# The Compositional Dependence of Octahedral Tilting in Orthorhombic and Tetragonal Perovskites 

Noel W. Thomas<br>School of Materials, University of Leeds, Leeds LS2 9JT, England<br>(Received 6 August 1994; accepted 10 May 1995)

#### Abstract

A new parameterization is defined for the quantitative description of octahedral tilting in orthorhombic and tetragonal perovskites. It contains six parameters, $s_{1}, s_{2}$, $s_{3}, \theta_{x}, \theta_{y}$ and $\theta_{z} . s_{1}, s_{2}$ and $s_{3}$ refer to the lengths of the lines or 'stalks' joining pairs of opposite octahedral vertices, and $\theta_{x}, \theta_{y}$ and $\theta_{z}$ to the angles subtended by these stalks with pseudo-cubic axes $x, y$ and $z$. An equation is derived for the dependence of polyhedral volume ratio, $V_{A} / V_{B}$, on these parameters: $V_{A} / V_{B}=6 \cos ^{2} \theta_{m} \cos \theta_{z}-1$, where $\theta_{m}=\left(\theta_{x}+\theta_{y}\right) / 2$. To a good approximation, lengths $s_{1}, s_{2}$ and $s_{3}$ do not affect $V_{A} / V_{B}$. The validity of this equation is tested by reference to the known crystal structures of 48 ternary oxide and fluoride perovskites, and its versatility demonstrated by application to the structures of some ternary palladium and platinum hydrides. The relationship of the approach to Glazer's system of nomenclature for octahedral tilting in perovskites is considered, in particular concerning the numbers of tilts operative in a given structure. A comparison is also made with the parameterization proposed for octahedral tilting and distortion in rhombohedral perovskites [Thomas \& Beitollahi (1994). Acta Cryst. B50, 549-560]. Factors governing the choice of rhombohedral or orthorhombic symmetry are discussed, with the significance of rhombohedral symmetry in obtaining ferroelectric properties brought out. Through the compilation of a table of $A \mathrm{O}_{12}$ and $B \mathrm{O}_{6}$ polyhedral volumes, the prospect is identified of predicting both the degree of octahedral tilting and the likelihood of ferroelectric behaviour for novel, hypothetical oxide compositions.

## 1. Introduction

Perovskites are of widespread interest, not least because of their diverse physical and chemical properties. Moreover, a quantitative study of their crystal structures is particularly relevant to physical properties such as ferroelectricity, antiferroelectricity, piezoelectricity and optical activity, since these are fundamentally due to the dipole moments caused by ionic displacements. Earlier work (Thomas, 1989) has shown that the structures of perovskites ( $A B X_{3}$ ) may be meaningfully analysed in
terms of the volumes of the $A X_{12}$ and $B X_{6}$ cation coordination polyhedra, thereby giving insight into the compositional dependence of their crystal structures. The approach provides a framework for relating chemical composition with physical properties, where the mechanism of the relationship can be analysed in terms of the crystal structure. This capability is an important contribution to the chemical design of perovskites for particular desirable physical applications.

In essence, the perovskite structure consists of a threedimensionally linked network of $B X_{6}$ octahedra, with $A$ ions forming $A X_{12}$ cuboctahedra to fill the spaces between the octahedra. In view of these inviolable topological and geometrical constraints, there are only three structural degrees of freedom:
(a) displacement of cations $A$ and $B$ from the centres of their cation coordination polyhedra, $A X_{12}$ and $B X_{6}$;
(b) distortions of the anionic polyhedra coordinating $A$ and $B$ ions;
(c) tilting of the $B X_{6}$ octahedra about one, two or three axes.
In ferroelectric phases of rhombohedral symmetry, displacements ( $a$ ) and distortions (b) are correlated, so that relatively larger $B$ ions can be stabilized at an offcentre position. Potential energy calculations reveal also that parallel $A$ - and $B$-ion displacements, along the trigonal axis, are more favourable than anti-parallel displacements. In addition, any tilting of octahedra (c) in rhombohedral perovskites (whether ferroelectric or not) can be described by a single tilt angle about the trigonal axis (Thomas \& Beitollahi, 1994). Orthorhombic perovskites, by comparison, present a wider range of polyhedral distortions and tilting possibilities, which form the subject matter of this article. As well as orthorhombic perovskites, tetragonal perovskites with octahedral tilting are also considered, since the definition of tilt angles is identical in both cases.

The treatment and discussion of octahedral tilting in perovskites was initiated by Megaw $(1966,1969)$ and developed by Glazer (1972, 1975). The latter work demonstrated that the space group was largely determined by the pattern of octahedral tilting. Furthermore, a classification of octahedral tilting in terms of ten alternative tilt systems was proposed. Regular $B X_{6}$ octahedra were assumed, with all tilts considered as
combinations of component tilts about the three pseudocubic axes. Since the atomic coordinates in the final tilt arrangement depended on the order in which the component tilt operations were carried out, the approach was intended for a description of structures, rather than their quantitative derivation (Glazer, 1972). The definition of tilt angles employed here differs from Glazer's, since the objective is to formulate a quantitative relationship between tilting and polyhedral volume ratio.

The strength of Glazer's parameterization lies in the ease with which an evaluation of the numbers and directions of tilts may be carried out. It is intended that the alternative definition of tilt angles used here is sufficient to calculate the polyhedral volume ratio, $V_{A} / V_{B}$, but not to regenerate the coordinates of all ions unambiguously. This capability would require additional information about the axes of rotation, which would be too cumbersome to be quoted routinely. The parameterization to be developed here can also take octahedral irregularities into account, as the values of the tilt angles are derived by computational analysis of experimental structural data.

In articulating the quantitative relationship between octahedral tilt angles and $V_{A} / V_{B}$, the dependence of the various manifestations of octahedral tilting on chemical composition can be understood. The quantitative framework thus developed is sufficiently general to be applied to all perovskites in which tilting occurs. This generality is demonstrated by applying the analysis not merely to metal oxides and fluorides, but also to some novel ternary platinum and palladium hydrides, which have been found to crystallize with tilted perovskite structures.

## 2. Method

### 2.1. Derivation of the relationship between $V_{A} / V_{B}$ and octahedral tilt angles

The polyhedral volume ratio, $V_{A} / V_{B}$, is obtained by dividing the volume of the $A X_{12}$ cation coordination polyhedron by that of the $B X_{6}$ coordination polyhedron. Further, a feature of perovskites is that these polyhedra fill space (Thomas, 1989), such that

$$
\begin{equation*}
V_{u}=Z\left(V_{A}+V_{B}\right) . \tag{1}
\end{equation*}
$$

It follows that the ratio $V_{A} / V_{B}$ can be derived by calculating the unit-cell volume $V_{u}$ and the octahedral volume $V_{B}$.

The parameterization requires six parameters (Fig. 1): $s_{1}, s_{2}, s_{3}$ : separations of three pairs of opposite octahedral vertices (lengths of three 'octahedral stalks'); $\theta_{x}, \theta_{y}, \theta_{z}$ : tilt angles, defined as angles between octahedral stalks and pseudo-cubic axes $x, y$ and $z$. The structures of all perovskites, regardless of their symmetry, may be referred to a pseudocubic cell ( $a_{p} \approx b_{p} \approx c_{p}$, $\alpha \approx \beta \approx \gamma \approx 90^{\circ}$ ), whose axes are oriented closest to
the lines joining opposite octahedral vertices (stalks). Fig. 1 is a schematic representation of a typical tilted structure. It shows a projection of a three-dimensional tilt system in the $x y$ plane, referred to pseudo-cubic axes. The relevant pseudo-cubic cell is drawn as a solid line. $\theta_{x}$ and $\theta_{y}$ are the two angles subtended by the two octahedral 'stalks' lying close to or in the $x y$ plane with the $x$ and $y$ axes, i.e. $\theta_{x}$ corresponds to $\angle A B C$ and $\theta_{y}$ to $\angle D E F$. The + and - signs denote schematically the $z$ heights of octahedral vertices, either above ( + ) or below $(-)$ the $x y$ plane, according to a possible tilt system. This particular system is consistent with a smaller unit cell of orthorhombic symmetry, delineated with dashed lines. $s_{1}$ and $s_{2}$ represent the lengths of the two octahedral stalks lying close to the $x y$ plane, with $s_{3}$ (not shown) referring to the stalk closest in orientation to the plane-normal, i.e. the pseudo-cubic $z$ axis. Whenever $s_{1} \neq s_{2}, \theta_{x} \neq \theta_{y}$.

