#### Abstract

C}_{48} \mathrm{H}_{40} \mathrm{O}_{4} \mathrm{Si}_{4}, M_{r}=793.21, \quad P 2_{1} / c, a=\) 21.918 (8), $b=10.138$ (6), $c=21.743$ (8) $\AA, \beta=$ $116.0(1)^{\circ}, V=4342.4 \AA^{3}, Z=4, \lambda($ Mo $K a)=$ $0.7107 \AA, d_{\text {calc }}=1.22 \mathrm{Mg} \mathrm{m}^{-3}, \mu=0.140 \mathrm{~mm}^{-1}$. The structure was determined by direct methods and refined to $R=0.095$ for 3008 unique observed reflections. The eight-membered ring is almost planar; two types of $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$ angles have been found with mean values of 153.2 and $167.4^{\circ}$.

Introduction. Differential thermal analyses have shown that when pure octaphenylcyclotetra(siloxane) (OPCTS) is heated, two phase transitions are observed: a solid-solid transition at about 349 K and a solidmesomorphic one at about 461 K . The latter is optically isotropic and has been assumed to be a plastic crystalline phase, containing globular molecules, which extends from 461 K to the melting point at 478 K (Keyes \& Daniels, 1975).

Successive powder neutron diffraction studies have suggested that the mesophase is a smectic $A$ phase (Volino \& Dianoux, 1978). As the molecular conformation and the crystal packing were uncertain the interpretation of the diffraction patterns was difficult. We have determined the crystal and molecular structure of OPCTS at room temperature in order to obtain precise information on its molecular structure and to provide a valuable model of rationalization of the solidphase properties.

Transparent needle-shaped crystals of commercial OPCTS (Eastman Organics Chemicals) were obtained from a dichloromethane/hexane mixture.

The intensities were collected from a crystal approximately $0.35 \times 0.20 \times 0.10 \mathrm{~mm}$ on a Philips PW 1100 four-circle diffractometer, operating in the $\theta / 2 \theta$ scan mode (scan width $=1 \cdot 1^{\circ}$, scan speed $=0.033^{\circ} \mathrm{s}^{-1}$ ) with Mo $K a$ radiation monochromatized by a graphite crystal. 5832 independent reflections up to $\theta=23^{\circ}$ were collected; 3008 of these $[I>2 \cdot 5 \sigma(I)]$ were used for the structure determination. The intensities were

[^0]corrected for Lorentz and polarization effects, but not for absorption.

The structure was solved by the direct methods included in SHELX 76 (Sheldrick, 1976). An E map generated from the phase set ( 50 reflections, $E \geq 1.5$ ) located the tetra(siloxane) ring. The remaining nonhydrogen atoms were located from a difference Fourier synthesis. The structure was refined by full-matrix least squares, with the phenyl rings treated as rigid groups ( $D_{6 h}$ symmetry, $\mathrm{C}-\mathrm{C}=1.395 \AA, \mathrm{C}-\mathrm{H}=1.08 \AA$ ). Each C atom was assigned an individual isotropic thermal parameter; the remaining non-hydrogen atoms were allowed to vibrate anisotropically. The function minimized was $\sum w\left(\left|F_{o}\right|-\left|F_{\mathrm{c}}\right|\right)^{2}$ in which $w=$ $2.9\left[\sigma^{2}\left(F_{o}\right)+0.0011\left(F_{\mathrm{c}}\right)^{2}\right]$. The relatively high $R$ value is probably due to the limited number of structure parameters used in the refinement. $\dagger$

The calculations were carried out on the Cyber 76 computer of the CINECA centre with the SHELX 76 system of crystallographic programs (Sheldrick, 1976). All atomic scattering factors were those of International Tables for $X$-ray Crystallography (1974).

Discussion. A perspective view of the molecule is shown in Fig. 1. The final positional parameters with their e.s.d.'s in parentheses for the non-hydrogen atoms are listed in Table 1; bond lengths, and shorter intramolecular distances and angles are reported in Table 2. The $\mathrm{Si}-\mathrm{C}$ and $\mathrm{Si}-\mathrm{O}$ distances range from 1.855 to 1.867 (6) $\AA$ (mean $1.860 \AA$ ) and $1.606-1.619$ (6) $\AA$ (mean $1.613 \AA$ ), respectively, in very good agreement with those reported for 2,6-cis-diphenylhexamethylcyclotetra(siloxane) (Carlström \& Falkenberg, 1973), 2,2,4,4-tetramethyl-6,6,8,8-tetraphenylcyclotetra (siloxane) (Shklover, Kalinin \& Gusev, 1973), octamethylcyclotetra(siloxane) (Steinfink, Post \& Fan-

close to the expected tetrahedral value. However, the $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$ angles are significantly larger (from 152.8 to $167 \cdot 8^{\circ}$ ) than those found (from 142 to $145^{\circ}$ ) for the previously reported tetra(siloxane) compounds. The $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$ angles are of two types with mean values of 153.2 and $167.4^{\circ}$. The oxygen atoms $O(2)$ and $O(4)$, which exhibit the largest $\mathrm{Si}-\mathrm{O}-\mathrm{Si}$ angles, are also

involved in the highest number of shorter intramolecular distances from neighbouring $C$ atoms not directly bonded to Si (mean $3.24 \AA$ ), as can be seen in Table 2. The eight-membered $\mathrm{O}_{4} \mathrm{Si}_{4}$ ring is almost planar, the maximum deviation from the root-meansquare plane being $0.1 \AA$ (Table 3 ).

