(3) $s_{\text {max }}=2 \times \operatorname{MIN}[\mathrm{OX}(1), \mathrm{OX}(2)]$
$r_{\min }=1.0 \AA, r_{\text {max }}=2.5 \AA$ $s_{\min }=0.15 \times$ MAX [OX $(1)$, OX(2)]
$r_{\text {min }}=1.0 \AA$
$r_{\text {max }}=2 \cdot 0+0.075$
$\times[P(1)+P(2)] \AA$
(4) $s_{\max }=1.5$
$r_{\text {min }}=1.0 \AA$
$s_{\max }=0.38 \times \mathrm{OX}\left(C M^{*}\right) \quad r_{\max }=1.4+0.1 \times P(C M)+0.2$

$$
\times P(C T) A
$$

Exceptions: if $C M^{*}$ is $\mathrm{C}(+2)$

$$
\begin{aligned}
s_{\max } & =3.6 \\
s_{\min } & =0.038
\end{aligned}
$$

$r_{\text {min }}=1.0 \AA$
$r_{\text {max }}=3.0 \AA$
(5) $s_{\max }=2 \times \operatorname{MIN}[O X(1), O X(2)] \quad r_{\min }=1.0 \AA$ $s_{\text {min }}=0.15 \times$ MAX [OX $\left.(1), \mathrm{OX}(2)\right] \quad r_{\text {min }}=0.9+0.2$

$$
\times[P(1)+P(2)] \AA
$$

$r_{\text {min }}=1.0 \AA$
$r_{\max }=3.4 \AA$

Module (2). Calculation of bonds
If $\left|s_{\max }\right|>0$ and bond-valence parameters are available, set $r_{\text {max }}$ and $r_{\text {min }}$ from $s_{\min }$ and $s_{\text {mix }}$ respectively.

Calculate all distances lying between $r_{\text {min }}$ and $r_{\max }$.
If either atom is $C(+2), N(-1)$ or $N(-2)$, any interatomic vector closer than $55^{\circ}$ to a shorter vector is removed from the bond list. This is necessary to eliminate distances to second neighbours, e.g. metal $\cdots \mathrm{O}$ in $\mathrm{M}-\mathrm{C}-\mathrm{O}$ and $\mathrm{N}(1) \cdots \mathrm{H}$ in $\mathrm{N}(1)-\mathrm{N}(2)-\mathrm{H}$.

Module (3). Bond calculation check
(i) Calculate the bond valence from the bond lengths using $s=$ $\exp \left[\left(r_{0}-r\right) / B\right]$ based on tabulated values of $r_{0}$ and $B$ or, if these are not available, values calculated using the algorithm of Brown \& Altermatt (1985).
(ii) Modify the bond valence as follows:
(a) If either atom is H and $s>0.8$ set $s=0.8 \mathrm{v}$.u. (allows for unrealistically short $X-H$ bonds).
(b) If the terminal atom is a cation change sign of $s$.
(c) If OC (terminal) $<\mathrm{OC}($ central) set $s=[\mathrm{OC}(t) / \mathrm{OC}(c)] \times s$ (allows for cases where the terminal atom is substitutionally disordered).
(iii) Sum the valences of heteroionic bonds around the central atom

$$
\Sigma_{i}=\sum_{j} s_{i j}(C-A)
$$

(homoionic bonds do not contribute to the assigned oxidation number).
Add -0.8 v.u. for each dummy H atom attached to the central atom.
(iv) Check the difference between the oxidation number of the central atom and its bond-valence sum. Let $\Delta=0.25+(1 \cdot 1-\mathrm{OC})|\mathrm{OX}|$ be the permitted tolerance where OC and OX refer to the central atom. (This allows an increase in the tolerance for central atoms that have high oxidation states or low occupation numbers.)

