Structure of L-cystinediamide dihydrochloride. By M.O. CHANEY AND L.K. STEINRAUF, Biochemistry Department, Indiana University School of Medicine, Indianapolis, Indiana, U.S.A.

(Received 1 May 1968)

The crystal and molecular structure of L-cystinediamide dihydrochloride has been determined by threedimensional X-ray crystallography using Cu radiation. The unit cell is orthorhombic with a=17.37, b=7.50, C=5.16 Å and contains two molecules. The space group is $P2_12_12$.

The structure determination of L-cystinediamide dihydrochloride, $[SCH_2CH(NH_2.HCl)CONH_2]_2$, was undertaken to provide information concerning the observed anomalously high optical rotatory dispersion of this compound (Stapleton & Swan, 1962) and of cystine compounds in general. Equally important, studies of cystine structures could lead to information about the conformation and helical sense of the disulfide group in proteins under different environmental conditions.

Crystals of L-cystinediamide dihydrochloride (CDA) were obtained from Drs Ian Stapleton and Marvin Carmack (Indiana University, Bloomington). The crystals were, unfortunately, poorly formed and decomposed quickly. An irregularly shaped fragment with approximate dimensions $0.03 \times 0.03 \times 0.01$ cm³ was sealed inside a thin-walled glass capillary tube and three-dimensional data around the *c* axis (l=0-3) were collected with Ni-filtered Cu Ka radiation to obtain reflections with spacings greater than 1 Å. A total of 378 non-zero independent reflections were measured using a Supper-Pace Autodiffractometer. The unit-cell dimensions were obtained from Weissenberg photographs with calibration lines from aluminum powder super-imposed:

a = 17.37 (0.02) Å b = 7.50 (0.02) c = 5.16 (0.02) $g_{calc} = 1.541 \text{ g.cm}^{-3}$ $g_{obs} = 1.524 \text{ g.cm}^{-3} \text{ (flotation method)}$ Mol. wt. 311.3 Space group: $P2_12_12$ (h00 and 0k0 absent for h or k = 2n+1). In the above mentioned space group, with two molecules in the unit cell, each molecule must possess a twofold symmetry axis. All previously determined cystine compounds which are able to possess a twofold axis have been found to do so. From the three-dimensional Patterson synthesis the positions of the chlorine atoms were easily obtained. A three-dimensional electron density map based only on the chlorine atoms gave the positions of all other atoms. The positions and temperature factors were refined by the block-diagonal least-squares method to an R index of 0.130 with the sulfur and chlorine atoms anisotropic and the other atoms isotropic. The structure was then refined further by the Busing & Levy full-matrix least-squares program modified for mixed temperature factors.

Reflections were ordered on magnitude of F_o and grouped into blocks of 40 reflections each. The average F_o and $\Sigma(F_o - F_c)^2$ were found for each block. Weights w were then assigned so that $\Sigma w(F_o - F_c)^2$ would have the same value for each block. The final R index was 0.124, and the weighted R index, 0.144. The shifts in the final least-squares cycle were within 8% of its estimated standard deviations. The final positional and thermal parameters are listed in Table 1. The final bond lengths and angles with standard deviations are shown in Fig.1. The conformation is shown by the stereoscopic drawing in Fig.2 produced by Johnson's thermal ellipsoid plot program (Johnson, 1965).

All bond lengths and angles, except the S-C(1) bond and the S-C(1)-C(2) bond angle, were very close to those re-

ported for other L-cystine compounds. The S–C(1) bond length of 1.76 (0.02) Å is approximately 0.08 Å shorter when compared with that of L-cystine dihydrochloride (Steinrauf, Peterson & Jensen, 1958), L-cystine dihydrobromide (Peterson, Steinrauf & Jensen, 1960), and N,Ndiglycyl-L-cystine (Yakel & Hughes, 1954), and 0.04 Å shorter when compared with hexagonal L-cystine (Oughton & Harrison, 1957). This unusually short S–C(1) bond length may be the result of absorption errors and series termination errors due to the limited number of levels which could be collected.

After the refinement was completed it was recognized that the structure was isomorphous with L-cystine dihydrobromide which in turn is very similar to L-cystine dihydrochloride. It is quite interesting and rather unusual to replace the OH group with an NH₂ group and not alter appreciably the molecular packing. It appears that there may be slight differences in the coordinates of either the halide ion or the OH(NH₂) group, since the NH₂ group in CDA forms two hydrogen bonds with halide ions while the OH group in the cystine hydrohalide forms only one hydrogen bond. This isomorphism of the cystine hydrohalide compounds and, in general, the amino acid hydrohalides may suggest that the packing of these molecules in crystals is largely controlled by their backbone conformation and to a smaller extent by their hydrogen bonding interactions. Of those compounds of L-cystine determined thus far, CDA, L-cystine dihydrobromide, L-cystine dihydrochloride, and N, N-diglycyl-L-cystine are all of one conformation and are characterized as having a left-handed helical sense. The conformation of hexagonal L-cystine is different, but related by rotations about the C(1')-S', S'-S, and S-C(1)bonds and characterized as having a right-handed helical sense.

