#### Abstract

A polarized split-valence wavefunction was computed for the $\mathrm{H}_{3} \mathrm{PO}_{4}$ molecule at its neutron crystallographic valence geometry, and the wavefunction was used to map the molecular electron-density distribution and to simulate X-ray crystal structure factors for both static, at-rest and dynamic thermally averaged structures. The thermal vibrational averaging was approximated using anisotropic mean-square atomic displacements from $\sim 300 \mathrm{~K}$ neutron diffraction data. The simulated X-ray data were used to test pseudoatom multipole modeling of the valence electron-density distribution, in particular, radial modeling of the $M$ valence shell of the P atom, and deconvolution of the nonspherical density features from anisotropic vibrational smearing.

## Introduction

We have studied the electron-density distribution and chemical bonding in orthophosphoric acid, $\mathrm{H}_{3} \mathrm{PO}_{4}$, because it is the prototype for biochemical phosphates, in particular those involved in the ATP cycle of bioenergetics. In this paper we report computational studies based on a polarized split-valence wavefunction for the $\mathrm{H}_{3} \mathrm{PO}_{4}$ molecule as it occurs in its anhydrous crystals; in an accompanying paper (Souhassou, Espinosa, Lecomte \& Blessing, 1995) we report a corresponding experimental analysis.

[^0]Occurrences of the $\mathrm{H}_{3} \mathrm{PO}_{4}$ molecule in the crystalline state include: anhydrous phosphoric acid, $\mathrm{H}_{3} \mathrm{PO}_{4}$, m.p. 315 K (Furberg, 1955; Smith, Brown \& Lehr, 1955; Cole \& Peterson, 1964; Cole, 1966; Blessing, 1988, 1989); phosphoric acid hemihydrate, $2 \mathrm{H}_{3} \mathrm{PO}_{4} \cdot \mathrm{H}_{2} \mathrm{O}$, m.p. 302 K (Smith, Brown \& Lehr, 1955; Mighell, Smith \& Brown, 1969; Dickens, Prince, Schroeder \& Jordan, 1974); a co-crystallized, hydrogen-bonded adduct with acetic acid, $\mathrm{H}_{3} \mathrm{PO}_{4} . \mathrm{CH}_{3} \mathrm{CO}_{2} \mathrm{H}$, m.p. 307.5 K (Jönsson, 1972); a strongly hydrogen-bonded, almost ionized adduct with urea, $\left(\mathrm{H}_{2} \mathrm{~N}\right)_{2} \mathrm{CO} . \mathrm{H}_{3} \mathrm{PO}_{4}$ (Sundera-Rao, Turley \& Pepinsky, 1957; Wolfram, Arutunian, Antishkina \& Porai-Koshits, 1967; Kostansek \& Busing, 1972; Mootz \& Albrand, 1972; Savage, Blessing \& Wunderlich, 1987); and a solvate molecule of crystallization in a dihydrogen phosphate salt of histidine, L- $-\mathrm{HisH}^{+} \mathrm{H}_{2} \mathrm{PO}_{4}^{-} \cdot \mathrm{H}_{3} \mathrm{PO}_{4}$ (Blessing, 1986, 1987).

Previous $a b$ initio quantum chemical studies of simple phosphates have investigated: the conformational energetics of $\mathrm{H}_{3} \mathrm{PO}_{4}, \mathrm{H}_{2} \mathrm{PO}_{4}^{-}, \mathrm{HPO}_{4}^{2-}$ and $\left(\mathrm{CH}_{3} \mathrm{O}\right)_{2} \mathrm{PO}_{2}^{-}$ (Newton, 1973; Hayes, Kollman \& Rothenberg, 1977); the structure of the $1: 1$ hydrogen-bonded complex between $\mathrm{H}_{2} \mathrm{O}$ and $\left(\mathrm{CH}_{3} \mathrm{O}\right)_{2} \mathrm{PO}_{2}^{-}$(Alagona, Ghio \& Kollman, 1983); the relative stabilities of metal, metalaquo, metal-diaquo and metal-chloro-aquo complexes of $\mathrm{Li}^{+}, \mathrm{Na}^{+}, \mathrm{K}^{+}, \mathrm{Be}^{2+}, \mathrm{Mg}^{2+}$ and $\mathrm{Ca}^{2+}$ with $\mathrm{H}_{2} \mathrm{PO}_{4}^{-}$and $\left(\mathrm{CH}_{3} \mathrm{O}\right)_{2} \mathrm{PO}_{2}^{-}$(Marynick \& Schaefer, 1975); the energetics of hydrolysis of phosphoric and phosphoriccarboxylic anhydride molecules (Hayes, Kenyon \& Kollman, 1975, 1978); and the valence and conformational geometry of $\mathrm{OP}(\mathrm{OH})_{3}$ compared with $\mathrm{OP}(\mathrm{H})(\mathrm{OH})_{2}$ and $\mathrm{OP}(\mathrm{H})_{2} \mathrm{OH}$ (Ewig \& Van Wazer, 1985). These studies employed minimal STO-3G or split-valence 4-31G basis sets, which give reasonable molecular geometries and relative energies, but which are quite inadequate for mapping electron-density distributions. Polarized split-valence $6-31 \mathrm{G}^{* *}$ basis sets, which are adequate for electron-density mapping, were employed in a study of $a b$ initio geometry optimization for
phosphate species (O'Keefe, Domengès \& Gibbs, 1985), but the electron densities were not examined.

In the crystallographic literature on pseudoatom modeling of electron densities, there are numerous results for the first-row biochemical atoms, carbon, nitrogen and oxygen, in their various states of chemical combination, but there are few results for sulfur and even fewer for phosphorus. Phosphorus and sulfur are biologically essential second-row atoms with ten-electron $1 s^{2} 2 s^{2} 2 p^{6}[\mathrm{Ne}]$ cores and $M$ valence shells, which are more diffuse than the $L$ valence shells of first-row atoms with two-electron $1 s^{2}$ [He] cores. Often the most difficult aspect of crystallographic pseudoatom modeling has been the stable convergence of the radial parameters of the valence-density fitting functions, and radial modeling of the $M$ valence shell deserves particular attention for studies of phosphate species.

