MEASURE: The number of used bins, i.e., the number m of disjoint sets.

MINIMUM ORDERED BIN PACKING
INSTANCE: Finite set U of items, a size $s(u) \in Q \cap (0, 1]$ for each $u \in U$, and a partial order $\preceq$ on U.
SOLUTION: A partition of U into disjoint sets $U_1, U_2, \ldots, U_m$ such that the sum of the sizes of the items in each U_i is at most 1 and if $u \in U_i$ and $u' \in U_j$ with $u \preceq u'$, then $i \leq j$.
MEASURE: The number of used bins, i.e., the number m of disjoint sets.

MINIMUM DEGREE SPANNING TREE
INSTANCE: Graph $G = (V, E)$.
SOLUTION: A spanning tree for G.
MEASURE: The maximum degree of the spanning tree.

MINIMUM EDGE COLORING
INSTANCE: Graph $G = (V, E)$.
SOLUTION: A coloring of E, i.e., a partition of E into disjoint sets $E_1, E_2, \ldots, E_k$ such that, for $1 \leq i \leq k$, no two edges in E_i share a common endpoint in G.
MEASURE: Cardinality of the coloring, i.e., the number k of disjoint sets.

2. A new approximation preserving reducibility. The goal of this section is to define a new approximation preserving reducibility that can be used for as many approximation classes as possible and such that all reductions that have appeared in the literature still hold. We will justify the definition of this new reducibility by emphasizing the disadvantages of previously known ones. In the following, we will assume that, for any reducibility, an instance x such that $sol(x) \neq \emptyset$ is mapped into an instance x' such that $sol(x') \neq \emptyset$.

2.1. The L-reducibility. The first reducibility we shall consider is the L-reducibility (for *linear* reducibility) [38] which is often most practical to use in order to show that a problem is at least as hard to approximate as another.

DEFINITION 2.1. *Let A and B be two* NPO *problems. A is said to be* L-reducible *to B, in symbols $A \leq_{\mathrm{L}} B$, if there exist two functions f and g and two positive constants α and β such that:*

1. *For any $x \in I_A$, $f(x) \in I_B$ is computable in polynomial time.*
2. *For any $x \in I_A$ and for any $y \in sol_B(f(x))$, $g(x,y) \in sol_A(x)$ is computable in polynomial time.*
3. *For any $x \in I_A$, $\mathsf{opt}_B(f(x)) \leq \alpha \mathsf{opt}_A(x)$.*
4. *For any $x \in I_A$ and for any $y \in sol_B(f(x))$,*

$$|\mathsf{opt}_A(x) - m_A(x, g(x,y))| \leq \beta |\mathsf{opt}_B(f(x)) - m_B(f(x), y)|.$$

The 4-tuple (f, g, α, β) is said to be an L-reduction from A to B.

Clearly, the L-reducibility preserves membership in PTAS. Indeed, if (f, g, α, β) is an L-reduction from A to B then, for any $x \in I_A$ and for any $y \in sol_B(f(x))$, we have that

$$E_A(x, g(x,y)) \leq \alpha\beta E_B(f(x), y),$$

so that if $B \in$ PTAS then $A \in$ PTAS [38]. The above inequality also implies that if A is a minimization problem and there exists an r-approximate algorithm for B, then there exists a $(1 + \alpha\beta(r-1))$-approximate algorithm for A. In other words, L-reductions from minimization problems to optimization problems preserve membership in APX. The next result gives strong evidence that, in general, this is not true whenever the starting problem is a maximization one.

THEOREM 2.2. *The following statements are equivalent:*

1. *There exist two problems $A \in$* Max NPO *and $B \in$* Min NPO *such that $A \notin$* APX*, $B \in$* APX*, and $A \leq_{\mathrm{L}} B$.*
2. *There exist two* Max NPO *problems A and B such that $A \notin$* APX*, $B \in$* APX*, and $A \leq_{\mathrm{L}} B$.*
3. *There exists a polynomial-time recognizable set of satisfiable Boolean formulas for which no polynomial-time algorithm can compute a satisfying assignment for each of them.*

Proof. (1) $\Rightarrow$ (2). Assume that there exist two problems $A \in$ Max NPO and $B \in$ Min NPO such that $A \notin$ APX, $B \in$ APX, and $A \leq_{\mathrm{L}} B$. In section 3.1 of [28], it is shown that, for any minimization problem C in APX, there exists a maximization problem $C_{\max}$ in APX such that $C \leq_{\mathrm{L}} C_{\max}$. Since the L-reducibility clearly satisfies the transitive property, we thus have that there exists a maximization problem $B_{\max} \in$ APX such that $A \leq_{\mathrm{L}} B_{\max}$.

(2) $\Rightarrow$ (3). Assume that for any polynomial-time recognizable set of satisfiable Boolean formulas there is a polynomial-time algorithm computing a satisfying assignment for each formula in the set. Suppose that (f, g, α, β) is an L-reduction

from a maximization problem A to a maximization problem B and that B is r-approximable for some $r > 1$. Let x be an instance of A and let y be a solution of $f(x)$ such that $\mathsf{opt}_B(f(x))/m_B(f(x), y) \leq r$. For the sake of convenience, let $\mathsf{opt}_A = \mathsf{opt}_A(x)$, $m_A = m_A(x, g(x, y))$, $\mathsf{opt}_B = \mathsf{opt}_B(f(x))$, and $m_B = m_B(f(x), y)$. Let also $m_x = \max\{m_A, m_B/\alpha\}$. Since $m_A \leq \mathsf{opt}_A$ and $m_B/\alpha \leq \mathsf{opt}_B/\alpha \leq \mathsf{opt}_A$, we have that $m_x \leq \mathsf{opt}_A$. We now show that $\mathsf{opt}_A/m_x \leq 1 + \alpha\beta(r-1)$, that is, m_x is a nonconstructive approximation of opt_A. Let $\gamma = \frac{\alpha r}{1+\alpha\beta(r-1)}$. There are two cases.

1. $\mathsf{opt}_B \leq \gamma \mathsf{opt}_A$. By the definition of the L-reducibility, $\mathsf{opt}_A - m_A \leq \beta(\mathsf{opt}_B - m_B)$. Since $\mathsf{opt}_B \leq \gamma\mathsf{opt}_A$ and $\mathsf{opt}_B/m_B \leq r$, we have that

$$\frac{\mathsf{opt}_A - m_A}{\mathsf{opt}_A} \leq \gamma\beta\frac{\mathsf{opt}_B - m_B}{\mathsf{opt}_B} \leq \gamma\beta(1 - 1/r).$$

Hence,

$$\frac{\mathsf{opt}_A}{m_x} \leq \frac{\mathsf{opt}_A}{m_A} \leq \frac{1}{1 - \gamma\beta\frac{r-1}{r}} = 1 + \alpha\beta(r-1),$$

where the last equality is due to the definition of γ.

2. $\mathsf{opt}_B > \gamma\mathsf{opt}_A$. It holds that

$$\begin{aligned}
\frac{\mathsf{opt}_A}{m_x} &\leq \frac{\mathsf{opt}_A}{m_B/\alpha} \\
&< \frac{\alpha(\mathsf{opt}_B/\gamma)}{m_B} \text{ (since } \mathsf{opt}_A < \mathsf{opt}_B/\gamma) \\
&\leq \frac{\alpha(\mathsf{opt}_B/\gamma)}{(\mathsf{opt}_B/r)} \text{ (since } m_B \geq \mathsf{opt}_B/r) \\
&= \frac{\alpha r}{\gamma} \\
&= 1 + \alpha\beta(r-1).
\end{aligned}$$

Let us now consider the following nondeterministic polynomial-time algorithm.

begin {input: $x \in I_A$}
  x_B := $f(x)$;
  y_B := r-approximate solution of x_B;
  y_A := $g(x, y_B)$;
  m_x := $\max\{m_A(x, y_A), m_B(x_B, y_B)/\alpha\}$;
  guess $y \in sol_A(x)$;
  if $m_A(x, y) \geq m_x$ **then** accept **else** reject;
end;

By applying Cook's reduction [10] to the above algorithm, it easily follows that, for any $x \in I_A$, a satisfiable Boolean formula ϕ_x can be constructed in polynomial time in the length of x so that any satisfying assignment for ϕ_x encodes a solution of x whose measure is at least m_x. Moreover, the set $\{\phi_x : x \in I_A\}$ is recognizable in polynomial time. By assumption, it is then possible to compute in polynomial time a satisfying assignment for ϕ_x and thus an approximate solution for x. This contradicts the assumption that $A \notin$ APX.

(3) $\Rightarrow$ (1). Assume that there exists a polynomial-time recognizable set S of satisfiable Boolean formulas for which no polynomial-time algorithm can compute a satisfying assignment for each of them. Consider the following two NPO problems

$A = (I_A, sol_A, m_A, \max)$ and $B = (I_B, sol_B, m_B, \min)$, where $I_A = I_B = S$, $sol_A(x) = sol_B(x) = \{y : y \text{ is a truth assignment to the variables of } x\}$:

$$m_A(x,y) = \begin{cases} |x| & \text{if } y \text{ is a satisfying assignment for } x, \\ 1 & \text{otherwise} \end{cases}$$

and

$$m_B(x,y) = \begin{cases} |x| & \text{if } y \text{ is a satisfying assignment for } x, \\ 2|x| & \text{otherwise.} \end{cases}$$

Clearly, problem B is in APX; if A is in APX, then there is a polynomial-time algorithm that computes a satisfying assignment for each formula in S, contradicting the assumption. Moreover, it is easy to see that A L-reduces to B via $f \equiv \lambda x.x$, $g \equiv \lambda x \lambda y.y$, $\alpha = 1$, and $\beta = 1$. □

Observe that in [32] it is shown that the third statement of the above theorem holds if and only if the γ-reducibility is different from the many-one reducibility. Moreover, in [21] it is shown that the latter hypothesis is somewhat intermediate between P $\neq$ NP $\cap$ *co*-NP and P $\neq$ NP. In other words, there is strong evidence that, even though the L-reducibility is suitable for proving completeness results within classes contained in APX (such as Max SNP [38]), this reducibility cannot be used to define the notion of completeness for classes beyond APX. Moreover, it cannot be blindly used to obtain positive results, that is, to prove the existence of approximation algorithms via reductions. Finally, it is possible to L-reduce the maximization problem B defined in the last part of the proof of the previous theorem to Maximum 3-Satisfiability: this implies that the closure of Max SNP with respect to the L-reducibility is not included in APX, contrary to what is commonly believed (see, for example, [37, p. 314]).

2.2. The E-reducibility. The drawbacks of the L-reducibility are mainly due to the fact that the relation between the performance ratios is set by two separate linear constraints on both the optimum values and the absolute errors. The E-reducibility (for *error* reducibility) [28] instead imposes a linear relation directly between the performance ratios.

Definition 2.3. *Let A and B be two* NPO *problems. A is said to be* E-reducible *to B, in symbols $A \leq_{\mathrm{E}} B$, if there exist two functions f and g and a positive constant α such that the following hold:*

1. *For any $x \in I_A$, $f(x) \in I_B$ is computable in polynomial time.*
2. *For any $x \in I_A$ and for any $y \in sol_B(f(x))$, $g(x,y) \in sol_A(x)$ is computable in polynomial time.*
3. *For any $x \in I_A$ and for any $y \in sol_B(f(x))$,*

$$R_A(x, g(x,y)) \leq 1 + \alpha(R_B(f(x), y) - 1).$$

The 3-tuple (f, g, α) is said to be an E-reduction from A to B.

Observe that, for any function r, an E-reduction maps $r(n)$-approximate solutions into $(1+\alpha(r(n^h)-1))$-approximate solutions, where h is a constant depending only on the reduction. Hence, the E-reducibility not only preserves membership in PTAS but also membership in exp-APX, poly-APX, log-APX, and APX. As a consequence of this observation and of the results of the previous section, we have that NPO problems exist which are L-reducible to each other but not E-reducible. However, the following

result shows that within the class APX the E-reducibility is just a generalization of the L-reducibility.

PROPOSITION 2.4. *For any two* NPO *problems* A *and* B, *if* $A \leq_{\mathrm{L}} B$ *and* $A \in$ APX, *then* $A \leq_{\mathrm{E}} B$.

Proof. Let T be an r-approximate algorithm for A with r constant and let $(f_L, g_L, \alpha_L, \beta_L)$ be an L-reduction from A to B. Then, for any $x \in I_A$ and for any $y \in sol_B(f_L(x))$, $E_A(x, g_L(x,y)) \leq \alpha_L \beta_L E_B(f_L(x), y)$. If A is a minimization problem then, for any $x \in I_A$ and for any $y \in sol_B(f_L(x))$,

$$\begin{aligned} R_A(x, g_L(x,y)) &= 1 + E_A(x, g_L(x,y)) \\ &\leq 1 + \alpha_L \beta_L E_B(f_L(x), y) \\ &\leq 1 + \alpha_L \beta_L (R_B(f_L(x), y) - 1), \end{aligned}$$

and thus $(f_L, g_L, \alpha_L \beta_L)$ is an E-reduction from A to B. Otherwise (that is, A is a maximization problem) we distinguish the following two cases:

1. $E_B(f_L(x), y) \leq \frac{1}{2\alpha_L \beta_L}$: in this case we have that

$$\begin{aligned} R_A(x, g_L(x,y)) - 1 &= \frac{E_A(x, g_L(x,y))}{1 - E_A(x, g_L(x,y))} \\ &\leq \frac{\alpha_L \beta_L E_B(f_L(x), y)}{1 - \alpha_L \beta_L E_B(f_L(x), y)} \\ &\leq 2\alpha_L \beta_L (R_B(f_L(x), y) - 1). \end{aligned}$$

2. $E_B(f_L(x), y) > \frac{1}{2\alpha_L \beta_L}$: in this case we have that $R_B(f_L(x), y) - 1 \geq \frac{1}{2\alpha_L \beta_L}$ so that

$$R_A(x, T(x)) - 1 \leq r - 1 \leq 2\alpha_L \beta_L (r-1)(R_B(f_L(x), y) - 1),$$

where the first inequality is due to the fact that T is an r-approximation algorithm for A.

We can thus define a 3-tuple (f_E, g_E, α_E) as follows:

1. For any $x \in I_A$, $f_E(x) = f_L(x)$.
2. For any $x \in I_A$ and for any $y \in sol_B(f_E(x))$,

$$g_E(x,y) = \begin{cases} g_L(x,y) & \text{if } m_A(x, g_L(x,y)) \geq m_A(x, T(x)), \\ T(x) & \text{otherwise.} \end{cases}$$

3. $\alpha_E = \max\{2\alpha_L \beta_L, 2\alpha_L \beta_L (r-1)\}$.

From the above discussion, it follows that the 3-tuple (f_E, g_E, α_E) is an E-reduction from A to B. □

Clearly, the converse of the above result does not hold since no problem in NPO − NPO PB can be L-reduced to a problem in NPO PB while any problem in PO can be E-reduced to any NPO problem. Moreover, in [28] it is shown that MAXIMUM 3-SATISFIABILITY is (NPO PB∩APX)-complete with respect to the E-reducibility. This result is not obtainable by means of the L-reducibility: indeed, it is easy to prove that MINIMUM BIN PACKING is not L-reducible to MAXIMUM 3-SATISFIABILITY unless P = NP (see, for example, [6]).

The E-reducibility is still somewhat too strict. Indeed, in [16] it has been shown that there exist natural PTAS problems, such as MAXIMUM KNAPSACK, which are not E-reducible to polynomially bounded APX problems, such as MAXIMUM 3-SATISFIABILITY (unless a logarithmic number of queries to an NP oracle is as powerful as a polynomial number of queries).

2.3. The AP-reducibility. The above mentioned drawback of the E-reducibility is mainly due to the fact that an E-reduction preserves optimum values (see [16]). Indeed, the linear relation between the performance ratios seems to be too restrictive. According to the definition of approximation preserving reducibilities given in [14], we could overcome this problem by expressing this relation by means of an implication. However, this is not sufficient: intuitively, since the function g does not know which approximation is required, it must still map optimum solutions into optimum solutions. The final step thus consists of letting the functions f and g depend on the performance ratio.[1] This implies that different constraints have to be put on the computation time of f and g: on one hand, we still want to preserve membership in PTAS; on the other, we want the reduction to be efficient even when poor performance ratios are required. These constraints are formally imposed in the following definition of *approximation preserving* reducibility (which is a restriction of the PTAS-reducibility introduced in [16]).

DEFINITION 2.5. *Let A and B be two* NPO *problems. A is said to be* AP-reducible *to B, in symbols $A \leq_{\mathrm{AP}} B$, if there exist two functions f and g and a positive constant α such that the following hold:*

1. *For any $x \in I_A$ and for any $r > 1$, $f(x,r) \in I_B$ is computable in time $t_f(|x|,r)$.*
2. *For any $x \in I_A$, for any $r > 1$, and for any $y \in sol_B(f(x,r))$, $g(x,y,r) \in sol_A(x)$ is computable in time $t_g(|x|,|y|,r)$.*
3. *For any fixed r, both $t_f(\cdot,r)$ and $t_g(\cdot,\cdot,r)$ are bounded by a polynomial.*
4. *For any fixed n, both $t_f(n,\cdot)$ and $t_g(n,n,\cdot)$ are nonincreasing functions.*
5. *For any $x \in I_A$, for any $r > 1$, and for any $y \in sol_B(f(x,r))$,*

$$R_B(f(x,r),y) \leq r \qquad \Rightarrow \qquad R_A(x,g(x,y,r)) \leq 1 + \alpha(r-1).$$

The 3-tuple (f,g,α) is said to be an AP-reduction from A to B.

According to the above definition, functions like $2^{1/(r-1)}n^h$ or $n^{1/(r-1)}$ are admissible bounds on the computation time of f and g, while this is not true for functions like n^r or 2^n.

Observe that, clearly, the AP-reducibility is a generalization of the E-reducibility. Moreover, it is easy to see that, contrary to the E-reducibility, any PTAS problem is AP-reducible to any NPO problem.

As far as we know, this reducibility is the strictest one appearing in the literature that allows us to obtain natural APX-completeness results (for instance, the APX-completeness of MAXIMUM SATISFIABILITY [16, 28]).

3. NPO-complete problems. In this section we will prove that there are natural problems that are complete for the classes NPO and NPO PB (from now on, unless otherwise specified, we will always refer to the AP-reducibility). Previously, completeness results have been obtained just for Max NPO, Min NPO, Max PB, and Min PB [14, 35, 4, 26]. One example of such a result is the following theorem.

THEOREM 3.1. MINIMUM WEIGHTED ONES *is* Min NPO*-complete and* MAXIMUM WEIGHTED ONES *is* Max NPO*-complete (with respect to the E-reducibility), even if only a subset $\{v_1,\ldots,v_s\}$ of the variables has nonzero weight $w(v_i) = 2^{s-i}$ and any truth assignment satisfying the instance gives the value true to at least one v_i.*

[1] We also let the function f depend on the performance ratio because this feature will turn out to be useful in order to prove interesting characterizations of complete problems for approximation classes.

We will construct AP-reductions from maximization problems to minimization problems and vice versa. Using these reductions we will show that a problem that is Max NPO-complete or Min NPO-complete in fact is complete for the whole of NPO, and that a problem that is Max PB-complete or Min PB-complete is complete for the whole of NPO PB.

THEOREM 3.2. MINIMUM WEIGHTED ONES *and* MAXIMUM WEIGHTED ONES *are* NPO*-complete.*

Proof. In order to establish the NPO-completeness of MINIMUM WEIGHTED ONES we just have to show that there is an AP-reduction from a Max NPO-complete problem to MINIMUM WEIGHTED ONES. As the Max NPO-complete problem we will use the restricted version of MAXIMUM WEIGHTED ONES from Theorem 3.1.

Let x be an instance of MAXIMUM WEIGHTED ONES, i.e., a formula ϕ over variables $v_1, \ldots, v_s$ with weights $w(v_i) = 2^{s-i}$ and some variables with weight zero. We will first give a simple reduction that preserves the approximability within the factor 2, and then adjust it to obtain an AP-reduction.

Let $f(x)$ be the formula $\phi \wedge \alpha_1 \wedge \cdots \wedge \alpha_s$, where α_i is defined as

$$(z_i \equiv (\overline{v}_1 \wedge \cdots \wedge \overline{v}_{i-1} \wedge v_i)),$$

where $z_1, \ldots, z_s$ are new variables with weights $w(z_i) = 2^i$ and where all other variables (even the v-variables) have zero weight. If y is a satisfying assignment of $f(x)$, let $g(x, y)$ be the restriction of the assignment to the variables that occur in ϕ. This assignment clearly satisfies ϕ.

Note that exactly one of the z-variables is true in any satisfying assignment of $f(x)$. Indeed, if all z-variables were false, then all v-variables would be false and ϕ would not be satisfied. On the other hand, if both z_i and z_j were true with $j > i$, then v_i would be both true and false, which is a contradiction. Hence,

$$\begin{aligned} m(f(x), y) = 2^i &\Leftrightarrow z_i = 1 \\ &\Leftrightarrow v_1 = v_2 = \cdots = v_{i-1} = 0, v_i = 1 \\ &\Leftrightarrow 2^{s-i} \leq m(x, g(x, y)) < 2 \cdot 2^{s-i} \\ &\Leftrightarrow \frac{2^s}{m(f(x), y)} \leq m(x, g(x, y)) < 2\frac{2^s}{m(f(x), y)}. \end{aligned}$$

In particular this holds for the optimum solution. Thus the performance ratio for MAXIMUM WEIGHTED ONES is

$$R(x, g(x, y)) = \frac{\mathsf{opt}(x)}{m(x, g(x, y))} < \frac{2\dfrac{2^s}{\mathsf{opt}(f(x))}}{\dfrac{2^s}{m(f(x), y)}} = 2\frac{m(f(x), y)}{\mathsf{opt}(f(x))} = 2R(f(x), y),$$

which means that the reduction preserves the approximability within 2.

Let us now extend the construction in order to obtain $R(x, g(x, y)) \leq (1 + 2^{-k})R(f_k(x), y)$ for every nonnegative integer k. The reduction described above corresponds to $k = 0$.

For any $i \in \{1, \ldots, s\}$ and for any $(b_1, \ldots, b_{k(i)}) \in \{0, 1\}^{k(i)}$, where $k(i) = \min\{s - i, k\}$, we have a variable $z_{i,b_1,\ldots,b_{k(i)}}$. Let

$$f_k(x) = \phi \wedge \bigwedge_{\substack{i \in \{1,\ldots,s\} \\ (b_1,\ldots,b_{k(i)}) \in \{0,1\}^{k(i)}}} \alpha_{i,b_1,\ldots,b_{k(i)}},$$

where $\alpha_{i,b_1,\ldots,b_{k(i)}}$ is defined as

$$\left(z_{i,b_1,\ldots,b_{k(i)}} \equiv \left(\overline{v}_1 \wedge \cdots \wedge \overline{v}_{i-1} \wedge v_i \wedge (v_{i+1} = b_1) \wedge \cdots \wedge (v_{i+k(i)} = b_{k(i)})\right)\right).$$

Define $g(x, y)$ as above. Finally, define

$$w(z_{i,b_1,\ldots,b_{k(i)}}) = \left\lceil \frac{K \cdot 2^s}{w(v_i) + \sum_{j=1}^{k(i)} b_j w(v_{i+j})} \right\rceil = \left\lceil \frac{K \cdot 2^i}{1 + \sum_{j=1}^{k(i)} b_j 2^{-j}} \right\rceil$$

(by choosing K greater than 2^k we can disregard the effect of the ceiling operation in the following computations).

As in the previous reduction exactly one of the z-variables is true in any satisfying assignment of $f_k(x)$. If, in a solution y of $f_k(x)$, $z_{i,b_1,\ldots,b_{k(i)}} = 1$, then we have $m(f_k(x), y) = w(z_{i,b_1,\ldots,b_{k(i)}})$ and we know that

$$m(x, g(x, y)) \geq w(v_i) + \sum_{j=1}^{k(i)} b_j w(v_{i+j}) = 2^{s-i} \left(1 + \sum_{j=1}^{k(i)} b_j 2^{-j}\right).$$

On the other hand, if $k(i) = s - i$, then $m(x, g(x, y)) = 2^{s-i}(1 + \sum_{j=1}^{k(i)} b_j 2^{-j})$; otherwise

$$m(x, g(x, y)) \leq w(v_i) + \sum_{j=1}^{k} b_j w(v_{i+j}) + \sum_{j=k+i+1}^{s} w(v_j) < 2^{s-i} \left(1 + \sum_{j=1}^{k} b_j 2^{-j}\right)(1 + 2^{-k}).$$

In both cases, we thus get

$$\frac{K \cdot 2^s}{m(f_k(x), y)} \leq m(x, g(x, y)) < \frac{K \cdot 2^s}{m(f_k(x), y)}(1 + 2^{-k})$$

and therefore $R(x, g(x, y)) < (1 + 2^{-k})R(f_k(x), y)$. Given any $r > 1$, if we choose k such that $2^{-k} \leq (r - 1)/r$, e.g., $k = \lceil \log r - \log(r - 1) \rceil$, then $R(f_k(x), y) \leq r$ implies $R(x, g(x, y)) < (1 + 2^{-k})R(f_k(x), y) \leq r + r2^{-k} \leq r + r - 1 = 1 + 2(r - 1)$. This is obviously an AP-reduction with $\alpha = 2$.

A very similar proof can be used to show that Maximum Weighted Ones is NPO-complete. □

Corollary 3.3. *Any* Min NPO*-complete problem is* NPO*-complete and any* Max NPO*-complete problem is* NPO*-complete.*

As an application of the above corollary, we have that the Minimum $0-1$ Programming problem is NPO-complete.

We can also show that there are natural complete problems for the class of polynomially bounded NPO problems.

Theorem 3.4. Maximum PB $0-1$ Programming *and* Minimum PB $0-1$ Programming *are* NPO PB*-complete.*

Proof. Maximum PB $0-1$ Programming is known to be Max PB-complete [4] and Minimum PB $0-1$ Programming is known to be Min PB-complete [26]. Thus we just have to show that there are AP-reductions from Minimum PB $0-1$ Programming to Maximum PB $0-1$ Programming and from Maximum PB $0-1$ Programming to Minimum PB $0-1$ Programming.

Both reductions use exactly the same construction. Given a satisfying variable assignment, we define the *one-variables* to be the variables occurring in the objective

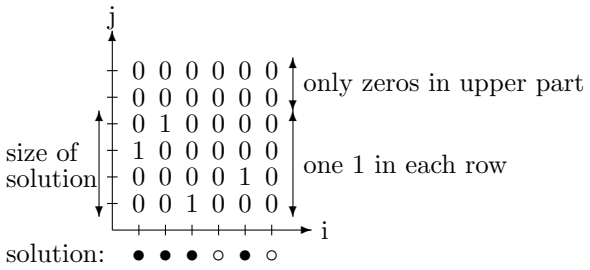

FIG. 3.1. *The idea of the reduction from* MINIMUM/MAXIMUM PB $0-1$ PROGRAMMING *to* MAXIMUM/MINIMUM PB $0-1$ PROGRAMMING. *The variable* $x_i^j = 1$ *if and only if* v_i *is the* j*th one-variable in the solution. There is at most one* 1 *in each column and in each row.*

function that have the value one. The objective value is the number of one-variables plus 1.

The objective value of a solution is encoded by introducing an order of the one-variables. The order is encoded by a squared number of $0-1$ variables (see Fig. 3.1). The idea is to invert the objective values, so that a solution without one-variables corresponds to an objective value of n of the constructed problem, and, in general, a solution with p one-variables corresponds to an objective value of $\left\lfloor \frac{n}{p+1} \right\rfloor$.

The reductions are constructed as follows. Given an instance of MINIMUM PB $0-1$ PROGRAMMING or MAXIMUM PB $0-1$ PROGRAMMING, i.e., an objective function $1 + \sum_{k=1}^{m} v_k$ and some inequalities over variables $V = \{v_1, \ldots, v_m\} \cup U$, construct m^2 variables x_i^j, $1 \le i, j \le m$, and the following inequalities:

$$\forall i \in [1 \ldots m] \qquad \sum_{j=1}^{m} x_i^j \le 1 \qquad \text{(at most one 1 in each column)}, \tag{3.1}$$

$$\forall j \in [1 \ldots m] \qquad \sum_{i=1}^{m} x_i^j \le 1 \qquad \text{(at most one 1 in each row)}, \tag{3.2}$$

$$\forall j \in [1 \ldots m-1] \ \sum_{i=1}^{m} x_i^j - \sum_{i=1}^{m} x_i^{j+1} \ge 0 \ \text{(only zeros in upper part)}. \tag{3.3}$$

Besides these inequalities we include all inequalities from the original problem, but we substitute each variable v_i with the sum $\sum_{k=1}^{m} x_i^k$. The variables in U (that do not occur in the objective function) are left intact.

The objective function is defined as

$$n - \sum_{p=1}^{m} \left(\left\lfloor \frac{n}{p} \right\rfloor - \left\lfloor \frac{n}{p+1} \right\rfloor \right) \sum_{i=1}^{m} x_i^p. \tag{3.4}$$

In order to express the objective function with only binary coefficients we have to introduce n new variables $y_1, \ldots, y_n$, where $y_j = 1 - \sum_{i=1}^{m} x_i^p$ for $\lfloor n/(p+1) \rfloor < j \le \lfloor n/p \rfloor$ and $y_j = 1$ for $j \le \lfloor n/(m+1) \rfloor$. The objective function then is $\sum_{j=1}^{n} y_j$. One can now verify that a solution of the original problem instance with s one-variables (i.e., with an objective value of $s+1$) will exactly correspond to a solution of the constructed problem instance with objective value $\lfloor n/(s+1) \rfloor$ and vice versa.

Suppose that the optimum solution to the original problem instance has M one-variables; then the performance ratio $(s+1)/(M+1)$ will correspond to the performance ratio

$$\frac{\left\lfloor \dfrac{n}{M+1} \right\rfloor}{\left\lfloor \dfrac{n}{s+1} \right\rfloor} = \frac{s+1}{M+1}\left(1 \pm \frac{m}{n}\right)$$

for the constructed problem, where $\frac{m}{n}$ is the relative error due to the floor operation. By choosing n large enough, the relative error can be made arbitrarily small. Thus it is easy to see that the reduction is an AP-reduction. □

COROLLARY 3.5. *Any* Min PB*-complete problem is* NPO PB*-complete and any* Max PB*-complete problem is* NPO PB*-complete.*

4. Query complexity and APX-intermediate problems. The existence of APX-intermediate problems (that is, problems in APX which are not APX-complete) has already been shown in [14] (assuming P $\neq$ NP) where an artificial such problem is obtained by diagonalization techniques similar to those developed to prove the existence of NP-intermediate problems [31]. In this section, we prove that "natural" APX-intermediate problems exist: for instance, we will show that MINIMUM BIN PACKING is APX-intermediate. In order to prove this result, we will establish new connections between the approximability properties and the query complexity of NP-hard optimization problems. To this aim, let us first recall the following definition.

DEFINITION 4.1. *A language L belongs to the* class $\mathrm{P}^{\mathrm{NP}[f(n)]}$ *if it is decidable by a polynomial-time oracle Turing machine which asks at most $f(n)$ queries to an* NP*-complete oracle, where n is the input size. The* class QH *is defined to be the union* $\bigcup_{k>1} \mathrm{P}^{\mathrm{NP}[k]}$.

Similarly, we can define the class of functions $\mathrm{FP}^{\mathrm{NP}[f(n)]}$ [30]. The following result has been proved in [23, 24].

THEOREM 4.2. *If there exists a constant k such that*

$$\mathrm{QH} = \mathrm{P}^{\mathrm{NP}[k]},$$

then the polynomial-time hierarchy collapses.

The query-complexity of the "nonconstructive" approximation of several NP-hard optimization problems has been studied by using hardness results with respect to classes of functions $\mathrm{FP}^{\mathrm{NP}[\cdot]}$ [7, 9]. However, this approach cannot be applied to analyze the complexity of "constructing" approximate solutions. To overcome this limitation, we use a novel approach that basically consists of considering how helpful is an approximation algorithm for a given optimization problem to solve decision problems.

DEFINITION 4.3. *Given an* NPO *problem A and a rational $r \geq 1$, A_r is a multivalued partial function that, given an instance x of A, returns the set of feasible solutions y of x such that $R(x,y) \leq r$.*

DEFINITION 4.4. *Given an* NPO *problem A and a rational $r \geq 1$, a language L belongs to P^{A_r} if there exist two polynomial-time computable functions f and g such that, for any x, $f(x)$ is an instance of A with $sol(f(x)) \neq \emptyset$, and, for any $y \in A_r(f(x))$, $g(x,y) = 1$ if and only if $x \in L$. The* class $\mathrm{AQH}(A)$ *is equal to the union* $\bigcup_{r>1} \mathrm{P}^{A_r}$.

The following result states that an approximation problem does not help more than a constant number of queries to an NP-complete problem. It is worth observing that, in general, an approximate solution, even though not very helpful, requires more than a logarithmic number of queries to be computed [8].

PROPOSITION 4.5. *For any problem A in* APX, $\mathrm{AQH}(A) \subseteq \mathrm{QH}$.

Proof. Assume that A is a maximization problem (the proof for minimization problems is similar). Let T be an r-approximate algorithm for A, for some $r > 1$, and let $L \in \mathrm{P}^{A_\rho}$ for some $\rho > 1$. Two polynomial-time computable functions f and g then exist witnessing this latter fact. For any x, let $m = m(f(x), T(f(x)))$, so that $m \leq \mathsf{opt}(f(x)) \leq rm$. We can then partition the interval $[m, rm]$ into $\lfloor \log_\rho r \rfloor + 1$ subintervals

$$[m, \rho m), [\rho m, \rho^2 m), \ldots, [\rho^{\lfloor \log_\rho r \rfloor - 1} m, \rho^{\lfloor \log_\rho r \rfloor} m], [\rho^{\lfloor \log_\rho r \rfloor} m, rm],$$

and start looking for the subinterval containing the optimum value. (A similar technique has been used in [7, 9].) This can clearly be done using $\lfloor \log_\rho r \rfloor + 1$ queries to an NP-complete oracle. One more query is sufficient to know whether there exists a feasible solution y whose value lies in that interval and such that $g(x, y) = 1$. Since y is ρ-approximate, it follows that L can be decided using $\lfloor \log_\rho r \rfloor + 2$ queries, that is, $L \in \mathrm{QH}$. □

Recall that an NPO problem admits an *asymptotic polynomial-time approximation scheme* if there exists an algorithm T such that, for any x and for any $r > 1$, $R(x, T(x, r)) \leq r + k/\mathsf{opt}(x)$ with k constant and the time complexity of $T(x, r)$ is polynomial with respect to $|x|$. The class of problems that admit an asymptotic polynomial-time approximation scheme is usually denoted by PTAS^∞. The following result shows that, for this class, the previous fact can be strengthened.

PROPOSITION 4.6. *Let $A \in \mathrm{PTAS}^\infty$. Then there exists a constant h such that* $\mathrm{AQH}(A) \subseteq \mathrm{P}^{\mathrm{NP}[h]}$.

Proof. Let A be a minimization problem in PTAS^∞. (The proof for maximization problem is very similar.) By definition, there exist a constant k and an algorithm T such that, for any instance x and for any rational $r > 1$,

$$m(x, T(x, r)) \leq r \cdot \mathsf{opt}(x) + k.$$

We will now prove that there exists a constant h such that, for any $r > 1$, a function $l_r \in \mathrm{FP}^{\mathrm{NP}[h-1]}$ exists such that, for any instance x of the problem A,

$$\mathsf{opt}(x) \leq l_r(x) \leq r \cdot \mathsf{opt}(x).$$

Intuitively, functions l_r form a nonconstructive approximation scheme that is computable by a constant number of queries to an NP-complete oracle. Given an instance x, we can check whether $sol(x) = \emptyset$ by means of a single query to an NP oracle, so that we can restrict ourselves to instances such that $sol(x) \neq \emptyset$ (and thus $\mathsf{opt}(x) \geq 1$). Note that for these instances, $T(\cdot, 2)$ is a $(k + 2)$-approximate algorithm for A. Let us fix an $r > 1$, let $\varepsilon = r - 1$, $y = T(x, 1 + \varepsilon/2)$, and $a = m(x, T(x, 2))$. We have to distinguish two cases.

1. $a \geq 2k(k + 2)/\varepsilon$: in this case, $\mathsf{opt}(x) \geq 2k/\varepsilon$, that is, $\mathsf{opt}(x)\varepsilon/2 \geq k$. Then

$$\begin{aligned} m(x, y) &\leq \mathsf{opt}(x)(1 + \varepsilon/2) + k \\ &\leq \mathsf{opt}(x)(1 + \varepsilon/2) + \mathsf{opt}(x)\varepsilon/2 \\ &= \mathsf{opt}(x)(1 + \varepsilon) = r\mathsf{opt}(x); \end{aligned}$$

that is, y is an r-approximate solution for x, and we can set $l_r(x) = m(x, y)$. (In this case l_r has been computed by only one query.)

2. $a < 2k(k+2)/\varepsilon$: in this case, $\mathsf{opt}(x) < 2k(k+2)/\varepsilon$. Then,

$$\mathsf{opt}(x) \leq m(x, y) \leq \mathsf{opt}(x) + \mathsf{opt}(x)\varepsilon/2 + k < \mathsf{opt}(x) + k(k+2) + k.$$

Clearly, $\lceil \log k(k+3) \rceil$ queries to NP are sufficient to find the optimum value $\mathsf{opt}(x)$ by means of a binary search technique: in this case $l_r(x) = \mathsf{opt}(x)$ has been computed by $\lceil \log k(k+3) \rceil + 1$ queries.

Let L now be a language in AQH(A); then $L \in \mathrm{P}^{A_r}$ for some $r > 1$. Let f and g be the functions witnessing that $L \in \mathrm{P}^{A_r}$. Observe that, for any x, $x \in L$ if and only if there exists a solution y for $f(x)$ such that $m(f(x), y) \geq l_r(f(x))$ and $g(f(x), y) = 1$; that is, given $l_r(f(x))$, deciding whether $x \in L$ is an NP problem. Since $l_r(f(x))$ is computable by means of at most $\lceil \log k(k+3) \rceil + 1$ queries to NP, we have that $L \in \mathrm{P}^{\mathrm{NP}[h]}$, where $h = \lceil \log k(k+3) \rceil + 2$. □

The next proposition, instead, states that any language L in the query hierarchy can be decided using just one query to A_r, where A is APX-complete and r depends on the level of the query hierarchy L belongs to. In order to prove this proposition, we need the following technical result to be realized.[2]

LEMMA 4.7. *For any* APX*-complete problem A and for any k, there exist two polynomial-time computable functions f and g and a constant r such that the following hold:*

1. *For any k-tuple $(x_1, \ldots, x_k)$ of instances of* PARTITION*, $x = f(x_1, \ldots, x_k)$ is an instance of A.*

2. *If y is a solution of x whose performance ratio is smaller than r, then $g(x, y) = (b_1, \ldots, b_k)$, where $b_i \in \{0, 1\}$ and $b_i = 1$ if and only if x_i is a yes-instance.*

Proof. Let $x_i = (U_i, s_i)$ be an instance of PARTITION for $i = 1, \ldots, k$. Without loss of generality, we can assume that the U_is are pairwise disjoint and that, for any i, $\sum_{u \in U_i} s_i(u) = 2$. Let $w = (U, s, \preceq)$ be an instance of MINIMUM ORDERED BIN PACKING defined as follows. (A similar construction has been used in [39].)

1. $U = \bigcup_{i=1}^{k} U_i \cup \{v_1, \ldots, v_{k-1}\}$, where the v_is are new items.
2. For any $u \in U_i$, $s(u) = s_i(u)$ and $s(v_i) = 1$ for $i = 1, \ldots, k-1$.
3. For any $i < j \leq k$, for any $u \in U_i$, and for any $u' \in U_j$, $u \preceq v_i \preceq u'$.

Any solution of w must be formed by a sequence of packings of $U_1, \ldots, U_k$ such that, for any i, the bins used for U_i are separated by the bins used for U_{i+1} by means of one bin which is completely filled by v_i. In particular, the packings of the U_is in any optimum solution must use either two or three bins: two bins are used if and only if x_i is a yes-instance. The optimum measure thus is at most $4k - 1$ so that any $(1 + 1/(4k))$-approximate solution is an optimum solution.

Since MINIMUM ORDERED BIN PACKING belongs to APX [43] and A is APX-complete, there then exists an AP-reduction (f_1, g_1, α) from MINIMUM ORDERED BIN PACKING to A. We can then define $x = f(x_1, \ldots, x_k) = f_1(w, 1 + 1/(4\alpha k))$ and $r = 1 + 1/(4\alpha k)$. For any r-approximate solution y of x, the fourth property of the AP-reducibility implies that $z = g_1(x, y, 1 + 1/(4\alpha k))$ is a $(1 + 1/(4k))$-approximate

[2] Recall that the NP-complete problem PARTITION is defined as follows: given a set U of items and a size function $s : U \to Q \cap (0, 1]$, does there exist a subset $U' \subseteq U$ such that

$$\sum_{u \in U'} s(u) = \sum_{u \notin U'} s(u) \ ?$$

solution of w and thus an optimum solution of w. From z, we can easily derive the right answers to the k queries $x_1, \ldots, x_k$. □

We are now able to prove the following result.

PROPOSITION 4.8. *For any* APX*-complete problem* A, $\mathrm{QH} \subseteq \mathrm{AQH}(A)$.

Proof. Let $L \in \mathrm{QH}$, then $L \in \mathrm{P}^{\mathrm{NP}[h]}$ for some h. It is well known (see, for instance, [3]) that L can be reduced to the problem of answering $k = 2^{h-1}$ nonadaptive queries to NP. More formally, there exist two polynomial-time computable functions t_1 and t_2 such that:

1. For any x, $t_1(x) = (x_1, \ldots, x_k)$, where $x_1, \ldots, x_k$ are k instances of the PARTITION problem.
2. For any $(b_1, \ldots, b_k) \in \{0,1\}^k$, $t_2(x, b_1, \ldots, b_k) \in \{0,1\}$.
3. If, for any j, $b_j = 1$ if and only if x_j is a yes-instance, then $t_2(x, b_1, \ldots, b_k) = 1$ if and only if $x \in L$.

Let now f, g, and r be the two functions and the constant of Lemma 4.7 applied to problem A and constant k. For any x, $x' = f(t_1(x))$ is an instance of A such that if y is an r-approximate solution for x', then $t_2(g(x', y)) = 1$ if and only if $x \in L$. Thus, $L \in \mathrm{P}^{A_r}$. □

By combining Propositions 4.5 and 4.8, we thus have the following theorem that characterizes the approximation query hierarchy of the hardest problems in APX.

THEOREM 4.9. *For any* APX*-complete problem* A, $\mathrm{AQH}(A) = \mathrm{QH}$.

Finally, we have the following result that states the existence of natural intermediate problems in APX.

THEOREM 4.10. *If the polynomial-time hierarchy does not collapse, then* MINIMUM BIN PACKING*,* MINIMUM DEGREE SPANNING TREE*, and* MINIMUM EDGE COLORING *are* APX*-intermediate.*

Proof. From Proposition 4.6 and from the fact that MINIMUM BIN PACKING is in PTAS^{∞} [27], it follows that AQH(MINIMUM BIN PACKING) $\subseteq \mathrm{P}^{\mathrm{NP}[h]}$ for a given h. If MINIMUM BIN PACKING is APX-complete, then from Proposition 4.8 it follows that $\mathrm{QH} \subseteq \mathrm{P}^{\mathrm{NP}[h]}$. From Theorem 4.2 we thus have the collapse of the polynomial-time hierarchy. The proofs for MINIMUM DEGREE SPANNING TREE and MINIMUM EDGE COLORING are identical and use the results of [20, 17]. □

Observe that the previous result does not seem to be obtainable by using the hypothesis $\mathrm{P} \neq \mathrm{NP}$, as shown by the following theorem.

THEOREM 4.11. *If* NP = *co*-NP*, then* MINIMUM BIN PACKING *is* APX*-complete.*

Proof. Assume NP = *co*-NP; we will present an AP reduction from MAXIMUM SATISFIABILITY to MINIMUM BIN PACKING. Since NP = *co*-NP, there exists a nondeterministic polynomial-time Turing machine M that, given in input an instance ϕ of MAXIMUM SATISFIABILITY, has an accepting computation and all accepting computations halt with an optimum solution for ϕ written on the tape. Indeed, M guesses an integer k, an assignment τ such that $m(\phi, \tau) = k$, and a proof of the fact that $\mathsf{opt}(\phi) \leq k$. From the proof of Cook's theorem it follows that, given ϕ, we can find in polynomial time a formula ϕ' such that ϕ' is satisfiable and that given any satisfying assignment for ϕ', we can find in polynomial time an optimum solution for ϕ. By combining this construction with the NP-completeness proof of the MINIMUM BIN PACKING problem, we obtain two polynomial-time computable functions t_1 and t_2 such that, for any instance ϕ of MAXIMUM SATISFIABILITY, $t_1(\phi) = x_\phi$ is an instance of MINIMUM BIN PACKING such that $\mathsf{opt}(x_\phi) = 2$ and, for any optimum solution y of x_ϕ, $t_2(x_\phi, y)$ is an optimum solution of ϕ. Observe that, by construction,

an r-approximate solution for x_ϕ is indeed an optimum solution provided that $r < 3/2$. Let T be a 4/3-approximate algorithm for MAXIMUM SATISFIABILITY [44, 19]. The reduction from MAXIMUM SATISFIABILITY to MINIMUM BIN PACKING is defined as follows: $f(\phi, r) = t_1(\phi)$;

$$g(\phi, y, r) = \begin{cases} T(\phi) & \text{if } r \geq 4/3, \\ t_2(t_1(\phi), y) & \text{otherwise.} \end{cases}$$

It is easy to verify that the above is an AP-reduction with $\alpha = 1$. □

Finally, note that the above result can be extended to any APX problem which is NP-hard to approximate within a given performance ratio.

4.1. A remark on MAXIMUM CLIQUE. The following lemma is the analogue of Proposition 4.5 within NPO PB and can be proved similarly by binary search techniques.

LEMMA 4.12. *For any* NPO PB *problem A and for any $r > 1$,*

$$\mathrm{P}^{A_r} \subseteq \mathrm{P}^{\mathrm{NP}[\log\log n + O(1)]}.$$

From this lemma, from the fact that $\mathrm{P}^{\mathrm{NP}[\log n]}$ is contained in $\mathrm{P}^{\mathrm{MC}_1}$, where MC stands for MAXIMUM CLIQUE [30], and from the fact that if there exists a constant k such that

$$\mathrm{P}^{\mathrm{NP}[\log\log n + k]} = \mathrm{P}^{\mathrm{NP}[\log n]},$$

then the polynomial-time hierarchy collapses [42], it follows that the next result solves an open question posed in [7]. Informally, this result states that it is not possible to reduce the problem of finding a maximum clique to the problem of finding a 2-approximate clique (unless the polynomial-time hierarchy collapses).

THEOREM 4.13. *If $\mathrm{P}^{\mathrm{MC}_1} \subseteq \mathrm{P}^{\mathrm{MC}_2}$ then the polynomial-time hierarchy collapses.*

5. Query complexity and completeness in approximation classes. In this final section, we shall give a full characterization of problems complete for poly-APX and APX, respectively—in terms of hardness of the corresponding approximation problems with respect to classes of partial multivalued functions and in terms of suitably defined combinatorial properties.

The classes of functions we will refer to have been introduced in [8] as follows.

DEFINITION 5.1. $\mathrm{FNP}^{\mathrm{NP}[q(n)]}$ *is the class of partial multivalued functions computable by nondeterministic polynomial-time Turing machines which ask at most $q(n)$ queries to an* NP *oracle in the* entire *computation tree.*[3]

In order to talk about hardness with respect to these classes we will use the following reducibility, which is an extension of both metric reducibility [30] and one-query reducibility [15] and has been introduced in [8].

DEFINITION 5.2. *Let F and G be two partial multivalued functions. We say that F many-one reduces to G (in symbols, $F \leq_{\mathrm{mv}} G$) if there exist two polynomial-time algorithms t_1 and t_2 such that, for any x in the domain of F, $t_1(x)$ is in the domain of G and, for any $y \in G(t_1(x))$, $t_2(x, y) \in F(x)$.*

The combinatorial property used to characterize poly-APX-complete problems is the well-known self-improvability (see, for instance, [36]).

[3] We say that a multivalued partial function F is computable by a nondeterministic Turing machine N if, for every x in the domain of F, there exists a halting computation path of $N(x)$ and any halting computation path of $N(x)$ outputs a value in $F(x)$.

DEFINITION 5.3. *A problem A is* self-improvable *if there exist two algorithms t_1 and t_2 such that, for any instance x of A and for any two rationals $r_1, r_2 > 1$, $x' = t_1(x, r_1, r_2)$ is an instance of A and, for any $y' \in A_{r_2}(x')$, $y = t_2(x, y', r_1, r_2) \in A_{r_1}(x)$. Moreover, for any fixed r_1 and r_2, the running time of t_1 and t_2 is polynomial.*

We are now ready to state the first result of this section.

THEOREM 5.4. *A poly-*APX *problem A is poly-*APX*-complete if and only if it is self-improvable and A_{r_0} is $\mathrm{FNP}^{\mathrm{NP}[\log\log n + O(1)]}$-hard for some $r_0 > 1$.*

Proof. Let A be a poly-APX-complete problem. Since MAXIMUM CLIQUE is self-improvable [18] and poly-APX-complete [28] and since the equivalence with respect to the AP-reducibility preserves the self-improvability property (see [36]), we have that A is self-improvable. It is then sufficient to prove that A_2 is hard for $\mathrm{FNP}^{\mathrm{NP}[\log\log n + O(1)]}$.

From the poly-APX-completeness of A we have that MAXIMUM CLIQUE $\leq_{\mathrm{AP}} A$: let α be the constant of this reduction. From Theorem 12 of [8] we have that any function F in $\mathrm{FNP}^{\mathrm{NP}[\log\log n + O(1)]}$ many-one reduces to MAXIMUM CLIQUE$_{1+\alpha}$. From the definition of AP-reducibility, we also have that MAXIMUM CLIQUE$_{1+\alpha} \leq_{\mathrm{mv}} A_2$ so that F many-one reduces to A_2.

Conversely, let A be a poly-APX self-improvable problem such that, for some r_0, A_{r_0} is $\mathrm{FNP}^{\mathrm{NP}[\log\log n + O(1)]}$-hard. We will show that, for any problem B in poly-APX, B is AP-reducible to A. To this aim, we introduce the following partial multivalued function `multisat`: given an input sequence $(\phi_1, \ldots, \phi_m)$ of instances of the satisfiability problem with $m \leq \log|(\phi_1, \ldots, \phi_m)|$ and such that, for any i, if ϕ_{i+1} is satisfiable then ϕ_i is satisfiable, a possible output is a satisfying truth assignment for ϕ_{i^*}, where $i^* = \max\{i : \phi_i \text{ is satisfiable}\}$. From the proof of Theorem 12 of [8] it follows that this function is $\mathrm{FNP}^{\mathrm{NP}[\log\log n + O(1)]}$-complete.

By making use of techniques similar to those of the proof of Proposition 4.5, it is easy to see that, since B is in poly-APX, there exist two algorithms t_1^B and t_2^B such that, for any fixed $r > 1$, $t_1^B(\cdot, r)$ and $t_2^B(\cdot, \cdot, r)$ form a many-one reduction from B_r to `multisat`. Moreover, since A_{r_0} is $\mathrm{FNP}^{\mathrm{NP}[\log\log n + O(1)]}$-hard, there then exists a many-one reduction (t_1^M, t_2^M) from `multisat` to A_{r_0}. Finally, let t_1^A and t_2^A be the functions witnessing the self-improvability of A.

The AP-reduction from B to A can then be derived as follows:

$$\begin{array}{ccccccc} x, r & \xrightarrow{t_1^B(x,r)} & x' & \xrightarrow{t_1^M(x')} & x'' & \xrightarrow{t_1^A(x'', r_0, r)} & x''' \\ & & & & & & \downarrow \\ y & \xleftarrow{t_2^B(x, y', r)} & y' & \xleftarrow{t_2^M(x', y'')} & y'' & \xleftarrow{t_2^A(x'', y''', r_0, r)} & y''' \end{array}$$

It is easy to see that if y''' is an r-approximate solution for the instance x''' of A, then y is an r-approximate solution of the instance x of B. That is, B is AP-reducible to A with $\alpha = 1$. □

The above theorem cannot be proved without the dependency of both f and g on r in the definition of AP-reducibility. Indeed, it is possible to prove that if only g has this property then, unless the polynomial-time hierarchy collapses, there exists a self-improvable problem A such that A_2 is $\mathrm{FNP}^{\mathrm{NP}[\log\log n + O(1)]}$-hard and A is not poly-APX-complete.

In order to characterize APX-complete problems, we have to define a different combinatorial property. Intuitively, this property states that it is possible to merge several instances into one instance in an approximation preserving fashion.

DEFINITION 5.5. *An* NPO *problem A is* linearly additive *if there exist a constant β and two algorithms t_1 and t_2 such that, for any rational $r > 1$ and for any sequence $x_1, \ldots, x_k$ of instances of A, $x' = t_1(x_1, \ldots, x_k, r)$ is an instance of A and, for any $y' \in A_{1+(r-1)\beta/k}(x')$, $t_2(x_1, \ldots, x_k, y', r) = y_1, \ldots, y_k$, where each y_i is an r-approximate solution of x_i. Moreover, the running time of t_1 and t_2 is polynomial for every fixed r.*

THEOREM 5.6. *An* APX *problem A is* APX*-complete if and only if it is linearly additive and there exists a constant r_0 such that A_{r_0} is* $\mathrm{FNP}^{\mathrm{NP}[1]}$*-hard.*

Proof. Let A be an r_A-approximable APX-complete problem. From the proof of Proposition 4.8 there exists a constant r_0 such that A_{r_0} is hard for $\mathrm{FNP}^{\mathrm{NP}[1]}$. In order to prove the linear additivity, fix any $r > 1$ and let $x_1, \ldots, x_k$ be instances of A. Without loss of generality, we can assume $r < r_A$ (otherwise the k instances can be r-approximated by using the r_A-approximate algorithm). For any $i = 1, \ldots, k$ the problem of finding an r-approximate solution y_i for x_i is reducible to the problem of constructively solving a set of $\lceil \log_r r_A \rceil$ instances of PARTITION. Observe that $\lceil \log_r r_A \rceil \leq c/(r-1)$ for a certain constant c depending on r_A. Moreover, we claim that there exists a constant γ such that constructively solving $kc/(r-1)$ instances of PARTITION is reducible to $(1 + \gamma(r-1)/kc)$-approximating a single instance of A (indeed, this can be shown along the lines of the proof of Proposition 4.8). That is, A is linearly additive with $\beta = \gamma/c$.

Conversely, let A be a linearly additive APX problem such that A_{r_0} is $\mathrm{FNP}^{\mathrm{NP}[1]}$-hard for some r_0 and let B be an r_B-approximable problem. Given an instance x of B, for any $r > 1$ we can reduce the problem of finding an r-approximate solution for x to the problem of constructively solving $c/(r-1)$ instances of PARTITION, for a proper constant c not depending on r. Each of these questions is reducible to A_{r_0}, since any NP problem can be constructively solved by an $\mathrm{FNP}^{\mathrm{NP}[1]}$ function. From linear additivity, it follows that r_0-approximating $c/(r-1)$ instances of A is reducible to $(1+\beta(r_0-1)(r-1)/c)$-approximating a single instance of A. This is an AP-reduction from B to A with $\alpha = c/(\beta(r_0-1))$. □

Note that linear additivity plays for APX more or less the same role of self-improvability for poly-APX. These two properties are, in a certain sense, opposites: while the ability of APX-complete approximation problems to solve decision problems depends on the performance ratio and does not depend on the size of the instance, the usefulness of poly-APX-complete approximation problems depends on the size of the instance and does not depend on the performance ratio. Indeed, it is possible to prove that no APX-complete problem can be self-improvable (unless P = NP) and that no poly-APX-complete problem can be linearly additive (unless the polynomial-time hierarchy collapses).

It is now an interesting question to find a characterizing combinatorial property of log-APX-complete problems. Indeed, we have not been able to establish this characterization; at present, we can state only that it cannot be based on the self-improvability property as shown by the following result.

THEOREM 5.7. *No log-*APX*-complete problem can be self-improvable unless the polynomial-time hierarchy collapses.*

Proof. Let us consider the following optimization problem.

MAX NUMBER OF SATISFIABLE FORMULAS (MNSF).

INSTANCE: Set of m Boolean formulas $\phi_1, \ldots, \phi_m$ in 3CNF, such that ϕ_1 is a tautology and $m \leq \log n$, where n is the size of the input instance.

SOLUTION: Truth assignment τ to the variables of $\phi_1, \ldots, \phi_m$.

MEASURE: The number of satisfied formulas, i.e., $|\{i : \phi_i \text{ is satisfied by } \tau\}|$.

Clearly, MNSF is in log-APX, since the measure of any assignment τ is at least 1, and the optimum value is always smaller than $\log n$, where n is the size of the input. We will show that, for any $r < 2$, MNSF_r is hard for $\text{FNP}^{\text{NP}[\log\log\log n-1]}$.

Given $\log\log n$ queries to an NP-complete language (of size polynomial in n) $x_1, \ldots, x_{\log\log n}$, we can construct an instance $\Phi = \phi_1, \ldots, \phi_m$ of MNSF, where ϕ_1 is a tautology and, for $i \geq 1$, the formulas $\phi_{2^i} = \cdots = \phi_{2^{i+1}-1}$ are satisfiable if and only if at least i instances among $x_1, \ldots, x_{\log\log n}$ are yes-instances (these formulas can be easily constructed using the standard proof of Cook's theorem). Note that $m = 2^{\log\log n+1} - 1$ and, by adding dummy clauses to some formulas, we can achieve the bound $m \leq \log|\phi_1, \ldots, \phi_m|$. Moreover, from an r-approximate solution for Φ we can decide how many instances in $x_1, \ldots, x_{\log\log n}$ are yes-instances, and we can also recover solutions for such instances. That is, any function in $\text{FNP}^{\text{NP}[\log\log\log n-1]}$ is many-one reducible to MNSF_r.

Let A be a self-improvable log-APX-complete problem. Then, for any function $F \in \text{FNP}^{\text{NP}[\log\log\log n-1]}$, $F \leq_{\text{mv}} \text{MNSF}_{1.5} \leq_{\text{mv}} A_{1+\alpha/2} \leq_{\text{mv}} A_{2^{16}}$, where α is the constant in the AP-reduction from MNSF to A and where the last reduction is due to the self-improvability of A. Thus, for any x, computing $F(x)$ is reducible to finding a 2^{16}-approximate solution for an instance x' with $|x'| \leq |x|^c$ for a certain constant c. Since $A \in$ log-APX, it is possible to find in polynomial time a $(k\log|x'|)$-approximate solution y for x' where k is a constant. From y, by means of binary search techniques, we can find a 2^{16}-approximate solution for x' using $\lceil\log\lceil\log_{2^{16}}(k\log|x'|)\rceil\rceil \leq \log\lceil\log\log|x|^{kc}\rceil - 3 \leq \log\log\log|x| - 2$ adaptive queries to NP where the last inequality surely holds for sufficiently large $|x|$. Thus,

$$\text{FNP}^{\text{NP}[\log\log\log n-1]} \subseteq \text{FNP}^{\text{NP}[\log\log\log n-2]}$$

which implies the collapse of the polynomial-time hierarchy [42]. □

As a consequence of the above theorem and of the results of [28], we conjecture that the minimum set cover problem is not self-improvable.

AN EFFICIENT DATA STRUCTURE FOR LATTICE OPERATIONS*

MAURIZIO TALAMO† AND PAOLA VOCCA‡

Abstract. In this paper, we consider the representation and management of an element set on which a lattice partial order relation is defined.

In particular, let n be the element set size. We present an $O(n\sqrt{n})$-space *implicit* data structure for performing the following set of basic operations:

1. Test the presence of an order relation between two given elements, in constant time.
2. Find a path between two elements whenever one exists, in $O(l)$ steps, where l is the path length.
3. Compute the successors and/or predecessors set of a given element, in $O(h)$ steps, where h is the size of the returned set.
4. Given two elements, find all elements between them, in time $O(k \log d)$, where k is the size of the returned set and d is the maximum in-degree or out-degree in the transitive reduction of the order relation.
5. Given two elements, find the least common ancestor and/or the greatest common successor in $O(\sqrt{n})$-time.
6. Given k elements, find the least common ancestor and/or the greatest common successor in $O(\sqrt{n} + k \log n)$time. (Unless stated otherwise, all logarithms are to the base 2.)

The preprocessing time is $O(n^2)$. Focusing on the first operation, representing the building-box for all the others, we derive an overall $O(n\sqrt{n})$-space $\times$ time bound which beats the order n^2 bottleneck representing the present complexity for this problem. Moreover, we will show that the complexity bounds for the first three operations are optimal with respect to the worst case. Additionally, a stronger result can be derived. In particular, it is possible to represent a lattice in space $O(n\sqrt{t})$, where t is the minimum number of disjoint chains which partition the element set.

Key words. data structure, lattices, reachability, least common ancestors, graph decomposition

1. Introduction.

The study of partial orders (*posets*) efficient representation, from either space or query time point of view, has been extensively tackled in the last few years, as it is a basic problem in many fields of applications. For instance, posets representation is needed when the elements are points in the d-dimensional space over which we wish to perform a dominance test or range query (computational geometry [16]); when the elements are sets and we want to perform a containment or intersection query (knowledge bases [1, 2]; object-oriented and semantic data models [19]); when the elements are vertices of a directed acyclic graph over which binary relations are defined (taxonomy, graph traversal, distributed computing [25, 26], etc.), and when we wish to perform the reachability test.

In general, posets are involved in all applications dealing with traversing sets of items over which an order relation is defined [28, 18, 33, 9].

When the order relation is complex, for example when the order dimension is proportional to the size of the element set, then these problems cannot be efficiently

solved using the well-known techniques.

In this paper we show that for partial lattices it is possible to efficiently compute a set of basic operations. In particular, adopting a graph theoretic notation, given a directed acyclic graph (*dag*) $G = (V, E)$, we present an *implicit* data structure for efficiently performing the following operations:

1. REACHABILITY(x, y). Given $x, y \in V$, tests the presence of a directed path from x to y; returns true if such a path exists, false otherwise.
2. PATH(x, y). Given $x, y \in V$, returns a path from x to y, if at least one such path exists.
3. SUCC(x). Given $x \in V$, returns the set of all successors of x.
4. PRED(x). Given $x \in V$, returns the set of all predecessors x.
5. RANGE(x, y). Given $x, y \in V$, returns all vertices in all the directed paths connecting x to y.
6. LUB(x, y). Given $x, y \in V$, returns the least upper bound between x and y.
7. GLB(x, y). Given $x, y \in V$, returns the greatest lower bound between x and y.
8. LUB$(x_1, \ldots, x_k)$. Given $x_1, \ldots, x_k \in V$, returns the least upper bound of $x_1, \ldots, x_k$.
9. GLB$(x_1, \ldots, x_k)$. Given $x_1, \ldots, x_k \in V$, returns the greatest lower bound of $x_1, \ldots, x_k$.

The idea is to minimize the storage complexity while efficiently performing the above operations. In particular, the aim is to be able to test REACHABILITY in $O(1)$. REACHABILITY captures connectivity information and hence is a basic operation for digraphs management.

Without loss of generality, we prove all theorems under the assumption that $G = (V, E)$ is connected; hence if $|V| = n$ and $|E^T| = m$, where E^T is the edge set of the transitive reduction graph, then $m \geq n - 1$. In the case of nonconnected *dags*, all our results can be applied to each connected component without any change in complexity bounds.

Although a lot of work has been done in this field, it is still an open problem of how to represent partial order relations with a worst case time $\times$ space complexity less than $o(n^2)$. This problem is difficult because of "naive" representations, such as explicitly representing the whole transitive closure G^*, at one extreme, or testing reachability on G by means of DFS traversal, for example, at the other. Both require $\Omega(n^2)$ time $\times$ space in the worst case.

There is an additional reason for the importance of this open problem: understanding the complexity of directed graph versus undirected graph traversal. In fact, there was considerable empirical evidence (in terms of the efficiency of algorithms that have been discovered) that reachability in directed graphs is "harder" than reachability in undirected graphs. This has been proven to be substantially true in [4]. For instance, although directed graphs can be traversed nondeterministically in polynomial time and logarithmic space simultaneously, there is evidence that they cannot be traversed deterministically in polynomial time and small space simultaneously [31]. In contrast, the undirected s-t connectivity can be performed deterministically in polynomial time and sublinear space [6], and undirected graphs can be generally traversed in polynomial time and logarithmic space probabilistically by using a random walk [5, 10]; this implies similar resource bounds on (nonuniform) deterministic algorithms [5]. Moreover, using simple techniques, efficient data structures for undirected graphs have been developed for the dynamic maintenance of several graph properties [14].

The gap in efficiency between directed graphs and nondirected graphs for reachability problem management is mainly due to the nonsymmetry of the reachability relation. Moreover, the harder case is when the graph is acyclic, in the sense that the problem for general graphs can be reduced in linear time to the acyclic case. In fact, we can partition the vertex set of the graph into strongly connected components (e.g., using depth-first search) and then shrink the components to form an acyclic graph (see [3]).

Therefore, efficient solutions to the reachability problem have been found for special classes of *dags* [17, 26, 30] exploiting the order dimension property of the associated posets [13]. In this context, the partial orders considered are those having a constant order dimension [21]. Informally speaking, a partial order having order dimension k, with $k \geq 1$ a constant value, can be represented using $\Theta(kn)$ space, where n is the element set size, while testing partial order relationship in $O(k)$ time.

Unfortunately, since posets can have nonconstant order dimension, this technique cannot be extended to general digraphs [24]. In particular, this is true for partial lattices. Another approach that was studied, allowing derivation of an efficient representation for interval orders and a distributive lattice, is based on the representation of a poset by subsets of an n set [23, 8].

Hence, although there are strategies for dealing with restricted classes of *dags* optimal for time $\times$ space complexity, there is no uniform approach for general directed graphs. This is due mainly to intrinsic deficiencies of the general schema adopted by most of the widely accepted strategies for reachability problem resolution. In fact, the key idea is to decompose a *dag* G into a collection $\mathcal{F}$ of sparse *dags* G_i representing a covering of the graph G^*, the transitive closure of G.

In particular, for any *dag* $G = (V, E)$, a collection $\mathcal{F} = \{G_1, \ldots, G_k\}$ must satisfy the following property:

(i) $\langle x, y\rangle \in G^* \Leftrightarrow \exists G_i \in \mathcal{F}$ such that $\langle x, y\rangle \in G_i^*$.

This property is nice for the design of efficient algorithms as it allows us to search locally only and not in the whole graph. On the other hand, using this approach presents two main problems.

The first problem is how to bound the overall space complexity. In fact, a trivial solution to the above approach is to represent a *dag* G by means of an n-element collection $\mathcal{F}$, with each element representing the subgraph induced by all vertices connected to a given vertex. However, it can be easily seen that this approach requires $O(n^2)$ space.

The second problem is how to derive connectivity information in an efficient way with respect to the time complexity. In fact, a "naive" application of the decomposition technique, optimal from the space complexity point of view, is based on a one-element set $\mathcal{F}$, containing the transitive reduction of G. Unfortunately, in this case, the time complexity is $O(m)$.

In this paper, we present a two-level decomposition strategy, previously introduced in [28, 29] but now extended to deal with a more general set of operations, which balances time and space complexities.

In particular, we will prove the following.

THEOREM 1.1. *Let $G = (V, E)$ be a dag satisfying lattice property, with $n = |V|$. An $O(n\sqrt{n})$-space implicit data structure exists allowing us to perform the following:*

1. REACHABILITY(x, y) *in time $O(1)$;*
2. PATH(x, y) *in time $O(l)$, where l is the path length;*
3. SUCC(x) *in time $O(h)$, where h is the size of the returned set;*

4. PRED(x) *in time* $O(h)$*, where* h *is the size of the returned set;*

5. RANGE(x, y) *in time* $O(k \log d)$*, where* k *is the size of the returned set and* d *is the maximum in-degree or out-degree in the transitive reduction graph;*

6. LUB(x, y) *in time* $O(\sqrt{n})$*;*

7. GLB(x, y) *in time* $O(\sqrt{n})$*;*

8. LUB$(x_1, \ldots, x_k)$ *in time* $O(\sqrt{n} + k \log n)$*;*

9. GLB$(x_1, \ldots, x_k)$ *in time* $O(\sqrt{n} + k \log n)$*;*

Moreover, the preprocessing time is $O(n^2)$ *and all bounds are worst case.*

Results of Theorem 1.1 are a bit surprising. In fact, in some cases, e.g., when $|E| = \Omega(n\sqrt{n})$, our decomposition technique makes a compression of $G = (V, E)$. It is worth noting that the complexity bounds obtained do not break any information theoretic lower bound and are optimal with respect to the worst case, as shown in the following proposition.

PROPOSITION 1.1 (see [22]). *Let* $\mathcal{L}(n)$ *be the number of labeled lattices with* n *elements. Then*

$$\mathcal{L}(n) < \alpha^{(n\sqrt{n}+o(n\sqrt{n}))},$$

where α *is a constant (about* 6.11343*).*

Furthermore, starting from Theorem 1.1, a stronger result can be derived. In particular, it is possible to represent a partial lattice in space $O(n\sqrt{t})$ with the same time bound for all the operations of Theorem 1.1, where t is the minimum number of disjoint chains which partition the element set. This is an important result, since it provides a tight characterization of the complexity of partial lattices. In fact, based on Dilworth's theorem [12], t is equal to the width of the lattice.

As will be evident in the following, the proposed data structure cannot be straightforwardly applied to general digraphs. Therefore, in this case, it could represent a good heuristic method for testing reachability which takes into account the sparseness of the graph.

The paper is organized as follows. In section 2, some basic definitions are given; in section 3, both the basic decomposition strategy and the data structure are presented; in section 4, using a classification of the vertex set, the final version of the decomposition strategy is given; in section 5, an extended version of the data structure is given and the overall space complexity is analyzed; in section 6, time bounds for all operations of the main theorem are stated; finally, in section 7, future research is described.

2. Preliminaries. In this section, we briefly describe the notation used and give some basic definitions useful for the following. More definitions on graphs and posets can be found in textbooks such as [7, 11, 15].

Directed graphs are denoted $G = (V, E)$, where V is the set of *vertices* or *elements* and E is the set of *edges* or *arcs*. Whenever the vertex set is not explicitly defined, it is denoted $Vert(G)$.

In a directed graph, the *in-degree* of a vertex x is the number of edges directed towards x, denoted $Indeg(x)$. Analogously, the *out-degree* of x ($Outdeg(x)$) is the number of edges directed away from v.

A partially ordered set (poset) $\mathcal{P} = (\prec, \mathcal{N})$ is an irreflexive, asymmetric, and transitive relation on the element set $\mathcal{N}$. We denote $\preceq$ the reflexive relation associated with $\mathcal{P}$. Two elements x, y are *incomparable* (denoted $x \sim y$), if neither $x \preceq y$ nor $y \preceq x$.

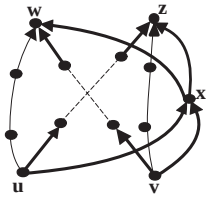

FIG. 1. *Lattice property.*

An element $z \in \mathcal{N}$ is an *upper bound* of $x, y \in \mathcal{N}$ if $x \preceq z$ and $y \preceq z$. The element z is called the *least upper bound* of x and y, denoted $\text{LUB}(x, y)$, if $z \preceq w$ for all upper bounds w of x and y. The *greatest lower bound*, denoted $\text{GLB}(x, y)$, is defined dually.

A *lattice* is a partial order $\mathcal{L} = (\prec, \mathcal{N})$ such that every two $x, y \in \mathcal{N}$ have both a least upper bound and a greatest lower bound.

For a given partial order $\mathcal{P} = (\prec, \mathcal{N})$, it is always possible to find a *linear extension* of $\mathcal{P}$, i.e., a total order which is consistent with $\mathcal{P}$. There always exists such a linear extension, and the intersection of all linear extensions of $\mathcal{P} = (\prec, \mathcal{N})$ is $\mathcal{P} = (\prec, \mathcal{N})$. A minimal set $\mathcal{R}$ of linear extensions of $\mathcal{P} = (\prec, \mathcal{N})$ whose intersection is $\mathcal{P} = (\prec, \mathcal{N})$ is called a *realizer* of $\mathcal{P} = (\prec, \mathcal{N})$, and the *order dimension* of $\mathcal{P} = (\prec, \mathcal{N})$ is the minimum cardinality of any realizer of $\mathcal{P} = (\prec, \mathcal{N})$.

Given a poset $\mathcal{P} = (\prec, \mathcal{N})$, its *st-completion* is the poset obtained by adding to $\mathcal{N}$ two elements labeled s and t and extending $\prec$ with the following order relations: $s \prec x$ and $x \prec t \ \forall x \in \mathcal{N}$.

Posets whose st-completion is a lattice are *partial lattices*. Other authors refer to this class of poset as *truncated lattices* [27].

Given a directed acyclic graph (*dag*) $G = (V, E)$, the *associated partial order* is the poset $\mathcal{P}_G = (\prec, V)$ such that, for all $u, v \in V$, $u \prec v$ if and only if $\langle u, v \rangle \in E^*$, where E^* is the edge set of the transitive closure graph $G^* = (V, E^*)$.

DEFINITION 2.1. *A dag $G = (V, E)$ satisfies the* lattice property *if and only if the associated partial order is a partial lattice.*

From the definition, the following property trivially follows and will be useful for the following (see Figure 1).

PROPOSITION 2.1. *A dag $G = (V, E)$ satisfies the lattice property if and only if, for every four vertices $(u, v, z, w) \in V$, if four directed paths exist, pairwise disjoint except for at most the extremal vertices, having as endpoints pairs of vertices $\langle u, w \rangle$, $\langle u, z \rangle$, $\langle v, w \rangle$, and $\langle v, z \rangle$, then there exist a vertex x and four paths having as endpoints pairs of nodes $\langle u, x \rangle$, $\langle v, x \rangle$, $\langle x, z \rangle$, and $\langle x, z \rangle$.*

Obviously, partial lattices always satisfy the above property.

3. Decomposition strategy: Basic version. Regarding what was said in the introduction, a general problem of a decomposition technique is the choice of the decomposition criteria. Our key idea is to use a two-stage decomposition, with each stage having its own decomposition criteria.

In particular, given a *dag* $G = (V, E)$ satisfying the lattice property, at the first stage we partition V in a sequence of sets, or *clusters*, denoted $Clus(c)$, where $c \in V$ is a representative vertex.

At the second stage, for each cluster $Clus(c)$, we choose a suitable collection of digraphs (*double tree* or $DT(u, c)$), representing all the connectivity information between vertices in $Clus(c)$ and vertices in $V - Clus(c)$.

Each double tree collection associated with a cluster represents the basic element of the proposed decomposition strategy.

For every two vertices x, y, with $x \in Clus(c)$, the corresponding collection $\{DT(u,c)|u \in Clus(c)\}$ satisfies the following property: x is connected to y in G if and only if at least one $DT(u_i,c) \in \{DT(u,c)\}$ exists such that x is connected to y in $DT(u_i,c)$.

As we will show in section 4, operating on the cluster size it is possible to bound the overall space complexity, while realizing, with the second level decomposition, a constant reachability test.

For the sake of simplicity, we first illustrate the decomposition strategy and the corresponding data structure with no constraint on cluster size.

3.1. Clusters. We now give a formal definition of a cluster and state its main properties.

DEFINITION 3.1. *Given a vertex $c \in V$, let $Clus^+(c) = \{Pred(c) \cup c\}$ and $Clus^-(c) = \{Succ(c) \cup c\}$, where $Pred(c)$ and $Succ(c)$ are the sets of predecessors and successors of c. A* cluster *is either $Clus^+(c)$ or $Clus^-(c)$ for some $c \in V$.*

In the following, when no confusion is possible, we will use $Clus(c)$ to denote either $Clus^+(c)$ or $Clus^-(c)$.

Let $v \in V - Clus(c)$. The following lemma shows an important relationship between two different clusters, $Clus(c)$ and $Clus(v)$.

LEMMA 3.1. *If $Clus^+(c) \cap Clus^+(v) = \mathcal{I}$, then $\text{LUB}(\mathcal{I}) \in \mathcal{I}$. Dually, if $Clus^-(c) \cap Clus^-(v) = \mathcal{I}$, then $\text{GLB}(\mathcal{I}) \in \mathcal{I}$.*

Proof. By the cluster definition, for any two elements $x, y \in Clus^+(c)$, $\text{LUB}(x,y) \in Clus^+(c)$. In fact, assume for contradiction that $\text{LUB}(x,y) \notin Clus^+(c)$. Then the following three conditions simultaneously hold:

(i) $x \prec c$,
(ii) $y \prec c$,
(iii) $\text{LUB}(x,y) \sim c$.

This contradicts Proposition 2.1.

In order to prove the lemma we have to show that $Clus^+(c) \cap Clus^+(v)$ does not have two distinct maximal elements. Let us now assume that two maximal elements $x, y \in Clus^+(c) \cap Clus^+(v)$ exist, with $x \neq y$. Then we have

(i) $\text{LUB}(x,y) \in Clus^+(c)$,
(ii) $\text{LUB}(x,y) \notin Clus^+(v) \Rightarrow \text{LUB}(x,y) \sim v$.

However, this once again contradicts Proposition 2.1. A similar reasoning holds for $Clus^-(c) \cap Clus^-(v)$. The lemma is so proved by contradiction. ∎

LEMMA 3.2. *Let $G = (V,E)$ be a dag satisfying the lattice property and $Clus(c)$ a cluster. Then $G' = (V - Clus(c), E')$ is a dag satisfying the lattice property, where E' is the set of edges of the subgraph induced by $V - Clus(c)$.*

Proof. The proof is an obvious consequence of the cluster definition. ∎

3.2. Double trees. Given a cluster $Clus(c)$, let us refer to vertices in $Clus(c)$ and in $V - Clus(c)$ as *internal* and *external vertices*, respectively. In particular, we denote by $Ext(Clus(c))$ the set of all external vertices *connected* to at least one internal vertex.

The problem of maintaining all the connectivity information related to a given cluster can be split into the following two subproblems: (i) the representation of the connectivity relationships between internal vertices and (ii) the representation of the connectivity relationships between internal and external vertices.

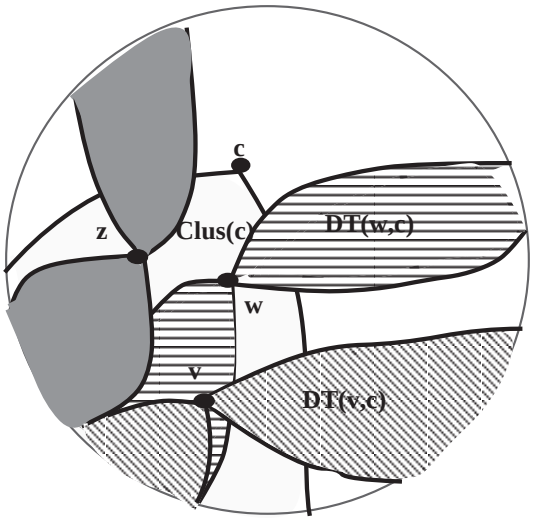

FIG. 2. *Double tree decomposition.*

We solve the first problem by computing for each internal vertex u a spanning tree of the graph induced by the set $Pred(u) \cap Clus(c)$ or by the set $Succ(u) \cap Clus(c)$, depending on whether $Clus(c)$ is a $Clus^+(c)$ or a $Clus^-(c)$. Hence, to each internal vertex $u \in Clus(c)$ there is associated a tree rooted at u, the *internal tree induced by* u, denoted $IntTree(u, c)$.

For the second problem, from Lemma 3.1, given an external vertex v, the pair $(v, Clus(c))$ univocally identifies a vertex $u \in Clus(c)$ representing either the LUB$(Clus^+(c) \cap Clus^+(v))$ or the GLB$(Clus^-(c) \cap Clus^-(v))$. This implies that, given a cluster $Clus(c)$ for each external vertex v connected to at least one vertex in $Clus(c)$, an internal vertex u, the *internal representative of the external vertex* v exists, univocally identifying the internal tree $IntTree(u, c)$ made up of all internal vertices connected to v.

Let $Ext(u)$ be the set of external vertices having u as an internal representative vertex. Obviously, we have

$$Ext(Clus(c)) = \bigcup_{u \in Clus(c)} Ext(u).$$

For each set $Ext(u)$, we compute a spanning tree, rooted at u, of the subgraph induced by $Ext(u)$. We refer to this tree as the *external tree induced by* u, denoted $ExtTree(u, c)$ (see Figure 2). The external trees in $\{ExtTree(u, c) | u \in Clus(c)\}$ have the nice property of being pairwise disjoint, as shown in the following lemma.

LEMMA 3.3. *Let* $v, w \in Clus(c)$*, with* $v \neq w$*. Then* $ExtTree(v, c) \cap ExtTree(w, c) = \emptyset$.

Proof. Let us assume for contradiction that $y \in ExtTree(v, c) \cap ExtTree(w, c)$. By the external tree definition, y is associated with both v and w. This contradicts the uniqueness of the representative vertex stated in Lemma 3.1. The proof follows by contradiction. □

DEFINITION 3.2. *Given a cluster* $Clus(c)$ *and the two collections* $\{IntTree(u, c)\}$ *and* $\{ExtTree(u, c)\}$ *of internal and external trees, for each* $u \in Clus(c)$ *a* double tree

is defined as

$$DT(u,c) = IntTree(u,c) \cup ExtTree(u,c).$$

A double tree represents the basic decomposition subgraph and, informally speaking, is the union of an internal tree and the external tree rooted at the same internal vertex, whenever the internal and external trees exist.

Each double tree $DT(u,c)$ is associated with a partial order having order dimension 2, because its *st*-completion is a planar poset with one greatest element and one least element [32]. The first consequence of the above property is that $DT(u,c)$ is representable with two linear extensions L_1 and L_2; that is, given two vertices $x, y \in DT(u,c)$, y is reachable from x if and only if $x < y$ in both linear extensions. In particular, two labels (*coordinates*) (x_1, x_2) are associated with any vertex $x \in DT(u,c)$, each one representing an x position within the first and second linear extensions, respectively.

The proof of the following proposition can be found in [20].

PROPOSITION 3.1. *Given* $x, y \in DT(u,c)$, REACHABILITY$(x,y) =$ **true** *in* $DT(u,c)$ *if and only if* $(x_1, x_2) < (y_1, y_2)$.

From the above proposition Corollary 3.4 easily follows.

COROLLARY 3.4. *Given a double tree* $DT(u,c)$, *such that* $|Vert(DT(u,c))| = K$, *an* $O(K)$*-space* implicit *data structure exists for performing a* REACHABILITY *test in* $O(1)$*-time.*

3.3. Basic decomposition strategy. The decomposition strategy we propose first generates a collection of clusters and then, for each cluster, builds the corresponding decomposition elements (double tree collection).

```
    procedure BasicBuildClusters;
1.  begin;
2.  C := ∅;        {Cluster Collection}
3.  while V ≠ ∅ do
4.      begin;
5.      Choose a cluster Clus(c);  {either Clus+(c) or Clus−(c)}
6.      C := C ∪ Clus(c);
7.      V := V − Clus(c);
8.      end;
9.  return C;
10. end.
```

The cluster collection returned is the input to the following procedure which builds, for each cluster, the associated double trees collection representing the decomposition elements on which we base our data structure.

```
    procedure BasicDecomposition (C : Cluster Collection);
1.  for each Clus(c) ∈ C;
2.  begin
3.      for each u ∈ Clus(c) Build {DT(u,c)};
4.      return Clus(c) and {DT(u,c)};
        {Returns the current cluster and double tree collection}
5.  end;
```

Hence, a *dag* $G = (V, E)$ induces two collections of subgraphs,

$\mathcal{C} = \langle Clus(c_1), \ldots, Clus(c_k)\rangle$,

$\mathcal{T} = \langle \{DT(u_{1,j}, c_1)\}, \ldots, \{DT(u_{k,j}, c_k)\}\rangle$ for all $u_{i,j} \in Clus(c_i)$,

satisfying the following invariants. Let $x \in V$.

(i) x belongs to one and only one cluster $Clus(c_i)$ (for construction, see line 7 of the `BasicBuildClusters` procedure);

(ii) given a cluster $Clus(c_j)$ different from the one to which x belongs according to (i), x belongs to at most one $DT(u_{j,i}, c_j)$ as an external vertex (Lemma 3.3);

(iii) given a cluster $Clus(c_i)$, each element of the collection $\{DT(u_{i,j}, c_i)\}$ is, by definition, univocally identified by the element $u_{i,j} \in Clus(c_i)$.

To prove the correctness of the proposed strategy we show that the double tree collection is a covering of the given graph.

THEOREM 3.5. *Given a dag* $G = (V, E)$ *satisfying the lattice property and* $x, y \in V$, REACHABILITY$(x, y) =$ **true** *in* $G = (V, E)$ *if and only* REACHABILITY$(x, y) =$ **true** *in* $DT(u, c)$, *for at least one* $DT(u, c) \in \mathcal{T}$.

Proof. ($\Rightarrow$) First, note that by Lemma 3.2 the graph $G' = (V - Clus(c), E')$ still satisfies the lattice property. Let REACHABILITY$(x, y) =$ **true** in $G = (V, E)$. We show that the decomposition strategy returns a double tree $DT(u, c) \in \mathcal{T}$ such that REACHABILITY$(x, y) =$ **true** in $DT(u, c)$. Note that, by construction, x and y must belong to one and only one cluster. Two different cases are possible according to which cluster they belong.

1. $x, y \in Clus(c)$.

If $Clus(c)$ is a $Clus^+(c)$, then line 3 of the `BasicDecomposition` procedure assures that x belongs to $IntTree(y, c)$, and hence $x \in DT(y, c)$. On the other hand, if $Clus(c)$ is a $Clus^-(c)$, then $y \in DT(x, c)$.

2. $x \in Clus(c_1)$ and $y \in Clus(c_2)$.

Without loss of generality, let us suppose that the decomposition algorithm first generates $Clus(c_1)$ and then $Clus(c_2)$. Since y is connected to a vertex in $Clus(c_1)$; it then has an internal representative vertex, say, w. Hence $y \in ExtTree(w, c_1)$. By Proposition 2.1, either $x \in IntTree(w, c_1)$ or $x = w$. Thus, REACHABILITY$(x, y) =$ **true** in $DT(w, c_1)$.

($\Leftarrow$) This part of the proof obviously follows from observing that the decomposition algorithm does not add any new edge. ∎

3.4. Basic data structure. In this section we briefly describe the basic data structure for representing a *dag* satisfying the lattice property and describe how to perform the REACHABILITY operation, since this is the basic operation for performing all the others.

From the previously described invariants and from applying Proposition 3.1, we derive the following simple implicit data structure based on look-up tables (see Figure 3).

The data structure is composed of one look-up table indexed on elements in V (data structure **A**) and two sets of look-up tables (data structures **B** and **C**).

Data structure **A** stores for each vertex the unique identifier of $Clus(c_i)$ to which it belongs (see invariant (i) above) and its sign ("+" or "−" for $Clus^+(c)$ or $Clus^-(c)$, respectively).

Data structure **B** is a set of look-up tables, each table associated with a vertex $x \in V$. For each double tree $DT(u, c_i)$ of the decomposition induced by the cluster $Clus(c_i)$ to which x belongs, data structure **B** stores x's coordinates with respect

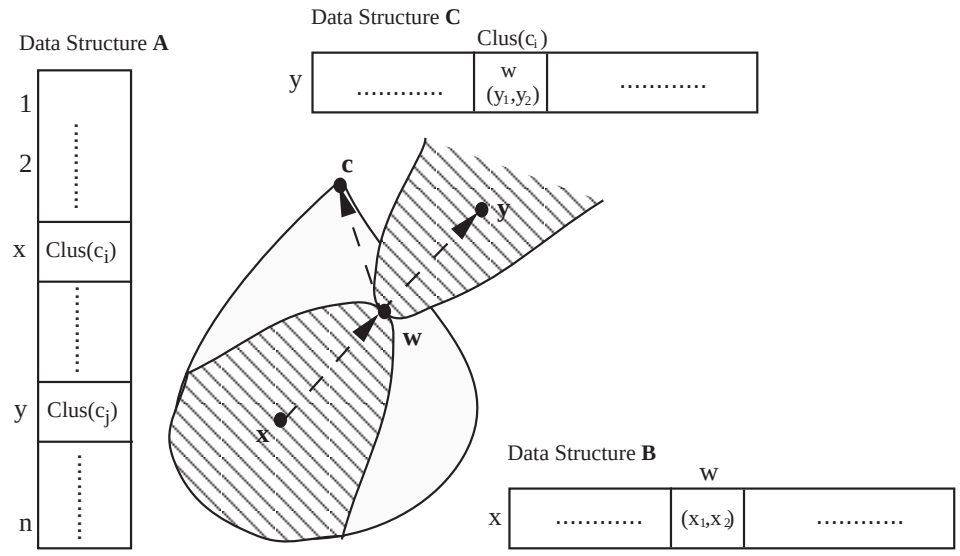

FIG. 3. *Data structure.*

to the representation of $DT(u, c_i)$, whenever x belongs to $DT(u, c_i)$; otherwise, it contains a null value.

Data structure **C** is a set of look-up tables, each table associated with an element $x \in V$. For each cluster $Clus(c_i)$ of the cluster collection $\mathcal{C}$, if $x \in Ext(Clus(c_i))$, then data structure **C** stores the identifier of the double tree associated with $Clus(c_i)$, to which x belongs as an external element, and stores x's coordinates with respect to this double tree representation.

Let us now describe how to perform REACHABILITY(x, y). From data structure **A** we derive the clusters to which x and y belong. Let $x \in Clus(c_i)$ and $y \in Clus(c_j)$. Two cases are possible.

(i) $Clus(c_i) = Clus(c_j)$.

In this case we look in the **B** table associated with x and y for their coordinates with respect to both: (1) the double tree rooted at x; (2) the double tree rooted at y. If, in one of the two double tree, x's coordinates are smaller than y's, then REACHABILITY$(x, y) =$ **true**; otherwise REACHABILITY$(x, y) =$ **false**.

(ii) $Clus(c_i) \neq Clus(c_j)$.

In this case, we first look in the table **C** associated with y, for the double tree identifier corresponding to cluster $Clus(c_i)$. Then we search in the **B** table associated with x, the coordinates of x with respect to this double tree. If x's coordinates are smaller than y's, then REACHABILITY$(x, y) =$ **true**; otherwise, we repeat the search, looking in the **C** table associated with x for the double tree identifier corresponding to cluster $Clus(c_j)$. Then we search in the table **B** associated with y, y's coordinates with respect to this double tree. If x's coordinates are smaller than y's, then REACHABILITY$(x, y) =$ **true**. If both searches fail, then REACHABILITY$(x, y) =$ **false** (see Figure 3).

From the above discussion it is possible to state the following lemma.

LEMMA 3.6. *The* REACHABILITY *operation can be performed in constant time.*

Obviously, for general clusters the space complexity is $O(n^2)$. Therefore, let us suppose, for instance, that the cluster collection $\mathcal{C}$ satisfies the following condition:

$$\forall\, Clus(c_i) \in \mathcal{C} \;\Rightarrow\; \frac{\sqrt{n}}{4} \leq |Clus(c_i)| \leq \frac{\sqrt{n}}{2} \quad .$$

In this case, it is trivial to show that the overall space occupancy is $O(n\sqrt{n})$. Unfortunately, this is a special case and, generally, this condition does not hold. Nevertheless, as shown in the following, it is possible to find a suitable cluster decomposition allowing us to keep the space occupancy within the required bound.

4. Decomposition strategy. As shown in section 3, a proper choice of cluster size permits us to bound the space complexity. We claim that a cluster size within $\frac{\sqrt{n}}{4}$ and $\frac{\sqrt{n}}{2}$ is, in fact, the answer to our problem because this size allows us to balance what is eliminated in one main iteration and what remains to be considered (see line 7 of the `BasicBuildClusters` procedure). When it is not possible to find clusters with the right size, we group them to form a *cluster forest.*

4.1. Elements classification. We need some more definitions.

DEFINITION 4.1. *A vertex $c \in V$ is*

1 good *if*

$$\frac{\sqrt{n}}{4} \leq |Clus^+(c)| \leq \frac{\sqrt{n}}{2} \;\; or \;\; \frac{\sqrt{n}}{4} \leq |Clus^-(c)| \leq \frac{\sqrt{n}}{2};$$

2 fat *if it is not good and if one of the following two conditions holds:*
- (i) $|Clus^+(c)| > \frac{\sqrt{n}}{2}$ *and* $\forall x \in Clus^+(c)$ *then* $|Clus^+(x)| < \frac{\sqrt{n}}{4}$*; or*
- (ii) $|Clus^-(c)| > \frac{\sqrt{n}}{2}$ *and* $\forall x \in Clus^-(c)$ *then* $|Clus^-(x)| < \frac{\sqrt{n}}{4}$*;*

3 thin *if it is neither good nor fat and if*

$$|Clus^+(c)| < \frac{\sqrt{n}}{4} \;\; or \;\; |Clus^-(c)| < \frac{\sqrt{n}}{4}.$$

We establish the correctness of our approach by first showing that it is always possible to find one of the above defined elements.

LEMMA 4.1. *Given a dag $G = (V, E)$ satisfying the lattice property, at least one good, fat, or thin vertex does exist which can be retrieved in time $O(n^2)$.*

Proof. Let us consider the following strategy. We first visit the graph, searching for good elements and meanwhile assigning a weight to each node to represent the size of the clusters (both $Clus^+$ and $Clus^-$) it induces. Whenever this search fails, we look for fat vertices.

If there is one node having weight greater than $\frac{\sqrt{n}}{2}$, then at least one fat vertex exists. In fact, without loss of generality, let c be a vertex such that $|Clus^+(c)| > \frac{\sqrt{n}}{2}$. We search the predecessors set of c for an element x inducing the smallest cluster satisfying condition $|Clus^+(x)| > \frac{\sqrt{n}}{2}$. If such a vertex x exists, then x is fat because there are no good vertices and, by a transitive property, none of its predecessors can induce a cluster of cardinality greater than $\frac{\sqrt{n}}{2}$. Otherwise, c is a fat vertex. If there are no fat vertices, then the vertex with the maximum weight is a thin vertex. Hence, this strategy always returns at least one element.

For the time complexity, let us consider a data structure for representing the graph which maintains for each vertex the number of its predecessors and an ordered list of

the number of predecessors of its immediate predecessors. With this data structure, which can be derived in time $O(n^2)$ by recursively visiting $G = (V, E)$, the above strategy can be implemented in time that is linear in the number of vertices. □

4.2. Cluster collection. Our aim is to show that, given a *dag* $G = (V, E)$, it is possible to build a cluster collection of clusters induced by either good vertices or thin vertices.

First we need to describe how to manage fat vertices.

LEMMA 4.2. *Given a fat vertex c, it is always possible to generate a sequence of clusters induced by good vertices which covers* $Clus(c)$.

Proof. Without loss of generality, let $|Clus^+(c)| > \frac{\sqrt{n}}{2}$. By definition, each one of c's immediate predecessors, $\langle c_1, \ldots, c_t \rangle$, satisfies the following condition:

$$|Clus^+(c_i)| < \frac{\sqrt{n}}{4} \quad for\ all\ 1 \leq i \leq t.$$

We can then group clusters induced by these vertices until the cardinality of each group is within $\frac{\sqrt{n}}{4}$ and $\frac{\sqrt{n}}{2}$.

Let $Clus(c_{i_1}, \ldots, c_{i_k})$, where $\langle c_{i_1}, \ldots, c_{i_k} \rangle \subset \langle c_1, \ldots, c_t \rangle$ is one group of clusters so obtained.

To prevent $Clus(c_{i_1}, \ldots, c_{i_k})$ from violating Lemma 3.1 (an external vertex y could be related to all $\langle c_{i_1}, \ldots, c_{i_k} \rangle$ through the fat vertex c), we add a *dummy good* vertex and the following directed edges (see Figure 4):

(i) $\langle d_i, c \rangle$;

(ii) $\langle c_{i_j}, d_i \rangle$ for $1 \leq j \leq k$.

By construction, the *dag* obtained by adding dummy vertices still satisfies the lattice property. Hence, to each fat vertex c there corresponds a collection $\{Clus(d_i)\}$ of clusters induced by dummy good vertices (see Figure 4) which covers $Clus^+(c)$. □

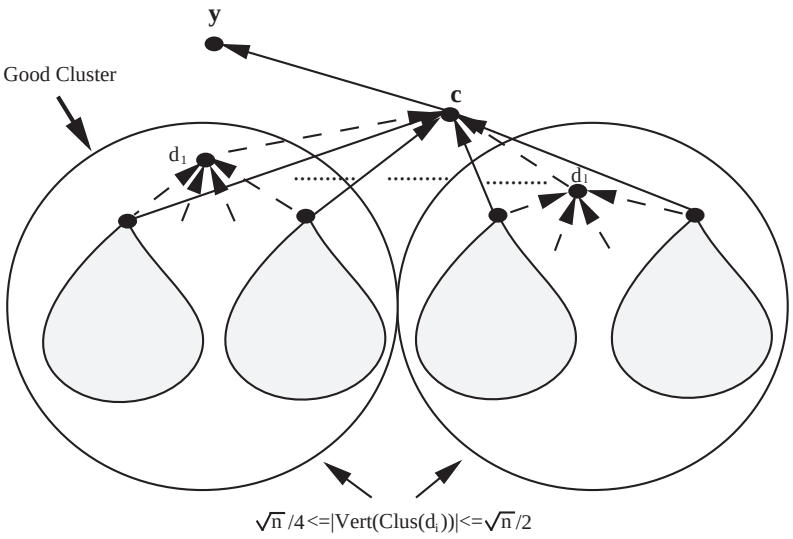

FIG. 4. *Fat node.*

The following procedure shows how our strategy chooses the required cluster collection. First, clusters induced by good vertices and by dummy good vertices

associated with fat vertices are chosen, then clusters induced by thin vertices are considered. More precisely, we have the following:

```
    procedure BuildClusters;
1.  begin;
2.  C := ∅;        {Cluster Collection}
3.  while V ≠ ∅ do
4.  begin;
5.      if  ∃c ∈ V s.t.  c is good then  C := C ∪ Clus(c);
6.      else  if  ∃c ∈ V s.t.  c is fat then
7.            begin
8.            Build the associated good cluster collection {Clus(d_i)};
9.            goto 5;
10.           end
11.       else
12.           begin
13.           Choose a thin vertex c s.t.  Clus(c) has maximum cardinality;
14.           C := C ∪ Clus(c);
15.           end;
16.     V := V − Clus(c);
17. end;
18. return  C;
19. end.
```

Let $\mathcal{C} = \langle Clus(c_1), \ldots, Clus(c_g), \ldots, Clus(c_{g+t})\rangle$ be the cluster collection so obtained, where for $1 \leq i \leq g$, $Clus(c_i)$ is a cluster induced by either actual or dummy vertices and for $g+1 \leq i \leq t$, $Clus(c_i)$ is induced by thin vertices.

To obtain the required space complexity, we group clusters induced by thin vertices. We define a *cluster forest* as any collection of clusters induced by thin vertices. Let $F = \langle Clus(c_1), \ldots, Clus(c_k)\rangle$ be a cluster forest. We define the *external vertex set of a forest* F, denoted $Ext(F)$, as the union of all the external vertex sets of each cluster composing the cluster forest; i.e.,

$$Ext(F) = \bigcup_{i=1}^{k} Ext(Clus(c_i)).$$

Note that according to our definitions, $F \cap Ext(F) \neq \emptyset$ in general. Therefore, for each cluster Lemma 3.3 still holds.

The following version of the decomposition procedure generates for each cluster in $\mathcal{C}$ the corresponding double tree collection. Moreover, it groups clusters induced by thin vertices into cluster forests.

Each forest $F = \langle Clus(c_1), \ldots, Clus(c_k)\rangle$ is generated by choosing clusters from the cluster collection in not increasing order of size until one of the following conditions holds:

1. $|F| \geq \frac{\sqrt{n}}{4}$, or
2. $mk \geq n$, where $m = |Ext(F)|$.

As we will see in section 5, condition 2 allows us to obtain the required space complexity.

```
    procedure Decomposition (C : Cluster Collection);
1.  for each Clus(c) ∈ C;
2.  begin
3.      for each u ∈ Clus(c) Build {DT(u, c)};
4.      return Clus(c) and {DT(u, c)};
5.  end;
6.  for each Clus(c) ∈ ⟨Clus(c_{g+1}), ..., Clus(c_{g+t})⟩;
        {the sequence is in not increasing order of size}
7.  begin
8.      F = ∅;
9.      k = 0;
10.     while |F| < √n/4 and mk < n.
11.     begin
12.         F = F ∪ Clus(c);
13.         k = k + 1;      {Number of clusters in a forest}
14.         m = |Ext(F)|;   {Number of external vertices}
15.         next Clus(c);
16.     end;
17.     return F;    {Returns the current forest}
18. end;
```

The above decomposition strategy returns a sequence $\langle F_1, \ldots, F_g, \ldots, F_{g+f} \rangle$ of clusters and cluster forests, where $F_i = Clus(c_i)$, for $1 \leq i \leq g$, is a cluster induced by either actual or dummy good vertices, while for $g+1 \leq i \leq f$, F_i is a cluster forest. Further, for each cluster the associated double tree collection is produced. Both collections are then inserted into the data structure. It is trivial to show that, even if clusters forests are considered, the double tree decomposition satisfies Theorem 3.5.

5. Data structure and space complexity. The clusters and cluster forests collection and the corresponding double tree decomposition returned by the `Decomposition` procedure satisfy the following invariants. Let $x \in V$:

(i) x belongs to one and only one F_i, where $1 \leq i \leq g + f$;

(ii) x belongs to one and only one cluster $Clus(c_{i,j})$;

(iii) given a cluster $Clus(c_{j,l})$ different from the one to which x belongs according to (ii), at most one $u \in Clus(c_{j,l})$ exists such that $x \in DT(u, c_{j,l})$;

(iv) given a cluster $Clus(c_{i,j})$, each element of the collection $\{DT(u, c_{i,j})\}$ is, by definition, univocally identified by the element $u \in Clus(c_{i,j})$.

To represent cluster forests, we modify the basic data structure described in section 3.3 to take into account the double indirection between a forest and its clusters (see Figure 5).

The new data structure **C** is again a set of look-up tables, each table associated with a vertex $x \in V$. For each forest F_i, if $x \in Ext(F_i)$, then data structure **C** maintains the identifier of a fourth kind of table, **D**, which stores connectivity information between x and F_i. If x is not connected to F_i, then it stores a null value.

Data structure **D** is a set of look-up tables, each table associated with a vertex x and a cluster forest F_i. Table $\mathbf{D}(F_i)$ exists if and only if $x \in Ext(F_i)$. For each cluster $Clus(c_{ij})$ in the cluster forest F_i, the corresponding field in the look-up table $\mathbf{D}(F_i)$ stores the identifier of the unique double tree associated with $Clus(c_{ij})$ to which x belongs as an external vertex and stores x's coordinates with respect to this double

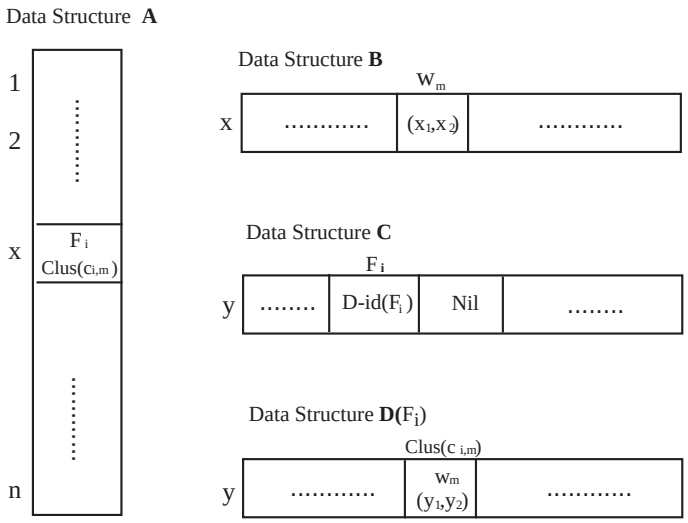

FIG. 5. *Extended Data Structure.*

tree representation.

Data structure **A** stores, for each vertex $x \in V$, the identifiers of both the cluster and forest to which it belongs, whenever they are different, and the cluster sign. Data structure **B** is the same as in section 3.3.

For the REACHABILITY test, it is easy to extend the basic strategy described in section 3.3 for the new data structure.

We now analyze the space complexity. With reference to the clusters and cluster forests sequence $\langle F_1, \ldots, F_g, \ldots, F_{g+f} \rangle$, by construction, the subsequence $\langle F_1, \ldots, F_g \rangle$, together with the corresponding double tree decomposition, requires $O(n\sqrt{n})$-space.

Let us now analyze the subsequence $\langle F_{g+1}, \ldots, F_{g+f} \rangle$ of cluster forests induced by thin vertices.

Recall that forests of clusters are generated choosing clusters in decreasing order until one of the following conditions holds:

1. $|F| \geq \frac{\sqrt{n}}{4}$, or
2. $mk \geq n$, where $m = |Ext(F)|$.

If we denote $m_i = |Ext(F_i)|$, then the overall space complexity of the **D** data structure is $O(\sum_{i=g+1}^{g+f} m_i k_i)$ since only vertices related to a cluster forest have the corresponding **D** look-up table, each table of size $O(k_i)$. Hence, the second condition is used to bound each term of the summation.

We now show that the decomposition strategy returns a number of cluster forests less than $\sqrt{n}$.

Obviously, if it is always possible to generate a forest satisfying both conditions, then the space complexity of the overall data structure is $O(n\sqrt{n})$. Unfortunately, the second condition could prevent us from generating an $O(\sqrt{n})$ collection of cluster forests; that is, each cluster forest could be of size less than $\frac{\sqrt{n}}{4}$. The following technical lemmas show how to manage this case.

First, it is important to underscore one property, shown in Lemma 5.1, of cluster forests useful for the following proofs.

LEMMA 5.1. *Let* $F = \langle Clus(c_1), \ldots, Clus(c_k)\rangle$ *be a cluster forest, where* $c_1, \ldots, c_k$ *are thin vertices, then*

$$|Clus(c_i)| = t \;\Rightarrow |Ext(Clus(c_i))| \leq t^2 \;\; \forall i \in \{1, \ldots, k\}\,.$$

Proof. The proof easily follows observing that, by construction, forests are generated only when there are neither good nor fat vertices. Moreover, each cluster is added to a forest in not increasing order of size. □

Without loss of generality, we denote the size of a cluster $Clus(c_{ij}) \in F_i$ as follows:

$$|Clus(c_{ij})| = n^{\frac{1}{2} - \sum_{p=1}^{j} \delta_{ip}}, \tag{1}$$

where $\delta_{ip} \geq 0 \; \forall\, p \in \{1, \ldots, j\}$.

In fact, if the ordered sequence of clusters $\langle Clus(c_{i1}), \ldots, Clus(c_{ik_i})\rangle$ composing a forest is generated by the `Decomposition` procedure above, then the corresponding sequence of cluster sizes is monotone and not increasing, and by hypothesis each size is less than $\frac{\sqrt{n}}{4}$. Moreover,

$$|F_i| = \sum_{j=1}^{k_i} n^{\frac{1}{2} - \sum_{p=1}^{j} \delta_{ip}}, \tag{2}$$

where $\langle \delta_{i1}, \ldots, \delta_{ik_i}\rangle$ is a sequence of nonnegative real values.

Let us suppose that the ith generated cluster forest satisfies the conditions

1. $|F_i| < \frac{\sqrt{n}}{4}$,
2. $m_i k_i \geq n$,

and let $Clus(c_{i,k_i})$ be the last cluster chosen. Then we have the following.

LEMMA 5.2. $|Clus(c_{i,k_i})| < \frac{n^{\frac{1}{2} - \delta_{i1}}}{4}$, *where* $n^{\frac{1}{2} - \delta_{i1}} = |Clus(c_{i,1})|$.

Proof. From Lemma 5.1, if $|Clus(c_{ij})| = t_{ij}$, then the number of external vertices related to $Clus(c_{ij})$ is at most t_{ij}^2. As a consequence, we have

$$m_i k_i \leq k_i \sum_{j=1}^{k_i} (t_{ij})^2 = k_i \sum_{j=1}^{k_i} \left(n^{\frac{1}{2} - \sum_{p=1}^{j} \delta_{ip}} \right)^2 \tag{3}$$

$$= k_i \sum_{j=1}^{k_i} n^{1 - 2\sum_{p=1}^{j} \delta_{ip}} \leq k_i \sum_{j=1}^{k_i} n^{1 - 2\delta_{i1}} = k_i^2 n^{1 - 2\delta_{i1}}. \tag{4}$$

Hence, by condition $m_i k_i \geq n$, we get

$$k_i^2 n^{-2\delta_{i1}} \geq 1 \implies k_i \geq n^{\delta_{i1}} > 4. \tag{5}$$

(The last inequality follows from a forest termination condition; i.e.,

$$|F_i| = \sum_{j=1}^{k_i} n^{\frac{1}{2} - \sum_{p=1}^{j} \delta_{ip}} < \frac{\sqrt{n}}{4};$$

hence, $n^{-\delta_{i1}} < \frac{1}{4}$.)

Moreover,

$$\frac{\sqrt{n}}{4} > \sum_{j=1}^{k_i} n^{\left(\frac{1}{2}-\sum_{p=1}^{j}\delta_{ip}\right)} \geq \sum_{j=1}^{k_i} n^{\left(\frac{1}{2}-\sum_{p=1}^{k_i}\delta_{ip}\right)} = k_i\left(n^{\left(\frac{1}{2}-\sum_{p=1}^{k_i}\delta_{ip}\right)}\right) \tag{6}$$

and, from relation (5),

$$k_i\left(n^{\left(\frac{1}{2}-\sum_{p=1}^{k_i}\delta_{ip}\right)}\right) \geq n^{\delta_{i1}} n^{\left(\frac{1}{2}-\sum_{p=1}^{k_i}\delta_{ip}\right)} = n^{\left(\frac{1}{2}-\sum_{p=2}^{k_i}\delta_{ip}\right)}. \tag{7}$$

Hence,

$$n^{\left(\frac{1}{2}-\sum_{p=2}^{k_i}\delta_{ip}\right)} < \frac{\sqrt{n}}{4}.$$

Dividing both terms by $n^{\delta_{i1}}$, we have

$$n^{\left(\frac{1}{2}-\sum_{p=1}^{k_i}\delta_{ip}\right)} < \frac{n^{\left(\frac{1}{2}-\delta_{i1}\right)}}{4}. \tag{8}$$

The left-hand side of inequality (8) is, by definition, the size of $Clus(c_{ik_i})$. □

With reference to the cluster forests sequence $\langle F_{g+1}, \ldots, F_{g+f}\rangle$, let $g+1 \leq i < g+f$. We have the following.

LEMMA 5.3. $|Clus(c_{i+1,1})| < \frac{n^{\frac{1}{2}-\delta_{i1}}}{4}$.

Proof. The proof follows trivially from Lemma 5.2, observing that clusters are taken in not increasing order of size. □

From the above technical lemmas, Lemma 5.4 easily follows.

LEMMA 5.4. *The decomposition strategy returns an* $O(\log n)$ *collection* $\langle F_{g+1}, \ldots, F_{g+f}\rangle$ *of clusters forests.*

From Lemma 5.4, we have the following.

THEOREM 5.5. *The data structure for the representation of dags satisfying the lattice property has an* $O(n\sqrt{n})$*-space complexity and allows us to perform the* REACHABILITY *operation in constant time.*

6. Queries implementation. In this section, we describe algorithms for the operations introduced in Theorem 1.1. A sketch of the algorithm for the REACHABILITY operation already has been given in section 3.4 and the time complexity has been proven in Theorem 5.5.

Let us now describe the PATH operation. For this operation we need to augment our data structure. First note that each double tree is, by construction, the union of two rooted trees. Hence, for each vertex x and for each double tree to which it belongs, it is possible to associate one and only one vertex u (the parent in the tree) which is on the path from x to the vertex inducing the double tree. We then store in the data structures **B** and **D** u's coordinates with respect to this double tree. The PATH operation is now straightforward. While testing the presence of a directed path between x and y using the REACHABILITY(x, y) test, we find the double tree to which they both belong, and then we look at the coordinates of the parents of x and y. These vertices are the immediate successors of x and y on the path from x to y. Then we recursively repeat the search starting from these vertices until we reach the root of the double tree.

In this paper, we will not furnish the full algorithm which, although simple, is quite lengthy. The net result is the following.

PROPOSITION 6.1. *The* PATH(x,y) *operation can be implemented in* $O(l)$ *time, where* l *is the path length.*

For implementing the PRED(x) and SUCC(x) operations, we add new data structures to those described in section 3.4. In particular, for each double tree $DT(u,c)$ of the double tree decomposition $\mathcal{T}$, we maintain the corresponding internal tree $IntTree(u,c)$. Moreover, for each vertex $x \in V$, let $Clus(c)$ be the cluster to which x belongs; if $Clus(c)$ is a $Clus^+(c)$, then we maintain the set of x's successors in $Clus^+(c)$; otherwise, we maintain the set of x's predecessors. Let us denote the first set $Succ(x,c)$ and the second $Pred(x,c)$. Finally, for each vertex $x \in V$ we store the set of double tree identifiers to which each vertex is connected as an external vertex. This information eliminates the need to visit all the **D** tables. By construction, the space complexity of the new data structure is still $O(n\sqrt{n})$.

Let us now introduce the PRED(x) operation. For SUCC(x) operation, the algorithm is similar.

```
    procedure PRED (x)
    begin;
1.     if A[x].sign = "+"
2.     then return (IntTree(x))
3.     else return (Pred(x,c)) ;
4.     for each double tree to which x is connected as external vertex
5.     begin;
6.        Let u be the internal representative vertex of x;
7.        return (IntTree(u));
8.     end; end;
```

PROPOSITION 6.2. *The* PRED(x) *and* SUCC(x) *operations require* $O(k)$ *time, where* k *is the size of the returned set.*

Proof. This follows observing that only actual predecessors (successors) are visited. □

For the RANGE(x,y) operation, we have the following result.

LEMMA 6.1. *Let* $x, y \in V$. *If* REACHABILITY(x,y) = **true**, *then one and only one double tree* $DT(u,c_i)$ *exists such that* RANGE$(x,y) \subseteq Vert(DT(u,c_i))$.

Proof. Let $x \in Clus(c)$ and $y \in Clus(c')$. Let us first suppose that $Clus(c)$ has been generated before $Clus(c')$.

Two cases are possible.

1. $Clus(c)$ is a $Clus^+(c)$.

Let u be the internal representative vertex of y with respect to $Clus(c)$. We claim that $DT(u,c)$ is the required double tree.

Let $z \in$ RANGE(x,y) and $z \in Clus(c'')$. $Clus(c'')$ cannot be generated before $Clus(c)$; otherwise, by cluster definition and according to $Clus(c'')$ sign, either $x \in Clus(c'')$ or $y \in Clus(c'')$.

Hence, $Clus(c'')$ has been generated after $Clus(c)$ and $z \in Ext(Clus(c))$. Since $x \prec z \prec y$, by double tree definition, $x, y, z \in Vert(DT(u,c))$.

2. $Clus(c)$ is a $Clus^-(c)$.

By cluster definition, we have $Clus(c) = Clus(c')$. In this case, we want to prove that $DT(x,c)$ is the required double tree. Since $x \prec y$, then $y \in Vert(DT(x,c))$.

Let $z \in$ RANGE(x,y) and $z \in Clus(c'')$. As before, $Clus(c'')$ cannot be generated before $Clus(c)$. Moreover, in this case, $Clus(c'')$ cannot also be generated after $Clus(c)$; then $Clus(c) = Clus(c'')$ and $z \in Vert(DT(x,c))$.

In a similar way, it is possible to prove that, if $Clus(c')$ has been generated before $Clus(c)$, then either $\text{RANGE}(x, y) \subseteq Vert(DT(u, c'))$, where u is the internal representative vertex of x with respect to $Clus(c')$, or $\text{RANGE}(x, y) \subseteq Vert(DT(y, c'))$, depending on the $Clus(c')$ sign. □

PROPOSITION 6.3. *The* $\text{RANGE}(x, y)$ *operation can be implemented in* $O(k \log d)$ *time, where* k *is the size of the returned set and* d *is the maximum vertex degree (either in-degree or out-degree) of the transitive reduction graph* $G^T = (V, E^T)$.

Proof. Representing all double trees using the implicit data structure of Corollary 3.4, we can first identify in constant time the unique double tree that contains $\text{RANGE}(x, y)$, and we can then report $\text{RANGE}(x, y)$ by visiting this double tree within the required time bound. □

It is important to emphasize that, by means of the $\text{RANGE}(x, y)$ and PATH operations, it is possible to report the transitive reduction subgraph having x as a source and y as a sink.

Let us now describe the $\text{GLB}(x, y)$ and $\text{LUB}(x, y)$ operations. We consider only the $\text{GLB}(x, y)$, as results obtained can be stated, mutatis mutandis, for $\text{LUB}(x, y)$.

Let $x \in Clus(c_h)$ and $y \in Clus(c_k)$ and let $\{Clus(c_1), \ldots, Clus(c_p)\}$ be the subset of clusters of the cluster collection generated by the `BuildCluster` procedure, having as internal vertices at least one predecessor of both x and y. Moreover, let $\{x_1, \ldots, x_p\}$ and $\{y_1, \ldots, y_p\}$ be the corresponding internal representative vertices of x and y, respectively.

Using an argument similar to the one used to prove Lemma 3.1, the following two lemmas can be established.

LEMMA 6.2. *If any* $Clus(c_i)$, *for* $1 \leq i \leq p$, *is a* $Clus^+(c_i)$, *then*

$$if\ IntTree(x_i, c_i) \cap IntTree(y_i, c_i) = \mathcal{I},\ then\ \ LUB(\mathcal{I}) \in \mathcal{I}.$$

LEMMA 6.3. *If any* $Clus(c_i)$, *for* $1 \leq i \leq p$, *is a* $Clus^-(c_i)$, *then*

$$if\ Pred(x_i, c_i) \cap Pred(y_i, c_i) = \mathcal{I},\ then\ \ LUB(\mathcal{I}) \in \mathcal{I}.$$

Let $\{u_1, \ldots, u_p\}$ be the corresponding set of least upper bounds. We have the following.

LEMMA 6.4. *The partial order associated with* $\{u_1, \ldots, u_p\}$ *is a total order.*

Proof. To prove the lemma we show that there exists a permutation $\langle u_{i_1}, \ldots, u_{i_p} \rangle$ such that $u_{i_j} \prec u_{i_m}$, for all $i_1 \leq i_j < i_m \leq i_p$.

Two cases are possible.

1. Either $Clus(c_h)$ is a $Clus^+(c_h)$ or $Clus(c_k)$ is a $Clus^+(c_k)$.

Let the clusters in $\langle Clus(c_1), \ldots, Clus(c_p) \rangle$ be ordered according to the generation order.

If $Clus(c_h)$ is a $Clus^+(c_h)$, then $p \leq h$. In fact, by cluster definition, once $Clus^+(c_h)$ has been taken, then all x's predecessors have been considered. Analogously, if $Clus(c_k)$ is a $Clus^+(c_k)$, then $p \leq k$.

Moreover, all $Clus(c_i)$ in the sequence are $Clus^+(c_i)$. In fact, suppose for contradiction that $Clus(c_j)$, for $1 \leq j \leq p$, is a $Clus^-(c_j)$. If $Clus(c_h)$ is a $Clus^+(c_h)$, then $x \in Clus^-(c_j)$, or, if $Clus(c_k)$ is a $Clus^+(c_k)$, then $y \in Clus^-(c_j)$, but this is a contradiction.

We claim that the sequence of least upper bounds $\langle u_1, \ldots, u_p \rangle$, ordered according to the order in which the corresponding clusters are generated, is the required permutation. Let us assume that two values $1 \leq i < j \leq p$ exist such that either $u_i \sim u_j$ or $u_j \prec u_i$. In the first case the following relations hold simultaneously:

(i) $u_i \prec x$ and $u_i \prec y$;
(ii) $u_j \prec x$ and $u_j \prec y$;
(iii) $u_i \sim u_j$.

However, this contradicts the lattice property.

In the second case, since by hypothesis $Clus(c_i)$ has been generated before cluster $Clus(c_j)$, we have $u_j \in Clus(c_i)$. The proof follows by contradiction.

2. $Clus(c_h)$ is a $Clus^-(c_h)$ and $Clus(c_k)$ is a $Clus^-(c_k)$.

Let us consider the ordered sequence of clusters

$$\langle Clus^+(c_{i_1}), \ldots, Clus^+(c_{i_m}), Clus^-(c_{i_{m+1}}), \ldots, Clus^-(c_{i_p})\rangle$$

defined as follows.

The subsequence $\langle Clus^+(c_{i_1}), \ldots, Clus^+(c_{i_m})\rangle$ is composed of all clusters in $\{Clus(c_1), \ldots, Clus(c_p)\}$ having sign "+" and ordered according to the generation order. The subsequence $\langle Clus^-(c_{i_{m+1}}), \ldots, Clus^-(c_{i_p})\rangle$ is made up of all clusters in $\{Clus(c_1), \ldots, Clus(c_p)\}$ having sign "−", ordered according to the inverse generation order.

We claim that the corresponding sequence $\langle u_{i_1}, \ldots, u_{i_m}, u_{i_{m+1}}, \ldots, u_{i_p}\rangle$ is the desired permutation.

By an argument similar to the one used in the previous case, it is possible to prove that the two subsequences $\langle u_{i_1}, \ldots, u_{i_m}\rangle$ and $\langle u_{i_{m+1}}, \ldots, u_{i_p}\rangle$ are totally ordered. We have to prove that for all $u_{i_j} \in \langle u_{i_1}, \ldots, u_{i_m}\rangle$ and for all $u_{i_l} \in \langle u_{i_{m+1}}, \ldots, u_{i_p}\rangle$, $u_{i_j} \prec u_{i_l}$. By the lattice property either $u_{i_j} \prec u_{i_l}$ or $u_{i_l} \prec u_{i_j}$. In the first case the claim is proved. Suppose for contradiction that $u_{i_l} \prec u_{i_j}$; then, by cluster definition, $u_{i_l} \in Clus^+(c_{i_j})$. This once again contradicts the hypothesis.

This completes the proof. □

Using the above lemma, it is possible to state the following proposition.

PROPOSITION 6.4. *The* GLB(x, y) *and* LUB(x, y) *operations can be implemented in* $O(\sqrt{n})$*-time.*

Proof. To implement these operations we augment the data structure as follows. For each internal tree of a cluster, we maintain the set of least upper bounds (greatest lower bounds) of the sets derived from the intersection with all the other internal trees in the same cluster. Analogously, we maintain for each vertex x the set of least upper bounds (greatest lower bounds) of the sets derived from the intersection between $Pred(x, c)$ ($Succ(x, c)$) and $Pred(y, c)$ ($Succ(y, c)$) for all y in $Clus(c)$.

By construction, the overall space occupancy is still $O(n\sqrt{n})$.

Given x and y, using data structures **D** and **B**, in $O(\sqrt{n})$-time, it is possible to find the set $\langle u_1, \ldots, u_p\rangle$. The maximal element of this sequence is the greatest lower bound of x and y. □

It is worth noting that, by means of LUB(x, y), GLB(x, y) and SUCC(x), PRED(x) operations it is possible to easily implement the following.

1. COMMANC(x, y). Given $x, y \in V$, returns the set of all common ancestors of x and y.

2. COMMSUCC(x, y). Given $x, y \in V$, returns the set of all common successors of x and y.

In particular, from Propositions 6.2 and 6.4, Proposition 6.5 is derived.

PROPOSITION 6.5. *The* COMMANC(x, y) *and* COMMSUCC(x, y) *operations can be implemented in* $O(\sqrt{n} + k)$ *time, where* k *is the size of the returned set.*

To prove Theorem 1.1, it remains to describe LUB$(x_1, \ldots, x_k)$ and GLB$(x_1, \ldots, x_k)$. Note that a straightforward application of Proposition 6.4 leads to an $O(k\sqrt{n})$

worst-case time bound. In order to obtain the desired complexity, we have to underscore some additional properties of the proposed decomposition.

Let us analyze only the GLB$(x_1, \ldots, x_k)$ operation, as LUB$(x_1, \ldots, x_k)$ can be dually derived.

LEMMA 6.5. *If all vertices* $(x_1, \ldots, x_k)$ *belong to the same cluster, then operation* GLB$(x_1, \ldots, x_k)$ *can be performed in* $O(k)$ *steps.*

Proof. The lemma easily follows by exploiting the information added for the GLB(x, y) operation. Starting from the internal trees of the k vertices, we can first compute the $\frac{k}{2}$ least upper bounds associated with pairs of internal trees. Iterating the process on the $\frac{k}{2}$ least upper bounds we find the GLB$(x_1, \ldots, x_k)$, whenever it exists. □

On the other hand, let the vertices $(x_1, \ldots, x_k)$ belong to different clusters. Consider any two vertices, say, x_1 and x_2.

Let $\langle u_1, \ldots, u_p \rangle$ be the sequence of least upper bounds of the set of common predecessors with respect to clusters $\langle Clus(c_1), \ldots, Clus(c_p) \rangle$ (see Lemma 6.4). By construction, any other vertex in the sequence $(x_1, \ldots, x_k)$ satisfies the following property.

LEMMA 6.6. *Let* $x_i \in (x_1, \ldots, x_k)$. *If* u_j *is the greatest vertex in the sequence* $\langle u_1, \ldots, u_p \rangle$ *such that* $u_j \prec x_i$, *then either* GLB$(x_1, x_2, x_i) = u_j$ *or* GLB$(x_1, x_2, x_i) \in IntTree(u_{j+1}, c_{j+1})$.

PROPOSITION 6.6. *The* LUB$(x_1, \ldots, x_k)$ *and* GLB$(x_1, \ldots, x_k)$ *operations can be implemented in* $O(\sqrt{n} + k \log n)$*-time.*

Proof. First observe that, by Proposition 6.4, we can derive the sequence $\langle x_1, \ldots, x_p \rangle$ in $O(\sqrt{n})$-time. Hence, by means of a binary search, in $O(k \log n)$-time, it is possible to derive the maximum element u_j such that $u_j \prec x_i$ for $1 < i < k$. Then, by Lemma 6.6 either GLB$(x_1, \ldots, x_k) = u_j$ or GLB$(x_1, \ldots, x_k) \in IntTree(u_{j+1}, c_{j+1})$. In the former case, the proposition is proved. In the latter case, let $(v_1, \ldots, v_k)$ be the internal representative vertices of $(x_1, \ldots, x_k)$ with respect to cluster $Clus(c_{j+1})$. Now the problem reduces to finding the GLB$(v_1, \ldots, v_k)$, where $(v_1, \ldots, v_k)$ belong to the same cluster. The proof follows by Lemma 6.5. □

By a straightforward application of Lemma 5.5 and Propositions 6.1–6.4 and 6.6, the proof of the main theorem (Theorem 1.1) is completed.

7. Conclusions and open problems. In this paper, a general technique for the representation of a *dag* satisfying the lattice property has been presented. This technique, based on a two-level graph decomposition strategy, is very efficient for the reachability problem resolution, from either a space or a time complexity point of view. In fact, when $m = \Omega(n\sqrt{n})$, it performs a compression of the given *dag*. Note that the complexity bound we derive is optimal, as it matches the theoretical lower bound for this problem (see Proposition 1.1).

The data structure proposed can be efficiently used not only for testing the presence of a path between two given vertices but also for performing a set of basic operations for this class of graphs: namely, find a path between two vertices whenever one exists; given two vertices, find all vertices on the directed paths connecting them in the transitive reduction graph; compute all the successors and/or predecessors of a given vertex; given two vertices, find the least common ancestor and/or the greatest common successor; given a set of vertices, find all common ancestors and/or all common successors.

Furthermore, a stronger result can be derived. In particular, it is possible to represent a partial lattice in space $O(n\sqrt{t})$ with the same time bound for all the

operations, where t is the minimum number of disjoint chains which partition the element set. It is worth noting that this represents an interesting result, since it provides a tight characterization of the complexity of partial lattices. In fact, based on Dilworth's theorem [12], t is equal to the width of the lattice.

Moreover, the graph decomposition strategy, introduced in this paper, has been implemented. Performance evaluations indicate that this strategy can provide a storage occupation substantially less than $O(n\sqrt{n})$-space while maintaining efficiency in reachability query resolution.

Note that the class of graphs under investigation has applications in many fields such as computational geometry, object oriented programming, and distributed systems.

An interesting research direction is to apply our approach for coping with secondary memory management problems. The digraphs representation introduced could represent a powerful clustering technique for minimizing the total number of accessed pages. Our conjecture is supported by results in [16], where two-dimensional lattices are used to produce efficient data structures on paged memory for the half-plane search in two dimensions.

A natural direction for further work is to adopt the same strategy for general directed graphs. In fact, the main problem in this case is that they usually violate Lemma 3.1. In fact, given a general *dag* $G = (V, E)$ and a cluster $Clus(c)$, let u be a vertex in $G - Clus(c)$; if $Clus^+(c) \cap Clus^+(u) \neq \emptyset$, then it can have more than one maximal element. Dually, if $Clus^-(c) \cap Clus^-(u) \neq \emptyset$, then it can have more than one minimal element. In such a case, a constant time reachability test cannot be guaranteed. This prevents us from obtaining a constant time reachability test. In fact, as there is not a one-to-one relation between a given cluster and an external vertex, it is not possible, given a pair of vertices $\langle x, y \rangle$, to univocally identify a double tree containing both x and y.

Nevertheless, the proposed decomposition strategy represents, in this case, a heuristic method for testing reachability which takes into account the sparseness of the graph.

Acknowledgments. The authors wish to thank Prof. Jaroslav Nešetřil for many interesting discussions on the topics presented here and Prof. Rao Kosaraju and the anonymous referee for their detailed comments and suggestions.

BANDWIDTH ALLOCATION WITH PREEMPTION*

AMOTZ BAR-NOY†, RAN CANETTI‡, SHAY KUTTEN§, YISHAY MANSOUR¶, AND BARUCH SCHIEBER‡

Abstract. Bandwidth allocation is a fundamental problem in the design of networks where bandwidth has to be reserved for connections in advance. The problem is intensified when the overall requested bandwidth exceeds the capacity and not all requests can be served. Furthermore, acceptance/rejection decisions regarding connections have to be made online, without knowledge of future requests. We show that the ability to *preempt* (i.e., abort) connections while in service in order to schedule "more valuable" connections substantially improves the throughput of some networks. We present bandwidth allocation strategies that use preemption and show that they achieve *constant competitiveness* with respect to the throughput, given that any single call requests at most a constant fraction of the bandwidth. Our results should be contrasted with recent works showing that nonpreemptive strategies have at most inverse logarithmic competitiveness.

Key words. bandwidth allocation, online algorithms, preemption, call control, call admission

1. Introduction.

Bandwidth allocation is one of the most important problems in the management of networks that have guaranteed bandwidth policy (e.g., asynchronous transfer mode (ATM) [5], PARIS [9], IBM BBNS [10]). In such networks the application has to reserve in advance sufficient bandwidth for its communication. The guaranteed bandwidth policy is contrasted with the more traditional policy (e.g., TCP/IP), where information packets are routed as they come to the network without prior knowledge about the connections. The advantages of the guaranteed bandwidth policy are many and include bounded latency for real-time tasks; fairness (e.g., one user cannot overtake the entire network's resources); and simple pricing (the application can be charged for the bandwidth it allocated). The major drawback of the guaranteed bandwidth policy is inefficiency: the communication links may be underutilized. Thus, a "good" bandwidth allocation strategy is crucial for such networks.

The bandwidth allocation problem becomes more difficult in view of the large variety of applications that use the network simultaneously. These applications have very different requirements in terms of bandwidth, duration, delay, information loss,

etc. Furthermore, since the communication volume may be much larger than buffer space, decisions regarding current requests cannot be delayed and have to be made without knowledge of future requests. The problem is further intensified when the available bandwidth cannot accommodate all requests for bandwidth and some have to be rejected.

In this context it is natural to consider the possibility of "softening" the rigidity of the guaranteed bandwidth policy by allowing preemption (i.e., abortion) of connections in service, in order to schedule "more valuable" connections that would otherwise be rejected. Preempting a connection has obvious disadvantages: all the work that was done so far may be lost, and the transmission, in some applications, has to start again later. However, the ability to preempt certain types of connections as a policy may greatly improve the performance of the network. Understanding the power of preemption in this context may shed new light on the value of the guaranteed bandwidth policy.

Indeed, some types of connections should never be preempted (e.g., phone calls). However, there exist other scenarios where preemption is acceptable and even essential. For instance, a high-priority (say, real-time) connection should be allowed to preempt a low-priority connection. (See [18] for an implementation of a channel where this type of preemption is used.) Another case is preempting other connections of the same user [19] or of different users based on a pricing model [21]. The willingness of users to communicate over preemptable, low-priority connections would probably depend on the price discount they would receive, compared to a nonpreemptable connection. Our work shows that preemptable connections allow far better utilization of the network, and thus users may be charged at a considerably lower rate.

In this work, we concentrate on preemption as a tool for enhancing the throughput, or utilization, of the network. We develop various preemption strategies (specifying *when* and *which connections* to preempt) for maximizing the throughput *of connections that eventually complete.* Our strategies perform provably and significantly better (in terms of throughput) than any nonpreemptive strategy for bandwidth allocation.

We study two models for bandwidth allocation. The first is a single link, where requests for connections (or *calls*) arrive one by one as time proceeds; each call has duration and bandwidth requirements (specified in advance). Requests have to be either served immediately or rejected (for example, due to limited buffer space). This model is an abstraction of a single *virtual path* in an ATM network that has a single entry and exit. A virtual path in an ATM network serves as a "highway" that is used by many *virtual circuits* (i.e., connections) simultaneously. The bandwidth of the virtual path has to be divided among the various virtual circuits. The second model is a line of processors where each connection has source, destination, and required bandwidth. Here we assume that all requests are for permanent connections (or, alternatively, that all calls arrive at the same time, in some arbitrary order, and have the same duration). This model can be viewed as an abstraction of a virtual path with multiple entries and exits.

As suggested by the online nature of the problem (decisions on current requests are made without knowledge of future requests), we use competitive analysis to measure the performance of bandwidth allocation algorithms. We define the performance of a bandwidth allocation algorithm on a sequence of requests as the throughput of completed calls (i.e., calls that are neither rejected nor preempted). This throughput can be measured as the sum, over completed calls, of the duration times the bandwidth

requirement, or equivalently as the integral over time of the bandwidth used by calls that eventually complete. The competitiveness of an algorithm is the *infimum* over all request sequences of the ratio of the performance of the algorithm to the performance of the best (offline) schedule for this sequence.

The competitiveness of our algorithms depends only on δ, the ratio between the largest bandwidth requested by any *single* call and the capacity of the line. We note that whereas the capacity of the network can be arbitrarily large, the ratio δ is typically a constant smaller than one. In both models we achieve constant competitiveness if δ is a constant smaller than one. We contrast our results with the fact that nonpreemptive bandwidth allocation strategies have inverse logarithmic competitiveness. (We elaborate on this point later.)

Our algorithms are simple and efficient, however surprising and nonintuitive at first. They suggest the following approach to bandwidth allocation: in deciding which calls to reject or preempt, the algorithms consider only the duration of a call and the time for which a call in service already has been running, *completely ignoring the throughput of calls.* In particular, a call with very large throughput may be preempted in order to make room for a call with longer duration and much smaller throughput. Still, our algorithms achieve constant competitiveness (if δ is bounded away from one) where more straightforward strategies fail.

We show that our algorithms have optimal competitiveness, up to a small constant, for all values of δ. Furthermore, we show that (i) deterministic algorithms have a very poor competitive ratio if a single call may request the entire bandwidth (that is, if $\delta = 1$); (ii) in the line model, if we let calls have arbitrary duration and δ be more than half, then constant competitiveness cannot be achieved by any deterministic algorithm. (Bounds on the competitiveness of *randomized* preemptive bandwidth allocation algorithms in this and related models are shown in [8].)

We also consider a special case of the single link model where all calls have identical bandwidth, which is $1/k$ of the capacity of the link for some integer k. This model can be visualized as k parallel links, each of unit capacity. Even for this restricted model, called the *parallel links* model, we show that any deterministic online algorithm has a competitive ratio of at most 0.66 (the bound holds *for all* k). The parallel links model is closely related to online preemptive task scheduling under overload [7, 6, 14, 15, 22, 20]. Our impossibility result applies to this problem as well.

Our work extends previous work of Garay and Gopal [12] and Garay et al. [13]. These papers also consider online bandwidth allocation with preemption on networks with line topology. However, they simplify the model by assuming that the bandwidth requirement of each call is equal to the bandwidth of the links (and thus, in particular, only one call at a time can be served on a link).

Considerable work has been recently done on nonpreemptive online bandwidth allocation (also referred to as call control); we mention here only some of this work. In [2] (and also in [1]) the problem of nonpreemptive online bandwidth allocation and virtual circuit routing on an arbitrary network was considered. Under the assumption that no call may request more than a logarithmic fraction of the bandwidth, Awerbuch, Azar, and Plotkin [2] and Aspnes et al. [1] presented a strategy with competitiveness inversely proportional to the logarithm of the size of the network times the ratio between the largest and smallest value of a call, and they proved that no online strategy has better performance. *Randomized* algorithms for nonpreemptive call control on tree-like networks are given in [3], where competitiveness inversely logarithmic in similar parameters is shown with matching impossibility results. Other

topologies are considered in [4] with similar results. Lipton and Tomkins [16] considered nonpreemptive online "interval scheduling" in a model similar to our line model. They achieved a slightly worse than inverse logarithmic competitive ratio and showed that no online algorithm can achieve an inverse logarithmic competitive ratio. In summary, whenever preemption is not allowed the "logarithmic barrier" seems to be unbreakable, even by randomized algorithms.

Finally, we remark that Faigle and Nawijn [11] also showed that preemption is a useful tool. They considered the special case in which all calls have identical bandwidth. However, their goal was to minimize the number of rejected calls, while our goal is to maximize the throughput. They described an optimal deterministic online algorithm (competitiveness 1) when preemption is allowed, whereas it was known before that without preemption no algorithm with constant competitiveness exists.

In section 2 we introduce the single link model and define bandwidth allocation algorithms in this model. In section 3 we describe our algorithms for the single link model. In section 4 we introduce the line model and show how our algorithms can be adapted to this model. In section 5 we demonstrate the optimality of our algorithms.

2. The single link model. Consider a communication link with bandwidth capacity $\mathcal{B}$ (where $\mathcal{B}$ may be very large). A call is a connection established between the two endpoints of the link. Each call c is characterized by the required bandwidth b_c, the request issue time t_c, and the duration d_c (known in advance). Let $e_c \stackrel{\text{def}}{=} t_c + d_c$ be the ending time of a call c. For simplicity we assume that the time is discrete. Our convention is that the minimum bandwidth requested by a call is 1. Let δ denote the maximum fraction of the capacity used by a single call. We have $\frac{1}{\mathcal{B}} \leq \delta \leq 1$.

The requests arrive one by one in an online fashion. A request for a call c can be either served immediately or rejected. The algorithm may *preempt* (i.e., stop or abort) calls during service. The operation of the algorithm run by the control center can thus be described as follows. Upon a request for a call c, if serving c does not violate the bandwidth capacity of the link, then serve c. Otherwise, either reject the request or preempt some calls that are currently being served so that call c can be served within the capacity of the link.

Let the throughput of a call c, denoted by v_c, be its bandwidth times its duration, i.e., $v_c = b_c \cdot d_c$. Once a call is completed, a value equal to the throughput of the call is gained. No gain is accrued for preempted calls. Note that the throughput of a completed call is a measure for the amount of information contained in it.

We use competitive analysis to measure the performance of our bandwidth allocation algorithms. The competitive ratio of an algorithm is the infimum over all possible request sequences of the total throughput of the algorithm on a sequence divided by the total throughput of the best (offline) algorithm on this sequence. More formally, for a sequence $S = c_1, \ldots, c_n$ of call requests, let the bandwidth requested by S at time t be

$$\tilde{B}_S(t) \stackrel{\text{def}}{=} \sum_{\{c \in S \mid t \in [t_c \ldots t_c + d_c]\}} b_c.$$

We say that S is *feasible* if $\tilde{B}_S(t) \leq \mathcal{B}$ for all times t. Let the *cover* of a sequence S be $V(S) \stackrel{\text{def}}{=} \sum_t B_S(t)$, where $B_S(t) \stackrel{\text{def}}{=} \min\{\mathcal{B}, \tilde{B}_S(t)\}$. If S is feasible, then we say that $V(S)$ is the throughput of S (that is, the cover equals the throughput). Note that if S is feasible, then $V(S) = \sum_{c \in S} v_c$.

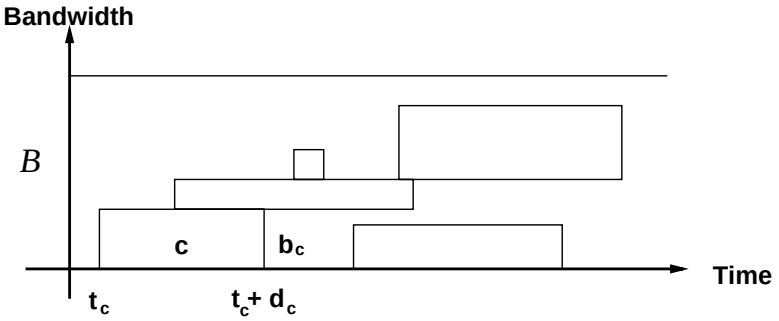

FIG. 3.1. *A geometric representation of calls on a single link.*

For an algorithm $\mathcal{A}$ and sequence S, let $A(S) \subseteq S$ be the sequence of calls completed by $\mathcal{A}$ on input S. (We use $S' \subseteq S$ to denote that S' is a subsequence of S.) Algorithm $\mathcal{A}$ is a valid *bandwidth allocation* algorithm if for any sequence of requests S, $A(S)$ is feasible. Algorithm $\mathcal{A}$ is ρ-*competitive* if

$$\rho \leq \inf_{S} \min_{\{S' \subseteq S | S' \text{ feasible}\}} \frac{V(A(S))}{V(S')}.$$

Note that $0 \leq \rho \leq 1$, and the closer ρ is to 1 the better the algorithm performs.

Remark. Say that algorithm $\mathcal{A}$ is *strictly* ρ-*competitive* if

$$\rho \leq \inf_{S} \frac{V(A(S))}{V(S)}.$$

Since the link cannot serve more than $\mathcal{B}$ bandwidth at any given time, the cover is an upper bound on the throughput of any feasible subsequence of S. Thus, any strictly ρ-competitive algorithm is also ρ-competitive. We show that our algorithms are strictly competitive. While for the positive results we consider this stronger notion of competitiveness, all our impossibility results (upper bounds) are for the regular notion of competitiveness.

3. Bandwidth allocation on a single link. We present two algorithms for bandwidth allocation on a single link. The first algorithm, called the left-right (LR) algorithm, is $(\frac{1}{2} - \delta)$-competitive for $\delta < \frac{1}{2}$. The second algorithm, called the effective time (EFT) algorithm, is $\frac{1-\delta}{4}$-competitive for all $\delta < 1$. For $\delta > \frac{1}{3}$ algorithm EFT has better competitiveness, whereas for $\delta < \frac{1}{3}$ algorithm LR has better competitiveness. In particular, for very small values of δ, the LR algorithm is about $\frac{1}{2}$-competitive. (In section 5 it is shown that for small δ no algorithm can have a better competitive ratio than 0.66.) We stress that, although $\mathcal{B}$ can be arbitrarily large, our algorithms have constant competitiveness whenever the fraction δ is a constant smaller than one. Furthermore, our algorithms do not depend on δ. Therefore, their performance on any request sequence depends on the δ fraction *of this particular sequence.*

The following geometric representation of the scenario may be helpful (see Figure 3.1). Let the x axis represent time and the y axis represent bandwidth. Each call c is a rectangle of length d_c and height b_c. We have to fit the rectangles above the x axis and below the line $y = \mathcal{B}$, under the constraint that the rectangle of call c has to start at $x = t_c$. Note, however, that a call need not use the same "bandwidth pieces" for its total duration. Thus we are allowed to "break" the rectangles vertically, as long

as enough bandwidth is allocated at all times. (This distinguishes our problem from many other problems, e.g., memory allocation.)

In subsection 3.1 we briefly and informally explain why some straightforward strategies for bandwidth allocation fail. We present our algorithms in the two subsections that follow.

3.1. First tries. We first show that basing a bandwidth allocation strategy on the throughput of the calls is a bad idea, although we want to maximize the total throughput of completed calls. This applies both to a greedy strategy (e.g., always prefer calls with larger throughput) and to a "double-the-gain" strategy (e.g., serve an incoming call if enough bandwidth can be freed by only preempting calls whose combined throughput is at most half of the throughput of the incoming call). Consider the following request sequence. First, $\sqrt{\mathcal{B}}$ calls are requested at time 0, each of bandwidth $\sqrt{\mathcal{B}}$ and duration $\sqrt{\mathcal{B}}$. Next, still at time 0, $\mathcal{B}$ calls, each of bandwidth 1 and duration $\frac{\mathcal{B}}{2}$, are requested. Serving any of the last $\mathcal{B}$ calls requires preempting one of the first $\sqrt{\mathcal{B}}$ calls. However, each of the last calls has smaller throughput than each of the first calls. Thus, both the greedy and the double-the-gain algorithms serve only the first $\sqrt{\mathcal{B}}$ calls, gaining $\mathcal{B}^{3/2}$. The best schedule is the last $\mathcal{B}$ calls with throughput $\frac{\mathcal{B}^2}{2}$; thus the competitiveness is at most $\frac{2}{\sqrt{\mathcal{B}}}$. The moral is that calls with longer duration are preferable *even if the longer calls have smaller throughput,* as there may be many similar calls coming in the future.

An alternative strategy may thus be to consider the duration of calls (say, use a "double-the-duration" algorithm). It turns out that considering only the duration is also not good enough (we omit further counterexamples). An additional parameter should be considered, namely the amount of time a call in service has been running (or, alternatively, the amount of time it will run in the future). Each of our algorithms considers a different combination of these parameters.

3.2. The LR algorithm. The LR algorithm implements a compromise between the need to hold on to jobs that have been running for the longest time (thus capitalizing on work done) and the need to hold on to jobs that will run for the longest time in the future (thus guaranteeing future work). The compromise is simple: half of the capacity is dedicated to each of these two classes of jobs. Surprisingly, this simple compromise yields a good competitive ratio. The LR algorithm is described in Figure 3.2.

THEOREM 3.1. *For $\delta < \frac{1}{2}$, algorithm* LR *is $(\frac{1}{2} - \delta)$-competitive.*

Proof. First, note that the total bandwidth required by the calls in $L \cup R$ at any time t is at most $B_L(t) + B_R(t) \le \frac{\mathcal{B}}{2} + \frac{\mathcal{B}}{2} = \mathcal{B}$. Thus the algorithm is valid. Next we show its competitiveness.

Consider an input sequence $S = c_1, \ldots, c_n$ of call requests and assume that $\delta \stackrel{\text{def}}{=} \max_i\{\frac{b_{c_i}}{\mathcal{B}}\}$ is at most $\frac{1}{2}$ (otherwise the competitive claim in the theorem is vacuous). Let $E \stackrel{\text{def}}{=} \text{LR}(S)$ be the set of calls completed by LR on input S. Let S_i be the prefix of S composed of the first i calls in S, and let E_i be the set of calls completed by the algorithm, assuming that the input sequence is only S_i. Note that E_i is the union of two sets: (i) the set of calls completed up to time t_{c_i} (that is, up to the time call c_i is requested), and (ii) the set of calls being served at time t_{c_i}. Below we show, by induction on i, that for all i and for all times t, $B_{E_i}(t) \ge \min\{B_{S_i}(t), (\frac{1}{2} - \delta)\mathcal{B}\}$. Since $S = S_n$ and $E = E_n$, we have $B_E(t) \ge (\frac{1}{2} - \delta)B_S(t)$ for all t. (The worst case is when $B_S(t) = \mathcal{B}$.) Thus the total throughput of the LR algorithm, $V(E)$, is at least $(\frac{1}{2} - \delta)V(S)$, and the theorem follows.

Let F be the set of calls currently in service. Upon the request of a call c do:

1. Add c to F.
2. Find the following two sets of calls, L and R:
   (a) Sort the calls by *increasing* order of *starting* time, and let L be the maximal set of calls at the top of the list (i.e., earliest starting times) such that the total bandwidth required by the calls in L is at most $\frac{\mathcal{B}}{2}$.
   (b) Sort the calls by *decreasing* order of *ending* time, and let R be the maximal set of calls at the top of the list (i.e., latest ending times) such that the total bandwidth required by the calls in L is at most $\frac{\mathcal{B}}{2}$.
3. Preempt/reject calls that are neither in L nor in R to fit in the link capacity.

FIG. 3.2. *Algorithm LR.*

The inductive claim trivially holds for $i = 0$. Let $i > 0$, and fix some $t' \geq 0$. We distinguish two cases.

Case 1. No call p that requested bandwidth for time t' was rejected or preempted in the ith step (that is, when processing the ith request). In this case, if the ith request, c_i, requests bandwidth for time t', then $B_{E_i}(t') - B_{E_{i-1}}(t') = b_c \geq B_{S_i}(t') - B_{S_{i-1}}(t')$. If c_i does not request bandwidth for time t', then $B_{S_i}(t') - B_{S_{i-1}}(t') = 0 = B_{E_i}(t') - B_{E_{i-1}}(t')$. Thus the inductive claim holds.

Case 2. There exist calls that requested bandwidth for time t' and were rejected or preempted in the ith step. We show that in this case $B_{E_i}(t') \geq (\frac{1}{2} - \delta)\mathcal{B}$. Let p be a call that was rejected or preempted in the ith step, for which $t' \in [t_p \dots e_p]$. (Otherwise, $B_{E_i}(t')$ is not affected by call p.) Since the bandwidth requested by p is at most $\delta\mathcal{B}$, both $B_L(t_{c_i})$ and $B_R(t_{c_i})$ must be at least $(\frac{1}{2} - \delta)\mathcal{B}$, otherwise p would be in either L or R. (See also Figure 3.3.) Furthermore, $p \notin L$; thus we must have $B_L(t) \geq (\frac{1}{2} - \delta)\mathcal{B}$ for all times $t \in [t_p \dots t_{c_i}]$. (In other words all the calls in L started before t_p and are still running at t_{c_i}.) Similarly, since $p \notin R$, we have $B_R(t) \geq (\frac{1}{2} - \delta)\mathcal{B}$ for all times $t \in [t_{c_i} \dots e_p]$. (In other words all the calls in R end after e_p and started running before t_{c_i}.) Thus, $B_{E_i}(t') = B_{L \cup R}(t') \geq (\frac{1}{2} - \delta)\mathcal{B}$. □

3.3. The EFT algorithm. The EFT algorithm implements a different compromise between banking on past profit and ensuring future profit. Rather than dividing the bandwidth between the two classes, this algorithm attaches a time-value, called the *effective time,* to each single call. Calls with later effective times are preempted first. The effective time τ_c of a call c is its arrival time minus its duration, i.e., $\tau_c \stackrel{\text{def}}{=} t_c - d_c$. This strategy reflects (in a way described below) the idea that work that is done is worth twice as much as work to be done. Algorithm EFT is described in Figure 3.4.

The effective time strategy may be viewed as a variant of a "doubling strategy" as follows. Let r be a requested call and c be a call in service. By preempting c and serving r, we "gain" the time interval $[e_c \dots e_r]$ and "lose" the time interval $[t_c \dots t_r]$. We will preempt c to make room for r if the time-gain is more than twice the loss, that is, if $e_r - e_c > 2(t_r - t_c)$. This condition is equivalent to $t_r - d_r < t_c - d_c$, or $\tau_r < \tau_c$.

THEOREM 3.2. *For $\delta < 1$, algorithm* EFT *is $(\frac{1-\delta}{4})$-competitive.*

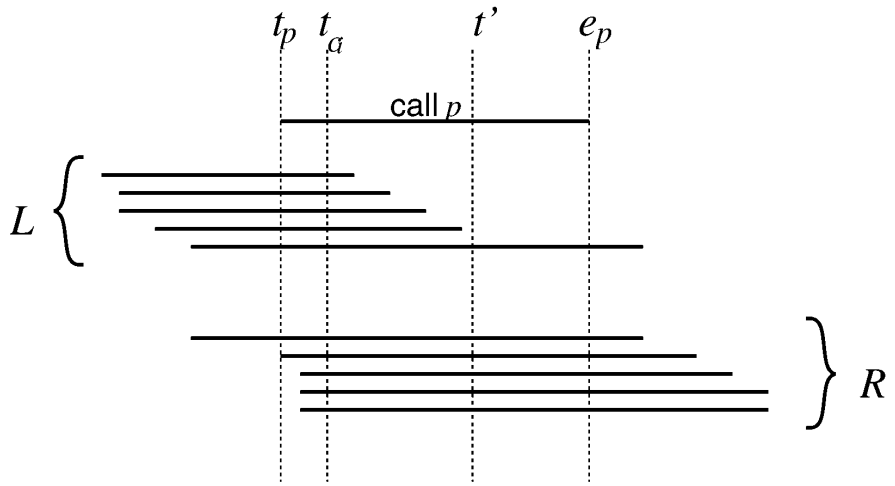

FIG. 3.3. *Call p was either rejected or preempted in the ith step. The total bandwidth of each of the sets L and R is at least $(\frac{1}{2}-\delta)\mathcal{B}$. Since t' intersects either all calls in L or all calls in R, we have $B_{E_i}(t') \geq (\frac{1}{2}-\delta)\mathcal{B}$.*

Let the effective time of a call c be $\tau_c \stackrel{\text{def}}{=} t_c - d_c$.
Maintain a list L of the calls in service, sorted by increasing order of effective time.
(Calls that have the same effective time are ordered arbitrarily.)
Upon the request of a call c, do:

1. Add c to L in place.
2. Reject/preempt calls from the end of the list (i.e., "latest" effective times), to fit in the link capacity.

FIG. 3.4. *Algorithm EFT.*

Proof. The validity of algorithm EFT is immediate from the description. We show its competitiveness. Unlike algorithm LR, here there may be times when the optimal schedule has the link used to capacity while algorithm EFT has almost no bandwidth allocated to calls that eventually complete. Therefore, we use a different "bookkeeping" method for proving the competitiveness of EFT.

Consider some input sequence $S = c_1, \ldots, c_n$ of call requests, and let $\delta \stackrel{\text{def}}{=} \max\{\frac{b_{c_i}}{\mathcal{B}}\}$. Let $E \stackrel{\text{def}}{=} \text{EFT}(S)$ be the set of calls completed by algorithm EFT on input S. We introduce a sequence, E', of "virtual calls" and show that $V(E) \geq \frac{1-\delta}{4} \cdot V(E')$ and $V(E') \geq V(S)$. Therefore, the total throughput of the algorithm (i.e., $V(E)$) is at least $\frac{1-\delta}{4} \cdot V(S)$.

We define virtual calls as follows. For each call c, let the virtual call c' have arrival time $t_{c'} = \tau_c = t_c - d_c$, ending time $e_{c'} = e_c + 2d_c$, and bandwidth $b_{c'} = \frac{1}{1-\delta} b_c$. For a set A of calls, let $A' \stackrel{\text{def}}{=} \{c' : c \in A\}$. Note that the duration of each virtual call is $e_{c'} - t_{c'} = (e_c + 2d_c) - (t_c - d_c) = 4d_c$ and therefore the throughput of each virtual call c' is $\frac{4}{1-\delta}$ times the throughput of the corresponding real call c. Thus, $V(E) \geq \frac{1-\delta}{4} \cdot V(E')$. In Lemma 3.4 below we show that $B_{E'}(t) \geq B_S(t)$ for all t. Thus, $V(E') \geq V(S)$, and the theorem follows. □

Let us first prove a technical claim. (See Figure 3.5.)

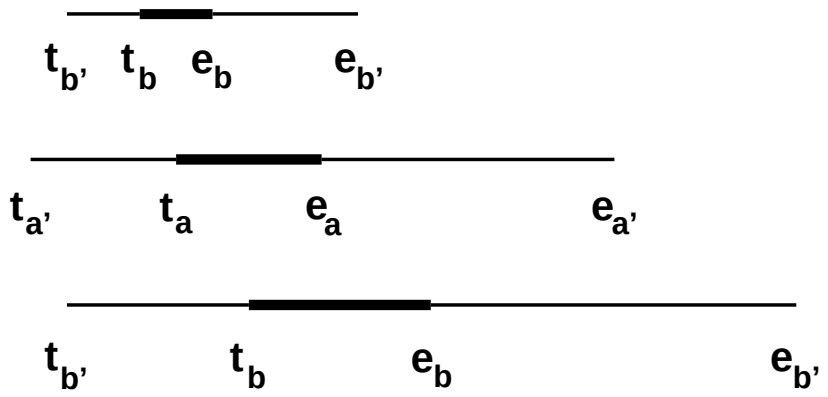

FIG. 3.5. *The proof of the technical claim.*

CLAIM 3.3. *Let a and b be two calls scheduled by the algorithm at time t.*
(1) *If $t_{a'} \le t_{b'}$ and $t_a \ge t_b$, then $e_{a'} \ge e_{b'}$.*
(2) *If $t_{a'} \le t_{b'}$, then $e_{a'} \ge e_b$.*
Proof. Part (1): If $t_a \ge t_b$ and $t_{a'} \le t_{b'}$, then it must be that $d_a \ge d_b$. Thus,

$$e_{a'} = t_a + 3d_a \ge t_b + 3d_b = e_{b'} .$$

Part (2): Consider the case not covered in part (1), i.e., $t_a < t_b$ and $t_{a'} \le t_{b'}$. Call a has not ended by time t_b, thus $d_a \ge t_b - t_a$. Also, it follows from $t_{a'} \le t_{b'}$ that $d_a \ge d_b - (t_b - t_a)$. Thus,

$$\begin{aligned} e_{a'} &= t_a + d_a + 2d_a \\ &\ge t_a + d_b - (t_b - t_a) + 2(t_b - t_a) \\ &= t_b + d_b = e_b. \end{aligned}$$

□

LEMMA 3.4. *For any request sequence S and for all times t we have $B_{E'}(t) \ge B_S(t)$.*

Proof. Say that a time t is *i-quiet* if, up to and including the ith request, all the calls that requested bandwidth for time t (that is, calls c such that $t \in [t_c \dots e_c]$) were completed by the algorithm. Note that if time t is i-quiet, it is also j-quiet for all $1 \le j \le i$. A time t is quiet if it is i-quiet for all i. If a time t is quiet, then certainly $B_{E'}(t) > B_E(t) = B_S(t)$. It remains to deal with times that are not quiet (i.e., times that are not i-quiet for some request i). Define S_i and E_i as in the proof of Theorem 3.1. (That is, S_i is the prefix of S composed of the first i calls in S, and E_i is the set of calls completed by the algorithm assuming that the input sequence is only S_i.) We show, by induction on i, that $B_{E'_i}(t) = \mathcal{B}$ for all times t that are not i-quiet. Since $E = E_n$ and $S = S_n$ we get $B_{E'}(t) \ge B_S(t)$ for all times t.

The inductive claim holds vacuously for $i = 0$. For $i > 0$ we distinguish three cases.

Case 1. The ith request, c_i, was served without preempting other calls. In this case, any time that is not i-quiet is also not $(i-1)$-quiet, and $B_{E'_i}(t) \ge B_{E'_{i-1}}(t)$ for all times t. Thus the claim follows from the induction hypothesis.

Case 2. The ith request was rejected without preempting other calls. In this case, the inductive hypothesis holds for any time t that is not $(i-1)$-quiet. Also, all times that are $(i-1)$-quiet and are not i-quiet are in the time range $[t_{c_i} \dots e_{c_i}]$. Thus it is

enough to show that $B_{E'_i}(t) = \mathcal{B}$ for all $t \in [t_{c_i} \dots e_{c_i}]$. Let F be the set of calls being served at time t_{c_i}. Since c_i is rejected, and $b_{c_i} \leq \delta\mathcal{B}$, the total bandwidth of the calls in F is at least $(1-\delta)\mathcal{B}$. We have $t_{f'} \leq t_{c'_i}$ for all $f \in F$; thus by Claim 3.3, part (2), we have $e_{c_i} \leq e_{f'}$. It follows that $B_{E'_i}(t) \geq B_{F'}(t) \geq \mathcal{B}$ for all times $t \in [t_{c_i} \dots e_{c_i}]$. (In fact this holds for all times $t \in [t_{c'_i} \dots e_{c_i}]$.)

Case 3. Calls were preempted while processing request i. Let P_i be the set of calls that were preempted (or rejected) while processing request i.[1] For a set A of calls let t_A (resp., e_A) denote the earliest starting time (resp., latest ending time) of a call in A. Here we have to consider the time range $[t_{P'_i} \dots e_{P'_i}]$ (rather than only $[t_{P_i} \dots e_{P_i}]$) since calls in P_i that contributed to $B_{E'_{i-1}}(t)$ are now preempted.

It can be seen, similar to the proof of Case 2, that $B_{E'_i}(t) \geq \mathcal{B}$ for all times $t \in [t_{P'_i} \dots e_{P_i}]$. It is left to show that $B_{E'_i}(t) \geq \mathcal{B}$ for all times in $[e_{P_i} \dots e_{P'_i}]$ that are not i-quiet.

Let t be a time in $[e_{P_i} \dots e_{P'_i}]$ that is not i-quiet. Thus there exists a request $j \leq i$ that caused either rejection or preemption of a call that requested bandwidth at time t. We complete the proof by showing, for each request k, $j \leq k \leq i$, a set $G_k \subseteq E_k$ of calls such that $B_{G'_k}(t) \geq \mathcal{B}$. These sets are defined inductively as follows. Define F_k to be the set of calls in service immediately after request k was processed. Let $G_j \stackrel{\text{def}}{=} F_j$. For $k > j$, if c_k is rejected or if c_k is placed in the ordered list L of calls in service after all the calls in G_{k-1}, then $G_k = G_{k-1} - P_k$. Otherwise, $G_k = G_{k-1} \cup \{c_k\} - P_k$. Certainly $G_k \subseteq E_k$. We show by induction on k that the following two properties hold for all $j \leq k \leq i$. (We are interested in Property 2.)

Property 1. For all calls $g \in G_k$, $t \in [t_{g'} \dots e_{g'}]$.

Property 2. $B_{G'_k}(t) = \mathcal{B}$.

Consider the case $k = j$. When request j was processed, a call asking bandwidth for time t was rejected or preempted, so therefore by Claim 3.3 all calls in $F_j = G_j$ have Property 1. Furthermore, the total bandwidth of all calls in G_j must be at least $(1-\delta)\mathcal{B}$; otherwise one of the calls that was either rejected or preempted while processing request j would have been kept by the algorithm. Property 2 thus follows as well.

Now fix some $k > j$ and assume that the two properties hold for G_{k-1}. We distinguish two subcases.

Case 3.1. Call c_k either is rejected or appears in the ordered list L of calls in service after all the calls in G_{k-1}. In this case, Property 1 holds since $G_k \subseteq G_{k-1}$. If call c_k is rejected, then Property 2 is shown as in the base case $k = j$. If call c_k is served, then since it appears after all the calls in G_{k-1} in the list L, all these calls are served as well, and $G_k = G_{k-1}$. In this case Property 2 follows from the induction hypothesis.

Case 3.2. Call c_k is served and appears in the sorted list L before some call $g \in G_{k-1}$. Here, $G_k = G_{k-1} \cup \{c_k\} - P_k$. We first show Property 1. From the induction hypothesis, Property 1 holds with respect to all calls in G_k other than c_k. Note that $t_g \leq t_{c_k}$. By our assumption also $\tau_{c_k} \leq \tau_g$, and thus it follows from Claim 3.3, part (1) that $t_{c'_k} \leq t_{g'}$ and $e_{g'} \leq e_{c'_k}$. Since $t \in [t_{g'} \dots e_{g'}]$ we have $t \in [t_{c'_k} \dots e_{c'_k}]$, which proves Property 1 for call c_k.

Next we show that G_k satisfies Property 2. If $P_k \cap G_{k-1} = \emptyset$, then $G_{k-1} \subseteq G_k$ and Property 2 holds. Otherwise, a call in G_{k-1} was preempted while processing

[1] It is possible that calls are preempted and also that the incoming call is rejected. For simplicity we include the rejected call with the preempted calls.

request k. From the definition of G_{k-1} it follows that in this case all calls not in G_{k-1} that were in service upon the arrival of request k must have been preempted as well. Consequently, $F_k = G_k$. However, the total bandwidth of calls in F_k must be at least $(1-\delta)\mathcal{B}$, otherwise one of the calls that was either rejected or preempted while request k was processed would have been kept by the algorithm. Thus, the total bandwidth of calls in G_k must be at least $(1-\delta)\mathcal{B}$. By Property 1, all calls in G_k request bandwidth for time t. Property 2 follows. □

4. Bandwidth allocation on a line within a single time slot. In this section we consider bandwidth allocation in the *line model*, in which a sequence of stations are connected on a line by communication links. For simplicity we assume that all links have unit length and the same bandwidth capacity, $\mathcal{B}$. Our results generalize to networks with individual capacities and lengths of the links. A call is a connection between two stations on the line. We consider the case where all calls arrive at the same time unit (in some arbitrary order) and have the same duration. In the next section we show that if we let calls have arbitrary duration, and if δ is more than half, then constant competitiveness cannot be achieved by any deterministic algorithm. (We note that this holds even if randomization is allowed [8].)

More formally, the line model is defined as follows. Assume the stations are labeled by consecutive integers increasing from left to right. A call c is characterized by its left endpoint l_c, its right endpoint r_c, and its bandwidth requirement b_c. Let the length of call c be $h_c \stackrel{\text{def}}{=} r_c - l_c$. The throughput of c is now $v_c = h_c \cdot b_c$. Again, bearing in mind that our goal is to maximize the throughput of the network, we define the additive throughput accrued from serving a completed call c to be its throughput v_c. Here the throughput can also be regarded as the amount of network resources allocated for the call. The definitions of the cover, feasibility, and throughput of a request sequence, as well as the competitiveness and validity of bandwidth allocation algorithms, are similar to those of the single link model (see section 2), where time t is replaced, in the natural way, by location (link) e on the line and earlier times are translated to locations with smaller labels. This model is a generalization of the single link model, in the sense that any algorithm for the line model is valid, and has the same performance, in the single link model (when "location" is translated to "time"). The converse is not true, due to reasons described later.

We adapt our algorithms to this more general scenario. The adapted LR algorithm, called ALR, is still $(\frac{1}{2}-\delta)$-competitive for $\delta < \frac{1}{2}$. The adapted EFT algorithm, called AEFT, is $\frac{1-\delta}{2\phi+1}$-competitive for all $\delta < 1$, where $\phi = 1 + \frac{1}{\phi} = \frac{1+\sqrt{5}}{2} \approx 1.6$ is the golden ratio. The first difficulty in adapting our algorithms to this model is as follows. In the single link model there is a "current time" at which all calls in service require bandwidth and where the new call must start; thus all bandwidth conflicts are at the current time. In the line model, bandwidth conflicts upon the arrival of a new call are not limited to a single location; at some locations, it may seem beneficial to accept the incoming call, where at other locations it may seem beneficial to reject. It turns out that the following technique provides a sufficient solution for this difficulty in both adapted algorithms. Upon the arrival of a request, we first add the requested call to the list of calls in service. Next, we go over the links one by one, in an arbitrary order, and resolve remaining conflicts on each link by rejecting or preempting calls according to a scheme similar to the original one (where "time" is replaced by "location"). The ALR algorithm requires no further modifications. The AEFT algorithm encounters an additional difficulty, described below.

Let LR* be the same algorithm as LR, where time is translated to location.
Let F be the set of calls currently in service. Upon the request of a call c do:

1. Add c to F.
2. While there are links e with a conflict (i.e., $\tilde{B}_F(e) > \mathcal{B}$) do:
   Let e be a link with a conflict, and let $F_e \subseteq F$ be the set of calls currently in service that are using link e. Run algorithm LR* on the set of calls F_e.
   Remark: Clearly, after running LR* on F_e link e has no conflict. However, since the rejected/preempted calls may span other links, this may also resolve conflicts along other links as well.

FIG. 4.1. *Algorithm ALR.*

4.1. The ALR algorithm. The ALR algorithm is described in Figure 4.1.

THEOREM 4.1. *For $\delta < \frac{1}{2}$, algorithm ALR is $(\frac{1}{2} - \delta)$-competitive.*

Proof. The proof is similar to the proof of Theorem 3.1. Consider a link e with a conflict. Let $L_e \subseteq F_e$ and $R_e \subseteq F_e$ be the two sets of calls computed by LR* when run on F_e. Note that the total bandwidth required by the calls in $L_e \cup R_e$ is at most $\frac{\mathcal{B}}{2} + \frac{\mathcal{B}}{2} = \mathcal{B}$. Thus the algorithm is valid. Next we show competitiveness.

Consider an input sequence $S = c_1, \ldots, c_n$ of call requests and assume that $\delta = \max_i\{\frac{b_{c_i}}{\mathcal{B}}\}$ is at most $\frac{1}{2}$. Let $E \stackrel{\text{def}}{=} \text{LR}^*(S)$ be the set of calls completed by LR*. Let S_i be the prefix of S composed of the first i calls in S, and let E_i be the set of calls completed by the algorithm, assuming that the input sequence is only S_i. Below we show, by induction on i, that for all i and for all links e, $B_{E_i}(e) \geq \min\{B_{S_i}(e), (\frac{1}{2} - \delta)\mathcal{B}\}$. Since $S = S_n$ and $E = E_n$, we have $B_E(e) \geq (\frac{1}{2} - \delta)B_S(e)$ for all e. Thus the total throughput of the ALR algorithm, $V(E)$, is at least $(\frac{1}{2} - \delta)V(S)$. The theorem follows.

The inductive claim trivially holds for $i = 0$. For $i > 0$ we distinguish two cases. Fix some link e.

Case 1 (identical to the proof of Theorem 3.1). No call p that requested bandwidth for link e (i.e., $e \in [l_p \ldots r_p]$) was rejected or preempted in the ith step (that is, when processing the ith request). In this case, if the ith request, c_i, requests bandwidth for link e, then $B_{E_i}(e) - B_{E_{i-1}}(e) = b_c \geq B_{S_i}(e) - B_{S_{i-1}}(e)$. If c_i does not request bandwidth for link e, then $B_{S_i}(e) - B_{S_{i-1}}(e) = 0 = B_{E_i}(e) - B_{E_{i-1}}(e)$. Thus the inductive claim holds.

Case 2. There exist calls that requested bandwidth for link e and were rejected or preempted in the ith step. We show that in this case $B_{E_i}(e) \geq (\frac{1}{2} - \delta)\mathcal{B}$. Let $p_1, \ldots, p_a$ be the calls that were rejected or preempted in the ith step, sequenced by the order of their rejection or preemption. We prove, by induction on $1 \leq j \leq a$, that when p_j is either rejected or preempted, the total bandwidth of the calls in service on e is at least $(\frac{1}{2} - \delta)\mathcal{B}$. Suppose that this was the case before the rejection or preemption of p_j. If $e \notin [l_{p_j} \ldots r_{p_j}]$, then this is clearly the case also after the rejection or preemption of p_j. Otherwise, let e' be the link such that p_j was rejected or preempted while LR* was run on $F_{e'}$, and let $L_{e'}$ (resp., $R_{e'}$) be the set L (resp., R) found by LR* when operating on e'. Assume e is to the left of e' (i.e., $e \in [l_{p_j} \ldots e']$). All the calls in $L_{e'}$ include e since they start to the left of (or at) l_{p_j}. Since $p_j \notin L_{e'}$, and the bandwidth requested by p_j is at most $\delta\mathcal{B}$, $B_L(e')$ and thus also $B_L(e)$ must be no less than $(\frac{1}{2} - \delta)\mathcal{B}$. Similarly, if e is to the right of e' (i.e., $e \in [e' \ldots r_{p_j}]$), then $B_R(e')$ and thus also $B_R(e)$ must be no less than $(\frac{1}{2} - \delta)\mathcal{B}$.

Let F be the list of calls currently in service. Upon the request of a call c do:

1. Add c to F.
2. While there are links e with a conflict (i.e., $\tilde{B}_F(e) > \mathcal{B}$) do:
   Let e be a link with a conflict, and let $F_e \subseteq F$ be the list of calls using e, sorted so that if $a \succ b$ then a is ahead of b in the list.
   Reject/preempt calls from the end of F_e to fit in the link capacity.

FIG. 4.2. *Algorithm AEFT.*

4.2. The AEFT algorithm. The following difficulty is encountered in adapting the EFT method to the line model. The original EFT algorithm weighed past work and future work differently, relying on the fact that time is directional (i.e., the starting time of a new call is no earlier than the starting time of the calls in service). In the line model, past and future lose their meaning: the left endpoint of a new call is not necessarily "more to the right" than the left endpoints of the calls in service. Instead, the adapted algorithm will use "effective endpoints" both to the left and to the right, as follows. For a call c with left endpoint l_c, right endpoint r_c, and length $h_c = l_c - r_c$, let the *effective span* be the range $s_c = [l_c - g \cdot h_c \ldots r_c + g \cdot h_c]$, where g is some constant to be computed later. We define a complete order, denoted $\succ$, on the calls. For calls a and b, $a \succ b$ either if the effective span of a contains the effective span of b (i.e., $s_b \subset s_a$), or if the effective spans of a and b are not contained in each other and a is requested before b. Algorithm AEFT is described in Figure 4.2.

THEOREM 4.2. *For $\delta < 1$, Algorithm AEFT is $(\frac{1-\delta}{2m+1})$-competitive, where $m = \max\{g, 1 + \frac{1}{g}\}$, and g is the constant used for determining effective spans.*

COROLLARY 4.3. *Let $g = \phi$ be the golden ratio (that is, $\phi = 1 + \frac{1}{\phi}$ and $\phi = \frac{1+\sqrt{5}}{2} \approx 1.6$). For $\delta < 1$, algorithm AEFT is $\frac{1-\delta}{2\phi+1}$-competitive.*

Proof of Theorem 4.2. We follow the outline of the proof of Theorem 3.2. (We also use the notation of Theorem 3.2.) Let $m = \max\{g, 1 + \frac{1}{g}\}$. Define virtual calls as follows. The virtual call c' that corresponds to a call c has left endpoint $l_{c'} = l_c - m \cdot h_c$ and right endpoint $r_{c'} = r_c + m \cdot h_c$ and requires bandwidth $b_{c'} = \frac{1}{1-\delta} b_c$. Consider a sequence S of incoming requests and let $E \stackrel{\text{def}}{=} AEFT(S)$. Clearly, $V(E) \geq \frac{1-\delta}{2m+1} V(E')$. We show below that $B_{E'}(e) \geq B_S(e)$ for all links e. Consequently $V(E') \geq V(S)$, and the algorithm is $\frac{1-\delta}{2m+1}$-competitive.

We show, by induction on the number of calls in the input sequence, that $B_{E'}(e) \geq \mathcal{B}$ for each link e where a call requested bandwidth and was rejected or preempted. Similar to the proofs of Theorem 3.2 and Lemma 3.4, the inductive claim is shown by proving the following: (1) Whenever a call c is *rejected* (when considering a link e), its span is contained in the spans of all the virtual calls that correspond to the calls that remain in service and use link e. (The span of a call c is the range $[l_c \ldots r_c]$.) (2) Whenever a call c is *preempted* (when considering a link e), the links that are not quiet in the span of the virtual call c' are contained in the spans of virtual calls of bandwidth at least $\mathcal{B}$ that remain in service.

Case 1. Suppose that an incoming call c is rejected while considering some link e in step 2 of Algorithm AEFT (given in Figure 4.2). Here it suffices to show that $l_{f'} \leq l_c$ and $r_c \leq r_{f'}$ for all remaining calls $f \in F_e$. This clearly holds for all calls in F_e whose effective span contains the effective span of c. Consider a call f that remained in F_e whose effective span does not contain the effective span of c. Without

loss of generality assume that f is to the right of c (that is, $l_c < l_f < r_c < r_f$). Since c was rejected, we have $f \succ c$, thus the effective span of c does not contain the effective span of call f. Observe that $l_c - gh_c < l_f - gh_f$ (otherwise $r_f + gh_f \geq r_c + gh_c$, implying that the effective span of f contains the effective span of c). This implies that $r_c + gh_c \leq r_f + gh_f$, or

$$gh_c \leq r_f - r_c + gh_f. \tag{4.1}$$

By our assumption that $l_f < r_c$, we have $r_f - r_c < h_f$. Substituting this inequality in (4.1) we get $gh_c < (1+g)h_f$, or equivalently

$$h_c < \left(1 + \frac{1}{g}\right) h_f \leq mh_f.$$

Therefore, $l_{f'} = l_f - mh_f \leq l_f - h_c \leq l_c$, and $r_{f'} = r_f + mh_f \geq r_f + h_c \geq r_c$.

Case 2. Suppose that a call p is preempted when a call c is requested (and call c is accepted). We show that in this case $l_{c'} \leq l_{p'}$ and $r_{p'} \leq r_{c'}$. The proof that the spans of the virtual calls that correspond to the rest of the calls that remain in service contain the links that are not quiet in the span of call c' is the same as in Case 1. We have $c \succ p$, since call c is accepted. Since call c was requested after call p, the only way for the relation $c \succ p$ to hold is if the effective span of c contains the effective span of p; that is, $l_c - gh_c \leq l_p - gh_p$ and $r_c + gh_c \geq r_p + gh_p$ (and at least one of these inequalities is strict). Since $m \geq g$, then $l_{c'} \leq l_{p'}$ and $r_{p'} \leq r_{c'}$. ∎

5. Optimality of the algorithms. We prove impossibility results for the competitive ratio of any *deterministic* online bandwidth allocation algorithm *on a single link*, demonstrating that our algorithms achieve close to optimal competitiveness for all values of δ. First we show that if a single call requires the entire bandwidth (i.e., $\delta = 1$), then no algorithm can be more than $\frac{1}{\mathcal{B}}$-competitive. (Note that $\mathcal{B}$ may be unboundedly large.) Next we show that if $\delta \geq \frac{1}{2}$, then no algorithm can be more than $\min\{\frac{1}{8}, (1-\delta)\}$-competitive. In particular, if $\delta = \frac{1}{2}$, then no algorithm can be more than $\frac{1}{8}$-competitive. Recall that algorithm EFT is $\frac{1-\delta}{4}$-competitive; therefore for $\delta = \frac{1}{2}$ EFT is optimal, for $\frac{1}{2} < \delta \leq \frac{7}{8}$ it is at most a factor of $\frac{1}{2(1-\delta)}$ from optimality, and for $\frac{7}{8} \leq \delta < 1$ it is at most a factor of 4 from optimality. For $\frac{1}{3} < \delta < \frac{1}{2}$ the competitiveness of any algorithm is shown to be at most $\frac{1}{2}$, therefore our algorithm is at most a factor of $\frac{2}{1-\delta}$ from optimality. Finally, for $0 < \delta \leq \frac{1}{3}$ the competitiveness of any algorithm is shown to be at most $\frac{2}{3}$, therefore our algorithm is at most a factor of $\frac{4}{3(1-2\delta)}$ from optimality. We summarize our results for the different ranges in Table 5.1 and the graph in Figure 5.1.

We show the impossibility results by demonstrating, for any algorithm, an input sequence of call requests which forces any algorithm to perform poorly compared to the best (offline) schedule. We describe input sequences as if they may change "on the fly," depending on the choices of the algorithm so far. Such a description is valid since the behavior of a deterministic algorithm on any prefix of the input sequence can be thought of as known beforehand. We sometimes call the sequence creator the *adversary*.

This section is organized as follows. First, we describe the known impossibility results for the case in which calls always request the whole bandwidth. Next we prove our impossibility result for the case $\delta = 1$. Using the techniques of these two bounds we show the $\frac{1}{8}$ bound for the case $\frac{1}{2} \leq \delta < 1$. Next we prove the $1 - \delta$ bound for the case $\frac{1}{2} < \delta < 1$. We proceed for the case $0 \leq \delta < \frac{1}{2}$ and prove our bounds using the

TABLE 5.1
All bounds in the different ranges of $0 < \delta \leq 1$.

Range	Lower bound (algorithm)	Upper bound (impossibility result)	Optimality ratio $\left(\frac{\text{upper bound}}{\text{lower bound}}\right)$
$\delta = 1$	$\frac{1}{\mathcal{B}}$	$\frac{1}{\mathcal{B}}$	1
$\frac{7}{8} \leq \delta < 1$	$\frac{1-\delta}{4}$	$1 - \delta$	4
$\frac{1}{2} \leq \delta \leq \frac{7}{8}$	$\frac{1-\delta}{4}$	$\frac{1}{8}$	$\frac{1}{2(1-\delta)} \leq 4$

$\delta \to 0$	$\frac{1}{2}$	$\frac{2}{3}$	$\frac{4}{3}$

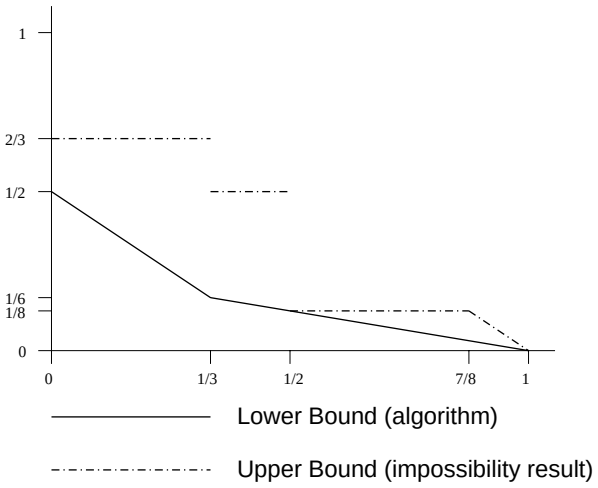

FIG. 5.1. *Graph of bounds in the different ranges of* $0 < \delta \leq 1$.

more restricted parallel links model (to be defined there). At the end of the section, we consider the more general case of calls with arbitrary durations on a general linear network. We show that any deterministic online algorithm for this case is at most $\frac{1}{\mathcal{B}}$-competitive, if $\delta > \frac{1}{2}$.

The whole bandwidth case. The sequence S is an adaptation of a sequence demonstrated in [13] to show that no algorithm can be more than $\frac{1}{4}$-competitive for the case where all calls require bandwidth *exactly* $\mathcal{B}$. (The sequence in [13] is an adaptation of a bound for scheduling algorithms in the presence of overload, shown in [6].) Let us review their construction. For any $\alpha > \frac{1}{4}$, construct a sequence $C = c_1, \ldots, c_n$ of calls where each call c_i arrives "just before call c_{i-1} ends" (i.e., $t_{c_i} = e_{c_{i-1}} - 1$, where $e_{c_i} \stackrel{\text{def}}{=} t_{c_i} + d_{c_i}$ is the ending time of c_i), and $d_{c_{i-1}} < \alpha e_{c_i}$ for all i, $d_{c_n} \leq d_{c_{n-1}}$. The offline algorithm is able to schedule calls that cover the entire duration $0 \leq t \leq e_i$, in a way described below. Since $d_{c_{i-1}} < \alpha e_{c_i}$ for all i, the online algorithm is always forced to preempt the single call in service (that is, c_{i-1}) when a new call arrives; otherwise it is not α-competitive since it covers only $d_{c_{i-1}}$ time units while the offline algorithm covers e_{c_i} time units. Thus the algorithm completes

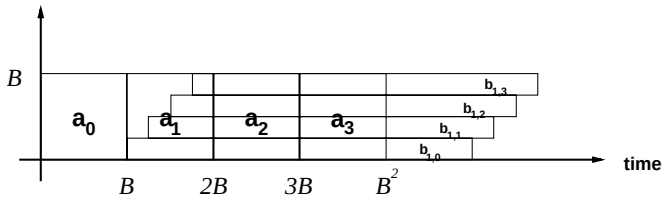

FIG. 5.2. *The impossibility result for the case* $\delta = 1$.

either only c_n or only c_{n-1} with value at most $d_{c_{n-1}}$, whereas the offline can cover the entire duration $0 \le t \le e_{c_n}$. Consequently, once the call c_n is requested the online algorithm can no longer be α-competitive. To complete the construction, set $d_{c_1} = \mathcal{B}$ and interleave the c_i calls with many additional service calls, each of duration 1. The service calls cannot be served by the online algorithm since once a service call is served the sequence stops and the algorithm is no longer competitive. The offline algorithm serves all service calls and accrues throughput e_{c_n}.

