyrimidine) on the HR was evaluated according to the method described by Montalbini (1992b). Allopurinol was applied to plants as a soil drench (250 ml of 0.4 mM solution daily). Application was started 7 d after the wheat was planted, and continued until the last sampling date. Allopurinol is a purine analogue and a competitive inhibitor of XO. It tightly binds to the reduced molybdenum component of the enzyme, thus inhibiting activity and the production of oxygen radicals cannot take place (Massey et al., 1970; Hille and Massey, 1981).

In Vitro Treatment with Allopurinol Allopurinol was added to the respective reaction mixtures for SOD, POD and chitinase to test for *in vitro* inhibition. Final concentration of allopurinol in the reaction mixtures was 0.4 mM.

Statistical Analysis Six leaf samples of each treatment were collected. Enzyme activities were repeated four times for every sample. Statistical analyses were performed using STATISTICA, version 9, from StatSoft®. The normality of the data was checked using the Shapiro-Wilkes test. A one-way ANOVA, using the Turkey HSD test, was performed at a significance level of 95%. The purpose of the ANOVA was to check whether there is a statistical difference in the enzyme activities between the infested resistant wheat and the corresponding controls.

Results

Hydrogen Peroxide Content An increase ($P<0.05$) in H_2O_2 was detected in the infested, resistant wheat as early as 8 h after infestation (Fig. 1a). Significantly increased H_2O_2 levels were observed over a 48 h period (Fig. 1b) with the highest levels detected 15 h after infestation in the infested, resistant wheat. At 15 h post infestation, the H_2O_2 was 112% higher in the infested, resistant wheat than in the non-infested resistant wheat. After 48 h, the H_2O_2 was 85% higher in the infested, resistant wheat compared to the infested, susceptible wheat. There were no significant differences between the H_2O_2 content of the non-infested, resistant, and susceptible wheat leaves.

In Vitro Effect of Allopurinol on Enzyme Activities The *in vitro* effect of allopurinol was tested on the activities of SOD, POD, and chitinase. Allopurinol did not inhibit the activities of SOD, POD, or chitinase *in vitro* (results not shown).

Effect of Allopurinol on Superoxide Dismutase Activity In Vivo RWA infestation significantly increased ($P<0.05$) SOD activity in infested, resistant wheat (Fig. 2). SOD activity did not change during the investigated period in susceptible, infested, or resistant wheat. SOD activity reached a peak 10 h after infestation in infested, resistant wheat. The allopurinol drench significantly ($P<0.05$) inhibited the induced SOD activity by 70% in infested, resistant wheat (Fig. 2).

Effect of Allopurinol on Peroxidase Activity RWA infestation significantly ($P<0.05$) induced POD activity in infested, resistant wheat, peaking at 24 h. Little change occurred in the controls where the activity remained constant. The allopurinol drench significantly ($P<0.05$)

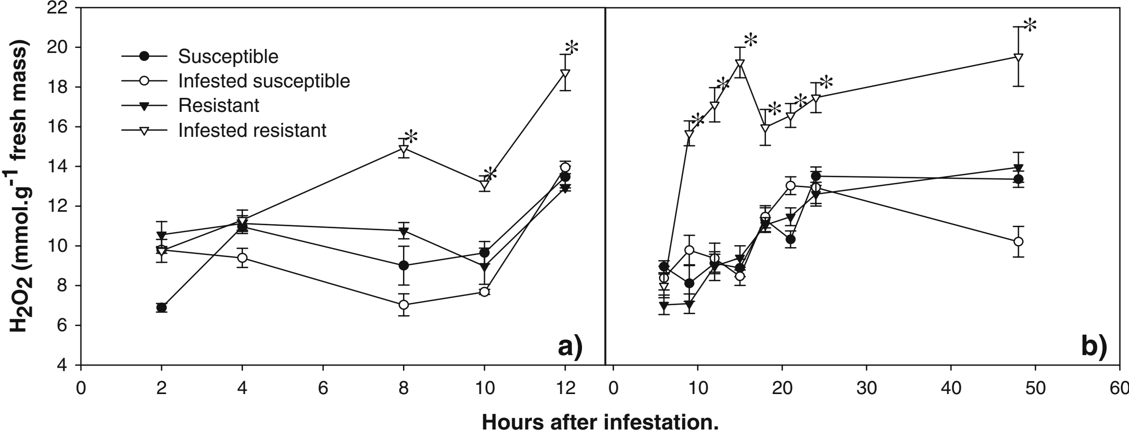


Fig. 1 Time course of H_2O_2 levels (**a**) for a 12 h period and (**b**) for a 48 h period. Error bars indicate standard deviation. Asterisks denote significant increases above the infested control ($P<0.05$)

inhibited the induced (24 h) POD activity by 80% (Fig. 3) in infested, resistant wheat.

Effect of Allopurinol on Chitinase Activity Aphid infestation induced chitinase activity ($P<0.05$) in infested, resistant wheat (Fig. 4). The selectively induced chitinase activity was significantly ($P<0.05$) inhibited by the allopurinol drench to levels similar to those of controls.

Discussion

H_2O_2 is responsible for induction of the defense genes as well as for cell death in the development of restricted lesions (Pellinen et al., 2002; Apel and Hirt, 2004). Felton et al. (1994, 1999) demonstrated differential increases in H_2O_2 in the incompatible interaction between plants and insects. During the incompatible interaction between wheat and the RWA, H_2O_2 elicited the accumulation of salicylic acid (Mohase and Van der Westhuizen, 2002), which is responsible for systemic acquired resistance.

A possible mechanism for the production of active oxygen species such as H_2O_2 during the HR is via the enzyme XO, which converts hypoxanthine xanthine, and xanthine to uric acid (Montalbini 1992a, b). Enhanced activity in XO and uricase preceded and accompanied the HR induced by *Uromyces phaseoli* infection in beans (Montalbini, 1991). Furthermore, active oxygen species drive the synthesis of cell-membrane structural proteins; oxidize cinnamyl alcohols to free radicals by peroxidase/ H_2O_2, leading to the formation of lignin (Karlsson et al., 2005); trigger programmed cell death; and diffuse to neighboring cells to induce defense genes (Mur et al., 2008).

In this study, the authors wanted to determine if oxygen radicals and, in particular, H_2O_2, are responsible for inducing the downstream defense response in wheat that is resistant to RWA. Allopurinol, which is an inhibitor of XO activity (Montalbini 1991, 1992a, b) was used to inhibit the production of O_2^- and consequently H_2O_2. The interaction between resistant wheat and the RWA was manifested as a differential increase in H_2O_2 that reached peak values quite soon after infestation (8 h).

The activity of SOD was dramatically reduced (Fig. 2a) in the infested, resistant wheat growing in the soil drenched with allopurinol, thus suggesting that no H_2O_2 was produced. The low SOD activity could be due to the

disappearance of its substrate (O_2^-), or it may be that the genes encoding for SOD were not induced.

It is well established that POD (Van der Westhuizen et al., 1998a, b) and chitinase (Van der Westhuizen et al., 1998b) activities are involved in the downstream defense response of wheat against the RWA, and they were used in this study to indicate whether the downstream defense response is activated or not. This study confirmed the selective induction of POD (Fig. 3) and chitinase (Fig. 4) activities in the infested, resistant wheat upon infestation with the RWA. Allopurinol drenching prevented differential induction of POD (Fig. 3). Loss of POD activity may be the result of insufficient substrate (H_2O_2) and/or insufficient gene induction due to low H_2O_2 levels. For this reason, the inhibition of POD activity by allopurinol does not necessarily prove that the H_2O_2 was necessary to induce the downstream defense response. The authors, therefore, additionally investigated the effect of allopurinol inhibition on the chitinase defense response.

The expression of chitinase has a defensive role when plants are infected with pathogens. Some chitinases have lysozymal activity and can hydrolyze the peptidoglycans in bacterial cell walls, whereas others have exohydrolytic activity (Punja and Zhang, 1993). Wheat infested with the RWA showed differential increases in chitinase activity (Van der Westhuizen et al., 1998b). In this study, we confirmed the differential induction of chitinase activity (Fig. 4). Allopurinol drenching resulted in a 97% decline in activity (Fig. 4). The successful induction of chitinase is, therefore, dependent on the activity of xanthine oxidase. Allopurinol applied *in vitro* had no effect on the activity of chitinase in infested resistant wheat.

Surprisingly, the leaves of resistant wheat displayed signs of rolling when allopurinol was applied (results not shown), a phenomenon seen only in susceptible plants when infested with the RWA. This can be explained because of the suppressed defense responses that resulted from the allopurinol drenching. Montalbini (1992a, Montalbini and Torre, 1996) has shown that defense responses associated with the HR are suppressed after allopurinol treatment.

Resistant wheat infected with the RWA showed differential increases in H_2O_2 levels and SOD activity. The importance of H_2O_2 during the defense response to induce the downstream defense mechanism was demonstrated by inhibiting XO activity with allopurinol. Allopurinol drenching resulted in suppressed SOD, POD, and chitinase activities, thus indicating that the generation of H_2O_2 via XO is necessary for the activation of downstream defense responses.

(Rudman, 1965; Chang et al., 1999, 2000; Cheng et al., 2005, 2008), there are few reports concerning the chemical components of conifer cones and the antifungal properties of abietane-type diterpenes. Research into natural antifungal compounds from *T. distichum* cones may be beneficial to chemical ecology, phytochemistry, and agrochemistry.

In our previous study, we reported the isolation and identification of abietane-type diterpenes from *T. distichum* cones. We found a relationship between ferruginol oxidized compounds and termicidal and antifeedant activities against the subterranean termite, *Reticulitermes speratus* Kolbe (Kusumoto et al., 2009). In this study, we report on twelve diterpenoids including ten abietane-type components and their antifungal activities against white- and brown-rot fungi.

Methods and Materials

Plant Material Cones of *T. distichum* (Taxodiaceae class) that were not seriously damaged or weathered were collected at the Yamagata Field Science Center (Faculty of Agriculture, Yamagata University, Japan) located in Tsuruoka City in western Yamagata prefecture. Cones were gathered from the ground and identified by the Yamagata Field Science Center.

General Experimental Procedures GC-FID analysis was performed with an HITACHI G-3000 gas chromatograph under the following conditions: DB-1 capillary column (30 m×0.32 mm i.d.; 0.25 μm film thickness; J&W Scientific, Folsom, CA, USA); column temperature from 100°C (1 min) to 320°C (10 min) at 5°C/min; injection temperature 230°C; detection temperature 250°C. GC-MS data were obtained with a SHIMADZU QP-5000 GC-MS: DB-1 capillary column (30 m × 0.32 mm i.d.; 0.25 μm film thickness; J&W Scientific, Folsom, CA, USA); column temperatures were programmed to be equal to GC-FID analysis. The acquisition mass range was 50–450 amu using helium as carrier gas (3.6 ml/min). ^{1}H-NMR, ^{13}C-NMR, DQF-COSY, HMBC, and HMQC spectra were obtained to aid structural identification. 1D and 2D NMR spectra were measured with a JEOL JNM-EX400 (^{1}H 400 MHz/^{13}C 100 MHz) spectrometer.

Extraction and Isolation The air-dried *T. distichum* cones (800 g) were milled and extracted successively at ambient temperature for 7 d with *n*-hexane (*n*-C_6H_{14}), ethyl acetate (EtOAc), and methanol (MeOH). These extracts were tested as potential inhibitors of fungal growth as described below. The *n*-C_6H_{14} soluble fraction (84.9 g) was partitioned with saturated $NaHCO_3$, 10% Na_2CO_3, and 1% NaOH aqueous solutions in a separatory funnel, and was purified by silica-gel 60 N (spherical 63–210 μm, neutral, Kanto Chemical Co., Japan) column chromatography. The 12 compounds (Fig. 1) that were isolated have been identified previously (Kusumoto et al., 2009): 6,7-Dehydroferruginol (**1**), ferruginol (**2**), 6,7-dehydroroyleanone (**3**), sandaracopimaric acid (**4**), taxodione (**5**), taxodal (**6**), sugiol (**8**), xanthoperol (**9**), salvinolone (**10**), 5,6-dehydrosugiol (**11**), and 14-deoxycoleon U (**12**). The structures of were determined by comparison of NMR spectral data with published data. The amounts of pure isolated compounds **1**, **2**, and **8** were too small to use for antifungal tests; therefore, we isolated compounds **2** and **8** from *Cryptomeria japonica* as in previous studies (Ashitani et al., 2001). Compound **1** was synthesized from **8** by chemical conversion (Matsui et al., 2004). In this study, the novel compound taxodone (**7**) was isolated from the neutral fraction of *n*-C_6H_{14} extract, and the chemical structure was identified by comparison of 1D NMR spectral data with published data (Kupchan et al., 1969). The configuration of **7** was confirmed and determined by decoupling experiments using 2D NMR spectral data.