For our study of $\mathrm{H}_{3} \mathrm{PO}_{4}$, we computed a polarized split-valence molecular wavefunction; used it to simulate X-ray crystal structure factors for both static, at-rest and dynamic thermally averaged structures, and fitted cystallographic pseudoatom models to the simulated data sets in order to compare the electron densities that came from the models with the density that went into the data. Earlier studies of this kind include analysis of simulated dynamic, 123 K data for urea (Swaminathan, Craven, Spackman \& Stewart, 1984) and static data for 2-methyl-4-nitroaniline (Howard, Hursthouse, Lehmann, Mallinson \& Frampton, 1992). These studies showed that crystallographic pseudoatom models can effectively recover theoretical electron densities, at least for $\mathbf{C}, \mathbf{H}$, N , or O structures of first-row atoms with small or zero amplitudes of thermal vibration. In our study of $\mathrm{H}_{3} \mathrm{PO}_{4}$ we were concerned with modeling the second-row $\mathbf{P}$ atom and with deconvolution from thermal smearing at temperatures up to $\sim 300 \mathrm{~K}$.

## The $\mathbf{H}_{\mathbf{3}} \mathbf{P O}_{\mathbf{4}}$ crystal structure

The non-H structure of anhydrous $\mathrm{H}_{3} \mathrm{PO}_{4}$ crystals was determined simultaneously and independently by Furberg (1955) and Smith, Brown \& Lehr (1955) using twodimensional photographic X-ray diffraction data. The hydrogen structure of the crystals was determined from three-dimensional neutron diffraction data measured by Cole \& Peterson (1964), analyzed by Cole (1966), and re-analyzed by Blessing (1988, 1989). Tables 1 and 2 and Fig. 1 summarize the crystallographic results. The $\mathrm{O}=\mathrm{P}(-\mathrm{OH})_{3}$ molecules form strong two-centered $\mathrm{P}-\mathrm{O}-\mathrm{H} \cdots \mathrm{O}=\mathrm{P}$ hydrogen bonds and weak threecentred $\mathrm{P}-\mathrm{O}-\mathrm{H}\left[\cdots \mathrm{O}(\mathrm{H})-\mathrm{P}_{2}\right.$ hydrogen bonds. The two-centered bonds and the stronger branches of the three-centered bonds link the molecules into layers parallel to (001); the layers are stacked in van der Waals contacts and cross-linked by the weaker branches of the three-centered bonds. The molecules are crystallographically asymmetric with site symmetry $1\left(C_{1}\right)$, and the

The neutron data have been re-analyzed (Blessing, 1988, 1989) with extinction corrections included in a joint refinement with two datasets measured at different wavelengths. This improved the statistics-of-fit and the mean-square displacement parameters, but produced no significant changes in molecular geometry.
$\mathrm{H}-\mathrm{O}-\mathrm{P}=\mathrm{O}$ conformation angles and the intermolecular and hydrogen bond geometry depart substantially from idealized $3 m\left(C_{3 v}\right)$ molecular symmetry. Nevertheless, the three $\mathrm{P}-\mathrm{O}(\mathrm{H})$ bond lengths and the three $\mathrm{O}=\mathrm{P}-\mathrm{O}(\mathrm{H}),(\mathrm{H}) \mathrm{O}-\mathrm{P}-\mathrm{O}(\mathrm{H})$ and $\mathrm{P}-\mathrm{O}-\mathrm{H}$ valence angles are almost within experimental error of threefold symmetry equivalence. Although the $\mathrm{P}=\mathrm{O}$ phosphoryl bond is significantly shorter than the $\mathrm{P}-\mathrm{O}(\mathrm{H})$ phosphohydroxyl bonds, the double bond and single bond notations are merely formal, and both bond types possess partial double-bond character. The $\mathrm{O}-\mathrm{H}$ and $\mathrm{P}-\mathrm{O}(\mathrm{H})$
bond lengths show hydrogen bonding effects: $\mathrm{O}-\mathrm{H}$ increases substantially and $\mathrm{P}-\mathrm{O}(\mathrm{H})$ decreases slightly, as the $\mathrm{H} \cdots \mathrm{O}$ distance decreases (Table 2 and Fig. 1 legend).

Fig. 1. Stereoscopic drawings (Johnson, 1971) of the crystal and molecular structure of $\mathrm{H}_{3} \mathrm{PO}_{4}$ (Blessing, 1988, 1989). The orientation of the crystallographic axes in the molecular drawings corresponds to the respective unit-cell drawings, and the thermal vibration ellipsoids are $50 \%$ equiprobability surfaces. H 2 and H 3 are single donors in strong two-centered hydrogen bonds to O 1 ( 1.55 and $1.59 \AA \mathrm{H} \cdots \mathrm{O}$ and 2.57 and $2.58 \AA \mathrm{O} \cdots \mathrm{O}$, respectively); H 4 is a double donor in much weaker three-centered hydrogen bonds to O 2 and O 3 (1.97 and $2.52 \AA \mathrm{H} \cdots \mathrm{O}$ and 2.85 and $3.10 \AA \mathrm{O} \cdots \mathrm{O}$, respectively).

Table 3. The polarized split-valence basis set for $\mathrm{H}_{3} \mathrm{PO}_{4}$

|  | Primitive | Contracted | Polarization |  |  |
| :--- | :--- | :---: | :--- | :--- | :--- | :--- |
| Atom | set | set | References | exponents | References |
| P | $(12 s 9 p)$ | $[6 s 4 p]$ | $(a),(d)$ | $d, \zeta=0.6$ | $(a)$ |
| O | $(9 s 5 p)$ | $[4 s 3 p]$ | $(b),(c)$ | $d, \zeta=0.75$ | $(a)$ |
| H | $(4 s, \zeta=1.2)$ | $[2 s]$ | (c) | $p, \zeta=0.8$ | $(e),(f)$ |

References: (a) Rothenberg, Young \& Schaefer (1970); (b) Dunning (1970); (c) Husinaga (1965); (d) Veillard (1968); (e) Moss (1981); ( $f$ ) Moss \& Blessing (1984).
The $\mathrm{H}_{3} \mathrm{PO}_{4}$ basis set was based on established results for $\mathrm{H}_{2} \mathrm{O}$ and for the isoelectronic series $\mathrm{SiH}_{4}, \mathrm{PH}_{3}, \mathrm{H}_{2} \mathrm{~S}$ and HCl . Polarization functions were $d_{x x}, d_{y y}, d_{z z}, d_{x y}, d_{x z}, d_{y z}$ on the P and O atoms and $p_{x}$, $p_{y}, p_{z}$ on the H atoms.

