The Crystal Structure of Ammonium Tris(pentasulfido)platinum(IV) Dihydrate

BY PHILIP E. JONES* AND LEWIS KATZ

Department of Chemistry and Institute of Material Science, University of Connecticut, Storrs, Connecticut, U.S.A.

(Received 14 May 1968)

Ammonium tris(pentasulfido)platinum(IV) dihydrate, $(NH_4)_2Pt(S_5)_3.2H_2O$, crystallizes in space group Cc with unit-cell dimensions a=15.67, b=9.925, c=12.94 Å, $\beta=92.74^{\circ}$ and Z=4. The final structure parameters were based on 2450 observed reflections collected by counter methods. The structure was refined by least-squares methods to a conventional R index of 5.2%. The anion consists of three bidentate five-membered sulfur chains octahedrally coordinated to a central platinum atom so as to form, with platinum, three six-membered rings in chair configurations. The ammonium ions and water molecules alternate in a chain through the structure. The range of Pt-S distances is 2.365 ± 0.007 to 2.428 ± 0.008 Å.

Introduction

Ammonium tris(pentasulfido)platinum(IV) dihydrate was first prepared by Hofmann & Höchtlen (1903). They suggested that the compound contained three pentasulfide ligands but offered no suggestions about the coordination to platinum. A structure suggestion given by R. A. Krause of this department was that there were three *cis* bidentate S_5 ligands octahedrally coordinated to the platinum ion. Since compounds for which pure sulfur ligands coordinated to metal ions have been suggested are rare,† it was decided to undertake the structure determination.

Experimental

 $(NH_4)_2Pt(S_5)_3.2H_2O$ was prepared according to the procedure of Hofmann & Höchtlen (1903) by R.A. Krause of this department. The red crystals formed in this preparation were found invariably to be twinned. Single crystals, which were in the form of triangular plates, were cut from these crystals and were used for intensity measurements.

After the structure of the anion was solved with preliminary film data, a set of intensity data was collected on a manually operated General Electric single crystal orienter with Zr-filtered Mo radiation, pulse height selection, and a scintillation counter. The reciprocal lattice nets were collected for which $h=0, \pm 1, \pm 2, \pm 3; k=0, -1, -2; l=0, \pm 1, \pm 2, \pm 3, \pm 4$ and for which 2θ was less than or equal to 50 degrees. A total of 2578 reflections were collected of which 128 were unobserved (no peak was observed on the recorder using the highest available sensitivity). The data were corrected for Lorentz-polarization effects and were also corrected for absorption by the procedure described by Wuensch & Prewitt (1965) with the use of Prewitt's program ACACA (1965). The crystal used for this part of the work was a triangular plate of dimensions $0.143 \times 0.143 \times 0.215$ mm and 0.072 mm thick.

Crystal data

The crystals were examined by precession and Weissenberg methods which indicated Laue symmetry of 2/m with systematic absences occurring only in the general *hkl* reflections for h+k=2n+1 and in the *h0l* reflections for l=2n+1. The probable space group was thus either C2/c or Cc.

The cell dimensions were determined from measurements taken on an accurately aligned single crystal orienter using Zr-filtered Mo radiation. They are: $a=15.674\pm0.004$, $b=9.925\pm0.005$, $c=12.937\pm0.007$ Å, and $\beta=92.74+0.05^{\circ}$.

The density was measured by the flotation method with a mixture of bromoform $(d=2.890 \text{ g.cm}^{-3})$ and 1,1,2,2-tetrachloroethane $(d=1.600 \text{ g.cm}^{-3})$. The observed density was $2.44 \pm 0.02 \text{ g.cm}^{-3}$ while the calculated densities, based on four molecules per unit cell and one or two water molecules per formula unit are 2.42 g.cm^{-3} and 2.47 g.cm^{-3} respectively. The compound was analyzed in duplicate for nitrogen, sulfur and platinum. The results are:

	%N	%S	%Pt	Number of H ₂ O

[†] An S₅ bidentate ligand coordinated to titanium has recently been reported for $(C_5H_5)_2TiS_5$ by Köpf, Block & Schmidt (1968). Their conclusion was based on nuclear magnetic resonance evidence.

Höchtlen (1903) both fit well with two water molecules per formula unit, *i.e.* $(NH_4)_2PtS_{15}$. $2H_2O$.