Taxodone (7) 7.8 mg. Pale orange amorphous solid. EI-MS *m/z*: 316 (M^+, $C_{20}H_{28}O_3$, 26%), 301 (7), 298 (8), 283 (9), 273 (12), 255 (9), 245 (13), 242 (12), 233 (19), 231 (21), 229 (24), 220 (43), 219 (37), 217 (24), 215 (30), 205 (33), 203 (27), 191 (25), 177 (28), 173 (21), 128 (27), 115 (33), 95 (21), 91 (35), 83 (31), 77 (28), 69 (50), 55 (100), 53 (26); ^{1}H-NMR ($CDCl_3$): δ 1.11 (3 H, *d*, *J*=6.8 Hz, 17-CH_3), 1.13 (3 H, *d*, *J*=6.8 Hz, 16-CH_3), 1.13 (3 H, *s*, 20-CH_3), 1.19 (3 H, *s*, 18-CH), 1.19 (3 H, *s*, 19-CH), 1.40 (2 H, *m*, 3-CH_2), 1.43 (2 H, *m*, 3-CH_2), 1.54 (1 H, *m*, 5-CH), 1.55 (2 H, *m*, 2-CH_2), 1.63 (2 H, *m*, 1-CH_2), 1.65 (2 H, *m*, 2-CH_2), 2.89 (2 H, *m*, 1-CH_2), 3.04 (1 H, *hept*, *J*= 6.8 Hz, 15-CH), 4.67 (1 H, *brd*, *J*=10.0 Hz, 6β-axial-CH), 6.52 (1 H, *d*, *J*=2.7 Hz, 7-CH), 6.79 (1 H, *s*, 14-CH), 7.46 (1 H, *s*, 11-OH); ^{13}C-NMR ($CDCl_3$): δ 18.8 (2-CH_2), 20.8 (16-CH_3), 21.4 (17-CH_3), 21.7 (20-CH_3), 22.8 (19-CH_3), 26.7 (15-CH), 34.1 (4-C), 36.7 (18-CH_3), 37.6 (1-CH_2), 40.7 (10-C), 43.2 (3-CH_2), 58.0 (5-CH), 70.0 (6-CH), 126.2 (9-C), 130.4 (13-CH), 135.7 (14-CH), 142.0 (11-C), 143.4 (8-C), 149.1 (7-CH), 181.7 (12-C).

Fungal Strains The wood-decay fungi *Trametes versicolor* (white-rot) (NBRC: 30340), and *Fomitopsis palustris* (brown-rot) (NBRC: 30339), were provided by the Natural Institute of Technology and Evaluation Biological Resource Center (NBRC; Tokyo, Japan). These fungi are chosen routinely for antifungal tests according to Japan Industrial Standard (JIS) K1571. Cultures of each fungus were maintained on potato dextrose agar (PDA) medium (Eiken Chemical Co., Japan) and stored at 4±1°C. Before antifungal tests, each strain was incubated on PDA medium

Fig. 1 Chemical structures of isolated diterpenes from n-C_6H_{14} extract of *Taxodium distichum* cones. 6,7-dehydroferruginol (**1**), ferruginol (**2**), 6,7-dehydroroyleanone (**3**), sandaracopimaric acid (**4**), taxodione (**5**), taxodal (**6**), taxodone (**7**), sugiol (**8**), xanthoperol (**9**), salvinolone (**10**), 5,6-dehydrosugiol (**11**), and 14-deoxycoleon U (**12**)

in a Petri dish at 26±1°C until the fungus covered most of the surface of the plate.

Antifungal Assays Antifungal assays were performed according to previously published methods (Kofujita et al., 2006; Sekine et al., 2009). Before fungal inoculation, test sample was dissolved in acetone or methanol (1 mg/ml), and 600 µl of each solution were applied to the surface of each 15 ml PDA medium in a Petri dish (88 mm diam) so that the final concentration was 10 µg/cm^2 in solid agar. After the application, each plate was air-dried on a clean bench for 1 hr. An equal amount of pure acetone or MeOH was spread on the control medium. An inoculum of each strain was obtained using a 5.5 mm diam cork-borer, and was placed on the center of the test medium. The dishes were cultured in the dark at 26±1°C and 70% relative humidity in an incubator. When mycelia reached the edge of the Petri dish of the control, the average mycelium diameter per treatment was calculated from the measurement of four radial directions. All results are expressed as means±SE. The antifungal assay was repeated three times for each sample and six times for the control. The antifungal activity was evaluated as a percentage of relative growth rates, and it was calculated as follows:

$$\text{Average growth rate}\ (\%) = 100 \times \text{Da}/\text{Db}$$

Da : Total average of the mycelium diam of each sample
Db : Average diam of control mycelium

Results and Discussion

Yields and Antifungal Properties of Successive Extracts The material extracted successively by n-C_6H_{14}, EtOAc, and MeOH extracts from 800 g of air-dried *T. distichum* cones ranged from 10.8% of the tissue mass (n-C_6H_{14}) to 3.53% (EtOAc) or 1.56% (MeOH). Both the n-C_6H_{14} and EtOAc extracts were potent mycelial growth inhibitors for *F. palustris* (Fig. 2). Similarly, both n-C_6H_{14} and EtOAc

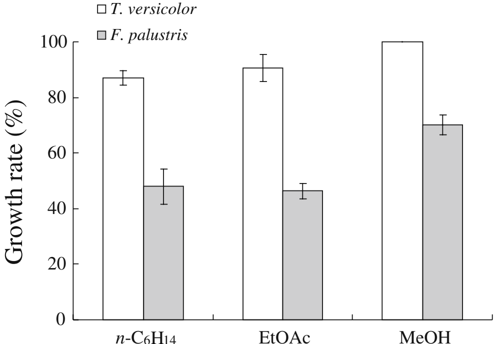

Fig. 2 Antifungal activities of successive extracts from *Taxodium distichum* cones against two wood-rot fungi

extracts were active against *T. versicolor*. On the other hand, the MeOH extract revealed mycelium growth inhibition for *F. palustris*, but not for *T. versicolor*.

Clearly the n-C_6H_{14} and EtOAc extracts had higher antifungal activities against both *T. versicolor* and *F. palustris* than the MeOH extract. Because the yield of the *n*-C_6H_{14} extract was about three times higher than that of EtOAc extract, we chose to characterize the hexane extract.

Chemical Compositions of n-C_6H_{14} Extract A quantitative analysis by GC-FID showed that 70% of *n*-C_6H_{14} extract was composed of diterpenes (Fig. 3). The percentage content of each component was calculated from the ratio between each component and the total diterpenoid peak area, which was measured by GC-FID (Table 1). The isolated compounds, excluding sandaracopimaric acid (**4**) and taxodal (**6**), were diterpenes with an abietane-type structure (Kusumoto et al., 2009). The amounts of 6,7-dehydroferruginol (**1**) and ferruginol (**2**) were remarkably high in the *n*-C_6H_{14} extract (Table 1). In addition, the amounts of taxodione (**5**), taxodone (**7**), salvinolone (**10**), and 14-deoxycoleon U (**12**) also were high. The GC-FID peak areas of compounds **4**, **6**, and **11** were too small to calculate their percentage content.

Table 1 Constituents of diterpenes in *n*-C_6H_{14} extract of *Taxodium distichum* cones

Compound	Retention time (min)	Contents (%)[a]
6,7-dehydroferruginol (1)	22.9	20.4
ferruginol (2)	23.0	39.4
6,7-dehydroroyleanone (3)	23.4	0.88
sandaracopimaric acid (4)	23.5	t[b]
taxodione (5)	24.8	12.3
taxodal (6)	25.5	t[b]
taxodone (7)	26.8	6.19
sugiol (8)	27.4	0.74
xanthoperol (9)	27.8	0.79
salvinolone (10)	28.4	4.80
5,6-dehydrosugiol (11)	28.5	t[b]
14-deoxycoleon U (12)	30.1	2.08

[a] Contents (%)=100×Each component peak area/Total diterpenoids peak area (GC-FID)

[b] Trace

The amounts of compound **1** and **2** were higher than any other compounds in the *n*-C_6H_{14} extract, suggesting that **1** and **2** were the major compounds in all extracts of this tissue. In order to evaluate the antifungal properties of *T. distichum* cones, it was necessary to confirm the relationship between the quantities and the activities of isolated compounds.

Antifungal Properties of Isolated Compounds The antifungal activities of isolated compounds **1** to **12** were tested at 10 μg/cm^2 against two wood-decay fungi (Fig. 4). 14-Deoxycoleon U (**12**), taxodione (**5**), and salvinolone (**10**) were strong mycelium growth inhbitors in *T. versicolor*. These three compounds also had antifungal activity against *F. palustris*, with mycelium growth inhibitions by **5** or **12**

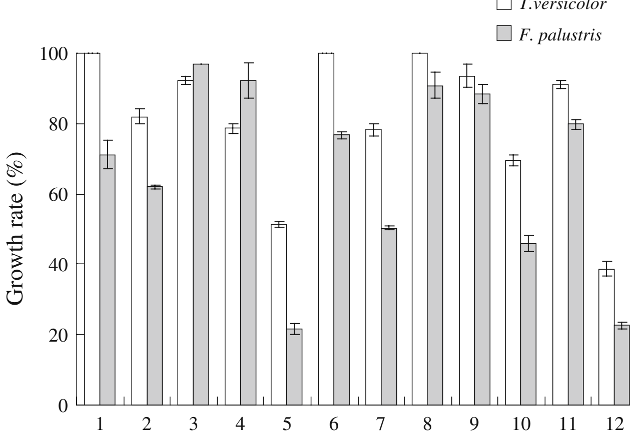

Fig. 4 Antifungal activities of isolated diterpenoids against two wood-rot fungi. 1-12; refer to Fig. 1

two times stronger than **10**. Taxodone (**7**) and ferruginol (**2**) also had antifungal activity against *F. palustris*.

6,7-Dehydroferruginol (**1**), taxodal (**6**), and sugiol (**8**) did not inhibit mycelial growth of *T. versicolor*; but they reduced growth rate of *F. palustris* (Fig. 4). Isolated compounds, except for **3** and **4**, had much stronger antifungal activities against brown-rot fungi (*T. versicolor*) than against white-rot fungi (*F. palustris*).

We evaluated the relationship between antifungal activity and chemical structure. Taxodione (**5**), which showed strong antifungal properties, is a hydroxyquinone. Some of the abietane-type diterpene quinones have antifungal properties (Kofujita et al., 2002) but 6,7-Dehydroroyleanone (**3**) is a hydroxybenzoquinone that does not have activity against either fungus. Quinones must not be the only chemical group required for antifungal activity. A comparison of taxodione (**5**) and taxodone (**7**) revealed that both compounds contain a ketone group, but that its position differs. The ketone group on **5** was at C-6, and several lines of evidence suggest that substitution at this position is associated with antifungal activity against wood decay fungi. Ferruginol (**2**) has more antifungal activity than 6,7-dehydroferruginol (**1**), which comprises a C-6 and C-7 dehydration of **2**. Sugiol (**8**), which is a hydroxyabietatrien structure with a C-7 carbonyl group, has no activity against either fungus; but 5,6-dehydrosugiol (**11**), which includes a C-5 and C-6 dehydration of **7**, is more growth inhibitory than **8**. Compounds **11**, **10**, and **12** reduced growth rates in both *T. versicolor* and *F. palustris*. Growth inhibition by compounds **11**, **10,** and **12** increased with an increasing number of hydroxyl groups at C-6 and C-11; the number of hydroxyl groups at these positions appeared to be related to the antifungal activities against *T. versicolor* and *F. palustris*. Only compounds **5**, **7**, **10,** and **12** had a hydroxyl group at C-11 suggesting that a strong relationship between antifungal activity and this chemical structure exists. In conclusion, several specific abietane-type antifungal compounds were investigated from *T. distichum* cones. Taxodione (**5**), salvinolone (**10**), and 14-deoxycoleon U (**12**) had strong antifungal properties. The activities of **5** and **12** against both wood-decay fungi were especially apparent. The n-C_6H_{14} extract contained high levels of 6,7-dehydroferruginol (**1**) and ferruginol (**2**), which had antifungal activity against *F. palustris*, but not against *T. versicolor*. Ferruginol (**2**) has been reported to be effective against wood-decay fungi (Rudman, 1965); but against *F. palustris*, the antifungal activity of **2** was only one third that of **5** and **12**, which were oxidized compounds of **2**. These results suggest that the quantity of abietane-type compounds is not the only factor influencing the antifungal activities of *T. distichum* cones, but that there is also an effect of oxidized abietane-type compounds. This illustrates that it is important to investigate the antifungal properties of both major compounds and minor oxidized compounds when evaluating potentially active compounds. We believe that identifying the notable antifungal abietane-type compounds from *T. distichum* cones could be meaningful for developing chemical defenses of coniferous species.

temperature, pH, alkalinity, mixing regime, and light, many of which show significant relationships to cyanobacteria biomass and dominance (Watson et al. 1997; Dokulil and Teubner 2000).