## Theoretical electron density for $\mathbf{H}_{3} \mathrm{PO}_{\mathbf{4}}$

A wavefunction for an isolated $\mathrm{H}_{3} \mathrm{PO}_{4}$ molecule, with the neutron crysallographic molecular geometry given in Table 2, was computed using the ab initio LCAO-MOSCF program HONDO (Dupuis, Rys \& King, 1976) and the polarized split-valence basis set summarized in Table 3. The electron-density distribution calculated (Moss, 1983) from this wavefunction is illustrated in Fig. 2 as sections of the deformation density

$$
\begin{equation*}
\Delta \rho(\mathbf{r})=\rho_{m}(\mathbf{r})-\sum_{a=1}^{N} \rho_{a}^{0}\left(\mathbf{r}-\mathbf{r}_{a}\right), \tag{1}
\end{equation*}
$$

where $\rho_{m}$ is the molecular electron density and $\rho_{a}^{0}$ are spherically averaged, ground-state, free-atom electron densities calculated from the same atomic basis functions. The superposition of the free-atom densities represented by the sum on the right in (1) gives the socalled promolecule density.
Several chemical characteristics of the deformation density shown in Fig. 2 (and in additional maps deposited with the supplementary material*) are worth noting. The chemically distinct $\mathrm{P}=\mathrm{O}$ and $\mathrm{P}-\mathrm{OH}$ groups have distinctive electron distributions, and the three $\mathrm{O}=\mathrm{P}-\mathrm{O}(-\mathrm{H})$ and $\mathrm{P}-\mathrm{O}-\mathrm{H}$ bonding regions, and $(\mathrm{P}-) \mathrm{O}(-\mathrm{H})$ lone-pair regions are essentiailly chemically equivalent, even though they are not crystallographically equivalent. To close approximations, the densities have local cylindrical symmetry $\infty m\left(C_{\infty V}\right)$ at the $\mathrm{P}=\mathrm{O}$ group, in-plane mirror symmetry $m\left(C_{s}\right)$ at each $\mathrm{P}-\mathrm{O}-\mathrm{H}$ group, and threefold rotation and reflection symmetry $3 m\left(C_{3 V}\right)$ at the P atom.

Both bond and lone-pair densities are more diffuse in the $\mathrm{P}=\mathrm{O}$ group than in the $\mathrm{P}-\mathrm{O}-\mathrm{H}$ groups, and the

[^1]- $\mathrm{O}-\mathrm{H}$ densities resemble extended basis-set densities for the water molecule (Hermansson, 1984). The lonepair densities peak only $\sim 0.2 \AA$ from the O nuclei. The $(\mathrm{P}-) \mathrm{O}(-\mathrm{H})$ lone pairs appear to occupy a pair of tetrahedral $s p^{3}$ hybrid orbitals. The ( $\mathrm{P}=$ ) O lone-pair density is almost circularly symmetric about the $\mathrm{P}=\mathrm{O}$ axis, and, although there is a slight peaking that suggests trigonal $s p^{2}$ hybridization in the $\mathrm{O}=\mathrm{P}-\mathrm{O} 3(\mathrm{H})$ plane, it
appears that the $(\mathrm{P}=0) \mathrm{O}$ lone pairs occupy a pair of $p \pi$ orbitals perpendicular to a hybrid $s p \sigma$ orbital.

The $\mathrm{P}=\mathrm{O}$ and $\mathrm{P}-\mathrm{O}(\mathrm{H})$ bond densities both peak at $0.5 \mathrm{e}^{\AA^{-3}}$; however, being more diffuse, the $\mathrm{P}=\mathrm{O}$ density would integrate to a larger electron count than the $\mathrm{P}-\mathrm{O}(\mathrm{H})$ densities. Moreover, since the $\mathrm{P}=\mathrm{O}$ bond is $\sim 0.05 \AA$ shorter than the $\mathrm{P}-\mathrm{O}(\mathrm{H})$ bonds, the difference density along the $\mathrm{P}=\mathrm{O}$ bond results from

Fig. 2. Static deformation density (1) plotted in the planes: (a) ( $\mathrm{H}-$ ) $\mathrm{O} 2-\mathrm{P}=\mathrm{O}$, (b) $\mathrm{P}-\mathrm{O} 2-$ H, (c) $(\mathrm{H}-) \mathrm{O} 3-\mathrm{P}=\mathrm{O}$, (d) $\mathrm{P}-$ $\mathrm{O} 3-\mathrm{H},(e)(\mathrm{H}-) \mathrm{O} 4-\mathrm{P}=\mathrm{O}$ and (f) $\mathbf{P}-\mathrm{O} 4-\mathrm{H}$. In the $(\mathrm{H}-) \mathrm{O}-\mathrm{P}=\mathrm{O}$ sections, the H atom is above the $\mathrm{O}-\mathrm{P}=\mathrm{O}$ plane by the indicated perpendicular distance. Contour interval $0.1 \mathrm{e}^{\AA^{-3}}$; negative contours dotted, zero contour dashed and positive contours solid.
subtraction of higher levels of the overlapping P and O atomic densities. Thus, equal difference-density peak heights in the $\mathrm{P}=\mathrm{O}$ and $\mathrm{P}-\mathrm{O}(\mathrm{H})$ bonds imply a higher level of total density in the shorter, stronger $\mathrm{P}=\mathrm{O}$ bond.

The $\mathrm{O} 2-\mathrm{H}, \mathrm{O} 3-\mathrm{H}$ and $\mathrm{O} 4-\mathrm{H}$ bond densities peak at $0.45,0.5$ and $0.6 \mathrm{e} \AA^{-3}$, respectively [Figs. $2(d)$, (e) and $(f)$ ]. This increase follows the decrease in $\mathrm{O}-\mathrm{H}$ bond lengths (Table 2), which follows from the increasing strength of $\mathrm{H} \cdots \mathrm{O}$ hydrogen bonding interactions in the crystals (Fig. 1 legend). Thus, in the $\mathrm{O}-\mathrm{H}$ bonds not only the total density, but also the difference density increases with decreasing bond length, despite the atomic subtraction effect evident in the $\mathrm{P}-\mathrm{O}$ bonds.

