(Received 11 December 1967 and in revised form 28 April 1968)

A crystalline substance that was assumed on chemical grounds to be 5-hydroxy-6-methoxy-8-nitroquinoline is shown by a three-dimensional X-ray analysis to consist predominantly of 6-methoxy-8nitro-5(1*H*)-quinolone (I), although the presence in small concentrations of the 5-hydroxy and acinitro tautomers could not be ruled out. The crystals are orthorhombic and the space group is $Pca2_1$. The unit-cell dimensions are $a=18.647\pm0.006$, $b=6.363\pm0.003$ and $c=7.730\pm0.003$ Å. V=917 Å³, Z=4and $D_m=1.62$ g.cm⁻³. The conventional R value based on 829 structure factors is 0.051. The structure contains a bifurcated hydrogen bond wherein the hydrogen atom attached to the quinoline nitrogen is hydrogen bonded intermolecularly to the oxo group and intramolecularly to one of the nitro oxygen atoms. An extraordinarily short C-N distance, 1.404 Å, is observed between C(8) of the quinoline ring and the nitro group, which deviates by only 7° from coplanarity with the ring. Dielectric and tangent loss measurements on powder samples indicated that conversion of (I) to a tautomeric form, through a proton transfer induced by the applied electric field, is not evident within the range of frequencies from 50 to 10^{10} Hz.

Introduction

The difference in color between the brick red crystals of the compound which Elderfield (1946) designated as 5-hydroxy-6-methoxy-8-nitroquinoline (II) and the nearly colorless crystals of 5-acetoxy-6-methoxy-8-nitroauinoline seemed irreconcilable with the similarity in the structural formulas proposed for these molecules. This apparent anomaly led us to speculate that a greater diverseness exists in their molecular structures than merely the substitution of an acetoxy by a hydroxy group. In order to compare the stereochemical details of these molecules, the crystal structures of both compounds were determined. The results of the analysis of the acetoxy compound have been reported previously (Sax & Desiderato, 1967). The crystal structure of the unesterified compound is considered in this paper. The unusual solubility of the red compound cast further doubt upon the validity of assuming structural formula (II) for this compound. For instance, although it is insoluble in most of the usual solvents at room temperature, it dissolves easily in 18N sulfuric acid to yield a pale yellow solution from which red crystals are grown by careful dilution with water. This reaction suggests that the red form is either the cross conjugated tautomer (I) or the acinitro compound (III), which transforms into the enolic form on dissolving in sulfuric acid. Our analysis shows that the molecules in the red crystals are predominantly (I), although the tautomeric forms (II) and (III) may be present also in lower concentrations. Dielectric constant measurements were made on the red crystals to see if interconversion of the tautomers could be induced by an applied electric field.

Experimental

X-ray diffraction

Single crystals of 6-methoxy-8-nitro-5(1*H*)-quinolone (I), $C_{10}H_{18}O_4N_2$, were prepared for us by Dr S. M. Sax. The compound crystallizes in the orthorhombic system. From the systematic absences, 0kl with *l* odd and *h0l* with *h* odd, the possible space groups are *Pcam* and *Pca2*₁. The latter space group was chosen to avoid a disordered model as would have been required in *Pcam*. The unit-cell dimensions and their estimated standard deviations were obtained from 2θ measurements of axial reflections that were made on a Picker full-circle diffractometer using Cu $K\alpha$ radiation $(\lambda\alpha = 1.5418, \alpha_1 = 1.5405, \alpha_2 = 1.5443$ Å). They are as follows $a = 18.647 \pm 0.006$. $b = 6.363 \pm 0.003$, $c = 7.730 \pm$

0.003 Å. Z=4. $D_m = 1.62$ g.cm⁻³ by the flotation method. $D_x = 1.595$ g.cm⁻³. M.W. 220.164. V = 917 Å³.

Both diffractometer and photographic data were collected using Cu $K\alpha$ radiation. Eight hundred twenty five independent reflections were measured in the sin θ range 0.083 through 0.899 on a Picker full-circle automated diffractometer. The crystallographic c axis was set to coincide with the φ axis. An additional six levels of photographic data were collected on multifilm equiinclination Wiessenberg photographs from a crystal rotated about the c axis. These intensities were measured visually by comparison with a calibrated film strip. They were scaled to the diffractometer data by a least-squares method after reduction to structure factor magnitudes. The photographic data used in the analysis were limited to 113 reflections that fell in the sin θ range 0.833 to 0.989 and were not measured on the diffractometer. Spot shape corrections (Phillips, 1956) were applied to the Weissenberg data. No corrections were made for absorption or extinction.