The case $\delta = 1$. We show that if $\delta = 1$, then for any online algorithm $\mathcal{A}$ there exists an input sequence S such that the throughput $V(A(S)) = \mathcal{B}^2$, whereas some feasible subsequence $S' \subseteq S$ has a gain $V(S') = \mathcal{B}^3$. Consequently, the competitiveness of $\mathcal{A}$ is at most $\frac{1}{\mathcal{B}}$. (See Figure 5.2.)

The sequence S consists of two types of calls: squares and slices. A square call has duration $\mathcal{B}$ time units and bandwidth $\mathcal{B}$. A slice call has duration $\mathcal{B}^2$ time units and bandwidth 1. Both have throughput $\mathcal{B}^2$. Observe that no algorithm can serve both a square and a slice call that intersect (that is, require bandwidth for the same time). The sequence S starts with a square call at time 0. The algorithm $\mathcal{A}$ must serve this call, otherwise it is 0-competitive. Next, the following procedure is repeated until S contains either $\mathcal{B}$ square calls or $\mathcal{B}$ slice calls:

(a) As long as $\mathcal{A}$ serves a square call, then at each time unit a slice call is requested.

(b) As long as $\mathcal{A}$ serves a slice call, then every $\mathcal{B}$ time units a square call is requested.

Analysis. At the end of the process A has completed at most one call, hence $V(A(S)) \le \mathcal{B}^2$. Conversely, a feasible $S' \subseteq S$ may contain $\mathcal{B}$ calls of the same type (either squares or slices) and be of value $V(S') = \mathcal{B} \cdot \mathcal{B}^2 = \mathcal{B}^3$.

The case $\delta = \frac{1}{2}$. Consider the sequence $C = c_1, \ldots, c_n$ as described above for a given $\alpha > \frac{1}{4}$. From now on we omit references to α and think of the sequence that is associated with $\alpha = \frac{1}{4} + \epsilon$, where ϵ is negligible. Rigorous proof follows in a straightforward way. Although we present the bound only for $\delta = \frac{1}{2}$, it will be clear from the presentation that the bound holds for any $\delta > \frac{1}{2}$.

The basic idea behind our proof is to force the algorithm to serve c_i with bandwidth $\frac{B}{2}$ while the offline can serve calls that cover the whole bandwidth until e_{i+1}. This will add an extra factor of 2 and therefore the $\frac{1}{8}$ bound.

In the sequence C, let the length of call c_i be γ_i and let its beginning time and ending time be τ_i and ϵ_i, respectively. Define a new call c_{n+1} with parameters $\tau_{n+1} = \tau_n$, $\gamma_{n+1} = \gamma_n$, and $\epsilon_{n+1} = \epsilon_n$, and choose $\mathcal{B} \gg n \cdot \epsilon_n$. We construct a sequence S that contains three types of calls. First, for each i there are two calls f_i with bandwidth $\frac{1}{2}\mathcal{B}$, arrival time $t_i = \mathcal{B}^3\tau_i$, ending time $e_i = \mathcal{B}^3\epsilon_i$, and duration $d_i = \mathcal{B}^3\gamma_i$. Next, there are many service calls of type a_i with duration $\mathcal{B}^3(2\epsilon_{i+1})$ and bandwidth 1 and many service calls of type b with duration $\mathcal{B}$ and bandwidth $\frac{1}{2}\mathcal{B}$.

The starting time of the service call would depend on the behavior of the algorithm, as explained later.

Recall that v_c is the throughput of call c. We get that $v_b = \frac{\mathcal{B}^2}{2}$, $v_{a_i} = \mathcal{B}^3(2\epsilon_{i+1}) = o(\mathcal{B}^4)$, and $v_{f_i} = \frac{1}{2}\mathcal{B}d_i = \frac{\mathcal{B}^4}{2}\gamma_i = O(\mathcal{B}^4)$. Note also that since $\epsilon_n \cdot n \ll \mathcal{B}$ it follows that $\sum_{j=1}^{n} v_{a_j} = o(\mathcal{B}^4)$. These equations, and the fact that

$$\frac{d_i}{e_{i+1}} = \frac{\gamma_i}{\epsilon_{i+1}} \to \frac{1}{4},$$

imply the following proposition.

PROPOSITION 5.1.

$$\frac{v_b + \sum_{j=1}^{i} v_{a_j}}{v_{f_i}} \ll \frac{1}{8}, \tag{5.1}$$

$$\frac{v_b + v_{f_i} + \sum_{j=1}^{i} v_{a_j}}{\mathcal{B}v_{a_i}} \le \frac{2v_{f_i} + \sum_{j=1}^{i} v_{a_j}}{\mathcal{B}v_{a_i}} = \frac{\gamma_i}{2\epsilon_{i+1}} + \frac{\sum_{j=1}^{i} v_{a_j}}{\mathcal{B}^4\epsilon_{i+1}} \to \frac{1}{8}, \tag{5.2}$$

$$\frac{v_{f_i} + \sum_{j=1}^{i+1} v_{a_j}}{\mathcal{B}e_{i+1}} = \frac{\gamma_i}{2\epsilon_{i+1}} + \frac{\sum_{j=1}^{i+1} v_{a_j}}{\mathcal{B}^4\epsilon_{i+1}} \to \frac{1}{8}. \tag{5.3}$$

Say that we are in the ith phase if the following three conditions hold.

Condition 1. The algorithm has not completed any calls of type b or f_j for $1 \le j < i$ before time t_i.

Condition 2. The algorithm serves one call of type f_i and possibly one call of type a_j for $1 \le j \le i$.

Condition 3. There exists a feasible subsequence $S' \subseteq S$, consisting only of calls of type b, that covers the entire bandwidth for times in $[0 \dots t_i]$.

The sequence S starts by requesting an f_1 call and an a_1 call, both at time 0. The algorithm must serve the f_1 call in order to be competitive. Hence, we are now in the first phase. We show below how to force the algorithm to reach the $(i+1)$st phase from the ith phase. The bound will follow once the nth phase is reached. At that stage, the gain of the online algorithm is at most $v_{f_n} + \sum_{j=1}^{n+1} v_{a_j} = v_{f_{n-1}} + \sum_{j=1}^{n+1} v_{a_j}$ while the gain of the offline is $\mathcal{B}e_n$. Equation (5.3) of Proposition 5.1 proves the $\frac{1}{8}$ bound.

Once in the ith phase, the $(i+1)$st phase is reached as follows.

1. At each time t, $t_i \le t \le e_i - \mathcal{B}$, request two calls of type b. In order to serve any of these calls, the algorithm has to preempt either the f_i call or the a_i call currently in service.
   (a) Suppose that the call f_i is preempted. In this case we stop. The algorithm serves a call of type b and calls of type a_j for $1 \le j \le i$, whereas the offline can serve an f_i call. The bound is yielded by (5.1).
   (b) Suppose that the call a_i is preempted. Request calls of type a_i at times $t+1, t+2, \dots$ until the algorithm preempts the f_i call, preempts the b type call, or rejects $\mathcal{B}$ calls of type a_i. The first case is the same as the previous case (a). In the second case we are back in the ith phase and we continue offering the calls of type b. In the third case we stop. The algorithm serves a call of type b, a call of type f_i, and some calls of type a_j for $1 \le j < i$, whereas the offline can serve $\mathcal{B}$ calls of type a_i. The bound is yielded by (5.2).

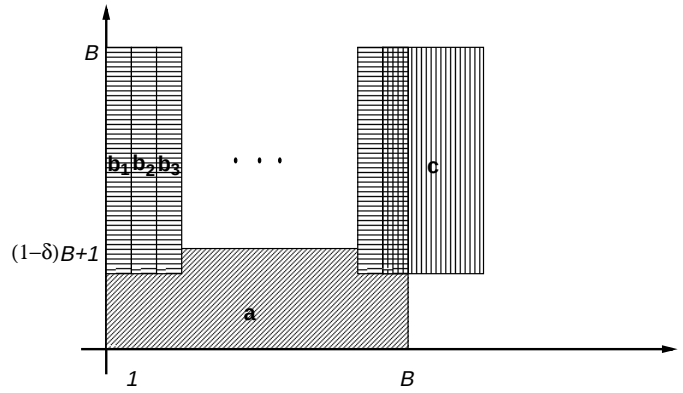

FIG. 5.3. *The impossibility result for the case* $\frac{1}{2} < \delta < 1$. *Here,* $\mathcal{B} = 12$ *and* $\delta = \frac{3}{4}$.

We thus assume that none of these b calls are served. Note that now there exists a feasible subsequence $S' \subseteq S$, consisting only of b calls, which covers the entire bandwidth for times in $[0 \dots e_i]$.

2. At time $e_i - \mathcal{B}$, when the f_i call is about to end, request two calls of type f_{i+1}. Now, the algorithm has several options.
   (a) The algorithm rejects both calls. In this case we stop. The offline can serve b type calls to cover the whole bandwidth up to t_{i+1} and the two f_{i+1} calls to cover the whole bandwidth up to e_{i+1}, whereas the algorithm can serve one f_i call and some a_j type calls for $1 \le j \le i$. The bound follows from (5.3).
   (b) The algorithm serves one of the f_{i+1} calls and preempts the f_i call. In this case we reached the $(i+1)$st phase.
   (c) The algorithm serves one of the f_{i+1} calls and preempts the a_i call. This means that at this stage, the algorithm serves a call of type f_i and a call of type f_{i+1}. In this case, request calls of type a_{i+1} at times $e_i - \mathcal{B}, e_i - \mathcal{B} + 1, \dots$ until the algorithm does one of the following: preempts the f_i call, preempts the f_{i+1} call, or rejects $\mathcal{B}$ calls of type a_{i+1}. In the first case we reach the $(i+1)$st phase. The second case is the same as the previous case (a) in which the algorithm rejects the two f_{i+1} calls. In the third case we stop. Since $v_{f_i} < v_{f_{i+1}}$ it follows that the throughput of the algorithm is at most $2v_{f_{i+1}} + \sum_{j=1}^{i} v_{a_j}$, whereas the throughput of the offline can be $\mathcal{B}v_{a_{i+1}}$. The bound is yielded by (5.2).
   (d) The algorithm serves both f_{i+1} calls. Again we request calls of type a_{i+1} at times $e_i - \mathcal{B}, e_i - \mathcal{B} + 1, \dots$ until the algorithm either preempts one of the f_{i+1} calls or rejects $\mathcal{B}$ calls of type a_{i+1}. Both cases appeared in the previous case (c).

The case $\frac{1}{2} < \delta < 1$. We show that in this case any online algorithm is at most $(1 - \delta + o(1))$-competitive. Note that for $\frac{1}{2} \le \delta \le \frac{7}{8}$ the previous bound (of $\frac{1}{8}$) is better. Consider the following request sequence to an online algorithm (see Figure 5.3):

1. Request a call a at time 0, with duration $\mathcal{B}$ time units and bandwidth $(1 - \delta)\mathcal{B} + 1$. If the algorithm does not serve this call, then end the sequence.
2. At each time $0 \le i < \mathcal{B}$ request a call b_i of duration 1 and bandwidth $\delta\mathcal{B}$. No b_i call can be served together with a. If the algorithm preempts a to serve one of the b_i calls, then end the sequence.

3. Request a call c at time $\mathcal{B}-1$ with duration $1+\frac{1-\delta}{\delta}\mathcal{B}$ and bandwidth $\delta\mathcal{B}$.

Analysis. Note that the value of a is $(1-\delta)\mathcal{B}^2+\mathcal{B}$, the value of c is $(1-\delta)\mathcal{B}^2+\delta\mathcal{B}$, and the value of any b_i is $\delta\mathcal{B}$. Assume call a is served (otherwise the algorithm is 0-competitive). If the algorithm preempts a to serve some b_i, then the algorithm is at most $\frac{\delta\mathcal{B}}{(1-\delta)\mathcal{B}^2+\mathcal{B}} = O\left(\frac{1}{\mathcal{B}}\right)$-competitive. Therefore, we can assume that all the b_i calls are rejected. Calls a and c both cannot be served. Thus, the value gained by the algorithm (by serving either a or c) is at most $(1-\delta)\mathcal{B}^2+\mathcal{B}$. The subsequence $S' = \{b_0, \ldots, b_{\mathcal{B}-2}, c\}$ is feasible with $V(S') = \mathcal{B}^2$. Hence, the competitive ratio of the algorithm is at most $\frac{(1-\delta)\mathcal{B}^2+\mathcal{B}}{\mathcal{B}^2} = (1-\delta)+o(1)$.

The case $\delta < \frac{1}{2}$. We show that for $\frac{1}{3} < \delta < \frac{1}{2}$ no algorithm can be more than $\frac{1}{2}$-competitive and that for $0 < \delta \le \frac{1}{3}$ no algorithm can be more than $\frac{2}{3}$-competitive. This impossibility result is shown for the parallel links model. In this model, the bandwidth of all calls is exactly $\frac{\mathcal{B}}{k}$ for some integer $k > 1$. This can be viewed as if the two stations are connected via k parallel links, and each call occupies exactly one link for its duration. (For convenience we assume that calls can be transferred between links during service at no cost.) Clearly, this model is a special case of our single link model.

Let r_k be an upper bound on the competitiveness of any online algorithm in the parallel links model. We show that in the single link model no online algorithm can be more than r_k competitive, in case a call may request at most $\delta\mathcal{B}$ bandwidth, for $\delta > \frac{1}{k+1}$. Consider any online algorithm $\mathcal{A}$ for the single link model. Let $\mathcal{A}'$ be the algorithm for the k parallel links model that corresponds to algorithm $\mathcal{A}$. Let $c_1, c_2, \ldots$ be a sequence of calls that causes $\mathcal{A}'$ to be at most r_k competitive in the k parallel links model. We claim that this sequence in which the bandwidth of each c_i is $\delta\mathcal{B}$ also causes $\mathcal{A}$ to be at most r_k competitive in the single link model. To see this, note that since $\delta > \frac{1}{k+1}$ it follows that there cannot be $k+1$ calls that are served concurrently. Therefore, at any point in time, the calls in service can be viewed as arranged on k parallel links such that the width of each link is $\delta\mathcal{B}$.

It remains to bound r_k. We remark that there exist algorithms for the parallel links model that have slightly better competitiveness than our algorithms for the single link model. Algorithms for $k = 1$ and $k = 2$ were previously known [13, 6]. A simple extension of them yields algorithms for even k with a competitive ratio of $\frac{1}{2}$ and for odd k with competitive ratio $\frac{1}{2} - \frac{1}{4k}$.

We first describe a simple impossibility result for $k = 2$ (the case $k = 1$ was dealt with in [13], as outlined above). At time 0, request two calls of length x. If the algorithm serves only one call, then we are done. At every time unit $0 \le i \le x-1$, request two service calls of length 1. If the algorithm takes one of these service calls it must preempt one of the original calls. In this case, the sequence ends and the algorithm achieves competitiveness of $\frac{x+1}{2x} = \frac{1}{2}+o(1)$. Otherwise, at time $x-1$ request two new requests of length x. In this case the competitiveness is $\frac{2x}{4x-2} = \frac{1}{2}+o(1)$. For the cases $k = 3$ and $k = 4$ we have an impossibility result of $\frac{1}{2}$ and $\frac{11}{20}$, respectively. However, the proofs are tedious and are omitted.

We now describe the impossibility result for the competitiveness of any bandwidth allocation algorithm in this model for all $k > 1$. We show by induction on k that the competitive ratio for k links is at most r, where r satisfies $e^r = \frac{r}{1-r}$, in particular $r \le \frac{2}{3}$.

The basic strategy is an extension of the strategy for the two lines case. At time 0, request k calls of length x and at time $x-1$ request another set of k calls of length

x. We refer to these calls as *long* calls. During the times $[0 \dots x-1]$ many service calls (*short* calls) will be offered in a way that the offline algorithm will be able to cover this range and therefore will have a throughput of $(2x-1)k$. We will choose $x \gg 1$ and therefore, without loss of generality, assume that the throughput of the offline is $2xk$. We do not know how to prevent the algorithm from serving all the service calls and thus to achieve a $\frac{1}{2}$ bound. In what follows we describe how to prevent the algorithm from serving some of the service calls to achieve the $\frac{2}{3}$ bound.

A general scenario of the execution of the online algorithm is as follows. The online algorithm starts by serving $w \leq k$ out of the k long calls requested at time 0 (and all the short calls that can be served). In case the adversary does not stop the request sequence, after t_1 units of time the online algorithm preempts one of the w calls to serve a service call. Again, in case the adversary does not stop the request sequence, after an additional t_2 units of time it preempts another long call and so on, for $w-z$ times. Note that by definition of $t_1, \dots, t_{w-z}$ we must have that $\sum_{j=1}^{w-z} t_j \leq x$.

At time $x-1$ the online algorithm remains with z long calls. In case the adversary does not stop the request sequence, k long calls are requested at this time. In this case the throughput of the online algorithm will be xk plus the sum of the lengths of all the service calls it served before time $x-1$.

Assume first a very simple strategy for the adversary. The sequence will have only two types of calls: long calls of length x and short calls of unit length. Assume further that the algorithm is r-competitive. Then the following inequalities must hold:

$$\begin{aligned}
\frac{xw}{xk} &\geq r && (0),\\
\frac{t_1(k-w)+x(w-1)}{xk} &\geq r && (1),\\
\frac{t_1(k-w)+t_2(k-w+1)+x(w-2)}{xk} &\geq r && (2),\\
&\vdots\\
\frac{\sum_{j=1}^{i} t_j(k-w+j-1)+x(w-i)}{xk} &\geq r && (i),\\
&\vdots\\
\frac{\sum_{j=1}^{w-z} t_j(k-w+j-1)+xz}{xk} &\geq r && (w-z),\\
\frac{\sum_{j=1}^{w-z} t_j(k-w+j-1)+xk}{2xk} &\geq r && (k).
\end{aligned}$$

Inequality (0) is true since otherwise the adversary could stop immediately after presenting the k long calls and thus preventing the algorithm from being r competitive. The rest of the inequalities are true since otherwise the adversary could stop after the jth preemption of a long call by the algorithm.

The value of r is maximized when all the inequalities become equalities. Note that although this solution may not correspond to a valid adversary strategy (in case it does not obey the integrality constraints) it can still be used to upper bound the

competitiveness. By comparing the $(j-1)$th equality with the jth equality we get that for $1 \le j \le w-z$

$$t_j(k-w+j-1) = x \ .$$

Thus equality (k) is equivalent to

$$\frac{w-z+k}{2k} = r \ .$$

The above equality together with equality (0) implies that

$$w+z = k \ .$$

In addition, plugging the value of t_j in the equality $\sum_{j=1}^{w-z} t_j = x$ we have

$$\sum_{j=1}^{w-z} \frac{x}{k-w+j-1} = x \ .$$

This is equivalent to

$$\frac{1}{k-w} + \frac{1}{k-w+1} + \cdots + \frac{1}{k-z-1} = 1 \ .$$

Using the estimation $\sum_{j=1}^{n} \frac{1}{j} = \ln n + O(1)$, we get that $\sum_{j=m}^{n} \frac{1}{j} > \sum_{j=m+1}^{n+1} \frac{1}{j} \approx \ln\left(\frac{n+1}{m}\right)$. Substituting $n = k-z-1$ and $m = k-w$, it follows that

$$\ln\left(\frac{k-z}{k-w}\right) < 1 \ .$$

This implies that $\frac{k-z}{k-w} < e$. Since $w = k-z$ we get that $\frac{w}{k-w} < e$, and since $w = kr$ we get that $\frac{r}{1-r} < e$, which is equivalent to

$$r < \frac{e}{1+e} \approx 0.731059 < \frac{3}{4} \ .$$

Now, assume a more complicated strategy for the adversary. Note that in the simple strategy the adversary does not try to minimize the number of service calls served by the online algorithm; that is, whenever the online algorithm has a "free" line it can use the line to serve service calls. In the more complicated strategy the adversary tries also to minimize the number of service calls served by the online algorithm. This is done by using the strategy "recursively." Whenever the algorithm is serving j long calls and has $k-j$ free lines (for $w \le j \le z$), the adversary offers service calls according to the strategy for $k-j$ parallel links. Namely, instead of offering service calls of a fixed size, the service calls become the long calls for $k-j$ parallel links, while scaling down the length of the service calls for the $k-j$ lines accordingly. Furthermore, we assume by induction that the bound r can be achieved for any number of lines less than k. We have already seen that the inductive claim holds for $k = 2$.

The analysis is almost the same as the one for the simpler adversary. Here, we add a factor of r in the inequalities as follows:

$$\frac{\sum_{j=1}^{i} t_j(k-w+j-1)r + x(w-i)}{xk} \ge r \ .$$

Again, the value of r is maximized when all the inequalities become equalities. This implies that

$$t_j(k-w+j-1)r = x,$$

which as before yields the equality

$$w + z = k\ .$$

In addition, we get that

$$\frac{1}{k-w} + \frac{1}{k-w+1} + \cdots + \frac{1}{k-z-1} = r$$

and therefore

$$\ln\left(\frac{k-z}{k-w}\right) < r\ .$$

Using arguments as before, we get that

$$r < \frac{e^r}{1+e^r}\ .$$

This inequality does not hold for $r > 0.66$. Hence, we proved that

$$r < \frac{2}{3}\ .$$

Line networks with arbitrary durations. Finally, we consider networks with a line topology in which the calls have arbitrary duration (rather than unit time duration). In this case the throughput of a call is the product of its length, bandwidth, and duration. Suppose that the line consists of $n+1$ stations, all the links have the same bandwidth $\mathcal{B}$, and the maximum allowable bandwidth of a single call is $\delta\mathcal{B}$, for $\delta > \frac{1}{2}$. We show that any deterministic online algorithm for this model is at most $1/n$-competitive. The sequence and the analysis are as in the case of the single link model with $\delta = 1$, where instead of bandwidth $\mathcal{B}$ we consider a line of nodes $0, \ldots, n$. Specifically, we simulate the procedure of the adversary presented in the impossibility result for the single link model with $\delta = 1$. In the simulation, whenever a square call a_i is requested in the procedure for the single link model with $\delta = 1$, the adversary here requests a square call of bandwidth $\delta\mathcal{B}$ at time in that connects nodes 0 and n, for n time units. Note that the throughput of this call is $n^2\delta\mathcal{B}$. Similarly, instead of requesting the jth slice call b that intersects the square call a_i as described in the impossibility result for the single link model with $\delta = 1$, the request made here is for a call at time $in + j$ that connects nodes j and $j+1$ for n^2 time units. Again, the throughput of this call is also $n^2\delta\mathcal{B}$. Since $\delta > \frac{1}{2}$, a square call and a slice call that intersect cannot both be served. Thus, following the analysis for the single link case with $\delta = 1$ we get the $1/n$ upper bound.

Acknowledgment. We are indebted to Hugo Krawczyk for very helpful discussions at the early stages of this work.

AN OPTICAL SIMULATION OF SHARED MEMORY*

LESLIE ANN GOLDBERG†, YOSSI MATIAS‡, AND SATISH RAO§

Abstract. We present a work-optimal randomized algorithm for simulating a shared memory machine (PRAM) on an optical communication parallel computer (OCPC). The OCPC model is motivated by the potential of optical communication for parallel computation. The memory of an OCPC is divided into modules, one module per processor. Each memory module only services a request on a timestep if it receives exactly one memory request.

Our algorithm simulates each step of an $n \lg \lg n$-processor EREW PRAM on an n-processor OCPC in $O(\lg \lg n)$ expected delay. (The probability that the delay is longer than this is at most $n^{-\alpha}$ for any constant α.) The best previous simulation, due to Valiant, required $\Theta(\lg n)$ expected delay.

Key words. PRAM, PRAM simulation, optical networks

1. Introduction.

The huge bandwidth of the optical medium makes it possible to use optics to build communication networks of very high degree. Eshaghian [8, 9] first studied the computational aspects of parallel architectures with complete optical interconnection networks. The OCPC model is an abstract model of computation which formalizes important properties of such architectures. It was first introduced by Anderson and Miller [2] and Eshaghian and Kumar [10]. In an n-processor *completely connected optical communication parallel computer* (n-OCPC) n processors with local memory are connected by a complete network. A computation on this computer consists of a sequence of communication steps. During each communication step each processor can perform some local computation and then send one message to any other processor. If a processor is sent a single message during a communication step, then it receives this message successfully, but if it is sent more than one message, then the transmissions are garbled and it receives none of them.

While the OCPC seems a reasonable model for optical computers, it has not been used as a programming model to date. The PRAM model, however, has been used extensively for parallel algorithmic design (e.g., [19, 22, 34]). The convenience of programming on the PRAM is largely due to the fact that the programmer does not have to specify interprocessor communication or to allocate storage in a distributed memory. For the very same reason, the PRAM is considered highly theoretical, and the task of emulating the PRAM on more realistic models has attracted considerable attention; emulations may enable automatic mapping of PRAM algorithms to weaker models, as well as a better understanding of the relative power of different models.

Indeed, many emulations of the PRAM on bounded degree networks were introduced (see, e.g., [1, 21, 23, 31, 32, 36, 37] or [24] for a survey).

In this paper, we present a simulation of an EREW PRAM on the OCPC. In particular, we present a randomized simulation of an $n \lg \lg n$-processor EREW PRAM on an n-processor OCPC in which, with high probability, each step of the PRAM requires $O(\lg \lg n)$ steps on the OCPC.[1] Our simulation is work optimal, to within a constant factor.

Our results are closely related to previous work on the well-studied *distributed memory machine* (DMM), which consists of n processors and n memory modules connected via a complete network of communication. Each processor can access any module in constant time, and each module can service at most one memory request (read or write) at any time. The DMM is thus a weaker model than the shared memory PRAM in that the memory address space is partitioned into modules with a restricted access imposed on them. We remark that there are several variants of DMM models that differ in their contention rules.

Several papers have studied the emulation of a PRAM on various DMM models [31, 21, 38, 35, 6, 20, 7]. Karp, Luby, and Meyer auf der Heide [20] present $O(\lg \lg n)$ expected delay simulations of various types of PRAM on a CRCW DMM in which each memory module allows concurrent read or write access to at most one of its memory locations during any step. Dietzfelbinger and Meyer auf der Heide [7] improve upon this paper by presenting an $O(\lg \lg n)$ expected delay simulation of an EREW PRAM on the (weaker) c-collision DMM in which any memory module that receives c or fewer read or write requests serves all of them. Although Dietzfelbinger and Meyer auf der Heide require $c \geq 3$ for their analysis to work, they report that experiments show that $c = 2$ works as well. The 1-collision DMM is equivalent to the OCPC.

Our result improves on the result of [7] in two ways. First, it is work-optimal. Second, it works for the OCPC (or 1-collision DMM). The previous best-known work-optimal simulation of a PRAM on the OCPC is an $O(\lg n)$ delay simulation of Valiant [39]. In addition, unlike [39, 7] we explicitly consider the construction and evaluation of the hash functions used in our simulation algorithm.

1.1. Related work.

1.1.1. The OCPC model. The OCPC model was first introduced by Anderson and Miller [2] and Eshaghian and Kumar [10] and has been studied by Valiant [39], Geréb-Graus and Tsantilas [12], Gerbessiotis and Valiant [11], Rao [33], Goldberg et al. [17], and Goldberg, Jerrum, and MacKenzie [18]. The feasibility of the OCPC from an engineering point of view is discussed in [2, 12]. See also the survey paper of McColl [30] and the references therein.

1.1.2. Computing *h*-relation on the OCPC. A fundamental problem that deals with contention resolution on the OCPC is that of realizing an *h-relation*. In this problem, each processor has at most h messages to send and at most h messages to receive. Following Anderson and Miller [2], Valiant [39], and Geréb-Graus and Tsantilas [12], Goldberg et al. [17] solved the problem in time $O(h + \lg \lg n)$ for an n-processor OCPC. A lower bound of $\Omega(\sqrt{\lg \lg n})$ expected time was recently obtained by Goldberg, Jerrum, and MacKenzie [18].

1.1.3. Simulating PRAMs on OCPCs. Valiant described a simulation of an EREW PRAM on an OCPC in [39]. More specifically, Valiant gave a constant delay

[1] We will refer to the time required to simulate one PRAM step as the *delay* of the simulation.

simulation of a bulk synchronous parallel (BSP) computer on the OCPC (there called the S*PRAM), and also gave an $O(\lg n)$ randomized simulation of an $n \lg n$-processor EREW PRAM on an n-processor BSP computer. A simpler simulation with delay $O(\lg n \lg\lg n)$ was given by Geréb-Graus and Tsantilas [12]. Valiant's result is the best previously known simulation of a PRAM on the OCPC.

Independently of our work, MacKenzie, Plaxton, and Rajaraman [28] and Meyer auf der Heide, Scheideler, and Stemann [27] have shown how to simulate an n-processor EREW PRAM on an n-processor OCPC. Both simulations have $\Theta(\lg\lg n)$ expected delay. However, neither simulation is work-optimal, and both simulations require $n^{\Omega(1)}$ storage at each processor.

1.1.4. Simulating PRAMs on DMMs. Mehlhorn and Vishkin [31] used a $(\lg n/\lg\lg n)$-universal class of hash functions to achieve a simple simulation of a CRCW PRAM on a CRCW DMM with expected delay $O(\lg n/\lg\lg n)$. An n-processor CRCW PRAM can be simulated on an n-processor EREW DMM in $O(\lg n)$ expected delay using techniques from [39]. The work of this simulation is thus a $\Theta(\lg n)$ factor away from optimality. The best work-optimal simulation of a PRAM on an EREW DMM has delay $O(n^{\epsilon})$ [23].

Recently, Karp, Luby, and Meyer auf der Heide [20] presented a simulation of an n-processor CRCW PRAM on an n-processor CRCW DMM with $O(\lg\lg n)$ delay. They also presented a work-optimal simulation of an $(n \lg\lg n \lg^* n)$-processor EREW PRAM on an n-processor CRCW DMM in $O(\lg\lg n \lg^* n)$ expected delay and a nearly work-optimal simulation of an $n \lg\lg n$-processor CRCW PRAM on an n-processor CRCW DMM with the same delay. Subsequently, Dietzfelbinger and Meyer auf der Heide [7] presented a simplified (nonoptimal) simulation of an n-processor EREW PRAM on an n-processor DMM with $O(\lg\lg n)$ expected delay. The simulation in [20] introduces a powerful technique that incorporates the use of two or three hash functions to map the memory address space into the memory modules, combined with the use of a CRCW PRAM algorithm for perfect hashing (see [16] and references therein). It heavily uses the concurrent read capability of the CRCW DMM. The simulation in [7] circumvents the need for using the CRCW PRAM perfect hashing by an elegant use of an idea from Upfal and Wigderson [38].

1.2. Overview of the algorithm. Our simulation algorithm incorporates techniques and ideas from the simulation algorithms of [20, 7], as well as from the h-relation routing algorithm of [17], as follows.

The simulation in [7] uses three hash functions to map each memory cell of the EREW PRAM to three processors (and memory cells) in the DMM. A write on an EREW memory cell is implemented by writing a value and a time stamp to at least two out of the three associated DMM memory cells. A read of an EREW memory cell is implemented by reading two out of three of the memory cells and choosing the value with the most recent time stamp. Dietzfelbinger and Meyer auf der Heide's proof that their simulation requires only $O(\lg\lg n)$ delay on a 3-collision DMM relies on the fact that, given a randomly generated tripartite hypergraph on $3n$ nodes with ϵn edges, one can, with high probability, remove all the nodes in the hypergraph by using the following process.

Repeat $O(\lg\lg n)$ times:

1. Remove all of the nodes with degree at most 3.
2. Remove all resulting trivial hyperedges (hyperedges in which only one incident node remains.)

Each hyperedge corresponds to a read or write of a PRAM memory location: the three vertices correspond to the three processors in the DMM associated with that memory location. Thus, one step of an ϵn node EREW PRAM is implemented by using the process above to deliver at least two out of three of the messages associated with each memory request.

Since we are simulating an $n \lg\lg n$-processor PRAM on an n-node OCPC, we must simultaneously implement the process above for $O(\lg\lg n)$ $3n$-node hypergraphs using only n processors. To do this, we start by sparsifying all of the hypergraphs using ideas from the $(\lg\lg n)$-relation routing algorithm in [17]. That is, we route all but $O(n/\lg^c n)$ messages and we ensure that at most one undelivered message remains at any processor. Even so, implementing the process above in parallel could still require $\Omega(\lg\lg n)$ timesteps per iteration since each destination may participate in as many as $(\lg\lg n/\epsilon)$ different hypergraphs. Thus, we must also "copy" each destination in such a manner that each message can locate the appropriate copy of its destination. We then perform the process in each hypergraph, ensuring that the process delivers at most a constant number of messages to each copy of a destination. After that, the messages can be sequentially forwarded to their true destinations in $O(\lg\lg n)$ time.

We remark that, in fact, we cannot directly perform the process above on any of the $O(\lg\lg n)$ hypergraphs since our processors can only receive one message in a timestep whereas the processors in [7] can receive three messages in a timestep. The details of our solution to this problem can be found in the technical sections.

1.3. Paper outline. We proceed in section 2 with a high-level description of our simulation. In section 3, we present our algorithm in detail and prove correctness. In section 4 we deal with the evaluation of the hash function that maps the virtual shared memory to the memory modules.

2. The simulation. Our objective is to show how to simulate one step of an $n \lg\lg n$ processor EREW PRAM in $O(\lg\lg n)$ timesteps on an n-processor OCPC. Our simulation follows [7] in using the following idea from [38]. The memory of the PRAM is hashed using three hash functions, h_1, h_2, and h_3. Thus, each memory cell of the PRAM is stored in three memory cells of the OCPC. To write memory cell x, a processor of the OCPC sends a message to at least two of the processors in $\{h_1(x), h_2(x), h_3(x)\}$. The message contains the new value for cell x and also a time stamp. To read memory cell x, a processor p of the OCPC sends a message to at least two of the processors in $\{h_1(x), h_2(x), h_3(x)\}$. Each of these two processors sends p the value that it has for cell x and also its time stamp for cell x. Processor p uses the value with the later timestep. The hash functions h_1, h_2, and h_3 are chosen from the "highly" universal family $\overline{R}^{d,j}_{m,n}$ from [20], which guarantees randomlike behavior.

Each OCPC processor will simulate $\lg\lg n$ PRAM processors. Thus, at the start of a PRAM step, each of the OCPC processors will wish to access up to $\lg\lg n$ cells of the PRAM memory. Each processor uses h_1, h_2, and h_3 to obtain the three destinations where each memory cell is stored. Thus, each OCPC processor wants to send messages to up to $3\lg\lg n$ destinations. Our objective is to deliver at least two of the messages associated with every request.

As in [17], we will divide the processors of the OCPC into target groups of size $k = \lg^c n$. We will also divide the $n \lg\lg n$ memory requests into $\lg\lg n/\epsilon$ groups of ϵn requests each for a sufficiently small constant ϵ. We will refer to the set of messages associated with a particular group of memory requests as a "group of messages." The messages will be delivered using the following procedures:

- *Thinning and deliver to target groups.* Initially, the number of messages destined for any given target group may be as high as $4k \lg\lg n$. (We will show that, with high probability, it is no larger than this.) We will use techniques from [17] to route the messages to their target groups. With high probability, when this procedure is finished every message will be in the target group of its destination. Furthermore, each processor will have at most one message left to send. For a sufficiently large constant c_2, we will allocate a contiguous block of c_2 processors from the target group to each unfinished message for that destination. All senders will know which processors are allocated for their destination. For a sufficiently large constant c_1, we will ensure that for any of the $\lg\lg n/\epsilon$ groups of ϵn messages, with high probability, all but $O(n/(\lg n)^{c_1})$ of the messages in the group will be delivered to their final destinations.
- *Divide into subproblems and duplicate.* We now divide the OCPC into $\lg\lg n/\epsilon$ sub-OCPCs, each with $n' = n\epsilon/\lg\lg n$ processors. Each sub-OCPC will work on the subproblem of delivering the messages corresponding to a particular group of messages. For each sub-OCPC we now make $\lg^2 n'$ copies of the relevant subproblem, all of which will reside in its processors $1, \ldots, n'/2$. We will also allocate its processors $n'/2 + 1, \ldots, n'$ as follows. For each outstanding memory request (i.e., for each memory request which has the property that at most one of its three messages was delivered during the previous procedure), we will allocate $\lg^2 n'$ processors. These $\lg^2 n'$ processors will do the bookkeeping concerning the request in the $\lg^2 n'$ copies of the subproblem. Each message will know the identity of the processors responsible for the bookkeeping concerning its memory request.
- *Route messages for each subproblem.* In each copy of each subproblem we route messages according to the c_2-collision access schedule from section 3 of [7]. Dietzfelbinger and Meyer auf der Heide prove that with high probability each subproblem is "good" (this term will be defined later on). We will prove that if a subproblem is good, then for any particular memory request in any particular copy of the subproblem, the probability that the memory request is satisfied in the c_2-collision access schedule routing is at least $1/2$. Also, no destination in any copy of any subproblem receives more than a constant number $(3c_2)$ of messages during the c_2-collision access schedule routing.
- *Combining problem copies and combining subproblems.* In this procedure we identify a subset S of the set of messages that were delivered by the various copies of the c_2-collision access schedule routing procedure. The messages in S are chosen in such a way that every processor is the destination of $O(\lg\lg n)$ messages in S. We show that with high probability every memory request in every subproblem that was created in the "divide into subproblems and duplicate" procedure will be satisfied if the messages in S are delivered. We deliver the messages in S, using the routing algorithm in [17].

3. Simulation details and analysis. Before giving the details and analysis, we define the class of hash functions $\overline{R}^{d,j}_{m,n}$ being used and describe its properties that are used in the analysis. In the subsequent subsections we will give the details of each of the procedures described in the previous section.

3.1. The hash functions. The class $\overline{R}^{d,j}_{m,n}$ is taken from [20] and is defined as follows.

DEFINITION OF $\overline{R}^{d,j}_{m,n}$. *A function from* $\overline{R}^{d,j}_{m,n}$ *is a combination of functions taken from several classes. Carter and Wegman* [4] *introduced* $H^d_{m,n} \subseteq \{g : [1,\ldots,m] \to [1,\ldots,n]\}$, *the class of universal functions* $P(x) \bmod n$, *where* P *is a polynomial of degree* $d-1$ *over* $[1,\ldots,m]$. *Siegel* [35] *introduced a class of functions* $\overline{H}_{n^j,n} \subseteq \{h : [1,\ldots,n^j] \to [1,\ldots,n]\}$. (*More details on this class are given in section* 4.1.) *To choose a random hash function* $h : [1,\ldots,m] \to [1,\ldots,n]$ *from* $\overline{R}^{d,j}_{m,n}$, *one first chooses*

- *a function* f, *chosen uniformly at random from* $H^d_{m,\sqrt{n}}$;
- *a function* r, *chosen uniformly at random from* $\overline{H}_{n^j,n}$;
- *a function* s, *chosen uniformly at random from* H^1_{m,n^j};
- $\sqrt{n}$ *integers* $a_1,\ldots,a_{\sqrt{n}}$, *each chosen uniformly at random from the range* $[1,\ldots,n]$.

The function h *is defined by* $h(x) = (r(s(x)) + a_{f(x)}) \bmod n$.

As in [20], we say that a family $H_{p,n}$ of hash functions is (μ,k)-universal if for each $x_1 < \cdots < x_j \in \{1,\ldots,p\}$, $\ell_1,\ldots,\ell_j \in \{1,\ldots,n\}$, $j \le k$, the following holds: If the hash function h is drawn uniformly at random from $H_{p,n}$, then $\Pr[h(x_1) = \ell_1,\ldots,h(x_j) = \ell_j] \le \mu/n^j$.

Let ℓ be an arbitrary constant and let j and d be large enough relative to ℓ. Let ϵ' be a sufficiently small positive constant. We will use the following properties of the hash functions with respect to a set $S \subseteq [1,\ldots,m]$, $n \le |S| \le n^{11/10}$. The first two properties are proven in [20].

PROPERTY 3.1. *Let* $\overline{R}^{d,j}_{m,n}(s)$ *be the restriction of* $\overline{R}^{d,j}_{m,n}$ *induced by fixing* $s \in H^1_{m,n^j}$. *If* s *is chosen uniformly at random from* H^1_{m,n^j}, *then* s *is "*1*-perfect" on* S, *with probability at least* $1 - n^{-\ell}$. *If* s *is "*1*-perfect" on* S, *then* $\overline{R}^{d,j}_{m,n}(s)$ *is* $(2, n^{\epsilon'})$*-universal. (Hence,* $\overline{R}^{d,j}_{m,n}(s)$ *is* $(2, n^{\epsilon'})$*-universal with probability at least* $1 - n^{-\ell}$.*)*

Remark. Karp, Luby, and Meyer auf der Heide actually prove a stronger version of Property 3.1, which states that $\overline{R}^{d,j}_{m,n}(s)$ is $(1,\sqrt{n})$-universal with probability at least $1 - n^{-\ell}$. We use the weaker version because (in section 4.1) we will use the space-efficient implementation of the class $\overline{H}_{n^j,n}$ from [35], which is $(2, n^{\epsilon'})$-universal (in fact, it is $((1+o(1)), n^{\epsilon'})$-universal) but is not necessarily $(1,\sqrt{n})$-universal (see Section 2 of [35]). Thus, with the space-efficient implementation, we get only the weaker version of Property 3.1.

PROPERTY 3.2. *Let* f *be drawn randomly from* $H^d_{m,\sqrt{n}}$. *Then with probability at least* $1 - n^{-\ell}$ *every set* $f^{-1}(i) \cap S$ *has size at most* $2|S|/\sqrt{n}$.

We can now derive the third property.

PROPERTY 3.3. *Let* Z *be a subset of* $[1,\ldots,n]$ *and let* i *be an integer in* $[1,\ldots,\sqrt{n}]$. *Suppose that* $\beta \le n^{\epsilon'}$. *Let* h *be chosen randomly from* $\overline{R}^{d,j}_{m,n}$. *(That is, let* f, r, s, *and* $a_1,\ldots,a_{\sqrt{n}}$ *be chosen as described above.) The probability that* β *or more members of* $S \cap f^{-1}(i)$ *are mapped to* Z *by* h *is at most* $2n^{-\ell} + \binom{2|S|/\sqrt{n}}{\beta} 2\left(\frac{|Z|}{n}\right)^{\beta}$.

Proof. By Property 3.2, with probability at least $1 - n^{-\ell}$ every set $f^{-1}(i) \cap S$ has size at most $2|S|/\sqrt{n}$. By Property 3.1, with probability at least $1 - n^{-\ell}$, the hash destinations are $(2, n^{\epsilon'})$-universal. ∎

3.2. Thinning and deliver to target groups. We start by running the "thinning" procedure from [17], which is based on the algorithm of Anderson and Miller [2]. The procedure runs for $O(\lg\lg n)$ steps. During each step each sender chooses a

message uniformly at random from the set of messages that it has not yet sent successfully, and it sends the message to its destination with a certain probability. Let $h = 32e \lg \lg n$. We prove further below the following lemma.

LEMMA 3.1. *With probability at least* $1 - 2n^{-\alpha}$ *(for any constant* α*), after the thinning procedure from* [17] *terminates, there are at most* $k/h\lceil c_3 \lg \lg n\rceil$ *undelivered messages destined for any particular target group.* (c_3 *is a constant which must be sufficiently large; it is the constant* c_2 *from* [17].)

The proof of Lemma 3.1 will use the following lemma.

LEMMA 3.2. *With probability at least* $1 - n^{-\alpha}$ *(for any constant* α*), each target group of size* k *is the destination of at most* $9k \lg \lg n$ *messages.*

Proof. Consider a target group T. By Property 3.1 of the the hash functions, $\overline{R}^{d,j}_{m,n}(s)$ is $(2, n^{\epsilon'})$-universal with high probability. If $\overline{R}^{d,j}_{m,n}(s)$ is $(2, n^{\epsilon'})$-universal, then the probability that at least $9k \lg \lg n$ messages have destinations in T is at most

$$\binom{3n \lg \lg n}{9k \lg \lg n} 2\left(\frac{k}{n}\right)^{9k \lg \lg n},$$

which is at most $2(e/3)^{9k \lg \lg n}$ by Stirling's approximation. □

In order to continue with the proof of Lemma 3.1 we need some notation. For every target group T let $S(T)$ denote the set containing all senders that have messages destined for target group T. We will say that a sender is *bad* if it has some message that have the same destination as at least h other messages. We will use the following lemma.

LEMMA 3.3. *With probability at least* $1 - n^{-\alpha}$ *(for any constant* α*) every set* $S(T)$ *contains at most* $k/(2h^2\lceil c_3 \lg \lg n\rceil)$ *bad senders.*

Proof. This proof is similar to the proof of Claim 2 in [17]. We include it here for completeness and also to demonstrate how the limited independence is handled. Let $h' = h/2$. For a given target group T let $M(S(T))$ denote the set of messages that are sent by senders in $S(T)$. We will say that a message is *externally bad* with respect to a target group T if the message has the same destination as at least h' other messages that are not sent from senders in $S(T)$. We will say that a message is *internally bad* with respect to a target group T if it has the same destination as at least h' other messages that are sent from senders in $S(T)$. We wish to prove that with probability at least $1 - n^{-\alpha}$ at most $k/(2h^2\lceil c_3 \lg \lg n\rceil)$ of the messages in $M(S(T))$ are either externally or internally bad.

First we consider externally bad messages. We will say that a processor P is *externally crowded* with respect to a target group T if there are at least h' messages which are not in $M(S(T))$ and have destination P. A set of b members of a target group are all externally crowded only if at least bh' messages have destinations in the set. Property 3.1 of the hash functions tells us that with high probability the destinations are chosen from a $(2, n^{\epsilon'})$-universal family of hash functions. In this case, as long as $b \le n^{\epsilon'}/h'$ the probability that there is a set of b members of a target group that are all externally crowded is at most $n^{-\alpha}$ (for any constant α),[2] plus

$$\binom{n}{k}\binom{k}{b}\binom{9k \lg \lg n}{bh'} 2\left(\frac{b}{k}\right)^{bh'}.$$

[2]By Lemma 3.2, $n^{-\alpha}$ is an upper bound on the probability that more than $9k \lg \lg n$ messages are destined for any target group.

We can use Stirling's approximation to show that for $b = k/h'^6$ this quantity is at most $(2n/k)(3/5)^{k/h'^5}$. Therefore, with probability at least $1-n^{-\alpha}-(2n/k)(3/5)^{k/h'^5}$ every target group has at most k/h'^6 processors which are externally crowded with respect the T. Suppose that this is the case. Since the family of hash functions is $(2, n^{\epsilon'})$-universal, the probability that $3\,|M(S(T))|/h'^6$ messages in $M(S(T))$ choose a destination which is externally crowded with respect to T is at most

$$2\binom{|M(S(T))|}{3\,|M(S(T))|/h'^6}\left(\frac{1}{h'^6}\right)^{3\,|M(S(T))|/h'^6},$$

which is at most $2(e/3)^{3\,|M(S(T))|/h'^6}$ by Stirling's approximation. Note that, as long as n is sufficiently large, $3\,|M(S(T))|/h'^6 \le k/(4h^2\lceil c_3 \lg\lg n\rceil)$. Also, as long as $|M(S(T))| \ge k/(4h^2\lceil c_3 \lg\lg n\rceil)$ and the constant c (in the definition of k) is sufficiently large, the sum of $(2n/k)(3/5)^{k/h'^5}$ and $(2n/k)(e/3)^{3\,|M(S(T))|/h'^6}$ is at most $n^{-\alpha}$.

We now consider internally bad messages. We start by calculating an upper bound on the probability that a message is internally bad. Lemma 3.2 tells us that with high probability at most $9k \lg\lg n$ messages are destined for any target group. Thus, with high probability, at most $9k \lg\lg n$ messages in $M(S(T))$ are destined for the same target group as the given message. Property 3.1 of the hash functions tells us that with high probability the destinations are chosen from a $(2, n^{\epsilon'})$-universal family of hash functions. Therefore, the probability that the given message is internally bad is at most

$$2\binom{9k \lg\lg n}{h'}\left(\frac{1}{k}\right)^{h'} \le (2/3)^h.$$

So the expected number of messages in $M(S(T))$ which are internally bad is at most $|M(S(T))|(2/3)^h$.

In order to prove that with high probability the number of internally bad messages is not far from the expectation we will use the following theorem of McDiarmid [29]. (The inequality is a development of the "Azuma martingale inequality"; a similar formulation was also derived by Bollobás in [3].)

THEOREM 3.4 (McDiarmid). *Let $x_1, \ldots, x_n$ be independent random variables, with x_i taking values in a set A_i for each i. Suppose that the (measurable) function $f : \prod A_i \to \mathbb{R}$ satisfies $|f(\overline{x}) - f(\overline{x}')| \le c_i$ whenever the vectors $\overline{x}$ and $\overline{x}'$ differ only in the ith coordinate. Let Y be the random variable $f(x_1, \ldots, x_n)$. Then for any $t > 0$,*

$$\Pr\big(|Y - \mathrm{E}(Y)| \ge t\big) \le 2\exp\big(-2t^2/\textstyle\sum_{i=1}^n c_i^2\big).$$

If the hash functions h_1, h_2, and h_3 were chosen uniformly at random from the set of functions from $[1, \ldots, m]$ to $[1, \ldots, n]$, the application of the bounded differences inequality would be straightforward. We would take as the random variable x_i the destination of the ith message in $M(S(T))$. We would let Y be the random variable denoting the number of internally bad messages in $M(S(T))$. If we change the value of one of the x_i, the value of Y would change by at most $h' + 1$. Plugging these values into the inequality, we would get a sufficiently small failure probability.

However, since h_1, h_2, and h_3 are in fact drawn from the family $\overline{R}_{m,n}^{d,j}$, the x_i are not independent so we cannot apply Theorem 3.4 to them. Instead, we follow the approach used in the proof of Lemma 6.1 in [20]. Consider the independent

random variables $a_1, \ldots, a_{\sqrt{n}}$. As before, let Y be a random variable denoting the number of internally bad messages in $M(S(T))$. Let Z be the set of all destinations of messages in $M(S(T))$. (The size of Z is at most $|M(S(T))|$, which is at most $27k(\lg\lg n)^2$ (with high probability), by Lemma 3.2.) Suppose that we change one of the a_i. By Property 3.3 of the hash functions, the probability that β or more members of $M(S(T))$ change destination is at most $2n^{-\alpha} + 2\binom{6n\lg\lg n/\sqrt{n}}{\beta}\left(\frac{27k(\lg\lg n)^2}{n}\right)^{\beta}$. This probability is sufficiently small as long as the constant β is sufficiently large. So suppose that at most β members of $M(S(T))$ change destination. Each of those may make at most $h'+1$ members of $M(S(T))$ become internally bad. Therefore, if we change one a_i we change Y by at most $\beta(h'+1)$. Therefore, by Theorem 3.4 the probability that $Y \geq k/(4h^2\lceil c_3 \lg\lg n\rceil)$ is at most

$$2\exp\left(\frac{-2\left(\frac{k}{4h^2\lceil c_3\lg\lg n\rceil} - \mathrm{E}(Y)\right)^2}{(|M(S(T))|\,\beta^2(h'+1)^2)}\right).$$

(The $|M(S(T))|$ appears in the denominator because there are $|M(S(T))|$ random variables in $\{a_1, \ldots, a_{\sqrt{n}}\}$ that affect the destinations of messages in $M(S(T))$. Changing any of these random variables could change Y by at most $\beta(h'+1)$. Changing any of the other random variables in $\{a_1, \ldots, a_{\sqrt{n}}\}$ does not change Y.) Since $\mathrm{E}(Y) \leq \frac{k}{8h^2\lceil c_3\lg\lg n\rceil}$ (for big enough n) and, with high probability (by Lemma 3.2), $|M(S(T))| \leq 27k(\lg\lg n)^2$, the probability is at most

$$2\exp(-k/(32h^4\lceil c_3\lg\lg n\rceil^2 27(\lg\lg n)^2\beta^2(h'+1)^2)).$$

This quantity is at most $\frac{1}{2}n^{-\alpha}\,(k/n)$ as long as c is sufficiently large. This concludes the proof of Lemma 3.3. □

The following lemma is proved in [17] (just after Lemma 3′). (The proof of the lemma uses the fact that $|S(T)| \leq 9k\lg\lg n$, which is true with high probability, according to Lemma 3.2.)

LEMMA 3.5. *With probability at least $1 - n^{-\alpha}$ the number of messages destined for any target group that start at good senders but are not delivered during the thinning procedure from* [17] *is at most $k/(2h\lceil c_3\lg\lg n\rceil)$.*

Proof of Lemma 3.1. We conclude that with probability at least $1 - 2n^{-\alpha}$ the number of undelivered messages destined for any given target group after the thinning procedure terminates is at most $k/(h\lceil c_3\lg\lg n\rceil)$. □

After the "thinning" procedure from [17] terminates we will use the "spreading" procedure from [17] to spread the unfinished requests so that each processor has at most one unfinished message to deliver. As part of the spreading procedure we will allocate one processor to do the bookkeeping associated with each memory request and we will ensure that all messages associated with the request know the identity of this processor. During this procedure of our simulation the three messages associated with a request may be sent to various processors, but they will keep the bookkeeping processor informed about their whereabouts.

After using "spreading," we will use the "deliver to target groups" procedure from [17] to deliver the rest of the messages to their target groups in $O(\lg\lg n)$ steps. With probability at least $1 - n^{-\alpha}$ (for any constant α) every message will be in its target group at the end of the "deliver to target group" procedure. Furthermore, each sender will have at most two undelivered messages to send, and (by Lemma 3.1) the

number of unfinished messages in a target group will be less than k. At this point we can sort the messages in the target groups by destination. After the sorting, each sender will have at most one message to send.

We now wish to allocate a contiguous block of c_2 processors from the appropriate target group to each unfinished destination (for a sufficiently large constant c_2). We wish to do the allocation in such a way that all senders know which processors are allocated for their destination. We do this as follows. If a destination is the destination of fewer than c_2 requests, we simply deliver them. Otherwise, we allocate c_2 processors for the destination. The processors allocated will be the first c_2 processors with requests for that destination.

At this point we wish to send all but $O(n2^{-c_1 \lg\lg n})$ of the messages in any group to their final destinations. We will say that a message is *bad* if its destination is also the destination of at least $c_1 \lg\lg n$ other messages. We will use the following lemma.

LEMMA 3.6. *With probability at least $1 - n^{-\alpha}$ (for any constant α) at most $O(n2^{-c_1 \lg\lg n})$ of the messages in any group of messages are bad.*

Proof. This proof is similar to the second part of the proof of Lemma 3.3. By Property 3.1 of the hash functions, the destinations are chosen from a $(2, n^{\epsilon'})$-universal family of hash functions with high probability. In this case, the probability that a given message is bad is at most $2\binom{3n \lg\lg n}{c_1 \lg\lg n} n^{-c_1 \lg\lg n}$. By Stirling's approximation, this is at most $2(3e/c_1)^{c_1 \lg\lg n}$, which is at most $2^{-c_1 \lg\lg n}$ for $c_1 \geq 7e$. Therefore, the expected number of bad messages in a group is at most $\epsilon n 2^{-c_1 \lg\lg n}$.

We now use Theorem 3.4 (the bounded differences inequality) to prove that with high probability the number of bad messages in a group is not much more than the expectation.

As in the case of Lemma 3.3, the bounded differences inequality would be straightforward if the hash functions h_1, h_2, and h_3 were chosen uniformly at random from the set of functions from $[1, \ldots, m]$ to $[1, \ldots, n]$. We would take as the random variable x_i the destination of the ith message and we would let Y be the random variable denoting the number of bad messages. If we change the value of one of the x_i, the value of Y would change by at most $c_1 \lg\lg n + 1$. Therefore, we would obtain the following inequality:

$$\Pr(Y \geq 2E) \leq 2\exp(-2E^2/(\epsilon n(c_1 \lg\lg n + 1)^2)).$$

However, since h_1, h_2, and h_3 are in fact drawn from the family $\overline{R}^{d,j}_{m,n}$, we again follow the approach used in the proof of Lemma 6.1 in [20]. Consider the independent random variables $a_1, \ldots, a_{\sqrt{n}}$. Let Y be a random variable denoting the number of bad messages. If we change the value of one of the a_i, then with high probability at most $6n \lg\lg n/\sqrt{n}$ messages get new destinations. (This follows from Property 3.2 of the hash functions.) Each new destination could cause at most $c_1 \lg\lg n + 1$ messages to become bad. Thus, changing one of the a_i could change Y by at most $6\sqrt{n} \lg\lg n(c_1 \lg\lg n + 1)$. Thus, by the bounded differences inequality,

$$\Pr(Y \geq 2E) \leq 2\exp(-2E^2/(\sqrt{n}36n(\lg\lg n)^2(c_1 \lg\lg n + 1)^2)),$$

which is sufficiently small. □

Given Lemma 3.6, it suffices to route $c_1 \lg\lg n$ messages to each destination. This can be done in $O(\lg\lg n)$ steps since the messages are sorted by destination. At this point we have finished the "thinning and deliver to target groups" procedure. The bookkeeping processor associated with every memory request now cancels the request

if at least two of its messages were delivered. If the request is canceled, then the third message is deleted.

3.3. Divide into subproblems and duplicate. Our goal is to divide the OCPC into $\lg\lg n/\epsilon$ sub-OCPSs, each of which has $n' = n\epsilon/\lg\lg n$ processors. Each sub-OCPC will work on the subproblem of delivering the messages corresponding to a particular group of messages. For each sub-OCPC we wish to make $\lg^2(n')$ copies of the relevant subproblem, all of which will reside in its processors $1, \ldots, n'/2$.

We will use an approximate compaction tool to divide the problem into subproblems and to make copies of the problem. (For similar tools see [5, 15, 25, 26].) Given

- an n-OCPC in which at most s senders each have one message to send,
- a set of βs receivers which is known to all of the senders,

the (s, β) *approximate compaction problem* is to deliver all of the messages to the set of receivers in such a way that each receiver receives at most one message.

The following lemma is from [17].

LEMMA 3.7. *For any positive constant α there is a positive constant c_3 such that the $(s, \lceil c_3 \lg\lg n\rceil)$ approximate compaction problem can be solved in $O(\lg\lg n)$ communication steps with failure probability at most $\alpha^{-\sqrt{s}} + s^{-\alpha}$.*

We proved in the previous subsection that with high probability, when the "thinning and deliver to target groups" procedure terminates, the number of undelivered messages is at most $3n\lg\lg n 2^{-c_1 \lg\lg n}$. Furthermore, every message is in the target group of its destination, and each processor will have at most one message left to send.

The number of unfinished target groups is at most the number of unfinished messages, which is at most

$$3n\lg\lg n 2^{-c_1\lg\lg n} \le \frac{n'}{2\lg^2(n')k^2\lceil c_3\lg\lg n\rceil}$$

for a sufficiently large c_1. Therefore, with high probability (by Lemma 3.7), we can compact one message from the first processor in each unfinished target group to the first $n'/(2\lg^2(n')k^2)$ processors in the n-OCPC. Having done that, we can copy each of the unfinished target groups to one of the first $n'/(2\lg^2(n')k)$ target groups in the n-OCPC. Next, we can use doubling to make $\lg^2(n')$ copies of each unfinished target group. All of these copies will reside in the first $n'/(2k)$ target groups in the n-OCPC.

At this point, the entire problem is copied $\lg^2(n')$ times into the first $n'/(2k)$ target groups in the n-OCPC. These $n'/(2k)$ target groups will form the first half of the processors in the first n'-processor sub-OCPC. Our objective is to use the first sub-OCPC to solve the subproblem of delivering the messages in the first group of messages. The sub-OCPC will do this by simply ignoring all messages that are not in the first group of messages.

The $\lg^2(n')$ copies of the entire problem can now be copied into the remaining $\lg\lg n/\epsilon - 1$ sub-OCPCs. The jth sub-OCPC will ignore all messages that are not in the jth group of messages.

Our next goal is to allocate the processors $n'/2, \ldots, n'$ of each sub-OCPC such that for each outstanding memory request (i.e., for each memory request which has the property that at most one of its three messages was delivered during the previous procedure) we allocate $\lg^2(n')$ processors. (These $\lg^2(n')$ processors will do the bookkeeping concerning the request in the $\lg^2(n')$ copies of the subproblem.)

The allocation can be done in the same way that the problem was split and copied because the number of remaining requests is at most $3n \lg\lg n 2^{-c_1 \lg\lg n}$.

3.4. Route messages for each subproblem. Consider a particular copy of a particular subproblem. Lemma 3.6 tells us that with high probability at most $O(n2^{-c_1 \lg\lg n})$ of the memory requests from the ϵn memory requests associated with this subproblem remain. Although each processor has at most one message to send, there is a bookkeeping processor allocated to each memory request and each message knows the identity of its bookkeeping processor. Furthermore, there is a block of c_2 contiguous processors allocated to each unfinished destination and each sender knows which processors are allocated to its destination. For $i \in \{1, 2, 3\}$ we will say that a message is an "i-message" if it obtained its destination using hash function i.

We now route messages according to the c_2-collision access schedule from Section 3 of Dietzfelbinger and Meyer auf der Heide's paper [7]. Each round of the access schedule is defined as follows.

For $i = 1, 2, 3$, do the following:

a. For all destinations d in parallel, repeat $\lceil c_2 \lg(2c_2) \rceil$ times: Each i-message with destination d that is not already waiting at one of the c_2 processors allocated to d picks a random processor from those allocated to d and sends there. Each of the allocated processors will accept only one message.

b. Each destination d now checks whether there are any other i-messages destined for d (that is, whether there are any i-messages with destination d that are not at the allocated processors). To do this, the first of the c_2 processors allocated to d sends to d. Also, any i-messages with destination d that have not yet been successful in reaching one of the c_2 processors allocated to d now send to d. Then the first of the c_2 processors allocated to d tells d whether or not it had a collision.

c. For each destination d, if all of the i-messages destined for d are at the processors allocated to d, then these messages are delivered. Otherwise, no requests are delivered.

d. The bookkeeping processor associated with each memory request checks which of the messages associated with the requests were delivered. If at least two of the messages associated with the request have been delivered, then the request is canceled and the third message is deleted.

Note that no destination receives more than $3c_2$ messages during the c_2-collision access schedule routing. We use the following lemma.

LEMMA 3.8. *During one round of the c_2-collision access schedule routing procedure any processor that is the destination of at most c_2 i-messages gets* all *of the i-messages with probability at least $\frac{1}{2}$ (and none of them with the remaining probability). Any processor that is the destination of more than c_2 i-messages receives none of them.*

Proof. If d is the destination of at most c_2 i-messages, then the probability that one of them fails to reach the allocated processors in $\ell = \lceil c_2 \lg(2c_2) \rceil$ attempts is at most $c_2(1 - 1/c_2)^{\ell} \leq \frac{1}{2}$. □

In their analysis of the c_2-collision access schedule routing procedure (as implemented on a c_2-collision DMM), Dietzfelbinger and Meyer auf der Heide define a hypergraph $H = (V, E)$ for a set of memory requests $x_1, \ldots, x_{\epsilon n}$ with vertex set $V = \{v_{rt} \mid 1 \leq r \leq 3, 1 \leq t \leq n\}$ and hyperedge set

$$E = \{\{v_{1,h_1(x_i)}, v_{2,h_2(x_i)}, v_{3,h_3(x_i)}\} \mid 1 \leq i \leq \epsilon n\}.$$

In light of Lemma 3.8, we can view the c_2-collision access schedule routing as a process on H. In each round, the process removes each node with degree at most c_2 (i.e., the i-messages destined for the processor are delivered) with probability at least $\frac{1}{2}$. Then the process removes each hyperedge that consists of only one node (i.e., memory requests are canceled if at least two of the messages associated with the request are delivered).

Following Dietzfelbinger and Meyer auf der Heide, we will say that H is s-good if

1. the largest connected component in H has at most $\alpha = \alpha(s) \lg n$ nodes,
2. every set $A \subseteq V$ intersects fewer than $|A| + s$ hyperedges from E in at least two points.

Dietzfelbinger and Meyer auf der Heide prove the following lemma. (The proof presented in [7] is based on the assumption that h_1, h_2, and h_3 are chosen uniformly at random from the set of functions from $[1, \ldots, m]$ to $[1, \ldots, n]$. However, the lemma is also true if h_1, h_2, and h_3 are chosen randomly from $\overline{R}^{d,j}_{m,n}$.)

LEMMA 3.9. *The probability that H is s-good is $1 - \mathrm{O}(n^{-s})$.*

We will prove the following lemma.

LEMMA 3.10. *Suppose that H is s-good for some positive constant s. Then the probability that any particular memory request is satisfied after $\mathrm{O}(\lg \lg n)$ rounds of routing according to the c_2-collision access schedule is at least $\frac{1}{2}$.*

Proof. Let H_t denote the hypergraph obtained by applying t rounds of the c_2-collision access schedule routing process to H. Dietzfelbinger and Meyer auf der Heide have made the following observation [7].

OBSERVATION 3.1. *If H is s-good and $A \subseteq V$ is a component of H_t for some $t \geq 0$, then A contains at most $3|A|/(c_2+1) + 3s/(c_2+1)$ nodes of degree larger than c_t in H_t.*

We will use the following lemma.

LEMMA 3.11. *Suppose that H is s-good. Let r be an edge in a component of size $\ell \geq s$ of H_t for some $t \geq 0$. If $c_2 \geq 23$, then with probability at least $1 - \exp(-\ell/54)$ the component of r in H_{t+1} has size at most $5\ell/6$.*

Proof. Let $b = 3(\ell+s)/(c_2+1)$. By Observation 3.1 and Lemma 3.8, the expected number of nodes in the component of r in H_{t+1} is at most $\ell/2 + b/2$. Using a Chernoff bound, we see that the probability that there are at most $4/3(\ell/2 + b/2) \leq 5\ell/6$ nodes is at least $1 - \exp(-(\ell/2 + b/2)/27)$. □

Using Lemma 3.11, we conclude that for some constant $c_4 \geq s$, with probability at least $\frac{3}{4}$, $\mathrm{O}(\lg \lg n)$ rounds of the c_2-collision access schedule routing procedure reduce the size of the component of a given memory request r to at most c_4. We conclude the proof of Lemma 3.10 by observing that, as long as $c_2 > 3s + 2$, $\mathrm{O}(1)$ rounds will, with probability at least $\frac{3}{4}$, further reduce the component to size 1. □

3.5. Combining problem copies and combining subproblems. Let us focus our attention on the jth subproblem. Let S_j be the set of messages that were in the subproblem when it was created. Let S'_j be the subset containing all messages in S_j that are delivered in at least $\lg^2(n')/9$ copies of the c_2-collision access schedule routing procedure.

Note that when the c_2-collision access schedule routing procedure terminates the $\lg^2(n')$ processors per memory request that were allocated in the "divide and copy" procedure to do bookkeeping can inform all of the messages in S_j (in the first copy of the subproblem) whether or not they are in S'_j.

We will prove the following lemma.

LEMMA 3.12. *With probability at least* $1 - n^{-\alpha}$ *(for any positive constant* α*), each set* S'_j *has the following properties.*

1. *Each processor is the destination of at most* $27c_2$ *messages in* S'_j.
2. *Each memory request in the* j*th subproblem will be satisfied if the messages in* S'_j *are delivered.*

If each set S'_j has the properties described in Lemma 3.12 (as it will, with high probability), then we can satisfy all of the memory requests in $O(\lg \lg n)$ steps by routing the messages in $S = \bigcup_j S'_j$. These messages form a $27c_2 \lg \lg n/\epsilon$-relation, so we can use the routing algorithm in [17] to route the messages.

To prove Lemma 3.12 we use the following lemma and the following observation.

LEMMA 3.13. *With probability at least* $1-n^{-\alpha}$ *(for any constant* α*) every memory request in every subproblem is satisfied in at least* $\lg^2(n')/3$ *of the* $\lg^2(n')$ *copies of the* c_2*-collision access schedule routing procedure.*

Proof. Suppose that every subproblem is such that the corresponding hypergraph is s-good. (Lemma 3.9 shows that this is so with high probability, as long as s is chosen to be sufficiently large.) Consider a particular memory request in a particular subproblem. Lemma 3.10 shows that the probability that this request is satisfied in any given copy of the subproblem is at least $\frac{1}{2}$. A Chernoff bound shows that with probability at least $1-ne^{-\lg^2(n')/54}$ the request is satisfied in at least $\lg^2(n')/3$ copies. The lemma follows by summing the failure probabilities over particular memory requests. □

OBSERVATION 3.2. *If* x_1*,* x_2*, and* x_3 *are the three messages in a memory request that is satisfied in at least* ℓ *copies of the* c_2*-collision access schedule routing procedure, then there is a pair of messages from* $\{x_1, x_2, x_3\}$ *such that both of the messages in the pair are satisfied in at least* $\frac{\ell}{3}$ *copies of the procedure. Similarly, if* x_1 *and* x_2 *are the two messages in a memory request that is satisfied in at least* ℓ *copies of the* c_2*-collision access schedule routing procedure, then at least one of* x_1 *and* x_2 *is satisfied in at least* $\frac{\ell}{2}$ *copies of the procedure.*

Proof of Lemma 3.12. The fact that (with high probability) each memory request in the jth subproblem will be satisfied if the messages in S'_j are delivered follows from Lemma 3.13 and from Observation 3.2. To see that each processor is the destination of at most $27c_2$ messages in S'_j note that a message is a member of S'_j only if it is delivered in at least $\lg^2(n')/9$ copies of the c_2-collision access schedule routing procedure. However, we proved in the previous section that each destination will receive at most $3c_2$ messages in each copy of the procedure. Therefore, at most $27c_2$ messages that have the same destination will be included in S'_j. This completes the proof of Lemma 3.12. □

4. Construction and evaluation of the hash function. In the simulation algorithm we have assumed that a hash function h was chosen uniformly at random from the family $\overline{R}^{d,j}_{m,n}$ and is available to every processor for constant time evaluation. When concurrent-read is available in the simulating model, a hash function in use can be kept in the shared memory and be read as necessary in constant time. The exclusive-read nature of the OCPC model, together with the fact that the function $h \in \overline{R}^{d,j}_{m,n}$ is represented by a polynomial number of memory words, imply a more subtle situation. A straightforward implementation is to keep a copy of the function h at each processor. However, this implies polynomial overheads both in the time of preprocessing for distributing all copies and in the space dedicated for this function at each processor. In the remainder of this section we describe an efficient implemen-

tation in which the function requires only a total of linear space and its evaluation increases the simulation delay by at most a constant factor.

4.1. The family of hash functions. Our basic approach is to (i) replace the class $\overline{R}^{d,j}_{m,n}$ with a class whose functions h have similar properties but can be represented in $O(n^\epsilon)$ space, where $\frac{1}{2} \le \epsilon < 1$ (the modified class will still satisfy Properties 3.1–3.3); (ii) make $O(n^{1-\epsilon})$ copies of the selected function h; and (iii) make sure that at each simulation step the number of processors that need to read a component of h is bounded by $O(n^{1-\epsilon} \lg\lg n)$, an average of $O(\lg\lg n)$ per copy, thereby enabling the use of an efficient $\lg\lg n$-relation algorithm for the read operation. (A similar approach of making duplicates to reduce contention was used in [14], in implementing a perfect hash function on the QRQW PRAM.) To implement the approach sketched above we first modify the definition of $\overline{R}^{d,j}_{m,n}$ from section 3.1 as follows. To choose a random hash function $h : [1, \ldots, m] \to [1, \ldots, n]$ from the modified class, one first chooses a function f uniformly at random from $H^d_{m,\sqrt{n}}$ and integers $a_1, \ldots, a_{\sqrt{n}}$ uniformly at random from $[1, \ldots, n]$ as before. Similarly, one chooses the function r uniformly at random from $\overline{H}_{n^j,n}$ as before. However, we will use Siegel's space-efficient implementation of the class $\overline{H}_{n^j,n}$ from [35], which we will explain below, and we will make sure that the implementation satisfies an additional property (see Lemma 4.2). The function s will no longer be chosen uniformly at random from H^1_{m,n^j}. Instead, it will be chosen as follows. Let $t = j/\epsilon$ and let d be a sufficiently large constant. We will choose functions $s_1, s_2, \ldots, s_t$ uniformly at random from the class H^d_{m,n^ϵ}, and we will define $s(x)$ to be the tuple $\langle s_1(x), \ldots, s_t(x)\rangle$. Finally, we will define $h(x) = (r(s(x)) + a_{f(x)}) \bmod n$ as before. The following lemma shows that Property 3.1 still holds for the new family of hash functions.

LEMMA 4.1. *Let $\ell \ge 1$ be arbitrary and let d and j be large enough relative to ℓ. Let $S \subseteq [1, \ldots, m]$, $n \le |S| \le n^{11/10}$. If s is chosen randomly as described above, then* $\Pr[s$ *is* 1*-perfect on* $S]$ *is at least* $1 - n^{-\ell}$.

Proof. The probability that two given distinct points $x, y \in S$ will collide under s, i.e., that $s(x) = s(y)$, is at most $(2/n^\epsilon)^t$, since the s_i are $(2, d)$-universal. The probability that any pair of points from S will collide is therefore at most

$$\binom{|S|}{2}(2/n^\epsilon)^t \le n^{22/10-j}2^{j-1}.$$

The lemma follows by taking $j > \ell + 22/10$. ∎

4.2. The implementation of $\overline{H}_{n^j,n}$. We now describe Siegel's space-efficient implementation of the class $\overline{H}_{n^j,n}$ from [35].

Siegel defines a (p, ϵ, d, h)*-weak concentrator* H as a bipartite graph on the sets of vertices I (inputs) and O (outputs), where $|I| = p$, and $|O| = p^\epsilon$, that has outdegree d for each node in $|I|$ and that has, for any h inputs, edges matching them one-by-one with some h outputs.

A (p, ϵ, d, h)-weak concentrator H is used to construct a function F by storing d random numbers from $[0, \ldots, p-1]$ at each node of O. On input i, $F(i)$ is computed by evaluating a polynomial hash function of degree $d-1$ whose coefficients are determined by the numbers stored at the neighbors of i in O. Siegel showed that the family of hash functions F so defined is a $(1, h)$-universal family of hash functions mapping $[0, p-1] \mapsto [0, p-1]$.

Let H be a $(n^\epsilon, \epsilon, d, n^{\epsilon'})$-weak concentrator. Siegel showed that the Cartesian product $G = H^t$ is a $(n^j, \epsilon, d^t, n^{\epsilon'})$-weak concentrator. The graph G can therefore be

used to construct a $(1, n^{\epsilon'})$-universal family of hash functions mapping $[1, \ldots, n^j]$ to $[1, \ldots, n^j]$. One obtains a $(2, n^{\epsilon'})$-universal family of hash functions mapping $[1, \ldots, n^j]$ to $[1, \ldots, n]$ by taking the results modulo n.

In the following lemma, we observe that Siegel's implementation of $\overline{H}_{n^j,n}$ requires only a graph H with small out-degree. This property will be useful in our OCPC implementation.

LEMMA 4.2. *There exists a graph H that is $(n^{\epsilon}, \epsilon, d, n^{\epsilon'})$-weak concentrator, and which also has the property that every output of H has degree at most $2dn^{\epsilon-\epsilon^2}$.*

Proof. We use a probabilistic construction, as in [35] for finding an $(n^{\epsilon}, \epsilon, d, n^{\epsilon'})$-weak concentrator. Suppose that each input of H chooses its d (distinct) neighbors uniformly at random. Siegel proves that the probability that H is not a $(n^{\epsilon}, \epsilon, d, n^{\epsilon'})$-weak concentrator is at most $n^{-(\epsilon^2-\epsilon')}$. (As long as ϵ' is sufficiently small.) We can now use a Chernoff bound to show that the degree of each output of H is sufficiently small as required. □

4.3. Constructing the hash functions. The graph H from Lemma 4.2 can be constructed and built into the machine when the machine is built. Each of the n^{ϵ} inputs has d neighbors. A set of $n^{1-\epsilon}$ processors is selected and each processor in the set is given the name of these dn^{ϵ} neighbors.

A new hash function h from the modified family is constructed in $O(\lg n)$ steps as follows.

1. Select (appropriately at random) $s_1, \ldots, s_t$ and f and distribute to all processors.
2. Each of the $n^{j\epsilon}$ output nodes of $G = H^t$ chooses d^t values in $[0, \ldots, n^j - 1]$. A set of $n^{1-j\epsilon}$ processors is selected for each given output node and each processor in the set is given the d^t values associated with the output node.
3. The values $a_1, \ldots, a_{\sqrt{n}}$ are generated. $\sqrt{n}$ sets of $\sqrt{n}$ processors are selected and each processor in a set i is given the value of a_i.

Recall that a new function may need to be constructed (a "rehash" operation) when the selected one does not satisfy the required properties. (This occurs with polynomially small probability for each parallel step and with high probability after a polynomial number of steps.)

4.4. Evaluating the hash function. At each simulation step, the hash function is computed for all memory addresses in $O(\lg \lg n)$ time, as described next. Let S be the set of $3n \lg \lg n$ requests from $[1, \ldots, m]$. Recall from section 4.1 that $h(x) = (r(s(x)) + a_{f(x)}) \bmod n$.

Each processor executes the following steps for each request x.

1. Compute $s_1(x), \ldots, s_t(x)$.
2. Compute the names of the neighbors of $\langle s_1(x), \ldots, s_t(x) \rangle$ in G.
3. Read the values corresponding to the neighbors of $\langle s_1(x), \ldots, s_t(x) \rangle$ in G.
4. Apply r to $\langle s_1(x), \ldots, s_t(x) \rangle$.
5. Compute $f(x)$.
6. Read $a_{f(x)}$.
7. Compute $r(s(x)) + a_{f(x)}$.

The executions of steps 1, 4, 5, and 7 are in constant time. The following lemma of Dietzfelbinger [23] is central to the analysis of the other steps.

LEMMA 4.3. *Let $X_1, \ldots, X_n$ be 0–1-valued, d-independent, equidistributed random*

variables. Let $\mu = E(X_i)$. *Then, for* $n \geq d/(2\mu)$,

$$\Pr\left(\sum_{i=1}^{n}(X_i - \mu) \geq \lambda\right) \leq \frac{\alpha(n\mu)^{d/2}}{\lambda^d},$$

where α *is a constant that depends on* d *but not on* n.

CLAIM 4.4. *In step* 2, *with high probability, for every* y *in* $[1, \ldots, n^\epsilon]$ *(i.e., for every input of* H*) there are at most* $O(n^{1-\epsilon} \lg\lg n)$ *pairs* (i, x) *such that* $x \in S$ *and* $s_i(x) = y$.

Proof. Note that the set of values $s_i(x) : 1 \leq x \leq m$ is d-independent. Following Kruskal, Rudolph, and Snir [23] we use Lemma 4.3. Fix a y and an i, and let X_b be a 0–1 random variable, which is 1 if and only if s_i maps the bth member of S to y. Here μ is $1/n^\epsilon$. Let λ be $|S|/n^\epsilon$. Then the probability that s_i maps more than 2λ to y is $O(n^{-d/2(1-\epsilon)})$. Choose d large enough to sum over all i and y. □

We conclude that at most $O(n^{1-\epsilon} \lg\lg n)$ processors want to read the information about input y, and so we have a "target group $O(\lg\lg n)$ relation." The requests can be routed by using [17].

CLAIM 4.5. *In step* 3, *with high probability, for every output* y *of* G *there are at most* $O(n^{1-j\epsilon} \lg\lg n)$ *values* x *in* S *such that* $\langle s_1(x), \ldots, s_t(x)\rangle$ *is a neighbor of* y *in* G.

Proof. Fix $y = \langle y_1, \ldots, y_t\rangle$. Let L_i denote the neighbors of y_i in H. Note that $|L_i| \leq 2dn^{\epsilon-\epsilon^2}$. If $s(x)$ has a neighbor y in G, then $s_i(x)$ is in L_i for $1 \leq i \leq t$.

The probability of this event is at most $(2d/n^{\epsilon^2})^t$. Let X_b be a 0–1 random variable, which is 1 if and only if the bth member x of S has $s(x)$ mapped to y in G. Apply Lemma 4.3: μ is at most $(2d/n^{\epsilon^2})^t$ by Lemma 4.2; let λ be $|S|(2d/n^{\epsilon^2})^t$. The probability that there are more than λ such values x is at most $\alpha n^{-(d/2)(1-j\epsilon)}$. □

Given the claim, we have a "target group $O(\lg\lg n)$ relation." The requests can be routed using [17].

Step 6 remains to be analyzed. By Property 3.2, with probability at least $1 - n^{-\alpha}$ each group needs to be read by at most $6\sqrt{n}\lg\lg n$ of the requests, so we have a "target group $6\lg\lg n$ relation." The requests can be routed by using [17].

5. Conclusions. In this paper we have described a work-optimal algorithm which simulates an $n\lg\lg n$-processor EREW PRAM on an n-processor OCPC with $O(\lg\lg n)$ expected delay. The probability that the delay is longer than this is at most $n^{-\alpha}$ for any constant α.

It would be interesting to determine whether this is the fastest possible work-optimal simulation. It would also be interesting to discover how much delay is required in order to simulate a CRCW PRAM. We have recently derived an algorithm that simulates an n-processor CRCW PRAM step on an n-processor OCPC in time $O(\lg k + \lg\lg n)$ with high probability, where k is the maximum memory contention of the CRCW step.

The simulation algorithm assumes that k is known. This assumption can be removed by augmenting the OCPC model to include a single bus which can be used to synchronize all of the processors: each processor can broadcast a 1 bit, and every processor can determine whether or not any processor is broadcasting a 1 at any given time.

We note that the $\lg k$ term in the simulation algorithm is provably necessary, as implied by an $\Omega(\lg k)$ expected time lower bound for broadcasting the value of a bit

to k processors on a QRCW PRAM (and hence on an ERCW) by Gibbons, Matias, and Ramachandran (see [14]).

Evidently, the performance of the CRCW simulation depends on the maximum contention. A model that accounts for memory contention was recently proposed in [13]. In this model the run time of each step is a function of the memory contention encountered at this step. Thus, in the submodel of SIMD-QRQW log PRAM, a step in which the maximum memory contention is k is assumed to take $\lg k$ time units.

The CRCW simulation implies that an n-processor SIMD-QRQW log PRAM algorithm can be simulated on an n-processor OCPC, augmented with a bus, with delay $O(\lg \lg n)$ with high probability. We note that the SIMD-QRQW log PRAM is strictly stronger than the EREW PRAM.

TIME-LAPSE SNAPSHOTS*

CYNTHIA DWORK†, MAURICE HERLIHY‡, SERGE PLOTKIN§, AND ORLI WAARTS¶

Abstract. A snapshot scan algorithm produces an "instantaneous" picture of a region of shared memory that may be updated by concurrent processes. Many complex shared memory algorithms can be greatly simplified by structuring them around the snapshot scan abstraction. Unfortunately, the substantial decrease in conceptual complexity quite often is counterbalanced by an increase in computational complexity.

In this paper, we introduce the notion of a *weak snapshot scan*, a slightly weaker primitive that has a more efficient implementation. We propose the following methodology for using this abstraction: first, design and verify an algorithm using the more powerful snapshot scan; second, replace the more powerful but less efficient snapshot with the weaker but more efficient snapshot, and show that the weaker abstraction nevertheless suffices to ensure the correctness of the enclosing algorithm.

We give two examples of algorithms whose performance is enhanced while retaining a simple modular structure: bounded concurrent timestamping and bounded randomized consensus. The resulting timestamping protocol dominates all other currently known timestamping protocols: it matches the speed of the fastest known bounded concurrent timestamping protocol while actually reducing the register size by a logarithmic factor. The resulting randomized consensus protocol matches the computational complexity of the best known protocol that uses only bounded values.

1. Introduction.

Synchronization algorithms for shared-memory multiprocessors are notoriously difficult to understand and to prove correct. Recently, however, researchers have identified several powerful abstractions that greatly simplify the conceptual complexity of many shared-memory algorithms. One of the most powerful of these is *atomic snapshot scan* (in this paper we sometimes omit the word "scan"). Informally, this is a procedure that makes an "instantaneous" copy of memory that is being updated by concurrent processes. More precisely, the problem is defined as follows. A set of n asynchronous processes share an n-element array A, where only process P writes $A[P]$.[1] An atomic snapshot is a read of all the elements in the array that appears to occur instantaneously. Formally, scans and updates are required to be *linearizable* [25], i.e., each operation appears to take effect instantaneously at some

[1] One can also define multiwriter algorithms in which any process can write to any location.

point between the operation's invocation and response. Thus, there exists a *total* "linearization" order on the scans and updates, such that a scan operation returns for each process P the value of the last update operation to $A[P]$, where *last* is with respect to the linearization order. Note that this implies that if processes p and q update their values from u_p, u_q to v_p, v_q, respectively, then if some atomic snapshot scan returns values v_p, u_q, no other atomic snapshot scan can return values u_p, v_q.

Prior to our work, atomic snapshot scan algorithms had been constructed by Anderson [3] (bounded registers and exponential running time), Aspnes and Herlihy [6] (unbounded registers and $O(n^2)$ running time), and Afek et al. [2] (bounded registers and $O(n^2)$ running time). More recent results, derived after the time this work was first published and requiring only bounded registers, include randomized algorithms of Attiya, Herlihy, and Rachman [10] ($O(n \log^2 n)$ time) and Chandra and Dwork [14] ($O(n) + C_n$, where C_n is the running time of the best randomized consensus algorithm for n processes) and the fastest deterministic algorithm to date, by Attiya and Rachman [11] ($O(n \log n)$ steps per operation). Here running time is measured by the number of accesses to shared memory. Chandy and Lamport [15] considered a closely related problem in the message-passing model.

Unfortunately, the substantial decrease in conceptual complexity provided by atomic snapshot scan is often counterbalanced by an increase in computational complexity. In this paper, we introduce the notion of a *weak snapshot scan*, called a *time-lapse snapshot*. The time-lapse snapshot is a slightly weaker abstraction than the atomic snapshot scan in which the linearization order is allowed to be partial, rather than total. This weaker notion of correctness allows two scans to disagree on the order of two updates, but only if all four operations are concurrent with one another. That is, if processes p and q update their values from u_p, u_q to v_p, v_q, respectively, and if scans S, S' are done concurrently with each other and with these updates, it is possible that scan S returns values v_p, u_q and scan S' returns u_p, v_q. The advantage of using weak snapshot is that it can be implemented in $O(n)$ time. Thus, the cost of our time-lapse snapshot is asymptotically the same as the cost of a simple "collect" of the n values, but the primitive is much more powerful. Letting v be the maximum number of bits in any element in the array A, our implementation of the time-lapse snapshot requires registers of size only $O(n + v)$. In contrast, all atomic snapshot algorithms known to us require registers of size $O(nv)$. Since in some applications v can be as large as n, this reduction in register size can be significant.

Our results indicate that weak snapshot scan can sometimes alleviate the tradeoff between conceptual and computational complexity. We focus on two well-studied problems: bounded concurrent timestamping and randomized consensus. In particular, we consider algorithms for these problems based on an atomic snapshot. In both cases, we show that one can simply replace the atomic snapshot scan with a weak snapshot scan, thus retaining the algorithms' structure while improving their performance.

The weak snapshot algorithm presented here was influenced by work of Kirousis, Spirakis, and Tsigas [30], who designed a linear-time atomic snapshot algorithm for a *single* scanner. In this special case our algorithm solves the original atomic snapshot problem as well.

In the bounded *concurrent timestamping* problem processes repeatedly choose labels, or timestamps, reflecting the real-time order of events. More specifically, processes can repeatedly perform two types of operations, called **labeling** and **scan**. In a **labeling** operation a process assigns itself a new label. A **scan** operation returns

a set of current labels, one per process, and a total order on these labels, consistent with the real-time order of their corresponding **labeling** operations.[2]

Israeli and Li [26] were the first to investigate bounded *sequential* timestamp systems; Dolev and Shavit [19] were the first to explore the *concurrent* version of the problem. The Dolev–Shavit construction requires $O(n)$-sized registers and labels, $O(n)$ time for a **labeling** operation, and $O(n^2 \log n)$ time for a **scan**. In their algorithm each process is assigned a single multireader–single-writer register of $O(n)$ bits. Extending the Dolev–Shavit solution in a nontrivial way, Israeli and Pinhasov [28] obtained a bounded concurrent timestamp system that is linear in time and label size but uses registers of size $O(n^2)$. An alternative implementation of their algorithm uses *single*-reader–single-writer registers[3] of size $O(n)$ but requires $O(n^2)$ time to perform a **scan**. Independently, and slightly later, Dwork and Waarts [20] obtained the first linear time solution, using a different approach not based on any of the previous solutions, with a simpler proof of correctness. The drawback of their construction is that it requires registers and labels of size $O(n \log n)$. After this work was first published, the Dwork–Waarts approach was pursued by Haldar [23], who presented a timestamping system that is slightly more memory efficient than the construction of [20] (although not asymptotically) but that also requires registers and labels of size $O(n \log n)$.

Dolev and Shavit observed that the *conceptual* complexity of their concurrent timestamping algorithm can be reduced by using atomic snapshot scan. We show that, in addition, the algorithm's *computational* complexity can be reduced by simply replacing the atomic snapshot with the weak snapshot, making no other changes to the original algorithm. The resulting bounded concurrent timestamping algorithm is linear in both time and the size of registers and labels and is conceptually simpler than the Dolev–Shavit and Israeli–Pinhasov solutions. We do not need to prove directly that our timestamping is correct; rather, we reduce the correctness of our solution to the correctness of the Dolev–Shavit algorithm.

Independent of our work, Gawlick, Lynch, and Shavit [22] actually structured the Dolev–Shavit algorithm around the atomic snapshot abstraction. The resulting algorithm is indeed significantly more simple and modular than that of Dolev and Shavit. Introducing new proof techniques, Gawlick, Lynch, and Shavit prove from scratch that their algorithm is a bounded concurrent timestamping system. At the time of the Gawlick, Lynch, and Shavit work, the (then) best atomic snapshot algorithm was the one in [2]. Using this in the construction in [22] effectively slowed down the original Dolev–Shavit timestamping algorithm, yielding a timestamping algorithm that requires $O(n^2)$ accesses to registers of size $O(n^2)$ for both **labeling** and **scan** operations. More than a year after initial publication of our results, Attiya and Rachman developed the $O(n \log n)$ atomic snapshot [11] mentioned above. Plugging this atomic snapshot algorithm into the timestamping construction of Gawlick, Lynch, and Shavit yields a timestamping algorithm that requires $O(n \log n)$ accesses to registers of size $O(n^2)$. In comparison, our construction requires only $O(n)$ accesses to registers of size only $O(n)$. Thus, our timestamping construction dominates all others of which we are aware.

In the *randomized consensus* problem, each of n asynchronous processes starts with an input value taken from a two-element set and runs until it chooses a *de-*

[2] Observe that the scan required by the timestamping is not necessarily identical to the atomic snapshot scan. Unfortunately, the two operations have the same name in the literature.

[3] All other results mentioned are in terms of multireader–single-writer registers.

cision value and halts. The protocol must be *consistent*—no two processes choose different decision values; *valid*—the decision value is the input value of some process; and randomized *wait-free*—each process decides after an expected finite number of steps. The consensus problem lies at the heart of the more general problem of constructing highly concurrent data structures [24]. Consensus has no deterministic solution in the asynchronous shared-memory model with only atomic reads and writes [18, 36]. Nevertheless, it can be solved by *randomized* protocols in which each process is guaranteed to decide after a finite *expected* number of steps. Randomized consensus protocols that use unbounded registers have been obtained by Chor, Israeli, and Li [17] (against a "weak" adversary), by Abrahamson [1] (exponential running time), by Aspnes and Herlihy [7] (the first polynomial algorithm), by Saks, Shavit, and Woll [40] (optimized for the case where processes run in lock step), and by Bracha and Rachman [12] (running time $O(n^2 \log n)$). After the time of our work, Aspnes and Waarts [8] presented a randomized consensus protocol that uses unbounded registers and in which the expected number of operations per process is $O(n \log^2 n)$.

Protocols that use bounded registers have been proposed by Attiya, Dolev, and Shavit [9] (running time $O(n^3)$), by Aspnes [5] (running time $O(n^2(p^2+n))$, where p is the number of active processors), and by Bracha and Rachman [13] (running time $O(n(p^2+n))$, the best known). The bottleneck in Aspnes's algorithm is atomic snapshot. Replacing this atomic snapshot with our more efficient weak snapshot improves the running time by $\Omega(n)$ (from $O(n^2(p^2+n))$ to $O(n(p^2+n))$) and yields a protocol that matches the protocol of Bracha and Rachman [13]. Both our consensus algorithm and the one in [13] are based on Aspnes's algorithm. The crucial difference is that the solution of Bracha and Rachman is specific to consensus, whereas our algorithm is an immediate application of the primitive developed in this paper.

The remainder of this paper is organized as follows. Section 2 gives our model of computation and defines the weak snapshot primitive. Some properties of weak snapshots appear in section 3. The remaining sections describe the weak snapshot algorithm and its applications.

2. Model and definitions. A *concurrent system* consists of a collection of n asynchronous *processes* that communicate through an initialized shared memory. Each memory location, called a *register*, can be written by one "owner" process and read by any process. Reads and writes to shared registers are assumed to be *atomic*, that is, they can be viewed as occurring at a single instant of time. In order to be consistent with the literature on the discussed problems, our time complexity measure is expressed in terms of read and write operations on single-writer–multireader registers, in our case of size $O(n)$. Polynomial-time algorithms for implementing large single-writer–multireader atomic registers from small, weaker registers are well known [31, 32, 38, 27, 29, 33, 34, 35, 37, 42, 44].

We view an execution of a protocol as an interleaving of atomic reads and writes. Sometimes it is convenient to assign *times* to these atomic operations. These times are not accessible to the processes. A register can undergo at most one atomic operation at a time, and a process can perform at most one atomic operation at a time.

An algorithm is *wait-free* if there is an a priori upper bound on the number of steps a process might take when running the algorithm, regardless of how its steps are interleaved with those of other processes. All algorithms discussed in this paper are wait-free.

An *atomic snapshot memory* supports two kinds of abstract operations: **update** modifies a location in the shared array, and **scan** instantaneously reads (makes a copy

of) the entire array. Let U_i^k (S_i^k) denote the kth **update** (**scan**) of process i, and v_i^k the value written by i during U_i^k. The superscripts are omitted where this cannot cause confusion. An operation A *precedes* operation B, written as $A \longrightarrow B$, if B starts after A finishes. Operations unrelated by precedence are *concurrent*. Processes are *sequential*: each process starts a new operation only when its previous operation has finished, hence its operations are totally ordered by precedence.

Correctness of an atomic snapshot memory is defined as follows. There exists a total order "$\Longrightarrow$" on operations such that

- if $A \longrightarrow B$, then $A \Longrightarrow B$;
- if **scan** S_p returns $\bar{v} = \langle v_1, \ldots, v_n \rangle$, then v_q is the value written by the latest **update** U_q ordered before S_p by $\Longrightarrow$.

The order $\Longrightarrow$ is called the *linearization* order [25]. Intuitively, the first condition says that the linearization order respects the "real-time" precedence order, and the second says that each correct concurrent computation is equivalent to some sequential computation where the **scan** returns the last value written by each process.

We define a *time-lapse* (or *weak*) *snapshot* memory as follows: we impose the same two conditions, but we allow $\Longrightarrow$ to be a *partial order*[4] rather than a total order. We call this order a *partial linearization order*. Since for each q all the updates U_q are linearized by the $\longrightarrow$ relation, the "latest **update** U_q ordered before S_p" is well defined, even though $\Longrightarrow$ is only a partial order. If $A \Longrightarrow B$ we say that B *observes* A.

Each **scan** and **update** operation takes place during the interval of time beginning with the first atomic action of the operation and ending with the last atomic action. Intuitively, we require that scanning processes agree about **update**s that happened (in real time) before the **scan**s began, but they may disagree about concurrent **update**s. That is, if processes p and q update their values from u_p, u_q to v_p, v_q, respectively, and if **scan**s S, S' start after the two **update**s terminate, then the values each with returns for p, q are at least as recent as v_p, v_q, respectively; however, if **scan**s S, S' are done concurrently with each other and with these updates, then it is possible that **scan** S returns values v_p, u_q and **scan** S' returns u_p, v_q. Thus, in a system with only one scanner, atomic snapshots and weak snapshots are equivalent. Similarly, the two types of snapshots are equivalent if no two **update**s occur concurrently (overlap in real time). However, in general, our weaker notion of correctness allows two **scan**s S and S' to disagree on the order of two **update**s U and U', but only if all four operations are concurrent with one another.

The weak snapshot is still more powerful than a simple **collect** of values written by atomic writes. To see this, consider three processes a, b, c. Let a perform an **update** U_a, writing the value v_a. Let b then perform a **scan** S_b, followed by an **update** U_b resulting in v_b. Assume that process c performs a **scan** S_c concurrent with all three of these operations and that returns v_b for process b. If the **update**s were simple writes and the **scan** a simple collect, then the fact that S_c returns v_b places no constraint upon whether S_c returns v_a or an earlier value for a. However, if the operations are instead operations of the weak snapshot primitive, then we have $U_a \Longrightarrow S_b$ (because S_b returns v_a), $S_b \Longrightarrow U_b$ (because $S_b \longrightarrow U_b$), and $U_b \Longrightarrow S_c$ (because S_c returns v_b). By transitivity we get $U_a \Longrightarrow S_c$, whence it follows that S_c returns v_a or a later value for a.

The following assumption is convenient and easily implemented.

Assumption 2.1. If an **update** is observed by a **scan**, then this **update** termi-

[4] In this paper, all partial orders are irreflexive.

nates before the **scan** does.

Assumption 2.1 is useful in modifying the bounded concurrent timestamping algorithm of [19], since it allows us to reduce the correctness of the resulting system to the correctness of the original algorithm of [19], thereby avoiding a full proof of correctness from scratch. Intuitively, it allows us to argue that anything written by an **update** and seen by a **scan** in the modified algorithm could have been written by a simple atomic write in a *corresponding execution* of the original Dolev–Shavit algorithm and seen by a simple **collect** in that execution. We explain this further in section 5.

We close this section with a brief review of some properties of atomic registers. We use the notation W_x^i (respectively, R_x^i) to denote the ith atomic write (respectively, read) of the register by process x.

Regularity of an atomic register says that for any value v written by a write W_a^i and returned by a read R_b^k, W_a^i begins before R_b^k terminates, and there is no write W_a^j for $j > i$ such that $W_a^i \longrightarrow W_a^j \longrightarrow R_b$.

Monotonicity of an atomic register says that if $R_b \longrightarrow R_c$ and if R_b returns v written by a write W_a^i, then R_c returns v' written by a write $W_a^{i'}$ for some $i' \geq i$.

3. Properties of weak snapshots. The reader can easily verify that weak snapshots satisfy the following properties:

- *Regularity.* For any value v_a^i returned by S_b^j, U_a^i begins before S_b^j terminates, and there is no U_a^k such that $U_a^i \longrightarrow U_a^k \longrightarrow S_b^j$.
- *Monotonicity of* **scan**s. If S_a^i and S_b^j are two **scan**s satisfying $S_a^i \longrightarrow S_b^j$ (a and b could be the same process), and if S_a^i observes **update** U_c^k (formally, $U_c^k \Longrightarrow S_a^i$), then S_b^j observes U_c^k.
- *Monotonicity of* **update**s. If U_a^i and U_b^j are two **update** operations (possibly by the same process) such that $U_a^i \longrightarrow U_b^j$, and if S_c^k is a **scan** operation, possibly concurrent with both U_a^i and U_b^j, such that S_c^k observes U_b^j ($U_b^j \Longrightarrow S_c^k$), then S_c^k observes U_a^i.

Variants of the regularity and monotonicity properties are part of the definitions of several basic shared-memory abstractions, including timestamping systems [26, 19, 22] and the traceable-use abstraction [20], and follow from the definitions of several other abstractions, including atomic registers [32] and atomic snapshots [2, 6].

Roughly speaking, time-lapse snapshots satisfy all the properties of atomic snapshots except for the consistency property which states that if **scan**s S_a^i, S_b^j return $\bar{v} = \langle v_1, \ldots, v_n \rangle$ and $\bar{v}' = \langle v'_1, \ldots, v'_n \rangle$, respectively, then either $U_k \not\longrightarrow U'_k$ for every $k = 1, \ldots, n$, or vice versa.

Define the *span* of a value v_p^i to be the interval from the start of U_p^i to the end of U_p^{i+1}, if U_p^{i+1} exists and terminates, or the infinite interval with the same start time if no U_p^{i+1} ever terminates. Clearly, values written by successive **update**s have overlapping spans. The following lemma formalizes the intuition that a weak snapshot **scan** returns a possibly existing state of the system.

LEMMA 3.1. *If a weak snapshot* **scan** *S returns a set of values $\bar{v}$, then their spans have a nonempty intersection.*

Proof. By definition of time-lapse snapshot, for all $v_p^i \in \bar{v}$, U_p^i is the latest **update** ordered before S by $\Longrightarrow$. Let v_p^i in $\bar{v}$ be such that the span of v_p^i is the latest to start. If all the spans of the values in $\bar{v}$ are infinite, then clearly they intersect at all times after U_p^i begins.

Assuming at least one span is finite, let v_p^i be as above and let v_q^j be in $\bar{v}$ such that the span of v_q^j is the first to end. Then, it is enough to show that the spans of v_p^i and v_q^j intersect. Suppose not. By choice of q, U_q^{j+1} completes. Since by assumption, the spans of v_p^i and v_q^j do not intersect, it follows from the definition of a span that $U_q^{j+1} \longrightarrow U_p^i$. Thus $U_q^{j+1} \Longrightarrow U_p^i$, and hence it follows from the transitivity of the partial linearization order that $U_q^{j+1} \Longrightarrow S$, violating the requirement that each **scan** return the latest value written by the latest **update** ordered before it by $\Longrightarrow$. □

Let a **scan** S of a weak snapshot start at time t_s, end at time t_e, and return a set of values $\bar{v}$. By Lemma 3.1, there is a point t in which the spans of all these values intersect. We now argue that at least one such point is in the interval $[t_s, t_e]$. There may be more than one such point; however, the regularity property of weak snapshots implies that there is at least one such point t such that $t_s \leq t \leq t_e$. This is because the first clause in the definition of regularity implies that the span of v_a^i begins before t_e, while the second clause implies that the span of v_a^i ends at or after t_s. We will refer to the latest such point t by t_{scan} of S.

4. Weak snapshot. Intuitively, in order to be able to impose a partial order on the **scan**s and **update**s, we need to ensure that if a **scan** S_c does not return value v_a^j of process a because v_a^j is too new (i.e., S_c returns v_a^k for $k < j$), then S_c will not return a value v_b^i that was written by process b *after* b returns v_a^j in some **scan** S_b.

This intuition follows from the definition of the time-lapse snapshot: if S_b returns v_a^j and $S_b \longrightarrow U_b^i$ we have $U_a^j \Longrightarrow S_b \Longrightarrow U_b^i$, by definition of time-lapse snapshot. Moreover, if S_c returns v_b^i, then S_c must be ordered after b's **update** in the partial order; that is, $U_b^i \Longrightarrow S_c$. We therefore have by transitivity that $U_a^j \Longrightarrow S_c$, or in other words, that a's **update** U_a^i is ordered before the **scan** S_c, and hence by definition of time-lapse snapshots S_c must return v_a^k for $k \geq j$.

If each value returned by the **scan** is the value written by the latest **update** that terminated before a specific point in the **scan**, the above situation does not occur. This observation by Kirousis, Spirakis, and Tsigas [30] motivates our solution. Roughly speaking, in our solution, at the start of a **scan**, the scanner produces a new number, called *color*, for each other process. When a process wants to perform an **update**, it reads the colors produced for it (one color by each scanner) and tags its new value with these colors. This enables the scanner to distinguish older values from newer ones.

The next section describes a solution that uses an unbounded number of colors. Later we will show how to simulate this solution using only a bounded number of colors. The simulation uses a simplification of the **Traceable Use** abstraction defined by Dwork and Waarts in [20].

4.1. Unbounded weak snapshot. We follow the convention that shared registers appear in upper case and private variables in lower case. In order to simplify the presentation, we assume that all the private variables are persistent. If a variable is subscripted, the first subscript indicates the unique process that writes it, and the second, if present, indicates the process that uses it. When the code says "atomically write ... for all ...," we mean a single atomic write operation in which all indicated variables are written at once. In contrast, a statement of the form "for each $x \in X$ write ..." means that the executing process must perform $|X|$ atomic writes. Each process b has variables VALUE_b, which stores b's current value; $\text{PCOLOR}_b, \text{QCOLOR}_b$, each of which stores an n-element array of colors; and VASIDE_{bc}, for each $c \neq b$. In keeping with convention [2, 20, 32], we frequently refer to $\text{PCOLOR}_b[c]$ as PCOLOR_{bc}

1. For all $c \neq b$, read $qcolor_b[c] :=$ PCOLOR$_{cb}$.
2. For all $c \neq b$, if $qcolor_b[c] \neq$ QCOLOR$_{bc}$
   then $vaside_b[c] :=$ VALUE$_b$.
3. Atomically write:
   VALUE$_b :=$ new value.
   For all $c \neq b$, VASIDE$_{bc} := vaside_b[c]$.
   For all $c \neq b$, QCOLOR$_{bc} := qcolor_b[c]$.

FIG. 4.1. **update** *operation for process b.*

1. Call **Produce**.
2. For all $c \neq b$ atomically read:
   $value_b[c] :=$ VALUE$_c$,
   $qcolor_b[c] :=$ QCOLOR$_{cb}$,
   $vaside_b[c] :=$ VASIDE$_{cb}$.
3. For all $c \neq b$
   If $qcolor_b[c] \neq pcolor_b[c]$
      then $data_b[c] := value_b[c]$,
      else $data_b[c] := vaside_b[c]$.
4. Return $(data_b[1], \ldots,$ VALUE$_b, \ldots, data_b[n])$.

FIG. 4.2. **scan** *operation for process b.*

(analogously for QCOLOR$_b[c]$). In this section, we assume that all these variables are stored in a single register. Section 4.4 describes how to eliminate this assumption. The code for the **update** and **scan** operations appears in Figures 4.1 and 4.2, respectively; the code for the **Produce** operation, called by the **scan**, appears in Figure 4.3.

At the start of a **scan**, the scanner b produces a new color for each updater c and stores it in PCOLOR$_{bc}$. (Colors produced *by* different processes or colors produced *for* different processes are considered different even if they have the same value.) It then reads VALUE$_c$, VASIDE$_{cb}$, and QCOLOR$_{cb}$ in a single atomic step. If QCOLOR$_{cb}$ is equal to the color produced by b for c (and stored in PCOLOR$_{bc}$), then b returns VASIDE$_{cb}$ as the value for c; otherwise b returns VALUE$_c$.

The updater b first reads PCOLOR$_{cb}$ and then writes its new VALUE$_b$ atomically with QCOLOR$_{bc} :=$ PCOLOR$_{cb}$ for all c. At the same time b updates VASIDE$_{bc}$ for all c that it detects as having started to execute a concurrent **scan**.

The intuition behind the use of the VASIDE variable can be best described if we consider an example where we have a "fast" updater b and a "slow" scanner c, where c executes a single **scan** while b executes many **update**s. In this case, the updater will update VALUE$_b$ each time but will update VASIDE$_{bc}$ only once, when it will detect that c is scanning concurrently. Intuitively, VASIDE$_{bc}$ allows the scanner c to return a value for process b that was written by b during an **update** that started no later than the end of the color producing step of the current **scan**. Therefore, such a value can depend only on values that are not more recent than the values returned by the **scan**.

We superscript the values of variables to indicate the execution of **update** or **scan** in which they are written. For example PCOLOR$^{\ell}_{bc}$ is the value of PCOLOR$_{bc}$ written during **scan** S^{ℓ}_b.

Next, we construct an explicit partial linearization order $\Longrightarrow$ as follows. Define $U^j_q \Rightarrow S^i_p$ to hold if S^i_p returns the value originally written by U^j_q. (Note that S^i_p may read this value from VASIDE$^k_{qp}$, where $k > j$). Define $\Longrightarrow$ to be the transitive closure of $\longrightarrow \cup \Rightarrow$. It follows from Lemmas 4.1 and 4.4 that the **scan** and **update** procedures

1. For all $c \neq b$ $pcolor_b[c] := \text{PCOLOR}_{bc} + 1$.
2. Atomically write for all $c \neq b$ $\text{PCOLOR}_{bc} := pcolor_b[c]$.

FIG. 4.3. *Unbounded* **Produce** *operation for process b.*

yield a weak snapshot memory.

LEMMA 4.1. *The relation* $\Longrightarrow$ *is a partial order.*

Proof. It suffices to check that $\Longrightarrow$ is acyclic. Suppose there exists a cycle $A_0, \ldots, A_k$, where adjacent operations are related by $\longrightarrow$ or $\Rightarrow$, and the cycle length is minimal. Because $\longrightarrow$ is acyclic and transitive, some of these operations must be related only by $\Rightarrow$. Since $\Rightarrow$ goes only from **update** to **scan** operations, there are no adjacent $\Rightarrow$ edges. Thus, if the cycle is of length 1, then we must have $A_0 \longrightarrow A_0$, which is a contradiction. Hence the cycle must be of length > 1. Since the cycle is minimal, and $\longrightarrow$ is transitive, there are no adjacent $\longrightarrow$ edges and therefore for each consecutive pair A_i and A_{i+1}, if $A_i \Rightarrow A_{i+1}$, then $A_i \not\longrightarrow A_{i+1}$. Therefore the edges of the cycle must alternate between $\Rightarrow$ and $\longrightarrow$. It follows that k is odd. Without loss of generality, assume $A_0 \Rightarrow A_1$.

We argue by induction that, for $\ell \geq 0$, we have that A_0 starts before $A_{2\ell+2}$ starts. Throughout the proof all subscripts are taken modulo $k+1$. (In particular, when $k = 1$ we have that A_2 is precisely A_0.) For the base case ($\ell = 0$), since by assumption $A_0 \Rightarrow A_1$, it follows that A_0 starts before A_1 finishes (otherwise A_1 would be returning a value written by an operation that had not even started and therefore might never start, contradicting the regularity of atomic registers). Since by construction $A_1 \longrightarrow A_2$ (alternating edges property), we have that A_1 finishes before A_2 starts, and the base case follows.

Assume the result for ℓ. We have $A_{2\ell+2} \Rightarrow A_{2\ell+3}$ (alternating edges), and hence again $A_{2\ell+2}$ starts before $A_{2\ell+3}$ finishes. By the inductive hypothesis, A_0 starts before $A_{2\ell+2}$ starts and hence A_0 starts before $A_{2\ell+3}$ finishes. To finish the argument, note that $A_{2\ell+3} \longrightarrow A_{2\ell+4}$ (alternating edges), which implies that A_0 starts before $A_{2\ell+4}$ starts, completing the induction.

Recall that the cycle has even length and that this length is at least 2. Thus, A_0 starts before A_{k+1} starts, but since all subscripts are modulo $k+1$ this says that A_0 starts before itself, which is a contradiction. ∎

To complete the proof that our implementation is a weak snapshot, we need only to show that for each process our weak **scan** returns the value written by the latest **update** ordered before that **scan**. We first show the two technical lemmas below.

LEMMA 4.2. *If a* **scan** *returns a value written by an* **update**, *then this* **update** *terminates before the* **scan** *reads* VALUE_q.

Proof. Recall that v_q^j denotes the value originally written by U_q^j. Assume **scan** S_p^i returns v_q^j. Recall that by design of the algorithm, there are two scenarios in which S_p^i returns v_q^j: either (a) in step 3 of S_p^i $qcolor_p^i[q] \neq pcolor_p^i[q]$ and v_q^j is the value p read from VALUE_q in step 2, or (b) $qcolor_p^i[q] = pcolor_p^i[q]$ and v_q^j is the value in VASIDE_{qp} that p read in step 2. Recall that v_q^j can be written into VASIDE_{qp} only by $U_q^{j'}$, $j' > j$ (by inspection of the code for an **update**).

Case (a) can occur only if q wrote v_q^j to VALUE_q before S_p^i reads that variable. Since (by inspection of the code) that write is the last atomic action in U_q^j, the claim follows. Case (b) can occur only if q wrote v_q^j to VASIDE_{qp} before S_p^i reads that variable. Since such a write must take place during $U_q^{j'}$, $j' > j$, it follows that the write must be after U_q^j terminates, and again the claim follows. ∎

LEMMA 4.3. *Let U_q^j be the last* **update** *by process q to be ordered before S_p^i by $\Longrightarrow$. U_q^j terminates before S_p^i reads VALUE_q. Moreover, in step 1 of U_q^j, q reads $\text{PCOLOR}_{pq}^{i'}$ for some $i' < i$.*

Proof. By definition of $\Longrightarrow$ there must be a sequence $A_0, \ldots, A_k$ where adjacent operations are related by $\longrightarrow$ or $\Rightarrow$ and where $A_0 = U_q^j$ and $A_k = S_p^i$. The proof proceeds by induction on the length k of a minimal such sequence.

For the base case, $k = 1$, observe that either $U_q^j \longrightarrow S_p^i$ or $U_q^j \Rightarrow S_p^i$. If $U_q^j \longrightarrow S_p^i$, then the first part of the claim is immediate, and the second part of the claim follows from the regularity of atomic registers.

We now consider the case in which $U_q^j \Rightarrow S_p^i$. By definition v_q^j is thus the value returned for q by S_p^i. Lemma 4.2 thus implies the first part of the claim.

To complete the proof of the base case, we will show by contradiction that U_q^j does not read PCOLOR_{pq}^i but instead reads $\text{PCOLOR}_{pq}^{i'}$ for some $i' < i$.

First, suppose for the sake of contradiction that U_q^j reads $\text{PCOLOR}_{pq}^{i'}$ for some $i' > i$ in step 1 of the **update**. Then U_q^j writes v_q^j only after S_p^i ends, so by the regularity of atomic registers S_p^i cannot return a value written by U_q^j; that is, $U_q^j \not\Rightarrow S_p^i$. It remains only to show that U_q^j does not read PCOLOR_{pq}^i.

Suppose otherwise; that is, suppose that, in step 1 of U_q^j, q reads PCOLOR_{pq}^i and thus $\text{QCOLOR}_{qp}^j = \text{PCOLOR}_{pq}^i = pcolor_p^i[q]$. It follows from step 3 of the **scan** operation that S_p^i could not have taken v_q^j from VALUE_q because $\text{QCOLOR}_{qp}^j = pcolor_p^i[q]$. So S_p^i must have taken v_q^j from VASIDE_{qp}. This implies that there is some $U_q^{j'}, j' > j$, that wrote v_q^j into VASIDE_{qp} and that terminated before S_p^i performed step 2. We show that there is no such $U_q^{j'}$. Since by assumption U_q^j reads PCOLOR_{pq}^i, the monotonicity of an atomic register implies that so does any later $U_q^{j'}$ that terminates before S_p^i's read from q in step 2, and hence it follows from the code of the **update** operation that any such later $U_q^{j'}$ sees $qcolor_q[p] = \text{QCOLOR}_{qp}$ and hence does not write v_q^j into VASIDE_{qp}. This completes the proof of the base case.

Assume the claim for k and suppose the minimal sequence from U_q^j to S_p^i is of length $k+1$. Then such a sequence has one of the following forms:

1. $U_q^j \longrightarrow U_z^l \Longrightarrow S_p^i$.
2. $U_q^j \longrightarrow S_g^m \Longrightarrow S_p^i$.
3. $U_q^j \Rightarrow S_g^m \Longrightarrow S_p^i$.

For case 1, without loss of generality we can assume that U_z^ℓ is the last **update** by process z to be ordered before S_p^i by $\Longrightarrow$. Then by the inductive hypothesis, U_z^ℓ reads $\text{PCOLOR}_{pz}^{i'}$ for some $i' < i$, and it terminates before S_p^i's read in step 2. Since $U_q^j \longrightarrow U_z^\ell$ we have, by the monotonicity of atomic registers, that U_q^j reads $\text{PCOLOR}_{pq}^{i''}$ for some $i'' \leq i' < i$, thereby establishing the second part of the claim. Now, p writes PCOLOR_{pz}^i during the **Produce** operation in step 1 of S_p^i. Since U_z^ℓ reads only an earlier value of PCOLOR_{pz}, it follows from the regularity of atomic registers that U_z^ℓ began before the **Produce** of S_p^i completed. Since $U_q^j \longrightarrow U_z^\ell$ we therefore have that U_q^j completed before this **Produce** is completed, and the claim follows.

For case 2, observe that since $\Rightarrow$ goes only from **update** to **scan** operations, we have that any sequence from S_g^m to S_p^i is either of the form (2.i) $S_g^m \longrightarrow U_z^l \Longrightarrow S_p^i$, or (2.ii) $S_g^m \longrightarrow S_p^i$. By transitivity of $\longrightarrow$, if (2.i) holds, then $U_q^j \longrightarrow U_z^l \Longrightarrow S_p^i$, and if (2.ii) holds, then $U_q^j \longrightarrow S_p^i$. This implies that a minimal sequence from U_q^j to S_p^i cannot be of the form of case 2.

For case 3, we have again that either (3.i) $S_g^m \longrightarrow U_z^l \Longrightarrow S_p^i$, or (3.ii) $S_g^m \longrightarrow S_p^i$. By Lemma 4.2, U_q^j must have completed before S_g^m has completed, and hence it follows analogously to the above that a minimal sequence from U_q^j to S_p^i cannot be of the form of case 3. □

Note that Lemma 4.3 implies that our implementation satisfies Assumption 2.1.

LEMMA 4.4. *For each process, our weak* **scan** *returns the value written by the latest* **update** *ordered before that* **scan** *by* $\Longrightarrow$.

Proof. Let U_q^j be the last **update** by process q to be ordered before S_p^i by $\Longrightarrow$. Since U_q^j is the last **update** of q ordered before S_p^i by $\Longrightarrow$, S_p^i could not have returned $v_q^{j'}$ for some $j' > j$. Therefore, it is enough to show that S_p^i does not return $v_q^{j'}$ for $j' < j$. Suppose otherwise.

From Lemma 4.3 it follows that U_q^j has completed before S_p^i performs its read from q in step 2. Thus before the time S_p^i performs this read, v_q^j is written into VALUE_q. It follows from the code for a **scan** operation that if, after v_q^j is written into VALUE_q, the **scan** S_p^i returns some $v_q^{j'}$ for $j' < j$, then this was the value read by S_p^i in VASIDE_{qp} and S_p^i reads some $\text{QCOLOR}_{qp}^{j''}$ that is the same as PCOLOR_{pq}^i.

Lemma 4.3 states that U_q^j reads $\text{PCOLOR}_{pq}^{i'}$ for some $i' < i$. Thus, when U_q^j reads PCOLOR_{pq} in step 1, PCOLOR_{pq} contains some $\text{PCOLOR}_{pq}^{i'}$ for $i' < i$. The monotonicity of atomic registers immediately implies that also when U_q^k, for $k \leq j$, reads PCOLOR_{pq} in step 1, it reads $\text{PCOLOR}_{pq}^{i''}$ for some $i'' \leq i' < i$. Thus, from step 1 of the **update** operation it follows that for each $k \leq j$, $\text{QCOLOR}_{qp}^k \neq \text{PCOLOR}_{pq}^i$. Thus, the j'' in the above paragraph must be $> j$.

Since, as reasoned above, $\text{QCOLOR}_{qp}^j \neq \text{PCOLOR}_{pq}^i$, there exists $j < j''' \leq j''$ such that $\text{QCOLOR}_{qp}^{j'''} \neq \text{QCOLOR}_{qp}^{j'''-1}$. But this implies that VASIDE_{qp} is updated with $v_q^{j'''-1}$ by **update** $U_q^{j'''}$, contradicting the assumption that S_p^i returns $v_q^{j'}$ read in VASIDE_{qp}, for some $j' < j$. □

4.2. Review of the Traceable Use abstraction. We use a simplified version of the **Traceable Use** abstraction of Dwork and Waarts [20] in order to convert the unbounded weak snapshot described in the previous section into a bounded one. Recall that in the unbounded solution, when process b produces a new color for process c, this new color was not previously produced by b for c. This feature implies that when b sees VALUE_c tagged by this new color it knows that this VALUE_c is too recent (was written after the **scan** began) and will not return it as the result of its **scan**. However, the same property will follow also if when b produces a new color for c, it will simply choose a color that is guaranteed not to tag a value of c unless b produces it for c again. To do this b must be able to detect which of the colors it produced for c may still tag c's values. This requirement can be easily satisfied by incorporating a simplified version of the **Traceable Use** abstraction.

In general, the goal of the **Traceable Use** abstraction is to enable the colors to be *traceable*, in that at any time it should be possible for a process to determine which of its colors might tag any current or future values, where by "future value" we mean a value that has been prepared but not yet written. That is, in the case of time-lapse snapshots, at any time a process p can determine, for each process q, which of p's colors currently appear, or may appear in the future, in PCOLOR_{pq} or QCOLOR_{qp}. Although we allow a color that is marked as "in use" not to be used at all, we require that the number of such colors be bounded.

Due to the asynchrony and concurrency, if revealing a color (i.e., writing a new

color) were done by a simple write, and obtaining a color (i.e., in order to tag a value) were done by a simple read, the colors would not have been traceable. Therefore, to achieve its goal, the **Traceable Use** requires the processes to communicate through three types of wait-free operations—**traceable-read**, **traceable-write**, and **garbage collection**:

- **traceable-read** allows the calling process to obtain the current color produced for it by another process—in other words, to *consume* a color. It takes two parameters: the name c of the process from which the color is being consumed (and to which the color belongs), and the name of the color (that is, the shared variable holding the color).[5] It returns the value of the consumed color.
- **traceable-write** allows a process to update a variable containing its colors—in other words, to *reveal* its new colors. It takes two parameters: the name of the variable and a new value for the variable.
- **garbage collection** allows a process to detect all of its colors that are currently in use. It takes a list of shared variables in which the garbage collector's colors reside (intuitively, the list of where to look for the collector's colors). It returns a list of colors that may currently be in use.

The processes will communicate through the **Traceable Use** abstraction as follows. For process b to obtain a color produced for it by another process, b invokes the **traceable-read** operation. To write a color that other processes may need to obtain from it through the **traceable-read** operation, the process will perform the **traceable-write** operation. Thus, if a variable written by b contains a color of $c \neq b$, this color must have been consumed earlier by b; on the other hand, colors of b appearing in variables owned by b (meaning variables residing in single-writer registers of which b is the writer) do not need to be consumed from anybody. When b writes a new color for itself in one of its variables without consuming it from anybody, we say that this color is *produced* at that time. Finally, to detect which of its colors are in use in the system, the process will perform **garbage collection**.

Each process has $n-1$ *pools* of available colors, one for each other process. When a color v is produced by a process b for process c, it is removed from the pool. The color v is not available for reuse by b (cannot be returned to the pool) before b invokes **garbage collection** and determines that v is not in use by the end of **garbage collection**.

Before we specify the properties of the **Traceable Use**, some notation is in order. First, it is important to distinguish between shared variables of an algorithm that uses the **Traceable Use** abstraction and auxiliary shared variables needed for the implementation of the abstraction. We call the first type of variables *principal* shared variables, and the second type *auxiliary*.[6] Only principal shared variables are obtained through the **traceable-read** operation, revealed through the **traceable-write** operation, and passed to the **garbage collection** procedure. For example, in the weak snapshot system PCOLOR_{pq} and QCOLOR_{pq}, for any p and q, are principal shared variables.

We now specify the situation in which a color is considered currently in use, and therefore not available for reuse. Let E be a finite prefix of an execution of a system in which communication is performed using the **Traceable Use** abstraction. Let E end

[5] For simplicity, the description here is slightly different from the corresponding one in [20].

[6] Sometimes the term *auxiliary variables* denotes variables introduced to facilitate a proof. We are simply using the adjective *auxiliary* in its English sense.

at time t. Then a color v belonging to b is *in use* at time t if there is some extension $\hat{E}$ of E, where b does not produce v in $\hat{E}$ after time t, and v appears as a color of b in some principal shared variable after time t of $\hat{E}$. (Recall that colors produced by b for different processes are considered different even if they have the same value; thus b can produce v only for a specific process, say c.)

Finally, for $1 \leq i \leq n$, let TW_i^k (respectively, TR_i^k) denote the kth **traceable-write** (respectively, **traceable-read**) operation performed by process i. X_i^k denotes a color written by i during TW_i^k. Then **Traceable Use** is required to have the following properties:

- *Regularity*: For any color X_p^a consumed by TR_i^k, TW_p^a begins before TR_i^k terminates, and there is no TW_p^b such that $TW_p^a \longrightarrow TW_p^b \longrightarrow TR_i^k$.
- *Monotonicity*: Let $TR_i^k, TR_j^{k'}$ (where i and j may be equal) be a pair of **traceable-read** operations returning the colors X_p^a, X_p^b, respectively. If $TR_i^k \longrightarrow TR_j^{k'}$, then $a \leq b$.
- *Detectability*: If, during **garbage collection**, a color v of process b was not determined by b to be in use, then v will not be in use before b again produces it.
- *Boundedness*: By taking the local pools to be sufficiently large, it is always possible to find some color not returned as in use by the **garbage collection** procedure.

The *regularity* and *monotonicity* properties of the **Traceable Use** guarantee the *regularity* and *monotonicity* properties of the bounded weak snapshot system. *Detectability* guarantees that a process will be able to safely recycle its colors. *Boundedness* guarantees that by taking the local pools to be sufficiently large, the producer will always find colors to recycle.

Dwork and Waarts [20] presented an implementation of the **Traceable Use** under four restrictions. Since the version we present here is a simplification of their abstraction, three of their restrictions (Uniqueness, Limited Indirection, and Limited Values) are already imposed by the simplification. The remaining restriction is conservation.

- *Conservation.* Let TR_b^k consume a color v from c, and let $TR_b^{k'}$ be the first **traceable-read** operation of b from c to follow TR_b^k. Denote by t' the time in which $TR_b^{k'}$ starts. Then if v appears in a principal shared variable of b at some time $t \geq t'$, it appears in this variable throughout the period $[t', t]$.

Very roughly, the intuition for this restriction is that in the implementation in [20], when b performs **garbage collection** it examines certain auxiliary variables as well as all the principal variables to see which colors are in use. Colors that are or will be in use by c must therefore be in one of those places at all times, and moreover should not be shifting back and forth between those places (because otherwise **garbage collection** could repeatedly miss seeing a color v, reading a register just after v has been moved to a different register and erased from the first one).

In the next section we prove that **Traceable Use** under these restrictions suffices for our weak snapshot algorithm.

4.3. Bounded time-lapse snapshots. For simplicity of exposition, we first present an algorithm that uses registers of size $O(nv)$, where v is the maximum number of bits in any process's value. In section 4.4 we show how to modify this algorithm so that registers of size $O(n + v)$ will suffice.

It is easy to see that the **Traceable Use** abstraction allows us to convert our unbounded solution to a bounded one. In the unbounded solution each time a process

1.a. For all $c \neq b$ $x[c] :=$ **garbage collection**($\text{PCOLOR}_{bc}, \text{QCOLOR}_{cb}$).
1.b. For all $c \neq b$, choose from your local pool for c $pcolor_b[c] \notin x[c]$.
2. **traceable-write** ($\text{PCOLOR}_b, pcolor_b$).

FIG. 4.4. *Bounded* **Produce** *operation for process b.*

performed a **scan** it produced a new color for each updater. In the bounded solution, the scanner will draw its colors from bounded pools, one pool for each updater. (Again, colors produced by different scanners or for different updaters are considered different.) The algorithm is exactly like the unbounded one, except that the processes communicate through the **Traceable Use** operations. Roughly speaking, to get a color produced for it by another process, the process uses the **traceable-read** operation; to write its new colors, it uses the **traceable-write** operation; and to find a color it can produce again, it performs **garbage collection**.

Using the **Traceable Use** abstraction, the process will be able to narrow the set of its colors suspected by it as colors that may tag values of another process, say c, to contain no more than six values (discussed below). We take the pools to be of size seven, thereby ensuring that whenever the process wants to perform a **scan**, it can find, for each updater, a color it can reuse.

More specifically, in the bounded solution, every process has $n-1$ pools of available colors, one pool for each other process. Each pool initially contains seven colors. When a scanner b wants to produce a new color for updater c, it performs **garbage collection** to determine which of its colors may currently be tagging values of c (and therefore cannot be reused at this time). Any color determined by **garbage collection** not to be in use can be recycled without causing confusion. In general, **garbage collection** ensures that when a process b produces v as its color for c for the kth time, there is not, and never will be, anything in the system that contains v from when it was produced by b for c for the $(k-1)$st time. For example, suppose b produces the color 5 at time t_1, later performs **garbage collection**, and then later, at time t_2, again produces the color 5. Thus, by definition, at time t_1, b performs an atomic write to PCOLOR_b, setting $\text{PCOLOR}_{bc} := 5^{t_1}$, where the t_1 in the superscript indicates that this is the value written at time t_1. Similarly, at time t_2, b performs an atomic write setting $\text{PCOLOR}_{bc} := pcolor_b[c] = 5^{t_2}$. Since this second write occurs as part of a **scan** operation, if b completes the **scan**, then at some time $t > t_2$, when performing step 2 of this **scan**, b sets $qcolor_b[c] := \text{QCOLOR}^i_{cb}$ and later, in step 3, tests $qcolor_b[c] = pcolor_b[c]$ $(= 5)$. Suppose that the two colors are equal, that is, that $\text{QCOLOR}^i_{cb} = 5$. Then the **garbage collection** procedure ensures that $\text{QCOLOR}^i_{cb} = 5^{t_2}$ and *not* 5^{t_1}, that is, the **update** operation U^i_c reads 5^{t_2}, the result of the more recent write of 5, in PCOLOR_{cb}.

In order to convert the unbounded solution to a bounded one, we replace the **Produce** operation shown in Figure 4.3 by the **Produce** operation shown in Figure 4.4. The meaning of the notation in step 2 of the new **Produce** operation is that all $n-1$ colors $pcolor_b[i]$, $i \neq b$, are written atomically to PCOLOR_{bi}.

Also, line 1 of the **update** operation shown in Figure 4.1 is replaced by the following:

1. For all $c \neq b$, $qcolor_b[c] :=$ **traceable-read**(c, PCOLOR_{cb}).

We refer to the modified **scan** and **update** as the bounded **scan** and bounded **update**, respectively.

We now prove that the resulting bounded construction is a time-lapse snapshot algorithm. The proof follows along the same lines as for the unbounded construction of section 4.1.

First, the partial linearization order $\Longrightarrow$ on the bounded **scan** and **update** operations is defined identically to the one defined in section 4.1 on the unbounded **scan** and **update** operations. It follows from Lemmas 4.5 and 4.8 that the bounded **scan** and **update** procedures yield a weak snapshot memory.

LEMMA 4.5. *The relation $\Longrightarrow$ is a partial order.*

Proof. The proof is analogous to the proof of Lemma 4.1, when "regularity of **Traceable Use**" is replacing "regularity of atomic registers." □

LEMMA 4.6. *If a bounded* **scan** *returns a value written by a bounded* **update**, *then this* **update** *terminates before the* **scan** *reads* VALUE_q.

Proof. The proof is identical to the proof of Lemma 4.2. □

LEMMA 4.7. *Let U_q^j be the last* **update** *by process q to be ordered before S_p^i by $\Longrightarrow$. U_q^j terminates before S_p^i reads VALUE_q. Moreover, in step 1 of U_q^j, q reads $\text{PCOLOR}_{pq}^{i'}$ for some $i' < i$.*

Proof. The proof is analogous to the proof of Lemma 4.3, when "regularity of **Traceable Use**" and "monotonicity of **Traceable Use**" are replacing "regularity of atomic registers" and "monotonicity of atomic registers," respectively, and in addition Lemma 4.6 is replacing Lemma 4.2. □

Note that Lemma 4.7 implies that our bounded construction satisfies Assumption 2.1.

LEMMA 4.8. *For each process, our bounded weak* **scan** *returns the value written by the latest bounded* **update** *ordered before that* **scan** *by $\Longrightarrow$.*

Proof. The proof is along the same lines of the proof of Lemma 4.4. The difference here is that in the bounded implementation, QCOLOR_{qp}^m may contain the same color as PCOLOR_{pq}^r even if U_q^m does not consume PCOLOR_{pq}^i but consumes some $\text{PCOLOR}_{pq}^{i'}$ for some $i' \neq i$.

Let U_q^j be the last **update** by process q to be ordered before S_p^i by $\Longrightarrow$. Since U_q^j is the last **update** of q ordered before S_p^i by $\Longrightarrow$, S_p^i could not have returned $v_q^{j'}$ for some $j' > j$. Therefore, it is enough to show that S_p^i does not return $v_q^{j'}$ for $j' < j$. Suppose otherwise.

From Lemma 4.7 it follows that U_q^j has completed before S_p^i performs its read from q in step 2. So before the time S_p^i performs this read, v_q^j is written into VALUE_q. It follows from the code for a **scan** operation that if, after v_q^j is written into VALUE_q, the **scan** S_p^i returns some $v_q^{j'}$ for $j' < j$, then this was the value read by S_p^i in VASIDE_{qp} and S_p^i reads some $\text{QCOLOR}_{qp}^{j''}$ that is the same as PCOLOR_{pq}^i.

Let QCOLOR_{qp}^k be the QCOLOR_{qp} read by S_p^i when S_p^i performs its **garbage collection** operation. Step 1.b of the bounded **Produce** operation implies that QCOLOR_{qp}^k contains a different color than the color contained in PCOLOR_{pq}^i.

Therefore, there exists $k < j''' \leq j''$ such that $\text{QCOLOR}_{qp}^{j'''} \neq \text{QCOLOR}_{qp}^{j'''-1}$. Step 2 of the **update** operation implies that VASIDE_{qp} is updated with $v_q^{j'''-1}$ by **update** $U_q^{j'''}$. Thus, if $j \leq k$, then we get a contradiction to the assumption that S_p^i returns $v_q^{j'}$ read in VASIDE_{qp}, for some $j' < j$. To complete the proof, assume $j \geq k$.

Lemma 4.7 states that U_q^j reads $\text{PCOLOR}_{pq}^{i'}$ for some $i' < i$. The detectability property of the **Traceable Use** implies that after the **garbage collection** done in step 1 of S_p^i, the color contained in PCOLOR_{pq}^i may appear in some $\text{QCOLOR}_{qp}^{k'}$ for $k' \geq k$ (and hence be in use) only if p produces it again and $U_q^{k'}$ consumes $\text{PCOLOR}_{pq}^{i''}$ for some $i'' \geq i$. Thus, QCOLOR_{qp}^j does not contain the same color as PCOLOR_{pq}^i.

Thus there exists $j < j''' \leq j''$ such that $\text{QCOLOR}_{qp}^{j'''} \neq \text{QCOLOR}_{qp}^{j'''-1}$. Step 2 of the **update** operation implies that VASIDE_{qp} is updated with $v_q^{j'''-1}$ by **update** $U_q^{j'''}$, contradicting again the assumption that S_p^i returns $v_q^{j'}$ read in VASIDE_{qp}, for some $j' < j$. □

Lemmas 4.5 and 4.8 immediately imply the following.

THEOREM 4.9. *The bounded construction is a time-lapse snapshot algorithm.*

Letting n be the number of processes in the system, the implementation of **Traceable Use** given in [20] requires $O(n)$ steps per **traceable-write** (that is, $O(n)$ reads and writes of shared variables) and $O(1)$ steps to consume one color using the **traceable-read** operation. Applied to our algorithm, the construction in [20] yields a cost of $O(k)$ for **garbage collection**, where k is the number of variables passed as parameters to the **garbage collection** procedure; moreover, when b invokes **garbage collection** to detect how many of its colors for c are in use, **garbage collection** detects at most six colors.[7]

Clearly, each **Produce** operation requires $O(n)$ invocations of **garbage collection**, each of which costs $O(1)$, and one invocation of **traceable-write**, and thus takes $O(n)$ steps. Each **scan** requires one invocation of **Produce** and $O(n)$ simple reads, and thus takes $O(n)$ steps. Each **update** requires one simple write and $O(n)$ invocations of **traceable-read**, and hence takes $O(n)$ steps.

4.4. Reducing the register size. The weak snapshot described above uses registers of size $O(nv)$ where v is the maximum number of bits in any variable VALUE_b. This is due to the fact that an updater b may set aside a different value for each scanner c in a variable VASIDE_{bc}, and all these values are kept in a single register. To reduce the size of the registers, each updater b stores VASIDE_{bc} in a separate register for each c. Only after this has been accomplished, b atomically updates VALUE_b and, for all $c \neq b$, QCOLOR_{bc}.

The modifications to the code are straightforward. Lines 2 and 3 of the code for the **scan** (Figure 4.2) are replaced by lines 2′ and 3′ below.

2′. For all $c \neq b$ atomically read
  $value_b[c] := \text{VALUE}_c$
  $qcolor_b[c] := \text{QCOLOR}_{cb}$.
3′. For all $c \neq b$
  If $qcolor_b[c] \neq pcolor_b[c]$
    then $data_b[c] := value_b[c]$
    else read $data_b[c] := \text{VASIDE}_{cb}$.

Lines 2 and 3 of the code for the **update** operation (Figure 4.1) are replaced by the following lines 2′ and 3′:

2′. For all $c \neq b$
  if $qcolor_b[c] \neq \text{QCOLOR}_{bc}$ then $vaside_b[c] := \text{VALUE}_b$
  $\text{VASIDE}_{bc} := vaside_b[c]$.
3′. Atomically write
  $\text{VALUE}_b :=$ new value
  For all $c \neq b$, $\text{QCOLOR}_{bc} := qcolor_b[c]$.

[7] This is because, in the notation of [20], when a process b wants to detect which of its colors for c may currently be in use, it needs only to read $Ai\text{-}PCOLOR_{bc}[b]$, for $i = 1, 2, 3$ (colors set aside by b for c when b detects that c is trying to consume b's color for c), $B\text{-}PCOLOR_{cb}[b]$ (color written by c for b when c is trying to consume b's color for it), and QCOLOR_{cb}; moreover, each **garbage collection** needs to read these variables only once because in our application colors have what [20] calls indirection of degree one (see section 8.3 of [20]).

Observe that the time complexity of the modified algorithm is the same as the original one.

THEOREM 4.10. *The modified algorithm is a time-lapse snapshot algorithm.*

Proof. Clearly, the only difference between the modified and the original algorithms is that the shared variables VASIDE_{qp} and VALUE_q are not written atomically together by the **update** and are not read atomically together by the **scan**. If in every execution of the modified algorithm whenever a scan S_p^i reads VALUE_q^k and $\text{VASIDE}_{qp}^{k'}$ (recall that VASIDE_{qp}^k is the value of VASIDE_{qp} written by U_q^k) either S_p^i returns VALUE_q^k or $\text{VASIDE}_{qp}^k = \text{VASIDE}_{qp}^{k'}$, then every execution of the modified algorithm has a corresponding execution of the original algorithm, in which corresponding **scan**s return the same sets of values, and the modified algorithm is correct because the original algorithm is correct.

Therefore, let us assume for the sake of contradiction that the **scan** S_p^i reads VALUE_q^k and $\text{VASIDE}_{qp}^{k'}$ and returns the latter, where the value of VASIDE_{qp}^k is different from the value of $\text{VASIDE}_{qp}^{k'}$. We now show that this cannot happen. Since VASIDE_{qp} is written before VALUE_q by an **update** and read after it by a **scan**, we have that $k' > k$. Since the **scan** S_p^i returns the value it read from VASIDE_{qp}, we have $\text{PCOLOR}_{pq}^i = \text{QCOLOR}_{qp}^k$. It follows from the detectability property of **Traceable Use** that, after GC_p^i, PCOLOR_{pq}^i is not in use it will not be used again until p produces it. So the chronology is: S_p^i performs **garbage collection**, denoted GC_p^i; S_p^i reads QCOLOR_{qp} during GC_p^i; S_p^i sets PCOLOR_{pq}^i to a value not currently in use; U_q^k writes $\text{QCOLOR}_{qp}^k = \text{PCOLOR}_{pq}^i$; S_p^i reads QCOLOR_{qp}^k. Thus, U_q^k consumes color PCOLOR_{pq}^i.

By monotonicity of **Traceable Use**, for all $k < k_1 \le k'$, $U_q^{k_1}$ consumes PCOLOR_{pq}^i and hence saw $qcolor_q[p] = \text{QCOLOR}_{qp}$ when performing step 2 of the **update** operation. Hence no such $U_q^{k_1}$ changed the value in VASIDE_{qp}, i.e., the value of VASIDE_{qp}^k is the same as the value of $\text{VASIDE}_{qp}^{k'}$. This is a contradiction. ∎

5. Applications. In this section, we explore two applications of the weak snapshot: bounded concurrent timestamping and randomized consensus. First we take the bounded concurrent timestamping protocol of Dolev and Shavit [19] and show that the labels can be stored in an abstract weak snapshot object, where each access to the labels is through either the weak snapshot **update** or the weak snapshot **scan**. The resulting protocol has running time, label size, and register size all $O(n)$.

We then take the elegant randomized consensus protocol of Aspnes [5], and show that replacing atomic snapshot with weak snapshot leads to an algorithm with an expected number $O(n(p^2+n))$ of operations, matching the fastest bounded algorithm known [12]. This is an improvement of $\Omega(n)$ over the original algorithm and an improvement of $\Omega(\log n)$ over what could be obtained by using the atomic snapshot of [11].

5.1. Efficient bounded concurrent timestamping. Our definition of a concurrent timestamping system is a slightly stronger version (due to Gawlick [21]) of the one given by Dolev and Shavit in [19]. In a *concurrent timestamping system*, processes repeatedly choose *labels*, or timestamps, reflecting the real-time order of events. More precisely, each process i has a label, denoted by ℓ_i. There are two kinds of operations: **labeling** generates a new timestamp for the calling process, and **scan** returns an indexed set of labels $\bar{\ell} = \langle \ell_1, \ldots, \ell_n \rangle$ and an irreflexive total order $\prec$ on the labels.

For $1 \le i \le n$, let L_i^k (S_i^k) denote the kth **labeling** (**scan**) operation performed

1. For all c, read $label_c := \text{LABEL}_c$.
2. $label_b := f(label_1, \ldots, label_n)$.
3. Atomically write $\text{LABEL}_b := label_b$.

FIG. 5.1. **labeling** *operation for process b (Dolev–Shavit* [21]*).*

by process i (process i need not keep track of k; this is simply a notational device allowing us to describe long-lived runs of the timestamping system). Analogously, ℓ_i^k denotes the label obtained by i during L_i^k. In order to handle initial conditions, we assume that each processor has an initial label denoted by ℓ_i^0. To avoid distinguishing between these initial labels and the labels assigned by **labeling** operations we say that label l_i^0 was assigned to process i by a fictitious initial **labeling** operation L_i^0 that took place just before the beginning of the execution. Moreover, we define the L_i^0's for all i as concurrent. Correctness is defined by the following properties:

- *Ordering.* There exists an irreflexive total order $\stackrel{ts}{\Longrightarrow}$ on the set of all **labeling** operations,[8] such that the following apply:
  - *Precedence.* For any pair of **labeling** operations L_p^a and L_q^b (where p and q may be equal), if $L_p^a \longrightarrow L_q^b$, then $L_p^a \stackrel{ts}{\Longrightarrow} L_q^b$.
  - *Consistency.* For any **scan** operation S_i^k returning $(\bar{\ell}, \prec)$, $\ell_p^a \prec \ell_q^b$ if and only if $L_p^a \stackrel{ts}{\Longrightarrow} L_q^b$.
- *Regularity.* For any label ℓ_p^a in $\bar{\ell}$ returned by S_i^k, L_p^a begins before S_i^k terminates, and there is no L_p^b such that $L_p^a \longrightarrow L_p^b \longrightarrow S_i^k$.
- *Monotonicity.* Let $S_i^k, S_j^{k'}$ (where i and j may be equal) be a pair of **scan** operations returning the vectors $\bar{\ell}, \bar{\ell}'$, respectively, which contain labels ℓ_p^a, ℓ_p^b, respectively. If $S_i^k \longrightarrow S_j^{k'}$, then $a \leq b$.
- *Extended regularity.* For any label l_p^a returned by S_i^k, if $S_i^k \longrightarrow L_q^b$, then $L_p^a \stackrel{ts}{\Longrightarrow} L_q^b$.

Dolev and Shavit describe a *bounded* concurrent timestamping system that uses atomic multireader registers of size $O(n)$ and whose **scan**[9] and **labeling** operations take time $O(n^2 \log n)$ and $O(n)$, respectively. Their **labeling** operation was simply the performance of a **collect** of all labels[10] and the writing of a new label based on the ones collected. A paraphrased version of their code appears in Figure 5.1, where the variables $label_c$ and LABEL_c are the local and global shared variables that contain the current labels of process c; and f denotes the function used by Dolev and Shavit to compute a new label. The exact details of this function are not relevant here, as will be seen. The Dolev–Shavit **scan** was more involved. A paraphrased version of their code appears in Figure 5.2, where g is a procedure for computing the order among the obtained labels. Again, the exact values of k and details about g are not relevant here.

Dolev and Shavit observed that the labels can be stored in an abstract atomic snapshot object, where each access to the labels is through either atomic snapshot **update** or **scan** operation. More specifically, they would replace the **collect** performed during the **labeling** operation by an atomic snapshot **scan**, replace the simple writing

[8] Observe that this order does not have to be consistent with the partial linearization order on the time-lapse snapshot **update** and **scan** operations.

[9] Note that this **scan** is different from our time-lapse snapshot **scan**.

[10] We say that a process *collects* a variable X if it reads X_c for every process c in some arbitrary order.

1. For $i = 1$ to k
   For all c, read $label_c^i := \text{LABEL}_c$.
2. Select for each c, $label_c := label_c^i$ for some i.
3. Order $(label_1, \ldots, label_n)$ using procedure g.
4. Return $(label_1, \ldots, label_n)$ and their order.

FIG. 5.2. *Timestamping* **scan** *operation for process b (Dolev–Shavit* [21]*).*

1. Perform a time-lapse **scan** to read for all c, $label_c := \text{LABEL}_c$.
2. $label_b := f(label_1, \ldots, label_n)$.
3. Perform a time-lapse **update** to write $\text{LABEL}_b := label_b$.

FIG. 5.3. *Our* **labeling** *operation for process b.*

of the new label with an atomic snapshot **update**, and replace their entire original **scan** with an atomic snapshot **scan**. As mentioned in the introduction, this approach was successfully pursued by Gawlick, Lynch, and Shavit [22].

However, as Dolev and Shavit note, this transformation has drawbacks. The size of the atomic registers in all known implementations of atomic snapshot memory is $O(nv)$, where v is the size of the value of each process, and hence the size of the atomic registers in the resulting timestamping system is $O(n^2)$ (because here v is a label, and their labels are of size n). Second, since both **update** and **scan** operations of the snapshot take $O(n \log n)$ steps [11],[11] so do both **labeling** and **scan** operations of the resulting timestamping system. Hence, while the number of steps performed by a timestamping **scan** in the resulting timestamping system improves, the running time of the **labeling** operation increases.

We show that when we modify the Dolev–Shavit timestamping system by replacing the **collect** performed during the **labeling** operation of [19] by a time-lapse snapshot **scan**, replacing their simple writing of the new label with a time-lapse snapshot **update**, and replacing their entire original **scan** with a time-lapse snapshot **scan**, we get a timestamping system with linear running time, register size, and label size. The code for the resulting **labeling** operation appears in Figure 5.3, where f is the same function appearing in Figure 5.1. The code for the resulting timestamping **scan** operation appears in Figure 5.4, where g is the same procedure as the one of Figure 5.2.

Next we prove that the resulting system is indeed a bounded concurrent timestamping system. The proof of correctness of the Dolev–Shavit algorithm is long and involved. Rather than prove from scratch the correctness of this new algorithm (a very involved process; see [19, 22]), we argue by reduction to the correctness of the original algorithm.

LEMMA 5.1. *Our modification of the Dolev–Shavit algorithm satisfies the* regularity *and* monotonicity *properties.*

Proof. Regularity follows directly from the regularity property of weak snapshots, and monotonicity follows directly from the monotonicity of **scans** property of weak snapshot. □

The following lemma will be used to show that our modification of the Dolev–

[11]The atomic snapshot algorithm in [11], obtained more than a year after the results of this paper were obtained, is the most efficient atomic snapshot algorithm using atomic single-writer–multireader registers currently known. At the time the results of the present paper were obtained, both **labeling** and **scan** operations of the best atomic snapshot algorithm [2] took $O(n^2)$ steps.

1. Perform a time-lapse **scan** to read for all c, $label_c := \text{LABEL}_c$.
2. Order $(label_1, \ldots, label_n)$ using procedure g.
3. Return $(label_1, \ldots, label_n)$ and their order.

FIG. 5.4. *Our timestamping* **scan** *operation for process b.*

Shavit algorithm satisfies the ordering property.

LEMMA 5.2. *For each execution E of our algorithm, there exists a corresponding execution of the Dolev–Shavit algorithm that produces the same sequence of* **labeling** *operations, with corresponding* **labeling** *operations producing the same labels in both executions.*

Proof. Consider an execution L_p of the **labeling** operation. In our algorithm, when a process performs a **labeling** operation it obtains the labels of the other processes using a time-lapse snapshot **scan** and then writes the new label using a time-lapse snapshot **update**, while in the original algorithm of Dolev and Shavit these labels are obtained using a simple **collect** (one atomic read from each other process), and are written using a simple atomic write. However, since when a process performs a **collect** it reads all labels once each in an arbitrary order, and since by definition each label returned by a weak snapshot **scan** was written by a **labeling** operation, say L_q^k, that by Assumption 2.1 terminated before the **scan** did and, by regularity of time-lapse **scan**, such that no later L_q terminated before the **scan** started, we have that the set of labels returned by the weak snapshot **scan** executed by L_p could also have been returned by a simple **collect** executed in the same time interval. The claim follows because the label written by the **labeling** operation in either algorithm depends only on the set of labels obtained during this operation. □

Next we show that the first part of the ordering property is satisfied.

LEMMA 5.3. *There exists an irreflexive total order on the* **labeling** *operations in the execution of our algorithm that is consistent with the precedence relation on the* **labeling** *operations.*

Proof. This is immediate from Lemma 5.2. The total order is simply the one guaranteed by the Dolev–Shavit algorithm for the corresponding execution. More specifically, given an execution the total order on the **labeling** operations is as follows: if one **labeling** operation reads (through a weak snapshot **scan**) the label produced by another **labeling** operation, then the first operation is ordered after the second. To get the total order, Dolev and Shavit take the transitive closure of this partial order and extend it to a total order by considering the values of the labels taken by the **labeling** operations. (The exact details of how these values are taken into consideration to determine the total order are not relevant here.) □

The following lemma shows that the second part of the ordering property also is satisfied.

LEMMA 5.4. *The order produced by a* **scan** *operation of our timestamping algorithm is consistent with the total order described in the proof of Lemma* 5.3.

Proof. A **scan** operation of our timestamping algorithm obtains a set of labels via an invocation of a weak snapshot **scan**. Consider a weak snapshot **scan**, say S, performed in an execution E of our algorithm, that returns a set of labels $\bar{\ell}$. To compute the order on these labels, our algorithm invokes the appropriate procedure in the Dolev–Shavit algorithm. Therefore, it remains to show that the order on these labels produced by this procedure is consistent with the total order on the **labeling** operations defined above.

We do this in two parts. In the first part we begin with **scan** S in an execution E

of our algorithm and construct a modified execution $E1$, also containing S. We then examine a corresponding execution $\hat{E}1$ of the Dolev–Shavit algorithm, containing a corresponding **scan** $\hat{S}$ and returning the same set of labels as does S. Since the two algorithms use the same procedure to order the labels returned by a **scan**, we have by the correctness of the Dolev–Shavit algorithm that the order determined by S is consistent with the total order on the **labeling** operations in $E1$. In the second part we show that the total order on the **labeling** operations in $E1$ is consistent with their order in E.

Define a modified execution $E1$ of our algorithm where we stop each process in E after it completes the **labeling** operation that generates its label in $\bar{\ell}$. Think of a **labeling** operation L_a as a pair of time-lapse snapshot operations (S_a, U_a), where $S_a \longrightarrow U_a$. We write $L_b \Longrightarrow' L_a$ (read, L_a *observes* L_b) if $U_b \Longrightarrow S_a$.

CLAIM 5.5. *If a* **labeling** *operation L_a appears in both $E1$ and E, and $L_b^i \Longrightarrow' L_a$ in E, then L_b^i is in $E1$.*

Proof. Since L_a is in $E1$ we have that $U_a \Longrightarrow S$ in E. By assumption $L_b^i \Longrightarrow' L_a$, and thus $U_b^i \Longrightarrow S_a$, and hence $U_b^i \Longrightarrow S_a \longrightarrow U_a \Longrightarrow S$, whence by transitivity $U_b^i \Longrightarrow S$. By definition of time-lapse snapshot, S returns $v_b^{i'}$ for $i' \geq i$. Hence L_b^i is in $E1$. □

It follows from Claim 5.5 that the set of current labels in the end of $E1$ is still $\bar{\ell}$. Now, consider an execution $\hat{E}1$ of the Dolev–Shavit algorithm that corresponds to our modified execution, and extend this corresponding execution by executing at the end a **scan**, say $\hat{S}$, of the Dolev–Shavit algorithm. Clearly, $\hat{S}$ returns the same labels as in $\bar{\ell}$. The order of the labels computed by the Dolev–Shavit **scan** $\hat{S}$ is consistent with the total order on the **labeling** operations in $\hat{E}1$ (by the correctness of the Dolev–Shavit algorithm). Since the order determined on $\bar{\ell}$ by S is exactly the same as their order determined by $\hat{S}$, and since the total order on the **labeling** operations in $E1$ was defined to be identical to their order in $\hat{E}1$, we have that the order on $\bar{\ell}$ determined by S is consistent with the total order on the **labeling** operations in $E1$.

To complete the proof of the ordering property we show that the total order on the **labeling** operations in $E1$ is consistent with their order in E. That is, we show that for any two **labeling** operations L_a and L_b that appear in both executions E and $E1$, L_a is ordered before L_b in the total order on **labeling** operations in E only if L_a is ordered before L_b in the total order on **labeling** operations in $E1$. Recall how the total order is determined (see the proof of Lemma 5.3). By Claim 5.5, $L_a \Longrightarrow' L_b$ in $E1$ if and only if $L_a \Longrightarrow' L_b$ in E (and vice versa). Thus, if L_a is ordered before L_b in E and after L_b in $E1$ it must be that the order between L_a and L_b in both executions is determined based on the values of the labels taken. Thus one of these operations, without loss of generality, L_a, results in a different value in E than in $E1$. However, for this to occur there must be **labeling** operation L_c such that $L_c \Longrightarrow' L_a$ in E but $L_c \not\Longrightarrow' L_a$ in $E1$, contradicting Claim 5.5. This completes the proof of the lemma. □

Finally we show the following.

LEMMA 5.6. *Our modification of the Dolev–Shavit algorithm satisfies the* extended regularity *property.*

Proof. Recall that our time-lapse snapshot algorithm satisfies Assumption 2.1: a value returned by a **scan** was written by an **update** operation that terminated before the **scan** does. Thus, since in our timestamping system the last operation performed by a **labeling** operation is writing a new label, and since this is done by a weak snapshot **update**, each label returned by a timestamping **scan** of our system is

assigned by a **labeling** operation, say L_1, that terminated before the **scan** does, and hence before the beginning of any **labeling** operation, say L_2, preceded by the **scan**. The precedence property of timestamping implies immediately that $L_1 \stackrel{ts}{\Longrightarrow} L_2$. □

Lemmas 5.1, 5.3, 5.4, and 5.6 immediately imply the following theorem.

THEOREM 5.7. *Our modification of the Dolev–Shavit algorithm yields a bounded concurrent timestamping system.*

5.2. Efficient randomized consensus. In a *randomized consensus protocol*, each of n asynchronous processes starts with a *preference* taken from a two-element set (typically $\{0, 1\}$), and runs until it chooses a *decision value* and halts. The protocol is correct if it is *consistent*—no two processes choose different decision values; *valid*—the decision value is some process's preference; and *randomized wait-free*—each process decides after a finite expected number of steps. When computing a protocol's expected number of steps, we assume that scheduling decisions are made by an *adversary* with unlimited resources and complete knowledge of the processes' protocols, their internal states, and the state of the shared memory. The adversary cannot, however, predict future coin flips.

Celebrated work of Rabin [39] reduces randomized consensus to the construction of a *global coin*: a source of randomness visible to all participants in the protocol. Virtually all randomized consensus algorithms rely on some form of a global coin; indeed, the construction of the coin is invariably the bulk of the effort (see [16] for a survey of results on this problem in the message-passing model).

The starting point for our algorithm is the randomized consensus protocol of Aspnes [5], and in particular Aspnes's *robust weak shared coin* protocol, which guarantees that all participating processes agree on the outcome of the coin flip, and an adversary scheduler has only a slight influence on the outcome. Roughly speaking, in this protocol the n processes collectively undertake a one-dimensional random walk centered at the origin with absorbing barriers at $\pm 2n$. The shared coin is implemented by a shared counter. Each process alternates between reading the counter's position and updating it. Eventually the counter reaches one of the absorbing barriers, determining the decision value. While the counter is near the middle of the region, each process flips an unbiased local coin to determine the direction in which to move the counter. If a process observes that the counter is within n of one of the barriers, however, the process moves the counter deterministically toward that barrier.

More specifically, Figure 5.5 shows pseudocode for each process's behavior in the randomized consensus protocol. The protocol uses three shared counters: the first two maintain a total of the number of participating processes that started with inputs 0 and 1, respectively, and the last is used as the counter for the robust weak shared coin protocol. All of the counters start with an initial value of 0.

The protocol is optimized for the case where few processes participate. A process is defined to be *active* if it takes at least one step before some process decides on a value, and p denotes the total number of active processes in a given execution. The protocol uses counters a_0 and a_1 to keep track of the number of active processes by having each process increment one or the other of these counters as it starts the protocol.

Aspnes implements each of the three shared counters as an n-element array of atomic single-writer–multireader registers, one per process. All three counters are read by a single atomic snapshot scan operation that reads the arrays implementing them; i.e., all three n-elements arrays are read in one atomic snapshot scan operation that returns a value for each of the three counters. To increment or decrement counter

```
Shared data:
counter a_0 with range [0, n] and initial value 0
counter a_1 with range [0, n] and initial value 0
counter c with range [−4n, 4n] and initial value 0

FUNCTION Consensus(input)
increment a_input
repeat
        read(a_0, a_1, c)
        if c ≤ −2n then decide 0
        else if c ≥ 2n then decide 1 fi
        else if c ≤ −(a_0 + a_1) or a_1 = 0 then decrement(counter) fi
        else if c ≥ (a_0 + a_1) or a_0 = 0 then increment(counter) fi
        else
                if coin() = 0 then decrement(counter)
                else increment(counter)
        fi
end
```

FIG. 5.5. *Randomized consensus protocol (Aspnes* [5]*).*

c, a process updates, through an atomic snapshot update operation that operates on all three counters, its own field in the n-element array that implements counter c. Careful use of modular arithmetic ensures that all values in the counter implementing the robust weak shared coin remain bounded.

The expected running time of this consensus protocol, expressed in primitive reads and writes, is $O(n^2(p^2 + n))$, where p is the number of processes that actually participate in the protocol.

Since the three counters are updated and read through atomic snapshot operations, each of these counters is *linearizable* [25]: There exists a total order "$\overset{c}{\Longrightarrow}$" on increment, decrement, and read operations on each counter such that

- if $A \longrightarrow B$, then $A \overset{c}{\Longrightarrow} B$;
- each *Read* operation returns, for each counter, the sum of all increments and decrements on the counter, ordered before the *Read* by $\overset{c}{\Longrightarrow}$.

We replace the linearizable counter with a different data abstraction: by analogy with the definition of weak snapshot, a *weak counter* imposes the same two restrictions but allows $\overset{c}{\Longrightarrow}$ to be a partial order instead of a total order. Informally, concurrent *Read* operations may disagree about concurrent increment and decrement operations, but no others. We can construct a weak counter implementation from Aspnes's linearizable counter implementation simply by replacing the atomic snapshot scan (update) with a weak snapshot scan (update). We now argue that the consensus protocol remains correct if we replace the linearizable counter with a more efficient weak counter.

First notice that counters a_0 and a_1 allow the protocol to guarantee validity, since the random walk is invoked only if both have nonzero values. These counters are also used to minimize the range of the random walk, as follows. Define the *true position* of the random walk at any instant to be the value the random walk counter would assume if all operations in progress were run to completion without starting any new operations.

For reads, increments, and decrements of the counter, let R_p^i denote the ith read operation of process p, let I_q^j denote the jth increment operation by q, and let D_q^j denote the jth decrement operation by q.

Recall the definition of t_{scan} from section 3 (the latest point during the interval of the **scan** in which the spans of all values returned by the **scan** intersect). Our discussion there implies that a **scan** observes all **update**s that terminate before its t_{scan}, and does not observe any **update** that starts after its t_{scan}.

Aspnes's proof of the expected running time of the protocol hinges on the following lemma, which holds even if we replace the atomic snapshot scan by a weak snapshot scan.

LEMMA 5.8. *Let τ be the true position of the random walk at t_{scan} of R_p. If R_p returns values c, a_0, and a_1 for the random walk counter and the two active counters, then $c - (a_0 + a_1 - 1) \leq \tau \leq c + (a_0 + a_1 - 1)$.*

Proof. A process q affects the random walk's true position only if it has started to increment or decrement the random walk counter by time t_{scan}. Any q that has started to modify the random walk counter by the t_{scan} of R_p has already finished incrementing the appropriate active counter before that time, so R_p observes that increment. Thus, R_p fails to observe at most $(a_0 + a_1 - 1)$ increments or decrements active at its t_{scan}, and the result follows. □

Aspnes [5] shows that Lemma 5.8 implies the following theorem.

THEOREM 5.9 (Lemma 13 in [5]). *Let n be the total number of processes and let p be the number of processes that take at least one step before some process decides on a value. Then the worst-case expected running time of the consensus protocol is $O(p^2+n)$ counter operations (i.e., scan or update operations on the shared counters).*

A detailed proof appears in [5]. Roughly speaking, since p is both an upper bound on the distance between the value c read by a process from the random walk counter and the true position τ, and on the value of $a_0 + a_1$, we have that if $|\tau| \geq 2p$, then $|c| \geq a_0+a_1$ and the true position will move away from 0 thereafter. Thus, the random walk has two absorbing barriers at $2p, -2p$, and hence takes expected $O(p^2)$ counter operations; to this value must be added $O(n)$ counter operations until termination.

Theorem 5.9 implies the running time of our modification of Aspnes's algorithm. Recall that in our modification of this algorithm each counter operation is implemented by a time-lapse **scan** or **update**, and hence each such operation takes $O(n)$ atomic steps. Thus, Theorem 5.9 implies that the worst-case expected running time of our modification of Aspnes's algorithm is $O(n(p^2 + n))$ atomic read and writes operations.

The proof that the modified consensus protocol is consistent depends on the following lemma, which is analogous to a similar lemma in [5] and which, roughly speaking, ensures that if any one process decides that the outcome of the coin is a given value, say v, then all other processes will see values that cause them to push the counter toward v (see the code in Figure 5.5).

LEMMA 5.10. *If R_p^i returns value $v \geq 2n$, then all reads whose t_{scan} is not smaller than the t_{scan} of R_p^i will return values $\geq n+1$. (The symmetric claim holds when $v \leq -2n$.)*

Proof. Suppose not. Pick an earliest (with respect to t_{scan}) R_q^j that violates the hypothesis. Denote the t_{scan}'s of R_p^i, R_q^j by t_p, t_q, respectively. Clearly, any difference in the values returned by R_q^j and R_p^i must be caused by **update**s observed by exactly one of them (not necessarily the same one for each such **update**). It follows from the definition of t_{scan} that each **update** that completed before time t_p was observed by

R_p^i; i.e., all these **update**s are ordered before it by $\Longrightarrow$. Moreover, since $t_q \geq t_p$, it follows that each such **update** was also observed by R_q^j. Thus, only **update**s that completed after t_p may be seen by exactly one of R_p^i, R_q^j.

Consider the set S containing all **update**s that completed at or after t_p excluding, for each $z \neq p$, the first such **update**. Since each of the **update**s in S started after t_p, none of them was observed by R_p^i. Let $S1$ denote the subset of S that contains all **update**s in S that were observed by R_q^j. To complete the proof it is enough to show that each **update** in $S1$ was an increment. This immediately gives a contradiction to our assumption that R_q^j returns a value $< n+1$.

Since processes alternate between reading and modifying the counter, any **update** U_z^k in $S1$ must follow a read R_z^k that started at or after t_p and hence the t_{scan} of this read (t_z) is not smaller than t_p. In addition, any such R_z^k completes before t_q (because, since U_z^k is observed by R_q^j, it must have started at or before t_q), and hence $t_p \leq t_z < t_q$. Since R_q^j is the first to violate the claim, we have that any such R_z^k returns a value $\geq n+1$. Any counter modification that follows such a read (R_z^k) must be an increment (see step 5), and we are done. □

6. Conclusions. We have defined the weak snapshot scan primitive and constructed an efficient implementation of it. We have given two examples of algorithms designed using the strong primitive of atomic snapshot scan for which it was possible to simply replace the expensive atomic snapshot with the much less expensive weak snapshot scan. Indeed, it seems that in many cases atomic snapshot scan simply can be replaced by weak snapshot scan. Our bounded construction relied on the **Traceable Use** abstraction of Dwork and Waarts [20]. Alternatively, we could have used the weaker primitives of Vitányi and Awerbuch [44], Tromp [43], Kirousis, Spirakis, and Tsigas [30], or Singh [41]. We also mentioned the implementation for the **Traceable Use** provided by [20]; another implementation for the **Traceable Use** was recently provided by Haldar [23].

In a similar spirit to the weak snapshot, one can define a weak concurrent timestamping system, which, roughly speaking, satisfies the properties of the standard timestamping system except that the ordering $\stackrel{ts}{\Longrightarrow}$ on **labeling** operations and the $\prec$ orders on labels are *partial* rather than total. Such a timestamping system is interesting for two reasons: it is conceptually simple and it can replace standard timestamping in at least one situation: Abrahamson's randomized consensus algorithm [1].

In conclusion, we can generalize our approach as follows. Consider a concurrent object with the following sequential specification:[12]

- *Mutator* operations modify the object's state but do not return any values. Mutator operations executed by different processes commute: applying them in either order leaves the object in the same state.
- *Observer* operations return some function of the object's state but do not modify the object.

A concurrent implementation of such an object is *linearizable* if the precedence order on operations can be extended to a total order $\Longrightarrow$ such that the value returned by each observer is the result of applying all the mutator operations ordered before it by $\Longrightarrow$. This kind of object has a straightforward wait-free linearizable implementation using atomic snapshot scan [6].[13] A *weakly linearizable* implementation is one that

[12] This definition is similar to Anderson's notion of a *pseudo read-modify-write* operation [4]. Anderson, however, requires that all mutators commute, not just those applied by different processes.

[13] This implementation uses unbounded space.

permits $\Longrightarrow$ to be a partial order instead of a total order. This paper's contribution is to observe that (1) weakly linearizable objects can be implemented more efficiently than any algorithm known for their fully linearizable counterparts, and (2) there are certain important applications where one can replace linearizable objects with weakly linearizable objects, preserving the application's modular structure while enhancing performance.

Acknowledgments. We would like to thank Jim Aspnes, Hagit Attiya, and Nir Shavit for helpful discussions.

THE CONSTRUCTION OF HUFFMAN CODES IS A SUBMODULAR ("CONVEX") OPTIMIZATION PROBLEM OVER A LATTICE OF BINARY TREES*

D. STOTT PARKER† AND PRASAD RAM‡

Abstract. We show that the space of all binary Huffman codes for a finite alphabet defines a *lattice*, ordered by the imbalance of the code trees. Representing code trees as path-length sequences, we show that the imbalance ordering is closely related to a majorization ordering on real-valued sequences that correspond to discrete probability density functions. Furthermore, this tree imbalance is a partial ordering that is consistent with the total orderings given by either the external path length (sum of tree path lengths) or the entropy determined by the tree structure. On the imbalance lattice, we show the weighted path-length of a tree (the usual objective function for Huffman coding) is a *submodular* function, as is the corresponding function on the majorization lattice. Submodular functions are discrete analogues of convex functions. These results give perspective on Huffman coding and suggest new approaches to coding as optimization over a lattice.

1. Introduction.

The Huffman algorithm has been used heavily to produce efficient binary codes for almost half a century now. It has inspired a large literature with diverse theoretical and practical contributions. A comprehensive, very recent survey is [1]. Although the algorithm is quite elegant, it is tricky to prove correct and to reason about. While there may be little hope of improving on the $O(n \log n)$ complexity of the Huffman algorithm itself,[1] there is still room for improvement in our understanding of the algorithm.

There is also plenty of room for improvement in our understanding of variants of Huffman coding. Although the Huffman algorithm is remarkably robust in general and has widespread use, it is far from optimal in many real applications. Huffman coding is optimal only when the symbols to be coded are random and occur with fixed probabilities. Time-varying dependencies are not captured by the Huffman coding model, and optimal encoding of finite messages is not captured either.

Our motivation came from analysis of dynamic Huffman coding, a specific extension of Huffman coding in which the code used evolves over time. Recently, dynamic coding algorithms have been studied heavily. Our initial idea was to define "rebalancing" operations on code trees and to use these dynamically ("on the fly") in producing

[1]The algorithm is closely related to sorting, in the sense that the sorted sequence of a sequence of integer values $\langle x_1 \cdots x_n \rangle$ is obtainable directly from the optimal code tree for the values $\langle 2^{x_1} \cdots 2^{x_n} \rangle$ (e.g., [26, p. 335]).

better codes, in situations where the distribution of symbols to be coded varies over time and/or is not accurately predictable in advance.

This paper reconstructs Huffman coding as an optimization over the space of binary trees. A natural representation for this space is sequences of ascending path-lengths, since this captures what is significant in producing optimal codes.

We show that the set of path-length sequences representing binary trees forms a lattice, which we call the *imbalance lattice*. This lattice orders trees by their imbalance and gives an organization for them that is useful in optimization. Our belief is that having a better mathematical (and not purely procedural) understanding of coding will ultimately pay off in improved algorithms.

The imbalance lattice and its imbalance ordering on trees depend on *majorization* in an essential way. Majorization is an important ordering on sequences that has many applications in pure and applied mathematics [27]. We have related it to greedy algorithms directly [33]. Earlier majorization was recognized as an important property of the internal node weights produced by the Huffman algorithm [13, 32], and in this work we go further to clarify its pervasive role.

By viewing the space of trees as a lattice, a variety of new theorems and algorithms become possible. For example, the objective functions commonly used in evaluating codes are *submodular* on this lattice. Submodular functions are closely related to convex functions (as we explain later; see Theorem 4.5) and are often easy to optimize [6, 9, 23, 24, 25]. Huffman coding gives a significant example of the importance of submodularity in algorithms.

2. Ordered sequences, rooted binary trees, and Huffman codes.

2.1. Ordered sequences. By a *sequence* we mean an ordered collection of nonnegative real values such as

$$\mathbf{x} \quad = \quad \langle\, x_1\ x_2\ \cdots\ x_n\,\rangle.$$

Repetition of values in the sequence is permitted: the values x_j need not be distinct. The *length* of this sequence is n, and for simplicity we also refer to the set of such sequences with the vector notation ${\Re_+}^n$.

We introduce several useful operators on sequences:

ascending sort	$\text{sort}\uparrow(\mathbf{x})$	$=$	$\langle\ \mathbf{x}$ put in ascending order $\rangle$,
descending sort	$\text{sort}\downarrow(\mathbf{x})$	$=$	$\langle\ \mathbf{x}$ put in descending order $\rangle$,
sequence exponential	$2^{-\mathbf{x}}$	$=$	$\langle\ 2^{-x_1}\ \cdots\ 2^{-x_n}\ \rangle$,
sequence logarithm	$-\log_2(\mathbf{x})$	$=$	$\langle\ -\log_2(x_1)\ \cdots\ -\log_2(x_n)\ \rangle$.

A *density sequence* is a nonnegative real-valued sequence whose entries sum to 1.

A *distribution sequence* is an ascending nonnegative sequence whose final entry is 1.

For simplicity, throughout this paper many sequences are implicitly sorted:

$\boldsymbol{\ell}$, $\mathbf{s}$, $\mathbf{t}$, $\mathbf{u}$	denote ascending sequences of positive integer values whose sequence exponentials $2^{-\ell}$, $2^{-\mathbf{s}}$, $2^{-\mathbf{t}}$ are density sequences.
$\mathbf{w}$	denotes a descending sequence of positive real values.
$\mathbf{v}$	denotes an ascending distribution sequence.
$\mathbf{x}$, $\mathbf{y}$, $\mathbf{z}$	denote descending density sequences.

Note since $\boldsymbol{\ell}$ is ascending, $2^{-\boldsymbol{\ell}}$ is descending; and since $\mathbf{x}$ is descending, $-\log_2(\mathbf{x})$ is ascending.

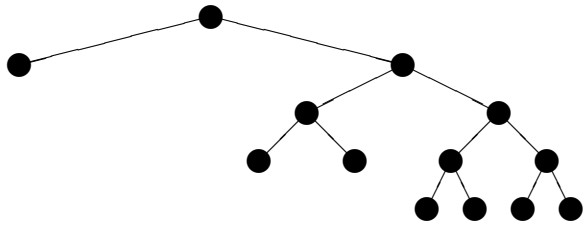

FIG. 2.1. *A binary tree having path-length sequence* $\langle\ 1\ 3\ 3\ 4\ 4\ 4\ 4\ \rangle$.

We also allow sequences to be operated upon as vectors. Thus, if $\mathbf{x}$ is a sequence (vector) of length n and A is an $n \times n$ matrix, then $A\,\mathbf{x}$ is a sequence (vector). Treating sequences as vectors allows us to define several useful operators using matrix algebra.

2.2. Rooted binary trees and path-length sequences. Rooted binary trees here are binary trees with a root node, in which every node is either a leaf node or an internal node having one parent and two children. The order of the leaves is insignificant, so a given tree is determined (up to permutation of the leaves) by the lengths of the paths from the root node to each leaf node (the distance of the leaf from the root). Thus we can represent equivalence classes of the rooted binary trees with n leaves by sequences of n nonnegative integers, which give the path-length of each leaf. For example, the path-length sequence

$$\langle\ 1\ 3\ 3\ 4\ 4\ 4\ 4\ \rangle$$

represents a binary tree with $n = 7$ leaves, of which one has path-length 1, two have path-length 3, and four have path-length 4; it is shown in Figure 2.1.

Path-length sequences obey what we call the *Kraft equality*, a special case of the Kraft inequality of noiseless coding theory (see, e.g., [10, p. 45]).

THEOREM 2.1. *For all* $n \geq 1$, $\langle\ \ell_1\ \cdots\ \ell_n\ \rangle$ *is the sequence of path-lengths in a rooted binary tree iff*

$$\sum_{i=1}^{n} 2^{-\ell_i} \quad = \quad 1.$$

Thus $\boldsymbol{\ell}$ *is a path-length sequence iff* $2^{-\boldsymbol{\ell}}$ *is a density sequence.*

Proof. The theorem is easily proven by induction on n. For the basis, with $n = 1$ we must have $\ell_1 = 0$. The induction step follows by noticing that the two principal subtrees of any binary tree must have sequences $\langle \ell'_1\ \cdots\ \ell'_p \rangle$ and $\langle \ell''_1\ \cdots\ \ell''_q \rangle$ satisfying the equality and that their composition has the sequence $\langle\ (\ell'_1+1)\ \cdots\ (\ell'_p+1)(\ell''_1+1)\ \cdots\ (\ell''_q+1)\ \rangle$, which again satisfies the equality. □

Henceforth we assume that tree path-length sequences are in ascending sorted order. Table 2.1 shows a lexicographic tabulation of all possible sequences for $1 \leq n \leq 7$, along with T_n, the total number of inequivalent sequences of length n. T_n is enumerated as sequence M0710 (A002572) in [39]. An upper bound on T_n can be obtained from the Catalan number C_n, which computes the number of unordered binary trees: for $n \geq 3$, $T_n \leq \frac{1}{2}C_n \leq 2^{n-3}$. Gilbert [12], using the notation $g(N)$ for T_N, points out that T_n is well approximated for $n \leq 30$ by

$$T_n \quad \simeq \quad 0.148\ (1.791)^n.$$

2.3. Huffman codes are optimal path-length sequences. A Huffman code for a given positive weight sequence

$$w_1 \;\geq\; w_2 \;\geq\; \cdots \;\geq\; w_n$$

consists of a binary tree, i.e., a path-length sequence $\boldsymbol{\ell} = \langle\, \ell_1\, \ell_2\, \cdots\, \ell_n \,\rangle$, which we evidently want to be in ascending order,

$$\ell_1 \;\leq\; \ell_2 \;\leq\; \cdots \;\leq\; \ell_n,$$

so that the weighted path-length

$$g_{\mathbf{w}}(\boldsymbol{\ell}) \quad = \quad \sum_{i=1}^{n} w_i\, \ell_i$$

is minimal. Beyond the Kraft equality of Theorem 2.1, it is difficult to characterize what it is that makes $\boldsymbol{\ell}$ optimal. For example, Table 2.2 shows all feasible codes and costs for the weight sequence $\mathbf{w} = \langle$ 189 95 73 71 28 23 21 $\rangle$, with $n = 7$.

Huffman's breakthrough [18] was to identify an efficient algorithm that finds an optimal tree, avoiding a search over the exponentially large space of trees. The algorithm repeatedly combines the two tree leaves with least weight, whose sum becomes the weight of a new leaf. The Huffman (optimal) tree in Table 2.2 has path lengths $\boldsymbol{\ell} = \langle$ 1 3 3 3 4 5 5 $\rangle$ and total weighted path-length 1238. The Huffman algorithm reflects a divide-and-conquer structure that has interesting properties on the space of trees, but because of its procedural nature does little to characterize optimal trees.

3. The imbalance lattice of binary trees. The optimality of a Huffman code is determined by the match between the balance (or imbalance) between the code tree and the weights of the symbols to be coded. In this section we show ternary balancing exchanges give an imbalance ordering on binary trees that defines a lattice.

The idea of using lattices in coding dates back at least to Shannon in 1950 [38]. However, we have not found the lattice characterization of tree imbalance elsewhere. Following considerable work in the early 1980s on enumeration of trees, Pallo classified trees by their *rotational* structure (e.g., [30, 31]) and showed that they then form a lattice. Our work differs from Pallo's in that we classify trees by their *path-length* (imbalance) structure.

3.1. Important properties of tree path-length sequences.

THEOREM 3.1. *Every path-length sequence* $\boldsymbol{\ell}$ *has the form*

$$\boldsymbol{\ell} \quad = \quad \langle \ \cdots \ (q-j) \ \overbrace{q \ \cdots \ q}^{2k} \ \rangle,$$

a sequence including $2k$ *copies of its largest value* q *(where* $j, k > 0$*). Also,* j *is at most the largest exponent of* 2 *in* $2k$*, and therefore* $j \leq \log_2(2k)$.

Proof. $\boldsymbol{\ell}$ must include $2k$ copies of its largest value q since otherwise $\left(2^q \cdot \sum_{i=1}^{n} 2^{-\ell_i}\right)$ is odd, contradicting the Kraft equality. Using this argument again on the shorter path-length sequence obtained by replacing the $2k$ copies of q with k copies of $(q-1)$, the Kraft equality requires not only that $j > 0$ but also that j be at most the number of times that 2 divides $2k$. ∎

THEOREM 3.2. *Except for the sequence* $\langle\ 1\ 2\ 3\ \ldots\ (n-2)\ (n-1)\ (n-1)\ \rangle$*, any path-length sequence contains at least three identical values.*

Proof. The proof is by induction on the length n of the sequence. For the basis, when $n = 3$ the only sequence is $\langle\ 1\ 2\ 2\ \rangle$, satisfying the theorem. For the induction step, suppose $n > 3$, and to the contrary of the theorem that there is a sequence does not have three identical values. Let q be the smallest value in the sequence appearing twice. We may assume $q < (n-1)$, since otherwise the sequence is $\langle\ 1\ 2\ 3\ \ldots\ (n-2)\ (n-1)\ (n-1)\ \rangle$. Construct the sequence of length $n-1$ that results from replacing the two values q with one value $(q-1)$. In this new sequence, q does not appear at all (since there were only two before), and $(q-1)$ appears at most twice. Therefore, by induction, since this sequence does not have three identical values it is $\langle\ 1\ 2\ 3\ \ldots\ (n-3)\ (n-2)\ (n-2)\ \rangle$. But since $q < (n-1)$ and q does not appear in the new sequence, this gives a contradiction. ∎

3.2. Ternary exchanges determine tree imbalance. The insight that inspired us to write this paper is that it is possible to generate all binary tree path-length sequences using ternary exchanges. Given any path-length sequence

$$\langle \cdots \qquad p \qquad \cdots\cdots\cdots \quad (q+1) \quad (q+1) \quad \cdots \rangle,$$

then the revision

$$\langle \cdots \quad (p+1) \quad (p+1) \quad \cdots\cdots\cdots \qquad q \qquad \cdots \rangle$$

is a path-length sequence also, because

$$2^{-p} + 2^{-(q+1)} + 2^{-(q+1)} \quad = \quad 2^{-p} + 2^{-q} \quad = \quad 2^{-(p+1)} + 2^{-(p+1)} + 2^{-q}.$$

Moreover, if the initial sequence is sorted in ascending order (so $p \leq q$) and we replace the rightmost p and leftmost two $(q+1)$s, then the resulting sequence is still sorted.

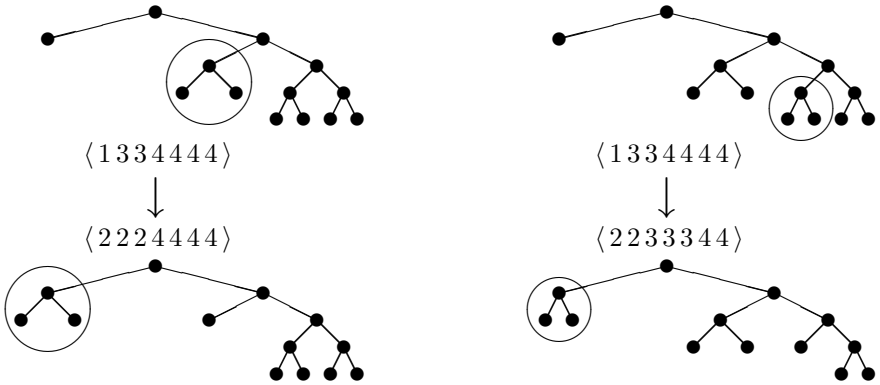

FIG. 3.1. *Balancing exchanges:* $\langle 1\,3\,3\,4\,4\,4\,4\rangle \rightarrow \langle 2\,2\,2\,4\,4\,4\,4\rangle$ *and* $\langle 1\,3\,3\,4\,4\,4\,4\rangle \rightarrow \langle 2\,2\,3\,3\,3\,4\,4\rangle$.

(When $p = q$ the two sequences are identical.) Dually, this exchange can be applied in reverse; with sorted sequences, if we replace the leftmost two $(p+1)$s and the rightmost $(q-1)$, the result will still be sorted in ascending order.

The net effect of this exchange is to transfer two leaves dangling from level q to level p. The two examples in Figure 3.1 show this pictorially.

DEFINITION 3.3. *Let p, q be integers such that $1 \le p < q < n$. A* balancing exchange *is a ternary exchange of the form*

$$\begin{array}{lccccccc} \langle\cdots & p & & \cdots\cdots & & (q+1) & (q+1) & \cdots\rangle \\ & \downarrow & \searrow & & \cdots & & \searrow & \downarrow \\ \langle\cdots & (p+1) & (p+1) & & & \cdots\cdots & q & \cdots\rangle. \end{array}$$

It is called a minimal balancing exchange *if $(p+1) = q$. An* imbalancing exchange *is of the reverse form,*

$$\begin{array}{lccccccc} \langle\cdots & (p+1) & (p+1) & & \cdots\cdots & & q & \cdots\rangle \\ & \downarrow & \swarrow & & \cdots & \swarrow & \downarrow & \\ \langle\cdots & p & & \cdots\cdots & & (q+1) & (q+1) & \cdots\rangle. \end{array}$$

Finally, we can define partial orders as the reflexive transitive closures of these relations among sequences. Given two sequences $\mathbf{s}$ *and* $\mathbf{t}$*, we say that* $\mathbf{s}$ *is at least as balanced as* $\mathbf{t}$*,*

$$\mathbf{s} \quad \trianglelefteq \quad \mathbf{t},$$

if there are sequences $\boldsymbol{\ell}_1, \ldots, \boldsymbol{\ell}_m$ $(m \ge 1)$ where $\mathbf{t} = \boldsymbol{\ell}_1$, $\boldsymbol{\ell}_m = \mathbf{s}$, and for each i, $1 \le i < m$, there is a balancing exchange from $\boldsymbol{\ell}_i$ to $\boldsymbol{\ell}_{i+1}$.

