to prove. Otherwise, since D is a dominating set in $\widehat{G}$, there is a vertex $u \in D$ such that (v, u) is an edge in $\widehat{G}$. If (v, u) is in G, then again we are done since $u \in \vec{N}(v) \subset \vec{N}_{\Delta/3}(v)$. The other possibility is that u is not a neighbor of v in G, but then it must be the case that $u \in \overrightarrow{PBFS}_s(v)$. The condition $|\vec{N}_{\Delta/3}(v)| \geq s$ implies that $\overrightarrow{PBFS}_s(v) \subset \vec{N}_{\Delta/3}(v)$, which in turn implies that $u \in \vec{N}_{\Delta/3}(v)$, and hence $u \in D \cap \vec{N}_{\Delta/3}(v)$. □

The reader should notice the similarity between the preceding lemma and Case 2 in Theorem 3.2. Lemma 3.8 follows from the more general set cover ideas used in the proof of Theorem 2.7 and as such it holds even if we replace $\Delta/3$ by some other fraction of Δ. The more crucial lemma is given below.

LEMMA 3.9. *Let S be the set of vertices v such that $|\vec{N}_{\Delta/3}(v)| < s$. If $S \neq \emptyset$ then the vertex w found in step 2 belongs to S. In addition if $\vec{\mathrm{B}}(w) < \frac{2}{3}\Delta$, then for every vertex v,*

$$\overrightarrow{PBFS}_s(w) \cap \overleftarrow{N}_{\Delta/3}(v) \neq \emptyset.$$

Proof. It can be verified that for any vertex $u \in S$, $\overrightarrow{\mathrm{PB}}(u) > \Delta/3$; conversely, for any vertex v in $V \setminus S$, $\overrightarrow{\mathrm{PB}}(v) \leq \Delta/3$. From this we can conclude that if S is nonempty, then the vertex of largest depth belongs to S.

Also, for each vertex $u \in S$, we must have $\vec{N}_{\Delta/3}(u) \subset \overrightarrow{PBFS}_s(u)$. If $\vec{\mathrm{B}}(w) < \frac{2}{3}\Delta$, then every vertex is within a distance $\frac{2}{3}\Delta$ from w. From this and the fact that $\vec{N}_{\Delta/3}(w) \subset \overrightarrow{PBFS}_s(w)$, it follows that $\overrightarrow{PBFS}_s(w) \cap \overleftarrow{N}_{\Delta/3}(v) \neq \emptyset$. □

The proof of the above lemma makes clear the reason why our estimate is only within $\frac{2}{3}$ of the diameter. Essentially, we need to ensure that the Δ/k neighborhood of w intersects the Δ/k neighborhood of every other vertex. This can happen only if $\vec{\mathrm{B}}(w)$ is sufficiently small. If it is not small enough, we want $\vec{\mathrm{B}}(w)$ itself to be a good estimate. Balancing these conditions gives us $k = 3$ and the ratio $2/3$.

THEOREM 3.10. *Algorithm approx-diameter gives an estimate E such that $\frac{2}{3}\Delta \leq E \leq \Delta$ in time $O(ms + ms^{-1}n \log n + ns^2)$. Choosing $s = \sqrt{n \log n}$ gives a running time of $O(m\sqrt{n \log n} + n^2 \log n)$.*

Proof. The analysis is partitioned into two cases. Let a and b be two vertices such that $d(a, b) = \Delta$.

Case 1. (*For all vertices v, $|\vec{N}_{\Delta/3}(v)| \geq s$.*)

If either a or b is in D, we are done. Otherwise from the proof of Lemma 3.8, the set D has a vertex $v \in \vec{N}_{\Delta/3}(a)$. Since in step 6 we compute $\overrightarrow{BFS}$ trees from each vertex in D, one of these is v and $\vec{\mathrm{B}}(v)$ is the desired estimate.

Case 2. (*There exists a vertex $v \in V$ such that $|\vec{N}_{\Delta/3}(v)| < s$.*)

Let w be the vertex in step 2. If $\vec{\mathrm{B}}(w) \geq \frac{2}{3}\Delta$, $\vec{\mathrm{B}}(w)$ is our estimate and we are done. Otherwise from Lemma 3.9, $\overrightarrow{PBFS}_s(w)$ has a vertex $v \in \overleftarrow{N}_{\Delta/3}(b)$. Since in step 3 we compute $\overleftarrow{BFS}$ trees from each vertex in $\overrightarrow{PBFS}_s(w)$, one of these is v and $\overleftarrow{\mathrm{B}}(v)$ is the desired estimate.

The running time is easy to analyze. Each partial-BFS in step 1 takes at most $O(s^2)$ time by Lemma 3.5; thus, the total time spent on step 1 is $O(ns^2)$. Step 2 can be implemented in $O(n)$ time. In step 3, we compute BFS trees from s vertices, which

requires a total of $O(ms)$ time. The time required in step 4 is dominated by the time required to compute the partial-BFS trees in step 1. Theorem 2.7 implies that step 5 requires only $O(n^2 + ns)$ time (note that the graph $\widehat{G}$ could have many more edges than m). By Lemma 3.7, step 6 takes $O(ms^{-1}n \log n)$ time. Finally, the cost of step 7 is dominated by the cost of computing the various BFS trees in steps 3 and 6. The running time is dominated by the cost of steps 1, 3, and 6, and adding the bounds for these gives the desired result. □

3.3. Extension to weighted graphs. The algorithm for estimating the diameter extends to the case of weighted graphs as well, provided all edge weights are positive. This requires some minor modifications to algorithm approx-diameter that are listed below.

- The BFS is replaced by Dijkstra's algorithm [10] for shortest paths, and the depth of the tree now refers to the distance to the farthest vertex found so far.
- In forming the new graph $\widehat{G}$ in step 4 we need to remove all the original edges of G before we add the new edges. Note that $\widehat{G}$ is an unweighted graph.

The last modification is necessary because in a weighted graph it is not necessarily the case that a neighbor of a vertex v belongs to $N_{\Delta/3}(v)$. The running time remains the same because the time required by Dijkstra's algorithm (implemented with Fibonacci heaps [10]) is $O(m)$ when $m = \Omega(n \log n)$.

We obtain the following theorem.

THEOREM 3.11. *Given a directed graph with positive edge weights, there is an algorithm that gives an estimate E such that $\frac{2}{3}\Delta \leq E \leq \Delta$ in time $O(m\sqrt{n \log n} + n^2 \log n)$.*

4. Estimating APSP. We now turn to the problem of approximate APSP computations. We restrict ourselves to undirected and unweighted graphs for the rest of the paper, although it should be noted that there is an obvious extension of the results below to the case of undirected graphs with edge weights that are small integers.

It is possible to determine not only the diameter but the APSP distances to within an additive error of 2. The basic idea is that a dominating set, since it contains a neighbor of every vertex in the graph, must contain a vertex that is within distance 1 of any shortest path. Since we can only find a small dominating set for vertices in $H(V)$, we have to treat $L(V)$ vertices differently, but their low degree allows us to manage with only a partial-BFS, which we can combine with the information we have gleaned from the dominating set.

We give a detailed description of the approximate APSP algorithm, algorithm approx-APSP, in Figure 4.1. In Figure 4.2 we illustrate the main ideas behind this algorithm.

THEOREM 4.1. *In algorithm approx-APSP, for all vertices $u, v \in V$, the distances returned in $\widehat{d}$ satisfy the inequality*

$$0 \leq \widehat{d}(u, v) - d(u, v) \leq 2.$$

Further, the algorithm can be modified to produce paths of length $\widehat{d}$ rather than merely returning the approximate distances. This algorithm runs in time $O(n^2 s + n^3 s^{-1} \log n)$; choosing $s = \sqrt{n \log n}$ gives a running time of $O(n^{2.5}\sqrt{\log n})$.

Proof. We first show that the algorithm can be easily modified to return actual paths rather than only the distances. To achieve this, in steps 3 and 4 we can associate with each updated entry in the matrix the path from the BFS tree used for the update. In step 5, we merely concatenate the two paths from step 3 that determine the minimum value of $\widehat{d}$.

Algorithm Approx-APSP

Comment: Define $G[L(V)]$ to be the subgraph of G induced by $L(V)$.

1. **initialize** all entries in the distance matrix $\widehat{d}$ to ∞
2. **compute** a dominating set D for $H(V)$ of size $s^{-1}n\log n$
3. **compute** a BFS tree from each vertex $v \in D$, and update $\widehat{d}$ with the shortest path lengths for v so obtained
4. **compute** a BFS tree in $G[L(V)]$ for each vertex $v \in L(V)$, and update $\widehat{d}$ with the shortest path lengths for v so obtained
5. **for all** $u, v \in V \setminus D$ **do**

$$\widehat{d}(u,v) \leftarrow \min\{\widehat{d}(u,v), \min_{w\in D}\{\widehat{d}(w,u) + \widehat{d}(w,v)\}\}$$

6. **return** $\widehat{d}$ as the APSP matrix, and its largest entry as the diameter.

FIG. 4.1. *Algorithm approx-APSP.*

For a vertex u, it is clear that the shortest path distance to any vertex $v \in V$ that is returned cannot be smaller than the correct values, since they correspond to actual paths. To see that they differ by no more than 2, we need to consider three cases.

Case 1. $(u \in D)$.

In this case, the BFS tree from v is computed in step 3 and so clearly the distances returned are correct.

Case 2. $(u \in H(V) \setminus D)$.

By the definition of D, it must be the case that u has a neighbor w in D. Clearly, the distances from u and w to any other vertex cannot differ by more than 1, and the distances from w are always correct as per Case 1. The assignment in step 6 guarantees $\widehat{d}(u,v) \le \widehat{d}(w,u) + \widehat{d}(w,v) = d(w,v) + 1 \le d(u,v) + 2$.

Case 3. $(u \in L(V))$.

Fix any shortest path from u to v. Suppose that the path from u to v is entirely contained in $L(V)$; then $\widehat{d}(u,v)$ is set correctly in step 4. Otherwise, the path must contain a vertex $w \in H(V)$. If w is contained in D, then the correct distance is computed as per Case 1. Finally, if $w \in H(V) \setminus D$, then D contains a neighbor x of w. Clearly, in step 6, one of the possibilities considered will involve a path from u to x and a path from x to v. Since the distances involving x are correctly computed in step 3, this means that $\widehat{d}(u,v) \le d(x,u) + d(x,v) \le d(w,u) + d(w,v) + 2 = d(u,v) + 2$.

Finally, we analyze the running time of this algorithm. Step 1 requires only $O(n^2)$ time, and Theorem 2.7 implies that we can perform step 2 in the stated time bound. Step 3 requires $ms^{-1}n\log n$ for computing the BFS trees. Step 4 may compute as many as $\Omega(n)$ BFS trees, but $G[L(V)]$ only has $O(ns)$ edges and so this requires only $O(n^2 s)$ time. Finally, step 5 takes all n^2 vertex pairs and compares them with the $s^{-1}n\log n$ vertices in D. This implies the desired time bound. ∎

Although the error in this algorithm is 2, it can be improved for the special case of distinguishing diameter 2 from 4 based on the following two observations.

FACT 4.2. *If $u \in H(V)$ is at distance Δ from some vertex v, then $\widehat{d}(u,v) \le \Delta + 1$.*

Proof. Consider w, the vertex that dominates u. If the algorithm were to have set $\widehat{d}(u,v) > \Delta + 1$, then step 5 of the algorithm would imply $\widehat{d}(w,v) > \Delta$. Since $\widehat{d}$ is exact for vertices in D, this is not possible. ∎

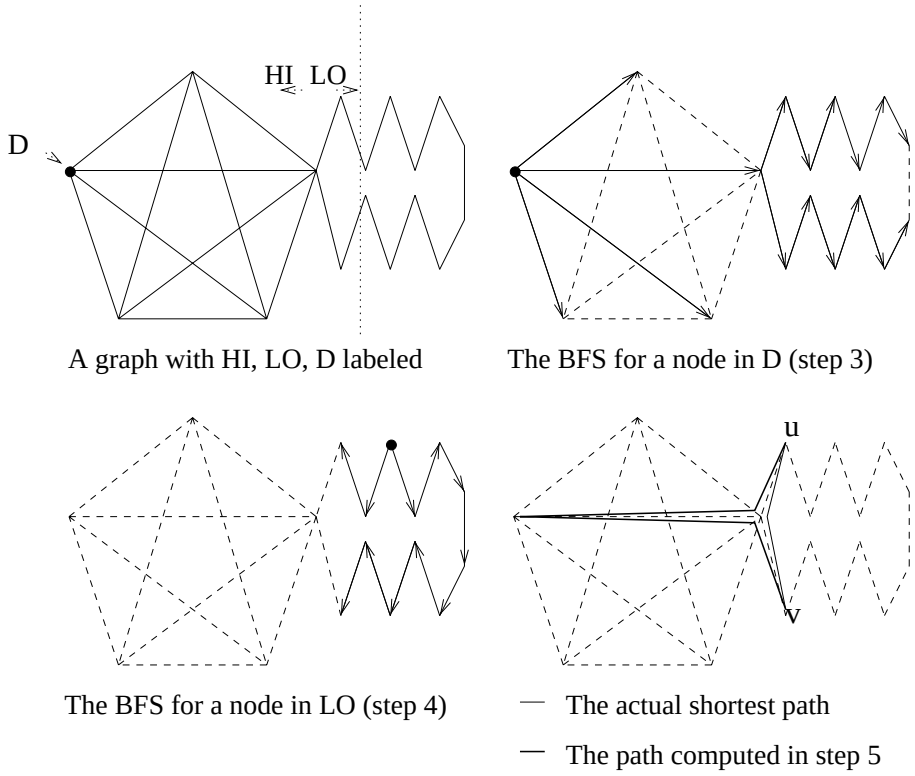

FIG. 4.2. *Illustration of algorithm approx-APSP.*

FACT 4.3. *If the algorithm reports for some* $u \in L(V)$ *that* $\text{B}(u) > 2$*, we can verify this in time* $O(ns)$ *per vertex.*

Thus, by performing a verification for each of the $L(V)$ vertices that report distance over 2, we can improve algorithm approx-APSP so that it always performs as well as the diameter approximation algorithms of the previous section. The first fact also appears to be useful in bringing the diameter error down to 1, but, unfortunately, the vertices in $L(V)$ cannot be handled as easily for larger diameters.

5. Estimating *k*-pairs shortest paths. In this section we consider the problem where we only seek to determine the distances between a given set of distinguished pairs of vertices denoted by P. We show that the algorithm approx-APSP can be generalized to handle this problem with the same error bounds. The generalized algorithm, called approx-kPSP, works in time $O(n^{1.5}\sqrt{k \log n} + n^2 \log^2 n)$, where k is the cardinality of the set P. When P contains all pairs of vertices, the behavior of approx-kPSP is identical to that of approx-APSP. However, for small k, the algorithm is significantly faster than approx-APSP.

The main idea behind the speed-up is the observation that the choice of $s = \sqrt{n \log n}$ is not optimal when we do not need to find the distances between all pairs. Step 5 of approx-APSP (the concatenation of paths) requires at most $O(kns^{-1} \log n)$ time (instead of $O(n^3 s^{-1} \log n)$), so the total time taken is $O(mns^{-1} \log n + n^2 s + kns^{-1} \log n)$. Now, the first term of the sum is not necessarily dominated by the last one. We have two cases: if $k \geq m$, the last term dominates the first but we get the

Algorithm approx-kPSP(i)

Comments:
define $s_i = \frac{n}{2^i}$ and $t = \log\left(\frac{n^{1.5}}{\sqrt{k \log n}}\right)$,
all $\widehat{d}(u,v)$ are initially equal to ∞ and $G_1 = (V_1, E_1)$ is set to G.

1. **if** $i = t$ **then** compute a BFS tree from each vertex $v \in V_i$ in G_i and update $\widehat{d}$ with the shortest path lengths obtained
2. **else let**
   $U_i = \{v \in V_i |$ degree of v in G_i is at least $s_i\}$,
   $V_{i+1} = V_i - U_i$, and
   G_{i+1} be the subgraph of G_i induced by V_{i+1}
   (a) **call** Approx-kPSP(i+1)
   (b) **compute** a dominating set D_i for U_i in G_i
   (c) **compute** a BFS tree from each $v \in D_i$ and update $\widehat{d}$ with the shortest path lengths obtained
   (d) **for each** $\{u,v\} \in P$ **do**

$$\widehat{d}(u,v) \leftarrow \min\{\widehat{d}(u,v), \min_{w \in D_i} \widehat{d}(w,u) + \widehat{d}(w,v)\}$$

3. **return**

FIG. 5.1. *Algorithm approx-kPSP.*

desired running time that depends on k when we balance the second and third terms; conversely, when $k < m$, we observe that the first term dominates the last. Note that the first term is the cost of performing BFS from all the dominating set vertices.

The intuition for the improvement comes from the following example: suppose that all vertices have degree d. Then we could take $s = d$, so $m = O(nd)$ and $|D| = O(\frac{n}{d} \log n)$, and the first term would be equal to $m|D| = O(n^2 \log n)$. This example shows that performing BFS from all the dominating set vertices is not expensive if the degrees are more or less uniform. Of course, in general, such an assumption is not true. However, we can exploit this observation by partitioning the vertex set into $O(\log n)$ classes, such that the ith class consists of vertices of degree between $\frac{n}{2^i}$ and $\frac{n}{2^{i-1}}$, and computing the dominating sets for each class separately. This effectively reduces the first term to $O(n^2 \operatorname{polylog}(n))$, and now we can balance the second and third terms as in the other case.

This algorithm, called approx-kPSP, is described in Figure 5.1. The algorithm is recursive and at the top level it is invoked with parameter value $i = 1$, assuming $G_1 = G$. The algorithms makes t recursive calls, where t is a parameter chosen so as to minimize the running time.

We begin the analysis by identifying the optimal choice of t.

LEMMA 5.1. *The parameter t can be chosen such that the running time of algorithm approx-kPSP is $O(n^{1.5}\sqrt{k \log n} + n^2 \log^2 n)$. This time is achieved for $t = \log(n^{1.5}/\sqrt{k \log n})$.*

Proof. Observe that for each i and $v \in V_i$, the degree of v in G_i is less than s_{i-1} (assume $s_0 = n$). This implies that $|E_i| = O(ns_{i-1})$. Let C_i denote the running time of the invocation of approx-kPSP with argument i. It is easy to see that $C_t = n|E_t|$ and that for $i < t$, C_i is dominated by the time required for steps 2(c) and 2(d) which

require $|D_i||E_i|$ and $k|D_i|$ time, respectively. The total time can now be estimated as follows:

$$\sum_{i=1}^{t} C_i = n|E_t| + \sum_{i=1}^{t-1} (|D_i||E_i| + k|D_i|) \leq \sum_{i=1}^{t-1} \frac{n}{s_i} n s_{i-1} \log n + k \sum_{i=1}^{t-1} \frac{n}{s_i} \log n + n^2 s_t$$
$$\leq 2n^2 \log^2 n + \frac{n}{s_t} k \log n + n^2 s_t.$$

Letting $t = \log(n^{1.5}/\sqrt{k \log n})$ we get $s_t = \Theta(\sqrt{(k \log n)/n}\,)$ which gives the desired bound on the running time of the algorithm. □

We can now complete the analysis of the algorithm.

THEOREM 5.2. *For all pairs $(u, v) \in P$, the distances returned in $\widehat{d}$ by approx-kPSP satisfy the inequalities:*

$$0 \leq \widehat{d}(u, v) - d(u, v) \leq 2.$$

The algorithm runs in time $O(n^2 \log^2 n + n^{1.5}\sqrt{k \log n})$.

Proof. Let $d_i(u, v)$ denote the distance between u and v in G_i. Clearly, it is sufficient to show by induction on i that $0 \leq \widehat{d}(u, v) - d_i(u, v) \leq 2$ after finishing approx-kPSP(i). The base case (for $i = t$) holds trivially since we compute the exact shortest paths. The proof of the inductive step is similar to the proof Theorem 4.1; hence we omit the details. The time bound follows from Lemma 5.1. □

5.1. Application: Randomized approximation scheme for diameter. Algorithm approx-kPSP can be used to obtain a randomized approximation scheme for the diameter of a graph. Let $u, v \in V$ be such that $d(u, v) = \Delta$. If we choose a vertex w uniformly at random from V, the probability of $d(u, w) \leq \frac{\epsilon}{2}\Delta$ is $\Theta(\frac{\epsilon\Delta}{n})$. This guarantees that a set P of $O(\frac{n^2}{\epsilon^2\Delta^2} \log n)$ vertices chosen uniformly at random contains vertices x, y such that $d(u, x) \leq \frac{\epsilon}{2}\Delta$ and $d(v, y) \leq \frac{\epsilon}{2}\Delta$; hence $d(x, y) \geq (1-\epsilon)\Delta$ with high probability. We can use algorithm approx-kPSP to approximate distances between all pairs of vertices in P in $O(n^{1.5}\sqrt{|P| \log n} + n^2 \log^2 n) = O(\frac{n^{2.5}}{\epsilon\Delta} \log n + n^2 \log^2 n)$ time. For large Δ, say, $\Delta = \Omega(n^\delta)$ for some $\delta > 0$, the improvement is significant. We obtain the following theorem.

THEOREM 5.3. *For any $0 < \epsilon < 1$ there exists a Monte Carlo algorithm which finds an estimate E such that $(1-\epsilon)\Delta \leq E \leq \Delta + 2$ in time $O(\frac{n^{2.5}}{\epsilon\Delta} \log n + n^2 \log^2 n)$.*

Note that while this randomized algorithm assumes knowledge of Δ, it is sufficient to provide it with a constant-factor approximation to Δ. The depth of a BFS tree rooted at an arbitrary vertex of G is a 2-approximation for Δ and can be used for this purpose.

6. Experimental results. To evaluate the usefulness of our algorithm, we ran it on two families of graphs and compared the results with a carefully coded algorithm based on BFS. The algorithm approx-APSP was tweaked with the following heuristic improvement to step 5 that avoids many needless iterations: when a node has a neighbor in D, we copy the distances of its neighbor (since they can differ by at most 1). This algorithm (called fast approx-APSP) occasionally has a higher fraction of incorrect entries but seems to be a faster way to solve the APSP problem.

The first family of graphs were random graphs from the $G_{n,m}$ model [5], which are graphs chosen uniformly at random from those with n vertices and m edges. In our experiments, we chose random graphs with n ranging from 10 to 1000, and $2m/n^2$

TABLE 6.1

Summary of experimental results. The speed-up numbers indicate the ratio of the execution time of the carefully coded BFS algorithm to that of the algorithms. The accuracy refers to the ratio of the total number of exact *entries in the distance matrix to the total number of entries in the matrix.*

		Approx-APSP		Fast approx-APSP	
		speed-up	accuracy	speed-up	accuracy
Random graphs	Median	0.52	0.39	5.30	0.51
	Average	0.63	0.39	4.75	0.55
	Std Dev	0.23	0.14	1.70	0.12
GraphBase	Median	0.59	0.69	3.95	0.53
	Average	2.44	0.72	10.18	0.47
	Std Dev	0.24	0.16	1.73	0.13

ranging from 0.03 to 0.90. On these graphs, fast approx-APSP runs about five times faster than the BFS implementation, and about half of the distances are off by one.

The second family of graphs comes from the Stanford GraphBase [14]. We tested all of the connected, undirected graphs from Appendix C in Knuth [14] (ignoring edge weights). This is a very heterogeneous family of graphs, including graphs representing highway connections for American cities, athletic schedules, five-letter English words, and expander graphs, as well as more combinatorial graphs. Thus the results here are quite indicative of practical performance. Although the BFS-based algorithm runs faster for certain subfamilies of the GraphBase, fast approx-APSP outperformed the other algorithms overall.

The results are summarized in Table 6.1. The speed-up numbers indicate the inverse of the ratio of the execution time of the algorithms to that of the carefully coded BFS algorithm. The accuracy refers to the ratio of the total number of *exact* entries in the distance matrix to the total number of entries in the matrix. In both of these families, the accuracy of approx-APSP could be improved by subtracting 1 in step 5. This did not seem necessary given that the BFS approach performed about as fast as approx-APSP, and that fast approx-APSP performed faster with roughly 50% accuracy. The numbers indicate that for general graphs where an additive factor error is acceptable, fast approx-APSP is the algorithm of choice, and for more specific families of graphs, the parameters can be adjusted for even better performance.

7. Conclusions and further work. Our work suggests several interesting directions for future work, the most elementary being the following: is there a combinatorial algorithm running in time $O(n^{3-\epsilon})$ for distinguishing between graphs of diameter 2 and 3? It is our belief that the problem of efficiently computing the diameter can be solved given such a decision algorithm, and our work provides some evidence in support of this belief. Subsequent to our work, Dor, Halperin, and Zwick [11] have shown that the problem of computing APSP with an additive error of at most 1 is as hard as Boolean matrix multiplication. This result still does not resolve the question of whether computing the diameter is easier and raises the interesting question of whether there is some strong equivalence between the diameter and APSP problems, e.g., that their complexity is the same within poly-logarithmic factors. Dor, Halperin, and Zwick have also extended our techniques to obtain tradeoffs between the additive error and the running time and to obtain approximate distances with multiplicative factors instead of additive factors. Finally, of course, removing the additive error from our results remains a major open problem.

Acknowledgments. We are grateful to Noga Alon for his comments and suggestions, and to Nati Linial for helpful discussions. We are also indebted to Edith Cohen for comments that helped us extend some of our results. Thanks also to Michael Goldwasser, David Karger, Sanjeev Khanna, and Eric Torng for their comments.

CONSTRUCTING APPROXIMATE SHORTEST PATH MAPS IN THREE DIMENSIONS*

SARIEL HAR-PELED†

Abstract. We present a new technique for constructing a data structure that approximates shortest path maps in $\mathbb{R}^d$. By applying this technique, we get the following two results on approximate shortest path maps in $\mathbb{R}^3$.

(i) Given a polyhedral surface or a convex polytope $\mathcal{P}$ with n edges in $\mathbb{R}^3$, a source point s on $\mathcal{P}$, and a real parameter $0 < \varepsilon \leq 1$, we present an algorithm that computes a subdivision of $\mathcal{P}$ of size $O((n/\varepsilon)\log(1/\varepsilon))$ which can be used to answer efficiently approximate shortest path queries. Namely, given any point t on $\mathcal{P}$, one can compute, in $O(\log(n/\varepsilon))$ time, a distance $\Delta_{\mathcal{P},s}(t)$, such that $d_{\mathcal{P},s}(t) \leq \Delta_{\mathcal{P},s}(t) \leq (1+\varepsilon)d_{\mathcal{P},s}(t)$, where $d_{\mathcal{P},s}(t)$ is the length of a shortest path between s and t on $\mathcal{P}$.

The map can be computed in $O(n^2 \log n + (n/\varepsilon)\log(1/\varepsilon)\log(n/\varepsilon))$ time, for the case of a polyhedral surface, and in $O((n/\varepsilon^3)\log(1/\varepsilon) + (n/\varepsilon^{1.5})\log(1/\varepsilon)\log n)$ time if $\mathcal{P}$ is a convex polytope.

(ii) Given a set of polyhedral obstacles $\mathcal{O}$ with a total of n edges in $\mathbb{R}^3$, a source point s in $\mathbb{R}^3 \setminus \operatorname{int}\cup_{O\in\mathcal{O}} O$, and a real parameter $0 < \varepsilon \leq 1$, we present an algorithm that computes a subdivision of $\mathbb{R}^3$, which can be used to answer efficiently approximate shortest path queries. That is, for any point $t \in \mathbb{R}^3$, one can compute, in $O(\log(n/\varepsilon))$ time, a distance $\Delta_{\mathcal{O},s}(t)$ that ε-approximates the length of a shortest path from s to t that avoids the interiors of the obstacles. This subdivision can be computed in roughly $O(n^4/\varepsilon^6)$ time.

1. Introduction.

The *three-dimensional Euclidean shortest path problem* is defined as follows: Given a set of pairwise-disjoint polyhedral objects in $\mathbb{R}^3$ and two points s and t, compute the shortest path between s and t which avoids the interiors of the given polyhedral "obstacles." This problem has received considerable attention in computational geometry. It was shown to be NP-hard by Canny and Reif [3], and the fastest available algorithms for this problem run in time that is exponential in the total number of obstacle vertices (which we denote by n) [20, 21]. The apparent intractability of the problem has motivated researchers to develop polynomial-time algorithms for computing approximate shortest paths and for computing shortest paths in special cases.

In the *approximate three-dimensional Euclidean shortest path* problem, we are given an additional parameter $\varepsilon > 0$, and the goal is to compute a path between s and t that avoids the interiors of the obstacles and whose length is at most $(1+\varepsilon)$ times the length of the shortest obstacle-avoiding path (we call such a path an *ε-approximate path*). Approximation algorithms for the three-dimensional shortest path problem were first studied by Papadimitriou [19], who gave an $O(n^4(L+\log(n/\varepsilon))^2/\varepsilon^2)$-time algorithm for computing an ε-approximate shortest path, where L is the number of bits used in each computation. A rigorous analysis of Papadimitriou's algorithm

was recently given by Choi, Sellen, and Yap [6]. A different approach was taken by Clarkson [7], resulting in an algorithm with roughly $O\left(n^2/\varepsilon^4\right)$ running time (the precise result is stated in Theorem 4.2).

The problem of computing a shortest path between two points along the surface of a single convex polytope is an interesting special case of the three-dimensional Euclidean shortest path problem. Sharir and Schorr [22] gave an $O(n^3 \log n)$ algorithm for this problem, exploiting the property that a shortest path on a polyhedron *unfolds* into a straight line. Mitchell, Mount, and Papadimitriou [16] improved the running time to $O(n^2 \log n)$; their algorithm works for nonconvex polyhedra (or polyhedral surfaces) as well. Chen and Han [5] gave another algorithm with an improved running time of $O(n^2)$. It is a rather long-standing and intriguing open problem whether the shortest path on a convex polytope can be computed in subquadratic time. This has motivated the problem of finding near-linear algorithms that produce only an approximation of the shortest path. The first result in this direction is by Hershberger and Suri [12]. They present a simple algorithm that runs in $O(n)$ time and computes a path whose length is at most $2d_P(s,t)$. Using the algorithm of [12], Agarwal et al. [1] present a relatively simple algorithm that computes an ε-approximate shortest path (i.e., a path on ∂P between two points $s,t \in \partial P$ whose length is at most $(1+\varepsilon)d_P(s,t)$) for any prescribed $0 < \varepsilon \leq 1$, where the running time of the algorithm is $O(n \log(1/\varepsilon)+1/\varepsilon^3)$. In a companion paper [11], we present an improved algorithm, with $O(n)$ preprocessing time that answers two-point ε-approximate shortest path queries in $O((\log n)/\varepsilon^{1.5} + 1/\varepsilon^3)$ time for *any* pair of points $s,t \in \partial P$. Recently, Varadarajan and Agarwal [24] gave a subquadratic time algorithm that computes a constant approximation to the shortest path on a polyhedral terrain. Other recent works by Mata and Mitchell [14] and also by Lanthier, Maheshwari, and Sack [13] implement various heuristics for computing approximate shortest paths on weighted terrains (i.e., each face f is being assigned a weight w_f, such that the distance between any two points $a,b \in f$ is $w_f \cdot |ab|$). Those programs give satisfactory results in practice, which are within an order of magnitude better than their worst case analysis.

In this paper, extending our work in [11], we present a new general technique for constructing a data structure that one can use to answer ε-approximate shortest path queries, for a source point s and approximation factor $\varepsilon > 0$ fixed in advance. Using this technique, we solve two problems involving approximate shortest path maps in $\mathbb{R}^3$.

Approximate shortest path maps. The exact algorithms of [16, 22] receive as input a convex polytope or a polyhedral surface $\mathcal{P}$ and a fixed source point s on $\mathcal{P}$, and they compute a map (i.e., a subdivision of $\mathcal{P}$) of complexity $\Theta(n^2)$ that can be used to answer (exact) shortest path queries from s to any point on $\mathcal{P}$ (along $\mathcal{P}$) in $O(\log n)$ time (such a query reports the *length* of the shortest path; reporting the path itself might require more time). This shortest path map can be stored in linear space, for the case of a convex polytope, by using a persistent data structure; see [17]. However, the time required to compute this compact representation of the shortest path map is quadratic in the worst case. This raises the problem of computing a map of near-linear size for approximate shortest path queries from s. We show in section 3 that this is indeed possible: Given a polyhedral surface $\mathcal{P}$ with n edges in $\mathbb{R}^3$, a source point $s \in \mathcal{P}$, and a prescribed $0 < \varepsilon \leq 1$, there exists a map (a subdivision of $\mathcal{P}$) of complexity $O((n/\varepsilon)\log(1/\varepsilon))$, such that for any $t \in \mathcal{P}$, one can compute the length of an ε-approximate shortest path between s and t on $\mathcal{P}$ in $O(\log(n/\varepsilon))$ time by locating t in the map.

We present an algorithm that constructs such an approximation map in $O(n^2 \log n + (n/\varepsilon) \log(1/\varepsilon) \log(n/\varepsilon))$ time for the case of a polyhedral surface, and in $O((n/\varepsilon^3) \log(1/\varepsilon) + (n/\varepsilon^{1.5}) \log(1/\varepsilon) \log n)$ time for the case of a convex polytope. Note that if $\mathcal{P}$ is a convex polytope, then our previous result [11] provides an alternative structure with similar properties. However, the dependence of the query time on ε is much better in the method we present here.

Approximate spatial shortest path maps. In section 4, we present a similar result for ε-approximate shortest paths among polyhedral obstacles in $\mathbb{R}^3$. Let $\mathcal{O}$ be a set of polyhedral obstacles in $\mathbb{R}^3$ with a total of n edges, s a source point in $\mathbb{R}^3$, and $0 < \varepsilon \leq 1$ a parameter. We show that there exists a spatial subdivision $\mathcal{M}$ of $\mathbb{R}^3$ such that for any $t \in \mathbb{R}^3$ one can compute in $O(\log(n/\varepsilon))$ time the length of an ε-approximate shortest path between s and t that avoids the interiors of the obstacles by performing a spatial point-location query with t in $\mathcal{M}$. The space needed to compute and preprocess $\mathcal{M}$ for spatial point-location is $O(n^2/\varepsilon^{4+\delta})$, for any $\delta > 0$, and the preprocessing time is

$$O\left(\frac{n^4}{\varepsilon^2}\left(\frac{\beta(n)}{\varepsilon^4}\log\frac{n}{\varepsilon} + \log(n\rho)\log(n\log\rho)\right)\log\frac{1}{\varepsilon}\right),$$

where ρ is the ratio of the length of the longest edge in $\mathcal{O}$ to the Euclidean distance between s and t, $\beta(n) = \alpha(n)^{O(\alpha(n))^{O(1)}}$, and $\alpha(n)$ is the extremely slowly growing inverse of the Ackermann function. This algorithm uses the algorithm of Clarkson [7] that computes an ε-approximate shortest path between two given points in $O\left(\frac{n^2}{\varepsilon^4}\beta(n)\log\frac{n}{\varepsilon} + n^2\log(n\rho)\log(n\log\rho)\right)$ time.

The paper is organized as follows. Section 2 introduces the notion of a *distance function* and shows how to compute a "small-size" additive weighted Voronoi diagram that enables us to ε-approximate this function. We present two applications of this result. In section 3, we present the algorithm mentioned above for constructing a map for approximate shortest path queries from a fixed source on a convex polytope or a polyhedral surface in $\mathbb{R}^3$. In section 4 we present the algorithm mentioned above for constructing a spatial subdivision for approximate shortest path queries from a fixed source among polyhedral obstacles in $\mathbb{R}^3$. We conclude in section 5 by mentioning a few open problems.

2. Approximating a distance function by a weighted Voronoi diagram.

In this section, we introduce the notion of a distance function and show how to compute a "small-size" additive weighted Voronoi diagram that approximates the function up to a factor of $1 + \varepsilon$. We use this result in sections 3 and 4 to derive our two main results.

DEFINITION 2.1. *Let $\mathcal{I}$ be a subset of $\mathbb{R}^d$. A function $f : \mathcal{I} \to \mathbb{R}$ is a* distance function *on $\mathcal{I}$ if*

(i) $f(x) + f(y) \geq |xy|$ *for any $x, y \in \mathcal{I}$,*
(ii) $f(x) + |xy| \geq f(y)$ *for any straight segment $xy \subseteq \mathcal{I}$,*

where $|xy|$ denotes the Euclidean distance between x and y.

Thus, a distance function has to satisfy two types of triangle inequalities. Since these inequalities are satisfied by the Euclidean distance from any fixed point, a distance function can be regarded as a certain generalization of the Euclidean distance.

Example 2.1. Figure 2.1 illustrates some of the geometric restrictions imposed on a univariate distance function.

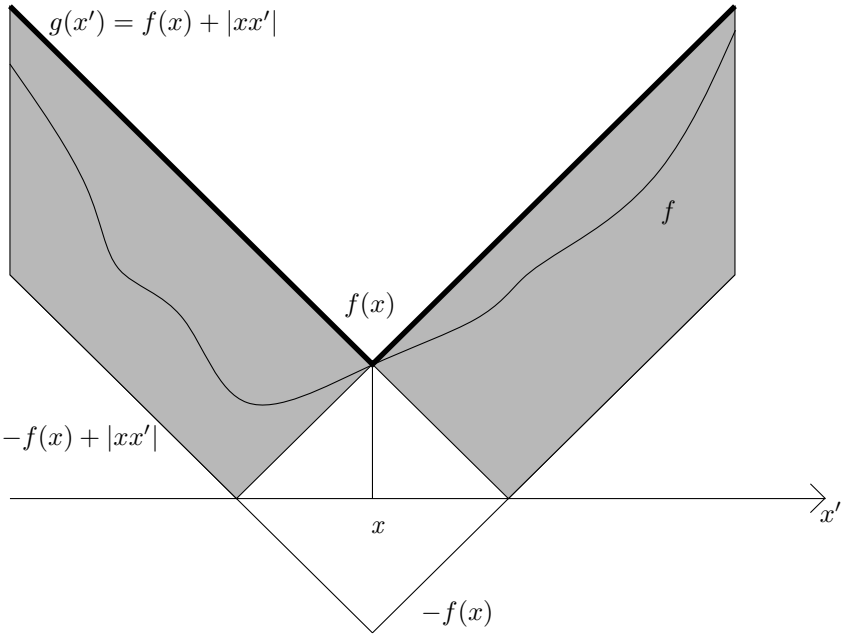

FIG. 2.1. *The graph of the distance function f must lie inside the gray area. This implies that the function* $g(x') = f(x) + |xx'|$ *approximates* $f(x')$ *"well" in a small neighborhood of* x *and for sufficiently large values of* x'.

Example 2.2. (i) Let $\mathcal{P}$ be a polyhedral surface in $\mathbb{R}^3$, and let s be a source point on $\mathcal{P}$. For any $t \in \mathcal{P}$, let $d_{\mathcal{P},s}(t)$ denote the length of a shortest path between s and t on $\mathcal{P}$. It is easy to verify that $d_{\mathcal{P},s}(t)$ is a distance function on $\mathcal{P}$.

(ii) Let $\mathcal{O}$ be a collection of pairwise-disjoint polyhedral obstacles in $\mathbb{R}^3$, and let s be a point in $FP(\mathcal{O}) = \mathbb{R}^3 \setminus \cup_{O \in \mathcal{O}} \text{int}O$. Let $FP(\mathcal{O}, s)$ denote the connected component of $FP(\mathcal{O})$ that contains s (i.e., the set of all the points in $\mathbb{R}^3$ that can be connected to s by a path that avoids the interiors of the obstacles of $\mathcal{O}$).

For any $t \in FP(\mathcal{O}, s)$, we denote by $d_{\mathcal{O},s}(t)$ the length of a shortest path between s and t that avoids the interior of the obstacles of $\mathcal{O}$. Clearly, $d_{\mathcal{O},s}$ is a distance function on $FP(\mathcal{O}, s)$.

DEFINITION 2.2. *A pair* $\mathcal{S} = (S, w)$ *is a* weighted set of points *if* $S = \{p_1, \ldots, p_m\}$ *is a finite set of points in* $\mathbb{R}^d$, *and* $w(\cdot)$ *is a function assigning nonnegative weights to the points of S. We define the distance of a point p from the point* p_i *to be* $V_{(p_i, w(p_i))}(p) = |pp_i| + w(p_i)$. *We define* $V_{\mathcal{S}}(p) = \min_{i=1}^{m} V_{(p_i, w(p_i))}(p)$. *The function* $V_{\mathcal{S}}(p)$ *induces a natural subdivision* $\mathcal{V}_{\mathcal{S}}$ *of* $\mathbb{R}^d$ *into cells, known as the (additive)* weighted Voronoi diagram *of* $\mathcal{S}$, *such that the ith cell is the locus of all points closest to* p_i *in this distance function. As is well known, in the planar case* $\mathcal{V}_{\mathcal{S}}$ *has complexity* $O(m)$, *and it can be computed in* $O(m \log m)$ *time (see* [10]).

Remark 2.1. For $d \geq 3$, the complexity of an additive weighted Voronoi diagram of m points in $\mathbb{R}^d$ is $O\left(m^{\lfloor d/2 \rfloor + 1}\right)$. This follows by reducing the computation of the diagram to the computation of a convex hull in $d + 2$ dimensions. Furthermore, we can compute the diagram in $O(m^{\lfloor d/2 \rfloor + 1})$ time (see [2]).

We next show how to approximate a distance function $f(\cdot)$ by a weighted Voronoi diagram. First, we compute a global minimum p_0 of f. As illustrated in Figure 2.1, the function $V_{(p_0, f(p_0))}(p)$ approximates $f(p)$ "well" for p sufficiently close to, or

sufficiently far from, p_0. In other words, f is well approximated in these regions by the weighted Voronoi diagram of the single site p_0 with weight $f(p_0)$. By adding extra sites to the diagram, we can make the distance induced by the resulting diagram an ε-approximation to f everywhere, as will be shown next.

DEFINITION 2.3. *Given a point $p \in \mathbb{R}^d$, and $r \geq 0$, let $B(p,r)$ denote the closed ball of radius r centered at p, and let $\overline{B}(p,r)$ denote the set $\mathbb{R}^d \setminus B(p,r)$. For $r' > r$, let $\mathcal{A}(p,r,r')$ denote the annulus (or shell) $B(p,r') \setminus B(p,r)$.*

The following sequence of technical lemmas provide the basis for approximating a given distance function by a weighted Voronoi diagram. The following lemmas are stated for arbitrary dimension d. We will apply them with $d = 1, 2$, or 3.

LEMMA 2.4. *Let $\mathcal{I}$ be a convex subset of $\mathbb{R}^d$, f a distance function defined over $\mathcal{I}$, and $\mathcal{S} = (S, w)$ a weighted set such that $S \subseteq \mathcal{I}$ and $f(x) \leq w(x)$ for all $x \in S$. Then $f(t) \leq V_{\mathcal{S}}(t)$ for all $t \in \mathcal{I}$.*

Proof. Let t be any point of $\mathcal{I}$, and let x denote the point of S realizing $V_{\mathcal{S}}(t)$. Then $V_{\mathcal{S}}(t) = w(x) + |tx| \geq f(x) + |tx| \geq f(t)$. ∎

Formalizing the intuition behind Figure 2.1, we have the following.

LEMMA 2.5. *Let $\mathcal{I}$ be a convex subset of $\mathbb{R}^d$, f a distance function defined over $\mathcal{I}$, $0 < \varepsilon \leq 1$ a parameter, p a point in $\mathcal{I}$, and w a real number such that $f(p) \leq w \leq (1+\varepsilon/8)f(p)$. Then $f(t) \leq V_{(p,w)}(t) \leq (1+\varepsilon)f(t)$ for all t in*

$$\mathcal{I} \cap \left(B\left(p, \frac{\varepsilon f(p)}{8}\right) \cup \overline{B}\left(p, \frac{6f(p)}{\varepsilon}\right)\right).$$

Proof. The first inequality $f(t) \leq V_{(p,w)}(t)$ follows immediately from Lemma 2.4.

As for the other inequality, for $t \in \mathcal{I} \cap B(p, \frac{\varepsilon f(p)}{8})$ we have

$$\frac{w}{(1+\varepsilon/8)} - \frac{\varepsilon w}{8} \leq f(p) - |pt| \leq f(t) \leq V_{(p,w)}(t) = w + |pt| \leq w + \frac{\varepsilon w}{8}.$$

However,

$$\frac{w + \varepsilon w/8}{\frac{w}{1+\varepsilon/8} - \varepsilon w/8} = \frac{1+\varepsilon/8}{\frac{1}{1+\varepsilon/8} - \varepsilon/8} \leq \frac{1+\varepsilon/8}{1-\varepsilon/8-\varepsilon/8} = \frac{1+\varepsilon/8}{1-\varepsilon/4} \leq 1+\varepsilon$$

since $\varepsilon \leq 1$. Thus, $V_{(p,w)}(t) \leq (1+\varepsilon)f(t)$ for all $t \in \mathcal{I} \cap B(p, \varepsilon f(p)/8)$.

For $t \in \mathcal{I} \cap \overline{B}(p, 6f(p)/\varepsilon)$, we have

$$|pt| - w \leq |pt| - f(p) \leq f(t) \leq V_{(p,w)}(t) = |pt| + w.$$

However,

$$\frac{|pt| + w}{|pt| - w} = 1 + \frac{2w}{|pt| - w} \leq 1 + \frac{2w}{3w/\varepsilon - w} \leq 1 + \frac{2w}{2w/\varepsilon} = 1 + \varepsilon$$

since $|pt| \geq 6f(p)/\varepsilon \geq 3w/\varepsilon$. Thus, $V_{(p,w)}(t) \leq (1+\varepsilon)f(t)$ for any such t. ∎

LEMMA 2.6. *Let $\mathcal{I}$ be a convex subset of $\mathbb{R}^d$, f a distance function defined over $\mathcal{I}$, $0 < \varepsilon \leq 1$ a parameter, and p a point in $\mathcal{I}$. Then for any $t \in \mathcal{I} \cap B(p, \varepsilon f(p)/9)$ and any number w_t such that $f(t) \leq w_t \leq (1+\varepsilon/8)f(t)$, we have $f(p) \leq V_{(t,w_t)}(p) \leq (1+\varepsilon)f(p)$.*

Proof. Since $|pt| \leq \varepsilon f(p)/9$, it follows that $f(t) \geq f(p) - |pt| \geq f(p)\,(1 - \varepsilon/9)$.

Thus,

$$\frac{\varepsilon f(t)}{8} \geq \frac{\varepsilon}{8} f(p) \left(1 - \frac{\varepsilon}{9}\right) \geq \frac{\varepsilon f(p)}{9} \geq |pt|,$$

implying that $p \in B(t, \varepsilon f(t)/8)$. By Lemma 2.5, we have $f(p) \leq V_{(t,w_t)}(p) \leq (1+\varepsilon)f(p)$. □

The preceding lemmas suggest the following strategy for constructing an approximation of a distance function f over (a convex portion of) $\mathbb{R}^d$: Pick a point p such that $f(p)$ is close to the global minimum of f. The Voronoi diagram $\mathcal{V}_{(p,w)}$ approximates f "well" near p and outside a larger ball centered at p, where w is an approximation of $f(p)$. We approximate f in the space between those two balls by partitioning it into concentric spherical shells whose radii form an increasing geometric progression and by covering each shell by a uniform grid (whose unit length increases with the radius of the shell). In this manner, the number of points needed is only a function of ε (the approximation factor) and d.

When approximating a distance function on a convex subset $\mathcal{I}$ of $\mathbb{R}^d$, we have to cope with the possibility that sites might be placed outside $\mathcal{I}$. We overcome this by projecting all such sites onto the boundary of $\mathcal{I}$.

DEFINITION 2.7. *Let $\mathcal{I}$ be a convex subset in $\mathbb{R}^d$, and let x be a point in $\mathbb{R}^d$. Let $\nu(x,\mathcal{I})$ denote the projection of x onto $\mathcal{I}$; that is, $\nu(x,\mathcal{I})$ is the closest point (in the Euclidean distance) in $\mathcal{I}$ to x. Clearly, if $x \in \mathcal{I}$, then $\nu(x,\mathcal{I}) = x$.*

When x is fixed, we call $\nu(x,\mathcal{I})$ the hook point *of $\mathcal{I}$.*

DEFINITION 2.8. *Let $r \geq r' > 0$ be real numbers, let p be a point in $\mathbb{R}^d$, and let $\mathcal{I}$ be a convex set in $\mathbb{R}^d$. We denote by $S(p,\mathcal{I},r,r')$ the set $\mathcal{I}_{r'} \cap B(p,r) \cap ((r'/\sqrt{d})\mathbb{Z}^d)$, where $\mathbb{Z}^d$ is the integer lattice and $\mathcal{I}_{r'} = \cup_{q\in\mathcal{I}} B(q,r')$ is the set of all points in $\mathbb{R}^d$ that are at distance at most r' from some point of $\mathcal{I}$. Clearly, $|S(p,\mathcal{I},r,r')| = O((r/r')^d)$ (with a constant of proportionality depending on d).*

The following technical lemma shows how to pick the sites of the additive weighted Voronoi diagram so that it ε-approximates a given distance function.

LEMMA 2.9. *Let $\mathcal{I}$ be a convex subset of $\mathbb{R}^d$, $f : \mathcal{I} \to \mathbb{R}$ a distance function, $0 < \varepsilon \leq 1$ a parameter, c a positive constant, and p a point in $\mathcal{I}$ such that $f(t) \geq f(p)/c$ for all $t \in \mathcal{I}$. Then one can compute a set S in $\mathcal{I}$ of size $O((1/\varepsilon)^d \log(1/\varepsilon))$ (the constant of proportionality depends on c) such that $p \in S$, and for any weight function w on S satisfying $f(x) \leq w(x) \leq (1+\varepsilon/8)f(x)$ for all $x \in S$, we have $f(t) \leq V_{\mathcal{S}}(t) \leq (1+\varepsilon)f(t)$ for all $t \in \mathcal{I}$, where $\mathcal{S} = (S,w)$.*

Proof. Let w_p be any number satisfying $f(p) \leq w_p \leq (1+\varepsilon/8)f(p)$.

Let $r_i = (2^i+1)w_p$, for $i = 1,\ldots,m$, where $m = \lceil \log_2(6/\varepsilon) \rceil$. Let $\mathcal{A}_1 = B(p,r_1)$, let $\mathcal{A}_i = \mathcal{A}(p,r_{i-1},r_i)$, for $i = 2,\ldots,m$, and let $\mathcal{A}_{m+1} = \overline{B}(p,r_m)$. Clearly, $\mathcal{I} = \cup_{i=1}^{m+1}(\mathcal{I} \cap \mathcal{A}_i)$.

Let $r'_1 = \varepsilon w_p/(18c)$ and let $r'_i = \varepsilon 2^{i-1} w_p/9$ for $i = 2,\ldots,m$. Let $S'_i = \mathcal{A}_i \cap S(p,\mathcal{I},r_i,r'_i)$ for $i = 1,\ldots,m$. Let $S = \{p\} \cup \bigcup_{i=1}^m S_i$, where $S_i = \{\nu(x,\mathcal{I}) | x \in S'_i\}$, for $i = 1,\ldots,m$. See Figure 2.2 for an illustration of the set S.

Let w be any weight function such that $f(x) \leq w(x) \leq (1+\varepsilon/8)f(x)$ for any $x \in S$, and let $\mathcal{S} = (S,w)$.

We claim that $\mathcal{S}$ is the required weighted set. Indeed, let $t \in \mathcal{I}$. If $t \in \mathcal{A}_{m+1}$, then $|pt| \geq (2^m+1)w_p \geq 6f(p)/\varepsilon$. Thus, $t \in \overline{B}(p, 6f(p)/\varepsilon)$, and by Lemmas 2.4 and 2.5, we have $f(t) \leq V_{\mathcal{S}}(t) \leq V_{(p,w_p)}(t) \leq (1+\varepsilon)f(t)$.

If $t \in B(p,r_m)$, let $\mathcal{A}_i$ be the shell containing t. Let x' be the closest point to t in S'_i. Let $x = \nu(x',\mathcal{I})$. By the definition of ν and S'_i and by the convexity of $\mathcal{I}$, we have $|tx| \leq |tx'| \leq r'_i$ (see Figure 2.3).

If $i = 1$, then the inequality $f(t) \geq f(p)/c \geq w_p/2c$ implies that $|tx| \leq r'_1 = \varepsilon w_p/(18c) \leq \varepsilon f(t)/9$. Thus, $x \in B(t, \varepsilon f(t)/9)$.

If $i > 1$, then we also have $|tx| \leq r'_i = \varepsilon 2^{i-1} w_p/9 \leq \varepsilon f(t)/9$, since $f(t) \geq$

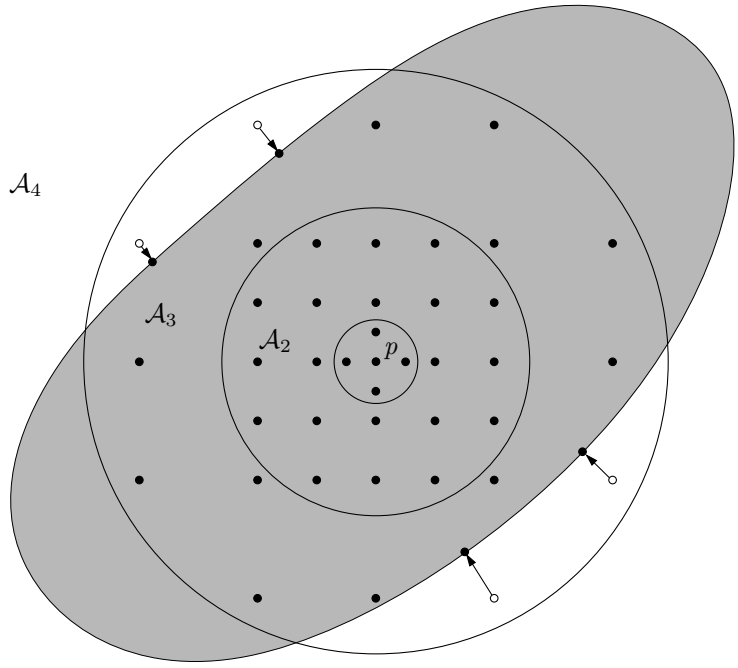

FIG. 2.2. *Illustration of the proof of Lemma* 2.9. *We pick our sites to be on a uniform grid inside each concentric shell around p.*

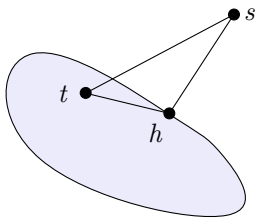

FIG. 2.3. $|st| \geq |ht|$ *for* $h = \nu(s, \mathcal{I})$.

$|pt| - f(p) \geq (2^{i-1}+1)w_p - f(p) \geq 2^{i-1}w_p$. Thus, $x \in B(t, \varepsilon f(t)/9)$.

By Lemmas 2.6 and 2.4, we have $f(t) \leq V_{\mathcal{S}}(t) \leq V_{(x,w(x))}(t) \leq (1+\varepsilon)f(t)$.

As for the size of S, we have

$$|S| = O\left(\sum_{i=1}^{m}\left(\frac{r_i}{r'_i}\right)^d\right) = O\left(\left(\frac{3w_p}{\varepsilon w_p/(18c)}\right)^d + \sum_{i=2}^{m}\left(\frac{(2^i+1)w_p}{\varepsilon 2^{i-1}w_p/9}\right)^d\right)$$
$$= O\left(\frac{1}{\varepsilon^d}\log\frac{1}{\varepsilon}\right). \qquad \square$$

To approximate a distance function $f(\cdot)$ using the constructive proof of Lemma 2.9, we need to find a point which is, within a constant factor, a global minimum of f over the given range. The following lemma shows that this can be easily done if f has a known zero point outside the given range.

LEMMA 2.10. *Let $\mathcal{I}'$ be a subset of $\mathbb{R}^d$, $f : \mathcal{I}' \to \mathbb{R}$ a distance function, $0 < \varepsilon \leq 1$ a parameter, $\mathcal{I}$ a convex subset of $\mathcal{I}'$, and s a point in $\mathcal{I}' \setminus \mathcal{I}$ such that $f(s) = 0$. Then $f(t) \geq f(h)/2$ for all $t \in \mathcal{I}$, where $h = \nu(s, \mathcal{I})$.*

Proof. Let t be any point in $\mathcal{I}$. Since h is the closest point in $\mathcal{I}$ to s and $\mathcal{I}$ is convex, it easily follows that $|st| \geq |ht|$ (see Figure 2.3). Since $f(t) = f(t) + f(s) \geq |st|$, we have $f(t) \geq |ht|$. Moreover, the segment ht is contained in $\mathcal{I}$, implying that $f(h) \leq f(t) + |ht| \leq 2f(t)$. □

Remark 2.2. The lemma also holds when $s \in \mathcal{I}$, but then it only yields the trivial bound $f(t) \geq 0$ for all $t \in \mathcal{I}$. Then, of course, s is the required global minimum.

Remark 2.3. Let $\mathcal{I}'$ be a set in $\mathbb{R}^d$, $\mathcal{I}$ a convex subset of $\mathcal{I}'$, $f : \mathcal{I}' \to \mathbb{R}$ a distance function, $0 < \varepsilon \leq 1$ a parameter, and s a point of $\mathcal{I}'$ such that $f(s) = 0$. Computing a weighted set $\mathcal{S} = (S, w)$ such that the weighted Voronoi diagram induced on $\mathcal{I}$ approximates f up to a factor of $(1 + \varepsilon)$ can be accomplished by following the proof of Lemma 2.9 in four stages:

(i) Compute the point $p = \nu(s, \mathcal{I})$. By Lemma 2.10, p is "almost" a minimum of f on $\mathcal{I}$.
(ii) Compute an $(\varepsilon/8)$-approximation w_p to $f(p)$ (as prescribed in the lemma).
(iii) Construct the set S of points in $\mathcal{I}$, as prescribed in the proof.
(iv) Approximate the distance function values of all the points of S, up to a factor of $1 + \varepsilon/8$, and use these values as the weights for the points of S.

Remark 2.4. The set of points S produced in the proof of Lemma 2.9 is made out of $O(\log(1/\varepsilon))$ subsets (i.e., $S_1, \ldots, S_m$) such that $f(x) \leq cf(t)$, for all $x, t \in S_i$, for $1 \leq i \leq m$, where c is an appropriate constant. This property enables us, in the case of shortest paths on a convex polytope, to approximate the value of the distance function to all the points of S_i simultaneously, yielding a more efficient algorithm. See Remark 3.1 for the details.

Remark 2.5. Let $\mathcal{I}'$ be a subset of $\mathbb{R}^d$, and let f, g be two distance functions defined over $\mathcal{I}'$. It is easy to verify that $h(x) = \max(f(x), g(x))$ is also a distance function. This implies that the distance function induced by any furthest neighbor Voronoi diagram of a finite set of points in $\mathbb{R}^d$ is a distance function in $\mathbb{R}^d$. Hence, by Lemma 2.9 we have the following.

COROLLARY 2.11. *Any furthest neighbor Voronoi diagram of points in $\mathbb{R}^d$ can be ε-approximated by a (nearest neighbor) weighted Voronoi diagram with $O((1/\varepsilon^d) \log(1/\varepsilon))$ sites.*

We can strengthen Lemma 2.9 by noticing that in the cases to which we are going to apply it, our distance function is the length of a shortest path from a fixed source point to the given point of $\mathcal{I}$. In such cases, if the source point lies outside $\mathcal{I}$, then a shortest path connecting any point in $\mathcal{I}$ to our source point must first pass through the boundary $\partial\mathcal{I}$. We next show that if we are able to ε-approximate the distance on the boundary of $\mathcal{I}$, then we can trivially ε-approximate the distance function to all the points of $\mathcal{I}$.

DEFINITION 2.12. *Let $\mathcal{I}$ be a convex polytope in $\mathbb{R}^d$. We call a function $f : \mathcal{I} \to \mathbb{R}$* boundary-induced *on $\mathcal{I}$, if f is a distance function, and for any $t \in \mathcal{I}$, there exists a point $x \in \partial\mathcal{I}$ such that $f(t) = f(x) + |tx|$.*

DEFINITION 2.13. *Given a convex polytope $\mathcal{I}$ in $\mathbb{R}^d$, we denote by $\phi(\mathcal{I})$ the set of all the facets ($(d-1)$-faces) of $\mathcal{I}$.*

LEMMA 2.14. *Let $\mathcal{I}$ be a convex polytope in $\mathbb{R}^d$, $f : \mathcal{I} \to \mathbb{R}$ a boundary-induced distance function, and $0 < \varepsilon \leq 1$ a parameter. For any facet F of $\mathcal{I}$, let $\mathcal{S}(F) = (S_F, w_F)$ be a weighted set of points in F such that $f(t) \leq V_{\mathcal{S}(F)}(t) \leq (1 + \varepsilon)f(t)$,*

for all $t \in F$. Then $f(t) \leq V_{\mathcal{S}}(t) \leq (1+\varepsilon)f(t)$ for all $t \in \mathcal{I}$, where $\mathcal{S} = (S, w) = \cup_{F \in \phi(\mathcal{I})} \mathcal{S}(F)$.

Proof. For any $t \in \mathcal{I}$, let x be the point in $\partial\mathcal{I}$ satisfying $f(t) = f(x) + |tx|$, and let F be a facet of $\mathcal{I}$ that contains x. By Lemma 2.4, we have

$$f(x) + |tx| = f(t) \leq V_{\mathcal{S}}(t) \leq V_{\mathcal{S}}(x) + |tx| \leq V_{\mathcal{S}(F)}(x) + |tx| \leq (1+\varepsilon)f(x) + |tx| \leq (1+\varepsilon)(f(x) + |tx|) = (1+\varepsilon)f(t). \qquad \square$$

Remark 2.6. Let $\mathcal{I}'$ be a set in $\mathbb{R}^d$, $\mathcal{I}$ a convex subset of $\mathcal{I}'$, $f : \mathcal{I}' \to \mathbb{R}$ a boundary-induced distance function, $0 < \varepsilon \leq 1$ a parameter, and s a point of $\mathcal{I}'$ such that $f(s) = 0$. Computing a weighted set $\mathcal{S} = (S, w)$ such that the weighted Voronoi diagram induced on $\mathcal{I}$ approximates f up to a factor of $(1+\varepsilon)$, can be done by applying the algorithm described in Remark 2.3 for each facet of $\mathcal{I}$. By Lemma 2.14, the union of all these weighted sets has the required properties.

3. Approximate shortest path map on a polyhedral surface in $\mathbb{R}^3$. Let $\mathcal{P}$ be a given polyhedral surface in $\mathbb{R}^3$ with n edges, let s be a source point on $\mathcal{P}$, and let $0 < \varepsilon \leq 1$ be a given parameter. In this section, we give an algorithm for constructing an approximation map on $\mathcal{P}$ of complexity $O((n/\varepsilon)\log(1/\varepsilon))$ such that given any $t \in \mathcal{P}$, one can compute in $O(\log(n/\varepsilon))$ time a distance $\Delta_{\mathcal{P}}(s,t)$ satisfying $d_{\mathcal{P}}(s,t) \leq \Delta_{\mathcal{P}}(s,t) \leq (1+\varepsilon)d_{\mathcal{P}}(s,t)$.

Although the following description is rather technical, one has to bear in mind that it is a straightforward implementation of the technique of Section 2. Namely, for each edge of our domain (polyhedral terrain, or a convex polytope) we compute a "small" set of points, the (geodesic) distance from the source point to all those points, and we construct the weighted additive Voronoi diagram that those points induce on each face of the domain.

DEFINITION 3.1. *A* polyhedral surface $\mathcal{P}$ *in* $\mathbb{R}^3$ *is the union of a collection of planar polygonal faces, with their edges and vertices, such that each edge is incident to at most two faces and any pair of faces intersect either at a common edge, a common vertex, or not at all. A face is a simple closed polygon (i.e., it contains its boundary), and an edge is a closed segment (i.e., it contains its endpoints). Without loss of generality we assume that all the faces are triangular (since simple polygons may be triangulated in linear time* [4] *and the number of new edges introduced by the triangulation is linear in the number of vertices). We also assume that $\mathcal{P}$ is connected.*

A polyhedral terrain *is a polyhedral surface that intersects every vertical line in at most a single point.*

DEFINITION 3.2. *Given a polyhedral surface $\mathcal{P}$ in $\mathbb{R}^3$ and any two points s, t on $\mathcal{P}$, we denote by $d_{\mathcal{P},s}(t)$ the length of a shortest path between s and t on $\mathcal{P}$.*

As noted in Example 2.2 (i), $d_{\mathcal{P},s}(\cdot)$ is a distance function on $\mathcal{P}$. Moreover, if F is a face of $\mathcal{P}$ and $s \notin F$, then $d_{\mathcal{P},s}$ is boundary induced on F. (If $s \in F$, then $d_{\mathcal{P},s}(t)$ is the Euclidean distance $|st|$.)

The following theorem is the main result of this section.

THEOREM 3.3. *Let $\mathcal{P}$ be a polyhedral surface in $\mathbb{R}^3$ with n edges, s a source point on $\mathcal{P}$, and $0 < \varepsilon \leq 1$ a real parameter. Then there exists a subdivision Π of $\mathcal{P}$ of complexity $O((n/\varepsilon)\log(1/\varepsilon))$, which facilitates ε-approximate shortest path queries from s on $\mathcal{P}$. That is, for any query point t on $\mathcal{P}$, one can compute, in $O(\log(n/\varepsilon))$ time, a distance $\Delta_{\mathcal{P}}(s,t)$ such that $d_{\mathcal{P},s}(t) \leq \Delta_{\mathcal{P}}(s,t) \leq (1+\varepsilon)\, d_{\mathcal{P},s}(t)$.*

The map can be computed in $O(n^2 \log n + (n/\varepsilon)\log(1/\varepsilon)\log(n/\varepsilon))$ time if $\mathcal{P}$ is an arbitrary polyhedral surface, and in $O((n/\varepsilon^3)\log(1/\varepsilon) + (n/\varepsilon^{1.5})\log(1/\varepsilon)\log n)$ time if $\mathcal{P}$ is a convex polytope.

The space used by the algorithm is $O((n/\varepsilon)\log(1/\varepsilon))$ if $\mathcal{P}$ is either a convex polytope or a polyhedral terrain, and $O(n^2 + (n/\varepsilon)\log(1/\varepsilon))$ otherwise.

Proof. For each face F of $\mathcal{P}$ that does not contain s, we construct a weighted Voronoi diagram that approximates $d_{\mathcal{P},s}$ on F. By Remark 2.6, this can be done by constructing a weighted Voronoi diagram on each edge of $\mathcal{P}$, as outlined in Remark 2.3.

For the general case, we compute the exact shortest path map of s on $\mathcal{P}$, using the algorithm of [16], in $O(n^2 \log n)$ time. The exact map enables us to compute the shortest distance from s to any point of $\mathcal{P}$ in $O(\log n)$ time. Thus, computing the distances from s to the n hooks of the edges of $\mathcal{P}$ takes additional $O(n \log n)$ time. The hook point of an edge is the closest point of the edge to s, and it can be computed in $O(1)$ time.

For the convex case, we approximate the distances on $\mathcal{P}$ to all the hooks on the edges of $\mathcal{P}$, up to a factor of $(1+\varepsilon/8)$. This takes $O(n/\varepsilon^3 + (n/\varepsilon^{1.5})\log n)$ time, using the algorithm of [1, section 6].

For each edge e of $\mathcal{P}$, we compute a set S_e of $O((1/\varepsilon)\log(1/\varepsilon))$ points on e, as specified in the proof of Lemma 2.9, taking the corresponding p to be the hook of e and w_p to be the approximated (exact in the nonconvex case) distance along $\mathcal{P}$ from s to p. Let $S = \cup_e S_e$, taken over all edges e of $\mathcal{P}$.

We now compute (or approximate) the distances from s to all the points in S. For the nonconvex case, this can be done in $O((n/\varepsilon)\log(1/\varepsilon)\log n)$ time, using the exact shortest path map.

For the convex case, we compute approximate distances from s to all points of S, up to a factor of $(1+\varepsilon/8)$. Using the observation of Remark 2.4, we partition S into $O(n\log(1/\varepsilon))$ sets, each of size $O(1/\varepsilon)$, such that the required distances to the points in each such set are within a fixed constant factor of each other (namely, for each edge e of $\mathcal{P}$, the set S_e is decomposed into $O(\log(1/\varepsilon))$ sets, as in the proof of Lemma 2.9). Using the algorithm described in Remark 3.1 below, we can compute the distances from s to all the points of S in $O((n/\varepsilon^3)\log(1/\varepsilon) + (n/\varepsilon^{1.5})\log(1/\varepsilon)\log n)$ time.

Next, we compute, for each face F of $\mathcal{P}$, the weighted Voronoi diagram induced by the weighted points of $\mathcal{S}$ that lie on ∂F. This takes $O((n/\varepsilon)\log^2(1/\varepsilon))$ overall time (see [10]), since each face contains $O((1/\varepsilon)\log(1/\varepsilon))$ points of $\mathcal{S}$. Let Π be the resulting map, consisting of the union of all those facial Voronoi diagrams.

By Lemmas 2.9 and 2.14, the map Π on $\mathcal{P}$ has the required properties. Moreover, we can preprocess each face F of $\mathcal{P}$ in $O((1/\varepsilon)\log^2(1/\varepsilon))$ time such that point location queries on F can be answered in $O(\log(1/\varepsilon))$ time (see [18]). Overall, this preprocessing takes $O((n/\varepsilon)\log^2(1/\varepsilon))$ time.

To answer an approximate shortest path query for a query point q, the algorithm must locate the face of $\mathcal{P}$ containing q. If $\mathcal{P}$ is a polyhedral terrain, we project the terrain into the xy-plane and preprocess it, in $O(n\log n)$ time, for planar point location. If $\mathcal{P}$ is a convex polytope, it can be preprocessed in linear time to answer point location queries in $O(\log n)$ time (see [9]). Otherwise, we preprocess $\mathcal{P}$ for spatial point-location in $O(n^2 \log n)$ time and $O(n^2)$ space with $O(\log n)$ query time, using the algorithm of [23].

Given any query point q on $\mathcal{P}$, the algorithm computes the face F of $\mathcal{P}$ that contains q in $O(\log n)$ time. Locating the face of the subdivision Π that contains q takes an additional $O(\log(1/\varepsilon))$ time. Thus, ε-approximate shortest path queries for $\mathcal{P}$ can be answered in $O(\log(n/\varepsilon))$ time. (If the face containing q is already known, the query time reduces to $O(\log(1/\varepsilon))$.) ∎

DEFINITION 3.4. *Let P be a convex body in $\mathbb{R}^3$. An* outer path *of P is a curve γ connecting two points on ∂P and disjoint from the interior of P.*

Remark 3.1. Let P be a convex polytope in $\mathbb{R}^3$, s a source point on P, T a set of points on P, and $0 < \varepsilon \leq 1$ a prescribed parameter. One can ε-approximate the length of the shortest path from s to all the points of T on P, in $O((n+|T|)/\varepsilon^3 + ((n+|T|)/\varepsilon^{1.5}) \log (n+|T|))$ time, by adding the points of T as vertices to P and by using the algorithm of [1, section 6].

The algorithm of [1] works by computing an approximation polytope for each point of T and by computing the exact distance from s to the point on this polytope.

Moreover, suppose that T can be partitioned into m sets $T_1, \ldots, T_m$ such that $d_{P,s}(t) \leq c \cdot d_{P,s}(t')$ for all $t, t' \in T_i$ and for each $i = 1, \ldots, m$, where c is a prescribed constant and all the points of T_i belong to the same edge of P, for any fixed $i = 1, \ldots, m$. Then it is possible to speed up the above algorithm, as follows. Instead of constructing an approximation polytope for each destination point separately, we construct an approximation polytope that can be used to approximate the distances from s to all the points of T_i, for $i = 1, \ldots, m$. This is done by ensuring that all the points of T_i lie on the boundary of the approximation polytope calculated by the algorithm, which can be enforced by intersecting it with a supporting plane of P passing through the edge containing the points of T_i (adding at most one new face to the approximation polytope). We also need to use a more refined approximation polytope, so as to achieve the claimed error bound, but since c is a constant this does not change the asymptotic complexity of the algorithm. See [1] for the technical details.

This improves the running time to

$$O\left(n + \frac{m}{\varepsilon^3} + \frac{m}{\varepsilon^{1.5}} \log n + \frac{|T|}{\varepsilon^{1.5}}\right)$$

by constructing an approximation polytope for the points of T_i (in $O(\frac{m}{\varepsilon^{1.5}} \log n)$ time), computing the exact distance map from the source point on the approximation polytope (in $O(1/\varepsilon^3)$ time), and extracting the shortest path to each point of T_i, repeating all this, for $T_1, \ldots, T_m$. Moreover, for each point $t \in T_i$, the algorithm computes a polygonal outer path of P, made up of $O(1/\varepsilon^{1.5})$ segments, that realizes the approximated distance.

Remark 3.2. The algorithm of [16] works for arbitrary polyhedral surfaces; in particular, it is not restricted to polyhedral terrains. Thus, the algorithm of Theorem 3.3 also works for general polyhedral surfaces.

Remark 3.3. For a convex polytope P with n edges in $\mathbb{R}^3$, one can compute an approximation map that can be used to compute an outer path that realizes the approximate distance. This is done by modifying the algorithm of Theorem 3.3 such that it stores an outer path from the source point to each of the constructed sites, where the outer path realizes its ε-approximate distance. Such a path is readily available from the procedure used to compute the approximate distance to the site, and the complexity of such a path is $O(1/\varepsilon^{1.5})$ (see [1]). The space needed to store the extended approximation map is $O(n/\varepsilon^{2.5} \log (1/\varepsilon))$, and the computation time remains $O((n/\varepsilon^3) \log(1/\varepsilon) + (n/\varepsilon^{1.5}) \log (1/\varepsilon) \log n)$.

The new map can be used to answer approximate shortest path queries, in $O(\log (n/\varepsilon))$ time, and also compute, in additional $O(1/\varepsilon^{1.5})$ time, an outer path of the convex polytope realizing this distance. Such an outer path can be projected onto the boundary of the convex polytope in additional $O\left(n \log (1/\varepsilon) + 1/\varepsilon^3\right)$ time,

resulting in a path on ∂P which is an ε-approximation to the shortest path (see [1]). Note, however, that the performance of the enhanced data structure is poorer in terms of both storage and query time.

4. Constructing spatial approximate shortest path maps in $\mathbb{R}^3$. Let $\mathcal{O}$ be a collection of pairwise-disjoint polyhedral obstacles in $\mathbb{R}^3$, s a source point in $\mathbb{R}^3 \setminus int \cup \mathcal{O}$, and $0 < \varepsilon \leq 1$ a parameter. In this section, we present an algorithm for preprocessing $\mathcal{O}$ such that for any point in $\mathbb{R}^3$ (or, more precisely, for any "free" point that can be reached from s without penetrating an obstacle) one can compute in $O(\log(n/\varepsilon))$ time a distance $\Delta_{\mathcal{O},s}(t)$ satisfying $d_{\mathcal{O},s}(t) \leq \Delta_{\mathcal{O},s}(t) \leq (1+\varepsilon)d_{\mathcal{O},s}(t)$, where $d_{\mathcal{O},s}(t)$ is the length of a shortest path between s and t that avoids the interiors of the obstacles.

The preprocessing time of the algorithm is roughly $O(n^4/\varepsilon^6)$, which shows that the problem of approximating the distance from a single source to all the "free" points in $\mathbb{R}^3$ is not much harder (computationally) than approximating the distance between any specific pair of points (which can be done in roughly $O(n^2/\varepsilon^4)$ time (see [7])). In fact, for a fixed source point and many destination points, our algorithm will actually be faster. The problem of computing the *exact* distance between two points in $\mathbb{R}^3$ among polyhedral obstacles is NP-hard, as shown by Canny and Reif [3], and the fastest available algorithms for this problem run in time that is exponential in the total number of obstacle vertices [20, 21, 22].

DEFINITION 4.1. *Let $\mathcal{O}$ be a collection of pairwise-disjoint polyhedral obstacles with a total of n edges in $\mathbb{R}^3$ and s a source point in $FP(\mathcal{O}) = \mathbb{R}^3 \setminus int \cup_{O \in \mathcal{O}} O$. Let $FP(\mathcal{O}, s)$ denote the set of all points in $FP(\mathcal{O})$ that can be connected to s by a path that avoids the interiors of the obstacles of $\mathcal{O}$.*

For any $t \in FP(\mathcal{O}, s)$, as above, we denote by $d_{\mathcal{O},s}(t)$ the length of a shortest path between s and t that avoids the interiors of the obstacles of $\mathcal{O}$.

As noted in Example 2.2 (ii), $d_{\mathcal{O},s}(\cdot)$ is a distance function over $FP(\mathcal{O}, s)$, and for any convex set $\mathcal{I} \subseteq FP(\mathcal{O}, s)$ such that $s \notin \mathcal{I}$, the function $d_{\mathcal{O},s}(\cdot)$ is boundary induced over $\mathcal{I}$.

THEOREM 4.2 (Clarkson [7]). *Given a set $\mathcal{O}$ of polyhedral obstacles in $\mathbb{R}^3$, and points s and t, an ε-approximate path between s and t that does not penetrate into any obstacle in $\mathcal{O}$ can be computed in*

$$O\left(\frac{n^2}{\varepsilon^4}\beta(n)\log\frac{n}{\varepsilon} + n^2\log(n\rho)\log(n\log\rho)\right)$$

time, where n is the number of obstacle edges, ρ is the ratio of the length of the longest edge in $\mathcal{O}$ to the Euclidean distance between s and t, $\beta(n) = \alpha(n)^{O(\alpha(n))^{O(1)}}$, and $\alpha(n)$ is the inverse of the Ackermann function.

The following theorem is the main result of this section.

THEOREM 4.3. *Let $\mathcal{O}$ be a collection of pairwise-disjoint polyhedral obstacles with n edges in $\mathbb{R}^3$, s a source point in $FP(\mathcal{O})$, and $0 < \varepsilon < 1$ a parameter. Then a subdivision $\mathcal{M}$ of $FP(\mathcal{O}, s)$ of complexity $O(n^2/\varepsilon^{4+\delta})$, for any $1 > \delta > 0$, can be computed in*

$$O\left(\frac{n^4}{\varepsilon^2}\left(\frac{\beta(n)}{\varepsilon^4}\log\frac{n}{\varepsilon} + \log(n\rho)\log(n\log\rho)\right)\log\frac{1}{\varepsilon}\right)$$

time, where ρ, and $\beta(n)$ are as above.

For any query point $t \in FP(\mathcal{O}, s)$, one can compute in $O(\log(n/\varepsilon))$ time a distance $\Delta_{\mathcal{O},s}(t)$ such that $d_{\mathcal{O},s}(t) \leq \Delta_{\mathcal{O},s}(t) \leq (1+\varepsilon)\ d_{\mathcal{O},s}\ (t)$.

Proof. First, we partition $FP(\mathcal{O})$ into $O(n^2)$ vertical prisms. This can be easily done by erecting a vertical wall from each edge of the obstacles. For an edge e of the obstacles, such a wall is the set of all points in $FP(\mathcal{O})$ that lie on vertical rays emanating from the edge and not intersecting the obstacles. Let $\mathcal{M}'''$ denote the resulting partition of $FP(\mathcal{O})$. It is easy to verify that the complexity of $\mathcal{M}'''$ is $O(n^2)$ and that it can be computed in $O(n^2 \log n)$ time.

We refine $\mathcal{M}'''$ by further partitioning each cell of $\mathcal{M}'''$ into vertical triangular prisms. This is done by projecting each cell of $\mathcal{M}'''$ into the xy-plane and by triangulating the resulting polygon in $O(m \log m)$ time (see [18]), where m is the number of vertices of the polygon. For each new edge created, we erect a corresponding vertical wall inside the cell. Let $\mathcal{M}''$ be the resulting subdivision of $FP(\mathcal{O})$. Clearly, the complexity of $\mathcal{M}''$ remains $O(n^2)$, and it can be computed in additional $O(n^2 \log n)$ time.

Let T_v be the vertical prism in $\mathcal{M}''$ that contains s. We construct an adjacency graph G on the vertical prisms of $\mathcal{M}''$. By computing the connected component of G that contains T_v, one obtains the subdivision $\mathcal{M}' = \mathcal{M}'' \cap FP(\mathcal{O}, s)$.

Each cell $\mathcal{I}$ of $\mathcal{M}'$ is a vertical prism, having at most five faces. We can approximate the distance function $d_{\mathcal{O},s}(t)$ inside $\mathcal{I}$ by computing a weighted set $\mathcal{S}_{\mathcal{I}} = (S_{\mathcal{I}}, w_{\mathcal{I}})$, as specified in the proofs of Lemmas 2.9 and 2.14. To do so, it is necessary to $(\varepsilon/8)$-approximate the value of $d_{\mathcal{O},s}(\cdot)$ for $O((1/\varepsilon^2)\log(1/\varepsilon))$ points (i.e., the points of $\mathcal{S}_{\mathcal{I}}$). By Theorem 4.2, this takes

$$O\left(\left(\frac{\beta(n)}{\varepsilon^4}\log\frac{n}{\varepsilon} + \log(n\rho)\log(n\log\rho)\right)\frac{n^2}{\varepsilon^2}\log\frac{1}{\varepsilon}\right)$$

time. The weighted Voronoi diagram $\mathcal{V}_{\mathcal{S}_{\mathcal{I}}}$ induced by $\mathcal{S}_{\mathcal{I}}$ inside $\mathcal{I}$ approximates $d_{\mathcal{O},s}$ inside $\mathcal{I}$ up to a factor of $1+\varepsilon$.

Let $\mathcal{S} = \cup_{\mathcal{I}\in\mathcal{M}'}\mathcal{S}_{\mathcal{I}}$. Clearly, one can $(\varepsilon/8)$-approximate the distance between s and all the sites of $\mathcal{S}$ in

$$O\left(\frac{n^4}{\varepsilon^2}\left(\frac{\beta(n)}{\varepsilon^4}\log\frac{n}{\varepsilon} + \log(n\rho)\log(n\log\rho)\right)\log\frac{1}{\varepsilon}\right)$$

time.

Let $\mathcal{M}$ be the subdivision $\cup_{\mathcal{I}\in\mathcal{M}'}\ (\mathcal{V}_{\mathcal{S}_{\mathcal{I}}} \cap \mathcal{I})$. We preprocess $\mathcal{M}$ for spatial point location by constructing a two-level spatial point location data structure. First, we preprocess $\mathcal{M}'$ for point location in $O(n^2 \log n)$ time, using the algorithm of [23]. Next, we preprocess each cell $\mathcal{I}$ of $\mathcal{M}'$ for nearest neighbor queries for the weighted set $\mathcal{S}_{\mathcal{I}}$. By Lemma 4.5, performing this preprocessing for all the cells of $\mathcal{M}'$ takes a total of $O\left(n^2/\varepsilon^{4+\delta}\right)$ randomized expected time and space, for any $\delta > 0$.

For any query point $t \in FP(\mathcal{O}, s)$, we can compute in $O(\log n + \log(1/\varepsilon)) = O(\log(n/\varepsilon))$ time the cell of $\mathcal{M}$ that contains t; that is, in $O(\log(n/\varepsilon))$ time, one can compute a distance $\Delta_{\mathcal{O},s}(t)$ such that $d_{\mathcal{O},s}(t) \leq \Delta_{\mathcal{O},s}(t) \leq (1+\varepsilon)d_{\mathcal{O},s}(t)$. ∎

To complete the description and analysis of the algorithm, we next show how to preprocess a weighted set in $\mathbb{R}^3$ so that one can perform efficient nearest neighbor queries in the additive weighted Voronoi diagram that it induces.

DEFINITION 4.4. *Let $\mathcal{S} = (S, w)$ be a weighted set in $\mathbb{R}^3$. We decompose the weighted Voronoi diagram $\mathcal{V}_{\mathcal{S}}$ into "simpler" cells in the following way: For each cell C in $\mathcal{V}_S$, we compute the spherical map S_C of the cell by projecting the boundary of the*

cell onto the sphere of directions centered at p_C, where p_C is the site of C in S. (We use here the well-known property that C is star-shaped with respect to p_C.) We decompose S_C into pseudovertical subcells on the sphere of directions by drawing a meridian arc upward and downward from each vertex S_C and from each locally longitude-extremal point on any arc of S_C, and by extending each of these meridian arcs until it hits another arc of S_C or, failing this, all the way to the poles of the sphere of directions. Clearly, the complexity of S_C is linear in the complexity of cell C.

We project each "vertical" trapezoid in S_C back into C to obtain the portion within C of the cone with apex p_C spanned by the trapezoid. This defines a decomposition of C into simple subcells such that each subcell is uniquely defined by at most six points of S. We decompose all the cells of $\mathcal{V}_S$ in a similar manner and let $\mathcal{C}(\mathcal{S})$ denote the resulting subdivision. We call $\mathcal{C}(\mathcal{S})$ the spherical decomposition *of $\mathcal{V}_\mathcal{S}$.*

For a weighted set $\mathcal{R} \subseteq \mathcal{S}$ and a subcell $\mathcal{T} \in \mathcal{C}(\mathcal{R})$, a weighted point $(p, w_p) \in \mathcal{S}$ conflicts with *$\mathcal{T}$ if there exists a point $t \in \mathcal{T}$ such that $V_{(p,w_p)}(t) < V_\mathcal{R}(t)$. Let $K(\mathcal{S}, \mathcal{T})$ denote the set of all the points of $\mathcal{S}$ that conflict with $\mathcal{T}$. The* conflict size *of $\mathcal{T}$ is $w(\mathcal{S}, \mathcal{T}) = |K(\mathcal{S}, \mathcal{T})|$.*

LEMMA 4.5. *Let $\mathcal{S} = (S, w)$ be a weighted set of m points in $\mathbb{R}^3$ and $\delta > 0$ a parameter. One can compute, in $O(m^{2+\delta})$ randomized expected time, a data structure for nearest-neighbor queries, of size $O(m^{2+\delta})$, such that for any point $p \in \mathbb{R}^3$ one can compute, in $O(\log m)$ time, the cell of $\mathcal{V}_\mathcal{S}$ that contains p, that is, the point in $\mathcal{S}$ realizing the distance $V_\mathcal{S}(p)$.*

Proof. We construct the data structure using a randomized divide and conquer algorithm. We randomly pick a subset R of S of size r, where r is a parameter to be specified later. One can compute the weighted Voronoi diagram of $\mathcal{R} = (R, w)$, in $O(r^2)$ time, by Remark 2.1 and construct the spherical decomposition $\mathcal{C}(\mathcal{R})$ in $O(r^2 \log r)$ additional time, using plane sweeping techniques on the sphere of directions (see [18]).

For each subcell $\mathcal{T}$ in $\mathcal{C}(\mathcal{R})$, we compute its conflict size $w(\mathcal{S}, \mathcal{T})$. Each subcell in $\mathcal{C}(\mathcal{R})$ is uniquely defined by at most six sites in $\mathcal{R}$, and if $K(\mathcal{S}, \mathcal{T}) \cap \mathcal{R} \neq \emptyset$, then $\mathcal{T} \notin C(\mathcal{R})$. We can thus apply the analysis of Clarkson and Shor. By [8, Corollary 3.8], $w(\mathcal{S}, \mathcal{T}) \leq c \cdot (n \log r)/r$ for all $\mathcal{T} \in \mathcal{C}(\mathcal{R})$, with probability at least $1/2$, where $c > 0$ is an appropriate constant. We sample $\mathcal{R}$ from $\mathcal{S}$ repeatedly until we get a sample that fulfills this condition. Overall, this stage takes $O(mr^2 + r^2 \log r)$ expected running time. For each cell $\mathcal{T} \in \mathcal{C}(\mathcal{R})$, we construct recursively a data structure for point-location in the Voronoi diagram $\mathcal{V}_{K(\mathcal{S},\mathcal{T})}$.

For any query point p, locating the subcell $\mathcal{T}$ in $\mathcal{C}(\mathcal{R})$ that contains p is done by a brute force search inside $\mathcal{C}(\mathcal{R})$ in $O(r^2)$ time. Then we compute the point realizing $V_\mathcal{S}(p)$ by recursively performing a nearest neighbor query in the data structure computed for $\mathcal{V}_{K(\mathcal{S},\mathcal{T})}$. Thus, a query takes $Q(m) = Q(c(m \log r)/r) + O(r^2)$ time, and the data structure can be computed in randomized expected time as

$$T(m) = T(r) + O(r^2)T\left(\frac{cm \log r}{r}\right) + O\left(mr^2 + r^2 \log r\right).$$

Choosing r to be a sufficiently large constant, we have $Q(m) = O(\log m)$, and $T(m) = O(m^{2+\delta})$ (where the constants of proportionality depend on δ). A similar bound holds for the space required by the algorithm. ∎

Remark 4.1. The only stage in the algorithm of Theorem 4.3 that uses randomization is the construction of the spatial point-location data described in Lemma 4.5. This can be replaced by a deterministic data structure as follows.

We observe that each spherical cell, in the decomposition described, can be parametrized by 24 parameters (6 sites and their respective weights). Thus, we define a range space $(\mathcal{S}, \mathfrak{R})$, where $\mathfrak{R}$ is the set of all possible subsets of $\mathcal{S}$ that are contained inside such a spherical cell. It is easy to verify that this is a range space having finite VC-dimension. By a result of Matoušek [15], we can compute in $O(mr^{O(1)})$ time a subset $\mathcal{R}$ of $\mathcal{S}$ having $O(r \log r)$ points, which is $(1/r)$-net of $(\mathcal{S}, \mathfrak{R})$. In particular, the set $\mathcal{R}$ can replace the random sample in the proof of Lemma 4.5; see [15]. This yields a deterministic algorithm with the same time/space complexity as in Lemma 4.5.

Alternatively, one can naively preprocess the Voronoi diagram $\mathcal{V}_{\mathcal{S}}$ for spatial point-location directly; see [23]. However, this approach is considerably less efficient than the approach proposed above.

5. Conclusions. In this paper we have presented two results for computing approximate maps that facilitate shortest path queries on the surface of a convex polytope or on a polyhedral surface in 3-space, or among polyhedral obstacles in 3-space. We conclude by mentioning the following open problems:

(i) Can an ε-approximate shortest path between two points on a polyhedral terrain, or on the surface of a nonconvex polyhedron, be computed in time that is near-linear in the number of edges? A recent subquadratic solution has been obtained by Varadarajan and Agarwal [24], but it computes only a constant-factor approximation to the shortest path.

(ii) Can the exact shortest path between two points on a convex polyhedron be computed in near-linear time? in subquadratic time?

(iii) Can the methods and techniques used in this paper be extended to handle shortest path queries for weighted surfaces (as in [13, 14])?

Acknowledgments. The author wishes to thank Pankaj Agarwal and Micha Sharir for helpful discussions concerning the problems studied in this paper and related problems. Micha Sharir also suggested Lemma 4.5. The author also wishes to thank the referees for their comments and suggestions.

NEW LOWER BOUNDS FOR CONVEX HULL PROBLEMS IN ODD DIMENSIONS*

JEFF ERICKSON†

Abstract. We show that in the worst case, $\Omega(n^{\lceil d/2\rceil-1}+n\log n)$ sidedness queries are required to determine whether the convex hull of n points in $\mathbb{R}^d$ is simplicial or to determine the number of convex hull facets. This lower bound matches known upper bounds in any odd dimension. Our result follows from a straightforward adversary argument. A key step in the proof is the construction of a quasi-simplicial n-vertex polytope with $\Omega(n^{\lceil d/2\rceil-1})$ degenerate facets. While it has been known for several years that d-dimensional convex hulls can have $\Omega(n^{\lfloor d/2\rfloor})$ facets, the previously best lower bound for these problems is only $\Omega(n\log n)$. Using similar techniques, we also obtain simple and correct proofs of Erickson and Seidel's lower bounds for detecting affine degeneracies in arbitrary dimensions and circular degeneracies in the plane. As a related result, we show that detecting simplicial convex hulls in $\mathbb{R}^d$ is $\lceil d/2\rceil$SUM-hard in the sense of Gajentaan and Overmars.

1. Introduction.

The construction of convex hulls is one of the most basic and well-studied problems in computational geometry [2, 3, 5, 10, 11, 12, 13, 15, 17, 18, 29, 34, 35, 38, 39, 47, 41, 45, 43, 44, 48]. Over 20 years ago, Graham described an algorithm that constructs the convex hull of n points in the plane in $O(n\log n)$ time [29]. The same running time was first achieved in three dimensions by Preparata and Hong [38]. Yao [48] proved a lower bound of $\Omega(n\log n)$ on the complexity of identifying the convex hull vertices, in the quadratic decision tree model. This lower bound was later generalized to the algebraic decision tree and algebraic computation tree models by Ben-Or [7]. It follows that both Graham's scan and Preparata and Hong's algorithm are optimal in the worst case. If the output size f is also taken into account, the lower bound drops to $\Omega(n\log f)$ [34], and a number of algorithms match this bound both in the plane [34, 12, 10] and in three dimensions [18, 16, 10].

In higher dimensions, the problem is not quite so completely solved. Seidel's "beneath-beyond" algorithm [41] constructs d-dimensional convex hulls in $O(n^{\lceil d/2\rceil})$ time. After a 10-year wait, Chazelle [15] improved the running time to $O(n^{\lfloor d/2\rfloor})$ by derandomizing a randomized incremental algorithm of Clarkson and Shor [18]; see also [44]. Since an n-vertex polytope in $\mathbb{R}^d$ can have $\Omega(n^{\lfloor d/2\rfloor})$ facets [27], Seidel's algorithm is optimal in even dimensions, and Chazelle's algorithm is optimal in all dimensions, in the worst case.

However, several faster algorithms are known when the output size f is also considered, at least when the input points are in general position. In 1970, Chand and Kapur [13] described a "gift-wrapping" algorithm that constructs convex hulls in ar-

bitrary dimensions in time $O(nf)$; see also [47]. Seidel's "shelling" algorithm runs in time $O(n^2 + f \log n)$ [43]. A divide-and-conquer algorithm of Chan, Snoeyink, and Yap [12] constructs four-dimensional hulls in time $O((n + f) \log^2 f)$, and a recent improvement by Amato and Ramos [2] constructs five-dimensional hulls in time $O((n + f) \log^3 f)$. In dimensions higher than five, the fastest algorithms are an improvement of the gift-wrapping algorithm by Chan [11] with running time $O(n \log f + (nf)^{1-1/(\lfloor d/2 \rfloor + 1)} \operatorname{polylog} n)$, an extension of Chan, Snoeyink, and Yap's divide-and-conquer algorithm [12] with running time $O((n + (nf)^{1-1/\lceil d/2 \rceil} + fn^{1-2/\lceil d/2 \rceil}) \operatorname{polylog} n)$, and an improvement of Seidel's shelling algorithm by Matoušek [35] with running time $O(n^{2-2/(\lfloor d/2 \rfloor + 1)} \operatorname{polylog} n + f \log n)$. For related results, see [6, 13, 17, 18, 34, 45].

Except when f is extremely small or extremely large, there are still large gaps between all these upper bounds and the lower bound $\Omega(n \log f + f)$. Moreover, most of these algorithms compute either the complete face lattice of the convex hull or a triangulation of its boundary, both of which can be significantly larger than the number of facets if the input is not in general position. Avis, Bremner, and Seidel [5] describe families of polytopes on which current convex hull algorithms perform quite badly, sometimes requiring exponential time (in d) even when the number of facets is only polynomial.

In this paper, we consider convex hull problems for which the result is a single integer, or even a single bit, although the convex hull itself may be large. We show that in the worst case, $\Omega(n^{\lceil d/2 \rceil - 1} + n \log n)$ sidedness queries are required to decide whether the convex hull of n points in $\mathbb{R}^d$ is simplicial or to determine the number of convex hull facets, where d is any fixed constant. This matches known upper bounds when d is odd [15]. The only lower bound previously known for either of these problems is $\Omega(n \log n)$, following from the techniques of Yao [48] and Ben-Or [7]. When the dimension is allowed to vary with the input size, deciding if a convex hull is simplicial is coNP-complete [14, 19], and counting the number of facets is #P-hard [19].

Our lower bounds follow from a straightforward adversary argument. We start by constructing a set whose convex hull contains a large number of independent degenerate facets. To obtain the adversary configuration, we perturb this set to eliminate the degeneracies, but in a way that the degeneracies are still "almost there." An adversary can reintroduce any one of the degenerate facets, by moving its vertices back to their original position, without changing the result of any other sidedness query.

Our argument is similar to earlier arguments of Erickson and Seidel [23]; however, many of the proofs in that paper were flawed [24]. Our proof technique yields correct and very simple proofs of Erickson and Seidel's claimed lower bounds for affine degeneracy detection in arbitrary dimensions and circular degeneracy detection in the plane.

The paper is organized as follows. Section 2 contains definitions and some preliminary results. In section 3, we describe some relative complexity results. Section 4 contains the proof of our main theorem. We discuss extensions of our model of computation in section 5. In section 6, we discuss the relevance of our results in light of existing convex hull algorithms. In section 7, we prove lower bounds for some related degeneracy-detection problems. Finally, in section 8, we summarize and suggest directions for further research.

2. Geometric preliminaries.

2.1. Definitions. We begin by reviewing basic terminology from the theory of convex polytopes. For a more detailed introduction, we refer the reader to Ziegler [49]

or Grünbaum [30].

The *convex hull* of a set of points is the smallest convex set that contains it. A *polytope* is the convex hull of a finite set of points. A hyperplane h *supports* a polytope if the polytope intersects h and lies in a closed half-space of h. The intersection of a polytope and a supporting hyperplane is called a *face* of the polytope. The *dimension* of a face is the dimension of the smallest affine space that contains it; a face of dimension k is called a *k-face*. The faces of a polytope are also polytopes. Given a d-dimensional polytope, its $(d-1)$-faces are called *facets*, its $(d-2)$-faces are called *ridges*, its 1-faces are called *edges*, and its 0-faces are called *vertices*.

A polytope is *simplicial* if all its facets, and thus all its faces, are simplices. A polytope is *quasi simplicial* if all of its ridges are simplices, or equivalently, if its facets are simplicial polytopes. A *degenerate facet* of a quasi-simplicial polytope is any facet that is not a simplex.

The basic computational primitive that we consider is the *sidedness query*: Given $d+1$ points $p_0, p_1, \ldots, p_d \in \mathbb{R}^d$, does the point p_0 lie "above," on, or "below" the oriented hyperplane determined by the other d points? Algebraically, the result of a sidedness query is given by the sign of the following $(d+1) \times (d+1)$ determinant, where p_{ij} denoted the jth coordinate of p_i:

$$\begin{vmatrix} 1 & p_{01} & p_{02} & \cdots & p_{0d} \\ 1 & p_{11} & p_{12} & \cdots & p_{1d} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & p_{d1} & p_{d2} & \cdots & p_{dd} \end{vmatrix}.$$

The value of this determinant is $d!$ times the signed volume of the simplex spanned by the points. The algorithms we consider can be modeled as a family of decision trees, one for each possible value of n, in which every decision is based on the result of a sidedness query. (We will consider other computational primitives in section 5.)

The *orientation* of a simplex $(p_0, p_1, \ldots, p_d)$ is the result of a sidedness query on its vertices (in the order presented). If the orientation is zero, we say that the simplex is *degenerate*. A set of points is *affinely degenerate* if any $d+1$ of its elements lie on a single hyperplane, or equivalently, if the set contains the vertices of a degenerate simplex. The convex hull of an affinely nondegenerate set of points is simplicial, but the converse is not true in general—consider the regular octahedron in $\mathbb{R}^3$. Note that any $d+1$ vertices of a degenerate facet are also the vertices of a degenerate simplex.

2.2. The weird moment curve. The *weird moment curve* in $\mathbb{R}^d$, denoted $\omega_d(t)$, is the set of points

$$\omega_d(t) = (t, t^2, \ldots, t^{d-1}, t^{d+1}),$$

where the parameter t ranges over the reals. The weird moment curve is similar to the standard moment curve $(t, t^2, \ldots, t^{d-1}, t^d)$, except that the degree of the last coordinate is increased by 1.

If we project the weird moment curve down a dimension by dropping the last coordinate, we get a standard moment curve. Since every set of points on the standard moment curve is in convex position, every set of points on the d-dimensional weird moment curve is in convex position if $d \geq 3$. Similarly, since every set of points on the standard moment curve is affinely nondegenerate, no d points on the d-dimensional weird moment curve lie on a single $(d-2)$-flat. It follows immediately that the convex

hull of any set of points on the weird moment curve is quasi-simplicial; however, degenerate facets are possible.

LEMMA 2.1. *Let $x_0 < x_1 < \cdots < x_d$ be real numbers. The orientation of the simplex $(\omega_d(x_0), \omega_d(x_1), \ldots, \omega_d(x_d))$ is given by the sign of $\sum_{i=0}^{d} x_i$. In particular, the simplex is degenerate if and only if $\sum_{i=0}^{d} x_i = 0$.*

Proof. The orientation of the simplex $(\omega_d(x_0), \omega_d(x_1), \ldots, \omega_d(x_d))$ is given by the sign of the determinant of the following matrix:

$$M = \begin{bmatrix} 1 & x_0 & x_0^2 & \cdots & x_0^{d-1} & x_0^{d+1} \\ 1 & x_1 & x_1^2 & \cdots & x_1^{d-1} & x_1^{d+1} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 1 & x_d & x_d^2 & \cdots & x_d^{d-1} & x_d^{d+1} \end{bmatrix}.$$

The determinant of M is an antisymmetric polynomial of degree $\binom{d+1}{2} + 1$ in the variables x_i, and it is divisible by $(x_i - x_j)$ for all $i < j$. It follows that

$$\frac{\det M}{\prod_{i<j}(x_j - x_i)}$$

is a symmetric polynomial of degree 1, and we easily observe that its leading coefficient is 1. (This polynomial is well defined, since the x_i's are distinct.) The only such polynomial is $\sum_{i=0}^{d} x_i$. □

This result, or at least its proof, is hardly new. If we replace the weird moment curve by any polynomial curve, the orientation of a simplex is given by the sign of a symmetric *Schur polynomial* [40]. A determinantal formula for Schur polynomials was discovered by Jacobi in the mid-1800s [32].[1]

The next lemma characterizes degenerate convex hull facets on the weird moment curve. The result is similar to Gale's "evenness condition" [27], which describes which vertices of a cyclic polytope form its facets.

LEMMA 2.2. *Let X be a set of real numbers, and let $x_0 < x_1 < \cdots < x_d$ be elements of X such that $\sum_{i=0}^{d} x_i = 0$. The points $\omega_d(x_0), \omega_d(x_1), \ldots, \omega_d(x_d)$ are the vertices of a degenerate facet of $\operatorname{conv}(\omega_d(X))$ if and only if, for any two elements $y, z \in X \setminus \{x_0, x_1, \ldots, x_d\}$, the number of elements of $\{x_0, x_1, \ldots, x_d\}$ between y and z is even.*

Proof. Let h be the hyperplane passing through the points $\omega_d(x_0), \omega_d(x_1), \ldots, \omega_d(x_d)$. For any real number x, the point $\omega_d(x)$ lies above, on, or below h according

[1] Jacobi proved that for any nonnegative integers $\gamma_0, \gamma_1, \ldots, \gamma_d$,

$$\begin{vmatrix} x_0^{\gamma_0} & x_0^{\gamma_1} & \cdots & x_0^{\gamma_d} \\ x_1^{\gamma_0} & x_1^{\gamma_1} & \cdots & x_1^{\gamma_d} \\ \vdots & \vdots & \ddots & \vdots \\ x_d^{\gamma_0} & x_d^{\gamma_1} & \cdots & x_d^{\gamma_d} \end{vmatrix} = \begin{vmatrix} \Sigma_{\gamma_0} & \Sigma_{\gamma_1} & \cdots & \Sigma_{\gamma_d} \\ \Sigma_{\gamma_0 - 1} & \Sigma_{\gamma_1 - 1} & \cdots & \Sigma_{\gamma_d - 1} \\ \vdots & \vdots & \ddots & \vdots \\ \Sigma_{\gamma_0 - d} & \Sigma_{\gamma_1 - d} & \cdots & \Sigma_{\gamma_d - d} \end{vmatrix} \cdot \prod_{0 \le i < j \le d} (x_j - x_i),$$

where Σ_k is the sum of all possible monomials of total degree k in the variables $x_0, x_1, \ldots, x_d$. In particular, $\Sigma_0 = 1$ and $\Sigma_k = 0$ for all $k < 0$.

to the sign of the determinant

$$\begin{vmatrix} 1 & x & x^2 & \cdots & x^{d-1} & x^{d+1} \\ 1 & x_1 & x_1^2 & \cdots & x_1^{d-1} & x_1^{d+1} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 1 & x_d & x_d^2 & \cdots & x_d^{d-1} & x_d^{d+1} \end{vmatrix} = \left(\prod_{1 \le i < j \le d} (x_j - x_i) \right) \left(\prod_{i=1}^{d} (x - x_i) \right) \left(x + \sum_{i=1}^{d} x_i \right)$$

$$= \left(\prod_{1 \le i < j \le d} (x_j - x_i) \right) \left(\prod_{i=0}^{d} (x - x_i) \right).$$

(See the proof of Lemma 2.1.) Since all factors of the form $(x_j - x_i)$ are positive, the sign of this determinant is equal to the sign of the polynomial $f(x) = \prod_{i=0}^{d}(x - x_i)$. The hyperplane h supports $\text{conv}(\omega_d(X))$ if and only if $f(x)$ has the same sign for all $x \in X \setminus \{x_0, x_1, \ldots, x_d\}$.

The polynomial $f(x)$ has degree $d+1$ and vanishes at each x_i. Thus, the sign of $f(x)$ changes at each x_i. In more geometric terms, the weird moment curve crosses the hyperplane h at each of the points $\omega_d(x_i)$. It follows that $f(y)$ and $f(z)$ both have the same sign if and only if an even number of x_i's lie between y and z. □

3. $\lceil d/2 \rceil$SUM hardness. Gajentaan and Overmars [26] define the class of 3*SUM-hard* problems, all of which are harder than the following base problem:

3SUM: Given a set of n distinct integers, do any three sum to zero?

This problem can be easily solved in $O(n^2)$ time, which is believed to be optimal, but the best lower bound in any general model of computation is only $\Omega(n \log n)$ [7].

Formally, a problem is 3SUM-hard if there is a subquadratic reduction from 3SUM to the problem in question. Thus, a subquadratic algorithm for any 3SUM-hard problem would imply a subquadratic algorithm for 3SUM, and a sufficiently powerful quadratic lower bound for 3SUM would imply similar lower bounds for every 3SUM-hard problem. (For this reason, some earlier papers call these problems "n^2-hard," but see [8].) Examples of 3SUM-hard problems include several degeneracy detection, separation, hidden surface removal, and motion planning problems in two and three dimensions.

More generally, we will say that a problem is *rSUM-hard* if the following problem can be reduced to it in $o(n^{\lceil r/2 \rceil})$ time:

rSUM: Given a set of n distinct integers, do any r sum to zero?

The problem rSUM can be solved in time $O(n^{(r+1)/2})$ when r is odd or in time $O(n^{r/2} \log n)$ when r is even. We conjecture that these algorithms are optimal; however, the best lower bound in any general model of computation, for any fixed r, is again only $\Omega(n \log n)$ [7]. Higher-dimensional versions of many 3SUM-hard problems are rSUM-hard for larger values of r. For example, Lemma 2.1 immediately implies that detecting affine degeneracies in $\mathbb{R}^d$ is dSUM-hard.

THEOREM 3.1. *Deciding whether the convex hull of n points in $\mathbb{R}^d$ is simplicial, for any fixed d, is $\lceil d/2 \rceil$SUM-hard.*

Proof. We describe the proof explicitly only for the case $d = 5$; generalizing the proof to higher dimensions is straightforward.

Given a set of integers $X = \{x_1, x_2, \ldots, x_n\}$, we first replace them with the larger set $X' = \{x_1^\flat, x_1^\sharp, x_2^\flat, x_2^\sharp, \ldots, x_n^\flat, x_n^\sharp\}$, where $x_i^\flat = x_i - 2^{-i}$ and $x_i^\sharp = x_i + 2^{-i}$ for all i.

We then consider the points $\omega_5(X')$ obtained by lifting X' onto the weird moment curve in $\mathbb{R}^5$. To prove the theorem, it suffices to show that the convex hull of the points $\omega_5(X')$ is nonsimplicial if and only if some three elements of X sum to zero.

Suppose that the convex hull of $\omega_5(X')$ is nonsimplicial. Then some six points in $\omega_5(X')$ lie on the same hyperplane. By Lemma 2.1, the corresponding six elements of X' sum to zero. These must consist of three matched pairs $a^\flat, a^\sharp, b^\flat, b^\sharp, c^\flat, c^\sharp$ for some $a, b, c \in X$. Otherwise, the various "fudge factors" $\pm 2^{-i}$ do not cancel out, and the sum of six elements is not even an integer. Thus, X has three elements whose sum is zero.

Conversely, suppose that $a + b + c = 0$ for some $a, b, c \in X$. This immediately implies $a^\flat + a^\sharp + b^\flat + b^\sharp + c^\flat + c^\sharp = 0$, and thus, by Lemma 2.1, the corresponding points in $\omega_5(X')$ all lie on a single hyperplane. Moreover, by Lemma 2.2, this hyperplane supports a facet of the convex hull of $\omega_5(X')$, since no other elements of X' lie in the intervals $(a^\flat, a^\sharp)$, $(b^\flat, b^\sharp)$, or $(c^\flat, c^\sharp)$. Thus, the convex hull of $\omega_5(X')$ is not simplicial. □

The best lower bound we can ever hope to derive using this reduction is $\Omega(n^{\lceil d/4 \rceil} + n \log n)$, which is significantly smaller than the best known upper bound $O(n^{\lfloor d/2 \rfloor} + n \log n)$, except for the single case $d = 5$. In particular, Theorem 3.1 tells us absolutely nothing about the four-dimensional case, since we already have a lower bound of $\Omega(n \log n)$ in all dimensions.

In an earlier paper [21], we derive an $\Omega(n^{\lceil r/2 \rceil})$ lower bound for rSUM in the r-linear decision tree model. In this model, decisions are based on the signs of arbitrary affine combinations of r or fewer input variables. Unfortunately, since the reduction described by the previous theorem does not follow this model, we do not automatically get similar lower bounds for detecting simplicial convex hulls. In the next section of the paper, we derive such lower bounds directly.

Remark. If r is not fixed, the problem rSUM is NP-complete, by a simple reduction to SUBSET SUM [28]. We can use this fact to give simple proofs that certain geometric problems in arbitrary dimensions are NP-hard. For example, Khachiyan [33] proves that detecting affine degeneracies is NP-complete. This result follows directly from Lemma 2.1. Chandrasekaran, Kabadi, and Murty [14] and Dyer [19] independently prove that deciding whether the convex hull of a set of points is simplicial is coNP-complete; this result also follows immediately from Theorem 3.1. Moreover, since the reductions are parsimonious [28], the corresponding counting problems (how many degenerate simplices/facets?) are #P-complete.

4. Lower bounds for convex hull problems. Our main result is based on the following combinatorial construction.

LEMMA 4.1. *For all n and d, there is a quasi-simplicial polytope in $\mathbb{R}^d$ with $O(n)$ vertices and $\Omega(n^{\lceil d/2 \rceil - 1})$ degenerate facets.*

Proof. First consider the case when d is odd, and let $r = (d-1)/2$. Without loss of generality, we assume that n is a multiple of r. Let X denote the following set of $n + 2n/r = O(n)$ integers:

$$X = \{-rn, -rn + r, \ldots, -r;\ r, r+1, 2r, 2r+1, \ldots, n, n+1\}.$$

We can specify a degenerate facet of $\omega_5(X)$ as follows. Choose r distinct elements $a_1, a_2, \ldots, a_r \in X$, all positive multiples of r. Let $a_0 = -\sum_{i=1}^{r} a_i$, let $b_0 = a_0 + r$, and for all $i > 0$, let $b_i = a_i + 1$. Each a_i and b_i is a unique element of X, and no element of X lies between a_i and b_i for any i. The $d+1$ points $\omega_d(a_0), \omega_d(b_0), \ldots, \omega(a_r), \omega(b_r)$

all lie on a single hyperplane by Lemma 2.1, since

$$\sum_{i=0}^{r}(a_i + b_i) = 2\sum_{i=0}^{r} a_i = 0.$$

Moreover, since any pair of elements of $X \setminus \{a_0, b_0, a_1, b_1, \ldots, a_r, b_r\}$ has an even number of elements of $\{a_0, b_0, \ldots, a_r, b_r\}$ between them, Lemma 2.2 implies that these points are the vertices of a single facet of $\text{conv}(\omega_d(X))$. There are at least $\binom{n/r}{r} = \Omega(n^r)$ ways of choosing such a degenerate facet.

In the case where d is even, let $r = d/2 - 1$, and assume without loss of generality that n is a multiple of r. Let X be the following set of $n + 2n/r + 1 = O(n)$ integers:

$$X = \{-n - rn, -n - rn + r, \ldots, -n - r;\ r, r + 1, 2r, 2r + 1, \ldots, n, n + 1;\ 2n\}.$$

Using similar arguments as above, we easily observe that the polytope $\text{conv}(\omega_d(X))$ has $\Omega(n^r)$ degenerate facets, each of which has $\omega_d(2n)$ as a vertex. □

This result is the best possible when d is odd, since an odd-dimensional n-vertex polytope has at most $O(n^{(d-1)/2})$ facets [49]. In the case where d is even, the best known upper bound is $O(n^{d/2})$, which is a factor of n bigger than the result we prove here. We conjecture that this upper bound is tight. However, if we consider only sets of points on the weird moment curve, the bound given in the lemma is tight. That is, the convex hull of any set of n points on ω_d has at most $O(n^{\lceil d/2 \rceil - 1})$ degenerate facets.

We now prove the main result of the paper.

THEOREM 4.2. *Any decision tree that decides whether the convex hull of a set of n points in $\mathbb{R}^d$ is simplicial, using only sidedness queries, must have depth $\Omega(n^{\lceil d/2 \rceil - 1} + n \log n)$.*

Proof. Let X be the set of numbers described in the proof of Lemma 4.1, and let $X' = X + 1/(2d+2) = \{x + 1/(2d+2) \mid x \in X\}$. Initially, the adversary presents the set of points $\omega_d(X')$. Since $\sum_{i=0}^{d} x'_i$ is always a half-integer, this point set is affinely nondegenerate, so its convex hull is simplicial.

It suffices to consider the case where d is odd. Let $r = (d-1)/2$. Choose distinct elements $a'_0, b'_0, a'_1, b'_1, \ldots, a'_r, b'_r \in X'$ so that $\sum_{i=0}^{r}(a'_i + b'_i) = 1/2$ and no other elements of X' lie between a'_i and b'_i for any i. The corresponding points $\omega(a'_0), \omega(b'_0), \ldots, \omega(a'_r), \omega(b'_r)$ form a *collapsible simplex*. To collapse it, the adversary simply moves the points back to their original positions in $\omega_d(X)$. Lemmas 2.1 and 2.2 imply that the collapsed simplex forms a degenerate facet of the new convex hull. Since the sum of any other $(d+1)$-tuple changes by at most $1/2 - 1/(2d+2)$, no other simplex changes orientation. In other words, the only way for an algorithm to distinguish between the original configuration and the collapsed configuration is to perform a sidedness query on the collapsible simplex.

Thus, if an algorithm does not perform a separate sidedness query for every collapsible simplex, then the adversary can introduce a degenerate facet that the algorithm cannot detect. There are $\Omega(n^{\lceil d/2 \rceil - 1})$ collapsible simplices, one for each degenerate facet in $\text{conv}(\omega_d(X))$.

Finally, the $n \log n$ term follows from the algebraic decision tree lower bound of Ben-Or [7]. □

A three-dimensional version of our construction is illustrated in Figure 4.1. (See also the proof of Theorem 7.4 below.)

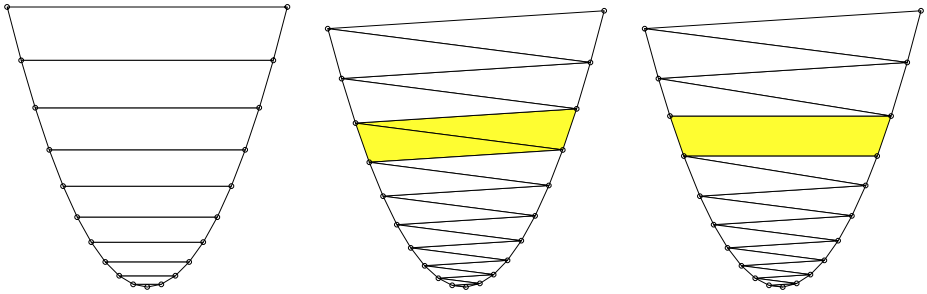

FIG. 4.1. *Our adversary construction in three dimensions. Bottom views of* (a) *a quasi-simplicial polytope with* $\Omega(n)$ *degenerate facets,* (b) *the simplicial adversary polytope with one collapsible simplex highlighted, and* (c) *the corresponding collapsed polytope.*

Our lower bound matches known upper bounds when d is odd [15]. We emphasize that if the points are known *in advance* to lie on the weird moment curve, this problem can be solved in $O(n^{\lceil d/4 \rceil})$ time if $\lceil d/2 \rceil$ is odd, and in $O(n^{\lceil d/4 \rceil} \log n)$ time if $\lceil d/2 \rceil$ is even, by an algorithm that uses more complicated queries not allowed by Theorem 4.2, namely, evaluating the signs of certain linear combinations of x_1-coordinates. (See [21].)

The convex hull of the adversary configuration $\omega_d(X')$ has $\lceil d/2 \rceil - 1$ more facets than the convex hull of any collapsed configuration. Thus, we immediately have the following lower bound.

THEOREM 4.3. *Any decision tree that computes the number of convex hull facets of a set of* n *points in* $\mathbb{R}^d$*, using only sidedness queries, must have depth* $\Omega(n^{\lceil d/2 \rceil - 1} + n \log n)$.

A simple modification of our argument implies the following "output-sensitive" version of our lower bound.

THEOREM 4.4. *Any decision tree that decides whether the convex hull of a set of* n *points in* $\mathbb{R}^d$ *is simplicial or computes the number of convex hull facets, using only sidedness queries, must have depth* $\Omega(f)$ *when* d *is odd and* $\Omega(f^{1-2/d})$ *when* d *is even, where* f *is the number of faces of the convex hull.*

Proof. Assume that $f > n$, since otherwise we have nothing to prove. We construct a modified degenerate polytope as follows. We start by constructing a degenerate polytope with f faces, exactly as described in the proof of Lemma 4.1. When d is odd, this polytope is the convex hull of $\Theta(f^{2/(d-1)})$ points on the weird moment curve and has $\Omega(f)$ degenerate facets. When d is even, the polytope is the convex hull of $\Theta(f^{2/d})$ points and has $\Omega(f^{1-2/d})$ degenerate facets.

By introducing a new vertex extremely close to the relative interior of any facet of a simplicial polytope, we can split that facet into d smaller facets. Each such split increases the number of polytope faces by $2^d - 2$. To bring the number of vertices of our adversary polytope up to n, we choose some facet and repeatedly split it in this fashion, being careful not to introduce any new degenerate simplices. The augmented polytope has at most $f + (2^d - 2)n = O(f)$ faces.

To get a modified *adversary* polytope, we slide the original vertices of the degenerate polytope along the weird moment curve, just enough to remove the degeneracies, leaving the new vertices in place. Each of the degenerate facets becomes a collapsible simplex. As long as we do not slide the vertices too far, collapsing a simplex will

not change the orientation of any simplex involving a new vertex. (In effect, we are treating sidedness queries involving new vertices as "allowable" queries; see below.) The lower bound now follows from the usual adversary argument. □

5. Other computational primitives. In this section, we identify a general class of computational primitives which, if added to our model of computation, do not affect our lower bounds. In fact, even if we allow any finite number of these primitives to be performed at no cost, the number of required sidedness queries is the same. These primitives include comparisons between coordinates of input points in any number of directions, comparisons between coordinates of hyperplanes defined by d-tuples of points, and in-sphere queries.

The primitives we consider are all *algebraic queries*. The result of an algebraic query is given by the sign of a multivariate *query polynomial*, evaluated at the coordinates of the input. If the sign is zero (resp., nonzero), we say that the input is *degenerate* (resp., *nondegenerate*) with respect to that query. For example, a set of points is affinely degenerate if and only if it is degenerate with respect to some sidedness query.

A *projective transformation* of $\mathbb{R}^d$ (or more properly, of the projective space $\mathbb{RP}^d$) is any map that takes hyperplanes to hyperplanes. If we represent the points of $\mathbb{R}^d$ in homogeneous coordinates, a projective transformation is equivalent to a linear transformation of $\mathbb{R}^{d+1}$. In Stolfi's two-sided projective model [46], projective maps preserve (or reverse) the orientation of every simplex in $\mathbb{R}^d$ and thus preserve the combinatorial structure of convex hulls. (See Chapter 14 of [46].)

Let X be the set of numbers described in the proof of Lemma 4.1. We call an algebraic query *allowable* if for some projective transformation ϕ the configuration $\phi(\omega_d(X))$ is nondegenerate with respect to that query. Our choice of terminology is justified by the following theorem.

THEOREM 5.1. *Any decision tree that decides whether the convex hull of n points in $\mathbb{R}^d$ is simplicial, using only sidedness queries and a finite number of allowable queries, requires $\Omega(n^{\lceil d/2\rceil-1})$ sidedness queries in the worst case.*

Proof. If *some* projective transformation makes $\omega_d(X)$ nondegenerate with respect to an algebraic query, then *almost every* projective transformation (i.e., all but a measure zero subset) makes $\omega_d(X)$ nondegenerate. Thus, for any finite set of allowable queries, almost every projective transformation makes $\omega_d(X)$ nondegenerate with respect to all of them. Let ϕ be such a transformation.

If $\phi(\omega_d(X))$ is nondegenerate with respect to some finite set of allowable queries, then for all X' in an open neighborhood of X in $\mathbb{R}^n$, the configuration $\phi(\omega(X'))$ is also nondegenerate with respect to that set of queries.

The theorem now follows from a slight modification of the proof of Theorem 4.2. Let $\varepsilon > 0$ be some sufficiently small real number. The set $\phi(\omega_d(X + \varepsilon))$ has a simplicial convex hull but has $\Omega(n^{\lceil d/2\rceil+1})$ collapsible simplices, each corresponding to a degenerate facet in $\phi(\omega_d(X))$. No allowable query can distinguish between $\phi(\omega_d(X + \varepsilon))$ and any collapsed configuration, or even between $\phi(\omega_d(X + \varepsilon))$ and $\phi(\omega_d(X))$. □

We characterize allowable queries algebraically as follows. Consider the degenerate configuration $\omega_d(X)$ as a single point in the configuration space $\mathbb{R}^{dn}$. Any algebraic query induces a surface in configuration space, consisting of all configurations that are degenerate with respect to that query. Since any projective map ϕ can be represented by a $(d + 1) \times (d + 1)$ matrix with determinant ± 1, the set of projectively transformed configurations $\phi(\omega_d(X))$ forms a $(d^2 + 2d)$-dimensional algebraic

variety in configuration space. Any query whose surface does not completely contain this variety is allowable.

We give below a (nonexhaustive!) list of allowable queries. We leave the proofs that these queries are in fact allowable as easy exercises.

- Comparisons of point coordinates, or more generally comparing inner products of two points with a fixed direction vector, is allowable. In fact, we can allow the input points to be presorted in any finite number of fixed directions. Seidel describes a similar result in the context of three-dimensional convex hull lower bounds [42, Theorem 5]. We emphasize that the directions in which these comparisons are made must be fixed in advance. No matter how we transform the adversary configuration, there is always *some* direction in which a point comparison can distinguish it from a collapsed configuration.
- More generally, deciding which of two points is hit first by a hyperplane rotating around a fixed $(d-2)$-flat is allowable. We can even presort the points by their cyclic orders around any finite number of fixed $(d-2)$-flats. If the $(d-2)$-flat is "at infinity," then "rotation" is just translation, and we have the previous notion of point comparison. We can interpret this type of query in dual space as a comparison between the intersections of two hyperplanes with a fixed line. Again, we emphasize that the $(d-2)$-flats must be fixed in advance.
- Sidedness queries in any fixed lower-dimensional projection are allowable. This is a natural generalization of point comparisons, which can be considered sidedness queries in a one-dimensional projection. We can even specify in advance the complete order types of the projections onto any finite number of fixed affine subspaces. (As a technical point, we would not actually include this information as part of the input, since this would drastically increase the input size; instead, knowledge of the projected order types would be hardwired into the algorithm.)
- "Second-order" comparisons between vertices of the dual hyperplane arrangement, in any fixed direction, are also allowable. Such a query can be interpreted in the primal space as a comparison between the intersections of two hyperplanes, each defined by a d-tuple of input points, with a fixed line. To prove that such a query is allowable, it suffices to observe that a projective transformation of the primal space induces a projective transformation of the dual space, and vice versa. Note that a second-order comparison is algebraically equivalent to a sidedness query if the two d-tuples share $d-1$ points.
- Since most projective transformations do not map spheres to spheres, in-sphere queries are allowable. Given $d+2$ points, an in-sphere query asks whether the first point lies "inside," on, or "outside" the oriented sphere determined by the other $d+1$ points. Similarly, in-sphere queries in any fixed lower-dimensional projection are allowable.
- Distance comparisons between pairs of points or pairs of projected points are allowable. More generally, comparing the measures of pairs of simplices of dimension less than d—for example, comparing the areas of two triangles when $d > 2$—defined either by the original points or by any fixed projection, are allowable.

However, comparing the volumes of arbitrary simplices of *full* dimension is not allowable. In any projective transformation of $\omega_d(X)$, all of the degenerate simplices

have the same (zero) volume. It is not possible to collapse a simplex in any adversary configuration while maintaining the order of the volumes of the other collapsible simplices.

6. Our models vs. real convex hull algorithms. A large number of convex hull algorithms rely (or can be made to rely) exclusively on sidedness queries. These include the "gift-wrapping" algorithms of Chand and Kapur [13] and Swart [47], the "beneath-beyond" method of Seidel [41], Clarkson and Shor's [18] and Seidel's [44] randomized incremental algorithms, Chazelle's worst-case optimal algorithm [15], and the recursive partial-order algorithm of Clarkson [17]. Seidel's "shelling" algorithm [43] and the space-efficient gift-wrapping algorithms of Avis and Fukuda (at least if Bland's pivoting rule is used) [6] and Rote [39] require only sidedness queries and second-order comparisons.

Matoušek [35] and Chan [11] improve the running times of these algorithms (in an output-sensitive sense) by finding the extreme points more quickly. Clarkson [17] describes a similar improvement to a randomized incremental algorithm. Since every point in our adversary configuration is extreme, our lower bound still holds even if the extremity of a point can be decided for free. We are not suggesting that the computational primitives used by these algorithms cannot be used to break our lower bounds, only that the ways in which these primitives are currently applied are inherently limited.

Chan [11] describes an improvement of the gift-wrapping algorithm that uses ray shooting data structures of Agarwal and Matoušek [1] and Matoušek and Schwarzkopf [36] to speed up the pivoting step. In each pivoting step, the gift-wrapping algorithm finds a new facet containing a given ridge of the convex hull. In the dual, this is equivalent to shooting a ray from a vertex of the dual polytope along one of its outgoing edges. The dual vertex that the ray hits corresponds in the primal to the new facet. A single pivoting step tells us the orientation of $n - d$ simplices, all of which share the d vertices of the new facet. However, at most one of these simplices can be collapsible, since two collapsible simplices share at most $d/2$ vertices. Thus, even if we allow a pivoting step to be performed in constant time, our lower bound still holds.

There are a few convex hull algorithms which seem to fall outside our framework, most notably the divide-and-conquer algorithm of Chan, Snoeyink, and Yap [12], and its improvement by Amato and Ramos [2]. The four-dimensional version of their algorithm uses primitives involving up to 22 points.[2] Higher-dimensional versions of their algorithm require the use of linear programming queries and ray-shooting queries in certain $(d-1)$-dimensional projections of the input; the fastest known algorithms to answer these queries [1, 11, 35, 36] do not even fit into the algebraic decision tree model.

7. Related problems.

7.1. Affine degeneracies.

THEOREM 7.1. *Any decision tree that decides whether a set of n points in $\mathbb{R}^d$ is affinely nondegenerate, using only sidedness queries, must have depth $\Omega(n^d)$. If*

[2]The most elaborate primitive is a sidedness query on a three-dimensional projection of four input points, where the direction of projection is defined by the intersection of three planes, each the affine hull of three points, each the intersection of a fixed hyperplane and the affine hull of two input points.

$d \geq 3$, this lower bound holds even when the points are known in advance to be in convex position.

Proof. Let X denote the set of integers from $-dn$ to n, and let $X' = X + 1/(2d+2)$. The adversary initially presents the point set $\omega_d(X')$. This point set is affinely nondegenerate, since the expression $\sum_i x'_i$ is always a half-integer.

Choose arbitrary distinct positive elements $x_1, x_2, \ldots, x_d \in X$, and let $x_0 = -\sum_i x_i$; this is also an element of X. Then the points $\omega_d(x'_i)$ form a collapsible simplex. To collapse it, the adversary just shifts the points back down to $\omega_d(x_i)$; the collapsed simplex is obviously degenerate. Since the expression $\sum_{i=0}^{d} x'_i$ changes by at most $1/2 - 1/(2d+2)$ for any other simplex, no other simplex changes orientation.

Thus, if an algorithm does not perform a sidedness query on every collapsible simplex, the adversary can introduce an affine degeneracy that the algorithm cannot detect. There are at least $\binom{n}{d} = \Omega(n^d)$ such simplices. If $d \geq 3$, the original point set and each collapsed point set is in convex position. □

Erickson and Seidel [23] prove an $\Omega(n^d)$ lower bound for a restricted problem: Do any $d+1$ points lie on a *nonvertical* hyperplane? Except in the two-dimensional case, where an explicit adversary construction is given, their extension to the general problem is flawed [24].

The previous theorem easily generalizes to allow additional queries, as described in section 5.

THEOREM 7.2. *Any decision tree that decides whether a set of n points in $\mathbb{R}^d$ is affinely nondegenerate, using only sidedness queries and a finite number of allowable queries, requires $\Omega(n^d)$ sidedness queries in the worst case. If $d \geq 3$, this lower bound holds even when the points are known in advance to be in convex position.*

7.2. An alternate proof in two dimensions. According to Grünbaum [31], A. H. Stone observed that a set of n integer points on the unit cubic can have $n^2/8$ collinear triples. Füredi and Palásti [25] discovered an elegant construction, which we describe below, that improves this lower bound to roughly $n^2/6$. We can use their construction to slightly improve our lower bound for the two-dimensional affine degeneracy problem. The resulting lower bound is the best that can be derived using our techniques, except possibly for some lower-order terms.

Füredi and Palásti describe their construction in the dual. Let $L(\alpha)$ be the line passing through the point $(\cos\alpha, \sin\alpha)$ at angle $-\alpha/2$ to the x-axis. The line $L(\alpha)$ also passes through the point $(cos(\pi - 2\alpha), \sin(\pi - 2\alpha))$; if this is the same point as $(\cos\alpha, \sin\alpha)$, then the line is tangent to the unit circle at that point. Three lines $L(\alpha), L(\beta), L(\gamma)$ are concurrent if and only if $\alpha + \beta + \gamma \equiv 0 \pmod{2\pi}$. It follows that the set of lines $\{L(2\pi i/n) \mid 1 \leq i \leq n\}$ has $1 + \lfloor n(n-3)/6 \rfloor$ concurrent triples. See Figure 7.1(a). See [25] for further details. Related results are described in [9, 20, 31].

The set of lines $\{L((2i-1)\pi/n) \mid 1 \leq i \leq n\}$ has no concurrent triples, but its arrangement has $\lceil n(n-3)/3 \rceil$ triangular cells, each bounded by a triple of lines of the form

$$L((2i-1)\pi/n),\ L((2j-1)\pi/n),\ L((2k-1)\pi/n),$$

where $i + j + k \equiv 1$ or $2 \pmod{n}$. See Figure 7.1(b). Each of these triangles is collapsible; to collapse such a triangle, we shift each of its three defining lines by $\pi/3n$, resulting in the lines

$$L((2i-2/3)\pi/n),\ L((2j-2/3)\pi/n),\ L((2k-2/3)\pi/n)$$

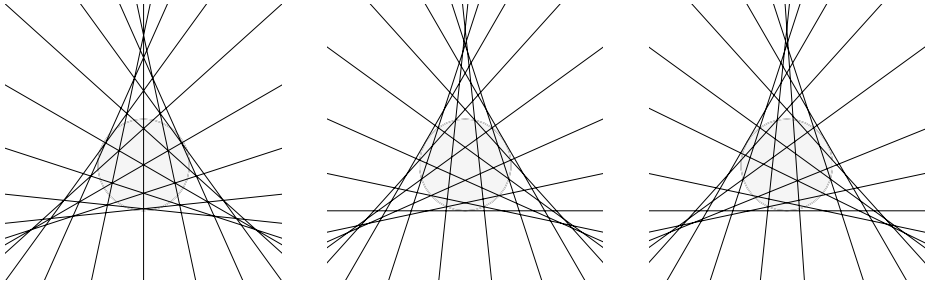

FIG. 7.1. *Another adversary construction for arbitrary degeneracies in the plane, following a construction of Füredi and Palásti.* (a) *The degenerate configuration.* (b) *The adversary configuration.* (c) *A collapsed configuration.*

if $i + j + k \equiv 1 \pmod{n}$, or

$$L((2i - 4/3)\pi/n),\ L((2j - 4/3)\pi/n),\ L((2k - 4/3)\pi/n)$$

if $i+j+k \equiv 2 \pmod{n}$; see Figure 7.1(c). We easily verify that the collapsed triangle is degenerate and that no other triangle changes orientation, since the sum of any other triple of defining angles changes by at most $2\pi/3n < \pi/n$.

THEOREM 7.3. *Any decision tree that decides whether a set of n points in $\mathbb{R}^2$ is affinely degenerate, using only sidedness queries, must have depth at least $\lceil n(n-3)/3 \rceil$.*

Grünbaum [31] proves that a simple arrangement of n lines in the projective plane can have at most $\lfloor n(n-1)/3 \rfloor$ triangular cells if n is even, and at most $\lfloor n(n-2)/3 \rfloor$ if n is odd. Thus, we cannot hope to prove a lower bound bigger than $n^2/3 + \Omega(n)$ using collapsible triangles.

7.3. Circular degeneracies. We also easily prove the following related theorem first proved in [23]. A set of points in the plane is *circularly degenerate* if any four points lie on a circle. The basic computational primitive used to detect circular degeneracies is the *in-circle query*: Given four points, is the first point inside, on, or outside the oriented circle defined by the other three points? In-circle queries can be answered by lifting the points to the unit paraboloid $z = x^2 + y^2$, or stereographically projecting them onto a sphere, and performing a three-dimensional sidedness query.

THEOREM 7.4. *Any decision tree that decides whether n points in $\mathbb{R}^2$ is circularly degenerate, using only in-circle queries, must have depth $\Omega(n^3)$.*

Proof. An in-circle query on four points on the unit parabola (t, t^2) is algebraically equivalent to a sidedness query for four points on the three-dimensional weird moment curve (t, t^2, t^2). Thus, Lemma 2.1 implies that four points, $(a, a^2), (b, b^2), (c, c^2)$, and (d, d^2), on the unit parabola are cocircular if and only if $a + b + c + d = 0$. Let X be the set of integers from $-n$ to n. There are $\Theta(n^3)$ 4-tuples in X whose sums are zero. The adversary presents a set of points on the unit parabola with x-coordinates taken from the set $X + 1/8$. This set is nondegenerate and has $\Omega(n^3)$ collapsible 4-tuples. □

We can extend the model of computation in a similar fashion as before, but with a different set of new queries. A *linear fractional transformation* of the plane (or more formally, of the Riemann sphere $\mathbb{CP}^1$) is any transformation that maps circles

to circles. If we represent the points of $\mathbb{R}^2$ in complex homogeneous coordinates—representing $(x, y) \in \mathbb{R}^2$ by any complex multiple of $(1 + 0i, x + yi) \in \mathbb{C}^2$—then a linear fractional transformation is equivalent to a linear transformation of $\mathbb{C}^2$.

We say that a query is *circularly allowable* if some linear fractional transformation of the set (X, X^2) is nondegenerate with respect to that query, where X is the set of numbers described in the proof of Theorem 7.4. Circularly allowable queries include first- and second-order point comparisons and sidedness queries but do not include comparisons between arbitrary in-circle determinants.

Arguments similar to those in section 5 give us the following theorem.

THEOREM 7.5. *Any decision tree that decides whether n points in $\mathbb{R}^2$ is circularly degenerate, using only in-circle queries and a finite number of circularly allowable queries, requires $\Omega(n^3)$ in-circle queries in the worst case.*

We conjecture that $\Omega(n^{d+1})$ insphere queries are required to decide if a set of n points in $\mathbb{R}^d$ is spherically degenerate, but we have been unable to generalize our proof of the two-dimensional case to higher dimensions. A proof would follow immediately from the construction of a set of numbers having $\Omega(n^{d+1})$ $(d+2)$-tuples in the zeroset of a certain symmetric polynomial, by applying our usual adversary argument. For example, in three dimensions, we need $\Omega(n^4)$ 5-tuples in the zeroset of the polynomial

$$1 + \sum_{1 \le i \le j \le 5} x_i x_j.$$

Erickson and Seidel [23] prove that $\Omega(n^{d+1})$ in-sphere queries are required to detect *proper* spherical degeneracies, i.e., sets of $d + 2$ points on a sphere of finite radius, but their proof for the general problem was flawed [24]. Unlike all the adversary sets in this paper, the adversary set they use is *not* obtained by perturbing a highly degenerate point set. Is there a set of n points in $\mathbb{R}^d$ with $\Omega(n^{d+1})$ independent spherical degeneracies? Such a set might lead to a proof of our conjecture.

8. Conclusions and open problems. We have presented new lower bounds on the worst-case complexity of detecting simplicial convex hulls or counting convex hull facets in a fairly natural model of computation. Our lower bounds follow from a simple adversary argument, based on the construction of a convex polytope with a large number of degenerate features. In order to be correct, any algorithm must individually check that each of those degenerate features is not present in the input. Similar arguments give us simple proofs of lower bounds for several degeneracy-detection problems.

Several open problems remain to be answered. While our lower bounds match existing upper bounds in odd dimensions, there is still a gap when the dimension is even. A first step in improving our lower bounds would be to improve the combinatorial bounds in Lemma 4.1. Is there a four-dimensional polytope with n vertices and $\Omega(n^2)$ degenerate facets? However, we conjecture that no such polytope (or even polyhedral 3-sphere) exists. Simple variations on the weird moment curve will not suffice, since an "evenness condition" like Lemma 2.2 always forces the number of degenerate facets to be linear. Arguments based on merging facets of cyclic or product polytopes also fail, as do variations on Amenta and Ziegler's deformed products [3, 4]. The best example we can construct is the connected sum of $n/5 - 1$ copies of a bipyramid over a cube, which has n vertices and $2n - 8$ facets, each a square pyramid.

A common application of convex hull algorithms is the construction of Delaunay triangulations and Voronoi diagrams. Are $\Omega(n^{\lceil d/2 \rceil})$ in-sphere queries required to decide if the Delaunay triangulation is simplicial (i.e., really a triangulation)? Again, a

first step is to construct a Delaunay triangulation with $\Omega(n^{\lceil d/2 \rceil})$ independent degenerate features.

Another similar problem is deciding, given a set of points, which ones are vertices of the set's convex hull. This problem can be decided in $O(n^2)$ time (using only sidedness queries!) by invoking a linear-time linear programming algorithm once for each point [37]. This upper bound can be improved to $O(n^{2\lfloor d/2 \rfloor/(\lfloor d/2 \rfloor - 1)} \operatorname{polylog} n)$ using an algorithm due to Chan [11]. Except for the polylogarithmic term, this algorithm is almost certainly optimal, but as usual the only known lower bound is $\Omega(n \log n)$ [7]. It seems unlikely that a collapsible simplex argument could be used to imply a reasonable lower bound for this problem.

Another interesting open problem is to strengthen the models in which our lower bounds hold. Quadratic lower bounds for either the five-dimensional convex hull problem or the two-dimensional affine degeneracy problem in stronger models of computation would imply similar lower bounds for a number of other 3SUM-hard problems. While the lower bounds we prove here and in earlier papers [23, 21] are in fairly natural models, there are still 3SUM-hard problems that cannot even be solved in these models. For example, one of the simplest problems for which our techniques fail is finding the minimum area triangle determined by a set of points in the plane. In order to prove a useful lower bound for this problem, we must consider a model that allows comparison of signed triangle areas. It seems impossible to apply our "collapsible simplex" adversary argument in such a model; a radically new idea is called for.

Ultimately, of course, we would like a lower bound bigger than $\Omega(n \log n)$ that holds in some general model of computation, such as algebraic decision trees or algebraic computation trees.

Acknowledgments. I would like to thank Raimund Seidel for several helpful discussions, David Bremner for pointing out the NP-hardness results in [14, 19], and Jack Snoeyink for pointing out [9].

THE HEIGHT AND SIZE OF RANDOM HASH TREES AND RANDOM PEBBLED HASH TREES*

LUC DEVROYE†

This paper is dedicated to the memory of Markku Tamminen, who died tragically in New York shortly after he finished his analysis of N-trees and random hash trees.

Abstract. The random hash tree and the N-tree were introduced by Ehrlich in 1981. In the random hash tree, n data points are hashed to values $X_1, \ldots, X_n$, independently and identically distributed random variables taking values that are uniformly distributed on $[0,1]$. Place the X_i's in n equal-sized buckets as in hashing with chaining. For each bucket with at least two points, repeat the same process, keeping the branch factor always equal to the number of bucketed points. If H_n is the height of tree obtained in this manner, we show that $H_n/\log_2 n \to 1$ in probability. In the random pebbled hash tree, we remove one point randomly and place it in the present node (as with the digital search tree modification of a trie) and perform the bucketing step as above on the remaining points (if any). With this simple modification,

$$\frac{H_n}{\sqrt{\frac{2\log n}{\log\log n}}} \to 1$$

in probability. We also show that the expected number of nodes in the random hash tree and random pebbled hash tree is asymptotic to $2.3020238\ldots n$ and $1.4183342\ldots n$, respectively.

Key words. data structures, probabilistic analysis, hashing with chaining, hash tables, N-trees, random hash trees, expected complexity

1. Introduction.

In this paper, we analyze the height of the random hash tree (Ehrlich, 1981) defined as follows. We are given $X_1, \ldots, X_n$, n independent uniform $[0,1]$ random numbers. If $n > 1$, we partition $[0,1]$ into n equal intervals of length $1/n$ each, and place all points in the intervals. Let $N_1, \ldots, N_n$ be the cardinalities of the intervals (thus, $\sum_i N_i = n$). Repeat the partition process for every interval containing at least two points and keep going until no further divisions are possible. The root node represents $[0,1]$, and each node represents a given interval. All internal nodes have at least two of the X_i's, while all leaf nodes have one or zero of the X_i's. If this structure is to be used for storing the data, then two important quantities are the number of nodes in the tree, S_n, and the height of the tree, H_n. The former quantity obviously measures the storage, while the latter is the worst-case search time. In addition, S_n is also proportional to the time needed to construct the hash tree. The model is appropriate for situations in which a hash function can be constructed that delivers a uniform $[0,1]$ random variate. This may be a debatable hypothesis.

The distributive partitioning method invented by Dobosiewicz (1978) led Ehrlich (1981) to define the N-tree. In N-trees, the X_i's are unrestricted on the real line, and given that a node has $k \geq 2$ of the X_i's, it spawns k equal child intervals of $[\min_i X_i, \max_i X_i]$. Note that there are always at least two nonempty subintervals (the first and the last) so that the size of the N-tree is limited to $n(n+1)/2$. A basic

study of N-trees and random hash trees was performed by Tamminen (1983). The results of Tamminen will be summarized in the next section. However, Tamminen did not study H_n. Hashing with several levels of buckets has been known since being introduced by Fagin et al. (1979) as extendible hashing. Its analysis was subsequently refined in several papers, including papers by Tamminen (1983, 1985) and Flajolet (1983). However, these structures differ fundamentally from the trees studied here.

The random hash tree and its modifications studied here are vaguely related to random tries (see Pittel (1985) for the main properties). We will show that the height H_n of the random hash tree is with high probability close to $\log_2 n$, which is rather disappointing. The reason for this phenomenon is the same reason why random binary tries have height close to $2\log_2 n$. This prompted us to consider a modification similar to the modification of a trie into the digital search tree of Coffman and Eve (1970): if n points belong to an interval associated with a node, remove one point uniformly at random and place it in the node ("pebble" the node). If $n > 1$, the interval is partitioned equally into $n-1$ child subintervals and the $n-1$ remaining points are placed in their subintervals. This process is repeated until all leaf nodes have cardinality zero or one. The tree thus obtained is called the random pebbled hash tree. We will show that this minor modification causes a major improvement in H_n, which is with high probability close to $\sqrt{2\log n/\log\log n}$.

Assuming that each bucketing operation is available at unit cost, the expected time for unsuccessful and for successful search (assuming all points are equally likely to be probed for) is $O(1)$ for both random hash tree and random pebbled hash tree, but the expected worst-case search time for the latter tree is much better than for classical hash structures in view of the behavior of H_n. For example, for standard hashing with chaining under the above model, $M_n \sim \log n/\log\log n$ in probability (Gonnet (1981); see Devroye (1985, 1986) for distributions with a bounded density), where M_n is the worst-case search time (or, equivalently, the maximal size of any chain).

The random pebbled hash tree is also superior to random binary search trees, where the height is in probability of the order of $\log n$ (under a simpler computational model, however). It also compares favorably with fusion trees (Fredman and Willard, (1990)) for standard dictionary operations. Unfortunately, hash trees are not appropriate without modifications for fully dynamic situations. A brief section is devoted to this issue.

There are hash structures with better expected worst-case search and insert times. Azar et al. (1994) have shown that the worst chain length in multihashing with $d > 1$ hash functions and insertion into the shortest chain leads to a maximum occupancy of about $\log_d \log n$ with high probability. This leads to expected worst-case search times about $d\log_d \log n$, which are much better than with random pebbled hash trees. However, multihashing is not an option when the table is to be used for sorting and order-preserving hash functions are called for. Also, the performance of multihashing is easily matched by bucketing followed by a binary search tree, known as the BSST structure, discussed below.

For a survey of known results on hashing and tries, we refer to Gonnet and Baeza-Yates (1991) and Vitter and Flajolet (1990). Throughout the paper, $B(n,p)$ denotes a binomial (n,p) random variable.

2. Survey of known results on N-trees and random hash trees. Assume that the X_i's are uniformly distributed on $[0,1]$. Then Tamminen (1983) shows the following for N-trees:

A. $\sup_n \frac{\mathbf{E}S_n}{n} \le 2$.

B. $1.64 \le \liminf_n \frac{\mathbf{E}S_n}{n} \le \limsup_n \frac{\mathbf{E}S_n}{n} \le 1.70$.

C. Let A_i be the depth of X_i in the N-tree so that $(1/n)\sum_{i=1}^n A_i$ is the average successful search time. Then

$$\mathbf{E}\left\{\frac{1}{n}\sum_{i=1}^n A_i\right\} \le 2$$

for all n.

D. $1.71 \le \liminf_n \mathbf{E}\left\{\frac{1}{n}\sum_{i=1}^n A_i\right\} \le \limsup_n \mathbf{E}\left\{\frac{1}{n}\sum_{i=1}^n A_i\right\} \le 1.80$.

If the X_i's have a density f bounded by $\|f\|_\infty$, then for the random hash tree, Tamminen (1983) obtained the following results:

A. $\sup_n \frac{\mathbf{E}S_n}{n} \le 3\|f\|_\infty$.

B. $\limsup_n \frac{\mathbf{E}S_n}{n} \le 4$.

C. Let A_i be the depth of X_i in the random hash tree so that $(1/n)\sum_{i=1}^n A_i$ is the average successful search time. Then

$$\limsup_n \mathbf{E}\left\{\frac{1}{n}\sum_{i=1}^n A_i\right\} \le 4.$$

Note in particular that the asymptotic bounds in parts B and C do not depend upon the density. Tamminen (1983) also offers heuristic arguments for densities with unbounded support and so-called hybrid trees, where the first level is split as in an N-tree and all other splits are as in a random hash tree.

3. The height of the random hash tree. In this section, we assume that $X_1, \ldots, X_n$ are independently and indentically distributed (i.i.d.) and have common density f on $[0,1]$. Let H_n be the height of the random hash tree. We show the following.

THEOREM 1. *For any increasing sequence a_n (however fast), there exists a density f for which $\mathbf{P}\{H_n \ge a_n\} \to 1$ as $n \to \infty$.*

Proof. Let F be the distribution function for f, supported on $[0,1]$. Let N_1 be the number of points in $[0, 1/n]$, N_2 the number of points in $[0, 1/n^2]$, and so forth. Clearly,

$$[N_{a_n} \ge 2] \subseteq [H_n \ge a_n].$$

But, putting $p = 1 - F(1/n^{a_n})$, we see that

$$\mathbf{P}\{N_{a_n} < 2\} = p^n + np^{n-1} \le (n+1)e^{-(n-1)F(1/n^{a_n})} \to 0$$

if $nF(1/n^{a_n})/\log n \to \infty$. It suffices to pick F such that $F(1/n^{a_n}) = 1/\sqrt{n}$ for all n. Then let f be a histogram with breakpoints at $1/n^{a_n}$. Conclude that $\mathbf{P}\{H_n \ge a_n\} \to 0$. □

THEOREM 2. *When f is the uniform distribution on $[0,1]$, we have*

$$\frac{H_n}{\log_2 n} \to 1 \text{ in probability.}$$

Proof. For a lower bound, it suffices to consider a subtree of the random pebbled hash tree. To do so, we consider only those nodes at depth one that contain precisely two points. Let L be the number of these nodes. Observe that

$$\mathbf{E}\{L\} = (n-1)\mathbf{P}\{B(n-1, 1/(n-1)) = 2\} = (n-1)\binom{n-1}{2}\left(\frac{1}{(n-1)^2}\right)\left(\frac{n-2}{n-1}\right)^{n-2} \sim \frac{n}{2e}$$

as $n \to \infty$. Furthermore, if one of the data points is changed, L changes by at most two. Thus, by McDiarmid's version of Azuma's inequality (McDiarmid, 1989),

$$\mathbf{P}\{L < \mathbf{E}\{L\}/2\} \le e^{-\frac{\mathbf{E}^2\{L\}}{8n}} = e^{-\frac{n}{32e^2+o(1)}}.$$

Each of the subtrees rooted at these nodes is independent of the others. Both points in one of these nodes are placed in the same subtree with probability 1/2. Thus, a subtree has height of at least $k-1$ with probability $1/2^{k-1}$. Therefore,

$$\begin{aligned}
\mathbf{P}\{H_n \le k\} &\le \mathbf{E}\left\{(1-1/2^{k-1})^L\right\} \\
&\le \mathbf{E}\left\{e^{-\frac{L}{2^{k-1}}}\right\} \\
&\le e^{-\frac{\mathbf{E}\{L\}}{2^k}} + \mathbf{P}\{L < \mathbf{E}\{L\}/2\} \\
&\le e^{-\frac{n}{(2e+o(1))2^k}} + e^{-\frac{n}{32e^2+o(1)}} \\
&\to 0,
\end{aligned}$$

as $n \to \infty$ if $k = \lfloor (1-\epsilon)\log_2 n \rfloor$ for $\epsilon \in (0,1)$.

For the upper bound, let $N_1, \ldots, N_n$ be the cardinalities of the children of the root (so that $\sum_i N_i = n$ unless $n = 1$). If X_i and X_j find themselves in the same child node of the root, then they will stay together at depth 2 with probability 1/2, at depth 3 with probability $1/2^2$, and at depth k with probability $1/2^{k-1}$. Let $A_{m,k}$ be the event that for the mth child of the root, one of the pairs of points in the node stays together to depth k. Clearly,

$$\begin{aligned}
\mathbf{P}\{H_n > k\} &\le \mathbf{P}\{\cup_{m=1}^n A_{m,k}\} \\
&\le n\mathbf{P}\{A_{1,k}\} \\
&\le n\mathbf{E}\left\{\frac{\binom{N_1}{2}}{2^{k-1}}\right\} \\
&= \frac{n-1}{2^k}
\end{aligned}$$

as N_1 is binomial $(n, 1/n)$. Therefore, for $\epsilon > 0$,

$$\lim_{n\to\infty} \mathbf{P}\{H_n > (1+\epsilon)\log_2 n\} = 0. \qquad \square$$

4. The height of the random pebbled hash tree. In this section, we assume that $X_1, \ldots, X_n$ are i.i.d. and have common density f on $[0,1]$. Let H_n be the height of the random pebbled hash tree. Clearly, $H_n \le n-1$. In a random pebbled hash tree we interchangeably speak of nodes, intervals (each node represents an interval), and cardinality (the number of X_i's that fall in a node's interval). We show the following.

THEOREM 3. *Consider a random pebbled hash tree. For any monotonically decreasing sequence $a_n \downarrow 0$ (however slow), there exists a density f for which $\mathbf{P}\{H_n \ge na_n\} \to 1$ as $n \to \infty$.*

Theorem 3 shows that no good universal results are possible for H_n unless the density of the X_i's is suitably restricted. As we may often assume that the hash function is very good, we will assume that the X_i's are uniformly distributed on $[0,1]$. It is worthwhile to note that Theorem 3 remains valid for the N-tree as well.

Proof. We take a density f that decreases monotonically on $[0,1]$ and has distribution function F. Remove one data point. Let N_1 be the number of points in $[0, 1/n]$.

Remove one point again, and let N_2 be the number of points in $[0, 1/n^2]$, and so forth. Assume without loss of generality that na_n is integer-valued and strictly increasing to ∞. Clearly,

$$[N_{na_n} \geq 2] \subseteq [H_n \geq na_n].$$

But N_k is binomial $(N_{k-1} - 1, F(1/n^k)/F(1/n^{k-1}))$, which is stochastically greater than a binomial $(N_{k-1}, F(1/n^k)/F(1/n^{k-1}))$ random variable minus one. Therefore, N_k is stochastically greater than a binomial $(n, F(1/n^k))$ random variable minus k. Thus, for n large enough, setting $p = F(1/n^{na_n}) = \sqrt{a_n + 1/n}$, we have, by Chebyshev's inequality,

$$\begin{aligned}
\mathbf{P}\{N_{na_n} < 2\} &\leq \mathbf{P}\{B(n,p) \leq na_n + 1\} \\
&= \mathbf{P}\{B(n,p) \leq np^2\} \\
&\leq \frac{np(1-p)}{(np(1-p))^2} \\
&\sim \frac{1}{n\sqrt{a_n + 1/n}} \\
&\to 0.
\end{aligned}$$

Now, take for f a histogram whose distribution function satisfies $F(1/n^{na_n}) = \sqrt{a_n + 1/n}$ for all n large enough. □

THEOREM 4. *When f is the uniform distribution on $[0,1]$, we have*

$$\frac{H_n}{\sqrt{\frac{2\log n}{\log\log n}}} \to 1 \text{ in probability.}$$

5. Proof of Theorem 4.

LEMMA 1. *For $t > 0$ and $t \geq c$,*

$$\mathbf{P}\{B(n, c/n) \geq t\} \leq e^{t - c - t\log t + t\log c}.$$

Proof. We write $B = B(n, c/n)$. By Chernoff's bounding method, for $\lambda > 0$,

$$\begin{aligned}
\mathbf{P}\{B \geq t\} &\leq \mathbf{E}\left\{e^{\lambda B - \lambda t}\right\} \\
&= \left(1 + \left(e^\lambda - 1\right)\frac{c}{n}\right)^n e^{-\lambda t} \\
&\leq e^{c\left(e^\lambda - 1\right) - \lambda t}.
\end{aligned}$$

The upper bound is minimized when $e^\lambda = t/c$, yielding the desired inequality. □

LEMMA 2. *If B is a binomial $(n, c/n)$ random variable and $t > 0$, then, for $t \geq c$,*

$$\mathbf{E}\left\{BI_{B \geq t}\right\} \leq ce^{t - c - t\log t + t\log c}.$$

Proof. By simple bounding, we have for $\lambda > 0$,

$$\begin{aligned}
\mathbf{E}\left\{BI_{B \geq t}\right\} &\leq \mathbf{E}\left\{Be^{\lambda B - \lambda t}\right\} \\
&= n\mathbf{E}\left\{\frac{c}{n}e^{\lambda B' - \lambda t}\right\} \\
&= c\mathbf{E}\left\{e^{\lambda B' - \lambda t}\right\},
\end{aligned}$$

where B' is binomial $(n-1, c/n)$. Here we made use of the linearity of expectation. By the Chernoff bound used in Lemma 1, we have

$$\begin{aligned}\mathbf{E}\{BI_{B\geq t}\} &\leq c\left(1+\left(e^{\lambda}-1\right)\frac{c}{n}\right)^{n-1}e^{-\lambda t}\\ &\leq c\left(1+\left(e^{\lambda}-1\right)\frac{c}{n-1}\right)^{n-1}e^{-\lambda t}\\ &\leq ce^{c\left(e^{\lambda}-1\right)-\lambda t}.\end{aligned}$$

The upper bound is minimized when $e^{\lambda}=t/c$. □

We are now ready to prove Theorem 4. For the upper bound, take $\epsilon>0$ and define $k=\left\lceil(1+\epsilon)\sqrt{\frac{2\log n}{\log\log n}}\right\rceil$. The tree is pruned by omitting the root node if its cardinality is less than k, all nodes at depth one with cardinality less than $k-1$, and in general all nodes at depth d of cardinality less than $k-d$. We call this tree the pruned tree. To compute $\mathbf{P}\{H_n\geq k\}$, the pruned tree and the random pebbled hash tree are equivalent as all deleted nodes are roots of subtrees that cannot reach past depth k. The expected number of nodes in the pruned tree at depth one is

$$\begin{aligned}(n-1)\mathbf{P}\{B(n-1,1/(n-1))\geq k-1\} &\leq (n-1)e^{k-1-1-(k-1)\log(k-1)}\\ &= \frac{n-1}{e}\left(\frac{e}{k-1}\right)^{k-1},\end{aligned}$$

where we used Lemma 1. Let the L nodes at depth one have cardinalities $N_1,\ldots,N_L$. Given N_1, the first node spawns an expected number of nodes at depth two equal to

$$\begin{aligned}(N_1-1)\mathbf{P}\{B(N_1-1,1/(N_1-1))\geq k-2\} &\leq (N_1-1)e^{k-2-1-(k-2)\log(k-2)}\\ &= \frac{N_1-1}{e}\left(\frac{e}{k-2}\right)^{k-2}.\end{aligned}$$

Given all the cardinalities, we thus have an expected number of nodes at depth two not exceeding

$$\frac{\sum_{i=1}^{L}(N_i-1)}{e}\left(\frac{e}{k-2}\right)^{k-2}.$$

But

$$\mathbf{E}\left\{\sum_{i=1}^{L}N_i\right\}=\mathbf{E}\left\{\sum_{i=1}^{n-1}M_iI_{M_i\geq k-1}\right\}\leq ne^{k-1-1-(k-1)\log(k-1)},$$

where $M_1,\ldots,M_{n-1}$ are the cardinalities of the $n-1$ intervals in the first partition. Here we used Lemma 2 with $c=1$. Therefore, the expected number of nodes at depth two does not exceed

$$\frac{n}{e^2}\left(\frac{e}{k-1}\right)^{k-1}\left(\frac{e}{k-2}\right)^{k-2}.$$

By induction, the expected number of nodes at depth $k-1$ does not exceed

$$\frac{n}{e^{k-1}}\prod_{i=1}^{k-1}\left(\frac{e}{i}\right)^{i}=ne^{(k-1)(k-2)/2-\sum_{i=1}^{k-1}i\log i}=ne^{-(1/2+o(1))k^2\log k}.$$

Thus,

$$\mathbf{P}\{H_n \geq k\} \leq ne^{-(1/2+o(1))k^2 \log k} \to 0$$

for the given choice of k.

For a matching lower bound, we argue by embedding and prune the tree even further. For $\epsilon \in (0,1)$, define $k = \left\lfloor (1-\epsilon)\sqrt{\frac{2\log n}{\log\log n}} \right\rfloor$. Of all nodes at depth one, we keep only those of exact cardinality k. These nodes spawn children at depth two, of which we keep only the first child and only if it is of cardinality precisely $k-1$. Continuing in this manner, the process either becomes extinct or it survives up to depth k with at least one node of cardinality one. In the latter case, $H_n \geq k$. A node at depth one has progeny that survives to depth k with probability

$$\frac{1}{(k-1)^{k-1}(k-2)^{k-2}\cdots 2^2 1^1} \stackrel{\text{def}}{=} q.$$

Clearly, $q = e^{-(1/2+o(1))k^2 \log k}$. Given that there are L nodes at depth one in the pebbled hash tree, we have

$$\mathbf{P}\{H_n < k | L\} \leq (1-q)^L.$$

Now, L is binomial $(n-1,p)$, where $p = \mathbf{P}\{B = k\}$ and B is binomial $(n-1, 1/(n-1))$. It is easy to verify that for $n \geq 3$,

$$p = \binom{n-1}{k}\frac{1}{(n-1)^k}\left(1-\frac{1}{(n-1)}\right)^{n-1-k} \geq \frac{1}{k!}\left(\frac{n-1-k}{n-1}\right)^k\left(1-\frac{1}{n-1}\right)^{n-1}$$
$$\geq \frac{1}{4\ k!}\left(1-\frac{k}{n-1}\right)^k \geq \frac{1-k^2/(n-1)}{4\ k!} \stackrel{\text{def}}{=} q'.$$

Hence L is stochastically greater than B', a binomial $(n-1,q')$ random variable. Thus,

$$\mathbf{P}\{H_n < k\} \leq \mathbf{E}\left\{(1-q)^L\right\} \leq \mathbf{E}\left\{(1-q)^{B'}\right\}$$
$$= (q'(1-q)+1-q')^{n-1} = (1-qq')^{n-1} \leq e^{-(n-1)qq'} \to 0$$

when $nqq' \to \infty$. This is easily verified for our choice of k. □

6. The size of random hash trees. The second parameter of primary interest is S_n. We will look only at $s_n = \mathbf{E}S_n$. By linearity of expectation, we have

$$s_n = \begin{cases} 1, & 0 \leq n \leq 1, \\ 1 + n\sum_{i=0}^n \mathbf{P}\{B(n,1/n) = i\}s_i, & n \geq 2. \end{cases}$$

Note that we provide storage for empty bins as well. The recurrence given above yields $s_0 = s_1 = 1$, $s_2 = 1+2(3/4+s_2/4)$ so that $s_2 = 5$. Hence we have the following theorem.

THEOREM 5. *For the random hash tree,*

$$\lim_{n\to\infty}\frac{\mathbf{E}S_n}{n} = 2.3020238\ldots.$$

The limiting constant is

$$\frac{1}{e}\sum_{i=0}^{\infty}\frac{s_i}{i!}\ ,$$

where $s_0, s_1, \ldots$ is given by the above recurrence.

Proof. The values s_n can be shown to be approximable by the values t_n, where

$$t_n = \frac{n}{e}\sum_{i=0}^{\infty}\frac{s_i}{i!}.$$

Indeed, note that

$$\frac{s_n - t_n}{n} = \frac{1}{n} + \sum_{i=0}^{n}\left(\mathbf{P}\{B(n,1/n)=i\} - \frac{1}{e\ i!}\right)s_i - \sum_{i>n}\frac{s_i}{e\ i!}.$$

But for $0 \le i \le n$,

$$\begin{aligned}\mathbf{P}\{B(n,1/n)=i\} - \frac{1}{e\ i!} &= \binom{n}{i}\frac{(n-1)^{n-i}}{n^n} - \frac{1}{e\ i!} \le \frac{n^i}{i!}\frac{(n-1)^{n-i}}{n^n} - \frac{1}{e\ i!}\\ &= \frac{1}{i!}\frac{(n-1)^{n-i}}{n^{n-i}} - \frac{1}{e\ i!} \le \frac{e^{\frac{i}{n}-1}}{i!} - \frac{1}{e\ i!} \le \frac{i}{n\ i!},\end{aligned}$$

and for $0 \le i \le n$,

$$\begin{aligned}\mathbf{P}\{B(n,1/n)=i\} - \frac{1}{e\ i!} &\ge \frac{(n-i+1)^i}{i!}\frac{(n-1)^{n-i}}{n^n} - \frac{1}{e\ i!}\\ &\ge \left(1-\frac{i-2}{n-1}\right)^i \frac{e^{-\frac{1}{1-1/n}}}{i!} - \frac{1}{e\ i!}\\ &\ge \frac{e^{-\frac{i^2}{n-i+1}-\frac{1}{1-1/n}}}{i!} - \frac{1}{e\ i!} \ge \frac{1}{e\ i!}\left(e^{-\frac{i^2}{n-i+1}-\frac{1}{n-1}}-1\right)\\ &\ge -\frac{1}{e\ i!}\left(\frac{i^2}{n-i+1}+\frac{1}{n-1}\right)\\ &\ge -\frac{1}{e\ i!}\left(\frac{i^2}{n/2}+i^2 I_{i\ge n/2}+\frac{1}{n-1}\right).\end{aligned}$$

Thus, we have $(s_n - t_n)/n \to 0$ if

$$\sum_{i=0}^{\infty}\frac{i^2 s_i}{i!} < \infty.$$

But that follows from the simple fact that $s_i = O(i)$, something that is easy to verify. Numerical computations show that

$$\frac{1}{e}\sum_{i=0}^{\infty}\frac{s_i}{i!} = 2.3020238\ldots. \qquad \square$$

For the random pebbled hash tree, the recurrences are slightly different. Indeed,

$$s_n = \begin{cases} 1, & 0 \le n \le 1,\\ 1 + (n-1)\sum_{i=0}^{n-1}\mathbf{P}\{B(n-1,1/(n-1))=i\}s_i, & n > 1.\end{cases}$$

The analysis is entirely similar as for Theorem 5, and we thus obtain the following theorem.

THEOREM 6. *For the random pebbled hash tree,*

$$\lim_{n\to\infty} \frac{\mathbf{E}S_n}{n} = 1.4183342\ldots.$$

The limiting constant is

$$\frac{1}{e}\sum_{i=0}^{\infty} \frac{s_i}{i!} ,$$

where $s_0, s_1, \ldots$ is given by the above recurrence.

In particular, note that random pebbled hash trees are smaller on the average than random N-trees.

7. BBST: Bucketing followed by binary search trees. Assume that we bucket n points into n equispaced buckets and that within each bucket we maintain a balanced binary search tree. Then, in view of the results of Gonnet (1981) and Devroye (1985), the expected worst-case search and insert times and indeed the expected value of the height of this hybrid structure is asymptotic to $\log_2 \log n$ for all bounded densities f on $[0,1]$. In fact, the height H_n satisfies $H_n/\log_2 \log n \to 1$ in probability. The expected average search time (if each element is equally likely to be probed for) and the expected unsuccessful search time (for a random element drawn independently from the same density f) are both $O(1)$.

8. Extension: m pebbles. We may extend the analysis to m pebbles, leaving m randomly selected points in every node before bucketing. If there are $m+k$ points, then there are k (with possibly $k=1$) child nodes, each corresponding to a subinterval $1/k$th of the length of the interval of the split node. This leads to random m-pebbled hash trees. A quick analysis not worth repeating here shows that in this case, $H_n \sim \sqrt{(2/m)\log n/\log\log n}$ in probability. However, the worst-case search time is roughly $(m+1)H_n$ when comparisons and bucket operations all take one time unit. Therefore, it seems wasteful to take $m > 1$, and thus the most important member of the family is the pebbled hash tree studied above. A rather obvious but unaesthetic modification, however, will improve matters exponentially. Let us set $m = c\log n/\log\log n$ for some constant c, and pick the m pebbles as follows for a node representing interval $[a,b]$: find the mth order statistic M in time linear in the number of points. The m points on $[a,M]$ are placed in a balanced binary search tree in time $m\log m = O(\log\log n)$. The remaining points on $(M,b]$ are bucketed as in a random hash tree, and the process is repeated. This tree has expected height $O(1)$ so that expected worst-case search times are $O(\log\log n)$. As this method is eclipsed by the simple BBST structure of the previous section, we will not analyze it in this paper.

9. Dynamic data structures. The data structures described above are of course useful in any static setting, in which case we have expected preprocessing time $O(n)$ and expected worst-case search times as given by the expected values of H_n in the analyses. Consider now the standard dictionary operations `insert` and `search`. We may introduce the load factor α, the number of elements stored divided by the branch factor of the root. The objective is to keep α at all times in a fixed range, such as $[1/2, 2]$. As soon as α reaches a boundary, a complete rehash is performed to make $\alpha = 1$. In an amortized sense, these rehash operations take $O(1)$

expected time. Expected worst-case search times remain asymptotically the same as for the static case. However, for a fully dynamic data structure with interspersed `delete` and `insert` operations, additional analysis is required.

Acknowledgment. I would like to thank all referees for their suggestions.

ON REARRANGEABILITY OF MULTIRATE CLOS NETWORKS*

GUO-HUI LIN†, DING-ZHU DU‡, XIAO-DONG HU§, AND GUOLIANG XUE¶

Abstract. Chung and Ross [*SIAM J. Comput.*, 20 (1991), pp. 726–736] conjectured that the multirate three-stage Clos network $C(n, 2n-1, r)$ is rearrangeable in the general discrete bandwidth case; i.e., each connection has a weight chosen from a given finite set $\{p_1, p_2, \ldots, p_k\}$ where $1 \geq p_1 > p_2 > \cdots > p_k > 0$ and p_i is an integer multiple of p_k, denoted by $p_k \mid p_i$, for $1 \leq i \leq k-1$. In this paper, we prove that multirate three-stage Clos network $C(n, 2n-1, r)$ is rearrangeable when each connection has a weight chosen from a given finite set $\{p_1, p_2, \ldots, p_k\}$ where $1 \geq p_1 > p_2 > \cdots > p_h > 1/2 \geq p_{h+1} > \cdots > p_k > 0$ and $p_{h+2} \mid p_{h+1}$, $p_{h+3} \mid p_{h+2}$, $\ldots$, $p_k \mid p_{k-1}$. We also prove that $C(n, 2n-1, r)$ is two-rate rearrangeable and $C(n, \lceil \frac{7n}{3} \rceil, r)$ is three-rate rearrangeable.

1. Introduction.

The multirate interconnection network is a research topic in asynchronous transfer mode (ATM) networks with applications in computer networks, telecommunications, and the Internet. The symmetric three-stage Clos network $C(n, m, r)$ has been widely used in the design of telecommunication networks [1]. $C(n, m, r)$ consists of r $n \times m$ crossbars (switches) in the first (or input) stage, m $r \times r$ crossbars in the second (or central) stage, and r $m \times n$ crossbars in the third (or output) stage. Every crossbar in the first stage has an outlet connected to an inlet of every crossbar in the second stage, and every crossbar in the second stage has an outlet connected to an inlet of every crossbar in the third stage (Fig. 1). There are totally rn inlets in the first stage, called *inputs*, and totally rn outlets in the third stage, called *outputs*. A *connection* (*request*, or *call*) in the network is a triple (i, j, w) where i is an input, j is an output, while w is the *weight* of this connection, and it represents the bandwidth required by the connection. A *route* is a path in the network joining an input crossbar (i.e., a crossbar in the first stage) to an output crossbar (i.e., a crossbar in the third stage) and a route r *realizes* a connection (i, j, w) if the input crossbar i and output crossbar j are connected by r with capacity w.

Usually, one assumes that each link has unit capacity. Therefore, the weight of each connection is in the interval $[0, 1]$. A set of connections is *compatible* if, at every

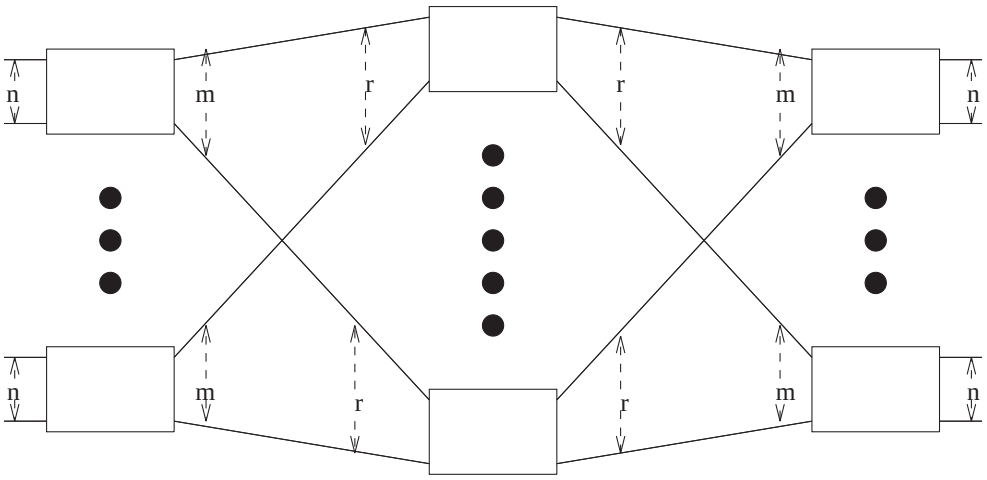

FIG. 1. *Symmetric three-stage Clos network.*

input and output, the sum of weights of all connections is at most one. A *request frame* is a compatible set of connections. A *configuration* is a set of routes, and it is *compatible* if the total weight of routes passing through each link is at most one. A request frame is said to be *realizable* if there exists a compatible configuration which contains routes realizing all connections in the request frame. A multirate network is said to be *(multirate) rearrangeable* if every request frame is realizable.

A connection c is said to be *compatible* with a request frame $\mathcal{F}$ if $\mathcal{F} \cup \{c\}$ is still compatible. A route r is said to be *compatible* with a compatible configuration $\mathcal{C}$ if $\mathcal{C} \cup \{r\}$ is still compatible. A network is said to be *strictly nonblocking* if for every compatible configuration $\mathcal{C}$ realizing a request frame $\mathcal{F}$ and every connection c compatible with $\mathcal{F}$, there exists a route r such that r realizes c and r is compatible with $\mathcal{C}$.

In circuit switching, all connections are assumed to have the same rate one. Namely, a network is said to be rearrangeable in circuit switching if every compatible request frame of connections with weight one is realizable, and it is well known that the symmetric three-stage Clos network $C(n, m, r)$ is rearrangeable in circuit switching if and only if $m \geq n$ [1]. Now, since multirate is involved, we may need more crossbars in the center stage to reach the rearrangeability. Chung and Ross [2] conjectured[1] that if a symmetric three-stage Clos network $C(n, m, r)$ is strictly nonblocking in circuit switching, then it is multirate rearrangeable in the discrete bandwidth case. That is, $C(n, 2n-1, r)$ is multirate rearrangeable if each connection has weight chosen from a given finite set $\{p_1, p_2, \ldots, p_k\}$ where $1 \geq p_1 > p_2 > \cdots > p_k > 0$ and p_i is an integer multiple of p_k, denoted by $p_k \mid p_i$, for $1 \leq i \leq k-1$. They verified their conjecture when $k = 2$ and $\{p_1, p_2, \ldots, p_k\} = \{1, p\}$.

Du et al. [3] recently proved that $C(n, m, r)$ for $m \geq 41n/16$ is multirate rearrangeable in general.

[1] After proving the result [2, Corollary 3] that a strictly nonblocking network for classical circuit switching is also rearrangeable if all connections have weight of either b or 1, Chung and Ross [2] stated that "It would be of interest to show that Corollary 3 holds for the general discrete bandwidth case with K distinct rates." For an easy reference, we call it the Chung–Ross conjecture. In this paper, we consider this conjecture only for three-stage Clos networks.

In this paper, we prove that the symmetric three-stage Clos network $C(n, 2n-1, r)$ is multirate rearrangeable when each connection has a weight chosen from a given finite set $\{p_1, p_2, \ldots, p_k\}$ where $1 \geq p_1 > p_2 > \cdots > p_h > 1/2 \geq p_{h+1} > \cdots > p_k > 0$ and $p_{h+2} \mid p_{h+1}$, $p_{h+3} \mid p_{h+2}, \ldots, p_k \mid p_{k-1}$. We also prove that $C(n, 2n-1, r)$ is two-rate rearrangeable and $C(n, \lceil \frac{7n}{3} \rceil, r)$ is three-rate rearrangeable.

2. Main results. In this section, we prove the following theorem.

THEOREM 2.1. *Symmetric three-stage Clos network $C(n, 2n-1, r)$ is multirate rearrangeable when each connection has a weight chosen from a given finite set $\{p_1, p_2, \ldots, p_k\}$ where $p_{h+2} \mid p_{h+1}$, $p_{h+3} \mid p_{h+2}, \ldots, p_k \mid p_{k-1}$, and $1 \geq p_1 > p_2 > \cdots > p_h > 1/2 \geq p_{h+1} > p_{h+2} > \cdots > p_k > 0$.*

Proof. For $k - h = 0$, since $p_\ell > 1/2$ for all $\ell = 1, 2, \ldots, k$, each link contains at most one call. Thus, we can treat the network as that used in circuit switching. From the result about circuit switching, $C(n, 2n-1, r)$ is nonblocking and hence rearrangeable. Next, we consider $k - h \geq 1$. Suppose α_ℓ for $\ell = 1, 2, \ldots, h$ and β are integers such that $p_\ell + \alpha_\ell p_k \leq 1 < p_\ell + (\alpha_\ell + 1)p_k$ and $\beta p_k \leq 1 < (\beta + 1)p_k$. First, route all calls with weights $p_1, p_2, \ldots, p_{k-1}$ on the $2n-1$ center switches. By the induction assumption, it is possible. Now we route all calls with weight p_k (or, say, p_k-call) in an arbitrary ordering. We will prove that we can always find a space for a p_k-call compatible with previous routed calls. In fact, for contradiction, suppose there exists a p_k-call (i, j, p_k) compatible with previous routed calls, but we cannot find space on a center switch to route this call (i, j, p_k). Let I be the input switch containing input i and J the output switch containing output j. Define the I-load (the J-load) of a center switch as the sum of weights of all calls from input switch I to the center switch (from the center switch to output switch J). Then every center switch has its I-load or its J-load greater than $1 - p_k$. Note that there are $2n-1$ center switches. Therefore, we can find either n center switches that each has I-load greater than $1 - p_k$ or n center switches that each has J-load greater than $1 - p_k$. Without loss of generality, we assume that the former occurs. This means that each of these n center switches has I-load equal to either $p_\ell + \alpha_\ell p_k$ for some $\ell \in \{1, 2, \ldots, h\}$ or βp_k. Note that input switch I has exactly n input, and each input can contain at most one p_ℓ-call for $\ell \in \{1, 2, \ldots, h\}$. Thus, every input in input switch I has a load equal to either $p_\ell + \alpha_\ell p_k$ or βp_k. It follows that the call (i, j, p_k) cannot exist, which is a contradiction. □

Melen and Turner [4] gave a routing algorithm CAP, and with CAP it can be showed that the multirate three-stage Clos network $C(n, 2n-1, r)$ is rearrangeable when each connection has a weight at most $1/2$. The outline of the algorithm CAP is as follows.

Divide all calls in each input/output switch into groups of size m. Then algorithm CAP can arrange m center switches, with flexible link capacity, to route all calls such that each center switch holds at most one call from every group in every input/output switch. Thus, if for each input/output switch the total weight of a set of calls chosen one from each group is never greater than one, then the line capacity can be restricted to be within one. Thus, algorithm CAP actually routes all calls with m center switch in the model considered in this paper.

The following is a corollary of Theorem 2.1.

COROLLARY 2.2. *The symmetric three-stage Clos network $C(n, 2n-1, r)$ is multirate rearrangeable when every connection has a weight chosen from a given set $\{p_1, p_2\}$.*

Proof. If $p_1 \leq 1/2$, then it follows from the result of Melen and Turner [4]. If

$p_1 > 1/2$, it follows from Theorem 2.1. □

The next result is obtained with algorithm CAP, too.

LEMMA 2.3. *Symmetric three-stage Clos network $C(n, 2n-1, r)$ is multirate rearrangeable when each connection has a weight bigger than* $1/3$.

Proof. Since every call has weight bigger than $1/3$, each input/output has at most two calls. Thus, each input/output switch has at most $2n$ calls. If it has fewer than $2n$ calls, we put them all into one group. If it has exactly $2n$ calls, then we place the one with the smallest weight among the $2n$ calls into one group and put the remaining $2n-1$ calls into another group. Note that when an input (output) switch has exactly $2n$ calls, each inlet (outlet) in this switch has exactly two calls. It follows from this fact that among weights of the $2n$ calls, the smallest one plus any other one cannot exceed one. This means that the total weight of any two calls, respectively, chosen from two groups is at most one. Therefore, algorithm CAP can route all calls with $2n-1$ center switches. □

The following is a result about three rates.

THEOREM 2.4. *Symmetric three-stage Clos network $C(n, \lceil \frac{7n}{3} \rceil, r)$ is multirate rearrangeable when every connection has a weight chosen from $\{p_1, p_2, p_3\}$ where $1 \geq p_1 > p_2 > p_3 > 0$.*

Proof. By Theorem 2.1 and Lemma 2.3, we can assume that $p_1 > 1/2 \geq p_2$ and $1/3 \geq p_3$. In the following, we consider two cases.

Case 1. $p_1 > 1/2$ and $1/3 \geq p_2 > p_3$. It was proved in [3] that if all calls with weights bigger than $1/f$ (f is an integer) can be routed with $c(\geq 2n)$ center switches, then at most $\lceil (c-2)/f - c + 2n \rceil$ additional center switches are needed to route all calls with weights at most $1/f$. Now we choose $f = 6$. If $p_3 \leq 1/6$, then all calls with weights bigger than $1/6$ are p_1- or p_2-calls. They can be routed with $2n$ center switches since all calls with the same weight can be routed with n center switches. Therefore, the total number of center switches for routing all calls is at most $2n + \lceil (2n-2)/6 \rceil < \lceil 7n/6 \rceil$. Hence, we may assume $p_3 > 1/6$.

Consider a bipartite graph G with two vertex sets, respectively, consisting of all inputs and all outputs and with all p_3-calls and p_2-calls as edges. Since $p_2 > p_3 > 1/6$, each vertex has degree at most five. By a lemma of de Werra [5], this graph can be decomposed into five edge-disjoint matchings. First, we can route calls in four matchings with $\lceil 4n/3 \rceil$ center switches since $1/3 \geq p_2 > p_3$. In fact, each matching for the bipartite graph G can be decomposed into n edge-disjoint matchings for the bipartite graph H between input switches and output switches, and hence four matchings for G give $4n$ matchings for H. Moreover, each center switch can route three matchings for H. Therefore, we need only $\lceil 4n/3 \rceil$ center switches to route four matchings for G.

Next, we consider calls in the fifth matching together with all p_1-calls. We will route them with n center switches in the following way.

If $p_1 + p_3 > 1$, then there are at most n considered calls in each input/output switch. Therefore, n center switches are enough to route them by classic routing algorithm.

If $p_1 + p_3 \leq 1$ and $p_1 + p_2 > 1$, then each input/output switch has at most $2n$ calls in which there are at most n p_1- or p_2-calls. Thus, we can divide them into two groups of at most size n such that one group contains only p_3-calls and the other one contains the remainders. Now, with the routing algorithm CAP of Melen and Turner [4], n center switches are enough to route all considered calls.

If $p_1 + p_2 \leq 1$, then each input/output switch has at most $2n$ calls in which there

are at most n p_1-calls. Thus, we can divide them into two groups of size at most n such that one group contains only p_2- or p_3-calls and the other one contains the remainders. Now, the routing algorithm CAP of Melen and Turner [4] can also use n center switches to route all considered calls.

Case 2. $p_1 > 1/2 \geq p_2 > 1/3 \geq p_3$. Furthermore, if $p_1 + p_2 \leq 1$, then each input switch has at most $2n$ p_1- or p_2-calls. These at most $2n$ calls can be divided into two groups such that each group contains at most n calls and only one group contains p_1-calls since each input switch has at most n p_1-calls. Since $p_1 + p_2 \leq 1$, the sum of two elements chosen, respectively, from the two group is at most one. Thus, we can use n center switches to route all p_1-calls and p_2-calls by the routing algorithm CAP of Melen and Turner [4]. It is shown in [3] that a network which is rearrangeable for the classical circuit switching is multirate rearrangeable if all weights are in the interval $[b, 1/\lfloor 1/b \rfloor]$ for some $0 < b \leq 1$. According to this result, n center switches are enough to route all p_3-calls. Therefore, totally, $2n$ center switches are enough when $p_1 + p_2 \leq 1$. Next, we may also assume $p_1 + p_2 > 1$. An argument similar to that in the proof of Theorem 2.1 will be employed.

First, route all calls with weights p_1 and p_2 on the $2n - 1$ center switches. By Corollary 2.2, it is possible. Now we route all calls with weight p_3 (or, say, p_3-call) in an arbitrary ordering. We will prove that we can always find a space for a p_3-call compatible with previous routed calls. In fact, for contradiction, suppose there exists a p_3-call (i, j, p_k) compatible with previous routed calls, but we cannot find space on a center switch to route this call (i, j, p_k). Let I be the input switch containing input i and J the output switch containing output j. Define the I-load (the J-load) of a center switch as the sum of weights of all calls from input switch I to the center switch (from the center switch to output switch J). Then every center switch has its I-load or its J-load greater than $1 - p_3$. Note that there are $\lceil 7n/3 \rceil$ center switches. Therefore, we can find either $\lceil 7n/6 \rceil$ center switches that each has I-load greater than $1 - p_3$ or $\lceil 7n/6 \rceil$ center switches that each has J-load greater than $1 - p_3$. Without loss of generality, we assume that the former occurs. Since $p_1 + p_2 > 1$, every I-load greater than $1 - p_3$ must be in the following forms:

$$p_1 + k_1 p_3 \left(k_1 = \left\lfloor \frac{1 - p_1}{p_3} \right\rfloor \right),$$

$$p_2 + k_2 p_3 \left(k_2 = \left\lfloor \frac{1 - p_2}{p_3} \right\rfloor \right),$$

$$2p_2 + k_3 p_3 \left(k_3 = \left\lfloor \frac{1 - 2p_2}{p_3} \right\rfloor \right),$$

$$k_4 p_3 \left(k_4 = \left\lfloor \frac{1}{p_3} \right\rfloor \right).$$

Suppose that there are x_1 center switches with I-load equal to $p_1 + k_1 p_3$, x_2 center switches with I-load equal to $p_2 + k_2 p_3$, x_3 center switches with I-load equal to $2p_2 + k_3 p_3$, and x_4 center switches with I-load equal to $k_4 p_3$. Then we have

$$x_1 + x_2 + x_3 + x_4 \geq \lceil 7n/6 \rceil.$$

Without loss of generality, assume

$$x_1 + x_2 + x_3 + x_4 = \lceil 7n/6 \rceil.$$

(If $x_1+x_2+x_3+x_4 > \lceil 7n/6 \rceil$, we delete some center switches from our consideration.) Now we consider p_1-calls and p_2-calls only in the I-loads of $\lceil 7n/6 \rceil$ center switches. Suppose that among n inputs of input switch I, there are y_1 inputs each containing such a p_1-call, y_2 ones each containing one such p_2-call, y_3 ones each containing two such p_2-calls, and y_4 containing only p_3-calls. Note that the number of considered p_1-calls and the number of considered p_2-calls does not change and the total number of p_3-calls in I-loads must be smaller than the maximum number of p_3-calls which can be put in the inputs. Thus, we have

$$\begin{aligned} x_1 &= y_1, \\ x_2 + 2x_3 &= y_2 + 2y_3, \\ k_1x_1 + k_2x_2 + k_3x_3 + k_4x_4 &< k_1y_1 + k_2y_2 + k_3y_3 + k_4y_4. \end{aligned}$$

That is,

$$\begin{aligned} (x_1 - y_1) &= 0, \\ (x_2 - y_2) + 2(x_3 - y_3) &= 0, \\ k_1(x_1 - y_1) + k_2(x_2 - y_2) + k_3(x_3 - y_3) + k_4(x_4 - y_4) &< 0. \end{aligned}$$

Therefore,

$$\begin{aligned} &(x_1 - y_1) + (x_2 - y_2) + (x_3 - y_3) + (x_4 - y_4) \\ <&\left(1 - \frac{k_1}{k_4}\right)(x_1 - y_1) + \left(1 - \frac{k_2}{k_4}\right)(x_2 - y_2) + \left(1 - \frac{k_3}{k_4}\right)(x_3 - y_3) \\ =&\frac{2k_2 - k_3 - k_4}{k_4} \cdot (x_3 - y_3). \end{aligned}$$

Note that

$$0 \le \left\lfloor \frac{2(1-p_2)}{p_3} \right\rfloor - (k_3 + k_4) \le 1,$$

$$0 \le \left\lfloor \frac{2(1-p_2)}{p_3} \right\rfloor - 2k_2 \le 1.$$

It follows that $|2k_2 - k_3 - k_4| \le 1$. Now, we consider two subcases.

Subcase 2.1. $p_3 \le 1/4$. In this case, we have $k_4 \ge 4$ and $|x_3 - y_3| = |y_2 - x_2|/2 \le \lceil 7n/6 \rceil/2$. Thus, we have

$$(x_1 - y_1) + (x_2 - y_2) + (x_3 - y_3) + (x_4 - y_4) < \lceil 7n/6 \rceil/8.$$

Therefore,

$$x_1 + x_2 + x_3 + x_4 < n + \lceil 7n/6 \rceil/8 \le \lceil 7n/6 \rceil(6/7 + 1/8) < \lceil 7n/6 \rceil,$$

which is a contradiction.

Subcase 2.2. $p_3 > 1/4$. In this case, we have $1 \le k_2 \le 2$, $0 \le k_3 \le 1$, and $k_4 = 3$. If $k_3 = 1$, then $2p_2 + p_3 \le 1$. Then we must have $k_2 = 2$. Thus, $2k_2 - k_3 - k_4 = 0$. Therefore,

$$x_1 + x_2 + x_3 + x_4 < y_1 + y_2 + y_3 + y_4 = n,$$

which is a contradiction. (Note: The proof here shows that $2n - 1$ center switches are enough in this special situation.) Next, we assume $k_3 = 0$, i.e., $2p_2 + p_3 > 1$. Consider a bipartite graph with two vertex sets, respectively, consisting of all inputs and all outputs and with all p_3-calls and p_2-calls as edges. Since $p_2 > p_3 > 1/4$, each vertex has degree at most three. By a lemma of de Werra [5], this graph can be decomposed into three edge-disjoint matchings. Clearly, we can route two matchings with n center switches since $1/2 \ge p_2 > p_3$. Put calls in the third matching together with all p_1-calls. We now consider p_1-calls and those calls in the third matching. If $p_1 + p_3 > 1$, then each input/output switch has at most n considered calls. They can be routed with n center switches. If $p_1 + p_3 \le 1$, then each input/output switch has at most $2n$ such calls in which there exist at most n p_1- or p_2-calls. Thus, we can route them with n center switches by the routing algorithm CAP of Melen and Turner [4]. Thus, totally, $2n$ center switches are enough in this case. □

Note that in Subcase 2.2, only $2n$ center switches are required. Moreover, if $1 \ge p_1 > 1/2$ and $1/3 \ge p_2 > p_3 > 1/4$, then we can route all p_1-calls with n center switches and route all p_2-calls and p_3-calls with n center switches. Therefore, we have the following corollary.

COROLLARY 2.5. *The symmetric three-stage Clos network $C(n, 2n, r)$ is multirate rearrangeable when every connection has a weight chosen from $\{p_1, p_2, p_3\}$ where $1 \ge p_1 > p_2 > p_3 > 1/4$.*

3. Discussion. The conjecture of Chung and Ross [2] on rearrangeability of multirate Clos networks seems true not only in the discrete bandwidth case but also in arbitrary rates. This is equivalent to the following conjecture: consider any double stochastic square matrix of order nr. Divide it into r^2 blocks, each of which is an $n \times n$ submatrix. Now we color all cells of the matrix such that the total value in the same color and in the same block-row is at most one and the total value in the same color and in the same block-column is at most one. The conjecture says that $2n - 1$ colors are enough. In this paper, we proved it in several special cases. Finally, we would like to mention that by an argument similar to the proof of Lemma 2.3, we can also prove that the conjecture is true for $r = 2$.

DESIGN OF ON-LINE ALGORITHMS USING HITTING TIMES*

PRASAD TETALI†

Abstract. Random walks are well known for playing a crucial role in the design of randomized off-line as well as on-line algorithms. In this work we prove some basic identities for ergodic Markov chains (e.g., an interesting characterization of *reversibility* in Markov chains is obtained in terms of first passage times). Besides providing new insight into random walks on weighted graphs, we show how these identities give us a way of designing competitive randomized on-line algorithms for certain well-known problems.

Key words. random walk, graph, Markov chain, reversibility, competitive ratio, first passage time, M-matrices

1. Introduction.

In a recent paper, Coppersmith et al. [8] made clever use of results from synthesis of electrical networks to design reversible random walks useful for certain randomized on-line algorithms.

At the heart of their methods lies the following problem on random walks. We are given a weighted (undirected) graph with n vertices, and with weight C_{ij} on edge $\{i, j\}$, for $1 \leq i, j \leq n$. Assume that the weights are symmetric and that they satisfy the triangle inequality. Every traversal of an edge $\{i, j\}$ costs C_{ij}.

Recall that a random walk on an undirected graph is the Markov chain whose state space is the vertex set of the graph, whose behavior is given by the rule that when the chain is at any given vertex the next transition is along an edge incident to that vertex that is chosen at random, according to some probability distribution. (The probability distribution could depend on the vertex, and the case of uniform distribution over the incident edges is often called a *simple* random walk.) We say that a random walk on G has *stretch* s (with respect to the cost matrix C) if, for any sequence of vertices $v_0, \ldots, v_k$, the expected cost of the random walk to traverse these nodes in the prescribed order is at most s times the optimal cost, up to an additive constant. Let e_{uv} denote the expected cost of the walk to go from vertex u to vertex v. If for every $v_0, \ldots, v_k$, $\sum_{i=1}^{k} e_{v_{i-1}v_i} \leq s \sum_{i=1}^{k} C_{v_{i-1}v_i} + a$, where $a \geq 0$, then the walk is said to have stretch s. Given the cost matrix C, the problem is to design a random walk with as low a stretch as possible.

Coppersmith et al. proved the following tight result for all symmetric cost matrices: Any random walk on a weighted (undirected) graph with n vertices has stretch $\geq (n-1)$, and every weighted (undirected) graph has a random walk with stretch $\leq (n-1)$.

Coppersmith et al. justified the relevance of this problem by providing bounds for the *cat and mouse* game, which they showed was central to the analysis of on-line

algorithms for well-known problems such as the metrical task system problem and the k-server problem. (We shall define these shortly for the nonspecialist.)

Symmetry of the costs is crucial to the basic technique used in [8] in designing the appropriate random walk, and thus an interesting question is left open on stretch under asymmetric costs—equivalently, the stretch of random walks on directed graphs. In this work we prove close-to-optimal lower and upper bounds on a stretch for a class of matrices, without the symmetry assumption. Moreover, under symmetry our results imply those of [8].

In a nutshell, Coppersmith et al. interpret a given cost matrix as an effective resistance matrix of a resistive network, and then they synthesize an actual network that has the desired properties. Classical analogues between resistive networks and reversible Markov chains yield a corresponding random walk that achieves the optimal stretch. We use a different way of synthesizing a random walk, the advantage being that we do not need reversibility of the walk (i.e., symmetry of the costs) for our techniques to work. We interpret the cost matrix as the hitting time (first passage time) matrix of an ergodic (not necessarily reversible) Markov chain and then describe how to find the unique chain that yields the desired hitting times, i.e., design the transition probabilities which yield the desired hitting times. While such a synthesis of an ergodic chain from a valid hitting time matrix is unique and efficient, it is not true that an arbitrary cost matrix is always a hitting time matrix.[1] (The consolation, however, is that we can check for the latter condition with essentially one matrix inversion.) We call a cost matrix *ergodic* if it can be interpreted as a certain hitting time matrix, and we call the corresponding random walk an *ergodic* walk. We show that this walk achieves optimal stretch when the costs are symmetric and is close to optimal when the costs are asymmetric. We show that our techniques also work when the cost matrix is essentially an effective resistance matrix, thus extending several results proved in [8].

Given a weighted (directed) graph with a weight (or *cost*) matrix $C = \{C_{ij}\}$, define the *cycle offset ratio* $\Psi(C)$ as follows. $\Psi(C)$ is the maximum over all sequences

$$v_0, \ldots, v_k = v_0 \text{ of } \frac{\sum_{i=1}^{k} C_{v_{i-1},v_i}}{\sum_{i=1}^{k} C_{v_i,v_{i-1}}}.$$

(Note that $1 \leq \Psi(C) \leq (n-1)$, since the costs satisfy the triangle inequality.)

We prove the following result.

Any random walk on a weighted graph with n vertices has stretch $\geq (n-1)/\Psi(C)$, and the ergodic walk has stretch $\leq (n-1)$, with equality under a symmetric C.

While we show examples that achieve equality in the lower bound, any tightening of the upper bound seems quite hard. However, it is interesting that the stretch of random walks on directed graphs can be brought down below $n-1$, while the counterpart on undirected graphs has an optimal bound of $n-1$.

The first application, for the *cat and mouse* game (see section 3), follows immediately from the above. It was mentioned in [8] that the cat and mouse game is at the core of several on-line algorithms. We show that for any $n \times n$ cost matrix C and any "blind" cat strategy (i.e., a random walk strategy), there is a mouse strategy that forces the competitiveness of the cat to be at least $(n-1)/\Psi(C)$, and the ergodic walk by the cat achieves a competitive ratio $\leq (n-1)$, on ergodic C.

[1] Similarly, an arbitrary cost matrix is not necessarily an effective resistance matrix for the techniques of [8] to work.

The second and more interesting application is for the notoriously hard k-server problem (see [11], [16], [20], [17]). The k-server problem (defined in [20]) is as follows. There are k mobile servers located on k vertices of a graph G with positive, real costs on the edges. (The costs can be thought of as distances between the positions.) An on-line algorithm manages the servers in such a way as to satisfy an on-line sequence of requests for service at vertices v_i, $i = 1, 2, \ldots$; i.e., servicing a request corresponds to moving a server to the requested vertex whenever a server isn't there. The algorithm pays a cost equal to the cost on the edge traversed by the server. The competitiveness of the algorithm is measured with respect to the cost an adversary pays, wherein the adversary moves the servers but also gets to choose the request sequence.

Due to the hardness of the k-server problem, it is significant to prove competitive ratios even for special cases such as special classes of graphs (e.g., [4], [8], [6]). Coppersmith et al. [8] provide one such example class. They use random walks to design optimal randomized k-competitive server algorithms when the cost matrix has a resistive inverse. We extend this class by allowing asymmetric costs, or equivalently, weighted *directed* graphs, with ergodic cost matrices.

Define *edge offset ratio* $\Psi'(C)$ to be $\max_{ij} \frac{C_{ij}}{C_{ji}}$. (Note that $\Psi(C) \leq \Psi'(C)$, and that $\Psi(C) = \Psi'(C) = 1$, for symmetric C.) We prove the following result for the *asymmetric* k-server problem. (This implies the result of [8].)

Let C be a cost matrix on n nodes. If every submatrix on $k+1$-nodes is ergodic, then we have a randomized $k\Psi'(C)$-competitive strategy for the k-server problem on C.

The final application is to the task system problem, defined as follows. We have a task system (S, C) for processing sequences of tasks wherein S is a set of states, and C is a cost matrix, describing the cost of changing from state i to state j. We assume that the costs satisfy the triangle inequality and that there is no cost of staying in the same state ($C_{ii} = 0$). Furthermore, when the costs are symmetric we refer to the task system as a *metrical* task system (MTS). Each task T has a cost vector v_T, where $v_T(i)$ is the cost of processing T in state i. A schedule for a given sequence of tasks $T_1, \ldots, T_k$ is a sequence of states $s_1, \ldots, s_k$, where s_i is the state in which T_i is processed. The *task system problem* is to design an *on-line* schedule (choose s_i only knowing $T_1, \ldots, T_i$) so that the algorithm is w-competitive—on any input sequence of tasks, the cost of the on-line algorithm is, barring an additive constant, at most w times that of the optimal off-line algorithm.

Borodin et al. [5] designed a deterministic algorithm with a competitive ratio of at most $(2n-1)\Psi(C)$ for the task system problem with asymmetric costs. If the costs are symmetric (i.e., an MTS), they prove a matching lower bound of $(2n-1)$. It is straightforward to extend their lower bound proof for the asymmetric case to get a lower bound of $(2n-1)/\Psi(C)$. Coppersmith et al. provided a simpler, *memoryless*, $(2n-1)$-competitive, randomized algorithm for any MTS, and also showed that no randomized algorithm can do better against an adaptive on-line adversary. We extend the results of [8] to the task system with ergodic cost matrices. In particular, we prove a lower bound of $(2n-1)/\Psi(C)$ for any randomized on-line scheduler. We also provide a randomized on-line scheduler with a competitive ratio of at most $(2n-1)$. While $(2n-1)$ is the best possible for symmetric cost matrices, our randomized scheduler achieves a competitive ratio of strictly less than $(2n-1)$, whenever the (ergodic) cost matrix is asymmetric. This shows that it is possible to design random walks with lower stretch on directed graphs than on undirected graphs. This also suggests that the deterministic algorithm of [5] (or a variant thereof) may have a competitive ratio

of at most $(2n-1)$ even under asymmetric costs.

Thus the novel technique of using the synthesis of random walks from hitting times for the design of on-line algorithms, while yielding the results of [8] for undirected graphs in a natural and simpler way, also yields results for directed graphs. We conclude this work with an interesting question on "approximating" an ergodic Markov chain, which will have useful implications in terms of extending our results to all cost matrices.

2. Results on ergodic Markov chains. In this section we prove two identities involving the first passage times and the transition probabilities. These results are crucial (later) to the analysis of our on-line algorithms. Lemma 2.1 and Theorem 2.2 below appeared in an earlier paper of this author [23]; however, the proofs are included here to keep the presentation self-contained.

Consider an electrical network on n nodes with resistors r_{ij} between nodes i and j. Let R_{ij} denote the *effective resistance* between the nodes. Then Foster's theorem asserts that

$$\sum_{i\sim j} \frac{R_{ij}}{r_{ij}} = n-1,$$

where $i \sim j$ denotes that i and j are connected by a finite r_{ij}. The proof appears in [13]. Also, [22] shows an alternative way (using random walks) of proving the same. In this section we prove an elementary identity for ergodic Markov chains which yields Foster's theorem when the chain is time-reversible.

Let P denote the transition probability matrix (size $n \times n$) of an ergodic Markov chain with stationary distribution π. Let $P_{ii} = 0\ \forall i$. Furthermore, let H denote the expected first-passage matrix (also size $n \times n$) of the above chain; i.e., H_{ij} denotes the expected time to reach state j starting from state i. We call these the *hitting times*. Then we have the following lemma.

LEMMA 2.1. $\sum_{i,j} \pi_j P_{ji} H_{ij} = n-1$.

Proof.

$$\sum_{i,j} \pi_j P_{ji} H_{ij} = \sum_j \pi_j \left(\sum_i P_{ji} H_{ij} \right) = \sum_j \pi_j [H_{jj} - 1]$$
$$= \sum_j \pi_j [1/\pi_j - 1] = n-1,$$

since $H_{jj} = 1/\pi_j$. □

We prove a stronger statement than Lemma 2.1 in the form of Corollary 2.7 below. Both Lemma 2.1 and Corollary 2.7 were formulated while attempting to interpret Foster's theorem in terms of ergodic Markov chains. For a proof that Lemma 2.1 implies Foster's theorem, see [23].

2.1. Synthesis of an ergodic walk. In the following we describe the construction (whenever one such exists) of an ergodic walk given an all-pairs hitting times matrix H. Given P as above, we define $\bar{P}$ to be the following $(n-1)\times(n-1)$ matrix. Let

$$\bar{P}_{ii} = \pi_i \left(= \sum_{\substack{j=1 \\ j\neq i}}^{n} \pi_i P_{ij} \right),$$

and $\bar{P}_{ij} = -\pi_i P_{ij}$, for $1 \le i, j \le n-1$.

Furthermore, let $\bar{H}_{jj} = H_{jn} + H_{nj}$, and $\bar{H}_{jk} = H_{jn} + H_{nk} - H_{jk}$, for $1 \le j, k \le n-1$. We use the standard notation of I_n for an identity matrix of size $n \times n$, and δ_{ij} to denote the entries of I. The following theorem is a generalization of the *resistive inverse identity* (well known in electrical network theory) used in [8].

THEOREM 2.2.

$$\bar{P}\bar{H} = I_{n-1}.$$

Proof. The basic identity we use is the triangle inequality for the hitting times. Using a "renewal type" theorem (see section 2.3 of [2] or Proposition 9-58 of [19]) one can show the following:

$$H_{xz} + H_{zy} - H_{xy} = \frac{N_y^{xz}}{\pi_y}, \tag{2.1}$$

$$H_{xz} + H_{zx} = \frac{N_x^{xz}}{\pi_x}. \tag{2.2}$$

(Recall that N_y^{xz} denotes the expected number of visits to y in a random walk from x to z.) From (2.1) and (2.2) we have

$$\bar{H}_{jk} = \frac{N_k^{jn}}{\pi_k} \quad \forall j, k.$$

Consider

$$\begin{aligned}
\sum_{j=1}^{n-1} \bar{P}_{ij}\bar{H}_{jk} &= \bar{P}_{ii}\bar{H}_{ik} + \sum_{\substack{j=1 \\ j\neq i}}^{n-1} \bar{P}_{ij}\bar{H}_{jk} \\
&= \pi_i \frac{N_k^{in}}{\pi_k} - \sum_{\substack{j=1 \\ j\neq i}}^{n-1} \pi_i P_{ij} \frac{N_k^{jn}}{\pi_k} \\
&= \frac{\pi_i}{\pi_k} \left[N_k^{in} - \sum_{\substack{j=1 \\ j\neq i}}^{n-1} P_{ij} N_k^{jn} \right] \\
&= \frac{\pi_i}{\pi_k} [\delta_{ik}] \qquad \text{(taking conditional means, given the first outcome)} \\
&= \delta_{ik}. \qquad \square
\end{aligned}$$

REMARK 1. *We have defined $\bar{P}$ and $\bar{H}$ by treating n as a special state of the chain. Clearly, we could have chosen any other state j and carried out a similar analysis.*

REMARK 2. *For reversible chains, we have $\bar{H}_{jk} = \bar{H}_{kj}$. This is because*

$$H_{jn} + H_{nk} + H_{kj} = H_{jk} + H_{kn} + H_{nj} \quad \forall i, j \quad (**).$$

The proof of this can be found in [9], or it can be verified directly by using the formula for the hitting times in terms of either resistances (see [22]) or the *fundamental*

matrix (see [18]). Thus the proof of Theorem 2.2 becomes simpler for the reversible case. (In particular, we do not need to use (2.1) and (2.2).)

An interesting consequence of Theorem 2.2 is that the property in (**) is sufficient (not only necessary) to imply reversibility. For (**) implies that $\bar{H}$ is symmetric which in turn implies that $\bar{P}$ is symmetric, i.e., $\pi_i P_{ij} = \pi_j P_{ji}\ \forall i, j$. This alternative characterization of reversibility is interesting for yet another reason: Interpreted in the electrical world, it can be shown (see [23]) to be equivalent to what is known as the *reciprocity theorem* (see [22]).

COROLLARY 2.3. *Given the hitting times, the chain can be tested for reversibility in $O(n^2)$ time.*

Proof. First we designate an arbitrary state as state n and then verify (**) for all pairs of vertices in $O(n^2)$ time. (Here we abuse notation by using n for both the number of states and the name of a particular state.) □

COROLLARY 2.4. *Given P and π, the hitting times (H_{ij}) can be computed with a single matrix inversion, and conversely, given the hitting times, P and π can be computed with a single matrix inversion.*

Proof. In view of Theorem 2.2, we need to show only (a) how to compute H from $\bar{H}$, and (b) how to compute P from $\bar{P}$.

(a) For $1 \le i, j \le n-1$, we have

$$H_{in} = \sum_k N_k^{in} = \sum_k \pi_k \bar{H}_{ik},$$

$$H_{ni} = \bar{H}_{ii} - H_{in},$$

$$H_{ij} = H_{in} + H_{nj} - \bar{H}_{ij}.$$

Thus we can first compute H_{in} and $H_{ni}\ \forall i < n$, and then compute H_{ij} for $1 \le i, j \le n-1$.

(b) We need to compute π_n and P_{ni}, since the rest of the information is available in $\bar{P}$. Since π is stochastic, and $\pi P = \pi$, we have

$$\pi_n = 1 - \sum_{i<n} \pi_i = 1 - \sum_{i<n} \bar{P}_{ii},$$

$$\pi_n P_{ni} = \pi_i - \sum_{j \ne i,n} \pi_j P_{ji} = \sum_{j \ne n} \bar{P}_{ji}. \qquad \square$$

We observe that Theorem 4.4.12 of [18] gives an alternative way of computing the chain, given all-pairs hitting times. However, the method outlined above seems simpler, since the solution can be written in essentially one equation; see Theorem 2.2.

2.2. A trace inequality. Based on some empirical results and Lemma 2.1 above, we conjectured that $\sum_{i,j} \pi_i P_{ij} H_{ij} \le n-1$, with equality under reversibility of the chain. This plays a crucial role in all our applications below, besides having an intrinsic importance. Recently, Aldous [1] proved this conjecture using a result due to Fiedler et al. [12]. We provide a slightly different proof using Theorem 2.2 and the main theorem in [12].

DEFINITION 2.5. *An M-matrix is an $n \times n$ matrix A of the form $A = \alpha I - P$ in which P is nonnegative and α is at least as big as the largest eigenvalue of P.*

An alternative characterization of nonsingular M-matrices (see [21]*) is that a nonsingular matrix A with nonpositive off-diagonal entries is an M-matrix iff $A^{-1} \geq 0$, meaning that all the nonzero entries are positive. From this, it is clear that the matrix $\bar{P}$ defined above is an M-matrix. The following theorem of Fiedler et al. is an interesting trace-inequality.*

THEOREM 2.6 (Fiedler et al. [12]). *For a nonsingular M-matrix A (size $n \times n$), $\mathrm{tr}(A^{-1}A^T) \leq n$, with equality holding iff A is symmetric.*

Now we are ready to state and prove the generalization of Lemma 2.1.

COROLLARY 2.7. *$\sum_{i,j=1}^{n} \pi_i P_{ij} H_{ij} \leq n-1$, with equality holding iff $P(,)$ is a reversible chain.*

Proof. Using Theorem 2.6 with $\bar{P}$ in place of A, we have $\mathrm{tr}(\bar{H}\bar{P}^T) \leq n-1$. We are done by noticing that

$$\begin{aligned}
&\mathrm{tr}(\bar{H}\bar{P}^T)\\
&= \sum_{i=1}^{n-1}\sum_{j=1}^{n-1} \bar{H}_{ij}\bar{P}_{ij}\\
&= \sum_i \bar{H}_{ii}\pi_i - \sum_{i\neq j} \bar{H}_{ij}\pi_i P_{ij}\\
&= \sum_i [H_{in}+H_{ni}]\pi_i - \sum_{i\neq j}[H_{in}+H_{nj}-H_{ij}]\pi_i P_{ij}\\
&= \sum_i [H_{in}+H_{ni}]\pi_i - \sum_i H_{in}\pi_i(1-P_{in})\\
&\quad - \sum_j H_{nj}(\pi_j - \pi_n P_{nj}) + \sum_{i,j=1}^{n-1} \pi_i P_{ij} H_{ij}\\
&= \sum_{i,j=1}^{n} \pi_i P_{ij} H_{ij}. \qquad \square
\end{aligned}$$

3. Lower and upper bounds on stretch. We recall the definition of stretch of a random walk from the introduction: a random walk is said to have stretch s if there exists an $a > 0$ such that, for every $v_0, \ldots, v_k$, $\sum_{i=1}^{k} e_{v_{i-1}v_i} \leq s \sum_{i=1}^{k} C_{v_{i-1}v_i} + a$. The following facts follow easily from the definition of stretch.

FACT 1. *If a random walk has stretch s on cost matrix $C = \{C_{ij}\}$, then the walk has the same stretch on $C' = \{\beta C_{ij}\}$, where β is any positive constant.*

FACT 2. *In computing the stretch of a random walk, it suffices to consider sequences of vertices, $v_0, v_1, \ldots, v_k = v_0$, that form simple cycles in the graph G.*

Note that if a random walk has a stretch of c on simple cycles, then since any cycle can be decomposed as the union of disjoint simple cycles, the random walk will have stretch c on arbitrary closed paths. Now, as shown on page 426 of [8], Fact 2 follows from the fact that we gave ourselves room by allowing for an additive constant in the definition of stretch.

Let $C = \{C_{ij}\}$ be the given cost matrix of size $n \times n$.

DEFINITION 3.1. *Let $\Psi(C)$ be defined as the maximum over all cycles $(v_0, \ldots, v_k = v_0)$ of the ratio*

$$\frac{\sum_{i=0}^{k-1} C_{v_i, v_{i+1}}}{\sum_{i=0}^{k-1} C_{v_{i+1}, v_i}}.$$

If we assume that the costs satisfy the triangle inequality, then it is easy to see that $\Psi(C) \leq n-1$. *(Note that* Ψ *is defined in* [5] *and is termed the cycle offset ratio.)*

THEOREM 3.2. *Any random walk over a directed weighted graph has stretch at least* $(n-1)/\Psi(C)$, *where* $C = \{C_{ij}\}$ *is an* $n \times n$ *matrix specifying weight* C_{ij} *on edge* (i,j).

Proof. Note that the lower bound is $n-1$, when C is symmetric, since $\Psi(C) = 1$. In fact, the proof is identical to Theorem 1 of [8], wherein the symmetric case was dealt with. □

We now introduce the notion of *ergodic* cost matrices, which subsumes the class of resistive cost matrices, introduced in [8]. First, we describe two types of cost matrices for which there exist random walks with stretch at most $n-1$.

Type I. Let $C_{ij} = H_{ij}$ $\forall i,j$, $i \neq j$, where H_{ij} denote the hitting times of an n-state ergodic Markov chain.

CLAIM 1. *Every cost matrix of Type* I *has a random walk with stretch at most* $n-1$.

Proof. Note that, in view of Fact 2, it suffices to bound stretch over all simple cycles; this can then be extended to all paths, with an additive constant such as $\max_{i,j} C_{ij}$. □

Consider the walk with H_{ij} as the hitting times. The expected cost per move is

$$E = \sum_{i,j} \pi_i P_{ij} C_{ij} = \sum_{i,j} \pi_i P_{ij} H_{ij} \leq (n-1)$$

by Corollary 2.7. The claim now follows by noticing that the expected cost of a traversal over any sequence $v_0, \ldots, v_k$ of vertices equals $E \times \sum_{i=0}^{k-1} H_{v_i v_{i+1}} = E \times \sum_{i=0}^{k-1} C_{v_i v_{i+1}}$.

Type II. Let $C_{ij} = \frac{1}{2}[H_{ij} + H_{ji}]$ $\forall i,j$, $i \neq j$, where H_{ij} now denote the hitting times of any *reversible* Markov chain.

CLAIM 2. *Every cost matrix of Type* II *has a random walk with stretch at most* $n-1$.

Proof. As in the proof of Claim 1, without loss of generality, it suffices to bound stretch over all simple cycles. □

The expected cost per move is

$$E = \sum_{i,j} \pi_i P_{ij} C_{ij} = \frac{1}{2} \sum_{i,j} \pi_i P_{ij} [H_{ij} + H_{ji}] = n-1$$

by Lemma 2.1 and reversibility of P. Moreover, the expected cost of a traversal over any (cyclic) sequence $v_0, \ldots, v_k = v_0$ of vertices is, as before, equal to

$$\begin{aligned}
& E \times \sum_{i=0}^{k-1} H_{v_i v_{i+1}} \\
&= E \times \frac{1}{2} \left[\sum_{i=0}^{k-1} H_{v_i v_{i+1}} + \sum_{i=0}^{k-1} H_{v_{i+1} v_i} \right] \quad \text{by (**)} \\
&= (n-1) \sum_{i=0}^{k-1} \frac{1}{2} [H_{v_i v_{i+1}} + H_{v_{i+1} v_i}] \\
&= (n-1) \times \sum_{i=0}^{k-1} C_{v_i v_{i+1}}.
\end{aligned}$$

Hence we have the claim.

REMARK 3. *Any quantitative sharpening of the trace inequality (Theorem* 2.6*) immediately gives an improved upper bound on stretch for cost matrices of Type* I.

DEFINITION 3.3. *A cost matrix is ergodic if it is either the hitting time matrix of an ergodic chain (Type* I*) or the commute time matrix of a reversible chain (Type* II*).*

Note that Theorem 2.2 *guarantees that we can test if a matrix is ergodic or not with essentially a single matrix inversion.*

THEOREM 3.4. *Every graph with an ergodic cost matrix has a random walk with stretch* $\leq n-1$*. Moreover, this walk (termed ergodic walk) can be designed with a single matrix inversion.*

Proof. From Claims 1 and 2, the first part of the theorem follows. We now show how Theorem 2.2 can be used to design the desired random walk. Let G be a graph with the ergodic cost matrix C. In view of (**) it is easy to see that $C_{in}+C_{nj}-C_{ij} = H_{in}+H_{nj}-H_{ij}$, regardless of whether C is of Type I or II. Define $\bar{H}_{ij} = C_{in}+C_{nj}-C_{ij}$, for $1 \leq i,j \leq n-1$. The rest should be obvious: We construct P, the transition probability matrix of the desired walk, by first computing $\bar{P}$ using Theorem 2.2. □

REMARK 4. *Recall that a cost matrix is resistive if the* C_{ij} *can be interpreted as effective resistance* R_{ij} $\forall i,j$*. Note that any resistive cost matrix is of Type* II *(modulo a constant factor), since effective resistance* R_{ij} *is essentially the commute time* $H_{ij}+H_{ji}$ *(modulo the same constant factor) of a reversible chain. This, together with Fact* 1*, shows that our results imply those of* [8].

The lower and upper bounds are obviously tight under symmetry, since $\Psi(C) = 1$. The following example shows that the lower bound is, in general, tight.

Example. Consider a directed cycle $1, 2, \ldots, n, 1$ with cost 1 on each directed edge $(i, i+1)$. Now put in all other edges to make a directed K_n and assign the distance along the original cycle to be the cost of each edge. Thus the cost matrix has $\Psi = n-1$. The optimal random walk (with stretch 1) is, in fact, the deterministic walk always going around the cycle. □

With each undirected cycle, we associate the following notion of a (strongly connected) "bicycle." A bicycle is a sequence of nodes $v_0, v_1, \ldots, v_{k-1}, v_0, v_{k-1}, \ldots, v_1, v_0$, i.e., the undirected cycle traversed once in either direction. The following asserts that our random walk is optimal over traversals of 1.

COROLLARY 3.5. *The stretch over any bicycle of any random walk is* $\geq (n-1)$*, and the ergodic walk achieves the equality.*

Proof. The equality is obvious in view of the preceding theorem. The proof of the lower bound is essentially the proof of Theorem 1 of [8]. □

The cat and mouse game. As mentioned in the introduction this game is a convenient tool in analyzing more complicated on-line strategies. For completeness, we describe the game here, but we refer the reader to [8] for further details and related interesting references. This is a game played for a fixed number of rounds between a cat and a mouse on a graph. Each round begins with both the cat and the mouse on the same vertex; the mouse moves once (and just once) at the beginning of the round to some (carefully chosen) vertex unknown to the cat. The rest of the round consists of the cat's moves (which could be deterministic or randomized) on the edges of the graph until the cat reaches the vertex that the mouse is at. Each move of the mouse can use information about all previous moves by the cat. A strategy for the cat is c-competitive if there exists an (additive) constant $a \geq 0$ such that for any number of rounds and any strategy of the mouse, the cat's expected cost is at most c times the

mouse's cost $+a$.

THEOREM 3.6. *For any $n \times n$ ergodic cost matrix C and for any random walk strategy by the cat, there is a mouse strategy that forces the competitiveness of the cat to be at least $(n-1)/\Psi(C)$, and the ergodic walk by the cat achieves a competitive ratio $\leq (n-1)$.*

Proof. It was pointed out in [8] that a random walk with stretch c defines a *memoryless* c-competitive strategy for the cat: in each round the cat, without recourse to its previous moves, executes a random walk with stretch c. Thus the upper bound is immediate from Theorem 3.4 above. For the lower bound, we use a standard argument (used, e.g., in [8] and [20]). Consider $(n-1)$ mice, one on each node except where the cat is. Whenever a cat moves from i to j, the mouse on j moves to i. Thus the mice together pay a cost of $\sum_{i=0}^{k-1} C_{v_{i+1},v_i}$, whenever the cat takes a walk $v_0, \ldots, v_k$ incurring a cost of $\sum_{i=0}^{k-1} C_{v_i,v_{i+1}}$. The single mouse strategy is going to be (just as in [8]) that we choose one of the $(n-1)$ strategies uniformly at random. By the definition of $\Psi(C)$, the mouse can always make the competitive ratio to be $\geq (n-1)/\Psi(C)$. □

4. *k*-servers with asymmetric costs. Consider the usual k-server problem with the triangle inequality constraint on the costs. An *adaptive on-line* adversary (provably different from the *oblivious* and the *adaptive off-line* ones) chooses the next request at each step, knowing the current position of the on-line algorithm and, if 1, moves one of its servers to satisfy the request. We describe here a randomized on-line algorithm that works well against such an adaptive on-line adversary. (The significance of results proved against such an adversary is as follows. It was shown in [3] that a c-competitive randomized on-line algorithm against an adaptive on-line adversary implies the existence of a c^2-competitive deterministic algorithm.) Let us assume that all the costs are positive and bounded. Let us, however, *not* make the assumption that the cost C_{ij} of moving a server from position i to j be the same as that of moving a server from j to i, C_{ji}. We also make the strong assumption that every $k \times k$ submatrix is *ergodic* in the sense defined above.

DEFINITION 4.1. *Let the edge offset ratio $\Psi'(C)$ be $\max_{i,j}(C_{ij}/C_{ji})$.*

We may simply write Ψ' to denote $\Psi'(C)$ as long as there is no confusion as to the underlying C. Note that $\Psi(C) \leq \Psi'(C)$, and when C is symmetric $\Psi(C) = \Psi'(C) = 1$.

We are now ready to state the main theorem of this section.

THEOREM 4.2. *Let C be a cost matrix on n nodes. If every submatrix on $k+1$-nodes is ergodic, then we have a randomized $k\Psi'(C)$ competitive strategy (against an adaptive on-line adversary) for the k-server problem on C.*

Proof. For convenience, we refer to the k-servers under our randomized on-line strategy as *randomized servers*. The strategy is as follows. Suppose the randomized servers are on positions 1 through k. Let the current request be on position x. We find the (unique) ergodic walk that corresponds to these $k+1$ vertices by interpreting the costs as the hitting times. (Note that this computation, for all choices of $k+1$ vertices, can be done once and for all at the beginning.) Let p_{ij} denote the transition probabilities of this walk. Then the strategy is to move the (randomized) server at j (for $j = 1, \ldots, k$) to x with probability $(p_{xj}/\sum_j p_{xj})$. (The probabilities clearly sum to 1, over all j.)

We can model the situation as a game between the randomized server and an adversary. The adversary controls k "off-line" servers. In each round of the game, the adversary picks the next request (vertex) and moves one of his servers to that vertex.

Then the randomized server uses her strategy to move one of her servers to the request. We want to show that the expected cost of the randomized server is within a constant factor of k times the cost incurred by the off-line server. Toward this, let us denote the positions of the randomized servers and the adversary's servers by $\mathbf{a} = \{a_1, \ldots, a_k\}$ and $\mathbf{b} = \{b_1, \ldots, b_k\}$, respectively. We define the following "potential function" Φ:

$$\Phi(\mathbf{a}, \mathbf{b}) = \sum_{i,j=1}^{n} C_{ij} - \sum_{x} \sum_{j} C_{xa_j} + k \min_{\sigma} \sum_{i} C_{b_i a_{\sigma(i)}},$$

where x ranges over nodes where there is currently no randomized server, and σ ranges over (directed) matchings between the adversary's positions and the randomized servers' positions. (The first term in the definition of Φ is introduced simply to make Φ positive and is thus not essential to the proof.) Let $Cost_R$ and $Cost_A$ denote the accumulated costs of the randomized servers and the adversary's servers, respectively.

Furthermore, let

$$\Delta = \Phi + Cost_R - k\psi' \times Cost_A.$$

We would like to show that Δ is always nonincreasing with every move of either the randomized servers or the adversary.

Adversary's move. Consider a move by the adversary's server from node b_j to $b_{j'}$. The adversary clearly pays cost $C_{b_j b_{j'}}$. We want to show that $\Delta(new) - \Delta(old) = \Phi(new) - \Phi(old) - k\psi' C_{b_j b_{j'}}$ is ≤ 0. Let the minimum matching in $\Phi(old)$ be $b_i \to a_i \forall i$. Then define a new matching as follows. Match b_i with a_i for $i \neq j'$, and match $b_{j'}$ with a_j. Clearly,

$$\begin{aligned}
&\Phi(new) - \Phi(old) - k\psi' C_{b_j b_{j'}} \\
&\leq kC_{b_{j'} a_j} - kC_{b_j a_j} - k\psi' C_{b_j b_{j'}} \\
&\leq kC_{b_{j'} a_j} - kC_{b_j a_j} - kC_{b_{j'} b_j} \qquad \text{(by the definition of } \psi') \\
&\leq 0, \qquad \text{since} \quad C_{b_{j'} b_j} + C_{b_j a_j} \geq C_{b_{j'} a_j}.
\end{aligned}$$

Randomized servers' move. For this half of the proof, it was shown in [8] that (restrictive as it may sound) it suffices to prove the case when the randomized servers and the adversary agree on (i.e., share the same vertices) $k-1$ positions and differ in only one position. The same justification applies in our situation as well, and we omit the straightforward proof.

Thus let us assume without loss of generality that the adversary occupies positions 1 through $m - 1 = k$, and the randomized servers occupy positions 2 through m. Let the request be on 1. So, the randomized server moves from j to 1 with probability $p_{1j}/(\sum_j p_{1j})$, paying a cost of C_{j1}. Here and in the claim below, $\sum_j$ represents $\sum_{j=2}^{m}$. Note that $\sum_j p_{1j}$ is equal to 1, if $p_{11} = 0$, but in general, $\sum_j p_{1j} = 1 - p_{11}$.

Claim.

$$\sum_{j} \frac{p_{1j}}{\sum_j p_{1j}} [\Phi(new) - \Phi(old) + C_{j1}] = 0.$$

Proof. Clearly, the minimum matching before the move has cost C_{1m}, since the minimium matching consists of the (directed) edge $(1, m)$. Similarly, after the move

(of the server from j to 1), the minimum matching has cost C_{jm} (match j with m), since the adversary and the randomized servers are identical everywhere else. Thus

$$\begin{aligned}
&[\Phi(new) - \Phi(old) + C_{j1}] \\
&= -\sum_{i=1}^{m} C_{ji} + \sum_{i=2}^{m} C_{1i} + kC_{jm} - kC_{1m} + C_{j1} \\
&= -\sum_{i=2}^{m} C_{ji} + \sum_{i=2}^{m} C_{1i} + kC_{jm} - kC_{1m} \\
&= -\sum_{i=2}^{m} H_{ji} + \sum_{i=2}^{m} H_{1i} + kH_{jm} - kH_{1m}.
\end{aligned}$$

Thus

$$\begin{aligned}
&\sum_j \frac{p_{1j}}{\sum_j p_{1j}} [\Phi(new) - \Phi(old) + C_{j1}] \\
&= \frac{1}{\sum_j p_{1j}} \left[-\sum_{i=2}^{m} \sum_j p_{1j} H_{ji} + \sum_{i=2}^{m} H_{1i} \sum_j p_{1j} \right] + \frac{1}{\sum_j p_{1j}} \left[k \sum_j p_{1j} H_{jm} - kH_{1m} \sum_j p_{1j} \right] \\
&= \frac{1}{\sum_j p_{1j}} \left[\sum_{i=2}^{m} \left(-\sum_j p_{1j} H_{ji} + H_{1i}(1 - p_{11}) \right) \right] \\
&+ \frac{1}{\sum_j p_{1j}} \left[k \left(\sum_j p_{1j} H_{jm} - H_{1m}(1 - p_{11}) \right) \right] \\
&= \frac{1}{\sum_j p_{1j}} \left[\left(\sum_{i=2}^{m} 1 \right) - k \right] \qquad (\text{since } H_{1i} = 1 + p_{11} H_{1i} + \textstyle\sum_{j=2}^{m} p_{1j} H_{ji}) \\
&= 0.
\end{aligned}$$

We showed that Δ is always nonincreasing. This concludes the proof that the randomized strategy is $k\Psi'$-competitive against an adaptive on-line adversary. □

5. Task systems. Recall the description of a task system from the introduction: We have a task system (S, C) for processing sequences of tasks wherein S is a set of states, and C is a cost matrix, describing the cost of changing from state i to state j. The *task system problem* is to design an *on-line* schedule (choose s_i only knowing $T_1, \ldots, T_i$) so that the algorithm is w-competitive—on any input sequence of tasks, the cost of the on-line algorithm is, barring an additive constant, at most w times that of the optimal off-line algorithm. In [5] it was shown that $w(S, C) = 2|S| - 1$ for every *metrical* task system (MTS), and $w(S, C) \leq (2|S| - 1)\Psi(C) = O(|S|^2)$, for every task system. Subsequently, [8] gave a $(2|S| - 1)$-competitive *randomized* on-line algorithm for every MTS. It is to be noted that although this is a weaker result in light of the deterministic algorithm of [5], the randomized algorithm is conceptually and otherwise much simpler and is, moreover, *memoryless*.

Our contribution is as follows. We prove the analogous simplification for the (nonmetrical) task systems using randomization. We prove a lower bound of $(2|S| - 1)/\Psi(C)$ on the competitive ratio of any randomized on-line algorithm and provide a randomized on-line scheduler with $w(S, C) \leq (2|S| - 1)$. Note that our results imply

those of [8] in the case of metrical task systems. In the asymmetric case, we provide improved bounds to those of [5] with simpler memoryless randomized schedulers. However, we do have the restriction that the cost matrix should essentially be a hitting time matrix of an ergodic chain. Thus the random walk we refer to below is the ergodic walk designed by interpreting the cost matrix as the hitting time matrix as explained in sections 2 and 3.

5.1. Lower and upper bounds. The following lower bound on the competitiveness of any deterministic or randomized algorithm for the task system problem is straightforward to prove from the proofs in [5] and [8] for the lower bounds of the MTS problem.

THEOREM 5.1. *Any deterministic or randomized on-line algorithm for the task system problem has a competitive ratio of at least* $(2n-1)/\Psi(C)$ *against an adaptive on-line adversary.*

Proof. The proof is similar to the proofs for the symmetric case. For the deterministic part, follow the proof of Theorem 2.2 of [5]. For the randomized part, the proof is essentially that of Theorem 11 of [8]. □

For the upper bound we use the basic traversal algorithm first described in [5] and also used in [8] in the following modified form:

(i) The positions are visited in a sequence, that is, prescribed by a random walk, but independent of the input task sequence $T_1, T_2, \ldots$.

(ii) There is a sequence of positive *threshold* costs $\beta_1, \beta_2, \ldots$ such that the transition from s_i to s_{i+1} occurs when the total task processing cost incurred since entering s_i reaches β_i.

Please refer to both [5] and [8] for a full account on such traversal algorithms, especially for the technical difficulties involved. The only originality on our part is in choosing an appropriate value for β_i. We simply choose β_i to be the return time $H_{s_i s_i}$; i.e., when in state j, the random scheduler leaves state j once the task processing cost incurred since reaching j equals the expected time for a random walk beginning from j to return to j for the first time. (This has an intuitive appeal!) Once again the analysis in our case turns out to be quite simple.

THEOREM 5.2. *There exists a randomized traversal algorithm for task systems (with ergodic cost matrices) which is* $(2n-1)$*-competitive.*

Proof. By *total cost* we mean the sum of the task processing costs and the moving costs. We can assume without loss of generality (see [8]) that the adversary is a "cruel taskmaster," i.e., changes position only at the time the randomized on-line algorithm reaches its current position. We further distinguish *moving phases*, where the adversary changes positions, and *staying phases*, where the adversary stays in the same position but the randomized server moves. Let the current position be i. We first consider the cost incurred by the (randomized) on-line algorithm. Recall that we set $\beta_i = H_{ii}$. Also, from our results in section 3, recall that the expected cost per move is $E \leq (n-1)$. The expected task processing cost per move is $\sum_i \pi_i \beta_i = \sum_i \pi_i H_{ii} = n$, since π_i is the steady state probability of being at i. So, the ratio of the expected total cost to expected cost per move (of the on-line algorithm) is $[n+E]/E$. Note that it suffices to show that the expected moving cost of the on-line algorithm is at most E times the cost of the adversary—we would then have a competitive ratio of $[n+E] \leq (2n-1)$. We show this in the following two phases, depending on when the adversary is moving (the moving phase) and when the adversary is staying (the staying phase):

1. *The moving phase.* The average cost in this phase can be analyzed as a cat

and mouse game, with the adversary playing the mouse's role, yielding a competitive ratio of E.

2. *The staying phase.* The cost of the adversary starting (and ending) at node i is β_i, whereas the expected moving cost of the on-line algorithm in that phase is $E \times H_{ii} = E\beta_i$. □

5.2. Memoryless counterpart. The above algorithm needs to store a current virtual position and a counter for the accumulated task processing cost at that position. However, this can also be made *memoryless* in the spirit of [8], without sacrificing the competitive ratio with the idea of using a *probabilistic counter*. We omit further discussion since the details are the same as those of [8], modulo the following aspect. We need to bound the stretch of a random walk while allowing for positive costs on self-loops. We merely state the requisite lemma and outline the proof idea.

LEMMA 5.3. *The ergodic walk has a stretch of at most* $(2n-1)$*, on a graph with cost matrix* C*, where* C_{ii} *are not necessarily zero.*

Proof idea. We adopt the procedure that was described in detail in [8]. We merely suggest the solution and omit the proof, since it is similar to that of Theorem 7 of [8]. Intuitively, the idea is to place a special vertex on each self-loop with the appropriate transition probabilities and appeal to the case of no self-loops. Since the number of vertices is doubled (in the worst case), the stretch is at most $2n-1$ rather than $n-1$. □

6. Loose ends. The most important issue here is in extending our results to *all* cost matrices (say, those that satisfy the triangle inequality). In particular, tighter upper and lower bounds on a stretch of random walks on directed graphs would constitute significant progress. Coppersmith et al. [8] extend their results from *resistive* cost matrices to all cost matrices (at least existentially, if not with an efficient construction); i.e., they show that given any symmetric cost matrix $\{C_{ij}\}$, satisfying the triangle inequality, there exists a resistive (approximation) network (with conductances c_{ij}) such that the effective resistance $R_{ij} \leq C_{ij}$ whenever $c_{ij} \geq 0$, with $R_{ij} = C_{ij}$ whenever $c_{ij} > 0$. Much in the same spirit we would like to aim for an ergodic Markov chain with the property that $H_{ij} \leq C_{ij}$, with equality whenever $p_{ij} > 0$. The existence of such an "approximate chain" is clearly implied by the result of [8] when we are seeking a reversible chain. The main hurdle in mimicking the approach taken in [8] for the nonreversible case is the following. Consider the space of all $n-1 \times n-1$ matrices, $\mathcal{P} = \{\bar{P}\}$, where $\bar{P}$ corresponds (as in Theorem 2.2) to an ergodic chain on n states. It is easy to see that for $0 \leq \alpha \leq 1$,

$$\bar{P}_1, \bar{P}_2 \in \mathcal{P} \quad \Rightarrow \quad \alpha\bar{P}_1 + (1-\alpha)\bar{P}_2 \in \mathcal{P}.$$

Let's even assume that $\mathcal{P}$ is a space of positive definite matrices. Now the function, log of the determinant, is concave over the space of positive definite *symmetric* (or Hermitian) matrices, and symmetry is crucial here. We have examples of asymmetric $\bar{P}$ (i.e., nonreversible chains) which show that the log of the determinant is neither concave nor convex over $\mathcal{P}$. This makes the analogous result for the nonreversible case much harder. On the other hand, Coppersmith et al. benefit from convexity as follows. They formulate the approximation as an appropriate convex programming problem; the existence of the approximate chain (resistive network) is then guaranteed by simply appealing to the "Kuhn–Tucker" (necessary and sufficient) conditions arising in the solution of the convex programming problem. It is still conceivable that a somewhat different approach works for the nonreversible case.

Acknowledgments. The author thanks Steve Phillips, Prabhakar Raghavan, Nick Reingold, and Emre Telatar for many useful discussions. The author would also like to thank Mike Saks (the no-longer-anonymous referee) for a careful reading and constructive criticism of the manuscript.

EFFICIENT GENERATION OF MINIMAL LENGTH ADDITION CHAINS*

EDWARD G. THURBER†

Abstract. An addition chain for a positive integer n is a set $1 = a_0 < a_1 < \cdots < a_r = n$ of integers such that for each $i \geq 1$, $a_i = a_j + a_k$ for some $k \leq j < i$. This paper is concerned with some of the computational aspects of generating minimal length addition chains for an integer n. Particular attention is paid to various pruning techniques that cut down the search time for such chains. Certain of these techniques are influenced by the multiplicative structure of n. Later sections of the paper present some results that have been uncovered by searching for minimal length addition chains.

Key words. addition chain, search tree, pruning bounds, backtracking, branch and bound

1. Introduction.

Dellac [6] asks what is the minimum number of multiplications required to raise a number A to the power m. Since exponents are added when powers of the same base are multiplied, this gives rise to the concept of an addition chain. This topic has been studied somewhat extensively over the intervening 100 years. Many questions have been posed concerning this deceptively simple problem. While some of these have been answered, others remain tantalizingly open.

This paper explores some of the computational aspects of generating minimal length addition chains for an integer n. The emphasis on computation is of interest in light of the surprising discoveries that the generation of minimal length addition chains has uncovered, some of which led Knuth [12] to say that perhaps no conjecture concerning addition chains is safe. Some of these discoveries will be mentioned in section 10.

The algorithm to be explored for generating minimal length addition chains is a backtracking algorithm that uses branch and bound methods to prune the search tree. Since the algorithm is exponential in nature, particular attention will be paid to pruning the search tree. The pruning bounds dramatically increase the efficiency of the search and increase the feasibility of pursuing a variety of questions concerning addition chains. For example, the determination of $c(r)$, the first integer requiring r steps in an addition chain of minimal length, is greatly facilitated by these methods.

Of course, the trick when pruning a search tree is not to cut off too much. Establishing the validity of the pruning bounds used in the backtracking algorithm will be a primary focus of what follows. It will be seen that certain classes of pruning bounds are affected by the multiplicative structure of n.

The paper is organized as follows. Section 2 includes some notation and prior results. Section 3 develops the notion of the search tree for addition chains. In section 4, an algorithm is discussed which will find all the minimal addition chains for the integer n. The algorithm is adapted easily to find just one such chain. In section 5, the pruning bounds that come most readily to mind are developed. In

section 6, improvements are made to class 1 bounds. Section 7 discusses pruning bounds that involve more than one member of an addition chain. In section 8, class 1 and class 2 bounds are applied to n and their effectiveness is explored. In section 9, class 1 pruning bounds are refined in a way that is influenced by the multiplicative nature of n, and a summary is given of the pruning bounds developed in the paper. Section 10 further explores the efficiency of the various classes of pruning bounds and presents some computational results found concerning the addition chain problem. Finally, in section 11 concluding remarks are made with some reference to future directions.

2. Preliminaries. An addition chain for a positive integer n is a set $1 = a_0 < a_1 < \cdots < a_r = n$ of integers such that for every $i \geq 1$, $a_i = a_j + a_k$ for some $k \leq j < i$. The minimal length, r, of an addition chain for n is denoted by $l(n)$. As in Knuth [12], $\lambda(n) = \lfloor \log_2 n \rfloor$, and $\nu(n)$ will denote the number of ones in the binary representation of n. The function NMC(n) was introduced by the author [19] and denotes the number of minimal addition chains for n. For $n = 29$, a minimal addition chain is $1, 2, 4, 8, 9, 13, 16, 29$. In base 2, $29 = 11101_2$. Thus, $\nu(29) = 4, \lambda(29) = \lfloor \log_2 29 \rfloor = 4$, $l(29) = 7$, and, as it turns out, NMC(29) = 132.

As Knuth observed, either $\lambda(a_i) = \lambda(a_{i-1})$ or $\lambda(a_i) = \lambda(a_{i-1}) + 1$. In the former case, step i is called a *small step* and is called a *big step* otherwise. There are exactly $\lambda(n)$ big steps in any chain for n. The number of steps, r, in an addition chain for n can be expressed as $r = \lambda(n) + N(n)$, where $N(n)$ denotes the number of small steps in the chain. It should be noted that $N(n)$ is chain dependent. Minimizing $N(n)$ will result in a minimal length addition chain for n. If $j = i - 1$, then step i is called a *star step*. An addition chain that consists entirely of star steps is called a *star chain*. If $j = k = i - 1$, then step i is called a *doubling*.

Theoretically developed lower bounds for $l(n)$ provide starting values from which to start looking for minimal length addition chains. It is conjectured [12] that $l(n) \geq \lambda(n) + \lceil \log_2 \nu(n) \rceil$. If $\nu(n) \geq 2^m + 1$, the conjecture states that $l(n) \geq \lambda(n) + m + 1$. The conjecture has been established for $m = 0, 1, 2, 3$ [17], and it is known that the conjecture holds for all $n \leq$ 327,678. Schönhage [14] has shown that $l(n) \geq \log_2 n + \log_2 \nu(n) - 2.13$. Thus, $l(n) \geq \lceil \log_2 n + \log_2 \nu(n) - 2.13 \rceil$ in any event.

3. The search tree. A tree organization for the solution space for finding addition chains for n is as follows:

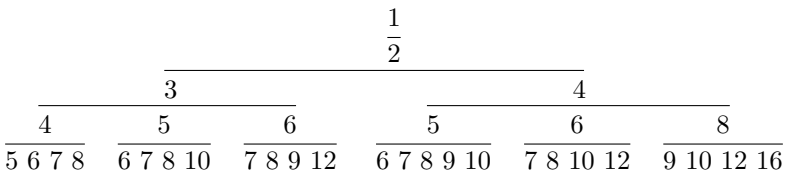

FIG. 3.1.

This tree organization is found in a paper by Chin and Tsai [5] in which they develop algorithms for finding minimal or near minimal addition chains for integers n. The tree shall be referred to as the search tree. The algorithm in this paper traverses the search tree in a fashion similar to that found in [5]. The search is depth first and considers larger numbers first (i.e., all paths that start $1, 2, 4$ are taken before any path that starts $1, 2, 3$). In what follows the emphasis is on developing and establishing the

validity of pruning bounds used in the branch and bound method to greatly speed up the search for minimal addition chains.

If $n = 1$ is at *level* 0, then 2 is at *level* 1, 3 and 4 are at *level* 2, etc. The children of a given node a_i at level i are all numbers $a_{i+1} > a_i$ formed as sums $a_j + a_k$, $k \le j \le i$ of numbers in the path from 1 to a_i. Any addition chain for an integer n can be found by taking the path from 1 down to the appropriate occurrence of n in the search tree. The tree grows exponentially as can be seen by the fact that each integer at level k in the tree has at least $k + 1$ children. This means that the number of paths to level k is at least $k!$ To find $l(n)$ and NMC(n) is to find on what level n appears first and how many times it appears on this level. If $1 = a_0, a_1, \ldots, a_i$ is a partial chain, then br$[a_i]$ is the branch of the search tree that has a_i for its root.

4. Algorithm for finding all minimal addition chains. The backtracking algorithm for finding all minimal addition chains for an integer n starts by setting $r = \lambda(n) + \lceil \log_2 \nu(n) \rceil$ if $n \le 327{,}678$ or $\nu(n) \le 16$. Otherwise, it sets $r = \lceil \log_2 n + \log_2 \nu(n) - 2.13 \rceil$. If no chain of length r is found, then set r to $r + 1$ and repeat. The process is continued until a length is tried for which chains for n exist. This length will be $l(n)$. By the binary chain method [12], $l(n) \le \lambda(n) + \nu(n) - 1$.

Starting with minimum estimates for $l(n)$ and working up is preferable to over estimating $l(n)$ and working down since it minimizes the number of small steps in the addition chains being generated. It is the increase in small steps that adds significantly to the search time.

In what follows, *lb*, which stands for lower bound, will be used in place of r. The search commences with a lower bound *lb* for $l(n)$ and increases this value incrementally if necessary. The following algorithm traverses the search tree and develops partial addition chains $1 = a_0, a_1, \ldots, a_i$ into minimal length addition chains for n. A stack is maintained which holds the possible children of a_i at each stage. The children of a_i constitute a stack segment.