Among the bloom-forming cyanobacteria, particular attention has been paid to *Microcystis*, a colonial, buoyancy controlling K-strategist (Benndorf and Henning 1989). Species of *Microcystis* are widely distributed in eutrophic (Reynolds 2006) and hypereutrophic lakes (Kotak et al. 1995) and rivers (Krogmann et al. 1986), where they can develop dense, potentially toxic blooms. Extensive research has focussed on the ecophysiology of these cyanobacteria, and several key mechanisms have been proposed that may provide these taxa with a competitive edge over other species. These studies have focused primarily on bottom-up factors related to light, mixing and nutrient uptake; others have recognized the potential importance of size-selective grazing (Hyenstrand et al. 1998). However, there is a growing body of evidence to suggest that more subtle grazer interactions controlled by allelochemicals play important but poorly understood roles (DeMott and Tessier 2002; Hansson et al. 2007).

Under natural conditions, the cells of *Microcystis* are embedded in a matrix of mucilage and form colonies with sizes up to 8 mm in diameter (Joosten 2006). Large colonies often exceed the maximum ingestible size range of even large freshwater crustaceans that is in the range of 75 μm for an adult *Daphnia magna* (Burns 1968). This provides little protection, however, for smaller *Microcystis* colonies and single cells, which remain within the food spectrum even of small sized crustaceans (Fulton and Paerl 1987a; Jarvis et al. 1987; Rohrlack et al. 1999a; Ghadouani et al. 2004). In addition to providing the colonial matrix, evidence suggests that a second protective function may be involved by the externally produced mucilage. *Daphnia* showed lower ingestion and increased its labral rejection rate of small colonies and single cells covered with robust mucilage compared to mucilage poor cells (Rohrlack et al. 1999a; Ghadouani et al. 2004). Indirect chemical interactions that promote grazer selectivity also may influence some top–down processes. For example, sterols are essential membrane constituents of animal grazers, and can only partially be synthesized by crustaceans (von Elert et al. 2003). A form of non-specific biochemical defense may be accomplished by the extremely low production of these sterols by all cyanobacteria including *Microcystis,* which may lead to reduced grazing losses as herbivores may prefer ingestion of food items of higher quality (Koski et al. 2006)

More direct chemical defense may be provided by the production of toxic microcystins, which are potent inhibitors of eukaryote protein phosphatase 1 and 2A. Comparisons of microcystin-producing and non-producing *Microcystis* strains as sole food for crustaceans have reported both toxic and non-toxic effects (Wilson et al. 2006). However, these experiments have failed to address some important confounding factors: Notably, i) differences in *Microcystis* chemotypes among studies or in field populations; ii) among- and within-strain variance in production of multiple microcystin congeners of different toxicity; iii) the co-production of other bioactive oligopeptides by *Microcystis* (Welker et al. 2006; Jüttner and Lüthi 2008); iv) differences in the genetic capacity for toxin production and its activation, even within the same bloom (Rinta-Kanto et al 2009); and v) the development of grazer resistance (DeMott et al. 1991). More definitive evidence has been obtained by using a mutant strain of *Microcystis* PCC 7806 that lacks the microcystin synthetase gene *mcy B*, but that does not affect synthesis of other oligopeptides (Rohrlack et al. 1999b). Only the wild type exhibited toxicity to *Daphnia galeata* and clearly showed the efficiency of microcystins. Other *Microcystis* secondary metabolites also have a direct inhibitive or toxic effect. The oligopeptides aeruginosins and cyanopeptolins are effective serine protease inhibitors (Ishida et al. 1999; Bister et al. 2004), microviridin J disrupts moulting (Rohrlack et al. 2003), and aerucyclamides are bioactive (Portmann et al. 2008) but the molecular targets are not yet known. Serine protease inhibitors severely affect the hydrolytic cleavage of serine proteases isolated from *Daphnia* gut, likely having a similar effect under natural conditions (von Elert et al. 2004).

As known in many examples from higher plants, unsuitable food organisms produce warning signals that alert grazers. Volatile organic compounds (VOCs) are widely used by different taxa to locate and evaluate other organisms in the environment by a form of 'remote sensing'. These allelochemicals include pheromones, attractants, and repellents (Watson 2003; Fink 2007). In terrestrial ecosystems, volatiles are airborne, and both primitive and highly advanced organisms have developed extremely sensitive odor receptors that detect trace concentrations of them. In aquatic ecosystems, the matrix for VOC distribution is water or biofilm mucilage (Jüttner 1999). Many of the allelochemicals identified to date are lipophilic, but they can induce behavioral responses in target organisms at trace levels. Hence, their signalling function is not impaired by their low water solubility—as seen, for example, with marine phaeophyte spermatozoids, which are attracted to mature eggs by pheromones (alkenes) at picomolar concentrations (Boland et al. 1995).

While VOCs may reduce ingestion and may have toxic properties, there has been little convincing evidence to suggest that they function in a more subtle manner, by influencing grazer behavior towards *Microcystis*. However, intriguing preliminary evidence has implicated a VOC derived from photosynthetic pigments that may, in fact,

function in this indirect manner. This was based on early studies, which demonstrated clearly that for all *Microcystis* strains tested, cell disruption activates the rapid cleavage of β-carotene by an unique carotene dioxygenase, forming two major derivatives, β-cyclocitral, a volatile that is released into the water, and crocetindialdehyde, a non-volatile product which remains associated with the cell debris (Jüttner 1984; Jüttner and Höflacher 1985). β-Cyclocitral is a well known odor compound that affects drinking water supplies, and gives *Microcystis* blooms a characteristic hay-tobacco odor, but its role in aquatic chemical defense against grazers has only recently been examined (Watson et al. 2007). As a lipophilic VOC, β-cyclocitral is well suited as a chemical signal. In recent experiments, we observed a strong and immediate increase in swimming velocity of *Daphnia magna* at low concentrations of this compound (Watson et al. 2007). In the present study, we elucidated this reaction in more detail, by testing the hypothesis that β-cyclocitral serves as a signal for food avoidance and induces a phobic response of *D. magna*. We also quantified this process on a molecular level, thus providing the basis for calculating this microscale biochemical interaction that occurs during *Daphnia*–*Microcystis* interactions.

Methods and Materials

Microcystis Microcystis NRC-1 (*Microcystis* sp. Zehnder 1954 / NRC-1, identical with SAG B14.85) was obtained originally from the Institute of Botany, Culture Collection of Autotrophic Organisms, Třěboň, Czechoslovakia in 1988, and since, it has been held at the Univerity of Zürich, Department of Limnology where it has been maintained in batch culture (120 ml) in 300-ml Erlenmeyer flasks at 20°C under continuous light of 7 $\mu mol\, m^{-2} sec^{-1}$ from fluorescent tubes in cyanobacterial mineral medium (Jüttner and Lüthi 2008). Experiments were carried out by using 16-d-old culture material with average cell diameter of 4.1 µm and cell volume 35 μm^3 (as determined by light microscopy).

Daphnia Magna Standardized, 1- to 2-d-old *D. magna* were raised from 3-wk-old mothers from a single genetic strain (Watson et al. 2007). Each behavior experiment was performed with individuals of equivalent size, taken from a single age-class cohort of *Daphnia*. Eight animals were held in each of two parallel flow-through glass cells (36 ml) of a bbe© *Daphnia* Toximeter (bbe Moldaenke, Kiel-Kronshagen, Germany), continually supplied with an inflow of untreated bank filtrate from the Limmat River, Zürich, at a constant flow rate and temperature (9 $ml\, min^{-1}$ at 20°C±0.2°C). The *Daphnia* were fed on a controlled supply of algal food (*Scenedesmus acuminatus*) added continually to the cell inflow. Animals were replaced each week, and acclimated for 2–3 days in the flow-through cells before experiments were carried out. The bbe© *Daphnia* Toximeter is a commercial instrument developed for biomonitoring of toxic compounds in raw water of drinking water industries. Detailed descriptions of the instrument setup, measuring and data system and a flow chart outlining the experimental protocol used here and in previous work are published by Lechelt et al. (2000) and Watson et al. (2007).

Determination of Chlorophyll a One-ml of the *Microcystis* suspension was applied in triplicate to a glass fiber filter (GF 6, Schleicher & Schuell, Dassel, Germany) as small spots under low vacuum. The spots were cut out, and each was extracted with 3 ml methanol overnight in a fridge. The full absorption spectrum of the extracts was measured on a spectrophotometer (Cary 3), and the absorption of the maximum at 666 nm was used to determine the amount of chlorophyll *a* (Ogawa and Vernon 1971).

Determination of Cell Counts by Flow Cytometry Twenty-ml suspensions of *Microcystis* first were preserved with 100 µl Lugol's solution (0.5%) and then with 2 ml 20% formaldehyde. After decolorization with 100 µl 0.1 mol/l sodium thiosulphate, 10 µl Sybr Green I solution (No 7563, Invitrogen, Basel, Switzerland) that had been diluted 1:100 with dimethylsulfoxide were added to 1 ml diluted cell suspension. After staining for 15 min, the cell concentration was determined with a CyFlow space (Partec GmbH, Münster, Germany). The excitation at 488 nm gave strong signals in the green emission range.

β-Cyclocitral in Live Microcystis Cells The concentration of β-cyclocitral in live *Microcystis* cells was determined by minimizing the activation of carotene oxygenase by addition of trifluoroacetic acid. A volume of 250 µl from a 16-d-old *Microcystis* suspension was suspended in fresh growth medium (3.5×10^7 cells / ml) and transferred into a 250 ml round bottom stripping vessel containing 250 µl of 0.05% (v/v) trifluoroacetic acid to immediately kill the cells. Ten ml of water then were added, and the suspension was neutralized with $NaHCO_3$. The volume was increased to 50 ml with water, 2 µl of a *R*-pulegone solution (11.2 ng / µl methanol) were added as the internal standard, and β-cyclocitral was analyzed by using the protocol described below.

Quantitative Analysis of β-Cyclocitral and Hydrocarbons β-Cyclocitral and other volatile hydrocarbons were extracted from the samples onto Tenax cartridges by using a closed-loop stripping technique, and analyzed quantitatively on a GC-MS as described previously (Durrer et al. 1999; Jüttner 2005) but at a capillary column temperature of 50°C during thermal desorption. The temperature program of the oven was 4 min at 50°C, then ramped 10°C / min up to 200°C.

Under these conditions, β-cyclocitral and pulegone eluted at 12.24 and 12.55 min, respectively. Single ion chromatograms (m/z 152 [M^+]) were extracted from the full mass spectra, and the peak areas were integrated. Calibration was performed with β-cyclocitral (BASF, Ludwigshafen, Germany) and *R*-pulegone (Fluka, Buchs, Switzerland). Straight chain hydrocarbons were obtained as reference compounds from Fluka. 7-Methylheptadecane was synthesized according to Han et al. (1968).

Age-Dependant Production of β-Cyclocitral by Microcystis Cells Batch cultures of *Microcystis* were grown for 16 to 207 days and used to investigate age-dependant production of β-cyclocitral. To remove cell clumps and allow quantitative centrifugation, *Microcystis* suspensions were passed through a 50 µm net and then pressurized in a stainless steel pressure cylinder (16 cm high, 10 cm i.d.) with 2 MPa argon to collapse gas vesicles. GC-MS analysis verified that β-cyclocitral formation was not initiated by this procedure. The treated suspensions were centrifuged, and the pellets were resuspended in 50% diluted cyanobacterial medium to a typical cell count of 2×10^7 cells / ml. A volume of 10 ml then was transferred into a 90-ml test tube and frozen by dipping into liquid nitrogen. After 15 min at −196°C, the pellet was melted 3 min under running tap water and transferred into a glass vial, and closed with a screw cap leaving a small headspace. The subsequent carotene oxygenase reaction was carried out in these tubes for 90 min at 23°C. Then 1 ml of the suspension was transferred into an Eppendorf vial with a cap and centrifuged for 1 min. A supernatant volume of 250 µl was removed immediately and added below the surface to a rotating 50 ml 20% NaCl solution containing *R*-pulegone as an internal standard. The quantitative determination of β-cyclocitral was done as outlined above. To determine the potential loss of β-cyclocitral by the centrifugation process, we analyzed a 100 µmolar solution under the same conditions. The integration values of the peak areas of m/z 152 were 0.63±0.10 before and 0.57±0.17 (mean±SD) after centrifugation. The concentrations were not statistically different (t-test for dependent samples, t=0.585; P= 0.590. The data met the assumptions of normality (Shapiro-Wilk W test) and homogeneity of variance (Levene's test). We therefore conclude that opening of the samples and subsequent centrifugation in closed Eppendorf vials did not result in a loss of β-cyclocitral.

Kinetics of β-Cyclocitral Formation The kinetics of β-cyclocitral formation were measured by using the above protocol. A volume of 20 ml of a 15-d-old culture of *Microcystis* was subjected to a freeze-thaw cycle. One ml-volumes were removed after different periods, transferred into an Eppendorf that was closed with a lid, and centrifuged. Further analysis was performed as outlined above. To obtain kinetics for osmotic shock conditions, 5 ml of a *Microcystis* suspension were mixed with 200 ml 20% (w/v) NaCl solution, and 50 ml-samples were removed after defined incubation times for quantitative analysis by stripping analysis.