Minimal balancing exchanges, in which $(p+1) = q$, are particularly significant. The balancing exchange $\langle\, 1\,3\,3\,4\,4\,4\,4\,\rangle \rightarrow \langle\, 2\,2\,2\,4\,4\,4\,4\,\rangle$ in Figure 3.1 gives an example. Minimal balancing exchanges are *ternary exchanges of consecutive length values*, so any tree path-length sequence of the form $\langle\cdots\ (q-1)\ \cdots\ (q+1)\ (q+1)\ \cdots\rangle$ determines the more balanced tree path-length sequence $\langle\cdots\ q\ \cdots\ q\ q\ \cdots\rangle$ and vice versa.

THEOREM 3.4. *If two path-length sequences differ, they differ in at least three values. Also, if they differ in exactly three values, there is a ternary exchange between the sequences.*

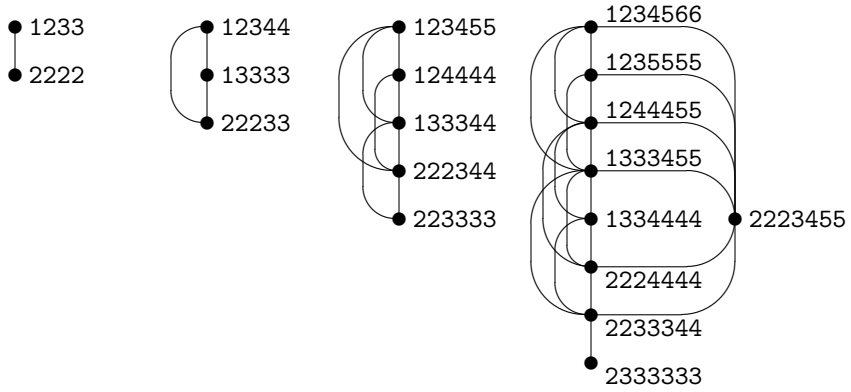

FIG. 3.2. *The path-length imbalance ordering for $n = 4,\ 5,\ 6,\ 7$; edges denote ternary exchanges.*

Proof. Direct consequence of the Kraft equality. The equality shows that two path-length sequences cannot differ in one value. Similarly, there cannot be sequences $\mathbf{s}$ and $\mathbf{t}$ differing in two values, since if the differences were the disjoint sequences of positive integers $\langle\ s_i\ s_j\ \rangle$ and $\langle\ t_i\ t_j\ \rangle$, then the Kraft equality would imply $2^{-s_i} + 2^{-s_j} = 2^{-t_i} + 2^{-t_j}$, which is false under the disjointness condition. Finally, sequences differing in three integer values $\langle\ s_i\ s_j\ s_k\ \rangle$ and $\langle\ t_i\ t_j\ t_k\ \rangle$ must satisfy $2^{-s_i} + 2^{-s_j} + 2^{-s_k} = 2^{-t_i} + 2^{-t_j} + 2^{-t_k}$, and a case analysis shows that this is solved only by $\langle\ s_i\ s_j\ s_k\ \rangle = \langle\ p\ (q{+}1)\ (q{+}1)\ \rangle$ and $\langle\ t_i\ t_j\ t_k\ \rangle = \langle\ (p{+}1)\ (p{+}1)\ q\ \rangle$, corresponding to a ternary exchange. ∎

THEOREM 3.5. *The path-length imbalance ordering is a partial order.*

Proof. It is reflexive and transitive by construction. Also the imbalance ordering is antisymmetric, since $\mathbf{s} \trianglelefteq \mathbf{t}$ and $\mathbf{t} \trianglelefteq \mathbf{s}$ together imply $\mathbf{s} = \mathbf{t}$. Otherwise there would be a sequence of balancing exchanges that transform $\mathbf{t}$ to $\mathbf{s}$ and ultimately back to $\mathbf{t}$; this is not possible, since each balancing exchange reduces by at least one the sum of the values in the sequence. ∎

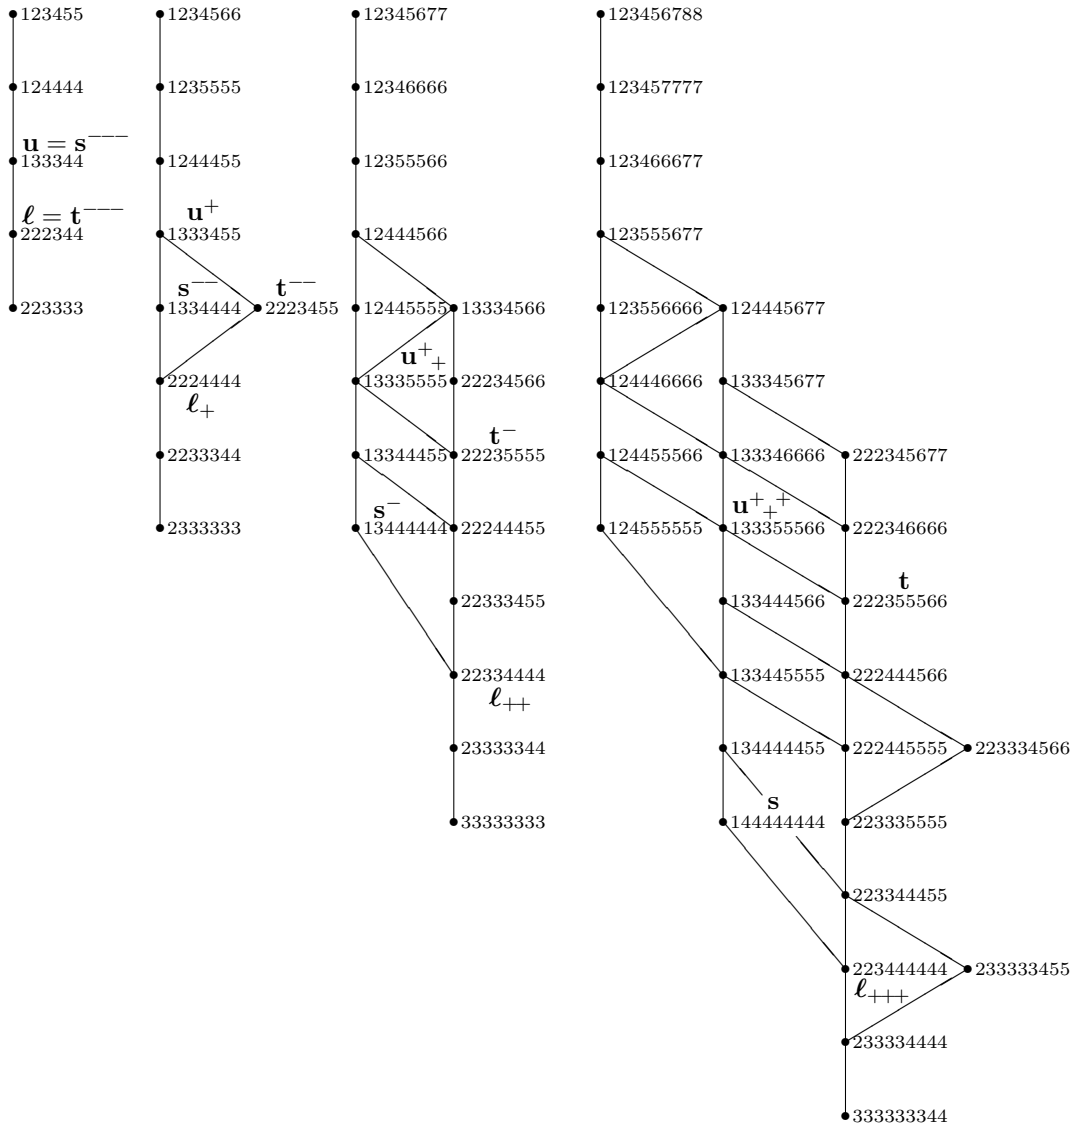
The imbalance partial order is straightforward to derive for small values of n. In Figure 3.2, it is displayed for $n = 4, 5, 6, 7$. The most imbalanced sequence appears at the top of the partial order, and an edge from a sequence $\mathbf{s}$ down to another $\mathbf{t}$ means that a balancing exchange is possible from $\mathbf{s}$ to $\mathbf{t}$. It is evident from Figure 3.2 that the minimal exchanges define the bulk of the ordering. In order to provide a deeper appreciation for its structure, Figure 3.3 presents the ordering for $n = 6, 7, 8, 9$. Figures 3.2 and 3.3 suggest a number of results about the imbalance ordering.

THEOREM 3.6. *A sequence is on level k of the imbalance partial order (counting from 0, the topmost and least balanced level)* iff *k minimal balancing exchanges are needed to derive it from the least balanced sequence $\langle\ 1\ 2\ 3\ \cdots\ (n{-}2)\ (n{-}1)\ (n{-}1)\ \rangle$. In this situation the sum of the values in the sequence is*

$$\frac{(n+2)(n-1)}{2} \quad - \quad k.$$

Thus the level of a sequence in the partial order is determined by the sum of its path-length values.

Proof. By induction on k. For the basis $k = 0$, the sum of the path-lengths in the least balanced sequence is $(\sum_{i=1}^{n-1} i) + (n{-}1) = (n+2)(n-1)/2$. For the induction step, consider a sequence whose sum of values is $\frac{(n+2)(n-1)}{2} - k$ with $k > 0$. By



s	t	s ∨ t	s ∧ t
⟨ 1 4 4 4 4 4 4 4 4 4 ⟩	⟨ 2 2 2 3 5 5 5 6 6 ⟩	⟨ 1 3 3 3 5 5 5 6 6 ⟩	⟨ 2 2 3 4 4 4 4 4 4 ⟩
⟨ 1 4 4 4 4 4 4 4 4 ⟩	⟨ 2 2 3 3 3 4 5 6 6 ⟩	⟨ 1 3 3 4 4 4 5 6 6 ⟩	⟨ 2 2 3 4 4 4 4 4 4 ⟩
⟨ 1 3 4 4 4 4 4 4 5 5 ⟩	⟨ 2 2 3 3 3 3 4 5 6 6 ⟩	⟨ 1 3 3 4 4 4 5 6 6 ⟩	⟨ 2 2 3 3 4 4 4 5 5 ⟩
⟨ 1 2 4 5 5 5 5 5 5 ⟩	⟨ 2 2 3 3 3 3 4 5 6 6 ⟩	⟨ 1 2 4 4 5 5 5 6 6 ⟩	⟨ 2 2 3 3 3 3 5 5 5 5 ⟩
⟨ 1 2 4 5 5 5 5 5 5 ⟩	⟨ 2 2 2 3 4 5 6 7 7 ⟩	⟨ 1 2 4 4 4 5 6 7 7 ⟩	⟨ 2 2 2 4 4 5 5 5 5 ⟩
⟨ 1 2 4 4 5 5 5 6 6 ⟩	⟨ 2 2 2 3 4 5 6 7 7 ⟩	⟨ 1 2 4 4 4 5 6 7 7 ⟩	⟨ 2 2 2 3 5 5 5 6 6 ⟩

FIG. 3.3. *The imbalance lattice, showing path-length sequences ordered by imbalance. The sequence* ⟨ 1 2 3 4 ⋯ ⟩ *is maximally imbalanced. The graphs display the (transitively reduced) path-length imbalance ordering for* $n = 6, 7, 8, 9$. *For clarity, only a minimal subset of the imbalance ordering is drawn; orderings in the transitive closure of the minimal set are omitted. The imbalance ordering is also a lattice, with well-defined upper bounds* $\mathbf{s} \vee \mathbf{t}$ *and lower bounds* $\mathbf{s} \wedge \mathbf{t}$ *for every pair of trees* $\mathbf{s}$ *and* $\mathbf{t}$. *Some trees are marked to clarify certain notions (contractions, lower expansions, and upper expansions), and their use in derivation of the first entry in the table of representative upper and lower bounds for* $n = 9$.

Theorem 3.2, this sequence must contain at least three identical values $\langle\, q\, q\, q \,\rangle$. Thus there is a minimal balancing exchange to this sequence from another that contains $\langle\, (q-1)\, (q+1)\, (q+1) \,\rangle$. This sequence is at level $k-1$ by construction, and by induction it has the stated sum. □

Theorem 3.6 shows the significance of the level of a sequence in the imbalance partial order.

DEFINITION 3.7. *The* level of balance *of a path-length sequence* $\mathbf{s}$ *is*

$$\frac{(n+2)(n-1)}{2} \quad - \quad (\textit{sum of the path-length values in } \mathbf{s}).$$

3.3. Contractions and expansions of path-length sequences.

DEFINITION 3.8. *Let* $\boldsymbol{\ell} = \langle\, \ell_1 \cdots \ell_n \,\rangle$ *be a tree path-length sequence of length* n. *The* contraction $\boldsymbol{\ell}^-$ *of* $\boldsymbol{\ell}$ *is the sequence of length* $(n-1)$ *defined by*

$$\boldsymbol{\ell}^- \quad = \quad \text{sort}\uparrow (\, \langle\, \ell_1 \ \cdots \ \ell_{n-2} \ \ (\ell_{n-1} - 1) \,\rangle \,).$$

The position i expansion of $\boldsymbol{\ell}$ *is the sequence of length* $(n+1)$ *defined by*

$$\text{sort}\uparrow (\, \langle\, \ell_1 \ \cdots \ \ell_{i-1} \ (\ell_i+1) \ (\ell_i+1) \ \ell_{i+1} \ \cdots \ \ell_n \,\rangle \,).$$

As permitted by Theorem 3.1, *if we write*

$$\boldsymbol{\ell} \quad = \quad \langle \ \cdots \ (q-j) \ \overbrace{q \ \cdots \ q}^{2k} \ \rangle$$

with j, $k > 0$, *then* $2k$ *is the* suffix length *of* $\boldsymbol{\ell}$, *and* j *is the* suffix increment *of* $\boldsymbol{\ell}$. *The* contraction $\boldsymbol{\ell}^-$ *is then*

$$\boldsymbol{\ell}^- \quad = \quad \langle \ \cdots \ (q-j) \ \ (q-1) \ \overbrace{q \ \cdots \ q}^{2k-2} \ \rangle.$$

The lower expansion $\boldsymbol{\ell}_+$ *is the position* $n - 2k$ *expansion of* $\boldsymbol{\ell}$:

$$\boldsymbol{\ell}_+ \quad = \quad \langle \ \cdots \ (q-j+1) \ \ (q-j+1) \ \overbrace{q \ \cdots \ q}^{2k} \ \rangle.$$

The upper expansion $\boldsymbol{\ell}^+$ *is the position* n *expansion of* $\boldsymbol{\ell}$:

$$\boldsymbol{\ell}^+ \quad = \quad \langle \ \cdots \ (q-j) \ \overbrace{q \ \cdots \ q}^{2k-1} \ \ (q+1) \ \ (q+1) \ \rangle.$$

Note the definition for $\boldsymbol{\ell}_+$ assumes $2k < n$. When $2k = n$, requiring n to be a power of 2 and $\boldsymbol{\ell} = \langle\, q \ \cdots \ q \,\rangle$, where $q = \log_2(n)$, the formula above does not define $\boldsymbol{\ell}_+$. In this very special case we define $\boldsymbol{\ell}_+ = \boldsymbol{\ell}^+$ rather than leave $\boldsymbol{\ell}_+$ undefined.

These definitions will be used heavily throughout the rest of the paper. Figure 3.4 and Table 3.1 give examples for $n = 7$. Figure 3.3 also gives examples illustrating the relationships these definitions produce among the imbalance orderings for successive values of n.

THEOREM 3.9. *If* $\boldsymbol{\ell}$ *is a path-length sequence,* $\boldsymbol{\ell}_+ \trianglelefteq \boldsymbol{\ell}^+$ *and* $(\boldsymbol{\ell}_+)^- \trianglelefteq (\boldsymbol{\ell}^+)^- = \boldsymbol{\ell}$. *Furthermore, either* $\boldsymbol{\ell} = (\boldsymbol{\ell}^-)_+$, *or* $\boldsymbol{\ell} = (\boldsymbol{\ell}^-)^+$. *Thus* $(\boldsymbol{\ell}^-)_+ \trianglelefteq \boldsymbol{\ell} \trianglelefteq (\boldsymbol{\ell}^-)^+$.

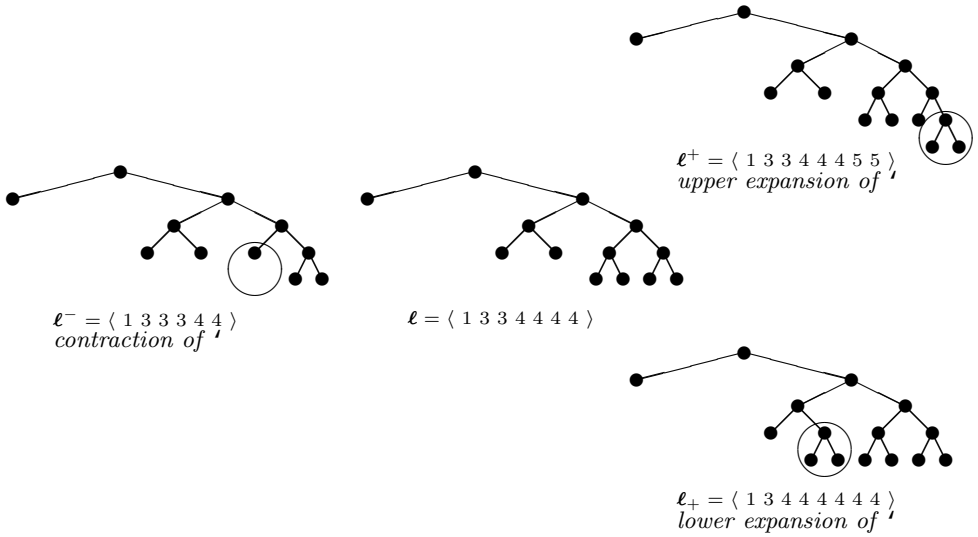

FIG. 3.4. *The contraction and expansions of the path-length sequence* $\boldsymbol{\ell} = \langle\ 1\ 3\ 3\ 4\ 4\ 4\ 4\ \rangle$.

Proof. $\boldsymbol{\ell}_+$ and $\boldsymbol{\ell}^+$ differ by a ternary exchange, so $\boldsymbol{\ell}_+ \trianglelefteq \boldsymbol{\ell}^+$. From Theorem 3.1 we can assume

$$\boldsymbol{\ell} \;=\; \langle \cdots (q{-}j)\, \overbrace{q \cdots q}^{2k} \rangle,$$

and thus $(\boldsymbol{\ell}^+)^- = \boldsymbol{\ell}$. Furthermore $(\boldsymbol{\ell}_+)^- = \boldsymbol{\ell}$ if $j = 1$ and

$$(\boldsymbol{\ell}_+)^- \;=\; \langle \cdots (q{-}j{+}1)(q{-}j{+}1)(q{-}1)\, \overbrace{q \cdots q}^{2k-2} \rangle \trianglelefteq \boldsymbol{\ell}$$

if $j > 1$. Finally $(\boldsymbol{\ell}^-)^+ = \boldsymbol{\ell}$ if $k = 1$ (necessitating $j = 1$) and $(\boldsymbol{\ell}^-)_+ = \boldsymbol{\ell}$ if $k > 1$. Consequently $\boldsymbol{\ell} \in \{\, (\boldsymbol{\ell}^-)_+,\ (\boldsymbol{\ell}^-)^+ \,\}$. □

THEOREM 3.10. *If* $\mathbf{s} \trianglelefteq \mathbf{t}$, *then* $\mathbf{s}^- \trianglelefteq \mathbf{t}^-$, $\mathbf{s}_+ \trianglelefteq \mathbf{t}_+$, *and* $\mathbf{s}^+ \trianglelefteq \mathbf{t}^+$.

Proof. Recall that if $\mathbf{s} \trianglelefteq \mathbf{t}$, then there are sequences $\boldsymbol{\ell}_1, \ldots, \boldsymbol{\ell}_m$ $(m \geq 1)$ such that $\mathbf{t} = \boldsymbol{\ell}_1$, $\boldsymbol{\ell}_m = \mathbf{s}$ and for each i, $1 \leq i < m$, there is a balancing exchange from

$\boldsymbol{\ell}_i$ to $\boldsymbol{\ell}_{i+1}$. Our approach here is very simple: to prove $\mathbf{s}^- \trianglelefteq \mathbf{t}^-$ we convert the derivation $\mathbf{t} = \boldsymbol{\ell}_1, \ldots, \boldsymbol{\ell}_m = \mathbf{s}$ directly to the derivation $\mathbf{t}^- = \boldsymbol{\ell}_1{}^-, \ldots, \boldsymbol{\ell}_m{}^- = \mathbf{s}^-$. For this it is sufficient to show that either each step from $(\boldsymbol{\ell}_i)^-$ to $(\boldsymbol{\ell}_{i+1})^-$ is a balancing exchange, or $(\boldsymbol{\ell}_i)^- = (\boldsymbol{\ell}_{i+1})^-$. The former must hold if $\boldsymbol{\ell}_i$ and $\boldsymbol{\ell}_{i+1}$ agree in the final two positions. If they disagree,

$$\begin{array}{rcccccccccc} \boldsymbol{\ell}_i & = & \langle & \cdots & & p & & a & \cdots & b & q \quad q & \rangle, \\ \boldsymbol{\ell}_{i+1} & = & \langle & \cdots & (p{+}1) & (p{+}1) & & a & \cdots & b & (q{-}1) & \rangle \end{array}$$

because they define a balancing exchange, and by Theorem 3.1 necessarily $b = (q{-}1)$. Then

$$\begin{array}{rcccccccccc} (\boldsymbol{\ell}_i)^- & = & \mathrm{sort}{\uparrow}(\langle & \cdots & & p & & a & \cdots & (q{-}1) \quad (q{-}1) & \rangle), \\ (\boldsymbol{\ell}_{i+1})^- & = & \mathrm{sort}{\uparrow}(\langle & \cdots & (p{+}1) & (p{+}1) & & a & \cdots & (q{-}2) & \rangle). \end{array}$$

If $(p{+}1) = b = (q{-}1)$, then $p = (q{-}2)$ and the two contractions are equal. If not, they still differ by a balancing exchange. Proving $\mathbf{s}_+ \trianglelefteq \mathbf{t}_+$ is similar, where $(\boldsymbol{\ell}_i)_+ = (\boldsymbol{\ell}_{i+1})_+$ iff $\boldsymbol{\ell}_i = \langle \cdots (q{-}j)\ q\ q \cdots q \rangle$, $\boldsymbol{\ell}_{i+1} = \langle \cdots (q{-}j{+}1)\ (q{-}j{+}1)\ (q{-}1) \cdots q \rangle$ and $j \geq 2$. Proving $\mathbf{s}^+ \trianglelefteq \mathbf{t}^+$ is also similar, but easier, since then it is never the case that $(\boldsymbol{\ell}_i)^+ = (\boldsymbol{\ell}_{i+1})^+$. ∎

3.4. The vector lattice and distribution lattice. Recall [5] that a *lattice* is an algebra $\langle \mathcal{S}, \sqsubseteq, \sqcap, \sqcup \rangle$ in which $\mathcal{S}$ is a set, $\sqsubseteq$ is a partial ordering on $\mathcal{S}$, and for all $a, b \in \mathcal{S}$, there is a unique *greatest lower bound (glb)* $a \sqcap b$ and *least upper bound (lub)* $a \sqcup b$. The lattice is called *distributive* if these operators satisfy the distributive law:

$$\text{for all } a, b, c \text{ in } \mathcal{S}, \quad a \sqcap (b \sqcup c) \quad = \quad (a \sqcap b) \sqcup (a \sqcap c).$$

Optionally the lattice can have a *greatest element* $\top$ and *least element* $\bot$.

DEFINITION 3.11. *Let* $\leq_{vec}$ *be the element-wise ordering on vectors (sequences) in* $\Re^n$. *Then*

$$\mathbf{x} \leq_{vec} \mathbf{y} \quad \textit{iff} \quad x_i \leq y_i \ \textit{for } 1 \leq i \leq n.$$

Also define vector element-wise minima and maxima as

$$\begin{array}{rcccccc} \mathbf{x} & \mathbf{min}_{vec} & \mathbf{y} & = & \langle & \min(x_1, y_1) \cdots \min(x_n, y_n) & \rangle, \\ \mathbf{x} & \mathbf{max}_{vec} & \mathbf{y} & = & \langle & \max(x_1, y_1) \cdots \max(x_n, y_n) & \rangle. \end{array}$$

THEOREM 3.12. *The nonnegative vectors* $\langle {\Re_+}^n, \leq_{vec}, \mathbf{min}_{vec}, \mathbf{max}_{vec} \rangle$ *form a distributive lattice called the* vector lattice.

The set $\mathcal{P}$ *of distribution sequences of length* n *(ascending nonnegative vectors* $\mathbf{v}$ *with* $v_n = 1$*) also form a distributive lattice,* $\langle \mathcal{P}, \leq_{vec}, \mathbf{min}_{vec}, \mathbf{max}_{vec} \rangle$, *called the* distribution lattice, *with least element* $\bot = \langle 0\,0 \cdots 0\,1 \rangle$ *and greatest element* $\top = \langle 1\,1 \cdots 1\,1 \rangle$.

Proof. The one-dimensional algebra $\langle \Re_+, \leq, \min, \max \rangle$ is a distributive lattice. The vector properties required here follow from this. ∎

3.5. The majorization lattice and density lattice. We reproduce basic majorization concepts developed in [34]. Majorization as defined here is an extension of the classical majorization of Muirhead and Hardy, Littlewood, and Pólya [16], which is useful in the study of inequalities. Marshall and Olkin [27] provide a very good account of the classical theory and its applications. The classical theory defines

a majorization ordering on descendingly ordered (or sometimes ascendingly ordered) multisets, and although quite beautiful it is also quite complex. We have transplanted the theory to rely only on linear algebra and convexity. Thus the definitions in this section are ours, and the results vary from those in [27].

DEFINITION 3.13. *The* zeta matrix $\int = (\zeta_{ij})$ *is defined by*

$$\zeta_{ij} \;=\; 1 \text{ if } i \geq j, \quad 0 \text{ otherwise.}$$

The Möbius matrix $\boldsymbol{\partial} = (\mu_{ij})$ *is defined by*

$$\mu_{ij} \;=\; 1 \text{ if } i = j, \quad -1 \text{ if } j = i-1, \quad 0 \text{ otherwise.}$$

The Möbius matrix is the inverse of the zeta matrix. For example, when $n = 5$:

$$\int \;=\; \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 \\ 1 & 1 & 1 & 1 & 1 \end{pmatrix} \qquad \boldsymbol{\partial} \;=\; \int^{-1} \;=\; \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 & 0 \\ 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & -1 & 1 \end{pmatrix}.$$

The Möbius matrix is also significant in that it corresponds directly to the concept of pairwise exchange (of adjacent elements in a sequence). The theory of Möbius inversion [36] gives a generalized notion of differential on partially ordered domains (although here we consider only totally ordered sequences). We can think of $\int$ as an integral operator (which transforms a sequence to its left-to-right "integral"), with $\boldsymbol{\partial}$ as its inverse differential operator.

THEOREM 3.14. *If* $\mathbf{x}$ *and* $\mathbf{y}$ *are density sequences (so* $\sum_{i=1}^{n} x_i = \sum_{i=1}^{n} y_i = 1$*), then*

$$\mathbf{x} \;\preceq\; \mathbf{y} \qquad \textit{iff} \qquad (\textstyle\int \mathbf{x}) \;\leq_{vec}\; (\int \mathbf{y}).$$

If $\mathbf{v}$ *and* $\mathbf{v}'$ *are distribution sequences, then* $\boldsymbol{\partial}\,\mathbf{v}$ *and* $\boldsymbol{\partial}\,\mathbf{v}'$ *are density sequences and*

$$\mathbf{v} \;\leq_{vec}\; \mathbf{v}' \qquad \textit{iff} \qquad (\boldsymbol{\partial}\,\mathbf{v}) \;\preceq\; (\boldsymbol{\partial}\,\mathbf{v}').$$

Proof. $(\int \mathbf{x}) \leq_{vec} (\int \mathbf{y})$ is equivalent to

$$x_1 \;\leq\; y_1, \qquad x_1 + x_2 \;\leq\; y_1 + y_2, \qquad \ldots, \qquad x_1 + x_2 + \cdots + x_n \;\leq\; y_1 + y_2 + \cdots + y_n.$$

Note that $\mathbf{x}$ is a density sequence iff $(\int \mathbf{x})$ is a distribution sequence. The second statement then follows since the Möbius and zeta transformations are inverses of one another. □

This isomorphism between $\leq_{vec}$ and $\preceq$ implies that majorization defines a lattice.

DEFINITION 3.15. *Majorization lub and glb operators are definable by*

$$\begin{aligned} \mathbf{x} \;\sqcup\; \mathbf{y} \;&=\; \boldsymbol{\partial}\,((\textstyle\int \mathbf{x}) \;\mathbf{max}_{vec}\; (\int \mathbf{y})), \\ \mathbf{x} \;\sqcap\; \mathbf{y} \;&=\; \boldsymbol{\partial}\,((\textstyle\int \mathbf{x}) \;\mathbf{min}_{vec}\; (\int \mathbf{y})). \end{aligned}$$

THEOREM 3.16. *The nonnegative reals ordered by majorization forms a distributive lattice* $\langle \Re_+{}^n, \preceq, \sqcap, \sqcup \rangle$ *called the* majorization lattice.

The set $\mathcal{D}$ *of density sequences of length* n *(nonnegative* $\mathbf{x}$ *with* $\sum_{i=1}^{n} x_i = 1$*) forms a distributive lattice* $\langle \mathcal{D}, \preceq, \sqcap, \sqcup, \bot, \top \rangle$ *called the* density lattice*, with least element* $\bot = \langle 0\,0 \cdots 0\,1 \rangle$ *and greatest element* $\top = \langle 1\,0 \cdots 0\,0 \rangle$.

Proof. The transformation $\mathbf{x} \mapsto \int\mathbf{x}$ defines a lattice isomorphism between the vector and majorization lattices and between the distribution and density lattices. Here $\mathbf{x} \sqcap \mathbf{y}$ and $\mathbf{x} \sqcup \mathbf{y}$ are defined just so as to be the majorization glb and lub:

$$\begin{array}{l|l}
\mathbf{z} \preceq \mathbf{x},\quad \mathbf{z} \preceq \mathbf{y} & \mathbf{x} \preceq \mathbf{z},\quad \mathbf{y} \preceq \mathbf{z} \\
\Leftrightarrow\quad (\textstyle\int\mathbf{z}) \leq_{vec} (\int\mathbf{x}),\ (\int\mathbf{z}) \leq_{vec} (\int\mathbf{y}) & \Leftrightarrow\quad (\textstyle\int\mathbf{x}) \leq_{vec} (\int\mathbf{z}),\ (\int\mathbf{y}) \leq_{vec} (\int\mathbf{z}) \\
\Leftrightarrow\quad (\textstyle\int\mathbf{z}) \leq_{vec} ((\int\mathbf{x})\ \mathbf{min}_{vec}\ (\int\mathbf{y})) & \Leftrightarrow\quad ((\textstyle\int\mathbf{x})\ \mathbf{max}_{vec}\ (\int\mathbf{y})) \leq_{vec} (\int\mathbf{z}) \\
\Leftrightarrow\quad \mathbf{z} \preceq \boldsymbol{\partial}((\textstyle\int\mathbf{x})\ \mathbf{min}_{vec}\ (\int\mathbf{y})) & \Leftrightarrow\quad \boldsymbol{\partial}((\textstyle\int\mathbf{x})\ \mathbf{max}_{vec}\ (\int\mathbf{y})) \preceq \mathbf{z} \\
\Leftrightarrow\quad \mathbf{z} \preceq \mathbf{x} \sqcap \mathbf{y}. & \Leftrightarrow\quad \mathbf{x} \sqcup \mathbf{y} \preceq \mathbf{z}.
\end{array}$$

Thus the majorization algebra also forms a distributive lattice. □

Even when $\mathbf{x}$ and $\mathbf{y}$ are in descending order, the sequences $(\mathbf{x} \sqcap \mathbf{y})$ and $(\mathbf{x} \sqcup \mathbf{y})$ defined here are not necessarily in descending order:

$$\mathbf{x} = \langle\, 2^{-2}\ 2^{-2}\ 2^{-3}\ 2^{-4}\ 2^{-4}\ 2^{-4}\ 2^{-4}\ 2^{-4}\ 2^{-4} \,\rangle$$

and

$$\mathbf{y} = \langle\, 2^{-2}\ 2^{-3}\ 2^{-3}\ 2^{-3}\ 2^{-3}\ 2^{-3}\ 2^{-4}\ 2^{-5}\ 2^{-5} \,\rangle$$

yield the least upper bound

$$\mathbf{x} \sqcup \mathbf{y} = \boldsymbol{\partial}(\textstyle\int\mathbf{x}\ \mathbf{max}_{vec}\ \int\mathbf{y}) = \langle\, 2^{-2}\ 2^{-2}\ 2^{-3}\ \boxed{2^{-4}}\ 2^{-4}\ \boxed{2^{-3}}\ 2^{-4}\ 2^{-5}\ 2^{-5} \,\rangle.$$

See Figure 3.6.

3.6. The imbalance lattice: A discrete cousin of the majorization lattice. Since every pair of sequences in Figures 3.2 and 3.3 has a unique glb and lub, the imbalance ordering is not only a partial order but also a *lattice*. In this section we prove this by showing that every pair of sequences $\mathbf{s}$, $\mathbf{t}$ has a glb $\mathbf{s} \wedge \mathbf{t}$ and lub $\mathbf{s} \vee \mathbf{t}$. We also relate the imbalance lattice directly to the majorization lattice, as illustrated in Figures 3.5–3.7.

THEOREM 3.17. *On tree path-length sequences, the imbalance ordering is isomorphic to the majorization ordering. Specifically, whenever* $\mathbf{s}$ *and* $\mathbf{t}$ *are tree path-length sequences, then*

$$\mathbf{s} \trianglelefteq \mathbf{t} \quad \textit{iff} \quad 2^{-\mathbf{s}} \preceq 2^{-\mathbf{t}}.$$

Proof. We show first that balancing exchanges cause a reduction in the majorization ordering. Let $\mathbf{s}$ be the result of a balancing exchange on $\mathbf{t}$ (so $\mathbf{s} \trianglelefteq \mathbf{t}$). Then the following holds:

$$\begin{array}{rcccccccccccc}
\mathbf{t} = & (& \cdot & \cdot & \cdot & p & u & \cdot & \cdot & v & (q+1) & (q+1) & \cdot & \cdot\ ) \\
\mathbf{s} = & (& \cdot & \cdot & \cdot & (p+1) & (p+1) & u & \cdot & \cdot & v & q & \cdot & \cdot\ ) \\
2^{-\mathbf{t}} = & (& \cdot & \cdot & \cdot & 2^{-p} & 2^{-u} & \cdot & \cdot & 2^{-v} & 2^{-(q+1)} & 2^{-(q+1)} & \cdot & \cdot\ ) \\
2^{-\mathbf{s}} = & (& \cdot & \cdot & \cdot & 2^{-(p+1)} & 2^{-(p+1)} & 2^{-u} & \cdot & \cdot & 2^{-v} & 2^{-q} & \cdot & \cdot\ ) \\
\textstyle\int 2^{-\mathbf{t}} = & (& \cdot & \cdot & S & S+2^{-p} & S+2^{-p}+2^{-u} & \cdot & \cdot & T & T+2^{-(q+1)} & T+2^{-q} & \cdot & 1\ ) \\
\textstyle\int 2^{-\mathbf{s}} = & (& \cdot & \cdot & S & S+2^{-(p+1)} & S+2^{-p} & \cdot & \cdot & T-2^{-v} & T & T+2^{-q} & \cdot & 1\ ) \\
\hline
 & (& 0 & \cdot & 0 & +2^{-(p+1)} & +2^{-u} & \cdot & \cdot & +2^{-v} & +2^{-(q+1)} & 0 & \cdot & 0\ )
\end{array}$$

Thus $\int 2^{-\mathbf{s}}$ and $\int 2^{-\mathbf{t}}$ differ only in the values appearing between p and q, and each element in $\int 2^{-\mathbf{t}} - \int 2^{-\mathbf{s}}$ is nonnegative, so $2^{-\mathbf{s}} \preceq 2^{-\mathbf{t}}$.

$$

$2^{-(\mathbf{s} \wedge \mathbf{t})} \preceq (2^{-\mathbf{s}} \sqcap 2^{-\mathbf{t}})$; the two differ where indicated. Nonintegral exponents occur for $n \geq 9$.

FIG. 3.7. *The imbalance lattice is not simply conjugate to a sublattice of the majorization lattice.*

The proof of the converse, that $2^{-\mathbf{s}} \preceq 2^{-\mathbf{t}}$ implies $\mathbf{s} \trianglelefteq \mathbf{t}$ for tree path-length

sequences $\mathbf{s}$, $\mathbf{t}$, can proceed by assuming a counterexample for which the difference in the levels of balance of

$$m \quad = \quad (\text{level of balance of } \mathbf{s}) \; - \; (\text{level of balance of } \mathbf{t})$$

is minimal. Since $2^{-\mathbf{s}} \preceq 2^{-\mathbf{t}}$ let a, b, c, d be the rightmost aligned pairwise-differing values among the two sorted sequences such that $\mathbf{s} = \langle \cdots \; a \; \cdots \; b \; \cdots \rangle$ and $\mathbf{t} = \langle \cdots \; c \; \cdots \; d \; \cdots \rangle$, where $c < a$, $b < d$ because of the majorization inequality, $a \leq b$ and $c \leq d$ because the sequences are ascending, $c \neq d$ since $c < a \leq b < d$, and finally $2^{-a} + \cdots + 2^{-b} = 2^{-c} + \cdots + 2^{-d}$, which is always possible by the Kraft equality. Because $b < d$ necessarily $\mathbf{t} = \langle \cdots \; c \; \cdots \; d \; d \; \cdots \rangle$, since otherwise we reach a contradiction (multiplying both sides of the equality by 2^d makes the left side even but the right side odd). Thus, if we define the result $\mathbf{t}' = \langle \cdots \; (c+1) \; (c+1) \; \cdots \; (d-1) \; \cdots \rangle$ of a balancing exchange on $\mathbf{t} = \langle \cdots \; c \; \cdots \; d \; d \; \cdots \rangle$, then the level difference between $\mathbf{s}$ and $\mathbf{t}'$ is at most $(m-1)$, and $2^{-\mathbf{t}'} \preceq 2^{-\mathbf{t}}$. Furthermore we claim $2^{-\mathbf{s}} \preceq 2^{-\mathbf{t}'}$, using the following schematic:

$$\begin{array}{rcccccccccc}
\mathbf{t} & = & (\cdot & \cdot & \cdot & c & u & \cdot & d & d & \cdot \; \cdot) \\
\mathbf{t}' & = & (\cdot & \cdot & \cdot & (c+1) & \cdot & \cdot & & (d-1) & \cdot \; \cdot) \\
\mathbf{s} & = & (\cdot & \cdot & \cdot & a & w & \cdot & \cdot & b & \cdot \; \cdot) \\
 & & & & & & & & & & \\
2^{-\mathbf{t}} & = & (\cdot & \cdot & \cdot & 2^{-c} & 2^{-u} & \cdot & 2^{-d} & 2^{-d} & \cdot \; \cdot) \\
2^{-\mathbf{t}'} & = & (\cdot & \cdot & \cdot & 2^{-(c+1)} & 2^{-(c+1)} & \cdot & \cdot & 2^{-(d-1)} & \cdot \; \cdot) \\
2^{-\mathbf{s}} & = & (\cdot & \cdot & \cdot & 2^{-a} & 2^{-w} & \cdot & \cdot & 2^{-b} & \cdot \; \cdot) \\
 & & & & & & & & & & \\
\int 2^{-\mathbf{t}} - \int 2^{-\mathbf{s}} & = & (0 & \cdot & 0 & +(2^{-c} - 2^{-a}) & +S_1 & \cdot & +S_k & 0 & \cdot \; 0) \\
\int 2^{-\mathbf{t}} - \int 2^{-\mathbf{t}'} & = & (0 & \cdot & 0 & +2^{-(c+1)} & +2^{-u} & \cdot & +2^{-d} & 0 & \cdot \; 0) \\
\hline
\int 2^{-\mathbf{t}'} - \int 2^{-\mathbf{s}} & = & (0 & \cdot & 0 & +(2^{-(c+1)} - 2^{-a}) & +(S_1 - 2^{-u}) & \cdot & +(S_k - 2^{-d}) & 0 & \cdot \; 0)
\end{array}$$

Because $2^{-\mathbf{s}} \preceq 2^{-\mathbf{t}}$, the running totals $S_1, \ldots, S_k$ are nonnegative. Also, $(2^{-(c+1)} - 2^{-a}) \geq 0$ since $c < a$. Furthermore $c \leq (a-1) \leq w$, implying $S_1 - 2^{-u} = (2^{-c} - 2^{-a}) - 2^{w} \geq 2^{-(a-1)} - 2^{-w} \geq 0$. Finally $S_k + 2^{-d} - 2^{-b} = 0$, so $b \leq (d-1)$ implies $S_k - 2^{-d} = (2^{-b} - 2^{-d}) - 2^{-d} = 2^{-b} - 2^{-(d-1)} \geq 0$. Thus $\int 2^{-\mathbf{s}} \leq_{vec} \int 2^{-\mathbf{t}'}$ (i.e., $2^{-\mathbf{s}} \preceq 2^{-\mathbf{t}'}$), contradicting the assumed minimality of m, and existence of a counterexample. ∎

THEOREM 3.18. *The imbalance ordering on binary trees determines a bona fide lattice in which, for all* $\mathbf{s}$ *and* $\mathbf{t}$*, the glb* $\mathbf{s} \wedge \mathbf{t}$ *and lub* $\mathbf{s} \vee \mathbf{t}$ *are defined with the following recursive algorithms, where the expansion used is chosen from among the lower and upper expansions:*

$$\mathbf{s} \wedge \mathbf{t} \quad = \quad \begin{cases} \mathbf{s} & \text{if} \quad \mathbf{s} \trianglelefteq \mathbf{t}, \\ \mathbf{t} & \text{if} \quad \mathbf{t} \trianglelefteq \mathbf{s}, \\ \textit{the greatest expansion of } \; \mathbf{s}^- \wedge \mathbf{t}^- & \\ \textit{that is also a lower bound for } \mathbf{s} \textit{ and } \mathbf{t} & \textit{otherwise}; \end{cases}$$

$$\mathbf{s} \vee \mathbf{t} \quad = \quad \begin{cases} \mathbf{t} & \text{if} \quad \mathbf{s} \trianglelefteq \mathbf{t}, \\ \mathbf{s} & \text{if} \quad \mathbf{t} \trianglelefteq \mathbf{s}, \\ \textit{the least expansion of } \; \mathbf{s}^- \vee \mathbf{t}^- & \\ \textit{that is also an upper bound for } \mathbf{s} \textit{ and } \mathbf{t} & \textit{otherwise}. \end{cases}$$

Proof. We must show that, whenever $\mathbf{s}$ and $\mathbf{t}$ are tree path-length sequences of length n, there are unique path-length sequences $\mathbf{s} \wedge \mathbf{t}$ and $\mathbf{s} \vee \mathbf{t}$ such that the following hold:

- $\mathbf{s} \wedge \mathbf{t} \trianglelefteq \mathbf{s}, \; \mathbf{t}$; also, if $\boldsymbol{\ell}$ is any path-length sequence, then $\boldsymbol{\ell} \trianglelefteq \mathbf{s}, \; \mathbf{t}$ iff $\boldsymbol{\ell} \trianglelefteq \mathbf{s} \wedge \mathbf{t}$.
- $\mathbf{s}, \; \mathbf{t} \trianglelefteq \mathbf{s} \vee \mathbf{t}$; also, if $\boldsymbol{\ell}$ is any path-length sequence, then $\mathbf{s}, \; \mathbf{t} \trianglelefteq \boldsymbol{\ell}$ iff $\mathbf{s} \vee \mathbf{t} \trianglelefteq \boldsymbol{\ell}$.

TABLE 3.2

Elaboration of the first example of representative bounds in Figure 3.3*, showing how* $\mathbf{s} \wedge \mathbf{t}$ *and* $\mathbf{s} \vee \mathbf{t}$ *can be derived with their recursive algorithms.*

n	$\mathbf{s}$	$\mathbf{t}$	$\mathbf{s} \wedge \mathbf{t}$	$\mathbf{s} \vee \mathbf{t}$
9	$\langle\ 1\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ \rangle$	$\langle\ 2\ 2\ 2\ 3\ 5\ 5\ 5\ 6\ 6\ \rangle$	$\langle\ 2\ 2\ 3\ 4\ 4\ 4\ 4\ 4\ 4\ \rangle$	$\langle\ 1\ 3\ 3\ 3\ 5\ 5\ 5\ 6\ 6\ \rangle$
	$\uparrow$ lower expansion	$\uparrow$ upper expansion	$\uparrow$ lower expansion	$\uparrow$ upper expansion
8	$\langle\ 1\ 3\ 4\ 4\ 4\ 4\ 4\ 4\ \rangle$	$\langle\ 2\ 2\ 2\ 3\ 5\ 5\ 5\ 5\ \rangle$	$\langle\ 2\ 2\ 3\ 3\ 4\ 4\ 4\ 4\ \rangle$	$\langle\ 1\ 3\ 3\ 3\ 5\ 5\ 5\ 5\ \rangle$
	$\uparrow$ lower expansion	$\uparrow$ lower expansion	$\uparrow$ lower expansion	$\uparrow$ lower expansion
7	$\langle\ 1\ 3\ 3\ 4\ 4\ 4\ 4\ 4\ \rangle$	$\langle\ 2\ 2\ 2\ 3\ 4\ 5\ 5\ \rangle$	$\langle\ 2\ 2\ 2\ 4\ 4\ 4\ 4\ \rangle$	$\langle\ 1\ 3\ 3\ 3\ 4\ 5\ 5\ \rangle$
	$\uparrow$ lower expansion	$\uparrow$ upper expansion	$\uparrow$ lower expansion	$\uparrow$ upper expansion
6	$\langle\ 1\ 3\ 3\ 3\ 4\ 4\ \rangle$	$\langle\ 2\ 2\ 2\ 3\ 4\ 4\ \rangle$	$\langle\ 2\ 2\ 2\ 3\ 4\ 4\ \rangle$	$\langle\ 1\ 3\ 3\ 3\ 4\ 4\ \rangle$

This can be done by induction on n. We consider only the glb here, the proof for the lub being similar. The theorem holds trivially for $n \leq 6$, since then the trees are totally ordered. Assume that it holds for sequences of size $n-1$ or less.

First, $\mathbf{s}$ and $\mathbf{t}$ must have a common lower bound: The glb $\mathbf{s}^- \wedge \mathbf{t}^-$ exists by induction, and (Theorems 3.9 and 3.10) lower expansion gives a lower bound

$$(\mathbf{s}^- \wedge \mathbf{t}^-)_+ \ \trianglelefteq\ (\mathbf{s}^-)_+ \ \trianglelefteq\ \mathbf{s}, \qquad (\mathbf{s}^- \wedge \mathbf{t}^-)_+ \ \trianglelefteq\ (\mathbf{t}^-)_+ \ \trianglelefteq\ \mathbf{t}.$$

Second, if $\mathbf{s}$ and $\mathbf{t}$ have two greatest lower bounds $\boldsymbol{\ell}$ and $\boldsymbol{\ell}'$, then they must be equal: From $\boldsymbol{\ell} \trianglelefteq \mathbf{s},\ \mathbf{t}$ and $\boldsymbol{\ell}' \trianglelefteq \mathbf{s},\ \mathbf{t}$ we infer $\boldsymbol{\ell}^- \trianglelefteq \mathbf{s}^- \wedge \mathbf{t}^-$ and $\boldsymbol{\ell}'^- \trianglelefteq \mathbf{s}^- \wedge \mathbf{t}^-$ by Theorem 3.10. Since furthermore $\boldsymbol{\ell}$ and $\boldsymbol{\ell}'$ are greatest lower bounds, $\mathbf{s}^- \wedge \mathbf{t}^- \trianglelefteq \boldsymbol{\ell}^-$ and $\mathbf{s}^- \wedge \mathbf{t}^- \trianglelefteq \boldsymbol{\ell}'^-$. Thus $\boldsymbol{\ell}^- = \boldsymbol{\ell}'^-$. By Theorem 3.9, the only way $\boldsymbol{\ell} \neq \boldsymbol{\ell}'$ can arise is that

$$\boldsymbol{\ell} = (\boldsymbol{\ell}^-)_+, \quad \boldsymbol{\ell}' = (\boldsymbol{\ell}^-)^+ \qquad \text{or} \qquad \boldsymbol{\ell} = (\boldsymbol{\ell}^-)^+, \quad \boldsymbol{\ell}' = (\boldsymbol{\ell}^-)_+$$

so $\boldsymbol{\ell} \trianglelefteq \boldsymbol{\ell}'$ or $\boldsymbol{\ell}' \trianglelefteq \boldsymbol{\ell}$, contradicting their both being greatest lower bounds. Thus $\boldsymbol{\ell} = \boldsymbol{\ell}'$.

Third, the algorithm produces a glb that is as good as any other lower bound: Assuming this for $(\mathbf{s}^- \wedge \mathbf{t}^-)$ by induction, there can be no lower bound $\boldsymbol{\ell} \neq (\mathbf{s} \wedge \mathbf{t})$ such that $(\mathbf{s}^- \wedge \mathbf{t}^-)^+ \trianglelefteq \boldsymbol{\ell}$, since otherwise $(\mathbf{s}^- \wedge \mathbf{t}^-) \trianglelefteq \boldsymbol{\ell}^- \trianglelefteq \mathbf{s}^-,\ \mathbf{t}^-$, contradicting our assumption. □

The table of nontrivial examples in Figure 3.3 gives an appreciation for glbs and lubs. The first example (which is illustrated in the figure) is expanded in Table 3.2. Note that the final pairs of entries in $\mathbf{s}$ and $\mathbf{t}$ are the same as the final pairs of entries in $\mathbf{s} \wedge \mathbf{t}$ and $\mathbf{s} \vee \mathbf{t}$ and that the suffix lengths of $\mathbf{s}$ and $\mathbf{t}$ are never shorter than those of $\mathbf{s} \wedge \mathbf{t}$ and $\mathbf{s} \vee \mathbf{t}$.

THEOREM 3.19. *If* $\mathbf{s}$ *and* $\mathbf{t}$ *are path-length sequences of length* n*, then*

$$\mathbf{s} \vee \mathbf{t} \ = \ \begin{cases} (\mathbf{s}^- \vee \mathbf{t}^-)^+ & \text{if} \quad \mathbf{s} = (\mathbf{s}^-)^+ \quad \text{and} \quad \mathbf{t} = (\mathbf{t}^-)^+, \\ (\mathbf{s}^- \vee \mathbf{t}^-)_+ & \text{if} \quad \mathbf{s} = (\mathbf{s}^-)_+ \quad \text{and} \quad \mathbf{t} = (\mathbf{t}^-)_+; \end{cases}$$

$$\mathbf{s} \wedge \mathbf{t} \ = \ \begin{cases} (\mathbf{s}^- \wedge \mathbf{t}^-)^+ & \text{if} \quad \mathbf{s} = (\mathbf{s}^-)^+ \quad \text{and} \quad \mathbf{t} = (\mathbf{t}^-)^+, \\ (\mathbf{s}^- \wedge \mathbf{t}^-)_+ & \text{if} \quad \mathbf{s} = (\mathbf{s}^-)_+ \quad \text{and} \quad \mathbf{t} = (\mathbf{t}^-)_+. \end{cases}$$

Otherwise, if either $\mathbf{s} = (\mathbf{s}^-)^+$ *and* $\mathbf{t} = (\mathbf{t}^-)_+$*, or* $\mathbf{s} = (\mathbf{s}^-)_+$ *and* $\mathbf{t} = (\mathbf{t}^-)^+$*, then either* $\mathbf{s} \wedge \mathbf{t} = (\mathbf{s}^- \wedge \mathbf{t}^-)^+$ *and* $\mathbf{s} \vee \mathbf{t} = (\mathbf{s}^- \vee \mathbf{t}^-)_+$*, or* $\mathbf{s} \wedge \mathbf{t} = (\mathbf{s}^- \wedge \mathbf{t}^-)_+$ *and* $\mathbf{s} \vee \mathbf{t} = (\mathbf{s}^- \vee \mathbf{t}^-)^+$.

Furthermore, if the final pairs of entries of $\mathbf{s}$ *and* $\mathbf{t}$ *are* $\langle p\ p \rangle$ *and* $\langle q\ q \rangle$*, where* $p \leq q$*, then the final pairs of entries of* $\mathbf{s} \wedge \mathbf{t}$ *and* $\mathbf{s} \vee \mathbf{t}$ *are, respectively,* $\langle p\ p \rangle$ *and* $\langle q\ q \rangle$.

Also, the suffix lengths of $\mathbf{s}$ *and* $\mathbf{t}$ *are at least as long as those of* $(\mathbf{s} \wedge \mathbf{t})$ *and* $(\mathbf{s} \vee \mathbf{t})$.

Proof. These properties follow by induction on n. For the basis, they all hold trivially when $n \leq 6$, since then the imbalance lattice is a total order and $\{\, \mathbf{s},\ \mathbf{t} \,\} = \{\, \mathbf{s} \vee \mathbf{t},\ \mathbf{s} \wedge \mathbf{t} \,\}$, and the final two entries of any path-length sequence are a pair by Theorem 3.1. For the induction step, we can write

$$\begin{array}{rclcrcl} \mathbf{s} & = & \langle\ \cdots\ (p{-}i)\ \overbrace{p\ \cdot\ \cdot\ \cdot\ p}^{2h}\ \rangle, & \quad & \mathbf{t} & = & \langle\ \cdots\ (q{-}j)\ \overbrace{q\ \cdot\ \cdot\ \cdot\ q}^{2k}\ \rangle, \\ \mathbf{s}^- & = & \langle\ \cdots\ (p{-}i)\ (p{-}1)\ \overbrace{p\ \cdots\ p}^{2h-2}\ \rangle, & \quad & \mathbf{t}^- & = & \langle\ \cdots\ (q{-}j)\ (q{-}1)\ \overbrace{q\ \cdots\ q}^{2k-2}\ \rangle, \end{array}$$

where $i, j, h, k > 0$, and we assume with no loss of generality that $p \leq q$. There are four cases to consider, depending on the suffix lengths $2h$ of $\mathbf{s}$ and $2k$ of $\mathbf{t}$. In the first, $h = 1$ and $k = 1$ (i.e., $\mathbf{s} = (\mathbf{s}^-)^+$ and $\mathbf{t} = (\mathbf{t}^-)^+$). Then $i = 1$ and $j = 1$ by Theorem 3.1. By induction $(\mathbf{s}^- \wedge \mathbf{t}^-)$ and $(\mathbf{s}^- \vee \mathbf{t}^-)$ have respective final pairs $\langle (p{-}1)\ (p{-}1) \rangle$ and $\langle (q{-}1)\ (q{-}1) \rangle$ and have suffix lengths not exceeding those of $\mathbf{s}^-$ and $\mathbf{t}^-$. Now, by Theorem 3.10 $(\mathbf{s}^- \wedge \mathbf{t}^-)^+ \trianglelefteq (\mathbf{s}^-)^+$ and $(\mathbf{s}^- \wedge \mathbf{t}^-)^+ \trianglelefteq (\mathbf{t}^-)^+$. Because $(\mathbf{s}^-)^+ = \mathbf{s}$ and $(\mathbf{t}^-)^+ = \mathbf{t}$, the recursive algorithm in Theorem 3.18 will find $(\mathbf{s}^- \wedge \mathbf{t}^-)^+ = \mathbf{s} \wedge \mathbf{t}$. Thus the final pair of $\mathbf{s} \wedge \mathbf{t}$ will be $\langle p\ p \rangle$, and it will have suffix length 2. Similarly $\mathbf{s} \vee \mathbf{t} = (\mathbf{s}^- \vee \mathbf{t}^-)^+$ because $\mathbf{s} \vee \mathbf{t} \in \{\, (\mathbf{s}^- \vee \mathbf{t}^-)_+, (\mathbf{s}^- \vee \mathbf{t}^-)^+ \,\}$, and choosing $(\mathbf{s}^- \vee \mathbf{t}^-)_+$ gives a contradiction: if $\mathbf{s} = (\mathbf{s}^-)^+ \trianglelefteq (\mathbf{s}^- \vee \mathbf{t}^-)_+$ and $\mathbf{t} = (\mathbf{t}^-)^+ \trianglelefteq (\mathbf{s}^- \vee \mathbf{t}^-)_+$, then (because of Theorem 3.10) $\mathbf{s}^- = ((\mathbf{s}^-)^+)^- \trianglelefteq ((\mathbf{s}^- \vee \mathbf{t}^-)_+)^- \neq ((\mathbf{s}^- \vee \mathbf{t}^-)^+)^- = \mathbf{s}^- \vee \mathbf{t}^-$ and correspondingly $\mathbf{t}^- = ((\mathbf{t}^-)^+)^- \trianglelefteq ((\mathbf{s}^- \vee \mathbf{t}^-)_+)^- \neq ((\mathbf{s}^- \vee \mathbf{t}^-)^+)^- = \mathbf{s}^- \vee \mathbf{t}^-$, so the lub of $\mathbf{s}^-$ and $\mathbf{t}^-$ is not $\mathbf{s}^- \vee \mathbf{t}^-$, a contradiction. Again the final pair of $\mathbf{s} \vee \mathbf{t}$ will be $\langle q\ q \rangle$, with suffix length 2.

The other three cases, where $h > 1$ and/or $k > 1$, are similar. ∎

4. Submodularity of weighted path-length over the lattices. Huffman codes for a positive descending weight sequence $\mathbf{w} = \langle\, w_1\, w_2\, \cdots\, w_n \,\rangle$ are binary tree path-length sequences $\boldsymbol{\ell} = \langle\, \ell_1\, \ell_2\, \cdots\, \ell_n \,\rangle$ that minimize the weighted path-length

$$g_{\mathbf{w}}(\boldsymbol{\ell}) \quad = \quad \sum_{i=1}^{n} w_i\, \ell_i.$$

In this section we show that $g_{\mathbf{w}}$ is submodular over the lattice of trees, which helps explain why efficient algorithms for finding optimal trees are possible at all.

4.1. Submodularity. Most work on submodular functions assumes that the lattice is the lattice of subsets of a given set, the case originally emphasized by Edmonds [6]. However, the definition applies to any lattice.

DEFINITION 4.1. *A real-valued function* $f : \mathcal{L} \to \Re$ *defined on a lattice* $\langle \mathcal{L}, \sqsubseteq, \sqcap, \sqcup \rangle$ *is* submodular *if*

$$f(x \sqcap y) + f(x \sqcup y) \quad \leq \quad f(x) + f(y)$$

for all $x, y \in \mathcal{L}$. *Equivalently,* f *is submodular if a "differential" inequality holds:*

$$\Delta^2 f(x, y) \stackrel{def}{=} f(x) + f(y) - f(x \sqcap y) - f(x \sqcup y) \geq 0.$$

Section 4.4 discusses the relationship between submodularity and convexity.

4.2. Submodularity of weighted path-length on the majorization lattice. In this section we show that weighted path-length on the imbalance lattice of trees (or a logarithmic variant on the majorization lattice of densities) is a submodular function.

Define the function $G_{\mathbf{w}}$ on the majorization lattice of densities by

$$G_{\mathbf{w}}(\mathbf{x}) \quad = \quad g_{\mathbf{w}}(-\log_2(\mathbf{x})) \quad = \quad -\sum_i \; w_i \; \log_2(x_i).$$

Notice that $G_{\mathbf{w}}$ is convex on $\Re_+{}^n$, since its Hessian

$$\nabla^2 G_{\mathbf{w}} = \left(\frac{\partial^2 G_{\mathbf{w}}(\mathbf{x})}{\partial x_i \partial x_j}\right) = \frac{1}{\ln(2)} \operatorname{diag}\left(\frac{w_i}{x_i^2}\right)$$

is positive semidefinite there [27, p. 448]. (Recall that we are assuming all weights are positive.)

$G_{\mathbf{w}}$ is actually also submodular on the majorization lattice. We prove this directly now and show later how submodularity can be established using only vector calculus.

THEOREM 4.2. *Assuming* $\mathbf{w}$ *is a descending positive sequence of length* n*,* $G_{\mathbf{w}}$ *is submodular on the majorization lattice. That is, for all nonnegative sequences* $\mathbf{x}$*,* $\mathbf{y}$ *of length* n*,*

$$G_{\mathbf{w}}(\mathbf{x} \sqcap \mathbf{y}) \; + \; G_{\mathbf{w}}(\mathbf{x} \sqcup \mathbf{y}) \quad \leq \quad G_{\mathbf{w}}(\mathbf{x}) \; + \; G_{\mathbf{w}}(\mathbf{y}).$$

Proof. By induction on n. For $n = 1$, the inequality is satisfied with equality. Let a_n and b_n be the nth entries of $(\mathbf{x} \sqcap \mathbf{y})$ and $(\mathbf{x} \sqcup \mathbf{y})$, respectively. The theorem follows by induction if we can show that

$$w_n \cdot (-\log_2(a_n)) \; + \; w_n \cdot (-\log_2(b_n)) \quad \leq \quad w_n \cdot (-\log_2(x_n)) \; + \; w_n \cdot (-\log_2(y_n)).$$

Recall that $\mathbf{x} \sqcap \mathbf{y} \;=\; \boldsymbol{\partial}\left((\textstyle\int \mathbf{x})\, \mathbf{min}_{vec}\, (\textstyle\int \mathbf{y})\right)$ and $\mathbf{x} \sqcup \mathbf{y} \;=\; \boldsymbol{\partial}\left((\textstyle\int \mathbf{x})\, \mathbf{max}_{vec}\, (\textstyle\int \mathbf{y})\right)$. There are four cases, depending on $\mathbf{X} = \int \mathbf{x}$ and $\mathbf{Y} = \int \mathbf{y}$ and specifically on the final values

$$X_{n-1} \;=\; \sum_{i=1}^{n-1} x_i, \qquad X_n \;=\; \sum_{i=1}^{n} x_i, \qquad Y_{n-1} \;=\; \sum_{i=1}^{n-1} y_i, \qquad Y_n \;=\; \sum_{i=1}^{n} y_i$$

as follows:

1. if $X_{n-1} \leq Y_{n-1}$ and $X_n \leq Y_n$, then $a_n = x_n$, $b_n = y_n$;
2. if $X_{n-1} \geq Y_{n-1}$ and $X_n \geq Y_n$, then $a_n = y_n$, $b_n = x_n$;
3. if $X_{n-1} \leq Y_{n-1}$ and $X_n \geq Y_n$, then $x_n \geq y_n$, $a_n = Y_n - X_{n-1} = y_n + \epsilon$, $b_n = X_n - Y_{n-1} = x_n - \epsilon$, where $\epsilon = (Y_{n-1} - X_{n-1}) \geq 0$ and $\epsilon \leq x_n - y_n = (x_n \max y_n) - (x_n \min y_n)$;
4. if $X_{n-1} \geq Y_{n-1}$ and $X_n \leq Y_n$, then $y_n \geq x_n$, $a_n = X_n - Y_{n-1} = x_n + \epsilon$, $b_n = Y_n - X_{n-1} = y_n - \epsilon$, where $\epsilon = (X_{n-1} - Y_{n-1}) \geq 0$ and $\epsilon \leq y_n - x_n = (x_n \max y_n) - (x_n \min y_n)$.

Each case satisfies $w_n \cdot (-\log_2(a_n)) + w_n \cdot (-\log_2(b_n)) \;\leq\; w_n \cdot (-\log_2(x_n)) + w_n \cdot (-\log_2(y_n))$ as needed; the first two cases satisfy it with equality, and in the last two we have

$$a_n \quad = \quad (x_n \; \min \; y_n) \; + \; \epsilon, \quad b_n \quad = \quad (x_n \; \max \; y_n) \; - \; \epsilon,$$

but then assuming that $x_n,\, y_n \geq 0$,

$$\log_2(a_n) + \log_2(b_n) \;=\; \log_2(a_n\, b_n) \;=\; \log_2(x_n\, y_n \,+\, \eta) \;\geq\; \log_2(x_n) + \log_2(y_n),$$

where $\eta = \epsilon\, ((x_n \max y_n) - (x_n \min y_n) - \epsilon) \geq 0$ and multiplying by $-w_n$ gives the theorem. □

4.3. Submodularity of weighted path-length on the imbalance lattice.

THEOREM 4.3. *Assuming that* $\mathbf{w}$ *is a descending positive sequence of length* n, $g_{\mathbf{w}}$ *is submodular on the imbalance lattice. That is, for all path-length sequences* $\mathbf{s}$, $\mathbf{t}$ *of length* n,

$$g_{\mathbf{w}}(\mathbf{s} \wedge \mathbf{t}) \;+\; g_{\mathbf{w}}(\mathbf{s} \vee \mathbf{t}) \quad\leq\quad g_{\mathbf{w}}(\mathbf{s}) \;+\; g_{\mathbf{w}}(\mathbf{t}).$$

Proof. The proof is also by induction on n. The theorem holds with equality for $n \leq 6$, since then the lattice of path-length sequences is totally ordered. We sketch the induction step from $n{-}1$ to n, showing $\Delta^2 g_{\mathbf{w}}(\mathbf{s}, \mathbf{t}) \;=\; (g_{\mathbf{w}}(\mathbf{s}) \;+\; g_{\mathbf{w}}(\mathbf{t})) - (g_{\mathbf{w}}(\mathbf{s} \wedge \mathbf{t}) \;+\; g_{\mathbf{w}}(\mathbf{s} \vee \mathbf{t})) \;\geq\; 0$ follows from $\Delta^2 g_{\mathbf{w}}(\mathbf{s}^-, \mathbf{t}^-) \;\geq\; 0$—where $g_{\mathbf{w}}$, when applied to sequences of length $(n{-}1)$, uses only the first $(n{-}1)$ entries of $\mathbf{w}$.

Recall that $2k$ is the suffix length of the path-length sequence

$$\boldsymbol{\ell} = \langle\; \cdots\; (q{-}j)\; \overbrace{q\; \cdots\; q}^{2k}\; \rangle,$$

and j is its suffix increment. The suffix increment is 1 when $(\boldsymbol{\ell}^-)^+ = \boldsymbol{\ell}$, so

$$g_{\mathbf{w}}(\boldsymbol{\ell}) \quad=\quad \begin{cases} g_{\mathbf{w}}(\boldsymbol{\ell}^-) \;+\; (w_{n-1} \;\;\;\;\;\;+\; q \cdot w_n) & \text{if } \boldsymbol{\ell} = (\boldsymbol{\ell}^-)^+ \quad \text{(i.e., } k = 1\text{)}, \\ g_{\mathbf{w}}(\boldsymbol{\ell}^-) \;+\; (w_{n-2k+1} \;+\; q \cdot w_n) & \text{if } \boldsymbol{\ell} = (\boldsymbol{\ell}^-)_+ \quad \text{(i.e., } k > 1\text{)}. \end{cases}$$

Thus $g_{\mathbf{w}}(\mathbf{s}) > g_{\mathbf{w}}(\mathbf{s}^-)$ and $g_{\mathbf{w}}(\mathbf{t}) > g_{\mathbf{w}}(\mathbf{t}^-)$ in all cases.

However, it can happen that $g_{\mathbf{w}}(\mathbf{s} \wedge \mathbf{t}) < g_{\mathbf{w}}(\mathbf{s}^- \wedge \mathbf{t}^-)$ or $g_{\mathbf{w}}(\mathbf{s} \vee \mathbf{t}) < g_{\mathbf{w}}(\mathbf{s}^- \vee \mathbf{t}^-)$ because it is possible either that $\mathbf{s}^- \wedge \mathbf{t}^- \neq (\mathbf{s} \wedge \mathbf{t})^-$ or that $\mathbf{s}^- \vee \mathbf{t}^- \neq (\mathbf{s} \vee \mathbf{t})^-$. Specifically, it is possible that

$$\mathbf{s} \wedge \mathbf{t} \;=\; \langle\; \cdots\; (q{-}j)\; (q{-}j)\; \overbrace{q\; \cdots\; q}^{2k}\; \rangle$$

and

$$\mathbf{s}^- \wedge \mathbf{t}^- \;=\; \langle\; \cdots\; (q{-}j{-}1)\; \overbrace{q\; \cdots\; q}^{2k}\; \rangle,$$

i.e., $\mathbf{s} \wedge \mathbf{t} = (\mathbf{s}^- \wedge \mathbf{t}^-)_+$ and $\mathbf{s} \wedge \mathbf{t}$ has suffix increment $j > 1$, in which case

$$g_{\mathbf{w}}(\mathbf{s} \wedge \mathbf{t}) \quad=\quad g_{\mathbf{w}}(\mathbf{s}^- \wedge \mathbf{t}^-) \;+\; (w_{n-2k+1} \;-\; j \cdot w_{n-2k} \;+\; q \cdot w_n)$$

and the parenthesized expression can be negative.

From Theorem 3.19, the final pairs of entries of $\mathbf{s}$ and $\mathbf{t}$ are always the same as the final pairs of entries of $\mathbf{s} \wedge \mathbf{t}$ and $\mathbf{s} \vee \mathbf{t}$, and the suffix lengths for each of $\mathbf{s}$ and $\mathbf{t}$ cannot be less than those for each of $(\mathbf{s} \wedge \mathbf{t})$ and $(\mathbf{s} \vee \mathbf{t})$. We now consider the same four cases addressed in the proof of Theorem 3.19.

In the case where both $\mathbf{s}$ is the upper expansion of $\mathbf{s}^-$ and $\mathbf{t}$ is the upper expansion of $\mathbf{t}^-$, then by Theorem 3.19, $\mathbf{s} \wedge \mathbf{t} = (\mathbf{s}^- \wedge \mathbf{t}^-)^+$ and $\mathbf{s} \vee \mathbf{t} = (\mathbf{s}^- \vee \mathbf{t}^-)^+$, so

$$\begin{aligned} \Delta^2 g_{\mathbf{w}}(\mathbf{s}, \mathbf{t}) &= (g_{\mathbf{w}}(\mathbf{s}) \;+\; g_{\mathbf{w}}(\mathbf{t})) \;-\; (g_{\mathbf{w}}(\mathbf{s} \wedge \mathbf{t}) \;+\; g_{\mathbf{w}}(\mathbf{s} \vee \mathbf{t})) \\ &= (g_{\mathbf{w}}(\mathbf{s}^-) \;+\; g_{\mathbf{w}}(\mathbf{t}^-)) \;-\; (g_{\mathbf{w}}(\mathbf{s}^- \wedge \mathbf{t}^-) \;+\; g_{\mathbf{w}}(\mathbf{s}^- \vee \mathbf{t}^-)) + 0 \\ &= \Delta^2 g_{\mathbf{w}}(\mathbf{s}^-, \mathbf{t}^-), \end{aligned}$$

with the analysis above for $g_{\mathbf{w}}(\boldsymbol{\ell})$ with $k = 1$. In this situation only the final pairs of entries of $\mathbf{s}$, $\mathbf{t}$ and of $\mathbf{s} \wedge \mathbf{t}$, $\mathbf{s} \vee \mathbf{t}$ can cause the two differences to be unequal, but we now know them to give the same two pairs. Therefore in this case the theorem follows by induction.

It remains to treat the cases where $\mathbf{s}$ is the lower expansion of $\mathbf{s}^-$ or $\mathbf{t}$ is the lower expansion of $\mathbf{t}^-$. In these cases it can happen that $g_{\mathbf{w}}(\mathbf{s} \wedge \mathbf{t}) < g_{\mathbf{w}}(\mathbf{s}^- \wedge \mathbf{t}^-)$ or $g_{\mathbf{w}}(\mathbf{s} \vee \mathbf{t}) < g_{\mathbf{w}}(\mathbf{s}^- \vee \mathbf{t}^-)$ as noted above.

In the case where either $\mathbf{s}$ is the lower expansion of $\mathbf{s}^-$ or $\mathbf{t}$ is the lower expansion of $\mathbf{t}^-$, but not both, then by Theorem 3.19, either $\mathbf{s} \wedge \mathbf{t} = (\mathbf{s}^- \wedge \mathbf{t}^-)_+$ and $\mathbf{s} \vee \mathbf{t} = (\mathbf{s}^- \vee \mathbf{t}^-)^+$, or $\mathbf{s} \wedge \mathbf{t} = (\mathbf{s}^- \wedge \mathbf{t}^-)^+$ and $\mathbf{s} \vee \mathbf{t} = (\mathbf{s}^- \vee \mathbf{t}^-)_+$. The lower expansions among these two cannot yield as large a $g_{\mathbf{w}}$ increase as the lower expansions giving $\mathbf{s}$ and $\mathbf{t}$, because they expand higher-indexed positions (their suffix lengths are never longer), and the suffix increment of $\mathbf{s}^- \wedge \mathbf{t}^-$ or $\mathbf{s}^- \vee \mathbf{t}^-$ can be greater than 1. Therefore $\Delta^2 g_{\mathbf{w}}(\mathbf{s}, \mathbf{t}) \geq \Delta^2 g_{\mathbf{w}}(\mathbf{s}^-, \mathbf{t}^-)$.

In the final case where $\mathbf{s}$ is the lower expansion of $\mathbf{s}^-$ and $\mathbf{t}$ is the lower expansion of $\mathbf{t}^-$, then $\mathbf{s} \wedge \mathbf{t} = (\mathbf{s}^- \wedge \mathbf{t}^-)_+$ and $\mathbf{s} \vee \mathbf{t} = (\mathbf{s}^- \vee \mathbf{t}^-)_+$ (see Theorem 3.19). Moreover, the lower expansions giving $\mathbf{s} \wedge \mathbf{t}$ and $\mathbf{s} \vee \mathbf{t}$ cannot yield as large a $g_{\mathbf{w}}$ increase as the lower expansions giving $\mathbf{s}$ and $\mathbf{t}$, so again $\Delta^2 g_{\mathbf{w}}(\mathbf{s}, \mathbf{t}) \geq \Delta^2 g_{\mathbf{w}}(\mathbf{s}^-, \mathbf{t}^-)$. □

To see an example, the submodularity of $g_{\mathbf{w}}$ can be verified on the lattice for $n = 9$ and the weight sequence shown in Figure 5.1.

4.4. Submodularity as a discrete analogue of convexity. Although it is very simply defined, submodularity is difficult to appreciate. Using only standard vector calculus, we now clarify some basic relationships between submodularity and notions of convexity. We have not seen this done elsewhere.

There are several reasons why submodularity plays an important role here, at the crossroads between information and coding theory. First, submodularity is directly related to the Fortuin–Kasteleyn–Ginibre (FKG) "correlation" inequalities, which generalize a basic inequality of Tchebycheff on mean values of functions (hence expected values of random variables). A fine survey of results with FKG-like inequalities is [15].

Second, submodularity is closely related to convexity. Book-length surveys by Fujishige [9] and Narayanan [28] review connections between submodularity and optimization (and even electrical network theory). The relationship between convexity and submodularity was neatly summarized by Lovász with the following memorable definition and result.

DEFINITION 4.4. *Given a finite set S of cardinality n, we can identify a* $\{0,1\}$-vector $\mathbf{t} \in {\Re_+}^n$ *with any subset $T \subseteq S$ specifying the incidence in T of the elements in S (indexed in some fixed order).*

Any nonnegative vector $\mathbf{x} \in {\Re_+}^n$ *can be decomposed uniquely into a sum of positive real values multiplied by "decreasing"* $\{0,1\}$*-vectors. Specifically,* $\mathbf{x} \in {\Re_+}^n$ *determines an integer k $(0 \leq k \leq n)$ such that* $\mathbf{x}$ *has a* unique greedy decomposition

$$\mathbf{x} \quad = \quad \sum_{i=1}^{k} \lambda_i \, \mathbf{s}_i,$$

where $\lambda_i > 0$, $S_1 \supset \cdots \supset S_k$ are distinct subsets of S, and $\mathbf{s}_i$ is the $\{0,1\}$*-vector identified with S_i. For any function $f : S \to \Re_+$, its* greedy extension $\widehat{f} : {\Re_+}^n \to \Re_+$

to nonnegative vectors is then defined by

$$\widehat{f}(\mathbf{x}) \quad = \quad \widehat{f}\left(\sum_{i=1}^{k} \lambda_i \ \mathbf{s}_i\right) \quad = \quad \sum_{i=1}^{k} \lambda_i \ f(S_i).$$

In fact, $\boldsymbol{\lambda} = \boldsymbol{\partial}\,(\mathrm{sort}{\uparrow}\,(\,\mathbf{x}\,))$, using our notation.

THEOREM 4.5 (see Lovász [25, p. 249]). *$f : S \to \Re_+$ is submodular iff its greedy extension $\widehat{f} : {\Re_+}^n \to \Re_+$ is convex.*

Proof. The essence is that for positive constants $\lambda \leq \kappa$ and sets $T \neq U$,

$$\widehat{f}(\lambda\,\mathbf{t}{+}\kappa\,\mathbf{u}) \ = \ \lambda\,f(T{\cup}U) + (\kappa{-}\lambda)\,f(U) \ \leq \ \lambda\,f(T) + \kappa\,f(U) \ = \ \widehat{f}(\lambda\,\mathbf{t}) + \widehat{f}(\kappa\,\mathbf{u}),$$

where $\mathbf{t}$ and $\mathbf{u}$ are the $\{0,1\}$-vectors corresponding to T and U. The central inequality is due to submodularity. Resisting $0 < \lambda < 1$ and $\kappa = (1-\lambda)$ shows $\widehat{f}$ is convex. □

Lovász goes on [25, p. 250–251] to point out that

$$\min\,\{\ f(X) \mid X \ \subseteq \ S\ \} \quad = \quad \min\,\{\ \widehat{f}(\mathbf{x}) \mid \mathbf{x} \ \in \ [0,1]^n\ \}$$

and that as a consequence there is a polynomial-time algorithm to minimize f.

The vector lattice $\langle {\Re_+}^n, \leq_{vec}, \mathbf{min}_{vec}, \mathbf{max}_{vec}\rangle$, is exactly the extension of the set lattice to nonnegative vectors. Vector lattices, also called *Riesz spaces*, can be more "natural" than set lattices in some ways. For example, submodularity has a natural characterization.

THEOREM 4.6 (see Lorentz [27, p. 150]). *When twice differentiable, f is submodular on the vector lattice $\langle {\Re_+}^n, \leq_{vec}, \mathbf{min}_{vec}, \mathbf{max}_{vec}\rangle$ iff*

$$\frac{\partial^2 f}{\partial x_i \partial x_j} \quad \leq \quad 0 \qquad\qquad (i \neq j,\ 1 \leq i,\, j \leq n).$$

Proof. The proof is essentially by definition. Using the shorthand $f\langle\ u\ v\ \rangle$ to denote the expression $f(\langle\ x_1\ \ldots\ x_{i-1}\ \ u\ \ x_{i+1}\ \ldots\ x_{j-1}\ \ v\ \ x_{j+1}\ \ldots\ x_n\ \rangle)$ gives

$$\begin{aligned}\frac{\partial^2 f}{\partial x_i \partial x_j} &= \lim_{\epsilon_i, \epsilon_j \to 0} \frac{f\langle\ (x_i{+}\epsilon_i)\ (x_j{+}\epsilon_j)\ \rangle - f\langle\ (x_i{+}\epsilon_i)\ x_j\ \rangle - f\langle\ x_i\ (x_j{+}\epsilon_j)\ \rangle + f\langle\ x_i\ x_j\ \rangle}{\epsilon_i \ \ \epsilon_j} \\ &\leq 0,\end{aligned}$$

where the inequality comes from the fact that f is submodular, since with respect to $\leq_{vec}$, the points $\mathbf{x} = \langle\ (x_i{+}\epsilon_i)\ x_j\ \rangle$ and $\mathbf{y} = \langle\ x_i\ (x_j{+}\epsilon_j)\ \rangle$ have the upper and lower bounds $\mathbf{x}\ \mathbf{max}_{vec}\ \mathbf{y} = \langle\ (x_i{+}\epsilon_i)\ (x_j{+}\epsilon_j)\ \rangle$ and $\mathbf{x}\ \mathbf{min}_{vec}\ \mathbf{y} = \langle\ x_i\ x_j\ \rangle$. For the converse, if f is not submodular on a rectangle defined by $\mathbf{x} = \langle\ (x_i{+}a)\ x_j\ \rangle$ and $\mathbf{y} = \langle\ x_i\ (x_j{+}b)\ \rangle$, Lorentz pointed out we can find a subrectangle on which $\partial^2 f / \partial x_i \partial x_j > 0$. □

Note: the derivatives $\frac{\partial^2 f}{\partial x_i^2}$ can still be positive. In fact, the Hessian $\nabla^2 f = (\frac{\partial^2 f}{\partial x_i \partial x_j})$ still can even be positive semidefinite (hence f can be convex), or be an M-matrix [3, Chap. 6].

THEOREM 4.7. *When twice differentiable, F is submodular on the majorization lattice $\langle {\Re_+}^n, \preceq, \sqcap, \sqcup\rangle$ iff for all $i \neq j$ between 1 and $n-1$,*

$$\frac{\partial^2 F(\mathbf{z})}{\partial z_i \partial z_j} \ - \ \frac{\partial^2 F(\mathbf{z})}{\partial z_{i+1} \partial z_j} \ - \ \frac{\partial^2 F(\mathbf{z})}{\partial z_i \partial z_{j+1}} \ + \ \frac{\partial^2 F(\mathbf{z})}{\partial z_{i+1} \partial z_{j+1}} \quad \leq \quad 0.$$

Proof. Theorem 3.16 shows that the Möbius transformation $\boldsymbol{\partial}$ gives a bijection between the majorization lattice $\langle {\Re_+}^n, \preceq, \sqcap, \sqcup \rangle$ and the vector lattice $\langle {\Re_+}^n, \leq_{vec}, \mathbf{min}_{vec}, \mathbf{max}_{vec} \rangle$. Thus $f(\mathbf{x}) = F(\boldsymbol{\partial}\,\mathbf{x})$ is submodular on the vector lattice when F is submodular on the majorization lattice. Expanding the inequality

$$\frac{\partial^2}{\partial x_i \partial x_j}(F(\boldsymbol{\partial}\,\mathbf{x})) \quad = \quad \frac{\partial^2}{\partial x_i \partial x_j}(f(\mathbf{x})) \quad \leq \quad 0$$

(which follows from the previous theorem) with the chain rule gives the stated result, because $\mathbf{z} = \boldsymbol{\partial}\,\mathbf{x} = \langle\, x_1 \;\; (x_2 - x_1) \;\; (x_3 - x_2) \;\; \cdots \;\; (x_n - x_{n-1}) \,\rangle$. ∎

Revisiting Theorem 4.2, $G_{\mathbf{w}}(\mathbf{z}) = -\sum_{i=1}^{n} w_i \;\log_2(z_i)$ satisfies

$$\frac{\partial^2 G_{\mathbf{w}}(\mathbf{z})}{\partial z_i \partial z_j} - \frac{\partial^2 G_{\mathbf{w}}(\mathbf{z})}{\partial z_{i+1} \partial z_j} - \frac{\partial^2 G_{\mathbf{w}}(\mathbf{z})}{\partial z_i \partial z_{j+1}} + \frac{\partial^2 G_{\mathbf{w}}(\mathbf{z})}{\partial z_{i+1} \partial z_{j+1}}$$
$$= \frac{1}{\ln(2)} \begin{cases} 0, & |i-j| > 1, \\ -w_i / z_i^2, & i = j+1, \\ -w_{i+1} / z_{i+1}^2, & j = i+1, \\ w_{i+1}/z_{i+1}^2 + w_i / z_i^2, & i = j, \end{cases}$$

and, e.g., $G_{\mathbf{w}}(\boldsymbol{\partial}\,\mathbf{x}) = -w_1 \;\log_2(x_1) - \sum_{i=1}^{n-1} w_i \;\log_2(x_{i+1} - x_i)$ satisfies

$$\frac{\partial^2}{\partial x_i \partial x_j}(G_{\mathbf{w}}(\boldsymbol{\partial}\,\mathbf{x})) \quad = \quad \frac{1}{\ln(2)} \;\; \frac{-w_{i+1}}{(x_{i+1} - x_i)^2} \quad \leq \quad 0 \qquad \text{when } j = i+1.$$

This gives two alternative proofs of Theorem 4.2, showing how such results can be derived more easily.

DEFINITION 4.8. *A function $F : {\Re_+}^n \to \Re$ is* Schur convex *if it preserves the majorization ordering, i.e., $\mathbf{x} \preceq \mathbf{y}$ implies $F(\mathbf{x}) \leq F(\mathbf{y})$.*

THEOREM 4.9. *F is Schur convex on the majorization lattice iff $f(\mathbf{x}) = F(\boldsymbol{\partial}\,\mathbf{x})$ is monotone on the vector lattice.*

Proof. Again a direct result of the bijection between the two lattices. If f is differentiable, f is monotone on the vector lattice iff $\nabla f(\mathbf{x}) = \langle\, \partial f/\partial x_1 \cdots \partial f/\partial x_n \,\rangle \geq_{vec} \mathbf{0}$, which implies

$$\frac{\partial F}{\partial x_i}(\boldsymbol{\partial}\,\mathbf{x}) - \frac{\partial F}{\partial x_{i+1}}(\boldsymbol{\partial}\,\mathbf{x}) \quad = \quad \frac{\partial}{\partial x_i}(F(\boldsymbol{\partial}\,\mathbf{x})) \quad = \quad \frac{\partial}{\partial x_i} f(\mathbf{x}) \quad \geq \quad 0 \qquad (1 \leq i \leq n-1).$$

This rederives the result that $\partial F/\partial z_i \geq \partial F/\partial z_{i+1}$ when F is Schur convex [34]. ∎

Since monotonicity and convexity are related, Theorems 4.5, 4.6, 4.7, and 4.9 connect convexity, submodularity, Schur convexity, and majorization. There are actually many connections. See the survey [27, Chap. 6], in which submodular functions are called *$\mathcal{L}$-subadditive functions*. Just as Lovász showed for submodular functions [25], Schur convex functions [37, 29] are closed under various operations: min, max, convolution, composition with convex functions, etc. [27, Chap. 3]. Theorem 4.5 is also reminiscent of *symmetric gauge* functions, which are Schur convex; see [27, p. 96].

5. Huffman coding as submodular dynamic programming. The results of the previous sections can now be applied to Huffman coding.

5.1. Nonmonotonicity of weighted path-length over the lattices. It is important to realize that weighted path-length is not monotone on the imbalance lattice, so greedy search may not always find its way to an optimal solution. This is illustrated by the example in Figure 5.1. For this problem the sequence $\langle\, 2\,2\,3\,3\,4\,4\,4\,5\,5 \,\rangle$ with cost 1298 is a local minimum: each of the 7 sequences reachable from it by imbalancing exchanges and each of the 3 sequences reachable from it by balancing exchanges have greater weighted path length. The diagram shows only the transitive reduction of the imbalance lattice, omitting many balancing exchanges (because they would clutter the picture), but it conveys the general situation for larger Huffman coding problems. It shows that, even though it may do very well in practice, simple hill-climbing along ternary exchanges is not guaranteed to find the optimum sequence.

Although weighted path-length $g_{\mathbf{w}}$ is not monotone on the imbalance lattice of trees, a monotone summary of weighted path-length ${g_{\mathbf{w}}}^{mon}$ has the properties we need.

In [25, p. 241], Lovász stated the following definition and theorem for set lattices (easily proved for general lattices) about the "monotonization" of a function f.

DEFINITION 5.1. *If $f : \mathcal{L} \to \Re_+$ is a real-valued function on a lattice $\mathcal{L}$ with ordering relation $\sqsubseteq$, define*

$$f^{mon}(\mathbf{x}) \quad = \quad \min\ \{\ f(\mathbf{x}') \mid \mathbf{x}' \sqsubseteq \mathbf{x}\ \}.$$

THEOREM 5.2. *If f is submodular, then f^{mon} is also submodular.*

Proof. From the definition of f^{mon}, for all $\mathbf{x}$, $\mathbf{y}$ in $\mathcal{L}$, there exists a $\mathbf{x}' \sqsubseteq \mathbf{x}$ such that $f^{mon}(\mathbf{x}) = f(\mathbf{x}')$ and a $\mathbf{y}' \sqsubseteq \mathbf{y}$ such that $f^{mon}(\mathbf{y}) = f(\mathbf{y}')$. But then $(\mathbf{x}' \sqcap \mathbf{y}') \sqsubseteq (\mathbf{x} \sqcap \mathbf{y})$ and $(\mathbf{x}' \sqcup \mathbf{y}') \sqsubseteq (\mathbf{x} \sqcup \mathbf{y})$, so

$$\begin{array}{rcccl} f^{mon}(\mathbf{x} \sqcap \mathbf{y}) & \le & f^{mon}(\mathbf{x}' \sqcap \mathbf{y}') & \le & f(\mathbf{x}' \sqcap \mathbf{y}'), \\ f^{mon}(\mathbf{x} \sqcup \mathbf{y}) & \le & f^{mon}(\mathbf{x}' \sqcup \mathbf{y}') & \le & f(\mathbf{x}' \sqcup \mathbf{y}'). \end{array}$$

$$\begin{array}{rcccl} f^{mon}(\mathbf{x} \sqcap \mathbf{y}) \ + \ f^{mon}(\mathbf{x} \sqcup \mathbf{y}) & \le & f(\mathbf{x}' \sqcap \mathbf{y}') \ + \ f(\mathbf{x}' \sqcup \mathbf{y}') & & \\ & \le & f(\mathbf{x}') \ + \ f(\mathbf{y}') & & \text{(as } f \text{ is submodular)} \\ & = & f^{mon}(\mathbf{x}) \ + \ f^{mon}(\mathbf{y}). & & \square \end{array}$$

Thus ${g_{\mathbf{w}}}^{mon}$ is both submodular and monotone on the tree imbalance lattice.

5.2. Dynamic programming reconstruction of the Huffman algorithm. Based the analysis above, we can derive Huffman codes by using a simple recursion.

DEFINITION 5.3. *The* Huffman contraction $\mathbf{w}^{\frown}$ *of a descending weight sequence* $\mathbf{w} = \langle\, w_1 \cdots w_n \,\rangle$ *is*

$$\mathbf{w}^{\frown} \quad = \quad \mathrm{sort}{\downarrow}\,(\,\langle\ w_1\ \cdots\ w_{n-2}\ (w_{n-1}{+}w_n)\ \rangle\,).$$

Parenthetically, note that $\boldsymbol{\ell}^{-} \ = \ -\log_2(\,(2^{-\boldsymbol{\ell}})^{\frown}\,)$ *for path-length sequences* $\boldsymbol{\ell}$. *If* $n \ge 1$ *is the length of* $\mathbf{w}$, *then the (most balanced)* Huffman code *for* $\mathbf{w}$ *is defined by*

$$\mathit{Huffman}(\mathbf{w}) \quad = \quad \begin{cases} \langle\ 0\ \rangle & \text{if } \ n = 1, \\ \mathit{better\_expansion}(\ \mathit{Huffman}(\ \mathbf{w}^{\frown}\ )\ , \mathbf{w}) & \text{if } \ n > 1; \end{cases}$$

$$\mathit{better\_expansion}(\ \boldsymbol{\ell}\ , \mathbf{w}) \quad = \quad \begin{cases} \boldsymbol{\ell}_+ & \text{if } \ g_{\mathbf{w}}(\ \boldsymbol{\ell}_+\ ) \ \le \ g_{\mathbf{w}}(\ \boldsymbol{\ell}^+\ ), \\ \boldsymbol{\ell}^+ & \text{otherwise.} \end{cases}$$

The transitively reduced imbalance lattice for $n = 9$ showing, for $\mathbf{w} = \langle$ 189 95 73 71 23 21 18 9 1 $\rangle$, the code cost $g_{\mathbf{w}}(\ell)$ for each path-length sequence ℓ. The Huffman code 133355566*, with cost* 1276*, is the global minimum. The code* 223344455*, with cost* 1298*, is a local minimum. (Because the graph shows only the transitive reduction of the lattice, it omits some edges corresponding to exchanges, but the minimum is localized.)*

FIG. 5.1. *Costs of all possible codes for the weights* $\mathbf{w} = \langle$ 189 95 73 71 23 21 18 9 1 $\rangle$.

For example, the example in Figure 5.1 can be traced through Figure 3.3 and Table 2.2:

$$\begin{array}{lcl}
\mathit{Huffman}(\ \langle\ 189\ 95\ 73\ 71\ 23\ 21\ 18\ 9\ 1\ \rangle\ ) & = & \langle\ 1\ 3\ 3\ 3\ 5\ 5\ 5\ 6\ 6\ \rangle, \\
\mathit{Huffman}(\ \langle\ 189\ 95\ 73\ 71\ 23\ 21\ 18\ 10\ \rangle\ ) & = & \langle\ 1\ 3\ 3\ 3\ 5\ 5\ 5\ 5\ \rangle, \\
\mathit{Huffman}(\ \langle\ 189\ 95\ 73\ 71\ 28\ 23\ 21\ \rangle\ ) & = & \langle\ 1\ 3\ 3\ 3\ 4\ 5\ 5\ \rangle, \\
\mathit{Huffman}(\ \langle\ 189\ 95\ 73\ 71\ 44\ 28\ \rangle\ ) & = & \langle\ 1\ 3\ 3\ 3\ 4\ 4\ \rangle, \\
\mathit{Huffman}(\ \langle\ 189\ 95\ 73\ 72\ 71\ \rangle\ ) & = & \langle\ 1\ 3\ 3\ 3\ 3\ \rangle, \\
\mathit{Huffman}(\ \langle\ 189\ 143\ 95\ 73\ \rangle\ ) & = & \langle\ 1\ 2\ 3\ 3\ \rangle, \\
\mathit{Huffman}(\ \langle\ 189\ 168\ 143\ \rangle\ ) & = & \langle\ 1\ 2\ 2\ \rangle, \\
\mathit{Huffman}(\ \langle\ 311\ 189\ \rangle\ ) & = & \langle\ 1\ 1\ \rangle, \\
\mathit{Huffman}(\ \langle\ 500\ \rangle\ ) & = & \langle\ 0\ \rangle.
\end{array}$$

This dynamic programming definition is similar to the standard Huffman algorithm, but it differs in a few ways. First, it considers only upper and lower expansions of $\mathit{Huffman}(\mathbf{w}^\frown)$; we prove momentarily that this is sufficient. Second, it produces a *unique* Huffman code, which is the most balanced possible because it uses lower expansions whenever possible. (This avoids the issue of multiplicity of solutions that arises in implementation of the standard Huffman algorithm. For example, if $\mathbf{w} = \langle\ 3\ 2\ 2\ 1\ \rangle$, then $\langle\ 1\ 2\ 3\ 3\ \rangle$ is a Huffman code, but the more balanced sequence $\langle\ 2\ 2\ 2\ 2\ \rangle$ is also and will be produced by the algorithm above.)

Actually, the definition of $\mathit{Huffman}(\mathbf{w})$ can be "simplified" somewhat. Note that when

$$\boldsymbol{\ell} \quad = \quad \mathit{Huffman}(\mathbf{w}^\frown) \quad = \quad \langle\ \cdots\ (q-j)\ \overbrace{q\ \cdots\ q}^{2k}\ \rangle$$

with suffix length $2k$ and suffix increment j, the condition on $\mathit{better\_expansion}(\boldsymbol{\ell}, \mathbf{w})$ is

$$\begin{array}{lrcl}
 & g_{\mathbf{w}}(\boldsymbol{\ell}_+) & \le & g_{\mathbf{w}}(\boldsymbol{\ell}^+) \\
\Leftrightarrow \quad g_{\mathbf{w}}(\boldsymbol{\ell}) + w_{n-2k-1} - (j-1)\,w_{n-2k} + q\,w_n & \le & g_{\mathbf{w}}(\boldsymbol{\ell}) + w_{n-1} + (q+1)\,w_n \\
\Leftrightarrow \quad w_{n-2k-1} - (j-1)\,w_{n-2k} & \le & w_{n-1} + w_n.
\end{array}$$

Going further, the proof of Theorem 5.5 below implies that this condition actually can be simplified to take $j = 1$, so that $\mathit{better\_expansion}(\boldsymbol{\ell}, \mathbf{w}) = \boldsymbol{\ell}_+$ if $w_{n-2k-1} \le w_{n-1} + w_n$.

THEOREM 5.4. *$\mathit{Huffman}(\mathbf{w})$ is the most balanced optimal code for $\mathbf{w}$.*

Proof. Let $\mathbf{s} = \mathit{Huffman}(\mathbf{w})$, so that $\mathbf{s}$ is the cheaper of $\mathit{Huffman}(\mathbf{w}^\frown)_+$ and $\mathit{Huffman}(\mathbf{w}^\frown)^+$, or is the former (which is more balanced) if they have equal cost.

Only these two expansions need be considered. Like the usual Huffman algorithm, this algorithm assigns w_{n-1} and w_n maximal path length. Therefore $(w_{n-1} + w_n)$ must appear in the "suffix" of $\mathbf{w}^\frown$, i.e., among the $2k+1$ final entries, where $2k$ is the suffix length of $\boldsymbol{\ell} = \mathit{Huffman}(\mathbf{w}^\frown)$; and so it has path length either $(q-1)$ or q, corresponding to the two possible expansions. Thus only Huffman codes are derived with the algorithm above.

Submodularity of ${g_{\mathbf{w}}}^{mon}$ now proves that there is a unique most balanced Huffman code (and thus greedy search will find this code). Suppose that $\mathbf{s}$ and $\mathbf{t}$ are maximally balanced Huffman codes that are noncomparable in the balance ordering. Then ${g_{\mathbf{w}}}^{mon}(\mathbf{t}) = g_{\mathbf{w}}(\mathbf{t}) = g_{\mathbf{w}}(\mathbf{s})$. Because $\mathbf{t}$ is optimal ${g_{\mathbf{w}}}^{mon}(\mathbf{s} \vee \mathbf{t}) = {g_{\mathbf{w}}}^{mon}(\mathbf{t})$.

Submodularity of ${g_{\mathbf{w}}}^{mon}$ then implies that ${g_{\mathbf{w}}}^{mon}(\mathbf{s} \wedge \mathbf{t}) \leq {g_{\mathbf{w}}}^{mon}(\mathbf{s})$. By the definition of ${g_{\mathbf{w}}}^{mon}$, ${g_{\mathbf{w}}}^{mon}(\mathbf{s} \wedge \mathbf{t}) = {g_{\mathbf{w}}}^{mon}(\mathbf{s})$. But then $\mathbf{s} \wedge \mathbf{t}$ is optimal—hence a Huffman code—and it is more balanced than both $\mathbf{s}$ and $\mathbf{t}$. This gives a contradiction. □

THEOREM 5.5. *Huffman*$(\mathbf{w}^\frown) = $ *Huffman*$(\mathbf{w})^-$.

Proof. We prove this by induction on the length n of $\mathbf{w}$. The base case $n = 2$ is trivial.

For the induction step, let $\mathbf{s} =$ *Huffman*$(\mathbf{w})$, so by the previous theorem $\mathbf{s}$ is the most balanced optimal code for $\mathbf{w}$. Let $\boldsymbol{\ell} =$ *Huffman*$(\mathbf{w}^\frown)$. Since $\mathbf{w}^\frown$ has length $(n-1)$, $\boldsymbol{\ell}$ is the most balanced optimal code for $\mathbf{w}^\frown$ by the induction hypothesis. By definition $\mathbf{s}$ is the better (cheaper or more balanced if equally cheap) of $\boldsymbol{\ell}^+$ or $\boldsymbol{\ell}_+$. We consider two possibilities.

First, if $\mathbf{s} = \boldsymbol{\ell}^+$, then $\boldsymbol{\ell} = \mathbf{s}^-$ as required, because $\boldsymbol{\ell} = (\boldsymbol{\ell}^+)^-$ by Theorem 3.9.

Second, if $\mathbf{s} = \boldsymbol{\ell}_+$, then $w_{n-2k-1} - (j-1)\, w_{n-2k} \;\leq\; w_{n-1} + w_n$, where $2k$ is the suffix length of $\boldsymbol{\ell}$, j is its suffix increment, and by Theorem 3.1, $j \leq \log_2(2k)$ or equivalently $2^{j-1} \leq k$. If $j = 1$ we find again $\boldsymbol{\ell} = \mathbf{s}^-$ as required.

We now claim that $j > 1$ cannot arise in this second possibility where $\mathbf{s} = \boldsymbol{\ell}_+$. Let us first understand intuitively why this is so. When the suffix length $j > 1$, $\boldsymbol{\ell} = \langle\, \cdots\ (q-j)\ q\ \cdots\ q\, \rangle$ describes a tree that is perfectly balanced over its suffix, but the rest is at least j levels shorter. The Huffman algorithm will construct such a tree only when the final $2k$ weights of $\mathbf{w}^\frown$ are all of similar size, but w_{n-2k-1} is much larger. Specifically, $w_{n-1} + w_n < w_{n-2k-1}$, and w_{n-2k-1} is constrained to be 2^{j-1} larger than the sum of the subsequent weights, or the Huffman algorithm would construct a different tree. But w_{n-2k-1} is also constrained to be small by the inequality in the definition of the Huffman algorithm; if it becomes too large, we get $\mathbf{s} = \boldsymbol{\ell}^+$ instead of $\mathbf{s} = \boldsymbol{\ell}_+$. These two constraints turn out not to be simultaneously satisfiable when $j > 1$.

Suppose that $j > 1$ and $\mathbf{s} = \boldsymbol{\ell}_+$; then, since $w_{n-1} + w_n < w_{n-2k-1}$ we have two cases.

1. $w_{n-3} \geq w_{n-1} + w_n$.
   Let $W = w_{n-3}$. Then $w_{n-2k-1} > w_{n-2k} + (2^{j-1}-1)\, W$ and $2W \geq w_{n-2k} \geq W$, since $j > 1$ implies $2k \geq 4$ by Theorem 3.1, $\ell_{n-2k-1} = (q-j)$, and $\boldsymbol{\ell} =$ *Huffman*$(\mathbf{w}^\frown)$ is constructed by the Huffman algorithm. These give the first bound
   $$\frac{w_{n-2k-1}}{w_{n-2k}} \quad > \quad 1 \;+\; (2^{j-1}-1)/2 \quad = \quad 2^{j-2} + 1/2.$$
   However, from $w_{n-2k-1} - (j-1)\, w_{n-2k} \;\leq\; w_{n-1} + w_n$ it follows that
   $$\begin{aligned} w_{n-2k-1} &> w_{n-2k} \;+\; (2^{j-1}-1)\, W \\ &\geq w_{n-2k} \;+\; (2^{j-1}-1)\, (w_{n-1} + w_n) \\ &\geq w_{n-2k} \;+\; (2^{j-1}-1)\, (w_{n-2k-1} - (j-1)\, w_{n-2k}). \end{aligned}$$
   When $j = 2$, this simplifies to $w_{n-2k-1} > w_{n-2k-1}$, a contradiction. When $j > 2$, it gives the second bound
   $$\frac{w_{n-2k-1}}{w_{n-2k}} \quad < \quad \frac{(j-1) \;-\; 1/(2^{j-1}-1)}{1 \;-\; 1/(2^{j-1}-1)}.$$
   However this contradicts the first bound for all $j > 2$.
2. $w_{n-2k-1} > w_{n-1} + w_n > w_{n-3}$.
   This is like the previous case, but this time when $W = w_{n-3}$ we can derive

only the weaker condition $W > (w_{n-1} + w_n)/2$, because $w_{n-3} \geq w_{n-1} \geq w_n$. Still, the same first bound, essentially the second bound (with $(2^{j-1} - 1)$ divided by 2), and the same contradictions, are derivable.

Thus all cases reach a contradiction, implying as required that, in the second possibility, $j = 1$ and $\boldsymbol{\ell} = \mathbf{s}^-$. □

5.3. The importance of submodularity in dynamic programming. Together, Theorems 5.4 and 5.5 show that Huffman coding (finding the most balanced code that minimizes $g_{\mathbf{w}}{}^{mon}$) is a dynamic programming problem that can be solved in various ways, because the problem enjoys elegant recursive properties.

Huffman coding gives another example of a dynamic programming problem that can be sped up considerably because the objective function is submodular over the solution space. Lawler [24] remarked:

> *If a discrete optimization problem can be solved efficiently, it is quite likely that submodularity is responsible. In recent years there has been a growing appreciation of the fact that submodularity plays a pivotal role in discrete optimization, not unlike that of convexity in continuous optimization.*

Submodularity has a long history in dynamic programming. By 1781, Monge had found a form of submodularity to be important in simplifying the transportation problem [17]. In 1970, Edmonds [6] related submodularity to matroids and greedily solvable optimization problems. In 1980, Yao [42] generalized upon Knuth's famous $O(n^2)$ algorithm for optimum binary search trees [21] by giving an $O(n^2)$ algorithm for the dynamic programming problem

$$\begin{aligned} c(i,i) &= 0, \\ c(i,j) &= w(i,j) + \min_{i<k\leq j} \left(c(i,k-1) + c(k,j) \right) \quad (i < j); \end{aligned}$$

$$\begin{aligned} w(i,j) &\leq w(i',j') && (i' \leq i \leq j \leq j'), \\ w(i,j) + w(i',j') &\leq w(i',j) + w(i,j') && (i \leq i' \leq j \leq j'). \end{aligned}$$

Yao called the final constraint the *quadrangle inequality*, noting that it implies the (inverse) triangle inequality. Writing $I = [i, j]$ and $J = [i', j']$, defining a lattice of intervals of indices in the dynamic programming array, these two constraints require the function $W([a, b]) = -w(a, b)$ to be *monotone decreasing* ($W(I) \geq W(J)$ if $I \subseteq J$) and *submodular* ($W(I) + W(J) \geq W(I \cap J) + W(I \cup J)$). Results from exploiting the quadrangle inequality in dynamic programming appear in [2, 7, 35] for problems ranging from DNA sequencing to minimum cost matching.

Mirroring Theorem 4.7, the *Monge condition* $w_{i,j} + w_{i+1,j+1} \leq w_{i+1,j} + w_{i,j+1}$ on an $n \times n$ weight matrix W is also equivalent to the requirement that, ignoring its first column and row, the matrix $\boldsymbol{\partial}\, W\, \boldsymbol{\partial}^{\top}$ is nonpositive. Burkard, Klinz, and Rudolf [4], compiled a comprehensive survey of many incarnations of the Monge condition.

Recently Klein [20] explored the connection between dynamic programming and submodularity. Golin and Rote [14] developed dynamic programming algorithms for prefix codes when the codeword letters have differing costs, a useful case not handled by Huffman's algorithm; they recently extended this work to exploit the Monge property.

6. Other applications. The results here also can be used to gain further insight about submodular dynamic programming, the Huffman coding problem, and perhaps

also about the applications of lattice concepts in coding. Almost all of the theorems proved here admit interesting extensions and/or special cases. For example, a direct corollary of Theorem 4.3 (using $\mathbf{w} = \langle\, 1 \cdots 1 \,\rangle$) is that the function mapping a path-length sequence to its level of balance is submodular on the imbalance lattice. It would be interesting to extend the work here for the t-ary codes discussed in [19].

Majorization, we believe, can be exploited further in characterizing optimal codes. We have established that the imbalance ordering on tree path-length sequences $\boldsymbol{\ell}$ is isomorphic to the majorization ordering on exponentiated tree path-length sequences $\mathbf{x} = 2^{-\boldsymbol{\ell}}$. Thus any function that is Schur convex (i.e., "majorization-preserving": monotone with respect to the majorization ordering) on exponentiated path-length sequences and hence monotone on the (continuous) majorization lattice will also be monotone on the (discrete) imbalance lattice. Negative entropy is an important example of such a function; related functions are discussed in [32].

Furthermore, the methods developed above hold out hope for entirely new approaches to Huffman coding. We sketch two possibilities.

6.1. Continuous approximation of Huffman codes. One possibility is that we can attack the combinatorial problem of Huffman coding with a continuous, real-valued optimization problem. Recall that Huffman coding can be expressed as an optimization problem:

$$\begin{aligned} &\text{minimize} && \sum_{i=1}^{n} w_i\, \ell_i \\ &\text{subject to} && \sum_{i=1}^{n} 2^{-\ell_i} \;=\; 1, \qquad \ell_i > 0, \;\; \text{integer} \;\; (1 \le i \le n). \end{aligned}$$

Dropping the integrality constraint gives an interesting continuous relaxation of Huffman coding that can be attacked numerically. For example, by treating the constraint as a penalty function, the problem above can be solved numerically with something like the system of equations $\partial/\partial\ell_j \left(\sum_{i=1}^{n} w_i\, \ell_i \;+\; 10^{10} \left(1 \;-\; \sum_{i=1}^{n} 2^{-\ell_i} \right)^2 \right) \;=\; 0$ $(1 \le j \le n)$. Using the example weight sequence $\mathbf{w} = \langle\, 189\ 95\ 73\ 71\ 23\ 21\ 18\ 9\ 1 \,\rangle$ studied earlier, a simple program found a unique real solution

$$\boldsymbol{\ell} \approx \langle\, 1.4\ 2.4\ 2.8\ 2.8\ 4.4\ 4.8\ 4.8\ 5.8\ 9.0 \,\rangle$$

for these equations, with objective ≈ 1241. As expected, this solution is near the optimal Huffman code $\langle\, 1\,3\,3\,3\,5\,5\,5\,6\,6 \,\rangle$, with cost 1276.

When the relaxation is faithful to the original, it will be possible to find optimal solutions quickly. The relaxed solution can be used to jump to the right neighborhood in the imbalance lattice, from which balancing exchanges will walk to the optimal code. The penalty function could clearly be varied, and perhaps could be changed to encourage near-integral solutions.

Interior point methods on the majorization lattice may also be possible. Among other things, it may be possible to define $\mathbf{s} \wedge \mathbf{t}$ in terms of $-\log_2 \left(2^{-\mathbf{s}} \sqcap 2^{-\mathbf{t}} \right)$ and $\mathbf{s} \vee \mathbf{t}$ in terms of $-\log_2 \left(2^{-\mathbf{s}} \sqcup 2^{-\mathbf{t}} \right)$: they are often identical and always satisfy

$$2^{-\mathbf{s} \wedge \mathbf{t}} \;\preceq\; 2^{-\mathbf{s}} \sqcap 2^{-\mathbf{t}}, \qquad\qquad 2^{-\mathbf{s}} \sqcup 2^{-\mathbf{t}} \;\preceq\; 2^{-\mathbf{s} \vee \mathbf{t}}$$

(because $2^{-\mathbf{s}} \sqcap 2^{-\mathbf{t}}$ and $2^{-\mathbf{s}} \sqcup 2^{-\mathbf{t}}$ are the glb and lub with respect to majorization).

For perspective, if $\alpha = 7 - \log_2(12) \approx 3.4150375$ and $\beta = (\alpha - 1)$, the following set of examples represent the unusual cases with $n = 9$ where $-\log_2 \left(2^{-\mathbf{s}} \;\sqcap\; 2^{-\mathbf{t}} \right) \neq$

$(\mathbf{s} \wedge \mathbf{t})$ or $-\log_2\left(2^{-\mathbf{s}} \sqcup 2^{-\mathbf{t}}\right) \neq (\mathbf{s} \vee \mathbf{t})$.

$\mathbf{s}$	$\mathbf{t}$	$-\log_2\left(2^{-\mathbf{s}} \sqcap 2^{-\mathbf{t}}\right)$	$\mathbf{s} \wedge \mathbf{t}$
$\langle\ 1\ 2\ 4\ 5\ 5\ 5\ 5\ 5\ 5\ \rangle$	$\langle\ 1\ 3\ 3\ 3\ 4\ 5\ 6\ 7\ 7\ \rangle$	$\langle\ 1\ 3\ 3\ \alpha\ 5\ 5\ 5\ 5\ 5\ \rangle$	$\langle\ 1\ 3\ 3\ 3\ 4\ 4\ 5\ 5\ 5\ 5\ \rangle$
$\langle\ 1\ 2\ 4\ 5\ 5\ 5\ 5\ 5\ 5\ \rangle$	$\langle\ 2\ 2\ 2\ 3\ 4\ 5\ 6\ 7\ 7\ \rangle$	$\langle\ 2\ 2\ 2\ \alpha\ 5\ 5\ 5\ 5\ 5\ \rangle$	$\langle\ 2\ 2\ 2\ 4\ 4\ 5\ 5\ 5\ 5\ \rangle$
$\langle\ 1\ 3\ 4\ 4\ 4\ 4\ 4\ 5\ 5\ \rangle$	$\langle\ 2\ 2\ 2\ 3\ 4\ 5\ 6\ 7\ 7\ \rangle$	$\langle\ 2\ 2\ \beta\ 4\ 4\ 4\ 4\ 5\ 5\ \rangle$	$\langle\ 2\ 2\ 3\ 3\ 4\ 4\ 4\ 5\ 5\ \rangle$
$\mathbf{s}$	$\mathbf{t}$	$-\log_2\left(2^{-\mathbf{s}} \sqcup 2^{-\mathbf{t}}\right)$	$\mathbf{s} \vee \mathbf{t}$
$\langle\ 1\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ \rangle$	$\langle\ 2\ 2\ 2\ 3\ 4\ 5\ 6\ 7\ 7\ \rangle$	$\langle\ 1\ 4\ \beta\ 3\ 4\ 5\ 6\ 7\ 7\ \rangle$	$\langle\ 1\ 3\ 3\ 3\ 4\ 5\ 6\ 7\ 7\ \rangle$
$\langle\ 1\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ \rangle$	$\langle\ 2\ 2\ 2\ 3\ 4\ 6\ 6\ 6\ 6\ \rangle$	$\langle\ 1\ 4\ \beta\ 3\ 4\ 6\ 6\ 6\ 6\ \rangle$	$\langle\ 1\ 3\ 3\ 3\ 4\ 6\ 6\ 6\ 6\ \rangle$
$\langle\ 1\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ \rangle$	$\langle\ 2\ 2\ 2\ 3\ 5\ 5\ 5\ 6\ 6\ \rangle$	$\langle\ 1\ 4\ \beta\ 3\ 5\ 5\ 5\ 6\ 6\ \rangle$	$\langle\ 1\ 3\ 3\ 3\ 5\ 5\ 5\ 6\ 6\ \rangle$
$\langle\ 1\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ \rangle$	$\langle\ 2\ 2\ 2\ 4\ 4\ 4\ 5\ 6\ 6\ \rangle$	$\langle\ 1\ 4\ \beta\ 4\ 4\ 4\ 5\ 6\ 6\ \rangle$	$\langle\ 1\ 3\ 3\ 4\ 4\ 4\ 5\ 6\ 6\ \rangle$
$\langle\ 1\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ 4\ \rangle$	$\langle\ 2\ 2\ 2\ 4\ 4\ 5\ 5\ 5\ 5\ \rangle$	$\langle\ 1\ 4\ \beta\ 4\ 4\ 5\ 5\ 5\ 5\ \rangle$	$\langle\ 1\ 3\ 3\ 4\ 4\ 5\ 5\ 5\ 5\ \rangle$

These examples suggest there may be algorithms that "round up" $-\log_2\left(2^{-\mathbf{s}} \sqcap 2^{-\mathbf{t}}\right)$ to give $\mathbf{s} \wedge \mathbf{t}$, and "round down" $-\log_2\left(2^{-\mathbf{s}} \sqcup 2^{-\mathbf{t}}\right)$ to give $\mathbf{s} \vee \mathbf{t}$.

6.2. Practical applications in adaptive coding. In many practical situations it is difficult or impossible to know a priori the weights $\mathbf{w}$ used in Huffman coding. A natural idea, which occurred independently to Faller [8] and Gallager [11], is to allow the weights to be determined dynamically and to have the Huffman code "evolve" over time. *Dynamic Huffman coding* is the strategy of repeatedly constructing the Huffman code for the input so far and using it in transmitting the next input symbol. Knuth presented an efficient algorithm for dynamic Huffman coding in [22], and his performance results for the algorithm show it consistently producing compression very near (though not surpassing) the compression attained with static Huffman code for the entire input.

Vitter [40, 41] then developed a dynamic Huffman algorithm that improves on Knuth's in the following way: rather than simply revise the Huffman tree after each input symbol, Vitter also finds a new Huffman tree of minimal external path length $\sum_i \ell_i$ and height $\max_i \ell_i$. With this modification Vitter was actually able to surpass the performance of static Huffman coding on several benchmarks.

A small contribution we can make is to clarify the improvement of Vitter. Basically, Vitter's algorithm differs from Knuth's in *constructing the optimal path-length sequence that is also as balanced as possible.* Note that minimizing the external path length $\sum_i \ell_i$ is identical to maximizing the level of balance. Since there can be more than one optimal code, and unnecessary imbalance tends to penalize the symbol currently being encoded, insisting on maximally balanced codes improves performance.

Another contribution of the lattice perspective here is to encourage development of new adaptive coding schemes. As suggested in section 5.1, a move between adjacent points in the lattice corresponds to minor alteration of codes, and by moving through the lattice we incrementally modify the cost of a code. Hill-climbing then gives greedy coding algorithms, and online hill-climbing gives adaptive coding algorithms. Although we have shown that the codes produced by hill-climbing are not guaranteed to be optimal, lattice-oriented adaptive coding algorithms may still have a role to play in some coding situations, since the Huffman notion of optimality is not really what is needed in the (currently popular and enormously important) adaptive context.

For example, adaptive coding algorithms can start at any point in the lattice, as long as both ends of the communication know which one. Rather than rely on the dynamic Huffman algorithm to derive reasonable operating points for the code, or rely on Knuth's "windowed" algorithm [22], one can immediately begin with a mutually

agreed upon, "reasonable" initial code (depending on the type of information being transmitted), and then adapt this code using some mutually agreed upon greedy algorithm for moving in the imbalance lattice.

Acknowledgments. We are very grateful to Pierre Hasenfratz for insightful comments that improved this paper. A conversation with Mordecai Golin, who provided us with an expanded version of [14], inspired us to discuss dynamic programming explicitly in this paper. He also pointed out the survey [4] to us. Also, we are indebted to two anonymous referees for clarifications of the exposition, especially of the significance of submodularity and of Shannon's work [38].

TRACTABILITY OF PARAMETERIZED COMPLETION PROBLEMS ON CHORDAL, STRONGLY CHORDAL, AND PROPER INTERVAL GRAPHS*

HAIM KAPLAN†, RON SHAMIR‡, AND ROBERT E. TARJAN§

Abstract. We study the parameterized complexity of three NP-hard graph completion problems.

The *minimum fill-in* problem asks if a graph can be triangulated by adding at most k edges. We develop $O(c^k m)$ and $O(k^2 mn + f(k))$ algorithms for this problem on a graph with n vertices and m edges. Here $f(k)$ is exponential in k and the constants hidden by the big-O notation are small and do not depend on k. In particular, this implies that the problem is fixed-parameter tractable (FPT).

The *proper interval graph completion* problem, motivated by molecular biology, asks if a graph can be made proper interval by adding no more than k edges. We show that the problem is FPT by providing a simple search-tree-based algorithm that solves it in $O(c^k m)$-time. Similarly, we show that the parameterized version of the *strongly chordal graph completion* problem is FPT by giving an $O(c^k m \log n)$-time algorithm for it.

All of our algorithms can actually enumerate all possible k-completions within the same time bounds.

1. Introduction.

The focus of this paper is the parameterized complexity of several graph completion problems. Many well-known NP-hard problems can be stated with a parameter k so that they have polynomial-time algorithms when k is fixed. (For example, given a graph, decide if it has a vertex cover of size at most k, an independent set of size at least k, or pathwidth at most k.) The way the complexity depends on k varies dramatically, however. Some problems (e.g., *vertex cover* and *pathwidth*) can be solved in linear time when k is fixed, but for others (like *independent set*) the best known algorithms require $\Omega(n^k)$ steps. How the complexity depends on k can be crucial for applications in which small, fixed parameter values are important, as in the problems we study here.

Downey and Fellows initiated a systematic complexity analysis of such problems [1, 9, 10]. They called those parameterized problems that have algorithms of complexity $O(f(k)n^\alpha)$ (with α a constant) *fixed-parameter tractable* (FPT) and defined

a hierarchy of parameterized decision problem classes, $FPT \subseteq W[1] \subseteq W[2] \subseteq \cdots$, with appropriate reducibility and completeness notions. They also conjectured that each of the containments in this hierarchy is proper. (See [1, 9, 10] for definitions and details.) Thus, for example, *vertex cover* and *pathwidth* are in FPT [3, 11, 24], but *independent set* is $W[1]$-complete [1] and *bandwidth* is W[t]-hard for all t [4].

Let Π be a family of graphs such that $K_n \in \Pi$ for every n. The Π-*completion* problem is defined as follows. Given a graph $G = (V, E)$, find a smallest set of edges A such that $G = (V, E \cup A) \in \Pi$. The parameterized version of the Π-completion problem, denoted by Π-*completion(k)*, asks whether there exists an edge set A such that $|A| \leq k$ and $G = (V, E \cup A) \in \Pi$.

In this paper we study the parameterized complexity of Π-*completion(k)* for three graph families Π; namely, chordal, proper interval, and strongly chordal graphs.

A graph is *chordal* (or *triangulated*) if every cycle of length four or more contains a chord (an edge between nonadjacent vertices on the cycle). The *chordal completion* problem is also known as the *minimum fill-in* problem and has received a lot of attention in the past due to its importance in sparse matrix computation (cf. [17]). Rose [33] has shown that for a sparse, symmetric matrix, finding an order of Gaussian elimination steps on diagonal elements that minimizes the number of nonzeros generated in the elimination process (assuming no lucky cancellation of nonzeros) is equivalent to solving the minimum fill-in problem on a corresponding graph.

Yannakakis [41] has shown that minimum fill-in is NP-complete. We focus here on *chordal completion(k)* or *fill-in(k)*, the parametrized version of the problem as defined above. Here k is fixed (to be thought of as a small constant) and is not part of the input. For a graph with n vertices and m edges, the problem can be solved by enumeration in $O(n^{2k}m)$-time, but we seek an algorithm with better dependence on k. In section 2 we describe two such algorithms. We first present a fairly simple, $O(c^k m)$-time search-tree-based algorithm, which already implies that the problem is in FPT. The same technique was previously used by Downey and Fellows [11] to prove parameterized tractability of *vertex cover*, *dominating set in planar graph, feedback vertex set,* and *face cover number of planar graph*. We then develop a more involved algorithm that gives a stronger complexity result: its multiplicative factor depending on k is *polynomial*, and the exponential in k appears only as an *additive* factor. Specifically, this algorithm has complexity $O(k^2nm + f(k))$, where $f(k)$ is exponential in k. For appropriate values of k (growing with the graph size), this algorithm will beat the simple algorithm. Here and throughout the paper we specify the dependence of the complexity on k explicitly, and the constants hidden by the big-O notation do not depend on k.

The second part of the paper deals with the parameterized complexity of the *proper interval completion* (PIC) problem. An *interval graph* is a graph for which one can assign an interval on the real line to each vertex so that two vertices are adjacent iff their intervals intersect. It is a *unit interval graph* if all intervals assigned have equal length. It is *proper interval* if it has an assignment in which no interval properly contains another. The last two notions are equivalent for finite graphs [30]. Interval completion problems arise in molecular biology and in the human genome project. In *physical mapping* of DNA, a set of long contiguous intervals of the DNA chain (called *clones*) is given, together with experimental information on their pairwise overlaps. The goal is to build a map describing the relative position of the clones [7, 27, 22, 4]. We concentrate here on the biologically important case in which all clones have equal length. In the presence of "false negative" errors (unidentified overlaps) the problem of

building a map with fewest errors is equivalent to PIC. This problem is NP-hard [18]. But what about its complexity for a small fixed number of errors? Let PIC(k) be the parameterized version of the problem, in which one asks for an augmenting set with no more than k edges if one exists. We prove parameterized tractability of PIC(k) by providing an $O(c^k m)$-time algorithm.

The third part of the paper considers the parameterized version of the *strongly chordal completion* problem (SCC(k)). The class of strongly chordal graphs was defined and characterized by Farber [12]. Denote by $N(v)$ the set of neighbors of a vertex v, including v itself. A *perfect elimination ordering* of a graph $G = (V, E)$ is an ordering $v_1, v_2, \ldots, v_n$ of V with the property that for each i, j, and l, if $i < j, i < l$, and $v_l, v_j \in N(v_i)$, then $v_l \in N(v_j)$. Rose [31] has shown that a graph is chordal iff it admits a perfect elimination ordering. A *strong elimination ordering* of a graph $G = (V, E)$ is an ordering $v_1, v_2, \ldots, v_n$ of V with the property that for each i, j, k, and l, if $i < j$, $k < l$, $v_k, v_l \in N(v_i)$, and $v_k \in N(v_j)$, then $v_l \in N(v_j)$. A graph is *strongly chordal* if it admits a strong elimination ordering. It is easy to see that every strong elimination ordering is also a perfect elimination ordering, and thus every strongly chordal graph is also a chordal graph. In addition every interval graph is strongly chordal. One can obtain a strong elimination order for an interval graph G by fixing a representation R of G and ordering the vertices in increasing right-endpoint order of their intervals in R. Interest in strongly chordal graphs arises in several ways. First, the problems of locating minimum weight dominating sets and minimum weight independent dominating sets in strongly chordal graphs with real vertex weights can be solved in polynomial time, whereas each of these problems is NP-hard for chordal graphs [13]. Second, these graphs have surprisingly nice structural properties and are intimately related to the class of totally balanced matrices [2]. We show that SCC(k) is FPT by describing an $O(c^k m \log n)$-time algorithm for it.

Section 2 contains the algorithms for chordal completion. Section 2.1 describes the simple search-tree–based algorithm, and section 2.2 gives the details of the more involved $O(k^2 nm + f(k))$-time algorithm. Section 3 extends the search tree algorithm of section 2.1 to solve PIC(k), and section 4 extends it to solve SCC(k). These extensions require additional ideas in order to handle the obstructions characterizing each particular graph family. Section 5 contains a summary and suggestions for some further research.

2. Minimum fill-in. In this section we present two algorithms for *fill-in(k)*. In section 2.1 we begin by describing an $O(c^k m)$-time algorithm for the problem. Then in section 2.2 we use additional new ideas to develop an $O(k^2 nm + f(k))$-time algorithm. Which of these algorithms is faster depends on the size of k compared to n and m. Both algorithms can actually enumerate all minimal k-triangulations of the input graph within the same time bounds.

We will use the following notation. Let $G = (V, E)$ be an undirected graph. For $X \subseteq V$, we denote by G_X the subgraph of G induced by the vertex set X. We define the *length* of a path (cycle) as the number of edges on the path (cycle). A *triangulation* of a graph $G = (V, E)$ is a set of edges F where $E \cap F = \emptyset$ and $\tilde{G} = (V, E \cup F)$ is a chordal graph. We will also say that the set of edges F *triangulates* G. If $|F| \leq k$, then F is a *k-triangulation*. We shall also refer to $\tilde{G}$ as a triangulation of G when there is no confusion. We assume without loss of generality that G is connected and $n \geq 2$; thus $n = O(m)$. A triangulation F is *minimal* if no proper subset of F triangulates G.

2.1. A linear algorithm for fixed k. A *triangulation of a chordless cycle* C is a set T of chords of C such that there is no induced chordless cycle in $C \cup T$. We

shall characterize and count the number of minimal triangulations of a cycle C. We call a cycle an *l-cycle* if it contains l vertices. A *triangle* is a 3-cycle. The proof of the following lemma is straightforward by induction.

LEMMA 2.1. *A minimal triangulation T of an n-cycle C consists of $n-3$ chords. It partitions C into $n-2$ triangles. Any two of these triangles are either disjoint or share a chord. Every chord in T is shared by exactly two triangles.*

The following lemma is well known (cf. [34] and the proof of Lemma 4.3, which is similar).

LEMMA 2.2. *There is a* 1-1 *correspondence between the minimal triangulations of a cycle with l vertices and the binary trees with $l-2$ internal nodes.*

Denote by c_l the lth Catalan number, i.e., $c_l = \binom{2l}{l}\frac{1}{l+1}$. Note that $c_l < 4^l$. Denote the number of binary trees with n internal nodes by b_n. The value b_n satisfies the recurrence $b_0 = 1$, $b_n = \sum_{i+j=n-1} b_i b_j$ for $n \geq 1$. The solution to this recurrence is $b_n = c_n$ (cf. [19]). Thus the following lemma is implied by Lemma 2.2.

LEMMA 2.3. *The number of minimal triangulations of an l-cycle is $c_{l-2} \leq 4^{l-2}$.*

The algorithm will traverse part of a search tree in which each node corresponds to a supergraph of G. This search tree is defined as follows. The graph G itself corresponds to the root of the tree. In order to generate the children of an internal node x that corresponds to a graph G', one needs to find a chordless cycle C in G'. Node x will have a child for each minimal triangulation of C. The graph corresponding to a child is obtained by adding the corresponding minimal triangulation to G'. If $|C| = l$, by Lemma 2.3 node x will have c_{l-2} children. Each leaf of the tree corresponds to a chordal supergraph of G. Note that every minimal triangulation of G is represented by at least one leaf.

One can find a chordless cycle C in a nonchordal graph with m edges in $O(m+n)$-time by the maximum cardinality search (MCS) algorithm described in [37, 38]. Using the algorithm described in [35] and the mapping described in Lemma 2.2, one can generate all minimal triangulations in $O(|C|)$-time per triangulation.

The algorithm actually visits only the nodes of the search tree that correspond to supergraphs of G with no more than k additional edges. If one such node is a leaf, then we have found a k-triangulation. Otherwise, no such triangulation exists.

THEOREM 2.4. *All minimal k-triangulations of a graph G can be found in $O(2^{4k}m)$-time.*

Proof. Let T be the subtree of the search tree traversed by the algorithm. For a node $x \in T$ let $G_x = (V, E_x)$ be the corresponding supergraph of G, d_x the maximum length of a path from x to a leaf of T, and $a_x = \max(\{|E_l| - |E_x| \mid l \text{ is a leaf descendant of } x\})$. Denote by l_x the total number of leaves among the descendants of x. By induction we prove that $l_x \leq 4^{d_x+a_x}$. Thus the total number of nodes in T is bounded by $2 \cdot 4^{2k}$. For each such node a linear amount of time is spent, consisting of the time to generate it and the time to find a chordless cycle in the graph corresponding to it.

Here is the induction argument. Assume the claim is true for all the children of a node x. Let l be the length of the cycle detected at x. Let $d_{\max} = \max\{d_y \mid y \text{ is a child of x}\}$, and let $a_{\max} = \max\{a_y \mid y \text{ is a child of x}\}$. Using the induction hypothesis, the number of leaf descendants of any of the c_{l-2} children of x is bounded by $4^{d_{\max}+a_{\max}}$. Thus the total number of leaf descendants of x is bounded by $4^{l-2}4^{d_{\max}+a_{\max}} = 4^{d_{\max}+1+a_{\max}+l-3} = 4^{d_x+a_x}$. The last equality follows from the fact that the size of a minimal triangulation of a chordless l-cycle is $l-3$, as stated in Lemma 2.1. ∎

The algorithm for enumerating minimal k-triangulations can actually list the same triangulation several times. We can eliminate this redundancy by storing solutions in a table and checking each new solution to see if it has been found already. If we use a k-dimensional search tree to store solutions, the extra time per search tree node to test for redundancy is $O(k \log k)$. Using universal hashing [39] or dynamic perfect hashing [16], the extra time per search tree node is $O(k)$, but the algorithm becomes randomized. These ideas apply equally well to the other enumeration algorithms proposed in this paper.

2.2. An algorithm with a polynomial multiplicative factor. To achieve an $O(k^2nm + f(k))$-time bound for minimal k-triangulation, we first describe an algorithm such that if G can be triangulated with no more than k edges, the algorithm partitions the vertex set of G into two subsets A, B such that the size of A is $O(k^3)$ and there are no chordless cycles in G that contain vertices in B. Then we prove that obtaining a k-triangulation of G is equivalent to obtaining a $(k-a)$-triangulation of A for some $a \geq 0$.

2.2.1. Partitioning the graph. The algorithm uses three main procedures, denoted P_1, P_2, P_3, executed in sequence. These procedures are described below.

(P_1) *Extracting independent chordless cycles.* This procedure starts with $B = V, A = \emptyset$ and repeatedly finds a chordless cycle in G_B using the MCS algorithm and moves its vertices to A. Note that when P_1 is finished, the induced subgraph on B is chordal.

Let $C_1, \ldots, C_j$ be the cycles extracted. The minimum number of chords needed to triangulate each C_i is $|C_i| - 3$. The algorithm maintains a dynamic lower bound cc on the minimum number of chords needed to triangulate G. After detecting the chordless cycle C_i, it increases cc by $|C_i| - 3$. Thus, if at some point $cc > k$, the algorithm can stop with a negative answer. Otherwise procedure P_1 ends when there are no more chordless cycles in B and $cc = \sum_{i=1}^{j}(|C_i| - 3) \leq k$.

The complexity of this part is $O(km)$. The MCS algorithm runs in linear time and the number of cycles detected is not greater than k since each cycle adds at least one to the dynamic lower bound cc. The size of the set A after performing this procedure is $O(k)$.

(P_2) *Extracting related chordless cycles with independent paths.* This procedure looks for chordless cycles that intersect both parts of the current partition, A and B, and contain at least two consecutive vertices in B, as long as such cycles exist. Let C be such a cycle, $|C| = l$. If $l > k + 3$, the algorithm stops with a negative answer. Otherwise every maximal subpath of C containing only vertices from B is moved into A if its length is at least one. The increase to cc depends on the structure of C. We need the following lemma in order to specify this increase precisely.

LEMMA 2.5. *Let C be a chordless cycle, and let p be a path in C of length l with $1 \leq l \leq |C| - 2$. If $l = |C| - 2$, then in every minimal triangulation of C there are at least $l - 1$ chords incident with at least one vertex of p. If $l < |C| - 2$, then in every minimal triangulation of C there are at least l chords incident with at least one vertex on p.*

Proof. If $l = |C| - 2$, then every chord in a minimal triangulation of C is incident with some vertex of p; thus the first part of the lemma holds. We prove the second part by induction on the path length. Obviously there must be a chord incident with at least one of the vertices on p; thus the lemma holds for paths of length one. Assume the result is true for every path with length less than l. Let p be a path with length l. Let (a, b) be a chord incident with p dividing the cycle C into two cycles C_1, C_2.

Case 1. $a, b \in p$. Let l_1 be the length of the subpath of p that connects a and b. Without loss of generality we can assume that $l_1 = |C_1| - 1$. Let p' be the path between the endpoints of p passing through (a, b) in C_2, and let $l_2 = |p'|$. There must be at least $l_1 - 2$ chords incident with p in C_1 and according to the induction hypothesis l_2 chords incident with p' in C_2. Thus the total number of chords incident with p will be at least $(l_1 - 2) + l_2 + 1 = l$.

Case 2. $a \in p$, $b \notin p$. Let $p_1 = p \cap C_1$, $p_2 = p \cap C_2$. For at least one $i = 1, 2$, $|p_i| < |C_i| - 2$. Without loss of generality assume that $|p_1| < |C_1| - 2$. By applying the induction hypothesis and using the previous part of the lemma, we find that the total number of chords incident with p is at least $l_1 + (l_2 - 1) + 1 = l$. □

Suppose that C is a chordless l-cycle that contains $j \geq 1$ disjoint maximal subpaths $p_1, \ldots, p_j$, each of length at least one, that are in B. Let $l_i = |p_i|$, $i = 1, \ldots, j$. Obviously if $l_1 = l - 2$, then $j = 1$, i.e., there is only one such subpath. Otherwise $l_i < l - 2$ for every $1 \leq i \leq j$. Using the previous lemma, we can increase our lower bound *cc* as follows. If there is only one such subpath, *cc* is increased by either $(l_1 - 1)$ if $l_1 = l - 2$ or l_1 if $l_1 < l - 2$. Otherwise *cc* is increased by the larger of $\frac{1}{2}\sum_{i=1}^{j} l_i$ (the factor $\frac{1}{2}$ is needed because a chord can be counted twice in the sum) and $\max\{l_i \mid 1 \leq i \leq j\}$. P_2 terminates whenever either *cc* is greater than k, in which case it stops with a negative answer, or when there are no more cycles of the appropriate kind.

In order to complete the description of P_2 we need to specify how to detect a chordless cycle C with consecutive vertices in B if such a cycle exists. The following observation is useful.

Observation 2.6. *There exists a chordless cycle C with at least two consecutive vertices in B iff there exists an edge (x, y), $x \in A$, $y \in B$ and a path between a vertex in $(N(y) - N(x)) \cap B$ and a vertex in $N(x) - N(y)$ that avoids any other vertices in $N(x) \cup N(y)$.*

One can detect whether such a path exists as follows: Delete $N(x) \cap N(y)$ and $(N(y) - N(x)) \cap A$ from G. Find the connected components of G induced on the other vertices. Check whether there is a vertex in $(N(y) - N(x)) \cap B$ and a vertex in $N(x) - N(y)$ in the same connected component. This process requires $O(m)$-time per edge (x, y) and can be implemented so that if the path exists, then the process will output a chordless cycle through (x, y) for which the other neighbor of y is also in B.

Recall that the size of A after the execution of P_1 is $O(k)$. The number of vertices added to A after the detection of each cycle by P_2 is at most twice the increase to *cc*. Since *cc* is never greater than k, the total number of vertices in A when P_2 ends remains $O(k)$.

(P_3) *Adding essential edges in G_A.* For every nonadjacent pair of vertices $y, z \in V$ define $A_{y,z}$ to be the set of all vertices x such that y, x, z appear consecutively on some chordless cycle in G.

Lemma 2.7. *If for some pair $y, z \in A$, $(y, z) \notin E$, $|A_{y,z}| > 2k$, then the edge (y, z) is in every k-triangulation of G.*

Proof. Assume that (y, z) is not in a k-triangulation $\overline{G} = (V, \overline{E})$ of G. Then there must be a chord in $\overline{E} - E$ incident with each vertex in $A_{y,z}$. Since no more than two such vertices can share a chord, $|\overline{E} - E| > k$, which is a contradiction. □

Edges (y, z) satisfying the lemma are called *essential*. For a triple y, x, z such that $(y, x) \in E$, $(x, z) \in E$, $(y, z) \notin E$ one can determine whether y, x, z appear consecutively on some chordless cycle in linear time: They appear consecutively on

a chordless cycle iff y and z are in the same connected component after deleting $N(x) - \{y, z\}$ from G.

P_3 first calculates the sets $A_{y,z}$ for every pair $y, z \in A$, $(y, z) \notin E$. Then for each pair $y, z \in A$ such that $|A_{y,z}| > 2k$, we add (y, z) to G'. Finally, we add to A all vertices in each computed set $A_{y,z}$ such that $|A_{y,z}| \leq 2k$.

We now analyze the overall complexity of the partitioning scheme.

LEMMA 2.8. (1) *The execution of P_2 takes $O(knm)$-time.* (2) *The execution of P_3 takes $O(k^2nm)$-time.*

Proof. (1) For each edge (x, y), $x \in A$, $y \in B$, it takes linear time to find a chordless cycle through (x, y) with consecutive vertices in B. The size of A is always $O(k)$; thus the total number of edges incident with vertices of A is always $O(kn)$. For each such edge we may have to run the test mentioned above once, giving a total time complexity $O(knm)$.

(2) Since the size of A when P_3 begins its execution is $O(k)$, the number of triples y, x, z such that $(y, x), (z, x) \in E$, $(y, z) \notin E$, $y, z \in A$, is $O(k^2n)$. For each triple we need to check whether there exists a path between y and z after deleting $N(x) - \{y, z\}$ from G. As mentioned above, this can be done by identifying connected components of G on the remaining vertices and then checking whether y and z are in the same connected component. □

Thus the overall complexity of the partitioning procedure is dominated by the complexity of P_3, which is $O(k^2nm)$. Before the call to P_3, the size of the set A is $O(k)$. Procedure P_3 may add $O(k)$ additional vertices to A for each pair of vertices in A prior to its execution so that we end up with $O(k^3)$ vertices in A.

Let E_s be the set of essential edges detected by P_3, and let $G' = (V, E \cup E_s)$. Denote by A_2, B_2 the partition of the vertex set before the execution of P_3 and by A, B the final partition.

The following lemma will be useful in establishing the correctness of the partitioning scheme and the completion algorithm.

LEMMA 2.9. *Let $G = (V, E)$ be a graph and $v \in V$. Let F be a set of edges between vertices of G such that*

(1) *each $e \in F$ is a chord in a chordless cycle C_e of G,*

(2) *$F \cap E = \emptyset$,*

(3) *v is not an endpoint of any $e \in F$.*

Denote by G^+ the graph obtained from G by adding the edges in F. If there exists a chordless cycle C in G^+ with v_1, v, v_2 occurring consecutively on C, then either there exists a chordless cycle in G on which v_1, v, v_2 occur consecutively or there exists a chordless cycle $D_e = v, x_1, \ldots, x_t, v$ in G such that the path $p = x_1, \ldots, x_t$ is part of a cycle C_e for some $e \in F$, and p contains one of the endpoints of e.

Proof. For an $e = (x, y) \in F$ let P_e^1 and P_e^2 denote the two paths on C_e between x and y with x and y removed from each path. Since C_e is chordless, for every e such that $v \in C_e$, v is not adjacent to any vertex either on P_e^1 or on P_e^2.

Case 1. For every $e \in F$ such that $v \notin C_e$, there exists a path $P_e \in \{P_e^1, P_e^2\}$ such that v is not adjacent in G to any vertex on P_e. Consider the cycle C. Replacing every edge $e \in F$ along C by P_e, one gets a cycle C' in G (not necessarily chordless or simple) with the property that v is not adjacent to any vertex in $C' - \{v_1, v_2\}$. Since edges in F are not incident with v, the edges (v, v_1) and (v, v_2) exist in G. Since C is chordless, $(v_1, v_2) \notin E$. Thus C' contains a chordless cycle in G on which v_1, v, v_2 occur consecutively.

Case 2. For some $e = (x, y) \in F$, v is adjacent to a vertex $u_1 \in P_e^1$ and a vertex

$u_2 \in P_e^2$. Since C is chordless in G^+, v must be nonadjacent either to x or to y in G. Without loss of generality assume v is not adjacent to x and that u_1 and u_2 are the closest to x among all vertices on P_e^1 and P_e^2, respectively, that are adjacent to v. D_e is the chordless cycle in G consisting of the path between u_1 and u_2 through x on C_e and v. □

The correctness of the partitioning scheme is captured by the following theorem.

THEOREM 2.10. *When the partitioning procedure ends, the graph G' has no chordless cycles with vertices in B.*

Proof. The proof is by contradiction. Suppose that there is a chordless cycle $C \in G'$ such that $C \cap B \neq \emptyset$, and let v be a vertex in $C \cap B$. Denote by v_1 and v_2 the two neighbors of v on C. Cycle C must contain at least one essential edge since otherwise C exists in G and either v would have been moved to A or (v_1, v_2) would have been added as an essential edge. Let F be the set of essential edges on C. By the definition of an essential edge, for each $e = (x, y) \in F$ there is a chordless cycle C_e in G in which e is a chord. Moreover, if P_e^1 and P_e^2 are the two paths connecting x and y on C_e, then either P_e^1 or P_e^2 consists of a single vertex $z_e \in B_2$. Since v is in B, it is not incident with any essential edge. Applying Lemma 2.9 we find that one of the following things must happen.

(1) There exists in G a chordless cycle on which v_1, v, v_2 occur consecutively. Thus either v should have been in A or (v_1, v_2) should have been added as an essential edge, and we obtain a contradiction.

(2) There exists a chordless cycle D_e in G on which v and z_e occur consecutively for some $e \in F$. Since both v and z_e are in B_2, they both should have been moved to A by P_2, and again we obtain a contradiction. □

2.2.2. Triangulating the graph. All that remains is to show that once we have partitioned the graph, it suffices to look for $(k-a)$-triangulations of the smaller graph with vertex set A, where a is the number of essential edges added during the partitioning algorithm. This is the content of Theorem 2.13 below. In order to prove the theorem we need some background and preliminary results.

We define the *elimination* of a vertex v from G as the operation that deletes v from G and adds an edge between every nonadjacent pair among v's neighbors. Let $\alpha = v_1, \ldots, v_n$ be an ordering of the vertices of a graph $G = (V, E)$. We denote by G_i, $0 \leq i \leq n$ the graph obtained from G after eliminating the first i vertices in α ($G_0 = G$). Let x and y be two vertices in $G = (V, E)$. An *x,y separator* of G is a set $S \subseteq V - \{x, y\}$ such that when S is deleted from G, x and y occur in different connected components.

The following characterization of minimal triangulations was proved by Ohtsuki, Cheung, and Fujisawa.

THEOREM 2.11 (see [28]). *A triangulation F of $G = (V, E)$ is minimal iff for each $(x, y) \in F$, there exists no x, y separator S of G such that S is a clique of the triangulated graph $\tilde{G} = (V, E \cup F)$.*

Using this theorem we prove the following lemma that is needed for the proof of Theorem 2.13.

LEMMA 2.12. *Let F be a minimal triangulation of a graph $G = (V, E)$. Any edge in F is a chord in a chordless cycle of G.*

Proof. Let $v_1, \ldots, v_n$ be a perfect elimination ordering of $\tilde{G} = (V, E \cup F)$. We use this ordering to eliminate vertices from G. Since F is minimal, for each edge $e = (u, w) \in F$ there exists an index k, $k \geq 1$, such that $e \in G_k$ but $e \notin G_{k-1}$.

We claim that u and w are connected in G_{k-1} by a path such that none of its

vertices is adjacent to v_k. Here is the proof of the claim. Assume that no such path exists. Then the set $N_{G_{k-1}}(v_k) - \{u, w\}$ separates u and w in G_{k-1}. But it follows from the definition of a perfect elimination ordering that this set is a clique in $\tilde{G}_{k-1}$. Since F is a minimal triangulation of G, we must also have that $\tilde{G}_{k-1}$ is a minimal triangulation of G_{k-1}. This contradicts Theorem 2.11 and the claim follows.

We obtain that e is a chord of a chordless cycle in G_{k-1}. This cycle consists of u, v_k, and w occurring consecutively and a shortest path between u and w that avoids the neighborhood of v_k in G_{k-1}. We finish the proof by showing that e is also a chord of a chordless cycle of G. This is done by arguing that if C is a chordless cycle in G_j for some j, $1 \leq j \leq n$, then there exists a chordless cycle C' in G_{j-1} that is either identical to C or contains one additional vertex. If all the edges in C are in G_{j-1}, then $C' = C$ is a chordless cycle in G_{j-1}. Otherwise there is an edge (x, y) in C that is not in G_{j-1}. For each such edge both its endpoints must be adjacent to v_j. Of the vertices on C only x and y can be adjacent to v_j since otherwise C is not chordless in G_j. Take C' to be C with the vertex v_j added between x and y. □

THEOREM 2.13. *Let A, B be a partition of the vertex set V of a graph $G = (V, E)$ such that the vertices of every chordless cycle in G are contained in A. A set of edges F is a minimal triangulation of G iff F is a minimal triangulation of G_A.*

Proof. Let F be a minimal triangulation of G_A. We need to prove that $\tilde{G} = (V, E \cup F)$ is chordal. Assume that $\tilde{G}$ is not chordal. Let C be a chordless cycle in $\tilde{G}$. Since $\tilde{G}$ induced on A is chordal, $C \cap B \neq \emptyset$. By assumption, G does not contain chordless cycles with vertices in B; hence C must not exist in G and thus it contains at least one edge from F and $|C \cap A| \geq 2$. Let v be a vertex in $C \cap B$. According to Lemma 2.12, each edge $e \in F$ is a chord in a chordless cycle C_e of G whose vertices are in A. Since F is a minimal triangulation of G_A, v is not an endpoint of any edge in F. Using Lemma 2.9 we conclude that there must be a chordless cycle with v on it in G, contradicting the assumptions of the theorem.

To prove the other direction, let F be a minimal triangulation of G. There exists $F' \subseteq F$ that is a minimal triangulation of G_A. According to the first part of the proof, F' also triangulates G. Since F is minimal, we conclude that $F' = F$. □

2.2.3. Overall running time. The final step of the algorithm is to look for $(k - a)$-triangulations in vertex set A, as justified by Theorem 2.13. One can find one or all such triangulations by the algorithm described in section 2.1. Since the size of A is $O(k^3)$, the running time for this step is $O(k^6 2^{4k})$. The total time for the three-step partitioning process is $O(k^2 nm)$, giving a time bound for the entire algorithm of $O(k^2 nm + k^6 2^{4k})$. This algorithm has a better bound than the simple algorithm only for $k = \Omega(\log n)$. It would be a nice result to obtain an algorithm with a running time of $O(km + f(k))$. We leave this as an open problem.

3. Proper interval completion. A proper interval supergraph $G = (V, E \cup F)$ of a graph $G = (V, E)$ with $|F| \leq k$ is called a *k-proper interval supergraph* of G.

The algorithm presented in section 2.1 can be easily modified to produce all possible k-proper interval supergraphs of a graph, using the following observations. Proper interval graphs are exactly the chordal graphs that do not contain any of the three obstructions in Figure 3.1 as an induced subgraph [40]. Deng, Hell, and Huang [8] have recently described an algorithm that checks whether a graph G is a proper interval graph. In case G is indeed a proper interval graph the algorithm can provide a proper interval representation for G. The running time of the algorithm is $O(m)$, and it does not use complicated data structures such as PQ-trees [5]. It is

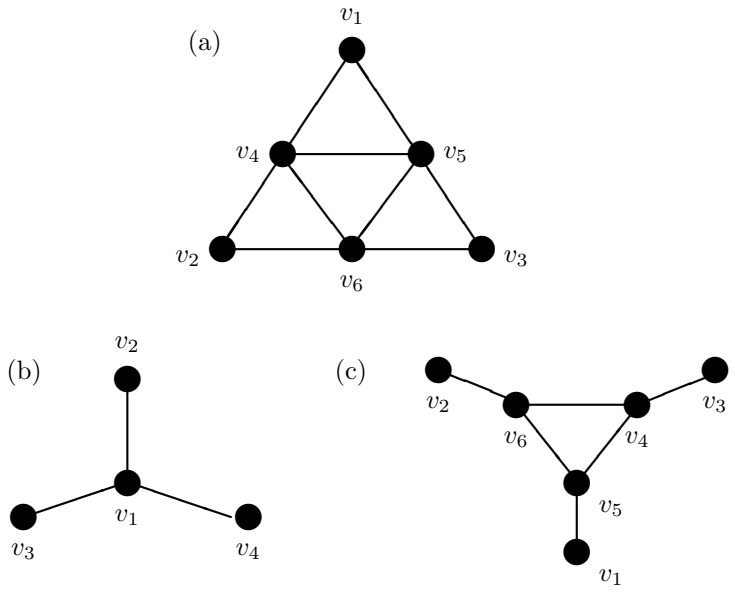

FIG. 3.1. *Obstructions for chordal graphs that are not proper interval.* (a) *Tent.* (b) *Claw.* (c) *Net.*

straightforward to check that in case the input graph is not a proper interval graph one can use the information maintained by the algorithm to extract either a chordless cycle or one of the obstructions in Figure 3.1 in linear time.

The k-completion algorithm will traverse part of a search tree defined as follows. The graph G itself corresponds to the root of the tree. Let x be a node of the search tree corresponding to a supergraph G_x of G that is not a proper interval graph. The children of x are obtained as follows. The algorithm by Deng, Hell, and Huang is applied to G_x to find either a chordless cycle or one of the obstructions in Figure 3.1. If a chordless cycle C is found in G_x, then every minimal triangulation of C gives rise to a child of x as in section 2.1. In case an obstruction is found, x has a child for every edge e between vertices of the obstruction that is not part of the obstruction. The supergraph corresponding to such a child is $G_x \cup \{e\}$. Thus if the obstruction found is a tent the node has six children, if it is a claw it has three, and if it is a net it has nine.

Each leaf in the search tree thus defined corresponds to a proper interval supergraph of G. Note that every minimal proper interval supergraph of G is represented by at least one leaf. As in section 2.1, the nodes of the search tree that are actually traversed correspond to supergraphs with no more than k additional edges. If one such node is a leaf, then we have found a k-proper interval supergraph. Otherwise, no such supergraph exists.

We summarize the result presented in this section in the following theorem. Its proof is analogous to the proof of Theorem 2.4 and is hence omitted.

THEOREM 3.1. *All k-proper interval supergraphs of a graph can be found in $O(2^{4k}m)$-time.*

Remark. Rose, Tarjan, and Lueker proved that if $G = (V, E)$ is triangulated and $G = (V, E \cup F)$ with $F \neq \emptyset$, $F \cap E = \emptyset$ is triangulated, then there exists an edge $e \in F$

such that $G = (V, E \cup \{e\})$ is also triangulated [32, Lemma 2]. Using this lemma, while traversing the search tree as described above one can avoid generating non-triangulated children of nodes that correspond to triangulations of G. Each minimal proper interval completion of G is still guaranteed to be represented by at least one leaf. In this version of the algorithm one uses the MCS algorithm to detect chordality and find a chordless cycle as long as a chordal supergraph has not been reached. When reaching a chordal supergraph, the algorithm by Deng, Hell, and Huang is applied to get one of the obstructions in Figure 3.1. The children of the node are then generated as described above. Finally, the MCS algorithm is applied to each of the children in order to avoid traversing those that are not chordal. Those that are chordal are further expanded. Such an implementation would use the algorithm of Deng, Hell, and Huang only on chordal graphs and hence a somewhat simpler version of it would suffice.

4. Strongly chordal completion. A chord (v, w) in an even cycle C is *odd* if the paths connecting v and w on C contain an odd number of edges.

The following characterization of strongly chordal graphs is due to Farber [12].

THEOREM 4.1. *A graph G is strongly chordal iff G is chordal and every even cycle of length at least six in G has an odd chord.*

An odd chord in an even cycle C partitions C into two smaller even cycles C_1 and C_2. Any odd chord in C_1 or C_2 is an odd chord in C as well. A 4-*cycle decomposition* of an even chordless cycle C is a minimal set T of odd chords in C such that there is no induced even chordless cycle of length at least six in $C + T$.

Next we characterize and count the number of minimal 4-cycle decompositions of an even cycle C. Let $|C| = n$.

The proof of the following lemma is straightforward by induction.

LEMMA 4.2. *A minimal 4-cycle decomposition T of an even n-cycle C consists of $(\frac{n}{2} - 2)$ chords. It partitions C into $(\frac{n}{2} - 1)$ 4-cycles. Every two of these 4-cycles are either disjoint or share a chord. Every chord is shared by exactly two 4-cycles.*

A *ternary tree* is a tree in which each internal node has three children. The following theorem establishes a correspondence between the set of 4-cycle decompositions of an even n-cycle and the set of ternary trees with $n - 1$ leaves and $\frac{n}{2} - 1$ internal nodes. This correspondence is similar to the one stated in Lemma 2.2 between minimal triangulations of a chordless n-cycle and binary trees with $n - 1$ leaves.

LEMMA 4.3. *The number of 4-cycle decompositions of an even n-cycle C is equal to the number of ternary trees with $\frac{n}{2} - 1$ internal nodes.*

Proof. For every even n-cycle C, construct an invertible mapping from the set of 4-cycle decompositions of C to the set of ternary trees with $\frac{n}{2} - 1$ internal nodes, as follows. The construction is by induction on the length of the cycle. Assume that one has constructed an invertible mapping for every cycle C', where $|C'| \leq n - 2$. Let C be an n-cycle, and let e be a fixed edge on C. Let T be a 4-cycle decomposition of C, and let $C_e = \{e, e_1, e_2, e_3\}$ be the 4-cycle in $C + T$ which includes e. If e_i, $i \in \{1, 2, 3\}$ is a chord, let C_i be the cycle $C - C_e + \{e_i\}$. The 4-cycle decomposition T induces a 4-cycle decomposition T_i of C_i. The tree which corresponds to T has a root (associated with the edge e); the ith child of the root is a leaf if $e_i \in C$ or the root of the ternary tree which corresponds to T_i under the mapping associated with C_i if e_i is a chord. It is straightforward to verify that the mapping defined above is indeed invertible. □

Denote the number of ternary trees with n internal nodes by t_n. The value t_n satisfies the following recurrence: $t_0 = 1$ and $t_n = \Sigma_{\{i+j+k=n-1\}} t_i t_j t_k$ if $n \geq$

1. According to Graham, Knuth, and Patashnik [19, p. 349], the solution to this recurrence is

$$t_n = \binom{3n+1}{n} \frac{1}{3n+1},$$

which is no greater than $2^{3n} = 8^n$. Together with Lemma 4.3 we obtain the following.

LEMMA 4.4. *The number of* 4*-cycle decompositions of an even* n*-cycle* C *is no greater than* $8^{\frac{n}{2}-1}$.

4.1. Finding an even cycle without odd chords. The *neighborhood matrix* of a graph is a symmetric 0-1 matrix with rows and columns indexed by the set of vertices of the graph and with an entry of 1 iff the corresponding two vertices are equal or adjacent in the graph. A *doubly lexical ordering* of a matrix is an ordering of the rows and of the columns so that the rows, as vectors, are lexically increasing and the columns, as vectors, are lexically increasing. *Lexical ordering* of vectors is the standard dictionary ordering, except that vectors will be read from highest to lowest coordinate. Thus row vectors will be compared from right to left and column vectors from bottom to top. A matrix M is *symmetric* if its rows and columns are indexed by the same set S and $M(s,t) = M(t,s)$ for all $s,t \in S$. A *symmetric ordering* of such an M is an ordering of S. It is not true that every symmetric matrix has a symmetric doubly lexical ordering. But it was proved by Lubiw [26] that a symmetric matrix that has a *dominant diagonal*, meaning that $M(s,s) \geq M(s,t)$ for all $s,t \in S$, has a symmetric doubly lexical ordering. In particular, the neighborhood matrix of any graph has a symmetric doubly lexical ordering.

A *cycle* matrix is a 0-1 $n \times n$ matrix, $n \geq 3$, with exactly two 1's in each row and in each column and such that no proper submatrix has this property. A *totally balanced matrix* is a 0-1 matrix with no cycle submatrices.

Farber [12] proved the following characterization of strongly chordal graphs.

THEOREM 4.5. *A graph is strongly chordal iff its neighborhood matrix is totally balanced.*

A Γ is an ordered 0-1-valued 2×2 matrix with exactly one 0, in the bottom right corner:

$$\Gamma = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}.$$

Lubiw proved the following property [26, Theorem 5.2] of a doubly lexical 0-1 matrix M with rows R and columns C.

THEOREM 4.6. *Let* M *be an ordered doubly lexical* 0-1 *matrix with rows* R *and columns* C. *Any* 2×2 *submatrix of* M *formed by* $r_1 < r_2 \in R$ *and* $c_1 < c_2 \in C$ *with* $M(r_1, c_2) = M(r_2, c_1) = 1$, $M(r_2, c_2) = 0$ *is, for some* $k \geq 3$, *embedded in a* $k \times k$ *submatrix of* M *formed by* $r_1 < r_2 < \cdots < r_k \in R$ *and* $c_1 < c_2 < \cdots < c_k \in C$ *with* $M(r_i, c_{i+1}) = M(r_{i+1}, c_i) = 1$ *for* $i = 1, \ldots, k-1$, $M(r_k, c_k) = 1$, *and* $M(r_i, c_j) = 0$ *for other* i, j *except possibly* $i = j = 1$. *In particular, any* Γ *submatrix is embedded in a cycle submatrix. See Figure* 4.1.

Together with the observation that in any ordering of a cycle submatrix there is a Γ submatrix, Theorem 4.6 reestablishes the following result.

THEOREM 4.7 (see [20, 2]). *A* 0-1 *matrix has a* Γ*-free ordering iff it is totally balanced. Moreover, a doubly lexical ordering of a totally balanced matrix is* Γ*-free.*

The following theorem makes a link between cycle submatrices in a neighborhood matrix of a graph G and chordless cycles or even cycles without odd chords in G.

	c_1	c_2	c_3	c_4			c_i			c_k
r_1	?	1	0	0						
r_2	1	0	1	0						
r_3	0	1	0	1			0			
r_4	0	0	1	0	.					
				.	.	.				
					.	0	1			
r_i						1	0	.		
			0				.	.	.	
								.	0	1
r_k									1	1

FIG. 4.1. *Every* Γ *submatrix can be embedded in a cycle submatrix.*

THEOREM 4.8. *Let* M *be a neighborhood matrix of a graph* G *and let* N *be a* $k \times k$ *cycle submatrix of* M *with rows* $r_1 < r_2 < \cdots < r_k$ *and columns* $c_1 < c_2 \cdots < c_k$. *Let* $V_N = \{v_l \mid l = r_i \text{ or } l = c_j, 1 \le i, j \le k\}$. *Then either the vertices of* V_N *form an even cycle without odd chords or there exists a subset* $C \subseteq V_N$ *that induces a chordless cycle.*

Proof. If $r_i \neq c_j$ for every $1 \le i, j \le k$, V_N clearly forms an even cycle without odd chords. Assume $r_i = c_j$ for some i and j. This implies that $N(i, j) = M(r_i, c_j) = 1$. Let i' be the other row in which column j has a 1 and let j' be the other column in which row i has a 1. $N(i', j') = 0$ since otherwise we get a contradiction to the fact that N is a cycle submatrix. Thus $r_{i'} \neq c_{j'}$. Among the vertices in V_N, v_{r_i} is adjacent only to $v_{r_{i'}}$ and $v_{c_{j'}}$. These two are not adjacent, but there is a path connecting them in $V - \{v_{r_i}\}$. Thus there exists a chordless cycle $C \subseteq V_N$ through v_{r_i}. □

Let M be a symmetric $n \times n$ neighborhood matrix of a connected graph G with m edges and n vertices. Using Paige and Tarjan's implementation [29] of the algorithm described by Lubiw [26], one can obtain a doubly lexical ordering of M in $O(m \log n)$-time. Lubiw [26] also shows how to search for a Γ submatrix in a doubly lexically ordered M in $O(m)$-time. Given a Γ submatrix in a doubly lexically ordered M, a cycle submatrix that contains it can also be found in $O(m)$-time [26]. According to Theorem 4.8, either the rows and columns of this cycle submatrix induce an even cycle without odd chords or a subset of them induce a chordless cycle in G. As suggested by the proof of Theorem 4.8, this cycle can be extracted from the cycle submatrix in $O(m)$-time.

4.2. The *k*-completion algorithm. As in sections 2.1 and 3, the k-completion algorithm will traverse part of a search tree in which each node corresponds to a supergraph of G. This search tree is defined as follows. The graph G itself corresponds to the root of the tree. In order to generate the children of an internal node x that corresponds to a graph G', one needs to find either a chordless cycle or an even cycle without odd chords in G'. In case a chordless cycle C is found, node x will have a child for each minimal triangulation T of C. If an even cycle without odd chords, C, is found, x will have a child for each 4-cycle decomposition of C. The graph corresponding to a child is obtained by adding the corresponding minimal triangulation or 4-cycle decomposition to G'. If C is a chordless l-cycle, by Lemma 2.3 node x will have at most c_{l-2} children. If C is an even l-cycle without odd chords,

then x will have $t_{\frac{l}{2}-1}$ children. Each leaf of the tree corresponds to a strongly chordal supergraph of G. Note that every such supergraph of G that is minimal is represented by at least one leaf.

Remark. In the case that a chordless cycle C is found in the graph corresponding to a node x, it will be more efficient to generate a child only for each triangulation T of C such that $C + T$ has no even cycles without odd chords.

One can find a chordless cycle C in a nonchordal graph with m edges and n vertices in $O(m)$-time by using the MCS algorithm described in [37, 38]. An even cycle without odd chords can be found in a chordal graph that is not strongly chordal in $O(m \log n)$-time using Paige and Tarjan's implementation [29] of Lubiw's algorithm [26], as described in section 4.1. Obviously, one can use Paige and Tarjan's algorithm for both tasks in order to simplify the implementation while getting some penalty in the performance. The algorithm described in [35] can be easily extended to enumerate all ternary trees with n internal nodes, spending $O(n)$-time for each. Applying Lemma 4.3, one obtains an algorithm that enumerates all 4-cycle decompositions of an even cycle C in $O(|C|)$-time for each. It is straightforward to check that a more involved enumeration procedure that enumerates all minimal strongly chordal triangulations of a chordless even cycle C in $O(|C|)$-time for each could be designed as well, based on the ideas in [35].

The nodes of this search tree that are actually traversed correspond to supergraphs of G with no more than k additional edges. If one such node is a leaf, then we have found a strongly chordal supergraph with no more than k additional edges. Otherwise, no such supergraph exists. The proof of the following theorem is analogous to the proof of Theorem 2.4.

THEOREM 4.9. *All minimal strongly chordal supergraphs of a graph G with no more than k additional edges can be found in $O(8^{2k} m \log n)$-time.*

Remark. An alternative implementation that avoids traversing nonchordal children of chordal supergraphs can be designed as described in the remark at the end of section 3.

Remark. For dense matrices, Spinrad describes a faster algorithm which can obtain a doubly lexical ordering in $O(n^2)$-time [36]. Hence the complexity of the algorithm described above can be improved for dense graphs to $O(8^{2k} \min(n^2, m \log n))$-time.

5. Concluding remarks. We have presented polynomial algorithms for the fixed-parameter version of three graph completion problems: *chordal completion(k)*, *strongly chordal completion(k)*, and *proper interval completion(k)*. Note that the class of proper interval graphs is a subset of the strongly chordal graphs, which are a subset of the chordal graphs. Our results immediately imply that *chordal completion*, *strongly chordal completion*, and *proper interval completion* have a polynomial-time algorithm when k is part of the input but restricted to be at most logarithmic in the size of the graph.

Another important graph family that we have not discussed in this paper is interval graphs. The *interval completion(k)* problem has an important application in molecular biology, as discussed in section 1. Its NP-completeness was proved in [23]. NP-completeness is also implied by the proof of Yannakakis [41] for *chordal graph completion*, as the graphs generated in that proof are chordal iff they are interval. To date the complexity status of the parametric version of the problem is open. It is not known whether the problem is in FPT or hard for some level of the W-hierarchy. The obstructions that have to exist in a chordal graph that is not interval are described

in [25]. An arbitrarily large obstruction X could exist in a graph that is not interval but could be made interval with the addition of any one out of $O(|X|)$ edges. This causes difficulties when one tries to apply the techniques of this paper to this graph class.

When the input is restricted to bounded-degree interval graphs for some fixed bound d, the obstruction size is bounded by $O(d)$ and the search tree technique applies to get a quadratic FPT result using the characterization of [25]. It is an open problem whether this obvious bound can be improved.

For the molecular biology application in physical mapping, one can assume that the ratio of sizes of the largest and the smallest clones is at most a small constant c (in practice, $c = 10$ suffices). Fishburn and Graham [15] (see also [14, Chapter 8]) provided characterizations for interval graphs which have such length restrictions. Their results, together with the characterizations of [25], imply that the obstruction size is $O(c)$ and thus for this case, too, the search tree technique applies and the k-completion problem is FPT.

After a preliminary version of this paper appeared in [21], Cai published a paper [6] that rediscovers our simple search-tree-based algorithm for *chordal completion(k)* (see section 2.1). Using a better-known bound on the lth Catalan number, namely, $c_l = O(4^l/l^{3/2})$, and a lemma showing that $c_{i+1}c_{j+1} \leq c_{i+j+1}$, Cai proves that our algorithm in fact runs in $O((4^k/(k+1)^{3/2})(m+n))$-time. Cai also proves a straightforward generalization of our Theorem 3.1. This generalization says that the parameterized version of the graph modification problem with respect to any graph property that can be characterized by a finite set of forbidden induced subgraphs is FPT. The proof of this generalization is similar to the proof of Theorem 3.1.

TREE DATA STRUCTURES FOR N-BODY SIMULATION*

RICHARD J. ANDERSON†

Abstract. In this paper, we study data structures for use in N-body simulation. We concentrate on the spatial decomposition tree used in particle-cluster force evaluation algorithms such as the Barnes–Hut algorithm. We prove that a k-d tree is asymptotically inferior to a spatially balanced tree. We show that the worst case complexity of the force evaluation algorithm using a k-d tree is $\Theta(n \log^3 n \log L)$ compared with $\Theta(n \log L)$ for an oct-tree. (L is the separation ratio of the set of points.)

We also investigate improving the constant factor of the algorithm and present several methods which improve over the standard oct-tree decomposition. Finally, we consider whether or not the bounding box of a point set should be "tight" and show that it is safe to use tight bounding boxes only for binary decompositions. The results are all directly applicable to practical implementations of N-body algorithms.

Key words. N-body simulation, Barnes–Hut algorithm, spatial data structures

1. Introduction.

The gravitational force computation problem is as follows: Given a set of n particles, compute the net gravitational force exerted on each particle by the other particles. The solution of this problem is required in the inner loop of N-body simulation. The problem can be solved by a direct method, which is to compute all pairwise interactions of particles. This yields an $O(n^2)$ algorithm. However, much faster algorithms have been developed that use hierarchical spatial data structures to cluster particles. In this paper we study different tree data structures with the goal of minimizing the number of force evaluations performed during the computation.

We concentrate on particle-cluster algorithms, where the data structure is traversed independently for each particle. The Barnes–Hut algorithm [3] is the standard particle-cluster algorithm now in use. We study issues which relate both to asymptotic performance and to the constant factors of the run time. Our performance measure is the number of force evaluations performed with respect to a fixed error threshold. We give a collection of results which show how different tree properties influence the performance of algorithms. In terms of impact, our most significant results are in section 6 and show that k-d trees are asymptotically less efficient than oct-trees. In section 7 we explore how to improve the constant factors of the algorithm by improving the data structure, and in section 8 we give some results for different definitions of the boundary of a cell.

1.1. Astrophysical simulation.

N-body simulation is a very important tool in astrophysical research. It is essentially the only way to perform experiments to investigate basic cosmological problems. Massive simulations are used to study problems such as the formation of large-scale structure in the universe. Simulations may use as many as 50 million particles and may run for tens of thousands of CPU hours. We consider the problem, How does the choice of a spatial data structure influence the

performance of the force evaluation algorithm? The work was specifically motivated by discussions with astrophysicists on whether it is better to base a code on k-d trees or on oct-trees.

Our efforts are directed toward the *astrophysical* N-body problem. Although the N-body problem arises in many scientific disciplines, there are important differences between the versions of the problem that have a strong influence on which algorithm is the most practical. An important aspect of the problem in astrophysics is that the data often have a very nonuniform distribution with regions of high concentration and regions of low concentration. This means that algorithms which are best for uniform distributions are not necessarily suggestive of the real cases of interest.

There is a debate on whether "$O(n)$" methods or "$O(n \log n)$" methods are best for N-body simulation. To date, all massive astrophysical simulations have been based on the "$O(n \log n)$" methods, so we concentrate on the methods in actual use, even though they are "asymptotically inferior."

1.2. Overview. The next two sections give background on the force computation algorithm and on the tree data structures. This is followed by a performance analysis of spatial and density decompositions. The results on density decompositions were surprising in that they established bounds which were substantially worse than anticipated and they debunked the use of k-d trees in N-body codes. We then consider the degree of decomposition and argue that binary decomposition is likely to be substantially better than higher-degree decomposition. Finally, we address the question of whether the boundary of a cell should be tightened to the smallest enclosing box. Our result is that the tighter bounds can be used for a binary decomposition, but for higher-degree cases tighter bounds can lead to substantially worse performance.

1.3. Related work. There has been very little theoretical research done on comparing data structures for N-body simulation. More attention has been paid to the asymptotic performance of the algorithms and to the accuracy properties of particular codes.

A series of papers introduced particle-cluster algorithms in the early- to mid-eighties [1, 12, 3], with the version developed by Barnes and Hut [3] receiving the most attention with respect to implementation.

The fastest bounds for the force computation problem are for the fast multipole method of Greengard and Rokhlin [11, 10, 7, 15], which is a cluster-cluster algorithm. Although the algorithm is $O(n)$ time, it is not used in astrophysical research. This is primarily because the constant factors in the algorithm are very large, although memory is also a problem. Greengard's algorithm is more suited for uniform distributions than for the concentrated distributions encountered in astronomy. The issue of asymptotic run time of the force computation is complicated by the fact that tree construction in general is $\Omega(n \log n)$ which dominates in the case of simulation. However, many of the ideas in Greengard's algorithm are applicable to the particle-cluster algorithms and practical N-body codes are becoming more Greengard-like by using higher-degree series expansions. There are also algorithms that may be viewed as a synthesis of Greengard's algorithm and a particle cluster algorithm [4, 5]. Many of the issues relating to the force evaluation algorithm are orthogonal to the data structure used, so some of the results of this paper may carry over to a larger context.

Papers that have addressed the accuracy of N-body simulations have generally compared different force evaluation strategies [6] or have studied the trade-off between accuracy and run time [18]. A paper by Makino [13] studies the performance of

oct-trees versus nearest-neighbor trees (a data structure outside of the scope of this paper.)

In terms of data structures, an important related paper is the fair-split tree paper by Callahan and Kosaraju [7]. Although they developed their data structure to get an improved result for cluster-cluster algorithms, it turns out to be very close to the data structure we advocate in this paper. Some work in mainstream computational geometry also ties in directly with this, in particular work on the all-nearest-neighbor problem [19, 8].

2. Particle-cluster algorithm. The particle-cluster algorithm approximates the force that a set of particles exerts on a single particle by first dividing the set of particles into clusters and then summing the approximate force that each cluster exerts on the particle. The division into clusters is based upon a *spatial decomposition tree*. One version of the particle-cluster algorithm was originally described by Barnes and Hut [3]. They described the algorithm in terms of an oct-tree, although the *definition* of the algorithm does not depend upon the particular type of tree.

A hierarchical decomposition of a set S can be represented by a tree T. Each node of the tree has an associated subset of S. The sets associated with the children of a node form a partition of the set associated with the node. We often refer to the tree nodes as *cells*. Given a tree T, the following recursive algorithm computes the force on a particle x:

ForceEval(x, T)
  if *GoodApproximation(x, T)*
    return *ApproxForce(x, T)*
  else
    return $\displaystyle\sum_{T' \text{ child of } T} ForceEval(x, T').$

Let T_{part} denote the set of particles associated with the root of T. The routine *GoodApproximation* returns **true** if all of the particles in T_{part} are far enough from x that the force approximation is considered accurate. This test is referred to as the *opening criterion*. In this paper the opening criterion is based on the ratio of the diameter of T_{part} to the distance from x to the center of mass of T_{part}. Let d be the distance from x to the center of mass of T_{part}, s the diameter of T_{part}, and θ an accuracy parameter; the good approximation test returns **true** if $s \leq \theta d$ and *false* otherwise.[1] (Note that with this definition of the opening criterion, the accuracy increases as the value of θ decreases.) The routine *ApproxForce* gives an approximation of the force that the particles in T_{part} exert on x. The simplest approximation treats all of the mass of T_{part} as being at the center of mass, although in practice more sophisticated approximations are used.

The run time of the algorithm that solves the N-body problem by calling *Force-Eval* on every particle is generally considered to be $O(n \log n)$, although it does depend upon the distribution of the particles and the height of the tree. The algorithm spends almost all of its time performing the force evaluations. We can measure how good a particular tree is by counting the number of force evaluations that take place—this is a very accurate model of the run time.

[1] The results in this paper are fairly robust with respect to different choices of opening criteria. For example, an alternate opening criterion uses the radius (distance from the center of mass of T_{part} to the farthest point in T_{part}) instead of the diameter. The parameter θ controls the accuracy of the simulation. In practice values close to 1.0 are chosen.

3. Trees. Our problem is to determine the best tree data structure to use in the particle-cluster algorithm. We consider the algorithm to be fixed (meaning there is a given opening criterion and force evaluation function), and we look at different options for the spatial decomposition tree. We measure how good a tree is by the number of force evaluations that the algorithm performs in computing the force.

As an abstract problem, we could consider the following: For a fixed N-body algorithm, given a set of points S, find a tree T that minimizes the number of force evaluations. Instead of tackling this general problem (which appears to be difficult), we restrict ourselves to several tree data structures based upon orthogonal decomposition. There are many different methods for constructing an orthogonal decomposition tree [17]. We consider three options that can be applied independently, yielding eight separate tree data structures.

The first option is the degree of the decomposition. The natural choices are either a binary decomposition or a decomposition into orthants (quadrants in two dimensions, octants in three).

The second option is the method that keeps the decomposition balanced. We can either balance spatially, so that each cut is equidistant from the cell boundary, or balance based upon density, where the number of particles on each side of the split is equal.[2] When performing a binary split, the longest dimension of the cell is split.[3] A quad-tree is a quaternary spatial balanced decomposition, and a k-d tree is a binary density decomposition.

The third option in constructing trees relates to the definition of cell boundary. We consider the particles associated with a cell to be enclosed in a rectangular box, which is the boundary of the cell. One method for choosing the rectangular boxes is to subdivide boxes when cells are split. This method is referred to as *loose bounds* and is the way that boundaries are generally defined for quad-trees. An alternate way of defining the boundary is to take the smallest rectangle that encloses the points. This is referred to as *tight bounds*. When cells are split, the location (and even the dimension) of the split depends upon the boundary. This means that the tight bound and loose bound tree for the same particle set will have a different structure. Note that when tight bounds are used, the bounding box is computed *before* the cell is split; this is different from using loose bounds for computing all of the splits and then using tight bounding boxes when evaluating the opening criterion.

3.1. Results. We give a series of results that suggest that a binary spatially balanced decomposition with tight bounds is the best choice of those considered. We use L to denote the *separation ratio* of a set of points. This is the ratio of the maximum distance between points to the minimum distance between points.

- For k-d trees, we establish an $\Theta(n \log^d n \log L)$ bound for the particle-cluster algorithm in dimension d (where $d = 1, 2$, or 3). This shows that the spatially balanced decomposition algorithms are asymptotically superior to the density decomposition algorithms.
- We show that the particle-cluster algorithm takes $\Theta(n \log L)$ time for loose spatial decompositions. This is asymptotically optimal.
- We give a heuristic argument that shows that binary trees are more efficient

[2] There are a number of possible definitions of density balancing when a nonbinary split is used. The performance of nonbinary density balancing is sufficiently poor that the details are not worth exploring.

[3] An alternate method is to cycle through the dimensions in order when splitting cells. The results in this paper are applicable to this variation.

than higher-degree trees. In two dimensions, the expected number of force evaluations of a binary tree is 75% of the number for a quad-tree, and in three dimensions the expected number of force evaluations of a binary tree is 53% of an oct-tree. We also investigate other methods for improving the constant factor in the number of force evaluations.

- Intuitively, tight bounds should reduce the number of force evaluations because the diameters of the cells will be smaller. For binary trees, we show that tight bounds have the same asymptotic behavior as loose bounds. However, for quad-trees we show that the worst case for tight bounds is $\Omega(n^{3/2})$, so tight bounds can hurt the performance of non–binary tree–based algorithms.

4. Particle-cluster algorithm performance. We begin with a general lower bound on the performance of the particle-cluster algorithm. The result is that there exists a set of n particles with separation ratio L that requires $\Omega(n \log L)$ evaluations per particle for any decomposition tree. Suppose the cell C has diameter s, and the center of mass of C is at distance d from the point of evaluation. The opening criterion is to expand the cell if $s \geq \theta d$ for some fixed parameter θ.

THEOREM 4.1. *For any L, $n < L < e^{\theta n}$, there exists a set of n particles with separation ratio L such that any decomposition tree requires $\Omega(n \log L)$ force evaluations.*

Proof. The bad case distribution consists of $\frac{n}{2}$ particles evenly spaced on the interval $[0, \frac{n}{2})$ (the lower interval) and $\frac{n}{2}$ particles with geometrically increasing spacing on the interval $[L^{1/2}, L]$ (the upper interval). The argument shows that for each particle in $[0, \frac{n}{2})$ there are at least $\alpha \log L$ force evaluations. The particles in the upper interval are $\{p_{\frac{n}{2}+1}, \ldots, p_n\}$, with p_j located at $\hat{L}^j$ where $\hat{L} = L^{1/n}$.

Suppose that there is some particle p_i in the lower interval for which there are fewer than $\frac{\ln L}{4\theta}$ force evaluations. There must be some cell C containing at least $x = \frac{2\theta n}{\ln L}$ particles from the upper interval which is evaluated when computing the force on p_i. (The bound on L ensures that x is at least 2.) We show that the *normalized size* of C is at least θ, so that it fails the *GoodApproximation* test. (The normalized size of a cell with respect to a fixed particle is the cell's size divided by its distance from the particle.) We can consider the case where C contains exactly x particles, since a cell with more particles will have a greater normalized size. Let $C = \{p_j, \ldots, p_{x-1}\}$. We compute the normalized size of C with respect to the particle at 0 (which gives the smallest normalized size for all particles in the lower interval). The diameter s of C is $\hat{L}^{j+x-1} - \hat{L}^j$. The distance from the evaluation point to C is the center of mass of C. This is

$$\frac{1}{x}\sum_{i=j}^{x-1} \hat{L}^i = \frac{1}{x}\hat{L}^j \sum_{i=0}^{x-1} \hat{L}^i = \frac{1}{x}\hat{L}^j \frac{\hat{L}^x - 1}{\hat{L} - 1}$$
$$\leq \frac{1}{x}\hat{L}^j \frac{\hat{L}^x - 1}{\ln \hat{L}}.$$

Thus

$$\frac{s}{d} \geq \frac{x\hat{L}^j(\hat{L}^{x-1} - 1)\ln \hat{L}}{\hat{L}^j(\hat{L}^x - 1)}$$
$$\geq \frac{x \ln \hat{L}}{\hat{L}} = \frac{x \ln L}{n\hat{L}} \geq \frac{x \ln L}{2n} \geq \theta.$$

The one detail we haven't covered yet is the possibility that a cell in the decomposition does not consist of a consecutive set of points. Let C' be a cell containing x points, starting at position j, and let C be the cell containing $\{p_j, \ldots, p_{j+x-1}\}$. We show that $\frac{s_{C'}}{d_{C'}} \geq \frac{s_C}{d_C}$, which implies that any cell containing more than x particles fails the approximation test. The cell with x particles, starting at p_j, ending at p_{k+x-2}, with minimum normalized size is $\{p_j, p_k, \ldots, p_{k+x-2}\}$ (since this is the distance that maximizes center-of-mass distance subject to the constraints). Now, to minimize the normalized size over all cells of the form $\{p_j, p_k, \ldots, p_{k+x-2}\}$, we take $k = j - 1$, getting the cell C. □

L is a measure of the lack of uniformity in a set of particles. Since matter is distributed nonuniformly throughout the universe, simulations exhibit areas of high mass density and areas of low mass density. However, in practice L is bounded since computation is done with fixed precision operations. Thus, although L is a relevant factor, it is not going to be extremely large. It is probably worth distinguishing between $\log L$ and $\log n$ in stating results, but $\log L$ should still be viewed as being a relatively small quantity.[4]

5. Spatial decomposition. Many implementations of the particle-cluster algorithm have used quad-trees or oct-trees, including the implementation of Barnes and Hut. We give a performance bound for the oct-tree–based algorithm which shows how its performance depends upon the number and the distribution of particles. The key for the result is the observation that a sphere of radius r can only intersect a constant number of disjoint cubes with radius at least αr. This is at the heart of the packing arguments we allude to. The proof is similar to the correctness proofs of several all-nearest-neighbor algorithms [19, 8]. The necessity of accounting for "below evaluations" has been ignored by papers in the physics literature.

THEOREM 5.1. *Let D_{ave} be the average leaf depth of an oct-tree T. The number of force evaluations performed by the particle-cluster algorithm on T is $O(nD_{ave})$.*

Proof. We need to account for all of the force evaluations. A force evaluation occurs when we compute the force that a cell C exerts upon a particle x. The depth of a particle x in the tree is the depth of the leaf cell that contains x.

We distinguish between two cases of force evaluation in this analysis. An *above evaluation* occurs between x and C if the depth of C is less than or equal to the depth of x, and a *below evaluation* occurs between x and C if the depth of C is greater than the depth of x.

