complete on the sub-units and a set complete on the gaps, both sets vanishing on the sub-unit boundaries. Clearly the original set of functions can give non-zero densities on the sub-unit boundaries. In one dimension, where the boundaries are points, this distinction is not important. In two- and three-dimensions where the boundaries become respectively closed curves and surfaces, the effect is significant and means that the observed gradient of the ( $m, N$ ) plots for two- and threedimensional examples is always less than $(2 U / V)$.

Most of the material described in this paper is taken from a Ph.D. thesis submitted to Cambridge Univer-
sity. The author is grateful to Dr D. M. Blow for helpful discussions during the preparation of this manuscript. The work was undertaken while the author was holder of a Medical Research Council Scholarship.

# The Crystal Structure of Tris(cyclopentadienyl)samarium (III).* 

By Chi-hsiang Wong, Tseng-yu Lee and Yuen-tseh Lee $\dagger$<br>Institute of Physics, National Tsing Hua University, Hsinchu, Taiwan, China

(Received 5 February 1969 and in revised form 28 April 1969)
The crystal structure of tris(cyclopentadienyl)samarium (III), $\mathrm{Sm}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)_{3}$, has been determined by analysis of three-dimensional X-ray diffraction data. The crystals are orthorhombic, space group Pbcm, with eight chemical formula units per unit cell. Cell dimensions are: $a=14 \cdot 23, b=17.40$ and $c=9.73 \AA$. The heavy atom positions were deduced from Patterson projections, and cyclopentadienyl rings were found from difference syntheses. The final $R$ value for the 1266 observed reflexions is $12.5 \%$. The eight $\mathrm{Sm}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)_{3}$ in the unit cell are divided into two symmetrically independent, and structurally different groups ( $A$ and $B$ ). The $A$ and $B$ groups form close-packed infinite chains along the $c$ axis and the $A$ and $B$ chains alternate in layers parallel to (100) with an average spacing of $\frac{1}{2} a$. In either group, the samarium atom could be described as having a distorted tetrahedral environment and approximately three pairs of electrons are responsible for the bonding between the metal atom and the cyclopentadienyl rings. Both types of structures are disordered, and a plausible mechanism for the disorder is discussed.

## Introduction

This paper deals with the crystal structure determination of tris(cyclopentadienyl) samarium(III), $\mathrm{Sm}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)_{3}$. The present work is the second of a series on the study of metal-cyclopentadienyls (Wong, Yen, \& Lee, 1965), and $\mathrm{Sm}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)_{3}$ is the first rare earth tris(cyclopentadienyl) complex ever to be studied.

This compound has been reported as having a pure electrostatic type of bonding (Birmingham \& Wilkinson, 1956). However, in view of the much darker colour of the compound in its crystalline state (orange red) as compared with the samarium ion (light yellow), and the low sublimation temperature ( $\sim 160^{\circ} \mathrm{C}$ in vacuum), we suspect that the bonding may be somewhat covalent. Also, there exists almost no structural information concerning bonding between rare earth metal

[^0]and organo-carbon atoms. For the above reasons, we feel that careful structural study of this compound is of interest.

## Experimental

The air and moisture sensitive compound was synthesized in this laboratory according to Birmingham \& Wilkinson (1956). The single crystals used were grown by sublimation at $\sim 160^{\circ} \mathrm{C}$ under reduced pressure in thin-walled Pyrex capillaries. Laue photographs showed it to be of mmm symmetry; zero-layer Weissenberg photographs taken along the three principal axes, with Mo $K \alpha$ radiation, showed the following systematic absences: $h 00$ for $h$ odd, $0 k l$ for $k$ odd and $h 0 l$ for $l$ odd, which would make the space groups Pbcm or $P b c 2_{1}$ most probable. However, in either case the extinction condition $h 00$ for $h$ odd had to be considered as incidental. The centrosymmetric space group Pbcm was tentatively chosen, and it was later shown to be correct. For data collection, the equi-inclination, mul-tiple-film Weissenberg technique was used with Zr -filtered Mo $K \alpha$ radiation. Copper foils were inserted be-