Structure determination and refinement

It was clearly evident from inspecting a three-dimensional E^2 -Patterson synthesis that the fused ring must be tilted relative to the *ab* plane. If *Pcam* were assumed as the space group, then with four molecules in the unit cell, this feature of the molecular packing would require disordering of the atoms across a mirror plane, since this is the point symmetry of the only special position in Pcam that is consistent with the observed systematic absences. Accordingly $Pca2_1$ was chosen for the structure determination. Although the interpretation by inspection of the Patterson function was complicated by the presence of a dominant hexagonal subcell, the structure was found straightforwardly by Patterson superposition methods (Buerger, 1959) which have been programmed for the IBM 1620 computer (Corfield, 1965). Initially the location in the unit cell of a hexagonal moiety of the fused ring was obtained from a '6-atom Symmetry Minimum Function' (Corfield & Rosenstein, 1966). Then a 24-atom multiple minimum function based upon the six-membered ring and its symmetry equivalents yielded twelve of the sixteen nonhydrogen atoms. The remaining four atoms were located in a three-dimensional difference Fourier synthesis phased on these twelve atoms and containing 183 terms with $|F_c| \ge |F_o|$. At this stage of the analysis, the conventional R index, calculated with a single overall temperature factor, was 0.34 for the diffractometer data.

The structure was refined by full matrix least-squares (Busing, Martin & Levy, 1962) using only the diffractometer data initially. The z coordinate of N(1) was fixed during the entire refinement, and the quantity minimized was $\Sigma w(F_o - KF_c)^2$. The weighting scheme was that of Hughes (1941) with $4F_{\min}$ equal to 8. Several very weak reflections and some that appeared to be affected significantly by systematic error were given zero weight. Then the photographic and diffractometer

data were combined, and two variable scale factors were introduced, one for each kind of data. After two more cycles of refinement, the R index was 0.096. At this point, seven of the eight hydrogen atoms were located unequivocally in a difference Fourier synthesis with peak heights ranging from 0.44 to 0.65 e.Å⁻³ for the hydrogen atoms on the ring and from 0.40 to $0.44 \text{ e.}\text{Å}^{-3}$ for those on the methoxy group. One background peak height equaled 0.47 e.Å⁻³ but the remainder of the background did not exceed $0.32 \text{ e.}\text{Å}^{-3}$. Positive regions at potential positions for the eighth hydrogen ranging from 0.36 to 0.470 e.Å⁻³ appeared near N(1), O(16) and O(13), corresponding to tautomers (1), (11), and (111) respectively. During six additional cycles of refinement the atomic coordinates of the seven hydrogen atoms were treated as variable parameters but they were arbitrarily assigned the anisotropic thermal factors of the atoms to which they were bonded. Although the R index was now at 0.064, all of the positive peaks at the various possible positions for the hydrogen atom in question persisted in the difference Fourier synthesis. These seemed plausible on the basis of the stereochemical details of the structural moieties that contained the H atom in question as the following data show: N(1)-H(1) 0.89, O(13)-H(13) 0.91, O(16)-H(16) 0.97 Å; C(2)-N(1)-H(1) 117, N(11)-O(13)-H(13) 119, C(5)-O(16)-H(16) 128° ; H(1)... O(13) 1.99, $H(1) \cdots O(16)$ 2.05, $H(13) \cdots N(1)$ 1.88, $H(13) \cdots O(16) 2 \cdot 28, H(16) \cdots O(13) 2 \cdot 10, H(16) \cdots N(1)$ 2.68 and 2.99 Å, where the latter two distances are to N(1) atoms related by the *c*-glide; H(1)-N(1)···O(13) 38, $H(1)-N(1)\cdots O(16)$ 29, $H(13)-O(13)\cdots N(1)$ 30, $H(13)-O(13)\cdots O(16)$ 35, $H(16)-O(16)\cdots N(1)$ 74 and 68, and H(16)–O(16)··· O(13) 23°.