We begin by arguing that if x is at depth D, x is involved in at most αD above evaluations for an appropriate constant α (which depends upon the accuracy parameter θ). Let C be a cell on level j that is involved in an above evaluation with x. Let C' be the parent of C, d' the distance from x to the center of mass of C', and s' the diameter of C'. Since the *GoodApproximation* test fails for C', we must have $d' < \frac{s'}{\theta}$. The number of cells of diameter s' that are of distance no more than $\frac{s'}{\theta}$ from x is bounded by a constant. This, in turn, bounds the number of above evaluations for x with cells on level j. (The straightforward analysis gives a bound of $\alpha = 3\sqrt{3}\pi(1+\frac{1}{\theta})^3$ in three dimensions.)

We now account for the below evaluations. Suppose that there is a below evaluation between x and C. This evaluation is charged to the closest particle y to x that is

[4] It is a mistake to place much emphasis on pathological examples that use exponential differences in separation. However, it is also a mistake to view uniformly random data as the typical case for simulation.

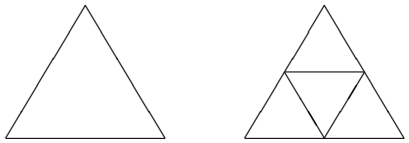

FIG. 5.1. *Triangular decomposition.*

inside of C. We now argue that if y is at depth D, y is charged for at most βD below evaluations for some constant β. The argument is similar to the above argument. Let x be a particle on level j that has a below evaluation charged to y. Suppose the evaluation is between x and the cell C, with C' the parent of C. Let d' be the distance from x to the center of mass of C', s the diameter of the leaf cell containing x, and s' the diameter of C'. We must have $d' < \frac{s'}{\theta}$ and $s \geq s'$. The number of cells of diameter s that are at a distance of no more than $\frac{s'}{\theta}$ from the center of mass of C' is bounded by a constant, giving the result. (The analysis gives a bound of $\beta = 4\sqrt{3}\pi(1 + \frac{1}{\theta})^3$ in three dimensions.)

Putting the two parts together, we have a bound of $O(nD_{ave})$ on the number of force evaluations. □

If the particles have separation ratio L, the depth of the oct-tree is $O(\log L)$, so we have an $O(n \log L)$ bound for the algorithm. The proof does not require that cells be cubes, just that they satisfy a packing lemma. The theorem is applicable to any decomposition that satisfies the following definition.

DEFINITION 5.2. *A decomposition is packable if there exists a constant β such that for every s, a sphere of radius s can interest at most β disjoint cells with diameter at least s.*

Since a binary spatial decomposition is packable, the run time of the particle-cluster algorithm for binary spatial trees also has an $O(n \log L)$ run time bound. One can come up with many other decompositions that are packable. For example, Figure 5.1 shows decomposition of the plane based upon equilateral triangles. This decomposition would satisfy the same asymptotic run time bound as a quad-tree.

6. Density decomposition.

***k*-d trees.** A k-d tree is a generalization of a balanced binary tree to higher dimensions. Each cell of a k-d tree divides a point set into two equal-size sets by splitting along a chosen dimension. A different dimension may be chosen at each level. (The implementation we consider is based upon splitting the longest side of each cell.) A k-d tree has the property that its height is logarithmic in the number of points. k-d trees have been used in a number of N-body implementations, including the early implementation of Appel [1] and in the University of Washington KD-grav code [9].

We show that in the worst case, an N-body algorithm using k-d trees is inferior to an algorithm with a spatially balanced decomposition. There is a bad case point set where the points all lie on a line. This one-dimensional bad case can then be repeated in two and three dimensions to get the worst-case results. We show that in dimension d (for $d = 1, 2$, or 3) the worst-case performance of the k-d tree algorithm is $\Theta(n \log^d n \log L)$, compared with $\Theta(n \log L)$ for spatially balanced trees such as oct-trees.[5] (We restrict attention to $d \leq 3$ since this is the range of practical interest.

[5]Since the lower bound is based upon contrived distributions, it is natural to ask if these apply to practice. It turns out that there are bad case examples based on data distributions used in real astrophysical simulations which give an $\Omega(n \log^2 n \log L)$ bound in three dimensions.

The results appear to generalize to higher dimensions.)

One-dimensional lower bound. We begin with the one-dimensional case. This is really the essence of the bad case for k-d trees. The two- and three-dimensional cases magnify the difficulty in order to get even worse bounds. We assume that L is in the range $n^2 \leq L \leq 3^{n^{1/2}}$ and give the proofs for the case where the accuracy parameter θ is equal to 1.

THEOREM 6.1. *The worst-case performance for the one-dimensional k-d tree–based particle-cluster algorithm is $\Omega(n \log L \log n)$.*

Proof. We construct the point set $P = \{p_1, \ldots, p_n\}$. Let $P_1 = \{p_1, \ldots, p_{n/2}\}$ and $P_2 = \{p_{n/2+1}, \ldots, p_n\}$. We get the bad case bound by counting the number of force evaluations that occur when determining the force that the points in P_2 exert on the points in P_1.

The points in P_1 are evenly spaced in the interval $[1, \frac{n}{2}]$.

The points in P_2 are divided into about $\log L$ intervals, with the sizes of the intervals increasing exponentially. When computing the force on a point in P_1, each one of these intervals is subdivided roughly $\log n$ times, giving the bound of $\Omega(\log L \log n)$ work per point in P_1.

Let I_k be the interval $[3^{k-1}, 3^k]$. Points from P_2 are assigned to the intervals $I_{\log_3 n+1}, \ldots, I_{\log_3 L}$. Let $w = \log_3 L - \log_3 n - 1$ be the number of intervals. For convenience, we assume that both n and w are powers of 2. (The argument can be modified to remove this assumption.) We assign $\frac{n}{2w}$ points to I_k ($\log_3 n < k \leq \log_3 L$). The points assigned to I_k are evenly spaced on the first half of the interval (meaning the subinterval $[3^{k-1} + 1, \frac{3}{2}3^{k-1}]$) with the exception of one point, which is assigned to the high end of the interval.

We now consider the cost of traversing the tree for P_2, using a point from P_1. The points in P_2 are represented by a tree, which has a node i_k corresponding to each of the intervals I_k, for $\log_3 n < k \leq \log_3 L$. From each point in P_1, we visit each of these nodes, and from these nodes we traverse the tree to some leaf. The node i_k has $n/2w$ descendents, so it has height $\log(n/2w)$. Since we are assuming $n^2 \leq L \leq 3^{n^{1/2}}$, it follows that the bound is $\Omega(n \log L \log n)$. □

The only modification necessary to handle the case of an arbitrary θ is to use a base of 3θ instead of a base of 3 in defining the intervals. This gives the bound of $\Omega(n \log_\theta L \log n)$ for arbitrary θ.

One-dimensional upper bound. We now prove a corresponding upper bound on the run time of the one-dimensional particle-cluster algorithm.

THEOREM 6.2. *The worst-case performance for the one-dimensional particle-cluster algorithm using a k-d tree is $O(n \log L \log n)$.*

Proof. A k-d tree has $\log n$ levels. For a fixed point p, consider the set of nodes visited while evaluating the force on p. These nodes can be divided into nodes for intervals to the left of p, including p, and to the right of p. There are at most $\log n$ intervals that contain p. We will now consider the nodes to the right of p and for convenience we assume that p is located at the origin.

Let I_1 and I_2 be on the same level with different parents, and suppose p visits both I_1 and I_2. Let the parents of I_1 and I_2 be I_1' and I_2', respectively, with $I_1' = [x_1, y_1]$ and $I_2' = [x_2, y_2]$. Assuming that I_2 is to the right of I_1, we must have $x_2 \geq (1+\theta)x_1$. (If that were not the case, then the interval I_1' would not have been expanded in the evaluation of p.) It follows that there are at most $\log_{(1+\theta)} L$ intervals to the right of p on a level that are evaluated for p. Thus the number of elements evaluated for p is at most $4 \log_{(1+\theta)} L \log n + \log n$, so the total work is $O(n \log L \log n)$. □

Higher dimensional lower bounds. The bad case generalizes to higher dimensions in a fairly natural manner. The way we do this is by repeating the one-dimensional construction $\log n$ times so that we have $\log n$ columns, each of which gives the one-dimensional bad case. We will have $\frac{n}{2}$ particles in the first column, $\frac{n}{4}$ in the second, $\frac{n}{8}$ in the third, and so on. This construction gives us the following results.

THEOREM 6.3. *The worst-case performance for the two-dimensional particle-cluster algorithm using a k-d tree is* $\Omega(n \log L \log^2 n)$.

Proof. We arrange the n particles in $\log n$ columns, where column C_i has $\frac{n}{2^i}$ particles and one additional particle. The particles in column C_i have x coordinate i and y coordinates that correspond to the one-dimensional construction on $\frac{n}{2^i}$ particles. The one other particle has coordinates $(2L, 0)$. The construction of the k-d tree creates the columns as skinny rectangles, since the extra point at $(2L, 0)$ leads to a series of vertical subdivisions. Figure 6.1 shows how the addition of the single point causes the skinny vertical rectangles to be formed. Each of the vertical rectangles contains points arranged as in the one-dimensional lower bound.

The columns contain about $\frac{n}{2}$ particles that are within distance $\frac{n}{2}$ of the origin. Each one of these particles is going to have $\log L(\log n - i - \log \log L)$ interactions with intervals from C_i, which gives the $\Omega(n \log L \log^2 n)$ bound. □

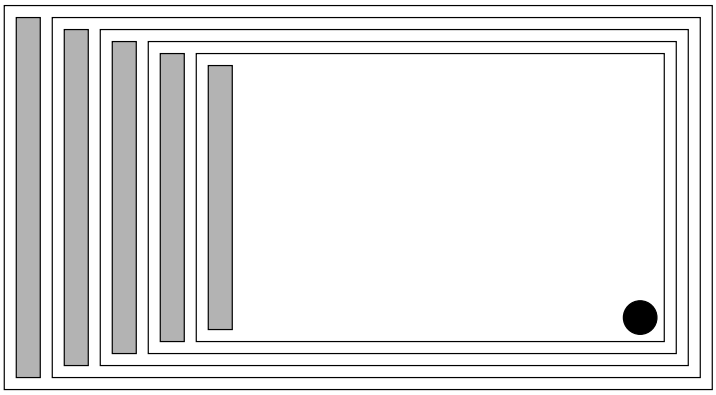

FIG. 6.1. *Decomposition in skinny rectangles.*

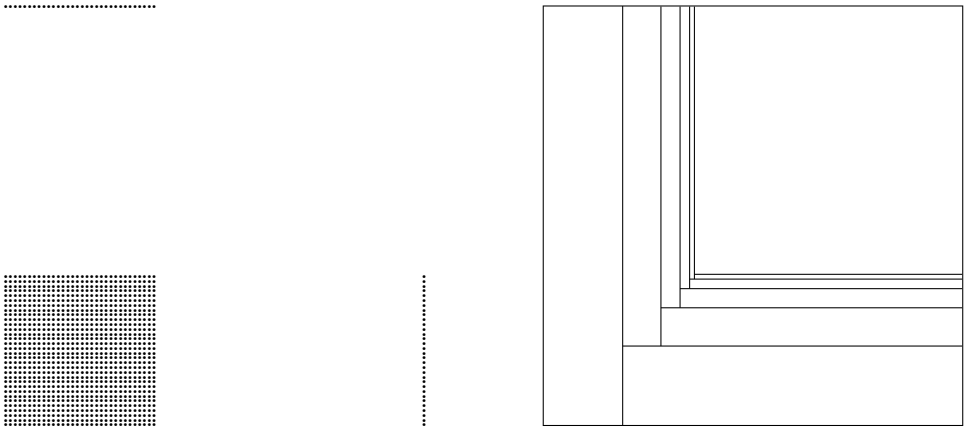
In three dimensions, we take a stack of $\log n$ two-dimensional bad case examples to pick up another factor of $\log n$. The same trick is used in which a single, far-off particle causes the k-d tree to have a collection of slices with a specific structure.

THEOREM 6.4. *The worst-case performance for the three-dimensional particle-cluster algorithm using a k-d tree is* $\Omega(n \log L \log^3 n)$.

These examples show that in the worst case k-d trees are a factor of $\log^3 n$ worse than spatially balanced trees. However, the bad case distributions are contrived and relatively delicate, so it is natural to ask if k-d trees are problematic from a practical point of view: Is the bad behavior observed in real simulations? Consider the two-dimensional distribution shown in Figure 6.2A, where n particles are placed on a $\sqrt{n} \times \sqrt{n}$ grid and additional particles are placed at (i, L) and (L, i) for $1 \leq i \leq \sqrt{n}$. When these particles are divided by a k-d tree, a collection of long skinny rectangles is generated, as shown in Figure 6.2B. Each of the long skinny rectangles is further decomposed in a collection of long skinny rectangles. When the force is computed on a particle, the long skinny rectangles will fail the *GoodApproximation* test. It is straightforward to verify that this leads to $\Omega(\log^2 n)$ force evaluations per

particle. Although this is not as bad as the construction used in Theorem 6.3, it is worse than the spatially balanced decomposition. Significantly, this distribution is similar to ones used in simulations that investigate how the internal structure of a galaxy is influenced by neighboring galaxies [14]. The main galaxy is modeled at high resolution, and the other galaxies are modeled as single particles; thus the particles near the origin correspond to the main galaxy, and the particles at (i, L) and (L, i) are the other galaxies in the cluster. Simulations of this type of structure using the k-d tree algorithm were observed to have serious performance problems.



A: Particle distribution B: Partial k-d tree decomposition

FIG. 6.2. *Bad case distribution from galaxy simulation.*

Higher dimensional upper bounds. We now generalize the upper bound result to cover two dimensions. The situation is more complex than the one-dimensional case because we must take the shape of the cells into account. We show that each particle evaluates $O(\log^2 n \log L)$ cells. We begin with a technical lemma, which restricts attention to cells of a given level that intersect a region.

LEMMA 6.5. *Let B be an $s \times s$ region. The number of cells of level j with diameter greater than s intersecting B is $O(\log n)$.*

Proof. A cell is said to be *fat* if both of its sides have length at greater than $\frac{s}{2}$, and it is *skinny* if one side has length longer than $\frac{s}{2}$ and the other has length at most $\frac{s}{2}$.

Our first observation is that the number of fat cells with two fat children that both intersect B is bounded by a constant. This implies that there are $O(\log n)$ fat cells intersecting B (since if we consider the subtree made up of fat cells that intersect B, the number of nodes of degree two is bounded by a constant, and the tree height is at most $\log n$). The number of skinny cells that intersect B and are children of fat cells is also $O(\log n)$. The descendents of a cell S on a given level form a partition of S. If S is skinny with a shorter side of length l, and S' is a skinny descendent of S, S' also has a shorter side of length l since the longest side is partitioned and once both sides of a cell have length at most $\frac{s}{2}$ the cell is no longer considered skinny. This means that S can have at most three skinny descendents on any given level that intersect B. This gives the $O(\log n)$ bound on the number of cells of diameter at least s intersecting B on any level. □

We can now give the bound on the number of evaluations on a fixed particle, which gives the bound on the performance of the algorithm.

THEOREM 6.6. *In two dimensions, a particle p is involved in $O(\log^2 n \log L)$ evaluations.*

Proof. Consider cells of diameter between s and $2s$ which are expanded when computing the force on p. Each one of these cells must be within a distance of $\frac{2s}{\theta}$, since they fail the *GoodApproximation* test. Lemma 6.5 implies that the number of cells of diameter at least s within this distance is $O(\log^2 n)$. Since the maximum cell size is L, we pick up the factor of $\log L$ to sum over all groups of cells. □

Extending the result to three dimensions does not require any new ideas. We pick up an extra logarithmic factor because we need to consider cells that have a small length on one or two sides.

THEOREM 6.7. *In three dimensions, a particle p is involved in $O(\log^3 n \log L)$ evaluations.*

Proof (sketch). The proof follows that of Theorem 6.6. A lemma analogous to Lemma 6.5 is used, which shows that a cube of size s can be intersected by at most $O(\log^2 n)$ cells of size s of a fixed level. □

7. Degree bounds. We now turn our attention to the problem of determining what the best decomposition strategy is for a spatially balanced decomposition. In our model, where we count only force evaluations, we can do better than an oct-tree decomposition. A binary decomposition splits the longest dimension of a cell evenly. This means that three levels of splitting accomplishes exactly the same decomposition as a single level of an oct-tree. However, the binary tree may require fewer force evaluations since there are cases where a single binary split is sufficient for cells to pass the accuracy test, so that two evaluations are done instead of eight. In this section, first we give an analysis that supports the use of binary trees over oct-trees, and then we consider other methods of decomposition which give additional improvements.

7.1. Interaction regions. It is possible to adapt Theorem 5.1 to give a bound that includes the constant factor, although it will be pessimistic. A more accurate "heuristic" analysis based upon the *interaction region* of a cell can be used to evaluate different decomposition strategies. A cell C partitions the points in space into two regions, G_C, the points where the force approximation of C is considered good, and B_C, the points where the approximation is bad. G_C and B_C are the outside and the inside of a sphere of radius $\theta^{-1}s$ centered at the center of mass of C. If C' is the parent of C, the interaction region of C is defined to be $G_C \cap B_{C'}$. The interaction region of C is roughly the set of points for which a force evaluation will use the approximation from the cell C. Figure 7.1 shows the interaction region for cell C (the upper right quadrant of C') as a doughnut with an off-center hole.

We can use the interaction region to determine the probability that the evaluation at a random point involves a particular cell. (The interaction regions can also be used for an average case analysis with respect to a random set of points [6, 16].) Experimental results show that the interaction area, or the size of the interaction region, is a very good predictor of the algorithm's run time [6, 2].

We give a pair of results which suggest that a binary tree requires fewer force evaluations than a quad-tree or an oct-tree for the same set of points.

THEOREM 7.1. *Assuming that the center of mass is at the center of each cell and $\theta < 1.19$, the total interaction area of a binary spatial decomposition tree is 75% of the interaction area of a quad-tree for the same set of points.*

Proof. Consider a $k \times k$ cell C. In a quad-tree, C has four children, each of size $\frac{k}{2} \times \frac{k}{2}$. Each child has an interaction region of size $\frac{3}{2}\pi\theta^{-2}k^2$, so the total interaction area of the children is $6\pi\theta^{-2}k^2$.

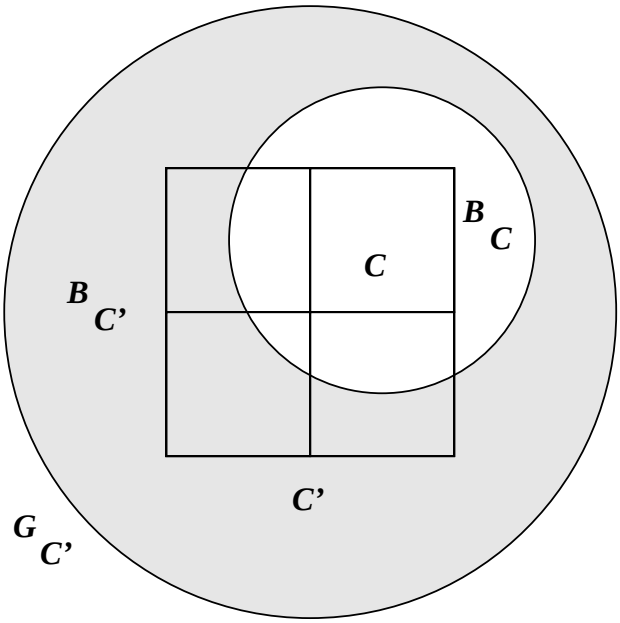


FIG. 7.1. *Interaction region.*

Now consider a $k \times k$ cell C in a binary tree. C has two $k \times \frac{k}{2}$ cells as children and has four $\frac{k}{2} \times \frac{k}{2}$ children as grandchildren. The interaction area of each of the children is $\frac{3}{4}\pi\theta^{-2}k^2$ and the interaction area of each of the grandchildren is also $\frac{3}{4}\pi\theta^{-2}k^2$, giving a total interaction area of $\frac{9}{2}\pi\theta^{-2}k^2$.

The bound on θ ensures that B_C and $G_{C'}$ are disjoint (otherwise a correction factor must be added to account for a small crescent where $G_{C'}$ intersects B_C). □

We can get an even stronger result in three dimensions.

THEOREM 7.2. *Assuming that the center of mass is at the center of each cell and* $\theta < 0.93$, *the total interaction area of a binary spatial decomposition tree is* 53% *of the interaction area of an oct-tree.*

7.2. Other decompositions. Even though it is only a heuristic argument that ties the size of the interaction region to the performance of N-body algorithms, a strong correlation with experimental evidence has been observed. We shall treat the interaction region as the figure of merit of a decomposition. When comparing different decompositions with the same degree, we want to look at the size of interaction regions of cells with the same volume, with the smaller interaction region giving better performance.

We begin by comparing a quad-tree decomposition with the triangular decomposition shown in Figure 5.1. We show that the triangular decomposition will probably be less effective than a quad-tree.

THEOREM 7.3. *A quad-tree cell of unit area has interaction region of area* $6\pi\theta^{-2}$, *and a triangular cell of unit area has interaction region of area* $\frac{12}{\sqrt{3}}\pi\theta^{-2}$.

Hence, the size of the interaction area of the triangular decomposition is 15% larger than the interaction area of the quad-tree decomposition.

A more interesting case is the comparison of a binary decomposition of a square

with a binary decomposition of a rectangle with aspect ratio $1 : \sqrt{2}$. The result is that the latter has an interaction region that is about 5% smaller than the former. This is interesting since it shows that the binary decomposition of the square is not optimal.

THEOREM 7.4. *In two dimensions, the interaction area of a binary tree based on cells with aspect ratio* $1 : \sqrt{2}$ *is* 94.2% *of the interaction area of a binary tree based on square cells.*

Proof. Let C be a unit square. C is decomposed into $1 \times \frac{1}{2}$ cells C_1' and C_2' that in turn are decomposed into $\frac{1}{2} \times \frac{1}{2}$ cells C_1'', C_2'', C_3'', and C_4''. C_1' has interaction area $\pi\theta^{-2}(2 - \frac{5}{4})$ and C_1'' has interaction area $\pi\theta^{-2}(\frac{5}{4} - \frac{1}{2})$. This gives a total interaction area of $\frac{9}{2}\pi\theta^{-2}$ for the six cells.

Let $\hat{C}$ be a $\sqrt[4]{2} \times \frac{1}{\sqrt[4]{2}}$ rectangle. $\hat{C}$ is decomposed into $\frac{1}{\sqrt[4]{2}} \times \frac{\sqrt[4]{2}}{2}$ cells $\hat{C}_1'$ and $\hat{C}_2'$ that in turn are decomposed into $\frac{\sqrt[4]{2}}{2} \times \frac{1}{2\sqrt[4]{2}}$ cells $\hat{C}_1''$, $\hat{C}_2''$, $\hat{C}_3''$, and $\hat{C}_4''$. $\hat{C}_1'$ has interaction area $\pi\theta^{-2}((\sqrt{2}+\frac{1}{\sqrt{2}})-(\frac{1}{\sqrt{2}}+\frac{\sqrt{2}}{4}))$ and $\hat{C}_1''$ has interaction area $\pi\theta^{-2}((\frac{1}{\sqrt{2}}+\frac{\sqrt{2}}{4})-(\frac{\sqrt{2}}{4}+\frac{1}{4\sqrt{2}}))$ This gives a total interaction area of $3\sqrt{2}\pi\theta^{-2}$ for the six cells.

If we evaluate the expressions, we see that the interaction area in the second case is 5.8% less. ∎

We can prove a similar result in three dimensions, giving about a 10% improvement over the decomposition from a cubical cell.

THEOREM 7.5. *In three dimensions, the interaction volume of a binary tree based on cells with aspect ratio* $1 : 2^{1/3} : 2^{2/3}$ *is* 89.7% *of the interaction volume of a binary tree based on cubical cells.*

We now consider a different approach for reducing the number of force evaluations: Instead of using a tree data structure to represent the data structure, use a directed acyclic graph (DAG). The DAG allows a choice of decompositions for cells. For example, with a binary decomposition, a square cell, $\square$, can be decomposed horizontally, $\boxminus$, or vertically, $\boxplus$. The idea is that based upon the location of the point that we are evaluating the force on, we choose the decomposition that minimizes the amount of work. The decompositions $\boxminus$ and $\boxplus$ both decompose into $\boxplus$, so the extra storage required is minimal.

We can show that this data structure reduces the interaction area of the binary spatial decomposition.

THEOREM 7.6. *Assume that the center of mass is at the center of each cell and* $\theta = 1.0$. *In two dimensions the interaction area of the DAG is* 93% *of the interaction area of a tree for a square cell, and in three dimensions the interaction volume of the DAG is* 88% *the interaction volume of a tree for a cubical cell.*

Proof. For the two-dimensional case, we superimpose two binary decompositions, one that is horizontal and one that is vertical. We consider the regions of space that result in different sets of force evaluations and choose the decomposition that minimizes the number of force evaluations. We need only to count the number of force evaluations with respect to the rectangular regions, since a square region will either be evaluated or not be evaluated independent of whether the vertical or horizontal decomposition is used. Figure 7.2 shows a decomposition of space into regions corresponding to how many evaluations a point requires with respect to large rectangles with a horizontal or a vertical decomposition. Figure 7.3 shows the regions (marked X and Y) where a horizontal decomposition gives a savings over a vertical decomposition. In the X region the two horizontal rectangles are used, instead of decomposing a rectangle into squares, and in the Y region one of the rectangles is used and the

TABLE 7.1
Interaction sizes for decomposition DAG.

θ	Two-d	Three-d
0.8	0.947	0.907
0.9	0.940	0.895
1.0	0.934	0.880
1.1	0.927	0.870
1.2	0.921	0.859

other is split into squares. Computing this area (which we did numerically) gives the cost savings.

In three dimensions, there are 12 separate decompositions to consider. The bound was computed numerically. Table 7.1 shows the interaction areas and volumes in two and three dimensions for selected values of θ. The results are scaled so that the tree has interaction volume 1.0. □

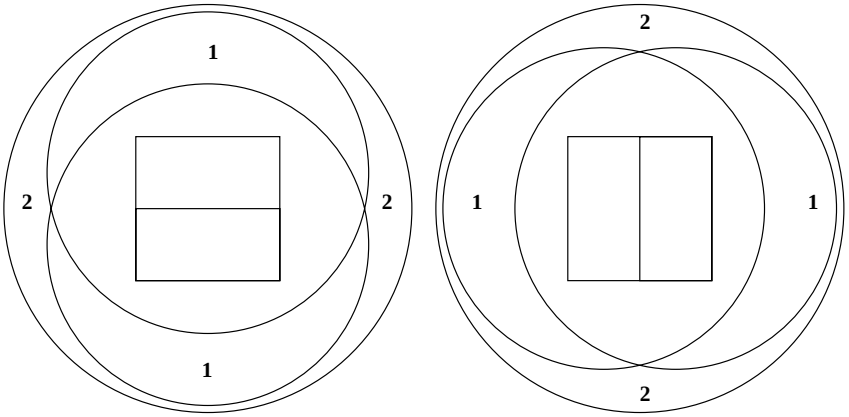

FIG. 7.2. *Interaction regions.*

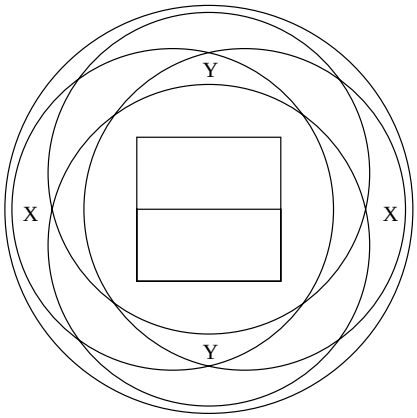

FIG. 7.3. *Regions with lower horizontal cost than vertical cost.*

The significance of these results is that they show that it is possible to improve over the natural decompositions with a small amount of extra work. (However, the

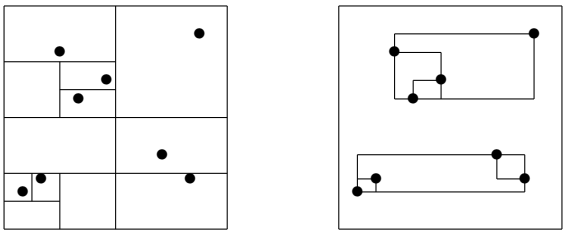

FIG. 8.1. *Binary decomposition with loose and tight bounds.*

two schemes—optimizing the aspect ratio and using a DAG instead of a tree—cannot be combined to gain additional benefit.) Given the tremendous amount of CPU time devoted to simulation algorithms, even a small improvement in the constant factor translates into a big real-time savings.

8. Cell bounds. When we compute the boundary of a cell, we have a choice of using either "loose" or "tight" bounds. The bounds are loose if they are inherited from the bounds of the parent cell, and they are tight if they are the actual bounds of the point set. See Figure 8.1 for an example that shows the distinction between the bound types. Note that the region boundaries are computed as the tree is constructed so that the tree structure depends upon the type of boundary.

The potential advantage of tight bounds is that region sizes will be smaller so that cells are more likely to pass the good approximation test and reduce the number of evaluations. Experimental results show that tight bounds generally do lead to a work savings, especially when the data is clustered.

To give theoretical support for using tight bounds, we show that binary spatial decomposition trees with tight bounds have the same asymptotic run time as the trees with loose bounds. However, this result holds only for binary trees. We show that for quad-trees, tight bounds can lead to trees that are much worse than trees with loose bounds.

8.1. Binary spatial decomposition with tight bounds. We now show that an algorithm that uses binary trees with tight bounds has the same asymptotic run time as an algorithm with loose bounds. We prove this by giving a packing lemma that says that only a constant number of disjoint cells with diameter at least s can intersect a sphere of radius θs. Using the lemma, the argument of Theorem 5.1 applies.

The following lemma is based on a packing lemma for fair-split trees proved by Callahan and Kosaraju [7]. (We establish the lemma in two dimensions; the generalization to three dimensions is straightforward.)

LEMMA 8.1. *The maximum number of disjoint cells of diameter at least s of a tight binary spatial decomposition tree that can intersect a ball of radius θs is bounded by a constant.*

Proof. For each cell C, we define an outer rectangle $C.outer$. If C has children C' and C'', then $C.outer$ is divided to give $C'.outer$ and $C''.outer$. C' and C'' are the contractions of $C'.outer$ and $C''.outer$ to the smallest rectangles enclosing the point sets. The outer rectangles give a valid spatial decomposition of the space. Figure 8.2 illustrates the outer rectangles for a cell C being split into cells C' and C''.

We show that if C' is a child of C, then

$$\min(C'.outer.height, C'.outer.width) \geq \frac{1}{2}\max(C.height, C.width).$$

If C is the root, then the bound holds (we assume that the outer rectangle of the root is a square). Suppose C is not the root. Let $\hat{C}$ be the parent of C and suppose the bound holds for C and $\hat{C}$. We can assume that C' is formed by a horizontal cut of C, so $C.height \geq C.width$. We have

$$C'.outer.height \geq \frac{1}{2}C.height \geq \frac{1}{2}C.width$$

and

$$C'.outer.width = C.outer.width \geq \frac{1}{2}\hat{C}.width \geq \frac{1}{2}C.width.$$

If a cell C' has diameter at least s, then

$$\max(C.height, C.width) \geq \max(C'.height, C'.width) \geq \frac{s}{\sqrt{2}},$$

with C the parent of C'. Thus, we have

$$\min(C'.outer.height, C'.outer.width) \geq \frac{s}{2\sqrt{2}}.$$

This implies that at most a constant number of disjoint cells with diameter at least s can intersect a ball of radius θs. □

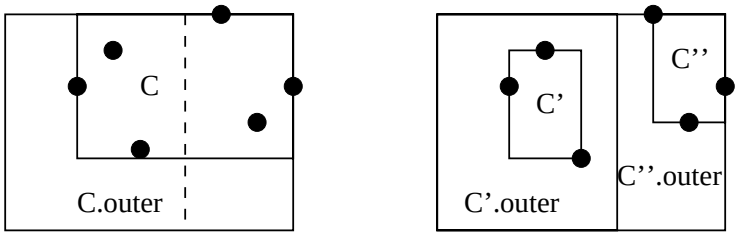

FIG. 8.2. *Cell decomposition into outer regions cost.*

THEOREM 8.2. *The run time of the particle-cluster algorithm using a tight binary spatial decomposition tree on a set of n particles with separation ratio L is* $O(n \log L)$.

Proof. We use Lemma 8.1 with Theorem 5.1 to get the bound. The height of the TBSD tree is $O(\log L)$. □

8.2. Tight bounds for quad-trees. The result that the use of tight bounds does not increase the asymptotic worst-case amount of work that a binary tree–based algorithm performs is not surprising—intuitively the use of more accurate cell bounds should speed up the computation. However, a similar result does not hold for higher degree trees. We show that the use of tight bounds can drastically increase the amount of work performed by a quad-tree–based algorithm. The bound below shows that the amount of work can increase by a factor of $\Omega(n^{1/2}/\log n)$.

The problem is that if tight bounds are used, the regions can have a high aspect ratio. The reason that this is bad is that long skinny regions do not satisfy a suitable packing lemma (such as Lemma 8.1) so that it is not possible to get a good bound on the number of interactions that a particle will have with regions of a particular size. The basic idea used to construct the bad example in two dimensions is to use a set of points distributed uniformly in a rectangle with dimensions h and w where $h \gg w$.

Since the bounds are tight, the bounding box for the region is an $h \times w$ rectangle. The quad-tree splits each dimension evenly so at each level rectangles with aspect ratio $h : w$ are formed. When the force on a particle is evaluated there are a large number of nearby rectangles that must be used. The two-dimensional example generalizes to three dimensions and gives an $\Omega(n^{5/3})$ bound.

THEOREM 8.3. *There exists a set of n points with separation ratio $n^{O(1)}$ for which the particle-cluster algorithm using a quad-tree with tight bounds has $\Omega(n^{3/2})$ run time.*

Proof. For convenience, assume that n is a power of 4 and $\theta = 1$. We place a particle at $(i, j\sqrt{n})$ for $0 \le i, j < n$. The quad-tree decomposition divides this set in cells with aspect ration $1 : \sqrt{n}$. The cells immediately above the leaves each contain four points and have dimensions $1 \times \sqrt{n}$. When computing the force on a particle, we examine at least $\sqrt{n}/2$ of these cells, giving $\Omega(n^{3/2})$ work over all. □

9. Conclusions and future work. The argument of this paper is that a binary, spatially balanced decomposition tree with tight bounds is the best data structure to use in N-body simulation algorithms. We have shown that spatial decompositions are asymptotically superior to density-based decompositions. The result led to changes in one of the major N-body codes in use for astrophysical research. By analyzing the interaction areas of cells, we expect close to a 50% reduction in the number of force evaluations for a binary tree as opposed to an oct-tree. We also show that tight bounding boxes can be used for binary trees without hurting run time bounds, while for higher degree tight bounding boxes can cause a substantial slowdown.

We have established a set of theoretical results that support specific design choices in practical N-body algorithms. The question of which is the best decomposition strategy to use is still open. Lemma 7.6 raises the intriguing possibility that DAG-based algorithms could be superior to tree-based algorithms. There is the potential to extend our results to other N-body algorithms beyond the particle-cluster algorithms and also to look at a wider collection of tree decompositions.

THE POWER OF VACILLATION IN LANGUAGE LEARNING*

JOHN CASE†

Abstract. Some extensions are considered of Gold's influential model of language learning by machine from positive data. Studied are criteria of successful learning featuring convergence in the limit to vacillation between several alternative correct grammars. The main theorem of this paper is that there are classes of languages that can be learned if convergence in the limit to up to $(n+1)$ exactly correct grammars is allowed but which cannot be learned if convergence in the limit is to no more than n grammars, where the no more than n grammars can each make finitely many mistakes. This contrasts sharply with results of Barzdin and Podnieks and, later, Case and Smith for learnability from both positive and negative data.

A subset principle from a 1980 paper of Angluin is extended to the vacillatory and other criteria of this paper. This principle provides a necessary condition for avoiding overgeneralization in learning from positive data. It is applied to prove another theorem to the effect that one can optimally eliminate half of the mistakes from final programs for vacillatory criteria if one is willing to converge in the limit to infinitely many different programs instead.

Child language learning may be sensitive to the order or timing of data presentation. It is shown, though, that for the vacillatory success criteria of this paper, there is no loss of learning power for machines which are *in*sensitive to order in several ways simultaneously. For example, *partly set-driven* machines attend only to the *set* and *length of sequence* of positive data, not the actual sequence itself. A machine $\mathbf{M}$ is *weakly n-ary order independent* $\stackrel{\text{def}}{\Leftrightarrow}$ for each language L on which, for some ordering of the positive data about L, $\mathbf{M}$ converges in the limit to a finite set of grammars, there is a finite set of grammars D (of cardinality $\leq n$) such that $\mathbf{M}$ converges to a subset of this same D for *each* ordering of the positive data for L. The theorem most difficult to prove in the paper implies that machines which are simultaneously partly set-driven and weakly n-ary order independent do not lose learning power for converging in the limit to up to n grammars. Several variants of this theorem are obtained by modifying its proof, and some of these variants have application in this and other papers. Along the way it is also shown, for the vacillatory criteria, that learning power is not increased if one restricts the sequence of positive data presentation to be computable. Some of these results are nontrivial lifts of prior work for the $n = 1$ case done by the Blums; Wiehagen; Osherson, Stob, and Weinstein; Schäfer; and Fulk.

1. Introduction.

In [46] Gold introduced his seminal model of language learning: Imagine, as pictured in (1.1) just below, a machine $\mathbf{M}$ being fed data about membership in a (formal) language L and, as a result, outputting over time a series of grammars $p_0, p_1, p_2, \ldots, p_t, p_{t+1}, \ldots$ *conjectured* to be for L:[1]

$$p_0, p_1, p_2, \ldots, p_t, p_{t+1}, \ldots \leftarrow \mathbf{M} \leftarrow \text{data re } L. \tag{1.1}$$

†Department of Computer and Information Sciences, University of Delaware, Newark, DE 19716 (case@cis.udel.edu).

[1] We have oriented the arrows in (1.1) so that elements later in the series $p_0, p_1, p_2, \ldots, p_t, p_{t+1}, \ldots$ will *correctly* appear to be coming out of the machine $\mathbf{M}$ later: they will appear closer to $\mathbf{M}$ than earlier elements of the series.

For our present purposes, it will suffice to consider two kinds of data presentation and one kind of success from [46]. For expository convenience, and, as noted in section 2 below, without loss of generality, we can consider all languages L to be subsets of the set of nonnegative integers.

Data about L are *either*

1. *informant*, a listing of every nonnegative integer with a clear indication of whether or not it is in L, *or*
2. *text*, an arbitrary listing of all and only the elements of L.

Gold took quite seriously, as a model of child language learning, the case of data presentation by arbitrary text, where $\mathbf{M}$ receives all and only *positive* information about L. Justification for this point of view can be found, for example, in [9, 13], where it is noted from field work that children don't need corrections to learn language.

Regarding successful language learning, referring to (1.1) above: for Gold, machine $\mathbf{M}$ *identifies* language $L \stackrel{\text{def}}{\Leftrightarrow} \mathbf{M}$ fed any text for L, outputs a corresponding sequence $p_0, p_1, p_2, \ldots$ such that, for some t, $p_t = p_{t+1} = p_{t+2} = \cdots$ and p_t is a correct grammar for L. In other words, $\mathbf{M}$ *identifies* $L \Leftrightarrow$ on each text for L, the corresponding conjectures of $\mathbf{M}$ converge, in the limit, to some fixed final conjecture, and that final conjecture is correct.[2] Gold showed that *no* $\mathbf{M}$ so identifies the entire class of regular languages [48], but *some* $\mathbf{M}$ *does* identify the class of finite languages. Angluin [1, 2] presents other classes $\mathcal{L}$ natural from the perspective of formal language theory such that some $\mathbf{M}$ identifies each language in $\mathcal{L}$.

Many *cognitive scientists* seek to model all of cognition by computer program [77, 50], and Gold's model of language learning from text (positive information) by machine has been very influential in contemporary theories of natural language and in mathematical work explicitly motivated by its possible connection to human language learning (see, for example, [76, 93, 94, 66, 68, 8, 44, 15, 69, 70, 38, 39, 53, 5]).

In the present paper we consider some new criteria of success extending Gold's basic model above. Suppose that we fix an integer $n > 0$. Consider the following criterion of success (again based on (1.1) above). We say that $\mathbf{M}$ $\mathbf{TxtFex}_n$-*identifies* $L \stackrel{\text{def}}{\Leftrightarrow} \mathbf{M}$, on any text for L, outputs corresponding conjectures $p_0, p_1, p_2, \ldots$ such that there is a t for which

1. the sequence $p_t, p_{t+1}, p_{t+2}, \ldots$ contains at most n distinct grammars, *and*
2. each of the grammars $p_t, p_{t+1}, p_{t+2}, \ldots$ is correct.

Of course, Gold's identification criterion above is just $\mathbf{TxtFex}_1$-identification. It is well known [82] that equivalent grammars (e.g., $p_t, p_{t+1}, p_{t+2}, \ldots$ as above) can be so different from one another that in some cases it is not possible to prove in Zermelo–Frankel set theory [49] that they are equivalent. This suggests that a suitably clever $\mathbf{M}$ might be able to $\mathbf{TxtFex}_{n+1}$-identify a larger class of languages than any machine, however clever, could $\mathbf{TxtFex}_n$-identify. Unfortunately, it was already known [12] that, at least in the case where the data are informant instead of text, one gets no more learning power with $(n+1)$ correct programs in the limit than with n. Surprisingly, then, the main theorem of the present paper (Theorem 3.3 in section 3 below) implies that, nonetheless, for learning from *text*, larger classes of languages *can* be learned with up to $(n+1)$ correct programs in the limit than with up to n.

Theorem 3.3 suggests, then, the *possibility* that evolutionary pressure for increased learning power may have resulted in human language learning strategies that

[2] N.B.: It is not required that $\mathbf{M}$ signal when it has reached its final conjecture—in general it doesn't know when and if it has.

involve convergence to *vacillating* between $n > 1$ correct grammars in the limit. This is examined more critically in section 7 below. Regarding, though, the size of n, we note that at least one of n distinct grammars would have to be of size proportional to the size of n (i.e., to $\log n$); hence, for extraordinarily *large* n, at least one of n distinct grammars would be too large to fit in our heads—unless, as seems unlikely, human storage mechanisms admit infinite regress. Osherson and Weinstein [71] introduced the case where the number of final grammars is finite but *unbounded*, and independently [28, 71] (see also [72]) introduced the case where the number of final grammars is infinite (**TxtBc**-identification). We briefly introduced the case, discussed above, of up to n final grammars in [15].

The proof of Theorem 3.3 employs an $(n+1)$-ary self-reference argument [18], and an informal thesis is presented and discussed after the statement of Theorem 3.3 that self-referential examples witnessing an existence theorem portend natural examples witnessing that theorem.

Case and Lynes [28] considered, among other things, the learning of grammars for languages where a *single* final grammar is allowed to have a bounded number of mistakes (*anomalies*). The mistakes are about which objects are (and which are not) in the corresponding language. In [30, 31, 15] there are discussion, motivation, and interpretation of results about inferring anomalous programs for functions. The results in [30, 31, 15] and in this paper show that allowing anomalies increases learning power. Clearly, anomalous programs are tolerable provided the number of anomalies is *small*. Hence, it is plausible that people have evolved language learning strategies that exploit the greater learning power achieved by converging to slightly incorrect grammars. Theorem 3.3 says, more generally than indicated above, that for each $n > 0$ some classes of languages can be algorithmically learned (in the limit) by converging to *up to* $n+1$ different, exactly correct grammars; *but* these classes can*not* be learned by converging (in the limit) to up to n different grammars, where the up to n grammars are each allowed to have a finite number of anomalies

Corollary 3.7 below specifies a two-dimensional hierarchy involving $\mathbf{TxtFex}_b^a$-identification: learning up to b final grammars each with up to a mistakes.

Theorem 3.11 implies that, in passing from learning finitely many anomalous grammars in the limit to learning infinitely many, one can eliminate half of the anomalies, and that's optimal! Intuitively, since (with positive data only) one is missing approximately half of the information, one can eliminate half of the anomalies only.

If L is a nonempty language, then *some* texts for L are *non*computable sequences, but in a completely computable universe, no parents can generate a noncomputable sequence of data for their children. Hence, it is interesting to consider $\mathbf{RecTxtFex}_b^a$-*identification*, which is similar to $\mathbf{TxtFex}_b^a$-identification except that success is required only on *computable* presentations of positive data, on all *recursive* texts. It might be expected that a suitably clever machine $\mathbf{M}$ might be able to exploit the recursiveness of texts to learn larger classes of languages than any machine required to succeed on arbitrary texts, but Corollary 3.1 below implies that this is not the case (generalizing the $b = 1$ case essentially from [96, 3]). We say, then, that *the restriction to recursive texts is circumvented*.

Angluin, in her seminal paper [1], presents a severe constraint on $\mathbf{TxtFex}_1$-identification of classes of languages: the *subset principle*. Basically, she shows that if $\mathbf{M}$ $\mathbf{TxtFex}_1$-identifies a class of languages $\mathcal{L}$, then for each $L \in \mathcal{L}$ there is a *finite* set D (called a *tell tale*) contained in L such that D is not contained in any proper sublanguage of L in $\mathcal{L}$. Intuitively, this necessary condition prevents overgeneralization in

learning from positive data [1, 8]. Theorem 4.4 below generalizes the subset principle to the criteria of success $\mathbf{TxtFex}^a_b$-identification and $\mathbf{TxtBc}^a$-identification, where the a in $\mathbf{TxtBc}^a$-identification allows each of the infinitely many final grammars converged to have up to a anomalies. Theorem 4.4 is also used to prove Theorem 3.11 below.

A child learning a language may or may not be sensitive to *the order or timing of presentation of positive data*. For $\mathbf{TxtFex}^a_b$-identification (and variants thereof) we mathematically consider several kinds of *in*sensitivity of a machine $\mathbf{M}$ to data order:

1. *set-driven:* $\mathbf{M}$'s output at any point depends only on the *set* of positive data it's seen up to that point (not on the sequence in which it was presented).
2. *partly set-driven:* $\mathbf{M}$'s output at any point depends only on the *set* of positive data it's seen up to that point *and on the length* of the sequence in which it was presented.
3. *b-ary order independent:* for languages L on which for some text $\mathbf{M}$ converges to a finite set of final grammars, $\mathbf{M}$ converges to the *same* set (of cardinality $\leq b$) of final grammars for each text for L.
4. *weakly b-ary order independent:* for languages L on which for some text $\mathbf{M}$ converges to a finite set of final grammars, there is a finite set of grammars D (of cardinality $\leq b$) such that $\mathbf{M}$ converges to a subset of this D for each text for L.

In section 5 below, we prove several theorems, each witnessing that, for suitably clever $\mathbf{M}$'s *simultaneously* exhibiting some insensitivities as above and circumventing the restriction to recursive texts, there is *no* loss of learning power (with respect to $\mathbf{TxtFex}^a_b$-identification or the variants thereof). For example, Theorem 5.5 implies that the power of $\mathbf{TxtFex}^a_b$-identification is unaffected by the restriction to $\mathbf{M}$'s which are simultaneously partly set-driven and weakly b-ary order independent and which circumvent the restriction to recursive texts. Theorem 5.5 is the hardest theorem herein to prove, and the other theorems in section 5 are proved by modifications and/or simplifications of the proof of Theorem 5.5. Some of the theorems in section 5 generalize predecessors for $\mathbf{TxtFex}^0_1$-identification [3, 93, 90, 38, 70, 39] but are much harder to prove. Some of the theorems in section 5 are applied in the present paper and in other papers.

In section 7 we discuss briefly computable universe hypotheses, present some critical discussion as promised above, and sketch some areas for future investigation.

2. Preliminaries. We now proceed more formally.

$\mathbf{N}$ denotes the set of *natural numbers*, $\{0, 1, 2, \ldots\}$.

φ denotes a fixed *acceptable* programming system for the partial computable functions: $\mathbf{N} \to \mathbf{N}$ [81, 65, 79, 80, 83]. φ_p denotes the partial computable function computed by the program (with code number) p in the φ-system.[3] Thanks to the device of Gödel or code numbering [82] we can treat languages over any finite alphabet as subsets of $\mathbf{N}$. $W_p \stackrel{\text{def}}{=}$ the domain of φ_p, the r.e. language ($\subseteq \mathbf{N}$) recognized (or enumerated) by program (grammar) p in the φ-system [82].

DEFINITION 2.1. *A* language learning function *is a computable mapping from finite sequences, of natural numbers and #'s, into* (*Gödel numbers of*) *programs* (*grammars*) *in the* φ*-system.*

[3] The *acceptable* systems are those universal programming systems such as Turing machines, C, and Lisp into which one can compile from any programming system. We characterized them as those universal systems for the partial computable functions in which one can implement any control structure [83].

$\mathcal{E}$ denotes the class of all r.e. languages ($\subseteq \mathbf{N}$).

DEFINITION 2.2. *A* text for *a language L is a mapping T from* $\mathbf{N}$ *into* $(\mathbf{N} \cup \{\#\})$ *such that L is the set of natural numbers in the range of T. T is said to be* for $L \Leftrightarrow T$ *is a text for L. The* content of *a sequence, of natural numbers and #'s, is the set of natural numbers in its range;* content$(\cdot)$ *denotes the content of its argument.*

Intuitively, one can think of a text for a language as an enumeration of the objects in the language with the #'s representing pauses in the listing of such objects. For example, the only text for the empty language is just an infinite sequence of #'s.

Intuitively, if $\mathbf{F}$ is a learning function and σ is a finite initial segment of a text for a language L, then $\mathbf{F}(\sigma)$ represents $\mathbf{F}$'s conjecture as to a grammar for L based on the data about L in σ.

Variables σ and τ (with or without decorations[4]) range over finite initial segments of texts T. $\|\sigma\|$ denotes the length of σ. $\sigma \diamond \sigma'$ denotes the sequence formed by adding σ' to the end of σ. Hence, if $\tau = \sigma \diamond \sigma'$, then, $\forall\, x \in \mathbf{N}$,

$$\tau(x) = \begin{cases} \sigma(x) & \text{if} \quad x < \|\sigma\|; \\ \sigma'(x - \|\sigma\|) & \text{if} \quad \|\sigma\| \leq x < \|\sigma\| + \|\sigma'\|; \\ \text{undefined} & \text{otherwise.} \end{cases}$$

Furthermore, $\sigma \diamond x$, where $x \in (\mathbf{N} \cup \{\#\})$, denotes $\sigma \diamond \sigma'$, where $\sigma' = \{(0, x)\}$.

card(D) denotes the cardinality of D. $\mathbf{I}^+$ denotes the set of positive integers. We take a and c to range over $(\mathbf{N} \cup \{*\})$ and b and d to range over $(\mathbf{I}^+ \cup \{*\})$. Intuitively, $*$ denotes the unbounded but finite. For example, "card$(D) \leq *$" means that D is finite. We adopt the convention that $(\forall i \in N)[i < * < \infty]$. $\mathbf{\Delta}$ is the symmetric difference operator for sets/languages. $L_1 =^a L_2 \Leftrightarrow \text{card}(L_1 \mathbf{\Delta} L_2) \leq a$. ("$=^0$" denotes, then, ordinary set equality.) $L_1 \neq^a L_2$ means that it is *not* the case that $L_1 =^a L_2$.

"$\subset$" denotes "is a *proper* subset of," and "$\supset$" denotes "is a *proper* superset of." Set theoretically, as in [47], we treat sequences as functions, and, in general, functions, finite, partial, or total, as *single-valued sets of ordered pairs.*[5] Hence, we can and do meaningfully compare them with "$\subseteq$," "$\subset$," "$\supseteq$," and "$\supset$." It *follows*, for example, that, if T is a text, "$\tau \subset T$" means that "the finite sequence τ is an initial segment of the infinite sequence T."

The quantifier "$\exists^\infty \tau$" means "there exists infinitely many τ."

We use "|" to mean "such that."

DEFINITION 2.3. *Suppose* $\mathbf{F}$ *is a learning function and T is a text. We say* $\mathbf{F}(T)$ converges (*written:* $\mathbf{F}(T)\Downarrow$) $\Leftrightarrow \{\mathbf{F}(\tau) \mid \tau \subset T\}$ *is finite. If* $\mathbf{F}(T)\Downarrow$, *then* $\mathbf{F}(T)$ *is defined* $= \{p \mid (\exists^\infty \tau \subset T)[\mathbf{F}(\tau) = p]\}$; *otherwise,* $\mathbf{F}(T)$ *is undefined.*

DEFINITION 2.4. *A language learning function,* $\mathbf{F}$, $\mathbf{TxtFex}_b^a$-identifies *an r.e. language $L \Leftrightarrow (\forall$ texts T for $L)[\mathbf{F}(T)\Downarrow =$ a set of cardinality $\leq b$ and $(\forall p \in \mathbf{F}(T))[W_p =^a L]]$.*

In $\mathbf{TxtFex}_b^a$-identification the b is a "bound" on the number of final grammars and the a a "bound" on the number of anomalies allowed in these final grammars. As above, a "bound" of $*$ just means *un*bounded but *finite.*

DEFINITION 2.5. $\mathbf{TxtFex}_b^a$ *denotes the class of all* classes $\mathcal{L}$ *of languages such that some learning function* $\mathbf{TxtFex}_b^a$*-identifies each language in* $\mathcal{L}$.

[4]Decorations are subscripts, superscripts, primes, and the like.

[5]Hence, the sequence of numbers $w_0, w_1, w_2, \ldots$ is identified with function f such that, for each $i \in \mathbf{N}$, $f(i) = w_i$, and this f is also identified with its graph $\{(i, f(i)) \mid i \in \mathbf{N}\}$.

Intuitively, $\mathcal{L} \in \mathbf{TxtFex}_b^a \Leftrightarrow$ there is an algorithm $\mathbf{p}$, computing a learning function $\mathbf{F}$, such that, if $\mathbf{p}$ is given any listing T of any language $L \in \mathcal{L}$, it outputs a sequence of grammars *converging* in a nonempty *set*, $\mathbf{F}(T)$, of no more than b grammars, and each of these grammars makes no more than a mistakes in generating L, i.e., if $\mathbf{p}$ is given any listing of any language $L \in \mathcal{L}$, it outputs a sequence of grammars, and, past some point in this sequence, each grammar seen (over and over) is from a set of no more than b grammars and each of these "final" grammars makes no more than a mistakes in generating L.

$\mathbf{TxtFex}_1^0$-identification is equivalent to Gold's [46] seminal notion of *identification*, also referred to as **TXTEX**-identification in [28] and (indirectly) as **INT** in [72, 71, 70]. $\mathbf{TxtFex}_1^a$-identification is just $\mathbf{TXTEX}^a$-identification from [28]. For $n > 0$, $\mathbf{TxtFex}_n^0$-identification is just our notion of $\mathbf{TXTFEX}_n$-identification from [15]. Osherson and Weinstein [71] were the first to define $\mathbf{TxtFex}_*^0$ and $\mathbf{TxtFex}_*^*$; they called them **BEXT** and **BFEXT**, respectively.

It is common in the literature to use $\mathbf{TXTEX}_b^a$ to mean the special case of $\mathbf{TXTEX}^a$ where the total number of changes of output (or *mind changes*) is bounded above by b. *N.B.: The b in $\mathbf{TxtFex}_b^a$ has a totally different meaning from the b in $\mathbf{TXTEX}_b^a$; the former is a bound on the number of different programs an associated machine eventually vacillates between in the limit*; *the latter is a bound on mind changes for convergence to a single final program.*

DEFINITION 2.6. *A text T is* recursive $\Leftrightarrow T$, *as a function:* $\mathbf{N} \to (\mathbf{N} \cup \{\#\})$, *is computable.*[6]

Learning power under $\mathbf{TxtFex}_b^a$-identification might be affected if one requires success only on all *recursive* texts for a language. This is interesting since, for example, if the universe is *completely* algorithmic, then all *real* language texts generated by parents for their children *are* recursive![7]

DEFINITION 2.7. *A language learning function*, $\mathbf{F}$, $\mathbf{RecTxtFex}_b^a$-identifies *an r.e. language $L \Leftrightarrow$* ($\forall$ recursive *texts T for L*)[$\mathbf{F}(T)\Downarrow =$ *a set of cardinality* $\leq b$ *and* $(\forall p \in \mathbf{F}(T))[W_p =^a L]$].

DEFINITION 2.8. $\mathbf{RecTxtFex}_b^a$ *denotes the class of all* classes $\mathcal{L}$ *of languages such that some learning function $\mathbf{RecTxtFex}_b^a$-identifies each language in $\mathcal{L}$.*

It is interesting to consider what happens to learning power if the final programs/grammars for $\mathbf{TxtFex}_b^a$-identification are required to be "nearly" minimal size and, hence, even more likely to fit in one's head.

Let mingrammar(L) denote $\min(\{\, p \mid W_p = L \,\})$.

DEFINITION 2.9. $\mathbf{F}$ $\mathbf{TxtMfex}_b^a$-identifies *a class of languages $\mathcal{L} \Leftrightarrow$* ($\exists$ *recursive h*) $(\forall L \in \mathcal{L})$[$\mathbf{F}$ $\mathbf{TxtFex}_b^a$-identifies $L \wedge (\forall T$ *for* $L)(\forall p \in \mathbf{F}(T))[p \leq h(\text{mingrammar}(L))]$].

h in Definition 2.9 plays the role of a computable amount by which the final programs can be larger than minimal size. This size restriction of course does not hold in general, and, for $\mathbf{TxtMfex}_1^0$-identification, it is not as severe as requiring that the final program be strictly minimal size. Mathematically, $\mathbf{TxtMfex}_b^a$-identification is well behaved, e.g., it turns out not to depend on the choice of acceptable system; it also does not depend on the choice of Blum program size measure [11] (by his recursive-relatedness result in [11]). The lack of dependence on the choice of acceptable system is in contrast with the variant of $\mathbf{TxtMfex}_1^0$-identification in which we require h to be the identity function (see [23]). The study of learning nearly minimal

[6] The r.e. languages are characterized as those which are the content of some recursive text [82].
[7] See further discussion in section 3 below.

size programs began with [35] in the context of learning programs for functions (see also [52, 19, 20, 37]).

DEFINITION 2.10. $\mathbf{TxtMfex}_b^a = \{\mathcal{L} \mid (\exists \mathbf{F})[\mathbf{F}\ \mathbf{TxtMfex}_b^a\text{-}identifies\ \mathcal{L}]\}$.

Similarly, we may define $\mathbf{RecTxtMfex}_b^a$-*identification* and $\mathbf{RecTxtMfex}_b^a$ as $\mathbf{TxtMfex}_b^a$-identification and $\mathbf{TxtMfex}_b^a$, respectively, restricted to recursive texts (see Definitions 2.7 and 2.8 above).

Next, for mathematical completeness and interest, we introduce the cases of success criteria for which the number of final grammars is possibly infinite, not necessarily finite as it is for $\mathbf{TxtFex}_b^a$-identification. Definitions 2.11 and 2.12 are from [28]. The $a \in \{0, *\}$ cases were independently introduced in [71, 72].

The quantifier "$\forall^\infty k$" means "for all but finitely many $k \in \mathbf{N}$."

DEFINITION 2.11. $\mathbf{F}$ $\mathbf{TxtBc}^a$-identifies $L \Leftrightarrow (\forall\ texts\ T\ for\ L)(\forall^\infty k)[W_{\mathbf{F}(T[k])} =^a L]$.

DEFINITION 2.12. $\mathbf{TxtBc}^a$ *denotes the class of all classes* $\mathcal{L}$ *of languages such that some learning function* $\mathbf{TxtBc}^a$*-identifies each language in* $\mathcal{L}$.

$\emptyset$ denotes the empty set of natural numbers.

Fix *canonical indexings* of the *finite* sets of natural numbers and of the finite initial segments of texts each one to one onto $\mathbf{N}$ [82, 65].[8] In the following, finite sets and segments are sometimes *identified* with their corresponding canonical indices. Hence, a reference to a *least* finite set or segment really refers to a finite set or segment with least canonical index. Also, *when we compare finite sets or segments by* $<, \leq, \cdots$ *we are comparing their corresponding canonical indices.*

$\langle \cdot, \cdot \rangle$ denotes a fixed *pairing function* [82], a computable, surjective, and injective mapping from $\mathbf{N} \times \mathbf{N}$ into $\mathbf{N}$.

For $A \subseteq \mathbf{N}$, $\overline{A}$ denotes $(\mathbf{N} - A)$, the *complement* of A.

We let $\mathbf{F}$ (with or without decorations) range over learning functions.

3. Results on vacillation in learning. This section presents our main results regarding the vacillatory learning criteria of the present paper.

In this section we defer proofs of three results until we have the benefit of some of the concepts and results from sections 4 and 5 below. Section 6 contains the three deferred proofs.

The definition of $\mathbf{TxtFex}_b^a$-identification (Definition 2.5 above) requires success for *each* order of data presentation. For each nonempty *r.e.* language, there are continuum many such orders (texts) [47] yet only countably many *recursive* ones (since there are only countably many Turing machine programs for computing the recursive texts [82]). In a completely computable universe (which ours might be), there are really only *recursive* texts available to be presented to learning machines. Of course the universe *may* be such that, while all the language learners are computable, there are some noncomputable phenomena too. As noted in [70], since the utterances of children's caretakers depend heavily on external environmental events, such influences might introduce a random component into naturally occurring texts. It is, then, interesting and important to compare learning power where success is required on *all* texts with the cases where it is required only on all *recursive* texts.

Wiehagen [96] essentially notes that $\mathbf{RecTxtFex}_1^0 = \mathbf{TxtFex}_1^0$ (a related result was first proved in [3]), and [28] essentially observes that $(\forall a)[\mathbf{RecTxtFex}_1^a =$

[8] The canonical index of a finite set or segment is, then, a numerical code of it.

$\mathbf{TxtFex}_1^a$]. We have, more generally, the following corollary.[9]

COROLLARY 3.1.

1. $(\forall a, b)[\mathbf{RecTxtFex}_b^a = \mathbf{TxtFex}_b^a]$.
2. $(\forall a, b)[\mathbf{RecTxtMfex}_b^a = \mathbf{TxtMfex}_b^a]$.

Hence, for all the vacillatory learning criteria of the present paper, it makes no difference in learning power whether or not we restrict the texts to be recursive! By contrast, for $\mathbf{TxtBc}^a$, learning procedures *can* exploit the assumption that they are receiving recursive texts; for $\mathbf{TxtBc}^a$, the restriction to recursive text *does* make a difference in learning power [28, 36].

The topic of learning nearly minimal size programs/grammars is treated in greater depth in [23]. Herein we present results about such criteria only in the contexts of recursive text (Corollary 3.1) and of restrictions on learning functions (section 5 below). There is a small amount of additional discussion below in section 7.

$\mathbf{RecTxtFex}_1^0 = \mathbf{TxtFex}_1^0$ entails that, if a given learning function $\mathbf{F}$ $\mathbf{RecTxtFex}_1^0$-identifies some class, *some* learning function $\mathbf{F}'$ will $\mathbf{TxtFex}_1^0$-identify it. However, by the following proposition, in some cases we can*not* have $\mathbf{F}' = \mathbf{F}$.

PROPOSITION 3.2. *There is a learning function which* $\mathbf{RecTxtFex}_1^0$*-identifies a language which it fails to* $\mathbf{TxtFex}_1^0$*-identify.*

Proof. Let $K = \{\, p \mid p \in W_p \,\}$, a well-known r.e., nonrecursive set [82]. Suppose k is a recursive function with range K [82]. Let $K_s = \{\, k(s') \mid s' < s \,\}$. C_A denotes the *characteristic function of* $A \subseteq \mathbf{N}$, the function 1 on A and 0 off A. Clearly, $(\forall x)[\lim_{s\to\infty} C_{K_s}(x) = C_K(x)]$. Let S_τ = the set of all $x \in$ the domain of τ such that $C_{K_{\|\tau\|}}$ agrees with τ on all inputs $\leq x$. Let

$$\operatorname{agree}(\tau) = \begin{cases} 0 & \text{if} \quad S_\tau = \emptyset; \\ 1 + \max(S_\tau) & \text{otherwise.} \end{cases}$$

It is easy to see that

$$[T = C_K \Rightarrow \lim_{\tau \subset T} \operatorname{agree}(\tau) = \infty]$$

and that

$$[T \neq C_K \Rightarrow \lim_{\tau \subset T} \operatorname{agree}(\tau) < \infty].$$

Let p_0 be a program such that $W_{p_0} = \{\, 0, 1 \,\}$. Let

$$\tau^- = \begin{cases} \emptyset & \text{if} \quad \tau = \emptyset; \\ \tau' & \text{if} \quad \tau = \tau' \diamond x. \end{cases} \tag{3.1}$$

Let

$$\mathbf{F}(\tau) = \begin{cases} \operatorname{agree}(\tau) & \text{if} \quad \operatorname{agree}(\tau) > \operatorname{agree}(\tau^-); \\ p_0 & \text{otherwise.} \end{cases}$$

Let $L = \{\, 0, 1 \,\}$. Clearly, C_K is a nonrecursive text T for L such that $\mathbf{F}(T)\Downarrow$, yet $\mathbf{F}$ on any recursive text for L converges to p_0, a program for L. □

Next is our main theorem. It says that, for each $n > 0$, some classes of languages can be algorithmically learned (in the limit) by converging to *up to* $n + 1$ different,

[9] The proof of Corollary 3.1 is deferred to section 6 since it employs Theorems 5.5 and 5.8 from section 5.

exactly correct grammars; *however,* these classes can*not* be learned by converging (in the limit) to up to n different grammars, where the up to n grammars are each allowed to have a finite number of anomalies! Allowing one more grammar in the limit makes a big difference in learning power.

Hence, it is *possible* that, for some $n > 0$, people have evolved language learning strategies that exploit the greater learning power achieved by converging in the limit to up to $n+1$ rather than to up to n grammars (see a critical discussion in section 7 below).

THEOREM 3.3. *Suppose* $n > 0$. *Let* $\mathcal{L}_{n+1}$ *equal*

$$\{L \mid L \text{ is } \infty \wedge (\exists e_0, \ldots, e_n)[W_{e_0} = \cdots = W_{e_n} = L \wedge (\forall^\infty \langle x, y\rangle \in L)[y \in \{e_0, \ldots, e_n\}]]\}.$$

Then $\mathcal{L}_{n+1} \in (\mathbf{TxtFex}^0_{n+1} - \mathbf{TxtFex}^*_n)$.

The detailed proof of Theorem 3.3 is deferred to section 6 since it depends, in part, on Definitions 5.1 and 5.4 and Theorem 5.6 in section 5.

The reader may note that the languages in the class $\mathcal{L}_{n+1}$ from Theorem 3.3 have an intriguing self-referential character. It is useful to discuss this feature a bit in the interest of anticipating and answering a possible objection to the use of self-reference in witnessing the separation result of Theorem 3.3.

In the proof of Theorem 3.3, to handle the self-referential character of $\mathcal{L}_{n+1}$, we employ the $(n+1)$-ary recursion theorem, a folk theorem generalizing the Kleene recursion theorem [82, p. 214] and the Smullyan double recursion theorem [87]; it is also a consequence of our operator recursion theorem [14], an infinitary analogue of the finitary recursion theorems.

Intuitively, the $(n+1)$-ary recursion theorem provides a means for transforming any sequence of $n+1$ programs $p_0, \ldots, p_n$ into a corresponding sequence of programs $e(p_0), \ldots, e(p_n)$ such that each $e(p_i)$ first creates quiescent copies of $e(p_0), \ldots, e(p_n)$ (including a self-copy, a copy of $e(p_i)$ itself), and then each $e(p_i)$ runs p_i on the quiescent copies of $e(p_0), \ldots, e(p_n)$ any together with any externally given input. Each $e(p_i)$, in effect, has complete (low level) knowledge of $e(p_0), \ldots, e(p_n)$ (including self-knowledge, knowledge of $e(p_i)$ itself), and p_i represents how $e(p_i)$ *uses* its self-knowledge, its knowledge of the other $e(p_j)$'s, and its knowledge of the external world. Infinite regress is not required since each $e(p_i)$ creates the copies of $e(p_0), \ldots, e(p_n)$ *externally* to itself. One mechanism to achieve this creation is a generalization of the self-replication trick isomorphic to that employed by single-celled organisms [14]. Another is for the programs $e(p_0), \ldots, e(p_n)$ to look in a common mirror to see which programs they are. Reference [18] provides a tutorial on thinking about and applying recursion theorems.[10] Herein, our application of the $(n+1)$-ary recursion theorem (to prove Theorem 3.3) will be informal and the sequence $p_0, \ldots, p_n$ will be implicit.

Now for the possible objection: On the one hand, we argue above that Theorem 3.3 suggests a possibility regarding human language learning; on the other hand, we prove it by self/other reference, and it is common to regard self-referential examples as *un*natural. For example, Gödel proved his famous incompleteness theorem by a self-reference argument [45, 62], and his self-referential sentence providing an unprovable truth of, for example, *First Order Peano Arithmetic* (**FOPA**) is not natural—no number or combinatorial theorist would care whether it was true or false.

We answer this objection about self-referential proofs of existence theorems with the following.

[10] See [78] for discussion and applications of recursion theorems in severely resource-limited contexts.

INFORMAL THESIS 1. *If a self-referential example witnesses the existence of a phenomenon, there are* natural *examples witnessing same!*

For this informal thesis we present a brief plausibility argument and one piece of empirical evidence. Plausibility: Self-reference arguments lay bare *an* underlying *simplest* reason for the theorems they prove [82, 18]; if a theorem is true for such a simple reason, the "space" of reasons for its truth may be broad enough to admit natural examples. Empirical: Although Gödel proved his famous first incompleteness theorem by a self-reference argument, many years afterwards, Paris and Harrington [75] and later Friedman [84, 85] found quite natural examples of combinatorial truths of first order arithmetic not provable in **FOPA**.[11] In fairness, regarding the above informal thesis, we note, for example, that the Blum speed-up theorem [10] was originally proved by a self-reference argument,[12] but natural witnesses to even exponential speed-up have not (yet) been found. However, even the self-reference proofs of this result are fairly complicated; hence, one might expect that natural examples are especially hard to find.

For some theoretical work instigated by Barzdin and dealing, in part, with eliminating dependence on self-referential examples, see Fulk's work on robust function learning in [40].

COROLLARY 3.4. $(\forall a)[\mathbf{TxtFex}^a_1 \subset \mathbf{TxtFex}^a_2 \subset \cdots \subset \mathbf{TxtFex}^a_*]$.

COROLLARY 3.5 (Osherson and Weinstein [71]). $\mathbf{TxtFex}^0_1 \subset \mathbf{TxtFex}^0_*$.

We announced in [15] that we could prove $\mathbf{TxtFex}^0_1 \subset \mathbf{TxtFex}^0_2$ by analyzing Osherson and Weinstein's proof of the immediately preceding corollary. Under our direction Karen Ehrlich generalized the combinatorics of this proof to get $\mathbf{TxtFex}^0_2 \subset \mathbf{TxtFex}^0_3$. The combinatorics for this approach to the general case are unpleasant. Reference [70] contains a recursion theorem proof of the immediately preceding corollary based on the proof in [71], but the same combinatorial difficulties occur in attempting to generalize this proof. We sought a combinatorially cleaner self-reference proof. A later conversation about this with Royer led to Royer and Kurtz supplying us with essentially the self-referential sets we use in Theorem 3.3 above. We believe their self-referential examples are somewhat simpler than those we had been working with. They also supplied some of the crucial combinatorics for the diagonal argument that goes with a special case.

It is interesting to note that if one modifies the definition of $\mathbf{TxtFex}^a_n$-identification to require that the learning function must converge to *exactly* n grammars, then the hierarchy of Corollary 3.4 above collapses.[13]

If we restrict our attention to languages which are the (pairing function coded) graphs of *total functions*, then it is essentially shown (the $a = 0$ case in [12] and the $a > 0$ cases in [31]) that the hierarchy again collapses. Hence, in the case of "scientific inference," i.e., the case of learning programs for computable functions, there is no power in vacillation.[14]

Therefore, Corollary 3.4 is very sensitive to minor perturbations. We should men-

[11] See [78] for an example from complexity theory.

[12] See also Young's version in [98] and our operator recursion theorem variant in [86].

[13] Just output every nth grammar.

[14] For computable functions f, one can think of input x as coding a scientific experiment and the output $f(x)$ as coding the corresponding experimental result. In this way results about learning programs for functions can be interpreted as results about finding predictive explanations for phenomena—as results about scientific induction. For more on this see [3, 31, 22, 7, 21, 56]. Regarding the names of the learning criteria studied in the present paper, originally [31] "**Ex**" stood for "explanatory," "**Fex**" stood for "finitely explanatory," and **Bc** for "behaviorally correct."

tion, however, that there *are* some interesting effects on learning power for vacillatory function learning wrought by bounding *suitably sensitive* measures of the computational complexity of the learning functions themselves [24] and by the introduction of noisy input data [25].

The next proposition provides a dual to Theorem 3.3. There are classes which can be learned with one program in the limit and with up to $m+1$ anomalies in that program which can*not* be learned with finitely many programs in the limit, but with each having no more than m anomalies.

PROPOSITION 3.6. $(\mathbf{TxtFex}_1^{m+1} - \mathbf{TxtFex}_*^m) \neq \emptyset$.

Proof. We identify total functions f with $\{\, \langle x, f(x)\rangle \mid x \in \mathbf{N} \,\}$. Let $\mathcal{L} = \{\, \text{total } f \mid \varphi_{f(0)} =^{m+1} f \,\}$. Clearly, $\mathcal{L} \in \mathbf{TxtFex}_1^{m+1}$. Also, $\mathcal{L} \in \mathbf{TxtFex}_*^m$ together with Theorems 2.6 and 2.9 from [31] yields a contradiction. □

In [4] it is shown that $\{\, L \mid L =^{m+1} \mathbf{N} \,\}$ also witnesses the separation of Proposition 3.6.

Clearly, from Theorem 3.3 and Proposition 3.6 we have our main corollary.

COROLLARY 3.7. $\mathbf{TxtFex}_b^a \subseteq \mathbf{TxtFex}_d^c \Leftrightarrow [b \leq d \text{ and } a \leq c]$.

In Corollary 3.7, we see that all *and only* the obvious inclusions hold. Hence, allowing more anomalies, final grammars, or both enhances learning power, but anomalies and final grammars cannot in general completely substitute for one another. For example, $\mathbf{TxtFex}_2^0$ is incomparable to $\mathbf{TxtFex}_1^1$. That is, there are classes which can be learned with no mistakes and up to two final grammars which cannot be learned with up to one mistake and one final grammar, and there are other classes which can be learned with up to one mistake and one final grammar which cannot be learned with no mistakes and up to two final grammars.

COROLLARY 3.8 (Case and Lynes [28]). $\mathbf{TxtFex}_1^0 \subset \mathbf{TxtFex}_1^1 \subset \cdots \subset \mathbf{TxtFex}_1^*$.

Osherson and Weinstein [71] independently showed the case of $\mathbf{TxtFex}_1^0 \subset \mathbf{TxtFex}_1^*$ from the previous corollary.

COROLLARY 3.9 (Osherson and Weinstein [71]). $\mathbf{TxtFex}_*^0 \subset \mathbf{TxtFex}_*^*$.

Next we spell out the connections between $\mathbf{TxtFex}_b^a$ and $\mathbf{TxtBc}^{a'}$. Of course, allowing infinitely many grammars in the limit is not so realistic for modeling language learning but, nonetheless, it is mathematically interesting to make the comparisons.

PROPOSITION 3.10. $\mathbf{TxtBc}^0 - \mathbf{TxtFex}_*^* \neq \emptyset$.

Proof. As in the proof of Proposition 3.6, we identify total functions f with $\{\, \langle x, f(x)\rangle \mid x \in \mathbf{N} \,\}$. Let $\mathcal{L} = \{\, \text{total } f \mid (\forall^\infty k)[\varphi_{f(k)} = f] \,\}$. Clearly $\mathcal{L} \in \mathbf{TxtBc}^0$. Also, $\mathcal{L} \in \mathbf{TxtFex}_*^*$ together with Theorems 2.12 and 3.1 from [31] yields a contradiction. □

REMARK 1. *Proposition* 3.10 *still holds even if we restrict* $\mathbf{TxtBc}^0$*-identification to recursive texts.*

The next theorem says that, in passing from learning finitely many anomalous grammars in the limit to learning infinitely many, one can eliminate half of the anomalies, and that's optimal! This contrasts with the function learning case [31], where, by a result of Steel, one can so eliminate *all* of finitely many anomalies. Intuitively, in the present context, since one is missing in the input data the negative information, i.e., since one is missing approximately half the information, one can eliminate only half of the anomalies.

THEOREM 3.11. $\mathbf{TxtFex}_*^m \subseteq \mathbf{TxtBc}^{m'} \Leftrightarrow m \leq 2.m'$; *furthermore*, $\{\, L \mid L =^{2m+1} \mathbf{N} \,\} \in (\mathbf{TxtFex}_1^{2m+1} - \mathbf{TxtBc}^m)$.

In Theorem 3.11 we see that some excluded inclusions are, at first glance, unexpected. Its proof is deferred to section 6 since it depends on Theorem 4.4 in section 4

below.

Clearly, we have the following corollary.

COROLLARY 3.12 (see [28]). *The class of cofinite sets is in*

$$\left(\mathbf{TxtFex}_1^* - \bigcup_{m\in\mathbf{N}} \mathbf{TxtBc}^m\right).$$

We have not yet worked out all the relationships analogous to those in Theorem 3.11 and Corollary 3.12 for the cases in which $\mathbf{TxtBc}^a$-identification is restricted to recursive texts. As noted above in this section, the restriction to recursive texts *does* affect $\mathbf{TxtBc}^a$-identification [28, 36].

4. Topological results. We next present several useful results which can be described as topological. The exact connections to topology (actually, to Baire category theory and Banach–Mazur games [49]) we will not pursue herein, but on that subject the interested reader can consult [67, 70].

DEFINITION 4.1. *Suppose that $\sigma \subseteq \tau \subset T$, with T a text. Then*

$$\mathbf{F}[\sigma,\tau] = \{\, p \mid (\exists \sigma' \supseteq \sigma \mid \sigma' \subseteq \tau)[p = \mathbf{F}(\sigma')] \,\}$$

and

$$\mathbf{F}[\sigma,T] = \{\, p \mid (\exists \sigma' \supseteq \sigma \mid \sigma' \subset T)[p = \mathbf{F}(\sigma')] \,\}.$$

Suppose that σ is a finite initial segment of a text T. Picture $\mathbf{F}$ being fed T one element at a time and imagine watching the successive corresponding output programs. Then, for example, from Definition 4.1 immediately above, $\mathbf{F}[\sigma,T]$ is the set of all these output programs one sees *from* the time $\mathbf{F}$ is fed all of σ.

DEFINITION 4.2. σ in $L \Leftrightarrow \text{content}(\sigma) \subseteq L$.

Just below is a variant of a fundamental lemma from [71] convenient for this paper. An original, not-so-general version of this lemma is from [3] (see also [67, 70]). Variations on its proof will appear in other proofs.

LEMMA 4.3. *Suppose $L \in \mathcal{E}$. Suppose that, for each text T for L, an arbitrary $\sigma_T \subset T$ is chosen. Then, for these choices, let*

$$P = \bigcup_{T \text{ for } L} \mathbf{F}[\sigma_T, T].$$

It follows that

$$(\forall \sigma \text{ in } L)(\exists \tau \supseteq \sigma \mid \tau \text{ in } L)(\forall \tau' \supseteq \tau \mid \tau' \text{ in } L)[\mathbf{F}(\tau') \in P]. \tag{4.1}$$

Proof. Suppose the hypotheses. Suppose for contradiction the negation of (4.1). Hence,

$$(\exists \sigma \text{ in } L)(\forall \tau \supseteq \sigma \mid \tau \text{ in } L)(\exists \tau' \supseteq \tau \mid \tau' \text{ in } L)[\mathbf{F}(\tau') \notin P]. \tag{4.2}$$

Let T be a fixed text for L. We recursively define another text T' for L as follows. Let $\tau_0 = \sigma$ and $\tau_0' = \tau_0 \diamond T(0)$. Suppose (recursively) that τ_n and $\tau_n' \supset \sigma$ are defined and in L. By (4.2) we may take τ_{n+1} to be the least $\supseteq \tau_n'$ such that $[\tau_{n+1} \text{ in } L \wedge \mathbf{F}(\tau_{n+1}) \notin P]$. Let $\tau_{n+1}' = \tau_{n+1} \diamond T(n+1)$. Let $T' = \bigcup_{n\in\mathbf{N}} \tau_n'$. Clearly, T' is a text for L and $T' = \bigcup_{n\in\mathbf{N}} \tau_n$ too, with $\tau_0 \subset \tau_1 \subset \tau_2 \subset \cdots$. By the choice of τ_n's, for each $n \in \mathbf{N}$, $\mathbf{F}(\tau_{n+1}) \notin P$. Therefore, $\mathbf{F}[\sigma_{T'}, T'] \not\subseteq P$, a contradiction. ∎

The $I = \mathbf{Fex}_1^0$ case of the following theorem is from [1]. She calls the finite sets D featured *tell tales*. The theorem witnesses a severe constraint called the *subset principle* on learning from positive data. See [1, 8] regarding the importance of the subset property for avoidance of *overgeneralization* in learning languages *from positive data*. See [54, 95] for discussion regarding the possible connection between this subset principle and a more traditionally linguistically oriented one in [64].

We let $2* \stackrel{\text{def}}{=} *$.

THEOREM 4.4. *Suppose* $I \in \{ \mathbf{Fex}_b^a, \mathbf{Bc}^a \}$ *and* $\mathbf{F}$ $\mathbf{Txt}I$*-identifies* L. *Then*

$$(\exists D \text{ finite } \subseteq L)(\forall L' \subseteq L \mid D \subseteq L' \wedge L' \neq^{2a} L)[\mathbf{F} \text{ does not } \mathbf{Txt}I\text{-identify } L']. \tag{4.3}$$

It would be interesting to have a complete characterization from Theorem 4.4. Some progress was made in [6], where it is essentially shown that, for any *uniformly decidable class of recursive languages* $\mathcal{L}$, a learning function $\mathbf{F}$ witnesses that $\mathcal{L}$ is in $\mathbf{TxtBc}^a \Leftrightarrow$ *each* $L \in \mathcal{L}$ satisfies (4.3) above.[15]

To prove Theorem 4.4 it is useful to have the following combinatorial lemma whose proof is omitted by reason of being straightforward.

LEMMA 4.5. *Suppose* $[A =^a B \wedge B =^a C]$. *Then* $A =^{2a} C$.

Proof. Suppose the hypotheses. For each T for L, choose a suitably large $\sigma_T \subset T$ that

$$(\forall \tau \supseteq \sigma_T \mid \tau \subset T)[W_{\mathbf{F}(\tau)} =^a L].$$

Let

$$P = \bigcup_{T \text{ for } L} F[\sigma_T, T].$$

Then $(\forall p \in P)[W_p =^a L]$. Hence, by Lemma 4.3,

$$(\exists \tau \supseteq \emptyset \mid \tau \text{ in } L)(\forall \tau' \supseteq \tau \mid \tau' \text{ in } L)[\mathbf{F}(\tau') \in P]. \tag{4.4}$$[16]

Let $D = \text{content}(\tau)$, a *finite* subset of L. Suppose $[D \subseteq L' \subseteq L \wedge L' \neq^{2a} L]$. Let T' be a text for L' such that $T' \supset \tau$. Then, since any $\tau' \subset T'$ is in L, we have by (4.4) that

$$(\forall \tau' \supseteq \tau \mid \tau' \subset T')[\mathbf{F}(\tau') \in P].$$

Hence, $(\forall \tau' \supseteq \tau \mid \tau' \subset T')[W_{\mathbf{F}(\tau')} =^a L \neq^{2a} L']$. Therefore, by Lemma 4.5, $(\forall \tau' \supseteq \tau \mid \tau' \subset T')[W_{\mathbf{F}(\tau')} \neq^a L']$. Hence, $\mathbf{F}$ does not $\mathbf{Txt}I$-identify L'. ∎

Clearly, in the proof of Theorem 4.4 there is *no* use of the computability of $\mathbf{F}$. The limitation Theorem 4.4 witnesses on learning from texts is purely topological having nothing to do with algorithmicity. Corollary 4.6 and the nonlearnability half of Theorem 3.11 above, proved from Theorem 4.4, likewise do not depend on algorithmicity.

[15] This complements a related characterization in [1] of the uniformly decidable classes of recursive languages in $\mathbf{TxtFex}_1^0$. Reference [6] also provides a related characterization of the uniformly decidable classes of recursive languages in $\mathbf{TxtFex}_1^*$. References [63, 57] contain characterizations of uniformly decidable classes of recursive languages in important special cases of $\mathbf{TxtFex}_1^0$, and [26] contains characterizations of language learning with noisy texts.

[16] τ is, then, what is suggestively called a *locking sequence* [70].

COROLLARY 4.6 (see [71, 28]). *Suppose that $\mathcal{L}$ contains an infinite language L and all its finite sublanguages. Then $\mathcal{L} \notin \mathbf{TxtBc}^*$. Hence, the class of regular languages $\notin \mathbf{TxtBc}^*$.*

Theorem 4.4 does *not* imply that if a learning function $\mathbf{TxtFex}_1^0$-identifies an infinite language, it must fail to $\mathbf{TxtFex}_1^0$-identify *each* proper sublanguage. In fact we have the following proposition, a variant of which, regarding function learning, appears in [18].

PROPOSITION 4.7. *There is in $\mathbf{TxtFex}_1^0$ an infinite r.e. collection of infinite languages of the form $\{ W_{e_0} \supset W_{e_1} \supset W_{e_2} \supset \cdots \}$.*

Proof. By the operator recursion theorem [14], there is an infinite r.e. sequence of self-other referential programs $e_0, e_1, e_2, \ldots$ such that, for each $i \in \mathbf{N}$,

$$W_{e_i} = \{ e_i, e_{i+1}, e_{i+2}, \ldots \}.$$

We omit the straightforward verification. □

Gold [46] proved Corollary 4.6 with $\mathbf{TxtFex}_1^0$ in place of $\mathbf{TxtBc}^*$ and was clearly concerned that his result meant that only rather puny language classes could be learned from positive data. However, Wiehagen [96] presents a class of r.e. languages in $\mathbf{TxtFex}_1^0$ which contains a finite variant of each r.e. language. Wiehagen's class is obviously quite hefty. Angluin presents examples natural from the perspective of formal language theory that also are in $\mathbf{TxtFex}_1^0$ [1, 2]. All these classes in $\mathbf{TxtFex}_1^0$ (of course) satisfy the subset principle (of Theorem 4.4), and, in particular, they are not closed under finite sublanguages as is the class of regular languages.

Suppose that $\mathcal{N}$ is a class of natural languages learnable from text and which contains some language L and also an infinitely different natural sublanguage L' of L. For example, L' might be the class of imperative sentences of L. Theorem 4.4 above causes no apparent problem since a finite tell-tale D for L need not (and should not) be contained in L'. It may be useful for linguists to try to find such tell-tale D's for natural languages L. Of course such a D shouldn't be contained in, for example, L', the set of imperative sentences of L, but should nonetheless be salient empirically to the learning of L.

The following stability property is useful for studying the criteria $\mathbf{RecTxtFex}_b^a$.

DEFINITION 4.8. *Suppose that L is r.e. Then L recursively b-stabilizes $\mathbf{F} \Leftrightarrow$*

$$(\forall \text{ recursive } T \text{ for } L)(\exists D \mid \operatorname{card}(D) \leq b)[\mathbf{F}(T)\Downarrow = D].$$

The following lemma, which is useful to this paper, combines the topological with the algorithmic. It generalizes predecessors from [3, 38, 70].

LEMMA 4.9. *Suppose that L is r.e. and recursively b-stabilizes $\mathbf{F}$. Then*

$$(\forall \sigma \text{ in } L)(\exists D \mid \operatorname{card}(D) \leq b)(\exists \tau \supseteq \sigma \mid \tau \text{ in } L)(\forall \tau' \supseteq \tau \mid \tau' \text{ in } L)[\mathbf{F}(\tau') \in D]. \tag{4.5}$$

Proof. Suppose the hypothesis on L and, for contradiction, the negation of (4.5). Hence,

$$(\exists \sigma \text{ in } L)(\forall D \mid \operatorname{card}(D) \leq b)(\forall \tau \supseteq \sigma \mid \tau \text{ in } L)(\exists \tau' \supseteq \tau \mid \tau' \text{ in } L)[\mathbf{F}(\tau') \notin D]. \tag{4.6}$$

Let T be a fixed recursive text for L. We recursively define another recursive text T' for L as follows. Let $\tau_0 = \sigma$ and $\tau_0' = \tau_0 \diamond T(0)$. Let $\tau_0'' =$ the *shortest* $\subseteq \tau_0'$ such that $\operatorname{card}(\mathbf{F}[\tau_0'', \tau_0']) \leq b$. (For $b = *$, τ_n'' will $= \emptyset$, for all $n \in \mathbf{N}$.) Let $D^0 = \mathbf{F}[\tau_0'', \tau_0']$. Suppose (recursively) that τ_n, τ_n', and τ_n'' are defined and in L, $\tau_n, \tau_n' \supset \sigma$, $\tau_n'' \subseteq \tau_n'$,

and that $D^n = \mathbf{F}[\tau''_n, \tau'_n]$. By (4.6) we may algorithmically find a $\tau_{n+1} \supseteq \tau'_n$ such that $[\tau_{n+1}$ in $L \ \wedge \ \mathbf{F}(\tau_{n+1}) \notin D^n]$. Let $\tau'_{n+1} = \tau_{n+1} \diamond T(n+1)$. Let $\tau''_{n+1} =$ the *shortest* $\subseteq \tau'_{n+1}$ such that $[\tau''_{n+1} \supseteq \tau''_n \ \wedge \ \text{card}(\mathbf{F}[\tau''_{n+1}, \tau'_{n+1}]) \leq b]$. Let $D^{n+1} = \mathbf{F}[\tau''_{n+1}, \tau'_{n+1}]$. Let $T' = \bigcup_{n \in \mathbf{N}} \tau'_n$. Clearly, T' is a recursive text for L and $T' = \bigcup_{n \in \mathbf{N}} \tau_n$ too, with $\tau_0 \subset \tau_1 \subset \tau_2 \subset \cdots$. By the choice of τ_n's, for each $n \in \mathbf{N}$, $\mathbf{F}(\tau_{n+1}) \notin D^n$. Therefore, $\mathbf{F}(T')\Downarrow$ to a set of cardinality $\leq b$, a contradiction to the hypothesis on L. □

5. Insensitive or restricted learning functions. It is interesting to ask whether or not child language learning exhibits sensitivity to *the order or the timing of presentation of data*. We consider herein some mathematical versions of this question. Several mathematical definitions have been given for various different notions of insensitivity to order, essentially for the case of $\mathbf{TxtFex}^0_1$-identification [3, 93, 90, 38, 70, 39].

We extend these definitions of insensitive or restricted learning functions naturally to the context of the vacillatory learning criteria of the present paper,[17] and we investigate the interesting mathematical questions of whether learning functions with these insensitivities or restrictions thereby lose learning power. Answering many of these questions for the vacillatory criteria is much more difficult than for the $\mathbf{TxtFex}^0_1$ case.[18]

As noted above, we also apply some of our results in this section to help us prove results in this and other papers.

DEFINITION 5.1 (Wexler [93, 70]). $\mathbf{F}$ *is called* set-driven $\Leftrightarrow (\forall \sigma, \tau \mid \text{content}(\sigma) = \text{content}(\tau))[\mathbf{F}(\sigma) = \mathbf{F}(\tau)]$.

Reference [93] essentially notes that *set-driven* learning functions are insensitive to *time* (unlike text learnability). The next defined restriction in effect provides some degree of sensitivity to timing.

DEFINITION 5.2 (Schäfer [90, 70], Fulk [38, 39]). $\mathbf{F}$ *is called* partly set-driven (*synonym* [38, 39]: rearrangement independent) $\Leftrightarrow (\forall \sigma, \tau \mid \|\sigma\| = \|\tau\| \ \wedge \ \text{content}(\sigma) = \text{content}(\tau))[\mathbf{F}(\sigma) = \mathbf{F}(\tau)]$.

Intuitively, $\mathbf{F}$ is set-driven (respectively, partly set-driven) iff, for each σ, $\mathbf{F}(\sigma)$ depends only on the *content* of σ (respectively, depends only on the *length and content* of σ).

First Schäfer [90, 70] and later Fulk [38, 39] independently showed that set-driven learning functions can't $\mathbf{TxtFex}^0_1$-identify some classes of languages that unrestricted learning functions can, but partly set-driven learning functions do not restrict learning power with respect to $\mathbf{TxtFex}^0_1$-identification. Fulk additionally showed that set-driven learning functions can't even $\mathbf{TxtBc}^0$-identify some language classes in $\mathbf{TxtFex}^0_1$. He interprets the difference in power between set-driven and partly set-driven learning functions as witnessing the need for time greater than the size of the content of the input to "think" about the input.

Osherson, Stob, and Weinstein [70] observed that the power of $\mathbf{TxtFex}^0_1$-identification on *infinite* r.e. languages is not limited by set-driveness.

[17] For the so-called order independence notions (Definition 5.4), in the interest of conceptual parsimony, but without loss of generality in theorems, we render them purely syntactically rather than as a mixture of syntactical and semantical (as their precursor notions are in the prior literature). The precursor notions required the final programs/grammars also to be correct, a *semantic* constraint which we eliminate from the definitions.

[18] In many cases it is especially difficult to prove that the *simultaneous* presence of several insensitivities leads to *no* loss of learning power. We had several painful experiences, for example, with subtly incorrect, alternative constructions to the one in the proof of Theorem 5.5.

The following definition presents a convenient term paralleling that from Definition 4.8.

DEFINITION 5.3. *A text T* stabilizes $\mathbf{F} \Leftrightarrow \mathbf{F}(T)\Downarrow$.

While identification of a language L requires identification for *each* order of presentation of (text for) L, the *final* (correct) grammar(s) converged to may be different for different texts. As noted in [70], this would seem to be a source of strength, since for a learning machine's forcing the final grammars to be the same for each text might involve its (algorithmically) recognizing *grammar equivalence*, i.e., recognizing $\{\langle x, y\rangle \mid W_x = W_y\}$, but as is well known [82], this set is *not* algorithmically recognizable (r.e.) (nor is its complement).[19]

Order independent machines are insensitive to which text is used for L in that their final grammars depend only on L, not on the order of presentation. Their grammars along the way can, of course, depend on the text.

If, for some $n > 0$ and for some a, humans $\mathbf{TxtFex}^a_{n+1}$-identify a language L but do not $\mathbf{TxtFex}^a_n$-identify it, it is interesting whether, nonetheless, *some* environments and corresponding texts for L cause them to output fewer final conjectures than $n + 1$. There is a corresponding and ostensibly weaker notion of order independence in which, for each text, the set of final grammars converged to is always *contained in* (but not necessarily equal to) some *finite* set of final grammars.

These order independence notions clearly capture a very different kind of insensitivity to order of data presentation than the set-driven notions above.[20] The formal definition for our order independence notions immediately follows.

DEFINITION 5.4.

1. *We call a learning function*, $\mathbf{F}$, b-ary order independent $\Leftrightarrow$ ($\forall$ L *r.e.* | some *text for* L *stabilizes* $\mathbf{F}$)($\exists D$ *of cardinality* $\leq b$)($\forall$ *texts* T *for* L)[$\mathbf{F}(T)\Downarrow = D$].
2. *We call a learning function*, $\mathbf{F}$, weakly b-ary order independent $\Leftrightarrow$ ($\forall$ L *r.e.* | some *text for* L *stabilizes* $\mathbf{F}$)($\exists D$ *of cardinality* $\leq b$)($\forall$ *texts* T *for* L)[$\mathbf{F}(T)\Downarrow \subseteq D$].

Osherson, Stob, and Weinstein [70], adapting a related result of L. Blum and M. Blum [3], essentially show that order independent learning functions can $\mathbf{TxtFex}^0_1$-identify the same classes of languages that unrestricted learning functions can.

The first theorem of the present section (Theorem 5.5 below) implies that learning power (with respect to $\mathbf{TxtFex}^a_b$-identification) is not decreased by restricting learning functions to be *simultaneously* partly set-driven and weakly b-ary order independent. Furthermore, it implies that one can also simultaneously circumvent the restriction to recursive texts. It generalizes parts of Fulk's kitchen sink theorem [39, Theorem 13, p. 6] and [38, Chapter 5, Theorem 21], which covered the $\mathbf{TxtFex}^0_1$ case only; however, the lift to Theorem 5.5 ostensibly requires a much more difficult proof.[21]

For nontrivially vacillatory criteria, it is open whether (full) order independence can be combined with partly set-driven without loss of learning power.

Theorem 5.5's proof is the most difficult of the present paper. Fortunately, the other proofs of theorems in this section are modifications and/or simplifications of the proof of Theorem 5.5.

---

[19] In fact, more importantly, since this set is Π^0_2-complete [82], it is not even algorithmically recognizable by a limiting [88] or mind-changing procedure (but its complement is).

[20] One can think of them as *global* and the set-driven notions as *local*.

[21] In the present paper we do not consider the restriction to so-called *prudence* [70], a primary concern of [39]. *Prudent learning functions* are those which never conjecture a grammar p without being able to learn W_p. On that subject the interested reader may also wish to consult [51, 55].

THEOREM 5.5. *There is an algorithm for transforming any b and (an algorithm for) a learning function $\mathbf{F}$ into a corresponding (algorithm for a) learning function $\mathbf{F}'$ such that*

1. *$\mathbf{F}'$ is both partly set-driven and weakly b-ary order independent, and*
2. *$(\forall$ r.e. $L)[\mathbf{F}$ $\mathbf{RecTxtFex}_b^a$-identifies $L \Rightarrow \mathbf{F}'$ $\mathbf{TxtFex}_b^a$-identifies $L]$.*

Proof. Suppose that pad is a one-to-one computable function such that $(\forall n, p)$ $[W_{\mathrm{pad}(p,n)} = W_p]$ [65, 83]. Intuitively, $\mathrm{pad}(p,0), \mathrm{pad}(p,1), \mathrm{pad}(p,2), \ldots$ are just padded variants of program p which have the same recognizing behavior as p but which differ from one another syntactically.

Suppose $\mathbf{F}$ and b are given. Define $\mathbf{F}'$ on τ thus. Set $n = \|\tau\|$ and $A = \mathrm{content}(\tau)$.

$(*$ In the definition of $\mathbf{F}'(\tau)$ the only dependence on τ will be on n and A to make sure $\mathbf{F}'$ is partly set-driven. $*)$

Search for the *least* $\langle D^1, \sigma^1 \rangle$ such that[22]

1. $\mathrm{card}(D^1) \leq b$,
2. $\mathrm{content}(\sigma^1) \subseteq A$, and
3. $(\forall \sigma' \supseteq \sigma^1 \mid \sigma' \leq n \ \wedge \ \mathrm{content}(\sigma') \subseteq A)[\mathbf{F}[\sigma^1, \sigma'] \subseteq D^1]$.[23]

$(*$ Clearly, such a $\langle D^1, \sigma^1 \rangle$ will always exist since σ^1 may be chosen big enough not to be contained in any $\sigma' \leq n$. $*)$

$(*$ Suppose τ in L. Clause 3 provides a bounded (by n) approximation to

$$(\forall \sigma' \supseteq \sigma^1 \mid \mathrm{content}(\sigma') \subseteq L)[\mathbf{F}[\sigma^1, \sigma'] \subseteq D^1]. \tag{5.1}$$

(5.1) is a useful stability condition. $*)$

Once $\langle D^1, \sigma^1 \rangle$ is found:

set $i = 1$;
while $[\mathrm{card}(D^i) > 1 \ \wedge$ a *least* $\langle D', \sigma' \rangle \leq n$ is found such that $D' \subset D^1 \ \wedge \ \sigma' \supset \sigma^i \ \wedge \ \mathrm{content}(\sigma') \subseteq A \ \wedge \ (\forall \sigma'' \supseteq \sigma' \mid \sigma'' \leq n \ \wedge \ \mathrm{content}(\sigma'') \subseteq A)[\mathbf{F}[\sigma', \sigma''] \subseteq D']]$[24]
do $(*$ Pump down from D^i and ratchet up from σ^i, preserving apparent stability. $*)$
increment i by 1;
set $\langle D^i, \sigma^i \rangle = \langle D', \sigma' \rangle$
endwhile;
set $\mathbf{F}'(\tau) = \mathrm{pad}(\mathbf{F}(\sigma^i), \langle D^1, \sigma^1 \rangle)$.

Clearly, by construction, $\mathbf{F}'$ is partly set-driven.

Intuitive discussion. Something like the while loop in (the algorithm for) $\mathbf{F}'$ is essential. It is crucial for establishing Claim 3 below. If stopping with a search for $\langle D^1, \sigma^1 \rangle$ sufficed, Theorem 3.3 above could not hold. Nothing like this while loop is needed to handle the cases of $\mathbf{TxtFex}_1^a$. The use of pad is a variant of its use in [38, 39] and serves below in the proof of $\mathbf{F}'$'s weak b-ary order independence in a combinatorially similar role.[25]

---

[22] It is useful to recall here that, from section 2, $\langle \cdot, \cdot \rangle$ is a numerical pairing function *and* that we identify finite sets and initial segments of texts with their corresponding canonical indices (numbers). The word *least*, then, refers to least *numerical* value.

[23] Again, it is useful to recall that, from section 2, we identify finite initial segments of texts with their corresponding canonical indices (numbers). Hence, in the inequality, "$\sigma' \leq n$," we are treating σ as its numerical canonical index.

[24] N.B.: It is useful to recall here that, from section 2 above, "$\subset$" denotes "is a *proper* subset of," and "$\supset$" denotes "is a *proper* superset of."

[25] Intuitively, it *helps* make weak b-ary order independence true by *preventing*, for many r.e. languages L, the presence of some text for L that stabilizes $\mathbf{F}'$.

Here's an intuitive way to think about this construction. Imagine a chimpanzee given an infinite collection of different kinds of sticks, some of which can be joined together to make longer sticks. Each stick points overhead in a particular direction with respect to the vertical. Above the chimp, but out of its sight, is a bunch of bananas it would like to knock down with a suitably large joined-together stick pointing in just the right direction to hit the bananas. However, it can't tell when it has actually reached the bunch of bananas even though it does reach them (so the poor thing never knows when it has succeeded and it never actually gets to eat the bananas). All it can tell is that some time after any choice of a (leaning) tower of sticks is not pointing quite right, one of the sticks will explode, knocking down all of the sticks above it, and it has to try again. The exploding sticks are quite like the injuries in a recursion-theoretic priority argument [88].

The sticks correspond to the σ's, and one should think of them as initial segments of branches in an infinite-branching, upward-pointing tree similar to the finite-branching (rightward pointing) tree in [82, p. 157]. For each input τ to $\mathbf{F}'$, when the while loop finishes, it provides some sequence of successively longer joined together sticks $\sigma^1 \subset \cdots \subset \sigma^m$, with m the final value of i. A larger input to $\mathbf{F}'$, $\tau' \supset \tau$, may result in a different sequence of sticks, $\sigma_1 \subset \cdots \subset \sigma_{m'}$, from the while loop. The stick that exploded is the σ^i with least i such that $\sigma^i \neq \sigma_i$. "Success" for the chimpanzee is described by Claim 1 below. We continue this discussion after the statement of that claim.

CLAIM 1. *If L recursively b-stabilizes $\mathbf{F}$, then, for each text T for L, there is a* maximum *$j \geq 1$ such that the algorithm for $\mathbf{F}'$ above on T* eventually *has stable values for $\langle D^1, \sigma^1\rangle, \ldots, \langle D^j, \sigma^j\rangle$, i.e., values that are the same for (the algorithm for) $\mathbf{F}'$'s calculation of $\mathbf{F}'(\tau)$ for all but finitely many $\tau \subset T$. This j will also be $\leq b$. Furthermore, if there is such a maximum j for* some *text for L, values of this maximum j and associated stable values of $\langle D^1, \sigma^1\rangle, \ldots, \langle D^j, \sigma^j\rangle$ will be* independent *of the choice of text for L.*

Continued discussion. If L recursively b-stabilizes $\mathbf{F}$ and T is a text for L, then this claim does *not* imply that, for all but finitely many $\tau \subset T$, the while loop on input τ stops with the same $\langle D^1, \sigma^1\rangle, \ldots, \langle D^j, \sigma^j\rangle$—only that the while loop stops with $\langle D^1, \sigma^1\rangle, \ldots, \langle D^i, \sigma^i\rangle$, for some $i \geq j$. Success for the chimpanzee discussed above is the stabilization on $\sigma^1 \subset \cdots \subset \sigma^j$, but even after this stability is reached, any sticks returned by the while loop, σ^i, for $i > j$, will "explode" on some longer input to $\mathbf{F}'$.

Suppose L recursively b-stabilizes $\mathbf{F}$ and T is a text for L. Suppose j is as in the previous paragraph. As $\mathbf{F}$ is being fed successively longer initial segments of T, eventually σ^j is reached. We also like to think about the changing σ^i's subsequently found, where $i > j$, as a *flickering flame* above σ^j. Stability implies that, for infinitely many $\tau \subset T$, the flame *may* die down to exactly the level of σ^j itself; however, for all but finitely many $\tau \subset T$, it does not dip below or destroy σ^j.

Proof of Claim 1. Suppose that L recursively b-stabilizes $\mathbf{F}$. Then by Lemma 4.9,

$$(5.2) \qquad (\exists D \mid \operatorname{card}(D) \leq b)(\exists \sigma \supseteq \emptyset \mid \sigma \text{ in } L)(\forall \sigma' \supseteq \sigma \mid \sigma' \text{ in } L)[\mathbf{F}(\sigma') \in D].$$

(The algorithm for) $\mathbf{F}'$ on texts for L will eventually stabilize in its choice of $\langle D^1, \sigma^1\rangle$ to be the *same for each T' for L:* it will stabilize its choice of $\langle D^1, \sigma^1\rangle$ to be the least $\langle D, \sigma\rangle$ satisfying (5.2). This is since, for all but finitely many $\tau \subset T$, $\|\tau\|$ and content(τ) will be big enough to find counterexamples to all the *finitely* many $\langle D', \sigma'\rangle <$ this least $\langle D, \sigma\rangle$ satisfying (5.2). Of course, once a $\langle D', \sigma'\rangle$ is rejected for

being $\langle D^1, \sigma^1\rangle$, it's not picked up again by (the algorithm for) $\mathbf{F}'$ on bigger input since counterexamples don't go away for bigger input. Once the choice of $\langle D^1, \sigma^1\rangle$ has stabilized on a T for L, say, on all sufficiently large $\tau \subset T$; on such suitably large τ, the while loop eventually terminates with a final value for i, say i_τ, which is $\leq b$ since $\mathrm{card}(D^1) \leq b$, and the while loop looks for *proper* subsets of the D^i's. Clearly, as above, on suitably large $\tau \subset T$, there is a maximum $i \leq$ the while loop's i_τ's with $\langle D^1, \sigma^1\rangle, \ldots, \langle D^i, \sigma^i\rangle$ eventually stable, and, also clearly, this maximum i is independent of texts for L. □

CLAIM 2. $\mathbf{F}'$ *is weakly b-ary order independent.*

Proof of Claim 2. Suppose that T for L stabilizes $\mathbf{F}'$. We need to show, then, that $(\exists D \text{ of cardinality} \leq b)[\bigcup_{T' \text{ for } L} \mathbf{F}'(T')\Downarrow \subseteq D]$. Once (the algorithm for) $\mathbf{F}'$ on (successively longer $\tau \subset$) T rejects a candidate for $\langle D^1, \sigma^1\rangle$, it cannot rechoose that candidate later since counterexamples to the stability demanded of $\langle D^1, \sigma^1\rangle$ do not go away. $\mathbf{F}'$ on T outputs programs of the form $\mathrm{pad}(\mathbf{F}(\sigma^i), \langle D^1, \sigma^1\rangle)$, where $\langle D^1, \sigma^1\rangle$ is a candidate for stability at the first level, so to speak. Since, by assumption just above, T *does* stabilize $\mathbf{F}'$ for some *finite* D, $\mathbf{F}'(T)\Downarrow = D$, and then, since pad is one-to-one, the $\langle D^1, \sigma^1\rangle$ argument to it cannot take on infinitely many values as $\mathbf{F}'$ is fed T. Since $\mathbf{F}'$ can't jump back to rejected previous choices of $\langle D^1, \sigma^1\rangle$, (the algorithm for) $\mathbf{F}'$ on T eventually finds a stable value for $\langle D^1, \sigma^1\rangle$. Hence, by a simple restatement of the proof of Claim 1 above, there is a maximum i such that (the algorithm for) $\mathbf{F}'$ on T eventually has stable values for $\langle D^1, \sigma^1\rangle, \ldots, \langle D^i, \sigma^i\rangle$, and the value of i is independent of texts for L. Let imax denote this maximum i. Hence, $(\forall \tau \supseteq \sigma^{\mathrm{imax}} \mid \tau \text{ in } L)[\mathbf{F}(\tau) \in D^{\mathrm{imax}}]$. Therefore,

$$\bigcup_{T' \text{ for } L} \mathbf{F}'(T')\Downarrow \subseteq \mathrm{pad}(D^{\mathrm{imax}}, \langle D^1, \sigma^1\rangle). \tag{5.3}$$

This latter set of programs has cardinality $\leq b$ since D^{imax} does. Therefore, $\mathbf{F}'$ is weakly b-ary order independent. □

N.B.: There is no guarantee that (5.3) is an equality since we may have that, on some T for L, for all but finitely many $\tau \subset T$, and for the corresponding σ^{i_τ}'s from the while loop, the programs $\mathrm{pad}(\mathbf{F}(\sigma^{i_\tau}), \langle D^1, \sigma^1\rangle)$ miss some values in $\mathrm{pad}(D^{\mathrm{imax}}, \langle D^1, \sigma^1\rangle)$.

CLAIM 3. *Suppose L recursively b-stabilizes* $\mathbf{F}$. *Let* imax *be the maximum i from Claim* 1 *(independent of the choice of text for L). Let*

$$D^{Rec} = \bigcup_{\substack{\text{recursive } T \text{ for } L \\ T \supset \sigma^{\mathrm{imax}}}} \mathbf{F}(T).$$

Equivalently,

$$D^{Rec} = \{\, \mathbf{F}(\tau) \mid \tau \text{ in } L \wedge \tau \supseteq \sigma^{\mathrm{imax}} \wedge (\exists \text{ recursive } T \text{ for } L)(\exists^\infty \tau' \subset T)[\mathbf{F}(\tau') = \mathbf{F}(\tau)]\}. \tag{5.4}$$

Then $D^{Rec} = D^{\mathrm{imax}}$.

Proof of Claim 3. Suppose the hypotheses. Clearly, $D^{\mathrm{Rec}} \subseteq D^{\mathrm{imax}}$. It remains to show $D^{\mathrm{imax}} \subseteq D^{\mathrm{Rec}}$. In that interest, suppose $p \in D^{\mathrm{imax}}$. We will show $p \in D^{\mathrm{Rec}}$. By the maximality of imax,

$$\neg(\exists \sigma' \supseteq \sigma^{\mathrm{imax}} \mid \sigma' \text{ in } L)(\forall \sigma'' \supseteq \sigma' \mid \sigma'' \text{ in } L)[\mathbf{F}[\sigma', \sigma''] \subseteq D^{\mathrm{imax}} - \{\, p \,\}].$$

Hence,

$$(\forall \sigma' \supseteq \sigma^{\text{imax}} \mid \sigma' \text{ in } L)(\exists \sigma'' \supseteq \sigma' \mid \sigma'' \text{ in } L)[\mathbf{F}(\sigma'') = p]. \tag{5.5}$$

Let T be a fixed recursive text for L. We recursively define another recursive text T' for L as follows. Let $\tau_0 = \sigma^{\text{imax}}$ and $\tau_0' = \tau_0 \diamond T(0)$. Suppose (recursively) that τ_n and $\tau_n' \supset \sigma^{\text{imax}}$ are defined and in L. By (5.5) we may algorithmically find a $\tau_{n+1} \supseteq \tau_n'$ such that $[\tau_{n+1} \text{ in } L \wedge \mathbf{F}(\tau_{n+1}) = p]$. Let $\tau_{n+1}' = \tau_{n+1} \diamond T(n+1)$. Let $T' = \bigcup_{n \in \mathbf{N}} \tau_n'$. Clearly, T' is a recursive text for L and $T' = \bigcup_{n \in \mathbf{N}} \tau_n$ too, with $\tau_0 \subset \tau_1 \subset \tau_2 \subset \cdots$. By the choice of τ_n's for each $n \in \mathbf{N}$, $\mathbf{F}(\tau_{n+1}) = p$. Hence, T' is a recursive text for L such that $[T' \supset \sigma^{\text{imax}} \wedge \mathbf{F} \text{ on } T' \text{ outputs } p \text{ infinitely often}]$. Therefore, by (5.4), $p \in D^{\text{Rec}}$. □

CLAIM 4. $(\forall$ *r.e.* $L)[\mathbf{F}$ **RecTxtFex**^a_b*-identifies* $L \Rightarrow \mathbf{F}'$ **TxtFex**^a_b*-identifies* $L]$.

Proof of Claim 4. Suppose that L is r.e. and $\mathbf{F}$ **RecTxtFex**^a_b-identifies L. It remains to be shown $\mathbf{F}'$ **TxtFex**^a_b-identifies L. Clearly, L recursively b-stabilizes $\mathbf{F}$. Therefore, by Claim 1, a maximum imax exists with eventually stable values for $\langle D^1, \sigma^1 \rangle, \ldots, \langle D^{\text{imax}}, \sigma^{\text{imax}} \rangle$ independent of texts for L in the operation of (the algorithm for) $\mathbf{F}'$. Clearly, $(\forall p \in D^{\text{Rec}})[W_p =^a L]$. By Claim 3, $D^{\text{Rec}} = D^{\text{imax}}$, so we have $(\forall p \in D^{\text{imax}})[W_p =^a L]$. Hence, $(\forall p \in \text{pad}(D^{\text{imax}}, \langle D^1, \sigma^1 \rangle))[W_p =^a L]$. Therefore, by (5.3), $\mathbf{F}'$ **TxtFex**^a_b-identifies L. □

This ends the proof of Theorem 5.5. □

The next theorem (Theorem 5.6) implies that learning power for *infinite* r.e. languages (with respect to **TxtFex**^a_b-identification) is not decreased by restricting learning functions to be *simultaneously* (completely) set-driven and weakly b-ary order independent. Furthermore, it implies that one can also simultaneously circumvent the restriction to recursive texts.

THEOREM 5.6. *There is an algorithm for transforming any* b *and (an algorithm for) a learning function* $\mathbf{F}$ *into a corresponding (algorithm for a) learning function* $\mathbf{F}'$ *such that*

1. $\mathbf{F}'$ *is both set-driven and weakly* b*-ary order independent, and*
2. $(\forall \infty$ *r.e.* $L)[\mathbf{F}$ **RecTxtFex**^a_b*-identifies* $L \Rightarrow \mathbf{F}'$ **TxtFex**^a_b*-identifies* $L]$.

Proof. Modify (the algorithm for) $\mathbf{F}'$ in the proof above of Theorem 5.5 by setting $n = \text{card}(\text{content}(\tau))$ (instead of setting $n = \|\tau\|$). Since for *infinite* L this n grows, one can apply the rest of the proof of Theorem 5.5 *mutatis mutandis*.[26] □

Royer and Kurtz suggested to us that the use of set-driven learning functions could simplify the proof of at least a special case of Theorem 3.3 and Jun Tarui pointed out to us that weak b-ary order independence would further simplify proving Theorem 3.3. The proof herein of Theorem 3.3 makes use of Theorem 5.6.

We believe it is not possible to replace weak b-ary order independence with b-ary order independence in Theorems 5.5 and 5.6, contrary to our slightly overzealous claims in [16]. However, we have the following result (Theorem 5.7) with Fulk (who is not responsible for the possibly incorrect claims in [16]). Theorem 5.7 implies that learning power (with respect to **TxtFex**^a_b-identification) is not decreased by simultaneously restricting learning functions to be (fully) b-ary order independent and circumventing the restriction to recursive texts. It also implies that one can also simultaneously have a technical property we call *determination by single text* (part 2 of the theorem).

This theorem has application in [23], and the (full) b-ary order independence is important for that application.

[26] With appropriate (and straightforward) changes being made.

THEOREM 5.7 (Case and Fulk). *There is an algorithm for transforming any b and (an algorithm for) learning function $\mathbf{F}$ into a corresponding (algorithm for a) learning function $\mathbf{F}'$ such that*

1. *$\mathbf{F}'$ is b-ary order independent,*
2. *$(\forall$ r.e. $L)[\mathbf{F}'$ $\mathbf{TxtFex}_b^a$-identifies L on* some *text for $L \Rightarrow$ $\mathbf{F}'$ $\mathbf{TxtFex}_b^a$-identifies $L]$, and*
3. *$(\forall$ r.e. $L)[\mathbf{F}$ $\mathbf{RecTxtFex}_b^a$-identifies $L \Rightarrow$ $\mathbf{F}'$ $\mathbf{TxtFex}_b^a$-identifies $L]$.*

Proof. Suppose that $\mathbf{F}$ and b are given. The algorithm for $\mathbf{F}'$ is much like that in the proof of Theorem 5.5 above, with some exceptions as noted below. τ^- is as defined in (3.1). In defining $\mathbf{F}'$ on τ, we assume we have iteratively (on successively larger $\tau' \subset \tau$) kept a priority queue of programs/grammars, which queue is initially empty. Proceed initially as in the algorithm in the proof of Theorem 5.5 above, but if the value of $\langle D^1, \sigma^1\rangle$ associated with τ is $\neq$ the value of $\langle D^1, \sigma^1\rangle$ associated with τ^-, empty the priority queue, and output $\|\tau\|$; otherwise, continue down through the end of the while loop and then let

$$\sigma = \sigma^{i_\tau}, \tag{5.6}$$

where, as in the proof of Theorem 5.5, i_τ is the final value of i from the while loop for input τ. Next, in increasing order of σ' such that σ' in A, $\sigma' \leq n$, and $\sigma' \supseteq \sigma$ (σ from (5.6)), put $\mathbf{F}(\sigma')$ on the *tail* of the priority queue; when that is all done, output the *front* of the priority queue.

The outputting of $\|\tau\|$ upon witnessing an instability in the choice of $\langle D^1, \sigma^1\rangle$ is essentially a combinatorial device from [3], and it plays the role that pad did in the proof of Theorem 5.5 above, similarly controlling thrashing in the choice of $\langle D^1, \sigma^1\rangle$ when some T for L stabilizes $\mathbf{F}'$. This makes $\mathbf{F}'$ weakly b-ary order independent. Clearly, if some text for L stabilizes $\mathbf{F}'$, by the priority queue mechanism, for any T for L, $\mathbf{F}'(T)\Downarrow = D^{\text{imax}}$, where D^{imax} is from the proof of Theorem 5.5. Hence, $\mathbf{F}'$ is b-ary order independent. Clause 2 of Theorem 5.7 clearly follows. To prove clause 3 of Theorem 5.7, one can apply appropriate portions of the proof of Theorem 5.5 *mutatis mutandis*. ∎

We do not know if there are analogues of Theorems 5.5 and 5.6 above for $\mathbf{TxtMfex}_b^a$-identification. The use of pad in the proofs of those theorems wreaks havoc with program/grammar size. However, we do have the next three theorems, the first of which has application in [23].

These theorems say that we can have, for $\mathbf{TxtMfex}_b^a$-identification, without loss of learning power, either

1. b-ary order independence, determination by single text, and circumvention of the restriction to recursive texts (Theorem 5.8);
2. partly set-driven learning functions and circumvention of the restriction to recursive texts (Theorem 5.9); *or*
3. (completely) set-driven learning functions and circumvention of the restriction to recursive texts (Theorem 5.10), *but this latter conjunction is guaranteed for infinite languages only.*

THEOREM 5.8 (Case and Jain). *There is an algorithm for transforming any b and (an algorithm for) a learning function $\mathbf{F}$ into a corresponding (algorithm for a) learning function $\mathbf{F}'$ such that*

1. *$\mathbf{F}'$ is b-ary order independent,*
2. *$(\forall$ r.e. $L)[\mathbf{F}'$ $\mathbf{TxtMfex}_b^a$-identifies L on* some *text for $L \Rightarrow$ $\mathbf{F}'$ $\mathbf{TxtMfex}_b^a$-identifies $L]$, and*

3. $(\forall$ *r.e.* $L)[\mathbf{F}$ $\mathbf{RecTxtMfex}^a_b$*-identifies* $L \Rightarrow \mathbf{F}'$ $\mathbf{TxtMfex}^a_b$*-identifies* $L]$.

Proof. The proof of Theorem 5.7 suffices *mutatis mutandis*. □

The next theorem was independently noticed by Jain.

THEOREM 5.9 (Case and Jain). *There is an algorithm for transforming any* b *and* (*an algorithm for*) *a learning function* $\mathbf{F}$ *into a corresponding* (*algorithm for* a) *learning function* $\mathbf{F}'$ *such that*

1. $\mathbf{F}'$ *is partly set-driven, and*

2. $(\forall$ *r.e.* $L)[\mathbf{F}$ $\mathbf{RecTxtMfex}^a_b$*-identifies* $L \Rightarrow \mathbf{F}'$ $\mathbf{TxtMfex}^a_b$*-identifies* $L]$.

Proof. The proof of Theorem 5.5 above with the elimination of any mention of pad and weak b-ary order independence, *mutatis mutandis*, suffices to prove the present theorem. □

Similarly, the proof of Theorem 5.6 above may be modified along the lines suggested in the proof of Theorem 5.9 to prove the following theorem.

THEOREM 5.10. *There is an algorithm for transforming any* b *and* (*an algorithm for*) *a learning function* $\mathbf{F}$ *into a corresponding* (*algorithm for* a) *learning function* $\mathbf{F}'$ *such that*

1. $\mathbf{F}'$ *is set-driven, and*

2. $(\forall \infty$ *r.e.* $L)[\mathbf{F}$ $\mathbf{RecTxtMfex}^a_b$*-identifies* $L \Rightarrow \mathbf{F}'$ $\mathbf{TxtMfex}^a_b$*-identifies* $L]$.

We expect that the theorems of this section will be generally useful for work in the area.

6. Proofs deferred from section 3. In section 3 we deferred proofs of three results until we had the benefit of some of the concepts and/or results from sections 4 and 5. The present section contains those deferred proofs and, for convenience, we restate each result being proved.

Clearly, the second conclusion of Theorem 5.5 and the third conclusion of Theorem 5.8 yield the following corollary.

COROLLARY 6.1.

1. $(\forall a, b)[\mathbf{RecTxtFex}^a_b = \mathbf{TxtFex}^a_b]$.

2. $(\forall a, b)[\mathbf{RecTxtMfex}^a_b = \mathbf{TxtMfex}^a_b]$.

As we noted in section 3, the proof of the next theorem depends, in part, on Definitions 5.1 and 5.4 and Theorem 5.6.

THEOREM 6.2. *Let* $\mathcal{L}_{n+1}$ *equal*

$$\{\, L \mid L \text{ is } \infty \wedge (\exists e_0, \ldots, e_n)[W_{e_0} = \cdots = W_{e_n} = L \wedge (\forall^\infty \langle x, y\rangle \in L)[y \in \{\, e_0, \ldots, e_n \,\}]] \,\}.$$

Then $\mathcal{L}_{n+1} \in (\mathbf{TxtFex}^0_{n+1} - \mathbf{TxtFex}^*_n)$.

Proof. Clearly, $\mathcal{L}_{n+1} \in \mathbf{TxtFex}^0_{n+1}$.[27]

Suppose for contradiction that $\mathbf{F}$ $\mathbf{TxtFex}^*_n$-identifies $\mathcal{L}_{n+1}$. Each member of $\mathcal{L}_{n+1}$ is infinite; hence, thanks to Theorem 5.6, we may suppose, without loss of generality, that $\mathbf{F}$ is set-driven *and* weakly n-ary order independent. Therefore, in particular, we may write $\mathbf{F}(D)$ for $\mathbf{F}(\sigma)$, where $D = \text{content}(\sigma)$. By implicit application of a padded version of the $n+1$-ary recursion theorem there are *distinct* self-other referentials $e_0, e_1, \ldots, e_n$ defining $W_{e_0}, W_{e_1}, \ldots, W_{e_n}$, respectively, in successive stages s as follows.[28]

For each $i \leq n$, let $W_{e_i,s}$ = the finitely much of W_{e_i} defined *before* stage s described below; also set $W_{e_i,0} = \emptyset$. Go to stage 0.

[27] The role of self-reference in this proof is, in part, to make this positive portion of the theorem immediate while scarcely affecting the difficulty of the negative portion.

[28] The padding is just to make $e_0, e_1, \ldots, e_n$ syntactically pairwise distinct. It should be clear in the staging construction how each e_i significantly uses its knowledge of $e_0, \ldots, e_i, \ldots, e_n$.

begin *stage s*
if $\text{card}(\{\, \mathbf{F}(W_{e_0,s}), \mathbf{F}(W_{e_1,s}), \ldots, \mathbf{F}(W_{e_n,s}) \,\}) \leq n$
then
for each $i \leq n$, set $W_{e_i,s+1} = W_{e_i,s} \cup \{\, \langle s, e_i \rangle \,\}$
else
for each $i \leq n$, set $W_{e_i,s+1} = [[\bigcup_{j \leq n} W_{e_j,s}] \cup \{\, \langle s, e_0 \rangle \,\}]$
endif;
go to stage $s+1$
end ($*$ *stage* s $*$).

Case 1. $(\forall^\infty s)[\text{card}(\{\, \mathbf{F}(W_{e_0,s}), \mathbf{F}(W_{e_1,s}), \ldots, \mathbf{F}(W_{e_n,s}) \,\}) \leq n]$. Then each of W_{e_0}, $W_{e_1}, \ldots, W_{e_n} \in \mathcal{L}_{n+1}$, yet they are pairwise $\neq^*$. Hence, since this is Case 1, at each sufficiently large stage s, for at least one of the $(n+1)$ i's $\leq n$, program/grammar $\mathbf{F}(W_{e_i,s})$ fails to generate a finite variant of W_{e_i}. Therefore, for at least one $i \leq n$, $(\exists^\infty s)[W_{\mathbf{F}(W_{e_i,s})} \neq^* W_{e_i}]$. Hence, *this* W_{e_i} is *not* $\mathbf{TxtFex}^*_n$-identified by $\mathbf{F}$, a contradiction.

Case 2. $(\exists^\infty s)[\text{card}(\{\, \mathbf{F}(W_{e_0,s}), \mathbf{F}(W_{e_1,s}), \ldots, \mathbf{F}(W_{e_n,s}) \,\}) = n+1]$ (say, at stages $s_0 < s_1 < s_2 < \cdots$). Then $W_{e_0} = W_{e_1} = \cdots = W_{e_n} \in \mathcal{L}_{n+1}$. Let $\vec{W}_{e_i,s}$ be an increasing order enumeration of $W_{e_i,s}$. Hence, $\vec{W}_{e_i,s}$ is also a finite initial segment of a text. Let $T_i = \vec{W}_{e_i,s_0} \diamond \vec{W}_{e_i,s_1} \diamond \vec{W}_{e_i,s_2} \diamond \cdots$. Clearly T_i is a text for W_{e_i}, which equals W_{e_0}. Since $\mathbf{F}$ is weakly n-ary order independent, there is a set D of cardinality $\leq n$ such that

$$\bigcup_{i \leq n} \mathbf{F}(T_i)\Downarrow \subseteq D. \tag{6.1}$$

However, since this is Case 2 and by the choice of $s_0, s_1, s_2, \ldots$, the left-hand side of (6.1) has cardinality $> n$, a contradiction. □

As we noted in section 3 above, the proof of the next theorem depends on Theorem 4.4.

THEOREM 6.3. $\mathbf{TxtFex}^m_* \subseteq \mathbf{TxtBc}^{m'} \Leftrightarrow m \leq 2.m'$; *furthermore*, $\{\, L \mid L =^{2m+1} \mathbf{N} \,\} \in (\mathbf{TxtFex}^{2m+1}_1 - \mathbf{TxtBc}^m)$.

Proof. This proof employs previously unpublished techniques used to prove a similar result for $\mathbf{TxtFex}^a_1$ in [28].

Suppose that $\mathbf{F}$ $\mathbf{TxtFex}^{2m}_*$-identifies $\mathcal{L}$. We will construct an $\mathbf{F}'$ which $\mathbf{TxtBc}^m$-identifies $\mathcal{L}$, and then it will suffice to prove the *furthermore* clause.

Define $\mathbf{F}'$ on τ thus. First calculate $p = \mathbf{F}(\tau)$. By Kleene's S-m-n theorem [82], find p_τ such that $W_{p_\tau} = ((W_p \cup \text{content}(\tau)) -$ the m least numbers not in $\text{content}(\tau))$. Output p_τ.

Suppose that T is a text for $L \in \mathcal{L}$. Let $D = \mathbf{F}(T)\Downarrow$. Hence, $(\forall p \in D)[W_p =^{2m} L]$. For all sufficiently large $\tau \in T$, $p = \mathbf{F}(\tau) \in D$ and p_τ patches any mistakes of omission of p; furthermore, p_τ removes m elements, including up to m of the mistakes of commission of p (if any) and, perhaps in the process, it creates new mistakes of omission.

Case 1. The number of mistakes of commission in such a p is $\geq m$. Of course this number of mistakes is $\leq 2m$. Then p_τ removes m of these mistakes of commission leaving a residue of $\leq m$ errors.

Case 2. The number m' of mistakes of commission in such a p is $< m$. Then p_τ removes *all* these errors of commission, but creates $m - m'$ new errors (of omission); however, this number is still $\leq m$.

In each case, for such p, p_τ has $\leq m$ errors. Therefore, $\mathbf{F}'$ $\mathbf{TxtBc}^m$-identifies $L \in \mathcal{L}$.

Let $\mathcal{L} = \{ L \mid L =^{2m+1} \mathbf{N} \}$. Clearly, $\mathcal{L} \in \mathbf{TxtFex}_1^{2m+1}$. Suppose for contradiction that $\mathcal{L} \in \mathbf{TxtBc}^m$ as witnessed by learning function $\mathbf{F}$. Hence, in particular, $\mathbf{F}$ $\mathbf{TxtBc}^m$-identifies $\mathbf{N}$. Therefore, by Theorem 4.4,

(6.2) $(\exists D \text{ finite })(\forall L \mid D \subseteq L \ \wedge \ L \neq^{2m} \mathbf{N})[\mathbf{F} \text{ does not } \mathbf{TxtBc}^m\text{-identify } L]$.

Pick $L \supseteq D$ such that $\text{card}(\overline{L}) = 2m + 1$. Then $L \in \mathcal{L}$, but by (6.2), $\mathbf{F}$ does not $\mathbf{TxtBc}^m$-identify L, a contradiction. □

7. Concluding remarks. In this section we discuss briefly computable universe hypotheses, present some critical discussion about the applicability to human language learning of Gold-style models and our main theorem (Theorem 3.3 above), and sketch some areas for future investigation.

We have considered (among other possibilities) computable models of learning on computable data sequences. The whole universe or humanly significant portions of it may be computable and/or discrete. Such possibilities are taken seriously—for example, in [99, 92, 91, 34, 17, 15, 29]. In a discrete, *random* universe with only computable probability distributions for its behavior (e.g., a discrete, quantum mechanical universe), the *expected* behavior will still be computable [32, 42, 43].[29] In such a universe any beings (e.g., humans) who have cognition, including language learning and scientific induction, will be subject to the constraint that at least their expected behavior will be computable; hence, any theorems about computable learning agents will inform us, to some extent, of the possible behaviors of those beings. It would appear that human genetic programs make use of error correction in an attempt to circumvent "random" influences, including those from the quantum mechanical level. It is plausible that human cognitive programs built on top of the wetware the genetic programs partly construct do likewise. Hence, computability of cognition may be a pretty good model.

Even if cognition is computable (although perhaps too complicated for mere humans to figure out how it's done), there are still problems realistically modeling human language learning with Gold's paradigm. References [58, 59] present empirical evidence that semantics in addition to positive information may be essential to human language learning. It seems clear that denotation and social reinforcers play crucial roles in the human case, but not in Gold's paradigm. In [15] the report on Chapter 6 of [38] is partly motivated by treating negative information as a more mathematically tractable possible substitute for semantic information. Reference [61] notes that in homes where parents do supply improvements to child utterances (a subtle form of correction or negative information), there is increased *speed* of language acquisition. It is not clear if the relation is causal, but Theorem 22 in [5] implies there are cases where a significant improvement in language learning *speed* (as calibrated by the number of mind-changes required to reach a single final correct grammar) results from the presence of minimal negative information. Largely unexplored, but of some interest, is the extension of [5] to $\mathbf{TxtFex}_b^a$-identification.

We originally suggested in [16] on the basis of our main corollary (Corollary 3.7 to Theorem 3.3) that Gold's model be extended to embrace the success criteria $\mathbf{TxtFex}_b^a$

[29] Sources such as [73, 74], sadly, seem to have overlooked the important result in [32] that the expected input/output behavior of a Turing machine with random oracle subject to a computable probability distribution is computable (and constructively so).

for "small" values of a and b. We consider next a possible difficulty. In the proof of Theorem 3.3, for each $\mathbf{F}$, the associated set(s) $W_{e_0}, W_{e_1}, \ldots, W_{e_n}$ may, in some cases, differ considerably in computational complexity from one another, and Osherson pointed out to us that there is no apparent corresponding vacillation in human language performance. However, in the proof of Theorem 3.3, for each $\mathbf{F}$, the associated set(s) $W_{e_0}, W_{e_1}, \ldots, W_{e_n}$ are each actually recursive; hence, for each $\mathbf{F}$, there is a Blum complexity measure Φ [10, 48] such that $\Phi_{e_0} = \Phi_{e_1} = \cdots = \Phi_{e_n}$; therefore, if performance were measured by such a Φ, vacillatory learning would increase learning power but without a corresponding vacillation in performance. Technical questions remain open regarding which stronger quantificational variants of the argument in the previous sentence can be made. In another direction, we note that the proof of Theorem 3.3 permits a modification so that the relative density of output of all the final programs/grammars but one is as small as we like. Hence, the performance vacillation may exist, but significant degradations in articulateness potential might be confined to rare episodes. Even if such episodes do not exist for humans, they might be tolerated in an artificial system.

In spite of the limitations to date of modeling human language learning with (extensions of) Gold's paradigm, we believe that many of the theorems (e.g., Theorem 4.4) in this area nonetheless give some insights. The state of the art is weakly analogous to modeling the thermodynamics of fluids without taking into account van der Waal's forces: one may still get some understanding of the reality so modeled.

Speaking of Theorem 4.4, it would be mathematically interesting to explore what happens to the subset principle for **TxtBc**-identification restricted to *recursive* texts.

It is interesting to place further feasibility restrictions on the criteria of success. As noted in section 5 above, [23] studies $\mathbf{TxtMfex}^a_b$-identification, the restricted variant of $\mathbf{TxtFex}^a_b$-identification which requires that final programs/grammars be nearly minimal size. For language learning, bounding complexity of learning machines as in [33] or [24] remains to be explored. Translating relative solvability results into relative feasibility results, as in [97], would be very interesting to pursue in the context of the present paper. In section 5 there are several results about no loss of learning power in passing from some learning function $\mathbf{F}$ to an insensitive or restricted learning function $\mathbf{F}'$. How does the complexity of such $\mathbf{F}'$'s compare to that of $\mathbf{F}$? If the complexity of $\mathbf{F}'$ in some cases must be significantly greater than that of $\mathbf{F}$, then one could plausibly conjecture that child language learning is highly sensitive to the order of data presentation.

Can we get versions of our separation results robust in the sense of [40]?

Much of the work in Gold-style learning theory on success criteria extending Gold's is motivated by attempts to assuage the negative results in this area. Reference [53] mentions a common argument to the effect that very strong negative results about language learnability in [46] provide evidence that human language learning must involve some innately stored information! The negative results suggest, among other things, that

1. general purpose learning is not possible, and
2. alleged human general purpose learning is an illusion brought about by our having innate information stored for a large and varied collection of domains [41, 89].

In the practical context of robot planning, McDermott [60] says, "Learning makes the most sense when it is thought of as filling in the details in an algorithm that is

already nearly right." In the context of function learning, [27] provides several models of learning from examples *together with approximately correct programs*. Included are models in which the maximal probability of learning *all* the computable functions is proportional to how tightly the approximately correct programs envelope the data. Unexplored, but very interesting, is how to provide such models for language learning from positive data. Success might provide some insight into the form of innate knowledge for human language learning.

Acknowledgments. The author thanks the University of Rochester's Computer Science Department for support and for providing an excellent working environment in the academic year 1987–88, during which some of the work on the present paper was completed. The author is also grateful to the anonymous referees and others mentioned in the text for many helpful comments.

AN ASSOCIATIVE BLOCK DESIGN ABD(8,5)*

A. E. BROUWER†

To Maja, on the occasion of her seventeenth birthday.

Abstract. An associative block design is a certain balanced partition of a hypercube into smaller hypercubes. We construct such a design, thus settling the smallest open case.

AMS subject classification. 05B30

PII. S0097539797316622

An ABD(k,w) is a $b \times k$ matrix (where $b = 2^w$) with entries from $\{0,1,*\}$ such that (i) the stars form a 1-design: each row has $k-w$ stars and each column $b(k-w)/k$ stars, and (ii) the rows represent disjoint subsets of $\{0,1\}^k$. Here a row represents the set of binary vectors of length k obtained by replacing its stars in all possible ways by 0s and 1s.

This concept was introduced in 1974 by Rivest [4, 5, 6] in order to find a hash function with good worst-case behavior with respect to partial-match queries. For example, the eight rows

```
00*0   11*1
100*   011*
*100   *011
1*10   0*01
```

form an ABD$(4,3)$.

In order to save space, let us extend our alphabet with the minus sign, where a row containing r minus signs stands for the 2^r rows obtained by replacing these minus signs in all possible ways by 0s and 1s. Then the only other ABD$(4,3)$ is the following:

```
*000
*111
-*10
-0*1
-10*
```

The theory is as follows (see [1, 2, 3, 6]).

PROPOSITION 0.1. (i) ([6]) *An* ABD(k,w) *has exactly* $bw/(2k)$ 0*s and* $bw/(2k)$ 1*s in each column. In particular,* $bw/(2k)$ *is an integer.*

(ii) ([1]) *In an* ABD(k,w) *with* $w > 0$ *any given star pattern occurs in an even number of rows. Moreover, among the rows with a given star pattern there are as many with an even number of* 1*s as with an odd number of* 1*s.*

(iii) *For* $w \le 4$ *the only* ABD(k,w) *are the trivial ones with* $w = 0$ *or* $w = k$ *(represented, respectively, by a single row of stars or minus signs only) and the two examples shown above.*

(iv) ([2]) *If* $w > 3$*, then* $k \le w(w-1)/2$.

*Received by the editors February 2, 1997; accepted for publication July 2, 1997; published electronically June 3, 1999.

http://www.siam.org/journals/sicomp/28-6/31662.html

†University of Technology, Den Dolech 2, P.O. Box 513, 5600 MB Eindhoven, the Netherlands (aeb@win.tue.nl).

(v) ([3]) *There is no* ABD$(10, 5)$.

(vi) ([6]) *If* ABD(k_i, w_i) *exist for* $i = 1, 2$, *then there also is an* ABD(k_1k_2, w_1w_2).

(vii) ([1]) *Suppose that* $k \geq w > 0$ *and* $k' \geq w' > 0$ *and* $k' \geq k$ *and* $w'/k' \geq w/k$. *Then if an* ABD(k, w) *exists, and* $2^{w'}w'/(2k')$ *is an integer, then* ABD(k', w') *also exists.*

One may use generating function arguments to get more detailed information on the possible star patterns. See [1].

The purpose of this note is to show that an ABD$(8, 5)$ exists:

```
-0000***  *01*10*0
-0001***  -*1*1*11
-001*0**  **11*001
-**1010*  *10*00*0
*0*1*110  *1*0*001
**01*111  *100**11
-**1110*  -1*0*10*
-*1*00*0  *1**0110
*010**01  *1**1000
-*1*0*11  -1**1*10
*010*1*0  *101*0*1
```

Now the smallest open case is the question of whether an ABD$(12, 6)$ exists.

Acknowledgment. This note was inspired by a letter from Knuth, who asked whether there had been any progress on ABDs since 1976 and in particular whether the existence of an ABD$(8, 5)$ was still open.

ON THE ROBUSTNESS OF FUNCTIONAL EQUATIONS*

RONITT RUBINFELD†

Abstract. In this paper, we study the general question of how characteristics of functional equations influence whether or not they are robust. We isolate examples of properties which are necessary for the functional equations to be robust. On the other hand, we show other properties which are sufficient for robustness. We then study a general class of functional equations, which are of the form $\forall x, y \quad F[f(x-y), f(x+y), f(x), f(y)] = 0$, where F is an algebraic function. We give conditions on such functional equations that imply robustness.

Our results have applications to the area of self-testing/correcting programs. We show that self-testers and self-correctors can be found for many functions satisfying robust functional equations, including algebraic functions of trigonometric functions such as $\tan x$, $\frac{1}{1+\cot x}$, $\frac{Ax}{1-Ax}$, $\cosh x$.

Key words. program testing, property testing, functional equations

1. Introduction.

The mathematical field of functional equations is concerned with the following prototypical problem: given a set of properties (functional equations) over a particular domain, completely characterize the set of functions that satisfy them. For example, the *linearity property* over the integers is $\forall x, y \in \mathcal{Z} \quad f(x+y) - f(x) - f(y) = 0$. The functions mapping from $\mathcal{Z}$ to $\mathcal{Z}$ that satisfy the linearity property, referred to as the *solution set* of the functional equation, is $\mathcal{F} = \{f | f(x) = c \cdot x, c \in \mathcal{Z}\}$. The linearity property is one of the famous, well-studied functional equations referred to as Cauchy's equations and has been studied over many other domains and ranges with various properties (see the text by Aczél [3]). Functional equations are used widely in the study of the various functions that arise in areas such as mathematics, physics, and economics. Several general classes of functional equations have been identified. For example, algebraic addition theorems, of the form

$$\forall x, y \quad F[f(x+y), f(x), f(y)] = 0,$$

where F is any algebraic function, were used as a starting point in the development of the theory of elliptic curves by Weierstrass. Other types of functional equations include difference equations, iteration equations, multivariate functional equations, and systems of functional equations.

In section 2, we present the definition of functional equations given in [3]. For the purposes of this introduction, we define functional equations as follows: let $\mathcal{D}, \mathcal{R}$ be an arbitrary domain and range. Let $\mathcal{T}$ be a range containing 0, and $F : \mathcal{R}^k \times \mathcal{D}^k \to \mathcal{T}$ be a function that is computable via applying a finite number of known functions (in this paper we use $-, +, \times, \backslash$, hyperbolic functions, trigonometric functions, and cth roots for constant c). Let a *neighborhood* over the domain $\mathcal{D}$ be an ordered k-tuple in $\mathcal{D}^k$ and let $\mathcal{N} \subseteq \mathcal{D}^k$. The general form of a functional equation is then

TABLE 1.1
Examples of functions satisfying addition theorems over the reals.

Equation	Solution
$f(x+y)=\frac{f(x)+f(y)}{1-f(x)f(y)}$	$f(x)=\tan Ax$
$f(x+y)=\frac{f(x)f(y)-1}{f(x)+f(y)}$	$f(x)=\cot Ax$
$f(x+y)=\frac{f(x)+f(y)}{1+[f(x)f(y)/a^2]}$	$f(x)=a\tanh Bx$
$f(x+y)=\frac{f(x)f(y)}{f(x)+f(y)}$	$f(x)=C/x$
$f(x+y)=\frac{f(x)+f(y)-2f(x)f(y)}{1-2f(x)f(y)}$	$f(x)=\frac{1}{1+\cot Ax}$
$f(x+y)=\frac{f(x)+f(y)-1}{2f(x)+2f(y)-2f(x)f(y)-1}$	$f(x)=\frac{1}{1+\tan Ax}$
$f(x+y)=\frac{f(x)+f(y)+2f(x)f(y)}{1-f(x)f(y)}$	$f(x)=\frac{Ax}{1-Ax}$
$f(x+y)=\frac{f(x)+f(y)-2f(x)f(y)}{1-f(x)f(y)}$	$f(x)=\frac{-Ax}{1-Ax}$
$f(x+y)=\frac{f(x)+f(y)-2f(x)f(y)\cos a}{1-f(x)f(y)}$	$f(x)=\frac{\sin Ax}{\sin(Ax+a)}$
$f(x+y)=\frac{f(x)+f(y)-2f(x)f(y)\cosh a}{1-f(x)f(y)}$	$f(x)=\frac{\sinh Ax}{\sinh(Ax+a)}$
$f(x+y)=\frac{f(x)+f(y)+2f(x)f(y)\cosh a}{1-f(x)f(y)}$	$f(x)=\frac{-\sinh Ax}{\sinh(Ax+a)}$
$f(x+y)=f(x)f(y)-\sqrt{1-f(x)^2}\sqrt{1-f(y)^2}$	$f(x)=\cos(Ax)$
$f(x+y)=f(x)f(y)+\sqrt{f(x)^2-1}\sqrt{f(y)^2-1}$	$f(x)=\cosh(Ax)$

$\forall(x_1,\ldots,x_k)\in\mathcal{N},\ F[f(x_1),\ldots,f(x_k),x_1,\ldots,x_k]=0$. We denote the functional equation by $(F,\mathcal{N})$ when $\mathcal{D},\mathcal{R},\mathcal{T}$ are understood from the context. A particular solution of a functional equation is a function $f:\mathcal{D}\to\mathcal{R}$ for which F evaluates to 0 on all choices of neighborhoods in $\mathcal{N}$. The general solution, $\mathcal{F}$, is the family of functions that are solutions to the functional equation. Tables 1.1 and 1.2 give several examples of functional equations and their solution sets over the reals [3], [25]. In section 2, we describe the formal definition of *characterizations* as given by Rubinfeld and Sudan in [38], which can be viewed as a generalization of functional equations.

All functional equations involve a "for all" quantifier. Here we are interested in comparing the solution with the functional equation when the "for all" quantifier is replaced by a "for most" quantifier. To illustrate, we give a simplified definition of *robustness*. For a given δ, define $\mathcal{G}\stackrel{\text{def}}{=}\{f|Pr_{(x_1,\ldots,x_k)\in\mathcal{N}}[F[f(x_1),\ldots,f(x_k),x_1,\ldots,x_k]=0]\geq 1-\delta\}$. Clearly $\mathcal{G}$ contains $\mathcal{F}$. However, is it the case that each function in $\mathcal{G}\backslash\mathcal{F}$ is essentially the same (equal on most inputs in $\mathcal{D}$) as some function in $\mathcal{F}$? Slightly more precisely, we say that two functions are ϵ-*close* over $\mathcal{D}$ if $\frac{|\{x\in\mathcal{D}|f(x)\neq g(x)\}|}{|\mathcal{D}|}\leq\epsilon$. For some small constant ϵ, if each function in $\mathcal{G}$ is ϵ-close to some function in $\mathcal{F}$, then in some sense, the "for most" quantifier is sufficient to characterize the same class of functions as the "for all" quantifier, and we say that the functional equation is (ϵ,δ)-

TABLE 1.2
Examples of functions satisfying $F[f(x-y), f(x+y), f(x), f(y)] = 0$ over the reals.

Equation	Solution
$f(x+y)+f(x-y)=2f(x)$	$f(x)=Ax+a$
$f(x+y)+f(x-y)=2f(x)f(y)$	$f(x)=0, \cos Ax, \cosh Ax$
$f(x+y)+f(x-y)=2[f(x)+f(y)]$	$f(x)=Ax^2$
$f(x+y)-f(x-y)=2f(y)$	$f(x)=Ax$
$f(x+y)f(x-y)=f(x)^2$	$f(x)=a$
$f(x+y)-f(x-y)=4\sqrt{f(x)f(y)}$	$f(x)=Ax^2$
$f(x+y)f(x-y)=f(x)^2-f(y)^2$	$f(x)=Ax,\ k\sin Ax,\ k\sinh Ax$

robust. A formal and more general definition due to [38] is given in section 2. Often it is the case that $\mathcal{N}$ and F are defined and are known to be (ϵ,δ)-robust over an infinite *set* $\mathcal{S}$ of domains and corresponding neighborhood sets. For example, the linearity property can be defined for all domains that are groups where for each group G, the corresponding neighborhood set is $\{x, y, x +_G y | x \in G\}$ ($+_G$ is the group operation for G), and the linearity property is $\forall x, y, x +_G y\ f(x +_G y) -_G f(x) -_G f(y) = 0$. The linearity property is known to be $(2\delta,\delta)$-robust when the domain and range are any finite group for any $\delta < \frac{2}{9}$ [26]. We are interested in the case when for all $\epsilon < 1$, there is a constant δ such that $(F,\mathcal{N})$ is (ϵ,δ)-robust over each of the domains in $\mathcal{S}$. In this case, we say that $(F,\mathcal{N})$ is robust over $\mathcal{S}$ (note that robustness is only interesting if $\frac{1}{\delta}$ is much smaller than $|\mathcal{N}|$).

Previous results on robust characterizations. Robustness and related notions are used implicitly in a number of works [19], [9], [29], [10], [7], [6]. In the following sections, we describe the applications of robustness to program testing and to the study of probabilistically checkable proof systems.

There are many characterizations that are known to be robust: the first nontrivial characterization shown to be robust for constant ϵ, δ was the linearity property over finite groups in the work of Blum, Luby, and Rubinfeld [19]. Coppersmith [26] gives a particularly elegant proof of the robustness of the linearity property as well as improves the allowable parameters of ϵ, δ to the following: if $f(x+y)-f(x)-f(y) = 0$ is satisfied for a constant greater than $\frac{7}{9}$ fraction of the choices of x, y in the group G, then there is some function $g(z) = c \cdot z$ such that $f(x) = g(x)$ for at least $\frac{5}{9}$ of the x in G. Coppersmith also gives an example which shows that $\delta = \frac{7}{9}$ is a type of a threshold; i.e., there is a function which satisfies $f(x+y) - f(x) - f(y) = 0$ for $\frac{7}{9}$ fraction of the choices of x, y in the group G, but which does not agree with any linear function on more than $\frac{1}{3}$ of the domain. Bellare et al. [11] show that one can get a tighter result on the range of δ that is useful over domains of the type $GF(2)^n$ where Coppersmith's example does not apply. Robust characterizations of total degree d polynomials are given in [38].[1] Robust characterizations of maximum degree d polynomials are given

[1]The total degree of a polynomial is the maximum over all terms of the total degree of a term. The total degree of a term is the sum of the individual degrees of each variable in the term.

in several works [9], [29], [10], [38].[2] These results apply to polynomials over finite fields $\mathcal{Z}_p$ (p prime) and finite subsets of rational domains. The first formal definition of robustness was given in [38]. Very recently, robust characterizations of functions satisfying linear recurrence relations have been given by Kumar and Sivakumar [33].

Our results. Our goal is to characterize the fundamental characteristics of functional equations that make them robust, in order to gain an understanding of how broadly robustness applies. It happens that the structure of the neighborhoods in $\mathcal{N}$ is very important to whether a characterization is robust. We present a graph theoretic characterization of neighborhood sets $\mathcal{N}$, which is used to quantify the connectivity of $\mathcal{N}$. In Theorem 3.2, we show that high connectivity of $\mathcal{N}$ is necessary for $\mathcal{N}$ to be robust. Since the functional equations which relate inputs that are linear functions of a single variable (e.g., $\forall x,\ f(x) - f(x+1) - 1 = 0$) are known not to have this connectivity property, we can conclude that they are not robust. On the other hand, in Theorem 3.4, we show that when $\mathcal{N} = \mathcal{D}^k$, and the set of solutions to $(\mathcal{F}, \mathcal{N})$ is rich enough, $(\mathcal{F}, \mathcal{N})$ is robust.

We next investigate conditions on the class of functional equations of the general form $\forall x, y\ \ F[f(x-y), f(x+y), f(x), f(y)] = 0$ that imply robustness. We focus on domains that are finite groups and certain types of subsets of infinite groups, such as those of the form $\mathcal{D}_{n,s} = \{\frac{i}{s} \big|\ |i| \leq n\}$ (see the beginning of subsection 2.1) and others that are of use in studying periodic functions. In the case of domains that are finite groups and domains used for studying periodic functions, testing that a function satisfies a functional equation over a domain will involve neighborhood sets that are chosen from the same domain. In the case of domains that are subsets of infinite groups of the form $\mathcal{D}_{n,s} = \{\frac{i}{s} \big|\ |i| \leq n\}$, testing that a function satisfies a functional equation will involve neighborhood sets that are chosen from a larger subset of the same infinite group. Our results apply to ranges that have a group structure. In Theorems 4.1 and 6.4, we show that if the equation can be written as $\forall x, y\ \ f(x+y) = G[f(x), f(y)]$ (a special case of algebraic addition theorems referred to as an *addition theorem*), then it is robust as long as G satisfies $G[a, G[b, c]] = G[G[a, b], c]\ \forall a, b, c$ (which is satisfied by all of our examples of addition theorems). The proofs for all types of domains rely on the same techniques. Since the proofs of the results over finite group domains are simpler to state, we give them first in order to highlight the main ideas. This work leads to self-testers for several families of trigonometric functions including $\tan Ax$, $\frac{1}{1+\cot x}$, $\frac{Ax}{1-Ax}$, $\cosh Ax$, and several examples from [3], [4], [22] given in Table 1.1. A general format for constructing self-testers is given in sections 5 and 6, and a self-tester for the particular example of the cosh function is given in section 6.3. We then give techniques that apply to functions which satisfy other functional equations (the first three examples in Table 1.2), including d'Alembert's equation $\forall x, y\ \ f(x+y) + f(x-y) = 2f(x)f(y)$ in section 4.2. In this case, the range must be a field containing 2.

Robustness and self-testing/correcting. In order to allow a programmer to use programs that are not known to be correct on all inputs, result checkers were introduced by Blum [15] and Blum and Kannan [18], and soon after, the related paradigms of self-testers and self-correctors were introduced by Blum, Luby, and Rubinfeld [19]. (A notion similar to self-correctors was independently proposed by Lipton [34].) The paradigm of self-testers and self-correctors is intended to fit into

[2]The maximum degree of a polynomial is the maximum over all variables of the maximum degree of the variable in any term.

the framework of result checkers, and in fact it is observed that a self-tester and a self-corrector for a function can be combined to give a checker [19]. If a function has a checker, then one can determine whether program P is giving the correct answer on a particular input or whether there is a bug in the program. If a function has a self-corrector, then given a program P for computing the function that is correct on most inputs, one can transform P into a new randomized program that is correct on each input with high probability and is almost as efficient as running P. Self-testers allow one to ascertain that P is correct on a large enough fraction of the inputs so that it is capable of being self-corrected. More formal definitions of self-testers and self-correctors are given in section 5. If a function has both a self-tester and a corresponding self-corrector, then an unreliable program can be used to reliably compute the function.

Problems that can be viewed as linear or low degree polynomial functions, such as matrix multiplication, integer division, sine/cosine, integer multiplication, the mod function, modular multiplication, polynomial multiplication, modular exponentiation, fast Fourier transform and determinant, have been shown to have self-testers and self-correctors [19], [8], [34], [23], [31], [37], [38], [2], [28], [21]. Although many functions can be viewed as linear functions or low degree polynomials over an appropriate group structure, one concern was that these might be the only examples of functions that have self-testers and self-correctors. Using the new robustness results, we show that self-testers and self-correctors can be found for numerical functions that previously did not have self-testers and self-correctors. The techniques used to derive our results seem amenable to further generalization and may apply to an even wider variety of numerical functions.

We concentrate on self-testers which operate by finding properties (such as functional equations) that should be satisfied by any correct program and then *testing that the program satisfies the properties for randomly chosen inputs*. In this work, we study the characteristics of the properties that make them usable for testing. Properties that can be tested more efficiently than computing the function f are particularly interesting for constructing good tests for programs.

The idea of testing programs by verifying that programs satisfy properties known to be satisfied by the functions being computed is not new to the self-testing/correcting approach. For example, matrix multiplication routines have been tested by verifying that the outputs satisfy the distributive property [39]. The work of Cody and Stoltz [25] proposes the use of Taylor series in order to test programs for exponential integrals. These techniques apply to Bessel functions and Dawson's integral. The work of Vainstein [42], [43], [44], [45] suggests the use of *polynomial checks* for testing and correcting programs. In the language previously defined, polynomial checks are those functional equations for which the function F is a polynomial and the neighborhoods are ordered sets of the form $(x, x+a_1, x+a_2, \ldots, x+a_k)$ for fixed constants $a_1, \ldots, a_k$. These functional equations can be used to test functions that are algebraic functions of trigonometric functions. The work of Cody [24] suggests the following test for programs computing the real gamma function over the reals:

$$\text{Pick random } x \text{ and verify that } P(2x) = (2\pi)^{-1/2} 2^{2x-1/2} P(x) P(x+\tfrac{1}{2}).$$

In all of the above cases, it is clear that any correct program for the function must pass these recommended tests. However, none of the works mentioned in this paragraph give any formal evidence that programs that pass these tests should be usable. On the contrary, it is easy to come up with examples of programs that pass the above tests but do not compute the correct function on a large fraction of inputs.

Still, it has been shown that in many cases using properties to test programs is mathematically justified (cf. [19], [37], [31], [38]). Essentially one can show that some of these tests can be used in conjunction with other simple tests in order to determine that a program is correct on most inputs. In order to show that such tests work, the main technique used has been to partition the problem into three tasks: first, find properties that characterize a family of functions, $\mathcal{F}$, containing the function f. For example, one can find functional equations satisfied by specific classes of finite degree rational functions of $x, e^x, \sin x$ using the results of [43], [16]. Second, show that these properties are robust, so that it is possible to efficiently test whether the program is computing a function that is close to some function in $\mathcal{F}$. We call this task *property testing*. Third, find other efficient tests which allow the user to determine whether or not the program is computing the correct function within $\mathcal{F}$. We call this latter task *equality testing*. Equality testing can often be done much more efficiently once it is known that the program is essentially computing some member of $\mathcal{F}$. For example, the function $f(x) = x \bmod R$ is uniquely specified by the properties that (1) f is linear, i.e., $\forall x, y \quad f(x) + f(y) \equiv f(x + y) \bmod R$, (2) f has slope 1, i.e., $\forall x \quad f(x)+1 \equiv f(x+1) \bmod R$. Using the robustness of linearity, if (1) is satisfied for *most* x, y (greater than a $\frac{7}{9}$ fraction), then there is some function $g(x) = cx \bmod R$ such that $f(x) = g(x)$ for most x. If in addition (2) is satisfied for most x then $f(x) = x \bmod R$ for most x. (Note that if R is considered to be part of the input, then it is not enough to test only that property (2) is satisfied for any constant fraction of the $x \in [0..R-1]$.) Thus, it is only necessary to check that the program satisfies the given properties at a relatively small number (in this case, a constant independent of $|x|, |R|$) of randomly selected inputs in order to guarantee that the program usually computes the correct values. This paper concentrates on the task of property testing.

It is shown in [19] that self-correctors exist for any function that is random self-reducible,[3] since if the program is known to be correct on most inputs, then the correct value of the function at any particular input x can be inferred, even though the program may be incorrect on input x. In particular, any function satisfying the linearity property is random self-reducible [19]. On a related note, the use of polynomial checks (or the functional equations that are defined by the polynomial checks) for the correction of programs with few errors is suggested in [43], and Blum et al. [16] build on the work of [43] to give self-correctors for the same functions. Here we observe that efficient self-correctors exist for functions satisfying any one of a *class* of functional equations, namely, those of the general form $\forall x, y \quad F[f(x - y), f(x + y), f(x), f(y)] = 0$, where F is an algebraic function that has the property that given three of $f(x-y), f(x+y), f(x), f(y)$, F can be used to efficiently solve for the remaining one. A similar result was obtained independently by Blum et al. [16], where self-correcting using functional equations is studied in much greater depth.

Organization of paper. In section 2 we present the formal definitions of exact and robust characterizations from [38]. In section 3 we investigate certain general properties of functional equations that influence whether they are robust. In section 4 we present technical theorems showing conditions under which the general functional equation $F[f(x - y), f(x + y), f(x), f(y)] = 0$ is robust on domains that are finite

[3] f is random self-reducible if f can be computed at any particular input x via $f(x) = G[f(y_1), \ldots, f(y_k), y_1, \ldots, y_k]$, where G can be computed asymptotically faster than f and the y_i's are uniformly distributed, although not necessarily independent [19]. This notion of random self-reducibility is somewhat different than other definitions given by [20], [1], [30], where the requirement on G is that it be computable in polynomial time.

groups. In section 5 we present the self-testers and self-correctors based on the general form of the functional equation $\forall x, y \;\; F[f(x-y), f(x+y), f(x), f(y)] = 0$. In section 6 we show how to convert the self-testers and self-correctors shown for finite groups into self-testers and self-correctors that apply to functions over rational domains. The completely specified self-tester and self-corrector for the particular example of the cosh function is described in section 6.3. In section 7 we discuss our conclusions and directions for further research.

2. Functional equations and characterizations. In this section, we give the definitions of functional equations and exact and robust characterizations. We also show a relationship between functional equations and probabilistically checkable proof systems.

2.1. Domains and ranges. Throughout this paper, we focus on the following three kinds of domains: The first are finite subsets of the rationals of the form $\mathcal{D}_{n,s} = \{\frac{i}{s} \big| \; |i| \leq n\}$, where n, s are integers. These domains are not necessarily closed under addition and multiplication. This class includes domains that can be internally represented in a computer, corresponding to fixed point arithmetic, which have been used in previous work on self-testing and self-correcting [31], [37]. The second type of domain that we are interested in are finite groups. Even for functions that are not defined over finite group domains, it is much simpler to first reason about the functional equations that they satisfy over finite group domains since they are closed under addition and then to use the techniques of [31], [37] (described in section 6) for converting results on finite group domains into results on rational domains. The third class of domains are of use when studying periodic functions: $\mathcal{D}_s^b = \{i \cdot s \big| \; i \in \mathcal{Z}\}$, where b/s is an integer, and addition and multiplication is performed mod b. For example, $\mathcal{D}_{2\pi/10}^{2\pi} = \{0, 2\pi/10, 4\pi/10, 6\pi/10, \ldots, 18\pi/10\}$. Note that any function $f : \mathcal{D}_s^b \to \mathcal{R}$ corresponds to a function $\hat{f} : \mathcal{Z}_{b/s} \to \mathcal{R}$ by $\hat{f}(i) = f(i \cdot s \bmod b)$. Thus results on the finite group domains can be immediately applied to this third class of domains. The range of the functions considered can in general be arbitrary. If not specified, the range is assumed to be the reals.

In Tables 1.1 and 1.2, solutions to functional equations over the reals are given. It may happen that the functional equation over the reals characterizes a family of functions that is a proper subset of the functions characterized by the same functional equation over $\mathcal{D}_{p,s}$. In section 5.2 we show that this does not limit the ability to construct self-testers for programs for these functions, due to the equality testing performed by self-testers.

2.2. Functional equations. In the text by Aczél [3, p. 1] , functional equations are defined by first defining a *term*.

DEFINITION 2.1 (term—[3, p. 1]).

1. *The independent variables $x_1, \ldots, x_k$ are terms.*
2. *Given that $A_1, \ldots, A_m$ are terms and that H is a function of m variables, then $H(A_1, \ldots, A_m)$ is also a term.*
3. *There are no other terms.*

DEFINITION 2.2 (functional equation—[3, p. 2]). *A* functional equation *is an equation $A_1 = A_2$ between two terms A_1, A_2 which contains k independent variables $x_1, \ldots, x_k$ and $n \geq 1$ unknown functions $H_1, \ldots, H_n$ of $j_1, \ldots, j_n$ variables, respectively, as well as a finite number of known functions.*

The known functions used in [3] include addition; subtraction; division; multiplication; and exponentiation, trigonometric, and hyperbolic functions. In this paper,

we will also include all functions computable by a Turing machine. Later in [3, p. 3] it is also noted that the functional equation must be identically satisfied for certain values of the variables $(x_1, \ldots, x_k)$ figuring in them, called the domain. (We use the term neighborhood set in this paper.) A *particular solution* of a functional equation is a function that satisfies the equation in the given domain (neighborhood set). The *general solution* is the set of all solutions belonging to the *class of admissible functions*, which can, for example, be defined by the analytic properties (measurability, differentiability, continuity, boundedness), other properties such as computability by a polynomial time Turing machine, by initial and boundary conditions and/or by conditions given in the form of another functional equation.

2.3. Exact and robust characterizations. We now present the definitions of characterizations and robust characterizations given by [38]. $\mathcal{D}$ is used to represent a finite domain. We consider families of functions $\mathcal{F}$ where $f \in \mathcal{F}$ maps elements from domain $\mathcal{D}$ to range $\mathcal{R}$ (we use $\mathcal{R}$ to denote the range of a function and $\Re$ to denote the set of real numbers). $\mathcal{T}$ is a range containing 0. We illustrate these definitions using the example of linear functions. Here $\mathcal{D} = \mathcal{R} = \mathcal{T} = \mathcal{Z}_p$ and the family of linear functions is $\{f_a | a \in \mathcal{Z}_p \text{ where } f_a(x) = a \cdot x\}$.

DEFINITION 2.3 (neighborhoods—[38]). *$N_{\mathcal{D}}$ is a k-*local neighborhood *if it is an ordered tuple of (not necessarily distinct) k points $(x_1, \ldots, x_k)$ from $\mathcal{D}^k$. A k-local collection of neighborhoods $\mathcal{N}_{\mathcal{D}}$ is a (multi)set of k-local neighborhoods. When $\mathcal{D}$ is understood from the context, we drop it from the subscript.*

DEFINITION 2.4 (properties—[38]). *$\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}$ is a k-*local property *if it is a function from $\mathcal{R}^k \times \mathcal{D}^k$ to $\mathcal{T}$. We say that a function $f : \mathcal{D} \to \mathcal{R}$* satisfies a property *$\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}$ over a neighborhood $N_{\mathcal{D}} = (x_1, \ldots, x_k)$ if $\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}(f(x_1), \ldots, f(x_k), x_1, \ldots, x_k) = 0$.[4] When $\mathcal{D}, \mathcal{R}, \mathcal{T}$ are understood from the context, we drop them as subscripts.*

DEFINITION 2.5 (exact characterizations—[38]). *We say that $(\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}, \mathcal{N}_{\mathcal{D}})$ is an* exact characterization *of a family $\mathcal{F}$ of functions if a function $f : D \to R$ satisfies $\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}$ over all neighborhoods $N_{\mathcal{D}} \in \mathcal{N}_{\mathcal{D}}$ exactly when $f \in \mathcal{F}$. The characterization is k-local if the property $\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}$ and the collection $\mathcal{N}_{\mathcal{D}}$ is k-local. When $\mathcal{D}, \mathcal{R}, \mathcal{T}$ are understood from the context, we drop them as subscripts.*

In our example, $\mathcal{R} = \mathcal{T} = \mathcal{D} = \mathcal{D}' = \mathcal{Z}_p$. The collection of neighborhoods is $\mathcal{N} = \{(x, y, x + y) | x, y \in \mathcal{Z}_p\}$. The property $\mathcal{P}$ which for $\{x_1, x_2, x_3\}$ computes $\mathcal{P}(f(x_1), f(x_2), f(x_3), x_1, x_2, x_3) = f(x_1) + f(x_2) - f(x_3)$ is 3-local. $(\mathcal{P}, \mathcal{N})$ is a 3-local characterization of the family of the linear functions $\{f | f(x) = c \cdot x, c \in \mathcal{Z}_p\}$.

DEFINITION 2.6 (robust characterizations—[38]). *Let $\mathcal{D}' \subseteq \mathcal{D}$. Let $\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}$ be a property over a collection of neighborhoods $\mathcal{N}_{\mathcal{D}}$; let $\mathcal{F}$ be such that $(\mathcal{D}, \mathcal{R}, \mathcal{T}, \mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}, \mathcal{N}_{\mathcal{D}})$ is an $(\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}, \mathcal{N}_{\mathcal{D}})$ is an exact characterization of $\mathcal{F}$. We say that the characterization $\mathcal{A} \equiv (\mathcal{D}', \mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}, \mathcal{N}_{\mathcal{D}})$ is an* (ϵ, δ)-robust characterization *of $\mathcal{F}$ in $\mathcal{G}$ if whenever a function $f \in \mathcal{G}$ satisfies $\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}$ on all but δ fraction of the neighborhoods in $\mathcal{N}_{\mathcal{D}}$, it is ϵ-close on domain $\mathcal{D}'$ to some function $g \in \mathcal{F}$.[5] When $\mathcal{D}, \mathcal{D}', \mathcal{R}, \mathcal{T}$ are understood from the context, we drop those parameters.*

We remark that in order for a robust characterization to be useful, membership

[4] This is a slight modification of the definition in [38], where the function f satisfies $\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}$ if $\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}(f(x_1), \ldots, f(x_k), x_1, \ldots, x_k) = 1$ and the range of the function $\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}$ is $\{0, 1\}$ instead of $\mathcal{T}$.

[5] It is convenient for our results in this paper to define $\mathcal{N}_{\mathcal{D}}$ as a multiset and to define robust characterizations in terms of picking neighborhood sets from the uniform distribution on $\mathcal{N}_{\mathcal{D}}$. Alternatively, one can define robust characterizations in terms of a distribution on ordered sets, where $\mathcal{N}_{\mathcal{D}}$ would correspond to the support of the distribution.

in $\mathcal{G}$ should be efficient to test, choosing a random neighborhood in $\mathcal{N}_{\mathcal{D}}$ should be efficient, and $\mathcal{D}'$ should be a fairly large subset of $\mathcal{D}$. All of our results have these properties. In most examples, $\mathcal{G}$ will be the set of all functions; however, we will see examples in which it is useful to have $\mathcal{G}$ be a smaller, efficiently recognizable, set of functions.

To continue with the example of linear functions, a theorem of [19] can be used to say that for any finite group G and any $\delta < \frac{2}{9}$, $(\mathcal{P}_G, \mathcal{N}_G)$ is a $(2\delta, \delta)$-robust characterization of the linear functions mapping G to G.

In order to test if f is close to some member of $\mathcal{F}$, one would need to sample at least $\frac{1}{\delta}$ of the neighborhoods in $\mathcal{N}$ and test if $\mathcal{P}$ holds on these neighborhoods. Thus, $\frac{1}{\delta}$ is referred to as the *efficiency* of the characterization.

We now define what it means for a characterization to be robust over a class.

DEFINITION 2.7. *Let $\mathcal{S} = \{(\mathcal{A}_1, \mathcal{F}_1, \mathcal{G}_1), (\mathcal{A}_2, \mathcal{F}_2, \mathcal{G}_2), \ldots\}$ be such that for all i, $\mathcal{A}_i = (\mathcal{D}_i', \mathcal{P}_{\mathcal{D}_i,\mathcal{R}_i,\mathcal{T}_i}, \mathcal{N}_{\mathcal{D}_i})$ and $(\mathcal{P}_{\mathcal{D}_i,\mathcal{R}_i,\mathcal{T}_i}, \mathcal{N}_{\mathcal{D}_i})$ is an exact characterization of $\mathcal{F}_i$. We say that $(\mathcal{P}, \mathcal{N})$ is* robust over the family $\mathcal{S}$ *if*

1. *there is a function $\mathcal{N}$ which takes as input i and returns a Turing machine M such that M on input a random string chooses a random member $N \in \mathcal{N}_{\mathcal{D}_i}$;*
2. *there is a function $\mathcal{P}$ which takes as input i and returns a Turing machine that on input $N \in \mathcal{N}_{\mathcal{D}_i}$ computes $\mathcal{P}_{\mathcal{D}_i,\mathcal{R}_i,\mathcal{T}_i}(N)$;*
3. *for all $\epsilon < 1$ there is a $\delta < 1$ such that for all i, $\mathcal{A}_i$ is an (ϵ, δ)-robust characterization.*[6]

In order for a robust characterization over a class to be useful, the functions $(\mathcal{P}, \mathcal{N})$ should have a uniform and concise description. In particular, functional equations have a natural interpretation as a concise description of robust characterizations over a class. In this paper, we consider variations of the following two basic types of classes.

In the first type of class, we capture the property that a functional equation is (ϵ, δ)-robust over all domains that have a certain structure, such as finite groups. The functional equation $\mathcal{P}, \mathcal{N}$ is described with a generic group or field operation. Let $\mathcal{D}_i = \mathcal{D}_i' = \mathcal{R}_i = \mathcal{T}_i = G_i$, where G_i is the ith group (for an arbitrary ordering of the groups) with group operator $+_{G_i}$. $\mathcal{P}_{\mathcal{D}_i,\mathcal{R}_i,\mathcal{T}_i}$ and $\mathcal{N}_{\mathcal{D}_i}$ are then the functions obtained by using the group operator $+_{G_i}$. In our linearity example, $\mathcal{P}(i) = \mathcal{P}_{\mathcal{D}_i,\mathcal{R}_i,\mathcal{T}_i}$ is the function $\mathcal{P}(f(x_1), f(x_2), f(x_3), x_1, x_2, x_3) = f(x_1) +_{G_i} f(x_2) -_{G_i} f(x_3)$. The collection of neighborhoods $\mathcal{N} = \{(x, y, x +_{G_i} y) | x, y \in G_i\}$.

In the second type of class, we concentrate on finite subsets of various sizes of an infinite group. The functional equation is defined over a large, possibly infinite domain such as the rationals. However, the robust characterization is defined over a finite subset of the domain. Let $\mathcal{D}_i = \mathcal{D}_{n_i,s}$, $\mathcal{D}_i' = \mathcal{D}_{i,s}$ for $n_i \geq i$ (the exact value of n_i is determined by the robust characterization) and $\mathcal{R} = \mathcal{T} = \Re$. $\mathcal{P}, \mathcal{N}$ always return the same function which maps the rationals to the reals. In our linearity example, $\mathcal{P}$ is the function $\mathcal{P}(f(x_1), f(x_2), f(x_3), x_1, x_2, x_3) = f(x_1) + f(x_2) - f(x_3)$ and $\mathcal{N}$ is a carefully chosen subset of $\{(x, y, x + y) | x \in \mathcal{D}_{n_i,s}, y \in \mathcal{D}_{n_i,s}\}$ (see section 6). Operations $+, -$ are the usual group operations over the reals.

Our results specify the class of domains and ranges over which the functional equation is robust. When $\mathcal{S}$ is understood from the context, we say that $(\mathcal{P}, \mathcal{N})$ is robust.

[6] The only interesting case is when the size of $\mathcal{S}$ is infinite, since otherwise there are always constants ϵ, δ such that all characterizations in the collection are (ϵ, δ)-robust.

2.4. Robustness and probabilistically checkable proofs. A language L in NP has a *probabilistically checkable proof system* if there is a probabilistic polynomial time Turing machine V (the verifier) that has read access to a source of random strings R and to a proof P for the membership of x in L, such that (1) if $x \in L$, there exists a proof P of membership in the language such that V accepts P with probability 1 (where the probability is over the random strings R) and (2) if x is not in L, for all proofs P', V accepts proof P' with probability at most $\frac{1}{4}$ [29]. The linearity test and tests for low total degree polynomial functions that are given in [19], [37], [6] have been used to construct probabilistically checkable proof systems in the recent results of [6], [14], [12] (tests that functions are low degree in each variable are given and used in [9], [29], [7]). Much recent research has been devoted to expanding the range of the robustness parameter δ for which these tests work, as it directly influences the strength of results showing that it is computationally difficult to approximate certain NP-complete problems [36], [11], [12].

Conversely, Sudan [41] has noted that the property of being a probabilistically checkable proof can actually be viewed as an example of a robust functional equation (where the definition of F is generalized to include all polynomial time circuits): in the work of Arora, Lund, Motwani, Sudan, and Szegedy [6], each probabilistically checkable proof P can be viewed as a truth table of a function. If P is n bits long, then P can be thought of as the function $P : [1 \dots n] \to \{0,1\}$; i.e., $P(i)$ is the ith bit of the proof. The protocol followed by V is to choose an r-bit random string y, perform a computation in order to determine a constant number of locations $\sigma_1(y), \dots, \sigma_k(y)$, query the proof at those locations, and then perform another computation on input $(y, P(\sigma_1(y)), \dots, P(\sigma_k(y)))$ in order to determine whether to accept or reject the proof. More formally, let $\mathcal{N} = \{(\sigma_1(y), \dots, \sigma_k(y)) | y \in \{0,1\}^r\}$. The verifier's choice of a random string in $\{0,1\}^r$ determines a choice of a neighborhood $(y_1, \dots, y_k)$ from $\mathcal{N}$ by the computation $y_i = \sigma_i(y)$. The verifier then tests whether a relationship $\forall (y_1, \dots, y_k) \in \mathcal{N},\ F[P(y_1), P(y_2), \dots, P(y_k), y] = 0$ is satisfied, where F is computable by a polynomial time Turing machine and describes the computation of the verifier that determines whether to accept or reject the proof. In [6] it is shown that one can construct an $(F, \mathcal{N})$ that characterizes the set of valid proofs; i.e., valid proofs are exactly those bit strings P for which $F[P(y), P(\sigma_1(y)), \dots, P(\sigma_k(y)), y] = 0$ is satisfied for all random strings y. Furthermore only proofs that are close (equal on most bits) to some valid probabilistically checkable proof are passed with probability $\geq 3/4$.

3. Characterizing robust functional equations. We turn to the general question of how to distinguish functional equations that are robust from those that are not in order to arrive at a better understanding of what makes a functional equation robust. It turns out that the structure of the neighborhood set is a very important determining factor to whether or not the functional equation is robust. To illustrate, the following are three characterizations of the lines $\mathcal{F} = \{f | f : Z_p \to Z_p, f(x) = ax + b \text{ for } a, b \in \mathcal{Z}_p\}$ (this family of lines is different from the one discussed previously) and over the class $\mathcal{S}$ in which $\mathcal{R}_i = \mathcal{T}_i = \mathcal{D}_i = \mathcal{D}'_i = \mathcal{Z}_{p_i}$ where p_i is the ith prime:

1. $\forall x_1, x_2, x_3 \in Z_{p_i}, \frac{f(x_1)-f(x_2)}{x_1-x_2} = \frac{f(x_2)-f(x_3)}{x_2-x_3}$.
2. $\forall x_1, x_2 \in Z_{p_i},\ f(x_1) - 2f(x_2) + f(2x_2 - x_1) = 0$ or, equivalently, $\mathcal{N}_{\mathcal{D}} = \{(x_1, x_2, 2x_2 - x_1) | x_1, x_2 \in Z_{p_i}\}$ and $\forall (x_1, x_2, x_3) \in \mathcal{N}_{\mathcal{D}}, f(x_1) - 2f(x_2) + f(x_3) = 0$.
3. $\forall x_1 \in Z_{p_i},\ f(x_1) - 2f(x_1+1) + f(x_1+2) = 0$ or, equivalently, $\mathcal{N}_{\mathcal{D}} = \{(x_1, x_1+$

$1, x_1 + 2)|x_1 \in Z_{p_i}\}$ and $\forall (x_1, x_2, x_3) \in \mathcal{N}_{\mathcal{D}}, f(x_1) - 2f(x_2) + f(x_3) = 0$.

In all three characterizations, the property is the same (although simplified in the latter two characterizations because of the specially chosen neighborhoods) and ensures that the points $(x_1, f(x_1)), (x_2, f(x_2)), (x_3, f(x_3))$ all lie on a single line. The only difference in the three characterizations is the collection of neighborhoods over which it is defined. However, the choice of neighborhoods heavily influences the robustness of the characterizations. A simple counting argument (similar to the one described later in section 3.2) shows that the first property is (δ, δ)-robust for all $\delta < 1$. The second property is $(2\delta, \delta)$-robust for $\delta < \frac{1}{1082}$ [38]. It is easy to see that for all ϵ, the third property is not (ϵ, δ)-robust over $\mathcal{S}$ for any constant δ. Thus the richness of the neighborhood set influences the robustness as well as the complexity of computing $\mathcal{P}_{\mathcal{D},\mathcal{R},\mathcal{T}}$. Another interesting quantity related to the neighborhood set is the number of random bits required to choose a random element of the neighborhood set (or the logarithm of the size of the neighborhood set). Reducing this quantity, even by a constant factor, while not significantly affecting the range of δ, ϵ achievable for maintaining a robust characterization (and thus not significantly reducing the efficiency of the characterization), has been useful for constructing more efficient probabilistically checkable proofs [14], [12].

We begin by investigating two extreme types of functional equations:

1. A *k-minimal neighborhood set* is one in which $\mathcal{N}_{\mathcal{D}}$ is described by $k-1$ functions $\sigma_1(x), \ldots, \sigma_{k-1}(x)$, where the σ_i's are arbitrary functions mapping $\mathcal{D}$ to $\mathcal{D}$. $\mathcal{N}_{\mathcal{D}}$ is of the form $\{(x, \sigma_1(x), \ldots, \sigma_{k-1}(x))|x \in \mathcal{D}\}$. Since once the first element of the neighborhood is chosen, the other elements are uniquely determined, the cardinality of the neighborhood set is at most $|\mathcal{D}|$. $\mathcal{N}_{\mathcal{D}}$ in the third example uses a 3-minimal neighborhood set. A *minimal functional equation* is one in which the neighborhood set is k-minimal for some constant k.
2. A *k-total neighborhood set* is one in which $\mathcal{N}_{\mathcal{D}} = \mathcal{D}^k$, relating the function at each input x to function values at *all* subsets of $k-1$ other inputs. $\mathcal{N}_{\mathcal{D}}$ in the first example uses a 3-total neighborhood set. A *total functional equation* is one in which the neighborhood set is k-total for some constant k.

We isolate a key combinatorial property of the neighborhood sets of functional equations and show that having this property is a necessary condition for robustness. We apply this combinatorial property to show a general condition under which functional equations with minimal neighborhood sets are not robust. As we will see later, this result implies that certain methods of testing programs used in practice are related to this class and are therefore provably faulty. For example, our techniques apply to the functional equation that is used to test the real gamma function [24, p. 5]. On the other hand, we mention an example, given by Sudan [41], of a minimal equation that is robust. We then show conditions under which k-total equations are always robust.

In the following, we assume that $\mathcal{D} = \mathcal{D}'$.

3.1. Minimal functional equations. One might conjecture that minimal equations cannot be robust, since for most inputs x, the function value at x is related to the function values at very few other inputs. We show a class of minimal equations that are provably not robust. We then describe an example of a minimal robust functional equation.

A combinatorial property of robustness. We first define a graph which captures much of the information in the neighborhood set $\mathcal{N}_{\mathcal{D}} = \{(x, \sigma_1(x, \bar{y}), \ldots,$

$\sigma_k(x,\bar{y}))|x \in \mathcal{D}, \bar{y} \in \mathcal{D}^k\}$: given the functional equation $\forall x \in \mathcal{D}, \bar{y} \in \mathcal{D}^k$, $F[f(x), f(\sigma_1(x,\bar{y})), \ldots, f(\sigma_k(x,\bar{y}))] = 0$, for $\sigma_i : \mathcal{D} \times \mathcal{D}^k \to \mathcal{D}$, we define the undirected multigraph $G_{\mathcal{N}_\mathcal{D}} = (V, E)$, where the vertices correspond to elements of $\mathcal{D}$ and the edges are $E = \{(x, \sigma_j(x,\bar{y}))|x \in \mathcal{D}, \bar{y} \in \mathcal{D}^k, 1 \le j \le k\}$ (there may be more than one edge between u and v if there is more than one $i, \bar{y}$ such that $\sigma_i(u,\bar{y}) = v$).

For example, the graph of $\forall x \in \mathcal{Z},\ f(x)+1-f(x+1) = 0$ corresponds to a path, and the graph of $\forall x, y,\ f(x) + f(y) - f(x+y) = 0$ corresponds to a complete graph with two edges between every pair of nodes.

The following result applies to functional equations defining classes of functions that can be thought of as codewords with very large ($>> \frac{1}{2}$) distance.

DEFINITION 3.1. *An α-separated function family $\mathcal{F}$ over domain $\mathcal{D}$ is one for which $|\mathcal{F}| \ge 2$ and $\forall f_i, f_j \in \mathcal{F},\ Pr_{x\in\mathcal{D}}[f_i(x) = f_j(x)] \le \alpha$.*

For example, for all of the functional equations mentioned in Tables 1.1, 1.2, for all α, there are integers n, s such that the functional equations over the domain $\mathcal{D}_{n,s}$ characterize α-separated function families.