Then agreement is satisfactory if
$|O X-\Sigma|<\Delta$

| $\|O X+\Sigma\|<\Delta$ | (bond valences may have wrong sign, e.g. for |
| ---: | :--- |
| $\|O X-\Sigma\|<0.5$ | CO and CN ) |
| if central atom is H |  |
| $-0.7<\mathrm{OX}-\Sigma<0.3$ | if central atom is $\mathrm{O}, \mathrm{S}, \mathrm{F}$ or Cl and the structure <br> contains undetermined H atoms (allows for <br> acceptor hydrogen bonds whose lengths cannot |
| $\|3-\Sigma\|<\Delta$ | be calculated) <br> if central atom is $\mathrm{C}(+2)$ (cyanide groups need |

$$
|3-\Sigma|<\Delta \quad \begin{array}{ll}
\text { if central atom is } C(+2) & \text { (cyanide groups need } \\
\text { snecial treatment) }
\end{array}
$$ special treatment).

Any atom whose bonding fails all the above tests is flagged as follows: WARNING if $|\mathrm{OX}-\Sigma|<0.8$ ERROR if $|O X-\Sigma|>0.8$.
In addition an ERROR flag is set
(i) if any atom is found to form no bonds, or
(ii) if distances are found with $r<r_{\min }$ and $O C(1)+O C(2)>1 \cdot 0$. (In this case it is impossible for the two sites to be simultaneously occupied.)

Module (4). Error analysis
If a WARNING or an ERROR is flagged, check:
(i) Does the cell correspond to space-group setting:
(a) For hexagonal, trigonal and rhombohedral (hexagonal setting) is $\gamma=120 .{ }^{\circ}$ ?
(b) For monoclinic, are the correct two angles $90^{\circ}$ for the setting used?
(ii) Does the number of assigned H atoms correspond to the number of dummy H atoms given? If not, how many H atoms would have to be attached to each anion to give the correct valence sums?
(iii) Is the coordination number of $\mathrm{P}(+5), \mathrm{S}(+6)$ and $\mathrm{Cl}(+7)$ equal to 4 ?
(iv) Does any bond exceed its maximum possible valence? i.e. is $s>$ MIN [OX(1), OX(2)].
(v) Does a halogen anion form no bonds in a structure where H -atom coordinates have not been determined? In this case the anion probably only forms hydrogen bonds.

All of the above tests will print an appropriate diagnostic statement if the error condition is found.

# Bond-Valence Parameters Obtained from a Systematic Analysis of the Inorganic Crystal Structure Database 

By I. D. Brown and D. Altermatt<br>Institute of Materials Research, McMaster University, Hamilton, Ontario, Canada L8S 4M1

(Received 11 December 1984; accepted 1 March 1985)

#### Abstract

The parameters needed to calculate bond valences from bond lengths have been determined for 750 atom pairs using the Inorganic Crystal Structure Database. The most accurate 141 are listed and an algorithm is

given which allows the calculation of the remainder as well as the calculation of parameters for over a thousand other bond types. Graphical bond-valence-bond-length correlations are presented for hydrogen bonds.

## Determination of bond-valence parameters

The preceding paper (Altermatt \& Brown, 1985) describes a program (SINDBAD) which determines the chemical connectivity in an inorganic crystal. Essential to the running of this program are the parameters required for calculating the bond valences. Two expressions are commonly used to describe the relationship between the bond length ( $r$ ) and the bond valence ( $s$ )

$$
\begin{equation*}
s=\left(r / r_{0}\right)^{-N} \tag{1}
\end{equation*}
$$

and

$$
\begin{equation*}
s=\exp \left[\left(r_{0}-r\right) / B\right], \tag{2}
\end{equation*}
$$

where $r_{0}, N$ and $B$ are empirically determined parameters, many of which have been tabulated (Brown \& Wu, 1976; Brown, 1980).
The bond file produced from the Inorganic Crystal Structure Database (ICSD) (Bergerhoff, Hundt, Sievers \& Brown, 1983) by the program SINDBAD provides an ideal resource to refine these parameters which are usually determined by fitting equation (3) (relating $V_{i}$, the oxidation state of cation $i$, to $s_{i j}$, the valence of the bond between the cation $i$ and the anion $j$ ) to the environments found around a number of cations (Brown \& Shannon, 1973):