Coordinates consistent with the structural formula (I) [*i.e.* N(1)-H] were then assigned on the basis of three observations. Firstly, the C(5)-O(16) and N(11)-O(13) bond lengths of 1.25 and 1.27 Å differ significantly from 1.35 and 1.33 Å which would be expected if protonation had occurred respectively at either O(16) or O(13). Secondly, the valency angle at N(1) is 123.8° , as compared with 116.2° in the unprotonated quinoline ring (Sax & Desiderato, 1967). Finally, 0.9 of the integrated electron count in the possible peaks for the hydrogen atom coincided with an N(1)-H bond even though the peak heights at the reasonable sites near N(1) and O(13) were both equal to $0.43 \text{ e.}\text{\AA}^{-3}$ while the one near O(16) was 0.31 e.Å-3. The refinement was terminated after three cycles had been run with a modification of the Hughes scheme, where $\sigma = C|F|$, if $|F| > 4_{\min}$, and $\sigma = C4F_{\min}$, if $|F| \le 4F_{\min}$. $4F_{\min}$ was set equal to 8 and C was a step function in sin θ that was derived from a plot of the range of $\omega \Delta^2$ as a function of sin θ . It was assigned the values 0.153, 0.072, 0.111 and 0.125 in sin θ ranges 0.0-0.2, 0.2-0.8, 0.8-0.9, and 0.9-1.0 respectively. The R factor for 788 reflections of non-zero weight is 0.051 and for all of the 829 reflections it is 0.062. The corresponding weighted R factors are 0.066 and 0.070 respectively.

Table 1. Observed and calculated structure factors of 6-methoxy-8-nitro-5(1H)-quinolone

In each group of reflections with the same k and l indices, the columns are, from left to right, the h index, $10|F_o|$, $10|F_c|$, $10A_c$ and $10B_c$. Following $10|F_o|$, a plus sign indicates that the intensity was collected photographically, while an asterisk denotes that the reflection was given zero weight in the least-squares refinement.

The standard deviation of an observation of unit weight $\{\Sigma w[F_o - KF_c]^2/(NO - NP)\}^{\ddagger}$, where NO is the number of observations and NP is the number of varied parameters, is 0.776. The observed and calculated structure factors appear in Table 1. The atomic coordinates, their thermal parameters and the estimated standard deviations are given in Tables 2 and 3. The key to atomic numbering is given in Fig. 1. The atomic form factors used in the refinement are taken from International Tables for X-ray Crystallography (1962).

Discussion

The molecular and crystal structure

Since positive peaks, estimated to be $1-2\sigma$ in the electron density, appear in the final difference synthesis

at positions near O(13) and O(16) consistent with (II) and (III) respectively, it is uncertain whether the molecule exists in tautomeric forms or in a single configuration of the atoms. The results in Table 4 would be regarded as weighted averages of parameters in the tautomers, whereas in a single configuration of atoms they could be analyzed in terms of resonance structures. In either case, the cross conjugated structure (I) makes the largest contribution to the observed molecular parameters, although the aromatic (II) and acinitro (III) structures are significant too, as is evident from the bond lengths in the keto and nitro groups. The C(8)-N(11) bond is considerably shorter than commonly observed in nitro groups (Williams, 1967) and the orientation of this group is favorable for π bonding between C(8) and N(11) as it deviates by only 7.0° from copla-

narity with the ring. This conformation and the negative charge on the nitro oxygen atoms is stabilized further by the internal hydrogen bond between N(1) and O(13). In 5-acetoxy-6-methoxy-8-nitroquinoline, on the other hand, the aromatic form contributes 91 percent to the resonance structure while the cross conjugated and quinoidal forms are negligible contributors, so that there is little π bonding between the ring and any of the substituents.

The shape and conformation of the molecule and the molecular packing are shown in Figs. 1 and 2. The ten atoms of the fused ring are within 0.015 Å of the least-squares plane, 0.01202X-0.48307Y-0.87549Z = -0.05052, where the coordinates are expressed in Å units and are referred to the crystallographic axes. However, the probability that the small displacements from the ring are non-random is ≥ 0.99 since the χ^2 value is 20. The respective displacements of atoms N(11), O(12), O(13), O(14), C(15) and O(16) from the plane are 0.059, 0.266, 0.028, -0.088, 0.081 and -0.030 Å. The method of Scho-

maker, Waser, Marsh & Bergman (1959) was used for the least-squares plane calculation. The plane of the fused ring system intersects the *ab* plane in a 28.9° angle, and fused rings in molecules related by the c-glide lie in planes that deviate 1.4° from parallel. The intermolecular contacts between c-glide related molecules are the normal van der Waals variety. In the bifurcated hydrogen bond shown in Fig.1, H(1) is shared by an intramolecular hydrogen bond between N(1) and O(13) and by a strong intermolecular hydrogen bond linking N(1) to O(16) in a molecule related by the c-glide and a unit translation -b. With the exception of two somewhat close intermolecular contacts involving H(2), which are listed in Table 5 together with the hydrogen bond parameters, the non-bonded contacts were the normally expected ones.