Algorithm find_minimum_chains(n).
begin
  if $n \le 327{,}678$ **or** $\nu(n) \le 16$ **then**
    $lb = \lambda(n) + \lceil \log_2 \nu(n) \rceil$
  else
    $lb = \lceil \log_2 n + \log_2 \nu(n) - 2.13 \rceil$
  end if
  $a_0 = 1$, $a_1 = 2$ (first two elements of an addition chain)
  loop *lb*_value
    determine pruning bounds
    $i = 1$
    loop find_chains
      if $i < lb$ **then**
        determine whether to retain a_i
        if a_i is retained **then**
          stack the possibilities for a_{i+1} in increasing order in next stack
            segment (all sums $a_j + a_k > a_i, k \le j < i + 1$)
          increment i by 1
          let a_i be the element on top of the stack
          if $a_i = n$ **then**
            chain is found

```
            back up in the search tree until a node is found that needs further
              expanding (i.e., take the next element off the stack that is not
              in the stack segment of a_i)
          end if
        else
          back up in the search tree until a node is found that needs further
            expanding (i.e., take the next element off of the stack)
          let a_i be the element on top of the stack
        end if
      else
        back up in the search tree until a node is found that needs further
          expanding (i.e., take the next element off of the stack that is not
          in the stack segment of a_i)
        let a_i be the element on top of the stack
      end if
    end loop find_chains
    if no chains found then
      increase lb by 1
    else
      exit loop lb_value
    end if
end loop lb_value.
```

When an element a_i is taken off of the top of the stack, it is either n, in which case a minimal addition chain for n has been found, or it becomes part of a partial chain $1 = a_0, a_1, \ldots, a_i$ provided that it is not pruned from the search tree. The possible children a_{i+1} of a_i are put on the stack in increasing order. Some pruning can take place at this point, also. Backing up in the search tree is accomplished by taking elements off the stack. The stack is popped until an element is found that cannot be pruned. If, for instance, it is determined that a_i is to be pruned and that this exhausts all possibilities from a_{i-1}, then the next element on the stack is the next child of a_{i-2} in decreasing order (if children of a_{i-2} still remain; otherwise, backtrack further). The next child of a_{i-2} (the new a_{i-1}) is added to the partial chain $1 = a_0, a_1, \ldots, a_{i-2}$ provided that it is not pruned, and its children are added to the stack. When the algorithm backs up to $a_1 = 2$, it will terminate since the $1, 2, 4$ and $1, 2, 3$ branches (br[4] and br[3]) will have been traversed, and these are the only possibilities from level 2 in the search tree. At this point, either all the minimal addition chains for n will have been found or none will have been found, in which case lb is increased by 1 and the process is repeated. The algorithm will exit loop find_chains when the stack is empty. A slight variation of the algorithm will terminate once the first addition chain for n is found.

It should be mentioned that this algorithm is particularly well suited for finding all the minimal length addition chains for n. If one were interested in finding only one such chain, other strategies might be employed such as limiting the search to star chains at first and checking only for nonstar chains if no star chains are found. The pruning bounds, however, apply to whatever strategy is employed for traversing the search tree.

Two classes of bounds will be discussed. The first class (class 1 bounds) concerns bounds for a_i, while the second class (class 2 bounds) concerns bounds for $a_i + a_{i-1}$. Class 1 bounds will be refined to further improve the efficiency of the search. Finally,

the somewhat curious phenomenon will be explored of how class 1 bounds can be improved for integers not divisible by integers of the form $2^i + 1$.

5. Pruning bounds (class 1). Since $a_i \le 2a_{i-1}$ for $1 \le i \le r$, it follows that if a_j and a_i are two members of an addition chain such that $a_i > 2^m a_j$, then it will require more than m steps to get from a_j to a_i no matter how the chain is constructed. This can be used as follows to prune the search tree.

The subscript, i, of an integer a_i in an addition chain for n represents the number of steps that have been taken to reach a_i. If a chain of a certain length, $lb = i + m$, is being sought for an integer n, and if $2^m a_i < n$, then it will be impossible to get to n from a_i in $m = lb - i$ steps. The branch br$[a_i]$ of the search tree emanating from a_i can be eliminated. If a chain of length 4 is being sought for $n = 16$, then the partial chain $1, 2, 3$ cannot lead to a 4-step chain for 16 since $2^2 3 < 16$. This eliminates br[3] which cuts out 12 possible paths to level 4 (or roughly half of the 25 paths to this level).

If lb has been set, then there will be $lb - i$ steps in the chain from a_i to n if such a chain exists. If $2^{lb-i} a_i < n$, then no chain for n which includes a_i exists of length lb, and the branch br$[a_i]$ can be pruned from the search tree. It follows that if $a_i < n/2^{lb-i}$, then br$[a_i]$ is pruned from the tree. This eliminates at least $lb!/i!$ paths to search.

If $a_i < \lceil n/2^{lb-i} \rceil$, there are two cases for the integer a_i. If $n/2^{lb-i}$ is an integer, then $a_i < n/2^{lb-i}$, and if it is not an integer, then $a_i < \lceil n/2^{lb-i} \rceil$ implies that $a_i \le \lfloor n/2^{lb-i} \rfloor$. Since $n/2^{lb-i}$ is not an integer, it follows that $a_i < n/2^{lb-i}$. In any event, if $a_i < \lceil n/2^{lb-i} \rceil$, then br$[a_i]$ can be pruned from the tree. This leads to the set of class 1 bounds

$$b_i = \lceil n/2^{lb-i} \rceil, \qquad i = 0, \ldots, lb. \tag{A}$$

We have the following theorem.

THEOREM 1. *Let $\{b_i\}$ denote bounding sequence* (A) *for a positive integer n. If for some step i in an addition chain for n, $a_i < b_i$, then the partial chain $a_0, a_1, \ldots, a_i$ cannot lead to a chain of length lb for n, and br$[a_i]$ can be pruned from the search tree.*

For example, suppose $n = 39 = 100111_2$. Then $lb = \lambda(39) + \lceil \log_2 \nu(39) \rceil = 5 + 2 = 7$. The set of bounds $\{\lceil 39/2^{7-i} \rceil\} = \{1, 1, 2, 3, 5, 10, 20, 39\}$. The partial chain $1, 2, 3, 5, 8, 9$ cannot lead to a chain of length 7 for 39 since $a_5 = 9 < 10 = b_5$.

At each stage in an addition chain's development, the possible choices for the next element a_{i+1} after a_i are added as a new stack segment. This includes all a_{i+1} such that $a_{i+1} = a_j + a_k$ for $0 \le k \le j \le i$ and $a_i < a_{i+1} \le n$. In the partial chain $1, 2, 3, 5, 8, 13$ for 39 the possible choices for the next element in the chain are $14, 15, 16, 18, 21$, and 26. The bound associated with the sixth step in the chain is 20. Since $18 < 20$, it can be discarded, as can $14, 15$, and 16. The numbers 21 and 26 are added to the stack.

The bounds $\{\lceil n/2^{lb-i} \rceil\}$ can be found by dividing n by 2 and each successive result by 2. At each stage the result is rounded up to the nearest integer if necessary. This follows from the fact that $\lceil \lceil n/2^{lb-i} \rceil / 2 \rceil = \lceil n/2^{lb-i+1} \rceil$. If $a_i \ge b_i = \lceil n/2^{lb-i} \rceil$, br$[a_i]$ is retained and all possibilities for a_{i+1} such that $a_i < a_{i+1} \le n$ and $a_{i+1} \ge b_{i+1} = \lceil n/2^{lb-(i+1)} \rceil$ are stored for future consideration.

6. Class 1 bounds refined. If n is not a power of 2, the bounds $\{\lceil n/2^{lb-i} \rceil\}$ can be improved by the following considerations. For an odd integer n, the last step

in an addition chain for n is $n = a_r = a_{r-1} + a_k$ for some $k < r-1$. The last step must be a star step in a minimal chain since otherwise, a_{r-1} could be eliminated, resulting in a shorter chain. Also, $k < r-1$, or else n would be even. Thus, if $r = lb$, then $n \le a_{lb-1} + a_{lb-2}$, which implies that $n \le 3a_{lb-2}$.

It follows that a_{lb-2} cannot lead to a chain of lb steps for n unless $a_{lb-2} \ge \lceil n/3 \rceil$. a_{lb-2} will not be greater than or equal to $\lceil n/3 \rceil$ unless $a_{lb-3} \ge \lceil n/(3 \cdot 2) \rceil$, $a_{lb-4} \ge \lceil n/(3 \cdot 2^2) \rceil$, etc. Thus, br$[a_i]$ is retained only when $a_i \ge \lceil n/(3 \cdot 2^{lb-(i+2)} \rceil$ for $i = 0, \ldots, lb-2$, and $a_{lb-1} \ge \lceil n/2 \rceil$. The bounds are

$$\text{(B)} \qquad b_i = \begin{cases} \lceil n/(3 \cdot 2^{lb-(i+2)}) \rceil & 0 \le i \le lb-2, \\ \lceil n/2^{lb-i} \rceil & lb-1 \le i \le lb. \end{cases}$$

For $n = 39$, the bounds are $\{1, 1, 2, 4, 7, 13, 20, 39\}$ which is a significant improvement over bounding sequence (A).

Regardless of whether n is even or odd, it can be expressed uniquely as $n = 2^t m$, where m is odd and $t \ge 0$. Bounding sequence (B) generalizes to

$$\text{(C)} \qquad b_i = \begin{cases} \lceil n/(3 \cdot 2^{lb-(i+2)} \rceil & 0 \le i \le lb-t-2, \\ \lceil n/2^{lb-i} \rceil & lb-t-1 \le i \le lb. \end{cases}$$

This leads to the following theorem.

THEOREM 2.[1] *Let $\{b_i\}$ denote bounding sequence* (C) *for a positive integer n. If for some step i in an addition chain for n, $a_i < b_i$, then the partial chain $a_0, a_1, \ldots, a_i$ cannot lead to a chain of length lb for n, and br$[a_i]$ can be pruned from the search tree.*

Proof. Suppose $n = 2^t m$ where m is odd. Bounding sequence (C) can be split into two parts.

Region 1. $n, n/2, n/2^2, \ldots, n/2^{t-1}, m = n/2^t, \lceil m/2 \rceil$.

These are the bounds in reverse order corresponding to steps i such that $lb-t-1 \le i \le lb$.

Region 2. $\lceil m/3 \rceil, \lceil m/(3 \cdot 2) \rceil, \ldots, \lceil m/(3 \cdot 2^{lb-t-(i+2)}) \rceil = \lceil n/(3 \cdot 2^{lb-(i+2)}) \rceil, \ldots$.

These are the bounds in reverse order corresponding to steps i such that $0 \le i \le lb-t-2$.

In Region 1, $b_i = \lceil n/2^{lb-i} \rceil$, while in Region 2, $b_i = \lceil n/(3 \cdot 2^{lb-(i+2)}) \rceil$. This latter bound is determined by noting that $b_{lb-t-2} = \lceil m/3 \rceil, b_{lb-t-3} = \lceil m/(3 \cdot 2) \rceil$, $\ldots, b_{lb-t-j} = \lceil m/(3 \cdot 2^{j-2}) \rceil = \lceil n/(3 \cdot 2^{t+j-2}) \rceil, \ldots$. If $i = lb-t-j$, then $t+j-2 = lb-(i+2)$.

For Region 1, if $a_i < \lceil n/2^{lb-i} \rceil$, then br$[a_i]$ can be pruned from the search tree by the same reasoning used in Theorem 1.

For Region 2, suppose $a_i < \lceil m/(3 \cdot 2^{lb-t-(i+2)}) \rceil = \lceil n/(3 \cdot 2^{lb-(i+2)}) \rceil$. Then $a_i < n/(3 \cdot 2^{lb-i-2})$. Assume n is not a power of two since, if it is a power of two, Region 2 does not apply. Then every step in a chain for n cannot be a doubling. Suppose step s is a nondoubling in which case $a_s \le a_{s-1} + a_{s-2}$. If $s > i+1$, then

$$\begin{aligned} a_s &\le a_{s-1} + a_{s-2} \le 2^{(s-1)-i} a_i + 2^{(s-2)-i} a_i \\ &= 2^{(s-2)-i}(2a_i + a_i) = 2^{(s-2)-i}(3a_i). \end{aligned}$$

[1] Note that in this theorem and following theorems, a_i will often be replaced by $2a_{i-1}$ in a set of inequalities since $a_i \le 2a_{i-1}$. More generally, for $j < i, a_i$ will be replaced by $2^{i-j}a_j$ since $a_i \le 2^{i-j}a_j$. Additional inequalities such as $4a_i + a_{i-1} \le 3(a_i + a_{i-1})$ also follow from the fact that $a_i \le 2a_{i-1}$. These and other similar inequalities will be used frequently.

It follows that $n = a_{lb} \le 2^{lb-s}a_s \le 2^{lb-s}2^{(s-2)-i}(3a_i) < (2^{lb-2-i})(3)(n/(3\cdot 2^{lb-i-2}) = n$. Of course $n < n$ is a contradiction. Thus, there can be no nondoubling step in the chain after step $i+1$. If every step in the chain after step $i+1$ is a doubling, then $n = a_{lb} = 2^{lb-(i+1)}a_{i+1}$. This means that 2^{lb-i-1} divides n. Since $i \le lb - t - 2$, it follows that $lb - i - 1 \ge t + 1$. This is a contradiction since t is the highest power of 2 dividing n.

Thus, for any a_i in Region 2 which is less than the corresponding bound, br$[a_i]$ can be pruned from the search tree. □

7. Pruning bounds (class 2). More can be done by way of pruning the search tree by considering the sum $a_i + a_{i-1}$. It is often the case that if this sum is less than b_{i+1} of bounding sequence (C), then br$[a_i]$ can be pruned from the search tree. Bounding sequences for $a_i + a_{i-1}$ will be called class 2 bounds. (Note: The same bounding sequence, when used for a_i, is called a class 1 bounding sequence and, when used for $a_i + a_{i-1}$, is called a class 2 bounding sequence.) It is a somewhat curious fact that if n is a multiple of 5, then bounding sequence (C) must be replaced by bounding sequence (A) when used as a class 2 bound. First, the case for odd n will be considered. Bounding sequence (B) is used when n is odd, and n is not a multiple of 5. It is convenient to split it into three regions.

Region 1. $n, \lceil n/2 \rceil$.

Region 2. $\lceil n/3 \rceil$.

Region 3. $\lceil n/(3\cdot 2) \rceil, \ldots, \lceil n/(3\cdot 2^{lb-(i+2)}) \rceil, \ldots$.

In Region 1, b_{i+1} is either n or $\lceil n/2 \rceil$; that is, $i = lb - 1$ or $i = lb - 2$.

$\boldsymbol{i = lb-1}$. In this case, $a_i + a_{i-1} < b_{i+1}$ implies that $a_{lb-1} + a_{lb-2} < b_{lb} = a_{lb} = n$. Thus, n must be $a_{lb-1} + a_{lb-1} = 2a_{lb-1}$. This contradicts the fact that n is odd.

$\boldsymbol{i = lb - 2}$. If $a_{lb-2} + a_{lb-3} < b_{lb-1} = \lceil n/2 \rceil$, then $a_{lb-2} + a_{lb-3} < n/2$. Since n is odd, $n \le a_{lb-1} + a_{lb-2} \le 2a_{lb-2} + 2a_{lb-3} < 2(n/2) = n$ which is a contradiction.

For Region 2, $i = lb - 3$. If $a_{lb-3} + a_{lb-4} < b_{lb-2} = \lceil n/3 \rceil$, then $a_{lb-3} + a_{lb-4} < n/3$. We assume that $a_i \ge b_i$ for $i = 1, \ldots, n$, since it has been shown previously (Theorem 2) that if $a_i < b_i$ for any i, then a chain of lb steps for n is not possible. This means that $a_{lb-2} \ge n/3$. Since $a_{lb-3} + a_{lb-4} < n/3$, it follows that $a_{lb-2} = 2a_{lb-3}$. Step $lb - 1$ must be a star step since step $lb - 2$ is a doubling. The possibilities for a_{lb-1} need to be considered. These can be drawn from the set $\{a_{lb-2} + a_j, j \le lb - 2\}$. In what follows, $n \le a_{lb-1} + a_{lb-2}$ since n is odd, and $a_{lb-2} = 2a_{lb-3}$.

(i) $a_{lb-1} = a_{lb-2} + a_{lb-4}$:

$$n = a_{lb} \le a_{lb-1} + a_{lb-2} = 4a_{lb-3} + a_{lb-4} \le 3(a_{lb-3} + a_{lb-4}) < 3(n/3) = n.$$

Clearly, no possibilities $a_{lb-2} + a_j, j < lb - 4$ need be considered.

(ii) $a_{lb-1} = a_{lb-2} + a_{lb-3}$:

Since n is odd and step lb is a star step, the possibilities for step lb can be drawn from the set $\{a_{lb-1} + a_j, j \le lb - 2\}$.

(iia) If $n = a_{lb-1} + a_{lb-2}$, then $n = 5a_{lb-3}$. Thus, 5 divides n. If $n = 95 = 1011111_2$, then $\lambda(95) = 6$, and $\nu(95) = 6$. $lb = \lambda(95) + \lceil \log_2 \nu(95) \rceil = 9$. The bounding sequence $\{b_i\}$ is $\{1, 1, 1, 2, 4, 8, 16, 32, 48, 95\}$. An addition chain for 95 is $1, 2, 3, 5, 8, 11, 19, 38, 76, 95$. Note that $a_{lb-3} + a_{lb-4} = 19 + 11 = 30 < 32 = b_{lb-2}$. Thus, when n is divisible by 5, there often exist minimal addition chains for n when $a_{lb-3} + a_{lb-4} < b_{lb-2}$.

(iib) If $n = a_{lb-1} + a_{lb-3}$, this leads to the contradiction that $n < n$ by similar reasoning as that used in (i). Again no possibilities $n = a_{lb-1} + a_j, j < lb - 3$ need be considered.

(iii) $a_{lb-1} = a_{lb-2} + a_{lb-2}$:
If $n = a_{lb-1} + a_{lb-2}$, then $n = 3(2a_{lb-3})$ is even, and if $n = a_{lb-1} + a_j, j < lb-3$, then $n < n$ as before. Since lb must be a star step, the only possibility is $n = a_{lb-1} + a_{lb-3}$ in which case $n = 5a_{lb-3}$. n is divisible by 5 and, as in case (iia), minimal chains for n often exist when $a_{lb-3} + a_{lb-4} < b_{lb-2}$.

For Region 3, $i \le lb-4$. If $a_i + a_{i-1} < b_{i+1} = \lceil n/(2^{lb-i-3} \cdot 3) \rceil$, then $a_i + a_{i-1} < n/(2^{lb-i-3} \cdot 3)$. It follows that

$$\begin{aligned} a_{lb-3} + a_{lb-4} &< 2^{(lb-3)-i} a_i + 2^{(lb-4)-(i-1)} a_{i-1} \\ &= 2^{(lb-3)-i}(a_i + a_{i-1}) < n/3. \end{aligned}$$

It follows from the same arguments as used for Region 2 that $\mathrm{br}[a_i]$ will be pruned from the search tree unless n is a multiple of 5.

These considerations establish the following theorem.

THEOREM 3. *Let n be odd, n not a multiple of 5, and let $\{b_i\}$ be bounding sequence* (B). *If $a_i + a_{i-1} < b_{i+1}$ for some i, then the partial chain $1 = a_0, a_1, \ldots, a_i$ cannot lead to a minimal addition chain for n.*

Comment. From Theorem 1, it is known that $a_i \ge b_i$ if $1 = a_0, a_1, \ldots, a_i$ is to lead to a minimal chain for n. The following example shows that additional branches can be pruned from the search tree when $a_i + a_{i-1} < b_{i+1}$.

For $n = 39, \{b_i\} = \{1, 1, 2, 4, 7, 13, 20, 39\}$. A partial chain $1, 2, 3, 5, 7$ satisfies the requirement that $a_i \ge b_i$. However, $a_4 + a_3 = 7 + 5 < 13 = b_5$. Thus, $\mathrm{br}[7] = \mathrm{br}[a_4]$ can be pruned from the search tree.

A generalization. Theorem 3 generalizes to the case where $n = 2^t m$ and m is odd. In this case, bounding sequence (C) is used, and it is convenient to split it into the following regions.

Region 1. $n, n/2, n/2^2, \ldots, n/2^{t-1}, m = n/2^t, \lceil m/2 \rceil$.

Region 2. $\lceil m/3 \rceil$.

Region 3. $\lceil m/(3 \cdot 2) \rceil, \ldots, \lceil m/(3 \cdot 2^{lb-t-(i+2)} \rceil = \lceil n/(3 \cdot 2^{lb-(i+2)}) \rceil, \ldots$.

THEOREM 4. *Suppose n is not a multiple of 5 and $\{b_i\}$ is bounding sequence* (C). *If $a_i + a_{i-1} < b_{i+1}$ for some i and $n \ne 2^{lb-i} a_i$ for i in Region 1, then the partial chain $1 = a_0, a_1, \ldots, a_i$ cannot lead to a minimal addition chain for n.*

Note. The condition that $n \ne 2^{lb-i} a_i$ for i in Region 1 is necessary as can be seen from the following example. $1, 2, 3, 5, 7, 14, 21, 42, 84, 168, 336$ is a minimal chain for $n = 336$. Bounding sequence (C) for 336 is $1, 1, 2, 4, 7, 11, 21, 42, 84, 168, 336$. Even though $a_6 + a_5 = 21 + 14 < 42 = b_7, \mathrm{br}[a_6]$ cannot be pruned from the search tree.

The proof of Theorem 4, while tedious, is analogous to the proof of Theorem 3, with $lb - t - i$ replacing $lb - i, i \ge 0$. Also, some step $s \ge lb - t$ will need to be a nondoubling or else 2^{t+1} will divide n, which contradicts the fact that 2^t is the highest power of 2 dividing n. The element a_s in Theorem 4 plays a role similar to that of n in Theorem 3 since they are both formed by nondoublings.

Proof.

Region 1. $lb - t - 2 \le i \le lb - 1$. Note that if $i \ge lb - t - 2$, then $i + 1 \ge lb - t - 1$, and b_{i+1} will be in Region 1. If $a_i + a_{i-1} < b_{i+1} = \lceil n/2^{lb-(i+1)} \rceil$, then suppose there exists a step $s > i$ that is not a doubling. Then

$$a_s \le a_{s-1} + a_{s-2} \le 2^{(s-1)-i} a_i + 2^{(s-2)-(i-1)} a_{i-1} = 2^{(s-1)-i}(a_i + a_{i-1}).$$

It follows that

$$n = a_{lb} \le 2^{lb-s} a_s \le 2^{lb-s} 2^{(s-1)-i}(a_i + a_{i-1}) < 2^{(lb-1)-i}(n/2^{(lb-1)-i}) = n.$$

Thus, every step after step i must be a doubling. This means that $n = 2^{lb-i}a_i$ if the partial chain $1 = a_0, a_1, \ldots, a_i$ can be extended to a chain of length lb for n.

Region 2. $i = lb - t - 3$ for $b_{i+1} = \lceil m/3 \rceil$.

If $a_{lb-t-3} + a_{lb-t-4} < \lceil m/3 \rceil = \lceil n/(2^t \cdot 3) \rceil$, then $a_{lb-t-3} + a_{lb-t-4} < n/(2^t 3)$. Since it is assumed that $a_i \geq b_i$ for $i = 1, \ldots, n$, then $a_{lb-t-2} \geq b_{lb-t-2} = \lceil n/(2^t \cdot 3) \rceil \geq n/(2^t 3)$, and it follows that $a_{lb-t-2} = 2a_{lb-t-3}$. Since step $lb-t-2$ is a doubling, step $lb-t-1$ must be a star step; that is, $a_{lb-t-1} = a_{lb-t-2} + a_k$ for some $k \leq lb-t-2$. It will be shown that $k = lb-t-2$ or $k = lb-t-3$. Suppose that $k \leq lb-t-4$ and that there is a nondoubling after step $lb-t-1$. Let s be the first such step. Then $a_{lb-t-1} \leq a_{lb-t-2} + a_{lb-t-4}$ and by using inequalities as noted in footnote 1 of Theorem 2, it follows that

$$\begin{aligned} a_s &\leq a_{s-1} + a_{s-2} \leq 2^{(s-1)-(lb-t-1)}a_{lb-t-1} + 2^{(s-2)-(lb-t-2)}a_{lb-t-2} \\ &= 2^{s-lb+t}(a_{lb-t-1} + a_{lb-t-2}) \leq 2^{s-lb+t}(2a_{lb-t-2} + a_{lb-t-4}) \\ &< 2^{s-lb+t}3(n/(2^t 3)) = 2^{s-lb}n. \end{aligned}$$

Thus, $n = a_{lb} \leq 2^{lb-s}a_s < 2^{lb-s}2^{s-lb}n = n$. This means that all steps after step $lb-t-1$ are doublings which, as noted, is not possible. Thus, either $a_{lb-t-1} = a_{lb-t-2} + a_{lb-t-3}$ or $a_{lb-t-1} = a_{lb-t-2} + a_{lb-t-2}$.

So far, if $a_{lb-t-3} + a_{lb-t-4} < n/(2^t 3)$, then it has been established that:

(1) $a_{lb-t-2} = 2a_{lb-t-3}$; and

(2) $a_{lb-t-1} = a_{lb-t-2} + a_{lb-t-3}$ or $a_{lb-t-1} = a_{lb-t-2} + a_{lb-t-2}$.

Suppose $\boldsymbol{a_{lb-t-1} = a_{lb-t-2} + a_{lb-t-3}}$. Then $a_{lb-t-1} = 3a_{lb-t-3}$. There must be a step $s \geq lb-t$ that is a nondoubling or as shown before 2^{t+1} divides n. Let s be the first nondoubling after step $lb-t-1$. The possibilities for step s that have a chance can be drawn from the set $\{a_{s-1} + a_{s-2}, a_{s-1} + a_{s-3}, 2a_{s-2}\}$.

(i) If $a_s = a_{s-1} + a_{s-3}$, then $a_s \leq 2^{(s-1)-(lb-t-1)}a_{lb-t-1} + 2^{(s-3)-(lb-t-3)}a_{lb-t-3}$. It follows by inequalities, as noted in footnote 1 that

$$\begin{aligned} a_s &\leq 2^{s-lb+t}(a_{lb-t-1} + a_{lb-t-3}) = 2^{s-lb+t}(4a_{lb-t-3}) \\ &< 2^{s-lb+t}3(a_{lb-t-3} + a_{lb-t-4}) < 2^{s-lb+t}3(n/(2^t 3)) = 2^{s-lb}n. \end{aligned}$$

Thus, $n = a_{lb} \leq 2^{lb-s}a_s < 2^{lb-s}2^{s-lb}n = n$.

(ii) If $a_s = a_{s-1} - a_{s-2}$, then if $\boldsymbol{s = lb - t}$, it follows that $a_{lb-t} = a_{lb-t-1} + a_{lb-t-2}$. Since $a_{lb-t-1} = a_{lb-t-2} + a_{lb-t-3}$ and $a_{lb-t-2} = 2a_{lb-t-3}$, this means that $a_{lb-t} = 5a_{lb-t-3}$. If there is a step $h > lb-t$ which is a nondoubling, then by reasoning similar to that discussed before, it can be shown that $n < n$. This means that all the steps after step $lb-t$ must be doublings. Thus

$$n = a_{lb} = 2^{lb-(lb-t)}a_{lb-t} = 2^t(5a_{lb-t-3}).$$

This contradicts the fact that n is not a multiple of 5.

Now, suppose $\boldsymbol{s > lb - t}$. This means that $a_{lb-t} = 2a_{lb-t-1}$, since step s is the first nondoubling after step $lb-t-1$. The reasoning used before concerning nondoubling steps can be combined with the fact that $a_{lb-t-3} + a_{lb-t-4} < n/(2^t 3)$ to show that $a_s < 2^{(s-lb+t)}3(n/(2^t 3)) = 2^{(s-lb)}n$, and $n = a_{lb} \leq 2^{lb-s}a_s < n$.

(iii) If $a_s = 2a_{s-2}$, then $a_s \leq 2(2^{(s-2)-(lb-t-2)}a_{lb-t-2}) = 2^{s-lb+t+1}a_{lb-t-2} = 2^{s-lb+t}(4a_{lb-t-3})$. As in case (i), this results in $n < n$.

Suppose $\boldsymbol{a_{lb-t-1} = 2a_{lb-t-2}}$. Since $a_{lb-t-2} = 2a_{lb-t-3}$, it follows that $a_{lb-t-1} = 4a_{lb-t-3}$. There must be a first step $s \geq lb-t$ that is a nondoubling or else 2^{t+1}

divides n as before. The possibilities for step s are $\{a_{s-1}+a_{s-2}, a_{s-1}+a_{s-3}, a_{s-1}+a_{s-4}, 2a_{s-2}\}$. It will become evident that these are the only cases that need to be considered.

(i) $a_s = a_{s-1}+a_{s-4} \le 2^{(s-1)-(lb-t-1)}a_{lb-t-1} + 2^{(s-4)-(lb-t-4)}a_{lb-t-4}$
$= 2^{s-lb+t}(4a_{lb-t-3}+a_{lb-t-4}) \le 2^{s-lb+t}3(a_{lb-t-3}+a_{lb-t-4})$
$< 2^{s-lb+t}3(n/(2^t3))$.

Thus, $a_s < 2^{s-lb}n$, and $n = a_{lb} \le 2^{lb-s}a_s < 2^{lb-s}2^{s-lb}n = n$.

(ii) $a_s = 2a_{s-2}$ leads to $n < n$ as in (iii) of the case where $a_{lb-t-1} = a_{lb-t-2} + a_{lb-t-3}$.

(iii) $a_s = a_{s-1}+a_{s-2}$. This is the most difficult case, since this is the largest possible value of a_s for the nondoubling step which must occur somewhere between steps $lb-t$ and lb. In what follows, $a_{lb-t-1} = 2a_{lb-t-2}$ and $a_{lb-t-2} = 2a_{lb-t-3}$. Suppose $\boldsymbol{s = lb-t}$. Then $a_{lb-t} = a_{lb-t-1}+a_{lb-t-2} = 6a_{lb-t-3}$. If there are no more nondoublings in the chain after step $lb-t$, then $n = a_{lb} = 2^{lb-(lb-t)}a_{lb-t} = 2^t6a_{lb-t-3}$ which means 2^{t+1} divides n. Thus, there must be a first nondoubling step $h > s$. The possibilities for a_h are drawn from the set $\{a_{h-1}+a_{h-2}, a_{h-1}+a_{h-3}, 2a_{h-2}\}$.

(iiia) $a_h = a_{h-1}+a_{h-3} \le 2^{(h-1)-(lb-t)}a_{lb-t} + 2^{(h-3)-(lb-t-2)}a_{lb-t-2}$
$= 2^{h-1-lb+t}6a_{lb-t-3} + 2^{h-1-lb+t}2a_{lb-t-3} = 2^{h-lb+t}4a_{lb-t-3}$.

From this it follows, as in prior cases, that $n < n$.

(iiib) $a_h = 2a_{h-2} \le 2(2^{(h-2)-(lb-t-1)}a_{lb-t-1} = 2^{h-lb+t}4a_{lb-t-3}$ which leads to $n < n$.

(iiic) $a_h = a_{h-1}+a_{h-2}$:

$$a_h = a_{h-1}+a_{h-2} \le 2^{(h-1)-(lb-t)}a_{lb-t} + 2^{(h-2)-(lb-t-1)}a_{lb-t-1}$$
$$= 2^{h-1-lb+t}6a_{lb-t-3} + 2^{h-1-lb+t}4a_{lb-t-3} = 2^{h-lb+t}5a_{lb-t-3}.$$

The 5 in the bound is not sufficient to conclude that $n < n$. If there is another step $l > h$ which is a nondoubling, then, as before, it can be shown that $a_l \le 2^{l-lb+t}4a_{lb-t-3}$ from which it follows that $n < n$. It follows that $n = a_{lb} = 2^{lb-h}a_h = 2^{lb-h}(a_{h-1}+a_{h-2})$. If $h > lb-t+1$, then

$$n = 2^{lb-h}(a_{h-1}+a_{h-2}) \le 2^{lb-h}(2^{(h-1)-(lb-t)}a_{lb-t} + 2^{(h-2)-(lb-t)}a_{lb-t})$$
$$= 2^{lb-h}(2^{h-1-lb+t}6a_{lb-t-3} + 2^{h-2-lb+t}6a_{lb-t-3})$$
$$= 2^{t-1}9a_{lb-t-3} \le 2^{t-1}6(a_{lb-t-3}+a_{lb-t-4}) < 2^t3(n/(2^t3)) = n.$$

If $h = lb-t+1$, then $n = 2^{lb-(lb-t+1)}(a_{lb-t}+a_{lb-t-1}) = 2^{t-1}10a_{lb-t-3}$.

From this it follows that 5 divides n.

Now we continue with the case $a_{lb-t-1} = 2a_{lb-t-2}$, where step s is the first nondoubling after step $lb-t-1$ and $a_s = a_{s-1}+a_{s-2}$. Suppose $\boldsymbol{s > lb-t}$; then step $s-1$ is a doubling. If there are no more nondoublings after step s, then

$$n = 2^{lb-s}a_s = 2^{lb-2}(a_{s-1}+a_{s-2}) = s^{lb-s}(3a_{s-2})$$
$$= 2^{lb-s}3(2^{(s-2)-(lb-t-1)}a_{lb-t-1}) = 2^{t-1}3a_{lb-t-1} = 2^{t-1}3(4a_{lb-t-3}).$$

This implies that 2^{t+1} divides n, which is a contradiction. As in the previous case, let step h be the first nondoubling step after step s. The only possibility for a_h that does not lead to $n < n$ is $a_h = a_{h-1}+a_{h-2}$. As in case (iiic), it can be shown that there can be no more nondoublings after step h or else $n < n$. Thus, $n = 2^{lb-h}a_h = 2^{lb-h}(a_{h-1}+a_{h-2})$. The cases $h = s+1$ and $h > s+1$ are handled separately.

Since $s > lb - t$, step $lb - t$ is a doubling, and $a_{lb-t} = 8a_{lb-t-3}$.

If $h = s + 1$, it can be shown by reasoning similar to that used before that $n = 2^t 5 a_{lb-t-3}$, which means that 5 divides n while if $h > s + 1$; then

$$\begin{aligned} n &= 2^{lb-h}a_h = 2^{lb-h}(a_{h-1} + a_{h-2}) = 2^{lb-h}(2^{h-1-s}a_s + 2^{h-2-s}a_s) \\ &= 2^{lb-h}2^{h-2-s}(3a_s) = 2^{lb-2-s}3(a_{s-1} + a_{s-2}) \\ &= 2^{lb-2-s}3(2^{(s-1)-(lb-t)}a_{lb-t} + 2^{(s-2)-(lb-t-1)}a_{lb-t-1}) \\ &= 3(2^{t-3}12a_{lb-t-3}) \le 3(2^{t-3}8(a_{lb-t-3} + a_{lb-t-4})) < 2^t 3(n/(2^t 3)) = n. \end{aligned}$$

(iv) $a_s = a_{s-1} + a_{s-3}$. As before, it can be shown that if there is a step $h > s$ that is a nondoubling, then $n < n$. Thus, $n = 2^{lb-s}a_s = 2^{lb-s}(a_{s-1} + a_{s-3})$. The cases $s = lb - t$, $s = lb - t + 1$, $s = lb - t + 2$, and $s \ge lb - t + 3$ must be considered. In all cases it can be shown that 5 divides n. It is important to note that s is the first step after $lb - t - 1$ that is a nondoubling. For instance, if $s = lb - t + 2$, then

$$\begin{aligned} n &= 2^{lb-s}(a_{s-1} + a_{s-3}) = 2^{lb-(lb-t+2)}(a_{lb-t+1} + a_{lb-t-1}) \\ &= 2^{t-2}(16a_{lb-t-3} + 4a_{lb-t-3}) = 2^t(5a_{lb-t-3}). \end{aligned}$$

Region 3. $i < lb - t - 3$.

For this region, the bound $a_i + a_{i-1} < b_{i+1}$ translates into $a_i + a_{i-1} < \lceil m/(3 \cdot 2^{lb-t-(i+3)} \rceil = \lceil n/(3 \cdot 2^{lb-(i+3)}) \rceil$ which implies $a_i + a_{i-1} < n/(2^{lb-i-3}3)$. It follows that

$$\begin{aligned} a_{lb-t-3} + a_{lb-t-4} &< 2^{(lb-t-3)-i}a_i + 2^{(lb-t-4)-(i-1)}a_{i-1} \\ &= 2^{(lb-t-3)-i}(a_i + a_{i-1}) < 2^{(lb-t-3)-i}n/(2^{lb-i-3}3) = n/(2^t 3). \end{aligned}$$

It follows from the same arguments as used for Region 2 that br$[a_i]$ will be pruned from the search tree unless n is a multiple of 5. □

It has been shown that if $n = 2^t m$, m odd, $\{b_i\}$ is bounding sequence (C), and $a_i < b_i$ for some i, then br$[a_i]$ can be pruned from the search tree and, furthermore, if n is not a multiple of 5, and $a_i + a_{i-1} < b_{i+1}$, then br$[a_i]$ can be pruned from the search tree provided that $n \ne 2^{lb-i}a_i$ for some step i in Region 1. If n is a multiple of 5 and if $\{b_i\}$ is bounding sequence (A), then if $a_i + a_{i-1} < b_{i+1} = n/2^{lb-(i+1)}$ for some i, br$[a_i]$ can be pruned from the search tree if there exists a step $s > i$ that is not a doubling since $a_s \le a_{s-1} + a_{s-2} \le 2^{(s-1)-i}a_i + 2^{(s-2)-(i-1)}a_{i-1} = 2^{(s-1)-i}(a_i + a_{i-1})$ from which it follows that $n < n$. Thus, when n is a multiple of 5, Theorem 4 holds for n provided that bounding sequence (C) is replaced by bounding sequence (A).

8. Pruning bounds applied. When the sequence $\{b_i\}$ is used as a class 1 bounding sequence, it will be called a *vertical* bounding sequence, and when it is used as a class 2 bounding sequence, it will be called a *slant* bounding sequence. If n is not a multiple of 5, then bounding sequence (C) can be used for both the vertical and slant bounds. The algorithm for generating addition chains checks to see: (1) if $a_i \ge b_i$; if this condition is satisfied, it next checks: (2) to see that if $n \ne 2^{lb-i}a_i$ for i in Region 1; then is $a_i + a_{i-1} \ge b_{i+1}$. If these conditions are met, then the partial chain $1 = a_0, a_1, \ldots, a_i$ is not rejected and candidates for a_{i+1} are considered. If (1) fails, then br$[a_i]$ is pruned from the search tree, and if (1) passes but (2) fails, br$[a_i]$ is pruned from the search tree.

If n is a multiple of 5, the same strategy is employed; however, bounding sequence (C) is used for the vertical bounds while bounding sequence (A) is used for the slant bounds.

The effect of these pruning bounds can be measured in terms of time required to search for chains as well as in terms of the number of "pops" off the stack. In the latter case, what is being popped off the stack for a given step i is the next candidate for a_i. The pruning bounds eliminate certain branches of the search tree, and the number of "pops" will diminish as the pruning bounds are put into effect. Several cases are considered for given values of n. The first case (no bds) has no pruning bounds. Case V (A) implements vertical pruning bounds using bounding sequence (A) while case V (C) implements vertical bounds using bounding sequence (C), etc. Case V/S (A) shows the effect of using bounding sequence (A) for both vertical and slant bounds. Case V/S (C) uses bounding sequence (C) for both vertical and slant bounds and when $n \equiv 0 \pmod 5$ replaces bounding sequence (C) with bounding sequence (A) for the slant bounds. Table 1 shows results for $n = 23$, 127, 191, 568, 607, and 1,015. These are interesting numbers from the standpoint of not giving trivial values yet not requiring so much time as to be unreasonable. The times, of course, are relative to the computer being used and are significant primarily in how they relate to each other as opposed to their actual values. It should be noted that when n is odd, bounding sequence (C) reduces to bounding sequence (B).

Table 1 records the number of "pops" that occur in an algorithm that finds all addition chains of minimal length for the given values of n. Also recorded is the time in seconds taken by each search. The times for $n = 23$ are too small to be significant.

A good check that the bounding sequences do not cut too much from the search tree is the observation that NMC(n) remains the same in all cases. As can be seen, there is significant improvement in going from V(A) to V/S(C).

9. Pruning bounds (class 1 further refined); the $2^i + 1$ phenomenon. For n odd, bounding sequence (B) can be improved as a vertical (class 1) bounding sequence depending on the multiplicative nature of n. If n is not a multiple of an integer of the form $2^i + 1$, then the following sequence can be used for the vertical bounding sequence.

$$\text{(D)} \qquad b_i = \begin{cases} \lceil n/(2^{lb-i-1}+1) \rceil & 0 \le i \le lb-1, \\ n & i = lb. \end{cases}$$

Suppose $a_i < \lceil n/(2^{lb-i-1}+1) \rceil$. Then $a_i < n/(2^{lb-i-1}+1)$. The cases $i = lb-1$ and $i = lb-2$ have been established previously. Let $i = lb-k$ for some k such that

[2]For $n = 1{,}015$, in the V/S (C) case bounding sequence (A) is used for the slant bounds since n is divisible by 5.

$3 \le k \le lb$.

$\boldsymbol{k = 3}$. $a_{lb-3} < n/5$. Since n is odd, step lb is not doubling. Yet it must be a star step. If $n = a_{lb} = a_{lb-1} + a_{lb-3}$, then $n \le 5a_{lb-3} < n$. If $n = a_{lb} = a_{lb-1} + a_{lb-2}$, then if $a_{lb-1} = 2a_{lb-2}$, it follows that 3 divides n, and if $a_{lb-1} = a_{lb-2} + a_{lb-3}$, then $n = a_{lb} = 2a_{lb-2} + a_{lb-3} \le 5a_{lb-3} < n$.

$\boldsymbol{k \ge 4}$. $a_{lb-k} < n/(2^{k-1}+1)$. If $n = a_{lb} = \boldsymbol{a_{lb-1} + a_{lb-k}}$, then

$$n = a_{lb} = a_{lb-1} + a_{lb-k} \le 2^{(lb-1)-(lb-k)} a_{lb-k} + a_{lb-k} = (2^{k-1}+1)a_{lb-k} < n.$$

Suppose $n = a_{lb} = \boldsymbol{a_{lb-1} + a_{lb-j}}$ for some $j, 2 \le j < k$. If $a_{lb-1} = 2^{j-1}a_{lb-j}$, then $2^{j-1}+1$ divides n. If $a_{lb-1} \ne 2^{j-1}a_{lb-j}$, then let s be the first integer greater than or equal to 1 such that step $lb - s$ is a nondoubling. Then $1 \le s < j$ and $n = a_{lb} = a_{lb-1} + a_{lb-j} = 2^{s-1}a_{lb-s} + a_{lb-j}$. This implies that

$$\begin{aligned} n &= 2^{s-1}a_{lb-s} + a_{lb-j} \le 2^{s-1}(a_{lb-s-1} + a_{lb-s-2}) + 2^{lb-j-(lb-k)}a_{lb-k} \\ &\le 2^{s-1}(2^{k-s-1}a_{lb-k} + 2^{k-s-2}a_{lb-k}) + 2^{k-j}a_{lb-k} \\ &= (2^{k-2} + 2^{k-3} + 2^{k-j})a_{lb-k}. \qquad \text{(Note: } s+2 \le k\text{)}. \end{aligned}$$

If $j \ge 3$, then $2^{k-2} + 2^{k-3} + 2^{k-j} < 2^{k-1} + 1$, and $n < n$. The only possibility is $j = 2$.

Consider $n = a_{lb} = \boldsymbol{a_{lb-1} + a_{lb-2}}$. Since $1 \le s < 2$, it follows that $s = 1$, and $a_{lb-1} \le a_{lb-2} + a_{lb-3}$. There are two cases for step $lb - 1$.

(i) $a_{lb-1} = a_{lb-2} + a_{lb-h}$. (Note: $h < k$. If $h = k$, then $n < n$.)

If $h = 2$, then 3 divides n. Thus, $a_{lb} = a_{lb-1} + a_{lb-2} = 2a_{lb-2} + a_{lb-h}$, where $h \ge 3$. Suppose there is a nondoubling between step $lb - h$ and step $lb - 2$. Suppose $lb - p$ is the first nondoubling going back in the chain from step $lb - 2$. Then $2 \le p < h$.

$$\begin{aligned} a_{lb} &= a_{lb-1} + a_{lb-2} = 2a_{lb-2} + a_{lb-h} = 2(2^{p-2}a_{lb-p}) + a_{lb-h} \\ &\le 2(2^{p-2}(a_{lb-p-1} + a_{lb-p-2})) + a_{lb-h}. \\ &\le 2^{p-1}(2^{k-p-1}a_{lb-k} + 2^{k-p-2}a_{lb-k}) + 2^{k-h}a_{lb-k} \\ &= (2^{k-2}a_{lb-k} + 2^{k-3}a_{lb-k}) + 2^{k-h}a_{lb-k} \\ &= (2^{k-2} + 2^{k-3} + 2^{k-h})a_{lb-k} < n \quad \text{since } h \ge 3. \end{aligned}$$

Thus, $a_{lb-2} = 2^{h-2}a_{lb-h}$ and $a_{lb} = a_{lb-1} + a_{lb-2} = 2a_{lb-2} + a_{lb-h} = 2(2^{h-2}a_{lb-h}) + a_{lb-h} = (2^{h-1}+1)a_{lb-h}$. This implies that $2^{h-1}+1$ divides n.

(ii) $a_{lb-1} = 2a_{lb-3}$. $n = a_{lb} = a_{lb-1} + a_{lb-2} = a_{lb-2} + 2a_{lb-3}$.

Then $n = a_{lb-2} + 2a_{lb-3} \le 2^{k-2}a_{lb-k} + 2(2^{k-3}a_{lb-k}) = 2^{k-1}a_{lb-k} < 2^{k-1}(n/(2^{k-1} + 1)) < n$.

This establishes the result that if n is not divisible by an integer of the form $2^i + 1, i \ge 0$, then the sequence (D) is a valid class 1 bounding sequence when generating addition chains for an integer n.

THEOREM 5. *If $2^j+1, j \ge 0$ does not divide n and $\{b_i\}$ denotes bounding sequence* (D), *then if $a_i < b_i$ for some i, $\mathrm{br}[a_i]$ can be pruned from the search tree.*

It appears that this result can generalized for $n = 2^t m$ (m odd) using the following bounding sequence.

$$\text{(E)} \qquad b_i = \begin{cases} \lceil n/2^t(2^{lb-t-(i+1)} + 1) \rceil & 0 \le i \le lb - t - 2, \\ \lceil n/2^{lb-i} \rceil & lb - t - 1 \le i \le lb. \end{cases}$$

Theorem 5 then would be restated substituting $j > 0$ for $j \ge 0$ and bounding sequence (E) for bounding sequence (D).

The numbers $23, 127, 191$, and 607 in Table 1 satisfy the hypothesis of Theorem 5. Table 2 shows results of using bounding sequence (D) for the vertical bounding sequence. Certain rows of the table use what is called VBEST for the vertical bounding sequence and bounding sequence (C) for slant bounds. VBEST is a bounding sequence that is obtained à posteriori by running the program and generating all minimal addition chains for n. For each i, b_i is the minimal a_i found among all the minimal addition chains for n. It is the best possible vertical bounding sequence, since lowering any b_i will cut out some of the minimal chains for n. In practice it is not a good bounding sequence since it cannot be determined until all the minimal addition chains have been found, but it is a good measure by which to judge the other vertical bounding sequences. As previously noted, bounding sequence (C) reduces to bounding sequence (B) when n is odd.

The V(D)/S (C) bounding sequence compares favorably with the VBEST/S (C) bounding sequence, and in all cases there is significant improvement over using just V(A) which is the obvious bounding sequence to try first.

While vertical bounding sequence (D) leads to a significant improvement in pruning the search tree, this sequence can only be used when n is not a multiple of an integer of the form $2^i + 1$. In other words, if n is a multiple of an integer of the form 2^i+1, then less aggressive pruning bounds must be used. More branches on the search tree must be explored. The search for minimal addition chains for such numbers is, in a sense, less efficient. Primes, on the other hand, (unless they are Fermat primes) can use bounding sequence (D) which results in a more efficient search.

A summary of the bounding sequences is included in Table 3.

10. Some test results. Algorithms for generating minimal length addition chains are significant from the standpoint of what their implementation in a computer program and the subsequent generation of data reveal about the addition chain

[3]For $n = 1015$, in the V/S (C) and VBEST/S(C) cases bounding sequence (A) is used for the slant bounds since n is divisible by 5. Also, sequence (D) cannot be used for vertical bounds since n is a multiple of 5.

TABLE 3

Bounding sequence	Sequence	Comments
A	$b_i = \lceil n/2^{lb-i} \rceil, i = 0, \ldots, lb$	vertical/slant bounds
B	$b_i = \begin{cases} \lceil n/(3 \cdot 2^{lb-(i+2)}) \rceil, & 0 \le i \le lb-2 \\ \lceil n/2^{lb-i} \rceil, & lb-1 \le i \le lb \end{cases}$	n odd, vertical bounds, slant bounds for $n \neq 5k$
C	$b_i = \begin{cases} \lceil n/(3 \cdot 2^{lb-(i+2)}) \rceil, & 0 \le i \le lb-t-2 \\ \lceil n/2^{lb-i} \rceil, & lb-t-1 \le i \le lb \end{cases}$	$n = 2^t m$, m odd, vertical bounds, slant bounds if $n \neq 5k$ and $n \neq 2^{lb-i} a_i$ for $i \ge lb-t-2$
D	$b_i = \begin{cases} \lceil n/(2^{lb-i-1}+1) \rceil, & 0 \le i \le lb-1 \\ n, & i = lb \end{cases}$	n odd, vertical bounds $n \neq (2^j+1)k$, $j \ge 0$
E	$b_i = \begin{cases} \lceil n/2^t(2^{lb-t-(i+1)}+1) \rceil, & 0 \le i \le lb-t-2 \\ \lceil n/2^{lb-i} \rceil, & lb-t-1 \le i \le lb \end{cases}$	$n = 2^t m$, m odd, vertical bounds $n \neq (2^j+1)k$, $j > 0$

problem. Knuth [12] found that $l(191) = l(382)$. He found other integers as well for which $l(2n) = l(n)$. This was a somewhat surprising discovery. Utz [20] had asked if $l(n) < l(2n)$ for all $n > 0$, and it had supposedly been proved earlier by Jonquières [11] that $l(2n) = l(n) + 1$. Subsequently, it has been proved [17, 18] that there are infinite classes of integers for which $l(2n) = l(n)$. If $h(x)$ denotes the number of integers $n \le x$ for which $l(2n) = l(n)$, then computer generated data suggest the possibility that $h(x)$ is bounded below by some constant times x.

While Hansen [10] proved that there exist integers that do not admit star chains among their minimal addition chains, Knuth's computer calculations revealed $n =$ 12,509 as the first number that does not admit a star chain among its minimal chains. It is very likely that $\{2^m(81) + 17, m \ge 8\}$ is an infinite class of such integers.

The addition chain problem is exponential in nature [8]. Improving pruning algorithms enables one to generate the next level of data which can reveal properties that had not previously been observed. For example, $n = 49{,}593$ and $n = 49{,}594$ are adjacent integers, neither of which has a star chain among its minimal chains. $n = 13{,}818$ and $n = 27{,}578$ are even numbers for which $l(2n) = l(n)$. If $n = 2k$, this is an example of an integer for which $l(4k) = l(2k)$. Are there integers for which $l(8k) = l(4k)$? The pairs $n = 22{,}453$, $n = 22{,}455$ and $n = 25{,}019$, $n = 25{,}021$ have the property that $l(2n) = l(n)$. Are there consecutive integers with this property? $n = 29{,}479$ is an integer, all of whose minimal chains start with $1, 2, 3$ which verifies a conjecture of Chin and Tsai [5]. Such integers appear very rarely. The first integer with over 1,000,000 minimal addition chains is 15,126. In fact, NMC(15, 126) $= 1{,}047{,}580$.

Knuth found $c(r)$, the first integer for which $l(n) = r$, for $1 \le r \le 18$. The algorithms discussed in the paper were instrumental in determining that $c(19) =$ $18{,}287, c(20) = 34{,}303, c(21) = 65{,}131$. Flammenkamp and Bleichenbacher have extended this sequence to $c(22) = 110{,}591$, $c(23) = 196{,}591$, $c(24) = 357{,}887$, $c(25) =$ $685,951$, $c(26) = 1,176,431$, and $c(27) = 2,211,837$. See [12] and the online version of [15]. $n = 65{,}131$ is the first integer that requires six small steps in a minimal addition chain. The increase in the required number of small steps in an addition chain greatly increases the computing time. Table 4 shows how the computing time increases with the number of small steps while $\lambda(n)$ is held constant. It also shows how the computing time increases with $\lambda(n)$ while holding the number of small steps constant.

TABLE 4

n	binary n	$\lambda(n)$	number of small steps in chain	pops time

Holding $\lambda(n)$ constant for odd n, while increasing the number of small steps, greatly increases the computing time. As the number of ones in the binary representation of n increases, the number of small steps increases in minimal addition chains for n. In fact $N(n)$, the number of small steps, appears to be bounded below by $\lceil \log_2 \nu(n) \rceil$. As can be seen, computation time is influenced much more strongly by the size of $\nu(n)$ than by the size of n. The minimal addition chains for $n = 1{,}048{,}577$ can be found much more quickly than the minimal addition chains for $n = 191$.

Increasing $\lambda(n)$, while holding the number of small steps constant, increases the computation time relatively slowly. Numbers of the form $n = 2^t m$ for m odd and $t \geq 1$ have longer computation times than odd integers with the same values of $\lambda(n)$ and $N(n)$. As t increases with $\lambda(n)$ and $N(n)$ held constant, the computing time increases. An examination of pruning bounds (C) shows that the bounds are less severe for integers with a large value of t.

The pruning bounds operate the best on odd integers not divisible by 5 and, in particular, on odd integers not divisible by integers of the form $2^i + 1, i \geq 1$.

Data generated by this algorithm have suggested theorems concerning NMC(n), some of which have been established in [19]. These mathematical proofs indirectly confirm the validity of the programs that generated the data that suggested the theorems.

11. Conclusion. The pruning bounds that have been developed significantly improve the efficiency of the search for minimal length addition chains for an integer. It is of interest to note that, for multiples of $2^i + 1$, the pruning bounds cannot be as tight. As can be seen, the best general vertical bounds compare favorably with the VBEST vertical bounds for the examples cited in Table 2.

Introducing slant bounds (bounds for $a_i + a_{i-1}$) increases the efficiency of the search. This class of bounds can be extended to bounds for $a_i + a_{i-2}$ and $a_{i-1} + a_{i-1}$ and perhaps other sums. It appears likely, however, that improvements in efficiency are slight and are negated by the time needed to run all the checks on the additional bounds.

The most famous unsolved problem in addition chains is the Scholz–Brauer con-

jecture which states that $l(2^n-1) \leq n+l(n)-1$. Brauer [4] proved that the conjecture is true when n includes a star chain among its minimal chains. Hansen [10] developed the concept of l^0-chains of which star chains are a proper subset. He proved that the Scholz–Brauer conjecture is true if n includes an l^0-chain among its minimal chains. It remains an open question as to whether every integer includes an l^0-chain among its minimal chains. Computer searches may prove useful in helping to settle this question.

Acknowledgments. This paper has benefited from fruitful discussions with Khalaf Haddad, a former student, and Dan Eilers, president of Irvine Compiler Corporation.

DISTRIBUTIONAL WORD PROBLEM FOR GROUPS*

JIE WANG†

Abstract. This paper studies the word problem for finitely presented groups under the restriction that words can only be rewritten for a bounded number of times. We obtain a similar result to the Novikov–Boone theorem in the setting of average-case NP-completeness. The word problem we consider here is to decide, when given a finite presentation of a group G, words x, y, z, and an integer k, whether $(x^{-1}yx)z$ can be derived from $z(x^{-1}yx)$ in the presentation of G in k steps. We show that when each component of the instance is chosen uniformly at random, the problem cannot be solved fast on average unless every NP problem under every reasonable distribution on instances can be solved fast on average.

Key words. average-case NP-completeness, finitely presented groups, word problem

1. Introduction.

The notion of NP-completeness, introduced by Cook [6] and independently by Levin [19], captures the intrinsic complexity of certain computational problems that are difficult to solve but whose solutions are easy to verify. Karp [17] introduced the methodology of many–one reductions and demonstrated the rich variety of NP-complete problems. By 1979, several hundred additional NP-complete problems were discovered [8]. Since then, many more problems from almost all areas involving computing have been identified as NP-complete.

Despite many years of intensive effort, no efficient algorithms have been found that can solve any NP-complete problem, and so NP-complete problems are generally thought of as being computationally intractable. However, NP-completeness is a worst-case concept. Being NP-complete does not provide information about how difficult a problem might be on the average case. Indeed, several NP-complete problems have been shown to be tractable "on average." For example, although Hamiltonian Path is NP-complete, Gurevich and Shelah [13] showed that if a graph is chosen under a commonly used distribution on random graphs, then the Hamiltonian Path problem can be solved by a deterministic algorithm in expected linear time. Thus, the average-case complexity of a problem is, in many respects, a more significant measure than its worst-case complexity.

Given a decision problem and a probability distribution on instances—such a pair is called a *distributional problem*—it is an important issue to either find an expected polynomial-time algorithm to solve the problem or prove that such an algorithm does not exist. Levin [20] provided two central notions for studying this issue. One is analogous to the class P and provides an *easiness* notion; the other is analogous to the class of NP-complete sets and provides a *hardness* notion. For the first, Levin defined a robust notion of what it means for the running time of an algorithm to be polynomial on average. For the second, Levin defined deterministic many–one reductions that preserve average-polynomial-time solvability. With this machinery in place,

a distributional problem is *average-case NP-complete* if the decision problem component belongs to NP and every distributional problem consisting of an NP problem and a reasonable distribution[1] is reducible to it. Levin [20] showed that distributional *tiling* with a simple distribution is average-case NP-complete, and so it cannot be solved fast on average unless every NP problem under every reasonable distribution can be solved fast on average.

It is considerably more difficult to obtain average-case completeness results than to obtain worst-case completeness results. Reductions that work for the worse case often do not work for the average case. For the reduction to work for the average-case completeness, the probability distribution of the target instance obtained from the reduction cannot be too small compared with that of the source instance. So far only a handful of distributional problems has been shown to be average-case NP-complete. These problems are the distributional tiling [20], halting [12], Post correspondence [9, 12], graph edge coloring [27], matrix transformation [4, 11], matrix representability [28], and string rewritings for semigroups [32]. To advance the theory of average-case NP-completeness, it is essential to identify a greater number of average-case NP-complete problems from various areas, which will also help develop the methodology of reductions to provide tools for proving average-case completeness results. This task is challenging and is a major concern in the research of average-case NP-completeness.

We contribute to the variety of the list of average-case NP-complete problems by showing that the distributional word problem for finitely presented groups is average-case NP-complete. This result may be interesting in its own right in group theory; for we show that, for all practical purposes, some elementary questions about finitely presented groups cannot be answered in average polynomial time, although they can be answered in deterministic exponential time. This paper is the full version of the extended abstract presented in [29].

The word problem for groups was first considered by Dehn [7] and Thue [25], which is to decide, when given a group G and words x, y, whether x is equivalent to y in G. The solution was given by Novikov [22] and, independently, by Boone (1954–1957), who showed that there exists a finitely presented group with an unsolvable word problem. In 1959, Boone [5] exhibited a much simpler group than any of those previously given, and he proved that it has an unsolvable word problem. In 1963, Britton proved Britton's lemma in the course of simplifying and shortening Boone's proof. Further improvements were made afterward by Boone, Collins, and Miller (see [24] for these citations). Groups that have finite presentations have nice combinatorics properties (see, for example, [21]). Moreover, a finite presentation of a group can be read in as an input to an ordinary computer. A possible application of the word problem in public-key cryptography was discussed in [33].

Let $X = Y$ be a relation given in a finite presentation of a group. Then $X^{-1}Y$, XY^{-1}, $Y^{-1}X$, and YX^{-1} are called relators. One can obtain an equivalent word by inserting or deleting a relator at any point on a given word. We assume that rewriting one symbol in a word takes one step. The word problem we consider here is to decide, when given a finite presentation of G, words $x,\ y,\ z$, and an integer k, whether $(x^{-1}yx)z$ can be derived from $z(x^{-1}yx)$ in the presentation of G in k steps. We show that when each component of the instance is chosen uniformly at random, the distributional word problem is average-case NP-complete. We prove it using a deterministic many–one reduction based on the Boone lemma.

[1] By reasonable distribution we mean a distribution that is polynomial-time computable or is dominated by a distribution that is polynomial-time computable. See section 2 for the definition.

This paper is structured as follows. Basic definitions and results of average-case NP-completeness are given in section 2. We define a distributional word problem for finitely presented groups in section 3. In section 4, we briefly outline the Boone–Collins–Miller proof of the Novikov–Boone theorem, which provides building blocks of our completeness proof. The completeness proof is then given in section 5. Some related results are given in section 6.

2. Preliminaries. We provide, in this section, basic definitions and results of average-case complexity theory that we will use in this paper. Motivations regarding the definitions will also be discussed. For a recent survey on average-case complexity theory, the reader is referred to Wang's article [30].

We use the binary alphabet $\Sigma = \{0, 1\}$ for encoding strings. Denote by $|x|$ the length of a binary string x. A *probability distribution* μ is a real-valued function from Σ^* to [0,1] such that $\sum_x \mu(x) = 1$. We assume that μ on the empty string is always 0. We may also use *distribution*, *probability*, *weight*, or *density* to denote probability distribution. The probability distributions we consider are on instances of computational problems. If a binary string does not encode an instance of the underlying problem, then that string has zero probability. The *distribution function* of μ, denoted by μ^*, is defined by $\mu^*(x) = \sum_{y \le x} \mu(y)$, where $\le$ is the standard lexicographical order on Σ^*. For a set $A = \{x : \phi(x)\}$, we use $\mu[\phi(x)]$ or $\mu[A]$ to denote $\sum_{x \in A} \mu(x)$, and we use $|A|$ to denote its cardinal. The conditional distribution of μ on a set A is equal to $\mu(x)/\mu[A]$ if $x \in A$ and $\mu[A] > 0$, and 0 otherwise. For a function f, we use $f^{\varepsilon}(x)$ to denote $(f(x))^{\varepsilon}$ for $\varepsilon > 0$ and we use f^{-1} to denote the inverse of f. We use $\mathbb{R}^+$ to denote the positive reals and $\mathbb{N}$ the natural numbers.

2.1. Average polynomial time. One would naturally intend to measure average-case efficiency of an algorithm using expected polynomial time. An algorithm runs in *expected polynomial time* over a probability distribution μ if there exist $k \ge 0$ such that for all n, $\sum_{x,|x|=n} t(x)\mu_n(x) \le O(n^k)$, where $t(x)$ is the running time of the algorithm on x, and $\mu_n(x)$ is the conditional distribution of μ on strings of length n. However, this definition is machine dependent and so cannot be used to build a robust theory. To define a robust measure of average time, we need to take care of the following subtle and important issues. These issues were either mentioned explicitly or hinted at by Levin [20], and various aspects of the issues have been elaborated on, for example, by Johnson [16], Gurevich [10, 12], Venkatesan [26], and Impagliazzo [14]. From this, Levin's notion of average polynomial time (given here as Definition 2.1) can be derived naturally and can be well justified.

Model independence. Let $\Sigma^n = \{x : |x| = n\}$. Let A be a subset of Σ^n and $|A|$ be proportional to $2^n(1 - 2^{-0.1n})$. Suppose an algorithm runs in polynomial time on every $x \in A$, and runs in $2^{0.09n}$ time on every $x \in \Sigma^n - A$. Then it is easy to see that the expected running time on strings of length n is bounded above by a polynomial in n. However, the expected running time will be exponential in a machine model that is quadratically slower. If a problem is easy on average in one model of computation, then it should be easy on average in all polynomially equivalent models. Even within the same model, if t is polynomial on average, then for any $k > 0$, t^k should also be polynomial on average. Moreover, if a problem is

polynomial on average under one encoding method, then it should be polynomial on average under all polynomially equivalent encodings.

Balancing. Let A be a subset of Σ^n and $|A|$ be proportional to $2^n(1-n^{-2})$. Suppose an algorithm solves a problem in polynomial time on every $x \in A$. Then we still have no guarantee of an algorithm that is fast on average, since the algorithm may take exponential time to solve the instances in $\Sigma^n - A$. A balance is therefore required between the portion of hard instances and the hardness of these instances. The portion of the hard instances should be polynomially related to the time needed to solve them. Clearly, it is at least necessary that only a subpolynomial portion of instances should require superpolynomial time, though this will not in general be sufficient.

Under the average-case measurement, an efficient algorithm with input distribution μ is allowed to run a longer time on instances with smaller weights. One may measure the "rareness" of instances by a real-valued function $r\colon \Sigma^+ \to \mathbb{R}^+$, defined in such a way that if the weight of an instance x is smaller, then the value of its rareness $r(x)$ is larger. As discussed above regarding the balancing issue, the portion of inputs x with high values of rareness should be small. Probably the most general way to satisfy this requirement is to have, for some positive constants k and c and for all $l \in \mathbb{R}^+$, $\mu[r(x) > l^k] < c/l$ or, equivalently, $\sum_x r^\varepsilon(x)\mu(x) < \infty$ for some $\varepsilon > 0$.[2] One may then measure the average-case running time of an algorithm on input x as a function of $|x|r(x)$ rather than $|x|$. This captures and formalizes the idea that a longer time is allowed on inputs with smaller weights, and it also guarantees model independence. The running time t of an algorithm is said to be *polynomial on average* if there exists a $k > 0$ such that, for all x, $t(x) \le (|x|r(x))^k$. Hence, $t^{1/k}(x)|x|^{-1} \le r(x)$. Let $\delta = \min\{\varepsilon, 1\}$. Then $\sum_x t^{\delta/k}(x)|x|^{-1}\mu(x) \le \sum_x (t^{1/k}|x|^{-1})^\delta \mu(x) < \sum r^\delta(x)\mu(x) < \infty$. This gives rise naturally to the following definition given by Levin [20].

DEFINITION 2.1. *A function $f\colon \Sigma^+ \to \mathbb{N}$ is* polynomial on μ-average *if there exists an $\varepsilon > 0$ such that $\sum_x f^\varepsilon(x)|x|^{-1}\mu(x) < \infty$.*

Definition 2.1 is model independent and encoding independent. It satisfies the balancing requirement as shown in footnote 2, based on that the following lemma is straightforward.

LEMMA 2.2. *A function f is polynomial on μ-average iff there are constants $k > 0$ and c such that, for all $l \in \mathbb{R}^+$, $\mu[f(x) > (l|x|)^k] < c/l$.*

Clearly, every polynomial is polynomial on average with respect to any distribution μ. If a function f is an expected polynomial over a distribution μ, then f is polynomial on μ-average. If f and g are polynomial on μ-average, then so are $\max(f, g)$, $f + g$, $f \cdot g$, and f^l for any positive real number l [12].

Let A be a problem and μ be a distribution on instances of A. Then (A, μ) is called a *distributional problem*. A distributional problem (A, μ) is solvable in average polynomial time if A can be solved by a *deterministic* algorithm whose running time is polynomial on μ-average. (A, μ) is called a *distributional decision problem* if A is a decision problem. We will focus on distributional decision problems in this paper; for simplicity, we will omit the word "decision" hereafter.

Let (D, μ) denote a distributional problem, where D is the set of all positive instances x with $\mu(x) > 0$. The problem is to decide, for a given instance x

[2] To see the equivalence, assume that $\mu[r(x) > l^k] < c/l$. Let $\varepsilon = \frac{1}{2k}$. Then, for all $l \in \mathbb{R}^+$, $\mu[r^\varepsilon(x) > l] < c/l^2$, and so $\sum_x r^\varepsilon \mu(x) \le \sum_{n=1}^\infty n\mu[n-1 < r^\varepsilon(x) \le n] = \sum_{n=0}^\infty \mu[r^\varepsilon(x) > n] < \infty$. The other direction is straightforward by a simple application of Markov's inequality.

with $\mu(x) > 0$, whether $x \in D$. If $D \in$ NP, then (D, μ) is called a distributional NP problem.

Denote by AP the class of all distributional problems that are solvable in average polynomial time.

REMARK 2.1. One may impose certain restrictions on the expressions that define average computation time. One such restriction [23] requires that the expressions that define average computation time be converged not just on one distribution but on all distributions of the same rank. Belanger and Wang [1] showed that the class of distributional NP problems defined with respect to the ranking of distributions does not provide harder problems than standard average-case NP-complete problems.

2.2. Polynomial-time reductions. Given two distributional problems, we wish to know which one is computationally more difficult. A standard technique for such comparisons is to find a reduction from one problem to another.

Let f be a function with input distribution μ. It is reasonable to define the output distribution on y, denoted by $f(\mu)(y)$, to carry all the weights of those instances x with $f(x) = y$. Namely, for all $y \in \text{range}(f)$, $f(\mu)(y) = \sum_{f(x)=y} \mu(x)$. Denote by $f^*(\mu)$ the distribution function of $f(\mu)$, so $f^*(\mu)(y) = \sum_{f(x)\leq y} \mu(x)$. Reductions f from (A, μ) to (B, ν) should be closed for AP, meaning that if $(B, \nu) \in$ AP then so is (A, μ). One way to guarantee this is to require that f efficiently reduces A to B as in the worst case and that it should not reduce an instance of A that has a large probability to an instance of B that has a very small probability. This means that the induced weight on the output $y = f(x)$ should be bounded above (within a polynomial factor) by the weight on y according to the distribution of B. Namely, $f(\mu)(y) \leq |y|^{O(1)}\nu(y)$.[3] If $|y| \leq |x|^{O(1)}$, it follows that there exists a distribution μ_1 such that, for all x, it holds that $\mu(x) \leq |x|^{O(1)}\mu_1(x)$ and $\nu(f(x)) = f(\mu_1)(f(x))$,[4] which turns out to be sufficient for defining reductions. The following definitions are due to Levin [20], and we state them following Gurevich [12].

DEFINITION 2.3. *Let μ and ν be distributions. Then μ is* dominated by ν*, written as $\mu \preceq \nu$, if there exists a polynomial p such that, for all x, $\mu(x) \leq p(|x|)\nu(x)$.*

DEFINITION 2.4. *Let μ and ν be distributions on instances of the decision problems A and B, respectively, and let f be a reduction from A to B. Then μ is* dominated by ν with respect to f*, written as $\mu \preceq_f \nu$, if there exists a distribution μ_1 on A such that $\mu \preceq \mu_1$ and $\nu(y) = f(\mu_1)(y)$ for all $y \in \text{range}(f)$, i.e., $\nu(y) = \sum_{f(x)=y} \mu_1(x)$.*

DEFINITION 2.5. *(A, μ) is* polynomial-time reducible *to (B, ν) if there is a polynomial-time computable reduction f such that for all x, $x \in A$ iff $f(x) \in B$, and $\mu \preceq_f \nu$.*

It is straightforward to see that, if a reduction f is one to one, then $\mu \preceq_f \nu$ iff $\mu \preceq \nu \circ f$ [12]. This observation is useful in proving completeness results. In the sequel, we will often use "p-time" to denote "polynomial-time." The following lemma is straightforward and a proof can be found, for example, in [12, 30].

LEMMA 2.6. (1) *If (A, μ) is p-time reducible to (B, ν) and (B, ν) is in* AP*, then so is (A, μ).* (2) *The p-time reductions are transitive.*

[3] Actually, we are dealing with the conditional probability distribution $\nu[y|Y]$ with $Y = \text{range}(f)$. Since $\nu[y|Y] = \nu(y)/\nu[Y]$ and $\nu[Y]$ is a positive constant, this is equivalent to using $\nu(y)$ in the inequality.

[4] The converse is also true if $|x|$ is bounded by a polynomial in $|f(x)|$ [12].

2.3. Polynomial-time computable distributions. Let (D, μ) be a distributional NP problem. If every other distributional NP problem is p-time reducible to it, then (D, μ) is average-case complete. In order for such a complete problem to exist, a certain condition on allowable distributions is needed.[5] Levin [20] suggested that it is reasonable to require distributions to be p-time computable. A real-valued function $f : \Sigma^* \to [0, 1]$ is p-time computable [18] if there is a deterministic algorithm which, on every string x and every positive integer k, outputs a finite binary fraction y in time bounded by a polynomial in $|x|$ and k and such that $|f(x) - y| \leq 2^{-k}$. Clearly, if μ^* is p-time computable then so is μ. Blass showed that the converse is not true unless P = NP (see [12]). With this fact in mind, we assume throughout this paper that when we say that a distribution μ is p-time computable we mean that both μ and μ^* are p-time computable.

Levin (see [16]) hypothesized that any natural distribution μ is either p-time computable or is dominated by a p-time computable distribution. Strong evidence that supports this hypothesis is the fact that all the commonly used discrete distributions do satisfy this hypothesis.

Denote by DistNP the class of all distributional NP problems (D, μ) such that $\mu \preceq \nu$ for some p-time computable distribution ν. By Levin's hypothesis, DistNP includes all natural distributional NP problems. A distributional problem (A, μ) is called *average-case* NP-*complete* (or *complete for* DistNP) if $(A, \mu) \in$ DistNP and every other distributional problem in DistNP is p-time reducible to (A, μ).

REMARK 2.2. Distributions μ that are p-time computable are *p-sampleable* [10, 2] meaning that there is a probabilistic algorithm that, without reading any input, outputs x with probability $\mu(x)$ in time polynomial in $|x|$. Although there are p-sampleable distributions that are not p-time computable under the assumption that one-way functions exist [2], Impagliazzo and Levin [15] showed that for NP search problems, p-sampleable distributions do not generate harder instances than simply picking instances uniformly at random. In particular, they showed that for any distributional NP search problem (A, μ), where μ is p-sampleable, there is a distributional NP search problem (B, ν), where ν is a p-time computable, uniform distribution, such that (A, μ) is reducible to (B, ν) under a randomized reduction.[6] For decision problems, the same result can be obtained using a randomized truth-table reduction [2] (see also [30]). Hence, as far as average-case NP-completeness is concerned, it is sufficient to focus on distributions that are p-time computable.

2.4. Uniform distributions. Distributions may be defined on all binary strings by first selecting lengths and then selecting strings of that length. Although it is mathematically impossible to select strings with equal chance from an infinite sample space, strings of the same length can be selected with equal likelihood. It is also impossible to select integers from $\mathbb{N}$ with the same probability, but one can select an integer with a probability close to being "uniform." A p-time computable distribution μ on Σ^* is called *uniform* if for all x, $\mu(x) = \pi(|x|)2^{-|x|}$, where $\sum_n \pi(n) = 1$ and there is a polynomial p such that for all but finitely many n, $\pi(n) \geq 1/p(n)$.

It is important to note that for the purpose of proving completeness results, $\pi(n) \geq 1/p(n)$ is the only requirement needed since domination allows a polyno-

[5] If arbitrary distributions are allowed, Wang and Belanger [31] showed that no complete distributional problems can exist with respect to one-to-one p-time reductions.

[6] We will only use deterministic reductions in this paper. Randomized reductions are weaker reductions that can be used to establish completeness results when deterministic reductions are not applicable [9, 12, 27, 32].

mial factor, and so some longer strings can certainly be given more weights than shorter ones. Levin [20] used n^{-2} for $\pi(n)$ for notational convenience (normalized by dividing by $\sum_n n^{-2} = \pi^2/6$), and $|x|^{-2}2^{-|x|}$ is often referred to as the default uniform distribution.

2.5. Distribution controlling lemma. Let μ be a p-time computable distribution. Then μ is dominated (with respect to p-time computable functions) by uniform distributions, which is an important property for proving completeness results. Levin [20] first proved this property using a "perfect rounding" technique. Gurevich [12] provided a different and easier proof, based on that Wang and Belanger [32] further showed that if $\mu(x) \geq 2^{-p(|x|)}$ for some fixed polynomial p, then μ will also dominate the same uniform distribution within a constant factor.

LEMMA 2.7 (distribution controlling lemma). *Let μ be a p-time computable distribution.*

1. *There exists a total, one to one, p-time computable, and p-time invertible function $\alpha\colon \Sigma^* \to \Sigma^*$ such that for all x, $\mu(x) < 4 \cdot 2^{-|\alpha(x)|}$.*
2. *If there exists a polynomial p such that for all x, $\mu(x) > 2^{-p(|x|)}$, then there is a total, one-to-one, p-time computable, and p-time invertible function $\beta\colon \Sigma^* \to \Sigma^*$ such that for all x, $4 \cdot 2^{-|\beta(x)|} \leq \mu(x) < 20 \cdot 2^{-|\beta(x)|}$.*

3. Finitely presented groups and word problems. A finite presentation of a group consists of a set of generators (abstract symbols) and a set of relations that relate the freely generated words. To be precise, let A be a finite set. The free group $[A]$ is a group including all elements that can be uniquely written as a reduced *word* in the form $a_1^{\pm}a_2^{\pm}\cdots a_n^{\pm}$, where $a_i \in A$, $a_i^{\pm}$ represents a_i or a_i^{-1}, and no a_i appears adjacent to a_i^{-1}. When $n = 0$, we get the empty word e, which is the identity of the group. A word is positive if it does not contain negative exponents. The empty word e is regarded as a positive word. Positive words are also called strings. Words are multiplied by juxtaposing with all expressions $a_i a_i^{-1}$ and $a_i^{-1}a_i$ canceled out until a reduced word is obtained. For each word w, the inverse word w^{-1} consists of all the symbols of w written in reverse order, where each a_i is replaced by a_i^{-1} and each a_i^{-1} is replaced by a_i.

A relation on A is an expression $X = Y$, where X and Y are words on A. Let R be a finite set of relations on A. Let $\mathcal{K}_R$ denote the normal subgroup of $[A]$ generated by the XY^{-1} for $X = Y \in R$. A group G has a set of generators A and a set of relations R on A if G is isomorphic to the quotient group $[A]/\mathcal{K}_R$. A and R form a finite presentation of G, denoted by $[A; R]$. We extend the notation $[A; R]$ to allow several generators or sets of generators before the semicolon and several relations or sets of relations after the semicolon.

A quantifier may also be used to describe a bunch of similar relations in a compressed form. For instance, $\forall x \in A : x^3 = x^2$ represents relations $a_i^3 = a_i^2$ for $i = 1, 2, \ldots, n$. In this case, we say that $a_i^3 = a_i^2$ for a given i is a relation specified by the quantified statement $\forall x \in A : x^3 = x^2$. For simplicity, we use the term "quantified relation" for such a quantified statement.

Recall that if $X = Y$ is a relation, then XY^{-1}, $X^{-1}Y$, YX^{-1}, and $Y^{-1}X$ are called relators. Obviously, if a is a generator, then aa^{-1} and $a^{-1}a$ are relators. Let u and v be (not necessarily reduced) words. Then $u \equiv v$ means that u and v have exactly the same spelling. An equivalent word can be obtained by eliminating or introducing relators at any point on the original word. We define the following elementary transformations (rewriting rules) for a finite presentation $[A; R]$ of a group, denoted by $\leftrightarrow_R$, where $\leftrightarrow_R$ is a symmetric operation.

DEFINITION 3.1. *Let y be a relator.*

1. *If x is an empty word, then $x \leftrightarrow_R y$.*
2. *If x is not empty and $X \equiv x_1x_2$ (x_1 or x_2 could be possibly null), then $x \leftrightarrow_R x_1yx_2$.*
3. *If $x \equiv x_1Xx_2$, $x' \equiv x_1X^{-1}x_2$ (x_1 and x_2 could be possibly null), and $X = Y$ is a relation, then $X \leftrightarrow_R x_1Yx_2$ and $x' \leftrightarrow_R x_1Y^{-1}x_2$.*

We assume that rewriting one symbol in a word takes one step. So if $u \leftrightarrow_R v$, then it will take at most $\max\{|u|, |v|\}+O(1)$ steps to derive v from u, or derive u from v. Also, if $x \equiv a_1^{\pm} \cdots a_m^{\pm}$, where each a_i is a symbol, then obtaining $x^{-1} = a_m^{\mp} \cdots a_1^{\mp}$ takes $O(\Sigma_{i=1}^m |a_i|)$ steps. Operations like this that do not involve relations are referred to as group operations.

DEFINITION 3.2. *Let $[A; R]$ be a finite presentation of a group. Let u and v be two words on A. Then u can be obtained from v in n elementary transformations in $[A; R]$, written as $u \overset{n}{\longleftrightarrow}_R v$, if there are words $u_1, \ldots, u_{n-1}$ on A such that $u \leftrightarrow_R u_1 \leftrightarrow_R \cdots \leftrightarrow_R u_{n-1} \leftrightarrow_R v$. Write $\overset{*}{\longleftrightarrow}_R$ to denote $\overset{k}{\longleftrightarrow}_R$ for some k. Write $u =_k v$ (in $[A; R]$) if v can be derived from u in k steps using relations in R and group operations.*

The subscript R is often omitted from $\leftrightarrow_R$ when there is no confusion. Let G be a finitely presented group. Then G has many different finite presentations. The number of steps used in derivations depends on the presentation. Let $[A; R]$ and $[A'; R']$ be two different presentations of G. If $u =_k v$ in $[A; R]$ for some k, then $u =_{k'} v$ in $[A'; R']$ for some k'. When we are not concerned with the number of steps used in derivations, we simply write $u = v$ (in G) to denote $u =_k v$ in some presentation of G.

Let A be a finite set of binary strings $\{a_1, \ldots, a_m\}$. We use $\| A \|_0$ to denote $\sum_{i=1}^m |a_i|$ and $\| A \|_1$ to denote $\prod_{i=1}^m |a_i|$. For a presentation $[A; R]$, we assume that words over A and relations (with or without quantifiers) in R are properly coded as binary strings.

We consider the following distributional word problem for finitely presented groups, which is a slight modification of the original word problem of Dehn and Thue.

DEFINITION 3.3. *The* distributional word problem for groups *is the following decision problem.*

Instance: *A finite presentation $[A; R]$ of a group, binary strings u, v, w, and a unary notation 1^n representing positive integer n, where $A = \{a_1, \ldots, a_l\}$ of generators and $R = \{r_1, \ldots, r_m\}$ of relations (with or without quantifiers), all coded in binary form.*

Question: *Is $(u^{-1}vu)w =_k w(u^{-1}vu)$ in $[A; R]$ for $k \leq n$? ($u^{-1}vu$ is called a conjugation of u on v, denoted by $u \diamond v$.)*

Distribution: *Randomly and independently select positive integers l, m, n, and binary strings u, v, and w. Then randomly and independently choose binary strings $a_1, \ldots, a_l$ and $r_1, \ldots, r_m$. The random choices are made with respect to the default uniform distributions on positive integers and binary strings. Hence, the probability distribution is proportional to*

$$\frac{2^{-(\|A \cup R\|_0 + |u| + |v| + |w|)}}{(lmn|u||v||w| \ \| A \cup R \|_1)^2}.$$

The distributional word problem for groups is in DistNP, for we can first guess a bounded sequence of relations and the locations where elementary transformations will

be applied and then verify whether we have a correct guess. We will show in section 5 that the distributional word problem for groups is average-case NP-complete.

We can similarly define a word problem for semigroups, where we start with generators and relations (also called string-rewriting rules) as before but without the inverses. In defining equivalent strings we can only replace any occurrence of X by Y and vice versa, where $X = Y$ is a string-rewriting rule. We can similarly define elementary string-rewriting operation $\leftrightarrow$ and operation $\overset{k}{\longleftrightarrow}$, which are symmetric operations. A string-rewriting system (i.e., the set of all string-rewriting rules) serves as a bridge in our proof to link a Turing machine computation to a finite presentation of a group.

We want to know what kind of relations in a finitely presented group would make the bounded word problem difficult (or easy) to solve in average polynomial time. Clearly, for free groups, the word problem can be solved in linear time. We also note that for finitely generated groups with relations $ab = ba$ for all symbols a and b, the word problem can be solved in polynomial time. To identify relations that will make the word problem difficult to solve, we will first investigate, in the next section, undecidable word problems for finitely presented groups.

4. Undecidable word problem for groups. For the reader's convenience, we briefly outline the Boone–Collins–Miller proof of the Novikov–Boone theorem in exactly the same form presented by Rotman [24]. We first describe the Boone lemma.

Let Γ be a semigroup with the following finite presentation:

$$\Gamma = [q, q_1, \dots, q_N, s_1, \dots, s_M; F_i q_{i_1} G_i = H_i q_{i_2} K_i, i \in I],$$

where F_i, G_i, H_i, K_i are (possibly empty) positive words on $\{s_1, \dots, s_M\}$ and q_{i_1}, $q_{i_2} \in \{q, q_1, \dots, q_N\}$. Here $|I|$ is the number of relations in the presentation. (The q and s symbols will be used to represent states and nonstate symbols of some fixed Turing machine that accepts the halting problem.)

The following notation is convenient. Let $X \equiv a_1^{\epsilon_1} \cdots a_m^{\epsilon_m}$ be a (not necessarily positive) word; then $\overline{X} \equiv a_1^{-\epsilon_1} \cdots a_m^{-\epsilon_m}$. If X and Y are words on $\{s_1, \dots, s_M\}$, define

$$(X q_j Y)^* \equiv \overline{X} q_j Y,$$

where $q_j \in \{q, q_1, \dots, q_N\}$.

A word w is *special* if $w \equiv \overline{X} q_j Y$, where X and Y are positive words on $\{s_1, \dots, s_M\}$, and $q_j \in \{q, q_1, \dots, q_N\}$. We now present a finitely presented group G that has an undecidable word problem. G has generators

$$q, q_1, \dots, q_N, s_1, \dots, s_M, r_i, i \in I, \chi, \tau, \kappa,$$

and relations, for all $i \in I$ and $b = 1, \dots, M$,

$$\begin{aligned}
\chi s_b &= s_b \chi^2, \\
r_i s_b &= s_b \chi r_i \chi, \\
r_i^{-1} \overline{F}_i q_{i_1} G_i r_i &= \overline{H}_i q_{i_2} K_i, \\
\tau r_i &= r_i \tau, \\
\tau \chi &= \chi \tau, \\
\kappa r_i &= r_i \kappa, \\
\kappa \chi &= \chi \kappa, \\
\kappa(q^{-1} \tau q) &= (q^{-1} \tau q) \kappa.
\end{aligned}$$

LEMMA 4.1. (see [5]). *If w is a special word, then $k(w^{-1}tw) = (w^{-1}tw)k$ in G iff $w^* = q$ in Γ.*

The proof of the Boone lemma is based on HNN (Higman–Neumann–Neumann) extensions on free products of finitely presented groups. For a detailed and comprehensive proof of Boone's lemma, the reader is referred to Rotman [24, pp. 363–371].

To obtain the Novikov–Boone theorem, we first state a special form of the Markov–Post theorem given as Lemma 4.2 below. Its proof can be found from [24, pp. 360–361].

LEMMA 4.2. *There is a finitely presented semigroup*

$$\Gamma = [q, q_1, \ldots, q_N, s_1, \ldots, s_M; F_i q_{i_1} G_i = H_i q_{i_2} K_i, i \in I]$$

with unsolvable word problem, where F_i, G_i, H_i, K_i are (possibly empty) positive words on $\{s_1, \ldots, s_M\}$ and q_{i_1}, $q_{i_2} \in \{q, q_1, \ldots, q_N\}$. There is no algorithm to determine, for arbitrary positive words X and Y on $\{s_1, \ldots, s_M\}$ and for q_j, $1 \le j \le N$, whether $Xq_jY = q$ in Γ.

The symbols $q, q_1, \ldots, q_N$ in Lemma 4.2 are sometimes referred to as states, for they correspond to states of some fixed Turing machine that accepts the halting problem.

From Boone's lemma, we know that if there were an algorithm to determine whether two words are equivalent in G, then there would be an algorithm to determine, for an arbitrary special word w, whether $w^* = q$ in Γ, which is impossible by Lemma 4.2. This gives the following Novikov–Boone theorem.

THEOREM 4.3 (see [22, 5]). *There exists a finitely presented group having an undecidable word problem.*

5. Main theorem.

THEOREM 5.1. *The distributional word problem for groups is average-case* NP*-complete.*

We will devote this entire section to proving this theorem. The proof is as follows. Given a distributional NP problem $(D, \mu) \in$ DistNP, we construct a reduction such that for any instance x of D, the reduction transforms x into a finitely presented group $G = [A; R]$, strings u, v, w, and a unary notation $1^{\eta(|x|)}$ with the following properties, where η is a polynomial:

1. $x \in D$ iff $(u^{-1}vu)w = w(u^{-1}vu)$ in G iff $(u^{-1}vu)w =_k w(u^{-1}vu)$ in $[A; R]$ for $k \le \eta(|x|)$.
2. μ is dominated by the distribution of the distributional word problem with respect to the reduction.

The reduction construction is based on the Boone lemma. There are some added difficulties, however. First, we need to show a similar result as Lemma 4.2 in the setting of average-case NP-completeness. Wang and Belanger [32] have shown that the distributional word problem for semigroups is average-case NP-complete. But the relations constructed in the proof there do not have the forms we desire. We would like all relations to be in the form of $EqF = HpK$, where p and q are states, E, F, H, and K are positive words on nonstate symbols. This can be achieved by carefully reengineering the proof given in [32].

Second, we note that it is often difficult to satisfy the domination property for distributions required in the reductions. In general, if the size of the output of a reduction is a linear growth on the size of its input, then the domination property could be damaged. To make this point clearer, let us consider the distributional halting problem.

Let $M_1, M_2, \ldots$ be a fixed enumeration of nondeterministic Turing machines in

which the index i is an integer in binary form that codes the symbols, states, and transition table of the ith Turing machine M_i. The distributional halting problem consists of binary strings i, x, and 1^n as instances, where i and n are integers. The question is to decide whether M_i accepts x within n steps. Denote by K the set of all positive instances. The probability distribution $\mu_K(i, x, 1^n)$ of instance $(i, x, 1^n)$ (positive or negative) is proportional to $2^{-(l+m)}l^{-2}m^{-2}n^{-2}$, where $l = |i|$ and $m = |x|$. The distributional halting problem (K, μ_K) is average-case NP-complete as mentioned in section 1. If we try to reduce (K, μ_K) to a distributional problem (D, μ) in an effort to show that (D, μ) is complete, we will need to find a reduction f such that $\mu_K \preceq_f \mu$. If the reduction f transforms $(i, x, 1^n)$ to z such that z has a parameter y with $|y| \geq c|x|$ for some $c > 1$, and $2^{-|y|}$ is an irreducible factor of μ, then μ cannot dominate μ_K with respect to f. The only possibility left in this connection is for y to satisfy $|y| = |x| + O(\log |x|)$. This motivated Gurevich [12] to invent a dynamic binary coding scheme to meet this requirement. Using such a coding scheme, Gurevich [12] showed that the distributional Post correspondence is average-case NP-complete. We will use this coding scheme to construct our reduction as well.

5.1. Dynamic coding scheme. Let A be a finite alphabet with $|A| > 2$. Given a binary string x (we also assume that x starts with 1), Gurevich [12] designed a dynamic binary coding scheme to encode symbols in A such that the following statements hold.

1. All coded symbols have the same length l, and $l = 2\log |x| + O(1)$.
2. String x (not coded) is distinguishable from each coded symbol. In other words, no coded symbol can be a substring of x.
3. If a nonempty suffix z of a coded symbol u is a prefix of a coded symbol v, then $z = u = v$.
4. x can be written as a unique concatenation of the following fixed binary strings 1, 10, 000, 100, which are not prefixes of any coded symbol.

The four strings 1, 10, 000, 100 are called *base strings*. Gurevich [12] originally used strings 1, 10, 00, and 000 as base strings, which, in general, does not form a unique concatenation for strings beginning with 1.

The construction of such a coding system can be done as follows. Let R be the regular set $0100(00 + 11)^*11$. Let l be the least even integer such that $2^{(l-6)/2} \geq |x| + |A|$. Hence, $l = 2\log |x| + O(1)$. The string x has at most $|x|$ substrings of length l. So we can select a set S of R-strings of length l such that $|S| = |A|$, no string in S is a substring of x, and every string in S starts with 01. Moreover, from R it is straightforward to show that the third condition also holds [12]. To see that the fourth condition is satisfied, let y be a string that does not start with 01 and is different from 0; then it is straightforward to show by induction that y forms a unique concatenation of the base strings.

So we can use S to code A by assigning one element in S to represent one symbol in A. This dynamic coding scheme satisfies all of the above four conditions.

5.2. Semigroup construction. For simplicity, we use the standard, nondeterministic, one-tape, single-headed Turing machines as our computation model. The tape is bounded on the left and unbounded to the right. At the initial state, the input is left justified on the tape and the head is positioned at the leftmost symbol of the input.

Let (D, μ) be an arbitrary distributional problem in DistNP. From distribution controlling lemma (1), there is a total, one-to-one, p-time computable, and p-time invertible function α such that $\mu(x) \preceq 2^{-|\alpha(x)|}$. Let M be a (nondeterministic) Turing

machine that accepts D in polynomial time. Without loss of generality we assume that all the computation paths of M are bounded by a polynomial in the length of inputs.

We construct a Turing machine M' with only one halting state. M' takes input $1w$ and determines whether $w = \alpha(x)$ for some x. If $\alpha^{-1}(w)$ is not defined, then M' goes into an infinite loop; otherwise, M' simulates M on x. If M on x reaches an accepting state, then M' erases all the tape symbols, moves the head to the left, and halts. If M on x reaches a rejecting state, then M' simply goes into an infinite loop. We assume that when M' enters an infinite loop, it does not change anything on the tape. Then for all x, M' on input $1\alpha(x)$ has a halting computation if and only if M accepts x. Because of the time bound on M, it is easy to see that if M' on input $1\alpha(x)$ halts, then the number of steps it takes is bounded by a polynomial in $|x|$. This proves the following lemma.

LEMMA 5.2. *$x \in D$ iff M' halts on $1\alpha(x)$ in time polynomial in $|x|$ iff M' halts on $1\alpha(x)$.*

We construct a set $\Pi = \Pi(M')$ of production rules to describe instantaneous descriptions of M'. Let h be the halting state, s the initial state, B the blank symbol, Q the set of states, and δ the transition function, all for M'. We use a symbol \$ as an end marker to handle the blank tape detail. Π consists of the following ordered pairs (productions).

1. For any $q \in Q - \{h\}$, $p \in Q$, $a, b, c \in \Sigma \cup \{B\}$, if $\delta(q, a) = (p, b, R)$, then Π contains $\langle qac, bpc\rangle$; Π also contains $\langle qa\$, bpB\$\rangle$.
2. For any $q \in Q - \{h\}$, $p \in Q$, $a, b, d, \in \Sigma \cup \{B\}$, and $c \in \Sigma \cup \{\$\}$, if $\delta(q, a) = (p, b, L)$, then Π contains $\langle dqB\$, pd\$\rangle$; Π also contains $\langle dqac, pdbc\rangle$ for $a \neq B$, $c \neq \$$, or $b \neq B$.

We now construct a finite string-rewriting system $\Gamma = \Gamma(M')$ based on Π. We first construct a new set of symbols S_1 and a disjoint new set of states Q_1. As we discussed earlier, we require that Γ contains rewriting rules only in the form of $EqF = HpK$, where p, q are states in Q_1, and E, F, H, K are strings on S_1.

Since Π is finite, we can fix an order $ord : \Pi \to \{1, 2, \ldots, |\Pi|\}$ for the ordered pairs in Π. We use new symbols d_i, $i = 1, \ldots, |\Pi|$ to handle nondeterminism in case the inverse of a production rule is applied. We use two extra states s_1 and s_2 to transform input $1\alpha(x)$ to its coded form before the actual simulation of M' on $1\alpha(x)$ begins. We use another two extra states s_3, s_4 and a set of new symbols $Q' = \{q' : q \in Q\}$ as markers to move d_i around when needed. Let

$$S_1 = \{0, 1, B, \$\} \cup \{d_i : i = 1, \ldots, |\Pi|\} \cup Q',$$
$$Q_1 = Q \cup \{s_1, s_2, s_3, s_4\}.$$

Γ will contain $\gamma = 24 + |Q| + 7|\Pi| + 3|\Pi||Q| + |\Pi|^2$ rules, which will be described later.

Let S_2 be a new set defined below:

$$S_2 = S_1 \cup Q_1 \cup \{\chi, \kappa, \tau, \xi\}.$$

Some extra symbols are needed for writing quantified relations. Let S_3 be a finite alphabet distinct from S_2 that is sufficient to describe quantified relations (given in the construction of G later). So S_3 contains quantifier symbols, relational operation symbols, and variable symbols, etc. We also assume that S_3 contains $\{!, \uparrow, (,)\}$. Symbols χ, κ, τ, ξ will be used to construct relations in the construction of finite presentations for groups, and symbols in S_3 will be used to describe relations.

Let $z = 1\alpha(x)$. Fix a dynamic binary coding scheme for z and the finite set

$$S_4 = S_2 \cup S_3.$$

It follows that all coded symbols have the same length $l = 2\log|\alpha(x)| + O(1) = O(\log|x|)$. For any positive word w on S_4, we use $\underline{w}$ to denote the coded word of w.

Let $\mathcal{B} = \{1, 10, 100, 000\}$. The string-rewriting system Γ on $S_1 \cup Q_1$ consists of the following rewriting rules:

$\Gamma 1$: $\forall u \in \mathcal{B}$:

$$\begin{aligned}
\underline{s}u &= \underline{\$us_1},\\
\underline{s_1}u &= \underline{us_1},\\
\underline{us_1\$} &= \underline{s_2u\$},\\
\underline{us_2} &= \underline{s_2u},\\
\underline{\$s_2} &= \underline{\$s}.
\end{aligned}$$

$\Gamma 2$: $\forall\langle\alpha,\beta\rangle \in \Pi$: $\underline{\alpha} = \underline{d_i\beta}$, where $i = ord(\langle\alpha,\beta\rangle)$.

$\Gamma 3$: $\forall a \in \{0,1\}, \forall q \in Q, \forall d_i, d_j$:

$$\begin{aligned}
\underline{d_iq} &= \underline{d_is_3q'},\\
\underline{d_iaq} &= \underline{d_ias_3q'},\\
\underline{d_ias_3} &= \underline{d_is_3a},\\
\underline{ad_is_3} &= \underline{d_is_3a},\\
\underline{d_jd_is_3} &= \underline{d_jd_is_4},\\
\underline{\$d_is_3} &= \underline{\$d_is_4},\\
\underline{s_4a} &= \underline{as_4},\\
\underline{s_4q'} &= \underline{q}.
\end{aligned}$$

$\Gamma 4$:

$$\begin{aligned}
\forall d_i : \underline{d_ih} &= \underline{h},\\
\underline{\$hB\$} &= \underline{h}.
\end{aligned}$$

Recall that a string-rewriting system defines a presentation of a semigroup.

LEMMA 5.3. *There is a polynomial ζ such that M' halts on input z iff $\underline{s}z\underline{\$} = \underline{h}$ in Γ iff $\underline{s}z\underline{\$} \overset{k}{\longleftrightarrow} \underline{h}$ in Γ for $k \le \zeta(|x|)$. Moreover, the length of each word ever obtained in the transformation process is bounded by $\zeta(|x|)$.*

Proof. Starting from string $\underline{s}z\underline{\$}$, the only rewriting rules that can be applied are the ones in $\Gamma 1$, starting with the first one, until $\underline{s}z\underline{\$}$ is transformed into $\underline{\$sz\$}$. In other words, the rules in $\Gamma 2$–$\Gamma 4$ can be applied only after $\underline{\$sz\$}$ is obtained. Since z can be uniquely written as $u_1 \cdots u_m$, where $u_i \in \mathcal{B}$, this transformation can be carried out in $2m+1$ steps: $\underline{s}z\underline{\$} \leftrightarrow \underline{\$u_1s_1}u_2 \cdots u_m\underline{\$} \overset{m-1}{\longleftrightarrow} \underline{\$u_1 \cdots u_ms_1\$} \leftrightarrow \underline{\$u_1 \cdots s_2u_m\$} \overset{m-1}{\longleftrightarrow} \underline{\$s_2u_1 \cdots u_m\$} \leftrightarrow \underline{\$sz\$}$.

Assume that M' halts on z in polynomial time $\theta(|x|)$. Using the rules in $\Gamma 2$, which duplicate the steps of M', and using the rules in $\Gamma 3$ as necessary, $\underline{\$sz\$}$ can be transformed into $\underline{\$d_{i_1}d_{i_2}\ldots d_{i_{g(z)}}hB\$}$. Note that after each application of a $\Gamma 2$ rule, it will be necessary to apply at most $g(z) \le 2\theta(|x|) + 3$ $\Gamma 3$ rules to move the symbol $\underline{d_i}$ as far left as possible. This can be seen as follows. When a $\Gamma 2$ rule is applied,

we obtain the following string: $\underline{\$ud_iaqv\$}$ or $\underline{\$ud_iqv\$}$, where u is a string with some d's (possibly null) as a prefix. We consider the second case (the first case is similar). That is, $\underline{\$ud_iqv\$} \leftrightarrow \underline{\$ud_is_3q'v\$}$. We assume that u contains some d's as prefixes (the case that u contains no d's is similar). Let $u = u'd_ju''$, where u' is a string of (possibly null) d's. Let $\ell = |u''|$. It follows that $\underline{\$ud_is_3q'v\$} \overset{\ell}{\longleftrightarrow} \underline{u'd_jd_is_3u''q'v\$} \leftrightarrow \underline{u'd_jd_is_4u''q'v\$} \overset{\ell}{\longleftrightarrow} \$u'd_jd_iu''s_4q'v\$ \leftrightarrow \$u'd_jd_iu''qv\$$.

So transforming $\underline{\$sz\$}$ into $\underline{\$d_{i_1}d_{i_2}\dots d_{i_{g(z)}}hB\$}$ takes at most $\theta(|x|)(2\theta(|x|)+3)$ steps. Finally, $\underline{\$d_{i_1}d_{i_2}\dots d_{i_{g(z)}}hB\$}$ can be transformed into $\underline{h}$ in $\theta(|x|)+1$ steps by $\Gamma 4$ rules.

Conversely, if $\underline{s}z\underline{\$}$ can be transformed into $\underline{h}$, then M' will halt on x. It is important to note that the inverse of a production in Π can undo a simulated step of M', but since each simulated step is kept track of through the d_i's using the $\Gamma 2$ rules, it can only bring the string back to a previous simulated ID of M'.

By Lemma 5.2, M' halts on z iff M' halts on z in time $\theta(|x|)$. So letting $\zeta(n) = (2\theta(n)(\theta(n)+2)+2m+1)l$, where l is the length of a coded symbol, completes the proof. □

Notice that $|\underline{s}z\underline{\$}| = |x| + O(\log|x|)$, which is what we desire. The following corollary is a direct consequence of Lemmas 5.2 and 5.3.

COROLLARY 5.4. *$x \in D$ iff $\underline{s}z\underline{\$} = \underline{h}$ in Γ.*

5.3. Group construction and the reduction. We now construct a finitely presented group G as in Boone's lemma based on the semigroup Γ constructed in section 5.2. However, there is an obstacle in the construction in the polynomial setting. By Boone's lemma, we know that $\underline{s}z\underline{\$} = \underline{h}$ in Γ iff $(\underline{s}z\underline{\$} \diamond \underline{\tau})\underline{\kappa} = \underline{\kappa}(\underline{s}z\underline{\$} \diamond \underline{\tau})$ in G. But there is no guarantee that $\underline{s}z\underline{\$} \overset{k}{\longleftrightarrow} \underline{h}$ in Γ with $k \le \zeta(|x|)$ would imply that $(\underline{s}z\underline{\$} \diamond \underline{\tau})\underline{\kappa} \overset{m}{\longleftrightarrow} \underline{\kappa}(\underline{s}z\underline{\$} \diamond \underline{\tau})$ in G with $m \le \eta(|x|)$ for some polynomial η. In fact, m will be in the exponential in $|x|$. We observe that such an exponential blow up comes from a very special type of strings. By carefully introducing some new generators and relations to serve as "cancellation" rules, we can eliminate the exponential blow up.

The set of generators of G is

$$A = \mathcal{B} \cup \{\underline{a} : a \in S_2\}.$$

The symbols $\underline{!}$ and $\underline{\uparrow}$ are used to represent negative and power words. The symbols in S_3 are used to represent quantified relations.

We will use words of the form $\underline{\xi}^{\pm n}$ in constructing group relations, where $\underline{\xi}^n \equiv \underline{\xi\xi\cdots\xi}$ for n ξ's, and $\underline{\xi}^{-n} \equiv \underline{\xi!\xi!\cdots\xi!}$ for n $\xi!$'s.

For any word w on S_4, we use $\underline{w}$ to denote the coded word of w.

Let x and y be variables; we write $\underline{x^y}$ to denote the concatenation of $\underline{x}$ for y times. Symbolically, $\underline{x^y}$ is written as $\underline{x \uparrow y}$ and $\underline{x^{-y}}$ is written as $\underline{x! \uparrow y}$.

We assume that all integers are written in the original binary form (i.e., not coded in the dynamic coding scheme). Recall that each coded symbol is a string of the form $0100(00+11)^*11$. We code a positive binary integer by replacing 1 with 10, and 0 with 01. A binary number so coded is easily distinguished from any coded symbol in S_4. Let $\mathrm{bin}(n)$ denote such a coded binary number for positive integer n. So $|\mathrm{bin}(n)| = 2|n|$.

We now define a finite set of relations $R = R(M')$ to construct a finite presentation of group

$$G = [A; R].$$

Fix an order for the rewriting rules in Γ. R consists of the following relations, where relations $R1$ to $R5$ are from the proof of the undecidable word problem given in section 4 and relations $R6$ to $R7$ are used to control the length of derivations.

$R1$: $\forall a \in S_1$: $\underline{\chi a} = \underline{a\chi^2}$.

$R2$: $\forall a \in S_1$ and $\forall r_i$: $\underline{r_i a} = \underline{a\chi r_i \chi}$.

$R3$: $\underline{r_i^{-1}\overline{E}qFr_i} = \underline{\overline{H}pK}$, if $\underline{EqF} = \underline{HpK}$ is the ith relation in Γ in the fixed order. Here p and q are states in Q_1.

$R4$:

$$\begin{aligned} \underline{\tau\chi} &= \underline{\chi\tau}, \\ \forall r_i: \ \underline{\tau r_i} &= \underline{r_i\tau}. \end{aligned}$$

$R5$:

$$\begin{aligned} \underline{\kappa\chi} &= \underline{\chi\kappa}, \\ \forall r_i: \ \underline{\kappa r_i} &= \underline{r_i\kappa}, \\ \underline{\kappa}(\underline{h^{-1}\tau h}) &= (\underline{h^{-1}\tau h})\underline{\kappa}. \end{aligned}$$

$R6$: Let W be a variable representing positive words on S_1; let t be a variable representing $|W|$. For all W with length $\leq \zeta(|x|)$ and for all r_i,

1.

$$\begin{aligned} \underline{r_i W} &= \underline{W\xi^t\chi^{-1}r_i\xi^t\chi^{-1}}, \\ \underline{\overline{W}r_i^{-1}} &= \underline{\xi^{-t}\chi r_i^{-1}\xi^{-t}\chi\overline{W}}, \\ \underline{r_i^{-1}W} &= \underline{W\xi^{-t}\chi r_i^{-1}\xi^{-t}\chi}, \\ \underline{\overline{W}r_i} &= \underline{\xi^t\chi^{-1}r_i\xi^t\chi^{-1}\overline{W}}; \end{aligned}$$

2.

$$\begin{aligned} \underline{\tau\xi^t\chi^{-1}} &= \underline{\xi^t\chi^{-1}\tau}, \\ \underline{\tau^{-1}\xi^{-t}\chi} &= \underline{\xi^{-t}\chi\tau^{-1}}, \\ \underline{\kappa\xi^t\chi^{-1}} &= \underline{\xi^t\chi^{-1}\kappa}, \\ \underline{\kappa^{-1}\xi^{-t}\chi} &= \underline{\xi^{-t}\chi\kappa^{-1}}. \end{aligned}$$

$R7$: Let u be a variable representing a number between 1 and $\zeta(|x|)$. Let v be a variable representing 2^u. For all u,

$$\underline{\xi^u} = \underline{\chi^v}.$$

It is easy to see that R contains finitely many relations. The number of relations and the number of quantified relations are independent of x. The length of each relation except for $R6$ and $R7$ is independent of x. For the quantified relations in $R6$ and $R7$, the only thing that depends on x is the value of $\zeta(|x|)$. Anything else can be symbolically written down as the way it is in our coding system (i.e., without further evaluations). For example, 2^u is symbolically written as $\mathrm{bin}(2) \uparrow u$, whose length is $4 + 2l$. The length of each relation is therefore $O(\log |x|)$.

Next, we show that M' halts on input z iff $(\underline{sz\$} \diamond \underline{\tau})\underline{\kappa} =_m \underline{\kappa}(\underline{sz\$} \diamond \underline{\tau})$ in $[A; R]$, where $m \leq$ a fixed polynomial.

LEMMA 5.5. *There is a polynomial η such that if $\underline{s}z\underline{\$} \overset{k}{\longleftrightarrow} \underline{h}$ in Γ with $k \le \zeta(|x|)$, then $(\underline{s}z\underline{\$} \diamond \underline{\tau})\underline{\kappa} =_m \underline{\kappa}(\underline{s}z\underline{\$} \diamond \underline{\tau})$ in $[A;R]$ with $m \le \eta(|x|)$.*

Proof. Assume that $\underline{s}z\underline{\$} \overset{k}{\longleftrightarrow} \underline{h}$ in Γ with $k \le \zeta(|x|)$. Then

$$\underline{s}z\underline{\$} \equiv W_1 \leftrightarrow W_2 \leftrightarrow \cdots \leftrightarrow W_k \equiv \underline{h},$$

and each $|W_i|$ is bounded by $c\zeta(|x|)\log|x|$ for a fixed constant c. Suppose $W_i \leftrightarrow W_{i+1}$ by applying a rewriting rule $\underline{EqF} = \underline{HpK}$; then either $W_i \equiv \underline{UEqFV}$ and $W_{i+1} \equiv \underline{UHpKV}$, or $W_{i+1} \equiv \underline{UEqFV}$ and $W_i \equiv \underline{UHpKV}$, where U and V are positive words on S_1.

Let X be of the form $\underline{UqV}$, where U and V are words on S_1 and $q \in Q_1$. Recall that X^* denotes $\underline{\overline{U}qV}$. We have

$$\underline{\overline{U}(\overline{E}qF)\underline{V}} \overset{2}{\longleftrightarrow} \underline{\overline{U}r_i(r_i^{-1}\overline{E}qFr_i)\underline{r_i^{-1}V}}.$$

Using one relation in $R3$ and two relations specified in $R6(1)$, we have

$$\begin{aligned}\underline{\overline{U}r_i(r_i^{-1}\overline{E}qFr_i)\underline{r_i^{-1}V}} &\leftrightarrow \underline{\overline{U}(r_i\overline{H}pKr_i^{-1})\underline{V}} \\ &\overset{2}{\longleftrightarrow} \mathbf{U}_i(\underline{\overline{UH}pKV})\mathbf{V}_i,\end{aligned}$$

where $\mathbf{U}_i = \underline{\xi^{|U|}\chi^{-1}r_i\xi^{|U|}\chi^{-1}}$ and $\mathbf{V}_i = \underline{\xi^{-|V|}\chi r_i^{-1}\xi^{-|V|}\chi}$. Since $|W_j|$'s are bounded by $O(\zeta(|x|)\log|x|)$, it is straightforward to see that $|\mathbf{U}_i| = 2l|U|+5l \le (2c\zeta(|x|)\log|x|+5)l$ and $|\mathbf{V}_i| = 4l|V| + 4l \le 4l(c\zeta(|x|)\log|x|+1)$. So we have

$$W_i^* \overset{5}{\longleftrightarrow} \mathbf{U}_i W_{i+1}^* \mathbf{V}_i.$$

Write $\mathbf{U}_i^{-1} \equiv \underline{\chi\xi^{-|U|}r_i^{-1}\chi\xi^{-|U|}}$, and $\mathbf{V}_i^{-1} \equiv \underline{\chi^{-1}\xi^{|V|}r_i\chi^{-1}\xi^{|V|}}$.

We can similarly obtain the same result if $W_i \equiv \underline{UHpKV}$ and $W_{i+1} \equiv \underline{UEqFV}$. In this case, $\mathbf{U}_i = \underline{\xi^{-|U|}\chi r_i^{-1}\xi^{-|U|}\chi}$ and $\mathbf{V}_i = \underline{\xi^{|V|}\chi^{-1}r_i\xi^{|V|}\chi^{-1}}$.

So we have

$$\underline{s}z\underline{\$} \equiv W_1 \equiv W_1^* \overset{O(k)}{\longleftrightarrow} \mathbf{U}W_k^*\mathbf{V} \equiv \mathbf{U}\underline{h}\mathbf{V} \text{ in } G, \tag{1}$$

where $\mathbf{U} = \mathbf{U}_1\mathbf{U}_2\cdots\mathbf{U}_{k-1}$, $\mathbf{V} = \mathbf{V}_{k-1}\cdots\mathbf{V}_2\mathbf{V}_1$, $|\mathbf{U}| \le k(2c\zeta(|x|)\log|x|+5)l \le O(\zeta^2(|x|)\log^2|x|)$, and, similarly, $|\mathbf{V}| \le O(\zeta^2(|x|)\log^2|x|)$. This implies that there is a polynomial ϑ such that $\underline{s}z\underline{\$} =_{k'} \mathbf{U}\underline{h}\mathbf{V}$ in $[A;R]$ and $k' \le \vartheta(|x|)$.

From (1), we have

$$(\underline{s}z\underline{\$})^{-1} \equiv \underline{(}\underline{s}z\underline{\$}\underline{)!} \overset{O(k)}{\longleftrightarrow} \underline{(}\mathbf{U}\underline{h}\mathbf{V}\underline{)!} \text{ in } G. \tag{2}$$

Thus,

$$(\underline{s}z\underline{\$})^{-1} =_{O(k')} \mathbf{V}^{-1}\underline{h^{-1}}\mathbf{U}^{-1} \text{ in } G, \tag{3}$$

where $\mathbf{U}^{-1} \equiv \mathbf{U}_{k-1}^{-1}\cdots\mathbf{U}_1^{-1}$ and $\mathbf{V}^{-1} \equiv \mathbf{V}_{k-1}^{-1}\cdots\mathbf{V}_1^{-1}$.

From (1) and (3), and using a polynomial number of relations in $R4$ and $R6(2)$ of R, we have

$$\begin{aligned}(\underline{s}z\underline{\$} \diamond \underline{\tau})\underline{\kappa} &=_{O(k')} \mathbf{V}^{-1}\underline{h^{-1}}(\mathbf{U}^{-1}\underline{\tau}\mathbf{U})\underline{h}(\mathbf{V}\underline{\kappa}) \\ &\overset{O(k)}{\longleftrightarrow} \mathbf{V}^{-1}[(\underline{h^{-1}\tau h})\underline{\kappa}]\mathbf{V} \\ &\leftrightarrow \mathbf{V}^{-1}[\underline{\kappa}(\underline{h^{-1}\tau h})]\mathbf{V} \\ &\overset{O(k)}{\longleftrightarrow} \underline{\kappa}\mathbf{V}^{-1}\underline{h^{-1}}\mathbf{U}^{-1}\underline{\tau}\mathbf{U}\underline{h}\mathbf{V} \\ &\overset{O(k)}{\longleftrightarrow} \underline{\kappa}(\underline{s}z\underline{\$} \diamond \underline{\tau}).\end{aligned}$$

Note that each elementary transformation above takes at most $O(\zeta(|x|)\log|x|)$ steps to rewrite words. This implies that $(\underline{s}z\underline{\$}\diamond\underline{\tau})\underline{\kappa} =_m \underline{\kappa}(\underline{s}z\underline{\$}\diamond\underline{\tau})$ in G for $m \le \eta(|x|)$, where η is some fixed polynomial. This completes the proof. □

From Lemmas 5.2, 5.3, and 5.5, we have Lemma 5.6.

LEMMA 5.6. *If $x \in D$, then $(\underline{s}z\underline{\$}\diamond\underline{\tau})\underline{\kappa} =_m \underline{\kappa}(\underline{s}z\underline{\$}\diamond\underline{\tau})$ in $[A;R]$ for $m \le \eta(|x|)$.*

We now consider the reverse direction of Lemma 5.6. We will first use Tietze transformations to show that G also has presentation $[A-\{\xi\}; R1, R2, R3, R4, R5]$. For the reader's convenience, we state the Tietze theorem as Lemma 5.7 below. The reader is referred to [21, pp. 48–51] for more details.

LEMMA 5.7. *Given a presentation*

$$[b_1, b_2, , \ldots; P_1, P2, \ldots] \tag{4}$$

for a group H, then any other presentation for H can be obtained by a repeated application of the following Tietze transformations to presentation (4)*:*

- **T1** *If the words $T_1, T_2 \ldots$ are derivable from $P_1, P_2, \ldots$, then add $T_1, T_2 \ldots$ to the defining relators in presentation* (4).
- **T2** *If some of the relators, say, $T_1, T_2, \ldots$, listed among the defining relators $P_1, P_2 \ldots$ are derivable from the others, delete $T_1, T_2, \ldots$ from the defining relators in presentation* (4).
- **T3** *If $K_1, K_2, \ldots$ are any words in $b_1, b_2, \ldots$, then adjoin the symbols $c_1, c_2, \ldots$ to the generating symbols in* (4) *and adjoin the relations $c_1 = K_1, c_2 = K_2, \ldots$ to the defining relators in presentation* (4).
- **T4** *If some of the defining relators in* (4) *take the form $a_1 = V_1, a_2 = V_2, \ldots$, where $a_1, a_2, \ldots$ are generators in presentation* (4) *and $V_1, V_2, \ldots$ are words in the generators other than $a_1, a_2, \ldots$, then delete $a_1, a_2, \ldots$ from the generators, delete $a_1 = V_1, a_2 = V_2, \ldots$ from the defining relations, and replace $a_1, a_2, \ldots$ by $V_1, V_2, \ldots$, respectively, in the remaining defining relators in presentation* (4).

So by Tietze transformation T4, we can obtain another presentation for G by removing ξ from the relator set A, removing relations $R7$, and replacing $\xi^{\pm t}$ in relations $R6$ with $\chi^{\pm 2^t}$. Next, we show that the relations specified in $R6$ (after replacing $\xi^{\pm t}$ with $\chi^{\pm 2^t}$) can be derived from relations in $R1$–$R5$.

LEMMA 5.8. *Relations specified in $R6$ (after replacing $\xi^{\pm t}$ with $\chi^{\pm 2^t}$) can be derived from relations in $R1$–$R5$.*

Proof. It suffices to demonstrate how to obtain $\underline{r_i V} \overset{*}{\longleftrightarrow} \underline{V\chi^{2^{|V|}}\chi^{-1}r_i\chi^{2^{|V|}}\chi^{-1}}$ using relations not in $R6$, where V is a positive word. The other ones can be similarly obtained. We prove it by induction on $|V|$. The case of $|V| = 1$ is obvious. For the general case, let $V = V'a$, where $a \in S_1$; then $\underline{r_i V} \overset{*}{\longleftrightarrow} \underline{V'\chi^{k'}\chi^{-1}r_i\chi^{k'}\chi^{-1}a}$, where $k' = 2^{|V'|}$. Keep using relations in $R1$ and $R2$; then we have $\underline{V'\chi^{k'}\chi^{-1}r_i\chi^{k'}\chi^{-1}a} = \underline{V'\chi^{k'-1}r_i\chi^{k'-2}\chi a} \leftrightarrow \underline{V'\chi^{k'}r_i\chi^{k'-1}a\chi^2} \overset{*}{\longleftrightarrow} \underline{V\chi^{2k'-1}r_i\chi^{2k'-1}} = \underline{V\chi^{2k'}\chi^{-1}r_i\chi^{2k'}\chi^{-1}}$. This completes the proof. □

REMARK 5.1. We note that exponentially many elementary transformations are required to obtain relations specified in $R6$ from relations in $R1$–$R5$. This is why there is exponential blow up without using the generator ξ and the relations specified in $R6$.

Hence, by Tietze transformation T2, we know that G also has a finite presentation $[A-\{\xi\}; R1, R2, R3, R4, R5]$, which is exactly the same construction as in the Boone lemma. So by Boone's lemma, $(\underline{s}z\underline{\$}\diamond\underline{\tau})\underline{\kappa} = \underline{\kappa}(\underline{s}z\underline{\$}\diamond\underline{\tau})$ in G iff $\underline{s}z\underline{\$} = \underline{h}$ in Γ. The following lemma is therefore straightforward.

LEMMA 5.9. *If* $(\underline{s}z\underline{\$} \diamond \underline{\tau})\underline{\kappa} =_m \underline{\kappa}(\underline{s}z\underline{\$} \diamond \underline{\tau})$ *in* $[A; R]$ *with* $m \leq \eta(|x|)$, *then* $\underline{s}z\underline{\$} = \underline{h}$ *in* Γ, *which implies that* $x \in D$ *by Corollary* 5.4.

From Lemmas 5.6 and 5.9, we get Corollary 5.10.

COROLLARY 5.10. $x \in D$ *iff* $(\underline{s}z\underline{\$} \diamond \underline{\tau})\underline{\kappa} =_m \underline{\kappa}(\underline{s}z\underline{\$} \diamond \underline{\tau})$ *in* $[A; R]$ *with* $m \leq \eta(|x|)$.

We are now ready to finish the proof of Theorem 5.1. By Corollary 5.10, we define a reduction f as follows:

$$f(x) = ([A; R], \underline{s}z\underline{\$}, \underline{\tau}, \underline{\kappa}, 1^{\eta(|x|)}).$$

Clearly, f is one to one. As shown earlier, A contains a constant number of symbols depending on M, and R contains a constant number of relations (some with quantifiers). The length of each coded symbol and the length of each of these relations are $O(\log |x|)$. So $\| A \cup R \|_0 = O(\log |x|)$, and $\| A \cup R \|_1 = O(\log^{O(1)} |x|)$. Note that $|\underline{s}z\underline{\$}| = |x| + O(\log |x|)$. Recall that $z = 1\alpha(x)$. Hence, the probability distribution of $f(x)$, which is proportional to

$$\frac{2^{-(\| A \cup R \|_0 + |\underline{s}z\underline{\$}| + |\underline{\kappa}| + |\underline{\tau}|)}}{(O(1)|\underline{s}z\underline{\$}||\underline{\kappa}||\underline{\tau}|\ \| A \cup R \|_1)^2} \geq \frac{1}{P(|x|)} 2^{-|\alpha(x)|}$$

for a polynomial P, dominates $\mu(x)$. This completes the proof of Theorem 5.1.

6. Some related results.

6.1. Worst-case NP-complete word problem. In the setting of worst-case complexity, we need not worry about preserving distributions for instances between the source problem and the target problem, and so we do not need to use dynamic coding schemes. Also, we can consider a simpler version of the bounded word problem for groups; namely, instead of taking x, y, z as inputs and asking whether $(x^{-1}yx)z$ can be derived from $z(x^{-1}yx)$, we will simply take x and y as inputs and ask whether x can be derived from y.

DEFINITION 6.1. *The* bounded word problem for groups *is the following decision problem.*

Instance: *A finite presentation* $[A; R]$ *of a group, strings* x, y, *and a unary notation* 1^n.

Question: *Is* $x =_k y$ *in* $[A; R]$ *for* $k \leq n$?

Similar to the proof of Theorem 5.1, we can obtain a much simpler proof to the following theorem.

THEOREM 6.2. *The bounded word problem for groups is (worst-case)* NP*-complete.*

6.2. Isomorphisms of average-case NP-complete problems. The issue of isomorphisms of complete sets is an interesting topic. Berman and Hartmanis [3] were the first to study isomorphisms of NP-complete sets. Two sets A and B are said to be p-isomorphic if there is a one to one, onto, p-time computable, and p-time invertible reduction f such that A is reducible to B via f, and B is reducible to A via f^{-1}. Berman and Hartmanis showed that all the known (worst-case) NP-complete sets are p-isomorphic. Wang and Belanger [32] generalized Berman and Hartmanis's notion of isomorphisms and defined a notion of isomorphism for distributional problems. Two distributional problems (A, μ_A) and (B, μ_B) are *p-isomorphic* if there exists a p-time computable and p-time invertible bijection ϕ such that (A, μ_A) is p-time reducible to (B, μ_B) via ϕ, and (B, μ_B) is p-time reducible to (A, μ_A) via ϕ^{-1}. They then showed the following version of the Cantor–Bernstein–Myhill theorem for distributional problems.

LEMMA 6.3 (see [32]). *Let f and g be one-to-one, p-time computable and p-time invertible reductions of (A, μ_A) to (B, μ_B) and (B, μ_B) to (A, μ_A), respectively, such that $f \circ g$ and $g \circ f$ are length increasing.*[7] *Assume also that $\mu_A \approx \mu_B \circ f$ and $\mu_B \approx \mu_A \circ g$, where $\mu \approx \nu$ means $\mu \preceq \nu$ and $\nu \preceq \mu$. Then (A, μ_A) and (B, μ_B) are p-isomorphic.*

Based on Lemma 6.3 and distribution controlling lemma (2), Wang and Belanger [32] showed that all the known average-case NP-complete problems under p-time many–one reductions are indeed p-isomorphic. Based on the proof of Theorem 5.1, we can show that the distributional word problem for groups is p-ismorphic to the distributional halting problem.

THEOREM 6.4. *The distributional word problem for groups is p-ismorphic to the distributional halting problem.*

Proof. We provide a sketch of the proof here. It was shown in [32] that if $A \in$ NP and ν satisfies the hypothesis of distribution controlling lemma (2), then there is a reduction g from (A, ν) to the distributional halting problem (K, μ_K) such that g is one to one, length-increasing, p-time computable, and p-time invertible. Moreover, $\mu \approx \mu_K \circ g$. Let (A, ν) denote the distributional word problem for groups. Then, clearly, ν satisfies the hypothesis of distribution controlling lemma (2).

In the proof of Theorem 5.1, let (D, μ) be (K, μ_K). Replace α by β from distribution controlling lemma (2) for μ_K, and use the same reduction f. Then f is one to one, length increasing, p-time computable, and p-time invertible. Moreover, $\mu_K \approx \nu \circ f$. This completes the proof by Lemma 6.3. □

Acknowledgments. I am grateful to Paul Duvall and Theresa Vaughan for helping me with some of my algebra questions. I thank Jay Belanger and R. Venkatesan for asking some interesting questions regarding an early version of this paper.

LINEAR TIME ALGORITHMS FOR DOMINATING PAIRS IN ASTEROIDAL TRIPLE-FREE GRAPHS*

DEREK G. CORNEIL†, STEPHAN OLARIU‡, AND LORNA STEWART§

Abstract. An independent set of three vertices is called an *asteroidal triple* if between each pair in the triple there exists a path that avoids the neighborhood of the third. A graph is asteroidal triple-free (AT-free) if it contains no asteroidal triple. The motivation for this investigation is provided, in part, by the fact that AT-free graphs offer a common generalization of interval, permutation, trapezoid, and cocomparability graphs.

Previously, the authors have given an existential proof of the fact that every connected AT-free graph contains a dominating pair, that is, a pair of vertices such that every path joining them is a dominating set in the graph. The main contribution of this paper is a constructive proof of the existence of dominating pairs in connected AT-free graphs. The resulting simple algorithm, based on the well-known lexicographic breadth-first search, can be implemented to run in time linear in the size of the input, whereas the best algorithm previously known for this problem has complexity $O(|V|^3)$ for input graph $G = (V, E)$. In addition, we indicate how our algorithm can be extended to find, in time linear in the size of the input, all dominating pairs in a connected AT-free graph with diameter greater than 3. A remarkable feature of the extended algorithm is that, even though there may be $O(|V|^2)$ dominating pairs, the algorithm can compute and represent them in linear time.

1. Introduction.

Considerable attention has been paid to exploiting algorithmically different aspects of the linear structure exhibited by various families of graphs. Examples of such families include interval graphs [15], permutation graphs [11], trapezoid graphs [6, 10], and cocomparability graphs [13].

The linearity of these four classes is usually described in terms of ad hoc properties of each of these classes of graphs. For example, in the case of interval graphs, the linearity property is traditionally expressed in terms of a linear order on the set of maximal cliques [4, 5]. For permutation graphs the linear behavior is explained in terms of the underlying partial order of dimension 2 [1]; for cocomparability graphs the linear behavior is expressed in terms of topological orderings of transitive orientations of comparability graphs [14], and so on.

As it turns out, the classes mentioned above are all subfamilies of a class of graphs called the asteroidal triple-free graphs (AT-free graphs). An independent set of three vertices is called an *asteroidal triple* if between any pair in the triple there exists a path that avoids the neighborhood of the third. AT-free graphs were introduced over

three decades ago by Lekkerkerker and Boland [15], who showed that a graph is an interval graph if and only if it is chordal and AT-free. Thus, Lekkerkerker and Boland's result may be viewed as showing that the absence of asteroidal triples imposes the linear structure on chordal graphs that results in interval graphs. Recently, we have studied AT-free graphs with the stated goal of identifying the "agent" responsible for the linear behavior observed in the four subfamilies. Specifically, in [9] we presented evidence that the property of being AT-free is what is enforcing the linear behavior of these classes.

One strong "certificate" of linearity is the existence of a *dominating pair* of vertices, that is, a pair of vertices with the property that every path connecting them is a dominating set. In [9], we gave an existential proof of the fact that every connected AT-free graph contains a dominating pair.

The main contribution of this paper is a constructive proof of the existence of dominating pairs in connected AT-free graphs. A remarkable feature of our approach is that the resulting simple algorithm, based on the well-known lexicographic breadth-first search of [16], can easily be implemented to run in time $O(|V| + |E|)$, where the input is a connected AT-free graph $G = (V, E)$. In addition, our algorithm can be extended to find, in time linear in the size of the input, all dominating pairs in a connected AT-free graph with diameter greater than 3.

It should be noted that the fastest algorithm known to us, which recognizes whether or not a graph $G = (V, E)$ is AT-free, runs in time $O(|V|^3)$.

To put our result in perspective, we observe that previously, the most efficient algorithm for finding a dominating pair in a graph $G = (V, E)$ was the straightforward $O(|V|^3)$ algorithm described in [2].

For each of the four families mentioned above, vertices that occupy the extreme positions in the corresponding intersection model [12] constitute a dominating pair. It is interesting to note, however, that a linear time algorithm for finding a dominating pair was not previously known, even for cocomparability graphs, a strict subclass of AT-free graphs.

The remainder of this paper is organized as follows. Section 2 contains some relevant terminology and background. Section 3 is a description of the lexicographic breadth-first search algorithm of [16] along with some properties of that algorithm. In section 4 we present an algorithm which finds a dominating pair in a connected AT-free graph. In sections 5 and 6, we show how to extend the dominating pair algorithm to find all dominating pairs in a connected AT-free graph with sufficiently large diameter. Section 7 contains our conclusions.

2. Background. All the graphs in this work are finite with no loops or multiple edges. In addition to standard graph theoretic terminology compatible with [3], we shall define some new terms. We let $d(v)$ denote the *degree* of vertex v; $d(u, v)$ denotes the *distance* between vertices u and v in a graph, that is, the number of edges on a shortest path joining u and v. In addition, we let $\mathrm{diam}(G)$ denote the *diameter* of the graph G, that is, $\max_{u,v \in G} d(u, v)$. Two vertices u and v with $d(u, v) = \mathrm{diam}(G)$ are said to *achieve the diameter*. Given a graph $G = (V, E)$ and a vertex x, we let $N(x)$ denote the set of neighbors of x; $N'(x)$ denotes the set of neighbors of x in the complement $\overline{G}$ of G.

Let $\pi = v_1, v_2, \ldots, v_k$ be a path of graph G. If the subgraph of G induced by $\{v_1, v_2, \ldots, v_k\}$ has exactly $k - 1$ edges, i.e., none other than the edges of the path, then π is said to be an *induced*, or *chordless*, path. All the paths in this work are assumed to be induced unless stated otherwise. We refer to a path joining vertices x

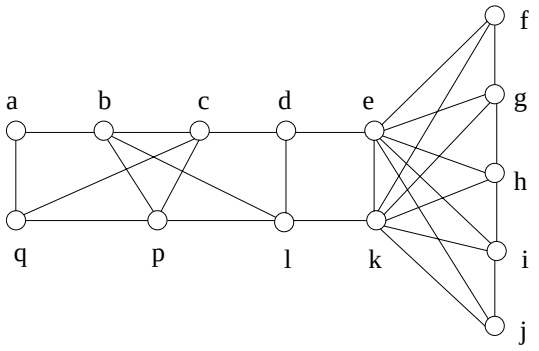

FIG. 1. *A connected AT-free graph G.*

and y as an x,y-path. We say that a vertex u *intercepts a path* π if u is adjacent to at least one vertex on π; otherwise, u is said to *miss* π. Let $G = (V, E)$ be a graph, π a path in G, x a vertex of G, and X a subset of V. Let $V(\pi)$ be the vertices of G that are on the path π. We shall use the following notation: $\pi - x$ refers to the subgraph of G induced by the vertices $V(\pi) - \{x\}$, $\pi + x$ refers to the subgraph of G induced by the vertices $V(\pi) \cup \{x\}$, and $\pi \cup X$ refers to the subgraph of G induced by the vertices $V(\pi) \cup X$.

For a connected AT-free graph with a pair of vertices x, y we let $D(x, y)$ denote the set of vertices that intercept all x,y-paths. Note that (x, y) is a dominating pair if and only if $D(x, y) = V$. We say that vertices u and v are *unrelated with respect to* x if $u \notin D(v, x)$ and $v \notin D(u, x)$. A vertex x of an AT-free graph G is called *pokable* if the graph obtained from G by adding a pendant vertex adjacent to x is AT-free. It is not hard to see that if an AT-free graph G contains no unrelated vertices with respect to x, then x is pokable. A *pokable dominating pair* is a dominating pair such that both vertices are pokable. A vertex x is a *pokable dominating pair vertex* if x is pokable and there exists y such that (x, y) is a dominating pair. To illustrate these definitions, consider the graph $G = (V, E)$ of Figure 1. In this graph, $D(c, l) = \{b, c, d, k, l, p, q\}$, $D(c, e) = V \backslash \{a\}$, and $D(a, e) = D(q, i) = V$. Any pair consisting of one vertex from $\{a, q\}$ and one vertex from $\{e, f, g, h, i, j, k\}$ is a dominating pair; a is pokable and h is not pokable (adding a pendant vertex h' adjacent to h would create the AT $\{f, j, h'\}$).

3. Lexicographic breadth-first search. Our dominating pair algorithm invokes Procedure LBFS (short for lexicographic breadth-first search), which, when given a connected graph G and a vertex x of G, returns a numbering of the vertices of G. We reproduce below the details of LBFS from [16].

PROCEDURE LBFS(G, x).
{Input: a connected graph $G = (V, E)$ and a distinguished vertex x of G;
Output: a numbering σ of the vertices of G}
begin
  label$(x) \leftarrow |V|$;
  for each vertex v in $V - \{x\}$ **do**
    label$(v) \leftarrow \Lambda$;
  for $i \leftarrow |V|$ **downto** 1 **do begin**
    pick an unnumbered vertex v with (lexicographically) the largest label;
    $\sigma(v) \leftarrow i$; {assign to v number i}
    for each unnumbered vertex u in $N(v)$ **do**

append i to label(u)
end
end; {LBFS}

Notice that the numbering returned by LBFS is not unique. One numbering that could result from LBFS(G, q), where G is the graph of Figure 1, is $\sigma(q) = 14$, $\sigma(p) = 13$, $\sigma(c) = 12$, $\sigma(a) = 11$, $\sigma(b) = 10$, $\sigma(l) = 9$, $\sigma(d) = 8$, $\sigma(k) = 7$, $\sigma(e) = 6$, $\sigma(i) = 5$, $\sigma(h) = 4$, $\sigma(j) = 3$, $\sigma(g) = 2$, $\sigma(f) = 1$.

A few definitions relating to LBFS are in order at this point. Let x be an arbitrary vertex of a connected graph G, and consider running LBFS(G, x). For vertices a, b of G we write $a \prec b$ whenever $\sigma(a) < \sigma(b)$, and we shall say that b is *larger* than a. To make the notation more manageable we shall sometimes write $v_1 \prec v_2 \prec \cdots \prec v_k$ as shorthand for $v_1 \prec v_2, v_2 \prec v_3, \ldots, v_{k-1} \prec v_k$. We shall denote by $\lhd$ the lexicographic total order of the set of LBFS labels. We let $\lambda(a, b)$ denote the label of a when b was about to be numbered. Given vertices a, b, c with $a \prec c$ and $b \prec c$, we shall say that a and b *are tied at* c if $\lambda(a, c) = \lambda(b, c)$. Given a vertex y, an a,b-path is said to be *y-majorizing* if all the vertices on the path are larger than y.

We assume that $G = (V, E)$ is an arbitrary connected graph and that LBFS(G, x) has been invoked, where x is an arbitrary vertex of G. The following fundamental properties of LBFS will be used later.

PROPOSITION 3.1. *Let a, b, and c be vertices of G satisfying $a \prec b$, $b \prec c$, $ac \in E$, and $bc \notin E$. Then there exists a vertex d in G adjacent to b but not to a and such that $c \prec d$.*

Proof. The existence of d follows immediately from the observation that when b was about to be processed by LBFS it could not have been tied with a. Since a inherited c's label, b must have inherited the label of a larger vertex nonadjacent to a; this is d. □

PROPOSITION 3.2 (monotonicity property). *Let a, b, c, and d be vertices of G such that $a \prec c$ or $a = c$, $b \prec c$ or $b = c$, and $c \prec d$. If $\lambda(a, d) \lhd \lambda(b, d)$, then $\lambda(a, c) \lhd \lambda(b, c)$.*

Proof. The proof follows directly from the lexicographic ordering of labels. □

LEMMA 3.3. *Let a, b, b', and c be vertices of G such that $a \prec b \prec c \prec b'$, $bb' \in E$, and $b'c \notin E$. Then a and c cannot be tied at b'.*

Proof. By Proposition 3.1 applied to vertices b, c, and b' we find a vertex c' adjacent to c but not to b and such that $b' \prec c'$. Write $C = \{t \mid tc \in E, tb \notin E, b' \prec t\}$. Clearly, $c' \in C$. In fact, we select c' to be the *largest* vertex in C.

If the statement is false, then a and c are tied at b'. Since $b' \prec c'$ and since $cc' \in E$, we must have $ac' \in E$. Now, Proposition 3.1 applied to vertices a, b, *and* c' yields a vertex b'' adjacent to b but not to a such that $c' \prec b''$.

Since $b' \prec b''$, the assumption that a and c are tied at b' guarantees that b'' is not adjacent to c. Therefore, Proposition 3.1 can be applied to vertices b, c, and b'', yielding a vertex c'' adjacent to c but not to b and such that $b'' \prec c''$. Since $b' \prec c' \prec b'' \prec c''$, it must be that $c'' \in C$, contradicting that c' is the largest vertex in C. □

LEMMA 3.4. *Let y, a, and b be pairwise nonadjacent vertices of G such that $y \prec a$ and $a \prec b$. If a and y are not tied at b, then y misses a y-majorizing a,b-path.*

Proof. Assume that a and y are not tied at b. We must exhibit a y-majorizing a,b-path missed by y.

Since $y \prec a$, $\lambda(y, a) \lhd \lambda(a, a)$ or $\lambda(y, a) = \lambda(a, a)$. Therefore, by the monotonicity property (Proposition 3.2), $\lambda(y, b) \lhd \lambda(a, b)$ or $\lambda(y, b) = \lambda(a, b)$. Now, since a and y

are not tied at b, $\lambda(y,b) \lhd \lambda(a,b)$. Consequently, we find a vertex a_1 adjacent to a but not to y and such that $b \prec a_1$. (Vertex a_1 is chosen to be the largest satisfying these conditions.) We may assume that a_1 is not adjacent to b, since otherwise the path a, a_1, b is the desired y-majorizing path.

Now, Lemma 3.3 guarantees that b and y cannot be tied at a_1. Thus, we find a vertex b_1 adjacent to b but not to y and such that $a_1 \prec b_1$. (As before, we select as b_1 the largest vertex with this property.) Trivially, we may assume that b_1 is adjacent to neither a nor a_1; else we have the desired y-majorizing path. Again, Lemma 3.3 tells us that a_1 and y cannot be tied at b_1 and so we find a vertex a_2 adjacent to a_1 but not to y and such that $b_1 \prec a_2$. (As before, we select as a_2 the largest vertex with this property.) It is easy to verify that a_2 is not adjacent to a (by the choice of a_1), b, or b_1.

Continuing as above, we obtain two chordless y-majorizing paths $a = a_0, a_1, a_2, \ldots$ and $b = b_0, b_1, b_2, \ldots$, both missed by y. If no vertex on the first path is adjacent to a vertex on the second one, then the paths are infinite, contradicting that G is finite. Therefore, such an adjacency must exist, yielding the desired a,b-path. ∎

4. The dominating pair algorithm. Our dominating pair algorithm takes as input a connected AT-free graph G and returns a pokable dominating pair of G. The algorithm provides a constructive proof of the existence of pokable dominating pairs in connected AT-free graphs. (An existential proof of this fact was given in [9].)

The four properties of LBFS specified in the preceding section hold for every connected graph G. The proof of correctness of the dominating pair algorithm relies on two additional properties of LBFS which hold when the input graph is a connected AT-free graph. We present these properties next.

THEOREM 4.1. *Let $G = (V, E)$ be a connected AT-free graph and let x and y be arbitrary vertices of G. Let $\prec$ be the vertex ordering corresponding to a numbering produced by LBFS(G, x). The subgraph of G induced by y and all vertices z with $y \prec z$ contains no unrelated vertices with respect to y.*

Proof. First, we give an overview of the proof. The existence of such unrelated vertices, u and v, and the fact that they are numbered before y in an LBFS from x, would imply that u and v are connected by a path through x. If y misses such a path, then $\{y, u, v\}$ is an AT.

In particular, if the statement is false, we find a vertex y and vertices u, v with $y \prec u \prec v$, such that u and v are unrelated with respect to y. This implies the existence of chordless paths $\pi(y,u) : y = u_1, u_2, \ldots, u_p = u$ missed by v, and $\pi(y,v) : y = v_1, v_2, \ldots, v_q = v$ missed by u, with the vertices on both paths, except for y, numbered by LBFS before y. We claim that

$$u \prec v_3. \tag{4.1}$$

If (4.1) is false, then $v_3 \prec u$ and $u \prec v$, and we must find a subscript i $(3 \leq i \leq q-1)$ such that $v_i \prec u$ and $u \prec v_{i+1}$. Now, Lemma 3.3 tells us that u and y cannot be tied at v_{i+1}. In turn, Lemma 3.4 guarantees the existence of a y-majorizing u,v_{i+1}-path missed by y. This path extends trivially to a y-majorizing u,v-path, implying that $\{y, u, v\}$ is an AT. Thus, (4.1) must hold.

Next, we claim that

$$u \text{ and } y \text{ are tied at } v_3. \tag{4.2}$$

The contrary would imply, by virtue of Lemma 3.4, the existence of a y-majorizing

u,v_3-path missed by y. This extends easily into a y-majorizing u,v-path missed by y, implying that $\{y, u, v\}$ is an AT. Thus, (4.2) must hold.

We note that $v_2 \prec v_3$; otherwise, since v_2 is adjacent to y and not to u, we would contradict (4.2). Further, we claim that

$$u \prec v_2. \tag{4.3}$$

Otherwise, by (4.1) we have $v_2 \prec u$ and $u \prec v_3$. Now, Lemma 3.3 specifies that u and y cannot be tied at v_3, contradicting (4.2). Thus, (4.3) must be true.

Proposition 3.1 applied to vertices $y \prec u$ and $u \prec v_2$ guarantees the existence of a vertex u' adjacent to u but not to y and such that $v_2 \prec u'$. Since u and y are tied at v_3, it must be the case that $y \prec u$, $u \prec v_2$, $v_2 \prec u'$, and $u' \prec v_3$. If u' is adjacent to v_3, then we have a u,v-path missed by y, contradicting that the graph is AT-free. Thus, u' is not adjacent to v_3. But now, Lemma 3.3 guarantees that y and u' cannot be tied at v_3. Further, Lemma 3.4 tells us that there must exist a y-majorizing u',v_3-path missed by y. This path extends in the obvious way to a y-majorizing u,v-path missed by y, contradicting that the graph is AT-free. This completes the proof of Theorem 4.1. □

We observe that, if G contains no unrelated vertices with respect to vertex v, then v is pokable. This observation and Theorem 4.1 combined imply that each vertex y of G is pokable in the subgraph of G induced by y and all vertices z with $y \prec z$. In particular, the last vertex numbered by LBFS(G, x) is pokable in G.

One additional theorem about LBFS, specialized to connected AT-free graphs, will lead to the dominating pair algorithm.

THEOREM 4.2. *Let $G = (V, E)$ be a connected AT-free graph and suppose that G contains no vertices unrelated with respect to vertex x of G. Let $\prec$ be a vertex ordering corresponding to a numbering produced by LBFS(G, x). Then, for all vertices u, v in V with $u \prec v$, $v \in D(u, x)$.*

Proof. The argument proceeds by noting that if $v \notin D(u, x)$, then there is a u,x-path missed by v and no v,x-path missed by u (since u and v cannot be unrelated with respect to x). However, an LBFS from x would number u before v, contradicting the conditions of the theorem.

Assume that the theorem is false and let v be the largest vertex in V for which there exists a vertex u with $u \prec v$ and $v \notin D(u, x)$. We now select a specific path π and a vertex u with $u \prec v$ such that π is a u,x-path missed by v. Let U be the set of all vertices u such that $u \prec v$ and $v \notin D(u, x)$ and let $\mathcal{P}$ be the set of all chordless u,x-paths in G that are missed by v. Among all minimum length paths in $\mathcal{P}$, we choose π to be the one that extends to the largest possible vertex at each step. Now u is the endpoint of π that is in the set U.

Formally, let $\mathcal{P}_{\mathcal{M}}$ be the subset of $\mathcal{P}$ consisting of all minimum length paths of $\mathcal{P}$. For paths $P = p_1, p_2, \ldots, p_k$ and $P' = p'_1, p'_2, \ldots, p'_k$ in $\mathcal{P}_{\mathcal{M}}$, we say that P' is greater than P if there exists a subscript i, $1 \le i \le k$, such that $\sigma(p'_j) = \sigma(p_j)$ for all $1 \le j < i$ and $\sigma(p'_i) > \sigma(p_i)$. Clearly, "greater than" is a total order on $\mathcal{P}_{\mathcal{M}}$. We choose $\pi : u = u_1, u_2, \ldots, u_k = x$ to be the unique greatest element of $\mathcal{P}_{\mathcal{M}}$.

Observe that $u_1 \prec v$ and $v \prec u_2$; otherwise we contradict the fact that π is in $\mathcal{P}_{\mathcal{M}}$. Now Proposition 3.1 guarantees the existence of a vertex v_2 adjacent to $v = v_1$ but not to u_1 and such that $u_2 \prec v_2$.

It is easily seen that v_2 is nonadjacent to u_i for all $i > 2$, since otherwise u and v are unrelated with respect to x. This immediately implies that $v_2 \prec u_3$ (otherwise we contradict the choice of v) and $u_2 v_2 \in E$ (otherwise we contradict the choice of both u and v).

Now apply Proposition 3.1 to vertices u_2, v_2, and u_3; we find a vertex v_3 adjacent to v_2 but not to u_2 and such that $u_3 \prec v_3$.

Since $u_2 \prec v_3$, v_3 cannot miss the path $u_2, u_3, \ldots, u_k = x$. Let t ($t \geq 3$) be the largest subscript for which $v_3u_t \in E$. Now v_3 must be adjacent to u_1; else u_1 and v_1 are unrelated with respect to x. (The v_1,x-path missed by u_1 is $v_1, v_2, v_3, u_t, \ldots, x$.) Note also that v_3 must be adjacent to v_1; otherwise we contradict the choice of π. (To see this, note that u_1, v_3 extends to a minimum length chordless u,x-path via u_t.) Now, $t = 3$; else the assignment $v \leftarrow u_2$ and $u \leftarrow v$ contradicts the initial choice of u and v.

Now assume that we have constructed a sequence $v = v_1, v_2, \ldots, v_i$ of vertices such that v_i ($i \geq 3$) satisfies the following conditions:

(a) $v_iv_{i-1}, v_iu_i \in E$;
(b) $u_i \prec v_i$ and $v_iu_{i-1} \notin E$;
(c) $v_iu_j \notin E$ for $j > i$;
(d) $v_iu_1, v_iv_1 \in E$.

We argue that there exists a vertex v_{i+1} satisfying conditions (a)–(d) with $i + 1$ in place of i. For this purpose, note that u_{i+1} exists since $u_i \prec v_i$ implies that $u_i \neq x$. Now, $v_i \prec u_{i+1}$ since otherwise the assignment $v \leftarrow v_i$ and $u \leftarrow u_{i+1}$ contradicts the initial choice of u and v.

Now, by (c), Proposition 3.1 applied to vertices u_i, v_i, and u_{i+1} guarantees the existence of a vertex v_{i+1} adjacent to v_i but not to u_i and such that $u_{i+1} \prec v_{i+1}$. Thus, (b) is verified. Let t be the largest subscript for which v_{i+1} is adjacent to u_t. (t exists and $t \geq i+1$, since otherwise the assignment $v \leftarrow v_{i+1}$ and $u \leftarrow u_i$ contradicts the initial choice of u and v.)

Note that u_{i-1} is adjacent to v_{i+1}, since if it is not, then u_{i-1} and v_1 are unrelated with respect to x. (By (b) and (d), the path contained in $v_1, v_i, v_{i+1}, u_t, u_{t+1}, \ldots, x$ is missed by u_{i-1}.) Also v_1 is adjacent to v_{i+1}, since otherwise we contradict the choice of π by going down π and picking the first edge u_jv_{i+1}, which we know exists (in particular, we know that $u_{i-1}v_{i+1} \in E$) and then going to u_t and on to x. Now u_1 is adjacent to v_{i+1}, since otherwise u_1 and v_1 are unrelated with respect to x (the path $v_1, v_{i+1}, u_t, \ldots, x$ would be missed by u_1). Thus, (d) holds.

Note that $t = i+1$; otherwise we should have picked u_i instead of v (for u_i misses the path u_1, v_{i+1}, u_t, etc.). Thus, both (a) and (c) hold.

But now we have reached a contradiction: v_k must exist and it must be that $x = u_k \prec v_k$, which is absurd. □

Theorem 4.2 implies that if G contains no vertices unrelated with respect to x, then (x, y) is a dominating pair in the subgraph of G induced by y and all vertices z with $y \prec z$. In particular, x and the last vertex numbered by LBFS(G, x) constitute a dominating pair of G.

We are now in a position to spell out the details of the dominating pair algorithm.

PROCEDURE DP(G).
{Input: a connected AT-free graph G;
Output: (y, z) a pokable dominating pair of G}
begin
  choose an arbitrary vertex x of G;
  if $N'(x) = \emptyset$ **then** return (x, x);
  LBFS(G, x);
  let y be the vertex numbered last by LBFS(G, x);
  LBFS(G, y);

let z be the vertex numbered last by LBFS(G, y);
return(y, z)
end; {DP}

As an example, we refer again to the graph G of Figure 1. We saw earlier that a possible numbering resulting from LBFS(G, q) corresponds to the ordering

$$f \prec g \prec j \prec h \prec i \prec e \prec k \prec d \prec l \prec b \prec a \prec c \prec p \prec q.$$

LBFS(G, f) may produce the ordering

$$a \prec q \prec b \prec p \prec c \prec l \prec d \prec j \prec i \prec h \prec g \prec k \prec e \prec f.$$

Thus, DP(G) may output the pokable dominating pair (a, f).

Finally, we state the following result.

THEOREM 4.3. *Procedure DP finds a pokable dominating pair in a connected AT-free graph, $G = (V, E)$, in $O(|V| + |E|)$ time.*

Proof. Clearly, (x, x) is a pokable dominating pair of G if $N'(x) = \emptyset$. Otherwise, by Theorem 4.1, G contains no unrelated vertices with respect to y and, hence, by Theorem 4.2, (y, z) is a dominating pair of G. In addition, Theorem 4.1 implies that both y and z are pokable in G. It is clear that a linear time implementation is possible (see [16] for details of a linear time implementation of LBFS). □

5. Computing dominated sets. Since dominating pairs play an important role in the study of AT-free graphs and, intuitively, correspond to the extreme endpoints of the linear structure of the graph, it is interesting to ask whether the above algorithm can be the basis of an efficient algorithm to find all of the dominating pairs in a connected AT-free graph. It turns out that we can indeed extend the algorithm to efficiently find all dominating pairs in a connected AT-free graph provided that the graph has diameter greater than 3. The diameter restriction is a consequence of Theorem 6.1, which states that the set of dominating pairs is precisely the Cartesian product of two subsets of vertices X and Y, provided the diameter of the graph is greater than 3. Thus, by computing X and Y, we have a linear-sized implicit representation of all dominating pairs. Such representations do not seem to hold for AT-free graphs with diameter less than 4.

Perhaps even more interesting in its own right, and a step in the direction of computing all dominating pairs, is a method that, given a connected AT-free graph G and a pokable dominating pair vertex x of G, computes the sets $D(v, x)$ for all vertices v of G. (Recall that $D(v, x)$ denotes the set of vertices that intercept all v,x-paths.) We describe this method first and, in the next section, we show how the information obtained can be used to compute all the dominating pairs in a connected AT-free graph with diameter greater than 3.

In order to understand our approach, which relies on a variant of LBFS, let us examine a few details of an efficient LBFS implementation. We use an adjacency list representation of a graph. Additionally, unnumbered vertices are stored in another data structure, specifically, a list of lists. At each stage of the algorithm, each list contains unnumbered vertices having the same label (i.e., vertices that are tied at the current stage), and lists are stored in decreasing lexicographic order of the corresponding labels. Thus, the largest label can be found in constant time. Let us examine the evolution of the list of lists during the execution of LBFS(G, x) where $G = (V, E)$. Initially, there are two lists: one contains the vertex x and corresponds to the label $|V|$, and the other contains all other vertices of G and corresponds to the label Λ.

Each time a new vertex u is numbered, it is removed from its list and its number is appended to the labels of its unnumbered neighbors. Each list that contains both an unnumbered neighbor of u and a vertex that is not adjacent to u, is split into two lists, one for the original label and one corresponding to the original label with $\sigma(u)$ appended. The first list follows the second in the ordered list of lists. It is important to note that, by the monotonicity property (Proposition 3.2), the relative order of the lists never changes. In order to access and move the neighbors of u in $O(d(u))$ time, an array of $|V|$ pointers indicates the location of each unnumbered vertex within the list of lists, and the lists are doubly linked.

We now return to the problem at hand, namely, given a connected AT-free graph $G = (V, E)$ and a pokable dominating pair vertex x of G, we wish to compute the sets $D(v, x)$ for all vertices v of G. We will modify LBFS to obtain a linear time algorithm for this problem. To begin, we observe that the sum of the cardinalities of the sets $D(v, x)$, for all $v \in V$, may be $O(|V|^2)$, and hence, a linear time algorithm must use an implicit representation of these sets. We handle this as follows: for each vertex v we compute a number, span(v), $1 \leq \text{span}(v) \leq \sigma(v)$, with the property that $D(v, x) = \{u | \sigma(u) \geq \text{span}(v)\} \cup N^-(v)$, where σ is a numbering resulting from LBFS(G, x) and $N^-(v) = N(v) \cap \{w | \sigma(w) < \sigma(v)\}$. Thus, span$(v)$ indicates an interval, with respect to σ, of vertices to be included in $D(v, x)$. When all vertices of a set $W \subseteq V$ have the same span value, we refer to that value as span(W).

The values of span(v) for all vertices v are computed incrementally. It is not necessary to update the values individually because all vertices on the same list will have the same span value. Thus, we store span values for each list, rather than for each vertex. The two initial lists have span values of $|V|$. Just before a vertex is numbered, the span value of its list is updated. When a list is split, the two new lists inherit the span value of the original list. A span value is assigned to an individual vertex when that vertex is finally numbered. As we maintain the lists, we store the size of each list. Thus, for the list W in each iteration, W, $|W|$, and span(W) can be accessed in constant time. Furthermore, over all iterations, all updates of span values can be accomplished in linear time. Thus, the overall complexity of the algorithm below is $O(|V| + |E|)$.

Procedure DSETS is a modified LBFS which computes implicit representations of $D(v, x)$ for all $v \in V$.

PROCEDURE DSETS(G, x).
{Input: a connected AT-free graph $G = (V, E)$ and a pokable dominating pair vertex x of G;
Output: a numbering σ of the vertices of G and, for each vertex v, span(v) such that $D(v, x) = \{u | \sigma(u) \geq \text{span}(v)\} \cup N^-(v)$ }
begin
label$(x) \leftarrow |V|$;
for each vertex v in $V - \{x\}$ **do**
label$(v) \leftarrow \Lambda$;
$W_1 \leftarrow \{x\}$; $W_2 \leftarrow V - \{x\}$; {Initialize two lists}
span$(W_1) \leftarrow$ span$(W_2) \leftarrow |V|$;
for $i \leftarrow |V|$ **downto** 1 **do begin** {main for loop}
pick an unnumbered vertex v with (lexicographically) the largest label;
let W be the list containing v and all vertices tied with v;
span$(W) \leftarrow$ min {span(W), $i + 1 - |W|$ };
remove v from W;

```
    σ(v) ← i; {assign to v number i}
    span(v) ← span(W);
    for each unnumbered vertex u in N(v) do
      append i to label(u);
    split lists as necessary so that there is a one-to-one correspondence between the
    resulting set of lists and the vertex labels
    end {main for loop}
  end; {DSETS}
```

Let us look again at the graph G of Figure 1. Suppose that the numbering returned by DSETS(G, q) corresponds to the ordering

$$f \prec g \prec j \prec h \prec i \prec e \prec k \prec d \prec l \prec b \prec a \prec c \prec p \prec q.$$

Now the span values computed by DSETS(G, q) will be

v	a	b	c	d	e	f	g	h	i	j	k	l	p	q
span(v)	11	10	11	8	6	1	1	1	1	1	7	9	11	14

It is easy to verify that the corresponding sets are correctly represented in this case. For example, $D(q, q) = \{a, c, p, q\}$, $D(l, q) = \{a, b, c, d, k, l, p, q\}$, and $D(e, q) = V$.

Before presenting the proof of correctness of Procedure DSETS, we examine the relationship between vertices x (such that there are no vertices unrelated with respect to x) and pokable dominating pair vertices. The following lemma acts as a bridge between the results of section 4 and the subsequent results of this section.

LEMMA 5.1. *Let G be a connected AT-free graph and let x be an arbitrary vertex of G. Then G contains no vertices unrelated with respect to x if and only if x is a pokable dominating pair vertex of G.*

Proof. The "only if" part follows from Theorem 4.2 and the fact that if G contains no vertices unrelated with respect to x, then x is pokable (since no AT can be created by adding a pendant vertex adjacent to x). To prove the "if" part, let y be a vertex of G such that (x, y) is a dominating pair of G, and consider unrelated vertices u and v with respect to x. Since (x, y) is a dominating pair, u and v intercept every path joining x and y. Let π be an x,y-path and let u' and v' be vertices on π adjacent to u and v, respectively. Trivially, both u' and v' are distinct from x. But now there exists a u,v-path in G that does not contain x (this path contains vertices u', v' and a subpath of π), implying that x is not pokable. □

The correctness of Procedure DSETS relies on the following theorem.

THEOREM 5.2. *Let x be a pokable dominating pair vertex of a connected AT-free graph $G = (V, E)$. For every vertex v of G, $D(v, x) = \{u | \sigma(u) \geq \text{span}(v)\} \cup N^-(v)$.*

Proof. Informally, notice that span(v) is the smallest numbered vertex that is tied with v at any point in the algorithm. Intuitively, all vertices in $\{u | \sigma(u) \geq \text{span}(v)\}$, as well as all neighbors of v, are in $D(v, x)$. The proof demonstrates that $D(v, x)$ is exactly equal to this set of vertices.

Formally, let $\sigma : V \mapsto \{1, 2, \ldots, n\}$ be a numbering returned by DSETS(G, x), let v be an arbitrary vertex of V, and let $D(v) = \{u | \sigma(u) \geq \text{span}(v)\} \cup N^-(v)$.

Our plan is to prove that $D(v) = D(v, x)$. To implement this plan we first prove that $D(v) \subseteq D(v, x)$. Suppose that $D(v) \not\subseteq D(v, x)$, and let u be a vertex in $D(v)$ but not in $D(v, x)$. Now $uv \notin E$ and, by Theorem 4.2 and Lemma 5.1, $\sigma(u) < \sigma(v)$. Thus, by the algorithm, $\text{span}(v) \leq \sigma(u) < \sigma(v)$. (To see this, notice that during the

iteration of the main for loop in which vertex v is numbered, the list W that contains v receives a span value less than or equal to $i+1-|W|$. Since W contains v, $|W| \geq 1$ and hence $\text{span}(W) \leq i$. Now, the desired inequality follows, since $\sigma(v)$ is assigned the value i and $\text{span}(v)$ is assigned the value $\text{span}(W)$.)

Let w be the vertex being processed when $\text{span}(v)$ was first set to its final value. (It could be that $w = v$.) Then u, v, and w were tied at w; that is, $N(u) \cap \{t|\sigma(t) > \sigma(w)\} = N(v) \cap \{t|\sigma(t) > \sigma(w)\} = N(w) \cap \{t|\sigma(t) > \sigma(w)\}$. Since $u \notin D(v,x)$ there exists a v,x-path $\pi : v = v_1, v_2, \ldots, v_k = x$ missed by u. By Theorem 4.2 and Lemma 5.1, all vertices of π are larger than u. Let i be the greatest index such that $\sigma(v_i) < \sigma(w)$. Clearly, $i < k$, since $\sigma(w) < \sigma(x)$. Now $\sigma(u) < \sigma(v_i) < \sigma(w)$ and thus, by the monotonicity property (Proposition 3.2), v_i was tied with u, v, and w at w. But v_i is adjacent to v_{i+1} with $\sigma(w) < \sigma(v_{i+1})$; thus, v_{i+1} belongs to $N(w) \cap \{t|\sigma(t) > \sigma(w)\}$ and is therefore adjacent to u, contradicting that π is missed by u. Thus, $D(v) \subseteq D(v,x)$.

We now prove that $D(v,x) \subseteq D(v)$, thereby completing the proof of the theorem. Suppose that $D(v,x) \not\subseteq D(v)$. Let u be a vertex in $D(v,x)$ but not in $D(v)$. Clearly, $uv \notin E$ and $\sigma(u) < \text{span}(v) \leq \sigma(v)$.

If at any stage u and v are tied with the vertex being processed, then $\text{span}(v)$ is set to a value less than or equal to $\sigma(u)$, and $\text{span}(v)$ is never increased. Thus, since $\text{span}(v) > \sigma(u)$, we know that u and v are never tied with the vertex being processed. Let z be the largest neighbor of v. Since u cannot be adjacent to any vertex greater than z (else $\sigma(u) < \sigma(v)$ is contradicted), and since there is a z,x-path consisting entirely of z and vertices larger than z (by the breadth-first nature of the search), u must be adjacent to z. (Otherwise we contradict the fact that $u \in D(v,x)$.) Now let Z be the vertices of $N(v) \cap \{t|\sigma(t) > \sigma(v)\}$ which have a neighbor greater than z, and let Z' be the remaining vertices of $N(v) \cap \{t|\sigma(t) > \sigma(v)\}$. Clearly, $z \in Z$. Note that u is adjacent to all vertices of Z; otherwise there is a v,x-path missed by u, which is a contradiction. We observe that for every $z \in Z$ and every $z' \in Z'$, it must be that $z' \prec z$. This follows from the monotonicity property (Proposition 3.2) and by the fact that, at z, all vertices of Z' have labels lexicographically less than all vertices of Z. Finally, all vertices of Z' are adjacent to all vertices of Z, since any vertex of Z' nonadjacent to a vertex of Z would have been processed after v. But when the first vertex of Z' is processed, all vertices of Z', u, and v are tied, contradicting our earlier statement that u and v are not tied at any stage. This completes the proof. □

Theorem 5.2, along with the discussion preceding Procedure DSETS, implies the following result.

THEOREM 5.3. *Let $G = (V,E)$ be a connected AT-free graph and let x be a pokable dominating pair vertex of G. Procedure DSETS computes implicit representations for the sets $D(v,x)$ for every vertex v of G in $O(|V| + |E|)$ time.*

6. Computing all dominating pairs. We now describe how to use the span values computed by Procedure DSETS to compute all dominating pairs in a connected AT-free graph with sufficiently large diameter. Our algorithm relies on the following result, the proof of which appears in [9].

THEOREM 6.1 (see [9]). *Let G be a connected AT-free graph with diam$(G) > 3$. There exist nonempty, disjoint sets X and Y of vertices of G such that (x,y) is a dominating pair if and only if $x \in X$ and $y \in Y$.*

We note that Theorem 6.1 is best possible in the sense that, for AT-free graphs of diameter less than 4, the sets X and Y are not guaranteed to exist. To wit, C_5 and the graph of Figure 2 provide counterexamples of diameters 2 and 3, respectively.

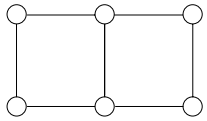

FIG. 2. *An AT-free graph of diameter* 3 *for which the sets* X *and* Y *do not exist.*

Procedure ALL-DPs takes as input a connected AT-free graph $G = (V, E)$ with diameter greater than 3, and returns X and Y, subsets of V such that (x, y) is a dominating pair if and only if $x \in X$ and $y \in Y$. Procedure DSETS is an integral part of Procedure ALL-DPs.

We begin with an informal description of Procedure ALL-DPs. The first step is to find a pokable dominating pair vertex, which is done by LBFS in linear time. Then, Procedure DSETS(G, x) computes span(v) for all vertices v in linear time. From the resulting span values, and by Theorem 6.1, it is easy to see how to proceed.

Now, Y is the set of all vertices y with $D(y, x) = V$ (whether or not $D(y, x) = V$ can be computed in $O(d(y))$ time by scanning the adjacency list of y and checking whether all vertices w with $\sigma(w) < \text{span}(y)$ are adjacent to v). Finally, we call DSETS(G, y), where y is the vertex that was numbered last by DSETS(G, x). The new set of span values can be used to compute the set X in a manner identical to the above method for computing Y. We now state the procedure more precisely.

PROCEDURE ALL-DPs(G).
{Input: connected AT-free graph $G = (V, E)$ with diam$(G) > 3$;
Output: $X \subseteq V$ and $Y \subseteq V$ such that (x, y) is a dominating pair of G if and only if $x \in X$ and $y \in Y$}
begin
  choose an arbitrary vertex w of G;
  LBFS(G, w);
  let x be the vertex numbered last by LBFS(G, w);
  DSETS(G, x);
  $Y = \emptyset$;
  for every $y \in V$ **do begin**
    count $\leftarrow |V| - \text{span}(y)$; {number of vertices not in $\{u | \sigma(u) \geq \text{span}(y)\}$
    for each $u \in N(y)$ **do**
      if $\sigma(u) < \text{span}(y)$ **then** *count* $\leftarrow$ *count* $- 1$;
    if *count* $= 0$ **then** $Y \leftarrow Y \cup \{y\}$
    end;
  let y be the vertex numbered last by LBFS(G, x);
  DSETS(G, y);
  $X = \emptyset$;
  for every $x \in V$ **do begin**
    count $\leftarrow |V| - \text{span}(x)$; {number of vertices not in $\{u | \sigma(u) \geq \text{span}(x)\}$
    for each $u \in N(x)$ **do**
      if $\sigma(u) < \text{span}(x)$ **then** *count* $\leftarrow$ *count* $- 1$;
    if *count* $= 0$ **then** $X \leftarrow X \cup \{x\}$
    end;
  return(X, Y)
  end; {ALL-DPs}

As an illustration, when run with the graph G of Figure 1 as input, Procedure ALL-DPs returns $X = \{a, q\}$, $Y = \{e, f, g, h, i, j, k\}$ or $X = \{e, f, g, h, i, j, k\}$, $Y = \{a, q\}$ (depending upon the initial choice of w).

THEOREM 6.2. *For a connected AT-free graph $G = (V, E)$ with diam(G) > 3, Procedure ALL-DPs computes sets X and Y such that (x, y) is a dominating pair of G if and only if $x \in X$ and $y \in Y$ in $O(|V| + |E|)$ time.*

Proof. We observe that, by Theorem 4.1 and Lemma 5.1, the vertex x in ALL-DPs is guaranteed to be a pokable dominating pair vertex. Similarly, by Theorem 4.1 and Lemma 5.1, the vertex y is a pokable dominating pair vertex. (This follows from the observation that the set of possible numberings produced by DSETS(G, x) is exactly the set of possible numberings of LBFS(G, x), since DSETS is simply LBFS with some additional computations.) Thus, the correctness of Procedure ALL-DPs follows from Theorem 5.3 and Theorem 6.1. Similarly, the complexity of ALL-DPs is the sum of the complexities of LBFS and DSETS plus an $O(|V| + |E|)$ term. □

Let $G = (V, E)$ be a connected AT-free graph with diam$(G) > 3$. Notice that, even though there may be $O(|V|^2)$ dominating pairs in G, Procedure ALL-DPs can compute and represent them in linear time, by virtue of Theorem 6.1. A similar comment applies to the sets $D(v, x)$ for all $v \in V$; even though the sum of the cardinalities of the sets may be $O(|V|^2)$, Procedure DSETS can compute an implicit representation of them in linear time.

We conclude with a corollary, which follows from the fact that some minimum cardinality connected dominating set must be a shortest path between the vertices of a dominating pair (proved in [9]). Once X and Y have been found, a minimum distance dominating pair can be found in linear time by performing a breadth-first search starting at X until a vertex of Y is encountered. In [7], we presented a linear time algorithm to compute a dominating path in an arbitrary connected AT-free graph, but that algorithm does not guarantee a minimum cardinality dominating path. The method of the present paper does guarantee a minimum cardinality dominating path for connected AT-free graphs with diameter greater than 3.

COROLLARY 6.3. *Let $G = (V, E)$ be a connected AT-free graph with diameter greater than 3. A minimum cardinality connected dominating set of G can be computed in $O(|V| + |E|)$ time.* □

7. Conclusions. We have presented a linear time algorithm, based on the well-known lexicographic breadth-first search of [16], for finding a pokable dominating pair in a connected AT-free graph, $G = (V, E)$. The algorithm provides a constructive proof of the existence of pokable dominating pairs in connected AT-free graphs (an existential proof of this fact was given in [9]). It is an improvement over the previously known $O(|V|^3)$ algorithm of [2]. In addition, we extended the dominating pair algorithm to find all dominating pairs in a connected AT-free graph, $G = (V, E)$, with diameter greater than 3. Even though there may be $O(|V|^2)$ dominating pairs, the extended algorithm can compute and implicitly represent them in $O(|V| + |E|)$ time. We remark that the simpler maximum cardinality search (MCS) of Tarjan and Yannakakis [17] cannot take the place of LBFS in these algorithms.

In [8], we presented a different linear time algorithm for finding a dominating pair in a connected AT-free graph. This other algorithm is based on a recursive use of a maximum cardinality breadth-first search. The method does not seem to allow linear time calculation of $D(v, x)$ for all vertices v where x is a pokable dominating pair vertex, or of sets X and Y when the diameter of the graph is greater than 3.

Abstract. We show that any polygonal subdivision in the plane can be converted into an "m-guillotine" subdivision whose length is at most $(1 + \frac{c}{m})$ times that of the original subdivision, for a small constant c. "m-Guillotine" subdivisions have a simple recursive structure that allows one to search for the shortest of such subdivisions in polynomial time, using dynamic programming. In particular, a consequence of our main theorem is a simple polynomial-time approximation scheme for geometric instances of several network optimization problems, including the Steiner minimum spanning tree, the traveling salesperson problem (TSP), and the k-MST problem.

1. Introduction.

We obtain a simple polynomial-time approximation scheme for geometric instances of some network optimization problems, including the Steiner minimum spanning tree, the traveling salesperson problem (TSP), and the k-MST problem.

The method is based on the concept of an "m-guillotine subdivision," a simple extension of the recent approximation method of Mitchell [9], which considered the case $m = 1$. Roughly speaking, an "m-guillotine subdivision" is a polygonal subdivision with the property that there exists a line ("cut"), whose intersection with the subdivision edges consists of a small number ($O(m)$) of connected components, and the subdivisions on either side of the line are also m-guillotine. The upper bound on the number of connected components allows one to apply dynamic programming to optimize over m-guillotine subdivisions, as there is a succinct specification of how subproblems interact across a cut.

Key to our method is a theorem showing that any polygonal subdivision can be converted into an m-guillotine subdivision by adding a set of edges whose total length is small: at most $\frac{c}{m}$ times that of the original subdivision (where $c = 1, \sqrt{2}$, depending on the metric). Then, using dynamic programming to optimize over an appropriate class of m-guillotine subdivisions, we obtain, for any fixed m, $(1 + \frac{c}{m})$-approximation algorithms that run in polynomial-time ($n^{O(m)}$) for various network optimization problems.

Related work. Over the last few decades, there has been a wealth of research on the problems studied here, both in the graph versions of the problems and in the geometric versions. Almost any standard textbook on algorithms and networks discusses them; e.g., see [4, 6, 12]. For a survey of work on the TSP, refer to the

book [7] edited by Lawler et al. For a survey on approximation algorithms, refer to the recent book [5] edited by Hochbaum.

All of the geometric optimization problems considered here are known to be NP-hard. Polynomial-time approximation algorithms were known, allowing one to get within a constant factor of optimal. However, it has been open as to whether or not one can, in polynomial time, achieve an approximation factor of $(1+\epsilon)$ for any fixed $\epsilon > 0$; i.e., no polynomial-time approximation scheme (PTAS) was known. In particular, no factor better than the Christofides bound of 1.5 was known for the Euclidean TSP.

In this paper, we point out how a minor modification to a previous result [9, 11] (see also [3]) leads to a PTAS for various geometric optimization problems, including the TSP, Steiner tree, and k-MST.

In an exciting recent development, Arora [1] announced that he had found a PTAS for the Euclidean TSP, as well as the other problems considered in this paper, thereby achieving essentially the same results that we report here, using decomposition schemes that are somewhat similar to our own. Arora's remarkable results predate this paper by several weeks. Arora has generalized his method also to higher dimensions, obtaining a running time of $n^{O(\log^{d-2} n)/\epsilon^{d-1}}$ in d dimensions. For the two-dimensional TSP, Arora estimates that his analysis yields a time bound of roughly $n^{100/\epsilon}$; he adds that a more careful analysis should yield roughly $n^{30/\epsilon}$. In this paper, we give analysis giving an explicit exponent: time $O(n^{20m+5})$ to get within factor $(1+\frac{2\sqrt{2}}{m})$ of optimal in the Euclidean planar TSP; in terms of ϵ, the time bound is $O(n^{\frac{40\sqrt{2}}{\epsilon}+5})$.

2. m-Guillotine subdivisions. We follow most of the notation of [9], only somewhat generalized. We consider a polygonal subdivision ("planar straight-line graph") S that has n edges (and hence $O(n)$ vertices and facets). Let E denote the union of the edge segments of S, and let V denote the vertices of S. We can assume (without loss of generality) that S is restricted to the unit square, B (i.e., $E \subset \text{int}(B)$). Then, each facet (2-face) is a bounded polygon, possibly with holes. The *length* of S is the sum of the lengths of the edges of S. If all edges E are horizontal or vertical, then we say that S is *rectilinear*.

A closed, axis-aligned rectangle W is a *window* if $W \subseteq B$. In the following definitions, we fix attention on a given window, W.

A line ℓ is a *cut* for E (with respect to W) if ℓ is horizontal or vertical and $\ell \cap \text{int}(W) \neq \emptyset$. The intersection, $\ell \cap (E \cap \text{int}(W))$, of a cut ℓ with $E \cap \text{int}(W)$ (the restriction of E to the window W) consists of a discrete (possibly empty) set of subsegments of ℓ. (Some of these "segments" may be single points, where ℓ crosses an edge.) The endpoints of these subsegments are called the *endpoints along* ℓ (with respect to W). (The two points where ℓ crosses the boundary of W are not considered to be endpoints along ℓ.) Let ξ be the number of endpoints along ℓ, and let the points be denoted by $p_1, \ldots, p_\xi$, in order along ℓ.

For a positive integer m, we define the *m-span*, $\sigma_m(\ell)$, of ℓ (with respect to W) as follows. If $\xi \leq 2(m-1)$, then $\sigma_m(\ell) = \emptyset$; otherwise, $\sigma_m(\ell)$ is defined to be the (possibly zero-length) line segment, $p_m p_{\xi-m+1}$, joining the mth endpoint, p_m, with the mth-from-the-last endpoints, $p_{\xi-m+1}$. (See Figure 2.1.)

A (horizontal or vertical) cut ℓ is an *m-perfect cut with respect to* W if $\sigma_m(\ell) \subseteq E$. In particular, if $\xi \leq 2(m-1)$, then ℓ is trivially an m-perfect cut (since $\sigma_m(\ell) = \emptyset$). Similarly, if $\xi = 2m-1$, then ℓ is m-perfect (since $\sigma_m(\ell)$ is a single point). Otherwise, if ℓ is m-perfect, and $\xi \geq 2m$, then $\xi = 2m$. See Figure 2.2 for an example.

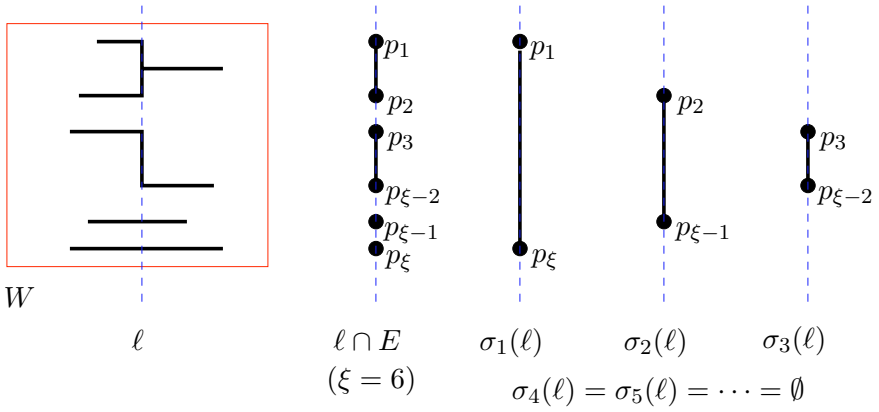

FIG. 2.1. *Definition of m-span.*

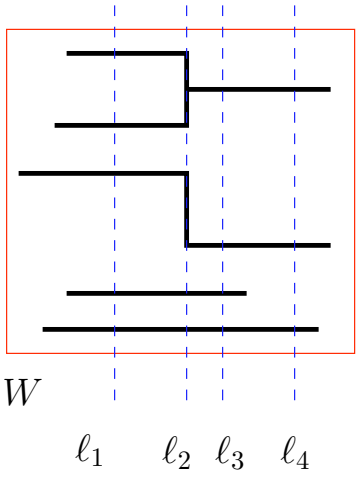

FIG. 2.2. *The vertical cuts $\ell_1, \ell_2, \ell_3, \ell_4$ are 3-perfect (also m-perfect, for $m \geq 4$). The cut ℓ_4 is also 2-perfect (but not 1-perfect).*

Finally, we say that S is an *m-guillotine subdivision with respect to window* W if either (1) $E \cap \text{int}(W) = \emptyset$; or (2) there exists an m-perfect cut, ℓ, with respect to W, such that S is m-guillotine with respect to windows $W \cap H^+$ and $W \cap H^-$, where H^+, H^- are the closed half-planes induced by ℓ. We say that S is an *m-guillotine subdivision* if S is m-guillotine with respect to the unit square, B. A 1-guillotine subdivision is illustrated in Figure 2.3, where "cut" is used to indicate where a 1-perfect cut can be made.

3. The main theorem. For rectilinear subdivisions, the proof of our main theorem directly follows that of [9] with only a very minor change: we use the concept of "m-darkness," in which we require m walls to block light from the boundary. The proof in [9] used $m = 1$; so we copy below the proof from [9] with "m" replacing "1".

THEOREM 3.1. *Let S be a rectilinear subdivision, with edge set E, of length L. Then, for any positive integer m, there exists an m-guillotine rectilinear subdivision, S_G, of length at most $(1 + \frac{1}{m})L$ whose edge set, E_G, contains E.*

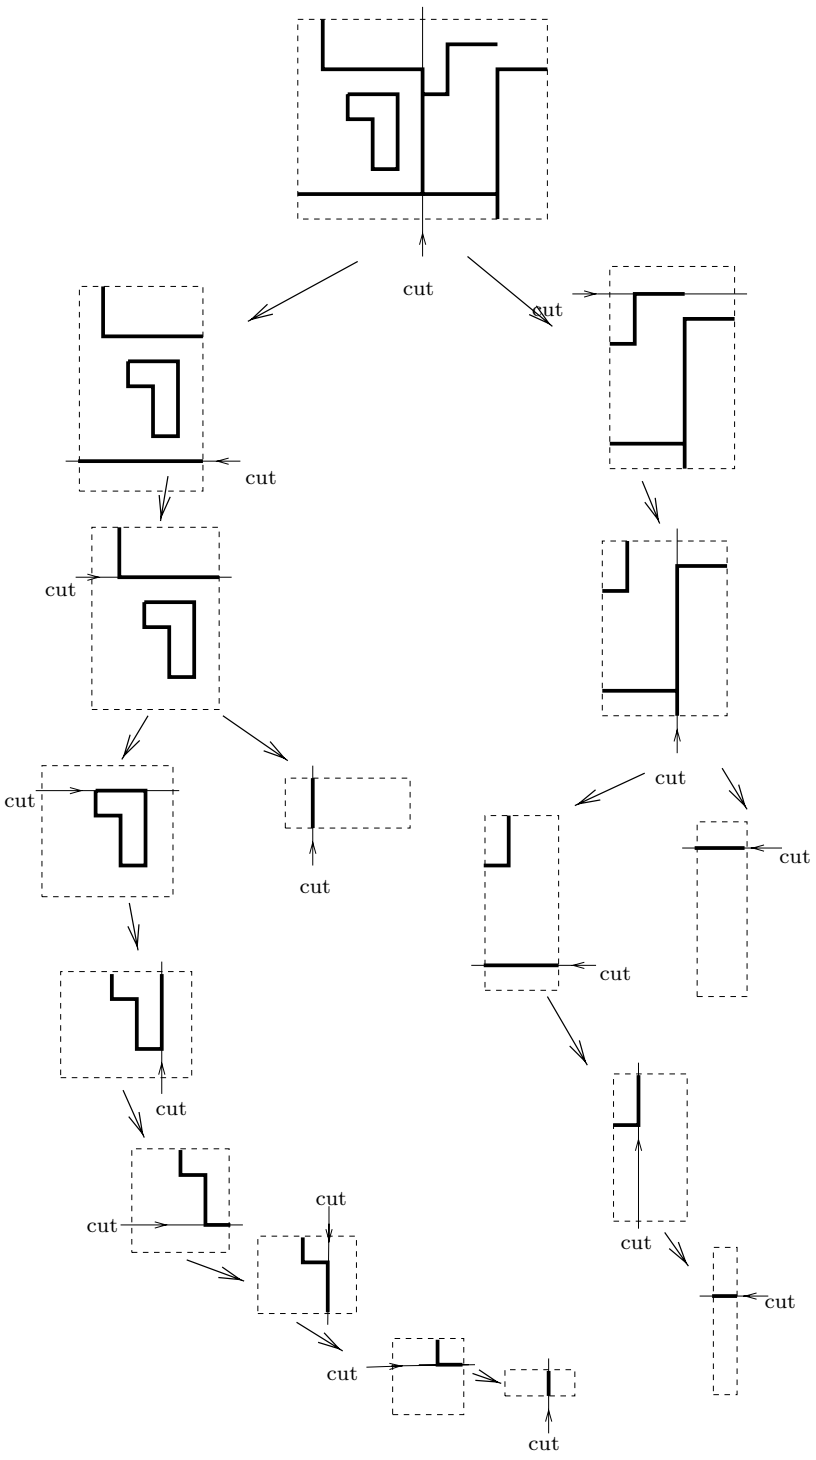

FIG. 2.3. *An example of a* 1*-guillotine rectilinear subdivision.*

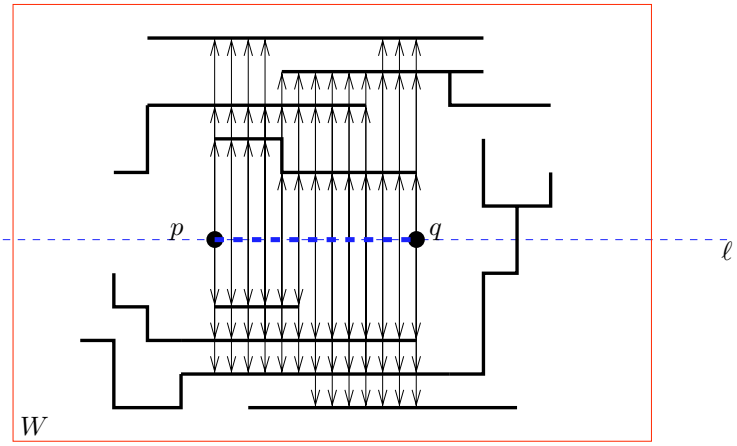

FIG. 3.1. *Subsegment $pq \subset \ell$ is 3-dark; its length is charged to the 3 levels of E that lie above it and the 3 levels of E that lie below it.*

Proof. We will convert S into an m-guillotine subdivision S_G by adding to E a new set of horizontal/vertical edges whose total length is at most $\frac{1}{m}L$. The construction is recursive; at each stage, we show that there exists a cut, ℓ, with respect to the current window W (which initially is the box B), such that we can afford to add the m-span $\sigma_m(\ell)$ to E, while appropriately charging off the length of $\sigma_m(\ell)$. (Once we add $\sigma_m(\ell)$ to E, ℓ becomes an m-perfect cut with respect to W.)

In fact, we will restrict ourselves to a special discrete set, $\mathcal{L}$, of horizontal/vertical cuts, namely those determined by the x- or y-coordinates of original vertices V of the subdivision, or by the midpoints between consecutive x- or y-coordinates of V.

First, note that if an m-perfect cut (with respect to W) exists, then we can simply use it and proceed, recursively, on each side of the cut.

We say that a point p on a cut ℓ is *m-dark with respect to ℓ and W* if, along $\ell^\perp \cap \text{int}(W)$, there are at least m endpoints (strictly) on each side of p, where $\ell^\perp$ is the line through p and perpendicular to ℓ.[1] We say that a subsegment of ℓ is *m-dark* (with respect to W) if all points of the segment are m-dark with respect to ℓ and W.

The important property of m-dark points along ℓ is the following. Assume, without loss of generality, that ℓ is horizontal. The m-dark portion of ℓ is, in general, a union of subsegments of $\ell \cap W$, some endpoints of which may not be themselves m-dark points. (In terms of the *length* (measure) of the m-dark portion, though, the discrete set of endpoints is not relevant.) Let pq be an open subsegment of the m-dark portion of ℓ. Then we can charge the length of pq off to the bottoms of the first m subsegments, $E^+ \subseteq E$, of edges that lie above pq, and the tops of the first m subsegments, $E^- \subseteq E$, of edges that lie below pq (since we know that there are at least m edges "blocking" pq from the top/bottom of W). We charge pq's length half to E^+ (charging each of the m levels of E^+ *from below*, with $\frac{1}{2m}$ units of charge) and half to E^- (charging each of the m levels of E^- *from above*, with $\frac{1}{2m}$ units of charge). In Figure 3.1 we illustrate how a 3-dark subsegment, pq, has its length charged off to the 3 levels of E that are above/below it.

[1] We can think of the edges E as being "walls" that are not very effective at blocking light—light can go through $m-1$ walls but is stopped when it hits the mth wall; then, p on a line ℓ is m-dark if p is not illuminated when light is shone in from the boundary of W, along the direction of $\ell^\perp$.

We call a cut ℓ *favorable* if the total length of the m-dark portion of ℓ is at least as great as the length of the m-span, $\sigma_m(\ell)$. The lemma below shows that a favorable cut always exists (even one in the special discrete set, $\mathcal{L}$). For a favorable cut ℓ, we add its m-span to the edge set (charging off its length, as above), and recurse on each side of the cut, in the two new windows. After a portion of E has been charged on one side, due to a cut ℓ, it will be within m levels of the boundary of the windows on either side of ℓ, and, hence, within m levels of the boundary of any future windows, found deeper in the recursion that contain the portion. Thus, *no portion of E will ever be charged more than once from each side* (top and bottom), so no portion of E will ever pay more than its total length, times $\frac{1}{m}$, in charge ($\frac{1}{2m}$ from each side). Also, the new edges added (the spans $\sigma_m(\ell)$) are never themselves charged, since they lie on window boundaries and cannot therefore serve to make a portion of some future cut m-dark.

(Note too that, in order for a cut ℓ to be favorable but not m-perfect, there must be at least one segment (in fact, at least m segments) of E parallel to ℓ in each of the two open half-planes induced by ℓ; thus, the recursion must terminate in a finite number of steps.)

Since the total length of all m-spans for all favorable cuts is at most $\frac{1}{m}L$, and the total length of all m-spans for all m-perfect cuts is at most L, we are done. □

We now prove our key lemma, which guarantees the existence of a favorable cut. The proof of the lemma uses a particularly simple argument, based on elementary calculus (reversing the order of integration). It appears already in [9], but we repeat it here for completeness.

LEMMA 3.2. *For any subdivision S and any window W, there is a favorable cut.*

Proof. We show that there must be a favorable cut that is either horizontal or vertical.

Let $f(x)$ denote the length of the m-span (with respect to W) of the vertical line through x. (We define $f(x) = 0$, if $x \in [0,1]$ lies outside of the projection of $W \subseteq B$ onto the x-axis.) Then, $\int_0^1 f(x)dx$ is simply the area, A_x, of the set R_x of points of W that are m-dark with respect to horizontal cuts. Similarly, define $g(y)$ to be the length of the m-span of the horizontal line through y, and let $A_y = \int_0^1 g(y)dy$.

Assume, without loss of generality, that $A_x \geq A_y$. We claim that there exists a horizontal favorable cut; i.e., we claim that there exists a horizontal cut, ℓ, such that the length of its m-dark portion is at least as large as the length of its m-span, $\sigma_m(\ell)$. To see this, note that A_x can be computed by switching the order of integration, "slicing" the region R_x horizontally, rather than vertically; i.e., $A_x = \int_0^1 h(y)dy$, where $h(y)$ is the length of the intersection of R_x with a horizontal line through y (i.e., $h(y)$ is the length of the m-dark portion of the horizontal line through y). Thus, since $A_x \geq A_y$, we get that $\int_0^1 h(y)dy \geq \int_0^1 g(y)dy \geq 0$. Thus, it cannot be that for all values of $y \in [0,1]$, $h(y) < g(y)$, so there exists a $y = y^*$ for which $h(y^*) \geq g(y^*)$. The horizontal line through this y^* is a cut satisfying the claim of the lemma. (If, instead, we had $A_x \leq A_y$, then we would get a *vertical* cut satisfying the claim.)

Finally, we note that, in the rectilinear case, f, g, and h are piecewise-constant, with discontinuities corresponding to vertices V of S. Then, we can always select y^* to be at a discontinuity or at a midpoint between two discontinuities. □

General polygonal subdivisions. Consider now a subdivision S whose edges E are *not* rectilinear. A moment's reflection reveals that our charging scheme and the key lemma are quite general and do not really use the rectilinearity of S (or even

the straightness of edges in E). In fact, the proof of the main theorem goes through, almost exactly as before, adding "favorable" cuts that are horizontal or vertical, and charging the added length off to the original length of the subdivision. However, we must address the issue of the discretization of cuts (e.g., in order to specify a dynamic program) and, thereby, the termination of the recursion that converts an arbitrary subdivision to an m-guillotine subdivision.

One approach (as in earlier drafts of this paper) is to use discretization of orientations, and/or discretization onto a sufficiently fine grid. Here, we opt instead to modify slightly our previous definition of m-guillotine subdivision as follows.

Assume, without loss of generality, that no two vertices have a common x- or y-coordinate. We let E_W denote the subset of E consisting of the union of segments of E having at least one endpoint inside (or on the boundary of) W. The *combinatorial type* (*with respect to* E) of a window W is an ordered listing, for each of the four sides of W, of the identities of the (closed) line segments of E_W that intersect it (the side of W, each considered to be an open line segment), as well as the identities of the line segments of E_W that intersect each of the four corners of W. We say that W is *minimal* (with respect to E) if there does not exist a $W' \subset W$, strictly contained in W, having the same combinatorial type as W. By standard critical placement arguments,[2] we see that, since it has four degrees of freedom, a minimal window is determined by four *contact pairs*, defined by a vertex $v \in V$ in contact with a side of W or by a corner of W in contact with a segment of E_W. (Thus, there are at most $O(n^4)$ minimal windows.) For any window W containing at least one vertex of E, we let $\overline{W}$ denote a minimal window, contained within W, having the same combinatorial type as W. (At least one such $\overline{W}$ must exist.)

Now, we say that S is an *m-guillotine subdivision with respect to window W* if either (1) $V \cap \mathrm{int}(W) = \emptyset$; or (2) there exists an m-perfect cut, ℓ, with respect to a minimal window, $\overline{W} \subseteq W$, such that S is m-guillotine with respect to windows $W \cap H^+$ and $W \cap H^-$, where H^+, H^- are the closed half-planes induced by ℓ. (Note that, since $\overline{W}$ is minimal, necessarily windows $W \cap H^+$ and $W \cap H^-$ will each have a combinatorial type different from that of W.)

THEOREM 3.3. *Let S be a polygonal subdivision, with edge set E, of length L. Then, for any positive integer m, there exists an m-guillotine polygonal subdivision, S_G, of length at most $(1 + \frac{\sqrt{2}}{m})L$ whose edge set, E_G, contains E.*

Proof. The proof exactly follows that of the rectilinear case (Theorem 3.1): We use a recursive construction, together with our charging scheme, and Lemma 3.2 applied

[2] In particular, an arbitrary window, W, can be made minimal by the following "shrinking" process: Slide the right side of W inward until the first *event*, when (a) the side hits a vertex, or (b) an endpoint of the side strikes a segment of E_W. In case (a), we have "pinned" the right side of W, and we move next to the top side (then the left side, and the bottom side). In case (b), we next move inwards *both* of the two sides incident on the corner (endpoint) that struck a segment, $s \subset E_W$, while keeping that corner in contact with segment s, until another event (of type (a) or (b)) occurs. (Since we know that $s \in E_W$ has one of its endpoints inside W, we know that as we slide the corner along s, the two sides either both move inward or both move outward.) Again, in case of an event of type (a), we are done moving those two sides (they are both pinned), and we proceed to move inwards other sides (processing unpinned sides in the order right, top, left, bottom). In case of an event of type (b), a second corner of the window has struck a segment, $s' \subset E_W$, and we then proceed to slide *three* sides of W inward simultaneously, while keeping both of the pinned corners sliding on their respective segments of E_W. We may end up having all four sides of W moving inwards at once, with three, or possibly even four (in a degenerate case), corners of W restricted to slide on specific segments of E_W. Since each of these segments of E_W must have one endpoint within W, we know that we will eventually have an event of type (a)—a collision with a vertex. When this happens, all four sides of W have been pinned.

to a minimal window $\overline{W} \subseteq W$, to show that we can convert S into an m-guillotine subdivision S_G by adding to E a new set of horizontal/vertical bridge segments whose total length is at most $\frac{\sqrt{2}}{m}L$. (Here, we do not restrict attention to any special subset of horizontal and vertical cuts (such as $\mathcal{L}$); cuts can be classified according to the combinatorial types of the new windows they create.)

The only difference that we should mention is the origin of the "$\sqrt{2}$" term in the bound. This comes from the fact that each side of an inclined segment of E may be charged *twice*, once vertically and once horizontally. Specifically, the charge assigned to a segment is at most $\frac{1}{m}$ times the sum of the lengths of its x- and y-projections, i.e., at most $\frac{\sqrt{2}}{m}$ times its length. □

4. Some applications. We now discuss how our main theorem can be applied, leading to polynomial-time approximation schemes for some NP-hard optimization problems on a set P of n sites in the plane.

Steiner tree problem: Determine a tree of minimum total length that spans (visits) the set of points P. In this problem, as opposed to the *minimum spanning tree* (MST) problem (solvable exactly in $O(n \log n)$ time for points in the Euclidean plane [13]), the tree is allowed to have vertices ("Steiner points") that are *not* among the points of P.

Steiner k-MST problem: For a given integer k ($k \leq n$), determine a tree, possibly with Steiner points, of minimum total length that spans at least k of the n points in P.

TSP: Determine a *tour* (cycle) of minimum length that visits each point of the set, P, of sites. Because it is of minimum length, a Euclidean TSP tour will necessarily visit each site exactly once, and will be a *simple* polygon (a closed polygonal walk that does not self-intersect). The k-TSP is to determine a minimum-length tour on a subset of at least k of the n points.

k-MST problem: For a given integer k ($k \leq n$), determine a tree, with vertices in the set P, of minimum total length that spans at least k of the n points in P.

4.1. Steiner tree. The dynamic programming algorithm of [9, 11], which computes a 2-approximation to the Steiner k-MST (and hence to Steiner tree, for $k = n$), in the L_1 metric, generalizes immediately to the case of m-guillotine subdivisions. Now, instead of a factor of $1 + \frac{1}{1} = 2$, as in [9] (for the case $m = 1$), we get a factor $1 + \frac{1}{m}$. Exactly the same algorithm works, only now there are up to $2m$ endpoints per side of the rectangular subproblem (instead of 2 per side, as in [9]). Thus, there are $O(k)$ choices of the integer k' that specifies the number of sites that must be visited within a subproblem, $O(n^4)$ choices of rectangle B bounding a subproblem, $O(n^{4 \cdot 2m})$ choices for the endpoints on each side of the rectangle, $O(n^{2m+1})$ choices of cut (and endpoints along the cut), and $O(k)$ choices for how to partition k'. Overall, we get time $O(k^2 n^{10m+5})$. In the case that $k = n$, we do not need to choose the value of k', or how to partition it when we select a cut, since we are forced to visit all sites within a subproblem; thus, the factor of k^2 drops, leaving us with a time bound of $O(n^{10m+5})$.

For the Euclidean metric, essentially the same algorithms work, but we first augment P with a set, G, of candidate (approximate) Steiner points, such that each Steiner point in an optimal tree can be rounded to one of the candidate points, without increasing the size of the tree by much. (In contrast, in the rectilinear case, we can assume that all Steiner points lie (exactly) at vertices of the grid induced by horizontal/vertical lines through points of P; thus, no new candidates need to be added,

since these grid points are potential subdivision vertices in the dynamic programming recursion that searches for a shortest possible m-guillotine subdivision.) One choice of set G that works is to let G be a regular (square) grid of $O(n^2M^2)$ points, with spacing $\frac{diam(P)}{nM}$, for some $M \geq m$. Then, each Steiner point in an optimal tree can be rounded to such a grid point by adding a segment of length less than $\frac{diam(P)}{nM}$; this adds an overall length of only $\frac{diam(P)}{M} \leq \frac{diam(P)}{m} \leq (\frac{1}{m})L^*$ to the optimal tree, where L^* is the length of the optimal tree. Our dynamic programming algorithm, then, searches for a minimum-length m-guillotine subdivision that spans all (or at least k) of the points of P, while allowing vertices of the subdivision to be placed at any of the points $P \cup G$.

COROLLARY 4.1. *Given any fixed positive integer m, and any set of n points in the plane, there is an $n^{O(m)}$-time algorithm to compute a Steiner spanning tree (or Steiner k-MST) whose length is within a factor $(1 + \frac{1}{m})$ of the minimum.*

4.2. TSP. For the TSP, we again apply dynamic programming, since the main theorem gives us an easy way to decompose the problem recursively.

COROLLARY 4.2. *For any fixed positive integer m, there is an $O(n^{20m+5})$ algorithm to compute an approximate TSP whose Euclidean length is within a factor $(1 + \frac{2\sqrt{2}}{m})$ of optimal. (For the L_1 metric, the factor is $(1 + \frac{2}{m})$, and the time bound $O(n^{10m+5})$.)*

Proof. (We present the details for the Euclidean metric; details for the L_1 metric are similar.) Let T^* be a minimum-length TSP tour for P, and let L^* denote its length.

The structure of the proof is typical of many approximation results: (a) We show that T^* can be transformed into a special type of subdivision of length at most $(1 + \frac{2\sqrt{2}}{m})L^*$; (b) we give a dynamic programming algorithm to compute (exactly) a shortest subdivision, having edge set E^*_G, of this special type; and (c) we show how to obtain a tour of P from the resulting subdivision, with the tour having length at most that of the subdivision.

(a) *Transforming T^*.* We know that T^* is a simple polygon with vertices P. Following the proof of Theorem 3.1, we add segments (m-spans of favorable cuts), called "bridges," to the subdivision T^*, in order to make it m-guillotine; *however*, when we add an m-span segment (corresponding to cut ℓ), we *double* it, creating a second copy that lies on top of the first copy. (The reason for the doubling will be made apparent below, in step (c).) Furthermore, we "slide" the doubled bridge, parallel to itself and in the direction that decreases (or does not increase) the length of the bridge, until it lies on a vertical/horizontal line through some point of P. The result is a *pinned double bridge*, "pinned" by this line through a point in P. We let S denote the resulting subdivision, and let E denote its edge set (including the doubled segments). The length of E is at most $(1+\frac{2\sqrt{2}}{m})L^*$, since, by Theorem 3.1, the bridges that we add have total length, prior to doubling, of at most $\frac{\sqrt{2}}{m}L^*$.

(b) *Dynamic programming algorithm.*

Input to Subproblem (see example in Figure 4.1):

1. A rectangle R, corresponding to a minimal window, determined by (up to) four points of P, together with some subset of the $O(m)$ edges defining the boundary information (below).
2. Boundary information specifying $\leq 2m$ crossing segments (each determined by a pair of points in P) that cross the boundary of R, and at most one

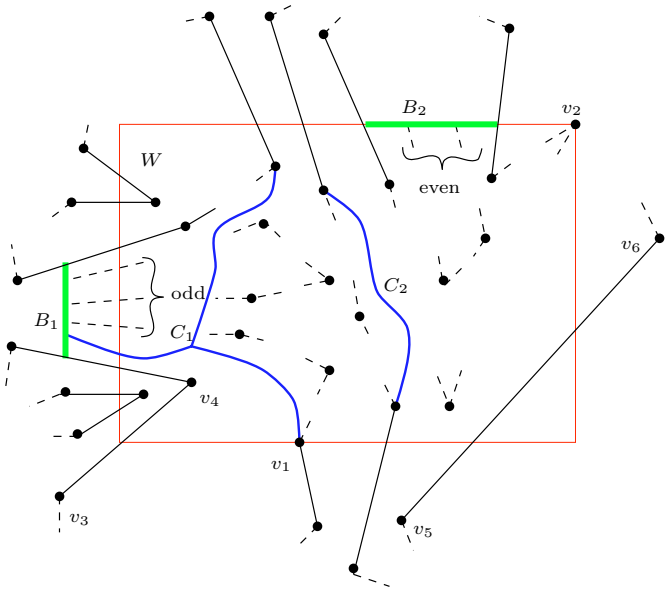

FIG. 4.1. *Example subproblem for TSP dynamic program: The window W is determined by the vertices v_1, v_2, and the segment v_3v_4 (on which its lower left corner is in contact). There are two bridges, B_1 (which is pinned at some coordinate left of the left boundary of W) and B_2 (pinned at the y-coordinate of v_2). Bridge B_1 is required to have an odd number of segments incident on it, while bridge B_2 is required to have an even number. The partition $\mathcal{P}$ specifies the interconnections indicated by trees C_1 and C_2. For vertex v_2, both incident edges are required to be within W; for vertex v_1, only one incident edge must be within W. All points within W, not yet incident on some segment crossing the boundary, are required to have degree two. Short dashed segments indicate a feasible possible set of interconnections.*

(pinned) bridge, per side of R, together with the parity (odd vs. even) of the number of edges of $E^*_G \cap R$ that must be incident on it.

3. Connectivity constraints, given in the form of a partition, $\mathcal{P}$, of the set of crossing segments and bridges, indicating which subsets are required to be connected within subproblem R.

Objective:

Compute a minimum-length m-guillotine subdivision, with edge set E^*_G, such that (1) the subdivision uses only segments joining points of P or *doubled* vertical/horizontal bridge segments that are pinned, (2) all boundary information is satisfied, (3) every point of P within R has degree two, and (4) all connectivity constraints within R are satisfied.

Note that there are $O(n^4 \cdot (n^{4m})^4) = O(n^{16m+4})$ possible inputs (subproblems), since there are $O(n^4)$ choices of R, and $O(n^{4m})$ choices of crossing segments on each of the four sides of R. (The number of possible connectivity constraints and boundary information is constant for fixed m.)

The initial call to the recursion will ask for a solution for the case that R is the bounding box of P, with empty boundary information, and connectivity constraints that simply say that all points of P inside R must be connected (with each point having degree 2).

In the base case, if R has no points of P in its interior, then the subproblem is solved by brute force, since it has only constant size (for fixed m). Otherwise, we can

solve the subproblem recursively, optimizing over all choices associated with a cut:

1. $O(n)$ choices of a horizontal/vertical cut.
2. $O(n^{4m})$ choices of new boundary information on the cut. In particular, we select $\leq 2m$ segments (each determined by a pair of points) that cross the cut, together with the information specifying a possible bridge segment. We require that boundary information of the new subproblems be consistent with boundary information of the given problem.
3. $O(1)$ (for fixed m) choices of connectivity constraints for the two new subproblems determined by the cut, subject to the requirement that these constraints be consistent with the constraints $\mathcal{P}$.

Since there are $O(n \cdot n^{4m})$ choices to make in partitioning a subproblem and there are overall $O(n^{16m+4})$ subproblems, we obtain an overall time complexity of $O(n^{20m+5})$.

(c) *Obtaining a tour.* Given the solution, S_G^*, to the dynamic program, we claim that there is an Eulerian subgraph of E_G^* (the edge set of S_G^*, *including* doubled bridges) that covers P, so that any Eulerian cycle defines a tour of P, and the length of this tour is at most the length of E_G^*.

Now, by the constraints imposed in the subproblems of the dynamic programming algorithm, all vertices of S_G^* have even degree, *except* possibly those that lie along a bridge segment (that is an m-span of some perfect cut). But the fact that bridge segments have their lengths *doubled* allows us to make all vertices along bridges have even degree as well, by keeping an appropriate subset (selection of subsegments) of the second copy of a bridge: Consider the vertices along a single copy of the bridge, and use subsegments from the second copy of the bridge to link, consecutively, those vertices along the bridge that have odd degree. There will necessarily be an even number of odd-degree vertices along a bridge, since we require that a bridge segment be incident to an even number of other segments.

Thus, by deleting some portions of the second copy of bridge segments, we obtain a subdivision covering P all of whose vertices have even degree. Then, an Eulerian cycle on the edges of this subdivision is a tour of P, whose length is at most $(1 + \frac{2\sqrt{2}}{m})L^*$. □

4.3. *k*-MST. Suppose now that we are given an integer $k \leq n$ and asked to find a minimum spanning tree on some subset of k of the n points P, without using Steiner points. Since we are not allowed to introduce Steiner points, e.g., where segments are incident on bridges, we use the same bridge-doubling trick as we did in writing the dynamic program for the TSP. This ensures that the only odd-degree vertices that we end up with in our optimized subdivision are those at original points of P, thereby allowing us to replace Eulerian paths, linking original sites of P, with shortcut paths that bend only at the sites P. (Naturally, we drop the requirement in the dynamic program that the points in P have degree two, and we add the parameter k to the specification of a subproblem.)

5. Conclusion. We suspect that there are many other potential applications and improvements of the results reported here. We do not yet know a characterization of the general class of problems for which our method leads to a PTAS.

While we have concentrated on L_1 and Euclidean metrics, our results generalize to other metrics on points in the plane. We are currently examining possible extensions to higher dimensions.

Finally, we mention some recent results that have been discovered since the time that this paper was originally submitted. Arora [2] has recently obtained a randomized

algorithm with expected running time that is nearly linear in n: $O(n \log^{O(1/\epsilon)} n)$. His new results also allow the d-dimensional problem to be solved in expected time $O(n(\log n)^{(O(\frac{d}{\epsilon}))^{d-1}})$.

Further, in a follow-up to this paper, Mitchell [10] has shown how a variant of m-guillotine subdivisions (termed "grid-rounded m-guillotine subdivisions") yields a (deterministic) PTAS with worst-case time bound $n^{O(1)}$, for any fixed $\epsilon > 0$, for the same set of (two-dimensional) problems we have studied in this paper.

Acknowledgments. I thank Esther Arkin, Rafi Hassin, Samir Khuller, Günter Rote, and the referees for several useful comments and suggestions that improved the presentation of the paper.

FINE SEPARATION OF AVERAGE-TIME COMPLEXITY CLASSES*

JIN-YI CAI† AND ALAN L. SELMAN†

Abstract. We extend Levin's definition of average polynomial time to arbitrary time-bounds in accordance with the following general principles: (1) It essentially agrees with Levin's notion when applied to polynomial time-bounds. (2) If a language L belongs to DTIME($T(n)$) for some time-bound $T(n)$, then every distributional problem (L, μ) is T on the μ-average. (3) If L does not belong to DTIME($T(n)$) *almost everywhere*, then no distributional problem (L, μ) is T on the μ-average.

We present hierarchy theorems for average-case complexity, for arbitrary time-bounds, that are as tight as the well-known Hartmanis–Stearns hierarchy theorem for deterministic complexity. As a consequence, for every time-bound $T(n)$, there are distributional problems (L, μ) that can be solved using only a slight increase in time but that cannot be solved on the μ-average in time $T(n)$.

Key words. computational complexity, average-time complexity classes, hierarchy, Average-P, logarithmico-exponential functions

1. Introduction.

One of the central issues for any complexity-theoretic measure is the question of fine hierarchies. Here we consider this issue for average-case complexity. The average complexity of a problem is, in many cases, a more significant measure than its worst-case complexity. This has motivated a rich area in algorithm research, but Levin [14] was the first to advocate the general study of average-case complexity. An average-case complexity class consists of pairs called distributional problems. Each pair consists of a decision problem and a probability distribution on problem instances. Most papers to date have focused their attention on polynomial time and on the concept of average polynomial time. The primary motivation has concerned the question of whether DistNP $\subseteq$ Average-P, where DistNP and Average-P are the distributional analogues of NP and P, respectively. Many beautiful results have been obtained. Levin, for example, has proved the existence of complete problems in DistNP.

Ben-David et al. [4] were the first to suggest a general formulation of average-case complexity for time-bounds other than polynomials. We will prove a fine hierarchy theorem using their definition for time-bounds that are bounded above by some polynomial. (Our proof uses properties of a class of functions defined by Hardy, called the logarithmico-exponential functions. We present this result in section 3.) However, we will observe that the definition of Ben-David et al. cannot distinguish time-bounds of the form 2^{cn} for different values of c. Thus, there fails to be a fine hierarchy for exponential or more general time-bounds.

Then, we will use the definition of Ben-David et al. as the point of departure from which we develop a new formulation of average-case complexity. A complexity class AVTIME($T(n)$) is to consist of all distributional problems (L, μ) such that L is solvable in "time $T(n)$ on the μ-average." This is the notion that we must make precise. We approach our formulation with the following intuitions in mind. If a language L

†Department of Computer Science, University at Buffalo, State University of New York, Buffalo, NY 14260 (cai@cse.buffalo.edu, selman@cse.buffalo.edu). The work of the second author was supported in part by NSF grant CCR-9400229.

belongs to DTIME($T(n)$) for some time-bound $T(n)$, then the distributional problem (L, μ) should belong to the class AVTIME($T(n)$). Furthermore, if L is outside of DTIME($T(n)$) *almost everywhere* (i.e., every Turing machine that accepts L requires more than $T(|x|)$ steps for all but a finite number of input words x), then it should follow that (L, μ) does not belong to AVTIME($T(n)$).

Our definition will satisfy these conditions and in addition will agree with the definitions of Levin [14] and Ben-David et al. [4] when we apply it to polynomial time-bounds and reasonable distributions. Readers who are familiar with Levin's theory of average polynomial time will recall that a naive, intuitive formulation suffers from serious problems. This issue is discussed in detail by previous authors including, notably, Gurevich [8] and Ben-David et al. [4]. Similarly, the path to a correct formulation of average-case complexity for arbitrary time-bounds is intricate. We will develop our new definition in section 4.

We will present a hierarchy theorem for average-case complexity, for arbitrary time-bounds, that is as tight as the well-known Hartmanis–Stearns [11] hierarchy theorem for deterministic complexity. As a consequence, for every time-bound $T(n)$, there are distributional problems (L, μ) that can be solved using only a slight increase in time but that cannot be solved on the μ-average in time $T(n)$.

2. Preliminaries. We assume that all languages are subsets of $\Sigma^* = \{0,1\}^*$, and we assume that Σ^* is ordered by standard lexicographic ordering denoted $\leq$. (We will ignore the empty string ϵ and start with 0. The predecessor of x in this order is denoted by $x-1$.) We use $\subset$ to denote proper inclusion.

2.1. Turing machine running times. Although Turing machine running times are frequently given as functions on the natural numbers, $T : \mathrm{N} \to \mathrm{N}$, we will often need the more accurate view that a Turing machine running time is a function $S : \Sigma^* \to \mathrm{N}$. In this case, the relation between the two interpretations is clear. Namely, $T(n) = \max\{S(x) \mid |x| = n\}$. For two functions T and T', where $T, T' : \mathrm{N} \to \mathrm{N}$, recall that $T'(n) = o(T(n))$ if $\lim_{n\to\infty} T'(n)/T(n) = 0$. Similarly, if $S, S' : \Sigma^* \to \mathrm{N}$, then $S'(x) = o(S(x))$ if $\lim_{|x|\to\infty} S'(x)/S(x) = 0$. We adhere to the customary convention that $T(n) \geq n+1$ ($S(x) \geq |x|+1$) for any Turing machine running time T (S, respectively).

The following proposition is one of the main theorems of Geske, Huynh, and Seiferas [6]. (See also the paper by Geske, Huynh, and Selman [7].)

PROPOSITION 2.1. *If $S(x)$ is fully time constructible, then there is a language $L \in$ DTIME($O(S(x))$) such that for every function S', if $S'(x)\log S'(x) = o(S(x))$, then every Turing machine M that accepts L requires more than $S'(x)$ steps for all but finitely many input strings x.*

2.2. Distributional problems. A *distribution function* $\mu : \{0,1\}^* \to [0,1]$ is a nondecreasing function from strings to the closed interval $[0,1]$ that converges to 1. The corresponding *density function* μ' is defined by $\mu'(0) = \mu(0)$ and $\mu'(x) = \mu(x) - \mu(x-1)$ for $x \neq 0$. Clearly, $\mu(x) = \sum_{y\leq x} \mu'(y)$. For any subset of strings S, we will denote by $\mu(S) = \sum_{x\in S} \mu'(x)$ the probability of the event S. Define $u_n = \mu(\{x \mid |x| = n\})$. For each n, let $\mu'_n(x)$ be the conditional probability of x in $\{x \mid |x| = n\}$. That is, $\mu'_n(x) = \mu'(x)/u_n$, if $u_n > 0$, and $\mu'_n(x) = 0$ for $x \in \{x \mid |x| = n\}$, if $u_n = 0$.

A function μ from Σ^* to $[0,1]$ is *computable in polynomial time* [13] if there is a polynomial time-bounded transducer T such that for every string x and every positive integer n, $|\mu(x) - T(x, 1^n)| < \frac{1}{2^n}$. We restrict our attention to distributions μ that

are computable in polynomial time. If the distribution function μ is computable in polynomial time, then the density function μ' is computable in polynomial time. (The converse is false unless P = NP [8].)

Levin [14] defines a function f from Σ^* to nonnegative reals to be *linear on μ-average* if

$$\sum_{|x|\geq 1} \mu'(x)\frac{f(x)}{|x|} < \infty, \tag{2.1}$$

and f is *polynomial on μ-average* if f is bounded by a polynomial of a function that is linear on μ-average. Thus, a function f is polynomial on μ-average if and only if there is an integer $k > 0$ such that

$$\sum_{|x|\geq 1} \mu'(x)\frac{(f(x))^{1/k}}{|x|} < \infty. \tag{2.2}$$

Finally, Levin defines Average-P to be the class of distributional problems (L, μ), where L is a language and μ is a polynomial time computable distribution, such that L can be decided by some Turing machine M whose running time T_M is polynomial on μ-average.

Starting with Levin, a number of researchers have observed that the more naive notion that for each length n the expectation of the running time T_M of a Turing machine M that accepts L is bounded above by a polynomial in n

$$\sum_{|x|=n} \mu'_n(x)T_M(x) \leq p(n), \tag{2.3}$$

is unsuitable for a number of good reasons [8, 4]. The definition that arises from using (2.3) is not robust under functional composition of algorithms. (There are distributional problems A and B so that A can be solved in average polynomial time by using an oracle B, B can be solved in average (or even deterministic) polynomial time, and A cannot be solved in average polynomial time.) Nor is the definition closed under application of polynomials. (There are functions f that satisfy (2.3) for which f^2 does not.) As a consequence, from (2.3), one loses machine independence of the definition of the class of average polynomial time.

Levin's definition is just as intuitively justified as that given by (2.3). This can be seen as follows: The worst-case time complexity for P requires for all n, and for all x such that $|x| = n$, that $T_M(x) \leq p(n)$. Therefore for the case of bounding complexity on the average by some polynomial $p(n)$, it appears natural to require for all n that (2.3) holds. However, $T_M(x) \leq n^k$ is equivalent to $T_M(x)/n^k \leq 1$, which is also equivalent to $(T_M(x))^{1/k}/n \leq 1$. Thus we might as well take the expectation now, after this manipulation, which results in the established definition. (We will discuss this point further in section 4.)

2.3. Hardy's class of logarithmico-exponential functions. We will need the notion of a class of functions $\mathcal{L}$ defined by Hardy [10], called the *logarithmico-exponential functions*. Every function in $\mathcal{L}$ is a real-valued function of one variable that is defined on all sufficiently large real numbers. The class $\mathcal{L}$ is defined to be the smallest class of functions containing

(i) every constant function $t(x) = c$ for all real c,
(ii) the identity function $t(x) = x$

and that are closed under the following operations:

(i) if $t(x)$ and $s(x)$ belong to $\mathcal{L}$, then so does $t(x) - s(x)$;
(ii) if $t(x)$ belongs to $\mathcal{L}$, then so does $e^{t(x)}$;
(iii) if $t(x)$ is eventually positive and belongs to $\mathcal{L}$, then so does $\ln(t(x))$.

The closure properties are more inclusive than perhaps they first appear. For example, if $t(x)$ and $s(x)$ are in $\mathcal{L}$, then so are $t(x) + s(x)$, $t(x)s(x)$, and $t(x)/s(x)$. Also, functions such as $\sqrt[k]{x} = e^{\frac{1}{k}\ln x}$ and $e^{c\sqrt{\ln x}/\ln\ln x}$ belong to $\mathcal{L}$.

Hardy [10] proved the following facts regarding the *logarithmico-exponential functions*. He showed that every function in $\mathcal{L}$ is either eventually positive or eventually negative or identically zero. Note that it is easily shown by induction that every function $t(x)$ in $\mathcal{L}$ is differentiable and its derivative $t'(x)$ is also in $\mathcal{L}$ (thus infinitely differentiable). Thus, it follows that every function in $\mathcal{L}$ is eventually monotonic. The main theorem of Hardy regarding the logarithmico-exponential functions is that they form an asymptotic hierarchy: for any $t(x)$ and $s(x)$ in $\mathcal{L}$, either $t(x) = o(s(x))$ or $s(x) = o(t(x))$, or there exists a nonzero constant c, such that $\lim_{x\to\infty} t(x)/s(x) = c$.

Let $f^{(\ell)}$ denote the function that iterates ℓ applications of f. That is, $f^{(1)}(x) = f(x)$ and $f^{(\ell+1)}(x) = f(f^{(\ell)}(x))$ for $\ell \geq 1$. Hardy proved [9] that for every function $t \in \mathcal{L}$, if $\lim_{x\to\infty} t(x) = \infty$, then there is some constant ℓ so that $\log^{(\ell)}(x) = o(t(x))$, as well as $t(x) = o(\exp^{(\ell)}(x))$. Informally, a logarithmico-exponential function that goes to infinity cannot increase more slowly than every iterated logarithm function nor faster than every iterated exponential function.

Hardy's purpose in introducing the class of logarithmico-exponential functions was to provide what he called "a scale of infinities." We propose to use only logarithmico-exponential functions as time-bounds in defining average-case complexity classes. Indeed, we propose that for most purposes it suffices to use only logarithmico-exponential functions as time-bounds for complexity classes in general. (To be pedantic for a moment, we believe that it suffices to consider as time-bounds for complexity classes only functions $f : \mathrm{N} \to \mathrm{N}$ that result from first restricting some logarithmico-exponential function to the domain of natural numbers and then further restricting the range to N by taking the floor of the result. For notational ease, we will call these logarithmico-exponential functions as well.) These functions are at the same time sufficiently well behaved and sufficiently expressive for the purpose of bounding time complexity of most meaningful classes of computational problems. While functions such as $x(1+\sin x)$ or $e^{x^2 \sin x}$ that gyrate infinitely often as $x \to \infty$ are excluded, as are functions that are, say, bounded on even length strings but tend to infinity on odd length strings, it is reasonable to assume that bounding the running time, average case or otherwise, of *a class of problems* by such a function is hardly necessary or natural. This is in contrast to the case of bounding the complexity of an individual problem, say, some number theoretic computation where the problem is interesting only for certain lengths. The elegance that results from the exclusion of these pathological cases compensates well for the price we pay for its restriction. However, by restricting to the logarithmico-exponential functions we do lose some very slow growing functions such as $\log^* x$ or the inverse of Ackermann's function. We leave it as an interesting open problem to extend the class of Hardy's logarithmico-exponential functions to include functions such as $\log^* x$ and still retain all its desirable properties.

Our proof of the first hierarchy theorem in the next section depends crucially on the properties of Hardy's logarithmico-exponential functions.

We will need the following lemma.

LEMMA 2.2. *If $t(n)$ belongs to $\mathcal{L}$, $\lim_{n\to\infty} t(n) = +\infty$, and $t(n)$ is polynomially bounded, then there exist a constant c and an integer k such that, for all $n \geq c$ and*

$a > 1$,

$$t(an) < a^k t(n).$$

Proof. Let k be an integer such that $\lim_{n\to\infty} t(n)/n^k = 0$. Since $t(n)$ is polynomially bounded, such an integer exists. Let $q(x) = t(x)/x^k$. Then $q(x)$ belongs to $\mathcal{L}$ and $\lim_{n\to\infty} q(n) = 0$. Since $q(n)$ is eventually positive and approaches 0, it is eventually monotonic decreasing. This is because $q(x)$ is not identically 0, it cannot possibly be monotonic increasing, and these are the only alternatives for functions in $\mathcal{L}$. Thus, for some constant c, if $x \geq c$, then $q(x)$ is monotonic decreasing. It follows that

$$\begin{aligned}\frac{t(an)}{a^k t(n)} &= \frac{q(an)(an)^k}{a^k q(n) n^k} \\ &= \frac{q(an)}{q(n)} \\ &< 1\end{aligned}$$

for all $n \geq c$ and for all $a > 1$. (Note that c does not depend on a.) This implies that $t(an) < a^k t(n)$. □

3. The first hierarchy theorem. Ben-David et al. [4] propose the following definition.

DEFINITION 3.1 (Ben-David et al.). *For a time complexity function $T : \mathrm{N} \to \mathrm{N}$, a function f is T* on *μ-average if f is bounded by T of a function that is linear on μ-average; i.e., $f(x) \leq T(\ell(x))$, where ℓ is linear on μ-average.* AverDTime($T(n)$) *denotes the class of distributional problems (L, μ), where L is a language and μ is a polynomial time computable distribution, such that L can be decided by some Turing machine M whose running time T_M is T on μ-average.*

If T is monotonically increasing and thus invertible, then f is T on μ-average if and only if

$$\sum_{|x|\geq 1} \mu'(x) \frac{T^{-1}(f(x))}{|x|} < \infty. \tag{3.1}$$

This definition is a direct adaptation of Levin's notion of average polynomial time, where the time-bound T is polynomially bounded. Indeed, Average-P = $\bigcup_k$ AverDTime(n^k).

3.1. Inadequacy of Definition 3.1. Definition 3.1 for time-bounds T beyond polynomial time has serious difficulties, which we will now explain.

It follows from the result of Geske, Huynh, and Seiferas [6], our Proposition 2.1, that there exists a language $L \in$ DTIME(2^{2^n}) that cannot be recognized in time 3^n almost everywhere—every Turing machine that accepts L requires more than 3^n steps on all but some finite number of inputs. Yet, it follows easily from the definition that every distributional problem that belongs to AverDTime(2^{2^n}) also belongs to AverDTime(2^n). This is inconceivable. How can a language L require more than 3^n time almost everywhere but be 2^n on the μ-average for *every* distribution μ?

To see that AverDTime(2^{2^n}) $\subseteq$ AverDTime(2^n), let M accept L in time T_M, where T_M is $2^{2n} = 4^n$ on μ-average. Then, by definition,

$$\sum_{|x|\geq 1} \mu'(x) \frac{\log_4(T_M(x))}{|x|} < \infty.$$

Thus,

$$2\sum_{|x|\geq 1}\mu'(x)\frac{\log_4(T_M(x))}{|x|}=\sum_{|x|\geq 1}\mu'(x)\frac{\log_2(T_M(x))}{|x|}<\infty$$

also; thus according to Definition 3.1, T_M is also 2^n on μ-average.

The same argument implies that $\mathrm{AverDTime}(2^n)=\mathrm{AverDTime}(c^n)$ for all constants $c>0$. This is another weakness of the definition. Usually a time complexity class should be defined in such a way that it is sufficiently fine to distinguish varying inherent time complexities of problems. In other words, one likes to have a fine time hierarchy theorem. The fact that $\mathrm{AverDTime}(2^n)=\mathrm{AverDTime}(4^n)$ prevents us from having such a *fine* theorem.

Previous researchers have raised the question of hierarchies for average time but in all cases have been implicitly stymied by the inadequacy that we illuminate here. For example, Li and Vitányi [15] and Ben-David et al. [4] obtain results demonstrating languages for which average-case and worst-case complexity are the same. However, both use distributions that cannot be computed in polynomial time, and the latter uses a nonstandard notion of worst-case complexity. Reischuk and Schindelhauer [20] introduce a concept of average-time complexity according to "rankable" distributions that possess a tight hierarchy. Their concept is different than Levin's notion. Belanger and Wang [3] contains a discussion. In addition, Belanger and Wang [3] obtain a weak hierarchy theorem for the notion of average time given by Definition 3.1.

We believe that it is interesting and useful to have a meaningful, robust definition of average exponential time. Our notion of average-time complexity is supported by the hierarchy theorem that we will develop in section 4, an important test of its meaningfulness and robustness. With regard to complexity theory studies, average-case exponential time is interesting for the same reasons as worst-case exponential time. For example, in general one would like to understand why certain problems are complete and to grasp the inherent properties that make a set complete. Natural complete problems are not as common for exponential time as they are for smaller classes such as NP. However, exponential time permits techniques and constructions that are not possible with smaller time-bounds. For this reason, much more is known about complete problems for exponential time than is currently known about NP complete problems [12]. We can anticipate the same situation for average-case complexity. With regard to applications of average-case complexity theory, here too, average-case exponential time is worth exploring. For example, any distributional problem that is complete for average exponential time is *provably* intractable even in the average case. Therefore, such a problem might be useful as a basis for cryptographic protocols.

3.2. First hierarchy theorem. We can prove a hierarchy theorem when we restrict our attention to functions that are bounded above by some polynomial. More precisely, we shall require that the time complexity bounds T and T' belong to Hardy's class of logarithmico-exponential functions $\mathcal{L}$ and that they are bounded above by a polynomial. Under these conditions, we show that if $T'(n)\log T'(n)=o(T(n))$, then there is a distributional problem (L,μ) in $\mathrm{AverDTime}(T(n))$ that does not belong to $\mathrm{AverDTime}(T'(n))$.

THEOREM 3.2. *Let T,T' : N $\to$ N be logarithmico-exponential functions and assume that T is fully time constructible. Assume that $T'(n)\log T'(n)=o(T(n))$ and that $T'(n)$ is bounded above by a polynomial. Then*

$$\mathrm{AverDTime}(T'(n))\subset\mathrm{AverDTime}(T(n)).$$

The general idea of the proof is to use Proposition 2.1 to obtain a language L that is in DTIME($T(n)$) but almost everywhere not in DTIME($T'(n)$). Then we use properties of the logarithmico-exponential functions to show that (L, μ) belongs to AverDTime($T(n)$) but does not belong to AverDTime($T'(n)$).

We need the following lemmas.

LEMMA 3.3. *Let T be a logarithmico-exponential and fully time constructible function. If $L \in$ DTIME($O(T(n))$), then for every polynomial time computable distribution μ, $(L, \mu) \in$ AverDTime($T(n)$).*

Proof. By the hypotheses, $T(n) \geq n + 1$ for all n, and T is monotonically increasing. Since T is logarithmico-exponential, either (i) $n = o(T(n))$ or (ii) for some constant $c \geq 1$, $T(n) \leq cn$ for all sufficiently large n. If case (i) holds, then the well-known linear-speedup theorem applies [11]. In this case $L \in$ DTIME($T(n)$) and the result follows immediately. If case (ii) holds, then $L \in$ DTIME(cn). Let M be a Turing machine that witnesses $L \in$ DTIME(cn), and let T_M be the running time of M. By definition, T_M is linear on μ-average. Thus, by Definition 3.1 and the fact that $T(n) \geq n + 1$, T_M is T on μ-average. This completes the proof. □

LEMMA 3.4. *If $a, b > 0$ and $1/h = 1/a + 1/b$, then $\min(a, b)/2 \leq h \leq \min(a, b)$.*

Proof.

$$h = \frac{1}{\frac{1}{a} + \frac{1}{b}} = \frac{ab}{a+b} = \min(a,b) \cdot \frac{\max(a,b)}{a+b} \leq \min(a,b).$$

Also,

$$\frac{1}{h} \leq \frac{2}{\min(a,b)},$$

and therefore $h \geq \min(a, b)/2$. □

As a corollary, if $a(n)$ and $b(n)$ are functions such that both $a(n), b(n) \to +\infty$, then $h(n) \to +\infty$ also, where

$$h(n) = \frac{a(n)b(n)}{a(n) + b(n)},$$

but no faster than either $a(n)$ and $b(n)$. Furthermore, if both $a(n), b(n) \in \mathcal{L}$, the class of logarithmico-exponential functions, then so is $h(n)$.

Now we prove our theorem.

Proof. Since $T'(n) = o(T(n))$, it follows that

$$\text{AverDTime}(T'(n)) \subseteq \text{AverDTime}(T(n)).$$

We need to show that the classes are distinct. Without loss of generality, we assume that $\lim_{n\to\infty} T'(n) = +\infty$. Otherwise, the theorem is trivial.

Define sequences α_n and β_n by

$$\alpha_n = \frac{T(n)}{T'(n) \log T'(n)}$$

and

$$\beta_n = \frac{\log T'(n)}{\log \log T'(n)}.$$

Then, both

$$\alpha_n \text{ and } \beta_n \to +\infty.$$

Take $B_n = \sqrt{\alpha_n \beta_n/(\alpha_n + \beta_n)}$. By Lemma 3.4, $B_n \to +\infty$, and yet $B_n = o(\alpha_n)$ and $B_n = o(\beta_n)$.

Define $S(n)$ by $S(n) = B_n \cdot T'(n)$. We claim that

$$\lim_{n\to\infty} \frac{S(n)\log S(n)}{T(n)} = 0.$$

In fact,

$$\begin{aligned}\frac{S(n)\log S(n)}{T(n)} &= \frac{B_n \cdot T'(n)\cdot(\log B_n + \log T'(n))}{T(n)} \\ &= B_n \log B_n \frac{T'(n)}{T(n)} + B_n \frac{1}{\alpha_n} \\ &= B_n \frac{1}{\alpha_n} + \frac{B_n \log B_n}{\log T'(n)} \cdot \frac{1}{\alpha_n}.\end{aligned}$$

We have $B_n/\alpha_n \to 0$. Also, $B_n/\beta_n \to 0$, which implies that $\log B_n \le \log \beta_n \le \log\log T'(n)$, so for the second term, we have

$$\frac{B_n \log B_n}{\log T'(n)} = o\left(\beta_n \cdot \frac{\log\log T'(n)}{\log T'(n)}\right) = o(1).$$

Thus, Proposition 2.1 applies: there is a language $L \in \mathrm{DTIME}(O(T(n)))$ such that for every Turing machine M that accepts L there is a constant n_0 such that the running time T_M requires more than $S(|x|)$ steps for all inputs of length $\ge n_0$. That is, $T_M(x) > S(|x|)$ for all x such that $|x| \ge n_0$. By Lemma 3.3, $(L,\mu) \in \mathrm{AverDTime}(T(n))$ for every polynomial time computable distribution μ. Now our task is to define a polynomial time computable distribution μ such that $(L,\mu) \notin \mathrm{AverDTime}(T'(n))$.

By our assumption that T' is bounded by a polynomial and belongs to $\mathcal{L}$, by Lemma 2.2, there is an integer k and a constant c such that $T'(an) < a^k T'(n)$, for all $a > 1$ and all $n \ge c$. In particular $T'(B_n^{1/k} \cdot n) < B_n \cdot T'(n)$. Since $T' \in \mathcal{L}$ and $\lim_{n\to\infty} T'(n) = +\infty$, it follows that T' is monotonically increasing. Hence,

$$T'^{-1}(B_n \cdot T'(n)) \ge B_n^{1/k} \cdot n. \tag{3.2}$$

Now, let $b_n = B_n^{1/k}$. Since $b_n \in \mathcal{L}$ and $b_n \to +\infty$, there is some constant ℓ so that $\log^{(\ell)}(n) = o(b_n)$. For this value ℓ, there is some value n_ℓ so that for all $n \ge n_\ell$, the expression

$$\frac{1}{n\log n \log\log n \cdots (\log^{(\ell)} n)^2}$$

is defined. Define

$$a_n = \frac{1}{n\log n \log\log n \cdots (\log^{(\ell)} n)^2}$$

for all $n \ge n_\ell$. Define $a_n = 1$ otherwise. Then, the series $\sum_{n=1}^{\infty} a_n$ converges, but the series $\sum_{n=1}^{\infty} a_n b_n$ diverges.

Let μ be the distribution function whose density function is defined by

$$\mu'(x) = \frac{1}{s} \cdot a_{|x|} \cdot \frac{1}{2^{|x|}},$$

where $\sum_{n=1}^{\infty} a_n = s$.

Clearly, μ is polynomial time computable.

Let M be a Turing machine that accepts L. For all x such that $|x| \geq n_0$, $T_M(x) > S(|x|) = B_{|x|}T'(|x|)$. Hence, by (3.2),

$$T'^{-1}(T_M(x)) \geq B_n^{1/k} \cdot |x| = b_{|x|}|x|.$$

Thus,

$$\sum_{|x|\geq \max(n_0,c)} \mu'(x) \cdot \frac{T'^{-1}(T_M(x))}{|x|} \geq \sum_{n\geq \max(n_0,c)} \frac{a_n b_n}{s} = \infty,$$

so $(L,\mu) \notin \text{AverDTime}(T'(n))$. □

COROLLARY 3.5. *For $c \geq 1$ and $\epsilon > 0$,* $\text{AverDTime}(n^c) \subset \text{AverDTime}(n^{c+\epsilon})$.

4. The new definition and second hierarchy theorem. We have shown that there is a problem with the existing definition of average-case complexity for time-bounds beyond those that are bounded by a polynomial. Now we will develop a new definition of "T on the μ-average," based on the following guiding principles.

1. Our definition should be essentially the same as Levin's notion when we apply it to polynomial time-bounds.

2. If L belongs to $\text{DTIME}(T(n))$ for some time-bound T, then any distributional problem (L,μ) is T on the μ-average.

3. If L is not in $\text{DTIME}(T(n))$ almost everywhere, then, for any distibutional problem (L,μ), L is not T on the μ-average.

To begin, let us revisit the intuitive justification that we discussed in section 2.2. Let $T \in \mathcal{L}$ be some fully time constructible function, let T_M be some Turing machine running time, and let μ be some polynomial time computable distribution, for which we want to say that T_M is T on the μ-average. As earlier, we might want to say that $T_M(x) \leq T(|x|)$ for a μ-average x. Equivalently, we want $T^{-1}(T_M(x)) \leq |x|$, or

$$\frac{T^{-1}(T_M(x))}{|x|} \leq 1,$$

for a μ-average x. Thus, let us require that the expectation be bounded above by 1:

$$\mathcal{E}\left[\frac{T^{-1}(T_M(x))}{|x|}\right] = \sum_{|x|\geq 1} \mu'(x) \cdot \frac{T^{-1}(T_M(x))}{|x|} \leq 1. \tag{4.1}$$

At this point Levin and subsequent researchers, including Ben-David et al., took (4.1) to say that the expectation $\mathcal{E}$ over all x is finite. But, the requirement of (4.1) adds nothing new. One can always modify M so that, for some fixed but arbitrarily long initial segment of inputs, M takes little time. However, the tail of a convergent sum can be made arbitrarily small, so the total sum with respect to the new machine is bounded by 1.

Since we are primarily concerned with the asympotic behavior of algorithms on average inputs, we want to avoid the possibility that the sum in the expectation is dominated by an initial segment. For this reason, it is perfectly reasonable, with identical justification, to require that for all $n \geq 1$ the expectation of $\frac{T^{-1}(T_M(x))}{|x|}$, for all x of length $|x| \geq n$, be bounded above by 1:

$$\mathcal{E}_{|x|\geq n}\left[\frac{T^{-1}(T_M(x))}{|x|}\right] = \sum_{|x|\geq n} \mu'_{\geq n}(x) \cdot \frac{T^{-1}(T_M(x))}{|x|} \leq 1, \tag{4.2}$$

where $\mu'_{\geq n}$ is the conditional probability distribution on $\{z \mid |z| \geq n\}$. That is, let $W_n = \mu(\{z \mid |z| \geq n\})$; for x of length $|x| \geq n$,

$$\mu'_{\geq n}(x) = \mu'(x)/W_n \text{ if } W_n > 0 \quad \text{and} \quad \mu'_{\geq n}(x) = 0 \text{ if } W_n = 0.$$

Thus (4.2) is equivalent to requiring that, for all $n \geq 1$,

$$\sum_{|x|\geq n} \mu'(x) \cdot \frac{T^{-1}(T_M(x))}{|x|} \leq W_n. \tag{4.3}$$

This is the condition that we will take for our definition.

Comparing this with the simpler requirement that

$$\sum_{|x|\geq 1} \mu'(x) \cdot \frac{T^{-1}(T_M(x))}{|x|} < \infty, \tag{4.4}$$

we require not only that the infinite sum converges but that it converges at a certain rate. Note that $W_n \to 0$ as $n \to \infty$.

A persistent criticism of the theory of average-time complexity is that for any reasonable definition of "default" distribution on the set of all positive integers, such as $u_n = 1/n^2$ or $1/n^3$, inevitably a disproportionate weight of the total distribution is on the first few (or few dozen?) integers. For instance, in (4.4), the first terms might be somewhat dominating, thus masking the true asymptotic behavior. The requirement that we impose in (4.3), which stipulates that each sum is bounded above, explicitly addresses this criticism. As it turns out, we will demonstrate in Theorem 4.2 that our definition agrees with Levin's definition for polynomial time-bounds and reasonable distributions. Thus, this criticism is indeed unfounded for those cases. However, this phenomenon of masking the asymptotic behavior by the concentration of measures on the initial few strings is magnified at superpolynomial time-bounds; in this case, the criticism is valid and our formulation corrects the problem.

Thus, we arrive at our definition.

DEFINITION 4.1. *For any time constructible function $T(n) \in \mathcal{L}$, a function f is T on the μ-average*[1] *if, for all $n \geq 1$,*

$$\sum_{|x|\geq n} \mu'(x) \cdot \frac{T^{-1}(f(x))}{|x|} \leq W_n. \tag{4.5}$$

AVTIME($T(n)$) *denotes the class of distributional problems (L, μ), where L is a language and μ is a polynomial time distribution, such that L can be decided by some Turing machine M whose running time T_M is T on the μ-average.*

To summarize, we departed from the previous definition by imposing two new criteria. We insist (i) that the expectation given in (4.1) is bounded by 1, rather than asking only that it be finite, and we insist (ii) that *each* conditional expectation given in (4.2) is bounded (indeed, bounded by 1). If we were to have added either one of these requirements without the other, the result would have been trivially equivalent to the previous definition. We have already shown that requirement (i) alone adds nothing new. To see that requiring each conditional expectation to converge adds nothing new, we simply note that every tail series of a convergent series converges as well. Thus, it is the combination of the two modifications, which amounts to restricting the *rate of convergence*, that adds something new.

[1] We are redefining this expression, and henceforth all references to this expression will refer to the meaning given herein.

4.1. Equivalence theorem. Before proceeding to establish that Definition 4.1 satisfies our guiding principles, we introduce the following Condition W. Condition W will limit our consideration to distributions that do not put too much weight on the first few strings. (For example, we don't consider $u_n = 2^{-n}$ to be an acceptable default distribution on the natural numbers.)

CONDITION W. *There exists $s > 0$ such that $W_n = \Omega\left(\frac{1}{n^s}\right)$.*

All the usual distributions that have been used in the past in this area satisfy Condition W. These include various uniform distributions on graph properties, as well as distributions used by Levin [14], Gurevich [8], and others to prove their average-case hard problems. We also note that all the previous work on average-case NP-hard problems is not altered by our reformulation of average-time complexity.

Now we prove that average polynomial time under Levin's definition is unchanged by our new definition, for distributional problems that satisfy Condition W.

THEOREM 4.2. *Let μ be a polynomial time computable distribution that satisfies Condition W. Then (L, μ) belongs to* Average-P *if and only if (L, μ) belongs to* $\bigcup_k \mathrm{AVTIME}(n^k)$.

Proof. Since our definition requires at least as much as the old definition, the inclusion in one direction is trivial. So, let μ be a polynomial time computable distribution that satisfies Condition W, let M accept L with running time T_M, and let k be a positive integer such that

$$\sum_{|x|\geq 1} \mu'(x)\frac{(T_M(x))^{1/k}}{|x|} = C < \infty.$$

Define $p(n) = (Cn)^k$, and observe that

$$\sum_{|x|\geq 1} \mu'(x)\frac{p^{-1}(T_M(x))}{|x|} \leq 1.$$

Since μ satisfies Condition W, there exists $s > 0$ such that $W_n = \Omega\left(\frac{1}{n^s}\right)$. Define the polynomial q by $q(n) = p(n^c)$ for $c > s + 2$. We will show that

$$\sum_{|x|\geq n} \mu'(x)\frac{q^{-1}(T_M(x))}{|x|} \leq W_n$$

for all but a finite number of n. Observe that this suffices to complete our proof. Namely, let n_0 be a fixed positive integer; if (4.5) holds for all $n \geq n_0$, then as we explained above, we can modify M to contain a lookup table in order to quickly decide all strings of length smaller than n_0. By doing so, we make the first terms of the sum sufficiently small so that the nth sum is bounded by W_n for all $n \geq 1$.

Now our goal is to estimate the sum

$$\sum_{k\geq n}\sum_{|x|=k} \mu'(x)\cdot\frac{q^{-1}(T_M(x))}{k}$$

for all $n \geq 1$.