It is assumed for the derivation of the relationship between $V_{A} / V_{B}$ and tilt angles $\theta_{x}, \theta_{y}$ and $\theta_{z}$ that the three octahedral stalks intersect at right angles. In general, this is only a small approximation. Given this assumption, inspection of Fig. 1 reveals that the angles between the $x$ and $y$ axes of the pseudo-cubic cell are $90^{\circ} \pm\left(\theta_{y}-\theta_{x}\right)$, with the area of the cell face in the $x y$ plane equal to $a_{\mathrm{pc}} b_{\mathrm{pc}} \sin \left(\pi / 2-\left(\theta_{y}-\theta_{x}\right)\right)=a_{\mathrm{pc}} b_{\mathrm{pc}} \cos \left(\theta_{y}-\theta_{x}\right)$. Inspection of Fig. 1 reveals that

$$
\begin{equation*}
a_{\mathrm{pc}}=b_{\mathrm{pc}}=s_{1} \cos \theta_{x}+s_{2} \cos \theta_{y} . \tag{2}
\end{equation*}
$$

Since all the octahedral stalks subtending smallest angles with the $z$ axis have length $s_{3}$, the $z$ axis is unique in this parameterization. This is to be compared with the $x$ and $y$ axes, along which the stalks subtending smallest angles alternate between lengths $s_{1}$ and $s_{2}$. Thus

$$
\begin{equation*}
c_{\mathrm{pc}}=2 s_{3} \cos \theta_{z} . \tag{3}
\end{equation*}
$$

Fig. 1. Definition of parameters $s_{1}, s_{2}, \theta_{x}$ and $\theta_{y}$ used to quantify octahedral tilting.

It follows that the pseudo-cubic cell constructed as above contains eight whole octahedra, i.e. $Z_{\mathrm{pc}}=8$. In cases where $\theta_{2}=0$, the $c$ cell parameter is equal to $c_{\mathrm{pc}} / 2$, i.e. $Z_{\mathrm{pc}}=4$. Other cases, where $Z_{\mathrm{pc}}=16$, or where $a_{\mathrm{pc}} \neq b_{\mathrm{pc}}$, are a consequence of either different tilt systems or of particular patterns of cation displacement. For the general development of the argument, however, it is assumed that $Z_{\mathrm{pc}}$ is equal to 8 .

The volume of the pseudo-cubic cell is given by

$$
\begin{equation*}
V_{u}=2\left(s_{1} \cos \theta_{x}+s_{2} \cos \theta_{y}\right)^{2} s_{3} \cos \theta_{z} \cos \left(\theta_{y}-\theta_{x}\right) \tag{4}
\end{equation*}
$$

Thus, the polyhedral volume ratio $V_{A} / V_{B}=$ $\frac{1}{8}\left(V_{u}-8 V_{B}\right) / V_{B}=V_{u} / 8 V_{B}-1$. As the three octahedral stalks are regarded as perpendicular to one another, $V_{B}=s_{1} s_{2} s_{3} / 6$ and

$$
\begin{align*}
V_{A} / V_{B}= & (3 / 2)\left[\left(s_{1} \cos \theta_{x}+s_{2} \cos \theta_{y}\right)^{2} / s_{1} s_{2}\right]  \tag{5}\\
& \times \cos \theta_{z} \cos \left(\theta_{y}-\theta_{x}\right)-1
\end{align*}
$$

Since $\theta_{x}$ and $\theta_{y}$ differ only slightly as a result of unequal $s_{1}$ and $s_{2}$ values, $\theta_{x}$ may be written as $\theta_{m}-\Delta$ and $\theta_{y}$ as $\theta_{m}+\Delta$, where $\theta_{m}$ is the mean of $\theta_{x}$ and $\theta_{y}$ and $\Delta$ is a very small angle. This permits a re-expression of the $s_{1} \cos \theta_{x}+s_{2} \cos \theta_{y}$ term in (5) as

$$
\begin{equation*}
\left(s_{1}+s_{2}\right) \cos \theta_{m} \cos \Delta+\left(s_{1}-s_{2}\right) \sin \theta_{m} \sin \Delta \tag{6}
\end{equation*}
$$

Since the second of these two terms is a product of three factors, two of which are very small, i.e. $s_{1}-s_{2}$ and $\sin \Delta$, it is considerably smaller than the first term and may be disregarded. It is also a very good approximation to write $\cos \Delta=1$. (5) can thus be simplified as

$$
\begin{equation*}
V_{A} / V_{B}=(3 / 2)\left[\left(s_{1}+s_{2}\right)^{2} / s_{1} s_{2}\right] \cos ^{2} \theta_{m} \cos \theta_{2} \cos 2 \Delta-1 \tag{7}
\end{equation*}
$$

Since the difference between $s_{1}$ and $s_{2}$ is generally not very large, the dependence of the $V_{A} / V_{B}$ ratio on the stalk lengths is weak, since $\left(s_{1}+s_{2}\right)^{2} / s_{1} s_{2} \simeq 4$. Writing $\left(s_{1}+s_{2}\right)^{2} / s_{1} s_{2}$ as equal to 4 and $\cos 2 \Delta$ equal to 1 (i.e. disregarding deviations of $\gamma_{\mathrm{pc}}$ from $90^{\circ}$ ), it follows that

$$
\begin{equation*}
V_{A} / V_{B}=6 \cos ^{2} \theta_{m} \cos \theta_{z}-1 \tag{8}
\end{equation*}
$$

Thus, the polyhedral volume ratio $V_{A} / V_{B}$ is determined largely by the average of tilt angles $\theta_{x}$ and $\theta_{y}$ in the $x y$ plane, $\theta_{m}$, and the angle subtended by the octahedral axes of length $s_{3}$ with the $z$ axis, $\theta_{z}$. The prediction is that the polyhedral volume ratio $V_{A} / V_{B}$ has the value 5 in the absence of tilting, falling to lower values in structures with tilted octahedra.

## 3. Examination of experimentally determined structures

Structures to be examined fall into two categories: (i) metal oxides and fluorides and (ii) hydrides of platinum or palladium with alkali ions. Although the
former compounds are more prevalent as perovskites, the second category is included to demonstrate the versatility of the methodology.

## (i) Metal oxides and fluorides

Table 1 gives the space groups, temperatures and derived pseudo-cubic cell constants for 48 orthorhombic and tetragonal oxides and fluorides, with structures retrieved from the Inorganic Crystal Structure Database (ICSD). Data for the final structure, $\mathrm{PbZrO}_{3}$, were taken from a recent publication by Glazer, Roleder \& Dec (1993). Atomic coordinates and pseudo-cubic cell constants were generated computationally in a four-stage procedure: (i) resetting, where necessary, of unit-cell axes as given in the ICSD into the standard setting; (ii) generation, from the symmetry operations of the relevant space group, of all the atomic coordinates within the orthorhombic or tetragonal unit cell; (iii) generation of atomic coordinates of nearest-neighbour translationally related unit cells and identification of the appropriate pseudo-cubic cell from these; (iv) calculation of pseudocubic lattice parameters and re-expression of atomic coordinates in terms of these.

In all cases, apart from space group 63 ( Cmcm ), $a_{\mathrm{pc}}=b_{\mathrm{pc}}$ and in all cases, $\alpha_{\mathrm{pc}}=\beta_{\mathrm{pc}}=90^{\circ}$. Except for the two $\mathrm{PbZrO}_{3}$ structures, $a_{\mathrm{pc}}$ is of the order $8 \AA$, indicating that the pseudo-cubic cell corresponds to $2 \times 2$ octahedra in the $x y$ plane, as shown in Fig. 1. Cells with $Z_{\mathrm{pc}}=4$ are associated with structures in which $\theta_{z}=0$. Since most structures have $Z_{\mathrm{pc}}$ values of 8, they are characterized by non-zero values of $\theta_{x}, \theta_{y}$ and $\theta_{z}$. Values of $Z_{\mathrm{pc}}$ greater than 8 are to be found in the $\mathrm{PbZrO}_{3}$ structures and in the room-temperature structure of $\mathrm{NaNbO}_{3}$. In the former, structures with $4 \times 4$ octahedra in the $x y$ plane are found, together with a non-zero $\theta_{z}$ value. The doubling of the $a_{\mathrm{pc}}$ axis is due to cationic displacements, rather than to the adoption of a complex octahedral tilting system. In the latter, a doubling of the $c_{\mathrm{pc}}$ axis is observed, corresponding to the adoption of a complex tilt system.