Apart from their essential role as polarization functions in the LCAO-MO formalism, the role of $3 d$ orbitals in phosphorus chemistry has been much discussed for a long time [see, e.g. Cruickshank (1961, 1985)]. In the second-row nonmetals $\mathrm{P}, \mathrm{S}$ and Cl , the $3 d$ orbitals are unoccupied in the free-atom ground states, but are energetically accessible for mixing into molecular ground states. This is expressed in qualitative valence bond terms by "expanded octets" for the central atoms in the oxyacids $(\mathrm{HO}-)_{3} \mathrm{P}=\mathrm{O}, \quad(\mathrm{HO}-)_{2} \mathrm{~S}(=\mathrm{O})_{2}$ and $\mathrm{HO}-\mathrm{Cl}(=\mathrm{O})_{3}$, and in this vein, we have discussed bond strengths in $\mathrm{H}_{3} \mathrm{PO}_{4}$ (Blessing, 1988, 1989) in terms of a simple picture of $p \pi(\mathrm{O}) \rightarrow d \pi(\mathrm{P})$ orbital overlap, as originally proposed by Cruickshank (1961). In light of later studies, however, Cruickshank (1985) has concluded that $p \pi \rightarrow d \pi$ bonding plays a relatively minor role in the tetrahedral second-row oxyanions, and that the major role of $d$-basis functions is to move substantial electron density from near the bound atoms into the bond region and thus strengthen the bonding in a very classical way. This $d$-function participation corresponds to $d$-orbital core penetration, which is enhanced for second-row compared with first-row atoms, due to the larger effective nuclear charges in the second-row valence shells. Among the results leading to this interpretation were theoretical deformation densities (Cruickshank \& Eisenstein, 1985) for sulfamic acid $\mathrm{H}_{3} \mathrm{NSO}_{3}$, which is isoelectronic with $\mathrm{H}_{3} \mathrm{PO}_{4}$, and for which maps of an $\mathrm{O}=\mathrm{S}-\mathrm{N}-\mathrm{H}$ section are similar to our $\mathrm{O}=\mathrm{P}-\mathrm{O}(\mathrm{H})$ maps.

## Simulated X-ray crystal structure factors from the molecular wavefunction

Following algorithms developed by Stewart (1969), and using a program written by Moss (1983), structure factors were simulated from the molecular wavefunction for a hypothetical static, at-rest $\mathrm{H}_{3} \mathrm{PO}_{4}$ crystal structure and for dynamic, thermally averaged structures at nominal temperatures of 75,150 and 300 K . Our simulations were similar to those by Swaminathan, Craven, Spackman \& Stewart (1984) for the urea crystal structure at 123 K . The same type of simulation has also been reported for a static 2-methyl-4-nitroaniline crystal
structure by Howard, Hursthouse, Lehmann, Mallinson \& Frampton (1992).

We emphasize that these simulated structure-factor magnitudes differ, even in principle, from experimentally measurable diffraction data in two important ways: First, static molecular and crystal structures are only imaginary; all real structures are dynamic. Even at extremely low temperatures, real structures undergo at least zeropoint vibrational motion, and diffraction experiments yield time and space averages over the vibrational displacements. Second, simulaton from a wavefunction for an isolated molecule yields structure factors for a molecular procrystal rather than a crystal. The simulated data will show artifactual effects of molecular superposition overlap, but not the physical effects of the molecular interactions responsible for crystal binding except insofar as they affect the 'in-crystal' molecular geometry adopted for computing the in vacuo molecular wavefunction.

The thermal averaging of the simulated structure factors

$$
\begin{align*}
F(\mathbf{h})= & \sum_{\text {sym }} \sum_{\mu} \sum_{\nu} P_{\mu \nu}\left\langle\chi_{\mu}\right| \exp (2 \pi i \mathbf{h} \cdot \mathbf{r})\left|\chi_{\nu}\right\rangle W_{\mu \nu}(\mathbf{h}) \\
& \times \exp \left(2 \pi i \mathbf{h} \cdot \mathbf{R}_{\mu \nu}\right) \tag{2}
\end{align*}
$$

was approximated by multiplying each, in general, twocentered (atom $a$, atom $b$ ) atomic orbital product by an effective two-centered Debye-Waller factor

$$
\begin{equation*}
W_{a b}(\mathbf{h})=\exp \left[-2 \pi^{2} \sum_{i=1}^{3} \sum_{j=1}^{3} h_{i} h_{j} a^{* i} a^{* j} g\left(U_{a}^{i j}+U_{b}^{i j}\right)\right] \tag{3}
\end{equation*}
$$

with $g=0.5$ corresponding to rigid-rod correlated motions (Stewart, 1969). The thermal vibration tensor components had values $q U^{i j}(\mathbf{T}, \mathbf{L}, \mathbf{S})$, where $U^{i j}(\mathbf{T}, \mathbf{L}, \mathbf{S})$ were as given in Table 4 , and on the assumption that $U_{i j} \propto T$, the values $q=0,0.25,0.5$ and 1 were used to simulate a static structure and dynamic structures at $T \approx 75,150$ and 300 K , respectively.

Equations (2) and (3) approximate the thermodynamic ensemble average over all nuclear configurations (Stewart \& Feil, 1980) from the wavefunction for the thermal mean equilibrium configuration in a very straightforward manner (Stewart, 1969). Other approximations have also been described (Ruysink \& Vos, 1974; Stevens, Rys \& Coppens, 1977).

The atomic-mass-weighted average of the $U^{i i}$ values from Table 4 gives an overall isotropic mean-square vibrational displacement $\left\langle u^{2}\right\rangle \approx 0.025 \AA^{2}$ at $T \approx 300 \mathrm{~K}$. Using the Debye relation

$$
\begin{equation*}
\left\langle u^{2}\right\rangle=3 h^{2} T /\left(4 \pi^{2} k_{B} m \Theta_{D}^{2}\right), \quad T>\Theta_{D} \tag{4}
\end{equation*}
$$

which is in principle applicable only to cubic monoatomic crystals (e.g. Willis \& Pryor, 1975, pp. 122 ff .), and taking $m$ to be the molecular mass, we estimate a

* The tabulated contributions are those from the crystallographically independent molecule. Since the crystal structure has a centre of symmetry at the origin, the imaginary components sum to zero when the contributions from the centrosymmetrically equivalent molecule are added.