Note that $q^{-1}(y) = (p^{-1}(y))^{1/c}$. Recall that $u_k = \mu(\{z \mid |z| = k\})$. By convexity, for all k such that $u_k > 0$,

$$\sum_{|x|=k} \frac{\mu'(x)}{u_k}\cdot\frac{q^{-1}(T_M(x))}{k} \leq \left[\sum_{|x|=k} \frac{\mu'(x)}{u_k}\cdot\frac{p^{-1}(T_M(x))}{k^c}\right]^{1/c}.$$

Thus,

$$\begin{aligned}\sum_{k\geq n}\sum_{|x|=k}\mu'(x)\cdot\frac{q^{-1}(T_M(x))}{k} &= \sum_{\substack{k\geq n\\ u_k>0}}\sum_{|x|=k}\mu'(x)\cdot\frac{q^{-1}(T_M(x))}{k}\\ &= \sum_{\substack{k\geq n\\ u_k>0}} u_k \sum_{|x|=k}\frac{\mu'(x)}{u_k}\cdot\frac{q^{-1}(T_M(x))}{k}\\ &\leq \sum_{\substack{k\geq n\\ u_k>0}} u_k \left[\sum_{|x|=k}\frac{\mu'(x)}{u_k}\cdot\frac{p^{-1}(T_M(x))}{k^c}\right]^{1/c}.\end{aligned}$$

Since for all $n \geq 1$,

$$\sum_{|x|=n}\mu'(x)\cdot\frac{p^{-1}(T_M(x))}{n}\leq 1,$$

we have

$$\begin{aligned}\sum_{k\geq n}\sum_{|x|=k}\mu'(x)\cdot\frac{q^{-1}(T_M(x))}{k} &\leq \sum_{\substack{k\geq n\\ u_k>0}} u_k\left[\frac{1}{u_k}\cdot\frac{1}{k^c}\cdot k\right]^{1/c}\\ &= \sum_{k\geq n}\left(\frac{u_k}{k}\right)^{1-1/c}.\end{aligned}$$

By Hölder's inequality,

$$\sum_{k\geq n}\left(\frac{u_k}{k}\right)^{1-1/c}\leq\left(\sum_{k\geq n}u_k\right)^{1/p}\left(\sum_{k\geq n}\frac{1}{k^{c-1}}\right)^{1/q},$$

where $1/p = 1 - 1/c$ and $q = c$. Hence,

$$\sum_{k\geq n}\sum_{|x|=k}\mu'(x)\cdot\frac{q^{-1}(T_M(x))}{k}\leq W_n^{1-1/c}\cdot\left(\sum_{k\geq n}\frac{1}{k^{c-1}}\right)^{1/c}.$$

Finally, we have

$$\begin{aligned}\sum_{k\geq n}\sum_{|x|=k}\mu'(x)\cdot\frac{q^{-1}(T_M(x))}{k} &\leq W_n^{1-1/c}\cdot\left(\int_{n-1}^{\infty}\frac{1}{x^{c-1}}dx\right)^{1/c}\\ &= W_n\cdot\left(\frac{1}{(c-2)n^{c-2}W_n}\right)^{1/c}.\end{aligned}$$

As we have taken $c > s + 2$, and $W_n = \Omega\left(\frac{1}{n^s}\right)$, the last term is at most W_n for almost all n. □

4.2. Second hierarchy theorem. Now we verify that our definition satisfies the remaining guiding principles, and we prove a tight hierarchy theorem for AVTIME classes.

THEOREM 4.3. *Let $T \in \mathcal{L}$ be fully time constructible. If $L \in \mathrm{DTIME}(T(n))$, then for every polynomial time computable distribution μ, $(L, \mu) \in \mathrm{AVTIME}(T(n))$.*

The proof is easy: for any Turing machine that accepts L in time T, the ratio $\frac{T^{-1}(T_M(x))}{|x|}$ is ≤ 1 for every input x.

THEOREM 4.4. *Let $T \in \mathcal{L}$ be fully time constructible and suppose that $L \notin$ DTIME$(T(n))$ almost everywhere. Then, for every polynomial time computable distribution μ, $(L, \mu) \notin$ AVTIME$(T(n))$.*

Again, the proof is easy. For any Turing machine that accepts L, choose n_M so that $T_M(x) > T(|x|)$ for all x such that $|x| \geq n_M$. Observe that the ratio $\frac{T^{-1}(T_M(x))}{|x|}$ is > 1 for every input x such that $|x| \geq n_M$. The proof follows immediately by observing that

$$\sum_{|x| \geq n_M} \mu'(x) \cdot \frac{T^{-1}(T_M(x))}{|x|} > W_{n_M}. \tag{4.6}$$

The fact that these theorems follow immediately attests to the naturalness of Definition 4.1.

THEOREM 4.5. *Let $T, T' : \mathrm{N} \to \mathrm{N}$ be logarithmico-exponential functions and assume that T and T' are fully time constructible. Assume $T'(n) \log T'(n) = o(T(n))$. Then*

$$\mathrm{AVTIME}(T'(n)) \subset \mathrm{AVTIME}(T(n)).$$

Further, there is a language L such that for every polynomial time computable distribution μ, $(L, \mu) \in$ AVTIME$(T(n))$, but $(L, \mu) \notin$ AVTIME$(T'(n))$.

When we use Proposition 2.1, the proof follows immediately from Theorems 4.3 and 4.4. This result is as tight as the well-known Hartmanis–Stearns hierarchy theorem [11] for deterministic time.

COROLLARY 4.6. *For all $c \geq 1$ and for all $\epsilon > 0$,* AVTIME$(n^c) \subset$ AVTIME$(n^{c+\epsilon})$. *For all $c > 1$ and for all $\epsilon > 0$,* AVTIME$(c^n) \subset$ AVTIME$((c+\epsilon)^n)$.

In analogy with traditional complexity theory, consider the following average-case complexity classes:

(i) AVP $= \bigcup_{k \geq 1}$ AVTIME(n^k).
(ii) AVE $= \bigcup_{k \geq 1}$ AVTIME(2^{cn}).
(iii) AVEXP $= \bigcup_{k \geq 1}$ AVTIME(2^{n^k}).

COROLLARY 4.7. AVP $\subset$ AVE *and* AVE $\subset$ AVEXP.

A language L is *bi-immune* to a complexity class $\mathcal{C}$ if L is infinite, no infinite subset of L belongs to $\mathcal{C}$, and no infinite subset of $\overline{L}$ belongs to $\mathcal{C}$. Balcázar and Schöning [1] proved that for every time constructible function T, L does not belong to DTIME$(T(n))$ almost everywhere if and only if L is bi-immune to DTIME$(T(n))$.

Recall that DistNP is the class of distributional problems (L, μ) such that $L \in$ NP and μ is computable in polynomial time [14, 4]. The important open question that motivates studies of average-time complexity classes is the question of whether DistNP $\subseteq$ AVP.

COROLLARY 4.8. *If* NP *contains a language L that is bi-immune to* P*, then for every polynomial time computable distribution μ, the distributional problem (L, μ) belongs to* DistNP *but does not belong to* AVP.

The proof follows from Theorem 4.4. A weaker conclusion is known to follow from a weaker hypothesis. To wit, Lutz and Mayordomo [16] proved that if NP contains a language L that is bi-immune to P, then E $\neq$ NE. Ben David et al. [4] proved that if E $\neq$ NE, then there is a tally language L in NP $-$ P such that the distributional problem (L, ν) belongs to DistNP but does not belong to Average-P, where $\nu'(1^n) = n^{-2}$.

Furthermore, Mayordomo [17] proved that if NP does not have p-measure 0, then NP contains a language that is bi-immune to P. Thus, the following corollary follows immediately.

COROLLARY 4.9. *If* NP *does not have p-measure* 0*, then there is a language* L *such that, for every polynomial time computable distribution* μ*, the distributional problem* (L, μ) *belongs to* DistNP *but does not belong to* AVP.

Schuler and Yamakami [21] have proved independently that if L is bi-immune to P, then there is a polynomial time computable distribution μ such that (L, μ) does not belong to Average-P. They observed from this result that if DistNP $\subseteq$ Average-P, then NP has p-measure 0. By Theorem 4.2, $(L, \mu) \notin$ Average-P for every bi-immune set L and every polynomial time computable distribution μ that satisfies Condition W. Thus, if NP does not have p-measure 0, then there is a language L such that for every polynomial time computable distribution μ that satisfies Condition W, the distributional problem (L, μ) belongs to DistNP but does not belong to Average-P.

4.3. Pathological distributions. We arrived at our current definition of average-case complexity for arbitrary time-bounds after a careful analysis of the intuitive justifications and after considering the demands of a well-formed complexity theory. The new definition is supported by the equivalence theorem, Theorem 4.2, and the second hierarchy theorem, Theorem 4.5.

Here we briefly address the exceptional cases where the distribution does not satisfy Condition W, so that our equivalence theorem, Theorem 4.2, does not apply. We show in this case that our notion of polynomial on the μ-average indeed *differs* from that of Levin. Thus, the restriction to distributions that satisfy Condition W in Theorem 4.2 is essential.

To illustrate, let's consider a (pathological) distribution μ where $u_n = 1/2^n$; i.e., all strings of length n have total measure $1/2^n$. It follows from the theorem of Geske, Huynh, and Seiferas [6], our Proposition 2.1, that there is a language L that is decidable in time $2^n/n$ but that almost everywhere requires more than, say, $2^n/n^3$ steps. Then according to Levin's definition, the distributional problem (L, μ) is in Average-P; indeed it is linear on the μ-average according to the definition in [4], since

$$\sum_{n \geq 1} \frac{1}{2^n} \frac{2^n}{n^2} < \infty.$$

However, according to our definition, by Theorem 4.4 the problem (L, μ) is not in time $2^n/n^3$ on the μ-average. Thus, the two definitions differ.

We believe that distributions, such as this μ, that fail to satisfy Condition W are pathological. Such distributions put too much weight on short strings, so that the problem we are really dealing with becomes essentially a finitary problem, not one with an asymptotic behavior. However, if we must consider such distributions in the context of average-case analysis, we still stand by our guiding principle that a language that requires more than polynomial time almost everywhere is not polynomial time on the average for any distribution.

Earlier we informally wrote of "default" distributions such as $u_n = 1/n^2$ or $1/n^3$. (More formally $u_n = 1/(\zeta(2)n^2)$ or $u_n = 1/(\zeta(3)n^3)$, where $\zeta(s) = \sum_{n=1}^{\infty} 1/n^s$ is the Riemann zeta function.) Indeed, we had in mind distributions that satisfy Condition W. It is not merely a matter of convenience that these are the common default distributions. As we show by the example here, Levin's notion of average polynomial time yields counterintuitive results when applied to pathological distributions; i.e., mere convergence of $\sum_{n=1}^{\infty} u_n < \infty$ is not sufficient.

4.3.1. Worst-case average case. In a discussion of a preliminary draft of this paper, Rackoff [19] suggested the following more stringent requirement as a possible definition for a distributional problem (L, μ) to be T on the μ-average: There exists a Turing machine M that accepts L such that, for all n, the running time T_M satisfies

$$\sum_{|x|=n} \mu'(x) \cdot \frac{T^{-1}(T_M(x))}{|x|} \leq u_n. \tag{4.7}$$

Clearly, if T_M satisfies (4.7) it also satisfies our definition in (4.3).

For the notion of polynomial time on average, Gurevich [8] has shown that the definition given by (4.7) is equivalent to Levin's, and therefore to ours, for distributions that satisfy the additional condition (call it condition W*) that there exists $s > 0$ such that $u_n = \Omega\left(\frac{1}{n^s}\right)$.

It is not hard to show that the class of distributional problems that are polynomial on the μ-average is not the same as the class that (4.7) defines for distributions that do not satisfy condition W*.

The notion expressed in (4.7) is an interesting one. For example, since it refines ours, one can prove a fine hierarchy theorem. Also, it reflects the intuitive notion of average-case problems when it is important to bound the average hardness of a problem for every length n. This is especially relevant in areas such as cryptography and number theoretic problems. In a sense it is a hybrid requirement, best described as the worst-case bound (over all lengths n) of the average-case complexity (within each length n).

4.4. Final comments. Levin [14] provided central notions toward the development of a theory of *average polynomial time*. One is the class Average-P, which provides a classification of *easy* problems on average; the other is the class Dist-NP, which, together with complete distributional problems under appropriate reductions, provides a *hardness* notion. In this paper we have focused on extending the classification to arbitrary time-bounds. We refer the reader to papers by Belanger, Pavan, and Wang [2] and Pavan and Selman [18] for research on issues concerning reductions and complete problems as they relate to the new definitions we have given here.

5. Random-access machines. In order to illustrate our technique one more time, we complete this paper by giving a hierarchy theorem for random-access machines.

THEOREM 5.1. *Let $T, T' : \mathrm{N} \to \mathrm{N}$ be logarithmico-exponential functions and assume that T and T' are fully time constructible. Assume that $T'(n) = o(T(n))$. Then there is a language L such that for every polynomial time computable distribution μ there is a random-access machine M that decides L, whose running time T_M is $O(T)$ on the μ-average, but for every random-access machine M' that decides L, the running time of M' is* not *T' on the μ-average.*

Proof. It is known [6] that there is a language L that is decided by a random-access machine in time $O(T(n))$ such that the running time of every random-access machine M' that decides L exceeds $T'(n)$ almost everywhere. (This result is an almost-everywhere version of a hierarchy theorem of Cook and Reckow for random-access machines [5].) Let μ be any polynomial time computable distribution that satisfies Condition W. It is immediately apparent that the running time of M is $O(T(n))$ on the μ-average. However, it is also immediately apparent, as in the proof of Theorem 4.4, that the running time of M' is *not* T' on the μ-average. □

Acknowledgments. We thank Steve Cook, Leonid Levin, Charlie Rackoff, and Jie Wang for helpful comments and discussions on a preliminary draft of this paper. We also thank the two anonymous referees for their comments and criticisms, which have improved the paper.

BUCKETS, HEAPS, LISTS, AND MONOTONE PRIORITY QUEUES*

BORIS V. CHERKASSKY†, ANDREW V. GOLDBERG‡, AND CRAIG SILVERSTEIN§

Abstract. We introduce the heap-on-top (hot) priority queue data structure that combines the multilevel bucket data structure of Denardo and Fox with a heap. Our data structure has superior operation bounds than either structure taken alone. We use the new data structure to obtain an improved bound for Dijkstra's shortest path algorithm. We also discuss a practical implementation of hot queues. Our experimental results in the context of Dijkstra's algorithm show that this implementation of hot queues performs very well and is more robust than implementations based only on heap or multilevel bucket data structures.

Key words. data structures, priority queues, shortest paths

1. Introduction.

A priority queue is a data structure that maintains a set of elements and supports operations `insert`, `decrease-key`, and `extract-min`. Priority queues are fundamental data structures with many applications. Typical applications include graph algorithms (e.g., [14]) and event simulation (e.g., [5]).

An important subclass of priority queues, used in applications such as event simulation and in Dijkstra's shortest path algorithm [13], is the class of *monotone* priority queues. In monotone priority queues, the extracted keys form a monotone, nondecreasing sequence. In this paper we develop a new data structure for monotone priority queues.

Consider an event simulation application, in which we use a monotone priority queue to maintain a set of items. Item keys are times at which the items will be processed. At each step, we extract an item with the smallest key t and process it. This precipitates several events $e_1, \ldots, e_i$, of nonnegative event durations $t_1, \ldots, t_i$. Each event j causes an item with key $t + t_j$ to be inserted into the queue. We denote the maximum event duration by C.

We refer to priority queues whose operations are more efficient when the number of elements on the queue is small as *s-heaps*.[1] For example, in a binary heap containing n elements, all priority queue operations take $O(\log n)$ time, so the binary heap is an s-heap. (Operation bounds may depend on parameters other than the number of elements.) The fastest implementations of s-heaps are described in [4, 14, 22].

[1]Here "s" stands for "size."

Alternative implementations of priority queues use buckets (e.g., [2, 8, 11, 12]). Operation times for bucket-based implementations depend on the maximum event duration C and are not very sensitive to the number of elements. See [3] for a related data structure.

s-heaps are particularly efficient when the number of elements on the s-heap is small. Bucket-based priority queues are particularly efficient when the maximum event duration C is small. Furthermore, some of the work done in bucket-based implementations can be amortized over elements in the buckets, so bucket-based priority queues actually have better bounds if the number of elements is large. In this sense, s-heaps and buckets complement each other.

We introduce *heap-on-top priority queues (hot queues)*, which combine the multilevel bucket data structure of Denardo and Fox [11] and a monotone s-heap.[2] The resulting implementation takes advantage of the best performance features of both data structures. In order to describe hot queues, we give an alternative and more insightful description of the multilevel bucket data structure. Independently, a similar description has been given in [18].

We illustrate efficiency of hot queues by implied bounds for Dijkstra's shortest path algorithm; detailed operation bounds appear in section 4. In the following discussion, n is the number of vertices, m the number of arcs, C the largest arc length, and ϵ any positive constant. We assume integral arc lengths.

The best time bounds in the standard RAM model of computation appear in [2, 3, 14]. Out of these algorithms, the algorithm of Ahuja et al., based on the radix heap data structure, is closest to our algorithm. Their algorithm runs in $O(m + n(\log C)^{\frac{1}{2}})$ time. Fredman and Willard [15] showed that better bounds are possible in a stronger RAM model; the fastest currently known algorithm [22] in this model runs in $O(m \log\log n)$ time.

Efficiency of a hot queue depends on that of the heap used to implement it. Using Fibonacci heaps [14], we match the radix heap bounds in the standard model. Our data structure, however, is simpler. In a stronger model, we use the s-heap of Thorup [22] to obtain better monotone priority queue bounds. In particular, we get an $O(m + n(\log C)^{\frac{1}{3}+\epsilon})$ expected time implementation of Dijkstra's shortest path algorithm.

Hot queues work well both in theory and in practice. This is often not the case for low-complexity data structures, including priority queues. Asymptotic bound improvements often come at the expense of constant factors, which come to dominate the running time for all reasonable problem sizes. A preliminary version of the hot queue data structure [6] did not perform well in practice. Based on experimental feedback, we modified the data structure to be more practical. As an added bonus, hot queues became simpler. We also developed implementation techniques that make hot queues efficient in practice.

We compare the implementation of hot queues to implementations of multilevel buckets and d-heaps [23] in the context of Dijkstra's shortest paths algorithm. Our experimental results show that hot queues perform best overall and are more robust than either of the other two data structures. This is especially significant because a multilevel bucket implementation of Dijkstra's algorithm compared favorably with other implementations of the algorithm in a previous study [8] and was shown to

[2] Actually, our data structure can use any heap. However, hot queues are designed so that the number of elements on the heap is small, so s-heaps lead to the best bounds.

be very robust [16]. For many problem classes, the hot queue implementation of Dijkstra's algorithm is the best both in theory and in practice.

This paper is organized as follows. Section 2 introduces basic definitions. Our description of the multilevel bucket data structure appears in section 3. Section 4 describes hot queues and their application to Dijkstra's algorithm. Details of our implementation, including heuristics we used, are described in section 5. Section 6 describes our experimental setup, including the problem families we use. Section 7 contains experimental results. Section 8 contains concluding remarks.

2. Preliminaries. A *priority queue* is a data structure that maintains a set of elements and supports operations `insert`, `decrease-key`, and `extract-min`. We assume that elements have *keys* used to compare the elements, and we denote the key of an element u by $\rho(u)$. Unless mentioned otherwise, we assume that the keys are integral. By the value of an element we mean the key of the element. The `insert` operation adds a new element to the queue. The `decrease-key` operation assigns a smaller value to the key of an element already on the queue. The `extract-min` operation removes a minimum element from the queue and returns the element. We denote the number of `insert` operations in a sequence of priority queue operations by N.

To gain intuition about the following definition, think of event simulation applications where keys correspond to event durations. An *event* is an `insert` or a `decrease-key` operation on the queue. Given an event, let v be the element that is inserted into the queue or has its key decreased. Let u be the most recent element extracted from the queue. The *event duration* is $\rho(v) - \rho(u)$. In Dijkstra's shortest path algorithm, event durations correspond to arc lengths. We denote the maximum event duration by C. A *monotone* priority queue is a priority queue for monotone applications. To make these definitions valid for the first insertion, we assume that during initialization, a special element is inserted into the queue and deleted immediately afterward. Without loss of generality, we assume that the value of this element is zero. (If it is not, we can subtract this value from all element values.)

In this paper, by *s-heap* we mean a priority queue that is sensitive to the number of elements in the queue and is more efficient if the number of elements on the queue is small.

We call a sequence of operations on a priority queue *balanced* if the sequence starts and ends with an empty queue. In particular, implementations of Dijkstra's shortest path algorithm produce balanced operation sequences.

All logarithms in this paper are base two.

Hot queues work in the *word RAM* model of computation (see, e.g., [1]): they need array addressing and the following unit-time word operations: addition, subtraction, comparison, and arbitrary shifts (which are equivalent to multiplication and division by powers of two). However, hot queues use s-heaps, and some heaps assume a *strong RAM* model where certain other word operations take unit time. The most common operations are AC0 operations and multiplication; different variants allow different operations. See [15, 22].

The multilevel bucket data structure, one of the main building blocks of hot queues, works in the word RAM model. In section 3, we describe a strong RAM variant of this data structure that uses word operations including bitwise logical operations and the operation of finding the index of the most significant bit in which two words differ. The latter operation is in AC0; see [10] for a discussion of a closely related operation. The use of this more powerful model does not improve the amor-

tized operation bounds, but it improves some worst case bounds and simplifies the description.

In the context of Dijkstra's algorithm, we assume that we are given a directed graph with n vertices, m arcs, and integral arc lengths in the range $[0, \ldots, C]$, where C fits in one machine word.

3. Multilevel buckets. In this section we describe the k-level bucket data structure of Denardo and Fox [11]. By using a strong RAM model, we give a simpler description of this data structure than that given in [11]. We treat the element keys as base-Δ numbers for a certain parameter Δ. Consider a bucket structure B that contains k levels of buckets, where k is a positive integer. Except for the top level, a level contains an array of Δ buckets. The top level contains infinitely many buckets. Each top level bucket corresponds to an interval $[i\Delta^k, (i+1)\Delta^k - 1]$. We chose Δ so that at most Δ consecutive buckets at the top level can be nonempty; we need to maintain only these buckets.[3]

We denote bucket j at level i by $B(i, j)$; i ranges from 1 (bottom level) to k (top), and j ranges from 0 to $\Delta - 1$. A bucket contains a set of elements in a way that allows constant-time insertion and deletion, e.g., in a doubly linked list.

Given k, we choose Δ as small as possible subject to two constraints. First, each top level bucket must span a key range of at least $(C+1)/\Delta$. Then, by the definition of C, keys of elements in B belong to at most Δ consecutive top level buckets. Second, Δ must be a power of two so that we can manipulate base-Δ numbers efficiently using RAM operations on words of bits. With these constraints in mind, we set Δ to the smallest power of two greater than or equal to $(C+1)^{1/k}$.

We maintain μ, the key of the latest element extracted from the queue. Consider the base-Δ representation of the keys and an element u in B. Let μ_{i-j} denote the ith through jth least significant digits of μ. $\mu_{i-\infty}$ denotes the ith and higher least significant digits, while μ_i denotes the ith least significant digit alone. Similarly, u_i denotes the ith least significant digit of $\rho(u)$, and likewise for the other definitions. By the definitions of C and Δ, μ and the k least significant digits of the base-Δ representation of $\rho(u)$ uniquely determine $\rho(u)$. Thus, $\rho(u) = \mu + (u_{0-k} - \mu_{0-k})$ if $u_{0-k} > \mu_{0-k}$ and $\mu + \Delta^k + (u_{0-k} - \mu_{0-k})$ otherwise.

Let i be the index of the most significant digit in which $\rho(u)$ and μ differ, or 1 if $\rho(u) = \mu$. (The least significant digit index is 1.) Given μ and u with $\rho(u) \geq \mu$, we denote the *position of u with respect to μ* by (i, u_i). If u is inserted into B, it is inserted into $B(i, u_i)$. For each element in B, we store its position. If an element u is in $B(i, j)$, then only the i least significant digits of $\rho(u)$ differ from the corresponding digits of μ. Furthermore, $u_i = j$.

The fact that keys of all elements on the queue are at least μ implies the following lemma.

LEMMA 3.1. *For every level i, buckets $B(i, j)$ for $0 \leq j < \mu_i$ are empty.*

At each level i, we maintain the number of elements at this level. We also maintain the total number of elements in B.

The `extract-min` operation can change the value of μ. As a side effect, positions of some elements in B may change. Suppose that a minimum element is deleted and the value of μ changes from μ' to μ''. By definition, keys of the elements on the queue after the deletion are at least μ''. Let i be the position of the most significant digit in which μ' and μ'' differ. If $i = 1$ (μ' and μ'' differ only in the last digit), then for

[3] The simplest way to implement the top level is to "wrap around" modulo Δ.

any element in B after the deletion its position is the same as before the deletion. If $i > 1$, then the elements in bucket $B(i, \mu_i'')$ with respect to μ' are exactly those whose position is different with respect to μ''. These elements have a longer prefix in common with μ'' than with μ', and therefore they belong to a lower level with respect to μ''.

The *bucket expansion* procedure moves these elements to their new positions. The procedure removes the elements from $B(i, \mu_i'')$ and puts them into their positions with respect to μ''. The two key properties of bucket expansions are as follows:

- After the expansion of $B(i, \mu_i'')$, all elements of B are in correct position with respect to μ''.
- Every element of B moved by the expansion is moved to a lower level.

Now we are ready to describe the multilevel bucket implementation of the priority queue operations.

`insert:` To insert an element u, compute its position (i, j) and insert u into $B(i, j)$.

`decrease-key:` Decrease the key of an element u in position (i, j) as follows. Remove u from $B(i, j)$. Set $\rho(u)$ to the new value and insert u as described above.

`extract-min:` (We need to find and delete the minimum element, update μ, and move elements affected by the change of μ.)

Find the lowest nonempty level i. Find j, the first nonempty bucket at level i. If $i = 1$, delete an element from $B(i, j)$, set $\mu = \rho(u)$, and return u. (In this case all element positions remain the same.)

If $i > 1$, examine all elements of $B(i, j)$ and delete a minimum element u from $B(i, j)$. Set $\mu = \rho(u)$ and expand $B(i, j)$. Return u.

Next we deal with efficiency issues.

LEMMA 3.2. *Given μ and u, we can compute the position of u with respect to μ in constant time.*

Proof. By definition, $\Delta = 2^\delta$ for some integer δ, so each digit in the base-Δ representation of $\rho(u)$ corresponds to δ bits in the binary representation. It is straightforward to see that if we use appropriate masks and the fact that the index of the first bit in which two words differ can be computed in constant time [10], we can compute the position in constant time. □

Iterating through the levels, we can find the lowest nonempty level in $O(k)$ time. Using binary search, we can find the level in $O(\log k)$ time. We can do even better using the power of the strong RAM model.

LEMMA 3.3. *If $k \le \log C$, then the lowest nonempty level of B can be found in $O(1)$ time.*

Proof. Define D to be a k-bit number with $D_i = 1$ if and only if level i is nonempty. If $k \le \log C$, D fits into one RAM word, and we can set a bit of D and find the index of the first nonzero bit of D in constant time. □

As we will see, the best bounds are achieved for $k \le \log C$.

A simple way of finding the first nonempty bucket at level i is to go through the buckets. This takes $O(\Delta)$ time.

LEMMA 3.4. *We can find the first nonempty bucket at a level in $O(\Delta)$ time.*

Remark. One can do better [11]. Divide buckets at every level into groups of size $\lceil \log C \rceil$, each group containing consecutive buckets. For each group, maintain a $\lceil \log C \rceil$-bit number with bit j equal to 1 if and only if the jth bucket in the group is not empty. We can find the first nonempty group in $O(\Delta / \log C)$ time and the first nonempty bucket in the group in $O(1)$ time. This construction gives a $\log C$ factor improvement for the bound of Lemma 3.4. By iterating this construction p times, we

get an $O(p + (\Delta/\log^p C))$ bound. Note that we can use word-size groups instead of $\lceil \log C \rceil$-size groups.

Although the above observation improves the multilevel bucket operation time bounds for small values of k, the bounds for the optimal value of k do not improve. To simplify the presentation, we use Lemma 3.4, rather than its improved version, in the rest of the paper.

THEOREM 3.5. *Amortized bounds for the multilevel bucket implementation of priority queue operations are as follows:* $O(k)$ *for* `insert`, $O(1)$ *for* `decrease-key`, *and* $O(C^{1/k})$ *for* `extract-min`.

Proof. The `insert` operation takes $O(1)$ worst case time. We assign it an amortized cost of k because we charge moves of elements to a lower level to the insertions of the elements.

The `decrease-key` operation takes $O(1)$ worst case time, and we assign it an amortized cost of $O(1)$.

The worst case time of the `extract-min` operation is $O(\log k + \Delta)$ plus the cost of bucket expansions. The cost of a bucket expansion is proportional to the number of elements in the bucket. This cost can be charged to the corresponding `insert` operations, because, except for the minimum element, each element examined during a bucket expansion is moved to a lower level. An element can move down at most $k - 1$ times. We charge the $\log k$ factor to the insertions as well. This completes the proof since $\Delta = O(C^{1/k})$. □

Note that in any sequence of operations the number of `insert` operations is at least the number of `extract-min` operations. In a balanced sequence, the two numbers are equal, and we can modify the above proof to obtain the following result.

THEOREM 3.6. *For a balanced sequence, amortized bounds for the multilevel bucket implementation of priority queue operations are as follows:* $O(1)$ *for* `insert`, $O(1)$ *for* `decrease-key`, $O(k + C^{1/k})$ *for* `extract-min`.

Remark. We can easily obtain an $O(1)$ implementation of the `delete` operation for multilevel buckets. Given a pointer to an element, we delete it by removing the element from the list of elements in its bucket.

For $k = 1$, the `extract-min` bound is $O(C)$. For $k = 2$, the bound is $O(\sqrt{C})$. The best bound of $O(\log C/\log\log C)$ is obtained for $k = \lceil \log C/2\log\log C \rceil$.

Remark. The original multilevel bucket data structure [11] works in the word RAM model of computation. This implementation maintains ranges for each bucket level and finds element positions by first finding the appropriate level (using sequential or binary search) and then computing the element's bucket index (using shifts). For this implementation, some operations take longer; for example, `insert` is not constant time. However, the amortized bounds of Theorem 3.5 are valid.

Remark. The k-level bucket data structure uses $\Theta(kC^{1/k})$ space for the buckets.

A major bottleneck of the multilevel bucket implementation is bucket scans. A natural idea is to maintain nonempty bucket indices in a heap. A variant of this idea leads to radix heaps, which maintain a heap containing all elements, with element positions serving as keys. The number of distinct keys is $O(kC^{1/k})$. Radix heaps use a modification of Fibonacci heaps with amortized $O(1)$ `insert` and `decrease-key` operations, and amortized $O(\log N')$ `extract-min` operation, where N' is the number of distinct keys on the heap. Setting $k = \sqrt{\log C}$ gives the following operation costs for the balanced case: $O(1)$ for `insert` and `decrease-key`, and $O(\sqrt{\log C})$ for `extract-min`.

We use a different idea to improve on multilevel buckets. We scan a bucket level

only if many elements "went through" this level and charge bucket scans to these elements.

4. Hot queues. A *hot queue* uses an s-heap H and a multilevel bucket structure B. Intuitively, the hot queue data structure works like the multilevel bucket data structure, except we do not expand a bucket containing fewer than t elements, where t is a parameter set to optimize performance. Elements of the bucket are copied into H and processed using the s-heap operations. If the number of elements in the bucket exceeds t, the bucket is expanded. In the analysis, we charge scans of buckets at the lower levels to the elements in the bucket during the expansion into these levels.

A k-level hot queue uses the k-level bucket structure. For technical reasons, we must add an additional *special* level $k+1$, which is needed to account for scanning of buckets at level k. Only two buckets at the top level can be nonempty at any time, μ_{k+1} and $\mu_{k+1}+1$. Note that if the queue is nonempty, then at least one of the two buckets is nonempty. Thus bucket scans at the special level add a constant amount to the work of processing an element found. We use wrap around at level $k+1$ instead of k.

An *active* bucket is the bucket whose elements are in H. At most one bucket is active at any time, and H is empty if and only if there is no active bucket. We denote the active bucket by $B(a,b)$. We make a bucket active by making H into a heap containing the bucket elements and inactive by resetting H to an empty heap. (Elements of the active bucket are both in the bucket and in H.)

To describe the details of hot queues, we need the following definitions. We denote the number of elements in $B(i,j)$ by $c(i,j)$. Given μ, $i : 1 \le i \le k+1$, and $j : 0 \le j < \Delta$, we say that an element u is *in the range of* $B(i,j)$ if $u_{(i+1)-\infty} = \mu_{(i+1)-\infty}$ and $u_i = j$. Using word operations, we can check if an element is in the range of a bucket in constant time.

We maintain the invariant that μ is in the range of $B(a,b)$ if there is an active bucket. The detailed description of the queue operations is as follows.

`insert:` If H is empty or if the element u being inserted is not in the range of the active bucket, we insert u into B as in the multilevel case. Otherwise u belongs to the active bucket $B(a,b)$. If $c(a,b) < t$, we insert u into H and $B(a,b)$. If $c(a,b) \ge t$, we make $B(a,b)$ inactive, add u to $B(a,b)$, and expand the bucket.

`decrease-key:` Decrease the key of an element u as follows. If u is in H, decrease the key of u in H. Otherwise, let (i,j) be the position of u in B. Remove u from $B(i,j)$. Set $\rho(u)$ to the new value and insert u as described above.

`extract-min:` If H is not empty, extract and return the minimum element of H. Otherwise, proceed as follows. Find the lowest nonempty level i. Find the first nonempty bucket at level i by examining buckets starting from $B(i,\mu_i)$. If $i = 1$, delete an element from $B(i,j)$, set $\mu = \rho(u)$, and return u. If $i > 1$, examine all elements of $B(i,j)$ and delete a minimum element u from $B(i,j)$. Set $\mu = \rho(u)$. If $c(i,j) > t$, expand $B(i,j)$. Otherwise, make $B(i,j)$ active. Return u.

Correctness of the hot queue operations follows from the correctness of the multilevel bucket operations, Lemma 3.1, and the observation that if u is in H and v is in B but not in H, then $\rho(u) < \rho(v)$.

Note that at any time, H contains a (possibly empty) subset of the smallest elements of the hot queue. Consider a time interval when H is nonempty. It is easy to see that during each time interval while H is nonempty, the sequence of operations

TABLE 4.1
The bounds for hot queues using Fibonacci heaps. The best bounds are obtained with $k = \log^{\frac{1}{2}} C$ *and* $t = 2^{\log^{\frac{1}{2}} C}$. *Radix heaps achieve the same bounds but are more complicated.*

Fibonacci heaps	Heap bounds	Hot queue bounds	Hot queue, best k and t
`insert`	$O(1)$	$O(k + \frac{kC^{1/k}}{t})$	$O(\log^{\frac{1}{2}} C)$
`decrease-key`	$O(1)$	$O(1)$	$O(1)$
`extract-min`	$O(\log N)$	$O(\log t)$	$O(\log^{\frac{1}{2}} C)$

TABLE 4.2
The bounds for hot queues using Thorup's heaps. Here ϵ *is any constant. The best bounds are obtained with* $k = \log^{\frac{1}{3}} C$ *and* $t = 2^{\log^{\frac{2}{3}} C}$.

Thorup's heaps	Heap bounds	Hot queue bounds	Hot queue, best k and t
`insert`	$O(1)$	$O(k + \frac{kC^{1/k}}{t})$	$O(\log^{\frac{1}{3}} C)$
`decrease-key`	$O(1)$	$O(1)$	$O(1)$
`extract-min`	$O(\log^{\frac{1}{2}+\epsilon} N)$	$O(\log^{\frac{1}{2}+\epsilon} t)$	$O(\log^{\frac{1}{3}+\epsilon} C)$

on H is monotone. Thus we can use a monotone s-heap H.

LEMMA 4.1. *The cost of finding the first nonempty bucket at a level, amortized over the* `insert` *operations, is* $O(k\Delta/t)$.

Proof. It is enough to bound the number of empty buckets scanned during the search. We scan an empty bucket at level i at most once during the period of time that $\mu_{i-\infty}$ remains unchanged. This can happen only if a higher-level bucket has been expanded during the period that $\mu_{i-\infty}$ does not change. We charge bucket scans to insertions into the queue of the elements contained in the expanded bucket. For each level scan, we charge Δ to a group of over t elements, and each element's share is less than Δ/t. Each time we charge an element it moves down at least one level, so the total charge for an element is less then $k\Delta/t$. □

THEOREM 4.2. *Let* $I(N)$, $D(N)$, *and* $X(N)$ *be the time bounds for monotone heap* `insert`, `decrease-key`, *and* `extract-min` *operations. Then amortized times for the hot queue operations are as follows:* $O(k+I(t)+\frac{kC^{1/k}}{t})$ *for* `insert`, $O(D(t)+I(t))$ *for* `decrease-key`, *and* $O(X(t))$ *for* `extract-min`.

Proof. The result follows from Lemma 4.1, Theorem 3.5, and the fact that the number of elements in H never exceeds t. □

Remark. All bounds are valid only when $t \le N$. For $t > N$, one should use an s-heap instead of a hot queue.

The bounds for Fibonacci heaps are given in Table 4.1. The bounds for Thorup's heaps are in Table 4.2. Similarly to Theorem 3.6, we can get bounds for a balanced sequence of operations.

THEOREM 4.3. *Let* $I(N)$, $D(N)$, *and* $X(N)$ *be the time bounds for heap* `insert`, `decrease-key`, *and* `extract-min` *operations, and consider a balanced sequence of the hot queue operations. The amortized bounds for the operations are as follows:* $O(I(t))$ *for* `insert`, $O(D(t) + I(t))$ *for* `decrease-key`, *and* $O(k + X(t) + \frac{kC^{1/k}}{t})$ *for* `extract-min`.

Using Fibonacci heaps, we get $O(1)$, $O(1)$, and $O(k + \log t + \frac{kC^{1/k}}{t})$ amortized bounds for the queue operations. Consider `extract-min`, the only operation with a nonconstant bound. Setting $k = 1$ and $t = \frac{C}{\log C}$, we get an $O(\log C)$ bound. Setting $k = 2$ and $t = \frac{\sqrt{C}}{\log C}$, we get an $O(\log C)$ bound. Setting $k = \log^{\frac{1}{2}} C$ and $t = 2^{\log^{\frac{1}{2}} C}$,

we get an $O(\log^{\frac{1}{2}} C)$ bound.

Remark. Consider the 1- and 2-level implementations. Although the time bounds are the same, the 2-level implementation has two advantages: it uses less space, and its time bounds remain valid for a wider range of values of C.

Using Thorup's heaps and setting $k = \log^{\frac{1}{3}} C$ and $t = 2^{\log^{\frac{2}{3}} C}$, we get $O(1)$, $O(1)$, and $O(\log^{\frac{1}{3}+\epsilon} C)$ expected amortized time bounds for the queue operations `insert`, `decrease-key`, and `extract-min`, respectively.

The above time bounds allow us to get an improved bound on Dijkstra's shortest path algorithm. The running time of Dijkstra's algorithm is dominated by a balanced sequence of priority queue operations that includes $O(n)$ `insert` and `extract-min` operations and $O(m)$ `decrease-key` operations (see, e.g., [21]). The maximum event duration for this sequence of operations is C. The hot queue bounds immediately imply the following result.

THEOREM 4.4. *On a network with n vertices, m arcs, and integral lengths in the range $[0, C]$, the shortest path problem can be solved in $O(m + n(\log C)^{\frac{1}{3}+\epsilon})$ expected time.*

This improves the deterministic bound of $O(m + n \log^{\frac{1}{2}} C)$ achieved using radix heaps [2].

Remark. Like multilevel buckets, hot queues do not need a strong RAM model unless the s-heap used needs it.

Space bounds. Suppose $\overline{n}$ is the maximum number of elements in a k-level hot queue and assume that the underlying s-heap requires constant space per element. Then the additional space needed for the hot queue is $O(kC^{1/k}+\overline{n})$. Here the first term reflects the space used by the buckets and the second term reflects the space needed to maintain element lists and the $O(t)$ space used by the s-heap. For comparison, the multilevel buckets require the same space minus the s-heap space.

The number of buckets needed for $C = 2^{60}$ by a 4-level hot queue is 2^{15}. The space needed for these buckets is comparable with cache sizes of current computers.

From a theoretical point of view, it is interesting to obtain a per-element space bound. We get such a bound by "lazy allocation": only the two special-level buckets are allocated unless the other buckets are needed, i.e., unless $\overline{n} > t$. Then the per-element space bound is constant unless the buckets are allocated, in which case the bound is $O(\frac{kC^{1/k}}{\overline{n}}) = O(\frac{kC^{1/k}}{t})$. Then, since k and $\frac{C^{1/k}}{t}$ are small, the per-element space is small as well. For example, for the $\sqrt{\log C}$-level hot queue using Fibonacci heaps, the per-element bound is $O(\sqrt{\log C})$. The corresponding space bounds for the faster hot queues described above are even better.

5. Implementation details. Our previous papers [8, 16] describe implementations of multilevel buckets. Our implementation of hot queues augments the multilevel bucket implementation of [16]. See [16] for details of the multilevel bucket implementation.

Consider a k-level hot queue. As in the multilevel bucket implementation, we set Δ to the smallest power of two greater than or equal to $C^{1/k}$. Based on the analysis of section 4 and experimental results, we set t, the maximum size of an active bucket, to $\lceil C^{1/k}/(4 \log C) \rceil$.

The number of elements in an active bucket is often small. For example, for $k = 3$ and $C = 100,000,000$, we have $t = 5$. We take advantage of this fact by maintaining elements of an active bucket in a sorted list instead of an s-heap until operations on the list become expensive. At this point we switch to an s-heap. We use a 4-heap, which worked best in our tests.

To implement priority queue operations using a sorted list, we use a doubly linked list sorted in nondecreasing order. Our implementation is tuned for the shortest path application. In this application, the number of `decrease-key` operations on the elements of the active bucket tends to be very small and elements inserted into the list or moved by the `decrease-key` operation tend to be close to the beginning of the list. A different implementation may be better for a different application.

The `insert` operation searches for the element's position in the list and puts the element at that position. One can start the search in different places. Our implementation starts the search at the beginning of the list. Starting at the end of the list or at the point of the last insertion, may work better in some applications.

The `extract-min` operation removes the first element of the list.

The `decrease-key` operation removes the element from the list, finds its new position, and puts the element in that position. Our implementation starts the search from the beginning of the list. Starting at the previous position of the element, at the end of the list, or at the place of the last insertion may work better in some applications.

When a bucket becomes active, we put its elements in a list if the number of elements in the bucket is below T_1 and in an s-heap otherwise. (Our code uses $T_1 = 2,000$.) We switch from the list to the heap using the following rule, suggested by Satish Rao [20]: Switch if `insert` and `decrease-key` operations examine more than $T_2 = 5,000$ list elements from the time the current bucket became active. An alternative, which may work better in some applications but which performed worse in ours, is to switch when the number of elements in the list exceeds T_1. Once we started using a heap, we continued using it until the next bucket expansion.

6. Experimental setup. Our experiments were conducted on a computer with a 166 MHz Pentium Pro processor running Solaris x86 2.5.1. The machine has 96 MHz of main memory and all problem instances fit into main memory. Our code was written in C++ and compiled using `gcc 2.7.2.2` with the `-O6` compilation option.

We made an effort to make our code efficient. In particular, we set the bucket array sizes to be powers of two. This allows us to use word shift operations when computing bucket array indices.

We report experimental results for five types of directed graphs. Two of the graph types were chosen to exhibit the properties of the algorithm at two extremes: one where the paths from the start vertex to other vertices tend to be order $\Theta(n)$, and one in which the path lengths are order $\Theta(1)$. The third graph type is random graphs. The fourth type was constructed to have a lot of `decrease-key` operations in the active bucket. This is meant to test the robustness of our implementations when we violate the assumption (section 5) that there are few `decrease-key` operations. The fifth type of graph is meant to be easy or hard for a specific implementation with a specific number of bucket levels.

We tested each type of graph on seven implementations: d-heaps, with d=4; k-level buckets, with k ranging from 1 to 3; and k-level hot queues, with k ranging from 1 to 3. Each of these has parameters to tune, and the results we show are for the best parameter values we tested.

Most of the problem families we use are the same as in our previous paper [16]. The next two sections describe the problem families.

6.1. Graph types. Two types of graphs we explored were grids produced using the GRIDGEN generator [8]. These graphs can be characterized by a length x and width y. The graph is formed by constructing x layers, each of which is a path of

TABLE 6.1
The graph types used in our experiments; p is the number of buckets at each level.

Name	Type	Description	Salient feature
long grid	grid	16 vertices high $n/16$ vertices long	path lengths are $\Theta(n)$
wide grid	grid	$n/16$ vertices high 16 vertices long	path lengths are $\Theta(1)$
random	random	degree 4	path lengths are $\Theta(\log n)$
cycle	cycle	$d(i,j) = (i-j)^2$	results in many `decrease-key` operations
hard	two paths	$d(S, \text{path } 1) = 0$ $d(S, \text{path } 2) = p-1$	vertices occupy first and last buckets in bottom level bins

length y. We order the layers, as well as the vertices within each layer, and we connect each vertex to its corresponding vertex on adjacent layers. All the vertices on the first layer are connected to the source.

The first type of graph we used, the LONG GRID, has a constant width—16 vertices in our tests. We used graphs of different lengths, ranging from 512 to 32,768 vertices. The arcs had lengths chosen independently and uniformly at random in the range from 1 to C. C varied from 1 to 100,000,000.

The second type of graph we used was the WIDE GRID type. These graphs have length limited to 16 layers, while the width can vary from 512 to 32,768 vertices. C was the same as for LONG GRIDS.

The third type of graph includes random graphs with uniform arc length distribution. A random graph with n vertices has $4n$ arcs.

The fourth type of graph is the only type that is new compared with [16]. These are based on a cycle of n vertices, numbered 1 to n. In addition, each vertex is connected to $d-1$ distinct random vertices.

The length of an arc (i,j) is equal to $2k^{1.5}$, where k is the number of arcs on the cycle path from i to j. The fifth type of graph includes HARD graphs. These are parameterized by the number of vertices, the desired number of levels k, and a maximum arc length C. From C we compute p, the number of buckets in each level assuming the implementation has k levels. The graphs consist of two paths connected to the source. The vertices in each path are at distance p from each other. The distance from the source to path 1 is 0; vertices in this path will occupy the first bucket of bottom level bins. The distance from the source to path 2 is $p-1$, making these vertices occupy the last bucket in each bottom level bin. In addition, the source is connected to the last vertex on the first path by an arc of length 1, and to the last vertex of the second path by an arc of length C.

A summary of our graph types appears in Table 6.1.

6.2. Problem families. For each graph type, we examined how the relative performance of the implementations changed as we increased various parameters. Each type of modification constitutes a *problem family.* The families are summarized in Table 6.2. In general, each family is constructed by varying one parameter while holding the others constant. Different families can vary the same parameter, using different constant values. For instance, one problem family modifies x as $C = 16$, another modifies x as $C = 10,000$, and a third modifies x as $C = 100,000,000$.

7. Experimental results. The results of this section should be taken in proper context. The 4-heap implementation has the *worst case* operation bound of $O(\log_4 n)$ with a relatively small constant. For most shortest path problems, only a fraction of

TABLE 6.2

The problem families used in our experiments. C is the maximum arc length; x and y the length and width, respectively, of grid graphs; d is the degree of vertices in the cycle graph; and p is the number of buckets at each level.

Graph type	Graph family	Range of values	Other values

			$n = 131,072, p = 3$

vertices are on the heap at any given time. The problems in our study are big enough to establish the relative performance of the codes but not big enough to see a drastic difference in performance.

A previous study [7] suggested that the multilevel bucket implementations compare well with other implementations of Dijkstra's algorithm. This motivated a further study of the multilevel buckets [16] and the discovery of hot queues. The problem families presented here are designed to test the multilevel bucket and hot queue codes at extremes, and not to test these codes against the 4-heap.

Another study [16] showed that the multilevel buckets are efficient and robust except on a limited class of problems which cause a large number of empty bucket scans. One cannot expect hot queues to outperform the buckets when the number of such scans is moderate. The data presented below show that the additional complexity of hot queues does not significantly increase the constant factors in our implementations. Hot queues are competitive with multilevel buckets when the latter scan a moderate number of empty buckets and outperform the buckets when the number is large. The improved robustness of hot queues comes at essentially no cost to typical performance.

In the following discussion of our computational results, we present data for some, but not all, problem families from Table 6.2. Qualitative results for the other problem families can be interpolated from the data we present. An earlier technical report [9] contains data for all listed problem families. Our codes are publicly available, and interested readers can run their own experiments.

We tabulate our experimental data. In all the tables, k denotes the implementation: "h" for heap, "bi" for buckets with i levels, and "hi" for hot queue with i levels. In addition to reporting running time, we report counts for operations that give insight into algorithm performance. For the heap implementation, we count the total number of `insert` and `decrease-key` operations. For the bucket implementations, we count the number of empty buckets examined (*empty operations*). For the hot

queue implementations, we count the number of empty operations and the number of `insert` and `decrease-key` operations on the active bucket.

For some problem families we also plot the data. The plots help to identify crossover points and asymptotic trends. In the plots, we use a logarithmic scale whenever appropriate. With one exception (the HARD-2 problem family), we omit the curves for the `b3` and `h3` implementations. These curves would always be close to those for `b2` and `h2`, respectively.

We were unable to run 1-level bucket and hot queue implementations on some problems because of memory limitations. We leave the corresponding table entries blank.

Network structure and arc length distribution determine the distribution of the priority queue operations. We organize the discussion according to graph types.

7.1. Long grids. For long grids, during a shortest path computation the priority queue contains a small number of elements. Because of this, the heap performs very well.

When C is small, all codes perform similarly, with the growth rate that is very close to linear. (See Table 7.1.) As C grows, the relative performance of `b1` becomes worse, due to the large number of empty operations it executes. In Table 7.2 we show results for $C = 100,000,000$. One can see that `b1` performs very poorly. In contrast, the dependence of `h1` on C is slight. For 2 and 3 levels, hot queues perform slightly better than the corresponding bucket codes.

Table 7.3 shows the dependence on C for long grids. With the exception of `b1`, the performance is robust. Even 1-level hot queues had consistent performance across a wide range of C values. On this family, `h`, `h2`, and `h3` are the best codes, and `b2` and `b3` perform somewhat worse than their hot queue counterparts.

Operation counts give insight into performance of the code. Consider, for instance, Table 7.3. For `b1`, the number of empty bucket operations grows with C. For $C = 1,000$, the number of empty operations exceeds the graph size $(n + m)$ and soon thereafter these operations dominate the running time. Note that at the values of C around $1,000$, operation distribution for the corresponding hot queue code, `h1`, changes. For the smaller values of C, `h1` performs almost no active bucket operations because t is small and the active bucket is usually expanded. For the larger values of C, the top level bucket is usually not expanded and the code performs no empty operations. Different hot queue codes have different trade-offs between empty operations and active bucket operations.

The data presented above show that, on long grids, hot queue codes, especially `h2` and `h3`, perform very well and are very robust. Other tests we conducted, including those where C grows with n, confirm this conclusion.

7.2. Wide grids and random graphs. For wide grids and random graphs, most of the time during a shortest path computation the priority queue contains a large number of elements. The distribution of the keys depends on the arc length distribution. For the same arc length distribution, computational results for the random graphs are similar to those for wide grids, and we present only the latter. For wide grids, `h` is consistently the worst performer because of the large heap size.

The key distribution is nonclustered and, when C is not much larger than the number of elements on the heap, one would expect bucket codes to perform well. The data presented in Table 7.4 confirm the expected behavior for large enough values of n. For $C = 100,000,000$, the 1-level bucket and hot queue codes outperform the heap code even for the smallest n.

Table 7.5 gives data for wide grids as C grows. All codes are robust; `b1` and `h1` show a slight dependence of C but outperform `h` for all values of C we test.

Further experiments confirm that on wide grids and random graphs, even if C grows with the graph size, all bucket and hot queue codes perform well, outperforming the heap for all but the smallest graphs.

7.3. Cycle graphs. For many shortest path problems, including our grid and random graph problems, the number of `decrease-key` operations is much less than the worst case bound of m. The average-case analysis of [17] gives a theoretical explanation for this phenomena.

For the cycle graph problems, the number of `decrease-key` operations is large. Table 7.6 gives data for the cycle family with $d = 200$. Cycle graphs cause many `decrease-key` operations and no empty operations. For $d = 200$, `decrease-key` operations dominate the running time.

Experimental results for this problem family are surprising. One would expect `b1` to perform the best, since it is not hampered by examining many empty buckets

and has constant-time `decrease-key` performance. Likewise, one would expect `h`, with its $O(\log n)$ implementation of `decrease-key`, to perform the worst. However, `h` is the fastest overall, while `b1` is the slowest.

To explain this phenomenon, we measured the average number of heap levels an element goes up during a `decrease-key` operation. This number is less then two even for the biggest problem size. As a result, for these problems the `decrease-key` operation in the heap is more efficient than in the buckets.

To decrease a key in the `b1` implementation, one needs to remove an element from a list, compute its new position, and insert it into a list. This is more work than moving an element up one level in our array-based implementation of the heap.

The 2- and 3-level bucket implementations perform better than the 1-level implementation. This is because in many cases a `decrease-key` operation does not move the element. We must compute the new bucket position in any case (as a witness

that the element does not move), and the work involved in this computation is non-negligible compared with the work to perform a `decrease-key` operation in the heap. Because of this, the 2- and 3-level buckets perform worse than the heap.

Next we discuss the hot queue implementations. Compared with `b1`, `h1` moves fewer elements from one bucket to another. This is because some of the operations happen within the active bucket, while others take place in the large, special top level bucket. Because of this, `h1` is a little faster. The `h2` and `h3` codes perform similarly to the corresponding bucket codes.

7.4. Hard problems. Hard problems were designed to separate the performance of various multilevel bucket implementations. Experimental results on these problems motivated the development of hot queues, which were designed to improve performance on such problems. Table 7.7 shows that, indeed, hot queues perform much better on HARD-2 than their bucket-only counterparts. With at most two elements on the heap at any time, the heap implementation is the most efficient on the hard problems.

For the hot queue implementations, no bucket is expanded and the action is confined to the two special top level buckets. Thus hot queues perform well, although not quite as well as the heap. The only exception is `h1` for the largest value of C it could handle, where its running time is significantly greater than for other values of C. We attribute this to the time taken to initialize the buckets, which we do even if the buckets are never used.

The HARD-2 problems are hard for `b1` and `b2`, and, as expected, these implementations are asymptotically worse than the other codes on this family. One can also design hard problems for buckets with more levels. In particular, we tested hard problems for 3-level buckets, with predictable results: `b3` performed asymptotically worse, although the difference between its performance and that of `h` and the hot queue codes was not as drastic as for the HARD-2 problems.

8. Concluding remarks. The hot queue data structure can use any monotone s-heap. Concurrently with our work, Raman [18] developed a deterministic s-heap that implies a deterministic hot queue that is almost as fast as that described in our paper; in particular, this result implies an $O(m + n(\log C)^{\frac{1}{3}} \log\log C)$-time deterministic implementation of Dijkstra's algorithm. In a latter paper, Raman [19] develops a faster randomized s-heap that leads to a faster randomized hot queue and to an improved shortest path bound.

The hot queue data structure combines the best features of heaps and multilevel buckets in a natural way. In theory, if C is very small compared with N, the data structure performs as the multilevel bucket structure. If C is very large, the data structure performs as the heap used in it. For intermediate values of C, the data structure performs better than either the heap or the multilevel bucket structure.

Implementing the hot queue data structure efficiently is nontrivial. Our implementation uses carefully chosen parameter values as well as the sorted list data structure for small heaps. Our experiments show that, in the context of Dijkstra's algorithm, the resulting implementations with appropriate number of levels are more robust than the heap or the multilevel bucket implementations. Our previous studies [8, 16] have shown that multilevel bucket implementations of Dijkstra's algorithm compare favorably with other implementations. The fact that in the current study, hot queues were always competitive with, and in some cases more efficient than, multilevel buckets is very interesting, in spite of the fact that the performance difference is often small.

The 3-level structure is very robust for a very wide range of values of C. For small values of C, 1- or 2-level hot queues may be more efficient, but the win is not big. It is possible that for extremely huge values of C more 3 levels are better. A variable number of levels, dependent on C, may be used in practice. Our data suggest that performance of the resulting data structure will not be sensitive to the exact switchover values.

The 1-level hot queue can be viewed as a robust version of the calendar queue [5], a data structure developed for event simulation applications. It would be interesting to see how hot queues perform for these applications.

Acknowledgments. We would like to thank Bob Tarjan and Rajeev Raman for stimulating discussions and insightful comments, Satish Rao for suggesting an adaptive strategy for switching from lists to heaps, and Harold Stone for useful comments on a draft of this paper.

DISTRIBUTED ANONYMOUS MOBILE ROBOTS: FORMATION OF GEOMETRIC PATTERNS*

ICHIRO SUZUKI† AND MASAFUMI YAMASHITA‡

Abstract. Consider a system of multiple mobile robots in which each robot, at infinitely many unpredictable time instants, observes the positions of all the robots and moves to a new position determined by the given algorithm. The robots are anonymous in the sense that they all execute the same algorithm and they cannot be distinguished by their appearances. Initially they do not have a common x-y coordinate system. Such a system can be viewed as a distributed system of anonymous mobile processes in which the processes (i.e., robots) can "communicate" with each other only by means of their moves. In this paper we investigate a number of formation problems of geometric patterns in the plane by the robots. Specifically, we present algorithms for converging the robots to a single point and moving the robots to a single point in finite steps. We also characterize the class of geometric patterns that the robots can form in terms of their initial configuration. Some impossibility results are also presented.

Key words. distributed algorithms, anonymous robots, mobile robots, multiagent systems, formation of geometric patterns

1. Introduction.

Suppose that a schoolteacher wants her 100 children in the playground to form a circle so that, for instance, they can play a game. She might draw a circle on the ground as a guideline or even give each child a specific position to move to. What if the teacher does not provide such assistance? Even without such assistance, the children may still be able to form a sufficiently good approximation of a circle if each of them moves adaptively based on the movement of other children and knowledge of the shape of a circle. If successful, this method can be called a *distributed* solution to the circle formation problem for children.

A similar distributed approach can be used for controlling a group of multiple mobile robots. The main idea is to let each robot execute a simple algorithm and plan its motion adaptively based on the observed movement of other robots, so that the robots as a group will achieve the given goal. The objective of this paper is to give a formal discussion on the power and limitations of the distributed control method in the context of the formation problems of geometric patterns in the plane.

The problem of forming an approximation of a circle having a given diameter by identical mobile robots was first discussed by Sugihara and Suzuki [13].[1] Assuming

[1] In our terminology, the problem they consider is a convergence problem for a circle.

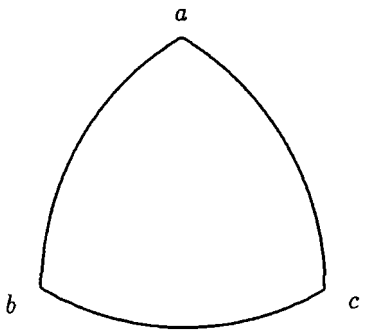

FIG. 1.1. *Reuleux's triangle.*

that the positions of the robots are the only information available, they proposed a simple heuristic distributed algorithm (to be executed independently by all robots), which, according to simulation results, sometimes brings the robots to a pattern reminiscent of a Reuleaux's triangle (Figure 1.1) rather than a circle. Tanaka [16] later improved their algorithm and demonstrated, using simulation, that his new algorithm avoids this problem and generates a better approximation of a circle. In essence, in his algorithm each robot simply adjusts its position regarding the midpoint of the positions of the nearest and farthest neighbors as the center of the circle to which the robots are converging, while moving away from its nearest neighbor if the distance to that midpoint is approximately equal to the given target radius. Figure 1.2 shows the behavior of 50 robots executing his algorithm starting from an initial distribution generated randomly. This extremely simple algorithm demonstrates the potential of the distributed method. The circle formation problem was also discussed recently by Debest [2] from the viewpoint of self-stabilization. A system is said to be *self-stabilizing* if it recovers from any finite number of transient errors [12], and thus self-stabilizing robot algorithms are robust against a finite number of sensor and control errors.

Formation problems of geometric patterns are closely related to certain agreement problems. Agreement on a common x-y coordinate system by the robots, for instance, can greatly reduce the complexity of motion coordination algorithms; e.g., convergence toward a single point can easily be solved by moving all the robots toward point $(0, 0)$ of the common coordinate system. However, such a simple solution is not possible if the robots have only their own local coordinate systems, whose origins may or may not agree. It is sometimes assumed in the literature, therefore, that either there exists a global coordinate system or that some navigation devices (e.g., a variety of potential functions [18], compasses [3], or beacons and lighthouses [4]) are available to compensate for the lack of such a system. Note here that the agreement problem on a common coordinate system can (partially) be reduced to certain formation problems: If the robots can form (i.e., gather at) a single point, then they can agree to use that point as the origin of the common coordinate system. Similarly, formation of a circle implies agreement on both the origin and the unit distance (i.e., the center and the radius of the circle). Formation of a symbol "$\top$" implies agreement on the origin, the unit distance, and the positive x-direction, i.e., agreement on a common x-y coordinate system.

Related work on the distributed robot control method includes the following. Wang and Beni [17] considered a cellular robotic system consisting of a large number

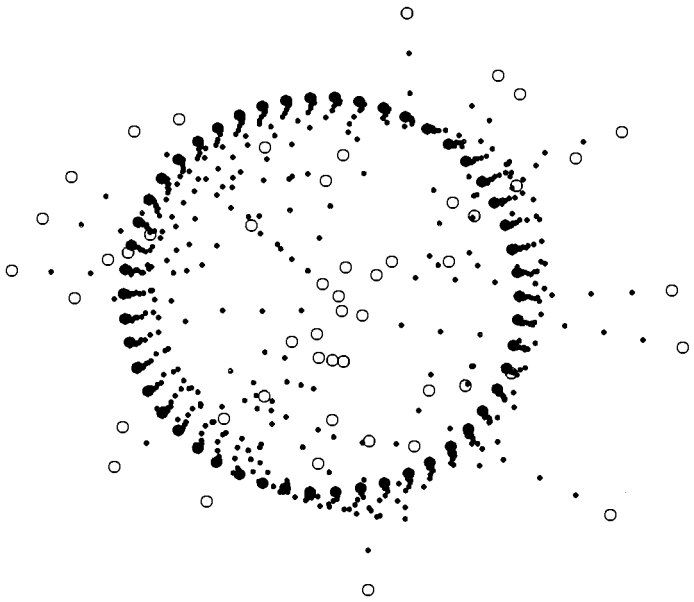

FIG. 1.2. *Hollow circles are the initial positions of* 50 *robots. Solid circles are their final positions after execution of Tanaka's algorithm. Small dots represent their intermediate positions.*

of robots that operate in a cellular space under distributed control. They discussed the problem of generating certain one- and two-dimensional cellular patterns using distributed control and showed how the technique can be applied to the design of sensor arrays and escape systems. Fukuda and Nakagawa [6] and Kawauchi, Inaba, and Fukuda [7] considered a dynamically reconfigurable robotic system called CEBOT, which consists of many simple cells that can detach and combine autonomously to change its overall shape, depending on the task and the environment. Kokaji [8] and Murata, Kurokawa, and Kokaji [10] designed self-reorganizing systems called Fractal Machine and Fractum, respectively, based on a similar idea (but unlike CEBOT, these systems consist of homogeneous units) and discussed dynamic reconfiguration based on a set of local rules. Fujimura [5] investigated how planning algorithms, knowledge about the environment, and action intervals of the robots affect the overall performance of two robots moving toward their respective goal positions while avoiding collision. Sugihara and Suzuki [13], [14], and Suzuki and Yamashita [15] considered formation and agreement problems for anonymous mobile robots in the plane. Work by others includes swarm intelligence [1] and collective behavior of multiple robots [9], [11].

The main emphasis of most of the work mentioned above has been on the development of heuristic algorithms for various problems, and rigorous proofs of the correctness of these algorithms have not been given. In contrast, as we stated earlier in this paper, we conduct a formal investigation on the power and limitations of the distributed control method.

We model a robot as a mobile processor with infinite memory and a sensor for detecting the positions of other robots[2] that repeatedly becomes *active* at infinitely

[2]We assume that the sensor cannot measure the velocity or acceleration of other robots and that other navigation devices such as compasses and beacons are not available.

many unpredictable time instants. (At other times it is *inactive*.) We assume that initially the robots do not have a common x-y coordinate system and that the local x-y coordinate systems of the robots may not agree on the location of the origin, the unit distance, or the direction of the positive x-axis. Each time a robot becomes active, using its sensor it observes the positions of all the robots in terms of its own local x-y coordinate system and moves to a new position determined by the given deterministic algorithm.[3] The algorithm is *oblivious* if the new position is determined only from the positions of the robots observed at that time instant. Otherwise, it is *nonoblivious*, and the new position may depend also on the observations made in the past. Note that oblivious algorithms are self-stabilizing by definition. To simplify the discussion and bring forth the fundamental issues of the problem, in this paper we assume that (1) the initial positions of the robots are all distinct, (2) the time it takes for a robot to move to its new position is negligibly small, and (3) a robot is a point (so two robots can occupy the same position simultaneously and never collide). The robots are anonymous in the sense that (1) they do not know their identifiers, (2) they all use the same algorithm for determining the next position, and (3) they cannot be distinguished by their appearances.

Let π be a predicate describing a geometric pattern, such as a point, a regular polygon, a line segment, etc. On the one hand, we say that an algorithm ψ solves the *convergence problem* for π if the robots' distribution converges to one that satisfies π, regardless of the number n of robots, their initial distribution, and the timing with which they become active. On the other hand, we say that ψ solves the *formation problem* for π if the robots eventually reach a distribution that satisfies π in a finite number of steps, regardless of n, their initial distribution, and the timing with which they become active. (See section 2 for formal definitions of these concepts.)

We begin with a simple problem of converging the robots toward a single point. (That is, this is the convergence problem for a predicate π that describes a point. Note that the process of convergence need not terminate in finite steps.) Note again that since the robots do not have a common x-y coordinate system, we cannot simply use an algorithm such as "move toward the origin $(0, 0)$." For this problem we give a simple oblivious algorithm.

We also consider the formation problem for a point, in which the robots must form (i.e., gather at) a single point in finite steps. We show that this problem can be solved by a nonoblivious algorithm for any $n \geq 2$ and by an oblivious algorithm for any $n \geq 3$, but it is not solvable by any oblivious algorithm for the case $n = 2$, where n is the total number of robots.

Finally, we characterize the class of geometric patterns for which the formation problem is solvable in our model. We do so by first examining the class of patterns that the robots can form, starting from a given initial configuration. Our main observation is that since the robots may happen to become active simultaneously all the time (i.e., their motions turn out to be synchronized) and (by definition) algorithms are required to solve the given problem regardless of the timing with which the robots become active, the robots may not be able to break the "symmetry" that exists in their initial distribution by executing an algorithm (which is deterministic by definition). Based on this and using techniques that have been developed for anonymous complete networks in [19], [20], we prove that the formation problem is solvable by an algorithm (in the sense defined above) only for two patterns: a point and a regular n-gon. The

[3] In this paper we do not consider nondeterministic algorithms that allow a robot to randomly select its next position from two or more candidates.

algorithm we present for the formation of a regular n-gon is nonoblivious. Whether an oblivious algorithm exists for this problem remains open.

We present necessary definitions and basic assumptions in section 2. Convergence and formation problems for a point are discussed in section 3. Section 4 gives a characterization of the class of geometric patterns that the robots can form in our model. Discussions and concluding remarks are presented in section 5.

2. Definitions and basic assumptions. We formalize the concepts described in section 1. Let $r_1, r_2, \ldots, r_n$ be the robots in a two-dimensional space. (The subscript i of r_i is used for convenience of explanation. The robots do not know their identifiers.) We denote by $Z_i = (o_i, d_i, u_i)$, $1 \leq i \leq n$, the local x-y coordinate system of r_i, where o_i, d_i, and u_i denote the position of the origin, direction of the positive x-axis, and size of the unit distance, respectively, under Z_i. It is possible that $Z_i \neq Z_j$ for some i and j, but the robots are assumed to have a common sense of orientation so that in each Z_i, the positive y-direction is 90 degrees counterclockwise from the positive x- direction. As we describe below, all robot positions that r_i observes and computes are given in terms of Z_i.

We assume discrete time $0, 1, 2, \ldots$ and let $p_i(t)$ be the position of r_i at time instant t, where $p_i(0)$ is the initial position of r_i. We assume that $p_1(0), p_1(0), \ldots, p_n(0)$ are all distinct. Define $P(t) = \{p_i(t) | 1 \leq i \leq n\}$ to be the multiset of the positions of the robots at time t. ($P(t)$ is a multiset, since we assume that two robots can occupy the same position simultaneously.) For any point p, we denote by $[p]_j$ the position of p given in terms of Z_j and define $[P(t)]_j = \{[p_i(t)]_j | 1 \leq i \leq n\}$. Thus $[P(t)]_j$ shows how r_j views the distribution $P(t)$ in terms of its own Z_j. Note that if $Z_j \neq Z_k$, then it is possible that $[P(t)]_j \neq [P(t)]_k$; i.e., r_j and r_k may observe distribution $P(t)$ differently. However, $[P(t)]_j = [P(t)]_k$ may hold even if $p_j(t) \neq p_k(t)$. In this case, r_j and r_k are located at different positions, but $P(t)$ looks identical to them.

At each time instant t, every robot r_i is either *active* or *inactive*. Without loss of generality we assume that at least one robot is active at every time instant. We use A_t to denote the set of active robots at t, and call the sequence $\mathcal{A} = A_0, A_1, \ldots$ an *activation schedule*. We assume that every robot becomes active at infinitely many time instants, but no additional assumptions are made on the timing with which the robots become active. Thus $\mathcal{A}$ need satisfy only the condition that every robot appears in infinitely many A_t's. Note that a special case is when every robot appears in A_t for every t; in this case we say that the robots are *synchronized*.

The algorithm that a robot uses is a function ψ such that, for any given sequence $(Q_1, p_1), (Q_2, p_2), \ldots, (Q_m, p_m)$ of pairs of a multiset Q_ℓ of points and a point $p_\ell \in Q_\ell$, $\psi((Q_1, p_1), (Q_2, p_2), \ldots, (Q_m, p_m))$ is a point such that the distance between p_m and $\psi((Q_1, p_1), (Q_2, p_2), \ldots, (Q_m, p_m))$ is at most 1. The position of a robot at $t \geq 1$ is determined by $P(0)$, $\mathcal{A}$, and ψ, as follows.

For any $t \geq 0$, if $r_i \notin A_t$ (r_i is inactive), then $p_i(t+1) = p_i(t)$; i.e., r_i does not move. If $r_i \in A_t$ (r_i is active), then let $0 \leq t_1 \leq t_2 \leq \cdots \leq t_m = t$ be the time instants when r_i has been active, and for each $1 \leq \ell \leq m$, let $Q_\ell = [P(t_\ell)]_i$ and $p_\ell = [p_i(t_\ell)]_i$ be the distribution that r_i observed and the position of r_i at t_ℓ, respectively. (Note that Q_ℓ and p_ℓ are given in terms of Z_i.) Then $p_i(t+1) = p$, where p is the point such that $[p]_i = \psi((Q_1, p_1), (Q_2, p_2), \ldots, (Q_m, p_m))$. That is, r_i moves to point $\psi((Q_1, p_1), (Q_2, p_2), \ldots, (Q_m, p_m))$ of Z_i. By the restriction on ψ stated above, the maximum distance that r_i can move in one step is the unit distance 1 of Z_i, which corresponds to some physical distance $\epsilon_i > 0$. Note that every robot is then capable of moving over distance at least $\epsilon = \min\{\epsilon_1, \epsilon_2, \ldots, \epsilon_n\} > 0$ in one step.

That is, r_i observes the distribution of the robots only when it is active, and its next position depends only on ψ and the distributions that r_i has observed so far. The p_ℓ in pair (Q_ℓ, p_ℓ) shows that r_i is always aware of its current position in Z_i. Algorithm ψ is said to be *oblivious* if $\psi((Q_1,p_1),(Q_2,p_2),\ldots,(Q_m,p_m)) = \psi((Q_m,p_m))$ for any $(Q_1,p_1),(Q_2,p_2),\ldots,(Q_m,p_m)$. In this case, the move of a robot depends only on the current configuration of the robots. Otherwise, ψ is *nonoblivious*. Note that the robots are anonymous in the following sense: (1) function ψ is common to all the robots, (2) the identifier i of robot r_i is not an argument of ψ, and (3) $[P(t)]_i$ contains only the positions of the robots (but not their identities).

Let π be a predicate over the set of multisets of points that is invariant under any rotation, translation, and uniform scaling. For example, π might be true iff the given points are on the circumference of a circle or on a line segment. For such π, we consider two types of problems: the *convergence problem* and the *formation problem*. An algorithm ψ is said to solve the convergence problem for π if, as t goes to infinity, $P(t)$ converges to a distribution that satisfies π, regardless of the number n of robots, initial distribution $P(0)$, and activation schedule $\mathcal{A}$. In contrast, in the formation problem the robots must reach a distribution satisfying π in finite steps and "halt." That is, an algorithm ψ is said to solve the formation problem for π if there exists some time instant t' such that $P(t')$ satisfies π and $p_i(t') = p_i(t'+1) = \cdots$ for all $1 \le i \le n$, regardless of n, $P(0)$, and $\mathcal{A}$. Since the robots have no knowledge of the underlying coordinate system, the robots can only converge to or form a pattern similar to the given goal pattern. The restriction on π stated above was introduced for this reason. All predicates discussed in the following sections satisfy this condition.

3. Convergence and formation problems for a point. Formally, the problem of converging the robots to a point is stated as the convergence problem for predicate π_{point}, where $\pi_{point}(p_1,\ldots,p_n) =$ true iff $p_i = p_j$ for any $1 \le i,j \le n$. We call this problem C-POINT. The corresponding formation problem for π_{point} is called F-POINT. Note that in F-POINT, all robots must occupy a single point in finite steps, whereas in C-POINT they need only converge to a single point. These are perhaps some of the simplest problems one could consider. Nevertheless, the discussions presented in this section can serve as an introduction to the technical results given in the rest of the paper. An algorithm that solves F-POINT also solves C-POINT.

For convenience, we present all algorithms by giving an informal description of the behavior of the robots executing it, instead of giving a formal definition of function ψ. Converting the informal description into a formal definition of ψ is straightforward.

It is easy to show that the following oblivious algorithm $\psi_{c-point(2)}$ solves C-POINT for the case $n = 2$.

ALGORITHM $\psi_{c-point(2)}$—OBLIVIOUS.

Each time r_i becomes active, it moves toward[4] the midpoint m of its current position and that of the other robot r_j. □

Suppose that we modify $\psi_{c-point(2)}$ so that each robot moves toward the position of the other robot. Then the two robots will continue to swap their positions if they are mutually reachable in one step and always become active simultaneously. (Recall that we assume robots never collide with each other.) Thus this modified algorithm does not solve C-POINT for $n = 2$.

Note that if exactly one robot becomes active at every time instant, then the

[4]Unless otherwise stated, "a robot moves toward point p" means that "a robot moves to the point p' closest to p that is reachable in one step from the current position." Of course, $p = p'$ if p is reachable in one step.

two robots executing $\psi_{c-point(2)}$ will never occupy the same point. Thus oblivious algorithm $\psi_{c-point(2)}$ does not solve F-POINT for $n = 2$. In fact, we have the following theorem.

THEOREM 3.1. *There is no oblivious algorithm for solving F-POINT for the case* $n = 2$.

Proof. Suppose that there is an oblivious algorithm ψ that solves F-POINT for two robots r_i and r_j. Note that since ψ is oblivious, the moves of the robots depend only on Z_i, Z_j and their current positions.

We first show that there exist distinct positions p and q of r_i and r_j, respectively, such that either (1) ψ moves r_i from p to q and r_j from q to q, or (2) ψ moves r_i from p to p and r_j from q to p. (That is, ψ moves exactly one robot to the position of the other if both robots become active simultaneously.) To see this, assume that such positions do not exist. Consider a scenario $\mathcal{S}$ in which r_i and r_j, located at distinct positions p and q, respectively, at time $t-1$ occupy the same position r at time t. Now we show that we can modify this scenario and obtain another scenario in which the robots never occupy the same position simultaneously. There are two cases.

Case 1. Both r_i and r_j are active at time $t-1$ in $\mathcal{S}$. By assumption, $r \neq p$ and $r \neq q$. Thus if exactly one robot, say, r_i, happens to be active at $t-1$, then at time t, r_i is located at r and r_j at q, where $r \neq q$.

Case 2. Exactly one robot is active at $t-1$ in $\mathcal{S}$. Suppose that r_i is active at $t-1$ but r_j is not. Then $r = q$. So if both robots happen to be active at $t-1$, then at time t, r_i is located at q and r_j at some point s, where by assumption $s \neq q$.

Using this argument repeatedly, we can construct an infinite sequence of moves in which the robots never occupy the same position simultaneously. (We can do so in such a way that each robot becomes active infinitely many times, since either of the robots can be chosen to be inactive in Case 1.) So ψ does not solve F-POINT. This is a contradiction.

Now consider an initial distribution $P(0) = \{p, q\}$ in which r_i and r_j are at p and q, respectively, and ψ moves r_i from p to q, and r_j from q to q; see Figure 3.1(a). (The case in which ψ moves r_j to the positions of r_i is similar.) Now, by modifying Z_i through translation and rotation, we can construct another configuration in which r_i observes distribution $P(0)$ the same way as r_j; i.e., $[P(0)]_i = [P(0)]_j$ and $[p]_i = [q]_j$; see Figure 3.1(b). Then ψ moves r_i and r_j in the same manner in the new configuration and, of course, ψ moves r_j in the same manner in both configurations (namely, from q to q). Therefore, in the new configuration ψ moves r_i from p to p and r_j from q to q. Then, since ψ is oblivious, both robots remain in their respective initial positions forever. Thus ψ does not solve F-POINT. This is a contradiction. □

However, F-POINT can be solved for two robots by the following *nonoblivious* algorithm $\psi_{f-point(2)}$.[5]

ALGORITHM $\psi_{f-point(2)}$—NONOBLIVIOUS.

When r_i becomes active for the first time, it translates and rotates its coordinate system[6] Z_i so that

1. r_i is at $(0, 0)$ of Z_i, and
2. the other robot r_j is on the positive y-axis of Z_i, say, at $(0, a)$ for some $a > 0$.

[5] If all robots are *known* to be active at every time instant (i.e., the robots are "synchronous"), then a simple oblivious algorithm that moves both robots toward the midpoint of their current positions solves F-POINT for two robots.

[6] Formally, r_i cannot modify Z_i in our framework, but the effect of such a transformation can easily be simulated within the framework.

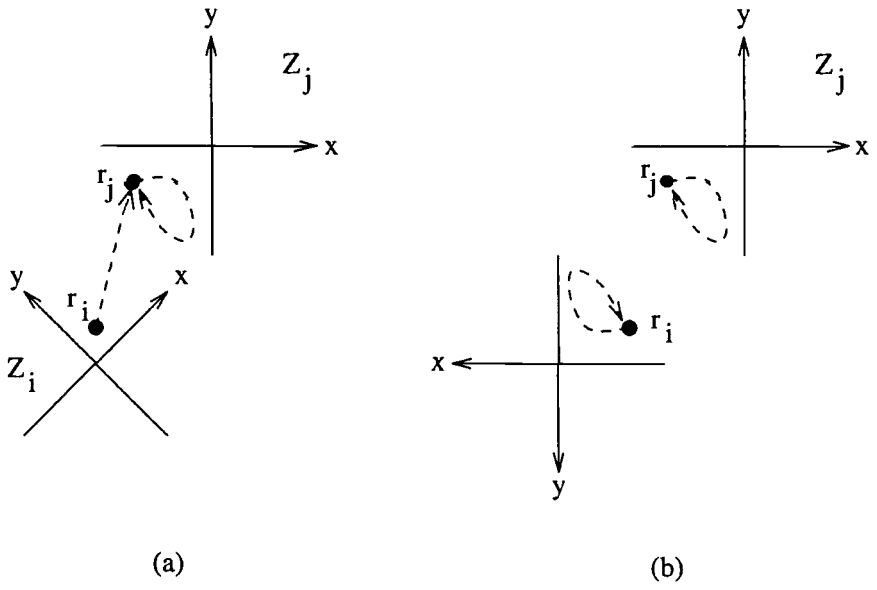

FIG. 3.1. (a) r_i *moves but* r_j *does not.* (b) *After modification of* Z_i.

Then it moves in the positive x direction of Z_i, over any nonzero distance. It then continues to move in the same direction each time it becomes active until it observes that the position of r_j has changed twice.

Now, r_i knows line ℓ that contains the first two distinct positions of r_j that r_i has observed. (Note that by symmetry ℓ is the x-axis of r_j's coordinate system Z_j.) Then using Lemma 3.2, r_i finds the initial position of r_j and moves to the midpoint of the initial positions of r_i and r_j. □

Lemma 3.2, which follows immediately from the description of $\psi_{f-point(2)}$, shows that robots r_i and r_j executing $\psi_{f-point(2)}$ eventually find out which of them became active first for the first time and what their initial distribution was.

LEMMA 3.2. *Let* t_i *and* t_j *be the time instants at which* r_i *and* r_j, *respectively, become active for the first time in* $\psi_{f-point(2)}$. *Then the following hold.*

1. *The trajectory of* r_i *and the trajectory of* r_j *are parallel iff* $t_i = t_j$. *In this case, each robot sees the other robot at its initial position at* $t_i (= t_j)$ (*Figure* 3.2(a)).
2. *The trajectory of* r_j *intersects the negative* x*-axis of* Z_i *iff* $t_i < t_j$. *In this case,* r_i *sees* r_j *at its initial position, and* r_i*'s initial position is the foot of the perpendicular drop from* r_j*'s initial position to the line containing the trajectory of* r_i (*Figure* 3.2(b)).
3. *The trajectory of* r_i *intersects the negative* x*-axis of* Z_j *iff* $t_j < t_i$. *In this case,* r_j *sees* r_i *at its initial position, and* r_j*'s initial position is the foot of the vertical drop from* r_i*'s initial position to the line containing the trajectory of* r_j.

THEOREM 3.3. *Algorithm* $\psi_{f-point(2)}$ *solves problem F-POINT for* $n = 2$.

Proof. A key observation is the following: When r_i observes that the position of r_j has changed twice, r_j must have already observed that r_i's position has changed at least once and thus r_j knows where the x-axis of Z_i is. Similarly, r_j will know that r_i knows where the x-axis of Z_j is. Then the correctness of $\psi_{f-point(2)}$ follows from Lemma 3.2. □

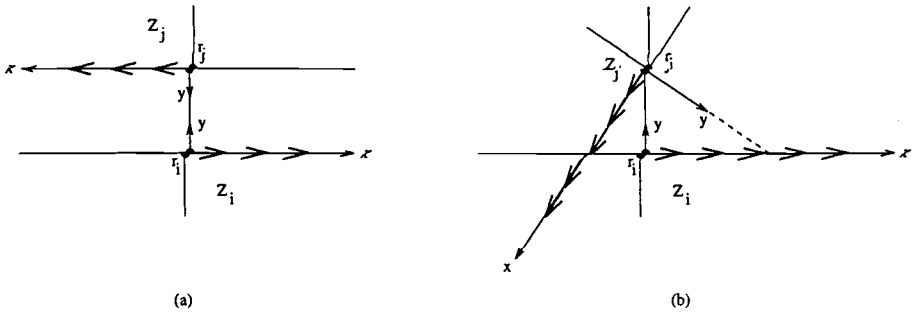

FIG. 3.2. *Illustration for* $\psi_{f-point(2)}$*;* (a) $t_i = t_j$, (b) $t_i < t_j$.

Finally, we have the following result on F-POINT and C-POINT for $n \geq 3$.

THEOREM 3.4. *There is an oblivious algorithm for solving F-POINT (and thus C-POINT) for* $n \geq 3$.

Proof. It suffices to give an oblivious algorithm $\psi_{f-point(n)}$ that solves F-POINT. The idea is the following. Starting from distinct initial positions, we move the robots in such a way that eventually there will be exactly one position, say, p, that two or more robots occupy. Once such a distribution is reached, all robots that are not located at p move toward p in such a way that no two robots will occupy the same position at any location other than p. Then all robots eventually occupy p, solving F-POINT.

Such a distribution can be obtained if each robot, each time it becomes active, determines which of the following cases applies and moves to a new position (or remains stationary) as specified. Since a robot's action is based only on the current robot distribution, this strategy can be implemented as an oblivious algorithm.

Case 1. $n = 3$; p_1, p_2, and p_3 denote the positions of the three robots.

1.1. If $n = 3$ and p_1, p_2, and p_3 are collinear with p_2 in the middle, then the robots at p_1 and p_3 move toward p_2 while the robot at p_2 remains stationary. Then eventually two robots occupy p_2.

1.2. If $n = 3$ and p_1, p_2, and p_3 form an isosceles triangle with $|\overline{p_1p_2}| = |\overline{p_1p_3}| \neq |\overline{p_2p_3}|$, then the robot at p_1 moves toward the foot of the perpendicular drop from its current position to $\overline{p_2p_3}$ in such a way that the robots do not form an equilateral triangle at any time, while the robots at p_2 and p_3 remain stationary. Then eventually the robots become collinear and the problem is reduced to part 1.1.

1.3. If $n = 3$ and the lengths of the three sides of triangle $p_1p_2p_3$ are all different, say, $|\overline{p_1p_2}| > |\overline{p_1p_3}| > |\overline{p_2p_3}|$, then the robot at p_3 moves toward the foot of the perpendicular drop from its current position to $\overline{p_1p_2}$ while the robots at p_1 and p_2 remain stationary. Then eventually the robots become collinear and the problem is reduced to part 1.1.

1.4. If $n = 3$ and p_1, p_2, and p_3 form an equilateral triangle, then every robot moves towards the center of the triangle. Since all robots can move up to at least a constant distance $\epsilon > 0$ in one step, if part 1.4 continues to hold then eventually either the robots meet at the center, or the triangle they form becomes no longer equilateral and the problem is reduced to part 1.2 or part 1.3.

Case 2. $n \geq 4$; C_t denotes the smallest enclosing circle of the robots at time t.

2.1. If $n \geq 4$ and there is exactly one robot r in the interior of C_t, then r moves toward the position of any one robot, say, r', on the circumference of C_t while all other robots remain stationary. Then eventually r and r' occupy the same position.

2.2. If $n \geq 4$ and there are two or more robots in the interior of C_t, then these robots move toward the center of C_t while all other robots remain stationary (so that the center of C_t remains unchanged). Then eventually at least two robots reach the center.

2.3. If $n \geq 4$ and there are no robots in the interior of C_t, then every robot moves toward the center of C_t. Since all robots can move up to at least a constant distance $\epsilon > 0$ in one step, if part 2.3 continues to hold, then eventually the radius of C_t becomes at most ϵ. Once this happens, then the next time some robot moves, say, at t', either (i) two or more robots occupy the center of C_t or (ii) there is exactly one robot r at the center of C_t, and therefore there is a robot that is not on $C_{t'}$ (and the problem is reduced to part 2.1 or part 2.2) since a cycle passing through r and a point on C_t intersects with C_t at most at two points. □

Suppose that for $1 \leq i \leq n$, robot r_i has (privately) chosen a directed line ℓ_i that passes through its initial position. Algorithm $\psi_{f-point(2)}$ uses a technique with which all robots can simultaneously "broadcast" the locations and directions of $\ell_1, \ell_2, \ldots, \ell_n$. The basic idea is that each robot r_i moves repeatedly along ℓ_i in the given direction until it observes that every r_j, $j \neq i$ has changed positions at least twice (i.e., until r_i sees r_j at three or more distinct positions). Then, as we explained in the proof of Theorem 3.3, every r_j, $j \neq i$ must have (become active and) seen r_i at two or more distinct positions along ℓ_i, and thus r_j can conclude that the ℓ_i that r_i has chosen passes through the first two distinct positions of r_i that r_j has observed and that ℓ_i is oriented in the direction from the first to the second positions of r_i that r_j has observed. Care must be taken so that r_i continues to move at least one more time (to any distinct position) after observing that every r_j has changed position at least twice, since at this moment some r_j might have observed r_i only at two distinct positions.

Another problem is that, since the robots are indistinguishable by their appearances, if $n > 2$, then r_j may not be able to determine how r_i has moved, given the robot distributions at two time instants. To cope with this, if $n > 2$, then we let each robot r_i memorize the distance $a_i > 0$ to its nearest neighbor when it becomes active for the first time and move at most distance $a_i/2^{k+1}$ in the kth move. Then each r_i will remain in the interior of the $a_i/2$-neighborhood of its initial position, and thus every robot can correctly determine which robot has moved to which position even after it has remained inactive for a long time.

4. Achievable geometric patterns. In this section we characterize the class of geometric patterns that the robots can form regardless of the activation schedule $\mathcal{A}$, starting from a fixed initial configuration. For simplicity of explanation we assume that each robot r_i is located at the origin of its coordinate system Z_i at time 0. Essentially the same result holds even without this assumption.

Whether or not a particular geometric pattern can be formed depends not only on the given initial positions of the robots but also on their local x-y coordinate systems. For example, suppose that, initially, four robots r_1, r_2, r_3, and r_4 form a square in counterclockwise order, where r_2 is at position $(1, 0)$ of Z_1, r_3 is at position $(1, 0)$

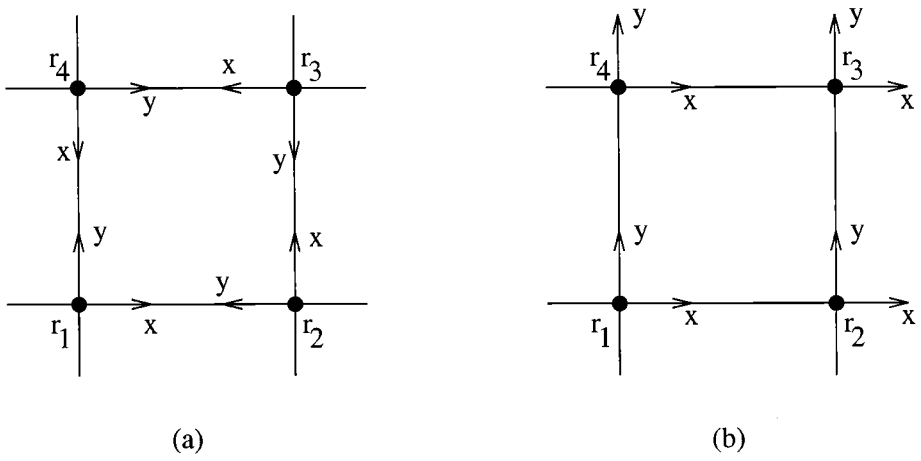

FIG. 4.1. *Two configurations of four robots that are* (a) *symmetric,* (b) *not symmetric.*

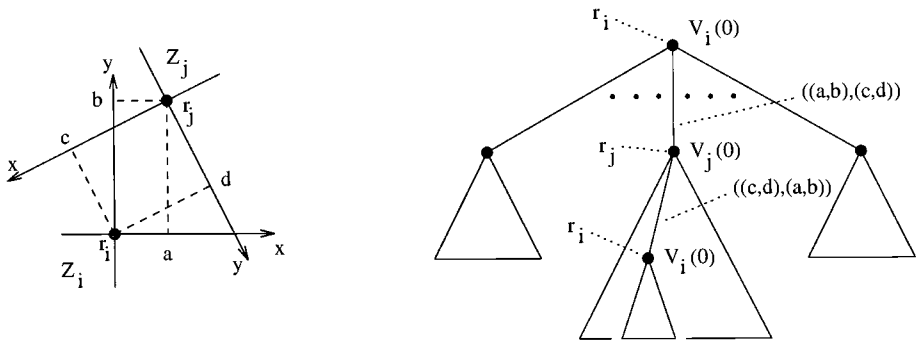

FIG. 4.2. r_i, r_j, *and views* $V_i(0)$ *and* $V_j(0)$.

of Z_2, and so on, as shown in Figure 4.1(a). Intuitively, the robots have the same "view," and thus, if they are synchronized, then they will never be able to break symmetry and form a pattern other than a square, but if the direction of the positive x-axis happens to be the same for all four robots, as shown in Figure. 4.1(b), then intuitively every robot has a unique "view," and hence the robots may be able break symmetry and form a pattern that is not a square. (In fact, the result given below shows that the robots can form *any* pattern for this case.) We now formalize this observation.

Following [19], [20], the *view* of robot r_i at time t, denoted $V_i(t)$, is defined recursively as a rooted infinite tree as follows. See Figure 4.2.

1. The root of $V_i(t)$ has $n-1$ subtrees, one for each robot r_j, $j \neq i$.
2. The edge from the root of $V_i(t)$ to the subtree corresponding to r_j is labeled $((a,b),(c,d))$, where (a,b) is the position of r_j in terms of Z_i and (c,d) is the position of r_i in terms of Z_j.
3. The subtree corresponding to r_j is the view $V_j(t)$ of r_j at time t.

Note that each vertex of $V_i(t)$ corresponds to a robot, but it is not labeled as such. Two views $V_i(t)$ and $V_j(t')$ are said to be *equivalent*, written $V_i(t) \equiv V_j(t')$, if they are isomorphic to each other, including the labels. A view is defined as an infinite tree

for convenience of discussion; the relevant information is contained in the subtree of height 2 from the root.

$V_i(0)$ is thus the view of r_i at time 0. Note that since the robots occupy distinct positions at time 0, the edges incident on the root of $V_i(0)$ have distinct labels. Since at time 0 the robots have no knowledge of other robots' local coordinate systems, at time 0 robot r_i does not know its view $V_i(0)$. Using the following algorithm, the robots can obtain sufficient information to construct their views at time 0.

ALGORITHM $\psi_{getview}$—NONOBLIVIOUS.

The robots first broadcast the x-axes of their respective local coordinate systems by moving in the respective positive x directions, return straight to their respective initial positions, broadcast the y-axes of their respective local coordinate systems by moving in the respective positive y directions, and finally return straight to their respective initial positions. Since different robots may start the second broadcast (of their local y-axes) at different time instants, every robot r_i broadcasting its y-axis must continue to move along its y-axis until it observes that every r_j, $j \neq i$ has changed positions at least twice along a line perpendicular to the first line that r_j broadcasted.

At this moment every robot r_i has discovered the initial distribution $P(0)$ (in terms of Z_i) as well as the direction of the positive x-axis of Z_j for every robot r_j. Then r_i measures the minimum distance d_i between any two robots in $P(0)$ in terms of Z_i and "announces" the value of d_i to all other robots by broadcasting the directed line through its initial position with direction $f(d_i)$ of Z_i, where for $x > 0$, $f(x) = (1 - 1/2^x) \times 360^\circ$ is a monotonically increasing function with range $(0^\circ, 360^\circ)$. Then, any robot observing the movement of r_i can determine the value of d_i (and hence the unit distance of Z_i) from its knowledge on the positive x direction of Z_i and direction $f(d_i)$ of Z_i. Finally, the robots return to their respective initial positions. □

When $\psi_{getview}$ is completed, each robot r_i can determine the positions of all other robots in terms of Z_j for any j. Using this information, r_i can construct its view $V_i(0)$.

Let m be the size of a largest subset of robots having an equivalent view at time 0. If $m = 1$, then every robot has a unique view, and thus once Algorithm $\psi_{getview}$ is executed the robots can be ordered using a suitable total ordering of the views. Then for any multiset F of n points, using a predetermined total ordering of the points in F, the ith robot in the ordering can compute the location of the ith point in F relative to some reference points (e.g., the positions of the first and second robots at time 0 if the first and second points of F are distinct) and move to that point. Therefore, if $m = 1$, the robots can form a pattern similar to F for arbitrary F.

Therefore, in the following, we consider the case $m \geq 2$. Lemmas 4.1, 4.2, 4.3, and 4.4 refer to a fixed initial configuration with $m \geq 2$.

LEMMA 4.1. *The robots can be partitioned into n/m groups of m robots each, such that two robots have an equivalent view iff they belong to the same group.*

Proof. The claim is trivial if $m = n$. Thus assume that $m < n$, and without loss of generality suppose that $V_1(0) \equiv V_2(0) \equiv \cdots \equiv V_m(0)$ but $V_1(0) \not\equiv V_{m+1}(0)$. That is, $r_1, r_2, \ldots, r_m$ have an equivalent view at time 0 but r_{m+1} does not. Let $((a, b), (c, d))$ be the label of the edge from the root of $V_1(0)$ to the vertex corresponding to r_{m+1}. Since $V_1(0) \equiv V_2(0) \equiv \cdots \equiv V_m(0)$ for each ℓ, $1 \leq \ell \leq m$, there exists an edge with label $((a, b), (c, d))$ from the root of $V_\ell(0)$ to a vertex corresponding to some robot r_{i_ℓ}, where $r_{i_1} = r_{m+1}$. Now we show that the robots $r_{i_1}, r_{i_2}, \ldots, r_{i_m}$ are all distinct. Note that by symmetry there is an edge with label $((c, d), (a, b))$ from the

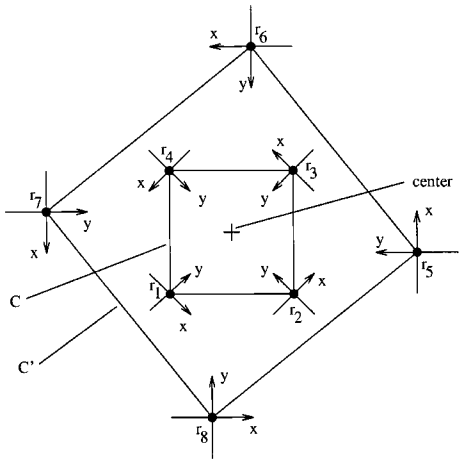

FIG. 4.3. *Illustration for the proof of Lemma* 4.2*, for the case* $m = 4$.

root of $V_{i_\ell}(0)$, leading to a vertex that corresponds to robot r_ℓ. Thus if $r_{i_1} = r_{i_2}$, for instance, then we have $r_1 = r_2$, a contradiction. Thus $r_{i_1}, r_{i_2}, \ldots, r_{i_m}$ are all distinct. Furthermore, since $V_1(0) \equiv V_2(0) \equiv \cdots \equiv V_m(0)$ and $V_{i_\ell}(0)$ is a subtree of $V_\ell(0)$ connected to the root of $V_\ell(0)$ by an edge with label $((a,b),(c,d))$ for each ℓ, we have $V_{i_1}(0) \equiv V_{i_2}(0) \equiv \cdots \equiv V_{i_m}(0)$. Thus there are at least m robots (including r_{m+1}) having a view equivalent to that of r_{m+1}. But then there must be exactly m such robots, since there cannot exist more than m such robots by the definition of m. The lemma follows from this observation. □

LEMMA 4.2. *At time* 0*, the robots in the same group form a regular* m*-gon, and the regular* m*-gons formed by all the groups have a common center.*[7] *(See Figure* 4.3*.)*

Proof. Suppose that $V_1(0) \equiv V_2(0) \equiv \cdots \equiv V_m(0)$, that is, $r_1, r_2, \ldots, r_m$ have an equivalent view at time 0. Consider the initial positions $p_1(0), p_2(0), \ldots, p_m(0)$ of these robots. Clearly, at least one of $p_1(0), p_2(0), \ldots, p_m(0)$ is a corner of the convex hull C of $\{p_1(0), p_2(0), \ldots, p_m(0)\}$. Then, since $V_1(0) \equiv V_2(0) \equiv \cdots \equiv V_m(0)$, each of $p_1(0), p_2(0), \ldots, p_m(0)$ must be a corner of C. Without loss of generality, assume that $p_1(0), p_2(0), \ldots, p_m(0)$ occur in counterclockwise order around the convex hull. (See Figure 4.3.)

Since $V_1(0) \equiv V_2(0) \equiv \cdots \equiv V_m(0)$, the internal angles of C at the corners $p_1(0), p_2(0), \ldots, p_m(0)$ must all be identical, and the lengths of the edges of the convex hull must all be identical. (If $\overline{p_1(0)p_2(0)}$ looks shorter than $\overline{p_2(0)p_3(0)}$ to r_2, then $\overline{p_2(0)p_3(0)}$ should look shorter than $\overline{p_3(0)p_4(0)}$ to r_3, and so on, leading to a conclusion that $\overline{p_1(0)p_2(0)}$ is shorter than $\overline{p_1(0)p_2(0)}$, a contradiction.) Thus $p_1(0), p_2(0), \ldots, p_m(0)$ form a regular m-gon.

Suppose that at time 0, $r_{m+1}, r_{m+2}, \ldots, r_{2m}$ also have an equivalent view and that their respective positions $p_{m+1}(0), p_{m+2}(0), \ldots, p_{2m}(0)$ appear in counterclockwise order around the regular m-gon they form. Then again, since $V_1(0) \equiv V_2(0) \equiv \cdots \equiv V_m(0)$, the position of $p_{m+1}(0)$ relative to p_1 is the same as the position of $p_{m+2}(0)$ relative to p_2, and so on. (See Figure 4.3.) So the regular m-gon formed by $p_1(0), p_2(0), \ldots, p_m(0)$ and the regular m-gon formed by $p_{m+1}(0), p_{m+2}(0), \ldots, p_{2m}(0)$ have the same center. □

[7] A regular 2-gon is simply a line segment whose center is the midpoint of the endpoints.

LEMMA 4.3. *For any algorithm ψ, if the robots are synchronized, then at any time instant t, the robots in the same group form a regular m-gon and the regular m-gons formed by all the groups have a common center.*

Proof. Suppose that $V_1(0) \equiv V_2(0) \equiv \cdots \equiv V_m(0)$, that is, $r_1, r_2, \ldots, r_m$ have an equivalent view at time 0. Now, since the initial distribution of the robots looks identical to $r_1, r_2, \ldots, r_m$, the new positions they compute using ψ in their respective $Z_1, Z_2, \ldots, Z_m$ are all identical. Also, since $V_1(0) \equiv V_2(0) \equiv \cdots \equiv V_m(0)$, the center of the regular m-gon that $r_1, r_2, \ldots, r_m$ form at time 0 has the same x-y coordinates in all of $Z_1, Z_2, \ldots, Z_m$. This means that $r_1, r_2, \ldots, r_m$ move in a symmetric manner relative to the center of the regular m-gon, and thus at time 1 they again form a regular m-gon with the same center. The same applies to all n/m groups, and since the robots are synchronized, at time 1 they together form a collection of n/m regular m-gons all having the same center. Since the robots in the same group have observed the same robot distributions, their next moves at time 1 are also symmetric relative to the center of the regular m-gon they currently form. Therefore, again, at time 2 the robots form a collection of n/m regular m-gons all having the same center. Continuing in the same manner, we can prove that at any time instant t the robots form a collection of n/m regular m-gons all having the same center. □

Since the robots may happen to be synchronized, by Lemma 4.3 there exists an algorithm ψ for forming a pattern similar to F starting from the given initial configuration only if F can be partitioned into n/m regular m-gons all having the same center. Conversely, we have the next lemma.

LEMMA 4.4. *For any multiset F of points that can be partitioned into n/m regular m-gons all having the same center, there exists an algorithm ψ for forming a pattern similar to F starting from the initial configuration. (The algorithm does not depend on the initial configuration.)*

Proof. We fix a total ordering over views and we fix an ordering of the n/m regular m-gons in F. The idea is to move the robots in the jth group in the ordering of the views to the corners of the jth regular m-gon, as in the case $m = 1$. Specifically, first the robots execute Algorithm $\psi_{getview}$ and obtain their views. The robots in the first group need not move any more, since the m-gon they form is similar to the corners of the first m-gon of F (except when the first m-gon is a point, in which case the robots must move to the center of the m-gon they form). Each robot in the second group computes the position of a corner of the second m-gon of F (relative to the location of the first m-gon of F) that is closest to its current position, breaking ties in any deterministic manner. (If the first m-gon is a point and the second m-gon is not, then the robots in the second group need not move.) The robots in other groups also compute their final positions in a similar manner. Then the robots move to their respective final positions and form a pattern similar to F. □

The following theorem summarizes the discussion given above.

THEOREM 4.5. *Let m be the size of a largest subset of robots having an equivalent view at time 0. Let F be a multiset of n points. There exists an algorithm ψ for forming a pattern similar to F, starting from the given initial configuration iff either (1) $m = 1$ or (2) $m \geq 2$ and F can be partitioned into n/m regular m-gons all having the same center.*

Proof. The theorem follows from Lemmas 4.3 and 4.4. □

We introduced in section 3 a predicate π_{point} such that $\pi_{point}(p_1, \ldots, p_n) =$ true iff $p_i = p_j$ for any $1 \leq i, j \leq n$. Consider another predicate $\pi_{regular}$, where $\pi_{regular}(p_1, \ldots, p_n) =$ true iff $p_1, \ldots, p_n$ form a regular n-gon. The following theo-

rem, which follows as a corollary to Theorem 4.5, states that these two are the only predicates for which the formation problem is solvable.

THEOREM 4.6. *There exists an algorithm for solving the formation problem for a predicate π iff either $\pi = \pi_{point}$ or $\pi = \pi_{regular}$.*

Proof. The if part for $\pi_{regular}$ follows immediately from Theorem 4.5, and that for π_{point} follows from Theorem 4.5 and the observation that, for any m that divides n, a point can be viewed as a collection of n/m degenerate regular m-gons all having the same center. The only-if part follows from the fact that if $m = n$, where m is the size of a largest subset of robots having an equivalent view at time 0, then by Theorem 4.5 an algorithm exists for the formation problem only for a single regular n-gon (which reduces to a point if the polygon is degenerate). □

5. Concluding remarks. We formally modeled the system of anonymous mobile robots and characterized the class of geometric patterns that the robots can form. In this section, we discuss other related issues.

5.1. Agreement on a common *x*-*y* coordinate system. In section 1 we briefly mentioned that the agreement problem on a common x-y coordinate system is reducible to the formation problem of certain geometric patterns. By Theorem 4.6 it is always possible for the robots to form a point and a regular n-gon, hence the robots can always agree on both the origin and unit distance (of a common x-y coordinate system). On the one hand, the agreement problem on direction is unsolvable in general, since otherwise the formation problem of a line segment would be solvable, contradicting Theorem 4.6. On the other hand, it can be shown that if the robots have a sense of direction (i.e., their local coordinate systems agree on the positive x direction), then they have distinct views at time 0 (i.e., $m = 1$ where m is as defined in section 4). As we have shown, in this case the robots can form (a pattern similar to) any geometric pattern. This means that the difficulty of forming certain geometric patterns lies in the difficulty of agreeing on direction (and break symmetry).

5.2. Issues of fault tolerance. As we mentioned in section 1, Debest [2] discussed the problem of forming a circle from the viewpoint of self-stabilizing systems. Algorithms for controlling robots must be sufficiently robust against sensor and control errors. Oblivious algorithms are, by definition, self-stabilizing in the sense that they achieve their goal even in the presence of a finite number of sensor and control errors. In contrast, nonoblivious algorithms are sensitive to errors in general, and it is a challenging open problem to enhance fault tolerance in such algorithms.

Another interesting issue in fault tolerance arises when the number of robots changes dynamically a finite number of times during the execution of an algorithm, where by this we mean that a robot becomes visible (or invisible) when it is added to (or removed from) the system. Again by definition, an oblivious algorithm correctly solves the given problem even if the number of robots changes a finite number of times. One way to make nonoblivious algorithms robust against such changes is to adopt an additional assumption that, if the number of robots changes, then it never changes again until all robots have noticed the change. Under this assumption, it can be shown that any nonoblivious algorithm works correctly when it is modified so that a robot noticing a change in the number of robots "resets its memory and restarts the algorithm" (i.e., it ignores the pairs (Q_ℓ, p_ℓ) for the observations made previously).

5.3. Time complexity. Since a robot may remain inactive for an unpredictable period of time, we cannot use the total number of steps for measuring the time complexity of a formation algorithm. An alternative measure of the complexity of

an algorithm is the total distance that a robot must move to form a given pattern. Under this measure, a robot moves over distance $O(d)$ by the method used in the proof of Lemma 4.4, where d is the diameter of the smallest enclosing circle of the initial positions of the robots. (Note that the total distance that a robot moves while executing $\psi_{getview}$ can be limited to $O(1)$.) The bound of $O(d)$ is tight for some patterns (e.g., a point), since a robot can move at most a constant distance at a time.

5.4. Other open problems. Algorithms for solving a formation problem based on the method given in the proof of Lemma 4.4 are nonoblivious. Thus Theorem 4.6 implies that a point and a regular n-gon can be formed by n robots regardless of the initial distribution $P(0)$ and the activation schedule $\mathcal{A}$, by a *nonoblivious* algorithm. An interesting question is whether these patterns can also be formed, regardless of $P(0)$ and $\mathcal{A}$, by an *oblivious* algorithm. For the case of a point we already have the answer: an oblivious algorithm for forming a point exists for the case $n \geq 3$ (Theorem 3.4), but not for the case $n = 2$ (Theorem 3.1). However, the question remains open for the formation of a regular n-gon. We are currently working on this issue and also are conducting similar investigations on (1) randomized algorithms, (2) the case in which the motion of a robot is not instantaneous, and (3) the three-dimensional case.

A PSEUDORANDOM GENERATOR FROM ANY ONE-WAY FUNCTION*

JOHAN HÅSTAD†, RUSSELL IMPAGLIAZZO‡, LEONID A. LEVIN§, AND MICHAEL LUBY¶

Abstract. Pseudorandom generators are fundamental to many theoretical and applied aspects of computing. We show how to construct a pseudorandom generator from *any* one-way function. Since it is easy to construct a one-way function from a pseudorandom generator, this result shows that there is a pseudorandom generator if and only if there is a one-way function.

Key words. one-way function, pseudorandom generator, cryptography, complexity theory

1. Introduction. One of the basic primitives in the study of the interaction between randomness and feasible computation is a pseudorandom generator. Intuitively, a *pseudorandom generator* is a polynomial time-computable function g that stretches a short random string x into a long string $g(x)$ that "looks" random to any feasible algorithm, called an adversary. The adversary tries to distinguish the string $g(x)$ from a random string the same length as $g(x)$. The two strings "look" the same to the adversary if the acceptance probability for both strings is essentially the same. Thus, a pseudorandom generator can be used to efficiently convert a small amount of true randomness into a much larger number of effectively random bits.

The notion of randomness tests for a string evolved over time: from set-theoretic tests to enumerable [K65], recursive, and finally limited time tests. Motivated by cryptographic applications, the seminal paper [BM82] introduced the idea of a generator which produces its output in polynomial time such that its output passes a general polynomial time test. The fundamental paper [Yao82] introduced the definition of a pseudorandom generator most commonly used today and proves that this definition and the original of [BM82] are equivalent.

The robust notion of a pseudorandom generator, due to [BM82], [Yao82], should be contrasted with the classical methods of generating random looking bits as described in, e.g., [Knuth97]. In studies of classical methods, the output of the generator is considered good if it passes a particular set of standard statistical tests. The linear congruential generator is an example of a classical method for generating random looking bits that pass a variety of standard statistical tests. However, [Boyar89] and [K92] show that there is a polynomial time statistical test which the output from this

generator does not pass.

The distinction between the weaker requirement that the output pass some particular statistical tests and the stronger requirement that it pass all feasible tests is particularly important in the context of many applications. As pointed out by [BM82], in cryptographic applications the adversary must be assumed to be as malicious as possible, with the only restriction on tests being computation time. A pseudorandom generator can be directly used to design a private key cryptosystem secure against all such adversaries.

In the context of Monte Carlo simulation applications, a typical algorithm uses long random strings, and a typical analysis shows that the algorithm produces a correct answer with high probability if the string it uses is chosen uniformly. In practice, the long random string is not chosen uniformly, as this would require more random bits than it is typically reasonable to produce (and store). Instead, a short random string is stretched into a long string using a simple generator such as a linear congruential generator, and this long string is used by the simulation algorithm. In general, it is hard to directly analyze the simulation algorithm to prove that it produces the correct answer with high probability when the string it uses is produced using such a method. A pseudorandom generator provides a generic solution to this problem. For example, [Yao82] shows how pseudorandom generators can be used to reduce the number of random bits needed for any probabilistic polynomial time algorithm and thus shows how to perform a deterministic simulation of any polynomial time probabilistic algorithm in subexponential time based on a pseudorandom generator. The results on deterministic simulation were subsequently generalized in [BH89], [BFNW96].

Since the conditions are rather stringent, it is not easy to come up with a natural candidate for a pseudorandom generator. On the other hand, there seem to be a variety of natural examples of another basic primitive: the one-way function. Informally, f is *one-way* if it is easy to compute but hard on average to invert. If $P{=}NP$, then there are no one-way functions, and it is not even known if $P \neq NP$ implies there are one-way functions. However, there are many examples of functions that seem to be one-way in practice and that are conjectured to be one-way. Some examples of conjectured one-way functions are the discrete logarithm problem modulo a large randomly chosen prime (see, e.g., [DH76]), factoring a number that is the product of two large randomly chosen primes (see, e.g., [RSA78]), problems from coding theory (see, e.g., [McEl78], [GKL93]), and the subset sum problem for appropriately chosen parameters (see, e.g., [IN96]).

The paper [BM82] is the first to construct a pseudorandom generator based on a one-way function. They introduce an elegant construction that shows how to construct a pseudorandom generator based on the presumed difficulty of the discrete logarithm problem. The paper [Yao82] substantially generalizes this result by showing how to construct a pseudorandom generator from any one-way permutation. (Some of the arguments needed in the proof were missing in [Yao82] and were later completed by [Levin87]. Also, [Levin87] conjectured that a much simpler construction would work for the case of one-way permutations, and this was eventually shown in [GL89].)

There are several important works that have contributed to the expansion of the conditions on one-way functions under which a pseudorandom generator can be constructed. [GMT82] and [Yao82] show how to construct a pseudorandom generator based on the difficulty of factoring, and this was substantially simplified in [ACGS88]. When f is a one-way permutation, the task of inverting $f(x)$ is to find x. In the case when f is not a permutation, the natural extension of successful inversion is finding

any x' such that $f(x') = f(x)$. The paper [Levin87] introduces one-way functions which remain one-way after several iterations and shows them to be necessary and sufficient for the construction of a pseudorandom generator. The paper [GKL93] shows how to construct a pseudorandom generator from any one-way function with the property that each value in the range of the function has roughly the same number of preimages. This expanded the list of conjectured one-way functions from which pseudorandom generators can be constructed to a variety of nonnumber theoretic functions, including coding theory problems.

However, the general question of how to construct a pseudorandom generator from a one-way function with no structural properties was left open. This paper resolves this question. We give several successively more intricate constructions, starting with constructions for one-way functions with a lot of structure and finishing with the constructions for one-way functions with no required structural properties.

This paper is a combination of the results announced in the conference papers [ILL89] and [H90].

1.1. Concepts and tools. Previous methods, following [BM82], rely on constructing a function that has an output bit that is computationally unpredictable given the other bits of the output, but is nevertheless statistically correlated with these other bits. [GL89] provide a simple and natural input bit which is hidden from (a padded version of) any one-way function. Their result radically simplifies the previous constructions of pseudorandom generators from one-way permutations and in addition makes all previous constructions substantially more efficient. We use their result in a fundamental way.

Our overall approach is different in spirit from previous constructions of pseudorandom generators based on one-way functions with special structure. Previous methods rely on iterating the one-way function many times, and from each iteration they extract a computationally unpredictable bit. The approach is to make sure that after many iterations the function is still one-way. In contrast, as explained below in more detail, our approach concentrates on extracting and smoothing entropy in parallel from many independent copies of the one-way function. Our overall construction combines this parallel approach with a standard method for iteratively stretching the output of a pseudorandom generator.

The notion of computational indistinguishability provides one of the main conceptual tools in our paper. Following [GM84] and [Yao82], we say that two probability distributions $\mathcal{D}$ and $\mathcal{E}$ are *computationally indistinguishable* if no feasible adversary can distinguish $\mathcal{D}$ from $\mathcal{E}$. In these terms, a pseudorandom generator is intuitively the following: let g be a polynomial time computable function that maps strings of length n to longer strings of length $\ell_n > n$. Let X be a random variable that is uniformly distributed on strings of length n and let Y be a random variable that is uniformly distributed on strings of length ℓ_n. Then g is a *pseudorandom generator* if $g(X)$ and Y are computationally indistinguishable.

The Shannon entropy of a distribution is a good measure of its information content. A fundamental law of information theory is that the application of a function cannot increase entropy. For example, because X has n bits of entropy, $g(X)$ can also have at most n bits of entropy (see Proposition 2.6). The work presented in this paper focuses on a computational analogue of Shannon entropy, namely computational entropy. We say the *computational entropy* of $g(X)$ is at least the Shannon entropy of Y if $g(X)$ and Y are computationally indistinguishable. If $g(X)$ is a pseudorandom generator, the computational entropy of $g(X)$ is greater than the Shannon entropy of

its input X, and in this sense g amplifies entropy.

We introduce the following generalizations of a pseudorandom generator based on computational entropy. We say that $g(X)$ is a *pseudoentropy generator* if the computational entropy of $g(X)$ is significantly more than the Shannon entropy of X. We say that $g(X)$ is a *false-entropy generator* if the computational entropy of $g(X)$ is significantly more than the Shannon entropy of $g(X)$.

We show how to construct a false-entropy generator from any one-way function, a pseudoentropy generator from any false-entropy generator, and finally a pseudorandom generator from any pseudoentropy generator. (The presentation of these results in the paper is in reverse order.)

We use hash functions and their analysis in a fundamental way in our constructions. This approach has its roots in [GKL93]. In [GL89], it turns out that the easily computable bit that is hidden is the parity of a random subset of the input bits, i.e., the inner product of the input and a random string. This random inner product can be viewed as a hash function from many bits to one bit.

Due to its importance in such basic algorithms as primality testing, randomness has become an interesting computational resource in its own right. Recently, various studies for extracting good random bits from biased "slightly random" sources that nevertheless possess a certain amount of entropy have been made; these sources model the imperfect physical sources of randomness, such as Geiger counter noise and Zener diodes, that would have to actually be utilized in real life. (See [Blum84], [SV86], [V87], [VV85], [CG88], and [McIn87].) One of our main technical lemmas (Lemma 4.8) can be viewed as a hashing lemma which is used to manipulate entropy in various ways: it can be viewed as a method for extracting close to uniform random bits from a slightly random source using random bits as a catalyst.

1.2. Outline. An outline of the paper is as follows.

In section 2 we give notation, especially as related to probability distributions and ensembles. In section 3, we define the basic primitives used in the paper and a general notion of reduction between primitives. We spend a little more time on this than is conventional in papers on cryptography, since we want to discuss the effects of reductions on security in quantitative terms.

Section 4 introduces the basic mechanisms for finding hidden bits and manipulating entropy with hash functions. The main result of the section is a reduction from a false-entropy generator to a pseudorandom generator via a pseudoentropy generator.

In section 5, we present a construction of a pseudorandom generator from a one-way function where preimage sizes can be estimated. Although such one-way functions are very common, and so this is an important special case, the main reason for including this is to develop intuition for general one-way functions.

Section 6 presents the most technically challenging construction: that of a false-entropy generator from any one-way function. Combined with section 4, this yields the main result of the paper: the construction of a pseudorandom generator from any one-way function.

In section 7, we present a somewhat more direct and efficient construction of a pseudorandom generator from any one-way function. This section uses the ideas from sections 4, 5, and 6, but avoids some redundancy involved in combining three generic reductions. Section 8 concludes by placing our results in the context of modern cryptographic complexity.

2. Basic notation. $\mathcal{N}$ is the set of natural numbers. If S is a set, then $\sharp S$ is the number of elements in S. If S and T are sets, then $S \setminus T$ is the set consisting of

all elements in S that are not in T. If a is a number, then $|a|$ is the absolute value of a, $\lceil a \rceil$ is the smallest integer greater than or equal to a, and $\log(a)$ is the logarithm base two of a.

Let x and y be bit strings. We let $\langle x, y \rangle$ denote the sequence x followed by y, and when appropriate we also view this as the concatenation of x and y. If $x \in \{0,1\}^n$, then x_i is the ith bit of x, $x_{\{i,\ldots,j\}}$ is $\langle x_i, \ldots, x_j \rangle$, and $x \oplus y$ is $\langle x_1 \oplus y_1, \ldots, x_n \oplus y_n \rangle$.

An $m \times n$ bit matrix x is indicated by $x \in \{0,1\}^{m \times n}$. We write $x_{i,j}$ to refer to the (i,j)-entry in x. We can also view x as a sequence $x = \langle x_1, \ldots, x_m \rangle$ of m strings, each of length n, where in this case x_i is the ith row of the matrix, or we can view x as a bit string of length mn, which is the concatenation of the rows of the matrix.

The $\odot$ operation indicates matrix multiplication over GF[2]. If $x \in \{0,1\}^n$ appears to the left of $\odot$, then it is considered to be a row vector, and if it appears to the right of $\odot$, it is considered to be a column vector. Thus, if $x \in \{0,1\}^n$ and $y \in \{0,1\}^n$, then $x \odot y = \sum_{i=1}^{n} x_i \cdot y_i \bmod 2$. More generally, if $x \in \{0,1\}^{\ell \times m}$ and $y \in \{0,1\}^{m \times n}$, then $x \odot y$ is the $\ell \times n$ bit matrix, where the (i,j)-entry is $r \odot c$, where r is the ith row of x and c is the jth column of y.

2.1. Probability notation. In general, we use capital and Greek letters to denote random variables and random events. Unless otherwise stated, all random variables are independent of all other random variables.

A distribution $\mathcal{D}$ on a finite set S assigns a probability $\mathcal{D}(x) \geq 0$ to each $x \in S$, and thus $\sum_{x \in S} \mathcal{D}(x) = 1$. We say a random variable X is distributed according to $\mathcal{D}$ on S if for all $x \in S$, $\Pr[X = x] = \mathcal{D}(x)$, and we indicate this by $X \in_{\mathcal{D}} S$. We write $\mathcal{D} : \{0,1\}^{\ell_n}$ to indicate that $\mathcal{D}$ is supported on strings of length ℓ_n. We sometimes, for convenience, blur the distinction between a random variable and its distribution. If X_1 and X_2 are random variables (that are not necessarily independent), then $(X_1 | X_2 = x_2)$ denotes the random variable that takes on value x_1 with the conditional probability $\Pr[X_1 = x_1 | X_2 = x_2] = \Pr[X_1 = x_1 \wedge X_2 = x_2] / \Pr[X_2 = x_2]$.

If f is a function mapping S to a set T, then $f(X)$ is a random variable that defines a distribution $\mathcal{E}$, where for all $y \in T$, $\mathcal{E}(y) = \sum_{x \in S, f(x) = y} \mathcal{D}(x)$. We let $f(\mathcal{D})$ indicate the distribution $\mathcal{E}$.

We let $X \in_{\mathcal{U}} S$ indicate that X is uniformly distributed in S; i.e., for all $x \in S$, $\Pr[X = x] = 1/\sharp S$. We let $\mathcal{U}_n$ indicate the uniform distribution on $\{0,1\}^n$; i.e., X is distributed according to $\mathcal{U}_n$ if $X \in_{\mathcal{U}} \{0,1\}^n$.

We sometimes want to indicate a random sample chosen from a distribution, and we do this by using the same notation as presented above for random variables except that we use lowercase letters; i.e., $x \in_{\mathcal{D}} S$ indicates that x is a fixed element of S chosen according to distribution $\mathcal{D}$.

If X is a real-valued random variable, then $\mathrm{E}[X]$ denotes the expected value X. If E is a probabilistic event, then $\Pr[E]$ denotes the probability that event E occurs.

DEFINITION 2.1 (statistical distance). *Let $\mathcal{D}$ and $\mathcal{E}$ be distributions on a set S. The* statistical distance *between $\mathcal{D}$ and $\mathcal{E}$ is*

$$\mathbf{L_1}(\mathcal{D}, \mathcal{E}) = \sum_{x \in S} \left| \Pr[\mathcal{D}(x)] - \Pr[\mathcal{E}(x)] \right| / 2.$$

PROPOSITION 2.2. *For any function f with domain S and for any pair of distributions $\mathcal{D}$ and $\mathcal{E}$ on S, $\mathbf{L_1}(f(\mathcal{D}), f(\mathcal{E})) \leq \mathbf{L_1}(\mathcal{D}, \mathcal{E})$.*

2.2. Entropy. The following definition of entropy is from [S48].

DEFINITION 2.3 (information and entropy). *Let $\mathcal{D}$ be a distribution on a set S. For each $x \in S$, define the* information *of x with respect to $\mathcal{D}$ to be $\mathbf{I}_{\mathcal{D}}(x) =$*

$-\log(\mathcal{D}(x))$. *Let* $X \in_{\mathcal{D}} S$. *The* (Shannon) entropy *of* $\mathcal{D}$ *is* $\mathbf{H}(\mathcal{D}) = \mathrm{E}[\mathbf{I}_{\mathcal{D}}(X)]$. *Let* $\mathcal{D}_1$ *and* $\mathcal{D}_2$ *be distributions on* S *that are not necessarily independent, and let* $X_1 \in_{\mathcal{D}_1} S$ *and* $X_2 \in_{\mathcal{D}_2} S$. *Then the* conditional entropy *of* $\mathcal{D}_1$ *with respect to* $\mathcal{D}_2$, $\mathbf{H}(\mathcal{D}_1|\mathcal{D}_2)$, *is* $\mathrm{E}_{x_2 \in_{\mathcal{D}_2} S}[\mathbf{H}(X_1|X_2 = x_2)]$.

We sometimes refer to the entropy $\mathbf{H}(X)$ of random variable X, which is equal to $\mathbf{H}(\mathcal{D})$. We sometimes refer to the conditional entropy $\mathbf{H}(X_1|X_2)$ of X_1 conditioned on X_2, which is equal to $\mathbf{H}(\mathcal{D}_1|\mathcal{D}_2)$.

The following variant definition of entropy is due to [Renyi70].

DEFINITION 2.4 (Renyi entropy). *Let* $\mathcal{D}$ *be a distribution on a set* S. *The* Renyi entropy *of* $\mathcal{D}$ *is* $\mathbf{H}_{\mathbf{Ren}}(\mathcal{D}) = -\log(\Pr[X = Y])$, *where* $X \in_{\mathcal{D}} S$ *and* $Y \in_{\mathcal{D}} S$ *are independent.*

There are distributions that have arbitrarily large entropy but have only a couple of bits of Renyi entropy.

PROPOSITION 2.5. *For any distribution* $\mathcal{D}$, $\mathbf{H}_{\mathbf{Ren}}(\mathcal{D}) \leq \mathbf{H}(\mathcal{D})$.

We sometimes use the following proposition implicitly. This proposition shows that a function cannot increase entropy in a statistical sense.

PROPOSITION 2.6. *Let* f *be a function and let* $\mathcal{D}$ *be a distribution on the domain of* f. *Then* $\mathbf{H}(f(\mathcal{D})) \leq \mathbf{H}(\mathcal{D})$.

The following definition characterizes how much entropy is lost by the application of a function f to the uniform distribution.

DEFINITION 2.7 (degeneracy of f). *Let* $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ *and let* $X \in_{\mathcal{U}} \{0,1\}^n$. *The* degeneracy *of* f *is* $\mathbf{D}_n(f) = \mathbf{H}(X|f(X)) = \mathbf{H}(X) - \mathbf{H}(f(X))$.

2.3. Ensembles. We present all of our definitions and results in asymptotic form. Ensembles are used to make the asymptotic definitions, e.g., to define primitives such as one-way functions and pseudorandom generators, and to define the adversaries that try to break the primitives. In all cases, we use $n \in \mathcal{N}$ as the index of the ensemble and, implicitly, the definition and/or result holds for all values of $n \in \mathcal{N}$.

In our definitions of ensembles, the input and output lengths are all polynomially related. To specify this, we use the following.

DEFINITION 2.8 (polynomial parameter). *We say parameter* k_n *is a* polynomial parameter *if there is a constant* $c > 0$ *such that for all* $n \in \mathcal{N}$,

$$\frac{1}{cn^c} \leq k_n \leq cn^c.$$

We say k_n *is a* $\mathbf{P}$-time polynomial parameter *if in addition there is a constant* $c' > 0$ *such that, for all* n, k_n *is computable in time at most* $c'n^{c'}$.

In many uses of a polynomial parameter k_n, k_n is integer valued, but it is sometimes the case that k_n is real valued.

DEFINITION 2.9 (function ensemble). *We let* $f : \{0,1\}^{t_n} \to \{0,1\}^{\ell_n}$ *denote a* function ensemble, *where* t_n *and* ℓ_n *are integer-valued* $\mathbf{P}$*-time polynomial parameters and where* f *with respect to* n *is a function mapping* $\{0,1\}^{t_n}$ *to* $\{0,1\}^{\ell_n}$. *If* f *is injective, then it is a* one-to-one function ensemble. *If* f *is injective and* $\ell_n = t_n$, *then it is a* permutation ensemble. *We let* $f : \{0,1\}^{t_n} \times \{0,1\}^{\ell_n} \to \{0,1\}^{m_n}$ *denote a function ensemble with two inputs. In this case, we sometimes consider* f *as being a function of the second input for a fixed value of the first input, in which case we write* $f_x(y)$ *in place of* $f(x,y)$.

DEFINITION 2.10 ($\mathbf{P}$-time function ensemble). *We say* $f : \{0,1\}^{t_n} \times \{0,1\}^{\ell_n} \to \{0,1\}^{m_n}$ *is a* T_n-time function ensemble *if* f *is a function ensemble such that, for all* $x \in \{0,1\}^{t_n}$, *for all* $y \in \{0,1\}^{\ell_n}$, $f(x,y)$ *is computable in time* T_n. *We say* f *is a* $\mathbf{P}$-

time function ensemble *if there is a constant c such that, for all n, $T_n \leq cn^c$. We say f is a* mildly nonuniform **P**-time function ensemble *if it is a* **P***-time function ensemble except that it has an additional input* $\mathbf{a}_n$ *called the* advice*, that is, an integer-valued polynomial parameter that is not necessarily* **P***-time computable.*

These definitions generalize in a natural way to functions with more than two inputs. Sometimes we describe functions that have variable length inputs or outputs; in these cases we implicitly assume that the string is padded out with a special blank symbol to the appropriate length.

In some of our intermediate reductions, we use certain statistical quantities in order to construct our new primitive. For example, we might use an approximation of the entropy of a distribution in our construction of a pseudoentropy generator. Although in many cases these quantities are not easy to approximate, the number of different approximation values they can take on is small. This is the reason for the definition of a mildly nonuniform **P**-time function ensemble in the above definition. In all the definitions we give below, e.g., of one-way functions, false-entropy generators, pseudoentropy generators, and pseudorandom generators, there is also an analogous mildly nonuniform version. In Proposition 4.17, we show how to remove mild nonuniformity in the final construction of a pseudorandom generator.

DEFINITION 2.11 (range and preimages of a function). *Let $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a function ensemble. With respect to n, define*

$$\text{range}_f = \{f(x) : x \in \{0,1\}^n\}.$$

For each $y \in \text{range}_f$, define

$$\text{pre}_f(y) = \{x \in \{0,1\}^n : f(x) = y\}.$$

DEFINITION 2.12 (regular function ensemble). *We say function ensemble $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ is* σ_n-regular *if $\sharp\text{pre}_f(y) = \sigma_n$ for all $y \in \text{range}_f$.*

DEFINITION 2.13 ($\tilde{\mathbf{D}}_f$). *Let $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a* **P***-time function ensemble. For $z \in \text{range}_f$, define the* approximate degeneracy of z *as*

$$\tilde{\mathbf{D}}_f(z) = \left\lceil \log(\sharp\text{pre}_f(z)) \right\rceil.$$

Notice that $\tilde{\mathbf{D}}_f(z)$ is an approximation to within an additive factor of 1 of the quantity $n - \mathbf{I}_{f(X)}(z)$. Furthermore, $\mathrm{E}[\tilde{\mathbf{D}}_f(f(X))]$ is within an additive factor of 1 of the degeneracy of f. If f is a σ_n-regular function then, for each $z \in \text{range}_f$, $\tilde{\mathbf{D}}_f(z)$ is within an additive factor of 1 of $\log(\sigma_n)$, which is the degeneracy of f.

DEFINITION 2.14 (probability ensemble). *We let $\mathcal{D} : \{0,1\}^{\ell_n}$ denote a* probability ensemble*, where ℓ_n is an integer-valued* **P***-time polynomial parameter and where $\mathcal{D}$ with respect to n is a probability distribution on $\{0,1\}^{\ell_n}$.*

DEFINITION 2.15 (**P**-samplable probability ensemble). *We let $\mathcal{D} : \{0,1\}^{\ell_n}$ denote a probability ensemble that, with respect to n, is a distribution on $\{0,1\}^{\ell_n}$ that can be generated from a random string of length r_n for some r_n; i.e., there is a function ensemble $f : \{0,1\}^{r_n} \to \{0,1\}^{\ell_n}$ such that if $X \in_{\mathcal{U}} \{0,1\}^{r_n}$ then $f(X)$ has the distribution $\mathcal{D}$. We say $\mathcal{D}$ is a* T_n-samplable probability ensemble *if, for all $x \in \{0,1\}^{r_n}$, $f(x)$ is computable in time T_n. We say $\mathcal{D}$ is* **P**-samplable *if f is a* **P***-time function ensemble, and $\mathcal{D}$ is* mildly nonuniformly **P**-samplable *if f is a mildly nonuniform* **P***-time function ensemble.*

DEFINITION 2.16 (copies of functions and ensembles). *Let k_n be an integer-valued* $\mathbf{P}$*-time polynomial parameter. If $\mathcal{D} : \{0,1\}^{\ell_n}$ is a probability ensemble, then $\mathcal{D}^{k_n} : \{0,1\}^{\ell_n k_n}$ is the probability ensemble where, with respect to parameter n, $\mathcal{D}^{k_n}$ consists of the concatenation of k_n independent copies of $\mathcal{D}$. Similarly, if $f : \{0,1\}^{m_n} \to \{0,1\}^{\ell_n}$ is a function ensemble, then $f^{k_n} : \{0,1\}^{m_n k_n} \to \{0,1\}^{\ell_n k_n}$ is the function ensemble where, for $y \in \{0,1\}^{k_n \times m_n}$,*

$$f^{k_n}(y) = \langle f(y_1), \ldots, f(y_{k_n}) \rangle.$$

3. Definitions of primitives and reductions. Primitives described in this paper include one-way functions and pseudorandom generators. The primitives we describe can be used in cryptographic applications but are also useful as described in the introduction in other applications. In the definition of the primitives, we need to describe what it means for the primitive to be secure against an attack by an adversary. We first introduce adversaries and security and then describe the basic primitives that we use thereafter.

3.1. Adversaries and security. An adversary is, for example, trying to invert a one-way function or trying to distinguish the output of a pseudorandom generator from a truly random string. The time–success ratio of a particular adversary is a measure of its ability to break the cryptographic primitive. (Hereafter, we use "primitive" in place of the more cumbersome and sometimes misleading phrase "cryptographic primitive.") The security of a primitive is a lower bound on the time–success ratio of *any* adversary to break the primitive.

In the constructions of some primitives, we allow both private and public inputs. A *public input* is part of the output of the primitive and is known to the adversary at the time it tries to break the primitive. When we construct one primitive based on another, the constructed primitive often has public inputs. At first glance it could seem that these public inputs are not useful because an adversary knows them at the time it tries to break the constructed primitive. On the contrary, public inputs turn out to be quite useful. Intuitively, this is because their value is randomly chosen, and the adversary cannot a priori build into its breaking strategy a strategy for all possible values.

The *private input* to a primitive is not directly accessible to the adversary. The security parameter of a primitive is the length of its private input. This is because the private input to the primitive is what is kept secret from the adversary, and thus it makes sense to measure the success of the adversary in terms of this.

DEFINITION 3.1 (breaking adversary and security). *An* adversary *A is a function ensemble. The* time–success ratio *of A for an instance f of a primitive is defined as $\mathbf{R}_{t_n} = T_n/sp_n(A)$, where t_n is the length of the private input to f, T_n is the worst-case expected running time of A over all instances parameterized by n, and $sp_n(A)$ is the success probability of A for breaking f. In this case, we say A is an* $\mathbf{R}$-breaking *adversary for f. We say f is* $\mathbf{R}$*-secure if there is no* $\mathbf{R}$*-breaking adversary for f.*

A mildly nonuniform adversary *for a mildly nonuniform* $\mathbf{P}$*-time function ensemble f that has advice $\mathbf{a}_n$ is a function ensemble A which is given $\mathbf{a}_n$ as an additional input. The success probability and time–success ratio for a mildly nonuniform adversary is the same as for uniform adversaries.*

The definition of the success probability $sp_n(A)$ for f depends on the primitive in question; i.e., this probability is defined when the primitive is defined. Intuitively, the smaller the time–success ratio of an adversary for a primitive, the better the adversary is able to break the primitive, i.e., it uses less time and/or has a larger

success probability.

The above definitions are a refinement of definitions that appear in the literature. Previously, an adversary was considered to be breaking if it ran in polynomial time and had inverse polynomial success probability. The advantage of the definition introduced here is that it is a more precise characterization of the security of a primitive. This is important because different applications require different levels of security. For some applications polynomial security is enough (e.g., $\mathbf{R}_{t_n} = {t_n}^{10}$) and for other applications better security is crucial (e.g., $\mathbf{R}_{t_n} = 2^{\log^2(t_n)}$, or even better $\mathbf{R}_{t_n} = 2^{\sqrt{t_n}}$).

3.2. One-way function.

DEFINITION 3.2 (one-way function). *Let* $f : \{0,1\}^{t_n} \to \{0,1\}^{\ell_n}$ *be a* $\mathbf{P}$*-time function ensemble and let* $X \in_{\mathcal{U}} \{0,1\}^{t_n}$. *The* success probability *of adversary* A *for inverting* f *is*

$$sp_n(A) = \Pr[f(A(f(X))) = f(X)].$$

Then f *is an* $\mathbf{R}$*-secure one-way function if there is no* $\mathbf{R}$*-breaking adversary for* f.

A function cannot be considered to be "one-way" in any reasonable sense in case the time to invert it is smaller than the time to evaluate it in the forward direction. Thus, for example, if there is an $\mathcal{O}(t_n)$-breaking adversary for f, then it is not secure at all. On the other hand, an exhaustive adversary that tries all possible inputs to find an inverse is $t_n^{\mathcal{O}(1)} \cdot 2^{t_n}$-breaking. Thus, the range of securities that can be hoped for falls between these two extremes.

3.3. Pseudorandom generator. The following definition can be thought of as the computationally restricted adversary definition of statistical distance. The original idea is from [GM84] and [Yao82].

DEFINITION 3.3 (computationally indistinguishable). *Let* $\mathcal{D} : \{0,1\}^{\ell_n}$ *and* $\mathcal{E} : \{0,1\}^{\ell_n}$ *be probability ensembles. The* success probability *of adversary* A *for distinguishing* $\mathcal{D}$ *and* $\mathcal{E}$ *is*

$$sp_n(A) = |\Pr[A(X) = 1] - \Pr[A(Y) = 1]|,$$

where X *has distribution* $\mathcal{D}$ *and* Y *has distribution* $\mathcal{E}$. $\mathcal{D}$ *and* $\mathcal{E}$ *are* $\mathbf{R}$*-secure* computationally indistinguishable *if there is no* $\mathbf{R}$*-breaking adversary for distinguishing* $\mathcal{D}$ *and* $\mathcal{E}$.

The following alternative definition of computationally indistinguishable more accurately reflects the trade-off between the running time of the adversary and its success probability. In the alternative definition, success probability is defined as $sp'_n(A) = (sp_n(A))^2$. This is because it takes $1/sp'_n(A)$ trials in order to approximate $sp_n(A)$ to within a constant factor.

DEFINITION 3.4 (computationally indistinguishable (alternative)). *This is exactly the same as the original definition, except the* success probability *of adversary* A *is* $sp'_n(A) = (sp_n(A))^2$.

In all cases except where noted, the strength of the reduction is the same under either definition of computationally indistinguishable, and we find it easier to work with the first definition. However, there are a few places where we explicitly use the alternative definition to be able to claim the reduction is linear-preserving.

Strictly speaking, there are no private inputs in the above definition, and thus by default we use n as the security parameter. However, in a typical use of this

definition, $\mathcal{D}$ is the distribution defined by the output of a **P**-time function ensemble (and thus $\mathcal{D}$ is **P**-samplable), in which case the length of the private input to this function ensemble is the security parameter. In some circumstances, it is important that both $\mathcal{D}$ and $\mathcal{E}$ are **P**-samplable; e.g., this is the case for Proposition 4.12.

The paper [Yao82] originally gave the definition of a pseudorandom generator as below, except that we parameterize security more precisely.

DEFINITION 3.5 (pseudorandom generator). *Let $g : \{0,1\}^{t_n} \to \{0,1\}^{\ell_n}$ be a* **P***-time function ensemble where $\ell_n > t_n$. Then g is an* **R***-secure pseudorandom generator if the probability ensembles $g(\mathcal{U}_{t_n})$ and $\mathcal{U}_{\ell_n}$ are* **R***-secure computationally indistinguishable.*

The definition of a pseudorandom generator only requires the generator to stretch the input by at least one bit. The following proposition provides a general way to produce a pseudorandom generator that stretches by many bits from a pseudorandom generator that stretches by at least one bit. This proposition appears in [BH89] and is due to O. Goldreich and S. Micali.

PROPOSITION 3.6. *Suppose $g : \{0,1\}^n \to \{0,1\}^{n+1}$ is a pseudorandom generator that stretches by one bit. Define $g^{(1)}(x) = g(x)$, and inductively, for all $i \geq 1$,*

$$g^{(i+1)}(x) = \langle g(g^{(i)}(x)_{\{1,\ldots,n\}}), g^{(i)}(x)_{\{n+1,\ldots,n+i\}} \rangle.$$

Let k_n be an integer-valued **P***-time polynomial parameter. Then $g^{(k_n)}$ is a pseudorandom generator. The reduction is linear-preserving.*

In section 3.6 we give a formal definition of reduction and what it means to be linear-preserving, but intuitively it means that $g^{(k_n)}$ as a pseudorandom generator is almost as secure as pseudorandom generator g.

3.4. Pseudoentropy and false-entropy generators. The definitions in this subsection introduce new notions (interesting in their own right) which we use as intermediate steps in our constructions.

The difference between a pseudorandom generator and a pseudoentropy generator is that the output of a pseudoentropy generator doesn't have to be computationally indistinguishable from the uniform distribution; instead it must be computationally indistinguishable from some probability ensemble $\mathcal{D}$ that has more entropy than the input to the generator. Thus, a pseudoentropy generator still amplifies randomness so that the output randomness is more computationally than the input randomness, but the output randomness is no longer necessarily uniform.

DEFINITION 3.7 (computational entropy). *Let $f : \{0,1\}^{t_n} \to \{0,1\}^{\ell_n}$ be a* **P***-time function ensemble and let s_n be a polynomial parameter. Then f has* **R***-secure* computational entropy *s_n if there is a* **P***-time function ensemble $f' : \{0,1\}^{m_n} \to \{0,1\}^{\ell_n}$ such that $f(\mathcal{U}_{t_n})$ and $f'(\mathcal{U}_{m_n})$ are* **R***-secure computationally indistinguishable and $\mathbf{H}(f'(\mathcal{U}_{m_n})) \geq s_n$.*

DEFINITION 3.8 (pseudoentropy generator). *Let $f : \{0,1\}^{t_n} \to \{0,1\}^{\ell_n}$ be a* **P***-time function ensemble and let s_n be a polynomial parameter. Then f is an* **R***-secure* pseudoentropy generator *with pseudoentropy s_n if $f(\mathcal{U}_{t_n})$ has* **R***-secure computational entropy $t_n + s_n$.*

If f is a pseudorandom generator, then it is easy to see that it is also a pseudoentropy generator. This is because $f(\mathcal{U}_{t_n})$ and $\mathcal{U}_{\ell_n}$ are computationally indistinguishable and by definition of a pseudorandom generator, $\ell_n > t_n$. Consequently, $\mathbf{H}(\mathcal{U}_{\ell_n}) = \ell_n \geq t_n + 1$; i.e., f is a pseudoentropy generator with pseudoentropy at least 1.

A false-entropy generator is a further generalization of pseudoentropy generator.

A false-entropy generator doesn't necessarily amplify the input randomness; it just has the property that the output randomness is more computationally than it is statistically.

DEFINITION 3.9 (false-entropy generator). *Let $f : \{0,1\}^{t_n} \to \{0,1\}^{\ell_n}$ be a* **P***-time function ensemble and let s_n be a polynomial parameter. Then f is an* **R***-secure* false-entropy generator *with false entropy s_n if $f(\mathcal{U}_{t_n})$ has* **R***-secure computational entropy $\mathbf{H}(f(\mathcal{U}_{t_n})) + s_n$.*

Note that, in the definition of computational entropy, the function ensemble f' that is computationally indistinguishable from f is required to be **P**-time computable. This is consistent with the definition of a pseudorandom generator, where the distribution from which the pseudorandom generator is indistinguishable is the uniform distribution. There is also a nonuniform version of computational entropy, where f' is not necessarily **P**-time computable, and corresponding nonuniform versions of a pseudoentropy generator and false-entropy generator. It turns out to be easier to construct a false-entropy generator f, where f' is not necessarily **P**-time computable from a one-way function, than it is to construct a false-entropy generator f, where f' is **P**-time samplable. Using this approach and a nonuniform version of Proposition 4.12, [ILL89] describes a nonuniform reduction from a one-way function to a pseudorandom generator. However, a uniform reduction using Proposition 4.12 requires that f' be **P**-time computable. Thus, one of the main difficulties in our constructions below is to build a false-entropy generator f, where f' is **P**-time computable.

3.5. Hidden bits. In the construction of a pseudorandom generator from a one-way function, one of the key ideas is to construct from the one-way function another function which has an output bit that is computationally unpredictable from the other output bits (it is "hidden") and yet statistically somewhat predictable from the other output bits. This idea is used in the original construction of a pseudorandom generator from the discrete logarithm problem [BM82] and has been central to all such constructions since that time.

DEFINITION 3.10 (hidden bit). *Let $f : \{0,1\}^{t_n} \to \{0,1\}^{\ell_n}$ and $b : \{0,1\}^{t_n} \to \{0,1\}$ be* **P***-time function ensembles. Let $\mathcal{D} : \{0,1\}^{t_n}$ be a* **P***-samplable probability ensemble, let $X \in_{\mathcal{D}} \{0,1\}^{t_n}$, and let $\beta \in_{\mathcal{U}} \{0,1\}$. Then $b(X)$ is* **R***-secure* hidden *given $f(X)$ if $\langle f(X), b(X)\rangle$ and $\langle f(X), \beta\rangle$ are* **R***-secure computationally indistinguishable.*

3.6. Reductions. All the results presented in this paper involve a reduction from one type of primitive to another.

We make the following definitions to quantify the strength of reductions. The particular parameterization of security and the different quantitative measures of the security-preserving properties of a reduction are derived from [Luby96], [HL92].

Intuitively, a reduction constructs from a first primitive f on inputs of length t_n a second primitive $g^{(f)}$ on inputs of length t'_n. The reduction also specifies an oracle TM $M^{(\cdot)}$ such that if there is an adversary A for breaking $g^{(f)}$, then $M^{(A)}$ is an adversary for breaking f. How much security is preserved by the reduction is parameterized by $\mathcal{S}$.

DEFINITION 3.11 (reduction). *Let t_n and t'_n be polynomial parameters and let $\mathcal{S} : \mathcal{N} \times \Re^+ \to \Re^+$. An* $\mathcal{S}$-reduction *from primitive* 1 *to primitive* 2 *is a pair of oracles $g^{(\cdot)}$ and $M^{(\cdot)}$ so that the following hold:*

- *For each* **P***-time function ensemble $f : \{0,1\}^{t_n} \to \{0,1\}^{\ell_n}$ that instantiates primitive* 1*, $g^{(f)} : \{0,1\}^{t'_n} \to \{0,1\}^{\ell'_n}$ instantiates primitive* 2*.*
- *$g^{(f)}$ is a* **P***-time function ensemble, and on inputs of length t'_n, it only makes calls to f on inputs of length t_n.*
- *Suppose A is an adversary with time–success ratio $\mathbf{R}'_{t'_n}$ for $g^{(f)}$ on inputs*

of length t'_n. Define $\mathbf{R}_{t_n} = \mathcal{S}(n, \mathbf{R}'_{t'_n})$. Then $M^{(A)}$ is an adversary with time–success ratio $\mathbf{R}_{t_n}$ for f on inputs of length t_n.

To discuss the security-preserving properties of the reduction, we compare how well A breaks $g^{(f)}$ with how well $M^{(A)}$ breaks f on inputs of similar size. We say the reduction is

- linear-preserving *if* $\mathbf{R}_N = N^{\mathcal{O}(1)} \cdot \mathcal{O}(\mathbf{R}'_N)$,
- poly-preserving *if* $\mathbf{R}_N = N^{\mathcal{O}(1)} \cdot \mathbf{R}'^{\mathcal{O}(1)}_{\mathcal{O}(N)}$,
- weak-preserving *if* $\mathbf{R}_N = N^{\mathcal{O}(1)} \cdot \mathbf{R}'^{\mathcal{O}(1)}_{N^{\mathcal{O}(1)}}$.

A mildly nonuniform reduction *has the same properties except that $g^{(\cdot)}$ and $M^{(\cdot)}$ are both allowed access to an integer-valued polynomial parameter $\mathbf{a}_n$ that depends on f. The same notions of security preservation apply to mildly nonuniform reductions.*

f can always be broken in time exponential in t_n. Therefore, if $\mathbf{R}'_{t'_n} \geq 2^{t_n}$, or even $\mathbf{R}'_{t'_n} \geq 2^{t_n^{\Omega(1)}} = 2^{n^{\Omega(1)}}$ in the case of a weak-preserving reduction, $M^{(A)}$ can ignore the oracle and break f by brute force. Therefore, we can assume without loss of generality that $\mathbf{R}'_{t'_n} \leq 2^{t_n}$.

Obvious from the definition of reduction are the following propositions that say that security is preserved by reductions and that reductions can be composed.

PROPOSITION 3.12. *If $(g^{(\cdot)}, M^{(\cdot)})$ is a (mildly nonuniform) $\mathcal{S}$-reduction from primitive 1 to primitive 2 and f is a (mildly nonuniform) $\mathbf{P}$-time function ensemble that instantiates primitive 1 with security $\mathbf{R}_{t_n}$, then $g^{(f)}$ is a (mildly nonuniform) $\mathbf{P}$-time function ensemble that instantiates primitive 2 with security $\mathbf{R}'_{t'_n}$.*

PROPOSITION 3.13. *If $(g_1^{(\cdot)}, M_1^{(\cdot)})$ is a (mildly nonuniform) $\mathcal{S}_1$-reduction from primitive 1 to primitive 2, and if $(g_2^{(\cdot)}, M_2^{(\cdot)})$ is a (mildly nonuniform) $\mathcal{S}_2$-reduction from primitive 2 to primitive 3, then $(g_1^{(g_2^{(\cdot)})}, M_1^{(M_2^{(\cdot)})})$ is a (mildly nonuniform) $\mathcal{S}$-reduction from primitive 1 to primitive 3, where $\mathcal{S}(N, R) = \mathcal{S}_2(N, \mathcal{S}_1(N, R))$.*

Although we phrase our definitions in terms of asymptotic complexity, one can easily interpret them for fixed length inputs in the context of an actual implementation, just as one does for algorithm analysis.

Clearly, in standard situations, $t'_n \geq t_n$ and $\mathbf{R}_{t_n} \geq \mathbf{R}'_{t'_n}$, and the closer these two inequalities are to equalities the more the security of f is transferred to g. We now describe how the slack in these inequalities affects the security-preserving properties of the reduction.

The number of calls $M^{(A)}$ makes to A is invariably either a constant or depends polynomially on the time–success ratio of A, and thus $\mathbf{R}_{t_n}$ is at most polynomial in $\mathbf{R}'_{t'_n}$. The slackness in this inequality turns out not to be the major reason for a loss in security in the reduction; instead the loss primarily depends on how much larger t'_n is than t_n. If t'_n is much larger than t_n, then $\mathbf{R}_{t_n}$ is much larger as a function of t_n than $\mathbf{R}'_{t'_n}$ is as a function of t'_n. We can formalize this as follows.

PROPOSITION 3.14.

- *If $t'_n = t_n$, $M^{(A)}$ runs in time polynomial in n (not counting the running time of A), and $sp_n(M^{(A)}) = sp_n(A)/n^{\mathcal{O}(1)}$, then the reduction is linear-preserving.*
- *If $t'_n = \mathcal{O}(t_n)$, $M^{(A)}$ runs in time polynomial in $\mathbf{R}'_{t'_n}$, and $sp_n(M^{(A)}) = sp_n^{\mathcal{O}(1)}(A)/n^{\mathcal{O}(1)}$, then the reduction is poly-preserving.*
- *If $t'_n = t_n^{\mathcal{O}(1)}$, $M^{(A)}$ runs in time polynomial in $\mathbf{R}'_{t'_n}$, and $sp_n(M^{(A)}) = sp_n^{\mathcal{O}(1)}(A)/n^{\mathcal{O}(1)}$, then the reduction is weak-preserving.*

It is important to design the strongest reduction possible. The techniques described in this paper can be directly used to yield poly-preserving reductions from regular or nearly regular (with polynomial time computable degree of regularity) one-way functions to pseudorandom generators [Luby96], and this covers almost all the conjectured one-way functions. However, the reduction for general one-way functions is only weak-preserving.

4. Hidden bits, hash functions, and computational entropy.

4.1. Constructing a hidden bit. How do we go about constructing a function such that one of its output bits is computationally unpredictable yet statistically correlated with its other output bits? The following fundamental proposition of [GL89] (strengthened in [Levin93]) provides the answer.

PROPOSITION 4.1. *Let $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a one-way function. Then $X \odot R$ is hidden given $\langle f(X), R\rangle$, where $X, R \in_{\mathcal{U}} \{0,1\}^n$. The reduction is linear-preserving with respect to the alternative definition of computationally indistinguishable.*

Proposition 4.1 presents an elegant, simple, and general method of obtaining a hidden bit from a one-way function. We need the following stronger proposition of [GL89] (see also [Levin93]) in some of our proofs.

PROPOSITION 4.2. *There is an oracle TM M with the following properties: Let A be any adversary that accepts as input n bits and outputs a single bit. Then $M^{(A)}$ on input parameter $\delta_n > 0$ outputs a list $\mathcal{L}$ of n-bit strings with the following property: For any fixed $x \in \{0,1\}^n$, if it is the case that*

$$|\Pr[A(R) = x \odot R] - \Pr[A(R) \neq x \odot R]| \geq \delta_n,$$

where $R \in_{\mathcal{U}} \{0,1\}^n$, then, with probability at least $1/2$, it is the case that $x \in \mathcal{L}$. (The probability here depends only on the values of the random bits used by $M^{(A)}$.) The running time of $M^{(A)}$ is polynomial in n, $1/\delta_n$, and the running time of A. Also, the number of n-bit strings in $\mathcal{L}$ is bounded by $\mathcal{O}(1/\delta_n^2)$.

The following proposition is an immediate consequence of Proposition 4.1 and Definition 3.10.

PROPOSITION 4.3. *Let $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a one-way function. Then $\langle f(X), R, X \odot R\rangle$ and $\langle f(X), R, \beta\rangle$ are computationally indistinguishable, where $X, R \in_{\mathcal{U}} \{0,1\}^n$ and $\beta \in_{\mathcal{U}} \{0,1\}$. The reduction is linear-preserving with respect to the alternative definition of computationally indistinguishable.*

4.2. One-way permutation to a pseudorandom generator. We describe a way to construct a pseudorandom generator from any one-way permutation which is substantially simpler (and has stronger security-preserving properties) than the original construction of [Yao82]. The construction and proof described here is due to [GL89].

PROPOSITION 4.4. *Let $f : \{0,1\}^n \to \{0,1\}^n$ be a one-way permutation. Let $x, r \in \{0,1\}^n$ and define $\mathbf{P}$-time function ensemble $g(x,r) = \langle f(x), r, x \odot r\rangle$. Then g is a pseudorandom generator. The reduction is linear-preserving with respect to the alternative definition of computationally indistinguishable.*

Proof. Let $X, R \in_{\mathcal{U}} \{0,1\}^n$, and $\beta \in_{\mathcal{U}} \{0,1\}$. Because f is a permutation, $\langle f(X), R, \beta\rangle$ is the uniform distribution on $\{0,1\}^{2n+1}$. By Proposition 4.3, $g(X,R)$ and $\langle f(X), R, \beta\rangle$ are computationally indistinguishable, where the reduction is linear-preserving with respect to the alternative definition of computationally indistinguishable. ∎

Proposition 4.4 works when f is a permutation because

(1) $f(X)$ is uniformly distributed and hence already looks random;
(2) for any $x \in \{0,1\}^n$, $f(x)$ uniquely determines x. So no entropy is lost by the application of f.

For a general one-way function neither (1) nor (2) necessarily holds. Intuitively, the rest of the paper constructs a one-way function with properties (1) and (2) from a general one-way function. This is done by using hash functions to smooth the entropy of $f(X)$ to make it more uniform and to recapture the entropy of X lost by the application of $f(X)$.

Proposition 4.4 produces a pseudorandom generator that only stretches the input by one bit. To construct a pseudorandom generator that stretches by many bits, combine this with the construction described previously in Proposition 3.6.

4.3. One-to-one one-way function to a pseudoentropy generator. We now describe a construction of a pseudoentropy generator from any one-to-one one-way function. This construction, together with Theorem 4.14, yields a pseudorandom generator from any one-to-one one-way function. The overall construction is different in spirit than the original construction of [GKL93]: it illustrates how to construct a pseudoentropy generator in a particularly simple way using [GL89]. Although the assumptions and the consequences are somewhat different, the construction is the same as described in Proposition 4.4.

PROPOSITION 4.5. *Let $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a one-to-one one-way function. Let $x, r \in \{0,1\}^n$ and define $\mathbf{P}$-time function ensemble $g(x,r) = \langle f(x), r, x \odot r\rangle$. Then g is a pseudoentropy generator$\tilde{}$with pseudoentropy 1. The reduction is linear-preserving with respect to the alternative definition of computationally indistinguishable.*

Proof. Let $X, R \in_{\mathcal{U}} \{0,1\}^n$ and $\beta \in_{\mathcal{U}} \{0,1\}$. Proposition 4.3 shows that $g(X,R)$ and $\langle f(X), R, \beta\rangle$ are computationally indistinguishable, where the reduction is linear-preserving with respect to the alternative definition of computationally indistinguishable. Because f is a one-to-one function and β is a random bit, $\mathbf{H}(f(X), R, \beta) = 2n+1$, and thus $g(X,R)$ has pseudoentropy 1. □

Note that it is not possible to argue that g is a pseudorandom generator. For example, let $f(x) = \langle 0, f'(x)\rangle$, where f' is a one-way permutation. Then f is a one-to-one one-way function and yet $g(X,R) = \langle f(X), R, X \odot R\rangle$ is not a pseudorandom generator, because the first output bit of g is zero independent of its inputs, and thus its output can easily be distinguished from a uniformly chosen random string.

4.4. Universal hash functions. The concept of a universal hash function, introduced in [CW79], has proved to have a far-reaching and broad spectrum of applications in the theory of computation.

DEFINITION 4.6 (universal hash functions). *Let $h : \{0,1\}^{\ell_n} \times \{0,1\}^n \to \{0,1\}^{m_n}$ be a $\mathbf{P}$-time function ensemble. Recall from Definition 2.9 that for fixed $y \in \{0,1\}^{\ell_n}$, we view y as describing a function $h_y(\cdot)$ that maps n bits to m_n bits. Then h is a (pairwise independent)* universal hash function *if, for all $x \in \{0,1\}^n$, $x' \in \{0,1\}^n \setminus \{x\}$, and for all $a, a' \in \{0,1\}^{m_n}$,*

$$\Pr[(h_Y(x) = a) \text{ and } (h_Y(x') = a')] = 1/2^{2m_n},$$

where $Y \in_{\mathcal{U}} \{0,1\}^{\ell_n}$.

Intuitively, a universal hash function has the property that every distinct pair x and x' are mapped randomly and independently with respect to Y.

In all of our constructions of function ensembles using universal hash functions, the description of the hash function y is viewed as a public input to the function

ensemble and thus is also part of the output. The following construction of a universal hash function is due to [CW79].

DEFINITION 4.7 (matrix construction). *Let*

$$h : \{0,1\}^{(n+1)m_n} \times \{0,1\}^n \to \{0,1\}^{m_n}$$

be the following **P***-time function ensemble: For* $x \in \{0,1\}^n$ *and* $y \in \{0,1\}^{(n+1)\times m_n}$, $h_y(x) = \langle x, 1\rangle \odot y$.

We concatenate a 1 to x in the above definition to cover the case when $x = 0^n$. Hereafter, whenever we refer to universal hash functions, one can think of the construction given above. However, any universal hash function that satisfies the required properties may be used. We note that there are more efficient hash functions in terms of the number of bits used in specification. One such example is using Toeplitz matrices (see for example [GL89] or [Levin93]). A Toeplitz matrix is a matrix that is constant on any diagonal, and thus to specify an $n \times m$ Toeplitz matrix we can specify values for the $m + n - 1$ diagonals. This is the simplest bit-efficient construction of a universal hash function, so we adopt it as the default for the remainder of the paper.

4.5. Smoothing distributions with hashing. The following lemma is a key component in most of the subsequent reductions we describe.

LEMMA 4.8. *Let* $\mathcal{D} : \{0,1\}^n$ *be a probability ensemble that has Renyi entropy at least* m_n. *Let* e_n *be a positive-integer-valued parameter. Let* $h : \{0,1\}^{\ell_n} \times \{0,1\}^n \to \{0,1\}^{m_n - 2e_n}$ *be a universal hash function. Let* $X \in_{\mathcal{D}} \{0,1\}^n$, $Y \in_{\mathcal{U}} \{0,1\}^{\ell_n}$, *and* $Z \in_{\mathcal{U}} \{0,1\}^{m_n - 2e_n}$. *Then*

$$\mathbf{L_1}(\langle h_Y(X), Y\rangle, \langle Z, Y\rangle) \le 2^{-(e_n+1)}.$$

This lemma is a generalization of a lemma that appears in [S83]. There, $\mathcal{D}$ is the uniform distribution on a set $S \subseteq \{0,1\}^n$ with $\sharp S = 2^{m_n}$. The papers [McIn87] and [BBR88] also proved similar lemmas. For the special case of linear hash functions, this lemma can be derived from [GL89] by considering unlimited adversaries. A generalization to a broader class of hash functions appears in [IZ89].

The lemma can be interpreted as follows: the universal hash function smooths out the Renyi entropy of X to the almost uniform distribution on bit strings of length almost m_n. The integer parameter e_n controls the trade-off between the uniformity of the output bits of the universal hash function and the amount of entropy lost in the smoothing process. Thus, we have managed to convert almost all the Renyi entropy of X into uniform random bits while maintaining our original supply of random bits Y.

Proof. Let $\ell = \ell_n$, $e = e_n$, $m = m_n$, and $s = m - 2e$. For all $y \in \{0,1\}^\ell$, $a \in \{0,1\}^s$, and $x \in \{0,1\}^n$, define $\mathcal{X}(h_y(x) = a) = 1$ if $h_y(x) = a$ and 0 otherwise. We want to show that

$$\mathrm{E}_Y\left[\sum_{a\in\{0,1\}^s} |\mathrm{E}_X[\mathcal{X}(h_Y(X) = a)] - 2^{-s}|\right]/2 \le 2^{-(e+1)}.$$

We show below that for all $a \in \{0,1\}^s$,

$$\mathrm{E}_Y\left[\left|\mathrm{E}_X[\mathcal{X}(h_Y(X) = a)] - 2^{-s}\right|\right] \le 2^{-(s+e)},$$

and from this the proof follows.

For any random variable Z, $\mathrm{E}[|Z|^2] \geq \mathrm{E}[|Z|]^2$ by Jensen's inequality. Letting $Z = \mathrm{E}[\mathcal{X}(h_Y(X) = a)] - 2^{-s}$, we see that it is sufficient to show for all $a \in \{0,1\}^s$,

$$\mathrm{E}_Y[(\mathrm{E}_X[\mathcal{X}(h_Y(X) = a)] - 2^{-s})^2] \leq 2^{-2(s+e)}.$$

Let $X' \in_{\mathcal{D}} \{0,1\}^n$. Using some elementary expansion of terms and rearrangements of summation, we can write the above as

$$\mathrm{E}_{X,X'}[\mathrm{E}_Y[(\mathcal{X}(h_Y(X) = a) - 2^{-s})(\mathcal{X}(h_Y(X') = a) - 2^{-s})]].$$

For each fixed value of X to x and X' to x', where $x \neq x'$, the expectation with respect to Y is zero because of the pairwise independence property of universal hash functions. For each fixed value of X to x and X' to x', where $x = x'$,

$$\mathrm{E}[(\mathcal{X}(h_Y(x) = a) - 2^{-s})^2] = 2^{-s}(1 - 2^{-s}) \leq 2^{-s}.$$

Because the Renyi entropy of $\mathcal{D}$ is at least m, it follows that $\Pr[X = X'] \leq 2^{-m}$. Thus, the entire sum is at most $2^{-(m+s)}$, which is equal to $2^{-2(s+e)}$ by the definition of s. □

In this lemma, $\mathcal{D}$ is required to have Renyi entropy at least m_n. In many of our applications, the distribution in question has at least Renyi entropy m_n, and thus the lemma applies because of Proposition 2.5. For other applications, we need to work with Shannon entropy. The following technical result due to [S48] allows us to convert Shannon entropy to Renyi entropy by looking at product distributions.

PROPOSITION 4.9. *Let k_n be an integer-valued polynomial parameter.*

- *Let $\mathcal{D} : \{0,1\}^n$ be a probability ensemble. There is a probability ensemble $\mathcal{E} : \{0,1\}^{nk_n}$ satisfying*
  - $\mathbf{H_{Ren}}(\mathcal{E}) \geq k_n \mathbf{H}(\mathcal{D}) - nk_n^{2/3}$,
  - $\mathbf{L_1}(\mathcal{E}, \mathcal{D}^{k_n}) \leq 2^{-k_n^{1/3}}$.
- *Let $\mathcal{D}_1 : \{0,1\}^n$ and $\mathcal{D}_2 : \{0,1\}^n$ be not necessarily independent probability ensembles; let $\mathcal{D} = \langle \mathcal{D}_1, \mathcal{D}_2 \rangle$. There is a probability ensemble $\mathcal{E} : \{0,1\}^{2nk_n}$, with $\mathcal{E} = \langle \mathcal{E}_1, \mathcal{E}_2 \rangle$, satisfying the following:*
  - *For every value $E_1 \in \{0,1\}^{nk_n}$ such that $\Pr_{\mathcal{E}_1}[E_1] > 0$, $\mathbf{H_{Ren}}(\mathcal{E}_2 | \mathcal{E}_1 = E_1) \geq k_n \mathbf{H}(\mathcal{D}_2|\mathcal{D}_1) - nk_n^{2/3}$.*
  - $\mathbf{L_1}(\mathcal{E}, \mathcal{D}^{k_n}) \leq 2^{-k_n^{1/3}}$.

COROLLARY 4.10. *Let k_n be an integer-valued $\mathbf{P}$-time polynomial parameter.*

- *Let $\mathcal{D} : \{0,1\}^n$ be a probability ensemble, let $m_n = k_n \mathbf{H}(\mathcal{D}) - 2nk_n^{2/3}$, and let $h : \{0,1\}^{p_n} \times \{0,1\}^{nk_n} \to \{0,1\}^{m_n}$ be a universal hash function. Let $X' \in_{\mathcal{D}^{k_n}} \{0,1\}^{k_n \times n}$ and let $Y \in_{\mathcal{U}} \{0,1\}^{p_n}$. Then*

$$\mathbf{L_1}(\langle h_Y(X'), Y \rangle, \mathcal{U}_{m_n + p_n}) \leq 2^{1 - k_n^{1/3}}.$$

- *Let $\mathcal{D}_1 : \{0,1\}^n$ and $\mathcal{D}_2 : \{0,1\}^n$ be not necessarily independent probability ensembles, and let $\mathcal{D} = \langle \mathcal{D}_1, \mathcal{D}_2 \rangle$. Let $m_n = k_n \mathbf{H}(\mathcal{D}_2|\mathcal{D}_1) - 2nk_n^{2/3}$. Let $h : \{0,1\}^{p_n} \times \{0,1\}^{nk_n} \to \{0,1\}^{m_n}$ be a universal hash function. Let $\langle X_1', X_2' \rangle \in_{\mathcal{D}^{k_n}} \{0,1\}^{k_n \times 2n}$ and let $Y \in_{\mathcal{U}} \{0,1\}^{p_n}$. Then*

$$\mathbf{L_1}(\langle h_Y(X_2'), Y, X_1' \rangle, \langle \mathcal{U}_{m_n + p_n}, X_1' \rangle) \leq 2^{1 - k_n^{1/3}}.$$

Proof. For the proof, combine Proposition 4.9, Lemma 4.8, Proposition 2.2, and Proposition 2.5. □

4.6. Pseudoentropy generator to a pseudorandom generator. Let $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a pseudoentropy generator with pseudoentropy s_n. In this subsection, we construct a pseudorandom generator based on f. We first start with two preliminary propositions. The following proposition is the computational analogue of Proposition 2.2.

PROPOSITION 4.11. *Let $\mathcal{D} : \{0,1\}^n$ and $\mathcal{E} : \{0,1\}^n$ be two probability ensembles and let $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a $\mathbf{P}$-time function ensemble. Let $\mathcal{D}$ and $\mathcal{E}$ be computationally indistinguishable. Then $f(\mathcal{D})$ and $f(\mathcal{E})$ are computationally indistinguishable. The reduction is linear-preserving.*

The following proposition first appeared in [GM84].

PROPOSITION 4.12. *Let k_n be an integer-valued $\mathbf{P}$-time polynomial parameter. Let $\mathcal{D} : \{0,1\}^{\ell_n}$ and $\mathcal{E} : \{0,1\}^{\ell_n}$ be $\mathbf{P}$-samplable probability ensembles. Let $\mathcal{D}$ and $\mathcal{E}$ be computationally indistinguishable. Then $\mathcal{D}^{k_n}$ and $\mathcal{E}^{k_n}$ are computationally indistinguishable. The reduction is weak-preserving.*

More precisely, there is a probabilistic oracle TM M with the following properties: If A is an $\mathbf{R}'_{nk_n}$-breaking adversary for distinguishing $\mathcal{D}^{k_n}$ and $\mathcal{E}^{k_n}$, then $M^{(A)}$ is an $\mathbf{R}_n$-breaking adversary for distinguishing $\mathcal{D}$ and $\mathcal{E}$, where $\mathbf{R}_n$ is essentially equal to $k_n\mathbf{R}'_{nk_n}$. It is crucial that $\mathcal{D}$ and $\mathcal{E}$ are $\mathbf{P}$-samplable because the sampling algorithms are used by M. The reduction is only weak-preserving because distinguishing $\mathcal{D}^{k_n}$ and $\mathcal{E}^{k_n}$ with respect to private inputs of length nk_n only translates into distinguishing $\mathcal{D}$ and $\mathcal{E}$ on private inputs of length n.

We now give the construction of a pseudorandom generator g from a pseudoentropy generator f.

CONSTRUCTION 4.13. *Let $f : \{0,1\}^n \to \{0,1\}^{m_n}$ be a $\mathbf{P}$-time function ensemble and let s_n be a $\mathbf{P}$-time polynomial parameter. Let $k_n = (\lceil (2m_n+1)/s_n \rceil)^3$ and $j_n = \lfloor k_n(n+s_n) - 2m_n k_n^{2/3} \rfloor$. Let $h : \{0,1\}^{p_n} \times \{0,1\}^{k_n m_n} \to \{0,1\}^{j_n}$ be a universal hash function. Let $u \in \{0,1\}^{k_n \times n}$, $y \in \{0,1\}^{p_n}$, and define $\mathbf{P}$-time function ensemble $g(u,y) = \langle h_y(f^{k_n}(u)), y\rangle$.*

THEOREM 4.14. *Let f and g be as described in Construction 4.13. Let f be a pseudoentropy generator with pseudoentropy s_n. Then g is a pseudorandom generator. The reduction is weak-preserving.*

Proof. Let $f' : \{0,1\}^{n'_n} \to \{0,1\}^{m_n}$ be the $\mathbf{P}$-time function ensemble that witnesses the pseudoentropy generator of f as guaranteed in Definition 3.7 of computational entropy; i.e., $f'(X')$ and $f(X)$ are $\mathbf{R}$-secure computationally indistinguishable and $\mathbf{H}(f'(X')) \geq n + s_n$, where $X \in_{\mathcal{U}} \{0,1\}^n$ and $X' \in_{\mathcal{U}} \{0,1\}^{n'_n}$. Let $U \in_{\mathcal{U}} \{0,1\}^{k_n \times n}$, $W \in_{\mathcal{U}} \{0,1\}^{k_n \times n'_n}$, and $Y \in_{\mathcal{U}} \{0,1\}^{p_n}$. By Proposition 4.12, $f^{k_n}(U)$ and $f'^{k_n}(W)$ are computationally indistinguishable. From Proposition 4.11, it follows that $g(U,Y) = \langle h_Y(f^{k_n}(U)), Y\rangle$ and $\langle h_Y(f'^{k_n}(W)), Y\rangle$ are computationally indistinguishable. Because $\mathbf{H}(f'(X')) \geq n + s_n$, by choice of k_n and j_n, using Corollary 4.10, it follows that $\mathbf{L}_{\mathbf{1}}(\langle h_Y(f'^{k_n}(W)), Y\rangle, \mathcal{U}_{j_n+p_n}) \leq 2^{-k_n^{1/3}}$. Thus, it follows that $g(U,Y)$ and $\mathcal{U}_{j_n+p_n}$ are computationally indistinguishable. Note that by choice of k_n, the output length $j_n + p_n$ of g is longer than its input length $nk_n + p_n$. ∎

4.7. False entropy generator to a pseudoentropy generator. Let $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a false-entropy generator with false entropy s_n. In this subsection, we construct a mildly nonuniform pseudoentropy generator based on f. An idea is to extract $\tilde{\mathbf{D}}_f(f(X))$ bits of entropy out of X without compromising the false entropy. (See section 2.3 for the definition of $\tilde{\mathbf{D}}_f$.) Let $X \in_{\mathcal{U}} \{0,1\}^n$. The major obstacles are that $\tilde{\mathbf{D}}_f$ is not necessarily a $\mathbf{P}$-time function ensemble and that f could

be a very nonregular function, and thus the variance of $\tilde{\mathbf{D}}_f(f(X))$ could be quite high as a function of X, and we cannot guess its value consistently with accuracy.

Let k_n be an integer-valued $\mathbf{P}$-time polynomial parameter and let $U \in_{\mathcal{U}} \{0,1\}^{k_n \times n}$. The intuition behind the following construction is that the false entropy of f^{k_n} is k_n times that of f and that the degeneracy of f^{k_n} is k_n times that of f. Furthermore, if k_n is large enough then, with high probability with respect to U, $\tilde{\mathbf{D}}_{f^{k_n}}(f^{k_n}(U))$ is close to the degeneracy of f^{k_n}. Thus we use a universal hash function h to extract roughly the degeneracy of $f^{k_n}(U)$ bits of entropy out of U without compromising the false entropy of $f^{k_n}(U)$.

CONSTRUCTION 4.15. *Let $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a $\mathbf{P}$-time function ensemble. Let s_n be a $\mathbf{P}$-time polynomial parameter and assume for simplicity that $s_n \leq 1$. Let $\mathbf{e}_n$ be an approximation of $\mathbf{H}(f(X))$ to within an additive factor of $s_n/8$, where $X \in_{\mathcal{U}} \{0,1\}^n$. Fix $k_n = \lceil (4n/s_n)^3 \rceil$ and $j_n = \lceil k_n(n - \mathbf{e}_n) - 2nk_n^{2/3} \rceil$. Let $h : \{0,1\}^{p_n} \times \{0,1\}^{nk_n} \to \{0,1\}^{j_n}$ be a universal hash function. For $u \in \{0,1\}^{k_n \times n}$ and $r \in \{0,1\}^{p_n}$, define $\mathbf{P}$-time function ensemble*

$$g(\mathbf{e}_n, u, r) = \langle f^{k_n}(u), h_r(u), r \rangle.$$

LEMMA 4.16. *Let f and g be as described in Construction 4.15. Let f be a false-entropy generator with false entropy s_n. Then g is a mildly nonuniform pseudoentropy generator with pseudoentropy 1. The reduction is weak-preserving.*

Proof. Let $Z \in_{\mathcal{U}} \{0,1\}^{j_n}$. First, note that $\mathbf{H}(X|f(X)) = n - \mathbf{H}(f(X)) = n - \mathbf{e}_n$. From this and Corollary 4.10 (letting $X_1 = f(X)$, $X_2 = X$ in the corollary), it follows that $\mathbf{L_1}(g(\mathbf{e}_n, U, R,), \langle f^{k_n}(U), Z, R \rangle) \leq 2^{-k_n^{1/3}}$.

We now prove that $g(\mathbf{e}_n, U, R)$ has computational entropy at least $p_n + nk_n + 1$. Let $\mathcal{D} : \{0,1\}^{\ell_n}$ be the $\mathbf{P}$-samplable probability ensemble such that $\mathcal{D}$ and $f(X)$ are computationally indistinguishable and such that

$$\mathbf{H}(\mathcal{D}) \geq \mathbf{H}(f(X)) + s_n.$$

Since $\mathcal{D}$ and $f(X)$ are computationally indistinguishable, $\langle f^{k_n}(U), Z, R \rangle$ and $\langle \mathcal{D}^{k_n}, Z, R \rangle$ are computationally indistinguishable by Proposition 4.12, which together with the first claim implies that $g(\mathbf{e}_n, U, R)$ and $\langle \mathcal{D}^{k_n}, Z, R \rangle$ are computationally indistinguishable. Now,

$$\mathbf{H}(\mathcal{D}^{k_n}, Z, R) \geq k_n \cdot (\mathbf{H}(f(X)) + s_n) + j_n + p_n \geq k_n(\mathbf{e}_n + 7s_n/8) + j_n + p_n,$$

and because by choice of k_n and j_n this is at least $p_n + nk_n + 1$. Thus g has computational entropy at least $p_n + nk_n + 1$, and the lemma follows. □

4.8. Mildly nonuniform to a uniform pseudorandom generator.

PROPOSITION 4.17. *Let $\mathbf{a}_n$ be any value in $\{0, \ldots, k_n\}$, where k_n is an integer-valued $\mathbf{P}$-time polynomial parameter. Let $g : \{0,1\}^{\lceil \log(k_n) \rceil} \times \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a $\mathbf{P}$-time function ensemble, where $\ell_n > nk_n$. Let $x' \in \{0,1\}^{k_n \times n}$ and define $\mathbf{P}$-time function ensemble $g'(x') = \oplus_{i=1}^{k_n} g(i, x'_i)$. Let g be a mildly nonuniform pseudorandom generator when the first input is set to $\mathbf{a}_n$. Then g' is a pseudorandom generator. The reduction is weak-preserving.*

Proof. Let $X \in_{\mathcal{U}} \{0,1\}^n$, $X' \in_{\mathcal{U}} \{0,1\}^{k_n \times n}$, and $Z \in_{\mathcal{U}} \{0,1\}^{\ell_n}$. Suppose there is an adversary A that has distinguishing probability

$$sp_n(A) = |\Pr[A(g'(X')) = 1] - \Pr[A(Z) = 1]|.$$

We describe an oracle TM M such that, for all $i = 1, \ldots, k_n$, $M^{(A)}(i)$ has $sp_n(A)$ distinguishing probability for $g(i, X)$ and Z. For all i, the running time for $M^{(A)}(i)$ is the running time for A plus the time to compute the output of g on $k_n - 1$ inputs. This works with respect to all i, in particular when $i = \mathbf{a}_n$, from which the result follows.

For each $i = 1, \ldots, k_n$, $M^{(A)}(i)$ works as follows. On input u (and i), $M^{(A)}(i)$ randomly generates $x'_1, \ldots, x'_{i-1}, x'_{i+1}, \ldots, x'_{k_n} \in_{\mathcal{U}} \{0,1\}^n$ and computes $v = \oplus_{j \neq i} g(j, x'_j) \oplus u$. Then $M^{(A)}(i)$ runs A on input v and outputs $A(v)$. By the nature of $\oplus$, if u is chosen randomly according to Z, then $M^{(A)}(i) = 1$ with probability $\Pr[A(Z) = 1]$, whereas if u is chosen randomly according to $g(i, X)$, then $M^{(A)}(i) = 1$ with probability $\Pr[A(g'(X')) = 1]$. Thus, for each value of i, $M^{(A)}(i)$ has distinguishing probability $sp_n(A)$ for $g(i, X)$ and Z. □

Note that it may be the case that, for most fixed values of $i \in \{1, \ldots, k_n\}$, $g(i, X)$ is completely predictable. On the other hand, even if there is a value $\mathbf{a}_n$ for each n such that $g(\mathbf{a}_n, X)$ is pseudorandom, the value of $\mathbf{a}_n$ may not be **P**-time computable. This is exactly the case when the lemma is useful; i.e., it is useful to transform the mildly nonuniform pseudorandom generator g into a pseudorandom generator g'.

Note that in the given construction the length of the output of g' on inputs of length nk_n is $\ell_n > nk_n$, and thus g' stretches the input to a string of strictly greater length.

This reduction is only weak-preserving, and the reason is the usual one; i.e., the breaking adversary for $g'(X')$ on inputs of length nk_n is transferred into a breaking adversary for $g(i, X)$ on inputs of length only n.

If g in Proposition 4.17 does not satisfy the property that $\ell_n > nk_n$, then for each fixed i we can use Proposition 3.6 to stretch the output of $g(i, x)$ (viewed as a function of x) into a string of length longer than nk_n and then exclusive-or together the stretched outputs.

4.9. Summary. Putting together the results in this section, we have

- a reduction from a one-way permutation to a pseudorandom generator (from subsection 4.2);
- a reduction from a one-to-one one-way function to a pseudorandom generator(combining subsections 4.3 and 4.6);
- a reduction from a pseudoentropy generator to a pseudorandom generator (from subsection 4.6);
- a reduction from a false-entropy generator to a pseudorandom generator (combining subsections 4.7, 4.6, and 4.8).

5. Extracting entropy from one-way functions. In this section we show how to construct a pseudoentropy generator from any one-way function f with the additional property that the number of inverses of f can be computed in polynomial time; i.e., the function $\tilde{\mathbf{D}}_f$ is a **P**-time function ensemble. Combined with the results summarized in subsection 4.9, this gives a construction of a pseudorandom generator from a one-way function with this property.

One of the reasons for giving the first construction is because it illustrates some of the additional ideas needed for our construction of a false-entropy generator from any one-way function. A general one-way function f does not necessarily have the property that $\tilde{\mathbf{D}}_f$ is a **P**-time function ensemble, and considerably more effort is needed to construct a pseudorandom generator from it. In the next section, we describe how to construct a false-entropy generator from any one-way function. Combined with the

results summarized in subsection 4.9, this gives a construction of a pseudorandom generator from any one-way function.

5.1. One-way function with approximable preimage sizes to a pseudoentropy generator. To see where we get into trouble with the construction given in Proposition 4.5, suppose $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ is a $2^{n/4}$-regular one-way function, and let $X, R \in_{\mathcal{U}} \{0,1\}^n$ and $\beta \in_{\mathcal{U}} \{0,1\}$. Then, although $\langle f(X), R, X \odot R\rangle$ and $\langle f(X), R, \beta\rangle$ are computationally indistinguishable, $\mathbf{H}(f(X), R, X \odot R)$ is only about $7n/4 + 1$, and thus we have lost about $n/4$ bits of the input entropy through the application of f. Similarly, although $X \odot R$ is hidden given $\langle f(X), R\rangle$, it is also almost completely statistically uncorrelated.

The way to overcome these problems is to create a new function which is the original one-way function concatenated with the degeneracy of the function number of bits hashed out of its input to regain the lost entropy. Then Proposition 4.5 can be applied to the new function to obtain a pseudoentropy generator. We first show how to construct a pseudoentropy generator in the case when $\tilde{\mathbf{D}}_f$ is a $\mathbf{P}$-time function ensemble.

CONSTRUCTION 5.1. *Let $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a $\mathbf{P}$-time function ensemble and suppose that $\tilde{\mathbf{D}}_f$ is a $\mathbf{P}$-time function ensemble. Let $h : \{0,1\}^{p_n} \times \{0,1\}^n \to \{0,1\}^{n+2}$ be a universal hash function. For $x \in \{0,1\}^n$ and $y \in \{0,1\}^{p_n}$, define $\mathbf{P}$-time function ensemble*

$$f'(x,y) = \langle f(x), h_y(x)_{\{1,\ldots,\tilde{\mathbf{D}}_f(f(x))+2\}}, y\rangle.$$

LEMMA 5.2. *Let f and f' be as described in Construction* 5.1.

(1) *Let f be a one-way function. Then f' is a one-way function. The reduction is poly-preserving.*

(2) *Let $X \in_{\mathcal{U}} \{0,1\}^n$ and $Y \in_{\mathcal{U}} \{0,1\}^{p_n}$. Then $\mathbf{H}(f'(X,Y)) \geq n + p_n - 1/2$.*

Proof of Lemma 5.2(1). Suppose adversary A inverts $f'(X,Y)$ with probability δ_n in time T_n. We prove that the following oracle TM M using A on input $z = f(x)$ finds $x' \in \mathrm{pre}_f(z)$ with probability at least $\delta_n^3/128$ when $x \in_{\mathcal{U}} \{0,1\}^n$.

Description of $M^{(A)}(z)$.
Compute $\tilde{\mathbf{D}}_f(z)$.
Choose $\alpha \in_{\mathcal{U}} \{0,1\}^{\tilde{\mathbf{D}}_f(z)+2}$.
Choose $y \in_{\mathcal{U}} \{0,1\}^{p_n}$.
If $A(z,\alpha,y)$ outputs x' with $f(x') = z$ then output x'.

Let $j_n = 2\lceil \log(2/\delta_n)\rceil$. For all $z \in \mathrm{range}_f$, for all $y \in \{0,1\}^{p_n}$, define random variable

$$\beta_{z,y} = h_y(W)_{\{1,\ldots,\tilde{\mathbf{D}}_f(z)-j_n\}},$$

where $W \in_{\mathcal{U}} \mathrm{pre}_f(z)$. Then the probability that there is a $\gamma \in \{0,1\}^{2+j_n}$ such that A inverts f on input $\langle f(X), \langle \beta_{f(X),Y}, \gamma\rangle, Y\rangle$ is at least δ_n.

Fix $z \in \mathrm{range}_f$, and let $\beta'_z \in_{\mathcal{U}} \{0,1\}^{\tilde{\mathbf{D}}_f(z)-j_n}$. By Lemma 4.8,

$$\mathbf{L_1}(\langle \beta_{z,Y}, Y\rangle, \langle \beta'_z, Y\rangle) \leq \delta_n/2.$$

Therefore, the probability that there is a $\gamma \in \{0,1\}^{2+j_n}$ such that A inverts f on input $\langle f(X), \langle \beta'_{f(X)}, \gamma\rangle, Y\rangle$ is at least $\delta_n/2$. If we choose $\gamma \in_{\mathcal{U}} \{0,1\}^{2+j_n}$, we have

that the probability that A inverts $f(X)$ on input $\langle f(X), \langle \beta'_{f(X)}, \gamma\rangle, Y\rangle$ is at least

$$2^{-(2+j_n)} \cdot \frac{\delta_n}{2} \geq \frac{\delta_n^3}{128}.$$

Note that this is the input distribution in the call to A within $M^{(A)}$. Note also that the run time of $M^{(A)}$ is dominated by the time to run A. Thus, the time–success ratio of $M^{(A)}$ for inverting f' is about $128T_n/\delta_n^3$.

Proof of Lemma 5.2(2). Fix $z \in \text{range}_f$ and let $x, x' \in \text{pre}_f(z)$ such that $x \neq x'$. From the properties of a universal hash function,

$$\Pr[h_Y(x)_{\{1,\ldots,\tilde{\mathbf{D}}_f(z)+2\}} = h_Y(x')_{\{1,\ldots,\tilde{\mathbf{D}}_f(z)+2\}}] = 2^{-(\tilde{\mathbf{D}}_f(z)+2)} \leq \frac{1}{4 \cdot \sharp\text{pre}_f(z)}.$$

By calculating the Renyi entropy it follows that

$$\mathbf{H}(f'(X,Y)) \geq -\log\left(\frac{5}{4} \cdot 2^{-n+p_n}\right) = n + p_n + 2 - \log(5).$$

The result follows since $\log(5) \leq 5/2$. □

COROLLARY 5.3. *Let f, h, and f' be as described in Construction* 5.1. *Let $r \in \{0,1\}^n$ and define $\mathbf{P}$-time function ensemble $g(x,y,r) = \langle f'(x,y), r, x \odot r\rangle$. Let f be a one-way function. Then g is a pseudoentropy generator with pseudoentropy* $1/2$. *The reduction is poly-preserving.*

Proof. The proof is the same as the proof of Proposition 4.5. Let $X, R \in_{\mathcal{U}} \{0,1\}^n$, $Y \in_{\mathcal{U}} \{0,1\}^{p_n}$, and $\beta \in_{\mathcal{U}} \{0,1\}$. From Lemma 5.2 (1) and Proposition 4.3 it follows that $g(X,Y,R)$ and $\langle f'(X,Y), R, \beta\rangle$ are computationally indistinguishable, where the reduction is poly-preserving. From Lemma 5.2 (2) it follows that $\mathbf{H}(f'(X,Y), R, \beta) \geq 2n + p_n + 1/2$. On the other hand, the input entropy to $g(X,Y,R)$ is $2n + p_n$, and thus it follows that g has pseudoentropy $1/2$. □

THEOREM 5.4. *A pseudorandom generator can be constructed from a one-way function f where $\tilde{\mathbf{D}}_f$ is a $\mathbf{P}$-time function ensemble. The reduction is weak-preserving.*

Proof. For the proof, combine Construction 5.1 with Construction 4.13, and use Corollary 5.3 and Theorem 4.14. □

The following theorem, an easy corollary of Theorem 5.4, was previously obtained by [GKL93] using a different construction and proof techniques.

THEOREM 5.5. *Let $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$ be a σ_n-regular one-way function, where σ_n is a $\mathbf{P}$-time polynomial parameter. Then a pseudorandom generator can be constructed from f. The reduction is weak-preserving.*

Proof. Note that in this case $\tilde{\mathbf{D}}_f(f(x)) = \lceil \log(\sigma_n) \rceil$ for all $x \in \{0,1\}^n$. Furthermore, $\lceil \log(\sigma_n) \rceil \in \{0, \ldots, n\}$. Using this, combining Construction 5.1 with Construction 4.13, and using Corollary 5.3 and Theorem 4.14 yield a mildly nonuniform pseudorandom generator. Then Proposition 4.17 shows how to construct a pseudorandom generator from this. □

Based on the ideas presented above, [Luby96, Theorems 10.1 and 9.3] gives versions of Theorems 5.4 and 5.5 where the reduction is poly-preserving when the security parameter is $\mathbf{P}$-time computable.

6. Any one-way function to a false-entropy generator.

6.1. Finding determined hidden bits. The final step in the general construction of a pseudorandom generator from a one-way function is to construct a false-entropy generator from any one-way function. This is the technically most difficult part of this paper. This construction uses some of the ideas from Construction 5.1. Let

$$f : \{0,1\}^n \to \{0,1\}^{\ell_n} \tag{6.1}$$

be a one-way function and let

$$h : \{0,1\}^{p_n} \times \{0,1\}^n \to \{0,1\}^{n+\lceil \log(2n) \rceil} \tag{6.2}$$

be a universal hash function. Similar to Construction 5.1, for $x \in \{0,1\}^n$, $i \in \{0,\dots,n-1\}$, and $r \in \{0,1\}^{p_n}$, define **P**-time function ensemble

$$f'(x,i,r) = \langle f(x), h_r(x)_{\{1,\dots,i+\lceil \log(2n) \rceil\}}, i, r \rangle. \tag{6.3}$$

Note that from Lemma 5.2, the restricted function $f'(x, \tilde{\mathbf{D}}_f(f(x)), r)$ is an almost one-to-one one-way function, except that this is not necessarily a **P**-time function ensemble since $\tilde{\mathbf{D}}_f$ may not be a **P**-time function ensemble, and this is the main difficulty we must overcome.

Let $X \in_{\mathcal{U}} \{0,1\}^n$, $R \in_{\mathcal{U}} \{0,1\}^{p(n)}$, $Y \in_{\mathcal{U}} \{0,1\}^n$, and $\beta \in_{\mathcal{U}} \{0,1\}$. From the proof of Lemma 5.2 and Corollary 5.3, we claim and formalize below that if $i \le \tilde{\mathbf{D}}_f(f(X))$, then a time limited adversary cannot distinguish $X \odot Y$ from β given Y and $f'(X,i,R)$.

Let

$$\mathcal{T} = \{\langle x,i\rangle | x \in \{0,1\}^n, i \in \{0,\dots,\tilde{\mathbf{D}}_f(f(x))\}\},$$
$$\overline{\mathcal{T}} = \{\langle x,i\rangle | x \in \{0,1\}^n, i \in \{\tilde{\mathbf{D}}_f(f(x))+1,\dots,n-1\}\}.$$

LEMMA 6.1. *Let $W = \langle \tilde{X}, \tilde{I} \rangle \in_{\mathcal{U}} \mathcal{T}$, $R \in_{\mathcal{U}} \{0,1\}^{p(n)}$, $Y \in_{\mathcal{U}} \{0,1\}^n$, and $\beta \in_{\mathcal{U}} \{0,1\}$. Let f be a one-way function. Then*

$$\langle f'(W,R), \tilde{X} \odot Y, Y \rangle \text{ and } \langle f'(W,R), \beta, Y \rangle$$

are computationally indistinguishable. The reduction is poly-preserving.

Proof. Let A be an $\mathbf{R}'$-breaking adversary for distinguishing the two distributions. Then A is also an $\mathbf{R}'$-breaking adversary for hidden bit $\tilde{X} \odot Y$ given $\langle f'(W,R), Y \rangle$. Then, from Proposition 4.2, there is an oracle TM M' such that $M'^{(A)}$ is an $\mathbf{R}''$-breaking adversary for inverting $f'(W,R)$, where $\mathbf{R}''(n) = n^{\mathcal{O}(1)} \cdot \mathbf{R}'(n)^{\mathcal{O}(1)}$. Finally, we use the same idea as in Lemma 5.2; i.e., the success probability of $M'^{(A)}$ on input $\langle f(x), \alpha, i, R \rangle$ for $\alpha \in_{\mathcal{U}} \{0,1\}^{i+\lceil \log(2n) \rceil}$ is at least inverse polynomial in the success probability of $M'^{(A)}$ on input $f'(x,i,R)$ for each fixed $\langle x,i \rangle \in \mathcal{T}$. Consider the following oracle TM N: N^A on input $f(x)$ chooses $i \in_{\mathcal{U}} \{0,\dots,n-1\}$, $\alpha \in_{\mathcal{U}} \{0,1\}^{i+\lceil \log(2n) \rceil}$, and $r \in_{\mathcal{U}} \{0,1\}^{p_n}$ and runs $M'^{(A)}$ on input $\langle f(x), \alpha, i, r \rangle$. Since $\Pr[\langle x,i \rangle \in \mathcal{T}] \ge 1/n$ when $i \in_{\mathcal{U}} \{0,\dots,n-1\}$, it follows that $N^A(f(X))$ produces an inverse with probability at least $1/n$ times the probability $M'^{(A)}(f'(W,R))$ produces an inverse. ∎

If $i \ge \tilde{\mathbf{D}}_f(f(X))$, then X is almost completely determined by $f'(X,i,R)$, and thus $X \odot Y$ is almost completely determined by $f'(X,i,R)$ and Y.

The interesting case is when $i = \tilde{\mathbf{D}}_f(f(X))$, in which case, from Lemma 6.1, the adversary is unable to distinguish $X \odot Y$ from β given Y and $f'(X, i, R)$, and yet from Lemma 5.2(2), $X \odot Y$ is almost completely determined by $f'(X, i, R)$ and Y. It is from this case that we can extract a little bit of false entropy.

6.2. Construction and main theorem. We now describe the construction of a false-entropy generator g based on f'. Let

$$k_n \geq 125n^3. \tag{6.4}$$

Part of the construction is to independently and randomly choose k_n sets of inputs to f' and concatenate the outputs. In particular, let $X' \in_{\mathcal{U}} \{0,1\}^{k_n \times n}$, $I' \in_{\mathcal{U}} \{0,1\}^{k_n \times \lceil \log(n) \rceil}$, $R' \in_{\mathcal{U}} \{0,1\}^{k_n \times p_n}$. Part of the construction is then $f'^{k_n}(X', I', R')$.

Let $I \in_{\mathcal{U}} \{0, \ldots, n-1\}$, let

$$\mathbf{p}_n = \Pr[I \leq \tilde{\mathbf{D}}_f(f(X))], \tag{6.5}$$

and let

$$m_n = k_n \mathbf{p}_n - 2k_n^{2/3}. \tag{6.6}$$

We show later that it is sufficient to have an approximation of $\mathbf{p}_n$ to within an additive factor of $1/n$ for the entire construction to work. We need this to be able to claim that g described below is mildly nonuniform. For now we assume we have the exact value of $\mathbf{p}_n$. Let $Y' \in_{\mathcal{U}} \{0,1\}^{k_n \times n}$. The value of k_n is chosen to be large enough so that with high probability it is the case that $I'_j \leq \tilde{\mathbf{D}}_f(f(X'_j))$ for at least m_n of the k_n possible values of j, and in this case, from Lemma 6.1, $X'_j \odot Y'_j$ looks like a random bit to a time limited adversary given Y'_j and $f'(X'_j, I'_j, R'_j)$.

The problem is that we don't know for which set of m_n values of j the bit $X'_j \odot Y'_j$ looks random to a time limited adversary. Instead, the idea is to hash m_n bits out of all k_n such bits and release the hashed bits. The intuition is that these m_n hashed bits will look random to a time limited adversary, even though there are really at most $(\mathbf{p}_n - 1/n)k_n$ bits of randomness left in these k_n bits after seeing Y' and $f'^{k_n}(X', I', R')$, and thus there are approximately $m_n - (\mathbf{p}_n - 1/n)k_n \approx n^2$ bits of false entropy. Let

$$h' : \{0,1\}^{p'_n} \times \{0,1\}^{k_n} \to \{0,1\}^{m_n} \tag{6.7}$$

be a universal hash function, let $U \in_{\mathcal{U}} \{0,1\}^{p'_n}$, and define $\mathbf{P}$-time function ensemble

$$\begin{aligned} &g(\mathbf{p}_n, X', Y', I', R', U) \\ &= \langle h'_U(\langle X'_1 \odot Y'_1, \ldots, X'_{k_n} \odot Y'_{k_n} \rangle), f'^{k_n}(X', I', R'), U, Y' \rangle. \end{aligned} \tag{6.8}$$

THEOREM 6.2. *Let f be a one-way function and g be as described above in* (6.1)–(6.8). *Then g is a mildly nonuniform false-entropy generator with false entropy $10n^2$. The reduction is weak-preserving.*

Proof. Let $Z \in_{\mathcal{U}} \{0,1\}^{m_n}$, and let

$$\begin{aligned} \mathcal{D} &= \langle h'_U(\langle X'_1 \odot Y'_1, \ldots, X'_{k_n} \odot Y'_{k_n} \rangle), f'^{k_n}(X', I', R'), U, Y' \rangle, \\ \mathcal{E} &= \langle Z, f'^{k_n}(X', I', R'), U, Y' \rangle. \end{aligned}$$

Note that $\mathcal{D}$ is the distribution of the output of g, and $\mathcal{E}$ is the same except that the m_n output bits of h' have been replaced by random bits. Lemma 6.4 shows that $\mathbf{H}(\mathcal{E}) \geq \mathbf{H}(\mathcal{D}) + 10n^2$. Corollary 6.6 shows that if f is a one-way function, then we have that $\mathcal{D}$ and $\mathcal{E}$ are computationally indistinguishable, where the overall reduction is weak-preserving. □

What remain to prove Theorem 6.2 are the proofs of Lemmas 6.4 and 6.5 of the next subsection. (Corollary 6.6 follows immediately from Lemmas 6.5 and 6.1.) Before we turn to this, we state the main result of this paper based on Theorem 6.2.

THEOREM 6.3. *There are one-way functions iff there are pseudorandom generators.*

Proof. That pseudorandom generators imply one-way functions follows from [Levin87]. The converse now follows from Theorem 6.2 and the results are summarized in subsection 4.9. □

6.3. The main lemmas.

LEMMA 6.4. $\mathbf{H}(\mathcal{E}) \geq \mathbf{H}(\mathcal{D}) + 10n^2$.

Proof. The entropy of $\mathcal{D}$ and $\mathcal{E}$ excluding the first m_n bits is exactly the same. The additional entropy in the first m_n bits of $\mathcal{E}$ is equal to m_n. An upper bound on the additional entropy in the first m_n bits of $\mathcal{D}$ is the additional entropy in $\langle X'_1 \odot Y'_1, \ldots, X'_{k_n} \odot Y'_{k_n} \rangle$. For each $j \in \{1, \ldots, k_n\}$ where $I'_j < \tilde{\mathbf{D}}_f(f(X'_j))$, the amount of entropy added by $X'_j \odot Y'_j$ is at most 1. On the other hand, under the condition that $I'_j \geq \tilde{\mathbf{D}}_f(f(X'_j))$, $X'_j \odot Y'_j$ is determined by $\langle f'(X'_j, I'_j, R'_j), Y'_j \rangle$ with probability at least $1 - 1/2n$, and thus the additional entropy under this condition is at most $1/2n$. Since $I'_j < \tilde{\mathbf{D}}_f(f(X'_j))$ with probability $\mathbf{p}_n - 1/n$, it follows that the additional entropy added by $X'_j \odot Y'_j$ is at most $\mathbf{p}_n - 1/2n$. Therefore, the additional entropy in the first m_n bits of $\mathcal{D}$ is at most $k_n(\mathbf{p}_n - 1/2n) = m_n + 2k_n^{2/3} - k_n/2n < m_n - 10n^2$ by choice of k_n. □

LEMMA 6.5. *Let A be an adversary with distinguishing probability*

$$\delta_n = \Pr[A(\mathcal{D}) = 1] - \Pr[A(\mathcal{E}) = 1]$$

for $\mathcal{D}$ and $\mathcal{E}$. (We assume without loss of generality that $\Pr[A(\mathcal{D}) = 1] > \Pr[A(\mathcal{E}) = 1]$.) Let $W = \langle \tilde{X}, \tilde{I} \rangle \in_{\mathcal{U}} \mathcal{T}$, $R \in_{\mathcal{U}} \{0,1\}^{p(n)}$, $Y \in_{\mathcal{U}} \{0,1\}^n$, and $\beta \in_{\mathcal{U}} \{0,1\}$. There is an oracle TM M such that $M^{(A)}$ distinguishes between

$$\langle f'(W, R), \tilde{X} \odot Y, Y \rangle \text{ and } \langle f'(W, R), \beta, Y \rangle$$

with probability at least $\delta_n/(16k_n)$. The running time of $M^{(A)}$ is polynomial in the running time of A.

The proof of Lemma 6.5 is the most technically involved in this paper. Before proving this lemma, we give the main corollary to this lemma, and then we give some motivation for the proof of the lemma.

COROLLARY 6.6. *Let f be a one-way function. Then $\mathcal{D}$ and $\mathcal{E}$ are computationally indistinguishable. The reduction is weak-preserving.*

Proof. For the proof, combine Lemma 6.1 with Lemma 6.5. □

We now give some intuition to the proof of Lemma 6.5. The oracle TM $M^{(A)}$ will use a nonstraightforward hybrid of distributions argument to be able to distinguish the two distributions in the statement of the lemma. To give some intuition about this nonstraightforward hybrid, we first describe a related straightforward hybrid argument that we do not know how to implement efficiently.

Consider the following distribution. For $j \in \{1, \ldots, k_n\}$, let $C_j = 1$ with probability $\mathbf{p}_n$ and $C_j = 0$ with probability $1 - \mathbf{p}_n$. For all j, if $C_j = 1$ then let $\langle \tilde{X}'_j, \tilde{I}'_j \rangle \in_{\mathcal{U}} \mathcal{T}$, and if $C_j = 0$ then let $\langle \tilde{X}'_j, \tilde{I}'_j \rangle \in_{\mathcal{U}} \overline{\mathcal{T}}$. Let R', Y', and U be as defined previously. If these random variables are used to define a distribution using the same construction as used to define $\mathcal{D}$, with $\langle \tilde{X}'_j, \tilde{I}'_j \rangle$ replacing $\langle X'_j, I'_j \rangle$, then the distribution is $\mathcal{D}$, except that it is described in a slightly different way. Now, suppose this distribution is altered as follows: if $C_j = 1$, then change the jth input bit of h_U from $\tilde{X}'_j \odot Y'_j$ to $B_j \in_{\mathcal{U}} \{0, 1\}$. Call this distribution $\mathcal{D}'$.

From Lemma 6.1 intuitively it should be the case that a time limited adversary should not be able to distinguish $\mathcal{D}$ from $\mathcal{D}'$. On the other hand, it is not hard to see using Lemma 4.8 that the statistical distance between $\mathcal{D}'$ and $\mathcal{E}$ is exponentially small in n. Thus, if adversary A can distinguish between $\mathcal{D}$ and $\mathcal{E}$, we should be able to use this to distinguish $\langle f'(W, R), \tilde{X} \odot Y, Y \rangle$ and $\langle f'(W, R), \beta, Y \rangle$ as in the statement of Lemma 6.5.

The question is whether we can really prove that $\mathcal{D}'$ is computationally indistinguishable from $\mathcal{D}$. Toward resolving this question, consider the following family of hybrid distributions. For all $j \in \{0, \ldots, k_n\}$, let $\mathcal{F}^{(j)}$ be the hybrid distribution between $\mathcal{D}$ and $\mathcal{E}$, which is the same as $\mathcal{D}'$ up to position j and the same as $\mathcal{D}$ thereafter; i.e., it is the same as $\mathcal{D}$ except that for all $i \leq j$, if $C_i = 1$ then change the ith input bit of h_U from $\tilde{X}'_i \odot Y'_i$ to $B_i \in_{\mathcal{U}} \{0, 1\}$. Then $\mathcal{F}^{(0)} = \mathcal{D}$ and $\mathcal{F}^{(k_n)} \approx \mathcal{E}$. Let $J \in_{\mathcal{U}} \{1, \ldots, k_n\}$. Then $\mathrm{E}_J[A(\mathcal{F}^{(J-1)}) - A(\mathcal{F}^{(J)})] = \delta_n / k_n$.

An inefficient oracle TM could work as follows on input $\langle f'(w, r), b, y \rangle$: the first phase chooses $j \in_{\mathcal{U}} \{1, \ldots, k_n\}$ and chooses a sample from $\mathcal{F}^{(j)}$. If $c_j = 0$, then the oracle TM produces a random bit and stops. In the more interesting case, where $c_j = 1$, it replaces the inputs corresponding to the jth position in the sample according to $f'(w, r)$ and y, and the jth input bit of h_u is set to $b \in_{\mathcal{U}} \{0, 1\}$. Then the second phase runs the adversary A on this input and outputs the bit produced by A. The distinguishing probability for this oracle TM is δ_n / k_n. The problem is that this is not an efficient oracle TM, because it may not be possible to efficiently uniformly sample from $\mathcal{T}$ and $\overline{\mathcal{T}}$ as required. However, it is possible to sample uniformly from $\{0, 1\}^n \times \{0, \ldots, n-1\}$: a $\mathbf{p}_n$ fraction of the samples will be randomly distributed in $\mathcal{T}$ and a $1 - \mathbf{p}_n$ fraction of the samples will be randomly distributed in $\overline{\mathcal{T}}$. This simple idea is used to construct the efficient adversary described below.

The efficient adversary $M^{(A)}$ described in detail in the proof of Lemma 6.5 proceeds in two phases similar to the inefficient oracle TM described above. The first phase of $M^{(A)}$ consists of k_n stages, where stage j produces a coupled pair of distributions, $\mathcal{D}^{(j)}$ and $\mathcal{E}^{(j)}$, both of which are polynomially samplable. Each stage consists of using adversary A and sampling from the distributions produced in the previous stage to produce the pair of output distributions for the current stage. Initially, $\mathcal{D}^{(0)} = \mathcal{D}$ and $\mathcal{E}^{(0)} = \mathcal{E}$, and it will turn out that $\mathcal{D}^{(k_n)} \approx \mathcal{E}^{(k_n)}$.

The first $j - 1$ positions in both $\mathcal{D}^{(j)}$ and $\mathcal{E}^{(j)}$ are already fixed in essentially the same way in $\mathcal{D}^{(j-1)}$ and $\mathcal{E}^{(j-1)}$, and these positions will be fixed the same way in $\mathcal{D}^{(j)}$ and $\mathcal{E}^{(j)}$. To fill in position j in $\mathcal{D}^{(j)}$ and $\mathcal{E}^{(j)}$, many samples of $\langle x_j, i_j \rangle$ are drawn uniformly from $\{0, 1\}^n \times \{0, \ldots, n-1\}$, and then with high probability many of them will be in $\mathcal{T}$ and many will be in $\overline{\mathcal{T}}$. We cannot directly tell for each sample whether it is in $\mathcal{T}$ or $\overline{\mathcal{T}}$. Thus, we must use another criterion to decide which of the samples to keep to fill in position j. The criterion employed is to use the sample for which the distinguishing probability of A between $\mathcal{D}^{(j)}$ and $\mathcal{E}^{(j)}$ is highest when the jth position is fixed according to the sample.

Let $\delta^{(j)} = \Pr[A(\mathcal{D}^{(j)}) = 1] - \Pr[A(\mathcal{E}^{(j)}) = 1]$. Because $\delta^{(0)} = \delta_n$ and $\delta^{(k_n)} \approx 0$, it follows that

$$\mathrm{E}_{j \in_{\mathcal{U}} \{1,\ldots,k_n\}}[\delta^{(j-1)} - \delta^{(j)}] \geq \delta_n / k_n.$$

It is because of this discrepancy between the value of $\delta^{(j)}$ and $\delta^{(j-1)}$ that f' can be inverted in the second phase.

Intuitively, stage j of the first phase works as follows. A bit c_j is chosen randomly to be one with probability $\mathbf{p}_n$ and to be zero with probability $1 - \mathbf{p}_n$. In the distribution $\mathcal{D}^{(j)}$, the jth input $\langle x'_j, i'_j, r'_j \rangle$ to ${f'}^{k_n}$ is chosen randomly, y'_j is chosen randomly, u is chosen randomly, and then the jth input bit of ${h'}_u$ is set to a random bit b_j if $c_j = 1$ and to the correct inner product bit if $c_j = 0$. In the distribution $\mathcal{E}^{(j)}$, the jth input of ${f'}^{k_n}$ is set the same way it is set in $\mathcal{D}^{(j)}$, and thus the two distributions $\mathcal{D}^{(j)}$ and $\mathcal{E}^{(j)}$ are correlated. The choice of the jth inputs is done several times (c_j is chosen only once at the beginning, i.e., it is not rechosen for each of the times) and each time the distinguishing probability of A for $\mathcal{D}^{(j)}$ and the corresponding $\mathcal{E}^{(j)}$ is approximated, and the choice that maximizes the difference between these accepting probabilities determines how $\mathcal{D}^{(j)}$ and $\mathcal{E}^{(j)}$ are finally set.

The second phase of $M^{(A)}$ chooses $j \in_{\mathcal{U}} \{1, \ldots, k_n\}$ and then uses the pair of distributions $\mathcal{D}^{(j)}$ and $\mathcal{E}^{(j)}$ produced in the first stage. The idea is to choose a random sample from both $\mathcal{D}^{(j)}$ and $\mathcal{E}^{(j)}$, modify portions of the $\mathcal{D}^{(j)}$ part according to the input to $M^{(A)}$, run A on both the modified $\mathcal{D}^{(j)}$ sample and the $\mathcal{E}^{(j)}$ sample, and, based on the outputs, produce a one bit output. The intuition is that the distinguishing probability will be $\delta^{(j)}$, which on average over all j is at least δ_n / k_n.

We now turn to the formal proof of Lemma 6.5.

Proof of Lemma 6.5. The oracle TM $M^{(A)}$ works as follows on input $\langle f'(w, r), b, y \rangle$.

Phase 1. Define $\mathcal{D}^{(0)} = \mathcal{D}$ and $\mathcal{E}^{(0)} = \mathcal{E}$. Let $B \in_{\mathcal{U}} \{0,1\}^{k_n}$. Let $\rho = \delta_n / (16 k_n)$ and $\tau = 64 n^2 / \rho$. Stage $j = 1, \ldots, k_n$ works as follows: randomly choose $c_j \in \{0,1\}$ so that $c_j = 1$ with probability $\mathbf{p}_n$. Choose $\hat{x}_1, \ldots, \hat{x}_\tau \in_{\mathcal{U}} \{0,1\}^n$ and $\hat{i}_1, \ldots, \hat{i}_\tau \in_{\mathcal{U}} \{0, \ldots, n-1\}$. For each $m \in \{1, \ldots, \tau\}$, define $w_m = \langle \hat{x}_m, \hat{i}_m \rangle$ and let $\mathcal{D}_{c_j}^{(j-1)}(w_m)$ be the same as $\mathcal{D}^{(j-1)}$ except that $\langle X'_j, I'_j \rangle$ is fixed to w_m and the jth input bit of h' is set to

$$\begin{cases} \hat{x}_m \odot Y'_j & \text{if } c_j = 0, \\ B_j & \text{if } c_j = 1. \end{cases}$$

Similarly, define $\mathcal{E}^{(j-1)}(w_m)$ to be the same as $\mathcal{E}^{(j-1)}$ except that $\langle X'_j, I'_j \rangle$ is fixed to w_m. Let

$$\delta_{c_j}^{(j-1)}(w_m) = \Pr[A(\mathcal{D}_{c_j}^{(j-1)}(w_m)) = 1] - \Pr[A(\mathcal{E}^{(j-1)}(w_m)) = 1].$$

Using A and sampling $\mathcal{O}(n/\rho^2)$ times from $\mathcal{D}_{c_j}^{(j-1)}(w_m)$ and $\mathcal{E}^{(j-1)}(w_m)$, produce an estimate $\Delta_{c_j}^{(j-1)}(w_m)$ so that

$$\Pr[|\Delta_{c_j}^{(j-1)}(w_m) - \delta_{c_j}^{(j-1)}(w_m)| > \rho] \leq 2^{-n}.$$

Let $m_0 \in \{1, \ldots, \tau\}$ be the index for which $\Delta_{c_j}^{(j-1)}(w_{m_0})$ is maximized. Set $\langle x'_j, i'_j \rangle = w_{m_0}$, $\mathcal{D}^{(j)} = \mathcal{D}_{c_j}^{(j-1)}(w_{m_0})$, $\mathcal{E}^{(j)} = \mathcal{E}^{(j-1)}(w_{m_0})$ and go to the next stage.

Phase 2. Pick $j \in_{\mathcal{U}} \{0, \ldots, k_n - 1\}$. Let $\mathcal{D}^{(j)}(w, r, b, y)$ be the distribution $\mathcal{D}^{(j)}$ except that $f'(X'_{j+1}, I'_{j+1}, R'_{j+1})$ is set to $f'(w, r)$ and the $j + 1^r$st input bit of h' is set to b and Y'_{j+1} is set to y. Let $\mathcal{E}^{(j)}(w, r, y)$ be the same as $\mathcal{E}^{(j)}$ except that $f'(X'_{j+1}, I'_{j+1}, R'_{j+1})$ is set to $f'(w, r)$ and Y'_{j+1} is set to y. Let $\beta \in_{\mathcal{U}} \{0, 1\}$, let D be a sample of $\mathcal{D}^{(j)}(w, r, b, y)$, and let E be a sample of $\mathcal{E}^{(j)}(w, r, y)$. If $A(D) = A(E)$, then output β else output $A(D)$.

We now prove that the oracle adversary $M^{(A)}$ as just described distinguishes as claimed in the lemma. Let $w = \langle x, i \rangle$, $d^{(j)}(w, r, b, y) = \mathrm{E}[A(\mathcal{D}^{(j)}(w, r, b, y))]$ and $e^{(j)}(w, r, y) = \mathrm{E}[A(\mathcal{E}^{(j)}(w, r, y))]$. Then

$$\Pr[M^{(A)}(f'(w, r), b, y) = 1] = 1/2 + (d^{(j)}(w, r, b, y) - e^{(j)}(w, r, y))/2.$$

Also, it follows directly from the definitions that

$$\mathrm{E}[d^{(j)}(w, R, x \odot Y, Y) - e^{(j)}(w, R, Y)] = \delta_0^{(j)}(w)$$

and

$$\mathrm{E}[d^{(j)}(w, R, \beta, Y) - e^{(j)}(w, R, Y)] = \delta_1^{(j)}(w).$$

Let $\epsilon^{(j)} = \mathrm{E}[\delta_0^{(j)}(W) - \delta_1^{(j)}(W)]$. Thus, the distinguishing probability of $M^{(A)}$ is

$$\begin{aligned} &\mathrm{E}[M^{(A)}(f'(W, R), \tilde{X} \odot Y, Y)] - \mathrm{E}[M^{(A)}(f'(W, R), \beta, Y)] \\ &= \mathrm{E}_j[\delta_0^{(j)}(W) - \delta_1^{(j)}(W)]/2 = \mathrm{E}_j[\epsilon^{(j)}]/2, \end{aligned}$$

where $j \in_{\mathcal{U}} \{0, \ldots, k_n - 1\}$ in the last two expectations. To prove the lemma, it is sufficient to show that $\mathrm{E}_j[\epsilon^{(j)}]/2 \geq \rho$ or, equivalently,

$$\mathrm{E}\left[\sum_{j \in \{0, \ldots, k_n - 1\}} \epsilon^{(j)}\right] \geq 2\rho k_n = \delta_n/8. \tag{6.9}$$

The expectation here is over the random choices of $M^{(A)}$ in the first phase. Let $\delta^{(j)} = \Pr[A(\mathcal{D}^{(j)}) = 1] - \Pr[A(\mathcal{E}^{(j)}) = 1]$. We prove (6.9) by showing the following below:

(a) $\mathrm{E}[\delta^{(k_n)}] \leq 2^{-n}$. The expectation is over the random choices of $M^{(A)}$ in the first phase.

(b) $\mathrm{E}[\delta^{(j)} - \delta^{(j+1)}] \leq \epsilon^{(j)} + 4\rho$. The expectation is over random choices in the $j + 1^r$st stage of Phase 1 conditional on any set of choices in the previous stages.

From (a) and (b), and because $\delta^{(0)} = \delta_n$, it follows that

$$\begin{aligned} \delta_n/2 &< \delta_n - \mathrm{E}[\delta^{(k_n)}] \\ &= \sum_{j \in \{0, \ldots, k_n - 1\}} \mathrm{E}[\delta^{(j)} - \delta^{(j+1)}] \\ &\leq 4k_n\rho + \mathrm{E}\left[\sum_{j \in \{0, \ldots, k_n - 1\}} \epsilon^{(j)}\right] \end{aligned}$$

$$= \delta_n/4 + \mathrm{E}\left[\sum_{j\in\{0,\ldots,k_n-1\}} \epsilon^{(j)}\right],$$

and this proves the bound in (6.9). Thus, it suffices to prove (a) and (b) above.

Proof of (a). Since $\Pr[c_j = 1] = \mathbf{p}_n$, applying Chernoff bounds (e.g., see [MR95]), we get that, with probability at least $1 - 2^{-n}$,

$$\sum_{j\in\{0,\ldots,k_n-1\}} c_j \geq k_n\mathbf{p}_n - k_n^{2/3} = m_n + {k_n}^{2/3}.$$

The entropy of the input to h' conditional on the rest of the bits of $\mathcal{D}^{(k_n)}$ is at least $\sum_{j\in\{0,\ldots,k_n-1\}} c_j$. So, if this sum is at least $m_n + {k_n}^{2/3}$, applying Lemma 4.8, $\mathbf{L_1}(\mathcal{D}^{(k_n)}, \mathcal{E}^{(k_n)}) \leq 2^{-n}$. Thus, $\delta^{(k_n)} = \mathrm{E}[A(\mathcal{D}^{(k_n)})] - \mathrm{E}[A(\mathcal{E}^{(k_n)})] \leq 2^{-n}$.

Proof of (b). Let $\bar{W} \in_{\mathcal{U}} \overline{\mathcal{T}}$, and recall that $W \in_{\mathcal{U}} \mathcal{T}$. Then, since the $j+1$st input of h' is always $X'_{j+1} \odot Y'_{j+1}$ in $\mathcal{D}^{(j)}$,

$$\begin{aligned}
\delta^{(j)} &= \mathbf{p}_n\mathrm{E}[\delta_0^{(j)}(W)] + (1-\mathbf{p}_n)\mathrm{E}[\delta_0^{(j)}(\bar{W})] \\
&= \mathbf{p}_n\mathrm{E}[\delta_1^{(j)}(W)] + \mathbf{p}_n(\mathrm{E}[\delta_0^{(j)}(W)] - \mathrm{E}[\delta_1^{(j)}(W)]) + (1-\mathbf{p}_n)(\mathrm{E}[\delta_0^{(j)}(\bar{W})]) \\
&= \mathbf{p}_n\mathrm{E}[\delta_1^{(j)}(W)] + \mathbf{p}_n\epsilon^{(j)} + (1-\mathbf{p}_n)(\mathrm{E}[\delta_0^{(j)}(\bar{W})]) \\
&< \epsilon^{(j)} + \mathbf{p}_n\mathrm{E}[\delta_1^{(j)}(W)] + (1-\mathbf{p}_n)(\mathrm{E}[\delta_0^{(j)}(\bar{W})]).
\end{aligned}$$

We now show that $\mathrm{E}[\delta^{(j+1)}] \geq \mathbf{p}_n\mathrm{E}[\delta_1^{(j)}(W)] + (1-\mathbf{p}_n)(\mathrm{E}[\delta_0^{(j)}(\bar{W})]) - 4\rho$, and this concludes the proof. Let $c \in \{0,1\}$ and consider stage j in Phase 1. From our choice of τ and the fact that $1/n \leq \mathbf{p}_n \leq 1 - 1/n$, it follows that, with probability at least $1 - 2^{-n}$, at least n/ρ of the w_m's are in $\mathcal{T}$, and at least n/ρ of the w_m's are in $\overline{\mathcal{T}}$. It then follows using Chernoff bounds that

$$\Pr[\max_{1\leq m\leq\tau}\{\delta_c^{(j)}(w_m)\} \geq \max\{\mathrm{E}[\delta_c^{(j)}(W)], \mathrm{E}[\delta_c^{(j)}(\bar{W})]\} - \rho]$$

is at least $1 - 2^{-n}$. Also, with probability at least $1 - 2^{-n}$, $\Delta_c^{(j)}(w_m)$ is within ρ of the corresponding $\delta_c^{(j)}(w_m)$, and thus (recalling how w_{m_0} is chosen above in stage j)

$$\begin{aligned}
\delta_c^{(j)}(w_{m_0}) &\geq \Delta_c^{(j)}(w_{m_0}) - \rho \\
&= \max_{m\in\{1,\ldots,\tau\}}\{\Delta_c^{(j)}(w_m)\} - \rho \\
&\geq \max_{m\in\{1,\ldots,\tau\}}\{\delta_c^{(j)}(w_m)\} - 2\rho \\
&\geq \max\{\mathrm{E}[\delta_c^{(j)}(W)], \mathrm{E}[\delta_c^{(j)}(\bar{W})]\} - 3\rho
\end{aligned}$$

with probability at least $1 - 3\cdot 2^{-n}$. Let $\delta_c^{(j+1)}$ be the value of $\delta^{(j+1)}$ conditional on $c_{j+1} = c$. From this we can conclude that

$$\mathrm{E}[\delta_c^{(j+1)}] \geq \max\{\mathrm{E}[\delta_c^{(j)}(W)], \mathrm{E}[\delta_c^{(j)}(\bar{W})]\} - 4\rho.$$

Since $c_{j+1} = 1$ with probability $\mathbf{p}_n$,

$$\begin{aligned}
\mathrm{E}[\delta^{(j+1)}] &= \mathbf{p}_n\mathrm{E}[\delta_1^{(j+1)}] + (1-\mathbf{p}_n)\mathrm{E}[\delta_0^{(j+1)}] \\
&\geq \mathbf{p}_n\mathrm{E}[\delta_1^{(j)}(W)] + (1-\mathbf{p}_n)(\mathrm{E}[\delta_0^{(j)}(\bar{W})]) - 4\rho. \qquad \square
\end{aligned}$$

Before we continue let us just check that a good approximation of $\mathbf{p}_n$ is sufficient. Suppose that $\mathbf{p}_n \le \tilde{\mathbf{p}}_n \le \mathbf{p}_n + \frac{1}{n}$ and do the entire construction with $\tilde{\mathbf{p}}_n$ replacing $\mathbf{p}_n$. Enlarge $\mathcal{T}$ to density $\tilde{\mathbf{p}}_n$ by making it contain some elements $\langle x, i\rangle$ with $i = \tilde{\mathbf{D}}_f(f(x))+1$. Lemma 6.1 is easily seen to remain valid, and Lemma 6.4 just becomes more true in that the entropy of $\mathcal{D}$ decreases. This implies that it is sufficient to try $\mathcal{O}(n)$ different values of $\mathbf{p}_n$.

7. A direct construction. We have shown how to construct a false-entropy generator from an arbitrary one-way function, a pseudoentropy generator from a false-entropy generator, and finally a pseudorandom generator from a pseudoentropy generator. The combinations of these constructions give a pseudorandom generator from an arbitrary one-way function as stated in Theorem 6.3. By literally composing the reductions given in the preceding parts of this paper, we construct a pseudorandom generator with inputs of length n^{34} from a one-way function with inputs of length n. This is obviously not a suitable reduction for practical applications. In this subsection, we use the concepts developed in the rest of this paper, but we provide a more direct and efficient construction. However, this construction still produces a pseudorandom generator with inputs of length n^{10}, which is clearly still not suitable for practical applications. (A sharper analysis can reduce this to n^8, which is the best we could find using the ideas developed in this paper.) The result could only be considered practical if the pseudorandom generator had inputs of length n^2, or perhaps even close to n. (However, in many special cases of one-way functions, the ideas from this paper are practical; see, e.g., [Luby96].)

The improvement in the direct construction given here comes from the observation that more than one of the reductions involves a product distribution, whereas only one product distribution is needed for the overall proof.

We start with a one-way function $f : \{0,1\}^n \to \{0,1\}^{\ell_n}$. We construct f' as in (6.3), and let $\mathbf{p}_n$ be the probability that $I \le \tilde{\mathbf{D}}_f(f(X))$ as in the previous section. Let $\mathcal{X} = \langle X, I, R\rangle$ represent the input distribution to f', and let c_n be the length of $\mathcal{X}$ and c'_n the length of $f'(\mathcal{X})$. Let $\mathbf{e}_n = \mathbf{H}(f'(\mathcal{X}))$. Let $b(\mathcal{X}, y) = x \odot y$. Set $k_n = 2000n^6$.

Intuitively, we generate pseudorandom bits as follows: let $\mathcal{X}' = \mathcal{X}^{k_n}$ and $Y' = Y^{k_n}$. We first compute $f'^{k_n}(\mathcal{X}')$ and $b^{k_n}(\mathcal{X}', Y')$. Intuitively, we are entitled to recapture

$$k_n c_n - \mathbf{H}\langle f'^{k_n}(\mathcal{X}'), b^{k_n}(\mathcal{X}', Y')\rangle$$

bits from $\mathcal{X}'$, because this is the conditional entropy left after we have computed f'^{k_n} and b^{k_n}. We are entitled to recapture $k_n\mathbf{p}_n$ bits from the $b^{k_n}(\mathcal{X}', Y')$ (since we get a hidden bit out of each copy whenever $I \le \tilde{\mathbf{D}}_f(f(X))$). Finally, we should be able to extract $\mathbf{e}_n k_n$ bits from $f'^{k_n}(\mathcal{X}')$, since $\mathbf{e}_n$ is the entropy of $f'(\mathcal{X})$. Since $b(n)$ is almost totally predictable for almost all inputs where $I \ge \tilde{\mathbf{D}}_f(f(X))$,

$$\mathbf{H}\langle f'(\mathcal{X}), b(\mathcal{X}, Y)\rangle \le \mathbf{e}_n + \mathbf{p}_n - 1/n + 1/(2n).$$

(See the proof of Lemma 6.4.) Thus, if we add up all the output bits, we are entitled to $k_n(c_n + 1/(2n))$, or $k_n/(2n)$ more bits than the input to f'^{k_n}. However, our methods of extracting entropy are not perfect, so we need to sacrifice some bits at each stage; to use Corollary 4.10, we need to sacrifice $2nk_n^{2/3}$ at each stage, so we chose k_n to satisfy $k_n/(2n) > 6nk_n{}^{2/3}$.

Formally, let $m_n = k_n(c_n - \mathbf{e}_n - \mathbf{p}_n + 1/(2n)) - 2nk_n{}^{2/3}$, $m'_n = k_n\mathbf{p}_n - 2nk_n{}^{2/3}$, and $m''_n = k_n\mathbf{e}_n - 2nk_n{}^{2/3}$. Let R_1, R_2, and R_3 be indices of hash functions so that

h_{R_1} maps $k_n c_n$ bits to m_n bits, h_{R_2} maps k_n bits to m'_n bits, and h_{R_3} maps $k_n c'_n$ bits to m''_n bits. Our construction is as follows.

CONSTRUCTION 7.1.

$$g(\mathcal{X}', Y', R_1, R_2, R_3) = \langle h_{R_1}(\mathcal{X}'), h_{R_2}(b^{k_n}(\mathcal{X}', Y')), h_{R_3}(f'^{k_n}(\mathcal{X}')), Y', R_1, R_2, R_3\rangle.$$

THEOREM 7.2. *If f is a one-way function and g is as in Construction* 7.1*, then g is a mildly nonuniform pseudorandom generator. The reduction is weak-preserving.*

Proof. It is easy to check that g outputs more bits than it inputs.

As noted above, the conditional entropy of $\mathcal{X}$ given $f'(\mathcal{X})$ and $b(\mathcal{X}, Y)$ is at least $c_n - \mathbf{e}_n - \mathbf{p}_n + (1/2n)$. Thus, from Corollary 4.10, we have that $\langle h_{R_1}(\mathcal{X}'), R_1\rangle$ is statistically indistinguishable from random bits given $\langle f'^{k_n}(\mathcal{X}'), b^{k_n}(\mathcal{X}', Y'), Y'\rangle$. Hence, $g(\mathcal{X}', Y', R_1, R_2, R_3)$ is statistically indistinguishable from

$$\langle Z_1, h_{R_2}(b^{k_n}(\mathcal{X}', Y')), h_{R_3}(f'^{k_n}(\mathcal{X}')), Y', R_1, R_2, R_3\rangle,$$

where $Z_1 \in_{\mathcal{U}} \{0,1\}^{m_n}$. Now, from Lemmas 6.5 and 6.1, it follows that $h_{R_2}(b^{k_n}(\mathcal{X}', Y'))$ is computationally indistinguishable from random bits given $\langle f'^{k_n}(\mathcal{X}'), R_2, Y'\rangle$. Thus, $g(\mathcal{X}', Y', R_1, R_2, R_3)$ is computationally indistinguishable from

$$\langle Z_1, Z_2, h_{R_3}(f'^{k_n}(\mathcal{X}')), Y', R_1, R_2, R_3\rangle,$$

where $Z_2 \in_{\mathcal{U}} \{0,1\}^{m'_n}$. Finally, from Corollary 4.10, $\langle h_{R_3}(f'^{k_n}(\mathcal{X}')), R_3\rangle$ is statistically indistinguishable from $\langle Z_3, R_3\rangle$, where $Z_3 \in_{\mathcal{U}} \{0,1\}^{m''_n}$. Thus, the output of g is computationally indistinguishable from a truly random output of the same length. □

If we use hash functions constructed as Toeplitz matrices, then $\mathcal{O}(m)$ bits are sufficient to construct a hash function on m bits and the inputs needed for the hash function is just a constant fraction of all inputs. Then the input length to g is $\mathcal{O}(nk_n) = \mathcal{O}(n^7)$.

We still need to use Proposition 4.17 to get rid of the mild nonuniformity. From the arguments above, it is clear that an approximation of both $\mathbf{e}_n$ and $\mathbf{p}_n$ that is within $1/(8n)$ of their true values is sufficient. Since $0 \le \mathbf{e}_n \le n$, and $0 \le \mathbf{p}_n < 1$, there are at most $\mathcal{O}(n^3)$ cases of pairs to consider. This means that we get a total of $\mathcal{O}(n^3)$ generators, each needing an input of length $\mathcal{O}(n^7)$. Thus the total input size to the pseudorandom generator is $\mathcal{O}(n^{10})$, as claimed.

8. Conclusions. A general problem is to characterize the conditions under which cryptographic applications are possible. By conditions we mean complexity theoretic conditions, e.g., $P \neq NP$, the existence of one-way functions, etc. Examples of cryptographic applications are private key cryptography, identification/authentication, digital signatures, bit commitment, exchanging secrets, coin flipping over the telephone, etc.

For a variety of cryptographic applications it is known that a secure protocol can be constructed from a pseudorandom generator, e.g., the work of [GGM86], [LR88], [GMR89], [Naor88], [GMW91], shows that applications ranging from private key encryption to zero-knowledge proofs can be based on a pseudorandom generator. The results presented in this paper show that these same protocols can be based on any one-way function. The paper [NY89] gives a signature scheme that can be based on any one-way permutation, and [R90] substantially improves this by basing such a scheme on any one-way function.

Using the notion of a false-entropy generator, [G89] shows that the existence of pseudorandom generators is equivalent to the existence of a pair of **P**-samplable distributions which are computationally indistinguishable but statistically very different.

The paper [IL89] provides complementary results; a one-way function can be constructed from a secure protocol for any one of a variety of cryptographic applications, including private key encryption, identification/authentication, bit commitment, and coin flipping by telephone. The paper [OW93] shows that a one-way function can be constructed from any nontrivial zero-knowledge proof protocol. Thus, secure protocols for any of these applications are equivalent to the existence of one-way functions.

The results described in this paper and the previous three paragraphs show that the existence of a one-way function is *central* to modern complexity-based cryptography.

Some applications seem unlikely to be shown possible based on any one-way function; e.g., [IR89] gives strong evidence that exchanging secrets over a public channel is an application of this type.

A fundamental issue is that of efficiency, both in size and time; the general construction we give for a pseudorandom generator based on any one-way function increases the size of the input by a large polynomial amount and thus is only weak-preserving. This is not good news for practical applications; it would be nice to have a general poly-preserving or a linear-preserving reduction.

Acknowledgments. This research evolved over a long period of time and was greatly influenced by many people. We thank Amos Fiat, Moni Naor, Ronitt Rubinfeld, Manuel Blum, Steven Rudich, Noam Nisan, Lance Fortnow, Umesh Vazirani, Charlie Rackoff, Oded Goldreich, Hugo Krawczyk, and Silvio Micali for their insights and contributions to this work. We in particular thank Charlie, Umesh, and Manuel for their advice and enthusiasm, and Oded and Hugo for exposing the fourth author to their wealth of insights on this problem. Finally, Oded's insightful comments on every aspect of earlier versions of this paper have improved the presentation tremendously.

LOCAL LABELING AND RESOURCE ALLOCATION USING PREPROCESSING*

HAGIT ATTIYA†, HADAS SHACHNAI†, AND TAMI TAMIR†

Abstract. This paper studies the power of nonrestricted preprocessing on a communication graph G, in a synchronous, reliable system. In our scenario, arbitrary preprocessing can be performed on G, after which a sequence of labeling problems has to be solved on different subgraphs of G. We suggest a preprocessing that produces an orientation of G. The goal is to exploit this preprocessing for minimizing the radius of the neighborhood around each vertex from which data has to be collected in order to determine a label. We define a set of labeling problems for which this can be done. The time complexity of labeling a subgraph depends on the topology of the graph G and is always less than $\min\{\chi(G), O((\log n)^2)\}$. On the other hand, we show the existence of a graph for which even unbounded preprocessing does not allow fast solution of a simple labeling problem. Specifically, it is shown that a processor needs to know its $\Omega(\log n/\log\log n)$-neighborhood in order to pick a label.

Finally, we derive some results for the resource allocation problem. In particular, we show that $\Omega(\log n/\log\log n)$ communication rounds are needed if resources are to be fully utilized. In this context, we define the *compact coloring* problem, for which the orientation preprocessing provides fast distributed labeling algorithm. This algorithm suggests efficient solution for the resource allocation problem.

1. Introduction.

The time required to perform certain computations in message-passing systems depends, in many cases, on the *locality* of information, i.e., the distance to which information should be forwarded. Clearly, within t communication rounds, a processor can get information only from processors located within distance t. The study of problems that are local, i.e., in which the value of a processor depends only on its local neighborhood, has attracted much attention, e.g., [13, 16, 12, 18, 11]. This study assumed that processors have no knowledge about the network topology. In many common scenarios, this is not the situation: If the same problem has to be solved many times on different subnetworks of a fixed network G, then it might be worthwhile to conduct some preliminary preprocessing on G.

We study *labeling problems*, in which each processor has to pick a label, subject to some restrictions on the labeling of the whole network. We allow arbitrary preprocessing on G. Afterward, several instances of the same labeling problem need to be solved on different subnetworks G' of G. All processors of G can participate in the algorithm when a particular subnetwork G' is labeling itself, but only the processors of G' have to pick labels. It is assumed that the system is synchronous and operates

in rounds; there is no bound on message length, and local computation is unlimited. Furthermore, we assume the system is completely reliable. The preprocessing attempts to increase the locality of the problem, that is, decrease the radius of the neighborhood a processor v needs to know in order to pick a label.

The preprocessing we present produces an orientation that assigns priorities to the processors. Later, when a processor has to compute its label in some subgraph G', it considers only processors with higher priorities. We define a parameter that quantifies the quality of these orientations, denoted by $t(G)$. $t(G)$ depends on the topology of G and it is always less than $\min\{\chi(G), O((\log n)^2)\}$.

We define *extendible labeling problems*, in which a labeled graph can be extended by an independent set of vertices to a larger labeled graph without invalidating the original labels. The maximal independent set problem and the $(\Delta+1)$-coloring problem are extendible. We suggest an efficient preprocessing on G which allows us to solve these problems within $t(G)$ rounds on any subgraph of G. We also discuss a distributed randomized preprocessing on G that takes $O((\log n)^2)$ rounds and enables us to solve these problems on any subgraph of G within $O((\log n)^2)$ rounds. This gives a distributed randomized algorithm for *compact coloring*. Bar-Noy et al. [6] have shown that this algorithm provides efficient solutions to the resource allocation problem for a large class of graphs.

We introduce a problem in which processors have to communicate with processors at a nonconstant distance, even after unbounded preprocessing. The problem is *k-dense coloring*, which is a restricted coloring problem. A coloring is k-dense if every vertex with color $c > k$ has a neighbor with color c', $c - k \leq c' \leq c - 1$. Note that validating that a coloring is k-dense requires only checking with the neighbors (i.e., processors that are at distance 1). We prove that there exists a network on which processors must know their $\Omega(\log n/\log\log n)$-neighborhood in order to pick a color. That is, for some networks, even unbounded preprocessing does not allow us to solve the problem locally.

The locality of distributed computations was first studied by Cole and Vishkin, who showed in [9] that a 3-coloring of a ring requires only the knowledge of an $O(\log^* n)$-neighborhood; this bound was shown to be tight by Linial [12]. The more general problem of computing labels locally was studied by Naor and Stockmeyer [16] in the case where no preprocessing is allowed. They present local algorithms for some labeling problems whose validity can be checked locally, and they also show that randomization does not help in making a labeling problem local. In follow-up work, Mayer, Naor, and Stockmeyer [15] consider the amount of initial symmetry-breaking needed in order to solve certain labeling problems.

Other, less related, works studied coloring and the maximal independent set problem in graphs (e.g., Goldberg, Plotkin, and Shannon [11], Szegendy and Vishwanathan [18], and Panconesi and Srinivasan [17]). Another use of graph-theoretic techniques for local algorithms appears in works on sparse partitions [2, 14]. In these works, preprocessing is applied in order to partition a graph into graphs with small diameters. Given such a partition, it is possible to solve the problem locally for each subgraph and then compose the resulting labels. See also the survey by Linial [13], which describes other works on locality in distributed computation.

Preprocessing is very helpful in the context of ongoing problems, such as *resource allocation* [7], where jobs with conflicting resource requirements have to be scheduled efficiently. An instance of the problem is a *communication graph* G. The vertices represent processors, and there is an edge between a pair of processors if they may

compete on a resource. The resource requirements of a processor may vary, and current requirements are represented by a dynamic *conflict graph* C, where the vertices are processors waiting to execute their jobs, and there is an edge between two processors that currently compete on some resource. (Note that $C \subseteq G$.)

We consider a restricted version of the resource allocation problem: A schedule is *k-compact* if, for every waiting processor p_i in every k rounds, either p_i runs or there exists some conflicting neighbor of p_i which runs. This guarantees that p_i is delayed only because one of its conflicting neighbors is running.

The lower bound for the k-dense coloring problem implies that no preprocessing enables a distributed k-compact schedule within less than $\Omega(\log n / \log\log n)$ rounds. We present a distributed algorithm which is μ-compact, where μ is a known upper bound on the execution time of a job; the algorithm uses preprocessing that produces a t-orientation. The response time of our algorithm is $\delta_i \mu + t(G)$, with δ_i the degree of p_i in C.

The resource allocation problem was introduced by Chandy and Misra [7]. In their definition, known as the *dining philosophers* problem, the resource requirements of the processors are static. We consider the dynamic version of the problem, known as the *drinking philosophers* problem. Several algorithms for the drinking philosophers problem are known. Without preprocessing, the best algorithm to date [5] achieves $O(\delta_i \mu + \delta \log n)$ response time, where δ_i is the degree of p_i in C and δ is the maximal degree in C. In contrast, by using preprocessing, our algorithm achieves a response time of $\delta_i \mu + t(G)$. An algorithm that relies on preprocessing (which colors the communication graph to induce priorities between processors) and achieves a response time of $O(\delta^2 \mu)$ was presented in [8].

The usage of a preprocessing that induces an orientation of the conflict graph was first considered in [7]; Barbosa and Gafni [4] present theoretical results concerning the maximal concurrence which may be achieved using orientation. Like our algorithms, in these papers the orientation is used to induce priorities between processors to decrease the waiting time of processors. However, in this work the quality of a graph orientation is measured as the maximal *directed* length in the graph, which corresponds to the maximal *waiting chain* for a particular processor. In contrast, our measure for the quality of an orientation is the maximal *undirected* distance between two processors that are connected by a directed path. This allows us to combine the orientation preprocessing with a local distributed labeling algorithm, such that the resulting waiting time for each processor is bounded by a small constant, although the length of the maximal directed path may be equal to the size of the graph.

The rest of this paper is organized as follows. In section 2 we give some basic definitions. In section 3 we study labeling problems: we derive a lower bound for a labeling problem that also holds for the case where *unbounded* preprocessing is allowed, we introduce the t-orientation preprocessing, and we prove that this preprocessing provides efficient labeling algorithms for certain problems. Section 4 deals with the resource allocation problem: we present the lower bound for k-compact resource allocation as well as a distributed algorithm for μ-compact resource allocation using t-orientation. We conclude in section 5 with some problems, which are left open by our work.

2. Preliminaries.

Model of computation. We consider a distributed message-passing system with n processors $p_1, \ldots, p_n$. The network connecting the processors is modeled as a graph where vertices correspond to processors and there is a bidirectional communication

link between every pair of adjacent processors.

We assume that the system is synchronous and operates in rounds. That is, at the beginning of round $k+1$, each processor receives all the messages sent to it by its neighbors at the end of round k; after some local computation, the processor may send a message to (some or all of) its neighbors. There is no bound on message length, and local computation is unlimited.

Graph-theoretic notions. Consider a directed/undirected graph $G = (V, E)$. For any two vertices $v, u \in V$, let $d(u, v)$ be the undirected distance between v and u in G; note that even if G is directed, the distance is measured on the shortest undirected path in G between v and u. The diameter of the G, $diam(G)$, is $\max_{v,u \in V} d(v, u)$. Given a vertex v, the *r-neighborhood* of v for some integer $r \geq 0$ is the subgraph of G induced by all vertices u such that $d(v, u) \leq r$. The *girth* of G, $g(G)$, is the length of the shortest cycle in G.

A set of vertices $V' \subseteq V$ is an *independent* if no two vertices in V' are adjacent. An independent set is *maximal* if it is not contained in a strictly larger independent set. A *c-coloring* of G is a partition of V into c independent sets. Equivalently, a c-coloring is a mapping $\Psi : V \to \{1, \ldots, c\}$ specifying for each vertex its *color*, such that two adjacent vertices do not have the same color. The *chromatic number* of G, $\chi(G)$, indicates the smallest number c for which G has a c-coloring.

Given a graph G, denote by $\delta(v)$ the degree of the vertex v, i.e., the number of vertices adjacent to it; let Δ be the maximal degree of a vertex in G.

If G is directed, then a vertex v is a *source* in G if it has no incoming edges.

Labeling problems. A *labeling* of a graph $G = (V, E)$ with some alphabet Σ is a mapping $\lambda : V \to \Sigma$. A *labeling problem* $\mathcal{L}$ is a set of labelings. Intuitively, this is the set of labelings that satisfy certain requirements. For example, c-coloring is a labeling problem with $\Sigma = \{1, \ldots, c\}$ and the requirement that for every edge $\langle v, u \rangle$, $\lambda(v) \neq \lambda(u)$.