Determination of β-Cyclocitral Odor Threshold for Daphnia The movement of each of the eight individuals of *D. magna* was tracked with a camera in the cell (36 ml net volume) of a toximeter. Mean values of the swimming velocity were recorded to a database every 50 sec by an intrinsic program. These data were used to determine the odor threshold of β-cyclocitral for this crustacean, using changes in swimming velocity as an index of compound detection, according to the basic protocol outlined in our previous work (Watson et al. 2007), but with the following modifications. The response to β-cyclocitral was tested at three different concentrations, 250 $nmol l^{-1}$, 750 $nmol l^{-1}$, and 2.5 $\mu mol l^{-1}$. To avoid changes in background water quality during an experiment, a total bank filtrate volume of 40-l of bank filtrate water was first collected at the beginning of each day and stored in 10-l glass bottles (using a supply flow rate of 72 ml / min). The water was supplemented with 5 µl ethanol per liter (= 86 µmol/l) to control for the solvent used in the β-cyclocitral treatment. Our earlier work had shown that this ethanol concentration caused no adverse effects or significant change in the swimming velocity of *D. magna* (Watson et al. 2007). To have the same age class of *Daphnia*, only one experiment was conducted per week.

The mean of four baseline measuring periods, two before and two after switching to β-cyclocitral spiked water in the inflow, was used to calculate the baseline swimming velocity of ca. 0.5–0.6 $cm s^{-1}$. Due to the large void volume of the system, the measurements at that time were actually performed with reference water. The response of swimming velocity of *Daphnia* was observed 15–18 min after switching to β-cyclocitral spiked water. This lag period was necessary to attain a detectable β-cyclocitral concentration in the toximeter cell. The lag period increased slightly with decreasing concentrations of β-cyclocitral.

Daphnia Behavioral Response to Live Microcystis Cells To show the effect on *D. magna* swimming velocity elicited by live *Microcystis* cells, the same experimental setup was used as for odor threshold concentration measurement. A 22-d-old culture of *Microcystis* was pressurized, and after centrifugation the cells were resuspended in fresh medium (4.7 nmol chl *a* / ml). A volume of 2 ml of this suspension was centrifuged in an Eppendorf vial and added to 1 ml of the same *Scenedesmus* suspension that was supplied continuously as food source in the toximeter. A volume of 0.35 ml of this mixed cell suspension was injected with a

syringe through the wall of the Tygon inflow tube directly before the peristaltic pump to avoid any pressure pulse in the cuvette. The time lag for the reaction was ca. 9 min.

Liberation of β-Cyclocitral by Daphnia The liberation of β-cyclocitral by feeding *Daphnia* was measured by using a young culture of *Microcystis* (5-d-old). To reduce sedimentation of the cells to a minimum, the cell suspensions were not pressurized before centrifugation (Sorvall SLA-1500, 5 min at 5,000 rpm). The cell pellets were resuspended in half strength cyanobacterial medium to a volume of 500 ml to achieve a cell abundance and chlorophyll *a* concentration of 1.7×10^{6} cells / ml and 188±13 pmol / ml, respectively. For the first experiment (A), we used 155 individuals of a mixed age class of *D. magna* with all stages of development. For the second experiment (B), 325 individuals of a more uniform age class (3.5-wk-old) were used. Incubations were carried out in 1-l glass bottles closed with a screw cap (to avoid loss of the liberated volatile β-cyclocitral) at 20°C and constant illumination of 2 $\mu mol m^{-2} s^{-1}$ (near the light compensation level of *Microcystis*). Liberation of β-cyclocitral was measured over 20.5 hr following the addition of *D. magna*. At different time intervals, the bottles were opened, allowing a short air exchange and retrieval of 5 ml of *Microcystis* suspension, from which the cells were removed by filtration through a glass fiber filter under low vacuum. The filtrate was added to 45 ml of water containing 2 µl internal standard solution and 10 g NaCl. Volatiles were recovered and analyzed by using closed-loop stripping and GC-MS analysis, as described above.

Liberation of β-Cyclocitral in a Microcystis Culture To determine the liberation of β-cyclocitral in a culture of *Microcystis*, 20 ml of a *Microcystis* suspension were centrifuged, and the cell pellet was resuspended in half strength cyanobacterial medium. The suspension was transferred into 1-l glass bottles and incubated under the same conditions as in the *Daphnia* experiment (see above). After different time intervals, 10 ml samples were removed, and the cells were separated by filtration through a glass fiber filter GF 6. The filtrate containing the liberated β-cyclocitral was stripped and analyzed by GC-MS. Single ion monitoring (*m/z* 152 for measurement and *m/z* 137 for control) was used for detection of β-cyclocitral and pulegon that was added as an internal standard. The filter with the *Microcystis* cells was transferred into a stripping vial, covered with 10 ml of 1/2 strength medium and frozen at −20°C. On the next day, the suspension was melted, amended with 40 ml of medium, and incubated for 1 hr to complete the activation of the β-carotene oxigenase. After stripping, full spectra were obtained by GC-MS analysis from which the molecular ion (*m/z* 152) was extracted to calculate the amount of β-cyclocitral.

Statistical Analysis We tested for effects of different concentrations of β-cyclocitral by pairwise comparison of the swimming velocity before and after the addition of the respective concentration of β-cyclocitral. As the same animals were used for the measurement of velocity before and after addition of β-cyclocitral, both values were regarded as dependent. Accordingly, *t*-tests for dependent samples were used to test for significant effects of a given concentration of β-cyclocitral. Data were tested for normality (Shapiro-Wilk *W* test) and for homogeneity of variance (Levene's test). A level of significance of P= 0.05 was applied. Analyses were performed using the software package Statistica 6.0.

Results

Microcystis NRC-1 produced a limited number of VOCs when activated by salt-induced cell rupture. The VOCs were dominated by β-cyclocitral and to a lesser extent by the long-chain hydrocarbons heptadecane, octadecane, 7-methylheptadecane (characteristic fragment ions at *m/z* 168 and *m/z* 112), and 6-methylheptadecane (*m/z* 182 and *m/z* 98). Isopropylthiol and its derivatives, known to be produced by other *Microcystis* strains (Jüttner 1984), were not detected. When *Microcystis* cells were killed by adding trifluoroacetic acid to minimize the activation of the carotene oxygenase by denaturation of the proteins, the per capita β-cyclocitral production was extremely low (2.6 amol / cell), indicating that minimal amounts of this VOC—less than 3.4% of the total production capacity—were present in intact cells.

When added to the toximeter inflow, a cell suspension containing *Microcystis* NRC-1 initiated an increase in *D. magna* swimming velocity from an average baseline level below 0.6 to 0.8 cm / sec (Fig. 1). In contrast, the injection of a pure *Scenedesmus* suspension did not cause a similar increase of swimming velocity

To investigate whether β-cyclocitral production by *Microcystis* is responsible for this grazer response, the toximeter inflow of riverbank filtrate was replaced by riverbank filtrate spiked with this VOC. Again, we observed an increase in swimming velocity following this treatment. However, with continued addition of β-cyclocitral a rapid acclimation also was apparent (as similarly observed in our earlier work; Watson et al. 2007). With prolonged application of spiked water, *Daphnia* swimming velocity finally decreased to the initial value before treatment. Based on the above results, we evaluated the odor threshold concentration for this grazer by exposing the animals to a series of different β-cyclocitral concentrations (Fig. 2). Upon the addition of 2.5 µmol / l β-cyclocitral, the swimming velocity of *Daphnia* increased

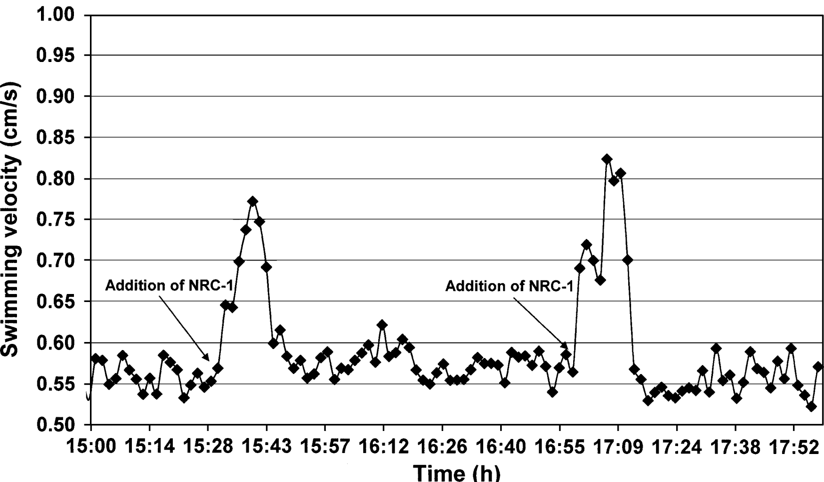

Fig. 1 Swimming velocity of *Daphnia magna* in the toximeter cell. Individual points represent mean values of measures from eight individuals, measured at 100 sec intervals. *Arrows* indicate addition of 0.35 ml of a *Microcystis* NRC-1 suspension to the inflowing water-*Scenedesmus* stream

significantly from 0.48 to 0.65 cm/sec (Fig. 2, Table 1). A similarly significant increase from 0.60 to 0.72 cm/sec was observed upon addition of 750 nmol / l β-cyclocitral (Fig. 2, Table 1). However, 250 nmol / l of β-cyclocitral did not affect *Daphnia*'s swimming velocity (Fig. 2, Table 1).

Experiments conducted to measure β-cyclocitral liberation from *Microcystis* by *Daphnia* grazing showed that initially, virtually no β-cyclocitral was detectable in the medium, but after a lag phase the concentration of this VOC increased continuously (Fig. 3). In experiment A, an older population of *Daphnia magna* was used that included individuals in all stages of development, while for experiment B, 3.5-wk-old mothers and their neonates were chosen. Following 20.5 hr of feeding on the *Microcystis* suspensions, the crustaceans liberated 65 and 55 fmol β-cyclocitral / *Daphnia* / min in experiment A and B, respectively. This cor6responded to an activation of 14 and 12 *Microcystis* cells / *Daphnia* / s, respectively, assuming the same activation efficiency of the carotene oxygenase as observed by a freeze-thaw cycle. The liberation of β-cyclocitral in a *Microcystis* culture exposed to the same environmental conditions is shown (Fig. 4). The data demonstrate that most cell production of β-cyclocitral occurs with cell rupture and activation of carotene oxygenase, while the amount liberated by intact cells and dissolved in the medium is extremely small. The relative proportion of liberated β-cyclocitral to the total maximum cell production capacity of this compound was 0.04% at the beginning and 0.15% at the end of the 42 hr incubation period.

To quantify the kinetics of β-cyclocitral production following cell damage, we applied two different techniques to activate the carotene oxygenase responsible for the formation of this VOC: a freeze-thaw cycle that used liquid nitrogen; and an application of a 20% NaCl solution. Both treatments caused rapid β-cyclocitral formation, but the activation by an osmotic shock required an incubation period considerably longer than 80 min to achieve the maximum potential yield per cell (Fig. 5). A more efficient activation of carotene oxygenase was achieved by using a freeze-thaw process with liquid nitrogen. This procedure was more effective than the activation by NaCl addition. About 48% of the final concentration of β-cyclocitral

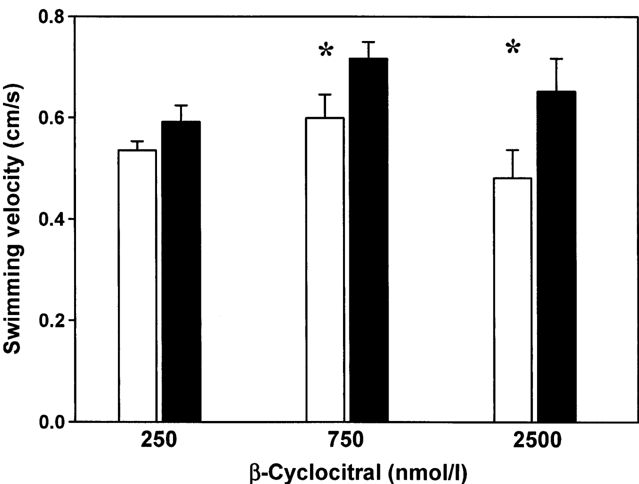

Fig. 2 Mean swimming velocity (+SE, $N=3$) of *Daphnia magna* before (*white columns*) and after (*black columns*) addition of different concentrations of β-cyclocitral. Mean values are based on independent experiments performed at different days. Statistically significant differences in swimming velocity between pre- and post-β-cyclocitral addition are indicated by an *asterisk*

Table 1 Results of pair-wise comparisons of swimming velocities of *Daphnia magna* before and after the addition of known concentrations of ß-cyclocitral (*t*-test for dependent samples)

ß-cyclocitral	*df*	*t*-value	*p*
250 nM	2	−2.6250	0.120
750 nM	2	−4.4900	**0.046**
2.5 μM	2	−11.798	**0.007**

P-values given in bold indicate significant differences

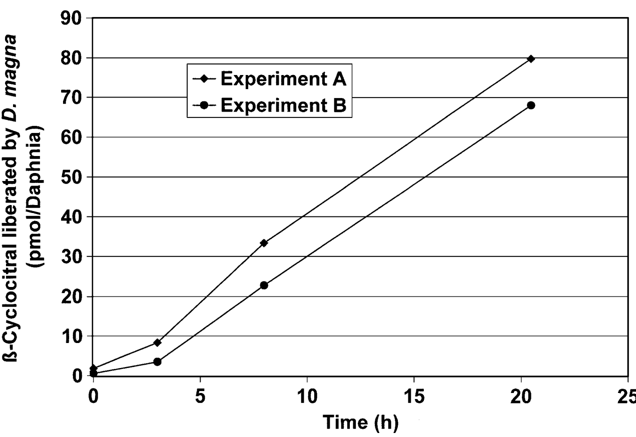

Fig. 3 Liberation of β-cyclocitral from *Microcystis* by *Daphnia magna* feeding (pmol / *Daphnia*). A—155 individuals of *Daphnia* at all developmental stages, B—3.5-wk-old mothers and neonates (325 individuals)

already was present by ~5 min (Fig. 6) using the freeze-thaw process. The completion of the oxygenase reaction occurred in less than 90 min with only a marginal further increase in β-cyclocitral formation in the total observation period of 1,440 min when the experiment was terminated. Although the first concentration measurements of β-cyclocitral in both Figs. 5 and 6 are labelled at 0 min, this in fact represents 5 min following the initial *Microcystis* cell activation by the osmotic shock or thawing process and subsequent centrifugation separation process.