$$
\begin{equation*}
V_{i}=\sum_{j} s_{i j} . \tag{3}
\end{equation*}
$$

Reliable values can be found with 10 to 20 cation environments, but the more that are used, the better the resulting parameters.
Equation (2) has a particular advantage over equation (1) because $B$, unlike $N$, varies very little from one atom pair to another. By refining $B$ (i.e. selecting the value of $B$ that gives the smallest value of $\sigma^{\prime}$ described below) it is found that $B$ could rarely be determined to better than 0.05 and that a value of 0.37 was consistent with most or all of the refined values. By assuming this value for $B$, only one parameter ( $r_{0}$ ) remains to be fitted and this can be done exactly for each cation environment by solving the equation

$$
\begin{equation*}
V_{i}=\sum_{j} s_{i j}=\sum_{j} \exp \left(\frac{r_{0}^{\prime}-r_{i j}}{B}\right) \tag{4}
\end{equation*}
$$

for $r_{0}^{\prime}$. A value of $r_{0}^{\prime}$ is calculated for each cation environment in the ICSD in which the ligands are chemically identical and in which there is no disorder. The resultant values are then averaged to give the best value for $r_{0}$ for a given ion pair.

The estimated standard deviation ( $\sigma^{\prime}$ ) of $r_{0}^{\prime}$ gives a measure of the extent to which the various cation environments give a consistent result. Except for the alkali metals where $\sigma^{\prime} \sim 0.09 \AA$, the standard deviation generally lies in the range 0.01 to $0.05 \AA$, giving rise to an estimated standard error $\left(\sigma_{e}\right)$ in the value
of $r_{0}$ that is usually less than $0.01 \AA$ when more than 10 cation environments are available for a given atom pair. In cases where the number of cation environments warranted, restricting the calculations to structures with crystallographic $R$ factors less than $0 \cdot 12$ generally lowered $\sigma^{\prime}$ except for the alkali metals. In these latter cases the large standard deviation represents a real physical variation in cation environment and not merely experimental error.
In total, 750 values of $r_{0}$ were determined from 15371 different cation environments obtained from the ICSD. Table 1 gives the 141 most reliable values of $r_{0}$ and includes $\sigma_{e}, \sigma^{\prime}$ and the number ( $n$ ) of cation environments used in calculating $r_{0}$. The criterion for inclusion of $r_{0}$ in Table 1 is that $\sigma_{e} \leqslant 0.01 \AA$ and $n \geqslant 10$.
The results of this analysis were examined for the systematic variation of $r_{0}$ with the position of the ions in the Periodic Table. The equation

$$
\begin{equation*}
r_{0}=r_{c}+A \times r_{a}+P-D-F \tag{5}
\end{equation*}
$$

can generally reproduce the well determined values to within about $0.013 \AA$ (standard deviation) or within about $3 \sigma_{e}$. In this equation $r_{c}$ and $r_{a}$ are contributions to $r_{0}$ from the cation and anion respectively as given in Table 2 ( $r_{a}$ for oxygen is arbitrarily chosen as zero). The multiplier $A$ is set to 0.8 for transitionmetal ions (groups 3-12) with $d$ electrons present, otherwise it is set to $1 \cdot 0$.
$P, D$ and $F$ are corrections required when the cation contains non-bonding $p, d$ and $f$ electrons respectively. The values of $D$ are given in Table 3; the values of $P$ and $F$ are calculated using:

$$
\begin{aligned}
& P=0.0175 \times(\text { cation period }-2) \\
& F=0.016 \times \text { number of } f \text { electrons. }
\end{aligned}
$$

The values of $r_{0}$ calculated using this algorithm are not as good as the selected experimental values given in Table 1 but for the remaining 609 (those with $\sigma_{e}>0.01 \AA$ or $n<10$ ) the calculated values are probably as good as or better than those determined experimentally. Furthermore, the program can be used to predict values of $r_{0}$ for over a thousand cation-anion combinations whose valence parameters have not yet been determined.