A distributed algorithm solves a labeling problem $\mathcal{L}$ if, after performing some rounds of communication, each processor picks a label such that the labeling of the graph is in $\mathcal{L}$.

3. Labeling problems.

3.1. A lower bound. We present a labeling problem and prove that every distributed algorithm for solving this problem requires at least $\Omega(\log n / \log \log n)$ rounds, even with unbounded preprocessing. The problem is a restricted coloring problem, where adjacent vertices should have different labels, and, in addition, the labels have to be close to each other. Formally, we have the following definition.

DEFINITION 3.1. *A coloring is* k-dense *for a fixed $k \geq 1$ if every vertex with color $c > k$ has a neighbor with color $c' \in [c - k, c - 1]$.*

Intuitively, in a k-dense coloring of a graph, every vertex with color $c > k$ has at least one neighbor with a smaller color which is relatively close to c; k captures the maximal gap between the colors. Given a labeling of a graph, every vertex v with color c can validate its label by examining its 1-neighborhood: the label is legal if v has no neighbor with label c, and if $c > k$, then v has a neighbor with color c', $c - k \leq c' \leq c - 1$. (This means that k-dense coloring is 1-checkable, in the terminology of [16].)

We now present our lower bound result. The proof shows a graph G and a vertex $v \in G$, such that v must pick different labels in two different subgraphs G_1 and G_2 of G, but v has the same $\frac{1}{2k}(\log n / \log \log n)$-neighborhoods in G_1 and G_2.

The proof uses graphs which have both a large chromatic number and a large girth; the existence of these graphs is guaranteed by the following theorem.

THEOREM 3.2 (Erdös [10]). *For any $n \geq 1$ and ℓ, $4 < \ell < n$, there exists a graph G with n vertices such that $\chi(G) > \frac{1}{2}(\log n)$ and $g(G) > \frac{1}{2}(\log n/\log \ell)$.*

The following is immediate when taking $\ell = \lfloor \log n \rfloor$ in the Theorem 3.2.

COROLLARY 3.3. *For any $n \geq 1$ and $2 \leq k < \frac{1}{2}\log n(1 - 1/\log\log n)$, there exists a graph G with n vertices such that $\chi(G) > \frac{1}{2}(\log n/\log\log n) + k$ and $g(G) > \frac{1}{k}(\log n/\log\log n)$.*

The next lemma shows that the maximal color in a k-dense coloring of a tree is a lower bound on the tree's depth.

LEMMA 3.4. *In every k-dense coloring of a tree T, if there is a vertex v with color c, then there is a vertex at distance at least $\frac{c}{k} - 1$ from v.*

Proof. Since the coloring is k-dense, v must have a neighbor v_1, such that $c(v_1) \geq c - k$. Similarly, v_1 must have a neighbor v_2, such that $c(v_2) \geq c - 2k$, and in general v_{i-1} must have a neighbor v_i with color at least $c - ik$. The path $v, v_1, v_2, \ldots, v_{i-1}$ can be extended to v_i as long as $i \leq (c-1)/k$. Therefore, the length of the path is at least $\frac{c}{k} - 1$. Clearly, this is a simple path. Since T is a tree, there is no other simple path from v to $v_{\lceil \frac{c}{k} \rceil - 1}$. Therefore, $d(v, v_{\lceil \frac{c}{k} \rceil - 1}) \geq \frac{c}{k} - 1$, which proves the lemma. □

We can now prove the main theorem of this section.

THEOREM 3.5. *For every $k > 1$ and $n \geq 1$ such that $k < \frac{1}{2}\log n(1 - 1/\log\log n)$, there is a communication graph G of size n and a subgraph G' of G such that every distributed algorithm that finds a k-dense coloring of G' requires at least $\frac{1}{2k}(\log n/\log\log n)$ rounds.*

Proof. Assume, by way of contradiction, that there exists an algorithm A which finds a k-dense coloring within R rounds such that $R < \frac{1}{2k}(\log n/\log\log n)$. Clearly, within R rounds a vertex knows only about its R-neighborhood, as we see in the following proposition.

PROPOSITION 3.6. *Let G_1 and G_2 be two subgraphs of G, and let v be a vertex of G. If the R-neighborhood of v in G_1 is identical to the R-neighborhood of v in G_2, then v picks the same label when executing A on G_1 and on G_2.*

By Corollary 3.3, there exists a graph G of size n such that $\chi(G) > kR + k$ and $g(G) > 2R$. By this assumption, A finds a k-dense coloring of any subgraph G' of G within R rounds. In particular, A finds a k-dense coloring of G itself. Since $\chi(G) > kR + k$ there exists a vertex v with color $c > kR + k$. Let G' be the R-neighborhood of v in G. Since $g(G) > 2R$ and G' includes only vertices at distance R from v, it follows that G' is a tree. Clearly, v has the same R-neighborhood in G and G'. Therefore, by Proposition 3.6, v is colored c also in G'.

Since G' is a tree, Lemma 3.4 implies that there is vertex at distance $\lceil \frac{c}{k} \rceil - 1$ from v. Hence, $R \geq \frac{c}{k} - 1$. On the other hand, since $c > kR + k$, it follows that $R < \frac{c}{k} - 1$, which is a contradiction. □

Remark. For stating the lower bound in Theorem 3.5 we assume that $k > 1$. For $k = 1$, the existence of a graph G_1 with n vertices, $\chi(G_1) > \frac{1}{2}(\log n/\log\log n) + 1$, and $g(G_1) > \frac{1}{2}(\log n/\log\log n)$, implies, in a similar way, that every distributed algorithm that finds a 1-dense coloring requires at least $\frac{1}{4}(\log n/\log\log n)$ rounds.

3.2. Efficient labeling using *t*-orientation. In this section we define a class of labeling problems, and show a specific preprocessing which allows us to solve them efficiently.

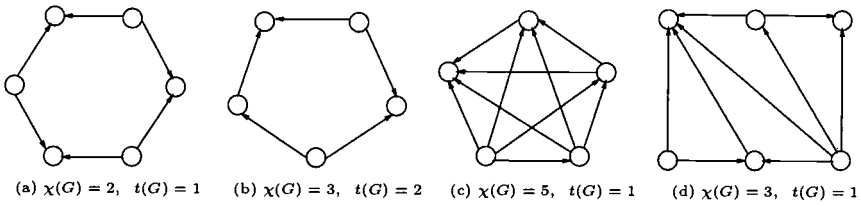

FIG. 3.1. *Optimal t-orientations of some graphs.*

Let $G' \subseteq G$ be a graph that has to be labeled. Clearly, within $diam(G')+1$ rounds, each processor $v \in G'$ can learn G', and therefore can pick a label.[1] Intuitively, the preprocessing presented in this section orients the edges between neighboring processors, thereby assigning priorities in such a way that a processor is close to vertices it is oriented to (i.e., with higher priority). We show that for some problems (including coloring and maximal independent set) there exists a labeling algorithm in which a processor's label depends only on the vertices with higher priority. This allows the processor to communicate only with these vertices, which by assumption are relatively close.

3.2.1. *t*-orientation of graphs. We require an acyclic orientation in which every vertex is close to vertices that have a directed path to it.

DEFINITION 3.7. *A* t-orientation *of a graph G is an acyclic orientation (that is, without any directed cycles) of G, such that for every two vertices v and u, if there is a directed path from v to u in the directed graph, then $d(u, v) \leq t$. The* orientation number *of a graph G, denoted by $t(G)$, is the smallest t such that G has a t-orientation.*

Note that for every graph G, topological sorting implies an acyclic orientation, and therefore, we have the following proposition.

PROPOSITION 3.8. *For every graph G, $t(G) \leq diam(G)$.*

However, in most cases we can do much better. For example, any c-coloring of G implies a $(c-1)$-orientation by directing each edge (v, u) from v to u if and only if $color(v) < color(u)$. This is a $(c-1)$-orientation since all directed paths have length at most c. This implies the following proposition.

PROPOSITION 3.9. *For every graph G, $t(G) < \chi(G)$.*

For example, the orientation number of a ring is 1 if the ring is of even length and 2 if the ring is of odd length (using a 2-coloring or 3-coloring, respectively). Figure 3.1 includes examples of optimal t-orientations for several graphs.

Recall that our definition of t-orientation requires only that the *undirected* distance between any two vertices u and v that are connected by a directed path is bounded by t. We note that Proposition 3.9 holds also for a stronger definition that requires the *directed* distance between u and v to be bounded by t. Therefore, we

[1] Note that if G' is not connected, then $diam(G') = \infty$. For some labeling problems, such as coloring, it is sufficient for a processor to know its connected component in G' in order to pick a label. For these problems, the number of rounds needed in order to label G' is $diam(G'_m)+1$, where G'_m is the connected component with maximal diameter in G'. For other labeling problems, such as finding the number of processors in G', the whole graph G' should be known. For this kind of problem, $diam(G)$ rounds are needed in order to label G'.

expect that the upper bound of $\chi(G)$, as given in Proposition 3.9, can be tightened.[2]

A simple way to construct an optimal t-orientation is by a preprocessing that collects the complete graph topology to some node and then locally finds the best orientation. (This relies on the fact that local computation power is unbounded.) It requires $O(diam(G))$ communication rounds. In the following we show that while a moderate computational effort may not yield an optimal orientation, it allows us to find orientations that are good, in the sense that t is always bounded by a small polylogarithm of n.

THEOREM 3.10. *For every graph G of size n, it is possible to find an $O((\log n)^2)$-orientation of G by a randomized distributed algorithm within $O((\log n)^2)$ rounds.*

Proof. Every graph can be partitioned into $O(\log n)$ subgraphs $V_1, V_2, \ldots$, such that the diameter of every connected component in these subgraphs is at most $O(\log n)$. This is done by the randomized distributed algorithm of Linial and Saks [14] within $O((\log n)^2)$ rounds. At the end of the algorithm, every vertex knows the identity, i, of the subgraph V_i to which it belongs, and the ids of the vertices that belong to its connected component in V_i.

This partition can be used to construct an $O((\log n)^2)$-orientation of G within $O(\log n)$ (additional) rounds as follows. Every connected component of every subgraph is oriented acyclically (e.g., by centralized topological sorting) within $O(\log n)$ rounds. Edges whose endpoints are at different subgraphs are oriented according to the ids of the subgraphs; that is, an edge $\langle v, u\rangle$, with $v \in V_i$ and $u \in V_j$, $i < j$, is oriented $v \to u$.

Clearly, this orientation is acyclic. Furthermore, assume that there is a directed path from v to u. That path visits the subgraphs defined for G in a strictly increasing order; therefore, it visits each subgraph at most once. Since the diameter of every connected component in each subgraph is at most $O(\log n)$, we have $d(v, u) = O((\log n)^2)$. □

3.2.2. Extendible labeling problems. We now define a class of labeling problems for which the t-orientation preprocessing is helpful. These are problems for which the labeling can be constructed by extending the part of the graph which is already labeled.

DEFINITION 3.11. *Let $G = (V, E)$ be a graph. An* extension *of G is a graph $G' = (V \cup V', E \cup E')$, where $V \cap V' = \emptyset$ and $E' \subseteq V \times V'$. Note that V' is an independent set in G'.*

DEFINITION 3.12. *Let $\mathcal{L}$ be a labeling problem. $\mathcal{A}$ is* an extension labeling algorithm for $\mathcal{L}$ *if, for every graph G with a labeling in $\mathcal{L}$ and every extension to $G' = (V \cup V', E \cup E')$, $\mathcal{A}$ gives a label for each $v \in V'$ such that*

- *the labeling of G' is in $\mathcal{L}$;*
- *for each $v \in V'$, the label of v depends only on the connected components of G to which v is connected—that is, the labeling of v is independent of the labeling of other vertices in V' and of the other components of G.*

DEFINITION 3.13. *A labeling problem is* extendible *if it has a deterministic extension labeling algorithm.*

We now argue that some important labeling problems are extendible. Consider the following extension algorithm for a labeling φ, denoted by A_m:

For every $v \in V'$, $\varphi(v) = 0$ if and only if v has a neighbor $u \in V$ with $\varphi(u) = 1$.

[2] The possible gap between $t(G)$ and $\chi(G)$ is well demonstrated in a clique G of n vertices, where $\chi(G) = n$ and $t(G) = 1$.

PROPOSITION 3.14. *Finding a maximal independent set is an extendible labeling problem.*

Proof. Let $G = (V, E)$ be a graph which is legally labeled; i.e., every vertex $v \in V$ has a label $\varphi(v) \in \{0, 1\}$ such that the vertices with $\varphi(v) = 1$ form a maximal independent set of G. Let $G' = (V \cup V', E \cup E')$ be an extension of G. A_m is clearly an extension algorithm for the maximal independent set problem. ∎

PROPOSITION 3.15. *$(\Delta + 1)$-coloring is an extendible labeling problem.*

Proof. Let $G = (V, E)$ be a graph which is legally colored; i.e., every vertex $v \in V$ has a label $\psi(v) \in \{1, \ldots, \Delta + 1\}$, and for every $c \in \{1, \ldots, \Delta + 1\}$ all vertices with $\psi(v) = c$ form an independent set. Let $G' = (V \cup V', E \cup E')$ be an extension of G. The following is clearly an extension algorithm for this problem:

For every $v \in V$, define $\psi(v)$ to be the smallest $c \in \{1, \ldots, \delta(v) + 1\}$ such that no neighbor u of v has $\psi(u) = c$. Such c exists because v has $\delta(v)$ neighbors, and therefore at most $\delta(v)$ colors are used by v's neighbors. For each $v \in V'$, $\delta(v) \leq \Delta$; thus G' is $(\Delta + 1)$-colored. ∎

An extension algorithm that labels a vertex with the smallest color not used by its neighbors is suitable for the k-dense coloring problem. Therefore, we have the following proposition.

PROPOSITION 3.16. *For every $k \geq 1$, the k-dense coloring problem is extendible.*

3.2.3. An algorithm for extendible labeling problems. Here we show the following theorem.

THEOREM 3.17. *Given a t-orientation of a graph G, for any extendible labeling problem $\mathcal{L}$ there is a distributed algorithm that solves $\mathcal{L}$ within t rounds on every subgraph of G.*

Proof. Let $\mathcal{L}$ be an extendible labeling problem, and let $\mathcal{A}$ be a deterministic extension algorithm for $\mathcal{L}$. We describe a distributed algorithm that solves $\mathcal{L}$ on any subgraph of G within t rounds.

Let G be a graph with an acyclic orientation, and let G' be a subgraph of G. Note that the t-orientation of G induces an acyclic orientation of G'. Consider a partition of G' into layers $L_0(G')$, $L_1(G')$, ..., $L_{max}(G')$, where max is the length of the longest directed path in G'. For any $v \in G'$, $v \in L_i(G')$ if and only if the longest directed path to v in G' is of length i. Note that this partition is well defined since G is finite and the orientation is acyclic.

CLAIM 3.1. *Each layer $L_i(G')$ forms an independent set.*

Proof. Let v and u be neighbors in G', such that $v \to u$. Every directed path to v can be extended to u, and in particular the longest path to v can be extended to u. Thus, u belongs to a layer higher than v's layer. ∎

For every vertex $v \in G'$, let $G'_{in}(v)$ be the subgraph of G' induced by v and all the vertices in G' that have a directed path to v. For each $v \in G'$, we partition $G'_{in}(v)$ into the layers $L_0(G'_{in}(v))$, $L_1(G'_{in}(v))$, ..., $L_k(G'_{in}(v))$, where k is the length of the longest directed path in $G'_{in}(v)$. This partition has the following properties:

- If $u \in G'_{in}(v)$, then every directed path to u in G' is in $G'_{in}(v)$; that is, $G'_{in}(u) \subseteq G'_{in}(v)$.
- In particular, if $u \in G'_{in}(v)$, then the longest directed path to u is in $G'_{in}(v)$; therefore, for every i and v, $L_i(G'_{in}(v)) \subseteq L_i(G')$.
- Consequently, if $u \in G'_{in}(v)$, then for every i, $L_i(G'_{in}(u)) \subseteq L_i(G'_{in}(v))$.

The algorithm consists of two stages. In the first stage, information is collected. Specifically, during the first t rounds, every vertex $v \in G'$ distributes to distance t the

$i \leftarrow 0$

repeat
    Execute $\mathcal{A}$(Already-labeled , $L_i(G'_{in}(v))$)
    Already-labeled $\leftarrow$ Already-labeled $\cup L_i(G'_{in}(v))$
    $i \leftarrow i + 1$
until v is labeled.

FIG. 3.2. *The labeling algorithm: code for $v \in G'$.*

fact that it belongs to G'. All the vertices of G participate in this stage. Since G is t-oriented, each vertex $v \in G'$ knows $G'_{in}(v)$ within t rounds.

In the second stage of the algorithm, every vertex $v \in G'$ uses $\mathcal{A}$, the extension algorithm, to label $G'_{in}(v)$. The labeling is computed in iterations. In the ith iteration, v labels $L_i(G'_{in}(v))$. The code for $v \in G'$ for this stage appears in Figure 3.2.

We denote by $\mathcal{A}(H, V)$ the application of $\mathcal{A}$ when the labeled graph $H \subseteq G'_{in}(v)$ is extended by an independent set V and all the edges which connect H and V in G'. On each iteration of the **repeat** loop, an additional layer of $G'_{in}(v)$ is labeled. Denote by $label_v(u)$ the label assigned by v to $u \in G'_{in}(v)$, when v executes $\mathcal{A}$. In particular, $label_v(v)$ is the label that v assigns to itself.

The next lemma shows that the labels v assigns to vertices in $G'_{in}(v)$ are identical to the labels those vertices assign to themselves.

LEMMA 3.18. *If $u \in G'_{in}(v)$, then $label_u(u) = label_v(u)$.*

Proof. We show, by induction on $i \geq 0$, that $label_u(u) = label_v(u)$ for every $u \in (G'_{in}(v) \cap L_i(G'))$.

The base case is $i = 0$. Note that $L_0(G')$ contains the sources of G'. Consider some $u \in L_0(G')$ and note that $label_u(u)$ is determined in the first iteration, when u executes $\mathcal{A}(\emptyset, u)$. Every v such that $u \in G'_{in}(v)$ assigns a label to u in the first iteration by executing $\mathcal{A}(\emptyset, L_0(G'_{in}(v)))$. There may be some other vertices in addition to u in $L_0(G'_{in}(v))$, but since the label of u depends only on its connected component which includes only u, and since $\mathcal{A}$ is deterministic, $label_u(u) = label_v(u)$.

For the induction step, assume that the claim holds for all vertices in $L_i(G')$ for $i < j$. Consider $u \in L_j(G')$, and note that $label_u(u)$ is determined in the jth iteration, when u executes $\mathcal{A}(\bigcup_{i<j} L_i(G'_{in}(u)), u)$. Every v such that $u \in G'_{in}(v)$ assigns $label_v(u)$ when it executes $\mathcal{A}(\bigcup_{i<j} L_i(G'_{in}(v)), L_j(G'_{in}(v)))$. The connected component of u in $\bigcup_{i<j} L_i(G'_{in}(v))$ is $\bigcup_{i<j} L_i(G'_{in}(u))$. By the induction assumption, all the vertices of both $\bigcup_{i<j} L_i(G'_{in}(u))$ and $\bigcup_{i<j} L_i(G'_{in}(v))$ are labeled identically by v and by u. Thus, since $\mathcal{A}$ is deterministic, $label_u(u) = label_v(u)$. □

The entire labeling of G' consists of the labels $label_v(v)$. By Lemma 3.18, it is identical to the labeling produced by $\mathcal{A}$ when applied to G' sequentially, layer by layer. Thus, it is in $\mathcal{L}$. □

By Theorem 3.10, we have the following corollary.

COROLLARY 3.19. *For every graph G of size n, after a randomized preprocessing that takes $O((\log n)^2)$ rounds, any extendible labeling problem can be solved on every $G' \subseteq G$ within $O((\log n)^2)$ rounds.*

Note that for the preprocessing suggested in the above results we assume that n is known in advance.

Proposition 3.16 and Theorem 3.17 imply that for every graph G and a fixed $k \geq 1$, a k-dense coloring of every $G' \subseteq G$ can be found distributively within t rounds,

assuming the existence of a t-orientation of G. In particular, by Corollary 3.19, there is a randomized distributed preprocessing that takes $O((\log n)^2)$ rounds, and enables us to find a k-dense coloring of every $G' \subseteq G$, within $O((\log n)^2)$ rounds. Note that the lower bound for k-dense coloring, from Theorem 3.5, is $\Omega(\log\, n/\log\log\, n)$.

Since the k-dense coloring problem is extendible, Theorem 3.5 and Theorem 3.17 imply the following corollary.

COROLLARY 3.20. *Let $t(n)$ be the maximal $t(G)$ among graphs of size n. Then $t(n) = \Omega(\log\, n/\log\log\, n)$.*

4. Resource allocation. In this section we study the resource allocation problem. This problem, in contrast to labeling problems, has an "ongoing" nature and has to be repetitively solved for each instance. However, as will be shown below, we employ techniques and results that were developed for labeling problems.

An instance of the resource allocation problem is a *communication graph* G, where the vertices represent processors, and there is an edge between any pair of processors that may compete on some resource. The resource requirements of a processor may vary. The current requirements are represented formally in a dynamic *conflict graph* C, where the vertices are processors waiting to execute their jobs, and there is an edge between two processors that compete on some resource. Clearly, $C \subseteq G$. We denote the degree of processor p_i in the conflict graph C by δ_i and the maximum number of rounds required to complete a job by μ.

An algorithm for the resource allocation problem decides when each waiting processor can use the resources and execute its job; it should satisfy the following properties:

1. *Exclusion:* No two conflicting jobs are executed simultaneously. (This is a safety property.)
2. *No starvation:* The request of any processor is eventually granted. (This is a liveness property.)

The *response time* for a request is the number of rounds that elapse from the processor's request to use resources until it executes the job. A good algorithm should minimize the response time. We also consider the following property, which guarantees better exploitation of the resources and reduces the average response time.

DEFINITION 4.1. *An algorithm for the resource allocation is* k-compact *for every waiting processor p_i if in every k rounds either p_i runs or some conflicting neighbor of p_i runs.*

In section 4.1 we prove by reduction to the lower bound for k-dense coloring (which was proved earlier) that for every $k \geq 1$ there is no efficient distributed algorithm which is k-compact. Specifically, we show a lower bound of $\Omega(\lg n/\lg\lg n)$ on the response time of any resource allocation algorithm that is k-compact for any $k \geq 1$. Section 4.2 presents the compact coloring problem, which is used later for compact resource allocation. In section 4.3 we present a distributed μ-compact algorithm for resource allocation, which uses the t-orientation preprocessing.

4.1. A lower bound for k-compact resource allocation. We show that given a conflict graph C and $k \geq 1$, any k-compact resource allocation algorithm can be used to label C such that the labeling is a $\lceil \frac{k}{\mu} \rceil$-dense coloring. Together with the lower bound proved in Theorem 3.5 this implies the lower bound for compact resource allocation.

Let G be a communication graph and let C be a conflict graph. The *one-shot resource allocation problem* is to schedule the resources for C in a way that satisfies the safety and liveness conditions. A *slow* execution for a given set of jobs is an

execution where each job uses the resources for exactly μ rounds. (This terminology is borrowed from Rhee [19].)

For a specific algorithm, consider a slow execution with respect to the one-shot resource allocation problem. That is, the algorithm has to schedule only one "batch" of jobs, each of which needs the resources for the same running time, μ. Clearly, this is a special case of the resource allocation problem and any lower bound for this case applies to the general problem.

Let t_0 be the first round in which some processor starts executing its job; the no-starvation property guarantees the existence of t_0. Associate with each processor p_i a label $\lambda(p_i)$ such that $\lambda(p_i) = c$ if and only if p_i starts executing its job in the interval $[t_0 + (c-1)\mu\,,\, t_0 + c\mu)$. Such an interval exists by the no-starvation property, and hence the labeling is well defined.

CLAIM 4.1. *The labeling λ is a $(\lceil \frac{k}{\mu} \rceil + 2)$-dense coloring of the conflict graph.*

Proof. By the mutual exclusion property, and since the execution is slow, λ is a legal coloring.

Assume now that $\lambda(p_i) = c > \lceil \frac{k}{\mu} \rceil + 2$. That is, p_i starts executing its job in the interval $[t_0 + (c-1)\mu\,,\, t_0 + c\mu)$. Since the algorithm is k-compact, in every k rounds, either p_i starts executing its job, or there exists some conflicting processor p_j which executes its job. In the latter case, there is a conflicting processor, p_j, which starts executing its job in the interval $[t_0 + (c-2)\mu - k\,,\, t_0 + (c-1)\mu)$. By the definition of λ, p_j is labeled c', $(c-2) - \frac{k}{\mu} \leq c' \leq c - 1$, as needed. □

Together with Theorem 3.5, this implies the following theorem.

THEOREM 4.2. *For every $k \geq 1$, there is no k-compact distributed algorithm for the resource allocation problem with response time less than $\frac{\mu}{2k+6\mu}(\log n / \log\log n)$.*

4.2. Compact coloring. In this section we introduce the compact coloring problem and its properties. In the next section, we use these properties to show that processors joining the conflict graph C at different times in our algorithm agree on the same colors for processors in C.

DEFINITION 4.3. *A coloring is* compact *if every vertex v with color j has neighbors with all colors $1, \ldots, j-1$.*

Note that every compact coloring is 1-dense. On the other hand, consider a graph that is a line of length 4, whose vertices are colored $1, 2, 3, 4$. This is a 1-dense coloring which is not compact.

For a given compact coloring, let C_i denote the set of vertices colored with i; since the coloring is compact, C_i is a maximal independent set in $V \setminus \bigcup_{j<i} C_j$. Consider the following extension algorithm for a labeling Ψ, denoted by A_c: For every $v \in V$, define $\Psi(v)$ to be the smallest number c such that no neighbor u of v has $\Psi(u) = c$. Clearly the following lemma holds.

LEMMA 4.4. *Compact coloring is an extendible labeling problem.*

The next lemma claims that if we remove all the vertices colored 1 by A_c from a graph G, we obtain a graph G' such that, for every vertex v in G', if v was colored c in G, then v is colored $c-1$ when applying A_c to G'.

LEMMA 4.5. *Let $G = (V, E)$ be a graph, and let $\Psi : V \to N$ be the compact coloring of G produced by A_c. Let $G' = (V', E')$ be the graph obtained by deleting all the vertices for which $\Psi(v) = 1$ from G, and let $\Psi' : V' \to N$ be the compact coloring of G' produced by A_c. Then for every $v \in V'$, $\Psi'(v) = \Psi(v) - 1$.*

Proof. To prove the lemma, we consider the algorithm A_m^* which iteratively executes the maximal independent set (MIS) extension algorithm, A_m, on a given graph G (see Figure 4.1). Recall that A_m labels a vertex v with 1 if v has no neighbor

$V_1 = V$
$E_1 = E$
$i \leftarrow 1$
Repeat
    Execute A_m on $G_i = (V_i, E_i)$
    $\mathrm{M}IS_i \leftarrow \mathrm{M}IS(G_i)$ produced by A_m
    For every $v \in \mathrm{M}IS_i$, $\Phi(v) \leftarrow i$
    $V_{i+1} \leftarrow V_i \setminus \mathrm{M}IS_i$
    $E_{i+1} \leftarrow E_i \setminus \{(u,v) \mid u, v \in \mathrm{M}IS_i\}$
    $i \leftarrow i + 1$
Until G_i is empty

FIG. 4.1. *Algorithm* A_m^*.

from a lower layer which is labeled 1; otherwise, v is labeled with 0. A_m^* is useful for studying A_c, due to the following claim.

CLAIM 4.2. *For every graph G, the labeling Φ produced by A_m^* is identical to the labeling Ψ produced by A_c.*

Proof. Recall that, given an acyclically oriented graph G, a vertex v is in the ith layer, $L_i(G)$, if and only if the longest directed path to v is of length i. The proof is by induction on the layers of G.

For the base case, consider a vertex $v \in L_0(G)$. Note that $L_0(G)$ contains the sources of G. Both A_c and A_m^* color every source v with 1.

For the induction step, assume that the claim holds for all vertices in $L_j(G), j < i$, and let $v \in L_i(G)$. Assume that $\Phi(v) = k$, that is, $v \in \mathrm{M}IS_k$. Consider the neighbors of v from lower layers at the end of iteration k of A_m^* in which v joins $\mathrm{M}IS_k$. By A_c, v is colored k if and only if v has neighbors from lower layers with all colors $\{1, \ldots, k-1\}$, and no neighbor from lower layers which is colored k.

Since every iteration of A_m^* produces a maximal independent set, v has neighbors from lower layers in $\mathrm{M}IS_1, \mathrm{M}IS_2, \ldots, \mathrm{M}IS_{k-1}$. By the induction hypothesis, this implies that v has neighbors which are colored $1, \ldots, k-1$ by A_c. By A_m, v joins $\mathrm{M}IS_k$ if and only if v has no neighbor from lower layers in $\mathrm{M}IS_k$. Thus, by the induction hypothesis, v has no neighbor from a lower layer which is colored k by A_c. Therefore, $\Psi(v) = k$, as needed. □

Proof of Lemma 4.4. By Claim 4.2, $\Phi(v) = \Psi(v)$ for every $v \in G$. In particular, $\mathrm{M}IS_1(G)$ is the set of vertices with $\Psi(v) = 1$. Remove $\mathrm{M}IS_1(G)$ from G. By Claim 4.2, the resulting graph is G'. Let Φ' be the coloring produced by applying A_m^* to G'.

Consider the execution of A_m^* on G. By A_m^*, $\mathrm{M}IS_1(G)$ is removed from G after the first iteration of that execution. Since the resulting graph is G', the remainder of this execution on G is identical to the execution of A_m^* on G'. That is, the execution of A_m^* on G' is identical to the suffix of the execution on G starting from the second iteration. Hence, $v \in \mathrm{M}IS_i(G)$ if and only if $v \in \mathrm{M}IS_{i-1}(G')$. This implies that for every $v \in V'$, $\Phi'(v) = \Phi(v) - 1$. By Claim 4.2, for every $v \in V'$, $\Psi'(v) = \Psi(v) - 1$. □

By repeatedly removing the set of vertices which are colored 1, we obtain the following corollary.

COROLLARY 4.6. *Let $G = (V, E)$ be a graph, and let $\Psi : V \to N$ be the compact coloring of G, produced by the extension algorithm A_c. For a fixed integer $z \geq 0$, let $G' = (V', E')$ be the graph obtained by deleting all the vertices for which $\Psi(v) \in$*

$\{1, \ldots, z\}$ from G, and let $\Psi' : V' \to N$ be the compact coloring of G' produced by A_c. Then for every $v \in V'$, $\Psi'(v) = \Psi(v) - z$.

This corollary is used in our resource allocation algorithm to show that processors joining the conflict graph C at different times agree on the same colors for processors in C.

4.3. A distributed μ-compact resource allocation algorithm. In this section we describe a μ-compact distributed algorithm for the resource allocation problem whose response time is $\delta_i\mu + 2(t(G)+1)$, where $t(G)$ is the orientation number of the communication graph G.

We assume that μ is known in advance and processors can fix *running phases*, each consisting of μ rounds. In addition, processors submit their requests for resources in *entrance phases*, each consisting of $t(G)+1$ rounds. A processor wishing to execute a job waits for the beginning of the next entrance phase and then submits its request. This adds at most $t(G)+1$ rounds to the response time of every request. The partitions of rounds to entrance phases and running phases are identical with respect to all the processors. Therefore, processors submit requests in batches, with $t(G)+1$ rounds between two successive batches.

The algorithm uses a preprocessing which finds an acyclic orientation of G which achieves the orientation number of G; we use $p_i \to p_j$ to denote that p_i is oriented to p_j. The orientation and entrance phases induce an orientation of the dynamic conflict graph C as follows: An edge $\langle p_i, p_j \rangle$ is directed $p_i \Rightarrow p_j$ if p_i requests resources in an earlier entrance phase than p_j or if p_j and p_i request resources in the same entrance phase and $p_i \to p_j$.

For each entrance phase, the processors are partitioned into the following three sets:

1. *Idle.* Processors that do not need resources, and processors that are currently executing their jobs.
2. *Requesting.* Processors that request resources in the current entrance phase.
3. *Waiting.* Processors that requested resources in previous entrance phases and are still waiting for their running phase.

The object of the algorithm is to use the t-orientation in order to merge the requesting processors with the waiting processors in a manner that does not delay the waiting processors and provides short response time for the new requests. The code for processor p_i appears in Figure 4.2. As in section 3.2, we denote by $C_{in}(p_i)$ the subgraph of C such that $p_j \in C_{in}(p_i)$ if and only if there is a directed path $p_j \Rightarrow \cdots \Rightarrow p_i$ in C.

Intuitively, the algorithm proceeds as follows. Each requesting processor p_i transmits its requests and collects the current state of $C_{in}(p_i)$. Upon having the initial state of $C_{in}(p_i)$, denoted by $C^0_{in}(p_i)$, the running phase of p_i is determined by a compact coloring of $C^0_{in}(p_i)$. If p_i is colored k, then p_i executes its job in the kth running phase, counting from the first running phase that begins after the end of the current entrance phase. The waiting processors update the conflict graph and transmit it to the requesting processors. At the beginning of each entrance phase the updated state of $C_{in}(p_i)$ is obtained from the previous state by deleting the set of processors that will begin executing their jobs in the next $t(G)+1$ rounds.

First, we prove that every requesting processor p_i learns about processors that may influence its color during its entrance phase.

LEMMA 4.7. *A requesting processor, p_i, knows $C^0_{in}(p_i)$ within at most $t(G)+1$ rounds after the beginning of its entrance phase.*

Proof. The proof is by induction on the entrance phase. For the base case,

Do every entrance phase:
  If you do not need resources:
    In the next $t(G)+1$ rounds:
      Transmit to your neighbors all the messages you receive.
  In order to execute a job:
    In the next round:
      Receive from your neighbors the part of $C_{in}(p_i)$ which consists of processors who made requests in previous entrance phases.
    In the next $t(G)$ rounds:
      Distribute that part of $C_{in}(p_i)$ and your request.
      Transmit to your neighbors all the messages you receive.
    Construct $C_{in}(p_i)$ by combining the old part you already know with the parts you received in the last $t(G)$ rounds.
    Use A_c to find a compact coloring of $C_{in}(p_i)$.
    If you are colored k, then execute your job in the kth running phase.
    For every $p_j \in C_{in}(p_i)$,
      If p_j is colored k, then p_j executes its job in the kth running phase.
  If you are waiting:
      Update $C_{in}(p_i)$:
        Remove processors that will start executing their job in the next $t(G)+1$ rounds according to your compact coloring.
        Remove processors which are not connected to you anymore.
      Distribute $C_{in}(p_i)$ to your neighbors.
    In the next $t(G)$ rounds:
      Transmit to your neighbors all the messages you receive.

FIG. 4.2. *The distributed algorithm: code for p_i.*

consider a processor p_i that requests resources in the first entrance phase. Directed paths to p_i contain only other processors that request resources in the first entrance phase. Since G was t-oriented, the distance between each processor in $C_{in}(p_i)$ and p_i is at most $t(G)$. Therefore, p_i knows $C_{in}(p_i)$ after at most $t(G)$ rounds.

For the induction step, let p_i be a processor that requests resources in the rth entrance phase, $r > 1$. Let $\rho = p_j \Rightarrow \cdots \Rightarrow p_i$ be a directed path to p_i in C. By the algorithm, no processor that enters with p_i is directed to a processor from an earlier entrance phase. Thus, ρ can be divided into two parts $p_j \Rightarrow \cdots \Rightarrow p_k \Rightarrow p_l \Rightarrow \cdots \Rightarrow p_i$ such that $p_j, \ldots, p_k$ request resources strictly before the rth entrance phase and $p_l, \ldots, p_i$ request resources in the rth entrance phase.

Two successive entrance phases are separated by $t(G)+1$ rounds. Therefore, by the inductive hypothesis, when p_i joins, p_k already knows the path $p_j \Rightarrow \cdots \Rightarrow p_k$. By the algorithm, p_l receives from p_k this part of ρ in the first round of the rth entrance phase. Since the graph is t-oriented, p_i receives messages from all the vertices in $p_l \Rightarrow \cdots \Rightarrow p_i$ within $t(G)$ rounds and can reconstruct ρ. □

The next lemma states that for every $p_j \in C^0_{in}(p_i)$, the assignments of a running phase to p_j as done by p_i and p_j are identical. That is, p_j is colored k in the compact coloring of $C^0_{in}(p_i)$ if and only if p_j is going to execute its job in the kth running phase, counting from the first running phase that begins after the end of p_i's entrance phase.

LEMMA 4.8. *For every requesting processor p_i and for every $p_j \in C^0_{in}(p_i)$, the*

running phase assigned to p_j by p_i is k if and only if p_j executes its job in phase k.

Proof. The proof is by induction on the entrance phase. For the base case, consider a processor p_i that requests resources in the first entrance phase. Since p_j is in $C^0_{in}(p_i)$, p_j also submits requests in the first entrance phase. By Lemma 4.7, p_i knows $C^0_{in}(p_i)$ within $t(G)+1$ rounds. By Lemma 4.4, the compact coloring problem is extendible. Therefore, by Lemma 3.18 (which refers to Algorithm A_c), p_j assigns color k to itself if and only if p_i assigns color k to p_j in $C^0_{in}(p_i)$. Since p_i and p_j start counting from the same round, the running phases are counted identically by p_i and p_j. This implies the lemma.

For the induction step, assume that the induction hypothesis holds for all processors that request resources before the rth entrance phase, and let p_i be a processor that submits requests at the rth entrance phase. By the algorithm, at the first round of phase r, every waiting processor p_l removes from $C_{in}(p_l)$ processors that will start executing their jobs during entrance phase r, according to the compact coloring calculated by p_l. $C_{in}(p_l)$ includes only processors that request resources before the rth entrance phase. Thus, by the induction hypothesis, these updates reflect correctly the current state of $C_{in}(p_l)$. This fact, together with Lemma 4.7, implies that p_i obtains $C^0_{in}(p_i)$ within $t(G)+1$ rounds. Consider a processor $p_j \in C^0_{in}(p_i)$. There are two cases.

Case 1. p_j is a processor that requests resources in entrance phase r. By the definition of $C_{in}(p)$, $C^0_{in}(p_j) \subseteq C^0_{in}(p_i)$, and using Lemma 3.18, p_j assigns color k to itself if and only if p_i assigns color k to p_j in $C^0_{in}(p_i)$.

Case 2. p_j is a processor that requests resources in entrance phase r'. Note that $r > r'$, since $C^0_{in}(p_i)$ does not include any processors that request resources after p_i. Let x be the ratio between the length of one entrance phase and the length of one running phase, that is, $t(G)+1 = x \cdot \mu$. Let s denote the number of the first running phase to begin after the rth entrance phase, and let s' denote the number of the first running phase to begin after the r'th entrance phase, that is, $s' = s - \lfloor x(r-r') \rfloor$. Assume that p_j assigns to itself color c' at entrance phase r'. By the algorithm, p_j will execute its job at running phase $s'+c'$. In addition, during the $r-r'$ entrance phases between r' and r, p_j removes from $C_{in}(p_j)$ all the processors that will start executing their jobs during that period. Formally, all the processors colored by p_j with $1, \ldots, \lfloor x(r-r') \rfloor$ are removed from $C_{in}(p_j)$. The induction hypothesis implies that the updated $C_{in}(p_j)$ at the beginning of the rth entrance phase contains only processors which are still waiting.

By Corollary 4.6, a compact coloring of the updated $C_{in}(p_j)$ assigns color $c = c' - \lfloor x(r-r') \rfloor$ to p_j. Since $C_{in}(p_j) \subseteq C^0_{in}(p_i)$, Lemma 3.18 implies that p_i assigns color c to p_j in $C^0_{in}(p_i)$. Thus, p_i determines that p_j executes its job in running phase number $s + c = s' + \lfloor x(r-r') \rfloor + c = s' + c'$, and that completes the proof. ∎

We can now prove the main properties of the algorithm.

LEMMA 4.9 (safety). *For every two processors p_i and p_j, if $need_i \cap need_j \neq \emptyset$, then p_i and p_j do not run simultaneously.*

Proof. If $need_i \cap need_j \neq \emptyset$, then p_i and p_j are neighbors in C. Assume, without loss of generality, that $p_i \Rightarrow p_j$ and hence $p_j \in C_{in}(p_i)$. Since $C_{in}(p_i)$ is legally colored, p_i and p_j have different colors in $C_{in}(p_i)$. By Lemma 4.8, the running phase that p_i determines for p_j is identical to the running phase that p_j determines for itself. Therefore, p_i and p_j belong to different running phases. Thus, by the algorithm, p_i and p_j do not run simultaneously. ∎

We now show that the schedule becomes μ-compact at most $2(t(G)+1)$ rounds

after a processor initiates a request for resources.

LEMMA 4.10. *For every waiting processor p_i, after the first $2(t(G)+1)$ rounds, in every μ rounds either p_i runs or some conflicting neighbor of p_i runs.*

Proof. By the algorithm, for every waiting processor p_i, the coloring of $C_{in}(p_i)$ is compact. Thus, if p_i is colored c, it has neighbors with all colors $1,\ldots,c-1$. Therefore, there is at least one neighbor of p_i which runs in each of the running phases $1,\ldots,c-1$. The first running phase in this count of the running phases begins at most $2(t(G)+1)$ rounds after the request was initiated by p_i. Hence, after that round the schedule is μ-compact. □

The response time for a processor p_i consists of three components: First, p_i waits for the beginning of the next entrance phase, which takes at most $t(G)+1$ rounds. Then, during the entrance phase, p_i collects $C^0_{in}(p_i)$. By Lemma 4.7, this takes $t(G)+1$ rounds. Finally, p_i waits for its running phase. By the μ-compact property (Lemma 4.10), p_i waits at most δ_i running phases, each taking μ rounds. This implies the following theorem.

THEOREM 4.11. *There exists an algorithm for the resource allocation problem whose response time is $\delta_i\mu + 2(t(G)+1)$.*

Remark. In our algorithm, δ_i captures the number of processors that issued competing resource requests before or simultaneously with p_i. That is, a processor is not delayed because of processors that request resources after it. Note that, in general, it does not mean that the algorithm guarantees a FIFO ordering. Thus, a processor p_j that issued its request later than p_i may execute its job earlier (while p_i is still waiting). This happens only if p_i needs a "popular" resource that was not requested by p_j.

4.4. Discussion. As presented, the algorithm assumes that the system is synchronous and that the local computing power at the processors is unlimited.

First, we remark that the algorithm can easily be changed to work in asynchronous systems by employing a simple synchronizer, such as α [1]. Since our algorithm relies on synchronization only between neighboring processors, synchronizer α allows us to run the algorithm correctly. The details, which are straightforward, are omitted.

Second, we remark that the local computation performed in our algorithm is fairly moderate. The most consuming step is the computation of a compact coloring; this is done by repeated application of A_m, which in turn greedily assigns colors to nodes. Furthermore, this computation can be integrated with the collection of information from neighboring nodes. In this way, the compact coloring is computed in iterations that overlap the iterations in which information is collected; the local computation at each node reduces to choosing a color based on the colors of its neighbors.

5. Conclusions and open problems. This work addressed the power of unrestricted preprocessing, in particular, the t-orientation preprocessing. Several open questions remain.

1. We derive a lower bound on the number of communication rounds needed for a k-compact resource allocation. Is there a lower bound on the number of communication rounds needed for a resource allocation algorithm that guarantees only the safety and liveness properties?
2. Our lower bound for k-dense coloring depends on k, while our upper bound for this problem is the same for all values of k. Can these bounds be tightened? In particular, is there an algorithm for k-dense coloring whose complexity depends on k?

3. We show that the t-orientation preprocessing helps in some labeling problems. Are there other helpful types of preprocessing?
4. We show that $t(G) \leq O((\log n)^2)$ for every graph G of size n, and that there exists a graph G of size n such that $t(G) = \Omega(\log n / \log\log n)$. Can the upper bound be reduced to $O(\log n / \log\log n)$? In particular, is there a distributed algorithm that achieves a better orientation? Is there a nonrandomized distributed algorithm that achieves a good orientation?
5. Is it NP-hard to determine $t(G)$ for a given graph?

Acknowledgments. We would like to thank Roy Meshulam for bringing Erdös' theorem to our attention and for pointing out the existence of graphs with $t(G) = \Omega(\log n / \log\log n)$. We also thank Amotz Bar-Noy for helpful discussions. An anonymous referee provided many comments that improved the presentation.

SPACE-EFFICIENT ROUTING TABLES FOR ALMOST ALL NETWORKS AND THE INCOMPRESSIBILITY METHOD*

HARRY BUHRMAN†, JAAP-HENK HOEPMAN‡, AND PAUL VITÁNYI†

Abstract. We use the incompressibility method based on Kolmogorov complexity to determine the total number of bits of routing information for almost all network topologies. In most models for routing, for almost all labeled graphs, $\Theta(n^2)$ bits are necessary and sufficient for shortest path routing. By "almost all graphs" we mean the Kolmogorov random graphs which constitute a fraction of $1-1/n^c$ of all graphs on n nodes, where $c>0$ is an arbitrary fixed constant. There is a model for which the average case lower bound rises to $\Omega(n^2\log n)$ and another model where the average case upper bound drops to $O(n\log^2 n)$. This clearly exposes the sensitivity of such bounds to the model under consideration. If paths have to be short, but need not be shortest (if the stretch factor may be larger than 1), then much less space is needed on average, even in the more demanding models. Full-information routing requires $\Theta(n^3)$ bits on average. For worst-case static networks we prove an $\Omega(n^2\log n)$ lower bound for shortest path routing and all stretch factors <2 in some networks where free relabeling is not allowed.

1. Introduction.

In very large communication networks, like the global telephone network or the Internet connecting the world's computers, the message volume being routed creates bottlenecks, degrading performance. We analyze a tiny part of this issue by determining the optimal space to represent routing schemes in communication networks for almost all static network topologies. The results also give the average space cost over all network topologies.

A universal *routing strategy* for static communication networks will, for every network, generate a *routing scheme* for that particular network. Such a routing scheme comprises a *local routing function* for every node in the network. The routing function of node u returns for every destination $v\neq u$, an edge incident to u on a path from u to v. This way, a routing scheme describes a path, called a *route*, between every pair of nodes u,v in the network. The *stretch factor* of a routing scheme equals the maximum ratio between the length of a route it produces and the shortest path between the endpoints of that route.

It is easy to see that we can do shortest path routing by entering a routing table in each node u, which for each destination node v indicates to what adjacent node w a message to v should be routed first. If u has degree d, it requires a table of at most $n\log d$ bits,[1] and the overall number of bits in all local routing tables never exceeds $n^2\log n$.

[1]Throughout, "log" denotes the binary logarithm.

The stretch factor of a routing strategy equals the maximal stretch factor attained by any of the routing schemes it generates. If the stretch factor of a routing strategy equals 1, it is called a *shortest path routing strategy* because then it generates for every graph a routing scheme that will route a message between arbitrary u and v over a shortest path between u and v.

In a *full-information* shortest path routing scheme, the routing function in u must, for each destination v, return all edges incident to u on shortest paths from u to v. These schemes allow alternative, shortest paths to be taken whenever an outgoing link is down.

We consider point to point communication networks on n nodes described by an undirected graph G. The nodes of the graph initially have unique labels taken from a set $\{1, \ldots, m\}$ for some $m > n$. Edges incident to a node v with degree $d(v)$ are connected to *ports*, with fixed labels $1, \ldots, d(v)$, by a so-called port assignment. This labeling corresponds to the minimal local knowledge a node needs to route: (a) a unique identity to determine whether it is the destination of an incoming message, (b) the guarantee that each of its neighbors can be reached over a link connected to exactly one of its ports, and (c) the guarantee that it can distinguish these ports.

1.1. Cost measures for routing tables. The space requirements of a routing scheme are measured as the sum over all nodes of the number of bits needed on each node to encode its routing function. If the nodes are not labeled with $\{1, \ldots, n\}$—the minimal set of labels—we have to add to the space requirement, for each node, the number of bits needed to encode its label. Otherwise, the bits needed to represent the routing function could be appended to the original identity yielding a large label that is not charged for but does contain all necessary information to route.

The cost of representing a routing function at a particular node depends on the amount of (uncharged) information initially there. Moreover, if we are allowed to relabel the graph and change its port assignment before generating a routing scheme for it, the resulting routing functions may be simpler and easier to encode. On a chain, for example, the routing function is much less complicated if we can relabel the graph and number the nodes in increasing order along the chain. We list these assumptions below and argue that each of them is reasonable for certain systems. We start with the options IA, IB, and II for the amount of information initially available at a node:

I. Nodes do not initially know the labels of their neighbors and use ports to distinguish the incident edges. This models the basic system without prior knowledge.
   - IA. The assignment of ports to edges is fixed and cannot be altered. This assumption is reasonable for systems running several jobs where the optimal port assignment for routing may actually be bad for those other jobs.
   - IB. The assignment of ports to edges is free and can be altered before computing the routing scheme (as long as neighboring nodes remain neighbors after reassignment). Port reassignment is justifiable as a local action that usually can be performed without informing other nodes.

II. Nodes know the labels of their neighbors and over which edge to reach them. This information is free. Or, to put it another way, an incident edge carries the same label as the node to which it connects. This model is concerned only with the additional cost of routing messages beyond the immediate neighbors and applies to systems where the neighbors are already known for various

other reasons.[2]

Orthogonal to that, the following three options regarding the labels of the nodes are distinguished:

- α Nodes cannot be relabeled. For large scale distributed systems, relabeling requires global coordination that may be undesirable or simply impossible.
- β Nodes may be relabeled before computing the routing scheme, but the range of the labels must remain $1, \ldots, n$. This model allows a bad distribution of labels to be avoided.
- γ Nodes may be given arbitrary labels before computing the routing scheme, but the number of bits used to store the node's label is added to the space requirements of a node. Destinations are given using the new, complex labels.[3] This model allows us to store additional routing information, e.g., topological information, in the label of a node. This sort of network may be appropriate for centrally designed interconnected networks for multiprocessors and communication networks. A common example of architecture of this type is the binary n-cube network, where the 2^n nodes are labeled with elements of $\{0,1\}^n$ such that there is an edge between each pair of nodes iff their labels differ in exactly one bit position. In this case one can shortest path route using only the labels by successively traversing edges corresponding to flipping successive bits in the positions where source node and destination node differ.

These two orthogonal sets of assumptions, IA, IB, or II and α, β, or γ, define the nine different models we will consider in this paper. We remark that the lower bounds for models without relabeling are less surprising and easier to prove than the bounds for the other models.

1.2. Outline. We determine the optimum space used to represent shortest path routing schemes on almost all labeled graphs, namely, the Kolmogorov random graphs with randomness deficiency at most $c \log n$, which constitute a fraction of at least $1 - 1/n^c$ of all graphs for every fixed constant $c > 0$. These bounds straightforwardly imply the same bounds for the average case over all graphs, provided we choose $c \geq 3$. For an overview of the results, refer to Table 1.1.[4]

We prove that for almost all graphs, $\Omega(n^2)$ bits are necessary to represent the routing scheme, if relabeling is not allowed and nodes know their neighbors (II $\wedge$ α) or nodes do not know their neighbors (IA $\vee$ IB).[5] Partially matching this lower bound, we show that $O(n^2)$ bits are sufficient to represent the routing scheme if the

[2]We do not consider models that give neighbors for free and, at the same time, allow free port assignment. Given a labeling of the edges by the nodes to which they connect, the actual port assignment doesn't matter at all and can in fact be used to represent $d(v) \log d(v)$ bits of the routing function. Namely, each assignment of ports corresponds to a permutation of the ranks of the neighbors—the neighbors at port i move to position i. There are $d(v)!$ such permutations.

[3]In this model it is assumed that a routing function cannot tell valid from invalid labels and that a routing function always receives a valid destination label as input. Requiring otherwise makes the problem harder.

[4]In this table, arrows indicate that the bound for that particular model follows from the bound found by tracing the arrow. In particular, the average-case lower bound for model IA $\wedge$ β is the same as the IA $\wedge$ γ bound found by tracing $\rightarrow$. The reader may have guessed that a ? marks an open question.

[5]We write A $\vee$ B to indicate that the results hold under model A or model B. Similarly, we write A $\wedge$ B to indicate the result holds only if the conditions of both model A and model B hold simultaneously. If only one of the two "dimensions" is mentioned, the other may be taken arbitrarily (i.e., IA is shorthand for (IA $\wedge$ α) $\vee$ (IA $\wedge$ β) $\vee$ (IA $\wedge$ γ)).

TABLE 1.1

Size of shortest path routing schemes, overview of results. The results presented in this paper are quoted with exact constants and asymptotically (with the lower order of magnitude terms suppressed). This table contains only results on shortest path routing, not the other results in this paper.

	No relabeling (α)	*Permutation* (β)	*Free relabeling* (γ)
Worst case—*lower bounds*			
Port assignment free (IB)	$\rightarrow$	$\Omega(n^2 \log n)$ [5]	$n^2/32$ [Thm 4.2]
Neighbors known (II)	$(n^2/9) \log n$ [Thm 4.4]	$\Omega(n^2)$ [4]	$\Omega(n^{7/6})$ [10]
Average case—*upper bounds*			
Port assignment fixed (IA)	$(n^2/2) \log n$ [Thm 3.6]	$\leftarrow$	$\leftarrow$
Port assignment free (IB)	$3n^2$ [Thm 3.1]	$\leftarrow$	$\leftarrow$
Neighbors known (II)	$3n^2$ [Thm 3.1]	$\leftarrow$	$6n \log^2 n$ [Thm 3.2]
Average case—*lower bounds*			
Port assignment fixed (IA)	$(n^2/2) \log n$ [Thm 4.3]	$\rightarrow$	$n^2/32$ [Thm 4.2]
Port assignment free (IB)	$n^2/2$ [Thm 4.1]	$\rightarrow$	$n^2/32$ [Thm 4.2]
Neighbors known (II)	$n^2/2$ [Thm 4.1]	?	?

port assignment may be changed or if nodes do know their neighbors (IB $\vee$ II). In contrast, for almost all graphs, the lower bound rises to asymptotically $(n^2/2) \log n$ bits if both relabeling and changing the port assignment are not allowed (IA $\wedge$ α), and this number of bits is also sufficient for almost all graphs. And, again for almost all graphs, the upper bound drops to $O(n \log^2 n)$ bits if nodes know the labels of their neighbors and nodes may be arbitrarily relabeled (II $\wedge$ γ).

Full-information shortest path routing schemes are shown to require, on almost all graphs, asymptotically $n^3/4$ bits to be stored if relabeling is not allowed (α), and this number of bits is also shown to be sufficient for almost all graphs. (The obvious upper bound for all graphs is n^3 bits.)

For stretch factors larger than 1 we obtain the following results. When nodes know their neighbors (II), for almost all graphs, routing schemes achieving stretch factors s with $1 < s < 2$ can be stored using a total of $O(n \log n)$ bits.[6] Similarly, for almost all graphs in the same models (II), $O(n \log \log n)$ bits are sufficient for routing with stretch factor ≥ 2. Finally, for stretch factors $\geq 6 \log n$ on almost all graphs again in the same model (II), the routing scheme occupies only $O(n)$ bits.

For worst-case static networks we prove, by construction of explicit graphs, an $\Omega(n^2 \log n)$ lower bound on the total size of any routing scheme with stretch factor < 2 if nodes may not be relabeled (α).

The novel incompressibility technique based on Kolmogorov complexity [9] has already been applied in many areas but not so much in a distributed setting. A methodological contribution of this paper is to show how to apply the incompressibility method to obtain results in distributed computing for *almost all* objects concerned, rather than for the *worst-case* object. This hinges on our use of Kolmogorov random graphs in a fixed family of graphs. Our results also hold *averaged over all* objects concerned.

Independent recent work [8, 7] applies Kolmogorov complexity to obtain related *worst-case* results mentioned in the next section. They show, for example, that for each n *there exist* graphs on n nodes which may not be relabeled (α) that require in the worst case $\Omega(n^3)$ bits to store a *full-information* shortest path routing scheme.

[6] For Kolmogorov random graphs which have diameter 2 by Lemma 2.6, routing schemes with $s = 1.5$ are the only ones possible in this range.

We prove for the same model that for *almost all* graphs, full-information routing $n^3/4$ bits in total is necessary and sufficient (asymptotically).

1.3. Related work. Previous upper and lower bounds on the total number of bits necessary and sufficient to store the routing scheme in worst-case static communication networks are due to Peleg and Upfal [10] and Fraigniaud and Gavoille [4].

In [10] it was shown that for any stretch factor $s \geq 1$, the total number of bits required to store the routing scheme for some n-node graph is at least $\Omega(n^{1+1/(2s+4)})$ and that there exist routing schemes for all n-node graphs, with stretch factor $s = 12k+3$, using $O(k^3 n^{1+1/k} \log n)$ bits in total. For example, with stretch factor $s = 15$ we have $k = 1$ and their method guarantees $O(n^2 \log n)$ bits to store the routing scheme. The lower bound is shown in the model where nodes may be arbitrarily relabeled and where nodes know their neighbors (II $\wedge$ γ). Free port assignment in conjunction with a model where the neighbors are known (II), however, cannot be allowed. Otherwise, each node would gain $n \log n$ bits to store the routing function (see footnote 2).

Fraigniaud and Gavoille [4] showed that for stretch factors $s < 2$ there are routing schemes that require a total of $\Omega(n^2)$ bits to be stored in the worst case if nodes may be relabeled by permutation (β). This was improved for shortest path routing by Gavoille and Pérennès [5], who showed that for each $d \leq n$ there are shortest path routing schemes that require a total of $\Omega(n^2 \log d)$ bits to be stored in the worst case for some graphs with maximal degree d if nodes may be relabeled by permutation and the port assignment may be changed (IB $\wedge$ β). This last result is clearly optimal for the worst case both for general networks ($d = \Theta(n)$) and bounded degree networks ($d < n$). In [7] it was shown that for each $d \geq 3$ there are networks for which any routing scheme with stretch factor < 2 requires a total of $\Omega(n^2/\log^2 n)$ bits.

Interval routing on a graph $G = (V, E)$, $V = \{1, \ldots, n\}$, is a routing strategy where for each node i, for each incident edge e of i, a (possibly empty) set of pairs of node labels represents disjoint intervals with wraparound. Each pair indicates the initial edge on a shortest path from i to any node in the interval, and for each node $j \neq i$ there is such a pair. We are allowed to permute the labels of graph G to optimize the interval setting.

Gavoille and Pérennès [5] show that there exist graphs for each bounded degree $d \geq 3$ such that for each interval routing scheme, each of $\Omega(n)$ edges are labeled by $\Omega(n)$ intervals. This shows that interval routing can be worse than straightforward coding of routing tables, which can be trivially done in $O(n^2 \log d)$ bits total. (This improves [7], showing that there exist graphs such that for each interval routing scheme some incident edge on each of $\Omega(n)$ nodes is labeled by $\Omega(n)$ intervals and that for each $d \geq 3$ there are graphs of maximal node degree d such that for each interval routing scheme some incident edge on each of $\Omega(n)$ nodes is labeled by $\Omega(n/\log n)$ intervals.)

Flammini, van Leeuwen, and Marchetti-Spaccamela [3] provide history and background on the compactness (or lack thereof) of interval routing using probabilistic proof methods. To the best of our knowledge, one of the authors of that paper, Jan van Leeuwen, was the first to formulate explicitly the question of what exactly is the minimal size of the routing functions, and he also recently drew our attention to this group of problems.

2. Kolmogorov complexity. The Kolmogorov complexity [6] of x is the length of the *shortest* effective description of x. That is, the *Kolmogorov complexity* $C(x)$ of a finite string x is simply the length of the shortest program, say, in Fortran

(or in Turing machine codes) encoded in binary, which prints x without any input. A similar definition holds conditionally in the sense that $C(x|y)$ is the length of the shortest binary program which computes x given y as input. It can be shown that the Kolmogorov complexity is absolute in the sense of being independent of the programming language up to a fixed additional constant term which depends on the programming language but not on x. We now fix one canonical programming language once and for all as a reference and thereby $C()$.

For the theory and applications, see [9]. Let $x, y, z \in \mathcal{N}$, where $\mathcal{N}$ denotes the natural numbers. Identify $\mathcal{N}$ and $\{0,1\}^*$ according to the correspondence $(0,\epsilon), (1,0), (2,1), (3,00), (4,01), \ldots$. Hence, the length $|x|$ of x is the number of bits in the binary string x. Let $T_1, T_2, \ldots$ be a standard enumeration of all Turing machines. Let $\langle \cdot, \cdot \rangle$ be a standard invertible effective bijection from $\mathcal{N} \times \mathcal{N}$ to $\mathcal{N}$. This can be iterated to $\langle \langle \cdot, \cdot \rangle, \cdot \rangle$.

DEFINITION 2.1. *Let U be an appropriate universal Turing machine such that $U(\langle \langle i, p \rangle, y \rangle) = T_i(\langle p, y \rangle)$ for all i and $\langle p, y \rangle$. The* Kolmogorov complexity *of x given y (for free) is*

$$C(x|y) = \min\{|p| : U(\langle p, y \rangle) = x, p \in \{0,1\}^*\}.$$

2.1. Kolmogorov random graphs. One way to express irregularity or *randomness* of an individual network topology is by a modern notion of randomness like Kolmogorov complexity. A simple counting argument shows that for each y in the condition and each length n, there exists at least one x of length n which is *incompressible* in the sense of $C(x|y) \geq n$; 50% of all x's of length n are incompressible but for one bit ($C(x|y) \geq n-1$), 75% of all x's are incompressible but for two bits ($C(x|y) \geq n-2$), and in general a fraction of $1 - 1/2^c$ of all strings cannot be compressed by more than c bits [9].

DEFINITION 2.2. *Each labeled graph $G = (V, E)$ on n nodes $V = \{1, 2, \ldots, n\}$ can be coded by a binary string $E(G)$ of length $n(n-1)/2$. We enumerate the $n(n-1)/2$ possible edges (u, v) in a graph on n nodes in standard lexicographical order without repetitions and set the ith bit in the string to 1 if the ith edge is present and to 0 otherwise. Conversely, each binary string of length $n(n-1)/2$ encodes a graph on n nodes. Hence we can identify each such graph with its corresponding binary string.*

We define the high complexity graphs in a particular family $\mathcal{G}$ of graphs.

DEFINITION 2.3. *A labeled graph G on n nodes of a family $\mathcal{G}$ of graphs has* randomness deficiency *at most $\delta(n)$ and is called $\delta(n)$-*random *in $\mathcal{G}$ if it satisfies*

$$C(E(G)|n, \delta, \mathcal{G}) \geq \log |\mathcal{G}| - \delta(n). \tag{2.1}$$

In this paper $\mathcal{G}$ is the set of all labeled graphs on n nodes. Then, $\log |\mathcal{G}| = n(n-1)/2$, that is, precisely the length of the encoding of Definition 2.2. In what follows we just say "$\delta(n)$-random" with $\mathcal{G}$ understood.

Elementary counting shows that *a fraction* of at least

$$1 - 1/2^{\delta(n)}$$

of all labeled graphs on n nodes in $\mathcal{G}$ has that high complexity [9].

2.2. Self-delimiting binary strings. We need the notion of self-delimiting binary strings.

DEFINITION 2.4. *We call x a* proper prefix *of y if there is a z such that $y = xz$ with $|z| > 0$. A set $A \subseteq \{0,1\}^*$ is* prefix-free *if no element in A is the proper*

prefix of another element in A. A 1:1 *function* $E : \{0,1\}^* \to \{0,1\}^*$ *(equivalently,* $E : \mathcal{N} \to \{0,1\}^*$*) defines a* prefix-code *if its range is prefix-free. A simple prefix-code we use throughout is obtained by reserving one symbol, say* 0*, as a stop sign and encoding*

$$\bar{x} = 1^{|x|}0x,$$
$$|\bar{x}| = 2|x| + 1.$$

Sometimes we need the shorter prefix-code x'*:*

$$x' = \overline{|x|}x,$$
$$|x'| = |x| + 2\lceil \log(|x| + 1)\rceil + 1.$$

We call $\bar{x}$ *or* x' *a* self-delimiting *version of the binary string* x*. We can effectively recover both* x *and* y *unambiguously from the binary strings* $\bar{x}y$ *or* $x'y$*. For example, if* $\bar{x}y = 111011011$*, then* $x = 110$ *and* $y = 11$*. If* $\bar{x}\bar{y} = 1110110101$*, then* $x = 110$ *and* $y = 1$*. The self-delimiting form* $x' \ldots y'z$ *allows the concatenated binary subdescriptions to be parsed and unpacked into the individual items* $x, \ldots, y, z$*; the code* x' *encodes a separation delimiter for* x *using* $2\lceil \log(|x| + 1)\rceil$ *extra bits, and so on* [9].

2.3. Topological properties of Kolmogorov random graphs. High complexity labeled graphs have many specific topological properties, which seems to contradict their randomness. However, randomness is not "lawlessness" but rather enforces strict statistical regularities, for example, to have diameter exactly 2. Note that randomly generated graphs have diameter 2 with high probability. In another paper [2] two of us explored the relationship between high probability properties of random graphs and properties of individual Kolmogorov random graphs. For this discussion it is relevant to mention that, in a precisely quantified way, *every* Kolmogorov random graph individually possesses all simple properties which hold with high probability for randomly generated graphs.

LEMMA 2.5. *The degree* d *of every node of a* $\delta(n)$*-random labeled graph on* n *nodes satisfies*

$$|d - (n-1)/2| = O\left(\sqrt{(\delta(n) + \log n)n}\right).$$

Proof. Assume that there is a node such that the deviation of its degree d from $(n-1)/2$ is greater than k, that is, $|d - (n-1)/2| > k$. From the lower bound on $C(E(G)|n, \delta, \mathcal{G})$ corresponding to the assumption that G is random in $\mathcal{G}$, we can estimate an upper bound on k, as follows.

In a description of $G = (V, E)$ given n, δ, we can indicate which edges are incident on node i by giving the index of the interconnection pattern (the characteristic sequence of the set $V_i = \{j \in V - \{i\} : (i,j) \in E\}$ in $n-1$ bits, where the jth bit is 1 if $j \in V_i$ and 0 otherwise) in the ensemble of

$$m = \sum_{|d-(n-1)/2|>k} \binom{n-1}{d} \leq 2^n e^{-2k^2/3(n-1)} \tag{2.2}$$

possibilities. The last inequality follows from a general estimate of the tail probability of the binomial distribution with s_n the number of successful outcomes in n experiments with probability of success $p = \frac{1}{2}$. Namely, by Chernoff's bounds, in the form used in [1, 9],

$$\Pr(|s_n - pn| > k) \leq 2e^{-k^2/3pn}. \tag{2.3}$$

To describe G, it then suffices to modify the old code of G by prefixing it with

(i) a description of this discussion in $O(1)$ bits;

(ii) the identity of node i in $\lceil \log(n+1) \rceil$ bits;

(iii) the value of k in $\lceil \log(n+1) \rceil$ bits, possibly adding nonsignificant 0's to pad up to this amount;

(iv) the index of the interconnection pattern in $\log m$ bits (we know n, k, and hence $\log m$); followed by

(v) the old code for G with the bits in the code denoting the presence or absence of the possible edges that are incident on node i deleted.

Clearly, given n we can reconstruct the graph G from the new description. The total description we have achieved is an effective program of

$$\log m + 2\log n + n(n-1)/2 - n + O(1)$$

bits. This must be at least the length of the shortest effective binary program, which is $C(E(G)|n, \delta, \mathcal{G})$, satisfying (2.1). Therefore,

$$\log m \geq n - 2\log n - O(1) - \delta(n).$$

Since we have estimated in (2.2) that

$$\log m \leq n - (2k^2/3(n-1))\log e,$$

it follows that $k \leq \sqrt{\frac{3}{2}(\delta(n) + 2\log n + O(1))(n-1)/\log e}$. □

LEMMA 2.6. *Every $o(n)$-random labeled graph on n nodes has diameter* 2.

Proof. The only graphs with diameter 1 are the complete graphs which can be described in $O(1)$ bits, given n, and hence are not random. It remains to consider $G = (V, E)$ is an $o(n)$-random graph with diameter greater than 2, which contradicts (2.1) from some n onwards.

Let i, j be a pair of nodes with distance greater than 2. Then we can describe G by modifying the old code for G as follows:

(i) a description of this discussion in $O(1)$ bits;

(ii) the identities of $i < j$ in $2\log n$ bits;

(iii) the old code $E(G)$ of G with all bits representing presence or absence of an edge (j, k) between j and each k with $(i, k) \in E$ deleted. We know that all the bits representing such edges must be 0 since the existence of any such edge shows that $(i, k), (k, j)$ is a path of length 2 between i and j, contradicting the assumption that i and j have distance > 2. This way we save at least $n/4$ bits since we save bits for as many edges (j, k) as there are edges (i, k), that is, the degree of i, which is $n/2 \pm o(n)$ by Lemma 2.5.

Since we know the identities of i and j and the nodes adjacent to i (they are in the prefix of code $E(G)$ where no bits have been deleted), we can reconstruct G from this discussion and the new description, given n. Since by Lemma 2.5 the degree of i is at least $n/4$, the new description of G, given n, requires at most

$$n(n-1)/2 - n/4 + O(\log n)$$

bits, which contradicts (2.1) for large n. □

LEMMA 2.7. *Let $c \geq 0$ be a fixed constant, and let G be a $c\log n$-random labeled graph. Then from each node i all other nodes are either directly connected to i or are directly connected to one of the least $(c+3)\log n$ nodes directly adjacent to i.*

Proof. Given i, let A be the set of the least $(c+3)\log n$ nodes directly adjacent to i. Assume by way of contradiction that there is a node k of G that is not directly connected to a node in $A \bigcup \{i\}$. We can describe G as follows:

(i) a description of this discussion in $O(1)$ bits;

(ii) a literal description of i in $\log n$ bits;

(iii) a literal description of the presence or absence of edges between i and the other nodes in $n-1$ bits;

(iv) a literal description of k and its incident edges in $\log n + n - 2 - (c+3)\log n$ bits;

(v) the encoding $E(G)$ with the edges incident with nodes i and k deleted, saving at least $2n-2$ bits.

Altogether the resultant description has

$$n(n-1)/2 + 2\log n + 2n - 3 - (c+3)\log n - 2n + 2$$

bits, which contradicts the $c \log n$-randomness of G by (2.1). □

In the description we have explicitly added the adjacency pattern of node i, which we deleted again later. This zero-sum swap is necessary to be able to unambiguously identify the adjacency pattern of i in order to reconstruct G. Since we know the identities of i and the nodes adjacent to i (they are the prefix where no bits have been deleted), we can reconstruct G from this discussion and the new description, given n.

3. Upper bounds. We give methods to route messages over Kolmogorov random graphs with compact routing schemes. Specifically, we show that in general (on almost all graphs) one can use shortest path routing schemes occupying at most $O(n^2)$ bits. If one can relabel the graph in advance, and if nodes know their neighbors, shortest path routing schemes are shown to occupy only $O(n \log^2 n)$ bits. Allowing stretch factors larger than 1 reduces the space requirements—to $O(n)$ bits for stretch factors of $O(\log n)$.

Let G be an $O(\log n)$-random labeled graph on n nodes. By Lemma 2.7 we know that from each node u we can shortest path route to each other node through the least $O(\log n)$ directly adjacent nodes of u. So we route through node v. Once the message reaches node v, its destination is either node v or a direct neighbor of node v (which is known in node v by assumption). Therefore, routing functions of size $O(n \log\log n)$ bits per node can be used to do shortest path routing. However, we can do better.

THEOREM 3.1. *Let G be an $O(\log n)$-random labeled graph on n nodes. Assume that the port assignment may be changed or nodes know their neighbors (*IB $\vee$ II*). Then for shortest path routing it suffices to have local routing functions stored in $3n$ bits per node. Hence the complete routing scheme is represented by $3n^2$ bits.*

Proof. Let G be as in the statement of the theorem. By Lemma 2.7 we know that from each node u we can route via shortest paths to each node v through the $O(\log n)$ directly adjacent nodes of u that have the least indexes. Assume we route through node v. Once the message has reached node v, its destination is either node v or a direct neighbor of node v (which is known in node v by assumption).

Let $A_0 \subseteq V$ be the set of nodes in G which are not directly connected to u. Let $v_1, \ldots, v_m$ be the $O(\log n)$ least indexed nodes directly adjacent to node u (Lemma 2.7) through which we can shortest path route to all nodes in A_0. For $t = 1, 2 \ldots, l$ define $A_t = \{w \in A_0 - \bigcup_{s=1}^{t-1} A_s : (v_t, w) \in E\}$. Let $m_0 = |A_0|$, and define $m_{t+1} = m_t - |A_{t+1}|$. Let l be the first t such that $m_t < n/\log\log n$. Then we claim that v_t is connected by an edge in E to at least $1/3$ of the nodes not connected by edges in E to nodes $u, v_1, \ldots, v_{t-1}$.

CLAIM 1. $|A_t| > m_{t-1}/3$ *for* $1 \leq t \leq l$.

Proof. Suppose, by way of contradiction, that there exists a least $t \leq l$ such that $||A_t| - m_{t-1}/2| \geq m_{t-1}/6$. Then we can describe G, given n, as follows:

(i) A description of this discussion in $O(1)$ bits;

(ii) a description of nodes u, v_t in $2 \log n$ bits, padded with 0's if necessary;

(iii) a description of the presence or absence of edges incident with nodes $u, v_1, \ldots, v_{t-1}$ in $r = n - 1 + \cdots + n - (t-1)$ bits. This gives us the characteristic sequences of $A_0, \ldots, A_{t-1}$ in V, where a *characteristic sequence* of A in V is a string of $|V|$ bits with, for each $v \in V$, the vth bit equal to 1 if $v \in A$ and the vth bit equal to 0 otherwise;

(iv) a self-delimiting description of the characteristic sequence of A_t in $A_0 - \bigcup_{s=1}^{t-1} A_s$, using Chernoff's bound (2.3), in at most $m_{t-1} - \frac{2}{3}(\frac{1}{6})^2 \, m_{t-1} \log e + O(\log m_{t-1})$ bits;

(v) the description $E(G)$ with all bits corresponding to the presence or absence of edges between v_t and the nodes in $A_0 - \bigcup_{s=1}^{t-1} A_s$ deleted, saving m_{t-1} bits. Furthermore, we also delete all bits corresponding to the presence or absence of edges incident with $u, v_1, \ldots, v_{t-1}$, saving a further r bits.

This description of G uses at most

$$n(n-1)/2 + O(\log n) + m_{t-1} - \frac{2}{3}\left(\frac{1}{6}\right)^2 m_{t-1} \log e - m_{t-1}$$

bits, which contradicts the $O(\log n)$-randomness of G by (2.1), because $m_{t-1} > n/\log\log n$. □

Recall that l is the least integer such that $m_l < n/\log\log n$. We construct the local routing function $F(u)$ as follows:

(i) A table of intermediate routing node entries for all the nodes in A_0 in increasing order. For each node w in $\bigcup_{s=1}^{l} A_s$ we enter in the wth position in the table the unary representation of the least intermediate node v with $(u, v), (v, w) \in E$ followed by a 0. For the nodes that are not in $\bigcup_{s=1}^{l} A_s$ we enter a 0 in their position in the table, indicating that an entry for this node can be found in the second table. By Claim 1, the size of this table is bounded by

$$n + \sum_{s=1}^{l} \frac{1}{3}\left(\frac{2}{3}\right)^{s-1} sn \leq n + \sum_{s=1}^{\infty} \frac{1}{3}\left(\frac{2}{3}\right)^{s-1} sn \leq 4n.$$

(ii) A table with explicitly binary coded intermediate nodes on a shortest path for the ordered set of the remaining destination nodes. Those nodes had a 0 entry in the first table and there are at most $m_l < n/\log\log n$ of them, namely, the nodes in $A_0 - \bigcup_{s=1}^{l} A_s$. Each entry consists of the code of length $\log\log n + O(1)$ for the position in increasing order of a node out of $v_1, \ldots, v_m$ with $m = O(\log n)$ by Lemma 2.7. Hence this second table requires at most $2n$ bits.

The routing algorithm is as follows: The direct neighbors of u are known in node u and are routed without a routing table. If we route from start node u to target node w, which is not directly adjacent to u, then we do the following: If node w has an entry in the first table, then route over the edge coded in unary; otherwise find an entry for node w in the second table.

Altogether, we have $|F(u)| \leq 6n$. Adding another $n-1$ in case the port assignment may be chosen arbitrarily, this proves the theorem with $7n$ instead of $6n$. Slightly

more precise counting and choosing l such that m_l is the first such quantity $< n/\log n$ shows $|F(u)| \leq 3n$. □

If we allow arbitrary labels for the nodes, then shortest path routing schemes of $O(n \log^2 n)$ bits suffice on Kolmogorov random graphs, as witnessed by the following theorem.

THEOREM 3.2. *Let $c \geq 0$ be a constant, and let G be a $c \log n$-random labeled graph on n nodes. Assume that nodes know their neighbors and that nodes may be arbitrarily relabeled ($\mathrm{II} \wedge \gamma$), and we allow the use of labels of $(1 + (c+3)\log n)\log n$ bits. Then we can shortest path route with local routing functions stored in $O(1)$ bits per node (hence the complete routing scheme is represented by $(c+3)n \log^2 n + n \log n + O(n)$ bits).*

Proof. Let c and G be as in the statement of the theorem. By Lemma 2.7 we know that from each node u we can shortest path route to each node w through the first $(c+3)\log n$ directly adjacent nodes $f(u) = v_1, \ldots, v_m$ of u. By Lemma 2.6, G has diameter 2. Relabel G such that the label of node u equals u followed by the original labels of the first $(c+3)\log n$ directly adjacent nodes $f(u)$. This new label occupies $(1 + (c+3)\log n)\log n$ bits. To route from source u to destination v do the following.

If v is directly adjacent to u, we route to v in one step in our model (nodes know their neighbors). If v is not directly adjacent to u, we consider the immediate neighbors $f(v)$ contained in the name of v. By Lemma 2.7, at least one of the neighbors of u must have a label whose original label (stored in the first $\log n$ bits of its new label) corresponds to one of the labels in $f(v)$. Node u routes the message to any such neighbor. This routing function can be stored in $O(1)$ bits. □

Without relabeling, routing using less than $O(n^2)$ bits is possible if we allow stretch factors larger than 1. The next three theorems clearly show a trade-off between the stretch factor and the size of the routing scheme.

THEOREM 3.3. *Let $c \geq 0$ be a constant, and let G be a $c \log n$-random labeled graph on n nodes. Assume that nodes know their neighbors (II). For routing with any stretch factor > 1 it suffices to have $n - 1 - (c+3)\log n$ nodes with local routing functions stored in at most $\lceil \log(n+1) \rceil$ bits per node and $1 + (c+3)\log n$ nodes with local routing functions stored in $3n$ bits per node (hence the complete routing scheme is represented by less than $(3c+20)n \log n$ bits). Moreover, the stretch is at most 1.5.*

Proof. Let c and G be as in the statement of the theorem. By Lemma 2.7 we know that from each node u we can shortest path route to each node w through the first $(c+3)\log n$ directly adjacent nodes $v_1, \ldots, v_m$ of u. By Lemma 2.6, G has diameter 2. Consequently, each node in V is directly adjacent to some node in $B = \{u, v_1, \ldots, v_m\}$. Hence it suffices to select the nodes of B as routing centers and store, in each node $w \in B$, a shortest path routing function $F(w)$ to all other nodes occupying $3n$ bits (the same routing function as constructed in the proof of Theorem 3.1 if the neighbors are known). Nodes $v \in V - B$ route any destination unequal to their own label to some fixed directly adjacent node $w \in B$. Then $|F(v)| \leq \lceil \log(n+1) \rceil + O(1)$, and this gives the bit count in the theorem.

To route from an originating node v to a target node w, the following steps are taken. If w is directly adjacent to v, we route to w in one step in our model. If w is not directly adjacent to v, then we first route in one step from v to its directly connected node in B and then via a shortest path to w. Altogether, this takes either two or three steps, whereas the shortest path has length 2. Hence the stretch factor is at most 1.5, which for graphs of diameter 2 (i.e., all $c \log n$-random graphs by Lemma 2.6) is the

only possibility between stretch factors 1 and 2. This proves the theorem. □

THEOREM 3.4. *Let $c \geq 0$ be a constant, and let G be a $c \log n$-random labeled graph on n nodes. Assume that the nodes know their neighbors (*II*). For routing with stretch factor* 2 *it suffices to have $n-1$ nodes with local routing functions stored in at most $\log \log n$ bits per node and one node with its local routing function stored in $3n$ bits (hence the complete routing scheme is represented by $n \log \log n + 3n$ bits).*

Proof. Let c and G be as in the statement of the theorem. By Lemma 2.6, G has diameter 2. Therefore the following routing scheme has stretch factor 2: Let node 1 store a shortest path routing function. All other nodes store only a shortest path to node 1. To route from an originating node v to a target node w, the following steps are taken: If w is an immediate neighbor of v, we route to w in one step in our model. If not, we first route the message to node 1 in at most two steps and then from node 1 through a node v to node w in, again, two steps. Because node 1 stores a shortest path routing function, either $v = w$ or w is a direct neighbor of v.

Node 1 can store a shortest path routing function in at most $3n$ bits using the same construction as used in the proof of Theorem 3.1 (if the neighbors are known). The immediate neighbors of 1 route either to 1 or directly to the destination of the message. For these nodes, the routing function occupies $O(1)$ bits. For nodes v at distance 2 of node 1 we use Lemma 2.7, which tells us that we can shortest path route to node 1 through the first $(c+3)\log n$ directly adjacent nodes of v. Hence, to represent this edge takes $\log \log n + \log(c+3)$ bits, and hence the local routing function $F(v)$ occupies at most $\log \log n + O(1)$ bits. □

THEOREM 3.5. *Let $c \geq 0$ be a constant, and let G be a $c \log n$-random labeled graph on n nodes. Assume that nodes know their neighbors (*II*). For routing with stretch factor $(c+3)\log n$ it suffices to have local routing functions stored in $O(1)$ bits per node (hence the complete routing scheme is represented by $O(n)$ bits).*

Proof. Let c and G be as in the statement of the theorem. From Lemma 2.7 we know that from each node u we can shortest path route to each node v through the first $(c+3)\log n$ directly adjacent nodes of u. By Lemma 2.6, G has diameter 2. So the local routing function—representable in $O(1)$ bits—is to route directly to the target node if it is a directly adjacent node, otherwise simply traverse the first $(c+3)\log n$ incident edges of the starting node and look in each of the visited nodes to see whether the target node is a directly adjacent node. If so, the message is forwarded to that node, otherwise it is returned to the starting node in order to try the next node. Hence each message for a destination at distance 2 traverses at most $2(c+3)\log n$ edges.

Strictly speaking we do not use routing tables at all. We use the fact that a message can go back and forth several times to a node. The header of the message can code some extra information as a tag "failed." In this case it is possible to describe an $O(1)$ bit size routing function which allows one to extract the destination from the header without knowing about $\log n$, for example, by the use of self-delimiting encoding. □

THEOREM 3.6. *Let G be an $O(\log n)$-random labeled graph on n nodes. Assume that nodes do not know their neighbors and relabeling and changing the port assignment are not allowed (*IA $\wedge$ α*). Then for shortest path routing it suffices that each local routing function uses $(n/2)\log n(1+o(1))$ bits (hence the complete routing scheme uses at most $(n^2/2)\log n(1+o(1))$ bits to be stored).*

Proof. At each node we can give the neighbors by the positions of the 1's in a binary string of length $n-1$. Since each node has at most $n/2 + o(n)$ neighbors by

Lemma 2.5, a permutation of port assignments to neighbors can have Kolmogorov complexity at most $(n/2)\log n(1+o(1))$ [9]. This permutation π describes part of the local routing function by determining, for each direct neighbor, the port through which to route messages for that neighbor. If G is $O(\log n)$-random, then by Theorem 3.1 we require only $O(n)$ bits of additional routing information in each node. Namely, because the assignment of ports (outgoing edges) to direct neighbors is known by permutation π, we can use an additional routing table in $3n$ bits per node to route to the remaining nonneighbor nodes as described in the proof of Theorem 3.1. In total this gives $(n^2/2)\log n(1+o(1))$ bits. □

Our last theorem of this section determines the upper bounds for full-information shortest path routing schemes on Kolmogorov random graphs.

THEOREM 3.7. *For full-information shortest path routing on $o(n)$-random labeled graphs on n nodes where relabeling is not allowed (α), the local routing function occupies at most $n^2/4+o(n^2)$ bits for every node (hence the complete routing scheme takes at most $n^3/4+o(n^3)$ bits to be stored).*

Proof. Since for $o(n)$-random labeled graphs on n the node degree of every node is $n/2+o(n)$ by Lemma 2.5, we can describe in each source node the appropriate outgoing edges (ports) for each destination node by the 1's in a binary string of length $n/2+o(n)$. For each source node it suffices to store at most $n/2+o(n)$ such binary strings corresponding to the nonneighboring destination nodes. In each node we can give the neighbors by the positions of the 1's in a binary string of length $n-1$. Moreover, in each node we can give the permutation of port assignments to neighbors in $(n/2)\log n(1+o(1))$ bits. This leads to a total of at most $(n^2/4)(1+o(1))$ bits per node and hence to $(n^3/4)(1+o(1))$ bits to store the overall routing scheme. □

4. Lower bounds. The first two theorems of this section together show that $\Omega(n^2)$ bits are indeed necessary to route on Kolmogorov random graphs in all models we consider, except for the models where nodes know their neighbors *and* label permutation or relabeling is allowed (II $\wedge$ β or II $\wedge$ γ). Hence the upper bound in Theorem 3.1 is tight up to order of magnitude.

THEOREM 4.1. *For shortest path routing in $o(n)$-random labeled graphs where relabeling is not allowed and nodes know their neighbors (*II $\wedge$ α*), each local routing function must be stored in at least $n/2-o(n)$ bits per node (hence the complete routing scheme requires at least $n^2/2-o(n^2)$ bits to be stored).*

Proof. Let G be an $o(n)$-random graph. Let $F(u)$ be the local routing function of node u of G, and let $|F(u)|$ be the number of bits used to store $F(u)$. Let $E(G)$ be the standard encoding of G in $n(n-1)/2$ bits as in Definition 2.2. We now give another way to describe G using some local routing function $F(u)$:

(i) a description of this discussion in $O(1)$ bits;

(ii) a description of u in exactly $\log n$ bits, padded with 0's if necessary;

(iii) a description of the presence or absence of edges between u and the other nodes in V in $n-1$ bits;

(iv) a self-delimiting description of $F(u)$ in $|F(u)|+2\log|F(u)|$ bits;

(v) the code $E(G)$ with all bits deleted corresponding to edges $(v,w)\in E$ for each v and w such that $F(u)$ routes messages to w through the least intermediary node v. This saves at least $n/2-o(n)$ bits since there are at least $n/2-o(n)$ nodes w such that $(u,w)\notin E$ by Lemma 2.5, and since the diameter of G is 2 by Lemma 2.6, there is a shortest path $(u,v),(v,w)$ for some v. Furthermore, we delete all bits corresponding to the presence or absence of edges between u and the other nodes in V, saving another $n-1$ bits. This corresponds to the $n-1$ bits for edges connected to u, which we

added in one connected block (item (iii)) above.

In the description, we have explicitly added the adjacency pattern of node u, which we deleted elsewhere. This zero-sum swap is necessary to be able to unambiguously identify the adjacency pattern of u in order to reconstruct G given n, as follows. Reconstruct the bits corresponding to the deleted edges using u and $F(u)$ and subsequently insert them in the appropriate positions of the remnants of $E(G)$. We can do so because these positions can be simply reconstructed in increasing order. In total this new description has

$$n(n-1)/2 + O(1) + O(\log n) + |F(u)| - n/2 + o(n)$$

bits, which must be at least $n(n-1)/2 - o(n)$ by (2.1). Hence, $|F(u)| \geq n/2 - o(n)$, which proves the theorem. □

THEOREM 4.2. *Let G be an $o(n)$-random labeled graph on n nodes. Assume that the neighbors are not known (*IA $\vee$ IB*) but relabeling is allowed (γ). Then for shortest path routing the complete routing scheme requires at least $n^2/32 - o(n^2)$ bits to be stored.*

Proof. In the proof of this theorem we need the following combinatorial result.

CLAIM 2. *Let k and n be arbitrary natural numbers such that $1 \leq k \leq n$. Let x_i for $1 \leq i \leq k$ be natural numbers such that $x_i \geq 1$. If $\sum_{i=1}^{k} x_i = n$, then*

$$\sum_{i=1}^{k} \lceil \log x_i \rceil \leq n - k.$$

Proof. The proof is by induction on k. If $k = 1$, then $x_1 = n$, and clearly $\lceil \log n \rceil \leq n - 1$ if $n \geq 1$. Supposing the claim holds for k and arbitrary n and x_i, we now prove it for $k' = k + 1$, n, and arbitrary x_i. Let $\sum_{i=1}^{k'} x_i = n$. Then $\sum_{i=1}^{k} x_i = n - x_{k'}$. Now

$$\sum_{i=1}^{k'} \lceil \log x_i \rceil = \sum_{i=1}^{k} \lceil \log x_i \rceil + \lceil \log x_{k'} \rceil.$$

By the induction hypothesis the first term on the right-hand side is less than or equal to $n - x_{k'} - k$, so

$$\sum_{i=1}^{k'} \lceil \log x_i \rceil \leq n - x_{k'} - k + \lceil \log x_{k'} \rceil = n - k' + \lceil \log x_{k'} \rceil + 1 - x_{k'}.$$

Clearly $\lceil \log x_{k'} \rceil + 1 \leq x_{k'}$ if $x_{k'} \geq 1$, which proves the claim. □

Recall that in model γ each router must be able to output its own label. Using the routing scheme we can enumerate the labels of all nodes. If we cannot enumerate the labels of all nodes using less than $n^2/32$ bits of information, then the routing scheme requires at least that many bits of information and we are done. So assume we can (this includes models α and β, where the labels are not charged for, but can be described using $\log n$ bits). Let G be an $o(n)$-random graph.

CLAIM 3. *Given the labels of all nodes, we can describe the interconnection pattern of a node u using the local routing function of node u plus an additional $n/2 + o(n)$ bits.*

Proof. Apply the local routing function to each of the labels of the nodes in turn (these are given by assumption). This will return for each edge a list of destinations reached over that edge. To describe the interconnection pattern, it remains to encode for each edge which of the destinations reached is actually its immediate neighbor. If edge i routes x_i destinations, this will cost $\lceil \log x_i \rceil$ bits. By Lemma 2.5 the degree of a node in G is at least $n/2 - o(n)$. Then in total, $\sum_{i=1}^{n/2-o(n)} \lceil \log x_i \rceil$ bits will be sufficient; separations need not be encoded because they can be determined using the knowledge of all x_i's. Using Claim 2 finishes the proof. □

Now we show that there are $n/2$ nodes in G whose local routing function requires at least $n/8 - 3\log n$ bits to describe (which implies the theorem).

Assume, by way of contradiction, that there are $n/2$ nodes in G whose local routing function requires at most $n/8 - 3\log n$ bits to describe. Then we can describe G as follows:

(i) a description of this discussion in $O(1)$ bits;

(ii) the enumeration of all labels in at most $n^2/32$ (by assumption);

(iii) a description of the $n/2$ nodes in this enumeration in at most n bits;

(iv) the interconnection patterns of these $n/2$ nodes in $n/8 - 3\log n$ plus $n/2 + o(n)$ bits each (by assumption and using Claim 3); this amounts to $n/2(5n/8 - 3\log n) + o(n^2)$ bits in total with separations encoded in another $n \log n$ bits;

(v) the interconnection patterns of the remaining $n/2$ nodes *only among themselves* using the standard encoding, in $1/2(n/2)^2$ bits.

This description altogether uses

$$\begin{aligned} &O(1) + n^2/32 + n + n/2(5n/8 - 3\log n) \\ &\quad + o(n^2) + n\log n + 1/2(n/2)^2 \\ &= n^2/2 - n^2/32 + n + o(n^2) - n/2\log n \end{aligned}$$

bits, contradicting the $o(n)$-randomness of G by (2.1). We conclude that on at least $n/2$ nodes, a total of $n^2/16 - o(n^2)$ bits are used to store the routing scheme. □

If neither relabeling nor changing the port assignment is allowed, the next theorem implies that for shortest path routing on almost all such "static" graphs one cannot do better than storing part of the routing tables literally, in $(n^2/2)\log n$ bits. Note that it is known [5] that there are *worst-case* graphs (even in models where relabeling is allowed) such that $n^2 \log n - O(n^2)$ bits are required to store the routing scheme, and this matches the trivial upper bound for all graphs exactly. But in our Theorem 4.3 we show that in a certain restricted model for *almost all* graphs asymptotically $(n^2/2)\log n$ bits are required and by Theorem 3.6 that many bits are also sufficient.

THEOREM 4.3. *Let G be an $o(n)$-random labeled graph on n nodes. Assume that nodes do not know their neighbors and relabeling and changing the port assignment are not allowed (*IA $\wedge$ α*). Then for shortest path routing each local routing function must be stored in at least $(n/2)\log n - O(n)$ bits per node (hence the complete routing scheme requires at least $(n^2/2)\log n - O(n^2)$ bits to be stored).*

Proof. If the graph cannot be relabeled and the port assignment cannot be changed, the adversary can set the port assignment of each node to correspond to a permutation of the destination nodes. Since each node has at least $n/2 - o(n)$ neighbors by Lemma 2.5, such a permutation can have Kolmogorov complexity as high as $(n/2)\log n - O(n)$ [9]. Because the neighbors are not known, the local routing function must determine, for each neighbor node, the port through which to route messages for that neighbor node. Hence the local routing function completely describes the

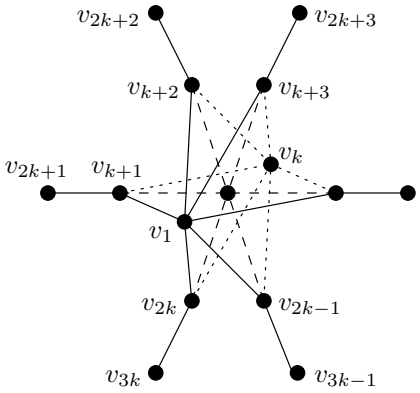

FIG. 4.1. *Graph* G_k.

permutation, given the neighbors, and thus it must occupy at least $(n/2)\log n - O(n)$ bits per node. □

Note that in this model (IA $\wedge$ α) we can trivially find by the same method a lower bound of $n^2 \log n - O(n^2)$ bits for specific graphs like the complete graph and this matches exactly the trivial upper bound in the worst case. However, Theorem 4.3 shows that for this model for *almost all* labeled graphs asymptotically 50% of this number of bits of total routing information is both necessary and sufficient.

Even if stretch factors between 1 and 2 are allowed, the next theorem shows that $\Omega(n^2 \log n)$ bits are necessary to represent the routing scheme in the worst case.

THEOREM 4.4. *For routing with stretch factor* < 2 *in labeled graphs where relabeling is not allowed* (α)*, there exist graphs on* n *nodes (almost* $(n/3)!$ *such graphs) where the local routing function must be stored in at least* $(n/3)\log n - O(n)$ *bits per node at* $n/3$ *nodes (hence the complete routing scheme requires at least* $(n^2/9)\log n - O(n^2)$ *bits to be stored).*

Proof. Consider the graph G_k with $n = 3k$ nodes depicted in Figure 4.1. Each node v_i in $v_{k+1}, \ldots, v_{2k}$ is connected to v_{i+k} and to each of the nodes $v_1, \ldots, v_k$. Fix a labeling of the nodes $v_1, \ldots, v_{2k}$ with labels from $\{1, \ldots, 2k\}$. Then any labeling of the nodes $v_{2k+1}, \ldots, v_{3k}$ with labels from $\{2k+1, \ldots, 3k\}$ corresponds to a permutation of $\{2k+1, \ldots, 3k\}$ and vice versa.

Clearly, for any two nodes v_i and v_j with $1 \le i \le k$ and $2k+1 \le j \le 3k$, the shortest path from v_i to v_j passes through node v_{j-k} and has length 2, whereas any other path from v_i to v_j has length at least 4. Hence any routing function on G_k with stretch factor < 2 routes such v_j from v_i over the edge (v_i, v_{j-k}). Then at each of the k nodes $v_1, \ldots, v_k$ the local routing functions corresponding to any two labelings of the nodes $v_{2k+1}, \ldots, v_{3k}$ are different. Hence each representation of a local routing function at the k nodes v_i, $1 \le i \le k$, corresponds one-to-one to a permutation of $\{2k+1, \ldots, 3k\}$. So given such a local routing function, we can reconstruct the permutation (by collecting the response of the local routing function for each of the nodes $k+1, \ldots, 3k$ and grouping all pairs reached over the same edge). The number of such permutations is $k!$. A fraction of at least $1 - 1/2^k$ of such permutations π has Kolmogorov complexity $C(\pi) = k \log k - O(k)$ [9]. Because π can be reconstructed given any of the k local routing functions, these k local routing functions must each have Kolmogorov complexity $k \log k - O(k)$, too. This proves the theorem for n a multiple of 3. For $n = 3k-1$ or $n = 3k-2$ we can use G_k, dropping v_k and v_{k-1}.

Note that the proof requires only that there be no relabeling; apart from that the direct neighbors of a node may be known and ports may be reassigned.

By the above calculation there are at least $(1 - 1/2^{n/3})(n/3)!$ labeled graphs on n nodes for which the theorem holds. □

Our last theorem shows that for full-information shortest path routing schemes on Kolmogorov random graphs one cannot do better than the trivial upper bound.

THEOREM 4.5. *For full-information shortest path routing on $o(n)$-random labeled graphs on n nodes where relabeling is not allowed (α), the local routing function occupies at least $n^2/4 - o(n^2)$ bits for every node (hence the complete routing scheme requires at least $n^3/4 - o(n^3)$ bits to be stored).*

Proof. Let G be a graph on nodes $\{1, 2, \ldots, n\}$ satisfying (2.1) with $\delta(n) = o(n)$. Then we know that G satisfies Lemmas 2.5 and 2.6. Let $F(u)$ be the local routing function of node u of G, and let $|F(u)|$ be the number of bits used to encode $F(u)$. Let $E(G)$ be the standard encoding of G in $n(n-1)/2$ bits as in Definition 2.2. We now give another way to describe G using some local routing function $F(u)$:

(i) a description of this discussion in $O(1)$ bits;

(ii) a description of u in $\log n$ bits (if it is less, pad the description with 0's);

(iii) a description of the presence or absence of edges between u and the other nodes in V in $n - 1$ bits;

(iv) a description of $F(u)$ in $|F(u)| + O(\log |F(u)|)$ bits (the logarithmic term to make the description self-delimiting);

(v) the code $E(G)$ with all bits deleted corresponding to the presence or absence of edges between each w and v such that v is a neighbor of u and w is not a neighbor of u. Since there are at least $n/2 - o(n)$ nodes w such that $(u, w) \notin E$ and at least $n/2 - o(n)$ nodes v such that $(u, v) \in E$, by Lemma 2.5, this saves at least $(n/2 - o(n))^2$ bits.

From this description we can reconstruct G, given n, by reconstructing the bits corresponding to the deleted edges from u and $F(u)$ and subsequently inserting them in the appropriate positions to reconstruct $E(G)$. We can do so because $F(u)$ represents a full-information routing scheme implying that $(v, w) \in E$ iff (u, v) is among the edges used to route from u to w. In total this new description has

$$n(n-1)/2 + O(\log n) + |F(u)| - n^2/4 + o(n^2)$$

bits, which must be at least $n(n-1)/2 - o(n)$ by (2.1). We conclude that $|F(u)| = n^2/4 - o(n^2)$, which proves the theorem.

Note that the proof requires only that there be no relabeling; apart from that the direct neighbors of a node may be known and ports may be reassigned. □

5. Average case. What about the average cost, taken over all labeled graphs of n nodes, of representing a routing scheme for graphs over n nodes? The results above concerned precise overwhelmingly large fractions of the set of all labeled graphs. The numerical values of randomness deficiencies and bit costs involved show that these results are actually considerably stronger than the corresponding average case results which are straightforward.

DEFINITION 5.1. *For each labeled graph G, let $T_S(G)$ be the minimal total number of bits used to store a routing scheme of type S (where S indicates shortest path routing, full-information routing, and the like). The* average *minimal total number of bits to store a routing scheme for S-routing over labeled graphs on n nodes is $\sum T_S(G)/2^{n(n-1)/2}$ with the sum taken over all graphs G on nodes $\{1, 2, \ldots, n\}$. (That is, the uniform average over all the labeled graphs on n nodes.)*

The results on Kolmogorov random graphs above have the following corollaries. The set of $(3\log n)$-random graphs constitutes a fraction of at least $(1-1/n^3)$ of the set of all graphs on n nodes. The trivial upper bound on the minimal total number of bits for all routing functions together is $O(n^2\log n)$ for shortest path routing on all graphs on n nodes (or $O(n^3)$ for full-information shortest path routing). Simple computation shows that the average total number of bits to store the routing scheme for graphs of n nodes is (asymptotically and ignoring lower order of magnitude terms as in Table 1.1) as follows:

1. $\leq 3n^2$ for shortest path routing in model IB $\vee$ II (Theorem 3.1);
2. $\leq 6n\log^2 n$ for shortest path routing in model II $\wedge$ γ, where the average is taken over the initially labeled graphs on n nodes with labels in $\{1,2,\ldots,n\}$ *before* they were relabeled with new and longer labels giving routing information (Theorem 3.2);
3. $\leq 38n\log n$ for routing with any stretch factor s for $1<s<2$ in model II (Theorem 3.3);
4. $\leq n\log\log n$ for routing with stretch factor 2 in model II (Theorem 3.4);
5. $O(n)$ for routing with stretch factor $6\log n$ in model II (Theorem 3.5 with $c=3$);
6. $\geq n^2/2$ for shortest path routing in model α (Theorem 4.1);
7. $\geq n^2/32$ for shortest path routing in model IA and IB (under all relabeling conventions, Theorem 4.2);
8. $=(n^2/2)\log n$ for shortest path routing in model IA $\wedge$ α (Theorems 3.6 and 4.3);
9. $=n^3/4$ for full-information shortest path routing in model α (Theorems 3.7 and 4.5).

6. Conclusion. The space requirements for compact routing for almost all labeled graphs on n nodes, and hence for the average case of all graphs on n nodes, are conclusively determined in this paper. We introduce a novel application of the incompressibility method. The next question arising in compact routing is the following: For practical purposes the class of all graphs is too broad in that most graphs have high node degree (around $n/2$). Such high node degrees are unrealistic in real communication networks for large n. So the question that arises is: How do we extend the current treatment to almost all graphs on n nodes of maximal node degree d, where d ranges from $O(1)$ to n? Clearly, for shortest path routing $O(n^2\log d)$ bits suffice, and [5] showed that for each $d<n$ there are shortest path routing schemes that require a total of $\Omega(n^2\log d)$ bits to be stored in the worst case for some graphs with maximal degree d, where we allow that nodes are relabeled by permutation and the port assignment may be changed (IB $\wedge$ β). This does not hold for average routing, since by our Theorem 3.1 $O(n^2)$ bits suffice for $d=\Theta(n)$. (Trivially, $O(n^2)$ bits suffice for routing in every graph with $d=O(1)$.) We believe it may be possible to show by an extension of our method that $\Theta(n^2)$ bits (independent of d) are necessary and sufficient for shortest path routing in almost all graphs of maximum node degree d, provided d grows unboundedly with n.

Another research direction is to resolve the questions addressed in this paper for Kolmogorov random unlabeled graphs, in particular with respect to the free relabeling model (insofar as they do not follow a fortiori from the results presented here).

Acknowledgments. We thank Jan van Leeuwen, Evangelos Kranakis, and Danny Krizanc for helpful discussions and the anonymous referees for comments and corrections.

COMPUTING WITH VERY WEAK RANDOM SOURCES*

ARAVIND SRINIVASAN† AND DAVID ZUCKERMAN‡

Abstract. We give an efficient algorithm to extract randomness from a very weak random source using a small additional number t of truly random bits. Our work extends that of Nisan and Zuckerman [*J. Comput. System Sci.,* 52 (1996), pp. 43–52] in that t remains small even if the entropy rate is well below constant. A key application of this is in running randomized algorithms using such a very weak source of randomness. For any fixed $\gamma > 0$, we show how to simulate RP algorithms in time $n^{O(\log n)}$ using the output of a δ-source with min-entropy R^γ. Such a weak random source is asked once for R bits; it outputs an R-bit string according to any probability distribution that places probability at most 2^{-R^γ} on each string. If $\gamma > 1/2$, our simulation also works for BPP; for $\gamma > 1 - 1/(k+1)$, our simulation takes time $n^{O(\log^{(k)} n)}$ ($\log^{(k)}$ is the logarithm iterated k times). We also give a polynomial-time BPP simulation using Chor–Goldreich sources of min-entropy $R^{\Omega(1)}$, which is optimal. We present applications to time-space tradeoffs, expander constructions, and to the hardness of approximation. Of independent interest is our randomness-efficient Leftover Hash Lemma, a key tool for extracting randomness from weak random sources.

1. Introduction.

Randomness plays a vital role in almost all areas of computer science, including simulations, algorithms, network constructions, cryptography, and distributed algorithms. In practice, programs get their "random" bits by using pseudorandom number generators. Yet even in practice there are reports of algorithms giving quite different results under different pseudorandom generators; see, e.g., [FLW] for such reports on Monte-Carlo simulations, and [Hsu, HRD] for the deviant performance of some *RNC* algorithms for graph problems.

Other approaches involve using a physical source of randomness, such as a Zener diode, or using the last digits of a real-time clock. Not only is it unclear whether such bits will be random, but it is impossible to test them for "randomness." We can run certain statistical tests on the bits, but we cannot run all possible ones. It is

therefore natural and important to ask whether randomness is just as helpful even if the source of randomness is defective or weak. Thus we model a weak random source as outputting bits that are slightly random but not perfectly random.

There have been two different directions taken in the study of weak random sources. The first is an attempt to describe a weak random source arising in practice. Thus Blum [Blu] looked at the model where bits are output by a Markov chain and showed how to extract perfectly random bits from such a source. Santha and Vazirani [SV] then looked at a model where the only fact known about the source is that each bit has some randomness. More precisely, we have the following.

DEFINITION 1.1 (see [SV]). *A semirandom source with parameter α outputs bits $X_1X_2,\ldots,X_R$, such that for all $i \le R$, and for all $x_1,\ldots,x_i \in \{0,1\}$,*

$$\alpha \le Pr[X_i = x_i | X_1 = x_1,\ldots,X_{i-1} = x_{i-1}] \le 1-\alpha.$$

Simulations must work for all such sources; we do not want to assume any knowledge about the source, except that it is semirandom with the value of the parameter α being known. Santha and Vazirani proved that it is impossible to extract even a single almost-random bit from one such source (so Vazirani [Va1, Va3] used two independent sources). In light of this result, one might give up hope of simulating randomized algorithms with one semirandom source. Nevertheless, [VV] and [Va2] showed how to efficiently simulate all algorithms in RP and BPP, with one semirandom source, for any constant $\alpha > 0$.

Note that these simulations use $R = poly(n)$ bits from the semirandom source, where n denotes the length of the input to the RP or BPP machine; we shall let n and R denote "length of the input" and "number of bits requested," respectively, when discussing RP or BPP simulations in this paper.

Chor and Goldreich [CG] generalized the Santha–Vazirani model by assuming that no sequence of l bits has too high a probability of being output. More precisely, we have the following.

DEFINITION 1.2 (see [CG]). *A blockwise δ-source outputs bits as blocks $Y_1,\ldots,Y_s$, where Y_i has length l_i, such that for all $i, y_1,\ldots,y_i$, $Pr[Y_i = y_i | Y_1 = y_1,\ldots,Y_{i-1} = y_{i-1}] \le 2^{-\delta l_i}$.*[1]

Note that δ and the block-lengths l_i are assumed to be known parameters of these sources. Later we will allow the l_i to vary, but for the first four sections we assume that all $l_i = l$. A semirandom source corresponds to $l = 1$. For $l = O(\log n)$ and constant $\delta > 0$, Chor and Goldreich showed how to efficiently simulate any BPP algorithm using one blockwise δ-source. They further showed how to obtain almost-random bits from four independent such sources at a constant rate.

The other direction researchers have taken is natural mathematically, although it does not appear to correspond as well to weak sources in practice. These models are called bit-fixing models: some of the bits are perfectly random, while others are controlled by an adversary. Cohen and Wigderson [CW] distinguish three models based on three different adversaries: oblivious bit-fixing sources [CG+], nonoblivious bit-fixing sources [BL, KKL], and adaptive bit-fixing sources [LLS]. Only for the first model could researchers do something better than they could for general weak random sources (see [CW]).

The two directions in weak random sources were united by the model of δ-sources [Zu1, Zu2], which generalizes all the previous models.

[1] We modify the notation in [CG] to better conform with ours.

DEFINITION 1.3. *For any number R of random bits requested, a δ-source outputs an R-bit string such that no string has probability more than $2^{-\delta R}$ of being output.*

As usual, we associate a source with its distribution D. Let $D(x)$ denote the probability assigned to x under distribution D.

DEFINITION 1.4. *The* min-entropy *of a distribution D is* $\min_x\{-\log_2 D(x) \mid D(x) > 0\}$.

Thus, a δ-source is equivalent to a source with min-entropy at least δR. We often go back and forth between these two terminologies.

In [Zu2], Zuckerman showed how to efficiently simulate any BPP algorithm using a δ-source, for any fixed $\delta > 0$. Because a δ-source is the most general model, this implies that BPP algorithms can be simulated using any model of a source where randomness is output at a constant rate. In light of this, what is left to do? The answer is to extend the result for subconstant δ. From an information-theoretic viewpoint, it is necessary for the R bits to have min-entropy only R^γ, for an arbitrary but fixed $\gamma > 0$ [CW]. (Of course, if BPP = P, then no random bits are necessary: this information-theoretic result holds for an abstract model of BPP, where random bits are really necessary. Such an abstract model, wherein the "witness set" W can be *any* sufficiently large set, is introduced in Definition 2.3.) Can we achieve this information-theoretic lower bound? Previously, the only weak source where this information-theoretic lower bound could be achieved was the oblivious bit-fixing source: Cohen and Wigderson showed how to simulate BPP even if the adversary fixes all but R^γ bits and leaves the other bits unbiased and independent, matching the above lower bound [CW].

In this paper, we come close to our goal: we give a time $n^{O(\log n)}$ simulation for any RP algorithm using a δ-source with min-entropy R^γ. For $\gamma > 1/2$, our simulations also work for BPP and approximation algorithms. Moreover, for $\gamma > 1 - 1/(k+1)$, our simulations take time $n^{O(\log^{(k)} n)}$, giving a polynomial-time simulation for $\gamma > 1 - 1/(2\log^* n)$. (Here $\log^{(k)}$ denotes the logarithm base 2, iterated k times; i.e., $\log^{(1)} x = \log_2 x$, $\log^{(2)} x = \log_2 \log_2 x$, etc.) Furthermore, we give a simple algorithm to simulate BPP and approximation algorithms using the Chor–Goldreich blockwise δ-source, as long as there are at least R^γ blocks and the min-entropy of the R bits is at least R^γ (i.e., $\delta R \geq R^\gamma$), for any fixed $\gamma > 0$. (The second condition may not be implied by the first condition if $\delta l < 1$.) Using $l = 1$, this gives a simulation of BPP and approximation algorithms for the Santha–Vazirani source with min-entropy R^γ. We also generalize Cohen and Wigderson's result on oblivious bit-fixing sources: it is not necessary for n^γ bits to be perfectly independent and uniform, but only "weakly independent" (see section 7). Our BPP simulations also work for approximation algorithms, such as the one for approximating the volume of a convex body [DFK].

Our BPP simulations are corollaries of something even stronger: extractor constructions. An extractor is an algorithm which extracts randomness from a weak source, using a small additional number t of truly random bits. We modify the definition given in [NZ] to account for general families of sources.

DEFINITION 1.5. *Let $E : \{0,1\}^n \times \{0,1\}^t \to \{0,1\}^m$, and $\epsilon > 0$ be a parameter. E is called an extractor with quasi-randomness ϵ for a family of sources $\mathcal{S}$ on $\{0,1\}^n$ if, for any $S \in \mathcal{S}$, the distribution of $E(x,y) \circ y$ induced by choosing x according to S and y independently and uniformly from $\{0,1\}^t$ is quasi-random (on $\{0,1\}^m \times \{0,1\}^t$) to within ϵ. In particular, when $\mathcal{S}$ is the class of δ-sources on $\{0,1\}^n$, E is called an*

TABLE 1

Min-entropy n^γ for	t truly random bits for extractor	(N, M, d, K)-disperser construction
$\gamma > 0$	NA	$(2^n, 2^{\Omega(n^{\gamma/2}/\log n)}, n^{O(\log n)}, 2^{n^\gamma})$
$\gamma > 1/2$	$O(\log^2 n)$	$(2^n, 2^{n^{2\gamma-1}/\log n}, n^{O(\log n)}, 2^{n^\gamma})$
$\gamma > 2/3$	$O((\log n)\log\log n)$	$(2^n, 2^{n^{3\gamma-2}/\log^3 n}, n^{O(\log\log n)}, 2^{n^\gamma})$
$\gamma > 1 - 1/k$	$O((\log n)\log^{(k)} n)$	$(2^n, 2^{n^{k\gamma-k+1}/\log^{2k-1} n}, n^{O(\log^{(k)} n)}, 2^{n^\gamma})$
$\gamma > 1 - 1/(2\log^* n)$	$O(\log n)$	$(2^n, 2^{\sqrt{n}}, n^{O(1)}, 2^{n^\gamma})$

$(n, m, t, \delta, \epsilon)$-*extractor.*[2]

As in [NZ], we observe that an extractor that adds t random bits yields a BPP simulation taking time $2^t poly(n)$.

In the case when $\mathcal{S}$ is the class of δ-sources, it is often convenient to view the extractors graph theoretically, as in [Sip, San, CW]. Namely, construct a bipartite graph on $\{0,1\}^n \times \{0,1\}^m$, where $x \in \{0,1\}^n$ is adjacent to $z \in \{0,1\}^m$ if and only if $z = E(x, y)$ for some y. Then any set in $\{0,1\}^n$ of size at least $2^{\delta n}$ expands almost uniformly into $\{0,1\}^m$. In particular, it yields efficient constructions of graphs, which are called dispersers in [CW].

DEFINITION 1.6. *An (N, M, d, K)-disperser is a bipartite graph with N nodes on the left side, each with degree at most d, and M nodes on the right side, such that every subset of K nodes on the left side is connected to at least $M/2$ nodes on the right. By an efficient construction of a disperser, we mean that given a node on the left side, its neighbor set can be found in poly$(\log N + \log M + d)$ time deterministically.*

LEMMA 1.7. *If there is an efficient $(n, m, t, \delta, \epsilon)$-extractor for $\epsilon \le 1/2$, then there is an efficiently constructible $(2^n, 2^m, 2^t, 2^{\delta n})$-disperser.*

Our RP simulation also yields a disperser, although it is not an extractor. In Table 1 we summarize our results for δ-sources. The simulations and running times for the five entries of the table are as follows: The first entry implies an RP simulation, while the other four are for BPP. The respective running times are $n^{O(\log n)}$, $n^{O(\log n)}$, $n^{O(\log\log n)}$, $n^{O(\log^{(k)} n)}$, and $poly(n)$.

Just as extractors and dispersers for constant δ have important applications [NZ, WZ], so, too, do our results for subconstant δ. The first application is to a relationship between the RP=P question and time-space tradeoffs. Sipser [Sip] showed that if certain expander graphs can be constructed efficiently, then for some $\epsilon > 0$ and any time bound $t(n)$, either RP = P or all unary languages in $DTIME(t(n))$ are accepted infinitely often in $SPACE(t(n)^{1-\epsilon})$. If we had a polynomial-time simulation of RP using a δ-source with min-entropy R^γ for some $\gamma < 1$, we could construct his expanders as a corollary. Because our simulations take time $n^{O(\log^{(k)} n)}$, we instead show unconditionally that either $RP \subseteq \bigcap_k DTIME(n^{\log^{(k)} n})$ or all unary languages in $DTIME(t(n))$ are accepted infinitely often in $\bigcap_k SPACE(t(n)^{1-1/\log^{(k)} n})$.

Our second application is to improve the expanders constructed in [WZ], and hence all of the applications given there. In [WZ], graphs on n nodes were constructed such that for every pair of disjoint subsets S_1 and S_2 of the vertices with $|S_1| \ge n^\delta$ and $|S_2| \ge n^\delta$, there is an edge joining S_1 and S_2; the graphs so constructed had

[2] To remember the five parameters, it may be helpful to note that the first three refer to lengths of inputs and outputs in (typically) decreasing order of length. The last two parameters refer to the quality of the sampler.

essentially optimal maximum degree $n^{1-\delta+o(1)}$. These expanders were used in [WZ] to explicitly construct

(i) a k-round sorting algorithm using $n^{1+1/k+o(1)}$ comparisons;

(ii) a k-round selection algorithm using $n^{1+1/(2^k-1)+o(1)}$ comparisons;

(iii) a depth-2 superconcentrator of size $n^{1+o(1)}$; and

(iv) a depth-k wide-sense nonblocking generalized connector of size $n^{1+1/k+o(1)}$.

The reader is referred to [WZ] for the definitions and motivations for these constructions. All of these results are optimal to within factors of $n^{o(1)}$. In [WZ], these $n^{o(1)}$ factors were $2^{(\log n)^{4/5+o(1)}}$, improved to $2^{(\log n)^{2/3+o(1)}}$ in the final version of [WZ]. Our results further improve these $n^{o(1)}$ factors to $2^{(\log n)^{1/2+o(1)}}$. In addition, explicit linear-sized n-superconcentrators of depth $(\log n)^{2/3+o(1)}$ were presented in [WZ]; we improve this to $(\log n)^{1/2+o(1)}$ depth. These might seem like small improvements, given the major improvement of simulations using δ-sources. The reasons for this are that our extractors require $n^{\Omega(1)}$ min-entropy from an n-bit source and that our extractors do not extract a sufficiently good fraction of the min-entropy.

Our third application is to the hardness of approximating $\log\log\omega(G)$, where $\omega(G)$ is the maximum size of a clique in an input graph G. Let $\tilde{P}$ denote quasi-polynomial time, $\cup_{c>0} DTIME(2^{(\log n)^c})$. In [Zu2], it was shown that if $N\tilde{P} \neq \tilde{P}$, then approximating $\log\omega(G)$ to within any constant factor is not in $\tilde{P}$. In [Zu3], a randomized reduction was given showing that any iterated log is hard to approximate under a slightly stronger assumption than $N\tilde{P} \neq ZP\tilde{P}$. In particular, if $N\tilde{P} \neq ZP\tilde{P}$, then approximating $\log\log\omega(G)$ to within a constant factor is not in $co - R\tilde{P}$. This used the fact that, with high probability, certain graphs are highly expanding. Our work allows us to deterministically construct graphs that are almost as highly expanding as the nonexplicit constructions, thus making this last reduction deterministic, with a slight loss of efficiency: if $N\tilde{P} \not\subseteq DTIME(2^{(\log n)^{O(\log\log n)}})$, then approximating $\log\log\omega(G)$ to within any constant factor is not in $\tilde{P}$.

As in [Zu1, Zu2, NZ], we achieve our results using only elementary methods; in particular, we do not need expander graphs. Our main technical tool is a modification of the Leftover Hash Lemma. This very useful lemma was first proved in [ILL] and has been used extensively in simulations using δ-sources [Zu1, Zu2, NZ]. This lemma is a pseudorandom property of hash functions. However, a drawback of the lemma is that to hash from s bits to t bits, one needs at least s random bits. We show how a similar lemma can be achieved using only $O(\log s + t)$ random bits. Because this modification was so useful to us here, we believe it will be useful elsewhere, too. A similar lemma was proved independently in [GW]; however, our proof is somewhat simpler. One key consequence of our lemma is an improvement of the extractor of [NZ]. That is, we show how to add a small number t of truly random bits to a δ-source in order to extract almost-random bits; we make t much smaller than in [NZ]. By using this with the ideas of [NZ], we get our first main extractor (see Theorem 5.7). Section 5.5 then introduces some new techniques for using such extraction procedures recursively; this helps improve the quality of our extractor when δ is not "too small."

Section 2 sets up the required preliminary notions. Section 3 presents our first technical tool, the improved Leftover Hash Lemma; section 4 shows how this new Leftover Hash Lemma can be used to run BPP algorithms using very weak Chor–Goldreich sources, and also serves in part as motivation for some of our techniques of sections 5 and 6. Sections 5 and 6 contain some of our main results: simulating BPP and RP algorithms using general weak sources with very low min-entropy. Section 7 uses the result of section 4 to generalize a result of [CW] on oblivious bit-fixing

sources. Applications of our results are presented in section 8. Section 9 concludes with some recent work that our work has led to, in part, and presents open questions. In the Appendix, we show some technical details that are largely borrowed from [NZ].

2. Preliminaries. We use capital letters to denote random variables, sets, distributions, and probability spaces; lowercase letters denote other variables. We often use a correspondence where the lowercase letter denotes an instantiation of the capital letter, e.g., $\vec{x}$ might be a particular input and $\vec{X}$ the random variable being uniformly distributed over all inputs. We ignore round-off errors, assuming when needed that a number is an integer; it can be seen that this does not affect the validity of our arguments. All logarithms are to base 2 unless specified otherwise.

2.1. Basic definitions.

DEFINITION 2.1. *RP is the set of languages $L \subseteq \{0,1\}^*$ such that there is a deterministic polynomial-time Turing machine $M_L(\cdot,\cdot)$ for which*

$$a \in L \Rightarrow Pr[M_L(a,x) \text{ accepts}] \geq 1/2,$$

and

$$a \notin L \Rightarrow Pr[M_L(a,x) \text{ accepts}] = 0,$$

where the probabilities are for an x chosen uniformly in $\{0,1\}^{p(|a|)}$ for some polynomial $p = p_L$. BPP is the set of languages $L \subseteq \{0,1\}^*$ such that there is a deterministic polynomial-time Turing machine $M_L(\cdot,\cdot)$ for which

$$a \in L \Rightarrow Pr[M_L(a,x) \text{ accepts}] \geq 2/3$$

and

$$a \notin L \Rightarrow Pr[M_L(a,x) \text{ accepts}] \leq 1/3,$$

where the probabilities are for an x chosen uniformly in $\{0,1\}^{p(|a|)}$ for some polynomial $p = p_L$.

As is well known, by running M_L on independent random tapes we can change the probabilities $1/2$, $2/3$, and $1/3$ above to $1 - 2^{-poly(|a|)}$, $1 - 2^{-poly(|a|)}$, and $2^{-poly(|a|)}$, respectively, while still retaining a polynomial running time.

Distance between distributions. Let D_1 and D_2 be two distributions on the same space X. The variation distance between them is

$$\|D_1 - D_2\| \doteq \max_{Y \subseteq X} |D_1(Y) - D_2(Y)| = \frac{1}{2} \sum_{x \in X} |D_1(x) - D_2(x)|.$$

A distribution D on X is called ϵ-quasi-random (on X) if the variation distance between D and the uniform distribution on X is at most ϵ.

A convenient fact to remember is that distance between distributions cannot be created out of nowhere. In particular, if $f : X \to Y$ is any function and D_1, D_2 are distributions on X, then $\|f(D_1) - f(D_2)\| \leq \|D_1 - D_2\|$. Also, if E_1 and E_2 are distributions on Y, then $\|D_1 \times E_1 - D_2 \times E_2\| \leq \|D_1 - D_2\| + \|E_1 - E_2\|$. Since this inequality holds for any function, it also holds for random functions f. Next, the triangle inequality is obvious: $\|D_1 - D_3\| \leq \|D_1 - D_2\| + \|D_2 - D_3\|$.

2.2. Simulations using weak random sources. A source that outputs R bits is a probability distribution on $\{0,1\}^R$; we often go back and forth between these two notions. By a simulation using, say, a Chor–Goldreich source, we really mean a simulation that will work for *all* Chor–Goldreich sources. Thus, we talk about a simulation for a family of sources.

To define what simulating RP means, say we wish to test whether a given string a is in an RP language L. If $a \notin L$, then all random strings cause M_L to reject, so there is nothing to do. Suppose $a \in L$; then we wish to find with high probability a witness to this fact. Let W be the set of witnesses, i.e., $W = \{x \in \{0,1\}^r | M_L(a,x) \text{ accepts}\}$, where r denotes the number of random bits used by M_L. One might think that to simulate RP using a source we would need a different algorithm for each language in RP. Instead, we exhibit one simulation that works for *all* W with $|W| \geq 2^{r-1}$; in particular, we do not use the fact that W can be recognized in P.

We note that $s \geq r - O(\log r)$ random bits are required for this "abstract-RP" problem. For if s random bits are used and the algorithm can output $r^{O(1)}$ r-bit strings, then the number of possible outputs $2^s r^{O(1)}$ must exceed 2^{r-1}. As we can ask for at most $r^{O(1)}$ bits from the source, this is what gives the R^γ min-entropy lower bound of [CW].

DEFINITION 2.2. *A polynomial-time algorithm simulates RP using a source from a family of sources $\mathcal{S}$ if, on input any constant $c > 0$ and $R = poly(r)$ bits from any $S \in \mathcal{S}$, it outputs a polynomial number of r-bit strings z_i, such that for all $W \subseteq \{0,1\}^r, |W| \geq 2^{r-1}$, $Pr[(\exists i) z_i \in W] \geq 1 - r^{-c}$.*

If we had a perfect random source, we could make the error exponentially small. Indeed, with sources like the Chor–Goldreich blockwise δ-source, where we can request more bits with independence conditions from the first bits, we can always repeat the algorithm to achieve an exponentially small error. However, with arbitrary sources, it is not obvious that this can be done. Yet it seems reasonable to insist only on a polynomially small error, as we want the error to fool polynomial-time machines.

For BPP, we have no "witnesses" to membership, but by an abuse of notation we use W to denote the set of random strings producing the right answer. As before, a simulation of BPP will produce strings z_i and use these to query whether $a \in L$. The simulation does not have to take the majority of these answers as its answer, but since we do so it makes it simpler to define it that way.

DEFINITION 2.3. *A polynomial-time algorithm simulates BPP using a source from a family of sources $\mathcal{S}$ if, on input any constant $c > 0$ and $R = poly(r)$ bits from any $S \in \mathcal{S}$, it outputs a polynomial number of r-bit strings z_i, such that for all $W \subseteq \{0,1\}^r, |W| \geq \frac{2}{3}2^r$, $Pr[\text{majority of } z_i\text{'s lie in } W] \geq 1 - r^{-c}$.*

Such an algorithm A can also be used to simulate approximation algorithms since, if a majority of numbers lie in a given range, then their median also lies in it. Thus by taking medians instead of majorities, a good approximation can be obtained with probability at least $1 - r^{-c}$.

Our BPP simulations are actually extractor constructions. As in [NZ], an extractor construction yields a BPP simulation; the idea is to run the extractor using all possible 2^t strings y, and then produce an appropriate output.

LEMMA 2.4. *If there is a polynomial-time extractor for $\mathcal{S}$ with parameters $\epsilon = n^{-\Omega(1)}$, $m = n^{\Omega(1)}$, and t, then there is a simulation of BPP using any source S from $\mathcal{S}$ and running in time $2^t n^{O(1)}$.*

Remark. In fact, as observed in [Zu2], for δ-sources we need only $\epsilon \leq 1/3$, say, to achieve even an exponentially small error for $\delta' > \delta$.

In order to make our statements cleaner and boost the size of the output from $\Omega(m)$ to m for reasonable m, we use the following lemma, which is a corollary of a lemma in [WZ].

LEMMA 2.5 (see [WZ]). *Suppose $m \leq \delta n/4$ and, for some integer k, $\epsilon \geq 2^{-\delta n/(5k)}$. If there is an efficient $(n, m/k, t, \delta/2, \epsilon/(2k))$-extractor, then there is an efficient $(n, m, kt, \delta, \epsilon)$-extractor.*

Finally, although we focus on extractors that run in polynomial time, all our extractors can actually be made to run in NC; see the remark at the end of section 3.

3. The Leftover Hash Lemma using fewer random bits. To understand the Leftover Hash Lemma intuitively, imagine that we have an element x chosen uniformly at random from an arbitrary set $A \subseteq \{0,1\}^s$ with $|A| = 2^t$, $t < s$. Thus we have t bits of randomness, but not in a usable form. If we use some additional random bits, the Leftover Hash Lemma allows us to convert the randomness in x into a more usable form. These extra bits are used to pick a uniformly random hash function h mapping s bits to $t - 2k$ bits, where k is a security parameter. Recall that given finite sets A and B, a family H of functions mapping A to B is a *universal family of hash functions* if for any $a_1 \neq a_2 \in A$, and any $b_1, b_2 \in B$, $Pr[h(a_1) = b_1 \text{ and } h(a_2) = b_2] = 1/|B|^2$, where the probability is over h chosen uniformly at random from H. The Leftover Hash Lemma guarantees that the ordered pair $(h, h(x))$ is almost random.

LEFTOVER HASH LEMMA (see [ILL]). *Let $A \subseteq \{0,1\}^s, |A| \geq 2^t$. Let $k > 0$, and let H be a universal family of functions mapping $\{0,1\}^s$ to $\{0,1\}^{t-2k}$. Then the distribution of $(h, h(x))$ is quasi-random within 2^{-k} (on the set $H \times \{0,1\}^{t-2k}$) if (h, x) is chosen uniformly at random from $H \times A$.*

One drawback of this lemma is that to pick a universal hash function mapping s bits to $t - 2k$ bits, one needs at least s bits. One way around this is to use the extractor of [NZ]; however, that is only useful if t/s is large. Here we show how to use only $O(t + \log s)$ bits and achieve a good result. We first recall the following.

DEFINITION 3.1 (see [NN]). *A "d-wise ρ-biased" sample space S of n-bit vectors has the property that if $\vec{X} = (X_1, \ldots, X_n)$ is sampled uniformly at random from S, then for all $I \subseteq \{1, 2, \ldots, n\}, |I| \leq d$, for all $b_1, b_2, \ldots, b_{|I|} \in \{0,1\}$,*

$$\left| Pr_{\vec{X} \in S} \left[\bigwedge_{i \in I} X_i = b_i \right] - 2^{-|I|} \right| \leq \rho. \tag{1}$$

Simplifying the construction in [NN], d-wise ρ-biased spaces of cardinality $O((d \log n/\rho)^2)$ were constructed explicitly in [AG+]. In addition, given the random bits to sample from S, any bit of $\vec{X}$ can be computed in $poly(d, \log n, \log(\rho^{-1}))$ time.

LEMMA 3.2. *Let $A \subseteq \{0,1\}^s, |A| \geq 2^t$, $k > 0$, and $\epsilon \geq 2^{1-k}$. There is an explicit construction of a family F of functions mapping s bits to $t - 2k$ bits, such that the distribution of $(f, f(x))$ is quasi-random within ϵ (on the set $F \times \{0,1\}^{t-2k}$), where f is chosen uniformly at random from F, and x uniformly from A. A random element from F can be specified using $4(t-k)+O(\log s)$ random bits; given such a specification of any $g \in F$ using $4(t-k) + O(\log s)$ bits and given any $y \in \{0,1\}^s$, $g(y)$ can be computed in time $poly(s, t-k)$.*

Proof. Any $g : \{0,1\}^s \to \{0,1\}^{t-2k}$ can be represented in the natural way by a vector in $\{0,1\}^\ell$, where $\ell = (t-2k)2^s$. Now let F be a $2(t-2k)$-wise ρ-biased sample space for ℓ-length bit vectors, where $\rho = (\epsilon^2 2^{2k} - 1)2^{-2t+2k}$; ρ is nonnegative since $\epsilon \geq 2^{1-k}$. (That is, F is a family of functions, where each element of F is a function that maps $\{0,1\}^s$ to $\{0,1\}^{t-2k}$.) F can be sampled using $2(\log(t-2k) + \log\log \ell +$

$\log \rho^{-1}) + O(1) \leq 4(t-k) + O(\log s)$ random bits. The lemma's claim about $g(y)$ being efficiently computable follows from the above mentioned fact that individual bits of any string in the support of a small-bias space can be computed efficiently.

We now show that the distribution of $(f, f(x))$ is quasi-random. We follow the proof of the Leftover Hash Lemma due to Rackoff (see [IZ]).

DEFINITION 3.3. *The* collision probability $cp(D)$ *of a distribution* D *on a set* S *is* $Pr[y_1 = y_2]$, *where* y_1 *and* y_2 *are chosen* independently *from* S *according to* D.

For the distribution D of $(f, f(x))$,

$$cp(D) = Pr_{x_1,x_2 \in A, f_1,f_2 \in F}[f_1 = f_2, f_1(x_1) = f_2(x_2)],$$

where all the random choices are uniform and independent. We show that the collision probability using F is almost the same as it would be using a universal family of hash functions. Now,

$$\begin{aligned} cp(D) &= \frac{1}{|F|} Pr_{x_1,x_2 \in A, f \in F}[f(x_1) = f(x_2)] \\ &\leq \frac{1}{|F|}(Pr_{x_1,x_2 \in A}[x_1 = x_2] + Pr_{x_1,x_2 \in A, f \in F}[f(x_1) = f(x_2) | x_1 \neq x_2]) \\ &= 2^{-t}/|F| + \frac{1}{|F|} Pr_{x_1,x_2 \in A, f \in F}[f(x_1) = f(x_2) | x_1 \neq x_2] \\ &\leq 2^{-t}/|F| + \frac{1}{|F|} \max_{a_1 \neq a_2} Pr_{f \in F}[f(a_1) = f(a_2)]. \qquad (2) \end{aligned}$$

For any $a_1, a_2 \in A$, $a_1 \neq a_2$,

$$\begin{aligned} \frac{1}{|F|} Pr_{f \in F}[f(a_1) = f(a_2)] &= \frac{1}{|F|} \textstyle\sum_{b \in \{0,1\}^{t-2k}} Pr_{f \in F}[f(a_1) = f(a_2) = b] \\ &\leq \frac{1}{|F|} \textstyle\sum_{b \in \{0,1\}^{t-2k}} (2^{-2(t-2k)} + \rho) \text{ (by (1))} \\ &= \frac{1}{|F| 2^{t-2k}} (1 + \epsilon^2 - 2^{-2k}). \end{aligned}$$

Thus, from (2), $cp(D) \leq (1+\epsilon^2)/(|F|2^{t-2k})$. Now, the rest of Rackoff's proof shows that if U is the uniform distribution on $F \times \{0,1\}^{t-2k}$, then $cp(D) \leq (1+\epsilon^2) cp(U) = (1+\epsilon^2)/(|F|2^{t-2k})$ implies the ϵ-quasi-randomness of D. This concludes the proof. □

COROLLARY 3.4. *The conclusion to Lemma* 3.2 *holds if* x *is chosen from any* δ*-source,* $\delta = t/s$.

Proof. The only place where the distribution of x is needed in the above proof is in showing that its collision probability is 2^{-t}; note that 2^{-t} is an upper bound on the collision probability if x is chosen from a δ-source with $\delta = t/s$. This concludes the proof. □

Remark. In order to use Lemma 3.2, we need an irreducible polynomial over $GF[2]$ for the d-wise ρ-biased spaces. For this we use an algebraic result stating that if an integer m is of the form $2 \cdot 3^t$, then $f(z) = z^m + z^{m/2} + 1$ is an explicit irreducible polynomial over $GF[2]$ of degree m (see exercise 3.96, page 146 of [LN]). This allows our extractors to run in NC.

4. Simulating BPP using a blockwise δ-source with min-entropy R^γ. We now show how to simulate BPP using a Chor–Goldreich source with min-entropy R^γ for any fixed $\gamma > 0$; in fact, we build an extractor for Chor–Goldreich sources. Note that δ-sources are much weaker than these sources: in these sources, we know that each block has "a lot of randomness," even conditional on the previous blocks' values. In a δ-source, an adversary can, for instance, locate a lot of the randomness in certain positions that are unknown to us. Nevertheless, there are two reasons for the material of this section: to motivate our main results and the reasons for their difficulty and to construct an extractor that works with sources of min-entropy R^γ for *any* fixed $\gamma > 0$. Furthermore, this section will be useful in generalizing a result of [CW] on oblivious bit-fixing sources; see also section 7.

Note that since we are talking about extractors, we use the more usual symbol n (rather than R) in this section to denote the number of random bits requested from the source.

Suppose we are given a blockwise δ-source with $m\ (= n/l) = n^{\Omega(1)}$ blocks and with the min-entropy δn of the n bits being at least $n^{\Omega(1)}$. First note that we may always increase the block length by grouping successive blocks together. Suppose we want the output of E to be quasi-random to within n^{-c}. By choosing the block-length l appropriately, we may assume that the min-entropy of a block, $b = \delta l$, satisfies $b \geq 4(c+2)\log n$. We may also assume that $b = \Theta(\log n)$, since a blockwise δ-source is trivially a blockwise δ-source, if $\delta' < \delta$. We then choose a family F that satisfies Lemma 3.2 with parameters $k = (c+2)\log n$ and $\epsilon = n^{-(c+1)}$. Now we use the following modification of a lemma from the final version of [Zu2] which, using the Leftover Hash Lemma in the manner of [IZ], essentially strengthened related lemmas in [Va2] and [CG].

LEMMA 4.1. *Let F be a function family mapping l bits to $b - 2k$ bits, satisfying Lemma 3.2 with parameters $k = (c+2)\log n$ and $\epsilon = n^{-(c+1)}$. Let D be a blockwise δ-source on $\{0,1\}^{ml}$. If $\vec{Y} = Y_1, \ldots, Y_m$ is chosen according to D, and f is chosen uniformly at random from F, then the distribution of $(f, f(Y_1), \ldots, f(Y_m))$ is quasi-random to within $m\epsilon$.*

Proof. The proof is by backward induction, as in [NZ]. We proceed by induction from $i = m$ to $i = 0$ on the statement that, for any sequence of values $y_1, \ldots, y_i$, the distribution of $(f, f(Y_{i+1}), \ldots, f(Y_m))$ conditioned on $Y_1 = y_1, \ldots, Y_i = y_i$ is quasi-random to within $(m-i)\epsilon$. This is obvious for $i = m$. Suppose it is true for $i+1$. Fix the conditioning $Y_1 = y_1, \ldots, Y_i = y_i$ from now on, and let D_{i+1} denote the induced distribution on Y_{i+1}. We now use the obvious fact that if a statement is true for each element of a set, then it is also true for an element chosen randomly from the set, using any probability distribution. Since, by the induction hypothesis, for every y_{i+1}, the induced distribution on $(f, f(Y_{i+2}), \ldots, f(Y_m))$ is quasi-random to within $(m-i-1)\epsilon$, we have that the distribution $(Y_{i+1}, f, f(Y_{i+2}), \ldots, f(Y_m))$ is within $(m-i-1)\epsilon$ of the distribution $D_{i+1} \times U_{i+1}$, where U_{i+1} is the uniform distribution on $F \times \{0,1\}^{(m-i-1)(b-2k)}$. Thus, the distribution of $(f, f(Y_{i+1}), \ldots, f(Y_m))$ is within $(m-i-1)\epsilon$ of the distribution of $(f, f(Y_{i+1}), z_{i+2}, \ldots, z_m)$ obtained by choosing Y_{i+1} according to D_{i+1}, and $(f, z_{i+2}, \ldots, z_m)$ independently and uniformly at random from $F \times \{0,1\}^{(m-i-1)(b-2k)}$ (since $\|g(D_1) - g(D_2)\| \leq \|D_1 - D_2\|$ for any two distributions D_1 and D_2 and any function g). Using Corollary 3.4, the distribution of $(f, f(Y_{i+1}), z_{i+2}, \ldots, z_m)$ is quasi-random to within ϵ, and the lemma follows from the triangle inequality for variation distance. ∎

Sampling from F requires $O(\log l + b + \log(1/\epsilon)) = O(\log n)$ random bits, and thus

we have a good extractor for these sources. Using Lemma 2.4, we get the following.

THEOREM 4.2. *For any fixed $\gamma > 0$, BPP can be simulated using a blockwise δ-source as long as there are at least n^γ blocks and if the min-entropy of the n bits is at least n^γ (i.e., $\delta n \geq n^\gamma$). In fact, an explicit extractor $E : \{0,1\}^n \times \{0,1\}^t \to \{0,1\}^s$ that runs in NC can be built for this family of sources, with $t = O(\log n)$, $s = n^{\Omega(1)}$, and with the quasi-randomness of the output being $n^{-\Omega(1)}$.*

5. Simulating BPP using a δ-source with min-entropy $R^{1/2+\epsilon}$. We first present some intuition and preliminary ideas behind our extractor construction.

5.1. Intuition and preliminaries. To construct an extractor for a given δ-source D outputting n-bit strings, we follow the same high-level approach as does [NZ]; the crucial differences arise from the fact that the work of [NZ] focused on constant δ, while we need to work with a δ that goes to zero (fairly quickly) with n. We then introduce additional new ideas to bootstrap this construction in subsection 5.5.

The high-level idea is to first convert the output of D into a blockwise δ'-source with suitable block-lengths $l_1, l_2, \ldots, l_s$; this construction is called a *blockwise converter* and is described in subsection 5.3. ($\delta' = \delta^{1-o(1)}$.) This construction is a slight modification of that in [NZ] and hence, many of the details are shown in the Appendix (one important difference is that the l_i values are chosen differently). We output $O(\log n)$ blocks, expending $O(\log n)$ truly random bits for each block; hence, we use $O(\log^2 n)$ random bits here in total. Once this is done, we need to extract quasi-random bits from such a blockwise δ'-source, and such a construction, called a *blockwise extractor*, is presented in subsection 5.2. Here is where we need to replace the application of the Leftover Hash Lemma by our improved version; only $O(\log n)$ truly random bits are needed for this task.

The reason why the above approach works only for min-entropy $n^{1/2+\Omega(1)}$ is as follows. In constructing the blockwise converter, our approach can ensure an output that is (close to) a blockwise δ'-source only if, in particular, $\sum_i l_i = O(\delta n)$. Given $O(\delta n)$ bits from a δ-source, one can intuitively expect these to have at most $O(\delta^2 n)$ bits of randomness; thus, since we wish to extract $n^{\Omega(1)}$ (quasi-)random bits, we need $\delta^2 n = n^{\Omega(1)}$, i.e., $\delta = n^{-1/2+\Omega(1)}$, which is equivalent to min-entropy $n^{1/2+\Omega(1)}$.

The above outline suggests an extractor for min-entropy $n^{1/2+\Omega(1)}$, using $O(\log^2 n)$ bits. How can this be improved (to $O(\log n)$ ideally)? We present a partial solution as a bootstrapping approach in subsection 5.5, which has a lesser randomness requirement for relatively "large" δ, e.g., for $\delta = n^{-1/3+\Omega(1)}$. An interesting open question is whether we can efficiently construct an appropriate blockwise converter that outputs a total of $O(n)$ bits using only $O(\log n)$ truly random bits; this will suffice to give a near-optimal extractor.

We now proceed formally. We use our new Leftover Hash Lemma to modify the extractor developed in [NZ]. Part of the extractor there used the original Leftover Hash Lemma to show how to extract quasi-random bits from a certain kind of blockwise δ-source B. However, since the original Leftover Hash Lemma needs a number of random bits proportional to the logarithm of the size of the domain of the hash functions, the block-sizes in B had to decrease at the rate of $(1 + \delta/4)$, thus requiring $O((\log n)/\delta)$ blocks overall. However, our new construction allows the block-sizes of B to decrease at a constant rate independent of δ, thus requiring only $O(\log n)$ blocks. This is because now, if we need to hash from a δ-source on l bits to $\delta l/2$ bits, Lemma 3.2 and Corollary 3.4 guarantee a hash function family having error $2^{1-\delta l/4}$ which can be described using $3\delta l + O(\log l)$ bits (this is at most $4\delta l$ bits, provided

$1/\delta \leq cl/\log l$ for a sufficiently small constant c). To see this, just plug in $s = l$, $t = \delta l$, $k = \delta l/4$, and $\epsilon = 2^{1-k}$ in Corollary 3.4.

As in [NZ], our extractor first converts a δ-source into a blockwise δ-source with blocks of varying lengths and then extracts good bits from the blockwise δ-source. Unlike [NZ], we define these two intermediate constructions explicitly here.

DEFINITION 5.1. (i) *$E : \{0,1\}^n \times \{0,1\}^t \to \{0,1\}^{l_1+\cdots+l_s}$ is an $(n, (l_1, \ldots, l_s), t, \delta, \delta', \epsilon)$ blockwise converter if, for x chosen from a δ-source on $\{0,1\}^n$ and y independently and uniformly at random from $\{0,1\}^t$, $E(x,y) \circ y$ is within ϵ of a distribution $D \times U$, where D is some blockwise δ'-source with block-lengths $l_1, \ldots, l_s$ and U is the uniform distribution on $\{0,1\}^t$.* (ii) *$E : \{0,1\}^{l_1+\cdots+l_s} \times \{0,1\}^t \to \{0,1\}^m$ is an $((l_1, \ldots, l_s), m, t, \delta, \epsilon)$ blockwise extractor if, for x chosen from a blockwise δ-source with block-lengths $l_1, \ldots, l_s$ and y independently and uniformly at random from $\{0,1\}^t$, $E(x,y) \circ y$ is ϵ-quasi-random on $\{0,1\}^m$.*

Lemma 5.2, implicit in [NZ], shows how to combine a blockwise converter and a blockwise extractor.

LEMMA 5.2. *Suppose we are given an efficient $(n, (l_1, \ldots, l_s), t_1, \delta, \delta', \epsilon_1)$ blockwise converter and an efficient $((l_1, \ldots, l_s), m, t_2, \delta', \epsilon_2)$ blockwise extractor. Then we can construct an efficient $(n, m, t_1 + t_2, \delta, \epsilon_1 + \epsilon_2)$-extractor.*

Proof. For the proof, just run the converter on the output of the δ-source and then run the extractor on the output of the converter. □

Given Lemma 5.2, we now focus on constructing an appropriate blockwise converter and a blockwise extractor; these are described in subsections 5.2 and 5.3, respectively.

5.2. A blockwise extractor. Lemma 4.1 gives a blockwise extractor. However, our blockwise converter will be useful only if the number of blocks s in the blockwise δ-source is small; Lemma 4.1 results in $s = n^{\Theta(1)}$, which is too high for our purposes. We therefore use the following blockwise extractor C, which is similar to the one in [NZ] except that we use our improved version of the Leftover Hash Lemma.

Function C. The function C has four parameters: r, the number of bits used to describe a member of the hash family; s, the number of blocks; l_s, the smallest block size; and δ, the quality of the source. (To avoid details that may be distracting at this point, we discuss the reasons for the bounds on some of these parameters at the end of this subsection.) C works only if r bits suffice to hash from l_s bits to $\delta l_s/2$ bits to get a distribution that is quasi-random to within $2^{1-r/16}$, as prescribed by Corollary 3.4. Thus, as explained in the last paragraph of this subsection,

$$c \log l_s \leq r \leq 3\delta l_s + O(\log l_s) \leq 4\delta l_s \tag{3}$$

for a suitably large constant c.

We define $r_s = r$ and $r_{i-1}/r_i = 9/8$, and then the block lengths $l_i = \max(r_i/(4\delta), l_s)$. Then Lemma 3.2 ensures for each i a fixed family of hash functions $H_i = \{h : \{0,1\}^{l_i} \to \{0,1\}^{\delta l_i/2}\}$ with $|H_i| \leq 2^{r_i}$, so we assume $|H_i| = 2^{r_i}$.

1. INPUT: $x_1 \in \{0,1\}^{l_1}, \ldots, x_s \in \{0,1\}^{l_s}$; $y \in \{0,1\}^r$.
2. $h_s \leftarrow y$.
3. For $i = s$ down to 1 do $h_{i-1} \leftarrow h_i \circ h_i(x_i)$.
4. OUTPUT (a vector in $\{0,1\}^{r_0 - r}$): h_0, excluding the bits of h_s.

By choosing s large enough, we can ensure that $l_0 = r_0/(4\delta)$. Specifically, suppose $s \geq \log_{9/8}(4\delta l_s/r)$. Then, $r_0/(4\delta) = r(9/8)^s/(4\delta) \geq l_s$ and hence, by the definition of l_i, $r_0 = 4\delta l_0$.

LEMMA 5.3. *C is an $((l_1, \ldots, l_s), r_0 - r, r, \delta, 4 \cdot 2^{-r/16})$ blockwise extractor.*

Proof. This proof is very similar to a corresponding proof in [NZ]. Let $\vec{X} = X_1, \ldots, X_l$ be chosen according to D, a blockwise δ-source on $\{0,1\}^{l_1+\cdots+l_s}$, and Y be chosen uniformly from $\{0,1\}^r$. Let $r_s = r$ and $r_{i-1}/r_i = 9/8$. Then $r_i \le 4\delta l_i$. We will prove by induction from $i = s$ down to $i = 0$ the following claim, which clearly implies the lemma.

Claim. For any sequence of values $x_1, \ldots, x_i$, the distribution of h_i conditioned on $X_1 = x_1, \ldots, X_i = x_i$ is quasi-random to within ϵ_i, where $\epsilon_i = \sum_{j=i+1}^{s} 2^{1-r_j/16}$.

This claim is clearly true for $i = s$. Now suppose it is true for $i+1$. Fix the conditioning $X_1 = x_1, \ldots, X_i = x_i$, and let D_{i+1} denote the induced distribution on X_{i+1}. Since, by the induction hypothesis, for every x_{i+1} the induced distribution on h_{i+1} is quasi-random, we have that the distribution (X_{i+1}, h_{i+1}) is within ϵ_{i+1} of the distribution $D_{i+1} \times U_{i+1}$, where U_{i+1} is the uniform distribution on H_{i+1}. Thus, the distribution of h_i is within ϵ_{i+1} of the distribution obtained by choosing x_{i+1} according to D_{i+1}, and h_{i+1} independently and uniformly at random in H_{i+1}. Using Corollary 3.4 this second distribution is quasi-random to within $2^{1-r_{i+1}/16}$. □

We now explain (3). If the upper bound on r does not hold, then the error cannot be made small enough: the error will be $O(2^{-\delta l_s/4})$ rather than $O(2^{-r/16})$. If the lower bound does not hold, then the domain is too large for our hash family to work. Next, to understand the equations $l_i = \max(r_i/(4\delta), l_s)$, the reader should first think of $r = 4\delta l_s$ and $l_{i-1}/l_i = 9/8$. The reason we choose l_s larger is to reduce the error ϵ of the blockwise converter in Lemma 5.5. Note that Lemma A.1 allows smaller errors for larger values of l.

5.3. A blockwise converter. Our blockwise converter is a small modification of that in [NZ]. For our simulations of RP and BPP, it would suffice to change the k-wise independence in [NZ] to pairwise independence, as was done in [Zu2]. However, by using an improved analysis of k-wise independence from [BR], we can give a good extractor for a wider range of parameters. The results of this subsection are essentially taken from [NZ], with the only changes being this improved analysis of [BR]. Thus, in order to not obscure the main new ideas, we just present a sketch of the blockwise converter and leave the necessary details to the Appendix.

In order to define our blockwise converter, we first show how to extract one block from a δ-source. The way to do this is as follows. Intuitively, a δ-source has many bits which are somewhat random. We wish to obtain l of these somewhat random bits. This is not straightforward, as we do not know which of the n bits are somewhat random. We therefore pick the l bits at random using k-wise independence.

Choosing l out of n elements. We divide the n elements into disjoint sets $A_1, \ldots, A_l$ of size $m = n/l$, i.e., $A_i = \{(i-1)m+1, (i-1)m+2, \ldots, im\}$. We then use $k \log n$ random bits to choose $X_1, \ldots, X_l$ k-wise independently, where the range of X_i is A_i. (In other words, each X_i is uniformly distributed in A_i, and any k of the X_i's are mutually independent.) Our (random) output is $S = \{X_1, \ldots, X_l\}$. Methods to construct such k-wise independent random variables using $k \log n$ random bits are well known; see, e.g., [ABI, Lub].

Extracting one block. The function B. B has two parameters: l, the size of the output, and k, the amount of independence used.

1. INPUT: $x \in \{0,1\}^n$; $y \in \{0,1\}^t$ (where $t = k \log n$).
2. Use y to choose a set $\{i_1, \ldots, i_l\} \subset \{1, \ldots, n\}$ of size l using k-wise independence, as described above.
3. OUTPUT (a vector in $\{0,1\}^l$): $x_{i_1}, \ldots, x_{i_l}$ (here x_j is the jth bit of x).

The next key lemma, Lemma 5.4, is proved in the Appendix.

LEMMA 5.4. *If D is a δ-source on $\{0,1\}^n$ and $\vec{X}$ is chosen according to D, then for all but an ϵ fraction of $y \in \{0,1\}^t$ the distribution of $B(\vec{X}, \vec{y})$ is within ϵ from a δ'-source. Here $\delta' = c\delta/\log \delta^{-1}$, $k \leq (\delta' l)^{1-\beta}$, and $\epsilon = (\delta' l)^{-c\beta k}$ for some sufficiently small positive constant c.*

5.3.1. The blockwise converter. We can now define our blockwise converter A. A has parameters $(l_1, \ldots, l_s)$, the lengths of the output blocks, and k, the amount of independence.

1. INPUT: $x \in \{0,1\}^n$; $y_1 \in \{0,1\}^{k \log n}, \ldots, y_s \in \{0,1\}^{k \log n}$.
2. For $i = 1, \ldots, s$ do $z_i \leftarrow B(x, y_i)$. (We use B with parameters l_i and k.)
3. OUTPUT: $z_1 \circ \cdots \circ z_s$.

Using essentially the same proof as in [NZ], we can show the following.

LEMMA 5.5. *Let $l_{min} = \min(l_1, \ldots, l_s)$, and suppose $k \leq (\delta' l_{min})^{1-\beta}$ and $l_1 + \cdots + l_s < \delta n/4$. Then A is an $(n, (l_1, \ldots, l_s), sk \log n, \delta, \delta', \epsilon)$ blockwise converter. Here $\delta' = c\delta/\log \delta^{-1}$ and $\epsilon = 2s(\delta' l_{min})^{-c'\beta k}$, where c' is from Lemma 5.4 and $c = c'/4$.*

In order to make the error small for the blockwise converter, we set the length of the smallest block $l_s = n^{\Theta(1)}$. This gives the following.

COROLLARY 5.6. *Suppose $l_1 + \cdots + l_s < \delta n/4$ and, for some constant $\beta > 0$, all $l_i \geq n^{\beta}(\log \epsilon^{-1})/\delta$. Then we can construct an efficient $(n, (l_1, \ldots, l_s), O(s \log \epsilon^{-1}), \delta, \delta', \epsilon)$ blockwise converter, where $\delta' = c\delta/\log \delta^{-1}$, c from Lemma 5.5.*

Proof. Choose $k = c''(\log \epsilon^{-1}/\log n)$ for a large enough constant c''. □

5.4. Choosing parameters and the basic extractor. It may help the reader, in the following discussion, to keep in mind the sample parameter values $\delta = n^{-1/4}$ and $\epsilon = 1/n$. The general parameter list for the extractor is given after Corollary 5.8 for reference.

From the discussion about the parameters of function C, all parameter lengths are determined by the smallest block-length l_s. We choose $l_s \geq n^{1/4}$ and large enough so that the error from C is small, but small enough to ensure $s \geq \log_{9/8}(4\delta l_s/r)$. Therefore, by the remark after the description of C, $r_0 = 4\delta' l_0$ and the output m is large enough. These choices are summarized below. E is our main extractor, obtained by combining the converter A with the blockwise extractor C and invoking Lemma 5.2 using the following values for the parameters.

Parameters of E for $\delta = n^{-1/4}$, $\epsilon = 1/n$, and $\beta = 1/4$.

1. The parameter n is given.
2. $\delta' = c\delta/\log \delta^{-1}$, where c is from Lemma 5.5. Thus $\delta' = \Theta(n^{-1/4}/\log n)$.
3. r is chosen to be the smallest integer such that $4 \cdot 2^{-r/16} \leq \epsilon/2$. So, $r = \Theta(\log n)$.
4. $l_s = n^{\beta/2} r/\delta'$; thus $l_s = \Theta(n^{3/8} \log^2 n)$.
5. Set $l_i = \max((r/4\delta')(9/8)^{s-i}, l_s)$.
6. s is chosen to be the largest integer such that $\sum_{i=1}^{s} l_i \leq \delta n/4$; thus $s = \Theta(\log n)$.
7. k is chosen so that $2s(\delta' l_s)^{-c'k\beta/2} \leq \epsilon/2$, where c' is from Lemma 5.4. So, $k = \Theta(1)$.
8. The length of the second parameter to E is given by $t = s(k \log n) + r$. Thus $t = \Theta(\log^2 n)$.
9. The length of the output of E is $m = 4\delta' l_0 - r = \Theta(\sqrt{n}/\log n)$.

Thus, by Lemmas 5.2 and 2.5, we deduce the following.

THEOREM 5.7. *For any $\beta > 0$ and any parameters $\delta = \delta(n)$ and $\epsilon = \epsilon(n)$ with $1/\sqrt{n} \le \delta \le 1/2$ and $2^{-\delta^2 n^{1-\beta}} \le \epsilon \le 1/n$, there is an efficient $(n, m = \delta^2 n/\log \delta^{-1}, t = O((\log n)\log \epsilon^{-1}), \delta, \epsilon)$-extractor.*

Proof. Using Lemma 5.2 gives output $m = \Omega(\delta^2 n/\log \delta^{-1})$; by applying Lemma 2.5 we can improve this to $m = \delta^2 n/\log \delta^{-1}$ while increasing t by a constant factor. □

Then Lemma 2.4 gives Corollary 5.8.

COROLLARY 5.8. *Any BPP algorithm can be simulated in $n^{O(\log n)}$ time using a δ-source, if the min-entropy of the R output bits is at least R^γ for any fixed $\gamma > 1/2$.*

We now present the parameter list of E in full generality.

Parameters of *E*. General case.

1. The parameters n, δ, and ϵ are given. We assume $1/\sqrt{n} \le \delta \le 1/2$ and for some constant $\beta > 0$, $2^{-\delta^2 n^{1-\beta}} \le \epsilon \le 1/n$.
2. $\delta' = c\delta/\log \delta^{-1}$, where c is from Lemma 5.5.
3. r is chosen to be the smallest integer such that $4 \cdot 2^{-r/16} \le \epsilon/2$. Thus $r = \Theta(\log \epsilon^{-1}) = O(\delta^2 n^{1-\beta})$.
4. $l_s = n^{\beta/2} r/\delta'$. We need $4\delta' l_s \ge r$ for function C. Also, $l_s = O(\delta n^{1-\beta/2} \log \delta^{-1})$.
5. Set $l_i = \max((r/4\delta')(9/8)^{s-i}, l_s)$.
6. s is chosen to be the largest integer such that $\sum_{i=1}^{s} l_i \le \delta n/4$. Since $s = O(\log n)$, $sl_s = o(\delta n)$; this and $l_0 = \Theta(\delta n)$ imply $(r/4\delta')(9/8)^s = \Theta(\delta n)$. Therefore $s \ge \log_{9/8}(4\delta' l_s/r)$, as required for the function C.
7. k is chosen so that $2s(\delta' l_s)^{-c'k\beta/2} \le \epsilon/2$, where c' is from Lemma 5.4. Since $\delta' l_s \ge n^{\beta/2}$, $k = \Theta((\log \epsilon^{-1})/\log n)$. Also, since $\delta' l_s \ge n^{\beta/2} \log \epsilon^{-1}$, $k \le (\delta' l)^{1-\beta/2}$.
8. The length of the second parameter to E is given by $t = s(k \log n) + r$. Thus $t = O((\log n)\log \epsilon^{-1})$.
9. The length of the output of E is given by $m = 4\delta' l_0 - r$. Thus $m = \Omega(\delta^2 n/\log \delta^{-1})$.

5.5. Bootstrapping to improve the extractor. We now use extractor E above recursively to get extractors which need fewer truly random additional bits, if δ is "much larger" than $n^{-1/2}$, say, $\delta = n^{-1/4}$. In particular, we show that BPP can be simulated in polynomial time if $\delta^{\log^* R} R = R^{\Omega(1)}$, where R is the number of random bits requested from the δ-source. Thus, taking $R \ge n^2$, say, as long as $\delta > n^{-1/\log^* n}$, we can simulate BPP in polynomial time; this is a significant extension of the work of [Zu2]. All of this follows from Lemma 5.9, which shows how, by bootstrapping, to get away with fewer truly random bits than E above needs. Basically, we replace one of the hash functions in the function C by the t bits output by an extractor. This way, we replace truly random bits by quasi-random bits that we extract from the source itself (i.e., we use the source's own randomness to further extract more bits). Therefore, instead of repeatedly hashing to build up an $n^{\Omega(1)}$-bit string, we need only build up a t-bit string and then apply the extractor.

LEMMA 5.9. *Suppose we are given an efficient $(n, (n_0, l_1, l_2, \ldots, l_{s-1}), t_1, \delta, \delta', \epsilon_1)$ blockwise converter A, an efficient $((l_1, \ldots, l_{s-1}), m_0, t_2, \delta', \epsilon_2)$ blockwise extractor C, and an efficient $(n_0, m, t_0 = m_0, \delta', \epsilon_3)$-extractor E. Then we can construct an efficient $(n, m, t_1 + t_2, \delta, \epsilon_1 + \epsilon_2 + \epsilon_3)$-extractor.*

Proof. Use A to add t_1 bits Y_1 and output a blockwise δ-source with blocks $X_0, X_1, \ldots, X_{s-1}$ with lengths $n_0, l_1, \ldots, l_{s-1}$. Use C to add t_2 bits Y_2 and convert $X_1, \ldots, X_{s-1}$ into a nearly uniform string Y_0 of length $m_0 = t_0$. As in the proof of

Lemma 5.3, the distribution of (X_0, Y_0, Y_1, Y_2) is within $\epsilon_1 + \epsilon_2$ of some distribution $D \times U$, where D is a δ'-source and U is the uniform distribution on $t_0 + t_1 + t_2$-bit strings. Therefore, by the extractor property for E, $(E(X_0, Y_0), Y_1, Y_2)$ is quasi-random to within $\epsilon_1 + \epsilon_2 + \epsilon_3$. □

Ideally, the extractor would add $O(\log \epsilon^{-1})$ truly random bits (for $\epsilon \leq 1/n$). The following corollary shows how an extractor using $u \log \epsilon^{-1}$ truly random bits can be improved to one using $O((\log u)(\log \epsilon^{-1}))$ additional bits.

COROLLARY 5.10. *Suppose n, δ, and ϵ are such that $1/\sqrt{n} \leq \delta \leq 1/2$ and for some constant $\beta > 0$, $2^{-\delta^2 n^{1-\beta}} \leq \epsilon \leq 1/n$. Set $n_0 = \delta n/8$ and $\delta' = c\delta/\log \delta^{-1}$, where c is from Lemma 5.5. Then, given an efficient $(n_0, m, t = u \log \epsilon^{-1}, \delta', \epsilon')$-extractor for $t \leq c'\delta n/\log n$ for a sufficiently small constant c', we can construct an efficient $(n, m, O((\log u)(\log \epsilon^{-1})), \delta, \epsilon + \epsilon')$-extractor.*

Proof. We first modify the blockwise extractor defined in subsection 5.2 so that its output is of length $t = u \log \epsilon^{-1}$. This requires only $s = O(\log u)$ blocks. More precisely, we define l_s and l_i as in subsection 5.4, but we choose s to ensure that the output length $r_0 - r = t$. Since $r = \Theta(\log \epsilon^{-1})$ and $r_{i-1}/r_i = 9/8$, this gives $s = O(\log u)$, as claimed. We therefore have an $((l_1, \ldots, l_s), t, O(\log \epsilon^{-1}), \delta', \epsilon/2)$ blockwise extractor.

We then use an $(n, (n_0, l_1, l_2, \ldots, l_{s-1}), O((\log u) \log \epsilon^{-1}), \delta, \delta', \epsilon/2)$ blockwise converter defined in subsection 5.3. Note that we have $n_0 + l_1 + l_2 + \cdots + l_s < \delta n/4$ as needed for Lemma 5.5. This inequality follows from $l_1 + l_2 + \cdots + l_s \leq s \cdot t \leq c' \cdot O(\delta n)$, and we can choose c' small enough. Now apply Lemma 5.9. □

Let $\log^{(k)}$ denote the logarithm iterated k times. We can now show the following.

THEOREM 5.11. *For any $\beta > 0$ and any parameters $\delta = \delta(n)$, $\epsilon = \epsilon(n)$, and $k = k(n)$ with $n^{-1/k} \leq \delta \leq 1/2$ and $2^{-\delta^k n^{1-\beta}} \leq \epsilon \leq 1/n$, there is an efficient $(n, m = \delta^k n/(\log \delta^{-1})^{2k-3}, t = O((\log^{(k-1)} n) \log \epsilon^{-1}), \delta, \epsilon)$-extractor. For the value $k = \log^* n - 1$, this gives an efficient $(n, m = (\delta/\log^2 \delta^{-1})^{\log^* n} n, t = O(\log \epsilon^{-1}), \delta, \epsilon)$-extractor for $\delta \geq n^{-1/2 \log^* n}$ and $2^{-\delta^{\log^* n} n^{1-\beta}} \leq \epsilon \leq 1/n$.*

Proof. Apply Corollary 5.10 repeatedly k times. Letting $m(n, \delta)$ denote the output length of the current extractor as a function of the input n and the quality δ, we see that each application of Corollary 5.10 causes the output length to decrease by a factor of $m(n_0, \delta')/m(n, \delta)$, which in our case is $\Theta(\delta/\log^2 \delta^{-1})$. Finally, use Lemma 2.5 to eliminate the Ω in front of the output m. □

COROLLARY 5.12. *For any constant $\gamma > 1 - 1/(k+1)$, any BPP algorithm can be simulated using a δ-source with min-entropy R^γ in time $n^{O(\log^{(k)} n)}$. For $\gamma > 1 - 1/(2 \log^* n)$, any BPP algorithm can be simulated using a δ-source in polynomial time.*

Remark. By applying random walks on expanders instead of k-wise independence, as in Lemma A.3, we can construct extractors for slightly smaller values of ϵ than given in Theorem 5.11: $\epsilon \geq 2^{-\delta^{2 \log^* n} n}$. However, this is not usually in the range of interest.

6. Simulating RP using a δ-source with min-entropy R^γ. Recall the RP simulation problem. We are given some fixed $\gamma > 0$, an error parameter $\kappa \in [0, 1)$, any r, and some hidden $W \subseteq \{0,1\}^r$ such that $|W| \geq 2^{r-1}$; we want to use a distribution on $\{0,1\}^R$ with min-entropy R^γ to produce a set of strings which intersects W with probability at least $1 - \kappa$. (Corollary 5.8 solves this for $\gamma > 1/2$; we now focus on an arbitrary fixed $\gamma > 0$.) Call this problem RPSIM(R, γ, κ, r). Since r will not change throughout our discussion (but R will), we let $T(R, \gamma, \kappa)$ denote its time complexity.

We shall focus on this problem for $R = R_0 \doteq r^{c(\gamma)}$, where the constant $c(\gamma)$ will be spelled out later; henceforth, R will denote an arbitrary integer in $[r^\gamma, R_0]$.

The difficulty in achieving any simulation with min-entropy less than $\sqrt{R}$ is that the basic extractor outputs a string of length less than $\delta^2 R$. One factor of δ is lost by the blockwise extractor, Lemma 5.3, and the other by the blockwise converter, Lemma 5.5. Our approach is to have the converter output a larger string with the hope of getting a larger blockwise source. If this works, we are done; if not, we show that the converter's output is a higher quality source than the original source. We can then proceed recursively.

This approach will lead to some problems with the error κ becoming too large. We handle this by using a remark in section 2.3 of [Zu2]. That remark implies the following useful inequality, which holds for any R, $\gamma' < \gamma$, and $\kappa < 1$:

$$T(R, \gamma, \kappa 2^{R^{\gamma'} - R^\gamma}) \leq T(R, \gamma', \kappa). \tag{4}$$

Here, it will be useful to think of κ as "large," i.e., close to 1. The bound (4) therefore says that we can get a high-quality solution for γ (i.e., the "error" $\kappa 2^{R^{\gamma'} - R^\gamma}$ is very low) as long as we can get even a rather low-quality solution (i.e., the error κ is "large") for an appropriate $\gamma' < \gamma$. Concretely, define $T_1(R, \gamma) \doteq T(R, \gamma, 1 - 1/\log^2 R)$ and $T_0(R, \gamma) \doteq T(R, \gamma, 1/\log^2 R_0)$ (the subscripts 0 and 1 refer to κ close to 0 and 1); recall that R denotes an arbitrary integer in $[r^\gamma, R_0]$. Then (4) shows, for instance, that

$$T_0(R, \gamma) \leq T_1(R, \gamma' = \gamma - 1/\log R_0). \tag{5}$$

Our approach will yield an algorithm upper bounding $T_1(R, \gamma')$ in terms of T_0, thus leading to a recurrence for T_0 via (5). Before that, we present some useful preliminaries.

6.1. Some useful results. Given random variables X and Y and elements x and y in the respective supports of X and Y, let $\mathcal{P}_{X,Y}(y|x)$ denote $Pr[(Y = y)|(X = x)]$. Given this, we can define $\mathcal{P}(Y|X)$ to be the random variable which, for all x and y in the respective supports of X and Y, takes on the deterministic value of $\mathcal{P}_{X,Y}(y|x)$ if $X = x$ and $Y = y$. Thus, for instance,

$$Pr_{X,Y}[\mathcal{P}(Y|X) > b] = \sum_{x,y:\ \mathcal{P}_{X,Y}(y|x) > b} Pr[(X = x) \wedge (Y = y)].$$

LEMMA 6.1. *Given a source outputting an R-bit string X with associated distribution D, partition $\{1, 2, \ldots, R\}$ into any two sets S_1 and S_2. Let X_1 and X_2 be the restrictions of X to S_1 and S_2, respectively, and let D_1 be the distribution induced on S_1. If $Pr_X[D(X) \leq 2^{-\ell}] \geq p$, then for any $p' \in [0, p]$, either $Pr_{X_1}[D_1(X_1) \leq 2^{-\ell/2}] \geq p'$ or $Pr_{X_1,X_2}[\mathcal{P}(X_2|X_1) \leq 2^{-\ell/2}] \geq p - p'$.*

Proof. Given any $x \in \{0,1\}^R$, let x_{S_1} and x_{S_2} denote its restrictions to S_1 and S_2, respectively. Now,

$$Pr_X[D(X) \leq 2^{-\ell}] = \sum_{x \in \{0,1\}^R:\ D(x) \leq 2^{-\ell}} D(x). \tag{6}$$

For any $x \in \{0,1\}^R$, $D(x) = D_1(x_{S_1}) \cdot \mathcal{P}_{X_1,X_2}(x_{S_2}|x_{S_1})$; thus, if $D(x) \leq 2^{-\ell}$, then $D_1(x_{S_1}) \leq 2^{-\ell/2}$ or $\mathcal{P}_{X_1,X_2}(x_{S_2}|x_{S_1}) \leq 2^{-\ell/2}$. Thus,

$$\sum_{x\in\{0,1\}^R:\ D(x)\le 2^{-\ell}} D(x) \le \sum_{x\in\{0,1\}^R:\ D_1(x_{S_1})\le 2^{-\ell/2}} D(x) + \sum_{x\in\{0,1\}^R:\ \mathcal{P}_{X_1,X_2}(x_{S_2}|x_{S_1})\le 2^{-\ell/2}} D(x). \tag{7}$$

However, by definition, the first and second terms in the right-hand side are, respectively, $Pr_{X_1}[D_1(X_1) \le 2^{-\ell/2}]$ and $Pr_{X_1,X_2}[\mathcal{P}(X_2|X_1) \le 2^{-\ell/2}]$. The lemma now follows from (6) and (7), using the given assumption that $Pr_X[D(X) \le 2^{-\ell}] \ge p$. □

LEMMA 6.2. *Suppose random variables $U \in \{0,1\}^{r_1}$ and $V \in \{0,1\}^{r_2}$ are such that $Pr_{U,V}[\mathcal{P}(V|U) > 2^{-\ell}] \le p$. Then, if $r_2 \ge \ell$, there is a random variable $W \in \{0,1\}^{r_2}$ such that* (i) *for all u and w in the respective supports of U and W, $Pr_{U,W}[(W = w)|(U = u)] \le 2^{-\ell}$; and* (ii) *the distribution of $U \circ V$ is within p of the distribution of $U \circ W$.*

Proof. Fix any u in the support of U, and let D_u denote the distribution of V conditional on $U = u$. Let $V_u = \{v : \mathcal{P}_{U,V}(v|u) > 2^{-\ell}\}$. Consider a distribution D'_u obtained by altering D_u such that for all $v \in V_u$, $D'_u(v) = 2^{-\ell}$; this is done by increasing the probabilities $D_u(v')$ for $v' \in \{0,1\}^{r_2} - V_u$ in some way. Now the condition $r_2 \ge \ell$ guarantees a way of doing this such that for all $v' \in \{0,1\}^{r_2} - V_u$, $D'_u(v') \le 2^{-\ell}$; it is now immediate that we have satisfied requirement (i) of the lemma.

In the above process, the only strings $u \circ v$ whose probabilities were decreased were those such that $\mathcal{P}_{U,V}(v|u) > 2^{-\ell}$. Now, it is easily seen that for any two distributions D_1 and D_2 on the same set S,

$$\|D_1 - D_2\| = \sum_{a\in S: D_1(a)>D_2(a)} (D_1(a) - D_2(a)) \le \sum_{a\in S: D_1(a)>D_2(a)} D_1(a).$$

Thus, since $Pr_{U,V}[\mathcal{P}(V|U) > 2^{-\ell}] \le p$ by assumption, requirement (ii) of the lemma is proved. □

6.2. The algorithm. We now present an algorithm for RPSIM$(R, \gamma' = \gamma - 1/\log R_0, 1 - 1/\log^2 R, r)$; we will bound its running time $T_1(R, \gamma')$ in terms of T_0. Fix a δ-source outputting R-bit strings with min-entropy $R^{\gamma'}$; thus, $\delta = \delta(R, \gamma')$ is given by $\delta R = R^{\gamma'}$ (so $\delta = R^{\gamma'-1}$). We may assume that the number of bits used to describe a hash function in the function C is $r = 4\delta l_s$, because a larger l_s was necessary only to reduce the error ϵ of the extractor. Since $r = \Theta(\log R)$, we have $l_s = \Theta(R^{1-\gamma'}/\log R)$. We also set $k = 2$ in the function B, i.e., use pairwise independence; thus, the error parameter ϵ in the statement of Lemma 5.4 is at most $R^{-\alpha}$, where α is a positive constant that depends only on γ. We also let δ' denote $c(\delta/2)/\log(2/\delta) = \Theta(\delta/\log R)$, where c is from the statement of Lemma 5.4. The block-lengths l_i are given by $l_i = l_s(9/8)^{s-i}$; we defer the presentation of s for now, but just note here that s will be $\Theta(\log R)$.

Since $k = 2$, the function B from subsection 5.3 uses strings of length $2\log R$ to index l-element subsets of $\{1, 2, \ldots, R\}$. For $y \in \{0,1\}^{2\log R}$, denote this subset by $S(l, y)$. Given $x \in \{0,1\}^R$ and any $S \subseteq \{1, 2, \ldots, R\}$, let x_S denote the sequence of bits of x indexed by S. Thus $B_l(x, y) = x_{S(y,l)}$ (note that we are subscripting the function B by the output length l). Recall that the output of the blockwise converter A, with parameters $(l_1, \ldots, l_s)$ and $k = 2$, is $A(x, (y_1, \ldots, y_s)) = B_{l_1}(x, y_1) \circ B_{l_2}(x, y_2) \circ \cdots \circ B_{l_s}(x, y_s)$.

The following lemma will be crucial.

LEMMA 6.3. *Let $\vec{X}$ denote a random string drawn from the given δ-source. For each i, $1 \le i \le s$, at least one of the following holds:*

(P1) *There exist $y_1, y_2, \ldots, y_i \in \{0,1\}^{2\log R}$ such that the distribution of $B_{l_1}(\vec{X}, y_1) \circ \cdots \circ B_{l_i}(\vec{X}, y_i)$ is within $i(\epsilon + 1/(3s))$ of the distribution of a blockwise δ'-source with block-lengths $l_1, l_2, \ldots, l_i$; or*

(P2) *there exist $y_1, y_2, \ldots, y_{i-1} \in \{0,1\}^{2\log R}$ such that the distribution of $B_{l_1}(\vec{X}, y_1) \circ \cdots \circ B_{l_{i-1}}(\vec{X}, y_{i-1})$ is within $1 - 1/(3s)$ of a distribution on $\{0,1\}^{l_1+l_2+\cdots+l_{i-1}}$ with min-entropy $R^{\gamma'}/2$.*

Proof. The proof is by induction on i. (P1) is true for the base case $i = 1$, by Lemma 5.4. We assume the lemma for $i = j \ge 1$ and prove for $i = j + 1$. If (P2) is true for $i = j$, so it is for $i = j + 1$; so we assume that (P1) is true for $i = j$ and prove the lemma for $i = j + 1$.

Let $y_1^*, y_2^*, \ldots, y_j^*$ be the values of $y_1, y_2, \ldots, y_j$ that make (P1) true for $i = j$. Let $S = S(y_1^*, l_1) \cup S(y_2^*, l_2) \cup \cdots \cup S(y_j^*, l_j)$, and let D_1 denote the distribution placed by the given δ-source on $\vec{X}_S$. Substituting $p = 1$, $p' = 1/(3s)$, $\ell = R^{\gamma'}$, $S_1 = S$, and $S_2 = \{1, 2, \ldots, n\} - S_1$ in Lemma 6.1, we see that one of two cases holds: (a) $Pr_{\vec{X}}[D_1(\vec{X}_S) \le 2^{-R^{\gamma'}/2}] \ge 1/(3s)$ or (b) $Pr_{\vec{X}}[\mathcal{P}(\vec{X}_{S_2} | \vec{X}_S) > 2^{-R^{\gamma'}/2}] \le 1/(3s)$.

If case (a) holds, we see by substituting $r_1 = 0$ in Lemma 6.2 that (P2) holds for $i = j + 1$, with $y_1^*, y_2^*, \ldots, y_j^*$ being the corresponding values of $y_1, y_2, \ldots, y_j$.

So, let us suppose case (b) holds. Then, it is easy to see that $Pr_{\vec{X}}[\mathcal{P}(\vec{X} | \vec{X}_S) > 2^{-R^{\gamma'}/2}] \le 1/(3s)$. So Lemma 6.2 shows that the distribution of $\vec{X}_S \circ \vec{X}$ is within $1/(3s)$ of the distribution of $\vec{X}_S \circ V$, where (i) $V \in \{0,1\}^R$; and (ii) for all x in the support of $\vec{X}_S$ and for all $v \in \{0,1\}^R$, $Pr[(V = v) | (\vec{X}_S = x)] \le 2^{-(\delta/2)R}$. Thus, by Lemma 5.4, there is at least one $y_{j+1}^* \in \{0,1\}^{2\log R}$ such that the distribution of $\vec{X}_S \circ \vec{X}_{S(y_{j+1}^*, l_{j+1})}$ is within $\epsilon + 1/(3s)$ of the distribution of $\vec{X}_S \circ V'$, where (i′) $V' \in \{0,1\}^{l_{j+1}}$; and (ii′) for all x in the support of $\vec{X}_S$ and for all $v' \in \{0,1\}^{l_{j+1}}$, $Pr[(V' = v') | (\vec{X}_S = x)] \le 2^{-\delta' l_{j+1}}$. This, combined with the inductive assumption that $y_1^*, \ldots, y_j^*$ are values of $y_1, \ldots, y_j$ that make (P1) true for $i = j$, shows that (P1) is also true for $i = j + 1$, with $y_1 = y_1^*, y_2 = y_2^*, \ldots, y_{j+1} = y_{j+1}^*$. □

Recall that if (P2) is true for i, it is also true for $i + 1$. Thus, substituting $i = s$ in Lemma 6.3 and noting that the min-entropy does not decrease if we add more bits, we deduce the following.

COROLLARY 6.4. *There exist $y_1, y_2, \ldots, y_s \in \{0,1\}^{2\log R}$ such that the distribution of $A(\vec{X}, (y_1, \ldots, y_s)) = B_{l_1}(\vec{X}, y_1) \circ B_{l_2}(\vec{X}, y_2) \circ \cdots \circ B_{l_s}(\vec{X}, y_s)$ is either* (a) *within $s\epsilon + 1/3 = 1/3 + o(1)$ of the distribution of a blockwise δ'-source with block-lengths $l_1, l_2, \ldots, l_s$; or* (b) *within $1 - 1/(3s)$ of a distribution on $\{0,1\}^{l_1+l_2+\cdots+l_s}$ with min-entropy $R^{\gamma'}/2$.*

Recall that we want an algorithm for RPSIM$(R, \gamma', 1 - 1/\log^2 R, r)$. Also recall that $l_i = l_s(9/8)^{s-i}$; we now choose $s = \Theta(\log R)$ as the largest integer such that $\sum_{i=1}^{s} l_i \le R^{1-\gamma'/2}$. We first apply our function C (we deterministically cycle through all the $R^{O(1)}$ possible choices for the random input seed for C) one by one on $\vec{X}_{S(y_1,l_1)} \circ \vec{X}_{S(y_2,l_2)} \circ \cdots \circ \vec{X}_{S(y_s,l_s)}$, for all the $R^{O(\log R)}$ possible choices for $(y_1, y_2, \ldots, y_s)$. Thus, if case (a) of Corollary 6.4 were true, at least one of the strings output would be quasi-random to within $1/3 + o(1)$. Note that all the output strings will have length $\Omega(\delta' l_1) = \Omega(R^{\gamma/2}/\log R)$. Thus, as long as this is at least r, the probability of at least one of the output strings hitting W is at least $1/2 - 1/3 - o(1) = 1/6 - o(1)$, which is much greater than the required $1 - (1 - 1/\log^2 R) = 1/\log^2 R$ for RPSIM$(R, \gamma', 1 - 1/\log^2 R, r)$.

However, since we do not know if case (a) of Corollary 6.4 holds, we also have to consider the remaining possibility (case (b) of Corollary 6.4) that there exist $y_1, y_2, \ldots, y_s \in \{0,1\}^{2\log R}$ such that the distribution of $A(\vec{X}, (y_1, \ldots, y_s)) = B_{l_1}(\vec{X}, y_1) \circ B_{l_2}(\vec{X}, y_2) \circ \cdots \circ B_{l_s}(\vec{X}, y_s)$ is within $1 - 1/(3s)$ of a distribution on $\{0,1\}^{l_1+\cdots+l_s}$ with min-entropy $R^{\gamma'}/2$. To handle this possibility, we once again exhaustively consider all the $R^{O(\log R)}$ possible choices for $(y_1, y_2, \ldots, y_s)$; for each such choice we run RPSIM$(R^{1-\gamma'/2}, \frac{\gamma' - 1/\log R}{1-\gamma'/2}, 1/\log^2 R_0, r)$ on $A(\vec{X}, (y_1, \ldots, y_s))$. Thus, if case (b) of Corollary 6.4 holds, then by the definition of RPSIM, we will hit W with probability at least $1 - (1 - 1/(3s)) - 1/\log^2 R_0 = \Theta(1/\log R)$, which is again greater than the required $1/\log^2 R$ for RPSIM$(R, \gamma', 1 - 1/\log^2 R, r)$.

The total time taken is

$$R^{O(\log R)} + R^{O(\log R)} T\left(R^{1-\gamma'/2}, \frac{\gamma' - 1/\log R}{1-\gamma'/2}, 1/\log^2 R_0\right),$$
$$= R^{O(\log R)} T_0\left(R^{1-\gamma'/2}, \frac{\gamma' - 1/\log R}{1-\gamma'/2}\right).$$

Thus, noting that $\frac{\gamma' - 1/\log R}{1-\gamma'/2} = (\gamma - \Theta(1/\log r))/(1 - \gamma/2)$, the time complexity of this algorithm can be summarized as

$$T_1(R, \gamma') \leq R^{O(\log R)} T_0(R^{1-\gamma'/2}, (\gamma - \Theta(1/\log r))/(1 - \gamma/2)).$$

Combining with (5), we see that

$$T_0(R, \gamma) \leq R^{O(\log R)} T_0(R^{1-\gamma'/2}, (\gamma - \Theta(1/\log r))/(1 - \gamma/2)). \tag{8}$$

The termination condition for this recurrence given by our extractor E is, say, $T_0(R, 2/3) = r^{O(\log r)}$. Letting $\gamma_0 = \gamma > 0$ be the initial value of γ, the sequence of values taken by the second argument in (8) is given by $\gamma_{i+1} \geq (\gamma_i - \Theta(1/\log r))/(1 - \gamma_i/2)$. Since the $\Theta(1/\log r)$ term can be made sufficiently small relative to γ_0 by taking r large enough, it is not hard to prove by induction on i that $\gamma_i \geq \gamma_0/(1-\gamma_0/4)^i$. Hence, the termination condition $\gamma_i \geq 2/3$ is achieved after a constant number of iterations, for any given constant $\gamma_0 > 0$; thus, $T_0(R, \gamma) = r^{O(\log r)}$. It is also not hard to check that all the output strings have length $\Omega(R^{\gamma/2}/\log R)$. Thus, there are constants $c_1(\gamma)$ and $c_2(\gamma)$ such that as long as we choose R_0 such that $R_0^{\gamma/2}/\log R_0 \geq c_1(\gamma) r$, i.e., as long as $R_0 \geq c_2(\gamma)(r \log r)^{2/\gamma}$, then all the output strings will have length at least r, which suffices for the above process to work.

THEOREM 6.5. *Any RP algorithm can be simulated in $n^{O(\log n)}$ time using a δ-source, if the min-entropy of the R output bits is at least R^γ for any fixed $\gamma > 0$. Correspondingly, there is an efficient construction of a $(2^n, 2^{\Omega(n^{\gamma/2}/\log n)}, n^{O(\log n)}, 2^{n^\gamma})$-disperser.*

7. Sources with many weakly independent bits. As an application of Theorem 4.2, we now show how to simulate BPP using a generalization of the oblivious bit-fixing source of [CW], using Lemma 4.1. Here again, we actually build an extractor for these sources. We need the following definition.

DEFINITION 7.1. *A bit X_i from a distribution on $X_1 X_2, \ldots, X_n$ has* weak independence α *if α is the maximum value in $[0, 1/2]$ such that for every setting $X_1 = x_1, \ldots, X_{i-1} = x_{i-1}, X_{i+1} = x_{i+1}, \ldots, X_n = x_n$ of all the other bits,*

$$\alpha \leq Pr[X_i = 0 | X_1 = x_1, \ldots, X_{i-1} = x_{i-1}, X_{i+1} = x_{i+1}, \ldots, X_n = x_n] \leq 1 - \alpha.$$

Thus, a bit of the oblivious bit-fixing source that is not fixed has weak independence 1/2. Note the difference between this definition and the semirandom source of [SV]: we look at a bit conditioned on all the other bits, not just on the previous bits. Indeed, it is not necessarily true that every bit of a semirandom source with parameter α has weak independence close to α.

THEOREM 7.2. *For a source S outputting n bits $(X_1, X_2, \ldots, X_n)$, let α_i denote the weak independence α_i of bit X_i. For any fixed $\gamma > 0$, there is an efficient (explicitly given) extractor $E : \{0,1\}^n \times \{0,1\}^t \to \{0,1\}^m$ for the class of sources with $\sum_{i=1}^n \alpha_i \geq n^\gamma$, where $t = O(\log n)$ and $m = n^{\Omega(1)}$; the output of the extractor is $n^{-\Theta(1)}$-quasi-random. The extractor need only know the value γ and not the quantities α_i.*

Note that this is best possible: if the X_i's are independent with $Pr(X_i = 0) = \alpha_i$, then the entropy of $(X_1, X_2, \ldots, X_n)$ is $k \doteq \sum_{i=1}^n H(\alpha_i)$, where $H(x) = -x \log_2 x - (1-x)\log_2(1-x)$ is the usual binary entropy function, with $H(0) = H(1) \doteq 0$. If $\sum_{i=1}^n \alpha_i = \beta$, then k is maximized when each α_i equals β/n, by the concavity of H; so $k = O(\beta \log(n/\beta))$. Thus if $\beta = n^{o(1)}$, then the entropy of $(X_1, X_2, \ldots, X_n)$ is also $n^{o(1)}$; hence such an extractor construction would not be possible. Thus we indeed need $\sum_{i=1}^n \alpha_i \geq n^\gamma$, for some fixed $\gamma > 0$.

Proof. Although the min-entropy is at least n^γ, we do not know as much about the "location" of the "good bits" as we do for Chor–Goldreich sources. We proceed by showing how to use $O(\log n)$ purely random bits to obtain a source that is a Chor–Goldreich source with high probability; the theorem then follows from Lemma 4.1. The idea is to take a pairwise independent permutation of the bits as in [Zu2] and then divide our string into blocks. We then argue that many weakly independent bits fall in each block. The reason we need weak independence is because a bit's weak independence does not change if the bits are permuted. Thus, we do not need to pick the blocks independently, as in [NZ], or use more complicated methods, as in [Zu2].

Assume, without loss of generality, that n is prime and that $\sum_{i=1}^n \alpha_i = n^\gamma$, and associate the finite field on n elements with $\{1, 2, \ldots, n\}$. Pick a to be a random *nonzero* element of the field and b to be a random field element; the map π is then $\pi(i) = ai + b$. Since $a \neq 0$, π is a permutation. Divide the n bits into $m = n^{\gamma/3}$ blocks $B_1, \ldots, B_m$ of length $l = n^{1-\gamma/3}$, according to π; i.e.,

$$B_i = (X_{\pi^{-1}((i-1)l+1)}, X_{\pi^{-1}((i-1)l+2)}, \ldots, X_{\pi^{-1}(il)}).$$

It suffices to show that with high probability, each of these blocks gets many weakly independent bits: this will give a Chor–Goldreich source. Fix $i \in \{1, 2, \ldots, m\}$ arbitrarily. Define the random variable W_i as the weak independence of block B_i, i.e., $\sum_{j=1}^n Y_j$, where $Y_j = \alpha_j$ if $\pi(j) \in \{(i-1)l+1, (i-1)l+2, il\}$, and 0 otherwise. Note that $E[Y_j] = \alpha_j l/n = \alpha_j/n^{\gamma/3}$ and hence, $E[W_i] = \sum_{j=1}^n E[Y_j] = n^{2\gamma/3}$. Now since π is a pairwise independent permutation, $Pr[\pi(i_1) = j_1 \text{ and } \pi(i_2) = j_2] = 1/(n(n-1))$, for any distinct i_1 and i_2, and any distinct j_1 and j_2. Thus for any j, k, $j \neq k$,

$$E[Y_j Y_k] = |B_i||B_i - 1|\frac{\alpha_j \alpha_k}{n(n-1)} \leq \frac{\alpha_j \alpha_k}{n^{2\gamma/3}} = E[Y_j]E[Y_k].$$

Thus, the variance $Var[W_i]$ of W_i is

$$\begin{aligned} Var[W_i] &= \sum_j (E[Y_j^2] - (E[Y_j])^2) + 2\sum_{j<k}(E[Y_j Y_k] - E[Y_j]E[Y_k]) \\ &\leq \sum_j (E[Y_j^2] - (E[Y_j])^2) \leq \sum_j E[Y_j^2] = \sum_j \frac{\alpha_j^2}{n^{\gamma/3}} \leq n^{2\gamma/3}/2. \end{aligned}$$

So, using Chebyshev's inequality, $Pr[W_i < n^{2\gamma/3}/2] \leq 2n^{-2\gamma/3}$ and hence, $Pr[(\exists i)W_i < n^{2\gamma/3}/2] \leq 2n^{-\gamma/3}$. Hence, with probability at least $1 - 2n^{-\gamma/3}$, we have the output of a Chor–Goldreich source with min-entropy $n^{\Omega(1)}$. Thus, if we now run the extractor of Lemma 4.1 on this output, the quasi-randomness of the final output is at most $\epsilon' + 2n^{-\gamma/3} = n^{-\Theta(1)}$, where $\epsilon' = n^{-\Theta(1)}$ is the amount of quasi-randomness introduced by the extractor of Lemma 4.1. □

8. Applications. Our applications rely heavily on previous work involving these applications. It is often helpful to use the graph-theoretic, or disperser, view of our results.

8.1. Time-space tradeoffs. Our first application is to time-space tradeoffs. Sipser defined the class strong-RP [Sip] as follows.

DEFINITION 8.1. *$A \in$ strong-RP if there is an RP machine accepting A using $q(n)$ random bits and achieving an error probability of at most $2^{-(q(n)-q(n)^\alpha)}$ for some fixed $\alpha < 1$.*

He then showed the following.

THEOREM 8.2 (see [Sip]). *P equals strong-RP or, for some $\epsilon > 0$ and for any time bound $t(n) \geq n$, all unary languages in DTIME($t(n)$) are accepted infinitely often in SPACE($t(n)^{1-\epsilon}$).*

We would like to replace strong-RP in the above theorem by RP. Note the relevance of δ-sources to strong-RP as follows.

LEMMA 8.3. *Strong-RP equals RP if and only if RP can be simulated using a δ-source with min-entropy R^α for some $\alpha < 1$. (For the equivalence, we assume nonoblivious simulations; i.e., the simulation could be different for different languages.)*

Proof of Lemma 8.3. Let $L \in RP$, and suppose M recognizes L using a δ-source with min-entropy R^α for some $\alpha < 1$. Then M errs on fewer than 2^{R^α} R-bit strings. Setting $q(n) = R$ shows that M is a strong-RP machine recognizing L. Conversely, suppose strong-RP equals RP, and again let $L \in RP$. Say M accepts L with error probability at most $2^{-(q(n)-q(n)^\alpha)}$ for some $\alpha < 1$. Then M errs on at most $2^{q(n)^\alpha}$ strings. Thus for a fixed β, $\alpha < \beta < 1$, M accepts L with error probability at most $2^{q(n)^\alpha - q(n)^\beta}$ if the random bits come from a δ-source with min-entropy R^β. □

As we did not quite show that RP equals strong-RP, substituting our result into Sipser's proof gives the following.

THEOREM 8.4. *$RP \subseteq \bigcap_k DTIME(n^{\log^{(k)} n})$ or, for any time bound $t(n) \geq n$, all unary languages in $DTIME(t(n))$ are accepted infinitely often in $\bigcap_k SPACE(t(n)^{1-1/\log^{(k)} n})$.*

8.2. Explicit expanders and related problems. Our second application is to improving the expanders constructed in [WZ], and hence all the applications given there. Call an N-vertex undirected graph N^δ-expanding if there is an edge connecting every pair of disjoint subsets of the vertices, of size N^δ each. In [WZ], such graphs with essentially optimal maximum degree $N^{1-\delta+o(1)}$ were constructed in polynomial time. They were used to explicitly construct some useful combinatorial structures, as mentioned in section 1. All of these results are optimal to within factors of $N^{o(1)}$. In [WZ], these $N^{o(1)}$ factors were $2^{(\log N)^{2/3+o(1)}}$. Our results improve these $N^{o(1)}$ factors to $2^{(\log N)^{1/2+o(1)}}$.

We first borrow the following lemmas from the final version of [WZ].

LEMMA 8.5 (see [WZ]). *If there is an $(n, m, t, \delta, 1/4)$-extractor computable in linear space, then there is an N^δ-expanding graph on $N = 2^n$ nodes with maximum degree $N2^{1+2t-m}$ constructible in Logspace.*

The next lemma shows how to modify an extractor so it extracts almost all the randomness of a δ-source. The intuition is that if x is output from a δ-source and the output of the extractor $E(x,y)$ has length $m=\beta n$, then the string $E(x,y)\circ x$ is close in distribution to a uniform m-bit string concatenated with a $(\delta-\beta)$-source. Thus, we can apply an extractor E' for a $(\delta-\beta)$-source with an independent t-bit string y', and output $E(x,y)\circ E'(x,y')$. The following is based on recursing on this idea.

LEMMA 8.6 (see [WZ]). *Fix positive integers n and k. Suppose that for each $\delta\in[\eta,1]$ we are given an efficient $(n,m(\delta),t(\delta),\delta,\epsilon(\delta))$-extractor, where t and ϵ are nonincreasing functions of δ. Let $f(\delta)=m(\delta)/(\delta n)$. Let $r=\ln(\delta/\eta)/f(\eta)$ or, if f grows at least linearly (i.e., $f(c\delta)\geq cf(\delta)$), let $r=2/f(\eta)$. Then we can construct an efficient $(n,(\delta-\eta)n-k,r\cdot t(\eta),\delta,r(\epsilon(\eta)+2^{-k}))$-extractor.*

We can now prove our improved construction.

THEOREM 8.7. *There is a polynomial-time algorithm that, on input N (in unary) and δ, where $0<\delta=\delta(N)<1$, constructs N^{δ}-expanding graphs on N nodes with maximum degree $N^{1-\delta}2^{(\log N)^{1/2+o(1)}}$.*

Proof. Assume, without loss of generality, that N is a power of 2, with $N=2^n$. Set $\eta=(\log^3 n/n)^{1/2}$, $\epsilon=1/n$, and $k=\log n$. If $\delta<2\eta$, then the complete graph satisfies the theorem. Otherwise, apply Lemma 8.6 to the extractor given by Theorem 5.7 to build an

$$(n,m=(\delta-\eta)n-\log n,t=O(\log^2 n\log\eta^{-1}/\eta),\delta,\epsilon=O(1/\eta n))\text{-extractor.}$$

Then Lemma 8.5 gives an N^{δ}-expanding graph with maximum degree $N^{1-\delta}2^{O(n\eta)}$, i.e., $N^{1-\delta}2^{(\log N)^{1/2+o(1)}}$. □

8.3. The hardness of approximating NP-hard problems. Our third application is to the hardness of approximating $\log\log\omega(G)$, where $\omega(G)$ is the clique number of G. In [Zu2], it was shown that if $N\tilde{P}\neq\tilde{P}$, then approximating $\log\omega(G)$ to within any constant factor is not in $\tilde{P}$ (recall that $\tilde{P}$ denotes quasi-polynomial time). In [Zu3], a randomized reduction was given showing that any iterated log is hard to approximate; in particular, if $N\tilde{P}\neq ZP\tilde{P}$, then approximating $\log\log\omega(G)$ to within a constant factor is not in $co-R\tilde{P}$. This used the fact that with high probability, certain graphs are dispersers. The disperser implied by our RP construction is almost as good. This makes the last reduction above deterministic, with a slight loss of efficiency: if $N\tilde{P}\not\subseteq DTIME(2^{(\log n)^{O(\log\log n)}})$, then approximating $\log\log\omega(G)$ to within any constant factor is not in $\tilde{P}$.

Let quasi-poly(x) be shorthand for $2^{(\log x)^{O(1)}}$. We now present a lemma, which is implicit in the results of [Zu2, Zu3] on the hardness of approximation.

LEMMA 8.8 (see [Zu2, Zu3]). *Suppose there is an explicit construction of an $(N=N(n),n^{\Theta(1)},d=d(n),K=K(n))$-disperser, for all integers n. Let $g_1,g_2\colon[1,\infty)\to\Re^+$ be functions satisfying $g_1(y)\leq g_2(y)$ for all $y\in[1,\infty)$. Suppose that for any input graph G, a number $h(G)\in[g_1(\omega(G)),g_2(\omega(G))]$ can be computed in $\tilde{P}$. Then if $g_1(N)>g_2(K)$, we have $NP\subseteq DTIME($ quasi-poly $(N+2^d))$.*

THEOREM 8.9. *If $N\tilde{P}\not\subseteq DTIME(2^{(\log n)^{O(\log\log n)}})$, then approximating $\log\log\omega(G)$ to within any constant factor is not in $\tilde{P}$. In other words, if we can compute, for some fixed $t>1$, a number in the range*

$$[2^{(\log\omega(G))^{1/t}},2^{(\log\omega(G))^{t}}]$$

in $\tilde{P}$, then $N\tilde{P}\subseteq DTIME(2^{(\log n)^{O(\log\log n)}})$.

Proof. For any fixed $\gamma \in (0,1]$, Theorem 6.5 implies that an $(N, n^{\Theta(1)}, d, K)$-disperser is efficiently constructible in the notation of Lemma 8.8, where $N = 2^{(\log n)^{O(1/\gamma)}}$, $d = (\log n)^{O(\log\log n)}$, and $K = 2^{(\log N)^{\gamma}}$. Thus, by taking $\gamma < 1/t^2, g_1(y) = 2^{(\log y)^{1/t}}$, and $g_2(y) = 2^{(\log y)^t}$, we invoke Lemma 8.8 to conclude that NP and hence $N\tilde{P}$, by a simple padding argument, is contained in $DTIME(2^{(\log n)^{O(\log\log n)}})$. □

9. Later work and open problems. Some of our main contributions—the improved Leftover Hash Lemma and its use in extractors—have served as building blocks for several recent results. First, Saks, Srinivasan, and Zhou [SSZ] have improved our RP simulation to $poly(n)$ time. Second, substantial progress on the BPP simulation question has been made by Ta-Shma [Ta-S], where an $R^{O(\log^{(k)} R)}$ algorithm is given for every fixed positive integer k. Third, ideas from this paper have been extended by Zuckerman to give optimal extractors for constant-rate sources, as well as randomness-optimal samplers [Zu4]. In an exciting new result, Andreev et al. have shown how to simulate BPP using δ-sources with min-entropy R^{γ} for any fixed $\gamma > 0$, in polynomial time [AC+].

An important open question is to efficiently construct, for the class of δ-sources with min-entropy R^{γ} for any fixed $\gamma > 0$, efficient extractors which use $O(\log R)$ purely random bits to extract as many as $(1 - o(1))R^{\gamma}$ bits, which are quasi-random to within $R^{-\Theta(1)}$. It is easy to show that such extractors exist nonconstructively. In [Ta-S] it is shown that polylog(R) bits suffice to do this. Constructing a near-optimal family of dispersers may be an interesting step in this direction.

See [Nis] for a survey of some of the recent results in this area.

Appendix. Details of the blockwise converter. A property of such k-wise independent random variables that we will require follows.

LEMMA A.1. *Let $T \subseteq \{1, 2, \ldots, n\}$, $|T|/n \geq \delta$. Suppose k is even, $4 \leq k \leq (\delta l)^{1-\beta}/8$ for some $\beta > 0$. If S is chosen at random as described above, then*

$$Pr[|S \cap T| \leq \delta l/2] \leq 8(\delta l)^{-\beta k/2}.$$

We use the following lemma from [BR].

LEMMA A.2. *For $k \geq 4$ an even integer, let $Y_1, \ldots, Y_l$ be k-wise independent* 0-1 *random variables, $Y = \sum_{i=1}^{l} Y_i$, and $\mu = E[Y]$. Then for $\alpha > 0$, $Pr[|Y - \mu| \geq \alpha] \leq 8((k\mu + k^2)/\alpha^2)^{k/2}$.*

Proof of Lemma A.1. Define the random variables Y_i to be 1 if and only if $X_i \in T$, and 0 otherwise. Then, $E[Y_i] = |T \cap A_i|/m$. Thus for $Y = \sum_{i=1}^{l} Y_i$, $E[Y] = \sum_{i=1}^{l} |T \cap A_i|/m = |T|/m \geq \delta l$. Setting $\alpha = \delta l/2$ in Lemma A.2 concludes the proof. □

We remark that for certain parameters of the extractor (e.g., if $\delta = \Omega(1)$), it may be better to use the following lemma from [NZ]. The parameters where this is useful are mostly uninteresting: $\epsilon = 2^{-\delta^2 n^{1-o(1)}}$.

LEMMA A.3 (see [NZ]). *There is an absolute constant $c > 0$ such that the following holds: Suppose $ck \leq \delta^2 l$. Then we can use $O(k/\delta + \log n)$ random bits to pick l random variables $X_1, \ldots, X_l$ in $\{1, 2, \ldots, n\}$ such that $Pr[\geq \delta^2 l/16$ of the X_i's lie in $T] \geq 1 - 2^{-k}$.*

Proof of Lemma 5.4**.** To prove Lemma 5.4, we proceed as in [NZ]. Fix a δ-source D. We need the following definitions that are relative to D.

DEFINITION A.4. *For $\vec{x} \in \{0,1\}^n$ and $1 \leq i \leq n$, let $p_i(\vec{x}) = Pr_{\vec{X} \in D}[X_i = x_i | X_1 = x_1, \ldots, X_{i-1} = x_{i-1}]$. Index i is called good in $\vec{x}$ if $p_i(\vec{x}) < 1/2$ or if $p_i(\vec{x}) = 1/2$ and $x_i = 0$.*

The part of the definition with $p_i(\vec{x}) = 1/2$ ensures that exactly one of $x_i = 0$ and $x_i = 1$ is good, for a given prefix.

DEFINITION A.5. *$\vec{x}$ is α-good if there are at least αn indices which are good in x. For $S \subseteq \{1, 2, \ldots, n\}$, $\vec{x}$ is α-good in S if there are at least $\alpha|S|$ indices in S which are good in $\vec{x}$; S is α-informative to within β if $Pr_{\vec{X} \in D}[\vec{X}$ is α-good in $S] \geq 1 - \beta$.*

Denote by S_y the set of l indices chosen using the (k-wise independent) random bits $\vec{y}$, as described in section 5.3. A useful result shown in [NZ] is that for any set of indices $\{i_1, \ldots, i_l\}$ that is δ'-informative to within ϵ, the distribution of $X_{i_1}, \ldots, X_{i_l}$ induced by choosing $\vec{X}$ according to D is ϵ-near a δ'-source. This result, together with Lemma A.6, will clearly prove Lemma 5.4.

LEMMA A.6. *$Pr_{\vec{Y}}[S_Y$ is δ'-informative to within $\epsilon] \geq 1 - \epsilon$.*

Proof. We first need the following result from [NZ]:

$$Pr_{\vec{X} \in D}[\vec{X} \text{ is not } \alpha\text{-good}] \leq 2^{-c_1 \delta n}, \tag{9}$$

where $\alpha = c_1 \delta / \log \delta^{-1}$ for some absolute positive constant c_1.

For any fixed α-good string $\vec{x}$, we can apply Lemma A.1 to the set of good indices and obtain $Pr_Y[\vec{x}$ has $\leq \alpha l/2$ good indices in $S_Y] \leq 8(\alpha l)^{-\beta k/2}$. Using (9), it follows that

$$Pr_{\vec{X},Y}[\vec{X} \text{ has } \leq \alpha l/2 \text{ good indices in } S_Y] \leq 8(\alpha l)^{-\beta k/2} + 2^{-c_1 \delta n}.$$

Set $\delta' = \alpha/2$ and $\epsilon = \sqrt{8(\alpha l)^{-\beta k/2} + 2^{-c_1 \delta n}}$. We will now use Markov's inequality in the following way: Let $A_y = Pr_{\vec{X} \in D}[\vec{X}$ is not δ'-good in $S_y]$. Thus A_Y is a random variable determined by Y. From the above analysis, $E_Y[A_Y] \leq \epsilon^2$. Therefore, by Markov's inequality, $Pr_Y[A_Y \geq \epsilon] \leq \epsilon$. In other words, $Pr_Y[S_Y$ is δ'-informative to within $\epsilon] \geq 1 - \epsilon$. □

Note that in the sources considered in section 4, we know that each block has "many" good bits; thus, since we know the block boundaries, working with the good bits was much easier there. Since we have no idea of the location of good bits in general δ-sources, we have to work much harder here.

Acknowledgments. We thank Avi Wigderson for helpful discussions, and the two referees for their detailed and helpful suggestions.

LOWER BOUNDS IN A PARALLEL MODEL WITHOUT BIT OPERATIONS*

KETAN MULMULEY†

Abstract. We define a natural and realistic model of parallel computation called the *PRAM model without bit operations*. It is like the usual PRAM model, the main difference being that no bit operations are provided. It encompasses virtually all known parallel algorithms for (weighted) combinatorial optimization and algebraic problems. In this model we prove that for some large enough constant b, the mincost-flow problem for graphs with n vertices cannot be solved deterministically (or with randomization) in $\sqrt{n}/b$ (expected) time using $2^{\sqrt{n}/b}$ processors; this is so even if we restrict every cost and capacity to be an integer (nonnegative if it is a capacity) of bitlength at most an for some large enough constant a. A similar lower bound is also proved for the max-flow problem. It follows that these problems cannot be solved in our model deterministically (or with randomization) in $\Omega(N^c)$ (expected) time with $2^{\Omega(N^c)}$ processors, where c is an appropriate positive constant and N is the total bitlength of the input. Since these problems were known to be P-complete, this provides concrete support for the belief that P-completeness implies high parallel complexity and for the $P \neq NC$ conjecture. Our lower bounds also extend to the *PRAM model with limited bit operations*, which provides instructions for parity and left or right shift by one bit.

Our proof is based on basic algebraic geometry. So we investigate if the algebrogeometric approach could also work for the P versus NC problem. Our results support this possibility, and a close analysis of the limitation of our technique in this context suggests that such a proof of $P \neq NC$ should somehow use geometric invariant theory in a deep way.

Key words. computational complexity, parallel algorithms, lower bounds

1. Overview.

1.1. Introduction.

One fundamental question in computer science is whether $P = NC$. It is generally believed that the answer is no. We are specifically interested in weighted combinatorial optimization problems in P, such as mincost-flow and max-flow, which have the so-called strongly polynomial time algorithms [17]—these are fast, i.e., polynomial time, sequential algorithms that do not use bit operations and the number of whose basic arithmetic steps depends polynomially only on the number of input parameters, not on the input bitlength. For these problems it is natural to ask if they also have fast parallel algorithms that do not use bit operations. Of course, if we assume that $P \neq NC$, then the answer for the mincost-flow and max-flow problems is no, whether bit operations are available or not, because they are P-complete [15]. In this paper we prove this unconditionally, i.e., without assuming $P \neq NC$, when bit operations are not available. This provides concrete support for the belief that P-completeness implies high parallel complexity, and for the $P \neq NC$ conjecture itself, by proving its implications in a model that is restricted but realistic.

The model. What do we mean by a parallel algorithm that does not use bit operations? Formally, we mean an algorithm in a *PRAM model without bit operations*

(section 2). It is like the usual PRAM model, the main difference being that it does not provide instructions for any bit operations such as $\wedge$, $\vee$, or *extract-bit*. The model provides usual arithmetic $(+, -, \times)$, comparison $(=, \leq, <)$, store, indirect reference, and branch operations. Each memory location can hold an integer; a rational number is represented by a pair of integers—its numerator and denominator—both of which can be accessed by the processors separately. The processors communicate as in the usual PRAM model. The model does not provide instructions for truncation or integer division with rounding. The lower bounds are proved in the conservative unit-cost model in which each operation is assigned unit cost regardless of the bitlengths of the operands. The PRAM model does not satisfactorily address the issue of interprocessor communication, so important in practice, but it is ideal for proving lower bounds since a lower bound in this model automatically applies to any other realistic parallel model of computation.

Although our model does not provide bit operations, the issue of bitlengths is not ignored. This means two things. First, the running time of an algorithm (in the unit-cost model) is allowed to depend on the input bitlength. For example, the running time of Neff's parallel algorithm [39] for computing approximate roots of a polynomial—which lies in our model—depends on the input bitlength and the bit precision level desired in the output. Second, our lower bounds are expressible in terms of the total bitlength of the input and are applicable even when this bitlength is small, i.e., polynomial in the number of input parameters. In other words, we prove existence of hard instances of small bitlength. Such a result allows connections to the P versus NC problem by expressing lower bounds in terms of bitlength of the input. In contrast, the lower bounds in the models such as the algebraic computation tree model [46, 53] are in terms of the number of input parameters and require their bitlengths to be extremely large or unbounded to be applicable.

Unlike some earlier models used for proving lower bounds, such as the constant-depth [12, 19, 52] or monotone circuit model [42, 1, 5], the PRAM model without bit operations is realistic and natural. It encompasses virtually all known parallel algorithms for weighted optimization and algebraic problems. These include fast parallel algorithms for solving linear systems [11]; minimum-weight-spanning trees [32]; shortest paths [32]; global mincuts in weighted, undirected graphs [30, 31]; blocking flows and max-flows [13, 45]; approximate computation of roots of polynomials [3, 39]; sorting [32]; and several problems in computational geometry [43].

If in our model we require that the running time of a parallel algorithm depend only on the number of input parameters but not on their bitlengths, the resulting *arithmetic PRAM model* is much weaker but still very interesting; many of the preceding parallel algorithms [11, 13, 30, 31, 32, 45] actually belong to this model. Our lower bounds in the PRAM model without bit operations automatically yield ones in the arithmetic PRAM model too—just ignore the bitlength restrictions in their statements.

Lower bounds. We show that for some large enough constant b, the mincost-flow problem for networks with n nodes cannot be solved in the PRAM model without bit operations deterministically (or with randomization) in $\sqrt{n}/b$ (expected) time using $2^{\sqrt{n}/b}$ processors; this is so even if we restrict every cost and capacity to be an integer (nonnegative if it is a capacity) of bitlength at most an for some large enough constant a. We prove the same lower bound for the max-flow problem, which holds even if we restrict every edge-capacity to be a nonnegative integer of bitlength at most an^2 for some large enough constant a. The restriction on the bitlengths implies that these

problems cannot be solved in our model deterministically (or with randomization) in $\Omega(N^c)$ (expected) time with $2^{\Omega(N^c)}$ processors, where c is an appropriate positive constant and N is the total bitlength of the input. Our lower bound also applies to the weighted s-t-mincut problem (for directed or undirected graphs) since it is the dual of the max-flow problem.

Our lower bounds hold for both the decision and the additive approximation versions of these problems. In the decision version, one is given an additional integer parameter w, called *threshold*, and the problem is to decide if the optimum exceeds w. (Thus for max-flow, the problem is to decide if the max-flow value exceeds w; for mincost-flow, the problem is to decide if there exists a flow with value v, specified in the input, and cost at most w.) In the additive approximation version, the goal is to compute the optimum within a small, say, less than 1/8, *additive* error.

Our lower bounds also imply some separation results of complexity theoretic nature. Let SP be the class of languages in P that have strongly polynomial time algorithms [17]; for example, the mincost-flow and max-flow problems belong to SP. (By a language we mean in this paper a set of integer sequences rather than boolean strings.) Let $C[t(N), p(N)]$ be the class of languages that can be recognized in the PRAM model without bit operations in $t(N)$ time (in the unit cost model) using $p(N)$ processors, where N denotes the input bitlength. The randomized class $RC[t(N), p(N)]$ is defined similarly. Let $C^i = C[O(\log^i(N)), \text{poly}(N)]$ be the analogue of the class NC^i and $C = \cup_i C^i$ the analogue of the class NC. For detailed definitions of these complexity classes see section 2.3.

In our model an analogue of the $P \not\subseteq NC$ conjecture would be that $SP \not\subseteq C$. This is not just an analogue but also an implication, i.e., $P \not\subseteq NC$ implies that $SP \not\subseteq C$ (Proposition 2.2). Since the mincost-flow and max-flow problems belong to SP, our lower bounds imply unconditionally that $SP \not\subseteq C$; in fact, they imply something much stronger:

$$SP \not\subseteq RC[N^c, 2^{N^c}]$$

for a suitable positive constant c.

We also prove that the hierarchies $\{C^i\}$ and $\{RC^i\}$, which are analogues of the hierarchies $\{NC^i\}$ and $\{RNC^i\}$, do not collapse. This follows from the following stronger statement: For some positive constant c,

$$C^i \not\subseteq RC^{\lfloor i/c \rfloor + 1}$$

for all i.

PRAM with limited bit operations. It appears that the $P \neq NC$ conjecture is hard essentially due to the issue of bits. There are actually two issues: (1) the running time of a parallel algorithm can depend on the input bitlength, and (2) the algorithm can access an arbitrary bit of the operand. The first issue is addressed satisfactorily in our model, the second issue is not. The higher order bits of an operand are easy to access in our model—it is the middle and lower order bits that are hard (though not impossible) to access (section 2.2). We can extend our lower bound to the *PRAM model with limited bit operations*, which provides instructions for parity and left or right shift by one bit; in this model even the lower order bits are easy to access. This is as far as one can go. If one allows shift by an arbitrary number of bits, the model would become as powerful as the usual unrestricted PRAM-model, and that is beyond the scope of our techniques for reasons outlined in section 7. Parity

is a nonalgebraic operation, or, if it is considered algebraic, it has high exponential degree. Therefore it is interesting that our techniques can handle it.

P versus NC. Our lower bounds are proved using basic algebraic geometry (Milnor–Thom result [34], Collins's decomposition [10], and transversality techniques [16]) in conjunction with diophontine techniques over integer lattices. We also need lower bounds for the so-called parametric complexity (section 3) of the mincost-flow and max-flow problems; these were proved earlier in some other contexts combinatorially [38, 14, 57, 7] (see also Theorem 3.8). Our proof should be contrasted with the combinatorial proofs of the lower bounds for, say, constant-depth [12, 19, 52] or monotone circuits [42, 1, 5, 56], and also with the proofs of the lower bounds in the algebraic computation tree model [2, 46, 53]—these are for sequential sorting-related problems, and the issue of bitlengths is not addressed.

In view of the effectiveness of the algebrogeometric approach in a restricted yet realistic PRAM model of computation in this paper, we investigate its potential in the unrestricted PRAM model. Toward this end, we formulate a certain conjecture (section 7), which if true would imply that $P \neq NC$. Of course, a proof of $P \neq NC$ may not go via this conjecture; it has been formulated mainly to bring out what is lacking in our current approach and what more is needed. Roughly, the conjecture says that for every positive constant a, linear pullbacks of the well-known algebraic group variety $SL_m(C)$, where m satisfies some dimension constraints, cannot have a certain *separation property* that depends on the constant a. We then prove the conjecture for every large enough constant a. Our technique is insufficient for proving the conjecture in full generality, i.e., for every positive constant a—as expected, since it relies on the restricted nature of the PRAM model without bit operations. But a careful analysis of its limitation reveals what a proof of $P \neq NC$ ought to exploit: it should somehow use properties of varieties admitting good group actions—as investigated in geometric invariant theory [6, 37]—in a deep way. (In the terminology of [44], these techniques would not be "natural," but calling them so would not do justice to their depth and beauty. The framework of [44] is not meaningful in the PRAM model without bit operations in this paper just as it is not in the monotone circuit model.[1])

1.2. The issue of bitlengths. Our lower bounds for mincost-flow and max-flow depend on the fact that the edge-capacities can have polynomial—i.e., $\Omega(n)$ or $\Omega(n^2)$—bitlengths. This is necessary: if the bitlengths were small, these problems can, in fact, be solved fast in parallel in our model. For example, consider the max-flow problem. Suppose all edge-capacities have $O(\log n)$ bitlengths. Then in our model all these bits can be extracted in parallel in logarithmic time using the available instructions (section 2.2). Once all bits in the input are extracted, the model becomes as powerful as the usual unrestricted PRAM model. One can thereafter use an RNC-algorithm for unweighted matching [24, 36] to get a polylogarithmic time algorithm. More generally, if all edge-capacities have polylog(n) bitlengths, the problem can be solved in our model in polylog(n) time using $2^{\text{polylog}(n)}$ processors; by a variation of our lower bound, this is close to optimal. The problem can also be solved in $O(n^2 \log n)$ time with $O(n)$ processors without any restriction on the bitlengths by a parallel algorithm of Shiloach and Vishkin [45] or of Goldberg and Tarjan [13], both

[1]This is because a lower bound in our model is meaningful only for a language that can be recognized by an efficient sequential algorithm that does not use bit operations (section 2.2); for a language in P, this means it should have a strongly polynomial time algorithm. But there is no natural way to define a random language of this kind as would be required in [44] for its largeness criterion to make sense.

of which lie in our model. Our lower bound should be contrasted with these upper bounds.

Recall that a strongly polynomial time sequential algorithm [17] is a polynomial time algorithm with poly(n) basic arithmetic steps, where n is the number of input parameters not the input bitlength. Similarly, let us define a *strongly polylogarithmic* time parallel algorithm to be an algorithm in the PRAM model without bit operations which runs in polylog(n) time. For example, the algorithms of Karger [30] and Karger and Motwani [31] for the global mincut problem for weighted undirected graphs are strongly polylogarithmic. Our lower bound implies that the mincost-flow and max-flow problems, which have strongly polynomial time sequential algorithms, have no analogous strongly polylogarithmic time parallel algorithms; but actually it even rules out in our model algorithms that work in $\Omega(N^c)$ (expected) time with $2^{\Omega(N^c)}$ processors, where c is a small enough positive constant and N is the total bitlength of the input. In other words, for each of these problems it rules out a fast parallel algorithm that has the main characteristic of the ellipsoid algorithm: namely, even if it does not use any bit operations, its running time can depend on the input bitlength—this may happen if the algorithm computes the optimum value or some other numerical quantities with high precision. One example of a parallel algorithm in our model that has this characteristic is Neff's algorithm [39] for computing approximate roots of polynomials.

Our lower bound also rules out in our model a fast parallel algorithm for mincost-flow or max-flow that computes the optimum value approximately with high precision—this is what the interior-point algorithm [22] does—and then rounds it up to get the exact value. This is because our lower bound also applies to the approximate computation of the optimum value within a small, say, less than 1/8, *additive* error. Hence, even though rounding is not available in our model, the final rounding can be ignored: all that matters is that the answer just before this rounding is within a small additive error of the exact answer.

Since truncations are not available in our model, they cannot be used to control the bitsizes as in the ellipsoid or the interior-point algorithm. But our lower bounds are proved in the unit-cost model, so the algorithm need not worry about intermediate bitsizes. The ellipsoid and the interior-point algorithms also perform some basic algebraic operations such as solving linear systems and computing approximate roots of polynomials—these can be simulated fast in parallel in our model using the algorithms in [11] and [3, 39], respectively.

1.3. Statement of the results. Now we shall formally state our main results.

THEOREM 1.1. *The mincost-flow problem for networks with k nodes cannot be solved in the PRAM model without bit operations deterministically (or with randomization) in $\sqrt{k}/b$ (expected) time using $2^{\sqrt{k}/b}$ parallel processors, even assuming that every cost and capacity is an integer with bitlength at most ak for some large enough positive constants a and b.*

Similarly, the max-flow problem for directed or undirected networks with k nodes cannot be solved in the PRAM model without bit operations deterministically (or with randomization) in $\sqrt{k}/b$ (expected) time using $2^{\sqrt{k}/b}$ parallel processors, even assuming that every capacity is a nonnegative integer of bitlength at most ak^2 for some large enough positive constants a and b. The same lower bound also applies to the dual s-t-mincut problem for weighted graphs.

All lower bounds apply for the decision as well as the additive approximation versions of the problems. The lower bounds also apply in the PRAM model with

limited bit operations.

The total bitsize N of a network with k-nodes and $O(k)$ or $O(k^2)$-bit edge-capacities and costs is polynomial in k. This allows us to express the preceding lower bounds in terms of the input bitlength N.

COROLLARY 1.2. *The mincost-flow or the max-flow problem cannot be solved in the PRAM model without bit operations (or with limited bit operations) deterministically (or with randomization) in $\Omega(N^c)$ (expected) time using $2^{\Omega(N^c)}$ processors for some positive constant c.*

Remark. The theorem implies $c = 1/6$ for mincost-flow and $c = 1/8$ for max-flow; for mincost-flow the value of c can be reduced to $1/4$ (see section 3.1.1).

Since the mincost-flow problem belongs to the class SP, we also conclude the following.

COROLLARY 1.3.

$$SP \not\subseteq RC[N^{1/4}/b, 2^{N^{1/4}/b}]$$

for a large enough constant b.

We shall also prove that the $\{C^i\}$ and $\{RC^i\}$ hierarchies do not collapse; these are analogues of the conjectures that the $\{NC^i\}$ and $\{RNC^i\}$ hierarchies do not collapse.

THEOREM 1.4. *$C^i \not\subseteq RC^{i/c}$ for some positive constant c.*

Corollary 1.5 follows.

COROLLARY 1.5. *The $\{C^i\}$ and $\{RC^i\}$ hierarchies do not collapse.*

For the P versus NC problem and related results, see section 7.

1.4. Basic idea of the proof. We shall actually prove a general result (Theorem 3.3), which says that if the so-called parametric complexity of the problem is high, then it is hard to parallelize in our model. This implies our lower bounds for the mincost-flow and max-flow problems because their parametric complexity is exponential, as was shown by Carstensen [7, 8] and Zadeh [57]. Our proof has two steps. In the first step we show that if the problem with high parametric complexity had a fast parallel algorithm in our model, then there would exist a certain low-degree algebraic decomposition of a small subset of the three-dimensional integer lattice. In the second step—the heart of the proof—we show that such algebraic decomposition cannot exist. We shall now elaborate this a bit more.

Let n denote the number of integer parameters in the input and N the total bitlength of the input. Let Z denote the set of integers. Suppose, to the contrary, that there is a (nonuniform) machine M in the PRAM model without bit operations that efficiently solves a given combinatorial optimization problem with high parametric complexity for all inputs with number of parameters n and bitlength at most N. Let $L \subseteq Z^n$ denote the language corresponding to the problem; i.e., L is the set of all points in Z^n for which the answer is yes. For reasons that will become clear soon, we shall parametrize input to this machine using a constant d number of integer parameters. The parameterization is given by an integral linear map $I : Z^d \to Z^n$. Thus any integer point $z \in Z^d$ corresponds to the input $I(z)$ to the machine. For example, if L is the max-flow language, one can choose a suitable flow network whose edge-capacities are integral linear forms in two integer parameters z_1 and z_2, and let z_3 denote the threshold. This specifies a linear map from $z = (z_1, z_2, z_3)$ to the input $I(z)$ consisting of a flow network and a threshold.

Since the machine works correctly only for inputs of bitlength at most N, we shall only be interested in those $z \in Z^d$ such that the bitlength of $I(z)$ is at most N—such z will be called *permissible*. Let us color a permissible point $z \in Z^d$ green if $I(Z)$

belongs to the language L; otherwise color it red. The points that are not permissible are colorless. The first step in our proof (Theorems 4.6 and 5.6) is to show that if M recognizes L efficiently, then the green and the red points in Z^d can be *separated* by a set of algebraic (hyper)surfaces of "small" total degree. Here the total degree depends exponentially on d; so we need d to be as small as possible—in fact, we shall be able to choose $d = 3$ in our parameterization. This first step uses the Milnor–Thom result [34] from algebraic geometry, which has also been used earlier [2, 46] in the algebraic computation tree model.

When the parametric complexity of the problem is high, one can choose a parameterization I so that the green and the red points are distributed badly in some sense. The heart of our proof (Theorem 5.9) lies in showing that when the permissible points are badly colored, the red and the green points cannot be separated by any set of algebraic surfaces of small degree. The algebraic surfaces that arise in our proof can be highly singular and they can intersect badly. Therefore, without disturbing the separation property, first we smooth the surfaces and ensure that their intersections and "silhouettes" are also smooth using transversality techniques from differential geometry [16]. Next we refine the partition formed by these surfaces further by Collins' decomposition method [10] so that all regions in the resulting partition are "cylinders" of simple shape. Then using diophontine techniques, especially the pigeonhole principle, we show that if this partition were to separate the green and the red points, then some region in it must be too warped. However, since all surfaces have small degree, this cannot happen, a contradiction.

It turns out that the parametric complexity of a combinatorial optimization problem is essentially the maximum number of pivot steps the simplex algorithm would need using the so-called Gass–Saaty pivot rule. It was studied in this and related contexts in operations research. Klee and Minty [26] had shown in their classic paper that the simplex algorithm can take exponentially many steps for some simple pivot rules. The same was shown for the Gass–Saaty pivot rule by Goldfarb [14] and Murty [38] for general linear programming, by Zadeh [57] for mincost-flow, and by Carstensen [7, 8] for max-flow. This provides exponential lower bounds for the parametric complexity of these problems. Lower bounds on their parallel complexity in our model then follow from our general lower bound (Theorem 3.3) mentioned above.

1.5. Organization of the paper. In section 2 we describe the PRAM model without bit operations formally. In section 3 we explain the connection between parametric and parallel complexity. In section 4 we first prove our general lower bound in a restricted linear PRAM model without bit operations; this model does not provide general multiplication. The proof here is elementary and shows the basic ideas in a very simple setting. Moreover, we even get a stronger lower bound that is sensitive to processor-time trade-off. In section 5 the proof is extended to the general PRAM model without bit operations. In section 6 we extend the lower bound to randomized algorithms and to the PRAM model with limited bit operations. In section 7 we analyze the limitations of our approach in the context of the general P versus NC problem and indicate what more may be needed.

2. The model. Here we shall formally define the PRAM model without bit operations. This model is like the usual PRAM model [23], the essential difference being that the instruction set of the processors does not contain any bit operations.

Input to the machine is supposed to be a sequence of integers, rather than boolean numbers. In other words, each integer in the input is used as a specification for itself;

each rational number is specified in terms of its numerator and denominator; and the remaining information, such as graph specification, is encoded as an integer sequence of zeroes and ones. The input is supposed to be divided into two parts: nonnumeric data and numeric data. For the max-flow problem, the nonnumeric data would specify the underlying graph and the numeric data would specify the nonnegative edge-capacities. Let n denote the cardinality of the input, i.e., the total number of its integer parameters and N its total bitlength.

2.1. PRAM without bit operations. First, we shall define the model in the nonuniform setting. A nonuniform machine for cardinality n and bitsize N is supposed to work correctly on all inputs of cardinality n and bitlength at most N. Our machine will consist of $p(n, N)$ processors ordered in some fashion, where $p(n, N)$ is some function of n and N. The processors have private memories, and they communicate through a shared global memory. EREW, CREW, and CRCW modes of communication are defined as usual. Each memory location can contain an integer of any size that can arise in the course of execution. Accordingly, instructions can be assigned costs that depend on the bitlengths of the operands. This is important when one proves an upper bound on the running time of an algorithm. However, our lower bounds also work in a stronger sense when one assigns unit cost to each instruction regardless of the bitsizes of the operands; since the actual cost of any instruction is $\Omega(1)$, such lower bounds hold in any cost model. For the purpose of lower bounds, we shall assume this unit-cost model in the paper.

In our machine, a rational number is represented as a pair of its denominator and numerator, which need not be relatively prime, and each of which can be accessed separately by a processor. Rational operations, including division, can then be simulated by integer operations. It is important that the machine can access the numerator and the denominator separately; if we were to treat a rational number as an abstract data type (i.e., a black box) so that only its value is visible to the outside world, then the model would be far weaker. Initially, the shared memory will contain n, the cardinality of the input, in its first location, followed by the nonnumeric data, followed by the numeric data. The remaining memory locations are initialized to zero. At the end of execution, the first location in the shared memory should contain the output value.

In the nonuniform setting, it is best to think that the program of each processor has been unfolded in the form of a computation tree, quite like in the algebraic computation tree model [2, 46]. This means the length of a program can depend on n and N. Each node in this tree has a label and an instruction associated with it. No instructions for bit manipulations are provided. The instructions are of the following kinds:

1. $w = u \circ v$, where w denotes a memory location, u and v denote either memory locations or constants, which in the nonuniform setting can depend on n and N. Finally, $\circ$ denotes a binary operation $+$, $-$, or $\times$.
2. **go to** l, where l is a label of some instruction.
3. **if** $u : 0$ **go to** l, where u denotes a memory location and $:$ denotes either $<$, $\leq$, or $=$.
4. $u := v$: Store contents of the memory location v into the location u.
5. $u :=\uparrow v$ (indirect reference): Treat the value in the memory location v as a pointer. Store into the memory location u the value in the pointed memory location. We assume that the value in v is a valid pointer in a sense specified below.

6. **stop**.

We assume that the pointer involved in an indirect reference is not some numeric argument in the input or a quantity that depends on it. For example, in the max-flow problem the algorithm should not use an edge-capacity as a pointer—which is a reasonable condition. To enforce this restriction, one initially puts an *invalid-pointer* tag on every numeric argument in the input. During the execution of an arithmetic instruction, the same tag is also propagated to the result if any operand has that tag. Trying to use a memory value with invalid-pointer tag results in error.

To allow randomization, we provide an additional instruction: *random-branch* l. When it is encountered, the processor flips a fair coin. If the toss is head, it branches to the instruction labeled l; otherwise, it proceeds to the next instruction. We allow two-sided errors in randomized algorithms.

In this model the higher order bits of an operand can be easily accessed using available instructions, but the lower order bits are hard to access (section 2.2): more precisely, the lth bit from the left can be extracted in $O(l+\log x)$ operations, where x is the value of the operand. Our model does not provide integer division with rounding, because if it did, an arbitrary bit in the input could be extracted fast and the model would become as powerful as the usual PRAM model. Nevertheless, small roundings in which the rounded quotient is guaranteed to have small, say, polylogarithmic, bitsize can be simulated efficiently using available operations. Since general truncations are not provided in our model, one cannot use them to control bitsizes as in the ellipsoid or the interior-point algorithm. This does not matter because our lower bounds are proved in the unit-cost model, and hence the algorithm need not worry about intermediate bitsizes.

The model just described was nonuniform. In its uniform version we assume that there is a Turing machine that, given n and N, generates programs for all $p(n, N)$ processors using space that is logarithmic in their total size. In the uniform version we also assume that the size of each processor's program is constant; in other words, it is not meant to be unfolded in the form of a computation tree. Since we have provided instructions for jump and indirect reference, unfolding is not necessary.

2.1.1. Arithmetic PRAM model. The arithmetic PRAM model is obtained when one restricts the PRAM model without bit operations by requiring the running time $t(n, N)$ and the number of processors $p(n, N)$ to depend only on n but not on the bitlength N. In this model the issue of bitlengths is ignored just as in Yao's algebraic computation tree model for integer inputs [53]. Nevertheless it is interesting because many parallel algorithms that have been designed for (weighted) combinatorial optimization or algebraic problems lie in this model. If one is interested only in showing that a given problem does not have a strongly polylogarithmic time parallel algorithm, as defined in section 1.2, then this is the model to be used. All our lower bounds automatically hold in this weaker model, just ignore the bitsize restrictions in their statements.

2.1.2. Linear PRAM model. The linear PRAM model results if we restrict the PRAM model without bit operations by requiring that at least one operand of the $\times$ instruction be a constant. If in addition we require that the running time $t(n, N)$ and the number of processors $p(n, N)$ depend only on n but not on the bitlength N, then the resulting model is called *the arithmetic linear PRAM model*.

2.1.3. Examples. We now list various versions of our models in the increasing order of power. For each model we give examples of algorithms which lie in that

model but not in the weaker model preceding it.

Arithmetic linear PRAM model. Contains parallel algorithms for many weighted combinatorial optimization problems, such as shortest paths [32], minimum-weight spanning trees [32], max-flows and blocking flows [45, 13], global mincuts in undirected weighted graphs [31], and many problems in computational geometry [43].

Arithmetic PRAM model. Also contains parallel algorithms for solving linear systems over rationals and other problems in linear algebra, due to Csanky [11] and others (e.g., [21]), and for evaluating arithmetic circuits (straight line codes) over rationals [55]. In Csanky's algorithm [11], as it is, the bitsizes of intermediate operands can become superpolynomial in the bitlength of the input. This is fine since we are using the unit-cost model. (Of course, one can keep the bitsizes under control, but this requires integer division with rounding, an operation not available in our model.)

PRAM model without bit operations. Also contains Neff's algorithm for computing approximate roots of polynomials [39], the earlier algorithm of Ben-Or et al. [3] for a restricted class of polynomials, the numerical algorithm of Pan and Reif [40] for solving linear systems iteratively, and numerical parallel algorithms for several other problems (see the book [4] for a survey). These algorithms use truncations, which are not available in our model, to keep intermediate bitsizes under control, but, again, this is not necessary in our unit-cost model, as we already pointed out.

We do not know a natural example that is in the linear PRAM model but not in the arithmetic linear PRAM model—in this paper the linear PRAM model is used more as a medium for showing basic ideas of the proof in an elementary setting.

As one nontrivial example in weighted combinatorial optimization, let us explain why Karger and Motwani's NC-algorithm [31] for computing global mincuts in undirected weighted graphs falls in our model; in fact, it lies in the arithmetic PRAM model. It begins by normalizing weights in the graph so that they have polynomial magnitudes, i.e., logarithmic bitsizes. This requires rounding a ratio of two integers to the nearest integer, where the ratio is guaranteed to have logarithmic bitsize. Such small roundings can be carried out efficiently in our model in logarithmic time using the available operations. After this, Karger and Motwani give an NC-algorithm to compute all approximate global mincuts in the resulting normalized graph. But since all bits of the edge-weights in the normalized graph are now known to our algorithm, it can simulate any algorithm in the unrestricted PRAM model hereafter. Thus the subsequent NC-computation on the normalized graph can be simulated in our model without any problem. Once all approximate global mincuts in the normalized graph are computed—which, by Karger's result [30], are polynomial in number—Karger and Motwani's algorithm computes the weights of these cuts in the original graph and selects one with minimum weight. This too poses no problem in our model.

2.1.4. Algebraic operations. Since the parallel algorithms in [3, 39] for computing of approximate roots of polynomials lie in the PRAM model without bit operations, this operation can be simulated efficiently. Thus all our lower bounds also hold with appropriate modifications to take into account the cost of simulation, even if we were to allow this approximate algebraic operation in the model. In the sequential setting it plays a crucial role in the ellipsoid and interior-point algorithms.

2.1.5. PRAM with limited bit operations. The PRAM with limited bit operations is obtained by extending the PRAM model without bit operations by adding to the instruction set operations for left or right shift by one bit and parity, or equivalently an assignment operation $u := \lfloor u/2 \rfloor$, or, more generally, an assignment

$u := \lfloor u/p \rfloor$ for any constant p. If we were to allow shift by arbitrary number of bits, the model would become as strong as the unrestricted PRAM model.

2.2. Bit extraction. In the arithmetic PRAM model the running time of an algorithm is required to depend only on the cardinality n but not on the total bitlength N, so extracting arbitrary bit of the operand is, in general, impossible. The situation here is like in the monotone circuit model [42], where the *not* operation is impossible, or like in Yao's algebraic computation tree model for integer inputs [53], where bit extraction is impossible.

In the PRAM model without bit operations, bits can be extracted using the available instructions but this can be hard, although not impossible. More precisely, all bits of an operand x with bitlength l can be extracted in $O(l)$ time sequentially as follows. First estimate the bitlength l in $O(\log l)$ operations, starting with 2 and squaring repeatedly until the value of x is exceeded. After this the bits of x can be extracted one by one, starting at the most significant bit, using available arithmetic and comparison operations. More generally, all bits can be extracted in $O(\sqrt{l})$ time using $2^{\sqrt{l}}$ processors as follows. Conceptually divide x into $\sqrt{l}$ blocks of equal length, and extract the blocks one by one, starting with the most significant block. For example, to extract the most significant block, one can guess in parallel all of its possible values. Whether a guessed value is the correct one can be verified easily using the available operations.

However, if l is large, bit extraction is hard. In fact, it is provably so (Proposition 2.1). Of course, a lower bound for bit extraction in our model does not have much meaning as a lower bound statement; saying that bit extraction is hard in the PRAM model without bit operations is analogous to saying that the *not* operation is impossible in the monotone circuit model or that bit extraction is impossible in the algebraic computation tree model or in the arithmetic PRAM model. Just as a lower bound in the monotone circuit model is interesting only if the problem is monotone, a lower bound in the PRAM model without bit operations is interesting only if the problem has an efficient sequential algorithm that does not use bit operations: for a problem in P, this means it should have a strongly polynomial time algorithm [17] (see also section 2.3 for more discussion of this issue). This is true of all combinatorial optimization problems we consider. One trivial example of a problem that does not have a strongly polynomial time algorithm is bit extraction itself (because such an algorithm for bit extraction must work within $O(1)$ arithmetic and comparison operations, which is impossible).

PROPOSITION 2.1. *The lowest order bit of an n-bit operand cannot be extracted in the PRAM model without bit operations in $\sqrt{n}/a$ time using $2^{\sqrt{n}/a}$ processors for some large enough constant a.*

Proof. Suppose, to the contrary, that there is a parallel machine M in the model that outputs the value of the lowermost bit in $t(n) = \sqrt{n}/a$ time using $p(n) = 2^{t(n)} = 2^{\sqrt{n}/a}$ processors; here a is a large enough constant to be chosen later. Given a nonnegative integer t, call two inputs x and $\bar{x}$ t-equivalent if the behavior of the machine M up to time t on the input x is the same as that on the input $\bar{x}$; more formally, the branches taken by all processors in M up to time t are the same for both x and $\bar{x}$. We say that x and $\bar{x}$ are equivalent if they are $t(n)$-equivalent.

Now assume that the input x to the machine is guaranteed to be in a fixed t-equivalence class σ. This fixes all branches taken by every processor in M up to time t; then each memory location is a certain fixed polynomial in the input x, and the degree of this polynomial is at most 2^t. Now consider all comparisons, at most $p(n)$ in

number, that M would execute at time $t+1$. Since the value of each memory location just before time $t+1$ is a predetermined polynomial in x, once we are told that $x \in \sigma$, each such comparison amounts to evaluating the sign of some polynomial, which is $+$, $-$, or 0. Let $f_1(x), \ldots f_p(x)$, where $p \leq p(n)$, be these polynomials. Each $f_i(x)$ has degree at most 2^t and hence at most 2^t real roots. Consider the set of all roots of all polynomials $f_i(x)$, $i \leq p$. They divide the real line into at most $2^t p(n) + 1$ intervals. If $x_1, x_2 \in \sigma$ lie in the same open interval, or if they are equal and coincide with some root, then the signs of $f_i(x_1)$ and $f_i(x_2)$ coincide for each i, and consequently all processors in M would take the same branching path at time $t + 1$. This means that any t-equivalence class σ is split into at most

$$2 \cdot 2^t p(n) + 1 \leq 2 \cdot 4^{t(n)} + 1$$

$(t + 1)$-equivalence classes. By induction, it follows that the total number of equivalence classes, i.e., $t(n)$-equivalence classes, is at most $(2 \cdot 4^{t(n)} + 1)^{t(n)} < 5^{t(n)^2}$.

Now consider a fixed equivalence class ζ. Once ζ is fixed, the branches taken by all processors during the entire execution of M are fixed and the comparison carried out at every such branch corresponds to evaluating the sign of a fixed polynomial in x of degree at most $2^{t(n)}$. Let $P(\zeta)$ denote the set of all these polynomials that correspond to all branches of all processors during the entire execution. The size of $P(\zeta)$ is at most $t(n)p(n)$. Let P be the union of all $P(\zeta)$, as ζ ranges over all equivalence classes, at most $5^{t(n)^2}$ in number. The size of P is at most $t(n)p(n)5^{t(n)^2}$, and each polynomial in P has degree at most $2^{t(n)}$. Consider the set R of real roots of all polynomials in P; its size is at most $t(n)p(n)5^{t(n)^2}2^{t(n)}$. These roots divide the real line into at most

$$t(n)p(n)5^{t(n)^2}2^{t(n)} + 1 < 6^{t(n)^2} = 6^{n/a^2}$$

intervals. If two inputs x_1 and x_2 lie in the same open interval, then the behavior of all processors in M on the input x_1 is the same as that on x_2; thus the output would be the same, too—in other words, the lowermost bits of x_1 and x_2 must be the same. However, we have already seen that the number of intervals is at most $6^{n/a^2}$. If a is large enough, this number is much less than $2^n/2$. But then, by the pigeonhole principle, at least one such open interval would contain two integers x_1 and x_2 with the same lowermost bit, a contradiction. □

More generally, the same method also proves that extracting the ith bit from the left is hard for every "large" i. In the PRAM model with limited bit operations, one can prove similarly that the middle bits are hard to extract.

The essential weakness of a machine in our model lies in accessing bits. But if the language is boolean, i.e., if all its input parameters are either 0 or 1, then all bits of the input are available to our machine right at the outset. In this case, our model is as powerful as the unrestricted PRAM model. Thus proving a lower bound for a boolean language in our model is equivalent to proving it in the unrestricted PRAM model. On the other hand, using our model for proving a lower bound for a boolean language would not make much sense.

2.3. Complexity classes. We shall now formally define, both in the sequential and the parallel setting, complexity classes of problems having efficient algorithms that do not use bit operations; however, their running times may or may not depend on the input bitlengths and we need to distinguish between these two cases carefully.

First consider the sequential setting. If we allow the running time to depend on the bitlength, then we need to be very careful. One cannot simply define a sequential

algorithm that does not use bit operations to be an algorithm in the restricted RAM model without bit operations. This is because all bits in the input of bitlength N can be extracted in this model sequentially with $O(n)$ arithmetic and comparison operations. After this, any algorithm in the unrestricted RAM model can be simulated in the restricted RAM model without bit operations. This means a polynomial time algorithm in the restricted RAM model without bit operations is as powerful as a polynomial time algorithm in the unrestricted RAM model. Thus it is somewhat tricky to define a fast sequential algorithm whose running time can depend on the input bitlength but which does not use bit operations in a "real sense." Intuitively, such an algorithm should be like the ellipsoid or the interior-point algorithm for linear programming [22, 25] (the truncations that occur in these algorithms for controlling bitlengths are not bit operations in a real sense). This can be made precise and formal, but we shall not do so here.