Examination of Table 1 reveals that the commonest space group is no. 62 (Pnma). For this reason, stalk lengths, tilt angles and polyhedral volumes for structures in this space group are listed separately from other structures, in Table 2. In Table 2, $s_{1}, s_{2}$ and $s_{3}$ correspond to octahedral stalk lengths as defined in equations (2) and (3). The factor $\left(s_{1}+s_{2}\right)^{2} / s_{1} s_{2}$ is equal to 4.000 in all structures, apart from three, $\mathrm{NaTaO}_{3}$ (ICSD No. 9090), $\mathrm{GdFeO}_{3}$ and $\mathrm{NaZnF}_{3}$, indicating that the approximation made in proceeding from equation (7) to (8) is a good one. In the first of these structures, the $\mathrm{TaO}_{6}$ octahedra are extremely distorted, to an extent not found in any other structure. For all structures, $\theta_{m}$ and $\theta_{2}$ values can be substituted into (8) to obtain the theoretical polyhedral volume ratio $\left[V_{A} / V_{B}\right]^{t}$. This is to be compared with the actual polyhedral volume ratio, $\left[V_{A} / V_{B}\right]^{a}$, which is

obtained by dividing $V_{A}$ by $V_{B} . V_{A}$ and $V_{B}$ are calculated computationally, using the methodology defined in an earlier paper (Thomas, 1991a). Agreement between $\left[V_{A} / V_{B}\right]^{a}$ and $\left[V_{A} / V_{B}\right]^{t}$ is generally very good, with most discrepancies, $\Delta\left[V_{A} / V_{B}\right]=\left[V_{A} / V_{B}\right]^{l}-\left[V_{A} / V_{B}\right]^{a}$, less than $\pm 0.003$. The main source of discrepancy lies in the approximation in the derivation of (8) that the three octahedral stalks, of lengths $s_{1}, s_{2}$ and $s_{3}$, intersect at right angles. This constraint is not imposed by Pnma symmetry, however, where small deviations from normal intersection frequently occur. The deviation from perpendicular intersection is quantified by the parameter
$\Delta_{\text {perp }}=1-\sin \alpha_{x y} \sin \alpha_{y z} \sin \alpha_{z x}$, as given in the righthand column of Table 2. $\alpha_{x y}$ represents the angle between the octahedral stalk of orientation closest to that of the $x$ axis and the stalk oriented closest to the $y$ axis etc. Thus, for perpendicular intersection of all three stalks, this parameter is equal to zero.

The largest discrepancy is found in the structure $\mathrm{NaTaO}_{3}$ (ICSD No. 9090), where $\Delta\left[V_{A} / V_{B}\right]=-0.478$, and in which the factor $\left(s_{1}+s_{2}\right)^{2} / s_{1} s_{2}$ also shows its largest deviation from 4. It is not immediately apparent why the room-temperature phase of $\mathrm{NaTaO}_{3}$ should have such distorted octahedra, particularly as the associated

octahedral volume, $V_{B}$, at $9.3647 \AA^{3}$, is significantly smaller than values for the three higher temperature structures (see Table 4).

In focusing on octahedral tilts and polyhedral volumes, only the positions of the anions ( $\mathrm{O}^{2-}$ or $\mathrm{F}^{-}$) are being taken into account. A full treatment of the structures also requires a consideration of the positions of the $A$ and $B$ cations within their coordination polyhedra, particularly as cationic displacements have a significant influence on physical properties such as ferroelectricity and antiferroelectricity. Such information is presented in Table 3, where use is made of the quantities quadratic elongation ( QE ) and bond angle variance (BAV). As introduced by Robinson, Gibbs \& Ribbe (1971) and applied previously to perovskites (Thomas, 1989), these parameters are defined as

$$
\begin{equation*}
\mathrm{QE}, \lambda=\sum_{i=1}^{n}\left(l_{1} / l_{0}\right)^{2} / n \tag{9}
\end{equation*}
$$

and

$$
\begin{equation*}
\mathrm{BAV}, \sigma=\sum_{i=1}^{n}\left(\theta_{i}-\theta_{0}\right)^{2} /(n-1) . \tag{10}
\end{equation*}
$$

It is conventional to define $l_{0}$ and $\theta_{0}$ as cation-anion bond lengths and anion-cation-anion bond angles in regular coordination polyhedra. However, in calculating the values in Tables 3 and $5, l_{0}$ and $\theta_{0}$ correspond to average values for the polyhedra concerned. This is
thought to be more appropriate for $A \mathrm{O}_{12}$ cuboctahedra in tilted systems, where deviations from regularity are considerable.

Table 3 is divided essentially into two parts, with columns 3-7 referring to $A O_{12}$ cuboctahedra and 8-12 to $B \mathrm{O}_{6}$ octahedra. $\mathrm{QE}^{i}(A)$ refers to the quadratic elongation of cation $A$ with the cation at its experimentally determined position, whereas $\mathrm{QE}^{8}(A)$ refers to the quadratic elongation which would arise if the ion were located at the geometrical centre of its coordination polyhedron. It is thus a measure of the distortion of the coordination polyhedron itself, independent of the position of the cation. Further, a value of $\mathrm{QE}^{i}(A)$ greater than $\mathrm{QE}^{g}(A)$ is indicative of a displacement of the $A$ cation from the centre of its coordination polyhedron. The magnitude of this displacement is given in the column headed $\operatorname{dsp}^{i}(A)$, with non-zero values obtained for all the structures in space group 62. Bond angle variances, calculated for angles in degrees, are typically greater than 100 for $A$ ions in the structures, indicating significant deviations from a regular geometry. These characteristics are to be contrasted with those of the $\mathrm{BO}_{6}$ octahedra, where the $B$ ions are always located at the centres of their respective conrdination octahedra. This is a consequence of the geometrical centres of the octahedra being located at positions of point symmetry $\overline{1}$ [Wyckoff position 4(b) in Pnma], whereby off-centre $B$-ion displacements and therefore dipole moments are precluded. It is to be noted that the octahedral distortions

inherent in the $\mathrm{NaTaO}_{3}$ room-temperature structure are reflected by the values of $\mathrm{QE}^{i}(B), \mathrm{QE}^{8}(B), \mathrm{BAV}^{i}(B)$ and $B A V^{8}(B)$ observed.

A similar treatment is given in Tables 4 and 5 for oxides and fluorides not in space group 62. In cases where there is more than one symmetry-independent $A \mathrm{O}_{12}$ and/or $B \mathrm{O}_{6}$ polyhedron, $\Delta\left[V_{A} / V_{B}\right]$ values are referred to mean $\left[V_{A} / V_{B}\right]^{a}$ values. The magnitudes of $\Delta\left[V_{A} / V_{B}\right]$ are generally small, indicating good agreement between equation (8) and experimentally determined structures. The two obvious exceptions are $\mathrm{PbZrO}_{3}$ (ICSD No. 15284) and $\mathrm{KCuF}_{3}$, with $\Delta\left[V_{A} / V_{B}\right]$ values of -0.057 and -0.049 , respectively. In the former case, the octahedra are very distorted, with $\Delta_{\text {perp }}=9.649 \times 10^{-3}$. Furthermore, the octahedral stalks do not intersect, which is not reflected in the value of $\Delta_{\text {perp. }}$. It is to be noted that, in the most recent structural determination of $\mathrm{PbZrO}_{3}$ (reference 25 in Table 1), the $\mathrm{ZrO}_{6}$ octahedra are less distorted, with a lower $\Delta\left[V_{A} / V_{B}\right]$ value. However, the octahedral stalks still do not intersect one another. Unique to this structural solution is the assumption of disorder between two substructure components (Glazer, Roleder \& Dec, 1993). The large magnitude of $\Delta\left[V_{A} / V_{B}\right]$ in $\mathrm{KCuF}_{3}$ is due entirely to the significant deviation of the $\left(s_{1}+s_{s}\right)^{2} / s_{1} s_{2}$ factor from 4.

It is seen in Table 5 that non-zero $\mathrm{dsp}^{i}(B)$ values are allowed in many of the space groups, in contrast to space group 62 (see Table 3). Non-zero $A$-ion displacements are found in all space groups apart from 59, 127
and 140, although $B$-ion displacements can occur in the first of these.

## (ii) Hydrides of platinum or palladium with alkali ions

Recent work concerning the synthesis and structures of some ternary platinum and palladium hydrides has revealed tilted perovskite-like structures, $A B X_{3}$, in which alkali metal cations $\left(\mathrm{K}^{+}, \mathrm{Rb}^{+}, \mathrm{Cs}^{+}\right)$serve as $X$ ions (as do the $\mathrm{O}^{2-}$ and $\mathrm{F}^{-}$anions above), with hydride or deuteride anions acting as $B$ ions and $\left[\mathrm{PdH}_{2}\right]^{2-},\left[\mathrm{PdH}_{4}\right]^{2-}$ or $\left[\mathrm{PtH}_{4}\right]^{2-}$ complex ions (or their deuteride equivalents) acting as $A$ ions. Despite the rôle-reversal of cations and anions, the analysis can also be applied to these systems, as given in Tables 6 and 7.