Age-dependent changes in β-cyclocitral production capacity by *Microcystis* were investigated by using batch cultures of *Microcystis* NRC-1 grown over periods between 16 and 207 days after transfer into new growth medium. With the exception of the 16-d-old culture, the cells were at a stationary growth phase. Activation was initiated by a liquid nitrogen freeze-thaw cycle, and β-cyclocitral production was measured over a 90 min incubation period. The results showed no consistent age-dependant change of the β-cyclocitral production capacity between cultures, but a significant increase in cellular chlorophyll *a* content with increasing age, translating to a lower β-cyclocitral production capacity per unit of chlorophyll *a*. (Table 2).

Discussion

The experiments provide new insight into grazer-cyanobacterial/algal interactions and show that chemical ecology may play a significant, taxon-specific role in facilitating grazer selectivity against bloom forming cyanobacteria. Our results showed a marked behavioral change in the common crustacean grazer *Daphnia magna* in response to the appearance of detectable levels of β-cyclocitral in the swimming medium. This implies that β-cyclocitral may provide a significant and exclusive competitive advantage to *Microcystis* among planktonic cyanobacterial/algal communities. However, while unique to this cyanobacterial genus, our related work indicates no apparent differentiation at the species level or relationship to toxicity. The specific β-carotene 7,8 (7′,8′) oxygenase involved in this process (Jüttner and Höflacher 1985) appears to be coded for by all *Microcystis* species, with β-cyclocitral production documented in all species tested to date (Jüttner 1984). These findings support our central hypothesis that β-cyclocitral acts as a genus-specific grazer repellent for these bloom forming cyanobacteria and facilitates optimal grazer foraging by acting as an effective signal of an unsuitable food source.

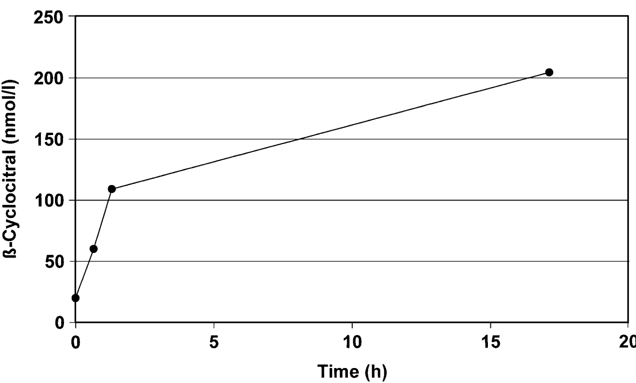

Fig. 5 Formation kinetics of β-cyclocitral (integration units / ml suspension) upon activation of *Microcystis* with an osmotic shock (20% NaCl). The time-scale (X-axis) starts at the point of complete solution of the solid NaCl and separation of the cell matter from the aqueous phase by centrifugation

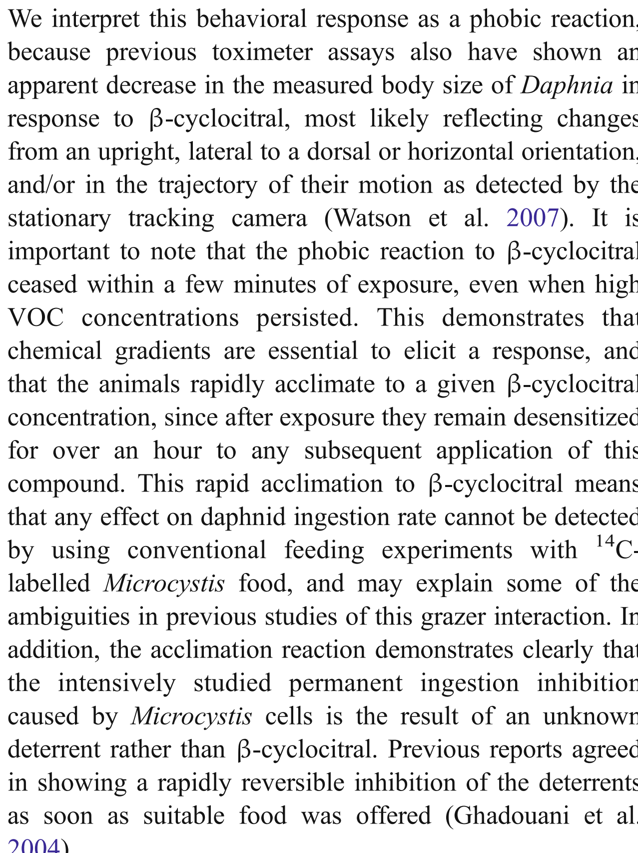
The tenet that some cyanobacteria are a poor food source and/or selectively avoided by crustaceans is as old as the study of Limnology (Birge 1898). The later development of quantitative measurements that used ^{14}C-labelled food organisms, showed clearly that compared to algae from other taxonomic groups, *Microcystis aeruginosa* strongly inhibited crustacean ingestion rates (Sorokin 1968). This selective prey uptake was manifested as strong changes in the beat and movement rates of the thoracic appendages, mandibules, maxillules, etc. (Lampert 1982; Fulton and Paerl 1987b; Rohrlack et al. 1999a; Ghadouani et al. 2004). To date, however, studies have failed to implicate the primary toxins produced by many *Microcystis* (microcystin, MC) with this behavioral reaction, and no other chemicals have been linked with this grazer response. For example, MC-producing and non-producing *Microcystis* strains exhibit the same inhibitory reaction among grazers, and MCs have been ruled out as the causative agents in the avoidance reaction (Rohrlack et al. 1999b; Ghadouani et al. 2004). Similarly, this has been shown for isopropylsulfide producing and deficient *Microcystis* strains (Jungmann et al. 1991).

Unlike calanoid copepods, which are highly cued raptoral grazers, *Daphnia* are not considered to be selective feeders (Friedman and Strickler 1975; Poulet and Marsot 1978; DeMott 1986; Fulton and Paerl 1987b). Nevertheless, daphnids may have developed mechanisms to select particles based on morphological, physical (Hartmann and Kunkel 1991), and chemical cues (Jensen et al. 2001). Our experiments demonstrate clearly that *Daphnia* can detect the presence of trace levels of β-cyclocitral and respond to this with a behavioral change. We propose that a phobic reaction is initiated in these crustaceans when they encounter sufficient concentration differences of β-cyclocitral near damaged *Microcystis* cells, or when release of this VOC has occurred through grazing attack or by disruptive agents of some cells of the *Microcystis* colony.



We interpret this behavioral response as a phobic reaction, because previous toximeter assays also have shown an apparent decrease in the measured body size of *Daphnia* in response to β-cyclocitral, most likely reflecting changes from an upright, lateral to a dorsal or horizontal orientation, and/or in the trajectory of their motion as detected by the stationary tracking camera (Watson et al. 2007). It is important to note that the phobic reaction to β-cyclocitral ceased within a few minutes of exposure, even when high VOC concentrations persisted. This demonstrates that chemical gradients are essential to elicit a response, and that the animals rapidly acclimate to a given β-cyclocitral concentration, since after exposure they remain desensitized for over an hour to any subsequent application of this compound. This rapid acclimation to β-cyclocitral means that any effect on daphnid ingestion rate cannot be detected by using conventional feeding experiments with ^{14}C-labelled *Microcystis* food, and may explain some of the ambiguities in previous studies of this grazer interaction. In addition, the acclimation reaction demonstrates clearly that the intensively studied permanent ingestion inhibition caused by *Microcystis* cells is the result of an unknown deterrent rather than β-cyclocitral. Previous reports agreed in showing a rapidly reversible inhibition of the deterrents as soon as suitable food was offered (Ghadouani et al. 2004).

We could only detect trace amounts of β-cyclocitral in intact *Microcystis* cells, and even these likely were the result of procedural artefacts caused by a small number of damaged cells. The formation of β-cyclocitral is achieved rapidly by activation of the β-carotene oxygenase pathway that cleaves β-carotene into crocetindial and two molecules of β-cyclocitral. Experimentally, this activation can be caused by any mechanism that disintegrates the physiological integrity of the cells, such as a freeze-thaw cycle,

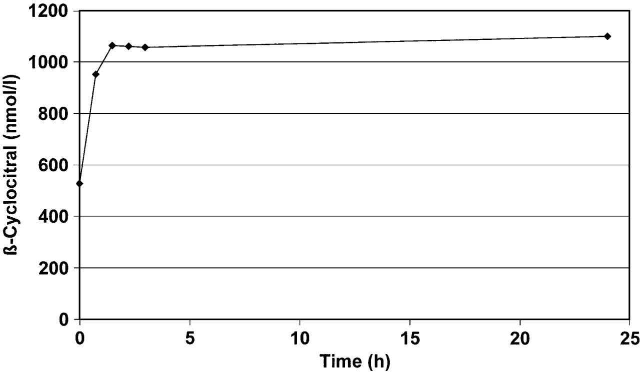


Fig. 6 Formation kinetics of β-cyclocitral upon activation of *Microcystis* (pmol β-cyclocitral / ml suspension) by a freeze-thaw cycle and subsequent reaction time at ambient temperature (23°C). The time-scale (X-axis) starts at the point of complete melting of the cell suspension and separation of the cell matter from the aqueous phase by centrifugation

Table 2 Age-dependant (days) capacity of *Microcystis* NRC-1 to form ß-cyclocitral (amol ß-cyclocitral per cell, SD in brackets, N=3). The chlorophyll *a* concentration per cell (amol chl *a* per cell) and the ratio amol chlorophyll *a* per amol ß-cyclocitral are also given

Culture age (d)	amol ß-cyclocitral/ cell	amol Chl *a* / cell	amol chl *a* / amol ß-cyclocitral
16	77(±5.5)	127(±4.3)	1.6
20	61(±17)	108(±1.6)	1.8
52	49(±7.6)	109(±1.7)	2.2
141	47(±5.9)	191(±7.8)	4.1
207	65(±2.2)	201(±2.5)	3.1

osmotic shock, mechanical damage, or addition of organic solvents. Under natural conditions, the formation of β-cyclocitral may be caused by *Daphnia* appendage bristles (Fryer 1991), which may puncture *Microcystis* cells and thus initiate β-carotene oxygenase activation. This activation may be continued and induced during ingestion and gut passage. Our feeding experiments with *Daphnia* and *Microcystis* NRC-1 under simulated natural conditions indicate that the activation of ~12–14 *Microcystis* cells per second per grazer is sufficient to elicit the behavioral response. In many lakes, a colonial matrix can contain up to several hundred *Microcystis* cells, and wounding one or several cells could produce a β-cyclocitral odor plume at sufficient concentrations to be detected by grazers. The adaptive function of this compound as a repellent would be afforded largely to *Microcystis* colonies, where a limited number of sacrificed cells can provide chemical protection to the majority. That is even more important because the growth rate of cells in colonies is comparable to that of single cells, and the energetic drawback of colonial growth is small (Nielsen 2006).

Our quantitative measurements estimate that the maximum theoretical intracellular β-cyclocitral concentration in an activated *Microcystis* cell (for a young cell, estimated to be 2.2 mM) would be some 3,000 times higher than the odor threshold concentration for *Daphnia magna* (750 nmol/l). Even where β-cyclocitral is rapidly diluted from the microzone around the activated cell(s), the concentration would be sufficient to initiate a phobic reaction by *Daphnia*, particularly where more than one cell is activated. This represents an effective chemical defense mechanism for *Microcystis*, since detection of the compound leads to a change in grazer orientation and an increase in swimming velocity, which we interpret as an avoidance reaction. In fact, olfactory receptors are widely distributed among invertebrate grazers including *Daphnia*, which may use the initial grazing-induced release of β-cyclocitral and other VOCs as a cue to reduce their ingestion of poor cyanobacterial and algal food.