If we do not allow the running time to depend on the input bitlength, the matter becomes much simpler. An efficient sequential algorithm that does not use bit operations and whose running time (in the unit-cost model) also does not depend on the input bitlength is nothing but a *strongly polynomial time* algorithm [17]. By this we mean that (1) the running time of the algorithm in the unit-cost model is polynomial in the number of integer parameters in the input, and (2) the bitsize of any intermediate operand that arises in the course of execution is bounded by a polynomial in the total bitlength of the input.

Let $SP \subseteq P$ (strongly polynomial) be the class of languages in P which can be recognized by strongly polynomial time algorithms. (Recall that a language in this paper means a set of integer sequences rather than boolean strings.) The class SP is quite rich. It contains decision problems associated with solving linear systems, network flow problems such as min-cost flow and max-flow, minimum-weight matching, *combinatorial* linear programming [47], ϵ-approximate knapsack problem [20], 3/2-approximate traveling salesman problem [9], and large-enough-constant-factor approximation of weighted MAX-SNP problems [41].

Next, let us turn to the parallel setting. Here an analogue of the class SP is the class SNC (strong-NC). It is the class of problems that have *strongly polylogarithmic time algorithms*, i.e., the algorithms in the PRAM model without bit operations that work in polylog(n) time using poly(n) processors, where n denotes the number of integer parameters in the input. Since we are following the unit-cost model, we are not requiring the bitlengths of intermediate operands to remain polynomial in the input bitlength. Therefore strictly speaking SNC need not be a subclass of NC; whether this is indeed so is open. The class SNC is also quite rich. Some problems in this class are solving linear systems over rationals [11], minimum-weight-spanning trees [32], shortest paths [32], global mincuts in undirected graphs [31], and several problems in computational geometry such as constructing convex hulls [43].

Now let us allow the running time of a parallel algorithm to depend on the input bitlength; however, it should not use any bit operations. Formally, let C be the class of problems that can be solved in the PRAM model without bit operations in polylog(N) time using poly(N) processors, where N denotes the input bitlength. Again, there is no restriction on the bitlengths of intermediate operands, so strictly speaking C need not be a subclass of NC or even P; the formal inclusion question remains open. An important problem that is in the class C but not in SNC is that of computing approximate roots of real polynomials up to a specified bit-precision level [3, 39]. Neff's algorithm [39] uses truncations, which are not available in our model, to

keep bitsizes of intermediate operands under control, but they can be ignored. Then bitsizes of intermediate operands can become superpolynomial, which is fine since we are following the unit-cost model. This also explains why we did not impose any restriction on the bitsizes of intermediate operands.

More generally, let $C[t(n,N),p(n,N)]$ be the class of languages that can be recognized in the PRAM model without bit operations in $t(n,N)$ time in the unit-cost model using $p(n,N)$ processors, where n is the number of parameters in the input and N is the total bitlength of the input. Let $C^i = C[O(\log^i(N)),\mathrm{poly}(N)]$ be the analogue of the class NC^i. One can define the randomized class RC, or more generally, $RC[t(n,N),p(n,N)]$ similarly. The class RC is the analogue of the class RNC.

In our model, an analogue of the $P \not\subseteq NC$ conjecture would be that $SP \not\subseteq SNC$ or, more strongly, that $SP \not\subseteq C$. This is not just an analogue but also an implication.

PROPOSITION 2.2. *$P \not\subseteq NC$ implies $SP \not\subseteq C$.*

Proof. Suppose $P \not\subseteq NC$. Consider the restricted linear programming problem in which all integer parameters in the input have $O(1)$ bitsizes. It belongs to SP [47]. It is also known to be P-complete, so it cannot belong to NC. If it belonged to C it would also belong to NC, because when all integer parameters in the input have $O(1)$ bitsizes the PRAM model without bit operations is as powerful as the unrestricted PRAM model (section 2.2). □

Our results in this paper imply, unconditionally, that $SP \not\subseteq C$ and much more (Corollary 1.3). They also imply that the hierarchies $\{C^i\}$ and $\{RC^i\}$ do not collapse.

3. Parametric versus parallel complexity. All our lower bounds follow from a general lower bound (Theorem 3.3) on the parallel complexity of a general optimization problem in our model in terms of its parametric complexity. In this section we explore the relationship between parametric and parallel complexity in detail. In section 3.1 we state our general lower bound and derive from it our main results stated in section 1.3. In section 3.2 we give a simpler proof of Carstensen's exponential lower bound [8] for the parametric complexity of the max-flow and the dual weighted s-t-mincut problem. In section 3.3 we prove a polynomial upper bound on the parametric complexity of the weighted global mincut problem for undirected graphs. This should explain why the weighted s-t-mincut problem for undirected graphs has no fast parallel algorithm in our model, whereas the global mincut problem has, e.g., the one in [30] or [31].

3.1. A general lower bound. First, let us define parametric complexity. For the max-flow problem it is defined as follows. Consider a graph with n vertices whose edge-capacities are linear functions of a parameter λ with rational coefficients of bitsize at most $\beta(n)$ for some function $\beta(n)$. We also require that all capacities remain nonnegative as λ varies over reals in some interval $[p,q]$ of definition. We use real capacities only for the sake of defining parametric complexity; the actual capacities in the input will always be nonnegative integers. Let $f(\lambda)$ be the max-flow value for a particular $\lambda \in [p,q]$. The function $f(\lambda)$ is piecewise linear. Let $\rho(f)$ be the number of breakpoints, i.e., slope changes in the function graph of f in the interval $[p,q]$. Parametric complexity $\phi(n,\beta(n))$ of the max-flow problem for cardinality n and bitsize $\beta(n)$ is defined to be the maximum possible value of $\rho(f)$ over all valid edge-capacity parameterizations, as above, of graphs with n vertices.

One can similarly define parametric complexity of an arbitrary homogeneous optimization problem. Consider a general combinatorial optimization problem, where the input consists of two parts: nonnumeric data and numeric data. Given an input I, the problem is to compute the optimum value of some quantity; we shall

denote this optimum value for I by $F(I)$. For example, in the max-flow problem the nonnumeric data would specify the network and the numeric data would specify the edge-capacities. Given an input I, $F(I)$ would be the max-flow value. In the decision version of the optimization problem one is given an additional integer parameter w, called *threshold*, and the problem is to decide if $w \leq F(I)$.

We will mainly be interested in the integral version of the optimization problem, wherein numeric parameters are integers. However, for the sake of defining parametric complexity we assume that the quantity $F(I)$ is well defined even when the numeric parameters are reals, possibly with some constraints; for example, we can require them to be nonnegative. We also assume that the problem is homogeneous; this means if we multiply all numeric parameters in I by a positive number α, then the optimum value $F(I)$ also gets multiplied by α. For example, the max-flow problem is well defined even when all capacities are nonnegative reals, and it is homogeneous, too.

DEFINITION 3.1. *By a linear parameterization for cardinality n, we mean a map $\mathcal{P}$ that associates with each real number λ in some interval $[p, q]$ an input $I(\lambda)$ such that the following hold:*

1. *The nonnumeric part of the input $I(\lambda)$ remains the same for every $\lambda \in [p, q]$.*
2. *The number of numeric parameters in $I(\lambda)$ is n for every $\lambda \in [p, q]$.*
3. *Each numeric parameter is a linear function of λ with rational coefficients and it satisfies any required constraints in the problem (such as nonnegativity) for every $\lambda \in [p, q]$.*
4. *The function graph of $F(\lambda) = F(I(\lambda))$ as λ varies over $[p, q]$ is piecewise linear and convex; we shall denote it by $G(\mathcal{P})$. (The function graph is convex for a maximization problem. For a minimization problem it would be concave.)*

The interval $[p, q]$ is called the interval of definition. The bitsize of $\mathcal{P}$ is defined to be the maximum among the bitsizes of the coordinates of the vertices of $G(\mathcal{P})$ and of the coefficients of the linear functions in $\mathcal{P}$ specifying numeric parameters. These coordinates and coefficients are in general rational. We define the bitsize of a rational to be the sum of the bitsizes of its denominator and numerator. We shall denote the bitsize of $\mathcal{P}$ by $\beta(\mathcal{P})$. The number of bounded linear segments in $G(\mathcal{P})$ is called the *complexity* of $\mathcal{P}$; it will be denoted by $\rho(\mathcal{P})$.

For example, in the max-flow problem, we can fix a graph with n edges and let the capacities of its edges be linear functions of λ so that as λ varies over some interval $[p, q]$ all these capacities remain nonnegative; this specifies a linear parameterization. It is well known that the optimum function of such parameterization is piecewise linear and convex.

DEFINITION 3.2. *Fix a homogeneous optimization problem. Its parametric complexity for cardinality n is defined to the maximum of $\rho(\mathcal{P})$ as $\mathcal{P}$ ranges over all linear parameterizations for cardinality n; we denote it by $\phi(n)$.*

More generally, parametric complexity for cardinality n and bitsize $\beta(n)$ is defined to the maximum of $\rho(\mathcal{P})$ as $\mathcal{P}$ ranges over all linear parameterizations for cardinality n with bitsize $\beta(n)$; we denote it by $\phi(n, \beta(n))$.

So far, n has denoted the number of numeric parameters in the input. We shall abuse the notation on some occasions and let n stand for something different but similar. For example, in the max-flow problem we shall let n denote the number of nodes in the flow network. The precise meaning of n in the given context should be clear.

We shall show that if the parametric complexity of a problem is high, then it is hard to parallelize in our model.

THEOREM 3.3. *Fix a homogeneous optimization problem. Let $\phi(n, \beta(n))$ be its parametric complexity for input cardinality n and bitsize $\beta(n)$. Then there exists a large enough constant b such that the decision version of the problem cannot be solved in the PRAM model without bit operations in $\sqrt{\log[\phi(n,\beta(n))]}/b$ time using $2^{\sqrt{\log[\phi(n,\beta(n))]}/b}$ processors; this is so even if we restrict every numeric parameter in the input to be an integer with bitlength at most $a\beta(n)$ for a large enough constant a.*

We shall prove this result in sections 4 and 5. It will be extended to the randomized setting in section 6.

COROLLARY 3.4. *The lower bound in Theorem* 3.3 *also applies to the additive approximation version of the problem in which the goal is to compute the optimum within a small, say, less than* 1/8, additive *error. (The constant* 1/8 *here is replaceable by any $\epsilon < 1/2$.)*

Proof. Suppose there is a fast parallel algorithm in our model for the additive approximation version. This will yield a fast parallel algorithm for the decision version as follows. First we compute the approximate optimum v with additive error less than, say, 1/8. Since we are assuming that the input is integral, we know that the exact optimum is integral. Thus we compare v with the integral threshold w in the input; w is less than or equal to the exact optimum iff $w \leq v + 1/8$. □

THEOREM 3.5.

1. *For combinatorial linear programming, $\phi(n, O(n)) = 2^{\Omega(n)}$, where n denotes the total number of variables and constraints* (see *Murty* [38]).
2. *For the mincost-flow problem, $\phi(n, O(n)) = 2^{\Omega(n)}$, where n denotes the number of nodes in the flow network* (see *Zadeh* [57]).
3. *For the max-flow problem for directed or undirected networks, $\phi(n, O(n^2)) = 2^{\Omega(n)}$, where n denotes the number of nodes in the flow network* (see *Carstensen* [8] *and Theorem* 3.8).

By combinatorial linear programming we mean restricted linear programming problem of the form "maximize $\{cx \mid Ax \leq b\}$," where all entries of A have logarithmic bitlengths; it has a strongly polynomial time algorithm [47]. The result of Murty [38] is subsumed by the later results [57, 7] since the max-flow and mincost-flow are instances of linear programming; however, Murty's proof is much simpler than these later ones.

3.1.1. Applications. We shall now derive the main results stated in section 1.3 from Theorem 3.3.

In the deterministic setting, our lower bounds for the mincost-flow and max-flow (Theorem 1.1) follow directly from Theorem 3.3, Corollary 3.4, and Theorem 3.5. For randomized algorithms and the PRAM model with limited bit operations, see section 6. (For the mincost-flow problem the improvement in the constant c mentioned after the statement of Corollary 1.2 follows from the fact that the total bitsize of Zadeh's [57] parametrized flow network with k nodes is only $O(k^2)$, even though some of its edges may have $O(k)$-bit costs.)

We now proceed to prove that $C^i \not\subseteq RC^{i/c}$ for some positive constant c (Theorem 1.4). Fix a positive integer j. From the usual max-flow problem, we shall first construct a *padded* language L that belongs to the class C. A valid input instance of L for cardinality n has the following form: It contains a flow network G on nodes $1, \ldots, \lfloor \log^j n \rfloor$ with edge-capacities of bitlength at most $a \log^{2j} n$ for a suitable constant a to be specified later. The remaining nodes are dummy and isolated. The input also specifies the threshold w.

The input is accepted iff the max-flow value for G is less than or equal to w. Let us show that $L \in C^{bj}$ for a suitable constant b. It is easy to check fast in parallel if

the input is valid, i.e., if the nodes $\lfloor \log^j n \rfloor + 1, \ldots, n$ are indeed dummy and isolated, and if all edge-capacities have bitlengths at most $a \log^{2j} n$. If the input is not valid it is rejected right away. Otherwise dummy nodes are discarded. After this, one is left with a small network G with $\lfloor \log^j n \rfloor$ nodes. The max-flow problem for G can be solved by just one processor using, say, a version of Dinic's strongly polynomial time algorithm [48] in $O(\log^{3j} n)$ time. If one uses the parallel algorithm of Shiloach and Vishkin [45] or Goldberg and Tarjan [13], it can be solved in $O(\log^{2j} n \log\log n)$ time using $O(\log^j n)$ processors. The total bitlength N of a valid input instance in L is $O(n + \log^{4j} n)$. Hence $L \in C^{bj}$ for a suitable constant b.

Now we shall get a lower bound on the parametric complexity of the padded problem. For this we use Carstensen's [8] or our (section 3.2) parametric construction with padding. This means we form a padded graph with n nodes in which all but $k = \log^j n$ nodes are dummy. The edge-capacities of the network G on the remaining k nodes are then linear functions of the parameter λ with coefficients of $O(k)$ bitsize as in [8] or section 3.2. It follows from Theorem 3.5 (third statement) that the parametric complexity $\phi(n, O(k^2))$ of the padded max-flow problem is $2^{\Omega(k)}$, where $k = \log^j n$. Therefore, by Theorem 3.3, it cannot be solved in the PRAM model without bit operations in $\log^{j/2} n/a'$ time using $2^{\log^{j/2} n/a'}$ processors for a large enough constant a', even assuming that every edge-capacity in the input has at most $a \log^{2j} n$ bitlength for a suitable large enough constant a. Thus L does not belong to $RC^{j/2-1}$. But we have already seen that $L \in C^{bj}$ for a suitable positive constant b. Thus it follows that $C^i \not\subseteq RC^{i/c}$ for a suitable positive constant c.

The role of the max-flow problem in this proof can be played by any problem in SP whose parametric complexity has a good exponential lower bound. For example, we could as well have used the mincost-flow problem or the general combinatorial linear programming problem. Then we have to use Zadeh's [57] or Murty's [38] parametric construction.

3.2. s-t-mincuts in weighted undirected graphs. Carstensen [8] proved that the parametric complexity of the s-t-mincut problem for weighted undirected graphs with n vertices is $2^{\Omega(n)}$. The same lower bound also applies to the dual max-flow problem for undirected graphs. Carstensen's proof is very intricate, however. In this section we give a much simpler proof using similar construction.

Let G be a weighted undirected graph with two distinguished vertices s and t. Each edge has a nonnegative weight. By an s-t-cut (U, V), we shall mean a disjoint partition (U, V) of the vertex set of G such that U contains s and V contains t. The weight $w(U, V)$ of this cut is the total weight of all edges going from U to V. By an *s-t-*mincut in G, we mean an s-t-cut (U, V) with minimum weight. We say that an s-t-cut $J = (U, V)$ contains a vertex u if $u \in U$.

For each positive integer n, we shall construct a weighted undirected graph G_n with $2n + 2$ vertices whose weights are linear functions of a parameter λ such that the following hold:

1. In the interval $(-T, T)$, where $T = 2^{n+1}$, all edge-weights are nonnegative.
2. Let $g(\lambda)$ denote the weight of a mincut in G for a particular λ. Then the function graph of $g(\lambda)$ has at least $2^n - 1$ breakpoints, i.e., slope changes in the interval $(-T, T)$.
3. The coefficients of the vertices of this function graph are rationals with $O(n^2)$ bitlengths.

The graph G_n is defined as follows. The vertices of G_n consist of s, t, the vertices labeled $1, \ldots, n$, and the vertices labeled $\bar{1}, \ldots, \bar{n}$. There are edges connecting s to

every vertex i and $\bar{i}$ and edges connecting every vertex i and $\bar{i}$ to t. For all $i \neq j$, there are also edges connecting the vertices i and $\bar{i}$ to the vertices j and $\bar{j}$. Let $w(u,v) = w(v,u)$ denote the weight of the edge between u and v. Let w_i for $1 \leq i \leq n$ be positive integers such that $w_n = 1$ and for $i < n$

$$w_i > 2T \sum_{i<l\leq n} w_l. \tag{3.1}$$

The choice $w_i = (2nT)^{n-i}$ for $i \leq n$ would suffice. Let $t_j = 2^{n-j+1}$. The edge-weights are then defined as follows:

1. For all i, $w(s,i) = w(s,\bar{i}) = w_i T$.
2. For all i, $w(i,t) = w_i(T+\lambda)$ and $w(\bar{i},t) = w_i(T-\lambda)$
3. For all $i > j$, $w(i,j) = w(\bar{i},\bar{j}) = w_i(T-t_j)$ and $w(i,\bar{j}) = w(\bar{i},j) = w_i T$.

Note that all edge-weights are positive in the interval $(-T,T)$ of interest to us.

THEOREM 3.6. *The graph of the mincut cost function $g(\lambda)$ for G_n has at least $2^n - 1$ breakpoints in the interval $(-T,T)$.*

Before we prove the theorem, we shall prove a lemma. Let part(0) denote the interval $(-T,T)$. For $i \geq 1$, define part(i) to be the partition obtained by splitting each interval of part($i-1$) at its midpoint. Thus part(i) contains 2^i intervals of length 2^{n+2-i}. Consider a complete binary tree of depth n whose nodes at depth i from the root are labeled with the intervals of part(i). Any sequence σ of $+1$'s and -1's with length $i \leq n$ denotes a unique node of this tree. Let $J(\sigma)$ denote the corresponding interval; it is the unique interval of part(i) containing the point $p(\sigma)$ with coefficient $t(\sigma) = \sum_{j\leq i} \sigma(j) t_j$, where $\sigma(j)$ denotes the jth symbol of σ. By convention $t(\sigma) = 0$ and $J(\sigma)$ denotes the interval $(-T,T)$ if σ is empty. Let $I(\sigma)$ be the interval of positive length $2^{n+2-i} - 2$ obtained by removing from both ends of $J(\sigma)$ intervals of length 1.

LEMMA 3.7. *Fix any $i \leq n$ and a sequence σ of length i. Fix any $\lambda \in I(\sigma)$. Let $C(\lambda) = (U(\lambda), V(\lambda))$ be a mincut in G_n at this λ; it need not be unique. Then, for every $j \leq i$,*

1. *$U(\lambda)$ contains j iff $\sigma(j) = -1$, and*
2. *$U(\lambda)$ contains $\bar{j}$ iff $\sigma(j) = +1$.*

Proof. Notice that the weighted graph G_n remains invariant if we switch all pairs $(i,\bar{i})$ of vertices and replace λ by $-\lambda$. Hence, the first statement is equivalent to the second so we shall prove only the former. The proof proceeds by induction on i.

Basis case, $i = 1$. Consider the case when $\sigma(1) = +1$. Suppose, to the contrary, that $U(\lambda)$ contains the vertex 1. If we move 1 from $U(\lambda)$ to $V(\lambda)$, the value of the cut would decrease by

$$\begin{aligned}
&w(1,t) + \textstyle\sum_{j>1:j\in V(\lambda)} w(j,1) + \sum_{j>1:\bar{j}\in V(\lambda)} w(\bar{j},1) \\
&\quad - w(s,1) - \textstyle\sum_{j>1:j\in U(\lambda)} w(j,1) - \sum_{j>1:\bar{j}\in U(\lambda)} w(\bar{j},1) \\
&= w_1(T+\lambda) + \textstyle\sum_{j>1:j\in V(\lambda)} w_j(T-t_1) + \sum_{j>1:\bar{j}\in V(\lambda)} w_j T \\
&\quad - w_1 T - \textstyle\sum_{j>1:j\in U(\lambda)} w_j(T-t_1) - \sum_{j>1:\bar{j}\in U(\lambda)} w_j T \\
&= w_1(\lambda) + h(\lambda,1),
\end{aligned}$$

where $h(\lambda, 1)$ is the lower order term

$$\sum_{j>1:j\in V(\lambda)} w_j(T-t_1) + \sum_{j>1:\bar{j}\in V(\lambda)} w_j T - \sum_{j>1:j\in U(\lambda)} w_j(T-t_1) - \sum_{j>1:\bar{j}\in U(\lambda)} w_j T;$$

it is bounded in absolute value by $2T\sum_{j>1} w_j$, which by (3.1) is strictly less than w_1. It follows that in the interval $I(\sigma) = [1, T-1]$ the decrease in the weight of the mincut is positive. This contradicts the fact that J is a mincut. Thus $U(\lambda)$ cannot contain 1. It follows similarly that if $\sigma(1) = -1$ and $V(\lambda)$ contained the vertex 1, then moving it from $V(\lambda)$ to $U(\lambda)$ would decrease the weight of the cut by

$$-w_1\lambda - h(\lambda, 1),$$

which is positive if $\lambda \in I(\sigma) = (-T, -1)$. Thus $V(\lambda)$ cannot contain 1 if $\sigma(1) = -1$. It follows that $U(\lambda)$ contains 1 iff $\sigma(1) = -1$.

Now let us turn to the general case. In general, let $\hat{\sigma}$ be the string obtained from σ by removing its last, i.e., the ith, symbol. Clearly, $I(\sigma) \subset I(\hat{\sigma})$. Hence, by the inductive hypothesis applied to $\hat{\sigma}$, $U(\lambda)$ at any $\lambda \in I(\sigma)$ must contain for every $j < i$ the vertex j iff $\sigma(j) = -1$ and the vertex $\bar{j}$ iff $\sigma(j) = 1$. It remains to show that $U(\lambda)$ contains i iff $\sigma(i) = -1$.

First, consider the case when $\sigma(i) = 1$. Suppose, to the contrary, that $U(\lambda)$ contains i. Then moving i from $U(\lambda)$ to $V(\lambda)$ would decrease the weight of the cut by

$$\begin{aligned} &w(i,t) - w(s,i) + \textstyle\sum_{j\neq i:j,\bar{j}\in V(\lambda)} w(i,j) + w(i,\bar{j}) \\ &\quad - \textstyle\sum_{j\neq i:j,\bar{j}\in U(\lambda)} [w(j,i) - w(\bar{j},i)] \\ &= w_i\lambda + \textstyle\sum_{j<i:j,\bar{j}\in V(\lambda)} w(i,j) + w(i,\bar{j}) \\ &\quad - \textstyle\sum_{j<i:j,\bar{j}\in U(\lambda)} [w(i,j) - w(i,\bar{j})] + h(\lambda, i), \end{aligned} \tag{3.2}$$

where $h(\lambda, i)$ is the lower order term

$$\sum_{j>i:j,\bar{j}\in V(\lambda)} w(j,i) + w(\bar{j},i) - \sum_{j>i:j,\bar{j}\in U(\lambda)} [w(j,i) - w(\bar{j},i)];$$

it is bounded in absolute value by $2T\sum_{j>i} w_j$, which by (3.1) is strictly less than w_i. By the inductive hypothesis, the decrease given by (3.2) is equal to

$$\begin{aligned} &w_i\lambda + \textstyle\sum_{j<i:\sigma(j)=1} w(i,j) + \sum_{j<i:\sigma(j)=-1} w(i,\bar{j}) \\ &\quad - \textstyle\sum_{j<i:\sigma(j)=-1} w(i,j) - \sum_{j<i:\sigma(j)=1} w(i,\bar{j}) + h(\lambda, i) \\ &= w_i\lambda + \textstyle\sum_{j<i:\sigma(j)=1} w_i(T-t_j) + \sum_{j<i:\sigma(j)=-1} w_i T \\ &\quad - \textstyle\sum_{j<i:\sigma(j)=-1} w_i(T-t_j) - \sum_{j<i:\sigma(j)=1} w_i T + h(\lambda, i) \\ &= w_i\lambda - \textstyle\sum_{j<i:\sigma(j)=1} w_i t_j + \sum_{j<i:\sigma(j)=-1} w_i t_j + h(\lambda, i) \\ &= w_i\lambda - w_i(\textstyle\sum_{j<i} \sigma(j) t_j) + h(\lambda, i) \\ &= w_i(\lambda - t(\hat{\sigma})) + h(\lambda, i), \end{aligned}$$

where $t(\hat{\sigma}) = \sum_{j<i} \hat{\sigma}(j)t_j = \sum_{j<i} \sigma(j)t_j$. If $\lambda \in I(\sigma)$ and $\sigma(i) = 1$, then $\lambda - t(\hat{\sigma}) \geq 1$. Since the absolute value of $h(\lambda, i)$ is less than w_i, this decrease is positive in that case. Hence moving i from $U(\lambda)$ to $V(\lambda)$ would strictly decrease the weight of the cut, which contradicts the fact the $C(\lambda)$ is a mincut. Thus $U(\lambda)$ cannot contain i if $\sigma(i) = 1$.

Now consider the case when $\sigma(i) = -1$. Suppose to the contrary that $V(\lambda)$ contains i. Then it follows similarly that moving i from $V(\lambda)$ to $U(\lambda)$ would decrease the weight of the cut by

$$w_i(t(\hat{\sigma}) - \lambda) - h(\lambda, i).$$

If $\lambda \in I(\sigma)$ and $\sigma(i) = -1$, then $t(\hat{\sigma}) - \lambda \geq 1$. Hence this decrease is strictly positive, which contradicts the fact that $C(\lambda)$ is a mincut. It follows that $V(\lambda)$ cannot contain i if $\sigma(i) = -1$.

Thus $U(\lambda)$ contains i iff $\sigma(i) = -1$. □

If σ is any sequence of 1 and -1 of length n, then it follows from the preceding lemma that throughout the interval $I(\sigma)$ the mincut remains the same; let us call it $C(\sigma) = (U(\sigma), V(\sigma))$. It also follows that $U(\sigma)$ contains i iff $\sigma(i) = -1$ and $\bar{i}$ iff $\sigma(i) = 1$. The weight of $C(\sigma)$ at any $\lambda \in I(\sigma)$ is of the form $A(\sigma)\lambda + B(\lambda)$, where $A(\sigma) = -\sum \sigma(i)w_i$. Thus the slopes of the weight functions of all 2^n cuts $C(\sigma)$ as σ ranges over all strings of 1 and -1 of length n are distinct. This proves Theorem 3.6. □

Bitlengths of the edge-capacities in our construction remain $O(n^2)$ in the interval $[-T, T]$ of interest. Hence Theorem 3.8 follows.

THEOREM 3.8. *Parametric complexity $\phi(n, O(n^2))$ of the s-t-mincut problem for weighted undirected graphs of cardinality n is $2^{\Omega(n)}$. This also holds for the dual max-flow problem.*

3.3. Global mincuts in weighted undirected graphs. In this section we show that the parametric complexity of the global mincut problem for weighted undirected graphs is at most polynomial in the number of vertices; this should explain why this problem has fast parallel algorithms in our model [30, 31]. By a global mincut we mean a nontrivial cut; there is no restriction that some distinguished vertices s and t be separated by the cut.

We shall make use of the following combinatorial result and its proof in [30].

LEMMA 3.9. *In any positively weighted undirected graph, the number of cuts within a constant multiplicative factor of a global mincut is polynomial in the number of vertices.*

We shall also use a result by Chandrasekharan and Gusfield [18] that the parametric complexity of the maximum-weight spanning tree problem is $O(n^4)$; this is in fact true for any matroidal optimization problem having a greedy algorithm.

Let G be an undirected graph with n vertices whose edge-weights are linear functions of a parameter λ. It is furthermore guaranteed that in some interval $[p, q]$ all edge-weights remain positive. Let $g(\lambda)$ denote the cost of a mincut in G at a given λ.

THEOREM 3.10. *The number of breakpoints in the function graph of $g(\lambda)$ in the interval $[p, q]$ is at most polynomial in n.*

Proof. The coefficients of the linear weight functions of the edges in G may be arbitrary reals. But one can show that without of loss of generality these coefficients can be assumed to be rationals with bitsizes at most polynomial in n. This follows from the fact that the parametric complexity of the mincut problem is the same as the maximum size of a two-dimensional projection of the corresponding combinatorial

polytope, which is the convex hull of the incidence vectors of all cuts in G. Since the coefficients of the linear weight functions have polynomial size bitlengths, all vertices of the function graph of $g(\lambda)$ have rational coefficients with polynomial bitlengths. For this reason one can also assume that p and q have polynomial bitlengths.

The parametric complexity of the maximum-weight spanning tree problem is $O(n^4)$ [18]. Thus by dividing $[p, q]$ into at most $O(n^4)$ subintervals if necessary, one can assume that a maximum-weight spanning tree in G remains the same throughout $[p, q]$, i.e., as λ varies in the interval $[p, q]$. This tree has n edges since G can be assumed to be connected. Thus subdividing $[p, q]$ further into at most n subintervals, one can also assume without loss of generality that the edge of minimum weight in this maximum-weight spanning tree remains the same throughout $[p, q]$. Let this edge be e and let its weight function be $w_e(\lambda)$. By subdividing the interval $[p, q]$ further into at most n subintervals if necessary, one can also assume that the set of edges whose weights exceed n^2 times the weight of e also remains the same throughout $[p, q]$. As in Karger [30], we can contract these edges in G without changing the mincut. Let us assume that all edges in G have weights at most n^2 times that of e throughout $[p, q]$. This means the weight of any cut at any $\lambda \in [p, q]$ is at most n^4 times the weight $w_e(\lambda)$ of e throughout $[p, q]$. It also follows, as in [30], that the weight of any cut at any $\lambda \in [p, q]$ is at least $w_e(\lambda)$.

By our assumption, both $w_e(p)$ and $w_e(q)$ must be positive. Assume without loss of generality that $w_e(p) < w_e(q)$, the other case being similar. Since the coefficients of the linear weight functions, and also p and q, have polynomial size bitlengths, $\log(w_e(q)) - \log(w_e(p))$ is polynomial in n. Thus by subdividing $[p, q]$ further into polynomially many subintervals, if necessary we can assume that $\log(w_e(q)) - \log(w_e(p)) \leq 1/n$, which means that $w_e(q) \leq 2w_e(p)$.

For any cut J, let $w_J(\lambda)$ denote its weight function. Then our interval $[p, q]$ has the following properties. First,

$$w_e(p) \leq w_e(q) \leq 2w_e(p). \tag{3.3}$$

Second, for any cut J and any $\lambda \in [p, q]$,

$$w_e(\lambda) \leq w_J(\lambda) \leq n^4 w_e(\lambda). \tag{3.4}$$

Divide $[p, q]$ further into, say, n^5 subintervals of equal length. Let $[a, b]$ denote any such subinterval.

Claim. For any $\lambda \in [a, b]$ and any cut J, $|w_J(\lambda) - w_J(b)| \leq 2w_e(b)/n$.

Proof of the claim. By (3.4), $w_J(q) \leq n^4 w_e(q)$, and similarly $w_J(p) \leq n^4 w_e(p) \leq n^4 w_e(q)$ by (3.4) and (3.3). Hence, the slope of the weight function $w_J(\lambda)$ is at most $n^4 w_e(q)/(q - p)$. Therefore, for any $\lambda \in [a, b]$, $|w_J(\lambda) - w_J(b)|$ is at most

$$\frac{n^4 w_e(q)(b - \lambda)}{(q - p)} \leq \frac{w_e(q) n^4}{n^5} = \frac{w_e(q)}{n} \leq \frac{2w_e(p)}{n} \leq \frac{2w_e(b)}{n}.$$

This proves the claim.

Let K denote a mincut at b.

Claim. A cut I whose weight becomes minimum at some $\lambda \in [a, b]$ has its weight at b at most twice that of K at b.

Proof of the claim. First, note that $w_I(b) - w_K(b)$ is equal to

$$(w_I(b) - w_I(\lambda)) + (w_I(\lambda) - w_K(\lambda)) + (w_K(\lambda) - w_K(b)).$$

Since K is a mincut at b, $w_I(b) - w_K(b)$ is nonnegative, and similarly $w_K(\lambda) - w_I(\lambda)$ is nonnegative. Therefore, $w_I(b) - w_K(b)$ is at most

$$(w_I(b) - w_I(\lambda)) + (w_K(\lambda) - w_K(b)) \leq 4w_e(b)/n$$

by the previous claim. But $w_K(b)$ is at least $w_e(b)$ by (3.4). Thus, the last quantity is at most $4w_K(b)/n$. Now the claim follows.

By Lemma 3.9 there are only polynomially many cuts whose weights at b are at most four times the weight of the mincut K at b. Let Γ_b denote the set of such cuts. Now the preceding claim implies that any cut that can become minimum during $[a, b]$ must belong to the set Γ_b whose size $|\Gamma_b|$ is polynomial in n. In other words, in the interval $[a, b]$ the mincut weight function is given by

$$g(\lambda) = \min\{w_K(\lambda) \mid K \in \Gamma_b\}$$

and so can have at most $|\Gamma_b|$ breakpoints within the interval $[a, b]$. This is true for each of the polynomially many subintervals into which $[p, q]$ was divided. Thus the theorem follows. □

4. Linear PRAM. In this section we prove our general lower bound (Theorem 3.3) for the linear PRAM model. Actually we get a stronger lower bound that takes into account processor-time trade-off.

THEOREM 4.1. *Fix any homogeneous optimization problem. Let $\phi(n, \beta(n))$ be its parametric complexity for input cardinality n and bitsize $\beta(n)$. Then there exists a large enough constant b such that the decision version of the problem cannot be solved in the linear PRAM model in $\sqrt{\log[\phi(n, \beta(n))]}/b$ time using $2^{\sqrt{\log[\phi(n,\beta(n))]}/b}$ processors or, more generally, in $\log[\phi(n, \beta(n))]/(b \log p)$ time using p processors; this is so even if we restrict every numeric parameter in the input to be an integer with bitlength at most $a\beta(n)$ for a large enough constant a.*

This also holds for approximate computation of the optimum within a small, say, less than $1/8$, additive error.

In conjunction with Theorem 3.5 this leads to a somewhat stronger lower bound for the linear PRAM than in Theorem 1.1.

THEOREM 4.2. *The mincost-flow problem for networks with k nodes cannot be solved in the linear PRAM model deterministically (or with randomization) in $k/(b \log p)$ (expected) time using p processors, even assuming that every cost and capacity is an integer with bitlength at most ak, for some large enough positive constants a and b; in particular, it cannot be solved in $o(k/\log k)$ time using polynomial number of processors. The same lower bound also applies for the max-flow problem with the bitlength restriction ak^2 instead of ak.*

Compare with the upper bound provided by the parallel algorithms of Shiloach and Vishkin [45] and Goldberg and Tarjan [13] (which lie in the linear PRAM model); these work in $O(k^2 \log k)$ time with $O(k)$ processors without any restriction on the bitlengths.

Here we shall consider only deterministic algorithms. For randomized algorithms, see section 6.1.

4.1. The number of possible branchings. In this section we describe a general technique for bounding the number of possible ways in which the processors can branch in the linear PRAM model. The technique is language independent. Thus we shall describe it in a general setting.

Let $\Sigma = \Sigma(x_1, \ldots, x_n)$, $x_i \in Z$, be the language for which we want to prove a lower bound. Here $x_1, \ldots, x_n$ denote the integer parameters in the input. We shall denote the total bitsize of the input by N. We shall denote the integer tuple $(x_1, \ldots, x_n)$ by x. Consider any nonuniform machine for n and N. It is required to work correctly only on inputs with n parameters of total bitlength at most N. Hence, we shall confine ourselves to only those values of x_i for which the total bitsize of x is bounded by N. Let $p(n, N)$ be the number of processors in the machine. Let $t(n, N)$ be the maximum time taken by the machine on any input of bitlength at most N. Let $x, x' \in Z^n$ be any two n-tuples of bitsize at most N. For any positive integer t, we say that x and x' are *t-equivalent* if on the input x the instruction executed by any processor in our machine at any time less than or equal to t is the same as the instruction that would have been executed if the input were x' instead. We say that x and x' are *equivalent* if they are t-equivalent for all $t \leq t(n, N)$. By a t-equivalence class, we mean the set of all t-equivalent k-tuples of bitsize at most N. An equivalence class is defined similarly. Let $\phi(t)$ be the number of t-equivalence classes and ϕ be the number of equivalence classes.

Ideally, we would like to get good bounds on $\phi(t)$ and ϕ. Unfortunately, this seems difficult. Therefore, we shall get around this problem by specializing the possible inputs to our machine; this corresponds to restricting one's attention to inputs that lie within some affine subspace. We shall then obtain a good bound on the number of equivalence classes among specialized inputs.

Specifically, let us imagine running our machine on the set of possible inputs defined by $x_i = l_i(z) = l_i(z_1, \ldots, z_d)$, where for each $i \leq n$, l_i is a certain integral linear form (possibly nonhomogeneous) in d variables and z_j ranges over all integer values of bitlength bounded by some integer r_j. When x_i is a nonnumeric parameter, we shall assume that $l_i(z)$ is constant. In other words, we assume that the nonnumeric parameters do not change as we change the parameters z_i. The forms l_i will depend on the problem under consideration. We shall turn to this issue in section 4.2. Here we need only to assume that the integers r_j and the forms l_i are such that the total bitsize of the tuple $x = (x_1, \ldots, x_n)$ remains bounded by N as we let z_i range over all permissible values. This implies that the machine must work correctly on this parametrized set of inputs within a given time bound $t(n, N)$. In what follows, we shall assume that every d-tuple $z = (z_1, \ldots, z_d)$ under consideration is *permissible*. This means each z_i is an integer of bitlength at most r_i. In our applications d will be constant.

Let $\Sigma(z_1, \ldots, z_d)$ denote the set of permissible d-tuples accepted by the machine. We say that z is accepted if $x = l(z) = (\ldots, l_i(z), \ldots)$ is accepted. Two permissible d-tuples z, z' are said to be t-equivalent if $l(z)$ and $l(z')$ are t-equivalent. The notion of equivalence is defined similarly. Let $\sigma(t)$ denote the number of t-equivalence classes among the permissible values of z. Let $\sigma = \sigma(t(n, N))$ denote the number of equivalence classes.

THEOREM 4.3. *For all t, $\sigma(t)$ is bounded by $[2p(n, N)]^{dt}$.*

Proof. Let C denote a fixed t-equivalence class. Let z denote a (permissible) integral value in this equivalence class. In what follows, we pretend that z is a generic variable. We are told that it belongs to C. But we are not told its actual value. We imagine running our machine on the input $x = l(z)$. We have to specify what is meant by executing an arithmetic operation in this setting. Naturally, we cannot expect the operands to be integers, unless they happen to be constants. Rather they will be functions of z. Since there is no general multiplication in the linear PRAM model,

these functions will be linear. By an arithmetic operation + or −, we simply mean the corresponding operation on the linear forms (functions). We are also allowed multiplication by constants. This amounts to multiplying the corresponding linear form by a constant. The nonnumeric parameters are fixed in our parameterization. Since in our model the memory pointers are allowed to depend only on the nonnumeric parameters, indirect memory references are no problem. In other words, whenever an instruction involving a memory pointer is encountered during the course of execution, the value of the pointer would be completely determined at that time, because it cannot depend on the generic parameter z. This in turn completely determines which memory locations are to be fetched (or stored into) during the execution of that instruction. In case several processors are planning to write into the same memory location, it is also determined which processor's writing is going to prevail (in the CRCW mode of communication). We assume that when a processor is executing a comparison it is simply told the result of that comparison, which, at any time less than or equal t, is completely determined by the class C; i.e., it is the same for all permissible values in C.

LEMMA 4.4. *Let C be a fixed t-equivalence class. For every memory location j, there exists a linear form $g_j[C,t](z)$ that gives the content of that location at time t for every $z \in C$.*

Proof. Once C is fixed, the execution path of each processor up to time t is fixed. Thus the lemma follows easily by induction on t. □

Let us now see what happens at time t given that the generic variable z belongs to a fixed t-equivalence class C as above. If a processor is to execute an arithmetic operation at time t, then the result of that operation will be a certain uniquely determined linear form to be stored in a certain uniquely determined location in the memory. If the operation is a branch, the branching path will be determined by a comparison between the contents of two uniquely determined memory locations, which are certain fixed linear forms in z. In other words, each branch is determined by testing a certain linear equality or inequality in z of the form $g(z) : 0$, where the comparison : is $>$, $\geq$, or $=$. The number of such linear constraints is at most $p(n,N)$, one per processor. Let $g_1(z), g_2(z), \ldots$ be the nonzero linear forms involved in these constraints. Consider the arrangement in R^d formed by the hyperplanes $g_i(z) = 0$. The hyperplanes naturally partition R^d into a disjoint union of (open) j-faces, where each j-face of the arrangement is a j-dimensional convex polytope. When d is fixed, the total number of faces in the arrangement (of all dimensions) is $O(m^d)$, or at most $(2m)^d$ to be more precise, where m is the number of hyperplanes, i.e., the number of linear forms g_i. There are at most $p(n,N)$ forms, one per processor. Hence the number of faces in the arrangement is at most $(2p(n,N))^d$.

Now we make the following crucial observation: Any two $z, z' \in C$ belong to the same $(t+1)$-equivalence class if they belong to the same face of this partition. This is because the sign of each linear function $g_i(z)$ is the same at any point of the face (the sign is either +, −, or 0). It immediately follows that

$$\sigma(t+1) \leq (2p(n,N))^d \sigma(t).$$

Induction on t proves Theorem 4.3.

The proof of the theorem also yields the following lemma.

LEMMA 4.5. *For every t-equivalence class C, there exists a set $\Phi(C,t)$ of at most $p(n,N)t$ linear constraints (equalities or inequalities) in d variables such that $z \in C$ iff all these constraints are satisfied.*

Proof. The constraints correspond to the branches before time t, at most t per processor, which are all fixed by the class C. □

By Lemma 4.5, each equivalence class D of permissible z-values is characterized by a set $\Phi(D) = \Phi(D, t(n, N))$ of linear constraints. Let $\Phi = \cup_D \Phi(D)$, where D ranges over all equivalence classes. By Theorem 4.3 and Lemma 4.5, it follows that Φ contains at most $[2p(n, N)]^{dt(n,N)} p(n, N)t(n, N)$ linear forms. Consider the arrangement in R^d formed by the hyperplanes defined by these linear forms. It is easy to see that each face of this arrangement can be labeled *yes* or *no* in such a way that a permissible z is accepted by the machine iff it lies in a face labeled *yes*. Thus we have proved the following.

THEOREM 4.6. *Assume that the language $\Sigma(z_1, \ldots, z_d)$ is accepted in the linear PRAM model using $p(n, N)$ processors in $t(n, N)$ time. Then R^d can be partitioned by a set of at most*

$$[2p(n, N)]^{dt(n,N)} p(n, N)t(n, N)$$

hyperplanes and each face of the arrangement can be labeled yes *or* no *so that a permissible $z \in Z^d$ belongs to $\Sigma(z_1, \ldots, z_d)$ iff it lies in a face labeled* yes.

4.2. Parameterization. The preceding theorem suggests the following strategy for reducing a global lower bound problem to a local problem in small dimensions. Parametrize the input to the machine using a small (constant) number of parameters. Then for this parameterization prove that a partition having the properties mentioned in Theorem 4.6 cannot exist. As a byproduct, we shall actually end up proving a stronger lower bound (Theorem 4.7) that is nonuniform with respect to parameterization. This means for any parameterization $\mathcal{P}$ we get a lower bound that applies even to nonuniform machines whose programs can depend on $\mathcal{P}$ arbitrarily. Theorem 4.1 would be a consequence of this stronger lower bound.

Fix a general optimization problem as in section 3.1 and any parameterization $\mathcal{P}$ for cardinality n and bitsize $\beta(n)$. Let the complexity of $\mathcal{P}$ be $\rho(n)$. For a given rational parameter λ, each numeric parameter in the input $\mathcal{P}(\lambda)$ is a linear function of the form $u\lambda + v$; we can assume that u and v are integers because if they are not, we can clear all denominators by multiplying all numeric parameters by a large enough integer, and since the problem is homogeneous, the optimum value gets multiplied by the same integer. When λ is rational, $u\lambda + v$ is in general rational, too. This is not allowed, since in our optimization problem every numeric parameter has to be integral. However, with every such parameterization $\mathcal{P}$, one can associate a homogeneous integral parameterization $\tilde{\mathcal{P}}$ with two integer parameters z_1 and z_2—which can be thought of as the denominator and numerator of the parameter λ—by replacing each linear form $u\lambda + v$ in the definition of $\mathcal{P}$ by the corresponding integral form $uz_2 + vz_1$. For any integer pair (z_1, z_2), each numeric parameter of the input $\tilde{\mathcal{P}}(z_1, z_2)$ is now an integer as required. The bitsize $\beta(n)$ or the complexity $\rho(n)$ of $\tilde{\mathcal{P}}$ is defined to be the same as that of $\mathcal{P}$.

Remark. Integral nature of our optimization problem—i.e., the assumption that $F(I)$ and each numeric parameter in I is an integer—is important; it is crucial in proving the lower bound for the approximate version (Corollary 3.4) from the one for the decision version (Theorem 3.3). Even if we were to allow rational values of numeric parameters, the situation would not be any easier or different, since the machine in our model can access the numerator and the denominator of a rational number separately.

Now given a large enough positive integer a, called the *permissibility constant*, let $\mathcal{I}$ be the set of inputs of the form (z_3, I) in the decision version of our optimization problem, where the following holds:

1. The integer $w = z_3$ denotes the threshold and its bitsize is at most $a\beta(n)$.
2. I is of the form $\tilde{\mathcal{P}}(z_1, z_2)$ for some integers z_1 and z_2 of bitsize at most $a\beta(n)$.

We shall prove the following theorem.

THEOREM 4.7. *Assume that the permissibility constant a is large enough. Then no machine in the linear PRAM model can decide whether $w \le F(I)$ correctly for every $I \in \mathcal{I}$ within $\sqrt{\log \rho(n)}/a'$ parallel time using $2^{\sqrt{[\log \rho(n)/a'}}$ processors for some large enough constant a' that does not depend on the permissibility constant a.*

More generally, no machine in the linear PRAM model can decide whether $w \le F(I)$ correctly for every $I \in \mathcal{I}$ within $\log \rho(n)/(a' \log p)$ parallel time using p processors for some large enough constant a' that does not depend on the permissibility constant a.

In the deterministic setting, Theorem 4.1 follows from this theorem by applying it to a parameterization $\mathcal{P}$ for cardinality n and bitsize $\beta(n)$ whose complexity is equal to $\phi(n, \beta(n))$, the maximum possible value. The randomized setting is considered in section 6.1. In what follows, we shall denote $\rho(n)$ and $\beta(n)$ by simply ρ and β, respectively.

Let us apply Theorem 4.6 with $d = 3$ to the linear parameterization of the input as in Theorem 4.7. It is defined by the linear map

$$(z_1, z_2, z_3) \to I(z_1, z_2, z_3) = (z_3, \tilde{\mathcal{P}}(z_1, z_2)).$$

Thus in Theorem 4.6 $\Sigma(z_1, z_2, z_3)$ consists of those tuples (z_1, z_2, z_3) such that $z_3 \le \tilde{\mathcal{P}}(z_1, z_2)$. This gives the following theorem.

THEOREM 4.8. *Let a' be any positive constant. If a linear PRAM machine works correctly on the input $I(z_1, z_2, z_3)$ for every permissible z_1, z_2, and z_3 in $t = \sqrt{\log \rho}/a'$ time using 2^t processors, then R^3 can be partitioned by at most 2^{5t^2} planes and each face of the resulting arrangement can be labeled* yes *or* no *so that a permissible integer point (z_1, z_2, z_3) lies in a face labeled* yes *iff $I(z_1, z_2, z_3)$ is feasible. (The constant 5 is just chosen to be large enough.)*

More generally, if a linear PRAM machine works correctly on the input $I(z_1, z_2, z_3)$ for every permissible z_1, z_2, and z_3 in $\log \rho/(a' \log p)$ time using p processors, then R^3 can be partitioned by at most $2^{(5 \log \rho)/a'}$ planes and each face of the resulting arrangement can be labeled yes *or* no *so that a permissible integer point (z_1, z_2, z_3) lies in a face labeled* yes *iff $I(z_1, z_2, z_3)$ is feasible.*

4.3. A lattice problem. We are thus led to the problem of showing that an arrangement as in Theorem 4.8 cannot exist for large enough constants a and a'; this will prove Theorem 4.7. Let $F(\lambda)$ be the optimum function associated with $\mathcal{P}$ (as in section 3.1) and $G = G(\mathcal{P})$ its function graph. Since our parameterization is assumed to be homogeneous, $I(z_1, z_2, z_3)$ is feasible iff $z_3 \le \tilde{\mathcal{P}}(z_1, z_2)$, i.e., $z_3/z_1 \le F(z_2/z_1)$. (Here and in what follows, we assume that a permissible z_1 is always positive.) This suggests that we think of G as lying in the affine plane $z_1 = 1$ in R^3, where R^3 is now considered as the two-dimensional projective space. We let z_2, z_3 play the role of coordinates in the affine plane. Then the point (z_1, z_2, z_3) in R^3 is naturally projected onto the point in the affine plane that lies on the ray emanating from the origin and passing through (z_1, z_2, z_3). In what follows, by the *projection* onto the affine plane we shall always mean this natural projection. Given any set ϕ of points

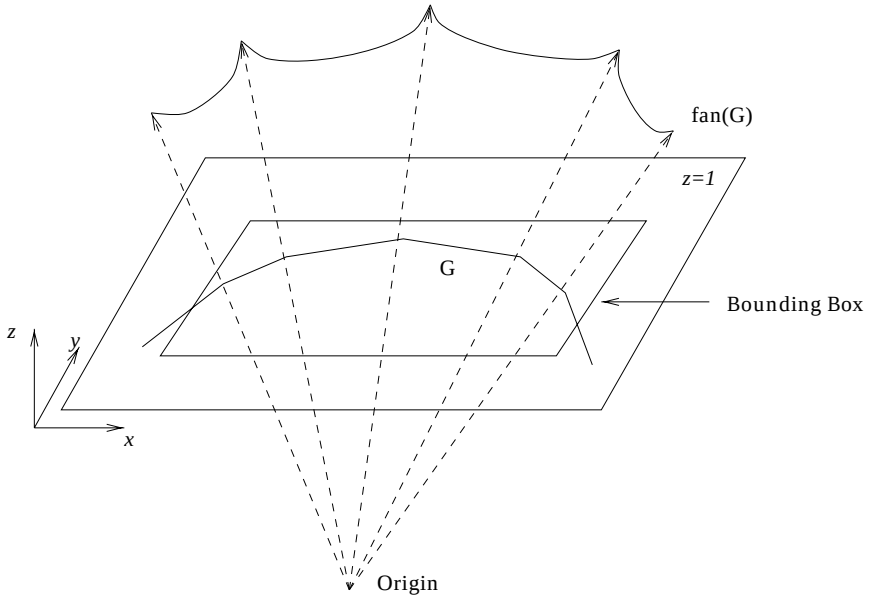

FIG. 4.1. *The graph G and its fan.*

in the affine plane, let fan(ϕ), the fan through ϕ, denote the points in R^3 that project onto the points in ϕ. Then $I(z_1, z_2, z_3)$ is feasible iff (z_1, z_2, z_3) lies below fan(G) in the z_3-direction; this also includes the case when (z_1, z_2, z_3) lies on fan(G).

For the sake of simplicity, let us rename the coordinates z_1, z_2, z_3 as z, x, and y, respectively. Thus $z = 1$ now serves as the affine plane in R^3. The preceding discussion implies that in the partition of Theorem 4.8, a permissible integer point in Z^3 is labeled *yes* iff it lies below fan(G) in the y-direction (Figure 4.1).

Since $\mathcal{P}$ has bitsize $\beta = \beta(n)$ and complexity $\rho = \rho(n)$ it follows that (1) the graph G is piecewise linear and convex with ρ bounded segments, and (2) all vertices of G have rational coordinates that can be expressed in terms of numerators and denominators of absolute value at most $\mu = 2^\beta$, or in other words, of bitsize at most $\beta = \log \mu$. Trivially $\rho \leq 4\mu^2$. Moreover, all vertices of G lie in the interior of the *bounding box* defined by $|x| \leq 2\mu$ and $|y| \leq 2\mu$ (Figure 4.1). Consider two horizontal planes, parallel to the affine plane, defined by $z = \bar{\mu}$ and $z = 2\bar{\mu}$, where $\bar{\mu}$ would be chosen to be much larger than μ. Let B denote the region (slab) between these two planes that is enclosed by the fan through the boundary of the bounding box in the affine plane. The coordinates of all integer points in this slab have bitsizes at most twice of $\bar{\beta} = \log \bar{\mu}$. The following theorem would imply that the partition as in Theorem 4.8 cannot exist.

THEOREM 4.9. *Let S be any set of δ planes in R^3. Assume that $\bar{\beta} = \log \bar{\mu}$ is greater than a large enough constant multiple of $\beta = \log \mu$ and that ρ is greater than a large enough constant multiple of δ^4. (Since $\rho \leq 4\mu^2$, this also means that $\log \bar{\mu}$ is greater than a sufficiently large constant multiple of $\log \delta$.) Then at least one face in the arrangement (partition) in B formed by the planes in S contains an integer point lying below* fan(G) *and also an integer point strictly above this fan.*

Remark. If ρ were less than δ, then one can let S be the set of planes that contain

the fans through the edges of G. No face in the resulting partition can contain an integer point below $\mathrm{fan}(G)$ and also an integer point strictly above $\mathrm{fan}(G)$ (in its interior). What the theorem says is that one cannot do much better than this trivial scheme.

Remark. It is possible to strengthen the theorem slightly so that ρ is only required to be greater than a large enough constant multiple of δ^3 instead of δ^4.

In the arithmetic linear PRAM model the issue of bitlengths is ignored; i.e., the running time of the algorithm cannot depend on the bitlengths of the input parameters. In that case we only need to prove the theorem when the slab B is unbounded, i.e., when its upper bounding plane goes to infinity. This is quite easy (as the reader can verify). In fact, then S must contain every plane containing the origin and an edge of G, so δ has to be at least ρ; this completes our lower bound proof for the arithmetic linear PRAM model.

Proof of Theorem 4.7 *from Theorem* 4.9. Before we prove the theorem, let us see why it implies that the partition as in Theorem 4.8 cannot exist. This will prove Theorem 4.7. Let $t = \sqrt{\log \rho}/a'$, as in Theorem 4.8. Let S be the set of planes mentioned in its statement. Their total number δ is at most 2^{5t^2}, so $\log \delta \leq 5t^2 = 5 \log \rho / a'^2$. Choose the constant a' large enough so that $\log \rho$ is sufficiently larger than $\log \delta$ as required in Theorem 4.9. Next fix $\bar{\mu}$ so that $\log \bar{\mu}$ is a sufficiently large multiple of $\log \mu$, also as required in Theorem 4.9. If we choose the permissibility constant a (cf. the statement of Theorems 4.1 and 4.7) large enough, then all integer points in the slab B will be permissible. Now Theorem 4.9 implies that the arrangement as in the first part of Theorem 4.8 cannot exist for such constants a and a'. The proof of the second part is similar. □

Proof of Theorem 4.9. Assume, to the contrary, that no face in the partition of B contains an integer point below $\mathrm{fan}(G)$ and also an integer point strictly above $\mathrm{fan}(G)$. In what follows, this property of the partition will be called the *separation property*. Without loss of generality, we can assume that no integer point in the slab B lies on any plane in S; otherwise, one can ensure this without losing the separation property by replacing each plane with two planes obtained by infinitesimal translation in the positive and negative normal directions. The regions of the partition of B are convex polytopes that can have many facets in general. Therefore we shall refine this partition, using a well-known idea in computational geometry (e.g., see [35]) so that each region in the resulting decomposition is a "cylinder" with at most six facets. Then using the pigeonhole principle we shall show that some cylinder in this decomposition must violate the separation property.

Decomposition. Let Q be the set that contains the planes in S and the planes bounding the slab B. Project onto the affine plane the intersection between every pair of planes in Q (restricted to the slab B). This yields an arrangement of lines within the bounding box in the affine plane (Figure 4.2). We refine this arrangement further by passing vertical lines (parallel to the y-axis) through all intersections among these lines and also intersections with the bounding box (Figure 4.2). Let us denote the resulting partition of the bounding box by $A(Q)$.

The affine partition $A(Q)$ can be lifted to the slab B in a natural fashion: We pass fans through all projected lines in the affine plane; these are the same as the fans through pairwise intersections of the planes in Q. We also pass fans through all auxiliary vertical lines that we added in the affine plane. These fans along with the planes in Q yield a decomposition of B; we shall denote it by $D(Q)$. The total number $d(Q)$ of cells (three-dimensional regions) in $D(Q)$ is $O(\delta^4)$, and each cell is a convex

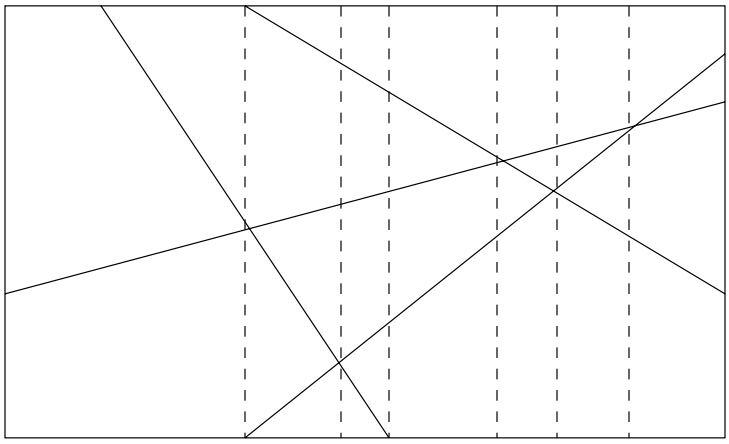

FIG. 4.2. *Decomposition $A(Q)$ in the affine plane.*

cylinder with at most six facets. By a cylinder we mean a convex polytope which has a unique top facet, called the *roof*, and a bottom facet, called the *floor*, as seen from the origin; by the floor we mean the facet that is hit first by any ray coming from the origin toward the cell, and the roof is defined similarly.

Sample points. Next, we choose rational sample points on all (bounded) edges of the graph G; in what follows we just ignore the two unbounded edges of G. Let c be a large enough positive integer constant to be specified later. Divide each edge of the graph into intervals of equal spans along the x-direction by placing δ^c points in its interior. These points will be called *sample points*. The x-coordinates of any two sample points differ by at least $1/(\mu\delta^c)$, because the coordinates of all vertices in G are rationals that can be expressed in terms of denominators and numerators of absolute value at most μ.

Given a sample point p on e, we say that a cell R in $D(Q)$ is *good* for p if its interior contains an integer (lattice) point lying on the ray through p (coming from the origin). We say that R is *good* for an edge e in the graph G if it is good for $[1/d(Q)]$th fraction of the sample points on e.

LEMMA 4.10. *$D(Q)$ contains a cell that is good for $[1/d(Q)]$th fraction of the edges in G.*

Proof. The number of cells in $D(Q)$ is at most $d(Q)$. Hence, by the pigeonhole principle, it suffices to show that for every edge e in the set there is at least one good cell in $D(Q)$. Applying the pigeonhole principle once again, it suffices to show that for every sample point p on e, there is at least one good cell in $D(Q)$. The ray through p is split into at most $\delta + 1$ intervals within B by the planes in Q. Thus the vertical span of at least one such interval—call it e_p—must be at least $\bar{\mu}/(\delta+1)$. The interior of e_p must contain an integer lattice point. This follows from the last property and the following:

1. The coordinates of the sample point p can be expressed as rationals with numerators and denominators of bitlength at most $\log \mu$, ignoring a constant factor.
2. By our assumption, $\log \bar{\mu}$ is greater than sufficiently large constant multiples

of $\log \mu$ and $\log \delta$.
Thus the cell in $D(Q)$ containing e_p is good for p. □

Given an integer point lying on the fan through an edge in G, let us define its neighbor to be the unique integer point with the same x and z coordinates but whose y coordinate is greater by one. Integer points on the fan through G are all feasible, whereas their neighbors are infeasible. This mean if a cell in $D(Q)$ contains an integer point on $\text{fan}(G)$ it cannot contain its neighbor.

The graph G contains ρ edges. By the preceding lemma, there is a cell C in $D(Q)$ that is good for at least $\bar{\rho} = \rho/d(Q)$ such edges. Their number is quite large since $d(Q) = O(\delta^4)$, and ρ is larger than a sufficiently large multiple of δ^4. This means there exist a large number of edges in the graph G such that C contains a large number of integer points on the fan through each of these many edges. But it cannot contain the neighbors of these integer points. Since C is a convex cylinder with at most six facets, this is impossible (as the reader can verify).

This proves Theorem 4.9.

5. PRAM without bit operations. In this section we shall prove our general lower bound for the PRAM model without bit operations (Theorem 3.3) by extending the proof in section 4. As there, we shall prove a stronger nonuniform lower bound (Theorem 5.7) from which Theorem 3.3 will follow. The main difference from the linear PRAM setting is the presence of general multiplication in the instruction set. This causes some algebraic geometry to enter the proof in an essential way.

5.1. The number of possible branchings. First, we extend the general technique for bounding the number of possible ways in which the processors can branch (section 4.1). We shall describe the technique in a language-independent setting, following the same notation as in section 4.1.

Let $\Sigma = \Sigma(x) = \Sigma(x_1, \ldots, x_n)$, $x_i \in Z$, be the language for which we want to prove a lower bound. Here $x_1, \ldots, x_n$ denote the integer parameters in the input. Fix a nonuniform machine in the PRAM model without bit operations with $p(n, N)$ processors, which works correctly on inputs with n parameters with total bitlength at most N in $t(n, N)$ time. We define the t-equivalence classes with respect to this machine just as in section 4.1, the main difference being that the processors can now multiply. The number of t-equivalence classes, in general, does not have a good upper bound. We get around this problem, as in section 4.1, by parametrizing the inputs to the machine and then bounding the number of t-equivalence classes among the parametrized inputs.

Let us imagine running our machine on the set of possible inputs defined by $x_i = l_i(z) = l_i(z_1, \ldots, z_d)$, where for each $i \leq n$ the parametrizing linear form l_i is exactly as in section 4.1. As there, let $\Sigma(z_1, \ldots, z_d)$ denote the set of permissible d-tuples accepted by the machine. We say that z is accepted if $x = l(z) = (\ldots, l_i(z), \ldots)$ is accepted. Two permissible d-tuples z, z' are said to be t-equivalent if $l(z)$ and $l(z')$ are t-equivalent. The notion of equivalence is defined similarly. Let $\sigma(t)$ denote the number of t-equivalence classes among the permissible values of z. Let $\sigma = \sigma(t(n, N))$ denote the number of equivalence classes. The following theorem generalizes Theorem 4.3.

THEOREM 5.1. *For all t, $\sigma(t)$ is bounded by $[2 + 2 \cdot 2^t p(n, N)]^{dt}$.*

Proof. Let C denote a fixed t-equivalence class. Let z denote a (permissible) integral value in this equivalence class. In what follows, we pretend that z is a generic variable. We are told that it belongs to C. But we are not told its actual value. We imagine running our machine on the input $x = l(z)$. We have to specify what is

meant by executing an arithmetic operation in this setting. Now the operand would be polynomials in z, rather than linear forms as in the linear PRAM setting. By an arithmetic operation $\times$, $+$, or $-$, we simply mean the corresponding polynomial operation. Since nonnumeric parameters are fixed by our parameterization, indirect memory references are no problem. We assume that when a processor is executing a comparison it is simply told the result of that comparison, which, at any time less than or equal t, is fixed by the class C. The following lemma generalizes Lemma 4.4.

LEMMA 5.2. *Let C be a fixed t-equivalence class. Then for every memory location j, there exists a polynomial $g_j[C,t](z)$ that gives the content of that location at time t for every $z \in C$. Moreover, the degree of g_j is at most 2^t.*

Proof. Once C is fixed, the execution path of each processor up to time t is fixed. Therefore, each memory location at time $\leq t$ is a completely determined function of $z_1, \ldots, z_d$, in fact, a polynomial function. At time $t = 0$, each memory location is either a constant or is equal to some $l_i(z)$; so it is a polynomial of degree at most one. Unlike in the linear PRAM setting, now we have general multiplication. This corresponds to multiplying two polynomials in $(z_1, \ldots, z_d)$; the degree of their product is the sum of their degrees. The lemma follows by induction on t. ∎

Let us now see what happens at time t, given that the generic variable z belongs to a fixed t-equivalence class C as above. If a processor is to execute an arithmetic operation at time t, then the result of that operation is a certain uniquely determined polynomial to be stored in a certain uniquely determined location in the memory. If the operation is a branch, the branching path is determined by comparing contents of two uniquely determined memory locations, which are certain fixed polynomials in z. In other words, each branch is determined by testing a certain polynomial equality or inequality in z of the form $g(z) : 0$, where the comparison : is $>$, $\geq$, or $=$. The number of such polynomial constraints is at most $p(n, N)$, one per processor. Let $g_1(z), g_2(z), \ldots$ be the nonzero polynomials involved in these constraints. Consider the partition (stratification) of R^d formed by the hypersurfaces $g_i(z) = 0$. A sign-invariant component of this stratification is defined to be the maximal set of points such that the sign of any g_i remains the same over the whole set; it need not be connected or even simply connected. The sign of a function at a given point is defined to $+$, $-$, or 0 depending on whether its value at the point is positive, negative, or zero. We say that a sign-invariant component is nonempty if it contains a permissible integer point.

THEOREM 5.3 (Milnor–Thom). *The number of nonempty sign-invariant components in the preceding stratification of R^d is bounded by $[2 + 2\sum \deg(g_i)]^d$.*

Proof. If no hypersurface under consideration contains any permissible integer point, then this follows directly from the Milnor–Thom bound [34, 49] on the number of connected components of the set $\bigcup_i \{g_i(z)^2 > 0\}$. Otherwise, we can replace each hypersurface $g_i(z) = 0$ by two hypersurfaces $g_i(z) = \epsilon$ and $g_i(z) = -\epsilon$, where ϵ is an infinitesimal positive real (Figures 5.1 and 5.2). Since the number of permissible integer points is finite, we can choose ϵ small enough so that no new hypersurface contains any permissible integer point and the partition of the permissible integer points induced by the sign-invariant components of the old stratification coincides with the partition induced by the sign-invariant components of the new stratification. Now we can apply the Milnor–Thom bound as before. ∎

Because the number of polynomials g_i is at most $p(n, N)$, one per processor, and $\deg(g_i)$ is at most 2^t, it follows from the preceding result that the total number of sign-invariant components in the preceding partition of R^d is at most $[2+2p(n, N)2^t]^d$.

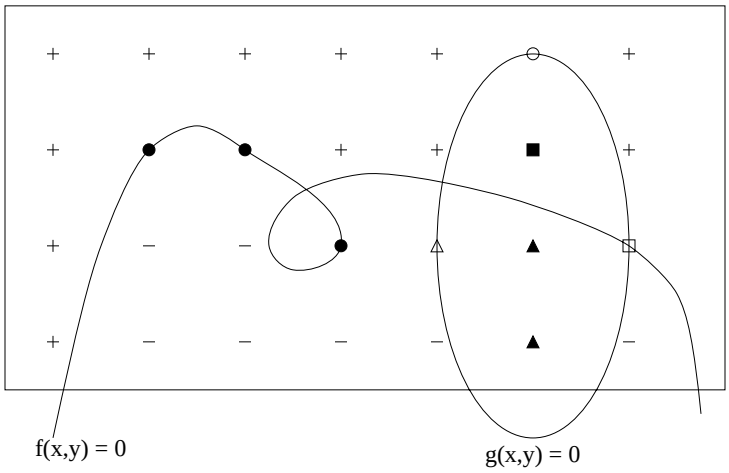

FIG. 5.1. *Before perturbation: integer points in different sign-invariant components are depicted differently.*

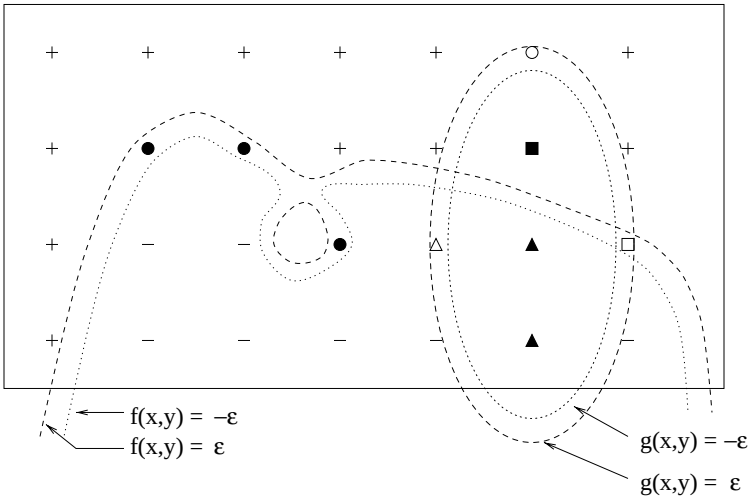

FIG. 5.2. *After perturbation: the sign-invariant partition of the integer points is unchanged.*

Now we make the crucial observation.

OBSERVATION 5.4. *Any two $z, z' \in C$ belong to the same $(t+1)$-equivalence class if they belong to the same sign-invariant component of this partition.*

It immediately follows that

$$\sigma(t+1) \leq [2 + 2p(n,N)2^t]^d \sigma(t).$$

Induction on t proves Theorem 5.1. □

The proof of Theorem 5.1 also yields the following lemma.

LEMMA 5.5. *For any t-equivalence class C, there exists a set $\Phi(C,t)$ of at most*

$p(n, N)t$ polynomial constraints (equalities or inequalities) in d variables such that $z \in C$ iff all these constraints are satisfied. Moreover, the degree of every polynomial occurring in $\Phi(C, t)$ is at most 2^t.

Proof. The constraints correspond to the branches taken by all processors before time t, which are all fixed by the class C. □

By Lemma 5.5, each equivalence class D of permissible z-values is characterized by a set $\Phi(D) = \Phi(D, t(n, N))$ of polynomial constraints. Let $\Phi = \cup_D \Phi(D)$, where D ranges over all equivalence classes. By Theorem 5.1 and Lemma 5.5, it follows that Φ contains at most

$$[2 + 2p(n, N)2^{t(n,N)}]^{dt(n,N)} p(n, N)t(n, N)$$

polynomials of degree at most $2^{t(n,N)}$. Consider the partition of R^d formed by the hypersurfaces defined by these polynomials. Each sign-invariant component of this partition can be labeled *yes* or *no* in such a way that a permissible z is accepted by the machine iff it lies in a sign-invariant component labeled *yes*. Thus we have proved the following.

THEOREM 5.6. *Assume that the language $\Sigma(z_1, \ldots, z_d)$ is accepted in the PRAM model without bit operations using $p(n, N)$ processors in $t(n, N)$ time. Then R^d can be partitioned by a set of at most*

$$[2 + 2p(n, N)2^{t(n,N)}]^{dt(n,N)} p(n, N)t(n, N)$$

polynomials of degree at most $2^{t(n,N)}$ and each sign-invariant component can be labeled yes *or* no *so that a permissible $z \in Z^d$ belongs to $\Sigma(z_1, \ldots, z_d)$ iff it lies in a sign-invariant component labeled* yes.

In the proof of this theorem, performance of the machine on N-bit inputs that do not lie in the parameterized family $\Sigma(z_1, \ldots, z_d)$ does not matter. In other words, the theorem holds even if $t(n, N)$ is defined to be the maximum time taken on any N-bit input in $\Sigma(z_1, \ldots, z_d)$.

5.2. Parameterization. We shall now prove a general lower bound in the PRAM model without bit operations that is nonuniform with respect to parameterization. It generalizes Theorem 4.7, and we follow the same notation as in section 4.2.

THEOREM 5.7. *Assume that the permissibility constant a is large enough. Then no machine in the PRAM model without bit operations can decide whether $w \leq F(I)$ correctly for every $I \in \mathcal{I}$ in $\sqrt{\log \rho(n)}/a'$ time using $2^{\sqrt{\log \rho(n)}/a'}$ processors for some large enough constant a' that does not depend on the permissibility constant a.*

In the deterministic setting, Theorem 3.3 follows from this theorem by applying it to a parameterization $\mathcal{P}$ for cardinality n with bitsize $\beta(n)$ whose complexity is equal to $\phi(n, \beta(n))$, the maximum possible value. Randomized setting is considered in section 6.1. In what follows, we shall denote $\rho(n)$ and $\beta(n)$ by simply ρ and β, respectively.

Let us apply Theorem 5.6 with $d = 3$ to the linear parameterization of the input as in Theorem 5.7. It is defined (as in section 4.2) by the linear map

$$(z_1, z_2, z_3) \to I(z_1, z_2, z_3) = (z_3, \tilde{\mathcal{P}}(z_1, z_2)).$$

Thus in Theorem 5.6 $\Sigma(z_1, z_2, z_3)$ consists of those tuples (z_1, z_2, z_3) such that $z_3 \leq \tilde{\mathcal{P}}(z_1, z_2)$. This gives the following theorem.

THEOREM 5.8. *Let a' be any positive constant. If a machine in the PRAM model without bit operations works correctly on the input $I(z_1, z_2, z_3)$ for every permissible*

z_1, z_2, and z_3, in $t = \sqrt{\log \rho}/a'$ time using 2^t processors, then R^3 can be partitioned by at most 2^{20t^2} algebraic surfaces of degree at most 2^t and each sign-invariant component of this partition can be labeled yes *or* no *so that a permissible integer point (z_1, z_2, z_3) lies in a sign-invariant component labeled* yes *iff $I(z_1, z_2, z_3)$ is feasible.*

5.3. A lattice problem. We shall prove Theorem 5.7 by showing that an algebraic partition as in Theorem 5.8 cannot exist for large enough constants a and a'. We proved this in the linear setting in section 4.3. We wish to generalize that proof to the algebraic setting.

Let G be the graph corresponding to the optimum function $\mathcal{P}$ as in section 4.3 (Figure 4.1). Let $\text{fan}(G)$ be its fan. Let us also rename the coordinates z_1, z_2, z_3 as z, x, and y, respectively. Thus $z = 1$ now serves as the affine plane in R^3. Then in the partition of Theorem 5.8, a permissible integer point in Z^3 is labeled *yes* iff it lies below $\text{fan}(G)$ in the y-direction.

Recall that (1) the graph G is piecewise linear and convex with ρ segments, and (2) all vertices of G have rational coordinates that can be expressed in terms of numerators and denominators of absolute value at most $\mu = 2^\beta$ or, in other words, of bitsize at most $\log \mu$. All vertices of G lie in the interior of the bounding box defined by $|x| \le 2\mu$ and $|y| \le 2\mu$. Consider two horizontal planes, parallel to the affine plane, defined by $z = \bar{\mu}$ and $z = 2\bar{\mu}$, where $\bar{\mu}$ would be chosen to be much larger than μ. Let B denote the region (slab) between the two planes that is enclosed by the fan through the boundary of the bounding box in the affine plane. The coordinates of all integer points in this slab have bitsizes at most twice $\bar{\beta} = \log \bar{\mu}$. The following theorem would imply that the partition as in Theorem 5.8 cannot exist.

THEOREM 5.9. *Let S be any set of surfaces in R^3 with total degree δ. Assume that $\bar{\beta} = \log \bar{\mu}$ is greater than a large enough constant multiple of $\beta = \log \mu$ and that $\log \rho$ is greater than a large enough constant multiple of $\log \delta$. Then at least one sign-invariant component in the partition of B formed by the surfaces in S contains an integer point lying below $\text{fan}(G)$ and also an integer point strictly above this fan.*

Remark. Since $\rho \le 4\mu^2$ trivially, the assumption in the theorem also implies that $\log \bar{\mu}$ is much greater than $\log \delta$.

Before we prove the theorem, let us see why it implies that the partition as in Theorem 5.8 cannot exist; this will prove Theorem 5.7. Let S be the set of surfaces that occur in Theorem 5.8. Their total degree δ is at most $2^t 2^{20t^2} = 2^{21t^2}$, where $t = \log \rho/a'$. Then choose the constant a' and the permissibility constant a large enough and apply Theorem 5.9 to this set S exactly as we applied Theorem 4.9 to the set of planes occurring in Theorem 4.8.

In the rest of this section we shall prove Theorem 5.9. Assume, to the contrary, that no sign-invariant component in the partition of B contains an integer point below $\text{fan}(G)$ and also an integer point strictly above $\text{fan}(G)$. In what follows, this property of the partition will be called the *separation property.* We shall first smooth and refine the partition of B so that the regions in the resulting partition have a simple shape. Then by the pigeonhole principle we shall show that some region in this partition must violate the separation property.

Transversality. The surfaces S in Theorem 5.9 depend on the nonuniform machine under consideration. In general, they can be highly singular; this cannot be helped, since we have no control over the nonuniform machine. Singularities can cause problems in our proof, but fortunately we can get rid of them as follows.

First, we can assume that no integer point in the slab B lies on any surface in S.

Otherwise, one can ensure this without losing the separation property by replacing each surface with two surfaces obtained by perturbing the constant term in its defining equation infinitesimally; since there are only finitely many integer points in B, we can choose the perturbation small enough so that the underlying partition of the integer points in B according to sign-invariant components does not change (see Figures 5.1 and 5.2). We can also add infinitesimal reals freely to the coefficients of the polynomials defining the surfaces in S without losing the preceding or the separation property. In other words, we can assume that the surfaces in S are in *general position*—this just means we have the freedom to perturb them by adding infinitesimal reals to the coefficients of their defining equations. The general position assumption lets one handle the technical problems mentioned above in a clean fashion, because then the transversality techniques from differential geometry (see [16, Chapter 2]) become fully applicable. For example, by perturbing the surfaces in S infinitesimally we can now assume that they are smooth (Sard's theorem), that they intersect transversally, that their *silhouettes* (to be defined soon) are smooth, and so forth.

Collins's decomposition. Let Q be the set that contains (1) the surfaces in S, (2) the planes bounding the slab B, and (3) 6δ horizontal *dividing* planes that subdivide the slab B into horizontal slabs of equal height. By horizontal, we mean parallel to the affine plane.

Consider the partition of B formed by the surfaces in Q. The regions in this partition can have very complicated shapes. Therefore, we shall refine the partition further so that the regions in the resulting partition have simple shapes following a variant of the method due to Collins [10]. Before we define the partition formally, let us make a definition.

Let s be a surface in S. We say that a point p on s belongs to the *silhouette* of s, as seen from the origin, if the line joining p and the origin is tangent to s at p. This happens iff

$$f(x,y,z) = 0 \text{ and } x\frac{\partial f}{\partial x} + y\frac{\partial f}{\partial y} + z\frac{\partial f}{\partial z} = 0, \tag{5.1}$$

where $f(x,y,z) = 0$ is the polynomial equation defining s. The silhouette of s, if nonempty, is a smooth space curve if s is in general position (see [16, Chapter 2]).

Let us project onto the affine plane (1) the silhouette of every surface in S (restricted to the slab B), and (2) the intersection between every pair of surfaces in Q; by our general position assumption, this intersection is a smooth space curve.

The preceding projection yields an arrangement of curves within the bounding box in the affine plane (Figure 5.3). We refine this arrangement further by passing vertical lines (parallel to the y-axis) through all intersections among the curves, singular[2] points on the curves, and also critical points on the curves where the tangents become parallel to the y-axis. Let us denote the resulting partition of the bounding box by $A(Q)$. It is a two-dimensional Collins' decomposition. Every region (cell) in this partition is monotone with respect to the y direction. In other words, its intersection with any line parallel to the y-axis is connected, if nonempty.

The affine partition $A(Q)$ can be lifted to the slab B in a natural fashion: We pass fans through all projected curves in the affine plane; these are the same as the fans through pairwise intersections and silhouettes of the surfaces in Q. We also pass fans through all auxiliary vertical lines that we added in the affine plane. These fans

[2]Transversality conditions cannot remove such singular points on projections.

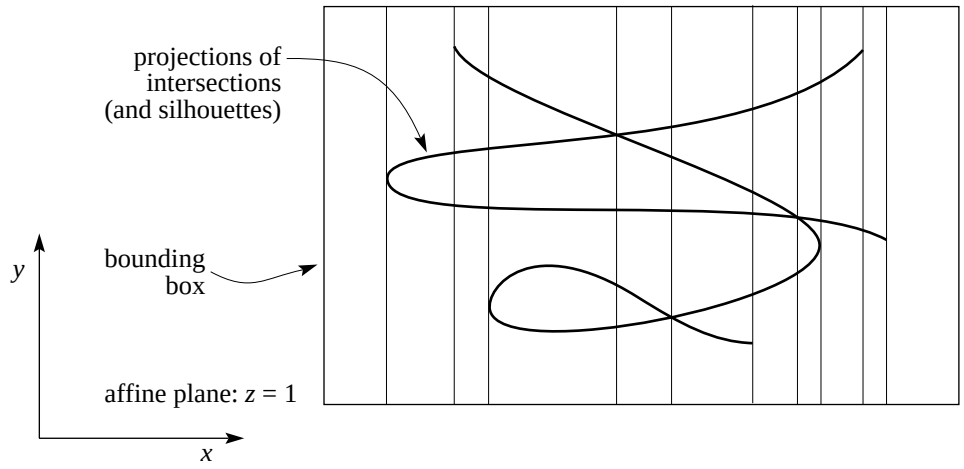

FIG. 5.3. *Decomposition $A(Q)$ in the affine plane.*

along with the surfaces in Q yield a decomposition of B. We shall denote it by $D(Q)$. It has the following properties [10]:

1. Each region, i.e., a three-dimensional cell in $D(Q)$, has at most six sides. It is monotone when viewed from the origin. In other words, its intersection with any ray is connected, if nonempty. By a ray, we mean here and in what follows a ray coming from the origin. (In Collins's original construction, the regions of $D(Q)$ are monotone with respect to the z-direction.) Monotonicity allows us to define the top side, the *roof*, and the bottom side, the *floor*, of each region unambiguously. Formally, the floor consists of all points on the boundary of the region that are hit first by the rays coming from the origin; the roof is defined similarly.
2. The floor of each region is contained in just one surface in Q; the same is true of the *roof*.
3. The remaining sides of the region are contained in fan surfaces.
4. The projection of each cell in $D(Q)$ is a cell in the affine partition $A(Q)$.
5. The total number $d(Q)$ of cells in $D(Q)$ is $O(\delta^{O(1)})$. This follows from the Milnor–Thom result [34, 49] because the total degree of the surfaces in Q, along with the fan surfaces, is $O(\delta^{O(1)})$.

Sample points. Next, we choose rational sample points on the edges of the graph G exactly as in section 4.3. The x-coordinates of any two sample points differ by at least $1/(\mu\delta^c)$.

Let us call a cell R in $D(Q)$ *flat* if its roof and also the floor are contained in the dividing horizontal planes. Given a sample point p on e, we say that R is *good* for p if its interior contains an integer (lattice) point lying on the ray through p. We say that R is *good* for a bounded edge e in the graph G if it is good for $[1/d(Q)]$th fraction of the sample points on e.

LEMMA 5.10. *$D(Q)$ contains a flat cell that is good for $[1/d(Q)]$th fraction of the edges in G.*

Proof. The number of flat cells in $D(Q)$ is at most $d(Q)$. Hence, by the pigeonhole

principle, it suffices to show that for every bounded edge e in G there is at least one good flat cell in $D(Q)$. Applying the pigeonhole principle once again, it suffices to show that for every sample point p on e, there is at least one good flat cell in $D(Q)$. The ray through p is split into $6\delta+1$ intervals by the 6δ dividing planes. At most δ of these intervals are intersected by the surfaces in S. To see this, note that the surfaces in S are in general position and the sample points do not depend on S. Hence, the ray through p is intersected by the surfaces in S in a finite number of points, and this number is at most δ, the total degree of the surfaces in S, by the simplest special case of the Milnor–Thom result (which is essentially Bezout's result). It follows that there is at least one such interval in the interior of B that is not intersected by any surface in S. Denote this interval by e_p. Let P_1 and P_2 be the consecutive dividing planes adjacent to this interval. Note the following:

1. The interval e_p is contained in some cell of $D(Q)$.
2. The endpoints of e_p lie on P_1 and P_2. But they do not lie on any surface in S if the surfaces in S are in general position. The latter fact follows because the rays through the sample points on the graph G as well as their intersections with the dividing planes are finite in number and they do not depend on S. Hence, we can perturb the surfaces in S infinitesimally before the construction of the decomposition $D(Q)$ begins and ensure that no surface in S contains any such intersection.
3. The preceding property, in conjunction with the properties of $D(Q)$, implies that the roof and the floor of the cell in $D(Q)$ containing e_p must be contained in the planes P_1 and P_2, respectively. Hence, this cell must be flat.
4. The vertical span of e_p is $\bar{\mu}/(6\delta+1)$.

The interior of e_p must contain an integer lattice point. This follows from the last property just as in the proof of Lemma 4.10. Thus the flat cell containing e_p is good for p. □

The graph G contains ρ bounded edges of distinct slopes. By the preceding lemma, there is a flat cell C in $D(Q)$ that is good for at least $\bar{\rho} = \rho/d(Q)$ such edges. Let these $\bar{\rho}$ edges be $e_1, e_2, \ldots$ ordered from left to right in the affine plane. Such ordering is possible because the graph G, being a function graph, is monotone with respect to the y direction. Let T be the projection of C onto the affine plane. It belongs to the affine partition $A(Q)$. Hence, it is monotone in the y direction. Let g denote the curve containing the upper side of T. By the definition of $A(Q)$, the upper side of T is monotone with respect to the y direction and contains no singularities. Hence, it defines a certain smooth function $y = \bar{g}(x)$ within the span of T along the x-axis.

LEMMA 5.11. *The second derivative of the function $\bar{g}(x)$ has at least $\bar{\rho}-1$ extrema within the span of T along the x-axis.*

Proof. The basic idea is to show that the curve g gets very close to several sample points on each segment e_i. Since these segments are not too far apart, and their slopes are sufficiently different, g must change its direction several times (Figure 5.4).

Fix any e_i. The cell C is good for e_i. Hence, it is good for at least $[1/d(Q)]$th fraction of the sample points on e_i. Since the number of sample points on e_i is δ^c and $d(Q)$ is $O(\delta^{O(1)})$, there are at least eight such sample points in the interior of each e_i, assuming that the constant c is large enough. In what follows, these eight sample points will be the only active sample points on e_i; all other sample points are discarded. Order these remaining sample points from left to right. Fix any such sample point p. It must lie within T because C contains an integer lattice point—call

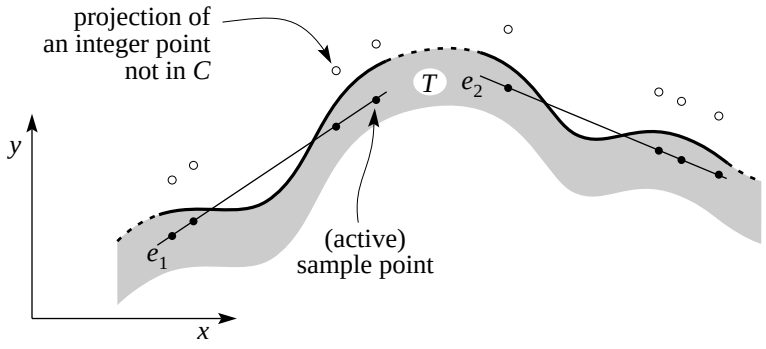

FIG. 5.4. *Upper side of T.*

it $\bar{p}$—on the ray through p.

Claim. The difference between the y-coordinate of p and the value of the function $\bar{g}(x)$ at the x coordinate of p is at most $1/\bar{\mu}$.

Proof of the claim. Consider the integer point $\hat{p}$ with the same x and z coordinates as the integer point $\bar{p}$ but whose y coordinate is one plus the y-coordinate of $\bar{p}$. This point certainly lies in the slab B since the bounded edge of G containing p is well within the interior of the bounding box in the affine plane. The point $\hat{p}$ does not lie on any ray through the graph G because p lies on G and G is monotone in the y direction. Since our partition has the separation property, the cell C cannot contain $\hat{p}$ because it already contains $\bar{p}$. Let q denote the projection of $\hat{p}$ onto the affine plane. It lies above p and has the same x-coordinate as p. Moreover, its y-coordinate differs from that of p by at most $1/\bar{\mu}$. This follows because the z-coordinate of $\hat{p}$—in fact, of every point in the slab B—is at least $\bar{\mu}$. Since the cell C does not contain $\hat{p}$ and T is monotone in the y direction, the upper side of T must separate p and q (Figure 5.4). This proves the claim.

Let $a_1, a_2, \ldots$ be the slopes of $e_1, e_2, \ldots$. They are all different. The difference between any two slopes, ignoring a constant factor, is at least $1/\mu^2$ because the coordinates of all vertices in G can be expressed as rationals with numerators and denominators of absolute value at most μ. The x-coordinates of any two sample points differ by at least $1/(\mu\delta^c)$, as we remarked earlier. These facts, in conjunction with the previous claim and Roelle's mean value theorem in elementary calculus, imply the following:

1. The derivative $d\bar{g}(x)/dx$ attains a value close to a_i between the x-coordinates of the jth and $(j+1)$st sample points on e_i for all $1 \le j < 8$. By close we mean that the error term is $O(\mu\delta^c/\bar{\mu})$.
2. This implies further that the second derivative attains a value close to zero between the x-coordinates of, say, the third and the sixth sample points on e_i. Similarly, somewhere between the x-coordinates of the seventh sample point on e_i and the second sample point on e_{i+1}, the absolute value of the second derivative is $\Omega(|a_{i+1} - a_i|/\mu)$, ignoring an additive $O(\mu^2\delta^{2c}/\bar{\mu})$ error term; here one also needs to use the fact that the x-coordinates of any two sample points differ by at most μ.
3. The preceding fact implies that every pair (e_i, e_{i+1}) contributes at least one

distinct extremum of the second derivative because $\log \bar{\mu}$ is greater than sufficiently large constant multiples of $\log \mu$ and $\log \delta$.

The lemma follows from the last fact. □

Claim. The second derivative of the function $\bar{g}(x)$ has at most $O(\delta^{O(1)})$ extrema in the span of T along the x-axis.

Proof. Let $g(x, y) = 0$ be the polynomial equation satisfied by the upper side of T. Its degree is at most $O(\delta^{O(1)})$ because the curve g containing the upper side results by projecting a silhouette or an intersection of two surfaces in S. Differentiating this equation three times in a row, we get four implicit equations satisfied by x, y and the three derivatives $y^{(1)}, y^{(2)}$, and $y^{(3)}$:

$$g(x, y) = 0,\ g_1(x, y, y^{(1)}) = 0, \ldots,$$

where $y^{(k)}$ is a formal variable that denotes the kth order derivative. In addition, the extrema satisfy $y^{(3)} = 0$. Because the surfaces in S are in a general position, these five equations in five variables have a finite number of real solutions. This number is $O(\delta^{O(1)})$, by the Milnor–Thom result.[3] Hence, the claim follows. (Formally, finiteness of the number solutions used above follows from the jet-transversality results; cf. [16, Chapter 2]. Alternatively, one can forget about transversality and just bound the number of connected components of the solution set using the Milnor–Thom result. The rest of the proof then needs to be modified a bit.)

The claim contradicts the preceding lemma because $\bar{\rho} = \rho/d(Q)$, $d(Q) = \delta^{O(1)}$, and $\log \rho$ is larger than a sufficiently large multiple of $\log \delta$.

This proves Theorem 5.9. □

6. Extensions.

6.1. Randomized algorithms.

All our lower bounds extend to randomized algorithms in the PRAM model without bit operations. The following result generalizes Theorem 3.3.

THEOREM 6.1. *Fix any homogeneous optimization problem. Let $\phi(n, \beta(n))$ be its parametric complexity for input cardinality n and bitsize $\beta(n)$. Then there exists a large enough constant b such that the decision version of the problem cannot be solved in the PRAM model without bit operations using randomization in $\sqrt{\log[\phi(n, \beta(n))]}/b$ expected time using $2^{\sqrt{\log[\phi(n,\beta(n))]}/b}$ processors; this is so even if we restrict every numeric parameter in the input to be an integer with bitlength at most $a\beta(n)$ for a large enough constant a.*

This also applies to the additive approximation version of the problem.

To prove it, we need only to extend Theorem 5.7. Its analogue in the randomized setting, following the same notation, is the next theorem.

THEOREM 6.2. *Assume that the permissibility constant a is large enough. Then no randomized machine in the PRAM model without bit operations can decide whether $w \leq F(I)$ correctly for every $I \in \mathcal{I}$ in $T = \sqrt{\log \rho(n)}/a'$ expected time using $p = 2^{\sqrt{[\log \rho(n)}/a'}$ processors with at most ϵ two-sided-error probability for some large enough constant a' that does not depend on the permissibility constant a.*

One can similarly extend Theorem 4.7 for the linear PRAM model; we leave this to the reader.

[3] Or one can also apply Bezout's theorem, but one has to be a bit careful. Bezout's theorem is applicable only if the number of complex solutions, not just the real solutions, is finite. This technicality can be taken care of as in Lemma 1 of Milnor [34].

Now we shall prove Theorem 6.2. In what follows, we shall denote $\rho(n)$ and $\beta(n)$ by simply ρ and β, respectively. Let $I(z_1, z_2, z_3)$ denote the total parametrized input, which includes the threshold, as in section 5.2. Let Φ be any suitably chosen subset of the permissible integer points in Z^3. Consider a probability distribution on Z^3 that is zero outside Φ and uniform on Φ. By Yao's lemma [54], it suffices to show, ignoring factors of two, that there is no deterministic machine M in the PRAM model without bit operations containing p processors that runs in expected time T, possibly erring on at most ϵ fraction of the points in Φ; here the expectation is meant to be with respect to the probability distribution on the input parameters. We can assume that ϵ is a small enough constant, say, $1/100$, by increasing T suitably.

Fix another positive constant $\bar{\epsilon} = 1/100$. Let us call a permissible integer point z in Φ *satisfactory* with respect to Φ, ϵ, and $\bar{\epsilon}$ if M stops on the corresponding input $I(z)$ in $t = T/\bar{\epsilon}$ time without any error. The proof of Theorem 5.8 can be extended *verbatim* to prove the following.

THEOREM 6.3. *Suppose a deterministic machine M as described above exists in the PRAM model without bit operations. Then R^3 can be partitioned by at most 2^{20t^2} algebraic surfaces of degree at most 2^t and each sign-invariant component of this partition can be labeled* yes *or* no *so that a satisfactory permissible integer point (z_1, z_2, z_3) lies in a sign-invariant component labeled* yes *iff $I(z_1, z_2, z_3)$ is feasible.*

Now we can generalize the proof of Theorem 5.7 to the randomized setting. First, let us specify the set Φ that fixes the input distribution. Let G be the graph as in section 5.3. Recall that the ray through each sample point on the graph G is split into exactly $6\delta+1$ intervals by the horizontal dividing planes. Moreover, each such interval contains a permissible integer point (cf. the proof of Lemma 5.10). Fix any such integer point on every such interval; in what follows, it will be called a *distinguished* point. The *neighbor* of this distinguished point is defined to be the integer point in the slab B with the same x and z coordinates as the distinguished point, but with the y coordinate greater by plus one. The graph G contains ρ (bounded) edges with distinct slopes. We shall let Φ be the set of distinguished points, along with their neighbors, on all rays through the sample points on these edges. Observe that the neighbors of all distinguished points are disjoint; this follows because G is monotone in the y-direction. Hence, exactly half of the points in Φ are distinguished. Let us call a distinguished point *satisfactory* if it is satisfactory and so is its neighbor. The number of unsatisfactory distinguished points is at most $2(\epsilon + \bar{\epsilon})$th fraction of the number of points in Φ. Let us call a sample point on an edge of G *satisfactory* if at least half of the distinguished points on the ray through it are satisfactory. Since the rays through all sample points have exactly the same number of distinguished points, the number of such unsatisfactory sample points is at most $4(\epsilon + \bar{\epsilon})$th fraction of the total number of sample points on the edges of G. Let us call an edge of G *satisfactory* if at least half of the sample points on that edge are satisfactory. Since all edges of G have the same number of sample points, the number of unsatisfactory edges is at most $8(\epsilon+\bar{\epsilon})\rho \leq 8\rho/50$. Discard all unsatisfactory edges and all unsatisfactory sample points on the satisfactory edges. We are still left with a large number of satisfactory quantities.

Now we can translate the proof of Theorem 5.7 with the use of Theorem 5.8 substituted with that of Theorem 6.3, making sure that everything involved is satisfactory. Thus, we say that a flat cell R in $D(Q)$ is good for a (satisfactory) sample point p; we mean that R contains a (satisfactory, distinguished) integer point on the ray through p. The proof of Lemma 5.10 can be translated easily since the number

of unsatisfactory intervals, i.e., the intervals containing unsatisfactory distinguished points, on any sample ray is at most $3\delta + 1$, and they can be thrown away. Similarly, Lemma 5.11 holds in this extended setting because the only integer points involved in its proof can be assumed to be satisfactory distinguished points and their satisfactory neighbors.

This proves Theorem 6.2.

6.2. PRAM with limited bit operations. We now indicate how our lower bounds can be extended to the PRAM model with limited bit operations.

THEOREM 6.4. *The lower bounds in Theorems* 3.3 *and* 6.1 *also hold in the PRAM model with limited bit operations.*

For the sake of simplicity, we shall consider only the deterministic setting.

We indicate only the changes that need to be made to the proof for the PRAM model without bit operations. Suppose there were to exist a machine M in this model for the problem under consideration that works in $t(n, N)$ time using $p(n, N)$ processors. Let $z_1, \ldots, z_d$ be the integer parameters that parametrize the input to this machine as in section 5.1. Let $\sigma(t)$ denote an equivalence class of parametrized inputs at time t, where two inputs belong to the same $\sigma(t)$ iff all processors in the machine follow the same branching path up to time t when the machine is started on either of the inputs.

Claim. Fix an equivalence class $\sigma(t)$ and the value of the parametrized input $z = (z_1, \ldots, z_d)$ modulo $2^{t(n,N)}$; i.e., z_i modulo $2^{t(n,N)}$ is fixed for every i. Then for all inputs z in this equivalence class having the same value modulo $2^{t(n,N)}$, and any time t, the value of any memory location modulo $2^{t(n,N)-t}$ at that time is the same.

Proof. Proof is by induction on t. The base case is clear. Consider $t > 1$. Once $\sigma(t)$ is fixed, so is the corresponding $\sigma(t-1)$. By the induction hypothesis, the values of all memory locations modulo $2^{t(n,N)-t+1}$ are fixed. Consider any memory location u. At time t, either u remains unchanged or is changed in accordance with an assignment of type:

1. $u := v\{+, -, \text{or}, *\}w$, where v and w are memory locations or constants; in this case the value of u at time t modulo $2^{t(n,N)-t}$, in fact, modulo $2^{t(n,N)-t+1}$ as well, is fixed by the values of v and w at time $t-1$ modulo $2^{t(n,N)-t+1}$; or
2. $u := \lfloor u/2 \rfloor$; in this case the value of u at time t modulo $2^{t(n,N)-t}$ is fixed by its value at time $t-1$ modulo $2^{t(n,N)-t+1}$. □

It follows that once we fix the input z modulo $2^{t(n,N)}$, and an equivalence class $\sigma(t)$, $t \leq t(n, N)$, then each assignment of type $u := \lfloor u/2 \rfloor$ that occurs on the computation path of any processor up to time t can be replaced unambiguously by a rational assignment $u := u/2$ or $u := u/2 - 1$. Now it can be checked that the proof of Theorem 5.6 goes through verbatim provided we confine ourselves to z-inputs having the same value modulo $2^{t(n,N)}$. For the sake of simplicity, we shall confine ourselves with z-inputs that are zero modulo $2^{t(n,N)}$; we call them *green* inputs. We are thus led to the following extension of Theorem 5.6 in the extended model.

THEOREM 6.5. *Assume that the language $\Sigma(z_1, \ldots, z_d)$ is accepted in the PRAM model with limited bit operations using $p(n, N)$ processors in $t(n, N)$ time. Then R^d can be partitioned by a set of at most*

$$[2 + 2p(n, N)2^{t(n,N)}]^{dt(n,N)} p(n, N)t(n, N)$$

polynomials of degree at most $2^{t(n,N)}$ and each sign-invariant component can be labeled yes *or* no *so that a* green *permissible $z \in Z^d$ belongs to $\Sigma(z_1, \ldots, z_d)$ iff it lies in a sign-invariant component labeled* yes.

Now we are ready to extend the proof of Theorem 5.7 to the extended model. For the rest of the proof, we simply confine ourselves to the green inputs. Note that the green z points form a sublattice of the original integer lattice. If we were to change our coordinate system so as to scale the green lattice by a factor of $1/2^{t(n,N)}$, then it would look like our original lattice. What is the effect of this scaling on the rest of the proof of Theorem 5.7? Well, the quantities μ and $\bar{\mu}$ that occur in section 5.3 have to be scaled by $1/2^{t(n,N)}$, but the remaining quantities such as ρ and δ are unaffected. If we choose the constant a' there large enough, $\log \mu$ and $\log \bar{\mu}$ are scaled down by at most the same constant factor, say, 2. But it can be checked that the rest of the proof in section 5.3 is robust with respect to a constant factor scaling of $\log \mu$ and $\log \bar{\mu}$. This proves Theorem 5.7 in the extended PRAM model with limited bit operations.

6.3. The number of iterations in sequential algorithms. Our lower bound for the mincost-flow and max-flow problems, which are instances of (combinatorial) linear programming, implies an interesting lower bound on the number of iterations in the sequential iterative algorithms for linear programming such as the ellipsoidal algorithm or the interior-point algorithm. These algorithms consist of a sequence of iterations, and each iteration can be accomplished—at least in theory—in $O(\log^2 n)$ parallel steps using a polynomial number of processors; this can be done using fast parallel algorithms for linear algebra [11] and approximate root extraction [3, 39]. It follows from Theorem 5.7 that given any parametrized family $\mathcal{I} = I(z)$ of inputs, these algorithms must require $\Omega(\sqrt{\log \rho(n)}/\log^2 n)$ iterations for some instance in the family; here $\rho(n)$ is defined for the family $\mathcal{I}$ as in Theorem 5.7. In the worst case—e.g., when $\mathcal{I}$ is a parametric family that attains maximum parametric complexity for the mincost-flow problem—this lower bound is $\Omega(n^{1/4}/\log^2 n)$. A similar lower bound applies to any iterative algebraic algorithm, deterministic or randomized. By an iterative algorithm, we mean an algorithm whose each iteration admits efficient parallelization in a theoretical sense. In practice, such an iteration may not be actually carried out in parallel, because parallel algorithms that are efficient in theory are not always practical. Rather, we think that parallelizability of a step indicates that it may be amenable to fast special-purpose algorithms. For example, fast algorithms for solving sparse linear systems seem to be useful in speeding up the iteration in the interior-point method. Hence, the number of iterations is an important criterion in practice.

Now suppose we are given an iterative algebraic algorithm, deterministic or randomized, whose each step can be efficiently parallelized in $\tau(n)$ parallel steps. It follows similarly that given any family $I(z)$ of inputs, this algorithm must require $\Omega(\sqrt{\log \rho(n)}/\tau(n))$ iterations for some instance in the family.

6.4. Weighted MAX-SNP problems. Once one has shown that one problem is hard to parallelize in the PRAM model without bit operations, it follows, as in the NP-completeness theory, that any problem that can be reduced to it fast in parallel in this model is also hard to parallelize. In this fashion one can show that several weighted MAX-SNP problems [41] are also hard to parallelize in the PRAM model without bit operations. For reasons stated in section 2.2 we consider only problems that have efficient sequential algorithms which do not manipulate bits (here this means strongly exponential time algorithms).

THEOREM 6.6. *The following problems cannot be solved in the PRAM model without bit operations (or with limited bit operations) deterministically (or with randomization) in $O(N^a)$ (expected) time using 2^{N^a} processors, where N denotes the input bitlength and a is a small enough positive constant. In all cases, the weights are*

meant to be nonnegative integers. (For the definitions of these problems, see [41].*)*

1. *Weighted* 3*-SAT-B, weighted* 3*-SAT-V, and weighted* 2*-SAT.*
2. *Weighted independent set-B.*
3. *Weighted vertex cover-B.*
4. *Weighted clique.*
5. *Weighted three-dimensional matching.*
6. *Weighted Steiner trees in graphs.*
7. *Weighted not-all-equal* 3*-SAT.*
8. *Weighted max-cut.*
9. *Traveling salesman.*
10. *Traveling salesman (metric).*

Proof. We have already shown that the weighted s-t-mincut problem is hard to parallelize in our model. It is easy to reduce one of the problems on the list, say, the weighted 3-SAT-B, to this problem, and then one can use standard reductions among weighted MAX-SNP-complete problems [41]. One has only to check that these reductions do not manipulate bits, i.e., they work fast in parallel in the PRAM model without bit operations. □

6.5. Higher order parametric complexity. The notion of parametric complexity as defined in section 3 can be readily generalized to allow any fixed number of parameters. Thus instead of a linear parameterization $\mathcal{P}$ in one rational parameter λ, as defined in section 3.1, one can consider a parameterization with any constant c number of rational parameters $\lambda_1, \ldots, \lambda_c$. The corresponding optimum function graph $G(\mathcal{P})$ should now be a convex c-dimensional simplicial complex. We define the complexity $\rho(n)$ of $\mathcal{P}$ to be the number of (bounded) facets of this complex. The bitsize of $\mathcal{P}$ is defined to be the maximum among the bitsizes of the coordinates of the vertices of $G(\mathcal{P})$ and of the coefficients of the linear functions in $\mathcal{P}$ specifying numeric parameters. We associate with $\mathcal{P}$ a $(c+1)$-dimensional homogeneous integral parameterization $\tilde{\mathcal{P}}$ very much as in section 3.1. Now given a large enough *permissibility constant* a, we can let $\mathcal{I}$ be the set of inputs of the form (z_{c+2}, I) in the decision version of our general optimization problem, where the following hold:

1. The integer z_{c+2} denotes the threshold and its bitsize is at most $a\beta(n)$.
2. I is of the form $\tilde{\mathcal{P}}(z_1, \ldots, z_{c+1})$ for some integers $z_1, \ldots, z_{c+1}$ of bitsize at most $a\beta(n)$.

Then the natural generalization of Theorem 5.7 to such parametric input families $\mathcal{I}$ holds. The proof generalizes because Collins' decomposition, the Milnor–Thom result, and the other techniques used in section 5.3 work in higher dimensions as well.

7. The P versus NC problem. Valiant [51] conjectured that over a field of characteristics other than two, the permanent of an $n \times n$ matrix cannot be expressed as a specialization—projection in his terminology—of the determinant of a matrix of poly(n) size. An evidence in support of this conjecture is #P-completeness of the permanent. Analogously we shall formulate for the mincost-flow problem a conjecture, which if true would imply that $P \neq NC$. We shall also prove its special case (Theorem 7.4). Evidence in support of the conjecture will be provided by this special case, our lower bound for the mincost-flow problem (Theorem 1.1) and the general belief that the perfect-matching problem for unweighted graphs does not belong to NC^1—it is not even known to belong to NC. The mincost-flow problem is chosen only for concreteness (see the discussion after the conjecture). In contrast to the setting in Valiant [51], which is purely algebraic, the issue of bitlengths is of paramount importance here.

Let C denote the set of complex numbers.

DEFINITION 7.1. *Given a hypersurface $H \in C^l$ and a linear map $F : C^k \to C^l$, $k \leq l$, let $F^{-1}(H)$ be the pullback (inverse image) of H under F.*

Here F can be nonhomogeneous, i.e., it can have constant additive terms in its defining forms.

We are mainly interested in the case when $l = m^2$ for some m and H is the determinant hypersurface $SL_m(C)$ in C^{m^2}. It is defined as follows. Let y_{ij}, $i, j \leq m$, denote the coordinates of C^{m^2}. Let Y denote the $m \times m$ matrix whose coefficients are the coordinates y_{ij}. Let $\det(Y)$ denote its determinant. Then $SL_m(C)$ is defined by the equation $\det(Y) = 1$; it is known to be a smooth hypersurface. In this case $F^{-1}(H)$ is defined by the equation $\det(F(x_1, \ldots, x_k)) = 1$, where $x_1, \ldots, x_k$ denote the coordinates of C^k; the image $F(x_1, \ldots, x_k)$ is an $m \times m$ matrix whose coefficients are linear forms in $x_1, \ldots, x_k$, possibly nonhomogeneous.

Now consider the decision version of the mincost-flow problem. Here we are given an n-vertex network whose each arc has integer cost and nonnegative integer capacity. Given an integer flow value v and an integer threshold w, the problem is to decide if there exists a flow with value v and cost at most w. The input can be identified with an integer tuple $I \in Z^k$ with $k = 2\binom{n}{2} + 2$ consisting of the costs, capacities, flow value, and threshold, where Z denotes the set of integers. Let $L(n) \subseteq Z^k$ denote the mincost-flow language, i.e., the set of tuples for which the answer is yes. For any positive constant a, let $B(a, n)$ denote the set of points in Z^k whose each coordinate has bitsize at most an, i.e., the integer points within the box defined by $|x_i| \leq 2^{an}$ for all $i \leq k$.

DEFINITION 7.2. *Given a hypersurface $H \subseteq C^l$ and a linear function $F : C^k \to C^l$, $l \geq k$, we say that the pullback $F^{-1}(H)$ separates $L(n)$ within $B(a, n)$ if the points in $B(a, n)$ that lie on it are precisely the ones in $L(n) \cap B(a, n)$.*

One can then make the following conjecture.

CONJECTURE. *Consider the hypersurface $H = SL_m(C)$, where $m \leq 2^{n/d}$ and $d > 0$ is a large enough constant ($d = 1$ may suffice). For any positive constant a and any one-to-one linear function $F : C^k \to C^{m^2}$, $k = 2\binom{n}{2} + 2$, the pullback $F^{-1}(H)$ cannot separate $L(n)$ within $B(a, n)$, assuming that n tends to infinity.*

The linear function F in the conjecture is over complex numbers. This is desirable because the methods of algebraic geometry work best over algebraically closed fields. We feel that if the conjecture is true when F ranges over some special integral functions—akin to Valiant's projections [51]—then it should also be true when F ranges over all complex linear functions. This will be borne out by Theorem 7.4, which holds over complex numbers.

We chose the mincost-flow problem in our formulation only for concreteness. One can choose any other problem that is not believed to be in NC, as long as it is suitable for an algebraic approach. If the problem is in P, it should have a strongly polynomial time algorithm. But it need not always be in P. For example, we can choose the permanent problem. This yields a conjecture, stronger than Valiant's [51], which if true would imply that the permanent does not belong to NC.

PROPOSITION 7.3. *If the conjecture is true for some positive $a < 1/(2d)$, then $P \neq NC$.*

Proof. The total bitlength of any tuple I in $B(a, n)$ is at most $kan = \text{poly}(n)$. Suppose, to the contrary, that $P = NC$. Then the mincost-flow problem belongs to NC. Hence there is a small arithmetic formula τ in the bits of I of size $2^{\text{polylog}(n)}$ such that the formula evaluates to one on such I in $B(a, n)$ iff it belongs to $L(n) \cap B(a, n)$.

(Here and in what follows we think of a bit as just an integer that is zero or one.) Each coordinate of I has bitsize at most an. Using Lagrange interpolation, one can construct for its every bit a formula in the coordinate of size $O(2^{2an})$: this formula evaluates to one iff that particular bit of the coordinate is one. Feeding these formulae for bits into the preceding formula τ, we get a formula of size $O(2^{2an+\mathrm{polylog}(n)})$ in the coordinates of I; this formula evaluates to one on $L(n) \cap B(a,n)$ but on no other point in $B(a,n)$. Using Valiant's reduction [51], one can now construct a matrix of almost the same size whose entries are linear forms in the coordinates of I and whose determinant is equal to the formula. This gives a one-to-one linear map $F : C^k \to C^{m^2}$, where $m = O(2^{2an+\mathrm{polylog}(n)})$ such that $F^{-1}[SL_m(C)]$ separates $L(n)$ within $B(a,n)$; moreover if $a < 1/(2d)$, this $m < 2^{n/d}$. This contradicts the conjecture. □

Here is the intuition behind the conjecture.

Our lower bound for the mincost-flow problem (Theorem 1.1) is undoubtedly far from optimal and holds only in the restricted PRAM model without bit operations. But for this problem our model is fairly realistic and the lower bound quite strong; it also holds when the bitsizes of the costs and capacities are restricted to be linear in n, the number of vertices. This suggests that in the presence of this restriction one probably cannot do much better than the following well-known parallel method, which we shall call the *explode-and-match* method.

Let n be the number of vertices in the flow network G, and let l be the maximum bitlength of a cost or capacity. The method first reduces the problem, by the well-known method [27] that "explodes" costs and capacities, to the maximum cardinality matching problem for an unweighted graph $\bar{G}$ of size $\bar{n} = O(2^l \mathrm{poly}(n))$. For the latter problem one can use a fast parallel algorithm in [24] or [36]. When $l = O(n)$, this method is better than the parallel algorithm of Shiloach and Vishkin [45] or of Goldberg and Tarjan [13] as far as the parallel time is concerned, though the processor count is very bad in comparison.

We are interested in the case when $l = an$ and a is the constant in the conjecture. Suppose the perfect-matching problem (and hence the maximum cardinality matching problem) for unweighted graphs belongs to NC^i for some i; so far this is open (it is known to be in RNC^2 [36]). Apply an NC^i-algorithm to the exploded graph $\bar{G}$. This gives a formula in the bits of the encoding of $\bar{G}$ which evaluates to one iff $\bar{G}$ has a matching of required cardinality; the size of this formula is $2^{c \log^i \bar{n}}$ for some constant c. In our case, $\bar{n} = O(2^l \mathrm{poly}(n)) = O(2^{an} \mathrm{poly}(n))$ with $l = an$. Hence the explode-and-match method gives us a formula in the bits of the edge-capacities and costs of G of size $2^{c(an)^i + O(\log^i n)}$ which evaluates to one iff the mincost-flow problem for the original graph G is feasible. Now one can feed into this formula the $O(4^{an})$-size formulae based on Lagrange interpolation for the bits of the costs and capacities (as in the proof of Proposition 7.3). This yields a formula of size

$$O(2^{c(an)^i + O(\log^i n)} 4^{an}) = O(2^{b(an)^i}),$$

where $b = c + 3$. Apply Valiant's reduction [51] to it. This gives a linear function $F : C^k \to C^{m^2}$, where $m = O(2^{b(an)^i})$. The pullback $F^{-1}[SL_m(C)]$ under this linear function separates $L(n)$ within $B(a,n)$.

If $i = 1$, i.e., if the perfect-matching problem belongs to NC^1, then one can choose a small enough so that the preceding $m < 2^{n/d}$. Then the conjecture, in fact, would be false for such small a. However, it is widely believed that the perfect-matching problem does not belong to NC^1; it is not even known to belong to NC.

Let us assume that $i > 1$. It need not be an integer. In other words, we are

even allowing a rather unlikely possibility that the perfect matching problem belongs to NC^i, where $i > 1$ is a real number arbitrarily close to one. In this case the quantity $2^{b(an)^i}$ above grows far faster than $2^{n/d}$ since i occurs in the exponent of the exponent. If we believe that when the costs and capacities have $O(n)$ bitlengths there is no parallel algorithm for the mincost-flow problem that is much better than the explode-and-match method—this is what our lower bound suggests—then, in turn, we are led to believe that one cannot come up with a separating linear function $F : C^k \to C^{m^2}$ with m that is much smaller than the $O(2^{b(an)^i})$ bound in the preceding scheme. But this bound grows much faster than $2^{n/d}$. That, roughly speaking, is the intuition behind the conjecture.

Remark. The belief that the perfect-matching problem does not belong to NC^1 is, in turn, tied to the belief that the determinant problem does not belong to NC^1 (it belongs to NC^2 [11]). This is because the parallel algorithm of Mulmuley, Vazirani, and Vazirani [36] reduces the matching problem to a calculation of determinants.

Another piece of evidence in support of the conjecture is the following.

THEOREM 7.4. *The conjecture is true for every large enough constant a (for the mincost-flow problem).*

Proof. This can be proved using Theorem 5.9.

Let a be a large enough positive constant to be chosen later. Assume that the conjecture is false. Then for some linear function $F : C^k \to C^{m^2}$, where $m \leq 2^{n/d}$, the inverse image $F^{-1}(SL_m(C))$ separates $L(n)$ within $B(a, n)$. Let $SL_m^+(C)$ and $SL_m^-(C)$ be hypersurfaces infinitesimally close to $SL_m(C)$ defined by the equations $\det(Y) = 1+\epsilon$ and $\det(Y) = 1-\epsilon$, respectively, where ϵ is infinitesimally small. Their inverse images—call them H_1 and H_2—partition $B(a, n)$ so that all points of $L(n)$ within it are contained in the same sign-invariant component which does not contain any other point of $B(a, n)$.

Now we shall confine our attention to only those integer points of $B(a, n)$ that lie within a three-dimensional affine subspace chosen as follows. We know that the parametric complexity $\phi(n, \beta(n))$ of the mincost-flow language is $2^{\Omega(n)}$ for $\beta(n) = O(n)$ (Theorem 3.5). Let $\mathcal{P}$ be a parameterization corresponding to the maximum value of the parametric complexity. Then the corresponding graph $G = G(\mathcal{P})$ (section 3.1) has $\rho = 2^{\Omega(n)}$ breakpoints. Let $\tilde{\mathcal{P}}$ be the corresponding homogeneous integral parameterization (section 5.2). Consider the integral parameterization of the input as defined before Theorem 5.8 by the map

$$E : (z_1, z_2, z_3) \to I(z_1, z_2, z_3) = (z_3, \tilde{\mathcal{P}}(z_1, z_2)).$$

We shall confine our attention to only those integer points in $B(a, n)$ that lie in the image of E, which is a three-dimensional integer lattice.

Let B be the region defined as in Theorem 5.9 by letting $\bar{\beta} = \log \bar{\mu} = an/2$; then the coordinates of all integer points in B have bitsizes at most an, which means $B \subseteq B(a, n)$. Let S be the set of surfaces $E^{-1}(H_1)$ and $E^{-1}(H_2)$. Their total degree δ is at most $2 \cdot 2^{n/d}$. Since $B \subseteq B(a, n)$, the partition of B formed by S has the separation property as defined in section 5.3. Choose a large enough so that $\bar{\beta} = \log \bar{\mu} = an/2$ is much larger than $\beta(n) = O(n)$ and d large enough so that $\log \rho = \Omega(n)$ is much larger than $\log \delta$, which is at most $n/d + \log 2$. Then it follows from Theorem 5.9 that this partition of B cannot have the separation property, a contradiction. □

Our technique cannot be used to prove this theorem for the permanent problem. It also cannot be used for proving the conjecture for all positive constants a. This is because all algebrogeometric results we used depend only on the low degree of the

surfaces that arise (actually the transversality results do not even depend on that). In particular, the same technique ends up proving Theorem 7.4 for any hypersurface $H \subseteq C^{m^2}$ of degree at most m (in place of $SL_m(C)$). This apparent strength of the technique is, in fact, its weakness, because of the following proposition.

PROPOSITION 7.5. *There exist hypersurfaces $H \subseteq C^{m^2}$, $m = 2^{n/d}$, of degree at most m for which the conjecture is false for $a < 1/(2d)$.*

Proof. Given an integer point $I \in B(a, n)$, let $\hat{I}$ denote its boolean encoding, which has length at most kan. Certainly there exists a (complicated) boolean formula of degree at most kan which evaluates to zero over $\hat{I}$ iff $I \in L(n)$. For any integer z of bitlength at most an, one can write down the Lagrange interpolation formula of degree at most 2^{2an} for each of its bits. Feeding such formulae into the preceding boolean formula, one gets a polynomial g which evaluates to zero on $I \in B(a, n)$ iff $I \in L(n)$. Its degree is at most $kan2^{2an} < 2^{n/d}$ if a is sufficiently smaller than $1/(2d)$. Let F be the trivial embedding of C^k in C^{m^2}, and let H be defined by the polynomial equation $g = 0$. □

This means if we wish to decrease the value of the constant a in Theorem 7.4 to something less than $1/(2d)$, as required in the conjecture, we must somehow use algebraic geometry of the *specific* hypersurface $SL_m(C)$ in the conjecture, or a similar one, in a deep way. What makes such hypersurfaces special is that they have a natural SL_m action. Such algebraic varieties have been investigated heavily in algebraic geometry and, more specifically, in geometric invariant theory [37] for over a century. One source of great difficulty in our context is that the natural SL_m action on such varieties need not carry over to their linear pullbacks. Therefore an important question here is, What is the algebraic geometry of linear pullbacks of such varieties? A good understanding of this, we feel, will greatly help in the P versus NC problem.

8. Conclusion. Our work shows that parametric complexity of a weighted optimization problem sets a good lower bound for its parallel complexity in the PRAM model without bit operations. In this way it may be possible to investigate parallel complexity of several other weighted optimization problems. This is especially important for problems that are neither known to be P-complete nor have fast parallel algorithms. A prime example is the minimum-weight perfect-matching problem. If the weights are in unary, it has fast parallel algorithms [24, 36]. In general, its parallel complexity is open. We conjecture that the parametric complexity of this problem is $2^{\Omega(n^\epsilon)}$ for some small enough positive ϵ. It would then follow from our general lower bound that it cannot be solved in our model in $o(N^{\epsilon'})$ time using $2^{o(N^{\epsilon'})}$ processors, where N is the input bitlength and ϵ' is a small enough positive constant. Several other problems may be investigated in this way, e.g., matroid intersection problems [28], matroid parity problems [28], construction of blocking flows [13], and problems in computational geometry.

Can one prove a good lower bound in our model for computing the permanent of an integer matrix? Valiant's result [50] leads one to expect that this problem should be even harder than the problems considered in this paper. And yet, paradoxically, it seems much harder to prove a good lower bound for the permanent. Csanky [11] shows that the determinant can be computed in our model in $O(\log^2 n)$ time using a polynomial number of processors. Can one show that it cannot be computed in our model in $O(\log n)$ time using a polynomial number of processors?

Most importantly, the role of algebrogeometric methods in computational complexity deserves to be studied further. Such methods have been useful in proving several combinatorial results; e.g., see [29, 33]. Can the same happen for a separation

question such as $P \neq NC$? Our work supports this possibility.

Acknowledgments. I wish to thank Allan Borodin, Steve Cook, Ajit Diwan, Charlie Rackoff, Donald Goldfarb, Laci Lovász, Katta Murty, Tushar Samant, L. V. Satyanarayana, and Milind Sohoni for illuminating discussions. I am also grateful to the referee for useful criticisms.

STACK AND QUEUE LAYOUTS OF DIRECTED ACYCLIC GRAPHS: PART I*

LENWOOD S. HEATH†, SRIRAM V. PEMMARAJU‡, AND ANN N. TRENK§

Abstract. Stack layouts and queue layouts of undirected graphs have been used to model problems in fault-tolerant computing and in parallel process scheduling. However, problems in parallel process scheduling are more accurately modeled by stack and queue layouts of *directed acyclic graphs* (dags). A *stack layout* of a dag is similar to a stack layout of an undirected graph, with the additional requirement that the nodes of the dag be in some topological order. A *queue layout* is defined in an analogous manner. The *stacknumber* (*queuenumber*) of a dag is the smallest number of stacks (queues) required for its stack layout (queue layout). In this paper, bounds are established on the stacknumber and queuenumber of two classes of dags: tree dags and unicyclic dags. In particular, any tree dag can be laid out in 1 stack and in at most 2 queues; and any unicyclic dag can be laid out in at most 2 stacks and in at most 2 queues. Forbidden subgraph characterizations of 1-queue tree dags and 1-queue cycle dags are also presented. Part II of this paper presents algorithmic results—in particular, linear time algorithms for recognizing 1-stack dags and 1-queue dags and proof of NP-completeness for the problem of recognizing a 4-queue dag and the problem of recognizing a 9-stack dag.

Key words. stack layout, queue layout, book embedding, graph embedding, directed acyclic graphs, dags, forbidden subgraph

Stack layouts and queue layouts of undirected graphs have appeared in a variety of contexts such as VLSI design, fault-tolerant processing, parallel process scheduling, sorting networks, and parallel matrix computations [3, 4, 7, 8]. Bernhart and Kainen [1] introduce the concept of stack layouts under the name *book embeddings*. Motivated by problems in fault-tolerant processing, Chung, Leighton, and Rosenberg [3] examine stack layouts of undirected graphs and construct optimal stack layouts for a variety of classes of graphs. Motivated by problems in parallel process scheduling, Heath, Leighton, and Rosenberg [4, 8] develop the notion of queue layouts and provide optimal queue layouts for many classes of undirected graphs. However, problems in parallel process scheduling are more accurately modeled by stack and queue layouts of directed acyclic graphs (dags). Bhatt et al. [2] provide an example of a control-memory tradeoff in parallel process scheduling, obtained by examining queue layouts of binary trees. Stack and queue layouts of dags are also closely related to stack and queue layouts of partially ordered sets (posets). Nowakowski and Parker [9] and Syslo [10] initiate the study of stack layouts of posets; Heath and Pemmaraju [6] extend the study to queue layouts of posets.

In this paper, we define stack and queue layouts of dags and develop combinatorial results for stack and queue layouts of some special classes of dags. Each of these classes arises from some property of the undirected graph underlying a dag. In particular, we consider the property of the underlying undirected graph being a path, a cycle, a tree, or a unicyclic graph. We also give forbidden subgraph characterizations of 1-queue tree dags and 1-queue cycle dags. In the companion paper [5], we develop algorithmic results for stack and queue layouts of dags. In particular, we show that 1-stack and 1-queue dags can be recognized in linear time, while the problems of recognizing 9-stack dags and 4-queue dags are both NP-complete.

The organization of this paper is as follows. Section 1 contains definitions, notations, and an initial discussion of 1-queue dags. In section 2, we examine stack layouts of tree dags and unicyclic dags. In section 3, we examine the queue layouts of tree dags and unicyclic dags. In section 4, we present a forbidden graph characterization of 1-queue tree dags and 1-queue cycle dags. Section 5 contains concluding remarks and a conjecture.

1. Preliminaries. Following a common distinction, we use the terminology *edge* for undirected graphs, and the terminology *arc* for directed graphs; we use the terminology *node* for both undirected and directed graphs. The definitions relevant to stack and queue layouts of undirected graphs are found in Heath and Rosenberg [8] and are reproduced here. Throughout these definitions, the concept of a total order σ on a set V of nodes is central; the notation $u <_\sigma v$, where $u, v \in V$, is used consistently to emphasize the particular total order currently under consideration.

Let $G = (V, E)$ be an undirected graph without multiple edges or loops. A *k-stack layout* of G consists of a total order σ on V along with an assignment of each edge in E to one of k stacks, $s_1, s_2, \ldots, s_k$. Each stack s_j operates as follows. The nodes of V are scanned in left-to-right (ascending) order according to σ. When a node v is encountered, any edges assigned to s_j that have v as their right endpoint must be at the top of the stack and are popped. Any edges that are assigned to s_j and have left endpoint v are pushed onto s_j in descending order (according to σ) of their right endpoints. The *stacknumber* $SN(G)$ of G is the smallest k such that G has a *k-stack layout*. G is said to be a *k-stack* graph if $SN(G) = k$.

A *k-queue layout* of G consists of a total order σ on V along with an assignment of each edge in E to one of k queues, $q_1, q_2, \ldots, q_k$. Each queue q_j operates as follows. The nodes of V are scanned in left-to-right (ascending) order according to σ. When a node v is encountered, any edges assigned to q_j that have v as their right endpoint must be at the front of the queue and are dequeued. Any edges that are assigned to q_j and have left endpoint v are enqueued into q_j in ascending order (according to σ) of their right endpoints. The *queuenumber* $QN(G)$ of G is the smallest k such that G has a *k-queue layout*. G is said to be a *k-queue* graph if $QN(G) = k$.

We now consider directed graphs. Let $G = (V, E)$ be an undirected graph, and let $\vec{G} = (V, \vec{E})$[1] be any dag obtained from G by directing the edges in G. More precisely, each edge $\{u, v\} \in E$ is replaced by either arc (u, v) or by arc (v, u) in $\vec{E}$, and the resulting directed graph $\vec{G} = (V, \vec{E})$ is a dag, i.e., there is no induced directed cycle in $\vec{G}$. G is the *covering graph* of the dag $\vec{G}$; the covering graph of an arbitrary dag is obtained by removing the direction from all the arcs. A dag is *connected* if its covering graph is connected. If $(u, v) \in \vec{E}$, then u is an *in-neighbor* of v and v is an

[1] The $\vec{}$ notation always distinguishes a directed graph from an undirected graph or a set of arcs from a set of edges.

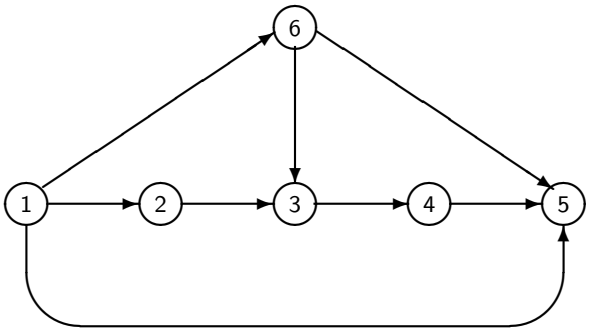

FIG. 1.1. *A* 2*-stack,* 2*-queue dag.*

out-neighbor of u. The *indegree* of v is its number of in-neighbors, while the *outdegree* of v is its number of out-neighbors. Two arcs, (u_1, v_1) and (u_2, v_2), are *independent* if the four nodes u_1, u_2, v_1, and v_2 are distinct. A *topological order* of $\vec{G} = (V, \vec{E})$ is a total order σ on V such that $(u, v) \in \vec{E}$ implies $u <_\sigma v$.

We are particularly interested in some special classes of dags. A *path dag* $\vec{G} = (V, \vec{E})$ is a dag whose covering graph $G = (V, E)$ is a path. Similarly, a *cycle dag* is a dag whose covering graph is a cycle, a *tree dag* is a dag whose covering graph is a tree, and a *unicyclic dag* is a dag whose covering graph contains a single cycle. A tree dag is *rooted* by selecting an arbitrary node to be its *root.* Note that a rooted tree dag does not correspond to the normal notion of a rooted tree, in which all arcs are uniformly directed away from (or toward) the root. Still, we wish the notions of parent and subtree to carry over to rooted tree dags. If a tree dag $\vec{T} = (V, \vec{E})$ is rooted at a node r, then every node v other than r has a *parent* that is its parent in the covering graph $T = (V, E)$ considered as a tree rooted at r. Note that the parent of a node may be either an in-neighbor or an out-neighbor. In a rooted tree dag $\vec{T} = (V, \vec{E})$, the *subtree* $\vec{T}_v$ rooted at v is the subdag of $\vec{T}$ corresponding to the subtree of T rooted at v.

The definition of a stack or a queue layout is now extended to dags. The key distinction is that such a layout is required to follow a topological order. A *k-stack (k-queue) layout of a dag* $\vec{G} = (V, \vec{E})$ is a k-stack (k-queue) layout of the covering graph G such that the total order used in the layout is a topological order of $\vec{G}$. As before, the *stacknumber* $SN(\vec{G})$ is the smallest k such that $\vec{G}$ has a k-stack layout, and the *queuenumber* $QN(\vec{G})$ is the smallest k such that $\vec{G}$ has a k-queue layout. If $SN(\vec{G}) = k$, then $\vec{G}$ is called a *k-stack dag*, and if $QN(\vec{G}) = k$, then $\vec{G}$ is called a *k-queue dag.* As an example, Figure 1.1 shows a dag, Figure 1.2 shows a 2-stack layout, and Figure 1.3 shows a 2-queue layout. In each of the layouts shown in Figures 1.2 and 1.3, the arcs above the line of nodes are assigned to one stack or queue, while the arcs below the line of nodes are assigned to the other stack or queue. The reader may check that the dag in Figure 1.1 has neither a 1-stack nor a 1-queue layout.

Suppose that $\vec{G} = (V, \vec{E})$ is a dag and that σ is a topological order of $\vec{G}$. Let $(u_1, v_1), (u_2, v_2) \in \vec{E}$ be distinct arcs with $u_1 <_\sigma u_2$. If $v_1 <_\sigma v_2$, then (u_1, v_1) and (u_2, v_2) *cross* in σ. If $v_2 <_\sigma v_1$, then (u_1, v_1) and (u_2, v_2) *nest* in σ. The definition of a stack layout of a dag requires that any two arcs that cross must be in different stacks; on the other hand, any two arcs that do not cross may be placed in the same stack. In Figure 1.2, arcs $(2, 3)$ and $(6, 5)$ cross; hence they must be in different stacks.

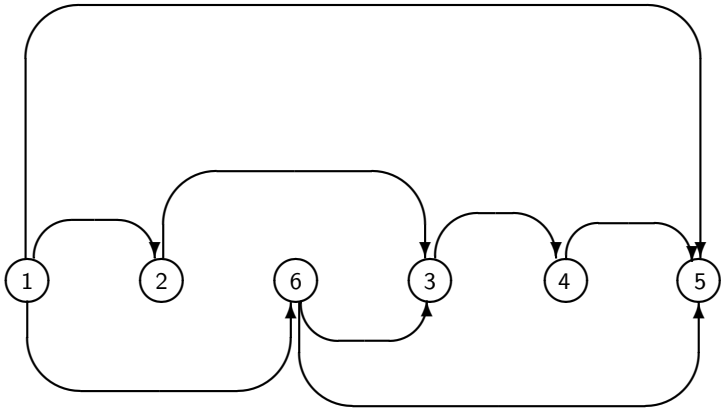

FIG. 1.2. *A 2-stack layout of the dag in Figure* 1.1.

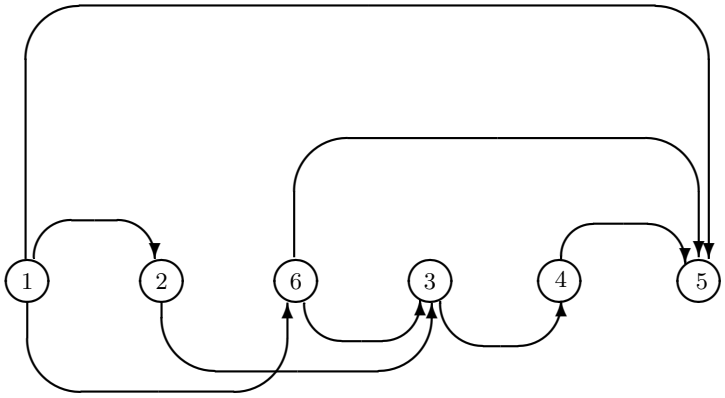

FIG. 1.3. *A 2-queue layout of the dag in Figure* 1.1.

Analogously, the definition of a queue layout of a dag requires that any two arcs that nest must be in different queues; on the other hand, any two arcs that do not nest may be placed in the same queue. In Figure 1.3, arcs $(1, 5)$ and $(2, 3)$ nest; hence they must be in different queues.

Heath and Rosenberg [8] characterize 1-queue undirected graphs as those graphs that have an arched leveled-planar embedding. In a similar manner, we characterize 1-queue dags as those that have a *directed arched leveled-planar embedding.* The definition of such an embedding is developed in the next five paragraphs.

Let $\vec{G} = (V, \vec{E})$ be a dag. A *leveling* of $\vec{G}$ is a function $lev : V \to \mathbf{Z}$ mapping the nodes of $\vec{G}$ to integers such that $lev(v) = lev(u) + 1$ for all $(u, v) \in \vec{E}$. If $lev(v) = j$, then v is a *level-j node.* $\vec{G}$ is a *leveled dag* if it has a leveling. Note that a connected leveled dag has a unique leveling up to an additive constant.

Let ℓ_j denote the vertical line in the Cartesian plane $\ell_j = \{(j, y) \mid y \in \mathbf{R}\}$, where $\mathbf{R}$ is the set of reals. Suppose that there is a partition of the set of nodes V into sets $V_p, V_{p+1}, \ldots, V_q$ for some integers p and q such that:

1. Each arc in $\vec{E}$ is from a node in V_j to a node in V_{j+1} for some integer j, $p \leq j < q$.

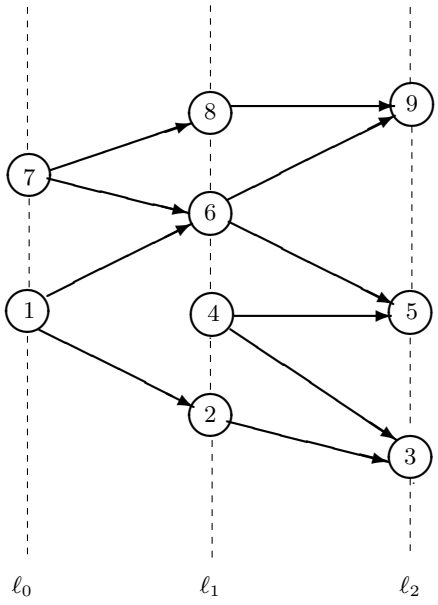

FIG. 1.4. *A leveled-planar dag.*

2. $\vec{G}$ has a planar embedding in which all nodes in V_j are placed on ℓ_j and each arc in $\vec{E}$ is drawn as a straight line segment between lines ℓ_j and ℓ_{j+1} for some integer j, $p \le j < q$; in particular, the drawings of two independent arcs do not intersect in the plane.

Then this planar embedding is called a *directed leveled-planar embedding* of $\vec{G}$. Figure 1.4 shows a directed leveled-planar embedding of a dag. A dag is called a *leveled-planar dag* if it has a directed leveled-planar embedding.

Now suppose that $\vec{G}$ is a leveled-planar dag and that $\mathcal{E}$ is a directed leveled-planar embedding of $\vec{G}$. The function $lev : V \to \mathbf{Z}$, where $lev(u) = j$ if $u \in V_j$, is the *leveling of $\vec{G}$ induced by the embedding $\mathcal{E}$*. The leveling induced by the directed leveled-planar embedding shown in Figure 1.4 is $lev(1) = lev(7) = 0$, $lev(2) = lev(4) = lev(6) = lev(8) = 1$, and $lev(3) = lev(5) = lev(9) = 2$. Thus every leveled-planar dag is a leveled dag. It is easy to see that the converse is not true (e.g., consider a 4-cycle with arcs alternating in direction).

A directed leveled-planar embedding of $\vec{G}$ induces a natural topological order of $\vec{G}$ called the *leveled-planar order,* obtained by scanning the lines $\ell_p, \ell_{p+1}, \ldots, \ell_q$, in that order, each from bottom to top. The leveled-planar order induced by the directed leveled-planar embedding of Figure 1.4 is $1, 7, 2, 4, 6, 8, 3, 5, 9$.

A directed arched leveled-planar embedding is obtained from a directed leveled-planar embedding as follows. Let σ be the leveled-planar order. For each j, $p \le j \le q$, let b_j be the *bottom node* on line ℓ_j, and let t_j be the *top node*. Let s_j be the bottommost node on line ℓ_j that is the in-neighbor of some node on line ℓ_{j+1}; if there are no arcs from V_j to V_{j+1}, then let $s_j = t_j$. For an integer j, $p \le j \le q$, a *level-j arch* is an arc from a node $x \in V_j$, where $b_j \le_\sigma x \le_\sigma s_j$ and $x <_\sigma t_j$, to node t_j. A directed leveled-planar dag augmented by any number of arches can be drawn in the plane by drawing the arches around ℓ_p; such an embedding is called a *directed arched leveled-planar embedding*. A dag that has a directed arched leveled-planar embedding

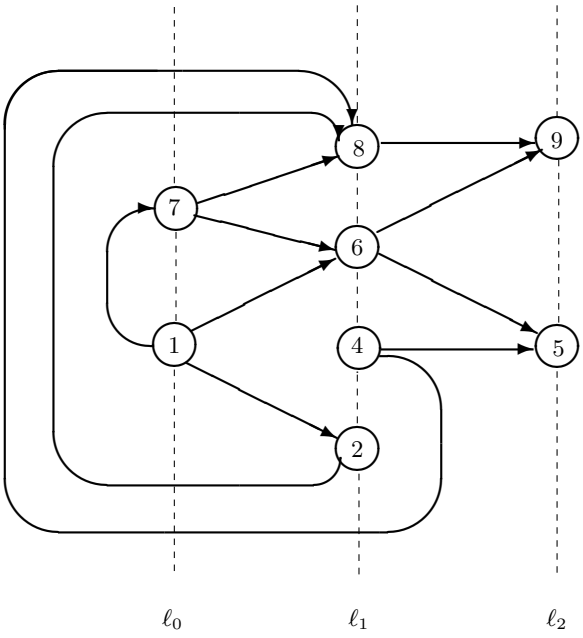

FIG. 1.5. *An arched leveled-planar dag.*

is called an *arched leveled-planar dag*. The arcs in the embedding that are not arches are called *level arcs*. Figure 1.5 shows a directed arched leveled-planar embedding of a dag.

The figure is the same as Figure 1.4 except that node 3 is deleted and arches $(1, 7)$, $(2, 8)$, and $(4, 8)$ are added.

We now state the characterization of 1-queue dags.

PROPOSITION 1.1. *Suppose $\vec{G}$ is a dag. Then $QN(\vec{G}) = 1$ if and only if $\vec{G}$ is an arched leveled-planar dag.*

The proof of this characterization is very similar to the proof that Heath and Rosenberg [8] use in establishing their characterization of 1-queue undirected graphs as exactly those graphs that have an arched leveled-planar embedding (see Theorem 3.2 in [8]).

2. Stack layouts of dags. In this section, we investigate stack layouts of tree dags and unicyclic dags. We need one definition. A node $v \in V$ is *exposed* in a layout with total order σ if there is no arc (x, y) in the layout with $x <_\sigma v <_\sigma y$.

We begin with the following theorem on the stacknumber of tree dags.

THEOREM 2.1. *The stacknumber of any tree dag with at least 2 nodes is 1.*

Proof. Let $\vec{T} = (V, \vec{E})$ be an arbitrary tree dag with $N \geq 1$ nodes. Root $\vec{T}$ at an arbitrary node r. We prove by induction on N that $\vec{T}$ can be laid out in at most 1 stack with the root r *exposed*.

Base case: When $N = 1$, the claim is trivially true.

Induction case: Suppose that $N \geq 2$ and that every tree dag with fewer than N nodes can be laid out in at most 1 stack with its root exposed. Let $u_1, u_2, \ldots, u_s$ be the in-neighbors of r, and let $v_1, v_2, \ldots, v_m$ be the out-neighbors of r. The induction hypothesis implies that each of the tree dags $\vec{T}_{u_p}$, where $1 \leq p \leq s$, and $\vec{T}_{v_q}$, where $1 \leq q \leq m$, can be laid out in one stack with their roots $u_1, u_2, \ldots, u_s, v_1, v_2, \ldots, v_m$

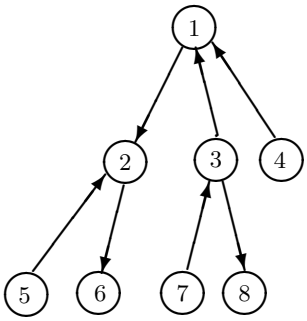

FIG. 2.1. *A tree dag.*

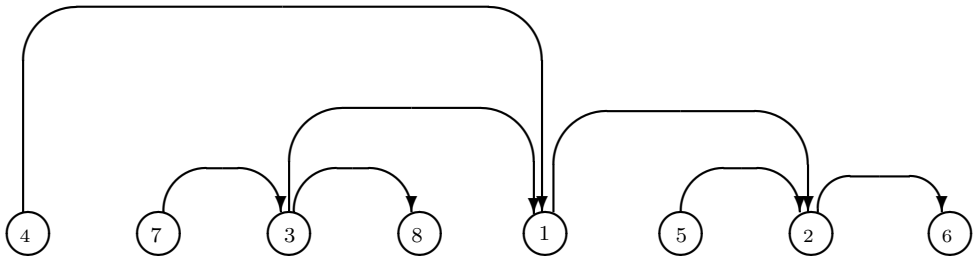

FIG. 2.2. *A 1-stack layout of the tree dag shown in the Figure* 2.1.

exposed. Concatenate these layouts, together with r, in this order:

$$\vec{T}_{u_1}, \vec{T}_{u_2}, \ldots, \vec{T}_{u_s}, r, \vec{T}_{v_1}, \vec{T}_{v_2}, \ldots, \vec{T}_{v_m}.$$

Add the arcs from $u_1, u_2, \ldots, u_s$ to r and from r to $v_1, v_2, \ldots, v_m$. It is clear that the nodes have been laid out in topological order, no two arcs in $\vec{T}$ cross, and r is exposed in the layout so obtained. A 1-stack layout is obtained.

By induction, every tree dag can be laid out in at most 1 stack. Since a tree dag with at least 2 nodes (at least 1 arc) requires at least 1 stack, the theorem follows. □

As an example, Figure 2.1 shows a tree dag, while Figure 2.2 shows the 1-stack layout constructed in the proof of the theorem, where node 1 is the root.

We now turn our attention to unicyclic dags. Not all unicyclic dags can be laid out in 1 stack. Figure 2.3 shows the smallest example of a unicyclic dag whose stacknumber is not 1.

In the remainder of this section, we show that any unicyclic dag can be laid out in 2 stacks and provide a simple characterization of 1-stack unicyclic dags. We first investigate stack layouts of cycle dags. A *directed Hamiltonian path* in a dag $\vec{G} = (V, \vec{E})$ is a directed path in $\vec{G}$ that contains every node in V. The following lemma shows that any cycle dag can be laid out in 2 stacks and that for each n there is exactly one cycle dag on n nodes with stacknumber 1.

LEMMA 2.2. *Let $\vec{C} = (V, \vec{E})$ be a cycle dag. If $\vec{C}$ contains a directed Hamiltonian path, then $SN(\vec{C}) = 1$; otherwise, $SN(\vec{C}) = 2$.*

Proof. First suppose that $\vec{C}$ contains a directed Hamiltonian path. This Hamiltonian path defines a unique topological order of $\vec{C}$, and no two arcs of $\vec{C}$ cross when the nodes of $\vec{C}$ are laid out according to this order. Hence, $SN(\vec{C}) = 1$, as desired.

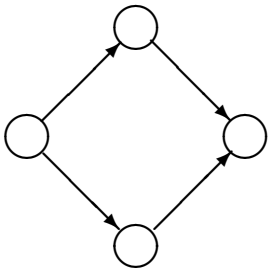

FIG. 2.3. *A unicyclic dag that cannot be laid out in* 1 *stack.*

Now suppose that $\vec{C}$ does not contain a directed Hamiltonian path. We first show that $SN(\vec{C}) \geq 2$ in this case. To obtain a contradiction, suppose that $SN(\vec{C}) = 1$. Let σ be a topological order that yields a 1-stack layout of $\vec{C}$. For any pair of nodes u and v in V such that $u <_\sigma v$, say that u and v are *consecutive nodes* in σ if there exists no w such that $u <_\sigma w <_\sigma v$. Since $\vec{C}$ has no directed Hamiltonian path, there exists a pair of nodes u and v that are consecutive nodes in σ satisfying the properties that $u <_\sigma v$ and $(u, v) \notin \vec{E}$.

Let the cycle $C = (V, E)$ be the covering graph of $\vec{C}$. Of course, the order σ yields a 1-stack layout of C. Let $X = \{w \in V \mid w \leq_\sigma u\}$ be the set of nodes that are no greater than u with respect to σ. Similarly, let $Y = \{w \in V \mid v \leq_\sigma w\}$ be the set of nodes that are no less than v with respect to σ. Note that $V = X \cup Y$. Let $x \in X$ be the greatest node with respect to σ that is adjacent to a node in Y. Of all the nodes in Y that are adjacent to x, let y be the least with respect to σ. If $x = u$ and $y = v$, then $(u, v) = (x, y) \in E$, contradicting the choice of u and v. Hence, either $x <_\sigma u$ or $v <_\sigma y$ (or both). We consider only the case $x <_\sigma u$, the other case being symmetric.

Let $Z = \{w \mid x <_\sigma w \leq_\sigma u\}$ consist of the nodes between x and u with respect to σ together with u. Because of our choice of the edge (x, y) in C, no node in Z has a neighbor in $W = \{w \mid v \leq_\sigma w \leq_\sigma y\}$. Because no two edges of C cross in σ and because (x, y) is an edge in E, any neighbor in C of a node in Z is in $Z \cup \{x\}$. Thus, every path from a node in Z to a node not in Z passes through x. Since $u \in Z$ and $v \notin Z \cup \{x\}$, every path between these two nodes passes through x, implying that x is a cutpoint of C. This is a contradiction because a cycle cannot have a cutpoint. Hence, the assumption that $SN(\vec{C}) = 1$ must be false. It follows that $SN(\vec{C}) \geq 2$.

To show that $SN(\vec{C}) = 2$, we construct a 2-stack layout of any cycle dag $\vec{C}$ as follows. Let u be a node in $\vec{C}$ with indegree 0, and let v and w be the two out-neighbors of u. Delete the node u from $\vec{C}$ and let $\vec{T}$ be the resulting tree dag. By Theorem 2.1, there is a topological order σ of $\vec{T}$ that yields a 1-stack layout of $\vec{T}$. To obtain a 2-stack layout of $\vec{C}$ from this, extend σ to satisfy $u <_\sigma v$, for all nodes v of $\vec{T}$, and assign the two arcs incident on u to a second stack. □

We now establish the stacknumber of unicyclic dags by showing that a unicyclic dag requires as many stacks as the cycle dag it contains.

THEOREM 2.3. *Let $\vec{U} = (V, \vec{E})$ be a unicyclic dag, and let $\vec{C} = (V_C, \vec{E}_C)$ be the unique cycle dag that is a subgraph of $\vec{U}$. Then $SN(\vec{U}) = SN(\vec{C})$.*

Proof. Clearly, $SN(\vec{U}) \geq SN(\vec{C})$. Let $SN(\vec{C}) = k$. By Lemma 2.2, either $k = 1$ or $k = 2$. Without loss of generality, we may assume that $v_1, v_2, \ldots, v_n$ is a topological order of $\vec{C}$ that yields a k-stack layout. By deleting all the arcs in $\vec{C}$ from $\vec{U}$ we obtain n connected components, each a tree dag. Let $\vec{T}_i$ denote the tree dag containing v_i.

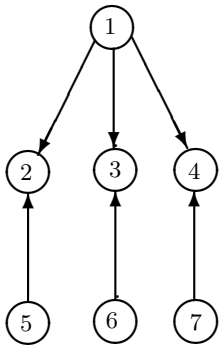

FIG. 3.1. *A tree dag that cannot be laid out in* 1 *queue.*

By the proof of Theorem 2.1, each tree dag $\vec{T}_i$ has a 1-stack layout in which node v_i is exposed. To obtain a 1-stack layout of $\vec{U}$, concatenate the 1-stack layouts of the k tree dags in the order $\vec{T}_1, \vec{T}_2, \ldots, \vec{T}_n$. Since the tree dags are laid out one after the other, no two arcs belonging to distinct tree dags cross. Since each node v_i is exposed, the arcs in the tree dags do not cross the arcs in $\vec{C}$. Hence the arcs in $\vec{T}_i$, for all i, can be assigned to one of the k stacks being used for the arcs in $\vec{C}$. We conclude that $SN(\vec{U}) = SN(\vec{C})$, as desired. □

3. Queue layouts of dags. In this section, we determine the queuenumber of tree dags and of unicyclic dags. We start with tree dags. It is easily verified that the tree dag shown in Figure 3.1 does not have a directed arched leveled-planar embedding and is therefore not a 1-queue dag. However, as shown in the following theorem, 2 queues suffice for any tree dag.

THEOREM 3.1. *Every tree dag has a* 2*-queue layout.*

Proof. Let $\vec{T} = (V, \vec{E})$ be a tree dag with covering graph $T = (V, E)$. Root $\vec{T}$ at an arbitrary node r. Partition $\vec{E}$ into sets $\vec{E}_b$ and $\vec{E}_f$, where

$$\vec{E}_f = \{(u, v) \in \vec{E} \mid u \text{ is the parent of } v \text{ in } \vec{T}\},$$
$$\vec{E}_b = \{(v, u) \in \vec{E} \mid u \text{ is the parent of } v \text{ in } \vec{T}\}.$$

Thus $\vec{E}_f$ contains the *forward arcs*, arcs directed away from r, while $\vec{E}_b$ contains the *backward arcs*, arcs directed towards r. For example, if the root of the tree dag in Figure 3.1 is 1, then $\vec{E}_f = \{(1,2), (1,3), (1,4)\}$ and $\vec{E}_b = \{(5,2), (6,3), (7,4)\}$. Let $\vec{G}_f = (V, \vec{E}_f)$ and $\vec{G}_b = (V, \vec{E}_b)$ be the subdags of $\vec{T}$ induced by the arc sets $\vec{E}_f$ and $\vec{E}_b$, respectively. We construct a 2-queue layout of $\vec{T}$ by placing the nodes of $\vec{T}$ in the Cartesian plane such that directed leveled-planar embeddings of the subgraphs $\vec{G}_f$ and $\vec{G}_b$ are induced. Let *lev* be the unique leveling of $\vec{T}$ such that $lev(r) = 0$. Place each node v in the Cartesian plane on the vertical line ℓ_j if and only if $lev(v) = j$. Let γ be some breadth-first order on V obtained by doing a breadth-first search of T starting at r. Two level-j nodes u and v are placed on ℓ_j such that node u is placed below node v when $u <_\gamma v$, that is, when u is reached in the breadth-first search before v.

We now verify that this placement of the nodes in the plane induces a directed leveled-planar embedding of $\vec{G}_f$. Clearly, each arc in $\vec{E}_f$ can be drawn as a line segment whose endpoints lie on vertical lines ℓ_j and ℓ_{j+1} for some integer j. The fact

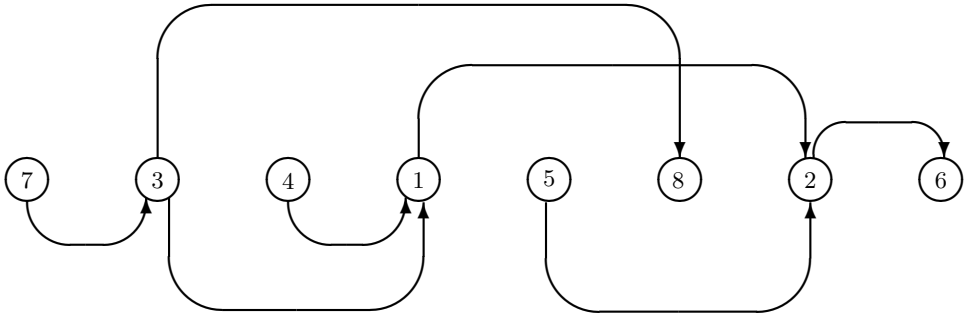

FIG. 3.2. *A 2-queue layout of the tree dag in Figure 2.1.*

that no two arcs in $\vec{E}_f$ intersect can be verified as follows. Consider an independent pair of arcs, (u_1, v_1) and (u_2, v_2) in $\vec{E}_f$, where $lev(u_1) \leq lev(u_2)$. If $lev(u_1) < lev(u_2)$, then $lev(v_1) < lev(v_2)$, so (u_1, v_1) and (u_2, v_2) do not intersect. Now suppose that $lev(u_1) = lev(u_2)$. Without loss of generality, we may assume that $u_1 <_\gamma u_2$. Since (u_1, v_1) is a forward arc and u_1 is the parent of v_1, we have $u_1 <_\gamma v_1$. Since (u_2, v_2) is a forward arc and u_2 is the parent of v_2, we have $u_2 <_\gamma v_2$. By the properties of breadth-first search, we have $v_1 <_\gamma v_2$; hence the arcs (u_1, v_1) and (u_2, v_2) do not intersect. A similar argument shows that this placement of nodes also induces a directed leveled-planar embedding of $\vec{G}_b$. Thus the leveled-planar order of V induced by the leveled-planar embedding of $\vec{G}_f$ yields a 2-queue layout of $\vec{T}$ in which arcs in $\vec{E}_f$ are assigned to one queue and arcs in $\vec{E}_b$ are assigned to the other queue. □

Figure 3.2 gives a 2-queue layout of the tree dag shown in Figure 2.1. This 2-queue layout is constructed as described in the proof of Theorem 3.1, with node 1 being the root.

Next we show that the construction of a 2-queue layout for a tree dag described in Theorem 3.1 actually yields a 1-queue layout for a path dag.

COROLLARY 3.2. *Every path dag has a 1-queue layout.*

Proof. Let $\vec{P} = (V, \vec{E})$ be a path dag with covering graph $P = (V, E)$. Let r be one of the endpoints of P. Consider the placement of the nodes in $\vec{P}$ in the plane as described in the proof of Theorem 3.1. Suppose that the arcs in $\vec{E}$ have been drawn as straight line segments. We have already verified that an independent pair of arcs $(u_1, v_1), (u_2, v_2) \in \vec{E}$ do not intersect if $lev(u_1) \neq lev(u_2)$ or if both arcs are forward arcs or both arcs are backward arcs. Assume that $(u_1, v_1) \in \vec{E}_f$, $(u_2, v_2) \in \vec{E}_b$, and $lev(u_1) = lev(u_2)$. Since $\vec{P}$ is a path dag, u_1 is visited before u_2 in the breadth-first search of P starting from an endpoint r if and only if v_1 is visited before v_2. This implies that the arcs (u_1, v_1) and (u_2, v_2) do not intersect, and we have a directed leveled-planar embedding of $\vec{P}$. We may conclude that $\vec{P}$ has a 1-queue layout, as desired. □

We postpone the problem of characterizing 1-queue tree dags (see section 4.1).

For now we turn our attention to cycle dags. Not all cycle dags can be laid out in 1 queue. As an example, Figure 3.3 shows a smallest cycle dag whose queuenumber is 2. However, the following argument shows that every cycle dag has a 2-queue layout. Let $\vec{C} = (V, \vec{E})$ be a cycle dag, and let u be a node with indegree 0. By Corollary 3.2, the path dag $\vec{C} - u$ has a 1-queue layout. Place the node u on the left of the 1-queue layout of $\vec{C} - u$ and assign the two arcs incident on u to a second queue. This gives

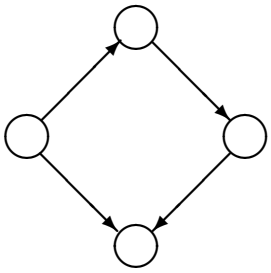

FIG. 3.3. *A smallest cycle dag whose queuenumber is* 2.

a 2-queue layout of $\vec{C}$. We obtain the following theorem.

THEOREM 3.3. *Every cycle dag has a* 2*-queue layout.*

As in the case of tree dags, we postpone characterizing 1-queue cycle dags (see section 4.2).

The observation that any cycle dag can be laid out in 2 queues motivates the question of whether any unicyclic dag can be laid out in 2 queues. A simple argument shows that 3 queues suffice. Let $\vec{U} = (V, \vec{E})$ be a unicyclic dag, and let $\vec{C}$ be the cycle dag that is the subgraph of $\vec{U}$. Let u be a node in $\vec{C}$ with indegree 0 (in $\vec{C}$). Delete the two outgoing arcs in $\vec{C}$ incident on u from $\vec{U}$ to obtain two tree dags $\vec{T}_1$ and $\vec{T}_2$, where $\vec{T}_1$ contains u. A 3-queue layout of $\vec{U}$ is obtained by placing a 2-queue layout of $\vec{T}_1$ to the left of a 2-queue layout of $\vec{T}_2$ and then assigning the two arcs in $\vec{C}$, incident on u, to a third queue. The following theorem gives a more subtle construction of a 2-queue layout of $\vec{U}$.

THEOREM 3.4. *Every unicyclic dag has a* 2*-queue layout.*

Proof. Let $\vec{U} = (V, \vec{E})$ be a unicyclic dag, and let $\vec{C} = (V_C, \vec{E}_C)$ be the unique cycle dag in $\vec{U}$. Without loss of generality, we may assume that $\vec{U}$ is connected. We start with the selection of a particular arc, call it the *closing arc,* to remove from the cycle dag $\vec{C}$. Let $u \in V_C$ be any node of indegree 0 (in $\vec{C}$), and let $v, w \in V_C$ be the out-neighbors of u in $\vec{C}$. Let $\vec{C} - u$ be the path dag obtained by removing u from the cycle dag. Choose a leveling *lev* of $\vec{C} - u$. Without loss of generality, we may assume that $1 = lev(v) \leq lev(w)$. Let $M = lev(w)$. Select (u, w) to be the closing arc. Let $\vec{P} = (V_C, \vec{E}_C - \{(u, w)\}) = (V_C, \vec{E_P})$ be the path dag obtained by removing the closing arc from the cycle dag; let $P = p_1, p_2, \ldots, p_k$ be its covering path, where $p_1 = u$, $p_2 = v$, and $p_k = w$. The leveling *lev* of $\vec{C}$ can be extended to $\vec{P}$ by setting $lev(u) = 0$. Since the minimum value of *lev* occurs at some node of in-degree 0 on $\vec{C}$, we may assume that $0 = lev(p_1) = \min\{lev(p_i) \mid 1 \leq i \leq k\}$. Let $\vec{T} = (V, \vec{E} - \{(p_1, p_k)\})$ be the tree dag obtained by removing the closing arc from the unicyclic dag. The leveling *lev* extends to a leveling of $\vec{T}$. Root $\vec{T}$ at p_1. Take the definitions of forward and backward arcs from the proof of Theorem 3.1; forward arcs are directed away from p_1, and backward arcs are directed toward p_1. Furthermore, partition $\vec{E} - \vec{E}_C$, the set of noncycle arcs, into the set $\vec{E_f}$ of forward arcs and the set $\vec{E_b}$ of backward arcs.

Our task is to construct a topological order σ for $\vec{U}$ while assigning its arcs to one of 2 queues, q_1 and q_2. The construction places each node x on one of the vertical lines ℓ_j, denoted both by $line(x) = j$ and by $\ell(x) = \ell_j$. The order σ is derived from this placement by exactly the same scan that finds the leveled-planar order from a directed leveled-planar embedding, that is, by scanning the lines in the order $\ldots, \ell_j, \ell_{j+1}, \ldots$,

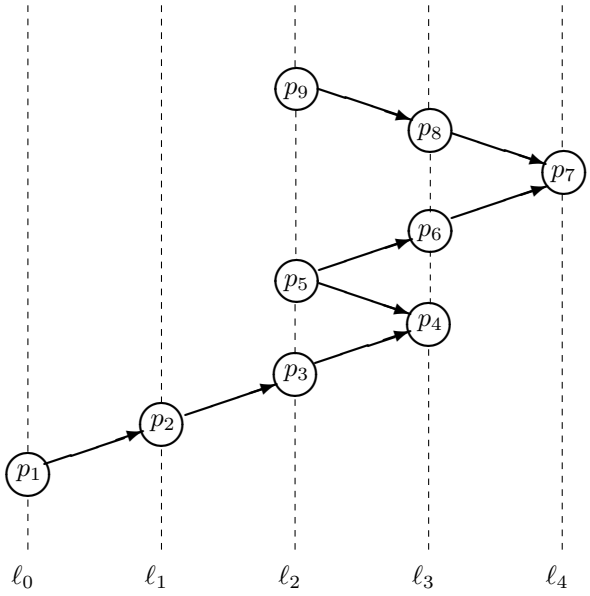

FIG. 3.4. *A leveled-planar layout of the path dag* $\vec{P}$.

each from bottom to top.

The initial phase of the construction places the nodes in $\vec{P}$ as in the proof of Corollary 3.2. See Figure 3.4 for an example. The arcs in $\vec{E_P}$ are assigned to queue q_1. The closing arc is assigned to queue q_2. A 2-queue layout of $\vec{C}$ results. Also, $line(p_i) = lev(p_i)$, for all $p_i \in V_C$. If $(p_i, p_{i+1}) \in \vec{E_P}$ is a forward arc, then define $next(p_i) \in V_C$ to be p_c, where c is smallest such that $i+2 \leq c \leq k$ and $lev(p_c) = lev(p_i)$; note that (p_c, p_{c-1}) must be a backward arc. If there is no such c, let $next(p_i)$ be undefined. In Figure 3.4, $p_9 = next(p_5)$, while $next(p_2)$ is undefined. Because we chose p_1 to have minimum level among nodes in $\vec{P}$, for any backward arc (p_c, p_{c-1}), there is some forward arc (p_i, p_{i+1}) such that $p_c = next(p_i)$. One may verify this assertion for the three backward arcs in Figure 3.4. The construction of Corollary 3.2 places $next(p_i)$ immediately above p_i on $\ell(p_i)$. By the definition of $next(p_i)$, the path from p_i to $next(p_i)$ is to the right of $\ell(p_i)$. Since every arc in that path is placed in queue q_1 and all arcs in $\vec{E_f}$ are to be assigned to queue q_1, there is an impediment to having an arbitrary tree of forward arcs grow from a node placed on line $\ell(p_i)$ between p_i and $next(p_i)$. We say that a node placed between p_i and $next(p_i)$ is in a *forbidden position.* In Figure 3.4, a node placed between p_3 and $p_5 = next(p_3)$ on ℓ_2 is in a forbidden position, while a node placed between p_4 and p_6 on ℓ_3 is not.

The second and final phase of the construction is an inductive extension of the 2-queue layout of $\vec{C}$ to a 2-queue layout of $\vec{U}$, with the addition of one node and one arc at each inductive step. The induction hypothesis is that at each step a 2-queue layout results satisfying these properties:

1. Each arc in $\vec{E_f}$ is assigned to queue q_1.
2. Each arc in $\vec{E_b}$ is assigned to queue q_2.
3. If $(x, y) \in \vec{E_b}$, then $line(x) \leq 0$ or $M \leq line(x)$.
4. No node is in a forbidden position.

Note that properties 1 and 2 imply these additional properties:

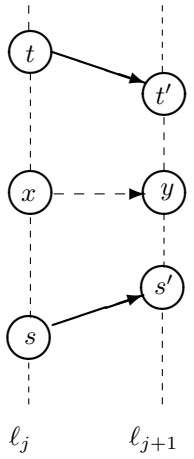

FIG. 3.5. *Illustration of the definitions of s, s', t, and t' for Case* 1.

5. If $x \in V$ and there are distinct arcs (y, x) and (z, x) assigned to queue q_1, then x is some p_i, where $2 \leq i \leq k-1$ and $\{y, z\} = \{p_{i-1}, p_{i+1}\}$. In particular, there exists no $x \in V - V_C$ with two in-neighbors y and z such that (y, x) and (z, x) are q_1 arcs.

6. There exists no $x \in V$ with two out-neighbors y and z such that (x, y) and (x, z) are q_2 arcs.

For the base case, take the construction of the 1-queue layout of $\vec{C}$. This 2-queue layout satisfies the induction properties. At each subsequent step, one remaining arc (x, y) is added; an arc can be added as soon as one of its nodes is already placed and the other is not yet placed. There are three cases for the addition of (x, y). In each case, we specify the placement of the new arc and show that the induction properties are maintained.

Case 1. *Adding a forward arc* $(x, y) \in \vec{E}_f$. Since x is the parent of y, x has already been placed on line $\ell(x)$ and ordered according to σ. Set $line(y) = line(x)+1$. Choose s on $\ell(x)$ largest (with respect to σ) such that $s \leq_\sigma x$, and s has an out-neighbor s' that has already been placed with (s, s'), a q_1 arc; choose s' as large as possible with respect to σ. Choose t on $\ell(x)$ smallest (with respect to σ) such that $x <_\sigma t$ and t has an out-neighbor t' that has already been placed with (t, t'), a q_1 arc; choose t' as small as possible. Either s or t may be undefined. Intuitively, (s, s') and (t, t') are the arcs that we need to place (x, y) between. See Figure 3.5 for an illustration of these arcs. If t is undefined, then place y above all other nodes in $line(y)$; in this case, (x, y) cannot nest with any q_1 arc. Now suppose that t is defined. Place y immediately below t'. If s is undefined, then (x, y) cannot nest with any q_1 arc. Suppose s is defined. Since (s, s') and (t, t') do not nest, we know that $s' \leq_\sigma t'$. If $s' \neq t'$, then (x, y) does not nest with any q_1 arc. Now suppose $s' = t'$. By property 5, (s, s') and (t, t') are consecutive arcs in $\vec{P}$. Moreover, $t = next(s)$. Since (by induction property 4) x is not in a forbidden position, we must have $x = s$. The placement of y cannot cause (x, y) to nest with any q_1 arc. In all cases, we can assign (x, y) to queue q_1, as required by induction property 1.

The continued truth of induction properties 1–3 is clear. It remains to show that y is not in a forbidden position. If y is placed above all other nodes on $\ell(y)$, then y

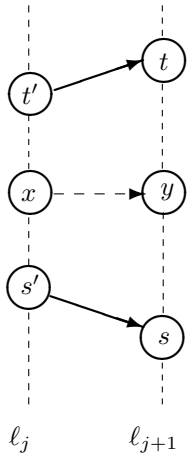

FIG. 3.6. *Illustration of the definitions of s, s', t, and t' for Case* 2.

cannot be in a forbidden position. If $t' \notin V_C$ and y is placed immediately below t', then y is not in a forbidden position, because t' is not. So suppose $t' \in V_C$ and y is placed immediately below t'. Then $(t, t') \in \vec{E_P}$, since otherwise (t, t') would be a q_2 arc. If (t, t') is a forward arc, then t' is not $next(p_i)$ for any $p_i <_\sigma t'$ and y is not in a forbidden position. So suppose (t, t') is a backward arc. Then $t = next(p_i)$ for some $p_i <_\sigma t$, and x is in a forbidden position. This contradicts induction property 4. We conclude that (t, t') is not a backward arc. In all cases, y is not in a forbidden position, and induction property 4 holds.

Case 2. *Adding a backward arc $(x, y) \in \vec{E_b}$ when $line(y) \leq 0$ or $M + 1 \leq line(y)$.* Since y is the parent of x, y has already been placed on line $\ell(y)$ and ordered according to σ. Set $line(x) = line(y) - 1$. Choose s on $\ell(y)$ largest (with respect to σ) such that $s \leq_\sigma y$ and s has an in-neighbor s' that has already been placed and (s', s) is a q_2 arc; choose s' as large as possible. Choose t on $\ell(y)$ smallest (with respect to σ) such that $y <_\sigma t$ and t has an in-neighbor t' that has already been placed and (t', t) is a q_2 arc; choose t' as small as possible. Either s or t may be undefined. See Figure 3.6 for an illustration of these arcs. If t is undefined, then place x above all other nodes on $\ell(x)$; this cannot cause (x, y) to nest with any q_2 arc. If t is defined, then place x just below t'. The only way this can cause (x, y) to nest with a q_2 arc is if s is defined and $s' = t'$; by property 6, this cannot happen. Assign (x, y) to queue q_2, as required by induction property 2.

The continued truth of induction properties 1–3 is clear. It remains to show that x is not in a forbidden position. If x is placed above all other nodes on $\ell(x)$, then x cannot be in a forbidden position. So suppose x is placed just below t'. Since $(t', t) \in \vec{E_b}$, we know that $t' \notin V_C$. Hence x is not in a forbidden position because t' is not. We conclude that x is not in a forbidden position and that induction property 4 holds.

Case 3. *Adding a backward arc $(x, y) \in \vec{E_b}$ when $1 \leq line(y) \leq M$.* Since y is the parent of x, y has already been placed on line $\ell(y)$ and ordered according to σ. Set $line(x) = 0$ to satisfy induction property 3. Choose s largest (with respect to σ) such that $s \leq_\sigma y$ and s has an in-neighbor s' that has already been placed, (s', s) is a q_2 arc, and $line(s') = 0$; choose s' as large as possible. Choose t smallest (with respect to σ) such that $y <_\sigma t$ and t has an in-neighbor t' that has already been placed, (t, t')

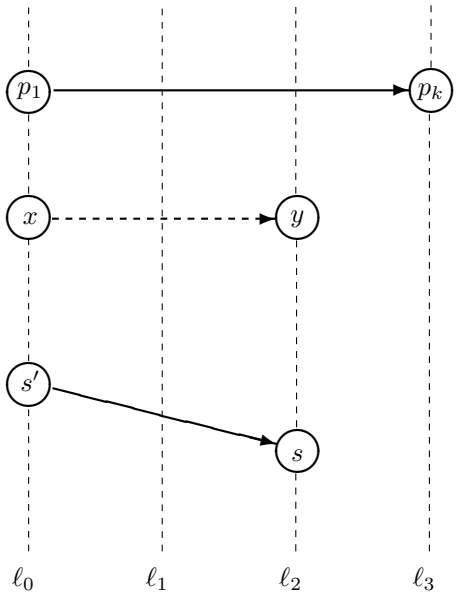

FIG. 3.7. *Illustration of the definitions of s, s', t, and t' for Case* 3.

is a q_2 arc, and $line(t') = 0$; choose t' as small as possible. Either s or t may be undefined but not both, because the closing arc meets the requirements of one of (s', s) and (t', t). See Figure 3.7 for an illustration of these arcs; here $(t', t) = (p_1, p_k)$, the closing arc. If t is undefined, then place x above all other nodes in $line(x)$; this cannot cause (x, y) to nest with any q_2 arc. If t is defined, then place x just below t'. The only way this can cause (x, y) to nest with a q_2 arc is if s is defined and $s' = t'$; by property 6, this cannot happen. Assign (x, y) to queue q_2, as required by induction property 2.

The continued truth of induction properties 1–3 is clear. It remains to show that x is not in a forbidden position. If x is placed above all other nodes on ℓ_0, then x cannot be in a forbidden position. So suppose x is placed just below t'. If $(t', t) \in \vec{E}_b$, then $t' \notin V_C$ and x is not in a forbidden position because t' is not. If (t', t) is the closing arc, then x is not in a forbidden position because it is placed below p_1 on ℓ_0. We conclude that x is not in a forbidden position and that induction property 4 holds.

By induction, we obtain a 2-queue layout of $\vec{U}$, as desired. □

Figure 3.8 shows a unicyclic dag $\vec{U}$ with 12 nodes. $\vec{U}$ contains a cycle dag induced by the nodes $\{1, 2, 3, 4, 5\}$. Figure 3.9 shows a 2-queue layout of $\vec{U}$. The cycle dag $\vec{C}$ is laid out in 2 queues, with closing arc $(1, 5)$ assigned to one queue and the rest assigned to another queue. The remainder of $\vec{U}$ is laid out as in the construction in the proof of Theorem 3.4.

4. Characterization of 1-queue directed trees and directed cycles. In this section we characterize 1-queue tree dags and 1-queue cycle dags. First we prove a theorem about leveled-planar dags used in both characterizations. We need the following definition. Suppose $\vec{G}$ is a leveled dag with leveling *lev*. A queue layout of $\vec{G}$ *respects lev* if all nodes in $lev^{-1}(j)$ appear contiguously in the layout for every j.

THEOREM 4.1. *Suppose that $\vec{G}$ is a leveled dag. Then, $\vec{G}$ is a* 1*-queue dag if and only if it has a directed leveled-planar embedding. Moreover, if lev is any leveling of*

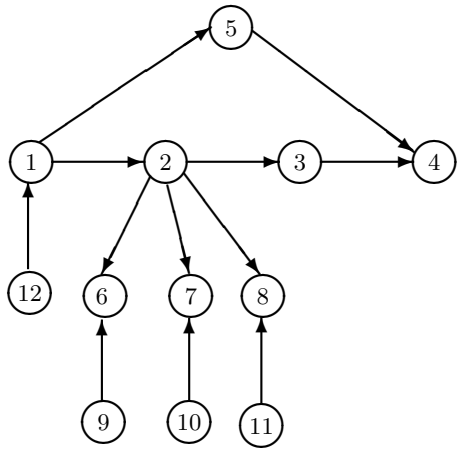

FIG. 3.8. *A unicyclic dag.*

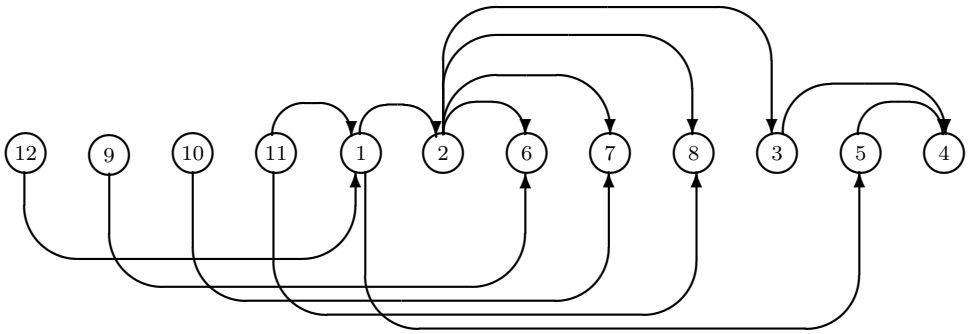

FIG. 3.9. *A 2-queue layout of the unicyclic dag shown in Figure* 3.8.

$\vec{G}$, then $\vec{G}$ has a 1-queue layout that respects lev.

Proof. By Proposition 1.1, if $\vec{G}$ has a directed leveled-planar embedding, then it is a 1-queue dag.

To show the converse, suppose that $\vec{G}$ is a 1-queue dag. Let σ be a total order on V that yields a 1-queue layout of $\vec{G}$. Let *lev* be any leveling of $\vec{G}$. Place each level-j node u on the vertical line ℓ_j. On each vertical line, place nodes bottom to top in the order prescribed by σ and draw each arc in $\vec{E}$ as a straight line segment connecting its two endpoints. We now show that this embedding is a directed leveled-planar embedding. It suffices to show that no two independent arcs (u_1, v_1) and (u_2, v_2) with $lev(u_1) = lev(u_2)$ intersect. Without loss of generality, we may assume that $u_1 <_\sigma u_2$ and that $lev(u_1) = lev(u_2) = j$ for some integer j. Since $u_1 <_\sigma u_2$, u_1 appears below u_2 on ℓ_j. Since σ defines a 1-queue layout, we have $v_1 <_\sigma v_2$. Hence v_1 appears below v_2 on ℓ_{j+1}. We conclude that the arcs (u_1, v_1) and (u_2, v_2) do not intersect. Hence $\vec{G}$ has a directed leveled-planar embedding, as desired.

To show the last assertion, suppose that *lev* is any leveling of $\vec{G}$. Then the above construction of a leveled-planar embedding of $\vec{G}$ yields a 1-queue layout of $\vec{G}$ that respects *lev*, as desired. □

An example of a leveled dag is a tree dag. The above theorem implies that any 1-queue tree dag has a leveled-planar embedding that respects any leveling. This is

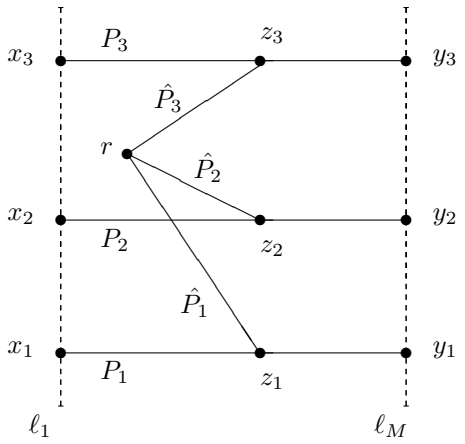

FIG. 4.1. *A typical dag in the forbidden set* $\mathcal{F}$.

a very useful result because it allows us to ignore the possibility that there might be arches in the embedding.

4.1. Characterization of 1-queue directed trees. The next theorem gives a forbidden graph characterization of tree dags with queuenumber equal to 1. We begin with some notation. Let $\vec{T} = (V, \vec{E})$ be a tree dag with covering graph $T = (V, E)$. Root $\vec{T}$ at an arbitrary node r. If u and v are nodes of T, then the (unique) path in T from u to v is denoted $P(u, v)$. For any $u \in V$, let $\vec{T}_u = (V_u, \vec{E}_u)$ be the subtree of $\vec{T}$ rooted of u. We extend this notation to *sets* of nodes: if S is a set of nodes in V, then $\vec{T}_S$ is the directed forest that is the union of the tree dags $\vec{T}_u$ for all $u \in S$.

For any subdag $\vec{D}$ of tree dag $\vec{T}$, with leveling function *lev*, we let $minlev(\vec{D}) = \min\{lev(v) \mid v \in V(\vec{D})\}$. When $\vec{D}$ is the subtree $\vec{T}_u$ for some node u, we shorten $minlev(\vec{T}_u)$ to $m\ell T(u)$. As an example, if the dag in Figure 4.2 is rooted at r, then $m\ell T(b) = 2$, $m\ell T(z_2) = m\ell T(z^*) = 1$, and $m\ell T(z_1) = 3$.

Next we define a set $\mathcal{F}$ of tree dags and show that the set of tree dags with queuenumber equal to 1 is characterized by forbidding the set $\mathcal{F}$. Each dag $\vec{F} = (V_F, \vec{E}_F)$ in $\mathcal{F}$ consists of two sets of three nontrivial path dags, to wit, $\{P_1, P_2, P_3\}$ and $\{\hat{P}_1, \hat{P}_2, \hat{P}_3\}$ (refer to Figure 4.1). There is an integer $M \geq 2$ and a leveling function *lev:* $V_F \to \mathbf{Z}$ for which $1 \leq lev(u) \leq M$ for all $u \in V_F$. Furthermore, the paths P_i, with endpoints x_i and y_i, are node disjoint and have $lev(x_i) = 1$ and $lev(y_i) = M$, for $i = 1, 2, 3$. The paths $\hat{P}_i$ have endpoints r and z_i and share exactly one node r. The paths $\hat{P}_i$ and P_j share precisely the node z_i if $i = j$ and are node disjoint otherwise. The general case is shown in Figure 4.1, where all arcs point from left to right (arc directions are omitted in that figure). Note that the dag in Figure 3.1, in which each of the paths is just a single arc, is the smallest dag in the set $\mathcal{F}$.

THEOREM 4.2. *Let* $\vec{T} = (V, \vec{E})$ *be a tree dag. Then* $\vec{T}$ *is a leveled-planar dag if and only if* $\vec{T}$ *has no subdag in the set* $\mathcal{F}$ *of forbidden dags described above.*

Proof. ($\Longrightarrow$) We show that the graphs in $\mathcal{F}$ are *not* leveled-planar dags. Let $\vec{F}$ be a dag in $\mathcal{F}$ consisting of the paths P_i and $\hat{P}_i$ for $i = 1, 2, 3$. Suppose there were a directed leveled-planar embedding of $\vec{F}$. Choose such an embedding of $\vec{F}$ so that

the leveling function associated with this embedding has the set $\{1, 2, \ldots, M\}$ as its range. The node disjoint paths P_1, P_2, and P_3 divide the strip between the lines ℓ_1 and ℓ_M into four regions (see Figure 4.1). The node r must lie in one of these regions and thus is cut off from at least one of the paths, say P_1. The path $\hat{P}_1$ must cross one of P_2, P_3, a contradiction. Hence $\vec{F}$ is not a leveled-planar dag, as desired.

($\Longleftarrow$) We now show that if $\vec{T}$ does not have a subgraph that belongs to $\mathcal{F}$, then $\vec{T}$ has a directed leveled-planar embedding. We proceed by induction on the number of nodes. Clearly the theorem is true for the graph with one node. Assume that all tree dags with fewer than N nodes, $N \geq 2$, satisfy Theorem 4.2. Let $\vec{T}$ be a tree dag with N nodes. Assume that $\vec{T}$ has no subgraph that belongs to $\mathcal{F}$. We show that $\vec{T}$ has a directed leveled-planar embedding.

Let v be a leaf of $\vec{T}$. Since the set $\mathcal{F}$ of forbidden graphs is symmetric with respect to reversing all arc directions, we may assume that the arc incident on v in $\vec{T}$ points towards v. Let x be the parent of v.

Since $\vec{T} - v$ has no subgraph in $\mathcal{F}$ and has $N - 1$ nodes, it is a leveled-planar dag by the induction hypothesis. Fix a directed leveled-planar embedding $\mathcal{E}$ of $\vec{T} - v$. Let *lev* be the leveling of $\vec{T}$ induced by $\mathcal{E}$ such that $1 \leq lev(u) \leq m$, for all $u \in V$, for some integer $m \geq 2$. Suppose that $lev(x) = j - 1$ for some j, $1 < j \leq m + 1$. If v can be placed on the line ℓ_j so that the line segment connecting x and v does not cause a crossing, then we have a directed leveled-planar embedding of $\vec{T}$, as desired.

Otherwise, it is not hard to see that there exists a level-j node r so that in the embedding $\mathcal{E}$, node r has in-neighbors on line ℓ_{j-1} both above and below x. Root $\vec{T}$ at the node r. Extend *lev* to the domain V by setting $lev(v) = lev(x) + 1 = j$. The dags $\vec{T}$ shown in Figures 4.2 through 4.5 are meant to illustrate the notation and arguments given in this proof. In each case the given embedding of $\vec{T} - v$ is leveled-planar, but the arc (x, v) crosses another arc.

Let S be the set of all in-neighbors of r other than x. Since $\mathcal{E}$ is a leveled-planar embedding of $\vec{T} - v$, the nodes of S all lie on line ℓ_{j-1}. Let B consist of those $u \in S$ such that the tree $\vec{T}_u$ lies entirely to the left of ℓ_j, i.e., $u \in B$ implies that, for all $w \in T_u$, we have $lev(w) \leq j - 1$. For the graph in Figure 4.2, we have $j = 4$, $S = \{z_1, z_2, b, y_1\}$, and $B = \{b\}$. For all $y \in S - B$, define

$$H(y) = V(\vec{T}_y) \cap lev^{-1}(j) \cap \left\{u \mid j = \max_{w \in P(u,y)} lev(w)\right\},$$

that is, $H(y)$ consists of the nodes at which the branches of $\vec{T}_y$ first touch the line ℓ_j. If possible, modify $\mathcal{E}$ so that for each y, the nodes in $H(y)$ lie on the same side of r (i.e., all above r or all below r). Let $h(y)$ be the node in $H(y)$ that is closest to the node r; if there are two possibilities w_1 and w_2 (one above and one below r), choose the one for which $minlev(P(r, w_i))$ is larger and choose arbitrarily if $minlev(P(r, w_1)) = minlev(P(r, w_2))$. By planarity, there can be at most one node y^* for which $H(y^*)$ contains nodes both above and below r on line ℓ_j. If our embedding has such a node y^*, and $h(y^*)$ was chosen above r on line ℓ_j, then reflect the entire embedding about the x-axis, so that $h(y^*)$ is now below r on line ℓ_j. Denote the element of $\{w_1, w_2\}$ which is *not* $h(y^*)$ by $h'(y^*)$. Thus $h'(y^*)$ is above r, $h(y^*)$ is below r, and $minlev(P(y^*, h'(y^*))) \leq minlev(P(y^*, h(y^*)))$. Again referring to the dag of Figure 4.2, we have $H(z_1) = \{g\}$, $h(z_1) = g$, $H(z_2) = \{i, h\}$, $h(z_2) = h$, $H(y_1) = \{e\}$, $h(y_1) = e$, and the node y^* is not present.

Recall that $m\ell T(y) = minlev(\vec{T}_y)$ is the minimum level the tree $\vec{T}_y$ reaches. We also find it useful to use $m\ell P(y)$ as an abbreviated notation for $minlev(P(y, h(y)))$

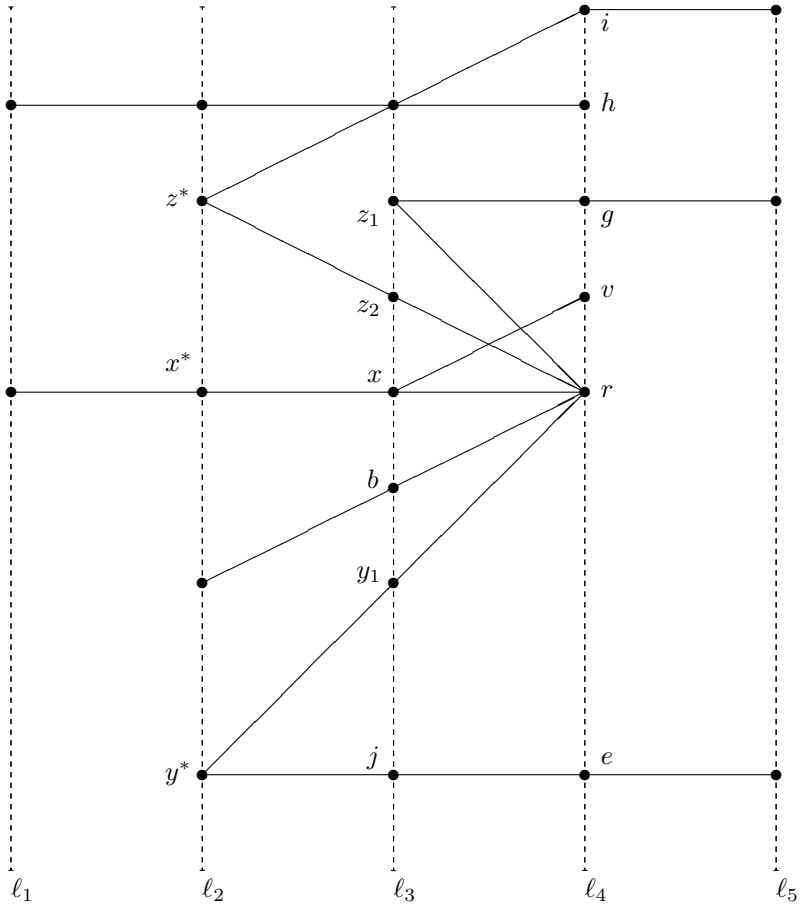

FIG. 4.2. *An example for Case* 1.

when y is a node in $S - B$. Thus $m\ell P(y)$ is the minimum level the path from y to $h(y)$ reaches. Clearly, we have $m\ell T(y) \leq m\ell P(y)$. In the tree dag of Figure 4.2, $m\ell T(z_1) = m\ell P(z_1) = 3$, $m\ell T(z_2) = 1$, and $m\ell P(z_2) = 2$.

We consider the cases $(x, r) \in \vec{E}$ and $(x, r) \notin \vec{E}$ separately.

Case 1. $(x, r) \in \vec{E}$. For this case, refer to Figure 4.2. Make a new embedding of $T - v$ in which the number of nodes z in $S - B$ with $h(z)$ above r is maximized while keeping nodes x and r and paths $P(y^*, h(y^*))$ and $P(y^*, h'(y^*))$ (if y^* is present) fixed in position. Write $S - B = A \cup C$, where the nodes $y \in A$ have $h(y)$ below r and the nodes $z \in C$ have $h(z)$ above r. Thus $|C|$ is as large as possible and y^* (if it is present) is in A.

Next we show that we can place the nodes in B above the nodes in A and below those in C. The embedding of the dag shown in Figure 4.2 has this form with $A = \{y_1\}$, $B = \{b\}$, and $C = \{z_1, z_2\}$. If a node $a \in A$ appeared above a node $c \in C$, then the paths $P(a, h(a))$ and $P(c, h(c))$ would cross, a contradiction. If the node y^* is not present, then there is a gap between the highest node of A and the lowest node of C

on line ℓ_{j-1} into which the nodes of B can be placed and the trees $\vec{T}_b$ for $b \in B$ will face no obstruction. If y^* is present, then by construction, $minlev(P(y^*, h'(y^*))) \leq minlev(P(y^*, h(y^*)))$, so any trees $\vec{T}_b$ with b below y^* can be transferred so that b lies directly above y^* and the trees $\vec{T}_b$ which fit inside $P(y^*, h(y^*))$ also fit inside $P(y^*, h'(y^*))$. Since y^* is the highest node of A (when it is present), this shows that the nodes of B can be placed above those of A and below those of C.

If $A = \emptyset$, then x can be placed as the lowest node on line ℓ_{j-1} and there is room for the entire tree $\vec{T}_x$ (including v) without causing a crossing. This would give a leveled-planar embedding of $\vec{T}$, as desired. Hence we may assume that $|A| \geq 1$. Similarly, we may assume that $|C| \geq 1$, because if $C = \emptyset$ and y^* is present, then x can be placed directly above node y^* on line ℓ_{j-1}, and there is room for the entire tree $\vec{T}_x$ (including v) without causing a crossing. Let $A = \{y_1, y_2, \ldots, y_m\}$, where $i < j$ implies that y_i is below y_j (and thus that $h(y_i)$ is above $h(y_j)$). Note that if y^* is present then $y^* = y_m$. Similarly, let $C = \{z_1, z_2, \ldots, z_n\}$, where $i < j$ implies that z_i is above z_j (and thus that $h(z_i)$ is below $h(z_j)$). The nodes of $A \cup C$ in Figure 4.2 are labeled in this way.

If $minlev(\vec{T}_x) > m\ell P(y_1)$, then the entire tree $\vec{T}_x$ can be placed inside the path $P(y_1, h(y_1))$ with x placed just below y_1 on ℓ_{j-1}. This allows room for v between $h(y_1)$ and r, and the arc (x, v) does not cause a crossing. Thus we would have a directed leveled-planar embedding of $\vec{T}$, as desired.

Otherwise, $minlev(\vec{T}_x) \leq m\ell P(y_1)$, as is the case for the embedding in Figure 4.2. Let t be the minimum positive integer such that $m\ell T(z_t) \leq m\ell P(y_1)$ (such a t exists; otherwise, y_1 could be placed just below z_n on ℓ_{j-1} and added to C, contradicting the maximality of $|C|$). If $t > 1$, then transfer the nested trees $\vec{T}_{z_1}, \ldots, \vec{T}_{z_{t-1}}$ to fit inside $P(y_1, h(y_1))$. In the embedding in Figure 4.2, we have $t = 2$, so $\vec{T}_{z_1}$ is transferred so that z_1 is placed between y_1 and j on line ℓ_3, and g is placed between r and e on line ℓ_4.

Now if $m\ell T(x) > m\ell P(z_t)$, then transfer the entire tree $\vec{T}_x$ inside the path $P(z_t, h(z_t))$. As before, this allows room for the arc (x, v) without causing a crossing, and thus we get a directed leveled-planar embedding of $\vec{T}$. In the embedding in Figure 4.2, $minlev(\vec{T}_x) = 1$ and $m\ell P(z_t) = m\ell P(z_2) = 2$ so the transfer does not take place.

Otherwise, $m\ell T(x) \leq m\ell P(z_t)$, as is the case for the embedding in Figure 4.2. Note that $m\ell T(y_1) \leq m\ell P(z_t)$, for otherwise the trees $\vec{T}_{y_1}, \vec{T}_{z_{t-1}}, \ldots, \vec{T}_{z_1}$ could be nested inside $P(z_t, h(z_t))$, violating the maximality of $|C|$. But now we have the following graph in $\mathcal{F}$ as a subgraph of $\vec{T}$, a contradiction. Let $M = \max\{m\ell P(y_1), m\ell P(z_t)\}$. Since $m\ell T(x) \leq M$, $m\ell T(y_1) \leq M$ and $m\ell T(z_t) \leq M$, we get the node disjoint paths: $P_1 : v \to x^*$, $P_2 : h(y_1) \to y^*$, and $P_3 : h(z_t) \to z^*$, where x^*, y^*, z^* are, respectively, nodes in $\vec{T}_x, \vec{T}_{y_1}, \vec{T}_{z_t}$ at level M. The connecting paths are $\hat{P}_1 : r \to x$, $\hat{P}_2 : r \to \hat{y}$, and $\hat{P}_3 : r \to \hat{z}$, where $\hat{y}$ (resp., $\hat{z}$) is the node farthest from r on both $P(r, y^*)$ and $P(r, h(y_1))$ (resp., $P(r, z^*)$ and $P(r, h(z_t))$). In the embedding in Figure 4.2, we have $M = 2$, $\hat{y} = y^*$, and $\hat{z} = z^*$.

Case 2. $(x, r) \notin \vec{E}$. Let w be the out- or in-neighbor of r such that $x \in \vec{T}_w$. There are two cases, depending on whether $(r, w) \in \vec{E}$ or $(w, r) \in \vec{E}$.

Case 2a. $(r, w) \in \vec{E}$, $lev(w) = j + 1$. For this case, refer to Figure 4.3. Without loss of generality, we may assume that the path $P(w, x)$ approaches x "from above," that is, the path in T from x to w first intersects the line ℓ_{j-1} at a node w_0 which lies above x.

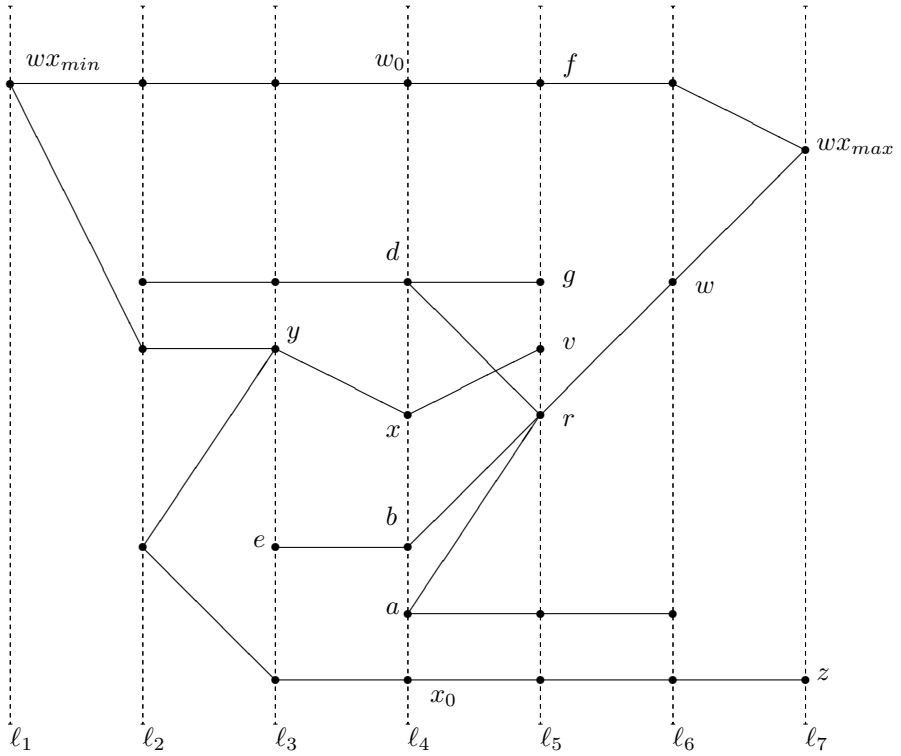

FIG. 4.3. *An example for Case* 2a.

Write $S - B = A \cup C \cup D$, where

$$A = \{u \in S - B \mid h(u) \text{ is below } r \text{ on line } \ell_j\},$$
$$C = \{u \in S - B - A \mid h(u) \text{ is above } r \text{ on line } \ell_j \text{ and } u \text{ is below } x \text{ on line } \ell_{j-1}\},$$
$$D = \{u \in S - B - A \mid h(u) \text{ is above } r \text{ on line } \ell_j \text{ and } u \text{ is above } x \text{ on line } \ell_{j-1}\}.$$

Without loss of generality, we may assume that the nodes of A are below those in B, which are below those in C, which are below those in D. The nodes of S in the embedding in Figure 4.3 are positioned in this way with $j = 5$, $A = \{a\}$, $B = \{b\}$, $C = \emptyset$, and $D = \{d\}$. Let wx_{min} be a node on $P(w, x)$ with $lev(wx_{min}) = \min\{lev(u) \mid u \in P(w, x)\}$ and let wx_{max} be a node on $P(w, x)$ with $lev(wx_{max}) = \max\{lev(u) \mid u \in P(w, x)\}$.

Move node x up so that it is above all nodes in $\vec{T}_D$ on line ℓ_{j-1} but below w_0. This allows room for v on ℓ_j so that the arc (x, v) does not cause a crossing. If the remainder of the tree $\vec{T}_{wx_{min}}$ can be embedded without causing a crossing, then we have a directed leveled-planar embedding of $\vec{T}$, as desired. This would be the case for the embedding in Figure 4.3 if node z were deleted. In that instance, node x would be placed on line ℓ_4 between nodes d and w_0, and v would be placed on line ℓ_5 between nodes g and f, and the rest of $\vec{T}_{wx_{min}}$ would lie above $\vec{T}_D$ but below $P(wx_{max}, wx_{min})$.

If a crossing is forced, then it must be the case that $C = \emptyset$, the node y^* is

not present, and there is a node y on $P(x, wx_{min})$ and a node $z \in \vec{T}_y$ with $lev(z) = lev(wx_{max})$ so that $minlev(P(y,z))$ is less than $minlev(\vec{T}_A)$ and $minlev(\vec{T}_B)$ but greater than or equal to $minlev(\vec{T}_D)$ (see Figure 4.3). In this case, let x_0 be the lowest node on ℓ_{j-1} that is also on $P(y,z)$. Place x just above x_0. This allows room for the arc (x,v) without causing a crossing. Since $lev(wx_{min}) < lev(\vec{T}_D) \leq minlev(P(y,z)) < \min\{minlev(\vec{T}_A), minlev(\vec{T}_B)\}$, each node of $\vec{T}_{wx_{min}}$ (other than wx_{min} itself) can be placed on its appropriate line ℓ_j below the nodes of $\vec{T}_A$ and $\vec{T}_B$. This allows room for the line segment from x to v without causing a crossing; hence we obtain a directed leveled-planar embedding of $\vec{T}$, as desired.

Case 2b. $(w,r) \in \vec{E}$, $lev(w) = j-1$. Write $S - B - \{w\} = A \cup C$, where

$$A = \{u \in S - B - \{w\} \mid h(u) \text{ is below } r\}$$

and

$$C = \{u \in S - B - \{w\} \mid h(u) \text{ is above } r\}.$$

Without loss of generality, we may assume that the nodes of A lie below w and x and those of C lie above w and x (refer to Figures 4.4 and 4.5). Let wx be a node on $P(w,x)$ with $lev(wx) = minlev(P(w,x))$, and let w^* be a node in $\vec{T}_w$ with $lev(w^*) = minlev(\vec{T}_w)$. Note that if y^* is present then the entire tree $\vec{T}_w$ lies inside the path $P(y^*, h'(y^*))$. In the arguments that follow, the node y^* can be treated like any other node of A because the existence of the path $P(y^*, h'(y^*))$ is not relevant.

Consider the integers $m\ell P(u)$ for each $u \in A \cup C$. If $m\ell P(u) < lev(w^*)$ for all $u \in A$, then w can be placed below all nodes in A and the entire tree $\vec{T}_w$ can be nested inside the trees $\vec{T}_u$ (for $u \in A$) without an arc crossing. This would leave room for the arc (x,v) and would give a directed leveled-planar embedding of $\vec{T}$, as desired. The same is true if $m\ell P(u) < lev(w^*)$ for all $u \in C$.

Thus we are left with the case in which there are nodes u of A and of C with $m\ell P(u) \geq lev(w^*)$. Let the set of all such u be $\mathcal{U}$. We consider the case in which there exists a node $z \in \mathcal{U} \cap C$ with $m\ell P(z) \leq m\ell P(u)$ for all $u \in \mathcal{U}$. The remaining case (there exists a $y \in \mathcal{U} \cap A$ with $m\ell P(y) \leq m\ell P(u)$ for all $u \in \mathcal{U}$) is similar. Choose an embedding of $\vec{T} - v$ that maximizes $|\mathcal{U} \cap C|$ and yet preserves the definitions of A and C and retains $z \in C$. Let $A = \{y_1, y_2, \ldots, y_m\}$, where $i < j$ implies that y_i is below y_j. Similarly, let $C = \{z_1, z_2, \ldots, z_n\}$, where $i < j$ implies that z_i is above z_j. Note that $i < j$ implies that $m\ell P(y_i) > m\ell P(y_j)$ and $m\ell P(z_i) > m\ell P(z_j)$.

Let i be the maximum integer such that $m\ell P(y_i) \geq lev(w^*)$, and let j be the maximum integer such that $m\ell P(z_j) \geq lev(w^*)$. By our assumptions, such i, j exist and $m\ell P(y_i) \geq m\ell P(z_j)$. In Figures 4.4 and 4.5, we have $i = 1$ and $j = 3$.

Subcase I. $m\ell P(z_j) \leq lev(wx)$ *and* $m\ell P(y_i) \leq lev(wx)$. For this subcase, refer to Figure 4.4. If $m\ell T(y_i) \leq m\ell P(z_j)$, then we have a forbidden graph in $\vec{T}$ with $M = m\ell P(z_j)$. Hence $m\ell T(y_i) > m\ell P(z_j)$ as is the case in Figure 4.4. If $j = 1$, then the tree $\vec{T}_{y_i}$ can be nested inside $P(z_1, h(z_1))$, contradicting the maximality of $|C|$. If $j > 1$ and $m\ell T(z_{j-1}) \leq m\ell P(y_i)$, we have a forbidden graph in $\vec{T}$ with $M = m\ell P(y_i)$. In the embedding in Figure 4.4, $m\ell T(z_2) = 4$ and $m\ell P(y_2) = 4$ and the forbidden dag consists of the paths $P_1 = P(a,e)$, $P_2 = P(wx,v)$, $P_3 = P(b,f)$, $\hat{P}_1 = P(r,a)$, $\hat{P}_2 = P(r,wx)$, and $\hat{P}_3 = P(r,d)$. Otherwise (e.g., if node "b" were deleted from the embedding in Figure 4.4), $\vec{T}_{y_i}$ could be nested between $P(z_{j-1}, h(z_{j-1}))$ and $P(z_j, h(z_j))$, contradicting the maximality of $|C|$.

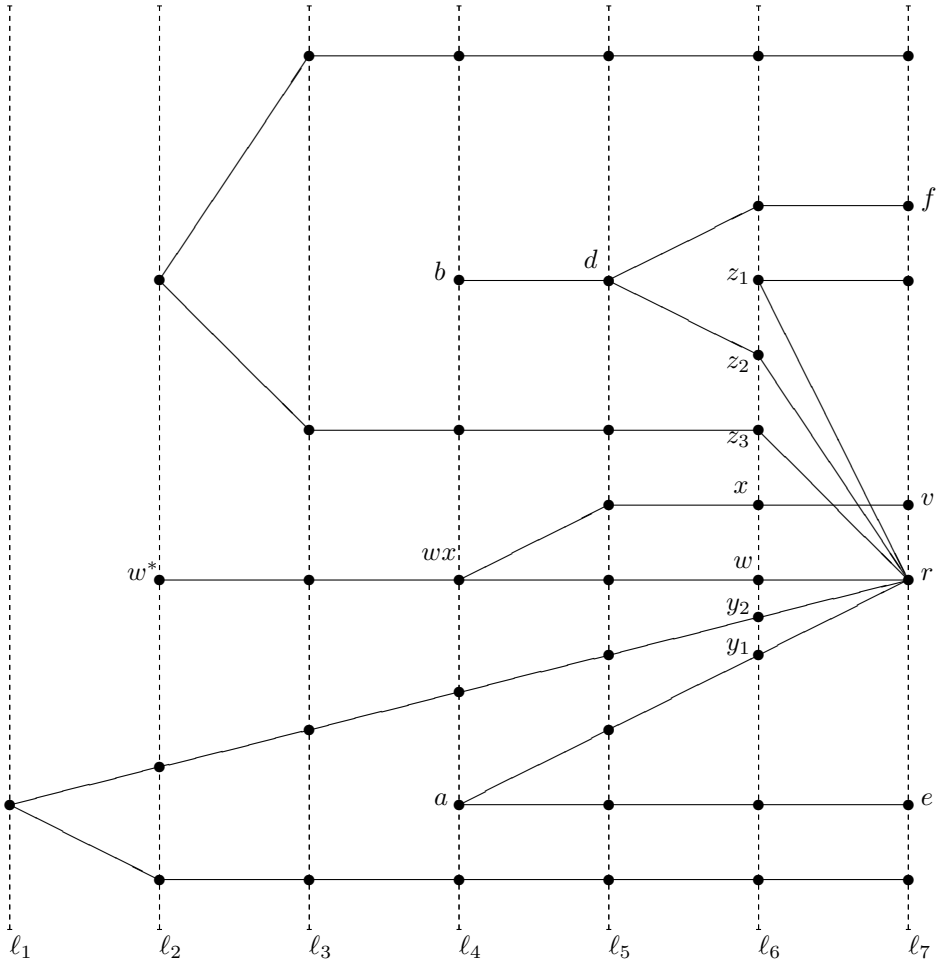

FIG. 4.4. *An example for Subcase* I *of Case* 2b.

Subcase II. $m\ell P(z_j) \leq lev(wx)$ *and* $m\ell P(y_i) > lev(wx)$. For this subcase, refer to the embedding in Figure 4.5 for which $i = 1$ and $j = 3$. If $m\ell T(y_i) \leq m\ell P(z_j)$, then we have a forbidden graph with $M = m\ell P(z_j)$. If $m\ell T(y_i) > lev(wx)$ (which would be the case if node "a" were removed from the embedding in Figure 4.5), then nest $\vec{T}_w$ around $\vec{T}_{y_i}$ and inside $P(y_{i+1}, h(y_{i+1}))$. This allows room for the arc (x, v) without causing a crossing and gives a directed leveled-planar embedding of $\vec{T}$, as desired.

Otherwise, as is the case for the embedding in Figure 4.5, $m\ell P(z_j) < m\ell T(y_i) \leq lev(wx)$. If there were a $c < j$ with $m\ell T(y_i) \leq m\ell P(z_c) \leq lev(wx)$, then we would have a forbidden graph with $M = m\ell P(z_c)$. Hence if we let p be the minimum integer for which $m\ell P(z_p) \leq lev(wx)$, then we have $m\ell T(y_i) > m\ell P(z_p)$. If $p = 1$ (as would be the case if the node z_1 were deleted from the embedding in Figure 4.5), then nest the trees $\vec{T}_{y_1}, \vec{T}_{z_2}, \ldots, \vec{T}_{y_i}$ inside the path $P(z_p, h(z_p))$ and nest $\vec{T}_w$ inside $P(y_{i+1}, h(y_{i+1}))$. This allows room for the arc (x, v) without causing a crossing and gives a directed leveled-planar embedding of $\vec{T}$, as desired.

If $p > 1$ and $m\ell T(z_{p-1}) \leq lev(wx)$, then we have a forbidden graph with

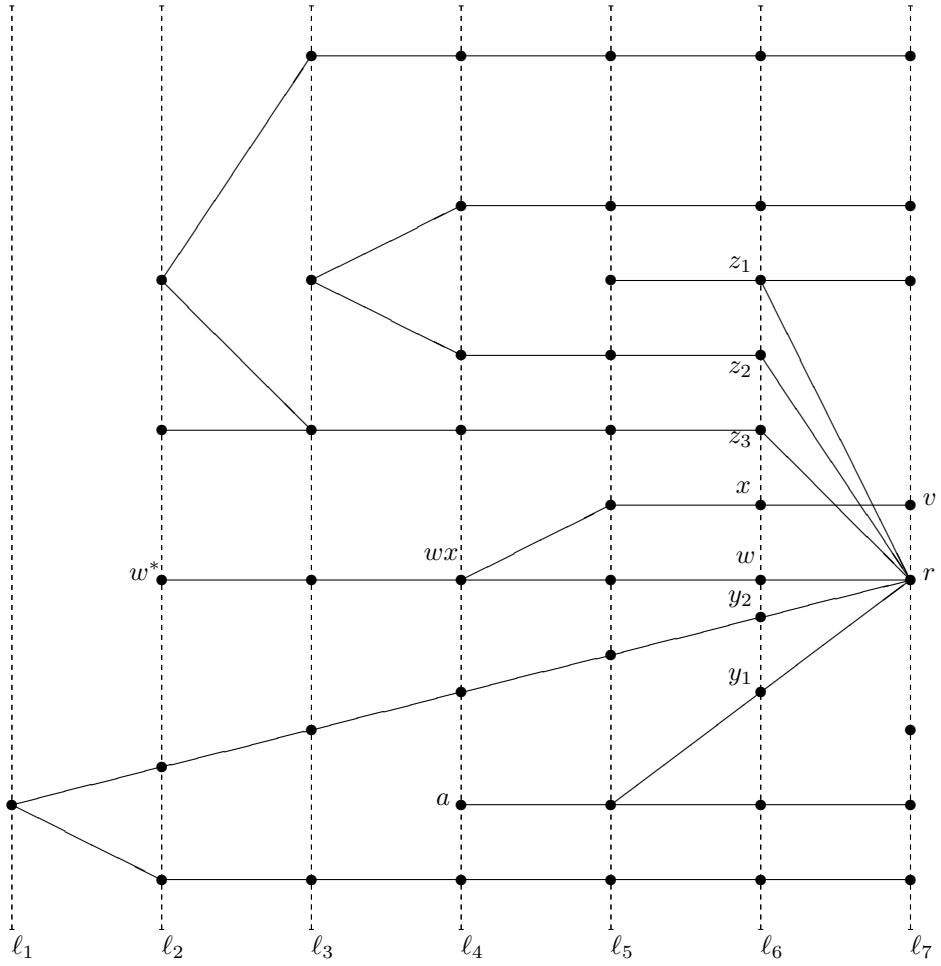

FIG. 4.5. *An example for Subcase* II *of Case* 2b.

$M = lev(wx)$. Otherwise, $p > 1$ and $m\ell T(z_{p-1}) > lev(wx)$. This is the case for the embedding in Figure 4.5 with $p = 2$. In this case, swap the nested trees $\vec{T}_{z_1}, \vec{T}_{z_2}, \ldots, \vec{T}_{z_{p-1}}$ with $\vec{T}_{y_1}, \vec{T}_{z_2}, \ldots, \vec{T}_{y_i}$ and nest $\vec{T}_w$ around $\vec{T}_{z_{p-1}}$ (now below x) and inside $\vec{T}_{y_{i+1}}$. This allows room for the arc (x, v) without causing a crossing and gives a directed leveled-planar embedding of $\vec{T}$, as desired.

Subcase III. $m\ell P(z_j) > lev(wx)$ *and* $m\ell P(y_i) > lev(wx)$. If $m\ell T(y_i) > lev(wx)$, nest $\vec{T}_w$ between $P(y_i, h(y_i))$ and $P(y_{i+1}, h(y_{i+1}))$. If $m\ell T(z_j) > lev(wx)$, nest $\vec{T}_w$ between $P(z_j, h(z_j))$ and $P(z_{j+1}, h(z_{j+1}))$. In either case, there is room for the arc (x, v) without causing a crossing.

Otherwise, $m\ell T(y_i) \leq lev(wx)$ and $m\ell T(z_j) \leq lev(wx)$, in which case we have a forbidden graph with $M = lev(wx)$.

In all cases, we obtain a leveled-planar embedding of $\vec{T}$. By induction, every tree dag having no subdag in $\mathcal{F}$ is a leveled-planar dag. The theorem follows. □

The following corollary to Theorems 4.1 and 4.2 is a complete characterization of 1-queue tree dags.

COROLLARY 4.3. *If $\vec{T}$ is a tree dag, then $\vec{T}$ is a directed* 1*-queue graph if and only if $\vec{T}$ has no subdag in the set $\mathcal{F}$.*

4.2. Characterization of 1-queue directed cycles. Throughout this section, we assume that $\vec{C} = (V, \vec{E})$ is a cycle dag with covering graph $C = (V, E)$. For notational convenience, we also assume that C is the cycle $u_1, u_2, \ldots, u_n$. Without loss of generality, we may assume that the indegree of node u_1 is 0. Choose a leveling *lev* of $\vec{C} - u_1$. Without loss of generality, we may assume that $1 = lev(u_2) \leq lev(u_n)$. Let $\vec{P} = (V, \vec{E_P})$ be the path dag $\vec{C} - (u_1, u_n)$. Extend *lev* to a leveling of $\vec{P}$, i.e., by making $lev(u_1) = 0$. We start with a partial characterization of 1-queue cycle dags based on the value of $lev(u_n)$, as given in the following lemma.

LEMMA 4.4. *Let $\vec{C}$, $\vec{P}$, and lev be as described above. If $lev(u_n) \geq 3$, then $\vec{C}$ is not a* 1*-queue dag. If $lev(u_n) = 2$, then $\vec{C}$ is a* 1*-queue dag and has a directed arched leveled-planar embedding with the single arch (u_1, u_2). If $lev(u_n) = 1$, then $\vec{C}$ is a* 1*-queue dag if and only if $\vec{C}$ has a directed leveled-planar embedding.*

Proof. We have three cases, based on the value of $lev(u_n)$.

Case 1. $lev(u_n) \geq 3$. To obtain a contradiction, suppose that $\vec{C}$ has a 1-queue layout. By Proposition 1.1, $\vec{C}$ has a directed arched leveled-planar embedding. Recall the terminology and notation from section 1. Let $\mathcal{E}$ be such an embedding with as few arches as possible.

We first argue that no level j has more than one arch. Suppose (x, t_j) and (y, t_j) are level-j arches, where $x <_\sigma y <_\sigma t_j$. By the definition of arches, $x <_\sigma y \leq_\sigma s_j$, so neither x nor any other node below y on ℓ_j has an out-neighbor on ℓ_{j+1}. Hence we can move t_j to the bottommost place on ℓ_{j+1} and still have an arched leveled-planar embedding with two fewer arches than $\mathcal{E}$. Since $\mathcal{E}$ was chosen to have as few arches as possible, we have a contradiction. This contradiction establishes that no level j has more than one arch.

We now define forward and backward arcs with respect to a traversal of C. A *forward arc* is some (u_i, u_{i+1}), where $1 \leq i < m$. A *backward arc* is either (u_1, u_m) or some (u_{i+1}, u_i), where $1 \leq i < m$. Let α be the number of forward arches, β the number of backward arches, γ the number of forward level arcs, and δ the number of backward level arcs. During the traversal of C, every forward level arc moves one vertical line to the right, while every backward level arc moves one vertical line to the left; arches cause no horizontal movement. Since $\vec{C}$ is a cycle dag, $\gamma = \delta$. We know that $\vec{C}$ contains $lev(u_n) - 1 \geq 2$ more forward arcs than backward arcs; that is, $\alpha + \gamma - (\beta + \delta) \geq 2$. Hence $\alpha - \beta \geq 2$.

Suppose (a, b) is a level-j_1 arch, (c, d) is a level-j_2 arch, $j_1 < j_2$, and there are no arches at levels strictly between j_1 and j_2. Then the cyclic order of these nodes in C is a, b, d, c because if the cyclic order was a, b, c, d, then the path between b and c that avoids a, plus the arch (c, d), would make it impossible to put the path from d to a that avoids c in the directed arched leveled-planar embedding. Hence, if (a, b) is a forward arc, then (c, d) is a backward arc and vice versa. Considering all arches, we obtain that $|\alpha - \beta| \leq 1$. This is a contradiction to $\alpha - \beta \geq 2$. This contradiction establishes that $\vec{C}$ does not have a 1-queue layout, as desired.

Case 2. $lev(u_n) = 2$. In this case, we construct a directed arched leveled-planar embedding of $\vec{C}$ in which the arc (u_1, u_2) is the only arch. First, construct a directed leveled-planar embedding of $\vec{C} - u_1$ by placing all level-j nodes on ℓ_j in decreasing order by index from bottom to top. This is the mirror image of the construction in the proof of Corollary 3.2. Note that node u_2 is the topmost node on line ℓ_1, and

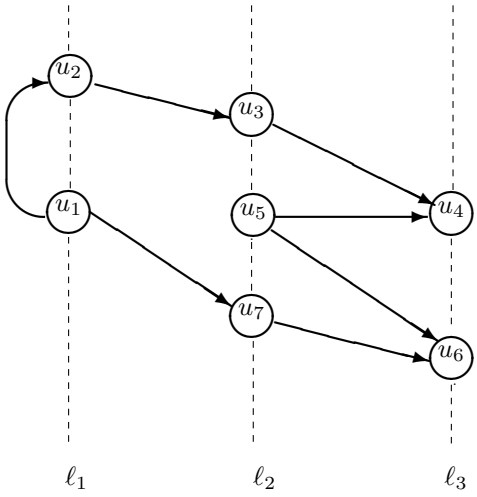

FIG. 4.6. *Construction of a directed arched leveled-planar embedding of $\vec{C}$ with exactly one arch, when $lev(u_n) = 2$.*

node u_n is the bottommost node on line ℓ_2. Now add node u_1 to the embedding as the bottommost node on line ℓ_1. Add arc (u_1, u_n) as a level arc and arc (u_1, u_2) as an arch. Figure 4.6 illustrates the above construction for a cycle dag of 7 nodes. The construction yields a directed arched leveled-planar embedding of $\vec{C}$ with the single arch (u_1, u_2), as desired.

Case 3. $lev(u_n) = 1$. If $lev(u_n) = 1$, then $\vec{C}$ is a leveled dag. By Theorem 4.1, $\vec{C}$ is a 1-queue dag if and only if it has a directed leveled-planar embedding, as desired.

From these three cases, the lemma follows. □

Recall that we assumed, without loss of generality, that $lev(u_n) \geq 1$. Thus the lemma completely characterizes all 1-queue cycle dags. When $lev(u_n) = 1$, $\vec{C}$ is a leveled cycle dag, and we can give a simple property that is equivalent to $\vec{C}$ being a 1-queue dag. Define

$$m = \min\{lev(u_i) \mid 1 \leq i \leq n\},$$
$$M = \max\{lev(u_i) \mid 1 \leq i \leq n\}.$$

$\vec{C}$ contains an *N-dag* if there exist four nodes, u_a, u_b, u_c, and u_d satisfying $1 \leq a < b < c < d \leq n$, such that either $lev(a) = lev(c) = m$ and $lev(b) = lev(d) = M$ or $lev(a) = lev(c) = M$ and $lev(b) = lev(d) = m$. Figure 4.7 shows a path dag in which $lev(u_1) = lev(u_7) = 0$ and $lev(u_3) = lev(u_8) = 2$. If we add the arc (u_{10}, u_9) to this path dag, then we obtain a cycle dag that contains an N-dag. Notice that the cycle dag so obtained is a leveled dag that does not have a directed leveled-planar embedding. Whether $\vec{C}$ contains an N-dag is independent of *lev*.

THEOREM 4.5. *Let $\vec{C}$ be a leveled dag. Then $\vec{C}$ is a 1-queue dag if and only if $\vec{C}$ does not contain an N-dag.*

Proof. First suppose that $\vec{C}$ is a leveled dag that contains an N-dag. To obtain a contradiction, assume that $\vec{C}$ is a 1-queue dag. By Theorem 4.1, $\vec{C}$ has a directed leveled-planar embedding—call it $\mathcal{E}$. Let *lev* be the leveling of $\vec{C}$ induced by $\mathcal{E}$. Let m and M be as defined above. Since $\vec{C}$ contains an N-dag, without loss of generality, we may assume that $lev(u_a) = lev(u_c) = m$, $lev(u_b) = lev(u_d) = M$, and

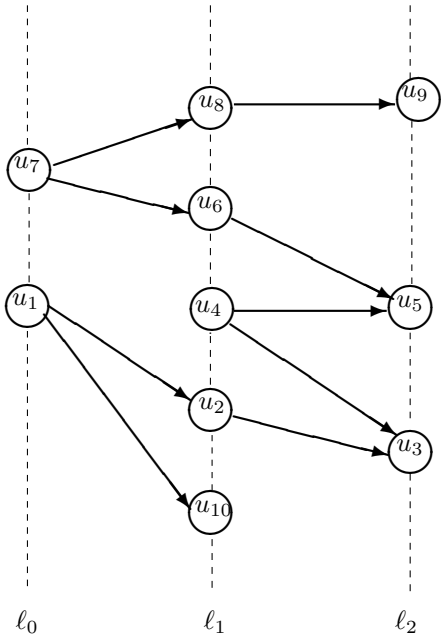

FIG. 4.7. *Illustration of an N-dag.*

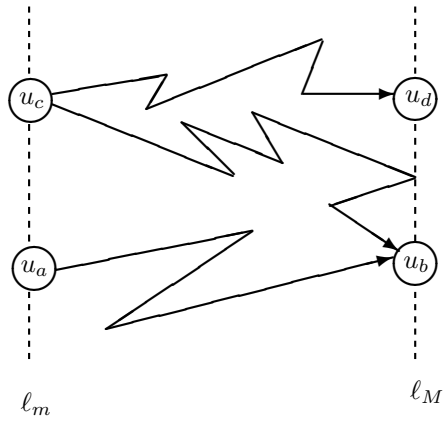

FIG. 4.8. *The path between u_c and u_b partitions the strip between ℓ_m and ℓ_M into disconnected regions.*

$1 \le a < b < c < d \le n$. As seen in Figure 4.8, the strip between the vertical lines ℓ_m and ℓ_M is partitioned into two disconnected regions by the path between u_c and u_b. The nodes u_a and u_d lie in distinct disconnected regions and cannot be connected by a path lying wholly between ℓ_m and ℓ_M without crossing the path between u_c and u_b. Hence, $\vec{C}$ does not have a directed leveled-planar embedding, a contradiction to the existence of $\mathcal{E}$. This contradiction establishes that $QN(\vec{C}) \neq 1$.

Now suppose that $\vec{C}$ is a leveled dag that does not contain an N-dag. We construct a directed leveled-planar embedding of $\vec{C}$, thus showing that $QN(\vec{C}) = 1$. Without

loss of generality, we may assume that $lev(u_1) = m$. Define

$$a = \min\{i \mid lev(u_i) = m\},$$
$$b = \max\{i \mid lev(u_i) = m\},$$
$$c = \min\{i \mid lev(u_i) = M\},$$
$$d = \max\{i \mid lev(u_i) = M\}.$$

Hence $a = 1$, $a \leq b$, and $c \leq d$. We consider three cases based on the relationships between a and b and between c and d.

First, suppose $a = b$. Embed $\vec{P}$ as in the proof of Corollary 3.2. Since there is only one level-m node, (u_1, u_2) is the only arc drawn between ℓ_m and ℓ_{m+1}. Since u_n is on line ℓ_{m+1}, the arc (u_1, u_n) can be added to the embedding without intersecting any arc, yielding a directed leveled-planar embedding of $\vec{C}$.

Now suppose $a \neq b$ and $c = d$. Let $\vec{C}^R$ be the cycle dag gotten by reversing all the arcs in $\vec{C}$. The construction of the last paragraph yields a directed leveled-planar embedding of $\vec{C}^R$, which is the mirror image of a directed leveled-planar embedding of $\vec{C}$.

Finally, suppose $a \neq b$ and $c \neq d$. Without loss of generality, we may assume that $1 = a < b < c < d < n$, since $\vec{C}$ does not contain an N-dag. First, construct a directed leveled-planar embedding $\mathcal{E}_1$ of the path dag $u_1, u_2, \ldots, u_c$, as in the proof of Corollary 3.2. Observe that all level-m nodes in $\vec{C}$ are in $\mathcal{E}_1$, u_1 is the lowest node on ℓ_m, and u_c is the only node on ℓ_M. Second, construct a directed leveled-planar embedding $\mathcal{E}_2$ of the path dag $u_{c+1}, \ldots, u_d$ so that the nodes of level-j are placed on ℓ_j in decreasing order by index. This embedding is the mirror image of the embedding in the proof of Corollary 3.2. Third, combine $\mathcal{E}_1$ and $\mathcal{E}_2$ into a directed leveled-planar embedding $\mathcal{E}_3$ of the path dag $u_1, u_2, \ldots, u_d$ by placing $\mathcal{E}_2$ below $\mathcal{E}_1$ and adding arc (u_{c+1}, u_c). Observe that all level-m and level-M nodes are in $\mathcal{E}_3$, u_1 is the lowest node on ℓ_m, and u_d is the lowest node on ℓ_M. Fourth, construct a directed leveled-planar embedding $\mathcal{E}_4$ of the path dag $u_{d+1}, \ldots, u_n$, as in the proof of Corollary 3.2. Fifth, construct a directed leveled-planar embedding of $\vec{C}$ by placing $\mathcal{E}_4$ below $\mathcal{E}_3$ and adding arcs (u_1, u_n) and (u_{d+1}, u_d).

In all cases, we have a directed leveled-planar embedding of $\vec{C}$. The theorem follows. □

5. Conclusion. In this paper, we have initiated the study of stack and queue layouts of dags and have established the stacknumber and queuenumber of path dags, cycle dags, tree dags, and unicyclic dags. We have also presented forbidden subgraph characterizations of 1-queue tree dags and 1-queue cycle dags. By comparing Theorem 2.1 to Theorem 3.1, one might think that stacks are more powerful than queues for laying out dags. However, in the following examples, we show that the truth is not so simple.

Example. Figure 5.1 shows a dag with 6 nodes whose covering graph is outerplanar. (Bernhart and Kainen [1] show that undirected outerplanar graphs are exactly the 1-stack graphs.) This dag has a unique topological order that yields stacknumber 1 and queuenumber 3. More generally, the path dag $v_1, v_2, \ldots, v_{2n}$ augmented with the arcs (v_i, v_{2n-i+1}) defines a sequence of dags with outerplanar covering graphs with stacknumber 1 and queuenumber n. An analogous sequence for undirected graphs is unknown (see Heath, Leighton, and Rosenberg [4] for discussion).

Example. Figure 5.2 shows a dag with 8 nodes whose covering graph is planar. This dag has a unique topological order that yields stacknumber 4 and queuenumber

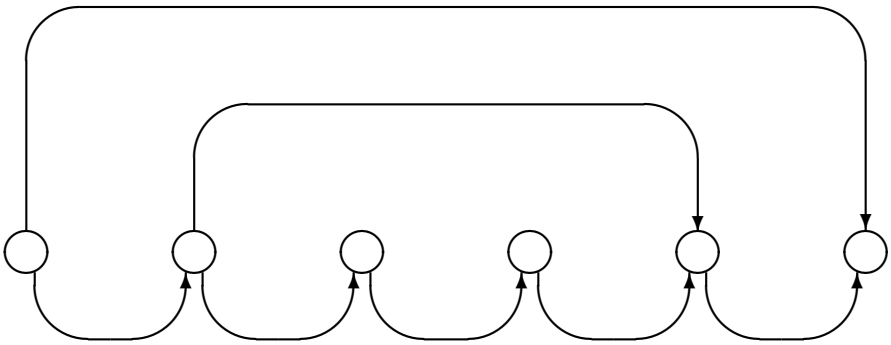

FIG. 5.1. *A dag with stacknumber* 1 *and queuenumber* 3.

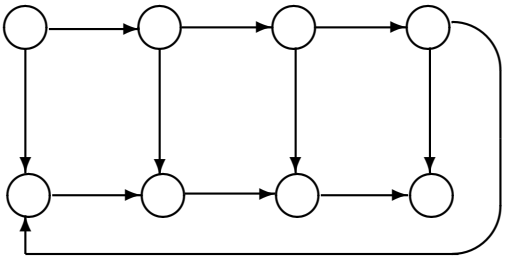

FIG. 5.2. *A dag with stacknumber* 4 *and queuenumber* 2.

2. By expanding the directed grid in this example to the right, we obtain a sequence of dags with planar covering graphs, in which each dag with $2n$ nodes has stacknumber n and queuenumber 2. By way of contrast, Yannakakis [11] shows that every undirected planar graph has stacknumber at most 4. Heath, Leighton, and Rosenberg [4] give an example of a sequence of undirected graphs for which the stacknumber is exponentially larger than the queuenumber.

Our investigation of dags with outerplanar covering graph has left us with the belief that there exists a constant c such that any dag with outerplanar covering graph can be laid out in c or fewer stacks. So we conclude with a conjecture.

CONJECTURE 1. *The stacknumber of the class of directed outerplanar graphs is bounded above by a constant.*

DIAGNOSIS OF WIRING NETWORKS: AN OPTIMAL RANDOMIZED ALGORITHM FOR FINDING CONNECTED COMPONENTS OF UNKNOWN GRAPHS*

WEIPING SHI† AND DOUGLAS B. WEST‡

Abstract. We want to find the vertex sets of components of a graph G with a known vertex set V and unknown edge set E. We learn about G by sending an oracle a query set $S \subseteq V$, and the oracle tells us the vertices connected to S. The objective is to use the minimum number of queries to partition the vertex set into components. The problem is also known as interconnect diagnosis of wiring networks in VLSI. We present a deterministic algorithm using $O(\min\{k, \lg n\})$ queries and a randomized algorithm using expected $O(\min\{k, \lg k + \lg\lg n\})$ queries, where n is the number of vertices and k is the number of components. We also prove matching lower bounds.

1. Introduction.

We study how to find the vertex sets of components of an unknown undirected graph $G = (V, E)$ on a known vertex set V. Vertices u and v are connected if there is a path between them. The components of G are its maximal connected subgraphs. The connection relation is an equivalence relation on the vertex set V, and the vertex sets of the components are the equivalence classes of the connection relation, also called the *connection classes*. When we say "finding the components," we mean finding the connection classes. In our problem, we are given V but not E. We do not know the number of components or their sizes. The only operation we may use to obtain information about G is to query an oracle. For any query set $S \subseteq V$, the oracle will tell us $Q(S)$, the set of vertices connected to vertices of S

$$Q(S) = \{v \in V : \text{ there exists } u \in S \text{ such that } u \text{ and } v \text{ are connected}\}.$$

Note that the response $Q(S)$ does not identify which vertex in S is connected to each vertex in $Q(S)$. The objective is to find the connection classes using the minimum number of queries.

This problem comes from the interconnect diagnosis of wiring networks of logic circuits. It has applications to design and testing of very large scale integration (VLSI), multichip module (MCM), and printed circuit board (PCB) systems [2, 3, 4, 5, 8]. A wiring network consists of a set of nets, each having one driver and one receiver. The logic value of a good net is controlled by its driver and observed by its receiver. When some nets are involved in a short fault, their receivers all receive the logical OR of the values of their drivers. To diagnose a wiring network, a test engineer sends a test vector of logical 0's and 1's from the drivers and observes the outputs from the receivers. Diagnosing a wiring network is the same as finding the

TABLE 1.1
Number of queries required to find connection classes.

Deterministic	$\Theta(\min\{k, \lg n\})$
Randomized	$\Theta(\min\{k, \lg k + \lg\lg n\})$
Nondeterministic	$\Theta(\lg k)$

connection classes of the graph of short faults, and applying test vectors to the nets is the same as querying the oracle for that graph.

Kautz [5] studied the problem for the special case of testing $G = \overline{K}_n$, which he phrased as testing whether there is any short among n nets. Garey, Johnson, and So [3] observed that if we are given partial information about the edge set of G, then finding an optimal algorithm to test $G = \overline{K}_n$ becomes NP-complete (reduction from chromatic number). For our problem of finding all connection classes, Jarwala and Yau [4] provided a heuristic using $\lg n + n - k$ queries, where k is the number of components. There is also a nonadaptive version of the problem where the inputs of all queries are decided before asking the oracle any question [2, 8, 9]. The nonadaptive version is used in applications where the query set is built into the computer hardware and the test is performed automatically. Shi and Fuchs [8] showed that $n-1$ queries are necessary and sufficient to find all connection classes nonadaptively. Shi and Fuchs also presented a recursive version of the deterministic algorithm of section 2, for the case of the interconnect diagnosis problem. Cheng, Lewandowski, and Wu [2] studied a variation of the nonadaptive diagnosis problem where the objective is to report all vertices in components that contain more than one vertex, without having to identify the connection classes. Chen and Hwang [1] studied the problem under a different model, called group testing. In group testing, the inputs of each query are two sets S and T, and the oracle answers yes or no depending on whether some vertex in S is connected to some vertex in T. Kavraki et al. [6] studied the problem of finding connection classes of an unknown graph, where the oracle looks at one entry of the adjacency matrix in each query. Recently, Shi and West [9] studied how to find the connection classes if partial information about the edge set of G is given.

Table 1.1 summarizes our results, where n is the number of vertices and k is the number of components, which is not given as part of the input. No assumption is made on k other than $1 \le k \le n$. All logarithms in this paper are base 2. We measure the query complexity in terms of both the input size n and the number of components k. We present algorithms achieving the upper bounds and prove matching lower bounds. Note that randomization may permit an exponential reduction in the number of queries compared to the deterministic algorithm.

2. Deterministic algorithm. There is a straightforward deterministic algorithm to find the connection classes in k queries: Iteratively pick a vertex v and make a query. Record $Q(\{v\})$ as one class, and delete $Q(\{v\})$ from the vertex set. Each query finds one new class. The upper bound k can be improved when $n < 2^k$. We present in Algorithm 1 and Procedure $\mathcal{D}$ an algorithm that uses $\lceil \lg n \rceil$ queries to find all connection classes. Procedure $\mathcal{D}$ will also be used by the randomized algorithm in section 3.

The algorithm iteratively maintains a *component structure* $P = \{(S_i, R_i) : i = 1, 2, \ldots, t\}$, where $S_1, S_2, \ldots, S_t$ are subsets of vertices that form a partition of V, and $R_1, R_2, \ldots, R_t$ are "chosen" subsets of vertices such that $R_i \subseteq S_i$ and $Q(R_i) = S_i$. This property of the chosen subsets implies that each S_i is a union of connection classes. Algorithm 1 initializes with the component structure $P = \{(V, V)\}$, and then

makes $\lceil \lg n \rceil$ calls to Procedure $\mathcal{D}$ to refine the partition, cutting the sizes of the chosen sets in half at each step. When the algorithm terminates, every R_i is reduced to a single vertex, and therefore every S_i is one connection class.

ALGORITHM 1.
Input: A vertex set V of size n.
Output: Vertex sets of all components of unknown G.
1: $P \leftarrow \{(V, V)\}$.
2: **For** $i \leftarrow 1$ **to** $\lceil \lg n \rceil$ **do**
3: $P \leftarrow \mathcal{D}(P)$.
4: **For** each $(S_j, R_j) \in P$
5: Report S_j as one class.

PROCEDURE $\mathcal{D}(P)$.
Input: A component structure $P = \{(S_j, R_j) : j = 1, 2, \ldots, t\}$.
Output: A refined component structure $P' = \{(S'_j, R'_j) : j = 1, 2, \ldots, t'\}$.
1: **For** $j \leftarrow 1$ **to** t **do**
2: Arbitrarily pick $R'_j \subseteq R_j$ such that $|R'_j| = \lceil \frac{1}{2}|R_j| \rceil$.
3: Perform the single query $\cup R'_j$, with result $S' \leftarrow Q(\cup R'_j)$.
4: $P' \leftarrow \emptyset$.
5: **For** $j \leftarrow 1$ **to** t **do**
6: Let $T_j = S_j \cap S'$.
7: $P' \leftarrow P' \cup \{(T_j, R'_j)\}$.
8: **If** $T_j \neq S_j$ **then** $P' \leftarrow P' \cup \{(S_j - T_j, R_j - T_j)\}$.
9: **Return** P'.

LEMMA 2.1. *Given a component structure in which the largest chosen subset has m vertices, $\lceil \lg m \rceil$ iterations of Procedure $\mathcal{D}$ finds all the connection classes.*

Proof. With each query, we divide the maximum size of the chosen subsets by 2. Hence there are at most $\lceil \lg m \rceil$ queries. To prove that the algorithm works it suffices to show that the property $Q(R_j) = S_j$ is maintained by Procedure $\mathcal{D}$. If so, then when all $|R_j| = 1$, all vertices in S_j are connected to the chosen vertex, and S_j is the connection class containing it.

For any $|R_j| > 1$, the procedure performs a query and splits S_j into T_j and $S_j - T_j$. Because $Q(R_j) = S_j$, the query $Q(\cup R'_j)$ tells us that $Q(R'_j) = T_j$ and there is no connection between T_j and $S_j - T_j$. If $S_j - T_j$ is nonempty, then since all of S_j were connected to R_j, we must have $Q(R_j - T_j) = S_j - T_j$. □

The following theorem is manifest.

THEOREM 2.2. *For any graph with n vertices, Algorithm* 1 *finds all connection classes using $\lceil \lg n \rceil$ queries.*

An algorithm using $2(\min\{k, \lceil \lg n \rceil\})$ queries can be obtained by combining the k-query algorithm and the $\lceil \lg n \rceil$-query algorithm. We alternately perform one query for each of the two algorithms, stopping whenever one of the two algorithms has found all the connection classes.

3. Randomized algorithm. In this section, we present a randomized algorithm that may reduce the number of queries exponentially. First the algorithm calls the randomized Procedure $\mathcal{R}$ for $\lceil \lg \lg n \rceil$ iterations, and then it calls the deterministic Procedure $\mathcal{D}$ to complete the refinement of the partition.

In Algorithm 2 we also maintain a partition and chosen subsets, and the idea is still to partition S_j into T_j connected to R'_j and $S_j - T_j$ connected to $R_j - T_j$. The only difference between Procedure $\mathcal{R}$ and Procedure $\mathcal{D}$ is in step 2, where we randomly pick $\lceil\sqrt{|R|}\rceil$ vertices in $\mathcal{R}$, instead of $\lceil\frac{1}{2}|R|\rceil$ vertices in $\mathcal{D}$. This difference leads to more rapid reduction in the size of the query set.

ALGORITHM 2.
Input: A vertex set V of size n.
Output: Vertex sets of all components of unknown G.
1: $P \leftarrow \{(V, V)\}$.
2: **For** $i \leftarrow 1$ **to** $\lceil \lg \lg n \rceil$ **do**
3: $P \leftarrow \mathcal{R}(P)$.
4: **While** there exists $(S_j, R_j) \in P$ such that $|R_j| > 1$
5: $P \leftarrow \mathcal{D}(P)$.
6: **For** each $(S_j, R_j) \in P$
7: Report S_j as one class.

PROCEDURE $\mathcal{R}(P)$.
Input: A component structure $P = \{(S_j, R_j) : j = 1, 2, \ldots, t\}$.
Output: A refined component structure $P' = \{(S'_j, R'_j) : j = 1, 2, \ldots, t'\}$.
1: **For** $j \leftarrow 1$ **to** t **do**
2: Randomly pick $R'_j \subseteq R_j$ such that $|R'_j| = \lceil\sqrt{|R_j|}\rceil$.
3: Perform the single query $\cup R'_j$, with result $S' \leftarrow Q(\cup R'_j)$.
4: $P' \leftarrow \emptyset$.
5: **For** $j \leftarrow 1$ **to** t **do**
6: Let $T_j = S_j \cap S'$.
7: $P' \leftarrow P' \cup \{(T_j, R'_j)\}$.
8: **If** $T_j \neq S_j$ **then** $P' \leftarrow P' \cup \{(S_j - T_j, R_j - T_j)\}$.
9: **Return** P'.

The correctness of Algorithm 2 follows as in Lemma 2.1. To estimate the number of queries used by Algorithm 2, we need to estimate the size of the largest chosen subset after $\lceil \lg \lg n \rceil$ calls to Procedure $\mathcal{R}$. Define a sequence of random variables $X_0, X_1, \ldots, X_{\lg \lg n}$, where $X_0 = n$, and X_i is the size of the largest chosen subset after i calls to Procedure $\mathcal{R}$.

LEMMA 3.1. *For any positive integer m and real number $\alpha \in [0, 1]$,*

$$\alpha(1 - \alpha)^m < \frac{1}{em},$$

where $e = 2.71828\ldots$ is the base of the natural logarithm.