Table 6 gives, in the main, the room-temperature crystallographic data for three classes of compound: (i) $A_{3} \mathrm{PdD}_{3} \quad\left(A=\mathrm{K}^{+}, \mathrm{Rb}^{+}\right)$; (ii) $A_{3} \mathrm{PtD}_{5} \quad\left(A=\mathrm{K}^{+}\right.$, $\left.\mathrm{Rb}^{+}, \mathrm{Cs}^{+}\right)$; (iii) $A_{3} \mathrm{PdD}_{5}\left(A=\mathrm{Rb}^{+}\right)$. The predominant space group is no. $127(P 4 / m b m)$, with $Z_{p c}=4$, indicating that $\theta_{z}=0 . \quad A_{3} \mathrm{PdD}_{3}$ compounds, by comparison, crystallize in either space group 136 or 139, where $Z_{\mathrm{pc}}=8$. Agreement between $\left[V_{A} / V_{B}\right]^{a}$ and $\left[V_{A} / V_{B}\right]^{t}$ in Table 7 is excellent for the compounds in space group 127, good for $\mathrm{K}_{3} \mathrm{PdD}_{3}$ and $\mathrm{Rb}_{3} \mathrm{PdD}_{3}$ (room temperature) and rather poor for the cubic phase of $\mathrm{Rb}_{3} \mathrm{PdD}_{3}$ (at 473 K ). The $\Delta\left[V_{A} / V_{B}\right]$ value of -0.092 is directly attributable to the large octahedral distortion, with $\Delta_{\text {perp }}=1.508 \times 10^{-2}$.

* Average value. †This structure is considered to be disordered, with two substructure components ( $a$ ) and ( $b$ ), each belonging to space group 55 .

Three trends are observed in the $V_{A}, V_{B}$ and $V_{A} / V_{B}$ values: (i) values of $V_{B}$ follow the expected variation with changing $X$ ion $\left(\mathrm{K}^{+}, \mathrm{Rb}^{+}, \mathrm{Cs}^{+}\right): V\left(\mathrm{DK}_{6}\right)$ (values 27.2590 and $\left.28.2334 \AA^{3}\right)<V\left(\mathrm{DRb}_{6}\right)$ (values 31.0419 , $31.8101,32.0531$ and $\left.32.4697 \AA^{3}\right)<V\left(\mathrm{DCs}_{6}\right)$ ( $36.6581 \AA^{3}$ ); (ii) values of $V_{A}$ also follow the expected trend with varying $X$ ion: $V\left(\left[\mathrm{PdD}_{2}\right] \mathrm{K}_{12}\right)=$ $123.5100<V\left(\left[\mathrm{PdD}_{2}\right] \mathrm{Rb}_{12}\right)=143.2054 ; V\left(\left[\mathrm{PtD}_{4}\right] \mathrm{K}_{12}\right)=$ $131.0517<V\left(\left[\mathrm{PtD}_{4}\right] \mathrm{Rb}_{12}\right)=147.7352<V\left(\left[\mathrm{PtD}_{4}\right] \mathrm{Cs}_{12}\right)=$ $169.3632 \AA^{3}$; (iii) for a given $X$ ion, values of $V_{A}$ follow the trend $V\left(\mathrm{PdD}_{4}^{2-}\right)>V\left(\mathrm{PtD}_{4}^{2-}\right)>V\left(\mathrm{PdD}_{2}^{2-}\right)$, e.g. for $X=\mathrm{Rb}^{+}$, these values are $149.6550>$ $147.7352>143.2054 \AA^{3}$. It is also to be noted that the polyhedral volumes of mixed alkali metal compounds, $\mathrm{K}_{2} \mathrm{RbPtH}_{5}$ and $\mathrm{K}_{2} \mathrm{CsPtH}_{5}$ are consistent with trends (i) and (ii). The third trend is in agreement with the observation of Bronger \& Auffermann (1992) that a relatively small increase in (unit cell) volume is to be found upon the substitution of $\left[\mathrm{PdH}_{4}\right)^{2-}$ (or $\left[\mathrm{PdD}_{4}\right]^{2-}$ )
for $\left[\mathrm{PdH}_{2}\right]^{2-}$, consistent with a complex ion of formal composition $\mathrm{Pd}^{0}\left(\mathrm{H}^{-}\right)_{2} \mathrm{H}_{2}$ rather than $\mathrm{Pd}^{\mathrm{I}}\left(\mathrm{H}^{-}\right)_{4}$.

The phase transitions to be found upon increasing the temperature are also susceptible to the analysis. This behaviour is summarized in the column headed $T_{\mathrm{p}>\mathrm{c}}$ in Table 6. Upon increasing the temperature, chemical decomposition occurs before a possible phase transition in three of the systems, $\mathrm{Rb}_{3} \mathrm{PdD}_{3}$ ( $\operatorname{lm} 3$ phase), $\mathrm{K}_{3} \mathrm{PtD}_{5}$ and $\mathrm{Rb}_{3} \mathrm{PdD}_{5}$. In the systems $\mathrm{K}_{3} \mathrm{PdD}_{3}, \mathrm{Cs}_{3} \mathrm{PtD}_{5}$ and $\mathrm{Rb}_{3} \mathrm{PtD}_{5}$, a transition to a cubic Pm3m phase occurs at elevated temperatures, in which there is no octahedral tilting and therefore $V_{A} / V_{B}$ is exactly equal to 5 (Thomas, 1989). In particular, $V_{A}=5 / 6 a_{\text {cubic }}^{3}$ and $V_{B}=1 / 6 a_{\text {cubic }}^{3}$, i.e.

References: (1) Bronger \& Auffermann (1990); (2) Bronger \& Auffermann (1992); (3) Bronger, Auffermann \& Müller (1988). * Phase transition to cubic Im3 phase ( $T=473 \mathrm{~K}$ structure), not to Pm 3 m phase.

$$
\begin{aligned}
V_{B, P m 3 m}\left(\mathrm{Cs}_{3} \mathrm{PtD}_{5}\right) & =36.018 \AA^{3} ; \\
V_{A, P m 3 m}\left(\mathrm{Rb}_{3} \mathrm{PtD}_{5}\right) & =157.847 \AA^{3} ; \\
V_{B, P m m}\left(\mathrm{Rb}_{3} \mathrm{PtD}_{5}\right) & =31.569 \AA^{3}
\end{aligned}
$$

It is interesting to note that in each of these cases, $V_{A}$ increases significantly in passing from the tetragonal to the cubic phase, whereas $V_{B}$ falls slightly. The implication is that the vibrational and rotational modes of the $\left[\mathrm{PdD}_{2}\right]^{2-}$ or $\left[\mathrm{PtD}_{4}\right]^{2-}$ groups give rise to a stronger dependence of volume on temperature than for simple ions such as $\mathrm{D}^{-}$, which occupy the $B$ sites.

In the case of $\mathrm{Rb}_{3} \mathrm{PdD}_{3}$, a transition occurs to a cubic phase of $\operatorname{Im} \overline{3}$ symmetry upon heating, with the structural characteristics as described in Tables 6 and 7 for the 473 K phase. Whereas there is essentially no change in $V_{B}\left(\mathrm{DRb}_{6}\right)$ compared with the room-temperature phase,
two of the eight $A X_{12}$, i.e. $\left[\mathrm{PdD}_{2}\right] \mathrm{Rb}_{12}$, polyhedra show a dramatic increase in polyhedral volume from 143.2 (average value) to $172.5 \AA^{3}$. The driving force for this phase transition is unclear, as is the significant increase in octahedral distortion in passing from the $14 / \mathrm{mmm}$ to the Im $\overline{3}$ phase.

It is seen that the analysis provides a helpful framework for interpreting the structural variations amongst these novel chemical compounds.
(iii) Evaluation of the proposed equation linking $V_{A} / V_{B}$ with tilt angles $\theta_{m}$ and $\theta_{2}$

The foregoing analysis of Tables 1-7 supports the widespread applicability of equation (8), the closeness of agreement between $\left[V_{A} / V_{B}\right]^{t}$ and $\left[V_{A} / V_{B}\right]^{a}$ being dependent upon the degree of regularity of the octahedra. Two

types of departure from regularity should be considered: (i) deviations of $\left(s_{1}+s_{2}\right)^{2} / s_{1} s_{2}$ from 4 wherever $s_{1} \neq s_{2}$ and (ii) departures of the angles of intersection of octahedral stalks form $90^{\circ}$, as expressed by the factor $\Delta_{\text {perp }}$.