Debye temperature $\Theta_{D} \approx 130 \mathrm{~K}$ for $\mathrm{H}_{3} \mathrm{PO}_{4}$ crystals. This would mean that $U^{i j} \propto T$ is a reasonable assumption for our $q=1(300 \mathrm{~K})$ and $q=0.5(150 \mathrm{~K})$ simulated data, but doubtful for the $q=0.25(75 \mathrm{~K})$ data.

We were surprised to find that a few structure-factor magnitudes actually increased slightly with increasing thermal motion. An example of this apparently counterintuitive result is shown in Table 5, which summarizes a test calculation of the static ( $q=0$ ) and dynamic ( $q=1$ ) structure factors for the (313) reflection. For each atom, the magnitude of the dynamic one-center term is smaller than that of the corresponding static term, because the dynamic term has been multiplied by an atomic DebyeWaller factor, $0<W<1$. Nevertheless, the (real) onecenter total is slightly larger for the dynamic than for the static terms, because the totals are sums of signed terms, each of which is multiplied by a different Debye-Waller factor.

On reflection, we realized that the same type of effect can occur in conventional crystallographic calculations of the structure factors, $\quad F(\mathbf{h})=\sum_{a=1}^{N} f_{a}(\mathbf{h})$ $\exp \left(2 \pi i \mathbf{h}^{T} \mathbf{r}_{a}-\mathbf{h}^{T} \beta_{a} \mathbf{h}\right)$, where $\beta^{i j}=2 \pi^{2} a^{* *} a^{* j} U i j$. With
increasing thermal motion, all the atomic Debye-Waller factors necessarily decrease because the $\beta$ matrices are positive definite; however, a decrease in $|F(\mathbf{h})|$ is an analytical requirement only if the Debye-Waller factors are the same for all atoms and factor out of the vectorial atomic summation. In general, and on average, $|F(\mathbf{h})|$ decrease, but exceptionally individual values may increase slightly.

## Pseudoatom modeling of the electron density

The simulated structure factor data were fitted using the program MOLLY (Hansen \& Coppens, 1978), which employs generalized atomic scattering factors that are the Fourier transforms of pseudoatom electron densities parameterized to model nonspherical electron redistributions due to chemical bonding (Coppens, 1993; Coppens \& Becker, 1992; Maslem, Fox \& O'Keefe, 1992). Each bound pseudoatom is modeled by a multipolar expansion about the free atom

$$
\begin{align*}
\rho(\mathbf{r})= & \rho_{c}(r)+P_{v} \kappa_{0}^{3} \rho_{v}\left(\kappa_{0} r\right) \\
& +\kappa_{1}^{3_{\max }} \sum_{l=0} R_{l}\left(\kappa_{l} r\right) \sum_{m=-1}^{+l} P_{l m} y_{l m}(\theta, \varphi), \tag{5}
\end{align*}
$$

where $\rho_{c}$ is the spherically symmetric Hartree-Fock core electron density, $\rho_{v}$ is the spherically averaged free- atom Hartree-Fock valence electron density normalized to one electron, $y_{l m}$ are real spherical harmonic angular functions normalized such that $\left|y_{l m}\right|$ integrates to $2-\delta_{01}$, and $R_{l}$ are Slater-type radial functions normalized to unity

$$
\begin{equation*}
R_{l}(r)=\alpha^{n+3} /(n+2)!r^{n} \mathrm{e}^{-\alpha r}, \quad n=n_{l} \geq l . \tag{6}
\end{equation*}
$$

The $\kappa_{0}$ and $\kappa_{1}$ are dimensionless radial scaling coefficients (Coppens, Guru Row, Leung, Stevens, Becker \& Yang, 1979) that allow for contraction ( $\kappa>1$ ) or expansion $(\kappa<1$ ) of the spherical valence shell and the directed valence multipoles, respectively. The $r, \theta$ and $\varphi$ coordinates refer to local atom-centered Cartesian axes; this facilitates imposition of local noncrystallographic chemical symmetry constraints to reduce the number of variable parameters. The variable electron-distribution parameters are the populations $P_{v}$ and $P_{l m}$, and the contraction-expansion coefficients $\kappa_{0}$ and $\kappa_{1}$. Since the $y_{l m}$ with $l>0$ integrate to zero, net atomic charges are given by $q=N_{v}-\left(P_{v}+P_{00}\right)$, where $N_{v}$ is the neutral-atom number of valence electrons; unitcell electrical neutrality is maintained by requiring that $\sum_{a} \Delta q_{a}=0$ in each least-squares cycle (Coppens, 1977).

Pseudoatom models were fitted by least-squares minimization of $\chi^{2}=\sum w \Delta^{2}$, where $\Delta=\left|F_{o}\right|-$ $k^{-1}\left|F_{c}\right|$ and $w=1$, since the simulated $F_{o}$ data were 'error free'. The scale factor $k$ was included to allow for numerical correlation with the vibrational parameters, but in all cases $k$ converged to values that
differed from unity by less than 0.003 . Agreement statistics were the conventional crystallographic residual $R=\sum|\Delta| / \sum\left|F_{o}\right|$, the normalized r.m.s. error-of-fit $R_{w}=\left[\chi^{2} / \sum w\left|F_{o}\right|^{2}\right]^{1 / 2}$, and the standardized r.m.s. error-of-fit $Z=\left[\chi^{2} /(n-m)\right]^{1 / 2}$, where $n=2698$ unique reflection data to $d_{\text {min }}=\lambda /\left(2 \sin \theta_{\max }\right)=0.5 \AA$, and $m=170$ parameters, of which 124 were pseudoatom parameters. Since $w=1$ for the simulated data, we expect $Z \rightarrow 0$ at convergence, rather than $Z \rightarrow 1$ as we should expect with $w=1 / \sigma^{2}\left(\left|F_{o}\right|\right)$ for experimental data.
The only noncrystallographic constraint imposed on the pseudoatoms was that only four values of $\kappa_{0}$ and $\kappa_{1}$ were fitted, viz. for the four chemically distinct atom types P, O1, O2 ( $=\mathrm{O} 3=\mathrm{O} 4)$ and $\mathrm{H} 2(=\mathrm{H} 3=\mathrm{H} 4)$. The $P_{v}$ population parameters were deemed sufficient for describing interatomic charge transfers, and the $l=0$ valence monopole populations were fixed at $P_{00}=0$. Atomic scattering factors for the core and valence shells of the spherically averaged free atoms were from the HFSCF calculations of Clementi (1965).
The valence multipole expansions extended to $l_{\max }=4,3$ and 2, i.e. hexadecapoles, octupoles and quadrupoles, for the $\mathrm{P}, \mathrm{O}$ and H atoms, respectively. Preexponential radial orders $n_{l} \geq l$ for the $l=1,2, \ldots, l_{\text {max }}$ multipoles were $N_{l}=6,6,7,7$ for $\mathrm{P} ; 2,2,3$ for O ; and 1 , 2 for H . The rationale for these choices is discussed below. Radial exponential coefficients for $\mathrm{P}, \mathrm{O}$ and H were $\alpha=3.5,4.5$ and 2.3 bohr $^{-1}$, respectively, which are approximately twice the valence-shell-averaged orbital exponents from the HF-SCF atomic ground state wavefunctions of Clementi \& Raimondi (1963).