The β-cyclocitral formation kinetics showed that the oxygenase reaction required some time to reach the maximum potential yield. Because the reaction mechanism is unclear, it is difficult to speculate which reaction step is rate-limiting. The ecological implication is that β-cyclocitral production continues for some time following cell damage, thus allowing the formation of a transient odor plume or a microzone around a *Microcystis* colony (Blackburn et al. 1998) and thus reducing the probability of further grazer attack. Furthermore, it is feasible that sequestration of the liberated β-cyclocitral by the colonial mucilage could occur, which would effectively prolong the persistence of the VOC plume.

The defense reaction that initiates β-cyclocitral formation is constitutively present in *Microcystis*, and minimal differences in this capacity were observed as a function of age. Cells at late stationary phase (207 days) still exhibited this capacity, although an increase in their cell chlorophyll *a* content translated to a decrease in β-cyclocitral production per chlorophyll *a*. Thus, under natural conditions, cells and colonies at all stages of growth maintain this grazer defense mechanism.

The formation of β-cyclocitral controls the residual amount of β-carotene in ingested *Microcystis* cells. Since two molecules of β-cyclocitral are formed from one molecule of β-carotene (Jüttner and Höflacher 1985), at least 30.5 amol β-carotene are required to produce 61 amol β-cyclocitral in a *Microcystis* cell. This is consistent with measured pigment content, assuming that most of the available β-carotene is oxidatively cleaved and that *Microcystis* NRC-1 has a chlorophyll *a* to β-carotene molar ratio comparable to that of other *Microcystis* strains (e.g., 2.4 and 4.0 in SAG 1450-1 and PCC 7806, respectively; Stransky and Hager 1970; Jüttner and Höflacher 1985). It can be hypothesized further that the above-described grazer defense mechanism also may act to reduce the food value of the *Microcystis* cells themselves. Photoreceptors are known for *Daphnia*, and constituents of vitamin A (retinal and opsin) are likely key components of these receptors (Kashiyama et al. 2009). The grazing-activated cleavage of β-carotene by 7,8 (7′,8′) carotene oxygenase yields a product that cannot be used as a precursor for retinal. Once *Microcystis* cells are attacked, this catalytic process hypothetically might contribute to vitamin A deficiency by decreasing available levels of the precursor in a food supply. Depletion of β-carotene supply, however, could only be expected in those cases where *Microcystis* is the major food component of a *Daphnia* population.

Effective defense strategies in predator-prey interactions often involve multi-tiered responses that are difficult to fully characterize. In this study, we demonstrated that the production of β-cyclocitral by *Microcystis* acts as a front-line chemical signal of an unsuitable food organism. It is triggered by grazer attack and is the first such infochemical identified in these cyanobacteria. From the grazer's perspective, this warning signal is justified by the presence of potent oligopeptides and other bioactive toxins in the cyanobacterial cells (Trubetskova and Haney 2006).To reinforce grazer recognition of *Microcystis* as an unsuitable food source, a logical next step in the signalling process would be through the production and intracellular storage of other chemical deterrents which, when present in the ingested food material, would act to reduce grazer ingestion rate. In fact, suppressed ingestion activity has been observed in a number of grazer feeding studies with *Microcystis* (e.g., Rohrlack et al. 1999a, b), but the chemical agent(s) have not been identified (although microcystins have been implicated by some authors, Kim et al. 2003). It is unlikely, however, that microcystins play a major role in grazer defense since microcystin-deplete colonies are frequently found in natural assemblages. On the other hand, digestive protease inhibitors are far more widely produced and found in almost every cyanobacterial bloom (Agrawal et al. 2005; Schwarzenberger et al. 2010), and it is possible that these compounds may act to suppress grazing. Future research in this area would contribute significant insight into the role of chemical ecology in top down regulation of noxious blooms.

volatiles emitted from the roots have not been as thoroughly explored (Lin et al., 2007; Ens and French, 2008; Ens et al., 2009b). 1,8-cineol is one of the few volatile organic compounds (VOCs) emitted from the roots of of *Arabidopsis thaliana*, and its root-specific terpene synthase have been characterized (Chen et al., 2004; Steeghs et al., 2004).

Recently, volatile terpenoids, especially monoterpenes, were identified by solvent and dynamic headspace extraction of roots and the rhizosphere of *Pinus* spp. (Lin et al., 2007). Ens and his co-workers (2009a) extracted volatiles from the roots and soil surrounding the invasive plant known as the bitou bush (*Chrysanthemoides monilifera*), analyzed them using gas chromatography and mass spectrometry (GC-MS), and demonstrated allelopathic effects of the detected sesquiterpenes. They also invented a novel technique to capture hydrophobic substances, including volatile sesqui- and diterpenes, in the rhizosphere of plants (Ens et al., 2009b). Some of the earliest work on the detection of volatile terpenoids in the soil was done by Halligan (1975) who distilled the leaves, leaf litter, and soils surrounding the shrub zones of *A. californica* in a "Clevenger orange still," and subjected the resulting essential oils to a germination bioassay against *Madia sativa* seeds. Camphor and 1,8-cineol were the most toxic substances, while isothojone, the major compound in the soil, had intermediate toxicity. A full decade before Halligan's work, Muller and colleagues examined the allelochmaical volatile terpenoids emitted from the aerial parts of sagebrush and sage plants, *Artemisia californica* and *Salvia leucophylla* (Muller et al., 1964). The selective phytotoxicity of the volatiles from *A. californica* against some species of the co-existing grasses together with the grazing of animals were both considered important reasons for the bare area between the grasses and the shrubs in the chaparral in California (Halligan, 1973).

Artemesia tridentata is an important shrub of western North America; it ranges from British Columbia to Mexico. The plant's ability to inhibit the establishment of competitors has been attributed to allelochemical volatile terpenoids emitted from its aerial parts; these terpenoids include camphor, 1,8-cineol, and α-pinene (Weaver and Klarich, 1977). A leaf litter extract of *A. tridentata* significantly inhibited the seed germinations of three native grasses in the sagebrush grass zone: *Stipa thurberiana, Sitanion hystrix*, and *Agropyron spicatum*; however, the litter did not have an inhibitory effect after the seeds had germinated (Schlatterer and Tisdale, 1969). Several authors have shown the allelopathic effects of volatiles and aqueous extracts from leaves or litter of big sagebrush, including the inhibition of seed germination and shoots and the radicle growth of test plants such as *Elymus cinereus, Agropyron cristatum*, and *Cucumis sativa* (Schlatterer and Tisdale, 1969; Weaver and Klarich, 1977; Groves and Anderson, 1981). The non-volatile sesquiterpene lactones from the shoots of *A. tridentata,* namely, arbusculin-A, achillin, desacetoxymatricarin, viscidulin-B, and viscidulin-C inhibit the growth of radicles and hypocotyls in cucumber (*Cucumis sativus*) and increase the plant's respiration (McCahon et al., 1973). In addition to the sesquiterpenes, the coumarin, esculin, isolated from the aerial parts of the sagebrush inhibits the growth of *C. sativus* especially of its radicles, but does not affect germination (McCahon et al., 1973). The essential oils from the aerial parts of different species of sagebrush, including *A. tridentata,* have been investigated (Kelsey et al., 1983; Epstein et al., 1984; Preston et al., 2001; Gunawardena et al., 2002), but thorough analyses of root volatiles of this genus have not been carried out (Kennedy et al., 1993; Blagojević et al., 2006; Goel et al., 2007).

Methyl jasmonate (MeJA), the volatile form of the endogenous plant hormone, is produced in allelopathic quantities from the aerial parts of *A. tridentata* (Preston et al., 2002) and can elicit the production of defensive compounds of *Nicotiana attenuata* plants growing nearby (Baldwin, 1998; Preston et al., 2002; Karban et al., 2000, 2003, 2006; Kessler et al., 2006). The germination of *N. attenuata* seeds is delayed by both airborne and water-transported MeJA released by *A. tridentata* (Preston et al., 2004). Moreover, when the seeds of *N. attenuata* were buried in soil near *A. tridentata*, or when the soil underneath the plant was used to germinate *N. attenuata* seeds, germination was delayed significantly (Preston et al., 2002). From 16 to 60% of the inhibitory activity of original litter extract of sagebrush could be attributed to MeJA (Preston et al., 2002). Therefore, it was concluded that in addition to the MeJA emitted from the shoots of big sagebrush, other compounds also play an allelopathic role in the soil near the plant (Preston et al., 2002). Although previously it was suggested that the toxic volatiles from the leaves of some plants such as *A. californica*, *S. leucophylla*, and *S. apiana* could be deposited by dew on seedlings growing nearby (Muller et al., 1964), this would require dissolving the hydrophobic substances in water, which seems an unlikely mechanism.

Here, we tested the hypothesis that root volatiles, in addition to airborne volatiles, affect the growth of *N. attenuata* seedlings growing adjacent to *A. tridentata* plants. We describe a novel approach for analyzing the VOCs released from the roots of intact *A. tridentata* plants [dynamic headspace extraction, headspace solvent-microextraction (HSME) and headspace solid phase-microextraction (HSPME) followed by GC-MS analysis] and examine the phytotoxicity of the indentified compounds against seedlings of the naturally co-occurring plant, *N. attenuata*.

Methods and Materials

Plant Material, General Procedure and Reagents *Artemisia tridentata* (Natt.) subspecies *tridentata* and *Nicotiana attenuata* were grown as described previously (Preston et al., 2002). ^{1}H- and ^{13}C NMR spectral experiments were measured on a Bruker Avance DRX 500 NMR. The test chemicals, camphor, 1,8-cineol, nerol, geraniol, α-thujone, and camphene, were purchased from Sigma and Aldrich. Neryl and geranyl isovalerates were synthesized according to the process described by Hassner and Alexanian (1978). Briefly, an equimolar solution of isovaleric acid, geraniol or nerol, N,N-dicyclohexylcarbodiimide, and catalytic amounts (0.1 mol) of 4-pyrrolidinopyridine in dry tetrahydrofurane (THF) was stirred at room temperature until the reaction was completed. The esters were purified by column chromatography over silica gel using hexane and dichloromethane (DCM) as the mobile phase.

Extraction of VOCs from the Roots of Big Sagebrush and the Growth Bioassay of N. Attenuata on Plant Agar The roots of *A. tridentata* (108 g) were extracted in 80% methanol (MeOH), and the extract (5.45 g) was partitioned between water and DCM. The DCM extract (1 g) was divided into methanol (MeOH/DCM ext.) and DCM-soluble fractions (DCM/DCM ext.). The DCM, MeOH, and water layers of the aqueous methanol extract (H_2O/80%MeOH ext.) were used in the root growth bioassay for *N. attenuata*.

Seeds of *N. attenuata* after treatment with liquid smoke were germinated on GB5 plant agar according to the process described previously (Krügel et al., 2002). After 4 d, seedlings were transferred to freshly prepared agar containing 0.25 µg/ml of the above extracts dissolved in 250 µl dimethylsulfoxide (DMSO). For the control, 250 µl DMSO were mixed well with 40 ml agar media. Root lengths were measured 6 d after transferring seedlings to the agar.

Dynamic Headspace Extraction of the Roots of Big Sagebrush Volatiles were collected from the head space of the sagebrush's roots with a procedure similar to those reported previously with some modifications (Karban et al., 2000; Preston et al., 2001). Roots were removed from the surrounding soils or sand and put into a desiccator. The aerial parts of the plant were separated by a plastic sheet from the roots in the desiccator, and the shoots were enclosed in a 1.5 l plastic bottle as shown (Fig. 1). The headspace of the roots and shoots was trapped for 2 h by pulling air using a vacuum diaphragm pump at a flow rate of approximately 500 ml/min through 30 mg Super-Q (Alltech, Deerfield, IL, USA) adsorbent in a Pasteur pipette. Two 1 ml plastic samplers were filled with 500 mg activated charcoal to filter the incoming air into the headspace of the plants' shoots and roots. After the adsorbent was eluted with DCM, the solution was analyzed by GC-MS to identify its constituents. Five µg geranyllinalool/10 µl hexane as an internal standard were added to the adsorbent prior to its elution with 250 µl DCM.