Table 1. The final parameters and their estimated standard deviations
The samarium parameters have been multiplied by a factor of $10^{5}$, and those of carbon by $10^{3}$. The isotropic temperature factor $B=10$ has been assigned to $A$ III and $B$ III. The quoted e.s.d.'s for $A \mathrm{I}, A \mathrm{II}, B \mathrm{I}$, and $B \mathrm{II}$ are obtained from conditioned least squares as described in the text. The anisotropic temperature factor is in the form

| $T=\exp \left[-\left(h^{2} B_{11}+k^{2} B_{22}+l^{2} B_{33}+h k B_{12}\right)\right]$. |  |  |  |  |  |  |  |  |

tween films to yield a film factor of $3 \cdot 6$. Intensity data were collected for the layers $0-12$ around $\mathbf{b}$, and for the layers $0-3$ around $\mathbf{c}$. Altogether 1741 independent reflexions were recorded, out of which 475 were unobserved. Intensities were estimated visually with the aid of a standard strip prepared with the same crystal. Lp corrections were made and the two sets of data were then put on a common scale. The agreement for about $480 F_{o}$ 's that had appeared on both sets was about $9 \%$. Crystals selected for intensity collection were those having maximum dimensions less than 0.2 $\mathrm{mm}(\mu R \sim 1 \cdot 0)$. Because of the irregular shape of the crystals, no absorption corrections were attempted. Corrections for anomalous dispersion were insignificant (Dauben \& Templeton, 1955) and were not applied. The density determined by the flotation method was $1.93 \mathrm{~g} . \mathrm{cm}^{-3}$ in fair agreement with the calculated value of $1.914 \mathrm{~g} . \mathrm{cm}^{-3}$ based on eight chemical formula units per unit cell. The cell dimensions $a$ and $c$ were determined from an $h 0 l$ Weissenberg photograph (Mo $K \alpha, \lambda=0.7107 \AA$ ) superposed with a diffraction pattern of gold ( $a=4.0702 \AA$ ) taken with $\mathrm{Cu} K \alpha$ radiation ( $\lambda=1 \cdot 5418 \AA$ ) and $b$ was determined from $b$ axis
oscillation photographs (Mo $K \alpha$ ), superposed with a diffraction pattern of $\mathrm{NaCl}(a=5 \cdot 6291 \AA)$. The results are: $a=14 \cdot 23 \pm 0 \cdot 02, b=17 \cdot 40 \pm 0 \cdot 01$, and $c=9 \cdot 73 \pm$ $0.02 \AA$.

## Nomenclature

In order to describe this structure more conveniently, a set of symbols are introduced:
$\operatorname{Sm}(A)$ and $\operatorname{Sm}(B) \quad \operatorname{Sm}$ in the $A \& B$ structures respectively,
$A \mathrm{I}, B \mathrm{I} \quad$ Cyclopentadienyl rings as defined in Fig. 1,
(AI) (BI)
$M(19,20)$
$C(18,21,22)$
Centres of respective cyclopentadienyl rings,
Midpoint of the bond $\mathrm{C}(19)-\mathrm{C}(20)$,
Centre of the triangle $\mathrm{C}(18), \mathrm{C}(21)$ and $\mathrm{C}(22)$.

## Determination and refinement of the structure

The Sm positions were deduced from Patterson projections along $\mathbf{b}$ and $\mathbf{c}$. The Sm atoms appeared to lie on the mirror-planes, and were separated into two sym-

Table 2. Observed and calculated structure factors*
The five columns in each group represent $h, k, l, \underline{4}\left|F_{o}\right|$ and $\frac{1}{4} F_{c}$. Minus signs before $\left\{\left|F_{c}\right|\right.$ indicate unobserved reflexions. Low order reflexions which were cut off by the camera were not included in the Table.