The least-squares refinements were carried out in a sequence of 13 three-cycle stages. Throughout, the $x_{i}$ and $U^{i j}$ parameters of the H atoms were held fixed at their values (Tables 1 and 4) from the experimental neutron analysis. At each stage the varied parameters were $k$ and: (1) $P_{v}$, (2) $\kappa_{0}$, (3) $P_{v}$, (4) $\kappa_{0}$, (5) $P_{l m}$, (6) $\kappa_{1}$, (7) $P_{l m}$, (8) $P_{v}+P_{l m}$, (9) $P_{v}+P_{l m}+$ non-H $\quad x_{i}$ and $U^{i j}$, (11) $\kappa_{0}+\kappa_{1}$, (12) $P_{v}+P_{l m}+$ non-H $x_{i}$ and $U^{i j}$, and, finally (13) all parameters except the H atom $x_{i}$ and $U^{i j}$.

## Radial modeling for the phosphorus pseudoatom

Since few pseudoatom analyses of phosphate molecules have been performed (Swaminathan \& Craven, 1984; Hansen, Protas \& Marnier, 1991; Klooster \& Craven, 1992; Klooster, 1992; Streltsov, Belokoneva, Tsirelson \& Hansen, 1993), we used the simulated static structure factors to investigate radial modeling of the phosphorus pseudoatom.
The Slater-type radial density functions (6), with $r$ replaced by $\kappa_{1} r$, give multipole maxima ( $\left(\mathrm{d} R_{l} / \mathrm{d} r=0\right)$ at radii $r_{\max l}=n_{l} /\left(\alpha \kappa_{1}\right)$, which depend on the chosen orders $n_{l}$ of the pre-exponential factor $r^{n}$ as well as on the chosen exponential coefficients $\alpha$ and fitted $\kappa_{1}$ values. Table 6 lists suitable choices for $\alpha$ values and Table 7

Table 6. Exponential coefficients $\alpha$ (bohr $^{-1}$ ) for Slatertype radial-density functions (6) from averaged orbital exponents $\zeta$ from wavefunctions for HF-SCF free atoms (Clementi \& Raimondi, 1963) and STO-NG small molecules (Hehre, Ditchfield, Stewart \& Pople, 1969)

|  | $\alpha=2 \zeta$ since $\rho \propto\|\psi\|^{2}$ |  |  |
| :--- | :---: | :---: | :---: |
| Valence |  | Free- <br> atom | Molecule- <br> optimized |
| shell | Atom | $\alpha$ | $\alpha$ |
| $K$-shell | H | 2 | $\alpha$ <br> $L$-shell |
|  | He | 3.38 | 2.48 |
|  | Li | 1.28 | 3.38 |
|  | Be | 1.91 | 1.60 |
|  | B | 2.52 | 2.30 |
|  | C | 3.18 | 3.00 |
|  | N | 3.84 | 3.42 |
|  | O | 4.47 | 3.90 |
|  | F | 5.11 | 4.50 |
|  | Ne | 5.76 | 5.10 |
|  | Na | 1.67 | 5.76 |
|  | Mg | 2.20 | 3.50 |
|  | Al | 2.73 | 3.40 |
|  | Si | 3.06 | 3.40 |
|  | P | 3.46 | 3.46 |
|  | S | 3.85 | 3.80 |
|  | Cl | 4.26 | 4.10 |
|  | Ar | 4.67 | 4.20 |
|  | Ar |  | 4.66 |

The differences between the free-atom and molecule-optimized values are large for H and the metallic elements, the valence shells of which are strongly contracted in the bound atoms. The differences are much smaller for the nonmetals, and they vanish for the noble gases.

Table 7. Values of $n=n_{l}$, as suggested by Hansen \& Coppens (1978) for Slater-type density-radial functions [(6) and (7)]

| Orbital | Density | Multipole | Density radial <br> product |
| :--- | :--- | :---: | :---: |
| multipole | order | pre-exponential |  |
| $n^{\prime} l^{\prime} n^{\prime \prime} l^{\prime \prime}$ | $R_{l} y_{l m}$ | $l$ | $r^{n}=r^{n^{\prime}+n^{\prime \prime}-2}$ |
| $2 s 2 s$ | Monopole | 0 | $r^{2}$ |
| $2 s 2 p$ | Dipole | 1 | $r^{2}$ |
| $2 p 2 p$ | Quadrupole | 2 | $r^{2}$ |
| $2 p 3 d$ | Octupole | 3 | $r^{3}$ |
| $3 d 3 d$ | Hexadecapole | 4 | $r^{4}$ |

gives $n_{l}$ values, as suggested by Hansen \& Coppens (1978). The suggested $n$ values are based on

$$
\begin{equation*}
r^{n}=r^{n^{\prime}-1} r^{n^{\prime \prime}-1}=r^{n^{\prime}+n^{\prime \prime}-2} \tag{7}
\end{equation*}
$$

for density functions corresponding to products ( $\psi_{n^{\prime}, 1}^{*} \psi_{n^{\prime \prime} l^{\prime \prime}}$ ) of Slater orbital wavefunctions $\psi_{n^{\prime}!}(r, \theta, \varphi)=N_{n^{\prime} l} r^{n^{\prime}-1} \mathrm{e}^{-\zeta r} Y_{l^{\prime} m^{\prime}}(\theta, \varphi)$, which have pre-exponential radial dependence $r^{n^{\prime}-1}$ by analogy with hydrogenic orbitals. The suggested values $n_{l}=2,2,2,3,4$ for $l=0,1,2,3,4$ satisfy the condition $n_{l} \geq 1$, which is required for proper Coulombic behavior satisfying Poisson's equation as $r \rightarrow 0$ (Stewart, 1977). These $n_{l}$ values have been found suitable for first-row atoms in numerous studies, and we adopted them for the O and H atoms.