The molecules of CDA are held together by a network of hydrogen bonds. The amino groups are charged and have chloride ions arranged in a rough tetrahedral manner about them. Although the N(1)-Cl distances, listed in Table 2, are slightly longer than the corresponding hydrogen bond distances reported for L-cystine dihydrochloride, they are still within hydrogen bonding distance. The neighboring oxygen atom, O(II), directly faces the amino nitrogen and does not participate in hydrogen bonding. The amide nitrogen, N(2), appears to form hydrogen bonds with two chloride ions. The N(2)-Cl(III) bond distance of 3.39 Å is slightly long and probably represents a weak hydrogen bond. The chloride ion, Cl(IV), lies very close to the plane of the amide group C(3), N(2), and O. The deviations of Cl(III) and Cl(IV) from the amide plane are 1.39 Å and -0.003 Å, respectively.

The C(1')-S'-S-C(1) dihedral angle for CDA is 81.4° , which compares quite well with the values 80.2° and 81.3°

Table 2. Intermolecular contacts less than 4.0 Å. Roman numerals indicate the relation of atom 2 to atom 1 at position x, y, z.

calculated for L-cystine dihydrochloride and L-cystine dihydrobromide, respectively; it is significantly different from the observed angle of 74° for hexagonal L-cystine. The interplanar distance between the almost parallel glycine-like groups for CDA is approximately 6.3 Å.

The equation of the mean plane through the atoms C(2), O, C(3) and N(2) is 0.9507X + 0.1510Y + 0.2709Z + 6.402 =0. The maximum deviation from the mean plane for the above atoms is 0.03 Å. The amino nitrogen, N(1), which was not used in the mean plane calculation, deviates by 0.32 Å.

The final observed and calculated structure factors are given in Table 3.

A note on the structure of MoZn_{~22}.* By STEN SAMSON, Arthur Amos Noyes Laboratory of Chemical Physics, California Institute of Technology, Pasadena, California 91109, U.S.A.

(Received 16 July 1968)

The powder data of Toussaint & Venker on the basis of which they assigned an orthorhombic structure to $MoZn_{-22}$ are explained better by assuming a f.c.c. structure with $a_0 = 18.41$ Å.

In a recent paper Toussaint & Venker (1968) reported to have found a new type of intermetallic compound of approximate composition MoZn₂₂. They show a list of powder data, in which each reflection is indexed satisfactorily on the assumption that the structure is orthorhombic with $a_0 =$ 6.510, $b_0 = 10.633$, $c_0 = 9.205$ Å.

This author found that each of the published powder data can be explained by assuming a face-centered cubic lattice with $a_0 = 18.41$ Å. The relationship between the edge lengths of the orthorhombic cell and the length of the cube edge is $6.510 \times 2 \times 1/2 = 10.633 \times 1/3 = 9.205 \times 2 = 18.41$ and the corresponding relationship between the indices is $h'^2 + k'^2 + 1'^2 = 8h^2 + 3k^2 + 4l^2$, where the primed indices refer to the cubic and the unprimed to the orthorhombic lattice.

The advantages of indexing the observed powder lines on the basis of a cubic lattice with one parameter rather than a tetragonal lattice with two parameters ($a_0 = 6.510 \times$ 1/2, $c_0 = 10.633$ Å), an orthorhombic lattice with three parameters, or a triclinic lattice seem obvious: (1) The chances that the metric relationship between the cell edges of the noncubic lattice would be so exact as to preclude splitting of lines seem very small, especially since the observed lines seem to be very well defined as is indicated by the extremely good fit between observed and calculated sin² θ values. (2) Within the range of observation (sin² $\theta_{max} = 0.4810$), there

* Contribution number 3723 from the Arthur Amos Noyes Laboratory.

are 129 possible powder lines for the orthorhombic case, of which 42 would not be indexable on the basis of the facecentered cubic lattice. None of these 42 lines is observed. There are 93 possible powder lines for the cubic case, but only six of these (none present) are capable of ruling out the orthorhombic case.

It is interesting to note that in the cubic case, the strongest peak $(I/I_1 = 100)$ corresponds to the 066 and 228 reflections. A characteristic feature of a series of other face-centered cubic structures having cell edges of lengths of the order of 18 or 19 Å, for example, Cd₋₆Ni and Sn₋₄Cu (Samson, unpublished), is the very high intensity of the 066 reflection.

The intermetallic compounds so far known to have the stoichiometry 1:22 are $ZrZn_{22}$ (Samson, 1961), ReBe₂₂ (Sands, Johnson, Zalkin, Krikorian & Kromholtz, 1962), and probably MoBe₂₂ and WBe₂₂ (Paine & Carrabine, 1960). These are face-centered cubic but have cell edges of lengths of the order of 13 or 14 Å. It thus appears that MoZn_{~22} represents a new type of cubic AB₂₂ structure.