Structure determination

The structure determination, until the final refinement stages, was carried out with photographic data. The preliminary investigation of this compound indicated the space group to be either C2/c, which is centrosymmetric, or Cc, which is non-centrosymmetric. The platinum atom must be placed in a special fourfold position if C2/c is chosen. This position was assumed to be $(0,0,0; \frac{1}{2},\frac{1}{2},0)+0, y,\frac{1}{4}; 0, \bar{y},\frac{3}{4}$ since the other special fourfold positions require both that additional reflections be weak (since Pt would make no contribution), which was not observed, and that the anion be centrosymmetric, which was not considered likely. This position would serve just as well in Cc with x=0and $z=\frac{1}{4}$ arbitrarily chosen for Pt to fix the origin.

A y parameter of 0.20 for the Pt was determined from a Patterson line synthesis along $[0, y, \frac{1}{2}]$. This positional parameter as well as scale and overall temperature factors were refined by the method of leastsquares using Busing, Martin & Levy's ORFLS program (1962). The y value converged to 0.2102 while the unweighted reliability factor, $R = \Sigma(||F_0| - |F_c||)/\Sigma |F_o|$, was 32.5%. This position is, of course, also compatible with the general fourfold position of space group *Cc*.

An electron density map was calculated using the observed amplitudes with phases calculated from the platinum atoms alone. Since the platinum arrangement is centrosymmetric, the resulting map was centrosymmetric. If the structure were also centrosymmetric, it should have been visible from this map. However, there were over thirty important peaks in one fourth of the cell volume, instead of the fifteen or so expected in the centrosymmetric case, which indicated that the structure belonged to space group Cc and was noncentrosymmetric.

From the initial Fourier result it was clear that we were faced with the familiar problem of a structure superimposed on its center related structure. The problem of sorting out the correct structure was accomplished (not without false attempts) by adding small groups of sulfur atoms, beginning with an assumed octahedral environment around Pt, and taking advantage of some enhancement effects as correctly placed atoms were added in the calculations. Each correct addition of a sulfur atom reduced R by about 1%. The prediction that the anion contained three five-membered sulfur rings coordinated to a central platinum ion, made by Professor Krause before we began the investigation, proved to be correct. (Hofmann & Höchtlen (1903) also suggested three five-membered sulfur groups, but, of course, they did not suggest a coordination scheme.) After least-squares refinement of individual layer scale factors, positional parameters, and individual atom isotropic temperature factors, the unweighted and weighted R indices were 18.7% and 20.6%.

The structure was refined further by the use of anisotropic temperature factors in the form

$$\exp[-(\beta_{11}h^2 + \beta_{22}k^2 + \beta_{33}l^2 + 2\beta_{12}hk + 2\beta_{13}hl + 2\beta_{23}kl)].$$

The refinement was carried out in stages using blocks of parameters until all parameters converged. The unweighted and weighted R indices were 13.3 and 16.4% at this stage.

A difference electron density map was then calculated in an attempt to locate the ammonium ions and water molecules. Only three peaks were found that seemed to be possible sites for H_2O and NH_4^+ , although four sites were needed for the two H_2O and the two NH_4^+ .

At this point in the refinement the bond length and angle ranges, average values and estimated standard deviations were: Pt-S, $2 \cdot 28 - 2 \cdot 54$, $2 \cdot 43$, $0 \cdot 03$ Å; S-S, $1 \cdot 98 - 2 \cdot 15$, $2 \cdot 05$, $0 \cdot 05$ Å; S-S-S, $97 \cdot 8 - 116 \cdot 1$, $104 \cdot 8$, 5° ; Pt-S-S, $103 \cdot 0 - 113 \cdot 0$, $109 \cdot 4$, $2 \cdot 5^{\circ}$; S-Pt-S, $90 \cdot 5 - 96 \cdot 4$, $92 \cdot 8$, $2 \cdot 5^{\circ}$ (Jones & Katz, 1967).

Refinement

The refinement of the anion and the placing of the ammonium ions and water molecules was determined by data collected on the single crystal orienter. In the initial stages of the refinement, Friedel-related structure factors were averaged. When R dropped to 8.6% with only the platinum and sulfur atoms included, a difference electron density map was calculated in order to locate the ammonium ions and water molecules. Six positive regions were found which were more than 2.2 Å away from the platinum and sulfur atoms. Two of the positions, which were within 2.5 Å of sulfur atoms, when refined isotropically as ammonium ions, resulted in temperature factors greater than 50. The other four positions, which were in fact the highest positive regions found, were also refined as ammonium ions. The unweighted and weighted R indices dropped to 7.3 and 8.8%, and the isotropic temperature factors all remained below 10.