For second-row atoms such as phosphorus, $n^{\prime}=n^{\prime \prime}=3$ for all valence orbitals, and the orbital product scheme (7) suggests $n_{l}=4$ for $l=0-4$. These $n_{l}$
are, however, too small for the P atom in $\mathrm{H}_{3} \mathrm{PO}_{4}$, as shown in Fig 3(a) by a map of the residual density

$$
\begin{equation*}
\Delta \rho(\mathbf{r})=V^{-1} \sum_{\mathbf{h}}\left(k\left|F_{o}\right|-\left|F_{c}\right|\right) \exp \left(i \varphi_{c}-2 \pi i \mathbf{h} \cdot \mathbf{r}\right) \tag{8}
\end{equation*}
$$

after a fit to the simulated static data. An extensive series of fitting trials, using different sets of $n_{l}$ for the $P$ atom and seeking to minimize the residual density, led finally to the set $n_{l}=6,6,7,7$ for $l=1,2,3,4$. Residual density features from this set, shown in Fig. 3(b), were reduced to levels comparable to usual levels of random experimental error. Of course, changing the $n_{l}$ values changed the fitted value of $\kappa_{1} \alpha$ : Expansion of the valence multipoles due to the larger $n_{l}$ was balanced by contraction due to a larger $\kappa_{1} \alpha$.

## Recovery of the theoretical electron density

With the empirically optimized $n_{l}$ values for phosphorus, the fit to the static simulated data gave the static deformation-density maps shown in Fig. 4. These maps show representative sections of the function

$$
\begin{equation*}
\Delta \rho(\mathbf{r})=\sum_{a=1}^{N} \rho_{a}\left(\mathbf{r}-\mathbf{r}_{a}\right)-\rho_{a}^{0}\left(\mathbf{r}-\mathbf{r}_{a}\right) \tag{9}
\end{equation*}
$$

where the $\rho_{a}$ are pseudoatom-modeled densities (4), and the $\rho_{a}^{0}$ are spherically averged $\mathrm{HF}-\mathrm{SCF}$ free-atom

Fig. 3. Residual density ( 8 ) in the ( $\mathrm{H}-) \mathrm{O} 2-\mathrm{P}=\mathrm{O}$ plane after pseudoatom fitting to the simulated static structure factor data with two different sets of $n_{l}$ values for the phosphorus pseudoatom.

| $n_{l}(\mathrm{P})$ |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :--- |
| $l=1,2,3,4$ | $R$ | $R_{w}$ | $Z$ | $k^{-1}$ | $\kappa_{1} \alpha(\mathrm{P})$ |
| $(a) 4,4,4,4$ | 0.0040 | 0.0041 | 0.06 | 0.9995 | 2.96 bohr $^{-1}$ |
| (b) $6,6,7,7$ | 0.0032 | 0.0035 | 0.05 | 0.9988 | 4.18 |

The two fitted values of $\kappa_{1} \alpha$ bracket both the valence-shell averaged value $2 \zeta=3.46$ bohr $^{-1}$ for a free, ground state, HF-SCF P atom (Clementi \& Raimondi, 1963) and the standard molecule-optimized value $2 \zeta=3.80$ bohr $^{-1}$ for STO-NG P atoms (Hehre et al., 1969). Our pseudoatom-optimized value $\kappa_{1} \alpha=4.18 \mathrm{bohr}^{-1}$ with $n_{l}=6,6,7,7$ for $l=1,2,3,4$ in fact agrees closely with the molecule-optimized value $2 \zeta=4.06 \mathrm{bohr}^{-1}$ obtained by Hehre et al. (1969) from STO-3G and STO-4G calculations for $\mathrm{H}_{3} \mathrm{PO}_{4}$. Contour interval $0.025 \mathrm{e}^{\AA^{-3}}$; zero contour omitted, negative contours dotted and positive contours solid. (a) $-0.28 \leq \Delta \rho \leq+0.14$ and $\sigma(\Delta \rho)=0.021 ; \quad$ (b) $\quad-0.09 \leq \Delta \rho \leq+0.09 \quad$ and $\quad \sigma(\Delta \rho)=$ $0.014 \mathrm{e} \AA^{-3}$.
densities. The function (9) from the pseudoatom model is to be compared with (1) from the molecular wavefunction.

The close similarity of Figs. 4(a) and (b) to Figs. 2(a) and ( $b$ ) shows how well the pseudoatom modeling recovers the wavefunction density that was incorporated into the simulated structure factors. The most noteworthy of the small differences between the two sets of maps are: (1) Sharp features very close to ( $\sim 0.1 \AA$ from) the $P$ and O nuclear positions in the infinite-resolution wavefunction maps are not reproduced in the finite-resolution $\left[d_{\min }=\lambda /\left(2 \sin \theta_{\max }\right)=0.5 \AA\right] \quad$ pseudoatom maps. (2) The density along the $\mathrm{O}-\mathrm{H}$ bonds peaks $\sim 0.2 \mathrm{e} \AA^{-3}$ higher and $\sim 0.15 \AA$ closer to the H atom in the pseudoatom maps than in the wavefunction maps. This is because a spherically contracted $\quad \zeta=$ 1.15 bohr $^{-1}$ ) H atom (Stewart, Davidson \& Simpson, 1965) was subtracted from the pseudoatom density, while an uncontracted ( $\zeta=1 \mathrm{bohr}^{-1}$ ) H atom was subtracted from the wavefunction density. (3) Peak densities along the $\mathrm{P}=\mathrm{O}$ and $\mathrm{P}-\mathrm{O}(\mathrm{H})$ bonds and in the $\left(\mathrm{P}-\mathrm{O}(-\mathrm{H})\right.$ atom lone-pair regions are $\sim 0.1 \mathrm{e} \AA^{-3}$ lower from the pseudoatom fit than from the wavefunction. This may be at least partly because Gaussian approximations to free-atom densities were subtracted from the Gaussian wavefunction density, while HF-SCF atomic densities were subtracted from the pseudoatommodeled density.