A concise and comprehensive overview of the relationship between $V_{A} / V_{B}$ and octahedral tilting may be obtained by defining a parameter $\Phi$ to represent the degree of tilt, where

$$
\begin{equation*}
\Phi=1-\cos ^{2} \theta_{m} \cos \theta_{z} \tag{11}
\end{equation*}
$$

This function has the essential attribute that it assumes the value of zero when there is no tilting, i.e. $\theta_{m}=\theta_{z}=0$. Thus, the following linear relationship between $V_{A} / V_{B}$ and $\Phi$ follows from (8)

$$
\begin{equation*}
V_{A} / V_{B}=5-6 \Phi . \tag{12}
\end{equation*}
$$

Fig. 2. Predicted variation of $V_{A} / V_{B}$ with degree of tilt $\Phi$ as defined in equation (12). Experimental points are represented as small squares. In cases of significant deviation from the straight line, numbers indicate the structure responsible: (1) $\mathrm{KCuF}_{3}$ (ICSD no. 31453), (2) $\mathrm{PbZrO}_{3}$ (ICSD no. 15284), (3) $\mathrm{KMnF}_{3}$ (ICSD no. 15943), (4) $\mathrm{NaTaO}_{3}$ (ICSD no. 9090) and (5) $\mathrm{Rb}_{3} \mathrm{PdD}_{3}$ ( 473 K phase). Each of these is characterized by large octahedral distortions.

A plot of actual $\left[V_{A} / V_{B}\right]^{a}$ values versus degree of tilt $\Phi$ is given in Fig. 2. $\left[V_{A} / V_{B}\right]^{a}$ values are extracted from Tables 2, 4 and 7 , and the corresponding $\Phi$ values calculated from the $\theta_{m}$ and $\theta_{z}$ values in these tables.

## 4. Discussion

### 4.1. Relationship of this parameterization to Glazer's tilt system

The system of analysis and nomenclature introduced by Glazer (1972) for tilting in perovskites permits an evaluation of the number and directions of tilts which are operative in a given structure. Thus, in a three-tilt system, tilting occurs about each of the pseudo-cubic $x, y$ or $z$ axes and in a two-tilt system about just two of these etc. Tilt directions are conveyed by a superscript,+- or 0 . Thus, the notation $a^{0} b^{-} c^{-}$, for example, signifies zero tilt about the $x$ axis and negative tilts about the $y$ and $z$ axes. Equality of tilts is denoted by repeated use of a particular axis symbol. For example, $a^{0} b^{-} b^{-}$signifies that the tilts about the $y$ and $z$ axes are of equal magnitude and direction.

Insight into the structural significance of different tilt systems may be gained by consideration of Fig. 3, where single layers of octahedra in tilted structures are shown. The sign of a particular tilt is determined by the sequence of clockwise or anticlockwise rotations about the relevant axis. Thus, in Fig 3(a), by moving along the $x$ axis in a positive direction, all the octahedra are tilted in the same sense (clockwise), giving rise to the notation $a^{+}$. By comparison, when moving along the positive $y$ axis, the octahedra are rotated alternatively anticlockwise and clockwise, leading to the notation $b^{-}$. Note that only the $a^{-} b^{-}$(Fig. 3c), $a^{0} b^{-}$(not shown) and $a^{0} a^{0}$ (untilted; not shown) systems are consistent with the existence of a smaller orthorhombic unit cell. In all other cases, the pseudo-cubic cell itself is the unit cell.

*Average calculated for oxides and fluorides. † Average calculated for ternary platinum and palladium hydrides. $\ddagger \mathrm{rt}=$ room temperature, $\mathrm{ht}=$ high temperature.

A second layer would be required, above the first, to determine possible tilt directions about the $z$ axis. The requirement that the octahedra form a three-dimensional connected network limits the possible basic tilt systems to the following ten (Glazer, 1972): $a^{+} b^{-} c^{-}$(derived from Fig. $3 a$ ); $a^{+} b^{+} c^{+}, a^{+} b^{+} c^{-}$(derived from Fig. $3 b$ ); $a^{-} b^{-} c^{-}$(derived from Fig. $3 c$ ); $a^{0} b^{+} c^{+}, a^{0} b^{+} c^{-}$(derived

Fig. 3. Only the $a^{-} b^{-}$tilt system is consistent with a smaller orthorhombic cell, represented by the dashed line in (c).
from Fig. $3 d$ ) ; $a^{0} b^{-} c^{-}$(derived from tilt system $a^{0} b^{-}$, not shown); $a^{0} a^{0} c^{+}, a^{0} a^{0} c^{-}, a^{0} a^{0} a^{0}$ (no tilting about the $x$ and $y$ axes).

The structures analysed here fall into 13 space groups, as given in Table 8, along with their associated tilt systems. The tilt analysis has been carried out computationally, by considering whether octahedral vertices lie above, below or in the pseudo-cubic planes $x y, y z$ and $z x$. This approach is consistent with the notation used to denote the $z$ height of octahedral vertices in Fig. 3.

It is to be noted that nine of the 13 space groups give rise to basic tilt systems of the type $a^{-} b^{-}, a^{0} b^{-}$or $a^{0} a^{0}$, which, apart from $C m c m$, are consistent with the existence of a smaller orthorhombic unit cell. In the unique case of Cmcm , the C -centring also causes the pseudo-cubic cell to be the unit cell, with $a_{\mathrm{pc}} \neq b_{\mathrm{pc}}$ (see Table 1). The other four space groups also have the pseudo-cubic cell as their unit cell, of which three are associated with ternary hydrides of platinum and palladium. It may be inferred that the basic $a^{-} b^{-}$tilt sub-system (and derivatives $a^{0} b^{-}, a^{0} a^{0}$ ), and consequently the smaller, orthorhombic unit cell, are predominant amongst oxides and fluorides. The association of some tilt systems with more than one space group is attributable to variations in the distortions of coordination polyhedra and in cationic displacements.

Glazer's notation leads immediately to the number of tilt systems operative in a given structure ( $N_{\text {tilt }}$ in Table 8). This is not quite so straightforward from the definition of tilt angles, $\theta_{m}$ and $\theta_{z}$, used here. However, the existence of a single-tilt system ( $a^{0} a^{0} c^{+}$or $a^{0} a^{0} c^{-}$) may be inferred directly from $\theta_{z}$ being equal to zero and a

zero-tilt system from both $\theta_{z}$ and $\theta_{m}$ being equal to zero. In order to discriminate between systems with two- and three-tilt systems, it is necessary to examine the axes of rotation to which angles $\theta_{m}$ and $\theta_{2}$ refer. As an example, the $\mathrm{NaNbO}_{3}$ (8460) and $\mathrm{NaTaO}_{3}$ (9092) structures are now considered. The first of these is a three-tilt system, $a^{+} b^{-} c^{+}$, and the second a two-tilt system, $a^{0} b^{-} c^{+}$. In $\mathrm{NaNbO}_{3}, \quad \theta_{m}$ angles refer to rotation axes [ $0,0.82202,0.56945$ ] and [ $0.82202,0,-0.56945$ ], where the coordinates are fractional coordinates referred to pseudo-cubic axes. The $\theta_{z}$ angle refers to axis [ $\left.2^{1 / 2} / 2,2^{1 / 2} / 2,0\right]$. In the two-tilt $\mathrm{NaTaO}_{3}$ structure, by comparison, $\theta_{m}$ angles refer to the rotation axis [ $0,-0.39683,-0.91789$ ] with respect to the $x$ axis and $[0,0,1]$ with respect to the $y$ axis. $\theta_{z}$ refers to the axis [ $0.02552,0.99967,0]$. It is significant here that the axis for rotation with respect to the $y$ axis is parallel to the $z$ axis. This implies that there can be no tilting about the $x$ axis, which is consistent with the operative tilt system, $a^{0} b^{-} c^{+}$.

For a full derivation of atomic coordinates from stalk lengths and $\theta_{x}, \theta_{y}$ and $\theta_{z}$ tilt angles, it would also be necessary to know the rotation axes, as given above. Since these do not affect $V_{A} / V_{B}$, however, they have not been routinely quoted for the structures analysed.

### 4.2. Trends in the observed tilt systems

Consideration of Table 9 reveals that there is a correlation between the number of operative tilt systems, $N_{\text {titt }}$, and mean polyhedral volume ratios, $\left\langle V_{A} / V_{B}\right\rangle$, with averages taken over all the structures analysed. As $\left\langle V_{A} / V_{B}\right\rangle$ falls, there is a general increase in $N_{\text {tilt }}$, with the exception of space groups 59 and 63 (sequence numbers 5 and 6) and space group 136. In the latter case, the assignation of tilt system should be regarded as provisional, as an $R$ factor as high as $14 \%$ was quoted (Bronger \& Auffermann, 1990). The authors noted that the 'structure of the low-temperature phase (of $\mathrm{K}_{3} \mathrm{PdD}_{3}$ ) should be refined by means of an extended data set of complementary neutron diffraction experiments'. It
follows that, as the degree of tilt $\Phi$ increases, as defined by equation (12), the number of operative tilt systems also increases.