The structure was then refined using all 2450 observed reflections (*i.e.* without averaging Friedel related pairs). The unweighted and weighted R indices were 8.4 and 10.2%. The refinement was continued with anomalous dispersion corrections, both real and imaginary parts, for platinum and sulfur. The weighted and unweighted R indices increased to 10.5 and 12.5%, which indicated that the correct structure was related by a center of symmetry to the one refined. Refinement of this center related structure resulted in final isotropic unweighted and weighted R indices of 7.3 and 9.2%.

As it was not possible to determine definitely which of the four peaks found were ammonium ions and which were water molecules, the scattering factor curves of the ammonium ion and oxygen (used for water) were simply averaged. The following Hughes-type weighting scheme, based on the assumption that intensities of intermediate magnitude should be weighted more than weak or strong intensities, was introduced: $|w| = |F_o|/130$ for $|F_o| \le$ 130; |w| = 1 for $130 < |F_o| < 260$; $|w| = 260/|F_o|$ for $|F_o| \ge 260$. After refinement the weighted R was 7.7% while the unweighted R was unchanged. The structure was then refined using aniosotropic temperature factors by full-matrix least-squares analysis until the final

parameter shifts were less than one-tenth the standard errors. The resulting unweighted and weighted R indices were 5.2 and 6.2%, and the standard deviation for an observation of unit weight was 1.45. The final positional parameters, anisotropic temperature factors, and observed and calculated structure factor amplitudes are listed in Tables 1, 2 and 3.

Computations for the initial part of the structure determination were carried out on an IBM-7040 computer. The refinement of the structure was carried out on an IBM360–65 computer. The scattering factor curves of S⁰ and O⁰ (used for water) were taken from *International Tables for X-ray Crystallography* (1962), while the Pt⁴⁺ curve was from Thomas & Umeda (1957) The ammonium scattering factor curve was that of Davis & Whitaker (1966), while anomalous dispersion values were those of Cromer (1965).

Discussion

Geometry of the anion

A stereoscopic illustration of the Pt $(S_5)_3^{2-}$ anion was drawn with the use of Johnson's program *ORTEP* (1965) and is shown in Fig. 1. The bond distances, angles, and their standard errors were calculated by the *ORFFE* program of Busing, Martin, & Levy (1964) and are listed in Table 4.

The platinum ion is octahedrally coordinated by six sulfur atoms at an average distance of 2.39 Å, which is approximately equal to the sum of their ionic radii*.

* Goldschmidt (1929) lists an atomic radius of 1.74 Å for S²⁻, and Ahrens (1952) gives the atomic radius of Pt⁴⁺ as 0.65 Å.

Table 2. Final thermal parameters and their standard deviations* of (NH₄)₂Pt(S₅)₃.2H₂O Anisotropic parameters are times 10⁴; isotropic parameters are times 10².

* Standard errors, as calculated by ORFFE, are given in parentheses.

The S-Pt-S bond angles differ significantly from the  $90^{\circ}$  expected for symmetrical octahedral coordination.

Bidentate five-member sulfur ligands in a *cis* configuration coordinate the platinum atom forming, with the platinum atom, six-membered rings in the chair configuration. The average S-S bond distance is 2.049 Å, and the individual bond distances agree with this value to within three times their standard errors. The average values of the angles between the 'head rest' (platinum at top) and 'seat' and 'foot rest' and 'seat' of the chairs are 69.4 and 56.3 respectively. The individual values are listed in Table 5. The S-S-S bond angles range from 100.7 to 109.8°, while the dihedral angles, listed in Table 6, range from 72.3 to 82.5°. These results all seem to indicate that the three rings are not completely equivalent.

Fig.2. Stereoscopic illustration of the unit cell and contents.

The structure of the orthorhombic form of sulfur has been refined by Abrahams (1955). If three contiguous sulfur atoms are removed from the eight-membered ring found in orthorhombic sulfur, the *cis* conformation of the pentasulfide ion results. The S–S bond lengths reported by Abrahams range from 2.031 to 2.043 Å. The S–S–S bond angles range from 98.3 to 100.6°. The bond distances agree quite well with the values we report, but the bond angle range is narrower than ours, which may be an indication of strain in the sulfur rings of the  $Pt(S_5)_3^{2-}$ anion.