Proof. The derivative of $f(\alpha) = \alpha(1 - \alpha)^m$ is

$$\frac{df(\alpha)}{d\alpha} = (1 - \alpha)^m - m\alpha(1 - \alpha)^{m-1} = (1 - \alpha)^{m-1}(1 - \alpha - m\alpha).$$

If $f'(\alpha) = 0$, then one of the factors $(1 - \alpha)$ and $(1 - \alpha - m\alpha)$ must be zero, which happens only at $\alpha = 1$ or $\alpha = \frac{1}{m+1}$. Checking the values of f at these points and the

boundary $\alpha = 0$, we find that $f(\alpha)$ reaches its maximum when $\alpha = \frac{1}{m+1}$. Therefore,

$$f(\alpha) \le \frac{1}{m+1}\left(1 - \frac{1}{m+1}\right)^m < \frac{1}{(m+1)}\frac{1}{\left(1-\frac{1}{m+1}\right)}\frac{1}{e} = \frac{1}{em}. \qquad \square$$

LEMMA 3.2. *For the sequence of random variables X_i defined above, the conditional expectation $E[X_i \mid X_{i-1}]$ is bounded by*

$$E[X_i \mid X_{i-1}] < \sqrt{X_{i-1}} \cdot k^2.$$

Proof. Assume after $i-1$ calls to $\mathcal{R}$ we have a component structure $P = \{(S_j, R_j) : j = 1, 2, \ldots, t\}$ in which the largest chosen subset is R_l of size X_{i-1}. At iteration i when we apply $\mathcal{R}(P)$, the pair (S_l, R_l) is split into $(Q(R'_l), R'_l)$, and possibly $(S_l - Q(R'_l), R_l - Q(R'_l))$, where $|R'_l| = \sqrt{X_{i-1}}$. Denote the chosen subset $R_l - Q(R'_l)$ by R''_l. The size of R''_l is a random variable with its value anywhere from 0 to $X_{i-1} - \sqrt{X_{i-1}}$. Consider the following conditional expectation.

$$\begin{aligned} E[\max\{|R'_l|, |R''_l|\} \mid X_{i-1}] &= E[\max\{\sqrt{X_{i-1}}, |R''_l|\} \mid X_{i-1}] \\ &\le E[\sqrt{X_{i-1}} + |R''_l| \mid X_{i-1}] \\ &= \sqrt{X_{i-1}} + E[|R''_l| \mid X_{i-1}]. \end{aligned}$$

Let the k components of G be $G_1, G_2, \ldots, G_k$, and their contributions to R_l have sizes $n_1, n_2, \ldots, n_k$, with $n_j = |V(G_j) \cap R_l|$. The vertices in R''_l belong to the components not hit by the query $Q(R'_l)$. Each successive vertex selected for R'_l has probability at least $n_j/|R_l|$ of belonging to G_j. Hence the probability of missing G_j completely is at most $(1 - n_j/|R_l|)^{\sqrt{|R_l|}}$. When we do miss G_j, it contributes n_j vertices to R''_l. Therefore,

$$\begin{aligned} E[|R''_l| \mid X_{i-1}] &\le \sum_{j=1}^{k} n_j \left(1 - \frac{n_j}{X_{i-1}}\right)^{\sqrt{X_{i-1}}} \\ &= X_{i-1} \sum_{j=1}^{k} \frac{n_j}{X_{i-1}} \left(1 - \frac{n_j}{X_{i-1}}\right)^{\sqrt{X_{i-1}}}. \end{aligned}$$

Letting $\alpha_j = n_j/X_{i-1}$, we have $\sum_{j=1}^{k} \alpha_j = 1$ and $0 \le \alpha_j \le 1$ for $j = 1, 2, \ldots, k$. Using Lemma 3.1 we obtain

$$\begin{aligned} E[|R''_l| \mid X_{i-1}] &\le X_{i-1} \sum_{j=1}^{k} \alpha_j (1-\alpha_j)^{\sqrt{X_{i-1}}} \\ &\le X_{i-1} \cdot k \cdot \max_{0 \le \alpha \le 1} \alpha(1-\alpha)^{\sqrt{X_{i-1}}} \\ &< \frac{X_{i-1} \cdot k}{e\sqrt{X_{i-1}}} = \frac{k\sqrt{X_{i-1}}}{e}. \end{aligned}$$

This computation depends only on $|R_l|$, which equals X_{i-1}. Because the expression grows with $|R_l|$, it also provides an upper bound on the expected size of the larger piece in the refinement of some other R_j. Also, although we don't know which piece will provide the new maximum, certainly its size will be less than the sum of maximum

sizes from all the pieces. These two comments yield an upper bound on $E[X_i \mid X_{i-1}]$ by taking k times the bound from R_l:

$$\begin{aligned} E[X_i \mid X_{i-1}] &\le k \cdot E[\max\{|R_l'|, |R_l''|\} \mid X_{i-1}] \\ &< k \cdot \left(\sqrt{X_{i-1}} + \frac{k\sqrt{X_{i-1}}}{e} \right). \end{aligned}$$

For $k \ge 2$, we conclude that $E[X_i \mid X_{i-1}] < \sqrt{X_{i-1}} \cdot k^2$. □

THEOREM 3.3. *For a graph with n vertices and k components, the expected number of queries used by Algorithm 2 to find all connection classes is $O(\lg k + \lg\lg n)$.*

Proof. Consider the maximum size X_i of the chosen subsets after i iterations. We prove by induction on i that $E[X_i] < n^{2^{-i}} k^4$. This is immediate for $i = 0$. Using Lemma 3.2, the inequality $E[f(X)] \le f(E[X])$ for concave f (such as square root), and the induction hypothesis, we have

$$\begin{aligned} E[X_i] = E(E[X_i|X_{i-1}]) &< E[\sqrt{X_{i-1}} \cdot k^2] \le \sqrt{E[X_{i-1}]} \cdot k^2 \\ &\le \sqrt{n^{2^{-(i-1)}} k^4} \cdot k^2 = n^{2^{-i}} k^4. \end{aligned}$$

With $i = \lceil \lg\lg n \rceil$, we obtain $E[X_{\lg\lg n}] < 2k^4$. From Markov's inequality,

$$\Pr[X_{\lg\lg n} \ge 2k^4 \lg n] < \frac{2k^4}{2k^4 \lg n} = \frac{1}{\lg n}.$$

If $X_{\lg\lg n} < 2k^4 \lg n$, then $\lg(2k^4 \lg n)$ additional queries suffice. With probability at most $\frac{1}{\lg n}$, we are left with chosen subsets greater than $2k^4 \lg n$ after $\lceil \lg\lg n \rceil$ iterations of Procedure $\mathcal{R}$. Procedure $\mathcal{D}$ can resolve these instances with at most $\lceil \lg n \rceil$ further queries. Therefore the expected number of queries used by Algorithm 2 is at most

$$\lg\lg n + \lg(2k^4 \lg n) + \frac{1}{\lg n} \lg n = 2\lg\lg n + 4\lg k + 2. \qquad \square$$

Again, an algorithm using $O(\min\{k, \lg\lg n + \lg k\})$ queries can be obtained by alternating between the k-query algorithm and Algorithm 2.

4. Lower bounds. In this section we obtain optimal lower bounds (within a constant multiplicative factor) on the number of queries for nondeterministic, deterministic, and randomized algorithms.

THEOREM 4.1. *For a graph with k components, every algorithm finding the connection classes uses at least $\lg k$ queries.*

Proof. Since the response to a query $Q(S)$ cuts each subset $U \subseteq V$ that is known to be a union of connection classes into at most two subsets, $U \cap Q(S)$ and $U - Q(S)$, with no edges between them, we need at least $\lg k$ queries to separate the set of vertices into k classes. □

Theorem 4.1 provides a lower bound for every algorithm. A nondeterministic algorithm can guess the connection classes and use $\lceil \lg k \rceil + 1$ queries to verify them.

THEOREM 4.2. *Let A be a deterministic algorithm finding the connection classes of unknown graphs. Over graphs with n vertices and k components, in the worst case A uses at least $\min\{k, \lg n\}$ queries.*

Proof. Consider the following adversary. In response to our first query S, the adversary makes a graph in which S induces a single component if $|S| \le n/2$, or a graph in which $V - S$ induces a single component if $|S| > n/2$. This leaves a subproblem with $k - 1$ components and at least $n/2$ vertices. □

The randomized lower bound is more involved. We first describe Yao's corollary [7] of von Neumann's minimax principle. By considering a matrix game in which the rows correspond to deterministic algorithms and the columns to input instances, Yao observed that the expected performance of the optimal randomized algorithm on the worst input instance for it equals the expected cost of the worst input distribution against the best deterministic algorithm for it. More precisely, let P denote a distribution over deterministic algorithms A; Q denote a distribution over input instances G, and $c(A, G)$ denote the cost of running algorithm A on input instance G. We then have

$$\min_P \max_G E_P[c(A,G)] = \max_Q \min_A E_Q[c(A,G)].$$

Hence, to provide a lower bound for a randomized algorithm, it suffices to prove a lower bound for the expectation of every deterministic algorithm against a particularly bad input distribution.

We will need several lemmas.

LEMMA 4.3 (randomized reduction lemma). *For $i \in \{1,2\}$, let $\mathcal{G}_i$ be a set of input instances, Π_i be a property for $\mathcal{G}_i$, and A_i be a deterministic algorithm for testing $\mathcal{G}_i \in \Pi_i$. Let $B : \mathcal{G}_1 \to \mathcal{G}_2$ be a deterministic or randomized transformation such that $G_1 \in \Pi_1$ if and only if $B(G_1) \in \Pi_2$. Let Q_1 be a distribution over $\mathcal{G}_1$ of a random input G_1, and let Q_2 be the resulting distribution of $B(G_1)$. Under these conditions,*

$$\min_{A_1} E_{Q_1}[c(A_1,G_1)] \le E_{Q_1}[c(B,G_1)] + \min_{A_2} E_{Q_2}[c(A_2,G_2)].$$

Proof. We may view B as an algorithm on the set $\mathcal{G}_1$. Our general cost function c uses an arbitrary cost measure; by $c(B, G_1)$ we mean the cost in this measure of performing the transformation. If B is deterministic, then combining B and A_2 gives a deterministic algorithm for recognizing Π_1. Thus the claim holds for deterministic transformations.

If B is randomized, then combining B and A_2 gives a randomized algorithm for Π_1. The performance of a randomized algorithm is a weighted average of the performance of deterministic algorithms, weighted by some distribution. The combination of B and A_2 costs at least as much as the best randomized algorithm; let P be the best distribution over deterministic algorithms. Since the expectation over P is a convex combination over deterministic algorithms, for each fixed input distribution Q_1 we have the inequality below, which completes the proof:

$$\min_{A_1} E_{Q_1}[c(A_1,G_1)] \le \min_P E_P[E_{Q_1}[c(A_1,G_1)]]. \qquad \square$$

We will apply Yao's corollary to a particular distribution $R(n,k)$ over graphs with $n + o(n)$ vertices and k components, where $k \le \frac{1}{2}\lg\lg n$. To select a graph according to $R(n,k)$, we form cliques $C_1, C_2, \ldots, C_k$ with vertex sets of sizes $n^{\epsilon_1}, n^{\epsilon_2}, \ldots, n^{\epsilon_k}$, respectively. We let $\epsilon_1 = 0$, $\epsilon_2 = 1$ and $\epsilon_3 = 1/2$. For $i \ge 4$, ϵ_i is chosen with the following distribution:

$$\Pr\left[\epsilon_i = \epsilon_{i-1} + \left(\frac{1}{2}\right)^{i-2}\right] = \Pr\left[\epsilon_i = \epsilon_{i-1} - \left(\frac{1}{2}\right)^{i-2}\right] = \frac{1}{2}. \tag{4.1}$$

This generates $\sum_{i=1}^{k} n^{\epsilon_i} = n + o(n)$ vertices in total. Finally, apply a random permutation to the vertex labels to complete the generation of a graph from $R(n,k)$. Figure 4.1 illustrates a selection of the exponents.

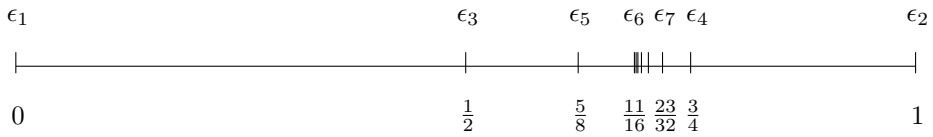

FIG. 4.1. *Example distribution of the exponents.*

In the above definition and the rest of this section, we omit the ceiling function $\lceil\rceil$ on the number of vertices for simplicity. To do so does not affect the claimed bound, since each time a ceiling is omitted the number of vertices is affected by an additive term of at most 1, while the smallest component that might be affected is of size at least $\lg n$.

Given $\epsilon_1, \ldots, \epsilon_k$, let π be the permutation of $\{1, 2, \ldots, k\}$ such that $\epsilon_{\pi(1)} < \epsilon_{\pi(2)} < \cdots < \epsilon_{\pi(k)}$. We call each interval $(\epsilon_{\pi(i)}, \epsilon_{\pi(i+1)}]$ an *ϵ-interval*. The length of $(\epsilon_{\pi(i)}, \epsilon_{\pi(i+1)}]$ is $\epsilon_{\pi(i+1)} - \epsilon_{\pi(i)}$. The real numbers $\epsilon_{\pi(1)}, \ldots, \epsilon_{\pi(k)}$ partition $(0, 1]$ into $k-1$ disjoint ϵ-intervals. Of the $k-1$ ϵ-intervals, there is one with length 2^{-i} for each $i = 1, 2, \ldots, k-3$, and there are two with length $2^{-(k-2)}$ that are consecutive.

LEMMA 4.4. *For any fixed integer $k \geq 3$ and fixed real number $x \in (0, 1]$, under the distribution of $R(n, k)$, the probability that x is in an ϵ-interval of length 2^{-i} is 2^{-i} when $1 \leq i \leq k-3$, and it is $2^{-(i-1)}$ when $i = k-2$.*

Proof. When $k = 3$, every x is in an ϵ-interval of length $1/2$. When $k > 3$, x remains in the interval of length $1/2$ with probability $1/2$; otherwise, x falls into some interval determined by applying the process for $k-1$ steps to an interval of length $1/2$. Multiplying all lengths and probabilities by $1/2$ in that distribution yields the remainder of the specified distribution for k, so the claim holds by induction. □

LEMMA 4.5. *Given positive integers $x_1, x_2, \ldots, x_k$, let $P(x_1, \ldots, x_k)$ be the distribution over graphs consisting of disjoint cliques having $x_1, \ldots, x_k$ vertices that is obtained by assigning vertices to components at random. For any positive integers $n_1, \ldots, n_k, c$, the expected number of queries used by a deterministic algorithm that finds the connection classes against $P_2 = P(n_1 \cdot c, \ldots, n_k \cdot c)$ is at least the expected number of queries used by an optimal deterministic algorithm against $P_1 = P(n_1, \ldots, n_k)$.*

Proof. We exhibit a randomized algorithm B that transforms P_1 to a distribution P' without making any query. By Lemma 4.3, the expected number of queries against P' is at least the expected number against P_1. We then observe that the expected number of queries against P' is the same as the expected number used by the same algorithm against P_2.

Given G_1 drawn from P_1, for each vertex $v_i \in V_1$ we add a clique Q_i having $c-1$ vertices and an edge between v_i and Q_i. We then apply a random permutation σ to the resulting set of vertices to obtain a graph G_2. We have changed each component having n_i vertices in G_1 to a component having $c \cdot n_i$ vertices in G_2, and we did not add any components or make any queries.

Permutation σ guarantees that vertices are assigned to components at random in G_2. Therefore, the probability of a particular partition of the vertices into connection classes depends only on the sizes of the connection classes, which are fixed. Thus the distribution over answers to the connection-class problem is the same for P' as for P_2. Furthermore, the two problems are solved by the same algorithms and with the same expected number of queries, because instances with the same probabilities can be paired up so that the responses to all queries are exactly the same. □

LEMMA 4.6. *Let k be a positive integer satisfying $k \le \frac{1}{2}\lg\lg n$. If F satisfies*

$$F(n,k) \ge 1 + \sum_{i=1}^{k-2} 2^{-i}\left(1 - \frac{1}{\lg n}\right) F(n^{2^{-i}}, k-i-2)$$

for $k \ge 2$, then $F(n,k) \ge k/5$ for all $k \ge 2$.

Proof. If $k \le \frac{1}{2}\lg\lg n$, then

$$k - i - 2 < k - \frac{i}{2} \le \frac{\lg\lg n}{2} - \frac{i}{2} = \frac{\lg\lg n^{2^{-i}}}{2}.$$

Thus we can apply induction on k. When $k = 2$, since empty sums equal 0, the initial condition is $F(n,k) \ge 1 > k/5$. When $k > 2$, the induction hypothesis yields $F(n,i) \ge i/5$ for $2 \le i < k$. Now

$$F(n,k) \ge 1 + \sum_{i=1}^{k-2} \frac{1}{2^i}\left(1 - \frac{1}{\lg n}\right)\frac{k-i-2}{5}.$$

To evaluate the sum, we first prove by induction on j that $\sum_{i=1}^{j-2} 2^{-i}(j-i) = j-2$. This is trivial for $j = 2$ or $j = 3$. For $j > 3$, we have

$$\sum_{i=1}^{j-2}\frac{j-i}{2^i} = \sum_{i=1}^{j-3}\frac{j-1-i}{2^i} + \sum_{i=1}^{j-3}\frac{1}{2^i} + \frac{2}{2^{j-2}} = j-3 + \left(1 - \frac{1}{2^{j-3}}\right) + \frac{1}{2^{j-3}} = j-2.$$

Also applying $\sum_{i=1}^{k-2} 2^{1-i} < 2$, we obtain

$$\begin{aligned} F(n,k) &> 1 + \left(1 - \frac{1}{\lg n}\right)\left(\frac{k-4}{5}\right) \\ &> \frac{k}{5} + \frac{1}{5} - \frac{k-4}{5\lg n} \\ &> \frac{k}{5} + \frac{1}{5} - \frac{\lg\lg n}{10\lg n} > \frac{k}{5}. \end{aligned}$$

□

LEMMA 4.7. *For $k \le \frac{1}{2}\lg\lg n$, the expected number of queries used by any deterministic algorithm A finding connection classes against distribution $R(n,k)$ is $\Omega(k)$.*

Proof. Let V be the set of vertices and $S \ne \emptyset$ be the set of vertices algorithm A picks to make the first query. We consider three cases concerning S, each of which leads to the same recurrence.

Define x by $|S| = n^{1-x}$. In Cases 1 and 2, we suppose that $|S| < n$, and thus $x > 0$. Since $x \in (0,1]$, there exists an ϵ-interval $(\epsilon_{\pi(i)}, \epsilon_{\pi(i+1)}]$ containing x. By Lemma 4.4, the probability is 2^{-j} that the ϵ-interval containing x has length 2^{-j}. Let us consider this possibility.

Intervals of length 2^{-j} are created when ϵ_{j+2} is selected, and ϵ_{j+2} lies between two such intervals. Further choices are made in one of those intervals, so ϵ_{j+2} is the bottom or top of the ϵ-interval of length 2^{-j} that remains. Thus $j+2$ is $\pi(i)$ or $\pi(i+1)$. We prove that in either case, with probability at least $1/\lg n$ we still have $C_{j+3}, \ldots, C_k$ within a single set of our partition.

Case 1. If $j + 2 = \pi(i)$, then

$$\epsilon_{\pi(i)} - 2^{-j} < \epsilon_{j+3}, \epsilon_{j+4}, \ldots, \epsilon_k \le \epsilon_{\pi(i-1)} < \epsilon_{\pi(i)} < x \le \epsilon_{\pi(i+1)}.$$

Consider the probability that S contains no vertex from components $C_{j+3}, C_{j+4}, \ldots, C_k$. With $C = C_{j+3} \cup \cdots \cup C_k$, we have

$$\Pr[S \cap C = \emptyset] = \frac{\binom{|V|-|C|}{|S|}}{\binom{|V|}{|S|}} > \left(\frac{|V|-|C|-|S|+1}{|V|-|S|+1}\right)^{|S|} = \left(1 - \frac{|C|}{|V|-|S|+1}\right)^{|S|}.$$

Since $x > \epsilon_{\pi(i)} \geq 2^{-k+2} \geq 4/\sqrt{\lg n} > 1/\lg n$ and $n^{-1/\lg n} = 1/2$, we have $|S| < n/2$. Using $|V| - |S| + 1 > n/2$, $|C| < 2n^{\epsilon_{\pi(i-1)}}$, and $|S| = n^{1-x}$, we have

$$\Pr[S \cap C = \emptyset] > \left(1 - \frac{4n^{\epsilon_{\pi(i-1)}}}{n}\right)^{n^{1-x}} > 1 - \frac{4}{n^{x-\epsilon_{\pi(i-1)}}} > 1 - \frac{4}{n^{\epsilon_{\pi(i)}-\epsilon_{\pi(i-1)}}}.$$

The middle inequality uses $(1-y)^z > 1 - yz$ for $z > 1$ and $0 < yz < 1$, which is verified by taking natural logarithms and expansions of both sides.

Since $\epsilon_{\pi(i)} - \epsilon_{\pi(i-1)} \geq 2^{-k+2} \geq \frac{4}{\sqrt{\lg n}}$, we have

$$\Pr[S \cap C = \emptyset] > 1 - \frac{1}{n^{4/\sqrt{\lg n}}} = 1 - \frac{1}{2^{4\sqrt{\lg n}}} > 1 - \frac{1}{2^{\lg\lg n}} = 1 - \frac{1}{\lg n}.$$

Thus $1 - 1/\lg n$ is a lower bound on the probability that all of $C_{j+3}, \ldots, C_k$ lie in $V - Q(S)$.

Case 2. If $j + 2 = \pi(i+1)$, then the various definitions yield

$$\epsilon_{\pi(i)} < x \leq \epsilon_{\pi(i+1)} < \epsilon_{\pi(i+2)} \leq \epsilon_{j+3}, \epsilon_{j+4}, \ldots, \epsilon_k < \epsilon_{\pi(i+1)} + 2^{-j}.$$

Let p be the probability that S intersects each of $C_{j+3}, \ldots, C_k$. The set S misses C_l with probability

$$\Pr[S \cap C_l = \emptyset] = \frac{\binom{|V|-|C_l|}{|S|}}{\binom{|V|}{|S|}} < \left(\frac{|V|-|C_l|}{|V|}\right)^{|S|} = \left(1 - \frac{n^{\epsilon_l}}{n+o(n)}\right)^{n^{1-x}}$$
$$< \left(1 - \frac{n^{\epsilon_l}}{2n}\right)^{n^{1-x}} \leq \exp\left(-\frac{n^{\epsilon_l - x}}{2}\right).$$

The last inequality uses $1 - z \leq e^{-z}$ for $0 \leq z \leq 1$. Avoiding each of the bad events separately yields

$$p \geq 1 - \sum_{l=j+3}^{k} \Pr[S \cap C_l = \emptyset] > 1 - k\Pr[S \cap C_{j+3} = \emptyset]$$
$$> 1 - k\exp\left(-\frac{n^{\epsilon_{j+3}-x}}{2}\right) \geq 1 - k\exp\left(-\frac{n^{\epsilon_{\pi(i+2)}-\epsilon_{\pi(i+1)}}}{2}\right).$$

Let $y = n^{\epsilon_{\pi(i+2)}-\epsilon_{\pi(i+1)}}$. Since $\epsilon_{\pi(i+2)} - \epsilon_{\pi(i+1)} \geq 2^{-k+2}$ and $k \leq \frac{1}{2}\lg\lg n$, we have $y > k$ and thus $ky < y^2 < e^{y/2}$ when y is sufficiently large, which yields $ke^{-y/2} < 1/y$. Therefore, $p > 1 - 1/n^{\epsilon_{\pi(i+2)}-\epsilon_{\pi(i+1)}}$. The same computation as in Case 1 now yields $p > 1 - 1/\lg n$.

Case 3. The remaining case is $|S| \geq n$; that is, $x \leq 0$. In Case 2, we proved that when $0 < x < 4/\sqrt{\lg n}$, the probability is at least $1 - 1/\lg n$ that S hits all of $C_{j+3}, \ldots, C_k$. When S becomes even larger, the probability of hitting all these components cannot decrease.

In each of Cases 1–3, we obtain the same recursive lower bound. Given the occurrence of one of these cases, with probability 2^{-j} the probability is at least $1 - 1/\lg n$

that the first query leaves us with components $C_{j+3}, C_{j+4}, \ldots, C_k$ all in $V - Q(S)$ or all in $Q(S)$. The numbers of vertices in $C_{j+3}, C_{j+4}, \ldots, C_k$ are $n^{\epsilon_{j+3}}, n^{\epsilon_{j+4}}, \ldots, n^{\epsilon_k}$, respectively. With $\delta = \epsilon_{j+2} - 2^{-j}$, the components of sizes $n^{\epsilon_{j+3}-\delta}$, $n^{\epsilon_{j+4}-\delta}$, $\ldots$, $n^{\epsilon_k-\delta}$ have the distribution $R(n^{2^{-j}}, k-j-2)$. According to Lemma 4.5, solving the problem for the graph induced by $V - Q(S)$ or $Q(S)$ expects to use at least as many queries as solving it against $R(n^{2^{-j}}, k-j-2)$.

Let $F(n,k)$ be the expected number of queries used by A against $R(n,k)$. We have the following recurrence relation:

$$F(n,k) \geq 1 + \sum_{j=1}^{k-2} \frac{1}{2^j} \cdot \left(1 - \frac{1}{\lg n}\right) \cdot F(n^{2^{-j}}, k-j-2))$$

and $F(n,2) \geq 1$. From Lemma 4.6, $F(n,k) = \Omega(k)$. □

THEOREM 4.8. *For every randomized algorithm finding connection classes of graphs with n vertices and k components, there is a graph in that class for which the expected number of queries used by the algorithm is $\Omega(\min\{k, \lg k + \lg\lg n\})$.*

Proof. If $k \geq \lg n$, then Theorem 4.1 yields $\lg k \geq \lg\lg n$ as a lower bound.

If $\lg n > k > \frac{1}{2}\lg\lg\frac{n}{2}$, consider the input distribution P formed by starting with a sample from $R(\frac{n}{2}, \frac{1}{2}\lg\lg\frac{n}{2})$ and then adding $k - \frac{1}{2}\lg\lg\frac{n}{2}$ arbitrary components so that the total number of vertices is n. Now we have a distribution over graphs with k components and n vertices. By Lemma 4.3, the expected number of queries used against distribution P is at least the expected number of queries used against distribution $R(\frac{n}{2}, \frac{1}{2}\lg\lg\frac{n}{2})$. By Lemma 4.7, this is $\Omega(\lg\lg n)$.

If $k \leq \frac{1}{2}\lg\lg\frac{n}{2}$, we start with $R(n/2, k-1)$ and add a single component to reach a total of n vertices. Lemma 4.3 yields an expected cost of at least the expected cost against $R(n/2, k-1)$. By Lemma 4.7, this is $\Omega(k)$.

By Theorem 4.1, $\lg k$ is always a lower bound. This completes the proof. □

PRODUCT RANGE SPACES, SENSITIVE SAMPLING, AND DERANDOMIZATION*

HERVÉ BRÖNNIMANN†, BERNARD CHAZELLE‡, AND JIŘÍ MATOUŠEK§

Abstract. We introduce the concept of a *sensitive ε-approximation* and use it to derive a more efficient algorithm for computing ε-nets. We define and investigate *product range spaces*, for which we establish sampling theorems analogous to the standard finite *VC-dimensional* case. This generalizes and simplifies results from previous works. Using these tools, we give a new deterministic algorithm for computing the convex hull of n points in $\mathbb{R}^d$. The algorithm is obtained by derandomization of a randomized incremental algorithm, and its running time of $O(n \log n + n^{\lfloor d/2 \rfloor})$ is optimal for any fixed dimension $d \geq 2$.

Key words. convex hull, deterministic algorithm, optimal

1. Introduction. During the last decade, randomized algorithms have been proposed as an efficient and elegant solution to several geometric problems [12, 13]. Derandomization aims at producing deterministic algorithms whose running times are within a constant factor of the running times of their randomized counterpart [9, 19, 23]. This process has successfully produced several geometric algorithms whose complexities are the best among those of the existing deterministic algorithms for the problems considered [5, 6, 7, 10]. For instance, the problem of computing the convex hull of n points in $\mathbb{R}^d$ is solved deterministically in [7] in time $O(n^{\lfloor d/2 \rfloor})$ for any $d \geq 4$, which is optimal. In section 3, we describe a new deterministic algorithm for computing the convex hull of n points in $\mathbb{R}^d$. Its running time of $O(n \log n + n^{\lfloor d/2 \rfloor})$ is optimal in any fixed dimension d. It uses a method similar to the one given in [7], but it is arguably simpler. Furthermore, there is no need to treat the two- and three-dimensional cases separately, as is done in [7].

Deterministic constructions of ε-nets and ε-approximations [10, 18, 20, 21] play a key role in the derandomization of probabilistic geometric algorithms [5, 6, 7, 9, 10, 19], and they also do for our convex hull algorithm. A *range space* $\Sigma = (X, \mathcal{R})$ is a pair of a set X and a collection $\mathcal{R}$ of subsets of X [17]. An *ε-approximation* for Σ is a subset A of X such that

$$\left| \frac{|R|}{|X|} - \frac{|R \cap A|}{|A|} \right| \leq \varepsilon$$

for every set R in $\mathcal{R}$. To be an *ε-net*, A only needs to intersect every set R in $\mathcal{R}$ whose size is greater than $\varepsilon|X|$. It is a classical result [17] that the existence of small subsets having these properties is linked to the finiteness of a parameter of the set system, called its *VC-dimension*. Namely, if the range space has finite VC-dimension d, there exists an ε-net of size $O(d\varepsilon^{-1}\log(d\varepsilon^{-1}))$ and an ε-approximation of size $O(d\varepsilon^{-2}\log(d\varepsilon^{-1}))$ (see section 2).

In geometric applications, it is common to use the range space $(X, \mathcal{R})$ consisting of a set X of hyperplanes and the collection $\mathcal{R}$ of all the subsets of X consisting of the hyperplanes stabbed by a line segment. By definition, an ε-approximation allows us to estimate how many hyperplanes separate any two points (with a level of accuracy depending on ε). It was shown in [6] that an ε-approximation can also be used to estimate how many vertices of the arrangement formed by X lie within a given simplex: this feature is essential in the recent work on point location [6], convex hull [7], and weak ε-nets for convex sets [8].

We generalize this idea by introducing the notion of a *product range space*. We discuss the problem of sampling such a space, and we explain the apparent paradox that product range spaces can be sampled even though they may have unbounded VC-dimension. We prove that the product of finite VC-dimensional range spaces can be sampled almost as efficiently as the original spaces, meaning that they admit ε-approximations and ε-nets of a size polynomial in $1/\varepsilon$ and, most importantly, independent of the size of the range spaces. We specialize these sampling theorems to a geometric setting, and we build tools for numerically integrating functions defined over the vertices of an arrangement of hyperplanes.

We also introduce the notion of *sensitive* sampling. Formally, we say that a subset $A \subseteq X$ is a *sensitive ε-approximation* for Σ if

$$\left| \frac{|R|}{|X|} - \frac{|R \cap A|}{|A|} \right| \leq \frac{\varepsilon}{2}\left(\sqrt{\frac{|R|}{|X|}} + \varepsilon\right)$$

for every set R in $\mathcal{R}$. The bound on the right-hand side may appear strange, but it arises naturally from what we expect of a random sample. Observe that a sensitive ε-approximation is at once both an ε-approximation and an ε^2-net. For a set system with finite VC-dimension d, we show the existence of a sensitive ε-approximation of size $O(d\varepsilon^{-2}\log(d\varepsilon^{-1}))$. We also modify an algorithm of [10] for computing ε-approximations so that it computes sensitive ε-approximations. If the underlying range space Σ has VC-dimension d, then, under standard computational assumptions given in section 2, a sensitive $(1/r)$-approximation of size $O(dr^2\log(dr))$ can be computed in time $O(d)^{3d}r^{2d}\log^d(dr)|X|$. This gives an algorithm for computing a $(1/r)$-net of size $O(dr\log(dr))$ for $(X, \mathcal{R})$ in time $O(r^d\log^d r)|X|$ time, which significantly improves on the bound $O(r^{2d}\log^d r)|X|$ given in [10].

In a preliminary version of this paper, we also claimed an $O(n\log^3 n)$-time algorithm for deterministically computing the diameter of n points in 3-space. This part contained an error (kindly pointed out to us by E. Ramos). In the meantime, a simpler deterministic algorithm with the same time complexity was found by Amato, Goodrich, and Ramos [3]. They use ideas akin to ours, but they use sampling over a different geometric range space $(X, \mathcal{R}')$ that contains ours: given a set X of hyperplanes, a range in $\mathcal{R}'$ consist of all the hyperplanes of X that intersect a given simplex of any dimension. We refer to their paper for a correct description of the algorithm. For further developments in the derandomization of geometric algorithms, we also refer to [4, 5].

2. Terminology and sampling theorems. In this section we consider general range spaces. First we review standard definitions and facts [17, 20]. A range space is a set system (or equivalently, a hypergraph), whose elements are called *points* and whose sets are called *ranges.* Let $\Sigma = (X^*, \mathcal{R}^*)$ be a (possibly infinite) range space. If $Y \subseteq X^*$, we denote by $(Y, \mathcal{R}^*|_Y)$ the *subspace induced by* Y, where $\mathcal{R}^*|_Y = \{\, R \cap Y : R \in \mathcal{R}^* \,\}$. A subset $Y \subseteq X^*$ is *shattered* (by $\mathcal{R}^*$) if $\mathcal{R}^*|_Y = 2^Y$. The maximum size of any shattered subset of X^* is called the VC-dimension of Σ; note that it can be infinite. We define the *shatter function* π_Σ of Σ as follows: $\pi_\Sigma(m)$ is the maximum possible number of sets in the subsystem of $(X^*, \mathcal{R}^*)$ induced by any m-point subset of X^*. It is well known that the shatter function of a range space of VC-dimension d is bounded $\Phi(m, d) = \binom{m}{0} + \cdots + \binom{m}{d}$, which is less that $m^d + 1$ (see, for instance, [2]). Conversely, if the shatter function is bounded by a polynomial, then the VC-dimension is bounded by a constant.

In practice, we usually deal with finite subsystems of a range space. Let X be a finite subset of X^*, and let $\mathcal{R}$ be a shorthand for $\mathcal{R}^*|_X$; by abuse of terminology we still call the pair $(X, \mathcal{R})$ a range space. As we mentioned earlier, given any $0 < \varepsilon < 1$, a subset $A \subseteq X$ is called an ε-approximation for the range space $(X, \mathcal{R})$ if

$$\left| \frac{|R|}{|X|} - \frac{|R \cap A|}{|A|} \right| \leq \varepsilon$$

for each $R \in \mathcal{R}$. A subset $N \subseteq X$ is an ε-net for $(X, \mathcal{R})$ if $|R| > \varepsilon |X|$ implies that $R \cap N \neq \emptyset$. An ε-approximation is also an ε-net, but the converse is false in general.

For instance, consider the range space $(X^*, \mathcal{R})$ mentioned in the introduction, where X^* is a set of hyperplanes in $\mathbb{R}^d$ and $\mathcal{R}^*$ is the collection of all the subsets of X^* consisting of the hyperplanes stabbed by a given line segment. Pick a finite subset X of m hyperplanes. Then it can be easily verified that the subsets of X^* consisting of the hyperplanes stabbed by two line segments are identical if the endpoints of the segments can be paired up so that a pair lie in the same cell of the arrangement of X. There are $O(m^d)$ such cells, therefore the shatter function $\pi_\Sigma(m)$ of $(X^*, \mathcal{R})$ is bounded above by $O(m^{2d})$. This in turn implies that the range space has finite VC-dimension.

Efficient deterministic constructions of ε-nets and ε-approximations were given in [20] for the particular range space described above; see also [10] for slightly simpler proofs that are expressed in terms of general range spaces. Let d be the VC-dimension of Σ, or for that matter, any constant such that $\pi_\Sigma(m) = O(m^d)$. We assume that the range space admits a *subsystem oracle of dimension* d, meaning that, given any $Y \subseteq X$, all the sets of $\mathcal{R}|_Y$ can be computed explicitly in time $O(|Y|^{d+1})$. This assumption is justified in practice, as can be checked for instance on the range space given above: one may simply construct the arrangement of Y, choose a point inside each cell, and each pair of points yields a segment s and a range R_s of the hyperplanes stabbed by s; moreover, each range is enumerated exactly once in this process. Given any $r > 1$, one can in time $O(d)^{3d} r^{2d} \log^d(dr)|X|$ compute a $(1/r)$-approximation for $(X, \mathcal{R})$ of size $O(dr^2 \log(dr))$ and a $(1/r)$-net of size $O(dr \log(dr))$. These time bounds are linear in $|X|$ if r is a constant.

2.1. Sensitive approximations. Let $\Sigma = (X, \mathcal{R})$ be a range space of a dimension bounded by a constant d. It is known that if one wants to get a $(1/r)$-approximation for Σ, it suffices to pick a random sample $A \subseteq X$ of size $O(r^2 \log r)$. Such a sample, however, has still better approximation properties if we are only interested in small ranges. The fact that A is, with high probability, a $(1/t)$-net for Σ

with t being almost r^2 can be seen as a manifestation of this phenomenon. If we look at the dependence of the error with which a random sample approximates a range on the size of that range, we arrive at the following definition. A subset $A \subseteq X$ is a sensitive ε-approximation for Σ if

$$\left| \frac{|R|}{|X|} - \frac{|R \cap A|}{|A|} \right| \leq \frac{\varepsilon}{2} \left(\sqrt{\frac{|R|}{|X|}} + \varepsilon \right)$$

for every set $R \in \mathcal{R}$. In [5], it is shown that a random sample of size $O(dr^2 \log(dr))$ possesses the sensitive $(1/r)$-approximation property. It follows from the definition that a sensitive ε-approximation is an ε-approximation as well as an ε^2-net. By this observation the next result gives an immediate improvement over the $O(d)^{3d} r^{2d} \log^d(dr)|X|$-time construction of a $(1/r)$-net given in [20], while at the same time keeping the same size bound.

THEOREM 2.1. *Let $(X, \mathcal{R})$ be a range space with a subsystem oracle of dimension d. Given any $r > 1$, in time $O(d)^{3d} r^{2d} \log^d(dr)|X|$ one can compute a sensitive $(1/r)$-approximation for $(X, \mathcal{R})$ of size $O(dr^2 \log(dr))$.*

COROLLARY 2.2. *Let $(X, \mathcal{R})$ be a range space with a subsystem oracle of dimension d. Given any $r > 1$, in time $O(d)^{3d} r^d \log^d(dr)|X|$ one can compute a $(1/r)$-net for $(X, \mathcal{R})$ of size $O(dr \log(dr))$.*

Proof of Theorem 2.1. We begin with a restriction of Theorem 2.1 to the case where ε is very small. We then adapt a recursive construction given in [10] to generalize this result and establish the theorem.

LEMMA 2.3. *Let $(X, \mathcal{R})$ be a range space of finite VC-dimension, where $|X| = n$ is even and large enough, and let $m = |\mathcal{R}|$. In $O(nm)$ time it is possible to compute a sensitive ε-approximation for $(X, \mathcal{R})$ of size $n/2$ for $\varepsilon = 15\sqrt{\ln(6m+6)/n}$.*

Proof. We select a random sample $A_1 \subseteq X$ of expected size $n/2$ by picking every element independently with probability $1/2$. Tail estimates show that A_1 (or its complement $X \setminus A_1$) has the sensitive ε-approximation property with high probability, to be made precise below. To obtain an approximation of size exactly $n/2$, we then show how to trim some elements from the bigger of A_1 and $X \setminus A_1$ while keeping the trimmed set a sensitive ε-approximation.

Given $0 < p < 1$, let $x_1, \ldots, x_n$ be independent random variables, each equal to $p-1$ with probability p, respectively, equal to p with probability $1-p$. The following tail estimate can be found in [2]:

$$\text{Prob}\left[\left| \sum_{i=1}^{n} x_i \right| > \Delta \right] < 2e^{-2\Delta^2/n}.$$

Select a subset $A_0 \subseteq X$ by picking each element of X with probability p. Define an auxiliary function

$$\Delta(x) = \sqrt{x \ln(6m+6)/2},$$

and let $\mathcal{R}' = \mathcal{R} \cup \{X\}$. Given $R \in \mathcal{R}'$, the previous tail estimate indicates that, for our choice of Δ, the following holds with a probability greater than $1 - 1/(3m+3)$:

$$\left| |R \cap A_0| - p|R| \right| \leq \Delta(|R|). \tag{2.1}$$

Assume that A_0 satisfies (2.1) for each $R \in \mathcal{R}'$. We call such a subset *p-good* for $(X, \mathcal{R}')$: note that a random A_0 is p-good with probability of at least $2/3$. Set

$p = 1/2$, and let A_1 be the larger of the two sets A_0 and $X \setminus A_0$. Trivially, A_1 consists of at least $n/2$ elements and is p-good. As an effect of adding X as a range, A_1 also has little more than $n/2$ elements, namely, at most $n/2 + \Delta(n)$.

We now want to remove some elements from A_1 so that it has exactly $n/2$ elements (this exact halving will be convenient in the forthcoming algorithm). If our goal was an ε-approximation only, we could remove an appropriate number of elements quite arbitrarily (as it is done in [20]). Removing arbitrary elements could, however, destroy the sensitive ε-approximation properties for small ranges, so we choose the elements to remove more carefully—we use a suitable random sample from A_1.

Let $q = 4\Delta(n)/n$; note that the finite VC-dimension hypothesis implies $m = n^{O(1)}$, so $q < 1$ for n large enough. With probability of at least $2/3$, a random sample $A_2 \subseteq A_1$ (with each element chosen independently with probability q) is a *q-good* subset for $(A_1, \mathcal{R}'|_{A_1})$. For such an A_2, since $A_1 = X \cap A_1$ is a range in $\mathcal{R}'|_{A_1}$, we have

$$|A_2| \geq q|A_1| - \Delta(|A_1|) \geq \frac{qn}{2} - \Delta(n) \geq \Delta(n) \geq |A_1| - \frac{n}{2},$$

and therefore we can pick $|A_1| - n/2$ elements in A_2 (any of them) and remove them from A_1, thus producing a subset $A \subseteq X$ of size $n/2$.

Note that our probabilistic construction of A can be derandomized in a straightforward fashion by using the method of conditional probabilities of Alon and Spencer [2], Raghavan [23], and Spencer [24]. With a little care, this can be accomplished in $O(nm)$ time; see [3, 20] for a similar construction.

It remains to show that A is a sensitive ε-approximation for $(X, \mathcal{R})$ for a choice of $\varepsilon = 15\sqrt{\log(6m+6)/n}$. We have

$$\begin{aligned}\left| |R \cap A| - \frac{|R|}{2} \right| &\leq \Big| |R \cap A| - |R \cap A_1| \Big| + \left| |R \cap A_1| - \frac{|R|}{2} \right| \leq |R \cap A_2| + \Delta(|R|) \\ &\leq q|A_1 \cap R| + 2\Delta(|R|) \leq \frac{q|R|}{2} + (q+2)\Delta(|R|)\,.\end{aligned}$$

As $q < 1$ for n large enough and $q|R|/2 = 2|R|\Delta(n)/n \leq 2\Delta(|R|)$, we obtain $\Big||R \cap A| - |R|/2\Big| \leq 5\Delta(|R|)$, and hence,

$$\left| \frac{|R \cap A|}{|A|} - \frac{|R|}{n} \right| \leq \frac{2}{n}\, 5\Delta(|R|) = \frac{10}{n}\sqrt{|R| \ln(6m+6)/2} \leq \frac{\varepsilon}{2}\sqrt{\frac{|R|}{n}},$$

which proves Lemma 2.3. □

Sensitive approximations can be *refined* (Lemma 2.4) and *composed* (Lemma 2.5) in a fashion similar to standard ε-approximations [10].

LEMMA 2.4. *If A is a sensitive ε-approximation for a range space $(X, \mathcal{R})$ and B is a sensitive δ-approximation for $(A, \mathcal{R}|_A)$, then B is a sensitive $(\varepsilon + 2\delta)$-approximation for $(X, \mathcal{R})$.*

Proof. Consider a range $R \in \mathcal{R}$. For short, we write $\rho_X = |R|/|X|$, $\rho_A = |R \cap A|/|B|$, $\rho_B = |R \cap B|/|B|$. We have

$$|\rho_X - \rho_B| \leq |\rho_X - \rho_A| + |\rho_A - \rho_B| \leq \frac{\varepsilon}{2}\left(\sqrt{\rho_X} + \varepsilon\right) + \frac{\delta}{2}\left(\sqrt{\rho_A} + \delta\right)$$

by the definition of a sensitive ε-approximation. We estimate

$$\sqrt{\rho_A} \leq \sqrt{\rho_X + \frac{\varepsilon}{2}\left(\sqrt{\rho_X} + \varepsilon\right)} \leq \sqrt{\rho_X} + \sqrt{\frac{\varepsilon}{2}\left(\sqrt{\rho_X} + \varepsilon\right)} \leq \sqrt{\rho_X} + \frac{\varepsilon/2 + \sqrt{\rho_X} + \varepsilon}{2}\,,$$

where we used the AG-mean inequality $\sqrt{ab} \le (a+b)/2$ in the last step. With this estimate, we calculate

$$|\rho_X - \rho_B| \le \frac{\varepsilon}{2}\left(\sqrt{\rho_X} + \varepsilon\right) + \frac{\delta}{2}\left(\frac{3}{2}\sqrt{\rho_X} + \frac{3}{4}\varepsilon + \delta\right) \le \frac{\varepsilon + 2\delta}{2}\left(\sqrt{\rho_X} + \varepsilon + 2\delta\right).$$

Since this is true for any $R \in \mathcal{R}$, the proof is complete. ∎

LEMMA 2.5. *Let $(X, \mathcal{R})$ be a range space, and let $\{X_i\}_{1 \le i \le m}$ be a partition of X into m equal-size subsets. If A_i is a sensitive ε-approximation for $(X_i, \mathcal{R}|_{X_i})$ and all the A_i's have the same size, then $A = \cup_i A_i$ is a sensitive ε-approximation for $(X, \mathcal{R})$.*

Proof. Consider any range $R \in \mathcal{R}$. For short, we put $\rho_{X_i} = |R \cap X_i|/|X_i|$, $\rho_{A_i} = |R \cap X_i|/|X_i|$, $\rho_X = |R|/|X|$, and $\rho_A = |R \cap A|/|A|$. Since the X_i's are disjoint, we have $\rho_X = \frac{1}{m}\sum_{i=1}^m \rho_{X_i}$ and $\rho_A = \frac{1}{m}\sum_{i=1}^m \rho_{A_i}$, where the factor $\frac{1}{m}$ accounts for the difference in the denominators of ρ_X and the ρ_{X_i}'s. Therefore,

$$|\rho_X - \rho_A| \le \frac{1}{m}\sum_{i=1}^m |\rho_{X_i} - \rho_{A_i}| \le \frac{\varepsilon}{2}\left(\frac{1}{m}\sum_{i=1}^m \sqrt{\rho_{X_i}} + \varepsilon\right) \le \frac{\varepsilon}{2}\left(\sqrt{\rho_X} + \varepsilon\right),$$

where the last inequality follows by the concavity of the square root function. ∎

We are now ready to build a sensitive $(1/r)$-approximation for any value of r. The algorithm is almost identical to the construction of nonsensitive ε-approximations given in [10]. We begin with a simplifying observation. If $n = |X|$ is not a power of two, let us pad X by adding up to $n-1$ artificial points so as to obtain a power of two. This gives us a new range space $\Sigma' = (X \cup X_0, \mathcal{R} \cup \{X_0\})$; note that the set X_0 of artificial points is added as a range. Let A be a sensitive $(\varepsilon/6)$-approximation for this new range space. It is not hard to show that $B = X \cap A$ is a sensitive ε-approximation for $(X, \mathcal{R})$. Here are the details: Given any $R \in \mathcal{R}$, we have

$$\begin{aligned}\left|\frac{|R|}{|X|} - \frac{|R \cap B|}{|B|}\right| &= \frac{|X \cup X_0|}{|X|}\left|\frac{|R|}{|X \cup X_0|} - \frac{|R \cap B|}{|B|} \cdot \frac{|X|}{|X \cup X_0|}\right| \\ &\le 2\left(\left|\frac{|R|}{|X \cup X_0|} - \frac{|R \cap B|}{|A|}\right| + \frac{|R \cap B|}{|B|}\left|\frac{|X|}{|X \cup X_0|} - \frac{|B|}{|A|}\right|\right). \qquad (2.2)\end{aligned}$$

Using the sensitive $(\varepsilon/6)$-approximation property of A, we get that the difference in the first absolute value is at most $\frac{\varepsilon}{12}\left(\sqrt{|R|/|X|} + \varepsilon/6\right) \le \varepsilon/6$, and so is the difference in the second absolute value. Substituting this and the trivial estimate $|R \cap B|/|B| \le 1$ into (2.2), we obtain

$$\frac{|R \cap B|}{|B|} \le \frac{|R|}{|X|} + \frac{2\varepsilon}{3}.$$

Substituting this improved upper bound into (2.2) then yields

$$\left|\frac{|R|}{|X|} - \frac{|R \cap B|}{|B|}\right| \le \frac{\varepsilon}{2}\left(\sqrt{\frac{|R|}{|X|}} + \varepsilon\right),$$

which shows that B is a sensitive ε-approximation. This allows us to assume that n is now a power of two.

We begin with one piece of terminology. Applying Lemma 2.3 to an even-sized subset $Y \subseteq X$ is called *halving* Y. Note that this results in a sensitive $h(|Y|)$-approximation, where

$$h(t) = 15\sqrt{\log(6t^d + 6)/t}.$$

It is easy to see that if $t = \Omega(d \log d)$, we have $h(t) < 1$ and $h(2t) \le \frac{3}{4}h(t)$. Moreover, it is also not hard to show that $h(dr^2 \log(dr)) = O(1/r)$ for any $r > 1$. We are now ready to describe the algorithm for constructing a sensitive $(1/r)$-approximation for $(X, \mathcal{R})$.

To begin, we divide up the set X into subsets of size 2^k (for some appropriate parameter k) and we associate each subset with the leaves of a complete binary tree. Next, we process the tree bottom-up level by level. At each internal node, we merge together the two sets associated with its children, and if the level of the node is not divisible by $d + 2$ (leaves being at level 0), we halve the union. The resulting set is *associated* with the node in question. Once the tree is completely processed, i.e., the set associated with its root has been computed, we say that the first phase is over and we move on to the second phase. We take the set associated with the root and we keep halving it until its size is equal to $c_1 dr^2 \log(dr)$ for some appropriate constant $c_1 > 0$.

The union of all the sets associated with the nodes at level i constitutes a sensitive ε_i-approximation for some ε_i, which we call the *error* at level i. During the first $d+1$ levels, each individual set remains of size 2^k (since halving and merging alternate). Note that halving is applied to sets of size 2^{k+1}. By Lemmas 2.4 and 2.5, the total error after the first $d + 1$ levels is $2(d + 1)h(2^{k+1})$. At level $d + 2$, no additional error is incurred since we skip the halving step. The next $d + 1$ steps are similar to the first batch of $d + 1$, except that the size of the individual sets has now doubled; thus, the total error incurred up to level $2d+3$ is $2(d+1)\left(h(2^{k+1}) + h(2^{k+2})\right)$. From level to level, the error follows a geometrically decreasing series, so the total error incurred at the end of the first phase is $O(d) \times h(2^k)$. If we choose $2^k = c_2 d^3 r^2 \log(dr)$, for some constant c_2 large enough, this makes the error at most $1/2r$. In the second phase, the error is still bounded by a geometrically increasing series whose last term is $O(h(c_1 dr^2 \log(dr)))$, meaning that the additional error contributed by the second phase is $O(h(c_1 dr^2 \log(dr)))$. Choosing c_1 large enough keeps this error under $1/2r$. Combining the two phases shows that the final set, which is of the desired size $O(d)r^2 \log(dr)$, is a sensitive $(1/r)$-approximation for $(X, \mathcal{R})$.

What is the running time of the algorithm? In the first halving step, we apply Lemma 2.3 to $|X|/2^k$ sets of size $2^k = O(d^3)r^2 \log(dr)$ each; the total time needed for these operations is $O(d)^{3d} r^{2d} \log^d(dr)|X|$. In the next $d + 1$ halving steps, the sets remain of the same size but their numbers decrease geometrically. Thus, the cost of processing the first level is dominant. At level $d + 2$, the size of each individual set doubles, which increases the cost of applying Lemma 2.3 by a factor of 2^{d+1}, but the $(d + 2)$ previous merging steps in the previous round have reduced the total number of sets by 2^{d+2}, so the running time of the following round is at most half of the time for a previous round. Similarly, in the second phase, the running time follows a geometrically decreasing sequence at each step. Thus, the total running time of the algorithm is $O(d)^{3d} r^{2d} \log^d(dr)|X|$, and the proof of Theorem 2.1 is complete. □

2.2. Product range spaces. Let $\Sigma_1 = (X, \mathcal{R})$ and $\Sigma_2 = (Y, \mathcal{S})$ be (finite) range spaces. We define the product range space $\Sigma_1 \otimes \Sigma_2$ to be $(X \times Y, \mathcal{T})$, where $\mathcal{T}$ consists

of all subsets $T \subseteq X \times Y$ such that all the *cross-sections* $S_x = \{ y \in Y : (x, y) \in T\}$ are sets of $\mathcal{S}$, and similarly, all $R_y = \{ x \in X : (x, y) \in T\}$ are sets of $\mathcal{R}$.

To illustrate this definition, consider the bichromatic arrangement of n red and n blue lines in $\mathbb{R}^2$. Ranges of the blue (resp., red) space consist of blue (resp., red) lines that intersect a given line segment. The product $\Sigma_1 \otimes \Sigma_2$ of the blue space by the red space is a range space $(Z, \mathcal{T})$, where Z consists of all the bichromatic intersections. A range is a subset T of Z such that the intersections in T that are incident upon any given line appear consecutively (among those of Z). For example, the bichromatic intersections that fall inside any convex set constitute a range. This suggests that the product of finite VC-dimensional spaces might not be itself of finite VC-dimension. Indeed, this can best be seen by observing that in our example, any bichromatic pairing of the lines gives a collection of n bichromatic intersections and that *any* of its 2^n subsets is a valid range!

THEOREM 2.6. *Let $\Sigma_1 = (X, \mathcal{R})$ and $\Sigma_2 = (Y, \mathcal{S})$ be two range spaces. If A (resp., B) is a δ-approximation (resp., ε-approximation) for Σ_1 (resp., Σ_2) for $0 \leq \delta, \varepsilon, \leq 1$, then $A \times B$ is a $(\delta + \varepsilon)$-approximation of $\Sigma_1 \otimes \Sigma_2$.* It is worth observing that even though an ε-approximation of a product space is of size $O(\varepsilon^{-4} \log^2 \varepsilon^{-1})$, its representation as a set product has size of only $O(\varepsilon^{-2} \log \varepsilon^{-1})$.

A range space of infinite VC-dimension has, for infinitely many n, a shattered subset A of size n, and clearly an ε-approximation for the subspace induced by such A must be of size at least $(1 - \varepsilon)n$. This might seem to contradict Theorem 2.6. To explain this apparent paradox, we must observe that, in general, a subspace of a product range space is not itself a product range space. In particular, even though the ground set contains very large shattered subsets, the subsystems induced by these subsets are not product range spaces; therefore, the fact that they cannot be sampled has no bearing on Theorem 2.6. In fact, the proper definition of a subspace in the context of product range spaces would be the product of subspaces of standard range spaces.

Proof of Theorem 2.6. Given two range spaces of finite VC-dimension, $\Sigma_1 = (X, \mathcal{R})$ and $\Sigma_2 = (Y, \mathcal{S})$, recall that the product $\Sigma_1 \otimes \Sigma_2$ is defined as $(Z, \mathcal{T})$, where $Z = X \times Y$ and $\mathcal{T}$ consists of all the subsets $T \subseteq Z$ such that for any $x \in X$ and $y \in Y$ the sets T^x and T_y are ranges of $\mathcal{S}$ and $\mathcal{R}$, resp., where

$$T^x = \{ y : (x, y) \in \mathcal{T} \},$$

$$T_y = \{ x : (x, y) \in \mathcal{T} \}.$$

As we observed, $\Sigma_1 \otimes \Sigma_2$ usually does not have finite VC-dimension. For example, if Σ_1 and Σ_2 are the (infinite) range spaces defined by two secant lines and their intervals, the product space ranges include all the convex regions of the plane.

It is helpful to use a slightly different formulation of an ε-approximation. Let Prob_X be a probability distribution on X, and $\mathrm{Prob}_X[\, R \,|\, A \,]$ be the conditional probability that a random element in X belongs to R, given that it is in A. Thus, for A to be a δ-approximation for Σ_1, it is equivalent to say that, for every $R \in \mathcal{R}$,

$$|\, \mathrm{Prob}_X[\, R \,|\, A \,] - \mathrm{Prob}_X[R] \,| \leq \delta \,.$$

A simple technical observation will greatly simplify our discussion below. In essence, it is nothing more than Fubini's theorem and asserts that we can sum the probabilities

first on x then on y, or first on y then on x, and obtain the same result. To put it in mathematical notation, given any $A \subseteq X$, $B \subseteq Y$, and $T \in \mathcal{T}$, we have

$$\mathrm{Prob}_Z\,[\,T \,|\, A \times B\,] = \begin{cases} \mathbf{E}_X\,[\,\mathrm{Prob}_Y\,[\,T^x \,|\, B\,]\,|\,A\,], \\ \mathbf{E}_Y\,[\,\mathrm{Prob}_X\,[\,T_y \,|\, A\,]\,|\,B\,], \end{cases}$$

where $\mathbf{E}_X[\cdot|A]$ denotes the expectation for a random element of X given that the element belongs to A, and $\mathbf{E}_Y[\cdot|B]$ is the analogous conditional expectation on Y. To prove Theorem 2.6, we apply this observation twice. Recall that A (resp., B) is a δ-approximation (resp., ε-approximation) of Σ_1 (resp., Σ_2); then

$$\begin{aligned} \mathrm{Prob}_Z\,[\,T \,|\, A \times B\,] &= \mathbf{E}_X\,[\,\mathrm{Prob}_Y\,[\,T^x \,|\, B\,]\,|\,A\,] \\ &= \mathbf{E}_X\,[\,\mathrm{Prob}_Y\,[T^x]\,|\,A\,] + \varepsilon' \\ &= \mathbf{E}_Y\,[\,\mathrm{Prob}_X[\,T_y \,|\, A\,]\,] + \varepsilon' \\ &= \mathbf{E}_Y\,[\,\mathrm{Prob}_X\,[T_y]\,] + \delta' + \varepsilon' \\ &= \mathrm{Prob}_Z\,[T] + \delta' + \varepsilon', \end{aligned}$$

where $|\varepsilon'| \le \varepsilon$, $|\delta'| \le \delta$, which completes the proof of Theorem 2.6. □

A similar result exists for sensitive approximations, but the formulas are a little more complicated. It is easy to show, however, that the product of a sensitive δ-approximation with a sensitive ε-approximation is a sensitive $\sqrt{2}(\delta + \varepsilon)$-approximation [5].

Finally, we should note that the product described here is associative. We can thus take the d-fold product $\Sigma \otimes \cdots \otimes \Sigma$ of a range space $\Sigma = (X, \mathcal{R})$. Theorem 2.6 may be extended straightforwardly.

COROLLARY 2.7. *If A is an ε-approximation for a range space Σ, then the d-fold Cartesian product A^d is a $(d\varepsilon)$-approximation of the d-fold product $\Sigma \otimes \cdots \otimes \Sigma$.* For sensitive approximations, the theorem can be extended similarly. It is easy to show that the d-fold product of a sensitive ε-approximation is a sensitive $(d^2\varepsilon)$-approximation [5].

Let us show, for instance, how to use this range space product to estimate the number of vertices of an arrangement of hyperplanes inside a convex region. The range space $\Sigma = (X, \mathcal{R})$ under consideration here is the one described above: given a set H of hyperplanes in $\mathbb{R}^d$, $\mathcal{R}$ is the collection of all the subsets of H consisting of the hyperplanes stabbed by a given line segment. We let Σ^d be the d-fold product of Σ. Of particular interest is the subset $H^{(d)}$ of H^d consisting of the d-tuples of hyperplanes of H in general position: such d-tuples intersect in a unique point of $\mathbb{R}^d$ which is a vertex of the arrangement of H. Let us denote by $V(H)$ the set of these vertices. For a convex region σ (not necessarily full-dimensional), consider the arrangement of the intersections of hyperplanes of H with the affine hull of σ, and let $V(H, \sigma)$ be the set of vertices of this arrangement lying inside σ.

THEOREM 2.8. *Let H be a set of hyperplanes in general position, and let A be an ε-approximation for $\Sigma = (H, \mathcal{R})$. Then, for any convex region σ of dimension j in $\mathbb{R}^d$,*

$$\left| \frac{|V(H,\sigma)|}{|H|^j} - \frac{|V(A,\sigma)|}{|A|^j} \right| \le \varepsilon.$$

Proof. This theorem was already shown in [6] for the particular case of simplices. The proof in terms of range space products is particularly simple. We may assume

that σ is d-dimensional; otherwise the result may be proved by considering the j-fold product of Σ.

Let $(h_1, \ldots, h_d)$ be a d-tuple in $H^{(d)}$, and let $f(h_1, \ldots, h_d) = h_1 \cap \ldots \cap h_d$ be the corresponding vertex of $V(H)$. Note that because the hyperplanes are in general position, f is a $d!$ to one map.

Given any convex region σ, the inverse image $T = f^{-1}(V(H, \sigma))$ is a range in Σ^d. Indeed, it suffices to prove that its sections $T^i_{(h_1,\ldots,h_d)}$ consisting of the hyperplanes h such that $(h_1, \ldots, h_{i-1}, h, h_{i+1}, \ldots, h_d)$ is in T are exactly the hyperplanes stabbed by some segment s in $\mathbb{R}^d$. Note that $\cap_{j \neq i} h_j$ is a line in $\mathbb{R}^d$ and that it intersects σ along such a segment s. Moreover, a d-tuple $(h_1, \ldots, h_{i-1}, h, h_{i+1}, \ldots, h_d)$ is in T if and only if h is stabbed by the line segment s.

Finally, we note that the size of $T = f^{-1}(V(H, \sigma))$ is $d!$ times the number of vertices of $V(H, \sigma)$. Using Corollary 2.7, we conclude that

$$\left| \frac{|V(H,\sigma)|}{|H|^d} - \frac{|V(A,\sigma)|}{|A|^d} \right| \leq \frac{d\varepsilon}{d!} \leq \varepsilon. \qquad \square$$

A similar result can be proved for sensitive approximations, with slightly worse approximation bounds. For instance, it is proved in [5] that

$$\left| \frac{|V(H,\sigma)|}{|H|^j} - \frac{|V(A,\sigma)|}{|A|^j} \right| \leq \frac{4\varepsilon}{2} \left(\sqrt{\frac{|V(H,\sigma)|}{|H|^j}} + 4\varepsilon \right)$$

for a set H of hyperplanes in general position, an ε-approximation A for $\Sigma = (H, \mathcal{R})$, and any convex region σ of dimension j in $\mathbb{R}^d$.

3. Computing convex hulls. We describe a new deterministic algorithm for computing the convex hull of n points. Its running time of $O(n \log n + n^{\lfloor d/2 \rfloor})$ is optimal in any fixed dimension d. Our strategy is similar to the derandomization scheme used in [7]. In particular, it is still built around Raghavan's [23], Spencer's [24], and Alon and Spencer's [2] methods of conditional probabilities. The main difference is in the underlying probabilistic model and the maintenance of approximation tools. The result is an algorithm that is arguably simpler.

The convex hull problem is reducible, by duality, to computing the intersection of n halfspaces. This problem can be solved in optimal expected time by a randomized incremental algorithm [13]: the halfspaces are inserted in random order, and the current intersection is maintained after each insertion.

We aim at derandomizing such an algorithm. For technical reasons, we use a slightly different randomized algorithm as a basis, to be described below.

3.1. Notation and preliminaries. Let H be a fixed collection of n hyperplanes in $\mathbb{R}^d$, and let O (the *origin*) be a given point not lying on any hyperplane of H. Using simulation of simplicity if necessary [16], we may assume that the hyperplanes of H are in general position. We also may enclose $\mathbb{R}^d$ in a box that contains all the vertices of the arrangement of H. The set H_0 of hyperplanes bounding this box is added to H. In what follows, when we let R be a subset of H, we assume that R is a subset of H that contains H_0. This ensures that we always deal with polytopes and not polyhedra and thus clears the issue of unboundedness.

Let R be a subset of H. We let $R^{\cap}$ denote the closure of the cell enclosing O of the arrangement of R. In what follows, the word "simplex" always means a *relatively*

open simplex. Similarly, the word "face" always means a relatively open face of a polytope or of an arrangement.

Given a simplex s, let $R_{|s}$ denote the subset of hyperplanes of R that intersect s but do not contain it.

Given a polytope P (such as $R^{\cap}$), we let $V(P)$ denote the set of vertices of P. If R is a set of hyperplanes, we let $V(R)$ be the set of vertices of the arrangement of R. For a simplex s (not necessarily full-dimensional), consider the arrangement of the intersections of hyperplanes of R with the affine hull of s, and let $V(R,s)$ be the set of vertices of this arrangement lying inside s.

For a vertex $v \in V(H)$, we define the *conflict list* of v, denoted $H_{|Ov}$, to be the set of hyperplanes separating v from the origin. The *level of* v, denoted by n_v, is the size of $H_{|Ov}$. Similarly we define the conflict list for a simplex s, denoted by $H_{|Os}$, as the set of hyperplanes of H intersecting the relative interior of the convex hull of $s \cup \{O\}$. We note that the conflict list of a simplex is the union of the conflict lists of its vertices. We set $n_s = |H_{|Os}|$ (but note that n_s and $|H_{|s}|$ may be different for simplices s on the boundary of $R^{\cap}$).

In our algorithm, we use a special kind of triangulation for $R^{\cap}$ called the *geode of* R that is denoted by $\mathcal{G}(R)$. Formal definitions and important properties are given in [7]. The geode consists of a triangulation of the boundary of $R^{\cap}$ along with a central lifting of that triangulation towards the origin O. The triangulation is defined recursively and is similar to the so-called *bottom vertex triangulation* [11]. To triangulate a face f of dimension k of $\partial R^{\cap}$, we first triangulate its faces of dimension $\le k-1$ and then we lift these triangulations to the *apex* of f, where the apex is the vertex contained in this face with the smallest conflict list (ties being broken using some systematic rule, such as taking the vertex with lexicographically smallest coordinate vector). The resulting geode contains $O(n^{\lfloor d/2 \rfloor})$ simplices, and the choice of the apex leads to the following property.

LEMMA 3.1 (see [7]). *For any integer c, and any $R \subseteq H$, there is a constant $b = b(c)$ such that for any $c' \le c$, we have*

$$\sum_{s \in \mathcal{G}(R)} n_s^{c'} \le b \sum_{v \in V(R^{\cap})} n_v^{c'}. \tag{3.1}$$

Proof. The proof is the same as in [7], but the result there is stated for $H_{|s}$ instead of n_s (even though the proof itself is actually stated in terms of n_s). We recall it for completeness.

We let $\bar{f}$ denote the closure of a face f of $R^{\cap}$. We prove by induction that, for any k-face of $R^{\cap}$, the sum $\sum_{s \in \mathcal{G}(R) \cap \bar{f}} n_s^c$, denoted A_f, is at most

$$k!(2^c+1)^k \sum_{v \in V(R^{\cap}) \cap \bar{f}} n_v^c \ .$$

The lemma follows from the case $k = d$, where f is the interior of $R^{\cap}$.

The case $k = 0$ is immediate, as the 0-faces of $R^{\cap}$ are precisely its vertices. Assume the induction hypothesis is true for some $k - 1 < d$. We observe that, by choosing the apex of f as the lifting vertex for the geode (or the origin, if $k = d$), $A_f \le (2^c+1) \sum_g A_g$, where g ranges over all the $(k-1)$-faces of $R^{\cap}$ incident upon f. The term 1 comes from the contribution of the faces incident upon f, while the term 2^c accounts (conservatively) for the effect of lifting g toward the apex w (or $w = O$ if $k = d$; note that $n_w \le n_s$ for any s contained in the closure of g, by definition

of w). By our general position assumption, a vertex cannot belong to more than k $(k-1)$-faces, so we cannot count it more than k times in the above sum ranging on g. Substituting for A_g with the induction hypothesis gives the result. ∎

In our algorithm and analysis, various constants will appear (dependent on d, as a rule). To avoid complicated implicit dependencies between them, we express most constants as functions of two basic parameters C and c. For all estimates to work, one first chooses c as a sufficiently large constant and then C as a still much larger constant. The $O()$ notation in the proofs may hide constants dependent on c (and d), but *not on* C; where the hidden constant does depend on C, we use the $O_C()$ notation.

We need an estimate for the higher moments of the binomial distribution.

LEMMA 3.2. *Let $X = X_{[1,n]} = X_1 + X_2 + \cdots + X_n$, where the X_i are independent random variables, each attaining value* 1 *with probability p and value* 0 *with probability $1-p$. Then for any natural number c, $\mathbf{E}[X^c] \le (c+np)^c$.*

This must be part of the folklore, but since we haven't discovered an explicit reference, we include a short proof.

Proof. We prove more generally that $\mathbf{E}[(X+a)^c] \le (c+np+a)^c$ for all natural numbers n, c, and a. The inequality is clear if $n = 0$ or $c = 0, 1$. Assuming this is true for some c and for all n and a, we derive by induction that

$$\begin{aligned}\mathbf{E}[(X+a)^{c+1}] &= \sum_{i=1}^{n} p\mathbf{E}[(X+a)^c | X_i = 1] + a\mathbf{E}[(X+a)^c] \\ &= np\mathbf{E}[(X_{[1,n-1]} + a + 1)^c] + a\mathbf{E}[(X+a)^c] \\ &\le np(c + (n-1)p + a + 1)^c + a(c+np+a)^c \\ &\le (c+1+np+a)^{c+1}. \qquad \blacksquare\end{aligned}$$

3.2. The underlying randomized algorithm. In our underlying randomized algorithm, hyperplanes are inserted in rounds. In the first round, a suitable constant number c of hyperplanes are chosen (arbitrarily, not necessarily at random) and inserted. Suppose that after the $(j-1)$st round, a set $R \subseteq H$ has been inserted, $|R| = r$. We assume a suitable representation of $\mathcal{G}(R)$, the geode of R. We also keep the conflict list of every simplex $s \in \mathcal{G}(R)$.

In the jth round, we fix a probability

$$p = \frac{2}{3}\,\frac{r}{n-r}$$

and we choose a random sample S from $H \setminus R$ by picking each hyperplane of $H \setminus R$ into S randomly and independently with probability p. For each simplex $s \in \mathcal{G}(R)$, we compute the portion of the arrangement of S lying within s; then we isolate the portion of $(R \cup S)^{\cap}$ within s from the portion of the arrangement, and we glue these pieces together, obtaining the facial lattice of $(R \cup S)^{\cap}$. Using the conflict lists of the vertices, we finally compute the geode $\mathcal{G}(R \cup S)$ and the conflict lists of its simplices.

The expected number of hyperplanes in S is $\frac{2}{3}r$, thus the size of R increases geometrically between rounds and the expected number of rounds is $O(\log n)$. When the number of hyperplanes in R exceeds n/c, we insert all the remaining hyperplanes of $H \setminus R$ (in a manner similar to adding a new sample S) and finish.

The work in the jth round of this algorithm is at most proportional to

$$\sum_{s \in \mathcal{G}(R)} \left(|S_{|Os}|^d + n_s \right) \tag{3.2}$$

(see also [7] for a more detailed description of the required computations and of their time complexity). Intuitively, we should expect the sizes n_s of the conflict lists to be about n/r and each $S_{|Os}$ to have about constant size. This is not quite true of *all* simplices in the randomized algorithm (and even less so in the derandomized version). However, as was observed by Clarkson in a somewhat different context [12], the averages of $|S_{|Os}|^c$ and of $\left(n_s \frac{r}{n}\right)^c$ over all simplices of $\mathcal{G}(R)$ are expected to be bounded by a constant in the randomized algorithm for any constant c, and this is what we will also aim at in the derandomized version. From this point of view, we might appropriately call the quantities $|S_{|Os}|$ and $n_s \frac{r}{n}$ *quasi constant*. To simplify the notation, we introduce the symbols

$$q_s = n_s \frac{r}{n} + 1\,,$$
$$r_s = |S_{|Os}| + 1\,.$$

The basic property of a quasi-constant quantity x_s is that its moment of order c is $\sum_{s\in\mathcal{G}(R)} x_s^c = O_C(1) r^{\lfloor d/2\rfloor}$ for a constant C that will be determined later. Note that this also implies the same property for the moments of order $c' \le c$ by a routine application of Hölder's inequality.

The rest of this section is devoted to proving that the above quantities q_s and r_s are expected to be quasi constant.

Following [7], we say that the geode of R is a *semicutting* if

$$\sum_{v\in V(R^\cap)} n_v^c \le N \stackrel{\text{def}}{=} C r^{\lfloor d/2\rfloor} \left(\frac{n}{r}\right)^c .$$

Again, a routine application of Hölder's inequality shows that

$$\sum_{v\in V(R^\cap)} n_v^{c'} \le C r^{\lfloor d/2\rfloor} \left(\frac{n}{r}\right)^{c'}$$

for any $0 \le c' \le c$. Note that the definition of semicutting involves only the conflict lists of the vertices and not of the simplices of the geode. This has no bearing on the analysis, however; recall from Lemma 3.1 that the particular triangulation of $R^\cap$ we use, the geode, is chosen in such a way that we also have

$$\sum_{s\in\mathcal{G}(R)} n_s^{c'} \le b \sum_{v\in V(R^\cap)} n_v^{c'}$$

for any $0 \le c' \le c$ and for some constant $b = b(c')$. Note that this implies that $\sum_{s\in\mathcal{G}(R)} q_s^{c'} = O_C(1) r^{\lfloor d/2\rfloor}$ and hence that q_s is quasi constant.

Inductively, we assume that the geode of R built in the previous rounds of the algorithm is a semicutting. For the sample S, we postulate the following conditions:

C1. $r/2 \le |S| \le r$.

C2. $\sum_{s\in\mathcal{G}(R)} r_s^c \le C^2 r^{\lfloor d/2\rfloor}$.

C3. The geode of $R \cup S$ is a semicutting.

As we will see shortly, the randomized algorithm yields these properties with high probability.[1]

[1] The reader might wonder why we look at high moments when the complexity of the randomized algorithm only involves n_s and the dth power of r_s. The reason is that in the derandomization, we need auxiliary computations whose complexity is a larger polynomial in q_s and r_s.

Corresponding to these properties, we introduce three functions measuring the quality of the sample S. We put

$$F_1(S) = \frac{1}{4r}\left(|S| - \frac{2}{3}r\right)^2,$$
$$F_2(S) = \frac{1}{C^2 r^{\lfloor d/2 \rfloor}} \sum_{s \in \mathcal{G}(R)} r_s^c,$$
$$F_3(S) = \frac{1}{N} \sum_{v \in V((R \cup S)^{\cap})} n_v^c .$$

Further we define the quantities

$$\mathcal{E}_j = \mathbf{E} F_j(S)$$

for $j = 1, 2, 3$, where the expectation is taken with respect to a random choice of S (it implicitly depends on R, which we consider fixed). We put $\mathcal{E} = \mathcal{E}_1 + \mathcal{E}_2 + \mathcal{E}_3$. The quantities $\mathcal{E}$ and $\mathcal{E}_j$ will be referred to as *energy* (for reasons more apparent later). We now bound $\mathcal{E}$.

LEMMA 3.3. *We have* $\mathcal{E}_1 \le 1/6$.

Proof. It is immediate that $\mathcal{E}_1 = \frac{\mathbf{var}\,|S|}{4r} = \left(\frac{n-r}{4r}\right) p(1-p) \le \frac{1}{6}$. □

LEMMA 3.4. *If the geode of R is a semicutting, then $\mathcal{E}_2 = O(1/C)$.*

Proof. Consider a simplex $s \in \mathcal{G}(R)$. The contribution of every hyperplane $h \in H_{|Os}$ to $|S_{|Os}|$ is a 0/1 random variable attaining value 1 with probability p, and so by Lemma 3.2 we have $\mathbf{E}\,|S_{|Os}|^c \le (c + p|H_{|Os}|)^c \le (c + pn_s)^c = O(q_s^c)$. Summing over all the simplices $s \in \mathcal{G}(R)$ shows that the expectation of $\sum_{s \in \mathcal{G}(R)} r_s^c = O(\sum_{s \in \mathcal{G}(R)} q_s^c)$. Using (3.1), the latter expression is $O(Cr^{\lfloor d/2 \rfloor})$, which proves the lemma. □

The next lemma concerns $\mathcal{E}_3$. Unlike the previous lemma, it does not assume that the geode of R is a semicutting; thus, no matter how "bad" R might be, a random S guarantees that the geode of $R \cup S$ is a semicutting (with high probability). This robustness property will be crucial: in the derandomized version, the computed R presumably won't be as good as a true random sample would be, but the error will not propagate between rounds, as each new round alone would suffice to produce a semicutting for *any* R provided that S is random or imitates a random sample well enough.

LEMMA 3.5. *Let $R \subset H$ be arbitrary, $c \le |R| = r \le n/c$, and let S be a random sample from $H \setminus R$ obtained by choosing each hyperplane independently with probability p. Then*

$$\mathcal{E}_3 = \frac{1}{N} \sum_{v \in V(H) \cap R^{\cap}} p^{d_v} (1-p)^{n_v} n_v^c = O(1/C)\,, \tag{3.3}$$

where d_v denotes the number of hyperplanes of $H \setminus R$ passing thru v.

Proof. For a vertex $v \in V(H) \cap R^{\cap}$, the probability of appearing as a vertex in $V((R \cup S)^{\cap})$ is equal to $p^{d_v}(1-p)^{n_v}$, and thus the middle sum in (3.3) is the expectation of

$$\sum_{v \in V((R \cup S)^{\cap})} n_v^c\,,$$

which equals $N\mathcal{E}_3$. Recall that $N = Cr^{\lfloor d/2 \rfloor}(n/r)^c$.

To prove the upper bound of $O(1/C)$, we consider another sample $\bar{S}$ drawn from $H \setminus R$ with probability $\bar{p} = p/2$. Let Q denote the quantity

$$\sum_{v \in V(H) \cap R^\cap} \bar{p}^{d_v} (1 - \bar{p})^{n_v} .$$

This sum is nothing more than the expected number of vertices of $(R \cup \bar{S})^\cap$, which is at most $\mathbf{E}\,|R \cup \bar{S}|^{\lfloor d/2 \rfloor} = O(r^{\lfloor d/2 \rfloor})$, using the upper bound theorem and Lemma 3.2. We estimate

$$\frac{1 - \bar{p}}{1 - p} \geq 1 + \frac{p}{2} \geq e^{p/4} \geq e^{r/8n} .$$

Then we rewrite

$$Q = \sum_v p^{d_v} 2^{-d_v} (1 - p)^{n_v} \left(\frac{1 - \bar{p}}{1 - p} \right)^{n_v} \geq 2^{-d} \sum_v p^{d_v} (1 - p)^{n_v} e^{n_v r/8n} . \tag{3.4}$$

We have

$$n_v^c = \left(\frac{8cn}{r} \right)^c \left(\frac{n_v r}{8cn} \right)^c \leq \left(\frac{8cn}{r} \right)^c e^{n_v r/8n} .$$

Substituting this estimate into the middle sum in (3.3) and comparing with the lower bound for Q in (3.4), we obtain

$$\sum_v p^{d_v} (1 - p)^{n_v} n_v^c \leq 2^d \left(\frac{8cn}{r} \right)^c Q = O((n/r)^c r^{\lfloor d/2 \rfloor}) = O(N/C). \qquad \square$$

Putting these three lemmas together shows that $\mathcal{E} < 1/2$ for a suitable choice of C. Using Markov's inequality, this shows that $F_1(S) + F_2(S) + F_3(S) < 1$ or that conditions C1–C3 are satisfied, with probability of at least $1/2$.

We can now finish the running time analysis of the randomized algorithm under the condition that at each round, the sample S picked by the algorithm satisfies conditions C1–C3. Indeed, the work in the jth round is given in (3.2). Due to condition C2, the first term of the inner sum adds up to $O_C(r^{\lfloor d/2 \rfloor})$ over all the simplices of the geode, while condition C3 implies that the second term adds up to $O_C(r^{\lfloor d/2 \rfloor}) \frac{n}{r} = O_C(n r^{\lfloor d/2 \rfloor - 1})$. Suppose that after the $(j-1)$st round, r hyperplanes have been inserted. The work in the jth round is then $O_C(r^{\lfloor d/2 \rfloor} + n r^{\lfloor d/2 \rfloor - 1})$. Finally, condition C1 implies that the size of the sample grows geometrically between rounds. Thus, if conditions C1–C3 are satisfied at every round, the total running time sums up as $O_C(n \log n + n^{\lfloor d/2 \rfloor})$.

In the derandomized algorithm, conditions C1–C3 will be fulfilled at all rounds. The total running time of the deterministic algorithm will thus be $O_C(n \log n + n^{\lfloor d/2 \rfloor})$ plus whatever time is needed to perform the deterministic computation of a suitable sample at each round.

The randomized algorithm does not check if the conditions are satisfied, however. Thus a bad sample at a given round could severely slow down the algorithm, however unprobable this may be. Nevertheless, the expected time of the algorithm is, by linearity of expectations, the sum of the expected times of all the rounds, and the expected time of a round is bounded by $O_C(r^{\lfloor d/2 \rfloor} + n r^{\lfloor d/2 \rfloor - 1})$, as shown by Lemmas 3.3–3.5. Therefore, the expected time of the randomized algorithm is $O_C(n \log n + n^{\lfloor d/2 \rfloor})$.

3.3. Derandomization—a first attempt. Let us first consider a straightforward derandomization of the above described algorithm by the Raghavan–Spencer method, recalling the basic strategy of that method and introducing some more notation. We are at the beginning of a round, with the geode of R as a semicutting, and we want to find $S \subseteq H \setminus R$ such that $F_1(S) + F_2(S) + F_3(S) \le 1$ (thus satisfying conditions C1–C3). We order the hyperplanes of $H \setminus R$ into a sequence $h_1, h_2, \dots, h_{n-r}$ (arbitrarily), and we process them one by one, deciding for each h_i whether to *accept* it (that is, to include it in S) or to *reject* it (not to include it in S).

Having processed $h_1, \dots, h_k$, let $S^{(k)}$ denote the set of accepted hyperplanes among them. We define the energies $\mathcal{E}_j^{(k)}$ as the conditional expectations

$$\mathcal{E}_j^{(k)} = \mathbf{E}\left(F_j(S) \,|\, S \cap \{h_1, \dots, h_k\} = S^{(k)}\right),$$

and $\mathcal{E}^{(k)}$ is again their sum. Further we let

$$\mathcal{E}_j^{(k|A)} = \mathbf{E}\left(F_j(S) \,|\, S \cap \{h_1, \dots, h_k\} = S^{(k)},\, h_{k+1} \in S\right)$$

measure what the energy would be after accepting h_{k+1}, and similarly we let

$$\mathcal{E}_j^{(k|R)} = \mathbf{E}\left(F_j(S) \,|\, S \cap \{h_1, \dots, h_k\} = S^{(k)},\, h_{k+1} \notin S\right)$$

measure what the energy would be after rejecting h_{k+1}.

The strategy dictated by the Raghavan–Spencer method is as follows: the hyperplane h_{k+1} is accepted or rejected, whichever decision gives a lower total energy $\mathcal{E}^{(k+1)}$. The key property of the energy is

$$\mathcal{E}^{(k)} = p\,\mathcal{E}^{(k|A)} + (1-p)\,\mathcal{E}^{(k|R)}. \tag{3.5}$$

This, together with the decision rule, implies that $\mathcal{E}^{(k+1)} \le \mathcal{E}^{(k)}$ for $k = 0, 1, \dots, n-r-1$; therefore, the final energy is at most 1, and since it equals $\sum_j F_j(S^{(n-r)})$ for the (already fixed) sample $S^{(n-r)}$, this sample will satisfy the required conditions.

The evaluation of $\mathcal{E}_1^{(k)}$ and $\mathcal{E}_2^{(k)}$ is easy (at least with a limited but sufficient accuracy) and requires no more time than the other operations of the randomized algorithm itself. On the other hand, $\mathcal{E}_3^{(k)}$ appears much more demanding, and we cannot evaluate it exactly, so we use a suitable approximation instead, denoted by $\mathcal{AE}_3^{(k)}$. The sum $\mathcal{AE}^{(k)} = \mathcal{E}_1^{(k)} + \mathcal{E}_2^{(k)} + \mathcal{AE}_3^{(k)}$ will be called the *approximate energy*.

Here is a rough outline of our strategy. We shall be careful to define $\mathcal{AE}_3^{(k)}$ in such a way that it obeys an equation analogous to (3.5). Then we apply the Raghavan–Spencer method with the approximate energy instead of the actual energy, producing a sample $S^{(n-r)}$ for which the approximate energy does not exceed the initial approximate energy $\mathcal{AE}^{(0)}$. To make everything work, we show the following lemma.

LEMMA 3.6. *For every* $k = 0, 1, \dots, n-r$, $|\mathcal{E}_3^{(k)} - \mathcal{AE}_3^{(k)}| < 1/3$.

The lemma is proved in the next section, where we explain how to compute the approximate energy. Using this for $k = 0$, together with $\mathcal{E}^{(0)} < 1/3$ (which follows from the results of section 3.2), we see that the initial approximate energy is smaller than 2/3 and hence so is the final approximate energy. This in turn implies that the final energy $\mathcal{E}^{(n-r)}$ is less than 1 and hence that the sample $S^{(n-r)}$ satisfies conditions C1–C3.

3.4. Approximating the energy. In this section we define the approximate energy $\mathcal{AE}_3^{(k)}$ and establish Lemma 3.6, assuming the existence of a certain oracle. The implementation of the oracle is discussed in the next section.

We begin by setting the initial value $\mathcal{AE}_3^{(0)}$. Consider the expression for $\mathcal{E}_3 = \mathcal{E}_3^{(0)}$ in (3.3). We split the sum according to the simplices of $\mathcal{G}(R)$ containing the respective vertices, and we get

$$\mathcal{E}_3^{(0)} = \frac{1}{N} \sum_{s\in\mathcal{G}(R)} \sum_{v\in V(H)\cap s} p^{d_v}(1-p)^{n_v} n_v^c \,.$$

By a suitable general position assumption, we may suppose that a j-dimensional simplex $s \in \mathcal{G}(R)$ contains no vertices of $V(H)$ unless it is a part of a j-face of the polytope $R^{\cap}$; thus a vertex of $V(H)$ in such a j-simplex is contained in $d-j$ hyperplanes of R and j hyperplanes of $H\backslash R$, or in other words, $d_v = j = \dim s$. In this sense, all the vertices within s are of the same type, and we have $V(H)\cap s = V(H,s)$. This implies that

$$\mathcal{E}_3^{(0)} = \frac{1}{N} \sum_{s\in\mathcal{G}(R)} \sum_{v\in V(H,s)} p^{d_v}(1-p)^{n_v} n_v^c \,. \tag{3.6}$$

We describe an oracle, to be constructed later, that performs an approximate evaluation of the sums over a given simplex s. Let $\mathcal{O}$ be an oracle whose input is a j-simplex $s \in \mathcal{G}(R)$ and whose output is a number $\mathcal{O}(s)$, satisfying

$$\Big|\mathcal{O}(s) - \sum_{v\in V(H,s)} p^j(1-p)^{n_v} n_v^c\Big| \le E_s \stackrel{\text{def}}{=} \frac{1}{C^2 q_s^{\sqrt{c}}} n_s^c \,. \tag{3.7}$$

(Here is an attempt to give the reader some intuition about the choice of the error term E_s: the simplex s contains at most n_s^j vertices of $V(H)$, and for each vertex the summand is at most $p^j n_s^c$; thus the exact sum does not exceed $n_s^c q_s^d$. The approximation's relative accuracy is thus a suitable quasi-constant factor.)

We then define the initial approximate energy by

$$\mathcal{AE}_3^{(0)} \stackrel{\text{def}}{=} \frac{1}{N} \sum_{s\in\mathcal{G}(R)} \mathcal{O}(s) \,.$$

Assuming (3.6) and (3.7), we have

$$\Big|\mathcal{AE}_3^{(0)} - \mathcal{E}_3^{(0)}\Big| \le \frac{1}{N} \sum_{s\in\mathcal{G}(R)} E_s \le \frac{1}{C^3 r^{\lfloor d/2\rfloor}} \sum_{s\in\mathcal{G}(R)} q_s^{c-\sqrt{c}} = O(1/C^2) \tag{3.8}$$

by the semicutting property of R, which establishes Lemma 3.6 for $k=0$, provided C is big enough.

We proceed to the definition of $\mathcal{AE}_3^{(k)}$. For a vertex $v \in V(H) \cap (R \cup S^{(k)})^{\cap}$, let m_v denote the number of hyperplanes *among* $\{h_{k+1}, \ldots, h_{n-r}\}$ in its conflict list[2] (that is, not counting the rejected hyperplanes). We also let d_v be the number of

[2]To be formally consistent, we should also superscript m_v by (k), but this would overburden the notation.

hyperplanes among $\{h_{k+1}, \ldots, h_{n-r}\}$ passing through v. In a manner analogous to the above expression for $\mathcal{E}_3$, we can write

$$\mathcal{E}_3^{(k)} = \frac{1}{N} \sum_v p^{d_v} (1-p)^{m_v} n_v^c \,, \tag{3.9}$$

where the summation is taken over all vertices v of the arrangement of $R \cup S^{(k)} \cup \{h_{k+1}, \ldots, h_{n-r}\}$ lying in the (closed) polytope $(R \cup S^{(k)})^{\cap}$.

We describe an oracle $\mathcal{O}^{(k)}$, which can approximately evaluate a part of this sum over a suitable cell (the oracle $\mathcal{O}$ above can be seen as a weaker version of $\mathcal{O}^{(0)}$). The input of $\mathcal{O}^{(k)}$ is a j-dimensional cell σ. We assume that the affine span of σ is either $\mathbb{R}^d$ or contained in the intersection of hyperplanes of H (under a suitable general position assumption, other cells do not contain any relevant vertices) and that σ is completely contained in a single simplex $s \in \mathcal{G}(R)$ (this latter requirement is not so important for the current section, but it is needed in the construction of the oracle). The oracle returns a number $\mathcal{O}^{(k)}(\sigma)$ with

$$\left| \mathcal{O}^{(k)}(\sigma) - \sum_{v \in V(\{h_{k+1}, \ldots, h_{n-r}\}, \sigma)} p^j (1-p)^{m_v} n_v^c \right| \le E_s = \frac{1}{C^2 q_s^{\sqrt{c}}} n_s^c, \tag{3.10}$$

where E_s is defined as in (3.7).

It might now seem natural to evaluate the approximate energy $\mathcal{AE}_3^{(k)}$ as follows: keep the portions of the arrangement of $S^{(k)}$ within each simplex $s \in \mathcal{G}(R)$, and call the oracle $\mathcal{O}^{(k)}$ on each cell from the resulting arrangements. It turns out that the error introduced in this way would be too large. Instead we compute the approximate energy incrementally, using the oracle to approximate the *difference* in energy caused by adding or rejecting a hyperplane.

Let us look at what happens with the contribution of various vertices to the total energy $\mathcal{E}_3$ when a hyperplane h_{k+1} is accepted or rejected; we begin with the accepting case. The contribution of vertices strictly above h_{k+1} remains unchanged (we say "above" meaning "on the same side of h_{k+1} as the origin"). The contribution of all vertices strictly below h_{k+1} becomes zero and finally, for each vertex on h_{k+1}, d_v, decreases by one so that its contribution to the energy is multiplied by $1/p$. Denoting the contribution of the vertices on h_{k+1} to the sum (3.9) by $\mathcal{E}_{on}^{(k)}$ and the contribution of the vertices below by $\mathcal{E}_{below}^{(k)}$, we have

$$\mathcal{E}_3^{(k|A)} = \mathcal{E}_3^{(k)} - \mathcal{E}_{below}^{(k)} + \left(\frac{1}{p} - 1\right) \mathcal{E}_{on}^{(k)} \,.$$

Thus, an appropriate action after accepting h_{k+1} is the following: we let Σ_{on} be the set of all faces σ of the polytope $(R \cup S^{(k)})^{\cap} \cap h_{k+1}$ within s for all $s \in \mathcal{G}(R)$. We set

$$\mathcal{AE}_{on}^{(k)} \stackrel{\text{def}}{=} \frac{p}{N} \sum_{\sigma \in \Sigma_{on}} \mathcal{O}^{(k)}(\sigma) \,.$$

(Note that the oracle includes the $p^{\dim \sigma}$ multiplicative factor, while an appropriate factor for a vertex on h_{k+1} in $\mathcal{E}_{on}^{(k)}$ is $p^{\dim \sigma + 1}$; this is why the factor p appears in the definition.)

Then we gather the portion of $(R \cup S^{(k)})^{\cap}$ (strictly) below h_{k+1} inside each s, obtaining a set Σ_{below} of cells, and we set

$$\mathcal{AE}_{below}^{(k)} \stackrel{\text{def}}{=} \frac{1}{N} \sum_{\sigma \in \Sigma_{below}} \mathcal{O}^{(k)}(\sigma)\,.$$

We define

$$\mathcal{AE}_3^{(k+1)} \stackrel{\text{def}}{=} \mathcal{AE}_3^{(k|A)} = \mathcal{AE}_3^{(k)} - \mathcal{AE}_{below}^{(k)} + \left(\frac{1}{p} - 1\right) \mathcal{AE}_{on}^{(k)}\,.$$

The discussion of the case when h_{k+1} is rejected is similar. The contribution of all vertices lying on h_{k+1} to the energy vanishes, and the number m_v for all vertices below h_{k+1} decreases by one; thus their contribution to the energy is multiplied by $1/(1-p)$. Hence an appropriate incremental definition is

$$\mathcal{AE}_3^{(k+1)} \stackrel{\text{def}}{=} \mathcal{AE}_3^{(k|R)} = \mathcal{AE}_3^{(k)} + \left(\frac{1}{1-p} - 1\right) \mathcal{AE}_{below}^{(k)} - \mathcal{AE}_{on}^{(k)}\,.$$

From these definitions, the promised analogy to (3.5), namely

$$\mathcal{AE}_3^{(k)} = p\,\mathcal{AE}_3^{(k|A)} + (1-p)\,\mathcal{AE}_3^{(k|R)}\,, \tag{3.11}$$

follows immediately.

As usual, we accept h_{k+1} if $\mathcal{AE}^{(k|A)} < \mathcal{AE}^{(k|R)}$ (otherwise, we reject it). Let us remark that since we have already established $\mathcal{AE}_3^{(0)} \le 2/3$, we know that the final approximate energy $\mathcal{AE}^{(n-r)} < 2/3$ and, in particular, that conditions C1 and C2 hold for the final sample $S^{(n-r)}$. Thus, any intermediate sample $S^{(k)}$ satisfies $|S^{(k)}| \le r$ as well as condition C2. We are thus free to use these conditions further. From now on, the quantity r_s will be defined with respect to the final sample $S^{(n-r)}$ computed by the algorithm; that is, $r_s = |S^{(n-r)}_{|Os}| + 1$.

Proof of Lemma 3.6. Let us analyze the approximation error. We have

$$\begin{aligned}\left|\mathcal{E}_3^{(k)} - \mathcal{AE}_3^{(k)}\right| \le{}& \left|\mathcal{E}_3^{(0)} - \mathcal{AE}_3^{(0)}\right| \\ &+ \sum_{i;\ h_i \in S^{(k)}} \left(\left|\mathcal{E}_{below}^{(i-1)} - \mathcal{AE}_{below}^{(i-1)}\right| + \frac{1-p}{p}\left|\mathcal{E}_{on}^{(i-1)} - \mathcal{AE}_{on}^{(i-1)}\right|\right) \\ &+ \sum_{i \in \{1,\ldots,k\};\ h_i \notin S^{(k)}} \left(\frac{p}{1-p}\left|\mathcal{E}_{below}^{(i-1)} - \mathcal{AE}_{below}^{(i-1)}\right| + \left|\mathcal{E}_{on}^{(i-1)} - \mathcal{AE}_{on}^{(i-1)}\right|\right)\,.\end{aligned}$$

From (3.8), we know that the first term is $O(1/C)$. Let us consider the contribution of a single simplex $s \in \mathcal{G}(R)$ to the second and third terms; we consider the accepting and rejecting cases separately. The sets Σ_{on} and Σ_{below} have no more than $O(r_s^d)$ cells, and there are fewer than r_s accepted hyperplanes cutting s or separating it from O. For an accepted hyperplane h_i, the error of the oracle given by (3.10) is multiplied by $(1-p)/N \le 1/N$ for the cells in Σ_{on}, and by $1/N$ for the cells in Σ_{below}. The total error for the accepted hyperplanes is thus $O(r_s^{d+1}E_s/N)$.

For a rejected hyperplane h_i, the error for cells in Σ_{on} gets multiplied by p/N and by $p/(1-p)N \le 2p/N$ for cells in Σ_{below}. Thus, the contribution to the error is at most $O(n_s r_s^d p E_s/N) = O(q_s r_s^d E_s/N)$. Substituting for E_s and N, we get that the total contribution to the error for s does not exceed $O(q_s^{c-\sqrt{c}+1} r_s^{d+1}/C^3 r^{\lfloor d/2 \rfloor})$.

We have bounds for the sums of cth moments of the r_s and of the q_s. In order to deal with the product of their powers, we use the inequality $xy \le x^u + y^v$, where the exponents satisfy $1/u + 1/v = 1$. In our case we have $x = r_s^{d+1}$, $y = q_s^{c-\sqrt{c}+1} \le q_s^{c-\sqrt{c}/2}$, $u = 2\sqrt{c}$, $v = 1/(1-1/u) = c/(c-\sqrt{c}/2)$. Then $r_s^{d+1} q_s^{c-\sqrt{c}+1} \le r_s^{2(d+1)\sqrt{c}} + q_s^c$. The total error over all simplices thus becomes

$$\frac{O(1)}{C^3 r^{\lfloor d/2 \rfloor}} \left(\sum_{s \in \mathcal{G}(R)} r_s^{2(d+1)\sqrt{c}} + \sum_{s \in \mathcal{G}(R)} q_s^c \right).$$

The first sum is less than $C^2 r^{\lfloor d/2 \rfloor}$ by condition C2, and the second sum is $O(Cr^{\lfloor d/2 \rfloor})$ by the semicutting property of the geode of R; hence the whole expression is $O(1/C)$. This proves Lemma 3.6. ∎

It now remains for us to implement the oracle.

3.5. Implementing the oracle.

LEMMA 3.7. *It is possible to maintain a data structure for each simplex $s \in \mathcal{G}(R)$ such that a call to the oracle $\mathcal{O}^{(k)}$ with a cell σ, as described in the previous sections, can be answered in $O_C(\mathrm{compl}(\sigma) q_s^{b\sqrt{c}})$ time for an absolute constant b, where $\mathrm{compl}(\sigma)$ denotes the combinatorial complexity of σ. The total time needed for updating the data structure for s during the round is bounded by $O_C(n_s r_s^d q_s^{b\sqrt{c}})$.*

Proof. The proof follows a similar construction in [7]. We define another quasi-constant quantity

$$\rho_s \stackrel{\text{def}}{=} C^{3d+6} q_s^{3d\sqrt{c}}.$$

Let $H_s^{(k)}$ denote the set of yet unprocessed hyperplanes in the conflict list of s; that is, $H_s^{(k)} = \{h_{k+1}, \ldots, h_{n-r}\}_{|Os}$. Whenever we want to call the oracle $\mathcal{O}^{(k)}$, we make sure we have an ε-approximation $A_s^{(k)}$ for the set $H_s^{(k)}$ (with ranges defined by segments) available, where ε is such that the absolute error of the approximation does not exceed n_s/ρ_s, and $|A_s^{(k)}| = O(\rho_s^2 \log \rho_s)$. A simple way to maintain such an ε-approximation under the deletion of hyperplanes is to start with, say, a $(1/2\rho_s)$-approximation $A_s^{(0)}$, keep it unchanged for a while, and recompute a fresh $(1/2\rho_s)$-approximation after every $n_s/2\rho_s$ deletion. By the results of [20] (or by Theorem 2.1), each $(1/2\rho_s)$-approximation is computed in time conservatively estimated as $O(\rho_s^{2d+1} n_s)$, so the total time for the maintenance of the ε-approximations is $O_C(n_s q_s^{b\sqrt{c}})$ as claimed.

Suppose that we want to answer a call to the oracle $\mathcal{O}^{(k)}$ with a j-cell σ, that is, approximate the sum

$$\sum_{v \in V(H_s^{(k)}, \sigma)} p^j (1-p)^{m_v} n_v^c.$$

Let us set

$$\alpha_s \stackrel{\text{def}}{=} \frac{|H_s^{(k)}|}{|A_s^{(k)}|}.$$

We are ready to define the oracle value

$$\mathcal{O}^{(k)}(\sigma) \stackrel{\text{def}}{=} \sum_{v \in V(A_s^{(k)}, \sigma)} \alpha_s^j p^j (1-p)^{m_v} n_v^c. \tag{3.12}$$

Note that the quantities m_v and n_v can be computed exactly for all the vertices $v \in V(A_s^{(k)}, \sigma)$, in time conservatively estimated as $O_C(\rho_s^{3d} n_s)$ (we remark that we use them as well in (3.7), (3.10) for a vertex $v \in V(\{h_{k+1}, \ldots, h_{n-r}\}, \sigma)$, but these quantities are never actually computed). Up to easy details, we have thus completely described the algorithm implementing the oracle, and the times it takes to answer a call or maintain the data structure can easily be shown to stay within the claimed bounds. It remains to establish the bound on the accuracy.

In order to have a notationally simpler proof, we only deal with the case $k = 0$ (then $n_v = m_v$, and we can omit all the (k) superscripts). The case of a general k is entirely similar and is treated in detail in [5].

Our procedure replaces a summation over a discrete but large set of vertices by summation over a smaller suitably chosen set, and this very much resembles a numerical integration procedure. The notation is chosen to stress this analogy, and also the reasoning in the proof resembles simple estimates for the error of numerical integration. From a result of [7], we know that the number of vertices of the ε-approximation within any simplex multiplied by a suitable scaling factor approximates the number of vertices of H within the simplex with relative accuracy ε. Theorem 2.8 shows that this is even valid for cells of arrangements (since they are convex). Our strategy is to subdivide σ into small enough cells so that the variation of the summand within each cell is small but at the same time the number of small cells is not too large. Within each small cell, we treat the summand as essentially constant and use the vertex number approximation bound.

Here is a more detailed treatment. Our specific function f to be integrated (over the discrete set of vertices) is

$$f(t) = p^j (1-p)^t t^c \,.$$

We let $M_{f,T}$ stand for its *modulus of continuity* $M_{f,T}$ over a set T (as is done in a somewhat different context in [22]):

$$M_{f,T}(h) = \sup_{\substack{t_1, t_2 \in T \\ |t_2 - t_1| \le h}} |f(t_2) - f(t_1)| \,.$$

For a j-dimensional cell $\xi \subseteq \sigma$, let us denote

$$\Sigma_\xi f = \sum_{v \in V(H,\xi)} f(n_v) \tag{3.13}$$

and

$$\tilde{\Sigma}_\xi f = \sum_{v \in V(A_s,\xi)} \alpha_s^j f(n_v) \,. \tag{3.14}$$

We want to obtain a bound for the difference $|\Sigma_\xi f - \tilde{\Sigma}_\xi f|$. Let $T_\xi = \{n_v : v \in V(H,\xi)\}$, $f_\xi^{min} = \min_{t \in T_\xi} f(t)$, $f_\xi^{max} = \max_{t \in T_\xi} f(t)$, and $\Delta_\xi(f) = f_\xi^{max} - f_\xi^{min}$. We have

$$|V(H,\xi)| f_\xi^{min} \le \Sigma_\xi f \le |V(H,\xi)| f_\xi^{max} \,,$$

and similarly

$$\alpha_s^j |V(A_s,\xi)| f_\xi^{min} \le \tilde{\Sigma}_\xi f \le \alpha_s^j |V(A_s,\xi)| f_\xi^{max} \,.$$

From this we get

$$\left|\Sigma_\xi f - \tilde{\Sigma}_\xi f\right| \le \left|\alpha_s^j |V(A_s,\xi)| - |V(H,\xi)|\right| f_\xi^{max} + |V(H,\xi)|\Delta_\xi(f)\,. \tag{3.15}$$

Theorem 2.8 shows that, for any j-dimensional cell ξ within s, we have

$$\left|\alpha_s^j |V(A_s,\xi)| - |V(H,\xi)|\right| \le \frac{n_s^j}{\rho_s}\,. \tag{3.16}$$

To estimate the total error within σ, we subdivide σ into smaller cells. Namely, we fix a parameter

$$\nu_s \stackrel{\text{def}}{=} C^3 q_s^{2\sqrt{c}}\,,$$

and we choose a $(1/\nu_s)$-net $\mathcal{N} \subseteq H_{|Os}$ (with respect to ranges defined by segments) of size $O(\nu_s \log \nu_s)$. We let Ξ be the portion of the arrangement of $\mathcal{N}$ within σ (by a suitable general position assumption, we may consider only j-dimensional cells in Ξ). Ξ is thus a subdivision of σ into $|\Xi| = O((\nu_s \log \nu_s)^j) = O(\nu_s^{d+1})$ cells.

LEMMA 3.8. *For any $T \subseteq [0,\tau]$, $M_{f,T}(h) \le h\, p^j \tau^{c-1}(c - \log(1-p)\tau)$.*

Proof. We have $f'(t) = p^j(1-p)^t(ct^{c-1} + \log(1-p)t^c)$. By the mean value theorem, for any $t_1, t_2 \in T$,

$$|f(t_2) - f(t_1)| \le |t_2 - t_1| \sup_{t\in[t_1,t_2]} |f'(t)|,$$

from which the result follows. (The reader should keep in mind that $1-p<1$, hence the minus sign in front of the logarithm when taking the absolute values of f'.) ∎

It now suffices to note, by the $(1/\nu_s)$-net property and since for any $\xi \in \Xi$ we have $\sup T_\xi \le n_s$, that

$$\Delta_\xi(f) \le M_{f,T_\xi}\left(\frac{n_s}{\nu_s}\right) = O\left(\frac{n_s}{\nu_s} p^j (1 + \frac{r}{n} n_s) n_s^{c-1}\right) = O\left(\frac{q_s p^j}{\nu_s} n_s^c\right) \tag{3.17}$$

for any $\xi \in \Xi$, where we have taken into account the fact that $-\log(1-p) = O(r/n)$.

To obtain the total approximation error made by the oracle, we substitute (3.16), (3.17) into (3.15), and this yields

$$\begin{aligned}\left|\Sigma_\sigma f - \tilde{\Sigma}_\sigma f\right| &\le \sum_{\xi\in\Xi} \left|\Sigma_\xi f - \tilde{\Sigma}_\xi f\right| \le O(\nu_s^{d+1})\,\frac{n_s^j}{\rho_s} f_\sigma^{max} + O(n_s^j)\frac{q_s p^j}{\nu_s} n_s^c \\ &= O\left(\frac{\nu_s^{d+1} q_s^d}{\rho_s} + \frac{q_s^{d+1}}{\nu_s}\right) n_s^c = O(E_s/C)\,,\end{aligned}$$

which validates (3.7), (3.10). ∎

As mentioned in the lemma, the time needed to answer a call to the oracle within a cell σ also depends on the complexity $\mathrm{compl}(\sigma)$ of that cell. However, the total complexity of all the cells in the sets Σ_{below} and Σ_{on} introduced in processing a hyperplane h_i is easily seen to be in $O(r_s^d)$; hence, the total time spent by the oracle when processing a hyperplane is $O_C(r_s^d q_s^{b\sqrt{c}})$.

With this lemma we can finish the time analysis of the whole algorithm. We have already seen at the end of section 3.2 that the running time of the deterministic algorithm is no more than the expected running time of the randomized algorithm

plus the cost of computing the good sample and that of the oracle calls. The total time spent for computing local arrangements and testing each hyperplane during the round is easily shown to be $O_C(nr^{\lfloor d/2\rfloor-1})$ using the fact that the geode of R defines a semicutting. This does not account for the oracle costs. There are at most n_s hyperplanes to process within the simplex s during the computation, so the total time needed will be at most proportional to

$$\sum_{s\in\mathcal{G}(R)} n_s r_s^d q_s^{b\sqrt{c}} \le \frac{n}{r}\left(\sum_{s\in\mathcal{G}(R)} r_s^{2d} + \sum_{s\in\mathcal{G}(R)} q_s^{2b\sqrt{c}+2}\right),$$

which is $O_C(nr^{\lfloor d/2\rfloor-1})$, by a calculation similar to that given at the end of the proof of Lemma 3.6. This is also the total running time for one round, which is then bounded by the expected running time of one round for the randomized algorithm. To summarize see the following theorem.

THEOREM 3.9. *The algorithm presented above computes the convex hull of n points deterministically in time $O(n\log n + n^{\lfloor d/2\rfloor})$ for any fixed dimension $d \ge 2$.*

One final note is needed for the model of computation. The algorithm given here works in the so-called real-RAM model [1], where elementary arithmetic operations take unit time regardless of the size of the numbers. This is the traditional model used in computational geometry, to be contrasted with the so-called bit-model [1], where the size of the numbers also contributes to the time complexity. Note that exponentially large quantities are needed in the course of the algorithm. Nevertheless, because the algorithm runs in polynomial time, it is possible, while computing over logarithmic-size words, to approximate any intermediate number in our algorithm with a relative error smaller than an arbitrarily small constant. It is easily seen that such errors are too small to be of consequence in the derandomization technique we use.

AUTOMATIC NONZERO STRUCTURE ANALYSIS*

AART J. C. BIK† AND HARRY A. G. WIJSHOFF‡

Abstract. The efficiency of sparse codes heavily depends on the size and structure of the input data. Peculiarities of the nonzero structure of each sparse matrix must be accounted for to avoid unsatisfying performance. Therefore, it is important to have an efficient analyzer that automatically determines characteristics of nonzero structures. In this paper, some efficient algorithms are presented that automatically detect particular nonzero structures.

Key words. nonzero structures, sparse computations, sparse matrices

1. Introduction.

Many methods have been developed that exploit the sparsity of matrices to reduce the storage requirements and computational time of particular applications (see, e.g., [9, 12, 15, 17, 20, 23]). The efficiency of each individual method, however, heavily depends on the specific characteristics of the nonzero structure of each sparse matrix. For example, although a particular band method may perform extremely well when actually applied to matrices with a small bandwidth, the explicit storage and manipulation of all elements within the band makes this method infeasible for sparse matrices in which the nonzero elements are scattered over the entire matrix. Because peculiarities of nonzero structures must be accounted for to obtain satisfactory performance, it is important to have an efficient analyzer that automatically determines certain characteristics of nonzero structures.

Such a nonzero structure analyzer can be used in a number of different fashions. First, if sparse applications are explicitly coded by hand, a nonzero structure analyzer can provide a programmer with useful insights about the characteristics of the matrices for which an application must be developed in case a representative set of sparse matrices is available beforehand. Although in this situation the efficiency of the analyzer is less important, excessively long running times would disable the analysis of large sets of matrices.

Second, in the past we have proposed a completely different approach to the development of sparse codes [1]. Rather than explicitly dealing with the sparsity of matrices at programming level, as done traditionally, this sparsity is dealt with at compilation level by a special kind of restructuring compiler, referred to as a "sparse compiler." We must refer to [1, 3, 4, 5] for a detailed presentation of this approach and some preliminary experiments with a prototype sparse compiler. It is obvious, however, that the automatically generated sparse code becomes more efficient if the sparse compiler can account for characteristics of the nonzero structures. For this,

the compiler requires an automatic nonzero structure analyzer. Since in this approach analysis time contributes to compile time, it is again desirable to keep analysis time limited.

In most practical cases, however, sparse matrices are not all available beforehand. A possible approach to deal with this situation is to generate multiple versions of an application (either explicitly by hand or automatically by means of a sparse compiler), each of which has been optimized specifically for a particular class of nonzero structures. At run-time, the analyzer is invoked to determine which version is probably the most efficient. This version is subsequently executed. Using run-time analysis has the major advantage that nonzero structures do not have to be known in advance. In this case, however, the analyzer must be very efficient to avoid the situation in which savings in execution time using an optimized version are outweighed by analysis time. In general, it is desirable to keep analysis time proportional to the number of nonzero elements and order of a sparse matrix [11].

In this paper, some efficient algorithms are presented that can be used by an analyzer to automatically detect particular nonzero structures of square sparse matrices. The presented algorithms examine each matrix as it is; i.e., no attempts are made to permute the matrix into a particular form (as is frequently done in the context of LU-factorization, for example, to confine fill-in to certain regions in the matrix [6, 7, 8, 10, 12, 14, 15, 16, 17, 22]). Even if such a permutation is applied to the matrix, however, the analyzer can be used afterwards to determine whether an unforeseen nonzero structure arises (information about the specific form for which the permutation is intended is usually obtained as a side effect of computing the permutation).

2. Nonzero structures. We can distinguish between general sparse matrices and sparse matrices having a particular nonzero structure. In this section, some important nonzero structures of square matrices are identified [12, 18, 19, 20, 21].

2.1. Band forms. The *lower* and *upper semibandwidth* of an $N \times N$ matrix A are defined as the smallest integers $b_l \geq 0$ and $b_u \geq 0$, respectively, for which $(a_{ij} \neq 0) \Rightarrow (-b_u \leq i - j \leq b_l)$ still holds. Minimum values reveal the most information about the nonzero structure, because this constraint is trivially satisfied for semibandwidths $N - 1$. Allowing for negative semibandwidths would enable the specification of an arbitrary band in which the main diagonal is not necessarily included. However, in this paper we will assume that all matrices have a full transversal (i.e., all elements on the main diagonal are nonzero).

If the semibandwidths are relatively small, we say that the matrix is in *band form*, which means that all nonzero elements are confined to a small band. We define the shape count of a band form as the total number of elements that reside within the band:

$$N \cdot (b_l + b_u + 1) - (b_l^2 + b_l)/2 - (b_u^2 + b_u)/2.$$

Note that this number is likely to exceed the total number of nonzero elements, because the band is not necessarily full.

2.2. Block forms. Consider a block partition of a square matrix A into submatrices A_{ij}:

$$A = \begin{pmatrix} A_{11} & \dots & A_{1p} \\ \vdots & \ddots & \\ A_{p1} & & A_{pp} \end{pmatrix}.$$

Each submatrix A_{ii}, referred to as a *diagonal block*, is a square $n_i \times n_i$ submatrix. Hence, each submatrix A_{ij} with $i \neq j$, referred to as an *off-diagonal block*, is an $n_i \times n_j$ submatrix. The off-diagonal blocks A_{pi} and A_{ip} for $1 \leq i < p$ are referred to as the *lower border* and *upper border*, respectively. If a block A_{ij} contains at least one nonzero element, the block is called a *nonzero block*, denoted by $A_{ij} \neq 0$.

If $(A_{ij} \neq 0) \Rightarrow (i = j)$, then the matrix is in *block diagonal form*. Likewise, if $(A_{ij} \neq 0) \Rightarrow (i \geq j)$, or if $(A_{ij} \neq 0) \Rightarrow (i \leq j)$, then the matrix is in *block lower triangular form* or *block upper triangular form*, respectively. If a matrix is in block diagonal form except for some nonzero blocks in the borders, then the matrix is in *doubly bordered block diagonal form*. Matrices in *singly bordered block lower triangular form* or *singly bordered block upper triangular form* are defined likewise. Finally, if $p = 2$, $A_{21} \neq 0$, $A_{12} \neq 0$, and A_{11} is in band form, we say that the matrix is in *doubly bordered band form*.

For these forms, the shape count is defined as the total number of elements in the diagonal blocks (but only counting elements in the band of A_{11} for a bordered band form), *all* border blocks for the bordered forms, and, for the triangular forms, *all* remaining off-diagonal blocks in the lower or upper triangular part, even if not all these blocks are nonzero. Again, this number is likely to exceed the total number of nonzero elements, since the blocks are not necessarily full (and some of them may even be zero).

Although, depending on which blocks are nonzero, a particular form of a matrix is defined once a block partition of that matrix is given, it is possible that *different* block partitions into one particular form differ in the accuracy of describing the nonzero structure. In Figure 2.1, for example, two different block partitions of a matrix into block diagonal form are shown with shape counts 15 and 25, respectively. Therefore, we say the most accurate description for a particular form is defined by a *minimum block partition into that form*, which means that there are no other block partitions of the matrix into the same form with a smaller shape count.

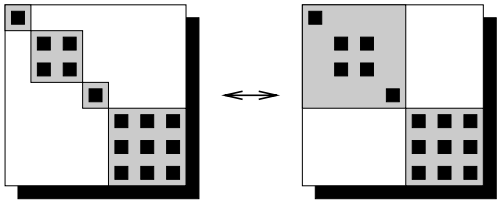

FIG. 2.1. *Two different block partitions into BDF.*

A square matrix has a unique minimum block partition into block diagonal form, which satisfies the following property (similar statements hold for block lower or upper triangular forms).

PROPOSITION 2.1. *A block partition of a square matrix into block diagonal form is minimum if and only if there is no diagonal block with a nontrivial block partition into block diagonal form.*

We will see that a matrix can have several minimum block partitions into a bordered band or block form.

3. Automatic nonzero structure analysis. In this section, efficient algorithms are presented that detect (bordered) band and (bordered) block forms. We assume that the nonzero structure of each $N \times N$ sparse matrix A to be analyzed is available on file in coordinate scheme. In this scheme, the file consists of the order N and an integer nnz that indicates the number of nonzero elements, followed by an unordered set of nnz triples (i, j, a_{ij}), indicating the row index, column index, and value of each individual nonzero element.

First, sky-line information is computed. Thereafter, this information is used to detect particular nonzero structures.

3.1. Preparatory analysis. Sky-line information, i.e., the lower and upper semibandwidth for each single row and column, respectively, can be obtained in a single pass over a file by executing the following procedure. In this fragment, the lower and upper sky-line are computed in the arrays `lsky` and `usky`, respectively:

```
procedure comp_skylines()
begin
  read(N, nnz);

  allocate lsky[1:N] and usky[1:N]
  for i := 1, N do
    lsky[i] := 0;
    usky[i] := 0;
  endfor

  for k := 1, nnz do
     read(i, j, aij);
     lsky[i] := max(lsky[i], (i-j));
     usky[j] := max(usky[j], (j-i));
  endfor
end
```

Sky-lines are computed under the assumption that the matrix has a full transversal, so that all elements of the arrays `lsky` and `usky` can be initialized to zero. All information requires $\Theta(N)$ storage and can be obtained in $\Theta(nnz + N)$ time.

Example. The following lower and upper sky-lines are obtained for the 15×15 sparse matrix that is depicted in Figure 3.1:

	1														15
lsky	0	0	1	0	4	0	1	0	1	0	0	0	0	0	3
usky	0	0	2	0	1	0	0	0	3	0	0	0	0	3	2

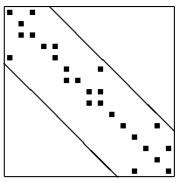

FIG. 3.1. *Band form.*

3.2. Band forms. Once the lower and upper sky-lines of a matrix have been computed, the lower and upper semibandwidths of this matrix are determined in $\Theta(N)$ time as follows:

```
procedure comp_bandform()
begin
  b_l := 0; b_u := 0;
  for i := 1, N do
    b_l := max(b_l, lksy[i]);
    b_u := max(b_u, uksy[i]);
  endfor
end
```

These semibandwidths directly determine the band form of a matrix.

Example. For the sparse matrix of Figure 3.1, the semibandwidths $b_l = 4$ and $b_u = 3$ result. This gives rise to the band form with shape count 104 that is shown in the same figure.

3.3. Bordered band forms. By slightly extending the previous procedure, an algorithm is derived that constructs a minimum block partition into bordered band form in $\Theta(N)$ time:

```
procedure comp_bord_bandform()
begin
  b_l := 0; b_u := 0;
  tsz := N*N;

  for i := 1, N do
    b_l := max(b_l, lksy[i]);
    b_u := max(b_u, uksy[i]);
    if (bf_size(b_l, b_u, N-i) <= tsz) then
      t_l := b_l; t_u := b_u; b := N-i;
      tsz := bf_size(b_l, b_u, N-i);
    endif
  endfor
end
```

In this algorithm, the auxiliary function `bf_size` computes the shape count of a bordered band matrix with border size `b` and semibandwidths `bl` and `bu`:

```
integer function bf_size(bl, bu, b)
begin
  return ( (N-b) * (bl+bu+1) - (bl*bl+bl) / 2
           - (bu*bu+bu) / 2 + 2*N*b - b*b );
end
```

After the semibandwidths are updated in each step `i`, we test whether the shape count of a bordered band form with border size `N-i` is less than or equal to the best shape count seen so far. If this is true, we record this shape count and corresponding border size and semibandwidths. Consequently, after applying the algorithm, variables `b`, `t_l`, and `t_u` contain the border size and semibandwidths of a *minimum* block partition into block band form. If `b=0` holds, then effectively a band form results. For example, applying `comp_bord_bandform()` to the matrix of Figure 3.1 yields exactly the same band form as computed by `comp_bandform()`.

Example. In Figure 3.2, we present the resulting bordered band forms for some matrices, with shape counts 125, 119, 153, and 131, respectively. The last example shows that, although a minimum block partition into a *doubly* bordered band form is constructed, it is possible that only a single border block is actually nonzero.

Example. A matrix may have different minimum block partitions into bordered band form, as illustrated in Figure 3.3, where the shape count of all forms is 93. Our algorithm solves such ties in favor of the smallest border size.

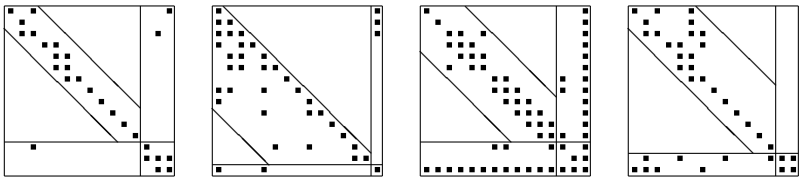

FIG. 3.2. *Bordered band forms.*

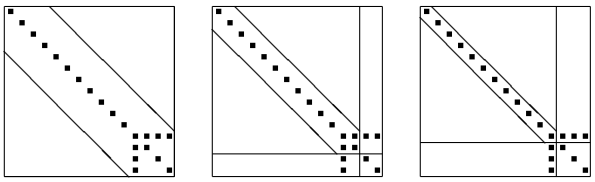

FIG. 3.3. *Different minimum block partitions into bordered band forms.*

3.4. Block forms. The following procedure constructs a block partition into diagonal block form in $\Theta(N)$ time by determining the size `k` of each next diagonal block with the lower right corner at row and column index `B` during a backward scan over the sky-lines:

```
procedure comp_blockdiag()
begin
  p := 0; k := 1; B := N;
  for i := N, 1, -1 do
S1: k := max(k, max(lsky[i],usky[i])+B-i+1);
    if (i = B-k+1) then
       p := p + 1;  part[p] := i;  /* Record Block */
       B := i - 1;        k := 1:  /* Next Block   */
    endif
  endfor
end
```

After application of this algorithm, `p` contains the number of diagonal blocks. The row (or column) indices of the upper left corners of all diagonal blocks of the block partition are recorded in reverse order in the first `p` locations of array `part`.

The following proposition states that the *minimum* block partition into block diagonal form is found. Likewise, if only the value `lsky[i]` or `usky[i]` is used in statement `S1`, then the minimum block partition into block lower, or block upper triangular form, respectively, is obtained in $\Theta(N)$ time.

PROPOSITION 3.1. *Application of* `comp_blockdiag()` *to the lower and upper sky-line of a matrix yields the minimum block partition into block diagonal form.*

Proof. By construction, each nonzero element is incorporated in a diagonal block. Now assume that the resulting block partition is not a minimum block partition into diagonal form. Then Proposition 2.1 implies that there is a certain $k \times k$ diagonal block with the lower right corner at a row and column index B that has a nontrivial

block partition into block diagonal form; i.e., there is $1 \leq k' < k$ such that $\forall B - k' < i \leq B : \max(l_i, u_i) + (B - i) < k'$. Since no diagonal block is recorded during iterations $\texttt{i} = B \ldots B - k' + 1$, during at least one of these iterations a value is assigned to `k` that is greater than k'. However, this can only occur if $\max(l_i, u_i) + B - i + 1 > k'$ for some $B - k' < i \leq B$. This contradicts the assumption.

Example. Application of the different versions of this algorithm to the matrix of Figure 3.1 yields the block diagonal, block lower, and upper triangular forms shown in Figure 3.4, with shape counts 67, 140, and 138, respectively. Note that although in the block triangular forms many off-diagonal blocks are zero, the elements of these blocks are also included in the shape count.

The contents of array `part` for the first block partition are shown below:

part	11	10	6	1

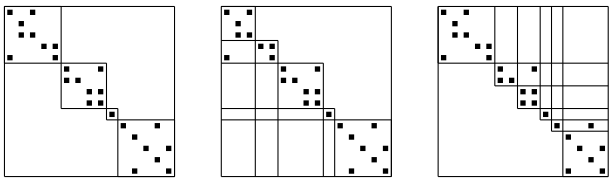

FIG. 3.4. *Block forms.*

3.5. Bordered block forms. Let $E(b)$ denote the shape count of a bordered block diagonal form with border size $b \in [0, N]$ arising from the minimum block partition of the remaining $(N - b) \times (N - b)$ matrix into block diagonal form. We define the improvement of using border size b' instead of b as $I(b', b) = E(b) - E(b')$, satisfying the following property.

PROPOSITION 3.2. *For $b, b', b'' \in [0, N]$, we have $I(b', b'') = I(b', b) + I(b, b'')$.*

Proof. $I(b', b'') = E(b) - E(b') + E(b'') - E(b) = I(b', b) + I(b, b'')$.

Suppose that for a given border size $b \in [0, N]$, we construct the minimum block partition of the remaining $(N - b) \times (N - b)$ submatrix into block diagonal form using the procedure `comp_diagblock()`. At any iteration $\texttt{i} = i$, the block partition found so far may be discarded and the algorithm may be restarted with $B = i - 1$ and $k = 1$ for a new border size $b' = N - i + 1$.

Obviously, selection of this border is only profitable if eventually we are able to determine that $I(b', b) > 0$. However, rather than constructing both block partitions completely, we are already able to compute the improvement during an iteration $\texttt{i} = i'$ in which the last diagonal block of the new block partition that overlaps with the diagonal block that was assumed during iteration $\texttt{i} = i$ has been found. This is *because the block partition of the remaining part of the matrix will be identical for both block partitions.* This new diagonal block may be contained in the old diagonal block (which occurs if the value of `k` would not have been incremented while constructing the old block partition), or these blocks may partially overlap.

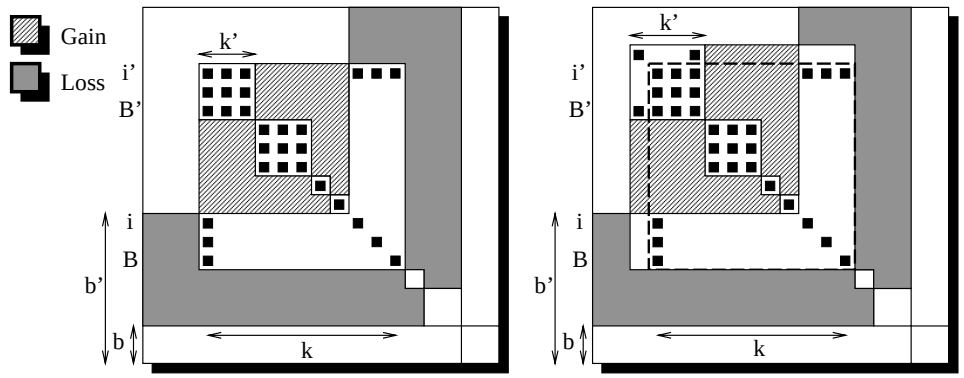

FIG. 3.5. *Gain and loss for border.*

Both cases are illustrated in Figure 3.5. In any case, the improvement is equal to the difference of the number of elements included in the border (*loss*) and the number of elements that do not have to be included in a diagonal block (*gain*). Let B, k and B', k' denote the value of `B` belonging to the iterations `i` $= i$ and `i` $= i'$, respectively. Furthermore, let Z and Z' denote the number of elements in the off-diagonal zero blocks of the old and new block partition below rows B and B', respectively. Then the improvement of using a new border size b' with respect to the old border size b is equal to the difference between the gain and the loss:

$$I(b', b) \quad = \quad Z' - Z - 2 \cdot (B' - k')(B - B').$$

If the gain exceeds the loss, i.e., $I(b', b) > 0$, then it is profitable to continue with the new block partition and border size b'. Moreover, border size b may be discarded from further consideration, since Proposition 3.2 implies that $I(b', b'') > I(b, b'')$ for all $b'' \in [0, N]$. If no improvement has been obtained, i.e., $I(b', b) \leq 0$, then the block partition corresponding to border size b must be restored and the algorithm can proceed with the search for the next diagonal block (which has at least size $\max(k, B - B' + k')$). In that case, we may discard border size b' from further consideration, since Proposition 3.2 implies that $I(b', b'') \leq I(b, b'')$ for all $b'' \in [0, N]$.

These observations enable us to construct a minimum block partition into block diagonal form in one pass over the sky-lines. At each step in which no diagonal block is recorded, the current status is saved on a stack, and a new border size is tried. If a diagonal block is recorded, no improvement can be obtained by trying a new border size. Instead, previously constructed block partitions belonging to smaller border sizes that can be verified are restored if an improvement is obtained (which is simply done by restoring the value of `p`), or discarded otherwise. The following slightly more complex version of procedure `comp_blockdiag()` results:

```
procedure comp_bord_blockdiag()
begin
  Z := 0; b := 0; s := 0;
  p := 0; k := 1; B := N;
  for i := N, 1,  -1 do
S2: k := max(k, max(lsky[i],usky[i])+B-i+1);
    if (i = B-k+1) then
       /* Last Overlapping Block? */
       while ( (s > 0) && (i == stackB[s]-new_k()+1) ) do /* Conditional AND */
          /* Improvement? */
          if (I() > 0) then
            s := s - 1;            /* Discard         */
          else
            pop_restore();         /* Restore         */
          endif
       endfor
       Z := Z + 2 * k * (B-k);
       p := p + 1;  part[p] := i;  /* Record Block    */
       B := i - 1;        k := 1:  /* Next Block      */
    else
       push();                     /* Save State      */
       Z := 0; B := i - 1;         /* New Search      */
       k := 1; b := N - i + 1;
    endif
  endfor
end
```

In this algorithm, the following auxiliary procedures are used to implement stack-like operations that save and restore states:

```
procedure push()
begin
  s := s + 1;
  stackk[s] := k;
  stackZ[s] := Z;
  stackB[s] := B;
  stackp[s] := p;
  stackb[s] := b;
end
```

```
procedure pop_restore()
begin
  k := new_k();
  Z := stackZ[s];
  B := stackB[s];
  p := stackp[s];
  b := stackb[s];
  s := s - 1;
end
```

The following auxiliary functions are used to compute the improvement and the new value of `k` for the block partition on top of the stack:

```
integer function I()
begin
 I := Z - stackZ[s] - 2 *
      (B-k) * (stackB[s]-B);
end
```

```
integer function new_k()
begin
  new_k := max(stackk[s],
               stackB[s]-B+k);
end
```

Although a while-loop occurs inside the `i`-loop, this algorithm still runs in $\Theta(N)$ time because each border size can only be pushed and popped from the stack once. Because the algorithm simply applies `comp_blockdiag()` to the submatrix that remains for the most profitable border size, it is clear that this extended algorithm constructs a *minimum* block partition into bordered block diagonal form.

After application of this algorithm, the scalar `b` contains the selected border size

(and hence the size of the last diagonal block). The first `p` locations of array `part` represent the block partition into block diagonal form of the remaining submatrix. If a zero border size is selected, the last diagonal block is empty and, effectively, a block partition into block diagonal form results.

If only the value `lsky[i]` or `usky[i]` is used in statement `S2`, then a minimum block partition into, respectively, singly bordered block lower or upper triangular form is obtained. In these cases, the constant 2 must be removed from the assignment to `Z` and the computation in function `I()` to compute the appropriate improvement.

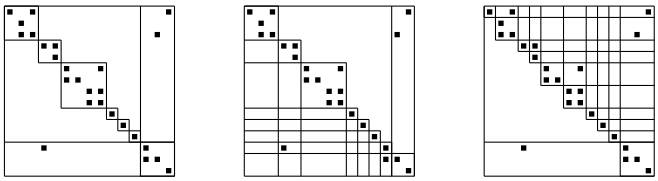

FIG. 3.6. *Bordered block forms.*

Example. In Figure 3.6, the bordered block forms that result for a matrix are shown, having shape counts $225 - 112 = 113$, $225 - 68 = 157$, and $176 - 14 = 162$, respectively. The contents of array `part` for the bordered block diagonal form having `b=3` are shown below:

part	12	11	10	6	4	1

Example. Applying the version operating only on `lsky[i]` to the matrix with 22 nonzero elements of Figure 3.7 yields a minimum partition into bordered block upper triangular form with border size 1 and shape count 166. However, the shape counts of similar forms with border sizes 2 and 3 are also 166. This example illustrates that a matrix may have different minimum block partitions into a particular bordered block form. Because a border is denied for a zero improvement (viz., $I(3,2) = 0$ and $I(2,1) = 0$ in the example), ties are solved in favor of the smallest border size.

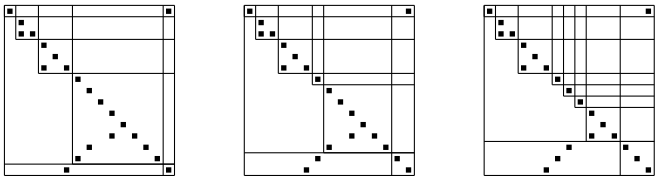

FIG. 3.7. *Different minimum block partitions into BBUTF.*

3.6. Classification. After the minimum block partitions into (doubly bordered) band form, (doubly bordered) block diagonal form, and (singly bordered) block lower and upper triangular forms have been constructed, shape counts can be used to determine which form most accurately describes the nonzero structure of a matrix. Moreover, the density of this form (i.e., *nnz* divided by the shape count) can be compared with a user-defined threshold to decide whether this nonzero structure is

used for the classification of the sparse matrix or whether the matrix is classified as a general sparse matrix.

Example. For the 59×59 matrix "impcol_b" of the Harwell–Boeing sparse matrix collection [13] with 312 nonzero elements, for example, the shape counts of the different forms are 2620, 3461, 3206, and 2930, respectively. In Figure 3.8, we show the band form and bordered block upper triangular form. Here, we classify this matrix as a band matrix if 312/2620 exceeds the threshold, or as a general sparse matrix otherwise.

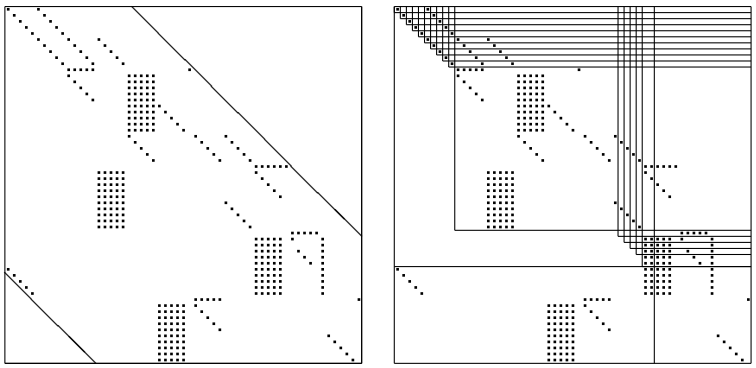

FIG. 3.8. *Classification of "impcol_b."*

4. Conclusions. In this paper, we have presented some efficient algorithms that automatically detect particular nonzero structures of sparse matrices. First, we have extended an algorithm that constructs a band form into an algorithm that constructs a minimum block partition into bordered band form (possibly yielding a band form as a special case). Likewise, an algorithm that constructs a minimum block partition into block diagonal or triangular form has been extended into an algorithm that constructs a minimum block partition into bordered block diagonal or triangular form (possibly yielding a block form with an empty border as a special case). All algorithms require only sky-line information, which can be obtained in $\Theta(N + nnz)$ time for an $N \times N$ sparse matrix with nnz nonzero elements, and have a running time of $\Theta(N)$.

STACK AND QUEUE LAYOUTS OF DIRECTED ACYCLIC GRAPHS: PART II*

LENWOOD S. HEATH† AND SRIRAM V. PEMMARAJU‡

Abstract. Stack layouts and queue layouts of undirected graphs have been used to model problems in fault tolerant computing and in parallel process scheduling. However, problems in parallel process scheduling are more accurately modeled by stack and queue layouts of *directed acyclic graphs* (dags). A *stack layout* of a dag is similar to a stack layout of an undirected graph, with the additional requirement that the nodes of the dag be in some topological order. A *queue layout* is defined in an analogous manner. The *stacknumber* (*queuenumber*) of a dag is the smallest number of stacks (queues) required for its stack layout (queue layout). This paper presents algorithmic results—in particular, linear time algorithms for recognizing 1-stack dags and 1-queue dags, and proofs of NP-completeness for the problem of recognizing a 4-queue dag and the problem of recognizing a 6-stack dag. The companion paper (Part I [*SIAM J. Comput.,* 28 (1999), pp. 1510–1539.]) presents combinatorial results.

Introduction. This is a companion paper to Heath, Pemmaraju, and Trenk [9]; we assume familiarity with the definitions, notation, and results in section 1 of that paper. There, we define stack and queue layouts of directed acyclic graphs (dags) and establish the stacknumber and queuenumber of path dags, cycle dags, tree dags, and unicyclic dags. We also provide a forbidden subgraph characterization of 1-queue tree dags and 1-queue cycle dags. In the current paper, we study stack and queue layouts of dags from an algorithmic point of view and present four algorithmic results.

First, we present a linear time algorithm that recognizes 1-stack dags. Recall that the class of 1-stack undirected graphs is equal to the class of outerplanar graphs (see Bernhart and Kainen [1]). Therefore, the linear time outerplanar graph recognition algorithm of Syslo and Iri [12] can be used to determine whether or not an undirected graph has a 1-stack layout. However, not all dags with outerplanar covering graphs are 1-stack dags and this makes it more difficult to recognize 1-stack dags (for an example, see Figure 1.1).

Second, we present a linear time algorithm to recognize 1-queue dags. Our algorithm uses a variation of the PQ-tree data structure introduced by Booth and Lueker [2]. This result solves an open problem of Heath, Pemmaraju, and Trenk [10] and brings out a contrast between 1-queue undirected graphs and 1-queue dags, because Heath and Rosenberg [11] have shown that the problem of recognizing 1-queue undirected graphs is NP-complete. The main step of our 1-queue dag recognition algorithm determines whether a given dag has a leveled-planar embedding. This result extends

the work of Di Battista and Nardelli [5] and Chandramouli and Diwan [3, 4]. These authors assume certain restrictions on the given dag. In particular, Di Battista and Nardelli present an algorithm to determine if a dag with a single source (node with in-degree 0) has a leveled-planar embedding. Chandramouli and Diwan present an algorithm to determine if a triconnected dag has a leveled-planar embedding.

Third, we prove that the problem of recognizing a 4-queue dag is NP-complete. In fact, our result is stronger: we show that recognizing a 4-queue poset (a 4-queue dag with certain restrictions) is NP-complete. Fourth and finally, we prove that recognizing a 6-stack dag is also NP-complete.

The organization of the rest of the paper is as follows. In section 1, we present a linear time algorithm for recognizing 1-stack dags. In section 2, we present a linear time algorithm for recognizing 1-queue dags. In section 3, we show that the problem of recognizing 4-queue dags is NP-complete, and finally, in section 4, we show that the problem of recognizing 6-stack dags is NP-complete.

1. Recognizing 1-stack dags. In this section, we present an $O(|V|)$ time algorithm for determining whether a dag $\vec{G} = (V, \vec{E})$ is a 1-stack dag. If $\vec{G}$ is a 1-stack dag, then the algorithm constructs a 1-stack layout of $\vec{G}$. A dag is a 1-stack dag if and only if each of its connected components is a 1-stack dag. Hence we assume, without loss of generality, that $\vec{G}$ is connected. Also, for $\vec{G}$ to be a 1-stack dag its covering graph $G = (V, E)$ has to be a 1-stack graph. By Bernhart and Kainen's characterization [1], this means that G has to be outerplanar, which in turn means that $|E| \leq 2|V| - 3$. Since $|\vec{E}| = |E|$, without loss of generality, we assume that $|\vec{E}| \leq 2|V| - 3$.

Bernhart and Kainen show that the stacknumber of an undirected graph is the maximum of the stacknumbers of its biconnected components. The analogous result does not hold for dags, as shown in Figure 1.1. The dag shown in this figure contains three biconnected components: one induced by the nodes $\{1, 2, 3, 4\}$, one induced by the nodes $\{2, 5\}$, and one induced by the nodes $\{5, 6, 7, 8\}$. For emphasis, each of the biconnected components is enclosed in an oval in Figure 1.1. Each of the biconnected components is a 1-stack dag, but we may verify that the dag itself cannot be laid out in one stack. Therefore, to verify that a dag is a 1-stack dag, it is not sufficient to check that each biconnected component is a 1-stack dag.

We organize our algorithm to recognize 1-stack dags in two steps. In the first step (section 1.1), we verify that each biconnected component of $\vec{G}$ is a 1-stack dag. If the

algorithm finds a biconnected component that is not a 1-stack dag, then it terminates immediately with failure. In the second step (section 1.2), we combine the 1-stack layouts of the biconnected components of $\vec{G}$ into a 1-stack layout of $\vec{G}$.

1.1. Biconnected dags. This step decomposes $\vec{G}$ into biconnected components and verifies that each biconnected component of $\vec{G}$ is a 1-stack dag. The verification depends on the following lemma.

LEMMA 1.1. *A biconnected dag $\vec{B} = (V, \vec{E})$ is a 1-stack dag if and only if $\vec{B}$ is an outerplanar dag and contains a directed Hamiltonian path obtained by traversing the outer face of an outerplanar embedding of $\vec{B}$.*

Proof. Suppose that $\vec{B}$ is an outerplanar dag containing a directed Hamiltonian path obtained by traversing the outer face of some outerplanar embedding of $\vec{B}$. This directed Hamiltonian path gives a unique topological order, say σ, of $\vec{B}$. It follows immediately from Bernhart and Kainen's characterization of 1-stack undirected graphs that σ yields a 1-stack layout of B. Since σ is a topological order of $\vec{B}$, σ also yields a 1-stack layout of $\vec{B}$.

To establish the converse, suppose that $\vec{B}$ is a biconnected 1-stack dag. Since its covering graph B is a 1-stack graph, B is outerplanar. Since B is biconnected and outerplanar, it contains a unique Hamiltonian cycle; call it C. Let $\vec{C}$ be the dag that is a subgraph of $\vec{B}$ and that has C as its covering graph. Clearly $\vec{C}$ is a 1-stack dag. By Lemma 2.2 of [9], $\vec{C}$ contains a unique directed Hamiltonian path; say it is given by $v_1, v_2, \ldots, v_n$. As a dag can have at most one Hamiltonian path, this is also the unique Hamiltonian path in $\vec{B}$. Then $\sigma = v_1, v_2, \ldots, v_n$ is the unique topological order of $\vec{B}$ that yields a 1-stack layout of $\vec{B}$. This 1-stack layout of $\vec{B}$ can be viewed, in a natural way, as an outerplanar embedding whose outer face can be traversed in the order given by σ. The lemma follows. □

Depth-first search on $\vec{G}$ can be used to decompose $\vec{G}$ into biconnected components. This requires $O(|V|)$ time, since depth-first search of G requires $O(|V| + |E|)$ time and $|E| \leq 2|V| - 3$. For each biconnected component $\vec{B}$ of $\vec{G}$, it is easy to combine a topological sort with a verification that $\vec{B}$ contains a directed Hamiltonian cycle and that the topological order yields a 1-stack layout of $\vec{B}$. The time complexity of the first step is $O(|V|)$.

1.2. General dags. This step combines the 1-stack layouts of the biconnected components of $\vec{G}$ into a 1-stack layout of $\vec{G}$. By Lemma 1.1, each of the 1-stack biconnected components of $\vec{G}$ has a unique source (node with in-degree 0), a unique sink (node with out-degree 0), and a unique 1-stack layout. For this step, we need the notion of a block-cutpoint tree, defined by Harary and Prins [6]. The *block-cutpoint tree* $T(\vec{G})$ of a dag $\vec{G}$ is the undirected graph with vertex set

$$\left\{\vec{B} \mid \vec{B} \text{ is a biconnected component of } \vec{G}\right\} \cup \left\{u \mid u \text{ is a cutpoint in } \vec{G}\right\}$$

and edge set

$$\left\{\{\vec{B}, u\} \mid u \text{ is a cutpoint in } \vec{B}\right\}.$$

Figure 1.2 shows the block-cutpoint tree of the dag in Figure 1.1. The larger circles, labeled $\vec{B}_1$, $\vec{B}_2$, and $\vec{B}_3$, represent the three biconnected components, while the smaller circles, labeled 2 and 5, represent cutpoints. Harary and Prins [6] show that $T(\vec{G})$ is a tree if and only if $\vec{G}$ is connected.

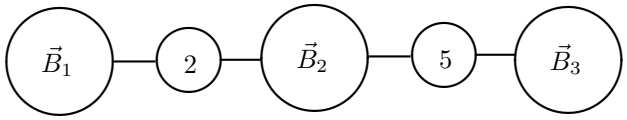

FIG. 1.2. *The block-cutpoint tree of the dag shown in Figure* 1.1.

An *intermediate node* in a biconnected component $\vec{B}$ is a node in $\vec{B}$ that is neither the source nor the sink in $\vec{B}$. In Figure 1.1, node 2 is an intermediate node in $\vec{B}_1$, and node 5 is an intermediate node in $\vec{B}_5$. For any biconnected component $\vec{B}$ in $\vec{G}$, we use $T(\vec{G}, \vec{B})$ to denote $T(\vec{G})$ rooted at $\vec{B}$. If x is a node in $\vec{B}$ that is a cutpoint of $\vec{G}$, then we use $D(\vec{B}, x)$ to denote the set of nodes in the subtree of $T(\vec{G}, \vec{B})$ rooted at x. For example, for the dag and its block-cutpoint tree shown in Figures 1.1 and 1.2, $D(\vec{B}_3, 5) = \{5, \vec{B}_2, 2, \vec{B}_1\}$ and $D(\vec{B}_1, 2) = \{2, \vec{B}_2, 5, \vec{B}_3\}$.

Two cutpoints u and v of $\vec{G}$ constitute a *conflicting pair of cutpoints* if u is an intermediate node in a biconnected component $\vec{B}_i$, v is an intermediate node in a biconnected component $\vec{B}_j$, $\vec{B}_i \in D(\vec{B}_j, v)$, and $\vec{B}_j \in D(\vec{B}_i, u)$. For example, the dag in Figure 1.1 contains the conflicting pair of cutpoints 2 and 5. This is because 2 is an intermediate node in $\vec{B}_1$, 5 is an intermediate node in $\vec{B}_3$, $\vec{B}_1 \in D(\vec{B}_3, 5)$, and $\vec{B}_3 \in D(\vec{B}_1, 2)$. Note that it is possible that u and v coincide.

The following lemma gives a partial characterization of 1-stack dags.

LEMMA 1.2. *Suppose the dag $\vec{G}$ contains a conflicting pair of cutpoints. Then $\vec{G}$ is not a* 1*-stack dag.*

Proof. Let u and v be a conflicting pair of cutpoints in $\vec{G}$. Let $\vec{B}_i$ and $\vec{B}_j$ be as in the definition of a conflicting pair. If either $\vec{B}_i$ or $\vec{B}_j$ is not a 1-stack dag, then $\vec{G}$ is not a 1-stack dag, and we are done. So assume that each of these biconnected component is a 1-stack dag. By Lemma 1.1, each biconnected component has a unique 1-stack layout, where the topological order is given by the unique Hamiltonian path in the biconnected component. Let $u_1, u_2, \ldots, u_t$ be that order on the nodes in $\vec{B}_i$ that yields a unique 1-stack layout of $\vec{B}_i$. By Lemma 1.1, (u_1, u_t) is an arc of $\vec{B}_i$. Since u is an intermediate node in $\vec{B}_i$, $u = u_k$, for some k, $1 < k < t$. Since $\vec{B}_i \in D(\vec{B}_j, v)$ and $\vec{B}_j \in D(\vec{B}_i, u)$, there is an undirected path P in G between cutpoints u and v such that no internal node in P belongs to either $\vec{B}_i$ or $\vec{B}_j$. Let σ be any topological ordering of $\vec{G}$. Clearly, $u_1, u_2, \ldots, u_t$ is a subsequence of σ. Based on where v occurs in σ relative to this subsequence, there are five cases:

1. $u = v$. Then $v = u_k$. Since v is an intermediate node in $\vec{B}_j$, there is a node v' immediately before v in the 1-stack layout of $\vec{B}_j$; moreover, v' is not in $\vec{B}_i$. Note that we may assume that $v' <_\sigma u_{k-1}$; if not, just switch the roles of $\vec{B}_i$ and $\vec{B}_j$. We consider two possibilities for the order of v' with respect to the nodes of $\vec{B}_i$. In the first case, suppose that the order σ satisfies

$$v' <_\sigma u_1 <_\sigma u_2 <_\sigma \cdots <_\sigma u_k = v <_\sigma u_{k+1} <_\sigma \cdots <_\sigma u_t.$$

In this case, the arc (u_1, u_t) crosses the arc (v', v), and σ does not yield a 1-stack layout of $\vec{G}$. In the second case, suppose that the order σ satisfies

$$u_m <_\sigma v' <_\sigma u_{m+1} <_\sigma \cdots <_\sigma u_k = v <_\sigma u_{k+1}$$

for some m with $1 \leq m < k-1$. In this case, the arc (u_m, u_{m+1}) crosses the arc (v', v), and σ does not yield a 1-stack layout of $\vec{G}$. Hence, in both cases, σ does not yield a 1-stack layout of $\vec{G}$.

2. $v <_\sigma u_1$ or $u_t <_\sigma v$. In either case, an edge in P crosses (u_1, u_t) and therefore σ does not yield a 1-stack layout of $\vec{G}$.
3. $u_m <_\sigma v <_\sigma u_{m+1}$, where $1 \leq m < k-1$ or $k+1 \leq m < t$. In either case, an edge in P crosses (u_m, u_{m+1}) and therefore σ does not yield a 1-stack layout $\vec{G}$.
4. $u_{k-1} <_\sigma v <_\sigma u_k$. Then, for any node w in $\vec{B}_j$, it is the case that $u_{k-1} <_\sigma w <_\sigma u_k$, because otherwise an arc in $\vec{B}_j$ would cross arc (u_{k-1}, u_k). But the fact that $u_{k-1} <_\sigma w <_\sigma u_k$ for all nodes w in $\vec{B}_j$ implies that an edge in P crosses arc (v', v''), where v' and v'' are the source and sink, respectively, of $\vec{B}_j$ (here we use the fact that v is an intermediate node in $\vec{B}_j$). Therefore, σ does not yield a 1-stack layout of $\vec{G}$.
5. $u_k <_\sigma v <_\sigma u_{k+1}$. An argument similar to the one employed in case 3 shows that σ does not yield a 1-stack layout of $\vec{G}$.

In all cases, σ does not yield a 1-stack layout of $\vec{G}$. But σ is an arbitrary topological ordering. Hence $\vec{G}$ is not a 1-stack dag, as desired. □

To combine the biconnected components of $\vec{G}$ into a 1-stack layout of $\vec{G}$, we first order the biconnected components of $\vec{G}$ via a breadth-first search of $T(\vec{G})$. Let an arbitrary biconnected component $\vec{B}_1$ be the root of the breadth-first search, and let $\vec{B}_1, \vec{B}_2, \ldots, \vec{B}_m$ be the order obtained for the biconnected components. Also, let T be the rooted version of $T(\vec{G})$ so obtained.

For each i, where $1 \leq i \leq m$, let $\vec{G}_i$ denote the subgraph of $\vec{G}$ induced by the biconnected components $\vec{B}_1, \vec{B}_2, \ldots, \vec{B}_i$. In particular, $\vec{G}_1 = \vec{B}_1$ and $\vec{G}_m = \vec{G}$. Let u be a cutpoint of $\vec{G}$, and let $\vec{B}_k$ be the parent of u in T. Then u is *restricted in* $\vec{G}_i$ if u belongs to $\vec{G}_i$ and some cutpoint $v \in D(\vec{B}_k, u)$ is an intermediate node in some biconnected component $\vec{B}_j$, where $j > i$ and $\vec{B}_j$ is a child of v. Note that it is possible that $v = u$ in which case $\vec{B}_j$ is a child of u. Consider Figure 1.3. Assume that v is an intermediate node in $\vec{B}_7$. Then the cutpoint u is restricted in both $\vec{G}_2$ and $\vec{G}_3$.

The following lemma places an upper bound on the number of cutpoints in $\vec{B}_i$ that can be restricted in $\vec{G}_i$.

LEMMA 1.3. *Suppose that $\vec{G}$ does not contain a conflicting pair of cutpoints. Then the number of cutpoints in $\vec{B}_i$ that are restricted in $\vec{G}_i$ is at most* 1. *Further suppose that $\vec{G}$ contains a restricted cutpoint u whose parent in T is $\vec{B}_k$. Then u is either the source or the sink of $\vec{B}_k$.*

Proof. Suppose that u is a restricted cutpoint in $\vec{G}_i$, and $\vec{B}_k$ is its parent in T. By definition, $k \leq i$ and there exists some cutpoint $v \in D(\vec{B}_k, u)$ that is an intermediate node in some biconnected component $\vec{B}_j$, where $j > i$ and $\vec{B}_j$ is a child of v. First suppose that u is an intermediate node of $\vec{B}_k$. Then $\vec{B}_i \in D(\vec{B}_j, v)$ and $\vec{B}_j \in D(\vec{B}_i, u)$, implying that u and v constitute a conflicting pair of cutpoints in $\vec{G}$, contrary to assumption. Hence only two nodes in $\vec{B}_k$, the source and the sink of $\vec{B}_k$, may be restricted in $\vec{G}_i$.

Now suppose that u and u' are distinct restricted cutpoints in $\vec{G}$. Suppose that $\vec{B}_k$ is the parent of u in T and $\vec{B}_{k'}$ the parent of u'. Note that it is possible that $k = k'$, in which case one of u and u' is the source and the other the sink of $\vec{B}_k$. By definition, $k \leq i$ and there exists some cutpoint $v \in D(\vec{B}_k, u)$ that is an intermediate

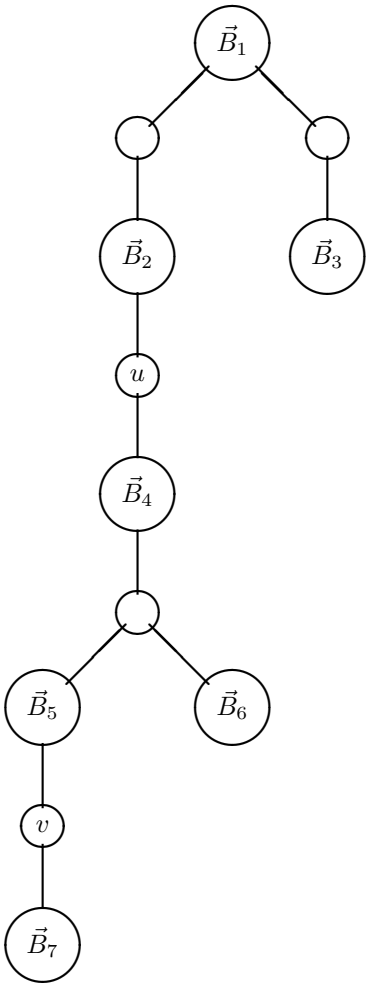

FIG. 1.3. *Node u is restricted in both $\vec{G}_2$ and $\vec{G}_3$.*

node in some block $\vec{B}_j \in D(\vec{B}_k, u)$, where $j > i$ and $\vec{B}_j$ is a child of v. Similarly, $k' \leq i$ and there exists some cutpoint $v' \in D(\vec{B}'_k, u')$ that is an intermediate node in some block $\vec{B}_{j'} \in D(\vec{B}'_k, u')$, where $j' > i$ and $\vec{B}_{j'}$ is a child of v'. It is easy to see that $v \neq v'$, that $v \in D(\vec{B}_{j'}, v')$, and that $v' \in D(\vec{B}_j, v)$. Hence, v and v' constitute a conflicting pair of cutpoints in $\vec{G}$, contrary to assumption.

We conclude that at most one cutpoint in $\vec{G}$ is restricted in $\vec{G}_i$. The lemma follows. □

The main result is now given by the following theorem.

THEOREM 1.4. *Let $\vec{G} = (V, E)$ be a dag that does not contain a pair of conflicting cutpoints and that does not contain a biconnected component with stacknumber exceeding* 1. *Then $\vec{G}$ is a* 1*-stack dag. Further, a* 1*-stack layout of $\vec{G}$ can be constructed in $O(|V| + |E|)$ time.*

Proof. The proof consists of an algorithm that actually constructs a 1-stack layout of $\vec{G}$. The algorithm first preprocesses the biconnected components of $\vec{G}$ in the order $\vec{B}_m, \vec{B}_{m-1}, \ldots, \vec{B}_1$ so as to compute information about any restricted node in each

$\vec{G}_i$. Clearly, $\vec{B}_m$ does not contain any nodes that are restricted in $\vec{G}_m$. For each i, $1 \leq i < m$, we can compute the set of nodes in $\vec{B}_i$ that are restricted in $\vec{G}_i$ as follows. Let u be a node in $\vec{B}_i$ that is a cutpoint of $\vec{G}$. Then, u is restricted in $\vec{G}_i$ if and only if u is shared by a biconnected component $\vec{B}_j$, $j > i$, and either u is an intermediate node in $\vec{B}_j$ or $\vec{B}_j$ contains nodes that are restricted in $\vec{G}_j$. Based on the above observation, for each u in $\vec{B}_i$ that is a cutpoint in $\vec{G}$, in the worst case, it takes time proportional to the number of children u has in T to determine whether u is restricted in $\vec{G}_i$. Thus, the entire preprocessing step takes time proportional to the number of edges in T. Since the number of nodes in T is at most $3|V| - 3$, the time complexity of the entire preprocessing step is $O(|V|)$.

After the preprocessing step, if we find that some $\vec{B}_i$ has two or more cutpoints that are restricted in $\vec{G}_i$, then (by Lemma 1.3) $\vec{G}$ contains a conflicting pair of cutpoints and (by Lemma 1.2) $\vec{G}$ does not have a 1-stack layout. So we may assume, without loss of generality, that after the preprocessing step each biconnected component $\vec{B}_i$ has at most one cutpoint that is restricted in $\vec{G}_i$.

A node u is said to be *exposed* in a topological order σ of $\vec{G}$ if there is no arc $(v, w) \in \vec{E}$ such that $v <_\sigma u <_\sigma w$. The algorithm now proceeds to process the biconnected components of $\vec{G}$ in forward order so as to maintain the following induction hypothesis.

INDUCTION HYPOTHESIS. *For each $i \geq 1$, we have that*

(a) *$\vec{G}_i$ has a 1-stack layout;*

(b) *if u is restricted in $\vec{G}_i$, then $\vec{G}_i$ has a 1-stack layout in which u is exposed.*

Note that Lemma 1.3 implies that there is at most one cutpoint that is restricted in any $\vec{G}_i$. We now prove the base case and the inductive step.

Base case. $\vec{B}_1$ has a unique 1-stack layout in which the source and the sink are exposed and the rest of the nodes are not. Thus item (a) of the induction hypothesis is satisfied. Lemma 1.3 implies that if a cutpoint in $\vec{B}_1$ is restricted in $\vec{G}_1$, then it is either the source or the sink of $\vec{B}_1$, both of which are exposed. Thus item (b) of the induction hypothesis is satisfied.

Inductive step. We now add the 1-stack layout of $\vec{B}_{i+1}$, as computed in section 1.1, to the 1-stack layout of $\vec{G}_i$ already constructed, and show that a 1-stack layout of $\vec{G}_{i+1}$ results that satisfies the induction hypothesis. Let $\sigma = u_1, u_2, \ldots, u_t$ be the unique order on the nodes in $\vec{B}_{i+1}$ that yields the 1-stack layout. Let u_m, $1 \leq m \leq t$, be the cutpoint of $\vec{G}$ through which $\vec{B}_{i+1}$ is connected to $\vec{G}_i$. There are two cases depending on whether or not $\vec{B}_{i+1}$ contains a cutpoint that is restricted in $\vec{G}_{i+1}$:

1. *$\vec{B}_{i+1}$ contains a cutpoint v that is restricted in $\vec{G}_{i+1}$.* This implies that the cutpoint u_m is restricted in $\vec{G}_i$ because either $v = u_m$ or u_m has a child $\vec{B}_{i+1}$ in T and $\vec{B}_{i+1}$ has a child in T, namely v, that is restricted in $\vec{G}_{i+1}$. Therefore, by the induction hypothesis item (b), u_m is exposed in the 1-stack layout of $\vec{G}_i$ constructed so far. Place the nodes $u_1, u_2, \ldots, u_{m-1}$ in that order to the left of the nodes in $\vec{G}_i$ and place the nodes $u_{m+1}, u_{m+2}, \ldots, u_t$ in that order to the right of the nodes in $\vec{G}_i$. Since u_m is exposed in the layout of $\vec{G}_i$, we obtain a 1-stack layout of $\vec{G}_{i+1}$, thus satisfying item (a) in the induction hypothesis.

   By Lemma 1.3, v is either a source ($v = u_1$) or v is a sink ($v = u_t$) in $\vec{B}_{i+1}$. Since both the source and the sink are exposed in the 1-stack layout of $\vec{G}_{i+1}$ constructed, item (b) of the induction hypothesis is satisfied.
2. *$\vec{B}_{i+1}$ does not contain a cutpoint that is restricted in $\vec{G}_{i+1}$.* To obtain a 1-stack

layout of $\vec{G}_{i+1}$, we place the nodes $u_1, \ldots, u_{m-1}$ in that order immediately to the left of u_m and the nodes $u_{m+1}, \ldots, u_t$ in that order immediately to the right of u_t. To show that this placement of the nodes in $\vec{B}_{i+1}$ yields a 1-stack layout of $\vec{G}_{i+1}$, we need to consider two possibilities with respect to cutpoint u_m. Either u_m is restricted in $\vec{G}_i$ or u_m is not restricted in $\vec{G}_i$.

If u_m is restricted in $\vec{G}_i$, then by induction hypothesis item (b), it is exposed in the 1-stack layout of $\vec{G}_i$ constructed so far. Hence, placing the nodes in $\vec{B}_{i+1}$ as described above yields a 1-stack layout of $\vec{G}_{i+1}$, thus satisfying induction hypothesis item (a). If u_m is restricted in $\vec{G}_{i+1}$ also, then by Lemma 1.3, u_m is either a source ($m = 1$) or a sink ($m = t$) of $\vec{B}_{i+1}$ and remains exposed in the layout of $\vec{G}_{i+1}$.

If u_m is not restricted in $\vec{G}_i$, then u_m cannot be an intermediate node in $\vec{B}_{i+1}$. Hence u_m is either the source ($m = 1$) or the sink ($m = t$) of $\vec{B}_{i+1}$. Again, placing the nodes in $\vec{B}_{i+1}$ as described above yields a 1-stack layout of $\vec{G}_{i+1}$. Item (b) of the induction hypothesis is satisfied because the cutpoints that are restricted in $\vec{G}_{i+1}$ are the same as the cutpoints that are restricted in $\vec{G}_i$ and all nodes that are exposed in the 1-stack layout of $\vec{G}_i$ remain exposed in the 1-stack layout of $\vec{G}_{i+1}$.

By induction, a 1-stack layout of $\vec{G}$ results.

Because the 1-stack layout of $\vec{B}_{i+1}$ is constructed in linear time in section 1.1, it takes $O(|\vec{B}_{i+1}|)$ time to extend the 1-stack layout of $\vec{G}_i$ to the 1-stack layout of $\vec{G}_{i+1}$. Thus constructing the 1-stack layout of $\vec{G}_m$ takes a total of $O(m)$ time. Since $m \leq |\vec{E}| \leq 2|V| - 3$, the time complexity of the algorithm is $O(|V|)$. □

In contrast to the ease of recognizing 1-stack dags, witness the NP-completeness of recognizing 6-stack dags shown in Theorem 4.1.

2. Recognizing 1-queue dags. In this section, we present an $O(|V|)$ time algorithm to determine whether a dag $\vec{G} = (V, \vec{E})$ is a 1-queue dag and, if so, to construct a 1-queue layout of $\vec{G}$. Heath and Rosenberg [11] characterize 1-queue undirected graphs as arched leveled-planar graphs and show that the problem of recognizing arched leveled-planar graphs is NP-complete. Analogously, Heath, Pemmaraju, and Trenk [9] characterize 1-queue dags as arched leveled-planar dags. In this section, we present a linear time algorithm for recognizing arched leveled-planar dags. Thus, recognizing 1-queue dags turns out to be significantly simpler than recognizing 1-queue undirected graphs. The development of our algorithm requires two steps, which are outlined here and subsequently elaborated upon:

1. *Recognize leveled-planar dags.* The first step is an algorithm that takes a leveled dag as input and determines whether or not the dag has a leveled-planar embedding. This is the more complicated of the two steps. Note the contrast with Heath and Rosenberg's result [11] in which they show that the problem of recognizing leveled-planar undirected graphs is NP-complete.
2. *Recognize* 1*-queue dags.* The second step is an extension of the first step and is the algorithm we seek. Given a dag as input, it first finds a maximal leveled subgraph of a particular kind by removing certain nonleveled arcs. It then applies the algorithm from the first step to determine whether the subgraph is a leveled-planar dag, while modifying the algorithm to take into account the nonleveled arcs.

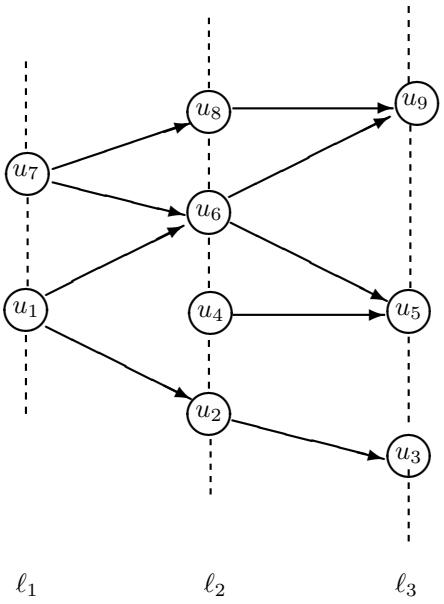

FIG. 2.1. *A leveled-planar dag.*

The first step of our algorithm, the one that recognizes leveled-planar dags, was sketched in [7] and extends the work of Di Battista and Nardelli [5] and Chandramouli and Diwan [3, 4]. These authors assume certain restrictions on the given dag. In particular, Di Battista and Nardelli [5] present a linear time algorithm to determine if a given *hierarchy* has a leveled-planar embedding. A hierarchy is a leveled dag with a single source. Hierarchies are widely used in many fields of social and mathematical sciences, and a common procedure for improving the readability of a drawing of a hierarchy is to minimize the number of edge crossings. Chandramouli and Diwan [3] present a linear time algorithm to determine if a given triconnected dag has a leveled-planar embedding. They point out that their algorithm can be used to solve a problem related to grid intersection graphs. These authors leave open the problem of determining whether or not an arbitrary dag is leveled-planar.

We proceed as follows. Section 2.1 discusses the problem of recognizing leveled-planar dags. Section 2.2 defines the data structures (PQ-trees and collections) that we need to represent sets of permutations of nodes in a particular level. We outline the algorithm to recognize a leveled-planar dag in section 2.3. Section 2.4 defines the operations we use to restrict or combine sets of permutations. Section 2.5 presents the details of our linear time algorithm for recognizing leveled-planar dags and proves its correctness and time complexity. Section 2.6 extends that algorithm to a linear time algorithm for recognizing 1-queue dags. The reader should review the definitions and notation from section 1 of [9], especially topological order, leveling, directed leveled-planar embedding, and directed arched leveled-planar embedding. Figure 2.1 shows a directed leveled-planar embedding of a dag.

2.1. The problem of recognizing leveled-planar dags. We concentrate first on the problem of recognizing whether a dag $\vec{G} = (V, \vec{E})$ is a leveled-planar dag. It is easy to check in linear time, using a graph traversal technique such as depth-first search, whether a dag $\vec{G} = (V, \vec{E})$ is leveled. If it is, then fix a leveling lev :

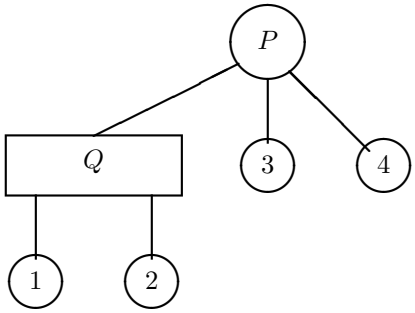

FIG. 2.2. *A PQ-tree.*

$V \to \{1, 2, \ldots, m\}$ of $\vec{G}$, for some integer m. Define $V_i = lev^{-1}(i)$. Without loss of generality, we may assume that $V_i \neq \emptyset$ for every i with $1 \leq i \leq m$. We write $\vec{G} = (V_1, V_2, \ldots, V_m; \vec{E})$ and henceforth assume that $\vec{G}$ is a connected, leveled dag.

The problem remaining is to determine whether $\vec{G}$ has a directed leveled-planar embedding.

Suppose $\vec{G}$ has a directed leveled-planar embedding $\mathcal{E}$. As $\vec{G}$ is connected, without loss of generality, we may assume that the leveling induced by $\mathcal{E}$ is *lev*. For each j, where $1 \leq j \leq m$, $\mathcal{E}$ determines a total order $\leq_j$ on V_j given by the bottom-to-top order of the nodes on ℓ_j. Conversely, if a total order $\leq_j$ on V_j is given for each j, then it is easy to check whether these total orders yield a directed leveled-planar embedding of $\vec{G}$. It suffices to check that there are no two arcs (u, v) and (x, y) such that $lev(u) = lev(x) = j$, $u <_j x$, and $y <_{j+1} v$. In Figure 2.1, the total orders are given by $u_1 <_1 u_7$, $u_2 <_2 u_4 <_2 u_6 <_2 u_8$, and $u_3 <_3 u_5 <_3 u_9$.

The problem of recognizing whether a connected leveled dag $\vec{G}$ is a leveled-planar dag is then equivalent to determining whether there are total orders on all m levels that together yield a leveled-planar embedding of $\vec{G}$. Each total order is a permutation of the nodes in that level. As our algorithm needs to represent many such permutations for each level, we introduce suitable data structures in the next section.

2.2. PQ-trees and collections. A classical data structure used to represent sets of permutations is the PQ-tree of Booth and Lueker [2]. A PQ-tree T for a set S is a rooted tree that contains three types of nodes: leaves, P-nodes (each drawn as a circle), and Q-nodes (each drawn as a box). The leaves in T are in one-to-one correspondence with the elements of S. The set S is called the *yield* of T, denoted YIELD(T). It is clear that we can iterate over the set YIELD(T) in time Θ(YIELD(T)) by simply traversing the tree in, say, preorder. The PQ-tree T represents permutations of YIELD(T) according to the following rules:

- The children of a P-node may be permuted arbitrarily.
- The children of a Q-node must occur in the given order or in the reverse order.

As a special case, the empty PQ-tree ϵ represents the empty set of permutations. For example, the PQ-tree shown in Figure 2.2 represents these 12 permutations

$$\begin{array}{llllll} 1,2,3,4 & 1,2,4,3 & 4,1,2,3 & 3,1,2,4 & 3,4,1,2 & 4,3,1,2 \\ 2,1,3,4 & 2,1,4,3 & 4,2,1,3 & 3,2,1,4 & 3,4,2,1 & 4,3,2,1 \end{array}$$

of $S = \{1, 2, 3, 4\}$. The set of permutations represented by a PQ-tree T is denoted by PERM(T). The *yield* YIELD(r) of a node r in T is the yield of the subtree rooted

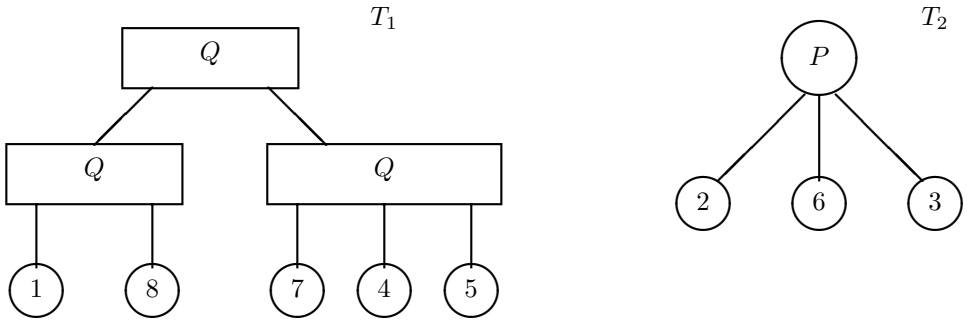

FIG. 2.3. *A collection.*

at r. Without loss of generality, we may assume that every P-node has three or more children and that every Q-node has two or more children.

A *collection* C is a finite set of PQ-trees with pairwise disjoint yields. The *yield* of C, denoted YIELD(C), is the union of the yields of its constituent trees. PERM(C), the set of permutations represented by C, consists of those permutations π of YIELD(C) such that, for each $T \in C$, π restricted to YIELD(T) is in PERM(T). An example of a collection containing two PQ-trees is shown in Figure 2.3. The PQ-tree T_1 represents these eight permutations

$$\begin{array}{cccc} 1,8,7,4,5 & 1,8,5,4,7 & 8,1,7,4,5 & 8,1,5,4,7 \\ 7,4,5,1,8 & 5,4,7,1,8 & 7,4,5,8,1 & 5,4,7,8,1 \end{array}$$

of $\{1,4,5,7,8\}$. The PQ-tree T_2 represents all six permutations of $\{2,3,6\}$. The collection C represents all $8 \cdot 6 \cdot (\frac{8!}{5! \cdot 3!}) = 2688$ permutations of $\{1,2,3,4,5,6,7,8\}$ that are consistent with both T_1 and T_2.

We wish to represent all possible leveled-planar embeddings of a connected, leveled dag by permutations of nodes in its "rightmost" level. To this end, we make the following definition: Suppose that $\vec{F}$ is a leveled, connected dag. Fix a leveling of $\vec{F}$. Suppose that level k is the largest nonempty level. We say that a PQ-tree T *mirrors* $\vec{F}$ if PERM(T) is the set of all permutations of the level-k nodes in $\vec{F}$ that witness some leveled-planar embedding of $\vec{F}$. If we take $\vec{F}$ to be the dag in Figure 2.1, then a PQ-tree consisting of a Q-node as root with children $3,5,9$ (in that order) mirrors $\vec{F}$.

For some $\vec{F}$, the PQ-tree $T[\vec{F}]$ that mirrors $\vec{F}$ is easily described. For example, suppose that $\vec{F}$ is a tree dag with a single source s and all arcs directed away from s. Such a dag is clearly a leveled-planar dag, with a unique leveling such that $lev(s) = 1$. Then the PQ-tree $T[\vec{F}]$ is essentially isomorphic to $\vec{F}$. To obtain $T[\vec{F}]$ from $\vec{F}$ simply replace each internal (nonleaf) node in $\vec{F}$ by a P-node. The root of $T[\vec{F}]$ is the node that replaced s. $T[\vec{F}]$ might contain P-nodes that have fewer than three children. To get rid of such nodes, iteratively replace every P-node, whose only child is a leaf, by that leaf. Then replace every P-node with two children by a Q-node.

This definition of mirroring does not extend to a leveled dag that is not connected. As an illustration, suppose $\vec{F}'$ is the leveled dag induced by the left two levels in Figure 2.1. In a leveled-planar embedding of $\vec{F}'$, the nodes 2, 6, and 8 must appear in that order or in the reverse order, but the node 4 may appear anywhere with respect to these nodes. It is clear that a single PQ-tree cannot represent the corresponding set of permutations, although a collection of two PQ-trees can.

2.3. Overview of the algorithm to recognize leveled-planar dags. In this section, we give an overview of our algorithm that determines whether a given connected, leveled dag $\vec{G} = (V_1, V_2, \ldots, V_m, \vec{E})$ is leveled-planar. For any j, $1 \leq j \leq m$, let $\vec{G}_j$ denote the subgraph of $\vec{G}$ induced by $V_1 \cup V_2 \cup \cdots \cup V_j$. Note that, unlike $\vec{G}$, the subgraph $\vec{G}_j$ is not necessarily connected. For each level V_j, we say that a permutation π of the nodes in V_j is a *witness* to a directed leveled-planar embedding $\mathcal{E}$ of $\vec{G}_j$ if the nodes in V_j appear in a bottom-to-top order on line ℓ_j according to π in $\mathcal{E}$. For each j, there is a set of permutations Π_j that contains all witnesses to directed leveled-planar embeddings of $\vec{G}_j$. So to recognize whether $\vec{G}$ is a leveled-planar dag, we need only compute Π_m and check that it is nonempty. Our basic approach to doing this efficiently is to perform a left-to-right sweep processing the levels in the order $V_1, V_2, \ldots, V_m$. For any dag $\vec{H}$, let $\mathrm{COMP}(\vec{H})$ be the set of connected components of $\vec{H}$. For each $\vec{F} \in \mathrm{COMP}(\vec{G}_j)$, we construct a PQ-tree $T[\vec{F}]$ that mirrors $\vec{F}$. We use a collection C_j to contain PQ-trees $T[\vec{F}]$ for all $\vec{F} \in \mathrm{COMP}(\vec{G}_j)$. Clearly, $\mathrm{YIELD}(C_j) = V_j$. Furthermore, any permutation of V_j that is a witness to a directed leveled-planar embedding of $\vec{G}_j$ is in $\mathrm{PERM}(C_j)$. However, if $\vec{G}_j$ is not connected, then there may be a permutation in $\mathrm{PERM}(C_j)$ that is not a witness to any directed leveled-planar embedding of $\vec{G}_j$. The algorithm then processes V_{j+1} and derives the collection C_{j+1} from the collection C_{j+1}. The collections maintained by our algorithm satisfy the following invariant.

Collection invariant. *For each j, where $1 \leq j \leq m$, and for each $\vec{F} \in \mathrm{COMP}(\vec{G}_j)$, there is a corresponding PQ-tree $T[\vec{F}]$ in C_j that mirrors $\vec{F}$.*

Since $\vec{G} = \vec{G}_m$ is connected, the collection invariant implies that C_m contains a single PQ-tree $T[\vec{G}]$ that represents $\vec{G}$. So C_m contains a nonempty PQ-tree if and only if $\vec{G}$ has a directed leveled-planar embedding. Thus the goal of our algorithm is to compute C_m.

The evolution of C_{j+1} from C_j requires that some information be maintained in each nonleaf node of a PQ-tree and one additional piece of information be maintained at the root. Let $\vec{F}$ be any connected component of $\vec{G}_j$. By the collection invariant, $T[\vec{F}]$ is the PQ-tree in C_j that mirrors $\vec{F}$. For any subset S of the set of nodes in V_j that belongs to $\vec{F}$, define $\mathrm{MEETLEVEL}(S)$ to be the greatest $d \leq j$ such that $V_d, \ldots, V_j$ induces a dag in which all nodes of S occur in the same connected component. For example, in Figure 2.1, $\mathrm{MEETLEVEL}(\{u_3, u_5\}) = 1$ and $\mathrm{MEETLEVEL}(\{u_5, u_9\}) = 2$. Note that if $|S| > 1$, then $\mathrm{MEETLEVEL}(S) < j$. For a Q-node q in $T[\vec{F}]$ with ordered children $r_1, r_2, \ldots, r_t$, maintain in node q, integers denoted $\mathrm{ML}(r_i, r_{i+1})$, where $1 \leq i < t$, that satisfy

$$\mathrm{ML}(r_i, r_{i+1}) = \mathrm{MEETLEVEL}(\mathrm{YIELD}(r_i) \cup \mathrm{YIELD}(r_{i+1})).$$

For a P-node p in $T[\vec{F}]$, maintain in node p a single integer denoted $\mathrm{ML}(p)$ that satisfies

$$\mathrm{ML}(p) = \mathrm{MEETLEVEL}(\mathrm{YIELD}(p)).$$

Let S be the set of nodes in V_j that belong to $\vec{F}$. Define $\mathrm{LEFTLEVEL}(S)$ to be the smallest d such that $\vec{F}$ contains a node in V_d. We always have

$$\mathrm{LEFTLEVEL}(S) \leq \mathrm{MEETLEVEL}(S),$$

and inequality is possible. At the root of $T[\vec{F}]$, maintain a single integer denoted $\mathrm{LL}(T[\vec{F}])$ satisfying

$$\mathrm{LL}(T[\vec{F}]) = \mathrm{LEFTLEVEL}(\mathrm{YIELD}(T[\vec{F}])).$$

When our algorithm computes the collection C_{j+1} from C_j, it also maintains the values of ML and LL in the PQ-trees in C_{j+1}. Note that since every PQ-tree in C_1 is a leaf, ML values are not defined, while $\mathrm{LL}(T) = 1$ for each tree $T \in C_1$.

It is easy to see that the ML values satisfy the following two propositions.

PROPOSITION 2.1. *Suppose that u is the least common ancestor of a pair of leaves v and w in a PQ-tree. If u is a P-node, then*

$$\mathrm{MEETLEVEL}(\{v, w\}) = \mathrm{ML}(u).$$

PROPOSITION 2.2. *Suppose that u is the least common ancestor of a pair of leaves v and w in a PQ-tree. Further suppose that u is a Q-node with ordered children $u_1, u_2, \ldots, u_t$ such that $v \in \mathrm{YIELD}(u_p)$ and $w \in \mathrm{YIELD}(u_q)$, where $1 \le p < q \le t$. Then*

$$\mathrm{MEETLEVEL}(\{v, w\}) = \min\{\mathrm{ML}(u_i, u_{i+1}) \mid p \le i < q\}.$$

The following proposition formalizes the notion that, as we follow a path in a PQ-tree from a leaf to the root, the ML values we encounter are nonincreasing.

PROPOSITION 2.3. *Suppose that node u is the parent of a nonleaf node v in a PQ-tree. Define x as follows:*

$$x = \begin{cases} \mathrm{ML}(u) & \text{if } u \text{ is a P-node;} \\ \max\{\mathrm{ML}(v, w) \mid w \text{ is a child of } u \text{ adjacent to } v\} & \text{if } u \text{ is a Q-node.} \end{cases}$$

Define y as follows:

$$y = \begin{cases} \mathrm{ML}(v) & \text{if } v \text{ is a P-node;} \\ \min\{\mathrm{ML}(v_i, v_{i+1}) \mid 1 \le i < t\} & \text{if } u \text{ is a Q-node with ordered} \\ & \text{children } v_1, v_2, \ldots, v_t. \end{cases}$$

Then $x \le y$.

2.4. Operations. We now describe two operations on a PQ-tree that serve as building blocks of the algorithm that constructs C_{j+1} from C_j. In each operation, the PQ-tree is transformed so that the set of permutations represented is restricted to be a potentially smaller set. In the case of the second operation, the yield of the PQ-tree is slightly modified. The LL value of the PQ-tree remains unchanged. The ML values are updated appropriately. We first describe what the operations are, then we describe how they are implemented:

1. ISOLATE(T, x), where T is a PQ-tree and $x \in \mathrm{YIELD}(T)$. This operation transforms T so that $\mathrm{PERM}(T)$ is restricted to permutations in which x is either the first or the last element. If there is no permutation in $\mathrm{PERM}(T)$ that has x as its first or last element, then T becomes ϵ.
2. IDENTIFY(T, x, y, z), where T is a PQ-tree, $x, y \in \mathrm{YIELD}(T)$, $x \ne y$, and z is a new node not in $\mathrm{YIELD}(T)$. Let P be the subset of permutations in $\mathrm{PERM}(T)$ in which x and y appear consecutively. Let P' be obtained from P as follows: If P contains the permutation $a, \ldots, b, x, y, c, \ldots, d$, then put in P' the permutation $a, \ldots, b, z, c, \ldots, d$, obtained by replacing x, y by z. The operation IDENTIFY(T, x, y, z) transforms T so that $\mathrm{PERM}(T) = P'$. Note that P' may be empty, in which case $T = \epsilon$.

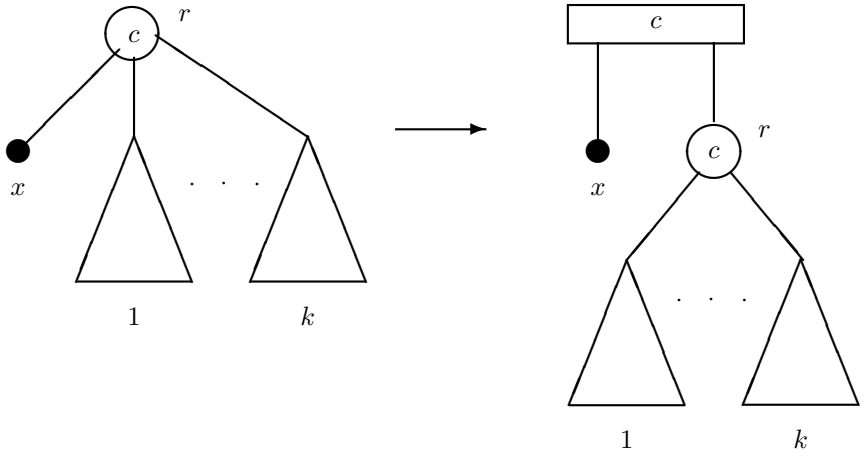

FIG. 2.4. *The transformation of T in the first case of* ISOLATE(T, x).

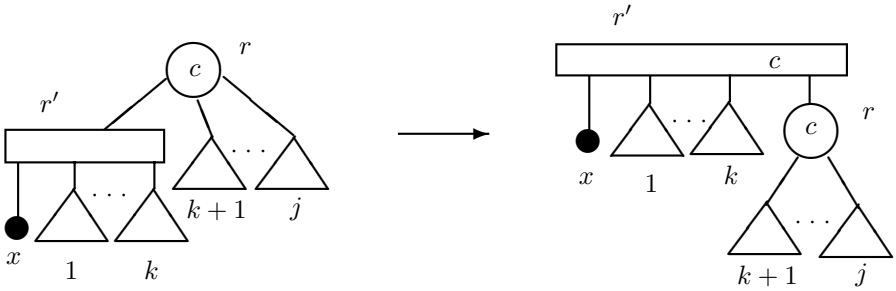

FIG. 2.5. *The transformation of T in the second case of* ISOLATE(T, x) *when r is a P-node.*

We first describe an implementation of ISOLATE(T, x). Let r be the root of T. If $x = r$, then ISOLATE(T, x) simply returns T. Otherwise, there are two cases based on whether or not x is a child of r.

1. x is a child of r. If r is a Q-node and x is not its first or last child, then there are no permutations in PERM(T) with x at the end or at the beginning, so the operation returns ϵ. If r is a Q-node and x is either the first or the last child of r, then T is unchanged. If r is a P-node, then T is transformed as shown in Figure 2.4. Before the operation, the tree consists of the root r, the child x, and subtrees labeled 1 through k. The ML(r) value is c. After the operation, a Q-node has been added as the root of T, x has been moved to be the first child of that Q-node, and the P-node r becomes the second and last child of that Q-node. The ML values are set as indicated.
2. x is not a child of r. Let T' be the subtree rooted at a child of r whose yield contains x. Perform ISOLATE(T', x). If $T' = \epsilon$, then ISOLATE(T, x) results in $T = \epsilon$. Otherwise, the root r' of T' is a Q-node with x as either its first or its last child. Without loss of generality, we may assume that x is the first child of r' and that the remaining subtrees attached to r' are labeled 1 through k. If r is a P-node, perform the transformation on T shown in Figure 2.5. The subtrees attached to r are T' together with subtrees labeled $k + 1$ through j. The ML(r) value is c. In this transformation, r' is rotated up to

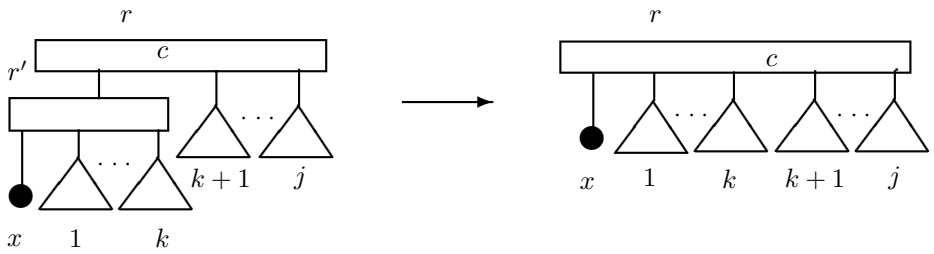

FIG. 2.6. *The transformation of T in the second case of* ISOLATE(T, x) *when r is a Q-node.*

be the root of T, while r becomes the last child of r'. The ML values are set as indicated. If r is a Q-node and r' is not the first or the last child of r, then set $T = \epsilon$. Otherwise, we may assume, without loss of generality, that r' is the first child of r. Perform the transformation on T shown in Figure 2.6. The subtrees attached to r are T' together with subtrees labeled $k + 1$ through j. In this transformation, r' is rotated up to be the root of T, while the subtrees $k + 1$ through j become the remaining subtrees attached to r'. The ML values are set as indicated.

The running time of ISOLATE(T, x) is proportional to the depth of x in T.

The operation IDENTIFY(T, x, y, z) can be implemented in the following four steps.

Step 1. Locate r, the node in T that is the least common ancestor of x and y.

Step 2. Let T_1 and T_2 be the subtrees of T rooted at children of r such that $x \in$ YIELD(T_1) and $y \in$ YIELD(T_2). Perform ISOLATE(T_1, x) and ISOLATE(T_2, y). If either $T_1 = \epsilon$ or $T_2 = \epsilon$, then set $T = \epsilon$. Otherwise, let r_1 be the root of T_1 and r_2 the root of T_2. Then r_1 is a Q-node with x being its first or last child, while r_2 is a Q-node with y being its first or last child.

Step 3. This step brings x and y together, if possible. The details depend on whether r is a P-node or a Q-node.

- *r is a P-node.* T is transformed as shown in Figure 2.7. The two Q-nodes r_1 and r_2 are merged so as to make x and y adjacent. The ML values c_1, c_2, and c_3 are repositioned as shown.
- *r is a Q-node.* If the subtrees T_1 and T_2 are not adjacent children of r, then set $T = \epsilon$. Otherwise, T is transformed as shown in Figure 2.8. The three Q-nodes r, r_1, and r_2 are merged so as to make x and y adjacent. The ML values c_1, c_2, and c_3 are repositioned as shown.

Step 4. Leaf z replaces leaves x and y.

The running time of IDENTIFY(T, x, y, z) is proportional to the sum of the depths of x and y in T.

In the transformations described for ISOLATE and IDENTIFY, we have ignored several special cases arising from the possibility that a transformation might lead to the birth of a P-node with two children. Instead of dealing with these cases separately, we simply note that whenever this happens, the P-node is replaced by a Q-node.

2.5. Recognizing leveled-planar dags. We are now ready to present our algorithm for determining whether the connected, leveled dag $\vec{G} = (V_1, \ldots, V_m; \vec{E})$ is a leveled-planar dag. In parallel, we develop the proof of correctness for the algorithm. The overall structure of the algorithm is an iteration that builds the collection C_{j+1} from the collection C_j for each j, $1 \leq j < m$. Hence, the proof of correctness is by

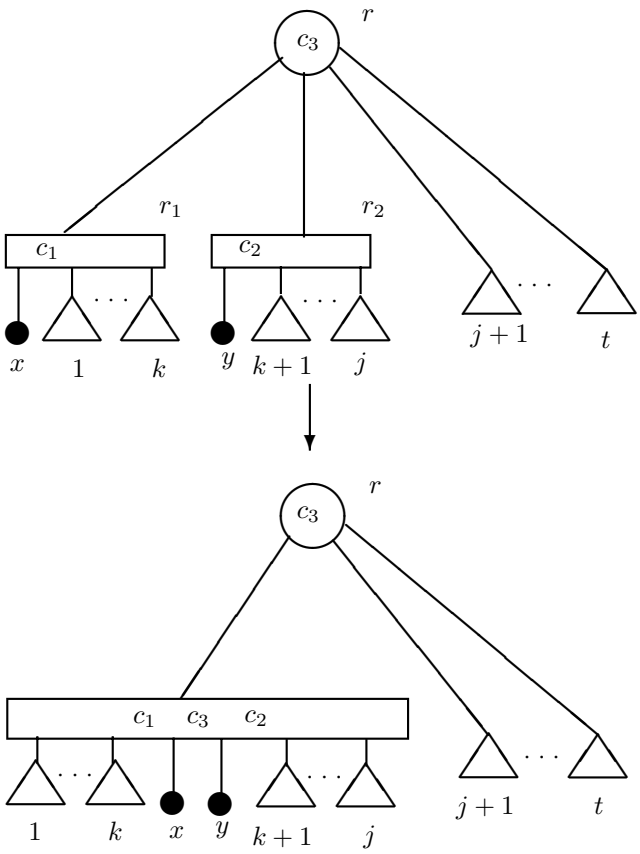

FIG. 2.7. *The transformation of T in* IDENTIFY(T, x, y, z) *when r is a P-node.*

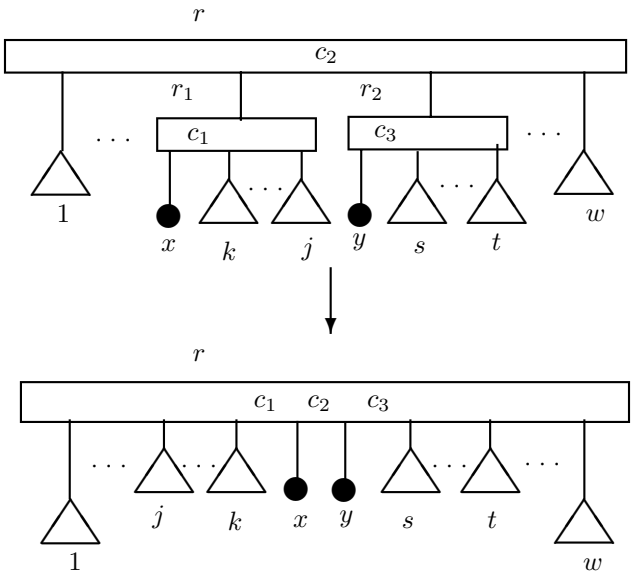

FIG. 2.8. *The transformation of T in* IDENTIFY(T, x, y, z) *when r is a Q-node.*

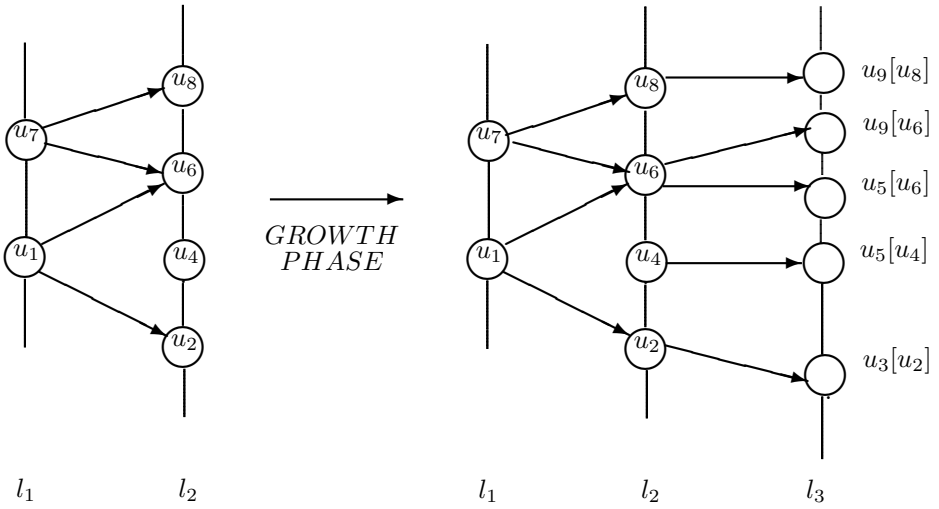

FIG. 2.9. *Illustration of the growth phase.*

induction on j with the collection invariant being the inductive hypothesis. The base case is $j = 1$. In this case, $\vec{G}_1 = (V_1, \emptyset)$ and C_1 contains, for each $v \in V_1$, one PQ-tree that contains only the node v.

When $1 \leq j < m$, the iterative step extends $\vec{G}_j$ to $\vec{G}_{j+1}$, while at the same time extending C_j to C_{j+1}. Let $\vec{E}_j$ be the set of *level-j arcs* from nodes in V_j to nodes in V_{j+1}. To extend $\vec{G}_j$ to $\vec{G}_{j+1}$, we must add the arcs in $\vec{E}_j$ and the nodes in V_{j+1} to $\vec{G}_j$. In describing the iterative step, it will be helpful to imagine that the arcs in $\vec{E}_j$ are added first and that the nodes in V_{j+1} are subsequently identified in a series of substeps. In particular, the iterative step can be thought of as working in four distinct phases: (i) GROWTH PHASE, (ii) FIRST MERGE PHASE, (iii) SECOND MERGE PHASE, and (iv) CLEANUP PHASE. We now describe each of the phases separately.

GROWTH PHASE. For a node v, let $\text{IN}(v)$ be the set of in-neighbors of v, and let $\text{OUT}(v)$ be the set of out-neighbors of v. For each $v \in V_{j+1}$ and for each $u \in \text{IN}(v)$, let $v[u]$ be a new node called a *copy* of v. In the growth phase, to $\vec{G}_j$, we add arcs $(u, v[u])$, for every node $v \in V_{j+1}$ and every $u \in \text{IN}(v)$. Thus, every connected component in $\vec{G}_j$ grows by a level and in this manner $\vec{G}_j$ is transformed into a leveled-planar dag $\vec{H}$ that has $j + 1$ levels. Note that $\vec{H}$ approximates $\vec{G}_{j+1}$ in the sense that every arc in $\vec{G}_{j+1}$ is represented in $\vec{H}$. An illustration of the growth phase can be found in Figure 2.9, where the first two levels of the dag of Figure 2.1 are extended to the third level. Note the two copies of the node u_9, namely, $u_9[u_8]$ and $u_9[u_6]$, and the two copies of the node u_5, namely, $u_5[u_6]$ and $u_5[u_4]$, that are created in this phase.

FIRST MERGE PHASE. In the two merge phases, all nodes of the form $v[u]$ that are created in the growth phase are identified to obtain the node v. In the first merge phase nodes belonging to the same connected component are identified, while in the second merge phase nodes belonging to distinct connected components are identified, as a result merging two connected components into one. If $v \in V_{j+1}$ and $X \subseteq \text{IN}(v)$, then let $v[X]$ be a new node that we think of as the result of identifying

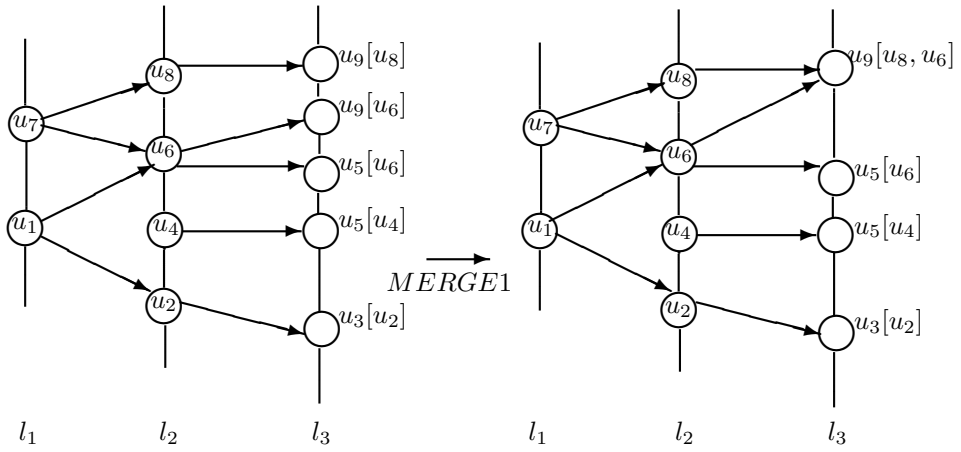

FIG. 2.10. *Illustration of the first merge phase.*

all nodes of the form $v[u]$, $u \in X$. (We think of the X in this notation as being an unordered list of the elements of X. Then we can write $v[X, Y]$ for $v[X \cup Y]$ and even $v[u, X]$ for $v[\{u\} \cup X]$.)

Consider any connected component $\vec{F}$ in $\vec{H}$. Recall that $\vec{F}$ was created in the growth phase by extending a connected component in $\vec{G}_j$ to $j+1$ levels. Also recall that each level-$(j+1)$ node in $\vec{F}$ is of the form $v[u]$, where $v \in V_{j+1}$ and $u \in V_j$. For each $v \in V_{j+1}$, let S_v be the set of all nodes u in $\vec{F}$ such that $v[u]$ is a node in $\vec{F}$. In the first merge phase all copies, $v[u]$, of v are identified into one node $v[S_v]$. This identification is done pairwise and in a certain order. For any permutation $\pi \in \text{PERM}(T[\vec{F}])$ of the nodes in $\text{YIELD}(T[\vec{F}])$, let

$$v[u_1], v[u_2], \ldots, v[u_t]$$

be the subsequence of π containing all copies of v in $\vec{F}$. The identification of the copies of v is done in the order prescribed by the above sequence. More precisely, for each i, $1 \leq i < t$, the nodes $v[u_1, u_2, \ldots, u_i]$ and $v[u_{i+1}]$ are identified into a single node $v[u_1, u_2, \ldots, u_{i+1}]$. The reason for respecting the above order is motivated by the following example. Suppose that $v[u_1]$, $v[u_2]$, and $v[u_3]$ are the only copies of v in $\vec{F}$. Further suppose that in every directed leveled-planar embedding of $\vec{F}$, $v[u_2]$ occurs between $v[u_1]$ and $v[u_3]$ on line ℓ_{j+1}. This implies that even though it may be possible to identify the nodes $v[u_1]$, $v[u_2]$, and $v[u_3]$ into a single node $v[u_1, u_2, u_3]$, it is not possible to do this identification pairwise starting with the pair $v[u_1]$ and $v[u_3]$ because $v[u_2]$ is an obstacle. The solution to this problem is to respect an order on the nodes $v[u_1], v[u_2], \ldots, v[u_t]$ that is a subsequence of some witness to a directed leveled-planar embedding of $\vec{F}$.

At the end of this phase, each connected component in $\vec{H}$ contains at most one copy of any node $v \in V_{j+1}$. The first merge phase is illustrated in Figure 2.10.

SECOND MERGE PHASE. In this phase duplicate copies of any level-$(j+1)$ node that occur in different connected components are identified. Thus, this phase eliminates any remaining duplicate copies of level-$(j+1)$ nodes by completing the identification that was started in the first merge phase. Suppose that connected components $\vec{F}_1$ and $\vec{F}_2$ of $\vec{H}$ share copies of a level-$(j+1)$ node. Note that, because

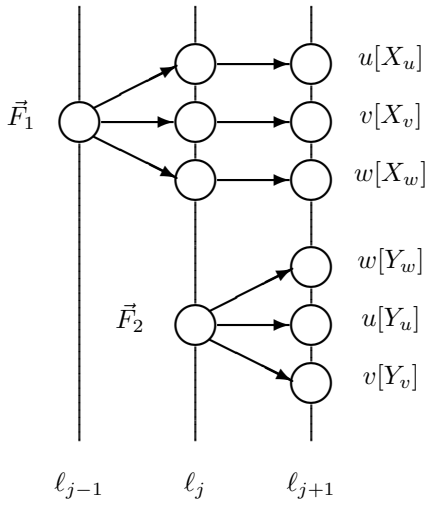

FIG. 2.11. *If $\vec{F}_1$ and $\vec{F}_2$ share copies of three level-$(j+1)$ nodes, then their merger cannot be leveled-planar.*

of the first merge phase, $\vec{F}_1$ and $\vec{F}_2$ each contain exactly one copy of any level-$(j+1)$ node. However, it is possible that they share copies of more than one level-$(j+1)$ node. Let U be the set of all $v \in V_{j+1}$ such that there is a copy $v[X]$ of v in $\vec{F}_1$ and a copy $v[Y]$ of v in $\vec{F}_2$. Let U be the set of all $v \in V_{j+1}$ such that there is a copy $v[X]$ of v in $\vec{F}_1$ and a copy $v[Y]$ of v in $\vec{F}_2$. If $|U| \geq 3$, then it is easy to see that $\vec{F}_3$ cannot be a leveled-planar dag. Figure 2.11 shows an example illustrating this fact for $|U| = 3$. Suppose $U = \{v_1, v_2\}$, where $v_1[X_1]$ (respectively, $v_2[X_2]$) is a copy of v_1 (respectively, v_2) in $\vec{F}_1$ and $v_1[Y_1]$ (respectively, $v_2[Y_2]$) is a copy of v_1 (respectively, v_2) in $\vec{F}_2$. Then, in the second merge phase, the connected components $\vec{F}_1$ and $\vec{F}_2$ are replaced by the connected component $\vec{F}$ that is obtained by identifying $v_1[X_1]$ and $v_1[Y_1]$ into a single node $v_1[X_1, Y_1]$. Now $\vec{F}$ contains two copies of v_2, namely, $v_2[X_2]$ and $v_2[Y_2]$. These are identified into a single node $v_2[X_2, Y_2]$. The second merge phase is illustrated in Figure 2.12.

CLEANUP PHASE. The dag $\vec{H}$ passes through the three earlier phases before it reaches the cleanup phase. The earlier phases ensure that for every node $v \in V_{j+1}$, there is exactly one copy, $v[\mathrm{IN}(v)]$, in $\vec{H}$. In this phase, each level-$(j+1)$ node in $\vec{H}$ with label $v[\mathrm{IN}(v)]$ is relabeled v so as to match its name in $\vec{G}_{j+1}$. For example, the dag obtained after the second merge phase in Figure 2.12 contains nodes $u_9[u_8, u_6]$, $u_5[u_4, u_6]$, and $u_3[u_2]$ which are relabeled u_9, u_5, and u_3 in the CLEANUP PHASE. More importantly, all level-$(j+1)$ sources in $\vec{G}$ are added to $\vec{H}$. This completes the transformation of $\vec{H}$ into $\vec{G}_{j+1}$.

Figure 2.13 shows the algorithm that transforms G_j into G_{j+1} using the four phases described above. In this algorithm, $\vec{H}$ is initialized to $\vec{G}_j$ and then transformed into $\vec{G}_{j+1}$ in four phases.

Having described the sequence of operations that transforms $\vec{G}_j$ into $\vec{G}_{j+1}$, we now describe the parallel sequence of operations that transforms C_j into C_{j+1}. We emphasize again that it is the transformations on the collections that are actually performed; the algorithm in Figure 2.13 merely gives a framework within which to

explain the rationale for the transformations. In particular, for each of the statements marked (1), (2), and (3) in the algorithm in Figure 2.13, we perform corresponding operations on collections. So we now describe the transformations applied to collections during the four phases of the algorithm.

GROWTH PHASE. We need to describe the effect on the PQ-tree $T[\vec{F}]$ of adding the arcs of the form $(u, v[u])$ to the dag $\vec{F}$. Let $\vec{F}'$ be the dag that results from adding all these arcs to $\vec{F}$. All the outgoing arcs from u in $\vec{F}'$ must appear together in such an embedding. Conversely, as long as they appear together, the outgoing arcs from u in $\vec{F}'$ can appear in any order. We mirror this constraint in the PQ-tree $T[\vec{F}]$ as follows. Start with $T[\vec{F}'] = T[\vec{F}]$. Suppose $u \in \text{YIELD}(T[\vec{F}])$. If u has no out-neighbors, then delete the leaf u from $T[\vec{F}']$. If u has only one out-neighbor v, then replace the leaf u in $T[\vec{F}']$ with the leaf $v[u]$. If u has two out-neighbors v_1 and v_2, then replace the leaf u in $T[\vec{F}']$ with a Q-node having two children $v_1[u]$ and $v_2[u]$ that are leaves. If u has more than two out-neighbors $v_1, v_2, \ldots, v_t$, $t > 2$, then replace the leaf u in $T[\vec{F}']$ with a P-node having children that are leaves $v_1[u], v_2[u], \ldots, v_t[u]$. From the preceding discussion, it should be clear that the resulting $T[\vec{F}']$ mirrors $\vec{F}'$.

FIRST MERGE PHASE. In this phase, each dag $\vec{F} \in \text{COMP}(\vec{H})$ is transformed by repeatedly identifying level-$(j+1)$ nodes $v[X]$ and $v[Y]$ into a single node $v[X, Y]$. Identifying $v[X]$ and $v[Y]$ into a single node $v[X, Y]$ first forces the nodes $v[X]$ and $v[Y]$ to appear consecutively on line ℓ_{j+1} and then contracts these two nodes into a single node $v[X, Y]$. Thus, we are interested only in those permutations in $\text{PERM}(T[\vec{F}])$ in which $v[X]$ and $v[Y]$ appear together. In all such permutations, $v[X]$ and $v[Y]$ need to be replaced by $v[X, Y]$. The PQ-tree operation $\text{IDENTIFY}(T[\vec{F}], v[X], v[Y], v[X, Y])$ does precisely this. Hence repeated IDENTIFY operations on the PQ-trees in the collection result in a collection that mirrors the dag $\vec{H}$ obtained after this phase. Note that the order in which these IDENTIFY operations are applied to the collection has to be identical to the order in which pairs of nodes in $\vec{H}$ are identified.

SECOND MERGE PHASE. For this phase, we must describe how identifying $v[X]$ and $v[Y]$ belonging to different connected components $\vec{F}_1$ and $\vec{F}_2$ in $\vec{H}$ is reflected by a corresponding operation on the current collection. This operation is the most complicated PQ-tree operation and requires some initial intuition before we dive into the details. Let $T_1 = T[\vec{F}_1]$ and $T_2 = T[\vec{F}_2]$. One result of identifying $v[X]$ and $v[Y]$ is that the two connected components $\vec{F}_1$ and $\vec{F}_2$ are merged into one component, call it $\vec{F}_3$, hence decreasing the number of connected components of $\vec{H}$ by one. Similarly, the operation on the current collection results in a merger of T_1 and T_2 into a new PQ-tree $T_3 = T[\vec{F}_3]$.

The merging of T_1 and T_2 should mirror the merging of the directed leveled-planar embeddings of $\vec{F}_1$ and $\vec{F}_2$. When two such embeddings are joined at $v[X, Y]$, then one embedding must nestle inside the other embedding (unless both $v[X]$ and $v[Y]$ were at the ends of the embeddings of $\vec{F}_1$ and $\vec{F}_2$). For there to be room for this nestling, we must consider the structure of the dags at earlier levels. The values ML and LL stored at the nodes in T_1 and T_2 allow us to do so. We now describe the operation for this case in detail.

Without loss of generality, we may assume that $\text{LL}(T_1) \leq \text{LL}(T_2)$. The trees T_1 and T_2 are merged in two steps. In the first step, the PQ-tree T_2 is attached to T_1 at an appropriate location. We will call the resulting tree T_3'. The tree T_3' contains the leaves $v[X]$ and $v[Y]$. In the second step, these two leaves in T_3' are identified into

one leaf $v[X, Y]$ using the operation IDENTIFY. The resulting tree is called T_3. The two steps are discussed in detail below.

Step 1. *Attaching* T_2 *to* T_1. Start with the leaf $v[X]$ in T_1 and proceed upward in T_1 until a node r' and its parent r are encountered satisfying one of these five conditions:

1. r is a P-node with $\mathrm{ML}(r) < \mathrm{LL}(T_2)$. T_3' is obtained by attaching T_2 as a child of r in T_1.
2. r is a Q-node with ordered children $r_1, r_2, \ldots, r_t$, $r' = r_1$, and $\mathrm{ML}(r_1, r_2) < \mathrm{LL}(T_2)$. T_3' is obtained by replacing r_1 in T_1 with a Q-node q having two children, r_1 and the root of T_2. The case where $r' = r_t$ and $\mathrm{ML}(r_{t-1}, r_t) < \mathrm{LL}(T_2)$ is symmetric.
3. r is a Q-node with ordered children $r_1, r_2, \ldots, r_t$, $r' = r_i$, for some i, $1 < i < t$, and both $\mathrm{ML}(r_{i-1}, r_i) < \mathrm{LL}(T_2)$ and $\mathrm{ML}(r_i, r_{i+1}) < \mathrm{LL}(T_2)$. T_3' is obtained by replacing r_i in T_1 with a Q-node q having two children, r_i and the root of T_2.
4. r is a Q-node with children $r_1, r_2, \ldots, r_t$, $r' = r_i$, $1 < i < t$, and
$$\mathrm{ML}(r_{i-1}, r_i) < \mathrm{LL}(T_2) \leq \mathrm{ML}(r_i, r_{i+1}).$$
T_3' is obtained by attaching T_2 as a child of r between r_{i-1} and r_i. The case where
$$\mathrm{ML}(r_i, r_{i+1}) < \mathrm{LL}(T_2) \leq \mathrm{ML}(r_{i-1}, r_i)$$
is symmetric.
5. r' is the root of T_1. In this case, construct T_3' by making its root a Q-node q with two children, r' and the root of T_2.

Step 2. *Identifying* $v[X]$ *and* $v[Y]$ *into a single node* $v[X, Y]$. T_3 is obtained by performing $\mathrm{IDENTIFY}(T_3', v[X], v[Y], v[X, Y])$.

Steps 1 and 2 also update ML and LL values; this update is a straightforward extension of the updates in the ISOLATE and IDENTIFY operations. The following lemma establishes the correctness of Steps 1 and 2.

LEMMA 2.4. T_3 *mirrors* $\vec{F}_3$.

To prove Lemma 2.4 we need two observations.

OBSERVATION 1. *Let* $\pi_1 \in \mathrm{PERM}(T_1)$ *be a permutation in which the nodes in* $\mathrm{YIELD}(r')$ *are immediately followed by a node* x *such that* $\mathrm{MEETLEVEL}(\mathrm{YIELD}(r') \cup \{x\}) < \mathrm{LL}(T_2)$. *For any* $\pi_2 \in \mathrm{PERM}(T_2)$, *there is a permutation* $\pi \in \mathrm{PERM}(T_3')$ *that is consistent with* π_1 *and* π_2 *and in which the nodes in* $\mathrm{YIELD}(T_2)$ *occur immediately after* $\mathrm{YIELD}(r')$ *and just before* x.

Proof of Observation 1. Permute the leaves in T_1 according to π_1 and the leaves in T_2 according to π_2. For each of the four ways of constructing T_3' from T_1 and T_2, explained in Step 2 above, we show that the leaves of T_3' can be permuted to obtain the desired permutation. Let s denote the root of T_2.

1. T_2 *is attached as a child of a P-node* r. In this case, permute the children of r so that s immediately follows r' and the remaining children stay in the same relative order. This places the nodes in $\mathrm{YIELD}(T_2)$ immediately after the nodes in $\mathrm{YIELD}(r')$, without changing the relative order of the nodes in $\mathrm{YIELD}(T_1)$ or $\mathrm{YIELD}(T_2)$.
2. T_2 *is attached as a child of a Q-node* q *that has one other child* r' *and parent* r. In this case, reverse the order of the children of q, if necessary, so as to have s follow r'. This places the nodes in $\mathrm{YIELD}(T_2)$ immediately after the nodes

in YIELD(r'), without changing the relative order of the nodes in YIELD(T_1) or YIELD(T_2).

3. *T_2 is attached between r_{j-1} and $r' = r_j$, where $1 < j < t$, as a child of a Q-node r.* Since x immediately follows nodes in YIELD(r') in π_1, we have $x \in$ YIELD(r_{j-1}) or $x \in$ YIELD(r_{j+1}). We now show that $x \notin$ YIELD(r_{j+1}). We know that ML(r_j, r_{j+1}) $\geq$ LL(T_2) and this implies that for all $w \in$ YIELD(r_{j+1}), we have MEETLEVEL(YIELD(r_j) $\cup \{w\}$) $\geq$ LL(T_2). Since we assumed that MEETLEVEL(YIELD(r') $\cup \{x\}$) $<$ LL(T_2), we have $x \notin$ YIELD(r_{j+1}). This implies that $x \in$ YIELD(r_{j-1}) and since x follows nodes in YIELD(r') in π_1, the children of r in T_1 are permuted so that r_{j-1} occurs after r_j. This means that s occurs immediately after r_j in T_3. As a result the nodes in YIELD(T_2) immediately follow after the nodes in YIELD(r'), without changing the relative order of the nodes in YIELD(T_1) or YIELD(T_2).
4. *T_2 is attached to a Q-node q that has two children, r' and s, and has no parent.* We show that this case is not possible. We know that if T_2 is being attached to T_1 as described above, then MEETLEVEL(YIELD(T_2)) $\geq$ LL(T_1). This implies that

$$\text{MEETLEVEL}(\text{YIELD}(r') \cup \{x\}) \geq \text{LL}(T_1),$$

a contradiction. □

OBSERVATION 2. *Let $\pi \in$ PERM(T_1) be a permutation in which the nodes in* YIELD(r') *occur at the end. Let $\pi_2 \in$ PERM(T_2) be an arbitrary permutation of* YIELD(T_2). *Then, there is a permutation $\pi \in$ PERM(T_3') that is consistent with π_1 and π_2 and in which the nodes in* YIELD(T_2) *occur after* YIELD(r').

Proof of Observation 2. Permute the leaves in T_1 according to π_1 and the leaves in T_2 according to π_2. For each of the four ways of constructing T_3 from T_1 and T_2, explained in Step 2 above, we show that the leaves of T_3 can be permuted to obtain the desired permutation. Let s denote the root of T_2.

1. *T_2 is attached as a child of a P-node r or T_2 is attached as a child of a Q-node q that has one other child r' and parent r.* As explained in the proof of Observation 1, in either of these cases the leaves of T_3 can be permuted so as to have nodes in YIELD(T_2) immediately follow nodes in YIELD(r') without changing the relative order of the nodes in YIELD(T_1) and in YIELD(T_2).
2. *T_2 is attached between r_{j-1} and $r' = r_j$, where $1 < j < t$, as a child of a Q-node r.* This case is not possible since nodes in YIELD(r') cannot appear at the end of π_1 in this case.
3. *T_2 is attached to a Q-node q that has two children r' and s and has no parent.* Reverse the children of q, if necessary, so as to have s follow r'. □

Proof of Lemma 2.4. To show that T_3 mirrors $\vec{F}_3$, we need to show that PERM(T_3) is the set of all witnesses to directed leveled-planar embeddings of $\vec{F}_3$. We first show that any $\pi \in$ PERM(T_3) is a witness to some directed leveled-planar embedding $\mathcal{E}_3$ of $\vec{F}_3$. We then show that any permutation π that is a witness to some directed leveled-planar embedding $\mathcal{E}_3$ of $\vec{F}_3$ is in PERM(T_3).

If $\pi \in$ PERM(T_3), then π is a witness to some directed leveled-planar embedding $\mathcal{E}_3$ of $\vec{F}_3$. Recall that T_3 is the result of IDENTIFY($T_3', v[X], v[Y], v[X, Y]$) in Step 2. Since $\pi \in$ PERM(T_3), by the definition of the IDENTIFY operation, there is a permutation $\pi' \in$ PERM(T_3') in which $v[X]$ and $v[Y]$ occur together and replacing them by $v[X, Y]$ yields π. Clearly, in π' the elements in YIELD(T_2) occur contigu-

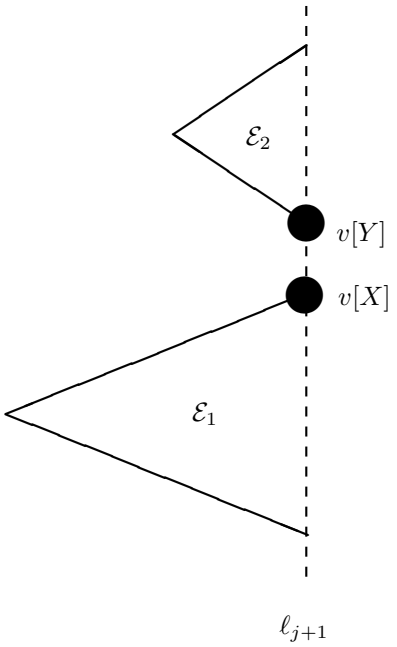

FIG. 2.14. *Construction of $\mathcal{E}_3$ from $\mathcal{E}_1$ and $\mathcal{E}_2$.*

ously and the elements in YIELD(r') occur contiguously. So without loss of generality, assume that in π' the nodes in YIELD(r') are immediately followed by the nodes in YIELD(T_2). Thus, among the nodes in YIELD(r'), $v[X]$ occurs last and among the nodes in YIELD(T_2), $v[Y]$ occurs first. Therefore π' can be written as $\pi_1\pi_2\pi_3$, where $\pi_2 \in \text{PERM}(T_2)$ and $\pi_1\pi_3 \in \text{PERM}(T_1)$. By the induction hypothesis, π_2 (respectively, $\pi_1\pi_3$) is a witness to a directed leveled-planar embedding $\mathcal{E}_2$ (respectively, $\mathcal{E}_1$) of $\vec{F}_2$ (respectively, $\vec{F}_1$). Two possible cases arise based on whether or not π_3 is empty:

(a) π_3 is empty. A planar embedding $\mathcal{E}_3$ of $\vec{F}_3$ can be constructed by placing $\mathcal{E}_2$ on "top" of $\mathcal{E}_1$ as shown in Figure 2.14 and then merging nodes $v[X]$ and $v[Y]$ into a single node $v[X, Y]$. Clearly, the level-$(j+1)$ nodes in $\vec{F}_3$ appear in bottom-to-top order on line ℓ_{j+1} according to π. Hence, π is a witness to the directed leveled-planar embedding $\mathcal{E}_3$ of $\vec{F}_3$.

(b) π_3 is nonempty. Suppose that $x \in \text{YIELD}(T_1)$ is the first element in π_3. Since $x \notin \text{YIELD}(r')$, the least common ancestor y of $v[X]$ and x is an ancestor (not necessarily proper) of r in T_1. Because of the way T_2 is attached to T_1, and due to Propositions 2.1, 2.2, and 2.3, we have

$$\text{MEETLEVEL}(\{v[X], x\}) < \text{LL}(T_2).$$

Hence, the embedding $\mathcal{E}_2$ of $\vec{F}_2$ can be "nested inside" the embedding $\mathcal{E}_1$ of $\vec{F}_1$ as shown in Figure 2.15. By merging nodes $v[X]$ and $v[Y]$ in this embedding, we get the leveled-planar embedding $\mathcal{E}_3$ of $\vec{F}_3$ in which the level-$(j+1)$ nodes appear in bottom-to-top order on ℓ_{j+1} according to π. Hence, π is a witness to the directed leveled-planar embedding $\mathcal{E}_3$ of $\vec{F}_3$.

If π is a witness to some directed leveled-planar embedding $\mathcal{E}_3$ of $\vec{F}_3$, then $\pi \in \text{PERM}(T_3)$. The level-$(j+1)$ nodes in $\vec{F}_3$ can be partitioned into three sets: S_1, the

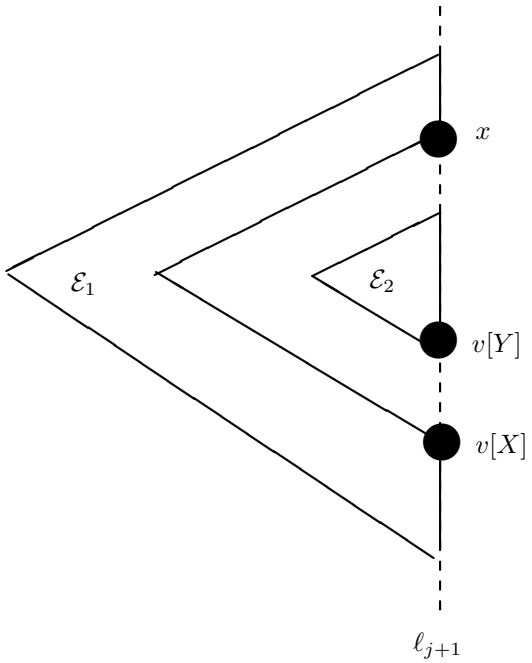

FIG. 2.15. *Construction of $\mathcal{E}_3$ from $\mathcal{E}_1$ and $\mathcal{E}_2$.*

set of all level-$(j+1)$ nodes in $\vec{F}_1$ except $v[X]$; S_2, the set of all level-$(j+1)$ nodes in $\vec{F}_2$ except $v[Y]$; and $\{v[X,Y]\}$. It is easy to see that in π, the nodes in S_2 appear consecutively, either immediately followed by or immediately preceded by $v[X,Y]$. Without loss of generality, we assume that in π, $v[X,Y]$ is immediately followed by nodes in S_2. Let $\vec{F}_3'$ be the dag that contains the two connected components $\vec{F}_1$ and $\vec{F}_2$. Replacing the node $v[X,Y]$ in π by node $v[X]$ followed by node $v[Y]$, we have a permutation π' that witnesses a directed leveled-planar embedding $\mathcal{E}_3'$ of $\vec{F}_3'$. Denote the subembedding of $\vec{F}_1$ in $\mathcal{E}_3'$ by $\mathcal{E}_1$ and the subembedding of $\vec{F}_2$ in $\mathcal{E}_3'$ by $\mathcal{E}_2$. Clearly, π' can be written as $\pi_1\pi_2\pi_3$, where π_1 ends with $v[X]$, π_2 begins with $v[Y]$ and is a witness to $\mathcal{E}_2$, and $\pi_1\pi_3$ is a witness to $\mathcal{E}_1$. By the induction hypothesis, $\pi_1\pi_3 \in \text{PERM}(T_1)$ and $\pi_2 \in \text{PERM}(T_2)$. We will now show that $\pi' \in \text{PERM}(T_3')$. This immediately implies that $\pi \in \text{PERM}(T_3)$. There are two cases depending on whether or not π_3 is empty:

(a) π_3 is nonempty. Suppose that the first element in π_3 is x. Clearly, since the nodes in $\text{YIELD}(T_2)$ occur consecutively between nodes $v[X]$ and x and since the embedding $\mathcal{E}_3'$ is leveled-planar, it has to be the case that

$$\text{MEETLEVEL}(\{u,x\}) < \text{LL}(T_2).$$

Let r be the node in T_1 that is a least common ancestor of $v[X]$ and x and let r' be a child of r such that $v[X] \in \text{YIELD}(r')$. Since $\text{MEETLEVEL}(\text{YIELD}(r') \cup \{x\}) \leq \text{MEETLEVEL}(\{v[X],x\})$, from Observation 1, it follows that $\pi' \in \text{PERM}(T_3)$.

(b) π_3 is empty. By Observation 2, it follows that $\pi' \in \text{PERM}(T_3)$. □

CLEANUP PHASE. Like the other phases, the cleanup phase applied to a collection mimics the cleanup phase applied to the corresponding dag. In this phase,

all the leaves of the PQ-trees in C_{j+1} are relabeled from $v[\mathrm{IN}(v)]$ to v. More significantly, any source s of $\vec{G}$ that is in V_{j+1} results in the addition of a PQ-tree $T[s]$ to C_{j+1} that consists of one leaf labeled s.

This completes the description of our algorithm. The following theorem summarizes what has been accomplished.

THEOREM 2.5. *A leveled-planar dag can be recognized in linear time. Moreover, a leveled-planar embedding for a leveled-planar dag can be constructed in linear time.*

Proof. The correctness of our algorithm follows from the proceeding discussion by induction. The linear time complexity of the algorithm follows from an amortized analysis given here. It suffices to show that the time complexity of all the identification operations together is linear. Each arc in the dag G is allocated three credits; since G is planar, the total number of credits is linear. In identifying two nodes belonging to the same connected component, there are two paths in the dag involved in forming a new face; since each arc is in two faces, two credits from each arc in the face pay for this identification. In identifying two nodes that belong to distinct connected components, the work is proportional to the height of the shorter dag; there is always a path in the dag that has a credit on each arc. We conclude that the allocated credits are sufficient and that the time complexity is linear.

Once our algorithm has recognized that a dag $\vec{G}$ is a leveled-planar dag, the actual construction of a leveled-planar embedding for $\vec{G}$ is straightforward. We outline how to construct an embedding for $\vec{G}$ from right to left. Choose any total order $\leq_m$ on V_m that is consistent with C_m. Choose any total order $\leq_{m+1}$ on V_{m-1} that is consistent with C_{m-1} and that, together with $\leq_m$, induces a leveled-planar embedding on the subgraph of $\vec{G}$ induced by $V_{m+1} \cup V_m$. Extend the construction one level at a time until a leveled-planar embedding of $\vec{G}$ results. Details are left to the reader. □

2.6. Recognizing 1-queue dags. The algorithm to recognize 1-queue dags builds on the one to recognize leveled-planar dags by first finding a maximal leveled subgraph, following the previous algorithm to obtain a leveled-planar embedding of that subgraph, and modifying the computation of C_i in the right-to-left sweep to accommodate the nonleveled arcs.

Let $\vec{G}$ be a connected dag. Let $\vec{H}$ be a spanning subgraph of $\vec{G}$. An *unnecessary* sink in $\vec{H}$ is one that is not also a sink in $\vec{G}$.

LEMMA 2.6. *For any connected dag $\vec{G}$, one may construct in linear time a spanning tree of G that has no unnecessary sinks.*

Proof. Give the connected dag $\vec{G}$ as input to the following program:

$T = (\emptyset, \emptyset)$;
WHILE T is not a spanning subgraph of $\vec{G}$ **DO**
  IF there exists an arc $(u, v) \in \vec{G}$ such that u is in T and v is not in T
    THEN $v_0 = v$;
    ELSE $v_0 =$ any source of $\vec{G}$ that is not in T;
  find a path $P = v_0, v_1, \ldots, v_j$ such that none of $v_0, \ldots, v_{j-1}$ is in T and such that either v_j is a sink in $\vec{G}$ or v_j is in T;
  add P to T;

Since $\vec{G}$ is connected, whenever T is not a spanning subgraph of $\vec{G}$, any node in $\vec{G}$ that is not in T must be reachable either by a path starting at a node of T or at a source of $\vec{G}$ that is not in T. Hence the program makes progress during each iteration of the while loop and terminates with T being a spanning subgraph of $\vec{G}$. By the way T is constructed, it is always acyclic. Hence the final T is a spanning tree of $\vec{G}$.

Linear time is easily accomplished by finding the paths P using depth-first search. Finally, every node added to T has at least one outgoing arc in T unless it is a sink of $\vec{G}$. Hence T has no unnecessary sinks. □

Now suppose $\vec{G}$ is a connected 1-queue dag. Use Lemma 2.6 to find a spanning tree T that has no unnecessary sinks. T also provides a leveling of $\vec{G}$. Add any arcs (u, v) such that $lev(v) = lev(u) + 1$ to obtain a maximal leveled subgraph $\vec{H}$ of $\vec{G}$. The following theorem tells us what additional arcs we must contend with.

THEOREM 2.7. *Let $\vec{G}$ be a connected 1-queue dag, and let $\vec{H}$ be a maximal leveled subgraph of $\vec{G}$ having no unnecessary sinks. Consider any arc (x, y) of $\vec{G}$ that is not in $\vec{H}$. Then either $lev(y) = lev(x)$ or $lev(y) = lev(x) + 2$. Furthermore, there cannot exist an arc (p, q) such that $lev(p) = lev(x)$; $lev(q) = lev(y)$; and $x \neq p$.*

Proof. To obtain a contradiction, we assume the existence of such an arc (p, q). Since neither x nor p is a sink in $\vec{G}$, neither is a sink in $\vec{H}$. Let (x, z) and (p, r) be arcs in $\vec{H}$ ($z = r$ is a possibility). Without loss of generality, we may assume that there is a 1-queue layout of $\vec{G}$ with x occurring before p (since $x \neq p$). Now we consider the two cases individually.

Case 1. The nodes of the independent arcs (x, z) and (p, q) must occur in the layout in the order x, p, q, z because x, p, and q are at level $lev(x)$ and z is at level $lev(x) + 1$. Hence these arcs nest and we have a contradiction.

Case 2. The nodes of the independent arcs (x, y) and (p, r) must occur in the layout in the order x, p, r, y because x and p are at level $lev(x)$, r is at level $lev(x) + 1$, and y is at level $lev(x) + 2$. Hence these arcs nest and we have a contradiction. □

The algorithm first computes the maximal leveled subgraph promised in Lemma 2.6. Then it runs the leveled-planar dag algorithm on the subgraph. The algorithm is modified appropriately to take into account the nonleveled arcs described in Theorem 2.7. For example, if (x, y) is an arc with $lev(x) = lev(y) = i$, then we force the tree T in D_i during the right-to-left sweep to place x and y on opposite ends of the level. This can be done by replacing T with a PQ-tree having a Q-node at the root with three children x, $T - \{x, y\}$, and y. The modifications do not add to the time complexity obtained for the previous algorithm. We obtain the desired linear time algorithm to recognize 1-queue dags, establishing the contrast with the NP-completeness result for recognizing 1-queue undirected graphs [11].

3. Recognizing 4-queue dags is NP-complete. In this section and the next, we show that the problem of determining whether a dag has a 4-queue layout and the problem of determining whether a dag has a 6-stack layout are both NP-complete. In fact we prove a stronger result for queue layouts. An arc (u, v) in a dag $\vec{G}$ is called a transitive arc if $\vec{G} - (u, v)$ contains a directed path from u to v. We show that even when a dag belongs to a restricted class of dags, namely, the class of dags without *transitive arcs*, the problem of determining whether the dag has a 4-queue layout is NP-complete. The motivation for restricting the class of dags to those without transitive arcs comes from our study of stack and queue layouts of posets in [8]. A *stack layout* (respectively, *queue layout)* of a poset P is a stack layout (respectively, queue layout) of its Hasse diagram $\vec{H}(P)$. Thus, our NP-completeness result related to queue layouts of dags shows that the problem of determining whether the queuenumber of a poset is 4 is NP-complete. Our results are in the spirit of the result of Yannakakis [13] who showed that the problem of determining whether or not the dimension of a poset is 3 is NP-complete. Define the decision problem, POSETQN, as follows:

POSETQN
INSTANCE: A poset P.
QUESTION: Can P be laid out in four queues?
Define the decision problem, DAGSN as follows:
DAGSN
INSTANCE: A dag $\vec{G} = (V, \vec{E})$.
QUESTION: Can $\vec{G}$ be laid out in six stacks?
This section proves that POSETQN is NP-complete. Section 4 proves that DAGSN is also NP-complete. The reduction in both proofs is from the NP-complete problem 3-SATISFIABILITY (3-SAT), defined below.
3-SATISFIABILITY
INSTANCE: Collection $C = \{c_1, c_2, \ldots, c_m\}$ of clauses on a set $X = \{x_1, x_2, \ldots, x_n\}$ of variables such that $|c_i| = 3$ for all i, $1 \leq i \leq m$.
QUESTION: Is there a truth assignment of X that satisfies all the clauses in C?

The remainder of this section is devoted to the proof of the following theorem.

THEOREM 3.1. POSETQN *is NP-complete.*

Proof. The queuenumber of a fixed layout of an undirected graph $G = (V, E)$ can be determined in $O(|E| \log\log |V|)$ time [11]. POSETQN is in NP because a nondeterministic Turing machine can guess an ordering of the nodes of the Hasse diagram $\vec{H}(P)$, check if the ordering is a topological ordering, and determine the queuenumber of the layout corresponding to that ordering in polynomial time.

POSETQN is shown to be NP-hard by reduction from 3-SAT. Let the collection of clauses $C = \{c_1, c_2, \ldots, c_m\}$ on the set of variables $X = \{x_1, x_2, \ldots, x_n\}$ be an instance of 3-SAT. The Hasse diagram $\vec{H}(P)$ of a poset P is constructed such that $\vec{H}(P)$ has a 4-queue layout if and only if there exists a truth assignment for the variables in X such that all clauses in C are satisfied. Corresponding to each clause c_i, $1 \leq i \leq m$, $\vec{H}(P)$ contains a subgraph called the *truth-setting dag* $\vec{TS}_i$. First, we describe the construction of $\vec{TS}_i$ and then show how the truth-setting dags are connected together to form $\vec{H}(P)$. The truth-setting dag $\vec{TS}_i$ can itself be thought of as consisting of four distinct subgraphs connected together. These are

1. *literal dag* $\vec{X}_i$,
2. *clause dag* $\vec{C}_i$,
3. *small enforcer dag* $\vec{F}_i$, and
4. *big enforcer dag* $\vec{F}'_i$.

We now describe the construction of $\vec{X}_i$, $\vec{C}_i$, $\vec{F}_i$, and $\vec{F}'_i$ and then show how they connect together to form $\vec{TS}_i$. We use $N(\vec{G})$ to denote the set of nodes of a dag $\vec{G}$ and $A(\vec{G})$ to denote its set of arcs.
Literal dag $\vec{X}_i$*:*

$$\begin{aligned} N(\vec{X}_i) = &\{x_{i,j} \mid 0 \leq j \leq n\} \\ &\cup \{\overline{x}_{i,j} \mid 0 \leq j \leq n\} \\ &\cup \{y_{i,j} \mid 1 \leq j \leq n\}, \\ A(\vec{X}_i) = &\{(y_{i,j}, x_{i,j}),\ (y_{i,j}, \overline{x}_{i,j}) \mid 1 \leq j \leq n\} \\ &\cup \{(x_{i,j}, y_{i,j+1}),\ (\overline{x}_{i,j}, y_{i,j+1}) \mid 0 \leq j \leq n-1\}. \end{aligned}$$

Figure 3.1 shows a literal dag $\vec{X}_i$. Note that there are no transitive arcs in $\vec{X}_i$. Any topological ordering of $\vec{X}_i$ contains the nodes $x_{i,j}$ and $\overline{x}_{i,j}$ followed by $y_{i,j+1}$ followed by $x_{i,j+1}$ and $\overline{x}_{i,j+1}$ for each j, $0 \leq j < n$. But, for each j, there is a choice in the

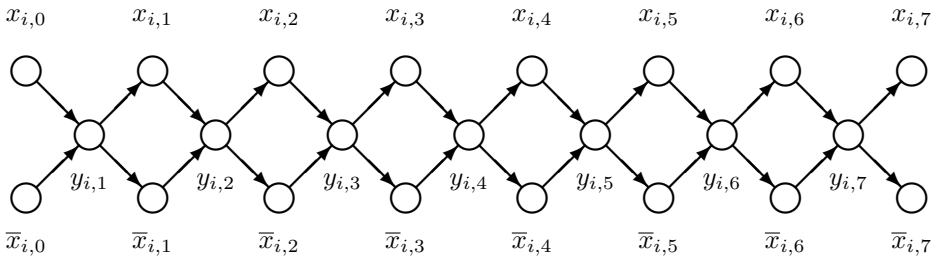

FIG. 3.1. *The literal dag* $\vec{X}_i$.

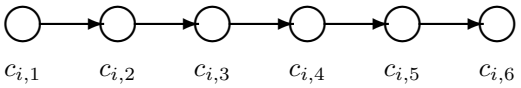

FIG. 3.2. *The clause dag* $\vec{C}_i$.

order in which nodes in the set $\{x_{i,j}, \overline{x}_{i,j}\}$ can appear. The choice of a particular order on the set $\{x_{i,j}, \overline{x}_{i,j}\}$ in the topological ordering of $\vec{H}(P)$ will be interpreted as a particular truth assignment to the variable x_j.

Clause dag $\vec{C}_i$*:*

$$N(\vec{C}_i) = \{c_{i,j} \mid 1 \le j \le 6\},$$
$$A(\vec{C}_i) = \{(c_{i,j}, c_{i,j+1}) \mid 1 \le j < 6\}.$$

The clause dag $\vec{C}_i$ is simply a directed path of length 5 and has a unique topological ordering. Clearly, $\vec{C}_i$ has no transitive arcs. Later we will show how nodes in $\vec{X}_i$ are connected to nodes in $\vec{C}_i$ so as to ensure that a smaller nesting is caused when there is at least one true literal in c_i, then when there is no true literal in c_i. Figure 3.2 shows a clause dag $\vec{C}_i$.

Enforcer dags $\vec{F}_i$ *and* $\vec{F}_i'$*:* The small enforcer dag $\vec{F}_i$ and the big enforcer dag $\vec{F}_i'$ are members of a class of dags

$$\{\vec{F}(q) \mid q \text{ is a positive integer}\}$$

defined as follows:

$$\begin{aligned} N(\vec{F}(q)) &= U(q) \cup V(q) \cup W(q), \\ U(q) &= \{u_j \mid 0 \le j \le q\}, \\ V(q) &= \{v_j \mid 0 \le j \le q\}, \\ W(q) &= \{w_j \mid 0 \le j \le q\}. \\ A(\vec{F}(q)) &= \{(u_j, u_{j-1}) \mid 0 < j \le q\} \\ &\quad \cup \{(v_j, v_{j+1}) \mid 0 \le j < q\} \\ &\quad \cup \{(u_j, w_j) \mid 0 \le j \le q\} \cup \{(w_j, v_j) \mid 0 \le j \le q\}. \end{aligned}$$

Figure 3.3 shows $\vec{F}(3)$. The small enforcer dag $\vec{F}_i$ is isomorphic to $\vec{F}(s)$ for some integer $s \ge 1$, whose value will be determined later. For each j, $0 \le j \le s$, node u_j in $\vec{F}(s)$ is mapped into node $u_{i,j}$ in $\vec{F}_i$; node v_j in $\vec{F}(s)$ is mapped into a node $v_{i,j}$ in $\vec{F}_i$;

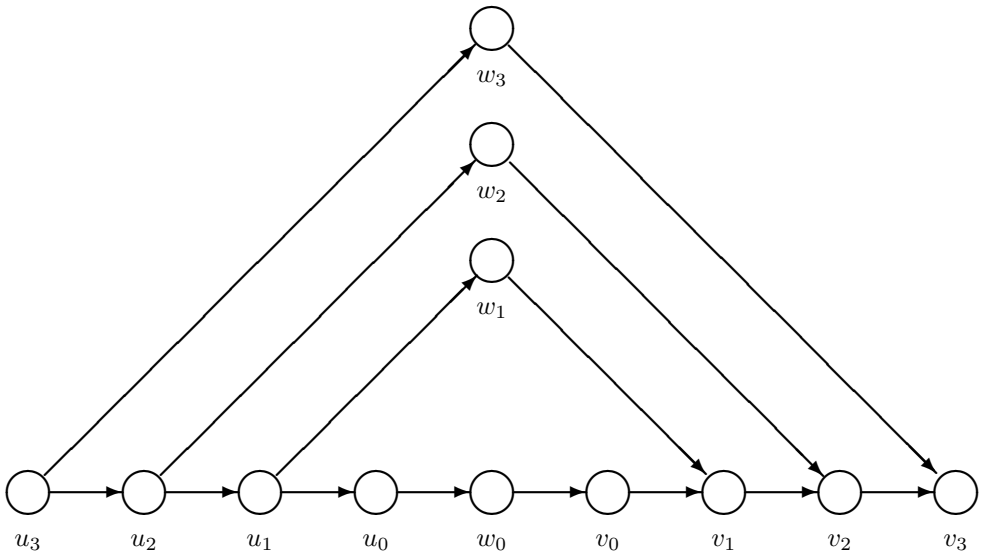

FIG. 3.3. *The dag* $\vec{F}(3)$.

and node w_j is mapped into a node $w_{i,j}$ in $\vec{F}_i$. The big enforcer dag $\vec{F}'_i$ is isomorphic to $\vec{F}(s+t+5)$ for some integer $t \geq 1$, whose value will also be determined later. For each j, $0 \leq j \leq s+t+5$, node u_j in $\vec{F}(s+t+5)$ is mapped into node $u'_{i,j}$ in $\vec{F}'_i$; node v_j in $\vec{F}(s+t+5)$ is mapped into node $v'_{i,j}$ in $\vec{F}'_i$; and node w_j in $\vec{F}(s+t+5)$ is mapped into node $w'_{i,j}$ in $\vec{F}'_i$.

Based on their role, the arcs of $\vec{F}(q)$ can be partitioned into two classes: *base arcs* and 2-*path arcs*. A *base arc* is an arc that belongs to the set

$$\{(u_j, u_{j-1}) \mid 1 \leq j \leq q\} \cup \{(v_j, v_{j+1}) \mid 0 \leq j \leq q-1\}.$$

Any arc that is not a base arc is a 2-*path arc*. Thus the set of 2-path arcs is

$$\{(u_j, w_j), (w_j, v_j) \mid 0 \leq j \leq q\}.$$

The base arcs in $\vec{F}(q)$ along with the 2-path arcs (u_0, w_0) and (w_0, v_0) enforce a unique ordering on the nodes in $U(q) \cup V(q) \cup \{w_0\}$. On the other hand, it is the 2-path arcs that mainly contribute to a rainbow in a layout of $\vec{F}(q)$. To be more precise, we provide the following definitions: Given a total ordering σ on the nodes of a dag $\vec{G}$ and a pair of 2-paths (a_1, b_1, c_1) and (a_2, b_2, c_2) in $\vec{G}$, we say that (a_1, b_1, c_1) and (a_2, b_2, c_2) *nest* in σ if the nodes in $\{a_1, c_1, a_2, c_2\}$ occur in the order a_1, a_2, c_2, c_1 or a_2, a_1, c_1, c_2 in σ. It is easy to see that if a pair of 2-paths nest in a layout, then the queuenumber of that layout is at least 2. Given an ordering σ on the nodes of $\vec{G}$ and a set S of 2-paths in $\vec{G}$, we say that S forms a 2-*path rainbow* in $\vec{G}$ if every pair of 2-paths in S nest in σ. Notice that in any layout of $\vec{F}(q)$ the set of 2-paths $\{(u_j, w_j, v_j) \mid 0 \leq j \leq q\}$ forms a 2-path rainbow of size $q+1$. It is this 2-path rainbow that forces $\vec{F}(q)$ to have a certain queuenumber. Given that we are constructing a dag with no transitive arcs, a simple way to force a certain queuenumber on the layout of the dag is to force a 2-path rainbow of a certain size. This is the key idea that is repeatedly used in our construction.