The following theorem shows a relationship between the connectivity of $G_{\mathcal{N}_\mathcal{D}}$ and the robustness of the functional equation $(F, \mathcal{N}_\mathcal{D})$: if $(F, \mathcal{N}_\mathcal{D})$ is (ϵ, δ)-robust, then more than δ/k fraction of the edges in the graph $G_\mathcal{N}$ must be removed in order to separate $G_\mathcal{N}$ into two "large" components, each of size $\ge (\epsilon + \alpha)|V|$.

THEOREM 3.2. *Let $\mathcal{N} = \{(x, \sigma_1(x,\bar{y}), \ldots, \sigma_k(x,\bar{y}))|x \in \mathcal{D}, \bar{y} \in \mathcal{D}^k\}$. Suppose that $\mathcal{F}$, characterized by $(F, \mathcal{N})$, is an α-separated function family. If $G_\mathcal{N}$ has a set of edges E' such that (1) $|E'| \le \frac{\delta}{k}|E|$ and (2) removing E' separates the vertices of $G_\mathcal{N}$ into two components, each of size $\ge (\epsilon+\alpha)|V|$, then $(F, \mathcal{N})$ is not an (ϵ, δ)-robust characterization.*

Proof. Suppose E' separates G_F into sets A, B. Consider the function h which labels vertices in A according to f_1 and vertices in B according to f_2 for some $f_1, f_2 \in \mathcal{F}$. Since $\mathcal{F}$ is α-separated, we have that $\forall f_i \in \mathcal{F}, Pr_{x\in\mathcal{D}}[f_i(x) \ne h(x)] \ge \epsilon$. However, only tests using edges that cross the cut will fail. Since $x, \bar{y}$ are chosen uniformly, the edges are also chosen uniformly. Thus tests will fail with probability $\le \delta$. □

Application to minimal functional equations. It is easy to see that for any minimal equation F of the form $F[f(x), f(\sigma(x))] = 0$, G_F can be separated into two large components by removing very few edges (by Theorem 3.2), and thus for all classes $\mathcal{S}$ in which the domain size is not bounded, the functional equation $(F, \mathcal{N})$ for $\mathcal{N} = \{(x, \sigma(x))|x \in \mathcal{D}\}$ over $\mathcal{S}$ is not robust.

It was shown by Klawe [32] that for any given ϵ, any graph on n nodes whose edges are defined by a constant number of linear functions has a cut containing $o(n)$ edges which separates the graph into two large portions, each containing an ϵ fraction of the nodes. The following corollary applies to functional equations relating points x to points that are linear functions of x.

COROLLARY 3.3. *Given n, s, let $\mathcal{D}_{n,s} = \mathcal{D} = \mathcal{D}'$. $\mathcal{R} = \mathcal{T} = \Re$. Let $\sigma_1, \ldots, \sigma_k$ be any family of linear functions over the rationals of the form $\sigma_i(x) = ax + b$, where a, b are rational, and let $\mathcal{F}$ be an α-separated function family satisfying the equation $F[f(x), f(\sigma_1(x)), f(\sigma_2(x)), \ldots, f(\sigma_k(x))] = 0$. Then there exists a constant $0 < \epsilon < 1$ such that $(F, \mathcal{N})$ is not (ϵ, δ)-robust for any constant δ.*

Thus, if $\mathcal{S}$ is a class such that $\mathcal{D}_{i,s} = \mathcal{D}_i = \mathcal{D}_i'$, then $\mathcal{R}_i = \mathcal{T}_i = \Re$, and $\sigma_1, \ldots, \sigma_k$ are any family of linear functions over the rationals of the form $\sigma_i(x) = ax + b$, where a, b are rational, the functional equation $(F, \mathcal{N})$ for $\mathcal{N} = \{(x, \sigma_1(x), \ldots, \sigma_k(x))|x \in \mathcal{D}\}$ over $\mathcal{S}$ is not robust. A similar result applies for linear functions over finite groups.

This corollary shows that many tests that are used in practice to test programs should be used with more care. For example, in the functional equation

$$\forall x,\ f(2x) - (2\pi)^{-1/2} 2^{2x-1/2} f(x) f(x+1/2) = 0$$

used for testing the real gamma function by [24], all of the σ_i's are linear functions ($\sigma_1(x) = 2x, \sigma_2(x) = x + \frac{1}{2}$). Thus the corollary implies that there exist programs which are very different from any solution to this functional equation, yet pass the test most of the time. The direct use of polynomial checks suggested in [43] also yields functional equations which are not robust due to Corollary 3.3; however, the work of [16] shows how to transform the polynomial checks into more general functional equations for which the negative results in this section do not apply.

A robust minimal functional equation. Previous examples of robust functional equations have always been usable for self-correction as well. This might lead one to think that usability for self-correction might be another necessary condition for robustness. However, this may note be the case: it is not known how to use minimal functional equations for self-correction. Even so, there are minimal functional equations that are robust and can therefore be used to self-test. We describe an example of a minimal functional equation that is robust. The following example was given by Sudan [41].

We say that a graph $G(V, E)$ is an α-expander if for all $S \subseteq V, |S| \leq |V|/2$, the set of nodes that are neighbors of S (not including nodes in S), is of size $\geq \alpha|S|$. Fix constants d and α. Let $G_i(V, E)$ be any degree d α-expander on i nodes, such that the vertices are labelled by elements of the domain D. Let the functional equation be $\forall (u, v) \in E,\ f(u) - f(v) = 0$. Since G_i is connected, the only functions which are solutions to this functional equation are the constant functions. Assume that the functional equation is satisfied for most $(u, v) \in E$. Suppose one deletes all edges for which the functional equation does *not* hold. Since G_i is an expander, there must exist a large connected component in G_i (containing at least a constant fraction of the nodes), even after deleting the edges. The large connected component will correspond to elements of the domain that agree with a single constant function. Let $\mathcal{S}$ be the class corresponding to the above functional equation on $G_0, G_1, \ldots$. Then for all ϵ, there is a δ such that the above functional equation is (ϵ, δ)-robust on $\mathcal{S}$.

3.2. Total functional equations. On the other end of the spectrum, we consider a class of functional equations where there are no restrictions on the way inputs are related, and we show that if some technical conditions are satisfied, then they are always robust.

Given $\mathcal{D}$ and $\mathcal{R}$, let $F[f(x), f(y_1), \ldots, f(y_{k-1}), x, y_1, \ldots, y_{k-1}] = 0,\ \forall x, y_1, \ldots, y_k$ be a k-total functional equation characterizing functions $f : \mathcal{D} \to \mathcal{R}$. Assume further that F can be solved for $f(x)$, namely, $f(x) = G[f(y_1), \ldots,\ f(y_{k-1}),\ x, y_1, \ldots, y_{k-1}]$ $\forall y_1, \ldots, y_{k-1}$ (because of the totality of the equation, F and G depend on $x, y_1, \ldots, y_{k-1}$ as well as the function values at those points). We say that the solution $\mathcal{F}$ to equation F is $(k-1)$-*complete* if $\forall((y_1, w_1), \ldots, (y_{k-1}, w_{k-1})) \in (\mathcal{D}, \mathcal{R})^{k-1},\ \exists f \in \mathcal{F}$ such that $f(y_i) = w_i$ for all $1 \leq i \leq k-1$. An example of a $(k-1)$-complete function family is the family of degree $(k-1)$ polynomials. The following theorem, which says that k-total functional equations that characterize $k-1$-complete function families are necessarily robust, can be viewed as a generalization of a known theorem for degree $(k-1)$ univariate polynomials (cf. [40]).

THEOREM 3.4. *Let $\mathcal{N} = \mathcal{D}^k$. Suppose the k-total functional equation $F[f(x), f(y_1), \ldots, f(y_{k-1}), x, y_1, \ldots, y_{k-1}] \equiv f(x) - G[f(y_1), \ldots, f(y_{k-1}), x,\ y_1, \ldots,\ y_{k-1}] = 0$*

$\forall x, y_1, \ldots, y_{k-1}$ *has a* $k-1$*-complete solution* $\mathcal{F}$*. Then* $(F, \mathcal{N})$ *is* (δ, δ)*-robust* $\forall 0 < \delta < 1$.

Proof. Suppose f satisfies $Pr_{x,\bar{y}}[f(x) = G[f(y_1), \ldots, f(y_{k-1}), x, y_1, \ldots, y_{k-1}]] \geq 1 - \delta$. Then there exists $z_1, \ldots, z_{k-1}$, a particular setting of the y_i's, such that the test works for $\geq 1 - \delta$ of the x's. Let $g(x)$ be the function in $\mathcal{F}$ determined by the values of the program at $z_1, \ldots, z_{k-1}$. Then $Pr_x[g(x) = f(x)] \geq 1 - \delta$. Thus $\forall x, y_1, \ldots, y_{k-1}\ g(x) - G[g(y_1), \ldots, g(y_{k-1}), x, y_1, \ldots, y_{k-1}] = 0$. □

Any function f that satisfies such a total functional equation F can be computed, given the value of the function at any fixed k locations, as efficiently as evaluating the functional equation G. Thus, if F and G have the same complexity, the functional equation is not useful for self-testing, since it does not have the "little-oh property" described in [18]. However, it is possible that more efficient self-testers can be constructed by looking at a smaller, carefully chosen, set of neighborhoods $\mathcal{N}$ and showing that the functional equation is still robust over $\mathcal{N}$. Given $\vec{\sigma} = (\sigma_1, \ldots, \sigma_{k-1})$, such that $\sigma_i : \mathcal{D} \times \mathcal{D}^{k-1} \to \mathcal{D}$, suppose functional equations $F[f(x), f(y_1), \ldots, f(y_{k-1}), x, y_1, \ldots, y_{k-1}] = 0\ \ \forall x, y_1, \ldots, y_{k-1}$, and $F[f(x), f(\sigma_1(x, \bar{z})), \ldots, f(\sigma_{k-1}(x, \bar{z})), x, \sigma_1(x, \bar{z}), \ldots, \sigma_{k-1}(x, \bar{z})] = 0\ \ \forall x, \bar{z}$ both have the same complete solution $\mathcal{F}$. Due to the structure of the σ's, it might be the case that F is easier to compute on those tuples defined by the σ's (for example, efficient polynomial degree tests have been constructed by only performing tests on points that are evenly spaced: $\sigma_i(x, z) = x + iz$ [38]). If F is also robust over random choices of $x, \bar{z}$, then a more efficient tester can be constructed.

We use a bound on the runtime of the program being tested to devise a tester. The works of Blum et al. [17] and Micali [35] also construct checkers based on bounds on the runtime of the program being checked but use very different methods. Let the distribution $\mathcal{V}_{\vec{\sigma}}$ be the distribution defined by picking $x \in \mathcal{D}, \bar{z} \in \mathcal{D}^{k-1}$ randomly, and outputting $(x, \sigma_1(x, \bar{z}), \ldots, \sigma_{k-1}(x, \bar{z}))$. Let $\mathcal{U}$ be the distribution defined by picking $x, y_1, \ldots, y_{k-1} \in \mathcal{D}$ and outputting $(x, y_1, \ldots, y_{k-1})$. If the σ's look "random enough," we have the following theorem showing a sense in which F is robust over random choices of $x, \bar{z}$. This theorem implies that it is enough to test points related by the σ's.

THEOREM 3.5. *Let* $Time(c) \equiv \{f | f$ *is computable on inputs of length* n *in time* $n^c\}$*. Let* c *be an arbitrary constant, and fix* $0 \leq \epsilon \leq 1$ *and* $0 \leq \delta \leq 1$*. Let* E_1 *denote the functional equation* $F[f(x), f(y_1), \ldots, f(y_{k-1}), x, y_1, \ldots, y_{k-1}] = 0\ \forall x \in \mathcal{D}, \bar{y} \in \mathcal{D}^{k-1}$*, and* E_2 *denote the functional equation* $F[f(x), f(\sigma_1(x, \bar{z})), \ldots, f(\sigma_{k-1}(x, \bar{z})), x, \sigma_1(x, \bar{z}), \ldots, \sigma_{k-1}(x, \bar{z})] = 0\ \forall x \in \mathcal{D}, \bar{z} \in \mathcal{D}^{k-1}$*. Assume that*

1. E_1 *and* E_2 *have the same complete solution* $\mathcal{F}$*,*
2. F *can be computed by a circuit of size* $(\log |\mathcal{D}|)^c$*,*
3. *no circuit of size* $\leq (k+1)(\log |\mathcal{D}|)^c$ *can distinguish inputs from* $\mathcal{V}_{\vec{\sigma}}$ *and* $\mathcal{U}$ *with more than* δ *advantage,*
4. E_1 *is* $(\epsilon, 2\delta)$*-robust.*

Then E_2 *can be used to test all programs running in time* $(\log |\mathcal{D}|)^c$*: if* $Pr_{x,R}[F[P(x), P(\sigma_1(x, \bar{z})), \ldots, P(\sigma_{k-1}(x, \bar{z})), x, \sigma_1(x, \bar{z}), \ldots, \sigma_{k-1}(x, \bar{z})] = 0] \geq 1 - \delta$*, and* P *runs in* $\leq (\log |\mathcal{D}|)^c$ *steps, then there is a* $f \in \mathcal{F}$ *such that* $Pr_x[P(x) = f(x)] \geq 1 - \epsilon$*. Thus,* $(\mathcal{F}, \mathcal{D}^k)$ *is an* (ϵ, δ)*-robust characterization of* $\mathcal{F}$ *in* $Time(c)$*.*

Proof. Suppose that there exists some program P running in time $(\log |\mathcal{D}|)^c$ which is wrong at $\geq \epsilon$ inputs in $\mathcal{D}$ but passes the tester with probability $> 1 - \delta$. We use it to construct a program $\mathcal{A}$ of size $\leq (k+1)(\log |\mathcal{D}|)^c$ that can distinguish between outputs from distributions $\mathcal{V}$ and $\mathcal{U}$ with more than δ advantage (which contradicts (3)). $\mathcal{A}$ re-

ceives $w, z_1, \ldots, z_{k-1}$, and tests whether $F[P(x),P(z_1),\ldots,P(z_{k-1}),x,z_1,\ldots,z_{k-1}] = 0$. $\mathcal{A}$ outputs 1 if P passes the test and 0 if P fails. By Theorem 3.4, $Pr_{x,y_1,\ldots,y_{k-1}\in\mathcal{U}}[F[P(x),\ P(y_1),\ \ldots,\ P(y_{k-1}),\ x,\ y_1,\ \ldots,\ y_{k-1}] \neq 0] \geq 2\delta$, and by the assumption, $Pr_{x,y_1,\ldots,y_{k-1}\in\mathcal{V}}[F[P(x),\ P(y_1),\ldots,\ P(y_{k-1}),\ x,\ y_1,\ldots,y_{k-1}] \neq 0] < \delta$. □

4. Robustness of $\forall x, y,\ F[f(x-y), f(x+y), f(x), f(y)] = 0$. We study conditions under which any member of the general class of functional equation $\forall x,\ y\ F[f(x-y), f(x+y), f(x), f(y)] = 0$ is robust. We show that addition theorems $\forall x, y\ f(x+y) = G[f(x), f(y)]$ for which G satisfies $G[a, G[b,c]] = G[G[a,b],c]\ \forall a, b, c$ (which all of our examples satisfy) are robust over the class $\mathcal{S}$, such that the domains in $\mathcal{S}$ are finite groups, and then we give a technique which applies to a number of functional equations that are not addition theorems. Our techniques apply to all functional equations in Table 1.1 as well as the first three functional equations in Table 1.2. We conjecture that all functional equations in this class are robust.

All results can be extended to rational domains of the form $\mathcal{D}_{p,s} = \{\frac{i}{s} \big| |i| \leq p\}$ using standard techniques from [31], [37]. We give an example of such an extension in section 6. Our only assumption on $\mathcal{R}$ in subsection 4.1 is that it is a (possibly infinite) group. In subsection 4.2 we assume that $\mathcal{R}$ is a field.

4.1. Addition theorems. We show that any addition property $\forall x, y\ \ f(x+y) = G[f(x), f(y)]$ is $(2\delta, \delta)$-robust for $\delta < \frac{1}{8}$ and G that satisfies $G[a, G[b,c]] = G[G[a,b],c]\ \forall a, b, c$ (we do not attempt to optimize the relationship between ϵ and δ in our proofs of (ϵ, δ)-robustness—see [13], [26], and [11] for techniques for improving this relationship). Therefore, knowing that $f(x+y) = G[f(x), f(y)]$ holds at more than a $\frac{7}{8}$ fraction of the (x, y) pairs is enough to conclude that f agrees with some solution of the addition theorem G on at least $\frac{3}{4}$ fraction of the inputs. One can verify that G satisfies $G[a, G[b,c]] = G[G[a,b],c]\ \forall a, b, c$ in all of the examples given in Table 1.1.

At the end of this subsection, we consider the requirement that $G[a, G[b,c]] = G[G[a,b],c]\ \forall a, b, c$. We show that that if the domain is a subset of a field, such that rational functions are defined (a function $f(x,y) = p(x,y)/q(x,y)$ where p, q are polynomials), then we can make a general claim for any constant degree rational function G that is based on the number of zeros that a rational function can have. Similar results that apply to algebraic functions can be proven for domains over which algebraic functions are defined (see [46]).

We now show that any additional theorem satisfying $\forall a, b, c\ \ G[a, G[b,c]] = G[G[a,b],c]$ is robust. This proof follows an outline similar to Coppersmith's version of the proof of robustness of the linearity test which is described in [19]. However, the inner manipulations are different. Hence, whereas Coppersmith's proof works for any $\delta \leq \frac{2}{9}$, here we require $\delta \leq \frac{1}{8}$.

THEOREM 4.1. *Let $\mathcal{D} = \mathcal{D}'$ be a finite group and $\mathcal{R} = \mathcal{T}$ a group. Let $\mathcal{N}^{\text{add}} = \{(x, y, x+y) | x, y \in \mathcal{D}\}$. Let G be such that G satisfies $\forall a, b, c \in \mathcal{R}\ \ G[a, G[b,c]] = G[G[a,b],c]$. Let $F(x_1, x_2, x_3) = f(x_3) - G[f(x_1), f(x_2)]$ on neighborhoods $(x_1, x_2, x_3) \in \mathcal{N}^{\text{add}}$. Then for all $\delta < \frac{1}{8}$, $(F, \mathcal{N}^{\text{add}})$ is $(2\delta, \delta)$-robust. Letting $\mathcal{S}$ be a class such that $\mathcal{D}_i = \mathcal{D}_i'$ are finite groups and $\mathcal{R}_i = \mathcal{T}_i$ are groups, then since for all $\epsilon < \frac{1}{4}$, $(F, \mathcal{N}^{\text{add}})$ is $(\epsilon, \frac{\epsilon}{2})$-robust, $(F, \mathcal{N}^{\text{add}})$ is robust over $\mathcal{S}$.*

Proof of Theorem 4.1. To prove the theorem, we will show that if $Pr_{x,y\in_R\mathcal{D}}[f(x+y) = G[f(x), f(y)]] \geq 1 - \delta$, for $\delta < \frac{1}{8}$, then there exists a function g such that (1) $Pr_{x\in_R\mathcal{D}}[f(x) = g(x)] \geq 1 - 2\delta$ and (2) $\forall x, y\ \ g(x+y) = G[g(x), g(y)]$. □

Define $g(x)$ to be $\text{maj}_{z\in\mathcal{D}}\{G(f(x-z), f(z))\}$, where maj of a set is the function

that picks the element occurring most often (choosing arbitrarily in the case of ties). We first show that g is 2δ-close to f.

LEMMA 4.2. *g and f agree on more than $1-2\delta$ fraction of the inputs from $\mathcal{D}$.*

Proof. Consider the set of elements x such that $\Pr_z[f(x) = G[f(x-z), f(z)]] < \frac{1}{2}$. If the fraction of such elements is more than 2δ, then it contradicts the condition that $\Pr_{x,y}[f(x+y) = 0G[f(x),\ f(y)\ ]\ ] \geq 1 - \delta$. For all remaining elements, $f(x) = g(x)$. □

Next we show a sense in which g is well-defined.

LEMMA 4.3. *For all x, $\Pr_z[g(x) = G[f(x-z), f(z)]] \geq 1 - 2\delta$.*

Proof.[7]

$$\begin{aligned}\Pr_{y,z}\big[G[f(x-y), f(y)]\big] &= G[G[f(x-y-z), f(z)], f(y)] \\ &= G[f(x-y-z), G[f(z), f(y)]] \\ &= G[f(x-(y+z)), f(y+z)]] \qquad \geq 1-2\delta.\end{aligned}$$

The first and third equality hold with probability $1-\delta$ by our assumption on f and since $x-y, y, z, x-y-z, z+y$ are all uniformly distributed in $\mathcal{D}$. The second equality always holds since $G[a, G[b,c]] = G[G[a,b],c]\ \forall a,b,c$.

The lemma now follows from the well-known fact that the probability that the same object is drawn twice from a set in two independent trials lower bounds the probability of drawing the most likely object in one trial: suppose the objects are ordered so that p_i is the probability of drawing object i. Without loss of generality $p_1 \geq p_2 \geq \cdots$. Then the probability of drawing the same object twice is $\sum_i p_i^2 \leq \sum_i p_1 p_i = p_1$. □

Finally, we prove that g satisfies the addition theorem everywhere.

LEMMA 4.4. *For all x, y, $g(x+y) = G[g(x), g(y)]$.*

Proof.

$$\begin{aligned}\Pr_{u,v}\big[G[g(x), g(y)]\big] &= G[G[f(u), f(x-u)], G[f(v), f(y-v)]] \\ &= G[f(u), G[f(x-u), G[f(v), f(y-v)]]] \\ &= G[f(u), G[G[f(x-u), f(v)], f(y-v)]] \\ &= G[f(u), G[f(x-u+v), f(y-v)]] \\ &= G[f(u), f(x+y-u)] \\ &= g(x+y)\big] \\ &> 1 - 8\delta > 0.\end{aligned}$$

By Lemma 4.3, the first equality holds with probability $1-4\delta$ and the last equality holds with probability $1-2\delta$. By the assumption on f, the fourth and fifth equalities each hold with probability $1-\delta$. The other equalities always hold, since $G[a, G[b,c]] = G[G[a,b],c]\ \forall a,b,c$. Since the statement is independent of u, v and holds with positive probability, it must hold with probability 1. This also proves Theorem 4.1. □

4.1.1. Addition theorems that satisfy $G[a, G[b,c]] = G[G[a,b],c]\ \forall a,b,c$. If the domain is a large enough subset of a field, such that rational functions are defined (a function $f(x,y) = p(x,y)/q(x,y)$ where p, q are polynomials), and if G is a rational function such that the numerator has bounded degree, then one can show that G satisfies $G[a, G[b,c]] = G[G[a,b],c]\ \forall a,b,c$.

[7] For conciseness, we use a somewhat nonstandard notation: for random variables a, b, c, we reason about the probability that $a = c$ by using an intermediate variable b, using $Pr[a=c] \geq Pr[a=b=c] \geq 1 - Pr[a \neq b] - Pr[b \neq c]$.

THEOREM 4.5. *Let G be a constant degree rational function such that the degree in each variable of the numerator of the rational function $H(a,b,c) \equiv G[a,G[b,c]] - G[G[a,b],c]$ is bounded by N. Assume that G is such that one of the solutions f to the functional equation $\forall x,y \;\; f(x+y) = G[f(x),f(y)]$ takes on at least $(N+1)^3$ values (in particular, $|\mathcal{R}| > (N+1)^3$). Then G satisfies $G[a,G[b,c]] = G[G[a,b],c]$ $\forall a,b,c \in \mathcal{R}$.*

Proof. Since H is a rational function, it will suffice to show that H evaluates to 0 on many inputs and therefore must be identically 0. The inputs for which we show that H evaluates to 0 will correspond to outputs of functions f that satisfy the addition theorem at all x,y.

Given any function f satisfying $\forall x,y \;\; f(x+y) = G[f(x),f(y)]$, since $\mathcal{D}$ is associative we have that $f(x+y+z) = G[f(x),f(y+z)] = G[f(x+y),f(z)]$, and so $G[f(x),G[f(y),f(z)]] = G[G[f(x),f(y)],f(z)]$.

Suppose that there exists a solution f of $f(x+y) = G[f(x),f(y)]$ that takes on at least N^3 distinct values $V = \{v_1,\ldots,v_{N^3}\}$. Since $\forall a,b,c \in V,\; H(a,b,c) = 0$, we know that $H(a,b,c) \equiv 0$ [47]. □

4.2. d'Alembert's equation and others. In this section, we show that the robustness of functional equations of the form $\forall x,y \;\; F[f(x-y),f(x+y),f(x),f(y)] = 0$, is not limited to addition theorems by showing that when the domain $\mathcal{D}$ is a finite group, and the range $\mathcal{R} = \mathcal{T}$ is a field containing 2, d'Alembert's equation $\forall x,y \;\; f(x+y) + f(x-y) = 2f(x)f(y)$ is a robust property on $\mathcal{G} = \{f | Pr_{x\in\mathcal{D}}[f(x) = 0] \leq \frac{1}{20}\}$. Since membership in $\mathcal{G}$ is easy to test, these robustness results lead to self-testers as described later. The techniques in this section can also be used to show that the equations $\forall x,y \;\; f(x+y)+f(x-y) = 2[f(x)+f(y)]$ and $\forall x,y \;\; f(x+y)+f(x-y) = 2f(x)$ are robust over $\mathcal{G}$.

This result does not allow us to test functions that are in $\mathcal{F}$ but not in $\mathcal{G}$ such as the 0-function. For carefully chosen domains, other functions that are solutions to these functional equations (see Table 1.2) can also take the value 0 on more than $\frac{1}{20}$ fraction of the domain: for example, $\cos x$ takes the value 0 on half of the domain $\mathcal{D} = \{i \cdot \pi/2 | 0 \leq i \leq 3\}$. The result can still be used to construct self-testers for functions satisfying d'Alembert's equation. We discuss this further in section 5.

For the following three robustness results, let $\mathcal{N}^{\text{d'Alembert}} = \{(x,y,x+y,x-y) | x,y \in \mathcal{D}\}$.

THEOREM 4.6. *Let $F(x_1,x_2,x_3,x_4) = 2f(x_1)\cdot f(x_2) - f(x_3) - f(x_4)$. Let $\mathcal{F}$ be the function family characterized by $(F,\mathcal{N}^{\text{d'Alembert}})$. Then for $\delta \geq \frac{1}{80}$, $(F,\mathcal{N}^{\text{d'Alembert}})$ is a $(4\delta,\delta)$-robust characterization of $\mathcal{F}$ in $\mathcal{G}$. In particular, if $Pr_{x,y}[f(x+y)+f(x-y) = 2f(x)f(y)] \geq 1-\delta \geq \frac{79}{80}$ and $f \in \mathcal{G}$, then the function $g(x) \equiv \text{maj}_{y\in\mathcal{D},\; f(y)\neq 0}\{\frac{f(x+y)+f(x-y)}{2f(y)}\}$ satisfies (1) $Pr_x[f(x) = g(x)] \geq 1-4\delta$ and (2) $\forall x,y \;\; g(x+y) + g(x-y) = 2g(x)g(y)$.*

THEOREM 4.7. *Let $F(x_1,x_2,x_3,x_4) = 2f(x_1)+2f(x_2)-f(x_3)-f(x_4)$. Let $\mathcal{F}$ be the function family characterized by $(F,\mathcal{N}^{\text{d'Alembert}})$. Then for $\delta \geq \frac{1}{80}$, $(F,\mathcal{N}^{\text{d'Alembert}})$ is a $(4\delta,\delta)$-robust characterization of $\mathcal{F}$ in $\mathcal{G}$. In particular, if $Pr_{x,y}[f(x+y) + f(x-y) = 2(f(x)+f(y))] \geq 1-\delta \geq \frac{79}{80}$ and $f \in \mathcal{G}$, then the function $g(x) \equiv \text{maj}_{y\in\mathcal{D},\; f(y)\neq 0}\{\frac{f(x+y)+f(x-y)}{2} - f(y)\}$ satisfies (1) $Pr_x[f(x) = g(x)] \geq 1-4\delta$ and (2) $\forall x,y \;\; g(x+y) + g(x-y) = 2(g(x)+g(y))$.*

THEOREM 4.8. *Let $F(x_1,x_2,x_3,x_4) = 2f(x_1) - f(x_3) - f(x_4)$. Let $\mathcal{F}$ be the function family characterized by $(F,\mathcal{N}^{\text{d'Alembert}})$. Then for $\delta \geq \frac{1}{80}$, $(F,\mathcal{N}^{\text{d'Alembert}})$ is a $(4\delta,\delta)$-robust characterization of $\mathcal{F}$ in $\mathcal{G}$. In particular, if $Pr_{x,y}[f(x+y)+f(x-y) = 2f(x)] \geq 1-\delta \geq \frac{79}{80}$ and $f \in \mathcal{G}$, then the function $g(x) \equiv \text{maj}_{y\in\mathcal{D},\; f(y)\neq 0}\{\frac{f(x+y)+f(x-y)}{2}\}$*

satisfies (1) $Pr_x[f(x) = g(x)] \geq 1 - 4\delta$ *and* (2) $\forall x, y \;\; g(x+y) + g(x-y) = 2g(x)$.

The proofs in this section are similar in flavor to the proofs of the robustness of the addition theorems, but since the functional equation is defined on inputs that are related in different ways, we have to take advantage of different aspects of the structure of their relationship in order to get the desired results. The proofs of all three theorems follow the same outline. In the following, we give the proof of Theorem 4.6.

Proof of Theorem 4.6. Using techniques identical to those in Lemma 4.2, we have the following lemma.

LEMMA 4.9. *g and f agree on more than $1 - 4\delta$ fraction of the inputs from $\mathcal{D}$.*

LEMMA 4.10. *For all x, $\Pr_y[g(x) = \frac{f(x+y)+f(x-y)}{2f(y)}] \geq 1-\delta'$ where $\delta' = 4\delta+2\cdot\frac{1}{20}$.*

Proof. $\Pr_{y,z}[f(y) \neq 0$ *and* $f(z) \neq 0$ *and*

$$\begin{aligned} 2f(z)(f(x+y) + f(x-y)) & \\ &= (f(x+y+z) + f(x+y-z)) \\ &\quad +(f(x-y-z) + f(x-y+z)) \\ &= (f(x+y+z) + f(x-y+z)) \\ &\quad +(f(x-y-z) + f(x+y-z)) \\ &= 2f(y)(f(x+z) + f(x-z))] \\ &\geq 1 - 4\delta - 2 \cdot \tfrac{1}{20}. \end{aligned}$$

$f(y) = 0$ or $f(z) = 0$ with probability at most $2 \cdot \frac{1}{20}$. The first and third equalities each hold with probability $1 - 2\delta$ by our assumption on f and since all the references to f are uniformly distributed in $\mathcal{D}$. The second equality always holds. If $f(y), f(z)$ are both nonzero and all equalities hold, then $\frac{f(x+y)+f(x-y)}{2f(y)} = \frac{f(x+z)+f(x-z)}{2f(z)}$. The lemma now follows from the fact that the probability that the same object is drawn twice from a set in two independent trials lower bounds the probability of drawing the most likely object in one trial. □

Finally, we can prove that g satisfies d'Alembert's equation everywhere.

LEMMA 4.11. *For all x, y, $2g(x)g(y) = g(x+y) + g(x-y)$.*

Proof.

$$\begin{aligned} \Pr_z \big[f(z) \neq 0 \text{ and } & f(z) \cdot (g(x+y) + g(x-y)) \\ &= \tfrac{f(x+y+z)+f(x+y-z)+f(x-y+z)+f(x-y-z)}{2} \\ &= \tfrac{2g(x)f(y+z)+2g(x)f(y-z)}{2} \\ &= 2g(x) \cdot g(y) \cdot f(z)\big] \\ &> 1 - 5\delta' - \tfrac{1}{20} > 0. \end{aligned}$$

$f(z) = 0$ with probability at most $\frac{1}{20}$. By Lemma 4.10, the first, second, and third equalities hold with probability $1 - 2\delta'$, $1 - 2\delta'$, and $1 - \delta'$, respectively. If $f(z) \neq 0$ and all equalities hold, then $2g(x)g(y) = g(x+y) + g(x-y)$. Since the statement is independent of z and holds with positive probability, it must hold with probability 1. □

5. Self-testing/correcting from functional equations. We give informal definitions of self-testers and self-correctors. Formal definitions are given in [19]. An (ϵ_1, ϵ_2)-*self-tester* $(0 \leq \epsilon_1 < \epsilon_2)$ for f on D must fail any program that is not $(1-\epsilon_2)$-close to f on D and must pass any program that is $(1 - \epsilon_1)$-close to f on D (the behavior of the tester is not specified for programs that are $(1 - \epsilon_2)$-close but not $(1 - \epsilon_1)$-close to f). The tester should satisfy these conditions with error probability at most β, where β is a confidence parameter input by the user. For simplicity, we

assume that $\epsilon_1 = 0$, and we drop that parameter from our claims. An *ϵ-self-corrector* for f on D is an algorithm C that uses program P as a black box, such that for every $x \in D$ and β, $\Pr[C^P(x) = f(x)] \geq 1 - \beta$ for *every* P which is $(1-\epsilon)$-close to f on D. Furthermore, all require only a small multiplicative overhead over the running time of P and are different, simpler, and faster than any correct program for f in a precise sense defined in [18]. Checkers can be constructed by finding both a self-tester and a self-corrector for the function [19].

In this section, we give self-correctors and self-testers that are based on the class of functional equations of the form $F[f(x-y), f(x+y), f(x), f(y)] = 0$. We will use the robustness theorems proved earlier for the self-testers but not for the self-correctors. We refer to the function computed by the program as P, and the correct function as $f : \mathcal{D} \to \mathcal{R}$. For purposes of exposition, we assume that $\mathcal{D}$ is a finite group. All results can be extended to rational domains of the form $\mathcal{D}_{p,s} = \{\frac{i}{s} \big| |i| \leq p\}$ using known techniques from [31], [37] (see section 6). We assume that $\mathcal{R}$ is an (possibly infinite) abelian group.

5.1. Self-correctors. The following self-corrector works for any function satisfying $\forall x, y \quad f(x) = G[f(x-y), f(x+y), f(y)]$. This includes functions satisfying an addition theorem of the form $f(x+y) = G[f(x), f(y)]$, since letting $z = x + y$, $f(z) = G[f(z-y), f(y)]$. Self-correctors for functions that are not solvable for $f(x)$, but are solvable for another of $f(x-y), f(x+y), f(y)$ can be similarly constructed.

Program self-correct(x, β)

$N \leftarrow O(\ln(1/\beta))$
Do for $m = 1, \ldots, N$
  Pick $y \in_R \mathcal{D}$
  $answer_m \leftarrow G[P(x-y), P(x+y), P(y)]$
Output the most common answer in $\{answer_m : m = 1, \ldots, N\}$

THEOREM 5.1. *Given $\mathcal{D}$ a finite group, and P and f functions over domain $\mathcal{D}$. If P is $\frac{1}{12}$-close to f over $\mathcal{D}$, then $\forall x$, Pr*[Self-Correct$(x, \beta) = f(x)] \geq 1 - \beta$.

The proof of this theorem follows the format in [19] and is based on the fact that since calls to P are made on uniformly distributed inputs in $\mathcal{D}$, at each iteration, all calls are answered correctly by P with probability at least $\frac{3}{4}$.

The existence of an ϵ-self-corrector for a class of functions $\mathcal{F}$ trivially implies that for any two functions $f_1, f_2 \in \mathcal{F}$, the quantity $Pr_x[f_1(x) \neq f_2(x)]$, or the *distance* between f_1 and f_2, must be large. Thus, the existence of self-correctors for $\mathcal{F}$ implies that the functions in $\mathcal{F}$ can be thought of as a collection of codewords with large distance.

5.2. Self-testers. In this section we show self-testers based on robust functional equations of the form $F[f(x-y), f(x+y), f(x), f(y)] = 0$. In all of our examples only a constant number of additions and multiplications are required to perform a test. Furthermore, only a constant number of tests need to be performed. It often happens that more than one functional equation can be used to specify a function family; the user can determine which of the robust functional equations is best to use for testing based on criteria such as efficiency and ease of programming.

When a family of functions satisfies the property, equality testing must be done to determine that the program is computing the correct function within the family. Although equality testing is often easier than the original testing task, it may still be inefficient, as in the case of multivariate polynomials [38]. For the functions considered in this paper, the problem of equality testing can be solved efficiently. We assume that

the function values are given at a constant number of inputs, such that these values in conjuction with the property F are enough to completely specify the function. For example, for functions satisfying addition theorems, the function values at 0 and all generators of the group suffice to completely specify the function. In particular, if the group is cyclic and generated by 1, only $f(0)$ and $f(1)$ are required since $f(x+1) = G[f(x), f(1)]$. Similarly, over $\mathcal{D}_{p,s}$ it is enough to specify the function at $0, \frac{1}{s}, \frac{-1}{s}$. It is often the case that there are certain inputs at which the function is much easier to compute and that these inputs can be used for the equality testing.

It may happen that the functional equation over the reals characterizes a different family of functions than the same functional equation over $\mathcal{D}_{p,s}$. For example, suppose we are given $\mathcal{F}$, a set of functions that is a solution to the functional equation over the reals. The set of functions that we are interested in testing is $\mathcal{F}' = \{g \mid g : \mathcal{D}_{p,s} \to \mathcal{R}, \exists f \in \mathcal{F}$ such that $\forall x \in \mathcal{D}_{p,s}, f(x) = g(x)\}$, the set of functions that are restrictions of functions in $\mathcal{F}$ to the domain $\mathcal{D}_{p,s}$. Consider also $\mathcal{F}''$, the solutions to the functional equation over $\mathcal{D}_{p,s}$. Then, since functions in $\mathcal{F}''$ must satisfy a subset of the constraints satisfied by $\mathcal{F}'$, $\mathcal{F}' \subseteq \mathcal{F}''$. It can happen that $\mathcal{F}'$ is a proper subset of $\mathcal{F}''$. Nevertheless, to test that a program purporting to compute function $f \in \mathcal{F}'$ is correct, the property test determines whether the program agrees on most inputs with some function g in $\mathcal{F}''$, and the equality test will then determine that $g = f$ as long as it is given the correct values of f at the inputs required for the equality test.

We concentrate on functions that can be tested by testers of the form given below. In the following, δ_0 is the maximum δ for which the functional equation is robust (see Theorems 4.1, 4.6, 4.7, 4.8), and the function values specifying f are given as a list $(x_i, y_i), 0 \le i \le c$ where $y_i = f(x_i)$.

Program self-test$((x_0, y_0), (x_1, y_1), \ldots, (x_c, y_c), \delta_0, \beta)$

$N \leftarrow O(\max\{\frac{1}{\delta_0}, 24\} \ln(2/\beta))$
Do for $m = 1, \ldots, N$ {*Property Test*}
  Pick $u, v \in_R \mathcal{D}$
  if $F[P(u-v), P(u+v), P(u), P(v)] \neq 0$ output FAIL and halt
Do for $i = 1, \ldots, c$ {*Equality Test*}
  If self-correct$(x_i, \beta/c) \neq y_i$ output FAIL and halt
Output PASS

THEOREM 5.2. *Given domain $\mathcal{D}$ a finite group, range $\mathcal{R}$ an abelian group, and functions P and f mapping $\mathcal{D}$ to $\mathcal{R}$. If F is $(2\delta, \delta)$-robust over domain $\mathcal{D}$, and if P is not $(\frac{1}{12})$-close to f on $\mathcal{D}$, then Pr[Self-Test$(x, \beta) =$ FAIL$] \ge 1 - \beta$. If $P \equiv f$, then Self-Test outputs PASS. Thus, Self-Test is a $\frac{1}{12}$-self-testing program for f on $\mathcal{D}$.*

The proof of the theorem is based on the robustness of F, which tells us that if there is no function g such that (1) g is usually equal to P and (2) g satisfies the property everywhere, then P is reasonably likely to fail the test. Furthermore, if there is such a function g, the equality tests are likely to fail unless $g(x_0) = f(x_0), \ldots, g(x_c) = f(x_c)$ which ensures that $g \equiv f$. Thus P fails unless it is usually equal to f. It is easy to see that by altering the choice of N, one can construct ϵ-self-testers for any $\epsilon < \frac{1}{12}$.

The above self-tester is not sufficient for testing functions using d'Alembert's equation, since we have proved its robustness only under the condition that the function P is 0 on $\le \frac{1}{20}$ of the inputs. To fix this, one may use an algorithm that depends on the fraction of inputs on which f takes the value 0. The solution to d'Alembert's equation over $\Re$ is all functions of the form $0, \cos Ax, \cosh Ax$. The 0 function is trivial to test. The $\cosh Ax$ functions are never 0, so a program purporting to compute $\cosh Ax$ can

be first tested to ensure that it does not output 0 on more than $\frac{1}{20}$ of the domain, and then the above tester may be used. The $\cos Ax$ functions are 0 only at odd multiples of $\frac{\pi}{(2A)}$. If the odd multiples of $\frac{\pi}{(2A)}$ constitute at most $\frac{1}{20}$ of the domain, then a similar procedure to the one for $\cosh Ax$ may be used. Otherwise one can use a different functional equation for which $\cos Ax$ is a solution. Alternatively, suppose the program can be modified to compute over a larger domain $\hat{\mathcal{D}}$ which contains $\mathcal{D}$ such that $f(x) = 0$ on at most $\frac{1}{20}$ of $\hat{\mathcal{D}}$. (For example, if $f(x) = \cos x, \mathcal{D} = \{i \cdot \pi/2 | 0 \leq i \leq p-1\}$, then choose $\hat{\mathcal{D}} = \{i \cdot \pi/20 | 0 \leq i \leq 10p-1\}$.) Then one can test the program over $\hat{\mathcal{D}}$. If the program passes the test, it is possible to test the program on $\mathcal{D}$ by using the self-corrector based on d'Alembert's equation to correctly compute f at any input in $\mathcal{D} \subseteq \hat{\mathcal{D}}$.

6. Extensions to rational domains. In this section, we show the self-testers and self-correctors that result from extending the results in section 5 to rational domains. We consider rational domains of the form $\mathcal{D}_{n,s} = \{\frac{i}{s} \big| \ |i| \leq n\}$.

The theorems follow the same outline as in the finite fields case, but certain additional technical details must be addressed. These technical details are similar to those used in [31], [38].

6.1. Self-correctors. The following self-corrector works for any function satisfying $\forall x, y \ \ f(x) = G[f(x-y), f(x+y), f(y)]$. Self-correctors for functions that are not solvable for $f(x)$, but are solvable for another of $f(x-y), f(x+y), f(y)$ can be similarly constructed.

As in [31], we assume that the program has been tested over a larger domain $\mathcal{D}_{m,s}$ in order to self-correct over the domain $\mathcal{D}_{n,s}$ (this requires the more general definitions of self-correcting given in [31]). It suffices that $m > 12n$.

Program self-correct(x, β)

$N \leftarrow O(\ln(1/\beta))$
Do for $i = 1, \ldots, N$
  Pick $y \in_R \mathcal{D}_{m,s}$
  $answer_i \leftarrow G[P(x-y), P(x+y), P(y)]$
Output the most common answer in $\{answer_i : i = 1, \ldots, N\}$

THEOREM 6.1. *Let m, n be such that $m > 12n$. If P is $(\frac{1}{24})$-close to f over $\mathcal{D}_{m,s}$, then $\forall x \in \mathcal{D}_{n,s}$, $Pr[\text{Self-Correct}(x, \beta) = f(x)] \geq 1 - \beta$.*

The proof of this theorem follows the format in [31].

Proof of Theorem 6.1. By the assumption on P, $P(y)$ is correct with probability at least $1 - \frac{1}{24}$. Two bad events can happen when picking $x + y$: either $x + y$ is not in $\mathcal{D}_{m,s}$ in which case we know nothing about the probability that $P(x+y)$ is correct, or $x + y$ is in $\mathcal{D}_{m,s}$ but happens to be one of the inputs for which P is incorrect. By our choice of m, the first bad situation happens with probability $\leq \frac{1}{24}$. The second bad situation happens with probability $\leq \frac{1}{24}$. If neither of these happens, then $P(x+y) = f(x+y)$. The same argument can be made for $P(x-y)$. Thus, at each iteration, $answer_i = f(x)$ with probability at least $1 - 2\frac{1}{24} - 3\frac{1}{24} > \frac{3}{4}$. □

6.2. Self-testers. The following is a self-tester for addition theorems over the rational domain $\mathcal{D}_{m,s}$. We test the program over a larger domain $\mathcal{D}_{p,s}$ in order to certify that it is usually correct over $\mathcal{D}_{m,s}$. It suffices that $p > 11m$. As in section 5.2, we assume the function values specifying f are given as a list of pairs $(x_i, y_i), 0 \leq i \leq c$ where $y_i = f(x_i)$. In addition we assume that $x_i \in \mathcal{D}_{n,s}$ for all i.

The self-tester is based on finding a neighborhood $\mathcal{N}^{\text{add}'}{}_{\mathcal{D}_{p,s}}$ such that $(\mathcal{D}_{m,s}, F_{\mathcal{D}_{p,s},\Re,\Re}, \mathcal{N}^{\text{add}'}{}_{\mathcal{D}_{p,s}})$ is an $(\epsilon, \epsilon/2)$-robust characterization.

Program self-test$((x_0, y_0), (x_1, y_1), \ldots, (x_c, y_c), n, m, \delta_0, \beta)$

$N \leftarrow O(\max\{\frac{4}{\delta_0}, 48\} \ln(2/\beta))$
{*Property Test*}
Do for $m = 1, \ldots, N$
  Choose $i \in \{1, 2, 3, 4\}$
  If $i = 1$ then $\{x_1 \leftarrow x, x_2 \leftarrow x - y, x_3 \leftarrow y\}$
   Pick $x \in_R \mathcal{D}_{m,s}$ and $y \in_R \mathcal{D}_{p,s}$
     if $P(x) \neq G[P(x - y), P(y)]$ output FAIL and halt
  Else if $i = 2$ then $\{x_1 \leftarrow x, x_2 \leftarrow x - y, x_3 \leftarrow y\}$
   Pick $x, y \in_R \mathcal{D}_{p,s}$
     if $P(x) \neq G[P(x - y), P(y)]$ output FAIL and halt
  Else if $i = 3$ then $\{x_1 \leftarrow x + y, x_2 \leftarrow x, x_3 \leftarrow y\}$
   Pick $x, y \in_R \mathcal{D}_{p,s}$
     if $P(x + y) \neq G[P(x), P(y)]$ output FAIL and halt
  Else $\{i = 4\}$ $\{x_1 \leftarrow x, x_2 \leftarrow y, x_3 \leftarrow x - y\}$
   Pick $x, y \in_R \mathcal{D}_{p,s}$
     if $P(x) \neq G[P(y), P(x - y)]$ output FAIL and halt
{*Equality Test*}
Do for $i = 1, \ldots, c$
  If self-correct$(x_i, \beta/c) \neq y_i$ output FAIL and halt
Output PASS

We have the following theorem.

THEOREM 6.2. *Let p, m, n be such that $p > 11m$ and $m > 12n$. Let the function values (x_i, y_i) specifying f be such that $x_i \in \mathcal{D}_{n,s}$. If P is not $\frac{1}{24}$-close to f on $\mathcal{D}_{m,s}$, then Pr[Self-Test(x, β) = FAIL] $\geq 1 - \beta$. If $P \equiv f$, then Self-Test outputs PASS. Thus, Self-Test is a $\frac{1}{24}$-self-testing program for f on $\mathcal{D}_{m,s}$.*

In order to show the above theorem, we need the following to show that the addition theorems are robust properties over rational domains.

LEMMA 6.3. *If (1) $Pr_{x \in \mathcal{D}_{m,s}, y \in \mathcal{D}_{p,s}}[P(x + y) = G[P(x), P(y)]] \geq 1 - \delta$, (2) $Pr_{x,y \in \mathcal{D}_{p,s}}[P(x) = G[P(x-y), P(y)]] \geq 1-\delta$, (3) $Pr_{x,y \in \mathcal{D}_{p,s}}[P(x+y) = G[P(x), P(y)]] \geq 1 - \delta$, (4) $Pr_{x,y \in \mathcal{D}_{p,s}}[P(x) = G[P(y), P(x - y)]] \geq 1 - \delta$, for $\delta < \frac{1}{48}$, then there exists a function g such that*

1. $Pr_{x \in \mathcal{D}_{m,s}}[P(x) = g(x)] \geq 1 - 2\delta = 1 - \frac{1}{24}$,
2. $\forall x, y \in \mathcal{D}_{m,s}$ $g(x + y) = G[g(x), g(y)]$.

Let $\mathcal{N}^{\text{add}'}$ be the multiset such that picking random $(x_1, x_2, x_3) \in \mathcal{N}^{\text{add}'}$ is the same as picking inputs from the above distribution. If the functional equation is satisfied with probability at least $1 - \frac{\delta}{4}$ when neighborhoods are chosen from $\mathcal{N}^{\text{add}'}$, then each of the four conditions of the theorem are met. Thus we have the following theorem.

THEOREM 6.4. *Let $\mathcal{R} = \mathcal{T}$ be a group. Let G be such that G satisfies $\forall a, b, c \in \mathcal{R}$ $G[a, G[b, c]] = G[G[a, b], c]$. Let $F(x, y) = P(x + y) - G[P(x), P(y)]$. Then for all $\delta < \frac{1}{48}$, $(\mathcal{D}_{m,s}, F_{\mathcal{D}_{p,s},\mathcal{R},\mathcal{T}}, \mathcal{N}^{\text{add}'}{}_{\mathcal{D}_{p,s}})$ is $(2\delta, \frac{\delta}{4})$-robust.*

Proof of Lemma 6.3. Define $g(x)$ to be $\text{maj}_{z \in \mathcal{D}_{p,s}}\{G(P(x - z), P(z))\}$.

The Lemma 6.5 follows from the first condition on P and a counting argument.

LEMMA 6.5. *g and P agree on more than $1 - 2\delta$ fraction of the inputs from $\mathcal{D}_{m,s}$.*

For the following lemmas, set $\gamma = \frac{m}{2p}$.

LEMMA 6.6. *For all* $x \in \mathcal{D}_{2m,s}$, $\Pr_{z\in\mathcal{D}_{p,s}}[g(x) = G[P(x-z), P(z)]] \geq 1-\delta'$ *where* $\delta' = 2\delta + 2\gamma$.

Proof. For $x \in \mathcal{D}_{2m,s}$, $Pr_{y\in\mathcal{D}_{p,s}}[x + y \in \mathcal{D}_{p,s}] \geq 1 - \gamma$. Thus,

$$\begin{aligned}\Pr_{y,w\in\mathcal{D}_{p,s}}&\left[G[P(x-y), P(y)]\right.\\ &= G[G[P(x-w), P(w-y)], P(y)]\\ &= G[P(x-w), G[P(w-y), P(y)]]\\ &= G[P(x-w), P(w)]]\\ &\geq 1 - 2\delta - 2\gamma.\end{aligned}$$

By the fourth condition on P, the first equality holds with probability $1 - \delta - 2\gamma$. By the second condition on P, the third equality holds with probability $1 - \delta$. The second equality always holds.

The lemma now follows from the observation that the probability that the same object is drawn twice from a set in two independent trials lower bounds the probability of drawing the most likely object in one trial. □

Finally, we prove that g satisfies the addition theorems everywhere.

LEMMA 6.7. *For all* $x, y \in \mathcal{D}_{m,s}$, $g(x + y) = G[g(x), g(y)]$.

Proof.

$$\begin{aligned}\Pr_{u,v\in\mathcal{D}_{p,s}}&\left[G[g(x), g(y)]\right.\\ &= G[G[P(u), P(x-u)], G[P(v), P(y-v)]]\\ &= G[P(u), G[P(x-u), G[P(v), P(y-v)]]]\\ &= G[P(u), G[G[P(x-u), P(v)], P(y-v)]]\\ &= G[P(u), G[P(x-u+v), P(y-v)]]\\ &= G[P(u), P(x+y-u)]\\ &= g(x+y)\big]\\ &\geq 1 - 3\delta' - 2\delta - 3\gamma = 1 - 8\delta - 9\gamma > 0.\end{aligned}$$

By Lemma 6.6, the first equality holds with probability $1 - 2\delta'$ and the last equality holds with probability $1-\delta'$ (since $x+y \in \mathcal{D}_{2m,s}$). By the third assumption on P, the fourth equality holds with probability $1-\delta-\gamma$. By the second assumption on P, the fifth equality holds with probability $1-\delta-2\gamma$. The other equalities always hold, due to the structure of G.

Since the statement is independent of u, v and holds with positive probability, it must hold with probability 1. This also proves Lemma 6.3. □

6.3. An example: Testing the cosh function. In this subsection we will illustrate how to apply the above techniques to construct a self-tester and self-corrector for a particular function, namely, the cosh function, over a given domain. Suppose that one would like to reliably use a program that purports to compute the cosh function over the domain $\mathcal{D}_{2^k,2^k} = \{\frac{i}{2^k}\big|\ |i| \leq 2^k\}$ (the numbers between –1 and 1 with k bits of precision). Assume that the correct values of $\cosh 0, \cosh\frac{-1}{2^k}, \cosh\frac{1}{2^k}$ are given and that the program purports to compute cosh over the larger domain $\mathcal{D}_{2^{k+8},2^k} = \{\frac{i}{2^k}\big||i| \leq 2^{k+8}\}$. Recall that cosh is one of the solutions to the functional equation $\forall x, y f(x + y) = f(x)f(y) + \sqrt{f(x)^2 - 1}\sqrt{f(y)^2 - 1}$. Furthermore, $\cosh(x)$ is the only solution to the functional equation that agrees with the given values of $\cosh 0, \cosh\frac{-1}{2^k}, \cosh\frac{1}{2^k}$, since $f(0), f(\frac{1}{2}^k), f(\frac{-1}{2^k})$ determine the values of f over the

whole domain $\mathcal{D}_{2^{k+8},2^k}$ via $f(\frac{i+1}{2^k}) = f(\frac{1}{2^k})f(\frac{i}{2^k}) + \sqrt{f(1/2^k)^2 - 1}\sqrt{f(i/2^k)^2 - 1}$ and $f(\frac{i-1}{2^k}) = f(\frac{-1}{2^k})f(\frac{i}{2^k}) + \sqrt{f(-1/2^k)^2 - 1}\sqrt{f(i/2^k)^2 - 1}$.[8]

One should first test the program over the domain $\mathcal{D}_{2^{k+4},2^k} = \{\frac{i}{2^k} \big|\ |i| \leq 2^{k+4}\}$, using the tester given in subsection 6.2 (with $\delta_0 = \frac{1}{48}, s = 2^k, m = 2^{k+4}, p = 2^{k+8}, n = 2^k$ so that $p > 11m$ and $m > 12n$). By Theorem 6.2 (which in turn uses Theorem 6.4), if the program is always correct on domain $\mathrm{q}\mathcal{D}_{2^{k+8},2^k} = \{\frac{i}{2^k} \big|\ |i| \leq 2^{k+8}\}$ the tester will output PASS, and if the program is incorrect on greater than $\frac{1}{24}$ fraction of the domain $\mathcal{D}_{2^{k+4},2^k} = \{\frac{i}{2^k} \big|\ |i| \leq 2^{k+4}\}$, then the tester will output FAIL. If the program is incorrect on less than $\frac{1}{24}$ fraction of the domain $\mathcal{D}_{2^{k+4},2^k}$, one can use the self-corrector in subsection 6.1 (with $s = 2^k, m = 2^{k+4}, n = 2^k$ so that $m > 12n$) in order to compute the correct value of $\cosh x$ for all $x \in \mathcal{D}_{2^k,2^k} = \{\frac{i}{2^k} \big|\ |i| \leq 2^k\}$. The correctness of the self-corrector is guaranteed by Theorem 6.1.

7. Conclusions and directions for further research. We have studied the question of when functions characterized by functional equations of the form $\forall x, y$ $F[f(x-y), f(x+y), f(x), f(y)] = 0$ are robust. However, we still do not have a complete answer to this question. Even for addition theorems $\forall x, y \quad f(x+y) = G[f(x), f(y)]$, we do not know what happens when G does not satisfy $G[a, G[b, c]] = G[G[a, b], c]$ $\forall a, b, c$. More generally, many other general types of functional equations have been identified, including those on multivariate functions and systems of functional equations, but we do not know which ones are robust. Given a functional equation, is there an (efficient) algorithm to determine whether or not it is robust? Is it the case that any property that leads to a self-corrector is robust?

Systems of functional equations can be used to define more than one unknown function by their joint properties. For example, Pexider's equations are $f(x+y) = g(x) + h(y)$, $f(x+y) = g(x)h(y)$, $f(xy) = g(x) + h(y)$, and $f(xy) = g(x)h(y)$, which are generalizations of Cauchy's original functional equations. These equations have applications to the library setting [19], where programs for several functions can be used to self-test and self-correct each other, as long as none of the answers are a priori assumed to be correct. The library setting has been used to find checkers that are significantly more efficient for functions such as determinant and rank. Are there any other examples of functions where their mutual properties lead to more efficient testers?

It is important to find methods to extend all robustness results to the case of real-valued computation as in [31], [5], [27]. One point of difficulty is that in real-valued computation, none of the functional equations will be satisfied exactly, even when the program is giving very good approximations to the correct answers. Thus, the area of functional inequalities, which is the investigation of which families of functions satisfy inequalities such as $|f(x+y) - f(x) - f(y)| \leq \epsilon$, directly applies to this setting. Much of the work in [31], [5], [27] has been in relating the class of functions that are solutions to functional inequalities to the class of functions that are solutions of the corresponding functional equations. Several functional inequalities have been shown to be robust in [31], [5], [27]. Other related results used for testing matrix multiplication, linear system solution, matrix inversion, and determinant computation are in [5].

Acknowledgments. We wish to thank Mike Luby, for initial conversations that eventually led to the idea behind this work, and Nati Linial for directing us to the

[8] Self-testers and self-correctors for $\cosh x$ can be constructed via other functional equations that $\cosh x$ satisfies as long as they are shown to be robust and equality testing is possible.

area of functional equations as well as to many of the references. We thank Madhu Sudan for many interesting conversations, comments, and insights on this work. We also thank Richard Zippel for his technical advice on the zero testing of algebraic functions and for guiding us through the literature regarding the scope of the theorems in this paper. We thank S. Ravi Kumar and Funda Ergün for discussions regarding the definitions in this paper and comments on the write-up. We thank S. Ravi Kumar and D. Sivakumar for pointing out an error. We thank Lucian Bebchuk, Ran Canetti, Oded Goldreich, Diane Hernek, Sandy Irani, Mike Luby, Dana Ron, and especially the anonymous referee for greatly improving the presentation of this paper.

NEW RESULTS ON THE OLD k-OPT ALGORITHM FOR THE TRAVELING SALESMAN PROBLEM*

BARUN CHANDRA†, HOWARD KARLOFF‡, AND CRAIG TOVEY§

Abstract. Local search with k-change neighborhoods is perhaps the oldest and most widely used heuristic method for the traveling salesman problem, yet almost no theoretical performance guarantees for it were previously known. This paper develops several results, some worst-case and some probabilistic, on the performance of 2- and k-opt local search for the traveling salesman problem, with respect to both the quality of the solution and the speed with which it is obtained.

Key words. graph algorithms, analysis of algorithms, explicit machine computation and programs (in optimization heading), explicit machine computation and programs (in computer science heading)

AMS subject classifications. 05C85, 68Q25, 49-04, 68-04

1. Introduction.

Local search with k-change neighborhoods is perhaps the oldest and most widely used heuristic method for the traveling salesman problem (TSP) [12, 16]. Given a graph $G = (V, E)$ and a tour T of G ("tour" is synonymous with "Hamiltonian cycle"), a tour T' is said to be obtained from T by an *improving k-change* if T' is shorter than T, and T' is obtained by removing k edges from T and adding a disjoint set of k edges. The k-opt algorithm starts with an arbitrary initial tour and incrementally improves on this tour by making successive improving k'-changes for any $k' \leq k$, terminating when no such improving changes can be made. This paper develops several results, some worst-case and some probabilistic, on the performance of 2- and k-opt algorithms for the TSP, with respect to the two principal criteria, quality and speed. Regarding quality: how good is a locally optimal solution? The only results on this question that we are aware of are due to Grover [6] and Lueker [15]. Grover proves that for any (symmetric) TSP instance, any 2-optimal tour has length at most the average of all tour lengths. (This result also was credited to Edelberg [15, p. 7] but without reference.) Lueker gives a construction for which this bound is tight when tour lengths differ. Our results regarding solution quality are as follows:

- For TSPs satisfying the triangle inequality (i.e., the distances are those in an n-point metric space), the worst-case performance ratio of 2-opt is at most $4\sqrt{n}$ for all n and at least $\frac{1}{4}\sqrt{n}$ for infinitely many n. The k-opt algorithm can have a performance ratio that is at least $\frac{1}{4}n^{\frac{1}{2k}}$ for infinitely many n.
- For TSPs embedded in the normed space $\mathbb{R}^m$, the worst-case performance ratio of 2-opt, and hence k-opt, is $O(\log n)$. If the points are embedded in $\mathbb{R}^2$ and the distances are Euclidean, then there is a $c > 0$ such that the worst-case performance ratio of 2-opt is at least $c \cdot \frac{\log n}{\log \log n}$ for infinitely many n.

- For all norms on $\mathbb{R}^m$, there exists a constant c such that any 2-optimal tour on any TSP instance in the unit hypercube (with norm-induced distances) has length less than $cn^{1-1/m}$. A corollary is that for random instances in the hypercube, i.e., points are sampled independently and identically distributed (i.i.d.) from the uniform distribution on the hypercube, with high probability, the performance ratio of 2-opt, even if it makes the worst possible sequence of improvements, is $O(1)$. Furthermore, the expected value of the performance ratio is also $O(1)$.

Regarding speed: how many iterations does local search require? There seem to be three previous results on this question. The first two of these are worst-case. Lueker [15] constructs a TSP instance for which there exists an exponentially long sequence of improving 2-changes. Johnson, Papadimitriou, and Yannakakis [7] and Krentel [10] prove the existence of instances with exponentially long improving sequences with respect to k-changes, for all sufficiently large k. (In fact, [7] and [10] prove something much stronger: there are an integer k, instances of the TSP, and initial tours such that, starting with the initial tour, *every* sequence of moves each of which is an improving k'-change (for some $k' \leq k$) and which terminates with a k-optimal tour has exponential length. Furthermore, Krentel [11] claims that $k = 8$ suffices.)

Here we extend Lueker's construction for all $k > 2$, giving explicit instances with exponentially long improving sequences.

The third previously known result is probabilistic. Kern [9] shows that for random Euclidean instances on the unit square, the probability is at least $1 - c/n$ that the expected number of iterations required by 2-opt is $O(n^{16})$, where c is a constant independent of the number of points n. It was not known if the expected number of iterations is polynomial. Our main probabilistic results regarding speed are:

- For random Euclidean instances in the unit square, the expected number of iterations required by 2-opt is $O(n^{10} \log n)$.
- For random L_1 instances in the unit hypercube, the expected number of iterations required by 2-opt is $O(n^6 \log n)$.

Taken together, our results provide the first theoretical proof of the quality of 2-opt as a heuristic for random TSP instances in the unit square. In particular, the expected time is polynomial, and the expected worst-case performance ratio is bounded by a constant.

2. Preliminaries. We begin by stating some definitions and notation that will be used throughout the paper.

A *metric space* (V, d) is a nonempty set V of points and a function $d : V \times V \to \mathbb{R}$, called *distance*, satisfying the following properties for all $x, y, z \in V$:

(i) $d(x, y) \geq 0$ and $d(x, y) = 0$ if and only if $x = y$;
(ii) $d(x, y) = d(y, x)$;
(iii) $d(x, z) \leq d(x, y) + d(y, z)$.

A *norm* N on $\mathbb{R}^m$ is a function $||\cdot|| : \mathbb{R}^m \to \mathbb{R}$ satisfying the following properties:

(i) For all $x \in \mathbb{R}^m$, $\|x\| \geq 0$, and $\|x\| = 0$ if and only if $x = 0$;
(ii) $\|cx\| = |c| \cdot \|x\|$ for every $c \in \mathbb{R}$ and $x \in \mathbb{R}^m$;
(iii) $\|x + y\| \leq \|x\| + \|y\|$ for every $x, y \in \mathbb{R}^m$.

A norm N induces a distance function defined as $d_N(x, y) = \|x - y\|$. If the norm of an m-dimensional vector $x = (x_1, x_2, \ldots, x_m)$ is defined as $\sqrt[p]{|x_1^p| + |x_2^p| + \cdots + |x_m^p|}$, where p is a positive integer, then the corresponding metric is called the L_p metric. The L_2 metric is called the *Euclidean metric*.

A *geometric graph* is given by a finite nonempty set V of points in $\mathbb{R}^m$ and a norm

N on $\mathbb{R}^m$. The graph is a complete weighted graph on V with the weight of edge $\{x, y\}$ being $d_N(x, y) = ||x - y||$. When the metric considered is the Euclidean metric, the graph is called a *Euclidean graph.* Given a weighted graph $G = (V, E)$ we refer to the weight or length of an edge $e \in E$ by $wt(e)$. Given a collection of edges $E' \subseteq E$, the weight $wt(E')$ of E' is the sum of the weights of the edges in E'; if the edges in E' form a tour T', we also refer to $wt(T')$ as the *length* of the tour. We denote an optimal tour by $OPT(G)$. Since we work only in complete graphs in a metric space (so given V, $G = (V, E)$ is completely determined), we also abuse notation slightly and refer to $OPT(V)$.

Given a weighted graph $G = (V, E)$ and a tour T of G, a tour T' is said to be obtained from T by an *improving k-change* if T' is shorter than T, and T' is obtained by removing a set of k edges from T and adding a disjoint set of k edges. A tour T is said to be *k-optimal* if for all $k' \leq k$, no improving k'-change can be made to T. The *k-opt algorithm* starts with an arbitrary initial tour T_0 and incrementally improves on this tour by finding $T_1, T_2, \ldots, T_z$, where T_{i+1} is obtained from T_i by an improving k'-change for some $k' \leq k$, and T_z is k-optimal.

The k-opt algorithm can start from many different initial tours, and even starting from the same initial tour, k-opt can end up in many different k-optimal tours. All the upper bounds in this paper are proved for the worst possible outcome of k-opt.

3. Bounds on performance ratios in metric spaces.

3.1. An upper bound for 2-opt. In this subsection we show that if the points are chosen from a metric space, then the worst-case performance ratio of 2-opt is bounded by $4\sqrt{n}$.

As a preliminary, we first prove that the performance ratio of k-opt cannot be bounded by a function of n if the triangle inequality is not imposed.

THEOREM 3.1. *For all $k \geq 2$, for all $n \geq 2k + 8$, for all $M > 0$, there exists a complete weighted graph G on n vertices, with strictly positive weights, containing a k-optimal tour T' such that $wt(T')/OPT(G) > M$.*

Proof. We prove the result for all k even and $n \geq 2k + 6$. The result will follow for k odd since k-optimality implies $(k - 1)$-optimality. The idea of the construction is to take a pair of Hamiltonian cycles in G which differ by a $(k + 1)$-change. We set the weights of all edges in these cycles to ϵ; all other edges in G are given very large weight. For one special edge in the first cycle, we change the weight to 1. This keeps the first cycle k-optimal but now its weight is many times that of the second cycle.

The graph G has n vertices denoted $1, 2, \ldots, n$. Its edge weights are as follows.

1. $wt(1, 2) = 1$.
2. $wt(i, i + 1) = \epsilon$ for all $i > 1$, and $wt(n, 1) = \epsilon$.
3. $wt(k + 3, 2k + 4) = \epsilon$.
4. $wt(j, 2k + 4 - j) = \epsilon$ for all $1 \leq j \leq k$.
5. All other edges have weight kn.

The two tours, the optimal T and the k-optimal T', differ only in the order in which they visit $1, 2, 3, \ldots, 2k+4$. Both tours visit $2k+4, 2k+5, 2k+6, \ldots, n-2, n-1, n, 1$ in that order. T' starts with $1, 2, 3, 4, \ldots, 2k + 3, 2k + 4$, whereas T starts with $1; 2k+3, 2k+2, 2, 3; 2k+1, 2k, 4, 5; 2k-1, 2k-2, 6, 7; \ldots; k+5, k+4, k, k+1; k+2, k+3, 2k+4$. (The semicolons appear only to help the reader.) This tour has weight $n\epsilon$. For $k = 2$, T is $1; 7, 6, 2, 3; 4, 5, 8; 9, 10, 11, 12, \ldots, n$. When $k = 8$ and $n = 26$, the optimal tour T is $1; 19, 18, 2, 3; 17, 16, 4, 5; 15, 14, 6, 7; 13, 12, 8, 9; 10, 11, 20; 21, 22, 23, 24, 25, 26$. See Figure 1.

The tour T' is $1, 2, 3, \ldots, n$ with weight $1+(n-1)\epsilon$. To verify that T' is k-optimal,

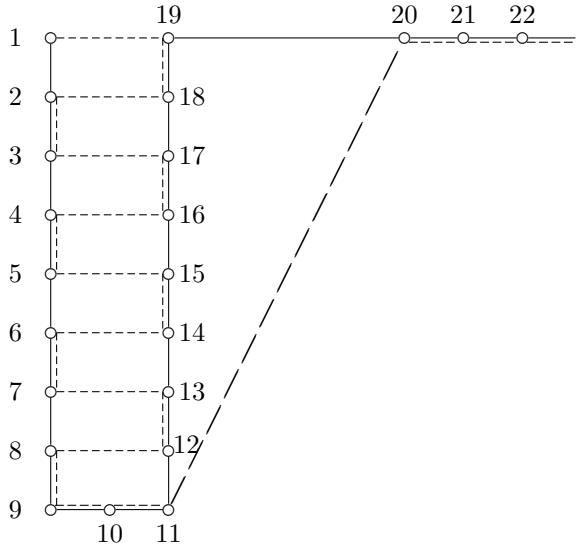

FIG. 1. *Part of the optimal tour T (dashed edges) and part of the k-optimal tour T' (solid edges) for $k = 8$.*

observe that when $\epsilon < 1$, any tour which can be obtained from T' by an improving k'-change, $k' \leq k$, must have weight $n\epsilon$, but T is the unique Hamiltonian cycle in G consisting entirely of ϵ-cost edges and T cannot be obtained from T' by an improving k' change (T' has $k+1$ edges not in T). If we set $\epsilon = 1/((M+1)n)$, the performance ratio will exceed M, as desired. □

The performance ratio can be bounded by a function of n if the triangle inequality is imposed. We will prove that if the points are chosen from a metric space, then the worst-case performance ratio of 2-opt is bounded by $4\sqrt{n}$.

Let M be any arbitrary metric space with a distance function d. Let V be a set of points in M, and let $n = |V|$. Let $OPT(V)$ be an optimal tour on V and let $T(V)$ be *any* 2-opt tour. We first state a simple fact which follows from the triangle inequality.

FACT 3.2. $V' \subseteq V \Rightarrow wt(OPT(V')) \leq wt(OPT(V))$.

LEMMA 3.3. *For any $k \in \{1, 2, \ldots, n\}$, let $E_k = \{$edges $e \in T(V) | wt(e) > \frac{2 \cdot wt(OPT(V))}{\sqrt{k}}\}$. Then $|E_k| < k$.*

Proof. Suppose otherwise; so for some k, $r := |E_k| \geq k$. Orient the edges of $T(V)$ in a consistent manner, i.e., so that the directed edges form a directed Hamiltonian cycle. Consider the directed edges (with the same orientation) of E_k, $(t_1, h_1), (t_2, h_2), \ldots, (t_r, h_r)$, where the t_i's are the tails and the h_i's are the heads of these directed edges.

We first see that not too many tails can be clustered very closely together. Consider any sphere of radius $\frac{wt(OPT(V))}{\sqrt{k}}$ around some point in the metric space. We show that the number of tails (of edges from E_k) in this sphere is less than $\sqrt{k}$.

Suppose otherwise, so that the tails $t_{i_1}, t_{i_2}, \ldots, t_{i_p}$ all lie in the sphere for some $p \geq \sqrt{k}$. Let $h_{i_1}, h_{i_2}, \ldots, h_{i_p}$ be the corresponding heads. For any $u \neq v$, $d(t_{i_u}, t_{i_v}) \leq \frac{2 \cdot wt(OPT(V))}{\sqrt{k}}$, since t_{i_u} and t_{i_v} lie in the sphere. This implies that $d(h_{i_u}, h_{i_v}) \geq \frac{2 \cdot wt(OPT(V))}{\sqrt{k}}$, since otherwise we get a shorter valid tour $(T(V) \cup \{(t_{i_u}, t_{i_v}), (h_{i_u}, h_{i_v})\})$ $-\{(t_{i_u}, h_{i_u}), (t_{i_v}, h_{i_v})\}$ with a 2-change operation. But since, by supposition, we have

$p \geq \sqrt{k}$ heads and these heads are pairwise at a distance at least $\frac{2 \cdot wt(OPT(V))}{\sqrt{k}}$ apart, the optimal tour on these heads is of length at least $2 \cdot wt(OPT(V))$, which contradicts Fact 3.2.

Now we show that a large number of tails have to be at a large distance apart. Pick any arbitrary tail t_i and consider the sphere of radius $\frac{wt(OPT(V))}{\sqrt{k}}$ centered around t_i. "Kill" all the tails within this sphere. By the above argument, fewer than $\sqrt{k}$ tails can have been killed. Now pick any remaining "live" tail and kill all tails in the sphere centered at this tail. Repeat this process until all tails have been killed. Since there are at least k tails and in a single iteration we kill fewer than $\sqrt{k}$ tails, this process can be repeated more than $\sqrt{k}$ times. Clearly, the tails at the center of the spheres are at a distance greater than $\frac{wt(OPT(V))}{\sqrt{k}}$ apart from each other, and there are greater than $\sqrt{k}$ of them; therefore, the optimal tour on the tails is of length greater than $wt(OPT(V))$, which contradicts Fact 3.2. □

THEOREM 3.4. $\frac{wt(T(V))}{wt(OPT(V))} \leq 4\sqrt{n}$.

Proof. Note that Lemma 3.3 implies that the weight of the kth largest edge is at most $\frac{2 \cdot wt(OPT(V))}{\sqrt{k}}$. Hence

$$\begin{aligned} wt(T(V)) &= \sum_{k=1}^{n} wt(k\text{th largest edge}) \\ &\leq \sum_{k=1}^{n} \frac{2 \cdot wt(OPT(V))}{\sqrt{k}} \\ &= 2 \cdot wt(OPT(V)) \sum_{k=1}^{n} \frac{1}{\sqrt{k}} \\ &\leq 2 \cdot wt(OPT(V)) \int_{x=0}^{n} \frac{1}{\sqrt{x}} \\ &= 4 \cdot wt(OPT(V)) \cdot \sqrt{n}. \end{aligned}$$ □

3.2. Lower bounds for 2-opt and *k*-opt. Next we show that the upper bound for 2-opt's performance ratio given by Theorem 3.4 is tight to within a factor of 16. We also provide lower bounds for k-opt.

THEOREM 3.5. *For any $k \geq 2$, for infinitely many values of n, there exists a complete weighted n-node graph $G_{k,n}$ with positive edge weights satisfying the triangle inequality, and a k-optimal tour $T_{k,n}$ of $G_{k,n}$, such that $\frac{wt(T_{k,n})}{wt(OPT(G_{k,n}))} \geq \frac{1}{4} \cdot n^{1/2k}$ if $k \geq 3$, and $\frac{wt(T_{k,n})}{wt(OPT(G_{k,n}))} \geq \frac{1}{4}\sqrt{n}$ if $k = 2$.*

Define the *girth* of a graph as the number of edges in its smallest cycle, provided it is not a forest.

LEMMA 3.6. *Suppose there exists a connected unweighted graph $G_{k,n,m}$, with n vertices and m edges, having girth at least $2k$, in which every vertex has even degree. Then there is an m-vertex complete weighted graph G_1 with positive edge weights satisfying the triangle inequality and a k-optimal tour T of G_1 such that $\frac{wt(T)}{wt(OPT(G_1))} \geq \frac{m}{2n}$.*

Proof. Assume that we are given $G_{k,n,m} = G = (V, E)$. Since G is connected and every vertex has even degree, G has an Eulerian tour ET.

Using G and ET, we construct a complete weighted graph $G_1 = (V_1, E_1)$ and a tour T for G_1. Let $V(G) = \{x_1, x_2, \ldots, x_n\}$. We think of each vertex x_i in G as a

"supervertex" corresponding to $deg_G(x_i)/2$ vertices in G_1, so

$$V_1 = \{x_{1,1}, \ldots, x_{1,deg_G(x_1)/2}, \ldots, x_{n,1}, \ldots, x_{n,deg_G(x_n)/2}\}.$$

The number of vertices in G_1 is $(deg_G(x_1) + \cdots + deg_G(x_n))/2 = m$.

Let $d_G(x_i, x_j)$ be the length of the shortest path from x_i to x_j in G. The edge weights of G_1 are as follows:

1. for all $i, s, t, s \neq t$, $wt(x_{i,s}, x_{i,t}) = \epsilon$, where $\epsilon = \frac{1}{n^2}$;
2. for all i, j, s, t, $i \neq j$, $wt(x_{i,s}, x_{j,t}) = d_G(x_i, x_j)$.

By inspection, it is easy to see that the edge weights of G_1 satisfy the triangle inequality.

The tour T on G_1 is constructed as follows. Suppose that the rth vertex of the Eulerian tour ET of G is vertex x_i. Suppose that this is the lth time ET has entered and exited vertex x_i, $1 \leq l \leq deg(x_i)/2$. Then the rth vertex of tour T of G_1 is $x_{i,l}$. Since ET enters and exits each vertex x_i of G exactly $deg_G(x_i)/2$ times and there are precisely $deg_G(x_i)/2$ vertices in each supervertex, this procedure gives us a tour T. Note that for all $\{x_i, x_j\} \in E$ there is a unique pair s, t such that $\{x_{i,s}, x_{j,t}\} \in T$.

Since the weight of the minimum spanning tree of G_1 is at most $(n-1) + (n \cdot n \cdot \epsilon) = n$ and edge weights satisfy the triangle inequality, $wt(OPT(G_1)) \leq 2n$. In the tour T, there are m edges each of weight 1, and so $wt(T) = m$. Hence we get $\frac{wt(T)}{wt(OPT(G_1))} \geq \frac{m}{2n}$, so all we need to prove Lemma 3.6 is the following.

CLAIM 3.7. *T is k-optimal.*

Proof. If not, then there is a tour T' of G_1 which is obtained from T by a k'-change operation, $k' \leq k$, such that $wt(T') < wt(T)$.

A *closed walk* is a walk which begins and ends at the same vertex, repeated edges and vertices allowed. A *simple closed walk* is a closed walk with no repeated edges.

CLAIM 3.8. *Viewing T and T' as sets of edges, there are sets $C \subseteq T - T'$ and $C' \subseteq T' - T$ such that $C \cup C'$ is the edge set of a simple closed walk, $|C| = |C'| \leq k$, $wt(C) > wt(C')$, and every vertex in V_1 is incident to the same number* (0, 1, *or* 2) *of edges of C as C'.*

Proof. Let Δ denote symmetric difference. Since for all $v \in V_1$, $deg_{T \Delta T'} v$ is either 0, 2, or 4, $T \Delta T'$ can be partitioned into a collection of vertex-disjoint simple closed walks $P_1, P_2, \ldots, P_s$. Further, since $wt(T) > wt(T')$, at least one of the P_i, say, P_1, has to satisfy $wt(P_1 \cap T) > wt(P_1 \cap T')$. Since $|P_1 \cap T| = |P_1 \cap T'|$, it is easy to verify that $C = P_1 \cap T$ and $C' = P_1 \cap T'$ have the desired properties. □

Let C, C' be as in Claim 3.8. Let $G_2 = (V, E_2)$ be a weighted multigraph with the following edges. Between every pair of distinct vertices there will be one edge of positive integral weight and zero or one edge of weight -1. Specifically, between x_i and x_j, $i \neq j$, there is an edge in E_2 of weight $d_G(x_i, x_j)$, which is a positive integer. For that x_i and x_j, if there are s, t such that $\{x_{i,s}, x_{j,t}\} \in C$, then ($s$ and t are unique and) in addition to the edge of positive weight between x_i and x_j, there is an edge in E_2 between x_i and x_j of weight $-d_G(x_i, x_j)$. A crucial fact is that $-d_G(x_i, x_j) = -1$ in this case, because every edge in T is of weight 1. Let us denote the set of edges of positive weight in E_2 as D' and let us denote the set of edges of weight -1 as D. Each edge in C gives rise to exactly one edge in D, so $|D| = |C| \leq k$.

Note that there is an obvious correspondence between the edges of G_1 and the edges of positive weight in G_2: the vertices inside a supervertex in G_1 are merged into a single vertex in G_2, with the intrasupervertex edges in G_1 "disappearing."

Edges from C', like arbitrary edges of G_1, are either of weight ϵ or of positive integral weight. An edge in C' of positive integral weight is an edge $\{x_{i,s}, x_{j,t}\}$ for some

$i \neq j$ having weight $d_G(x_i, x_j)$ and is said to correspond to the edge in D' between x_i and x_j of weight $d_G(x_i, x_j)$. An edge in C' of weight ϵ is said to correspond to nothing. An edge in C is of unit length and is an edge $\{x_{i,s}, x_{j,t}\}$ such that $d_G(x_i, x_j) = 1$, i.e., $\{x_i, x_j\} \in E$. Such an edge is said to correspond to the edge in D (of weight -1) between x_i and x_j. (Several edges of C' may correspond to the same edge in D'. However, different edges in C correspond to different edges in D.) With this correspondence, the simple closed walk in G_1 which uses each edge in $C \cup C'$ exactly once corresponds to a closed walk P in G_2. (Edges of weight ϵ are not needed and do not appear.) P need not be simple since edges in D' may have several "preimages" in C'. Since each edge in $C \cup C'$ is traversed exactly once and different edges in C correspond to different edges in D, it follows that no edges in D are traversed twice. Each, in fact, is traversed exactly once by P. The weight of P, which is the sum of the weights of the edges it traverses, counting multiplicities, is at most $wt(C') - wt(C) < 0$.

Let $G_3 = (V, E_3)$ be a weighted multigraph obtained by replacing each edge from G by two edges, one of weight $+1$ and one of weight -1. An edge of G_2 of positive integral weight is an edge between some x_i and x_j with $i \neq j$. Such an edge has weight $d_G(x_i, x_j)$ and is said to correspond to some fixed (shortest) path in G_3 between x_i and x_j consisting of $d_G(x_i, x_j)$ edges of weight $+1$. An edge of G_2 of weight -1 between, say, x_i and x_j, is said to correspond to the identical edge in G_3. (There will be many more negative edges in G_3 than there are in G_2, since C is small.) With this correspondence, the closed walk P in G_2 corresponds to a closed walk W in G_3 of the same weight. Edges of weight $+1$ may be traversed many times, but no edge of weight -1 can be traversed even twice, since no edge of weight -1 is traversed twice by P. Let the edges of weight $+1$ in W be edges $c_1, c_2, \ldots, c_r$ occurring in W $m_1, m_2, \ldots, m_r$ times, respectively. The number of edges of weight $+1$ in W, including multiplicities, of course, equals $\sum_{j=1}^{r} m_j$. Since $wt(W) = wt(P) < 0$ and $wt(W) = (\sum_{j=1}^{r} m_j) + |D|(-1)$, we have $m_1 + m_2 + \cdots + m_r < |D|$. Also, the number of edges in W is $(\sum_{j=1}^{r} m_j) + |D| < 2|D| \leq 2k$.

One of the following must be true:

- For every edge in W of weight -1, there is another edge in W with the same endpoints. But since W never has two negative edges with the same endpoints, this other edge must have weight $+1$. We infer that $wt(W) \geq 0$, a contradiction.
- There is some edge in W of weight -1 such that there is no other edge in W with the same endpoints. But since W is a closed walk, this implies that there is some set $S \subseteq W$ of edges, $|S| > 2$, such that S is the edge set of a cycle (without repeated vertices, of course). Since $S \subseteq W$ and W has fewer than $2k$ edges, S also has fewer than $2k$ edges. But then there is a cycle in G corresponding to S, and this cycle has fewer than $2k$ edges since S has fewer than $2k$ edges, a contradiction since the girth of G is at least $2k$. □

LEMMA 3.9. *For all $k \geq 2$, for infinitely many n the graphs $G_{k,n,m}$ of Lemma 3.6 exist with $\frac{m}{2n} \geq \frac{m^{1/2k}}{4}$.*

Proof. To prove that these graphs exist for infinitely many n, it suffices to show that for any n_0, there exists such a graph $G_{k,n,m}$ with $n > n_0$.

We first present an extremal graph-theoretic lemma [4, Theorem 1.4′, Chapter III].

FACT 3.10. *Let q, δ, and g be positive integers such that $q \geq \frac{(\delta-1)^{g-1}-1}{\delta-2}$. Then there exists a δ-regular graph (all vertices have degree δ) having $2q$ vertices and girth at least g.*

Let $p \geq n_0$ be a positive integer. Let $q = (2p)^{2k-1}$, $\delta = 2p$, and $g = 2k$. The parameters q, δ, g satisfy the hypothesis of Fact 3.10; let G' be the graph from Fact 3.10. G' has $2q$ vertices, girth at least $2k$, and is $(2p)$-regular. Let G be the largest connected component of G'. We claim that G has the desired properties.

Clearly, G is connected, every vertex has even degree, and the girth is at least $2k$. Let $n = |V(G)|$. Since $p \geq n_0$ and G is $2p$-regular, we get $n > 2p > n_0$. Let $m = |E(G)|$. Since G is $2p$-regular, $m = pn \leq p(2q) = 2p(2p)^{2k-1} = (2p)^{2k}$, which implies that $\frac{m}{2n} = \frac{p}{2} \geq \frac{m^{1/2k}}{4}$. This completes the proof of Lemma 3.9. □

LEMMA 3.11. *For infinitely many n the graphs $G_{2,n,m}$ of Lemma 3.6 exist with $\frac{m}{2n} = \frac{\sqrt{m}}{4}$.*

Proof. We will prove the result for all values of n which are multiples of 4. Let $p = n/4$. Let $G = K_{2p,2p}$, i.e., a complete bipartite graph with $2p$ vertices on each side. G is connected, every vertex has even degree, and G has no cycles of length 3. G has exactly $m = 4p^2$ edges so $m/n = p = \sqrt{m}/2$. □

Theorem 3.5 now follows from Lemmas 3.6, 3.9, and 3.11.

4. Bounds on performance ratios for geometric graphs. In the previous section we found that the triangle inequality by itself ensures a $\Theta(\sqrt{n})$ worst-case performance ratio. Now we put stronger conditions on the distances, requiring them to be induced by a norm on $\mathbb{R}^m$, and show that the worst-case performance ratio is between $c \log n / \log \log n$ and $O(\log n)$.

4.1. The upper bound. We find an upper bound on the performance ratio of any 2-optimal tour for geometric graphs, under any norm and in any dimension. A large portion of this subsection is based on concepts presented in [5].

We begin by stating a well-known property about norms and introducing a few definitions. Consider any positive integer $m \geq 2$ and any norm N on $\mathbb{R}^m$. Let $d_N(x, y)$ denote the distance between x and y in the metric generated by N. Let $d(x, y)$ denote the Euclidean distance between x and y. By the well-known comparability of norms [14, p. 132], there exist $l_N, u_N > 0$ such that for every x and y,

$$l_N \cdot d_N(x, y) \leq d(x, y) \leq u_N \cdot d_N(x, y). \tag{1}$$

In this section we use the concept of angles. As usual, angles are defined by the inner product and the Euclidean metric. The angle between a and b in $\mathbb{R}^m$ is

$$\arccos \frac{a \cdot b}{||a||_2 ||b||_2},$$

which we take to be in the interval $[0, \pi]$.

Consider any norm N on $\mathbb{R}^m$. For l_N and u_N satisfying (1), let $\theta_N = \arctan(\frac{l_N}{4u_N})$. Define the angle between directed line segments $\overrightarrow{ux}$ and $\overrightarrow{vy}$ to be the angle between the vectors $x-u$ and $y-v$. ($\overrightarrow{ab}$ denotes a line segment directed from a to b.) Two directed line segments $\overrightarrow{ux}$ and $\overrightarrow{vy}$ are said to be *similar-directional* (with respect to N, l_N, and u_N) if the angle between them is at most θ_N. More intuitively, similar-directional means that the two directed line segments point in almost the same direction, since the angle θ_N is small. Note that for $\theta_N < \pi/2$, if $\overrightarrow{ux}$ and $\overrightarrow{vy}$ are similar-directional, then $\overrightarrow{ux}$ and $\overrightarrow{yv}$ are *not* similar-directional. N, l_N, and u_N will be implicit when we write *similar-directional* instead of *similar-directional with respect to N, l_N, and u_N.*

Let V be a finite nonempty set of points in $\mathbb{R}^m$ with norm N. Let G be the geometric graph induced by V. Let T' be a 2-optimal tour of G with (directed) edge set E' (2-optimality is with respect to distances on the metric induced by N).

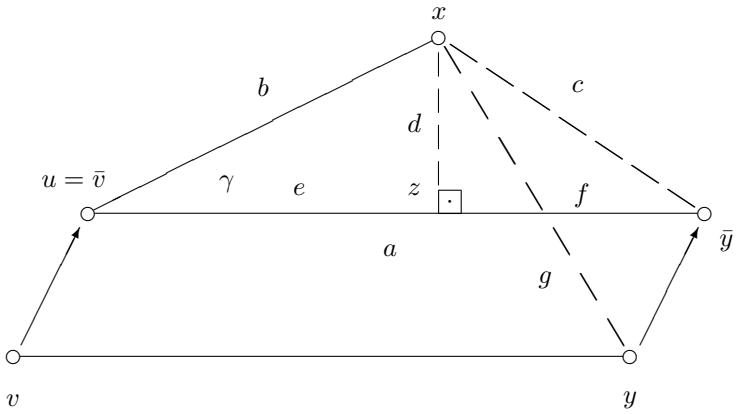

FIG. 2. *Illustration for Lemma* 4.1 (*Case* 1).

Build a set $\boldsymbol{E'}$ of directed line segments in $\mathbb{R}^m$ corresponding to E' as follows. Suppose the tour $T' = (v_1, v_2, \ldots, v_n, v_1)$. Then $\boldsymbol{E'} = \{\overrightarrow{v_1v_2}, \overrightarrow{v_2v_3}, \ldots, \overrightarrow{v_{n-1}v_n}, \overrightarrow{v_nv_1}\}$. Every vertex is the tail of exactly one line segment in $\boldsymbol{E'}$ and the head of exactly one line segment in $\boldsymbol{E'}$.

We now present an important technical lemma. Intuitively, this lemma says that, if there are two similar-directional directed line segments $\overrightarrow{ux}$ and $\overrightarrow{vy}$ in $\boldsymbol{E'}$, then u and v must be separated by a distance greater than half the length of the shorter segment. Consequently, the originating points of two similar-directional segments cannot be too close together.

LEMMA 4.1. *Let $G = (V, E)$ be a geometric graph in $\mathbb{R}^m$ under norm N. Let T' be a 2-optimal tour of G having (directed) edge set E'. Let $\overrightarrow{ux}$ and $\overrightarrow{vy}$ be any two similar-directional segments in $\boldsymbol{E'}$. If $d_N(u, x) \le d_N(v, y)$, then $d_N(u, v) > \frac{1}{2} \cdot d_N(u, x)$.*

Proof. Let $l_N, u_N > 0$ be the constants defined in (1) and $\theta_N = \arctan \frac{l_N}{4u_N}$. Let γ be the angle between directed segments $\overrightarrow{ux}$ and $\overrightarrow{vy}$. To prove the lemma we assume that

$$d_N(u, x) \le d_N(v, y), \qquad \gamma \le \theta_N, \qquad \text{and} \qquad d_N(u, v) \le \frac{1}{2} \cdot d_N(u, x) \tag{2}$$

and we derive a contradiction.

Note that since $l_N \le u_N$, $\tan \theta_N = \frac{l_N}{4u_N} < 1$. Therefore, if $\gamma \ge \pi/4$, $\gamma > \theta_N$. Thus, we may assume that $\gamma < \pi/4$.

Consider the configuration obtained by translating $\overrightarrow{vy}$ in space such that v coincides with u. Let $\bar{v} = u$ be the translate of v, and let $\bar{y}$ be the translate of y. Points $u = \bar{v}, x, \bar{y}$ lie in a 2-dimensional plane. The situation is illustrated by Figures 2 and 3.

Throughout this proof we use primed lower-case letters, $a', b', c', \ldots$ to denote distances in the N metric, while unprimed lower-case letters denote distances in the Euclidean metric. For example, if $a' = d_N(x, y)$, then $a = d(x, y)$, and vice versa.

Let $a' = d_N(v, y)$, $b' = d_N(u, x)$, $c' = d_N(x, \bar{y})$, and $g' = d_N(x, y)$. (Recall that $a = d(v, y)$, $b = d(u, x)$, $c = d(x, \bar{y})$, and $g = d(x, y)$ are the corresponding Euclidean distances.) Using this notation, (2) implies that

$$b' \le a' \qquad \text{and} \qquad d_N(u, v) \le \frac{1}{2} b'. \tag{3}$$

CLAIM 4.2. $g' \ge a'$.

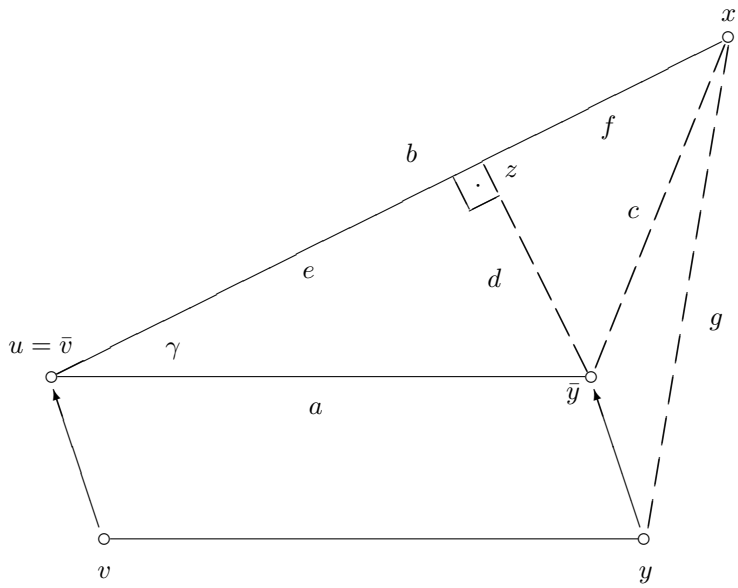

FIG. 3. *Illustration for Lemma* 4.1 (*Case* 2).

Proof. Suppose otherwise. We first see that $|\{u, x, v, y\}| = 4$. Clearly, $u \neq x$ and $v \neq y$. Clearly, $u \neq v$, since otherwise u is the tail of two line segments in E', $\overrightarrow{ux}$ and $\overrightarrow{uy}$. Similarly, $x \neq y$. If $u = y$, then $d_N(u, v) = d_N(v, y)$ and $d_N(u, v) \leq \frac{1}{2} d_N(u, x) \leq \frac{1}{2} d_N(v, y)$, which is a contradiction. If $v = x$, then $d_N(u, v) = d_N(u, x)$ and $d_N(u, v) \leq \frac{1}{2} d_N(u, x)$, which is a contradiction. Hence, $|\{u, x, v, y\}| = 4$.

By assumption, $d_N(u, v) \leq \frac{1}{2} d_N(u, x) < d_N(u, x)$, and $g' < a'$, so $d_N(u, v) + d_N(x, y) < d_N(u, x) + d_N(v, y)$. Also, (u, v) is not in E', because if it were, either $\overrightarrow{uv} \in \boldsymbol{E'}$ or $\overrightarrow{vu} \in \boldsymbol{E'}$. But if $\overrightarrow{uv} \in \boldsymbol{E'}$, then the vertex u is the tail of two line segments in E', namely, $\overrightarrow{ux}$ and $\overrightarrow{uv}$, and if $\overrightarrow{vu} \in \boldsymbol{E'}$, then the vertex v is the tail of two line segments in E', namely, $\overrightarrow{vy}$ and $\overrightarrow{vu}$. Similarly, $(x, y) \notin E'$. However, now we can interchange two edges from the tour T', (u, x) and (v, y), with the two edges (v, u) and (y, x) which are not in the tour, to get a smaller valid tour, which contradicts the 2-optimality of T'. □

We now consider two cases: $a \geq b$ and $a < b$.

The case in which $a \geq b$ is illustrated in Figure 2 where z is on the line containing $\bar{v}$ and $\bar{y}$ and xz is perpendicular to that line, $d' = d_N(x, z)$, $e' = d_N(\bar{v}, z)$, and $f' = d_N(z, \bar{y})$. Since $\gamma < \pi/4$ and $a \geq b$, z does belong to the segment $\bar{v}\bar{y}$.

The case in which $a < b$ is illustrated in Figure 3, where z is on the line containing u and x and $\bar{y}z$ is perpendicular to that line, $d' = d_N(\bar{y}, z)$, $e' = d_N(u, z)$, and $f' = d_N(z, x)$. Since $\gamma < \pi/4$ and $a < b$, z does belong to the segment ux.

Case 1. $a \geq b$ (a and b are Euclidean distances). See Figure 2.

Using (3) and the triangle inequality several times, we obtain

$$g' \leq c' + d_N(y, \bar{y}) = c' + d_N(u, v) \leq c' + \frac{1}{2} b' \leq d' + f' + \frac{1}{2} b',$$

implying

$$d' \geq g' - \frac{1}{2} b' - f' \geq a' - f' - \frac{1}{2} b' = e' - \frac{1}{2} b' \geq e' - \frac{1}{2}(d' + e'),$$

which implies

$$d'\left(1+\frac{1}{2}\right) \geq e'\left(1-\frac{1}{2}\right).$$

Using (1) we have

$$\frac{1-\frac{1}{2}}{1+\frac{1}{2}} \leq \frac{d'}{e'} \leq \frac{u_N d}{l_N e} = \frac{u_N}{l_N}\tan\gamma,$$

implying

$$\tan\gamma \geq \frac{l_N(1-\frac{1}{2})}{u_N(1+\frac{1}{2})} = \frac{l_N}{3u_N} > \frac{l_N}{4u_N} = \tan\theta_N.$$

Since $\tan\gamma > \tan\theta_N$, we have $\gamma > \theta_N$, a contradiction.

Case 2. $a < b$ (a and b are Euclidean distances). See Figure 3.

Using (3) and the triangle inequality several times, we obtain

$$g' \leq c' + d_N(y,\bar{y}) = c' + d_N(u,v) \leq c' + \frac{1}{2}b' \leq d' + f' + \frac{1}{2}b',$$

implying

$$d' \geq g' - \frac{1}{2}b' - f' \geq b' - f' - \frac{1}{2}b' = e' - \frac{1}{2}b' \geq e' - \frac{1}{2}a' \geq e' - \frac{1}{2}(d'+e')$$

(the second inequality follows from $g' \geq a' \geq b'$), which implies

$$d'\left(1+\frac{1}{2}\right) \geq e'\left(1-\frac{1}{2}\right).$$

As in Case 1, we obtain $\gamma > \theta_N$, a contradiction.

This completes the proof of Lemma 4.1. □

We now analyze the weight of the tour T'. In $\mathbb{R}^m$, for any angle $\alpha > 0$, consider a cover of $\mathbb{R}^m$ by some finite number $B(d,\alpha)$ of circular (overlapping) cones, all having the same origin P, such that two distinct points different from P in the same cone form, at P, an angle at most α. We use in Theorem 4.3 the well-known fact that $B(d,\alpha)$ is finite for every $\alpha > 0$ and every d. This *covering problem* has been extensively studied. We mention the following upper bound due to Rogers [17]:

$$B(m,\alpha) \text{ is } O\left(m^{3/2}\left(\log\frac{m}{\sin(\alpha/2)}\right)\left(\frac{1}{\sin(\alpha/2)}\right)^m\right).$$

THEOREM 4.3. *Fix m and a norm N on $\mathbb{R}^m$. Let $G = (V,E)$ be an n-vertex geometric graph in $\mathbb{R}^m$ under norm N. Let OPT be the weight of the optimal tour on G. Let T' be any 2-optimal tour of G. Then the weight of T' is $O(\log n)\cdot OPT$. (The constant implicit in the big O depends on m and N.)*

Proof. Let $\theta_N = \arctan(\frac{l_N}{4u_N})$, where the constants $l_N, u_N > 0$ are according to (1). At some arbitrary point P in $\mathbb{R}^m$, we cover the space by a constant number of circular cones $C_1, C_2, \ldots, C_{B(m,\theta_N)}$, such that every two line segments containing P and lying within the same cone subtend, at P, an angle at most θ_N. As noted, $B(m,\theta_N)$ depends only on d and N.

Call these the *original cones*. Construct $B(m,\theta_N)$ congruent cones around each of the n vertices of G by translating each original cone so that its origin shifts from

P to that vertex. Hence, corresponding to each vertex of G are $B(m,\theta_N)$ cones, one cone corresponding to each of the original cones $C_1, C_2, \ldots, C_{B(m,\theta_N)}$. Let C_{ji} be the cone with its origin at vertex j that is a translate of original cone C_i.

Let E' be the edge set of the 2-optimal tour T'. Let $\boldsymbol{E'}$ be the set of directed line segments corresponding to E'. Let $\boldsymbol{E'_i}$ be the set of directed line segments in $\boldsymbol{E'}$ that appear in $\cup_j C_{ji}$. We claim that the sum of the weights of the segments in $\boldsymbol{E'_i}$ is bounded by $O(\log n) \cdot wt(OPT)$, for $1 \le i \le B(m,\theta_N)$. Since the sets $\boldsymbol{E'_i}$ cover the set $\boldsymbol{E'}$ and the number of cones is a constant, proving this claim is enough to prove the lemma.

Clearly, all the directed line segments in $\boldsymbol{E'_i}$ are similar-directional. Hence, by Lemma 4.1, if $\overrightarrow{u_1v_1}$ and $\overrightarrow{u_2v_2}$ are two directed line segments in $\boldsymbol{E'_i}$ and if the former one is shorter, then $d_N(u_1,u_2) > \frac{1}{2} d_N(u_1,v_1)$.

Let T be an optimal tour on G, so $wt(T) = OPT$. We are now going to account for the length of the line segments in $\boldsymbol{E'_i}$, using the length of the edges in T. For integer l, call an edge in $\boldsymbol{E'_i}$ *long* if its length is at least OPT/l. Consider a walk along the edges of T starting from an arbitrary vertex and ending at the same vertex. As we walk along the path, we encounter the originating points of the long line segments in $\boldsymbol{E'_i}$. Let the order of the long line segments encountered from $\boldsymbol{E'_i}$ be $\overrightarrow{e_1}, \ldots, \overrightarrow{e_q}$.

We claim that for all $l \ge 2$, $\boldsymbol{E'_i}$ contains fewer than $2l$ long line segments. Consider the first two long directed line segments encountered, $\overrightarrow{e_1}$ and $\overrightarrow{e_2}$. By Lemma 4.1, the distance between the originating points of $\overrightarrow{e_1}$ and $\overrightarrow{e_2}$ is longer than $\frac{1}{2}OPT/l$. Hence the distance along T between the originating points of $\overrightarrow{e_1}$ and $\overrightarrow{e_2}$ is also longer than $\frac{1}{2}OPT/l$. Continuing along T from the originating point of $\overrightarrow{e_2}$ to the originating point of $\overrightarrow{e_3}$, and so on to the portion of T from the originating point of $\overrightarrow{e_q}$ back to the originating point of $\overrightarrow{e_1}$, we find that OPT, the total length of T, is longer than $q[OPT/(2l)]$. This is only possible if the number q of long line segments satisfies $q < 2l$.

This means, if $l = 2^j$, $j \ge 1$, that the sum of the lengths of all the line segments in $\boldsymbol{E'_i}$ of length in $[OPT/2^j, OPT/2^{j-1}]$ is at most $(2 \cdot 2^j)[OPT/2^{j-1}] = 4 \cdot OPT$. Now setting $l = 2^j$, $j = 1, \ldots, \lceil \lg n \rceil$, the sum of the lengths of line segments in $\boldsymbol{E'_i}$ is less than

$$OPT + \sum_{j=1}^{\lceil \lg n \rceil} 4 \cdot OPT \le (5 + \lg n) OPT.$$

Since $B(m,\theta_N)$ is constant (dependent only on m and N), we conclude that $wt(\boldsymbol{E'})$ is $O(\log n) \cdot OPT$. □

4.2. A lower bound for 2-opt under L_2.

THEOREM 4.4. *There exists a constant $c > 0$ such that for infinitely many values of n, there exists an n-node graph G_n embedded in the Euclidean plane under the L_2 metric and a 2-optimal tour T_n of G_n such that $\frac{wt(T_n)}{wt(OPT(G_n))} \ge c \cdot \frac{\log n}{\log \log n}$.*

We will prove the result for those values of n which satisfy $n = 2(1 + p^2 + p^4 + p^6 + \cdots + p^{2p}) + 2p + p^{2p} + 1$ for any positive odd integer $p \ge 3$. Note that $p > c' \frac{\log n}{\log \log n}$ for some $c' > 0$.

We exhibit a set of n vertices V (all lying on the $n \times n$ grid in the Euclidean plane) such that $wt(OPT(V))$ is at most $18 \cdot p^{2p}$. We then construct a 2-optimal tour T on V of weight at least $2p \cdot p^{2p} \ge 2c' \frac{\log n}{\log \log n} \cdot p^{2p}$. Hence, we will get that $\frac{wt(T)}{wt(OPT(V))} \ge \frac{c'}{9} \cdot \frac{\log n}{\log \log n}$.

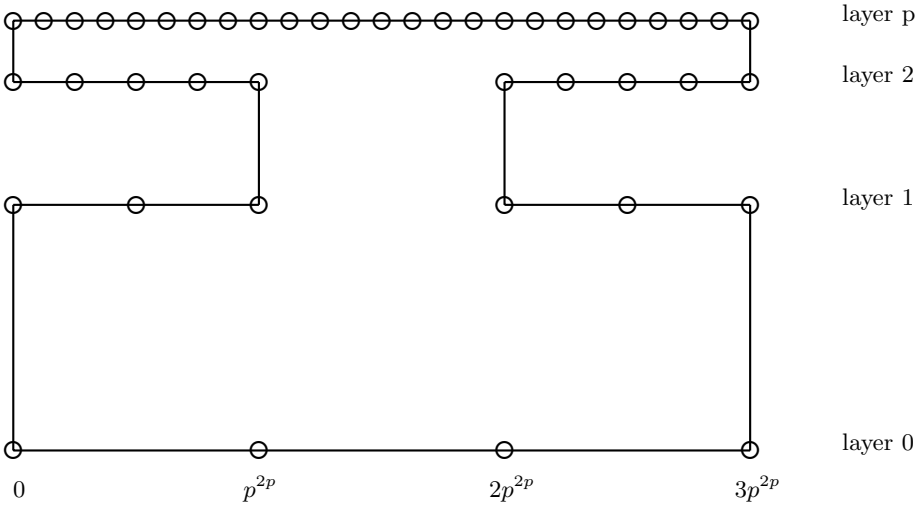

FIG. 4. *The tour T.*

Our construction is a modification of a construction by Alon and Azar [1]. (Also see Bentley and Saxe [3].)

We construct V in three parts, V_1, V_2, and V_3. The vertices in V_1 are in $p+1$ layers, where each layer is a set of equally spaced points on a horizontal line of length p^{2p}. The coordinates of the points in level i, $0 \le i \le p$, are (ja_i, b_i), where $a_i = p^{2p-2i}$ and $0 \le j \le p^{2p}/a_i$, and b_i will be defined later. Thus $a_0 = p^{2p}$, $a_1 = p^{2p-2}, \ldots$, and $a_p = 1$. Hence in layer 0 there are only two points, in layer 1 there are p^2+1, in layer i there are $p^{2i}+1 = \frac{p^{2p}}{a_i}+1$ points, up to layer p, which contains $p^{2p}+1$ points. Let $b_0 = 0$. The vertical distance between layer i and layer $i+1$ (i.e., $b_{i+1} - b_i$) is $c_i = p^{2p-1-2i}$, for all i. Note that $p \cdot a_{i+1} = p \cdot p^{2p-2i-2} = c_i = \frac{p^{2p-2i}}{p} = \frac{a_i}{p}$.

V_2 is a copy of V_1 shifted to the right. For every vertex in V_1 with coordinates (e, f), there is a vertex in V_2 with coordinates $(e+2p^{2p}, f)$. These are the only vertices in V_2.

Finally, we fill in the gaps in the topmost layer to get V_3. Since $a_p = 1$, let $V_3 = \{(j, b_p) | p^{2p} < j < 2 \cdot p^{2p}\}$. The set of all the vertices is $V = V_1 \cup V_2 \cup V_3$. Note that $|V| = n$.

CLAIM 4.5. $wt(OPT(V)) \le 18p^{2p}$.

Proof. Since $wt(OPT(V))$ is no more than twice the weight of the optimal spanning tree, it suffices to show that there is a spanning tree of weight at most $9p^{2p}$. Consider the spanning tree built as follows: for every point in every layer, other than the bottom layer, draw a vertical line to the point directly above it in the next higher layer. Also draw the horizontal line in the topmost layer (layer number p). The total length of this tree is at most

$$3p^{2p} + 2\sum_{i=0}^{p-1} c_i \left(\frac{p^{2p}}{a_i} + 1\right) \le 3p^{2p}\left(1 + \sum_{i=0}^{p-1} \frac{2c_i}{a_i}\right) = 3p^{2p}\left(1 + p\frac{2}{p}\right) = 9p^{2p}. \qquad \square$$

Define the tour T on V to be as shown in Figure 4. Note that since $p+1$ is even, we can always construct this tour.

CLAIM 4.6. $wt(T(V)) > 2p \cdot p^{2p}$.

Proof. Consider just the horizontal edges in T. Each layer has horizontal edges whose combined weight is at least $2p^{2p}$ and there are $p+1$ layers. ∎

CLAIM 4.7. *T is 2-optimal.*

We first present some simple notation. For any point A, let A_x, A_y be its x and y coordinates. We use AB to refer to both the edge (line segment) and its length. $(AB)_x$ is the length of the projection of AB onto the x-axis; i.e., $(AB)_x = |A_x - B_x|$. We define $(AB)_y$ similarly. Note that $AB \geq (AB)_x, (AB)_y$. We say that two edges AB and CD, which are either both vertical or both horizontal, *overlap* if the following holds: let the projection of AB onto the infinite line containing CD be $A'B'$. Then $A'B' \cap CD$ consists of more than a single point.

We next state and prove a simple geometric lemma.

LEMMA 4.8. *Let EF and GH be horizontal line segments in the Euclidean plane, $G_x \leq E_x < F_x \leq H_x$. Let $EF = 1$, $GH = q^2$, $q \geq 1$, so $G_x \leq E_x \leq H_x - 1$. Let the vertical distance between EF and GH be z. If $z \geq q$, then* $\min\{EG+FH, EH+FG\} \geq EF + GH$.

Proof. Let $z \geq q$. Clearly, $EH + FG > EG + FH$, so all we need to prove is that $EG + FH \geq EF + GH$. For $0 \leq a \leq q^2 - 1$, define $f(a) = \sqrt{a^2+q^2} + \sqrt{(q^2-1-a)^2+q^2}$. Let $a = E_x - G_x$. Then $H_x - F_x = (q^2-1) - a$. $EG + FH = \sqrt{a^2+z^2} + \sqrt{(q^2-1-a)^2+z^2} \geq \sqrt{a^2+q^2} + \sqrt{(q^2-1-a)^2+q^2} = f(a)$. Since $EF + GH = q^2 + 1$, in order to show that $EG + FH \geq EF + GH$, it suffices to show, for $0 \leq a \leq q^2 - 1$, that $f(a) \geq q^2 + 1$.

We will show that the minimum value of $f(a)$ in the interval $[0, q^2-1]$ occurs at $a = (q^2-1)/2$. This suffices since $f(\frac{q^2-1}{2}) = q^2 + 1$.

$$\begin{aligned} f'(a) &= \frac{a}{\sqrt{a^2+q^2}} - \frac{(q^2-1-a)}{\sqrt{(q^2-1-a)^2+q^2}} \\ &= \frac{1}{\sqrt{1+(\frac{q}{a})^2}} - \frac{1}{\sqrt{1+(\frac{q}{q^2-1-a})^2}}. \end{aligned}$$

In the interval $[0, \frac{q^2-1}{2})$, $a < q^2 - 1 - a$, and hence $f'(a) < 0$. In the interval $(\frac{q^2-1}{2}, q^2-1]$, $a > q^2 - 1 - a$, and hence $f'(a) > 0$. Hence, the minimum value of $f(a)$ in the interval $[0, q^2-1]$ occurs at $a = (q^2-1)/2$. ∎

Proof of Claim 4.7. Suppose otherwise. Thus, in a single 2-change operation, from T we can get another tour T' such that $wt(T') < wt(T)$. Label the four vertices involved as A, B, C, D so that $E(T) - E(T') = \{AB, CD\}$, $E(T') - E(T) = \{AC, BD\}$, and $AC + BD < AB + CD$. Note that the vertices A, B, C, D have to be distinct, since in a single 2-change operation we cannot replace two edges out of one vertex.

Since all edges in $E(T)$ are either horizontal or vertical, there are three cases.

Case 1: AB and CD are both vertical edges. If AB and CD overlap, then they are the two vertical edges which face each other. But then $(AC)_x + (BD)_x \geq 2p^{2p} \geq AB + CD$. If AB and CD don't overlap, assume without loss of generality that $A_y, B_y \leq C_y < D_y$. If $A_y < B_y$, then $(AC)_y \geq AB$ and $(BD)_y \geq CD$. If $A_y > B_y$, then $(BD)_y \geq AB + CD$.

Case 2: One of AB or CD is horizontal and the other is vertical. Assume without loss of generality that AB is horizontal and CD is vertical. By construction, and since A, B, C, D are all distinct, exactly one of the following subcases has to be true.

Subcase (i): Either $C_y = A_y = B_y$ or $D_y = A_y = B_y$. Then, by construction, $A_x, B_x < C_x = D_x$ or $A_x, B_x > C_x = D_x$. If $C_y = A_y$, then $(BD)_y = CD$ and, by construction, $(AC)_x \geq AB$. Similarly, if $D_y = B_y$, then $(AC)_y = CD$ and $(BD)_x \geq AB$.

Subcase (ii): $C_y, D_y > A_y = B_y$. Since AB is horizontal ($A_x \neq B_x$) and CD is vertical ($C_x = D_x$), either $C_x \neq A_x$ or $D_x \neq B_x$. If $C_x \neq A_x$, then, by construction, $(AC)_x \geq AB$ and, by construction, $(BD)_y > CD$. Similarly, if $D_x \neq B_x$, then $(BD)_x \geq AB$ and $(AC)_y > CD$.

Subcase (iii): $C_y, D_y < A_y = B_y$. If $C_y < D_y$, then $(AC)_y = (AD)_y + CD$ and, by construction, $(AD)_y > AB$, implying $(AC)_y > AB + CD$. Similarly, if $D_y < C_y$, then $(BD)_y > AB + CD$.

Case 3: AB and CD are both horizontal edges.

Subcase (i): AB and CD are nonoverlapping. Assume without loss of generality that $A_x, B_x \leq C_x < D_x$. If $A_x < B_x$, then $(AC)_x \geq AB$ and $(BD)_x \geq CD$. If $B_x < A_x$, then $(BD)_x \geq AB + CD$.

Subcase (ii): AB and CD are overlapping. Assume without loss of generality that AB is the smaller, higher edge and that $C_x \leq D_x$, so $C_x \leq A_x, B_x \leq D_x$. Suppose AB is l levels above CD, $l \geq 1$. Then $CD = p^{2l} \cdot AB$. The difference in height between them is $AB \cdot (p + p^3 + \cdots + p^{2l-1}) \geq AB \cdot p^l$. Scaling all three quantities so that $AB = 1$, we see that the hypotheses of Lemma 4.8 are satisfied, and hence $AC + BD \geq AB + CD$. ∎

5. Bounds on the length of 2-optimal tours in the unit hypercube. In this section we show that for every m and every norm on $\mathbb{R}^m$ there is a $O(n^{1-1/m})$ upper bound on the length of any 2-optimal tour on n points in the m-dimensional unit hypercube. (The constant implicit in the big O depends on m and the norm.)

Notation: an arc is an ordered pair (h, t), $h, t \in \mathbb{R}^m$. The Euclidean norm of v is denoted $||v||_2$, the Euclidean distance between h and t is denoted $d_2(h, t) := ||h - t||_2$, and the (directed) line segment between them is denoted $\overline{ht}$. The *orientation* of an arc (h, t) is the (Euclidean) unit-length vector $(h - t)/||h - t||_2$, if $h \neq t$. The difference between two orientations r and s is the angle between them as defined in section 4, i.e., $\arccos(r \cdot s)$. Thus the orientations of (h, t) and (t, h) differ by π.

Given a norm N on $\mathbb{R}^m$, we can define a metric d_N by $d_N(x, y) := ||x - y||_N$ for all $x, y \in \mathbb{R}^m$.

THEOREM 5.1. *For any dimension $m \geq 2$, for any norm N on $\mathbb{R}^m$, there exists a constant $c_{m,N}$ such that, for any set S of n points in $[0, 1]^m$, any tour on S which is 2-optimal with respect to the metric d_N has length (defined by d_N) less than $c_{m,N} \cdot n^{1-1/m}$.*

Proof. Choose m and N. As in section 4.1, by the comparability of norms, there exists a constant $K_N \geq 1$ such that $d_2(x, y)/K_N \leq d_N(x, y) \leq K_N \cdot d_2(x, y)$ for all x, y. For a given $\epsilon > 0$, define the *long arcs* in T as those of length at least ϵ in d_N. For each long arc (h, t), define the *heart* of the arc as the interior of the hypercylinder of Euclidean radius $r = (1/K_N)\epsilon/8$ and length $d_N(h, t)/2$ in the metric d_N, with the height oriented parallel to $\overline{ht}$ and the center of the hypercylinder at the midpoint of segment $\overline{ht}$. In the 2-dimensional case the heart is a rectangle of Euclidean width $(1/K_N)\epsilon/4$.

We say that arc (h^1, t^1) *attacks* arc (h^2, t^2) if and only if the line segment $\overline{h^1 t^1}$ intersects the heart of $\overline{h^2 t^2}$. Note that attacking is not a symmetric relation.

At times it will be convenient to refer to the heart of a segment, or to say that

a line segment attacks another, even if the segment's endpoints are not tour points. The intended meaning is obvious.

Let $0 < \theta < \pi/2$ be an angle whose value will be chosen later. A *family* of arcs is any collection of long arcs in $\mathbb{R}^m$ from a 2-optimal tour, whose orientations differ pairwise by at most θ.

LEMMA 5.2. *No arc attacks another arc in the same family.*

Proof. We prove the lemma in three steps. First, it suffices to consider the case where arcs have length exactly ϵ (in norm N). Second, if two arcs are parallel, of N-length ϵ, and one attacks the other, then they violate 2-optimality by at least $\epsilon/4$. Third, if two arcs are oriented within θ and one attacks the other, and both are of N-length ϵ, then they can be made parallel while still attacking, while changing things by less than $\epsilon/4$.

Step 1 begins with a simple geometric definition.

DEFINITION 5.3. *If the line segment $\overline{HT}$ contains the line segment $\overline{ht}$, and their orientations are consistent (so $d(H,h) \le d(H,t)$), then we say $\overline{HT}$ is an* extension *of $\overline{ht}$.*

For any four points h^1, t^1, h^2, t^2, define the function

$$G_N(h^1,t^1,h^2,t^2) := d_N(h^1,t^1) + d_N(h^2,t^2) - d_N(h^1,h^2) - d_N(t^1,t^2).$$

The function G_N measures the decrease in tour length if arcs (h^1,t^1) and (h^2,t^2) are removed in a 2-change operation. The two arcs cannot both be in a 2-optimal tour if G_N is strictly positive. (If G_N is positive, we can swap out arcs (h^1,t^1), (h^2,t^2) and swap in either arcs (h^1,h^2), (t^1,t^2) or arcs (h^2,h^1), (t^2,t^1). The tour remains connected.) The following lemma implies that if a pair of arcs has positive G_N value, then so does any pair of extensions of these arcs.

LEMMA 5.4. *Let $\overline{h^it^i}$ for $i = 1,2$ be two directed line segments. Now let $\overline{H^iT^i}$, $i = 1,2$, be extensions of $\overline{h^it^i}$, $i = 1,2$, respectively. Then $G_N(h^1,t^1,h^2,t^2) \le G_N(H^1,T^1,H^2,T^2)$.*

Proof. Observe how G_N changes as the shorter segments are stretched by extending the endpoints in turn. Because H^1, h^1, and t^1 are collinear and any norm scales, $d_N(h^1,t^1) = d_N(H^1,t^1) - d_N(H^1,h^1)$. By the triangle inequality, $d_N(H^1,h^2) - d_N(h^1,h^2) \le d_N(H^1,h^1) = d_N(H^1,t^1) - d_N(h^1,t^1)$. Thus extending h^1 to H^1 cannot decrease G_N. By a symmetric argument the other components of G_N are nondecreasing as the segments are extended and Lemma 5.4 follows. ∎

Suppose long arc (H^1,T^1) attacks long arc (H^2,T^2). Obviously, the segment $\overline{H^1T^1}$ is an extension of some segment $\overline{h^1t^1}$ that has length $d_N(h^1,t^1) = \epsilon$ and that also attacks (H^2,T^2). Now consider all segments that are of N-length ϵ and can be extended to $\overline{H^2T^2}$. The union of the hearts of these segments is a hypercylinder of Euclidean radius $(1/K_N)\epsilon/8$ and N-length $d_N(H^2,T^2) - \epsilon/2 \ge d_N(H^2,T^2)/2$, with the same center as that of the heart of (H^2,T^2), so it contains the heart of (H^2,T^2). Therefore, at least one of these segments is attacked by $\overline{h^1t^1}$. Denote an attacked segment by $\overline{h^2t^2}$.

By Lemma 5.4, if $G_N(h^1,t^1,h^2,t^2) > 0$, then $G_N(H^1,T^1,H^2,T^2) > 0$. To prove our lemma it therefore suffices to consider the case $d_N(h^1,t^1) = d_N(h^2,t^2) = \epsilon$. This completes step 1 of the proof.

For step 2, we consider the case of arc $\overline{h^1t^1}$, which attacks $\overline{h^2t^2}$ and is parallel to it, with both of N-length ϵ. Thus $d_N(h^1,t^1) = d_N(h^2,t^2) = \epsilon$. We have

$$G_N(h^1,t^1,h^2,t^2) = d_N(h^1,t^1) + d_N(h^2,t^2) - d_N(h^1,h^2) - d_N(t^1,t^2).$$

Let P be a point on the infinite line containing h^1 and t^1 so that $\overline{h^1P}$ is perpendicular to $\overline{Ph^2}$. We have

$$d_N(h^1, h^2) \leq d_N(h^1, P) + d_N(P, h^2).$$

Now

$$d_N(P, h^2) \leq K_N d_2(P, h^2) \leq K_N r = \frac{1}{8}\epsilon.$$

Now

$$d_N(h^1, P) \leq \frac{3}{4} d_N(h^1, t^1) = \frac{3}{4}\epsilon.$$

So

$$d_N(h^1, h^2) \leq \frac{3}{4}\epsilon + \frac{1}{8}\epsilon = \frac{7}{8}\epsilon.$$

Similarly, let Q be a point on the infinite line containing h^2 and t^2 such that $\overline{Qt^2}$ is perpendicular to $\overline{Qt^1}$. Then

$$d_N(t^1, t^2) \leq d_N(t^1, Q) + d_N(Q, t^2) \leq K_N d_2(t^1, Q) + \frac{3}{4} d_N(h^2, t^2) \leq K_N r + \frac{3}{4}\epsilon = \frac{7}{8}\epsilon.$$

Therefore,

$$G_N(h^1, t^1, h^2, t^2) \geq 2\epsilon - \frac{7}{8}\epsilon - \frac{7}{8}\epsilon = \frac{\epsilon}{4}.$$

For step 3, suppose that two segments $\overline{h^1t^1}, \overline{h^2t^2}$ of N-length ϵ have orientation differing by at most θ. Without loss of generality assume that the first attacks the second. Let R be a point on the segment $\overline{h^1t^1}$ which lies in the heart of $\overline{h^2t^2}$. Holding R fixed, rotate the segment $\overline{h^1t^1}$ so that it becomes parallel to $\overline{h^2t^2}$. Let the angle by which the segment is rotated be ξ; note that $0 \leq \xi \leq \theta$. Let $\tilde{h}^1$ and $\tilde{t}^1$ be the points that h^1 and t^1 are rotated into, respectively. We have

$$G_N(h^1, t^1, h^2, t^2) = d_N(h^1, t^1) + d_N(h^2, t^2) - d_N(h^1, h^2) - d_N(t^1, t^2),$$

$$G_N(\tilde{h}^1, \tilde{t}^1, h^2, t^2) = d_N(\tilde{h}^1, \tilde{t}^1) + d_N(h^2, t^2) - d_N(\tilde{h}^1, h^2) - d_N(\tilde{t}^1, t^2),$$

and therefore

$$|G_N(h^1, t^1, h^2, t^2) - G_N(\tilde{h}^1, \tilde{t}^1, h^2, t^2)|$$

$$\leq |d_N(h^1, t^1) - d_N(\tilde{h}^1, \tilde{t}^1)| + |d_N(h^1, h^2) - d_N(\tilde{h}^1, h^2)| + |d_N(t^1, t^2) - d_N(\tilde{t}^1, t^2)|.$$

Consider first $|d_N(h^1, t^1) - d_N(\tilde{h}^1, \tilde{t}^1)|$. By the triangle inequality,

$$-d_N(\tilde{h}^1, h^1) - d_N(t^1, \tilde{t}^1) \leq d_N(\tilde{h}^1, \tilde{t}^1) - d_N(h^1, t^1) \leq d_N(\tilde{h}^1, h^1) + d_N(t^1, \tilde{t}^1).$$

Thus

$$|d_N(\tilde{h}^1, \tilde{t}^1) - d_N(h^1, t^1)| \leq d_N(\tilde{h}^1, h^1) + d_N(t^1, \tilde{t}^1) \leq K_N[d_2(\tilde{h}^1, h^1) + d_2(t^1, \tilde{t}^1)].$$

Now

$$|d_N(h^1,h^2)-d_N(\tilde{h}^1,h^2)|\le d_N(h^1,\tilde{h}^1)\le K_N d_2(h^1,\tilde{h}^1)$$

and

$$|d_N(t^1,t^2)-d_N(\tilde{t}^1,t^2)|\le d_N(t^1,\tilde{t}^1)\le K_N d_2(t^1,\tilde{t}^1).$$

Therefore,

$$|G_N(h^1,t^1,h^2,t^2)-G_N(\tilde{h}^1,\tilde{t}^1,h^2,t^2)|\le K_N d_2(\tilde{h}^1,h^1)+K_N d_2(t^1,\tilde{t}^1)+K_N d_2(h^1,\tilde{h}^1)$$
$$+K_N d_2(t^1,\tilde{t}^1)$$

$$=2K_N[d_2(h^1,\tilde{h}^1)+d_2(t^1,\tilde{t}^1)]$$
$$=2\sqrt{2}K_N[(\sqrt{1-\cos\xi})(d_2(R,h^1)+d_2(R,t^1))]\quad(\text{bythelawofcosines})$$
$$=2\sqrt{2}K_N(\sqrt{1-\cos\xi})d_2(h^1,t^1)$$
$$\le 2\sqrt{2}K_N(\sqrt{1-\cos\xi})[K_N d_N(h^1,t^1)]$$
$$=2\sqrt{2}K_N^2(\sqrt{1-\cos\xi})\epsilon$$
$$\le[2\sqrt{2}K_N^2\sqrt{1-\cos\theta}]\epsilon.$$

Now choose $0<\theta<\pi/2$ such that $2\sqrt{2}K_N^2\sqrt{1-\cos\theta}<1/4$. This completes the third and final step of the proof of Lemma 5.2. □

DEFINITION 5.5. *The* soul *of an arc $\overline{ht}$ is the hypercylinder defined as is the heart of the arc but with Euclidean radius $(1/K_N)\epsilon/16$ and N-length $d_N(h,t)/4$, which is half that of the heart.*

LEMMA 5.6. *If the souls of two long arcs intersect, then they attack each other.*

Proof. Let p be a point of intersection of the souls of (h^1,t^1) and (h^2,t^2). Let p^i denote the point on segment $\overline{h^it^i}$ of minimum Euclidean distance to p. Then, on the one hand, p^i is in the soul of (h^i,t^i) and $d_2(p,p^i)<(1/K_N)\epsilon/16$ for $i=1,2$. By the triangle inequality we have $d_2(p^1,p^2)<(1/K_N)\epsilon/8$.

On the other hand, the heart of (h^1,t^1) has Euclidean radius $(1/K_N)\epsilon/8$, and it extends (in metric d_N) $d_N(h^1,t^1)/8\ge\epsilon/8$ beyond the soul along the arc in both directions as well. Therefore, for any point q of the arc that is in the soul, its open Euclidean ball of radius $(1/K_N)\epsilon/8$ (the set of points at Euclidean distance less than $(1/K_N)\epsilon/8$ from q) is completely contained in the heart.

Taking $q=p^1$, it follows that p^2 is in the heart of (h^1,t^1). Therefore, (h^2,t^2) attacks (h^1,t^1). Taking $q=p^2$, it follows that p^1 is in the heart of (h^2,t^2) and (h^1,t^1) attacks (h^2,t^2). □

Any soul is contained in the slightly larger than unit hypercube of (Euclidean) side length $1+2(1/K_N)\epsilon/16$ and volume at most $k_1=(9/8)^m$ (if $\epsilon\le 1$). By Lemmas 5.2 and 5.6 the sum of the volumes of the souls in a family F is at most k_1.

Now the volume of the soul of arc (h,t) is $k_2\epsilon^{m-1}d_N(h,t)$ for some constant $k_2=k_2(N)$. So

$$k_2\epsilon^{m-1}\sum_{(h,t)\in F}d_N(h,t)\le k_1$$

and hence

$$\sum_{(h,t)\in F} d_N(h,t) \le k_1 \epsilon^{1-m}/k_2.$$

This bounds the sum of the lengths of long arcs in a single family.

For every possible orientation $||u||_2 = 1$, define a corresponding set $F_u = \{v \mid ||v||_2 = 1, v \cdot u > \cos(\theta/2)\}$. Notice that for any T the set F_u induces a family of arcs of T. The set of all F_u is an open cover of the compact unit sphere $\{u| \, ||u||_2 = 1\}$. Extract a finite subcover of cardinality k_3. Note that k_3 is independent of T and n. However, since θ depends on N (and m), so does k_3.

For all T the subcover provides a finite collection of families whose union is the set of all long arcs in the tour T. Therefore, the sum of the lengths of all long arcs in T is bounded by $k_3[k_1\epsilon^{1-m}/k_2]$.

The total N-length of all short arcs is obviously bounded by $n\epsilon$. Choose $\epsilon = n^{-1/m}$. The sum of the N-lengths of all arcs in T is less than $n\epsilon + \frac{k_1k_3}{k_2}\epsilon^{1-m} = n^{1-1/m} + \frac{k_1k_3}{k_2}n^{-(1-m)/m} = c_{m,N}n^{1-1/m}$ with $c_{m,N} = 1 + k_1k_3/k_2$, and Theorem 5.1 is proved. □

For the 2-dimensional case we can use a region larger than the soul and change a few other details to get an explicit bound on tour length.

COROLLARY 5.7. *In the 2-dimensional Euclidean case, the length of any 2-optimal tour is less than* $8\sqrt{51}\sqrt{n} + 459$ *if* $n \ge 816$.

Proof. Define the *left heart* of a long arc as that half of the arc's heart which lies strictly to the left of the arc when we are walking from tail to head. In this Euclidean case, the radius of the heart is $\epsilon/8$ and its length is $d_2(h,t)/2$. Also, θ is any positive angle with cosine exceeding 127/128.

LEMMA 5.8. *The left hearts of arcs in a family are mutually disjoint.*

Proof. Suppose that two long arcs (h^1,t^1) and (h^2,t^2) have intersecting left hearts. Suppose further that the two arcs' orientations differ by η where $0 \le \eta \le \theta$. We show that one of the arcs attacks the other and that the result follows from Lemma 5.2.

Let q be a point of intersection of the left hearts. Drop a perpendicular from q to segment $\overline{h^it^i}$ at intersection point $q^i, i = 1, 2$. Consider without loss of generality the case $d_2(q,q^1) \le d_2(q,q^2)$. We prove that in this case arc (h^1,t^1) attacks (h^2,t^2).

Extend the line segment $\overline{qq^2}$ to point q^{22} so that q^2 is the midpoint of the other points: $q^2 = (q + q^{22})/2$. Observe that the entire segment $\overline{qq^{22}}$ is within the heart (not necessarily the left heart) of (h^2,t^2). Therefore, all we have to do to prove that (h^2,t^2) is attacked is to verify that the segment $\overline{h^1t^1}$ intersects this segment $\overline{qq^{22}}$.

Let p denote the point of intersection of the (infinite) lines h^1t^1 and qq^{22}. The intersection p is sure to exist because $\eta < \pi/2$. First, we show that p is "between" q and q^{22} or simply that $d_2(q,p) \le d_2(q,q^{22})$. Since $\eta \le \theta$, we have

$$\frac{d_2(q,q^1)}{d_2(q,p)} = \cos\eta \ge 1/2.$$

Hence $d_2(q,p) \le 2d_2(q,q^1) \le 2d_2(q,q^2) = d_2(q,q^{22})$ as desired.

Second, we show that p is between h^1 and t^1. Now

$$\frac{d_2(q^1,p)}{d_2(q,q^1)} = \tan\eta \le \tan\theta \le \sqrt{3}.$$

Also, q is in the left heart of (h^1,t^1) and q^1 lies on that arc. Therefore, $d_2(q,q^1) \le \epsilon/8$. Finally, recall that the arc (h^1,t^1) is long, whence $d_2(h^1,t^1) \ge \epsilon$. Putting these

inequalities together, we find that q^1 and p are near each other:

$$d_2(q^1,p) \le \sqrt{3}d_2(q,q^1) \le \epsilon\sqrt{3}/8 < \epsilon/4 \le d_2(h^1,t^1)/4.$$

Since q^1 is in the middle half of the arc, $d_2(q^1,p) \le d_2(h^1,t^1)/4$ implies that p lies in the arc (h^1,t^1). Therefore, p is the desired point of intersection of the two segments, (h^2,t^2) is attacked, and the lemma is proved. □

Any left heart is contained in the square of side $1+\epsilon/4$ and area at most $1+9\epsilon/16$ (since $\epsilon \le 1$). By Lemma 5.8 the sum of the areas of the left hearts in a family F is at most $1+9\epsilon/16$.

The area of the left heart of arc (h,t) is $\epsilon d_2(h,t)/16$. Thus

$$(\epsilon/16)\sum_{(h,t)\in F} d_2(h,t) \le 1+9\epsilon/16$$

and hence

$$\sum_{(h,t)\in F} d_2(h,t) \le 16/\epsilon + 9.$$

The number of families needed to cover the circle is $\lceil \frac{2\pi}{\arccos\,(127/128)} \rceil = 51$. Therefore, the sum of the lengths of all long arcs in T is bounded by $51(16/\epsilon+9) = 816/\epsilon + 459$.

Choose $\epsilon = \sqrt{816}/\sqrt{n}$, which is at most 1 if $n \ge 816$. The sum of the lengths of all arcs in T is less than $\sqrt{816}\sqrt{n}$ (for the short arcs) $+(\sqrt{816}\sqrt{n}+459) = 8\sqrt{51}\sqrt{n}+459$ and Corollary 5.7 is proved. □

6. Expected value of the performance ratio in the unit hypercube. In this section we combine Theorem 5.1 with well-known distributional properties of optimal tour lengths to show that the expected performance ratio is bounded by a constant.

Let S_n be any set of n points in the m-dimensional unit hypercube $[0,1]^m \subset \mathbb{R}^m$. Let $OPT(S_n)$ be an optimal tour (under norm N) on S_n, and let $T(S_n)$ be a 2-optimal tour (under norm N). Let I_n be n points picked i.i.d. from the m-dimensional unit hypercube under the uniform distribution.

As an immediate corollary to Theorem 5.1 and a lower bound of $\Omega(n^{(m-1)/m})$ on $E[OPT(I_n)]$ [8], we infer that there exists a constant $\gamma_{m,N}$ such that $\frac{E[wt(T(I_n))]}{E[OPT(I_n)]} \le \gamma_{m,N}$ for all n; the ratio of the expected values is bounded. We now show that $\frac{wt(T(I_n))}{wt(OPT(I_n))}$ is $O(1)$ with high probability and that the expected value of this ratio is $O(1)$.

The following is easily obtainable from [8, Lemma 3, p. 190]: There exist constants $F_N > 0$ and $0 < \rho < 1$ such that for all $n > 1$,

$$P\left[wt(OPT(I_n)) \le F_N \cdot n^{\frac{m-1}{m}}\right] \le \rho^n.$$

From this and Theorem 5.1 we get the following theorem.

THEOREM 6.1.

$$P\left[wt(T(I_n)) \ge \frac{c_{m,N}}{F_N} \cdot wt(OPT(I_n))\right] \le \rho^n.$$

COROLLARY 6.2. *For all m and all norms N on $\mathbb{R}^m$ there exists a constant $c'_{m,N}$ such that*

$$E\left[\frac{wt(T(I_n))}{wt(OPT(I_n))}\right] \le c'_{m,N},$$

where $T(I_n)$ (respectively, $OPT(I_n)$) is the length of the longest 2-optimal tour (respectively, the shortest tour) on the points I_n with respect to N.

Proof. We first note that for any set of points S_n, $\frac{wt(T(S_n))}{wt(OPT(S_n))} \le n$; this follows, since if the diameter (under norm N) of S_n is D, then $wt(T(S_n)) \le nD$ and $wt(OPT(S_n)) \ge D$.

Let n_0 be such that for all $n \ge n_0,\ n\rho^n \le 1$. Let

$$\delta_N = \max_{2\le n\le n_0} E\left[\frac{wt(T(I_n))}{wt(OPT(I_n))}\right].$$

Now consider $n \ge n_0$.

$$\begin{aligned}
&E\left[\frac{wt(T(I_n))}{wt(OPT(I_n))}\right] \\
&= P[wt(T(I_n)) < \frac{c_{m,N}}{F_N}\cdot wt(OPT(I_n))]\cdot E\left[\frac{wt(T(I_n))}{wt(OPT(I_n))}\middle| wt(T(I_n)) < \frac{c_{m,N}}{F_N}\cdot wt(OPT(I_n))\right] \\
&+P[wt(T(I_n)) \ge \frac{c_{m,N}}{F_N}\cdot wt(OPT(I_n))]\cdot E\left[\frac{wt(T(I_n))}{wt(OPT(I_n))}\middle| wt(T(I_n)) \ge \frac{c_{m,N}}{F_N}\cdot wt(OPT(I_n))\right] \\
&< \frac{c_{m,N}}{F_N} + \rho^n n \\
&\le \frac{c_{m,N}}{F_N} + 1.
\end{aligned}$$

Taking $c'_{m,N} = \max\{\delta_N, \frac{c_{m,N}}{F_N} + 1\}$, we are done. ∎

7. Expected running time of 2-opt. This section gives polynomial upper bounds on the average number of iterations of 2-opt under the L_2 and L_1 norms.

7.1. The L_2 metric. In the first subsection, we prove that the average number of iterations done by the 2-opt local-improvement algorithm on n random points in the Euclidean unit square is $O(n^{10}\log n)$. Prior to this paper, no polynomial upper bound on the expected time was known. However, Kern proved a related result [9].

THEOREM 7.1. *There is a c such that the probability that 2-opt does more than n^{16} iterations is at most c/n.*

Kern's proof allows the possibility that 2-opt does exponentially many iterations with probability $\Omega(1/n)$. Kern writes: "Our approach does not seem to yield interesting results about average running times." We will prove that the expected time is polynomial, and we will rely heavily on Kern's lemmas in doing so.

The basic idea of Kern's proof is to show that, with probability at least $1 - c/n$, every iteration decreases the cost by at least $\epsilon(n) > 0$; the initial tour being of length at most $\sqrt{2}n$, the number of iterations can then not exceed $\frac{\sqrt{2}n}{\epsilon(n)}$.

To prove that the expected number of iterations is polynomial, we need the following definitions and lemma from [9].

DEFINITION 7.2. *Given points $P, Q, R, S \in [0,1]^2$, define $G(P,Q,R,S) = [d(P,Q) + d(R,S)] - [d(P,R) + d(Q,S)]$.*

DEFINITION 7.3. *Given three points P, Q, R in the unit square and $\epsilon > 0$, define $B_\epsilon(P,Q,R)$ to be the set of points S in the unit square such that $|G(P,Q,R,S)| \le \epsilon$.*

LEMMA 7.4 (see [9]). *There is a $K \ge 1$ with the following property. For any three points P, Q, R in the unit square with $P \ne Q$, the area of $B_\epsilon(P,Q,R)$ (which is the conditional probability that $|G(P,Q,R,S)| \le \epsilon$, given P, Q, R) is bounded above by $K\sqrt{\epsilon}/d(P,Q)$.*

Let $X_1, X_2, \ldots, X_n$ be points chosen independently and uniformly at random from the unit square.

DEFINITION 7.5. *If i, j, k, l are distinct elements of $\{1, 2, \ldots, n\}$, define $F(i,j,k,l) = G(X_i, X_j, X_k, X_l)$.*

DEFINITION 7.6. *Define $H = \{(i,j,k,l,i',j',k',l')$ such that $i,j,k,l,i',j',k',l' \in \{1,2,\ldots,n\}$, $|\{i,j,k,l\}| = |\{i',j',k',l'\}| = 4$, and $\{i,j,k,l\} \ne \{i',j',k',l'\}\}$.*

DEFINITION 7.7. *Given n random points $X_1, X_2, \ldots, X_n$ in the unit square, define*

$$\hat{F} = \min\{F(i',j',k',l') : (i,j,k,l,i',j',k',l') \in H$$

$$\text{and } 0 < F(i,j,k,l) \le F(i',j',k',l')\}.$$

DEFINITION 7.8. *Let $N = \min\{n!, 1/\hat{F}\}$.*

We now give a very rough road map of the proof that the expected number of iterations done by 2-opt is $O(n^{10} \log n)$. It is not hard to see that any two consecutive improving 2-changes involve distinct 4-sets of vertices. By the definition of $\hat{F}$, 2-opt must decrease the cost of the tour by at least $\hat{F}$ in any two consecutive iterations. The cost of the initial tour being at most $\sqrt{2}n$, the number of iterations cannot exceed $2\sqrt{2}n/\hat{F}$. Clearly, the number of iterations never exceeds $n!$. Thus the number of iterations done is at most $\min\{(2n\sqrt{2})\cdot n!, 2n\sqrt{2}/\hat{F}\} = (2n\sqrt{2})N$. Our goal is therefore to bound $E[N]$.

Notice that if $\hat{F} \in [\frac{\epsilon}{2}, \epsilon)$, then N, which is at least $\frac{1}{2n\sqrt{2}}$ times the number of iterations, is bounded by $\frac{2}{\epsilon}$. The chance that $\hat{F}$ is in this interval is bounded by $Cn^8\epsilon$, since $P[\hat{F} \le \epsilon] \le Cn^8\epsilon$ (this is Lemma 7.11). Hence the contribution to the expected value of N due to $[\frac{\epsilon}{2}, \epsilon)$ is bounded by $2Cn^8$. Since $N = n!$ if $\hat{F} < \frac{1}{n!}$ and $\hat{F} \le 2$ always, we need consider only $\lg n! + O(1)$ intervals, each of which contributes at most $2Cn^8$ to $E[N]$. Thus $E[N]$ is $O(n^8 \lg n!)$, and the expected number of iterations is $O(n^{10} \log n)$.

Now we continue with the proof.

LEMMA 7.9. *Let $\epsilon > 0$. Choose points $X_1, X_2, \ldots, X_n$ in the unit square independently and uniformly at random. Let $(i,j,k,l,i',j',k',l') \in H$. Suppose that $l \notin \{i',j',k',l'\}$ and that $l' \notin \{i,j,k,l\}$.*

1. *If $\{i,j\} \ne \{i',j'\}$, then $P[|F(i,j,k,l)| \le \epsilon, |F(i',j',k',l')| \le \epsilon] \le 64\pi^2K^2\epsilon$.*
2. *If $\{i,j\} = \{i',j'\}$, then $P[|F(i,j,k,l)| \le \epsilon, |F(i',j',k',l')| \le \epsilon] \le 14\pi K^2\epsilon \cdot \lg \frac{1}{\epsilon}$ if $\epsilon \le \frac{1}{2}$.*

Proof. From Lemma 7.4 we have

$$P[X_l \in B_\epsilon(X_i,X_j,X_k) : X_i, X_j, X_k] = P[|F(i,j,k,l)| \le \epsilon : X_i, X_j, X_k] \le \frac{K\sqrt{\epsilon}}{d(X_i,X_j)}.$$

Then

$$P[|F(i,j,k,l)| \le \epsilon, |F(i',j',k',l')| \le \epsilon : X_i, X_j, X_k, X_{i'}, X_{j'}, X_{k'}]$$

(notice that l and l' must be distinct from each other and from i, j, k, i', j', k', although the latter six need not be distinct)

$$\begin{aligned}
&= P[X_l \in B_\epsilon(X_i, X_j, X_k), X_{l'} \in B_\epsilon(X_{i'}, X_{j'}, X_{k'}) : X_i, X_j, X_k, X_{i'}, X_{j'}, X_{k'}] \\
&\le \frac{K\sqrt{\epsilon}}{d(X_i, X_j)} \frac{K\sqrt{\epsilon}}{d(X_{i'}, X_{j'})} \\
&= \frac{K^2\epsilon}{d(X_i, X_j) d(X_{i'}, X_{j'})}.
\end{aligned}$$

Therefore,

$$\begin{aligned}
&lP[|F(i,j,k,l)| \le \epsilon, |F(i',j',k',l')| \le \epsilon : X_i, X_j, X_k, X_{i'}, X_{j'}, X_{k'}] \\
&\qquad \le \frac{K^2\epsilon}{d(X_i, X_j) d(X_{i'}, X_{j'})}
\end{aligned}$$

and therefore

$$P[|F(i,j,k,l)| \le \epsilon, |F(i',j',k',l')| \le \epsilon : X_i, X_j, X_{i'}, X_{j'}] \le \frac{K^2\epsilon}{d(X_i, X_j) d(X_{i'}, X_{j'})}. \tag{4}$$

If $\{i,j\} \ne \{i',j'\}$, then

$$\begin{aligned}
&P[|F(i,j,k,l)| \le \epsilon, |F(i',j',k',l')| \le \epsilon] \\
&= \sum_{r=0}^{\infty} \sum_{s=0}^{\infty} P[|F(i,j,k,l)| \le \epsilon, |F(i',j',k',l')| \le \epsilon : \\
&\qquad\qquad d(X_i, X_j) \in [2^{-r}, 2^{-r+1}), d(X_{i'}, X_{j'}) \in [2^{-s}, 2^{-s+1})] \\
&\cdot P[d(X_i, X_j) \in [2^{-r}, 2^{-r+1}), d(X_{i'}, X_{j'}) \in [2^{-s}, 2^{-s+1})]
\end{aligned}$$

Now

$$\begin{aligned}
&P[d(X_i, X_j) \in [2^{-r}, 2^{-r+1}), d(X_{i'}, X_{j'}) \in [2^{-s}, 2^{-s+1})] \\
&\quad \le P[d(X_i, X_j) \le 2^{-r+1}, d(X_{i'}, X_{j'}) \le 2^{-s+1}] \\
&\quad \le \pi(2^{-r+1})^2 \pi(2^{-s+1})^2
\end{aligned}$$

since $\{i,j\} \ne \{i',j'\}$. Thus

$$P[|F(i,j,k,l)| \le \epsilon, |F(i',j',k',l')| \le \epsilon]$$

$$\leq \sum_{r=0}^{\infty}\sum_{s=0}^{\infty} P[|F(i,j,k,l)| \leq \epsilon, |F(i',j',k',l')| \leq \epsilon : d(X_i,X_j) \in [2^{-r},2^{-r+1}), d(X_{i'},X_{j'}) \in [2^{-s},2^{-s+1})] \cdot P[d(X_i,X_j) \in [2^{-r},2^{-r+1}), d(X_{i'},X_{j'}) \in [2^{-s},2^{-s+1})]$$

$$\leq \sum_{r=0}^{\infty}\sum_{s=0}^{\infty} \frac{K^2\epsilon}{2^{-r}2^{-s}}\pi(2^{-r+1})^2\pi(2^{-s+1})^2$$
$$= 16\pi^2 \sum_{r=0}^{\infty}\sum_{s=0}^{\infty} K^2\epsilon 2^r 2^s 2^{-2r} 2^{-2s}$$
$$= 16\pi^2 K^2\epsilon \leq \sum_{r=0}^{\infty}\sum_{s=0}^{\infty} 2^{-r}2^{-s}$$
$$= 16\pi^2 K^2\epsilon \left(\sum_{r=0}^{\infty} 2^{-r}\right)\left(\sum_{s=0}^{\infty} 2^{-s}\right)$$
$$= 64\pi^2 K^2\epsilon.$$

If instead $\{i,j\} = \{i',j'\}$, we have

$$P[X_l \in B_\epsilon(X_i,X_j,X_k) : X_i,X_j,X_k] = P[|F(i,j,k,l)| \leq \epsilon : X_i,X_j,X_k] \leq \frac{K\sqrt{\epsilon}}{d(X_i,X_j)}.$$

From (4) we know that

$$P[|F(i,j,k,l)| \leq \epsilon, |F(i',j',k',l')| \leq \epsilon : X_i,X_j] \leq \frac{K^2\epsilon}{d(X_i,X_j)^2}.$$

Thus

$$P[|F(i,j,k,l)| \leq \epsilon, |F(i',j',k',l')| \leq \epsilon]$$

$$= \sum_{s=0}^{\infty} P[|F(i,j,k,l)| \leq \epsilon, |F(i',j',k',l')| \leq \epsilon : d(X_i,X_j) \in [2^{-s},2^{-s+1})] \cdot P[d(X_i,X_j) \in [2^{-s},2^{-s+1})].$$

Since

$$P[|F(i,j,k,l)| \leq \epsilon, |F(i',j',k',l')| \leq \epsilon : d(X_i,X_j) \in [2^{-s},2^{-s+1})] \leq \min\left\{\frac{K^2\epsilon}{(2^{-s})^2}, 1\right\}$$
$$= \min\{K^2\epsilon 2^{2s}, 1\},$$

we have

$$P[|F(i,j,k,l)| \leq \epsilon, |F(i',j',k',l')| \leq \epsilon]$$
$$\leq \sum_{s=0}^{\infty} P[d(X_i,X_j) \in [2^{-s},2^{-s+1})] \cdot \min\{K^2\epsilon 2^{2s}, 1\}$$

$$\leq \sum_{s=0}^{\infty} P[d(X_i, X_j) \leq 2^{-s+1}] \cdot \min\{K^2 \epsilon 2^{2s}, 1\}$$

$$\leq \sum_{s=0}^{\infty} 4\pi 2^{-2s} \cdot \min\{K^2 \epsilon 2^{2s}, 1\}.$$

Now $K^2\epsilon 2^{2s} < 1$ if and only if $s < \frac{1}{2} \lg \frac{1}{K^2\epsilon}$. Therefore, the quantity is at most

$$\sum_{s=0}^{\lfloor \frac{1}{2} \lg \frac{1}{K^2\epsilon} \rfloor} 4\pi 2^{-2s} K^2 \epsilon 2^{2s} + \sum_{s=\lceil \frac{1}{2} \lg \frac{1}{K^2\epsilon} \rceil}^{\infty} 4\pi 2^{-2s} \cdot 1$$

$$\leq 4\pi K^2 \epsilon \left(1 + \frac{1}{2} \lg \frac{1}{K^2\epsilon}\right) + 8\pi K^2 \epsilon.$$

If $\epsilon \leq \frac{1}{2}$, then since $K \geq 1$ we have

$$4\pi K^2 \epsilon \left(1 + \frac{1}{2} \lg \frac{1}{K^2\epsilon}\right) + 8\pi K^2 \epsilon \leq 14\pi K^2 \epsilon \cdot \lg \frac{1}{\epsilon}. \qquad \square$$

LEMMA 7.10. *Let $\epsilon > 0$. Let $(i, j, k, l, i', j', k', l') \in H$.*

1. *If $|\{i, j, k, l\} \cap \{i', j', k', l'\}| \leq 1$, then $P[|F(i, j, k, l)| \leq \epsilon, |F(i', j', k', l')| \leq \epsilon] \leq 64\pi^2 K^2 \epsilon$.*
2. *If $|\{i, j, k, l\} \cap \{i', j', k', l'\}| \geq 2$ and $\epsilon \leq \frac{1}{2}$,then*

$$P[|F(i, j, k, l)| \leq \epsilon, |F(i', j', k', l')| \leq \epsilon] \leq 64\pi^2 K^2 \epsilon \cdot \lg \frac{1}{\epsilon}$$

.

Proof. By the symmetry in F, we have $F(a, b, c, d) = F(c, d, a, b) = F(b, a, d, c)$. This means that it is possible to move any one of the indices into the final position without changing the value of $F(a, b, c, d)$. Formally, if $x \in \{a, b, c, d\}$, then there is a permutation (a', b', c', d') of $\{a, b, c, d\}$ such that $d' = x$ and $F(a', b', c', d') = F(a, b, c, d)$ always.

Since $\{i, j, k, l\} \neq \{i', j', k', l'\}$, we can find an x in $\{i, j, k, l\} - \{i', j', k', l'\}$ and a y in $\{i', j', k', l'\} - \{i, j, k, l\}$. By moving x and y to the last position, without loss of generality we may assume that $l \notin \{i', j', k', l'\}$ and $l' \notin \{i, j, k, l\}$.

Now we invoke Lemma 7.9. If $|\{i, j, k, l\} \cap \{i', j', k', l'\}| \leq 1$, clearly $\{i, j\} \neq \{i', j'\}$. Lemma 7.9 implies that $P[|F(i, j, k, l)| \leq \epsilon, |F(i', j', k', l')| \leq \epsilon] \leq 64\pi^2 K^2 \epsilon$.

If $|\{i, j, k, l\} \cap \{i', j', k', l'\}| \geq 2$, then possibly $\{i, j\} = \{i', j'\}$ and possibly not. In the former case, $P[|F(i, j, k, l)| \leq \epsilon, |F(i', j', k', l')| \leq \epsilon] \leq 14\pi K^2 \epsilon \cdot \lg \frac{1}{\epsilon} \leq 64\pi^2 K^2 \epsilon \cdot \lg \frac{1}{\epsilon}$ (if $\epsilon \leq \frac{1}{2}$). In the latter case, $P[|F(i, j, k, l)| \leq \epsilon, |F(i', j', k', l')| \leq \epsilon] \leq 64\pi^2 K^2 \epsilon$. $\square$

Recall the definition of $\hat{F}$:

$$\hat{F} = \min\{F(i', j', k', l') : (i, j, k, l, i', j', k', l') \in H \text{ and } 0 < F(i, j, k, l) \leq F(i', j', k', l')\}.$$

LEMMA 7.11. *Let $n \geq 8$ and let $C = 9280\pi^2 K^2$. Let $2^{-n^2} \leq \epsilon \leq \frac{1}{2}$. Then $P[\hat{F} \leq \epsilon] \leq Cn^8\epsilon$.*

In $P[\hat{F} \le \epsilon] \le Cn^8\epsilon$, the n^8 comes from the fact that H in the definition of $\hat{F}$ has at most n^8 8-tuples. The ϵ comes from Lemma 7.4, which has a $\sqrt{\epsilon}$. Very roughly, because $\hat{F}$ involves *two* 4-tuples, we will be able to replace the $\sqrt{\epsilon}$ in Lemma 7.4 with its *square*, ϵ.

Proof. In this terminology, $\hat{F} \le \epsilon$ if and only if there is an 8-tuple $(i, j, k, l, i', j', k', l') \in H$ such that $0 < F(i, j, k, l) \le \epsilon$ and $0 < F(i', j', k', l') \le \epsilon$. Then

$$P[\hat{F} \le \epsilon] \le \sum P[|F(i, j, k, l)| \le \epsilon, |F(i', j', k', l')| \le \epsilon],$$

where the summation is over H. There are at most n^8 8-tuples $(i, j, k, l, i', j', k', l') \in H$ such that $|\{i, j, k, l\} \cap \{i', j', k', l'\}| \le 1$. There are at most 12^2n^6 8-tuples such that $|\{i, j, k, l\} \cap \{i', j', k', l'\}| \ge 2$. By Lemma 7.10, if $0 < \epsilon \le \frac{1}{2}$, then

$$P[\hat{F} \le \epsilon] \le n^8(64\pi^2K^2\epsilon) + 144n^6\left(64\pi^2K^2\epsilon \lg \frac{1}{\epsilon}\right).$$

Since $2^{-n^2} \le \epsilon \le \frac{1}{2}$, $\frac{1}{\epsilon} \le 2^{n^2}$ and $\lg \frac{1}{\epsilon} \le n^2$. Thus the preceding expression is no more than $n^8(64\pi^2K^2)\epsilon + 144n^6(64\pi^2K^2n^2)\epsilon = n^8(9280\pi^2K^2)\epsilon$. Let $C = 9280\pi^2K^2$. Therefore, $P[\hat{F} \le \epsilon] \le Cn^8\epsilon$ if $2^{-n^2} \le \epsilon \le \frac{1}{2}$ and $n \ge 8$. ∎

Recall that $N = \min\{n!, 1/\hat{F}\}$.

LEMMA 7.12. *$E[N] \le 4Cn^9 \lg n$ if $n \ge 8$.*

Proof. We have

$$\begin{aligned} E[N] &\le \sum_{r=-1}^{\lceil \lg n! \rceil} P[\hat{F} \in [2^{-r}, 2^{-r+1})] \cdot 2^r + P\left[\hat{F} < \frac{1}{n!}\right] \cdot n! \\ &\le \sum_{r=-1}^{\lceil \lg n! \rceil} P[\hat{F} \le 2^{-r+1}]2^r + P\left[\hat{F} < \frac{1}{n!}\right] n!. \end{aligned}$$

Thus

$$\begin{aligned} E[N] &\le \sum_{r=-1}^{1} P[\hat{F} \le 2^{-r+1}]2^r + \sum_{r=2}^{\lceil \lg n! \rceil} P[\hat{F} \le 2^{-r+1}]2^r + P\left[\hat{F} < \frac{1}{n!}\right] n! \\ &\le \left(\frac{1}{2} + 1 + 2\right) + \sum_{r=2}^{\lceil \lg n! \rceil} (Cn^8 2^{-r+1})2^r + Cn^8 \frac{1}{n!} n! \\ &= 3.5 + 2Cn^8(\lceil \lg n! \rceil - 1) + Cn^8 \\ &\le 3.5 + 2Cn^8(n \lg n) \\ &\le 4Cn^9 \lg n, \end{aligned}$$

since we are assuming $n \ge 8$. ∎

THEOREM 7.13. *The average number of 2-changes made by algorithm 2-opt when run on n i.i.d. uniform random points in the Euclidean unit square is at most $(8C\sqrt{2})n^{10} \lg n$, for any $n \ge 8$.*

Proof. If a 2-change is made, replacing edges (x_i, x_j) and (x_k, x_l) by (x_i, x_k) and (x_j, x_l), then the same four vertices $\{i, j, k, l\}$ cannot be used in an improving 2-change in the next iteration. Therefore, any two consecutive improving 2-changes involve distinct 4-tuples of vertices.

By the definition of $\hat{F}$, 2-opt must decrease the cost of the tour by at least $\hat{F}$ in any two consecutive iterations. The cost of the initial tour being at most $\sqrt{2}n$, the number of iterations cannot exceed $2\sqrt{2}n/\hat{F}$. Clearly, the number of iterations never exceeds $n!$.

The number of iterations done is at most

$$\begin{aligned} & \min\left\{(2n\sqrt{2})\cdot n!, \frac{2n\sqrt{2}}{\hat{F}}\right\} \\ = \; & (2n\sqrt{2})\cdot \min\left\{n!, \frac{1}{\hat{F}}\right\} \\ = \; & (2n\sqrt{2})N. \end{aligned}$$

Thus the average number of iterations is at most $(2n\sqrt{2})E[N] \le (8C\sqrt{2})n^{10}\lg n$ for all $n \ge 8$. ∎

7.2. The L_1 metric. In this subsection we bound the expected number of iterations of 2-opt under the L_1 norm. In contrast with Theorem 7.13 the proof is somewhat nonconstructive, but it is fairly short and the polynomial is of lower order.

THEOREM 7.14. *Let n points be independently sampled from the uniform distribution in the m-dimensional unit hypercube. Let 2-opting be performed with respect to the L_1 norm. Then the expected number of iterations required is $O(n^6 \log n)$.*

Proof. Let I^m denote the unit hypercube. Suppose v^1, v^2, v^3, v^4 are four points sampled independently from the uniform distribution on I^m. Let Z denote the random variable equal to $G(v^1, v^2, v^3, v^4) = ||v^1 - v^2||_1 + ||v^3 - v^4||_1 - ||v^1 - v^3||_1 - ||v^2 - v^4||_1$. Note that distances are computed according to the L_1 norm.

We study the distribution of Z. For clarity we focus on the case $m = 2$ and use remarks to extend the proof to the m-dimensional case.

The four points in I^2 are defined by eight $(4m)$ random variables, denoted $x_i, y_i : i = 1, \ldots, 4$, and drawn independently from the uniform distribution on $[0, 1]$. Let $g(x_1, \ldots, x_4) = |x_1 - x_2| + |x_3 - x_4| - |x_1 - x_3| - |x_2 - x_4|$. Then Z is the sum of the i.i.d. variables X and Y where $X = g(x_1, x_2, x_3, x_4)$ and $Y = g(y_1, y_2, y_3, y_4)$. The key is to understand the distribution of X, because $X + Y$ will have a distribution found as the convolution of two i.i.d. variables with this distribution. (In m dimensions, Z is the m-fold convolution of i.i.d. variables with this distribution.)

LEMMA 7.15. *With probability $1/3$ the variable $X = 0$; with probability $2/3$ the variable X is distributed according to a continuous density function $\bar{h}$ on $[-2, 2]$.*

Proof. Consider the conditional distribution of X, conditioned on the event $\pi_1 = \{x_1 \ge x_2 \ge x_3 \ge x_4\}$. Notice that $X = 2x_3 - 2x_2$ under this condition. Now if we take four samples i.i.d. from the uniform distribution and let W equal the difference between the third and second largest, then obviously W has a continuous density function. Therefore, X has continuous conditional density function conditioned on event π_1. We denote the conditional probability density by h_{π_1}.

By symmetry, for seven other π's we can make the same argument, and for each we get a continuous conditional probability density function h_{π_i}. For eight additional π_i's the conditional distribution is like $-W$, i.e., twice the difference between the second and third largest.

For the last eight π_i, the conditional distribution of X is degenerate with all its mass at zero. This occurs when the projections of the arcs on the x-axis overlap and have opposite orientations.

The unconditional density function of X is

$$h = \sum_{i=1}^{24} \frac{1}{24} h_{\pi_i}.$$

Therefore, X has a hybrid distribution. It has a mass point of weight $8/24 = 1/3$ at 0. The remaining $2/3$ of the mass has continuous density because each of the 16 contributing h_{π_i}'s is continuous. □

When the distribution of X is convolved with itself to get Z, the result is a hybrid distribution: $Z = 0$ with probability $1/9$; Z is distributed according to a continuous density, denoted $\bar{h}^2$, with probability $8/9$. This is because X and Y are independent. (In higher dimensions each additional convolution is of two independent hybrid distributions, each containing one mass point at zero, and continuous everywhere else, and these properties are obviously preserved in the sum of the distributions.) In m dimensions, the probability is $(1/3)^m$ that a given random 4-tuple of points has $Z = 0$; Z is distributed according to a continuous density, denoted $\bar{h}^m$, with probability $1 - (1/3)^m$.

A local improvement algorithm will not make any of the 2-changes corresponding to 4-tuples where $Z = 0$. The algorithm will be fast if there are no very small *positive* Z values.

Now consider the density function $\bar{h}^m$. It is continuous everywhere on $[-2m, 2m]$ and is symmetric around 0. Since a continuous function on a compact set attains its maximum, $\bar{h}^m$ has a maximum M. This implies that

$$P[0 < |Z| \le \epsilon] \le 2M\epsilon \quad \text{for all } \epsilon > 0.$$

Now let S denote a sample of n points on I^m. Let Δ denote the smallest of all nonzero absolute differences in tour length from 2-changes:

$$\Delta = \min_{\substack{v^1, v^2, v^3, v^4 \in S \\ G(v^1, v^2, v^3, v^4) \neq 0}} |G(v^1, v^2, v^3, v^4)|$$

(where the minimum is over distinct points). Since the minimum is taken over fewer than n^4 4-tuples, we get

$$P[\Delta < \epsilon] < n^4(2M\epsilon) = cn^4\epsilon.$$

By the same argument as in Lemma 7.12, with an n^4 instead of an n^8 term, we have $E[\min\{n!, 1/\Delta\}] \le 4cn^5 \log n$. The cost of the initial tour being at most $2n$, the expected number of iterations is at most $(2n)4cn^5 \log n$, which is $O(n^6 \log n)$. □

8. Extending Lueker's construction. In 1976, Lueker [15] constructed, for each $n \geq 4$, a family of n-node weighted cliques G_n on vertex set $\{x_0, x_1, x_2, \ldots, x_{n-1}\}$ with the property that the naive 2-opt algorithm can do at least $2^{\lfloor n/2 \rfloor - 2}$ iterations. Although the only thing we need from his construction is that each of the tours includes the edge $\{x_0, x_{n-1}\}$, we give Lueker's (unpublished) construction here: For each $0 \leq i < j \leq n-1$, define the weight w_{ij} of edge $\{x_i, x_j\}$ as follows.

1. j is even.
   (a) If i=0, then $w_{ij} = 2^{2j}$.
   (b) If i is positive and odd, then $w_{ij} = 2^{2i+3}$.
   (c) If i is positive and even, then $w_{ij} = 2^{2i}$.
2. j is odd.
   (a) If i=0, then $w_{ij} = 2^{2j+3}$.
   (b) If i is positive and odd, then $w_{ij} = 2^{2i+4}$.
   (c) If i is positive and even, then $w_{ij} = 2^{2i+3}$.

For $q \leq \lfloor n/2 \rfloor - 1$, let $a_q = \langle x_1, x_2, x_3, \ldots, x_{2q} \rangle$ and let a'_q be its reverse. Lueker proves the following theorem.

THEOREM 8.1. *Let T be a tour of G_n that contains the block $\langle x_0, a_q, x_{2q+1} \rangle$. Then there is a sequence of at least 2^{q-1} improving 2-changes which lead to the replacement of this block by $\langle x_0, a'_q, x_{2q+1} \rangle$ (and which leaves the rest of the tour unchanged).*

We refer to [15] for a proof, which converts the string $\langle x_0, a_q, x_{2q+1}, x_{2q+2}, x_{2q+3} \rangle$ to $\langle x_0, a'_q, x_{2q+1}, x_{2q+2}, x_{2q+3} \rangle$ in at least 2^{q-1} steps by induction, then to $\langle x_0, a'_q, x_{2q+2}, x_{2q+1}, x_{2q+3} \rangle$ in one step, then to $\langle x_0, x_{2q+1}, x_{2q+2}, a_q, x_{2q+3} \rangle$ in one step, then to $\langle x_0, x_{2q+1}, x_{2q+2}, a'_q, x_{2q+3} \rangle$ in at least 2^{q-1} steps by a clever use of the inductive assertion, and last to $\langle x_0, x_{2q+2}, x_{2q+1}, a'_q, x_{2q+3} \rangle$. Notice that, as claimed, edge $\{x_0, x_{n-1}\}$ is in all tours.

It is now our job to extend the result to all $k \geq 3$. Since $k \geq 4$ is easy, we do that case first.

THEOREM 8.2. *For any $k \geq 4$, for any $N \geq 2k$, there is an N-vertex weighted graph on which there exists a sequence of at least $2^{\lfloor N/2 \rfloor - k}$ improving k-changes.*

Proof. The idea is to take G_n and add $2(k-2)$ new vertices at distance one from each other and from the original vertices. Any 2-change in the original proof can be converted to a k-change in the new graph by flipping two original edges and $k-2$ new ones.

Let $l = k - 2$ and add to G_n $2l$ new vertices:

$$s, t, y_1, z_1, y_2, z_2, \ldots, y_{l-1}, z_{l-1}.$$

The distance between any pair of these vertices, as well as that between these new vertices and the n old ones, is 1. Let

$$A = \{\{y_1, z_1\}, \{y_2, z_2\}, \{y_3, z_3\}, \ldots, \{y_{l-1}, z_{l-1}\}\},$$

$$L = \{\{s, y_1\}, \{z_1, y_2\}, \{z_2, y_3\}, \ldots, \{z_{l-1}, t\}\},$$

and

$$R = \{\{s, z_1\}, \{y_1, z_2\}, \{y_2, z_3\}, \ldots, \{y_{l-1}, t\}\}.$$

The key fact is that $A \cup L$ is the edge set of a Hamiltonian path from s to t among the new vertices, $A \cup R$ is the edge set of a Hamiltonian path from s to t among the

new vertices, and A, L, R are pairwise disjoint. Furthermore, $A \cup L$ and $A \cup R$ differ in exactly l edges.

Now let S, T be the edge sets of any two tours of G_n that both contain edge $\{x_0, x_{n-1}\}$ and share exactly $n-2$ edges. Let $S' = (S - \{x_0, x_{n-1}\}) \cup (\{\{x_0, s\}, \{x_{n-1}, t\}\} \cup A \cup L)$ and $T' = (T - \{x_0, x_{n-1}\}) \cup (\{\{x_0, s\}, \{x_{n-1}, t\}\} \cup A \cup R)$. S' induces a tour of the new graph, T' induces a tour of the new graph as well, and S' and T' differ in exactly $2 + l = k$ edges. Since all the new edges have weight 1, if moving from S to T on the original graph is a cost-decreasing 2-change, then moving from S' to T' in the new graph is a cost-decreasing k-change. (In the next step, we can interchange the roles of the y's and z's, since they are symmetric.)

Lueker's proof gives a sequence of at least $2^{\lfloor n/2 \rfloor - 2}$ cost-decreasing 2-changes on an n-vertex graph (if $n \geq 4$). The new graph we built has $N = n + 2l = n + 2(k-2) = n + 2k - 4$ vertices, and there is a sequence of $2^{\lfloor n/2 \rfloor - 2}$ cost-decreasing k-changes. In terms of the number N of vertices in the new graph, the number of k-changes is at least $2^{\lfloor N/2 \rfloor - k}$. □

Now we tackle $k = 3$.

THEOREM 8.3. *For each even $N \geq 8$, there is an N-vertex weighted graph on which there exists a sequence of at least $2^{\lfloor N/4 \rfloor - 1}$ improving 3-changes.*

Proof. We use w_{ij} to denote the weight of $\{x_i, x_j\}$ in G_n. Let $w_{ii} = 0$ for all i. Take two copies of G_n. One copy has vertex set $V = \{x_0, \ldots, x_{n-1}\}$; the other has vertex set $V' = \{x'_0, \ldots, x'_{n-1}\}$. The weight of edge $\{x'_i, x'_j\}$, $i \neq j$, and that of $\{x_i, x'_j\}$ equals w_{ij}. Call the new $2n$-node graph H_n.

Let S be the edge set of any tour in G_n containing edge $\{x_0, x_{n-1}\}$. There is an obvious associated tour of H_n: Let $A = S - \{\{x_0, x_{n-1}\}\}$. Let $A^* = \{\{x'_i, x'_j\} | \{x_i, x_j\} \in A\}$. Then the associated tour contains edges $S' = \{\{x_0, x'_{n-1}\}, \{x'_0, x_{n-1}\}\} \cup A \cup A^*$. It is not hard to see that S' is the edge set of a tour in H_n.

We will prove the following. Let S be any tour of G_n containing $\{x_0, x_{n-1}\}$, and let S' be the associated tour of H_n. Let T be a tour of G_n obtained from S by one cost-decreasing 2-change, such that the 2-change does not involve the edge $\{x_0, x_{n-1}\}$. Then the tour T' of H_n associated with T can be obtained from S' via *two* cost-decreasing 3-changes. (We are implicitly identifying tours with their edge sets.)

Consider the tour S as directed from x_0 to x_{n-1}. Suppose that the 2-change involves swapping the edges $\{x_i, x_j\}, \{x_k, x_l\}$, where, in S, the vertex x_i is the first among the four visited by S, x_j is second, x_l is third, and x_k is fourth. Since the 2-change results in a tour T, it must replace the two missing edges by $\{x_i, x_l\}, \{x_k, x_j\}$. (If they were replaced by $\{x_i, x_k\}, \{x_l, x_j\}$, then the new "tour" would be disconnected.)

Let S' and T' be the tours of H_n associated with S and T, respectively. S' and T' differ only in that to get from S' to T' one drops the four edges $\{x_i, x_j\}$, $\{x'_i, x'_j\}$, $\{x_k, x_l\}$, $\{x'_k, x'_l\}$ and adds $\{x_i, x_l\}$, $\{x'_i, x'_l\}$ and $\{x_k, x_j\}$, $\{x'_k, x'_j\}$.

We know that switching from S to T decreased the cost; thus $(w_{ij} + w_{kl}) - (w_{il} + w_{kj}) > 0$. In S', we have the four edges $\{x_i, x_j\}$, $\{x_k, x_l\}$, $\{x'_i, x'_j\}$, $\{x'_k, x'_l\}$. We leave the last one unchanged and change the first three to $\{x_i, x_l\}$, $\{x_k, x'_j\}$, $\{x'_i, x_j\}$. It is easy to see that the new "tour" is indeed a tour, so this is a valid 3-change, provided that we have decreased the cost. The decrease in cost is

$$(w_{ij} + w_{kl} + w_{ij}) - (w_{il} + w_{kj} + w_{ij}) = (w_{ij} + w_{kl}) - (w_{il} + w_{kj}),$$

which we know to be positive. The next 3-change leaves edge $\{x_i, x_l\}$ unchanged. It flips $\{x_k, x'_j\}, \{x'_i, x_j\}, \{x'_k, x'_l\}$ to $\{x_k, x_j\}$, $\{x'_i, x'_l\}$, $\{x'_k, x'_j\}$. The decrease in cost is

$$(w_{kj} + w_{kl} + w_{ij}) - (w_{il} + w_{kj} + w_{kj}) = (w_{ij} + w_{kl}) - (w_{il} + w_{kj}),$$

which we know to be positive. The resulting edge set contains $\{x_k, x_j\}$, $\{x'_k, x'_j\}$, $\{x_i, x_l\}$, $\{x'_i, x'_l\}$ and is otherwise the same as S'; thus it is T' and therefore a tour.

Lueker's proof gave $2^{\lfloor n/2 \rfloor - 2}$ 2-changes on an n-vertex graph, $n \geq 4$. We have $N = 2n$, and we make two 3-changes for each original 2-change. In terms of N, we have $2^{\lfloor N/4 \rfloor - 1}$ 3-changes if $N \geq 8$ is even. □

9. Open problems.

- One of the best TSP algorithms in actual experiments [2] is the Lin–Kernighan algorithm [13], a local search algorithm with a more complex neighborhood structure. Since a Lin–Kernighan optimal tour is also 2-optimal, all the upper bounds on the performance ratio of 2-opt also hold for Lin–Kernighan. Can one do better for Lin–Kernighan?
- Our lower bounds on the performance ratio of k-opt are obtained by showing that there is some k-optimal tour of large weight. Suppose that we start with a random tour and then deterministically make improving k-changes. Can we get better performance guarantees?
- Can Lueker's results be extended to the Euclidean plane; i.e., is there a graph in the Euclidean plane for which there exists an exponential number of improving 2-changes?
- Can Theorem 3.4 be generalized to any k-opt algorithm; i.e., for arbitrary metric spaces can it be proved that, as k increases, the performance guarantee of the k-opt algorithm improves?

Acknowledgments. We thank Jim Dai, Bob Foley, Tony Hayter, Mark Krentel, Mike Todd, David Shmoys, and Sundar Vishwanathan for helpful discussions on the material of the paper and George Lueker for kindly permitting us to include his construction in section 8. We also thank the two anonymous referees for their remarks.

PARALLEL COMPLEXITY OF NUMERICALLY ACCURATE LINEAR SYSTEM SOLVERS*

MAURO LEONCINI†, GIOVANNI MANZINI‡, AND LUCIANO MARGARA§

Abstract. We prove a number of negative results about practical (i.e., work efficient and numerically accurate) algorithms for computing the main matrix factorizations. In particular, we prove that the popular Householder and Givens methods for computing the QR decomposition are P-complete, and hence presumably inherently sequential, under both real and floating point number models. We also prove that Gaussian elimination (GE) with a weak form of pivoting, which aims only at making the resulting algorithm nondegenerate, is likely to be inherently sequential as well. Finally, we prove that GE with partial pivoting is P-complete over GF(2) or when restricted to symmetric positive definite matrices, for which it is known that even standard GE (no pivoting) does not fail. Altogether, the results of this paper give further formal support to the widespread belief that there is a tradeoff between parallelism and accuracy in numerical algorithms.

Key words. P-complete problems, parallel complexity, NC algorithms, inherently sequential algorithms, matrix factorization, numerical stability

1. Introduction.

Matrix factorization algorithms form the backbone of many numerical libraries, such as LINPACK and LAPACK [7, 2]. They are also available as primitive routines in state-of-the-art scientific computing environments like MATLAB [17]. Indeed, factoring a matrix is almost always the first step of many scientific computations, and usually the one which places the heaviest demand in terms of computing resources. Some authors have investigated the parallel complexity of the most popular and important matrix factorizations, namely, the $(P)LU$ and $QR(\Pi)$ decompositions (see section 2 for definitions and simple properties). A list of positive known results follows.

1. LU decomposition is in arithmetic NC, whenever it exists, i.e., provided that the leading principal minors of the input matrix are nonsingular (in this case we will say that the matrix is *strongly nonsingular*) [19, 21].

2. QR decomposition is in arithmetic NC for matrices with full column rank, since it easily reduces to LU decomposition of strongly nonsingular matrices [19].

3. PLU decomposition is in arithmetic NC for nonsingular matrices [8]. The algorithm for finding a permutation matrix P such that P^TA is strongly nonsingular

builds upon the computation of the lexicographically first maximal independent subset (LFMIS) of the rows of a matrix, which is in NC^2 [3].[1]

4. $QR\Pi$ factorization of an arbitrary matrix A is in arithmetic NC [8]. A permutation Π such that the leftmost $n \times r$ submatrix of A has full column rank, for $r = \text{rank}(A)$, can be found by computing the LFMIS of sets of (column) vectors.

Unfortunately, none of the above algorithms seems to be of practical worth. Except for [21], they boil down to fast parallel determinant or inverse matrix computations (see, e.g., [5, 9]), and the few experiments and theoretical analyses that have been performed indicate that these are very unstable in general [4, 6, 22]. Moreover, the analysis in [4] of Reif's LU factorization algorithm [21] suggests that the latter can be highly unstable as well. Indeed, finding a numerically stable NC algorithm to compute the LU (or QR) decomposition of a matrix can be regarded as one important open problem in parallel computation theory [11].

That a positive solution to the above problem may not be just around the corner is confirmed by the negative complexity results that can be proved for the *stable* algorithms adopted in practice to compute the LU and QR decompositions, namely, Gaussian elimination (GE) and the Householder and Givens methods (HQR and GQR, respectively).

In 1989 Vavasis proved that GE with partial pivoting (GEP), which is the standard method for computing the PLU decomposition, is P-complete over the reals or the rationals [24]. Note that, strictly speaking, membership in P could not be defined for the real number model. When dealing with real matrices and real number computations, we then assume implicitly that the class P be defined to include the problems solvable in polynomial time on such models as the real RAM (see [20]). The result in [24] was proved by showing that a decision problem defined in terms of GEP's behavior was P-complete. For parallel complexity theory the P-completeness result implies that GEP is likely to be inherently sequential, i.e., admitting no NC implementations unless $P = NC$. Leoncini proved then that GEP is probably even harder to parallelize, in the sense that no $O(n^{\frac{1}{2}-\epsilon})$ time PRAM implementation can exist unless all the problems in P admit polynomial speedup [13].

In this paper we prove new negative results for the classical factorization algorithms. We consider the methods of Householder's reflections and of Givens' rotations to compute the QR decomposition of a matrix. The main use of the QR decomposition is within iterative methods for the computation of the eigenvalues of a matrix and to compute least squares solutions to overdetermined linear systems [10]. Moreover, even though QR decomposition is usually not adopted to solve systems of linear equations on uniprocessor machines, both HQR and GQR are potential competitors of GE to solve linear systems stably in parallel. To date, the fastest stable parallel solver is based on GQR and is characterized by $O(n)$ parallel time on an $O(n^2)$ processor PRAM [23], while both GEP and HQR run in $O(n \log n)$ time with $O(\frac{n^2}{\log n})$ processors. Also, GQR is especially suitable for solving large sparse systems, given its ability to annihilate selected entries of the input matrix at very low cost.

We also consider the application of GEP to special classes of matrices and study a weaker form of pivoting which we will call *minimal* pivoting (GEM). Under minimal pivoting, the pivot chosen to annihilate a given column is the first nonzero on or below the main diagonal. Minimal pivoting is especially suitable for systolic-like implementations of linear system solvers (see, e.g., [12], although it is not referred

[1] Not to be confused with the analogous LFMIS problem of graph theory, which is known to be P-complete [11].

to by this name). Minimal pivoting can be regarded as the minimum modification required for GE to be nondegenerate on arbitrary input matrices. Finally, we consider GEP over GF(2), where it clearly coincides with GEM.

The results we obtain are listed below.

1. We prove that HQR and GQR are P-complete over the real or floating point numbers. We exhibit reductions from the NAND circuit value problem (NANDCVP) with fanout ≤ 2. In particular, what we prove to be P-complete is deciding the sign of a given diagonal element of the upper triangular matrices R computed by either HQR or GQR. Our reductions seem to be more intricate than the simple one in [24]. This is probably a consequence of the apparently more complex effect of reflections and rotations with respect to the linear combinations of GE. We would like to stress that the P-completeness proofs for the case of floating point arithmetic apply directly to, and have been checked with, the algorithms available in MATLAB using the IEEE 754 standard for floating point arithmetic. In other words, the negative results apply to widely "in-use" software.

2. We extend Vavasis' result proving that GEP is P-complete on input strongly nonsingular matrices. This class includes matrices which naturally arise in practical applications, namely, diagonally dominant and symmetric positive definite matrices. Note that plain GE (no pivoting) is guaranteed not to fail on input a strongly nonsingular matrix. However, since it is usually unstable, one still uses GEP.

3. We prove that GEM is P-complete on input nonsingular matrices. By this result we also obtain a different proof that GEP is P-complete. In fact, GEP and GEM compute the same factorization on input the special class of matrices that correspond to fanout 2 nand circuits.

4. We prove that GEP is P-complete over GF(2). The general status (P-complete or NC-computable) of GEP over finite fields is one of the open problems in [11].

5. We show that a known NC algorithm for computing a PLU decomposition of a nonsingular matrix corresponds to GE with a nonstandard pivoting strategy which differs only slightly from minimal pivoting. Also, we prove that GE with such a nonstandard strategy is P-complete on input arbitrary matrices, which somehow accounts for the difficulty of finding an NC algorithm to compute the PLU decomposition of possibly singular matrices.

The completeness results have been proved by using a general framework for reducing circuit computations to matrix factorization algorithms with a common structural kernel. The development of such a framework is by itself a major contribution of this paper.

The results presented here give further evidence of the pervasiveness of a phenomenon that also has been observed by numerical analysts (from a more practical perspective)—namely, that there is a "tradeoff" between the degree of parallelism, on the one hand, and nondegeneracy and accuracy properties of numerical algorithms, on the other [6].

The rest of this paper is organized as follows. In section 2 we introduce a little notation and give some preliminary definitions. In section 3 we describe the general framework for proving the P-completeness of the factorization algorithms. In sections 4 and 5 we address QR decomposition via Householder's reflections and Givens' rotations, respectively. In section 6 we prove our negative results for GE with partial and minimal pivoting. In section 7 we show a correspondence between a known NC PLU decomposition algorithm and GE. We conclude with some further considerations and

open problems. In Appendix A we describe the factorization algorithms considered in this paper. In Appendix B we give some basic definitions about the floating point number representation. More material about the algorithms and the computer arithmetic can be found in many excellent textbooks (in particular, see [10]). Finally, we include one technical proof in Appendix C.

