## Note

# Determination of partition coefficients by liquid chromatography 

ROBERT M. CARLSON, ROBERT E. CARLSON and HERBERT L. KOPPERMAN<br>Department of Chemistry, University of Minnesota, Duluth, Minn. 55812 (U.S.A.)

(First received August 22nd, 1974; revised manuscript received November 4th, 1974)

The availability of a rapid and accurate technique for the determination of partition coefficients (or their equivalent) became desirable when it was observed that the partition coefficient between $n$-octanol and water ( $P_{0 / w}$ ) was dominant in the successful Hansch correlation of phenol toxicity to aquatic species ${ }^{1}$. This concern has led to the development of a method using a permanently bonded long-chain alkyl packing in a high-pressure liquid chromatographic system and subsequently relating the capacity factor $k^{\prime}\left[k^{\prime}=\left(t_{R}-t_{0}\right) / t_{0}\right.$, i.e. the net retention time relative to the nonadsorbed time] to the partition coefficient $P_{\mathrm{o} / \mathrm{w}}$.

## EXPERIMENTAL

The separations were performed on $2 \frac{1}{8} \mathrm{in} . \times 2 \mathrm{ft}$. Bondapak C-18/Porasil B columns that were mounted in a Waters Associates Model ALC 201 with refractive index detector. The various mole percentages of distilled water and acetone (MCBACS grade) were eluted at $24-26^{\circ}$ and a fow-rate of $0.9-1.0 \mathrm{ml} / \mathrm{min}$.

## DISCUSSION

It is well recognized that a separation (i.e., a difference in retention volume) in reversed-phase chromatography depends upon the partitioning characteristics of the solute between the mobile phase and the stationary phase as represented by the value of the partition coefficient. In the development of the overall approach for evaluating the elution data in the current study, it was therefore necessary to consider the relative number of moles of eluting solvent. However, the use of mole per cents resulted in a significant increase in the deviation from linearity from that previously observed in the analysis of thin-layer partition data ${ }^{2}$ when $R_{M}\left\{R_{M}=\log \left[1 /\left(R_{F}-1\right)\right]\right\}$ was plotted $v s$. volume per cent.

For example, Figs. 1 and 2 contain plots of $\log k^{\prime} v s$. volume per cent ${ }^{*}$ (sigma $Y=0.012$ ) and $\log k^{\prime} v s$. mole per cent (sigma $Y^{\prime}=0.035$ ), respectively, for a representative compound ( $o$-chlorophenol). It was subsequently found that the linearity could be maintained and substantially extended for all the compounds studied by

[^0]

Fig. 1. Plot of $\log k^{\prime} v$. volume per cent of water.

Fig. 2. Plots of $\log \left[1 /\left(k^{\prime}+1\right)\right]$ and $k^{\prime} v s$. mole per cent of water.
plotting $\log \left[1 /\left(k^{\prime}+1\right)\right]$ vs. mole per cent (e.g., o-chlorophenol, Fig. 2, sigma $Y=$ 0.009 ). Such a linear correlation is observed for all compounds studied (Table I). This change is valid as both the correlations of $R_{M}$ and $k^{\prime}$ are made over a range of percentages and the modification is therefore only from one empirical relationship to another.

The correlations of $\log k^{\prime}$ to $\log P$ and $\pi\left(\pi=\log P_{\text {substituted }}-\log P_{\text {parent }}\right)$ to $\kappa\left(\kappa=\log k^{\prime}\right.$ substtuted $-\log k^{\prime}$ purent $)$ for some phenols and anilines are contained, along with their corresponding residuals, in Table II. The coefficients obtained from the individual regression analyses are found to be quite satisfactory. However, when the results from the two families of compounds are combined, the correlation of log $P$ to $\log k^{\prime}$ decreases $(r=0.86)$.

Phenols: $\log P=A \log k^{\prime}+C ; r=0.96 ; \pi=\kappa+C ; r=0.96$.
Anilines: $\log P=A \log k^{\prime}+C ; r=0.97 ; \pi=\kappa+C ; r=0.97$.

* Mole per cent water.
** $\log \left[1 /\left(k^{\prime}+1\right)\right]=M X+B$.

Although this is still an acceptable value for a regression analysis of this type, it, not unexpectedly, indicates that $P$ and/or $k^{\prime}$ reflect more than just lipophilic character.

Related to these observations is the work of Collander ${ }^{4.5}$, which has shown that although any two alcohol-water systems will provide a linear relationship be-

* Toxicity to Daphnia magna.
tween $\log P$ values, it is not possible to extend the correlation over a wide range of solvent types (alcohols, esters, ketones, halogenated hydrocarbons). The successful correlation in the present study therefore indicates that either there is a good approximation of the solvent forces in Bondapak C-18/acetone-water to those of alcoholwater systems or that the chemical potential of either the lipophilic ( $\mu_{t}$ ) or hydrophilic ( $\mu_{h}$ ) components of the solute remains constant ${ }^{6,7}$.

$$
\log P=\frac{m \Delta \mu_{1}+j \Delta \mu_{n}}{2.3 R T}
$$

In addition, although neither the $n$-octanol-water system nor the Bondapak C-18/ acetone-water chromatographic system can be construed to be structurally representative of a biological membrane, the somewhat comparable results upon substitution of $\kappa$ for $\pi$ in a Hansch-type biological correlation ${ }^{8-11}$ (determined for the nine phe-
nols listed in Table III) indicate the predictive powers of $k^{\prime}$ and $P$ in evaluating the ability of an organic molecule to pass through biological tissue ${ }^{12}$.
$\log (1 / c)=\pi ; r=0.76$
$\log (1 / c)=\kappa ; r=0.68$

## ACKNOWLEDGEMENTS

We wish to acknowledge support of this research by the Environmental Protection Agency (EPA R800675) and to express our appreciation to Professor D. K. Harriss for his assistance in developing the multiple regression analysis program.