metry-independent sets ( $0, \frac{1}{8}, \frac{3}{4}$ ) for $A$, and $\left(\frac{1}{2}, \frac{5}{12}, \frac{3}{4}\right)$ for $B$. A structure factor calculation with all the Mo data gave an $R$ value of about $50 \%$. Comparing carefully the calculated and observed structure factors, we discovered that for all the reflexions with $h+k / 2$ even (about 800, and most of these were strong) reasonably good agreement was obtained ( $R \sim 20 \%$ ), whereas for the rest of them (all weak) the calculated values were much too weak as compared with the observed values. Four cycles of least-squares calculations with unit weights on the positional and isotropic thermal parameters of Sm for all the $h+\frac{1}{2} k$ even reflexions improved $R$ to about $14 \%$. However, the resulting temperature factor for $\operatorname{Sm}(A)$ was only one half of that for $\operatorname{Sm}(B)$. An $F_{o}-F_{\mathrm{Sm}}$ synthesis calculated with only the $h+\frac{1}{2} k$ even terms revealed cyclopentadienyl rings $A \mathrm{I}, A \mathrm{II}, B \mathrm{I}$ and $B \mathrm{II}$ (see Fig. 1 for identification). Spurious peaks up to 10 e. $\mathrm{A}^{-3}$ were found on and around the positions where rings $A$ III and BIII were expected to lie. Further calculations including the four rings improved but little the agreement for the reflexions with $h+\frac{1}{2} k$ even, and almost no improvement was achieved for the remaining reflexions. At this stage a thorough re-examination of the whole situation was made. The structure factors were shown to have the following three characteristic features. If we let $F_{A}$ and $F_{B}$ represent the contribution to the structure factors
from set $A$ and set $B$ respectively, then we have:
(1) for $h+\frac{1}{2} k$ even, $F=F_{A}+F_{B}$, (2) for $h+\frac{1}{2} k$ odd, $F=F_{A}-F_{B}$, and (3) for $k$ odd $F$ is the difference between the contributions of the structure factors from the two subcells, $b=0$ to $b=\frac{1}{2}$, and $b=\frac{1}{2}$ to $b=1$. In order that the reflexions of class (2) are non-zero, either there should be defects in $A$ or $B$, or $A$ and $B$ should be of two different atomic arrangements. Density measurement ruled out the first possibility, and we had to explore the second. To fit (3), a slight deviation from the structure deduced from the Patterson syntheses for $\operatorname{Sm}(A)(x=0)$ and $\operatorname{Sm}(B)\left(x=\frac{1}{2}\right)$ must be considered.

Full-matrix least-squares refinement was carried out on positional and anisotropic thermal parameters of samarium atoms only, using all the observed data. Weights used were those suggested by Hughes (1941). Three cycles later the $R$ value for the complete data was $17 \%$. However, for a considerable number of low order reflexions the agreement was still poor, and also the average thermal parameter of $\operatorname{Sm}(B)$ was about five times greater than that of $\operatorname{Sm}(A)$.* A difference synthesis was calculated, and the results were still disappointing: only rings $A \mathrm{I}, A \mathrm{II}, B \mathrm{I}$ and $B \mathrm{II}$ could be

found as in the previous synthesis, and no sensible interpretation of $A$ III and BIII was possible. Nevertheless, in this map, $A \mathrm{I}-A \mathrm{II}$ as well as $B \mathrm{I}-B \mathrm{II}$ were shown to be related by a mirror plane, and the two pairs ( $A \mathrm{I}-A \mathrm{II}$ and $B \mathrm{I}-B \mathrm{II}$ ) differed slightly in their inclination angles with respect to (010), as well as in their distances from their respective metal atoms. The positions of the carbon atoms of $A \mathrm{I}, A \mathrm{II}, B \mathrm{I}$ and $B \mathrm{II}$ were deduced from the difference map based on the assumption that the rings are rigid pentagons with edge lengths of $1.41-1.42 \AA$. A structure factor calculation including the four rings ( $B=10 \cdot 0$ ) reduced the agreement index to $14 \%$. However, the agreement for a few low order reflexions, notably $022,102,062$ and 222 , was still very poor, and could only be improved if $A$ III and $B$ III were to have considerably different positions with respect to the metal atoms. At this stage, in order to reduce the anomalous peaks mentioned above, a correction for extinction was made. After a

Fig.3. Illustration of steps involved for the transition of $A$ III and BIII from one position to their respective mirror images, (100) projection. Dashed lines indicate the alternate positions for $A$ III and BIII that appeared on the difference map; solid lines are the positions $A$ III and BIII are assumed to have taken during the transition; solid circles for $\operatorname{Sm}(A)$, open circles for $\operatorname{Sm}(B)$.
rough estimation of the extinction coefficient from a plot of $I_{c} / I_{o}$ against $I_{c}$, this extinction coefficient was included as a variable for least-squares calculations. This correction improved $R$ to $13 \%$. Another $F_{o}-F_{\mathrm{Sm}}$ synthesis was then computed and the situation was greatly improved: not only could AIII and BIII (identification see Fig. 1) be interpreted from the map (see Fig. 2), but also the other rings were much sharper and better defined. Background fluctuations were about 1.5 e. $\AA^{-3}$, except at the sites of the Sm atoms, where holes of about six electrons still remained. A full-matrix least-squares refinement was made on the following parameters: positional and anisotropic thermal parameters of $\operatorname{Sm}(A)$ and $\operatorname{Sm}(B)$; positional and anisotropic thermal parameters of $A \mathrm{I}, A \mathrm{II}, B \mathrm{I}$ and $B \mathrm{II}$ (with the restrictions that each is a rigid pentagon with edge length $1.41-1.42 \AA$ and that $A \mathrm{I}-A \mathrm{II}$ and $B \mathrm{I}-B \mathrm{II}$ are mirror pairs, and also that their inclination angles with respect to ( 010 ) were fixed); positional and thermal parameters of $A$ III and $B$ III were not varied; isotropic temperature factors assigned for $A$ III and BIII were $B=10 \cdot 0$. Refinement was stopped after three cycles of such calculations which reduced $R$ to $12 \cdot 5 \%$. In the final cycle all the shifts were less than half their respective standard deviations, and the agreement for the above mentioned lower order reflexions was also satisfactorily improved. The resulting parameters are listed in Table 1, and the final set of structure factors in Table 2. The resulting positions of the carbon atoms are superposed on the final difference Fourier synthesis as shown in Fig. 2.