2. Preliminaries. We use standard notation for matrices and matrix-related concepts (see [10]). Matrices are denoted by capital letters. The (i, j) entry of a matrix A is referred to by either a_{ij} or $[A]_{ij}$. Vectors are designated by lowercase letters, usually taken from the end of the alphabet, e.g., x, y, etc. Note that the notation x refers to a *column* vector, i.e., an $n \times 1$ matrix, for some $n \geq 1$.

The ith row (resp., column) of a matrix A is denoted by a_{i*} (resp., a_{*i}). A *minor* of a matrix A is any submatrix of A. A *principal* minor is any square submatrix of A defined by the same set of row and column indices.

The symbols I and O denote the identity matrix (with $[I]_{ij} = 1$ if $i = j$ and 0 otherwise) and the zero matrix (such that $[O]_{ij} = 0$), respectively. The zero vector is denoted using the symbol 0. The transpose of A is the matrix B such that $b_{ij} = a_{ji}$. B is denoted by A^T. A matrix Q is orthogonal when $Q^T Q = I$. A permutation matrix P is a matrix which is zero everywhere except for just one 1 in each row and column. Any permutation matrix is orthogonal. The transpose of a (column) vector x is the *row* vector x^T, i.e., a matrix of size $1 \times n$, for some n.

Let A be a square matrix of order n.

(i) The LU decomposition of A is a pair of matrices $\langle L, U \rangle$, such that L is lower triangular (i.e., $l_{ij} = 0$ for $j > i$) with unit diagonal elements, U is upper triangular, and $A = LU$. For an arbitrary (even nonsingular) matrix A the LU decomposition might not be defined. A sufficient condition for its existence (and uniqueness) is that A be strongly nonsingular.

(ii) The PLU decomposition of A is a triple of matrices $\langle P, L, U \rangle$ such that L and U are as above, P is a permutation matrix, and $P^T A = LU$ (or, equivalently, $A = PLU$). The PLU decomposition is always defined but not unique.

(iii) The QR decomposition of A is a pair of matrices $\langle Q, R \rangle$, such that Q is orthogonal, R is upper triangular, and $A = QR$. The QR decomposition always exists.

In all the above cases, if A is $m \times n$, with $m < n$, and when the factorization exists, we get a matrix that is properly said to be in *row echelon* form (rather than upper triangular). Its leftmost $m \times m$ minor is upper triangular while its rightmost $m \times (n - m)$ minor is, in general, a dense submatrix. However, when no confusion is possible, we will always speak of the triangular factor of a given factorization.

A detailed description of the algorithms considered in this paper can be found in Appendix A. The details, however, are not necessary to understand the common structure of the reductions. Some details will be required in the proofs of Theorems 4.3 and 5.3, which deal with the floating point version of the QR algorithms. Except for these, the following general description is sufficient. It defines a class $\mathcal{F}$ of matrix factorization algorithms that includes, among others, the classical QR algorithms and GE.

Let A be the input matrix. The algorithms in $\mathcal{F}$ take A to upper triangular form by applying a series of transformations that introduce zeros in the strictly lower triangular portion of A, from left to right. The notation $A^{(k)}$ is usually adopted to indicate the matrix obtained after $k-1$ transformations, and its elements are referred to by $a_{ij}^{(k)}$. $a_{ij}^{(k)}$ is zero for $j < \min\{i, k\}$. A transformation is applied during one *stage*

of the algorithm.

Every algorithm $\mathcal{A} \in \mathcal{F}$ satisfies the following properties.

p1. If $a_{ij} = 0$, for $j = 1, \ldots, s$, then $a_{i*}^{(k)} = a_{i*}$, $k = 1, \ldots, s$. In other words, if the first s entries in row i are zero, then the first s stages of $\mathcal{A}$ do not modify row i.

p2. If column k has a complementary nonzero structure with respect to columns $j = 1, \ldots, k-1$ (by which we mean $a_{ij} \neq 0 \Rightarrow a_{ik} = 0$ for any i), then $a_{*k}^{(j)} = a_{*k}$, i.e., column k is not affected by the first $k-1$ transformations.

p3. This is a property that we will call *proper embedding* of a matrix A into a larger matrix E. Let A be of order k and let R be the triangular factor computed by $\mathcal{A}$ on input A. Also, let E be a matrix having a minor $E_A = A$. Suppose that, as a consequence of the repeated applicability of **p1** and **p2**, the first $k-1$ stages of algorithm $\mathcal{A}$ on input E affect only E_A and possibly some columns with higher indices. Then $E^{(k)}$ contains R as the minor corresponding to E_A. In other words, the factorization of A, viewed as a part of E, is the same as the factorization of A alone.

p4. Stage k modifies the entry (i, j) only if $i, j \geq k$. In particular, it introduces zeros in the kth column of $A^{(k-1)}$ without destroying the previously introduced zeros. In view of this, and to avoid some redundant descriptions, in the rest of this paper we will use the notation $A^{(k)}$ to indicate the submatrix of $A^{(k)}$ with elements from $a_{kk}^{(k)}$ rightward and downward.

3. A framework for reductions to $\mathcal{F}$. Our P-completeness results are all based on reductions from the NANDCVP, a restricted version of the CVP (circuit value problem) which we now briefly recall.

> *Input*: the description of a k-input Boolean circuit C composed entirely of fanin 2 nand gates, and Boolean values $x_1, \ldots, x_k$.
>
> *Output*: the value $C(x_1, \ldots, x_k)$ computed by C on input $x_1, \ldots, x_k$.

NANDCVP is P-complete, as reported in [11]. In order to simplify the proofs we will further assume, without loss of generality, that each gate of C has fanout at most 2. We shall prove in this section the following general result, which applies to any factorization algorithm $\mathcal{A} \in \mathcal{F}$:

> There is an encoding scheme of logical values and a logspace bounded transducer M with the following properties: given the description of a fanout 2 nand circuit C and Boolean inputs $x_1, \ldots, x_k$ for C, M builds a matrix A_C of order n_C such that, if $A_C = XR$ is the factorization computed by algorithm $\mathcal{A}$, with R upper triangular, then $[R]_{n_C, n_C}$ is the encoding of $C(x_1, \ldots, x_k)$.

We shall prove (Theorem 3.1) that the transducer does exist provided that there are certain elementary matrices with well-defined properties. We will later show that such matrices actually exist for the algorithms considered in this paper.

Unfortunately, a formal description and the proof of correctness of the transducer will require quite a large amount of details. In spite of this, the idea behind the construction is easy. Hence we first describe the reduction in an informal way and only afterward proceed to a formal derivation. Moreover, we have actually implemented the transducer as a collection of MATLAB m-files. These and the elementary matrices for the floating point versions of HQR and GQR, and of GEM as well (whose real and floating point versions are coincident), are available electronically [16].

3.1. Informal description. Let $\mathcal{A} \in \mathcal{F}$ and let $\mathbf{a}$ and $\mathbf{b}$ denote appropriate numerical encodings of arbitrary truth values a, b. We need three kinds of (square) elementary matrices for $\mathcal{A}$ to simulate basic logical operations.

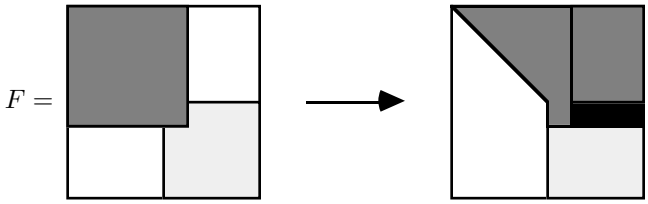

FIG. 1. *N-D matrix composition: effect of the first $\nu - 1$ stages.*

The first such matrix is the *nand* N. It has $[N]_{11} = \mathbf{a}$ and $[N]_{22} = \mathbf{b}$ and, if we apply $\mathcal{A}$ to compute the factorization of N, we get the encoding of $\texttt{NAND}(a, b)$ in the right bottom entry of the upper triangular factor.

The second elementary matrix is the *duplicator* D. It has $[D]_{11} = \mathbf{a}$. Let d be the order of D. Then the application of $d - 2$, rather than $d - 1$, stages of $\mathcal{A}$ to D is sufficient to triangularize D. The trailing 2×2 principal minor of the triangular factor is $\left(\begin{smallmatrix} \mathbf{a} & 0 \\ 0 & \mathbf{a} \end{smallmatrix}\right)$.

The third elementary matrix is the *copier* or *wire* W. It has $[W]_{11} = \mathbf{a}$, and if we compute the factorization of W we get $\mathbf{a}$ in the right bottom entry of the triangular factor.

Using these matrices as the building blocks we can construct a matrix A_C that simulates the circuit C. The structure of A_C is close to block diagonal, with one N block for each nand gate in the circuit C. Duplicator blocks are used to simulate fanout 2 nand gates, and wire blocks to route the computed values according to the circuit's structure. As the factorization of a block diagonal matrix could be performed by independently factoring the single blocks, a certain degree of overlapping between the blocks is necessary to pass around the computed values. The key idea is to repeatedly use the proper embedding property of the factorization algorithms.

To illustrate how the preceding scheme can work in practice, and to see where the difficulties may appear, consider first the construction of a submatrix which simulates a fanout 2 nand gate. The basic idea is to append a duplicator to a nand block as shown in Figure 1 (left). The dark gray area is a minor F_N of F such that $F_N = N$. Analogously, the light gray area is a minor F_D equal to D (in principle). Finally, the white zones contain zeros. The right bottom entry of F_N coincides with the top left entry of F_D. This is an example of proper embedding, for, if N has order ν, the first $\nu - 1$ steps affect only F_N (and the first ν entries of the columns with indices greater than the indices of F_N). This is a consequence of property **p1**. However, after $\nu - 1$ stages of $\mathcal{A}$ the encoding of $\texttt{NAND}(a, b)$ is exactly where required, i.e., in the top left entry of F_D, from where it can be duplicated. Note, however, that the whole first row of F_D has possibly been modified (i.e., the black-colored entries of Figure 1 (right)). Hence, for the simulation to proceed correctly, it is required that the black entries store the rest of the first row of D *by the time the algorithm reaches stage* ν. We cannot rely on their initial contents.

As a second example, Figure 2 describes how a W block, of order w, can be used to pass a value to a possibly far away place. The dark gray area represents a minor of T equal to a W block. Note that the minor is split across nonconsecutive rows and columns, namely, those with indices 1 through $w - 1$ and the one with index t (t = order of T). As before, the white zones contain zeros, while the light gray area is of arbitrary size and stores arbitrary values. This situation again represents

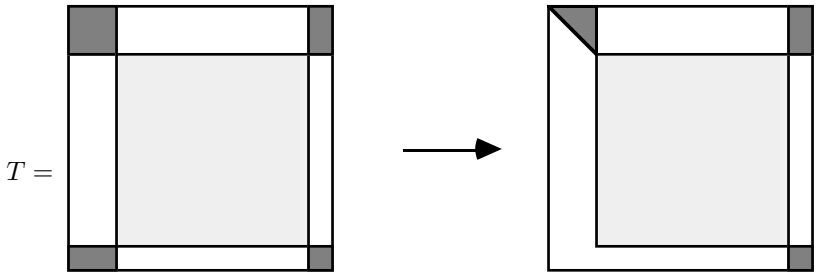

FIG. 2. *Routing of a logical value.*

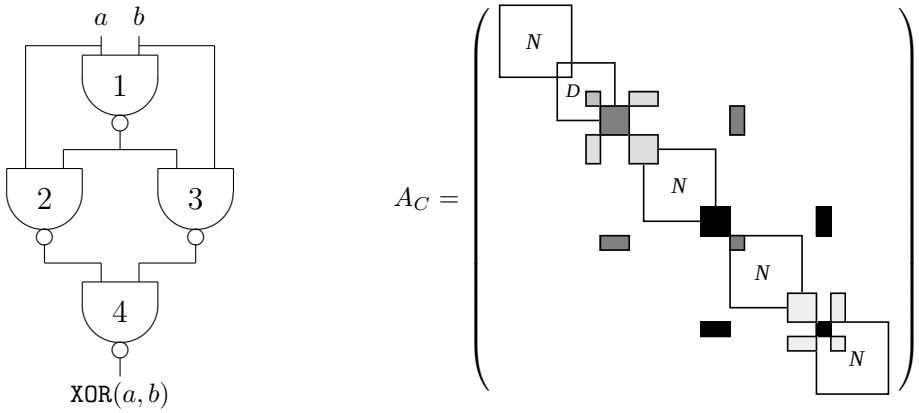

FIG. 3. *Circuit C computing* $\texttt{XOR}(a, b)$ *(left) and the structure of the corresponding matrix A_C (right).*

a proper embedding, so that the first $w-1$ stages of $\mathcal{A}$ on input T will result in the factorization of the W block. This implies that (the encoding of) the logical value initially in the top left entry has been copied to the right bottom entry.

To get an idea of what a complete matrix might looks like, see Figure 3, where the circuit C computing the *exclusive or* of two bits is considered. The corresponding matrix A_C has four N blocks, one D block, and four W blocks denoted by different gray levels. Note, however, that Figure 3 does not yet incorporate the solution to the "black entries" problem mentioned above.

3.2. Elementary matrices. To prove the correctness of the transducer (see Theorem 3.1 below) it is convenient to introduce a block partitioning of the elementary matrices defined in the previous section. Let $E \in \{N, D, W\}$ denote one such matrix. We partition E as

$$E = \begin{pmatrix} E_I & \bar{E}_I & \hat{E}_I \\ \bar{E}_M & E_M & \hat{E}_M \\ \bar{E}_O & \hat{E}_O & E_O \end{pmatrix}, \tag{1}$$

where the diagonal blocks E_I, E_M, and E_O are square matrices and E_I and E_O are also diagonal (i.e., with nonzero entries only on the main diagonal). We will refer to E_I and E_O as the *input* and *output* submatrices and let i and o denote their orders, respectively. Note that an elementary matrix actually defines a set of matrices. In fact,

we regard the i diagonal entries of E_I as the *input places*. A particular elementary matrix is obtained by filling the input place(s) with the encoding of some logical value(s).

We can now formally define the "behavior" of the elementary matrices with respect to the factorization algorithm $\mathcal{A}$.

Nand matrix (N). We let ν denote the order of N, which has $i = 2$ and $o = 1$ in the block partitioning (1), and set $[N]_{11} = \mathbf{a}$, $[N]_{22} = \mathbf{b}$. If $XN = R$ is the factorization computed by $\mathcal{A}$, we have

$$R = \begin{pmatrix} * & \dots & \dots & * \\ & \ddots & & \vdots \\ & & * & * \\ & & & \mathbf{c} \end{pmatrix},$$

where $\mathbf{c}$ is the encoding of $\texttt{NAND}(a, b)$. If, as is often required in practice, R overwrites the input matrix, the value $\mathbf{c}$ will replace N_O, and this is the reason why we defined E_O in (1) as the output submatrix. The same remark applies to the other elementary matrices. We also require that, for any real value x, an *auxiliary vector* $a_N = a_N(x) = (0, 0, a_3, \dots, a_\nu)^T$ can be defined such that $Xa_N = (*, \dots, *, x)^T$. Using the auxiliary vectors we can solve the "black entries" problem outlined in section 3.1. Intuitively, by appending auxiliary vectors to the right of N in A_C (instead of simply zeros, as in Figure 1 (left)), we can obtain the desired values in the black-colored entries of Figure 1 (right). As we will see in the proof of Theorem 3.1, the initial zeros in the auxiliary vector prevent the problem from pumping up in the construction of A_C.

Duplicator matrix (D). Let d denote the order of D, which has $i = 1$ and $o = 2$ in the block partitioning (1), and set $[D]_{11} = \mathbf{a}$. If $XD = R$ is the incomplete factorization computed by $\mathcal{A}$, i.e., X represents the first $d-2$ transformations applied to D by $\mathcal{A}$, we obtain

$$R = \begin{pmatrix} * & \dots & \dots & \dots & * \\ & \ddots & & & \vdots \\ & & * & \dots & * \\ & & & \mathbf{a} & 0 \\ & & & 0 & \mathbf{a} \end{pmatrix}.$$

We also require that, for any pair of real numbers x and z, an auxiliary vector $a_D = a_D(x, z) = (0, a_2, \dots, a_d)^T$ can be defined such that $Xa_D = (*, \dots, *, x, z)^T$.

Wire matrix (W). Let w denote the order of W, which has $i = o = 1$ in the block partitioning (1), and set $[W]_{11} = \mathbf{a}$. If $XW = R$ is the factorization computed by $\mathcal{A}$, we get

$$R = \begin{pmatrix} * & \dots & \dots & * \\ & \ddots & & \vdots \\ & & * & * \\ & & & \mathbf{a} \end{pmatrix}.$$

We also require that, for any real number x, an auxiliary vector $a_W = a_W(x) = (0, a_2, \dots, a_w)^T$ can be defined such that $Xa_W = (*, \dots, *, x)^T$.

As we shall see, elementary matrices (including auxiliary vectors) exist for both Householder's and Givens' methods and for GE as well.

3.3. Construction and correctness. In this section we present our main result (Theorem 3.1) on the existence of a single reduction scheme that works for any algorithm in $\mathcal{F}$. We still require some definitions.

Suppose that C has k input variables and let $k' \geq k$ be the number of places (i.e., inputs to the gates) where the variables are used. k' is the number of inputs counting multiplicities. Let the gates of C be sorted in topological order. Given a specific assignment of logical values to the input variables, we may then refer to the ith *actual input* as the ith value from the input set that is required at some gate, $1 \leq i \leq k'$.

When we say that A_C *has an input row at position* i, we mean that, initially, row i is either

$$\left(\overbrace{0, \ldots, 0}^{i-1}, \mathbf{a}, 0, [\bar{N}_I]_{1*}, [\hat{N}_I]_{1*}, 0^T \right) \tag{2}$$

or

$$\left(\overbrace{0, \ldots, 0}^{i-2}, 0, \mathbf{a}, [\bar{N}_I]_{2*}, [\hat{N}_I]_{2*}, 0^T \right), \tag{3}$$

where $\mathbf{a}$ is the encoding of one of the actual inputs to C.

THEOREM 3.1. *Let elementary matrices N, D, and W be given for $\mathcal{A} \in \mathcal{F}$. For any fanout 2 nand circuit C with input variables $x_1, \ldots, x_k$ and any truth assignment to $x_1, \ldots, x_k$, we can build a square matrix A_C such that the following hold:*

(a) *A_C has order $n_C = O(n)$, where n is the number of gates in C.*

(b) *If $A_C = XR$ is the factorization computed by $\mathcal{A}$, then $[R]_{n_C,n_C}$ is the encoding of $C(x_1, \ldots, x_k)$.*

(c) *A_C has a number of input rows which equals the number $k' \geq k$ of actual inputs to C; the ith such row has either the structure* (2) *or* (3) *depending on whether the ith actual input to C enters the first or the second input of some gate.*

(d) *Any actual input affects A_C only through one input place.*

The construction can be done by using $O(\log n)$ work space.

Proof. We prove the result by induction on n. Let $z_1, \ldots, z_{k'}$, for $k' \geq k$, be the actual inputs to C and let $\mathbf{a}$ and $\mathbf{b}$ be the encodings of z_1 and z_2, respectively. The case $n = 1$ is easy. We only have to set $A_C = N$, with $[A_C]_{11} = \mathbf{a}$ and $[A_C]_{22} = \mathbf{b}$. Clearly $n_C = O(1)$. Property (b) follows from the definition of N. Properties (c) and (d) are easily verified as well. In particular, A_C has exactly two input rows at positions 1 and 2, with structure (2) and (3), respectively, and this clearly matches the number of actual inputs to C. Finally, the actual inputs affect A_C only through the input places $[A_C]_{11}$ and $[A_C]_{22}$.

Now suppose that the number of gates in C is $n > 1$, and let $g_1, \ldots, g_n$ be a topological ordering of the DAG representing C. Clearly, all the inputs to g_1 are actual inputs to C. Let C' be the circuit with g_1 removed and any of its outputs replaced with x_1, the first input variable. Since C' has $n - 1$ gates, we may assume that $A_{C'}$ can be constructed which satisfies the induction hypothesis. To build A_C we simply extend $A_{C'}$ to take g_1 into account. There are two cases, depending on the fanout of g_1. We fully work out only the case of fanout 1. The other case is similar but is more tedious to develop fully (and for the reader to follow).

1. Let g_h be the gate connected to the output of g_1. Suppose, without loss of generality, that g_1 provides the first input to g_h. By the induction hypothesis (in particular, by (c)) $A_{C'}$ has the following structure:

$$A_{C'} = \begin{array}{c} \\ \\ \\ \end{array} \begin{array}{c} \begin{array}{cccccc} & & i_h & & & \\ & & \downarrow & & & \end{array} \\ \begin{pmatrix} X_1 & x_1 & x_2 & X_2 & X_3 & X_4 \\ 0^T & \mathbf{a} & 0 & [\bar{N}_I]_{1*} & [\hat{N}_I]_{1*} & 0^T \\ y_1^T & 0 & \gamma & y_2^T & y_3^T & y_4^T \\ Z_1 & z_1 & z_2 & Z_2 & Z_3 & Z_4 \end{pmatrix} \end{array} \begin{array}{l} \\ \\ \leftarrow i_h. \\ \\ \end{array}$$

$A_{C'}$ has an input row at some position i_h corresponding to the first input to gate g_h and $\mathbf{a}$ is the encoding of x_1. Note that, by property (d), the actual logical value encoded by $\mathbf{a}$ affects only the definition of $A_{C'}$ through the entry (i_h, i_h). Using $A_{C'}$ and N and W elementary matrices we define A_C as follows:

$$A_C = \begin{pmatrix} N_I & \bar{N}_I & \hat{N}_I & \boxed{O} & O & \boxed{0} & 0 & O & O & O \\ \bar{N}_M & N_M & \hat{N}_I & \boxed{A_1} & O & \boxed{a_1'} & 0 & O & O & O \\ \bar{N}_O & \hat{N}_O & N_O & \boxed{a_1^T} & 0^T & \boxed{\alpha} & 0 & 0^T & 0^T & 0^T \\ O & O & \bar{W}_M & W_M & O & \hat{W}_M & 0 & A_2 & A_3 & O \\ O & O & 0 & O & X_1 & x_1 & x_2 & X_2 & X_3 & X_4 \\ 0^T & 0^T & \bar{W}_O & \hat{W}_O & 0^T & W_O & 0 & a_2^T & a_3^T & 0^T \\ 0^T & 0^T & 0^T & 0^T & y_1^T & 0 & \gamma & y_2^T & y_3^T & y_4^T \\ O & O & 0 & O & Z_1 & z_1 & z_2 & Z_2 & Z_3 & Z_4 \end{pmatrix}.$$

We set $[A_C]_{11} = \mathbf{a}$ and $[A_C]_{22} = \mathbf{b}$. The minor enclosed in boxes is a set of $w-1$ (w is the order of W) auxiliary column vectors for N that we choose such that

$$X \begin{pmatrix} O & 0 \\ A_1 & a_1' \\ a_1^T & \alpha \end{pmatrix} = \begin{pmatrix} * & * \\ * & * \\ \bar{W}_I & \hat{W}_I \end{pmatrix},$$

where X is the matrix that factorizes N. Observe that only the i_hth row of $A_{C'}$ has been modified by replacing $\mathbf{a}$, $[\bar{N}_I]_{1*}$, and $[\hat{N}_I]_{1*}$ with W_O, a_2^T, and a_3^T, respectively.

In what follows we regard A_C as a block 8×10 matrix, and when we refer to the ith row (or column) we really mean the ith block of rows (columns). Nonetheless, A_C is square, if $A_{C'}$ is, with order $\nu + w - 2$ plus the size of $A_{C'}$. Using property (a) of the induction hypothesis we then see that $n_C = O(n)$. It is easy to prove that A_C enjoys properties (b) through (d) as well. Assume C has k' actual inputs. Since g_1 has fanout 1, C' has $k'-1$ actual inputs and, by induction, $A_{C'}$ has $k'-1$ input rows. Now, by the above construction, A_C has exactly $(k'-1)-1+2 = k'$ input rows, which proves (c). Property (d) also easily holds. To prove (b) we use the properties of $\mathcal{F}$. By **p1**, the application of $\nu - 1$ stages of $\mathcal{A}$ to A_C affects only the first three (blocks of) rows. Thus N (including its auxiliary vectors) is properly embedded in A_C, and hence after the first $\nu - 1$ stages of $\mathcal{A}$, we get

$$A_C^{(\nu-1)} = \begin{pmatrix} W_I & \bar{W}_I & 0^T & \hat{W}_I & 0 & \boxed{0^T} & \boxed{0^T} & 0^T \\ \bar{W}_M & W_M & O & \hat{W}_M & 0 & \boxed{A_2} & \boxed{A_3} & O \\ 0 & O & X_1 & x_1 & x_2 & X_2 & X_3 & X_4 \\ \bar{W}_O & \hat{W}_O & 0^T & W_O & 0 & \boxed{a_2^T} & \boxed{a_3^T} & 0^T \\ 0^T & 0^T & y_1^T & 0 & \gamma & y_2^T & y_3^T & y_4^T \\ 0 & O & Z_1 & z_1 & z_2 & Z_2 & Z_3 & Z_4 \end{pmatrix},$$

where $W_I = \mathbf{c}$ is the encoding of $\mathtt{NAND}(z_1, z_2)$. The submatrix enclosed in boxes is a

set of $\nu - 2$ auxiliary vectors for W that we choose such that

$$X \begin{pmatrix} 0^T & 0 \\ A_2 & A_3 \\ a_2^T & a_3^T \end{pmatrix} = \begin{pmatrix} * & * \\ * & * \\ [\bar{N}_I]_{1*} & [\hat{N}_I]_{1*} \end{pmatrix},$$

where X is the transformation matrix that triangularizes W. Note that the entries corresponding to the first elements of auxiliary vectors contain zeros, as required. If the first element (in the definition) of auxiliary vectors were not zero, we would be faced with the additional problem of guaranteeing that the first $\nu - 1$ stages would set these entries to the required values.

It is easy to see that W (including its auxiliary vectors) is properly embedded in $A_C^{(\nu-1)}$ so that additional $w - 1$ stages of $\mathcal{A}$ lead to

$$A_C^{(n+w-2)} = \begin{pmatrix} X_1 & x_1 & x_2 & X_2 & X_3 & X_4 \\ 0^T & N_I & 0 & [\bar{N}_I]_{1*} & [\hat{N}_I]_{1*} & 0^T \\ y_1^T & 0 & \gamma & y_2^T & y_3^T & y_4^T \\ Z_1 & z_1 & z_2 & Z_2 & Z_3 & Z_4 \end{pmatrix},$$

with $N_I = W_I = \mathbf{c}$. The correctness now follows from the induction hypothesis and property **p4**.

2. The full description of the fanout 2 case is definitely more tedious but does not introduce additional difficulties. A_C extends $A_{C'}$ by means of an initial N block, followed by a D block, followed by two W blocks. Taking the partial overlapping into account, it immediately follows that the order of A_C is $\nu + d - 1 + 2(w - 2)$ plus the order of $A_{C'}$.

The construction of matrix A_C can be done in space proportional to $\log n$ by simply reversing the steps of the above inductive process. That is, instead of constructing $A_{C'}$ and using it to build A_C, which would require more than logarithmic work space, we compute and immediately output the first $\nu + w - 2$ (or $\nu + d - 1 + 2(w - 2)$ in case of a first gate with fanout 2) rows and columns. We also compute and output row i_h (or the two rows where the output of a fanout 2 gate has to be sent). All of this essentially can be done in space $O(\log n)$ by copying the elementary matrices N, D, and W to the output medium. The only possible problem might be the computation of i_h, but this is not the case. In fact, for any $1 \leq i \leq n$, let $f_2(i)$ be the number of fanout 2 nand gates preceding gate i in the linear ordering of C. This information can be obtained, when required, by repeatedly reading the input and using only $O(\log n)$ work space for counting. It easily follows from the above results that the index of the top left entry $\pi(h)$ of the hth N block is

$$\begin{aligned} \pi(h) &= f_2(h)(2(w-2) + \nu + d - 1) + (h - 1 - f_2(h))(\nu + w - 2) + 1 \\ &= (h-1)(\nu + w - 2) + f_2(h)(d + w - 3) + 1. \end{aligned}$$

Hence i_h will be either $\pi(h)$ or $\pi(h) + 1$, depending on whether the value under consideration is the first or second input to g_h.

The MATLAB program that implements the transducer [16] is indeed logspace bounded. It uses only the definition of the blocks and simple variables (whose contents never exceed the size of A_C) in magnitude. No data structure depending on n is required. Clearly, as it is implemented using double precision IEEE 754 arithmetic, it can properly handle only the circuits with up to approximately 2^{53} gates. ∎

$$N = \begin{pmatrix}
\mathbf{a} & 0 & 0 & 0 & 0 & 0 & 0 & -\frac{5}{4} & 0 & 0 \\
0 & \mathbf{b} & -1 & -2 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 2 & 0 & 0 & 0 & -\frac{579}{145} & -\frac{211}{145} & 0 & 0 & 0 \\

\end{pmatrix}.$$

FIG. 4. *The N block for HQR.*

4. Householder's *QR* decomposition algorithm. In this section we prove that HQR is presumably inherently sequential under both exact and floating point arithmetic. This is done by proving that a certain set H, defined in terms of HQR's behavior, is logspace complete for P.

$H = \{A\colon A \text{ is } n\times n,\ A = QR \text{ is the factorization computed by HQR, and } [R]_{nn} > 0\}$.

Note that by HQR we mean the classical Householder's algorithm presented in many numerical analysis textbooks. In particular we refer to the one in [10]. This is also the algorithm available as a primitive routine in scientific libraries (such as LINPACK's `ZQRDC` [7]) and environments (like MATLAB's `qr` [17]).

We begin with the simple result about the membership in P.

THEOREM 4.1. *H is in P under both exact and floating point arithmetic.*

Proof. The proof follows from standard implementations, which perform $O(n^3)$ arithmetic operations and $O(n)$ square root computations (see, e.g., [10]). □

According to the result of section 3, to prove that H is also logspace hard for P it is sufficient to exhibit an encoding scheme and the elementary matrices required in the proof of Theorem 3.1. As we will see, however, the floating point case requires additional care to rule out the possibility of fatal roundoff error propagations.

THEOREM 4.2. *H is logspace hard for P under the real number model of arithmetic.*

Proof. We simply list the three elementary matrices required by Theorem 3.1. For each elementary matrix E, the corresponding auxiliary vector a_E is shown as an additional column of E. That the matrices enjoy the properties defined in section 3.2 can be automatically checked using any symbolic package, such as Mathematica.

N is the 9×10 matrix of Figure 4, where $\mathbf{a}, \mathbf{b} \in \{-1, 1\}$ are the encoding of logical values (1 for `True` and -1 for `False`) and x is an arbitrary real number. Performing eight steps of HQR on input N gives $N = QR$ with $[R]_{9,9} = \mathbf{c}$ and $[R]_{9,10} = x$, where $\mathbf{c} = \frac{1-\mathbf{a}-\mathbf{b}-\mathbf{ab}}{2}$ is the arithmetization of $\mathtt{NAND}(a, b)$ under the selected encoding.

D is the 6×7 matrix shown in Figure 5 (left). Performing four steps of HQR on input D gives $D = QR$ with $[R]_{5,5} = [R]_{6,6} = \mathbf{a}$, $[R]_{5,6} = [R]_{6,5} = 0$, $[R]_{5,7} = z$, and $R_{6,7} = x$, where z and x are arbitrary real numbers.

W is the 2×3 matrix of Figure 5 (right). Performing one step of HQR on input W gives $W = QR$ with $[R]_{2,2} = \mathbf{a}$ and $[R]_{2,3} = x$, for x an arbitrary real number. □

Applying a floating point implementation of HQR to any single block defined in Theorem 4.2[2] results in approximate results. For instance, we performed the QR

[2]More precisely, to the best possible approximations of the blocks under the particular machine arithmetic.

$$D = \begin{pmatrix} \mathbf{a} & -1 & -2 & 0 & 0 & 0 & 0 \\ 2 & 0 & 0 & 0 & -\frac{579}{145} & -\frac{211}{145} & 0 \\ 2 & 0 & 0 & 0 & -\frac{23}{116} & -\frac{70}{29} & 0 \\ 0 & 3 & 1 & 0 & 0 & 0 & 0 \\ 0 & \frac{4}{3} & 1 & 0 & 0 & 0 & \frac{27\,x+254\,z}{222} \\ 0 & \frac{4}{3} & \frac{33}{8} & 0 & 0 & 0 & \frac{4767\,x+256\,z}{1776} \end{pmatrix} \qquad W = \begin{pmatrix} \mathbf{a} & -\frac{5}{4} & 0 \\ \frac{4}{3} & 0 & \frac{5\,x}{3} \end{pmatrix}$$

FIG. 5. *The D and W blocks for HQR.*

decomposition of the four N matrices using the built-in function `qr` available in MATLAB. We found that the relative error affecting the computed encoding of $\texttt{NAND}(a, b)$ ranged from a minimum of 0.5ϵ to a maximum of 3ϵ. Here ϵ is the roundoff unit and equals $2.2204 \cdot 10^{-16}$ under IEEE 754 standard arithmetic. These might appear to be insignificant errors. However, for a matrix containing an arbitrary number of blocks, the roundoff error may accumulate to a point where it is impossible to recover the exact (i.e., 1 or -1) result. Clearly, direct error analysis is not feasible here, since it should apply to an infinite number of reduction matrices. Our solution is to control the error growth by "correcting" the intermediate results as soon as they are "computed" by nand blocks. Note that, by referring to the values *computed* by a certain elementary matrix E, we mean precisely the nonzero values one finds in the last row of the triangular factor computed by HQR on input E (including the auxiliary vectors). Analogously, the input values to E are the ones computed by the elementary matrix preceding E in A_C.

THEOREM 4.3. *H is logspace hard for P under finite precision floating point arithmetic.*

Proof. We take duplicator and wire blocks as in Theorem 4.2 and provide a new definition for nand blocks so that they always compute exact results. To do this, we have to consider again the structure of A_C, as resulting from Theorem 3.1.

Let g_i be the ith gate in the topological ordering of C, and let g_j and g_k be the gates providing the inputs to g_i. Let $N^{(l)}$ denote the N block of A_C corresponding to g_l, according to the construction of Theorem 3.1. To prove the result we maintain the invariant that the values computed by $N^{(1)}, N^{(2)}, \ldots, N^{(i-1)}$ are exact. This is clearly true for $i = 1$. Using the invariant we first verify that the errors affecting the values computed by $N^{(i)}$ can be bounded by a small multiple of the roundoff unit. We then use the bound to show how to redefine N so that it computes exact results, thus extending the invariant to $N^{(i)}$.

From the proof of Theorem 3.1 we know that the output of $N^{(j)}$ (and similarly of $N^{(k)}$) is placed in one of the input rows of $N^{(i)}$ as a consequence of the factorization of possibly a D followed by a W block. It follows that the error affecting the output of $N^{(i)}$ is due only to the above factorizations *and* to the factorization of $N^{(i)}$ itself. Since there is a limited number of structural cases (depending on the fanout of gates j and k) and considering all the possible combinations of logical values involved, the largest error ever affecting the output of $N^{(i)}$ can be determined by direct (but tedious) error analysis or, more simply, by test runs. For the purpose of the following discussion we may safely assume that the relative errors affecting the computed quantities are bounded by $c\epsilon$, for some constant c of order unit (c is actually smaller than 10). In other words, we may assume that the actual outputs of $N^{(i)}$ are $\mathbf{a}(1+\delta)$ and $x(1+\eta)$, with $|\delta|, |\eta| \leq c\epsilon$. Recall that x is the last entry of the generic auxiliary vector $a_N(x)$

of N after the factorization (see the definition of N in section 3.2). Here, however, we require that x be a machine number (i.e., a rational number representable without error under the arithmetic under consideration).

Having a bound on the error, we are now ready to show how to "correct" the erroneous outputs. The new nand block, denoted by N_{corr}, extends N with two additional rows and columns, as shown below:

$$N_{\text{corr}} = \begin{pmatrix} N & a_N(-1) & 0 \\ b^T & 0 & -(2^m+1) \\ 0^T & 2^m & 0 \end{pmatrix},$$

where

$$b^T = (\overbrace{0,\ldots,0}^{8}, 2^m)$$

and m is some positive integer (to be specified below). Note that $a_N(-1)$ is precisely that auxiliary vector for the old N that produces -1 as output, i.e.,

$$a_N(-1) = (\overbrace{0,\ldots,0}^{8}, -\frac{25}{12})^T.$$

The auxiliary vector for N_{corr} is

$$(\overbrace{0,\ldots,0}^{10}, (2^m+1)x).$$

Thus, a first requirement on m is that the quantity $(2^m+1)x$ be a computer number. As the length of the significand of 2^m+1 is $m+1$, we see that a sufficient condition is that the length of the significand of x does not exceed $t-m-1$ (for the definition of t see Appendix B). Now, let us apply HQR to N_{corr} extended by its auxiliary vector. As N is properly embedded in N_{corr}, after eight stages of HQR we get (using the above result on the error)

$$N_{\text{corr}}^{(9)} = \begin{pmatrix} \mathbf{a}(1+\delta) & -1+\eta & 0 & 0 \\ 2^m & 0 & -(2^m+1) & 0 \\ 0 & 2^m & 0 & (2^m+1)x \end{pmatrix}.$$

A second condition that we place on m is that $2^m + \mathbf{a}(1+\delta) = 2^m + \mathbf{a}$, to get rid of the error δ. An easy argument shows that this implies $m > \lceil \log c \rceil$. Thus, recalling the bound on $|\delta|$ and $|\eta|$, we see that $m \geq 5$ is sufficient. As a consequence, the length of x cannot exceed $t-6$. The actual reflection matrix applied to $N_{\text{corr}}^{(9)}$ is then

$$I - \frac{1}{2^m(2^m+1)} \begin{pmatrix} \mathbf{a}(2^m+1) \\ 2^m \end{pmatrix} \begin{pmatrix} \mathbf{a}(2^m+1) & 2^m \end{pmatrix},$$

which, by easy floating point computation, gives

$$N_{\text{corr}}^{(10)} = \begin{pmatrix} \mathbf{a}(1-\delta) & -1 & 0 \\ 2^m & 0 & (2^m+1)x \end{pmatrix}.$$

Applying one more stage now leads to the correct results $\mathbf{a}$ and x. The above requirement on x is by no means a problem. In fact, the only auxiliary values ever required are the nonzero elements in the input rows of the blocks that possibly follow nand elementary matrices, i.e., D and W blocks. These are simply -1, -2, and $-5/4$, all of which can be represented exactly with a three-bit significand. ∎

The elementary matrices of Theorem 4.3 are available for the general transducer implemented in MATLAB. In particular, N_{corr} is defined with $m = 30$.

5. *QR* decomposition through Givens' rotations. In this section we prove that the set

$$G = \{A\colon A \text{ is } n \times n,\ A = QR \text{ is the factorization computed by GQR, and } [R]_{nn} > 0\}$$

is logspace complete for P. The way we present the results of this section closely follows the methodology of section 4. Here, however, we need to further discuss the particular algorithm considered. In fact, the computation of the QR decomposition can be done in various ways using plane (or Givens') rotations. Different from Householder's reflections, a single plane rotation annihilates only one element of the matrix to which it is applied, and different sequences of annihilation result in different algorithms. By the way, this degree of freedom has been exploited to obtain the currently faster (among the known accurate ones) parallel linear system solvers [23, 18]. We also note that there is no GQR algorithm available in MATLAB (nor in libraries such as LINPACK or LAPACK), which instead provides the primitive `planerot` to compute a plane rotation. The hardness results of this section apply to the particular algorithm that annihilates the subdiagonal elements of the input matrix by proceeding downward and rightward. This choice places GQR in the class $\mathcal{F}$ defined in section 2, with the position that one stage of the algorithm is the sequence of plane rotations that introduce zeros in one column.

THEOREM 5.1. *G is in P under both exact and floating point arithmetic.*

Proof. For the proof, see, e.g., [10]. We point out only that the membership in P holds independently of the annihilation order. ∎

THEOREM 5.2. *G is logspace hard for P under real number arithmetic.*

Proof. As in Theorem 4.2, we simply list the three elementary matrices extended with the generic auxiliary vector. The matrices are shown in Figures 6 through 8, where $\mathbf{a}, \mathbf{b} \in \{-1, 1\}$ are encodings of logical values (1 for `True` and -1 for `False`) and x and z are arbitrary real numbers. Again, that the matrices enjoy the properties defined in section 3.2 can be verified with the help of a symbolic package. ∎

We now switch to the more delicate case of finite precision arithmetic.

THEOREM 5.3. *G is logspace hard for P under finite precision floating point arithmetic.*

Proof. We apply the ideas of Theorem 4.3. That is, we extend the definition of N so that it always computes the exact results. Here, however, there is a subtle problem whose solution requires a different definition of the duplicator block. Let us look at the details. If we apply a floating point implementation of GQR to the block of Figure 7, we clearly get approximate results. In particular, instead of $\left(\begin{smallmatrix} \mathbf{a} & 0 \\ 0 & \mathbf{a} \end{smallmatrix}\right)$, in the bottom right corner of R we get $\left(\begin{smallmatrix} \mathbf{a}(1+\delta') & \epsilon' \\ \epsilon'' & \mathbf{a}(1+\delta'') \end{smallmatrix}\right)$. Even if δ', δ'', ϵ', and ϵ'' are of the order of the roundoff unit ϵ, the fact that ϵ'' is not zero causes the whole construction to fail. Note that the same kind of approximate results are obtained under HQR, but with no damage there. For suppose that ϵ'' is in column k of A_C and consider stage k of both algorithms. In HQR one single transformation annihilates the whole column so that the contribution of a tiny ϵ'' to the kth transformation matrix is negligible. On the other hand, in GQR the elements are annihilated selectively and, if ϵ'' is not a true zero, one additional plane rotation is triggered between rows k and $k+1$ which places zero in the entry $(k+1, k)$. Unfortunately, this rotation also has the effect of placing a positive value in position (k, k), thus (possibly) altering the sign that encoded the logical value being passed around and causing the whole simulation to fail in general.

We thus need to replace the duplicator with one that returns a true zero in the entry $(d, d-1)$ of the incomplete factor R. To do this we must exploit the proper-

$$N = \begin{pmatrix}
\mathbf{a} & 0 & 1 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 \\
0 & \mathbf{b} & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
2 & 0 & 3 & 0 & 0 & 0 & \frac{3-3\sqrt{65}}{16} & \frac{-3+\sqrt{65}}{4} & -\frac{183+25\sqrt{65}}{64} & -\frac{723+125\sqrt{65}}{384} & 0 \\
0 & 1 & 0 & 2 & 0 & \frac{39\sqrt{\frac{13}{7}}}{2} + 4\sqrt{30} & \frac{-19\zeta}{14} & 0 & 0 & \alpha & 0 \\
0 & 1 & 0 & 3 & 0 & 6\sqrt{\frac{13}{7}} + \sqrt{30} & \frac{-4\zeta}{7} & 0 & 0 & \beta & 0 \\
0 & 1 & 0 & 4 & 0 & \frac{29\sqrt{\frac{13}{7}}}{2} + 3\sqrt{30} & \frac{-17\zeta}{14} & 0 & 0 & \gamma & 0 \\
0 & 1 & 0 & 5 & 0 & \frac{7\sqrt{30}+5\sqrt{91}}{2} & \frac{\sqrt{10}-3\zeta}{2} & 0 & 0 & \delta & 0 \\
2 & 0 & 4 & 0 & 0 & 0 & \frac{5-3\sqrt{65}}{8} & \frac{-1+\sqrt{65}}{2} & -\frac{97+25\sqrt{65}}{32} & -\frac{357+125\sqrt{65}}{192} & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & \frac{-5x}{3} \\
0 & 0 & 0 & 0 & 0 & \frac{4}{3} & 0 & -1 & 0 & -\frac{125}{96} & 0
\end{pmatrix}.$$

$$\alpha = \frac{-16625\sqrt{\frac{5}{2}}}{504} + \frac{875\sqrt{\frac{15}{2}}}{112} - \frac{4875\sqrt{91}}{1792} + \frac{2375\sqrt{371}}{1008}, \quad \beta = \frac{125}{64}\left(3\sqrt{\frac{53}{7}} - 3\sqrt{\frac{13}{7}} - 6\sqrt{\frac{5}{2}} + \sqrt{\frac{15}{2}}\right),$$

$$\gamma = \frac{-14875\sqrt{\frac{5}{2}}}{504} + \frac{2625\sqrt{\frac{15}{2}}}{448} - \frac{3625\sqrt{91}}{1792} + \frac{2125\sqrt{371}}{1008}, \quad \delta = 125\left(\frac{\sqrt{371}}{48} - \frac{5\sqrt{\frac{5}{2}}}{18} + \frac{7\sqrt{\frac{15}{2}}}{128} - \frac{5\sqrt{91}}{256}\right)$$

$\zeta = 7\sqrt{10} + \sqrt{371}$.

FIG. 6. *The N block for GQR.*

$$D = \begin{pmatrix}
\mathbf{a} & 1 & 0 & 0 & 0 & 0 \\
1 & 2 & 0 & \frac{39\sqrt{\frac{13}{7}}}{2} + 4\sqrt{30} & \frac{-19\zeta}{14} & \left(\frac{-39\sqrt{\frac{13}{7}}}{2} + 4\sqrt{30}\right)x + \left(-19\sqrt{\frac{5}{2}} + \frac{19\sqrt{\frac{53}{7}}}{2}\right)z \\
1 & 3 & 0 & 6\sqrt{\frac{13}{7}} + \sqrt{30} & \frac{-4\zeta}{7} & \left(-6\sqrt{\frac{13}{7}} + \sqrt{30}\right)x + \left(4\sqrt{\frac{53}{7}} - 4\sqrt{10}\right)z \\
1 & 4 & 0 & \frac{29\sqrt{\frac{13}{7}}}{2} + 3\sqrt{30} & \frac{-17\zeta}{14} & \left(\frac{-29\sqrt{\frac{13}{7}}}{2} + 3\sqrt{30}\right)x + \left(-17\sqrt{\frac{5}{2}} + \frac{17\sqrt{\frac{53}{7}}}{2}\right)z \\
1 & 5 & 0 & \frac{7\sqrt{30}+5\sqrt{91}}{2} & \frac{\sqrt{10}-3\zeta}{2} & \left(7\sqrt{\frac{15}{2}} - \frac{5\sqrt{91}}{2}\right)x + \left(-10\sqrt{10} + \frac{3\sqrt{371}}{2}\right)z
\end{pmatrix}$$

$\zeta = 7\sqrt{10} + \sqrt{371}$.

FIG. 7. *The D block for GQR.*

ties of floating point arithmetic. Let m and M denote the length of the significand and the largest exponent e such that 2^e can be represented in the arithmetic under consideration, respectively. For the standard IEEE 754, $m = 53$ and $M = 1023$. The nonzero entries of the floating point D block, shown in Figure 9, are powers of 2. In this way any operation will be either exact or simply a no operation.

As the new auxiliary vector, we define

$$a_D(x, y) = \left(0, y2^{M-2}, 1, 1, x2^m, 2^{-M}, 2^m, 2^m, 2^{m-\lceil \frac{m}{2} \rceil}, 2^{m-\lceil \frac{m}{2} \rceil}\right)^T.$$

Note that the only assignments to x and y we need are 0 and 1 or 1 and 0.

The rest of the proof is now similar to that of Theorem 4.3. We show how to correct the slightly erroneous values computed by an N block, assuming that the previous N blocks return exact results. Let N stand for the nand block adopted for

$$W = \begin{pmatrix} \mathbf{a} & 1 & 1 & 0 \\ 2 & 3 & \frac{-3+\sqrt{65}}{4} & -\frac{15\,x}{4} - \frac{\sqrt{65}\,x}{4} \\ 2 & 4 & \frac{-1+\sqrt{65}}{2} & -\frac{9\,x}{2} - \frac{\sqrt{65}\,x}{2} \end{pmatrix}.$$

FIG. 8. *The W block for GQR.*

$$D = \begin{pmatrix} \mathbf{a} & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 2^{-m} & 2^{-M+2m+1} & -2^{M-1} & 0 & 0 & 0 & 0 & 0 \\ 2^{-m} & 2^{-3m} & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 2^{-M+3m+2} & 1 & 2^{M-1} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 2^{-M+1+m} & 0 & 2^{-M+2m+1} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2^{-m} & 2^{M-1-m} & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 2^{-\lfloor \frac{m}{2} \rfloor} & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 2^{-\lfloor \frac{m}{2} \rfloor} & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 2^{-\lceil \frac{m}{2} \rceil} & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 2^{-\lceil \frac{m}{2} \rceil} & 0 & 1 \end{pmatrix}.$$

FIG. 9. *The D block for floating point GQR.*

the exact arithmetic version of GQR (Figure 6). The new nand block is then

$$N_{\text{corr}} = \begin{pmatrix} N & 0 & 0 \\ c^T & 1 & 0 \\ 0^T & 2^{-\lceil \frac{m}{2} \rceil} & 1 \end{pmatrix},$$

where

$$c^T = (\overbrace{0, \ldots, 0}^{9}, 2^{-\lfloor \frac{m}{2} \rfloor}).$$

As the new auxiliary vector, we take

$$a_{N_{\text{corr}}}(x) = \left(\overbrace{0, \ldots, 0}^{8}, -\frac{5}{3} x 2^m, 0, 2^m, 2^{m-\lceil \frac{m}{2} \rceil} \right)^T,$$

i.e., the first 10 entries of $a_{N_{\text{corr}}}(x)$ coincide with $a_N(x2^m)$. Now, let us apply GQR to N_{corr} extended by its auxiliary vector. As N is properly embedded in N_{corr}, after nine stages of GQR we get

$$N_{\text{corr}}^{(10)} = \begin{pmatrix} \mathbf{a}(1+\delta) & 0 & 0 & x2^m(1+\eta) \\ 2^{-\lfloor m/2 \rfloor} & 1 & 0 & 2^m \\ 0 & 2^{-\lceil m/2 \rceil} & 1 & 2^{m-\lceil m/2 \rceil} \end{pmatrix},$$

where $|\delta|, |\eta| \leq c\epsilon$, for some small constant c of order unit. The plane rotation to annihilate the entry $(2,1)$ of $N_{\text{corr}}^{(10)}$ is represented by

$$G_1 = \frac{1}{\sqrt{\mathbf{a}^2(1+\delta)^2 \oplus 2^{-2\lfloor m/2 \rfloor}}} \otimes \begin{pmatrix} \mathbf{a}(1+\delta) & 2^{-\lfloor m/2 \rfloor} \\ -2^{-\lfloor m/2 \rfloor} & \mathbf{a}(1+\delta) \end{pmatrix} = \begin{pmatrix} \mathbf{a} & \frac{2^{-\lfloor m/2 \rfloor}}{1+\delta} \\ -\frac{2^{-\lfloor m/2 \rfloor}}{1+\delta} & \mathbf{a} \end{pmatrix},$$

and its application in floating point gives

$$N_{\text{corr}}^{(10)} = \begin{pmatrix} \mathbf{a} & 0 & \mathbf{a}2^m \ominus x2^{\lceil m/2 \rceil}(1+\zeta) \\ 2^{-\lceil m/2 \rceil} & 1 & 2^{m-\lceil m/2 \rceil} \end{pmatrix},$$

where $1+\zeta = \frac{1+\eta}{1+\delta}$ and $|\zeta| \leq 2\epsilon + O(\epsilon^2)$. The crucial point is that, if x can be represented with no more than $2^{\lfloor m/2 \rfloor}$ significant bits, the alignment of the fractional part performed during the execution of $\mathbf{a}2^m \ominus x2^{\lceil m/2 \rceil}(1+\zeta)$ will simply cause the contribution $x2^{\lceil m/2 \rceil}\zeta$ to be lost. Hence, the computed element in the entry $(1,3)$ will be $\mathbf{a}2^m - x2^{\lceil m/2 \rceil}$. However, one more rotation produces the exact values $\mathbf{a}$ and x in the last row. Note that the only value required in place of x is 1. □

6. GE with pivoting. In this section we consider the algorithm of GE with partial pivoting, or simply GEP, a technique that avoids nondegeneracies and ensures (almost always) numerical accuracy. We also consider the lesser-known minimal pivoting technique, GEM, one that guarantees only that a PLU factorization is found. Minimal pivoting has been adopted for systolic-like implementations of GE [12]. A brief description of these algorithms is reported in Appendix A.

We prove that GEM is P-complete, unless applied to strongly nonsingular matrices, while GEP is P-complete even when restricted to strongly nonsingular matrices. Finally, we prove that GEP is P-complete over GF(2).

6.1. Partial pivoting. The proof we give here builds on the original proof in [24] and hence does not share the common structure of the other reductions in this paper. Essentially we show that, with little additional effort with respect to Vavasis' proof, we can exhibit a reduction in which the matrix obtained is strongly nonsingular. As already pointed out, strongly nonsingular matrices are of remarkable importance in practical applications. This class contains symmetric positive definite (SPD) and diagonally dominant matrices, which often arise from the discretization of differential problems. Observe that, with any such matrix in input, plain GE (no pivoting) is nondegenerate, but it is not stable in general and hence is not the algorithm of choice.

As in [24], what we actually prove to be P-complete is the following set:

$$L = \{(i,j,A) : \ A \text{ is strongly nonsingular and, on input } A, \text{ GEP uses row } i \text{ to eliminate column } j \ \}.$$

THEOREM 6.1. *The set L is logspace complete for P over the real or rational numbers.*

We postpone the technical proof of Theorem 6.1 to Appendix C but give an example that shows the way the matrix given in [24] is modified. Figure 10 depicts the reduction matrix $\mathbf{M}_C$ corresponding to the circuit of Figure 3, obtained according to the rules in [24]. The matrix is nonsingular; however, it can be seen that the leading principal minor of order 2 is singular. The matrix we obtain, according to Theorem 6.1, is shown in Figure 11. It can be easily seen that our matrix is strongly diagonally dominant by rows and hence strongly nonsingular.

6.2. Minimal pivoting. The technique of minimal pivoting, i.e., selecting as the pivot row at stage k the first one with a nonzero entry (below or on the main diagonal) in column k, is probably the simplest modification that allows GE to cope with degenerate cases. However, such a simple technique is sufficient to make GE P-complete. Note that, even if no formal error analysis is available for GEM, it is not difficult to exhibit matrices (that can plausibly appear in real applications) such that the error incurred by GEM is very large. Actually, GEM is likely to be as unstable as standard GE (no pivoting).

Consider the following set:

$$L' = \{A : \ A \text{ is } n \times n,\ PA = LU \text{ is the factorization computed by GEM, and } [U]_{nn} > 0\}.$$

$$\begin{pmatrix}
-3.9 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\
\mathbf{a} & \cdot & 1 & 1 & \cdot & \cdot & 1 & \cdot & \cdot & \cdot & \cdot & \cdot \\
\cdot & -3.9 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\
\cdot & \mathbf{b} & 1 & \cdot & 1 & \cdot & \cdot & 1 & \cdot & \cdot & \cdot & \cdot \\
\cdot & \cdot & -3.9 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\
1 & 1 & 4 & 1 & 1 & \cdot & \cdot & \cdot & 1 & \cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot & -3.9 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\
1 & \cdot & 1 & 4 & \cdot & 1 & \cdot & \cdot & \cdot & 1 & \cdot & \cdot \\
\cdot & \cdot & \cdot & \cdot & -3.9 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\
\cdot & 1 & 1 & \cdot & 4 & 1 & \cdot & \cdot & \cdot & \cdot & 1 & \cdot \\
\cdot & \cdot & \cdot & \cdot & \cdot & -3.9 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot & 1 & 1 & 4 & \cdot & \cdot & \cdot & \cdot & \cdot & 1
\end{pmatrix}$$

FIG. 10. *Matrix* $\mathbf{M}_C$ *corresponding to the* exclusive or *circuit. The symbol* $\cdot$ *stands for a zero entry.*

$$\begin{pmatrix}

\end{pmatrix}$$

FIG. 11. *The matrix* $\mathbf{A}_C$ *for the computation of* $\texttt{XOR}(a, b)$.

THEOREM 6.2. *The set* L' *is logspace complete for* P *under both real and finite precision floating point arithmetic.*

Proof. The set is clearly in P, as GEM runs in time $O(n^3)$ under both models of arithmetic. We first show that L' is also logspace hard for P when the input matrices are singular and then show how to restrict the input set. As GEM belongs to the class $\mathcal{F}$, to prove the hardness of L' we simply list the three elementary matrices required by Theorem 3.1. Note that the matrices are the same for both models of arithmetic, as the operations performed by GEM in floating point are exact. The encoding of logical values here is 0 for `False` and 1 for `True`. The matrices are depicted in Figures 12 and 13.

A_C is clearly singular. Now consider the following matrix B_C of order $2n_C$, where n_C is the order of A_C:

$$B_C = \begin{pmatrix} A_C & E \\ E & O \end{pmatrix}, \tag{4}$$

where E is the matrix with 1 on the antidiagonal and 0 elsewhere. The determinant of B_C can be easily proved to be ± 1. Moreover, if $\bar{P}B_C = \bar{L}\bar{U}$ is the factorization computed by GEM, then $[\bar{U}]_{n_C,n_C} = [U]_{n_C,n_C}$, where U is the upper triangular factor computed by GEM on input A_C. Note, then, that what we prove to be P-complete is not exactly L' but a set with a slightly more complicated definition.

As usual, in the following the notation $A_C^{(k)}$ will be used to denote the matrix

$$N = \begin{pmatrix} \mathbf{a} & 0 & 0 & 0 & 0 & 0 \\ 0 & \mathbf{b} & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & -1 & 0 \\ 0 & 1 & 0 & 0 & -1 & 0 \\ 1 & 1 & 0 & 0 & 0 & x \end{pmatrix} \qquad W = \begin{pmatrix} \mathbf{a} & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ -1 & 0 & 0 & x \end{pmatrix}$$

FIG. 12. *The nand (left) and wire (right) blocks for GEM.*

$$D = \begin{pmatrix} \mathbf{a} & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\ -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & x \\ -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & z \\ 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & z \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

FIG. 13. *The D block for GEM.*

obtained after $k-1$ stages of GEM on input A_C and considering only the entries (i,j) with $i,j \geq k$. However, by writing $B_C^{(k)}$ we mean the submatrix obtained after $k-1$ stages of GEM (on input B_C) and considering only the entries (i,j) such that $k \leq i,j \leq n_C$. With this position, to prove that the output of C can be read off entry (n_C, n_C) of the U factor of B_C, we show that the executions of GEM on input A_C and on input B_C result in identical submatrices $A_C^{(k)}$ and $B_C^{(k)}$, for $0 \leq k \leq n_C$. The proof is by induction. Initially, for $k = 1$, the equality follows from the definition of B_C. Consider stage $k \geq 1$. If column k of $A_C^{(k)}$ contains a nonzero element below or on the main diagonal, say, at row index i, then the selected pivot row is the ith under both executions. The result follows then from the induction hypothesis and the fact that exactly the same operations are performed on the elements of the submatrices. If no nonzero element is found in column k of $A_C^{(k)}$, then stage k of the first execution has no effect, and hence $A_C^{(k+1)} = A_C^{(k)}$. Under the second execution (the one on input B_C) by construction the pivot is taken from row $2n_C - k + 1$. However, the pivot is the only nonzero element in row $2n_C - k + 1$ and thus the effect of this step is simply the exchange of rows k and $2n_C - k + 1$. However, once more $B_C^{(k+1)} = B_C^{(k)}$. □

Two concluding remarks are in order. First, we note that the application of GEP to the elementary matrices of Theorem 6.2 would return the same factors determined by GEM. This is because the only nonzero elements appearing during the factorizations are -1 and 1, and hence the first nonzero in a column is also the largest magnitude element in that column. Within our general framework, this observation represents another proof that GEP is presumably inherently sequential. The first such proof was given in [24].

As the second observation, we note that the set L' of Theorem 6.2 would be NC computable if the input set were restricted to the class of strongly nonsingular matrices. In fact, on input these matrices GEM and standard GE behave exactly the same.

6.3. Completeness over GF(2). The status of GEP over finite fields (i.e., whether P-complete or NC-computable) is mentioned as an open problem in [11]. Over finite fields there is clearly no question of stability, so the only problem is to find a nonzero pivot at each stage. Under these circumstances GEP is intended to select, as the pivot for stage l, the first nonzero element in column l below or on the main diagonal and thus coincides with GEM. Consider the set

$$F = \{(A, l, k) : \ A \text{ is } n \times n \text{ with entries over a finite field, and the pivot for the } l\text{th stage of GEP is taken from row } k\}$$

mentioned in [11].

THEOREM 6.3. *The set F is logspace complete for P over GF(2).*

Proof. We first show that deciding whether the element $[U]_{nn}$ (where U is the upper triangular factor computed by GEM on input A) is 0 or 1 is P-complete. This is easy using our general framework. The elementary matrices are exactly the ones given in Theorem 6.2, where -1 has to be interpreted as the additive inverse of 1 in GF(2) (and thus replaced by 1). Next we prove that this decision problem can be easily reduced to membership in F. To see this, it is sufficient to observe the behavior of GEP on input a nand elementary matrix. It is easy to check that the following row permutations take place:

(i) $1 \leftrightarrow 3$ and $2 \leftrightarrow 4$, if the logical inputs are both 0;
(ii) $1 \leftrightarrow 3$ if the inputs are 0 and 1 (in this order);
(iii) $2 \leftrightarrow 3$ if the inputs are 1 and 0;
(iv) no permutation if the inputs are both 1.

It follows that the first nonzero is taken from row 3 in either the first or the second stage provided that some input is 0, and hence if the output is 1. By our construction, no row corresponding to the last nand block in the reduction matrix A_C is used to eliminate previous columns. Hence, to decide whether the element $[U]_{nn}$ is 0 or 1 is equivalent to asking whether $(A_C, n_C - 4, n_C - 2) \in F$ or $(A_C, n_C - 3, n_C - 2) \in F$, where n_C is the size of A_C. ∎

7. On *NC* algorithms for the *PLU* decomposition. In this section we show that a known NC algorithm for computing a PLU decomposition of a nonsingular matrix (see [8]) corresponds to GE with a nonstandard pivoting strategy which is only a minor variation of minimal pivoting. This result seems to be just a "curiosity"; however, we can prove that the same strategy is inherently sequential on input arbitrary matrices, which can be seen as further evidence of the difficulties of finding an NC algorithm to compute the PLU decomposition of possibly singular matrices.

The new strategy will be referred to as minimal pivoting with circular shift and the corresponding elimination algorithm referred to simply as GEMS. The reason for its name is that GEMS, like GEM, searches the current column (say, column k) for the first nonzero element. Once one is found, say in row i, a circular shift of rows k through i is performed to bring row i in place of row k (and the latter in place of row $k + 1$).

THEOREM 7.1. *Computing the PLU factorization returned by GEMS on input a nonsingular matrix is in arithmetic NC^2.*

Proof. We consider the algorithm of Eberly [8]. Given A, nonsingular of order n, let A_i denote the $n \times i$ matrix formed from the first i columns of A, $i = 1, \ldots, n$. If S_i denotes the set of indices of the lexicographically first maximal independent subset of the rows of A_i, then $|S_i| = i$, since A_i has full column rank. Moreover, $S_i \subseteq S_{i+1}$, $i = 1, \ldots, n - 1$. Note that the computation of all the S_i is in NC^2 (see [3]). Now,

let $S_1 = \{j_1\}$, and, for $i = 2, \ldots, n$, $S_{i+1} - S_i = \{j_{i+1}\}$. Then a permutation P such that $P^T A$ has LU factorization is simply

$$P = (e_{j_1} | e_{j_2} | \ldots | e_{j_n}),$$

where e_i is the ith unit (column) vector. Clearly, once P has been determined, computing the LU factorization of $P^T A$ can be done in polylogarithmic parallel time using known algorithms. We now show by induction on the column index k that P is the same permutation determined by GEMS. The basis is trivial, since j_1 is the index of the first nonzero element in column 1 of A. Now, for $k > 1$, let

$$(e_{j_1} | \ldots | e_{j_k} | e_{l_{k+1}} | \ldots | e_{l_n})^T A = L_k U_k = L_k \begin{pmatrix} R_k & B_k \\ O & \mathcal{A}_k \end{pmatrix} \tag{5}$$

be the (partial) factorization computed by GEMS, where R_k is upper triangular with nonzero diagonal elements (since A is nonsingular) and the unit vectors $e_{l_{k+1}}, \ldots, e_{l_n}$ extend $e_{j_1}, \ldots, e_{j_k}$ to form a permutation matrix. Clearly, minimal pivoting ensures that $l_{k+1} < \cdots < l_n$. Now, the next pivot row selected by GEMS is the one corresponding to the first nonzero element in the first column of $\mathcal{A}_k$. Let $k + 1 \le i \le n$ denote the index of the pivot row. Since GE does nothing but linear combinations between rows, it follows that the initial matrix A_{k+1} satisfies

$$\det\left((e_{j_1} | \ldots | e_{j_k} | e_{l_m})^T A_{k+1}\right) = 0,$$

for any $m \in \{k + 1, \ldots, i - 1\}$, and

$$\det\left((e_{j_1} | \ldots | e_{j_k} | e_{l_i})^T A_{k+1}\right) \neq 0.$$

This in turn implies that $S_{i+1} = \{j_1, \ldots, j_k, l_i\}$, i.e., that $l_i = j_{k+1}$. □

We now show that GEMS is inherently sequential by proving that the set

$$L'' = \{A\colon\ A \text{ is } n \times n,\ PA = LU \text{ is the factorization computed by GEMS, and } [U]_{nn} > 0\}$$

is P-complete. Clearly, that L'' is in P is obvious, so what remains to prove is the following.

THEOREM 7.2. *L'' is logspace hard for P.*

Proof. Once more, GEMS is in the class $\mathcal{F}$. So we simply give the elementary matrices. This is very easy. Everything is the same as in the first part of the proof of Theorem 6.2, *except for the auxiliary vector of D.* The new definition for $a_D(x, z)$ is

$$a_D(x, z) = (x - z, z, -x, x - z, 0, 0, 0, 0, 0, 0, 0)^T. \qquad \square$$

It is an easy but interesting exercise to understand why the second part of Theorem 6.2, which extends the P-completeness result to nonsingular matrices, does not work here. (We know that it cannot work, in view of Theorem 7.1.)

8. Conclusions and open problems. The matrices corresponding, for both Householder's and Givens' algorithms, to a circuit C are singular, in general. More precisely, the duplicator elementary matrix is singular, so that all the matrices that do not correspond to simple formulas (fanout 1 circuits) are bound to be singular. All the attempts we made to extend the proofs to nonsingular matrices failed. The reason for this state of affairs could be an interesting subject in itself. To see that

TABLE 1
Parallel complexity of GE with different pivoting strategies and for different classes of input matrices. The results proved in this paper are in boldface.

	General matrices	Nonsingular matrices	Strongly nonsingular matrices
GEP	Inherently seq.	Inherently seq.	**Inherently seq.**
GEM	**Inherently seq.**	**Inherently seq.**	*NC*
GEMS	**Inherently seq.**	***NC***	*NC*

the reason for these failures might be deeper than simply our technical inability, we mention a result of Allender et al. [1] about the "power" of singular matrices. They prove that the set of singular integer matrices is complete for the complexity class $C_=L$.[3] The result extends to the problem of verifying the rank of integer matrices. Of course, our work is at a different level: we are essentially dealing with presumably inherently sequential algorithms for problems that parallelize very well (using different approaches). However, the coincidence suggests that nonsingular matrices might not have enough power to map a general circuit. This is the major open problem for the QR algorithms.

Also, for general matrices, it would be interesting to know the status of Householder's algorithm with column pivoting, which is particularly suitable for the accurate rank determination under floating point arithmetic.

For what concerns Givens' rotations, an obvious open problem is to determine the status of other annihilation orderings, especially the ones that proved to be very effective in limited parallelism environments [23, 18]. We suspect that these lead to inherently sequential algorithms as well.

Finally, Table 1 provides a summary of the known results for the three pivoting strategies investigated in this paper for GE.

As already mentioned, the results of this paper support the belief that there is a tradeoff between parallelism, on the one hand, and nondegeneracy and accuracy, on the other, in numerical algorithms [6]. We suspect that far deeper work is needed to either prove such a tradeoff on a solid theoretical ground or to exhibit stable algorithms substantially more efficient than the ones adopted by numerical analysts for decades.

Appendix A. Algorithms for matrix factorization. In this appendix we describe the factorization algorithms considered in this paper.

Gaussian elimination (GE). GE computes the LU decomposition of A (whenever it exists) by determining a sequence of $n-1$ elementary transformations $M^{(k)}$ with the following properties:

$$\begin{cases} A^{(1)} &= A, \\ A^{(k+1)} &= M^{(k)}A^{(k)}, & k = 1, \ldots, n-1, \\ a_{ij}^{(k)} &= 0, & i > j \text{ and } j < k, \\ U &= A^{(n)}, \\ L &= \prod \left(M^{(k)}\right)^{-1}. \end{cases}$$

In other words, the transformation $A^{(k+1)} = M^{(k)}A^{(k)}$ sends to zero the elements in column k of $A^{(k)}$ below the main diagonal, leaving the already introduced zeros

[3] A set A is in $C_=L$ provided that there is a nondeterministic logspace bounded Turing machine M such that $x \in A$ iff M has the same number of accepting and rejecting computations on input x.

unchanged. The kth transformation $M^{(k)}$ is defined as $I - \tau e_k^T$, where

$$\tau^T = (0, \ldots, 0, \tau_{k+1}, \ldots, \tau_n)$$

and $\tau_i = a_{ik}^{(k)}/a_{kk}^{(k)},\ i = k+1, \ldots, n$. If, for some k, $a_{kk}^{(k)} = 0$, the algorithm fails. However, it can be proved that, if A is strongly nonsingular, $a_{kk}^{(k)} \neq 0,\ k = 1, \ldots, n$.

GE with partial pivoting (GEP). GEP computes a PLU decomposition of A. GEP never fails. As in GE, the matrices L and U are built using a sequence of elementary transformations. However, before applying $M^{(k)}$ to $A^{(k)}$, GEP determines the minimum index h such that

$$|a_{hk}^{(k)}| = \max_{k \leq i \leq n} |a_{ik}^{(k)}|$$

and swaps the rows k and h of $A^{(k)}$. If the maximum above is 0, the algorithm sets $A^{(k+1)} = A^{(k)}$. The rule used for choosing the index h is an example of *pivoting strategy*, and the row h itself is called the *pivot row*.

GE with minimal pivoting (GEM). This is similar to GEP, with the only difference being that h is the minimum among the indices i, $k \leq i \leq n$, such that $a_{ik}^{(k)} \neq 0$. If no such index exists, the algorithm sets $A^{(k+1)} = A^{(k)}$.

QR factorization via Householder's reflections (HQR). HQR applies a sequence of $n-1$ elementary orthogonal transformations $Q^{(k)}$ to A, i.e.,

$$\begin{cases} A^{(0)} & = & A, & \\ A^{(k+1)} & = & Q^{(k)} A^{(k)}, & k = 1, \ldots, n-1, \\ a_{ij}^{(k)} & = & 0, & i > j \text{ and } j < k, \\ R & = & A^{(n-1)}. & \end{cases}$$

Since the $Q^{(k)}$ are orthogonal, we can write

$$A = (Q^{(1)})^T (Q^{(2)})^T \cdots (Q^{(n-1)})^T R = QR,$$

which represents the factorization computed by the algorithm. The matrix $Q^{(k)}$ is defined as follows. Let

$$a = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ a_{kk}^{(k-1)} \\ \vdots \\ a_{nk}^{(k-1)} \end{pmatrix}, \quad \text{and define} \quad v = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ a_{kk}^{(k-1)} \\ \vdots \\ a_{nk}^{(k-1)} \end{pmatrix} + \begin{pmatrix} 0 \\ \vdots \\ 0 \\ \theta\sqrt{a^T a} \\ \vdots \\ 0 \end{pmatrix}, \tag{6}$$

where $\theta = a_{kk}^{(k-1)}/|a_{kk}^{(k-1)}|$ is the sign of $a_{kk}^{(k-1)}$. Then

$$Q^{(k)} = \begin{cases} I - \frac{2}{v^T v} v v^T & \text{if } v \neq 0, \\ I & \text{otherwise.} \end{cases} \tag{7}$$

The important point to observe is that there are other possible strategies for choosing θ in (6) that would produce the same effect of annihilating the kth column. However, the choice adopted here is be preferred for stability reasons.

QR factorization via Givens' rotations (GQR). GQR applies to general real matrices. It computes a sequence of $\frac{n(n-1)}{2}$ transformations (called *rotations*), such that each transformation annihilates one element below the main diagonal, leaving all the already introduced zeros unchanged. GQR annihilates the subdiagonal part of the matrix in the natural order (left to right and top to bottom).

The rotation used to annihilate a selected entry a_{ji} of a matrix A is the orthogonal matrix G_{ij} defined as follows:

$$G_{ij} = \begin{pmatrix} 1 & \cdots & 0 & \cdots & 0 & \cdots & 0 \\ \vdots & \ddots & \vdots & & \vdots & & \vdots \\ 0 & \cdots & c & \cdots & s & \cdots & 0 \\ \vdots & & \vdots & \ddots & \vdots & & \vdots \\ 0 & \cdots & -s & \cdots & c & \cdots & 0 \\ \vdots & & \vdots & & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & \cdots & 0 & \cdots & 1 \end{pmatrix} \begin{matrix} \\ \\ \longleftarrow i \\ \\ \longleftarrow j \\ \\ \\ \end{matrix},$$

where $c = \frac{a_{ii}}{\sqrt{a_{ii}^2+a_{ji}^2}}$ and $s = \frac{-a_{ji}}{\sqrt{a_{ii}^2+a_{ji}^2}}$. One can easily verify that G_{ij} is indeed orthogonal and that the entry j, i of $G_{ij} \cdot A$ is zero.

Appendix B. Floating point number representation. A floating point system $\mathcal{S}$ is characterized, on a particular computer, by four integers: the *base* b of the representation (usually $b = 2$), the *precision* t, and the *range* of the exponent $[\ell, L]$. A number $f \in \mathcal{S}$ has the form

$$f = \pm .b_1 b_2 \cdots b_t \times b^e,$$

where $0 \le b_i < b$ and $\ell \le e \le L$. It is also required that $b_1 \neq 0$, which is a normalization condition. The sequence $.b_1 b_2 \cdots b_t$ is the *significand*, while e is the *exponent*.

If $\mathrm{fl}(x)$ is the (rounded or chopped) floating point representation of a real x, then

$$\mathrm{fl}(x) = x(1+\delta)$$

(if no exceptional condition occurs), where $|\delta| \le \epsilon$ and

$$\epsilon = \begin{cases} \frac{1}{2} b^{1-t} & \text{for rounded arithmetic,} \\ \\ b^{1-t} & \text{for chopped arithmetic.} \end{cases}$$

ϵ is the so-called *machine precision* or *roundoff unit* and is used for roundoff error analysis. In particular, let $\odot$ denote the floating point implementation of the arithmetic operation $\cdot \in \{+, -, \times, /\}$. If $x, y \in \mathcal{S}$, then

$$x \odot y = \mathrm{fl}(x \ \cdot \ y) = (x \ \cdot \ y)(1+\eta), \tag{8}$$

where $|\eta| \le \epsilon$. Equation (8) is known as the *standard model* of arithmetic. A property that plays a crucial role in our reduction is the following. Let a and b be floating point numbers such that $|b| < \epsilon |a|$. Then $a \oplus b = a$.

Appendix C. Proof of Theorem 6.1. The set is clearly in P. Now, given a nand circuit C with n inputs and gates together, we define a strongly nonsingular

matrix $\mathbf{A}_C$ such that, for $k = 1, \ldots, n$, if the output of node k of C (either an input or a nand gate) is `True`, the pivot for step $2k-1$ will be taken from row $2k-1$, or else the pivot will be taken from row $2k$.

For the benefit of the reader, we first briefly recall the P-completeness proof for nonsingular matrices given in [24]. Let $\mathbf{M}_C$ denote the matrix corresponding to the circuit C according to [24] (see Figure 10). If the circuit has n inputs and gates, the matrix $\mathbf{M}_C$ has order $2n$. However, the circuit simulation takes place while performing the elimination of the first n columns, with columns $n+1, \ldots, 2n$ having the only purpose of ensuring nonsingularity. For example, in the matrix of Figure 10 the first two columns correspond to the inputs a, b, while, for $i = 3, \ldots, 6$, column i corresponds to gate $i-2$. For the circuit inputs a logical value `False` is represented by the value 4, while a logical value `True` is represented by the value 3.75. When one executes GEP on $\mathbf{M}_C$, a logical value `False` for a certain input or gate yields a pivot 4 in the corresponding column, whereas a logical value `True` yields a pivot -3.9. Therefore, the sequence of rows selected by GEP provides us with the output of each gate in the circuit C.

The proof in [24] is based on the observation that a nand gate outputs `False` unless one of its inputs is `False`. This fact is mirrored in the matrix $\mathbf{M}_C$, where the pivot of each column is 4 unless that value is modified in a previous elimination step. The structure of the matrix is such that the processing of a pivot 4, corresponding to a `False` output, changes the status of the gates receiving that output from `False` to `True`. This change of status is achieved by subtracting 0.25 from an entry initially set to 4. This ensures that at the due time the pivot in the corresponding column will be -3.9. For example, in the matrix of Figure 10 the selection of the pivot 4 in column 4 (corresponding to a `False` output for gate 2) reduces the 4 entry in column 6 by 0.25, ensuring that the pivot for that column will be -3.9 (corresponding to a `True` output for gate 4). Note that the 1's in the first n columns of $\mathbf{M}_C$ correspond to the wires of the circuit, one pair of 1's for each wire. Below and to the right of each 4 entry there is a number of 1's equal to the fanout of the corresponding gate, which in the following we assume be at most two.

Our matrix $\mathbf{A}_C$ has order $3n$. The $2n \times 2n$ leading principal submatrix of $\mathbf{A}_C$, denoted by $\mathbf{A'}_C$, is the *main submatrix*. The odd-numbered columns of $\mathbf{A'}_C$ are precisely the columns of the first half of the matrix $\mathbf{M}_C$. The even-numbered columns of $\mathbf{A'}_C$ are called the *auxiliary columns*; for $k = 1, \ldots, n$, column $2k$ of $\mathbf{A'}_C$ contains the entry 10 in position $2k$, and zero elsewhere. Outside the main submatrix, the entries a_{ij} of $\mathbf{A}_C$ are all zero except for $a_{2n+k,2k} = 20$ and $a_{2n+k,2n+k} = 30$, $k = 1, \ldots, n$. For example, for the circuit of Figure 10, the corresponding matrix $\mathbf{A}_C$ is shown in Figure 11. Note that $\mathbf{A}_C$ is strongly diagonally dominant and hence strongly nonsingular.

Define the *circuit area* of the matrix $\mathbf{A}_C$ to be the set of odd-numbered columns of the main submatrix. Also, for $i = 1, \ldots, n$, let

$$w_i = \sum_{j=2i+1}^{2n} |a_{2n+i,j}|.$$

The value w_i can be seen as the *weight* of certain entries in row $2n+i$ (see Figure 14).

The proof of the theorem is now a consequence of property **p1** (defined in section 2) and of the following lemma.

LEMMA C.1. *For $k = 1, \ldots, n$ the following facts hold for GEP on input A_C:*

(a) *The pivot for step $2k-1$ is either -3.9 or 4;*

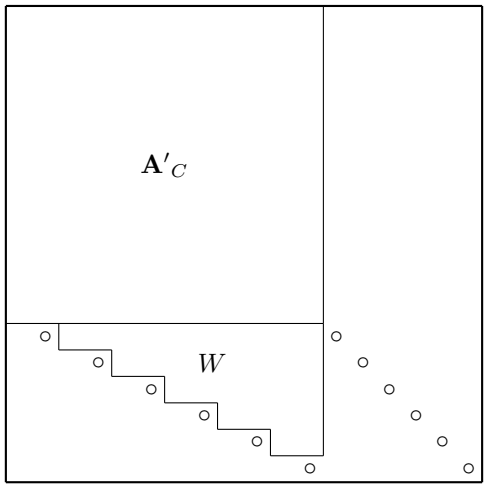

FIG. 14. *The structure of the matrix* $\mathbf{A}_C$. *The area labeled* W *contains the entries which contribute to the weights* w_i*'s. The symbol* $\circ$ *denotes the position of the initial nonzero entries outside the main submatrix* $\mathbf{A'}_C$.

(b) *step* $2k-1$ *modifies the circuit area as the* k*th step in the elimination of matrix* $\mathbf{M}_C$*;*

(c) *step* $2k-1$ *does not affect the auxiliary (even-numbered) columns with index greater than* $2k$*;*

(d) *the pivot for step* $2k$ *is* 20.0;

(e) *step* $2k$ *affects neither the circuit area nor the auxiliary columns with index greater than* $2k$*;*

(f) *at the end of step* $2k$, $w_i \leq 2.5$, *for* $i = 1, 2, \ldots, n$.

Proof. The proof is by complete induction on k. The basis is trivial. For the induction hypothesis, let $k > 1$ and suppose that (a) through (f) hold for any $i < k$.

Consider step $2k-1$ of GEP. By the induction hypothesis, the entries in column $2k-1$ with row index less than $2n$ contain the same values generated during the elimination process on the matrix $\mathbf{M}_C$. This means that $a_{2k-1,2k-1} = -3.9$ and

$$a_{2k,2k-1} = \begin{cases} 4 & \text{if the output of gate } k \text{ is } \texttt{False}, \\ 3.75 \text{ or } 3.50 & \text{otherwise.} \end{cases}$$

Moreover, for $2k < i \leq 2n$, we have $|a_{i,2k-1}| \leq 1.5$ (see part (d) of Lemma 3.2 in [24]). For the entries with row index larger than $2n$, we have, for $2n < i < 2n + k$,

$$|a_{i,2k-1}| \leq w_{i-2n} \leq 2.5,$$

because of (f), and, for $i \geq 2n + k$, we have $a_{i,2k-1} = 0$ by property **p1**. It follows that the pivot is 4 if the output of the gate k is `False`, and -3.9 otherwise, hence proving part (a) and, consequently, part (b).

To prove (c) we first observe that the pivot at step $2k-1$ is either $a_{2k-1,2k-1}$ or $a_{2k,2k-1}$. By the induction hypothesis we know that the first $2k-2$ elimination steps did not affect the auxiliary columns $2k, 2k+2, \ldots, 2n$. Hence, for j even, $2k < j \leq 2n$, at the beginning of step $2k-1$ both $a_{2k-1,j}$ and $a_{2k,j}$ are zero. It follows that, regardless of the pivot, step $2k-1$ does not affect column j.

In order to prove (d), consider step $2k$ of GEP. We need to show that the element with the largest modulus in column $2k$ at the beginning of step $2k$ is $a_{2n+k,2k}$ which,

$$\begin{pmatrix} -3.9 & 0 & \cdots & 0 & \cdots & 0 \\ 4 & 10 & \cdots & 1 & \cdots & 1 \\ \vdots & \vdots & & \vdots & & \vdots \\ 1 & 0 & \cdots & y_r & \cdots & y_s \\ \vdots & \vdots & & \vdots & & \vdots \\ 1 & 0 & \cdots & z_r & \cdots & z_s \\ \vdots & \vdots & & \vdots & & \vdots \\ \vdots & \vdots & & \vdots & & \vdots \\ \alpha_1 & \alpha_2 & \cdots & \alpha_r & \cdots & \alpha_s \end{pmatrix} \longrightarrow \begin{pmatrix} 4 & 10 & \cdots & 1 & \cdots & 1 \\ 0 & \frac{39}{4} & \cdots & \frac{39}{40} & \cdots & \frac{39}{40} \\ \vdots & \vdots & & \vdots & & \vdots \\ 0 & -\frac{5}{2} & \cdots & y_r - \frac{1}{4} & \cdots & y_s - \frac{1}{4} \\ \vdots & \vdots & & \vdots & & \vdots \\ 0 & -\frac{5}{2} & \cdots & z_r - \frac{1}{4} & \cdots & z_s - \frac{1}{4} \\ \vdots & \vdots & & \vdots & & \vdots \\ \vdots & \vdots & & \vdots & & \vdots \\ 0 & \alpha_2 - \frac{5}{2}\alpha_1 & \cdots & \alpha_r - \frac{1}{4}\alpha_1 & \cdots & \alpha_s - \frac{1}{4}\alpha_1 \end{pmatrix}.$$

FIG. 15. *The effect of the elimination of column $2k-1$ over columns $2k, r, s$ when the pivot is 4. Since the fanout of each gate is at most 2 no other column in the main submatrix is affected. We also show how step $2k-1$ modifies a row outside the main submatrix.*

by property **p1**, is equal to 20.0. Also by property **p1**, we know that at step $2k$ we have $a_{i,2k} = 0$ for $2n + k < i \leq 3n$. Hence, we need only to prove that $|a_{i,2k}| < 20.0$ for $2k \leq i < 2n + k$. We consider two cases. If at step $2k - 1$ the pivot is -3.9, the annihilation of column $2k - 1$ does not affect column $2k$. Hence, at the beginning of step $2k$ we have $a_{2k,2k} = 10$, $a_{i,2k} = 0$, for $2k < i \leq 2n$, and, for $2n < i < 2n + k$, $|a_{i,2k}| \leq w_{i-2n} \leq 2.5$. Vice versa, if at step $2k - 1$ the pivot is 4, the elimination of column $2k-1$ does affect column $2k$. As a result, at the beginning of step $2k$ we have $a_{2k,2k} = 39/4$, and two entries in column $2k$ are equal to $-5/2$. For the entries $a_{i,2k}$, with $2n < i < 2n + k$, we have (see Figure 15) $a_{i,2k} = \alpha_2 - \frac{5}{2}\alpha_1$, where $|\alpha_i| \leq 2.5$ (by part (f) of the induction). Hence, $a_{2n+k,2k} = 20.0$ is the largest entry in column $2k$ and is the pivot chosen by GEP.

To prove (e) we simply note that all the entries in the pivot row with column index less than or equal to $2n$ are zero. Therefore, the annihilation of column $2k$ does not affect the main submatrix outside column $2k$.

To prove (f), we fix an index i and analyze how steps $2k - 1$ and $2k$ affect the weight $w_i = \sum_{j=2i+1}^{2n} |a_{2n+i,j}|$. Again we consider two cases, depending on the pivot chosen at step $2k - 1$. If this is -3.9, GEP sends $a_{2n+i,2k-1}$ to zero without affecting the other entries in row $2n + i$. Similarly, step $2k$ sends $a_{2n+i,2k}$ to zero without side effects. Thus, the weight w_i remains bounded by 2.5. A special case is when $i = k$. In fact, at the beginning of step $2k$ GEP swaps rows $2k$ and $2n + k$. In this case the new value w_k depends on the entries $a_{2k,j}$, with $2k < j \leq 2n$. By parts (b), (c), and (e) of the induction, one can see that at the beginning of step $2k$ there are at most four entries $a_{2k,j} \neq 0$ and that $\sum_{2k<j\leq 2n} |a_{2k,j}| \leq 2.5$. Hence, at the end of step $2k$ we have $w_k \leq 2.5$, as claimed. Suppose now that the pivot at step $2k - 1$ is 4. In this case the effects of step $2k - 1$ on row $2n + i$, $i \neq k$, are shown in Figure 15. Since step $2k$ simply sends to zero the entry in column $2k$ (i.e., $\alpha_2 - \frac{5}{2}\alpha_1$), the weight w_i decreases by an amount of at least $|\alpha_1|/2 + |\alpha_2|$. Finally, for $i = k$, reasoning as for the previous case, we get $w_k \leq 2.5$. □

APPROXIMATE COMPLEX POLYNOMIAL EVALUATION IN NEAR CONSTANT WORK PER POINT*

JOHN H. REIF†

Abstract. Given the n complex coefficients of a degree $n-1$ complex polynomial, we wish to evaluate the polynomial at a large number $m \geq n$ of points on the complex plane. This problem is required by many algebraic computations and so is considered in most basic algorithm texts (e.g., [A. V. Aho, J. E. Hopcroft, and J. D. Ullman, *The Design and Analysis of Computer Algorithms*, Addison-Wesley, 1974]). We assume an arithmetic model of computation, where on each step we can execute an arithmetic operation, which is computed exactly. All previous exact algorithms [C. M. Fiduccia, *Proceedings 4th Annual ACM Symposium on Theory of Computing*, 1972, pp. 88–93; H. T. Kung, *Fast Evaluation and Interpolation*, Carnegie-Mellon, 1973; A. B. Borodin and I. Munro, *The Computational Complexity of Algebraic and Numerical Problems*, American Elsevier, 1975; V. Pan, A. Sadikou, E. Landowne, and O. Tiga, *Comput. Math. Appl.*, 25 (1993), pp. 25–30] cost at least work $\Omega(\log^2 n)$ per point, and previously, *there were no known approximation algorithms for complex polynomial evaluation within the unit circle with work bounds better than the fastest known exact algorithms.* There are known approximation algorithms [V. Rokhlin, *J. Complexity*, 4 (1988), pp. 12–32; V. Y. Pan, J. H. Reif, and S. R. Tate, in *Proceedings 32nd Annual IEEE Symposium on Foundations of Computer Science*, 1992, pp. 703–713] for polynomial evaluation at real points, but these do not extend to evaluation at general points on the complex plane.

We provide approximation algorithms for complex polynomial evaluation that cost, in many cases, near constant amortized work per point. Let $k = \log(|P|/\epsilon)$, where $|P|$ is the sum of the moduli of the coefficients of the input polynomial $P(z)$. Let $\tilde{P}(z_j)$ *be an* ϵ*-approx of* $P(z)$ if ϵ upper bounds the modulus of the error of the approximation $\tilde{P}(z_j)$ at each evaluation point z_j, that is, $|P(z_j) - \tilde{P}(z_j)| \leq \epsilon$; note that ϵ is an absolute error bound rather than a relative error bound. In many applications (particularly in signal processing) the evaluation points z_j are fixed and require only polylogarithmic $k = \log(|P|/\epsilon) = O(\log^{O(1)} n)$; for these cases we get a surprising reduction in work by use of approximation algorithms, as compared to the fastest known exact algorithms.

We ϵ-approx complex degree $n-1$ polynomial evaluation at $m \geq n \log n / \log^2 k$ fixed points on or within the unit disk in the complex plane in amortized work $O(\log^2 k)$ per point, which is $O(\log^2 \log n)$ for polylogarithmic k. If the m points are not fixed, then we have increased amortized work $O(\log^2 k + \log m)$ per point, which is $O(\log m)$ for polylogarithmic k and $m \geq n \log n / \log k$, and is still substantially below the previous bound of $\Omega(\log^2 m)$ for known exact algorithms. We further reduce our amortized bounds for special sets of evaluation points widely used in signal processing applications. The *chirp transform* is equivalent to evaluating a complex degree $n-1$ polynomial at the *chirp points*, which are $\zeta^j, j = 0, \ldots, m-1$, for some fixed complex number ζ. We ϵ-approx complex degree $n-1$ polynomial evaluation at these m chirp points, where $m \geq n \log n / \log^2 k$ and $|\zeta| \leq 1$ in amortized work $O(\log k)$ per point, whereas the previous best bounds for exact evaluation (via the chirp transform) were $\Omega(\log m)$ per point [A. V. Aho, K. Steiglitz, and J. D. Ullman, *SIAM J. Comput.*, 4 (1975), pp. 533–539]. All these results use an interesting reduction to fast multipole algorithms for solving Trummer's problem.

Using instead a reduction to approximate real polynomial evaluation (by interpolation at the Chebyshev points), in total work $O(n \log k)$, we

- ϵ-approx the evaluation of a degree n polynomial at the first n powers of the n'th root of unity, where $n' \geq \Omega(n^2/k)$, and
- ϵ-approx the n-point DFT for certain inputs with descending coefficient magnitude.

All of our results require polylogarithmic (that is, $\log^{O(1)} n$) depth with the same work bounds. We also provide a lower bound for a wide class of schemes for approximate evaluation of a degree $n-1$ polynomial on the unit circle; namely, we prove that if a scheme uses an approximation polynomial of degree $k-1$, then it can be convergent only over a small fraction $O(k/n)$ of the unit circle. We believe this is the first lower bound of this sort proved, and the proof uses an interesting reduction

1. Introduction.

The following subsections give an extended description of motivation, statement of the problem, and comparison with prior work.

1.1. Machine model.

For most of this paper, we assume an arithmetic circuit model of sequential computation, where each basic arithmetic or logical operation such as addition, subtraction, multiplication, division, and comparison over the domain of rational numbers can be exactly computed in one step. The floor and ceiling operations are not allowed in this model. (One of our results assumes an *extended arithmetic model*, where given a real θ, then $e^{i\theta} = \cos(\theta) + i\sin(\theta)$ can be computed in $O(1)$ steps. The assumptions made for the extended arithmetic model will be stated during presentation of our algorithms.) We also assume an arithmetic (EREW) PRAM model of parallel computation, where the processors can execute these arithmetic operations in parallel, with exclusive reading and exclusive writing into locations of the shared memory. The computation is *sequential* if there is only one processor. The resource metrics of this model are: *parallel time* (the time to compute the outputs) and *work*, which is the total number of such steps summed over all processors.

1.2. Multipoint polynomial evaluation and interpolation.

The *multipoint polynomial evaluation problem* over ring $\mathcal{D}$ is defined as follows:
Input: n coefficients $p_0, \ldots, p_{n-1} \in \mathcal{D}$ defining a polynomial

$$P(z) = \sum_{j=0}^{n-1} p_j z^j$$

of degree $n-1$ and m evaluation points

$$z_0, \ldots, z_{m-1} \in \mathcal{D}.$$

Output: The values $P(z_0), \ldots, P(z_{m-1})$.

The *multipoint polynomial interpolation problem* over ring $\mathcal{D}$ is defined as follows:
Input: n distinct interpolation points $z_0, \ldots, z_{n-1} \in \mathcal{D}$ and n values $y_0, \ldots, y_{n-1} \in \mathcal{D}$.
Output: coefficients $p_0, \ldots, p_{n-1} \in \mathcal{D}$ defining the unique polynomial

$$P(z) = \sum_{j=0}^{n-1} p_j z^j$$

of degree $n-1$ such that $y_j = P(z_j)$ for $j = 0, \ldots, n-1$.

The multipoint *complex (real)* polynomial evaluation and interpolation problems restrict $\mathcal{D}$ to the complex numbers $\mathcal{C}$ (real numbers $\mathcal{R}$, respectively). Exact algorithms for multipoint polynomial evaluation and interpolation use modular techniques developed in the initial work of Moenck and Borodin [27], Borodin and Munro [4], Horowitz [25], Fiduccia [16], and Kung [26] and were improved by Borodin and Munro [5] to the best known work bounds: $O((n+m)\log^2(n+m))$ for evaluation and $O(n\log^2 n)$ for interpolation. An error analysis for these algorithms is given by Newbery [28]. Pan et al. [31] also gave polynomial evaluation and interpolation algorithms with at least this same work, which in certain cases provide improved numerical stability.

1.3. Multipoint polynomial evaluation at a small number of points. A special case of the multipoint polynomial evaluation problem is where the polynomial $P(z)$ has degree $n-1$, where n is much larger than the number m of evaluation points $z_0, \ldots, z_{m-1}$. This special case has been well known since the early days of algebraic computation and is frequently used in recursive algorithms for multipoint polynomial evaluation.

PROPOSITION 1.1. *The work to evaluate a polynomial $P(z)$ of degree $n-1$ at $m < n$ evaluation points $z_0, \ldots, z_{m-1}$ is $O(n)$ plus $\lceil n/m \rceil$ times the work to evaluate a polynomial of degree $m-1$ at m evaluation points over the same domain.*

Proof. Given $P(z)$ of degree $n-1$, we define $\lceil n/m \rceil$ polynomials

$$P_0(z), \ldots, P_{\lceil n/m \rceil - 1}(z)$$

of degree at most $m-1$, where

$$P(z) = \sum_{j=0}^{\lceil n/m \rceil - 1} P_j(z) z^{jm}.$$

To initialize, we precompute the (trivial) multipoint evaluation z_k^m for each $k = 0, \ldots, m-1$. Then for each $j = 0, \ldots, \lceil n/m \rceil - 1$ we do the multipoint evaluation $P_j(z_k)$ for $k = 0, \ldots, m-1$ and also compute each z_k^{jm} by multiplication of z_k^m times $z_k^{(j-1)m}$. ∎

By application of Proposition 1.1, combined with previous exact algorithms [27, 16, 26, 5] for m point polynomial evaluation for $\lceil n/m \rceil$ polynomials of degree $m-1$, which require work $O(m \log^2 m)$ each, we have the m point polynomial evaluation problem, for $m \leq n$, which can be computed within work

$$\lceil n/m \rceil (m \log^2 m) \leq O(n \log^2 m).$$

Also, the multipoint polynomial evaluation problem, for $m \geq n$, can be solved within work

$$m/n O(n \log^2 n) \leq O(m \log^2 n).$$

Hence we have the following proposition.

PROPOSITION 1.2. *The multipoint polynomial evaluation problem costs work* $\leq O((m+n) \log^2 \min(n, m))$.

1.4. The DFT and generalizations. An nth root of unity ω satisfies $\omega^n = 1$ and $\omega^j \neq 1$ for $1 \leq j < n$. The *nth root of unity over the complex numbers* $\mathcal{C}$ is $\omega = e^{i2\pi/n}$, where $i = \sqrt{-1}$. The *n roots of unity over* $\mathcal{C}$ are $\omega^0, \omega^1, \ldots, \omega^{n-1}$.

The *discrete Fourier transform (DFT) problem* over the complex numbers $\mathcal{C}$ is defined as follows:

Input: coefficients $p_0, \ldots, p_{n-1} \in \mathcal{D}$ defining a polynomial

$$P(z) = \sum_{j=0}^{n-1} p_j z^j$$

of degree $n-1$.

Output: The values

$$P(\omega^0), P(\omega^1), \ldots, P(\omega^{n-1}).$$

The celebrated *fast Fourier transform (FFT)* algorithm of Cooley and Tukey [9] (which, according to Cooley, Lewis, and Welch [8], originates with early work by Runge and König [36] and had early use in the works of Danielson and Lanczos [11] and Good [20]) provides the DFT in work $O(n \log n)$ (also see Gentleman and Sande [17] and Rabiner and Rader [32] for efficient implementations of the DFT).

The DFT^{-1}, which is the inverse problem to the DFT (that is, interpolation from the n roots of unity), reduces to multiplying $\frac{1}{n}$ by the evaluation of a given polynomial at the inverses of each of the n roots of unity. Since for each of the n roots of unity ω^j, the inverse $\omega^{-j} = \omega^{n-j}$ is also one of the n roots of unity (now reverse ordered), the DFT^{-1} can also be solved via the FFT in work $O(n \log n)$. The chirp transform generalizes the FFT to the evaluation of a polynomial of degree $n-1$ over the points ζ^j, for a complex constant ζ. The chirp transform can be computed in work $O(n \log n)$ by a generalization of the FFT algorithm. By a reduction to convolution and thus DFT, the following has also been shown.

PROPOSITION 1.3 (see Aho, Steiglitz, and Ullman [2]). *For fixed complex constants s_0, s_1, ζ, the generalized chirp transform problem of evaluation of a polynomial of degree $n-1$ over the points $s_0 + s_1\zeta^j$ for $j = 0, \ldots, n-1$ (and also the inverse of this problem, that of interpolation from these chirp points) can be solved within work $O(n \log n)$.*

By application of Proposition 1.1, we have the following proposition.

PROPOSITION 1.4. *For fixed complex constants s_0, s_1, ζ, the generalized chirp transform problem of evaluation of a polynomial of degree $n-1$ for over the points $s_0 + s_1\zeta^j$ for $j = 0, \ldots, m-1$ can be solved within work $O((m+n)\log \min(n, m))$.*

Recently, Dutt and Rokhlin, [14] gave an ϵ-approx algorithm for evaluation of a degree $n-1$ polynomial at $n-1$ points on a unit circle with work $O(n \log n + n \log(1/\epsilon))$ and Dutt, Gu, and Rokhlin [12] gave an ϵ-approx algorithm for interpolation of a degree $n-1$ polynomial from $n-1$ Chebyshev points on a unit circle with work $O(n \log(1/\epsilon))$.

1.5. Organization of this paper. The results of this paper are summarized in the abstract. Section 1 provides the standard definitions of the assumed arithmetic model of computation, multipoint polynomial evaluation and interpolation, the DFT, and generalizations to the chirp transform (see also Aho, Steiglitz, and Ullman [2]).

Section 2 gives our *main result*, Theorem 2.7, an approximate complex polynomial evaluation algorithm using a reduction to Trummer's problem which we approximately solve by multipole algorithms. We first define Trummer's problem in subsection 2.1 and describe Multipole methods for approximately solving Trummer's problem in section 2.2. We then give an algorithm for multipoint complex polynomial re-evaluation by reduction to Trummer's problem in section 2.3, and finally in section 2.4 we use this reduction to do approximate complex polynomial evaluation via DFT and multipole algorithms.

Note. Our computational model assumes each arithmetic operation yields exact results; thus, it is not yet known if our algorithm yields the performance given in theory if each arithmetic operation is computed in approximate floating point. However, implementations (see [22, 15]) of fast multipole algorithms using approximate floating point operation do give excellent performance in practice.

Section 3 describes known results for approximate real polynomial evaluation; section 3.1 defines the Chebyshev point evaluation problem and known algorithms; section 3.2 bounds the errors of interpolation at the Chebyshev points; and section 3.3

describes known methods for approximate real polynomial evaluation via interpolation at the Chebyshev points.

Section 4 has a *secondary (less general) result:* it gives approximate polynomial evaluation on a circle in a number of interesting cases, using classical methods of real approximation by interpolation at the Chebyshev points. Subsection 4.1 describes approximate polynomial evaluation on a circle via interpolation at the Chebyshev angles and section 4.2 gives an alternative method which is proved in Appendix A.

Section 5 proves a lower bound for a wide class of schemes for polynomial evaluation on the unit circle; namely, there is no general approximation method, using a low degree polynomial, that is convergent over a large fraction of the unit circle.

Appendix B gives an algorithm for exact Chebyshev point evaluation in $O(n \log n)$ work, which is useful for the approximate real polynomial evaluation results of section 3 (this can be used as an alternative for a somewhat more complex algorithm for Chebyshev point evaluation of Gerasoulis [18]).

2. Approximate complex polynomial evaluation via the multipole methods.

2.1. Trummer's problem. We define the *(generalized) Trummer's problem* over the complex plane $\mathcal{C}$:

Input: n points $a_0, \ldots, a_{n-1} \in \mathcal{C}$, n weights $c_0, \ldots, c_{n-1} \in \mathcal{C}$, defining a rational function $\psi(z) = \sum_{j=0}^{n-1} \frac{c_j}{z-a_j}$, and also $m \geq n$ evaluation points $z_0, \ldots, z_{m-1} \in \mathcal{C}$.

Output: The values $\psi(z_0), \ldots, \psi(z_{m-1})$.

Trummer's problem has widespread application to calculation of electrostatic and gravitational forces. Gerasoulis [18] (also see Gerasoulis, Grigoriadis, and Sun [19]) gave an exact algorithm for Trummer's problem, requiring $O(m \log^2 m)$ work. For the case where $m = n$ and $a_j = z_j$, for $j = 1, \ldots, n$, Gerasoulis defined a polynomial $\sigma(z) = \Pi_{j=0}^{n-1}(z - a_j)$ and its derivative $\sigma^{(1)}(z) = \frac{d\sigma(z)}{dz}$. By *l'Hôpital's* rule (the limit is preserved by taking derivatives), we have the following proposition.

PROPOSITION 2.1.

$$\psi(a_j) = \frac{c_j}{\sigma^{(1)}(a_j)}$$

for $j = 0, \ldots, n-1$

Thus Gerasoulis gave a reduction of the probem of evaluation of $\psi(z)$ to evaluation of $\sigma^{(1)}(z)$ at the n points $a_0, \ldots, a_{n-1}$, which requires $O(n \log^2 n)$ work for the exact solution of Trummer's problem. The result of Gerasoulis also easily extends (e.g., by use of additional weights c_j with value 0) to allow for exact solution of the generalized Trummer's problem, as defined above, in $O(m \log^2 m)$ work.

2.2. Multipole methods. Let $k = \log(|C|/\epsilon)$, where $|C| = \sum_{j=0}^{n-1} |c_j|$ is the sum of the moduli (the modulus of complex number $re^{i\theta}$ is r) of the weights $c_0, \ldots, c_{n-1}$ and ϵ is a given absolute error bound on each output. Greengard and Rokhlin [21] (also see Carrier, Greengard, and Rokhlin [7]) gave an ϵ-approx algorithm, known as the multipole algorithm, for Trummer's problem using an $O(k)$ term rational series expansion of $O(k)$ terms and requiring $O(mk^2)$ work over the complex plane. They computed ϵ-approx values $\widetilde{\psi}(a_0), \ldots, \widetilde{\psi}(a_m)$ such that $|\psi(a_j) - \widetilde{\psi}(a_j)| \leq \epsilon$ for $j = 0, \ldots, m-1$. Given the n points $a_0, \ldots, a_{n-1} \in \mathcal{C}$ for Trummer's problem, rational function $\psi(z)$, and also $m \geq n$ evaluation points $z_0, \ldots, z_{m-1} \in \mathcal{C}$, the multipole algorithm requires using these $m+n$ points to construct a certain tree-like data structure known as the *well-separated decomposition*; see Callahan and Kosaraju [6] for details.

Given these $m+n$ points, the well-separated decomposition algorithm of Callahan and Kosaraju [6] costs work $O(m \log m)$. Also, Pan, Reif, and Tate [30] (see Reif and Tate [33] for the full paper) gave an $O(m \log\log m)$ algorithm for the well-separated decomposition in the case where the input points have logarithmic bit-precision. Assuming a well-separated decomposition, the Multipole algorithm over the complex plane was improved by Greengard and Rokhlin [22] to $O(mk \log k)$ work by use of the FFT, to do each of the $O(m)$ operations on $O(k)$ term power series required by this multipole algorithm, each within work $O(k \log k)$. Later work by Pan, Reif, and Tate [30] (see Reif and Tate [34] for the full paper) gave a further substantial improvement, which remains the most efficient known algorithm for approximate solution of the Trummer's problem.

LEMMA 2.2. *Given a well-separated decomposition of the set of the input points, a Trummer's problem for m evaluation points can be ϵ-approx on every output within work $O(m \log^2 k)$, where $k = \log(|C|/\epsilon)$.*

The algorithm of [30, 34] uses a reduction from Trummer's problem for m evaluation points to ϵ-approx solution of a (slightly generalized) Trummer's problem of size $m' \leq m/k^c$ for a constant c with cost $O(m'k \log k) \leq O(m)$, and also solves $O(m')$ instances of Trummer's problem; each has $m/m' \leq k^c$ evaluation points costing $O((m/m') \log^2 k)$ per such instance, resulting in the total cost

$$O(m'(m/m') \log^2 k) \leq O(m \log^2 k).$$

Note. In the special case that the m evaluation points are chirp points, the algorithm of [30, 34] can be sped up as follows: again we compute an ϵ-approx solution of a (slightly generalized) Trummer's problem of size $m' \leq m/k^c$ with cost $O(m'k \log k)$ $\leq O(m)$ and also solve $O(m')$ instances of Trummer's problem with $m/m' \leq k^c$ chirp evaluation points, with the reduced cost $O((m/m') \log k)$ for each such instance, resulting in a somewhat reduced total cost $O(m'(m/m') \log k) \leq O(m \log k)$.

2.3. Reduction to Trummer's problem. The *multipoint polynomial re-evaluation problem* over $\mathcal{C}$ is defined as follows:

Input: n distinct points $a_0, \ldots, a_{n-1} \in \mathcal{C}$ and n values $y_0, \ldots, y_{n-1} \in \mathcal{C}$ defining a unique polynomial $P(z)$ of degree $n-1$ such that $y_j = P(a_j)$ for $j = 0, \ldots, n-1$, and m re-evaluation points $z_0, \ldots, z_{m-1} \in \mathcal{C}$, which are distinct from these points $a_0, \ldots, a_{n-1}$.

Output: The values $P(z_0), \ldots, P(z_{m-1})$.

Note that in the polynomial re-evaluation problem, the coefficients of the input polynomial are not explicitly given.

Given as input n distinct points $a_0, \ldots, a_{n-1} \in \mathcal{C}$, and values $y_0, \ldots, y_{n-1}$, let $\sigma(z) = \Pi_{j=0}^{n-1}(z - a_j)$. Our basic approach is as follows. We construct the rational function $\psi(z) = P(z)/\sigma(z)$, which can be expanded as a Trummer's function $\psi(z)$ $= \sum_{j=0}^{n-1} \frac{c_j}{z-a_j}$. The weights $c_0, \ldots, c_{n-1} \in \mathcal{C}$ are determined by reversing the formula of Proposition 2.1, as follows in this proposition.

PROPOSITION 2.3. *Suppose we set $c_j = y_j/\sigma^{(1)}(a_j)$ for $j = 0, \ldots, n-1$, where $\sigma^{(1)}(z) = \frac{d\sigma(z)}{dz}$. Then $P(z) = \psi(z)\sigma(z)$ for all z, where $\psi(z) = \sum_{j=0}^{n-1} \frac{c_j}{z-a_j}$, and $P(z)$ is the unique degree $n-1$ polynomial such that $P(a_0) = y_0, \ldots, P(a_{n-1}) = y_{n-1}$.*

Proof. If $P(z) = \psi(z)\sigma(z)$, then for $j = 0, \ldots, n-1$,

$$c_j = \lim_{z \to a_j} (z - a_j)\psi(z) = \lim_{z \to a_j} (z - a_j)(P(z)/\sigma(z))$$

$$= P(a_j)/\sigma^{(1)}(a_j) = y_j/\sigma^{(1)}(a_j). \qquad \square$$

We will exactly compute the values $\sigma^{(1)}(a_j)$, $j = 0, \ldots, n-1$. We will compute or approximate (as in certain specialized cases described below) the values $\sigma(z_j)$, $j = 0, \ldots, m-1$. Next we apply the efficient multipole method of [30, 34] (Lemma 2.2) to construct an ϵ-approx solution $\widetilde{\psi}(z_0), \ldots, \widetilde{\psi}(z_{m-1})$ of this Trummer's problem, such that $|\psi(z_j) - \widetilde{\psi}(z_j)| \leq \epsilon$ for $j = 0, \ldots, m-1$. If we exactly compute $\sigma(z_j)$, then we approximate each $P(z_j)$ by $\widetilde{P}(z_j) = \widetilde{\psi}(z_j)\sigma(z_j)$. Otherwise, we approximate each $P(z_j)$ by $\widetilde{P}(z_j) = \widetilde{\psi}(z_j)\widetilde{\sigma}(z_j)$, where $\widetilde{\sigma}(z_j)$ is an ϵ^*-approx to $\sigma(z_j)$ (as determined below).

PROPOSITION 2.4. *For $j = 0, \ldots, m-1$, the $\widetilde{P}(z_j)$ are an $\widehat{\epsilon}$-approx to the $P(z_j)$, where if the $\sigma(z_j)$ are exactly computed, then*

$$\widehat{\epsilon} \leq \epsilon \max_j |\sigma(z_j)|,$$

and if each $\sigma(z_j)$ is ϵ^*-approx by $\widetilde{\sigma}(z_j)$, then

$$\widehat{\epsilon} \leq (\epsilon^* + \max_j |\sigma(z_j)|)\epsilon + (2 + 3\epsilon^*/\min_j |\sigma(z_j)|)|P|,$$

where $|P| = \sum_{j=0}^{n-1} |p_j|$.

Proof. First suppose the $\sigma(z_j)$ are exactly computed, so $\epsilon^* = 0$. By definition, $P(z_j) = \psi(z_j)\sigma(z_j)$ and $\widetilde{P}(z_j) = \widetilde{\psi}(z_j)\sigma(z_j)$, so we have

$$\begin{aligned} |P(z_j) - \widetilde{P}(z_j)| &= |\psi(z_j)\sigma(z_j) - \widetilde{\psi}(z_j)\sigma(z_j)| \\ &= |\psi(z_j) - \widetilde{\psi}(z_j)||\sigma(z_j)| \leq \epsilon|\sigma(z_j)|. \end{aligned}$$

Otherwise, suppose each $\sigma(z_j)$ is ϵ^*-approx by $\widetilde{\sigma}(z_j)$. We have $|\psi(z_j)| \leq |P|/|\sigma(z_j)|$, and $|\widetilde{\psi}(z_j)| \leq \epsilon + |\psi(z_j)| \leq \epsilon + |P|/|\sigma(z_j)|$, so

$$|\widetilde{\psi}(z_j)||\sigma(z_j)| \leq |\sigma(z_j)|\epsilon + |P|,$$

and also

$$|\psi(z_j)| + |\widetilde{\psi}(z_j)| \leq \epsilon + 2|\psi(z_j)| \leq \epsilon + 2|P|/|\sigma(z_j)|.$$

Furthermore, $|\sigma(z_j) - \widetilde{\sigma}(z_j)| \leq \epsilon^*$, so $|\widetilde{\sigma}(z_j)| \leq \epsilon^* + |\sigma(z_j)|$, and

$$|\psi(z_j)\widetilde{\sigma}(z_j)| \leq \epsilon^*|\psi(z_j)| + |P| = \epsilon^*(|P|/|\sigma(z_j)|) + |P|.$$

Also,

$$(|\psi(z_j)| + |\widetilde{\psi}(z_j)|)|\sigma(z_j) - \widetilde{\sigma}(z_j)| \leq \epsilon^*(\epsilon + 2|P|/|\sigma(z_j)|).$$

Note that

$$\begin{aligned} P(z_j) - \widetilde{P}(z_j) &= \psi(z_j)\sigma(z_j) - \widetilde{\psi}(z_j)\widetilde{\sigma}(z_j) \\ &= (\psi(z_j) + \widetilde{\psi}(z_j))(\sigma(z_j) - \widetilde{\sigma}(z_j)) + \psi(z_j)\widetilde{\sigma}(z_j) - \widetilde{\psi}(z_j)\sigma(z_j). \end{aligned}$$

Hence

$$\begin{aligned} |P(z_j) - \widetilde{P}(z_j)| &= |\psi(z_j)\sigma(z_j) - \widetilde{\psi}(z_j)\widetilde{\sigma}(z_j)| \\ &\leq (|\psi(z_j)| + |\widetilde{\psi}(z_j)|)|\sigma(z_j) - \widetilde{\sigma}(z_j)| + |\psi(z_j)\widetilde{\sigma}(z_j)| + |\widetilde{\psi}(z_j)\sigma(z_j)| \\ &\leq \epsilon^*(\epsilon + 2|P|/|\sigma(z_j)|) + (\epsilon^*(|P|/|\sigma(z_j)|) + |P|) + (|\sigma(z_j)|\epsilon + |P|) \\ &= (\epsilon^* + |\sigma(z_j)|)\epsilon + (2 + 3\epsilon^*/|\sigma(z_j)|)|P|. \qquad \square \end{aligned}$$

To approximately compute each of the $\sigma(z_j)$, given z_j (and with fixed a_j) for $j = 0, \ldots, m-1$, we define a *unitary* Trummer's problem of size m where we specialize the y_j to 1 but keep the a_j fixed as before. Hence, since the a_j are fixed, the weights are fixed as $c_j = 1/\sigma^{(1)}(a_j)$, and so can be assumed to be precomputed. This corresponds to defining a constant polynomial $P^*(z) = 1 = \psi^*(z)\sigma(z)$; with this specialization, $\psi^*(z) = 1/\sigma(z)$. Next we can apply again Lemma 2.2 to construct an ϵ-approx solution: $\widetilde{\psi}^*(z_0), \ldots, \widetilde{\psi}^*(z_{m-1})$ of the unitary Trummer's problem. Then we define $\widetilde{\sigma}(z) = 1/\widetilde{\psi}^*(z)$, and use $\widetilde{\sigma}(z_j)$ as an approximation to $\sigma(z_j)$.

PROPOSITION 2.5. *For $j = 0, \ldots, n-1$, each*

$$\widetilde{\sigma}(z_j) = 1/\widetilde{\psi}^*(z_j)$$

is an ϵ^*-approx to $\sigma(z_j)$, where

$$\epsilon^* = \frac{\epsilon|\sigma(z_j)|^2}{1 - |\sigma(z_j)|\epsilon}.$$

Proof. The error is bounded as

$$|\widetilde{\sigma}(z_j) - \sigma(z_j)| = |\frac{1}{\widetilde{\psi}^*(z_j)} - \frac{1}{\psi^*(z_j)}| = |\frac{\widetilde{\psi}^*(z_j) - \psi^*(z_j)}{\psi^*(z_j)\widetilde{\psi}^*(z_j)}| = \frac{|\widetilde{\psi}^*(z_j) - \psi^*(z_j)|}{|\psi^*(z_j)\widetilde{\psi}^*(z_j)|}$$
$$\leq \frac{\epsilon}{|\psi^*(z_j)||\widetilde{\psi}^*(z_j)|} \leq \frac{\epsilon}{|\psi^*(z_j)|(|\psi^*(z_j)| - \epsilon)} = \epsilon^*$$

for

$$\epsilon^* = \frac{\epsilon|\sigma(z_j)|^2}{1 - |\sigma(z_j)|\epsilon},$$

since $\sigma(z) = 1/\psi^*(z)$, and

$$|\widetilde{\psi}^*(z_j)| \geq |\psi^*(z_j)| - \epsilon = \frac{1 - |\sigma(z_j)|\epsilon}{|\sigma(z_j)|}. \qquad \square$$

2.4. Approximate complex polynomial evaluation via DFT and multipole algorithms. Let $\omega = e^{i2\pi/n}$ be the nth root of unity $\in \mathcal{C}$. We assume the n roots of unity ω^j, for $j = 1, \ldots, n-1$ are precomputed. Let us specialize the points $a_0, \ldots, a_{n-1}$ to be the n roots of unity, so $a_j = \omega^j$ for $j = 0, \ldots, n-1$. Then it is known (e.g., see Aho, Hopcroft, Ullman [1]) that $\sigma(z) = \Pi_{j=0}^{n-1}(z - \omega^j) = z^n - 1$. In this case, each $\sigma(z_j) = z_j^n - 1$ can be exactly computed by repeated squaring with work only $O(\log n)$. Since $\sigma^{(1)}(z) = nz^{n-1}$ in this case, and $\omega^n = 1$, each

$$\sigma^{(1)}(a_j) = \sigma^{(1)}(\omega^j) = n\omega^{j(n-1)} = n/\omega^j = n\omega^{n-j}.$$

Thus each $\sigma^{(1)}(a_j)$ costs one multiplication to compute from the known (precomputed) root of unity ω^{n-j}. Also,

$$\max_j |\sigma(z_j)| \leq 1 + \max_j |z_j|^n.$$

Note that if all the re-evaluation points z_j, for $j = 0, \ldots, m-1$, are on or within the unit disk,

$$\max_j |{z_j}^n| \leq \max_j |z_j|^n \leq 1.$$

This implies that

$$\max_j |\sigma(z_j)| \leq 1 + \max_j |{z_j}^n| \leq 2,$$

so by Proposition 2.4 (where we fix $\epsilon^* = 0$ since the $\sigma(z_j)$ are exactly computed) we have the following lemma.

LEMMA 2.6. *Let the points $a_0, \ldots, a_{n-1}$ be the n roots of unity, and all the re-evaluation points z_j, $j = 0, \ldots, m-1$ be on or within the unit disk, so $|z_j \leq 1$, and let the z_j be distinct from the n roots of unity. We construct an ϵ-approx solution $\widetilde{\psi}(z_0), \ldots, \widetilde{\psi}(z_{m-1})$ of the resulting Trummer's problem. Then for $j = 0, \ldots, m-1$, each $P(z_j)$ is 2ϵ-approx by*

$$\widetilde{P}(z_j) = \widetilde{\psi}(z_j)\sigma(z_j).$$

Now we bound the work. Given as input the coefficients of a degree $n-1$ polynomial $P(z)$, we can exactly evaluate $P(z)$ at the n roots of unity by applying the DFT algorithm to the coefficients of $P(z)$ in work $O(n \log n)$. Now given m evaluation points $z_0, \ldots, z_{m-1}$ on or within the unit disk, and distinct from the n roots of unity, we apply the above reduction to Trummer's problem. Let $|P| = \sum_{j=0}^{n-1} |p_j|$. Since $\sigma^{(1)}(z) = \frac{d\sigma(z)}{dz} = nz^{n-1}$, it follows that $|\sigma^{(1)}(\omega^j)| = n$. Hence the coefficients $c_j = P(\omega^j)/\sigma^{(1)}(\omega^j)$ of Trummer's problem have magnitude

$$|c_j| = |P(\omega^j)|/n = |P|/n$$

and have summed magnitude

$$|C| = \sum_{j=0}^{n-1} |c_j| = |P|.$$

We compute all the $\sigma(a_j)$ by $O(n)$ multiplications (of n times each of the precomputed roots of unity). If the input evaluation points $z_0, \ldots, z_{m-1}$ are fixed, then we can assume a precomputed well-separated decomposition of the set containing all the n roots of unity and the set of m evaluation points. Also, when the input evaluation points are fixed, we can assume precomputed $\sigma(z_j)$, $j = 0, \ldots, m-1$.

By the efficient multipole algorithm of [30, 34] (Lemma 2.2) the resulting Trummer's problem of size m can be ϵ-approx on every output within work $O(m \log^2 k)$, where $k = O(\log(|C|/\epsilon)) = O(\log(|P|/\epsilon))$. Thus if $m \geq (n \log n)/\log^2 k$, then the total work for m fixed evaluation points is $O(m \log^2 k)$. By Proposition 2.4, for $j = 0, \ldots, m-1$, the $\widetilde{P}(z_j)$ are an $\widehat{\epsilon}$-approx to the $P(z_j)$, where

$$\widehat{\epsilon} = \epsilon \max_j |\sigma(z_j)| \leq 2\epsilon,$$

since $\max_j |\sigma(z_j)| \leq 2$. Thus the approximation errors are upper bounded by 2ϵ, and rescaling (to simplify notation) 2ϵ to ϵ, we have the following theorem.

THEOREM 2.7. *Suppose we are given a complex degree $n-1$ polynomial $P(z)$, m fixed evaluation points on or within the unit disk (with a precomputed well-separated decomposition), and a given $\epsilon > 0$. Let $k = O(\log(|P|/\epsilon))$. Then we can compute an ϵ-approx of this complex polynomial evaluation problem within work $O(m \log^2 k + n \log n)$. If $m \geq (n \log n)/\log^2 k$, the amortized work per evaluation point is bounded by $O(\log^2 k)$.*

Note. For practical implementation of approximate polynomial evaluation via Theorem 2.7, one may substitute a theoretically less efficient multipole algorithm in place of the efficient multipole algorithm of [30, 34] (Lemma 2.2), which costs $O(m \log^2 k)$ work. For example, the FFT-accelerated fast multipole algorithm of Greengard and Rokhlin [22], which requires $O(mk \log k)$ work, in theory gives an improvement over the bounds of $O(n \log^2 n)$ for exact algorithms if $k \leq o((\log^2 n)/\log \log n)$ and moreover is known to be very efficient in practice. This FFT-accelerated fast multipole algorithm was implemented by Elliott and Board [15] on a variety of high performance machines, gives the currently fastest running multipole algorithm implementation known in practice (as opposed to theory) on these machines, and is used in many molecular simulation applications. Another approach would be to do a careful implementation of the multipole algorithm of Reif and Tate [30, 34], which may provide improved performance in practice, over the FFT-accelerated fast multipole algorithm.

Further note. We can reduce the work bounds of Theorem 2.7 for the special case of m chirp evaluation points, a Trummer's problem for m chirp evaluation points can be ϵ-approx on every output within work $O(m \log k)$. Thus the work bounds given in Theorem 2.8 can in this case be reduced by replacing $\log^2 k$ by $\log k$.

The case where the m evaluation points are not fixed. For small $k = o(n)$, the most costly parts of the above approximate complex polynomial evaluation algorithm is the computation of the $\sigma(z_j)$ and the well-separated decomposition, both costing work $O(m \log m)$ in the worst case. We now describe how to reduce this cost by approximate computation of the $\sigma(z_j)$ and, in certain cases, more efficient computation of the well-separated decomposition.

Again, we will assume that the input evaluation points $z_0, \ldots, z_{m-1}$ are on or within the unit disk; however, we redefine $a_j = r\omega^j$ where ω is the nth root of unity. Let $r = (1 + \frac{1}{n})$ and note $r^n \approx e$. Recall (e.g., see Aho, Hopcroft, Ullman [1]) that $\Pi_{j=0}^{n-1}(z - \omega^j) = z^n - 1$. In this case we redefine

$$\sigma(z) = \prod_{j=0}^{n-1}(z - r\omega^j) = r^n \prod_{j=0}^{n-1}\left(\frac{z}{r} - \omega^j\right) = r^n\left(\left(\frac{z}{r}\right)^n - 1\right) = z^n - r^n.$$

Since $|z_j| \leq 1$, we have

$$|\sigma(z_j)| = |z_j^n - r^n| \leq |z_j|^n + r^n \leq 1 + r^n \approx 1 + e.$$

Also,

$$|\sigma(z_j)| = |z^n - r^n| \geq |r^n| - |z^n| \leq r^n - 1 \approx e - 1.$$

Since we again have

$$\sigma^{(1)}(z) = \frac{d\sigma(z)}{dz} = nz^{n-1}$$

in this specialized case, and since $|a_j| = 1$, each

$$\sigma^{(1)}(a_j) = \sigma^{(1)}(r\omega^j) = n(r\omega^j)^{n-1},$$

so

$$|\sigma^{(1)}(a_j)| = nr^{n-1} \approx ne/r.$$

1. *Approximate computation of the $\sigma(z_j)$ via the unitary Trummer's problem.* If the input evaluation points are not fixed, we might exactly compute all the $\sigma(z_j) = z_j^n - r^n$ by powering in $O(m \log n)$ work. Instead, we will approximately compute the $\sigma(z_j)$, $j = 0, \ldots, m-1$. To do this, as described above, define a unitary Trummer's problem of size m where we specialize the weights to be 1, so $\psi^*(z) = 1/\sigma(z)$. Since for each j, the $a_j = r\omega^j$ are fixed, we can assume the $\sigma^{(1)}(a_j) = n(r\omega^j)^{n-1}$ are precomputed, thus providing the weights $c_j = 1/\sigma^{(1)}(a_j)$. Applying Lemma 2.2 again, the resulting unitary Trummer's problem of size n is ϵ-approx on every output $\widetilde{\sigma}(z_j)$, so $|\sigma(z_j) - \widetilde{\sigma}(z_j)| \leq \epsilon$, with the same work $O(m \log^2 k)$. We assume $\epsilon \leq 1/4$. By Proposition 2.5, each $\widetilde{\sigma}(z) = 1/\widetilde{\psi}^*(z_j)$ is an ϵ^*-approx to $\sigma(z_j)$, where

$$\epsilon^* = \max_j \frac{\epsilon|\sigma(z_j)|^2}{1 - |\sigma(z_j)|\epsilon} \leq \frac{\epsilon(1+e)^2}{1-(1+e)\epsilon} \leq O(\epsilon),$$

since we have shown $\max_j |\sigma(z_j)| \leq 1 + e$ and we have assumed $\epsilon \leq 1/4$. By Proposition 2.4, for $j = 0, \ldots, m-1$, each $\widetilde{P}(z_j)$ are an $\widehat{\epsilon}$-approx to $P(z_j)$, where

$$\widehat{\epsilon} \leq (\epsilon^* + \max_j |\sigma(z_j)|)\epsilon + (2 + (3\epsilon^*)/\min_j |\sigma(z_j)|)|P| \leq O(\epsilon|P|).$$

2. *Computation of the well-separated decomposition.* We can compute a well-separated decomposition of the set union of the $m \geq n$ evaluation points and the $a_j = r\omega^j$, $j = 0, \ldots, n-1$ within work $O((n+m)\log(n+m)) \leq O(m \log m)$ by the algorithm of Callahan and Kosaraju [6]. Alternatively, if the points have logarithmic bit-precision, then the algorithm of [30, 34] computes, within work $O((n+m)\log\log(n+m)) \leq O(m \log\log m)$, a well-separated decomposition the set of m evaluation points. Furthermore, since the $a_j = r\omega^j$, $j = 0, \ldots, n-1$ are regularly spaced on the radius r circle, a simple modification of the well-separated decomposition algorithm of [30, 33] can be used to compute a well-separated decomposition of the set union of n roots of unity and the set of m evaluation points, within work $O(m \log\log m)$.

In either case, we proceed as follows. We apply the above construction, for re-evaluation via Trummer's problem, to $P(z)$. Since $|\sigma^{(1)}(r\omega^j)| \approx ne/r$, the coefficients $c_j = P(\omega^j)/\sigma^{(1)}(\omega^j)$ of the Trummer's problem have summed magnitude $|C| \approx |P|r/e \leq O(|P|)$, so we may let

$$k = O(\log(|C|/\epsilon)) = O(\log(|P|/\epsilon)).$$

Again the resulting Trummer's problem of size m can be ϵ'-approx on every output using the efficient multipole algorithm of [30, 34] (Lemma 2.2) within work $O(m \log^2 k)$. For $j = 0, \ldots, m-1$, let

$$\widetilde{P}(z_j) = \widetilde{\psi}(z_j)\widetilde{\sigma}(z_j)$$

be the resulting approximation of $P(z_j)$. In either case, the error of approximation of $P(z_j)$ by $\widetilde{P}(z_j)$ is bounded as $|\widetilde{P}(z_j) - P(z_j)| \leq \widehat{\epsilon}$. Thus, by rescaling (to simplify notation) the total error $O(\widehat{\epsilon})$ to ϵ, we have the following theorem.

THEOREM 2.8. *Suppose we are given a complex degree $n-1$ polynomial $P(z)$, m evaluation points (which are not fixed) on or within the unit disk, and a given $\epsilon, 0 < \epsilon < 1/4$. Let $k = O(\log(|P|/\epsilon))$. Then we can compute an ϵ-approx of this complex*

polynomial evaluation problem within work $O(m(\log m + \log^2 k) + n \log n)$. *Thus, if* $m \geq (n \log n)/(\log m + \log^2 k)$, *then we require amortized work* $O(\log m + \log^2 k)$ *per evaluation point.*

Note. If the m evaluation points have logarithmic bit-precision, then the complexity bounds of Theorem 2.8 can be improved by application of the well-separated decomposition algorithm of [30, 33]; in this case each appearance of $\log m$ in Theorem 2.8 can be replaced with $\log \log m$.

Further note. In the special case that the m evaluation points are chirp points, a Trummer's problem for m chirp evaluation points can be ϵ-approx on every output within work $O(m \log k)$. Thus the work bounds given in Theorem 2.8 can in this case be reduced by replacing $\log^2 k$ by $\log k$.

3. Chebyshev points and approximate real polynomial evaluation.

3.1. The Chebyshev point evaluation problem. Let $\omega = e^{i2\pi/n'}$ be the n'th root of unity over the complex numbers $\mathcal{C}$. Note that

$$\omega^j = \cos(j2\pi/n') + i\sin(j2\pi/n').$$

Let $m \leq n'$. The (n', m)-*Chebyshev points* are the set of m real parts $x_j = \cos(j2\pi/n')$ of the powers ω^j, for $j = 0, 1, \ldots, m-1$. (This is slightly nonstandard notation, but convenient for our purposes.) Given real constants s_0, s_1 the *shifted* (n', m)-*Chebyshev points* are real values

$$x'_j = s_0 + s_1 \cos(j2\pi/n').$$

The *(shifted)* (n', m)-*Chebyshev point evaluation problem* is the multipoint real evaluation problem of evaluating a polynomial of degree $n-1$ at the set of m (shifted, respectively) (n', m)-Chebyshev points. The *(shifted)* (n', n)-*Chebyshev point interpolation problem* is the multipoint real interpolation problem of interpolating a polynomial of degree $n-1$ from the set of n (shifted, respectively) (n', n)-Chebyshev points.

Pan [29] has given an $O(n \log^2 n)$ algorithm for the $(4n, n)$-Chebyshev point evaluation problem and the shifted version of this problem. The results of Gerasoulis [18] imply an $O(n \log n)$ algorithm for (n', n)-Chebyshev point evaluation, for $n' = O(n)$, which uses a reduction to Trummer's problem for Chebyshev points. In the appendix we give an alternative algorithm (using a recursive algorithm and a reduction to the DFT and by application of Proposition 1.1) for (n', n)-Chebyshev point evaluation (and also interpolation) with these same work bounds but yielding a simpler algorithm.

LEMMA 3.1. *For* $n' \leq O(n)$, *the* (n', m)-*Chebyshev point evaluation problem can be solved in work* $O((n+m) \log \min(n, m))$, *and the* (n', n)-*Chebyshev point interpolation problem can be solved in work* $O(n \log n)$. *(The circuit depth is* $O(\log n)$.*) Also, the shifted version of these problems can be solved within the same work bounds.*

3.2. Approximate real evaluation via interpolation at the Chebyshev points. Interpolation at the Chebyshev points is a well-known classical method for approximation of real functions (see, for example, Dahlquist and Björck [10] and Henry [24]). Fix an interval $I = [L, U]$ of the real line of length $|I| = U - L$. Let $f(x)$ be any real function over I. We say $\widetilde{f}(x)$ is an ϵ-approx of $f(x)$ over I if $|f(x) - \widetilde{f}(x)| \leq \epsilon$ for any $x \in I$. Fix $\widetilde{f}(x)$ to be the degree k polynomial derived by interpolating $f(x)$ at the shifted $(2k, k)$-Chebyshev points $x'_j = \frac{U+L}{2} + \frac{U-L}{2}\cos(\frac{j\pi}{k})$, for $j = 0, \ldots, k-1$,

which are on the interval $I = [L, U]$. Thus $\widetilde{f}(x)$ is the unique degree k polynomial such that $\widetilde{f}(x'_j) = f(x'_j)$ for $j = 0, \ldots, k-1$. Let

$$f^{(k)}(x) = \frac{d^k f(x)}{d^k x}$$

be the kth derivative of $f(x)$ with respect to x.

PROPOSITION 3.2 (see Dahlquist and Björck [10]). *For any $x \in I$, $\widetilde{f}(x)$ is an ϵ-approx of $f(x)$, for*

$$\epsilon = \frac{2(|I|/4)^k}{k!} \max_{y \in I} |f^{(k)}(y)|.$$

3.3. Approximate real polynomial evaluation via interpolation at the Chebyshev points. Rokhlin [35] applied Proposition 3.2 for a fast algorithm for the discrete Laplace transformation. Fix $P(x)$ to be a real polynomial of degree $n-1$. As observed in Pan, Reif, and Tate [30], direct application of the well-known Proposition 3.2 immediately gives an ϵ-approx to the real multipoint evaluation problem for $P(x)$ at any given m real points $x_0, \ldots, x_{m-1}$. By Lemma 3.1, the shifted $(2k, k)$-Chebyshev point evaluation problem for $P(x)$ can be solved within work $O(n \log k)$. Known exact algorithms [16, 26, 5] for k-point polynomial interpolation require work $O(k \log^2 k)$. By Proposition 1.2, the multipoint polynomial evaluation problem for $\widetilde{P}(x)$ at the real points $x_0, \ldots, x_{m-1} \in I$ can be solved within work $O(m \log^2 k)$. Thus an ϵ-approx of the multipoint polynomial evaluation problem for $P(x)$ at any m real points $\in I$ can be solved within work $O(m \log^2 k)$, where $\epsilon = \frac{2(|I|/4)^k}{k!} \max_{y \in I} |P^{(k)}(y)|$. Let $\beta = \log(|P|/\epsilon)$, where $|P|$ is the sum of the moduli of the coefficients of P. Assuming without loss of generality (w.l.o.g.) $k = o(n)$, note that if we fix $I = [-1, 1]$ we have that

$$\max_{y \in I} |P^{(k)}(y)| \leq \max_{y \in I} \max_{k \leq j < n} \frac{j!}{(j-k)!} y^{-(j-k)} |P| \leq \max_{k \leq j < n} \frac{j!}{(j-k)!} 2^{-(j-k)} |P|,$$

which is maximized when $j = k$, so

$$\max_{y \in I} |P^{(k)}(y)| \leq \frac{j!}{(j-k)!} 2^{-(j-k)} |P| \leq k! |P|.$$

Setting the degree of $\widetilde{P}$ to be $k-1$, where $k = \log(|P|/\epsilon)$, we have that

$$\epsilon \leq \frac{2(|I|/4)^k}{k!} \max_{y \in I} |P^{(k)}(y)| \leq |P|/2^{k-1},$$

implying, by Proposition 3.2, the following known result.

LEMMA 3.3 (see Pan, Reif, and Tate [30] and also Bini and Pan [3]). *An ϵ-approx of the multipoint polynomial evaluation problem for a degree $n-1$ polynomial $P(x)$ at any $m \geq n$ real points $\in [-1, 1]$ can be solved within work $O(m \log^2 \min(n, k))$, where $k = \log(|P|/\epsilon)$.*

So far we have assumed that $P(x)$ has only real coefficients. Note that if $P(x)$ has complex coefficients, then we can let $P(x) = P_0(x) + iP_1(x)$ where $P_0(x), P_1(x)$ have only real coefficients. Then application of Lemma 3.3 for each of the $P_0(x), P_1(x)$

implies that for $k = \log(|P|/\epsilon)$, the resulting error of approximation for evaluation of $P(x)$ is a $\sqrt{2}$ factor more, that is, $\sqrt{2}\epsilon$. Hence rescaling (to simplify notation) the error $\sqrt{2}\epsilon$ to ϵ, we have the following lemma.

LEMMA 3.4. *An ϵ-approx of the multipoint polynomial evaluation problem for a degree $n-1$ polynomial $P(x)$ with complex coefficients at any $m \geq n$ real points $\in [-1,1]$ is solved in work*

$$\leq O(m \log^2 \min(n, \log(|P|/\epsilon))).$$

By Lemma 3.1, the (n', m)-Chebyshev point evaluation problem for the degree $k-1$ polynomial $\widetilde{P}(x)$ at shifted (n', m)-Chebyshev points can be solved within work $O(m \log k)$. All Chebyshev points are within the interval $I = [-1, 1]$. Setting $k = \log(|P|/\epsilon)$, we have again that $\epsilon \leq |P|/2^{k-1}$ implying the improved result.

LEMMA 3.5. *An ϵ-approx of the (n', m)-Chebyshev point evaluation problem for a degree $n-1$ polynomial $P(x)$ is solved in work*

$$O((m+n) \log \min(n, \log(|P|/\epsilon))).$$

(The parallel time is $O(\log \min(n, \log(|P|/\epsilon)))$.)

4. Approximate evaluation on a circle.

4.1. Approximate polynomial evaluation on a circle via interpolation at the Chebyshev angles. We further reduce our amortized work bounds for special sets of evaluation points. By reduction to approximate evaluation of Trummer's problem via the Multipole algorithm, we have already shown how to ϵ-approx complex degree $n-1$ polynomial evaluation at $m \geq n \log n$ chirp points $\zeta^j, j = 0, \ldots, m-1$, for some fixed complex number ζ, $|\zeta| \leq 1$ in amortized work $O(\log k)$ per point. Using quite distinct techniques, we give in this section a reduction from ϵ-approx complex degree $n-1$ polynomial evaluation at $m \geq n$ points on a circle of radius r to approximate real polynomial evaluation, again in amortized work $O(\log^2 k)$ per point. Let $i = \sqrt{-1}$. Fix a complex polynomial $P(z) = \sum_{j=0}^{n-1} p_j z^j$ of degree $n-1$ and let

$$|P| = \sum_{j=0}^{n-1} |p_j|.$$

Let $\epsilon > 0$ be a given error bound. Let $z = re^{i\theta}$ range on a circle of radius r, and define the angle of z to be $\theta(z) = \theta$. We now consider the evaluation of $P(z)$ at a set of points $z_j = re^{i\theta_j}$ for $j = 1, \ldots, m$ over an interval of a circle of radius r with angular bounds $\theta_j \in [0, \Delta]$, for a positive real $\Delta \leq 2\pi$. The set of points $re^{i\theta_j}$, for $j = 0, \ldots, m-1$, are *regularly spaced* on the circle of radius r if the θ_j are a linear function of j (for example, the n roots of unity are regularly spaced on the unit circle). The polynomial $P(z)$ is (k, t)-*descending* if the magnitude of the coefficients drops as

$$|p_j| \leq n^{O(1)} |P| \left(\frac{t}{j}\right)^k,$$

for $j = k, \ldots, n-1$. Here we prove the following.

THEOREM 4.1. *Suppose we are given a complex polynomial $P(z) = \sum_{j=0}^{n-1} p_j z^j$ of degree $n-1$, and a fixed set of evaluation points $z_j = re^{i\theta_j}$ for $j = 0, \ldots, m-1$ on a circle of radius r with angular range $\theta_j \in [0, \Delta]$. Let $c = 1$ if the evaluation points are*

regularly spaced and otherwise $c = 2$. *Then an* ϵ*-approx of this multipoint polynomial evaluation problem can be computed within work* $O(m \log^c k)$ *if either* 1. $r = 1$ *and* $\Delta \leq \frac{k}{e(n-1)}$, *or* 2. $r = 1$ *and* $P(z)$ *is* $(k, k/(e\pi))$*-descending, or* 3. $r \leq 1/(e\pi)$. *Here* $k = \frac{1}{2}\log(|P|/\epsilon) + O(1)$ *in cases* 1 *and* 3 *and* $k = O(\log(n|P|/\epsilon))$ *in case* 2.

Proof. Restrict z to the upper half circle of radius r, so $z = re^{i\theta}$, where $i = \sqrt{-1}$, and $0 \leq \theta \leq \pi$. Let $Q(\theta) = P(re^{i\theta}) = \sum_{j=0}^{n-1} q_j e^{ij\theta}$, where $q_j = r^j p_j$, and $P(z) = \sum_{j=0}^{n-1} p_j z^j$. Fix a number k which divides n, to be determined below. The exact evaluation of $P(z)$ at the evaluation points z_j, for $j = 0, \ldots, m-1$, can be done by an exact evaluation of $Q(\theta)$ at the real points $\theta_0, \ldots, \theta_{m-1}$, where $z_j = re^{i\theta_j}$. Instead, we will do an ϵ-approximate evaluation of $P(z)$ at the evaluation points $z_0, \ldots, z_{m-1}$, as follows. We can assume w.l.o.g. that each $0 \leq \theta_j \leq \pi$. Since $P(-z) = \sum_{j=0}^{n-1} p_j(-z)^j = \sum_{j=0}^{n-1} p'_j z^j$, where $p'_j = -p_j$ if j is odd, and else $p'_j = p_j$, the case where the evaluation points $z_j = re^{i\theta_j}$ are on the lower half circle can be reduced to this case by multiplication of the z_j by $e^{i\pi} = -1$, and switching the sign of the coefficients p_j of $P(z)$ where j is odd. We construct a degree $k-1$ polynomial $\widetilde{Q}(\theta)$ which gives an ϵ-approx of polynomial $Q(\theta)$. To construct $\widetilde{Q}(\theta)$, we do an exact evaluation of $Q(\theta)$ at the shifted $(2k, k)$-Chebyshev points $\theta'_j = \pi\cos(j\pi/k)$ for $j = 0, \ldots, k-1$ over the real interval $I = [0, \Delta]$, for a given $\Delta, 0 < \Delta \leq 2\pi$. To do this first step, we can exactly evaluate $P(z)$ at $re^{i\theta'_j}$ for $j = 0, \ldots, k-1$, which in general costs work $O(n \log^2 k)$ by Proposition 1.1; or if the evaluation points are regularly spaced, then by Proposition 1.4 this costs $O(n \log k)$. We could now exactly interpolate a degree $k-1$ polynomial $\widetilde{Q}(\theta)$ from $Q(\theta'_j) = P(re^{i\theta'_j})$, for $j = 0, \ldots, k-1$, which are the values of $Q(\theta)$ at these shifted $(2k, k)$-Chebyshev points $\theta'_0, \theta'_1, \ldots, \theta'_{k-1}$. By the known algorithms of [16, 26, 5], the exact interpolation of polynomial $\widetilde{Q}(\theta)$ at these k points cost work $O(k \log^2 k)$. Also, by known algorithms (see Proposition 1.2), we can exactly evaluate $\widetilde{Q}(\theta_j)$ for $j = 0, \ldots, m-1$, in work $O(m \log^2 k)$, and if these evaluation points are regularly spaced, then this costs work $O(m \log k)$ by the chirp transform (Proposition 1.4).

LEMMA 4.2. *For* $k = o(n)$, *and* $0 \leq \theta \leq \Delta$, *then*

$$|Q^{(k)}(\theta)| = \left|\frac{d^k Q(\theta)}{d^k \theta}\right|$$

is bounded by $O(k!|P|\Delta^{-k})$ *if either* 1. $r = 1$ *and* $\Delta \leq \frac{k}{e(n-1)} \leq \pi$, *or* $\Delta = \pi$ *and either* 2. $r = 1$ *and* $P(z)$ *is* $(k, k/(e\pi))$*-descending, or* 3. $r \leq 1/(e\pi)$.

Proof.

$$\frac{d^k e^{ij\theta}}{d^k \theta} = \frac{j!}{(j-k)!}(ij)^k e^{ij\theta},$$

so

$$Q^{(k)}(\theta) = \frac{d^k Q(\theta)}{d^k \theta} = \sum_{j=k}^{n-1} q_j \frac{j!}{(j-k)!}(ij)^k e^{ij\theta}.$$

Since $|i| = |e^i| = 1$, and $|q_j| = |p_j| r^j$, we have

$$|Q^{(k)}(\theta)| = \sum_{j=k}^{n-1} |q_j| j^k = \sum_{j=k}^{n-1} |p_j| r^j j^k.$$

1. Now suppose $r = 1$ and $\Delta \leq \frac{k}{e(n-1)}$. Then by the Stirling approximation to factorial, $k! \geq (k/e)^k$ and so

$$j^k \leq (k/e)^k \Delta^{-k} \leq k! \Delta^{-k}.$$

Hence we have

$$|Q^{(k)}(\theta)| \leq \sum_{j=k}^{n-1} |p_j| j^k \leq O(|P| k! \Delta^{-k}).$$

2. Next, suppose $r = 1$, and $\Delta = \pi$, and $P(z)$ is $(k, k/(e\pi))$-descending; so by definition, the magnitude of the coefficients of $P(z)$ drops as

$$|p_j| \leq n^{O(1)} |P| (\frac{k}{je\pi})^k,$$

for $j = k, \ldots, n-1$. Then

$$|p_j| r^j j^k \leq n^{O(1)} |P| (k/(e\pi))^k \leq O(n^{O(1)} |P| k! \Delta^{-k}).$$

Thus,

$$|Q^{(k)}(\theta)| \leq \sum_{j=k}^{n-1} |p_j| r^j j^k \leq \sum_{j=k}^{n-1} O(n^{O(1)} |P| k! \Delta^{-k}) \leq O(n^{O(1)} |P| k! \Delta^{-k}).$$

3. Finally, suppose $r \leq 1/(e\pi)$ and $\Delta = \pi$. Since $|Q^{(k)}(\theta)|$ increases with r, to upper bound $|Q^{(k)}(\theta)|$ we can assume w.l.o.g. that r is at its maximum value $r = 1/(e\pi)$. By taking derivatives, it is easy to verify that $1/(e\pi) \leq (se\pi)^{-1/s}$ for any $s \geq 1$. So

$$1/(e\pi) = \min_{s \geq 1} (se\pi)^{-1/s} = \min_{j \leq k} \left(\frac{k}{je\pi} \right)^{k/j}$$

(by the substitution $j = sk$). Hence for each $r \leq 1/(e\pi)$, we can bound $r^j \leq (\frac{k}{je\pi})^k$ and so for all $j \geq k$ we have

$$r^j j^k \leq (k/(e\pi))^k \leq k! \Delta^{-k},$$

since $\Delta = \pi$ and $k! \geq (k/e)^k$. Thus,

$$|Q^{(k)}(\theta)| \leq \sum_{j=k}^{n-1} |p_j| r^j j^k \leq \sum_{j=k}^{n-1} |p_j| k! \Delta^{-k} \leq O(|P| k! \Delta^{-k}). \qquad \square$$

To complete the proof of Theorem 4.1, we need to bound the approximation errors for evaluation of $\widetilde{Q}(\theta)$ at all the given evaluation points; this is implied by the following proof of ϵ-approximate evaluation of $P(z)$. Since $|I| = \Delta$, then by Lemma 4.2 and Proposition 3.2 the error in the approximation of $P(z) = Q(\theta)$ by $\widetilde{Q}(\theta)$, for $\theta \in I = [0, \Delta]$ is upper bounded by

$$\frac{2}{k!} (|I|/4)^k \max_{\theta \in I} |Q^{(k)}(\theta)| \leq O(|P| (\Delta/4)^k \Delta^{-k}) \leq O(|P| 4^{-k})$$

in cases 1 and 3, and in case 2, the error is upper bounded by $O(n^{O(1)}|P|4^{-k})$. Hence the error is upper bounded by $O(\epsilon)$ if in cases 1 and 3 we set $k = \frac{1}{2}\log(|P|/\epsilon) + O(1)$ and in case 2 we set $k = O(\log(n|P|/\epsilon))$. Finally, note that the (empty) restriction $0 \le \theta \le \pi = \Delta$ in cases 2 and 3 allows z to range over any point on the upper half circle of fixed radius r, so we have the following lemma.

LEMMA 4.3. *$\widetilde{Q}(\theta)$ is an ϵ-approx of $P(z)$ at any point $z = re^{i\theta}$ on the upper half circle of fixed radius r, where $0 \le \theta \le \Delta$, if either* 1. *$r = 1$ and $\Delta \le \frac{k}{e(n-1)} \le \pi$, or* 2. *$r = 1$ and $P(z)$ is $(k, k/(e\pi))$-descending, or* 3. *$r \le 1/(e\pi)$.*

Thus, we have proven Theorem 4.1. □

Cases 1 and 2 of Theorem 4.1 imply the following corollary.

COROLLARY 4.4. *In total work $O(n \log k)$ we can*

1. *ϵ-approx the evaluation of a degree n polynomial at the first n powers of the n'th root of unity, where $n' \ge \Omega(n^2/k)$, and*
2. *ϵ-approx the n-point DFT in total work $O(n \log k)$ for inputs with $(k, k/(e\pi))$-descending coefficient magnitude.*

Note. If the input set of evaluation points are not fixed, the result as given in Theorem 4.1 holds with the same work bounds, assuming an *extended arithmetic model* where, given a real θ, then $e^{i\theta} = \cos(\theta) + i\sin(\theta)$ can be computed in $O(1)$ steps. This assumption is not required if the points are fixed, as assumed in Theorem 4.1, or regularly spaced (as in Corollary 4.4). Also this assumption is not required in the alternative construction given in subsection 4.2, even if the input set of evaluation points are not fixed.

4.2. An alternative approach to approximate evaluation on a circle via approximate real polynomial evaluation. We now give an alternative construction for a similar, but slightly weaker, result as Theorem 4.1, by use of a surprisingly simple algorithm (the proof is somewhat more involved, however), which uses complex polynomials rather than real polynomials.

Input: The coefficients of degree $n-1$ complex polynomial $P(z)$, and $m \ge n$ evaluation points $z_j = re^{i\theta_j}$, for $j = 0, \ldots, m-1$ on an interval of a circle of radius $r = 1$ with $|\cos(\theta_j)| \le \Delta$. We assume either 1. $\Delta \le \frac{k}{e(n-k)}$, or 2. $P(z)$ is $(k, \sqrt{2}/8)$-descending. In case 1. let k be the smallest power of 2 which is $\ge \log(\sqrt{2}|P|/\epsilon)$, and in case 2. let k be the smallest power of 2 which is $O(\log(n|P|/\epsilon))$. In any case we assume $k = o(n)$.

[0] Partition the set of evaluation points $\{z_j | j = 1, \ldots, m-1\}$ into 4 sets

$$\{z_{j,h} | j = 0, \ldots, m_h - 1\}, \qquad h = 0, \ldots, 3,$$

such that $|i^h\theta_{j,h} - \pi/2| \le \pi/4$ for each $j = 0, \ldots, m_h$.

Comment: Multiplication by $i = e^{i\pi/2}$ shifts the angle by $\pi/2$.

For $h = 0, \ldots, 3$ **do**

1. Define polynomial $P_h(z) = P(i^h z)$. Evaluate $P_h(z)$ at

$$z'_j = r(x'_j + i\sqrt{1 - (x'_j)^2}),$$

where

$$x'_j = \cos(j\pi/k)/\sqrt{2},$$

for $j = 0, \ldots, k-1$, in work $O(n \log^2 k)$ (by Proposition 1.1).

2. Interpolate the degree $k-1$ complex polynomial $\widetilde{P}_h(z)$ from the values $P_h(z'_j)$, for $j = 0, \ldots, k-1$, in work $O(k \log^2 k)$.

3. Evaluate polynomial $\widetilde{P}_h(z)$ at the given evaluation points $z_{j,h}$ for $j = 0, \ldots, m_h - 1$. If these evaluation points are regularly spaced, then this costs work $O(m_h \log k)$ by the chirp transform (Proposition 1.4) and otherwise costs work $O(m_h \log^2 k)$ by Proposition 1.1. This gives $\widetilde{P}_h(z_j)$ which ϵ-approx $P_h(z_j)$, for $j = 0, \ldots, m_h - 1$.

Output: $\widetilde{P}(z_j)$ which ϵ-approx $P(z_j)$, for $j = 0, \ldots, m-1$.

We prove the following in Appendix A.

THEOREM 4.5. *$\widetilde{P}(z)$ is an ϵ-approx of $P(z)$ at any point $z = r(x+iy)$ on the unit circle of fixed radius $r = 1$ where $|\theta(z) - \pi/2| \leq \pi/4$ and $|x| \leq \Delta$ if either* 1. $\Delta \leq \frac{k}{e(n-k)}$ *or* 2. *$P(z)$ is $(k, \sqrt{2}/8)$-descending.*

The work is again $O(n \log^2 k) + O(m \log^c k) \leq O(n \log^2 k + m \log^c k)$. Also, the circuit depth can be seen to be $O(\log^c k)$ with this same work bound.

4.3. Dutt and Rokhlin's approximation of a polynomial on the unit circle. A further method for approximation of a polynomial over an interval of the unit circle is proposed by Dutt and Rokhlin [14], who give an approximation to a polynomial $P(z)$, as follows. Fix a real constant α, $0 < \alpha < \pi/3$. They define a mapping τ from complex numbers $z = e^{i\theta}$ on the unit circle to real $x = \tau(z) = 3 \tan\alpha \cot(\theta/2)$ and use this mapping to define the real function $f(x) = P(z)$. They use a degree $k-1$ polynomial $\widetilde{f}(x)$ to approximate $P(z)$ at angular positions θ, $6\alpha \leq \theta \leq 2\pi - 6\alpha$. The polynomial $\widetilde{f}(x)$ interpolates $f(x)$ at the shifted $(2k, k)$-Chebyshev points $a_j = -\cos((j - 1/2)\pi/k)$ and is defined, for $|x| \leq 1$, as $\widetilde{f}(x) = \sum_{j=1}^{k-1} f(a_j) \prod_{\ell \neq j} (\frac{x - a_\ell}{a_j - a_\ell})$. Note that $\widetilde{f}(a_j) = f(a_j)$ for $j = 1, \ldots, k-1$. Dutt and Rokhlin [14] prove that $\widetilde{f}(x)$ approximates $f_h(x) = P(z)$, with relative error $O(1/5^k)$ over some portion of this interval. Our Theorem 5.1 implies that the length of the interval where these error bounds can be obtained must be very small.

5. Approximation everywhere on the unit circle is not possible. Here we show that it is not possible to approximate an arbitrary polynomial by a small degree polynomial over a large portion of the unit circle. Fix an angular interval $[0, \Delta]$ for $0 \leq \Delta \leq 2\pi$ and an error ϵ, $0 \leq \epsilon < 1$. Let us define an (k, Δ) *circle ϵ-approx evaluation scheme* for a degree $n-1$ polynomial $P(z)$ to be a degree $k-1$ polynomial $\widetilde{f}(x)$ which ϵ-approx $P(z) = f(x)$ at all angular positions $\theta \in [0, \Delta]$, where τ is a mapping from complex numbers $z = e^{i\theta}$ on the interval of the unit circle, $\theta \in [0, \Delta]$ to real $x = \tau(z)$. We now prove that any (k, Δ) circle ϵ-approx evaluation scheme in general only can be convergent for angular positions $\theta \in [0, \Delta]$, where $\Delta \leq O(k/n)$.

THEOREM 5.1. *There is no (k, Δ) circle ϵ-approx evaluation scheme for every degree $n-1$ polynomial $P(z)$, where $k\lceil 2\pi/\Delta \rceil < n$ and $\epsilon(\epsilon + 2|P|) < 1$.*

Proof. Let $H = \lceil 2\pi/\Delta \rceil$. We can use the (k, Δ) circle ϵ-approx evaluation scheme to define for each $h, 0 \leq h < H$ a degree $k-1$ polynomial $f_h(x)$ that ϵ-approx $P(z)$ for $x = \tau(z\omega^{-2\pi h/H})$. For a complex number z, define $h(z)$ to be the integer h such that $2\pi h/H \leq |\text{angle}(z)| < 2\pi(h+1)/H$.

PROPOSITION 5.2. *Given a complex degree $n-1$ polynomial $P(z)$, and a (k, Δ) circle ϵ-approx evaluation scheme, we can construct $H = \lceil 2\pi/\Delta \rceil$ polynomials $(f_0(x), \ldots, f_{H-1}(x))$=POLY-APPROX$_k(P)$, each of degree $k-1$, such that for any z on the unit circle, $f_h(x)$ is an ϵ-approx of $P(z)$, for $h = h(z)$ and $x = \tau(z\omega^{-2\pi h/H})$.*

Polynomial Convolution is defined as follows:

Input: Complex coefficients $p_0, \ldots, p_{n-1}, q_0, \ldots, q_{n-1}$, defining degree $n-1$ polyno-

mials $P(z) = \sum_{j=0}^{n-1} p_j x^j$ and $Q(z) = \sum_{j=0}^{n-1} q_j x^j$.
Output: Complex coefficients $q_0, \ldots, q_{2n-2}$, defining degree $2n-2$ product polynomial $R(z) = P(z)Q(z) = \sum_{\ell=0}^{2n-2} r_\ell x^\ell$, where

$$r_\ell = \sum_{j=0, 0 \le \ell - j < n}^{n-1} p_j q_{\ell - j}.$$

Next we show the following.

LEMMA 5.3. *Suppose there is a (k, Δ) circle ϵ-approx evaluation scheme. Then, given complex n-vectors $\mathbf{u}$, $\mathbf{v}$, we can construct vectors $\widetilde{\mathbf{u}} = ROW\text{-}COMPRESS_{\,k}(\mathbf{u})$, $\widetilde{\mathbf{v}}^T = COLUMN\text{-}COMPRESS_k(\mathbf{v}^T)$ of size $O(k)$ (where $\widetilde{\mathbf{u}}$ depends only on $\mathbf{u}$ and not on $\mathbf{v}$, and furthermore $\widetilde{\mathbf{v}}$ depends only on $\mathbf{v}$ and not on $\mathbf{u}$) such that $\widetilde{\mathbf{u}}^T \widetilde{\mathbf{v}}$ is an ϵ_1-approx of $\mathbf{u}^T\mathbf{v}$ for $\epsilon_1 \le \epsilon(\epsilon + |\mathbf{u}| + |\mathbf{v}|)$.*

Proof. Given complex n-vectors $\mathbf{u} = (u_0, \ldots, u_{n-1})^T$, $\mathbf{v} = (v_0, \ldots, v_{n-1})^T$, we can compute the inner product

$$\mathbf{u}^T\mathbf{v} = \sum_{j=0}^{n-1} u_j v_j$$

by computing the nth coefficient

$$r_n = \sum_{j=0}^{n-1} p_j q_{n-j} = \sum_{j=0}^{n-1} u_j v_j = \mathbf{u}^T\mathbf{v}$$

of the product polynomial $R(z) = P(z)Q(z)$ as defined above and where $p_j = u_j$ and $q_j = v_{n-j}$, for $j = 0, \ldots, n-1$. Let $\omega = e^{i\pi/n}$ be the $(2n)$th root of unity, where $i = \sqrt{-1}$. By the convolution theorem, $\mathbf{u}^T\mathbf{v} = r_n = \frac{1}{2n} \sum_{j=0}^{2n-1} \omega^{-nj} P(\omega^j) Q(\omega^j)$. For each of $P(z), Q(z)$ defined above, by Proposition 5.2 we can construct $H = \lceil 2\pi/\Delta \rceil$ degree $k-1$ polynomials $(f_0(x), \ldots, f_{H-1}(x)) =$ POLY-APPROX$_k(P)$, and $(g_0(x), \ldots, g_{H-1}(x)) =$ POLY-APPROX$_k(Q)$, such that for any z on the unit circle, $\widetilde{P}_h(z) = f_h(x)$ is an ϵ-approx of $P(z)$, and $\widetilde{Q}_h(z) = g_h(x)$ is an ϵ-approx of $Q(z)$, for $h = h(z)$ and $x = \tau(z\omega^{-2\pi h/H})$. For $h = 0, \ldots, H-1$ let $f_h(x) = \sum_{a=0}^{k-1} f_{h,a} x^a$ and $g_h(x) = \sum_{b=0}^{k-1} g_{h,b} x^b$. Let $\delta = n/H$. For each integer $j, 0 \le j < 2n$, let h_j be the number $h \in \{0, \ldots, H-1\}$ such that $\delta h \le j < \delta(h+1)$. Then we have that $\widetilde{P}_{h_j}(\omega^j)$ is an ϵ-approx of $P(\omega^j)$, and $\widetilde{Q}_{h_j}(\omega^j)$ is an ϵ-approx of $Q(\omega^j)$. We will approximate $r_n = \frac{1}{2n} \sum_{j=0}^{2n-1} \omega^{-nj} P(\omega^j) Q(\omega^j)$ by $\widetilde{r}_n = \frac{1}{2n} \sum_{j=0}^{2n-1} \omega^{-nj}\ \widetilde{P}_{h_j}(\omega^j) \widetilde{Q}_{h_j}(\omega^j)$.

PROPOSITION 5.4. $|r_n - \widetilde{r}_n| \le \epsilon(\epsilon + |P| + |Q|)$.

Proof. Since $|\omega^{-nj}| = 1$ and for $h = h_j$,

$$|P(\omega^j)Q(\omega^j) - \widetilde{P}_h(\omega^j)\widetilde{Q}_h(\omega^j)| \le |P(\omega^j)(Q(\omega^j) - \widetilde{Q}_h(\omega^j)) + (P(\omega^j) - \widetilde{P}_h(\omega^j))\widetilde{Q}_h(\omega^j)|$$

$$\le |P(\omega^j)||Q(\omega^j) - \widetilde{Q}_h(\omega^j)| + |P(\omega^j) - \widetilde{P}_h(\omega^j)||\widetilde{Q}_h(\omega^j)| \le \epsilon(|P| + \epsilon + |Q|).$$

Thus we have

$$|r_n - \widetilde{r}_n| \le \frac{1}{2n} \sum_{j=0}^{2n-1} |\omega^{-nj}||P(\omega^j)Q(\omega^j) - \widetilde{P}_{h_j}(\omega^j)\widetilde{Q}_{h_j}(\omega^j)|$$

$$\leq \frac{2n}{2n}\epsilon(\epsilon + |P| + |Q|) = \epsilon(\epsilon + |P| + |Q|). \qquad \square$$

Surprisingly, we can contract the expansion of $\widetilde{r}_n$ as follows in this proposition.

PROPOSITION 5.5. *$\widetilde{r}_n = \sum_{h=0}^{H-1} \sum_{a=0}^{k-1} f_{h,a} s_{h,a}$, where $s_{h,a} = \sum_{b=0}^{k-1} g_{h,b} c_{h,a+b}$, and the $c_{h,\ell}$ are complex scalar constants dependent only on h, ℓ, n, and δ.*

Proof. The $(2n)$th root of unity is defined $\omega = e^{i\pi/n}$. For a fixed small constant α, each power ω^j, for $0 \leq j < n$, is mapped to the real $d_j = \tau(\omega^j)$ which is a constant (that is, the d_j need not be computed, and instead are provided by the algebraic circuit that we construct) for fixed n and α. For $h = h_j$, we have defined $\widetilde{P}_h(\omega^j) = f_h(d_{j-\delta h}) = \sum_{a=0}^{k-1} f_{h,a} d_{j-\delta h}^a$ and similarly,

$$\widetilde{Q}_h(\omega^j) = g_h(d_{j-\delta h}) = \sum_{b=0}^{k-1} g_{h,b} d_{j-\delta h}^b.$$

Thus for $h = h_j$, we can expand

$$\widetilde{P}_h(\omega^j)\widetilde{Q}_h(\omega^j) = \left(\sum_{a=0}^{k-1} f_{h,a} d_{j-\delta h}^a\right)\left(\sum_{b=0}^{k-1} g_{h,b} d_{j-\delta h}^b\right) = \sum_{a,b=0}^{k-1} f_{h,a} g_{h,b} d_{j-\delta h}^{a+b}.$$

Interchanging the order of summation (bringing the summation of j inside and a summation of h outside), we get

$$\widetilde{r}_n = \frac{1}{2n}\sum_{j=0}^{2n-1} \omega^{-nj} \widetilde{P}_{h_j}(\omega^j)\widetilde{Q}_{h_j}(\omega^j) = \sum_{h=0}^{H-1}\sum_{a=0}^{k-1} f_{h,a} s_{h,a},$$

where we define the *associated prefix sums* to be

$$\begin{aligned} s_{h,a} &= \frac{1}{2n}\sum_{b=0}^{k-1} g_{h,b} \sum_{j=\delta h}^{\delta(h+1)-1} \omega^{-nj} d_{j-\delta h}^{a+b} \\ &= \sum_{b=0}^{k-1} g_{h,b}\left(\frac{1}{2n}\sum_{j=\delta h}^{\delta(h+1)-1} \omega^{-nj} d_{j-\delta h}^{a+b}\right) = \sum_{b=0}^{k-1} g_{h,b} c_{h,a+b}, \end{aligned}$$

and where we define the *associated scalar constants* to be

$$c_{h,\ell} = \frac{1}{2n}\sum_{j=\delta h}^{\delta(h+1)-1} \omega^{-nj} d_{j-\delta h}^{a+b}.$$

Thus, Proposition 5.5 follows. $\square$

Note that the $s_{h,a}$ are defined independently of the $f_{h,a}$. To complete the proof of Lemma 5.3, we define $\widetilde{\mathbf{u}} =$ ROW-COMPRESS$_k(\mathbf{u})$ and $\widetilde{\mathbf{v}}^T =$ COLUMN-COMPRESS$_k(\mathbf{v}^T)$, where for each $h = 0, \ldots, H-1$ and for each $a = 0, \ldots, k-1$,

$$\widetilde{\mathbf{u}}_{hk+a} = f_{h,a}$$

and

$$\widetilde{\mathbf{v}}_{hk+a} = s_{h,a}.$$

Thus by the convolution theorem and Proposition 5.5,

$$\widetilde{r}_n = \sum_{h=0}^{H-1}\sum_{a=0}^{k-1} f_{h,a}s_{h,a} = \sum_{\ell=0}^{Hk-1} \widetilde{\mathbf{u}}_\ell \widetilde{\mathbf{v}}_\ell = \widetilde{\mathbf{u}}^T\widetilde{\mathbf{v}}.$$

Note that

$$|\mathbf{u}| = \sum |u_j| = \sum |p_j| = |P|$$

and

$$|\mathbf{v}| = \sum |v_j| = \sum |q_j| = |P|.$$

Now, given an error bound $\epsilon_1 > 0$, let

$$\epsilon = \epsilon_1/(\epsilon + |P| + |Q|) = \epsilon_1/(\epsilon + |\mathbf{u}| + |\mathbf{v}|).$$

By Proposition 5.4, approximation error $\epsilon_1 \le \epsilon(\epsilon + |\mathbf{u}| + |\mathbf{v}|)$, so we have proved Lemma 5.3. ∎

Given two $n \times n$ matrices A, B (with rows and columns indexed from 0 to $n-1$), we now approximate the inner product AB, where $(AB)_{\ell,m} = \sum_{j=0}^{n-1} A_{\ell,j}B_{j,m}$; this is the inner product of the ℓth row of A times the mth column of B. Now again fix an error bound $\epsilon_1 > 0$. Let

$$k = O(\log((\|A\|_\infty + \|B^T\|_\infty)/\epsilon_1),$$

where $\|A\|_\infty$ is the maximum, for any row of A, of the sum of the moduli of elements of the row, and $\|B^T\|_\infty$ is the maximum, for any column of B, of the sum of the moduli of elements of the column. We can precompute approximation polynomials of degree $k-1$ and their associated prefix sums for each of the rows of A and each of the columns of B. That is, we define an $n \times (Hk)$ matrix $\widetilde{A} =$ ROWS-COMPRESS$_k(A)$ and an $(Hk) \times n$ matrix $\widetilde{B} =$ COLUMNS-COMPRESS$_k(B)$ such that for each $\ell = 0, \ldots, n-1$ we define row $\widetilde{A}_\ell =$ ROW-COMPRESS$_k(A_\ell)$ (where $A_\ell, \widetilde{A}_\ell$ denote the ℓth row vectors of matrices $A, \widetilde{A}$, respectively) and for each $m = 0, \ldots, n-1$ we define column $\widetilde{B}_{-,m} =$ COLUMN-COMPRESS$_k(B_{-,m})$ (where $B_{-,m}, \widetilde{B}_{-,m}$ denote the mth columns of matrices $B, \widetilde{B}$, respectively). Then by Lemma 5.3, $\widetilde{A}_\ell\widetilde{B}_{-,m}$ is an ϵ-approx to $A_\ell B_{-,m}$. Hence, for each $0 \le \ell, m < n$, $(\widetilde{A}\widetilde{B})_{\ell,m}$ is an ϵ-approx to $(AB)_{\ell,m}$. Hence we have the following lemma.

LEMMA 5.6. *Suppose there is a (k, Δ) circle ϵ-approx evaluation scheme. Then given two $n \times n$ matrices A, B, we can ϵ_1-approximate the inner product AB by $\widetilde{A}\widetilde{B}$ for*

$$\epsilon_1 \le \epsilon(\epsilon + |\mathbf{u}| + |\mathbf{v}|).$$

PROPOSITION 5.7. *An $n \times n$ matrix of rank $< n$ cannot ϵ_1-approximate an $n \times n$ identity matrix, for any $\epsilon_1 < 1$.*

Proof. Suppose, for the sake of contradiction, that an $n \times n$ matrix $\widetilde{M}$ of rank $< n$ is an ϵ_1-approx of $n \times n$ matrix I, so $\|\widetilde{M} - I\|_\infty \le \epsilon_1$. Then since $\widetilde{M}$ has rank $< n$, there is an $x \ne 0$ such that $\|x\|_\infty = 1$ and $\widetilde{M}x = 0$. Thus

$$\|\widetilde{M}x - Ix\|_\infty = \|Ix\|_\infty = \|x\|_\infty = 1,$$

so

$$\|\widetilde{M} - I\|_\infty \geq \|\widetilde{M}x - Ix\|_\infty / \|x\|_\infty$$

$$= 1 > \epsilon_1,$$

a contradiction. □

We now consider the case where A, B are $n \times n$ identity matrices. Their product $M = AB$ is also an identity matrix. But $\widetilde{M} = \widetilde{A}\widetilde{B}$ is the product of an $n \times (kH)$ matrix and a $(kH) \times n$ matrix and thus has rank $\leq kH$. Recall that the statement of Theorem 5.1 makes the assumption that $kH = k\lceil 2\pi/\Delta \rceil < n$, so $\widetilde{M}$ has rank $< n$. But Lemma 5.6 states that $\widetilde{M}$ is an ϵ_1-approximation to $I = AB$, a contradiction of Proposition 5.7. Hence Theorem 5.1 follows. □

Appendix A. Proof of an alternative approximate evaluation on a circle.

Proof of Theorem 4.5. We give a proof of this alternative construction in stages, first considering a somewhat more complex algorithm.

An approach to approximate evaluation on a circle via approximate real polynomial evaluation. We will derive and prove the alternative algorithm given in subsection 4.2 by the use of classic real polynomial approximation techniques which provide our error analysis, but we observe at the end of this subsection that we do not need to explicitly construct the real approximation polynomials. Restrict z to the circle of radius r, so $z = r(x + iy)$, where x, y are real and $x + iy$ is on the unit circle, so $y = \sqrt{1 - x^2}$. Note that an expansion of $P(z)$ in terms of x, y gives $P(z) = R(x) + iS(x)y$, for polynomials $R(x), S(x)$ of degree $n - 1$. For simplicity, let us assume, w.l.o.g., $P(z)$ has real coefficients $p_0, \ldots, p_{n-1} \in \mathcal{R}$, so $R(x), S(x)$ are real polynomials. The exact evaluation of $P(z)$ at the evaluation points z_j, for $j = 0, \ldots, n-1$, might be done by an exact evaluation of $R(x), S(x)$ at the real points $x_0, \ldots, x_{n-1}$, where $z_j = x_j + iy_j$, so $P(z_j) = R(x_j) + iS(x_j)y_j$. Instead, we consider (see also Bini and Pan [3]) an approach for an ϵ-approximate evaluation of $P(z)$ at the evaluation points $z_0, \ldots, z_{m-1}$ using approximation of real polynomials (we will later show we can avoid explicit construction of these real polynomials). Fix a number k which divides n, to be determined below. We could construct degree $k-1$ polynomials $\widetilde{R}(x), \widetilde{S}(x)$, which give an ϵ'-approx of polynomials $R(x), S(x)$, where $\epsilon' = \epsilon/\sqrt{2}$. Then $\widetilde{P}(z) = \widetilde{R}(x) + i\widetilde{S}(x)y$ is an ϵ-approx of $P(z)$ over the circle of radius r, since

$$|P(z) - (\widetilde{R}(x) + i\widetilde{S}(x)y)| \leq \sqrt{(R(x) - \widetilde{R}(x))^2 + (S(x) - \widetilde{S}(x))^2} \leq \sqrt{2}\epsilon' = \epsilon.$$

To construct $\widetilde{R}(x), \widetilde{S}(x)$, we could do an exact evaluation of $R(x), S(x)$ at the shifted $(2k, k)$-Chebyshev points $x'_j = \Delta cos(j\pi/k)$, for $j = 0, \ldots, k-1$ over the real interval $I = [-\Delta, \Delta]$, for a positive real $\Delta \leq 1$. To do this first step, we can exactly evaluate $P(z)$ at

$$z'_j = r\left(x'_j + i\sqrt{1 - (x'_j)^2}\right),$$

for $j = 0, \ldots, k-1$, which costs work $O(n \log k)$ by Proposition 1.4. Then, we could exactly interpolate a degree $k-1$ real polynomial $\widetilde{R}(x)$ from the real parts $R(x'_j)$ of $P(z'_j)$, for $j = 0, \ldots, k-1$. We could also interpolate a degree $k-1$ real polynomial $\widetilde{S}(x)$ from the real values $s_0, s_1, \ldots, s_{k-1}$, where

$$is_j\sqrt{1 - (x'_j)^2}$$

is the complex part of $P(z'_j)$. By Lemma 3.1, the exact interpolation of polynomials $\widetilde{R}(x), \widetilde{S}(x)$ at these $(2k, k)$-Chebyshev points cost work $O(k \log k)$.

Exponential coefficient growth: The key difficulty with this approach. Next we need to bound the approximation errors for evaluation of $\widetilde{R}(x), \widetilde{S}(x)$ at all the evaluation points. To apply Proposition 3.2 we need to upper bound, the maximum moduli of $R^{(k)}(x) = \frac{d^k R(x)}{d^k x}$ (the kth derivative of $R(x)$ with respect to x), and $S^{(k)}(x) = \frac{d^k S(x)}{d^k x}$ over the interval $I = [-\Delta, \Delta]$. Unfortunately, straightforward application of the binomial expansion (in terms of x and y) to bound the moduli of coefficients of $R(x)$ and $S(x)$ give bounds on $|R|, |S|$ (the sums of the moduli of the coefficients of $R(x), S(x)$) that grow exponentially with the degree $n-1$. Thus application of Lemma 3.4 to evaluate $\widetilde{R}(x), \widetilde{S}(x)$ at all the evaluation points gives the work bound of the form

$$O(n \log \log(|R|/\epsilon')) = O(n \log(n + \log(1/\epsilon'))),$$

since in this case

$$\log(2^n/\epsilon') = n + \log(1/\epsilon').$$

The same difficulty occurs for ϵ'-approximate evaluation of the polynomial $S(x)$.

Evaluation at restricted intervals. To avoid this difficulty, we will do only an ϵ-approximate evaluation of $P(z)$ at a restricted interval on the radius r circle, where $|\cos(\theta(z))| \leq \Delta$ or, for the case of descending input coefficients,

$$|x| \leq \frac{1}{\sqrt{2}} \leq \Delta = \frac{1}{\max(\sqrt{2}, 8(n-1-k)/\sqrt{2})}.$$

Then we can do an ϵ-approximate evaluation of $P(z)$ over the entire circle of radius r by a number of separate evaluations of $P(z)$, each at a consecutive segment of the circle. The following lemma provides useful bounds on the k derivatives of $R(x), S(x)$.

LEMMA A.1. *Suppose $r = 1$ and either 1. $\Delta \leq \frac{k}{e(n-k)}$ or 2. $P(z)$ is $(k, \sqrt{2}/8)$-descending. For*

$$|x| \leq \Delta \leq \frac{1}{\sqrt{2}},$$

the modulus of the kth derivative (with respect to x) of $z = r(x + iy)$ (where $x + iy$ is on the unit circle) is bounded as

$$\left|\frac{d^k z}{d^k x}\right| \leq O(rk!8^k).$$

Also,

$$\left|\frac{d^k P(z)}{d^k x}\right|, \left|R^{(k)}(x)\right|,$$

and $|S^{(k)}(x)|$ are bounded in case 1 by $O(k!|P|\Delta^{-k})$ and in case 2 by $O(k!n^{O(1)}|P|\Delta^{-k})$.

Proof. We shall show that $\frac{dz}{dx} = r(1 - if_1(x))$ and, for $k \geq 2$, $\frac{d^k z}{d^k x} = -ir f_k(x)$, where $f_k(x)$ is a sum of at most 2^{k-1} terms, each of the form $c(k)\frac{x^a}{y^{2b+1}}$, where $|c(k)| \leq O(k!2^k)$ is the term's coefficient, and $0 \leq a, b \leq k$ are integers. We prove this by

construction of a *derivative tree*, which is a binary tree whose nodes are such terms. Since $y = \sqrt{1-x^2}$, $\frac{dy}{dx} = \frac{-x}{y^3}$, we have $\frac{dz}{dx} = 1 - if_1(x)$ where $f_1(x) = \frac{x}{y^3}$, so we define the root to be $f_1(x)$. Note that for $k > 1$,

$$\frac{d^k z}{d^k x} = -i\frac{d^{k-1} f_1(x)}{d^{k-1} x}.$$

Inductively, assume the label of a node is a term of form $c(k)\frac{x^a}{y^{2b+1}}$ labeling a node, since the derivative of $c(k)\frac{x^a}{y^{2b+1}}$ with respect to x is the sum of terms $c(k)(2b+1)$ $\frac{x^a}{y^{2(b+1)+1}}$ and $c(k)a\frac{x^{a-1}}{y^{2b+1}}$, we let its left and right children be labeled by these two terms, respectively. Note that since we take k derivatives, the tree has depth $k-1$, and so there are at most 2^{k-1} terms at the leaves of the tree. The leaves will be the terms of $\frac{d^{k-1} f_1(x)}{d^{k-1} x}$. The leaf with largest coefficient modulus is reached by a length $k-1$ path of left branches down the tree, so the maximum coefficient modulus of any leaf can be upper bounded as

$$|c(k)| \leq (2k-1)(2k-3)\cdots 3 \cdot 1 \leq k! 2^{k-1}.$$

Since $|x| \leq \frac{1}{\sqrt{2}}$,

$$y \geq \sqrt{1-x^2} \geq 1/\sqrt{2},$$

so

$$1/y^{2b+1} \leq (\sqrt{2})^{2k+1} \leq 2^{k+1}.$$

Thus the modulus of each leaf term $c(k)\frac{x^a}{y^{2b+1}}$ is upper bounded by $|c(k)|2^{k+1} \leq k!2^{k-1}2^{k+1}\ O(k!4^k)$. Hence $|f_k(x)| \leq$ the product of the number 2^{k-1} of terms at the leaves times their maximum modulus $O(k!4^k)$, so $|f_k(x)| \leq O(k!8^k)$. This implies

$$\left|\frac{d^k z}{d^k x}\right| \leq r(1 + |f_k(x)|) \leq O(rk!8^k).$$

Note that for $j > k$,

$$\frac{j!}{(j-k)!} \approx (j-k)^k$$

for $k = o(n)$, since by the Stirling approximation to factorial,

$$j! \approx (j)^j e^{-j}\sqrt{2\pi j},$$

$$(j-k)! \approx (j-k)^{j-k} e^{-(j-k)}\sqrt{2\pi(j-k)},$$

and

$$\left(\frac{j}{j-k}\right)^{j-k} = \left(1 + \frac{k}{j-k}\right)^{j-k} \approx e^k;$$

so

$$\frac{j!}{(j-k)!} \approx \frac{j^j}{(j-k)^{j-k}} e^{-k} \approx (j-k)^k e^{-k} e^k \approx (j-k)^k.$$

Since $|z| \le r$, we have $|\frac{d^k P(z)}{d^k z}| \le \sum_{j=k}^{n-1} \frac{j!}{(j-k)!} r^{j-k} |p_j|$. By the chain rule of derivatives,

$$\frac{d^k P(z)}{d^k x} = \frac{d^k z}{d^k x} \frac{d^k P(z)}{d^k z},$$

so

$$\left| \frac{d^k P(z)}{d^k x} \right| \le \left| \frac{d^k z}{d^k x} \right| \left| \frac{d^k P(z)}{d^k z} \right| \le O(rk!8^k) \sum_{j=k}^{n-1} \frac{j!}{(j-k)!} r^{j-k} |p_j|.$$

Thus

$$\left| \frac{d^k P(z)}{d^k x} \right| \le O(rk!8^k) \sum_{j=k}^{n-1} \frac{j!}{(j-k)!} r^{j-k} |p_j| \le O(rk!8^k) \sum_{j=k}^{n-1} (j-k)^k r^{j-k} |p_j|.$$

1. Now suppose $r = 1$ and $\Delta \le \frac{1}{8(n-k)}$. Then $\sum_{j=k}^{n-1} (8(j-k))^k |p_j| \le |P| \Delta^{-k}$, so

$$(8(j-k))^k |p_j| \le |P| (1/\sqrt{2})^k \le O(|P| \Delta^{-k}).$$

   Thus,

$$\left| \frac{d^k P(z)}{d^k x} \right| \le O(rk!8^k) \sum_{j=k}^{n-1} (j-k)^k r^{j-k} |p_j| \le O(k!) \sum_{j=k}^{n-1} (8(j-k))^k r^{j-k+1} |p_j|$$

$$\le O(k! |P| \Delta^{-k}).$$

   Since $P(z) = R(x) + iS(x)y$, we have

$$\frac{d^k P(z)}{d^k x} = R^{(k)}(x) + i \left(S^{(k)}(x) y + \frac{x S(x)}{y} \right).$$

   Hence for $|x| \le \Delta$,

$$|R^{(k)}(x)| \le \left| \frac{d^k P(z)}{d^k x} \right| \le O(k! |P| \Delta^{-k}).$$

   Also, $|\frac{xS(x)}{y}| \le |P(z)| \le |P|$, so

$$\begin{aligned} |S^{(k)}(x)| &\le \left| \frac{d^k P(z)}{d^k x} \right| + \left| \frac{x S(x)}{y} \right| \le \left| \frac{d^k P(z)}{d^k x} \right| + |S(x)| \left| \frac{x}{y} \right| \\ &\le \left| \frac{d^k P(z)}{d^k x} \right| + O(|P|) \\ &\le O(k! |P| \Delta^{-k}). \end{aligned}$$

2. Next suppose $r = 1$. If $P(z)$ is $(k, \sqrt{2}/8)$-descending, then, by definition, the magnitude of the coefficients of $P(z)$ drops as

$$|p_j| \le n^{O(1)} |P| \left(\frac{\sqrt{2}}{j8} \right)^k$$

for $j = k, \ldots, n-1$. Then $\sum_{j=k}^{n-1}(8(j-k))^k|p_j| \leq |P|\Delta^{-k})$, so

$$(8(j-k))^k|p_j| \leq n^{O(1)}|P|(1/\sqrt{2})^k \leq O(n^{O(1)}|P|\Delta^{-k}).$$

Thus in this case,

$$\left|\frac{d^k P(z)}{d^k x}\right| \leq O(rk!8^k)\sum_{j=k}^{n-1}(j-k)^k|p_j| \leq O(k!)\sum_{j=k}^{n-1}(8(j-k))^k|p_j|$$
$$\leq O(k!n^{O(1)}|P|\Delta^{-k}).$$

Also,

$$|S^{(k)}(x)| \leq O(k!n^{O(1)}|P|\Delta^{-k}).$$

Since $|I| = 2\Delta$, for $I = [-\Delta, \Delta]$, by Propositions 3.2 and A.1, the error in the approximation of $R(x)$ by $\widetilde{R}(x)$, for $|x| \leq \Delta$, is upper bounded in case 1 by

$$\frac{2}{k!}(|I|/4)^k \max_{x\in I} R^{(k)}(x) \leq O(|P|(\Delta/2)^k\Delta^{-k}) \leq O(|P|2^{-k})$$

and in case 2 by $O(n^{O(1)}|P|2^{-k})$. This error is upper bounded by $O(\epsilon')$ if we set $k = \log(|P|/\epsilon) + O(1)$ in case 1 or $k = O(\log(n|P|/\epsilon))$ in case 2. Also, the error in the approximation of $S(x)$ by $\widetilde{S}(x)$, for $|x| \leq \Delta$, is upper bounded by

$$\frac{2}{k!}(|I|/4)^k \max_{y\in I} S^{(k)}(y) \leq \epsilon'.$$

Hence

$$|P(z) - (\widetilde{R}(x) + i\widetilde{S}(x)y)| \leq ((R(x) - \widetilde{R}(x))^2 + (S(x) - \widetilde{S}(x))^2)^{1/2} \leq \sqrt{2}\epsilon' = \epsilon.$$

Thus we have proved the error bounds given in Theorem 4.5 for the case

$$\widetilde{P}(z) = \widetilde{R}(x) + i\widetilde{S}(x)y.$$

A simplification avoiding construction of real polynomials. Finally, we observe that we do not need to explicitly construct real approximation polynomials defined above. For simplicity, we assume, w.l.o.g., for each evaluation point z_j that $|\theta(z_j) - \pi/2| \leq \pi/4$. Instead, we do the following:

- In work $O(n\log^2 k)$, interpolate the degree $k-1$ complex polynomial $\widetilde{P}(z)$ from the values $P(z'_j)$, for $j = 0, \ldots, k-1$, where $z'_j = r(x'_j + i\sqrt{1-(x'_j)^2})$, and $x'_j = \cos(j\pi/k)/\sqrt{2}$, for $j = 0, \ldots, k-1$.
  Comment: Thus we construct $\widetilde{P}(z) = (\widetilde{R}(x) + i\widetilde{S}(x)y)$, without explicitly constructing $\widetilde{R}(x), \widetilde{S}(x)$.
- Evaluate polynomial $\widetilde{P}(z)$ exactly at the given evaluation points $z_0, \ldots, z_{m-1}$, within work $O(m\log^c k)$, where $c = 2$ by Proposition 1.1 (or $c = 1$ by Proposition 1.4 if these evaluation points are regularly spaced).
  Comment: Thus we evaluate $\widetilde{P}(z) = (\widetilde{R}(x)+i\widetilde{S}(x)y)$, at the given evaluation points, without explicitly evaluating $\widetilde{R}(x), \widetilde{S}(x)$.