The dielectric constant

The two maxima at positions for the hydrogen atoms in (II) and (III) were 0.14 and 0.12 e.Å⁻³ respectively

Table 5. Some intermolecular distances and angles

Atoms*	Distance	Angle
$N(1) \cdots O(16)$	2·779 (5) Å	
$N(1) \cdots O(13)$	2.620 (5)	
$O(13) \cdots O(16)$	2.963 (5)

$H(2)-C(2)\cdots O(16)$		41 (4)

* H(1), N(1) and O(13) are in the same molecule but O(14) and O(16) are in the molecule related by the *c*-glide and the translation (0, b, 0).

in the final difference map compared with an average background peak of 0.12 e.Å⁻³, so that they are possibly errors in the electron density. On the other hand, Cady & Larson (1965) interpreted similar peaks in the difference map of 1,3,5-triamine-2,4,5-trinitrotoluene as N-H bonding electrons delocalized in the H...O region of the N-H...O hydrogen bond. They repre-

sented the bonding by resonance structures $N-H \circ O$

and N H-O. The same explanation could apply here i.e. that these two residual peaks are N-H bonding electrons delocalized in the region near O(16) and O(13). Since the crystal structure analysis of (I) indicated an orientation of the polar hydrogen atom, which is attached to nitrogen, facing the keto-oxygen and one of the strongly polar oxygens of the nitro group (Fig. 1), it was conjectured whether this hydrogen might be labile enough to be transferred by an electric field to an adjacent oxygen atom. This would be expected to result in a high polarizability and dielectric constant, and if the proton were transferred intermolecularly an abnormally high dielectric loss should also occur since the crystal would be rendered conductive by the proton transfer. The dielectric constant and loss tangent of this compound were determined over a range of frequencies from 60 Hz to 1010 Hz to find evidence for the proton transfer polarization, if it occurs.

The dielectric measurements on the crystalline powder were made by compacting the powder into a measurable volume in some tests, and in others by vacuum impregnating the powder with a pure paraffin wax. Measurements on these specimens were made over a wide frequency range, up to 10^5 Hz with a General Radio 716 bridge and from 10^6 Hz to 5×10^7 Hz with the susceptance variation method resonant circuit technique. Several measurements were made with a resonant cavity at 2×10^8 Hz A single measurement was made at 9.5×10^9 Hz in a shorted wave guide. In this latter case, a paraffin impregnated powder was formed into a rectangular parallelopiped. The apparent density of the dry powder specimens varied, depending on the compression, between 0.77 and 0.95. From these values and the crystal density, 1.595, the volume fraction of the powder during measurement could be computed, and it ranged in different tests between 0.48 and 0.59.

The experimentally obtained dielectric constants were, of course, lower than that of the crystal because part of the volume measured was air or paraffin. The formula developed by Böttcher (1945) and confirmed by van Vessem & Bijvoet (1948) gave consistent and reasonable values of the solid crystal dielectric constant. These values ranged from 2.24 to 3.19 for the specimen and yielded calculated values for the crystal of 4.37 to 4.47, with one value out of this range at 4.05. These values were calculated from three different apparent density specimens, and one wax-filled specimen. The Böttcher equation (rearranged) is:

$$K_1 = \frac{2(K - K_2) + 2K_2\delta}{3K\delta - (K - K_2)} K,$$

where K_1 is the dielectric constant of the solid, K_2 of the suspending medium and K of the mixture, and δ is the volume fraction of solid.

The dielectric constant values for these crystals are at a level which is typical of compounds of a similar nature, where no proton transfer is suspected. For example, the dielectric constant of 2-methoxy-4-nitroaniline is 3.91 and of 2-methoxy-5-nitroanaline is 4.01, as reported by Rao (1965). The very small dispersion (decline) in dielectric constant between 60 and 10^{10} Hz indicates that no proton transfer or other very significant polarization process is limited within this frequency range. Very likely the polarization in the crystal is of an atomic (intramolecular polar vibration or rotation) process whose absorption and dispersion region lies in the infrared frequency range.

The resistivity of this material was shown to be very high and the loss tangent $(\tan \delta)$ was found to be quite low (0.0006 to 0.0018) over most of the frequency range. There was some evidence of a small (specimen tan $\delta_{max} < 0.006$) dispersion region in the vicinity 10⁷ to 10⁸ Hz but this was not delineated exactly. This low conductivity and low loss was consistent with the nearly constant level of dielectric constant over the wide frequency range studied. It certainly precluded any very significant continuous or discontinuous charge transfer through these crystals.

This research is supported by the U.S. Public Health Service, National Institutes of Health under Grant No. HE-09068 and in part under Grant No. AIO-3949. We wish to thank Dr R.D. Rosenstein for helping us with the application of the IBM 1620 minimum function programs in the solution of the structure.