## Deconvolution of nonspherical electron distribution from anisotropic vibrational smearing

The maps shown in Fig. 4 resulted from the 13-stage pseudoatom fit to the simulated static data, with the atomic positional parameters fixed at the experimental neutron diffraction values (Table 2) and the vibrational displacement parameters fixed at zero. To test the deconvolution from anisotropic thermal smearing, the pseudoatom model from the fit to the simulated static data was used as a starting point for refinements with the

Fig. 4. Static deformation density (9) in the planes (a) $(\mathrm{H}-) \mathrm{O} 2-\mathrm{P}=\mathrm{O}$ and (b) $\mathrm{P}-\mathrm{O} 2-\mathrm{H}$ from our best pseudoatom fit [Fig. 3(b)] to the simulated static structure factors. Contours as in Fig. 2. Compare with Figs. 2(a) and (b).
simulated 75,150 and 300 K dynamic data. These refinements were begun with a refinement of the $U^{i j}$ of all atoms - including H atoms - with the positional and pseudoatom density parameters fixed. This was then followed by the 13 -stage pseudoatom refinement. The pseudoatom parameters, which are tabulated in the deposited supplementary material, remained very stable
in these refinements, as can be seen by comparing Figs. $5(a),(c)$ and (e) with Fig. 4(a). $U^{i j}$ also refined to proper values, as indicated in Table 8. The fitted $U^{i j}$ differed from the values given in Table 4 by at most $\sim 1 \%$ for the non- H atoms and $\sim 10 \%$ for the H atoms.

As a further test of the deconvolution, each of the simulated dynamic data sets was independently treated

Fig. 5. Static deformation density (9) in the $(\mathbf{H}-) \mathrm{O} 2-\mathrm{P}=\mathrm{O}$ plane after pseudoatom fitting to the simulated dynamic structure factor data: (a) and (b) 75 K , (c) and (d) 150 K , and $(e)$ and $(f) 300 \mathrm{~K}$. Contours as in Fig. 2. For refinements $(a),(c)$ and ( $e$ ) the starting model was the pseudoatom model fitted to the simulated static data. For refinements $(b),(d)$ and $(f)$ the starting model was a sphericalatom model fitted to the respective simulated dynamic data set.

just as the experimental $\mathrm{H}_{3} \mathrm{PO}_{4}$ data set described in the accompanying paper (Souhassou, Espinosa, Lecomte \& Blessing, 1995): With the H atom $x_{i}$ and $U^{i j}$ fixed at their neutron diffraction values, the non-H atom $x_{i}$ and $U^{i j}$ were refined, starting from the neutron values and fitting the spherical-atom model to the high-angle data with $(\sin \theta) / \lambda \geq 0.8 \AA^{-1}$. The 13-stage pseudoatom refinements were then carried out from the spherical-atom starting points. $U^{i j}$ again refined properly, as indicated in Table 8, and the pseudoatom model gave very much the same results as the earlier refinements, as can be seen in Figs. $5(b),(d)$ and $(f)$. The most noticeable difference was the strong, tight density dipole that developed at the O 1 atom of the $\mathrm{P}=\mathrm{O}$ phosphoryl group in the fit to the simulated 300 K data [Fig. $5(f)$ ]. This corresponded to the O atom refining to a false position $0.00037 \AA$ too close to the P atom, as shown in Table 9. This tendency was also just barely perceptible in the fit to the simulated 150 K data, which gave a much smaller tight dipole at O1 [Fig. $5(d)$ ] and shortened $\mathrm{P}=\mathrm{O}$ by $0.0008 \AA$ (Table 9).

Apart from these small correlated errors in the position and the dipolar deformation density of the phosphoryl O atom, the pseudoatom model very effectively recovered the theoretical electron density that went into the calculation of the simulated structure factors. The multipolar valence-density features were effectively deconvoluted from anisotropic vibrational smearing, even up to $T \approx 300 \mathrm{~K}$ at which temperature the r.m.s. atomic displacement in crystalline $\mathrm{H}_{3} \mathrm{PO}_{4}$ is $\left\langle u^{2}\right\rangle^{1 / 2} \approx 0.16 \AA$.

We thank Professors Robert Stewart and Harry King for helpful discussions. We are also grateful for the support of this research by USDHHS PHS NIH grants GM34073 (RHB, MS and CL) and DK 19856 (GRM and RHB) and by a project grant DGICYT PB90-0134 and a fellowship from the Commissionat per a Universitats Recerca de la Generalitat de Catalunya (EE).

Table 9. Bond lengths ( $\AA$ ) in the hypothetical static $\mathrm{H}_{3} \mathrm{PO}_{4}$ molecule and changes from them $(\AA)$ after first spherical-atom then pseudoatom refinements with the simulated structure factors

|  | Fixed bond lengths |  | Refined changes |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Static | 75 K | 150 K | 300 K |
| $\mathrm{P}=\mathrm{Ol}$ | 1.4958 | 0.0003 | -0.0008 | -0.0037 |
| $\mathrm{P}-\mathrm{O} 2$ | 1.5461 | 0.0007 | 0.0005 | 0.0005 |
| $\mathrm{P}-\mathrm{O} 3$ | 1.5458 | 0.0007 | 0.0005 | 0.0003 |
| $\mathrm{P}-\mathrm{O} 4$ | 1.5497 | 0.0009 | 0.0007 | 0.0007 |
| $\mathrm{O} 2-\mathrm{H}$ | 1.0146 | -0.0001 | -0.0006 | -0.0005 |
| $\mathrm{O} 3-\mathrm{H}$ | 1.0044 | -0.0001 | -0.0006 | -0.0003 |
| $\mathrm{O} 4-\mathrm{H}$ | 0.9479 | -0.0002 | -0.0006 | -0.0005 |