Information on coordination patterns of $A$ and $B$ ions in the different space groups is given in the two righthand columns of Table 8. The notation refers to the distribution of $A-X$ and $B-X$ distances within the coordination polyhedra. For example, [1, 4r, 2r, 4r, 1] indicates that there is one $A-X$ interaction of minimum length, a cluster of four interactions of equal, but longer length, followed by two of equal length, then four of equal length and finally a single interaction of maximum length. The notation ' $i$ ' and ' $r$ ' is used to denote whether the distances within a given cluster are equal ( $r$, regular) or unequal, but close together ( $i$, irregular). It is seen that essentially all $a^{-} a^{-} c^{+}$systems have [4i,4i,4i] $A X_{12}$ polyhedra, but differences are observed in the $B X_{6}$ octahedra: space group 62 is the most regular, $[2 r, 2 r, 2 r]$ and 55 the least regular $[1,1,1,1,1,1]$, with 33 of intermediate regularity, $[3 i, 3 i]$.

Polymorphic systems, such as $\mathrm{NaNbO}_{3}$, are particularly informative, since a sequence of changes in tilt systems and $A X_{12} / B X_{6}$ geometries can be observed. The overall reduction in $V_{A} / V_{B}$ from 5 in the Pm3m cubic phase at 923 K to 4.702 in the 20 K rhombohedral phase is seen in Table 10. The room-temperature structure is of interest because of its complex tilt system. In this connection, the doubling of the pseudo-cubic $c$-parameter permits an alternation between $c^{+}$and $c^{-}$in the $z$ axis tilting. Also observed are two types of $A O_{12}$ cuboctahedron as regards $A-\mathrm{O}$ distances: $[3 i, 6 i, 3 i]$ and $[1,3 i, 4 i, 4 i]$ (Table 8), with the first of these found in $a^{-} a^{-} c^{-}$tilt regions and the second in $a^{-} a^{-} c^{+}$regions. The first type of cuboctahedron is suggestive of rhombohedral symmetry (Thomas \& Beitollahi, 1994), for which the appropriate tilt system is $a^{-} a^{-} a^{-}$(Glazer, 1972). This is closely related to $a^{-} a^{-} c^{-}$. It is as if the room-temperature phase is an intergrowth, within each unit cell, of a pseudo-rhombohedral and an orthorhombic structure. Furthermore, it acts as a precursor to the $R 3 c$ rhombohedral phase which is formed at temperatures below 163 K (Darlington \& Megaw, 1973; see Table 10).

It is also likely that the ternary platinum and palladium hydrides will be strongly polymorphic. This follows from the strong temperature dependence of $V_{A}$, owing to the vibrations and rotations of complex rather than simple ions. The expected wide variation in $V_{A} / V_{B}$ will be associated with several different tilt systems. Thus, cooling $A_{3} \mathrm{PtH}_{5}$ and $A_{3} \mathrm{PdH}_{5}$ below room temperature is expected to lead to phases with $N_{\text {tilt }}>1$ (i.e. lower $V_{A} / V_{B}$ ), as vibrations of the $\left[\mathrm{PdH}_{4}\right]^{2-}$ and $\left[\mathrm{PtH}_{4}\right]^{2-}$ complex ions 'freeze out'.

### 4.3. Treatment of rhombohedral perovskites

It has been shown recently (Thomas \& Beitollahi, 1994) that the relationship between polyhedral volume

ratio, $V_{A} / V_{B}$, and mean octahedral tilt angle in rhombohedral perovskites, $\langle\omega\rangle_{r}$, corresponds to

$$
\begin{equation*}
V_{A} / V_{B}=6 K^{2} \cos ^{2}\langle\omega\rangle_{r}-1, \tag{13}
\end{equation*}
$$

where $K \simeq 1$ and $\omega$ is the angle of octahedral rotation about the trigonal axis. Since all perovskite structures can be defined in pseudo-cubic axes, it follows that the tilting in rhombohedral systems can also be quantified in terms of tilt angles $\theta_{m}$ and $\theta_{2}$, as defined in equation (8) and the preceding derivation. By comparison with orthorhombic and tetragonal perovskites, the derived pseudo-cubic axes for rhombohedral structures have no unique $z$ axis, i.e. $\theta_{2}=\theta_{m}$. If this common angle is denoted as $\theta_{\mathrm{PC}}, \mathrm{a}$ comparison of equations (8) and (13) leads to the result

$$
\begin{equation*}
\theta_{\mathrm{PC}}=\cos ^{-1}\left\{\cos ^{2 / 3}\langle\omega\rangle_{r}\right\} . \tag{14}
\end{equation*}
$$

The applicability of this result is investigated in Table 11 for four structures, one from each of the rhombohedral space groups $R 3 m$ (no. 160), $R 3 c$ (no. 161), $R \overline{3} m$ (no. 166) and $R 3 c$ (no.167). $a_{\mathrm{PC}}$ and $\alpha_{\mathrm{PC}}$ are the parameters of the derived pseudo-cubic cell, which is also rhombohedral. $\theta_{\mathrm{PC}}$ is the measured tilt angle for the structures, i.e. the angle subtended by octahedral stalks with their nearest pseudo-cubic axes; $\langle\omega\rangle_{r}$ is the rhombohedral tilt angle (Thomas \& Beitollahi, 1994) and $\theta_{\mathrm{PC}}^{\text {alc }}$ the value of $\theta_{\mathrm{PC}}$ calculated from (14). For non-zero $\theta_{\mathrm{PC}}$ values $\left(\mathrm{LiNbO}_{3}\right.$ and $\left.\mathrm{LaCoO}_{3}\right)$, it is seen that the agreement between $\theta_{\mathrm{PC}}$ and $\theta_{\mathrm{PC}}^{\text {cal }}$ is only approximate. Furthermore, the value of $V_{A} / V_{B}$ calculated from (13), $\left[V_{A} / V_{B}\right]^{r}$, is considerably more accurate than the value calculated from (8), $\left[V_{A} / V_{B}\right]_{\mathrm{PC}}$. Therefore, it is always advisable to use the parameterization developed explicitly for rhombohedral perovskites, based on (13).

The reasons for the discrepancies between calculated and experimental pseudo-cubic tilt angles and $V_{A} / V_{B}$ ratios are straightforward. First, the pseudo-cubic $z$ axis is no longer perpendicular to the $x y$ plane, as was assumed in the derivation of (9) for orthorhombic and tetragonal systems, and $\gamma_{\text {PC }}$ is always different from $90^{\circ}$. A correction for this would lead to the result

$$
\begin{equation*}
V_{A} / V_{B} \simeq 6 \cos ^{2} \theta_{m} \cos \theta_{z} \sin \alpha_{\mathrm{pc}}-1 \tag{15}
\end{equation*}
$$

The $\sin \alpha_{\mathrm{pc}}$ correction factor is equal to 0.9979 for $\mathrm{LiNbO}_{3}$, leading to a corrected $\left[V_{a} / V_{b}\right]_{\mathrm{pc}}$ value of 4.085 , in closer agreement with the experimental value. The second source of the discrepancy results from the assumption that the stalks of the octahedra intersect at right angles to one other. This is not generally the case. In connection with the octahedral distortions to be found in rhombohedral perovskites, the parameterization developed previously (Thomas \& Beitollahi, 1994) is again superior, with just one parameter, $\Delta s$, required.
4.4. Structural requirements for ferroelectricity and antiferroelectricity; inter-relationship of octahedral and rhombohedral symmetry

The vast majority of structures analysed are neither ferroelectric nor antiferroelectric. Since ferroelectric materials necessarily belong to a polar space group, the only candidates for ferroelectric properties are $\mathrm{PbZrO}_{3}$ (ICSD no. 15284), $\mathrm{CdTiO}_{3}$ (ICSD no. 26635), $\mathrm{BaTiO}_{3}$ (ICSD no. 15285) and $\mathrm{KNbO}_{3}$ (ICSD no. 3838). Of these, $\mathrm{BaTiO}_{3}$ and $\mathrm{KNbO}_{3}$ are well known ferroelectrics. However, the degree of tilt in these systems is zero. The question arises as to whether ferroelectricity occurs in tilted systems of orthorhombic symmetry such as $\mathrm{PbZrO}_{3}$ and $\mathrm{CdTiO}_{3}$. In the first case, the dielectric behaviour is
known to correspond to that of an antiferroelectric. Moreover, the latest structural determination of $\mathrm{PbZrO}_{3}$ has suggested a disordered structure with two substructure components, each of non-polar symmetry Pbam, as quoted in Tables 1, 4 and 5. In the latter case, the proposed structure (Pna2 ${ }_{1}$; ICSD no 26635) was investigated only as an alternative to the centrosymmetric Pnma structure [ICSD No. 26634 (Sasaki, Prewitt, Bass \& Schulze, 1987)]. The authors concluded, on the grounds of their structural determination and the lack of observable ferroelectric behaviour, that the roomtemperature structure of $\mathrm{CdTiO}_{3}$ could be better described in Pnma.