The structure of  $BaS_4$ .  $H_2O$ , a compound with a  $S_4^2$  group, has also been reported by Abrahams (1954). The S-S bond distances and S-S-S bond angles are 2.02, 2.03, 2.07 Å and 104.1 and 104.9°, and the dihedral angles are 74.1 and 77.2°. These values are similar to those observed in the  $S_5^2$ -ligand.

#### Determination of the water and ammonium ions

As previously discussed, four peaks which could be attributed to the two water molecules and two ammonium ions were located on a difference electron density map. Since the total number of electrons is ten for  $NH_4^+$  as well as for  $H_2O$ , distinguishing  $NH_4^+$  from  $H_2O$  is not always easy. In this case we did not succeed in making the distinction.

The four positions located formed a chain through holes in the anion packing. We must assume that  $H_2O$ and  $NH_{4}^{+}$  alternate in this chain, since it is not reasonable to assume that two  $NH_4^+$  ions would be next to each other. Both charge repulsion and the difficulty of establishing hydrogen bonding argue against a scheme in which  $NH_4^+$  and  $H_2O$  do not alternate. Not only does alternation maintain a coordination number of four for N, it permits the same coordination number for O and in addition makes possible a continuous chain of NH⁺ to H₂O hydrogen bonds. The distances found between adjacent peaks are 2.78, 2.83, 2.85, and 2.93 Å, which agree well with observed values for hydrogen bond lengths. Fuller (1959) has listed the range for hydrogen bonds of the type  $R-NH_3^+\cdots OH_2$  as 2.68 to 2.96 Å. Battelle & Trueblood (1965), for example, reported in  $(NH_4)_2SO_3$ .  $H_2O$  a  $NH_4^+ \cdots OH_2$  hydrogen bond length of 2.82 Å. Assuming alternation of  $NH_{4}^{+}$  and  $H_{2}O$ then, if one could identify definitely even one of the peaks as an ammonium ion or as a water molecule. a complete assignment could be made. However, we were unable to make any definite assignment, since neither peak heights nor isotropic temperature factors alternated. A consideration of the environment of the groups did not provide us with the necessary clues either; all have reasonably close approaches to sulfur atoms and would, as ammonium ions, be reasonably well placed to balance the anion charges. This final assignment was therefore not made, and, to that extent, the structure determination is incomplete.

## Effect of refinement on parameters

Some bond distances and angles changed considerably during the course of the refinement. At different stages anomalous dispersion corrections were introduced and then anisotropic thermal parameters. Allowing for vibration anisotropy had a much greater effect on the position parameters than correcting for anomalous dispersion.

Cruickshank & McDonald (1967) have discussed the the errors in position and thermal parameters caused by neglect of the imaginary part of the dispersion correction, or even worse, the inclusion of  $\Delta f''$  but for the inverse of the true structure. In class m (b axis unique) which is a polar class and the class to which  $(NH_4)_2$ PtS₁₅. 2H₂O belongs, there could be errors in x or in z if the measurements were for h or l of one sign only. However, we measured the hemisphere with kof one sign only, so that both signs for h and l were measured. (Indeed, since there is a true mirror, not Friedel symmetry, the other hemisphere is also produced.) Thus there should be no first-order errors in xor z from an uncorrected least-squares calculation, or even the  $\Delta f''$  correction were of the wrong sign. Of course, the thermal parameters should be too large and the observed and calculated structure factor agreement should be poorer if the anomalous dispersion corrections were omitted or included incorrectly. These conclusions are generally borne out by the data of Table 7 (no anomalous dispersion corrections), Table 8 (anomalous dispersion accounted for incorrectly), and Table 9 (anomalous dispersion accounted for correctly). The corresponding R indices, as indicated earlier, change dramatically: 8.4, 10.5, and 7.3%.

It can be seen by comparing Table 1 with Table 9 that some positional parameters changed considerably during anisotropic refinement. The effects on bond distances and angles are pronounced: some bond dis-

tances changed by almost 0.1 Å and some bond angles changed by as much as  $0.8^{\circ}$ . One would, of course, not be surprised by any great changes in parameters if there were high correlation among parameters; however, no such correlation was observed.