Thus we have derived the algorithm as defined in subsection 4.2, which provides a somewhat simpler implementation of Theorem 4.5. ∎

Appendix B. Exact Chebyshev point evaluation in $O(n \log n)$ work.

Let $P(x)$ be a polynomial of degree $n-1$. Let $\omega = e^{i2\pi/n'}$ be the n'th root of unity over the complex numbers $\mathcal{C}$, for some $n' \geq n$, such that n divides n'. We wish to exactly evaluate $P(x)$ at the (n', n)-Chebyshev points, which we defined to be the real parts $x_{0,j} = \cos(j2\pi/n')$ of the powers $z_{0,j} = \omega^j = e^{ji2\pi/n'}$, for $j = 0, \ldots, n-1$.

For simplicity, we assume n is a power of 2 and $n' = 2n$. For each $\ell = 0, \ldots, \log n$,

- let $n_\ell = n/2^\ell, n'_\ell = n'/2^\ell$,
- let $z_{\ell,j+n_\ell} = -z_{\ell,j}$, and if $\ell > 0$ then let $z_{\ell,j} = 2z^2_{\ell-1,j} - 1$, and
- let $x_{\ell,j} = \text{ real}(e^{ji2\pi/n'_\ell}) = \cos(j2\pi/n'_\ell)$ denote the (n'_ℓ, n_ℓ)-Chebyshev points.

By the identities $\cos(2\theta) = 2\cos^2(\theta) - 1$ and $\cos(\theta + \pi) = -\cos(\theta)$, we have a recursive definition of these (n'_ℓ, n_ℓ)-Chebyshev points.

PROPOSITION B.1. *For each $\ell = 0, \ldots, \log n$ and all $j = 0, \ldots, n_\ell - 1$, $x_{\ell,j+n_\ell} = -x_{\ell,j}$ and if $\ell > 0$ then $x_{\ell,j} = 2x^2_{\ell-1,j} - 1$.*

The key idea behind our algorithm is as follows:

- Starting with the polynomial P to be evaluated, we define two polynomials P_0 and P_1 as the unique polynomials such that $P(x) = P_0(2x^2-1) + xP_1(2x^2-1)$.
- The map from x to $2x^2 - 1$ sends $\cos\theta$ to $\cos 2\theta$, that is, it maps Chebyshev points to Chebyshev points. If the original set of Chebyshev points contains both x and $-x$, then this map collapses them, so the number of points to be evaluated is halved. Thus the problem of evaluating P at the (n', n)-Chebyshev points reduces to evaluating P_0 and P_1 at $(n'/2, n/2)$-Chebyshev points.
- To apply this argument recursively, we compute the polynomials at each node of a logarithmic depth tree, by their evaluations on suitably defined points. This process can be initiated at the leaves, since there evaluation is the same as the coefficient itself.

We define a full binary tree of depth $\log n$ which we call the (n', n)-*Chebyshev evaluation tree*, whose nodes of depth $\ell = 0, \ldots, \log n$ are the set $\{0,1\}^\ell$ of binary strings of length ℓ. The root is labeled with the input polynomial $P_\lambda(x) = P(x)$, where λ is the empty string. Each node $\beta \in \{0,1\}^\ell$ of the tree is labeled with a degree $n_\ell - 1$ polynomial $P_\beta(x)$ and if $\ell < \log n$, node β has two children $\beta 0, \beta 1$ with labels consisting of the unique degree $n_{\ell+1} - 1$ polynomials $P_{\beta 0}(x), P_{\beta 1}(x)$ such that $P_\beta(x) = P_{\beta 0}(2x^2 - 1) + xP_{\beta 1}(2x^2 - 1)$. In contrast with the $O(n \log^2 n)$ algorithm of Pan [29], we will not actually compute these polynomials, but they will aid us in definition of our algorithm. However, we will compute for each node $\beta \in \{0,1\}^\ell$ two sets of values

$$\{F_{\beta,j} = P_\beta(z_{\ell,j}) | j = 0, \ldots, n_\ell - 1\}$$

and

$$\{\phi_{\beta,j} = P_\beta(x_{\ell,j}) | j = 0, \ldots, n_\ell - 1\}.$$

PROPOSITION B.2. *For each $\beta \in \{0,1\}^{\log n}$, $\phi_{\beta,0} = F_{\beta,0}$. For each $\ell = 0, \ldots, (\log n) - 1$, $\beta \in \{0,1\}^\ell$ and $j = 0, \ldots, n_\ell - 1$,*

1. *$F_{\beta,j} = F_{\beta 0,j} + z_{\ell,j}F_{\beta 1,j}$, $F_{\beta,j+n_\ell} = F_{\beta 0,j} - z_{\ell,j}F_{\beta 1,j}$, and so*
2. *$F_{\beta 0,j} = (F_{\beta,j} + F_{\beta,j+n_\ell})/2$, $F_{\beta 1,j} = (F_{\beta,j} - F_{\beta,j+n_\ell})/(2z_{\ell,j})$, and similarly*
3. *$\phi_{\beta,j} = \phi_{\beta 0,j} + x_{\ell,j}\phi_{\beta 1,j}$, $\phi_{\beta,j+n_\ell} = \phi_{\beta 0,j} - x_{\ell,j}\phi_{\beta 1,j}$, and so*

4. $\phi_{\beta 0,j} = (\phi_{\beta,j} + \phi_{\beta,j+n_\ell})/2$, $\phi_{\beta 1,j} = (\phi_{\beta,j} - \phi_{\beta,j+n_\ell})/(2x_{\ell,j})$.

Proof. For $\ell = |\beta| = \log n$, since P_β is a degree 0 polynomial, we have $\phi_{\beta,0} = P_\beta = F_{\beta,0}$.

1. By definition, for $\ell \geq 0$, $F_{\beta,j} = P_\beta(z_{\ell,j}) = P_{\beta 0}(z_{\ell+1,j}) + z_{\ell,j}P_{\beta 1}(z_{\ell+1,j}) = F_{\beta 0,j} + z_{\ell,j}F_{\beta 1,j}$. Also by definition, $z_{\ell,j+n_\ell} = -z_{\ell,j}$, so $F_{\beta,j+n_\ell} = P_\beta(z_{\ell,j+n_\ell}) = P_\beta(-z_{\ell,j}) = P_{\beta 0}(2(-z_{\ell,j})^2 - 1) - z_{\ell,j}P_{\beta 1}(2(-z_{\ell,j})^2 - 1) = P_{\beta 0}(z_{\ell+1,j}) - z_{\ell,j}P_{\beta 1}(z_{\ell+1,j}) = F_{\beta 0,j} - z_{\ell,j}F_{\beta 1,j}$.
2. The reverse formulas for $F_{\beta 0,j}, F_{\beta 1,j}$ follow from linear solution of the previous two equations.
3. By definition, for $\ell \geq 0$, $\phi_{\beta,j} = P_\beta(x_{\ell,j}) = P_{\beta 0}(x_{\ell+1,j}) + x_{\ell,j}P_{\beta 1}(x_{\ell+1,j}) = \phi_{\beta 0,j} + x_{\ell,j}\phi_{\beta 1,j}$. By Proposition B.1, $x_{\ell,j+n_\ell} = -x_{\ell,j}$, so $\phi_{\beta,j+n_\ell} = P_\beta(x_{\ell,j+n_\ell}) = P_\beta(-x_{\ell,j}) = P_{\beta 0}(2(-x_{\ell,j})^2 - 1) - x_{\ell,j}P_{\beta 1}(2(-x_{\ell,j})^2 - 1) = P_{\beta 0}(x_{\ell+1,j}) - x_{\ell,j}P_{\beta 1}(x_{\ell+1,j}) = \phi_{\beta 0,j} - x_{\ell,j}\phi_{\beta 1,j}$.
4. The reverse formulas for $\phi_{\beta 0,j}, \phi_{\beta 1,j}$ follow from linear solution of the previous two equations. □

Our algorithms for exact Chebyshev point evaluation and interpolation. We now show how to do (n', n)-Chebyshev point evaluation by a recursive algorithm and reduction to the DFT.

For each $\ell = 0, \ldots, (\log n) - 1$, we precompute $x_{\ell,j} = \cos(j2\pi/n')$, and $z_{\ell,j}$ for $j = 0, \ldots, n_\ell - 1$ as defined above. We then compute the $(2n, n)$-Chebyshev point evaluation of a given $P(x)$ as follows:

$(2n, n)$-Chebyshev point evaluation algorithm.

Input: The n coefficients $p_0, \ldots, p_{n-1} \in \mathcal{C}$ polynomial $P(x)$ of degree $\leq n - 1$.

1. In work $O(n \log n)$, compute the values $F_{\lambda,j} = P(\omega^j), j = 0, \ldots, n - 1$, where λ is the empty string (this can be done as stated in Proposition 1.3 within work $O(n \log n)$ by the chirp transform, which generalizes the DFT to this case).
2. Traverse the Chebyshev evaluation tree from root to leaves:
   For each $\ell = 0, \ldots, (\log n) - 1$ **do** apply Proposition B.2, part 2:
   For each $j = 0, \ldots, n_\ell - 1$ and $\beta \in \{0, 1\}^\ell$ **do**
   let $F_{\beta 0,j} = (F_{\beta,j} + F_{\beta,j+n_\ell})/2$, $F_{\beta 1,j} = (F_{\beta,j} - F_{\beta,j+n_\ell})/(2z_{\ell,j})$.
3. **For each** $j = 0, \ldots, n_\ell - 1$ and $\beta \in \{0, 1\}^\ell$ **do**
   let $\phi_{\beta,0} = F_{\beta,0}$, as given by Proposition B.2.
4. Traverse the Chebyshev evaluation tree from leaves to root:
   For each $\ell = (\log n) - 1, \ldots, 0$ **do** apply Proposition B.2, part 3:
   For each $j = 0, \ldots, n_\ell - 1$ and $\beta \in \{0, 1\}^\ell$ **do**
   let $\phi_{\beta,j} = \phi_{\beta 0,j} + x_{\ell,j}\phi_{\beta 1,j}$, $\phi_{\beta,j+n_\ell} = \phi_{\beta 0,j} - x_{\ell,j}\phi_{\beta 1,j}$.

Output: $\phi_{\lambda,j} = P(x_{\lambda,j}), j = 0, \ldots, n - 1$, which is the $(2n, n)$-Chebyshev evaluation of $P(x)$.

For each $\ell = 0, \ldots, \log n$, the work is $O(n_\ell) = O(n/2^\ell)$ for each of the 2^ℓ nodes $\beta \in \{0, 1\}^\ell$ of depth ℓ, so the total work is $O(n_\ell 2^\ell \log n) = O(n \log n)$, plus $O(n \log n)$ work for computing the chirp transform by Proposition 1.3.

We can apply this $(2n, n)$-Chebyshev point evaluation algorithm to compute an (n', n)-Chebyshev point evaluation of degree $n-1$ polynomial $P(x)$, for any $n' = O(n)$ such that n divides n'. In the case $n' \geq 2n$, we can view the polynomial $P(x)$ to be of degree $(n'/2) - 1$, and apply the $(n', n'/2)$-Chebyshev point evaluation algorithm. In the case $n' < 2n$, since n divides n', we can decompose $P(x) = \sum_{j=0}^{c-1} P_j(x)x^{jn}$, where $c = n'/(2n) = O(1)$ and each polynomial $P_j(x)$ is of degree $\leq (n/c) - 1$, and then apply the $(2n/c, n/c)$-Chebyshev point evaluation algorithm a constant c number of

times.

Thus we have proved that the (n', n)-Chebyshev point evaluation problem for a polynomial of degree $n-1$ can be solved within work $O(n \log n)$ for any $n' = O(n)$ such that n divides n'. Since the Chebyshev evaluation tree has depth $\log n$, and there are $2 \log n$ stages, each taking $O(1)$ time with n work, and the DFT takes $O(\log n)$ with $O(n \log n)$ work, it follows that the total circuit depth is $O(\log n)$ with $O(n \log n)$ work. This completes the first part of the proof of Lemma 3.1. We next show how to do (n', n)-Chebyshev point interpolation by reduction to the DFT. We compute the interpolation of a polynomial from a set of n values at $(2n, n)$-Chebyshev points, as follows:

$(2n, n)$-Chebyshev point interpolation algorithm.

Input: The values $v_0, \ldots, v_{n-1} \in \mathcal{C}$ at the $(2n, n)$-Chebyshev points: $x_{0,0}, \ldots, x_{0,n-1}$.

1. Let $\phi_{\lambda,j} = v_j), j = 0, \ldots, n-1$.
2. Traverse the Chebyshev evaluation tree from root to leaves:
   For each $\ell = 0, \ldots, (\log n) - 1$ **do** apply Proposition B.2, part 4:
   For each $j = 0, \ldots, n_\ell - 1$ and $\beta \in \{0,1\}^\ell$ **do**
   let
$$\phi_{\beta 0,j} = (\phi_{\beta,j} + \phi_{\beta,j+n_\ell})/2,$$
$$\phi_{\beta 1,j} = (\phi_{\beta,j} - \phi_{\beta,j+n_\ell})/(2x_{\ell,j}).$$
3. **For each** $j = 0, \ldots, n_\ell - 1$ and $\beta \in \{0,1\}^\ell$ **do**
   let $F_{\beta,0} = \phi_{\beta,0}$, as given by Proposition B.2.
4. Traverse the Chebyshev evaluation tree from leaves to root:
   For each $\ell = (\log n) - 1, \ldots, 0$ **do** apply Proposition B.2, part 1:
   For each $j = 0, \ldots, n_\ell - 1$ and $\beta \in \{0,1\}^\ell$ **do**
   let
$$F_{\beta,j} = F_{\beta 0,j} + z_{\ell,j} F_{\beta 1,j},$$
$$F_{\beta,j+n_\ell} = F_{\beta 0,j} - z_{\ell,j} F_{\beta 1,j}.$$
5. In work $O(n \log n)$, compute the inverse DFT of the values $F_{\lambda,j} = P(\omega^j), j = 0, \ldots, n-1$ (this can be done within work $O(n \log n)$ as stated in Proposition 1.3), giving:

Output: The n coefficients of the unique interpolated polynomial $P(x)$.

For each $\ell = 0, \ldots, \log n$, the work is again $O(n_\ell) = O(n/2^\ell)$ for each of the 2^ℓ nodes $\beta \in \{0,1\}^\ell$ of depth ℓ, so the total work is again $O(n_\ell 2^\ell \log n) = O(n \log n)$, plus $O(n \log n)$ work for computing the DFT as in Proposition 1.3.

We can also apply this $(2n, n)$-Chebyshev point interpolation algorithm to compute an (n', n)-Chebyshev point interpolation of degree $n-1$ polynomial $P(x)$ for any $n', n \le n' < 2n$, such that n divides n'. We apply the $(2\bar{n}, \bar{n})$-Chebyshev point interpolation algorithm, for $\bar{n} = n'/c$, to interpolate c polynomials of degree $\bar{n}-1$ from the given (n', n)-Chebyshev points, and then construct $P(x)$ in further work $O(n \log n)$ by the well-known divide-and-conquer interpolation methods of [16, 26, 5, 1]. Thus we have proved that the (n', n)-Chebyshev point interpolation problem for a polynomial of degree $n-1$ can be solved within work $O(n \log n)$ for any $n' \le 2n$ such that n divides n'. The shifted version of these evaluation and interpolation problems can

be solved within the same work bounds using the same techniques by initializing the recurrences at the leaves to the appropriate values corresponding to the shifts. Again, since the Chebyshev evaluation tree has depth $\log n$, and there are $2 \log n$ stages, each taking $O(1)$ time with n work, and the inverse DFT takes $O(\log n)$ with $O(n \log n)$ work, it follows that the total circuit depth is $O(\log n)$ with $O(n \log n)$ work. To complete the proof of Lemma 3.1, we apply the technique of Proposition 1.1 to solve the (n', m)-Chebyshev point evaluation problem, for $n' = O(n)$, in work $O(n + m \log \min(n, m))$. □

Acknowledgments. The author sincerely thanks Chris Lambert, Victor Pauca, Kathy Redding, Ken Robinson, Steven Tate, and especially Deganit Armon, Octavian Procopiuc, and D. Sivakumar for comments improving the presentation of the results in this paper. Don Coppersmith suggested the reduction to the approximation of a matrix by small rank used in the proof of Theorem 5.1. Donald Rose described to us a simple proof of Proposition 5.7.

OPTIMAL SEARCH IN TREES*

YOSI BEN-ASHER†, EITAN FARCHI‡, AND ILAN NEWMAN†

Abstract. It is well known that the optimal solution for searching in a finite total order set is binary search. In binary search we divide the set into two "halves" by querying the middle element and continue the search on the suitable half. What is the equivalent of binary search when the set P is partially ordered? A query in this case is to a point $x \in P$, with two possible answers: "yes" indicates that the required element is "below" x or "no" if the element is not below x. We show that the problem of computing an optimal strategy for search in posets that are tree-like (or forests) is polynomial in the size of the tree and requires at most $O(n^4 \log^3 n)$ steps.

Optimal solutions of such search problems are often needed in program testing and debugging, where a given program is represented as a tree and a bug should be found using a minimal set of queries. This type of search is also applicable in searching classified large tree-like databases (e.g., the Internet).

Key words. optimal search, search in trees, binary search, search in graphs, posets

1. Introduction.

Binary search is a well-known technique used for searching in total order sets. Let $S = \{s_1, \ldots, s_n\}$ be a total ordered set such that $s_i < s_{i+1}$ for all $i \in \{1, \ldots, n-1\}$. A binary search usually is used to find out whether a given element s is a member of S. However, a different interpretation can be used, namely, that one of the elements in S is "buggy" and needs to be located. In a binary search, we query the middle element $s_{\frac{n}{2}}$. If the answer is "yes," then the bug is in $S' = \{s_1, \ldots s_{\frac{n}{2}}\}$ and we continue the search on S'; otherwise we search on the complement of S', namely $\{s_{\frac{n}{2}+1}, \ldots, s_n\}$. It is well known that the binary search is optimal for this case.

In this work we consider the generalization of searching in partially ordered sets (poset). A query is to a point x in the poset, with two possible answers: "yes" indicates that the required element is "below" x (less than or equal to x) or "no" if the element is not below x. Equivalently, P can be represented as a directed acyclic graph; G, a query is to a node $x \in G$; a "yes"/"no" answer indicates that the answer is at a node $y \in G$ reachable/not reachable from x, correspondingly. We are interested in the problem of computing the optimal search algorithm for a given input poset. The complexity measure here is the number of queries needed for the worst-case input (buggy node). We concentrate on posets that are tree- (forest-) like (every element except one has one element that covers it). In this case, the partial order set is represented as a rooted tree T, whose nodes are the elements of S. A query can be made to any node $u \in T$. A "yes"/"no" answer indicates whether the buggy node is in the subtree rooted at u, or in its complement. Our results extend naturally to forest-like posets, too. Some comments are made for Cartesian product posets.

An example of a (optimal) search on a tree of 5 nodes is shown in Figure 1.1. The arrow points to the next query node. The search takes 3 queries in the worst case.

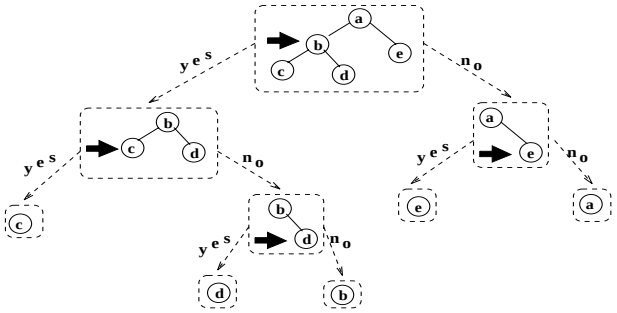

FIG. 1.1. *Searching in a tree.*

One motivation for the study of searches in trees (and posets in general) is that it forms a generalization of the search in linear orders to more complex sets: The known binary search is optimal for the path of length n with $\lceil \log n \rceil$ cost. Another extreme example is the search in a completely nonordered set of size n. This is equivalent to search in a star with n leaves. Here, as we must query each leaf separately, the search takes n queries. Searching in trees spans a spectrum between these two examples in terms of the cost function as well as poset type.

There is also a practical motivation: consider the situation where a large tree-like data structure is being transferred between two agents. Such a situation occurs when a file system (database) is sent across a network or a back/restore operation is done. In such cases, it is easy to verify the total data in each subtree by checksum-like tests (or randomized communication complexity equality testing). Such equality tests easily detect faults but give no information on which node of the tree is corrupted. Using a search on the tree (by querying the correctness of the subtrees) allows us to find the buggy node and avoid retransmitting the whole data structure.

Software testing is another motivation for studying search problems in posets (and in particular in trees). In general, program testing can be viewed as a two-person game, namely the tester and his "adversary." The adversary injects a fault into the program and the tester has to find the fault while minimizing the number of tests. A typical scenario in software testing is that the user tests his program by finding a "test bucket" (a set of inputs) that meets a certain coverage criteria, e.g., branch coverage or statement coverage [1, 2, 3]. It is plausible that in certain situations it might be possible to embed such a set of tests (e.g., the union over all test buckets that meet branch coverage) in a poset or in a tree such that the requirement for covering all tests can be replaced by a requirement for searching in this poset or tree. Finding an optimal search can save a lot of tests as the cost of a search might be considerably smaller than the size of the domain. For example, the syntactic structure of a program forms a tree; thus, if suitable tests are available, statement coverage might be replaced by a search in the syntactic tree of the program.

Finally, a possible motivation and direct application is in the area of information retrieval: Consider a Yahoo-like search scenario. The Yahoo contains an immense tree that classifies home pages (currently estimated as about 1–2% of the total number of web homepages). In a typical search, a node is reached and it exposes the next level of the tree (or part of it). The user chooses the appropriate branch according to the query he has in mind. As it turns out, this tree is quite deep, which often results in numerous queries before reaching the target. Clearly, such a top-down search might

be inefficient compared to the possibility of the optimal search of the Yahoo tree (e.g., searching in a chain of n nodes (a tree of depth n) requires n queries if we search top down and only $\log n$ queries if we allow to query arbitrary nodes).

A different notion of searching in posets was considered by Linial and Saks [5, 4]. They consider the case of a set of real numbers that are "stored" in a poset so that their natural order is consistent with the poset order. A search in this case is to determine if a real x is stored in the set. The possible queries in this case are, as in our case, the poset elements. The two possible answers for a query z is either "yes" (means $x \le e(z)$ where $e(z)$ is the element stored in z), or "no" ($x > e(z)$). The first answer results in excluding all elements greater than z from the poset and the later excludes all elements below z. Note that the difference between the two models is the resulting poset after a "yes" answer. It turns out that in spite of the similarity in definition the two models are quite different, e.g., the product of two paths (see section 5). Linial and Saks proved lower and upper bounds for the number of queries needed to search in posets in terms of some of the poset properties; however, they presented no algorithm to find the exact cost.

Our main result is a polynomial time algorithm (in the size of the tree) that finds the *optimal* search strategy for any tree (forest). Let $T(v)$ be the subtree of T rooted at v. The answer to a query $v \in T$ results in a search on either the subtree rooted at v or its complement $T - T(v)$. Thus, the optimal complexity, $w(T)$, of the search for T is defined by minimizing over all $v \in T$ the expression $1 + \max\{w(T(v)), w(T - T(v))\}$. Direct use of this formula to compute $w(T)$ would give an exponential time algorithm. Another possible approach is trying to compute $w(T)$ in a bottom-up manner; however, it seems that this, too, needs exponential time. Knowing the cost of the subtrees is not enough to compute the cost of the complete tree: a complement subtree produced by querying a node results in a new subtree whose cost has to be computed all over. Our approach is to get rid of this difficulty by using further relevant information on subtrees (rather than just the cost of the optimal search for them). We use a somewhat nonstandard decomposition of a tree into subtrees, so that the cost of a tree can be determined using the relevant information of its subtrees. Next, we generalize the results for forests and draw some conclusions for Cartesian product posets.

We note that for bounded degree trees, an approximation of the optimal strategy may be obtained by finding a "splitting" vertex that splits the tree into two parts that are not too big. However, such an approach totally fails for unbounded degree trees.

2. Basic definitions and preliminary facts. Let us start with some notations: The subtree of T that is rooted at u is denoted by $T(u)$. When it is clear from the context, we identify $T(u)$ with u. Deleting all nodes of a subtree T_1 from a tree T is denoted by $T - T_1$, in particular $T - u = T - T(u)$.

DEFINITION 2.1. *A search algorithm Q_T for a tree T with root r is defined recursively as follows. If $|T| = 1$, the search is trivial and gives as output the only node in T. For $|T| \ge 2$ a search algorithm is a triplet (v, Q_v, Q_{T-v}), where $v \in T - r$ (a "first query"), Q_v is a search algorithm for $T(v)$ (corresponds to a "yes" answer), and Q_{T-v} is a search algorithm for $T - v$ ("no" answer).*

Graphically, we denote Q_T as

$$Q_T = \begin{array}{ccc} v & \xrightarrow{\text{no}} & Q_{T-v}. \\ \downarrow & & \\ Q_v & & \end{array}$$

The cost of a search algorithm Q, denoted by $w(Q)$, is the number of queries needed to find any buggy node in the worst case. The cost of an optimal search algorithm for T, $w(T)$, is

$$w(T) = \min_{Q_T} w(Q_T).$$

An optimal algorithm is any search algorithm Q_T such that $w(Q_T) = w(T)$. Note that the above definition conforms with the convention that there is always a buggy node; thus the cost of a single node is zero since this node must be buggy and no query is needed. The case of a search in which there is a possible "un-found" answer is easily obtained from the above definition (with the expense of one additional query). See section 5 for more details.

The following is immediate from the definitions.

FACT 2.1. *For a tree T, with $|T| > 1$, $w(T) = 1 + \min_{v \in T} \max\{w(v), w(T-v)\}$.*

A useful property of the cost is that it is monotone.

OBSERVATION 2.1. *Let T_1 be a subtree of T_2 (namely, T_1 is obtained from T_2 by deleting some nodes), then $w(T_1) \leq w(T_2)$.*

Fact 2.1 suggests that we might as well start the search by querying a node $u \in T$ for which $w(u) < w(T)$ and $w(T-u)$ is minimal. Applying this idea further leads us to the definition of the "sequence of complements." We start by defining a lexicographic order on finite sequences.

DEFINITION 2.2. *Let $\mu = [\mu_1, \mu_2, \ldots, \mu_k]$ and $\rho = [\rho_1, \rho_2, \ldots, \rho_n]$ be two sequences of natural numbers. Then μ is lexicographically smaller than ρ ($\mu <_L \rho$) if there exists i such that $\mu_i < \rho_i$ and for every $j < i$, $\mu_j = \rho_j$.*

DEFINITION 2.3. *The sequence of complements $\mu(T) = [\mu_0, \mu_1, \mu_2, \ldots, \mu_l]$ for a given tree T is defined recursively as follows:*

$\mu_0 = w(T)$.

If $|T| = 1$, then $l = 0$ and $\mu(T) = [0]$.

For $|T| > 1$,

$$[\mu_1, \mu_2, \ldots, \mu_l] = \min \{\mu(T-u) |\ w(T(u)) < w(T)\},$$

where min *is taken according to the lexicographic order.*

For example, $\mu(L)$ of a path L with five nodes is $[3, 0]$, as its cost is 3; and the node u that achieves the smallest $\mu(L-u)$ is the son of the root for which $w(T-u) = 0$. The reader can verify that μ of a star with n leaves is $[n, n-1, \ldots, 2, 1, 0]$. The following properties are immediate from the definition: Let $\mu(T) = [\mu_0, \mu_1, \ldots, \mu_l]$. Then

1. $\mu_0 > \mu_1 > \cdots > \mu_l = 0$.
2. $l \leq w(T)$.

As the sequence of complements is always strictly decreasing, we restrict the order L to all *strictly decreasing* finite sequences of nonnegative integers with the last element being 0. The order L is a *discrete total* order on this set of sequences. In particular, every sequence has a rank in this total order, and every sequence has a successor. Thus, it also follows that $\mu(T)$ is a unique, well-defined sequence for every tree T.

DEFINITION 2.4. *For T with $|T| \geq 2$, $\lambda_T \in T$ is any node in T for which $\mu(T-\lambda_T)$ is the smallest and $w(T(\lambda_T)) < w(T)$. Namely λ_T is such that $\mu(T) = [w(T), \mu(T-\lambda_T)]$. Note that for $|T| = 1$, λ_T is not defined.*

It is immediate from the definition that λ_T is an optimal node, i.e., there exists an optimal search algorithm whose first query is λ_T. Figure 2.1 illustrates λ_T, $\mu(T)$, and an optimal search algorithm that starts in λ_T for a particular example. In the

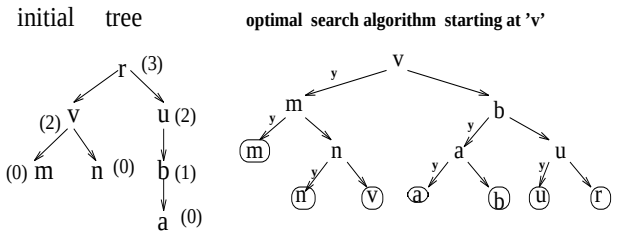

FIG. 2.1.

above tree (left side) the cost of each subtree is marked by its root. Here $\lambda_T = v$, since $\mu(T - v) = [2, 1, 0]$ compared (for example) to $\mu(T - u) = [3, 0]$.

3. The decomposition of T and the role of $\mu(T)$. As mentioned before, it is not obvious how to efficiently compute the cost of T using the formula of Fact 2.1 in a bottom-up manner. Our solution is to decompose T into subtrees, so that we can characterize $\mu(T)$ as a function of the μ's of its subtrees. We define the following operations:

T': "Rerooting" operation. T' is the tree obtained from T by adding a new node x whose only child is the root of T.

$T'_1 + \cdots + T'_k$: "grouping" operation. $T = T'_1 + T'_2 + \cdots + T'_k$ (also denoted by $\sum_{i=1}^{k} T'_i$) is obtained from disjoint trees $T_1, T_2, \ldots, T_k$ by attaching $T_1, T_2, \ldots, T_k$ as the children of a new root x. Note that we write it as an operation on the *rerooted* trees $T'_1, \ldots, T'_k$ rather than on $T_1, \ldots, T_k$, as we will relate $\mu(T)$ to $\mu(T'_1), \ldots, \mu(T'_k)$. In the grouping operation, we will always order $T_1, T_2, \ldots, T_k$ so that $\mu(T'_1) \leq_L \cdots \leq_L \mu(T'_k)$.

FACT 3.1. *Every rooted tree can be constructed from single nodes using the above operations.*

In the following two sections we will show how $\mu(T)$ is determined by the μ's of the subtrees used to decompose T according to the operations defined above.

3.1. Properties of the rerooting operation. We relate here the sequence of complements of any tree T to the sequence of complements of the tree T' that is obtained from T by rerooting. As it will turn out this can simply be characterized by the following theorem.

THEOREM 3.1. *Let T be a rooted tree and let T' be the tree obtained from T by rerooting. Then $\mu(T') = succ(\mu(T))$, where succ is the successor according to the order L on strictly decreasing nonnegative finite sequences, ending with* 0.

The key ingredient in the proof of the theorem is based on the observation that a "jump" in the coordinates of the sequence $\mu(T)$ is a necessary and sufficient condition for the cost of T' to remain the same. The term "jump" indicates that the difference between two consecutive coordinates of $\mu(T)$ is greater than 1. The intuition is that such a jump can compensate for the expected increase in $w(T')$ caused by the extra node added above the root of T. To demonstrate this on an example, consider a path P with three nodes, for which $\mu(P) = [2, 0]$; namely, it contains a jump. Indeed, P' is a path with 4 nodes and its cost remains 2. The reason why $w(P')$ did not increase is that we can start a search in P' by querying λ_P. For a "yes" answer we proceed as we would have done in P and the cost certainly won't change. For a "no" answer we are left with $P' - \lambda_P = (P - \lambda_P)'$ but $(P - \lambda_P)$ is a single node with zero cost. Thus $w(P' - \lambda_P) = 1$ which increased comparing to $P - \lambda_P$ but not enough to increase

$w(P')$. Another example is the rerooting T' of the tree T in Figure 2.1, showing that the cost does increase if $\mu(T)$ contains no jump. For T of Figure 2.1 $\lambda_T = v$ and $\mu(T) = [3, 2, 1, 0]$. Indeed, the reader can verify the cost increases, and $w(T') = 4$.

We proceed now with the proof of Theorem 3.1.

PROPOSITION 3.2. *For a given tree T, $w(T) \leq w(T') \leq w(T) + 1$*

Proof. The left inequality is immediate from Observation 2.1. The right inequality follows from the search that starts by querying the (old) root of T. □

PROPOSITION 3.3. *If $w(T') = w(T) + 1$, then $\lambda_{T'} = root(T)$ and $\mu(T') = [w(T'), 0]$.*

Proof. Querying $v = root(T)$ leads to $w(T' - v) = 0$ and thus $\mu(T') \geq [w(T'), 0]$, but $[w(T'), 0]$ is the smallest sequence $[\mu_0, \ldots, \mu_l]$ (according to $<_L$) for which $\mu_0 = w(T')$. □

LEMMA 3.4. *Let $\mu(T) = [\mu_0, \ldots, \mu_l]$. If there exists $i \geq 0$ such that $\mu_i < w(T) - i$, then $w(T') = w(T)$.*

Proof. Note that the condition of the lemma states that there is a jump between μ_i and μ_{i-1}. Let $\alpha = w(T)$. We will use induction on $|T|$ to show that there exists a search algorithm Q for T', with $w(Q) = \alpha$. The premise of the lemma is possible only for a tree with cost greater than 1; hence the induction base includes only a path P with three nodes or a star with two leaves. For the latter, the sequence of complements $\mu()$ is $[2, 1, 0]$ and the premise of the lemma is not met. For the path P, the sequence of complements is $[2, 0]$, and indeed $w(P') = w(P) = 2$.

Let T be a tree with $w(T) = \alpha \geq 3$, and consider the following search algorithm for T':

$$Q = \begin{array}{ccc} \lambda_T & \xrightarrow{\text{no}} & Q_1, \\ \downarrow & & \\ Q_2 & & \end{array}$$

where Q_1 is an optimal search algorithm for $T' - \lambda_T$ and Q_2 is an optimal search algorithm for $T(\lambda_T)$. Here, $w(Q) \leq 1 + \max(w(Q_2), w(T' - \lambda_T))$, but, by the definition of λ_T, $w(Q_2) \leq \alpha - 1$ and thus $w(Q) \leq \max(\alpha, 1 + w(T' - \lambda_T)) = \max(\alpha, 1 + w((T - \lambda_T)'))$. Hence, it is enough to show that $w((T - \lambda_T)') \leq \alpha - 1$.

Let us first consider the case where the jump is for $i = 1$, namely, $\mu_1 = w(T - \lambda_T) \leq \alpha - 2$. By Proposition 3.3 for $T - \lambda_T$ we have that $w((T - \lambda_T)') \leq w(T - \lambda_T) + 1 \leq \mu_1 + 1 \leq \alpha - 1$.

Consider the case where $i > 1$. Let $T_1 = T - \lambda_T$; then by the definition of μ we get that $\mu(T_1) = [\mu_1, \ldots, \mu_l]$, with $\mu_1 = w(T - \lambda_T) \leq \alpha - 1$. Thus, the premise of the lemma holds for T_1 (with $i' = i - 1$), so by the induction hypothesis $w(T_1') = w(T_1) \leq \alpha - 1$. □

The opposite of Lemma 3.4 is also true.

LEMMA 3.5. *Let $\mu(T) = [\mu_0, \ldots, \mu_l]$. If $w(T') = w(T)$, then there exists $i \in \{1, \ldots, l\}$ such that $\mu_i < w(T) - i$.*

Proof. Let $w(T) = w$. It is sufficient to show that if the condition is not met, i.e., $\forall i,\ \mu_i \geq w - i$, then $w(T') = w + 1$. We prove this by induction on $|T|$. The base case is a single node whose $\mu = [0]$ and for which T' is a path of length 1 with cost $= 1$.

For $|T| > 1$ the assumption above implies that $\mu(T) = [w, w - 1, w - 2, \ldots, 1, 0]$. Let Q be an optimal algorithm for T' starting with a vertex x. We show that Q must spend $w + 1$ queries. If $w(T(x)) \geq w$, then on a "yes" answer we are left with $T(x)$ (on which additional w queries are needed) and we are done. Thus we may assume that

$w(T(x)) \leq w-1$. Therefore by the definition of λ_T we get that $\mu(T-x) \geq_L \mu(T-\lambda_T)$. But this means that $\mu(T-x) = \mu(T-\lambda_T) = [w-1, w-2, \ldots, 1, 0]$ as the successor of $\mu(T-\lambda_T)$ has a first coordinate equal to w. Thus, by the induction hypothesis on $T-x$ (whose μ has no jump), $w(T'-x) \geq w(T-x)+1 = w-1+1 = w$. Hence $w(Q) \geq 1 + w(T'-x) = 1+w$. ∎

The above two lemmas yield the following theorem.

THEOREM 3.6. *Let $\mu(T) = [\mu_0, \ldots, \mu_l]$. Then $w(T') = w(T)$, iff there exists $i \geq 0$ such that $\mu_i < w(T) - i$.*

We now conclude with the proof of Theorem 3.1.

Proof. If for a tree T there is no jump, namely, $\mu(T) = [w, w-1, \ldots, 1, 0]$, where $w = w(T)$, then by Theorem 3.6 $w(T') = w+1$. Moreover, by Proposition 3.3, $\mu(T') = [w+1, 0]$, which is the successor of $[w, w-1, \ldots, 1, 0]$ in the order L.

Assume then that there is a jump in $\mu(T)$, and let i be the largest index for which $\mu_{i-1} \geq l-i+2$, namely,

$$\mu(T) = [\mu_0, \mu_1, \ldots, \mu_{i-1}, \overbrace{l-i}^{\mu_i}, l-i-1, \ldots, 2, 1, 0].$$

Then we prove by induction on $w(T)$ that $\mu(T') = succ(\mu(T))$ and that $\lambda_{T'} = \lambda_T$. By Theorem 3.6 $w(T') = w(T) = \mu_0$. Assume $\lambda_{T'} = x$ then $\mu(T') = [\mu_0, \mu(T'-x)]$. But $T'-x = (T-x)'$ and, by the induction hypothesis for $(T-x)'$, $\mu(T-x)' = succ(\mu(T-x))$. However, by the definition of λ_T,

$$\mu(T-x) \geq \mu(T-\lambda_T) = [\mu_1, \ldots, \mu_{i-1}, l-1, l-i-1, \ldots, 1, 0].$$

However,

$$succ([\mu_1, \ldots, \mu_{i-1}, l-i, l-i-1, \ldots, 1, 0]) = [\mu_1, \ldots, l-i+1, 0],$$

thus we get that $\mu(T'-x) = succ(\mu(T-x) \geq [\mu_1, \ldots, l-i+1, 0]$. On the other hand, by the definition of the node x in T', we have that $\mu(T'-x) \leq \mu(T'-\lambda_T) = \mu((T-\lambda_T)') = succ(\mu(T-\lambda_T)) = [\mu_1, \ldots, l-i+1, 0]$. Thus we conclude that

$$\mu(T') = [\mu_0, \mu_1, \ldots, l-i+1, 0] = succ([\mu_0, \mu_1, \ldots, \mu_{i-1}, l-i, l-i-1, \ldots, 1, 0]).$$

Moreover, as we get that $\mu(T'-x) = \mu(T'-\lambda_T)$ this also proves that $\lambda_T = \lambda_{T'}$. ∎

3.2. Properties of the grouping operation. We now relate the sequence of complements of grouping k rerooted trees $T_1'+T_2'+\cdots+T_k'$ to the individual sequences. First a simpler operation is defined as follows.

DEFINITION 3.7. *The "amalgamation" operation $T_1' + T_2$ on disjoint trees T_1', T_2 is the tree that is obtained by amalgamating the roots of T_1' and T_2 into one node.*

Note that in the amalgamation operation it is required that one of the trees be a rerooted tree. The amalgamation operation exhibits a certain monotonicity.

LEMMA 3.8. *Let T_1, T_2, T be trees; then $\mu(T_1') \leq_L \mu(T_2') \implies w(T_1'+T) \leq w(T_2'+T)$.*

Proof. This proof is by induction on the sum $n = |T| + k$ where $|T|$ is the number of nodes in T and k is the rank of $\mu(T_1')$ defined by the total order $<_L$.

The induction base is for $n = 2$, and T that has one node. Since the amalgamation of one node to any tree does not change the tree at all, the base of the induction is trivially true.

First case—$w(T) \le w(T_1')$: Let $w = w(T_1')$ and assume Q is any search algorithm for $T+T_2'$ with cost $w(Q)$. We give an algorithm for $T+T_1'$ with cost of at most $w(Q)$. Indeed let $u \neq root(T_2')$ be the first query of Q. If $u \in T$ then obviously $w(Q) \ge w+1$, as $w((T-u)+T_2') \ge w(T_2) \ge w$. However, the algorithm that first queries the root of T_1 and then proceeds optimally for T_1 if the answer is "yes" and optimally for T if the answer is "no" also achieves $w+1$ and we are done.

If $u \in T_2$, then we may assume that $w(T(u)) \le w-1$ (otherwise $w(Q) \ge w+1$ and we are done as before). We also may assume that $w(T_2') = w$, as if $w(T_2') \ge w+1$, then $w(Q) \ge w+1$, but as we have shown, we can clearly search $T+T'$ in $w+1$ queries. Thus $\mu(T_2' - \lambda_{T_2}) \ge \mu(T_1' - \lambda_{T_1})$ (as $\mu(T_2') \ge \mu(T_1')$ and the first coordinate in both sequences is equal to w). In this case by querying λ_{T_1} we get that $w(T+T_1') \le 1 + \max(w-1, w(T + (T_1 - \lambda_{T_1})'))$. However, by our assumption $\mu(T_2' - u) \ge_L \mu(T_2' - \lambda_{T_2'}) \ge_L \mu(T_1' - \lambda_{T_1'})$. Thus by induction $w(T+(T_2'-u)) \ge w(T+(T_1' - \lambda_{T_1'}))$, so that $w(Q) \ge 1 + w(T + T_2' - u) \ge 1 + w(T + T_1' - \lambda_{T_1})$. On the other hand, as $w(Q) \ge w$, it follows that $w(Q) \ge 1 + \max(w-1, w(T + (T_1' - \lambda_{T_1'})) = w(T+T_1')$.

Second case—$w(T) > w(T_1')$: Consider an optimal search algorithm Q for $T+T_2'$. We may assume that $w(Q) \le w(T)$; otherwise, a search algorithm for $T+T_1'$ that starts by querying the root of T_1 will use at most $w(T)+1$ queries (as $w(T) > w(T_1)$), so that $w(T+T_1') \le w(T+T_2')$. The lemma follows.

Let y be the first query of Q. It follows that $y \in T$. Consider a search algorithm Q' for $T'+T_1$ that also starts by querying y. We are left with two trees $(T-y)+T_1'$ and $(T-y)+T_2'$. Here, $|T-y| < |T|$ so that we can use the induction assumption and obtain that $w((T-y)+T_1') \le w((T-y)+T_2')$. The lemma follows. □

We now consider grouping of several trees.

PROPOSITION 3.9. *Let $T = \sum_{i=1}^{k} T_i'$ (i.e., $T = T_1' + \cdots + T_k'$) and assume that $\mu(T_1') \le \cdots \le \mu(T_k')$. Then $w(T_k') \le w(T) \le w(T_k') + k - 1$.*

Proof. The left inequality is immediate from Fact 3.1. The other inequality is obvious by the following search algorithm for T.

Start by querying $root(T_1), root(T_2), \ldots, root(T_{k-1})$. If the answer is "yes" on, say, the ith query, then proceed by an optimal search on T_i. Otherwise proceed by an optimal search in T_k. Clearly this search takes at most $w(T_k') + k - 1$ queries. □

The criterion for determining the exact cost of the grouping operation is given by the following lemma.

LEMMA 3.10. *Let $T = T_1' + \cdots + T_k'$. Then*

(a) $w(T) = w(T_k')$ *iff* $w(T_1' + \cdots + T_{k-1}' + (T_k' - \lambda_{T_k'})) \le w(T_k') - 1$;

(b) *for any $\alpha > w(T_k')$, we have that $w(T) \le \alpha$ iff $w(T_1' + \cdots + T_{k-1}') \le \alpha - 1$.*

Proof. The "if" direction for (a) is trivial since, if $w(T_1' + \cdots + T_{k-1}' + (T_k' - \lambda_{T_k'})) \le w(T_k')$, then by querying $\lambda_{T_k'}$ we are done. Similarly querying $root(T_k)$ if $w(T_1' + \cdots + T_{k-1}') \le \alpha - 1$ proves the "if" direction for (b).

For the other direction of (a)—assume by negation that $w(T_1' + \cdots + T_{k-1}' + (T_k' - \lambda_{T_k'})) \ge w = w(T_k')$—we show that $w(T_1' + \cdots + T_k') \ge w+1$. Let Q be a search algorithm for $T_1' + \cdots + T_k'$ that starts by querying x. If $x \notin T_k'$, then clearly $w(Q) \ge 1+w$. Assume that $x \in T_k'$ and $w(T(x)) \le w-1$ (otherwise, for a "yes" answer $w(Q) \ge 1 + w(T(x)) \ge w+1$). Then, by the definition of μ, $\mu(T_k' - x) \ge_L \mu(T_k' - \lambda_{T_k'})$.

Now, let $\tilde{T} = T_1' + \cdots + T_{k-1}'$. Then by Lemma 3.8 we get $w((T_k - x)' + \tilde{T}) \ge w((T_k - \lambda_{T_k'})' + \tilde{T}) \ge w$; hence

$$w(Q) = 1 + w((T_k - x)' + \tilde{T})) \ge 1 + w((T_k - \lambda_{T_k'})' + \tilde{T}) \ge 1 + w.$$

For (b), let $\alpha > w(T'_k)$ and assume that $w(T'_1 + \cdots + T'_{k-1}) \geq \alpha$. Let Q be a search algorithm for T that first queries x. If $x \in T'_k$, then $w(Q) \geq 1 + w(T'_1 + \cdots + T'_{k-1} + T'_k - \lambda_{T'_k}) \geq 1 + w(T'_1 + \cdots + T'_{k-1}) \geq \alpha + 1$. If $x \in T'_i$, where $i \neq k$, then let $\tilde{T} = T'_1 + \cdots + T'_{i-1} + T'_{i+1} + \cdots + T'_{k-1}$. By Lemma 3.8 $w(T'_1 + \cdots + T'_{k-1}) = w(\tilde{T} + T'_i) \leq w(\tilde{T} + T'_k)$. Considering the "no" answer after query x, this implies that $w(Q) \geq 1 + w(\tilde{T} + T'_k) \geq 1 + w(\tilde{T} + T'_i) \geq 1 + \alpha$. ∎

Finally we relate the sequences of complements.

LEMMA 3.11. *Let $T = T'_1 + \cdots + T'_k$. Then*

(a) *if $w(T) = w(T'_k)$, then $\lambda_T = \lambda_{T'_k}$, $\mu(T) = [\mu_0, \ldots, \mu_l]$, where $\mu_0 = w(T'_k)$ and $[\mu_1, \ldots, \mu_l] = \mu(T'_1 + \cdots + T'_{k-1} + (T'_k - \lambda_{T'_k}))$;*

(b) *if $w(T) > w(T'_k)$, then $\lambda_T = root(T'_k)$, $\mu(T) = [\mu_0, \ldots, \mu_l]$, where $\mu_0 = w(T)$ and $[\mu_1, \ldots, \mu_l] = \mu(T'_1 + \cdots + T'_{k-1})$.*

Proof. The proof immediately follows from the proof of Lemma 3.10 ∎

4. Constructing the optimal search algorithm. In this section we show that computing $\mu(T)$ (and in fact λ_T) for a given tree T, can be done in polynomial time (in the size of T). The algorithm constructs $\mu(T), \lambda_T$ bottom up using the rerooting and grouping operations.

We need the following notation: for a given tree T, let $\mu(T) = [\mu_0, \mu_1, \ldots, \mu_l]$; we denote $\partial\mu = [\mu_1, \ldots, \mu_l] = \mu(T - \lambda_T)$. Note that $\partial\mu$ is computed from μ just by dropping out the first entry. (Although formally it depends on λ_T, one does not need to know it explicitly.) Depending on the current operation in the decomposition, the algorithm performs the following computations.

Rerooting operation: Let $T = T'_1$.

1. Compute $\mu(T) = succ(\mu(T_1))$ (Theorem 3.1).
2. If $w(T) = w(T_1) + 1$, then $\lambda_T = root(T_1)$; otherwise (if $w(T) = w(T_1)$), $\lambda_T = \lambda_{T_1}$.

   This can be done in $O(w(T))$ steps.

Grouping operation: Let $T = T'_1 + \cdots + T'_k$.

1. The μ sequences of $T'_1, \cdots, T'_k$ are sorted so that $\mu(T'_1) \leq_L \cdots \leq_L \mu(T'_k)$. Each sequence is of length at most $w(T)$, and each entry is bounded by $w(T)$. Thus sorting can be done (treating each sequence as a number) by $min(w^2(T) \log w(T), |T| \log |T|)$.
2. For any α it can be determined whether $w(T'_1 + \cdots + T'_k) \leq \alpha$. This is done using the following recursive test as suggested by Lemma 3.10. The test is applied to the vectors of complement of subtrees $T'_1, \ldots, T'_k$, such that $test(\mu(T'_1), \ldots, \mu(T'_k), \alpha)$ returns true iff $w(T'_1 + \cdots + T'_k) \leq \alpha$.

   a) For $\alpha \geq \mu_0(T'_k) + k$

$$test(\mu(T'_1), \ldots, \mu(T'_k), \alpha) = true.$$

   b) For $w \leq \mu_0(T'_k) - 1$

$$test(\mu(T'_1), \ldots, \mu(T'_k), \alpha) = false.$$

   c) For $\alpha = \mu_0(T'_k)$

$$test(\mu(T'_1), \ldots, \mu(T'_k), \alpha) = test(\mu(T'_1), \ldots, \mu(T'_{k-1}), \partial\mu(T'_k), \alpha - 1),$$

$$\text{i.e., } test(T'_1 + \cdots + T'_k, \alpha) = test(T'_1 + \cdots + T'_{k-1} + T'_k - \lambda_{T'_k}, \alpha - 1).$$

d) For $\mu_0(T'_k) < w \leq \mu_0(T'_k) + k - 1$

$$test(\mu(T'_1), \ldots, \mu(T'_k), \alpha) = test(\mu(T'_1), \ldots, \mu(T'_{k-1}), \alpha - 1),$$

i.e., $test(T'_1 + \cdots + T'_k, \alpha) = test(T'_1 + \cdots + T'_{k-1}, \alpha - 1)$.

The validity of a) and b) is due to Proposition 3.9, and that of c) and d) is due to Lemma 3.11.

After every application of test it might be required to sort the remaining sequences of complements. The worst case is if the first coordinate of $\mu(T'_k)$ is deleted for which the correct place of $\mu(T'_k)$ among the k sequences can be found in $w(T) \log w(T)$ comparisons. The time needed to compute $test(T'_1 + \cdots + T'_k, \alpha)$ is therefore $O(w^2(T) \log w(T))$.

We compute the cost $w(T'_1 + \cdots + T'_k)$ by binary searching for the correct α in the range $w(T'_k), \ldots, w(T'_k) + k - 1$. This may require $\log k$ applications of $test()$, Hence the maximal number of steps needed to compute the exact α is $O(w^2(T) \log^2 w(T))$ (not including the sorting of phase 1).

Note that the computation of $w(T'_1 + \cdots + T'_k)$ also determines λ_T at the same time (as implied by Lemma 3.11).

3. After determining the exact cost $\alpha = w(T) = \mu_0(T)$, we proceed to find the next component of $\mu(T)$ according to the two cases of Lemma 3.11.
(a) if $w(T) = w(T'_k)$, then $\lambda_T = \lambda_{T'_k}$ and $\mu(T)_1 = w(T'_1 + \cdots + T'_{k-1} + (T'_k - \lambda_{T'_k}))$;
(b) if $w(T) > w(T'_k)$, then $\lambda_T = root(T'_k)$ and $\mu(T)_1 = w(T'_1 + \cdots + T'_{k-1})$.
In this way we find each entry of $\mu(T)$. Note that resorting $\mu(T'_1), \ldots, \mu(T'_k - \lambda_{T'_k})$ is done in $w(T) \log w(T)$ steps; therefore the whole process takes $O(w^3(T) \log^3 w(T))$ steps.

THEOREM 4.1. *Let T be a tree with n nodes; then $\mu(T)$ and λ_T can be computed in $O(n \cdot w^3(T) \log w^3(T)) = O(n^4 \log^3 n)$ steps.*

Proof. We compute $\mu(T)$ by constructing T from subtrees working bottom up, starting from the leaves to the root. At each intermediate step we compute $\mu(T_1)$ for a subtree T_1 in $O(w^3(T) \log^3 w(T))$ steps using the above algorithm. Thus the whole process for a tree T with $|T| = n$ takes at most $O(n \cdot w^3(T) \log^3 w(T))$ steps. For bounded degree trees where $w(T) = O(\log n)$ this gives $O(n \log^4 n)$. For general trees this might be $O(n^4 \log^3 n)$. Note that each time we compute $w(T^i)$ of a subtree T^i, we also determine λ_{T^i}. Thus λ_T is computed in the same time bound, and an optimal search algorithm can be constructed. ∎

An example of the main stages of the algorithm is given in the appendix.

5. Search in forests and Cartesian products posets.

Forests. Our results hold for forests as well. Recall that in our model we assumed that one of the nodes in the given tree must be buggy. Let $\tilde{w}(T_1, T_2, \ldots, T_k)$ denote the cost of searching in a forest with k trees, where we do not assume that one of the nodes in $T_1, \ldots, T_k$ is buggy. It is easy to see that $\tilde{w}(T_1, T_2, \ldots, T_k) = w(T'_1 + T'_2 + \cdots + T'_k)$, where $T'_1 + T'_2 + \cdots + T'_k$ is the grouping operation defined in section 3. The reason is that if none of the nodes in the forest is buggy, then an optimal search algorithm will identify the root of $(T'_1 + T'_2 + \cdots + T'_k)$ as the buggy node. On the other hand $T'_1 + T'_2 + \cdots + T'_k$ can be searched by applying a search algorithm for the forest $T_1, T_2, \ldots, T_k$; if this search gives as a result "no buggy element," then the answer for $T'_1 + T'_2 + \cdots + T'_k$ is its root.

Rooted Cartesian products. A rooted poset is a poset with unique greatest element.

CLAIM 5.1. *Let P_1, P_2 be two rooted posets and let $P = P_1 \times P_2$ be the (rooted) product poset of P_1 and P_2. Then $w(P) \leq w(P_1) + w(P_2)$.*

Proof. One may search P by first querying (a, x), where a is the greatest element of P_1 and x is optimal first query for P_2. This results in either searching in $P_1 \times P_2(x)$ or $P_1 \times (P_2 - P_2(x))$, where $P_2(x)$ is the poset of all elements below x in P_2. Going on in this way by following the optimal strategy for P_2 for at most $w(P_2)$ queries we are left with a sub-poset that is isomorphic to P_1 for which additional $w(P_1)$ queries is enough.

As it is clear that $w(P) \geq max(w(P_1), w(P_2))$, the above observation gives $w(P)$ up to a factor of two.

An interesting example (the simplest nontrivial) of a rooted product is a product of two chains which is a rectangular lattice. □

CLAIM 5.2. *Let P_1, P_2 be disjoint chains and let $P = P_1 \times P_2$. Then $w(P_1) + w(P_2) - 2 \leq w(P) \leq w(P_1) + w(P_2)$.*

Proof. The upper bound follows from Claim 5.1. The lower bound follows from the fact that $w(L) \geq \lceil \log |P| \rceil$. If one or both lengths of P_1, P_2 is a power of 2, then in fact $\lceil \log |P| \rceil$ is the exact answer.

It is interesting to confront the above with the result of [5] for the Cartesian products of chains for their model. Let P_n be the n element chain. In both models $w(P_n) = \lceil \log n \rceil$. However, in the Linial–Saks model $w(P_n \times P_n) = 2n - 1$, while in our model $w(P_n \times P_n) = 2\lceil \log n \rceil$. □

6. Conclusions. We have presented a polynomial time algorithm for computing the optimal search strategy for forest-like Posets. The crux of the proof, and the algorithm, is the observation that the structure of a given tree T can be represented by a sequence of numbers $\mu(T)$. As an example, the cost of an optimal search of a complete binary tree (T) with n nodes is $\log n + \log^* n + \theta(1)$. We do not know any direct method for proving this result rather than computing $\mu(T)$ recursively (following our algorithm).[1]

Some problems are left open.

1. The main open problem is to give an algorithm that determines the cost (optimal strategy) for general posets (namely, searching in directed acyclic graphs).
2. The randomized complexity is quite interesting, too. For a given tree T and any buggy node, can one do better on the average using a randomized search algorithm? (A randomized search algorithm can be viewed as a probability distribution on a set of deterministic search algorithms.) For example, let T be a rooted star with n leaves; then it is easy to see that any randomized search algorithm will pay, on the average, n queries. The reason is that an adversary will put the "bug" in the root of the star, using the fact that any deterministic algorithm must query all the leaves first (this corresponds to the fact that the nondeterministic complexity of the star of n leaves is n). Randomization can help for some trees. For example, for d regular tree of height h, $w(T) = h \cdot d$ while its randomized complexity is $\leq \frac{d \cdot (h+1)}{2}$. Our conjuncture is that for every tree T, its randomized complexity is at least $\frac{1}{2} w(T)$.
3. While our algorithm gives the exact cost for any tree, it would be interesting to prove tight upper and lower bounds as a function of some natural property

[1] Further details are left to the reader.

of the tree. For example, $\log size(T)$ and d are lower bounds, where d is the maximal degree of T. However, none of these is tight in general. Another example is that for trees with maximum degree d, $\log_{\frac{d+1}{d}} size(T)$ is an upper bound, simply demonstrated by querying a node that splits the tree into two parts of size $\leq \frac{d}{d+1} size(T)$ each.

4. For the product of rooted posets we have seen that the cost is at most the sum of the costs. Is this tight (up to an additive $O(1)$ term) for every rooted product?

7. Appendix.

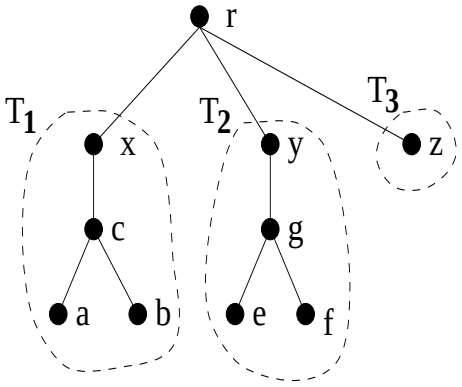

FIG. 7.1.

7.1. A detailed example of the algorithm. This section contains a detailed example showing the main phases of the algorithm combing three subtrees $T = T_3' + T_2' + T_1'$ as described in Figure 7.1. In early stages, the algorithms have computed $\mu(T_i'), \lambda_{T_i'},\ i = 1, 2, 3$, such that

$$\mu(T_1') = [3,1,0]\ \lambda_{T_1'} =' c',\quad \mu(T_2') = [3,1,0]\ \lambda_{T_2'} =' g',\quad \mu(T_3') = [1,0]\ \lambda_{T_3'} =' z'.$$

We proceed according to the three stages of the grouping operation in the algorithm to compute $\mu(T)$. After sorting the vectors of complements we obtain (the number of subtrees is $k = 3$) the possible cost of $w(T)$ is $3 \leq w(T) \leq 3 + 2 = 5$. Next, $test(T_3' + T_2' + T_1', \alpha)$ is applied for $\alpha = 4$ and is computed as follows (the label on the arrow $\xrightarrow{x)}$ denotes one of the four cases of $test()$ as described in section 4):

$$\begin{bmatrix} test(T_3' + T_2' + T_1', 4) \\ \mu(T_1') = [3,1,0] \\ \mu(T_2') = [3,1,0] \\ \mu(T_3') = [1,0] \end{bmatrix} \xrightarrow{d)} \begin{bmatrix} test(T_3' + T_2', 3) \\ \mu(T_2') = [3,1,0] \\ \mu(T_3') = [1,0] \end{bmatrix}$$

$$\xrightarrow{c)} \begin{bmatrix} test(T_3' + T_2' - \lambda_{T_2'}, 2) \\ \partial\mu(T_2') = [1,0] \\ \mu(T_3') = [1,0] \end{bmatrix} \xrightarrow{a)} TRUE.$$

We continue to check if $w = 3$ using

$$\begin{bmatrix} test(T_3' + T_2' + T_1', 3) \\ \mu(T_1') = [3,1,0] \\ \mu(T_2') = [3,1,0] \\ \mu(T_3') = [1,0] \end{bmatrix} \xrightarrow{c)} \begin{bmatrix} test(T_3' + T_2' + T_1' - \lambda_{T_1'}, 2) \\ \partial\mu(T_1') = [1,0] \\ \mu(T_2') = [3,1,0] \\ \mu(T_3') = [1,0] \end{bmatrix} \xrightarrow{b)} FALSE.$$

Hence, we have computed the first component in the vector of complements, namely, $\mu(T)_0 = 4$.

The second coordinate, $\mu(T)_1$, is obtained by computing $w(T'_3 + T'_2)$ since $\lambda_T = root(T_1)$ and the complement is $T'_3 + T'_2$. The possible range for $\mu(T)_1$ is $3 \leq \mu(T)_1 \leq 3 + 2 - 1 = 4$. However, "true" is obtained for the minimal value $\mu(T)_1 = 3$,

$$\begin{bmatrix} test(T'_3 + T'_2, 3) \\ \mu(T'_2) = [3, 1, 0] \\ \mu(T'_3) = [1, 0] \end{bmatrix} \xrightarrow{c)} \begin{bmatrix} test(T'_3 + T'_2 - \lambda_{T'_2}, 2) \\ \partial\mu(T'_2) = [1, 0] \\ \mu(T'_3) = [1, 0] \end{bmatrix} \xrightarrow{a)} TRUE,$$

and we get that $\mu(T)_1 = 3$. The third coordinate is computed in a similar way, namely, $1 \leq \mu(T)_2 \leq 1 + 2 - 1 = 2$, yet

$$\begin{bmatrix} test(T'_3 + T'_2 - \lambda_{T'_2}, 1) \\ \partial\mu(T'_2) = [1, 0] \\ \mu(T'_3) = [1, 0] \end{bmatrix} \xrightarrow{c)} \begin{bmatrix} test(T'_3, 0) \\ \mu(T'_3) = [1, 0] \end{bmatrix} \xrightarrow{b)} FALSE;$$

hence $\mu(T)_2 = 2$.

The set of nodes that were used in the different stages of $test(T'_3 + T'_2 + T'_1, 4)$ forms the backbone of the optimal search algorithm, i.e.,

$$\begin{array}{rccccccc} Q_T = & x & \xrightarrow{\text{no}} & g & \xrightarrow{\text{no}} & z & \xrightarrow{\text{no}} & y \xrightarrow{\text{no}} \quad r\ . \\ & \downarrow & & \downarrow & & \downarrow & & \downarrow \\ & Q_{T_1} & & Q_{T(g)} & & z & & y \end{array}$$

WEAK RANDOM SOURCES, HITTING SETS, AND BPP SIMULATIONS*

ALEXANDER E. ANDREEV†, ANDREA E. F. CLEMENTI‡, JOSÉ D. P. ROLIM§, AND LUCA TREVISAN¶

Abstract. We show how to simulate any BPP algorithm in polynomial time by using a weak random source of r bits and min-entropy r^γ for any $\gamma > 0$. This follows from a more general result about *sampling* with weak random sources. Our result matches an information-theoretic lower bound and solves a question that has been open for some years. The previous best results were a polynomial time simulation of RP [M. Saks, A. Srinivasan, and S. Zhou, *Proc. 27th ACM Symp. on Theory of Computing*, 1995, pp. 479–488] and a quasi-polynomial time simulation of BPP [A. Ta-Shma, *Proc. 28th ACM Symp. on Theory of Computing*, 1996, pp. 276–285].

Departing significantly from previous related works, we do not use extractors; instead, we use the OR-disperser of Saks, Srinivasan, and Zhou in combination with a tricky use of hitting sets borrowed from [Andreev, Clementi, and Rolim, *J. ACM*, 45 (1998), pp. 179–213].

1. Introduction.

Randomized algorithms are often the simplest ones that can be used to solve a given problem, or the most efficient, or both (see [MR95]). For some problems, including primality testing and approximation of #P-complete counting problems, only randomized solutions are known.

The practical applicability of such randomized methods depends on the effective possibility for an algorithm to access *truly random bits*. Since it is questionable whether truly random sources really exist, much research has been devoted in the last decade to finding weaker notions of randomness that are still sufficient to run BPP algorithms in polynomial time [VV85, SV86, V86, V87, CG88, Z90]. Several definitions of *weak random source* have been proposed in the literature, the most general being the following [CG88, Z90]: for $\gamma > 0$, an (r, r^γ)-source is a random source that outputs a string in $\{0,1\}^r$, and no string has probability of being output larger than 2^{-r^γ} (such an object is also called *random source of min-entropy* r^γ). An information-theoretic argument shows that a black-box simulation of BPP using an $(r, r^{o(1)})$-source is impossible when r is polynomial in the number of random bits used by the simulated algorithm.

Dispersers and extractors. The usual method of simulating a BPP algorithm using a weak random source is as follows. Say that, for a given input, the algorithm

requires m (truly) random bits; then we ask the source r bits (note that only one access to the weak random is required), and we use them to produce a sample space (a set of m-bit strings). Such strings are fed into the algorithm, and then the majority rule is used to decide whether to accept or reject. The procedure that computes the sample space starting from the output of the source is *independent* of the algorithm that we want to derandomize. This simulation is basically equivalent [Z90, Z96, NZ96, SZ94, SSZ95, T96] to a bipartite graph $G = (V, W, E)$ having 2^r nodes in the left component V, 2^m nodes in the right component W, and degree d, and such that if we select a node v in the left component according to an (r, r^γ)-source and then a random neighbor of v, the induced distribution in W is ϵ-close to the uniform distribution over W. Such a graph is a $(2^r, 2^m, d, r^\gamma, \epsilon)$-*extractor*. The left nodes are seen as possible outcomes of the random source and the right nodes as possible random strings for the algorithm to be simulated. The simulation amounts to selecting a node on the left side according to the weak random source and then selecting as sample space the set of its neighbors. If, for some fixed γ, one could achieve d and r polynomial in m, then a polynomial time simulation of BPP would be possible, using an (r, r^γ)-source. However, the best present construction of extractors for fixed $\gamma > 0$ and $r = \text{poly}(m)$ has $d = n^{log^{(k)}n}$ [T96]. This implies a quasi-polynomial time simulation of BPP. A polynomial-time simulation of BPP, using weak random sources of min-entropy r^γ for any fixed $\gamma > 0$, was one of the major open questions in the field.

It is not difficult to show that, to simulate RP by means of a weak random source, *OR dispersers* [CW89] (from now on, we will simply call them *dispersers*) are sufficient. A $(2^r, 2^m, 2^{r^\gamma})$-disperser is again a bipartite graph $G = (V, W, E)$ with parameters r, m, and d as before, but now the property is that for any set $V' \subseteq V$ of at least 2^{r^γ} vertices on the left side and any set $W' \subseteq W$ of more than $2^m/2$ vertices on the right side, there is at least one edge joining V' and W'. This construction is somewhat easier to obtain, and indeed Saks, Srinivasan, and Zhou [SSZ95] give a disperser with $d = \text{poly}(n)$, for any constant $\gamma > 0$, allowing for a polynomial time simulation of RP.

See [N96] for a complete survey on extractors, dispersers, and weak random sources.

Pseudorandom generators and hitting sets. A more ambitious goal than simulating BPP with weak random sources is the *deterministic* simulation of BPP. Research on this subject tries to isolate reasonable complexity assumptions under which deterministic simulations of randomized algorithms are possible [Y82, BM84, N90, BFNW93, NW94, IW97, ACR97].

In some cases, combinatorial objects developed in the study of weak random sources have been used to give derandomization [NZ96]. Here we reverse this connection and use a derandomization method to take full advantage of a weak random source.

Two basic combinatorial objects are studied in the theory of derandomization: pseudorandom generators (whose efficient construction immediately implies a deterministic simulation of BPP) and hitting-set generators (whose efficient construction allows us to simulate RP algorithms). Informally speaking, in the context of derandomization, pseudorandom generators play the role of extractors and hitting-set generators play that of dispersers. A recent result of Andreev, Clementi, and Rolim [ACR98] shows how to deterministically simulate BPP algorithms by using hitting set generators. This suggests that perhaps dispersers could be used to simulate BPP with weak random sources.

A *quick δ-hitting set generator* (quick δ-HSG) is an algorithm that, given a pa-

rameter n, finds in poly(n) time a set $H_n \subseteq \{0,1\}^*$ such that, for any finite Boolean function f of circuit complexity n, if $\mathbf{Pr}_x[f(x) = 1] > \delta$, then $f(a) = 1$ for some $a \in H_n$,[1] where the probability is taken uniformly over $\{0,1\}^n$. The main technical result of [ACR98] can be stated as follows.

LEMMA 1 (see [ACR98]). *For any choice of constants $\epsilon, \delta > 0$, there is a deterministic algorithm that, given access to a quick δ-HSG and given in input any circuit C of size n, returns in* poly(n) *time a value D such that $|\mathbf{Pr}_x[C(x) = 1] - D| \leq \epsilon$, where the probability is taken uniformly over all possible $x \in \{0,1\}^n$.*

Lemma 1 immediately implies the following general derandomization result.

THEOREM 2. *If for some $\delta > 0$ a quick δ-HSG exists, then $P = BPP$.*

Andreev et al. [ACR98] prove Lemma 1 by constructing a set S of size poly(n) that is ϵ-discrepant for C, i.e., such that $\mathbf{Pr}_{x \in S}[C(x) = 1]$ approximates the value $\mathbf{Pr}_x[C(x) = 1]$ up to an additive error ϵ. A basic ingredient is the definition of a *discrepancy test* that, given a circuit C, a "candidate" set S, and a parameter ϵ, tests whether S is ϵ-discrepant for C. The test also needs an auxiliary set H in input, and, provided that H has a certain hitting property, the test is "sound;" that is, if the set S is accepted, then S is ϵ-discrepant for C. The fact that the test is sound only if the auxiliary set H is hitting is not a major restriction—since we are assuming that a hitting-set generator exists, we can use it to generate H. Thus, proving the theorem amounts to find a set S that passes the test. This task is solved in [ACR98] by means of a rather involved (and inherently sequential) algorithm. The algorithm indeed proves a somewhat stronger result than Lemma 1 and has also been used in [ACR97] in a different context. For the sake of proving Lemma 1, it might however be overkill.

Our results. We show how to use *dispersers* and weak random sources to simulate BPP in polynomial time and to even solve a more general *sampling* problem.

The sampling problem we are interested in is as follows: Given oracle access to a function $f : \{0,1\}^n \to \{0,1\}$ and a weak source of randomness, we want to find a set S of size poly(n) that with high probability is ϵ-discrepant for f. It should be clear that simulating a given BPP algorithm reduces to the above problem: the computation of a BPP algorithm on a fixed input is an (easy to compute) function f of the outcomes of the random coins. Being able to approximate the fraction of random coin outcomes that make f accept, allows us to decide whether or not the algorithm accepts the input.

We show that dispersers are sufficient for the above sampling problem. The starting point is the observation that, using a disperser and a weak random source, it is possible to generate polynomially many small sets $S_1, \ldots, S_k$ and $H_1, \ldots, H_k$ such that, with high probability, one of the S_i's is ϵ-discrepant for f and one of the H_i's has the hitting property required by the discrepancy test (see Theorem 21). Then, we define $H = \bigcup H_i$. Since the hitting property is *monotone* (adding elements to a set cannot decrease its hitting properties), we have that H will be a hitting set with high probability. We can thus run the discrepancy test on the sets $S_1, \ldots, S_k$, using H as the reference hitting set. We shall then prove that, with high probability, one of the S_i's will pass the test and thus be ϵ-discrepant for f as required.

The main difference between our method and the extractor-based method (mentioned at the beginning) is that the ϵ-discrepant set that is given in output *depends on* the specific function f that is accessed as oracle. The source of this nonobliviousness is the selection of a good set S_j among the candidates $S_1, \ldots, S_k$. As a result,

[1] In the next section we will give a seemingly weaker (but in fact equivalent) formal definition.

our sampling algorithm is not *oblivious* according to the definition of Bellare and Rompel [BR94]; however, it is *nonadaptive*. See [G97] for definitions of these notions and for a survey on sampling.

Our main result can be stated in the following way.

THEOREM 3 (main theorem). *For any $\gamma > 0$, there exist a polynomial p and a deterministic algorithm A such that the following holds. For any $\epsilon > 0$, $n > 0$, any $(p(n/\epsilon), p(n/\epsilon)^\gamma)$-source X, and any $f : \{0,1\}^n \to \{0,1\}$, on input (ϵ, n, X) and oracle access to f, A computes, in time polynomial in n/ϵ, a value D such that with probability at least $1 - 2^{-\mathrm{poly}(n)}$ over the outcomes of the source,*

$$|\mathbf{Pr}_x[f(x) = 1] - D| \leq \epsilon.$$

Note that since the algorithm runs in polynomial time it will make $\mathrm{poly}(n/\epsilon)$ queries to f.

COROLLARY 4. *For any $\gamma > 0$, any BPP algorithm can be simulated in polynomial time, using an (r, r^γ)-source.*

The idea of generating candidate discrepancy sets $S_1, \ldots, S_k$ and then applying the discrepancy test to them also yields a simple proof of Lemma 1. This simplified proof is presented in a preliminary version of this paper [ACRT97] and also in an appendix of the final version of [ACR98]. More recently, Fortnow has observed that an even simpler proof of Theorem 2 can be given by using a previous result of Lautemann [L83]. Fortnow's proof of Theorem 2 does not use the discrepancy test. To the best of our understanding, this new proof does not extend to the context of dispersers and weak random sources, and it seems that we still need the discrepancy test in order to prove Theorem 3. An additional, and fairly surprising result observed by Fortnow is that BPP can be simulated by an RP machine having oracle access to a promise-RP problem. We present both of Fortnow's results in section 5.

Overview of the paper. We give some definitions in section 2. In section 3 we describe the discrepancy test and its properties. In section 4 we prove Theorem 3. Fortnow's proof of Theorem 2 is presented in section 5. Section 6 is devoted to some concluding remarks.

2. Preliminaries. Unless otherwise stated, probabilities are with respect to the uniform distribution. For any positive integer n we denote by $\mathcal{F}_n$ the set of all n-ary Boolean functions $f : \{0,1\}^n \to \{0,1\}$. For a vector $a \in \{0,1\}^n$, and a function $f : \{0,1\}^n \to \{0,1\}$, we define a function $f^{\oplus a} : \{0,1\}^n \to \{0,1\}$ as $f^{\oplus a}(x) = f(x \oplus a)$.

We say that a Boolean function f *accepts* x if $f(x) = 1$.

DEFINITION 5 (weak random source). *A probability distribution D over the set $\{0,1\}^r$ is an (r, r^γ)-source* (weak random source of min entropy r^γ) *if, for any $x \in \{0,1\}^r$, $D(x) \leq 2^{-r^\gamma}$.*

For a vertex v of a graph $G = (V, E)$ we let $\Gamma(v) \subseteq V$ be the set of vertices that are adjacent to v. For a subset $S \subseteq V$, we define $\Gamma(S) = \bigcup_{v \in S} \Gamma(v)$. We give here a definition of dispersers which is more convenient than that given in section 1 to describe our results. It is easy to verify that the two definitions are in fact equivalent.

DEFINITION 6 (disperser). *A bipartite multigraph $G(V, W, E)$ with $|V| = R$ and $|W| = N$ is said to be an (R, N, T)-disperser if, for any subset $S \subseteq V$ such that $|S| \geq T$, it holds that $\Gamma(S) \geq N/2$.*

DEFINITION 7 (circuit complexity). *For a Boolean function $f : \{0,1\}^n \to \{0,1\}$ we denote by $L(f)$ the minimum size of a circuit computing f (here, for* circuit *we mean* a circuit whose gates have fan-in at most 2 and arbitrary fan-out*).*

DEFINITION 8 (Kolmogorov complexity). *Let us fix a universal Turing machine U with alphabet $\{0,1\}$ for programs allowing oracle queries. Given two Boolean functions $f : \{0,1\}^k \to \{0,1\}$ and $g : \{0,1\}^n \to \{0,1\}$, we define the* conditional Kolmogorov complexity of g given f, *denoted $K_U(g|f)$, as the length of the shortest program for U that evaluates g having oracle access to f.*

For example, $K_U(f|f) = O(1)$. As usual, if we fix another universal Turing machine U', it holds that $K_{U'}(g|f) = K_U(g|f) + \Theta(1)$. We will usually omit the subscript. See, e.g., [LV90] for an introduction to Kolmogorov complexity. In this paper we use only the obvious fact that, for any fixed f, the number of functions g such that $K(g|f) \leq k$ is at most 2^k.

DEFINITION 9 (hitting set). *A (multi)set $H \subseteq \{0,1\}^n$ is said to be δ-hitting for a family of functions $\mathcal{G} \subseteq \mathcal{F}_n$ if, for any $f \in \mathcal{G}$ with $\mathbf{Pr}_x[f(x) = 1] > \delta$, there exists $x \in H$ such that $f(x) = 1$.*

Recall that by our convention $\mathbf{Pr}_x(\cdot) = \mathbf{Pr}_{x \in \{0,1\}^n}(\cdot)$.

DEFINITION 10 (discrepancy set). *A (multi)set $S \subseteq \{0,1\}^n$ is said to be ϵ-discrepant for a family of functions $\mathcal{G} \subseteq \mathcal{F}_n$ if, for any $f \in \mathcal{G}$,*

$$|\mathbf{Pr}_{x \in S}[f(x) = 1] - \mathbf{Pr}_x[f(x) = 1]| \leq \epsilon.$$

Note that if a set is ϵ-discrepant for a family $\mathcal{G}$, then it is also ϵ-hitting for $\mathcal{G}$, but the converse is not necessarily true.

The definition below is a slight variant of the definition of *quick δ-HSG of price $O(\log n)$* given in [ACR98].

DEFINITION 11 (hitting-set generator). *A quick δ-HSG is a polynomial-time algorithm $\mathcal{H}$ that, on input a number n in unary, returns a multiset $\mathcal{H}(n) \subseteq \{0,1\}^n$ that is δ-hitting for the set $\{f : \{0,1\}^n \to \{0,1\} : L(f) \leq n\}$.*

It may seem awkward to restrict the above definition to functions having circuit complexity equal to the number of inputs. However, any n-ary function of circuit complexity N can be seen as a N-ary function of circuit complexity N whose value is independent of $N - n$ of its inputs. (This point of view does not change the fraction of satisfying inputs as long as we consider constant fractions as done below.) As a consequence of this observation, the set $\mathcal{H}(n)$ returned by the HSG hits *any* function of circuit complexity at most n.

Using straightforward amplification, it is easy to show the following useful property of HSGs.

LEMMA 12 (see [ACR98]). *Let $\delta(n)$ and $k(n)$ be polynomial-time computable functions such that $0 < \delta(n) < 1$ and $k(n) \leq \mathrm{poly}(n)$. Then if a quick $(1-\delta(n))$-HSG exists, there also exists a quick $(1 - (\delta((k(n)+1) \cdot n))^{1/k(n)})$-HSG. In particular, for any two constants $0 < \delta, \delta' < 1$, if there exists a quick δ-HSG, then there exists a quick δ'-HSG.*

Proof. We use the standard *sequential repetition* method. For an input n, $\mathcal{H}'$ first computes (using $\mathcal{H}$) a set $H \subseteq \{0,1\}^{(k(n)+1) \cdot n}$ that is $(1 - \delta((k(n)+1) \cdot n))$-hitting for all the functions $g : \{0,1\}^{(k(n)+1)n} \to \{0,1\}$ such that $L(g) \leq (k(n)+1)n$. Then, it generates a set $H' \subseteq \{0,1\}^n$ by "parsing" each element of H into $k(n)+1$ strings of length n.

We claim that H' is $(1 - (\delta((k(n)+1) \cdot n))^{1/k(n)})$-hitting for functions of circuit size n. Let $f : \{0,1\}^n \to \{0,1\}$ be such that $L(f) \leq n$ and

$$\mathbf{Pr}_x[f(x) = 1] \;>\; 1 - (\delta((k(n)+1) \cdot n))^{1/k(n)}.$$

DISC-TEST(f, S, H, ϵ)
begin
  $p_{\min} := \min\{p(a, f, S) : a \in H \cup \{\vec{0}\}\}$;
  $p_{\max} := \max\{p(a, f, S) : a \in H \cup \{\vec{0}\}\}$;
  if $p_{\max} - p_{\min} \leq \epsilon$ **then return** (1)
  else return (0)
end

FIG. 1. *The discrepancy test.*

Let $f^k : \{0,1\}^{(k(n)+1)n} \to \{0,1\}$ be the function that takes $k(n)+1$ strings of $\{0,1\}^n$ and whose value is 1 if and only if f evaluates to 1 on at least one of the first $k(n)$ strings. Note that $L(f^k) \leq k(n)L(f) + k(n) = k(n) \cdot (n+1)$. We have

$$\mathbf{Pr}_y[f^k(y) = 1] \;=\; 1 - (\mathbf{Pr}_x[f(x) = 0])^{k(n)} \;>\; 1 - \delta((k(n)+1) \cdot n).$$

Due to its hitting property, H contains an input that satisfies f^k and thus H' contains an input that satisfies f. The main claim follows.

For the second claim, if $\delta' \geq \delta$, then there is nothing to prove since, by definition, a δ-HSG is also a δ'-HSG for any $\delta' \geq \delta$. If $\delta' < \delta$, then we take a large enough k such that $\delta' \geq (1 - (1-\delta)^{1/k})$ and then we use the main claim. □

Observe that by applying Lemma 12 with $k(n) = \text{poly}(n)$, it is possible to show that, for any $0 < \epsilon < 1$, the existence of a quick $(1 - 2^{-n^{1-\epsilon}})$-HSG implies the existence of a quick $(1/\text{poly}(n))$-HSG. By using random walks on expander graphs instead of simple repetition, Andreev, Clementi, and Rolim [ACR97] show that, for $c > 1/2$, even the existence of a $(1 - 2^{-cn})$-HSG is an equivalent condition.

3. The discrepancy test. In this section we describe the discrepancy test from [ACR98]. We present a slight variation of the proof of [ACR98] that the test is sound and also prove a "completeness" property of the test.

For any vector $a \in \{0,1\}^n$, function $f : \{0,1\}^n \to \{0,1\}$, and set $S \subseteq \{0,1\}^n$, define

$$p(a, f, S) = \mathbf{Pr}_{x \in S}[f(x \oplus a) = 1]. \tag{1}$$

For any two subsets $S, H \subseteq \{0,1\}^n$, constant $\epsilon > 0$, and function $f : \{0,1\}^n \to \{0,1\}$, we define in Figure 1 a discrepancy test, denoted DISC-TEST(f, S, H, ϵ). In this test, the set S is tested to be ϵ-discrepant for f by using the auxiliary (hitting) set H.

THEOREM 13 (soundness of DISC-TEST [ACR98]). *A constant c_1 exists such that, for any $\epsilon > 0$, integer n, function $f : \{0,1\}^n \to \{0,1\}$, and sets $S, H \subseteq \{0,1\}^n$, if* DISC-TEST$(f, S, H, \epsilon) = 1$ *and H is δ-hitting for the set of functions g such that $K(g|f) \leq c_1 \cdot |S| \cdot n$, then S is $(\epsilon + \delta)$-discrepant for f.*

Theorem 13 is the core of the results of [ACR98]. Note that it says that a set H with a certain *one-sided* pseudorandom property (the hitting property) can be used to test S for a *two-sided* pseudorandom property (the discrepancy property). However, H has to be hitting for *a whole set* of functions while S is tested for discrepancy *on a single function* (i.e., f). Therefore, roughly speaking, the theorem trades off "globality" and "two-sidedness." The version of Theorem 13 proved in [ACR98] requires f to be computable by a small circuit and H to be δ-hitting for a family of functions of low circuit complexity. Here we have no requirement on f, and H is required to be hitting for a set of functions directly "related" to f.

```
function BAD(a)
constants
  p_min, p_max, m;
  s_1, ..., s_m;
begin
  count := 0;
  for i := 1 to m do
    count := count + f(a ⊕ s_i);
  if count > m p_max or count < m p_min then
    return (1)
  else
    return (0)
end.
```

FIG. 2. *How to compute* BAD. *The algorithm has oracle access to* f. *It first computes the number of* 1*s of* $f(a \oplus s_i)$ *for* $i = 1, \ldots, m$ *and then decides whether to accept or reject by comparing this number with* $p_{\min}$ *and* $p_{\max}$.

Proof of Theorem 13. Let f, $S = \{s_1, \ldots, s_m\}$, H, ϵ be fixed throughout the proof, and suppose H is δ-hitting for all gs with $K(g|f) \leq c_1 mn$. Let us define the function $\text{BAD} : \{0,1\}^n \to \{0,1\}$ as

$$\text{BAD}_{f,S,H}(a) \stackrel{\text{def}}{=} \text{BAD}(a) = \begin{cases} 0 & \text{if } p_{\min} \leq p(a,f,S) \leq p_{\max}, \\ 1 & \text{otherwise,} \end{cases}$$

where $p_{\min}$ and $p_{\max}$ are as defined in Figure 1.

CLAIM 14. $K(\text{BAD}|f) \leq mn + 2\log m + O(1)$.

Proof. We observe that BAD can be computed with the pseudocode depicted in Figure 2.

Let us bound the length of such a program. All the elements of S have to be defined explicitly, and this can be done by using mn bits; $p_{\min}$ and $p_{\max}$ have to be defined too, and since they are integral multiples of $1/m$, $\log m$ bits are sufficient to encode each of them. The rest of the program has constant length. We can conclude that the total length of the program is $mn + 2\log m + O(1)$. □

We fix c_1 large enough so that, using the hypothesis of the theorem, H is δ-hitting for BAD.

CLAIM 15. $\mathbf{Pr}_{a \in \{0,1\}^n}[\text{BAD}(a) = 1] \leq \delta$.

Proof. Assume, by contradiction, that $\mathbf{Pr}_{a \in \{0,1\}^n}[\text{BAD}(a) = 1] > \delta$. Then by the hitting property of H, there exists some $a \in H$ such that $\text{BAD}(a) = 1$, which is impossible by definition of BAD, $p_{\min}$ and $p_{\max}$ (as for any $a \in H$, we have $p_{\min} \leq p(a,f,S) \leq p_{\max}$). □

Let $\mathbf{E}[p(a,f,S)]$ be the average of $p(a,f,S)$ over all the choices of $a \in \{0,1\}^n$.

CLAIM 16. $\mathbf{E}[p(x,f,S)] = \mathbf{Pr}_x[f(x) = 1]$.

Proof.

$$\begin{aligned} \mathbf{E}[p(x,f,S)] &= \mathbf{Pr}_{x \in \{0,1\}^n,\ y \in S}[f(x \oplus y) = 1] \\ &= \frac{1}{|S|} \sum_{y \in S} \mathbf{Pr}_x[f(x \oplus y) = 1] \\ &= \frac{1}{|S|} \sum_{y \in S} \mathbf{Pr}_x[f(x) = 1] \end{aligned}$$

$$= \mathbf{Pr}_x[f(x) = 1] \,. \qquad \square$$

From Claim 15 we have the following inequalities (where the first term is due to a's for which $\text{BAD}(a) = 0$ and the second term is due to the rest):

$$\mathbf{E}\,[p(a, f, S)] \leq (1 - \delta) \cdot p_{\max} + \delta \cdot 1 \leq p_{\max} + \delta, \tag{2}$$

$$\mathbf{E}\,[p(a, f, S)] \geq (1 - \delta) \cdot p_{\min} \geq p_{\min} - \delta. \tag{3}$$

Recall that whenever the test accepts, $p_{\max} - p_{\min} \leq \epsilon$. Also, by definition,

$$p_{\min} \leq p(0, f, S) = \mathbf{Pr}_{x \in S}[f(x) = 1] \leq p_{\max}.$$

By Claim 16 and (2), we obtain

$$\mathbf{Pr}_x[f(x) = 1] - \mathbf{Pr}_{x \in S}[f(x) = 1] \leq (p_{\max} + \delta) - p_{\min} \leq \epsilon + \delta,$$

and, similarly,

$$\mathbf{Pr}_{x \in S}[f(x) = 1] - \mathbf{Pr}_x[f(x) = 1] \leq p_{\max} - (p_{\min} - \delta) \leq \epsilon + \delta.$$

Thus, S is indeed $(\epsilon + \delta)$-discrepant for f, and Theorem 13 follows. $\square$

We now give a sufficient condition for DISC-TEST to accept.

THEOREM 17 (completeness of DISC-TEST). *If S is $(\epsilon/2)$-discrepant for the set $\{f^{\oplus a} : a \in \{0,1\}^n\}$, then* $\text{DISC-TEST}(f, S, H, \epsilon) = 1$ *for any set $H \subseteq \{0,1\}^n$.*

Proof. Fix $H \subseteq \{0,1\}^n$ and let a_1 (respectively, a_2) be a point where $p_{\min} = p(a_1, f, S)$ (respectively, $p_{\max} = p(a_2, f, S)$).

$$\begin{aligned} p_{\min} &= \mathbf{Pr}_{x \in S}[f^{\oplus a_1}(x) = 1] \\ &\geq \mathbf{Pr}_x[f^{\oplus a_1}(x) = 1] - \epsilon/2 \\ &= \mathbf{Pr}_x[f(x) = 1] - \epsilon/2, \end{aligned}$$

where the first inequality is due to the discrepancy property of S. Similarly, we have

$$\begin{aligned} p_{\max} &= \mathbf{Pr}_{x \in S}[f^{\oplus a_2}(x) = 1] \\ &\leq \mathbf{Pr}_x[f^{\oplus a_2}(x) = 1] + \epsilon/2 \\ &= \mathbf{Pr}_x[f(x) = 1] + \epsilon/2, \end{aligned}$$

and thus $p_{\max} - p_{\min} \leq \epsilon$. $\square$

4. Proof of Theorem 3. The starting point of our proof is the following easy observation: If we have a set $I \subseteq \{0,1\}^N$ such that $\mathbf{Pr}_x[x \in I] > 1/2$, then using a weak random source and the dispersers of [SSZ95], we can generate a polynomial-sized (in N) set of vectors $x_1, \ldots, x_k$ such that, with high probability, $\{x_1, \ldots, x_k\} \cap I \neq \emptyset$. This is formalized in Corollary 19 below.

A naive way of using this fact would be to take the set I as the family of ϵ-discrepant sets S for f of size m. For large enough m ($m = O(1/\epsilon^2)$ would suffice) the set I will be such that $\mathbf{Pr}_{S \subseteq \{0,1\}^m}[S \in I] > 1/2$, and so we can use the weak random source and the disperser to generate a family of sets $S_1, \ldots, S_k$ such that, with high probability, one of them is ϵ-discrepant for f. But now the problem is that we are not able to recognize which of these sets has the discrepancy property

(note that an efficient Las Vegas algorithm to test the discrepancy property would imply $ZPP = BPP$). Theorem 13 gives indeed a way to test for discrepancy, provided that we have a hitting set at hand.

We thus define $I \subseteq \{0,1\}^{(m+M)\cdot n}$ as the family of pairs of sets (H, S) such that H has M elements and the hitting property as in the hypothesis of Theorem 13 and S has m elements and the discrepancy property as in the hypothesis of Theorem 17. As shown in Lemma 20, for an appropriate choice of m and M, the set I is such that $\mathbf{Pr}_{(H,S)}[(H,S) \in I] > 1/2$. Using the weak random source, we can thus obtain a set of pairs $(H_1, S_1), \ldots, (H_k, S_k)$ such that, for some j, the set S_j has the required discrepancy property and H_j the required hitting property (with high probability). The next important observation is that the hitting property is *monotone*, that is, if a set H has a certain hitting property and J is any set, then $H \cup J$ has at least the same hitting property of H (the reader may note that the discrepancy property is *not* monotone). As a consequence, the set $\bigcup_i H_i$ has (with high probability) the hitting property required by Theorem 13.

We start by quoting the disperser construction of Saks, Srinivasan, and Zhou.

THEOREM 18 (construction of dispersers [SSZ95]). *For any $0 < \lambda < \alpha \leq 1$, for any sufficiently large r, and for any $2^{r^\alpha} \leq T \leq 2^r$, there exists an efficient construction of a $(2^r, 2^{r^\lambda}, T)$-disperser $G = (V, W, E)$ of degree* $\mathrm{poly}(r)$.

In Theorem 17, by "efficient construction" we mean the existence of an algorithm that for any vertex of V finds its neighbors in time $\mathrm{poly}(r)$.

COROLLARY 19. *For any choice of constants $0 < \gamma < 1$ and $c > 0$ there exist a polynomial p and an algorithm A such that the following property holds. For any $n > 0$, any set $I \subseteq \{0,1\}^n$ with $|I| > 2^{n-1}$, and any $(p(n), p(n)^\gamma)$-source X, algorithm A, on input (n, X), outputs a set $C \subseteq \{0,1\}^n$ of size* $\mathrm{poly}(n^{c/\gamma})$ *such that*

$$\mathbf{Pr}[C \cap I = \emptyset] \leq 2^{-n^c},$$

where the probability is taken over the outcomes of the source.

We will use Corollary 19 by taking I as the set of pairs (S, H) such that S has a certain discrepancy property and H has a certain hitting property. Observe that algorithm A computes the set of "candidates" C without "knowing" which set I has been fixed.

Proof of Corollary 19. Fix constants α and λ such that $0 < \lambda < \alpha < \gamma$ and $n^{c\lambda} \leq n^\gamma - n^\alpha$. Let $r = n^{1/\lambda}$. Consider a $(2^r, 2^n, 2^{r^\alpha})$-disperser $G = (V, W, E)$ which can be efficiently constructed, as in Theorem 18. We identify V with $\{0,1\}^r$ and W with $\{0,1\}^n$. Let $B \subseteq V$ be the set of "bad" vertices v such that $\Gamma(v) \subseteq W - I$. We claim that $|B| < 2^{r^\alpha}$; otherwise, we reach a contradiction since, by definition of disperser, we would have $|\Gamma(B)| \geq 2^n/2$ while $|W - I| < 2^n/2$. Let us select an element v of V using an (r, r^γ)-source, and let C be the set of its neighbors. On the one hand, the probability that we picked a bad vertex $v \in B$ is at most $2^{r^\alpha} \cdot 2^{-r^\gamma} = 2^{n^{\alpha/\lambda} - n^{\gamma/\lambda}} \leq 2^{-n^c}$. On the other hand, if $v \notin B$, then $C \cap I \neq \emptyset$; the corollary thus follows. □

As preparation for using Corollary 19, we show that, for a randomly chosen pair of sets (S, H) of sufficiently large sizes, with high probability S has a certain discrepancy property and H has a certain hitting property.

LEMMA 20. *There exist two constants c_2 and c_3 such that for any $\epsilon > 0$, $n > 0$, $f : \{0,1\}^n \to \{0,1\}$, $c > 0$ and for $m = c_2 n/\epsilon^2$ and $M = c_3 cmn/\epsilon$, for a randomly chosen element (v, u) (where $v \in \{0,1\}^{Mn}$ and $u \in \{0,1\}^{mn}$) the following hold with probability larger than* $1/2$*:*

1. *v, regarded as a multiset of $\{0,1\}^n$ of size M, is $\epsilon/2$-hitting for the set of functions g such that $K(g|f) \leq cmn$;*

2. *u, regarded as a multiset of $\{0,1\}^n$ of size m, form a set that is $\epsilon/4$-discrepant for $\{f^{\oplus a} : a \in \{0,1\}^n\}$.*

Proof. It suffices to prove that each event holds with probability larger than 3/4.

Regarding the first event, the number of functions $g \in \mathcal{F}_n$ such that $K(g|f) \leq cmn$ is clearly at most 2^{cmn}. If one such g has $\mathbf{Pr}_x[g(x) = 1] \geq \epsilon/2$, then the probability that M randomly chosen elements from $\{0,1\}^n$ do not hit g is at most

$$(1 - \epsilon/2)^M \leq e^{-\epsilon M/2}.$$

Since $M = c_3 cmn/\epsilon$, it follows that, for an appropriate choice of c_3, the probability that all the functions g are hit is at least

$$1 - 2^{cmn} e^{-\epsilon M/2} > 3/4.$$

For the second claim, observe that a set of m randomly chosen elements from $\{0,1\}^n$ is not $\epsilon/4$-discrepant for a given function with probability at most $2^{-\Omega(m\epsilon^2)}$ (this follows from the Chernoff bound). Since

$$|\{f^{\oplus a} : a \in \{0,1\}^n\}| \leq 2^n,$$

we have that the probability that a randomly chosen set of $m = (1/\epsilon^2)c_2 n$ elements of $\{0,1\}^n$ is not $\epsilon/4$-discrepant for $\{f^{\oplus a} : a \in \{0,1\}^n\}$ is at most

$$2^n \cdot 2^{-\Omega(m\epsilon^2)} \leq 1/4$$

for an appropriate choice of c_2. ∎

The next theorem gives a method for generating (with high probability) a hitting set and a sequence of candidates for the discrepancy test by using the output of a weak random source.

THEOREM 21. *For any $\gamma > 0$, there exist a polynomial p and an algorithm which for any $\epsilon > 0$, $c > 0$, $n > 0$, and $(p(cn/\epsilon), p(cn/\epsilon)^\gamma)$-source X, given in input (ϵ, c, n, X) and having oracle access to a function $f : \{0,1\}^n \to \{0,1\}$, computes, in time polynomial in n/ϵ, sets $H, S_1, \ldots, S_k \subseteq \{0,1\}^n$ such that the following hold with probability at least $1 - 2^{-\mathrm{poly}(n)}$:*

1. *$|S_1| = |S_2| = \cdots = |S_k|$;*

2. *H is $\epsilon/2$-hitting for the set of functions g such that $K(g|f) \leq c|S_1|n$;*

3. *for some $j \in \{1, \ldots, k\}$, S_j is $\epsilon/4$-discrepant for the set of functions $\{f^{\oplus a} : a \in \{0,1\}^n\}$.*

We will use Theorem 21 by taking c as the constant c_1 introduced in the statement of Theorem 13 (soundness of DISC-TEST).

Proof of Theorem 21. Let us apply Corollary 19 to the set I of binary strings (u, v) satisfying properties 1 and 2 in Lemma 20. Then we can use a weak random source to generate sets $S_1, \ldots, S_k$ and $H_1, \ldots, H_k$ such that, with probability at least $1 - 2^{-\mathrm{poly}(n)}$, for some j the set S_j (respectively, H_j) has the required discrepancy (respectively, hitting) property item 2 (respectively, 1) of Lemma 20. Since the hitting property is *monotone*, we also have that, with at least the same probability, $H = \bigcup_j H_j$ is $\epsilon/2$-hitting for the set of functions g with $K(g|f) \leq c|S_1|n$. ∎

We are now ready to prove Theorem 3.

Proof of Theorem 3. We generate a set H and sets $S_1, \ldots, S_k$ as in Theorem 21. With probability at least $1 - 2^{-\mathrm{poly}(n)}$ these sets satisfy properties 1–3 of Theorem 21. From now on we assume that this is the case. We then run DISC-TEST$(f, S_i, H, \epsilon/2)$ for $i = 1, \ldots, k$, and we return S_j where j is the smallest index such that DISC-TEST(f, S_j, H, ϵ) accepts. From Theorem 17 (completeness of DISC-TEST) and condition 3 of Theorem 21 we have that at least one such index exists, and from Theorem 13 (soundness of DISC-TEST) we have that the selected set is ϵ-discrepant for f. We then output $D = \mathbf{Pr}_{x \in S}[f(x) = 1]$. □

5. A new proof of Theorem 2 and more (by Fortnow). In this section we will present a simple proof of Theorem 2 from Fortnow. We first have to introduce some new notation.

For a set S and a property Π we denote by $\exists^+ x \in S.\Pi(x)$ the statement "at least half the elements of S have property Π." A promise problem [ESY84] is a pair of disjoint sets of strings (Y, N). An algorithm A solves a promise problem (Y, N) if A accepts any element of Y and rejects any element of N. Languages can be seen as a special case of promise problems where N is the complement of Y. We denote by prRP the promise version of the class RP. That is, a promise problem (Y, N) belongs to prRP if and only if there is a polynomial-time algorithm $A(\cdot, \cdot)$ and a polynomial $p(\cdot)$ such that for any x of length n

$$x \in Y \Rightarrow \exists^+ y \in \{0,1\}^{p(n)}.A(x, y) = 1,$$
$$x \in N \Rightarrow \forall y \in \{0,1\}^{p(n)}.A(x, y) = 0.$$

We will use the following result of Lautemann [L83] (which is an improvement on a previous result by Sipser [S83]).

THEOREM 22 (Lautemann [L83]). *If $L \in BPP$, then there exists a polynomial time computable Boolean function $A(\cdot, \cdot, \cdot)$ and two polynomials $p(\cdot)$ and $q(\cdot)$ such that for any x of length n*

$$x \in L \Rightarrow \exists^+ y \in \{0,1\}^{p(n)}.\forall z \in \{0,1\}^{q(n)}.A(x, y, z) = 1,$$

$$x \notin L \Rightarrow \forall y \in \{0,1\}^{p(n)}.\exists^+ z \in \{0,1\}^{q(n)}.A(x, y, z) = 0.$$

It has been observed by Fortnow that Theorem 22 implies that $BPP \subseteq RP^{prRP}$, where we denote RP^{prRP} as the class of languages that are decidable by RP oracle machines having access to a prRP oracle.

THEOREM 23 (Fortnow). $BPP \subseteq RP^{prRP}$.

Proof. Let L be a BPP language, and let A, p, and q be as in Theorem 22. Consider the following promise problem (Y, N):

$$Y = \{(x, y) : |y| = p(|x|) \wedge \exists^+ z \in \{0,1\}^{q(n)}.[A(x, y, z) = 0]\};$$

$$N = \{(x, y) : |y| = p(|x|) \wedge \forall z \in \{0,1\}^{q(n)}.A(x, y, z) = 1\}.$$

By definition $(Y, N) \in prRP$. In Figure 3 an RP oracle algorithm that solves L by using one query to (Y, N) is described.

We now prove the correctness of the algorithm. If $x \in L$, then for at least half the choices of y we have that $(x, y) \in N$; thus the algorithm accepts with probability at least half. If $x \notin L$, then for any y we have $(x, y) \in Y$, so the algorithm accepts with probability 0. □

Theorem 2 follows from Theorem 23, since it is easy to see that if a δ-HSG exists for some constant $0 < \delta < 1$, then any RP problem and any prRP promise problem is solvable in P.

```
input : x;
begin
  Pick a random y ∈ {0,1}^{p(|x|)};
  Ask the oracle query (x, y);
  if the oracle answers YES then reject
  else accept;
end.
```

FIG. 3. *The RP^{prRP} algorithm solving a generic BPP problem.*

6. Conclusions. We have demonstrated how to simulate BPP algorithms in polynomial time by using weak random sources of r bits and min-entropy r^γ for any $\gamma > 0$.

The main novelty in our result has been the use of *dispersers* in a context where *extractors* seemed to be necessary. Extractors have other applications besides the use of weak random sources (see, e.g., [N96, Z96:stoc]). It could be the case that techniques similar to ours can give stronger results or simplified proofs in these other applications as well. It remains an open question whether it is possible, for any $\gamma > 0$ and any m, to efficiently construct a $(2^r, 2^m, d, r^\gamma, 1/7)$-extractor with r and d polynomial in m. Such a construction would provide an alternative proof of the main result of this paper and would have other interesting applications.

We also emphasize that our simulation runs in NC. This is due to the parallel nature of our construction and to the fact that it is possible to give an NC construction of the SSZ-dispersers [SSZ97]. Thus, our method provides also an efficient simulation of $BPNC$ algorithms using weak random sources.

Likewise, the proof of Lemma 1 as appeared in a preliminary version of this paper [ACRT97], as well as the proof of Theorem 2 described in section 5, implies an NC simulation of randomized algorithms when both the algorithm and the hitting set are given as oracles. In contrast, the proof of Lemma 1 that appeared in [ACR97] seems to be inherently sequential. Andreev, Clementi, and Rolim [ACR97] have recently used the NC proof of Theorem 2 in order to provide sufficient conditions (in terms of worst-case circuit complexity) for $NC = BPNC$.

Our main result (Theorem 3) can be generalized to the case where the function f that we want to sample is not Boolean but takes real values in the range $[0, 1]$. The proof of Theorem 3 contained in this paper can be easily generalized to the case of such functions. We choose, however, to state and prove only the case of Boolean functions since proofs are cleaner and since, as proved in [G97], sampling real-valued functions is reducible to sampling Boolean functions. We can thus get the following result as a corollary of Theorem 3 and of [G97, Theorem 5.5].

COROLLARY 24. *For any $\gamma > 0$, there exist a polynomial p and a deterministic algorithm A such that the following holds. For any $\epsilon > 0$, $n > 0$, any $(p(n/\epsilon), p(n/\epsilon)^\gamma)$-source X, and any $f : \{0,1\}^n \to [0,1]$, on input (ϵ, n, X) and oracle access to f, A computes, in time polynomial in n/ϵ, a value $\tilde{f}$ such that with probability at least $1 - 2^{-\mathrm{poly}(n)}$ over the outcomes of the source,*

$$|\bar{f} - \tilde{f}| \leq \epsilon,$$

where $\bar{f} = 2^{-n} \sum_x f(x)$ is the average of f.

Acknowledgments. We are grateful to Oded Goldreich for several valuable comments and suggestions on preliminary versions of this paper. In particular, the use of a counting argument à la Kolmogorov is due to Oded. We thank Lance Fortnow for his permission to mention his results in this paper. We thank Madhu Sudan and Avi Wigderson for helpful discussions on Fortnow's results and Michael Saks, Aravind Srinivasan, and Shiyu Zhou for showing us that OR-dispersers can be obtained by an NC construction, and for other helpful conversations.

DOMINATORS IN LINEAR TIME*

STEPHEN ALSTRUP†, DOV HAREL‡, PETER W. LAURIDSEN†,
AND MIKKEL THORUP†

Abstract. A linear-time algorithm is presented for finding dominators in control flow graphs.

Key words. control flow analysis, dominators, algorithms

AMS subject classifications. 68Q25, 68N20

PII. S0097539797317263

1. Introduction. Finding the dominator tree for a control flow graph is one of the most fundamental problems in the area of global flow analysis and program optimization [2, 3, 4, 6, 12, 17]. The problem was first raised in 1969 by Lowry and Medlock [17], where an $O(n^4)$ algorithm for the problem was proposed (as usual, n is the number of nodes and m the number of edges in a graph). The result has been improved several times (see, e.g., [1, 2, 19, 22]), and in 1979 an $O(m\alpha(m,n))$ algorithm was found by Lengauer and Tarjan [16]. Here α is the inverse Ackermann's function. Finally, in 1985 Dov Harel [13] announced a linear-time algorithm. Based on Harel's results, linear-time algorithms have been found for many other problems (see, e.g., [4, 6, 12]). Harel's description was, however, incomplete. In this paper, we give a complete description of a different and simpler linear-time dominator algorithm.

The paper is divided as follows. In section 2 the main definitions are given. In section 3 we outline the Lengauer–Tarjan algorithm. In section 4 we give a linear-time dominator algorithm. A detailed comparison with Harel's approach [13] is given in section 4.7. Finally, in section 5 we briefly discuss dominators in the simpler case of reducible control flow graphs. The appendix contains implementation details of the algorithm in section 4.

2. Definitions. A *control flow graph* is a directed graph $G = (V, E)$, with $|V| = n$ and $|E| = m$, in which $s \in V$ is a start node, from which all nodes in V are reachable through the edges in E (see, e.g., [2]). If $(v, w) \in E$, we say that node v is a *predecessor* of node w and w is a *successor* of v. Node v *dominates* w if and only if all paths from s to w pass through v. Node v is the *immediate dominator* of node w, denoted $idom(w) = v$ if v dominates w and every other node that dominates w also dominates v. The tree T induced by the edges $(idom(w), w)$ is called the *dominator tree* of G. Hence, the root of T is the start node s, and for all other nodes v, its parent in T is its immediate dominator.

3. Lengauer and Tarjan's algorithm. In this section we outline Lengauer and Tarjan's algorithm, since the idea behind our algorithm is to optimize subroutines used in this algorithm.

Lengauer and Tarjan's algorithm [16] runs in $O(m\alpha(m,n))$ time. Initially a depth-first search (DFS) [21] is performed in the graph, resulting in a DFS-tree $\mathcal{T}$, in which

the nodes are assigned a DFS-number. In this paper we will not distinguish between a node and its DFS-number. The nodes are thus ordered such that $v < w$ if the DFS-number of v is smaller than the DFS-number of w.

The main idea of the Lengauer–Tarjan algorithm is first to compute the so-called *semidominators*, $sdom(v)$, for each node $v \in V \backslash \{s\}$ as an intermediate step for finding dominators. The semidominator of a node v is an ancestor of v defined as

$$sdom(v) = \min\{u | \text{ a path} u, w_1, \ldots, w_k, v \text{ exists, where } w_i > v \text{ for all } i = 1, \ldots, k\}.$$

The semidominators are found by traversing the tree $\mathcal{T}$ in decreasing DFS-number order while maintaining a dynamic forest, $\mathcal{F}$, which is a subgraph of the DFS-tree $\mathcal{T}$. Hence, an edge $(v, w) \in \mathcal{T}$, included in $\mathcal{F}$, is in $\mathcal{F}$ connecting the parent v with its child w. The following operations should be supported on $\mathcal{F}$:

- LINK(v, w): Adds the edge $(v, w) \in \mathcal{T}$ to $\mathcal{F}$. The nodes v and w are root nodes of trees in $\mathcal{F}$.
- EVAL(v): Finds the minimum *key* value of nodes on the path from r to v, where r is the root of the tree in $\mathcal{F}$ to which v belongs.[1]
- UPDATE(v, k): Sets $key(v)$ to be k, where the node v must be a singleton tree.

We will now give a more detailed description of the Lengauer–Tarjan algorithm. The forest $\mathcal{F}$ initially contains all nodes as singleton trees and the computation of semidominators is done as follows:

- Initially we set $key(v) = v$ for all nodes $v \in V$.
- The nodes are then visited in decreasing DFS-number order, i.e., v is visited before w if and only if $v > w$. When visiting a node v, we call UPDATE(v, k), where $k = \min\{\text{EVAL}(w) | (w, v) \in E\}$.
- After visiting v, a call LINK(v, w) is made for all children w of v.

After running this algorithm we have $key(v) = sdom(v)$. The correctness of the algorithm (i.e., that when a node is updated, it is with the correct *sdom*-value) follows from the following theorem given by Lengauer and Tarjan [16, Theorem 4]:

THEOREM 3.1. *For any node* $v \neq s$, $sdom(v) = \min(S_1 \bigcup S_2)$ *where* $S_1 = \{w | (w, v) \in E \ \wedge w < v\}$ *and* $S_2 = \{sdom(u) | u > v \ \wedge (w, v) \in E \ \wedge u$ *is an ancestor of* $w\}$. □

To see the connection between Theorem 3.1 and the algorithm above consider the visit of node v in the algorithm. Since EVAL$(w) = w$ for $w < v$, $S_1 = \{\text{EVAL}(w) | (w, v) \in E \wedge w < v\}$. To see that $S_2 = \{\text{EVAL}(w) | (w, v) \in E \wedge w > v\}$, note that if $u > v$, $(w, v) \in E$, and u is an ancestor of w in $\mathcal{T}$, then u and w have already been visited. Thus u is an ancestor of w in a tree in $\mathcal{F}$, so EVAL(w) includes $sdom(u)$.

Tarjan and Lengauer show that having found the semidominators, the immediate dominators can be found within the same complexity.

The EVAL-LINK operations in the algorithm are performed using a slightly modified version of Tarjan's UNION-FIND algorithm for disjoint sets [23]. Since n LINK and m EVAL operations are performed, the complexity is $O(m\alpha(m, n))$. Thus a linear-time algorithm can be obtained if the EVAL and LINK operations can be performed in $O(n + m)$ time.

[1] In [16], EVAL is defined to consider the root only if the root is the argument of the EVAL. In the process of finding a dominator tree, this happens only if the tree is a singleton node. We have given the definition above to avoid confusion, as it is this definition which will be used in our algorithm. The Lengauer–Tarjan algorithm presented here is therefore a slight modification of the original algorithm. More specifically, the modification consists of performing the LINK(v, w) operation when v is visited instead of when w is visited.

4. A linear-time algorithm. In this section we present a linear-time dominator algorithm. The overall idea is to convert the on-line EVAL-LINK algorithm to an off-line algorithm by exploiting the fact that the tree resulting from LINK operations is known in advance. The inspiration for this stems from the linear UNION-FIND algorithm for disjoint sets by Gabow and Tarjan [11]. In the Gabow–Tarjan algorithm, the tree, T, resulting from all UNION operations is known in advance. More specifically this means that a UNION(v, w) operation is only permitted if the edge (v, w) is in T. The FIND queries are then defined as usual, whereas UNION(v, w) is defined as the union of the sets to which v and w belong. The linear time is achieved by tabulating the behavior of UNION-FIND within small *microtrees* of size $O(\log n)$.

The original approach of Harel was to convert this linear UNION-FIND algorithm into an EVAL-LINK algorithm [13]. Roughly speaking, the basic idea was to define a new parameter of nodes, referred to as pseudodominator, which satisfy the following two conditions: (a) pseudodominators can be propagated in linear time, and (b) using pseudodominators, we can compute semidominators in linear time. This approach had a couple of drawbacks, further elaborated upon in section 4.7. Here we do not involve pseudodominators, but calculate the semidominators directly. Not only do we know the structure of the tree resulting from the links, we also know that the LINKS occur in reverse-DFS order. Instead of converting the linear UNION-FIND algorithm, we end up using it as a black box. Moreover, the information needed for tabulating EVAL is found using Fredman and Willard's Q-heaps [9], which were not available at the time of [13]. Finally, our choice of microtrees leads to simpler calculations.

4.1. An $O(n \log n + m)$algorithm. We consider a forest, $\mathcal{F}$, of trees. Recall that to each node a *key* is associated, which initially contains the DFS-number of the node. Let T_v denote the tree in $\mathcal{F}$ to which v belongs. We will use the term *self-contained* for nodes, for which EVAL$(v) = key(v)$. Hence a node v is self-contained if all ancestors of v in T_v have key values $\geq key(v)$. Note that the definition implies that all root nodes in $\mathcal{F}$ are self-contained. A node v stops being self-contained when T_v is linked to a root node u, for which $key(u) < key(v)$.

LEMMA 4.1. *Let $nsa(v)$ denote the nearest self-contained ancestor of v.*

(a) *For any node $v \in V$, we have $EVAL(v) = key(nsa(v))$.*

(b) *For any node pair $u, v \in V$, if $nsa(v) = u$ at some point in the Lengauer–Tarjan algorithm, then $nsa(v) = nsa(u)$ in the remainder of the algorithm.*

Proof.

(a) By the definition of self-contained nodes, $key(nsa(v))$ is the least *key* value of nodes on the path from the root of T_v to $nsa(v)$. By the same definition, if nodes with *key* values $< key(nsa(v))$ were on the path from $nsa(v)$ to v in T_v, the node with least depth among these nodes would be self-contained.

(b) By definition, $nsa(u)$ is the nearest self-contained ancestor of u. The fact that $nsa(v) = u$ implies that $T_v = T_u$ and that all nodes on the path from u to v in T_v have *key* values $> key(u)$. By the definition of UPDATE none of these nodes will change *key* values again. The node $nsa(v)$ will therefore always be the nearest self-contained ancestor of u. □

By Lemma 4.1(b) we can represent the *nsa*-relation efficiently by using disjoint sets. Let each self-contained node, u, be the *canonical element* of the set $\{v | nsa(v) = u\}$. By Lemma 4.1(a), an EVAL(v) operation is then reduced to finding the canonical element of the set to which v belongs; hence EVAL$(v) = key(SetFind(v))$.

When a LINK(u, v) operation is performed, the node v will no longer be the root of T_v. Therefore a set A of nodes in T_v may stop being self-contained. A node $w \in A$

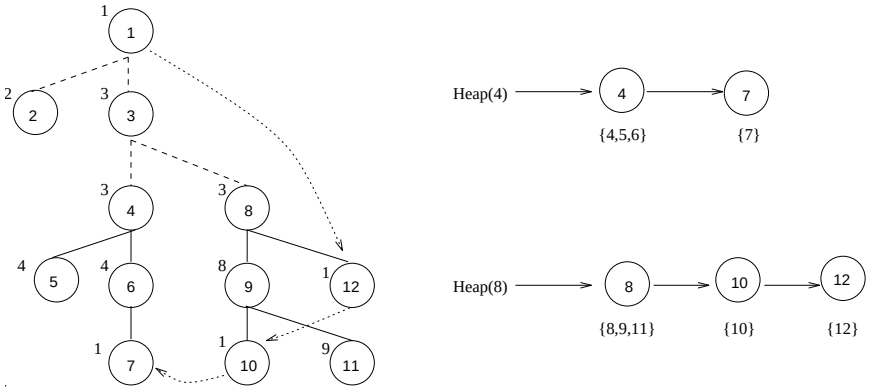

FIG. 4.1. *To the left a sample DFS-tree in which the nodes are labeled by their DFS-numbers is given. The full lines indicate the part of the tree which has been linked, hence the node to be processed is node "3." The dotted arrows are graph edges. The numbers beside the nodes are their key values. To the right the two nontrivial heaps containing self-contained nodes are illustrated as lists. Below the self-contained nodes the sets associated with them are listed.*

is the canonical element of the set of nodes whose EVAL values change from $key(w)$ to $key(u)$. We can thus maintain the structure by unifying the sets associated with nodes in A with the set associated with u.

To find the set A, a heap, supporting HeapFindMax, HeapExtractMax, and Heap Union (e.g., [8, 24]), is associated with each root of a tree in $\mathcal{F}$. Each heap contains the self-contained nodes in the tree (see Figure 4.1). The set A can then be found by repeatedly extracting the maximum element from the heap associated with v until the maximum element of this heap is $\leq key(u)$.

The algorithm LINK(u, v) is as follows:

- **While not** $Empty(Heap(v))$ **and** $key(FindMax(Heap(v))) > key(u)$ **do**
- $w := ExtractMax(Heap(v))$;
- $SetUnion(u, w)$; /* The canonical element of the resulting set is u */
- **od**;
- $Heap(u) := HeapUnion(Heap(u), Heap(v))$;

LEMMA 4.2. *The algorithm presented performs the n LINK and UPDATE operations interspersed with m EVAL operations in $O(m + n \log n)$ time.*

Proof. At most $O(n)$ $HeapExtract$, $HeapFindMax$, and $HeapUnion$ operations are performed. Each of these operations can be done in $O(\log n)$ time using an ordinary heap (e.g. [8, 24]). Since the tree structure is known in advance, the set operations can be computed in linear time using the result from [11].[2] It will, however, suffice to use a simple disjoint set algorithm which rearranges the smallest of the two sets. □

4.2. Decreasing roots. In section 4.4 we will need the ability to decrease the *key* value of a node, while it is the root of a tree. We will therefore extend the algorithm from the previous section to handle the $DecreaseRoot(v, k)$ operation, which sets $key(v) = k$, where v is the root of T_v. The $DecreaseRoot(v, k)$ operation should be done in constant time.

[2] If this result is used, the $SetUnion$ operation should be changed according to the description given earlier in this section. More specifically, the call would be $SetUnion(parent(w), w)$ and the canonical element of the resulting set would be the canonical element of the set that includes $parent(w)$.

Assume that a $DecreaseRoot(v, k)$ operation has been performed. Analogous to the LINK operation from the previous section, this may imply that some self-contained nodes in T_v are no longer self-contained. We should therefore remove such nodes from the heap and unify the sets associated with them with the set associated with v, as was done in the LINK operation. However, in the algorithm from the previous section, the root node v is the maximum element in the heap associated with it. In order to remove nodes from the heap, we would first have to remove v, which would require $O(\log n)$ time. We should note that since the heap returns maximum values the usual *decreasekey* operation for heaps cannot be used. We can, however, take advantage of the fact that the root node will always be the maximum element in the heap it belongs to. It is therefore not necessary to explicitly insert the root into the heap until it is linked to its parent. The $DecreaseRoot(v, k)$ operation is performed as follows.

- **While not** $Empty(Heap(v))$ **and** $key(FindMax(Heap(v))) > k$ **do**
- $w := ExtractMax(Heap(v))$;
- $SetUnion(v, w)$;
- **od**;
- $key(v) := k$;

LEMMA 4.3. *We can perform d DecreaseRoot and n LINK and UPDATE operations interspersed with m EVAL operations in $O(n \log n + m + d)$ time.*

Proof. We change the algorithm from the previous section by postponing the insertion of a root node, r, into $Heap(r)$, until r is linked to its parent. This has no effect on the complexity of EVAL and UPDATE operations stated in Lemma 4.2. Since each node may be deleted from a heap at most once, the total number of $ExtractMax$ and $SetUnion$ operations invoked by LINK and $DecreaseRoot$ is still limited by the number of nodes in the tree. The cost of these operations can therefore be charged to the LINK operations. Since the remaining operations invoked by $DecreaseRoot$ are each done in constant time, the additional complexity of the d $DecreaseRoot$ operations is $O(d)$. □

4.3. A linear-time algorithm for paths. We consider the situation in which the tree $\mathcal{T}$ is a path. Recall that in the algorithms from the previous two subsections we needed a heap to order self-contained nodes. The property which distinguishes paths from trees in this context is that this ordering is induced by the path. More specifically, any pair u, v of self-contained nodes on the part of the path which has been linked are ordered, such that $key(v) \geq key(u)$ if and only if $depth(v) \leq depth(u)$. To perform LINK operations on a path, we can therefore use the algorithm from the previous section, where the heap is replaced by a stack. The algorithm for the operation LINK(u, v) on a path is as follows.

- **While not** $StackEmpty$ **and** $key(StackTop) > key(u)$ **do**
- $w := StackPop$;
- $SetUnion(u, w)$;/* The canonical element of the resulting set is u */
- **od**;
- $StackPush(u)$;

An EVAL operation on a path is performed in analogy with the previous section, hence EVAL$(v) = key(SetFind(v))$.

LEMMA 4.4. *If the tree $\mathcal{T}$ is a path, we can perform the n LINK and UPDATE operations and the m EVAL operations in $O(n + m)$ time.*

Proof. The stack operations are done in linear time since each node will only be on the stack once. By using the result from [11] the set operations are performed in amortized constant time. □

4.4. A faster algorithm for trees with few leaves. We can take advantage of the linear time algorithm from the previous section by using it on the paths in $\mathcal{T}$. More specifically, we define *I-paths* to be maximal paths of $\mathcal{T}$ consisting of at least two unary nodes, i.e., nodes with at most one child. We now define the forest R as the forest $\mathcal{F}$ with each maximal segment of an I-path from $\mathcal{T}$ contracted into a single node, called an *I-node*. In the process of linking, the correspondence between R and the forest $\mathcal{F}$ is as follows.

- When the node with largest depth on an I-path is linked to its child, c, in $\mathcal{F}$, the *I-node* is linked to c in R.
- When the node with least depth on an I-path is linked to its parent, p, in $\mathcal{F}$, the *I-node* is linked to p in R.

We will use the result from section 4.2 for nodes in R and the result from the previous section for nodes on I-paths. The above correspondence means that EVAL queries on nodes in R correspond to EVAL queries in $\mathcal{F}$ if, for any I-path P, $key(I\text{-}node(P))$ is the least *key* value on the part of P which has been linked. In other words, we use $I\text{-}node(P)$ to represent the minimum self-contained node on P in R. During the processing of an I-path P, the *key* value of $I\text{-}node(P)$ should thus be properly updated. This is done by invoking a $DecreaseRoot(I\text{-}node(P), k)$ operation each time a new minimum *key* value k is found on P.

The EVAL queries on nodes on an I-path, P, will be correct as long as the node with least depth on P has not yet been linked to its parent. We can therefore construct an interface between R- and I-paths as follows. We associate a pointer, *I-root*, with each node on an I-path. The pointer is initially set to be NULL and when the node with least depth on an I-path is linked to its parent p, we set $I\text{-}root(v) = p$, for all nodes v belonging to the I-path. The algorithm for EVAL(v) is as follows (we use subscripts to distinguish between the structures EVAL operations are performed in):

- **if** v belongs to an I-path P **then**
- **if** $I\text{-}root(v)$ =NULL **then return** $\text{EVAL}_P(v)$
- **else return** min $\{\text{EVAL}_P(v), \text{EVAL}_R(I\text{-}root(v))\}$
- **else return** $\text{EVAL}_R(v)$.

LEMMA 4.5. *Let l denote the number of leaves in $\mathcal{T}$. We can perform m EVAL and n LINK and UPDATE operations in $O(l \log l + m + n)$ time.*

Proof. The I-paths are processed in linear time by Lemma 4.4 and since the I-root pointer is updated only once, this can also be done in linear time. Since the I-paths have been contracted R contains $O(l)$ nodes. Thus by Lemma 4.3, R can be processed in time $O(l \log l + m + d)$, where d is the number of *DecreaseRoot* operations. The number of *DecreaseRoot* operations is, however, bounded by the number of nodes on I-paths. □

4.5. Reducing to small subtrees. By lemma 4.5 we have that the EVAL-LINK algorithm can be performed effectively on trees with few leaves. However, the number of leaves is only bounded by the number of nodes. To reduce the number of leaves in $\mathcal{T}$, subtrees of size $\leq \log n$ can be removed from the bottom of $\mathcal{T}$ (a technique also used in [7]). We will refer to such subtrees as *S-trees*. Assume that all S-trees have been removed from the tree $\mathcal{T}$. Then each leaf in the remaining tree must be a node in $\mathcal{T}$ with at least $\log n$ descendants. Thus the remaining tree has at most $n/\log n$ leaves. By Lemma 4.5 we can therefore perform amortized constant-time EVAL, LINK, and UPDATE operations in the remaining tree.

We now show how to process the S-trees. Recall that the LINK operations are performed in decreasing DFS-number order. This implies that EVAL operations of

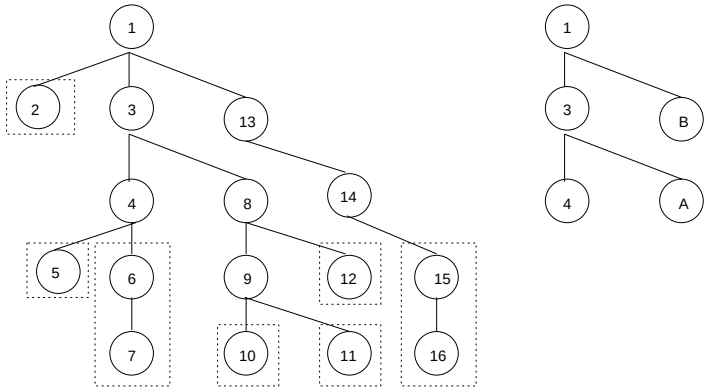

FIG. 4.2. *To the left a sample DFS-tree is given. The boxes indicate S-trees of size* ≤ 2. *To the right the reduced tree is given. The nodes "A" and "B" are replacing I-paths. Note that if S-trees of size* $\leq \log_2 16 = 4$ *were removed, the tree would be reduced to a single node representing the I-path* $1, 3, 8$.

nodes in S-trees, induced by nodes outside, will only take place at a time when all links have been performed inside the structure. Furthermore, the links inside S-trees are performed successively; hence, each S-tree can be processed independently. Analogously with I-paths, we can associate a pointer *S-root* with each node in each S-tree, which points to the parent of the root of the S-tree after the LINK between the root and its parent has been performed. Then an EVAL operation on a node v in an S-tree becomes

$$\begin{array}{ll} \text{EVAL}_S(v), & \text{if } S\text{-}root(v)\text{=NULL}, \\ min\{\text{EVAL}_S(v), \text{EVAL}(S\text{-}root(v))\} & \text{otherwise.} \end{array}$$

To perform EVAL, LINK, and UPDATE operations inside an S-tree we could use lemma 4.2. Alternatively, we could repeat the removal of subtrees on the S-trees because of the independent nature of S-trees. Let $T(m, n, a)$ denote the time it takes to support the m EVAL and n LINK and UPDATE operations in the Lengauer–Tarjan algorithm within subtrees of $\mathcal{T}$ each of size $\leq a$. For example, the construction of Lemma 4.2 gives $T(m, n, a) = O(m + n \log a)$.

LEMMA 4.6. $T(m, n, a) = O(m + n) + T(m, n, \log a)$.

Proof. We process each subtree S as follows. Remove maximal subtrees of size at most $\log a$ from S. Then, in the upper tree of S we have at most $|S|/\log a$ leaves. Since $a \geq |S|$, by Lemma 4.5 the cost of the LINKs and UPDATEs in S is $O(|S|)$, resulting in a total cost of $O(n)$ over all S-trees. An EVAL query in the upper tree of S has constant cost by Lemma 4.5. An EVAL query to an subtree may propagate to the root via the root-pointer in the subtree, but it takes only additional constant time. □

Since $T(m, n, 1) = O(m + n)$, repeating the above recurrence $\log^* n$ times, we immediately get

$$T(m, n, n) = O((m + n) \log^* n).$$

However, in this paper we need only to repeat it twice, giving the following corollary.

COROLLARY 4.7. $T(m, n, n) = O(m + n) + T(m, n, \log \log n)$. □

In the next subsection, we will show that $T(m, n, \log \log n) = O(m+n)$, implying a linear-time algorithm for finding dominators.

Figure 4.2 illustrates the division of a tree into I-paths and S-trees on one level.

4.6. Tabulation of small trees. In this section we show how to perform constant-time EVAL, UPDATE, and LINK operations on trees of size $\leq \log\log n$, henceforth denoted as *microtrees*. We will do this by constructing a table containing EVAL values for all possible forest permutations. We first show how to compute such a table assuming that a superset of *sdom* values is known for each microtree. Following that we show how to choose this superset. Combining these results we show that the microtrees can be processed in linear time. Finally we give the theorem, which completes the dominator algorithm. We start out by giving a lemma by Fredman and Willard [9].

LEMMA 4.8. *The Q-heap performs insertion, deletion, and search operations in constant time and accommodates as many as* $(\log n)^{1/4}$ *items given the availability of* $O(n)$ *time and space for preprocessing and word size* $\geq \log n$. □

For a set M' of different values we define the rank of a value $x \in M'$ as the number of values $< x$ in M'.

THEOREM 4.9. *Assume that to each microtree* M, $|M| \leq \log\log n$, *we are given a set of values* M', *where* $|M'| = O(|M|)$, *and that for all UPDATE*(v, k) *operations,* $v \in M \Rightarrow k \in M'$. *Assume also that the order in which LINK operations occur is known. It is then possible to perform constant-time EVAL, LINK, and UPDATE operations, given the availability of* $O(n)$ *time and space for preprocessing and word size* $\geq \log n$.

Proof. First we sort the set M' of size $O(\log\log n)$ in linear time using Lemma 4.8. The *key* value of each node is replaced by its rank in M', which simply is an index into the sorted set. In order to perform UPDATE and EVAL operations efficiently, we need a table which maps *key* values to ranks and vice versa. Since all *key* values are $< n$, this table requires only $O(n)$ space. Given this table we can now maintain the microtree using the rank of the node instead of its *key* value. Thus an EVAL output from the microtree should be mapped to a *key* value using the above table. Since the size of the rank is exponentially smaller than the *key* value, we can now use tabulation for microtrees as follows. We construct each possible tree of size $\leq \log\log n$. Since in general there are at most $O(2^k)$ trees of size k (all trees of size k can be uniquely represented by a bitmap of size $2k$), there are at most $\log n$ such trees. Due to the reverse-DFS order of LINKs, in each of the trees there are only $\log\log n$ ways the nodes can be partially linked. Finally for each of these forests of partially linked trees, we construct copies holding all possible permutations of ranks to nodes. In each of these forests we compute the EVAL value for each node. We then construct a table which outputs the computed EVAL values. This computation can be done in a time proportional to the number of nodes in the trees: For each tree with root r, traverse the tree top-down and set EVAL(r)=r, and for each node $v \neq r$ set EVAL(v)=min($key(v)$,EVAL($parent(v)$)). The number of nodes is the product of the number of trees ($\log n$), the number of LINK's ($\log\log n$), the number of rank permutations (($C_1 * \log\log n)^{\log\log n}$), and the number of nodes in each tree ($\log\log n$); thus the number of nodes is (C_i are constants):

$$\begin{aligned}
&\log n * \log\log n * (C_1 * \log\log n)^{\log\log n} * \log\log n \\
&= \log n^{C_2} * (\log\log n)^2 * \log\log n^{\log\log n} \\
&\leq \log n^{C_3} * \log\log n^{\log\log n} \\
&= \log n^{C_3} * \log n^{\log\log\log n} \\
&= \log n^{C_3 + \log\log\log n} = O(n).
\end{aligned}$$

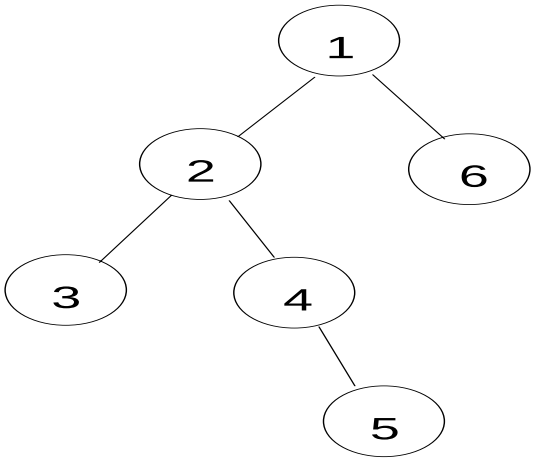

FIG. 4.3. *A sample tree labeled by DFS-numbers. The bitmap of the tree is "*11011000100*."*

To store each forest, the forest table from [11], which requires $\log\log n$ space, can be used. The rank of each node requires $\log\log\log n$ space. If we attach a new number to each node inside the forest we can identify each node using $\log\log\log n$ space. Hence, each entry to the table requires $\log\log n + \log\log\log n * \log\log n + \log\log\log n$ space, which will fit into a computer word of size $\geq \log n$. The size of the table is thus $O(n)$. To carry out the operations given a microtree, we first compute the table entry for the tree without any links. The EVAL operations are done by looking up the table and the LINK and UPDATE operations are done by updating the entry. Finally, in order to perform UPDATE and EVAL operations, we use the table which maps *key* values to ranks and vice versa. Next we will be a little more specific on how to maintain the forest table. The forest table from [11] supports any ordering of the LINK operations, whereas in the dominator algorithm the links are performed in decreasing DFS-number order. We can therefore simplify the representation by using the DFS-traversal to represent each tree. More specifically, we start at the root and use a bitmap in which "1" means that an edge is followed down in the tree and "0" means that we move to the parent of the current node. The tree traversal is finished when "0" is encountered while the root is the current node. As a special case this means that a single node tree is represented by the bitmap "0." The mapping is illustrated in Figure 4.3. Instead of representing the LINK's explicitly we can save the number of nodes in the tree, which at some point in time has been processed by the algorithm. Since the size of the forests can differ, we also need to save the size of each tree. Finally the *key* and EVAL values of the nodes can be saved in order of the DFS-traversal. The bitmap of an entry can thus have the following configuration [SIZE‖TREE‖KEYS‖EVAL‖LINK], where SIZE and LINK are blocks of $\log\log\log n$ bits, EVAL and KEYS use SIZE bits, and TREE uses (2*SIZE-1) bits.

To construct the entry of a microtree we traverse it in DFS-order and set the bits of TREE and SIZE accordingly. The KEYS are initialized to the rank of the DFS-numbers and LINK is initialized to 0. A microLINK operation is performed by incrementing the LINK value and the microUPDATE(v, k) operation is done by replacing the value of v in the entry with k. □

Theorem 4.9 requires a superset M' of *sdom* values for nodes in a microtree M. The next lemma shows how M' can be chosen.

LEMMA 4.10. *Let* $M_1 = \bigcup_{v \in M} \min\{(EVAL(w))|\ (w,v) \in E \wedge w \notin M\}$ *and* $M' = M \bigcup M_1$. *For all* $v \in M$ *we have that* $sdom(v) \in M'$.

Proof. The lemma is obviously true in case $sdom(v) \in M$. Assume therefore that $u = sdom(v) \notin M$ and that $u \notin M'$. By the definition of semidominators, a path $u = w_0, w_1, \ldots, w_{k-1}, w_k = v$ exists where $w_i > v$ for $i = 1, \ldots, k-1$. Let w_j be the last node on the path not in M. Since $u \notin M'$, the node w_{j+1} must have a predecessor x for which $\text{EVAL}(x) < u$. This means that a path exists from a node u', with $u' < u$, to w_{j+1} on which all nodes except u' are $> v$. This path can be concatenated with the path $w_{j+1}, \ldots, w_k, v$, contradicting that $sdom(v) = u$. □

We now complete the microtree algorithm by showing how to compute the sets M' of Lemma 4.10.

THEOREM 4.11. *Let* M *be a microtree of size* $\leq \log\log n$. *Each EVAL, UPDATE, and LINK operation inside* M *in the Lengauer–Tarjan algorithm can be performed in constant time, given the availability of* $O(n)$ *time and space for preprocessing and word size* $\geq \log n$.

Proof. By Theorem 4.9 and Lemma 4.10 we need only to show how to compute the sets M' defined in Lemma 4.10 in $O(|M'|)$ time. We will show this by induction on the visits of microtrees. Recall that the Lengauer–Tarjan algorithm visits nodes in decreasing DFS-number order. When the first microtree is reached all nodes with larger DFS-numbers have thus been processed. By Corollary 4.7, EVAL queries on processed nodes outside microtrees can be done in constant time. Furthermore, all nodes with smaller DFS-numbers will at this stage be singleton trees. The EVAL queries required in Lemma 4.10 can thus be performed in constant time for the first microtree. Given an arbitrary microtree M we can therefore assume that constant time EVAL queries can be performed in microtrees containing nodes with larger DFS-numbers than the nodes in M. For nodes not in microtrees, we can compute the EVAL values needed in Lemma 4.10 in constant time by the same arguments as above. By induction this is also the case for nodes in previously visited microtrees.

Finally we should note that in the proof of Theorem 4.9, $O(n)$ space was used for the table, which maps *key* values to ranks for a microtree. Since the microtrees are computed independently, this space can be reused, so that the overall space requirement is $O(n)$. □

We can now combine the results of this section in the following theorem.

THEOREM 4.12. *The EVAL, LINK, and UPDATE operations in the Lengauer–Tarjan algorithm can be performed in linear time.*

Proof. Follows directly from Corollary 4.7 and Theorem 4.11. □

4.7. Relation to Harel's algorithm. The proof of Theorem 1 of [13], which is omitted, employs a linear–time-table construction using a variant of dynamic programming. The details of this construction are beyond the scope of this paper.

Harel's original value propagation required the construction of supersets of the sets of *sdom* values for all microtrees in a separate phase, in order to presort the values. The main drawback of the technique is that it leads to a rather complicated case analysis, and checking correctness is pretty tedious. In fact, the original value propagation algorithm in [13] contains an error (more precisely Theorem 3b in [13] is false as stated and a concrete counterexample is given in [15, Section 4, p. 12]).

The algorithm described in this paper avoids the above problems [13] by using the following technique. We change the construction so that microsets are removed only from the bottom of the tree, which simplifies value propagation. The tables required to prove Theorem 1 of [13] are replaced by the use of Fredman and Willard's priority

queues. This technique is more general and allows us to propagate semidominator values on a per microset basis, just prior to computing the exact semidominator values for all members of a microset.

5. Algorithms for reducible graphs. The problem of finding dominators in reducible graphs has been investigated in several papers (e.g., [1, 18, 20]). The reason why reducible graphs are considered is that the control flow graphs of certain programming languages (e.g., Modula-2 [25]) are reducible. A graph is reducible if the edges can be partitioned into two disjoint sets E' and E'' so that

- the graph induced by the edges in E' is acyclic
- for all edges $(v, w) \in E''$, w dominates v.

Since the edges E'' have no influence on the dominance relation, the problem of finding dominators in reducible graphs is analogous to finding dominators in acyclic graphs. In this section we therefore assume that graphs are acyclic.

5.1. The former algorithm is not linear. In 1983, Ochranova [18] gave an algorithm which is claimed to have complexity $O(m)$[3]. Unfortunately the paper does not contain a complexity analysis. In order to disprove the complexity of the algorithm, it is therefore necessary to outline the behavior of the algorithm. For an acyclic graph we have the following facts:

(a) If a node, x, has a single predecessor, y, then $idom(x) = y$.
(b) If each of the successors of a node x has more than one predecessor then no node is dominated by x.

Since at least one successor of the start node s will satisfy the condition in (a), the dominators can be found by starting at s and using the two facts interchangeably as follows:

1. If (a) is true for a successor, v, of the current node, w, then set $idom(v) = w$ and the current node to v.
2. If (b) is true for all successors of the current node w then merge w and $idom(w)$ (by unifying their successor and predecessor sets respectively). Set the current node to be the merged node.

In order for the algorithm to be linear, the detection of whether (a) is true in 1 should have constant-time complexity. Furthermore, the merging of two nodes in 2, which involves union of two sets which are not disjoint, should also have constant-time complexity. The authors are not aware of a general algorithm with the above properties.

5.2. A linear-time algorithm. In this section we give a simple linear-time algorithm for finding dominators in reducible graphs. The algorithm is constructed by combining new techniques [10] with previously presented ideas (see, e.g., [1, 20]). In other words, the algorithm is a compilation.

LEMMA 5.1. *Let T be the dominator tree and let $W(w) = \{v|(v, w) \in E'\}$ be the set of predecessors of a node $w \neq s$ in G. Furthermore, let x be the node in T with the largest depth which is an ancestor in T to all the nodes in $W(w)$. Then $idom(w) = x$.*

Proof. x is an ancestor to the nodes in $W(w)$ and therefore dominates w. By definition of dominators a path from x to $idom(w)$ must exist in T. Conversely, $idom(w)$ is an ancestor to all nodes in $W(w)$; thus a path from $idom(w)$ to x must exist. Hence $idom(w) = x$. □

The computation is divided into two main steps as follows:

[3]Citation: "At least no counterexample was found."

1. The graph $G = (V, E')$ is acyclic and can therefore be topologically sorted [14] ensuring that if $(v, w) \in E'$, then v has a lower topological number than w.
2. Now the dominator tree T can be constructed dynamically. Set s to be the root of the dominator tree T and process each node $w \in (V \backslash \{s\})$ in increasing topological order as described below. Note that the part of T built so far, is used for determining *idom* for the rest of the nodes.
   - Let $B = W(w)$. From lemma 5.1 we have that $idom(w)$ now can be computed by repeatedly deleting two arbitrary nodes from B and inserting the nearest common ancestor (nca) of these nodes into the set B until the set contains only one node.
   - After computing $idom(w)$ the edge $(idom(w), w)$ is added to T.

The only unspecified part of the algorithm is the computation of *nca* in a tree T which grows under the addition of leaves. In [10] an algorithm is given which processes *nca* and the addition of leaves in constant time per operation.

THEOREM 5.2. *The algorithm above computes the dominator tree for a reducible control flow graph with n nodes and m edges in $O(n + m)$ time.*

Proof. Step 1 in the algorithm has complexity $O(n + m)$. In step 2 each node is visited and each edge can result in a query about *nca* in T, so at most m *nca*-queries are performed, which establishes the complexity. □

6. Concluding remarks. A linear-time algorithm has been presented for finding dominators. The result, as presented, is purely theoretical, in the sense that Fredman and Willard's Q-heaps require that $n \geq 2^{12^{20}}$ [9]. Some of our ideas may still be of practical relevance. If, for example, we take Corollary 4.7, giving a rather simple linear-time reduction to subtrees of size at most $\log \log n$, and then use Lemma 4.2 within each of these, we get a simple $O(m + n \log \log \log n)$ algorithm, which in practice may be competitive with that of Lengauer and Tarjan [16].

The problem with the large constant using RAM Q-heaps has recently been overcome by a linear-time pointer-machine algorithm to find dominators, due to Buchsbaum et al. [5].

In the following appendices we present the pseudocode of our algorithm.

Appendix A. Implementation details. We assume that a DFS-search has been performed in the graph. The I-paths are removed from the tree in the following way: The child pointer of the parent to the first node and the parent pointer of the child of the last node are removed. An *I-node* is inserted in its place (see Figure A.1). The *I-node* is numbered by a unique number larger than n. Furthermore, the I-paths are numbered by a number > 0.

The algorithm uses the following arrays in which the DFS-number of nodes are used as indices (the arrays marked * are also used in the Lengauer–Tarjan algorithm):

- $pred(v)^*$: The set of nodes w such that $(w, v) \in E$.
- $parent(v)^*$: The parent of v in the DFS-tree. To simplify the EVAL operation we set $parent(v) = 0$ if $v = 0$.
- $child(v), sibling(v)$: Pointer to the first child and first sibling of v, respectively, in the DFS-tree.
- $I\text{-}path(v)$: If v does not belong to an I-path, $I\text{-}path(v) = 0$. Otherwise $I\text{-}path(v)$ contains the number of the I-path to which v belongs.
- $S\text{-}tree(v)$: True if v belongs to an S-tree.
- $microtree(v)$: True if v belongs to a microtree.
- $root(v)$: This field is defined for nodes in S-trees, microtrees, and I-paths. Before the root of the structure has been linked to its parent, p, $root(v) = 0$.

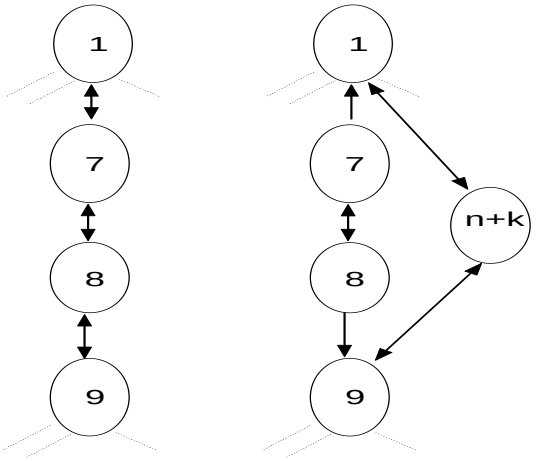

FIG. A.1. *An I-path and the representation of the I-path in the tree. Both child and parent pointers are illustrated.*

Afterwards $root(v)$ contains the number of p.

- $first(v)$: If v belongs to an I-path, this field contains the number of the first node on the I-path.
- $stack(v)$: If v is the first node on an I-path, this field contains the stack used for the I-path.
- $microroot(v)$: If v belongs to a microtree then $microroot(v)$ is the number of the root of the microtree.
- $key(v)$*[4]: After the semidominator of v has been computed, $key(v)$ is the number of the semidominator of v. Initially $key(v) = v$.
- $bucket(v)$*: The set of nodes whose semidominator is v.
- $dom(v)$*: A number which will eventually be the number of the immediate dominator of v.

The main algorithm is a slight modification of the Lengauer–Tarjan algorithm:

```
Begin
 constructmicrotable; /* This procedure computes the microtable */
 for v := 1 to n do bucket(v) := ∅;
 v := n;
 While v > 1 do begin
  if microtree(v) then begin
   microdominator(v, microroot(v)); /* see below */
   v := microroot(v) − 1;
  end else begin
   For each w ∈ pred(v) do begin
    k :=EVAL(w);
    if k < key(v) then UPDATE(v, k);
   end;
   /* The remainder of the algorithm computes dominators */
   /* from semidominators and is analogous to [16] */
   For each child w of v do LINK(v, w);
   bucket(key(v)) := bucket(key(v)) ⋃ {v};
   For each w ∈ bucket(parent(v)) do begin
```

[4]In the Lengauer–Tarjan algorithm, this array is called *semi*.

```
      bucket(parent(v)) := bucket(parent(v))\{w};
      k :=EVAL(w)
      if k < key(w) then dom(w) := k
      else dom(w) := parent(v);
    end;
    v := v − 1;
  end; /* While /*
 end; /* While /*
 for v := 2 to n do
  if dom(v) ≠ key(v) then dom(v) := dom(dom(v));
  else dom(v) := key(v);
End;
```

Procedure *microdominator*$(v, root : integer)$;
The *microdominator* procedure is analogous to the main algorithm. The only real difference is that EVAL, LINK, and UPDATE operations are replaced by microEVAL, microLINK, and microUPDATE operations. Furthermore there are no I-paths in a microtree.

For the EVAL and LINK operations we need the following additional fields:

- $heap(v)$: A heap associated with v.
- $I\text{-}node(v)$: If v is the root of an I-path then $I\text{-}node(v)$ is the number of the node which represents the I-path.

```
Function EVAL(v: integer):integer;
begin
 if v = 0 then EVAL:=∞
 else if microtree(v) then EVAL:=min(EVAL(root(v),microEVAL(v)))
 else if I-path(v) or S-tree(v) then EVAL:=min(EVAL(root(v)), key(SetFind(v)))
 else EVAL:=key(SetFind(v));
end;

Procedure LINK(v, w: integer);
begin
 if microtree(w) then /* w is the root of a microtree */
  For each u in the microtree to which w belongs do root(u) := v
 else if S-tree(w) and not S-tree(v) then /* w is the root of an S-tree */
  For each u in the S-tree to which w belongs do root(u) := v
 else if I-path(v) > 0 then begin
  if first(v) = v then Init-I-path(v, w) /*see below */
  else if I-path(w) = I-path(v) then begin
   S := stack(first(v));
   While not StackEmpty(S) and key(StackTop(S)) > key(v) do begin
    u := StackPop(S);
    SetUnion(v, u);
   end;
   if key(I-node(v)) > key(v) then DecreaseRoot(I-node(v), key(v));
   StackPush(v, S);
  end;
 end else if I-path(w) > 0 then begin /* the path is fully linked */
  For each u on the I-path do root(u) := v;
  /* Add I-node(w) to heap(I-node(w)) */[5]
  LINK(v, I-node(w));
 end else begin /* Neither v nor w is on an I-path */
  While not Empty(heap(w)) and key(HeapFindMax(heap(w))) > key(v) do begin
   u := HeapExtractMax(heap(w));
```

[5]The *I-node* has not been a member of the heap while the I-path has been processed. The pseudocode for this operation is omitted to improve program clarity, as it involves creating a dummy heap and performing a *HeapUnion* operation on the dummy heap and $heap(I\text{-}node(w))$.

```
      SetUnion(v, u);
    end;
    HeapUnion(heap(v), heap(w));
  end;
end;

Procedure Init-I-path(v, w: integer);
/* v is the first node on an I-path and should be linked to its child w */
begin
  CreateStack(S);
  stack(v) := S;
  StackPush(v, S);
  While not Empty(heap(w)) and key(HeapFindMax(heap(w))) > key(v) do begin
    w := HeapExtractMax(heap(w));
    SetUnion(I-node(v), w);
  end;
  heap(I-node(v)) := heap(w);
  key(I-node(v)) := key(v);
end;

Procedure DecreaseRoot(v, k: integer);
begin
  While not Empty(heap(v)) and key(HeapFindMax(heap(v))) > k do begin
    w := HeapExtractMax(heap(v));
    SetUnion(v, w);
  end;
  key(v) := k;
end;

Procedure UPDATE(v, k: integer);
begin
  key(v) := k;
end;
```

The pseudocode of the microalgorithm is rather tedious and therefore is omitted.

APPROXIMATING CAPACITATED ROUTING AND DELIVERY PROBLEMS*

PRASAD CHALASANI† AND RAJEEV MOTWANI‡

Abstract. We provide approximation algorithms for some capacitated vehicle routing and delivery problems. These problems can all be viewed as instances of the following k-delivery TSP: given n source points and n sink points in a metric space, with exactly one item at each source, find a minimum length tour by a vehicle of finite capacity k to pick up and deliver exactly one item to each sink. The only known approximation algorithm for this family of problems is the 2.5-approximation algorithm of Anily and Hassin [*Networks*, 22 (1992), pp. 419–433] for the special case $k = 1$. For this case, we use matroid intersection to obtain a 2-approximation algorithm. Based on this algorithm and some additional lower bound arguments, we devise a 9.5-approximation for k-delivery TSP with arbitrary finite k. We also present a 2-approximation algorithm for the case $k = \infty$.

We then initiate the study of dynamic variants of k-delivery TSP that model problems in industrial robotics and other applications. Specifically, we consider the situation where a robot arm (with finite or infinite capacity) must collect n point-objects *moving* in the Euclidean plane, and deliver them to the origin. The point-objects are moving in the plane with known, identical velocities—they might, for instance, be on a moving conveyor belt. We derive several useful structural properties that lead to constant-factor approximations for problems of this type that are relevant to the robotics application. Along the way, we show that maximum latency TSP is implicit in the dynamic problems, and that the natural "farthest neighbor" heuristic produces a good approximation for several notions of latency.

Key words. capacitated vehicle routing, capacitated delivery, maximum latency problem, matroid intersection, approximation algorithms, traveling salesperson problem, NP-hard

1. Introduction.

This paper considers two variations on the classical traveling salesperson problem (TSP): (a) the permissible routes are constrained by the requirement that objects must be delivered from sources to sinks by a vehicle of finite capacity k, and (b) the points to be visited may be moving with a known velocity. We define the k-delivery TSP: Given n source points and n sink points in some metric space, with exactly one item placed at each source, compute a minimum length route for a vehicle of capacity k to deliver exactly one item to each sink, *starting and ending at a fixed location.* Note that sources and sinks need not lie at distinct locations. This problem is an instance of vehicle routing or scheduling problems that have been the subject of intensive study in the literature [14, 23]. The problem is easily seen to be NP-hard via a reduction from TSP: place a source and a sink very close to each point of the TSP problem, and set $k = 1$; now, an optimal solution to the 1-delivery TSP is an optimal solution to the TSP instance. Similar reductions can be devised for arbitrary finite k and for infinite k.

We provide what appear to be the first known polynomial-time constant-factor approximation algorithms for this problem. Motivated by applications in areas such as robotics, we formulate a novel dynamic version of TSP where the points are moving in the plane, and we partially extend our results to that case. In the process we obtain an approximation algorithm for maximum latency TSP. All our algorithms run in time polynomial in n and, where meaningful, k. Some of our approximation factors have been improved upon by Charikar, Khuller, and Raghavachari [12].

In section 2, we begin by considering 1-delivery TSP, or bipartite TSP. This is closely related to the *swapping problem* for which Anily and Hassin [2] present a 2.5-approximation algorithm. We use matroid intersection to obtain a 2-approximation algorithm for this problem. In section 2.1, based on the 1-delivery approximation algorithm and additional lower bound arguments, we devise a 9.5-approximation algorithm for k-delivery TSP with arbitrary finite k. It turns out that for infinite capacity k, the resulting problem is a special case of the "TSP with delivery and backhauls" for which Anily and Mosheiov [3] obtain a factor-2 approximation.

The k-collect TSP is a well-studied vehicle routing problem [1, 23]: it is the special case of the k-delivery TSP where all sinks are at the starting location of the vehicle. Altinkemer and Gavish [1] have shown a 2.5-factor approximation algorithm for this problem and also established its NP-hardness (for $k \geq 2$). In this paper we motivate and present approximation algorithms for the dynamic k-collect TSP: n point-objects are moving in the Euclidean plane with fixed, identical velocities and a robot arm (starting at the origin) with capacity k must pick up and deliver these objects to the origin. Observe that the dynamic ∞-collect TSP, or simply dynamic TSP, is a generalization of standard TSP to the case of moving points. There does not appear to have been any prior theoretical work on dynamic TSP. As described in section 4, the dynamic problem arises in industrial robotics in the context of rapid deployment automation [10]. This problem also has some features of the *time-dependent* TSP [18, 32] wherein the distance function varies with time. We restrict ourselves to the case where the moving points' velocities are sufficiently smaller than that of the robot arm. This is essential to ensure that the robot arm is able to retrieve all objects and is certainly a valid assumption in the motivating application. An interesting variant, which we do not explore here, concerns the model where the velocities are unrestricted and the goal is to maximize the number of points visited, with possible restrictions on the total time available. Clearly, this would involve generalizing the *prize-collecting TSP* [5] to the case of moving points.

Two complications arise in the case of moving points. First, we lose symmetry in the distance matrix; fortunately, though, since the points are all moving at the same velocity, there is some structure in this asymmetry. The second problem is that the distance of points to the origin is time-dependent, although the distances between moving points are time-independent. In addition, the dynamic variants have some interesting and counterintuitive aspects. For instance, suppose $k = 1$ and there are two points, initially at $(10, 0)$ and $(15, 0)$. The robot is initially at the origin. Assuming that the robot can move at speed 1 and the points move at speed $1/2$ in the negative x direction, which point should be visited first? It is easy to check that visiting the *farther* point first produces a smaller total time (20) than the other way round (roughly 22)! In general, the more time we spend visiting points early in the tour, the closer the later points would have moved to the origin, and so we would spend less time visiting them from the origin.

Thus, the dynamic problem has some features of maximum latency TSP: given a set of n points $P = \{p_1, \ldots, p_n\}$ and a symmetric distance matrix (d_{ij}) satisfying the

triangle inequality, find a path starting at p_1 and visiting all other points so as to *maximize* the total latency of the points, where the latency of a point p_i is the length of the path to that point. In section 3, we give a 1/2-approximation algorithm for maximum latency TSP. We also study some variants that arise implicitly in the dynamic settings. While approximation algorithms for *minimum* latency TSP are known [7, 22], there does not appear to be any prior work on our version of the problem.

In section 4.1 we establish some basic properties of travel times involving moving points (such as the triangle inequality) that are not as obvious as they might seem. In section 4.6, we show that an optimal dynamic 1-collect tour must visit points in decreasing order of distances to the origin and that the case $k = \infty$ is an asymmetric TSP with bounded asymmetry. We then present a constant factor approximation for the dynamic k-collect problem for arbitrary finite k. Finally, some extensions are mentioned in section 4.8.

In the rest of the paper we will refer to the sources as blue points and the sinks as red points. We will also assume for convenience that n is a multiple of k; our results can be extended to the general case by introducing a few dummy sources and sinks close to one of the original points.

1.1. Other related work. Capacitated delivery problems have been studied extensively in the literature [14, 23], although the focus has mostly been on finding the optimal solution (using sophisticated branch and bound techniques, for example) and not on finding provably good approximations. Examples of such work include the following.

(a) *The capacitated vehicle routing problem* (CVRP) [1, 25, 23]: given n points in a metric space and an infinite fleet of vehicles of capacity k, find a collection of vehicle routes starting at origin such that every point is visited by exactly one vehicle. Typical objective functions to be minimized included number of vehicles, total distance traveled, maximum distance traveled by a vehicle, or some combination thereof.

(b) *The dial-a-ride problem* [6, 34, 27]: compute an optimal route for a k-capacity van to pick up and drop off n persons between different origin–destination pairs. Note that this problem differs from the k-delivery TSP in that each person must be dropped off at a specific destination.

(c) *The precedence-constrained TSP* [6]: for each vertex i there is a set $P(i)$ of vertices that must be visited before visiting i, and we are required to find an optimal TSP satisfying these constraints.

Although there does not appear to be any prior theoretical work on TSP with moving points, heuristics for related problems have been studied in the robotics literature (see, for example, Li and Latombe [30]). The *static* k-collect TSP has received considerable attention in the literature and the best-known result is the 2.5-approximation algorithm of Altinkemer and Gavish [1]. Also, the *k-person TSP* is a related problem and has a 1.5-approximation algorithm due to Frieze [20] (see also Frederickson, Hecht, and Kim [19]).

2. The k-delivery TSP. We begin by presenting an approximation algorithm for the 1-delivery TSP that underlies our algorithm for the general case. When the vehicle has unit capacity, any delivery route must alternately pick up and deliver one item at a time. The corresponding graph problem is the following.

BIPARTITE TRAVELING SALESPERSON PROBLEM. *Given an edge-weighted graph G satisfying the triangle inequality, with n blue vertices (sources) and n red vertices (sinks), find the optimal* bipartite *tour starting and ending at a designated blue vertex*

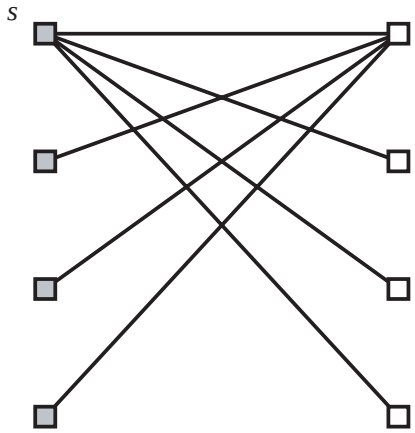

FIG. 1. *A bipartite spanning tree for which no depth-first traversal yields a bipartite tour.*

s and visiting all vertices. A tour is bipartite if no two consecutively visited vertices have the same color.

Anily and Hassin [2] have shown a 2.5-approximation algorithm for a generalization of this problem, known as the swapping problem. Their algorithm finds a perfect matching M consisting of edges that connect red and blue vertices, and it uses Christofides's heuristic [13] to find a tour T of the blue vertices. The final delivery route consists of visiting the blue vertices in the sequence specified by the tour T, using the matching edges in M to deliver an item to a sink and return to the blue vertex (or "shortcut" to the next blue vertex on T). If OPT is the optimal delivery tour, clearly $T \leq 1.5\text{OPT}$ and $M \leq 0.5\text{OPT}$, whereas the total length of the delivery tour is at most $T + 2M \leq 2.5\text{OPT}$. We exploit some combinatorial properties of bipartite spanning trees and matroid intersection to improve this factor to 2.

A naive approach toward a 2-approximation is to mimic the well-known 2-approximation algorithm for the TSP problem: pick a *bipartite* spanning tree of G and then perform a depth-first traversal followed by short-cutting. A spanning tree of G is bipartite if each edge connects a red and blue vertex. Given a bipartite spanning tree T, we can think of it as a tree rooted at s and do a depth-first traversal of T with short-cuts (there may in general be several ways to short-cut) and obtain a tour of G. However, such a tour may not be bipartite; there are bipartite spanning trees that do not yield a bipartite tour regardless of how we do the depth-first traversal and short-cuts (see Figure 1).

Our 2-approximation algorithm is based on the following very simple observations (these observations were communicated to us by Hassin and helped simplify our argument considerably).

Observations. Let T be a bipartite spanning tree where each blue vertex has degree at most 2; then, T has exactly one blue vertex v_1 of degree 1. If T is rooted at v_1 then every blue vertex has exactly 1 (red) child. Clearly, if we traverse this rooted tree T in (any) depth-first order, then the sequence of vertices visited are of alternating color.

Clearly, the OPT bipartite tour contains a bipartite spanning tree where all blue vertices have degree at most 2. Therefore the weight of the minimum-weight bipartite spanning tree whose blue vertices have degree at most 2 is a lower bound on OPT.

Again, if we can find (in polynomial time) the minimum-weight bipartite spanning tree T whose blue vertices have degree at most 2, then a depth first traversal of T with short-cuts will yield a tour whose length is at most twice OPT.

We now claim that the problem of finding T can be viewed as that of finding the minimum-weight, maximum-cardinality subset in the *intersection* of two matroids [29, 15, 16]. The matroids in this case are M_1, the matroid of all bipartite forests, and M_2, the matroid of all bipartite subgraphs whose blue vertices have degree at most 2. For completeness we review the definition of a matroid, following the standard text [29].

DEFINITION. *A* matroid $M = (E, \mathcal{I})$ *is a structure in which* E *is a finite set of elements and* $\mathcal{I}$ *is a family of subsets (called* independent sets*) of* E*, such that* $\phi \in \mathcal{I}$ *and all proper subsets of a set* $I \in \mathcal{I}$ *are in* $\mathcal{I}$*; and if* I_p *and* I_{p+1} *are sets in* $\mathcal{I}$ *containing* p *and* $p+1$ *elements, respectively, then there exists an element* $e \in I_{p+1}$ *such that* $I_p \cup \{e\} \in \mathcal{I}$*.*

An example of a matroid is the *graphic matroid* $M = (E, \mathcal{I})$, where E is the set of edges of an undirected graph, and a subset $I \subset E$ is in $\mathcal{I}$ if and only if I is cycle-free. Another example is the *matrix matroid* $M = (C, \mathcal{I})$, where C is the set of columns of a fixed matrix A, and a subset S of columns is in $\mathcal{I}$ if and only if the columns of S are linearly independent. A maximal-cardinality independent subset of a matroid is called a *base* of a matroid; all bases of a matroid have the same cardinality.

Returning to our problem, let E be the set of all edges that connect red vertices to blue vertices. Let $\mathcal{F}$ denote the collection of all subsets of E that are cycle-free, and let $\mathcal{D}$ denote the collection of subsets S of E such that no more than two edges of S are incident on any blue vertex. Then it is easily shown that $M_1 = (E, \mathcal{F})$ and $M_2 = (E, \mathcal{D})$ are matroids. In addition, the problem of finding *a minimum-weight bipartite spanning tree where the blue vertices have degree at most two* is equivalent to the problem of finding *a minimum-weight common base of* M_1 *and* M_2*.*

This is a special case of the *matroid intersection* problem, which was first solved in polynomial time by Edmonds [15, 16]. Other authors [9] have exploited the special structure of problems such as ours to improve running times. We obtain the following theorem.

THEOREM 2.1. *There is a polynomial-time* 2*-approximation algorithm for the bipartite TSP.*

2.1. Extension to finite capacity vehicles. We will now show how to obtain a constant-factor approximation for the case of arbitrary finite k using the algorithm for the unit capacity case. First, however, we will establish some lower bounds on the optimal solution. Let C_k denote the (length of the) optimal k-delivery tour, and let C^r and C^b denote the (length of the) optimal tours on the red and blue points, respectively. Let A denote the weight of the minimum-weight perfect matching in the bipartite graph with red vertices on one side and blue vertices on the other. To keep the notation simple, we will often use the same symbol to denote a graph and its weight; the context will make it clear which one is intended.

LEMMA 2.2. (a) $A \leq C_1/2$.

(b) $\frac{1}{2k} C_1 \leq C_k$.

Proof. Part (a) is easy to see since C_1 consists of two perfect matchings and each is at least as heavy as A. To see part (b), start with an optimal k-delivery tour C_k: this defines an ordering $r_1, r_2, \ldots, r_n$ on the red points and an ordering $b_1, b_2, \ldots, b_n$ on the blue points. We then construct a 1-delivery tour T starting at the blue vertex b_1 as follows. Consider the blue vertices in the order imposed by C_k, connecting the ith blue vertex b_i to the earliest red vertex in the C_k-ordering that has not already

been connected to a blue vertex; then add another edge connecting this red vertex to the next blue vertex b_{i+1} (if this red vertex is the last one, connect it to the starting blue vertex b_1). By the triangle inequality, each edge e of T is no longer than the sum of the C_k-edges connecting the endpoints of e; we can thus "charge off" each edge of T to a collection of edges of C_k. Since there is never a surplus of more than k blue points in the tour C_k, it follows that no edge of T is charged more than $2k$ times. Thus $T \leq 2kC_k$, from which part (b) follows since $C_1 \leq T$. □

The following lemma is straightforward.

LEMMA 2.3. (a) $C^r \leq C_k$. (b) $C^b \leq C_k$.

We now use the lower bounds just presented to design a constant-factor approximation algorithm for the k-delivery problem. We first use Christofides's heuristic to obtain a 1.5-approximate tour T_r of the red vertices and a 1.5-approximate tour T_b of the blue vertices. Next, we decompose T_r and T_b into paths of k vertices each, by deleting a set of edges that are spaced along the tour at intervals of length k. In fact, there are k such sets of edges in a tour, and we delete the set of maximum weight. It will be convenient to view each k-path as a "supernode" in the following. We now overlay the minimum-weight perfect matching of cost A on this graph. Note that any (red or blue) supernode now has degree exactly k and that there may be several edges between two given supernodes. Thus we obtain a k-regular bipartite multigraph. The following result due to König [26, 31] is crucial to the design of our algorithm:

LEMMA 2.4. *The edges of a d-regular bipartite multigraph can be partitioned into d perfect matchings.*

Using this result, we can partition the perfect matching A into k perfect matchings on the supernodes. We pick the least-weight matching M out of these and delete all other edges of A. Clearly, $M \leq A/k \leq \frac{1}{2k}C_1$. At this stage we have a collection of n/k subgraphs $H_1, H_2, \ldots, H_{n/k}$, each consisting of a red supernode connected via an edge of M to a blue supernode. Now we reintroduce the edges of T_b that were removed when breaking T_b into k-paths; this imposes a cyclic ordering on the subgraphs H_i; let us relabel them $H_1, H_2, \ldots, H_{n/k}$ with this cyclic ordering, where H_1 contains the start blue vertex. We now traverse the subgraphs $H_1, H_2, \ldots, H_{n/k}$ in sequence as follows. Within each subgraph H_i, first visit all the blue vertices and then use the edge of M to go to the red side and visit all the red vertices; then return to the blue side, go to the blue vertex that is connected via an edge e of T_b to the next subgraph H_{i+1}, and use the edge e to go to H_{i+1} (or H_1 if $i = n/k$).

We claim that this tour T is within a constant factor of the optimal k-delivery tour. To verify this, notice that in short-cutting, by triangle inequality, we "charge" each edge of T_b (that was not deleted) no more than three times, each edge of T_r (that was not deleted) no more than two times, and each edge of M at most two times. Notice also that the set of deleted edges in T_b and T_r have total weight at least a $1/k$ fraction of the tour's weight. Thus, we obtain

$$\begin{aligned} T &\leq 3\left(1-\frac{1}{k}\right)T_b + 2\left(1-\frac{1}{k}\right)T_r + 2M \\ &\leq 3\left(1-\frac{1}{k}\right) \times 1.5C^b + 2\left(1-\frac{1}{k}\right) \times 1.5C^r + \frac{2}{2k}C_1 \\ &\leq 7.5\left(1-\frac{1}{k}\right)C_k + 2C_k \\ &\leq 9.5\left(1-\frac{7.5}{9.5k}\right)C_k. \end{aligned}$$

Note that, while for large k the approximation ratio is 9.5, for small k we do much better (e.g., 5.75 for $k = 2$).

THEOREM 2.5. *The above algorithm gives a* $9.5\left(1 - \frac{7.5}{9.5k}\right)$*-approximation to the optimal* k*-Delivery TSP.*

3. Maximum latency TSP. A variant of the following problem arises in the moving points case and is also of independent interest. Given a set of n points $\{p_1, \ldots, p_n\}$ in a metric space, find a path visiting all points, starting at a given point p_0, such that the total *latency* of the points is *maximized*. If in a given path P the length of the ith edge traversed is e_i, then the latency of the jth point visited ($j > 0$) is $L_j = \sum_{i=1}^{j} e_i$ and the total latency $L(P)$ is

$$L(P) = \sum_{j=1}^{n} L_j = \sum_{i=1}^{n} (n - i + 1)e_i.$$

We would like to find a path P for which $L(P)$ is maximized. We can show that this problem is NP-hard by reducing from the maximum Hamiltonian path (MaxHP) problem. A related problem, *minimum* latency TSP, has been addressed in [7, 22] where constant-factor approximations are obtained.

We show that the greedy strategy of at any stage, visiting the farthest unvisited point from the current point achieves a total latency at least half that of the maximum latency path. (In fact, it can also be shown from our proof that the greedy path has *length* at least half that of the MaxHP from the starting point p_0. This result was obtained previously by Fisher, Nemhauser, and Wolsey [17].) The key observation is the following lemma.

LEMMA 3.1. *Let* G_i *be the length of the first* i *edges in the greedy path starting from* p_0*. Let* P_i *be the length of the maximum* i*-path, i.e., the longest path that visits* i *vertices from* p_0*. Then for* $i \leq n$*,* $G_i \geq P_i/2$*.*

Proof. For brevity, paths/edges and their lengths are denoted by the same symbols. Consider the maximum matching M in the maximum i-path P_i, i.e., the maximum-length collection M of independent edges from P_i. Let the (lengths of) edges of M be $m_1 \geq m_2 \geq \cdots \geq m_k$. Note that $P_i \leq 2(m_1 + m_2 + \cdots + m_k)$. We will argue that $G_i \geq (m_1 + m_2 + \cdots + m_k)$.

Consider the edges in G_i as being *directed* in the direction of travel, starting from p_0. Call an edge m of M an *anchor* if there is an edge of G_i that *starts* at an endpoint of m; the *earliest* such edge g of G_i is said to be *anchored* at m.

CLAIM A. *If* g *is anchored at* m*, then* $g \geq m$*, since* G_i *is greedy and the other endpoint of* m *has not yet been visited at the time* g *was traversed by the greedy path.*

CLAIM B. *If* $m \in M$ *is not an anchor, then* every *edge of* G_i *has length at least* $m/2$*. To see this, note that neither endpoint of* m *is visited by* G_i *(except possibly at the end). By the triangle inequality, from any point* p*, at least one of the endpoints of* m *is at distance at least* $m/2$*. Since* G_i *is greedy, its edges have length at least* $m/2$*.*

Now suppose $m_1, m_2, \ldots, m_u$ are anchors and m_{u+1} is not; i.e., m_{u+1} is the heaviest edge of M that is *not* an anchor. (Note that u could be 0.) Let $g_1, g_2, \ldots, g_u$ be the corresponding anchored edges of G_i. Then Claims A and B imply that $g_1 + g_2 + \cdots + g_u \geq m_1 + m_2 + \cdots + m_u$ and that every edge of G_i has length at least $m_{u+1}/2$. There are now two cases to be considered. Recall that $k = |M|$.

Case 3.1 ($u = 0$ and $i = 2k - 1$). If $u = 0$, then m_1 is not an anchor, so all edges of G_i have length at least $m_1/2$. Also $i = 2k - 1$ implies that the starting point p_0

must occur in the matching M. Thus, the first edge of G_i must be anchored at an edge m' of M, and the total length of G_i is at least

$$m' + \frac{(i-1)m_1}{2} \;\geq\; m' + \frac{(2k-2)m_1}{2} \;=\; m' + (k-1)m_1 \geq m_1 + m_2 + \cdots + m_k).$$

Case 3.2 ($u \geq 1$ or $i \geq 2k$). Note that the total length L of unanchored edges of G_i is at least $(i-u)m_{u+1}/2$. If $u \geq 1$,

$$L \geq \frac{(2k-1-u-(u-1))m_{u+1}}{2} = (k-u)m_{u+1},$$

and if $i \geq 2k$,

$$L \geq \frac{(2k-u-u)m_{u+1}}{2} = (k-u)m_{u+1}.$$

Thus, G_i is at least $(m_1+m_2+\cdots+m_u)+(k-u)m_{u+1} \geq m_1+m_2+\cdots+m_k$. □

Clearly the latency of the ith point in the maximum latency path is at most P_i, so the lemma implies that the total latency of the greedy path is at least half that of the maximum latency path. Since P_n is the MaxHP, it also follows that the greedy path is a $\frac{1}{2}$-approximation of the MaxHP. Lemma 3.1 implies our result.

THEOREM 3.2. *The greedy strategy of always visiting the farthest unvisited point achieves a total latency at least half that of the maximum latency path.*

We can also show that the greedy heuristic works well for a different "latency measure" that arises implicitly in dynamic k-collect TSP.

THEOREM 3.3. *Let $\alpha < 1$ be a positive constant. For a Hamiltonian path P starting at p_0, define the cost $L_\alpha(P) = \sum_{i=1}^{n-1}(1-\alpha^{n-i})e_i$. The greedy heuristic produces a path whose L_α cost is at least $(1-\alpha)/2$ that of the maximum-L_α path.*

Proof. Let G denote the greedy path and H^* denote the MaxHP. Let P^*_α denote the path that maximizes $L_\alpha(.)$ and P^* be the path that maximizes $L(.)$. Since $(1-\alpha^{n-i}) < 1$ for $i = 1, 2, \ldots, n-1$, we have

$$L_\alpha(P^*_\alpha) \leq length(P^*_\alpha) \leq length(H^*),$$

and since $(1-\alpha^{n-i}) \geq 1-\alpha$ for $i = 1, 2, \ldots, n-1$, we have

$$L_\alpha(G) \geq (1-\alpha)length(G).$$

The desired result then follows from the fact that $length(G) \geq length(H^*)/2$ (Theorem 3.2). □

4. TSP for moving-points: Dynamic *k*-collect TSP. The dynamic k-collect TSP (defined in the introduction) is inspired by the following application in industrial robotics. After manufacture, parts are dumped onto a conveyor belt in arbitrary positions and orientations. Prior to packaging (or assembly), the parts must be collected by a robot arm of capacity k and delivered to an empty pallet at a fixed location (not on the belt) that can be treated as the origin of the coordinate space. Once filled, the pallet is moved away by another conveyor belt, and a new empty pallet appears at the origin. The general scenario of designing configurations and algorithms for robots working in their cells to handle parts as they come down a conveyor belt has been termed *rapid deployment automation* [4, 10, 30].

For convenience, we switch to the L_1 metric, and assume that the robot translates only parallel to the x- and y-axes. While there are situations where this applies

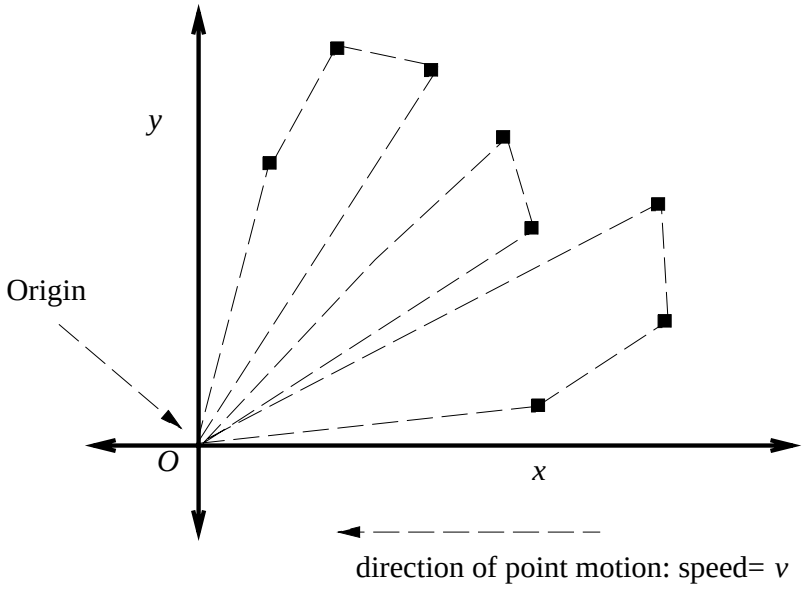

FIG. 2. *Illustrating the moving-points model. A* 3*-collect tour is shown.*

directly, it is also easy to see that this causes an error of only factor $\sqrt{2}$ with respect to the L_2 metric. We assume that the points $p_1, p_2, \ldots, p_n$ are always within the positive quadrant of the coordinate frame centered at the origin $p_0 = (0, 0)$ (see Figure 2). The robot moves with speed 1, and the belt (and each point p_i) moves with a velocity v directed in the negative x-direction. The y-axis represents the end of the conveyor belt, and to obtain meaningful results we must assume at the very least that v is suitably bounded below 1, since a slow robot may be unable to catch up with some points. In fact, to prove our approximation results it is sufficient to assume that $v \leq \frac{k}{2n}$, which is necessary to ensure that no p_i crosses the y-axis while the robot is in the process of executing the tour. *We will assume this upper bound on* v *throughout the rest of this paper.* Also, we define $\alpha = \frac{1-v}{1+v}$.

Some remarks are in order about our restriction to the case where the moving points' velocities are sufficiently smaller than that of the robot arm. As further explicated in section 4.6, this is essential to ensure that the robot arm is able to retrieve all objects and is certainly a valid assumption in the motivating application. An interesting variant, which we do not explore here, concerns the model where the velocities are unrestricted and the goal is to maximize the number of points visited, with possible restrictions on the total time available. Clearly, this would involve generalizing the *prize-collecting TSP* [5] to the case of moving points.

For clarity, we refer to a fixed point in space (such as the origin) as a *space-point*, to distinguish it from a *moving-point*, p_i. Define (x_i, y_i) as the coordinates of point p_i at time 0, and let $d_i = x_i + y_i$ denote the L_1 distance of p_i from the origin at time 0. Clearly the x-coordinate of p_i at time t is $x_i - vt$ and the y-coordinate doesn't change. The distance of p_i from the origin at time t is therefore $x_i + y_i - vt = d_i - vt$.