The molecule as a whole does not possess symmetry elements, but, owing to the planarity of the $\mathrm{O}_{4} \mathrm{Si}_{4}$ ring and the almost perfect tetrahedral hybridization of the Si atoms, the $\mathrm{O}_{4} \mathrm{Si}_{4} \mathrm{C}_{8}$ moiety has idealized $D_{4 h}$ symmetry. This structure, unusual for this kind of ring, may be determined by the steric hindrance of the eight phenyl rings, which are rotated in a different way with respect to the inner ring (Table 3). The eight phenyls, anyway, are roughly pointing towards the eight vertices of a parallelepiped, with approximate dimensions $6.5 \times 6.5 \times 4.7 \AA$.

This conformation is quite different from that predicted by Volino \& Dianoux (1978). Consequently, the interpretation of neutron diffraction data on the high-temperature behaviour of OPCTS should be reconsidered.

The crystal packing is determined by van der Waals forces, the closest $\mathrm{C}-\mathrm{C}$ approach being $3.63 \AA$, greater than the sum of the van der Waals radii. The eightmembered rings are almost parallel to the (101) plane and approximately arranged on planes spaced at $5 \AA$ along (010); on these planes the molecules are disposed on alternate strips along the [101] or [202] directions in turn, with an extra repeat after $10 \AA$.

The authors are indebted to Professors S. Melone and F. Rustichelli for suggesting the problem and for helpful discussions.

Note added in proof: After revising the proofs of this work we received information of an earlier publication of the same structure in this journal (Hossain, Hursthouse \& Malik, 1979). A comparison of the results of these two independent structure determinations is useful and suggests the following comments.

The first structure was determined using 4009 reflections and a structure model of 545 parameters (all non-hydrogen atoms having been treated independently and anisotropically, observations/parameters ratio: 7.4). We used 3008 reflections and a structure model of 170 parameters (all the phenyl groups being treated as rigid with regular hexagonal geometry, observations/ parameters ratio: 17.7 ). These data account for the lower $R$ factor ( 0.0711 ) found in the first structure determination.

A comparison of the atomic coordinates shows that there are no significant differences between the two sets of values.

When a comparison of the bond parameters is made the average values are found to be equal within experimental errors, but the individual values of the $\mathrm{Si}-\mathrm{C}$ and $\mathrm{Si}-\mathrm{O}$ bond parameters are less scattered in our structure, as shown by the following figures (the values for the first structure are in parentheses): $\mathrm{Si}-\mathrm{C}$ : range 1.855-1.867 $\AA$ (1.837-1.857), mean: $1.860 \AA$ (1.849); $\mathrm{Si}-\mathrm{O}$ : range $1.606-1.619 \AA(1.604-1.623)$, mean: $1.613 \AA(1.615)$.

The only significant difference has been found for the $\mathrm{Si}-\mathrm{C}$ (phenyl) distance which in our structure is $0.01 \AA$ longer. This is the only drawback of our model, which is one that ignores the well established deformation of substituted phenyl rings (Domenicano, Vaciago \& Coulson, 1975).

The bond angles are equal within experimental errors [Si-O-Si: $167.4^{\circ}(167 \cdot 1), 153 \cdot 2^{\circ}$ (152.4); O-Si-O: $109.1^{\circ}$ (109.7); $\mathrm{C}-\mathrm{Si}-\mathrm{C}: 111.6^{\circ}(112.0)$ ] and even the smallest deviations from the idealized symmetry are unambiguously detectable in both structure models, indicating that there are true packing effects.

However, we were particularly interested in the molecular conformation and crystal packing and felt that our model was appropriate. In summary, we feel that it was well worth using a reduced structure model
as considerable computing time was saved and we obtained exactly the same values for the bond parameters that were of interest to us.

#### Abstract

C}_{9} \mathrm{H}_{13} \mathrm{NO}_{3} \mathrm{~S} . \frac{1}{2} \mathrm{H}_{2} \mathrm{O}\), m.p. $532-533 \mathrm{~K}$ (decomposition), Pbna, $a=13.588$ (3), $b=14.885$ (4), $c=$ 10.616 (3) $\AA, Z=8, D_{x}=1.585, D_{m}\left(\mathrm{C}_{6} \mathrm{H}_{6}-\mathrm{CCl}_{4}\right)=$ $1.58 \mathrm{Mg} \mathrm{m}^{-3}$, Mo $K \alpha(\lambda=0.7093 \AA), 1017$ reflections, $2 \theta<40^{\circ}, 217<3 \sigma\left(F_{o}\right)$. The structure was solved by MULTAN with magic integers. Full-matrix leastsquares refinement converged with $R(F)=0.040$. This confirms the previous assignment of structure to the racemic degradation product of $(-)$-epinephrine in the presence of aqueous bisulfite.

Introduction. The degradation of ( - )-epinephrine (1) in the presence of aqueous bisulfite or sulfite was first reported by Schroeter, Higuchi \& Schuler (1958). They speculated that ( $\pm$-epinine $\beta$-sulfonate (2) is the reaction product. Although there has been general acceptance of the identity of the product based upon its elemental analysis, melting point, ultraviolet spectrum, pKa and X-ray powder diffraction pattern, there have been occasional reports of confusion in the literature regarding its identity (Kawazu, Inoue, Tomino \& Iwao, 1973, and references therein). The kinetics of degradation have been thoroughly studied but fail to unambiguously characterize the mechanism or course of the reaction (Hajratwala, 1975, and references

[^2]therein) or the structure of the product. The occurrence of the $o$ - or $p$-hydroxybenzyl alcohol structure in this and other molecules appears to favor this type of reactivity (Higuchi \& Schroeter, 1959) in which dienones (3) have been implicated (Cohen \& Jones,