Using Hamilton's (1965) significance test, we tested the hypothesis that all atoms vibrate isotropically. The *R* factor ratio is 1.48, the dimension of the hypothesis is 80, and the number of degrees of freedom for the refinement is 2345. From Hamilton's table we find  $\Re_{80,2345,0.005} = 1.04$ . Since 1.04 is less than the *R* factor ratio of 1.48, the hypothesis that all atoms vibrate isotropically can be rejected at the 0.5% significance level, *i.e.* we are quite sure that there is anisotropic motion.

#### Packing of the unit cell

A stereoscopic illustration of the unit cell and its contents was drawn using Johnson's (1965) *ORTEP* program and is shown in Fig. 2. The origin is in the lower left corner, and the right handed coordinate system has the z axis vertical, the x axis horizontal, and the y axis pointing away from the viewer.

The large circles in the drawing indicate the positions of the water molecules and the ammonium ions. These units are seen to form chains weaving around the anions in the z direction. This is particularly noticeable around the best resolved ring in the Figure.

The authors are grateful for financial assistance for this work provided by the National Science Foundation through grant GP-5934 and to the National Aeronautics and Space Administration for a predoctoral fellowship (to P.E.J.). Computations were carried out in Computer Center of the University of Connecticut, which is supported in part by grant GP-1819 of the National Science Foundation.

#### (Received 13 May 1968)

Crystals of the 2:1 complex between antimony trichloride and naphthalene are monoclinic, a=9.154, b=9.368, c=11.989 Å,  $\beta=122^{\circ}40'$ , space group  $P2_1/c$ . The structure consists of SbCl₃ molecules stacked in the *bc* plane alternating with layers of naphthalene molecules in the plane  $x=\frac{1}{2}$ . The antimony atoms exist in a 4-coordinate, distorted  $sp^{3}d$  trigonal bipyramidal environment, with two chlorine atoms occupying equatorial positions, 2.347 and 2.348 Å away while the third equatorial position is filled by the antimony lone electron pair. The third chlorine atom occupies one axial position 2.367 Å from antimony, while the other axial position is utilized in bonding to the  $\pi$ -system of the naphthalene molecule. The distances from the antimony atom to the plane of the ring is 3.2 Å. The structure has been refined using anisotropic full-matrix least-squares refinement, the final *R* index being 0.091 for all 2566 reflexions used, and 0.072 for the 2034 observed terms only.

#### Introduction

Complexes between antimony trichloride and aromatic hydrocarbons have been known for many years. In the earliest work (Smith & Davies, 1882), the complex between antimony trichloride and naphthalene was reported, and incorrectly analysed as a 3:2 adduct. Menshutkin (1911, 1912a, b), who studied the eutectic diagrams of antimony trihalides with a large number of organic compounds, defined the composition of these intermolecular compounds as maxima in the phase diagrams. He showed that a series of complexes of antimony trihalides with aromatic hydrocarbons or substituted hydrocarbons could be made, and that the most common ratios for these were 1:1, 2:1 or 4:1. He found that the melting point of the antimony trichloride-naphthalene 2:1 adduct (85°) was higher than that of antimony trichloride (73°) or of naphthalene (80°). To determine the nature of the bonding forces between the constituents, an extensive study of antimony trihalide-aromatic hydrocarbon complexes was undertaken. Preliminary reports on some of these compounds have already been published (Szymański, 1963; Hulme, 1966; Cushen, Hulme & Szymański, in press). A knowledge of the structure of these compounds is important in view of the known catalytic properties of antimony trichloride in Friedel–Crafts reactions (Olah, 1963), and the possible relation of these structures to the reaction intermediates. We here report a more detailed account of the 2:1 adduct between antimony trichloride and naphthalene, whose structure was previously solved in projection and described elsewhere (Szymański, 1963).

#### Experimental

Antimony trichloride and naphthalene in 2:1 molar ratio were dissolved in hot  $60-80^{\circ}$  petroleum spirit The solution on cooling deposited a mass of fine crystals, which were then left to stand in the mother liquor for several weeks in a sealed flask. From the mass a number of excellently formed acicular crystals grew. The forms exhibited were {011}, {100}, and less prominently {110}. Chemical analysis, and quantitative estimation of the naphthalene ultraviolet absorption