## Determining the valence of hydrogen bonds

Hydrogen bonds are of particular interest because of their importance in solid-state chemistry. All distances between 0.95 and $3.2 \AA$ have been observed for $\mathrm{O}-\mathrm{H}$ bonds and over a range of this magnitude it would be surprising if any equation as simple as (1) or (2) could give a good fit. Furthermore, the study of hydrogen bonding is complicated by the fact that the H atom itself is often not well located. Both these considerations require that hydrogen bonds be

Table 1. The bond-valence parameter $r_{0}$ for selected bonds
$B$ has been set to 0.37 . An $R$ in the last column indicates that the averaging was restricted to structures with agreement index less than $0 \cdot 12$. Other symbols are defined in the text.

treated specially in any careful analysis of bond valences.

Fig. 1 gives the correlation between bond valence and $H \cdots X$ distance for a variety of anions ( $X$ ) and is an extension of that given by Brown (1976b). It
has been found to give good valences for hydrogen bonds where the donor is O or C but it gives values a little low where the donor is N . In using this graph it is important to remember that since X -ray diffraction locates the centroid of the electron density rather
than the position of the nucleus, the H atom appears to be closer to the donor anion than it actually is. This fact, combined with the large uncertainties in the determination of the H position, make it desirable to move the H atom to a position about $1 \cdot 0 \AA$ from the donor ( $0.95 \AA$ for $\mathrm{O}, 1 \cdot 10 \AA$ for C , etc.) before using the figure.
Although the position of the H atom is still uncertain even after the shift, the valence of the $\mathrm{H} \cdots \boldsymbol{X}$ (acceptor) bond can be well determined because the valence is not sensitive to small uncertainties in bond length. By contrast the (donor) $X-H$ bond valence is extremely sensitive to small uncertainties in distance. Consequently the (donor) $X-\mathrm{H}$ valence is best determined by subtracting the sum of the $\mathrm{H} \cdots X$ (acceptor) valences from $1 \cdot 0$.
When the position of the H atom is not known and cannot be predicted a different approach is needed. In the case of $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ bonds one can use Fig. 2 which shows the correlation between the $\mathrm{H} \cdots \mathrm{O}$ bond valence and the O-O distance. This graph has been constructed on the assumption that the degree of bending in the hydrogen bond follows the trend

Fig. 1. Bond-valence-bond-length correlation for $H \cdots X$ bonds. The different horizontal scales are to be used depending on the nature of $X$, e.g. an $\mathrm{H} \cdots \mathrm{N}$ bond of length $2.5 \AA$ has a valence of $0 \cdot 08$.

Fig. 2. Bond valence for $\mathrm{H} \cdots \mathrm{O}$ as a function of $\mathrm{O} \cdots \mathrm{O}$ distance assuming normal $\mathrm{O}-\mathrm{H} \cdots \mathrm{O}$ bond angles.

Table 2. Values of $r_{c}(\AA)$ and $r_{a}(\AA)$
(a) Values of $r_{c}$

Table 3. Correction for non-bonded d electrons

| Number of <br> $d$ electrons | $D(\AA)$ | Number of <br> $d$ electrons | $D(\AA)$ |
| :---: | :---: | :---: | ---: |
| 0 | 0.0 | 6 | 0.033 |
| 1 | 0.020 | 7 | -0.007 |
| 2 | 0.040 | 8 | 0.140 |
| 3 | 0.060 | 9 | 0.220 |
| 4 | 0.030 | 10 | 0.380 |
| 5 | -0.005 |  |  |

observed by Brown (1976a). This may not be true in individual cases but the difference will not be large and for many purposes Fig. 2 can give adequate results.