The conclusion to be drawn is that whereas tilted orthorhombic and tetragonal perovskites have the capability of showing ferroelectric properties, by means of appropriate cationic displacements, no system has been found to date in which this capability has been exploited. It follows that the most promising way of obtaining ferroelectric properties in a tilted system is through a perovskite of rhombohedral $R 3 c$ symmetry (tilt system $a^{-} a^{-} a^{-}$), where the symmetry dictates that any octahedral distortions give rise to parallel $B$-ion displacements (Thomas \& Beitollahi, 1994). In the paper of Thomas \& Beitollahi (1994), several systems in space group $R 3 c$ were identified, thereby showing ferroelectric properties, including $\mathrm{NaNbO}_{3}$ at 123 K and $\mathrm{LiNbO}_{3}$, over a wide temperature range from room temperature up to 1483 K , its Curie point.

Consideration of $\mathrm{NaNbO}_{3}$ in Table 10 shows that $V_{B}$ adopts its maximum values in the two rhombohedral structures, although these are at the lowest temperatures. These large volumes are also associated with maximum $B$-ion displacements from the centres of their octahedra. Upon heating from 20 K to room temperature, at which an orthorhombic phase is stabilized, it is seen that $V_{B}$ falls, as does $\operatorname{dsp}^{i}(B)$. In the room-temperature phase, the $\mathrm{NbO}_{6}$ octahedra give rise to electric dipoles, but the parallel alignment is lost, giving rise to antiferroelectric behaviour. In all the phases at higher temperatures, $\operatorname{dsp}^{i}(B)$ is equal to zero, which is consistent with their paraelectric behaviour. It appears also that the $B$-ion octahedral volume $V_{B}$ can be correlated with the existence or otherwise of a $B \mathrm{O}_{6}$ dipole moment: when $V\left(\mathrm{NbO}_{6}\right)$ takes on a value equal to $10.364 \AA^{3}$ or greater, the niobium ion is stabilized at an off-centre position.

Although tantalum is chemically and geometrically similar to niobium, $\mathrm{NaTaO}_{3}$ does not give rise to antiferroelectric properties, even though the tilt sequence is analogous to that of $\mathrm{NaNbO}_{3}$ : [ICSD no. 9090; room temperature; space group 62; $\left.a^{-} a^{-} c^{+}\right] \longrightarrow[$ ICSD no. 9091; 803 K ; space group $\left.63 ; a^{0} b^{-} c^{+}\right] \longrightarrow$ [ICSD no. 9092; 873 K ; space group 63; $\left.a^{0} b^{-} c^{+}\right] \longrightarrow$ [ICSD no. 9093; 893 K ; space group 127; $a^{0} b^{0} c^{+}$]. In all cases, the $\mathrm{Ta}^{5+}$ ions are constrained to lie at the centres of their coordination octahedra, since they occupy special positions of symmetry $\overline{1}, \overline{1}$ and $4 / m$ in space groups

Table 12. Summary of polyhedral volumes, A-ion displacements and radii (Shannon, 1976) in orthorhombic and rhombohedral aluminates

* $R \overline{3} c$ symmetry changes to $R \overline{3} m$ in the absence of tilting $\left(V_{A} / V_{B}=5\right)$.

62, 63 and 127 , respectively. In this connection, a correlation between $V_{B}$ and $\operatorname{dsp}^{i}(B)$ is again found. $V_{B}$ values in orthorhombic perovskites range between 10.184 and $10.240 \AA^{3}$, less than the value of $10.374 \AA^{3}$ in ferroelectric $\mathrm{LiTaO}_{3}$, in which an off-centre displacement of $0.2017 \AA$ is found (Thomas \& Beitollahi, 1994).

In general, the factors governing whether rhombohedral or orthorhombic structures are preferentially stabilized are far from clear, although the issue is of great importance in obtaining ferroelectric behaviour in systems with tilted octahedra. In $\mathrm{LiNbO}_{3}$, for example, the $A$ ion (i.e. $\mathrm{Li}^{+}$) is also instrumental in stabilizing the rhombohedral phase up to 1483 K . In $\mathrm{NaNbO}_{3}$, the $\mathrm{Na}^{+}$ ion is less effective in this regard, with a transition to orthorhombic symmetry at 163 K . The issue also arises in connection with non-polar tilted rhombohedral structures, which crystallize in space group $167(R \overline{3} c)$ : what governs whether a particualr structure crystallizes in $R \overline{3} c$ or in orthorhombic Pnma? A clue is to be found in that both $A$ - and $B$-ion off-centre displacements are constrained to be zero in $R \overline{3} c$, whereas in Pnma, $A$-ion displacements are permitted. This feature is immediately apparent in a consideration of the four aluminates, $\mathrm{YAlO}_{3}, \mathrm{SmAlO}_{3}$ (Tables 2 and 3), $\mathrm{NdAlO}_{3}$ and $\mathrm{PrAlO}_{3}$ (Thomas \& Beitollahi, 1994), as summarized in Table 12. By using the ionic radius in sixfold coordination as the criterion for ionic size (Shannon, 1976), it is seen that the larger ions $\mathrm{Nd}^{3+}$ and $\mathrm{Pr}^{3+}$ give rise to rhombohedral symmetry, with the structures consisting of smaller $A$ ions crystallizing in Pnma. In this orthorhombic space group, the smaller ions are able to adopt larger coordination polyhedra, merely by off-centre displacements as a compensation. This is seen in the case of $\mathrm{SmAlO}_{3}$, where, although the ionic radius of $\mathrm{Sm}^{3+}$ is less than that of $\mathrm{Nd}^{3+}$, the $V_{A}$ cuboctahedral volumes are comparable. The energetic advantage to be gained from adopting a larger $A \mathrm{O}_{12}$ polyhedron lies in a reduction of oxygen-ion repulsive energy.

Note that off-centre $A$-ion displacements are also possible within rhombohedral symmetry, but only within the polar space group R3c. Such an option would give rise to a net dipole moment, with consequences for electrostatic energy, which would not arise in non-polar Pnma. An intuitive understanding of the widespread adoption of Pnma in tilted perovskites may be stated as follows. The $B$-ion tends to adopt an octahedral volume
consistent with its ionic radius, whereby the centrosymmetric symmetry of the $B \mathrm{O}_{6}$ octahedron prohibits offcentre displacement. The $A$ ion adopts a $V_{A}$ volume larger than would be suggested from its ionic radius, in order to minimize oxygen-ion repulsions within the coordination polyhedron. As a consequence, the degree of tilt is also reduced. It is able to fulfil its bonding requirements, however, by an off-centre displacement within the $\mathrm{O}_{12}$ polyhedron, in order to achieve closer coordination by oxygen ions.

Examination of Table 3 confirms that significant $\mathrm{dsp}^{i}(A)$ values are found for all compositions. Amongst the ternary iron oxides, for example, the largest displacement, $0.4930 \AA$, occurs in $\mathrm{LuFeO}_{3}$, with the smallest in $\mathrm{LaFeO}_{3}, 0.1843 \AA$. This reflects that $\mathrm{Lu}^{3+}$ has the smallest ionic radius amongst these compounds and $\mathrm{La}^{3+}$ the highest $\left[r^{\mathrm{VI}}\left(\mathrm{Lu}^{3+}\right)=0.861 ; r^{\mathrm{VI}}\left(\mathrm{La}^{3+}\right)=1.032 \AA\right.$ (Shannon, 1976)]: smaller ions require larger displacements in order to optimize their coordination by oxygen ions. Although there is a parallel reduction in $V_{A}$ in proceeding in from $\mathrm{LaFeO}_{3}$ to $\mathrm{LuFeO}_{3}, A$-ion displacement is an important complementary mechanism for stabilizing smaller $A$ ions in the Pnma space group.

The question of orthorhombic versus rhombohedral symmetry in tilted perovskites is an important issue in the current generation of ceramic fuel cells, in which perovskites frequently function as cathodes and interconnect in a composite structure. The symmetry has a direct bearing on interfacial bonding between components of the composite and on the compatibility of their thermal expansion coefficients. A common interconnect material is based on $\mathrm{LaCrO}_{3}$, which is orthorhombic at room temperature, but undergoes a transition to rhombohedral symmetry at 553 K . It has been found that doping $\mathrm{LaCrO}_{3}$ with $\mathrm{Sr}^{2+}$ stabilizes the rhombohedral phase at room temperature, whereas doping with $\mathrm{Ca}^{2+}$ stabilizes the orthorhombic phase to temperatures higher than 553 K (Minh, 1993). This trend is consistent with the behaviour of the aluminates, which has been rationalized above. $\mathrm{Ca}^{2+}$, being a smaller ion than the parent $\mathrm{La}^{3+}$ ion, promotes the $A$-ion displacements associated with orthorhombic Pnma symmetry, whereas $\mathrm{Sr}^{2+}$, which is larger than $\mathrm{La}^{3+}$, reduces the tendency towards $A$-ion displacement, thereby promoting rhombohedral symmetry.