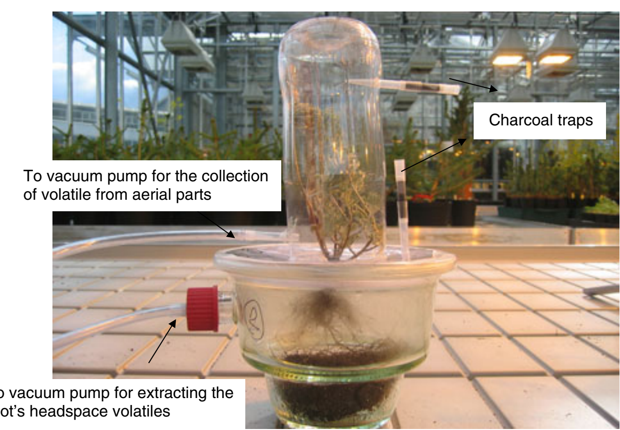

Fig. 1 A homemade apparatus for the simultaneous extraction of headspace volatiles from roots and shoots; the roots' volatiles are adsorbed on a Super-Q trap in a glass tube and the incoming air is filtered by a column of ground charcoal. The trapped volatiles adsorbed on the solid phase are then eluted by dichloromethane (DCM) containing geranyllinalool as the internal standard and subjected to gas chromatography-mass spectrometry (GC-MS)

Gas Chromatography-Mass Spectrometry (GC-MS) GC-MS analysis was carried out on a Varian 3800 gas chromatograph, coupled to a Varian Saturn 2000 mass spectrometer operating in EI mode at 70 ev. The GC was equipped with a DB-5 MS (J & W Scientific column, 30 m×0.25 mm i.d., 0.25 µm film thickness). The oven temperature was programmed from 60°C to 220°C at 5°C/min and kept for 10 min at 220°C. The carrier gas was helium (He) with a flow rate of 1 ml/min, and the injector temperature was set at 260°C in splitless mode. The injection volume was 1 µl for all samples. Volatiles were identified by comparing their retention times, indices, and mass spectra with those of the authentic samples (from Fluka, http://www.sigmaaldrich.com, and Sigma) or those published in the literature (Adams, 2007).

Identification of the Major Constituents by ^{13}C NMR Spectroscopy The fractions collected from the column chromatography, after analysis by GC-MS, were subjected to NMR experiments in $CDCl_3$ using TMS as the internal standard. For identification of some of the compounds (Table 1), ^{13}C NMR spectral data were compared to those published in the literature (Uchio et al., 1981; Formacek and Kubeczka, 1982; Martínez et al., 1987).

Headspace Solvent Micro-Extraction (HSME) of the Roots of Big Sagebrush Headspace solvent micro-extraction (HSME) was performed using a 10 µl Hamilton syringe

[a] Identification of compounds was performed by calculated relative retention index (RRI) on a DB-5 capillary column and mass spectrum (GC-MS), for the major compounds in the dichloromethane extract (DCM) the identification was further confirmed by ^{13}C NMR spectral data in $CDCl_3$ at 125 MHz (NMR) and in some cases ([d]) with co-injection of authentic (co-inj.) samples on the capillary GC. [b] GC-MS area normalized percentage of the volatiles identified in the DCM extract and in the phytotoxic active fraction obtained from the DCM extract. [c] Means of GC peak area%±*SE* of three biological replicates of the volatiles from the sagebrushe's roots-headspace adsorbed on SPME fiber. [e] The calculated RRI are different in various experiments, but they have the same elution sequence as those reported in the literature.

model 1701 N. A hole (diam. 3×10 cm) was dug in the soil approximately 10 cm from the plant's stem. By inserting in the hole, a 50 ml-open end Falcon-tube, the headspace of the rhizosphere was captured in the tube (Fig. 2). The syringe was inserted through a narrow hole on the cap of the tube and sealed with parafilm. Two µl hexadecane were extruded from the tip of the syringe as a single drop to adsorb the volatiles in the head space of the rhizosphere of the plant (Fig. 2). After overnight exposure, the drop was retracted in the micro-syringe and injected directly into the GC-MS.

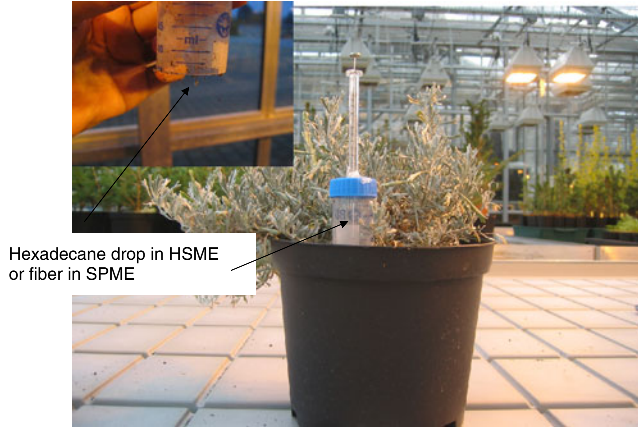

Fig. 2 Headspace solvent micro-extraction (HSME) for detecting volatiles emitted from plant roots; the volatiles are adsorbed onto a single drop of hexadecane overnight, retracted into a syringe, and injected into the GC-MS for analysis of the constituents. The same arrangement was used for solid-phase micro-extraction (SPME) of the volatiles replacing the syringe by a SPME apparatus

Solid Phase Micro-Extraction-GC-MS Analyses (SPME-GC-MS) The experimental design for the adsorption of the volatiles was the same as for the HSME experiment, but instead of the micro-syringe a stableFlex Divininylbenzene/Carboxen/PDMS (DVB/CAR/PDMS) SPME fiber (Supelco, Bellefonte PA, USA) was used to adsorb the volatiles from the rhizosphere of the plant (Fig. 2). Volatiles emitted from below-ground parts of the plants were adsorbed on the SPME fiber for 1 h; after retracting the fiber, it was injected into the injector of the GC-MS. The fiber was conditioned about 15 min before each injection at 220°C.

Germination and Post-Germination Bioassay Nerol, geraniol, their isovalerates esters, camphor, 1,8-cineol, camphene, methyl jasmonate, *E*-caryophyllene, and α-thujone were dissolved in 50 μl acetone and applied to filter paper (Macherey- Nagel, MN 85/70 diam. 25 mm: www.mn-net.com) at 50 to 0.1 μmol amounts in two-chambered Petri dishes (diam. 10 cm). After treatment with liquid smoke, 12–13 seeds of *N. attenuata* were placed on GB5 agar (15 ml) poured into one compartment of the Petri dish; after 6 d at 28/24°C 16/8 hL/D, the number of germinated seeds was counted. To determine the toxicity of the volatiles on *N. attenuata* seedlings, seeds were germinated on agar and after 4 d, they were exposed to the volatiles applied to a paper disc in the divided Petri dish. The appearance and development of the leaves of the seedlings were evaluated at d 10.

Statistical Analyses Student's*t-tests* were performed with the algorithms embedded in the StatView.

Results

Root Extracts from Big Sagebrush Added to Plant Agar Inhibit the Growth of N. Attenuata Seedlings To test for phytotoxic effects of extracts, we extracted the roots of big sagebrush with different solvents and added the extracts to the agar media (0.25 μg/ml) used to grow the seedlings of *N. attenuata*. Only the methanolic layer of the dichlromethane (DCM) extract at 0.25 μg/ml agar inhibited the growth of *N. attenuata* seedlings significantly (56% of the control, unpaired *t-test*, $P<0.001$).

The active extract was subjected to silica gel-column chromatography fractionation. The hexane-dominant fractions were active at a concentration of 3.75 μg/ml agar in the root growth bioassay, and inhibited seedling growth rates to 74% of that of control plants (unpaired *t-test*, $P<0.001$). All fractions collected from column chromatography were analyzed by GC-MS and ^{13}C NMR spectroscopy. In addition to an acetylenic spiroether compound previously isolated from some species of *Artemisia* and *Chrysanthemum* (Uchio et al., 1981; Martínez et al., 1987), geranyl- and neryl-esters were found as the major phytotoxic constituents in the active fractions eluted with hexane (Table 1).

Dynamic Headspace GC-MS Analyses of the Roots of A. tridentata To determine whether or not the phytotoxic volatiles are emitted from the roots of growing plants, the root headspace was collected from intact plants grown under different conditions (Fig. 1) and analyzed by GC-MS. Camphor, the most abundant monoterpene in the roots' headspace, was emitted at 1846.2±474.0, 344.5±147.7, and 231.1±126.4 ng$L^{-1}h^{-1}$ for plants grown in soil, sand, or under hydroponic conditions, respectively (Table 2). The other major compounds were 1,8-cineol, which was emitted at 398.7±220.9, 41.3±12.0, and 25.9±13.4 ng$L^{-1}h^{-1}$, respectively, and the monoterpene hydrocarbon, camphene, emitted at 508.2±189.8, 84.3±28.6, and 46.9±26.8 ngL^{-1} h^{-1}, respectively. From the roots of a 1-yr-old plant cultured in soil, γ-himachalene (34.8%; peak area normalized%) and other sesquiterpenes were detected as the major emitted volatiles, while neryl isovalerate (6.3%) and geranyl esters were the minor volatile constituents. The head space of the roots of a 2-mo-old plant composed of neryl isovalerate (46.9%) while γ-himachalene (6.7%) was detected as a minor compound.

Headspace Solvent Micro-Extraction (HSME) of the Roots of Big Sagebrush In order to determine whether or not volatiles were emitted from the roots of the plant, we used headspace solvent micro-extraction (HSME) with a single 2 μl drop of hexadecane hanging from a micro-syringe to adsorb the volatiles; the syringe was placed above a hole

Table 2 Volatiles emitted from the roots of *Artemisia tridentata,* cultured in different media and analyzed by dynamic HS-GC-MS

Compounds	Volatiles from-soil-grown roots ng L^{-1} h^{-1}	Volatiles from sand-grown roots ng L^{-1} h^{-1}	Volatiles from hydroponically grown roots ng L^{-1} h^{-1}
α-pinene	150.2±40.7	36.1±12.0	13.2±7.8
camphene	508.2±189.8	84.3±28.6	46.9±26.8
β-pinene	72.2±25.5	16.1±5.0	11.8±6.9
1,8-cineol	398.7±220.9	41.3±12.0	25.9±13.4
α-thujone	19.0±12.8	11.4±9.7	6.3±0.0
camphor	1846.2±474.0	344.5±147.7	231.1±126.4
nerol	3.7±1.3	15.1±7.5	1.8±0.7
longifolene	4.8±0.7	9.1±3.1	0.5±0.1
β-caryophyllene	1.4±0.0	–	0.2±0.0
neryl isovalerate	5±2.0	60.1±28.1	4.8±1.2

The mean value (ng L^{-1} h^{-1}) of the emitted compounds from each plants' root±SE of 5 different biological replicates were calculated for some selected compounds by measuring their response factors compared to the internal standard

(diam. 3×10 cm) excavated in the soil near the plant (Fig. 2). Camphene, 1,8-cineol, camphor, neryl isovalerate, and γ-himachalene were detected by GC-MS in the headspace.

Headspace Solid Phase-Microextraction GC-MS Analysis (HSPME-GC-MS) of the Volatiles Emitted From the Rhizosphere of A. tridentata In addition to HSME, we used SPME to reconfirm the emission of volatiles from the roots of intact plants and to identify the emitted volatiles more precisely. We placed the SPME fiber in a hole near the roots to collect the VOCs emitted from the rhizosphere of the plants, exactly as we had done for the HSME (Fig. 2). After the roots' volatiles were adsorbed on the SPME fiber and subjected to GC-MS analysis, the analysis revealed that the roots of *A. tridentata* produced different types of secondary metabolites compared with those released by the shoots (Table 1). Monoterpenes constituted 39.8% and 45.5% of the volatiles emitted from the shoots and roots of the plant. Of these, camphor was the most abundant constituent in roots (27.5±3.0%) and in shoots (31.3±9.5%). In the headspace of the shoots, different green leaf alcohols and their esters, constituted 26.5% of the total volatiles, while none of these green leaf volatiles were detected in the roots or in the rhizosphere; however, sesquiterpenes were detected at 8.8% of the total volatiles emitted from the roots, while only traces of these were detected in the shoots' headspace. The other major compounds detected in the roots but not in the shoots were the geranyl and neryl esters and γ-himachalene: these compounds were never detected in the shoots' volatiles. The headspace of the roots and shoots of *Artemisia annua* was analyzed by SPME-GC-MS to determine if the same pattern of volatile distribution that was detected in *A. tridentata* could be observed; sesquiterpenes were the major constituents in the roots, and monoterpenes and green leaf volatiles were the major constituents in the shoot volatiles of *A. annua* (unpublished data).

Effects of the Chemical Constituents of VOCs from the Roots of Big Sagebrush on Seed Germination in N. attenuata After identifying the main VOCs emitted from the roots of big sagebrush grown under differing conditions, the following compounds, which the literature suggested might be phytotoxic, were tested for their ability to influence seedling growth and seed germination of *N. attenuata*. Nerol, geraniol, their isovalerate esters, camphor, 1,8-cineol, camphene, methyl jasmonate, and α-thujone were applied to paper discs at 50 to 0.1 μmol dose amounts in two-chambered Petri dishes (see Fig. S1), and their effects on the germination of 12–13 seeds growing on GB5 agar were evaluated after 6 d. Among the tested compounds, MeJA completely inhibited seed germination at all concentrations tested (Fig. 3). In the presence of nerol, α-thojone, and camphor, at 10 μmol/disc, 51.9±8.5, 46.2±5.7, and 49.2±8.6% of the seeds, respectively, germinated. By applying geraniol at 1, 5, and 10 μmol/disc, 65.4±11.9, 23.1±8.3, and 1.9±1.9% of the seeds germinated. Camphene did not inhibit seed germination in any concentrations applied. When geranyl isovalerate was applied at 25 and 50 μmol/disc 30.8±17.4 and 2.4±1.6% of the *N. attenuata* seeds germinated, but neryl isolvalerate was nearly inactive (Fig. 3). The oxygenated monoterpene 1,8-cineol was active only at 50 μmol/disc, which allowed 36.5±5.8% of the seeds to germinate.