Heath and Pemmaraju [8] have determined nearly exact bounds on the queuenumber of $\vec{F}(q)$:

$$\lfloor \sqrt{q} \rfloor + 1 \leq QN(\vec{F}(q)) \leq \lfloor \sqrt{q} + 2 \rfloor .$$

In addition, we also know that

$$QN(\vec{F}(6)) = 3; \quad QN(\vec{F}(9)) = 4; \quad QN(\vec{F}(12)) = 4; \quad QN(\vec{F}(16)) = 5.$$

These results provide the basis for our choice of s and t. For notational convenience, denote $QN(\vec{F}(q))$ by $f(q)$. The constants s and t are chosen such that

$$\begin{aligned} f(s+5)+1 &= f(s+5+1) \\ &= f(s+5+t) \\ &= f(s+5+t+1) \\ &= f(s+5+t+2)-1. \end{aligned} \tag{3.1}$$

From the known values of $f(6)$, $f(9)$, $f(12)$, and $f(16)$ shown above it is easy to see that there exist s and t such that (3.1) is satisfied. More specifically, we can choose integers $s, t \geq 1$, such that

$$\begin{aligned} f(s+5) &= 3, \\ f(s+5)+1 &= f(s+5+1) \\ &= f(s+5+t) \\ &= f(s+5+t+1) \\ &= 4, \\ f(s+5+t+2) &= 5. \end{aligned}$$

Having described the four main components of a truth-setting dag $\vec{TS}_i$, we now describe the connections between them. The first set of connections simply ensures that the four dags appear in the order $\vec{X}_i, \vec{F}_i, \vec{C}_i, \vec{F}'_i$ in any topological ordering of $\vec{TS}_i$. These connections are

- $(x_{i,n}, u_{i,s}), (\overline{x}_{i,n}, u_{i,s})$ from $\vec{X}_i$ to $\vec{F}_i$.
- $(v_{i,s}, c_{i,1})$ from $\vec{F}_i$ to $\vec{C}_i$.
- $(c_{i,6}, u'_{i,s+t+5})$ from $\vec{C}_i$ to $\vec{F}'_i$.

The second set of connections depends on the literals that the clause c_i contains, and these are the connections which cause a 2-path rainbow of varying size depending on truth values of the literals in the clause. For these connections we need a set of additional nodes

$$Z_i = \{z_{i,j} \mid 1 \leq j \leq 6\}.$$

These nodes are connected to the clause dag $\vec{C}_i$ through the arcs

$$\{(z_{i,j}, c_{i,j}) \mid 1 \leq j \leq 6\}.$$

The connections between nodes in $\vec{X}_i$ and the nodes in Z_i depend on the literals in clause c_i. Let x_a, x_b, and x_c be the three variables that make up the literals in clause c_i. Without loss of generality, assume that $a < b < c$. If $x_a \in c_i$, then TS_i

contains the arcs $(x_{i,a}, z_{i,5})$ and $(\overline{x}_{i,a}, z_{i,6})$. Otherwise, if $\overline{x}_a \in c_i$, then TS_i contains the arcs $(x_{i,a}, z_{i,6})$ and $(\overline{x}_{i,a}, z_{i,5})$. Similarly, if $x_b \in c_i$, then TS_i contains the arcs $(x_{i,b}, z_{i,3})$ and $(\overline{x}_{i,b}, z_{i,4})$. Otherwise, if $\overline{x}_b \in c_i$, then TS_i contains the arcs $(x_{i,b}, z_{i,4})$ and $(\overline{x}_{i,b}, z_{i,3})$. Finally, if $x_c \in c_i$, then TS_i contains the arcs $(x_{i,c}, z_{i,1})$ and $(\overline{x}_{i,c}, z_{i,2})$. Otherwise, if $\overline{x}_c \in c_i$, then TS_i contains the arcs $(x_{i,c}, z_{i,2})$ and $(\overline{x}_{i,c}, z_{i,1})$. For example, suppose that $c_i = \{x_2, \overline{x}_4, x_7\}$. Then $\vec{TS}_i$ contains the arcs $(x_{i,2}, z_{i,5})$ and $(\overline{x}_{i,2}, z_{i,6})$, corresponding to the positive literal x_2; $(x_{i,4}, z_{i,4})$ and $(\overline{x}_{i,4}, z_{i,3})$ corresponding to the negative literal $\overline{x}_4$; and $(x_{i,7}, z_{i,1})$ and $(\overline{x}_{i,7}, z_{i,2})$ corresponding to the positive literal x_7. Note that the relative order of the pairs of nodes $(x_{i,2}, \overline{x}_{i,2})$, $(x_{i,4}, \overline{x}_{i,4})$, and $(x_{i,7}, \overline{x}_{i,7})$ determines the size of the 2-path rainbow between $\vec{X}_i$ and $\vec{C}_i$. This size could be as small as 3 if the pairs of nodes occurred in the order $(x_{i,2}, \overline{x}_{i,2})$, $(\overline{x}_{i,4}, x_{i,4})$, and $(x_{i,7}, \overline{x}_{i,7})$ and as large as 6 if the pairs of nodes occur in reverse order. This completes the description of a truth-setting dag $\vec{TS}_i$.

Now we describe how the truth-setting dags are connected together to form $\vec{H}(P)$. The arcs

$$(v_{i,s+t+5}, x_{i+1,0}), \qquad (v_{i,s+t+5}, \overline{x}_{i+1,0})$$

ensure that $\vec{TS}_{i+1}$ appears after $\vec{TS}_i$ for all i, $1 \leq i < m$, in any topological ordering of $\vec{H}(P)$. In addition, each truth-setting dag $\vec{TS}_i$ is connected to the truth-setting dag $\vec{TS}_{i+1}$ via 2-paths from nodes in $\vec{X}_i$ to nodes in $\vec{X}_{i+1}$. For these 2-paths we need for each i, $1 \leq i \leq m$, the additional nodes

$$R_i = \{r_{i,j}, \overline{r}_{i,j} \mid 0 \leq j \leq n\}.$$

For each i, $1 \leq i \leq m$, and for each j, $0 \leq j \leq n$, add arcs $(x_{i,j}, r_{i,j})$ and $(\overline{x}_{i,j}, \overline{r}_{i,j})$ to the dag. Complete the 2-paths by adding for each i, j, $1 \leq i < m$, $0 \leq j \leq n$, the arcs $(r_{i,j}, x_{i+1,j})$ and $(\overline{r}_{i,j}, \overline{x}_{i+1,j})$. In addition, to take care of the special case of $\vec{X}_m$, we introduce a new node x with incident arcs:

$$\{(r_{m,j}, x), (\overline{r}_{m,j}, x) \mid 0 \leq j \leq n\} \cup \{(v'_{m,s+t+5}, x)\}.$$

Thus, x is an additional node that occurs at the end of any layout of $\vec{H}(P)$ and to which there are 2-paths from nodes in $\vec{X}_m$. The 2-paths from $\vec{TS}_i$ to $\vec{TS}_{i+1}$ introduced above serve the purpose of causing a 2-path rainbow whose size depends on the order of the pair of nodes $(x_{i,j}, \overline{x}_{i,j})$ in the literal dag $\vec{X}_i$ relative to the order on the pair of nodes $(x_{i+1,j}, \overline{x}_{i+1,j})$ in the literal dag $\vec{X}_{i+1}$. If all the pairs of nodes occur in the same relative order, then the size of the 2-path rainbow is 1; otherwise it is 2. As we shall establish later, this relationship between the relative order of pairs of nodes in the literal dags $\vec{X}_i$ and $\vec{X}_{i+1}$ and the size of the 2-path nesting between $\vec{X}_i$ and $\vec{X}_{i+1}$ is responsible for truth-values "flowing" consistently from clause to clause.

This completes the description of $\vec{H}(P)$.

Let σ be a topological ordering of $\vec{H}(P)$. If $x_{i,j}$ occurs before $\overline{x}_{i,j}$ in σ, then we say that the node $x_{i,j}$ *is assigned true* in σ; otherwise, we say that $x_{i,j}$ *is assigned* $false$ in σ. If $x_{i,j}$ is assigned *true* in σ and $x_j \in c_i$ or if $x_{i,j}$ is assigned $false$ in σ and $\overline{x}_j \in c_i$, then we say that the subgraph C_i is assigned *true* in σ. A topological ordering σ of $\vec{H}(P)$ is said be *satisfiable* if and only if

1. every subgraph C_i is assigned *true* in σ, and
2. for each j, $1 \leq j \leq n$, either $x_{i,j}$ occurs before $\overline{x}_{i,j}$ for all i, $1 \leq i \leq m$, or $x_{i,j}$ occurs after $\overline{x}_{i,j}$ for all i, $1 \leq i \leq m$, in σ. In other words, for each j,

$1 \leq j \leq n$, the pair of nodes $x_{i,j}$ and $\overline{x}_{i,j}$ occur in the same relative order in all literal dags $\vec{X}_i$, $1 \leq i \leq m$, in σ.

Clearly, there exists a satisfiable topological ordering σ of $\vec{H}(P)$ if and only if the given instance of 3-SAT is satisfiable.

Finally, we show that there exists a satisfiable topological ordering of $\vec{H}(P)$ if and only if $QN(\vec{H}(P)) = f(s+t+6) = 4$. The two directions of the "if and only if" are proved separately.

If $QN(\vec{H}(P)) = 4$, then there exists a satisfiable topological ordering of $\vec{H}(P)$. Since $QN(\vec{H}(P)) = 4$, there exists a topological ordering σ of $\vec{H}(P)$ that yields a 4-queue layout of $\vec{H}(P)$. We will show that σ is satisfiable. To obtain a contradiction, assume that σ is not satisfiable. This implies that σ violates conditions 1 or 2 required of a satisfiable topological order. If σ violates condition 2, then there exist some $k, p, 1 \leq k \leq m, 1 \leq p \leq n$, such that the pairs of nodes $(x_{k,p}, \overline{x}_{k,p})$ and $(x_{k+1,p}, \overline{x}_{k+1,p})$ occur in reverse order relative to each other. In other words, $x_{k,p}$ precedes $\overline{x}_{k,p}$ in σ if and only if $x_{k+1,p}$ follows $\overline{x}_{k+1,p}$ in σ. Thus the set

$$\{(x_{k,p}, r_{k,p}, x_{k+1,p}), (\overline{x}_{k,p}, \overline{r}_{k,p}, \overline{x}_{k+1,p})\}$$

forms a 2-path rainbow. This 2-path rainbow nests over the big enforcer dag F'_k and this yields a 2-path rainbow of size $s+t+7$. Therefore the subgraph of $\vec{H}(P)$ induced by the nodes in $\vec{TS}_k$ and $\vec{TS}_{k+1}$ requires at least $f(s+t+7)$ queues to be laid out. But, by our choice of s and t, $f(s+t+7) = f(s+t+6)+1 = 5$. Thus σ yields a layout of $\vec{H}(P)$ that requires at least five queues—a contradiction.

We now show that if σ yields a queue layout of $\vec{H}(P)$ in $f(s+t+6) = 4$ queues, then σ satisfies condition 1. If σ yields an $f(s+t+6)$-queue layout of $\vec{H}(P)$, then all nodes in R_i for all $i, 1 \leq i \leq m$, have to appear between $u_{i,s+t+5}$ (the first node in the layout of $\vec{F}'_i$) and $w_{i,s+t+5}$ (the last node in the layout of $\vec{F}'_i$). This is because, for any i, $1 \leq i < m$, if a node $r \in R_i$ appears to the left of $u'_{i,s+t+5}$, then there is an arc from r to a node in $\vec{TS}_{i+1}$ that nests over $\vec{F}'_i$. If a node in R_m appears to the left of $u'_{m,s+t+5}$, then there is an arc from a node in R_m to x that nests over the layout of $\vec{F}'_m$. Similarly, for any i, $1 \leq i \leq m$, if a node $r \in R_i$ appears to the right of $w_{i,s+t+5}$, then there is an arc from a node in $\vec{TS}_i$ to r that nests over $\vec{F}'_i$. Since, the queuenumber of $\vec{F}'_i$ is $f(s+t+5) = 4$, the arc incident on r that nests over $\vec{F}'_i$ increases the nesting size to $f(s+t+5)+1 = f(s+t+6)+1 = 5$. Therefore, we can assume that in any 4-queue layout of $\vec{H}(q)$ all nodes in R occur between $u_{i,s+t+5}$ and $v_{i,s+t+5}$ in σ.

To obtain a contradiction, suppose that σ does not satisfy condition 1 that satisfiable topological orderings are required to satisfy. Then there exists a clause subgraph C_k that is assigned false. This implies that the 2-paths between the literal dag $\vec{X}_k$, the set of nodes Z_k, and the clause dag $\vec{C}_k$ form a 2-path rainbow of size 6. This 2-path rainbow of size 6 nests over the small enforcer dag $\vec{F}_i$ to yield a 2-path rainbow of total size $s+6$. Thus the subgraph induced by the nodes in $\vec{X}_k$, Z_k, $\vec{C}_k$, and F_k requires at least $f(s+6)$ queues in σ. In addition, the arc $(x_{k,0}, r_{k,0})$ nests over any layout of the subgraph described above to yield a total nesting of size $f(s+6)+1 = 5$. Thus σ requires at least five queues—a contradiction.

If σ is a satisfiable topological ordering, then σ yields a 4-queue layout of $\vec{H}(P)$. If σ is satisfiable, then the largest nesting of 2-paths between $\vec{X}_i$ and $\vec{C}_i$ for any $i, 1 \leq i \leq n$, is of size 5 and the largest nesting of 2-paths between $\vec{X}_i$ and $\vec{X}_{i+1}$ for

any $i, 1 \leq i \leq n-1$, is of size 1. The following is an assignment of arcs of $\vec{H}(P)$ to $f(s+t+6)$ queues such that if $\vec{H}(P)$ is laid out according to σ, then no two arcs assigned to the same queue nest. For some $i, 1 \leq i \leq n$, consider the subgraph of $\vec{H}(P)$ induced by the nodes in $\vec{X}_i$, $\vec{C}_i$, Z_i, and $\vec{F}_i$. The largest 2-path nesting in any layout of this subgraph is of size $s+5$ and hence this subgraph can be laid out in $f(s+5)$ queues. Now consider the subgraph induced by the 2-paths from $\vec{X}_i$ to $\vec{X}_{i+1}$ and the nodes in $\vec{F}'_i$. The largest 2-path nesting in any layout of this subgraph is of size $s+t+6$. Therefore, this subgraph can be laid out in $f(s+t+6)$ queues. Queues can be reused for the assignment of arcs in the two subgraphs to yield a layout for the whole dag in $f(s+t+6)$ queues.

This completes the reduction. Clearly, the reduction can be achieved in polynomial time, thereby showing that POSETQN is NP-complete. □

4. Recognizing 6-stack dags is NP-complete. In this section, we show that DAGSN is also NP-complete.

THEOREM 4.1. *DAGSN is NP-complete.*

Proof. DAGSN is in NP because a nondeterministic Turing machine can guess an ordering of the nodes in $\vec{G}$ and an assignment of the arcs in $\vec{G}$ to six stacks, check if the ordering is a topological ordering, and determine if any two arcs assigned to a stack cross, in polynomial time.

As with POSETQN, DAGSN is shown to be NP-hard by reduction from 3-SAT. Let the collection of clauses $C = \{c_1, c_2, \ldots, c_m\}$ on the set of variables $X = \{x_1, x_2, \ldots, x_n\}$ constitute an instance of 3-SAT. A dag $\vec{G}$ is constructed such that $\vec{G}$ has a 6-stack layout if and only if there exists a truth assignment for the variables in X such that all clauses in C are satisfied.

The construction of $\vec{G}$ from an instance of 3-SAT is much simpler than the corresponding construction of $\vec{H}(P)$ presented in the proof of Theorem 3.1. Corresponding to each clause c_i, $\vec{G}$ contains a *truth-setting dag* $\vec{TS}_i$. Each truth-setting dag $\vec{TS}_i$ consists of three subgraphs connected together:

1. *Literal dag* $\vec{X}_i$,
2. *clause dag* $\vec{C}_i$, and
3. *enforcer dag* E_i.

We will describe each of these three dags, one by one.

Literal dag. The literal dag $\vec{X}_i$ contains two subgraphs $\vec{A}_i$ and $\vec{B}_i$ connected together. The dag $\vec{A}_i$ is as follows:

$$N(\vec{A}_i) = \{x_{i,j} \mid 1 \leq j \leq n\} \cup \{\overline{x}_{i,j} \mid 1 \leq j \leq n\} \cup \{a_{i,1}a_{i,2}\},$$
$$V(\vec{A}_i) = \{(x_{i,j}, x_{i,j+1}), (x_{i,j}, \overline{x}_{i,j+1}), (\overline{x}_{i,j}, x_{i,j+1}), (\overline{x}_{i,j}, \overline{x}_{i,j+1})\}$$
$$\cup \{(a_{i,1}, x_{i,1}), (a_{i,1}, \overline{x}_{i,1}), (x_{i,n}, a_{i,2}), (\overline{x}_{i,n}, a_{i,2})\}.$$

Figure 4.1 shows $\vec{A}_i$. For simplicity we assume that $n = 4$. Any topological ordering of $\vec{A}_i$ contains the node $a_{i,1}$ followed by the nodes in the set $\{x_{i,j}, \overline{x}_{i,j} \mid 1 \leq i \leq n\}$, followed by the node $a_{i,2}$. The nodes in the set $\{x_{i,j}, \overline{x}_{i,j} \mid 1 \leq j \leq n\}$ occur in any order in which the nodes $x_{i,j}$ and $\overline{x}_{i,j}$ are followed by $x_{i,j+1}$ and $\overline{x}_{i,j+1}$ for all j, $1 \leq j < n$. However, for each j, $1 \leq j \leq n$, there is a choice in the order in which the pair of nodes $(x_{i,j}, \overline{x}_{i,j})$ occurs. It is this choice that we exploit to cause a twist of varying size depending on whether the given instance of 3-SAT is satisfiable. Recall that for any ordering σ of the nodes in a dag, a twist in σ is a set of arcs $\{(a_i, b_i) \mid 1 \leq i \leq p\}$ in the dag such that the end-points of the arcs occur in the order

$$a_1, a_2, \ldots, a_p, b_1, b_2, \ldots, b_p$$

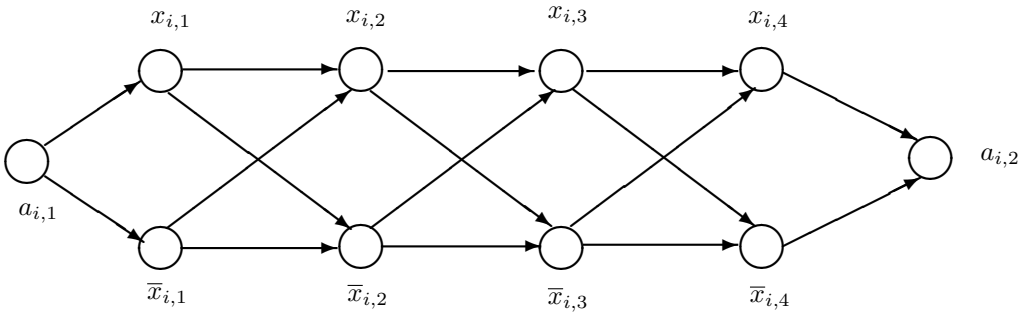

FIG. 4.1. *The dag $\vec{A}_i$ for $n = 4$.*

in σ.

To construct $\vec{B}_i$, first construct a dag $\vec{B}'_i$ that is isomorphic to $\vec{A}_i$. Each node $x_{i,j}$ in $\vec{A}_i$ is mapped into a node $y_{i,j}$ in $\vec{B}'_i$; each node $\overline{x}_{i,j}$ in $\vec{A}_i$ is mapped into a node $\overline{y}_{i,j}$ in $\vec{B}'_i$; each node $a_{i,j}$ in $\vec{A}_i$ is mapped into a node $b_{i,j}$ in $\vec{B}'_i$. To construct $\vec{B}_i$ from $\vec{B}'_i$, simply reverse the direction of all the arcs in $\vec{B}'_i$.

The literal dag $\vec{X}_i$ is constructed by connecting $\vec{A}_i$ and $\vec{B}_i$ using the following arcs:

$$\{(a_{i,1}, b_{i,1}), (a_{i,2}, b_{i,2})\} \cup \{(x_{i,j}, y_{i,j}) \mid 1 \le j \le n\} \cup \{(\overline{x}_{i,j}, \overline{y}_{i,j}) \mid 1 \le j \le n\}.$$

Thus, from each node in $\vec{A}_i$ there is an arc to the corresponding node in $\vec{B}_i$. Note that in any topological ordering of $\vec{G}$ in which the nodes in $\vec{B}_i$ occur in "reverse" order relative to the nodes in $\vec{A}_i$, all arcs connecting $\vec{A}_i$ to $\vec{B}_i$ nest and can be assigned to one stack.

Clause dag. The clause dag $\vec{C}_i$ is simply a directed path of length 5. More precisely,

$$N(\vec{C}_i) = \{c_{i,j} \mid 1 \le j \le 6\},$$
$$A(\vec{C}_i) = \{(c_{i,j}, c_{i,j+1}) \mid 1 \le j < 6\}.$$

Enforcer dag. The enforcer dag $\vec{E}_i$ contains two connected components, $\vec{E}_{i,1}$ and $\vec{E}_{i,2}$. Each of these is simply a directed path of length 4. More precisely,

$$N(\vec{E}_{i,1}) = \{e_{i,j} \mid 1 \le j \le 5\},$$
$$A(\vec{E}_{i,1}) = \{(e_{i,j}, e_{i,j+1}) \mid 1 \le j < 5\},$$

and

$$N(\vec{E}_{i,2}) = \{e_{i,j} \mid 6 \le j \le 10\},$$
$$A(\vec{E}_{i,2}) = \{(e_{i,j}, e_{i,j+1}) \mid 6 \le j < 10\}.$$

We now describe how $\vec{X}_i$, $\vec{C}_i$, and $\vec{E}_i$ are connected together to form the truth-setting dag $\vec{TS}_i$. The arcs $(a_{i,2}, c_{i,1})$, $(c_{i,6}, e_{i,1})$, $(e_{i,5}, b_{i,2})$, and $(b_{i,1}, e_{i,6})$ are added to $\vec{G}$ to force the subgraphs of $\vec{TS}_i$ to occur in the order

$$\vec{A}_i, \vec{C}_i, \vec{E}_{i,1}, \vec{B}_i, \vec{E}_{i,2}$$

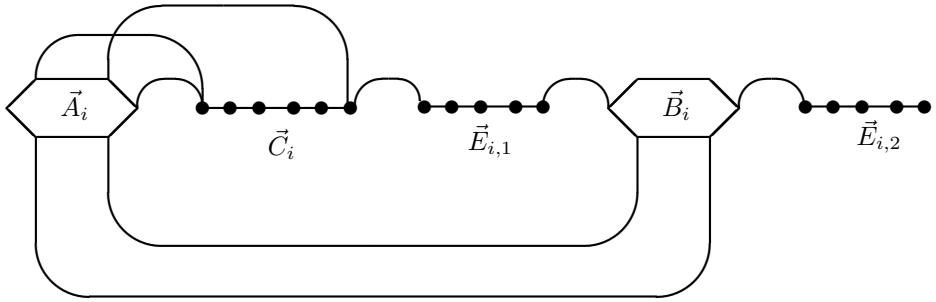

FIG. 4.2. *The overall structure of the truth-setting dag* $\vec{TS}_i$.

in any topological ordering of $\vec{G}$.

In addition we connect $\vec{A}_i$ to $\vec{C}_i$ by six arcs that depend on the literals in the clause c_i. Let x_a, x_b, and x_c be the three variables that make up the literals in clause c_i. Without loss of generality, assume that $a < b < c$. If $x_a \in c_i$, then TS_i contains the arcs $(x_{i,a}, c_{i,2})$ and $(\overline{x}_{i,a}, c_{i,1})$. Otherwise, if $\overline{x}_a \in c_i$, then TS_i contains the arcs $(x_{i,a}, c_{i,1})$ and $(\overline{x}_{i,a}, c_{i,2})$. Similarly, if $x_b \in c_i$, then TS_i contains the arcs $(x_{i,b}, c_{i,4})$ and $(\overline{x}_{i,b}, c_{i,3})$. Otherwise, if $\overline{x}_b \in c_i$, then TS_i contains the arcs $(x_{i,b}, c_{i,3})$ and $(\overline{x}_{i,b}, c_{i,4})$. Finally, if $x_c \in c_i$, then TS_i contains the arcs $(x_{i,c}, c_{i,6})$ and $(\overline{x}_{i,c}, c_{i,5})$. Otherwise, if $\overline{x}_c \in c_i$, then TS_i contains the arcs $(x_{i,c}, c_{i,5})$ and $(\overline{x}_{i,c}, c_{i,6})$. For example, suppose that $c_i = \{x_2, \overline{x}_4, x_7\}$. Then $\vec{TS}_i$ contains the arcs $(x_{i,2}, c_{i,2})$ and $(\overline{x}_{i,2}, c_{i,1})$ corresponding to the positive literal x_2; $(x_{i,4}, c_{i,3})$ and $(\overline{x}_{i,4}, c_{i,4})$ corresponding to the negative literal $\overline{x}_4$; and $(x_{i,7}, c_{i,6})$ and $(\overline{x}_{i,7}, c_{i,5})$ corresponding to the positive literal x_7. Depending on the order of the pairs of nodes $(x_{i,a}, \overline{x}_{i,a})$, $(x_{i,b}, \overline{x}_{i,b})$, and $(x_{i,c}, \overline{x}_{i,c})$ these arcs form a twist of size at least 3 and at most 6. In particular, we will try to ensure that these arcs form a twist of size 6 if and only if all literals in c_i are false.

This completes the description of the truth-setting dag $\vec{TS}_i$. The overall structure of $\vec{TS}_i$ is shown in Figure 4.2. We now describe how $\vec{TS}_i$ is connected to $\vec{TS}_{i+1}$ for each i, $1 \le i < m$. To ensure that $\vec{TS}_{i+1}$ occurs after $\vec{TS}_i$ in any topological ordering of $\vec{G}$, we add the arc $(e_{i,10}, a_{i+1,1})$. In addition we have the following arcs from $\vec{B}_i$ to $\vec{A}_{i+1}$:

$$\{(y_{i,j}, x_{i+1,j}) \mid 1 \le j \le n\} \cup \{(\overline{y}_{i,j}, \overline{x}_{i+1,j}) \mid 1 \le j \le n\}.$$

To complete the description of the dag $\vec{G}$ we need to describe a final component, called a *gate-keeper* dag, $\vec{GK}$, which is simply a directed path of length 5. More precisely, the gate-keeper dag is as follows:

$$N(\vec{GK}) = \{g_k \mid 1 \le k \le 5\},$$
$$A(\vec{GK}) = \{(g_k, g_{k+1}) \mid 1 \le k < 5\}.$$

An additional arc $(g_5, a_{1,1})$ ensures that the gate-keeper dag occurs before the rest of the dag in any topological ordering of $\vec{G}$. This completes the description of $\vec{G}$.

Let σ be a topological ordering of $\vec{G}$. If $x_{i,j}$ occurs before $\overline{x}_{i,j}$ in σ, then we say that the node $x_{i,j}$ *is assigned true* in σ; otherwise, we say that $x_{i,j}$ *is assigned false* in σ. If $x_{i,j}$ is assigned *true* in σ and $x_j \in c_i$ or if $x_{i,j}$ is assigned *false* in σ and $\overline{x}_j \in c_i$, then we say that the clause dag $\vec{C}_i$ is assigned *true* in σ; otherwise, we say

that the clause dag $\vec{C}_i$ is assigned *false* in σ. A topological ordering σ of $\vec{G}$ is said be *satisfiable* if and only if

1. every clause dag $\vec{C}_i$ is assigned *true* in σ, and
2. for each j, $1 \leq j \leq n$, either $x_{i,j}$ occurs before $\overline{x}_{i,j}$ for all i, $1 \leq i \leq m$, or $x_{i,j}$ occurs after $\overline{x}_{i,j}$ for all i, $1 \leq i \leq m$, in σ. In other words, for each j, $1 \leq j \leq n$, the pair of nodes $x_{i,j}$ and $\overline{x}_{i,j}$ occurs in the same relative order in all literal dags $\vec{X}_i$, $1 \leq i \leq m$, in σ.

Clearly, there exists a satisfiable topological ordering σ of $\vec{H}(P)$ if and only if the given instance of 3-SAT is satisfiable.

Finally, to complete our proof, we show that there exists a satisfiable topological ordering of $\vec{G}$ if and only if $SN(\vec{G}) = 6$. The two directions of the "if and only if" are proved separately.

If $SN(\vec{G}) = 6$, then there exists a satisfiable topological ordering of $\vec{G}$. Let σ be any topological ordering of $\vec{G}$ that yields a 6-stack layout of $\vec{G}$. We will show that σ is satisfiable. To obtain a contradiction assume that σ is not satisfiable. Therefore, σ violates one of the two conditions required of a satisfiable topological ordering. Suppose that σ violates condition 1. In particular, suppose that there exists a clause dag $\vec{C}_i$ that is not assigned *true* in σ. This implies that the set of six arcs from $\vec{A}_i$ to $\vec{C}_i$ forms a twist of size 6. The arc $(a_{i,2}, b_{i,2})$ adds to this twist to cause a twist of size 7. This implies that the layout of $\vec{G}$ according to σ requires at least seven stacks—a contradiction. Now suppose that σ violates condition 2. Thus there exist k, p, $1 \leq k \leq m$, $1 \leq p \leq n$, such that the pairs of nodes $(x_{k,p}, \overline{x}_{k,p})$ and $(x_{k+1,p}, \overline{x}_{k+1,p})$ do not occur in the same relative order. In other words, $x_{k,p}$ precedes $\overline{x}_{k,p}$ if and only if $x_{k+1,p}$ follows $\overline{x}_{k+1,p}$. Without loss of generality, suppose that $x_{k,p}$ precedes $\overline{x}_{k,p}$. This implies that $x_{k+1,p}$ follows $\overline{x}_{k+1,p}$. The pair of nodes $(y_{k,p}, \overline{y}_{k,p})$ can occur in one of two possible orders in σ. If $y_{k,p}$ precedes $\overline{y}_{k,p}$ in σ, then the arcs in the set

$$\{(x_{k,p}, y_{k,p}), (\overline{x}_{k,p}, \overline{y}_{k,p})\}$$

form a twist of size 2. The five arcs from the gate-keeper dag $\vec{GK}$ to the enforcer dag component $\vec{E}_{i,1}$

$$\{(g_j, e_{i,j}) \mid 1 \leq j \leq 5\}$$

add to the above twist to yield a twist of size 7. Therefore, the layout of $\vec{G}$ according to σ requires at least seven stacks—a contradiction. Similarly, if $y_{k,p}$ follows $\overline{y}_{k,p}$, it is easy to see that the arcs in the set

$$\{(y_{k,p}, x_{k+1,p}), (\overline{y}_{k,p}, \overline{x}_{k+1,p})\}$$

along with the five arcs from the gate-keeper dag to the second component of the enforcer dag $\vec{E}_{i,2}$ form a twist of size 7, yet again leading to a contradiction.

If there exists a satisfiable topological ordering of $\vec{G}$, then $SN(\vec{G}) = 6$. Let σ be a satisfiable topological ordering of $\vec{G}$. Without loss of generality, we assume that in σ for all i, $1 \leq i \leq m$, the nodes in $\vec{B}_i$ occur in a "reverse" order relative to the order of nodes in $\vec{A}_i$. This ensures that the arcs from $\vec{A}_i$ to $\vec{B}_i$ can be assigned to one stack and the arcs from $\vec{B}_i$ to $\vec{A}_{i+1}$ can also be assigned to one stack. We demonstrate an assignment of the arcs of $\vec{G}$ to six stacks so that when the nodes in $\vec{G}$ are laid out according to σ, no two arcs assigned to a stack cross.

It does not matter how we deal with arcs that connect nodes that are adjacent in σ. In particular, we will ignore the arcs in the gate-keeper dag $\vec{GK}$, the arcs in the

clause dag $\vec{C}_i$, $1 \leq i \leq m$, and the arcs in the enforcer dag $\vec{E}_i$, $1 \leq i \leq m$. We will also ignore some arcs that connect different subgraphs, namely, the arc $(g_5, a_{1,1})$, and for all i, $1 \leq i \leq m$, the arcs

$$(a_{i,2}, c_{i,1}), (c_{i,5}, e_{i,1}), (e_{i,5}, b_{i,2}), (b_{i,1}, e_{i,6}).$$

We will assign the rest of the arcs to six stacks, s_k, $1 \leq k \leq 6$. Start with the arcs incident on the gate-keeper dag. For each k, $1 \leq k \leq 4$, assign all arcs incident on g_k to stack s_k. Assign the arcs incident on g_5 to two stacks as follows. First assign the arcs from g_5 to the enforcer dag component $\vec{E}_{i,1}$ to s_5 for all i, $1 \leq i \leq m$. Then assign the arcs from g_5 to the enforcer dag component $\vec{E}_{i,2}$ to s_6 for all i, $1 \leq i \leq m$. This partial assignment of arcs of $\vec{G}$ to stacks fixes, to a large extent, the assignment of the rest of the arcs to stacks. In particular, the arcs from $\vec{A}_i$ to $\vec{B}_i$, for all i, $1 \leq i \leq m$, cross the arcs from $G\vec{K}$ to $\vec{E}_{i,1}$ and therefore have to be assigned to the stack s_6. Similarly, the arcs from $\vec{B}_i$ to $\vec{A}_{i+1}$, for all i, $1 \leq i < m$, cross the arcs from $G\vec{K}$ to $\vec{E}_{i,2}$ and therefore have to be assigned to the stack s_5. Since σ is a satisfiable topological ordering of $\vec{G}$, we know that the arcs from $\vec{A}_i$ to $\vec{C}_i$ form a twist of size at most 5. Since these arcs cross the arcs from $\vec{A}_i$ to $\vec{B}_i$, assign these arcs to stacks s_1 through s_5. It is easy to reuse the stacks s_1 through s_5 for the arcs in $\vec{A}_i$ and in $\vec{B}_i$.

Thus DAGSN is NP-complete. □

5. Conclusions. This paper presents fundamental algorithmic results concerning the computational complexity of determining the stacknumber and queuenumber of dags. For both stacks and queues, there remains a gap between the number of stacks or queues for which an NP-completeness result is known and the number for which a polynomial-time algorithm is known. We conjecture that recognition of both 2-stack and 2-queue dags is NP-complete. A more fruitful line of research is to identify classes of graphs for which the layout problem can be solved efficiently.

MEMBERSHIP IN CONSTANT TIME AND ALMOST-MINIMUM SPACE*

ANDREJ BRODNIK† AND J. IAN MUNRO‡

Abstract. This paper deals with the problem of storing a subset of elements from the bounded universe $\mathcal{M} = \{0, \ldots, M-1\}$ so that membership queries can be performed efficiently. In particular, we introduce a data structure to represent a subset of N elements of $\mathcal{M}$ in a number of bits close to the information-theoretic minimum, $B = \left\lceil \lg \binom{M}{N} \right\rceil$, and use the structure to answer membership queries in constant time.

Key words. information retrieval, search strategy, data structures, minimum space, dictionary problem, efficient algorithms hashing, lower bound

1. Introduction.

A basic problem in computing is to store a finite set of elements so that one can quickly determine whether or not a query element is a *member* of this set. In this paper we study a version of the problem in which elements are drawn from the bounded universe $\mathcal{M} = \{0, \ldots, M-1\}$ using an extended random access machine (RAM) model that permits constant-time arithmetic and Boolean bitwise operations on these elements. Such a very realistic model enables us to decrease the space needed to store a set of N elements almost to the information-theoretic minimum of $B = \lceil \lg \binom{M}{N} \rceil$ bits, while answering queries in constant time.

Fich and Miltersen [12] have shown that, under a RAM model whose instruction set does not include division, $\Omega(\log N)$ operations are necessary to answer a membership query if the size of a data structure is at most M/N^{ϵ} words of $\lceil \lg M \rceil$ bits each. Thus a sorted array is optimal in that context. Our model includes integer division along with the other standard operations in its instruction set. This permits us to use perfect hash tables (functions) and bitmaps, both of which have constant-time worst-case behavior. However, hash tables generally require that key values be stored explicitly, and so are succinct only when relatively few elements are present. On the other hand, a bitmap is succinct only if about half of the elements are present. In this paper we focus primarily on the range in which N is at least M^{ϵ}, but still $o(M)$, with the goal of introducing a data structure whose size is within a lower-order term of the minimum.

In general terms, our basic approach is to use either perfect hashing or a bitmap whenever one of them achieves the optimum space bound; otherwise we split the

universe into subranges of equal size. We discover that, after a couple of careful iterations of this splitting, the subranges are small enough so that succinct indices into a single table of all possible configurations of these subranges (*table of small ranges*) permit the encoding in the minimal space bound. This is an example of what we call *word-size truncated recursion* (cf. [15, 16]). That is, the recursion continues only to a level of "small enough" subproblems, at which point indexing into a table of all solutions suffices. We can do this because at this level a single word in the machine model is large enough to encode a complete solution to each of these small problems.

We proceed with definitions, notation, and background literature. In section 3 we present a constant-time solution with space bound within a small constant factor of the minimum required. The solution has the merit of providing a reasonably practical implementation, and can be tuned to specific problem sizes as is illustrated in giving the space requirements for two specific examples. In section 4 the solution is further tuned to achieve the asymptotic space bound of $B + o(B)$. The results of sections 3 and 4 are extended in section 5 to the dynamic case.

2. Notation, definitions, and background.

2.1. The problem. We use lg to denote the logarithm base 2 and ln to denote the natural logarithm. $\lg^{(i)}$ indicates lg applied i times and $\lg^*$ indicates the number of times lg can be applied before reducing the parameter to at most 1.

DEFINITION 2.1. *Given a universe $\mathcal{M} = \{0, 1, \ldots, M-1\}$ with an arbitrary subset $\mathcal{N} = \{e_0, e_1, \ldots, e_{N-1}\}$, where N and M are known, the* static membership problem *is to determine whether a query value $x \in \mathcal{M}$ is in $\mathcal{N}$.*

This problem has an obvious dynamic extension leading to the following definition.

DEFINITION 2.2. *The* dynamic membership problem *is the static membership problem extended by two operations: insertion of an element $x \in \mathcal{M}$ into $\mathcal{N}$ (if it is not already in $\mathcal{N}$) and deletion of x from a set $\mathcal{N}$ (if it is in $\mathcal{N}$).*

Since solving either problem for $\mathcal{N}$ trivially gives a solution for $\overline{\mathcal{N}}$, we assume $0 \le N \le M/2$.

Our model of computation is an extended version of the RAM machine model (cf. [1]; see also MBRAM in [9]). Memory consists of words of $m = \lceil \lg M \rceil$ bits, which means that one memory register (word) can be used to represent a single element of $\mathcal{M}$, specify an arbitrary subset of a set of m elements, refer to some portion of the data structure, or have some other role that is an m-bit blend of these. For convenience, we measure space in bits rather than in words. Our word size, then, matches the problem size, and so the model is *transdichotomous* in the sense of Fredman and Willard [14]. The usual operations, including integer multiplication, division, and bitwise Boolean operations, are performed in unit time.

We take as parameters of our problem M and N. Hence,

$$B = \left\lceil \lg \binom{M}{N} \right\rceil \tag{2.1}$$

is an information-theoretic lower bound on the number of bits required to describe any possible subset of N elements chosen from M elements. Since we are interested only in solutions that use $O(B)$ or $B + o(B)$ bits for a data structure, there is no need to pay attention to rounding errors, and so we can omit the ceiling and floor functions.

Using Stirling's approximation for the factorial function and Robbins' refinement for its error term (cf. [20, p. 184]), we compute from (2.1) a lower bound on the

number of bits required,

$$\begin{aligned} B &= \lg \binom{M}{N} = \lg M! - \lg N! - \lg(M-N)! \\ &\approx M \lg M - N \lg N - (M-N)\lg(M-N) \quad \text{error} \le \lg N + \mathrm{O}(1) \\ &= M \lg M - N \lg N \\ &\quad -(M-N)(\lg M + \lg(1 - N/M)) \\ &= N \lg(M/N) - (M-N)\lg(1-N/M). \end{aligned} \tag{2.2}$$

Defining the *relative sparseness* of the set $\mathcal{N}$ as

$$r = M/N \tag{2.3}$$

and observing that $2 \le r \le \infty$, we rewrite the second term of (2.2) as

$$N \le -N((r-1)\lg(1-r^{-1})) \le N/\ln 2 \approx 1.4427\ldots N. \tag{2.4}$$

Thus, for the purposes of much of this work, we can use

$$B \approx N \lg(M/N) \equiv N \lg r \tag{2.5}$$

with an error bounded of $\Theta(N)$ bits as given in (2.4). Note that the error term is positive and hence (2.5) is an underestimate.

An intuitive explanation of (2.5) is that $\mathcal{N}$ is fully described when each element in $\mathcal{N}$ "knows" its successor. Since there are N elements in $\mathcal{N}$, the average distance between them is $r = M/N$; to encode this distance we need $\lg r$ bits. Moreover, it is not hard to argue that the worst case, and indeed the average one, occurs when elements are fairly equally spaced. This is exactly what (2.5) says.

2.2. Some background literature. This paper deals with one of the most heavily studied problems in computing, in a context in which the exact model of computation is critical. Therefore, we suggest [9] and [18] as general background and focus on those papers that most heavily shaped the authors' approach. We address three aspects of the problem: the static and dynamic cases of storing a table with little auxiliary data and the information-theoretic trade-offs. In the first two cases, it is usually assumed that there is enough space to list those keys that are present (in a hash table or similar structure) or to list the answers to all queries (by using a bitmap). Here we deal with the situation in which we cannot always afford the space needed to use either structure directly. Nonetheless, we start with the idea of storing keys and little else.

Yao [24] extended the notion of an implicit data structure [21] to the domain of the bounded universe and addressed the problem of storing the value N and an array of N words, each containing a $\lg M$ bit data item. He showed that if no more information is stored, then there always exists some value of N and subset of size N that requires at least logarithmic search time. Adding almost any storage, however, changes the situation. For example, with one more register ($\lg M$ bits) Yao [24] showed that there exists a constant-time solution for $N \approx M$ or $N \le \frac{1}{4}\sqrt{\lg M}$, while Tarjan and Yao [23] presented a more general $\mathrm{O}(\lg M/\lg N)$ time, $\mathrm{O}(N \lg M)$ bit solution. Fredman, Komlós, and Szemerédi [13, sec. 4] developed a constant-time algorithm with a data structure of $N \lg M$ bits for the portion of the data, plus an additional $\mathrm{O}(N\sqrt{\lg N} + \lg^{(2)} M)$ bits. Fiat et al. [11] decreased the extra bits to

$6 \lg N + 3\lceil \lg^{(2)} M \rceil + O(1)$. Moreover, combining their result with Fiat and Naor's [10] construction of an implicit search scheme for $N = \Omega((\lg M)^p)$, they produced a scheme using fewer than $(1+p)\lceil \lg^{(2)} M \rceil + O(1)$ additional bits.

Mairson [17] took a different approach. He assumed all structures are implicit in Yao's sense and the additional storage represents the complexity of a searching program. Following a similar path, Schmidt and Siegel [22] proved a lower bound of $\Omega(N/(k^2 e^k) + \lg^{(2)} M)$ bits spatial complexity for k-probe oblivious hashing. In particular, for constant-time hashing this gives a spatial complexity of $\Theta(\lg^{(2)} M + N)$ bits.

For the dynamic case, Dietzfelbinger et al. [5] proved an $\Omega(\lg N)$ worst-case lower bound for a realistic class of hashing schemes. In the same paper they also presented a scheme which, using results of [13] and a standard doubling technique, achieved constant amortized expected time per operation. However, the worst-case time per operation (nonamortized) was $\Omega(N)$. Later Dietzfelbinger and Meyer auf der Heide [6] upgraded the scheme and achieved constant worst-case time per operation with a high probability. A similar result was also obtained by Dietzfelbinger et al. [4].

In the data compression technique described by Choueka et al. [3], a bit vector is hierarchically compressed. First, the binary representations of elements stored in the dictionary are split into pieces of equal size. Then the elements with the same value as the most significant piece are put in the same bucket and the technique is recursively applied within each bucket. When the number of elements which fall in the same bucket becomes sufficiently small, the data are stored in a compressed form. The authors experimentally tested their ideas but did not formally analyze them. They claim their result gives a relative improvement of about 40% over similar methods.

An information-theoretic approach was taken by Elias [7] in addressing a more general version of the static membership problem which involved several different types of queries. For these queries he discussed a trade-off between the size of the data structure and the average number of bit probes required to answer the queries. In particular, for the set membership problem he described a data structure of a size $N \lg(M/N) + O(N)$ (using (2.5), $B + o(B)$) bits, which required an average of $(1+\epsilon)\lg N + 2$ bit probes to answer a query. However, in the worst case the method required N bit probes. Elias and Flower [8] further generalized the notion of a query into a database. They defined the set of data and a set of queries and, in a general setting, studied the relation between the size of the data structure and the number of bits probed, given the set of all possible queries. Later, the same arrangement was more rigorously studied by Miltersen [19].

3. Static solution using $O(B)$ space. Our solution breaks down to a number of cases, based on the relative sparseness of $\mathcal{N}$. As noted earlier, we can assume that at most half the elements are present, since the complementary problem could otherwise be solved. We are left with four cases as r ranges between 2 and ∞ (cf. Table 3.1). The crucial dividing point between the sparse and dense cases comes when r is in the range $\Theta(\lg M)$. For purposes of tuning the method, we find it convenient to define this *separation point* in terms of a parameter $\lambda(>1)$, namely,

$$r_{sep} = \log_\lambda M, \tag{3.1}$$

or the size of sets

$$N_{sep} = M/r_{sep} = M/\log_\lambda M. \tag{3.2}$$

TABLE 3.1
Cases considered for the static version of the problem.

Sparseness	Range of r			Range of N			Section
Very sparse	∞	to	M^ϵ	0	to	$M^{1-\epsilon}$	3.1
Moderately sparse	M^ϵ	to	$\log_\lambda M$	$M^{1-\epsilon}$	to	$M/\log_\lambda M$	3.2
Moderately dense	$\log_\lambda M$	to	$1/\alpha$	$M/\log_\lambda M$	to	αM	3.3
Very dense	$1/\alpha$	to	2	αM	to	$M/2$	3.1

The very sparse and very dense cases are rather straightforward, though their boundaries with the more difficult moderately sparse and moderately dense cases are subject to tuning as well. After handling these easy cases, we address the moderately sparse case and subsequently extend its solution to handle the moderately dense.

3.1. Very sparse and very dense cases. When $\mathcal{N}$ is very dense, i.e., $N \geq \alpha M$ for $0 < \alpha \leq 1/2$, we can afford to use a bitmap of size $M = \Theta(B)$ to represent it. When $\mathcal{N}$ is very sparse, i.e., $N \leq M^{1-\epsilon}$ for $0 < \epsilon \leq 1$, we are allowed $\Theta(N \log M)$ bits which is enough to list all the elements of $\mathcal{N}$. For $N \leq c = \mathrm{O}(1)$ we simply list them. Beyond this we use a perfect hashing function of some form (cf. [10, 11, 13]). Note that all of these structures allow us to answer a membership query in constant time and are, indeed, reasonably practical methods.

3.2. Moderately sparse case—indexing. The range in which $r \approx r_{sep}$ typifies the case in which neither the straightforward listing of the elements nor a bitmap minimizes the storage requirements. In this range, the $N \lg M$ bits needed to list all elements is of the same order as the M for a bitmap, but $B = \Theta(N \lg^{(2)} M)$. Indeed, thoughts of this specific case lead not only to a solution to the entire moderately sparse range, but also to the first step in the solution for the moderately dense case.

LEMMA 3.1. *If $N \leq N_{sep} = M/\log_\lambda M$ for $\lambda > 1$, then there is an algorithm which answers a membership query in constant time using an $\mathrm{O}(B)$ bit data structure.*

Proof. The idea is to split the universe, $\mathcal{M}$, into p buckets, where p is as large as we can make it without exceeding our space constraints. The data falling into individual buckets are then organized using perfect hashing. The buckets cover contiguous ranges of equal sizes, $M_1 = \lfloor M/p \rfloor$, so that a key $x \in \mathcal{M}$ falls into bucket $\lfloor x/M_1 \rfloor$. To reach individual buckets, we index through an array of pointers.

Each pointer occupies $\lceil \lg M \rceil$ bits. Hence, the total size of the *index* (the array of pointers) is $p \lceil \lg M \rceil$ bits. We store all elements that fall in the same bucket in a perfect hash table [10, 11, 13] for that bucket. Since the ranges of all buckets are of equal size, the space required to describe each element in a hash table is $\lceil \lg(M/p) \rceil$ bits, and so to describe all elements in all buckets we require only $N \lceil \lg(M/p) \rceil$ bits. We also need some extra space to describe individual hash tables. If we use the method of Fiat et al. [11], the additional space for bucket i is bounded by $6\lceil \lg N_i \rceil + 3\lceil \lg^{(2)} M_1 \rceil + \mathrm{O}(1)$, where N_i is the number of elements in bucket i. Thus, the additional space to describe all hash functions is bounded by $p(6 \lg N + 3 \lg^{(2)} M + \mathrm{O}(1))$. Putting the pieces together, we get the expression for the size of the structure:

$$S = p \lg M + N \lg(M/p) + p(6 \lg N + 3 \lg^{(2)} M + \mathrm{O}(1)).$$

Choosing p to minimize this value leads to a rather complex formula. However, a simple approximation is adequate, and so we take

$$p = N/\lg M. \tag{3.3}$$

This gives

$$\begin{aligned} S &= N + N(\lg M/N + \lg^{(2)} M) + \\ &\quad N(6\lg N + 3\lg^{(2)} M + \mathrm{O}(1))/\lg M \qquad \text{by (2.3)} \\ &\le N\lg r + (N\lg r)(\lg^{(2)} M/\lg r) + N + \\ &\quad N(6\lg N + 3\lg^{(2)} M + \mathrm{O}(1))/\lg M \qquad \text{by (2.5)} \\ &= B + B\lg^{(2)} M/\lg r + \mathrm{o}(B). \end{aligned} \tag{3.4}$$

Hence, for a moderately sparse subset, i.e., $r \ge r_{sep}$, the size of the structure is $\mathrm{O}(B)$ bits. It is also easy to see that the structure permits constant-time search. □

Note that if $r_{sep} \ge \lg M$ (i.e., in (3.1) $\lambda < 2$), the lead term of (3.4) is less than $2B$.

3.3. Moderately dense case—word-size truncated recursion. In this section we consider sets of size N (or sparseness r) in the range

$$\begin{array}{rccccccc} N_{sep} = M/\log_\lambda M & \le & N & \le & \alpha M & \le & M/2, \\ r_{sep} = \log_\lambda M & \ge & r & \ge & 1/\alpha & \ge & 2. \end{array} \tag{3.5}$$

For such *moderately dense* $\mathcal{N}$ we apply the technique of Lemma 3.1—that is, split the universe $\mathcal{M}$ into equal-range buckets. However, this time the buckets remain too full to use hash tables and therefore we apply the splitting scheme again. In particular, we treat each bucket as a new, separate-but-smaller, universe. If its relative sparseness falls in the range defined by (3.5) (with respect to the size of its smaller universe) we recursively split it.

Such a straightforward strategy leads, in the worst case, to a $\Theta(\lg^* M)$ level structure and therefore to a $\Theta(\lg^* M)$ search time. However, we observe that at each level the number of buckets with the same range increases and ultimately there must be so many small subsets that not all can be different. Therefore we build a table of all possible subsets of universes of size up to a certain threshold. This *table of small ranges* (TSR) allows replacement of buckets in the main structure by pointers (indices) into the table. Although the approach is not new (cf. [15, 16]), it does not appear to have been given a name. We refer to the technique as *word-size truncated recursion*. In our structure the truncation occurs after two splittings. In fact, because all our second-level buckets have the same range, our TSR consists of all possible subsets of only a single small universe. In the rest of this section we give a detailed description of the structure and its analysis.

On the first split we partition the universe into

$$p = N_{sep}/\lg M = M/(\log_\lambda M \lg M) \tag{3.6}$$

buckets, each of which has a range $M_1 = M/p$. At the second level we have, again, relatively sparse and dense buckets which now separate at the relative sparseness

$$r'_{sep} = \log_\lambda M_1 = \log_\lambda(M/p) = \mathrm{O}(\lg^{(2)} M). \tag{3.7}$$

For sparse buckets we apply the solution of section 3.2, and for very dense ones with more than the fraction α of their elements present we use a bitmap. For the moderately dense buckets, with relative sparseness within the range defined in (3.5), we reapply the splitting. However, this time the number of buckets is (cf. (3.6))

$$p_1 = M_1/(r'_{sep}\lg M_1), \tag{3.8}$$

so that each of these smaller buckets has the same range,

$$M_2 = M_1/p_1 = \mathrm{O}((\lg^{(2)} M)^2), \tag{3.9}$$

because $\lg M_1 = \mathrm{O}(\lg^{(2)} M)$.

At this point we use the TSR. This table consists of bitmap representations of all subsets of the universe of size M_2. Thus we can replace buckets in the main structure with "indices" (pointers of varying sizes) into the table. We order the table first according to the number of elements in the subset and then lexicographically. We store a pointer in the TSR as a record consisting of two fields: ν, the number of elements in the bucket, which takes $\lceil \lg M_2 \rceil$ bits; and β, the rank of this bucket with respect to the lexicographic order among all buckets containing ν elements. To store β, by (2.1), takes $B_\nu = \lceil \lg \binom{M_2}{\nu} \rceil$ bits. The actual position (index) of the corresponding bitmap of the bucket in the TSR is thus

$$\sum_{i=1}^{\nu-1} \binom{M_2}{i} + \beta - 1. \tag{3.10}$$

The sum is found by table lookup and so a search is performed in constant time.

This concludes the description of the data structure also presented in Algorithm 3.1. As demonstrated in Algorithm 3.2, the data structure allows constant-time membership queries, but it remains to be seen how much space it occupies. The algorithm uses functions `LookUpBM`—look up bitmap; `FindOL`—find in ordered list; and `FindHT`—find in hash table, whose descriptions are omitted. However, their particular implementation suggests the constants c, ϵ, λ, and α used for the fine tuning of Algorithm 3.2.

In analyzing the space requirements, we are interested only in moderately dense subsets, as otherwise we use the structures of sections 3.1 and 3.2. First we analyze the main structure, i.e., the data structure without a TSR, and begin with the following lemma.

LEMMA 3.2. *Suppose we are given a subset of N elements from the universe M, and B is as defined in* (2.1). *If this universe is split into p buckets of ranges of sizes M_i containing N_i elements, respectively (now, using* (2.1), $B_i = \lceil \lg \binom{M_i}{N_i} \rceil$ *for $1 < i \le p$), then $B + p > \sum_{i=1}^{p} B_i$.*

Proof. If $\sum_{i=1}^{p} M_i = M$ and $\sum_{i=1}^{p} N_i = N$, we know that $0 < \prod_{i=1}^{p} \binom{M_i}{N_i} \le \binom{M}{N}$ and therefore $\sum_{i=1}^{p} \lg \binom{M_i}{N_i} \le \lg \binom{M}{N}$. On the other hand, from (2.1) we have $B_i = \lceil \lg \binom{M_i}{N_i} \rceil$ and therefore $B_i - 1 < \lg \binom{M_i}{N_i} \le B_i$. This gives us $\sum_{i=1}^{p} (B_i - 1) < B$ and finally $B + p > \sum_{i=1}^{p} B_i$. □

In simpler terms, Lemma 3.2 proves that if subbuckets are encoded at close to the information-theoretic bound, then the complete bucket also uses an amount of space close to the information-theoretic minimum, provided that the number of buckets is small enough ($p = o(B)$) and that the index does not take too much space.

We analyze the main structure itself from the top to the bottom. The first-level index consists of p pointers of $\lg M$ bits each. Therefore, using (3.6) and (3.2), the size of that complete index is

$$p \lg M = M/\log_\lambda M = N_{sep} = o(B). \tag{3.11}$$

For the sparse buckets on the second level we use the solution presented in section 3.2. For the very dense buckets ($r \leq 1/\alpha$) we use a bitmap. Both of these structures guarantee space requirements within a constant factor of the information-theoretic bound on the number of bits. If the same also holds for the moderately dense buckets, then, using Lemma 3.2 and (3.11), the complete main structure uses $O(B)$ bits. Note that we can apply Lemma 3.2 freely because the number of buckets, p, is $o(B)$.

Next we determine the size of the encoding of the second-level moderately dense buckets, that is, the encoding of buckets with sparseness in the range of (3.5). For this purpose we first consider the size of bottom-level pointers (indices) into the TSR. As mentioned, the pointers are records consisting of two fields. The first field, ν (number of elements in the bucket), occupies $\lceil \lg M_2 \rceil$ bits, and the second field takes at most B_ν. Since $B_\nu \geq \lceil \lg M_2 \rceil$, the complete pointer[1] takes at most twice the information-theoretic bound on the number of bits, B_ν. On the other hand, the size of an index is bounded using an expression similar to (3.11). Subsequently, this, together with Lemma 3.2, also limits the size of space needed to store representation of moderately dense buckets on the second level to be within a constant factor of the information-theoretic bound. This, in turn, limits the size of the complete main structure to $O(B)$ bits.

It remains to compute the size of the TSR. There are 2^{M_2} entries in the table and each of the entries is M_2 bits wide. By (3.9) $M_2 = O((\lg^{(2)} M)^2)$. This gives us the total size of the table

$$\begin{aligned} M_2 2^{M_2} &= O((\lg^{(2)} M)^2 (\log M)^{\lg^{(2)} M}) \\ &= O((\lg \lg M \lg M)(\lg^{(2)} M (\lg M)^{1+\lg^{(2)} M})) \\ &= o(\lg r_{sep} M / r_{sep}) \qquad \text{by (3.1)} \\ &= o(N_{sep} \lg r_{sep}) = o(B). \end{aligned} \tag{3.12}$$

Finally, this also bounds the size of the whole structure to $O(B)$ bits and hence in conjunction with Lemma 3.1 proves the following theorem.

THEOREM 3.3. *There is an algorithm which solves the static membership problem in $O(1)$ time using a data structure of size $O(B)$ bits.*

Note the constants in order notation of Theorem 3.3 are relatively small. Algorithm 3.2 performs at most two recursive calls of `Member` and eight probes of the data structure:

- two probes in the first call of `Member`: one to get N and one to compute M_1;
- two probes in the second call of `Member`: same as above; and
- four probes in the last call of `Member`: two probes to get the number of elements in the bucket, ν, and the lexicographic order of the bucket, β; the next probe to get the sum in (3.10) by lookup in table `binomials`; and the final probe into the `TSR`.

[1] Note that the size of a pointer depends on the number of elements that fall into the bucket.

TABLE 3.2
Space usage for sets of primes and SINs for various data structures.

Example	M	N	B	ours	hash	bit map
Primes	$1.0 \cdot 2^{32}$	$1.4 \cdot 2^{27}$	$1.6 \cdot 2^{29}$	$1.9 \cdot 2^{30}$	$1.4 \cdot 2^{32}$	$1.0 \cdot 2^{32}$
SINs	$1.9 \cdot 2^{29}$	$1.7 \cdot 2^{24}$	$1.1 \cdot 2^{27}$	$1.2 \cdot 2^{28}$	$1.6 \cdot 2^{29}$	$1.9 \cdot 2^{29}$

If perfect hashing is used in one of the steps, the number of probes remains comparable.

It is easy to see that by setting $\alpha = 1/2$ and $\epsilon = 1$, thereby eliminating the two extreme cases, at most $2B + o(B)$ bits are required for the structure. In the next section we reduce this bound to $B + o(B)$ bits while retaining the constant query time. However, in practice the $o(B)$ term can be as much of a concern as the factor of 2. Indeed the reader of the next section is justified in questioning the notion of $(\lg^{(2)} M_1 - 5)/6$ becoming large in practice. We therefore first illustrate the tuning of the method to specific values of M and N with two examples.

The first is the set of primes that fit in a single 32-bit word, so $M = 2^{32}$ and N is of size approximately $M/\ln M$. We pretend that the set of primes is random and that we are to store them in a structure to support the query of whether a given number is prime. Clearly, we could use some kind of compression (e.g., implicitly omit the even numbers or sieve more carefully), but for the purpose of this example we will not do so. In the second example we consider Canadian Social Insurance Numbers (SINs) allocated to each individual. Canada has approximately 28 million people and each person has a nine-digit SIN. One may want to determine whether or not a given number is allocated. This query is in fact a membership query in the universe of size $M = 10^9$ with a subset of size $N = 28 \cdot 10^6$. One of the digits is a check digit, but we will ignore this issue.

Both examples deal with moderately sparse sets and we can use the method of section 3.2 directly, using buckets and a perfect hashing function described in [11]. On the other hand, no special features of the data are used, which makes our space calculations slightly pessimistic. Using an argument similar to that of Lemma 3.2, we observe that the worst-case distribution occurs when all buckets are equally sparse, and therefore we can assume that in each bucket there are N/p elements. Table 3.2 contains the sizes of data structures for both examples comparing a hash function, a bitmap, and a tuned version of our structure (computed from (3.4)) with the information-theoretic bound.

4. Static solution using $B + o(B)$ space. We now return to the tuning of our technique for asymptotically large sets, achieving a $B + o(B)$ bit space bound.

First, we observe that for very dense sets ($r \leq 1/\alpha$) we cannot afford to use a bitmap because it always takes $B + \Theta(B)$ bits. Similarly we cannot afford to use hash tables for very sparse sets (i.e., $r \geq M^{1-\epsilon}$). Therefore, we categorize sets *only* as sparse or dense (and not moderately dense). The key point in decreasing the space bound, however, is redefining the separation point between sparse and dense set to

$$r_{sep} = (\lg M)^{\lg^{(2)} M}, \tag{4.1}$$

and so

$$N_{sep} = M/(\lg M)^{\lg^{(2)} M}. \tag{4.2}$$

While we intend B to indicate the exact value from (2.1), for sparse sets we can

still use the approximation $N \lg r$ from (2.5) since the error in (2.4) is bounded by $\Theta(N) = o(B)$.

4.1. Sparse subsets. Again, sparse subsets are those whose relative sparseness is greater than r_{sep}. For such subsets we *always* apply the two-level indexing of section 3.2. All equations from section 3.2, and in particular (3.4), still hold. However, the second term of (3.4) can be tightened to $o(B)$, because now the relative sparseness, r, is at least r_{sep} defined in (4.1). This proves the following lemma.

LEMMA 4.1. *If $\infty > r \geq r_{sep}$ as in* (4.1) *(i.e., $N \leq N_{sep}$ as in* (4.2)*), then there is an algorithm to answer membership queries in constant time using a $B + o(B)$ bit data structure.*

4.2. Dense subsets. Dense subsets are treated in the same way as moderately dense subsets were treated in section 3.3. Thus most of the analysis can be taken from that section with the appropriate changes of r_{sep} (cf. (3.1)) and r'_{sep} (cf. (3.7)). To compute the size of the main structure, we first bound the size of pointers into the TSR. Recall that each pointer consists of two fields: the number of elements in the bucket, ν, and the rank (in lexicographic order) of the bucket in question among all buckets with ν elements, β. Although the number of bits needed to describe ν can be as large as the information-theoretic minimum for some buckets, this is not true on the average. By Lemma 3.2, all pointers together occupy no more than $B + o(B)$ bits, where B is the exact one from (2.1). Furthermore, the indices are small enough so that all of them together occupy $o(B)$ bits (cf. (3.11)). As a result we conclude that the main structure occupies $B + o(B)$ bits of space. It remains to bound the size of the TSR at the redefined separation points.

With the redefinition of r_{sep} in (4.1), (3.6) now gives

$$p = M/(r_{sep} \lg M) = M/(\lg M)^{1+\lg^{(2)} M} \tag{4.3}$$

buckets on the first level. Each of these has a range of

$$M_1 = M/p = r_{sep} \lg M = (\lg M)^{1+\lg^{(2)} M}. \tag{4.4}$$

To simplify further analysis we set the redefined separation point between first-level sparse and dense buckets (cf. (3.7)) to

$$r'_{sep} = (\lg M_1)^{(\lg^{(2)} M_1 - 5)/6}, \tag{4.5}$$

which is adequate to keep the space requirement of the sparse buckets to $o(B)$ (cf. (3.4)). The position of this separation point r'_{sep} is further bounded by

$$\begin{aligned}
r'_{sep} &= (\lg(r_{sep} \lg M))^{(\lg^{(2)}(r_{sep} \lg M)-5)/6} && \text{using (4.4)} \\
&< (2 \lg r_{sep})^{(\lg(2 \lg r_{sep})-5)/6} && \text{since } r_{sep} > \lg M \text{ by (4.1)} \\
&< (2(\lg^{(2)} M)^2)^{(\lg((\lg^{(2)} M)^2)-4)/6} && \text{again using (4.1)} \\
&< ((\lg^{(2)} M)^3)^{(} \lg^{(3)} M - 2)/3 && \text{since } 2 < \lg^{(2)} M \\
&< (\lg^{(2)} M)^{\lg^{(3)} M - 1}/3 && \text{since } (\lg^{(2)} M)^{-1} < 1/3. \qquad (4.6)
\end{aligned}$$

Next, the first-level dense buckets are further split into p_1 (cf. (3.8)) subbuckets, each of range $M_2 = M_1/p_1 = r'_{sep} \lg M_1$. Finally, since M_2 is also the range of buckets in the TSR, the size of the table is

$$
\begin{aligned}
M_2 2^{M_2} &= r'_{sep}(\lg M_1) M_1^{r'_{sep}} \\
&= r'_{sep} \lg(r_{sep} \lg M)(r_{sep} \lg M)^{r'_{sep}} && \text{by (4.4)} \\
&< 2(\lg r_{sep}) r'_{sep} {r_{sep}}^{2r'_{sep}} && \text{since } r_{sep} = (\lg M)^{\omega(1)} \\
&< (\lg r_{sep}) {r_{sep}}^{3r'_{sep}-1} \\
&< \lg r_{sep}((\lg M)^{\lg^{(2)} M})^{(\lg^{(2)} M)^{\lg^{(3)} M - 1}}/r_{sep} && \text{by (4.6) and (4.1)} \\
&< \lg r_{sep}(\lg M)^{(\lg^{(2)} M)^{\lg^{(3)} M}}/r_{sep} \\
&= o(M \lg r_{sep}/r_{sep}) = o(N_{sep} \lg r_{sep}) \\
&= o(B)
\end{aligned}
$$

for $r \le r_{sep}$. This brings us to the main asymptotic result.

THEOREM 4.2. *There is an algorithm which solves the static membership problem in* $O(1)$ *time using data structure of size* $B + o(B)$ *bits.*

Proof. The discussion above dealt only with the space bound. However, since the structure is more or less the same as that of section 3, the time bound can be drawn from Theorem 3.3. □

With Theorem 4.2 we proved only that the second term in space complexity is $o(B)$. In fact, using a very rough estimate from the second term of sparse first-level buckets we get the bound $O(B/\lg^{(3)} M)$. To improve the bound one would have to refine values r_{sep} and r'_{sep}.

5. Dynamic version. There are several options for converting our ideas for a static structure into one that supports insertions and deletions. In the interest of simplicity we sketch and demonstrate only one.

THEOREM 5.1. *There exists a data structure requiring* $O(B)$ *bits which supports searches in constant time and insertions and deletions in constant expected amortized time.*

The basic approach is simple, and we make no attempt here to minimize the space bound other than to retain the $O(B)$ requirement. We use the method of section 3 but substitute dynamic perfect hashing [5] for the static perfect hashing scheme used there.

A key observation is that, given a set of N elements, our structure can be built in expected time $O(N)$ and $O(B)$ space if we use dynamic perfect hashing for the hashing aspect. Indeed, any of our substructures can be built in linear time and in space within a constant factor of that suggested in the preceding section. This also applies to the TSR in that it can be created in time linear in its size.

Like dynamic perfect hashing itself, our dynamic scheme operates in phases. At the beginning of a phase, a structure of N_0 elements is built, but each dynamic perfect hashing structure is given $1 + \kappa$ times as much space as it requires. Here κ is an arbitrary positive constant. In addition the entire space allocated for the structure is increased globally by another factor of $1 + \kappa$.

As insertions and deletions are made, two critical conditions can arise. The number of elements in the table may drop, say to $N_0/(1 + \kappa)$, in which case we obtain a new block of space appropriate for a table of the new, reduced, size. A new table is constructed in the new space and the old table is released. The other condition is that we run out of space either in one of the hash tables or in the structure as a whole. It is unlikely that we will run out of space in a single dynamic perfect hashing structure until a number of updates proportional to its original size is made. However,

with our multilevel structure we could have a large number of insertions fall into the same bucket, which could cause a dynamic perfect hashing structure to overflow after a rather small number of updates relative to the size of the entire structure. If this happens, we simply rebuild this subtable using the extra space allocated globally.

6. Discussion and conclusions. In this paper we have presented a solution to a static membership problem. Our initial solution answers queries in constant time and uses space within a small constant factor of the minimum required by the information-theoretic lower bound. Subsequently, we improved the solution reducing the required amount of space to the information-theoretic lower bound plus a lower-order term. We also addressed the dynamic problem and proposed a solution based on a standard doubling technique.

Data structures used in solutions consist of three major substructures which are used in different ranges depending on the relative sparseness of the set at hand (that is, depending on the ratio between the size of the set and the universe). When the set is relatively sparse we use a perfect hashing; when the set is relatively dense we use a bitmap; and in the range between we use recursive splitting (indexing). The depth of the recursion is bounded by the use of *word-size truncation* and in our case it is 2.

The feasibility of the data structure was addressed through a couple of examples. However, to make the structure more practical one would need to tune the parameters c, ϵ, λ, and α mentioned in Algorithm 3.2. Moreover, for practical purposes it is helpful to increase the depth of recursive splitting to cancel out the effect of a constant hidden in the order notation and, in particular, to decrease the size of the TSR below the information-theoretic minimum defined by N and M at hand. For example, in the case of currently common 64- and 32-bit architectures, the depths can be increased to 4 and 5, respectively.

There are several open problems. One may be able to reduce the space requirement of the dynamic structure to $B+o(B)$ by first reexamining the details of dynamic perfect hashing and reducing its storage requirements to $N + o(N)$ words, assuming the universe is large relative to N. Another intriguing problem is to decrease the second-order term in the space complexity as there is still a substantial gap between our result, $B + O(B/\lg^{(3)} M)$, and the information-theoretic minimum, B. But do we need a more powerful machine model to close this gap?

Acknowledgments. We thank Martin Dietzfelbinger and the referees for many very helpful comments that improved this paper.

DERANDOMIZING APPROXIMATION ALGORITHMS BASED ON SEMIDEFINITE PROGRAMMING*

SANJEEV MAHAJAN† AND H. RAMESH‡

Abstract. Remarkable breakthroughs have been made recently in obtaining approximate solutions to some fundamental NP-hard problems, namely Max-Cut, Max k-Cut, Max-Sat, Max-Dicut, Max-bisection, k-vertex coloring, maximum independent set, etc. All these breakthroughs involve polynomial time *randomized* algorithms based upon *semidefinite programming*, a technique pioneered by Goemans and Williamson.

In this paper, we give techniques to derandomize the above class of randomized algorithms, thus obtaining polynomial time deterministic algorithms with the same approximation ratios for the above problems. At the heart of our technique is the use of spherical symmetry to convert a nested sequence of n integrations, which cannot be approximated sufficiently well in polynomial time, to a nested sequence of just a constant number of integrations, which can be approximated sufficiently well in polynomial time.

Key words. NP-hard, approximation algorithm, derandomization, semidefinite programming

1. Introduction.

The application of *semidefinite programming* to obtaining approximation algorithms for NP-hard problems was pioneered by Goemans and Williamson [9]. This technique involves relaxing an integer program (solving which is an NP-hard problem) to a semidefinite program (which can be solved with a sufficiently small error in polynomial time).

Recall the Max-Cut problem which requires partitioning the vertex set of a given graph into two so that the number of edges going from one side of the partition to the other is maximized. In a remarkable breakthrough, Goemans and Williamson showed how semidefinite programming could be used to give a *randomized* approximation algorithm for the Max-Cut problem with an approximation ratio of .878. This must be contrasted with the previously best known approximation ratio of .5 obtained by the simple random cut algorithm. Subsequently, techniques based upon semidefinite programming have led to randomized algorithms with substantially better approximation ratios for a number of fundamental problems.

Goemans and Williamson [9] obtained a .878 approximation algorithm for Max-2Sat and a .758 approximation algorithm for Max-Sat, improving upon the previously best known bound of 3/4 for both [18]. Max-2Sat requires finding an assignment to the variables of a given 2Sat formula which satisfies the maximum number of clauses. Max-Sat is the general version of this problem, where the clauses are no longer constrained to have two variables each. Goemans and Williamson [9] also obtained a .796 approximation algorithm for Max-Dicut, improving the previously best known ratio of .25 given by the random cut algorithm. This problem requires partitioning the vertex set of a given directed graph into two so that the number of edges going from the left side of the partition to the right is maximized. Feige and

Goemans [6] obtained further improved approximation algorithms for Max-2Sat and Max-Dicut.

Karger, Motwani, and Sudan obtained an algorithm for coloring any k-colorable graph with $O(n^{1-3/(k+1)} \log n)$ colors [12]; in particular, for 3-colorable graphs, this algorithm requires $O(n^{.25} \log n)$ colors. This improves upon the deterministic algorithm of Blum [3], which requires $O(n^{1-\frac{1}{k-4/3}} \log^{\frac{8}{5}} n)$ colors for k-colorable graphs.

Frieze and Jerrum [7] obtained a .65 approximation algorithm for Max-bisection improving the previous best known bound of .5 given by the random bisection algorithm. This problem requires partitioning the vertex set of a given graph into two parts of roughly equal size such that the number of edges going from one side of the partition to the other is maximized. They also obtained a $1-\frac{1}{k}+2\frac{\ln k}{k^2}$ approximation algorithm for the Max k-Cut problem, improving upon the previously best known ratio of $1-\frac{1}{k}$ given by a random k-Cut.

Alon and Kahale [1] obtained an approximation algorithm for the maximum independent set problem on graphs, which requires finding the largest subset of vertices, no two of which are connected by an edge. For any constant $k \geq 3$, if the given graph has an independent set of size $n/k+m$, where n is the number of vertices, they obtain an $\Omega(m^{\frac{3}{k+1}} \log m)$-sized independent set, improving the previously known bound of $\Omega(m^{\frac{1}{k-1}})$ due to Boppana and Halldorsson [4].

All the new developments mentioned above are *randomized* algorithms. All of them share the following common paradigm. First, a semidefinite program is solved to obtain a collection of n vectors in n-dimensional space satisfying some properties dependent upon the particular problem in question. This step is deterministic. (In the Feige and Goemans paper [6], there is another intermediate step of generating a new set of vectors from the vectors obtained above.) Second, a set of independent random vectors is generated, each vector being *spherically symmetric*, i.e., equally likely to pass through any point on the n-dimensional unit sphere centered at the origin. Finally, the solution is obtained using some computation on the n given vectors and the random vectors.

It is not obvious how to derandomize the above randomized algorithms, i.e., to obtain a "good" set of random vectors deterministically. A natural way to derandomize is to use the method of conditional probabilities [14, 16]. The problem that occurs then is to compute the conditional probabilities in polynomial time.

Our contribution. The main contribution of this paper is a technique which enables derandomization of all approximation algorithms based upon semidefinite programming listed above. This leads to deterministic approximation algorithms for Max-Cut, Max k-Cut, Max-bisection, Max-2Sat, Max-Sat, Max-Dicut, k-vertex coloring, and maximum independent set with the same approximation ratios as their randomized counterparts mentioned above. However, we must mention that running times of our deterministic algorithms, though polynomial, are quite slow, for example, $O(n^{30})$ or so for 3-vertex coloring. In this paper, we do not make an effort to pinpoint the exact polynomial or to reduce the running time (within the realm of polynomials, that is).

Our derandomization uses the conditional probability technique. We compute conditional probabilities as follows. First, we show how to express each conditional probability computation as a sequence of $O(n)$ nested integrals. Performing this sequence of integrations with a small enough error seems hard to do in polynomial time. The key observation which facilitates conditional probability computation in

polynomial time is that, using spherical symmetry properties, the above sequence of $O(n)$ nested integrals can be reduced to evaluating an expression with just a constant number of nested integrals for each of the approximation algorithms mentioned above. This new sequence of integrations can be performed with a small enough error in polynomial time. A host of precision issues also crops up in the derandomization. Conditional probabilities must be computed only at a polynomial number of points. Further, each conditional probability computation must be performed within a small error. We show how to handle these precision issues in polynomial time.

As mentioned above, our derandomization techniques apply to all the semidefinite programming based approximation algorithms mentioned above. Loosely speaking, we believe our techniques are even more general, i.e., applicable to any scheme which follows the above paradigm and in which the critical performance analysis boils down to an "elementary event" involving just a constant number of the n vectors at a time. For example, in the graph coloring algorithm, only two vectors, corresponding to the endpoints of some edge, need to be considered at a time. An example of an elementary event involving three vectors is the Max-Dicut algorithm of Goemans and Williamson. Another example of the same is the algorithm of Alon et al. [2] for coloring 2-colorable 3-uniform hypergraphs approximately.

The paper is organized as follows. In section 2, we outline the Goemans and Williamson Max-Cut algorithm and the Karger–Motwani–Sudan coloring algorithm. We then describe our derandomization scheme. Since the Karger–Motwani–Sudan coloring algorithm appears to be the hardest to derandomize amongst the algorithms mentioned above, our exposition concentrates on this algorithm. The derandomization of the other algorithms is similar. Section 3 describes the derandomization procedure. The following sections describe the derandomization procedure in detail.

2. The semidefinite programming paradigm. It is known that any concave polynomial time computable function can be maximized (within some tolerance) over a convex set with *a weak separation oracle* in polynomial time [8]. A weak separation oracle (see [8, p. 51],) is one which, given a point y, either asserts that y is in or close to the convex set in question or produces a hyperplane which "almost" separates all points well within the convex set from y.

One such convex set is the set of *semidefinite matrices*, i.e., those matrices whose eigenvalues are all nonnegative. A set formed by the intersections of half-spaces and the set of semidefinite matrices is also a convex set. Further, this convex set admits a weak separation oracle. A semidefinite program involves maximizing a polynomial time computable concave function over one such convex set. Semidefinite programs are therefore solvable (up to an additive error exponentially small in the input length) in polynomial time. Goemans and Williamson first used this fact to obtain an approximation algorithm for Max-Cut.

The Goemans–Williamson Max-Cut algorithm. Goemans and Williamson took a natural integer program for Max-Cut and showed how to relax it to a semidefinite program. The solution to this program is a set of n unit vectors, one corresponding to each vertex of the graph in question. These vectors emanate from the origin. We call these vectors *vertex vectors*. These are embedded in n-dimensional space. This leads to the question as to how a large cut is obtained from these vectors.

Goemans and Williamson chose a random hyperplane through the origin whose normal is spherically symmetrically distributed; this hyperplane divides the vertex vectors into two groups, which define a cut in the obvious manner. The expected

number $\mathbf{E}(W)$ of edges[1] across the cut is $\sum_{(v,w)\in E} \Pr(sign(v \cdot R) \neq sign(w \cdot R)) = \sum_{(v,w)\in E} \arccos(v \cdot w)/\pi$, where E is the set of edges in the graph and v, w denote both vertices in the graph and the associated vertex vectors. Goemans and Williamson show that $\mathbf{E}(W)$ is at least .878 times the maximum cut.

Note that the n random variables involved above are the n coordinates which define the normal R to the random hyperplane. Let $R_1, R_2, \ldots, R_n$ be these random variables. For R to be spherically symmetrically distributed, it suffices that the R_i's are independent and identically distributed with a mean 0 and variance 1 normal distribution; i.e., the density function is $\frac{1}{\sqrt{2\pi}} e^{-x^2/2}$ [5]. Derandomizing the above algorithm thus requires obtaining values for $R_1, \ldots, R_n$ deterministically so that the value of the cut given by the corresponding hyperplane is at least $\mathbf{E}(W)$.

The Goemans–Williamson derandomization procedure. Goemans and Williamson actually gave the following derandomization procedure for their algorithm, which turned out to have a subtle bug described below.

From the initial set of vertex vectors in n dimensions, they obtain a new set of vertex vectors in $n-1$ dimensions satisfying the property that the expected size of the cut obtained by partitioning the new vertex vectors with a random hyperplane in $n-1$ dimensions is at least $\mathbf{E}(W)$. This procedure is repeated until the number of dimensions is down to 1, at which point partitioning the vectors becomes trivial. It remains to show how the new vertex vectors in $n-1$ dimensions are obtained from the older vertex vectors.

Consider an edge v, w, with vertex vector $v = (v_1, \ldots, v_{n-1}, v_n)$ and vertex vector $w = (w_1, \ldots, w_{n-1}, w_n)$. Recall that $R = (R_1, \ldots, R_n)$ is the normal to the random hyperplane. Goemans and Williamson obtain v', w', R' from v, w, R as follows: $R' = (R_1, \ldots, R_{n-2}, sign(R_{n-1})\sqrt{R_{n-1}^2 + R_n^2})$, $v' = (v_1, \ldots, v_{n-2}, x\cos(\alpha - \gamma))$, and $w' = (w_1, \ldots, w_{n-2}, y\cos(\beta - \gamma))$, where $\gamma = \arctan(R_n/R_{n-1})$, $\alpha = \arctan(v_n/v_{n-1})$, $\beta = \arctan(w_n/w_{n-1})$, $x = sign(v_{n-1})\sqrt{v_{n-1}^2 + v_n^2}$, and $y = sign(w_{n-1})\sqrt{w_{n-1}^2 + w_n^2}$.

These new definitions have the property that $v' \cdot R' = v \cdot R$ and $w' \cdot R' = w \cdot R$. To obtain the new vectors, one needs to decide on the value of γ. By the above property, there exists a value of γ such that $\sum_{(v,w)\in E} \Pr(sign(v' \cdot R') \neq sign(w' \cdot R') | \gamma) \geq \mathbf{E}(W)$. This value of γ is found by computing $\sum_{(v,w)\in E} \Pr(sign(v' \cdot R') \neq sign(w' \cdot R') | \gamma)$ for a polynomial number of points in the suitably discretized interval $[-\frac{\pi}{2}, \frac{\pi}{2}]$. At this point, Goemans and William claim that the vector R' is spherically symmetric for any fixed value of γ, and therefore $\Pr(sign(v' \cdot R') \neq sign(w' \cdot R') | \gamma) = (\frac{v' \cdot w'}{|v'||w'|})/\pi$ and is thus easy to compute.

The flaw lies in the fact that $r = sign(R_{n-1})\sqrt{R_{n-1}^2 + R_n^2}$ is not distributed normally with mean 0 and variance 1, even for a fixed value of γ. In fact, given γ, it can be shown to be distributed according to the density function $\frac{|r|}{2} e^{-r^2/2}$. It is not clear how $\Pr(sign(v' \cdot R') \neq sign(w' \cdot R') | \gamma)$ can be computed for this distribution of R'.

The Karger–Motwani–Sudan coloring algorithm. Our description of this algorithm is based on the conference proceedings version of their paper [12].

The Karger–Motwani–Sudan algorithm shows how to color a 3-colorable graph of n vertices with $O(n^{1/4} \log n)$ colors. The authors use a semidefinite program to obtain a set of vertex vectors such that $v \cdot w \leq -\frac{1}{2}$ for all edges (v, w). Note that

[1] For simplicity, we consider the unweighted Max-Cut problem.

if these vectors are somehow constrained to be in two dimensions, then there are at most three distinct vectors, which would specify a 3-coloring. However, the output to the semidefinite program are vectors in an n-dimensional space. It remains to be described how a coloring is obtained from these vectors. This is done as follows.

Karger, Motwani, and Sudan choose r vectors, $t_1, \ldots, t_r$, independently and at random; each is spherically symmetric. These vectors are called *centers*. The number of centers r will be spelled out in a few paragraphs. Let the jth coordinate of t_i be denoted by $t_i[j]$, $1 \leq j \leq n$. Spherical symmetry is obtained by the following procedure: each $t_i[j]$ is chosen independently at random from a normal distribution with mean 0 and variance 1. The color that vertex v gets is simply c, where $t_c \cdot v = \max_{1 \leq i \leq r} t_i \cdot v$. In other words, the color assigned to a vertex v corresponds to that amongst the r centers which has the largest projection on the vector v. Ties in choosing the vector with the largest projection occur with probability 0 and can therefore be ignored.

To determine how good the above procedure is, it is necessary to determine the probability that an edge is *bad*; i.e., both its endpoints get the same color. Consider two vertex vectors v, w, such that (v, w) is an edge e in $G = (V, E)$. The probability that v and w get the same color in the algorithm is given by $\Pr(E^e) = \sum_{k=1}^{r} \Pr(E_k^e)$, where E_k^e is the event that both get color t_k. E_k^e can be written as

$$\mathrm{E}_k^e : t_k \cdot v = \max\{t_1 \cdot v, \ldots, t_r \cdot v\} \wedge t_k \cdot w = \max\{t_1 \cdot w, \ldots, t_r \cdot w\}.$$

Karger, Motwani, and Sudan [12] show the following theorem (see Theorem 7.7, Corollary 7.8, and Lemma 7.9 of [12]).

THEOREM 2.1. *For $r = O(d^{1/3} \log^{4/3} d)$, if edge $e = (v, w)$ satisfies $v \cdot w \leq -1/2 + O(1/\log r)$, then $\Pr(E^e) = O(\frac{1}{d})$, where d is the maximum degree of the graph. Thus $\sum_{e \in E} \Pr(E^e)$, i.e., the expected number of bad edges, can be made less than $n/4$ by an appropriate choice of constants.*

Thus, at the end of the above procedure, the expected number of bad edges is less than $n/4$. All vertices except those upon which these bad edges are incident are discarded (the colors assigned to them are final). The expected number of remaining vertices is at most $n/2$. Markov's inequality helps to bound their number with a reasonable probability. These vertices are recolored by repeating the above procedure $O(\log n)$ times, using a fresh set of colors each time. This gives an $O(d^{1/3} \log^{4/3} d \log n)$ coloring of a 3-colorable graph. This, combined with a technique due to Wigderson [17], gives an $O(n^{1/4} \log n)$ coloring of a 3-colorable graph.

Derandomizing the above algorithm entails deterministically obtaining values for $t_i[j]$'s so that the number of bad edges is at most the expected number of bad edges above, i.e., $n/4$. Actually it suffices to obtain values for $t_i[j]$'s such that the number of bad edges is at most $n/4 + O(1)$. This is what we will do.

Note that the Goemans–Williamson algorithm uses a random hyperplane while the Karger–Motwani–Sudan algorithm uses a set of random centers. Although these two methods seem different, the hyperplane method can be interpreted as just the center method with two centers.

3. The derandomization scheme. We give an overview of our derandomization scheme in this section. For simplicity, we restrict our exposition here to the derandomization of the Karger–Motwani–Sudan algorithm for coloring 3-colorable graphs. Our procedure easily generalizes to all other known semidefinite programming based approximation algorithms listed in section 1.

Notation. For a vector u, we denote by $u[l \dots m]$ the vector formed by the lth to mth coordinates of u.

Our derandomization procedure has two steps. The first step described in section 3.1 is a discretization step. It is necessary for reasons which will become clear later. This step obtains a new set of vertex vectors which are "close" to the initial vertex vectors. The new vertex vectors satisfy the property that the Karger–Motwani–Sudan randomized algorithm continues to give the claimed theoretical performance on these vectors as well. This justifies the use of the new vectors in the actual derandomization process, which is the second step and is described in section 3.2.

3.1. Preprocessing vertex vectors: Discretization. Before we describe our derandomization scheme, we discretize the vertex vectors obtained from the semidefinite program so as to satisfy the following properties. Let ϵ be a parameter which is $\Theta(\frac{1}{n^2})$.

1. Each component of each vector is at least inverse polynomial (more precisely, $\Omega(\epsilon)$) in absolute value.
2. The dot product of any pair of vectors changes only by an inverse polynomial (more precisely, $O(n\epsilon)$) in absolute value.
3. For each pair of vectors v, w and every h, $1 \leq h < n$, when the coordinate system is rotated so that $v[h \dots n] = (b_1, 0, \dots, 0)$ and $w[h \dots n] = (b_1', b_2', 0, \dots, 0)$, b_1 and b_2' are at least some inverse polynomial (more precisely, $\Omega(\epsilon)$ and $\Omega(\epsilon^2)$, respectively) in absolute value.

The method for performing the discretization is given in Appendix 1. The purpose of the above discretization will become clear in the next subsection. Of course, we have to show that the above discretization does not cause much error. This is true because $v \cdot w$, which was at most $-\frac{1}{2}$ before the discretization, is at most $-\frac{1}{2} + O(\frac{1}{n})$ now for each edge $e = (v, w)$. Then, by Theorem 2.1, the theoretical bounds of the Karger–Motwani–Sudan randomized algorithm continue to hold for discretized vectors as well.

From now on, all our references to vectors will be to the discretized vectors.

3.2. Outline of the derandomization procedure. The scheme is essentially to use the method of conditional expectations to deterministically find values for the vectors $t_1, \dots, t_r$ so that the number of bad edges is just $n/4 + O(1)$.

We order the conditional variables as follows: $t_1[1] \dots t_1[n], t_2[1] \dots t_2[n], \dots, t_r[1] \dots t_r[n]$. The values of these are fixed one by one, in order. So suppose that the values $t_1[1 \cdots n], t_2[1 \cdots n], \dots, t_i[1 \cdots j-1]$ have been determined. We will show how a value for $t_i[j]$ is determined.

Notation. Let $\mathcal{E}$ be an event. Then $\Pr(\mathcal{E}|i, j, \delta)$ denotes the probability that the event $\mathcal{E}$ occurs when the values for all conditional variables before $t_i[j]$ have been fixed as above and $t_i[j]$ itself is assigned value δ. So, for example, $\Pr(E_k^e|i, j, \delta)$ denotes the probability that event E_k^e occurs (i.e., that both endpoints of edge e get the color associated with center t_k) when the values for all conditional variables before $t_i[j]$ have been fixed as above and $t_i[j]$ itself is assigned value δ. For notational brevity, sometimes we use $f_{e,k}(\delta)$ to denote $\Pr(E_e^k|i, j, \delta)$.

Let $p(\delta)$ be the expected number of bad edges when the values for all conditional variables before $t_i[j]$ are fixed as above and $t_i[j]$ is assigned value δ; $p(\delta) = \sum_{e \in E} \sum_{k=1}^{r} f_{e,k}(\delta)$.

Note that both $f_{e,k}(\delta)$ and $p(\delta)$ implicitly refer to some fixed values of i and j. This will be the case throughout this paper.

Problem to be solved now. The problem now is to find a value of δ for which $p(\delta) \leq \sum_{e \in E} \sum_{k=1}^{r} \Pr(E_e^k | t_1[1 \ldots n], t_2[1 \ldots n], \ldots, t_i[1 \ldots j-1])$. In other words, we want a value of δ with the following property: the expected number of bad edges with $t_i[j]$ assigned δ and $t_1[1 \ldots n], t_2[1 \ldots n], \ldots, t_i[1 \ldots j-1]$ fixed as above, is at most the expected number of bad edges with just $t_1[1 \ldots n], t_2[1 \ldots n], \ldots, t_i[1 \ldots j-1]$ fixed as above.

Fixing $t_i[j]$. Let $\tau = \sum_{e \in E} \sum_{k=1}^{r} \Pr(E_e^k | t_1[1 \ldots n], t_2[1 \ldots n], \ldots, t_i[1 \ldots j-1])$. We want to compute a value δ such that $p(\delta) \leq \tau$. We will not be able to compute such a δ. However, we will show the following.

In Theorem 3.1, we claim that working with the discretized vertex vectors, we can compute a value κ, such that $p(\kappa)$ is within $O(1/n^2)$ of τ. Corollary 3.2 then shows that this suffices to obtain the required bound on the number of colors.

THEOREM 3.1. *A value κ for $t_i[j]$ satisfying the following property can be computed in polynomial time: $p(\kappa) \leq \tau + O(1/n^2)$.*

From the above theorem, we get the following corollary.

COROLLARY 3.2. *After all $t_i[j]$'s have been fixed and colors assigned to vertices as in the randomized algorithm, the number of bad edges is at most $n/4 + O(1)$.*

Proof. Note that the number of conditional variables $t_i[j]$ is $nr \leq n^2$ (actually for 3-colorable graphs r is much smaller, namely $d^{1/3} \log^{4/3} d$, where d is the maximum degree).

Recall that the expected number of bad edges before any of the random variables was fixed is at most $n/4$. By Theorem 3.1, the expected number of bad edges after the first conditional variable is fixed is at most $n/4 + O(1/n^2)$. An easy inductive argument shows that the expected number of bad edges after the lth conditional variable is fixed is at most $n/4 + O(1/n^2)$. After all the $nr \leq n^2$ conditional variables have been fixed, the expected number of bad edges (which is just the number of bad edges since all conditional variables are now fixed) is at most $n/4 + O(1)$. ∎

Note that while the Karger–Motwani–Sudan algorithm ensures that the number of bad edges is less than $n/4$, our deterministic algorithm shows a slightly weaker bound, i.e., at most $n/4 + O(1)$. However, it can be seen easily that this weaker bound on the number of bad edges also suffices to obtain the bound of $O(n^{1/4} \log n)$ colors for coloring a 3-colorable graph deterministically.

The rest of this paper will be aimed at proving Theorem 3.1. This is accomplished by performing the following steps, each of which is elaborated in detail in the following sections.

Remark. The purpose of discretizing the vertex vectors earlier can be explained now. The intention is to ensure that derivatives of the functions $f_{e,k}(\delta)$ and $p(\delta)$ (with respect to δ) are bounded by a polynomial in n. This, in turn, ensures that the values of the above functions between any two nearby points will not be too different from their values at these two points, thus facilitating discrete evaluation, which we will need to do.

3.3. Steps required to prove Theorem 3.1. The following steps are performed in our algorithm to obtain the value κ described above. Recall again that we are working with fixed values of i, j and assuming that $t_1[1 \ldots n], t_2[1 \ldots n], \ldots, t_i[1 \ldots j-1]$ have already been fixed.

Step 1. In order to compute κ, we would like to evaluate $p(\delta)$ at a number of points. However, we can afford to evaluate $p(\delta)$ only for a polynomial number of points. In section 4, we show how to obtain a set S of polynomial size such that

$\min_{\delta \in S} p(\delta) - \tau = O(\frac{1}{n^2})$. Therefore, in order to compute κ, it suffices to evaluate $p(\delta)$ at points in S, as long as the evaluation at each point in S is correct to within an additive $O(\frac{1}{n^2})$ error.

Step 2. We now need to show how $p(\delta)$ can be evaluated within an additive $O(\frac{1}{n^2})$ error for any particular point δ in polynomial time. Of course, we need to do this computation for points in S only, but the description of this step is for any general point δ.

To compute $p(\delta)$, we need to compute $f_{e,k}(\delta)$ to within an $O(\frac{1}{n^5})$ additive error, for each edge e and each center k (using the rather liberal upper bounds of $O(n^2)$ for the number of edges and $O(n)$ for the number of centers). We will describe this computation for a particular edge e and a particular center k. This will involve two substeps. The first substep will develop an expression involving a nested sequence of integrations for $f_{e,k}(\delta)$, and the second substep will actually evaluate this expression within the required error.

Substep 2a. We show how to write $f_{e,k}(\delta)$ as an expression involving a nested sequence of integrations of constant depth. This is done is two stages. In the first stage, in section 5, $f_{e,k}(\delta)$ is expressed as a nested sequence of integrations of constant depth, with the integrand comprising only basic functions and a function I, defined below. Subsequently, in section 6, we express the function I itself as an expression involving a constant number of nested integrations. This requires the use of spherical symmetry properties. The fact that the depth of integration is a constant will be significant in Substep 2b. If this were not the case, then it is not clear how $f_{e,k}(\delta)$ could be computed within the required error bounds at any point δ in polynomial time.

DEFINITION 3.3. *Let b, b' be vectors of the same dimension, which is at least* 2. *Let a be another vector of the same dimension whose entries are independent and normally distributed with mean* 0 *and variance* 1. *Let $x \leq y$ and $x' \leq y'$ be in the range $-\infty \ldots \infty$. Then $I(b, b', x, y, x', y')$ denotes* $\Pr((x \leq a \cdot b \leq y) \wedge (x' \leq a \cdot b' \leq y'))$.

Substep 2b. The expression for $f_{e,k}(\delta)$ obtained in Substep 2a is evaluated to within an $O(\frac{1}{n^5})$ additive error in this step in polynomial time. This is described in section 7.

Remarks on $\frac{\mathrm{d} f_{e,k}(\delta)}{\mathrm{d}\delta}$. We will also be concerned with the differentiability of $p(\delta)$ and therefore $f_{e,k}(\delta)$ for each edge e and each center k. From the expressions derived for $f_{e,k}(\delta)$ in section 5, the following properties about the differentiability of $f_{e,k}(\delta)$ will become clear. These properties will be used in section 4, i.e., to obtain the set S as described in Step 1. We state these properties in a lemma for future reference. The proof of this lemma in section 5 will not rely on any usage of the lemma in section 4.

LEMMA 3.4. *When $j < n-1$, $f_{e,k}(\delta)$ is differentiable (with respect to δ) for all δ. When $j = n-1$ or $j = n$, $f_{e,k}(\delta)$ is differentiable for all but at most* 2 *values of δ.*

4. Step 1: Determining set *S*. We show how to obtain a set S of polynomial size such that $\min_{\delta \in S} p(\delta) - \tau = O(\frac{1}{n^2})$. Recall from section 3.2 that $p(\delta) = \sum_{e \in E} \sum_{k=1}^{r} f_{e,k}(\delta) = \sum_{e \in E} \sum_{k=1}^{r} \Pr(E_e^k | i, j, \delta)$.

We will use the following theorem from [5, Chapter 7, Lemma 2].

THEOREM 4.1. *For every $a > 0$, $\int_a^\infty \mathrm{e}^{\frac{-\delta^2}{2}} \mathrm{d}\delta \leq \frac{1}{a} \mathrm{e}^{-\frac{a^2}{2}}$.*

First, we show that we can restrict δ to the range $-3\sqrt{\ln n} \ldots 3\sqrt{\ln n}$.

LEMMA 4.2. $\min_{-3\sqrt{\ln n} < \delta < 3\sqrt{\ln n}} p(\delta) - \tau = O(\frac{1}{n^2})$.

Proof. Note that $\tau = \sum_{e \in E} \sum_{k=1}^{r} \Pr(E_k^e | t_1[1] \ldots t_i[j-1]) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} p(\delta) \mathrm{e}^{-\frac{\delta^2}{2}} \mathrm{d}\delta$.

Let δ_{min} be the point in the above range at which $p(\delta)$ is minimized in this range. Then

$$p(\delta_{min}) \leq \frac{\int_{-3\sqrt{\ln n}}^{3\sqrt{\ln n}} p(\delta) \mathrm{e}^{-\frac{\delta^2}{2}} \mathrm{d}\delta}{\int_{-3\sqrt{\ln n}}^{3\sqrt{\ln n}} \mathrm{e}^{-\frac{\delta^2}{2}} \mathrm{d}\delta} \leq \frac{\tau}{(1 - 2\int_{3\sqrt{\ln n}}^{\infty} \mathrm{e}^{-\frac{\delta^2}{2}} \mathrm{d}\delta)} \leq \frac{\tau}{1 - O(\frac{1}{n^{4.5}})}$$

by Theorem 4.1. Therefore, $p(\delta_{min}) \leq \tau(1 + O(\frac{1}{n^{4.5}})) \leq \tau + O(\frac{1}{n^{2.5}})$ as required. □

The set S we choose will comprise points which are multiples of $\Theta(1/n^9)$ in the range $-3\sqrt{\ln n} \ldots 3\sqrt{\ln n}$. In addition, it will contain all those points in the above range at which $p(\delta)$ is not differentiable. By Lemma 3.4, there will be at most $2r|E| = O(n^3)$ such points, at most 2 for each edge-center pair. These points will be obtained in the process of writing down the expressions for $f_{e,k}(\delta)$ in section 5. The size of S is thus $O(n^9\sqrt{\ln n})$.

We need to show that evaluating $p(\delta)$ at just points in S suffices to approximate $\min_{-3\sqrt{\ln n} < \delta < 3\sqrt{\ln n}} p(\delta)$ to within $O(\frac{1}{n^2})$. For this, we will need to bound the derivative of $p(\delta)$ with respect to δ, wherever it exists, in the above range. This is done in Lemma 4.3.

LEMMA 4.3. *At any point δ, $|\frac{\mathrm{d}p(\delta)}{\mathrm{d}\delta}| = O(n^7)$ whenever it exists. Consider any $\Delta = O(\frac{1}{n^9})$. Then it follows that $|p(\delta + \Delta) - p(\delta)| \leq O(\frac{1}{n^2})$, for any δ, such that $p(\delta)$ is differentiable everywhere in the range $]\delta \ldots \delta + \Delta[$.*

Proof. The second part follows from the fact that $\frac{|p(\delta+\Delta)-p(\delta)|}{\Delta} = O(n^7)$. This is because the slope of $p()$ must equal $\frac{p(\delta+\Delta)-p(\delta)}{\Delta}$ at some point in the range $]\delta \ldots \delta+\Delta[$.

To show the first part, we show in Appendix 2 that the derivative of each $f_{e,k}(\delta)$ is bounded by $O(n^4)$ wherever it exists. Thus the derivative of $p(\delta)$ will be bounded by $O(r|E|n^4) = O(n^7)$ as claimed. □

COROLLARY 4.4. *If δ_{min} is the point in the range $-3\sqrt{\ln n} < \delta < 3\sqrt{\ln n}$ at which $p(\delta)$ is minimized in this range, then $p(\delta_{min})$ can be approximated to within an $O(\frac{1}{n^2})$ additive error by evaluating $p(\delta)$ at the nearest point in S which is bigger than δ_{min}.*

From Lemma 4.2 and Corollary 4.4, we conclude that $\min_{\delta \in S} p(\delta) - \tau = O(\frac{1}{n^2})$ as required.

5. Substep 2a: Deriving expressions for $f_{e,k}(\delta)$. Recall that $f_{e,k}(\delta) = \Pr(E_k^e | i, j, \delta)$ is the probability that both endpoints v, w of e are assigned the color corresponding to center t_k when the values for all conditional variables before $t_i[j]$ have been determined and $t_i[j]$ is assigned δ. For a fixed edge $e = (v, w)$ and some fixed k, we show how to express $f_{e,k}(\delta)$ in terms of some basic functions and the function $I()$ defined earlier. The exact expression will depend upon which of a number of cases occurs. However, the thing to note is that the expression in each case will have only a constant number of nested integrals. For each case, we will also determine points δ, if any, at which $f_{e,k}(\delta)$ is not differentiable. Recall that these points are necessary in defining S in section 4. Then, in section 6, we will show how $I()$ itself can be expressed in terms of basic functions and nested integrals of depth just 2.

Notation. For convenience, we use the notation $\Pr((x \leq t_k \cdot v \leq x + \mathrm{d}x) \wedge (y \leq t_k \cdot w \leq y + \mathrm{d}y))$ to denote the density function of the joint probability distribution of $t_k \cdot v$ and $t_k \cdot w$, multiplied by $\mathrm{d}x\mathrm{d}y$. Informally speaking, the above term denotes the probability that $t_k \cdot v$ is in the infinitesimal range $x \ldots x + \mathrm{d}x$ and $t_k \cdot w$ is in the infinitesimal range $y \ldots y + \mathrm{d}y$. Similarly, we use the notation $I(v, w, x, x + \mathrm{d}x, y, y + \mathrm{d}y)$

to denote $\Pr((x \le a \cdot b \le x+\mathrm{d}x) \wedge (y \le a \cdot b' \le y+\mathrm{d}y))$, where a is as in the definition of I (see section 3.3). So what $I(v, w, x, x+\mathrm{d}x, y, y+\mathrm{d}y)$ effectively denotes is the density function of the joint probability distribution of $a \cdot b, a \cdot b'$ multiplied by $\mathrm{d}x\mathrm{d}y$. The expression we derive for $f_{e,k}(\delta)$ will have terms of the form $I(v, w, x, x+\mathrm{d}x, y, y+\mathrm{d}y)$. In section 6, we will expand this term out in terms of the actual density function.

Before giving the expressions for $f_{e,k}(\delta)$, we need to reiterate a basic fact.

Fact 1. Note that $t_{i+1}, t_{i+2}, \ldots, t_r$ are all completely undetermined, mutually independent, independent of $t_1, \ldots, t_i$, and identically distributed in a spherically symmetric manner in n dimensions. $t_i[j+1 \ldots n]$ is also undetermined and is spherically symmetrically distributed in $n-j$ dimensions and is independent of $t_{i+1}, \ldots, t_r$ and of all the previously fixed components of t_i.

The cases to be considered. There are three cases, depending upon whether $k < i$, $k = i$, or $k > i$. Each case has three subcases, depending upon whether $j < n-1$, $j = n-1$, or $j = n$. We have to consider these three subcases separately for the following reason: When $j < n-1$, we will express the above probability in terms of the function $I()$. For $j = n-1$ and $j = n$, we cannot express the above probability in terms of $I()$. (Recall that $I()$ was only defined when its argument vectors are at least two-dimensional.) Therefore, in these two subcases, we have to express the probability directly. These two subcases themselves need to be separated because the derivative of $f_{e,k}(\delta)$ behaves differently in these two subcases, and the behavior is crucial to the analysis (setting up S in section 4). Recall Lemma 3.4 in this context.

Note from property 1 of section 3.1 that $v[n], w[n]$ are nonzero. We will need to divide by these quantities at points.

Notation. For vectors a, b, let $a \cdot b[l, m]$ denote $a[l \ldots m] \cdot b[l \ldots m] = \sum_{h=l}^{m} a[h]b[h]$. Let $\alpha' = t_i \cdot v[1 \ldots j-1]$, and let $\beta' = t_i \cdot w[1 \ldots j-1]$.

Case 1 ($k < 1$). In this case, the center t_k already has been determined. Let $t_k \cdot v = \alpha$ and $t_k \cdot w = \beta$. Centers $t_1, \ldots, t_{i-1}$ have also been determined. If one of $t_1 \cdot v, \ldots, t_{i-1} \cdot v$ is greater than α or if one of $t_1 \cdot w, \ldots, t_{i-1} \cdot w$ is greater than β, then $\Pr(E_k^e | i, j, \delta)$ is 0. Otherwise, it is

$$f_{e,k}(\delta) = \Pr(\wedge_{l=i}^{r}(t_l \cdot v \le \alpha \wedge t_l \cdot w \le \beta) | i, j, \delta).$$

Note that the events $t_l \cdot v \le \alpha \wedge t_l \cdot w \le \beta$, $i \le l \le r$, are all independent.

Case 1.1 ($j < n-1$). By Fact 1,

$$\begin{aligned}
f_{e,k}(\delta) &= \Pr(t_i \cdot v \le \alpha \wedge t_i \cdot w \le \beta | i, j, \delta) \times \Pr(t_r \cdot v \le \alpha \wedge t_r \cdot w \le \beta)^{r-i} \\
&= \Pr(\alpha' + \delta v[j] + t_i \cdot v[j+1 \ldots n] \le \alpha \wedge \beta' + \delta w[j] + t_i \cdot w[j+1 \ldots n] \le \beta) \\
&\quad \times \Pr(t_r \cdot v \le \alpha \wedge t_r \cdot w \le \beta)^{r-i} \\
&= \Pr(t_i \cdot v[j+1 \ldots n] \le \alpha - \alpha' - \delta v[j] \wedge t_i \cdot w[j+1 \ldots n] \le \beta - \beta' - \delta w[j]) \\
&\quad \times \Pr(t_r \cdot v \le \alpha \wedge t_r \cdot w \le \beta)^{r-i} \\
&= I(v[j+1 \ldots n], w[j+1 \ldots n], -\infty, \alpha - \alpha' - \delta v[j], -\infty, \beta - \beta' - \delta w[j]) \\
&\quad \times I^{r-i}(v, w, -\infty, \alpha, -\infty, \beta).
\end{aligned}$$

Based on the following lemma, we claim that the derivative of $f_{e,k}(\delta)$ with respect to δ is always defined for the above case. The same will be true for Cases 2.1 and 3.1.

LEMMA 5.1. *$I(b, b', \mathcal{A}(\delta), \mathcal{B}(\delta), \mathcal{C}(\delta), \mathcal{D}(\delta))$ is differentiable with respect to δ for all δ, where $\mathcal{A}(), \mathcal{B}(), \mathcal{C}(), \mathcal{D}()$ are linear functions of δ.*

Proof. The proof of Lemma 5.1 will be described in section 6, after the expression for $I()$ is derived. □

Case 1.2 ($j = n-1$). We derive the expression for $f_{e,k}(\delta)$ for the case when $v[n]$ and $w[n]$ are both positive. The other cases are similar. By Fact 1 and the fact that $t_i[n]$ is normally distributed,

$$\begin{aligned}
f_{e,k}(\delta) &= \Pr(t_i \cdot v \le \alpha \wedge t_i \cdot w \le \beta | i, n-1, \delta) \\
&\quad \times \Pr(t_r \cdot v \le \alpha \wedge t_r \cdot w \le \beta)^{r-i} \\
&= \Pr(t_i[n]v[n] \le \alpha - \alpha' - \delta v[n-1] \wedge t_i[n]w[n] \le \beta - \beta' - \delta w[n-1]) \\
&\quad \times \Pr(t_r \cdot v \le \alpha \wedge t_r \cdot w \le \beta)^{r-i} \\
&= \Pr\left(t_i[n] \le \min\{\frac{\alpha - \alpha' - \delta v[n-1]}{v[n]}, \frac{\beta - \beta' - \delta w[n-1]}{w[n]}\}\right) \\
&\quad \times \Pr(t_r \cdot v \le \alpha \wedge t_r \cdot w \le \beta)^{r-i} \\
&= \left(\frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\min\{\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]}, \frac{\beta-\beta'-w[n-1]\delta}{w[n]}\}} \mathrm{e}^{-z^2/2} \mathrm{d}z\right) \times I^{r-i}(v, w, -\infty, \alpha, -\infty, \beta).
\end{aligned}$$

Note that the derivative of $f_{e,k}(\delta)$ with respect to δ is undefined at only one point, namely, the value of δ for which $\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]} = \frac{\beta-\beta'-w[n-1]\delta}{w[n]}$.

Case 1.3 ($j = n$). If $t_i \cdot v = \alpha' + v[n]\delta > \alpha$ or $t_i \cdot w = \beta' + w[n]\delta > \beta$, then t_i has a bigger dot product than t_k with at least one of v or w, and therefore, $f_{e,k}(\delta) = 0$. Otherwise

$$\begin{aligned}
f_{e,k}(\delta) &= \Pr(t_i \cdot v \le \alpha \wedge t_i \cdot w \le \beta | i, j, \delta) \Pr(t_r \cdot v \le \alpha \wedge t_r \cdot w \le \beta)^{r-i} \\
&= \Pr(t_r \cdot v \le \alpha \wedge t_r \cdot w \le \beta)^{r-i} \\
&= I^{r-i}(v, w, -\infty, \alpha, -\infty, \beta).
\end{aligned}$$

Note that the derivative of $f_{e,k}(\delta)$ with respect to δ is undefined only for two values, namely, when $\alpha = \alpha' + v[n]\delta$ and $\beta = \beta' + w[n]\delta$.

Case 2 ($k > i$). Let $\max\{t_1 \cdot v, \ldots, t_{i-1} \cdot v\} = \alpha$ and $\max\{t_1 \cdot w, \ldots, t_{i-1} \cdot w\} = \beta$. $t_k \cdot v$ must be greater than α and $t_k \cdot w$ must be greater than β for t_k to be the color assigned to both v and w. Then let A be the event $t_k \cdot v \ge \alpha \wedge t_k \cdot w \ge \beta$ and B_l be the event $t_l \cdot v \le t_k \cdot v \wedge t_l \cdot w \le t_k \cdot w$, $l \ge i, l \ne k$.

Note that the events B_l in this case are not independent. However, they are independent for fixed values of $t_k \cdot v$ and $t_k \cdot w$. In what follows, we will, at appropriate points, fix $t_k \cdot v$ and $t_k \cdot w$ to be in some infinitesimal intervals and then integrate over these intervals. Within such an integral, the values of $t_k \cdot v$ and $t_k \cdot w$ may be treated as fixed, and therefore, the events corresponding to the B_l's with the above values fixed become independent. Note that we do not do any discretization or approximation here. Rather, what we derive here is an exact integral using the slightly nonstandard but intuitively illustrative notation $\Pr((x \le t_k \cdot v \le x + \mathrm{d}x) \wedge (y \le t_k \cdot w \le y + \mathrm{d}y))$ defined earlier in this section.

Case 2.1 ($j < n-1$).

$$\begin{aligned}
f_{e,k}(\delta) &= \Pr(A \wedge B_i \wedge \cdots B_{k-1} \wedge B_{k+1} \wedge \cdots B_r | i, j, \delta) \\
&= \int_{x=\alpha}^{\infty} \int_{y=\beta}^{\infty} (\Pr((x \le t_k \cdot v \le x + \mathrm{d}x) \wedge (y \le t_k \cdot w \le y + \mathrm{d}y)) \\
&\qquad \times \quad \Pr(t_i \cdot v \le x \wedge t_i \cdot w \le y | i, j, \delta)
\end{aligned}$$

$$\times \prod_{l=i+1,\ldots,k-1,k+1,\ldots,r} \Pr(t_l \cdot v \le x \wedge t_l \cdot w \le y | i, j, \delta)$$

$$= \int_{x=\alpha}^{\infty} \int_{y=\beta}^{\infty} (I(v, w, x, x + \mathrm{d}x, y, y + \mathrm{d}y)$$
$$\times \Pr(\alpha' + \delta v[j] + t_i \cdot v[j+1, n] \le x \wedge \beta' + \delta w[j] + t_i \cdot w[j+1, n] \le y)$$
$$\times I^{r-i-1}(v, w, -\infty, x, -\infty, y))$$
$$= \int_{x=\alpha}^{\infty} \int_{y=\beta}^{\infty} (I(v, w, x, x + \mathrm{d}x, y, y + \mathrm{d}y)$$
$$\times I(v[j+1 \ldots n], w[j+1 \ldots n], -\infty, x - \alpha' - v[j]\delta, -\infty, y - \beta' - w[j]\delta)$$
$$\times I^{r-i-1}(v, w, -\infty, x, -\infty, y)).$$

By Lemma 5.1, $f(\delta)$ is always differentiable with respect to δ in this case.

Case 2.2 ($j = n - 1$). Assume that $v[n]$ and $w[n]$ are positive. The remaining cases are similar. Then $f_{e,k}(\delta) = \Pr(A \wedge B_i \wedge \cdots \wedge B_{k-1} \wedge B_{k+1} \wedge \cdots \wedge B_r | i, n-1, \delta)$

$$= \int_{x=\alpha}^{\infty} \int_{y=\beta}^{\infty} (\Pr((x \le t_k \cdot v \le x + \mathrm{d}x) \wedge (y \le t_k \cdot w \le y + \mathrm{d}y))$$
$$\times \prod_{l=i,\ldots,k-1,k+1,\ldots,r} \Pr(t_l \cdot v \le x \wedge t_l \cdot w \le y | i, n-1, \delta))$$
$$= \int_{x=\alpha}^{\infty} \int_{y=\beta}^{\infty} (I(v, w, x, x + \mathrm{d}x, y, y + \mathrm{d}y)$$
$$\times \Pr(\alpha' + \delta v[n-1] + t_i[n] v[n] \le x \wedge \beta' + \delta w[n-1] + t_i[n] w[n] \le y)$$
$$\times \prod_{l=i+1,\ldots,k-1,k+1,\ldots,r} \Pr(t_l \cdot v \le x \wedge t_l \cdot w \le y))$$
$$= \int_{x=\alpha}^{\infty} \int_{y=\beta}^{\infty} (I(v, w, x, x + \mathrm{d}x, y, y + \mathrm{d}y) \left(\frac{1}{\sqrt{2\pi}} \int_{z=-\infty}^{\min\{\frac{x-\alpha'-v[n-1]\delta}{v[n]}, \frac{y-\beta'-w[n-1]\delta}{w[n]}\}} \mathrm{e}^{-z^2/2} \mathrm{d}z \right)$$
$$\times I^{r-i-1}(v, w, -\infty, x, -\infty, y))$$
$$= \frac{1}{\sqrt{2\pi}} \int_{z=-\infty}^{\infty} \int_{x=\max\{\alpha, \alpha'+v[n]z+v[n-1]\delta\}}^{\infty} \int_{y=\max\{\beta, \beta'+w[n]z+w[n-1]\delta\}}$$
$$(I(v, w, x, x + \mathrm{d}x, y, y + \mathrm{d}y) \times I^{r-i-1}(v, w, -\infty, x, -\infty, y) \mathrm{e}^{-z^2/2}) \mathrm{d}z.$$

Note that the derivative of $f_{e,k}(\delta)$ with respect to δ is undefined only when $\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]} = \frac{\beta-\beta'-w[n-1]\delta}{w[n]}$. We see this by the following argument. Consider the values of δ for which $\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]} < \frac{\beta-\beta'-w[n-1]\delta}{w[n]}$. The above expression for $f_{e,k}(\delta)$ can then be split up into a sum of three terms described below. From the resulting expression, it is clear that it is differentiable for all values of δ such that $\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]} < \frac{\beta-\beta'-w[n-1]\delta}{w[n]}$. A similar argument shows that $f_{e,k}(\delta)$ is differentiable for all values of δ such that $\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]} > \frac{\beta-\beta'-w[n-1]\delta}{w[n]}$.

$$f_{e,k}(\delta) = \tfrac{1}{\sqrt{2\pi}} \int_{z=-\infty}^{\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]}} \int_{x=\alpha}^{\infty} \int_{y=\beta}^{\infty} (I(v, w, x, x + \mathrm{d}x, y, y + \mathrm{d}y)$$
$$\times I^{r-i-1}(v, w, -\infty, x, -\infty, y) \mathrm{e}^{-\frac{z^2}{2}} \mathrm{d}z)$$

$$+\frac{1}{\sqrt{2\pi}}\int_{z=\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]}}^{\frac{\beta-\beta'-w[n-1]\delta}{w[n]}}\int_{x=\alpha'+v[n]z+v[n-1]\delta}^{\infty}\int_{y=\beta}^{\infty}(I(v,w,x,x+\mathrm{d}x,y,y+\mathrm{d}y)$$
$$\times\quad I^{r-i-1}(v,w,-\infty,x,-\infty,y)\mathrm{e}^{-\frac{z^2}{2}}\,\mathrm{d}z)$$
$$+\frac{1}{\sqrt{2\pi}}\int_{z=\frac{\beta-\beta'-w[n-1]\delta}{w[n]}}^{\infty}\int_{x=\alpha'+v[n]z+v[n-1]\delta}^{\infty}$$
$$\int_{y=\beta'+w[n]z+w[n-1]\delta}^{\infty}(I(v,w,x,x+\mathrm{d}x,y,y+\mathrm{d}y)$$
$$\times\quad I^{r-i-1}(v,w,-\infty,x,-\infty,y)\mathrm{e}^{-\frac{z^2}{2}}\,\mathrm{d}z).$$

Case 2.3 ($j=n$). Since $t_i[n]$ is assigned to δ and all other components of t_i are fixed, $t_k\cdot v>\max\{\alpha,\alpha'+v[n]\delta\}$ and $t_k\cdot w>\max\{\beta,\beta'+w[n]\delta\}$ for t_k to be the color assigned to both v and w. Then $f_{e,k}(\delta)=\Pr(A\wedge B_i\wedge\cdots,B_{k-1}\wedge B_{k+1}\wedge\cdots,B_r|i,n,\delta)$

$$=\int_{y=\max\{\beta,\beta'+w[n]\delta\}}^{\infty}\int_{x=\max\{\alpha,\alpha'+v[n]\delta\}}^{\infty}(\Pr((x\le t_k\cdot v\le x+\mathrm{d}x)\wedge(y\le t_k\cdot w\le y+\mathrm{d}y))$$
$$\times\prod_{l=i+1,\ldots,k-1,k+1,\ldots,r}\Pr(t_l\cdot v\le x\wedge t_l\cdot w\le y|i,n,\delta))$$
$$=\int_{y=\max\{\beta,\beta'+w[n]\delta\}}^{\infty}\int_{x=\max\{\alpha,\alpha'+v[n]\delta\}}^{\infty}(\Pr((x\le t_k\cdot v\le x+\mathrm{d}x)\wedge(y\le t_k\cdot w\le y+\mathrm{d}y))$$
$$\times\prod_{l=i+1,\ldots,k-1,k+1,\ldots,r}\Pr(t_l\cdot v\le x\wedge t_l\cdot w\le y))$$
$$=\int_{\max\{\beta,\beta'+w[n]\delta\}}^{\infty}\int_{\max\{\alpha,\alpha'+v[n]\delta\}}^{\infty}(I(v,w,x,x+\mathrm{d}x,y,y+\mathrm{d}y)$$
$$\times\ I^{r-i-1}(v,w,-\infty,x,-\infty,y)).$$

Note that the derivative of the above expression with respect to δ is undefined only for two values, namely, when $\alpha=\alpha'+v[n]\delta$ and $\beta=\beta'+w[n]\delta$.

Case 3 ($k=i$). Let $\max\{t_1\cdot v,\ldots,t_{i-1}\cdot v\}=\alpha$ and $\max\{t_1\cdot w,\ldots,t_{i-1}\cdot w\}=\beta$. $t_i\cdot v>\alpha$ and $t_i\cdot w>\beta$ for t_i to be the color assigned to both v and w. Then, let A be the event $t_i\cdot v\ge\alpha\wedge t_i\cdot w\ge\beta$ and B_l be the event $t_l\cdot v\le t_i\cdot v\wedge t_l\cdot w\le t_i\cdot w$, $l>i$.

Again, note that the events B_l in this case are not independent. However, they are independent for fixed values of $t_i\cdot v$ and $t_i\cdot w$.

Case 3.1 ($j<n-1$).

$$f_{e,k}(\delta)=\Pr(A\wedge B_{i+1}\wedge\cdots\wedge B_r|i,j,\delta)$$
$$=\int_{x=\alpha}^{\infty}\int_{y=\beta}^{\infty}(I(v[j+1\ldots n],w[j+1\ldots n],x-\alpha'-v[j]\delta,x+\mathrm{d}x-\alpha'-v[j]\delta,$$
$$y-\beta'-w[j]\delta,y+\mathrm{d}y-\beta'-w[j]\delta)$$
$$\times\ I^{r-i}(v,w,-\infty,x,-\infty,y)).$$

By Lemma 5.1, $f(\delta)$ is always differentiable with respect to δ in this case.

Case 3.2 ($j=n-1$). Assume that $v[n]$ and $w[n]$ are positive. The other cases are similar.

$$f_{e,k}(\delta) = \Pr(A \wedge B_{i+1} \wedge \cdots \wedge B_r | i, n-1, \delta)$$
$$= \frac{1}{\sqrt{2\pi}} \int_{z=\max\{\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]}, \frac{\beta-\beta'-w[n-1]\delta}{w[n]}\}}^{\infty} \times (I^{r-i}(v, w, -\infty, \alpha'+v[n-1]\delta+v[n]z, -\infty, \beta'+w[n-1]\delta+w[n]z)\mathrm{e}^{-z^2/2}\mathrm{d}z).$$

Note that the derivative of the above expression with respect to δ is undefined only when $\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]} = \frac{\beta-\beta'-w[n-1]\delta}{w[n]}$.

Case 3.3 ($j = n$). If $v[n]\delta + \alpha' < \alpha$ or $w[n]\delta + \beta' < \beta$ then this probability is 0. Otherwise,

$$f_{e,k}(\delta) = \Pr(A \wedge B_{i+1} \wedge \cdots \wedge B_r | i, j, \delta) = I^{r-i}(v, w, -\infty, \alpha' + v[n]\delta, -\infty, \beta' + w[n]\delta).$$

Note that the derivative of the above expression with respect to δ is possibly undefined only for at most two values, namely, when $\alpha = \alpha' + v[n]\delta$ and $\beta = \beta' + w[n]\delta$.

6. Substep 2a: Expressing $I(b, b', x, y, x', y')$. Recall that $I(b, b', x, y, x', y')$ denotes $\Pr((x \le a \cdot b \le y) \wedge (x' \le a \cdot b' \le y'))$, where a is a vector whose entries are independent and normally distributed with mean 0 and variance 1. We show how to derive an expression for this probability in terms of nested integrals of depth 2, with the integrand comprising only basic functions. Let b and b' be h-dimensional. Note that $h \ge 2$. Consider the h-dimensional coordinate system with respect to which b, b' are specified.

The naive way. Note that a naive way to compute I is to perform a sequence of h nested integrals, one over each of $a[1] \ldots a[h]$, the coordinates of the vector a. The following is the naive expression for the case when $b[h]$ and $b'[h]$ are both positive. A similar expression holds for other cases.

$$\left(\frac{1}{\sqrt{2\pi}}\right)^h \int_{a[1]=-\infty}^{\infty} \int_{a[2]=-\infty}^{\infty} \cdots \int_{a[h-1]=-\infty}^{\infty} \int_{a[h]=\alpha}^{\beta} \mathrm{e}^{-\frac{\sum_{l=1}^{h} a[l]^2}{2}} \mathrm{d}a[h]\mathrm{d}a[h-1]\cdots\mathrm{d}a[1],$$

where

$$\alpha = \max\left\{ \left(x - \sum_{1}^{h-1} a[i]b[i]\right)/b[h], \left(x' - \sum_{1}^{h-1} a[i]b'[i]\right)/b'[h] \right\},$$

$$\beta = \min\left\{ \left(y - \sum_{1}^{h-1} a[i]b[i]\right)/b[h], \left(y' - \sum_{1}^{h-1} a[i]b'[i]\right)/b'[h] \right\}.$$

Computing this integral to within the required error bounds in polynomial time seems hard. We use the following method instead.

Our method. Note that since each coordinate of a is normally distributed with mean 0 and variance 1, a has a spherically symmetric distribution. We rotate the coordinate system so that $b = (b_1, 0, \ldots, 0)$ and $b' = (b'_1, b'_2, 0, \ldots, 0)$, where $b_1, b'_2 \ge 0$. As we will show shortly, both b_1, b'_2 will be strictly positive for all our calls to I. Let $a'[1]a'[2]\ldots a'[h]$ be the coordinates of a under the rotated coordinate system. The following lemma is key.

LEMMA 6.1. *The probability distribution of a' is identical to that of a. That is, all the coordinates of a' are independently distributed according to the normal distribution with mean* 0 *and variance* 1.

Proof. Let $x_1, \ldots, x_h$ denote the initial coordinate system, and let $x'_1, x'_2, \ldots, x'_h$ denote the coordinate system after rotation. Then $(x_1, x_2, \ldots, x_h)A = (x'_1, x'_2, \ldots, x'_h)$, where A is the orthonormal rotation matrix; i.e., $AA^T = I$.

Next, recall that the probability density function of $a[l]$ is $\frac{1}{\sqrt{2\pi}}\mathrm{e}^{-\frac{x_l^2}{2}}$ for $l = 1 \ldots h$. We show that the probability density function of $a'[l]$ is $\frac{1}{\sqrt{2\pi}}\mathrm{e}^{-\frac{(x'_l)^2}{2}}$ for $l = 1 \ldots h$. We also show that the joint probability density function of the $a'[l]$s is just the product of their individual density functions. The lemma then follows.

The density function of the joint distribution of $a[1], \ldots, a[h]$ is $\frac{1}{(\sqrt{2\pi})^h}\mathrm{e}^{-\frac{\Sigma_1^h x_l^2}{2}}$. We now derive the joint distribution of $a'[1], \ldots, a'[h]$. Since $(x_1, x_2, \ldots, x_h)A = (x'_1, x'_2, \ldots, x'_h)$ and A is orthonormal, $\sum_1^h x_l^2 = \sum_1^h (x'_l)^2$. Using the standard method for performing coordinate transformation, the density function of the joint distribution of $a'[1], \ldots, a'[h]$ is $\frac{1}{(\sqrt{2\pi})^h}\mathrm{e}^{-\frac{\Sigma_1^h (x'_l)^2}{2}} \det(B)$, where B is the matrix whose p, qth entry is $\frac{\partial x_p}{\partial x'_q}$. Since $(x_1, x_2, \ldots, x_h) = (x'_1, x'_2, \ldots, x'_h)A^T$, the matrix B is easily seen to be identical to A. Since A is orthonormal, $\det(A) = 1$, and therefore, the density function of the joint distribution of $a'[1], \ldots, a'[h]$ is just $\frac{1}{(\sqrt{2\pi})^h}\mathrm{e}^{-\frac{\Sigma_1^h (x'_l)^2}{2}}$.

Finally, the density function of $a'[l]$ can be seen to be $\frac{1}{\sqrt{2\pi}}\mathrm{e}^{-\frac{(x'_l)^2}{2}}$ by integrating away the other terms, i.e.,

$$\int_{x_1=-\infty}^{\infty}\int_{x_2=-\infty}^{\infty}\cdots\int_{x_{l-1}=-\infty}^{\infty}\int_{x_{l+1}=-\infty}^{\infty}\cdots\int_{x_h=-\infty}^{\infty}\left(\frac{1}{(\sqrt{2\pi})^h}\mathrm{e}^{-\frac{\sum_1^h (x'_l)^2}{2}}\right) \times \mathrm{d}x'_h\mathrm{d}x'_{h-1}\cdots\mathrm{d}x'_{l+1}\mathrm{d}x'_{l-1}\cdots\mathrm{d}x'_1 = \frac{1}{\sqrt{2\pi}}\mathrm{e}^{-\frac{(x'_l)^2}{2}}. \qquad \square$$

Having rotated the coordinate axes, note that $a' \cdot b = a'[1]b_1$ and $a' \cdot b' = a'[1]b'_1 + a'[2]b'_2$. Now $I(b, b', x, y, x', y')$ denotes $\Pr((x \le a'[1]b_1 \le y) \wedge (x' \le a'[1]b'_1 + a'[2]b'_2 \le y'))$. We give the expression for $I(b, b', x, y, x', y')$ in the following lemma for future reference.

LEMMA 6.2.

$$I(b, b', x, y, x', y') = \Pr((x \le a'[1]b_1 \le y) \wedge (x' \le a'[1]b'_1 + a'[2]b'_2 \le y'))$$

$$= \Pr\left(\left(\frac{x}{b_1} \le a'[1] \le \frac{y}{b_1}\right) \wedge \left(\frac{x' - a'[1]b'_1}{b'_2} \le a'[2] \le \frac{y' - a'[1]b'_1}{b'_2}\right)\right)$$

$$= \frac{1}{2\pi}\int_{\frac{x}{b_1}}^{\frac{y}{b_1}} e^{-\frac{z^2}{2}}\left(\int_{\frac{(x' - zb'_1)}{b'_2}}^{\frac{(y' - zb'_1)}{b'_2}} e^{-\frac{z'^2}{2}}\ \mathrm{d}z'\right)\ \mathrm{d}z.$$

LEMMA 6.3. *$|b_1| = \Omega(\epsilon) = \Omega(\frac{1}{n^2})$ and $|b'_2| = \Omega(\epsilon^2) = \Omega(\frac{1}{n^4})$.*

Proof. Note that b, b' are of the form $v[h \ldots n], w[h \ldots n]$ for vertex vectors v and w and $h \le n-1$ in all the calls we make to $I()$. The lemma now follows from property 3 of the discretization of vertex vectors in section 3.1. $\square$

Two remarks. We remark that Lemma 5.1 can be easily seen to hold by inspecting the expression derived in Lemma 6.2, with x, x', y, y' replaced by linear functions of δ. Second, recall from section 5 that some of the expressions involve occurrences of $I()$ with $y = x + \mathrm{d}x$ and $y' = x' + \mathrm{d}x'$. It can be easily seen that

$$\Pr((x \le a{\cdot}b \le x{+}\mathrm{d}x){\wedge}(x' \le a{\cdot}b' \le x'{+}\mathrm{d}x')) = \frac{1}{2\pi}\frac{1}{b_1 b_2'}\mathrm{e}^{-\frac{(x/b_1)^2}{2}}\mathrm{e}^{-\frac{(x'-xb_1'/b_1)^2}{2(b_2')^2}}\ \mathrm{d}x'\ \mathrm{d}x.$$

7. Substep 2b: Evaluating $f_{e,k}(\delta)$. Sections 5 and 6 derived expressions for $f_{e,k}(\delta)$, which were nested integrals with constant depth (at most five). We now show how to evaluate these expressions at any given value of δ in polynomial time with just $O(\frac{1}{n^5})$ error.

First, in Lemma 7.1, we show that all the expressions we derived in sections 5 and 6 involve integrations where the integrand has a particular form. This enables us to focus on only integrations of this form. We show how to perform each such integration within an inverse polynomial error, with the polynomial being chosen so that the final error in computing $f_{e,k}(\delta)$ is $O(\frac{1}{n^5})$ as required.

To perform each such integration, we have to do two things: first, restrict the range of the limits of integration and, second, convert the integration to a summation and compute the summation. Each of these steps will incur an error, which we will show can be made inverse polynomial, with the actual polynomial chosen to keep the overall error within the stated bounds. The error in restricting the range of the limits of integration is bounded in Lemma 7.2. To bound the error in converting the integrations to summations, we give Lemma 7.3, which states that it suffices to bound the absolute value of the derivative of the integrands. In Lemma 7.4, we show that the derivative of each integrand is bounded by some polynomial in n. Together Lemmas 7.1, 7.2, 7.3, and 7.4 imply that each integration can be computed to within an inverse polynomial error. Finally, since expressions for $f_{e,k}(\delta)$ involve up to five nested integrations, the inverse polynomial error terms in each integration have to be chosen so that the final combined error of all five integrations is $O(\frac{1}{n^5})$. This is described under the heading Algorithm for Performing Integrations. Lemma 7.1 obtains the general form of each integration.

LEMMA 7.1. *Each integration we perform can be expressed in the following form:*

$$\int_l^m \frac{1}{\sqrt{2\pi}} e^{-\frac{h^2}{2}} H(\mathcal{G}(h))\mathrm{d}h$$

for some function $\mathcal{G}(h)$, where $H()$ is such that $0 \le H(e) \le 1$ for all e.

Proof. This is easily verified by an inspection of the expressions to be integrated in section 5 and the integral for $I()$ in section 6. The functions $H()$ are always probabilities. The only fact to be noted is that $I(v, w, x, x + \mathrm{d}x, y, y + \mathrm{d}y)$, which appears in the integrals in Case 2 of section 5, equals

$$\frac{1}{\sqrt{2\pi}}\frac{1}{b_1}\mathrm{e}^{-\frac{x^2}{2b_1^2}}\frac{1}{\sqrt{2\pi}}\frac{1}{b_2'}\mathrm{e}^{-\frac{\left(y-x\frac{b_1'}{b_1}\right)^2}{2(b_2')^2}}\mathrm{d}y\mathrm{d}x = \frac{1}{\sqrt{2\pi}}\mathrm{e}^{-\frac{h^2}{2}}\frac{1}{\sqrt{2\pi}}\mathrm{e}^{-\frac{(h')^2}{2}}\mathrm{d}h'\mathrm{d}h,$$

where $v = (b_1, 0, \ldots, 0)$ and $w = (b_1', b_2', 0, \ldots, 0)$ in the rotated coordinate system, as in section 6, and the last equality is obtained by a change of variables $h = \frac{x}{b_1}$ and $h' = \frac{y - xb_1'/b_1}{b_2'}$. This change of variables affects the limits of the integration, but we are not claiming any special properties for the limits.

Similarly,

$$I(v[j+1\ldots n], w[j+1\ldots n], x-\alpha'-v[j]\delta, x+\mathrm{d}x-\alpha'-v[j]\delta, y-\beta'-w[j]\delta, y+\mathrm{d}y-\beta'-w[j]\delta),$$

which appears in the integrals in Case 3 of section 5, equals

$$\frac{1}{\sqrt{2\pi}}\mathrm{e}^{-\frac{h^2}{2}}\frac{1}{\sqrt{2\pi}}\mathrm{e}^{-\frac{(h')^2}{2}}\mathrm{d}h'\mathrm{d}h,$$

where $v[j+1\ldots n] = (b_1, 0, \ldots, 0)$ and $w[j+1\ldots n] = (b'_1, b'_2, 0, \ldots, 0)$ in the rotated coordinate system, as in section 6, and the last equality is obtained by a change of variables $h = \frac{x-\alpha'-v[j]\delta}{b_1}$ and $h' = \frac{y-\beta'-w[j]\delta-\frac{(x-\alpha'-v[j]\delta)b'_1}{b_1}}{b'_2}$. □

The next lemma shows that limits of each integration we perform can be clipped to some small range.

LEMMA 7.2.

$$\int_{\max\{l,-a\sqrt{\ln n}\}}^{\min\{m,a\sqrt{\ln n}\}} \frac{1}{\sqrt{2\pi}} e^{-\frac{h^2}{2}} H(\mathcal{G}(h))\mathrm{d}h \le \int_l^m \frac{1}{\sqrt{2\pi}} e^{-\frac{h^2}{2}} H(\mathcal{G}(h))\mathrm{d}h$$

$$\le \int_{\max\{l,-a\sqrt{\ln n}\}}^{\min\{m,a\sqrt{\ln n}\}} \frac{1}{\sqrt{2\pi}} e^{-\frac{h^2}{2}} H(\mathcal{G}(h))\mathrm{d}h + O\left(\frac{1}{n^{a^2/2}}\right)$$

for all $a > 0$.

Proof. The first inequality is obvious. The second is derived using Theorem 4.1 as follows:

$$\begin{aligned}
&\int_l^m \frac{1}{\sqrt{2\pi}}\left(\mathrm{e}^{-\frac{h^2}{2}} H(\mathcal{G}(h))\right)\mathrm{d}h \\
&\le \int_{\max\{l,-a\sqrt{\ln n}\}}^{\min\{m,a\sqrt{\ln n}\}} \frac{1}{\sqrt{2\pi}}\left(\mathrm{e}^{-\frac{h^2}{2}} H(\mathcal{G}(h))\right)\mathrm{d}h + \int_{-\infty}^{-a\sqrt{\ln n}} \frac{1}{\sqrt{2\pi}}\left(\mathrm{e}^{-\frac{h^2}{2}} H(\mathcal{G}(h))\right)\mathrm{d}h \\
&\quad + \int_{a\sqrt{\ln n}}^{\infty} \frac{1}{\sqrt{2\pi}}\left(\mathrm{e}^{-\frac{h^2}{2}} H(\mathcal{G}(h))\right)\mathrm{d}h \\
&\le \int_{\max\{l,-a\sqrt{\ln n}\}}^{\min\{m,a\sqrt{\ln n}\}} \frac{1}{\sqrt{2\pi}}\left(\mathrm{e}^{-\frac{h^2}{2}} H(\mathcal{G}(h))\right)\mathrm{d}h + \int_{-\infty}^{-a\sqrt{\ln n}} \frac{1}{\sqrt{2\pi}}\left(\mathrm{e}^{-\frac{h^2}{2}}\right)\mathrm{d}h \\
&\quad + \int_{a\sqrt{\ln n}}^{\infty} \frac{1}{\sqrt{2\pi}}\left(\mathrm{e}^{-\frac{h^2}{2}}\right)\mathrm{d}h \\
&\le \int_{\max\{l,-a\sqrt{\ln n}\}}^{\min\{m,a\sqrt{\ln n}\}} \frac{1}{\sqrt{2\pi}}\left(\mathrm{e}^{-\frac{h^2}{2}} H(\mathcal{G}(h))\right)\mathrm{d}h + 2\int_{a\sqrt{\ln n}}^{\infty} \frac{1}{\sqrt{2\pi}}\left(\mathrm{e}^{-\frac{h^2}{2}}\right)\mathrm{d}h \\
&\le \int_{\max\{l,-a\sqrt{\ln n}\}}^{\min\{m,a\sqrt{\ln n}\}} \frac{1}{\sqrt{2\pi}}\left(\mathrm{e}^{-\frac{h^2}{2}} H(\mathcal{G}(h))\right)\mathrm{d}h + O\left(\frac{1}{n^{a^2/2}}\right).
\end{aligned}$$

Theorem 4.1 is used in the last step above. The fact that $0 \le H() \le 1$ is used in the second step. □

The next lemma is classical and will be used to show that each integration can be converted to a summation by discretizing the range between the limits of integration.

LEMMA 7.3. $|\int_l^{l+\rho} \frac{1}{\sqrt{2\pi}}(e^{-\frac{h^2}{2}} H(\mathcal{G}(h)))\mathrm{d}h - \frac{1}{\sqrt{2\pi}} e^{-\frac{l^2}{2}} H(\mathcal{G}(l))\rho| \leq \frac{M\rho^2}{2}$, *where* M *upper bounds the derivative of* $\frac{1}{\sqrt{2\pi}}(e^{-\frac{h^2}{2}} H(\mathcal{G}(h)))$ *with respect to* h.

LEMMA 7.4. *The derivative of* $\frac{1}{\sqrt{2\pi}}(e^{-\frac{h^2}{2}} H(\mathcal{G}(h)))$ *with respect to* h *is at most a polynomial in* n *in absolute value in all our integrations.*

Proof. The proof of Lemma 3 is found in Appendix 3. □

ALGORITHM FOR PERFORMING INTEGRATIONS. The four lemmas above lead to the following algorithm for performing integrations. Consider a particular integral $\int_l^m \frac{1}{\sqrt{2\pi}}(\mathrm{e}^{-\frac{h^2}{2}} H(\mathcal{G}(h)))\mathrm{d}h$. We first replace the above integral with

$$\int_{\max\{l,-a\sqrt{\ln n}\}}^{\min\{m,a\sqrt{\ln n}\}} \frac{1}{\sqrt{2\pi}} \left(\mathrm{e}^{-\frac{h^2}{2}} H(\mathcal{G}(h))\right) \mathrm{d}h.$$

Here a will be a constant to be fixed later. Next, we convert this integral to a sum by dividing the range between the limits of integration into steps of size $\Theta(\frac{1}{n^b})$ for some b to be fixed later.

Suppose the derivative of $\frac{1}{\sqrt{2\pi}}(\mathrm{e}^{-\frac{h^2}{2}} H(\mathcal{G}(h)))$ is bounded by $O(n^c)$. We compute the total error incurred above.

By Lemma 7.2, clipping the limits of integration incurs an error of $O(\frac{1}{n^{a^2/2}})$. By Lemma 7.3, the error incurred in each step of the summation is $O(\frac{n^c}{n^{2b}})$, assuming there is no error in computing $\frac{1}{\sqrt{2\pi}}\mathrm{e}^{-\frac{l^2}{2}} H(\mathcal{G}(h))$. However, $H()$ itself may have been obtained as a result of performing a nested integration or as a product of $O(n)$ distinct integrations nested one level deeper (as in Case 2.2 of section 5, for example). This implies that the value of $H()$ computed itself will have some error. So suppose we have computed each of these nested integrations within an error of $O(\frac{1}{n^f})$. Then the error in $H()$ is $O(\frac{1}{n^{f-1}})$. Therefore, the error incurred in each step of the summation is $O(\frac{n^c}{n^{2b}} + \frac{1}{n^{f-1}n^b})$; this sums to $O(\sqrt{\ln n}\frac{n^c}{n^b} + \frac{\sqrt{\ln n}}{n^{f-1}})$ over all $O(\sqrt{\ln n}nn^b)$ steps. The total error is thus $O(\frac{1}{n^{a^2/2}} + \sqrt{\ln n}\frac{n^c}{n^b} + \frac{\sqrt{\ln n}}{n^{f-1}})$ and the time taken for this integration (ignoring the time taken for the nested integrals in $H()$) is $O(\sqrt{\ln n}nn^b)$.

Finally, note that the depth of nesting in our integrals is at most five (in Case 2.2 of section 5, it is five). It can be easily seen that starting with the innermost integral and working outward, values a, b can be chosen for these successive integrals based upon the respective c, f values so that the final error is $O(\frac{1}{n^5})$.

8. Comments on derandomizing the Max-Cut algorithm. We need to show that discretizing the vectors in this case so as to satisfy properties 1–3 (with ϵ chosen appropriately) of section 3.1 is justified. In the case of the Karger–Motwani–Sudan algorithm, it was justified using Theorem 2.1.

To compensate for this theorem we need only to observe that the value of the Goemans and Williamson objective function (that is, $\sum_{i,j} w_{ij}\frac{1-v_i.v_j}{2}$) for the discretized vector configuration is at least $(1 - \frac{1}{poly(n)})$ times that for the initial vector set (this is because the sum of the edge weights is at most twice the value of the objective function for the initial vector set). The rest is just a matter of choosing the appropriate inverse polynomial terms.

9. Conclusions. We believe that the techniques used here can be used to derandomize a general class of randomized algorithms based on semidefinite programming. Loosely speaking, this class would comprise those whose expected value calculations

involve just a constant number of vectors in each "elementary" event. This class contains all randomized semidefinite programming based algorithms known so far. It would be nice to obtain a general theorem to this effect.

Also, it would be nice to obtain a more efficient derandomization scheme, since the running time of our algorithm is a large polynomial, around $O(n^{30})$ for the 3-coloring problem.

Appendix 1. Discretizing vertex vectors. Let ϵ be a parameter which is $\Theta(\frac{1}{n^2})$. In this section, we show how to discretize the vertex vectors so as to satisfy the three properties specified in section 3.1.

The vertex vectors are considered one by one in the order $v_1, v_2, \ldots, v_n$. We describe the processing of vector v_i.

First, each entry in v_i is rounded upward (in absolute value) to the nearest nonzero multiple of ϵ. Next, up to $2n\epsilon$ is added to $v_i[n-1]$ so that $|v_i[n-1]v_j[n] - v_i[n]v_j[n-1]| > \epsilon^2$ for every $j < i$. This is done to satisfy property 3. Property 1 is clearly satisfied for v_i now. Property 2 is also satisfied because each component of v_i other than $v_i[n-1]$ changes by $O(\epsilon)$ and $v_i[n-1]$ changes by $O(n\epsilon)$. However, note that in this process the vertex vectors no longer remain unit vectors. In fact, $1 \leq |v_i|^2 \leq 2$ now, for small enough ϵ, i.e., for large enough n. So we divide each vector v_i by its new norm and make it a unit vector. Since we divide by a number between one and two, property 1 and property 2 continue to hold.

It remains to show that property 3 holds. We need the following lemma.

LEMMA 9.1. *For each pair of vertex vectors v, w and every h, $1 \leq h < n$, when the coordinate system is rotated so that $v[h \ldots n] = (b_1, 0, \ldots, 0)$ and $w[h \ldots n] = (b_1', b_2', 0, \ldots, 0)$, b_1 and b_2' are at least some inverse polynomial (more precisely, $\Omega(\epsilon)$ and $\Omega(\epsilon^2)$, respectively) in absolute value.*

Proof. Let $v' = v[h \ldots n]$ and $w' = w[h \ldots n]$. Note that b_1 is just the norm of v' which is $\Omega(\epsilon)$ by property 1. Also note that $|b_2'| = \sqrt{||w'|^2 - \frac{(v' \cdot w')^2}{|v'|^2}|}$, since b_2' is just the projection of w' on the line orthogonal to v' in the plane containing v' and w'. So we need to show that $||w'|^2 - \frac{(v' \cdot w')^2}{|v'|^2}| = \Omega(\epsilon^4)$ for every h $1 \leq h < n$.

First consider $h = n-1$. $(v' \cdot w')^2 = (v[n-1]w[n-1] + v[n]w[n])^2 = (v[n-1]^2 + v[n]^2)(w[n-1]^2 + w[n]^2) - (v[n-1]w[n] - w[n-1]v[n])^2 \leq |v'|^2|w'|^2 - \Omega(\epsilon^4)$. Therefore, $|w'|^2 - \frac{(v' \cdot w')^2}{|v'|^2} = \Omega(\epsilon^4)$.

Next consider $h < n-1$. Let $l = v[h \ldots n-2]$ and $m = w[h \ldots n-2]$. Let $l' = v[n-1, n]$ and $m' = w[n-1, n]$; $(v' \cdot w')^2 = (l \cdot m + l' \cdot m')^2 = (l \cdot m)^2 + (l' \cdot m')^2 + 2(l' \cdot m')(l \cdot m) \leq |l|^2|m|^2 + (l' \cdot m')^2 + 2|l'||m'||l||m|$. By the previous paragraph, $(l' \cdot m')^2 \leq |l'|^2|m'|^2 - \Omega(\epsilon^4)$. Therefore, $(v' \cdot w')^2 \leq |l|^2|m|^2 + |l'|^2|m'|^2 + |l'|^2|m|^2 + |l|^2|m'|^2 - \Omega(\epsilon^4) \leq (|l|^2 + |l'|^2)(|m|^2 + |m'|^2) - \Omega(\epsilon^4) = |v'|^2|w'|^2 - \Omega(\epsilon^4)$. Therefore, $||w'|^2 - \frac{(v' \cdot w')^2}{|v'|^2}| = \Omega(\epsilon^4)$. ∎

Appendix 2. Proof of Lemma 4.3. We show that for each edge e and each center k, the derivative of $f_{e,k}(\delta)$ (with respect to δ) is $O(n^4)$.

Recall from section 5 that the expression for $f_{e,k}(\delta)$ depends upon which one of Cases 1, 2, and 3 and which one of the conditions $j < n-1, j = n-1, j = n$ hold.

We show the above claim only for one representative case, i.e., Case 2.1, where $j < n-1$. The other cases can be shown similarly. For Case 2.1

$$f_{e,k}(\delta) = \int_{\alpha}^{\infty} \int_{\beta}^{\infty} g(x, y) h(x, y, \delta) \mathrm{d}y \mathrm{d}x,$$

where

$$g(x,y)\mathrm{d}y\mathrm{d}x = I(v,w,x,x+\mathrm{d}x,y,y+\mathrm{d}y)I^{r-i-1}(v,w,-\infty,x,-\infty,y)$$

and

$$\begin{aligned}h(x,y,\delta) =& I(v[j+1\ldots n],w[j+1\ldots n],-\infty,x-t_i\cdot v[1\ldots j-1]-v[j]\delta,-\infty,\\ & y-t_i\cdot w[1\ldots j-1]-w[j]\delta).\end{aligned}$$

Now

$$|f'_{e,k}(\delta)| \le \int_\alpha^\infty \int_\beta^\infty |g(x,y)|\left|\frac{\partial h(x,y,\delta)}{\partial\delta}\right|\mathrm{d}y\mathrm{d}x \le \max_{x,y}\left|\frac{\partial h(x,y,\delta)}{\partial\delta}\right|$$

since $\int_\alpha^\infty \int_\beta^\infty g(x,y)\mathrm{d}y\mathrm{d}x$ is a probability and therefore ≤ 1. We show that $|f'_{e,k}(\delta)| = O(n^4)$ by estimating $\max_{x,y}|\frac{\partial h(x,y,\delta)}{\partial\delta}|$. Let $c(x,\delta) = x - t_i\cdot v[1\ldots j-1] - v[j]\delta = c' - v[j]\delta$ and $d(y,\delta) = y - t_i\cdot w[1\ldots j-1] - w[j]\delta = d' - w[j]\delta$.

By Lemma 6.2, $h(x,y,\delta) = \frac{1}{2\pi}\int_{-\infty}^{c(x,\delta)/b_1} \mathrm{e}^{-\frac{z^2}{2}}(\int_{-\infty}^{(d(y,\delta)-zb'_1)/b'_2}\mathrm{e}^{-\frac{z'^2}{2}}\ \mathrm{d}z')\mathrm{d}z$, where b_1, b'_1, b'_2 are obtained by rotating the coordinates, as in section 6. Let $G(y,\delta,l) = \frac{1}{\sqrt{2\pi}}\int \mathrm{e}^{-\frac{l^2}{2}}H(y,\delta,l)\mathrm{d}l$, where $H(y,\delta,l) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{(d(y,\delta)-lb'_1)/b'_2}\mathrm{e}^{-\frac{z'^2}{2}}\ \mathrm{d}z'$. Then $\frac{\partial h}{\partial\delta}$ can be expressed as $A+B$, where

$$A = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{c(x,\delta)/b_1}\mathrm{e}^{-\frac{l^2}{2}}\frac{\partial H(y,\delta,l)}{\partial\delta}\mathrm{d}l$$

and

$$B = \frac{\partial G}{\partial l}_{l=c(x,\delta)/b_1}\frac{\partial l}{\partial\delta}_{l=c(x,\delta)/b_1}.$$

Therefore, $|\frac{\partial h}{\partial\delta}| = |A+B| \le |A|+|B|$. Next, we bound $|A|$ and $|B|$ separately.

$|B|$ is bounded as follows: Note that $|\frac{\partial G}{\partial l}| = |\frac{1}{\sqrt{2\pi}}\mathrm{e}^{-\frac{l^2}{2}}H(y,\delta,l)| \le 1$ for all l, since $0 \le H(y,\delta,l) \le 1$. Further, $|\frac{\partial l}{\partial\delta}_{l=c(x,\delta)/b_1}| = |v[j]/b_1| = O(n^2)$, by Lemma 6.3. Therefore, $|B| = O(n^2)$.

$|A|$ is bounded as follows: $|A| = |\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{c(x,\delta)/b_1}\mathrm{e}^{-\frac{l^2}{2}}\frac{\partial H(y,\delta,l)}{\partial\delta}\mathrm{d}l| \le \max_{y,\delta,l}|\frac{\partial H(y,\delta,l)}{\partial\delta}|$. It remains to bound $\max_{y,\delta,l}|\frac{\partial H(y,\delta,l)}{\partial\delta}|$. This is done below using the same technique as above. Recall that

$$H(y,\delta,l) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{(d(y,\delta)-lb'_1)/b'_2}\mathrm{e}^{-\frac{z'^2}{2}}\ \mathrm{d}z'.$$

Let $J(m) = \frac{1}{\sqrt{2\pi}}\int \mathrm{e}^{-\frac{m^2}{2}}\ \mathrm{d}m$. Then $|\frac{\partial H}{\partial\delta}| = |\frac{\mathrm{d}J}{\mathrm{d}m}_{m=(d(y,\delta)-lb'_1)/b'_2}||\frac{\partial m}{\partial\delta}_{m=(d(y,\delta)-lb'_1)/b'_2}| \le |w[j]/b'_2| = O(n^4)$, by Lemma 6.3. Therefore, $|f'_{e,k}(\delta)| \le |A|+|B| = O(n^4)$.

Appendix 3. Proof of Lemma 7.4.

Bounding derivatives of integrands in $I()$. Recall that

$$I(b,b',x,y,x',y') = \frac{1}{\sqrt{2\pi}} \int_{\frac{x}{b_1}}^{\frac{y}{b_1}} \mathrm{e}^{\frac{-z^2}{2}} \left(\int_{\frac{(x'-zb_1')}{b_2'}}^{\frac{(y'-zb_1')}{b_2'}} \frac{1}{\sqrt{2\pi}} \mathrm{e}^{\frac{-z'^2}{2}} \mathrm{d}z' \right) \mathrm{d}z.$$

Here b, b' have been rotated so that $b = (b_1, 0, \ldots, 0)$ and $b' = (b_1', b_2', 0, \ldots, 0)$.

The derivative of $\frac{1}{\sqrt{2\pi}} \mathrm{e}^{\frac{-z'^2}{2}}$ with respect to z' is $-\frac{1}{\sqrt{2\pi}} z' \mathrm{e}^{\frac{-z'^2}{2}}$, which is bounded in absolute value by $\frac{1}{\sqrt{2\pi}} \mathrm{e}^{\frac{-1}{2}}$, a constant.

Next, we compute the derivative of the outer integrand. We first denote the inner integral by $h(z)$. Then we compute the derivative of the function to be integrated; that is, $\frac{1}{\sqrt{2\pi}} h(z) \mathrm{e}^{\frac{-z^2}{2}}$ is

$$\frac{1}{\sqrt{2\pi}} \left(-z \mathrm{e}^{\frac{-z^2}{2}} h(z) + \frac{1}{2\pi} \mathrm{e}^{\frac{-z^2}{2}} (-b_1'/b_2') \left(\mathrm{e}^{\frac{-1}{2}\left(\frac{y'-zb_1'}{b_2'}\right)^2} - \mathrm{e}^{-\frac{1}{2}\left(\frac{x'-zb_1'}{b_2'}\right)^2} \right) \right).$$

The first term in this sum is bounded in absolute value by a constant as $h(z) \leq 1$, and the second term is bounded by $O(n^4)$ by Lemma 6.3. Hence the derivative is bounded by $O(n^4)$.

Bounding derivatives of other integrands. We bound the derivatives for the integrands in Case 2.2 of section 5. This is the most complicated case. For other cases, a similar procedure works.

Recall that in this case, the conditional probability $f_{e,k}(\delta)$ can be split into three terms. We show how the derivatives of the integrands involved in the first term can be bounded by polynomial functions of n. The remaining two terms are similar.

The first term is

$$g(\delta) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]}} \int_{x=\alpha}^{\infty} \int_{y=\beta}^{\infty} I(v,w,x,x+\mathrm{d}x,y,y+\mathrm{d}y) \times I^{r-i-1}(v,w,-\infty,x,-\infty,y) \mathrm{e}^{\frac{-z^2}{2}} \mathrm{d}z.$$

To simplify notation, we denote by c the value $\frac{\alpha-\alpha'-v[n-1]\delta}{v[n]}$. As in section 6, let the coordinate system be so rotated that the new coordinates of v are $(b_1, 0, \ldots, 0)$ and the new coordinates of w are $(b_1', b_2', 0, \ldots, 0)$, where $b_1, b_2' \geq 0$. Recall from section 6 that

$$I(v,w,x,x+\mathrm{d}x,y,y+\mathrm{d}y) = \frac{1}{\sqrt{2\pi}} \frac{1}{b_1} \mathrm{e}^{\frac{-x^2}{2b_1{}^2}} \frac{1}{\sqrt{2\pi}} \frac{1}{b_2'} \mathrm{e}^{-\frac{1}{2}\left(\frac{y-\frac{x}{b_1}b_1'}{b_2'}\right)^2} \mathrm{d}y\mathrm{d}x.$$

Therefore,

$$g(\delta) = \int_{z=-\infty}^{c} \int_{x=\alpha}^{\infty} \int_{y=\beta}^{\infty} I^{r-i-1}(v,w,-\infty,x,-\infty,y) \frac{1}{(2\pi)b_1 b_2'} \mathrm{e}^{\frac{-x^2}{2b_1{}^2}} \mathrm{e}^{-\frac{1}{2}\left(\frac{y-\frac{x}{b_1}b_1'}{b_2'}\right)^2} \times \frac{1}{\sqrt{2\pi}} \mathrm{e}^{-z^2/2} \mathrm{d}y\mathrm{d}x\mathrm{d}z.$$

We first consider innermost integral, that is, with respect to y. The term to be integrated is

$$I^{r-i-1}(v,w,-\infty,x,-\infty,y) \frac{1}{\sqrt{2\pi}b_2'} \mathrm{e}^{-\frac{1}{2}\left(\frac{y-\frac{x}{b_1}b_1'}{b_2'}\right)^2}.$$

The other terms are independent of y. Its derivative with respect to y is

$$\frac{1}{\sqrt{2\pi}b_2'}(r-i-1)I^{r-i-2}(v,w,-\infty,x,-\infty,y)\frac{\partial I(v,w,-\infty,x,-\infty,y)}{\partial y}\mathrm{e}^{-\frac{1}{2}\left(\frac{y-\frac{x}{b_1}b_1'}{b_2'}\right)^2}$$
$$-\frac{1}{\sqrt{2\pi}b_2'}I^{r-i-1}(v,w,-\infty,x,-\infty,y)\left(\frac{y-\frac{x}{b_1}b_1'}{{b_2'}^2}\right)\mathrm{e}^{-\frac{1}{2}\left(\frac{y-\frac{x}{b_1}b_1'}{b_2'}\right)^2}.$$

Now

$$\frac{\partial I(v,w,-\infty,x,-\infty,y)}{\partial y}=\frac{1}{2\pi b_2'}\int_{-\infty}^{\frac{x}{b_1}}\mathrm{e}^{-\frac{1}{2}z^2}\mathrm{e}^{-\frac{1}{2}\left(\frac{y-b_1'z}{b_2'}\right)^2}\mathrm{d}z=O\left(\frac{1}{b_2'}\right).$$

Observe that as the functions I, $x\mathrm{e}^{-x^2/2}$ are all bounded by constants, the value of the above derivative is bounded in absolute value by $O\left(\frac{(r-i-1)}{(b_2')^2}+\frac{1}{(b_2')^2}\right)$. Since $r-i-1\le n$, $b_1=\Omega(\frac{1}{n^2})$, b_2' is $\Omega(\frac{1}{n^4})$ by Lemma 6.3, the above derivative is bounded by $O(n^9)$.

The second innermost integral, i.e., the one with respect to x, is considered next. The function inside the integral is $h(x)\frac{1}{\sqrt{(2\pi)}b_1}\mathrm{e}^{\frac{-x^2}{2b_1^2}}$, where

$$h(x)=\int_{y=\beta}^{\infty}I^{r-i-1}(v,w,-\infty,x,-\infty,y)\frac{1}{\sqrt{2\pi}b_2'}\mathrm{e}^{-\frac{1}{2}\left(\frac{y-\frac{x}{b_1}b_1'}{b_2'}\right)^2}\mathrm{d}y.$$

Since $0\le I()\le 1$, $h(x)=O(1)$. The derivative with respect to x is

$$-\frac{x}{\sqrt{2\pi}b_1^3}\mathrm{e}^{-\frac{x^2}{2b_1^2}}h(x)$$
$$+\frac{1}{\sqrt{2\pi}b_1}\mathrm{e}^{-\frac{x^2}{2b_1^2}}\int_{\beta}^{\infty}(r-i-1)I^{r-i-2}(v,w,-\infty,x,-\infty,y)\frac{\partial I(v,w,-\infty,x,-\infty,y)}{\partial x}$$
$$\times\frac{1}{\sqrt{2\pi}b_2'}\mathrm{e}^{-\frac{1}{2}\left(\frac{y-\frac{x}{b_1}b_1'}{b_2'}\right)^2}\mathrm{d}y$$
$$+\frac{1}{\sqrt{2\pi}b_1}\mathrm{e}^{-\frac{x^2}{2b_1^2}}\int_{\beta}^{\infty}I^{r-i-1}(v,w,-\infty,x,-\infty,y)\frac{1}{\sqrt{2\pi}b_2'}\frac{b_1'(y-\frac{xb_1'}{b_1})}{(b_2')^2b_1}\mathrm{e}^{-\frac{1}{2}\left(\frac{y-\frac{x}{b_1}b_1'}{b_2'}\right)^2}\mathrm{d}y.$$

Here,

$$\frac{\partial I(v,w,-\infty,x,-\infty,y)}{\partial x}=\frac{1}{2\pi b_1}\mathrm{e}^{-\frac{x^2}{2b_1^2}}\int_{-\infty}^{\frac{y-xb_1'/b_1}{b_2'}}\mathrm{e}^{-\frac{1}{2}(z')^2}\mathrm{d}z'=O\left(\frac{1}{b_1}\right).$$

Since $x\mathrm{e}^{-\frac{x^2}{2}}, h(x), I()$ are all $O(1)$, $r-i-1\le n$, and

$$\int_{\beta}^{\infty}\frac{1}{b_2'}\mathrm{e}^{-\frac{1}{2}\left(\frac{y-\frac{x}{b_1}b_1'}{b_2'}\right)^2}\mathrm{d}y=O(1),\int_{\beta}^{\infty}\frac{b_1'(y-\frac{x}{b_1}b_1')}{b_1(b_2')^3}\mathrm{e}^{-\frac{1}{2}\left(\frac{y-\frac{x}{b_1}b_1'}{b_2'}\right)^2}\mathrm{d}y=O\left(\frac{b_1'}{b_1b_2'}\right)$$
$$=O\left(\frac{1}{b_1{b_2'}^2}\right),$$

the above derivative is bounded by $O(\frac{n}{{b_1}^2} + \frac{1}{{b'_2}^2 b_1^2}) = O(n^{12})$, by Lemma 6.3.

This leaves only the outermost integration, where the integrand is

$$\frac{1}{\sqrt{2\pi}} \mathrm{e}^{-\frac{1}{2}z^2} \int_{x=\alpha}^{\infty} h(x) \frac{1}{\sqrt{2\pi} b_1} \mathrm{e}^{-\frac{x^2}{2b_1^2}} \, \mathrm{d}x,$$

whose derivative with respect to z is $O(1)$.

Acknowledgments. We thank Naveen Garg, Kurt Mehlhorn, David Williamson, Michel Goemans, and Madhu Sudan for comments. We thank Aravind Srinivasan for reading a draft of the manuscript and for his detailed comments. We thank the anonymous referees for many comments which have improved the readability of this paper and also for pointing us to the tighter tail bounds for the normal distribution, which improves the running time of some parts of the algorithm.

THE DYNAMIC PARALLEL COMPLEXITY OF COMPUTATIONAL CIRCUITS*

GARY L. MILLER† AND SHANG-HUA TENG‡

Abstract. We establish connections between parallel circuit evaluation and uniform algebraic closure properties of unary function classes. We use this connection in the development of time-efficient and processor-efficient parallel algorithms for the evaluation of algebraic circuits. Our algorithm provides a nontrivial upper bound on the parallel complexity of the circuit value problem over $\{\mathbb{R}, \min, \max, +\}$ and $\{\mathbb{R}^+, \min, \max, \times\}$. We partially answer an open question of Miller, Ramachandran, and Kaltofen by showing that circuits over a polynomial-bounded noncommutative semiring and circuits over infinite noncommutative semirings with a polynomial-bounded dimension over a commutative semiring can be evaluated in polylogarithmic time in their size and degree using a polynomial number of processors. We also present an improved parallel algorithm for Boolean circuits.

Key words. algebraic computations, Boolean circuits, complexity, NC problems, parallel algorithms, the circuit value problem

1. Introduction.

The *circuit value problem* has been recognized as an important problem in parallel computation [3, 5, 7, 18]. In 1975, Ladner [5] showed that the problem of the evaluation of Boolean circuits is P-complete. Goldschlager [3] extended Ladner's result to monotone Boolean circuits and planar Boolean circuits.

In spite of the P-completeness result, NC algorithms have been developed for several restricted classes of circuits that arise in parsing, Huffman code generation, compiler optimization, and numeric and algebraic computation [7, 8, 9, 10, 16, 18]. In 1983, Valiant et al. [18] showed that if a circuit over $\{+, -, \times\}$ can be evaluated in C time sequentially, then with preprocessing it can be evaluated in parallel $O(\log d \log Cdn)$ time using $C^{O(1)}$ processors. Miller, Ramachandran, and Kaltofen [7] improved and simplified this result by showing that any circuit with size n and degree d (see section 2.2 for the definition) over a commutative semiring can be evaluated without preprocessing in $O(\log n \log nd)$ time using $M(n)$ processors, where $M(n)$ is the number of processors needed for multiplying $n \times n$ matrices over the semiring in $O(\log n)$ time. Ramachandran and Yang [12] showed that the general planar monotonic circuit value problem can be evaluated in parallel polylogarithmic time with a linear number of processors. Miller, Reif, and Teng [6, 9, 10] showed that trees over

$\{+, -, \times, \div\}$ and $\{\min, \max, +, -, \times, \div\}$ can be evaluated in parallel $O(\log n)$ time using n processors.

However, there is no similar result for noncommutative semirings [7], and we know of no previous result on the parallel evaluation of circuits with three or more operators—for example, circuits over $\{\mathbb{R}, \min, \max, +\}$ and $\{\mathbb{R}^+, \min, \max, \times\}$. In fact, Kosaraju [4] and Nisan [11] showed that in general it is impossible to perform circuit evaluation in polylogarithmic time for noncommutative circuits.

In this paper, we propose a systematic method that facilitates the design of processor-efficient parallel algorithms for the circuit value problem. Our method utilizes the *uniform closure properties* of certain unary function classes.

Using this method, we give the first nontrivial upper bound on the parallel complexity for evaluating circuits over $\{\mathbb{R}, \min, \max, +\}$ and $\{\mathbb{R}^+, \min, \max, \times\}$. In particular, we show that a circuit over $\{\mathbb{R}, \min, \max, +\}$ or $\{\mathbb{R}^+, \min, \max, \times\}$ of n nodes and degree d can be evaluated in $O(\log n \log dn)$ time, using $nM(n)$ processors, where the degree of a min–max-plus circuit $\mathcal{C}$ is defined as the *formal arithmetic degree* (see section 2.2) of the arithmetic circuit obtained from $\mathcal{C}$ by mapping min to $+$ and max and $+$ to $\times$. We also extend the previously known results of circuits over commutative semirings to several noncommutative semirings. For instance, if a noncommutative semiring is *polynomially bounded* (see section 7) or has a *polynomially bounded dimension* over a commutative semiring (also see section 7), then circuits over it can be evaluated in polylogarithmic time in its size and degree by using a polynomial number of processors. Our results partially answer an open question of Miller, Ramachandran, and Kaltofen [7].

We also consider *structured parallel computation.* We use the circuit value problem over *matrix rings* as an example. Let $\mathcal{CR} = \{\mathcal{D}_1, +, \times\}$ be a commutative semiring, and let $\mathcal{MR} = \{D, +, \times\}$ be a *matrix ring* of *dimension* m over $\mathcal{CR}$, where

$$\mathcal{D} = \{A^{m\times m} \mid A^{m\times m} \in \mathcal{D}_1, 1 \le i, j \le m\}.$$

$\mathcal{MR}$ is an infinite noncommutative semiring whenever $\mathcal{CR}$ is infinite. The best known result to this problem, achieved by Miller, Ramachandran, and Kaltofen [7], is that circuit $\mathcal{C}$ of size n and degree d can be evaluated in $O(\log \max(n, m) \log dn)$ time using $M(m^3 n)$ processors. They obtained this result by expanding the matrix operation to the underlying commutative ring operations and then applying the parallel circuit evaluation algorithm in [7]. We call a method of this kind *nonstructured* because it replaces the structured matrix operations with the lower-level operations. We present a *structured algorithm* based on our parallel method; our method does not replace matrix operations by lower-level underlying commutative ring operations. It reduces the processor count to $M(m^2 n)$ without increasing the time complexity, $O(\log \max(n, m) \log dn)$. Our structured algorithm can also be used to reduce the processor count for context-free language circuits when the size of the grammar is not a constant.

Using the *duality* property of Boolean algebra, we give an improved parallel algorithm for Boolean circuits. It evaluates a Boolean circuit in $O(\log n \log(\min(d_{\wedge\vee}, d_{\vee\wedge})))$ time, using $M(n)$ processors. We also show that there are Boolean circuits with exponential $d_{\wedge\vee}$ and $d_{\vee\wedge}$ that can be evaluated by our algorithm in polylogarithmic time, using $M(n)$ processors, where $d_{\wedge\vee}$ ($d_{\vee\wedge}$) is the degree of the Boolean circuit when $\vee$ ($\wedge$) is viewed as addition in the semiring formed by the Boolean algebra.

The parallel algorithms are designed on *parallel random access machines* (*PRAMs*), which are shared memory computers where many processors work together synchronously. The communication among processors is done through the information

exchange in a common random-access memory. Models in this family can be further partitioned according to the conventions for solving read and write conflict. The algorithms are developed on the CRCW model in which concurrent reads and concurrent writes to a cell in the common memory are allowed.

An extended abstract of this work appeared in [8]. In our preparation of this journal version, we have obtained several new results and also improved some of the original results.

2. Preliminaries. A *computation circuit* is a triple $(\mathcal{A}, \mathcal{F}, \mathcal{C}\}$ where the following hold:

1. $\mathcal{A} = \{\mathcal{D}, \odot_1, \ldots, \odot_k\}$ is an algebraic system whose *domain* is $\mathcal{D}$ and whose operator set is $\mathcal{OP} = \{\odot_1, \ldots, \odot_k\}$.
2. $\mathcal{F}$ is a set of unary functions over $\mathcal{D}$. We assume that $\mathcal{F}$ includes the identity function.
3. $\mathcal{C}$ is a labeled directed acyclic simple graph whose leaf nodes, the nodes with zero indegree, are labeled with values from $\mathcal{D}$, whose internal nodes are labeled with operators from $\mathcal{OP}$, and whose edges are labeled with unary functions from $\mathcal{F}$.

If there is an edge from u to v in $\mathcal{C}$, we call u a *child* of v and v a *parent* of u.

The *value* of a node v in $\mathcal{C}$, denoted by $value(v)$, is defined inductively.

- If v is a leaf, then $value(v)$ is equal to its label.
- If v is an internal node, labeled by $\odot$ and with children $w_1, \ldots, w_l$, then

$$value(v) = \odot(f_1(value(w_1)), \ldots, f_l(value(w_l))),$$

where $f_1, \ldots, f_k$ are the unary functions of edges $(w_1, v), \ldots, (w_k, v)$, respectively.

DEFINITION 2.1 (circuit value problem). *Given a computation circuit* $\{\mathcal{A}, \mathcal{F}, \mathcal{C}\}$, *compute the values of all its internal nodes.*

We consider $\mathcal{A}$ and $\mathcal{F}$ fixed and analyze the parallel complexity of the circuit value problem for a given circuit $\mathcal{C}$. To apply our parallel circuit evaluation algorithm, we require that the set of unary functions $\mathcal{F}$ satisfies certain closure properties. We will discuss these requirement in section 3.

2.1. Semirings. An algebraic system $\{\mathcal{D}, \oplus, \otimes\}$ is a *semiring* if $\oplus$ is associative and commutative, and $\otimes$ is associative and distributive over $\oplus$. If $\otimes$ is also commutative, then semiring $\{\mathcal{D}, \oplus, \otimes\}$ is a *commutative semiring*; otherwise, it is a *noncommutative semiring*. A semiring $\{\mathcal{D}, \oplus, \otimes\}$ is *finite* if $\mathcal{D}$ is finite.

For example, $\{R, +, \times\}$ is an infinite and commutative semiring.

Let $\mathcal{CR} = \{\mathcal{D}, \oplus, \otimes\}$ be a commutative semiring. A *matrix semiring* over $\mathcal{CR}$ of *dimension* k is the semiring $\mathcal{MR} = \{\mathcal{MD}, \oplus, \otimes\}$, where

$$\mathcal{MD} = \{A^{k \times k} \mid A_{ij} \in \mathcal{D}, 1 \leq i, j \leq k\}.$$

Clearly, $\mathcal{MR}$ is a noncommutative semiring with infinite domain whenever $\mathcal{CR}$ is infinite.

For example, the set of all k by k real matrices together with $+$ and $\times$ form an infinite matrix semiring of dimension k.

2.2. CE-algebras and CE-circuits. The algebraic systems considered in this paper is restricted to a family of algebraic systems called *CE-algebra*s. An algebraic system $\mathcal{A} = \{\mathcal{D}, \mathcal{OP}\}$ is a CE-algebra if there is one operator $\oplus \in \mathcal{OP}$ that is *associa-*

tive and commutative, and all other operators in $\mathcal{OP}-\{\oplus\}$ are *distributed* over $\oplus$. The operator $\oplus$ is called the *cheap operator* and rest of the operators are called *expensive operator*s. In the remainder of this paper, the operator set $\mathcal{OP}$ of a CE-algebra with $k+1$ operators is written as $\mathcal{OP} = \{\oplus, \otimes_1, \ldots, \otimes_k\}$.

For example, $\{R, +, \times\}$ is a CE-algebra, where $+$ is cheap and $\times$ is expensive. In general, every semiring $\{\mathcal{D}, \oplus, \otimes\}$ is a CE-algebra in which $\oplus$ is cheap and $\otimes$ is expensive. $\{\mathbb{R}, \min, \max, +\}$, $\{\mathbb{R}^+, \min, \max, +, \times\}$, and $\{\mathbb{R}^+, \min, \max, \times\}$ are other examples of CE-algebras, where we regard either min or max but not both as the cheap operator. A circuit over a CE-algebra is called a *CE-circuit*. We call a node of a CE-circuit an *expensive node* if it is labeled with an expensive operator. Similarly, we call a node with a cheap operator a *cheap node*. In most of our discussions, we will make the following two technical restrictions in order to simplify our presentation.

ASSUMPTION 2.2.

1. *The indegree of each expensive node is two.*
2. *There is no edge from an expensive node to another expensive node.*

In section 5, we will not impose those restrictions when we consider Boolean circuits.

The *degree* of a CE-circuit $\mathcal{C}$ is defined as the *formal arithmetic degree* of the arithmetic circuit obtained from $\mathcal{C}$ by relabeling each cheap node by $+$ and each expensive node by $\times$. In other words, we can define the degrees of nodes in a CE-circuit inductively.

- If v is a leaf, then $degree(v) = 1$.
- If v is an expensive internal node with children $w_1, \ldots, w_l$, then

$$degree(v) = \sum_{j=1}^{l} degree(w_j).$$

- If v is a cheap internal node with children $w_1, \ldots, w_l$, then

$$degree(v) = \max_{j=1}^{l} degree(w_j).$$

3. The general paradigm. In this section, we first review the parallel arithmetic circuit-evaluation algorithm of Miller, Ramachandran, and Kaltofen [7]. We then show how to extend their algorithm to CE-circuits. Our extension is based on certain closure properties of the unary functions.

3.1. Arithmetic circuits. We will refer to circuits over $\{\mathbb{R}, +, \times\}$ as arithmetic circuits. Following [7], we will consider only the following set of unary functions $\mathcal{F} = \{f(x) = ax | a \in \mathbb{R}\}$. We can express an arithmetic circuit $\mathcal{C}$ of n nodes with unary function set $\mathcal{F}$ by a matrix U when entries are given as

$$Z_{ij} = \begin{cases} z_{ij} & \text{if } (i,j) \text{ is an edge in } \mathcal{C} \text{ with unary function } f_{ij}(x) = z_{ij}x, \\ 0 & \text{if there no edge from } i \text{ to } j. \end{cases}$$

The Miller–Ramachandran–Kaltofen algorithm consists of repeated applications of three elementary procedures on the circuit and its matrix. At a high level, these procedures transform an arithmetic circuit to a circuit of smaller degree or depth on the same node set so that the value of each node is preserved in the new circuit.

The first procedure is `rake`. It simply evaluates each node in the circuit whose children are leaves and removes all incoming edges to make it a leaf.

FIG. 1. *Rake.*

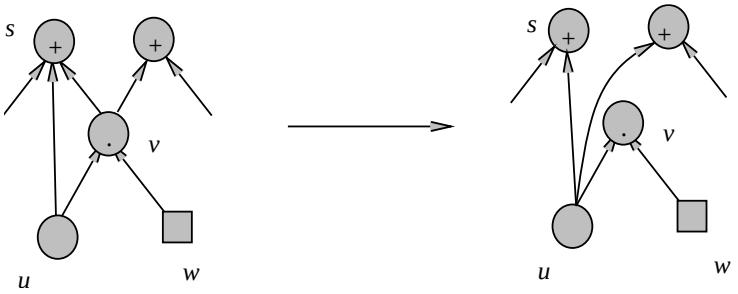

FIG. 2. *Shunt.*

PROCEDURE `rake`$(\mathcal{C}, Z)$ (Figure 1). For each node v whose children $w_1, \ldots, w_k$ are leaves,

1. if v is an addition node, then

$$value(v) = \sum_{j=1}^{k} Z_{w_j,v} value(w_j);$$

if v is a multiplication node (and hence $k = 2$), then

$$value(v) = (Z_{w_1,v} value(w_1))(Z_{w_2,v} value(w_2));$$

2. for each j in the range $1 \le j \le k$, remove the edge between v and w_i and let $Z_{w_j,v} = 0$.

The next procedure is `shunt`, which handles the case when a multiplication node v has one leaf child w and one nonleaf child u. It merges the contribution of w (namely, $Z_{vw} value(w)$) to a parent s of v into the edge from u to s. Thus u will bypass v in its connection to s. Note that v may have many parents.

PROCEDURE `shunt`$(\mathcal{C}, Z)$ (Figure 2). For each multiplication node v with children u and w in which one of u or w is a leaf (say, w),

1. let $h_{uv} = Z_{uv}(Z_{wv} value(w))$;
2. for each s such that v is a child of s (s has to be a cheap node by Assumption 2.2),
   - let $Z_{us} = Z_{us} + Z_{vs} h_{uv}$,
   - remove the edge (v, s) and let $Z_{vs} = 0$.

Finally, `compress` is used to transform long paths of addition nodes into paths of about half their lengths.

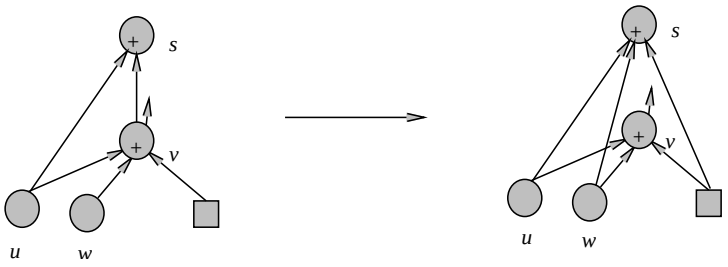

FIG. 3. *Compress.*

PROCEDURE `compress`$(\mathcal{C}, Z)$ (Figure 3). For each edge (v, s) in $\mathcal{C}$ such that both v and s are addition nodes,

1. for each child u of v, $Z_{us} = Z_{us} + Z_{vs}Z_{uv}$;
2. remove (v, s) and let $Z_{vs} = 0$.

Miller, Ramachandran, and Kaltofen [7] observed that one can use the following matrix expression for the `compress`:

$$Z = Z_{X,C}Z_{C,C} + U_{X,X},$$

where

$$Z(C,C)_{uv} = \begin{cases} Z_{uv} & \text{if both } u \text{ and } v \text{ are addition nodes,} \\ 0 & \text{otherwise;} \end{cases}$$

$$Z(X,C)_{uv} = \begin{cases} Z_{uv} & \text{if } v \text{ is an addition node,} \\ 0 & \text{otherwise;} \end{cases}$$

$$Z(X,X)_{uv} = \begin{cases} Z_{uv} & \text{if either } u \text{ or } u \text{ is a multiplication node,} \\ 0 & \text{otherwise.} \end{cases}$$

We now summarize their main result [7].

THEOREM 3.1 (Miller–Ramachandran–Kaltofen [7]). *An arithmetic circuit of n nodes and degree d can be evaluated in $O(\log n \log dn)$ time, using $M(n)$ processors.*

3.2. CE-circuits. In this subsection, we will extend the Miller–Ramachandran–Kaltofen algorithm from arithmetic circuits to CE-circuits. The high-level idea is the same as for arithmetic circuits. We will simplify a CE-circuit by repeated applications of three elementary procedures: `rake`, `shunt`, and `compress`. These procedures transform an arithmetic circuit to a circuit of smaller degree or depth on the same node set so that the value of each node is preserved in the new circuit.

We now define these three elementary procedures for CE-circuits. We consider a CE-algebra $\{\mathcal{D}, \oplus, \otimes_1, \ldots, \otimes_k\}$. Like an arithmetic circuit, a CE-circuit can be represented by a matrix Z whose entries are the unary functions used in the circuit. The entry Z_{uv} is defined as

$$Z_{uv} = \begin{cases} f_{uv} & \text{if } (u, v) \text{ is an edge with label } f_{uv}, \\ 0 & \text{otherwise,} \end{cases}$$

where 0 is the *zero function*.

The `rake` is the same as in arithmetic circuit. It evaluates each node in the circuit whose children are leaves and removes all incoming edges to make it a leaf.

PROCEDURE `rake`$(\mathcal{C}, Z)$. For each node v whose children $w_1, \ldots, w_k$ are leaves, let $\odot$ be the operator of v. Then

1. $$value(v) = \odot(Z_{w_1,v}(value(w_1)), \ldots, Z_{w_k,v}(value(w_k)));$$
2. for each j in the range $1 \leq j \leq k$, remove the edge between v and w_i and let $Z_{w_j,v} = 0$.

The procedure `shunt` handles the case when an expensive node v has one leaf child w and one nonleaf child u.

PROCEDURE `shunt`$(\mathcal{C}, Z)$. For each expensive node v with children u and w in which one of u or w is a leaf, let $t \in \{u, w\}$ denote the nonleaf child and $\otimes$ be the label of v. Then

1. if u is a leaf, let $h_{tv}(x) = Z_{uv}(value(u)) \otimes Z_{wv}(x)$, and if w is a leaf, let $h_{tv}(x) = Z_{uv}(x) \otimes Z_{uv}(value(w))$;
2. for each s such that v is a child of s (s must be an addition node by Assumption 2.2),
   - let $Z_{ts}(x) = Z_{ts}(x) \oplus Z_{vs}(h_{tv}(x))$,
   - remove the edge (v, s) and let $Z_{vs} = 0$.

Finally, `compress` is used to transform long paths of cheap nodes into paths of about half their lengths.

PROCEDURE `compress`$(\mathcal{C}, Z)$. For each edge (v, s) in $\mathcal{C}$ such that both v and s are cheap nodes,

1. for each child u of v, $Z_{us}(x) = Z_{us}(x) \oplus Z_{vs}(Z_{uv}(x))$;
2. remove (v, s) and let $Z_{vs} = 0$.

We can also describe `compress` with the following matrix expression:

$$Z = Z_{X,C} \circ Z_{C,C} \oplus U_{X,X},$$

where

$$Z(C,C)_{uv} = \begin{cases} Z_{uv} & \text{if both } u \text{ and } v \text{ are cheap nodes,} \\ 0 & \text{otherwise;} \end{cases}$$

$$Z(X,C)_{uv} = \begin{cases} Z_{uv} & \text{if } v \text{ is a cheap node,} \\ 0 & \text{otherwise;} \end{cases}$$

$$Z(X,X)_{uv} = \begin{cases} Z_{uv} & \text{if either } u \text{ or } u \text{ is an expensive node,} \\ 0 & \text{otherwise;} \end{cases}$$

and $\circ$ is the composition operator, i.e., for each pair of f and g in $\mathcal{F}$, $f \circ g(x) = f(g(x))$.

Lemma 3.2 follows directly from the definition of these three procedures.

LEMMA 3.2. *The application of* `rake`, `shunt`, *and* `compress` *preserves the values of all nodes in the circuit.*

Note that if the input circuit is an arithmetic circuit, then the above parallel circuit evaluation algorithm is equivalent to the parallel arithmetic circuit evaluation algorithm of Miller, Ramachandran, and Kaltofen [7]. Therefore, $O(\log n \log dn)$ applications `rake`, `shunt`, and `compress` will evaluate an arithmetic circuit of n nodes and degree d [7].

Our circuit evaluation algorithm can now be specified as follows.

ALGORITHM CIRCUIT-REDUCTION$(\mathcal{C}, Z)$

1. `rake`$(\mathcal{C}, Z)$.
2. `shunt`$(\mathcal{C}, Z)$.
3. `compress`$(\mathcal{C}, Z)$.

3.3. Unary functions and their closure properties. The basic idea of the Miller–Ramachandran–Kaltofen algorithm is to use `rake`, `shunt`, and `compress` to partially evaluate some subcircuits and reduce them to equivalent unary functions. It then represents these functions as weights on the edges of the circuit. The correctness of the algorithm relies on the fact that the unary function class $\{f(x) = ax | a \in \mathbb{R}\}$ is closed under composition; i.e., if $f(x) = ax$ and $g(x) = bx$, then $f \circ g(x) = (ab)x$, which is still a function in $\mathcal{F}$. Moreover, it takes a constant time to compute the composition.

The basic idea of our algorithm is the same: `shunt` computes a unary function $Z_{ts}(x) = Z_{ts}(x) \oplus Z_{vs}(h_{tv}(x))$ and writes it on edge (t, s); `compress` computes and writes a unary function $Z_{us}(x) = Z_{us}(x) \oplus Z_{vs}(Z_{uv}(x))$ on edge (u, s).

The idea behind our algorithm is to reduce the circuit value on CE-circuits to a circuit value problem over the semiring $\{\mathcal{F}, \oplus, \circ\}$. Hence we can apply the analysis from [7].

The correctness of our algorithm is based on the following closure properties:

- *Composition:* A unary function class $\mathcal{F}$ is *closed under composition* if for all $f_1, f_2 \in \mathcal{F}$, $f_2 \circ f_1 \in \mathcal{F}$.
- *Combination:* A unary function class $\mathcal{F}$ is *closed under combination* over a binary, associative, and commutative operator $\oplus$ if for all $f, g \in \mathcal{F}$, $f(x) \oplus g(x) \in \mathcal{F}$, where $\oplus$ of two unary functions $f(x)$ and $g(x)$ is $F(x) = f(x) \oplus g(x)$.
- *Projection:* A unary function class $\mathcal{F}$ is *closed under projection* over a set of binary operators $\mathcal{OP}$ if for all $f \in \mathcal{F}$, $\odot \in \mathcal{OP}$, and $a \in \mathcal{D}$, $x \odot a \in \mathcal{F}$ and $a \odot x \in \mathcal{F}$, where x is a variable with domain $\mathcal{D}$.
- *Linear:* A unary function class $\mathcal{F}$ is *linear over* an operator $\oplus$ if for all $f \in \mathcal{F}$, $x, y \in \mathcal{D}$, $f(x \oplus y) = f(x) \oplus f(y)$.

Clearly, if $\oplus$ is the cheap operator in a CE-algebra and $\mathcal{F}$ is a set of unary functions which is linear over $\oplus$, then the *closure* of $\mathcal{F}$ under composition, combination over $\oplus$, and projection over the expensive operations is still linear over $\oplus$.

DEFINITION 3.3. *A class of unary functions $\mathcal{F}$ is closed over $\mathcal{OP} = \{\oplus, \otimes_1, \ldots, \otimes_k\}$ if $\mathcal{F}$ is closed under composition, combination over $\oplus$, linear over $\oplus$, and projection over $\{\otimes_1, \ldots, \otimes_k\}$.*

LEMMA 3.4. *If $\mathcal{F}$ is linear over $\oplus$ and closed under combination over $\oplus$, then $\{\mathcal{F}, \oplus, \circ\}$ forms a semiring.*

Proof. Let f, g, h be functions in $\mathcal{F}$. Because $\oplus$ is communicative, $f(x) \oplus g(x) = g(x) \oplus f(x)$. By the linearity of $\mathcal{F}$, we have $f(g(x) \oplus h(x)) = f(g(x)) + f(h(x))$ and hence $\circ$ is distributive over $\oplus$. ∎

To efficiently support our algorithm, we need to show that composition and projection over $\{\mathcal{F}, \oplus, \circ\}$ can be computed efficiently. Moreover, we need to represent these functions economically. In arithmetic circuit evaluation, each unary function in $\{f(x) = ax | a \in \mathbb{R}\}$ can be expressed by a single real number and can be evaluated in a constant time. However, for the CE-circuits that we will consider, the complexity of the unary functions may grow after each application of `rake`, `shunt`, and `compress`. Therefore, we need to show that they do not grow too fast.

The class of unary functions that we use can be defined by a restricted class of CE-circuits.

DEFINITION 3.5. *A* restricted CE-circuit *in one free variable x is a CE-circuit C in which*

1. *there exists a unique leaf node whose value is the variable x, and*
2. *every expensive node has at most two children, one of which is a leaf.*

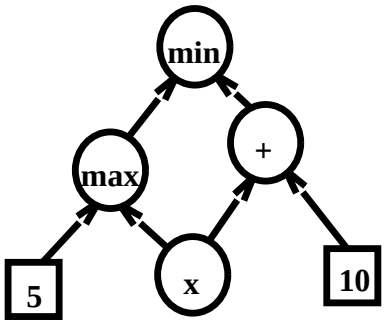

FIG. 4. *A restricted circuit that defines* $f(x) = \min(\max(5, x), (10 + x))$.

A restricted CE-circuit C defines a unary function f at each of its nodes v in variable x. If C has a distinguished output node whose function is $f(x)$, then f is called the function of C, and we denote it by f_C.

A unary function f is a *restricted CE-function* over an operator $\mathcal{OP}$ and a unary function class $\mathcal{F}$, if there is a restricted CE-circuit over $\mathcal{OP}$ and $\mathcal{F}$ that defines f (see Figure 4).

Let $\mathcal{RCE}_{(\mathcal{OP},\mathcal{F})}$ denote all restricted CE-functions over $\mathcal{OP}$ and $\mathcal{F}$. For simplicity, let $\mathcal{RCE}_{\mathcal{OP}}$ denote all restricted CE-functions over $\mathcal{OP}$ and $\{identity\ function\}$. By definition, we have the following proposition.

PROPOSITION 3.6. *$\mathcal{RCE}_{\mathcal{OP}}$ is closed over $\mathcal{OP}$.*

The *size* of a restricted CE-circuit is the number of nodes and edges in the circuit. The *circuit size* of a restricted CE-function f is defined to be the minimum size of the restricted CE-circuit that defines f.

DEFINITION 3.7 (uniform closure properties). *$\mathcal{F}$ is (T, P)-uniform closed over $\mathcal{OP}$ if $\mathcal{F}$ is closed over $\mathcal{OP}$, and for all $f \in \mathcal{F}$ of circuit size n, f can be evaluated in $O(T(n))$ time, using $P(n)$ processors. The composition and combination of two functions f and $g \in \mathcal{F}$ of circuit size no more than n can be computed in $O(T(n))$ time, using $P(n)$ processors, where $T(n)$ and $P(n)$ are two integer functions.*

LEMMA 3.8. *Let $\mathcal{C}$ be a CE-circuit of n nodes and degree d. Then $O(\log n \log dn)$ applications of circuit-reduction will evaluate $\mathcal{C}$.*

Proof. If we replace each cheap operator with $+$ and all expensive operators with $\times$, we obtain an arithmetic circuit $\mathcal{A}(\mathcal{C})$ which also has n nodes and degree d. If $\mathcal{C}_1$ is the circuit obtained by applying circuit-reduction to $\mathcal{C}$ and A_1 is the circuit obtained by applying the circuit-reduction to $\mathcal{A}(\mathcal{C})$, then $\mathcal{A}_1 = \mathcal{A}(\mathcal{C}_1)$. Hence, this lemma follows directly from Theorem 3.1. □

Therefore, we have the following theorem.

THEOREM 3.9 (circuit theorem). *Let $\mathcal{C}$ be a CE-circuit of size n and degree d over operator set $\mathcal{OP}$. If there exists a unary function class $\mathcal{F}$ which is (T, P)-uniformly closed over $\mathcal{OP}$, then $\mathcal{C}$ can be evaluated in $O(T(n) \log n \log nd)$ time, using $P(n)M(n)$ processors.*

Proof. Because $\mathcal{F}$ is (T, P)-uniformly closed over $\mathcal{OP}$, `rake` can be performed in $O(T(n))$ time, using $P(n)n$ processors, and `shunt` can be performed in $O(T(n))$ time, using $P(n)n^2$ processors. In addition, because $\{\mathcal{F}, \oplus, \circ\}$ is a semiring, `compress` can be performed in $O(T(n) \log n)$ time, using $P(n)M(n)$ processors. Therefore, the theorem follows from Lemma 3.8. □

4. A lemma on closure properties. As we have shown in the previous section, the correctness of our algorithm relies on the closure properties of the unary function classes, while the efficiency of our algorithm depends on the *uniformity* of the unary function classes. Thus, it is important to develop a general theory and a systemic method to study the closure properties and to prove the uniformity of the classes. The following is a simple yet important lemma for proving the closure properties of certain unary function classes.

LEMMA 4.1 (closure property lemma). *If $\mathcal{F} = \{L(x)\}$ is a class of monotonically increasing unary functions over a domain $\mathcal{D} \subseteq \mathbb{R}$ and is closed under composition and projection over $\mathcal{OP}_1$, then*

$$\mathcal{F}_{\min} = \{\min(L_1(x), \ldots, L_i(x)) \mid i \in \mathcal{N}, L_j(x) \in \mathcal{F}_1\}$$

is closed over $\{\min, \mathcal{OP}_1\}$, and

$$\mathcal{F}_{\max} = \{\max(L_1(x), \ldots, L_i(x)) \mid i \in \mathcal{N}, L_j(x) \in \mathcal{F}_1\}$$

is closed over $\{\max, \mathcal{OP}_1\}$.

Proof. $\mathcal{F}_{\min}$ is closed under composition because for all $f(x) = \min(L_1(x), \ldots, L_i(x)) \in \mathcal{F}_{\min}$ and $g(x) = \min(L'_1(x), \ldots, L'_j(x)) \in \mathcal{F}$, since all functions in $\mathcal{F}_1$ are monotonically increasing, and $\mathcal{F}_i$ is closed under composition,

$$\begin{aligned} g \circ f(x) &= \min(L'_1(f(x)), \ldots, L'_j(f(x))) \\ &= \min(L'_1(L_1(x)), \ldots, L'_1(L_i(x)), \ldots, L'_j(L_i(x))) \in \mathcal{F}_{\min}. \end{aligned}$$

$\mathcal{F}_{\min}$ is closed under combination over $\{\min\}$ because

$$\min(f, g) \;=\; \min(L_1(x), \ldots, L_i(x), L'_1(x), \ldots, L'_j(x)) \in \mathcal{F}_{\min}.$$

$\mathcal{F}_{\min}$ is linear over $\{\min\}$ because all functions in $\mathcal{F}_1$ are monotonically increasing.

$\mathcal{F}_{\min}$ is closed under projection over $\mathcal{OP}_1$ because $\mathcal{F}_1$ is closed under projection under $\mathcal{OP}_1$.

The second part of the lemma is proved by duality. ∎

The following are some consequences of Lemma 4.1. Those facts will be used later in this paper.

- $\mathcal{F}_{(\min,\max,+)} = \{\min(L_1(x), \ldots, L_i(x)) \mid i \in \mathcal{N}, L_1, \ldots, L_i \in \mathcal{F}_{(\max,+)}\}$ is closed over $\{\min, \max, +\}$, where $\mathcal{F}_{(\max,+)} = \{\max(x + a, b) \mid a, b \in \mathbb{R}\}$.
- $\mathcal{F}_{(\min,\max,\times)} = \{\min(L_1(x), \ldots, L_i(x)) \mid i \in \mathcal{N}, L_1, \ldots, L_i \in \mathcal{F}_{(\max,\times)}\}$ is closed over $\{\min, \max, \times\}$, where $\mathcal{F}_{(\max,\times)} = \{\max(ax, b) \mid a, b \in \mathbb{R}^+\}$.
- $\mathcal{F}_{(\min,\max,+,\times)} = \{\min(L_1(x), \ldots, L_i) \mid i \in \mathcal{N}, L_1, \ldots, L_i \in \mathcal{F}_{(\max,+,\times)}\}$ is closed over $\{\min, \max, +, \times\}$, where $\mathcal{F}_{(\max,+,\times)} = \{\max(a, b \cdot x + c) \mid a, b, c \in \mathbb{R}^+\}$.

5. Min–max-plus circuits. We know of no previous results on the parallel evaluation of circuits with three or more operators. In this section, we consider circuits over $\{\mathbb{R}, \min, \max, +\}$. Our result can be extended directly to circuits over $\{\mathbb{R}^+, \min, \max, \times\}$. Min–max-plus circuits (and even min–max-plus trees) are used in computational artificial intelligence (AI) and game theory. Moreover, several dynamic programming problems can be reduced to the min–max-plus circuit value problem. Note that a circuit over any pair of operators is easy to evaluate in parallel, since $\{\mathbb{R}, \min, \max\}$ forms a Boolean algebra; and $\{\mathbb{R}, \min, +\}$ and $\{\mathbb{R}, \max, +\}$ form commutative semirings.

5.1. Unary functions. It is natural to view $\{\min, \max\}$ as the cheap operators and $\{+\}$ as the expensive operators. However, if $\mathcal{NC} \neq \mathcal{P}$, then there is no class of unary functions which is uniformly closed over $\{\min, \max, +\}$. By this observation, min (or max) is taken as the cheap operator.

The class of unary functions $\mathcal{F}$ for min–max-plus is defined as follows.

DEFINITION 5.1 (unary function). *Let $L_{a,b}$ denote the linear form $\max(a+x, b) = (a+x) \wedge b$, where we use $\wedge$ to denote* max*; for all $i \in \mathcal{N}$, let $L_{a_1,b_1} \vee \cdots \vee L_{a_i,b_i}$ denote $\min(L_{a_1,b_1}(x), \ldots, L_{a_i,b_i}(x))$. The class of unary functions of min–max-plus is defined as*

$$F = \bigcup_{i=1}^{+\infty} \{L_{a_1,b_1} \vee \cdots \vee L_{a_i,b_i} \mid a_1, \ldots, a_i, b_1, \ldots, b_i \in R\}.$$

This is called the linear form representation *of f. The* size of the representation *is the number of linear forms presented in the representation. The* minimum representation *of f is a linear form representation containing the minimum number of forms.*

Note that the unary function class $\mathcal{F}$ defined above is equal to the $\mathcal{F}_{(\min,\max,+)}$ defined in section 4. Therefore, we have the following lemma.

LEMMA 5.2. *$\mathcal{F}$ is closed over $\{\min, \max, +\}$.*

These unary functions allow the partial evaluation of parts of the circuit so that certain subcircuits can be replaced by a single edge that has a unary function on it. These subcircuits are restricted CE-circuits defined in section 3; the unary functions used to replace subcircuits are restricted CE-functions defined in section 3.

The main question considered in this and the next section is the size (to be defined in the next subsection) of a restricted CE-function f as a function of the size of the original circuit. This size will affect the time and number of processors needed to evaluate the circuit.

LEMMA 5.3. *Any unary function f produced during the evaluation of a CE-circuit $\mathcal{C}$ by repeated applications of the circuit-reduction algorithm is computable by a restricted CE-circuit obtained from $\mathcal{C}$ by* `rake`*,* `compress`*, and* `shunt`*. Thus, f is computable by a restricted circuit of size at most $|C|$.*

Proof. We will prove the lemma by induction on the number of applications of the circuit-reduction algorithm performed on the circuit. If no application of the procedure is performed, the lemma is trivially true. Circuit-reduction is performed by sequentially applying `rake`, `shunt`, and `compress`, where `rake` simply deletes parts of the circuit, `shunt` partially evaluates some part of the circuit, and `compress` combines two subcircuits under composition to get each unary function. The lemma then follows from the induction hypothesis. □

5.2. Uniformity of $\mathcal{F}$.

DEFINITION 5.4 (size of functions in $\mathcal{F}$). *The size of a function $f \in \mathcal{F}$ is the number of forms in its minimum linear form representation, denoted size(f).*

During the evaluation of the circuit, we need to reduce unary functions to its minimum linear form representation.

LEMMA 5.5. *A linear form representation of size n can be reduced to a minimum in $O(\log n)$ time, using n processors.*

Proof. Let $L_{a_1,b_1} \vee \cdots \vee L_{a_n,b_n}$ be an arbitrary linear form representation. We first sort the forms in increasing order by their $b_i - a_i$ values. It takes $O(\log n)$ time, using n processors [1, 13]. Without loss of generality, we assume that no two forms have the same $b_i - a_i$ value. Now we assume that $L_{a_1,b_1} \vee \cdots \vee L_{a_n,b_n}$ are sorted as above.

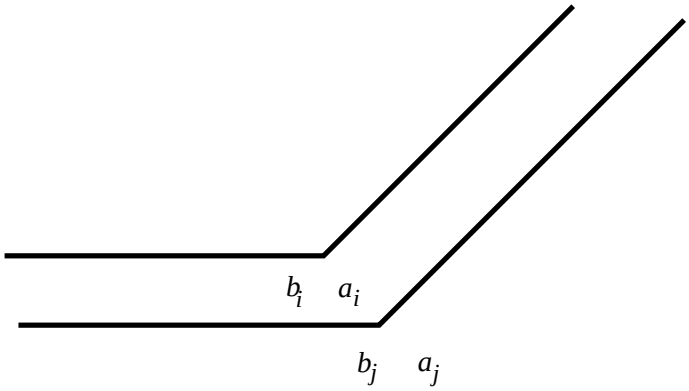

FIG. 5. *The case when* $b_i - a_i < b_j - a_j$.

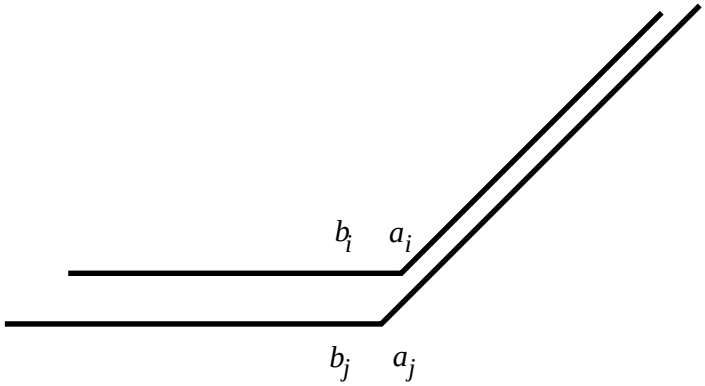

FIG. 6. *The case when* $b_i - a_i > b_j - a_j$.

There are two cases by which L_{a_i,b_i} can be eliminated by L_{a_j,b_j} in the minimum representation:

1. When $b_i - a_i < b_j - a_j$ (Figure 5), then L_{a_i,b_i} is eliminated by L_{a_j,b_j} if and only if $b_j < b_i$.
2. When $b_i - a_i > b_j - a_j$ (Figure 6), then L_{a_i,b_i} is eliminated by L_{a_j,b_j} if and only if $a_i < a_j$.

It follows that a linear form L_{a_i,b_i} is in the minimum representation if a_i is strictly smaller than a_j for $1 \leq j < i$ and b_i is strictly larger than a_j

Thus, by a prefix max of $(a_1, \ldots, a_n)$ we can determine the first case in $O(\log n)$ time using $n/\log n$ processors. Thus, by a prefix min of $(b_n, \ldots, b_1)$ we can determine the second case in $O(\log n)$ time by using $n/\log n$ processors. Hence, the minimum representation can be determined in $O(\log n)$ time by using n processors. □

Given a sorted minimum representation for a function f, it follows that the value of f at x can be computed in constant time, using n processors, or in $O(\log n)$ time, using one processor. We now show that the minimum representation of unary functions used during the evaluation of the circuit is not too large. Let the *breakpoints* of a linear form function f be the set of $(b - a)$'s in the minimum representation of f.

DEFINITION 5.6. *The* breakpoints *of a restricted CE-circuit C for the operations* $\{\min, \max, +\}$ *are the union over the breakpoints of all functions computed by C.*

LEMMA 5.7. *The number of breakpoints of a restricted CE-circuit that occur over* $\{\min, \max, +\}$ *is bounded by the sum of the number of max nodes and the total number of breakpoints of the edge functions of* $\mathcal{C}$.

Proof. We will prove only the case when the functions on the edge are all identity functions. If a function on the edge has p breakpoints, then we can replace the edge by a restricted CE-circuit of size $O(p)$ where all edges have identify functions. Thus, our proof can be directly extended to the general case. Note that if f has p breakpoints and g has q breakpoints, then $g \circ f$ has at most $p + q$ breakpoints. This statement was proved in Lemma 7.3 in [9]. See also Lemma 5.9.

We will prove the lemma by an induction on the size of the restricted CE-circuit. A single node is a restricted CE-circuit, and the only function it computes is a constant function. Thus, it has no breakpoints, as stated in the lemma.

Suppose that the lemma is true for all circuits of size n or less. We now prove the lemma for circuits of size $n + 1$. Let C be such a circuit of size $n + 1$ and v be one of its output nodes. If v is removed from C and all the edges associated with v are removed, then a circuit C' of size n is obtained, which is possibly a disconnected circuit. By induction, the lemma holds for C'. To prove the lemma for C, we consider the following three cases, depending on whether v is a min, max, or plus node. Let $v_1, \ldots, v_k$ be the children of v.

First, suppose that v is a min node. In this case the value computed at v is just the min of the values computed at $v_1, \ldots, v_k$. Thus, the breakpoints of v are at most the union of the breakpoints of $v_1, \ldots, v_k$. Thus, no new breakpoint has been introduced by v.

Second, suppose that v is a max node. In this case v has at most two children, v_1 and v_2, where v_1 is a leaf with value a and v_2 computes the value of $f(x)$. It follows that the max of the constant function a with f will introduce at most one new breakpoint, the point where curve a intersects the monotone increasing curve f. If they intersect in a line, then no breakpoint is introduced. Since C has one more max node than C' this case also follows.

Third, suppose that v is a plus node. Here, the value of v is the sum of a constant a and a function f. But, the breakpoints of f are unchanged by translation of f by an additive constant. Thus, the breakpoints of the function computed by v are just the breakpoints of f. Therefore, the breakpoints of C are the same as the breakpoints of C'. □

LEMMA 5.8. *If* $\mathcal{C}$ *is a* min–max-plus *circuit with* m *max nodes and* e *edges and all unary functions on the edges of* $\mathcal{C}$ *have sizes bounded by a constant* c*, then the size of a unary function used by circuit-reduction during the evaluation of* C *will have size of at most* $ce + m$*. In the case where the edge functions are trivial, the size of the functions are all bounded by* m.

Proof. By Lemma 5.3 every unary function is computed by a subcircuit of C. Furthermore, by Lemma 5.7 the number of breakpoints in any restricted CE-subcircuit is bounded by the number of breakpoints contributed by the edge function, which is at most $c \cdot e$, plus the number of max nodes, m. □

It follows from Lemma 5.8 that $\mathcal{F}$, the unary function class used for evaluating min–max-plus circuits, is $(\log n, n)$-uniformly closed over $\{\min, \max, +\}$. Therefore, by Theorem 3.9, circuits over $\{\min, \max, +\}$ of n nodes, m max nodes, and degree d can be evaluated in $O(\log^2 n \log dn)$ time, using $mM(n)$ processors.

In the following, it will be shown that the time count for evaluating a min–max-plus circuit can be reduced from $O(\log^2 n \log dn)$ to $O(\log n \log dn)$ without increasing

the processor count.

Note that the most time consuming step in *circuit-reduction* is the MM_C operation, where matrix–matrix multiplication of matrices whose entries are unary functions given in minimum linear form representation is performed. The product is over the semiring $\{\min, \mathit{composition}\}$. The matrices are assumed to be of size n, and the total number of breakpoints of all the functions, including those in the product, is bounded by n. Thus, the performance of composition in $O(\log n)$ time and n processors will be shown as well as the computation of the min of n functions in the same amount of time, using the same number of processors.

LEMMA 5.9. *If f and g are two functions of size at most n, then their composition and minimum representation can be computed in $O(\log n)$ time, using n processors. In general, the composition of any two monotone, piecewise linear functions each with n breakpoints can be computed in $O(\log n)$ time, using $n/\log n$ processors.*

Proof. See Lemma 7.3 in [9]. □

LEMMA 5.10. *The min of a set of n functions, each of size at most n, can be computed in $O(\log n)$ time, using n^2 processors.*

Proof. The min of n functions can be computed by first concatenating the representations of the n functions together and then applying the method in Lemma 5.5 to get a minimum representation for the answer. □

THEOREM 5.11. Min–max-plus *circuits with m max nodes, n nodes, and degree d can be evaluated in $O(\log n \log dn)$ time, using $mM(n)$ processors.*

Section 4 showed that $\mathcal{F}_{(\min,\max,\times)}$ is closed over $\{\min, \max, \times\}$. Using the similar uniformity proof in this section, we can prove $\mathcal{F}_{(\min,\max,\times)}$ to be $(\log n, n)$-uniformly closed over $\{\mathbb{R}^+, \min, \max, \times\}$.

THEOREM 5.12. Min–max-times *circuits over $\mathbb{R}^+$ with m max nodes, n nodes, and degree d, can be evaluated in $O(\log n \log dn)$ time, using $mM(n)$ processors.*

REMARK 5.13. *It can be shown that there is a class of unary functions which is $(\log n, n)$-uniformly closed over $\{\min, \max, +\}$ as well as $\{\max, \min, +\}$. Therefore, a parallel evaluation algorithm similar to the parallel Boolean circuit-evaluation algorithm (see next section) and which has dynamic adaptivity for evaluating min–max-plus circuits can be developed.*

6. Boolean circuits. We will present an algorithm for the parallel evaluation of Boolean circuits. The time complexity $T_{\mathcal{C}}$ of this algorithm always satisfies $T_{\mathcal{C}} \leq O(\log n \ \log n(\min(d_{\wedge\vee}, d_{\vee\wedge})))$. Moreover, there are Boolean circuits with exponential $d_{\wedge\vee}$ and $d_{\vee\wedge}$ which can be evaluated in polylogarithmic time using $M(n)$ processors according to our algorithm without the structure of the circuit being known in advance.

Boolean algebra $\mathcal{B} = \{\mathcal{D}, \vee, \wedge\}$ itself forms a commutative semiring; and therefore, as a consequence of results in [7], the simple Boolean circuit can be evaluated in $O(\log n \log nd)$ time with $M(n)$ processors. But this does not tighten the upper bound because the definition of the degree of a Boolean circuit is not clear, since either $\vee$ or $\wedge$ can be viewed as the addition operator in the semiring defined by the Boolean algebra. The corresponding degrees are denoted by $d_{\wedge\vee}$ and $d_{\vee\wedge}$, respectively.

One naive method to evaluate a Boolean circuit is to apply the algorithm in [7] to compute $d_{\wedge\vee}$ and $d_{\vee\wedge}$ first and then choose the semiring with smaller degree. Another method is first to make two copies of a Boolean circuit and then to apply the parallel algorithm from [7] to evaluate one circuit by viewing $\vee$ as the addition operator and to evaluate the other circuit by viewing $\wedge$ as the addition operator.

However, both methods are not uniform. In the first one, the evaluation of an arithmetic circuit has to be introduced, and it is not easier to compute the degree of a Boolean than to evaluate the circuit. In the second method, two evaluation processes have to be coordinated. If $d_{\wedge\vee}$ and $d_{\vee\wedge}$ are both exponential, no $\mathcal{NC}$ parallel algorithm can be deduced. Moreover, in order to use the parallel algorithm in [7], the indegrees of $\vee$-nodes or $\wedge$-nodes must be 2.

6.1. Closure properties.

LEMMA 6.1 (duality lemma). *For all $a, b \in \mathcal{D}$ in a Boolean algebra $\{\mathcal{D}, \vee, \wedge\}$, there is $c \in \mathcal{D}$, such that*

$$(a \wedge x) \vee b = (b \vee x) \wedge c.$$

LEMMA 6.2 (symmetric lemma). *$\mathcal{F} = \{(a \wedge x) \vee b \mid a, b \in \mathcal{D}\}$ is closed over $\{\vee, \wedge\}$ as well as $\{\wedge, \vee\}$.*

Proof. Due to the duality lemma, it suffices to prove that $\mathcal{F}$ is closed over $\{\vee, \wedge\}$.

Let $f_{(a,b)}(x) = (a \wedge x) \vee b$.

$\mathcal{F}$ is closed under composition, since $f_{(a_2,b_2)}(f_{(a_1,b_1)}(x)) = f_{(a_1 \wedge a_2, a_2 \wedge b_1 \vee b_2)} \in \mathcal{F}$.

$\mathcal{F}$ is closed under combination over $\vee$, since $f_{(a_1,b_1)} \vee f_{(a_2,b_2)} = f_{(a_1 \vee a_2, b_1 \vee b_2)} \in \mathcal{F}$.

$\mathcal{F}$ is linear over $\vee$, since $f_{(a,b)}(x \vee y) = f_{(a,b)}(x) \vee f_{(a,b)}(y)$.

$\mathcal{F}$ is closed under projection over $\wedge$, since for all $c \in \mathcal{D}$, $c \wedge x = (c \wedge x) \vee 0 \in \mathcal{F}$. □

6.2. The algorithm. Because of the duality lemma, there is no reason to view one of $\vee$ or $\wedge$ as the cheap operator and another as the expensive one. However, since the Boolean circuit value problem is $\mathcal{P}$-complete [5], one of them should be expensive. However, Lemma 6.2 implies that operations `shunt` and `compress` can be applied to both $\vee$-nodes and $\wedge$-nodes. Those operations are denoted $\texttt{shunt}_\vee$, $\texttt{shunt}_\wedge$, $\texttt{compress}_\vee$, and $\texttt{compress}_\wedge$, respectively.

We will use this symmetry in our algorithm, which applies two parallel evaluation phases. The first phase views $\vee$ as the expensive operation, while the second phase views $\wedge$ as the expensive operation. These two phases are denoted by $Phase(\wedge, \vee)$ and $Phase(\vee, \wedge)$, respectively. A Boolean circuit is evaluated by alternating applications of $Phase(\wedge, \vee)$ and $Phase(\vee, \wedge)$.

In order to make this work, we need to address the following three problems:

1. the problem caused by the unbounded fan-in of expensive nodes,
2. the problem caused by edges from expensive node to expensive node, and
3. the problem caused by alternation.

We will use the following operation to resolve the problem caused by the unbounded fan-in of expensive nodes.

PROCEDURE TRIMMING(U).

for all v whose children $w_1, \ldots, w_k$ are all leaves **do**
$v := \odot(U_{w_1 v}(w_1), \ldots, U_{w_k v}(w_k))$;;
$U_{w_i v} := 0$;; /* where $\odot$ is the operator of v */
for all v with children $w_1, \ldots, w_k$, w.l.o.g, $w_1, \ldots, w_t$ are leaves $(t < k)$ **do**
$a := \odot(U_{w_1 v}(w_1), \ldots, U_{w_t v}(w_t))$;;
$U_{w_{t+1} u}(x) := a \odot U_{w_{t+1} u}(x)$;;
$U_{w_1 v}, \ldots, U_{w_t v} := 0$;; /* where $\odot$ is the operator of v */

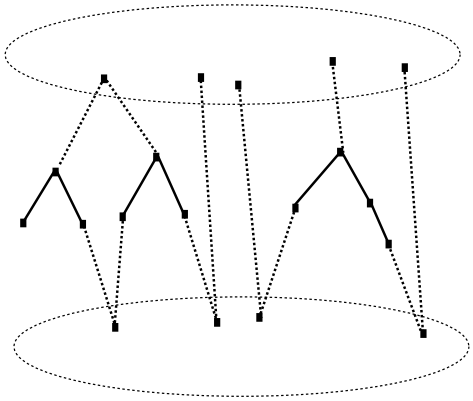

FIG. 7. *Forest formed by nodes of indegree* 1.

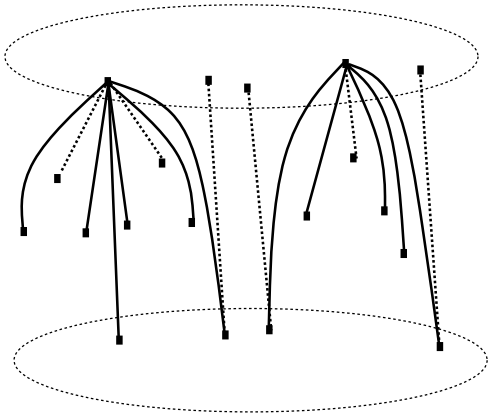

FIG. 8. *Forest removal for the example pictured in Figure* 1.

Graphically, the *Trimming* operation simply disconnects all leaves from their parents. This operation can be performed in $O(\log n)$ time, using n^2 processors. It can be easily proven that the *Trimming* operation preserves the value of each node in the circuit.

In general, *Trimming* will introduce many nodes with fan-in 1, and these nodes form a forest (subcircuit) in the circuit (see Figure 7).

The forest will be removed and replaced by equivalent unary functions. The equivalent unary functions of all nodes in the forest are the composition of the unary functions from the child of its root to itself (see Figure 8).

Using the parallel tree contraction technique [2, 6], the equivalent unary functions for all nodes in the forest can be found in $O(\log n)$ time, using only $n/\log n$ processors,

PROCEDURE FOREST-REMOVAL(U).
for all v in the forest **do**
find the equivalent unary function f_v;;
/* let r denote the root of v and $c(r)$ and $c(v)$ be the */
/* children of r and v in the circuit respectively */
$U_{c(v)v} := 0$;;

$U_{c(r)v} := f_v$;;
for all w and u where w is a child of some roots in the forest
and u is an $\odot$-node with some of its children $v_1, \ldots, v_k$
being nodes in the forest rooted by some parents of w **do**
$g_u := \odot_{i=1}^{k}(U_{v_i u} \circ f_{v_i})$;;
$U_{c(r)u} := U_{c(r)u} \odot g_u$;;
$U_{v_i u} := 0$;;

LEMMA 6.3. *The procedure Forest-Removal eliminates any node which is not an output node but has indegree* 1 *and preserves the value of each node. Moreover, Forest-Removal can be performed in* $O(\log n)$ *time, using* n^2 *processors.*

The following specifies the two phases of the parallel Boolean circuit evaluation algorithm.

Phase($\vee, \wedge$**)**
Trimming;; Trimming;; Trimming;;
Forest-Removal;; $\texttt{compress}_{\vee}$;;

Phase($\wedge, \vee$**)**
Trimming;; Trimming;; Trimming;;
Forest-Removal;; $\texttt{compress}_{\wedge}$;;

Algorithm Parallel Boolean Circuit Eval
Forest-Removal;;
repeat
Phase($\vee, \wedge$);; Phase($\wedge, \vee$);;
until all nodes are output nodes.

LEMMA 6.4. *After the application of Phase(*$\vee, \wedge$*) or Phase(*$\wedge, \vee$*), the indegrees of all the nonoutput nodes are at least two.*

Proof. Clearly, after the application of *Forest-Removal*, all nonoutput nodes have indegree at least 2. For all nonoutput nodes v, $\texttt{compress}_{\vee}$ and $\texttt{compress}_{\wedge}$ either make no change on v or connect all the children of some of its children to it. Hence, after the application of Phase($\vee, \wedge$) or Phase($\wedge, \vee$), v has at least two children. ∎

DEFINITION 6.5. *The* $\wedge\vee$*-height of a node* v*, denoted by* $\underline{h}_{\wedge\vee}(v)$*, in a Boolean circuit is defined inductively.*

- *If* v *is a leaf, then* $\underline{h}_{\wedge\vee}(v) = 1$.
- *If* v *is a* $\vee$*-node, then* $\underline{h}_{\wedge\vee}(v) = \sum_{u \in C(v)} \underline{h}_{\wedge\vee}(u)$.
- *If* v *is a* $\wedge$*-node, then*

$$\underline{h}_{\wedge\vee}(v) = \max\left(\max_{u \in CC(v)} \underline{h}_{\wedge\vee}(u) + 1/2, \max_{u \in EC(v)} (\underline{h}_{\wedge\vee}(u))\right),$$

where $C(v)$*,* $CC(v)$*, and* $EC(v)$ *are the set of children,* $\wedge$*-children, and* $\vee$*-children or leaf children of* v*, respectively.*

The $\wedge\vee$-height of a circuit is the maximum height over its nodes. A child w of a $\wedge$-node v is *dominant* if either w is a $\vee$-node and $\underline{\mathrm{h}}_{\wedge\vee}(w)=\underline{\mathrm{h}}_{\wedge\vee}(v)$ or w is a $\wedge$-node and $\underline{\mathrm{h}}_{\wedge\vee}(w)+1/2=\underline{\mathrm{h}}_{\wedge\vee}(v)$. The $\vee\wedge$-height, denoted by $\underline{\mathrm{h}}_{\vee\wedge}(v)$, is defined similarly.

The following lemma is proven as Theorem 4.2 in [7].

LEMMA 6.6. *The* $\wedge\vee$*-height (or* $\vee\wedge$*-height) of a Boolean circuit of* e *edges is bounded by* $ed_{\wedge\vee} + d_{\wedge\vee}$ *(*$ed_{\vee\wedge} + d_{\vee\wedge}$*).*

From now on, let $\mathcal{C}$ denote a Boolean circuit in which all nonoutput nodes have indegree at least 2.

LEMMA 6.7. *Let $\mathcal{C}'$ be the circuit after the application of Phase($\vee, \wedge$) on $\mathcal{C}$, and v' be the image of v. If v' is a leaf and there exists at least one $\wedge$-node u' such that (v', u') is an edge in $\mathcal{C}'$, then $\vee\wedge$-height of v is at least 2.*

Proof. Suppose that the $\vee\wedge$-height of v is less than 2: If its height is 1, then either v is a leaf or all its children are leaves. Hence, after the first *Trimming* operation, v becomes a leaf. If the height of v is 3/2, then v must be a $\vee$ node whose children are either leaves or $\vee$-nodes with all leaf children. Hence, the second *Trimming* makes v a leaf. Therefore, in each case, the application of the third *Trimming* disconnects v' and u'—a contradiction. □

LEMMA 6.8. *Let $\mathcal{C}'$ be the circuit after the application of Phase($\vee, \wedge$) on $\mathcal{C}$, and let v' be the image of v. Then $\underline{h}_{\vee\wedge}(v') \leq \underline{h}_{\vee\wedge}(v)/2$.*

Proof. The proof is done by induction on the *level* of v, the length of the longest path from a leaf to v. Suppose that all the children of v' are leaves.

- If v' is a $\wedge$-node, then by definition, the height $\underline{\mathrm{h}}_{\vee\wedge}(v')=k$, where k is the indegree of node v'. By Lemma 6.7, $\underline{\mathrm{h}}_{\vee\wedge}(v)\geq 2k$.
- If v is a $\vee$-node, then by definition, $\underline{\mathrm{h}}_{\vee\wedge}(v')=1$. Suppose that $\underline{\mathrm{h}}_{\vee\wedge}(v)\leq 3/2$; then after the second *Trimming* operation, v become a leaf—a contradiction.

Suppose that all the children of v' are either leaf nodes or internal nodes in C'.

- If v is a $\wedge$-node, then the lemma follows from Lemma 6.7 and the assumption.
- If v is a $\vee$-node and u' is a dominant child of v', then if u is a $\wedge$-node, clearly $\underline{h}_{\vee\wedge}(v') \leq \underline{h}_{\vee\wedge}(v)/2$. Now, suppose that u is a $\vee$-node. Since u and v are all $\vee$-nodes, there must be some other nodes on one of the paths from u to v; otherwise u' will not be a child of v' after the application of the `compress`$_{\vee}$ operation. Because all nodes have indegree at least 2, following from the definition of height, $\underline{\mathrm{h}}_{\vee\wedge}(u)+1\leq\underline{\mathrm{h}}_{\vee\wedge}(v)$. Hence, $\underline{\mathrm{h}}_{\vee\wedge}(v)\geq 2\cdot\underline{\mathrm{h}}_{\vee\wedge}(v')$. □

The following lemma can be proven by a simple induction on the level of nodes.

LEMMA 6.9. *For all nodes v in a Boolean circuit $\mathcal{C}$, the application of Phase($\vee, \wedge$) (Phase($\wedge, \vee$)) will not increase $\underline{h}_{\wedge\vee}(v)(\underline{h}_{\vee\wedge}(v))$.*

THEOREM 6.10. *Boolean circuits can be evaluated in time no more than $O(\log n \log n(\min(d_{\wedge\vee}, d_{\vee\wedge})))$, using $M(n)$ processors. Moreover, there are Boolean circuits with exponential $d_{\wedge\vee}$ and $d_{\vee\wedge}$ which can be evaluated in polylogarithmic time, using $M(n)$ processors, without the structure of the circuit being known in advance.*

Proof. The first part of the theorem is a consequence of Lemmas 6.8 and 6.9. The second part follows from the fact that for all nodes v in Boolean circuits $\mathcal{C}$, if at least one of $d_{\wedge\vee}(v)$ and $d_{\vee\wedge}(v)$ is no more than $O(2^{(\log n)^*})$, then v will get its value in polylogarithmic time. It is easy to construct Boolean circuits of exponential $d_{\wedge\vee}$ and $d_{\vee\wedge}$, but all nodes v in it have one of $d_{\wedge\vee}(v)$ and $d_{\vee\wedge}(v)$ is no more than $O(2^{(\log n)^*})$.

Figure 9 shows Boolean circuit with exponential $d_{\wedge\vee}$ and $d_{\vee\wedge}$ that can be evaluated in polylogarithmic time with $M(n)$ processors by our algorithm but not the Miller–Ramachandran–Kaltofen algorithm. □

The beauty of the above parallel algorithm lies in its dynamic adaptability to the structure of the circuit. This power comes from the symmetric structure of the unary function class. However, the tight bound on the running time of this parallel algorithm is still unknown, as are some stronger characterizations of the circuits which have $\mathcal{NC}$ solution. Nevertheless, this algorithm can be used to define the *dynamic degree* of a Boolean circuit.

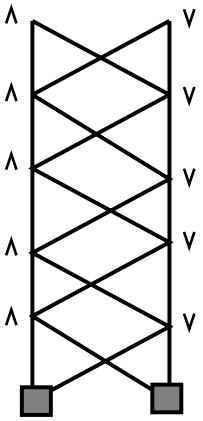

FIG. 9. *A Boolean circuit with exponential $d_{\wedge\vee}$ and $d_{\vee\wedge}$ that can be evaluated in polylogarithmic time with $M(n)$ processors by our algorithm but not the Miller–Ramachandran–Kaltofen algorithm.*

DEFINITION 6.11 (dynamic degree). *If Boolean circuit $\mathcal{C}$ can be evaluated by using the parallel Boolean circuit evaluation algorithm in $T_{\mathcal{C}}$ time, then the dynamic degree of $\mathcal{C}$ (denoted by $d_{\mathcal{C}}$) is defined as $d_C = 2^{T_C/(\log n)-\log n}$.*

7. Circuits over noncommutative semirings. In this section, we will extend the previously known results from circuits over commutative semirings to many noncommutative semirings. We will show that all circuits over *polynomial bounded* noncommutative semirings and circuits over infinite noncommutative semirings which have *polynomial bounded dimensions* over commutative semirings can be evaluated in polylogarithmic time in their size and degree using a polynomial number of processors. This provides a partial answer to the open problem raised in [7].

7.1. General case. Let $\mathcal{NR} = \{\mathcal{D}, \oplus, \odot\}$ be a noncommutative semiring. Let

$$\mathcal{F} = \{\Sigma_{i=1}^{k} a_i \odot x \odot b_i \mid k \in \mathcal{N}, a_i, b_i \in D\},$$

where $a_i \odot x \odot b_i$ is called an *item*. The *size* of a function in $\mathcal{F}$ is defined as the minimum number of items that define it.

LEMMA 7.1. *$\mathcal{F}$ is closed over $\{\oplus, \odot\}$.*

Let $\mathcal{INR} = \{\mathcal{D}, \oplus, \odot\}$, a noncommutative semiring with infinite domain $\mathcal{D}$. $\mathcal{INR}$ is *noncombinable* if for all $a, b, c, d \in \mathcal{D}$, there exists s and $t \in \mathcal{D}$ such that $(a \odot x \odot b) \oplus (c \odot x \odot d) = s \odot x \odot t$ if and only if $a = b$ or $c = d$. It is not difficult to give a constructive proof that for all noncombinable infinite noncommutative semirings, $\mathcal{F}$ is not uniformly closed over $\{\oplus, \odot\}$. That is, there exists a restricted CE-circuit $\mathcal{C}$ over $\mathcal{INR}$, which generates a function in $\mathcal{F}$ whose size is exponential in the size of the circuit. However, it will be shown that there are infinite noncommutative semirings such that all circuits over them can be evaluated in time logarithmic in their degree and size.

7.2. Finite case.

THEOREM 7.2. *For all finite, noncommutative semirings $\mathcal{FNR} = \{\mathcal{D}, \oplus, \odot\}$ and for all computational circuits $\mathcal{C}$ over $\mathcal{FNR}$ with size n and degree d, $\mathcal{C}$ can be evaluated in $O((\log n)(\log dn))$ time, using $M(n)$ processors on CRCW PRAMs.*

Proof. Let the unary function class for $\mathcal{C}$ be

$$\mathcal{F} = \{\Sigma_{i=1}^{k} a_i \odot x \odot b_i \mid k \leq \mid D \mid^2, a_i, b_i \in D\}.$$

It suffices to prove that $\mathcal{F}$ is closed over $(\{\oplus, \odot\})$. Clearly, $\mathcal{F}$ is linear over $\oplus$, and $\mathcal{F}$ is closed under projection over $\odot$. Let $f(x) = \Sigma_{i=1}^{k_1} a_i \odot x \odot b_i$ and $g(x) = \Sigma_{i=1}^{k_2} c_i \odot x \odot d_i$. $f \oplus g = (\Sigma_{i=1}^{k_1} a_i \odot x \odot b_i) \oplus (\Sigma_{i=1}^{k_2} c_i \odot x \odot d_i)$. If $k_1 + k_2 \leq \mid \mathcal{D} \mid^2$, then clearly $f \oplus g \in \mathcal{F}$. Otherwise, since $\mathcal{D}$ is finite and there are at most $\mid \mathcal{D} \mid^2$ different items, there must exist a $t \leq \mid \mathcal{D} \mid^2$, $u_1, \ldots, u_t, v_1, \ldots, v_t \in \mathcal{D}$, such that $f \oplus g = \Sigma_{i=1}^{k_1} u_i \odot x \odot v_i$. Hence, $\mathcal{F}$ is closed under combination. Similarly, we can prove that $\mathcal{F}$ is closed under composition. □

7.3. Examples of finite noncommutative rings. Let $G = \{V, \Sigma, P, S\}$ be a context-free grammar in Chomsky normal form. Let the domain be $\mathcal{D}_G = 2^{(V-\Sigma)}$ and operator set be $\mathcal{OP}_G = \{\cup, \lhd\}$, where $\cup$ is the conventional union operator in set theory and $\lhd$ is a binary operator such that for all $S, T \in \mathcal{D}$, $\lhd(S, T) = \{C \mid \exists A \in S, B \in T, C \to AB\}$. The circuits are defined over domain $\mathcal{D}_G$ and operator set $\mathcal{OP}_G$ and are called *CFL-circuits*.

It is clear that $\{\mathcal{D}_G, \cup\}$ forms a group and $\{\mathcal{D}_G, \lhd\}$ forms a semigroup. Since $\lhd$ is distributive over $\cup$, $\{\mathcal{D}_G, \cup, \lhd\}$ forms a finite, noncommutative semiring.

COROLLARY 7.3. *A CFL-circuit of size n and degree d can be evaluated in $O((\log n)(\log(nd)))$ time, using $M(n)$ processors.*

A *context-free language recognition problem* can be reduced to a *CFL-circuit* evaluation problem in polylogarithmic time since the corresponding *CFL-circuit* has a polynomial size and linear degree in the length of input string. This leads to the following corollary.

COROLLARY 7.4. *The context-free language recognition problem lies in $\mathcal{NC}$.*

Ruzzo [14, 15] was the first to show that there are Boolean circuits that simultaneously have polynomial size and polylogarithmic depth, which recognize context free languages. Valiant et al. [18] showed that the Boolean circuits defined by the Cocke–Kasami–Younger algorithm have a linear degree; therefore the context-free language recognition problem lies in $\mathcal{NC}$. The difference between our solution and their solutions is that they break the operation of context-free language recognition down to Boolean operations, while we implement context-free language recognition by using higher-level, structured operations.

We can also reduce the logical query programs [17] to a circuit whose size is a polynomial in the size of the program. Also, it is easy to prove that if the basic logic program has a polynomial fringe [17], then the degree of the circuit is a polynomial in the size of the program. This is expressed in the next corollary,

COROLLARY 7.5. *A basic logic program with the polynomial fringe property is in $\mathcal{NC}$.*

7.4. Noncommutative semirings with variable size. The *coalescing problem* arises when the composition and combination of functions is computed in $\mathcal{F}$. For all $f \in \mathcal{F}$, the size of f, defined to be the minimum possible number of items representing f, is less than m, the size of the semiring. Can we find the minimum representation of each function in $\mathcal{F}$ efficiently in parallel?

DEFINITION 7.6 (optimal coalescing problem). *Given a formula $f(x) = \Sigma_{i=1}^{n} a_i x b_i$, find a minimum representation for $f(x)$.*

THEOREM 7.7. *If $\mathcal{PNR}$ is noncombinable, then the optimal coalescing problem is $\mathcal{NP}$-hard.*

Proof. The partition problem can be reduced in polynomial time to the optimal coalescing problem. For $a_1, \ldots, a_n \in D$, let $s = \Sigma_{i=1}^{n} a_i$. Suppose there exists d such that $s = d + d$. If no such d exists, trivially, there is no partition. Let $f(x) =$

$\Sigma_{i=1}^{n} a_i x b + dxc$, for some $b \neq c$. Clearly, $a_1, \ldots, a_n$ is partitionable if and only if the optimal representation contains only one item, $dx(b+b+c)$. □

DEFINITION 7.8 (minimal coalescing problem). *A representation $f(x) = \Sigma_{i=1}^{k} a_i x b_i$ is minimal if for all i and $j \leq k (i \neq j), a_i \neq a_j, b_i \neq b_j$. The minimal coalescing problem is defined as follows: given a formula $f(x) = \Sigma_{i=1}^{n} c_i x d_i$, find a minimal representation for $f(x)$.*

Since $\mathcal{D}$ contains only m elements, there is a one-to-one onto function from $\mathcal{D}$ to $\{1, \ldots, m\}$. Let π be such a function. For all input $\Sigma_{i=1}^{n} a_i x b_i$, a_i's are sorted according to $\pi(a_i)$; then all items with the same a part are combined; next b part is sorted and combined. This procedure is one phase. The phase is repeated until all a parts and b parts are distinct from each other. Note that the number of items is reduced at least by 1 with each phase; therefore, n iterations are sufficient to find a minimal representation.

LEMMA 7.9. *The minimal coalescing problem can be solved in $O(n^2 \log n)$ time sequentially.*

CONJECTURE 7.10 (minimal coalescing problem). *The minimal coalescing problem is complete in $\mathcal{P}$.*

Because of the $\mathcal{NP}$-hardness of the optimal coalescing problem and the sequentiality of the minimal coalescing problem, the unary functions are not expected to be minimally represented. A weaker version called one-sided minimal representation is used.

DEFINITION 7.11. *A representation $\Sigma_{i=1}^{k} a_i x b_i$ is* left-hand side minimal *if for all i and $j \leq k (i \neq j), a_i \neq a_j$. The left-hand side minimal coalescing problem is defined as follows: given a formula, $f(x) = \Sigma_{i=1}^{n} c_i x d_i$, find a left-hand side minimal representation for $f(x)$.*

Clearly, if a representation, $\Sigma_{i=1}^{k} a_i x b_i$, is left-hand side minimal, then $k \leq m$.

LEMMA 7.12. *For all $f(x) = \Sigma_{i=1}^{n} c_i x d_i$, the left-hand side minimal representation can be found in $O(\log n)$ time, using n processors.*

Proof. A left-hand side minimal representation can be found after the first step (half phase) of the algorithm for finding minimal representation. Hence, the complexity is equal to sorting n elements. □

Following from Lemma 7.12, for all left-hand side minimally represented functions $f(x) = \Sigma_{i=1}^{k} a_i x b_i$ and $g(x) = \Sigma_{j=1}^{l} c_i x d_i$, a left-hand side minimal representation of $h_1(x)$ and $\mathrm{h}_2(x)$ can be computed in $O(\log(k+l))$ and $O(\log kl)$ time, using $O(k+l)$ and $O(kl)$ processors, respectively, where $h_1(x) = f(x) + g(x)$ and $h_1(x) = (f \circ g)(x)$. This leads to the following theorem.

THEOREM 7.13. *Let $\mathcal{PNR} = \{\mathcal{D}, \oplus, \odot\}$ be a noncommutative semiring of size m. Using $m^2 M(n)$ processors, all circuits over $\mathcal{PNR}$ of size n and degree d can be evaluated in $O((\log \max(m,n))(\log nd))$ time. Therefore, if m is a polynomial of n, then all circuits over $\mathcal{PNR}$ can be evaluated in polylogarithmic time in their size and degree, using only a polynomial number of processors.*

7.5. Semiring over matrices. Let $\mathcal{CR}$ be any commutative semiring and $\mathcal{MR} = \{\mathcal{D}, \oplus, \odot\}$ be a *matrix ring* over $\mathcal{CR}$, i.e.,

$$\mathcal{D} = \{A^{k \times k} \mid A_{ij} \in \mathcal{CR}, 1 \leq i, j \leq k\}.$$

Clearly, $\mathcal{MR}$ is a noncommutative semiring with infinite domain, whenever $\mathcal{CR}$ is infinite.

THEOREM 7.14. *All circuits $\mathcal{C}$ over $\mathcal{MR}$ with n nodes and degree d can be evaluated in $O((\log n)(\log nd))$ time, using $M(n)$ processors.*

Proof. Let $\mathcal{F} = \{C^{m^2\times m^2} \oslash X \mid C^{m^2\times m^2} \in \mathcal{D}_1\}$. The theorem follows from the next lemma. ∎

LEMMA 7.15. *$\mathcal{F}$ is closed over $\{\oplus, \odot\}$.*

Proof. For all $A^{k\times k} \in \mathcal{D}$, $A^{k\times k}X^{k\times k}$ and $X^{k\times k}A^{k\times k}$ are linear transformations of $(x_{1,1}, \ldots, x_{k,k})$ in space ICR^{k^2}. Let $\mathcal{D}_1 = \{C^{k^2\times k^2} \mid C_{i,j} \in \mathcal{CR}, 1 \le i, j \le k^2\}$. Therefore, there exists $B^{k^2\times k^2}$ and $C^{k^2\times k^2} \in \mathcal{D}_1$ such that

$$B^{k^2\times k^2} \oslash \begin{bmatrix} x_{1,1} & x_{1,2} & . & x_{1,k} \\ x_{2,1} & . & . & x_{2,k} \\ . & . & . & . \\ . & . & . & . \\ . & . & . & . \\ x_{k,1} & x_{k,2} & . & x_{k,k} \end{bmatrix} = B^{k^2\times k^2} \begin{pmatrix} x_{1,1} \\ x_{1,2} \\ . \\ . \\ . \\ x_{k,k} \end{pmatrix}$$

$$= A^{k\times k} \begin{pmatrix} x_{1,1} & x_{1,2} & . & x_{1,k} \\ x_{2,1} & . & . & x_{2,k} \\ . & . & . & . \\ . & . & . & . \\ . & . & . & . \\ x_{k,1} & x_{k,2} & . & x_{k,k} \end{pmatrix},$$

$$C^{k^2\times k^2} \oslash \begin{bmatrix} x_{1,1} & x_{1,2} & . & x_{1,k} \\ x_{2,1} & . & . & x_{2,k} \\ . & . & . & . \\ . & . & . & . \\ . & . & . & . \\ x_{k,1} & x_{k,2} & . & x_{k,k} \end{bmatrix} = C^{k^2\times k^2} \begin{pmatrix} x_{1,1} \\ x_{1,2} \\ . \\ . \\ . \\ x_{k,k} \end{pmatrix}$$

$$= \begin{pmatrix} x_{1,1} & x_{1,2} & . & x_{1,k} \\ x_{2,1} & . & . & x_{2,k} \\ . & . & . & . \\ . & . & . & . \\ . & . & . & . \\ x_{k,1} & x_{k,2} & . & x_{k,k} \end{pmatrix} A^{k\times k}.$$

Therefore, $\mathcal{F}$ is closed under projection over $\times$. Note that the composition of two functions in $\mathcal{F}$ is the matrix multiplication; hence, $\mathcal{F}$ is closed under composition. Clearly, $\mathcal{F}$ is linear and closed under combination over $+$. ∎

7.6. The power of structured computation. The power of *structured computation* in parallel computation is considered in the example of the circuit value problem over a matrix ring. Let $\mathcal{CR} = \{\mathcal{D}_1, +, \times\}$ be an infinite commutative semiring; let $\mathcal{D} = \{A^{m\times m} \mid A^{m\times m}_{ij} \in \mathcal{D}_1, 1 \le i, j \le m\}$ and $\mathcal{MR} = \{\mathcal{D}, +, \times\}$. Let $\mathcal{C}$ be a circuit of size n and degree d over an $\mathcal{MR}$. In order to evaluate $\mathcal{C}$ in parallel, the best known solution is to expand the matrix operations down to the operations defined on $\mathcal{CR}$, a commutative semiring, i.e., replacing each node in $\mathcal{C}$ by a subcircuit which simulates the operation. The corresponding circuit is denoted by $\mathcal{C}'$. Note that the degree of $\mathcal{C}'$ is also d. Therefore, the algorithm presented in [7] can be applied.

The complexity of this solution is now analyzed. If m is a constant, then the algorithm takes $O(\log n \ \log nd)$ time, using n^3 processors.[1] However, when m is a

[1] The number of processors to compute the multiplication of two matrices of dimension n in $O(\log n)$ time is charged to be n^3. The effect of the advanced matrix multiplication algorithm will be discussed in a later subsection.

polynomial of n, for instance, $m = n$. Since each multiplication node in $\mathcal{C}$ is replaced by a subcircuit of size m^3 and each addition node in $\mathcal{C}$ is replaced by a subcircuit of size m^2, in the worst case $\mathcal{C}'$ has a size of $O(n^4)$. Thus, this method takes $O(\log n \log nd)$ time, using n^{12} processors!

We will show that the same circuit can be evaluated in $O(\log n \log nd)$ time, using n^9 processors. The n^3 saving of processors is achieved by using *structured computation.*

Note that the proof of Lemma 7.15 is independent of m, the dimension of the matrix-ring. Now, we show that projection, combination, and composition can be computed in parallel efficiently.

LEMMA 7.16.