All the calculations were made on an IBM 1620 with programs written in this laboratory. Form factors used for Sm and C were those listed in International Tables for X-ray Crystallography (1962).

## Results and discussion

All relevant distances and angles are listed in Table 3. In our interpretation of the difference Fourier syntheses (Fig. 2) $A \mathrm{I}, A \mathrm{II}, B \mathrm{I}$ and $B \mathrm{II}$ are definite, but $A \mathrm{III}$ and BIII are not so definite because peaks representing a single carbon atom in $A$ III and $B$ III are only 3 e. $\AA^{-3}$ or less, which is only slightly higher than the background fluctuation. Nevertheless, we feel that this seems to be the most sensible interpretation we could suggest.

The quoted estimated standard deviations for carbon atoms (see Table 1) are indeed small for this type of structure containing heavy atoms. This is reasonable in view of the number of intrinsic conditions which have been incorporated into the least-squares calculations. In this way, a more detailed discussion of this structure becomes possible. The standard deviations for the inclination angles of rings were estimated directly from the final difference map.

A view along the [120] direction of the structure without disorder is shown in Fig. 1. In the $A$ structure the Sm atom has three rings at nearly equal distances
$[(2.49 \pm 0.03 \AA$ for $(A \mathrm{I})-\mathrm{Sm}(A)$ and $(A \mathrm{II})-\operatorname{Sm}(A)$, and $2 \cdot 55 \pm 0 \cdot 10 \AA$ for ( $A \mathrm{IIII}$ ) $-\operatorname{Sm}(A)] \pi$-bonded to it as in other sandwich compounds. $A \mathrm{I}$ and $A \mathrm{II}$ are mirror pairs, and $\angle(A \mathrm{I})-\operatorname{Sm}(A)-(A \mathrm{II})$ is $123 \cdot 5 \pm 4^{\circ}$. Ring $A$ III has been rotated downwards (or upwards), with the Sm atom as the pivot point, by about $30.8^{\circ}$ from the $(A \mathrm{I})-\operatorname{Sm}(A)-(A \mathrm{II})$ plane (also the mirror plane). In this way, there will be room for $\operatorname{Sm}(A)$ to be bonded to a fourth ring $A \mathrm{III}^{\prime \prime}$, which is itself ring $A$ III for the $\operatorname{Sm}(A)$ atom a half period away and related to the original $\operatorname{Sm}(A)$ by a $c$ glide plane normal to $\mathbf{b}$. The fourth bond $\left[\operatorname{Sm}(A)-M^{\prime \prime}(7,11)\right]$ is a long $\pi$-bond $(3 \cdot 06 \pm 0 \cdot 10 \AA)$. In this way all the type $A \operatorname{Sm}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)_{3}$ molecules are joined to one another to form infinite zigzag chains along the c direction, the long crosssection of the chain lying nearly on $x=0$.

As for the $B$ structure, the Sm atom has only two rings ( $B \mathrm{I}$ and $B \mathrm{II}$ ) sandwich-bonded to the metal in
the same way as in $A$, although their ring to $\operatorname{Sm}$ distances $(2 \cdot 55 \pm 0.03 \AA)$ and $\angle(B I)-\operatorname{Sm}(B)-B I I(120.5 \pm$ $4^{\circ}$ ) are not significantly ( 2 e.s.d.'s for distances, 1 e.s.d. for the angle) different from the $A$ structure values.
The most remarkable differences between these two types of structures are the positions of $A$ III and $B$ III on one hand and the temperature factors of $\operatorname{Sm}(A)$ and $\operatorname{Sm}(B)$ on the other. $B$ III, which has nearly the same inclination angle with respect to ( 001 ) as $A$ III, is as much as $0.6 \AA$ further away along the plane of the ring from the AIII position (see Fig. 1 and Fig. 3). In this way, all the $B$ type $\operatorname{Sm}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)_{3}$ molecules are joined up to form similar infinite chains as in the $A$ type. The second remarkable difference between the $A$ and $B$ structures is the observed temperature factor, that for $\operatorname{Sm}(B)$ being about four times greater than that for $\operatorname{Sm}(A)$. The best explanation that we can offer is that $\operatorname{Sm}(B)$ is disordered and therefore has several