Effect of Some of the Chemical Constituents of VOCs from the Roots of Big Sagebrush on Seedlings of N. attenuata after the Seeds Germinated Four days after the seeds of

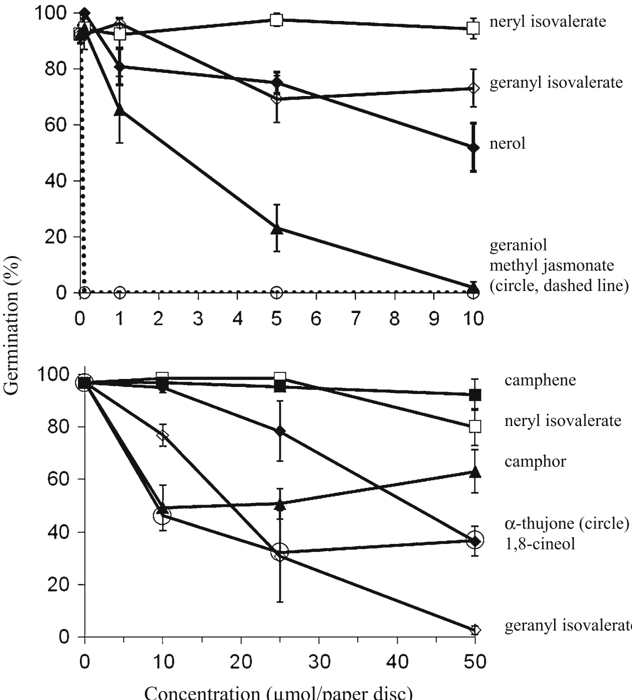

Fig. 3 Germination of the seeds of *Nicotiana attenuata* are inhibited by the presence of volatiles detected in the roots of *Artemisia tridentata* at different concentrations applied to paper discs in two-chambered Petri dishes. The germination% mean value [(number of germinated seeds/total number of seeds)×100]±*SE* of five biological replicates for each concentration of the volatiles in 50 µl acetone were compared with those for the control treatments in which 50 µl acetone was applied on the paper disc

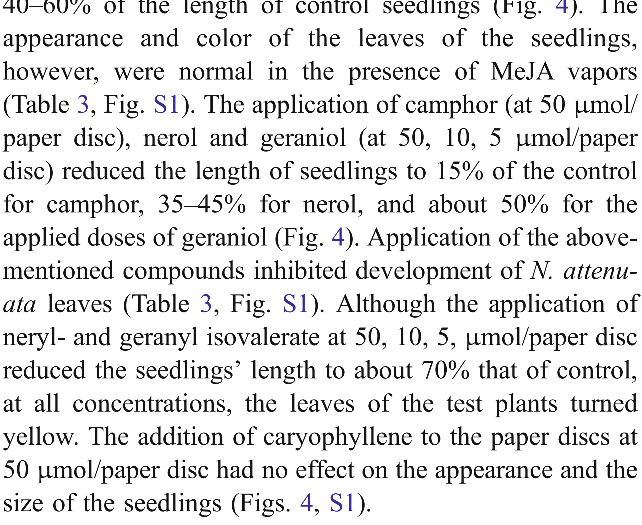
N. attenuata germinated, seeds were transferred to fresh agar in one compartment of a two-chambered Petri dish; in the other, the selected volatiles were applied to paper discs and their effects on the seedlings were evaluated by measuring the seedlings' length on day10 after the beginning of tests (Figs. 4, S1). MeJA in all doses applied at 50, 10, 5, and 1 µmol to the paper discs reduced the seedlings' length to



40–60% of the length of control seedlings (Fig. 4). The appearance and color of the leaves of the seedlings, however, were normal in the presence of MeJA vapors (Table 3, Fig. S1). The application of camphor (at 50 µmol/paper disc), nerol and geraniol (at 50, 10, 5 µmol/paper disc) reduced the length of seedlings to 15% of the control for camphor, 35–45% for nerol, and about 50% for the applied doses of geraniol (Fig. 4). Application of the above-mentioned compounds inhibited development of *N. attenuata* leaves (Table 3, Fig. S1). Although the application of neryl- and geranyl isovalerate at 50, 10, 5, µmol/paper disc reduced the seedlings' length to about 70% that of control, at all concentrations, the leaves of the test plants turned yellow. The addition of caryophyllene to the paper discs at 50 µmol/paper disc had no effect on the appearance and the size of the seedlings (Figs. 4, S1).

Discussion

The release of metabolites into the environment is the first requirement for a compound to play a role as an allelochemical (Inderjit and Nilsen, 2003). Therefore, volatilization from aerial parts was considered as one of the modes of release of allelochemicals into the media in addition to the exudation of water-soluble metabolites from the roots (Inderjit and Duke, 2003). Direct volatilization from roots has not been well studied.

Here, we demonstrated that the *A. tridentata* roots release volatiles deep into the rhizosphere and showed that some of the roots' volatiles have phytotoxic effects on seed germination and seedling growth of the co-occuring plant, *N. attenuata*. The different volatiles detected in the shoots and roots, and the fact that the emitted compounds are found in the root extracts, demonstrated that the compounds detected in the rhizosphere originate from the roots and not transferred from aerial parts of the plant. As dry soil can better adsorb toxic volatile terpenes than moist soil (Muller

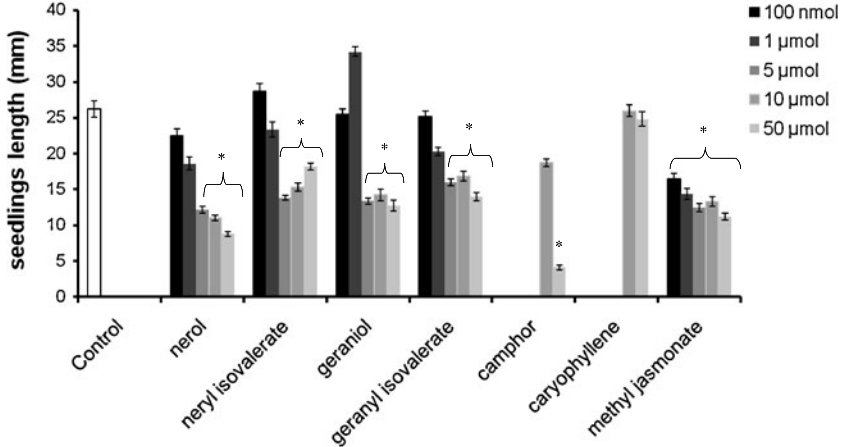


Fig. 4 Growth inhibition potential expressed as means±*SE* of the seedlings length of the germinated seeds in the presence of the volatile compounds identified in the headspace of roots of *Artemisia tridentata* on *Nicotiana attenuata* seedlings in five different replicates (each replicate contained 12–13 seedlings) of the post-germination bioassay after 10 d. * significantly different from control seedlings; $P<0.05$

Table 3 The appearance of the leaves and shoots (L&S) of *Nicotiana attenuata* seedlings after six days of exposure to root volatiles applied to paper discs on plant agar media in the post-germination tests (Figs. S1, 4)

Compound	L&S (50 μmol/PD)	L&S (10 μmol/disc)	L&S (5 μmol/disc)	L&S (1 μmol/disc)	L&S (0.1 μmol/disc)
Nerol	ND[a]	ND	Yellow	Yellow	Normal[b]
Neryl isovalerate	Yellow	Yellow	Yellow	Yellow	Normal
Geraniol	ND	ND	ND	ND	Normal
Geranyl isovalerate	Yellow	Yellow	Yellow	Yellow	Normal
Camphor	ND	Normal	–	–	–
Caryophyllene	Normal	Normal	–	–	–
Methyl jasmonate	Normal-small[c]	Normal-small	Normal-small	Normal-small	Normal-small

[a] leaves did not develop, [b] the leaves were green as they were observed in the control, [c] the leaves were green but the seedlings were smaller than those of the control

and del Moral, 1966), this form of release may be particularly effective in making soils phytotoxic to competitors. The phytotoxicity of soils exposed to the volatile terpenoids of the leaves of *Salvia leucophylla* was sustained up to four months (Muller and del Moral, 1966).

Previously, several methods have been used to detect allelochemicals in soils, mostly based on the extraction of chemicals from the soil (Inderjit and Nilsen, 2003; Lin et al., 2007; Ens and French, 2008; Ens et al., 2009b; Mohney et al., 2009), but by using organic or inorganic solvents, the non-volatile metabolites and those which do not originate from roots or those which are transformed by soil microbes, may also be extracted. Here, with the assistance of headspace solvent microextraction (HSME) and solid phase microextraction (SPME), we confirmed that live roots introduce phytotoxic substances into the soil; these may last for a long time or may be microbially transformed and subsequently inhibit the germination or the growth of competing plants.

Quantification of allelochemicals in the soil is one of the main tasks in the allelopathic studies (Inderjit and Nilsen, 2003). To accomplish this, we used dynamic HS-GC-MS analyses; the calculated total emitted substances per day from a single plant's roots were used to load the test compounds onto paper disc in the germination bioassays with the seeds of *N. attenuata* on agar. Lin and his coworkers (2007) recently used a similar apparatus to quantify the volatiles from the roots of different *Pinus* species. The two methods of dynamic headspace extraction differed in the shape of apparatus and the mode of adsorption-desorption of the volatiles. Both methods, however, disturb the roots by removing the adjacent soil and, therefore, the roots may release different types of volatiles when wounded (Inderjit and Nilsen, 2003). In our experiment, we extracted the headspace of the plants' roots as quickly as possible to avoid this problem. Analyzing the roots' volatiles by both HSME- and SPME-GC-MS allowed us to address a disadvantage of the HSME method namely that the solvent peak in the GC chromatogram overlaps with a relatively broad area of the chromatogram and, therefore, some compounds may be missed.

Our results demonstrate that the roots of *A. tridentata* release a rich source of different secondary metabolites (Tables 1 and 2). Depending on the method of extraction, age of the plants, and the media used for the culturing, different kinds and quantities of volatile substances were identified in the roots' headspace (Tables 1, 2). Some of the volatiles identified in the shoots of *A. tridentata,* such as camphor, 1,8-cineol, α-pinene, and nerol, are phytotoxic (Asplund, 1968; Romagni et al., 2000; Kordali et al., 2007). Among these, the phytotoxicity of the monoterpene alcohols is higher than that of the ketones, and the monoterpene hydrocarbons are the least toxic (Asplund, 1968; Kordali et al., 2007). These previous results are consistent with our finding that the monoterpene alcohols nerol and geraniol are more active than their isovalerate esters, and even more active than the monoterpenes with a ketone functionality, namely camphor and α-thujone. The monoterpene and sesquiterpene hydrocarbons, camphene and caryophyllene, were inactive on *N. attenuata* seedlings and seeds at all concentrations tested. The higher toxicity of the oxygenated-monoterpenes compared to their hydrocarbon derivatives purportedly is due to the higher solubility of oxygenated-monoterpenes in the media (Weidenhamer et al., 1993; Kordali et al., 2007). However, as we have shown here in the paper disc-agar bioassay, the vapor of the hydrocarbon- and oxygenated-monoterpenes can be transferred to the seedlings of the test plants on agar, but the oxygenated monoterpenoids have a greater phytotoxic effect on the seedlings than do the hydrocarbon terpenoids. Thus, we conclude that the phytotoxicity of the monoterpenes is likely due to their chemical structures rather than to their water solubility.

In summary, this research suggests that big sagebrush uses below-ground volatile terpenoids as phytotoxic substances against competing plants including *N. attenuata* in

addition to its well-studied shoot-derived volatiles. Because the conditions under which plants are grown are different in the field and in the glasshouse, and because the natural soil contains microorganisms that are absent in the agar or are different from those in the potting soil that we used in our experiments, additional bioassays and analytical studies will be required to demonstrate conclusively the allelochemical potential of the compounds emitted from the roots and shoots of field-grown plants.

SPME-GC-MS analyses showed that the plant's roots emitted types of volatiles different from those released by the shoots. For absolute quantification, it is necessary to perform the experiments under standard analytical conditions (Romeo, 2009). In addition, new germination and growth bioassays that use the field soils, and that quantify the potential allelochemicals in the soil and rhizosphere surrounding the sage brush are essential to confirm allelopathy originating from root volatiles.

Acknowledgments We thank Alexander von Humboldt foundation and Max Planck Society for research grants for ARJ and SZ, the glasshouse team for growing the plants and Emily Wheeler for editorial assistance of the paper.