1. *The projection over* $\times$ *can be computed in* $O(\log m)$ *time, using* m^4 *processors.*
2. *The combination of the two functions in* $\mathcal{F}$ *can be computed in constant time, using* m^4 *processors.*
3. *The composition of the two functions in* $\mathcal{F}$ *can be computed in* $O(\log m)$ *time, using* m^6 *processors.*

Proof. 1. The projection operation over a $\times$ node is a linear transformation of a vector in m^2 dimension. As shown in the proof of Lemma 7.15, it is not difficult to see that this linear transformation ($B^{m^2 \times m^2}, C^{m^2 \times m^2}$ in the proof of Lemma 7.15) can be computed by using the time and processors specified in the Lemma.

2. The combination of the two functions in $\mathcal{F}$ is simply a result of performing a matrix addition.

3. The composition of the two functions is derived by performing a matrix multiplication. □

Let $\mathcal{D}_2 = \{U^{n \times n} \mid U_{i,j} \in \mathcal{F}\}$. Since $\mathcal{F}$ is closed under composition and linear over $+$, $\{\mathcal{F}, \circ, +\}$ forms a semiring. Therefore, $\{\mathcal{D}_2, \circ, +\}$ forms a semiring.

LEMMA 7.17. *For all* $U_1, U_2 \in \mathcal{D}_2$, $U_1 \circ U_2$ *can be computed in* $O(\log \max(m, n))$ *time, using* $O(n^3 m^6)$ *processors.* $U_1 + U_2$ *can be computed in constant time, using* $n^2 m^4$ *processors.*

Proof. Each entry of U_i is an $m^2 \times m^2$ matrix; and $\Sigma_{k=1}^{n} (U_1)_{i,k} (U_2)_{k,j}$, $1 \le i, j \le n$, can be computed in $O(\log \max(m, n))$ time, using $O(n^3 m^6)$ processors. The second part of this lemma follows Lemma 7.16. □

Therefore, the `compress` operation can be computed in $O(\log \max(m, n))$ time, using $n^3 m^6$ processors. The following theorem results.

THEOREM 7.18. *For all circuits* $\mathcal{C}$ *over* $\mathcal{MR}$ *with* n *nodes and degree* d, $\mathcal{C}$ *can be evaluated in* $O((\log \max(m, n))(\log nd))$ *time, using* $n^3 m^6$ *processors.*

7.7. The effect of advanced matrix multiplication algorithms. The above discussion is based on the assumption that the simplest $O(\log n)$ time, the n^3 processor, matrix multiplication algorithm is used. *What is the effect of advanced matrix multiplication algorithms?*

Let $M_{\mathcal{CR}}(n)$ be number of processors used to multiply two $n \times n$-matrices over commutative semiring $\mathcal{CR}$ in $O(\log n)$ time. Let $M_{\mathcal{MR}}(n)$ be number of processors used to multiple two $n \times n$-matrices over matrix semiring $\mathcal{MR} = \{\mathcal{D}, +, \times\}$, where $\mathcal{D} = \{A^{m^2 \times m^2} \mid A_{ij}^{m^2 \times m^2} \in \mathcal{CR}, 1 \le i, j \le m\}$, in $O(\log n)$ time, when the time and processors needed to multiply and add two $m^2 \times m^2$ matrices are charged as a constant. Clearly, the multiplication of any two $n \times n$-matrices over $\mathcal{MR}$ can be computed in $O(\log \max(m, n))$ time, using no more than $M_{\mathcal{MR}}(n) M_{\mathcal{CR}}(m^2)$ processors.

Using the above notations, the processor count for nonstructured and structured method to evaluate a matrix circuit is $P_{ns}(n, m) = M_{\mathcal{CR}}(nM_{\mathcal{CR}}(m))$ and $P_s(n, m) =$

$M_{\mathcal{CR}}(n)M_{\mathcal{MR}}(m^2)$, respectively. Since $M_{\mathcal{CR}}(n_1n_2) = M_{\mathcal{CR}}(n_1)M_{\mathcal{CR}}(n_2)$,

$$\frac{P_{ns}(n,m)}{P_s(n,m)} = M_{\mathcal{CR}}(M_{\mathcal{CR}}(m)/m^2)\frac{M_{\mathcal{CR}}(n)}{M_{\mathcal{MR}}(n)}.$$

It is reasonable to assume that $n^3 \geq M_{\mathcal{MR}}(n) \geq M_{\mathcal{CR}}(n) \geq n^2$. If $M_{\mathcal{CR}} > n^2$, then the larger the m, the more saving the structured method has. However, if $M_{\mathcal{CR}}(n) = n^2$ (possible?), then there is no reason to use the structured method.

8. Open problems.

- It is interesting and important to have a general theory for unary function class construction when an operator set is given and to have a theory for proving closure properties of certain classes of unary functions.
- The dynamic complexity of min–max-plus-times circuit over $\mathbb{R}^+$ is unknown even though we construct a class of unary functions which is closed over $(\{\min\}, \{\max, +, \times\})$ by means of reduction lemma in section 3; i.e., the uniformity of $\mathcal{F}_{(\min,\max,+,\times)}$ is still open.
- Is there an operator set whose cheap operation has more than one operator?
- What is the tight bound on the running time of the parallel Boolean circuit evaluation algorithm?
- What is the dynamic complexity of circuit over a ring with division?

Acknowledgments. We would like to thank both referees for carefully reading an earlier version of this paper and for their technical and editorial comments and suggestions that greatly improved this paper.

THE RELATIONSHIP BETWEEN BREAKING THE DIFFIE–HELLMAN PROTOCOL AND COMPUTING DISCRETE LOGARITHMS*

UELI M. MAURER† AND STEFAN WOLF†

Abstract. Both uniform and nonuniform results concerning the security of the Diffie–Hellman key-exchange protocol are proved. First, it is shown that in a cyclic group G of order $|G| = \prod p_i^{e_i}$, where all the multiple prime factors of $|G|$ are polynomial in $\log |G|$, there exists an algorithm that reduces the computation of discrete logarithms in G to breaking the Diffie–Hellman protocol in G and has complexity $\sqrt{\max\{\nu(p_i)\}} \cdot (\log |G|)^{O(1)}$, where $\nu(p)$ stands for the minimum of the set of largest prime factors of all the numbers d in the interval $[p - 2\sqrt{p} + 1, p + 2\sqrt{p} + 1]$. Under the unproven but plausible assumption that $\nu(p)$ is polynomial in $\log p$, this reduction implies that the Diffie–Hellman problem and the discrete logarithm problem are polynomial-time equivalent in G. Second, it is proved that the Diffie–Hellman problem and the discrete logarithm problem are equivalent in a uniform sense for groups whose orders belong to certain classes: there exists a polynomial-time reduction algorithm that works for all those groups. Moreover, it is shown that breaking the Diffie–Hellman protocol for a small but nonnegligible fraction of the instances is equally difficult as breaking it for all instances. Finally, efficient constructions of groups are described for which the algorithm reducing the discrete logarithm problem to the Diffie–Hellman problem is efficiently constructible.

1. Introduction.

Two challenging open problems in cryptography are to prove or disprove that breaking the Diffie–Hellman (DH) protocol [13] is computationally equivalent to computing discrete logarithms in the underlying group and that breaking the Rivest–Shamir–Adleman system [40] is computationally equivalent to factoring the modulus. This paper is concerned with the first of these problems.

1.1. The discrete logarithm problem.

Let G be a finite cyclic group (written multiplicatively) generated by g. The *discrete logarithm* (DL) *problem* for the group G can be stated as follows: Given g and $a \in G$, find the unique integer s in the interval $[0, |G| - 1]$ such that $g^s = a$. The number s is called the discrete logarithm of a to the base g.

1.2. The DH key-exchange protocol and the DH problem.

The DH protocol [13] allows two parties, Alice and Bob, connected by an authenticated but otherwise insecure channel (for instance an insecure telephone line over which Alice and Bob authenticate each other by speaker recognition), to generate a mutual secret

*Received by the editors April 29, 1996; accepted for publication (in revised form) January 20, 1998; published electronically May 7, 1999. Preliminary versions of this paper appeared as [U. M. Maurer, *Towards the equivalence of breaking the Diffie–Hellman protocol and computing discrete logarithms*, in Advances in Cryptology—CRYPTO'94, Lecture Notes in Comput. †Department of Computer Science, Swiss Federal Institute of Technology, ETH Zürich, CH-8092 Zürich, Switzerland (maurer@inf.ethz.ch, wolf@inf.ethz.ch).

key which appears to be computationally infeasible to determine for an eavesdropper overhearing the entire conversation between Alice and Bob.

The protocol works as follows. Let $G = \langle g \rangle$ be a cyclic group generated by g for which the DL problem is believed to be hard. In order to generate a mutual secret key, Alice and Bob secretly choose integers s_A and s_B, respectively, at random from the interval $[0, |G| - 1]$. Then they compute secretly $a_A = g^{s_A}$ and $a_B = g^{s_B}$, respectively. Note that there exist efficient algorithms for exponentiation in groups. Finally, they exchange these group elements over the insecure public channel and compute $a_{AB} = a_B^{s_A} = g^{s_A s_B}$ and $a_{BA} = a_A^{s_B} = g^{s_B s_A}$, respectively. Since $a_{AB} = a_{BA}$, this quantity can be used as a secret key shared by Alice and Bob. More precisely, they need to apply a function mapping elements of G to the key space of a cryptosystem.

It is unknown whether a group exists for which the DL problem is hard, but several candidate groups have been proposed. Examples are the multiplicative groups of large finite fields (prime fields [13] or extension fields), the multiplicative group of residues modulo a composite number [31], [32], elliptic curves over finite fields [36], [21], the Jacobian of a hyperelliptic curve over a finite field [20], and the class group of imaginary quadratic fields [7].

The security of the DH protocol is based on the assumptions that the DL problem is hard to solve in G and that this implies that it is hard to compute $g^{s_A s_B}$ from g^{s_A} and g^{s_B}. We will refer to the problem of computing $g^{s_A s_B}$ from g^{s_A} and g^{s_B} as the *DH problem*. This paper is mainly concerned with the relationship between the DH and DL problems. It is clear that the DH problem cannot be more difficult than the DL problem because exponentiation in a group is efficient. Conversely, even when we are using a group for which the DL problem is hard, this does not immediately imply that the DH protocol is secure. However, we will show that, for every group whose order is not divisible by the square of a large prime number, the DH problem cannot be substantially easier than the DL problem. Moreover, for certain classes of groups an efficient algorithm reducing the DL problem to the DH problem not only exists but is efficiently constructible.

1.3. Outline of the paper. The paper is organized as follows. In section 2 a general index-search problem is defined and investigated, and some algorithms for computing discrete logarithms are described. In sections 3 and 4 a technique for proving the equivalence of the DH and DL problems, using so-called auxiliary groups, is presented, and examples of suitable auxiliary groups—for instance, elliptic curves or subgroups of the multiplicative group of a finite field—are described. These two sections contain the main results of this paper. More precisely, a generalization of the result of [26] is proved in section 3, which states that the DH and DL problems are equivalent for groups G for which appropriate auxiliary groups are given. The first result of section 4 is a nonuniform reduction of the DL problem to the DH problem: it is shown (under an unproven but plausible number-theoretic conjecture) that there exists, for every group whose order does not contain a multiple large prime factor, a polynomial-time algorithm computing discrete logarithms and making calls to an oracle solving the DH problem. The second result of section 4 is a list of smoothness conditions (depending on $|G|$) which make the DH and DL problems equivalent in a uniform sense; i.e., an efficient reduction algorithm not only exists but also can be found efficiently. In section 5, several variants of the DH problem are defined, and it is shown that they are (almost) as hard as the original DH problem. For instance, breaking the DH problem with small probability is equally hard as breaking it with arbitrarily high probability.

In Appendix A we describe an algorithm for finding generating sets of Abelian groups. Appendix B contains some basic facts about Gröbner basis computations which are required in section 4. In Appendix C we obtain results which are stronger than those of sections 3 and 4 under the assumption that efficient *algorithms* exist for solving the DH problem in certain groups. In Appendix D, we show how to construct DH groups for which the DH and DL problems are provably equivalent.

1.4. Related work. Considerations on related topics can be found in [3], [4], [10], [11], [12], [28], [29], [42], and [45]. In [4], the notion of a black-box field is introduced, which makes more explicit the concept of computation with implicitly represented elements presented in [26]. Furthermore, the existence of a uniform reduction of the DL problem to the DH problem of subexponential complexity was proved in [4], using methods related to those of [26] and of section 3 and Appendix C of this paper.

In [45], the hardness of the DH problem (and hence of the DL problem) is proved in the generic model, i.e., for general-purpose algorithms that do not exploit any special property of the representation of the group elements. However, it was shown in [28] that the DH and DL problems are *not* computationally equivalent in a generic sense if the group order contains multiple large prime factors. In [11], the hardness of the DL and DH problems modulo p is proved in special computational models. For example it was shown that the DH function cannot be interpolated by a low-degree polynomial.

An alternative construction to that of section 5 for correcting a faulty oracle solving the DH problem is described in [45]. Finally, a comparison of the security of different DL based systems is given in [42].

2. The index-search problem and algorithms for computing discrete logarithms.

2.1. The index-search and DL problems. Let $A = (a_i)_{i=0,\dots,n-1}$ be a list of elements of some set S such that for a given i it is easy to compute a_i. We call the problem of computing for a given $b \in S$ an index i such that $b = a_i$ the *index-search problem*. It can trivially be solved by exhaustive search which requires at most n comparisons. If the list has the property that the permutation $\sigma : a_i \mapsto a_{i+1}$ (where the index is reduced modulo n) can efficiently be computed, then the search can be sped up by a time-memory trade-off known as *the baby-step giant-step* algorithm. Using a table of size M to store the sorted list of values $b, \sigma(b), \dots, \sigma^{M-1}(b)$, one can compute the elements $a_0, a_M, a_{2M}, \dots$ until one of them, say, a_{iM}, equals an element $\sigma^j(b)$ contained in the table. Then the index of b is $iM - j$. For the choice $M := \lceil \sqrt{n} \rceil$, the running time of the algorithm is $O(\sqrt{n} \log n)$.

The DL problem in a cyclic group H of order $|H|$ with generator h is the index-search problem for the list $(1, h, \dots, h^{|H|-1})$. Multiplication with h corresponds to the above-mentioned permutation σ. Hence the baby-step giant-step algorithm is applicable for solving the DL problem. It is a general-purpose algorithm that uses no particular properties of the representation of the group elements other than the uniqueness of the representation.

2.2. The Pohlig–Hellman algorithm. We describe a generic algorithm due to Pohlig and Hellman [37] which reduces the computation of discrete logarithms to the same problem in the minimal nontrivial subgroups. It plays a central role in this paper.

THEOREM 1 (see [37]). *Let $H = \langle h \rangle$ be a cyclic group with order $|H| = \prod_{i=1}^{r} q_i^{f_i}$, and let $a = h^x \in H$ be given. The discrete logarithm x of a can be computed by $O(\sum f_i(\log |H| + q_i))$ group operations and equality tests of group elements. If memory space for storing $\lceil \sqrt{q} \rceil$ group elements (where q is the greatest prime factor of $|H|$) is available, the running time can be reduced to $O(\sum f_i(\log |H| + \sqrt{q_i} \log q_i))$.*

Proof. To solve $a = h^x$ for x, we first compute x modulo $q_i^{f_i}$ for all i. This is done by determining, modulo q_i, the coefficients x_{ij} of the q_i-adic representation of x modulo $q_i^{f_i}$,

$$x \equiv \sum_{j=0}^{f_i-1} x_{ij} q_i^j \pmod{q_i^{f_i}}.$$

The number x_{i0} is the discrete logarithm of $a^{|H|/q_i} = h^{x \cdot |H|/q_i} = h^{x_{i0} \cdot |H|/q_i}$ in the group $H^{(i)} := \langle h^{|H|/q_i} \rangle$ of order q_i. Assume now that $x_{i0}, \ldots, x_{i,k-1}$ have already been computed. The number x_{ik} is the discrete logarithm of

$$\left(a \cdot h^{-(x_{i0} + \cdots + x_{i,k-1} q_i^{k-1})} \right)^{|H|/q_i^{k+1}} = h^{x_{ik} \cdot |H|/q_i}$$

in the same group $H^{(i)}$. The computation of a discrete logarithm in $H^{(i)}$ has complexity $O(q_i)$ with exhaustive search and can be sped up by a factor M when a table of size M is used (that can be sorted in time $O(M \log M)$).

Given x modulo $q_i^{f_i}$ for all i, Chinese remaindering yields the discrete logarithm x of a modulo $|H|$. The complexity of the entire algorithm is

$$O\left(\sum f_i(\log |H| + q_i) \right)$$

or

$$O\left(\sum f_i(\log |H| + \sqrt{q_i} \log q_i) \right)$$

when the baby-step giant-step algorithm with $M = \lceil \sqrt{q_i} \rceil$ is used. □

The algorithm is efficient only if $|H|$ is smooth, i.e., if $q_i \le B$ for a small *smoothness bound* B. If this condition is satisfied, we have in the worst case that $q_i \approx B$ for all i; i.e., the number of factors is $\log |H| / \log B$, and the complexity is

$$O\left((\log |H|)^2 + \frac{B}{\log B} \log |H| \right)$$

or

$$O\left((\log |H|)^2 + \sqrt{B} \log |H| \right)$$

when the baby-step giant-step trade-off is used.

It is crucial in the following that the algorithm be generic, i.e., that it use operations in H and equality tests of group elements only. Shoup showed in [45] that no general-purpose algorithm can solve the DL problem faster than the Pohlig–Hellman algorithm together with the baby-step giant-step trade-off. For special groups such as the multiplicative group of a finite field, more efficient algorithms are known. We refer the reader to [33] for a detailed discussion of the DL problem and algorithms for solving it.

3. A general technique for reducing the DL problem to the DH problem. In this section we describe a technique that allows us to reduce the DL problem to the DH problem efficiently in groups G (more precisely, in all groups of certain orders) which satisfy certain conditions.

In section 3.1 we define the notion of a DH oracle, and the subsequent sections deal with the problem of computing discrete logarithms in a group G when given such an oracle for G. As a preparation for this, it is investigated in section 3.2 what kind of computations are possible in the exponents (i.e., in the unknown discrete logarithms) of group elements when given a DH oracle. In section 3.3, the concept of auxiliary groups is defined, and in sections 3.4 and 3.5 it is shown that these auxiliary groups are a tool for reducing the DL problem to the DH problem.

3.1. Computing discrete logarithms with an oracle solving the DH problem. In order to prove results concerning the equivalence of breaking the DH protocol and computing discrete logarithms we assume the availability of an oracle that solves the DH problem.

DEFINITION 1. *A DH oracle for a group G with respect to a given generator g takes as inputs two elements $a, b \in G$ (where $a = g^u$ and $b = g^v$) and returns the element g^{uv}.*

In the following we describe a polynomial-time reduction of the DL problem to the DH problem for certain classes of groups. Let G be a cyclic group generated by g for which the prime factorization of the order $|G|$ is known, and let $a = g^s$ be a given group element for which we want to compute the discrete logarithm s using a DH oracle for G. It is sufficient to compute s modulo each prime factor of $|G|$ (or modulo the prime powers if $|G|$ contains multiple prime factors) and to combine these values by Chinese remaindering. Only large prime factors are relevant because the Pohlig–Hellman algorithm allows us to compute s modulo powers of small prime factors of $|G|$. Hence we can restrict our attention to the problem of computing s modulo p for a large prime factor p of $|G|$. We assume that p is a *single* prime factor of $|G|$; the case of $|G|$ having multiple large prime factors is discussed in section 3.5. Let x be the element of $GF(p)$ defined by $s \equiv x \pmod{p}$. In the following sections, the problem of computing x from the group element g^s is investigated.

3.2. Computing with implicit representations using a DH oracle. Every element y of the field $GF(p)$ can be interpreted as corresponding to a set of elements of G, namely, those whose discrete logarithm is congruent to y modulo p. Every element of this set is then a representation of the field element y.

DEFINITION 2. *Let G be a cyclic group with a fixed generator g, and let p be a prime divisor of the group order. Then, a group element $a = g^{y'}$ is called an* implicit representation *(with respect to G and g) of the element $y \in GF(p)$ if $y \equiv y' \pmod{p}$. We write $y \rightsquigarrow a$.*

Note that the implicit representation of a field element is not unique if $|G| \neq p$.

The following operations on elements of $GF(p)$ can be performed efficiently on implicit representations of these elements (i.e., by operating in the group G), where the result is also in implicit form. Let y and z be elements of $GF(p)$, with

$$y \rightsquigarrow a, \quad z \rightsquigarrow b.$$

Because

$$y = z \text{ if and only if } a^{|G|/p} = b^{|G|/p},$$

equality of two implicitly represented elements of $GF(p)$ can be tested by $O(\log |G|)$ group operations. Furthermore we have

$$\begin{aligned} y + z &\rightsquigarrow a \cdot b, \\ yz &\rightsquigarrow \mathrm{DH}_g(a, b), \\ -y &\rightsquigarrow a^{-1} = a^{|G|-1} \end{aligned}$$

(where DH_g stands for the DH function with respect to the generator g), and these implicitly executed operations on $GF(p)$ elements require a group operation in G, a call to the DH oracle, and $O(\log |G|)$ group operations, respectively.

In order to simplify the notation, we also introduce the notion of an eth-*power* DH oracle ($\mathrm{PDH}_{g,e}$ oracle) that computes an implicit representation of the eth power of an implicitly represented element. A possible implementation of a $\mathrm{PDH}_{g,e}$ oracle is to use a "square and multiply" algorithm for obtaining an implicit representation of y^e, denoted by $\mathrm{PDH}_{g,e}(a)$, by $O(\log e)$ calls to a normal DH oracle (remember that $y \rightsquigarrow a$). In particular we can compute inverses of implicitly represented elements because

$$y^{-1} \rightsquigarrow \mathrm{PDH}_{g,p-2}(a) \ .$$

We call addition, subtraction, multiplication, division, and equality testing in $GF(p)$ *algebraic* operations. Any efficient computation in $GF(p)$ can be performed equally efficiently on implicit representations whenever it makes use only of algebraic operations. Examples are the evaluation of a rational function, testing quadratic residuosity of y by comparing

$$(\mathrm{PDH}_{g,(p-1)/2}(a))^{|G|/p} \text{ and } \ g^{|G|/p} \ ,$$

or the computation of square roots using an algorithm of Massey [25]. We will crucially rely on the fact that algorithms based on exhaustive search (for example generic algorithms for solving the index-search problem, in particular the DL problem) can be executed on implicitly represented arguments and lead to explicit results.

3.3. Auxiliary groups. When given a DH oracle for G, the computation of x is shown to work efficiently if an auxiliary group H over $GF(p)$ with certain properties exists. (Remember that $s \equiv x \pmod p$, where p is a large prime factor of $|G|$, and that s is the discrete logarithm we want to compute.) The basic idea is to embed the unknown x into an implicitly represented element c of H and to compute the discrete logarithm of this element explicitly. We now define a first required property of the auxiliary group H.

DEFINITION 3. *A finite group H is said to be* defined (m, α)-algebraically over $GF(p)$ *if the elements of H can be represented as m'-tuples (for some $m' \leq m$) of elements of $GF(p)$ such that the group operation in this representation can be carried out by at most α algebraic operations in $GF(p)$.*

We will need the following stronger property for auxiliary groups.

DEFINITION 4. *A group H is* defined strongly (m, α)-algebraically over $GF(p)$ *if H is defined (m, α)-algebraically over $GF(p)$ and if there exist two algorithms,* EMBED *and* EXTRACT*, with the following properties.*

1. *For all $(x, e) \in GF(p)^2$ the* EMBED *algorithm with input (x, e) either outputs a group element c of H or reports failure.*

2. *If the* EMBED *algorithm is run with the input* (x, e) *for fixed* x *and randomly chosen* e *until the algorithm does not fail, then the expected running time until an element* $c \in H$ *is computed is at most* α *algebraic operations in* $GF(p)$.
3. *If the* EMBED *algorithm does not fail for the input* (x, e), *then*

$$\text{EXTRACT}(\text{EMBED}(x, e), e) = x.$$

4. *The* EXTRACT *algorithm runs in time at most* α.

In the examples of section 4, the EMBED algorithm computes a group element c that contains $x + e$ as a coordinate, and the EXTRACT procedure outputs this particular coordinate minus e.

In the next section we show how an Abelian group H with bounded rank, defined strongly algebraically over $GF(p)$, and with smooth order can be used as an auxiliary group in the reduction of the computation of discrete logarithms modulo p in G to break the DH protocol for G.

3.4. The reduction algorithm. First we extend the definition of implicit representations from elements of $GF(p)$ to m-tuples over $GF(p)$.

DEFINITION 5. *Let* p *and* G *be as above and let* $a_i \in G$ *and* $y_i \in GF(p)$ *(for* $i = 1, \ldots, m$*). We say that* $(a_1, \ldots, a_m)$ *is an implicit representation of* $(y_1, \ldots, y_m)$ *if* $y_i \rightsquigarrow a_i$ *for* $1 \le i \le m$.

THEOREM 2. *Let* P *be a fixed polynomial. Let* G *be a cyclic group with generator* g *such that* $|G|$ *and its factorization* $|G| = \prod_{i=1}^{s} p_i^{e_i}$ *are known. If there exist* m, α, *and* B, *all upper bounded by* $P(\log |G|)$, *such that every prime factor* p *of* $|G|$ *greater than* B *is single, and for every such* p, *a finite Abelian group* H_p *with rank* $r = O(1)$, *defined strongly* (m, α)*-algebraically over* $GF(p)$, *exists whose order* $|H_p|$ *is* B*-smooth, then breaking the DH protocol for* G *with respect to* g *is probabilistic polynomial-time equivalent to computing discrete logarithms in* G *to the base* g.

The expected complexity of the computation of a discrete logarithm in G *when given a DH oracle for* G *is* $O(m^2 B^r (\log |G|)^2 / \log B + m^2 \alpha (\log |G|)^3)$ *group operations in* G, $O(m^2 \alpha (\log |G|)^3)$ *calls to the DH oracle for* G, *and* $O(m^2 \alpha (\log |G|)^3 + m \alpha B^r (\log |G|)^2 / \log B)$ *field operations in* $GF(p)$ *for* $p \le |G|$. *The complexities can be reduced by a time-memory trade-off.*

Proof.[1] Let p be a single prime factor of $|G|$ larger than B. Assume that an auxiliary group H is given that is defined strongly (m, α)-algebraically over $GF(p)$ with B-smooth order $|H| = \prod q_i^{f_i}$. It is clear that H has the property that when given an implicitly represented field element $x \in GF(p)$, an implicitly represented *group* element c of H (and an explicit element e of $GF(p)$) can be found efficiently with the property that from the *explicit* representation of c (and from e), the EXTRACT algorithm leads to the element x. The reason is that because the EMBED procedure uses only algebraic operations, it works also on implicitly represented inputs (where the group element of the output is also implicitly represented). This fact allows us to reduce the computation of discrete logarithms in G (modulo p) to the same problem in the group H. The field element x is computed from an implicit representation of x in four steps.

Step 1. Use the EMBED algorithm to obtain, when given an implicit representation of x and a random $e \in GF(p)$, an implicit representation of a group element c of H.

[1] The reader may wish to consult the survey paper [27], where a special case of this theorem is proved. More precisely, the proof is given under the assumption that all the auxiliary groups are cyclic elliptic curves over $GF(p)$.

Step 2. Compute the discrete logarithm of c in H (with respect to some generator set).

Step 3. Compute c explicitly.

Step 4. Use the EXTRACT algorithm to obtain x explicitly:

$$x = \text{EXTRACT}(c, e) \ .$$

We have to prove the stated complexity bounds for Step 2. The group H is Abelian of rank r; i.e., H is isomorphic to $\mathbf{Z}_{n_1} \times \cdots \times \mathbf{Z}_{n_r}$ for some $n_1, \ldots, n_r$ satisfying $\prod_{j=1}^{r} n_j = |H|$ and such that n_{j+1} divides n_j for $j = 1, \ldots, r-1$. Let $h_1, \ldots, h_r$ be a set of generators of H such that $|\langle h_j \rangle| = n_j$ and H is the internal product of the cyclic subgroups $\langle h_1 \rangle, \ldots, \langle h_r \rangle$:

$$H = \langle h_1 \rangle \times \cdots \times \langle h_r \rangle \ .$$

(If no generator set for H is known, it can be computed by the method described in Appendix A.)

The element $c \in H$ has a unique representation:

$$c = \sum_{j=1}^{r} k_j h_j, \qquad 0 \le k_j < n_j.$$

(The group H is written additively.) We address the problem of computing the coefficients k_j. This can be done by a generalization of the Pohlig–Hellman algorithm (see section 2), applied to implicitly represented group elements. The following is repeated for every prime q dividing $|H|$. We describe the first and second iteration step of an algorithm that computes k_j modulo the highest power of q dividing n_j for all $j = 1, \ldots, r$. The algorithm uses v_j $(j = 1, \ldots, r)$ as local variables (initialized by $v_j \leftarrow 0$).

For the first step, let α_1 be the number of generators h_j whose order contains the same number of factors q as n_1. In other words, $(n_1/q)h_j$ is different from the unity e of H exactly for $j = 1, \ldots, \alpha_1$. Because H is defined algebraically over $GF(p)$, an implicit representation of

$$\frac{n_1}{q} c$$

can be efficiently computed from an implicit representation of c. For all $(t_1, \ldots, t_{\alpha_1}) \in \{0, \ldots, q-1\}^{\alpha_1}$, we compute (explicitly)

$$\frac{n_1}{q} t_1 h_1 + \cdots + \frac{n_1}{q} t_{\alpha_1} h_{\alpha_1},$$

transform the coordinates to an implicit representation, and test equality with $(n_1/q)c$. Equality indicates that the t_j are congruent to the coefficients k_j modulo q. We set $v_j \longleftarrow t_j$ for these t_j, and for $1 \le j \le \alpha_1$.

For the second step, let α_2 be the number of elements h_j whose order contains at most one factor q less than n_1, i.e., $(n_1/q^2)h_j \neq e$ exactly for $j = 1, \ldots, \alpha_2$. Implicit representations of the group elements

$$\frac{n_1}{q^2}(t_1 q + v_1)h_1 + \cdots + \frac{n_1}{q^2}(t_{\alpha_1} q + v_{\alpha_1})h_{\alpha_1} + \frac{n_1}{q^2} t_{\alpha_1+1} h_{\alpha_1+1} + \cdots + \frac{n_1}{q^2} t_{\alpha_2} h_{\alpha_2}$$

are computed for all $(t_1, \ldots, t_{\alpha_2}) \in \{0, \ldots, q-1\}^{\alpha_2}$ until equality with the implicitly represented element

$$\frac{n_1}{q^2} c$$

holds. Then assign

$$v_j \longleftarrow t_j q + v_j \quad (j = 1, \ldots, \alpha_1) \ ,$$

$$v_j \longleftarrow t_j \quad (j = \alpha_1 + 1, \ldots, \alpha_2) \ .$$

After repetition of this process up to the maximal q power, q^g dividing n_1, the resulting v_j satisfy

$$\frac{n_1}{q^g} c = \sum_{j=1}^{r} \frac{n_1}{q^g} v_j h_j;$$

i.e., k_j is congruent to v_j modulo the highest power of q dividing $n_j = \operatorname{ord} h_j$ for $j = 1, \ldots, r$.

After running the algorithm for all primes q dividing $|H|$, one can compute the coefficients k_j modulo $\operatorname{ord} h_j$ by Chinese remaindering. The complexity of the algorithm is

$O((\log |H|)^2)$ operations in H with implicitly represented elements,
$O(m \frac{B^r}{r \log B} \log |H| \log |G| + \alpha \log |G|)$ operations in G,
$O(\alpha \log |G|)$ calls to the DH oracle for G, and
$O(r(\log |H|)^2 + \log |H| \frac{B^r}{\log B}$ explicit operations in H.

The first part of the number of group operations comes from the comparisons of implicitly represented elements of H. Note that $|H| \leq p^m$ because H is defined (m, α)-algebraically over $GF(p)$. The implicit and explicit operations in H can be further reduced to operations and DH oracle calls in G and operations in $GF(p)$. Then, one obtains the following complexities.

$O(m^2 \frac{B^r}{r \log B} \log p \log |G| + m^2 (\log p)^2 \alpha \log |G|)$ group operations in G,
$O(m^2 (\log p)^2 \alpha \log |G|)$ calls to the DH oracle for G, and
$O((m^2 (\log p)^2 + m \log p \frac{B^r}{r \log B}) \cdot \alpha \log p)$ field operations in $GF(p)$.

The complexities can be reduced by a time-memory trade-off if memory space is available. The running time is polynomial in $\log |G|$ because m, α, and B are polynomial in $\log |G|$, and because $r = O(1)$. □

3.5. The case of multiple large prime factors in $|G|$. In the previous sections we assumed that all the large prime factors of $|G|$ are single. Under certain additional conditions one can also treat the case of multiple large prime factors of $|G|$. If p^e divides $|G|$ (with $e > 1$), the discrete logarithm s must be computed explicitly modulo p^e instead of modulo p. This can be done if either an additional DH oracle for a certain subgroup of G is given (Case 1) or pth roots can efficiently be computed in G (Case 2).

Case 1. Assume that a DH oracle for the group $\langle g^{|G|/p} \rangle$ is given. We write

$$x \equiv \sum_{i=0}^{e-1} x_i p^i \pmod{p^e}$$

with $x_i \in GF(p)$ for $i = 0, \ldots, e-1$. Let $k \leq e-1$, assume that $x_0, \ldots, x_{k-1}$ are already computed (note that x_0 can be computed as described in the previous section), and consider the problem of computing x_k. Let $a' := a \cdot g^{-x_0 - \cdots - x_{k-1}p^{k-1}}$. Then

$$\begin{aligned} a' &= g^{x_0 + x_1 p + \cdots + x_{e-1}p^{e-1}} \cdot g^{-x_0 - \cdots - x_{k-1}p^{k-1}} \\ &= g^{x_k p^k + x_{k+1}p^{k+1} + \cdots + x_{e-1}p^{e-1}} = \left(g^{p^k}\right)^{x_k + p \cdot l} \end{aligned}$$

for some l. From a', compute

$$a'' := (a')^{|G|/p^{k+1}} = \left(g^{|G|/p}\right)^{x_k},$$

and from a'', x_k can be computed as described in the previous section by using the DH oracle for $\langle g^{|G|/p} \rangle$. More generally, this also works when a DH oracle for any group $\langle g^{d \cdot p^{e-1}} \rangle$, where $d \cdot p^{e-1}$ divides $|G|/p$, is given.

Case 2. Assume that a' (see Case 1) is computed. If an element a''' of the form

$$a''' = g^{x_k + p \cdot l'}$$

for some l' is computed, x_k can again be obtained as in section 3.4, with the DH oracle for $\langle g \rangle$. Such an element a''' can be obtained by computing a p^kth root, i.e., k times the pth root, of a'. Any p^kth root of a' is of the required form because p divides $|G|/p^k$.

However, it has been shown that in the model of *generic* algorithms, it is *not* possible to compute discrete logarithms in a group G more efficiently than in time $\Omega(\sqrt{p})$ with a DH oracle for G, if p is a *multiple* prime factor of $|G|$ [28], [49]. The model of generic algorithms was introduced by Shoup [45]. Intuitively, a generic algorithm is a general-purpose algorithm that works for all groups of a certain order and does not make use of any particular property of the representation of the group elements. Of course this result implies that in the generic model a DH oracle cannot be efficiently used to construct the required subgroup oracles of Case 1 (a result which had already been proved in [45]) and that for large p, pth roots cannot be computed efficiently by a generic algorithm in a group of which the order is divisible by p^2, even when a DH oracle is given for this group (Case 2) [28], [49].

4. Applicable auxiliary groups over $GF(p)$. In this section, two classes of possible auxiliary groups satisfying the requirements specified in the previous section are described: elliptic curves over finite fields and subgroups of the multiplicative groups of finite fields. The applicability of Jacobians of hyperelliptic curves (see [20] and [9]) as auxiliary groups was demonstrated in [48].

Two types of results are derived as a consequence of the applicability of these classes of groups as auxiliary groups. First, a nonuniform reduction of the DL to the DH problem is shown. Under an unproven assumption on the existence of smooth numbers in small intervals, the complexity of this reduction is polynomial in $\log |G|$; i.e., for every group (if no squares of large primes divide the order) there exists an algorithm for computing discrete logarithms in polynomial time if it is allowed to make calls to a DH oracle for this group. As mentioned already, such a reduction does not exist (in the model of generic algorithms) if the group order contains multiple large prime factors.

Moreover, we give a list of expressions $A(p)$ in p with the property that an auxiliary group H_p with order $A(p)$ over $GF(p)$ can efficiently be constructed. Theorem 2 then implies that if for each prime factor p of $|G|$ one of the expressions in this list is smooth, then breaking the DH protocol and computing discrete logarithms are equivalent for G (if $|G|$ has no multiple large prime factors). The equivalence of the DH and DL problems holds in a uniform sense for these groups because an efficient reduction algorithm, whose existence is guaranteed by the nonuniform result, can even be found efficiently.

4.1. Elliptic curves.

4.1.1. Applicability as auxiliary groups. Let $\mathbf{F}$ be a field (whose characteristic is not 2 or 3) and let $A, B \in \mathbf{F}$ with $4A^3 + 27B^2 \neq 0$ (in $\mathbf{F}$). The elliptic curve $E_{A,B}(\mathbf{F})$ (with parameters A and B in $\mathbf{F}$) is the set

$$\{(x, y) \in \mathbf{F}^2 : y^2 = x^3 + Ax + B\} \cup \{\mathcal{O}\}.$$

(The additional point $\mathcal{O}$ is called "point at infinity.") Together with a certain operation on the set of points, $E_{A,B}(\mathbf{F})$ forms an Abelian group of rank at most 2. We refer to [35] for an introduction to elliptic curves.

Here we show that an elliptic curve E over the field $GF(p)$ is defined strongly $(2, O((\log p)^2))$-algebraically over $GF(p)$. Therefore it can be used as an auxiliary group if it has smooth order. Note that the order of an elliptic curve can be computed in polynomial time [44],[6]. The points of E can be represented as pairs of $GF(p)$-elements, and the group operation can be executed in this representation by a constant number of additions, multiplications, divisions, and equality tests in $GF(p)$. We describe the EMBED algorithm. Let $x, e \in GF(p)$ be given. First the expression $D = (x + e)^3 + A(x + e) + B$ is computed and its quadratic residuosity is tested. If D is not a quadratic residue, the algorithm reports failure (and a new value for e is chosen). If D is a quadratic residue, then a square root y of D is computed by an algorithm due to Massey [25] (see also Lemma 3 in section 5.4). Then the EMBED algorithm outputs $c = (x + e, y)$. The necessary executions of the EMBED algorithm require $O((\log p)^2)$ algebraic operations in $GF(p)$.

One can show in a completely analogous manner that an elliptic curve over an extension field $GF(p^n)$ of $GF(p)$, where n is polynomial in $\log p$, can also be used as an auxiliary group.

4.1.2. Existence. It is well-known that for any $A, B \in GF(p)$

$$p - 2\sqrt{p} + 1 \leq |E_{A,B}(GF(p))| \leq p + 2\sqrt{p} + 1 \ ,$$

and that for every $d \in [p - 2\sqrt{p} + 1, p + 2\sqrt{p} + 1]$, there exists a cyclic elliptic curve over $GF(p)$ with order d [41]. This implies the following non-uniform reduction of the DL problem to the DH problem.

DEFINITION 6. *For a number n, let $\nu(n)$ be the minimum, taken over all d in the interval $[n - 2\sqrt{n} + 1, n + 2\sqrt{n} + 1]$, of the largest prime factor of d.*

THEOREM 3. *Let P be a fixed polynomial. For every finite cyclic group G with order $|G| = \prod p_i^{e_i}$ and such that all multiple prime factors p_i of $|G|$ are smaller than $B := P(\log |G|)$, there exists an algorithm that makes calls to a DH oracle for G and computes discrete logarithms of elements of G in time*

$$\max\{\nu(p_i)\} \cdot (\log |G|)^{O(1)} \ .$$

The quantity $\nu(p)$ is directly linked with the existence of a smooth number in the interval $[p-2\sqrt{p}+1, p+2\sqrt{p}+1]$. Unfortunately, very little is known about smooth numbers in such intervals. However, it is known [8] that for every fixed u,

$$\psi(n, n^{1/u}) = n/u^{(1+o(u))u}, \tag{1}$$

where $\psi(n, y)$ denotes the number of y-smooth integers $\leq n$. This fact suggests that $\nu(n)$ is polynomial in $\log n$.

Smoothness Assumption. $\nu(n) = (\log n)^{O(1)}$.

This assumption implies that the algorithms of Theorem 3 run in time polynomial in $\log |G|$, and this yields a polynomial-time nonuniform reduction of the DL problem to the DH problem for all groups whose orders are free of multiple large prime factors. Moreover, the reduction algorithms are generic, i.e., they depend only on the group order $|G|$ of G, and they have a description of length linear in $\log |G|$, namely the large prime factors of $|G|$ and parameters of suitable elliptic curves.

COROLLARY 4. *Let P be a fixed polynomial. If the smoothness assumption is true, then for every group $G = \langle g \rangle$ whose order is free of multiple prime factors greater than $B := P(\log |G|)$, there exists a side-information string S of length at most $3 \log |G|$ such that when given S, breaking the DH protocol for G is polynomial-time equivalent to computing discrete logarithms in G.*

Remark. The group order of Jacobians of hyperelliptic curves of genus 2 varies in a larger interval of size $[n-\Theta(n^{3/4}), n+\Theta(n^{3/4})]$, but the results about the distribution of the orders which are proved in [1] are not sufficient to prove the existence of the side-information string without unproven assumption. The reason is that in [1] the existence of Jacobians with *prime* order is proved, whereas Jacobians with *smooth* order are required for our purpose.

In the model of generic algorithms the results described in section 3.5 (see [28], [45]) and in this section imply the following complete characterization of group orders n for which there exists an efficient generic algorithm computing discrete logarithms, making calls to a DH oracle for the same group.

COROLLARY 5. *If the smoothness assumption is true, then there exists a polynomial-time generic algorithm computing discrete logarithms in cyclic groups of order n, making calls to a DH oracle for the same group, if and only if all the multiple prime factors of n are of order $(\log n)^{O(1)}$.*

4.1.3. Construction of elliptic curves. For certain expressions $A(p)$, elliptic curves over $GF(p)$ with order $A(p)$ can explicitly be constructed. The curve over $GF(p)$ defined by the equation

$$y^2 = x^3 - Dx \tag{2}$$

has order $p+1$ if $p \equiv 3 \pmod 4$, and the curve

$$y^2 = x^3 + D \tag{3}$$

has also order $p+1$ if $p \equiv 2 \pmod 3$. Thus if $p \not\equiv 1 \pmod{12}$, elliptic curves of order $p+1$ are explicitly constructible over $GF(p)$. (We will show in the next section that the subgroup of order $p+1$ of $GF(p^2)^*$ is a useful auxiliary group for all p.) The following statements about the orders of curves of the form (2) or (3) in the case they are *not* $p+1$ are proved in [19] (see also [18]).

If $p \equiv 1 \pmod 4$, then p can uniquely be represented as the sum of two squares, i.e., $p = a^2 + b^2$. Then the curves $y^2 = x^3 - Dx$ have the orders

$$p + 1 \pm 2a \ , \quad p + 1 \pm 2b \ , \tag{4}$$

and the four orders occur equally often over the choices of D.

If $p \equiv 1 \pmod 3$, then p can uniquely be represented as $p = a^2 - ab + b^2$ with $a \equiv 2 \pmod 3$ and $b \equiv 0 \pmod 3$. Then the curves $y^2 = x^3 + D$ have the orders

$$p + 1 \pm 2a \ , \quad p + 1 \pm a \mp 2b \ , \quad p + 1 \pm (a + b) \ , \tag{5}$$

and the six orders occur equally often over the choices of D.

If $p \equiv 1 \pmod 4$ or $p \equiv 1 \pmod 3$, curves with the orders listed in (4) and (5) are explicitly constructible by varying D.

4.2. Subgroups of the multiplicative group of an extension field of $GF(p)$. In this section we investigate under what conditions a subgroup H of $GF(p^n)^*$ satisfies the properties of an auxiliary group in the technique for reducing the DL problem to the DH problem.

4.2.1. Representation with normal bases. We refer to [24] or [34] for an introduction to finite fields. For a prime power q, the field $GF(q^n)$ is an n-dimensional vector space over $GF(q)$ and hence its elements can be represented as n-tuples of $GF(q)$-elements with respect to some basis. Let α be an element of $GF(q^n)$, and let $\alpha_i := \alpha^{q^i}$ for $i = 0, \ldots, n-1$. Then $\{\alpha_0, \ldots, \alpha_{n-1}\}$ is called a *normal basis* if it is linearly independent in which case α is called a *normal element*. Let $\vec{\alpha} := (\alpha_0, \ldots, \alpha_{n-1})$. The matrix T in $(GF(q))^{n \times n}$ satisfying $\alpha_0 \vec{\alpha} = \vec{\alpha} T$ is called the *multiplication table* of the basis.

Normal elements can be found efficiently by trial and error, and when given q, n, and a normal element $\alpha \in GF(q^n)$, the multiplication table can be determined by solving a system of linear equations over $GF(q)$.

4.2.2. The use of subgroups H of $GF(p^n)^*$ as auxiliary groups. Let H be a subgroup of $GF(p^n)^*$. We derive conditions under which such subgroups are defined strongly algebraically over $GF(p)$. The group operation of H is a multiplication in $GF(p^n)^*$ and requires, in a normal basis representation, $O(n^3)$ multiplications in $GF(p)$. We conclude that every subgroup of $GF(p^n)^*$ (for n polynomial in $\log p$) is defined $(n, (\log p)^{O(1)})$-algebraically over $GF(p)$. For all n, $GF(p^n)^*$ is a cyclic group. This implies that a subgroup of $GF(p^n)^*$ is uniquely determined by its order $|H|$, or more precisely, for every divisor d of $|H|$ there exists exactly *one* subgroup of $GF(p^n)^*$ with $|H| = d$. Furthermore, all these subgroups are cyclic.

The next theorem states conditions on n and $|H|$ under which H is defined *strongly* algebraically over $GF(p)$.

THEOREM 6. *Let P be a fixed polynomial and c be a fixed constant. Let H be the subgroup of $GF(p^n)^*$ of order $|H|$. Then H is defined strongly (m, α)-algebraically over $GF(p)$ for $m, \alpha = (\log p)^{O(1)}$ if one of the following two conditions is satisfied.*

Condition 1. *$n \le P(\log p)$, and there exists a divisor $k < n$ of n such that*

$$|H| = \frac{p^n - 1}{p^k - 1} = p^{n-k} + p^{n-2k} + \cdots + p^k + 1 \ .$$

Condition 2. *$n \le c$, and there exists a non-constant polynomial $f(x)$ (with integer coefficients) dividing $x^n - 1$ such that $|H| = f(p)$.*

Remark. An alternative formulation of Condition 2 is that $|H|$ is a multiple of $\Phi_n(p)$ for some $n = O(1)$, where Φ_n stands for the n-th cyclotomic polynomial (see [24] and Appendix B). Examples are

$$\Phi_6(p) = p^2 - p + 1 \ ,$$
$$\Phi_8(p) = p^4 + 1 \ ,$$
$$\Phi_9(p) = p^6 + p^3 + 1 \ .$$

The alternating sums

$$p^{2l} - p^{2l-1} + - \cdots - p + 1$$

also satisfy Condition 2 for $l = O(1)$.

Proof. We show that if one of the conditions is satisfied there exists an EMBED algorithm that takes as input two elements x and e of $GF(p)$ and computes coordinates $\beta_1, \ldots, \beta_{n-1}$ (still in the normal basis representation) in $GF(p)$ by a polynomial number of algebraic operations such that $\beta = (x + e, \beta_1, \ldots, \beta_{n-1}) \in H$.

One possibility of designing the EMBED algorithm is to express membership of an element $\beta = (\beta_0, \ldots, \beta_{n-1})$ to the subgroup H by an equation (or a system of equations) in the coordinates. Then, the element $x + e$ can be assigned to one of the coordinates, say β_0, and the equation is solved for the remaining coordinates (by using only algebraic operations in the field $GF(p)$).

For an element β of $GF(p^n)^*$, we have that $\beta \in H$ if and only if $\beta^{|H|} = 1$. Clearly, this equation corresponds to a set of polynomial equations (with coefficients in $GF(p)$) in the coordinates β_i.

We will show that if the first condition is satisfied, then it is sufficient to solve one univariate polynomial equation over a subfield $GF(p^k)$ of $GF(p^n)$ for finding such a β, and that this can be reduced to a polynomial number of algebraic operations in the field $GF(p)$. The situation when the second condition is satisfied is more difficult. Here, a *system of multivariate* polynomial equations over $GF(p)$ has to be solved by algebraic operations. This can be achieved by Gröbner basis computations. The proof that Condition 2 is sufficient is given in Appendix B.

Proof that Condition 1 is sufficient. The EMBED algorithm works as follows in this situation. Let $x, e \in GF(p)$ be given. For $l := n/k$ let $\{\alpha_0, \ldots, \alpha_{k-1}\}$ and $\{\alpha'_0, \ldots, \alpha'_{l-1}\}$ be normal bases of $GF(p^k)$ over $GF(p)$ and of $GF(p^n)$ over $GF(p^k)$, respectively. For an element $\beta = (\beta_0, \ldots, \beta_{l-1}) \in GF(p^n)$ (with $\beta_i \in GF(p^k)$), we have that $\beta \in H$ is equivalent to

$$\beta^{(p^n-1)/(p^k-1)} = 1 \ . \tag{6}$$

Equation (6) is equivalent to

$$\left(\sum_{i=0}^{l-1} \beta_i \alpha'_i\right)^{p^{(l-1)k}+p^{(l-2)k}+\cdots+p^k+1} = 1 \ . \tag{7}$$

Now, we have $(\beta_i)^{p^{jk}} = 1$ (because $\beta_i \in GF(p^k)$) and $(\alpha'_i)^{p^{jk}} = \alpha'_{i+j}$ (where the index is reduced modulo l) by the definition of the normal basis. Hence (7) is equivalent to

$$\left(\sum_{i=0}^{l-1} \beta_i \alpha'_{i+l-1}\right) \cdot \left(\sum_{i=0}^{l-1} \beta_i \alpha'_{i+l-2}\right) \cdots \left(\sum_{i=0}^{l-1} \beta_i \alpha'_i\right) = 1 \tag{8}$$

(where the indices are reduced modulo l).

Because $(\beta^{(p^n-1)/(p^k-1)})^{p^k-1} = \beta^{p^n-1} = 1$, $\beta^{(p^n-1)/(p^k-1)}$ is an element of the subfield $GF(p^k)$ of $GF(p^n)$. Such elements are easy to characterize in terms of their coordinates. An element $(\gamma_0, \ldots, \gamma_{l-1})$ is an element of $GF(p^k) \subset GF(p^n)$ if and only if $\gamma_0 = \gamma_1 = \cdots = \gamma_{l-1}$. The reason for this fact is that $\alpha'_0 + \alpha'_1 + \ldots + \alpha'_{l-1}$ (the trace $\mathrm{Tr}(\alpha'_0)$ of α'_0) is also an element of $GF(p^k)$. Because both $\beta^{(p^n-1)/(p^k-1)}$ and 1 are elements of $GF(p^k)$, they are equal if and only if their first coordinates are equal. The equation coming from (8), restricted to the first coordinate, is equivalent to

$$g(\beta_0, \ldots, \beta_{l-1}) = 1/\mathrm{Tr}(\alpha'_0) \tag{9}$$

for some l-degree polynomial g with $GF(p^k)$-coefficients.

The construction of a group element β of H with the desired property now works as follows. Let the first coordinate $\beta_{0,0}$ of β_0 (note that β_i corresponds to a k-tuple $(\beta_{i,0}, \ldots, \beta_{i,k-1})$ of $GF(p)$-elements with respect to the normal basis $\alpha_0, \ldots, \alpha_{k-1}$) be equal to $x+e$. Choose the coefficients $\beta_{0,1}, \ldots, \beta_{0,k-1}$ and the coefficients $\beta_1, \ldots, \beta_{l-2}$ randomly in $GF(p)$ and in $GF(p^k)$, respectively. Then (9) is equivalent to a polynomial equation for β_{l-1} with coefficients in $GF(p^k)$.

The roots of a polynomial $f(\gamma)$ over a finite field $GF(p^k)$ can be computed in probabilistic polynomial time by the Cantor-Zassenhaus algorithm (see [34], [24]). The key idea of this algorithm is to factor the polynomial $f(\gamma)$ into

$$\gcd(f(\gamma), (\gamma+\delta)^{\frac{p^k-1}{2}} - 1) \quad \text{and} \quad \gcd(f(\gamma), (\gamma+\delta)^{\frac{p^k-1}{2}} + 1)$$

for random $\delta \in GF(p^k)$. This is repeated with different δ and leads to the linear factors of $f(\gamma)$.

The computation of polynomial gcd's, and thus the entire root-finding algorithm, require only algebraic operations in $GF(p^k)$, and the latter can be reduced to algebraic operations (and equality tests) in $GF(p)$ (with respect to the normal basis representation). The expected number of solutions for β_{l-1} is roughly 1 because $|H|/p^n \approx 1/p^k$. If no solution is found, then failure is reported.

Because the Cantor-Zassenhaus algorithm has probabilistic running time polynomial in n and $\log p$ and uses only algebraic operations in $GF(p)$, the required executions of the EMBED procedure run in a probabilistic polynomial (in $\log |G|$) number of algebraic operations if n is polynomial in $\log p$. □

4.3. Summary. The following corollary is an immediate consequence of Theorem 2, combined with the results of this section.

COROLLARY 7. *Let P be a fixed polynomial, let G be a cyclic group with generator g, and let $B := P(\log |G|)$. Then there exists a list of expressions $A(p)$ in p with the following property: if every prime factor p of $|G|$ greater than B is single and if for every such prime factor at least one of the expressions $A(p)$ is B-smooth, then breaking the DH protocol in G with respect to g is polynomial-time equivalent to computing discrete logarithms in G to the base g. The list contains the following expressions:*

$$p-1\ ,\ p+1\ ,\ p+1\pm 2a\ ,$$

if $p \equiv 1 \pmod 4$, where $p = a^2 + b^2$,

$$p+1\pm 2a\ ,\ p+1\mp a\pm 2b\ ,\ p+1\pm(a+b)\ ,$$

if $p \equiv 1 \pmod 3$, *where* $p = a^2 - ab + b^2$, $a \equiv 2 \pmod 3$, *and* $b \equiv 0 \pmod 3$,

$$\frac{(p^k)^l - 1}{p^k - 1} = (p^k)^{l-1} + \cdots + p^k + 1 \ ,$$

where $k, l = (\log p)^{O(1)}$, *and* $f(p)$, *where* $f(x) \in \mathbf{Z}[x]$ *is a nonconstant polynomial dividing* $x^n - 1$ *for some* $n = O(1)$. □

5. Equivalence between variants of the DH problem.

5.1. Introduction. In the previous sections we have proved results concerning the relationship between the security of the DH protocol and the hardness of the DL problem. However, in order to prove that the DH protocol is secure for a group in which the DL problem is hard, one has to show that the DH problem cannot be solved efficiently even with small probability of, say, 1%. Motivated by this, we show in this section that the assumption of a *perfect* DH oracle for the reduction process is unnecessarily strong and can be relaxed in many ways. In 5.2 we prove that a (probabilistic) DH oracle answering correctly with small probability is virtually as strong as a perfect DH oracle. For example, an oracle answering correctly with probability 1% can efficiently be transformed into an oracle that answers correctly with arbitrarily high probability.

In section 5.3, it is shown that the same holds for a DH oracle that answers correctly for the input (g^u, g^v) only if $u = v$. Finally, the relationship between the DH problem in G and in subgroups of G is investigated in section 5.4.

5.2. ε-DH-oracles. This section deals with DH oracles that answer correctly only with small (but nonnegligible) probability. It is shown that such oracles are virtually as strong as perfect DH oracles. The problem of correcting faulty DH oracles was considered independently by Shoup [45], who described a quite different approach. We introduce the notion of an ε-DH-oracle for a cyclic group G with respect to a generator g. Note that such an "oracle" is probabilistic in general rather than deterministic.

DEFINITION 7. *For* $\varepsilon > 0$, *an* ε-DH-oracle *is a probabilistic oracle which returns for an input* (g^u, g^v) *the correct answer* g^{uv} *with probability at least* ε *if the input is uniformly distributed over* $G \times G$.

The offset *of the oracle's answer* g^t *to the input* (g^u, g^v) *is defined as* $t - uv \pmod{|G|}$. *A* translation-invariant ε*-DH-oracle is an* ε*-DH-oracle whose offset distribution is the same for every input* (g^u, g^v).

A special case of (nontranslation-invariant) ε-DH-oracles are *deterministic* oracles answering correctly for a fraction ε of all inputs. We proceed in two steps to prove that an ε-DH-oracle can be transformed into a virtually perfect DH oracle. First, the oracle is made translation-invariant by randomization of the input, and then, the translation-invariant oracle is "amplified" to an (almost) perfect oracle.

LEMMA 1. *An* ε*-DH-oracle for a cyclic group* G *with order* $|G|$ *can efficiently be transformed into a translation-invariant* ε*-DH-oracle. More precisely, implementing one call to the latter requires one call to the former and* $O(\log |G|)$ *group operations.*

Proof. Given the group elements $a = g^u$ and $b = g^v$ we can randomize the input by choosing r and s at random from $[0, |G| - 1]$, providing the oracle with $a' = ag^r$ and $b' = bg^s$ and multiplying the oracle's answer $g^{(u+r)(v+s)+t} = g^{uv+rv+su+rs+t}$ with $(a^{-1})^s \cdot (b^{-1})^r \cdot g^{-rs} = g^{-(rv+su+rs)}$ to obtain g^{uv+t}. Note that a' and b' are random group elements and statistically independent of a and b. The ε-DH-oracle with randomized input is thus a translation-invariant ε-DH-oracle. □

Remark. If $|G|$ is unknown the input can also be randomized, where the random numbers are chosen from a larger interval. The resulting ε-DH-oracle is then "almost translation-invariant" and applicable in the proof of Theorem 8 if the interval is of size at least $2 \cdot |G|/(\varepsilon^2 \cdot \min\{s, 0.1\})$ (where s is as in Theorem 8). This is the reason for the greater number of group operations for this case in Theorem 8.

In the proof of Theorem 8 it is shown that a translation-invariant ε-DH-oracle can be transformed into an almost-perfect DH oracle. The straightforward approach to using a translation-invariant ε-DH-oracle may at first sight appear to be to run it $O(1/\varepsilon)$ times until it produces the correct answer. However, because the Diffie–Hellman decision problem is difficult, a more complicated approach must be used. (The Diffie–Hellman decision problem, which was first mentioned in [5], is, for given g^u, g^v, and g^w, to decide whether $g^w = g^{uv}$, and is of course at most as difficult as the DH problem.)

THEOREM 8. *For every cyclic group G with generator g and known order $|G|$ and for every $\beta > 0$ there exists an algorithm for solving the DH problem in G which makes calls to an ε-DH-oracle and whose answer is correct with probability at least $1 - \beta$. The number of required oracle calls is $O(\log(1/\beta\varepsilon)/\varepsilon^4)$. If the order of G is unknown, then the reduction is also possible if all the prime factors of $|G|$ are greater than $(1 + s)/\varepsilon$ for some $s > 0$. The number of required calls to the ε-DH-oracle is then*

$$O\left(\frac{1}{(\varepsilon^2 \cdot \min\{s, 1\})^2} \cdot \log \frac{1}{\beta\varepsilon}\right) .$$

The number of required group operations is $O(\log |G|)$ times the number of oracle calls if $|G|$ is known and $O(\log(|G|/(\varepsilon^2 \cdot \min\{s, 1\})))$ times this number if $|G|$ is not known, respectively.

For the proof of Theorem 8 we need the following lemma.

LEMMA 2. *Let $X_1, X_2, X_3, \ldots$ be independent binary random variables with identical distribution P_{X_i} with $P_{X_i}(1) = p$. Let further $\alpha, \delta' > 0$. If t is the smallest number such that the event*

$$\frac{X_1 + \cdots + X_t}{t} \in [p - \delta', p + \delta']$$

has probability at least $1 - \alpha$, then $t = O(\log(1/\alpha)/\delta'^2)$.

Proof. Since the random variables X_i are independent, we have

$$\frac{\mathrm{Var}(X_1 + \cdots + X_t)}{t} = \frac{t \cdot \mathrm{Var}(X_i)}{t^2} = \Theta(1/t) .$$

Hence the number of standard deviations corresponding to δ' is of order $\Theta(\delta'\sqrt{t})$. The normal approximation of the binary distribution (see for example [15]) leads to $\delta'\sqrt{t} = \Theta((\log(1/\alpha))^{1/2})$ or $t = \Theta(\log(1/\alpha)/\delta'^2)$. □

Proof of Theorem 8. The basic idea of the amplification of the DH oracle is as follows. In a precomputation phase, which is independent of the actual input, the oracle's offset distribution is determined. Then, the oracle is called with the given input to compute the correct solution with overwhelming probability.

More precisely, the reduction from an ε-DH-oracle to an oracle answering correctly with high probability consists of the following steps which we first describe intuitively.

Step 1. The ε-DH-oracle is transformed into a *translation-invariant* ε-DH-oracle.

Step 2. We compute an estimate ε' for the probability that the (translation-invariant) oracle answers correctly.

Step 3. A list L_1 of group elements g^e is computed with the property that g^e is contained in L_1 if and only if the probability of the offset e is close to ε'.

Step 4. A second list L_2 of group elements is generated which contains exactly those group elements that occur with frequency close to ε' when the oracle is called with the input (g^u, g^v).

Step 5. The lists L_1 and L_2 have (with high probability) the property that the elements of L_2 are exactly the elements of L_1 multiplied by the group element g^{uv} (which is itself contained in L_2). In order to determine this switch element, the lists aL_1 are generated for all elements a in L_2 (the list aL_1 contains exactly the elements al_1, where l_1 is contained in L_1). The list L_2 is compared to all the lists aL_1, and equality yields a candidate a for g^{uv}.

Step 6. In case of one single candidate a for g^{uv}, this is the output of the algorithm. In the case of *several* candidates and if the group order $|G|$ is known, the discrete logarithms of all the candidates and of g^u and g^v are determined modulo the smooth part of $|G|$. This yields the correct candidate for g^{uv}, which is then the output of the algorithm.

Note that the first three steps are a precomputation which is independent of the particular input (g^u, g^v). The list L_1 which is generated in these steps is a reference list describing the offset behavior of the faulty oracle. We describe the steps in detail and analyze their correctness and efficiency.

Step 1. According to Lemma 1, one can construct a translation-invariant ε-DH-oracle which uses $O(\log |G|)$ group operations and one call to an ε-DH-oracle per call if $|G|$ is known. If $|G|$ is unknown, the number of group operations is $O(\log(|G|/(\varepsilon^2 \cdot \min\{s, 1\})))$.

Step 2. Let $\alpha := \beta\varepsilon/8$. An event with probability at least $1 - \alpha$ will be called *almost certain*. Let $\delta := \varepsilon/10$ and $\delta' := \delta\varepsilon/100 = \varepsilon^2/1000$.[2] If ε is not known, we take a lower bound. In order to determine the probability of a correct answer, the translation-invariant oracle is called repeatedly with the input (g^0, g^0), and ε' is the fraction of correct answers g^0. The number t of oracle calls is such that the true probability of a correct answer lies almost certainly in the interval $[\varepsilon' - \delta', \varepsilon' + \delta']$. It follows from Lemma 2 that $t = O(\log(1/\alpha)/\delta'^2)$.

Step 3. In this step the reference list L_1 is generated as follows. The faulty oracle is called t times (for the same value of t as in the previous step), and all the occurring group elements are stored. Let the list L_1 consist of those group elements whose fraction in the set of all answers lies in the interval $[\varepsilon' - (\delta + \delta'), \varepsilon' + (\delta + \delta')]$. According to Lemma 2, and because $2/\varepsilon$ is an upper bound on the number of offsets occurring with probability at least $\varepsilon/2$, with probability $(1 - \alpha)^{4/\varepsilon}$ the following two statements are both true.

1. If e is an offset with probability in $[\varepsilon' - \delta, \varepsilon' + \delta]$, then g^e is contained in L_1.
2. If g^e is in L_1, then the offset e has probability in $[\varepsilon' - (\delta + 2\delta'), \varepsilon' + (\delta + 2\delta')]$.

Step 4. The translation-invariant faulty oracle is called repeatedly wth the input (g^u, g^v), where (g^u, g^v) is the input to the DH algorithm for G. Let the list L_2 then consist of those group elements which occur as answers of the oracle with a frequency in $[\varepsilon' - (\delta + 3\delta'), \varepsilon' + (\delta + 3\delta')]$. Then, for the same number of trials t as in the previous step, with probability at least $(1 - \alpha)^{4/\varepsilon}$ the following statements are true.

1. If e is an offset with probability in $[\varepsilon' - (\delta + 2\delta'), \varepsilon' + (\delta + 2\delta')]$, then g^{uv+e} is contained in L_2.

[2] The proof does not depend on the choice of the constants (e.g., 1/10), which is somewhat arbitrary. Intuitively, we need that $\delta \ll \varepsilon$ and $\delta' \ll \varepsilon\delta$.

2. If g^{uv+e} is in L_2, then the offset e has probability in $[\varepsilon'-(\delta+4\delta'), \varepsilon'+(\delta+4\delta')]$.

Step 5. With high probability, the list L_2 is equal to L_1, switched by g^{uv} (which is itself in L_2). This allows to determine g^{uv}. More precisely, it follows from the analysis of steps 1 to 4 that the probability that L_1 contains *all* the offsets which have their probability in the interval $[\varepsilon' - \delta, \varepsilon' + \delta]$, that all the offsets of L_1 also occur in L_2, and that all the offsets of L_2 have probability in $[\varepsilon' - (\delta + 4\delta'), \varepsilon' + (\delta + 4\delta')]$ is at least

$$(1-\alpha)^{8/\varepsilon} \geq 1 - \frac{8\alpha}{\varepsilon} = 1 - \beta \; . \tag{10}$$

If this is fulfilled, then L_2 contains more elements than L_1 only if there exists an offset whose probability is in the set

$$[\varepsilon' - (\delta + 4\delta'), \varepsilon' - \delta] \cup [\varepsilon' + \delta, \varepsilon' + (\delta + 4\delta')] \; . \tag{11}$$

In this case we replace δ by $\delta + i \cdot 5\delta'$ (for an integer i randomly chosen in $[-2/\varepsilon, 2/\varepsilon]$), leave δ' unchanged, and run the entire algorithm (except Steps 1 and 2) again. Because the sets (11) are disjoint for different i, and because there can be at most $2/\varepsilon$ offsets with probability at least $\varepsilon/2$, L_1 and L_2 contain the same number of elements for at least half of the possible choices for i.

If the lists L_1 and L_2 have equal length, then with probability at least $1 - \beta$ we have that g^{uv} is contained in L_2 and $L_2 = g^{uv}L_1$, i.e., L_2 contains exactly the elements $g^{uv}l_1$ for l_1 in L_1. The lists aL_1 are computed for all elements a of L_2 and compared to L_2. If equality holds, then a is a candidate for g^{uv}.

Step 6. Let c be the number of elements of L_1 and L_2. If there exists only *one* candidate for g^{uv}, then this group element is the output of the algorithm. If there exist *several* such elements, this means that the lists have a nontrivial translation symmetry, or more precisely, that they are invariant under a multiplication with $g^{|G|/c'}$ for a divisor c' of c and $|G|$. Let c' be the maximal number with this property. Note that $|G|$ has a factor $c' \leq c \leq 1/(\varepsilon' - (\delta + 2\delta'))$ in this case. There are c' candidates for g^{uv}, namely

$$g^{uv}, \; g^{uv+\frac{|G|}{c'}}, \ldots, \; g^{uv+(c'-1)\frac{|G|}{c'}} \; .$$

We show that if $|G|$ is known, the correct candidate can be determined. Let $p_1, \ldots, p_l$ be the distinct prime factors of c' (they can be found in time $O((\log(1/\varepsilon))^2/\varepsilon)$ because $c' = O(1/\varepsilon)$), i.e., $c' = \prod_{i=1}^{l} p_i^{f_i}$. Let further $d = \prod_{i=1}^{l} p_i^{e_i}$ be the product of the maximal powers of the p_i dividing $|G|$. The number d can be computed in time $O((\log|G|)^3)$ and is $(2/\varepsilon)$-smooth because $c' \leq c \leq 2/\varepsilon$. Hence u and v (and consequently uv) are computable modulo d from g^u and g^v by the Pohlig–Hellman algorithm by $O((\log|G|)^2 + \log|G|/\varepsilon)$ group operations. Analogously, we can also compute the discrete logarithms of all the candidates modulo d.

The discrete logarithm of exactly one of the candidates has the correct remainder with respect to d. This is true because for every i, exactly every $p_i^{f_i}$-th candidate has the correct remainder with respect to $p_i^{e_i}$. The primes are distinct; thus the $p_i^{f_i}$ are relatively prime, and hence every $\prod_{i=1}^{l} p_i^{f_i}$-th candidate, that is *exactly one* of them, has the correct remainder. This group element is the output of the algorithm.

In the case where $|G|$ is *not* known, this last step of finding the correct candidate does not work. The only possibility is to choose a smaller value for δ. This is always successful if all the prime factors of $|G|$ are greater than $(1 + s)/\varepsilon$ for some positive

s. Then δ must be chosen smaller than $s\varepsilon/2$, such that $1/(\varepsilon' - (\delta + 2\delta')) < (1+s)/\varepsilon$ holds. The last inequality implies that such a symmetry of the lists L_1 and L_2 (this symmetry is a necessary condition for the case of more than one candidate for g^{uv}) is not possible. □

Remark. Examples of ε-DH-oracles which can *not* be transformed into perfect oracles with our method when $|G|$ is unknown are those which answer the input (g^u, g^v) by one of the values $g^{uv+i|G|/z}$, where $z \leq 1/\varepsilon$ is a factor of $|G|$, and where all the values of i between 0 and $z-1$ are equally likely.

Note that a DH oracle as obtained in Theorem 8 is virtually equivalent to a perfect DH oracle in a polynomial-time (or subexponential-time) reduction of the DL to the DH problem because the correctness of the output of a probabilistic algorithm computing discrete logarithms can be tested, and because only a polynomial (or subexponential) number of oracle calls is required for the computation of a discrete logarithm.

5.3. The squaring oracle. We describe an example of an oracle that is weaker than an ε-DH-oracle with respect to the fraction of correctly answered inputs. Nevertheless, the oracle turns out to be as strong as the perfect oracle. We call an oracle that answers the input g^u by $g^{(u^2)}$ (where u and u^2 are in $\mathbf{Z}_{|G|}$) a *squaring-DH-oracle*.

From g^u and g^v one can compute $g^{u+v} = g^u \cdot g^v$, and with the squaring-DH-oracle

$$g^{(u+v)^2} \cdot \left(g^{(u^2)}\right)^{-1} \cdot \left(g^{(v^2)}\right)^{-1} = g^{(u+v)^2-u^2-v^2} = g^{2uv} = (g^{uv})^2 \ . \tag{12}$$

When given $|G|$, the square root g^{uv} of $(g^{uv})^2$ can efficiently be computed. If $|G|$ is odd, the square root is unique, but if $|G|$ is even, there exist two square roots,

$$g^{uv} \quad \text{and} \quad g^{uv+\frac{|G|}{2}}$$

which can be computed efficiently (see Lemma 3). Let $|G|$ be even, and let 2^e be the maximal power of 2 dividing $|G|$. From g^u and g^v, one can compute u and v, and hence uv, modulo 2^e with $O((\log|G|)^2)$ group operations by the Pohlig–Hellman algorithm. Because $|G|/2$ is not a multiple of 2^e, we have

$$uv \not\equiv uv + \frac{|G|}{2} \pmod{2^e} \ ,$$

and one can determine the correct root g^{uv} by computing the discrete logarithms of one of the roots modulo 2^e. Hence a squaring-DH-oracle is equally powerful as a perfect DH oracle in a group G whose order is known.

A probabilistic squaring-DH-oracle for a group with known order that answers correctly only with probability ε (an *ε-squaring-DH-oracle*) can be transformed into a translation-invariant ε^3-DH-oracle by randomizing the inputs in (12). The complexity is $O((\log|G|)^2)$ group operations per call. This proves the following theorem.

THEOREM 9. *For every cyclic group G with generator g and known order $|G|$ and for every $\beta > 0$ there exists an algorithm solving the DH problem in G which makes calls to an ε-squaring-DH-oracle and whose answer is correct with probability at least $1-\beta$. The number of oracle calls is $O(\log(1/\beta\varepsilon^3)/\varepsilon^{12})$. The number of required group operations is $O((\log|G|)^2)$ times the number of oracle calls.*

5.4. The security of subgroups. Throughout this section we assume that the order of G and its factorization are known. We address the question whether a

subgroup is more or less secure than the entire group with respect to the DH protocol. Although the statement of Corollary 12 below is very intuitive (and an analogous result holds for the computation of discrete logarithms), the proofs of Theorems 10 and 11 are not trivial. First we give a criterion when a DH oracle for $\langle g\rangle$ can be efficiently transformed into a DH oracle for $\langle g^r\rangle$. More precisely, we will show that a subgroup of G is at most as secure as G with respect to the DH protocol if every large prime factor of the index of the subgroup occurs with the same multiplicity in the index and in the group order. We need the following lemma on the computation of p-th roots in a cyclic group G if p is a multiple prime factor of $|G|$. Note that for *single* prime factors p of $|G|$, a p-th root can be obtained by computing the z-th power for $z :\equiv p^{-1} \pmod{|G|/p}$.

LEMMA 3. *Let G be a cyclic group with generator g, and let p be a multiple prime divisor of $|G|$. One of the p-th roots of a p-th power in G can be computed in time $O((\log|G|)^2 + p\log|G|)$.*

Proof. The square root algorithm of Massey [25] can be generalized as follows. Let $|G| = p^j s$ (where $j \geq 2$ and $(p,s) = 1$), and let h be a p-th power in G. By the Pohlig–Hellman algorithm we can compute the remainder k of the discrete logarithm of h to the base g with respect to p^j. Note that k is a multiple of p because h is a p-th power. Let $d :\equiv -s^{-1} \pmod{p}$. The element

$$\left(g^{s\cdot\frac{k}{p}\cdot d}\right)^{-1} \cdot h^{\frac{sd+1}{p}}$$

is a p-th root of h. This algorithm requires $O((\log|G|)^2 + p\log|G|)$ operations in G. □

Remark. When memory space is available, this algorithm can be sped up to $O(\sqrt{p}\cdot(\log|G|)^{O(1)})$ by the baby-step giant-step trade-off in the Pohlig–Hellman algorithm. This running time is optimal: it was shown in [28] that no generic algorithm can compute p-th roots substantially faster in a group whose order is divisible by p^2 (even when given a DH oracle for this group).

THEOREM 10. *Let P be a fixed polynomial. Let G be a cyclic group with generator g. If the number r is such that every prime factor of r is either smaller than $B := P(\log|G|)$ or has at least the same multiplicity in r as in G, then there exists an algorithm solving the DH problem in the group $\langle g^r\rangle$, making one call to the DH oracle for $\langle g\rangle$ and using a polynomial number of group operations per call.*

Remark. Again, the conditions of the theorem are optimal. Shoup [45] has shown that if the conditions are not satisfied, then the construction of a subgroup oracle from an oracle for G is hard in the generic model.

Proof. Let $|G| = \prod p_i^{e_i}$ and $r = \prod p_i^{f_i}$ (where $f_i > e_i$, $e_i = 0$, or $f_i = 0$ is possible). The DH algorithm for the group $\langle g^r\rangle$ takes as inputs two elements $(g^r)^a$ and $(g^r)^b$ and must output $(g^r)^{ab}$. Using the DH oracle for the group $G = \langle g\rangle$ with the same input, one obtains g^{r^2ab}, i.e., the r-th power of g^{rab}. Now, g^{rab} is computed from g^{r^2ab} by computing the r-th root. More precisely, the $p_i^{f_i}$-th root of g^{r^2ab} has to be computed for all i with $f_i > 0$, and the correct root, i.e., the particular root that is a power of g^{rab}, must be determined. Assume that we have already computed

$$g^{p_1^{f_1}\cdots p_{i-1}^{f_{i-1}} p_i^{2f_i}\cdots p_s^{2f_s} ab} = g^{cp_i^{2f_i}ab} =: d_i\ ,$$

where c is explicitly known. We describe the computation of the correct $p_i^{f_i}$-th root of this group element separately for the cases $f_i \geq e_i$ and $p_i \leq B$.

Case 1: $f_i \geq e_i$. We compute z with

$$z :\equiv (p_i^{f_i})^{-1} \pmod{|G|/p_i^{e_i}}$$

and d_i^z, which is the desired group element. First, it is a $p_i^{f_i}$-th root of d_i. Additionally, it is the only $p_i^{f_i}$-th root of this element which is a power of $g^{p_i^{f_i}}$ (the $p_i^{e_i} - 1$ different roots are

$$g^{cp_i^{2f_i}abz+i|G|/p_i^{e_i}}$$

for $i = 1, \ldots, p_i^{e_i} - 1$, and they are not even powers of $g^{p_i^{e_i}}$).

Case 2: $p_i \leq B$ and $f_i < e_i$. Here we repeat the following two steps f_i times.

Step 1. Compute the p_i-th roots of the group element.

Step 2. Decide which of the roots is a power of g^{rab} and continue with this element.

Assume for some $k = 2f_i - 1, 2f_i - 2, \ldots, f_i$ that we have already computed

$$g^{p_1^{f_1} \cdots p_{i-1}^{f_{i-1}} \cdot p_i^{k+1} \cdot p_{i+1}^{2f_{i+1}} \cdots p_s^{2f_s} ab} = g^{c' p_i^{k+1} ab} ,$$

where c' is explicitly known. Then the two steps work as follows.

Step 1. According to Lemma 3 we can compute a p_i-th root of the group element in time $O((\log |G|)^2 + p_i \log |G|)$.

Step 2. Because a and b can be obtained modulo $p_i^{e_i - f_i}$ directly from g^{ra} and g^{rb} by the Pohlig–Hellman algorithm and c' is explicitly known, and because $k \geq f_i$, we can compute $c' p_i^k ab$ modulo $p_i^{e_i}$. From the root obtained in Step 1, all the roots

$$g^{c' p_i^k ab + j \cdot |G|/p_i} \qquad (j = 0, \ldots, p_i - 1)$$

can be computed. We have $j \cdot |G|/p_i \equiv 0 \pmod{p_i^{e_i}}$ only for $j = 0$, and the correct group element $g^{c' p_i^k ab}$ can be determined by computing the discrete logarithms of the candidates modulo $p_i^{e_i}$, using the Pohlig–Hellman algorithm.

The entire procedure, executed for all prime factors p_i of r, ends up with g^{rab}, and the running time of the algorithm is polynomial in $\log |G|$. □

Remark. It has been pointed out in a preliminary version of [4] that in case of a generator change, i.e., if $(r, |G|) = 1$, it is not even necessary to know r. Let $h = g^r$, and let DH_g and DH_h be the DH functions in G with respect to the generator g and h, respectively. Then

$$\begin{aligned} \mathrm{DH}_h(h^a, h^b) &= h^{ab} = g^{rab} = \mathrm{DH}_g(g^{r^2 ab}, g^{r^{-1}}) \\ &= \mathrm{DH}_g(\mathrm{DH}_g(h^a, h^b), \mathrm{PDH}_{g,\varphi(|G|)-1}(h)) , \end{aligned}$$

and the last expression can be computed by $O(\log |G|)$ applications of the oracle with respect to the basis g.

In many cases a DH oracle for a subgroup of G or a set of such oracles can be transformed into a DH oracle for the entire group, and the following theorem gives a criterion for when this is the case.

THEOREM 11. *Let P be a fixed polynomial. Let G be a cyclic group with generator g and order $|G| = \prod_{i=1}^{r} p_i^{e_i}$, and let $B := P(\log |G|)$ be a smoothness bound. If for all $p_i > B$ a number s_i, where p_i does not divide s_i, and a DH oracle for the group $\langle g^{s_i} \rangle$ is given, then there exists a polynomial-time algorithm solving the DH problem in G with respect to g which calls each oracle for such a subgroup once.*

Proof. Let g^u and g^v be given. We compute g^{uv} using the available oracles for subgroups. Let $m_i := p_i^{e_i}$, $M_i := |G|/m_i$, and $N_i :\equiv M_i^{-1} \pmod{m_i}$. For prime factors $p_i \leq B$, u and v, and hence also uv, can be computed in polynomial time modulo m_i by the Pohlig–Hellman algorithm. For a prime factor $p_i > B$, assume that a DH oracle for the subgroup $\langle g^{s_i} \rangle$ is given, where p_i does not divide s_i. We apply the oracle for $\langle g^{s_i} \rangle$ to $(g^{s_i})^u = (g^u)^{s_i}$ and $(g^{s_i})^v$ to obtain $(g^{s_i})^{u \cdot v}$, where u, v and $u \cdot v$ are modulo $|G|/s_i$. Let $z_i :\equiv s_i^{-1} \pmod{m_i}$ and

$$U_i := \left(g^{s_i(u \cdot v)}\right)^{M_i \cdot z_i} = g^{M_i \cdot (u \cdot v)} \ ,$$

where $u \cdot v$ is modulo m_i. Finally, g^{uv} is computable by Chinese remaindering with implicitly represented arguments by applying only group operations in G:

$$g^{uv} = g^{\sum_i M_i N_i (u \cdot v)} = \prod_i U_i^{N_i}. \qquad \square$$

The following result is an immediate consequence of the above theorems.

COROLLARY 12. *Consider a group $G = \langle g \rangle$ and a subgroup $H = \langle g^k \rangle$ of G with $(\log |G|)^{O(1)}$-smooth index. The DH problem for H is polynomial-time equivalent to the DH problem for G.*

6. Concluding remarks. We have presented a technique for reducing the DL problem in a group G to the DH problem in the same group efficiently when suitable auxiliary groups are given. One conclusion of this fact is that, under a plausible but unproven assumption on the existence of smooth numbers, for every group whose order does not contain a multiple large prime factor there exists a polynomial-time algorithm computing discrete logarithms and making calls to a DH oracle for the same group. In the generic model, it was proven that such a reduction cannot exist for groups whose order is divisible by the square of a large prime. A second conclusion is that solving the DH and DL problems is computationally equivalent for many classes of groups in a uniform sense. These are the groups for which suitable auxiliary groups can be efficiently constructed.

Throughout this paper, we have assumed to know the group order and its factorization. Let p be a large prime factor of $|G|$. If an appropriate auxiliary group over $GF(p)$ such as a subgroup of the multiplicative group of a finite field or an elliptic curve is given that has smooth order, then p can be found efficiently as a factor of $|G|$ (see [23] and [2]). This fact indicates a close relationship between the problems of integer factoring and proving the equivalence between the DH and DL problems.

In Appendix C we describe a technique, presented in [48] and independently considered in [4], for obtaining stronger results under the assumption that efficient algorithms exist for solving the DH problem in certain groups, and which use only algebraic operations. The idea is to execute these algorithms on implicitly represented arguments. This allows to iterate the technique by computing with multiply implicitly represented elements. It is then no longer necessary that for every large prime factor p of $|G|$ a smooth auxiliary group H_p is known. For example, a cyclic auxiliary group H_p whose order contains a large prime factor q and a smooth auxiliary group H_q over $GF(q)$ are sufficient under the assumption that a polynomial-time DH algorithm exists for H_p which uses only algebraic operations in $GF(p)$.

Appendix A: Finding generator sets of the auxiliary groups. We show how a generator set can be found efficiently in a (additively written) finite Abelian

group H of rank r and with B-smooth order $|H| = \prod_{i=1}^{l} q_i^{f_i}$. Suppose $H \cong \mathbf{Z}_{n_1} \times \cdots \times \mathbf{Z}_{n_r}$ (such that n_{j+1} divides n_j for $j = 1, \ldots, r-1$), where the numbers r and $n_1, \ldots, n_r$ are not known a priori, and suppose that we have already found n_i and points h_i with order n_i in $H/\langle h_1, \ldots, h_{i-1}\rangle$ for $i = 1, \ldots, j-1$. Let $n_1 = \prod q_i^{g_i}$, and let π_{j-1} denote the canonical projection to the quotient group $H/\langle h_1, \ldots, h_{i-1}\rangle$, i.e., $\pi_{j-1}(u)$ is the element of $H/\langle h_1, \ldots, h_{j-1}\rangle$ containing u. For the construction of h_j such that $\pi_{j-1}(h_j)$ has maximal order in $H/\langle h_1, \ldots, h_{j-1}\rangle$, we choose $O(\log\log|H|)$ points h in H at random and compute $\mathrm{ord}_{H/\langle h_1,\ldots,h_{j-1}\rangle}\pi_{j-1}(h)$ by comparing

$$\frac{n_1}{q_i^k}\pi_{j-1}(h) = \pi_{j-1}\left(\frac{n_1}{q_i^k}h\right) \quad (\text{for } i = 1, \ldots, l \text{ and } k = g_i, g_i - 1, \ldots, 0)$$

with the unity $e_{H/\langle h_1,\ldots,h_{j-1}\rangle}$ of the quotient group. Comparing $\pi_{j-1}(h')$ and $e_{H/\langle h_1,\ldots,h_{j-1}\rangle}$ is equivalent to deciding if $h' \in \langle h_1, \ldots, h_{j-1}\rangle$, which is done by the generalized Pohlig–Hellman DL algorithm described in section 3. This leads to an element h_j with maximal order in $H/\langle h_1, \ldots, h_{j-1}\rangle$.

It is possible that the algorithm makes a mistake here, i.e., that the generated element does not have maximal order. Such an error occurs only with probability exponentially small in the number of trials and can be detected as follows. In the case where $\mathrm{ord}_{H/\langle h_1,\ldots,h_{j-1}\rangle}\pi_{j-1}(h_j)$ does not divide $\mathrm{ord}_{H/\langle h_1,\ldots,h_{j-2}\rangle}\pi_{j-2}(h_{j-1})$, the process must be restarted because one of the preceding points has not had maximal order. The same holds if $j > \max\{f_i\}$. The latter is a bound for the rank r of H.

The algorithm stops if $\langle h_1, \ldots, h_r\rangle = H$, that is

$$H/\langle h_1, \ldots, h_r\rangle = \{e\} \ ,$$

and $\{h_1, \ldots, h_r\}$ is then a generator set of H. Every element c of H has a unique representation $c = \sum_{j=1}^{r} k_j h_j$ with $k_j \in \{0, \ldots, n_j - 1\}$ with respect to this set. The expected number of operations in H to determine the generator set is

$$O\left(r^2 \log\log|H| \cdot \frac{\sqrt{B^r}}{\log B}(\log|H|)^3\right)$$

(using the time-memory trade-off in the Pohlig–Hellman algorithm).

Appendix B: Gröbner basis computations and the completion of the proof of Theorem 6. The goal of this appendix is to complete the proof of Theorem 6, i.e., to show that the second condition also implies that H is defined strongly algebraically over $GF(p)$. In the first part of the proof of Theorem 6 (given in section 4.2), the key argument was that the Cantor-Zassenhaus algorithm allows to solve a univariate polynomial equation over a finite field efficiently and with algebraic operations only. This led to an EMBED algorithm with the required properties.

For the second part of this proof the result is required that a *system* of such equations can be solved. In section B.1 we shortly describe the concept of Gröbner bases, which are a tool for solving such systems. Section B.2 completes the proof of Theorem 6.

B.1 Gröbner bases. Let $\mathbf{F}$ be a field and R be the ring $\mathbf{F}[x_1, \ldots, x_n]$ of the polynomials in $x_1, \ldots, x_n$ over $\mathbf{F}$. Let further $p_i = 0$ (where $i = 1, \ldots, l$ and $p_i \in R$ for all i) be a system of polynomial equations. We also write $P = 0$, where $P := \{p_i\}$. Every basis of the generated ideal $\langle P\rangle$ in the ring R leads to an equivalent system of

equations. Gröbner bases with respect to the lexicographic term ordering have the property that the system can be solved if univariate equations can be solved. The lexicographic term ordering is defined as follows:

$$\prod x_j^{i_j} <_L \prod x_j^{i'_j}$$

if and only if $i_j = i'_j$ for $j = 1, \ldots, l-1$ and $i_l < i'_l$ for some l.

We motivate the definition of Gröbner bases[3]. Let f and g be polynomials, and let t be the leading term of g. One can reduce f modulo g if a monomial of f is a multiple of t, $f = \alpha t + r$. The reduction of f modulo g is then

$$f - \frac{\alpha t}{\mathrm{M}(g)} \cdot g \ , \tag{13}$$

where $\mathrm{M}(g)$ denotes the leading monomial of g. Let Q be a set of polynomials. The *reducer set* of the polynomial f with respect to Q are the polynomials g in Q with the property that the leading monomial of f can be reduced modulo g. There exists a simple algorithm for a maximal reduction of a polynomial f modulo a set Q of polynomials based on (13). Since R is not a principal ideal domain (if $n > 1$), the maximal reduction is not unique, and an element q of $\langle Q \rangle$ can be irreducible modulo Q. A Gröbner basis G (with respect to a term ordering) is defined and characterized by the following equivalent conditions:

1. Maximal reductions modulo G are unique.
2. If $f \in \langle G \rangle$, then f reduces to 0 modulo G.
3. For all f and g in G,

$$\mathrm{lcm}\,(\mathrm{M}(f), \mathrm{M}(g)) \cdot \left(\frac{f}{\mathrm{M}(f)} - \frac{g}{\mathrm{M}(g)} \right) =: \text{s-poly}(f, g)$$

reduces to 0 modulo G.

For given P, the third criterion leads to a simple algorithm for the computation of a Gröbner basis G of $\langle P \rangle$ by extending P.

Algorithm (Buchberger) *Choose any pair (f_1, f_2) in $P \times P$ and compute a maximal P-reduction of* s-poly(f_1, f_2). *If it is different from zero, extend P by this polynomial. Repeat the process for all pairs, including the pairs with components added to P during the execution of the algorithm.*

This algorithm can be improved by criteria stating whether s-poly(f, g) reduces to 0, such that the number of s-polynomial reductions is decreased. The complexity of Gröbner basis computations is a subject of ongoing research. If the system $P = 0$ has only finitely many solutions over $\mathbf{C}$, the computation of a lexicographic Gröbner basis for $\langle P \rangle$ has complexity $O(D^{n^2})$, where n is a bound for the number of variables and polynomials and D is the maximal degree. The degrees of the polynomials in the Gröbner basis are of order $O(D')$, where

$$D' := (nD)^{(n+1)^{2^{s+1}}} , \tag{14}$$

and s is the dimension of the ideal, $s \leq n$.

The following are key properties of Gröbner bases. Let P be a set of polynomials and G a monic Gröbner basis for $\langle P \rangle$ (where monic means that the coefficients of the leading monomials of all the polynomials are 1).

[3]For an introduction to Gröbner bases, see for example [16].

Property 1. $P = 0$ has a solution if and only if $1 \notin G$.

Property 2. Let H be the set of all leading terms occurring in G. Then the following statements are equivalent:

1. P has finitely many solutions over $\mathbf{C}$,
2. For all i, there exists m_i such that $(x_i)^{m_i} \in H$.

The first property is a criterion for solvability, and the second property implies, when using the lexicographic ordering, that a subset of the equations coming from the polynomials of the Gröbner basis is a system of triangular form and can be solved if univariate polynomial equations can be solved. The fact that $(x_i)^{m_i}$ is the leading term of a polynomial implies that the variables $x_1, \ldots, x_{i-1}$ do *not* occur in the polynomial. For example the polynomial with $(x_n)^{m_n}$ as leading term is *univariate* (with the only variable x_n). Analogously, there is a polynomial containing x_{n-1} and x_n only, etc.

B.2 Completing the proof of Theorem 6.

Proof that Condition 2 *is sufficient.* Let $|H| = f(p)$ for some nonconstant polynomial (with integer coefficients) $f(x)$ dividing $x^N - 1$, where $N = O(1)$.

We show first that we can assume without loss of generality that $f(x)$ equals a cyclotomic polynomial $\Phi_n(x)$ for some $n = O(1)$. The cyclotomic polynomials are the irreducible factors of the polynomials $x^N - 1$ over the ring $\mathbf{Z}$ of integers (see for example [24]). More precisely, we have

$$x^N - 1 = \prod_{d|N} \Phi_d(x) \ ,$$

and the polynomials Φ_d are irreducible over $\mathbf{Z}$. The degree of $\Phi_n(x)$ is $\varphi(N)$, where φ is Euler's totient function. Because the cyclotomic polynomials are irreducible over $\mathbf{Z}$, the (nonconstant) polynomial $f(x)$ (that divides $x^N - 1$) must be a multiple of at least one cyclotomic polynomial $\Phi_n(x)$.

We show that a subgroup H of $GF(p^n)^*$ with $|H| = \Phi_n(p)$ (for $n = O(1)$) is defined strongly (n, α)-algebraically over $GF(p)$ for some $\alpha = (\log p)^{O(1)}$. This proves the second part of Theorem 6, because a group which has a subgroup with this property has the property itself (the same EMBED algorithm can be used). Let

$$\Phi_n(x) = \sum_{j=0}^{\varphi(n)} c_j x^j$$

(with $c_j \in \mathbf{Z}$). Let further $\alpha_0, \ldots, \alpha_{n-1}$ be a normal basis of $GF(p^n)$ over $GF(p)$.

We describe the EMBED algorithm for H. Let $x, e \in GF(p)$ be given. We compute, by a polynomial number of algebraic operations in $GF(p)$, an element $\beta = (\beta_0, \ldots, \beta_{n-1})$ such that $x+e$ is one of the coordinates of β, for instance $x+e = \beta_0$. Again, we need an alternative characterization of the fact that $\beta \in H$ in terms of the $GF(p)$-coordinates of β. The following conditions are equivalent for $\beta = \sum \beta_i \alpha_i$.

$$\begin{aligned} \beta \in H &\Leftrightarrow \beta^{|H|} = 1 \\ &\Leftrightarrow \left(\sum_{i=0}^{n-1} \beta_i \alpha_i \right)^{\sum_{j=0}^{\varphi(n)} c_j p^j} = 1 \end{aligned}$$

$$\Leftrightarrow \prod_{j=0}^{\varphi(n)} \left(\left(\sum_{i=0}^{n-1} \beta_i \alpha_i \right)^{p^j} \right)^{c_j} = 1$$

$$\Leftrightarrow \prod_{j=0}^{\varphi(n)} \left(\sum_{i=0}^{n-1} \beta_i \alpha_{i+j} \right)^{c_j} = 1$$

$$\Leftrightarrow \prod_{c_j \geq 0} \left(\sum_{i=0}^{n-1} \beta_i \alpha_{i+j} \right)^{c_j} - \prod_{c_j < 0} \left(\sum_{i=0}^{n-1} \beta_i \alpha_{i+j} \right)^{-c_j} = 0 \ .$$

In the fourth step, we have made use of $\beta_i^{p^j} = \beta_i$ (because $\beta_i \in GF(p)$) and $\alpha_i^{p^j} = \alpha_{i+j}$ (by the definition of the normal basis). The last condition corresponds to a system of n polynomial equations (with $GF(p)$-coefficients) in the β_i, where the maximal degree D of the polynomials is bounded by

$$D \leq \max \left\{ \sum_{c_j > 0} c_j, \sum_{c_j < 0} |c_j| \right\} \leq \varphi(n) \cdot \max_j |c_j| \ .$$

As in the first part of the proof, the EMBED algorithm assigns $x + e$ to one of the β_i's, random values to some of the other β_i's, and solves the arising equations over $GF(p)$ for the remaining β_i's. Because $|H|/p^n \approx 1/p^{n-\varphi(n)}$, i.e., approximately every $p^{n-\varphi(n)}$-th element β of $GF(p^n)$ is also an element of H, we have to solve the equations for $n - \varphi(n)$ different coordinates β_i simultaneously in order to have an expectation of one solution. (If no solution is found, the algorithm reports failure.)

Using Gröbner bases, this system of polynomial equations can now be transformed into an equivalent system of triangular form (see section B.1). The computation of the Gröbner basis uses only algebraic operations in $GF(p)$, and its complexity is of order $O(D^{n^2})$ (see [16]). The triangular system of equations can be solved by the Cantor-Zassenhaus algorithm for solving *univariate* polynomial equations (see in the first part of the proof of Theorem 6).

According to the result of Gianni and Kalkbrener (see [16]), it suffices to solve a subset of $n - \varphi(n)$ equations. The first polynomial has to be solved once, the second one D' times (where D' is defined as in (14); the reason is that in the worst case, the first polynomial has D' different solutions), the third one $(D')^2$ times, etc. This yields $O((D')^n)$ executions of the Cantor-Zassenhaus algorithm. (The *effective* number of executions will be much smaller in a typical case, since only about one solution is expected.)

The expected complexity of the required executions of the EMBED algorithm is polynomial in $\log p$ (and the algorithm uses only algebraic operations in $GF(p)$) if $n = O(1)$. □

Appendix C: Algebraic algorithms solving the DH problem. The results described in this appendix are based on the following observation. Assume that not only a DH oracle for a group G, but also an efficient *algorithm* which solves the DH problem in an entire class of groups, such as elliptic curves over a finite field or the groups $GF(p)^*$, is given. If this algorithm additionally has the property that it uses only algebraic operations in the underlying field, then it can be executed on inputs that are not explicitly known, but only implicitly represented (in the sense of section 3). This allows to iterate the reduction algorithm described in section 3,

i.e., computing discrete logarithms in G is reduced to the same problem in a group $GF(p)^*$, which is further reduced to the DL problem of another group $GF(q)^*$, and so on.

We give an example. Assume that a uniform polynomial-time algorithm exists for solving the DH problem in all the groups $GF(p)^*$, and that these algorithms use algebraic operations in $GF(p)$ only. Let again $B = (\log |G|)^{O(1)}$ be a smoothness-bound, p_0 a prime factor of $|G|$ greater than B, and let p_1 be the only prime factor of $p_0 - 1$ greater than B. Assume further that p_i is the only prime factor of $p_{i-1} - 1$ greater than B for all $i = 2, \ldots, k$, and that $p_k - 1 =: T = \prod_i r_i^{n_i}$ is B-smooth, and $k = O(1)$. Given $a = g^s$, it is possible to compute $x_0 \equiv s \pmod{p_0}$, $x_0 \in GF(p_0)$, in polynomial time as follows when given a DH oracle for G. Let

$$h_0 := \frac{|G|}{p_0}, \quad h_i := \frac{p_{i-1} - 1}{p_i} \quad (\text{for } i = 1, \ldots, k) \ ,$$

and let

$$GF(p_i)^* = \langle c_i \rangle \quad (\text{for } i = 0, \ldots, k-1) \ .$$

If $x_0 \neq 0$, then $x_0 = c_0^{w_0}$ (in $GF(p_0)$), and g^s is an implicit representation of x_0. Since $p_0 - 1$ has a large prime factor p_1, w_0 modulo p_1 cannot be obtained directly. But $x_1 \equiv w_0 \pmod{p_1}$ (with $x_1 \in GF(p_1)$) can be written as $x_1 = c_1^{w_1}$ (in $GF(p_1)$, if $x_1 \neq 0$), and g^s is a "double-implicit" representation of x_1. Our assumptions allow efficient computation with these elements of $GF(p_1)$ which are "double-implicitly" represented. For example, an addition of two $GF(p_1)$-elements requires multiplication of the corresponding implicitly represented $GF(p_0)^*$-elements and can be obtained by a call to the DH oracle for G. A multiplication in $GF(p_1)^*$ is done by an oracle call for $GF(p_0)^*$ with implicitly represented arguments and an implicitly represented answer. This works (in polynomial time) because of the stated properties of the DH algorithm for $GF(p_0)^*$.

Analogously, computation with $(k+1)$-times implicitly represented arguments is possible in the smooth group $GF(p_k)^*$. The index-search problem for the list

$$\left(g^{h_0 c_0^{h_1 c_1^{\cdots^{h_k c_k^{\frac{T}{r_i} t}}}}} \right)_{t=0,\ldots,r_i-1}$$

and the element

$$g^{h_0 c_0^{h_1 c_1^{\cdots^{h_k c_k^{\frac{T}{r_i} w_k}}}}}$$

which can be obtained in polynomial time by computation with multiply implicitly represented arguments, is solved and leads to w_k modulo r_i. When this is done for all prime powers $r_i^{n_i}$, w_k is computable modulo T. Then $x_k = c_k^{w_k}$ (in $GF(p_k)$), and one can get w_{k-1} modulo $p_{k-1} - 1$ in polynomial time because the other prime factors of $p_{k-1} - 1$ are smaller than B. Finally, we obtain w_0 modulo $p_0 - 1$ and x_0.

Remark. The reason for assuming that $p_{i-1} - 1$ has *only one* large prime factor p_i is that otherwise it would not be possible to find the factors of $p_{i-1} - 1$ in polynomial time. When these factors are given, then the condition is unnecessary.

THEOREM 13. *Let P be a fixed polynomial. Let G be a cyclic group with the property that all prime factors p_0 of $|G|$ greater than $B := P(\log|G|)$ are single, and that for all such prime factors there exist $k = O(1)$ and primes p_i $(i = 1, \ldots, k)$ such that p_i is the only prime factor of $p_{i-1} - 1$ greater than B for $i = 1, \ldots, k$, and $p_k - 1$ is B-smooth. Assume further that a polynomial-time algorithm is given which solves the DH problem in the groups $GF(p)^*$ and uses algebraic operations in $GF(p)$ only. Then, breaking the DH protocol and computing discrete logarithms are polynomial-time equivalent in G.* □

The process works in an analogous way if some of the used groups are cyclic elliptic curves or Jacobians, provided an efficient algebraic (with respect to the underlying field $GF(p)$) DH algorithm is given for these groups.

Appendix D: Construction of groups for which a reduction of the DL problem to the DH problem is efficiently constructible. It appears desirable to use a group G in the DH protocol for which the algorithm reducing the DL problem to the DH problem can easily be found. However, such reasoning should be used with care because it is conceivable that knowledge of the auxiliary groups makes computing discrete logarithms easier. There are three possible scenarios:

1. When given G it is easy (also for the opponent) to find suitable auxiliary groups.
2. The designer of the group G knows suitable auxiliary groups but they are difficult to find for an opponent.
3. The designer of the group G knows that suitable auxiliary groups exist, without knowing them.

Note that the second case can always be transformed into the first by publishing the suitable auxiliary groups. Of course, because this information can only help an opponent in breaking the DH protocol, there is no reason for the designer of the group to make it public.

Constructing a group G of the third type is not difficult: choose a (secret) arbitrary large smooth number m and search for a prime p in the interval $[m - 2\sqrt{m} + 1, m + 2\sqrt{m} + 1]$. A group G whose order contains only such large prime factors satisfies the third property. Note that it is easy to construct, for a given n, a group G for the DH protocol whose order is a multiple of n. One possibility is to find a multiple l of n (where l/n is small) such that $l + 1$ is prime and to use $G = GF(l + 1)^*$. An alternative is to use the construction of Lay and Zimmer [22] for finding an elliptic curve of order n.

The second case is somewhat more involved. Primes p for which the designer knows an auxiliary group over $GF(p)$ can be obtained by choosing a large smooth number m and using the method of Lay and Zimmer [22] for constructing a prime p together with an elliptic curve of order m. When given such prime factors of the group order, a group G can be found as described.

We now consider efficient constructions for the first case. We generalize an algorithm, presented in [47] by Vanstone and Zuccherato, for constructing a large prime p such that either a quarter of the curves $y^2 = x^3 - Dx$ or every sixth curve of the form $y^2 = x^3 + D$ have smooth order. First, we construct primes $p = a^2 + (k \pm 1)^2$ (for a fixed k with l digits) such that $a^2 + k^2$, which is then one of the possible orders of the curves $y^2 = x^3 - Dx$ over $GF(p)$ (see (4)), is smooth.

Let l'-digit numbers x_1, x_2, y_1, and y_2 be chosen at random. Define

$$u + vi := (x_1 + y_1 i)(x_2 + y_2 i);$$

that is,

$$u = x_1x_2 - y_1y_2, \quad v = x_1y_2 + x_2y_1 \ .$$

Then u and v have at most $2l'$ digits. If $\gcd(u, v)$ divides k (otherwise choose again), one can compute numbers c and d (of at most $2l' + l$ digits) such that

$$cv + du = k \ .$$

Define

$$a := cu - dv \ ,$$

and restart the process if a is even. Then

$$a + ki = (c + di)(u + vi) = (c + di)(x_1 + y_1i)(x_2 + y_2i)$$

and

$$a^2 + k^2 = (c^2 + d^2)(x_1^2 + y_1^2)(x_2^2 + y_2^2) \ .$$

The process is repeated until a^2+k^2 is s-digit-smooth, which happens with probability approximately

$$\left(\frac{4l' + 2l}{s}\right)^{-\frac{4l'+2l}{s}} \cdot \left(\frac{2l'}{s}\right)^{-\frac{2l'}{s}} \cdot \left(\frac{2l'}{s}\right)^{-\frac{2l'}{s}}$$

(according to (1)), and smoothness can be tested with the elliptic curve factoring algorithm [23]. Because a and k are odd, exactly one of the expressions $a + (k \pm 1)i$ is congruent to 1 modulo $2 + 2i$. Let $\alpha := a + (k \pm 1)i$, respectively. Repeat the computations until

$$p := \alpha\overline{\alpha} = a^2 + (k \pm 1)^2$$

is prime. According to (4), a quarter of the curves $y^2 = x^3 - Dx$ over $GF(p)$ have smooth order $a^2 + k^2$. Hence p is an $(8l' + 2l)$-digit prime such that an elliptic curve with s-digit-smooth order is constructible over $GF(p)$. The expected number of trials is

$$O\left(\left(\frac{4l' + 2l}{s}\right)^{\frac{4l'+2l}{s}} \cdot \left(\frac{2l'}{s}\right)^{\frac{4l'}{s}} \cdot (8l' + 2l)\right) \ . \tag{15}$$

In a similar way, primes can be constructed such that curves of type $y^2 = x^3 + D$ have smooth order. More precisely, one can generate primes $p = a^2 - a(k\pm1) + (k\pm1)^2$ such that $a^2 - ak + k^2$ is one of the possible orders of the curves $y^2 = x^3 + D$ over $GF(p)$ (see (5)) and s-digit-smooth.

In case of a small k, an L-digit prime p such that an s-digit-smooth curve is constructible over $GF(p)$ can be found by

$$O\left(\left(\frac{L}{\sqrt{8} \cdot s}\right)^{\frac{L}{s}} \cdot L\right)$$

trials instead of

$$O\left(\left(\frac{L}{s}\right)^{\frac{L}{s}} \cdot L\right)$$

trials when varying p among L-digit numbers until p is prime and one of the considered curves is s-digit-smooth. For example, a 100-digit prime p such that a 10-digit-smooth curve over $GF(p)$ is constructible can be found by approximately $3 \cdot 10^6$ trials (instead of about 10^{11} trials when using the straightforward strategy).

Acknowledgment. The authors thank Dan Boneh, Dima Grigoriev, Hendrik Lenstra, Markus Metzger, Victor Shoup, and Igor Shparlinsky for interesting discussions on the subject of this paper, and two anonymous referees for their very helpful comments for improving the presentation.

SELECTING THE MEDIAN*

DORIT DOR† AND URI ZWICK†

Abstract. Improving a long-standing result of Schönhage, Paterson, and Pippenger [*J. Comput. System Sci.*, 13 (1976), pp. 184–199] we show that the *median* of a set containing n elements can always be found using at most $c \cdot n$ comparisons, where $c < 2.95$.

Key words. median selection, comparison algorithms, concrete complexity

1. Introduction.

The *selection problem* is defined as follows: Given a set X containing n distinct elements drawn from a totally ordered domain, and given a number $1 \leq i \leq n$, find the ith *order statistic* of X, i.e., the element of X larger than exactly $i-1$ elements of X and smaller than the other $n-i$ elements of X. The *median* of X is the $\lceil n/2 \rceil$th order statistic of X.

The selection problem is one of the most fundamental problems of computer science and it has been extensively studied. Selection is used as a building block in the solution of other fundamental problems such as sorting and finding convex hulls. It is somewhat surprising therefore that only in the early 1970s was it shown, by Blum et al. [BFP+73], that the selection problem can be solved in $O(n)$ time. As $\Omega(n)$ time is clearly needed to solve the selection problem, the work of Blum et al. completely solves the problem. Or does it?

A very natural setting for the selection problem is the *comparison model*. An algorithm in this model can access the input elements only by performing pairwise comparisons between them. The algorithm is charged only for these comparisons; all other operations are free. The comparison model is one of the few models in which *exact* complexity results may be obtained. What then is the exact comparison complexity of finding the median?

The comparison complexity of many comparison problems is exactly known. It is clear, for example, that exactly $n-1$ comparisons are needed, in the worst case, to find the maximum or minimum of n elements. Exactly $n + \lceil \log n \rceil - 2$ comparisons are needed to find the second largest (or second smallest) element (Schreier [Sch32], Kislitsyn [Kis64]). Exactly $\lceil 3n/2 \rceil - 2$ comparisons are needed to find both the maximum and the minimum of n elements (Pohl [Poh72]). Exactly $2n-1$ comparisons are needed to merge two sorted lists each of length n (Stockmeyer and Yao [SY80]). Finally, $n \log n + O(n)$ comparisons are needed to sort n elements (e.g., Ford and Johnson [FJ59]).

A relatively large gap, considering the fundamental nature of the problem, still remains, however, between the known lower and upper bounds on the exact complexity of finding the median. After presenting a basic scheme by which an $O(n)$ selection algorithm can be obtained, Blum et al. [BFP+73] try to optimize their algorithm and

†Department of Computer Science, School of Mathematical Sciences, Raymond and Beverly Sackler Faculty of Exact Sciences, Tel Aviv University, Tel Aviv 69978, Israel (ddorit@math.tau.ac.il, zwick@math.tau.ac.il).

present a selection algorithm that performs at most $5.43n$ comparisons. They also obtain the first nontrivial lower bound and show that $1.5n$ comparisons are required, in the worst case, to find the median. The result of Blum et al. is subsequently improved by Schönhage, Paterson, and Pippenger [SPP76], who present a beautiful algorithm for the selection of the median, or any other element, using at most $3n + o(n)$ comparisons. In this work we improve the long-standing result of Schönhage, Paterson, and Pippenger and present a selection algorithm that uses at most $2.95n$ comparisons.

Bent and John [BJ85] (see also John [Joh88]), improving previous results of Kirkpatrick [Kir81], Munro and Poblete [MP82], and Fussenegger and Gabow [FG78], obtained a $(1 + H(\alpha))\cdot n - o(n)$ lower bound on the number of comparisons needed to select the αnth element of a set of n elements, where $H(\alpha) = \alpha \log \frac{1}{\alpha} + (1-\alpha) \log \frac{1}{1-\alpha}$ is the binary entropy function (all logarithms in this paper are taken to base 2). We have shown recently [DZ96a] (using somewhat different methods from the ones used here) that the αnth element can be selected using at most $(1 + \alpha \log \frac{1}{\alpha} + O(\alpha \log\log \frac{1}{\alpha}))\cdot n$ comparisons. This for small values of α is almost optimal. The bound of Bent and John gives in particular a $2n - o(n)$ lower bound on the number of comparisons needed to find the median. We have recently improved this lower bound slightly to $(2+\epsilon)n$ ([DZ96b]; see also [Dor95] and [DHUZ96]).

Our work slightly narrows the gap between the best known lower and upper bounds on the comparison complexity of the median problem. Although our improvement is quite modest, many new ideas were required to obtain it. These new ideas shed some more light on the intricacy of the median finding problem.

Algorithms for selecting the ith element for small values of i were obtained by Hadian and Sobel [HS69], Hyafil [Hya76], Yap [Yap76], and Ramanan and Hyafil [RH84]. See also Aigner [Aig82] and Eusterbrock [Eus93].

All the results mentioned so far deal with the number of comparisons needed in the *worst case*. Floyd and Rivest [FR75] showed that the ith element can be found using an *expected* number of $n + i + o(n)$ comparisons. Cunto and Munro [CM89] had shown that the bound of Floyd and Rivest is tight.

The central idea used by Schönhage, Paterson, and Pippenger in their $3n + o(n)$ median algorithm is the idea of *factories*. They use factories for the mass production of certain partial orders at a much reduced cost. To obtain our results we extend the notion of factories. We introduce *green* factories and perform an *amortized* analysis of their production costs. We obtain improved green factories, with which we can improve the $3n + o(n)$ result of Schönhage, Paterson, and Pippenger.

The performance of a green factory is mainly characterized by two parameters u_0 and u_1 (the *upper* and *lower* element costs). Using a green factory with parameters u_0 and u_1 we obtain an algorithm for the selection of the αnth element using at most $(u_0\alpha + u_1(1-\alpha))\cdot n + o(n)$ comparisons. To select the median, we use a factory with $u_0, u_1 \approx 2.95$. Actually, there is a trade-off between the lower and upper costs of a factory. For every $0 < \alpha \le 1/2$ we may choose a factory that minimizes $u_0\alpha + u_1(1-\alpha)$. We can select the $n/4$th element, for example, using at most $2.69n$ comparisons, by using a factory with $u_0 \approx 4$ and $u_1 \approx 2.25$. In this paper, we concentrate on factories for median selection. It is easy to verify that the algorithm described here, as the median finding algorithms of both Blum et al. and Schönhage, Paterson, and Pippenger, can be implemented in linear time in the RAM model.

The best green factories that we have explicitly constructed have lower and upper element costs $u_0, u_1 \simeq 2.942$, yielding a median selection algorithm that uses at

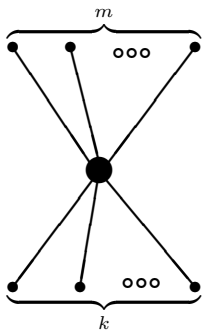

FIG. 2.1. *The partial order* S_k^m.

most $2.942n$ comparisons. These factories are extremely complicated. They employ in particular 16 different subfactories (subfactories are introduced in section 5). A full description of these factories is too long for a journal paper but may be found in [Dor95]. We describe instead a simpler, although still quite complicated, construction that uses only four different subfactories and has $u_0, u_1 \simeq 2.956$. This simpler construction depicts all the ideas used in the construction of the more complicated factories. After describing these simpler factories in full, we give a partial description of the more complicated factories.

A preliminary version of this paper appeared in [DZ95]. There we sketched the construction of a factory that uses only two subfactories and achieves $u_0, u_1 \simeq 2.968$. These are about the simplest factories with which the $3n$ median algorithm of Schönhage, Paterson, and Pippenger can be improved. They do not demonstrate, however, all the ideas required to obtain the $u_0, u_1 \simeq 2.956$ and $u_0, u_1 \simeq 2.942$ factories.

We believe that further small improvements can be obtained by building more complicated factories that use even more subfactories. It seems, however, that new ideas will be needed to obtain a more substantial improvement (see in particular the comments at the end of section 9).

In the next section we describe in more detail the concept of factory production and introduce our notion of a green factory. We also state the properties of the improved factories that we obtain. In section 3 we explain the way in which green factories are used to obtain efficient selection algorithms. The selection algorithm that we describe is a generalization of the median algorithm of [SPP76] and is similar to the selection algorithm that we describe in [DZ96a]. The subsequent sections are then devoted to the construction of our improved green factories. We end with some concluding remarks and open problems.

2. Factory production. Denote by S_k^m a partial order composed of a *center* element, m elements larger than the center and k elements smaller than the center (see Figure 2.1). An S_k^m is sometimes referred to as a *spider*. Schönhage, Paterson, and Pippenger [SPP76] show that producing l disjoint copies of S_k^m usually requires fewer comparisons than l times the number of comparisons required to produce a single S_k^m. The best way, prior to this work, for producing a single S_k^k, for example, required about $6k$ comparisons (find the median of $2k+1$ elements using the $3n+o(n)$ median algorithm). The cost per copy can be cut by almost half if the S_k^k's are mass-produced using factories.

A factory for a partial order P is a comparison algorithm with continual input and output streams. The input stream of a simple factory consists of single elements. When enough elements are fed into the factory, a new disjoint copy of P is produced. A factory is characterized by the following quantities: the *initial cost* I, which is the number of comparisons needed to initialize the factory; the *unit cost* U, which is the number of comparisons needed to generate each copy of P; and finally the *production residue* R, which is the maximum number of elements that can remain in the factory when lack of inputs stops production. For every $l \geq 0$, the cost of generating l disjoint copies of P is at most $I + l \cdot U$. Schönhage, Paterson, and Pippenger [SPP76] construct factories with the following characteristics.

THEOREM 2.1. *There is a factory F_k for S_k^k with initial cost I_k, unit cost U_k, and production residue R_k satisfying $U_k \sim 3.5k$, $I_k = O(k^2)$, $R_k = O(k^2)$.*

The notation $U_k \sim 3.5k$ here means that $U_k = 3.5k + o(k)$. Schönhage, Paterson, and Pippenger also show that if there exist factories F_k, for S_k^k's, satisfying $U_k \sim Ak$, for some $A > 0$, and $I_k, R_k = O(k^2)$, then the median of n elements can be found using at most $An + o(n)$ comparisons. The above theorem therefore immediately implies the existence of a $3.5n + o(n)$ median algorithm.

The way factories are used by selection algorithms is described in the next section. For now, we just mention that most S_k^m's generated by a factory employed by a selection algorithm are eventually broken, with either their upper elements eliminated and their lower elements returned to the factory or vice versa. While constructing an S_k^m, a factory may have compared elements that turned out to be on the same side of the center. If such elements are ever returned to the factory, the known relations among them may save the factory some of the comparisons it has to perform. To capture this, we extend the definition of factories and define green factories (factories that support the recycling of known relations). This extension is implicit in the work of [SPP76]. Making this notion explicit simplifies the analysis of our factories. The $3n + o(n)$ median algorithm of Schönhage, Paterson, and Pippenger is in fact obtained by replacing the factory F_k of Theorem 2.1 by a simple green factory.

A green factory for S_k^m's is mainly characterized by the following two quantities: the *lower element cost* u_0 and the *upper element cost* u_1. Using these quantities, the *amortized* production costs of the factory can be calculated as follows: the amortized production cost of an S_k^m whose upper m elements are eventually returned (together) to the factory is $k \cdot u_0$. The amortized production cost of an S_k^m whose lower k elements are eventually returned (together) to the factory is $m \cdot u_1$. The amortized production cost of an S_k^m such that none of its elements is returned to the factory is $k \cdot u_0 + m \cdot u_1$. Note that in this accounting scheme we attribute all the production cost to elements that are *not* returned to the factory. The initial cost I and the production residue R of a green factory are defined as before. A somewhat different definition of green factory was given by us in [DZ96a]. The definition given here uses amortized costs per *element*, whereas our previous definition used amortized costs per partial order. A green factory does not know in advance whether the lower or upper part of a generated S_k^m will be recycled. This is set by an adversary. Although not stated explicitly, the following result is implicit in [SPP76].

THEOREM 2.2. *There is a green factory G_k for S_k^k with lower and upper element costs $u_0, u_1 \sim 3$, initial cost $I_k = O(k^2)$, and production residue $R_k = O(k^2)$.*

The notation $u_0, u_1 \sim 3$ here means that $u_0, u_1 = 3 + o(1)$, where the $o(1)$ is with respect to k.

We shall see in the next section that a green factory for S_k^k with lower and upper

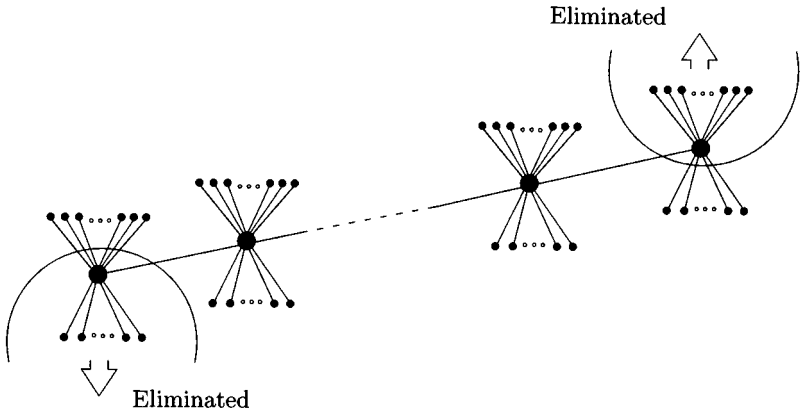

FIG. 3.1. *The ordered list of* $\tilde{\mathcal{S}}_k^k$*'s.*

element costs u_0 and u_1 yields a $(u_0+u_1)/2n+o(1)$ median algorithm. To improve the algorithm of Schönhage, Paterson, and Pippenger it is enough therefore to construct an S_k^k factory with $(u_0+u_1)/2 < 3$. Unfortunately, we are not able to construct such a factory.

However, we are able to reduce the upper and lower element costs if we allow variation among the partial orders generated by the factory. Let $\tilde{\mathcal{S}}_k^k = \{S_{k'}^{k''} : k \le k' \le 2k\ ,\ k \le k'' \le 2k\}$. We construct improved green factories that generate partial orders that are members of $\tilde{\mathcal{S}}_k^k$. These factories can be easily incorporated into the selection algorithm described in the next section. To obtain our $2.95n$ median algorithm we use green $\tilde{\mathcal{S}}_k^k$ factories $\mathcal{G}_k$ with the following characteristics.

THEOREM 2.3. *There is a green* $\tilde{\mathcal{S}}_k^k$ *factory* $\mathcal{G}_k$ *with* $u_0, u_1 \simeq 2.942$, $I_k = O(k^2)$, $R_k = O(k^2)$.

An outline of the ideas used to construct the factories $\mathcal{G}_k$ is given in section 5. The full details are then given in sections 6 through 9.

3. Selection algorithms. In this section we describe our selection algorithm. This algorithm uses an $\tilde{\mathcal{S}}_k^k$ factory. The complexity of the algorithm is completely determined by the characteristics of the factory used. This algorithm is a generalization of the median algorithm of Schönhage, Paterson, and Pippenger and is a slight variation of the selection algorithm that we describe in [DZ96a].

THEOREM 3.1. *Let* $0 < \alpha \le 1/2$. *Let* $\mathcal{F}_k$ *be an* $\tilde{\mathcal{S}}_k^k$ *factory with lower element cost* u_0, *upper element cost* u_1, *initial cost* $I_k = O(k^2)$, *and production residue* $R_k = O(k^2)$. *Then, the* αn*th smallest element, among* n *elements, can be selected using at most* $(\alpha \cdot u_0 + (1-\alpha)\cdot u_1)\cdot n + o(n)$ *comparisons.*

Proof. We refer to the αnth smallest element among the n input elements as the percentile element. The algorithm uses the factory $\mathcal{F}_k$ where $k = \lfloor n^{1/4} \rfloor$. The n input elements are fed into this factory, as singletons, and the production of partial orders $S \in \tilde{\mathcal{S}}_k^k$ commences. The centers of the generated S's are inserted, using binary insertion, into an ordered list L, as shown in Figure 3.1. When the list L is long enough we know either, as we shall soon show, that the center of the upper (i.e., last) S in L and the elements above it are too large to be the percentile element, or that the

center of the lower (i.e., first) S and the elements below it are too small to be the percentile element. Elements too large or too small to be the percentile element are eliminated. The lower elements of the upper S and the upper elements of the lower S are returned to the factory for recycling.

Let t be the current length of the list L and let r be the number of elements currently in the factory. The number of elements that have not yet been eliminated is therefore $N = \Theta(k)\cdot t + r$. Let i be the rank of the percentile element among the noneliminated elements. Initially $N = n$ and $i = \lceil \alpha n \rceil$.

The number of elements in the list known to be smaller than or equal to the center of the upper S of the list is $N_0 = \Theta(k)\cdot t$. The number of elements known to be greater than or equal to the center of the lowest S of the list is $N_1 = \Theta(k)\cdot t$. Note that $N_0 + N_1 = N + t - r$ as the centers of all the S's in the list satisfy both these criteria, the r elements currently in the factory satisfy neither, and all the other noneliminated elements satisfy exactly one of these criteria.

The algorithm consists of the following interconnected processes:

(i) Whenever sufficiently many elements are supplied to the factory $\mathcal{F}_k$, a new partial order $S \in \tilde{\mathcal{S}}_k^k$ is produced and its center is inserted into the list L using binary insertion.

(ii) Whenever $N_0 > i$, the center of the upper partial order $S \in \tilde{\mathcal{S}}_k^k$ in the list and the elements above it are eliminated, because they are too big to be the percentile element. The lower elements of S are recycled.

(iii) Whenever $N_1 > N - i + 1$, the center of the lowest partial order $S \in \tilde{\mathcal{S}}_k^k$ in the list and the elements below it are eliminated, because they are too small to be the percentile element. The upper elements of S are recycled. The value of i is updated accordingly, i.e., i is decremented by the number of elements in the lower part of S (including the center).

If (ii) and (iii) are not applicable, then $N_0 \le i$ and $N_1 \le N - i + 1$. Thus $N + t - r = N_0 + N_1 \le N + 1$ and $t - 1 \le r$. If (i) is not applicable, then by the factory definition we have $r \le R_k$. When none of (i), (ii), and (iii) can be applied we get that $t - 1 \le r \le R_k = O(k^2)$. At this stage $N = O(k^3)$, which is $O(n^{3/4})$, and the ith element among the surviving elements is found using any linear selection algorithm.

We now analyze the comparison complexity of the algorithm. Whenever (ii) is performed, the upper partial order $S \in \tilde{\mathcal{S}}_k^k$ of the list is broken. Its center and upper elements are eliminated and its lower elements are returned to the factory. The amortized production cost of the partial order S is at most u_1 comparisons per each element above the center.

Whenever (iii) is performed, the lowest partial order $S \in \tilde{\mathcal{S}}_k^k$ of the list is broken. Its center and lower elements are eliminated and its upper elements are returned to the factory. The amortized production cost of the partial order S is at most u_0 comparisons per each element below the center.

The algorithm can eliminate at most $(1-\alpha)n$ elements larger than the percentile element and at most αn elements smaller than the percentile element. The total production cost of all partial orders $S \in \tilde{\mathcal{S}}_k^k$ that are eventually broken is therefore at most $(\alpha u_0 + (1-\alpha)u_1)\cdot n + o(n)$. At most $O(k^2)$ generated partial orders $S \in \tilde{\mathcal{S}}_k^k$ are not broken. Their total production cost is $O(k^3)$. The initial production cost is $O(k^2)$. The total number of comparisons performed by the factory is therefore $(\alpha u_0 + (1-\alpha)u_1)\cdot n + o(n)$.

Let t^* be the final length of the list L (when none of (i), (ii), and (iii) is applicable). The total number of partial orders generated by $\mathcal{F}_k$ is at most $n/k + t^*$, as at least k elements are eliminated whenever a partial order is removed from L. The total cost of the binary insertions into the list L is at most $O((n/k + t^*) \cdot \log n) = O((n/k + k^2) \log n)$ which is $o(n)$. The total number of comparisons performed by the algorithm is therefore at most $(\alpha u_0 + (1 - \alpha)u_1) \cdot n + o(n)$, as required. □

Using the factories of Theorem 2.3, we obtain our main result, as follows.

THEOREM 3.2. *Any element, among n elements, can be selected using at most $2.942n + o(n)$ comparisons.*

4. Basic principles of factory design. In this section we give some of the basic principles used to construct efficient factories. The section is divided into three subsections. In the first subsection we remind the reader what *hyperpairs* are and what their *pruning cost* is. In the second subsection we describe the notion of *grafting*. In the third subsection we sketch the construction of the S_k^k factories of Schönhage, Paterson, and Pippenger [SPP76]. These factories are briefly described to illustrate the basic design principles. All the results of this section, except for Theorems 4.5 and 4.6, which are new, are essentially taken from [SPP76]. Some of the proofs are therefore omitted.

Before going into details, we describe a clever accounting principle introduced by Schönhage, Paterson, and Pippenger to simplify the complexity analysis of factories. The information we care to remember on the elements that pass through the factory can always be described using a Hasse diagram. Each comparison made by the algorithm adds an edge to the diagram and possibly deletes some edges that become redundant. At some stages we may decide to "forget" the result of some comparisons, and the edges that correspond to them are removed from the diagram. Schönhage, Paterson, and Pippenger noticed that instead of counting the number of comparisons made, we can count the number of edges cut! To this we should add the number of edges in the eliminated parts of the partial orders as well as the edges that remain in the factory when the production stops. The second number, in our factories, is at most a constant times the production residue of the factory and it can be attributed to the initial cost.

4.1. Hyperpairs. A factory usually starts the production of a partial order from $\tilde{\mathcal{S}}_k^k$ by producing a large partial order, a hyperpair, that contains a partial order from $\tilde{\mathcal{S}}_k^k$.

DEFINITION 4.1. *A hyperpair P_w, where w is a binary string, is a finite partial order with a distinguished element, the center, defined recursively by* (i) *P_λ is a single element (λ here stands for the empty string)*; (ii) *P_{w1} is obtained from two disjoint P_w's by comparing their centers and taking the larger as the new center. P_{w0} is obtained in the same way but taking the smaller of the two centers as the new center.*

The Hasse diagrams of some small hyperpairs are shown in Figure 4.1 (the meaning of the notation H_r will become clear later). Some basic properties of hyperpairs are given in the following lemma.

LEMMA 4.2. *Let c be the center of a hyperpair P_w. Let w_i be the prefix of w of length i. Let h_0 be the number of 0's in w and h_1 be the number of 1's in w. Then*

(1) *the center c together with the elements greater than it form a $P_{0^{h_0}}$ with center c. The elements greater than c form a disjoint set of hyperpairs P_λ, P_0, ..., $P_{0^{h_0-1}}$. The center c together with the elements smaller than it form a $P_{1^{h_1}}$ with center c. The elements smaller than c form a disjoint set of hyperpairs P_λ, P_1, ..., $P_{1^{h_1-1}}$.*

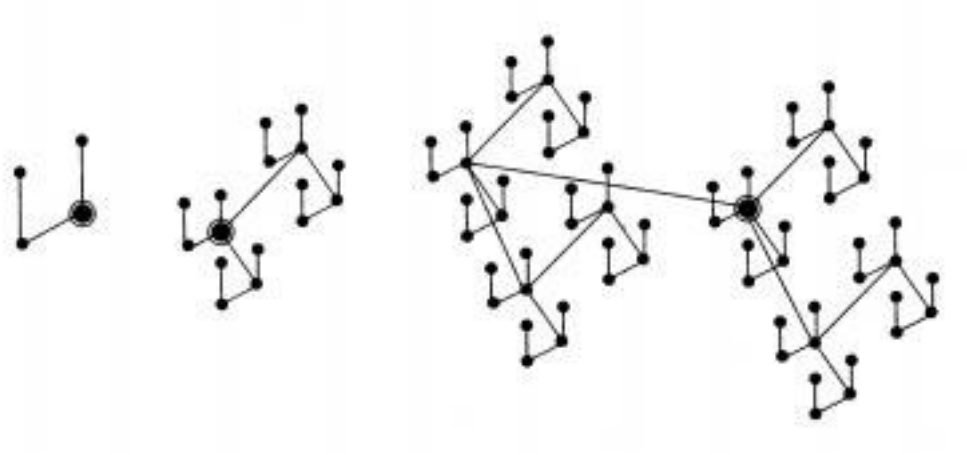

FIG. 4.1. *Some small hyperpairs* ($H_2 = P_{01}$, $H_4 = P_{0110}$, *and* $H_6 = P_{011010}$).

(2) *the hyperpair* P_w *can be parsed into its center* c *and into a disjoint set* $\{P_{w_i} \mid 0 \leq i < |w|\}$ *of smaller hyperpairs. Moreover, the center of* P_{w_i} *is above* c *if* w_{i+1} *ends with* 0 *and below* c *if* w_{i+1} *ends with* 1.

The lemma can be easily proved by induction. Note, in particular, that if $m < 2^{h_0}$ and $k < 2^{h_1}$, then P_w contains an S_k^m. No edges are cut during the construction of hyperpairs. But, before outputting an S_k^m contained in a hyperpair, all the edges connecting the elements of this S_k^m with elements not contained in this S_k^m have to be cut. This rather costly operation is referred to as *pruning*.

The *downward pruning* of a hyperpair P_w is the operation of removing from the hyperpair all the elements that are not known to be smaller or equal to its center c. The *downward pruning cost* $PR_0(w)$ of a hyperpair P_w is the cost of this operation. This cost is equal to the number of edges of the hyperpair that connect the center of P_w and the elements below it to the other elements of P_w. The *upward pruning* and the *upward pruning cost* $PR_1(w)$ of a hyperpair P_w are defined analogously. Let w be a binary string and let h_0 and h_1 be the number of 0's and 1's in it. The pruning costs can be computed using the following recursive relations.

LEMMA 4.3.

(i) $PR_0(\lambda) = 0$, $\quad PR_0(w0) = PR_0(w) + 1$, $\quad PR_0(w1) = 2PR_0(w)$.

(ii) $PR_1(\lambda) = 0$, $\quad PR_1(w0) = 2PR_1(w)$, $\quad PR_1(w1) = PR_1(w) + 1$.

Proof. A P_{w0} is composed of two P_w's and an edge connecting their two centers. If c_1 and c_2 are the centers of these P_w's and $c_1 < c_2$, then c_1 is the center of the hyperpair P_{w0}. To downward prune the hyperpair P_{w0}, all we have to do is downward prune the hyperpair P_w whose center is c_1 and then cut the edge between c_1 and c_2. The cost of this operation is therefore $PR_0(w) + 1$. The other cases are proved similarly. □

We also define the amortized, per element, pruning costs of a hyperpair P_w. Let h_0 and h_1 be the number of 0's and 1's in w and let $h = h_0 + h_1$. We define $pr_0(w) = PR_0(w)/2^{h_1}$ and $pr_1(w) = PR_1(w)/2^{h_0}$ to be the *lower element pruning cost* and the *upper element pruning cost* of w. An immediate consequence of Lemma 4.3 is the following lemma, which is easily proved by induction.

LEMMA 4.4. *Let* $w = \gamma_1\gamma_2 \ldots \gamma_h$ *be a binary string, let* w_i *be the prefix of* w *of length* i, *and let* $h_0(w_i)$ *and* $h_1(w_i)$ *be the number of* 0*'s and* 1*'s, respectively, in* w_i.

Then,

$$pr_0(w) = \sum_{i|\gamma_i=0} 2^{-h_1(w_i)}, \qquad pr_1(w) = \sum_{i|\gamma_i=1} 2^{-h_0(w_i)}.$$

Note, in particular, that if w_i is a prefix of w, then $pr_0(w_i) \leq pr_0(w)$ and $pr_1(w_i) \leq pr_1(w)$.

Usually, especially if grafting processes are also used, we do not want to prune all the elements above or below the center c of a hyperpair P_w. We next estimate the cost of pruning k elements below or above the center of a hyperpair P_w, i.e., the cost of pruning the hyperpair P_w so that all that remains of it is its center and k elements either above or below the center. We show that the cost of pruning k elements below the center of P_w is at most $k \cdot pr_0(w) + h$ while the cost of pruning k elements above the center of P_w is at most $k \cdot pr_1(w) + h$, where h is the length of w. Note that h is also the number of edges connected to the center c of the hyperpair P_w. The h terms in the above estimates will usually be negligible compared to the other terms.

By Lemma 4.2, a hyperpair P_w with center c can be parsed into h_0 hyperpairs $\{P_i^1 \mid 0 \leq i \leq h_0 - 1\}$ whose centers are above c and h_1 hyperpairs $\{P_i^0 \mid 0 \leq i \leq h_1 - 1\}$ whose centers are below c. It is easy to check that the number of elements in P_i^1 which are above the center of this P_i^1, and the number of elements in P_i^0 which are below the center of this P_i^0, are both 2^i (this follows from the fact that the string corresponding to the hyperpair P_i^1 contains exactly i 0's and the string corresponding to the hyperpair P_i^0 contains exactly i 1's). To upward prune $k = k_0 2^0 + k_1 2^1 + \cdots + k_{h-1} 2^{h-1}$ elements from P_w, we upward prune all P_i^1's for which $k_i = 1$ and cut the edges connecting c with the centers of all the other hyperpairs. As the string corresponding to P_i^1 is a prefix of w, the cost of upward pruning P_i^1 is at most $2^i \cdot pr_1(w)$. The cost of cutting the other edges is at most h. Thus, the cost of pruning k elements above the center c is at most $\sum_{i|k_i=1} 2^i \cdot pr_1(w) + h = k \cdot pr_1(w) + h$. All the "wastes" of this process are hyperpairs whose strings are prefixes of w and they can be used therefore for the construction of the next P_w. The cost of pruning k elements below the center is estimated in the same way.

To produce partial orders from $\tilde{\mathcal{S}}_k^k$ for larger and larger values of k, we have to construct larger and larger hyperpairs. When we design a family $\{\mathcal{F}_k\}_{k=1}^{\infty}$ of factories, we usually choose a (semi-) infinite binary string $\mathcal{W}$ and in each member $\mathcal{F}_k$ of this family we construct a hyperpair whose string is a long enough prefix of $\mathcal{W}$. Let w_i be the finite prefix of $\mathcal{W}$ of length i. The lower and upper element pruning costs of an infinite string $\mathcal{W}$ are defined as the limits $pr_0(\mathcal{W}) = \lim_{i\to\infty} pr_0(w_i)$ and $pr_1(\mathcal{W}) = \lim_{i\to\infty} pr_1(w_i)$. We will see in a minute that these limits do exist (they may be $+\infty$).

Let $\mathcal{W} = \gamma_1\gamma_2\ldots$ be an infinite binary string. As before, let $w_i = \gamma_1 \ldots \gamma_i$ be the prefix of $\mathcal{W}$ of length i, and let $h_0(w_i)$ and $h_1(w_i)$ be the number of 0's and 1's in w_i, respectively. It is easy to check that Lemma 4.4 holds also for infinite strings.

Schönhage, Paterson, and Pippenger base their factories on the infinite string $\mathcal{W} = 01(10)^\omega$ for which, as can be easily verified, $pr_0(\mathcal{W}) = pr_1(\mathcal{W}) = 1.5$. (Here and in what follows, we let x^ω denote the infinite string obtained by concatenating an infinite number of copies of the string x, and we let X^ω denote the set of infinite strings obtained by concatenating an infinite number of strings from the set X.) In our factories, we also need hyperpairs with cheaper lower element pruning cost and, alas, more expensive upper element pruning cost, or vice versa. For an infinite binary string $\mathcal{W}$, we let $pr(\mathcal{W}) = pr_0(\mathcal{W}) + pr_1(\mathcal{W})$. The next theorem shows that for every string $\mathcal{W}$ we have $pr(\mathcal{W}) \geq 3$. Theorem 4.6 then shows that for any real number $1 \leq a \leq 2$, there exists an infinite string $\mathcal{W}$ for which $pr_0(\mathcal{W}) = a$ and $pr_1(\mathcal{W}) = 3 - a$.

THEOREM 4.5. *For any $\mathcal{W} \in \{0,1\}^\omega$ we have $pr(\mathcal{W}) \geq 3$ with equality holding if and only if $\mathcal{W} \in \{01,10\}^\omega$.*

Proof. Let $\mathcal{W}$ be an infinite string. As before, we let w_i stand for the prefix of $\mathcal{W}$ of length i. If $\mathcal{W}$ contains only a finite number of 0's or a finite number of 1's, then $pr(\mathcal{W}) = +\infty$. Assume therefore that $\mathcal{W}$ contains an infinite number of 0's and an infinite number of 1's. Using Lemma 4.4 we get that

$$pr(\mathcal{W}) = \sum_{i|\gamma_i=0} 2^{-h_1(w_i)} + \sum_{i|\gamma_i=1} 2^{-h_0(w_i)} = \sum_{i=1}^{\infty} 2^{-h_1(w_i)} + \sum_{i=1}^{\infty} 2^{-h_0(w_i)} - 2,$$

since $\sum_{i|\gamma_i=1} 2^{-h_1(w_i)} = \sum_{i|\gamma_i=0} 2^{-h_0(w_i)} = 1$. Let x_i be the index of the ith 0 in $\mathcal{W}$ and let y_i be the index of the ith 1 in $\mathcal{W}$. Also let $x_0 = y_0 = 1$. It is easy to check that

$$\sum_{i=1}^{\infty} 2^{-h_0(w_i)} = \sum_{i=0}^{\infty} 2^{-i}(x_{i+1} - x_i) = \sum_{i=1}^{\infty} 2^{-i} x_i - 1.$$

A similar relation holds, of course, for $\sum_{i=1}^{\infty} 2^{-h_1(w_i)}$. As a consequence we get that

$$pr(\mathcal{W}) = \sum_{i=1}^{\infty} 2^{-i} x_i + \sum_{i=1}^{\infty} 2^{-i} y_i - 4.$$

This expression is clearly minimized when for every $1 \leq i < j$ we have $x_i, y_i \leq x_j, y_j$. Because all the elements in the sequences $\{x_i\}$ and $\{y_i\}$ are integral and distinct, we get that the minimum is attained when for every $i \geq 1$, either $x_i = 2i-1$ and $y_i = 2i$ or vice versa. This corresponds to strings from $\{01,10\}^\omega$. It is easy to check that for a string $\mathcal{W} \in \{01,10\}^\omega$ we have $pr(\mathcal{W}) = 3$. □

THEOREM 4.6. *For any real number $1 \leq a \leq 2$ there exists a binary sequence $\mathcal{W} \in \{01,10\}^\omega$ for which $pr_0(\mathcal{W}) = a$ and $pr_1(\mathcal{W}) = 3 - a$.*

Proof. Let $0.\alpha_1\alpha_2\ldots$ be the binary representation of $a-1$. Let $\mathcal{W} = \overline{\alpha}_1\alpha_1\overline{\alpha}_2\alpha_2\ldots$, where $\overline{\alpha}$ is the complement of the bit α. Using Lemma 4.4, we get that

$$pr_0(\mathcal{W}) = \sum_{i=1}^{\infty} 2^{-(i-\alpha_i)} = \sum_{i=1}^{\infty} 2^{-i} + \sum_{i|\alpha_i=1} 2^{-i} = 1 + (a-1) = a.$$

Since $\mathcal{W} \in \{01,10\}^\omega$, using the previous theorem we get that $pr_1(\mathcal{W}) = 3 - a$. □

Note, as an example, that if $a = 1.5$, then $a - 1$ is either $0.1000\ldots$ or $0.0111\ldots$ and both $\mathcal{W} = 01(10)^\omega$ and $\mathcal{W} = 10(01)^\omega$ satisfy $pr_0(\mathcal{W}) = pr_1(\mathcal{W}) = 1.5$.

We are already in a position to describe a simple but complete S_k^k factory. Select a string $\mathcal{W}$. Construct a hyperpair P_w that contains the partial order S_k^k, where w is a long enough prefix of $\mathcal{W}$. Prune k elements above and k elements below the center of this P_w. These $2k+1$ elements form a copy of S_k^k. By Lemma 4.2(ii), the remaining elements of P_w form a disjoint collection of partial orders each of the form P_{w_i}, where w_i is some prefix of w. These partial orders are used to construct a new copy of P_w that will be used to construct the next S_k^k. Before we output an S_k^k, we cut the $2k$ edges it contains. When some part of an S_k^k generated by the factory is recycled, the elements returned to the factory (as singletons) are used again for the construction of hyperpairs. It is easy to check that the lower and upper element costs of this simple factory are both $u_0, u_1 \sim pr_0(\mathcal{W}) + pr_1(\mathcal{W}) + 2 = pr(\mathcal{W}) + 2$. For any $\mathcal{W} \in \{01,10\}^\omega$ we get that the lower and upper element costs are $u_0, u_1 \sim 5$.

The above factory can be turned into a green factory by noticing that the elements can be returned to the factory as pairs and not as singletons. The edges of a generated S_k^k are not cut when this S_k^k leaves the factory. Instead, we wait until the elements on one of the sides of this S_k^k are eliminated by the selection algorithm. We then cut the k edges connecting the eliminated elements to the center. By cutting about $k/2$ edges we can break the k noneliminated elements into about $k/2$ pairs, which we then return to the S_k^k factory. These pairs can be used for the construction of the next large hyperpair. The lower and upper element costs of this simple green factory are $u_0, u_1 \sim pr(\mathcal{W}) + 1.5$. For any $\mathcal{W} \in \{01, 10\}^\omega$ we get $u_0, u_1 \sim 4.5$. A slightly more careful consideration shows that the elements of one of the sides can actually be recycled as quartets (P_{00}'s or P_{11}'s), thus cutting only $k/4$ edges. This gives us $u_0 \sim 4.25$ and $u_1 \sim 4.5$ or vice versa.

4.2. Grafting. The costs of the simple factories described above can be significantly improved using *grafting*. We can cheaply find elements that are smaller than the center, or elements that are larger than the center, but usually not both. The process of finding such elements is called grafting. Pruning is then used to obtain elements on the opposite side.

We demonstrate this notion using a simple example, the grafting of singletons. Take an element x, not contained in the hyperpair, and compare it to the center c of the hyperpair. Continue is this way, comparing new elements to the center, until either k elements above the center or k elements below the center are found. Note that no edges are cut in this process. All the grafted elements are put in the output partial order. The pruning process is then used to complete the partial order into an S_k^k. Adding this process to our simple factory for S_k^k, the upper and lower element costs are reduced to $u_1, u_0 \sim \max\{pr_0(\mathcal{W}), pr_1(\mathcal{W})\} + 2$ (note that now we have to prune elements from at most one side). Thus $u_0, u_1 \sim 3.5$ if we take $\mathcal{W} = 01(10)^\omega$ or $\mathcal{W} = 10(01)^\omega$. This supplies a proof to Theorem 2.1. Note that the obtained factory is a degenerate green factory since no relations are recycled. At least one side of each generated S_k^k is composed of singletons, and if this side is recycled, no comparisons can be reused.

4.3. The factories of Schönhage, Paterson, and Pippenger. We now sketch the operation of the green factories G_k obtained by Schönhage, Paterson, and Pippenger [SPP76]. These factories improve upon the simple factories described above by grafting and recycling pairs. They are described here using a new terminology that we also use in the next sections to describe our improved factories.

The factories of Schönhage, Paterson, and Pippenger use two simple pair grafting processes which we refer to as the P_0 and P_1 grafting processes. The two processes are mirror images of each other.

We start with the description of the P_0 grafting process. Let $x < y$ be a pair. Compare x with c, the center of the hyperpair. If $c < x$, then stop. Otherwise, compare y with c. The three possible outcomes of this process are (i) $c < x < y$, (ii) $x < y < c$, and (iii) $x < c < y$. These three outcomes are shown on the left of Figure 4.2 and are denoted, respectively, by X_0^2, X_2^0, and X_1^1. Note that in the second case, the result $x < c$ of the first comparison becomes redundant and the edge corresponding to it, shown dashed in the figure, is cut. Similarly, in the third case, the relation $x < y$ becomes redundant and the corresponding edge is cut.

The P_1 grafting process is, as mentioned, the mirror image of the P_0 grafting process. Let $x < y$ be a pair. Compare y with c and if $c < y$, also compare x with c. The three possible outcomes of this process, denoted by Y_2^0, Y_0^2, and Y_1^1, are shown

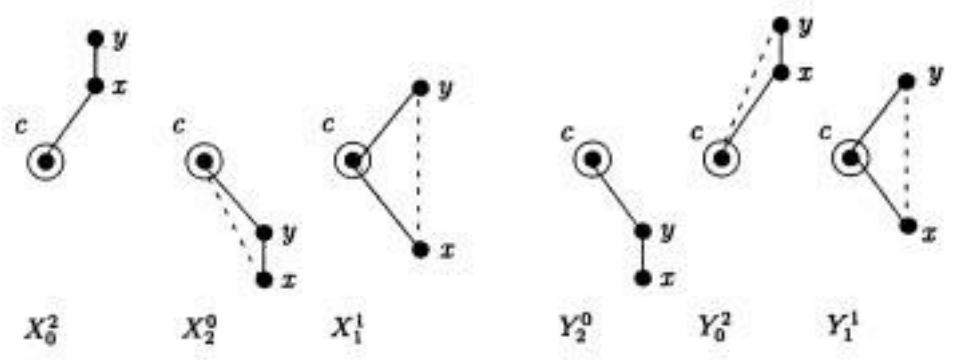

FIG. 4.2. *Possible outcomes of the simple pair grafting processes.*

TABLE 4.1
The costs of the possible outcomes of the simple pair grafting processes.

Outcome	Above	Below	*gen*	rec_0	rec_1
X_0^2	P_0	—	0	2	1
X_2^0	—	P_0	1	1	2
X_1^1	P_λ	P_λ	1	2	2
Outcome	Above	Below	*gen*	rec_0	rec_1
Y_2^0	—	P_0	0	1	2
Y_0^2	P_0	—	1	2	1
Y_1^1	P_λ	P_λ	1	2	2

on the right of Figure 4.2. Note that the outcome of Y_1^1 of the P_1 grafting process is identical to the outcome X_1^1 of the P_0 grafting process. The outcomes Y_2^0 and X_2^0, and Y_0^2 and X_0^2 have the same forms but different costs are associated with them. No edges are cut while producing X_0^2 and Y_2^0, while a single edge is cut while producing X_2^0 and Y_0^2.

The costs associated with each one of the outcomes obtained by these processes are summarized in Table 4.1. If X is an outcome of a grafting process, then $gen(X)$ is the number of edges cut during the generation of X, $rec_0(X)$ is the number of edges cut when the lower part of the spider to which the outcome X belongs is recycled while the upper part is eliminated, and $rec_1(X)$ is defined analogously as the number of edges cut when the upper part of X is recycled and the lower part eliminated.

The factory G_k starts by producing hyperpairs corresponding to prefixes of the string $\mathcal{W} = 01(10)^\omega$ (the string $\mathcal{W} = 10(01)^\omega$ could also be used). Let w_i be the prefix of $\mathcal{W}$ of length i and let $H_i = P_{w_i}$. Some small H_i's are shown in Figure 4.1. By Lemma 4.2, an H_{2r}, where $r = \lceil \log(k+1) \rceil$, contains an S_k^k. After constructing an H_{2r}, the factory initiates the pair grafting processes. The algorithm keeps two counters n_0 and n_1 of the number of grafted elements already obtained above and below the center c of the hyperpair H_{2r}. If $n_0 > n_1$, then the P_1 grafting process is applied. If $n_0 \leq n_1$, then the P_0 grafting process is applied. The grafting continues until either $n_0 \geq k$ or $n_1 \geq k$. All the elements on at least one side of the spider are thus obtained using grafting. Missing elements on the opposite side are then obtained using pruning. The operation of the algorithm is summarized in Figure 4.3.

The intuition behind this algorithm is simple. If we already have many grafted

```
Construct a hyperpair H_{2r}, where r = ⌈log(k+1)⌉.
Initialize n_0, n_1 ← 0.
while n_0 < k and n_1 < k do
{
      if n_0 > n_1 then
      {
         Apply the P_1 grafting process on a pair x < y;
         if x < y < c then n_0 ← n_0 + 2 ;  /* Y_2^0 */
         if c < x < y then n_1 ← n_1 + 2 ;  /* Y_0^2 */
         if x < c < y then n_0 ← n_0 + 1 ; n_1 ← n_1 + 1 ;  /* Y_1^1 */
      }
      else
      {
         Apply the P_0 grafting process on a pair x < y;
         if c < x < y then n_1 ← n_1 + 2 ;  /* X_0^2 */
         if x < y < c then n_0 ← n_0 + 2 ;  /* X_2^0 */
         if x < c < y then n_0 ← n_0 + 1 ; n_1 ← n_1 + 1 ;  /* X_1^1 */
      }
}

if n_0 < k then prune k − n_0 elements below the center c of H_{2r}.
if n_1 < k then prune k − n_1 elements above the center c of H_{2r}.
```

FIG. 4.3. *The factory of Schönhage, Paterson, and Pippenger.*

elements below the center, then by comparing c with the larger element y of a pair $x < y$, we force the adversary to select one of the following two options: (1) give us another pair below the center; (2) give us at least one additional element above the center. In both cases we stand to gain. In the first case, the elements below the center are organized in pairs, not in singletons, and their recycling cost is therefore reduced. In the second case, we get relatively cheap elements above the center, in addition to cheap elements that were already obtained below the center.

The elements above the center of the generated S_k^k form a collection of disjoint P_{0^i}'s and the elements below the center form a collection of disjoint P_{1^i}'s. When the lower or upper part of an S_k^k is returned to the factory, some of the existing relations among the elements returned are utilized. The amortized analysis of the green factory G_k encompasses a trade-off between the cost of generating an S_k^k and the utility obtained from its lower or upper parts when these parts are recycled. Although the S_k^k's generated by the factory of Schönhage, Paterson, and Pippenger may contain P_{0^i}'s and P_{1^i}'s, where $i > 1$, their factory is capable only of utilizing pairwise disjoint relations among the elements returned to it (as their grafting processes can use only pairs). If a P_{0^i} or a P_{1^i}, with $i > 1$, is returned to the factory, it is immediately broken into 2^{i-1} P_0's or P_1's. Note that both P_0 and P_1 simply stand for a pair of elements. It can be checked (see [SPP76]) that the upper and lower element costs of this factory are $u_1, u_0 \sim 3$. This is the best factory obtained by Schönhage, Paterson, and Pippenger.

5. Advanced principles of factory design. In this section, we outline the principles used to construct our improved factories. The first of these principles was already mentioned.

- Allowing variations in the produced partial orders.
  Our factories construct partial orders from $\tilde{\mathcal{S}}_k^k$. The exact proportion between the number of elements below and above the center of a generated partial order is not fixed in advance.
- Recycling larger relations.
  The factories of Schönhage, Paterson, and Pippenger are capable only of recycling singletons and pairs (i.e., P_0's, P_1's, and P_λ's). Our factories recycle larger constructs such as quartets (P_{00}'s and P_{11}'s), octets (P_{000}'s and P_{111}'s), 16-tuples (P_{0000}'s and P_{1111}'s), as well as pairs, singletons, and other structures (e.g., I_3's, sorted lists of three elements) which are not hyperpairs (see Figure 9.1). The nonhyperpair constructs are obtained by the more sophisticated grafting processes used.

  As pairs can be used both as P_0's and P_1's, they can be used to construct a hyperpair P_w, no matter what the string w is. This is one of the reasons why recycling pairs is easier than recycling larger hyperpairs. Quartets such as P_{00}'s (or their equivalent P_{01}'s), for example, can be used to construct a hyperpair P_w only if w starts with 0. More limitations are imposed when larger hyperpairs are considered. Nonhyperpairs cannot be used directly for the construction of hyperpairs.

  To enable the recycling of larger relations, we must be able to use them for the construction of hyperpair-like relations. We should also be able to use them for grafting.
- Constructing hyper-products.
  As mentioned, our factories may receive partial orders that could not be used for the construction of hyperpairs. These partial orders are used instead for the construction of *hyper-products*. A hyper-product $P_w \circ I$, where I is some partial order with a distinguished element, which is again called a center, is a hyperpair P_w in which each of its elements is also the center of a disjoint copy of the partial order I. Hyperpairs are, of course, special cases of hyper-products as $P_w \circ P_0 = P_{0w}$ and $P_w \circ P_1 = P_{1w}$.

  Some of the partial orders I used for hyper-products construction are unbalanced. To counter this, they are composed with oppositely unbalanced hyperpairs.
- Grafting larger relations and mass-grafting.
  The factories of Schönhage, Paterson, and Pippenger use a simple pair of pair grafting processes. We use more complicated grafting processes, even for grafting pairs. For each input construct we have several different grafting processes. Some of our grafting processes use the technique of mass production.

  Our factories apply each grafting process a certain number of times and record the number of times each outcome is obtained. From time to time, they decide to place a combination of outcomes, that tend to balance each other nicely, in the output partial order. The factory algorithms ensure that for any adversary strategy, if each grafting process is applied a certain number of times, then at least one such balanced combination can be put in output partial order. The output combinations are chosen to have low "local" lower and upper unit costs. The maxima of all these local upper and lower element

costs are the overall upper and lower element costs of the factory.

- Using subfactories.
  The factories of Schönhage, Paterson, and Pippenger generate only a single family of hyperpairs (corresponding to $\mathcal{W} = 01(10)^\omega$). Our factories generate several types of hyperpairs and hyper-products, as mentioned above. The construction of each one of these hyper-products is carried out in a separate subproduction unit that we refer to as a subfactory. Different subfactories also differ in the "raw materials" that they can process.
- Using credits in an amortized complexity analysis.
  The last principle is an accounting principle. The different constructs recycled by our factories are of different quality. Some of them, like pairs and I_3's (sorted lists of three elements), can be used very efficiently for the construction of partial orders from $\tilde{\mathcal{S}}_k^k$. Others, like P_{000}'s and P_{0000}'s, are not so appropriate for this process as they are extremely unbalanced, and using them as raw materials for the construction of partial orders from $\tilde{\mathcal{S}}_k^k$ results in a much higher production cost. To equalize these costs, each construct used by our factories is assigned a *credit*, which may be either positive or negative. The credit assigned to a construct Q is denoted by $credit(Q)$. When a construct Q is recycled, extra $credit(Q)$ comparisons are charged to the partial order from $\tilde{\mathcal{S}}_k^k$ that is being broken. These $credit(Q)$ comparisons can then be deducted from the cost of the partial order from $\tilde{\mathcal{S}}_k^k$ that will be constructed using this construct Q. High-quality materials, such as I_3's, carry negative credits. The credits attached to singletons (P_λ's) must be zero since the singletons initially fed into the factory carry no credit.

In the next section we describe the general framework of our improved factories. This framework combines the principles put forth in this and in the previous sections. We also give a general description of the complexity analysis.

6. The framework of the improved factories. A factory $\mathcal{G}$ of the type we are using is composed of several subfactories $g_1, \ldots, g_r$. These subfactories are activated in "parallel." Each subfactory is either working on the construction of a partial order from $\tilde{\mathcal{S}}_k^k$ or waiting for additional raw materials. Whenever the construction of a partial order from $\tilde{\mathcal{S}}_k^k$ in one of subfactories is finished, this partial order is output and the subfactory begins to work on the construction of a new partial order from $\tilde{\mathcal{S}}_k^k$. While designing such a factory we have to make sure that if enough materials are fed into the whole factory, then at least one of its subfactories can make progress in constructing the next partial order from $\tilde{\mathcal{S}}_k^k$. The production residue of the factory $\mathcal{G}$ is the sum of the production residues of the subfactories $g_1, \ldots, g_r$.

The operation of each subfactory is essentially independent of the operation of the other subfactories. Each subfactory processes a specific type (or in some cases, specific types) of input constructs. There may be, for example, a P_{00}-processing subfactory, an I_3-processing subfactory, and so on. A construct recycled to the factory $\mathcal{G}$ is immediately fed to an appropriate subfactory. A Q-processing subfactory (a Q subfactory for short) may sometimes produce, as by-products, partial orders which are not Q's. These partial orders are immediately fed into subfactories that can consume them.

The upper and lower element costs of $\mathcal{G}$ are the maxima of the (amortized) upper and lower element costs of $g_1, \ldots, g_r$. The credits attached to the different constructs are used to equalize the costs of the different subfactories, thereby reducing their maximum. The credits selected optimize a natural trade-off between the generation cost

of an output partial order that contains a partial order Q and the cost of utilizing Q when it is recycled.

The factory $\mathcal{G}$ can be viewed as the "union" of the subfactories $g_1, \ldots, g_r$. In the next subsection we describe the structure of a generic subfactory. In subsection 6.2 we then describe the cost analysis of a generic subfactory.

6.1. The structure of a generic subfactory. Each subfactory g is composed of a hyper-product generation process, a hyper-product pruning process, a collection $A_1, A_2, \ldots, A_\ell$ of grafting processes, and a list $C_1, C_2, \ldots, C_m$ of output combinations.

The operation of each subfactory, like the simple factories described in section 4, is composed of three main phases. In the first phase a large hyper-product is constructed using the hyper-product generation process. In the second stage the grafting processes $A_1, A_2, \ldots, A_\ell$ are activated. Whenever a combination of outcomes from the list $C_1, C_2, \ldots, C_m$ is encountered, this combination is placed in the output partial order. The process continues until at least k grafted elements are obtained either above or below the center c of the hyper-product. An appropriate number of elements, determined by the output combinations that were used, is then pruned using the hyper-product pruning process. The factory then outputs the partial order generated.

The hyper-product construction process of a subfactory must be able to use all the constructs that may be fed into the subfactory as inputs. For each possible input construct there should also be at least one grafting process that can utilize it. Typically, a subfactory would have more than one such grafting process for each possible input construct. This gives the subfactory the freedom to choose different grafting processes in different circumstances and helps balance the upper and lower costs of the subfactory.

Each grafting process A_i has a list $a_{i,1}, a_{i,2}, \ldots, a_{i,l_i}$ of possible outcomes. Let $c_1(a_{i,j})$ and $c_0(a_{i,j})$ denote the upper and lower costs of $a_{i,j}$ (these costs are defined in the next subsection) and let $n_1(a_{i,j})$ and $n_0(a_{i,j})$ denote the number of elements above and below c, respectively, in the outcome $a_{i,j}$. When applying the grafting process A_i we do not know in advance which outcome will result. This is decided by the adversary.

For accounting purposes, it is convenient to view pruning as a special grafting process. We therefore refer to pruning as the 0th grafting process A_0 and let $a_{0,0}$ and $a_{0,1}$ stand for lower and upper pruned elements. The costs $c_0(a_{0,0})$ and $c_1(a_{0,1})$ are just and lower and upper element pruning costs. This special "grafting" process is different from the other grafting processes in two major respects. The first is that the algorithm, and not the adversary, chooses the outcome. The second is that elements are not pruned one at a time. Instead, two counters are used to maintain the number of elements that should be pruned above and below the center. The required numbers of elements are then pruned after all the grafting processes have finished.

An output combination $C_i = (r_{i,1} \times b_{i,1}, r_{i,2} \times b_{i,2}, \ldots, r_{i,s_i} \times b_{i,s_i})$ is a weighted list of outcomes, where $r_{i,1}, r_{i,2}, \ldots, r_{i,s_i} > 0$ are *real* numbers and each $b_{i,j}$ is an outcome $a_{i',j'}$ of one of the grafting processes A_0 and $A_1, \ldots, A_\ell$ employed by the subfactory (the use of real numbers will be justified later). Note that A_0 is the pruning process of the subfactory, disguised as a grafting process, and an output combination may therefore involve elements that should be obtained by pruning. In our factories most combinations involve only two outcomes.

For each possible outcome $a_{i,j}$ of the grafting processes, the subfactory maintains a counter $\#(a_{i,j})$ of the number of outcomes of type $a_{i,j}$ which were obtained but not

yet consumed. Initially $\#(a_{i,j}) = 0$ for every $i \geq 1$ and $j \geq 1$, and $\#(a_{0,j}) = 2k$, for $j = 0, 1$. Recall that $a_{0,0}$ and $a_{0,1}$ represent pruned elements. The initial values given to $\#(a_{0,0})$ and $\#(a_{0,1})$ reflect the fact that up to $2k$ elements can be pruned on either side of the hyper-product constructed by the subfactory. Two more counters k_0 and k_1 maintain the number of elements below and above the center c that were already placed in the output partial order. The counters k_0 and k_1 are initially set to 0.

An output combination $C_i = (r_{i,1} \times b_{i,1}, r_{i,2} \times b_{i,2}, \ldots, r_{i,s_i} \times b_{i,s_i})$ can be applied if $\#(b_{i,j}) \geq r_{i,j}$ for every $1 \leq j \leq s_i$. If these conditions are satisfied, then $r_{i,j}$ copies of outcome $b_{i,j}$, for $1 \leq j \leq s_i$, are "placed" in the output partial order and all the counters are updated accordingly. The output combination C_i contains $n_0(C_i) = \sum_{j=1}^{s_i} r_{i,j} n_0(b_{i,j})$ elements below the center c and $n_1(C_i) = \sum_{j=1}^{s_i} r_{i,j} n_1(b_{i,j})$ elements above the center c of the hyper-product. All the combinations used in our factories satisfy the condition $\frac{1}{2} < n_0(C_i)/n_1(C_i) < 2$. The partial orders produced by our factories are therefore of the form $S_{k'}^{k''}$, where $k \leq k' \leq 2k$ and $k \leq k'' \leq 2k$, and hence members of $\tilde{\mathcal{S}}_k^k$. The factor 2 used in the definition of $\tilde{\mathcal{S}}_k^k$ is arbitrary and can be increased if necessary.

The subfactory applies each grafting process A_i, where $1 \leq i \leq \ell$, sufficiently many times so that there is at least one outcome $a_{i,j}$ for which $\#(a_{i,j}) \geq \mathit{quota}$, where *quota* is some sufficiently large constant. A suitable choice for quota is the maximum $\max_{i,j} r_{i,j}$ of the coefficients that appear in the output combinations of the subfactory. The combination list of the subfactory should have the property that if for each $1 \leq i \leq l$ there exists at least one $1 \leq j \leq l_i$ such that $\#(a_{i,j}) \geq$ quota, then at least one of the output combinations can be applied. This ensures that the subfactory will never get "stuck," no matter what the outcomes of the grafting processes will be.

In the above description, we speak freely about placing $r_{i,j}$ copies of an outcome $b_{i,j}$ in the output partial order, although $r_{i,j}$ was not necessarily an integer. This was done, however, only for accounting purposes. The outcomes (or fractions of outcomes) placed in the output partial order are the outcomes whose cost was already accounted for. At most a fixed number of outcomes of each type are unaccounted for by this analysis. Their contribution to the cost, therefore, is negligible. These unaccounted-for outcomes can either be placed in the output partial order or be used to construct the next output partial order.

A pseudocode describing the operation of a generic subfactory is given in Figure 6.1.

6.2. The analysis of a generic subfactory. We now turn to the complexity analysis of a generic subfactory. We start by defining the lower and upper costs of each outcome $a_{i,j}$ of the grafting processes. Let $I_1, \ldots, I_r$ be the input constructs consumed by the flow of the grafting process A_i that produces $a_{i,j}$. Let $V_1, \ldots, V_s$ be the constructs above the center c of the hyper-product from which the outcome $a_{i,j}$ is composed, and let $\Lambda_1, \ldots, \Lambda_t$ be the constructs below the center c from which $a_{i,j}$ is composed. Let $R_1, \ldots, R_p$ be the leftovers of this process, i.e., the parts of $I_1, \ldots, I_r$ that do not become parts of either $V_1, \ldots, V_s$ or $\Lambda_1, \ldots, \Lambda_t$. The leftovers $R_1, \ldots, R_p$ are recycled to the appropriate subfactory.

The *generation cost*, $\mathit{gen}(a_{i,j})$, of an outcome $a_{i,j}$ is the number of edges cut during the generation of an $a_{i,j}$. The *lower separation cost*, $\mathit{sep}_0(a_{i,j})$, of an $a_{i,j}$ is the number of edges that have to be cut to separate the constructs $\Lambda_1, \ldots, \Lambda_t$ from the center c of the hyper-product. The *lower elimination cost*, $\mathit{elm}_0(a_{i,j})$, of an $a_{i,j}$ is the number of edges that have to be cut to turn all the elements of $\Lambda_1, \ldots, \Lambda_t$ into singletons (and disconnect them from the center). The Hasse diagram of most

1. Generate a hyper-product with at least $2k$ elements on either side of its center c.
2. Initialize the counters:
   $\#(a_{0,j}) \leftarrow 2k$ for $j = 0, 1$;
   $k_0, k_1 \leftarrow 0$;
3. Perform the following steps until $k_0 \geq k$ and $k_1 \geq k$:
   (a) `for` $i \leftarrow 1$ `to` l `do` /* Activate grafting processes */
   `while` $\max\{\#(a_{i,1}), \ldots, \#(a_{i,l_i})\} < quota$ activate grafting process A_i.
   (b) `for` $i \leftarrow 1$ `to` m `do` /* Find appropriate output combinations */
   `if` $\#(b_{i,j}) \geq r_{i,j}$ `for` $1 \leq j \leq s_i$ `then`
   {
   $\#(b_{i,j}) \leftarrow \#(b_{i,j}) - r_{i,j}$ for $1 \leq j \leq s_i$;
   $k_0 \leftarrow k_0 + \sum_{j=1}^{s_i} r_{i,j} \cdot n_0(b_{i,j})$;
   $k_1 \leftarrow k_1 + \sum_{j=1}^{s_i} r_{i,j} \cdot n_1(b_{i,j})$
   }
4. Let $p_0 \leftarrow 2k - \#(a_{0,0})$ and $p_1 \leftarrow 2k - \#(a_{0,1})$;
   Prune p_0 and p_1 elements below and above c, respectively.
5. Output the partial order and return to 1.

FIG. 6.1. *The generic subfactory algorithm.*

outcomes is acyclic and the lower elimination cost in such a case is just the number of elements contained in the constructs $\Lambda_1, \ldots, \Lambda_t$. The *upper separation cost*, $sep_1(a_{i,j})$, and the *upper elimination cost*, $elm_1(a_{i,j})$, are defined analogously.

When the lower side of an outcome $a_{i,j}$ is recycled, the upper side is eliminated and vice versa. Hence, we define the *lower recycling cost*, $rec_0(a_{i,j})$, of the outcome $a_{i,j}$ as $sep_0(a_{i,j}) + elm_1(a_{i,j})$. The *upper recycling cost*, $rec_1(a_{i,j})$, of $a_{i,j}$ is defined analogously as $sep_1(a_{i,j}) + elm_0(a_{i,j})$.

Each input construct I_l, where $1 \leq l \leq r$, used in the flow of the grafting process that generates the outcome $a_{i,j}$ carries a credit of $credit(I_l)$ units. These credit units help "finance" the generation of $a_{i,j}$. If the lower part of the partial order generated using the outcome $a_{i,j}$ is eventually eliminated and its upper part recycled, we have to attach $credit(V_l)$ credit units to each of the constructs $V_1, \ldots, V_s$. If, on the other hand, the upper part is eliminated and the lower part recycled, we have to attach $credit(\Lambda_l)$ credit units to each of the constructs $\Lambda_1, \ldots, \Lambda_t$. Similarly, we have to attach $credit(R_l)$ credit units to each of the leftover $R_1, \ldots, R_p$. The *lower cost* $c_0(a_{i,j})$ and the *upper cost* $c_1(a_{i,j})$ of the outcome $a_{i,j}$ are thus defined as

$$c_0(a_{i,j}) = gen(a_{i,j}) + rec_1(a_{i,j}) - \sum_{l=1}^{r} credit(I_l) + \sum_{l=1}^{s} credit(V_l) + \sum_{l=1}^{p} credit(R_l),$$

$$c_1(a_{i,j}) = gen(a_{i,j}) + rec_0(a_{i,j}) - \sum_{l=1}^{r} credit(I_l) + \sum_{l=1}^{t} credit(\Lambda_l) + \sum_{l=1}^{p} credit(R_l).$$

As mentioned before, our grafting procedures may use mass production. Hence, the costs $gen(a_{i,j})$, $rec_0(a_{i,j})$, and $rec_1(a_{i,j})$ are amortized costs and $I_1, \ldots, I_r$ are the constructs used for the construction of a single copy of the outcome $a_{i,j}$.

Let $C_i = (r_{i,1} \times b_{i,1}, \ldots, r_{i,s_i} \times b_{i,s_i})$ be an output combination. The *local upper element cost*, $u_1(C_i)$, and the *local lower element cost*, $u_0(C_i)$, of the combination C_i are defined, temporarily, as

$$u_0(C_i) = \sum_{j=1}^{s_i} r_{i,j} \cdot c_0(b_{i,j}) \Big/ \sum_{j=1}^{s_i} r_{i,j} \cdot n_0(b_{i,1}) \ , \ u_1(C_i) = \sum_{j=1}^{s_i} r_{i,j} \cdot c_1(b_{i,j}) \Big/ \sum_{j=1}^{s_i} r_{i,j} \cdot n_1(b_{i,1}).$$

This definition, however, is not completely adequate. So far, we have attached credits to individual constructs. We would sometimes like to attach credits to combinations of constructs. It turns out that there are some constructs that can be more efficiently utilized when constructs of a different kind are also available. As a concrete example, we will see in the next sections that quartets (P_{00}'s and P_{11}'s) can be utilized much more efficiently if some pairs (P_0's and P_1's) are also available. More specifically, we will be in a situation in which $credit(P_0) = 0$ and $credit(P_{00}) > 0$, i.e., pairs carry no credit while each quartet on its own should carry some positive credit. In contrast, a combination composed of a quartet and pair, and in fact a combination composed of up to a fixed constant $\gamma > 1$ of quartets and of a single pair, could be recycled without any credit, i.e., $credit(P_0, \gamma \times P_{00}) = 0$. The credit that needs to be attached to a collection of constructs may therefore be smaller than the sum of the individual credits that should be attached to each member of this collection.

The above temporary definition of $u_0(C_i)$ and $u_1(C_i)$ does not take such considerations into account. It is not enough to replace the sums $\sum_{l=1}^{s} credit(V_l)$, $\sum_{l=1}^{t} credit(\Lambda_l)$, and $\sum_{l=1}^{p} credit(R_l)$ in the definitions of $c_0(a_{i,j})$ and $c_1(a_{i,j})$ with $credit(V_1, \ldots, V_s)$, $credit(\Lambda_1, \ldots, \Lambda_t)$, and $credit(R_1, \ldots, R_p)$, respectively, as good combinations may be formed using constructs obtained while constructing or recycling different outcomes that participate in the output combination. As an example, pairs are perhaps obtained when the $b_{i,1}$'s outcomes that participate in the output combination are recycled while quartets are perhaps obtained when the $b_{i,2}$'s outcomes are recycled. We therefore amend the definitions of $u_0(C_i)$ and $u_1(C_i)$ in the following way:

$$u_0(C_i) = \frac{\left\lfloor \sum_{j=1}^{s_i} r_{i,j} \cdot (gen(b_{i,j}) + rec_1(b_{i,j})) \right\rfloor - \sum_{I \in \mathcal{I}_i} credit(I) + credit(\mathcal{V}_i) + credit(\mathcal{R}_i)}{\sum_{j=1}^{s_i} r_{i,j} \cdot n_0(b_{i,j})}, \tag{6.1}$$

$$u_1(C_i) = \frac{\left\lfloor \sum_{j=1}^{s_i} r_{i,j} \cdot (gen(b_{i,j}) + rec_0(b_{i,j})) \right\rfloor - \sum_{I \in \mathcal{I}_i} credit(I) + credit(\Lambda_i) + credit(\mathcal{R}_i)}{\sum_{j=1}^{s_i} r_{i,j} \cdot n_1(b_{i,j}))}, \tag{6.2}$$

where $\mathcal{I}_i$, Λ_i, $\mathcal{V}_i$, and $\mathcal{R}_i$ are the (weighted) collections of all input constructs, recycled constructs, and leftovers involved in the generation and the recycling of all the outcomes composing the combination C_i. The terms $credit(\mathcal{V}_i)$, $credit(\Lambda_i)$, and $credit(\mathcal{R}_i)$ represent the credits that should be attached to the collections $\mathcal{V}_i$, Λ_i, and $\mathcal{R}_i$.

In practice, credits are attached separately to most constructs involved in the collections Λ_i, $\mathcal{V}_i$, and $\mathcal{R}_i$. In the factory described in section 8, for example, the only exception to this is the grouping of pairs and quartets together and the formation of compound constructs of the form $(P_0, \gamma \times P_{00})$.

In general, each factory $\mathcal{G}$ has a set $\mathcal{P}$ of both simple and compound constructs to which credits are assigned. The set $\mathcal{P}$ includes all the basic constructs that can be consumed and that are recycled by the factory. Every collection Λ_i, $\mathcal{V}_i$, or $\mathcal{R}_i$ of constructs is then treated as a combination of constructs taken from $\mathcal{P}$ in a way that minimizes the total credit that should be attached to the collection.

The lower and upper element costs $u_0(g)$ and $u_1(g)$ of the subfactory g with a list $C_1, \ldots, C_m$ of output combinations are defined to be

$$u_0(g) = \max_{i=1}^{m} u_0(C_i), \qquad u_1(g) = \max_{i=1}^{m} u_1(C_i).$$

We are now in a position to state the following theorem.

THEOREM 6.1. *If $\mathcal{G}$ is a factory that employs the subfactories $g_1, g_2, \ldots, g_r$, then the lower and upper element costs of the factory $\mathcal{G}$ are*

$$u_0(\mathcal{G}) \sim \max_{j=1}^{r} u_0(g_j), \qquad u_1(\mathcal{G}) \sim \max_{j=1}^{r} u_1(g_j).$$

Proof. Let $\mathcal{P}$ be the set of basic and compound constructs recycled by the factory $\mathcal{G}$. We assume that for each construct from $\mathcal{P}$ there is at least one subfactory among $g_1, g_2, \ldots, g_r$ that can consume it. We also assume that each subfactory g_j, where $1 \le j \le r$, has an adequate list of output combinations, in the sense that if each grafting process employed by g_j is applied sufficiently many times, then at least one output combination can be used. We also assume that if enough input constructs are fed into the factory, then at least one subfactory can generate a partial order from $\tilde{\mathcal{S}}_k^k$.

Each construct from $\mathcal{P}$ has a specific amount of credit attached to it. The credit attached to singletons (P_λ's) is zero. The singletons that are initially fed into the factory thus carry the required amount of credit. Whenever constructs from $\mathcal{P}$ are recycled, we make sure that they too carry the correct credit. Each amount of credit used in the construction of a partial order from $\tilde{\mathcal{S}}_k^k$ is therefore paid for in full during the generation of other partial orders from $\tilde{\mathcal{S}}_k^k$.

The local upper and lower element costs of a combination C_i used in one of the factories were defined as $u_0(C_i) = c_0(C_i)/n_0(C_i)$ and $u_1(C_i) = c_1(C_i)/n_1(C_i)$, where $c_0(C_i)$ and $c_1(C_i)$ are the amortized lower and upper costs of the combination C_i (the numerators of (6.1) and (6.2)), and $n_0(C_i)$ and $n_1(C_i)$ are the number of elements in C_i above and below the center (the denominators of (6.1) and (6.2)). Let $u_0 = \max_{j=1}^{r} u_0(g_j)$ and $u_1 = \max_{j=1}^{r} u_1(g_j)$. It follows that for every combination C_i used in one of the subfactories $g_1, \ldots, g_r$ we have $u_0(C_i) \le u_0$ and $u_1(C_i) \le u_1$.

Suppose that an output partial order is generated in subfactory g_j. Suppose that $C_{i_1}, C_{i_2}, \ldots, C_{i_a}$ are the output combinations that contribute to this output partial order. The total amortized cost of producing the partial order, eliminating its lower side and recycling its upper side, is $\sum_{l=1}^{a} c_0(C_{i_l})$. The total number of elements below the center of the produced partial order is $\sum_{l=1}^{a} n_0(C_{i_l})$. The amortized, per-element cost of the produced partial order is therefore $\sum_{l=1}^{a} c_0(C_{i_l}) \Big/ \sum_{l=1}^{a} n_0(C_{i_l})$. As for each $1 \le l \le a$ we have $c_0(C_{i_l})/n_0(C_{i_l}) \le u_0$, we get that $\sum_{l=1}^{a} c_0(C_{i_l}) \Big/ \sum_{l=1}^{a} n_0(C_{i_l}) \le u_0$.

Similarly, we also get that the amortized, per-element, upper cost of the produced partial order is at most u_1.

The above accounting did not take into account the cost of breaking the unused parts of the hyper-product. The cost of this operation is negligible, however, compared with the generation cost of the output partial order. It also did not take into account the generation and recycling costs of the outcomes of the grafting processes that were not used to construct the output partial order. However, there may be only a constant number of such outcomes and the costs associated with them are therefore also negligible.

As a result, we get that $u_0(\mathcal{G}) = u_0 + o(1)$ and $u_1(\mathcal{G}) = u_1 + o(1)$ and the theorem is proved. □

Our concrete factories are described in sections 8 and 9. For each one of our factories we specify the set $\mathcal{P}$ of basic and compound constructs used and the credit attached to each one of its elements. We then describe the subfactories employed by the factory. For each subfactory we specify the hyper-product generation process and grafting processes used and, finally, its list of output combinations. We verify that each construct from $\mathcal{P}$ can indeed be consumed by at least one subfactory and that the list of output combinations of each subfactory is adequate. For each output combination we then compute its local lower and upper element costs, using the definitions given in (6.1) and (6.2). As implied by Theorem 6.1, the maxima of these values are then the lower and upper element costs of the whole factory. We begin the description of our factories by describing, in the next section, the grafting processes used by them.

7. Advanced grafting processes. In this section we describe the grafting processes used by our improved factories.

7.1. Recursive pair grafting. The recursive pair grafting is, as its name suggests, a recursive version of the basic pair grafting procedure described in subsection 4.2. There are two variants of this process depending on whether the upper elements or lower elements of pairs are compared to the center of the hyper-product. We describe the variant in which lower elements are compared. The other variant is symmetric.

The recursive pair grafting recursively builds hyperpairs which are *dominated* by the center c of the hyper-product. A hyperpair $P = P_{1^i}$ with center c' is dominated by c if every element of P, except possibly c', is known to be smaller than c. A dominated hyperpair P_{1^i} is said to be of *level* i.

The process is composed of rounds. The ith round receives two dominated hyperpairs P^1 and P^2 (with centers c_1 and c_2, respectively) of level i and attempts to construct a dominated hyperpair of level $i+1$. This is done by first comparing the centers c_1 and c_2 of these two dominated hyperpairs, thus obtaining a hyperpair $P = P_{1^{i+1}}$. We may assume, without loss of generality, that $c_2 > c_1$ and c_2 is therefore the center of the new hyperpair formed. We then compare c_1 (i.e., *not* c_2, the center of the hyperpair P) with c. The two possible outcomes are as follows:

(1) $c_1 < c$ and P is a dominated hyperpair of level $i+1$;

(2) $c_1 > c$ and P is not dominated by c (as $c_2 > c_1 > c$).

If (2) occurs, the process is stopped. For the purposes of $\mathcal{G}_k$ and $\mathcal{G}'_k$ (the factories described in sections 8 and 9) we also stop the process when a dominated hyperpair P_{111} of level 3 is generated. We then separate the generated hyperpair into two hyperpairs: a dominated hyperpair P^1 of level 2 and a hyperpair P^2 of level 2 all whose elements are known to be below the center. The hyperpair P^2 is an output

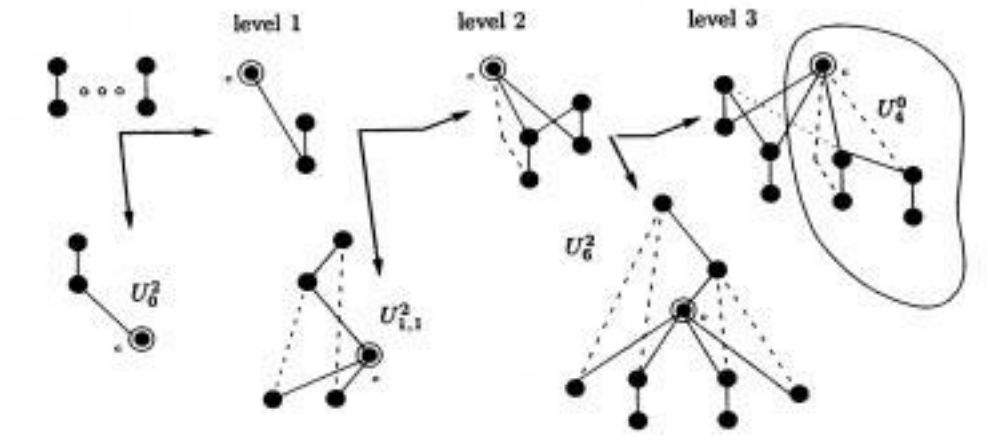

FIG. 7.1. *The recursive pair grafting process.*

of this grafting process. The dominated hyperpair P^1 is used to construct the next dominated hyperpair of level 3.

As described, the two hyperpairs P^1 and P^2 fed into the 0th round of the process are two singletons c_1 and c_2. The 0th round then starts by comparing these two singletons, thus forming a pair. Instead of feeding the 0th round of the process with singletons, we can therefore feed it with pairs and simply skip the first comparison of this round.

The recursive pair grafting process is described schematically in Figure 7.1. The dashed edges in the figure represent edges that became redundant. The four possible outcomes of this process are denoted by U_0^2, $U_{1,1}^2$, U_6^2, and U_4^0. These four outcomes, as well as the four outcomes L_2^0, $L_2^{1,1}$, L_2^6, and L_0^4 of the symmetric grafting process in which upper elements are compared to the center, are shown in Figure 7.2.

We now turn to the cost analysis of this grafting process. As explained, we do not count the number of comparisons made but rather the number of edges cut. Let us analyze the number of edges cut during the ith round of the process. Let P^1 and P^2 be the two dominated hyperpairs of level i fed to the ith round, let c_1 and c_2 be their centers, and assume, without loss of generality, that the first comparison of the round established that $c_1 < c_2$. It is easy to verify, using induction, that i edges connect c with elements of P^1 and that i edges connect c with elements of P^2. Similarly, i edges connect c_1 with other elements of P^1 and i edges connect c_2 with other elements of P^2. If the ith round results in a dominated hyperpair of level $i+1$, i.e., if $c_1 < c$ (case (1)), then the i edges connecting c with the elements of P^1 become redundant and therefore are cut. If on the other hand $c_1 > c$ (case (2)), then the $2i$ edges connecting c_1 and c_2 with elements of their hyperpairs become redundant and therefore are cut.

Finally, note that an additional edge is cut when a dominated hyperpair P_{111} of level 3 is separated into a dominated hyperpair of a level 2 and to a U_4^0. Using these observations, it is easy to verify that the generation costs of the different outcomes shown in Figure 7.2 are as shown in Table 7.1.

7.2. Balanced quartet grafting. The balanced quartet grafting process is a very straightforward process. We describe the process that grafts P_{00}'s. A symmetric

L_0^4	P_{00}	—	4	4	1

process can be used for grafting P_{11}'s. The grating process always consumes a single quartet and returns one of five possible outcomes.

Let u, v, w, z be the elements of a P_{00}, where $u < v$ and $u < w < z$. Start by comparing w with c. If $w > c$, cut the edge connecting w and u. The obtained outcome is denoted by Q_0^2. The remaining pair is recycled. If $w < c$, then compare v and z with c. The four different outcomes of these comparisons give rise to the outcomes $Q_2^{1,1}$, Q_3^1, and Q_4^0 depicted in Figure 7.3. Dashed edges in this figure again represent edges that became redundant during the grafting process.

The elements in a $\bar{Q}_3^1$ outcome satisfy all the relations satisfied by the elements of a Q_3^1 outcome. A $\bar{Q}_3^1$ outcome is therefore a special case of a Q_3^1 outcome and we shall not consider it separately. The generation and recycling costs of the remaining four possibilities are given in Table 7.2.

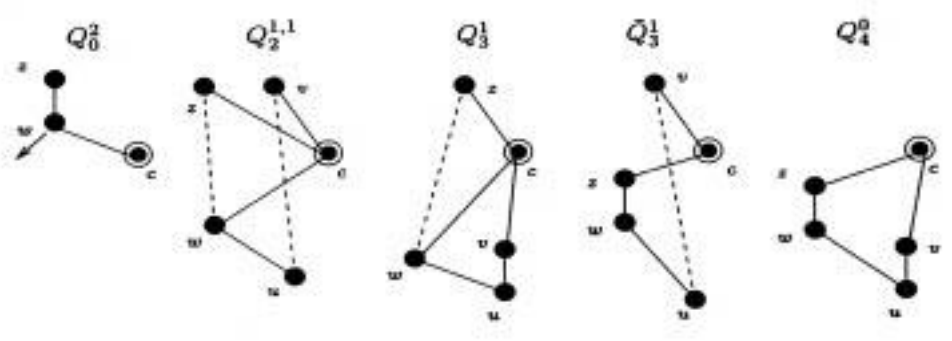

FIG. 7.3. *Possible outcomes of balanced quartet* (P_{00}) *grafting.*

7.3. Extended balanced quartet grafting. The grafting process described in this subsection is an extension of the simple grafting process described in the previous subsection. We again describe the process that grafts P_{00}'s. A symmetric process can be used for grafting P_{11}'s.

Let u, v, w, z be the elements of a P_{00}, where $u < v$ and $u < w < z$. The process starts again by comparing w and c. If $w < c$, continue as before, obtaining one of the outcomes $Q_2^{1,1}$, Q_3^1, or Q_4^0 shown in Figure 7.3. If, however, $w > c$, then instead of removing the redundant pair, activate the recursive pair grafting process, as described in subsection 7.1, on the redundant pair $u < v$. The four possible outcomes of this process are shown in Figure 7.4. The outcomes Q_0^4, Q_2^6, Q_6^{10}, and Q_4^4 are obtained, respectively, from the U_0^2, $U_{1,1}^2$, U_6^2, and U_4^0 outcomes of the recursive pair grafting process. The generation and recycling costs of all the outcomes of this grafting process are given in Table 7.3.

7.4. Unbalanced quartet grafting. The unbalanced quartet grafting process is another quartet grafting process used by our factories. Most of its outcomes are less balanced than the results obtained using the two previous quartet grafting processes. Again we describe the version of the process that grafts P_{00}'s. A symmetric version can be used to graft P_{11}'s.

Let u, v, w, z be the elements of a P_{00}, where $u < v$ and $u < w < z$. The two balanced quartet grafting processes started by comparing w with c, the center of the hyper-product. The unbalanced process, on the other hand, starts by comparing v and z to c. The possible outcomes are shown at the top of Figure 7.5.

In the first two cases, i.e., if $v, z < c$, or if $z < c < v$, the grafting process stops. The obtained outcomes are denoted, respectively, by R_4^0 and R_3^1. The other two cases, i.e., $v < c < z$ and $c < v, z$, are more complicated.

If $v < c < z$, use the pair $w < z$, and other pairs like it, as inputs to the

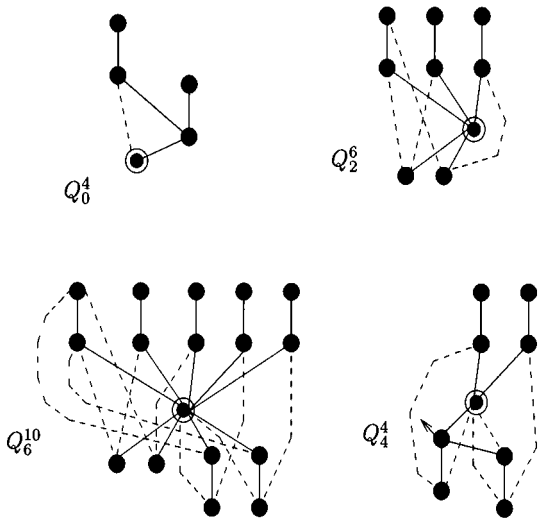

FIG. 7.4. *Possible outcomes of extended balanced grafting of P_{00}'s.*

TABLE 7.3
The costs of the different outcomes of the extended balanced P_{00} grafting process.

Q_4^4	$2\times P_0$	P_{11}	6	5	6

recursive P_0 grafting process, i.e., the mirror image of the grafting process described in subsection 7.1. The recursive pair grafting process results in the creation of $L_2^{1,1}$'s, L_2^6's, and L_0^4's. These $L_2^{1,1}$'s, L_2^6's, and L_0^4's are composed of w and z elements of P_{00}'s. By adding to the obtained constructs the u and the v elements of the quartets from which these w and z elements were taken, we obtain outcomes of the forms R_6^2, R_{10}^6, and R_4^4 shown in Figure 7.5.

Finally, if $c < v, z$, then the situation is identical to the situation after the first comparison of the second round of the recursive P_0 grafting. By continuing the recursive P_0 process from this point, possibly using another P_{00} for which $c < v, z$, we obtain an $L_2^{1,1}$, L_2^6, or L_0^4.

The unbalanced P_{00} grafting has eight outcomes in total: R_4^0, R_3^1, R_6^2, R_{10}^6, R_4^4, $L_2^{1,1}$, L_2^6, and L_0^4. The last three outcomes are excellent outcomes because we have been able to use quartets as if they were pairs. The costs associated with the outcomes R_4^0, R_3^1, R_6^2, R_{10}^6, and R_4^4 are given in Table 7.4. The costs of the outcomes $L_2^{1,1}$, L_2^6, and L_0^4 are as shown in Table 7.1.

8. A factory with $u_0, u_1 \sim 2.955$. The construction of the factory $\mathcal{G}_k$ satisfying the conditions of Theorem 2.3 is extremely involved. In this section we give a

complete description of a simplified version $\mathcal{G}'_k$ of the factory $\mathcal{G}_k$, thereby proving the following theorem, which is only slightly weaker than Theorem 2.3.

THEOREM 8.1. *There is a green factory $\mathcal{G}'_k$ for $\tilde{\mathcal{S}}_k^k$ with $u_0, u_1 \sim 2.955$.*

As was the case with all the other factories we considered, the initial cost and production residues of $\mathcal{G}'_k$ are $O(k^2)$.

The constructs processed by the factory $\mathcal{G}'_k$ are shown in Figure 8.1. They are singletons P_λ's, pairs P_0/P_1's, quartets P_{00}/P_{11}'s, chains of length three I_3's, and triples W_3/M_3's. The factory $\mathcal{G}'_k$ also processes compound constructs of the forms

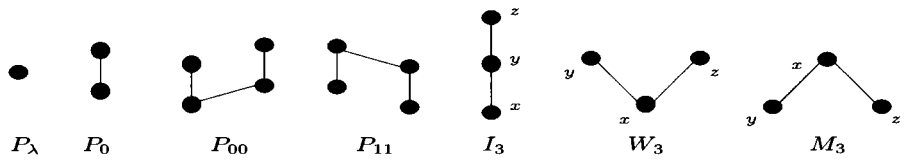

FIG. 8.1. *The basic input constructs of the factory* $\mathcal{G}'_k$.

TABLE 8.1
The credits attached to the constructs used by the factory $\mathcal{G}'_k$.

Construct	Credit
P_λ	0
P_0, P_1	0
P_{00}, P_{11}	0.1093
I_3, M_3, W_3	0.5000
$(P_0, \gamma \times P_{00}), (P_1, \gamma \times P_{11})$	0

$(P_0, \gamma \times P_{00})$ and $(P_1, \gamma \times P_{11})$, where $\gamma \simeq 2.6603$. The credits attached to these basic and compound constructs are given in Table 8.1. Note that singletons have zero credit attached to them. Note also that quartets have a positive credit attached to them while the constructs $(P_0, \gamma \times P_{00})$ and $(P_1, \gamma \times P_{11})$ have zero credit attached to them. This reflects the fact that quartets can be more efficiently utilized if pairs are also supplied with them.

The factories $\mathcal{G}'_k$ are composed of the following four subfactories:

1. $(P_0, \gamma \times P_{00})$ subfactory,
2. $(P_1, \gamma \times P_{11})$ subfactory,
3. P_{00} subfactory,
4. P_{11} subfactory.

The $(P_1, \gamma \times P_{11})$ subfactory is the mirror image of the $(P_0, \gamma \times P_{00})$ subfactory and the P_{11} subfactory is the mirror image of the P_{00} subfactory. The description of the $(P_0, \gamma \times P_{00})$ and the P_{00} subfactories are given in the next two subsections.

Because singletons (P_λ's) and pairs (P_0's) can be converted to quartets (P_{00}'s) at no cost, the $(P_0, \gamma \times P_{11})$ subfactory may also receive singletons and pairs.

The constructs W_3, M_3, and I_3 cannot be utilized directly by the four subfactories mentioned above. We therefore use the following simple process (carried out in a workshop?) to transform two W_3's into a P_0 and a P_{00}: Let $x_1, y_1 > z_1$ and $x_2, y_2 > z_2$ be two W_3's. Compare x_1 with x_2. Assume, without loss of generality, that $x_1 < x_2$. By removing the edge $x_2 > z_2$ we obtain the P_{00} x_1, y_1, z_1, x_2, where $z_2 < y_1$ and $z_2 < x_1 < x_2$, and the pair $z_2 < y_2$.

A single edge is cut in this process. As $\gamma > 1$, a combination of a P_0 and a P_{00} can be recycled without attaching any credit to it. Formally, this combination may be treated as $\frac{1}{\gamma} \times (P_0, \gamma \times P_{00})$ plus $(1 - \frac{1}{\gamma}) \times P_0$ and both these construct carry zero credit. The credits attached to two W_3's should therefore pay for cutting a single edge. This is exactly the case as $credit(W_3) = 0.5$.

Similarly, we can transform two M_3's into a P_1 and a P_{11}. An I_3 may be treated as either a W_3 or an M_3.

The factory $\mathcal{G}'_k$ described in this section can be improved if instead of using the above process for converting W_3's, M_3's, and I_3's into P_0's and P_{00}'s or P_{11}'s, we

used subfactories that could directly consume these constructs. The improved factory $\mathcal{G}_k$ (whose construction is sketched in the next section) includes, along with other additions and changes, a separate I_3 subfactory. The constructs I_3's turn out to be excellent raw materials for the construction of $\tilde{\mathcal{S}}_k^k$'s. Each I_3 carries, in $\mathcal{G}_k$, a credit of -0.4213 units and the presence of I_3's among the recycled elements becomes a boon, not a burden as in $\mathcal{G}'_k$.

We now describe the $(P_0, \gamma \times P_{00})$ subfactory and the P_{00} subfactory used by the $\mathcal{G}'_k$ factory.

8.1. The $(P_0, \gamma \times P_{00})$ subfactory. The input to this subfactory consists of constructs of the form $(P_0, \gamma \times P_{00})$, where $\gamma \simeq 2.6603$, with zero credit attached to each one of them. As singletons (P_λ's) and pairs (P_0's) can be converted to quartets (P_{00}'s) at no cost, the subfactory may also receive singletons and pairs with no credit attached to them. Equivalently, we can say that the input to this subfactory consists of singletons (P_λ's), pairs (P_0's), and quartets (P_{00}'s) with no credit attached to them, subject to the condition that each quartet is accompanied by at least $2/\gamma$ elements in singletons or pairs. The parameter γ is chosen to optimize the performance of the factory.

The $(P_0, \gamma \times P_{00})$ subfactory can also receive quartets with no accompanying singletons or pairs, provided that each such quartet carries a credit of $1/(1 + 2\gamma)$. Such a credit can pay for breaking a quartet P_{00} into $\frac{2}{2\gamma+1} \times (P_0, \gamma \times P_{00})$ which can be accepted with no credit. In the $\mathcal{G}'_k$ factory, $0.1093 \simeq credit(P_{00}) < 1/(1+2\gamma) \simeq 0.1582$. It is therefore cheaper to feed quartets without accompanying singletons or pairs into the P_{00} subfactory described in the next subsection.

Quartets fed into the subfactory are used for the construction of a hyper-product which, in this case, is simply a hyperpair. Quartets are also grafted using the balanced quartet grafting process described in subsection 7.2. Pairs are grafted using the recursive pair grafting process described in subsection 7.1.

8.1.1. The hyper-product generation process of the $(P_0, \gamma \times P_{00})$ subfactory. The hyper-products used in the $(P_0, \gamma \times P_{00})$ subfactory are simply the balanced hyperpairs constructed according to the string $\mathcal{W} = 01(10)^\omega$. Since P_{01}'s and P_{00}'s are in fact the same partial order (just the center is different), P_{00}'s can be used for the construction of such hyperpairs. The upper and lower element pruning costs of these hyperpairs are $pr_1(\mathcal{W}) = 1.5$ and $pr_0(\mathcal{W}) = 1.5$.

When r elements below the center of a hyperpair H_i are pruned, the hyperpair H_i is broken into a collection of smaller hyperpairs. This collection includes r singletons (P_λ's). All the other remaining hyperpairs are of size at least eight. A similar thing happens when r elements above the center of a hyperpair H_i are pruned. This time the collection of smaller hyperpairs obtained includes $\lfloor r/2 \rfloor$ pairs (P_0's). All the other hyperpairs are of size at least four. In both cases, when r elements are pruned, about r elements are obtained in singletons or pairs while all the other elements are contained in hyperpairs of size at least four. The hyperpairs of size at least four are immediately used for the construction of the next H_i hyperpairs. The singletons and pairs are too valuable to be used for this purpose. They are recycled. Their recycling enables the recycling of quartets, fed to the subfactory as parts of $(P_0, \gamma \times P_{00})$'s constructs, without the necessity of attaching credits to them.

If $r = \sum_{i=0}^{\ell} r_i$, where the r_i's are distinct powers of 2, then pruning r elements above the center c of a hyperpair H_i results in a collection of hyperpairs $P_{0^{r_1}}, P_{0^{r_2}}, \ldots, P_{0^{r_\ell}}$ all whose centers are above c. Similarly, pruning r elements below

TABLE 8.2
The costs of the pruning process of the $(P_0, \gamma \times P_{00})$ subfactory, viewed as a grafting process.

Outcome	Above	Below	Leftovers	*gen*	rec_0	rec_1
PR_0	—	$\frac{1}{4} \times P_{11}$	P_λ	1.5	0.25	1
PR_1	$\frac{1}{4} \times P_{00}$	—	$\frac{1}{2} \times P_0$	1.5	1	0.25

the center c of H_i results in a collection of hyperpairs $P_{1^{r_1}}, P_{1^{r_2}}, \ldots, P_{1^{r_\ell}}$, all whose centers are below c. All but at most three of such r pruned elements are contained in quartets (we can also assume, if convenient, that r is divisible by 4, in which case all the pruned elements are contained in quartets). All but at most seven of the pruned elements are contained in octets. The subfactories of the factory $\mathcal{G}'_k$ are not capable of utilizing octets. When pruned elements are recycled in the subfactories of the factory $\mathcal{G}'_k$, we have to break them, therefore, into a collection of quartets at a cost of 1/4 of a comparison per element. Some of the subfactories of the factory $\mathcal{G}_k$, described in the next section, are capable of utilizing 16-tuples (P_{0000}'s and P_{1111}'s). In the subfactories of $\mathcal{G}_k$, it is therefore enough to break recycled pruned elements into P_{0000}'s or P_{1111}'s at a cost of 1/16th of a comparison per element. In both cases, when these quartets or 16-tuples are recycled, an appropriate amount of credit should be attached to them.

As was already explained, it is convenient, for accounting purposes,to consider pruning as a special grafting process. It follows from the discussion above that we can consider the pruning process of the $(P_0, \gamma \times P_{00})$ subfactory as a grafting process with the characteristics described in Table 8.2. The pruning processes used in other subfactories will have other characteristics. We denote a downward pruned element by PR_0 and an upward pruned element by PR_1. This notation is used in all subfactories.

8.1.2. The output combinations of the $(P_0, \gamma \times P_{00})$ subfactory. The output combinations used by the $(P_0, \gamma \times P_{00})$ subfactory are given in Table 8.3. Each combination involves just two outcomes. The exact proportion of the two outcomes in each combination is chosen so that the lower and upper element costs of the combination become equal, thereby minimizing their maximum.

Before analyzing the costs of these combinations, we verify that if enough outcomes of each of the three grafting processes used by the subfactory are available, then at least one output combination can indeed be used. Suppose that at least one outcome of each of the two recursive pair grafting processes (i.e., at least one outcome of $U_0^2, U_{1,1}^2, U_6^2$, and U_4^0 and at least one outcome of $L_2^0, L_2^{1,1}, L_2^6$, and L_0^4) is available and that at least nine outcomes of the P_{00} grafting process (i.e., at least nine outcomes out of $Q_2^{1,1}, Q_3^1, Q_4^0$, and Q_0^2) are available. Each of the outcomes U_0^2, L_2^0, and $Q_2^{1,1}$ can immediately be used in conjunction with pruned elements (combinations 1, 2, or 3), since pruned elements are always available. If none of these outcomes are available, then we have at least three outcomes of either Q_3^1, Q_4^0, or Q_0^2, at least one of $U_{1,1}^2, U_6^2$, and U_4^0, and at least one of $L_2^{1,1}, L_2^6$, and L_0^4. If three Q_3^1's are available, we can therefore activate one of combinations 4, 5, or 6. If three Q_4^0's are available (actually two are enough here), we can activate one of combinations 7, 8, or 9. Finally, if three Q_4^0's are available, we can activate one of combinations 10, 11, or 12.

We now turn to the cost analysis of these combinations. We perform explicitly the computations for combinations 2 and 7. The other computations are similar.

- $(1. \times U_0^2, 2.1995 \times PR_0)$.

  The number $r \simeq 2.1995$ of pruned elements used in conjunction with U_0^2

TABLE 8.3
The output combinations of the $(P_0, \gamma \times P_{00})$ *subfactory.*

	Combination	Lower and upper element cost
1	$(\ 1.\times Q_2^{1,1}\ ,\ 0.4639\times PR_0\ )$	2.9059
2	$(\ 1.\times U_0^2\ ,\ 2.1995\times PR_0\ )$	2.9546
3	$(\ 1.\times L_2^0\ ,\ 2.1995\times PR_1\ )$	2.9546

5	$(\ 1.\times L_2^6\ ,\ 2.4546\times Q_3^1\ )$	2.9499
6	$(\ 1.\times L_0^4\ ,\ 2.0254\times Q_3^1\ )$	2.9001
7	$(\ 1.\times L_2^{1,1}\ ,\ 0.1134\times Q_4^0\ )$	2.9546
8	$(\ 1.\times L_2^6\ ,\ 1.2271\times Q_4^0\ )$	2.9517
9	$(\ 1.\times L_0^4\ ,\ 1.0000\times Q_4^0\ )$	2.8954
10	$(\ 1.\times U_{1,1}^2\ ,\ 0.2038\times Q_0^2\ )$	2.9538
11	$(\ 1.\times U_6^2\ ,\ 2.2042\times Q_0^2\ )$	2.9483
12	$(\ 1.\times U_4^0\ ,\ 1.8150\times Q_0^2\ )$	2.9075

is chosen so that the lower and upper element costs of the combination would become equal. We demonstrate the computation that leads to this optimal choice of r.

Remembering that the input to the $(P_0, \gamma \times P_{00})$ subfactory consists of $(P_0, \gamma \times P_{00})$'s, we get that the generation of a U_0^2 consumes one pair P_0 and leaves $\gamma \times P_{00}$ as leftovers. Similarly, the generation of $r \times PR_0$ consumes $\frac{r}{2} \times P_{00}$ and leaves $r \times P_\lambda$ (consult Table 8.2) and $\frac{r}{2\gamma} \times P_0$ as leftovers. The leftover singletons are immediately joined into pairs. The leftovers from the two processes are therefore $\frac{r}{2}(1+\frac{1}{\gamma}) \times P_0$ and $\gamma \times P_{00}$. Provided that $\frac{r}{2}(1+\frac{1}{\gamma}) \geq 1$, these leftovers can be recycled without having to attach any credit to them.

The combination $(1.\times U_0^2, r \times PR_0)$ is composed of a P_0 above the center and $\frac{r}{4} \times P_{11}$ below the center. As no credit is attached to the inputs, nor paid for the leftovers, the local lower and upper element costs of this combination are

$$u_0(C_2) = \frac{1.\times(gen(U_0^2)+rec_1(U_0^2)) + r\times(gen(PR_0)+rec_1(PR_0)) + credit(P_0)}{1.\times n_0(U_0^2)+r\times n_0(PR_0)},$$

$$u_1(C_2) = \frac{1.\times(gen(U_0^2)+rec_0(U_0^2)) + r\times(gen(PR_0)+rec_0(PR_0)) + \frac{r}{4}\times credit(P_{11})}{1.\times n_1(U_0^2)+r\times n_1(PR_0)}.$$

Consulting Table 7.1 we get that $gen(U_0^2) = 0, rec_0(U_0^2) = 2, rec_1(U_0^2) = 1$, and of course that $n_0(U_0^2) = 0$ and $n_1(U_0^2) = 2$. Consulting Table 8.2 we get that $gen(PR_0) = 1.5, rec_0(PR_0) = 0.25, rec_1(PR_0) = 1$, and of course that $n_0(PR_0) = 1$ and $n_1(PR_0) = 0$. We also have $credit(P_{11}) = 0.1093$ and $credit(P_0) = 0$. Substituting these values into the above expressions and

equating the two costs we obtain the equation

$$\frac{1.\times(0+1)+r\times(1.5+1)}{1.\times 0+r\times 1}=\frac{1.\times(0+2)+r\times(1.5+0.25)+\frac{r}{4}\times 0.1093}{1.\times 2+r\times 0}\,.$$

It is easy to check that the solution of this equation is $r\simeq 2.1995$ and the values of both the lower and upper element costs in this case are $u_0(C_2)=u_1(C_2)\simeq 2.9546$.

- $(1.\times L_2^{1,1}, 0.1134\times Q_4^0)$.

  We again compute the lower and upper element costs of a combination $(1.\times L_2^{1,1}, r\times Q_4^0)$ and choose r so that both these costs would become equal. The generation of an $L_2^{1,1}$ consumes $2\times P_0$ and leaves $2\gamma\times P_{00}$ as leftovers. The generation of $r\times Q_4^0$ consumes $r\times P_{00}$ and leaves $\frac{r}{\gamma}\times P_0$ as leftovers. The proportion of quartets among the leftovers is much higher than in the previous case and they cannot all be recycled by pairing them with pairs. The $\frac{r}{\gamma}\times P_0$ can be paired with $r\times P_{00}$ of the leftovers to form $\frac{r}{\gamma}\times(P_0,\gamma\times P_{00})$ which can be recycled without credit. Credit, however, should be attached to the remaining $(2\gamma-r)\times P_{00}$ (assuming, as will be the case, that $2\gamma-r>0$).

  The combination $(1.\times L_2^{1,1}, r\times Q_4^0)$ is composed of $2\times P_\lambda$ above the center and a P_0 and a $r\times P_{00}$ below the center. The lower part is recycled to the $(P_0,\gamma\times P_{00})$ subfactory with no attached credit, as $r<\gamma$. The local lower and upper element costs of this combination are therefore

$$u_0(C_7)=\frac{1.\times(gen(L_2^{1,1})+rec_1(L_2^{1,1}))+r\times(gen(Q_4^0)+rec_1(Q_4^0))+(2\gamma-r)\times credit(P_{00})}{1.\times n_0(L_2^{1,1})+r\times n_0(Q_4^0)},$$
$$u_1(C_7)=\frac{1.\times(gen(L_2^{1,1})+rec_0(L_2^{1,1}))+r\times(gen(Q_4^0)+rec_0(Q_4^0))+(2\gamma-r)\times credit(P_{00})}{1.\times n_1(L_2^{1,1})+r\times n_1(Q_4^0)}.$$

Substituting the values $gen(L_2^{1,1})=2, rec_0(L_2^{1,1})=3, rec_1(L_2^{1,1})=4$, and $n_0(L_2^{1,1})=n_1(L_2^{1,1})=2$, found in Table 7.1, and the values $gen(Q_4^0)=1, rec_0(Q_4^0)=2, rec_1(Q_4^0)=5$, and $n_0(Q_4^0)=4, n_1(Q_4^0)=0$, found in Table 7.2, together with the value $credit(P_{00})=0.1093$ and equating these costs, we obtain the following equation:

$$\frac{1.\times(2+4)+r\times(1+5)+(2\cdot 2.6603-r)\cdot 0.1093}{1.\times 2+r\times 4}$$
$$=\frac{1.\times(2+3)+r\times(1+2)+(2\cdot 2.6603-r)\cdot 0.1093}{r\times 0+1.\times 2}\,.$$

It is easy to check that the solution of this equation is $r\simeq 0.1134$ and the values of both the lower and upper element costs in this case are $u_0(C_7)=u_1(C_7)\simeq 2.9546$.

The analysis of the other 10 cases is similar. Combinations 2, 3, and 7 turn out to be the worst combinations of this subfactory.

8.2. The P_{00} subfactory. The input to the P_{00} subfactory consists of P_{00}'s. Each P_{00} fed to the subfactory carries a credit of $credit(P_{00})\simeq 0.1093$. The subfactory constructs hyper-products using the process described below. The subfactory uses the extended balanced and the unbalanced P_{00} grafting processes described in subsections 7.3 and 7.4.

TABLE 8.4
The costs of the pruning process of the P_{00} subfactory, viewed as a grafting process.

Outcome	Above	Below	*gen*	rec_0	rec_1
PR_0	—	$\frac{1}{4}\times P_{11}$	1.4366	0.25	1
PR_1	$\frac{1}{4}\times P_{00}$	—	1.6268	1	0.25

TABLE 8.5
The output combinations of the P_{00} subfactory.

	Combination	Lower and upper element cost
1	$(\ 1.\times R_4^0 \quad , \quad 4.0000\times PR_1\ )$	2.9267
2	$(\ 1.\times R_3^1 \quad , \quad 2.0000\times PR_1\ )$	2.7481
3	$(\ 1.\times R_6^2 \quad , \quad 3.5464\times PR_1\ )$	2.9546
4	$(\ 1.\times R_{10}^6 \quad , \quad 3.5456\times PR_1\ )$	2.9508
5	$(\ 1.\times R_4^4 \quad , \quad 0.4096\times PR_1\ )$	2.8972
6	$(\ 1.\times Q_0^4 \quad , \quad 4.0000\times PR_0\ )$	2.7366
7	$(\ 1.\times Q_2^6 \quad , \quad 4.0000\times PR_0\ )$	2.9546
8	$(\ 1.\times Q_6^{10} \quad , \quad 4.0000\times PR_0\ )$	2.9509
9	$(\ 1.\times Q_4^4 \quad , \quad 0.4131\times PR_0\ )$	2.8790

Additional combinations involve $Q_2^{1,1}$, Q_3^1, Q_4^0, $L_2^{1,1}$, L_2^6, L_0^4 and pruning.

8.2.1. The hyper-product generation process of the P_{00} subfactory. The hyper-products used by the P_{00} subfactory are generated according to an infinite string $\mathcal{W}' = 011\mathcal{W}''$, where $\mathcal{W}''$ is an infinite string with $pr_0(\mathcal{W}'') \simeq 1.7465$ and $pr_1(\mathcal{W}'') \simeq 1.2535$. Such a string exists according to Theorem 4.6. According to Lemma 4.4 we get that $pr_0(\mathcal{W}') = \frac{1}{4}pr_0(\mathcal{W}'') + 1 \simeq 1.4366$ and that $pr_1(\mathcal{W}') = \frac{1}{2}pr_1(\mathcal{W}'') + 1 \simeq 1.6268$. As the string $\mathcal{W}'$ begins with 01, the hyperpairs constructed according to it are indeed hyper-products of P_{00}'s. We let H'_i denote the hyper-product generated according to the prefix of length i of $\mathcal{W}'$.

The generation of the hyper-products H'_i consumes P_{00}'s. Each such P_{00} carries a credit of $credit(P_{00}) = 0.1093$. As we have seen in the $(P_0, \gamma\times P_{00})$ subfactory, the pruning process may be viewed as a pruning process that receives $\frac{1}{2}\times P_{00}$ and returns either $\frac{1}{4}\times P_{11}$ below the center, or $\frac{1}{4}\times P_{00}$ above the center, as well as a leftover of $\frac{1}{2}\times P_0$ (or a P_λ which can be converted into $\frac{1}{2}\times P_0$ at no cost). The leftover $\frac{1}{2}\times P_0$ can be joined with $\frac{\gamma}{2}\times P_{00}$ from the input stream to form $\frac{1}{2}\times(P_0, \gamma\times P_{00})$. Such constructs can be recycled without any credit attached to them. The cost of pruning an element can therefore be "subsidized" by the credit attached to $\frac{1}{2}(1+\gamma)\times P_{00}$. The costs of the pruning process of the P_{00} subfactory are given in Table 8.4.

8.2.2. The output combinations of the P_{00} subfactory. The output combinations used by the P_{00} subfactory are given in Table 8.5. This list includes all the combinations that involve the outcomes Q_0^4, Q_2^6, and Q_6^{10} of the extended balanced P_{00} grafting and the outcomes R_4^0, R_3^1, R_6^2, R_{10}^6, and R_4^4 of the unbalanced P_{00} grafting. As can be seen, each of these outcomes can be used in conjunction with pruned elements to obtain low local lower and upper element costs. The balanced grafting process may also produce outcomes $Q_2^{1,1}$, Q_3^1, and Q_4^0, and the unbalanced grafting process may also produce outcomes $L_2^{1,1}$, L_2^6, and L_0^4. These outcomes are combined using the

combinations of the $(P_0, \gamma \times P_{00})$ subfactory given in Table 8.3. It is easy to verify that when each of the two grafting processes is applied a sufficient number of times, at least one output combination is applicable.

The costs of all the combinations involving $Q_2^{1,1}$, Q_3^1, and Q_4^0 and $L_2^{1,1}$, L_2^6, and L_0^4 are strictly smaller than their costs in the $(P_0, \gamma \times P_{00})$ subfactory. This is due to the fact that the input constructs to the P_{00} subfactory carry (positive) credits while the inputs to the $(P_0, \gamma \times P_{00})$ subfactory do not, and it is because the effective pruning costs $pr'_0(\mathcal{W}') \simeq 1.4366 - \frac{1+\gamma}{2}\, credit(P_{00}) \simeq 1.2366$ and $pr'_1(\mathcal{W}') \simeq 1.6268 - \frac{1+\gamma}{2}\, credit(P_{00}) \simeq 1.4267$ in the P_{00} subfactory are lower than the pruning costs $pr_0(\mathcal{W}) = pr_1(\mathcal{W}) = 1.5$ of the $(P_0, \gamma \times P_{00})$ subfactory.

It is therefore enough to analyze the costs of the combinations listed in Table 8.5. We present, as examples, the analyses of combinations 3 and 7 which, together with combinations 2, 3, and 7 of the $(P_0, \gamma \times P_{00})$ subfactory, determine the worst-case behavior of the whole factory. The analysis of all the other cases is similar.

- $(1. \times R_6^2, 3.5464 \times PR_1)$.

  The local lower and upper element costs of the combination $(1. \times R_6^2, r \times PR_1)$ are

$$u_0(C_3) = \frac{1. \times (gen(R_6^2) + rec_1(R_6^2)) + r \times (gen(PR_1) + rec_1(PR_1)) - (2 + \frac{r}{2}(1+\gamma))\, credit(P_{00})}{1. \times n_0(R_6^2) + r \times n_0(PR_1)},$$

$$u_1(C_3) = \frac{1. \times (gen(R_6^2) + rec_0(R_6^2)) + r \times (gen(PR_1) + rec_0(PR_1)) - (2 + \frac{r}{2}(1+\gamma))\, credit(P_{00})}{1. \times n_1(R_6^2) + r \times n_0(PR_1)},$$

  No credits should be attached to recycled elements, assuming that $\frac{r}{4} \leq \gamma$, since the proportion of quartets among the recycled elements is low enough. Solving the equation

$$\frac{1. \times (3+9) + r \times (1.6268 + 0.25) - (2 + \frac{r}{2}(1 + 2.6603)) \cdot 0.1093}{1. \times 6 + r \times 0} = \frac{1. \times (3+5) + r \times (1.6268 + 1) - (2 + \frac{r}{2}(1 + 2.6603)) \cdot 0.1093}{1. \times 2 + r \times 1}$$

  we get that $r \simeq 3.5464$ and $u_0(C_3) = u_1(C_3) \simeq 2.9546$.

- $(1. \times Q_2^6, 4.0000 \times PR_0)$.

  The local lower and upper element costs of the combination $(1. \times Q_2^6, r \times PR_0)$ are

$$u_0(C_7) = \frac{1. \times (gen(Q_2^6) + rec_1(Q_2^6)) + r \times (gen(PR_0) + rec_1(PR_0)) - (2 + \frac{r}{2}(1+\gamma))\, credit(P_{00})}{1. \times n_0(Q_2^6) + r \times n_0(PR_0)},$$

$$u_1(C_7) = \frac{1. \times (gen(Q_2^6) + rec_0(Q_2^6)) + r \times (gen(PR_0) + rec_0(PR_0)) - (2 + \frac{r}{2}(1+\gamma))\, credit(P_{00})}{1. \times n_1(Q_2^6) + r \times n_0(PR_0)}.$$

  Again, no credits should be attached to recycled elements, assuming that $\frac{r}{4} \leq \gamma$. Solving the equation

$$\frac{1. \times (4+5) + r \times (1.4366 + 1) - (2 + \frac{r}{2}(1 + 2.6603)) \cdot 0.1093}{1. \times 2 + r \times 1} = \frac{1. \times (4+8) + r \times (1.4366 + 0.25) - (2 + \frac{r}{2}(1 + 2.6603)) \cdot 0.1093}{1. \times 6 + r \times 0}$$

  we get that $r \simeq 4.0000$ and $u_0(C_7) = u_1(C_7) \simeq 2.9546$.

This completes the description and the analysis of the factory $\mathcal{G}'_k$.

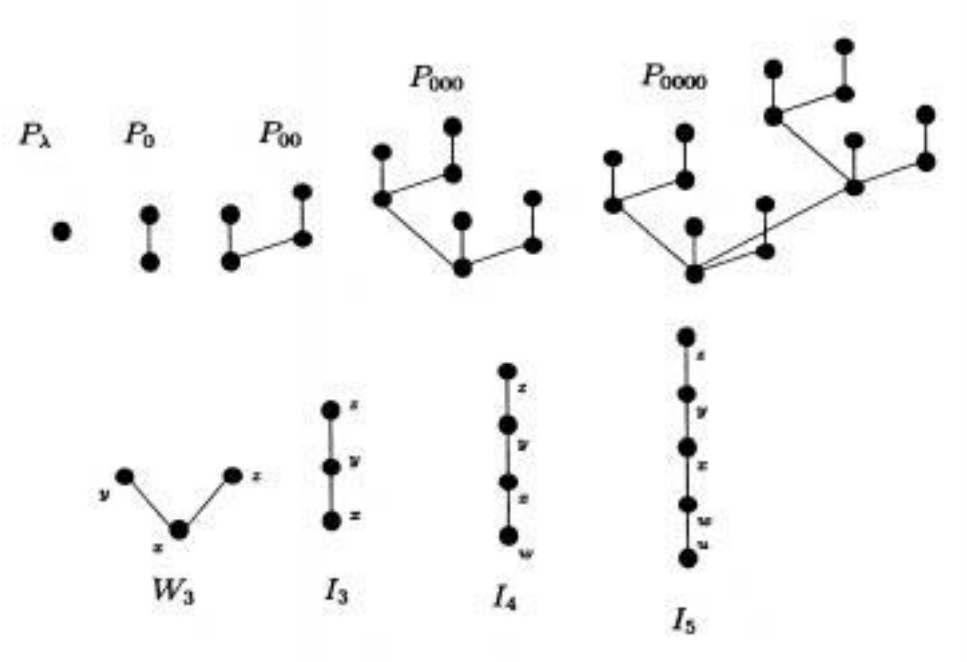

FIG. 9.1. *The basic input constructs of the factory* $\mathcal{G}_k$.

9. A factory with $u_0, u_1 \sim 2.942$. In this section we sketch the construction of factories $\mathcal{G}_k$ with lower and upper element costs $u_0, u_1 \sim 2.942$ whose existence was claimed in Theorem 2.3. A complete description of the factories $\mathcal{G}_k$ can be found in [Dor95].

The general structure of the factories $\mathcal{G}_k$ is similar to the structure of the factories $\mathcal{G}'_k$ described in the previous section. The $\mathcal{G}_k$ factories, however, recycle many more constructs. The structures recycled by the factories G_k are the structures shown in Figure 9.1 and their mirror images (compare this with the much smaller set of constructs recycled by the factories $\mathcal{G}'_k$, shown in Figure 8.1).

The factory $\mathcal{G}_k$ is composed of 13 subfactories: a $(P_0, \gamma \times P_{00})$ subfactory, a $(P_1, \gamma \times P_{11})$ subfactory, a P_{00} subfactory, a P_{11} subfactory, a P_{000} subfactory, a P_{111} subfactory, a P_{0000} subfactory, a P_{1111} subfactory, a $(P_\lambda, P_0, \beta \times P_{000})$ subfactory, a $(P_\lambda, P_1, \beta \times P_{111})$ subfactory, an I_3 subfactory, an I_4 subfactory, and an I_5 subfactory, where $\beta \simeq 1.6500$ and $\gamma \simeq 2.0500$.

The credits attached to the basic and compound constructs are $credit(P_\lambda) = 0$, $credit(P_0) = 0$, $credit(P_0, \gamma \times P_{00}) = 0$, $credit(P_{00}) = 0.1330$, $credit(P_{000}) = 0.8630$, $credit(P_{0000}) = 2.4847$, $credit(I_3) = -0.4213$, $credit(I_4) = -0.9230$, $credit(I_5) = -1.2000$, $credit(W_3) = 0.5000$, and $credit(P_\lambda, P_0, \beta \times P_{000}) = 1.2259$. The credit attached to a construct is equal to the credit attached to its mirror image.

The first four subfactories employed by $\mathcal{G}_k$ are essentially identical to the corresponding subfactories used by $\mathcal{G}'_k$. The main difference is that different parameters are used and that pruned elements are recycled as 16-tuples (i.e., P_{0000}'s or P_{1111}'s) and not as quartets. The value of the parameter γ is decreased to $\gamma \simeq 2.0500$. The credit attached to a quartet is increased to $credit(P_{00}) \simeq 0.1330$. These changes change the costs of these subfactories but the analysis is very similar to the one carried out in

the previous section. The other nine subfactories are new.

As can be seen, there is no W_3 subfactory. As before, a workshop is used to convert two W_3's into a P_0 and a P_{00} at the price of cutting a single edge.

The second output combination of the $(P_0, \gamma \times P_{00})$ subfactory is again one of the worst cases of the factories $\mathcal{G}_k$. We describe the analysis of this case and compare it with the analysis of the same case in the $\mathcal{G}'_k$ factories.

- $(1. \times U_0^2, 2.2613 \times PR_0)$.

  The local lower and upper element costs of the combination $(1. \times U_0^2, r \times PR_0)$ are

$$u_0(C_2) = \frac{1. \times (gen(U_0^2) + rec_1(U_0^2)) + r \times (gen(PR_0) + rec_1(PR_0)) + credit(P_0)}{1. \times n_0(U_0^2) + r \times n_0(PR_0)},$$

$$u_1(C_2) = \frac{1. \times (gen(U_0^2) + rec_0(U_0^2)) + r \times (gen(PR_0) + rec_0(PR_0)) + \frac{r}{16} \times credit(P_{0000})}{1. \times n_1(U_0^2) + r \times n_1(PR_0)}.$$

  The expression for $u_0(C_2)$ is identical to the expression for $u_0(C_2)$ in $\mathcal{G}'_k$. The expression for $u_1(C_2)$ differs from the corresponding expression in $\mathcal{G}'_k$ as pruned elements are now recycled as P_{1111}'s. The recycling costs of pruned elements are now $rec_0(PR_0) = 0.0625$ and $rec_1(PR_0) = 1$. Each recycled P_{1111} should carry a credit of $credit(P_{0000}) \simeq 2.4847$. Substituting these updated values into the above expressions and equating the two costs we obtain the equation

$$\frac{1. \times (0 + 1) + r \times (1.5 + 1)}{1. \times 0 + r \times 1} = \frac{1. \times (0 + 2) + r \times (1.5 + 0.0625) + \frac{r}{16} \times 2.4847}{1. \times 2 + r \times 0}.$$

  It is easy to check that the solution of this equation is $r \simeq 2.2613$ and the values of both the lower and upper element costs in this case are $u_0(C_2) = u_1(C_2) \simeq 2.9422$.

We believe that it is possible to obtain further *small* improvements by recycling more and yet larger constructs and by designing a new subfactory for each such construct or combination of constructs. The $(P_0, \gamma \times P_{00})$ subfactory serves as a keystone in all our factories and in all such possible extensions. Recall that one of the worst cases of the $(P_0, \gamma \times P_{00})$ subfactory is the combination of U_0^2 and pruning. The lower part of an output partial order generated using this combination is essentially a hyperpair of the form $P_{1^{k'}}$, where $k \leq k' \leq 2k$. It is not hard to verify that even if we could recycle such a large hyperpair without attaching any credit to it, the lower and upper element costs of this combination would still be about $u_0(C_2) = u_1(C_2) \simeq 2.895$. It seems, therefore, that some new ideas are required to obtain a major improvement to our median selection algorithm.

10. Concluding remarks and open problems. We have improved the result of Schönhage, Paterson, and Pippenger [SPP76] and obtained an algorithm for the selection of the median that uses slightly less than $3n$ comparisons. Our algorithm is much more complicated than the algorithm of Schönhage, Paterson, and Pippenger, and it is perhaps a bit disappointing that the improvement obtained is so small. As mentioned at the end of the previous section, further small improvements are possible but it seems that new ideas are required to obtain a more substantial improvement.

Further narrowing the gap between the known upper and lower bounds on the number of comparisons needed to select the median remains a challenging open problem. Paterson has conjectured, for a long time, that the number of comparisons required for selecting the median, in the worst case, is about $\log_{4/3} 2 \cdot n \approx 2.41n$. This conjecture has now finally appeared in print; see Paterson [Pat96].

Schönhage, Paterson, and Pippenger [SPP76] show that a conjecture of Yao [Yao74] implies the existence of a median-finding algorithm that uses at most $2.5n + o(n)$ comparisons. Proving or disproving Yao's conjecture is also a challenging open problem.

The factories constructed in this paper are $\tilde{\mathcal{S}}_k^k$ factories and not S_k^k factories, as were the factories of Schönhage, Paterson, and Pippenger. Is it possible to improve the S_k^k factories of Schönhage, Paterson, and Pippenger and obtain S_k^k factories whose lower and upper element costs are below 3?

Schönhage, Paterson, and Pippenger [SPP76] describe nongreen S_k^k factories with unit cost $U_k \sim 3.5k$. Is it possible to improve this result?

Acknowledgment. The authors would like to thank Mike Paterson for some helpful discussions and for his comments on an earlier version of this paper.

STRUCTURE IN APPROXIMATION CLASSES*

PIERLUIGI CRESCENZI†, VIGGO KANN‡, RICCARDO SILVESTRI§, AND LUCA TREVISAN¶

Abstract. The study of the approximability properties of NP-hard optimization problems has recently made great advances mainly due to the results obtained in the field of proof checking. The last important breakthrough proves the APX-completeness of several important optimization problems and thus reconciles "two distinct views of approximation classes: *syntactic* and *computational*" [S. Khanna et al., in *Proc. 35th IEEE Symp. on Foundations of Computer Science*, IEEE Computer Society Press, Los Alamitos, CA, 1994, pp. 819–830]. In this paper we obtain new results on the structure of several computationally-defined approximation classes. In particular, after defining a new approximation preserving reducibility to be used for as many approximation classes as possible, we give the first examples of natural NPO-complete problems and the first examples of natural APX-intermediate problems. Moreover, we state new connections between the approximability properties and the query complexity of NPO problems.

Key words. complexity classes, reducibilities, approximation algorithms

1. Introduction.

In his pioneering paper on the approximation of combinatorial optimization problems [22], David Johnson formally introduced the notion of an approximable problem, proposed approximation algorithms for several problems, and suggested a possible classification of optimization problems on the grounds of their approximability properties. Since then it has been clear that, even though the decision versions of most NP-hard optimization problems are many-one polynomial-time reducible to each other, they do not share the same approximability properties. The main reason is that many-one reductions usually do not preserve the objective function and, even when they do, they rarely preserve the quality of the solutions. It is then clear that a stronger kind of reducibility has to be used. Indeed, an approximation preserving reduction not only has to map instances of a problem A to instances of a problem B, but it also has to be able to come back from "good" solutions for B to "good" solutions for A. Surprisingly, the first definition of this kind of reducibility [35] was given a full 13 years after Johnson's paper; after that, at least seven different approximation preserving reducibilities appeared in the literature (see Fig. 1.1). These reducibilities are identical with respect to the overall scheme but differ essentially in the way they preserve approximability: they range from the Strict reducibility in which the error cannot increase to the PTAS-reducibility in which there are basically no restrictions (see also Chapter 3 of [25] and [11]).

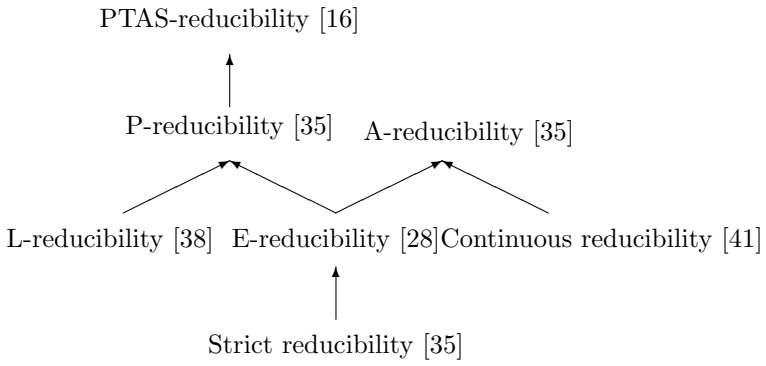

FIG. 1.1. *The taxonomy of approximation preserving reducibilities.*

By means of these reducibilities, several notions of completeness in approximation classes have been introduced and, basically, two different approaches have been followed. On one hand, the attention has been focused on computationally defined classes of problems, such as NPO (the class of optimization problems whose underlying decision problem is in NP) and APX (the class of constant-factor approximable NPO problems): along this line of research, however, almost all completeness results dealt either with artificial optimization problems or with problems for which lower bounds on the quality of the approximation were easily obtainable [14, 35]. On the other hand, researchers focused on the logical definability of optimization problems and introduced several syntactically defined classes for which natural completeness results were obtained [29, 36, 38]: unfortunately, the approximability properties of the problems in these latter classes were not related to standard complexity-theoretic conjectures. A first step towards the reconciling of these two approaches consisted of proving lower bounds (modulo $P \neq NP$ or some other likely condition) on the approximability of complete problems for syntactically defined classes [1, 33]. More recently, another step has been performed since the closure of syntactically defined classes with respect to an approximation preserving reducibility which has been proved to be equal to the more familiar computationally-defined classes [28].

In spite of this important achievement, beyond APX we are still forced to distinguish between maximization and minimization problems as long as we are interested in completeness proofs. Indeed, a result of [29] states that it is not possible to rewrite every NP maximization problem as an NP minimization problem unless NP = *co*-NP. A natural question is thus whether this duality extends to approximation preserving reductions.

Finally, even though the existence of "intermediate" artificial problems—that is, problems for which lower bounds on their approximation are not obtainable by completeness results—was proved in [14], a natural question arises: do natural intermediate problems exist? Observe that this question is also open in the field of decision problems: for example, it is known that the graph isomorphism problem cannot be NP-complete unless the polynomial-time hierarchy collapses [40], but no result has ever been obtained giving evidence that the problem does not belong to P.

The first goal of this paper is to define an approximation preserving reducibility that can be used for as many approximation classes as possible and such that all

reductions that have appeared in the literature still hold. In spite of the fact that the L-reducibility has been the most widely used so far, we will give strong evidence that it cannot be used to obtain completeness results in "computationally defined" classes such as APX, log-APX (that is, the class of problems approximable within a logarithmic factor), and poly-APX (that is, the class of problems approximable within a polynomial factor). Indeed, in [16] it has been shown that the L-reducibility is too strict and does not allow reduction of some problems that are known to be easy to approximate to problems that are known to be hard to approximate. In this paper we show, somewhat surprisingly, that the L-reducibility is too weak and is not approximation preserving (unless $\mathrm{P} = \mathrm{NP} \cap \textit{co}\text{-NP}$). The weakness of the L-reducibility is, essentially, shared by all reducibilities of Fig. 1.1 except the Strict reducibility and the E-reducibility; the strictness of the L-reducibility is shared by all of them (unless $\mathrm{P}^{\mathrm{NP}} \subseteq \mathrm{P}^{\mathrm{NP}[O(\log n)]}$) except the PTAS-reducibility. The reducibility we propose is *a combination of the E-reducibility and of the PTAS-reducibility*. As far as we know, it is the strictest reducibility that allows us to obtain all approximation completeness results that have appeared in the literature, such as the APX-completeness of Maximum Satisfiability [16, 28] and the poly-APX-completeness of Maximum Clique [28].

The second group of results refers to the existence of natural complete problems for NPO. Indeed, both [35] and [14] provide examples of natural complete problems for the class of minimization and maximization NP problems, respectively. In section 3 we will show *the existence of both maximization and minimization* NPO*-complete natural problems*. In particular, we prove that Maximum $0-1$ Programming and Minimum $0-1$ Programming are NPO-complete. This result shows that making use of a natural approximation preserving reducibility is powerful enough to encompass the "duality" problem raised in [29]. (Indeed, in [28] it was shown that this duality does not arise in APX, log-APX, poly-APX, and other subclasses of NPO.) Moreover, the same result can also be obtained when we restrict ourselves to the class NPO PB (i.e., the class of polynomially bounded NPO problems). In particular, we prove that Maximum PB $0-1$ Programming and Minimum PB $0-1$ Programming are NPO PB-complete.

The third group of results refers to the existence of natural APX-intermediate problems. In section 4, we will prove that Minimum Bin Packing (and other natural NPO problems) cannot be APX-complete unless the polynomial-time hierarchy collapses. Since it is well known [34] that this problem belongs to APX and that it does not belong to PTAS (that is, the class of NPO problems with polynomial-time approximation schemes) unless $\mathrm{P} = \mathrm{NP}$, our result yields *the first example of a natural* APX*-intermediate problem* (under a natural complexity-theoretic conjecture). Roughly speaking, the proof of our result is structured into two main steps. In the first step, we show that if Minimum Bin Packing were APX-complete then the problem of answering any set of k nonadaptive queries to an NP-complete problem could be reduced to the problem of approximating an instance of Minimum Bin Packing within a ratio depending on k. In the second step, we show that the problem of approximating an instance of Minimum Bin Packing within a given performance ratio can be solved in polynomial time by means of a constant number of nonadaptive queries to an NP-complete problem. These two steps will imply the collapse of the query hierarchy which in turn implies the collapse of the polynomial-time hierarchy. As a side effect of our proof, we will show that *if a problem is* APX*-complete, then it does not admit an asymptotic approximation scheme*.

The previous results are consequences of new connections between the approximability properties and the query complexity of NP-hard optimization problems. In several recent papers the notion of query complexity (that is, the number of queries to an NP oracle needed to solve a given problem) has been shown to be a very useful tool for understanding the complexity of approximation problems. In [7, 9] upper and lower bounds have been proved on the number of queries needed to approximate certain optimization problems (such as MAXIMUM SATISFIABILITY and MAXIMUM CLIQUE): these results deal with the complexity of approximating the value of the optimum solution and not with the complexity of computing approximate solutions. In this paper, instead, the complexity of "constructive" approximation will be addressed by considering the languages that can be recognized by polynomial-time machines which have a function oracle that solves the approximation problem. In particular, after proving the existence of natural APX-intermediate problems, in section 4.1 we will be able to solve an open question of [7], proving that *finding the vertices of the largest clique is more difficult than merely finding the vertices of a* 2*-approximate clique* unless the polynomial-time hierarchy collapses.

The results of [7, 9] show that the query complexity is a good measure to study approximability properties of optimization problems. The last group of our results show that completeness in approximation classes implies lower bounds on the query complexity. Indeed, in section 5 we show that the two approaches are basically equivalent by giving *sufficient and necessary conditions for approximation completeness in terms of query-complexity hardness and combinatorial properties.* These results have a twofold importance: they give new insights into the structure of complete problems for approximation classes and they reconcile the approach based on standard computation models with the approach based on the computation model for approximation proposed in [8]. As a final observation, our results can be seen as extensions of a result of [28] in which general sufficient (but not necessary) conditions for APX-completeness are proved.

1.1. Preliminaries. We assume the reader is familiar with the basic concepts of computational complexity theory. For the definitions of most of the complexity classes used in the paper we refer the reader to one of the books on the subject (see, for example, [2, 5, 18, 37]). We now give some standard definitions in the field of optimization and approximation theory.

DEFINITION 1.1. *An* NP optimization problem A *is a* 4*-tuple* $(I, sol, m, type)$ *such that the following hold:*

1. I *is the set of the* instances *of* A *and it is recognizable in polynomial time.*
2. *Given an instance* x *of* I, $sol(x)$ *denotes the set of* feasible solutions *of* x. *These solutions are short, that is, there exists a polynomial* p *such that, for any* $y \in sol(x)$, $|y| \leq p(|x|)$. *Moreover, for any* x *and for any* y *with* $|y| \leq p(|x|)$, *it is decidable in polynomial time whether* $y \in sol(x)$.
3. *Given an instance* x *and a feasible solution* y *of* x, $m(x, y)$ *denotes the positive integer* measure *of* y *(often also called the value of* y*). The function* m *is computable in polynomial time and is also called the* objective *function.*
4. $type \in \{\max, \min\}$.

The goal of an NP optimization problem with respect to an instance x is to find an *optimum solution*, that is, a feasible solution y such that $m(x, y) = type\{m(x, y') : y' \in sol(x)\}$. In the following opt will denote the function mapping an instance x to the measure of an optimum solution.

The *class* NPO is the set of all NP optimization problems. Max NPO is the set of

maximization NPO problems and Min NPO is the set of minimization NPO problems.

An NPO problem is said to be *polynomially bounded* if there exists a polynomial q such that, for any instance x and for any solution y of x, $m(x,y) \leq q(|x|)$. The *class* NPO PB is the set of all polynomially bounded NPO problems. Max PB is the set of all maximization problems in NPO PB and Min PB is the set of all minimization problems in NPO PB.

DEFINITION 1.2. *Let A be an* NPO *problem. Given an instance x and a feasible solution y of x, we define the* performance ratio of y with respect to x *as*

$$R(x,y) = \max\left\{\frac{m(x,y)}{\mathsf{opt}(x)}, \frac{\mathsf{opt}(x)}{m(x,y)}\right\}$$

and the relative error of y with respect to x *as*

$$E(x,y) = \frac{|\mathsf{opt}(x) - m(x,y)|}{\mathsf{opt}(x)}.$$

It is easy to see that, for any instance x and for any feasible solution y of x,

$$R(x,y) - 1 \geq E(x,y) \geq 0.$$

Also, the performance ratio $R(x,y)$ (respectively, relative error $E(x,y)$) is as close to 1 (respectively, 0) as the value of the feasible solution y is close to the value of an optimum solution for x.

DEFINITION 1.3. *Given an* NPO *problem A and an arbitrary function $r : N \to [1,\infty)$, we say that an algorithm T is an* $r(n)$-approximate algorithm for A *if T runs in polynomial time and, for any instance x of A with $sol(x) \neq \emptyset$, T returns a feasible solution $T(x)$ such that*

$$R(x,T(x)) \leq r(|x|).$$

DEFINITION 1.4. *Given a class of functions F, an* NPO *problem A belongs to the* class F-APX *if there exists an $r(n)$-approximate algorithm T for A, for some function $r \in F$. In particular,* APX, *log-*APX, *poly-*APX, *and exp-*APX *will denote the classes F-*APX *with F equal to the set $O(1)$, to the set $O(\log n)$, to the set $O(n^{O(1)})$, and to the set $O(2^{n^{O(1)}})$, respectively.*

One could object that there is no difference between NPO and exp-APX since the polynomial bound on the computation time of the objective function implies that any NPO problem is $h2^{n^k}$-approximable for some h and k. This is not true, since NPO problems exist for which it is even hard to find a feasible solution. We will see examples of such problems in section 3.

DEFINITION 1.5. *An* NPO *problem A belongs to the* class PTAS *if there exists an algorithm T such that, for any fixed rational $r > 1$, $T(\cdot, r)$ is an r-approximate algorithm for A.*

Clearly, the following inclusions hold:

$$\text{PTAS} \subseteq \text{APX} \subseteq \text{log-APX} \subseteq \text{poly-APX} \subseteq \text{exp-APX} \subseteq \text{NPO}.$$

It is also easy to see that these inclusions are strict if and only if P $\neq$ NP.

1.2. A list of NPO problems. We here define the NP optimization problems that will be used in the paper (for a much larger list of NPO problems we refer to [12, 13]). Observe that in the following definitions we will not mention the type of the problem since it will be specified by the name of the problem itself.

MAXIMUM CLIQUE
INSTANCE: Graph $G = (V, E)$.
SOLUTION: A clique in G, i.e., a subset $V' \subseteq V$ such that every two vertices in V' are joined by an edge in E.
MEASURE: Cardinality of the clique, i.e., $|V'|$.

MAXIMUM WEIGHTED ONES and MINIMUM WEIGHTED ONES
INSTANCE: Set of variables X, Boolean quantifier-free first-order formula ϕ over the variables in X, and a weight function $w : X \to N$.
SOLUTION: Truth assignment that satisfies ϕ.
MEASURE: The sum of the weights of the true variables.

MAXIMUM PB $0-1$ PROGRAMMING and MINIMUM PB $0-1$ PROGRAMMING
INSTANCE: Integer $m \times n$-matrix A, integer m-vector b, binary n-vector c.
SOLUTION: A binary n-vector x such that $Ax \geq b$.
MEASURE: $1 + \sum_{i=1}^{n} c_i x_i$.

MAXIMUM SATISFIABILITY
INSTANCE: Set of variables X and Boolean CNF formula ϕ over the variables in X.
SOLUTION: Truth assignment to the variables in X.
MEASURE: The number of satisfied clauses.

MINIMUM BIN PACKING
INSTANCE: Finite set U of items, and a size $s(u) \in Q \cap (0, 1]$ for each $u \in U$.
SOLUTION: A partition of U into disjoint sets $U_1, U_2, \ldots, U_m$ such that the sum of the sizes of the items in each U_i is at most 1.