The fine energy balances between orthorhombic and rhombohedral symmetry in many compositions are worthy of experimental investigation, since they will provide structural data upon which a more complete understanding can be built. By varying the temperatures at which structural determinations are carried out, it is envisaged that the inherent polymorphism of these tilted systems can be revealed and analysed. The achievement of ferroelectric properties through the adoption of the polar space group $R 3 c$ is also a likelihood, since systems with small $A$ ions have an intrinsic tendency towards ionic displacements.

Table 13. Summary of minimum and maximum $A O_{12}$ and $\mathrm{BO}_{6}$ polyhedral volumes observed in oxide perovskites at room temperature

| $A$ ion | $V_{A, \min }\left(\AA^{3}\right)$ | $V_{A, \max }\left(\AA^{3}\right)$ | $B$ ion | $V_{B, \min }\left(\AA^{3}\right)$ | $V_{B, \max }\left(\AA^{3}\right)$ |

4.5. Definition of transferable polyhedral volume ranges; prediction of degree of tilt from chemical composition; strategies for developing new ferroelectric compositions

The analysis of perovskites, as carried out here and in preceding articles (Thomas, 1989; Thomas \& Beitollahi, 1994), has employed experimentally determined structural data as the starting point. In so doing, a body of data has been built up concerning the $A$ and $B$ polyhedral volumes adopted by cations in perovskites, which is transferable to novel hypothetical perovskite systems. This information is summarized in Table 13, which gives the minimum and maximum $A O_{12}$ and $B \mathrm{O}_{6}$ volumes observed in room-temperature structures. $V_{A}$ and $V_{B}$ values calculated in the two previous articles have also been used in compiling the table.

By combining $A$ and $B$ ions of total valence equal to six, a hypothetical composition may be formed, e.g. $\mathrm{K}^{+}$and $\mathrm{U}^{5+}$ form $\mathrm{KUO}_{6}$, for which $V_{A} / V_{B}$ would lie between these limits: 53.861/ $12.475<V_{A} / V_{B}<53.927 / 12.475$, i.e. $4.318<$ $V_{A} / V_{B}<4.323$. Application of equation (12) predicts a degree of tilt $\Phi$ in the range $0.1137>\Phi>0.1128$, which can be translated either into a rhombohedral tilt angle, $19.70>\langle\omega\rangle_{r}>19.63^{\circ}$, or into a mean orthorhombic tilt angle ( $\theta_{\text {mean }}=\theta_{m}=\theta_{z}$ ) of $16.142>\theta>16.079^{\circ}$. No attempt will be made here to speculate whether rhombohedral or orthorhombic symmetry would be adopted, nor, in the former case, whether the polar space group $R 3 c$ would be found, this being a necessary condition for ferroelectric properties to arise.

In applying this technique, it should be borne in mind that there are limits of stability for the perovskite phase,
which may be expressed in terms of an allowed range of $V_{A} / V_{B}$ values. The minimum observed $V_{A} / V_{B}$ ratio observed to date corresponds to 4.060 , this value being empirically determined from the structure $\mathrm{LuFeO}_{3}$. It is essentially oxygen-ion repulsions which impose a lower limit on $V_{A} / V_{B}$. The upper limit to $V_{A} / V_{B}$, which is found in the absence of tilting, is equal to 5 . Although exceptions to this upper limit arise in the $\mathrm{NaTaO}_{3}$ (ICSD no. 9090 ) and $\mathrm{KCuF}_{3}$ structures, this is at the expense of considerable octahedral distortion, which must be regarded as atypical. The usual consequence of the upper limit being exceeded is the adoption of an alternative structural type involving face-sharing octahedra (Thomas, 1991b).

In searching for new ferroelectric systems, it is probably most effective to investigate hypothetical compositions with predicted $V_{A} / V_{B}$ ratios close to the upper limit of 5 , particularly those with a hypothetical ratio slightly higher than 5 . Thus, adoption of an actual ratio of 5 would be achieved by expansion of the $B \mathrm{O}_{6}$ octahedron, a feature conducive to off-centre $B$-ion displacements. Any such structure would also be characterized by the absence of octahedral tilting, thereby reducing the possibility of polymorphism between (not necessarily ferroelectric) rhombohedral and (non-ferroelectric) orthorhombic phases. From Table 13, it may be deduced that the well known ferroelectric $\mathrm{BaTiO}_{3}$ would have a hypothetical $V_{A} / V_{B}$ ratio of between 4.976 and 7.375 , the broad range indicating the wide variation in $V_{A}$ volumes associated with the $\mathrm{Ba}^{2+}$ ion. In adopting the actual $V_{A} / V_{B}$ ratio of 5 in ferroelectric $\mathrm{BaTiO}_{3}$, it follows that the barium ion is tightly coordinated and the titanium ion loosely coordinated. Herein lies the driving force for displacements of the $\mathrm{Ti}^{4+}$ ion.

Formation of simple perovskite compositions is often limited by the valences of the $A$ and $B$ ions, necessitating the use of complex perovskites. For example, a likely ferroelectric composition containing the $\mathrm{Fe}^{3+}$ ion would require a minimum $V_{A}$ volume of $5 \times 10.913=$ $54.565 \AA^{3}$. Only the $\mathrm{Ba}^{2+}, \mathrm{K}^{+}$and $\mathrm{Pb}^{2+}$ ions are possible candidates here, although none have the required valence of three. By forming a complex perovskite, a ferroelectric composition may be postulated, e.g. $\mathrm{Pb}\left(\mathrm{Fe}_{0.5}^{3+} \mathrm{Nb}_{0.5}^{5+}\right) \mathrm{O}_{3}$. This composition is known to show ferroelectric properties (Stenger \& Burggraaf, 1980). The influence of mixed $B$-site ions on crystal symmetry is also worthy of further investigation. In this context, it is likely that the system $\mathrm{Pb}\left(\mathrm{Zr}_{x} \mathrm{Ti}_{1-x}\right) \mathrm{O}_{3}(0.52<x<0.93)$ is stabilized in fhombohedral symmetry ( $R 3 m$ and $R 3 c$ ) by the presence of both $\mathrm{Zr}^{4+}$ and $\mathrm{Ti}^{4+}$ ions on $B$ sites (Thomas \& Beitollahi, 1994). Also worthy of investigation is the extent to which certain ions promote off-centre displacements more than others, on the grounds of their electronic structures.

The analysis of octahedral tilting developed here may also be applied to layered and slab-like perovskite-related
structures, such as the Aurivillius compounds. Recent crystallographic data have been published on the ferroelectric phases of $\mathrm{Bi}_{3} \mathrm{TiNbO}_{9}$ (Thompson, Rae, Withers \& Craig, 1991) and $\mathrm{Bi}_{4} \mathrm{Ti}_{3} \mathrm{O}_{12}$ (Rae, Thompson, Withers \& Willis, 1990). Both of these show octahedral tilting, which can be analysed in terms of equation (8). Significant octahedral tilting is also to be found in the slab-like perovskite $\mathrm{Sr}_{2} \mathrm{Nb}_{2} \mathrm{O}_{7}$ (Ishizawa, Marumo, Kawamura \& Kimura, 1975). Each of these compositions has potential applications as a high-temperature ferroelectric or piezoelectric, by virtue of their high Curie points, $T_{c}$ : 948 K in $\mathrm{Bi}_{4} \mathrm{Ti}_{3} \mathrm{O}_{12}, 1213 \mathrm{~K}$ in $\mathrm{Bi}_{3} \mathrm{TiNbO}_{9}$ and 1613 K in $\mathrm{Sr}_{2} \mathrm{Nb}_{2} \mathrm{O}_{7}$. In each of these compositions the tilted octahedral configuration is imposed by the layered structure and it is stable at all temperatures up to the Curie point. Furthermore, the tilted structures act to stabilize the off-centre cationic displacements responsible for ferroelectricity. Such a stabilizing function is not found in the perovskite structures which have been analysed here.

It has been demonstrated in this article that an approach based on the calculation of polyhedral volumes provides a quantitative framework for understanding the dependence of all perovskite crystal structures on chemical composition. By virtue of its universal applicability, it is hoped that the methodology will act as a stimulus to further work in the various areas of research into perovskites, whether physical, chemical or mineralogical in emphasis.