Fig.4. Projection along c. All, III and III' have one half the weight. Large open circles represent carbon atoms, small solid circles are $\operatorname{Sm}$ on $\frac{1}{4}$, small open circles are Sm on $\frac{3}{4}$.
positions in the near vicinity of the mean position which it could occupy. This proposition conforms to some extent with the trend of $\operatorname{Sm}(A)-(A \mathrm{I})$ [or $(A \mathrm{II})$ ] to be slightly shorter than $\operatorname{Sm}(B)-(B \mathrm{I})$ [or $(B \mathrm{II})]$ and the angle $(A \mathrm{I})-\operatorname{Sm}(A)-(A \mathrm{II})$ to be a little greater than the angle $(B \mathrm{I})-\operatorname{Sm}(B)-(B \mathrm{II})$.* This situation is to some degree similar to our result on the crystal structure of $\mathrm{Be}\left(\mathrm{C}_{5} \mathrm{H}_{5}\right)_{2}$ at $-100^{\circ} \mathrm{C}$ (Wong, Chao, Chieh \& Lee, 1969) in which the Be is found to be able to occupy two alternative positions [not on the fivefold rotation axis, as suggested by the electron diffraction results (Almenningen, Bastiansen \& Haaland, 1964)].

A rough estimation on the basis of Pauling's single bond radii for $\operatorname{Sm}(1 \cdot 15 \AA)$ and for carbon ( $0.77 \AA$ ) (Pauling, 1960) and a Schomaker \& Stevenson (1941) correction indicates that approximately three pairs of electrons are reponsible for bonding between the metal atoms and cyclopentadienyl rings in both $A$ and $B$. There is about $37 \%$ partial ionic character in the $\mathrm{Sm}-\mathrm{C}$ bond, which suggests that the interaction between samarium and carbon is more covalent in character. This seems also to be closely related with the fact that the rings in this structure have a definite preferred orientation.

As for the disorder in the positions of $A$ III and $B$ III, it could be either static disorder, i.e. that there is equal probability that the crystal will grow along the $\mathbf{c}$ or along the - c direction, or dynamic disorder, i.e. that both $A$ III and $B$ III will not have to cross a very high potential barrier to obtain their respective mirror images. In Fig. 3, the junction structure (for static disorder) or the transition mechanism (for dynamic disorder) for $A$ III and $B$ III is illustrated in steps. In

[^2]the scheme proposed, a rough calculation shows that only small strains are involved in each step.

The temperature factor for $\operatorname{Sm}(A)$ is about 1.6 along b and $\mathbf{c}$, and about $1 \cdot 1$ along a. Temperature factors for $A \mathrm{I}, A \mathrm{II}, B \mathrm{I}$ and $B \mathrm{II}$ are of the same order within their respective estimated standard deviations. The component along the plane of the ring but normal to $\mathbf{c}$ ( $B=18$ ) is about twice as large as that normal to the plane of the ring $(B=9)$, whereas the component parallel to $\mathbf{c}$ is between the above two values $(B=12)$.

A projection of the structure along $\mathbf{c}$ is shown in Fig. 4 showing the close packing of the cross sections of the chains, and illustrating the slight difference between the two subcells mentioned above. All the interchain distances are normal van der Waals distances, from $3.55 \AA$ upwards.

The authors are grateful to Dr Li-chen Wang for assistance in preparing this compound, and to Mr Chueng-tan Chen for measuring the density.

[^1]:    * We tried the space group $P b c 2_{1}$, and placed the Sm atom initially slightly away from the mirror plane. However, this
    was shown to be incorrect.

[^2]:    * Neither $\operatorname{Sm}(A)$ nor $\operatorname{Sm}(B)$ is on the fivefold axes of $A \mathrm{I}$ (or $A \mathrm{II}$ ), and $B \mathrm{I}$ (or $B \mathrm{II}$ ) respectively. However, the deviations from the axes of $\operatorname{Sm}(B)$, ( 2 to 3 e.s.d.'s) are greater than that of $\operatorname{Sm}(A)(\sim 1$ e.s.d.). This feature is also consistent with the disorder of $\operatorname{Sm}(B)$.