4.1. Shortest paths and triangle inequality. We establish several basic properties of travel times that are not immediate. Henceforth, when we say that the robot moves from a point A to a space-point B or meets a moving-point p_i, we will assume

that the robot takes the shortest-time path. What is the quickest way for a robot to meet a moving-point p? The following lemma characterizes such paths. A robot path is said to be *monotone* if no two points on the path have the same x-coordinate or the same y-coordinate.

LEMMA 4.1 (shortest paths). *Suppose the robot is at a space-point A and meets moving-point p at the earliest possible time, say, at space-point B. Then the robot's path from A to B is necessarily a shortest path between those points, and the robot never stops at any time before it meets p.*

Proof. At any time the robot may "sit and wait," move parallel to the x-axis, or move parallel to the y-axis. Suppose the robot meets point p after time T. If the robot's path to B is not the shortest path to B (from A) or the robot stopped at some time, this means that the robot could have arrived at B at an earlier time $T' < T$ (by either using a shorter path to B or not waiting along the way). At this time T' the moving-point p must be to the right of B a distance $(T - T')v$ away on the same y-coordinate, and the robot can meet p in time $(T - T')\frac{v}{1+v}$ by moving toward it. Thus, the total time to meet p could be $T' + \frac{v}{1+v}(T - T')$, and the time saved would be $(T - T') - \frac{v}{1+v}(T - T') = \frac{1}{1+v}(T - T')$, which is positive. This contradicts our assumption that the robot met p at the earliest possible time. □

We have the following important corollaries of the above lemma.

COROLLARY 4.2 (monotone path). *Suppose the robot moves from space-point A to meet a moving-point p. Then the robot's path must be monotone. In particular a quickest way for the robot to meet p is to first move to the y-coordinate of p and then move toward p.*

Proof. The following fact will be useful in this and other proofs about shortest paths.

FACT 4.3. *The shortest (and therefore least travel-time) path for the robot to move from a given space-point A to a given space-point B is a monotone path; in particular the monotone path that first moves to the y-coordinate of B and then to the x-coordinate of B is shortest.*

The monotonicity follows from Lemma 4.1 and Fact 4.3. Any monotone path that meets p can be replaced by a path where all the x-motion is done after the y-motion, without changing the rendezvous time or coordinates. Clearly the y-motion consists simply of moving to the y-coordinate of p. At this time p may either be left or right of the robot. In case p is left of the robot, by monotonicity the quickest way to meet p is to move toward p. In case p is to the right of the robot, if the robot moves to the left, then either the path becomes nonmonotone before it meets p or it must stop and wait for p to catch up with it, both of which are not possible in a shortest path, by Lemma 4.1. Thus, in this case also the robot must move toward p. □

COROLLARY 4.4 (triangle inequality 1). *If the moving-points p_i and p_j are in the positive quadrant and the robot is at p_i, then the time t_{ij} to travel directly to p_j is bounded by the time to travel to p_j via the origin.*

Proof. If the composition of the robot's path from p_i to the origin and the path from the origin to p_j is not monotone, then by Corollary 4.2 it cannot be shorter than the shortest p_i–p_j path; if it is monotone, then it cannot be shorter than the particular shortest p_i–p_j path described in Lemma 4.2. □

COROLLARY 4.5 (triangle inequality 2). *Let t_{ij} denote the shortest time of travel from moving-point p_i to moving-point p_j. Then for any three points p_i, p_j, p_ℓ, $t_{ij} + t_{j\ell} \geq t_{i\ell}$*

4.2. Useful time expressions. The following time expressions are easily verified; we will use them in the proofs in this paper. In all of the following keep in mind that d_i denotes the distance of p_i from the origin at time 0.

- *Origin to moving-point.* The robot is at the origin at time τ and meets moving-point p_i. The earliest rendezvous time is

$$\tau + \frac{d_i - v\tau}{1+v} = \frac{\tau + d_i}{1+v}. \tag{1}$$

- *Moving-point to origin.* At time τ the robot is at a moving-point p_i, and it then returns to the origin. The time of return to the origin is

$$\tau + d_i - v\tau = d_i + (1-v)\tau. \tag{2}$$

- *Moving-point to origin to moving-point.* At time τ the robot is at a moving-point p_i; it then returns to the origin and goes to moving-point p_j. From (2), the time of arrival at the origin is $d_i + (1-v)\tau$, and during this time point p_j moves closer to the origin by a distance $v(d_i + \tau(1-v))$. Thus the time of arrival at p_j is

$$d_i + \tau(1-v) + \frac{d_j - v[d_i + \tau(1-v)]}{1+v} = \frac{d_i + d_j}{1+v} + \tau\frac{1-v}{1+v}. \tag{3}$$

4.3. Optimal rendezvous. We can use the above characterization to derive some expressions for the shortest time (or distance) needed to meet a moving-point. Suppose at time t_0 the robot is at space-point $A = (x_1, y_1)$, and moving-point p is at (x_2, y_2). Let $x = |x_1 - x_2|$ and $y = |y_1 - y_2|$. If the robot moves and meets moving-point p at the earliest possible time $t_0 + t$, then t equals one of the following. In view of Lemma 4.2 we may assume that the robot first moves to the y-coordinate of p and then meets p by moving parallel to the x-axis.

- If p is to the right of A at time t_0 and $vy \leq x$, then p remains to the right of the robot when it reaches the y-coordinate of p, so

$$t = y + \frac{x - vy}{1+v} = \frac{x+y}{1+v}. \tag{4}$$

- If p is to the right of A at time t_0 and $vy > x$, then moving-point p will be to the left of the robot by the time the robot reaches the y-coordinate of p, so

$$t = y + \frac{vy - x}{1-v} = \frac{y-x}{1-v}. \tag{5}$$

- If p is to the left of A at time t_0, then

$$t = y + \frac{vy + x}{1-v} = \frac{x+y}{1-v}. \tag{6}$$

4.4. Robot arms with capacity 1. In the remainder of the paper we write C_k to denote the (length of the) optimal dynamic k-collect tour.

In dynamic 1-collect TSP, the robot must visit the points one at a time, returning to the origin after visiting each point. We prove the following theorem.

THEOREM 4.6. *For dynamic* 1*-collect TSP, the minimum-time tour (under the* L_1 *metric) visits moving-points in decreasing order of their distance from the origin at time* 0.

Proof. Suppose that the robot visits points $p_1, \ldots, p_n$ in that order. We derive an expression for the total time $T^{(1)}$ taken by a 1-collect tour. Let T_m denote the time taken by the tour after it has visited m points and returned to the origin. We show by induction on m that

$$T_m = \frac{2}{1+v}\left(\sum_{i=1}^{m} \alpha^{m-i} d_i\right),$$

where we recall that $\alpha = \frac{1-v}{1+v}$. The base case, $m = 1$, follows from an application of (1), using $\tau = 0$ and $i = 1$; note that the factor of 2 comes from the requirement that the robot returns to the origin.

For the induction step, we assume that

$$T_{m-1} = \frac{2}{1+v} \sum_{j=1}^{m-1} \alpha^{m-(i+1)} d_i.$$

Suppose that at time T_{m-1} the robot has just returned to the origin after visiting the point p_{m-1} and that now it is ready to go visit point p_m. The time taken to reach p_m is given by an application of (1) with $\tau = T_{m-1}$ and $i = m$, which equals

$$\frac{d_m}{1+v} - \frac{vT_{m-1}}{1+v}.$$

The total time required is given by

$$\begin{aligned} T_m &= T_{m-1} + 2\left(\frac{d_m}{1+v} - \frac{vT_{m-1}}{1+v}\right) \\ &= \left(1 - \frac{2v}{1+v}\right) T_{m-1} + \left(\frac{2}{1+v} d_m\right) \;=\; \alpha T_{m-1} + \frac{2}{1+v} d_m \\ &= \frac{2}{1+v}\left(\sum_{i=1}^{m-1} \alpha^{m-(i+1)+1} d_i\right) + \frac{2}{1+v} d_m \;=\; \frac{2}{1+v}\left(\sum_{i=1}^{m} \alpha^{m-i} d_i\right). \end{aligned}$$

So the total time $T^{(1)}$ taken by a 1-collect tour is given by

$$T^{(1)} = \frac{2}{1+v} \sum_{i=1}^{n} \alpha^{n-i} d_i. \tag{7}$$

The theorem then follows. □

Thus the optimal dynamic 1-collect tour has some aspects of a maximum latency tour. In fact the maximum latency problem is implicit in the dynamic k-collect problem for arbitrary finite k. We make this formal in section 4.7 where we introduce the notion of geometric latency of a tour.

4.5. Robot arms with infinite capacity. In dynamic k-collect TSP with $k = \infty$, the robot must visit all the n moving-points before returning to the origin. For the optimal tour, suppose that the last moving-point visited is p and say that p is at

distance d from the origin at time 0. If the tour reaches p at time T_p, then by (2) the total time taken is $C_\infty = d + (1-v)T_p$.

Our strategy for approximating C_∞ is to "guess" the last point p visited by the optimal tour (there are only n possibilities for p) and approximate the minimum-length path T_p^* from the origin to p that visits every other moving-point before visiting p (i.e., the minimum Hamiltonian path from the origin to p).

The problem of approximating T_p^* can be set up as an asymmetric TSP instance on a graph with $n+1$ vertices $v_0, v_1, \ldots, v_n$, where v_0 represents the origin and v_i the moving-point p_i. The directed distance $d(v_i, v_j)$ is defined to be the appropriate distance among (4), (5), and (6). Note that the ratio of the two directed distances between a given pair of vertices is bounded by either $(1+v)/(1-v)$ or $(y+x)/(y-x)$, where in the second case $vy > x$, i.e., $x/y < v < 1$. Thus, the ratio never exceeds $1/\alpha$. The best-known approximation algorithm [28] for the minimum Hamiltonian path between two specified vertices for a *symmetric* distance matrix has a ratio $\frac{5}{3}$. Therefore, using this algorithm, we can approximate T_p^* to within a factor $\frac{5}{3\alpha}$ and thereby approximate C_∞ to within the same ratio.

THEOREM 4.7. *There is a $\frac{5}{3\alpha}$-approximation algorithm for dynamic k-collect TSP with $k = \infty$.*

4.6. Robot arms with finite capacity k. We now consider dynamic k-collect TSP. We derive an expression for the time $T^{(k)}$ taken by a k-collect tour. Let $m = n/k$ denote the number of returns to the origin. We note that when the arm capacity is k, *at least* n/k returns to the origin are required, and it may be necessary to return to the origin more often to minimize the tour length. However, it is easy to show that the assumption of exactly n/k returns affects our results by a factor of at most 2. Also, in our motivating application, the robot may be required to pick exactly k objects on each excursion from the origin, which would justify our assumption of exactly n/k returns.

The sequence of edges traversed can be viewed as

$$(p_0, p_{v(0)})\ \ L_1\ \ (p_{u(1)}, p_0), (p_0, p_{v(1)})\ \ L_2\ \ (p_{u(2)}, p_0), (p_0, p_{v(2)})\ \ L_3, \ldots, L_m\ \ (p_{u(m)}, p_0),$$

where each L_i denotes the sequence of edges involving nonorigin points in the ith excursion from the origin. We abuse notation and denote by L_i the time spent traversing the corresponding edges. Let $D_0 = d_{v(0)}$, $D_m = d_{u(m)}$, and, for $2 \le i \le m-1$, $D_i = d_{u(i)} + d_{v(i)}$.

Notice first that the time till the end of L_1 is $T_1 = D_0/(1+v) + L_1$ and that the time to the end of L_2 (from (1)) is

$$T_2 = \alpha\left(\frac{D_0}{1+v} + L_1\right) + \frac{D_1}{1+v} + L_2.$$

If we were to return to the origin after L_2 (and d denotes the time-0 distance of the end of L_2 to the origin) the total time would be

$$T' = d + (1-v)T_2 = D_0\alpha^2 + D_1\alpha + d + (1-v)[L_1\alpha + L_2].$$

Generalizing this gives the following expression for $T^{(k)}$:

$$T^{(k)} = D_0\alpha^m + D_1\alpha^{m-1} + \cdots + D_{m-1}\alpha + D_m + (1-v)[L_1\alpha^{m-1} + L_2\alpha^{m-2} + \cdots + L_m]. \tag{8}$$

It might appear from (8) that $T^{(k)} \to 0$ as $\alpha \to 0$. However, (8) is valid only if at all times, all unvisited moving points remain to the right of the origin (i.e., in the positive quadrant). In the moving belt scenario, the y-axis represents the end of the belt. A small α corresponds to a v close to 1, whereas the problem is meaningful only if v is small enough that the points do not cross the y-axis when the robot is in the process of grasping them. A reasonable restriction on v is that the time for an optimal k-collect TSP tour should not suffice for any point to cross the origin. This implies that $C_1/k \leq d_{av}/v$, where d_{av} denotes the average of the distances d_i and that C_1/k is a lower bound on the optimal in the static problem (see for instance [1]). Thus, we will assume that $v(2d_{av}n)/k \leq d_{av}$, i.e., $v \leq \frac{k}{2n}$. This bound on v, although sufficient to enable us to prove our approximation results, may not be sufficient to ensure that the points do not cross the y-axis while the robot arm is visiting them. For instance, if the points are very close to the y-axis or very far from the x-axis, a tighter bound on v is needed. Nevertheless, we point out that in practical applications, the bound is close to the correct one since (a) the conveyor belt is of a fixed width, so no point is too far from the x-axis, and (b) the parts initially appear at some reasonable distance from the y-axis.

Given that $v \leq \frac{k}{2n}$, in the expression (8) for $T^{(k)}$, the smallest coefficient on any term is

$$\alpha^m = \alpha^{n/k} \geq \frac{(1 - \frac{k}{2n})^{n/k}}{(1 + \frac{k}{2n})^{n/k}} \geq \frac{1}{e}.$$

This implies that $T^{(k)} \geq \frac{1}{e}(D_0 + L_1 + D_1 + L_2 + D_2 + \cdots + L_m + D_m)$.

Let us denote the sum of terms in the parentheses by T'. Minimizing T' is a static k-collect TSP problem on $n+1$ vertices $v_0, v_1, \ldots, v_n$, where the directed distances are defined as in the C_∞ approximation, except that for all $i > 0$, $d(v_0, v_i) = d_i = d(v_i, v_0)$. As we showed before, the ratio of the two directed distances between a pair of vertices never exceeds $1/\alpha$, so the k-collect TSP approximation algorithm of [1] can be used to approximate T' to within a factor $2.5/\alpha$ of optimal. Thus, we can approximate the optimal k-collect tour time C_k to within a factor $2.5e/\alpha$.

THEOREM 4.8. *For $v \leq k/2n$, there is a $(2.5e/\alpha)$-approximation algorithm for dynamic k-collect TSP.*

The following lower bound, although not used in this paper, may lead to a different approximation algorithm for C_k than the one we presented above.

THEOREM 4.9. *For any finite k, $C_\infty \leq C_k$.*

Proof. Consider the optimal tour C_k for capacity k. (We will abuse notation and use the same symbol for a tour as for its length.) Let d be the time-0 distance from the origin of the final moving-point p visited by C_k before returning to the origin, and let T_p be the time taken by T up to this final point p. From (2), the total time taken is $C_k = T_p(1 - v) + d$. Note that before reaching the final point p, T may do the following several times: go from a moving-point p_i to the origin and then to moving-point p_j. However by the Triangle Inequality I (Corollary 4.4), a direct path from p_i to p_j is no longer than the path via the origin, so we can short-circuit each such indirect path by a direct path and gain time. By applying these short-circuits to every origin-return except the last one, we can modify the optimal tour C_k to an infinite-capacity tour that reaches p at an earlier time $T'_p \leq T_p$, and the total time of this tour would be $(1 - v)T'_p + d$ which is no larger than C_k. □

4.7. Geometric latency. The somewhat unwieldy expression (8) for $T^{(k)}$ can be lower-bounded by a more pleasant cost expression, which we call the *geometric*

latency of a tour. We describe this below and show how a variant of the *maximum* latency problem arises implicitly in minimizing the geometric latency.

Consider the asymmetric k-collect TSP problem with directed distances as defined in section 4.6. Now consider a capacity-k tour on this graph and let $e_1, e_2, \ldots, e_u$ be the sequence of (weights of) edges traversed. Fix some positive $\beta < 1$, and define the *geometric latency* G_β of this tour to be $G_\beta = \sum_{i=1}^{u} \beta^{u-i} e_i$. Assuming for convenience that n is a multiple of k, $u = m + n$.

LEMMA 4.10. *Let $\beta = \alpha^{1/k}$ and fix a capacity-k tour of length $T^{(k)}$ for the moving-points problem. Let G_β be the geometric latency of the corresponding (i.e., same order of visiting points) tour in the corresponding asymmetric k-collect TSP instance as described above. Then $T^{(k)} \geq G_\beta$.*

Proof. Consider expression (8) for $T^{(k)}$. Since $(1 - v) \geq \alpha$,

$$T^{(k)} \geq (D_0 + L_1)\alpha^m \ + \ (D_1 + L_2)\alpha^{m-1} \ + \ \cdots \ + \ (D_{m-1} + L_m)\alpha \ + \ D_m.$$

The lemma follows by comparing weights of corresponding terms in this expression and the one for G_β. ∎

Thus, if we are able to find a constant-factor approximation to a capacity-k tour with minimum geometric latency G_β, we would have a constant factor approximation for the dynamic k-collect TSP problem. We know of no such algorithm that runs in polynomial time. It is worth noting that G_β may be rewritten as

$$G_\beta = \sum_{i=1}^{u} e_i - \sum_{i=1}^{u-1} (1 - \beta^{u-i} e_i),$$

so minimizing G_β roughly involves simultaneously minimizing the total tour length and maximizing the second term, which is a variant of the linear latency. As we mentioned in section 3, we can approximately maximize the second term, but we do not know how to simultaneously bound the length of the tour.

4.8. Extensions. In conclusion, we briefly mention some easy extensions of the model and results for the moving-point scenario. We omit the details.

- The first extension is to the case where all points are moving *away* from the origin at velocity v, as would be the case in midair refueling of a formation of planes. The results and analysis are similar to that presented above.
- The second extension is to the case where the conveyor belt is circular and is rotating around the origin. We can obtain a constant-factor approximation for the case where the rotation speed is bounded below the robot's speed.

Acknowledgments. We are grateful to Alan Frieze for suggesting the bipartite TSP and for his encouragement. We are deeply indebted to Ken Goldberg and Anil S. Rao for describing the robotics application and the dynamic TSP problem, and for their valuable feedback and constant encouragement during the course of this work. Some of the results reported in this paper are based on joint work with Anil Rao [11].

ON FLOOR-PLAN OF PLANE GRAPHS*

XIN HE†

Abstract. A floor-plan is a rectangle partitioned into a set of disjoint rectilinear polygonal regions (called *modules*). A floor-plan F represents a plane graph G as follows: Each vertex of G corresponds to a module of F and two vertices are adjacent in G iff their corresponding modules share a common boundary. Floor-plans find applications in VLSI chip design.

If a module M is a union of k disjoint rectangles, M is called a k-rectangle module. It was shown in [K.-H. Yeap and M. Sarrafzadeh, *SIAM J. Comput.*, 22 (1993), pp. 500–526] that every triangulated plane graph G has a floor-plan using 1-, 2-, and 3-rectangle modules. In this paper, we present a simple linear time algorithm that constructs a floor-plan for G using only 1- and 2-rectangle modules.

Key words. algorithm, plane graph, rectangular dual, floor-plan

1. Introduction.

Floor-planning is an early step in VLSI chip design where one decides the relative location of functional entities on a chip (see [25] and the references cited within). The most immediate representation of a floor-plan is a partition of a rectangular chip area into modules (usually rectilinear polygons) where each module represents a functional entity. In the floor-planning process, we are given a graph $G = (V, E)$. Each vertex of G represents a functional entity. The edges of G represent the adjacency requirements between the functional entities. We want to partition a rectangular chip area into a set of rectilinear polygonal modules and map each vertex of G to a module such that two vertices are adjacent in G iff their corresponding modules share a common boundary. If G has such a floor-plan, clearly G must be a plane graph.

For simplicity, most floor-planning systems are restricted to using rectangular modules. (In [25], a rectangular module is called a 0-concave rectilinear module or 0-CRM since it has no concave corners). In the literature, a floor-plan of G using only rectangular modules is called a *rectangular dual* of G. The problem of constructing rectangular duals has been extensively studied. The necessary and sufficient conditions for G to have a rectangular dual were given in [14, 15, 16]. An algorithm for solving this problem was developed in [1, 2]. Although it runs in linear time, this algorithm is fairly complicated. A simple linear time algorithm for solving the rectangular dual problem was developed in [7, 12, 13]. The coordinates of the rectangular duals constructed by this algorithm are integers and carry clear combinatorial meaning. A parallel implementation of this algorithm, working in $O(\log^2 n)$ time with $O(n)$ processors, was given in [8]. A necessary and sufficient condition for a plane graph to have a *rectangular drawing* was given in [22]. Based on this characterization, a linear time algorithm to obtain a rectangular drawing of a plane graph was given in [18]. A rectangular dual of a plane graph G can be obtained by applying this algorithm

to the dual graph of G. The applications of rectangular duals were also discussed in [5, 9, 17].

However, not every plane graph G has a rectangular dual. If G has a triangle (a cycle with three edges) that encloses some vertices in its interior (such triangles will be called *separating triangles* and were called *complex triangles* in [25]), then G cannot have a rectangular dual because at least four rectangles are needed in order to enclose a nonempty area on the plane.

The problem of constructing floor-plans for general plane graphs (which may have separating triangles) was investigated in [19, 25]. If G has separating triangles, any floor-plan of G must use nonrectangular modules. In the applications of floor-plans, it is desirable to use modules whose shapes are as simple as possible [25]. This raises a natural question: How complex must these modules be? In [19, 25], the number of concave corners of a module M is taken as its complexity measure. If M has k concave corners, it is called a k-CRM in [25]. Thus a 0-CRM is just a rectangle. A 1-CRM is an L-shaped module. The possible shapes of 2-CRMs are shown in Figure 1. The necessary and sufficient conditions for G to have a floor-plan consisting of only 0- and 1-CRMs were given in [19]. It was shown in [25] that, in order to design a floor-plan for an arbitrary plane graph, it is both necessary and sufficient to use 0-, 1-, and 2-CRMs.

A more natural measure on the complexity of a module M is the minimum number of disjoint rectangles whose union forms M. If M is the union of k disjoint rectangles, we call M a *k-rectangle module*. In particular, a 1-rectangle module is a rectangle. Some 2-CRMs shown in Figure 1 are 3-rectangle modules. Thus the results in [25] state that we can always construct a floor-plan of an arbitrary plane graph G using only 1-, 2-, and 3-rectangle modules. As mentioned above, the floor-plans of plane graphs with separating triangles must use k-rectangle modules for $k > 1$. The remaining question is: Can we always find a floor-plan for an arbitrary plane graph G using only 1- and 2-rectangle modules? In this paper, we answer this question affirmatively. We present a linear time algorithm that constructs a floor-plan for G using only 1- and 2-rectangle modules.

As mentioned above, the existence of separating triangles is the reason for using nonrectangular modules. The main problem in designing a floor-plan for G using low complexity modules is to "eliminate" all separating triangles of G in some way. The weighted separating triangle elimination problem has been shown to be NP-complete [20].

The floor-plan algorithm in [25] consists of two steps. The first step is to "assign" all separating triangles of G to the vertices of G so that each vertex is assigned at most twice. The second step constructs a floor-plan by using the separating triangle-vertex assignment computed in the first step. The algorithms in [25] for both steps use recursion and are fairly complex. The floor-plan algorithm presented here uses the same two steps as in [25]. However, our approaches are quite different from that in [25]. In the first step, we use the *canonical ordering* concept introduced in [6]. The

resulting algorithm is extremely simple. Our algorithm for the second step uses the *vertex expansion* operation to eliminate all separating triangles and then constructs a floor-plan of G by calling the rectangular dual algorithm in [7, 12, 13]. Although both our algorithm and the algorithm in [25] run in linear time, our algorithm is much simpler. In addition, the floor-plan constructed by our algorithm uses 1- and 2-rectangle modules and integer coordinates. In contrast, the floor-plans produced by the algorithm in [25] need 3-rectangle modules.

Instead of using the vertex expansion operation, there is another way to eliminate a separating triangle T from the input graph: Break an edge e of T by adding a new vertex at the middle of e. A heuristic algorithm based on this approach was given in [23]. Unfortunately, this approach does not work well. We will present a plane graph G and show that if the "break edge" approach is used to construct a floor-plan for G, we must use 3-rectangle modules. The construction of G requires sophisticated graph-theoretic arguments.

The present paper is organized as follows. Section 2 presents necessary definitions and background. In section 3, we present our simple floor-plan algorithm. In section 4, we describe a plane graph G whose floor-plan requires using 3-rectangle modules if the "break-edge" approach is taken.

2. Definitions and background. Most graph-theoretic definitions in this paper are standard [3]. Let $G = (V, E)$ be a planar graph with n vertices. In this paper, we always assume G is equipped with a fixed plane embedding. Namely G is a *plane* graph. The embedding of G divides the plane into a number of connected regions. Each region is called a *face*. The unbounded face of G is called its *exterior face*. Other faces are *interior faces*. The vertices and the edges on the boundary of the exterior face are called *exterior vertices* and *exterior edges*. Other vertices and edges are *interior vertices* and *interior edges*. $N(v)$ denotes the set of neighbors of a vertex v. Let $deg(v) = |N(v)|$.

In this paper, the terms *path* and *cycle* always mean *simple path* and *simple cycle* (i.e., the vertices of path and cycle are distinct). A *triangle* is a cycle consisting of three edges. A cycle C of G divides the plane into its interior and exterior regions. If x is a vertex of a cycle C, we say C *contains* x. If a vertex y is in the interior of C, we say C *encloses* y. If a triangle C encloses at least one vertex in its interior, C is called a *separating cycle*. (This definition differs from its standard meaning which requires that there exists at least one vertex in the interior and at least one vertex in the exterior of C.) An *internally triangulated* plane graph is a plane graph all of whose interior faces are triangles. A *triangulated* plane graph is a plane graph all of whose faces (including the exterior face) are triangles.

We assume the embedding information of G is given by the following data structure. For each $v \in V$, there is a doubly linked circular list containing all vertices of $N(v)$ in counterclockwise order. The two copies of an edge (u, v) are cross-linked to each other. This representation can be constructed as a by-product by using a planarity testing algorithm in linear time (e.g., [10]).

A *floor-plan* F is a rectangle partitioned into a set of disjoint rectilinear modules. If all modules of F are rectangles, F is called a *rectangular dual*. A floor-plan F represents a plane graph G as follows: Each module of F corresponds to a vertex of G. Two vertices of G are adjacent in G iff their corresponding modules in F share at least one line seqment as their common boundary. A floor-plan F of a plane graph G is shown in Figure 2. The vertices e, i, g form a separating triangle and the module for g is a nonrectangular module.

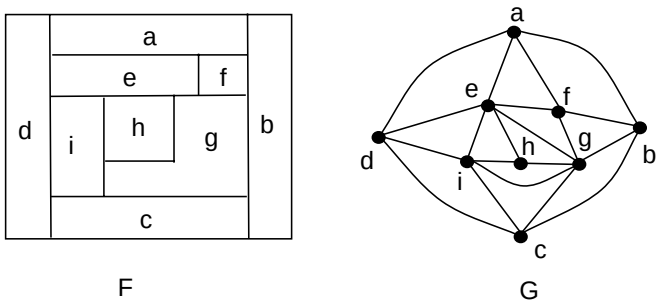

FIG. 2. *A floor-plan F of a plane graph G.*

Given a floor-plan F, the locations where at least two line segments meet are called the *points* of F. Since all modules of F are rectilinear polygons, at most four line segments can meet at the same point. We will assume the degree of any point of F is at most 3. This convention is used in most literature (see, for example, [25]). This convention considerably simplifies discussions and does not really limit the generality of the results. (The reason can be seen as follows. Each interior point of F corresponds to an internal face of G. Thus each internal face of G consists of either three or four vertices. If G has a face f consisting of four vertices u, v, w, x in counterclockwise order, we add a dummy edge (u, w) to triangulate the face f. In the floor-plan for the resulting graph, the modules for the vertices u and w share a common boundary. In the VLSI layout problem, we can simply ignore this common boundary. Alternatively, if four line segments meet at a point p of F, we can replace p by two degree-3 points connected by a line segment of zero length). Thus we assume all interior faces of G are triangles. When discussing rectangular duals, we assume that the exterior face of G has four vertices. (The conversion from the case of more than four exterior vertices to the case of four exterior vertices were discussed in [1, 7, 14]). When discussing floor-plans (where nonrectangular modules are allowed), we assume that G has either three or four exterior vertices. So under these conventions, we can restrict our discussion to internally triangulated plane graphs with either three or four exterior vertices. We will call such a graph a triangulated plane graph (TPG). Our floor-plan algorithm is based on the following theorem [7, 12, 13]:

THEOREM 2.1. *A TPG G has a rectangular dual iff it has four exterior vertices and has no separating triangles. Moreover, a rectangular dual of G with integer coordinates can be constructed in linear time.*

3. A simple floor-plan algorithm. Let $G = (V, E)$ be a TPG. We want to construct a floor-plan for G. The basic idea of our algorithm is as follows. First, we identify a subset $V' \subseteq V$ such that every separating triangle T of G contains at least one vertex $x \in V'$. (In this case, we say T is *assigned to* x). Then we convert G to a new TPG G_1 which has no separating triangles. G_1 is obtained from G by performing the *vertex expansion* operation on all vertices in V'. When this operation is performed on a vertex $x \in V'$, x is "split" into two vertices x_1 and x_2. The purpose of this operation is to "destroy" the separating triangles of G assigned to x. Next we run the rectangular dual algorithm in Theorem 2.1 on G_1 to obtain a rectangular dual F_1 of G_1. Finally, a floor-plan F of G is constructed from F_1 as follows: For each vertex $x \in V'$ that was expanded into two vertices x_1 and x_2 in G_1, the module of F representing x is the union of the two rectangles of F_1 corresponding to x_1 and x_2.

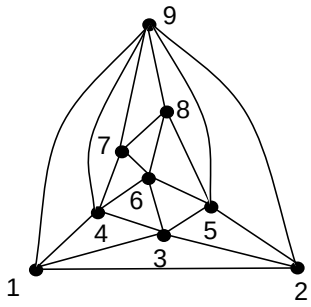

FIG. 3. *A canonical ordering of G.*

The rest of this section describes the details of our algorithm.

Let $\mathcal{T}(G)$ denote the set of all separating triangles of G. If a separating triangle $T_1 \in \mathcal{T}(G)$ is in the interior of another separating triangle $T_2 \in \mathcal{T}(G)$, T_1 is a *descendent* of T_2. If there is no $T_3 \in \mathcal{T}(G)$ such that T_1 is a descendent of T_3 and T_3 is a descendent of T_2, T_1 is a *child* of T_2. The child relation defines a forest structure on $\mathcal{T}(G)$.

Consider a separating triangle $T \in \mathcal{T}(G)$ with three vertices x, y, z. In any floor-plan of G, in order to satisfy the adjacency requirements of T, at least one of the three modules for x, y, z must be a nonrectangular module. We will *assign* T to one of x, y, z. If a vertex x is assigned a separating triangle, x will be represented by a nonrectangular module. Consider two separating triangles $T_1, T_2 \in \mathcal{T}(G)$ where T_1 is a descendent of T_2 and both T_1 and T_2 contain x. If we use a nonrectangular module for x, it is possible that the adjacency requirements for both T_1 and T_2 are satisfied. So we can assign both T_1 and T_2 to x. This observation was made in [25]. It leads to the following definition.

DEFINITION 3.1. *A* nesting sequence assigned to a vertex $x \in V$ *is a sequence* $T_1, T_2, \ldots, T_k$ *of separating triangles in* $\mathcal{T}(G)$ *such that each* T_i $(1 \le i \le k)$ *contains* x; *and* T_i *is a descendent of* T_{i+1} *for* $1 \le i \le k-1$.

In order to construct a floor-plan for G, we need to assign all separating triangles in $\mathcal{T}(G)$ to the vertices of G satisfying the following *valid assignment conditions*.

DEFINITION 3.2. *A* valid assignment *of G is a mapping of all separating triangles in* $\mathcal{T}(G)$ *to a set of nesting sequences such that:*

1. *Each* $T \in \mathcal{T}(G)$ *belongs to at least one nesting sequence.*
2. *Each vertex of G is assigned at most two nesting sequences.*

The first step of our floor-plan algorithm is to find a valid assignment of G. Our algorithm uses the following *canonical ordering* concept introduced in [6].

DEFINITION 3.3. *Let* $G = (V, E)$ *be a TPG with three exterior vertices* u, v, w. *A* canonical ordering *of G is an ordering of V by* $v_1, v_2, \ldots, v_n$ *such that* $v_1 = u$, $v_2 = v$, $v_n = w$ *and the following requirements hold for every* $4 \le k \le n$:

1. *The subgraph* G_{k-1} *of G induced by* $v_1, v_2, \ldots, v_{k-1}$ *is biconnected and the boundary of its exterior face is a cycle* C_{k-1} *containing the edge* (v_1, v_2).
2. v_k *is in the exterior face of* G_{k-1}, *and its neighbors in* G_{k-1} *form a subpath of the path* $C_{k-1} - \{(v_1, v_2)\}$ *consisting of at least two vertices. If* $k \le n-1$, v_k *has at least one neighbor in* $G - G_{k-1}$.

An example of a canonical ordering is shown in Figure 3.

The exterior face C_k of G_k is called the *contour* of G_k. The canonical ordering

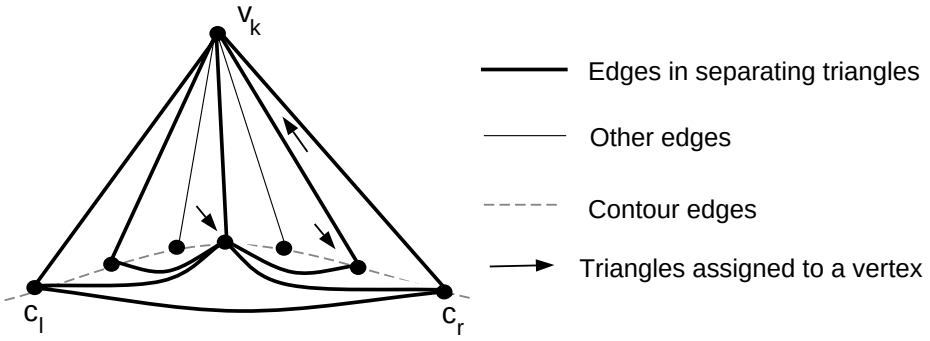

FIG. 4. *Assigning separating triangles to vertices.*

of G can be viewed as an ordering of adding the vertices one-by-one into the graph starting from the edge (v_1, v_2). Let $c_l, c_{l+1}, \ldots, c_r$ be the neighbors of v_k in G_{k-1} ordered from left to right. When v_k is added, it becomes a new contour vertex while the vertices $c_{l+1}, \ldots, c_{r-1}$ cease to be contour vertices. If v_k and two vertices c_i, c_j $(l \leq i < j \leq r)$ form a separating triangle T, (v_k, c_i) is called the *left edge* of T and (v_k, c_j) the *right edge* of T. The following algorithm computes a valid assignment of G.

ALGORITHM 1.
Input: A TPG G.
Output: A valid assignment of G.

1. Compute a canonical ordering $v_1, v_2, \ldots, v_n$ of G by calling the algorithm in [11]. (If G has four exterior vertices, a slight modification of the algorithm in [11] finds a canonical ordering of G. Let u, v, w, x be the four exterior vertices of G in counterclockwise order. If (v, x) is not an edge of G, u, v, x will be numbered as v_1, v_2, v_n. If (v, x) is an edge of G, u, v, w will be numbered as v_1, v_2, v_n).
2. For $k := 4$ to n Do:
   (a) Let $c_l, c_{l+1}, \ldots, c_r$ be the neighbors of v_k in G_{k-1} ordered from left to right. For each i $(l < i < r)$, the separating triangles of G (if any) that are introduced when v_k is added and have (v_k, c_i) as their right edge define a nesting sequence. Assign this sequence to c_i. (See Figure 4.)
   (b) The separating triangles of G (if any) that are introduced when v_k is added and have (v_k, c_r) as their right edge define a nesting sequence. Assign this sequence to v_k. (See Figure 4.)

End Algorithm 1.

LEMMA 3.1. *Algorithm* 1 *computes a valid assignment of* G *and runs in linear time.*

Proof. Consider an arbitrary separating triangle T of G. Let v_k be the highest numbered vertex among the three vertices of T. At the kth stage of the For loop, T belongs to a nesting sequence that is assigned to either a contour vertex c_i or to the vertex v_k. Since T is arbitrary, each separating triangle of G belongs to at least one nesting sequence.

Any vertex v_k of G can be assigned at most two nesting sequences: (i) when it first becomes a contour vertex (at step 2 (b)); and (ii) when it ceases to be a contour

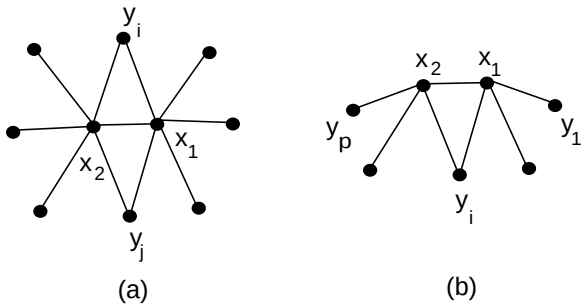

FIG. 5. *Vertex expansion operation.*

vertex (at step 2 (a)). Thus Algorithm 1 computes a valid assignment of G.

Next, we show Algorithm 1 can be implemented in linear time. A canonical ordering of G can be computed in $O(n)$ time [11]. By using the algorithm in [4], we can enumerate all triangles of G in linear time. For each triangle T of G identified, we can check if T is a separating triangle of G in $O(1)$ time by using the plane embedding data structure of G. Thus the set $\mathcal{T}(G)$ of all separating triangles of G can be identified in $O(n)$ time. Sort the separating triangles T in $\mathcal{T}(G)$ according to the highest numbered vertex in T. This can be done by using bucket sort in $O(n)$ time. Let $\mathcal{T}(v_k)$ be the separating triangles in $\mathcal{T}(G)$ with v_k as the highest numbered vertex.

The kth iteration of the For loop processes the separating triangles in $\mathcal{T}(v_k)$. Clearly, the number of separating triangles in $\mathcal{T}(v_k)$ is at most $O(deg(v_k))$. We sort the separating triangles T in $\mathcal{T}(v_k)$ according to the right vertex of T on the contour $c_l, \ldots, c_r$. This can be done in $O(deg(v_k))$ time by using bucket sort. For each c_i $(l < i < r)$, all separating triangles in $\mathcal{T}(v_k)$ with (c_i, v_k) as the right edge are assigned to c_i. All separating triangles with (c_r, v_k) as the right edge are assigned to v_k. Clearly, the kth iteration can be performed in $O(deg(v_k))$ time. So the total time to execute step 2 is $O(\sum_{k=4}^{n} deg(v_k)) = O(n)$. □

Remark 1. The vertices v_1 and v_2 are not assigned any sequence. If G has three exterior vertices, its exterior face is a separating triangle and the vertex v_n is assigned exactly one sequence. If G has four exterior vertices $u = v_1, v = v_2, w, x$, the vertices w and x are assigned at most one sequence each.

Next we describe the second step of our algorithm: Construct a floor-plan of G using a valid assignment of G. First we define the *vertex expansion* operation.

DEFINITION 3.4. *Let x be an interior vertex of G with neighbors $y_1, \ldots, y_p$ in clockwise order. The operation of* vertex expansion on x with respect to y_i, y_j $(1 \leq i < j \leq p)$ *is (see Figure* 5 (a)*):*

1. *Delete x. Create two new vertices x_1 and x_2. Add a new edge (x_1, x_2).*
2. *For $t = i+1, \ldots, j-1$, replace the edge (x, y_t) by (x_1, y_t). For $t = j+1, j+2, \ldots, p, 1, \ldots, i-1$, replace the edge (x, y_t) by (x_2, y_t).*
3. *Replace the two edges (x, y_i) and (x, y_j) by four new edges: (x_1, y_i), (x_2, y_i) and (x_1, y_j), (x_2, y_j).*

DEFINITION 3.5. *Let x be an exterior vertex of G with neighbors $y_1, \ldots, y_p$ in clockwise order where y_1 and y_p are exterior vertices. The operation of* vertex expansion on x with respect to y_i $(1 \leq i \leq p)$ *is as follows (see Figure* 5 (b)*).*

1. *Delete x. Create two new vertices x_1 and x_2. Add a new edge (x_1, x_2).*
2. *For $t = 1, \ldots, i-1$, replace the edge (x, y_t) by (x_1, y_t). For $t = i+1, \ldots, p$,*

replace the edge (x, y_t) *by* (x_2, y_t).

3. *Replace the edge* (x, y_i) *by two new edges:* (x_1, y_i), (x_2, y_i).

Note that after x is expanded, we always have $N(x) = N(x_1) \cup N(x_2)$. In a valid assignment of G, each vertex of G is assigned at most two nesting sequences. For each vertex x that is assigned at least one sequence, we perform the vertex expansion operation on x. There are three cases.

Case 1. x is an interior vertex and is assigned two sequences $\{T_1, T_2, \ldots, T_p\}$ and $\{S_1, S_2, \ldots, S_q\}$ (where T_1 is the innermost triangle in the first sequence and S_1 is the innermost triangle in the second sequence). Let y_i be a neighbor of x in the interior of T_1 (since T_1 is a separating triangle, y_i must exist) and y_j be a neighbor of x in the interior of S_1. Perform the vertex expansion operation on x with respect to y_i and y_j.

Case 2. x is an interior vertex and is assigned one sequence $\{T_1, T_2, \ldots, T_p\}$ (where T_1 is the innermost triangle in the sequence). Let y_i be a neighbor of x in the interior of T_1 and y_j be a neighbor of x in the *exterior* of T_1. (It is easy to see that y_j must exist). Perform the vertex expansion operation on x with respect to y_i and y_j.

Case 3. x is an exterior vertex. In this case, x is assigned one sequence $\{T_1, T_2, \ldots, T_p\}$ (where T_1 is the innermost triangle in the sequence). Let y_i be a neighbor of x in the interior of T_1. Perform the vertex expansion operation on x with respect to y_i.

After performing the vertex expansion operation on all vertices that are assigned at least one nesting sequence, the resulting graph G_1 is a TPG with no separating triangles. (This is because every separating triangle of G belongs to at least one nesting sequence assigned to a vertex v, and the expansion of v destroys such a separating triangle. On the other hand, no new separating triangles can be created by vertex expansion operation). Below we describe how to obtain a floor-plan for G.

First, assume G has three exterior vertices. By Remark 1, exactly one exterior vertex is assigned a sequence and is expanded. Thus G_1 has four exterior vertices. We use the algorithm in Theorem 2.1 to find a rectangular dual F_1 for G_1. A floor-plan F of G can be obtained from F_1 as follows. Consider any vertex x of G. If the vertex expansion operation is not performed on x, we take the rectangle in F_1 for x to be the module in F representing x. If the vertex expansion operation is performed on x, there are two vertices x_1 and x_2 in G_1 corresponding to x. The module in F representing x is the union of the two rectangles in F_1 for x_1 and x_2. Clearly, F is a floor-plan of G consisting of only 1- and 2-rectangle modules.

Next assume G has four exterior vertices. By Remark 1, either 0, or 1, or 2 exterior vertices of G are assigned a sequence and expanded. Thus G_1 has either 4, or 5, or 6 exterior vertices. In the first case, we can use the same construction described in the last paragraph. In the other two cases, in order to use Theorem 2.1, we have to modify the graph G_1. We consider the case where G_1 has 6 exterior vertices. (The case of 5 exterior vertices is similar). Let u, v, w, x be the four exterior vertices of G in counterclockwise order. Suppose that w is expanded to w_1 and w_2; and x is expanded to x_1 and x_2. The exterior face of G_1 is u, v, w_1, w_2, x_1, x_2 in counterclockwise order (Figure 6 (a).) It is easily seen that G_1 cannot have both edges (u, w_2) and (v, x_1). We modify G_1 to a new TPG G_2 as follows: Add two new vertices y, z and a new edge (y, z) in the exterior face of G_1. Connect y and z to the exterior vertices of G_1 according to the following conditions:

Case A. (u, w_2) is not an edge of G_1. Add edges $(z, u), (z, x_2), (z, x_1), (z, w_2)$ and the edges $(y, w_2), (y, w_1), (y, v)$. (See Figure 6 (a).) Let G_2 be the resulting graph. It is easy to check that G_2 has no separating triangles. So we can construct a rectangular dual F_2 of G_2 by using the algorithm in Theorem 2.1. By removing the two rectangles of F_2 corresponding to y and z (and modifying the rectangles for u and v if necessary),

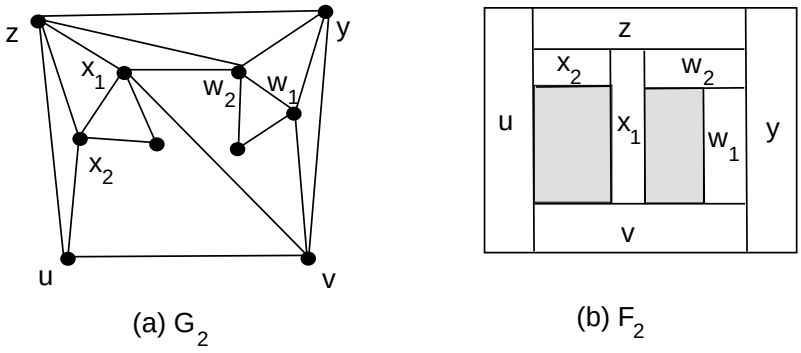

FIG. 6. *Convert G_1 to a TPG with four exterior vertices.*

we get a rectangular dual F_1 for G_1. (See Figure 6 (b).) By using the method described above, F_1 can be converted to a floor-plan F of G.

Case B. (v, x_1) is not an edge of G_1. Add edges: $(z, u), (z, x_2), (z, x_1), (y, x_1)$, $(y, w_2), (y, w_1), (y, v)$. Then the construction is the same as in Case A.

THEOREM 3.2. *Given an arbitrary TPG G, a floor-plan of G using* 1- *and* 2-*rectangle modules and integer coordinates exists and can be computed in linear time.*

Proof. The existence of such a floor-plan is proved in the above discussion. We only need to show it can be constructed in linear time. A valid assignment of G can be computed in linear time (Lemma 3.1). The vertex expansion operation on x can be performed in $O(deg(x))$ time by using the planar embedding data structure. Thus the total time for this step is $O(\sum_{x \in V} deg(x)) = O(n)$. After G_1 is constructed, its rectangular dual F_1 can be computed in $O(n)$ time by using the algorithms in [7, 12, 13]. The conversion from F_1 to the floor-plan F of G clearly takes linear time. □

4. A TPG requiring 3-rectangle models using break-edge method. A heuristic algorithm was proposed in [23] to construct a floor-plan for a triangulated plane graph G using low complexity modules. Instead of using vertex expansion, this algorithm uses *breaking edge* operation to eliminate the separating triangles. In this section, we show that this heuristic algorithm does not work well. We will describe a plane graph G and show that if the algorithm in [23] is applied to G, a 3-rectangle module must be used.

First we describe the "break edge" operation used in [23]. Consider a separating triangle T of G with three vertices x, y, z. In order to "eliminate" T, an edge of T, say (x, y) is selected. Let T' and T'' be the two interior triangular faces of G having (x, y) on their boundary. Let u and v be the third vertex of T' and T'', respectively (Figure 7 (a)). Now add a new vertex w at the middle of (x, y) and connect w to u and v. (If (x, y) is an exterior edge, there is only one interior face T' containing (x, y). In this case, we only connect w to u.) After this "break edge" operation, the resulting graph is still a TPG and T is no longer a separating triangle. We say the edge (x, y) *covers* T. The edge (x, y) is *assigned* to either x or y.

In order to find a floor-plan F of G, the algorithm in [23] performs this operation on all separating triangles of G. More precisely, for each separating triangle T, an edge $e = (x, y)$ of T is selected to cover T and e is assigned to either x or y. Let E_1 be the set of the selected edges. Then the "break edge" operation is performed on

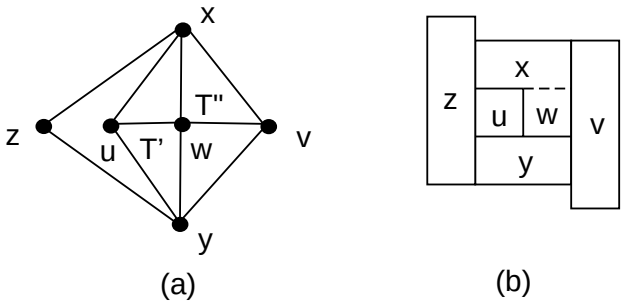

FIG. 7. *Break an edge.*

every edge in E_1. The resulting graph G_1 is a TPG with no separating triangles. A rectangular dual F_1 of G_1 is constructed. F_1 can be converted to a floor-plan F of G as follows: For each vertex x of G, the module in F representing x is the union of the rectangles in F_1 for x and for the added vertices on the edges that are assigned to x. (See Figure 7 (b). In this figure, the edge (x, y) is assigned to x. So the module for x is the union of the two rectangles labeled by x and w.) F is clearly a floor-plan of G. Note that F uses only 1- and 2-rectangle modules iff each vertex x of G is assigned at most one edge.

DEFINITION 4.1. *A* valid cover-assignment *of $G = (V, E)$ is a subset $E_1 \subseteq E$ and an assignment of each edge $e \in E_1$ to one of its two end vertices such that the following hold:*

1. *Each separating triangle T of G has at least one edge in E_1.*
2. *Each vertex of G is assigned at most one edge.*

Thus if G has a floor-plan consisting of only 1- and 2-rectangle modules by using this "break edge" approach, then G must have a valid cover-assignment. In this section, we describe a TPG $\bar{G}$ and show that $\bar{G}$ has no valid cover-assignment. Hence if the "break edge" approach is used to eliminate the separating triangles of $\bar{G}$, there must be a vertex v with at least two edges assigned to v. Therefore, in the floor-plan for $\bar{G}$ constructed by using this approach, the module for v is the union of at least three rectangles. In other words, we are forced to use 3-rectangle modules.

Consider a triangulated plane graph G with n vertices. Let $\bar{G}$ be the TPG obtained from G by adding a new vertex v_f in each internal face f of G and connecting v_f to the three vertices of f. We would like to find a floor-plan for $\bar{G}$. Note that all faces of G are separating triangles of $\bar{G}$. Let G^* be the dual graph of G. To avoid confusion, the vertices of G^* will be referred to as *nodes*. Each edge e^* of G^* corresponds to an edge e in G. e^* will be called the dual edge of e. Clearly, G^* is a 3-regular and 3-connected plane graph.

Our proof plan is as follows: First, we assume that $\bar{G}$ has a valid cover-assignment and derive the conditions that G and G^* must satisfy. Then we present a graph G and show that these conditions do not hold for G and G^*.

Define a *pseudotree* to be a connected graph with at most one cycle. In other words, a pseudotree is either a tree, or a tree T plus an additional edge connecting two vertices of T.

Let E_1 be a valid cover-assignment of $\bar{G}$. Since only the edges in G can be used to cover the separating triangles of $\bar{G}$, E_1 is actually a subset of the edges in G. Let $G[E_1]$ denote the subgraph of G spanned by E_1.

LEMMA 4.1. *Let E_1 be a valid cover-assignment of $\bar{G}$. Let $G[E_1]$ denote the subgraph of G spanned by E_1. Then any connected component of $G[E_1]$ is a pseudotree.*

Proof. Since each edge in E_1 is assigned to a unique vertex of G, we have $|E_1| \leq n$. Consider a connected component C of $G[E_1]$ with k vertices. Being connected, C has at least $k-1$ edges. On the other hand, since every edge of C is assigned to a unique vertex of C, C contains at most k edges. So C is a pseudotree. □

Consider the dual graph G^* of G. Each node of G^* corresponds to a face of G. Since G is a triangulated plane graph, G^* has $2n-4$ nodes. Let E_1^* be the set of dual edges of E_1. A face f of G is covered by an edge $e \in E_1$ iff the dual edge e^* of e is incident to the node in G^* corresponding to f. Since all of the $2n-4$ faces of G must be covered and each edge of E_1 can cover only two faces, we have $|E_1^*| = |E_1| \geq n-2$. Hence $|E_1^*| = n-2$, or $n-1$, or n. Consider the subgraph $G^* - E_1^*$ (which is obtained from G^* by removing the edges in E_1^*). Since G^* is 3-regular, we have the following three cases.

Case 1. $|E_1^*| = n-2$. Then each node in G^* is incident to exactly one edge in E_1^*. (Namely, E_1^* is a perfect matching of G^*). Thus, each node of G^* has degree 2 in $G^* - E_1^*$. Hence $G^* - E_1^*$ is a collection of disjoint cycles.

Case 2. $|E_1^*| = n-1$. Either one node in G^* is incident to three edges in E_1^* and all other nodes are each incident to one edge in E_1^*; or two nodes in G^* are each incident to two edges in E_1^* and all other nodes are each incident to one edge in E_1^*. In either case, $G^* - E_1^*$ is the union of a path and a collection of cycles. (A single node is considered as a path of length 0).

Case 3. $|E_1^*| = n$. Similar to Case 2, it can be shown that $G^* - E_1^*$ is the union of two paths and a collection of cycles.

This motivates the following definition.

DEFINITION 4.2. *A* Hamiltonian-like decomposition (HLD) *of a 3-regular plane graph G^* is a partition of the node set of G^* into subsets $P_1, P_2, \ldots, P_s$ such that each P_i $(1 \leq i \leq s)$ forms either a cycle or a path of G^*, and at most two P_i's are paths.*

Let $\mathcal{P} = \{P_1, P_2, \ldots, P_s\}$ be a HLD of G^*. Consider a cycle $P_k \in \mathcal{P}$. If $P_i \in \mathcal{P}$ $(i \neq k)$ is in the interior of P_k, we say P_i is a *descendent* of P_k. If there is no $P_j \in \mathcal{P}$ such that P_i is a descendent of P_j and P_j is a descendent of P_k, then P_i is a *child* of P_k. The child relation defines a forest structure on $\mathcal{P}$. Let $K(G^*, \mathcal{P})$ be the following graph: Its vertex set is $\mathcal{P}$. $P_i, P_j \in \mathcal{P}$ are adjacent in $K(G^*, \mathcal{P})$ iff P_i is a child of P_j.

DEFINITION 4.3. *A HLD $\mathcal{P}$ of G^* is called a* linear HLD *if the forest $K(G^*, \mathcal{P})$ has at most two trees and each of them is a linear path (i.e., each vertex has at most one child).*

THEOREM 4.2. *If $\bar{G}$ has a valid cover-assignment E_1, then $G^* - E_1^*$ is a linear HLD of G^*.*

Proof. In the above discussion, we have shown that if $\bar{G}$ has a valid cover-assignment E_1, then $\mathcal{P} = G^* - E_1^* = \{P_1, P_2, \ldots, P_q\}$ is a HLD of G^*. We will show $\mathcal{P}$ is linear. Suppose not. Then there exist $P_i, P_j, P_k \in \mathcal{P}$ such that one of the following two situations occurs:

(1) P_k is a cycle; P_i and P_j are children of P_k;

(2) P_i, P_j, P_k are not in the interior of any cycle in $\mathcal{P}$.

The theorem follows if we can prove both (1) and (2) are impossible. We first prove the situation (1) is impossible. Let $P_{l_1} = P_i, P_{l_2} = P_j, P_{l_3}, \ldots, P_{l_r}$ be the members in $\mathcal{P}$ that are children of P_k. Let $E_2^* \subset E_1^*$ be the subset of the edges in E_1^* that are in the interior of P_k but in the exterior of $P_{l_1}, P_{l_2}, \ldots, P_{l_r}$. Let E_2 be the subset of the

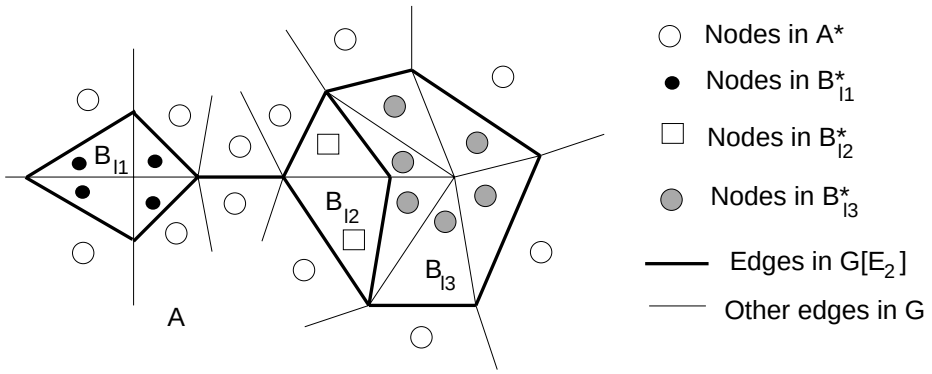

FIG. 8. *The proof of the claim.*

edges in G corresponding to the edges in E_2^*.

Claim. The subgraph of $G[E_2]$ of G is connected and is not a pseudotree.

Note: The claim implies that $G[E_2]$ is contained in a connected component of $G[E_1]$ and is not a pseudotree. Hence E_1 cannot be a valid cover-assignment of $\bar{G}$ by Lemma 4.1.

Let A^* be the set of the nodes of G^* that are on P_k or in the exterior of P_k. For each $1 \leq s \leq r$, let $B_{l_s}^*$ be the set of the nodes of G^* that are on P_{l_s} or in the interior of P_{l_s} (if P_{l_s} is a cycle).

Let A be the region on the plane that is the union of the faces of G corresponding to the nodes in A^*. Let B_{l_s} $(1 \leq s \leq r)$ be the region on the plane that is the union of the faces of G corresponding to the nodes in $B_{l_s}^*$.

It can be seen that $G[E_2]$ is exactly the common boundary of the regions A,$B_{l_1}, \ldots,$ B_{l_r}. (See Figure 8 where $r = 3$). It is easy to show that the common boundary of these regions are connected. The boundary of B_{l_1} is a cycle (not necessarily simple). The boundary of B_{l_2} is also a cycle. Thus, $G[E_2]$ is connected and has at least two cycles. Hence it is not a pseudotree. This proves the claim. So the situation (1) cannot occur.

To show the situation (2) cannot occur, let P_k be the member of $\mathcal{P}$ that contains the node of G^* corresponding to the exterior face of G and repeat the above argument. □

In the rest of this section, we present a 3-regular and 3-connected plane graph G^* that does not have a linear HLD. Then the corresponding graph $\bar{G}$ has no valid cover-assignment by Theorem 4.2. The construction of G^* is fairly complex. This is to be expected considering the following historical perspective (see [3], pp. 160–162). While attempting to prove the 4-color conjecture, Tait "proved" the following proposition in 1880 [21].

PROPOSITION. *Every* 3*-regular and* 3*-connected planar graph has a Hamiltonian cycle.*

The 4-color theorem follows easily from this proposition (see [3, pp. 158–159]). Over sixty years later, however, Tutte showed in [24] that this proposition is false by giving a counter-example shown in Figure 9 (a) (ignore the vertices a, b, c). This graph is commonly referred to as the Tutte's graph. Since the conditions of having a linear HLD is weaker than that of having a Hamiltonian cycle, it is harder to find a 3-regular and 3-connected planar graph without a linear HLD.

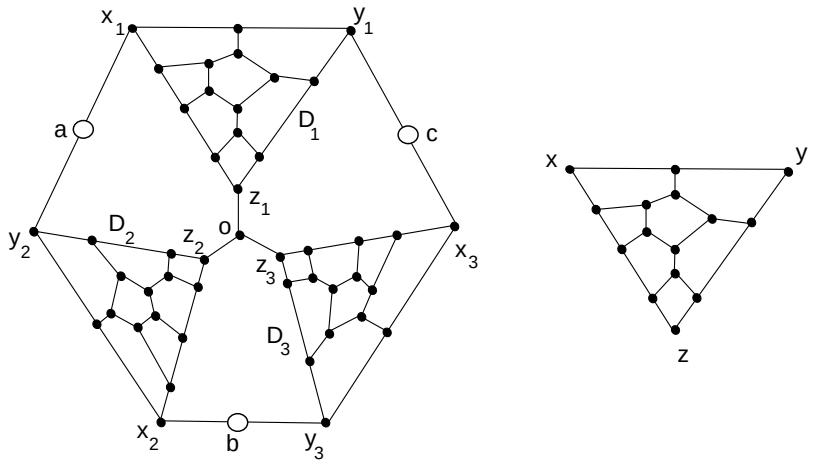

FIG. 9. *Tutte's graph.*

We use the Tutte's graph as a building block in constructing our graph G^*. Let S denote the graph shown in Figure 9 (a). It is obtained from the Tutte's graph by adding three new nodes a, b and c at the middle of three edges. In the following, HP stands for Hamiltonian path.

LEMMA 4.3. *In the graph S, there is no HP between a and b; no HP between b and c, no HP between c and a.*

Proof. Tutte's graph T consists of three copies of the graph D shown in Figure 9 (b). The following fact was proved in [24].

Fact 1. In the graph D, there is no HP between x and y. (However, D does have a HP between y and z and a HP between x and z.)

Toward a contradiction, suppose that S has a HP Q starting at a and ending at c.

Case 1. The second node of Q is x_1 and the second last node of Q is y_1. Then $Q - \{(a, x_1), (y_1, c)\}$ is a HP in the graph $S - \{(y_2, a), (a, x_1), (y_1, c), (c, x_3)\}$ between x_1 and y_1. This is impossible.

Case 2. The second node of Q is x_1 and the second last node of Q is x_3. Then $Q' = Q - \{(a, x_1), (x_3, c)\}$ is a HP in the graph $S - \{(y_2, a), (a, x_1), (y_1, c), (c, x_3)\}$ between x_1 and x_3. It is easy to see that Q' must have the following form:

A HP of D_1 from x_1 to z_1; the edges (z_1, o) and (o, z_2); a HP of D_2 from z_2 to x_2, the edges (x_2, b) and (b, y_3); a HP of D_3 from y_3 to x_3.

However, the last HP of D_3 does not exist by Fact 1. So Case 2 is impossible.

Case 3. The second node of Q is y_2 and the second last node of Q is y_1. This case is symmetric to Case 2. Similar to Case 2, this case is impossible.

Case 4. The second node of Q is y_2 and the second last node of Q is x_3. Then $Q - \{(a, y_2), (x_3, c)\}$ is a HP in the graph $S - \{(y_2, a), (a, x_1), (y_1, c), (c, x_3)\}$ between y_2 and x_3. Clearly, this is impossible.

Since all four cases are impossible, the assumed HP between a and c does not exist. Similarly, we can show S has no HP between a and b and no HP between c and b. □

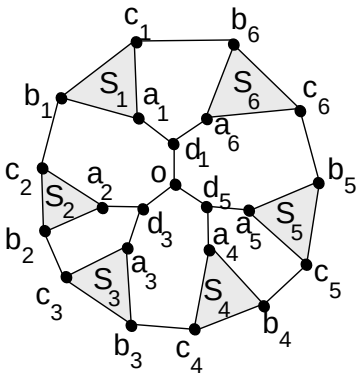

FIG. 10. *The graph G^*.*

Let G^* be the graph shown in Figure 10. G^* consists of six copies of S. Clearly, G^* is a 3-regular and 3-connected plane graph. We will show that G^* does not have a linear HLD. First, we prove a technical lemma.

LEMMA 4.4. *The node set of G^* cannot be partitioned into two paths.*

Proof. Towards a contradiction, suppose that the node set of G^* can be partitioned into two paths P_1 and P_2. At least one of S_i $(1 \leq i \leq 6)$, say S_1, does not contain any end nodes of P_1 and P_2. Since S_1 is connected to other parts of G^* by only three edges, all nodes of S_1 must be entirely contained in either P_1 or P_2. This can happen only if there is a HP in S_1 between a_1 and b_1, (or between b_1 and c_1, or between c_1 and a_1). This is impossible by Lemma 4.3. □

THEOREM 4.5. *G^* does not have a linear HLD.*

Proof. Consider any HLD $\mathcal{P} = \{P_1, P_2, \ldots, P_s\}$ of G^*. We show $\mathcal{P}$ cannot be a linear HLD. If no $P_i \in \mathcal{P}$ is a cycle, then we must have $s \leq 2$. This is impossible by Lemma 4.4. So at least one member of $\mathcal{P}$, say P_1, is a cycle. We will show that one of the following three cases hold for the graph $G^* - P_1$:

(a) $G^* - P_1$ has at least 3 connected components; or

(b) $G^* - P_1$ has two connected components and one of them cannot be enclosed in the interior of a cycle, nor can it have an HP; or

(c) $G^* - P_1$ has one connected component C and C cannot be enclosed in the interiors of two disjoint cycles; nor can C be partitioned into two paths; nor can some nodes of C be enclosed in a cycle and other nodes of C form a path.

If any of these three cases occurs, it is easily seen that $\mathcal{P}$ cannot be a linear HLD and we are done.

Case 1. The node o is on the cycle P_1. Without loss of generality, we assume the edges (o, d_1) and (o, d_3) are in P_1.

Case 1.1. The edges (d_1, a_6) and (d_3, a_3) are in P_1. Clearly, P_1 must contain either (i) the edge (b_4, c_5); (ii) the edge (b_1, c_2); or (iii) the node d_5.

(i) P_1 contains (b_4, c_5). Then P_1 passes through S_i $(i = 3, 4, 5, 6)$. (See Figure 11 (a). The solid lines indicate P_1.) By Lemma 4.3, P_1 cannot contain all nodes of S_i (for each $i = 3, 4, 5, 6$). So there must exist at least one *left-over* node u_i in S_i not belonging to P_1. Depending on whether u_i's $(i = 3, 4, 5, 6)$ are in the interior or the exterior of P_1, there are several subcases. If $G^* - P_1$ has at least three connected components, then by the remark at the beginning of the proof, $\mathcal{P}$ cannot be a linear HLD and we are done. The only case where $G^* - P_1$ has only two connected components is: u_4 and

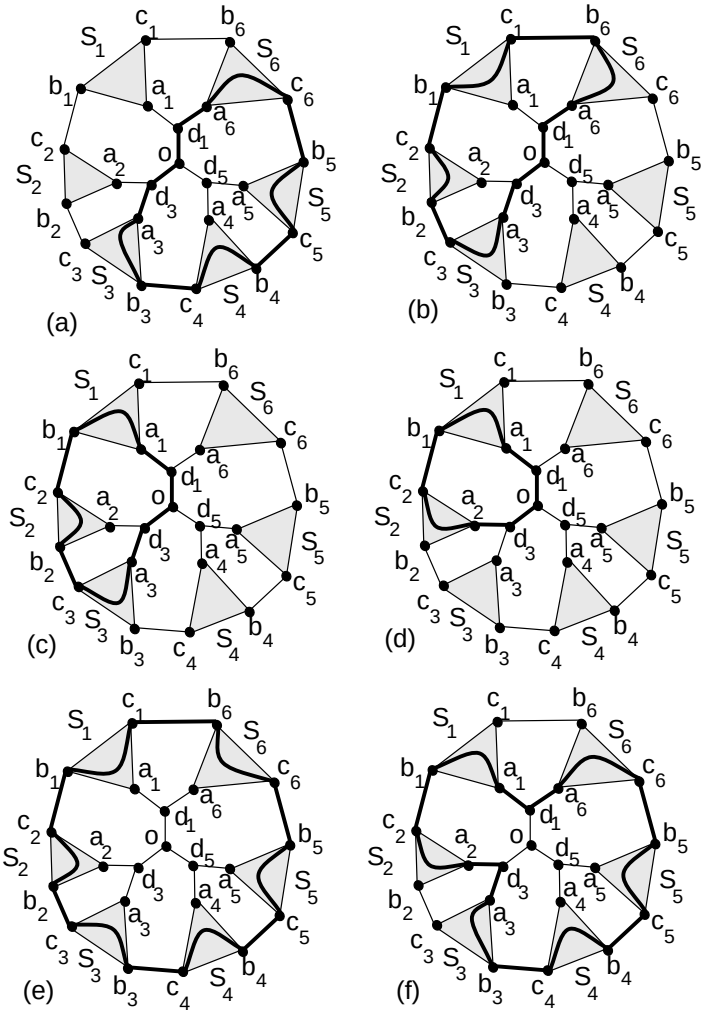

FIG. 11. *The proof of Theorem* 4.5.

u_5 are in the interior of P_1 and form a connected component C_1 (of $G^* - P_1$) through the node d_5; u_3 and u_6 are in the exterior of P_1 and form a connected component C_2 (of $G^* - P_1$) with the nodes in S_2 and S_1. However, C_2 does not have a HP (by Lemma 4.3); nor can its nodes be enclosed in a simple cycle (since the exterior face of C_2 is not a cycle). Thus, $\mathcal{P}$ cannot be linear.

(ii) P_1 contains the edge (b_1, c_2). Then P_1 passes through S_i $(i = 1, 2, 3, 6)$. (Figure 11 (b).) P_1 cannot contain all nodes in S_i. Thus, there must exist at least one left-over node u_i in S_i $(i = 1, 2, 3, 6)$ not belonging to P_1. Note that P_1 passes through the edges $(b_6, c_1), (b_1, c_2), (b_2, c_3)$ and the nodes o, d_1, d_3. Thus, $G^* - P_1$ has at least three connected components: one contains u_1, one contains u_2, and another contains the nodes in S_4 and S_5. Thus, $\mathcal{P}$ cannot be linear.

(iii) P_1 contains the node d_5. Then P_1 passes through the edges (b_3, c_4) and (b_5, c_6), but not the edge (b_4, c_5). Similar to the subcase (i), we can show $\mathcal{P}$ is not

linear.

Case 1.2. P_1 contains the edges (d_1, a_1) and (d_3, a_3). Then P_1 passes through either (i) the edge (b_4, c_5), (ii) the edge (b_1, c_2), or (iii) the node d_5.

(i) P_1 passes through (b_4, c_5). Then P_1 passes through S_i $(i = 1, 3, 4, 5, 6)$. Let u_i be the left-over node in S_i not belonging to P_1. Then $G^* - P_1$ has at least three connected components: one contains u_4 (and possibly u_5), one contains u_6, and another contains S_2. Thus, $\mathcal{P}$ cannot be linear.

(ii) P_1 passes through (b_1, c_2). Then P_1 passes through S_i $(i = 1, 2, 3)$. (See Figure 11 (c).) Let u_i $(i = 1, 2, 3)$ be the left-over node in S_i not belonging to P_1. Depending on whether u_1, u_2, u_3 are in the interior or the exterior of P_1, there are several subcases. If $G^* - P_1$ has at least three connected components, then $\mathcal{P}$ cannot be linear. The only case where $G^* - P_1$ has only two connected components C_1 and C_2 is that: C_1 contains u_2; and C_2 contains u_1, u_3 and the nodes in S_j $(j = 4, 5, 6)$. C_2 does not have a HP (by Lemma 4.3), nor can its nodes be enclosed in the interior of a cycle (since the exterior face of C_2 is not a cycle). Thus, $\mathcal{P}$ cannot be linear.

(iii) P_1 contains the node d_5. Similar to the subcase (i), we can show $\mathcal{P}$ is not linear.

Case 1.3. P_1 contains the edges (d_1, a_6) and (d_3, a_2). This case is symmetric to Case 1.2.

Case 1.4. P_1 contains the edges (d_1, a_1) and (d_3, a_2). Then P_1 must pass through either (i) the edge (b_4, c_5); or (ii) the edge (b_1, c_2); or the node d_5.

(i) P_1 passes through (b_4, c_5). Then P_1 passes through S_i $(i = 1, 2, 3, 4, 5, 6)$. Let u_i be the left-over node in S_i not belonging to P_1. Then $G^* - P_1$ contains at least four connected components: one contains u_3, one contains u_4 (and possibly u_5), one contains u_6, and another contains u_1 (and possibly u_2). Thus, $\mathcal{P}$ cannot be linear.

(ii) P_1 passes through (b_1, c_2). Let u_i $(i = 1, 2)$ be the left-over node in S_i not belonging to P_1. (See Figure 11 (d).) Depending on whether u_1 and u_2 are in the interior or the exterior of P_1, there are several subcases. One possible (the worst) subcase is that: both u_1 and u_2 are in the exterior of P_1 and are connected through S_i $(i = 3, 4, 5, 6)$. Thus, $G^* - P_1$ has only one connected component C containing u_1, u_2 and all nodes in S_i $(i = 3, 4, 5, 6)$. Note that C has at least six cut nodes: $c_3, b_3, c_4, b_5, c_6, b_6$. It is easily seen that C satisfies the condition (c) at the beginning of the proof. Thus, $\mathcal{P}$ cannot be linear.

(iii) P_1 contains the node d_5. Similar to the subcase (i), we can show $\mathcal{P}$ is not linear.

Case 2. P_1 does not contain the node o.

Case 2.1. P_1 does not contain the nodes d_1, d_3, d_5. Then P_1 must pass through the edges (b_i, c_{i+1}) (for $1 \leq i \leq 5$) and (b_6, c_1). (See Figure 11 (e).) Let u_i $(1 \leq i \leq 6)$ be the left-over node in S_i not belonging to P_1. Depending on whether u_i's are in the interior or the exterior of P_1, there are a number of subcases. One possible (the worst) case is that: All u_i are in the interior of P_1 and connected through the nodes d_1, d_3, d_5, o. Thus, $G^* - P_1$ has only one connected component C containing $o, d_1, d_3, d_5, u_1, \ldots, u_6$. Note that C contains a tree with at least six leaves. It is easily seen that C satisfies the condition (c) at the beginning of the proof. Thus, $\mathcal{P}$ cannot be linear.

Case 2.2. P_1 contains exactly one node from d_1, d_3, d_5, say d_1. Then P_1 passes through either (i) the edge (b_6, c_1), or (ii) the edge (b_3, c_4).

(i) P_1 passes through (b_6, c_1). Then P_1 passes through S_1 and S_6. Let u_i $(i = 1, 6)$ be the left-over node in S_i not belonging P_1. Depending on whether u_1 and u_6 are in

the interior or the exterior of P_1, there are a number of subcases. One possible (the worst) case is that: Both u_1 and u_6 are in the exterior of P_1 and are connected through the nodes in S_i $(i = 2, 3, 4, 6)$. Thus, $G^* - P_1$ has only one connected component C. It is easily seen that C satisfies the condition (c) at the beginning of the proof. Thus $\mathcal{P}$ cannot be linear.

(ii) P_1 passes through the edge (b_3, c_4). Then P_1 passes through S_i $(i = 1, 2, 3, 4, 5, 6)$. Let u_i $(i = 1, \ldots, 6)$ be the left-over node in S_i not belonging to P_1. Depending on whether u_i's are in the interior or the exterior of P_1, there are a number of subcases. If $G^* - P_1$ has at least three connected components, then $\mathcal{P}$ cannot be linear. The only case where $G^* - P_1$ has only two connected components is where u_1 and u_6 are in the exterior of P_1 and they form a connected component C_1 through the edge (b_6, c_1) and the nodes u_2, u_3, u_4, u_5 are in the interior of P_1 and they form a connected component C_2 through the nodes d_3, d_5, o. It is easily seen that C_2 does not have a HP, nor can its nodes be enclosed in a cycle. Thus, $\mathcal{P}$ cannot be linear.

Case 2.3. P_1 contains exactly two nodes from d_1, d_3, d_5, say P_1 contains d_1 and d_3. Since P_1 does not contain the node o, P_1 must be as shown in Figure 11 (f). Let u_i $(i = 1, 2, \ldots, 6)$ be the left-over node in S_i not belonging to P_1. In the best case, $G^* - P_1$ contains at least three connected components: one contains u_1 and u_6 connected through the edge (b_6, c_1); one contains u_2 and u_3 connected through the edge (b_2, c_3); and one contains u_4 and u_5 connected through the node d_5. Thus, $\mathcal{P}$ cannot be linear.

Case 2.4. P_1 contains the nodes d_1, d_3, d_5. Since P_1 does not contain the node o, it must pass through the edges $(b_1, c_2), (b_3, c_4), (b_5, c_6)$, but not the edges $(b_2, c_3), (b_4, c_5)$, (b_6, c_1). Let u_i $(1 \leq i \leq 6)$ be the left-over node in S_i not belonging to P_1. In the best case, $G^* - P_1$ has at least 4 connected components: one contains o alone; one contains u_1 and u_6; one contains u_2 and u_3; one contains u_4 and u_5. Thus, $\mathcal{P}$ cannot be linear.

Since $\mathcal{P}$ cannot be a linear HLD in all cases, the theorem is proved. □

HORN EXTENSIONS OF A PARTIALLY DEFINED BOOLEAN FUNCTION*

KAZUHISA MAKINO†, KEN-ICHI HATANAKA‡, AND TOSHIHIDE IBARAKI§

Abstract. Given a partially defined Boolean function (pdBf) (T, F), we investigate in this paper how to find a Horn extension $f : \{0,1\}^n \mapsto \{0,1\}$, which is consistent with (T, F), where $T \subseteq \{0,1\}^n$ denotes a set of true Boolean vectors (or positive examples) and $F \subseteq \{0,1\}^n$ denotes a set of false Boolean vectors (or negative examples). Given a pdBf (T, F), it is known that the existence of a Horn extension can be checked in polynomial time. As there are many Horn extensions, however, we consider those extensions f which have maximal and minimal sets $T(f)$ of the true vectors of f, respectively. For a pdBf (T, F), there always exists the unique maximal (i.e., maximum) Horn extension, but there are in general many minimal Horn extensions. We first show that a polynomial time membership oracle can be constructed for the maximum extension, even if its disjunctive normal form (DNF) can be very long. Our main contribution is to show that checking if a given Horn DNF represents a minimal extension and generating a Horn DNF of a minimal Horn extension can both be done in polynomial time. We also can check in polynomial time if a pdBf (T, F) has the unique minimal Horn extension. However, the problems of finding a Horn extension f with the smallest $|T(f)|$ and of obtaining a Horn DNF, whose number of literals is smallest, are both NP-hard.

Key words. partially defined Boolean function, extension, Horn function, knowledge acquisition

1. Introduction.

Knowledge acquisition in the form of Boolean logic has been intensively studied (e.g., [2, 4, 6, 18, 20, 24]): Given a set of data, represented as a set $T \subseteq \{0,1\}^n$ of binary "true n-vectors" (or "positive examples") and a set $F \subseteq \{0,1\}^n$ of "false n-vectors" (or "negative examples"), establish a (fully defined) Boolean function (i.e., *extension*) $f : \{0,1\}^n \mapsto \{0,1\}$ in a specified class $\mathcal{C}$, such that $T \subseteq T(f)$ and $F \subseteq F(f)$, where $T(f)$ (resp., $F(f)$) denotes the set of true (resp., false) vectors of f. A pair of sets (T, F) is called a *partially defined Boolean function* (*pdBf*) throughout this paper.

For instance, a vector x may represent the symptoms used to diagnose a disease; e.g., x_1 denotes whether temperature is high ($x_1 = 1$) or not ($x_1 = 0$), and x_2 denotes whether blood presure is high ($x_2 = 1$) or not ($x_2 = 0$), etc. Each vector x in T corresponds to a case of symptoms that caused the disease, while a vector in F describes a case with which the disease did not appear. Establishing an extension f, which is consistent with the given data, amounts to finding a logical diagnostic explanation of the given data.

In this paper, we consider the case in which f is a Horn function [15]. The class of Horn functions is at the heart of knowledge-based systems [1, 12, 5] and motivates increasing research, e.g., minimum representations [13, 14], their learning

and identification [1, 8], and constructing Horn approximations [17, 25]. One of the main reasons for this attention is that the *satisfiability problem (SAT)* of a Horn conjunctive normal form (CNF) (H-SAT in short) can be solved in polynomial time [7], whereas the SAT of a general CNF is NP-complete [11]. As problem SAT of CNF is fundamental, many problems related to Horn functions can be solved efficiently. In terms of sets $T(f)$ and $F(f)$, a Horn function has an elegant characterization: f is Horn if and only if $F(f)$ is closed under intersection of vectors (i.e., $v, w \in F(f)$ implies $v \bigwedge w \in F(f)$, where $\bigwedge$ denotes the componentwise AND operation).

Because there are in general many Horn extensions f for a given pdBf (T, F), we shall mainly consider those extensions that are *maximal* and *minimal* in the sense of set $T(f)$, respectively. We note here that most of the papers written on the representation by Horn theory (e.g., [4, 8, 17, 18]) are based on model theory, in which finding a Horn representation f of a given model $(T(g), F(g))$, where g is a Boolean function and sets $T(g)$ and/or $F(g)$ of vectors are explicitly given, is a primary target. For example, the problem of finding the best Horn approximation of a model $(T(g), F(g))$, i.e., finding the Horn function with the minimum $|F(f)|$ under the constraint $F(f) \supseteq F(g)$, has received some attention [18], and it is known [18, 19] that obtaining an irredundant disjunctive normal form (DNF) of such an f is at least as difficult as computing the DNF of the dual h^d of a positive (i.e., monotone) Boolean function h. The latter problem is a well-known open problem [3, 9, 16], for which the recent result of Fredman and Khachiyan [10] shows that there is an $O(m^{o(\log m)})$ time algorithm, where m is the total length of DNFs for both h and h^d. We emphasize that our problem setting is different from model theory in that the input (T, F) is only partially defined. However, the above problem of best Horn approximation is very close to the problem of finding a maximal Horn extension. We also note that, although the problem of finding a best approximation in terms of $T(g)$ is a bit artificial (since $T(g)$ is not closed under intersection), finding a minimal Horn extension of a pdBf (T, F) is quite a natural problem in our framework.

It is known [4] that the existence of at least one Horn extension of a given pdBf (T, F) can be checked in polynomial time. After preparing necessary notation and definitions in section 2 and introducing canonical Horn DNFs in section 3, we proceed to maximal and minimal Horn extensions. In section 4, by using an argument similar to the one used in model theory, we show that there exists the unique maximal Horn extension $f_{\max}$ (i.e., maximum) and we provide a polynomial time membership oracle for $f_{\max}$. In section 5, we investigate minimal Horn extensions. Contrary to the case of maximum Horn extension, there are in general many minimal Horn extensions. Our main contribution is to show that the minimality of f_φ, which denotes the function represented by a Horn DNF φ, can be checked in polynomial time. Based on this, a minimal Horn extension of a pdBf (T, F) can be generated in polynomial time and the uniqueness of a minimal extension can also be checked in polynomial time.

To derive the above results, we first show that any minimal Horn extension can be represented by a *canonical* Horn DNF, although the converse is not true. The nontriviality of finding a canonical DNF representing a minimal Horn extension may be exemplified by the existence of a canonical DNF that satisfies *local minimality* but does not represent a minimal Horn extension. To overcome this, we reduce the nonminimality condition to the condition that some CNF Φ_v, $v \in T$, is satisfiable, where Φ_v is a CNF derived from canonical DNF φ, $v \in T$, and (T, F). Although this does not immediately give a polynomial time algorithm, since Φ_v is not Horn, we then derive a series of lemmas, with which (non-Horn) CNFs Φ_v can be eventually

transformed into Horn CNFs Φ_v^*. Therefore, the minimality condition can be checked in polynomial time.

Finally, we show in sections 5 and 6 that the problems of computing a Horn extension f with the minimum $|T(f)|$ and of finding the shortest Horn DNF (i.e., having the smallest number of literals) that represents a Horn extension are both NP-hard. It is still not known whether there exists a polynomial total time algorithm to generate all minimal Horn extensions of a given pdBf (T, F).

2. Preliminaries. A *Boolean function* (or a *function*) is a mapping $f : \{0,1\}^n \mapsto \{0,1\}$, where $x \in \{0,1\}^n$ is called a *Boolean vector* (or a *vector*). If $f(x) = 1$ (resp., 0), then x is called a *true* (resp., *false*) vector of f. The set of all true vectors (resp., false vectors) is denoted by $T(f)$ (resp., $F(f)$). Denote, for a vector $v \in \{0,1\}^n$, $ON(v) = \{j \mid v_j = 1,\ j = 1,2,\ldots,n\}$ and $OFF(v) = \{j \mid v_j = 0,\ j = 1,2,\ldots,n\}$. For vectors $v, w \in \{0,1\}^n$, we write $v \le w$ (resp., $v \ge w$) if $v_i \le w_i$ (resp., $v_i \ge w_i$) holds for all $i = 1,2,\ldots,n$. Two special functions with $T(f) = \emptyset$ and $F(f) = \emptyset$ are, resp., denoted by $f = \bot$ and $f = \top$. For two functions f and g on the same set of variables, we write $f \le g$ if $f(x) = 1$ implies $g(x) = 1$ for any $x \in \{0,1\}^n$ and $f < g$ if $f \le g$ and $f \ne g$.

Boolean variables $x_1,\ldots,x_n$ and their negations $\bar{x}_1,\ldots,\bar{x}_n$ are called *literals*, where we call literals $x_1,\ldots,x_n$ *positive* and literals $\bar{x}_1,\ldots,\bar{x}_n$ *negative*. A *term* t is a conjunction of literals such that at most one of x_i and $\bar{x}_i$ appears for each i. The constant 1 (viewed as the conjunction of an empty set of literals) is also considered a term. We say that a term t *subsumes* a term t' if $t \ge t'$, where terms t and t' are considered the functions they represent. For example, a term $x\bar{y}$ subsumes a term $x\bar{y}z$. A term t is called an *implicant* of a function f if $t \le f$. An implicant t of a function is called *prime* if there is no implicant $t' > t$.

A DNF φ is a disjunction of terms. It is well known that a DNF φ defines a function, which we denote by f_φ, and any function can be represented by a DNF (however, such a representation may not be unique). In this paper, we do not always distinguish a DNF φ from the function f_φ it represents. For example, a term t is also considered as the function f_t. The number of literals in a DNF φ is denoted by $|\varphi|$. In this paper, we shall deal exclusively with DNF expressions, although some of the literature on Horn functions is based on CNFs. By complementing the involved concepts, all the results in this paper can be translated into the results for CNFs.

A term is called *positive* if it contains only positive literals and is called *Horn* if it contains at most one negative literal. A DNF is called *positive* if it contains only positive terms and is called *Horn* if it contains only Horn terms. For example, a DNF $\varphi = 123 \vee 245 \vee 156$ is positive and $\psi = 15\bar{7} \vee 24 \vee \bar{2}67$ is Horn. (Here, for simplicity, a positive literal x_i is denoted as i and a negative literal $\bar{x}_i$ as $\bar{i}$.) It is easy to see that, by complementing Horn DNFs, we obtain Horn CNFs, where a CNF $\Phi = \bigwedge_i C_i$ is Horn if each clause C_i contains at most one positive literal, e.g., $(1 \vee \bar{2} \vee \bar{3})(\bar{1} \vee \bar{3})(\bar{1} \vee \bar{3} \vee 4)$ is Horn, while $(1 \vee \bar{2} \vee \bar{3})(\bar{1} \vee \bar{3})(1 \vee \bar{3} \vee 4)$ is not Horn. A Boolean function is called *positive* (or *monotone*) if it can be represented by a positive DNF and *Horn* if it can be represented by a Horn DNF. It is known [14] that if f is a Horn function, then all prime implicants of f are Horn. It is important to know that the following two variants of SAT for a Horn CNF Φ can be solved in time linear in $|\Phi|$ [7, 22]:

Problem H-SAT
Input: A Horn CNF Φ of n variables.
Question: Is there a vector $u \in \{0,1\}^n$ satisfying $\Phi(u) = 1$?

Problem UNIQUE-H-SAT

Input: A Horn CNF Φ of n variables.

Question: Is there a unique vector $u \in \{0,1\}^n$ satisfying $\Phi(u) = 1$?

If the answer to these problems is "yes," the vector u satisfying $\Phi(u) = 1$ can also be output in linear time. If the answer to UNIQUE-H-SAT is "no," two vectors u and v satisfying $\Phi(u) = \Phi(v) = 1$ can also be output in linear time. Based on these, various problems associated with Horn functions can be solved in polynomial time. For example, given two Horn DNFs φ and ψ, the conditions such as $f_\varphi = f_\psi$ and $f_\varphi < f_\psi$ can be checked in $O(|\varphi||\psi|)$ time [14]. Also, for a term t (not necessarily Horn), condition $t \leq f_\varphi$ can be checked in $O(|\varphi|)$ time [14].

A pdBf is defined by a pair of sets (T, F) satisfying $T \cap F = \emptyset$, where $T, F \subseteq \{0,1\}^n$. A function f is an *extension* (or theory) of the pdBf (T, F) if $T \subseteq T(f)$ and $F \subseteq F(f)$, and it is a *Horn extension* if f is in addition Horn. We sometimes refer to a Horn DNF representing a Horn extension of a pdBf (T, F) as a Horn DNF of (T, F). A Horn extension f of a pdBf (T, F) is called *minimal* (resp., *maximal*) if there is no Horn extension f' satisfying $f' < f$ (resp., $f' > f$), that is, set $T(f)$ is minimal (resp., maximal). Furthermore, a Horn extension f of a pdBf (T, F) is *minimum* (resp., *maximum*) if there is no Horn extension f' such that $|T(f')| < |T(f)|$ (resp., $|T(f')| > |T(f)|$). Obviously, a minimum (resp., maximum) Horn extension is one of the minimal (resp., maximal) Horn extensions.

Example 2.1. Let (T, F) be a pdBf defined by $T = \{1110, 0011, 0101\}$ and $F = \{0010, 1100, 0110\}$. Then, by generating all extensions of (T, F), we can see that the unique maximum Horn extension of (T, F) is represented by the DNF

$$\varphi = 13 \vee 4 \vee 1\bar{2}$$

while there are two minimal Horn extensions:

$$\psi^{(1)} = 123\bar{4} \vee \bar{1}34 \vee \bar{1}24,$$
$$\psi^{(2)} = 123\bar{4} \vee \bar{2}34 \vee 2\bar{3}4.$$

Furthermore, $\psi^{(1)}$ represents a minimum Horn extension of (T, F).

3. Canonical Horn DNF. In this section, we first review the following fundamental problem, which was originally discussed in [4]:

Problem H-EXTENSION

Input: A pdBf (T, F).

Question: Is there a Horn extension f of (T, F)?

We point out that the following well-known characterization of a Horn function provides a polynomial time algorithm to solve H-EXTENSION. Call the componentwise AND operation $\bigwedge$ of vectors v and w the *intersection* of v and w. For example, if $v = (0101)$ and $w = (1001)$, then $v \bigwedge w = (0001)$. For a set $X \subseteq \{0,1\}^n$, the set of vectors $C(X)$ is called the *intersection closure* if it is a minimal set that contains X and is closed under intersection. Clearly, intersection closure is unique (i.e., "minimal" can be replaced by "minimum").

PROPOSITION 3.1 (see [21, 8]). *A function f is Horn if and only if $F(f) = C(F(f))$ (i.e., $F(f)$ is closed under intersection).*

The next definition provides a means to generate Horn DNFs from (T, F).

DEFINITION 3.1. *For a pdBf (T, F) and a vector $v \in T$, the set of terms $R(v)$ is*

defined by

$$R(v) = \begin{cases} \{\bigwedge_{j\in ON(v)} x_j\} & \text{if } OFF(v) = \emptyset, \\ \{(\bigwedge_{j\in ON(v)} x_j)\,\bar{x}_l \mid l \in I(v)\} & \text{if } OFF(v) \neq \emptyset \text{ and } I(v) \neq \emptyset, \\ \emptyset & \text{if } OFF(v) \neq \emptyset \text{ and } I(v) = \emptyset, \end{cases}$$

where

$$F_{\geq v} = \{w \in F \mid w \geq v\},$$
$$I(v) = (\cap_{w\in F_{\geq v}} ON(w)) \cap OFF(v).$$

By convention, we define $I(v) = OFF(v)$ *if* $F_{\geq v} = \emptyset$. *A DNF* φ *is called a* canonical *Horn DNF of* (T, F) *if* φ *is given by*

$$\varphi = \bigvee_{v\in T} t_v, \text{ where } t_v \in R(v), \tag{3.1}$$

i.e., by selecting one term from each $R(v)$, $v \in T$. *Note that the canonical Horn DNF is not defined if* $R(v) = \emptyset$ *holds for some* $v \in T$.

For a $v \in T$, there are many Horn terms t such that $t(v) = 1$. However, in order to satisfy $t(w) = 0$ for all $w \in F$, we can restrict the negative literal $\bar{x}_l$, which appears in t. The above definition says that $I(v)$ represents the set of such indices l and $R(v)$ represents the particular subset of terms t such that $t(v) = 1$ and $t(w) = 0$ for all $w \in F$. Construction of Horn DNFs in this manner can be found in the literature of learning theory [1], model theory [17], and Horn approximation [25]. Precisely speaking, however, the above canonical DNF is different from those used in the literature in that both T and F are explicitly taken into account.

Example 3.1. Let us define $T, F \subseteq \{0,1\}^9$ by

$$T = \left\{ \begin{array}{lcl} v^{(1)} & = & (111100100) \\ v^{(2)} & = & (111010100) \\ v^{(3)} & = & (111001010) \\ v^{(4)} & = & (001000100) \\ v^{(5)} & = & (100000100) \\ v^{(6)} & = & (011000001) \\ v^{(7)} & = & (110000001) \\ v^{(8)} & = & (111111000) \end{array} \right\}, \quad F = \left\{ \begin{array}{lcl} w^{(1)} & = & (111100110) \\ w^{(2)} & = & (111010111) \\ w^{(3)} & = & (111001110) \\ w^{(4)} & = & (111000101) \end{array} \right\}.$$

Then $F_{\geq v^{(1)}} = \{w^{(1)}\}$, $F_{\geq v^{(2)}} = \{w^{(2)}\}$, $F_{\geq v^{(3)}} = \{w^{(3)}\}$, $F_{\geq v^{(4)}} = F_{\geq v^{(5)}} = \{w^{(1)}, w^{(2)}, w^{(3)}, w^{(4)}\}$, $F_{\geq v^{(6)}} = F_{\geq v^{(7)}} = \{w^{(2)}, w^{(4)}\}$, and $F_{\geq v^{(8)}} = \emptyset$.

$$\begin{array}{ll} I(v^{(1)}) = \{8\}, & R(v^{(1)}) = \{12347\bar{8}\}, \\ I(v^{(2)}) = \{8,9\}, & R(v^{(2)}) = \{12357\bar{8}, 12357\bar{9}\}, \\ I(v^{(3)}) = \{7\}, & R(v^{(3)}) = \{1236\bar{7}8\}, \\ I(v^{(4)}) = \{1,2\}, & R(v^{(4)}) = \{\bar{1}37, \bar{2}37\}, \\ I(v^{(5)}) = \{2,3\}, & R(v^{(5)}) = \{1\bar{2}7, 1\bar{3}7\}, \\ I(v^{(6)}) = \{1,7\}, & R(v^{(6)}) = \{\bar{1}239, 23\bar{7}9\}, \\ I(v^{(7)}) = \{3,7\}, & R(v^{(7)}) = \{12\bar{3}9, 12\bar{7}9\}, \\ I(v^{(8)}) = \{7,8,9\}, & R(v^{(8)}) = \{1234567, 1234568, 1234569\}. \end{array}$$

There are $1 \times 2 \times 1 \times 2 \times 2 \times 2 \times 2 \times 3 = 96$ canonical Horn DNFs, among which we list the following two:

$$\begin{array}{rcl} \varphi^{(1)} & = & 12347\bar{8} \vee 12357\bar{9} \vee 1236\bar{7}8 \vee \bar{1}37 \vee 1\bar{3}7 \vee 23\bar{7}9 \vee 12\bar{7}9 \vee 123456\bar{7}, \\ \varphi^{(2)} & = & 12347\bar{8} \vee 12357\bar{9} \vee 1236\bar{7}8 \vee \bar{1}37 \vee 1\bar{3}7 \vee \bar{1}239 \vee 12\bar{3}9 \vee 123456\bar{9}. \end{array} \tag{3.2}$$

LEMMA 3.1 (see [4]). *Any canonical Horn DNF φ of a given pdBf (T, F) represents a Horn extension of (T, F), and (T, F) has no Horn extension if there is no canonical Horn DNF.*

Proof. Let $\varphi = \bigvee_{v \in T} t_v$ be a canonical Horn DNF of a pdBf (T, F). It is clear that, for each $v \in T$, we have $t_v(v) = 1$ and $t_v(w) = 0$ for all $w \in F$. This implies that φ represents a Horn extension. Conversely, if there is no canonical Horn DNF, then $R(v) = \emptyset$ holds for some $v \in T$, i.e., $OFF(v) \neq \emptyset$ and $I(v) = \emptyset$ holds for some $v \in T$. This means $(\cap_{w \in F_{\geq v}} ON(w)) \cap OFF(v) = \emptyset$; i.e., $\bigwedge_{w \in F_{\geq v}} w = v$. Therefore $F(f)$ of no Horn extension f of (T, F) is closed under intersection, and there is no Horn extension by Proposition 3.1. □

Therefore, we have the following results.

THEOREM 3.1 (see [4]). *Problem H-EXTENSION can be solved in $O(n|T||F|)$ time, and if a pdBf (T, F) has a Horn extension, one of its canonical Horn DNFs can be obtained in $O(n|T||F|)$ time.*

Proof. The proof is immediate from the above discussion and the fact that a canonical Horn DNF of (T, F) can be constructed in $O(n|T||F|)$ time. □

4. Maximum Horn extension. In this section, we first show the uniqueness of a maximal Horn extension.

THEOREM 4.1. *If a given pdBf (T, F) has a Horn extension, its maximal Horn extension is unique.*

Proof. By Proposition 3.1, $F(f)$ of any Horn extension f of (T, F) is closed under intersection. Let us define $f_{\max}$ by $F(f_{\max}) = C(F)$, that is,

$$f_{\max}(v) = \begin{cases} 0 & \text{if } v \in C(F), \\ 1 & \text{otherwise.} \end{cases} \tag{4.1}$$

Since $C(F)$ is the unique minimal set that contains F and is closed under intersection, this $f_{\max}$ is the unique maximal Horn extension (that is, $T(f)$ is maximal) of (T, F). □

Unfortunately, it is known [17] that there is a pdBf (T, F) for which the size of any DNF φ of $f_{\max}$ is exponential in n, $|T|$, and $|F|$. In other words, there may not be any compact DNF representation of $f_{\max}$. However, we can do better if we do not stick to the DNF representation. Note that $f_{\max}$ of (4.1) is defined by $C(F)$, for which $v \in C(F)$ holds if and only if

$$\bigwedge_{w \in F_{\geq v}} w = v.$$

As this condition can be checked in polynomial time in n and $|F|$ for a given v, we can build an oracle that answers membership queries for $f_{\max}$ in polynomial time.

A vector $x \in X \subseteq \{0, 1\}^n$ is called *extreme* [8] with respect to a set X if $x \notin C(X \setminus \{x\})$. The set of all extremal vectors of X is called the *characteristic set* of X [17, 19] (or its *base* [8]) and is denoted by $C^*(X)$. Note that every set $X \subseteq \{0, 1\}^n$ has the unique characteristic set $C^*(X)$ and that $C^*(X) \subseteq X$ is the minimum set satisfying $C(C^*(X)) = C(X)$. It is known [8] that $C^*(X)$ can be constructed from X in polynomial time in n and $|X|$; therefore $C^*(F) = C^*(C(F))$ can be computed from F of (T, F) in polynomial time. There are a number of papers on the relationship between $C^*(F(f))$ of a Horn function f and its Horn DNF expression φ [9, 17, 19]. For example, there is a *polynomial total time* algorithm (i.e., polynomial algorithm in the length of input and output) for computing from $C^*(F(f))$ all prime

implicants of Horn DNF φ that represents f if and only if there is a polynomial total time algorithm for dualizing a positive function h (i.e., computing all prime implicants of h^d from all prime implicants of h, where $h^d(x) = \bar{h}(\bar{x})$); if there is a polynomial total time algorithm for computing from $C^*(F(f))$ an *irredundant* Horn DNF φ that represents f (i.e., no term in φ can be dropped), then there is a polynomial total time algorithm for dualizing a positive function. From the viewpoint of $f_{\max}$ (whose $C^*(F(f_{\max})) = C^*(F)$ can be computed in polynomial time), this shows that computing an irredundant Horn DNF φ of $f_{\max}$ is at least as hard as dualizing a positive function. It is not known yet [3, 9, 16] whether or not the problem of dualizing a positive function has a polynomial total time algorithm. However, the recent result by Fredman and Khachiyan [10] shows that dualizing a positive function can be done in $O(m^{o(\log m)})$ time, where m denotes the number of prime implicants of f and f^d, and hence it is unlikely for the problem to be NP-hard.

5. Minimal Horn extensions. There are in general many minimal Horn extensions of a given pdBf (T, F). However, these minimal Horn extensions can all have canonical Horn DNFs of Definition 3.1.

LEMMA 5.1. *A minimal Horn extension f of a given pdBf (T, F) can always be represented by a canonical Horn DNF.*

Proof. Assume that there exists a minimal Horn extension f, which cannot be represented by a canonical DNF. Since f is a Horn extension, for every $v \in T$, there is a Horn implicant $t_v = \bigwedge_{i \in P} x_i \bigwedge_{i \in N} \bar{x}_i$ of f such that $t_v(v) = 1$ (i.e., $P \subseteq ON(v)$ and $N \subseteq OFF(v)$) and $|N| \leq 1$. Then by the definition of $R(v)$, there is a term $t'_v \in R(v)$ such that $t'_v \leq t_v$. Define a canonical Horn DNF $\varphi = \bigvee_{v \in T} t'_v$. This φ satisfies $f_\varphi < f$ since $f_\varphi \leq f$ holds and f cannot be represented by a canonical Horn DNF φ, contradicting the minimality of f. □

The converse, however, is not true (i.e., some canonical Horn DNFs do not represent minimal Horn extensions), as will be shown in Example 5.1 in the next subsection. Recall that a Horn DNF φ representing a Horn extension of (T, F) is called a Horn DNF of a pdBf (T, F). Furthermore, we say that a Horn DNF φ of (T, F) is *minimal* if f_φ is a minimal Horn extension of (T, F). It is interesting to know whether the following problem can be solved in polynomial time, where we assume that a Horn DNF φ (not necessarily canonical) is given as an input:

Problem MINIMAL-H-EXTENSION

Input: A pdBf (T, F) and a Horn DNF φ.

Question: Is φ a minimal Horn DNF of (T, F)?

In passing, we note an interesting implication of Lemma 5.1: all minimal Horn extensions of (T, F) have "short" DNFs in the sense that all canonical Horn DNFs have only $|T|$ terms, respectively. This contrasts with the fact that the DNFs of some maximum Horn extensions have exponentially many terms, as noted after Theorem 4.1.

5.1. Checking the minimality of a Horn DNF. We show via a series of lemmas in this subsection that MINIMAL-H-EXTENSION can be solved in polynomial time. In the following, we assume without loss of generality that $(1, 1, \ldots, 1) \notin T$ holds, because it can be shown that, for a pdBf (T, F) with $(1, 1, \ldots, 1) \in T$, $\varphi \vee (\wedge_{j=1}^n x_j)$ is a minimal Horn DNF of (T, F) if and only if φ is a minimal Horn DNF of $(T \setminus \{(1, 1, \ldots, 1)\}, F)$. For a pdBf (T, F), a vector $v \in T$, and a Horn DNF

φ of (T, F), define

$$I(v;\varphi) = \{l \in I(v) \mid (\textstyle\bigwedge_{j\in ON(v)} x_j)\,\bar{x}_l \le f_\varphi\},$$
$$R(v;\varphi) = \{t \in R(v) \mid t \le f_\varphi\}\ (= \{(\textstyle\bigwedge_{j\in ON(v)} x_j)\,\bar{x}_l \mid l \in I(v;\varphi)\}).$$

Note that Lemma 5.1 implies $I(v;\varphi) \neq \emptyset$ and $R(v;\varphi) \neq \emptyset$ for all $v \in T$. By Lemma 5.1, if a Horn DNF φ of (T, F) is not minimal, then there exists a canonical Horn DNF ψ of (T, F) such that $f_\psi < f_\varphi$, where ψ can be written as

$$\psi = \bigvee_{v\in T} t_v; \quad t_v \in R(v;\varphi).$$

It is known that the candidate set of terms $R(v;\varphi)$ can be computed in polynomial time. More precisely, given a canonical Horn DNF φ and a vector $v \in T$, set $I(v;\varphi)$ can be constructed in time linear in $|\varphi|$ by using the following forward chaining procedure [13].

Algorithm F-CHAINING

Input: A Horn DNF φ and a vector $v \in T$.

Output: Set $I(v;\varphi)$.

Step 1: $S := ON(v)$ and $I(v;\varphi) := \emptyset$.

Step 2: If there exists a term $t = (\wedge_{i\in S'} x_i)\bar{x}_l$ in φ such that $S' \subseteq S$ and $l \notin S$, let $S := S \cup \{l\}$. Repeat Step 2 until no term in φ satisfies the condition.

Step 3: $I(v;\varphi) := S \setminus ON(v)$.

The essential part of this algorithm comes from the *consensus* procedure [23]. Given a DNF φ, the consensus procedure generates a new implicant $\bigwedge_{j\in P_1\cup P_2} x_j \bigwedge_{j\in N_1\cup N_2} \bar{x}_j$ from two implicants $x_i\,(\bigwedge_{j\in P_1} x_j \bigwedge_{j\in N_1} \bar{x}_j)$ and $\bar{x}_i\,(\bigwedge_{j\in P_2} x_j \bigwedge_{j\in N_2} \bar{x}_j)$ such that $i \notin P_k \cup N_k$ for $k = 1, 2$, and $P_1 \cap N_2 = N_1 \cap P_2 = \emptyset$. For example, $2\bar{3}4\bar{5}6$ is generated from $1\bar{3}4\bar{5}$ and $\bar{1}2\bar{3}46$. It is known [23] that all prime implicants of f_φ eventually can be generated by the consensus procedure starting from the terms of φ. Since every prime implicant of a Horn function is Horn, Algorithm F-CHAINING works correctly.

Example 5.1. Consider the pdBf (T, F) given in Example 3.1 and choose two canonical Horn DNFs $\varphi^{(1)}$ and $\varphi^{(2)}$ of (3.2). Then

$$I(v^{(1)};\varphi^{(1)}) = \{8\},\quad I(v^{(1)};\varphi^{(2)}) = \{8\},$$
$$I(v^{(2)};\varphi^{(1)}) = \{9\},\quad I(v^{(2)};\varphi^{(2)}) = \{9\},$$
$$I(v^{(3)};\varphi^{(1)}) = \{7\},\quad I(v^{(3)};\varphi^{(2)}) = \{7\},$$
$$I(v^{(4)};\varphi^{(1)}) = \{1\},\quad I(v^{(4)};\varphi^{(2)}) = \{1\},$$
$$I(v^{(5)};\varphi^{(1)}) = \{3\},\quad I(v^{(5)};\varphi^{(2)}) = \{3\},$$
$$I(v^{(6)};\varphi^{(1)}) = \{1, 7\},\quad I(v^{(6)};\varphi^{(2)}) = \{1\},$$
$$I(v^{(7)};\varphi^{(1)}) = \{3, 7\},\quad I(v^{(7)};\varphi^{(2)}) = \{3\},$$
$$I(v^{(8)};\varphi^{(1)}) = \{7, 8, 9\},\quad I(v^{(8)};\varphi^{(2)}) = \{9\},$$

and

$$R(v^{(1)};\varphi^{(1)}) = \{1234\bar{7}\bar{8}\},\quad R(v^{(1)};\varphi^{(2)}) = \{1234\bar{7}\bar{8}\},$$
$$R(v^{(2)};\varphi^{(1)}) = \{123\bar{5}\bar{7}\bar{9}\},\quad R(v^{(2)};\varphi^{(2)}) = \{123\bar{5}\bar{7}\bar{9}\},$$
$$R(v^{(3)};\varphi^{(1)}) = \{12\bar{3}6\bar{7}\bar{8}\},\quad R(v^{(3)};\varphi^{(2)}) = \{12\bar{3}6\bar{7}\bar{8}\},$$
$$R(v^{(4)};\varphi^{(1)}) = \{\bar{1}37\},\quad R(v^{(4)};\varphi^{(2)}) = \{\bar{1}37\},$$
$$R(v^{(5)};\varphi^{(1)}) = \{1\bar{3}7\},\quad R(v^{(5)};\varphi^{(2)}) = \{1\bar{3}7\},$$
$$R(v^{(6)};\varphi^{(1)}) = \{\bar{1}239, 23\bar{7}9\},\quad R(v^{(6)};\varphi^{(2)}) = \{\bar{1}239\},$$
$$R(v^{(7)};\varphi^{(1)}) = \{12\bar{3}9, 12\bar{7}9\},\quad R(v^{(7)};\varphi^{(2)}) = \{12\bar{3}9\},$$
$$R(v^{(8)};\varphi^{(1)}) = \{1234567, 1234568, 1234569\},\quad R(v^{(8)};\varphi^{(2)}) = \{1234569\}.$$

The two functions $f_{\varphi^{(1)}}$ and $f_{\varphi^{(2)}}$ satisfy $f_{\varphi^{(1)}} \geq f_{\varphi^{(2)}}$, since both are canonical and $R(v^{(l)};\varphi^{(1)}) \supseteq R(v^{(l)};\varphi^{(2)})$ holds for all l. Furthermore, $23\bar{7}9 \leq f_{\varphi^{(1)}}$ and $23\bar{7}9 \not\leq f_{\varphi^{(2)}}$ imply $f_{\varphi^{(1)}} > f_{\varphi^{(2)}}$. Therefore, $\varphi^{(1)}$ is not minimal. However, this $\varphi^{(1)}$ satisfies local minimality in the sense that, after replacing one of its terms t_v by $t'_v \in R(v^{(l)};\varphi^{(1)}) \setminus \{t_v\}$ for any l with $|R(v^{(l)};\varphi^{(1)})| > 1$, the resulting DNF also represents $f_{\varphi^{(1)}}$. For example, the following two DNFs also represent the same $f_{\varphi^{(1)}}$:

$$\begin{aligned} \varphi^{(3)} &= 1234\bar{7}\bar{8} \vee 1235\bar{7}\bar{9} \vee 1236\bar{7}\bar{8} \vee \bar{1}\bar{3}7 \vee 1\bar{3}7 \vee 23\bar{7}9 \vee 12\bar{7}9 \vee 1234\bar{5}\bar{6}, \\ \varphi^{(4)} &= 1234\bar{7}\bar{8} \vee 1235\bar{7}\bar{9} \vee 1236\bar{7}\bar{8} \vee \bar{1}\bar{3}7 \vee 1\bar{3}7 \vee \bar{1}239 \vee 12\bar{7}9 \vee 1234\bar{5}\bar{7}. \end{aligned}$$

This result shows that local minimality of φ (in the above sense) does not always imply its minimality. Therefore, some other proof is necessary to ensure the minimality. Of course, if we replace more than one term in $\varphi^{(1)}$, the resulting DNF may represent a different function; $\varphi^{(2)}$ is such an example.

On the other hand, $\varphi^{(2)}$ is minimal since $|R(v^{(l)};\varphi^{(2)})| = 1$ for all $l = 1, 2, \ldots, 8$. However, this is not always the case, since there can be a minimal φ with $|R(v^{(l)};\varphi)| > 1$ for some l. For example, consider a pdBf (T, F) defined by $T = \{v^{(1)} = (1100), v^{(2)} = (1010), v^{(3)} = (0101)\}$ and $F = \emptyset$, and a canonical DNF $\varphi = 12\bar{3} \vee 13\bar{4} \vee 2\bar{3}4$. Then $I(v^{(1)};\varphi) = \{3, 4\}$, $I(v^{(2)};\varphi) = \{4\}$, and $I(v^{(3)};\varphi) = \{3\}$; that is, $R(v^{(1)};\varphi) = \{12\bar{3}, 12\bar{4}\}$, $R(v^{(2)};\varphi) = \{13\bar{4}\}$, and $R(v^{(3)};\varphi) = \{2\bar{3}4\}$. However, since it is easy to see that $\varphi' = 12\bar{4} \vee 13\bar{4} \vee 2\bar{3}4$ satisfies $f_{\varphi'} = f_\varphi$, there is no canonical DNF ψ such that $\psi < \varphi$; hence φ is minimal.

Example 5.1 may suggest that Problem MINIMAL-H-EXTENSION is not trivial. Let us now examine the condition when φ is *not* minimal.

Let f be a Horn extension of (T, F). Then f is not minimal if and only if there is a nonempty subset of $T(f)\backslash T$, whose removal from $T(f)$ results in a new Horn extension. This means that there exists a vector $u \in T(f)$ such that $C(F(f) \cup \{u\}) \cap T = \emptyset$ holds, where $C(X)$ denotes the intersection closure of X. In other words, $u \wedge \bigwedge_{w \in S} w$ is different from any vector in T for all $S \subseteq F(f)$. Since $u \wedge \bigwedge_{w \in S} w = a$ holds for some $a \in T$ and $S \subseteq F(f)$ if and only if it holds for $S = F(f)_{\geq a}$, where $F(f)_{\geq a} = \{w \in F(f) \,|\, w \geq a\}$, this argument leads to the following lemma.

LEMMA 5.2. *Let f be a Horn extension of a pdBf (T, F). Then f is not minimal if and only if there exists a vector $u \in T(f)$ such that*

$$u \wedge \bigwedge_{w \in F(f)_{\geq a}} w \neq a \quad \text{for all } a \in T. \tag{5.1}$$

Assume that f can be represented by a canonical Horn DNF φ of a pdBf (T, F) (i.e., $f = f_\varphi$). Then $y = \bigwedge_{w \in F(f)_{\geq a}} w$ for an $a \in T$ is given by $ON(y) = ON(a) \cup I(a;\varphi)$, because, by the definition of $I(a;\varphi)$, all vectors w such that $w \geq a$ and $w_l = 0$ for some $l \in I(a;\varphi)$ satisfy $\varphi(w) = 1$ (i.e., $w \notin F(f)$), and, for every $l \in OFF(a) \setminus I(a;\varphi)$, there is a vector $w \in F(f)_{\geq a}$ such that $w_l = 0$ (since otherwise l must be included in $I(a;\varphi)$). In other words, $u \wedge \bigwedge_{w \in F(f)_{\geq a}} w = a$ holds for an $a \in T$ if and only if u satisfies $ON(u) \supseteq ON(a)$ and $OFF(u) \supseteq I(a;\varphi)$. Thus, the condition (5.1) in Lemma 5.2 can be rewritten as follows.

LEMMA 5.3. *Let $\varphi = \bigvee_{v \in T} t_v$ be a canonical Horn DNF of a pdBf (T, F). Then φ is not minimal if and only if at least one of the following CNFs is satisfiable:*

$$\Phi_v = t_v \wedge \bigwedge_{a \in T} C_a, \quad v \in T, \tag{5.2}$$

where

$$C_a = \left(\bigvee_{j \in ON(a)} \bar{x}_j \vee \bigvee_{j \in I(a;\varphi)} x_j \right). \tag{5.3}$$

That is, there is a vector $u \in \{0,1\}^n$ such that $\Phi_v(u) = 1$ for some $v \in T$.

Proof. By the above discussion, φ is not minimal if and only if the formula

$$\varphi(x) \wedge \bigwedge_{a \in T} \left(\bigvee_{j \in ON(a)} \bar{x}_j \vee \bigvee_{j \in I(a;\varphi)} x_j \right)$$

is satisfiable, which is equivalent to (5.2). □

Example 5.2. Consider the pdBf (T, F) of Example 3.1. Recall that we have the following canonical DNF:

$$\varphi = \varphi^{(1)} = 12347\bar{8} \vee 12357\bar{9} \vee 1236\bar{7}8 \vee \bar{1}37 \vee 1\bar{3}7 \vee 23\bar{7}9 \vee 12\bar{7}9 \vee 1234\bar{5}67.$$

Using $I(v^{(l)}; \varphi^{(1)})$, $l = 1, 2, \ldots, 8$, listed in Example 5.1, (5.2) can be written as

$$\begin{aligned}
\Phi_{v^{(1)}} &= 12347\bar{8}(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{7} \vee 8)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{5} \vee \bar{7} \vee 9)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{6} \vee 7 \vee \bar{8})(1 \vee \bar{3} \vee \bar{7}) \\
&\quad (\bar{1} \vee 3 \vee \bar{7})(1 \vee \bar{2} \vee \bar{3} \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee 3 \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{5} \vee \bar{6} \vee 7 \vee 8 \vee 9), \\
\Phi_{v^{(2)}} &= 12357\bar{9}(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{7} \vee 8)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{5} \vee \bar{7} \vee 9)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{6} \vee 7 \vee \bar{8})(1 \vee \bar{3} \vee \bar{7}) \\
&\quad (\bar{1} \vee 3 \vee \bar{7})(1 \vee \bar{2} \vee \bar{3} \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee 3 \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{5} \vee \bar{6} \vee 7 \vee 8 \vee 9), \\
\Phi_{v^{(3)}} &= 1236\bar{7}8(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{7} \vee 8)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{5} \vee \bar{7} \vee 9)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{6} \vee 7 \vee \bar{8})(1 \vee \bar{3} \vee \bar{7}) \\
&\quad (\bar{1} \vee 3 \vee \bar{7})(1 \vee \bar{2} \vee \bar{3} \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee 3 \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{5} \vee \bar{6} \vee 7 \vee 8 \vee 9), \\
\Phi_{v^{(4)}} &= \bar{1}37(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{7} \vee 8)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{5} \vee \bar{7} \vee 9)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{6} \vee 7 \vee \bar{8})(1 \vee \bar{3} \vee \bar{7}) \\
&\quad (\bar{1} \vee 3 \vee \bar{7})(1 \vee \bar{2} \vee \bar{3} \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee 3 \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{5} \vee \bar{6} \vee 7 \vee 8 \vee 9), \\
\Phi_{v^{(5)}} &= 1\bar{3}7(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{7} \vee 8)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{5} \vee \bar{7} \vee 9)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{6} \vee 7 \vee \bar{8})(1 \vee \bar{3} \vee \bar{7}) \\
&\quad (\bar{1} \vee 3 \vee \bar{7})(1 \vee \bar{2} \vee \bar{3} \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee 3 \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{5} \vee \bar{6} \vee 7 \vee 8 \vee 9), \\
\Phi_{v^{(6)}} &= 23\bar{7}9(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{7} \vee 8)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{5} \vee \bar{7} \vee 9)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{6} \vee 7 \vee \bar{8})(1 \vee \bar{3} \vee \bar{7}) \\
&\quad (\bar{1} \vee 3 \vee \bar{7})(1 \vee \bar{2} \vee \bar{3} \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee 3 \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{5} \vee \bar{6} \vee 7 \vee 8 \vee 9), \\
\Phi_{v^{(7)}} &= 12\bar{7}9(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{7} \vee 8)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{5} \vee \bar{7} \vee 9)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{6} \vee 7 \vee \bar{8})(1 \vee \bar{3} \vee \bar{7}) \\
&\quad (\bar{1} \vee 3 \vee \bar{7})(1 \vee \bar{2} \vee \bar{3} \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee 3 \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{5} \vee \bar{6} \vee 7 \vee 8 \vee 9), \\
\Phi_{v^{(8)}} &= 1234\bar{5}67(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{7} \vee 8)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{5} \vee \bar{7} \vee 9)(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{6} \vee 7 \vee \bar{8})(1 \vee \bar{3} \vee \bar{7}) \\
&\quad (\bar{1} \vee 3 \vee \bar{7})(1 \vee \bar{2} \vee \bar{3} \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee 3 \vee 7 \vee \bar{9})(\bar{1} \vee \bar{2} \vee \bar{3} \vee \bar{4} \vee \bar{5} \vee \bar{6} \vee 7 \vee 8 \vee 9).
\end{aligned}$$

Now take a vector $u = (111000001)$. This u satisfies $\Phi_{v^{(6)}}(u) = 1$, showing that f_φ is not a minimal Horn extension of (T, F).

Note that CNFs Φ_v of (5.2) are not Horn, in general, and therefore their SATs in Lemma 5.3 may not be easy. However, we prove in the rest of this subsection that this can be done in polynomial time.

Let $\varphi = \bigvee_{v \in T} t_v$ be a canonical Horn DNF of (T, F). Given a $v \in T$, define

$$\hat{I}(v; \varphi) = I(v; \varphi) \setminus \{l_v\}, \tag{5.4}$$

where $\bar{x}_{l_v}$ is the negative literal in t_v. Now assume that Φ_v defined by (5.2) is satisfiable, i.e., there is a vector $u \in \{0,1\}^n$ such that $\Phi_v(u) = 1$. This means $t_v(u) = 1$, and hence

$$ON(u) \supseteq ON(v) \text{ and } l_v \in OFF(u). \tag{5.5}$$

Therefore, we can fix $u_j = 1$ for all $j \in ON(v)$ and $u_{l_v} = 0$. We also have

$$ON(u) \cap \hat{I}(v; \varphi) \neq \emptyset \tag{5.6}$$

in order to satisfy the clause $(\bigvee_{j\in ON(v)} \bar{x}_j \vee \bigvee_{j\in I(v;\varphi)} x_j)$ associated with $a = v$. Furthermore, we shall show below that we can fix

$$u_j = 0 \quad \text{for all } j \in OFF(v) \setminus I(v;\varphi) \tag{5.7}$$

without loss of generality. As a result of these observations, we denote by

$$\Phi'_v = \bigwedge_{a\in T} C'_a \tag{5.8}$$

the CNF obtained from Φ_v by fixing variables x_j to 1 for $j \in ON(v)$ and 0 for $j \in OFF(v) \setminus \hat{I}(v;\varphi)$, in which C'_a denotes the clause obtained from C_a in the same way. Then Φ_v is satisfiable if and only if Φ'_v is satisfiable. Note that only those x_j satisfying $j \in \hat{I}(v;\varphi)$ remain as variables in Φ'_v. In Example 5.2, it can be seen that $\Phi'_{v^{(i)}} = \bot$ for $i = 1,2,3,4,5$, $\Phi'_{v^{(6)}} = 1$, $\Phi'_{v^{(7)}} = 3$, and $\Phi'_{v^{(8)}} = \bar{8}(8 \vee 9)$. This may indicate that Φ'_v is much simpler than Φ_v to consider.

Now we prove the above claim (5.7) after showing the next lemma.

LEMMA 5.4. *Let $\varphi = \bigvee_{v\in T} t_v$ be a canonical Horn DNF of a pdBf (T,F). Let $\Phi_v = t_v \wedge \bigwedge_{a\in T} C_a$ and $\Phi'_v = \bigwedge_{a\in T} C'_a$ be defined as above for a $v \in T$. Then $C'_a \neq \top$ holds for an $a \in T$ if and only if the following two conditions hold:*

(i) $ON(a) \subseteq ON(v) \cup \hat{I}(v;\varphi)$,

(ii) $I(a;\varphi) \subseteq I(v;\varphi)$.

Proof. It is easy to see that if a satisfies (i) and (ii), then $C'_a \neq \top$ holds because C'_a is obtained from $C_a = (\bigvee_{j\in ON(a)} \bar{x}_j \vee \bigvee_{j\in I(a;\varphi)} x_j)$ by fixing $x_j = 1$ for $j \in ON(v)$ and 0 for $j \in OFF(v) \setminus \hat{I}(v;\varphi)$.

On the other hand, let us assume that $C'_a \neq \top$ holds. If there exists an $l \in ON(a) \setminus (ON(v) \cup \hat{I}(v;\varphi))\,(= ON(a) \cap (OFF(v) \setminus \hat{I}(v;\varphi)))$, then $C'_a = \top$ holds, because the x_l is fixed to 0, which is a contradiction to the assumption. This proves property (i).

Next, to prove (ii), assume that there exists an index $l \in I(a;\varphi) \setminus I(v;\varphi)$. The following two cases are possible:

(a) $l \in ON(v) \cap I(a;\varphi)$. Then, x_l is fixed to 1 and $C'_a = \top$ holds, which is a contradiction.

(b) $l \in OFF(v) \cap I(a;\varphi)$. Clearly, $l \in (OFF(v) \setminus I(v;\varphi)) \cap I(a;\varphi)$. Then $l \in I(a;\varphi)$ implies $(\bigwedge_{j\in ON(a)} x_j)\,\bar{x}_l \leq f_\varphi$, and therefore, by property (i),

$$\left(\bigwedge_{j\in ON(v)\cup I(v;\varphi)} x_j\right) \bar{x}_l \leq f_\varphi. \tag{5.9}$$

Now, $l \in OFF(v) \setminus I(v;\varphi)$ implies that $(\bigwedge_{j\in ON(v)} x_j)\,\bar{x}_l \not\leq f_\varphi$. However, since $(\bigwedge_{j\in ON(v)} x_j)\,\bar{x}_h \leq f_\varphi$ for all $h \in I(v;\varphi)$ and

$$\begin{aligned} &T\left(\left(\bigwedge_{j\in ON(v)\cup I(v;\varphi)} x_j\right)\bar{x}_l\right) \\ &\quad = T\left(\left(\bigwedge_{j\in ON(v)} x_j\right)\bar{x}_l\right) \setminus T\left(\left(\bigwedge_{j\in ON(v)} x_j\right)\left(\bigvee_{h\in I(v;\varphi)} \bar{x}_h\right)\bar{x}_l\right), \end{aligned}$$

we have $(\bigwedge_{j\in ON(v)\cup I(v;\varphi)} x_j)\,\bar{x}_l \not\leq f_\varphi$, which is a contradiction to (5.9). ∎

Now, we prove our claim.

LEMMA 5.5. *Let $\varphi = \bigvee_{v\in T} t_v$ be a canonical Horn DNF of a pdBf (T, F). If a vector u satisfies $\Phi_v(u) = 1$ for a vector $v \in T$, then the vector u' also satisfies $\Phi_v(u') = 1$, where u' is defined by*

$$u'_j = \begin{cases} u_j & \text{if } j \in ON(v) \cup I(v;\varphi), \\ 0 & \text{otherwise.} \end{cases} \tag{5.10}$$

Proof. Let $\Phi'_v = \bigwedge_{a\in T} C'_a$ and consider an $a \in T$ such that $C'_a \neq \top$. By $\Phi_v(u) = 1$, $C_a(u) = (\bigvee_{j\in ON(a)} \bar{u}_j \vee \bigvee_{j\in I(a;\varphi)} u_j) = 1$ holds. However, considering the condition $ON(a) \cup I(a;\varphi) \subseteq ON(v) \cup I(v;\varphi)$ (which follows from Lemma 5.4), we have $C_a(u') = C_a(u) = 1$. Furthermore, $C_b(u') = 1$ holds for all other clauses C_b with $C'_b = \top$, and also $t_v(u') = 1$ holds. These prove $\Phi_v(u') = 1$. □

Now, we summarize the above result as the following lemma.

LEMMA 5.6. *Let $\varphi = \bigvee_{v\in T} t_v$ be a canonical Horn DNF of a pdBf (T, F). Then φ is not minimal if and only if at least one of the CNFs Φ'_v, $v \in T$, is satisfiable, where Φ'_v is defined by* (5.8).

In order to find a vector u such that $\Phi'_v(u) = 1$, we can remove from Φ'_v all the clauses $C'_a = \top$. Furthermore, by (5.6), if a vector u satisfies $C'_v(u) = 1$, then all other clauses C'_a such that $I(a;\varphi) = I(v;\varphi)$ satisfy $C'_a(u) = 1$. Therefore, we can also remove from Φ'_v all the clauses C'_a satisfying $a \neq v$ and $I(a;\varphi) = I(v;\varphi)$. In the following, we write the resulting CNF also as Φ'_v. In other words, denoting by T_v the set of vectors $a \in T$ such that $C'_a \neq \top$ and $I(a;\varphi) \subset I(v;\varphi)$, where $\subset$ denotes proper inclusion, Φ'_v can be written as

$$\Phi'_v \;=\; C'_v \wedge \bigwedge_{a\in T_v} C'_a. \tag{5.11}$$

Note that $v \notin T_v$ holds by definition, and that a vector u satisfies $C'_v(u) = 1$ if and only if $ON(u) \cap \hat{I}(v;\varphi) \neq \emptyset$ holds (since $C'_v = \bigvee_{j\in\hat{I}(v;\varphi)} x_j$). Since C'_v is a special clause in Φ'_v (see the subsequent discussion), we check the conditions $C'_v(u) = 1$ and $\Phi''_v(u) = 1$ separately, where $\Phi''_v = \bigwedge_{a\in T_v} C'_a$. We emphasize here that these CNFs Φ''_v (and hence Φ'_v) may still be non-Horn. However, the following lemma shows that they can be transformed into Horn CNFs

$$\Phi^*_v \;=\; \bigwedge_{a\in T_v} C^*_a, \tag{5.12}$$

where C^*_a denotes the clause obtained from C'_a by removing all literals x_j, $j \in \hat{I}(a;\varphi)$. For example, if $C'_a = (\bar{1} \vee \bar{2} \vee 3 \vee 4 \vee 5)$ and $\hat{I}(a;\varphi) = \{4, 5, 6\}$, then $C^*_a = (\bar{1} \vee \bar{2} \vee 3)$ holds; in this case $\bar{x}_3$ is the negative literal in t_a. We can easily see that Φ^*_v is in fact Horn, because each clause C^*_a has at most one positive literal x_{l_a}, which appears negated in t_a.

LEMMA 5.7. *Let $\varphi = \bigvee_{v\in T} t_v$ be a canonical Horn DNF of a pdBf (T, F). Then φ is not minimal if and only if at least one of the Horn CNFs Φ^*_v, $v \in T$, has a vector $u \in \{0, 1\}^n$ such that $\Phi^*_v(u) = 1$ and $ON(u) \cap \hat{I}(v;\varphi) \neq \emptyset$.*

Proof. Let us first assume that some Φ^*_v has a vector u such that $\Phi^*_v(u) = 1$ and $ON(u) \cap \hat{I}(v;\varphi) \neq \emptyset$. Since $\Phi^*_v(u) = 1$ and $ON(u) \cap \hat{I}(v;\varphi) \neq \emptyset$, resp., imply $C'_a(u) = 1$ for all $a \in T_v$, and $C'_v(u) = 1$ (note that $C'_v = \bigvee_{j\in\hat{I}(v;\varphi)} x_j$), we have $\Phi'_v(u) = 1$. Thus Lemma 5.6 shows the if-part.

To prove the only-if part, let us assume by Lemma 5.6 that Φ'_v has a vector u such that $\Phi'_v(u) = 1$ and has the minimum $|I(v;\varphi)|$; i.e., no Φ'_w satisfies $|I(w;\varphi)| < |I(v;\varphi)|$. By (5.6), this u must satisfy $ON(u) \cap \hat{I}(v;\varphi) \neq \emptyset$. To show $\Phi^*_v(u) = 1$, let us assume the contrary, i.e., $C^*_b(u) = 0$ holds for some $b \in T_v$. Without loss of generality, we assume that the condition

$$u_j = 1 \text{ for all } j \in ON(v) \text{ and } 0 \text{ for all } j \in OFF(v) \setminus \hat{I}(v;\varphi) \tag{5.13}$$

holds, since Φ'_v consists of only those variables x_j satisfying $j \in \hat{I}(v;\varphi)$. Then $C^*_b(u) = 0$ implies $\overline{t_b}(u) = (\bigvee_{j \in ON(b)} \bar{u}_j \vee u_{l_b}) = 0$, where $\bar{x}_{l_b}$ is the negative literal in t_b. This is because C^*_b is obtained from the clause $(\bigvee_{j \in ON(b)} \bar{x}_j \vee x_{l_b})$ by fixing $x_j = 1$ for $j \in ON(v)$ and 0 for $j \in OFF(v) \setminus \hat{I}(v;\varphi)$ (which u also satisfies by (5.13)). Thus we have $t_b(u) = 1$. Since $\Phi_v = t_v \wedge \bigwedge_{a \in T} C_a$ and $\Phi_b = t_b \wedge \bigwedge_{a \in T} C_a$, $t_b(u) = 1$ and $\Phi_v(u) = 1$ imply $\Phi_b(u) = 1$. However, by Lemmas 5.3 and 5.6, this means that Φ'_b is satisfiable, which is a contradiction to our assumption that $|I(v;\varphi)|$ is the minimum (since $I(b;\varphi) \subset I(v;\varphi)$ holds by (ii) of Lemma 5.4 and the discussion following Lemma 5.6). □

Based on Lemma 5.7, we can propose an algorithm to solve problem MINIMAL-H-EXTENSION.

Algorithm CHECK-MINIMAL

Input: A pdBf (T, F) and a Horn DNF φ.

Question: Is φ a minimal Horn DNF of (T, F)?

Step 1: Check if f_φ is a Horn extension of (T, F). If not, output "no" and halt.

Step 2: Construct a canonical Horn DNF $\psi = \bigvee_{v \in T} t_v$ such that $f_\psi \leq f_\varphi$. If $f_\psi < f_\varphi$, then output "no" and halt; otherwise (i.e., $f_\psi = f_\varphi$), rewrite ψ as φ.

Step 3: For each $v \in T$, check if Φ^*_v has a vector u such that $ON(u) \cap \hat{I}(v;\varphi) \neq \emptyset$ and $\Phi^*_v(u) = 1$. Output "no" if some Φ^*_v has such a vector; otherwise, "yes." Halt.

THEOREM 5.1. *Given a pdBf (T, F) and a Horn DNF φ, Problem MINIMAL-H-EXTENSION can be solved in $O(|F||\varphi|+n|T||\varphi|+n|T|^2)$ time by Algorithm CHECK-MINIMAL, where $T, F \subseteq \{0,1\}^n$ and $|\varphi|$ denotes the number of literals in φ.*

Proof. The correctness of Algorithm CHECK-MINIMAL follows from Lemma 5.7. We therefore consider its time complexity. Step 1 can be executed in $O((|T|+|F|)|\varphi|)$ time, since we can check if $\varphi(v) = 1$ or 0 for each $v \in T \cup F$ in $O(|\varphi|)$ time. In Step 2, we first compute $I(v;\varphi)$ for all $v \in T$, which can be done in $O(|T||\varphi|)$ time by applying Algorithm F-CHAINING in subsection 5.1 to all $v \in T$. Choose an arbitrary term $t_v \in R(v;\varphi)$ for each $v \in T$, and then construct a canonical Horn DNF $\psi = \bigvee_{v \in T} t_v$, which satisfies $f_\psi \leq f_\varphi$ and $|\psi| \leq n|T|$. This can be done in $O(n|T|)$ time. Checking if two Horn DNFs ψ and φ satisfy $f_\psi < f_\varphi$ can then be done in $O(|\psi||\varphi|) = O(n|T||\varphi|)$ time [14]. Totally, Step 2 requires $O(n|T||\varphi|)$ time. In Step 3, for each $v \in T$, we can construct Φ^*_v in $O(n|T|)$ time, because $I(v;\varphi)$ was already obtained in Step 2.

Let us now consider how to check if there is a vector u such that $ON(u) \cap \hat{I}(v;\varphi) \neq \emptyset$ and $\Phi^*_v(u) = 1$. Since the variable set of Φ^*_v is $\hat{I}(v;\varphi)$, we regard Φ^*_v as a CNF of $|\hat{I}(v;\varphi)|$ variables in this proof. For notational convenience, given a $u \in \{0,1\}^n$, we write $\Phi^*_v(u|_{\hat{I}(v;\varphi)}) = 1$ instead of $\Phi^*_v(u) = 1$, where $u|_S$ is the projection of u to $S \subseteq \{1, 2, \ldots, n\}$. To check if there is a vector $u|_{\hat{I}(v;\varphi)} \neq (0, 0, \ldots, 0)$ such that $\Phi^*_v(u|_{\hat{I}(v;\varphi)}) = 1$, we consider two cases, $\Phi^*_v(0, 0, \ldots, 0) = 0$ and $\Phi^*_v(0, 0, \ldots, 0) = 1$. If $\Phi^*_v(0, 0, \ldots, 0) = 0$, then solve H-SAT for Φ^*_v (see section 2); if the output of H-SAT is "yes" (resp., "no"), there is a desired vector u (resp., no desired vector u).

On the other hand, if $\Phi_v^*(0,0,\ldots,0)=1$, then solve UNIQUE-H-SAT (see section 2) to see if $(0,0,\ldots,0)$ is the unique vector such that $\Phi_v^*(0,0,\ldots,0)=1$. There is no desired vector u if and only if $(0,0,\ldots,0)$ is the unique such vector. Since H-SAT and UNIQUE-H-SAT can be solved in time linear in the number of literals [7, 22], this can be done in $O(|\varphi|)=O(n|T|)$ time for each $v\in T$. Therefore, Step 3 can be executed in $O(n|T|)\times|T|=O(n|T|^2)$ time.

Summing up the time of all steps, we conclude that Algorithm CHECK-MINIMAL requires $O(|F||\varphi|+n|T||\varphi|+n|T|^2)$ time. □

If a given DNF φ is already a canonical Horn DNF, we can skip Steps 1 and 2 of CHECK-MINIMAL, leading to the following corollary.

COROLLARY 5.1. *Given a pdBf (T,F) and a canonical Horn DNF φ of (T,F), Problem MINIMAL-H-EXTENSION can be solved in $O(n|T|^2)$ time.*

Example 5.3. Consider the pdBf (T,F) and canonical Horn DNF $\varphi=\varphi^{(1)}$ of Example 3.1, to which we apply Algorithm CHECK-MINIMAL. Sets $I(v^{(l)};\varphi)$, $l=1,2,\ldots,|T|$, are listed in Example 5.1. It can be seen that $\Phi^*_{v^{(i)}}=\bot$ for $i=1,2,3,4,5$, $\Phi^*_{v^{(6)}}=\Phi^*_{v^{(7)}}=\top$, and $\Phi^*_{v^{(8)}}=\bar{8}$. Clearly, $\Phi^*_{v^{(i)}}$, $i=6,7,8$, has a vector u satisfying the condition in Step 3 of CHECK-MINIMAL. Consequently, this φ does not represent a minimal Horn extension of (T,F).

5.2. Generating a minimal Horn extension. In this subsection, we consider the generation of a minimal canonical Horn DNF of a given pdBf (T,F). To generate a minimal canonical Horn DNF of a given pdBf (T,F), we first construct a canonical Horn DNF φ and then recursively check if some Φ_v^*, $v\in T$, has a vector $u\in\{0,1\}^n$ satisfying $ON(u)\cap\hat{I}(v;\varphi)\neq\emptyset$, $\Phi_v^*(u)=1$, and (5.13). If no, output φ and halt. Otherwise, update φ to a canonical Horn DNF φ' such that $\varphi'(u)=0$ and $\varphi'<\varphi$.

Note that condition (5.13) for u is not restrictive, because Φ_v^* consists of only variables x_j satisfying $j\in\hat{I}(v;\varphi)$. Furthermore, by this restriction, $\Phi_v^*(u)=1$ implies $\Phi_v(u)=1$, and hence we can construct the above φ'. Formally, it can be written as follows.

Algorithm FIND-MINIMAL

Input: A pdBf (T,F).

Output: A minimal canonical Horn DNF φ of (T,F) if (T,F) has a Horn extension; otherwise, "no."

Step 1: If (T,F) has a Horn extension, construct a canonical DNF $\varphi=\bigvee_{v\in T}t_v$; otherwise, output "no" and halt.

Step 2: For each $v\in T$, check if Φ_v^* has a vector $u\in\{0,1\}^n$ satisfying $ON(u)\cap\hat{I}(v;\varphi)\neq\emptyset$, $\Phi_v^*(u)=1$, and (5.13). If no Φ_v^* has such a vector u, then output the current φ and halt. On the other hand, if Φ_v^* has such a vector u, based on this u, define

$$R_u(a;\varphi)=\{t\in R(a;\varphi)\,|\,t(u)=0\},\quad a\in T, \tag{5.14}$$

and reconstruct a canonical Horn DNF φ by

$$\varphi:=\bigvee_{a\in T}t_a,\quad t_a\in R_u(a;\varphi), \tag{5.15}$$

where $t_a\in R_u(a;\varphi)$ is chosen arbitrarily if $|R_u(a;\varphi)|\geq 2$. Return to Step 2.

In Step 2, if we have a desired vector u, $R_u(a;\varphi)$ of (5.14) can be easily obtained as follows:

$$R_u(a;\varphi)=\begin{cases} R(a;\varphi) & \text{if } ON(a)\cap OFF(u)\neq\emptyset,\\ \{(\bigwedge_{j\in ON(a)}x_j)\,\bar{x}_l\,|\,l\in ON(u)\cap I(a;\varphi)\} & \text{otherwise.}\end{cases}$$

THEOREM 5.2. *Given a pdBf (T, F), where $T, F \subseteq \{0,1\}^n$, a minimal canonical Horn DNF φ of (T, F) can be generated in $O(n|T|(|F| + n|T|^2))$ time if (T, F) has a Horn extension.*

Proof. FIND-MINIMAL is similar to CHECK-MINIMAL of subsection 5.1. To show its correctness, we need only prove that (i) $R_u(a;\varphi) \neq \emptyset$ holds for all $a \in T$ in (5.14) and (ii) FIND-MINIMAL will eventually halt.

(i) By the definition of Φ_v^* and the assumption (5.13) on u, $\Phi_v^*(u) = 1$ implies $\Phi_v(u) = 1$. This means that $C_a(u) = 1$ holds for all $a \in T$, where $C_a = (\bigvee_{j \in ON(a)} \bar{x}_j \vee \bigvee_{j \in I(a;\varphi)} x_j)$, and hence some $t \in R(a;\varphi)$ satisfies $t(u) = 0$, by the definition of $R_u(a;\varphi)$. Therefore, $R_u(a;\varphi) \neq \emptyset$ holds for all $a \in T$.

(ii) Let φ' be the DNF constructed by (5.15) from φ during an iteration. Then φ' is clearly a canonical Horn DNF of (T, F), and $f_{\varphi'} < f_\varphi$ holds since $u \in T(\varphi) \setminus T(\varphi')$. More precisely,

$$\sum_{a \in T} |R(a;\varphi')| \ < \ \sum_{a \in T} |R(a;\varphi)| \ \ \big(\leq \ n|T|\big)$$

holds. This is because $R(a;\varphi') \subseteq R(a;\varphi)$ holds for all $a \in T$, and t_v in φ is included in $R(v;\varphi)$ but not in $R(v;\varphi')$ (since $\Phi_v(u) = 1$ implies $t_v(u) = 1$). Thus the number of iterations is at most $n|T|$, which proves (ii).

Finally, let us consider its time complexity. By Theorem 3.1, Step 1 can be done in $O(n|T||F|)$ time. In Step 2, for each $v \in T$, we can obtain Φ_v^* from φ in $O(|\varphi|) = O(n|T|)$ time, since $I(v;\varphi)$ can be computed in $O(|\varphi|) = O(n|T|)$ time by applying F-CHAINING of subsection 5.1 to a vector v. Similar to the proof of Theorem 5.1, for each $v \in T$, a vector u satisfying $ON(u) \cap \hat{I}(v;\varphi) \neq \emptyset$, $\Phi_v^*(u) = 1$, and (5.13) can be computed in $O(n|T|)$ time, if there is at least one such u. Thus $O(n|T|) \times |T| = O(n|T|^2)$ time is required to find the desired vector u. Once we have such a vector u, $t_a \in R_u(a;\varphi)$ can be obtained in $O(n)$ time for each $a \in T$. (See the discussion below Algorithm FIND-MINIMAL.) This means that the new φ of (5.15) can be obtained in $O(n|T|)$ time. Hence each iteration of Step 2 requires $O(n|T|^2)$ time. Since the number of iterations is at most $n|T|$, Step 2 requires $O(n^2|T|^3)$ time in total.

Consequently, Algorithm FIND-MINIMAL can be executed in $O(n|T|(|F|+n|T|^2))$ time. □

Example 5.4. Consider again the pdBf (T, F) of Example 3.1. We demonstrate Algorithm FIND-MINIMAL by assuming that a canonical DNF $\varphi = \varphi^{(1)}$ of Example 3.1 is obtained in Step 1.

First iteration. Sets $I(v^{(l)};\varphi)$, $l = 1, 2, \ldots, 8$, are listed in Example 5.1. We have $\Phi^*_{v^{(i)}} = \bot$ for $i = 1, 2, \ldots, 5$, $\Phi^*_{v^{(6)}} = \Phi^*_{v^{(7)}} = \top$, and $\Phi^*_{v^{(8)}} = \bar{8}$, which are obtained in Example 5.3. For example, $\Phi^*_{v^{(6)}}$ has a vector $u = (111000001)$ satisfying the condition in Step 2 of FIND-MINIMAL. Based on this u, we construct $R_u(v^{(l)};\varphi)$ of (5.14): $R_u(v^{(1)};\varphi) = \{12347\bar{8}\}$, $R_u(v^{(2)};\varphi) = \{12357\bar{9}\}$, $R_u(v^{(3)};\varphi) = \{1236\bar{7}8\}$, $R_u(v^{(4)};\varphi) = \{\bar{1}37\}$, $R_u(v^{(5)};\varphi) = \{1\bar{3}7\}$, $R_u(v^{(6)};\varphi) = \{\bar{1}239\}$, $R_u(v^{(7)};\varphi) = \{12\bar{3}9\}$, and $R_u(v^{(8)};\varphi) = \{1234567, 1234568, 1234569\}$. By (5.15), we obtain a canonical Horn DNF

$$\varphi \ := \ 12347\bar{8} \vee 12357\bar{9} \vee 1236\bar{7}8 \vee \bar{1}37 \vee 1\bar{3}7 \vee \bar{1}239 \vee 12\bar{3}9 \vee 1234567,$$

if 1234567 is chosen from $R_u(v^{(8)};\varphi)$.

Second iteration. Construct $I(v^{(1)};\varphi) = \{8\}$, $I(v^{(2)};\varphi) = \{9\}$, $I(v^{(3)};\varphi) = \{7\}$, $I(v^{(4)};\varphi) = \{1\}$, $I(v^{(5)};\varphi) = \{3\}$, $I(v^{(6)};\varphi) = \{1\}$, $I(v^{(7)};\varphi) = \{3\}$, and $I(v^{(8)};\varphi) = \{7,8,9\}$. Then we have $\Phi^*_{v^{(i)}} = \bot$ for $i = 1,2,\ldots,7$ and $\Phi^*_{v^{(8)}} = \bar{8}$. $\Phi^*_{v^{(8)}}$ has a vector $u = (111111001)$ satisfying the condition in Step 2 of FIND-MINIMAL. By (5.14), we construct $R_u(v^{(1)};\varphi) = \{12347\bar{8}\}$, $R_u(v^{(2)};\varphi) = \{12357\bar{9}\}$, $R_u(v^{(3)};\varphi) = \{1236\bar{7}8\}$, $R_u(v^{(4)};\varphi) = \{\bar{1}37\}$, $R_u(v^{(5)};\varphi) = \{1\bar{3}7\}$, $R_u(v^{(6)};\varphi) = \{\bar{1}239\}$, $R_u(v^{(7)};\varphi) = \{12\bar{3}9\}$, and $R_u(v^{(8)};\varphi) = \{123456\bar{9}\}$. The next canonical Horn DNF φ constructed by (5.15) is

$$\varphi \quad := \quad 12347\bar{8} \vee 12357\bar{9} \vee 1236\bar{7}8 \vee \bar{1}37 \vee 1\bar{3}7 \vee \bar{1}239 \vee 12\bar{3}9 \vee 123456\bar{9}.$$

Third iteration. Construct $I(v^{(1)};\varphi) = \{8\}$, $I(v^{(2)};\varphi) = \{9\}$, $I(v^{(3)};\varphi) = \{7\}$, $I(v^{(4)};\varphi) = \{1\}$, $I(v^{(5)};\varphi) = \{3\}$, $I(v^{(6)};\varphi) = \{1\}$, $I(v^{(7)};\varphi) = \{3\}$, and $I(v^{(8)};\varphi) = \{9\}$. We have $\Phi^*_{v^{(i)}} = \bot$ for $i = 1,2,\ldots,8$. Therefore, the above φ obtained in the second iteration is a minimal Horn DNF of (T,F). This φ is equal to $\varphi^{(2)}$ of Example 3.1.

5.3. Minimum and unique minimal Horn extensions. In this subsection, we first consider the problem of computing a minimum (i.e., with the smallest $|T(f)|$) Horn extension f among all minimal Horn extensions and then the condition for the uniqueness of a minimal Horn extension.

Problem MINIMUM-H-EXTENSION

Input: A pdBf (T,F).

Output: A minimum Horn DNF φ of (T,F) if (T,F) has a Horn extension; otherwise, "no."

THEOREM 5.3. *Problem MINIMUM-H-EXTENSION is NP-hard, even if* $F = \emptyset$.

Proof. We transform Problem VERTEX COVER to this problem, where VERTEX COVER is known to be NP-hard [11]. Let $G = (V,E)$ be an undirected graph, where $V = \{1,\ldots,n\}$. Let us define $T, F \subseteq \{0,1\}^n$ as follows:

$$\begin{array}{lcl} T & = & \{x^A \mid A = V \setminus \{i,j\}, (i,j) \in E\} \text{ and} \\ F & = & \emptyset, \end{array}$$

where x^A denotes the characteristic vector of set $A \subseteq V$ (i.e., $x^A_j = 1$ if $j \in A$ and $x^A_j = 0$ if $j \notin A$). As $F = \emptyset$, this (T,F) obviously has a Horn extension. Let $\varphi = \bigvee_{v \in T} t_v$ with $t_v = (\bigwedge_{j \in P_v} x_j)\bar{x}_{l_v}$ be a canonical Horn DNF that represents a minimum Horn extension of (T,F). We claim that $|T(f_\varphi)| = |E| + \tau(G)$, where $\tau(G)$ denotes the cardinality of a minimum vertex cover of G. This will prove the theorem, since Problem VERTEX COVER (i.e., computing $\tau(G)$) is known to be NP-hard [11] and $|T(f_\varphi)|$ can be computed from such a φ in polynomial time.

To prove the claim, we first show that $|T(f_\varphi)| \geq |E| + \tau(G)$. Since φ is a canonical Horn DNF, we have $P_v = ON(v)$ (where $|ON(v)| = n-2$), $l_v \in I(v)\,(= OFF(v))$, and $T(t_v) = \{v, x^{V \setminus \{l_v\}}\}$. Therefore, $T(f_\varphi) = T \cup \{x^{V \setminus \{l_v\}} \mid v \in T\}$. Since $OFF(v)$ of each $v \in T$ corresponds to an edge of G, set $\{l_v \mid v \in T\}$ forms a vertex cover of G. Therefore,

$$\begin{aligned} |T(\varphi)| &= |T \cup \{x^{V \setminus \{l_v\}} \mid v \in T\}| \\ &= |E| + |\{l_v \mid v \in T\}| \\ &\geq |E| + \tau(G). \end{aligned}$$

Conversely, let $W \subseteq V$ be a minimum vertex cover with $|W| = \tau(G)$. Then define a Horn DNF $\varphi_W = \bigvee_{v \in T} t_v$, where $t_v = (\bigwedge_{j \in ON(v)} x_j)\, \bar{x}_{l_v}$ for some $l_v \in OFF(v) \cap W$. Then $T(t_v) = \{v, x^{V \setminus \{l_v\}}\}$ holds and φ_W is a Horn DNF of (T, F). Furthermore, $|T(\varphi_W)| = |T \cup \{x^{V \setminus \{k\}} \mid k \in W\}| = |E| + |W| = |E| + \tau(G)$. □

However, the uniqueness of a minimal Horn extension can be decided in polynomial time.

Problem UMIN-H-EXTENSION

Input: A pdBf (T, F).

Question: Does (T, F) have the unique minimal Horn extension?

LEMMA 5.8. *Let $\varphi = \bigvee_{v \in T} t_v$ be a minimal canonical Horn DNF of a pdBf (T, F). Then (T, F) does not have the unique minimal Horn extension (which is f_φ) if and only if at least one of the CNFs*

$$\Phi_v^\dagger \;=\; t_v \;\wedge\; \bigwedge_{a \in T} C_a^\dagger, \quad v \in T, \tag{5.16}$$

where $C_a^\dagger = (\bigvee_{j \in ON(a)} \bar{x}_j \vee \bigvee_{j \in I(a)} x_j)$, is satisfiable.

Proof. To show the if-part, let us first assume that a vector u satisfies $\Phi_v^\dagger(u) = 1$. Then obviously $\varphi(u) = 1$ holds, and, for each $a \in T$, there is a term t_a^* in $R(v)$ such that $t_a^*(u) = 0$. By choosing such a term t_a^* for each $a \in T$, we have a canonical Horn DNF $\psi = \bigvee_{a \in T} t_a^*$ of (T, F) such that $\psi(u) = 0$. Therefore, u satisfies $\varphi(u) = 1$ and $\psi(u) = 0$, which proves that (T, F) has at least two minimal Horn extensions.

Conversely, if no $\Phi_v^\dagger$ is satisfiable, then, for every vector u such that $\varphi(u) = 1$, some clause $C_a^\dagger$ satisfies $C_a^\dagger(u) = 0$. By the definition of $I(a)$, this implies that $t_a^*(u) = 1$ holds for all $t_a^* \in R(a)$. Therefore, if a vector u satisfies $\varphi(u) = 1$, then $\psi(u) = 1$ must hold for all canonical Horn DNFs $\psi = \bigvee_{a \in T} t_a^*$, which shows that (T, F) has the unique minimal Horn extension. □

Note that this lemma corresponds to Lemma 5.3, and all other lemmas, theorems, and algorithms in subsection 5.1 are valid, even if Φ_v and $I(v; \varphi)$ are replaced by $\Phi_v^\dagger$ and $I(v)$, respectively. (Recall that $I(v)$ becomes $I(v; \varphi)$ if φ represents $f_{\max}$.) Therefore, in order to solve Problem UMIN-H-EXTENSION, first construct a canonical DNF φ such that f_φ is a minimal Horn extension by Algorithm FIND-MINIMAL in subsection 5.2, and then check the condition in Lemma 5.8 by using Algorithm CHECK-MINIMAL with the above replacement incorporated.

THEOREM 5.4. *Problem UMIN-H-EXTENSION can be solved in $O(n|T|(|F| + n|T|^2))$ time.*

Proof. We consider only its time complexity. A minimal canonical Horn DNF φ can be constructed in $O(n|T|(|F| + n|T|^2))$ time by Theorem 5.2. We also can check the condition in Lemma 5.8 in $O(n|T|^2)$ time (Corollary 5.1) by using the modified CHECK-MINIMAL. □

6. Shortest Horn extensions. Finally, we show that the following problem, related to the knowledge compression for expert systems [13, 14], is intractable:

Problem SHORTEST-H-EXTENSION

Input: A pdBf (T, F) and a positive integer k.

Question: Is there a Horn DNF φ of (T, F) such that $|\varphi| \leq k$?

THEOREM 6.1. *Problem SHORTEST-H-EXTENSION is NP-complete.*

Proof. This problem is in NP, since we can check in polynomial time if a given DNF φ represents a Horn extension of (T, F) and satisfies $|\varphi| \leq k$. Now we transform

Problem VERTEX COVER to this problem, where VERTEX COVER is known to be NP-hard [11]. Let $G = (V, E)$ be an undirected graph, where $V = \{1, 2, \ldots, n\}$. Let us define $T, F \subseteq \{0,1\}^n$ as follows:

$$\begin{aligned} T &= \{x^A \mid A = V \setminus \{i,j\}, (i,j) \in E\}, \\ F &= \{e = (11\ldots1)\}, \end{aligned}$$

where x^A denotes the characteristic vector of set $A \subseteq V$.

We claim that there is a Horn DNF φ of (T, F) such that $|\varphi| \leq k$ if and only if $\tau(G) \leq k$, where $\tau(G)$ denotes the cardinality of a minimum vertex cover of G. Similar to the proof of Theorem 5.3, this will complete the proof.

Let $\varphi = \bigvee_{l \in L} t_l$, where $t_l = \bigwedge_{j \in P_l} x_j \bigwedge_{j \in N_l} \bar{x}_j$, be a Horn DNF of (T, F) such that $|\varphi| \leq k$. Then, for every $l \in L$, the following conditions hold:

(a) $N_l \neq \emptyset$, i.e., $|N_l| = 1$ holds since otherwise $t_l(e) = 1$, which is a contradiction.

(b) $P_l = \emptyset$ holds, since replacing P_l by $\emptyset$ produces a shorter good term t'_l such that $|t'_l| \leq |t_l|$, $t_l(a) = 1$ implies $t'_l(a) = 1$ for all $a \in T$, and $t'_l(e) = 0$.

Furthermore, since $\varphi(a) = 1$ for every $a \in T$, there must exist an $l \in L$ such that $t_l(a) = 1$ (i.e., $N_l \subseteq OFF(a) = \{i, j\}$ for the corresponding edge $(i, j) \in E$). Hence $\cup_{l \in L} N_l$ is a vertex cover of G such that $|\cup_{l \in L} N_l| = |\varphi| \leq k$.

Conversely, if W is a vertex cover with $|W| \leq k$, then $\varphi_W = \bigvee_{j \in W} \bar{x}_j$ is a Horn DNF of (T, F) such that $|\varphi_W| \leq k$. □

7. Conclusion and future research. Because there are in general many Horn extensions for a given pdBf (T, F), in this paper we considered Horn extensions with special properties. In particular, we investigated maximal and minimal Horn extensions and pointed out that the maximal Horn extension is always unique (i.e., maximum) but there are many minimal Horn extensions. The main contribution of this paper is to show that checking if a Horn DNF is minimal and generating a minimal Horn DNF of a pdBf (T, F) both can be done in polynomial time. We can also check in polynomial time if a minimal extension is unique. However, the problems of finding a Horn DNF of a minimum Horn extension and finding a shortest Horn DNF of a pdBf (T, F) are shown to be NP-hard.

A possible topic for future research is the development of an efficient algorithm to generate all minimal Horn extensions of a given pdBf (T, F).

Acknowledgments. The authors greatly appreciate the comments given by two anonymous reviewers, which helped improve the readability of this paper. In particular, one of the reviewers gave us an alternative proof of Lemma 5.7 and suggested a shorter presentation of subsection 5.1 (which was originally written in a form dual to the current version).

FAST APPROXIMATE GRAPH PARTITIONING ALGORITHMS*

GUY EVEN†, JOSEPH (SEFFI) NAOR‡, SATISH RAO§, AND BARUCH SCHIEBER¶

Abstract. We study graph partitioning problems on graphs with edge capacities and vertex weights. The problems of b-balanced cuts and k-balanced partitions are unified into a new problem called minimum capacity ρ-separators. A ρ-separator is a subset of edges whose removal partitions the vertex set into connected components such that the sum of the vertex weights in each component is at most ρ times the weight of the graph. We present a new and simple $O(\log n)$-approximation algorithm for minimum capacity ρ-separators which is based on spreading metrics yielding an $O(\log n)$-approximation algorithm both for b-balanced cuts and k-balanced partitions. In particular, this result improves the previous best known approximation factor for k-balanced partitions in undirected graphs by a factor of $O(\log k)$. We enhance these results by presenting a version of the algorithm that obtains an $O(\log \mathrm{OPT})$-approximation factor. The algorithm is based on a technique called spreading metrics that enables us to formulate directly the minimum capacity ρ-separator problem as an integer program. We also introduce a generalization called the simultaneous separator problem, where the goal is to find a minimum capacity subset of edges that separates a given collection of subsets simultaneously. We extend our results to directed graphs for values of $\rho \geq 1/2$. We conclude with an efficient algorithm for computing an optimal spreading metric for ρ-separators. This yields more efficient algorithms for computing b-balanced cuts than were previously known.

Key words. graph partitioning, approximation algorithms, graph separator, spreading metrics

1. Introduction.

Two well-studied graph partitioning problems are finding minimum capacity *b-balanced cuts* and *k-balanced partitions* in undirected and directed graphs. The input for these problems consists of a graph having edge capacities and also vertex weights. Given a parameter $0 < b \leq 1/2$, the *b-balanced cut problem* is to find a minimum capacity cut such that the weight of the vertex sets on each side of the cut is at least b times the weight of the graph. Given an integer k, the *k-balanced partitioning problem* is to find a minimum capacity subset of edges whose removal partitions the graph into at most k roughly equally weighted subgraphs that are disconnected from each other. (Section 2 formally defines these problems and their vertex counterparts.) These problems have many applications, among them VLSI layout, circuit testing and simulation, parallel scientific processing, and sparse linear system solving. In essence, graph partitioning is used in these applications either for divide-and-conquer algorithms or for facilitating parallelism.

Since these graph partitioning problems are NP-hard, two approaches have been taken. In the first approach, efficient heuristics were designed (e.g., [8]); however,

these heuristics did not make any guarantee on the quality of the solution. In the second approach, polynomial-time approximation algorithms were designed [13], and an upper bound on the ratio between the value of an approximate solution and an optimal solution is given. The techniques used by these two approaches differ greatly. Lang and Rao [14] conducted some experiments based on [13] and reported that the technique is successful for large graphs if long running times are allowed and if an additional clean-up phase [8] is used. (See also [1].)

We unify the problems of b-balanced cuts and k-balanced partitions into a new problem called *ρ-separators*. Given a parameter $0 < \rho < 1$, the *ρ-separator problem* is to find a minimum capacity cut that partitions the vertex set into connected components such that the weight of each is at most ρ times the weight of the graph. We also introduce a more general problem called *simultaneous separators*: a collection of subsets $U_1, \ldots, U_s$ of the vertex set is given together with separation parameters $\rho_1, \ldots, \rho_s$. The goal is to find a minimum capacity cut that partitions the vertex set into connected components such that each connected component contains at most ρ_i of the weight of subset U_i for all i.

We present a unified framework that allows us to obtain new graph partitioning algorithms. These algorithms help bridge the gap between heuristics and approximation algorithms in the following ways: First, we obtain improved approximation factors. Second, our algorithm is faster by a factor of $O(|V|)$. Third, our main technique may also be used in conjunction with techniques such as cutting planes. Thus, apart from yielding improved algorithms for graph partitioning, our techniques may be used to design new heuristics that differ significantly from the Kernighan and Lin algorithm [8] and simulated annealing [7].

Our framework is based on *spreading metrics* which provide a direct fractional relaxation of graph partitioning problems. Spreading metrics were introduced by Even et al. [3] to obtain improved approximation factors for certain NP-hard graph problems that are amenable to a divide-and-conquer approach. Informally, a spreading metric on a graph is an assignment of lengths to either the edges or the vertices, so that subgraphs on which the optimization problem is nontrivial are spread apart in the associated metric space. In addition, the volume of the spreading metric provides a lower bound on the cost of solving the optimization problem on the input graph. Spreading metrics are used to find a cut in the graph whose cost depends on the volume of the spreading metric in one of the resulting subgraphs. In [3] this cut defines the divide step, and then each subproblem is solved recursively.

1.1. Our results. We believe that the definition of ρ-separators captures the type of partitioning that is actually required in applications. Namely, instead of limiting the number of resulting parts, which is not always important for divide-and-conquer applications or for parallelism, we limit only the sizes or weights of each part. This enables us to unify the problems of b-balanced cuts and k-balanced partitions. We also consider a generalization called simultaneous separators.

Our approximation algorithms are simple and deal easily with the weighted version. The approximation factors for undirected graphs are summarized in Table 1.1, where n denotes the number of vertices in the graph. Note that in order to perform a fair comparison in Table 1.1, we assume that an optimal spreading metric is used. If an α-approximate spreading metric is used, then the approximation factor for the problems we solve is multiplied by α. (A similar issue applies for previous algorithms with regard to solving linear programs.) In particular, the approximation factor of our k-balanced partitioning algorithm improves over previous algorithms by a factor of

Problem	Our work	Previous work
ρ'-separator	$\left(\frac{\rho'}{\rho'-\rho}+o(1)\right)\cdot\ln n\cdot\text{OPT}_\rho$	$O(\log n\cdot\log 1/\rho')\cdot\text{OPT}_\rho$ [13, 12, 17]
b'-balanced cut ($b'\le 1/3$)	$\left(\frac{1-b'}{b-b'}+o(1)\right)\cdot\ln n\cdot\text{OPT}_b$	$8\cdot\left(\frac{1}{3(b-b')}+\ln\frac{1-b}{b-b'}\right)\cdot\ln n\cdot\text{OPT}_b$ [13, 6]
k-balanced partition	$(2+o(1))\cdot\ln n\cdot\text{OPT}_k$	$O(\log n\cdot\log k)\cdot\text{OPT}_k$ [12, 17]
separator	$(4+o(1))\cdot\ln n\cdot\text{OPT}_{1/2}$	$\sim 24.8\cdot\ln n\cdot\text{OPT}_{1/2}$ [13, 6]

$O(\log k)$, and our separator approximation improves over previous algorithms roughly by a factor of 6. Note that we compare the cost of the found solution with the cost of an optimal solution to a more restricted problem; this is the reason for the term "pseudoapproximation" used in the literature. For example, we compute a ρ'-separator and compare its cost with the cost of an optimal ρ-separator, for $\rho<\rho'$. The algorithm for approximating ρ-separators holds for directed graphs with constants four times as large if $\rho\ge 1/2$. Since we require for directed graphs that $\rho\ge 1/2$, we are not able to approximate k-balanced partitions in directed graphs for $k>4$, since this requires $\rho'=2/k<1/2$.

Our use of spreading metrics introduces a *direct* fractional relaxation of the partitioning problems. The connection between the fractional relaxation and the original problem is natural and a repeated evaluation of fractional edge lengths is not required, as opposed to the Leighton–Rao algorithm [13].

The running time of our algorithms is dominated by the complexity of finding a spreading metric. Spreading metrics can be computed by general linear programming algorithms (such as the ellipsoid algorithm). However, we present much more efficient approximate algorithms that are based on the framework presented in the papers of Plotkin, Tardos, and Shmoys [16] and Young [18]. These efficient algorithms apply only to undirected graphs. Specifically, the complexity of our deterministic algorithm which computes a constant approximation for a spreading metric is $\tilde{O}(m^2 n\cdot\frac{\rho'}{\rho'-\rho})$.[1] The randomized version has an expected running time of $\tilde{O}(m^2/(\rho'-\rho))$; moreover, this running time is achieved with probability $1-e^{-\Omega(m)}$. For balanced cuts, $(\rho'-\rho)$ is typically a constant. This improves over the implementation of the Leighton–Rao algorithm suggested by Leighton et al. [11], where the time complexity is $\tilde{O}(mn^3)$ with the use of expanders and $\tilde{O}(mn^4)$ without the use of expanders. (Expanders are needed to reduce the number of commodities from $\Omega(n^2)$ to $\Omega(n)$.)

Since our efficient algorithms approximate spreading metrics rather than compute them exactly, applying them increases the approximation factors for ρ-separators. Specifically, in the case of arbitrary vertex weights, the following error terms are

[1] The notation $\tilde{O}$ ignores polylogarithmic factors, and $|V|=n, |E|=m$.

generated by our approximate algorithm for spreading metrics: (a) a multiplicative error bounded by $2(1+\varepsilon)$ introduced in approximating the optimization oracle (see section 7.3.2); (b) a multiplicative error bounded by 2 introduced in the randomized version (see section 7.3.3); (c) an additive error bounded by $2 \cdot \text{OPT}_\rho$ introduced in the scaling procedure (needed for bounding the optimal cost) (see section 7.2); and (d) additional multiplicative error terms as specified in items (a) and (b) (for the randomized version) introduced in the transformation of a solution into a spreading metric (see section 7.4).

Finally, we present $O(\log \text{OPT})$-approximation factors for all these problems, which for small values of OPT is better than the $O(\log n)$-approximation factors.

1.2. Comparison with previous work. The seminal work of Leighton and Rao [13] is the only previous paper that provides a pseudoapproximation algorithm for b-balanced cuts. Given a graph and two parameters $0 < b \leq 1/2$ and $0 < b' \leq \min\{1/3, b\}$ (typically, $b = 1/2$ and $b' = 1/3$), Leighton and Rao presented an algorithm that finds a cut whose capacity is $O(\frac{\log n}{b-b'} \cdot \text{OPT}_b)$, where OPT_b denotes the capacity of an optimum b-balanced cut. Leighton and Rao approach the problem of finding b-balanced cuts indirectly. They define the notion of a sparse cut, whose fractional relaxation is the dual problem of a multicommodity flow problem. They present an $O(\log n)$-approximation algorithm for computing an optimal sparse cut. The Leighton–Rao algorithm proceeds by accumulating approximate optimal sparse cuts, cutting off in each iteration the smaller part of the graph, until a fraction of b' of the weight of the graph is accumulated. Approximating an optimal sparse cut in each iteration is done in two stages. First, a new linear program is solved. Then a good cut is searched for by trying to find a shallow depth subgraph that contains a majority of the vertices. Finding the right expansion ratio is done by trial and error until a right value is observed. Finally, Leighton and Rao show that the union of the $O(\log n)$-approximate sparse cuts results with an $O(\frac{\log n}{b-b'} \cdot \text{OPT}_b)$ capacity b'-balanced cut.

Our algorithm differs from the Leighton–Rao algorithm in several ways. First, we consider a direct linear programming formulation for ρ-separators. We need to solve this linear program only once; the Leighton–Rao algorithm needs to solve a new linear program after each cut is taken. The use of spreading metrics enables us to control the weight of the pieces that are chopped off in undirected graphs so that chopped off pieces need not be further partitioned. In contrast, in the Leighton–Rao algorithm the only guarantee is that the weight of the chopped off part is at most half the weight of the remaining subgraph. Controlling the weight of the chopped off pieces enables us to find k-balanced partitions in undirected graphs without having to recursively partition the chopped off pieces. Our criterion for finding good cuts (e.g., the expansion ratio) is known in advance, and we do not need a trial-and-error stage in order to compute a cut.

Garg, Vazirani, and Yannakakis [6] presented an $O(\log k)$-approximation algorithm for multicuts in undirected networks. They also described how to approximate sparse cuts and obtain an $8 \log n$-approximation. Our results are related to their work in the following ways. We use their credit scheme, and our cut procedure is basically identical to their region growing technique. In fact, although they present their algorithm as a "cut packing" algorithm, one may interpret it as an algorithm for finding "good" cuts in graphs that have constant diameter.

The k-balanced partitioning problem was considered by Leighton, Makedon, and Tragoudas [12] and by Simon and Teng [17]. Their suggested approximation algo-

rithm is based on recursive bisection or on recursively partitioning the graph with approximate separators, yielding an approximation factor of $O(\log n \log k)$.

In a recent paper, Even et al. [3] employed spreading metrics and improved the approximation factor from $O(\log^2 n)$ to $O(\log n \log\log n)$ for a variety of graph optimization problems. The graph partitioning framework presented here can be used to cast the problems we deal with into the paradigm of [3], yielding somewhat weaker approximation factors than the factors presented here. In fact, since we are unable to apply the algorithm presented here to the k-balanced partitioning problem in directed graphs, the best approximation algorithm for this problem is given by applying our framework along with the recursion presented in [3], yielding an $O(\log n \log\log n)$-approximation factor.

We are able to obtain $O(\log n)$-approximation factors as compared to the $O(\log n \log\log n)$-approximation factors in [3] because we can partition the graph in each iteration into two parts, the smaller part being small enough so that further partitioning of it is not required. Hence, we often refer to such a partitioning as "chopping off" a piece. In [3] we were not able to guarantee that one of the parts is trivial, and hence both parts needed to be recursively partitioned.

The simultaneous separation problem was considered previously only for the case where the number of sets to be partitioned is a constant, e.g., [9, p. 67]. These instances of the simultaneous separation problem have been solved by recursively applying the Leighton–Rao algorithm. Since the number of sets to be partitioned has a logarithmic effect on the approximation factor, this approach yields weaker approximation factors than the approximation factors we present. Note that the Steiner multicut problem, considered in Klein et al. [10], can be modeled as a simultaneous separation problem. However, the separation in the Steiner multicut problem is not required to be balanced at all, and thus our approximation algorithm yields inferior results as compared to [10].

Although the weighted b-balanced cut problem was considered previously by several researchers, the literature lacks a description of an approximation algorithm for the weighted case, and only a brief sketch is available in [13].

The paper is organized as follows. In section 2 we define the problems considered in this paper. In section 3 we consider spreading metrics for ρ-separators in undirected graphs. In section 4 we describe an approximation algorithm for finding a ρ'-separator in undirected graphs. In section 5 we consider ρ'-separators in directed graphs. In section 6 we consider simultaneous separators. Finally, in section 7 we describe an efficient algorithm for computing suboptimal spreading metrics.

2. The problems. In this section we define the problems considered in this paper. We start with the well-known problems of finding *balanced cuts* and *balanced partitions*. Then, we define the problem of finding ρ-separators that captures the two previous problems as a special case. We also define a more general problem that we call *simultaneous separators*. All of these problems are NP-complete [5].

To simplify the presentation, we define the "edge" version of the problems and consider only undirected graphs. We end this section with remarks about the "vertex" version of these problems and the directed case.

Let $G = (V, E)$ be an undirected graph with nonnegative edge capacities $\{c(e)\}_e$ and nonnegative vertex weights $\{w(v)\}_v$. For $S \subset V$, a cut $(S, V - S)$ is a subset of E that disconnects S from $V - S$. For $F \subseteq E$, let $c(F) \triangleq \sum_{e \in F} c(e)$. For $U \subseteq V$, let $w(U) \triangleq \sum_{v \in U} w(u)$.

The b-balanced cut problem. Given a balance parameter $0 < b \leq 1/2$ and a graph

$G = (V, E)$, a *b-balanced cut* in G is a cut $(S, V - S)$ that satisfies $b \cdot w(V) \leq w(S) \leq (1 - b) \cdot w(V)$. The b-balanced cut problem with input $G = (V, E)$ and b is to find a minimum capacity b-balanced cut in G.

When the balance parameter equals $1/2$, the balanced condition is often relaxed to $\lfloor b \cdot w(V) \rfloor \leq w(S) \leq \lceil (1 - b) \cdot w(V) \rceil$. This relaxation avoids having an infeasible constraint in the case of bisection due to "rounding" problems.

The (k, ν)-balanced partitioning problem. Given integer $k \geq 2$ and a real $\nu \geq 1$, a *(k, ν)-balanced partition* of $G = (V, E)$ is a subset of the edges whose removal partitions the graph into at most k parts, where each part consists of a union of connected components and the sum of the vertex weights in each part is at most $\frac{\nu}{k} \cdot w(V)$. The (k, ν)-balanced partitioning problem with input $G = (V, E)$, k, and ν is to find a minimum capacity (k, ν)-balanced partition of G.

The following claim implies that, without loss of generality, we may assume that $\nu \leq 2$.

Claim 2.1. Any (k, ν)-balanced partition, where $\nu \geq 2$, induces a (k', ν')-balanced partition, where $k' < k$ and $\nu' < 2$.

Proof. Let F denote a (k, ν)-balanced partition of $G = (V, E)$, where $\nu \geq 2$. Let $A_1, A_2, \ldots, A_s$ denote the vertex sets of the connected components in the graph $G' = (V, E - F)$, where $s \leq k$. Define $w_i = w(A_i)/w(V)$. By definition, $w_i \leq \frac{\nu}{k}$ for every $1 \leq i \leq s$. Merge connected components, until $w_i + w_j > \frac{\nu}{k}$, for every $i \neq j$. Let F' denote the edges connecting vertices belonging to different components (after the merging of small components). To simplify notation, assume that no merging took place. Below, we prove that $s < \frac{2k}{\nu} \leq k$. We get that F is an (s, ν')-balanced partition, where $\frac{\nu'}{s} = \frac{\nu}{k}$. Substituting $s < \frac{2k}{\nu}$, we get $\nu' < 2$.

We now prove that $s < \frac{2k}{\nu}$. Since $w_i + w_j > \frac{\nu}{k}$, for every $i \neq j$, there is at most one index ℓ for which $w_\ell \leq \frac{\nu}{2k}$. We distinguish between two cases.

Case 1. $w_i > \frac{\nu}{2k}$ for all $1 \leq i \leq s$. In this case $1 = \sum_{i=1}^{s} w_i > s\frac{\nu}{2k}$, and the upper bound on s follows.

Case 2. There exists an index $1 \leq \ell \leq s$ for which $w_\ell \leq \frac{\nu}{2k}$. In this case for all indices $1 \leq i \leq s$, where $i \neq \ell$, $w_i > \frac{\nu}{k} - w_\ell$. Summing up we get $1 = \sum_{i=1}^{s} w_i > (s - 1)(\frac{\nu}{k} - w_\ell) + w_\ell$. This implies

$$s < \frac{k + \nu - 2kw_\ell}{\nu - kw_\ell} = 2 + \frac{k - \nu}{\nu - kw_\ell} \leq 2 + \frac{k - \nu}{\nu - \nu/2} = \frac{2k}{\nu}. \qquad \square$$

From now on we refer to $(k, 2)$-balanced partitions as k-balanced partitions.

The ρ-separator problem. Given $0 < \rho \leq 1$, a *ρ-separator* in $G = (V, E)$ is a subset of edges whose removal partitions the graph into connected components such that the sum of the vertex weights in each component is at most $\rho \cdot w(V)$. The ρ-separator problem with input $G = (V, E)$ and ρ is to find a minimum capacity ρ-separator in G.

The simultaneous separator problem. Let $\boldsymbol{U} \triangleq \{U_1, U_2, \ldots, U_s\}$ denote a set of subsets of vertices, namely, $U_i \subseteq V$, for every i. Let $\boldsymbol{\rho} \triangleq \{\rho_1, \rho_2, \ldots, \rho_s\}$ denote a set of parameters that satisfies $0 < \rho_i \leq 1$, for every i. Given such $\boldsymbol{U}$ and $\boldsymbol{\rho}$, a *$(\boldsymbol{U}, \boldsymbol{\rho})$-simultaneous separator* is a subset of edges whose removal partitions the graph into connected components such that for each such component $H = (U', E')$

$$\forall\, 1 \leq i \leq s \;:\; w(U' \cap U_i) \leq \rho_i \cdot w(U_i).$$

The simultaneous separator problem with input $G = (V, E)$, $\boldsymbol{U}$, and $\boldsymbol{\rho}$ is to find a minimum capacity $(\boldsymbol{U}, \boldsymbol{\rho})$-simultaneous separator in G.

We note that our algorithm can be extended to solve the more general case in which each node v has s weight values associated with it, and the partitioning constraint for U_i and ρ_i is with respect to the ith weight measure.

We next exhibit certain connections between the problems defined herein. Clearly, every b-balanced cut is also a $(1-b)$-separator. The next claim shows that if $b \leq 1/3$, then every $(1-b)$-separator induces a b-balanced cut of at most the same cost. Together, these two assertions imply that the balanced cut problem for $b \leq 1/3$ is equivalent to the ρ-separator problem (where $\rho = 1 - b \geq 2/3$).

Claim 2.2. If $0 < b \leq 1/3$, then every $(1-b)$-separator, F, induces a b-balanced cut $(A, V-A)$ such that $c(A, V-A) \leq c(F)$.

Proof. Let $F \subseteq E$ denote a $(1-b)$-separator of $G = (V, E)$. Let $A_1, A_2, \ldots, A_s$ denote the vertex-sets of the connected components in the graph $G' = (V, E-F)$. If there exists an A_i such that $w(A_i) \geq b \cdot w(V)$, then the cut $(A_i, V - A_i)$ is a b-balanced cut whose capacity is at most the capacity of the ρ-separator. Otherwise, define $i_0 = \max\{i : w(\cup_{j \leq i} A_j) < b \cdot w(V)\}$. Let $A = A_1 \cup \cdots A_{i_0+1}$, then $w(A) < 2b \cdot w(V)$. Since $b \leq 1/3$, we conclude that $b \cdot w(V) \leq w(A) < (1-b) \cdot w(V)$, and hence $(A, V-A)$ is a b-balanced cut whose cost is at most the capacity of the ρ-separator. ∎

It follows from the definitions that every k-balanced partition induces a $2/k$-separator. We claim that every ρ-separator induces a $(\lceil 2/\rho \rceil - 1)$-balanced partition.

Claim 2.3. Every ρ-separator induces a $(\lceil 2/\rho \rceil)$-balanced partition.

Proof. Let F denote a ρ-separator of $G = (V, E)$. Let $A_1, A_2, \ldots, A_s$ denote the vertex sets of the connected components in the graph $G' = (V, E - F)$. Define $w_i = w(A_i)/w(V)$. By definition, $w_i \leq \rho$ for every $1 \leq i \leq s$. Merge connected components, until $w_i + w_j > \rho$, for every $i \neq j$. Let F' denote the edges connecting vertices belonging to different components (after the merging of small components). To simplify notation, assume that no merging took place. Similar to Claim 2.2 it can be shown that $s < 2/\rho$, and the claim follows.

We conclude with some remarks.

1. In the vertex version of the above problems, every vertex has both a capacity and a weight. The problem is then to find a minimum capacity subset of vertices whose removal partitions the graph into connected components, the weight of which satisfies the relevant constraint.
2. The edge version is reducible to the vertex case by introducing dummy vertices on each edge. Hence, we can also consider "heterogeneous" versions of the simultaneous separation problem in which the separation constraints are on subsets containing both edges and vertices.
3. All the problems can be extended to directed graphs. In this case, the definitions should be modified, and "connected components" should be replaced with "strongly connected components."

3. A spreading metric for ρ-separators in undirected graphs. A spreading metric is an assignment of edge lengths that satisfies two properties: (a) it provides a lower bound, and (b) it satisfies a radius guarantee. Obviously, we are also interested in computing spreading metrics efficiently. We obtain a spreading metric by writing a linear program and showing that its optimal solutions are spreading metrics. The integer program corresponding to the linear program is a direct formulation of ρ-separators, as shown in the lower bound property below.

We start by defining a spreading metric. Note that two parameters are involved: our lower bound is with respect to ρ-separators, and our goal is to find a ρ'-separator, for $\rho' > \rho$. Therefore, the radius guarantee is stated with respect to ρ'.

Notation. Given edge lengths $\{d(e)\}_{e\in E}$ and a subset of vertices S, let $\mathsf{dist}_S(v,u)$ denote the distance in the subgraph induced by S between the vertices v and u.

DEFINITION 3.1. *An assignment of nonnegative edge lengths $\{d(e)\}_{e\in E}$ is a spreading metric for ρ-separators which can be used for finding ρ'-separators (where $\rho' > \rho$), if it satisfies the following properties:*

1. *Lower bound: The* volume *of the assignment, defined by $\sum_{e\in E} c(e)d(e)$, is a lower bound on the minimum capacity of a ρ-separator.*
2. *Radius guarantee: Loosely speaking, every "heavy" subset of vertices has at least constant radius. Formally, for every subset $S \subseteq V$ for which $w(S) > \rho' \cdot w(V)$, and for every vertex $v \in S$,*

$$\mathsf{radius}(v,S) > \frac{\rho'-\rho}{\rho'},$$

where $\mathsf{radius}(v,S) \stackrel{\triangle}{=} \max\{\mathsf{dist}_S(v,u) : u \in S\}$.

We obtain a spreading metric for ρ-separators by writing a linear program that attaches edge lengths $d(e)$ to each edge $e \in E$. The linear program is defined as follows:

$$\text{(P1)} \qquad \min \sum_{e\in E} c(e)\cdot d(e)$$

$$\text{subject to (s.t.) } \forall S \subseteq V \quad \forall v \in S : \sum_{u\in S} \mathsf{dist}_V(v,u)\cdot w(u) \geq w(S) - \rho\cdot w(V)$$

$$\forall e \in E : \ 0 \leq d(e) \leq 1.$$

Note that the first type of constraints holds trivially if $w(S) \leq \rho \cdot w(v)$.

One could formulate the linear program using $\mathsf{dist}_S(v,u)$ rather than $\mathsf{dist}_V(v,u)$. Let ($\mathrm{P1}_S$) denote the linear program obtained from (P1) by using $\mathsf{dist}_S(v,u)$ instead of $\mathsf{dist}_S(v,u)$. Since $\mathsf{dist}_S(v,u)$ is never smaller than $\mathsf{dist}_V(v,u)$, it follows that the feasible solutions of (P1) are a subset of the feasible solutions of ($\mathrm{P1}_S$), and hence the cost of a minimum cost solution of ($\mathrm{P1}_S$) is not greater than the minimum cost of (P1). In section 3 we show that the feasible solutions of ($\mathrm{P1}_S$) are also feasible solutions of (P1), and hence the optima of the two linear programs are equal.

In section 7.1 we consider a modification of ($\mathrm{P1}_S$) in which only a subset of the constraints of ($\mathrm{P1}_S$) is kept, namely, constraints corresponding to subsets of weight greater than $\rho' \cdot w(V)$.

Notation. Let τ denote the cost of an optimal (fractional) solution of the linear program (P1).

We now show that an optimal solution of (P1) is a spreading metric, namely, that τ is a lower bound, and that the radius guarantee is satisfied. We then show that an optimal solution of (P1) can be computed in polynomial time.

Lower bound. We show that every ρ-separator, F, induces a feasible $\{0,1\}$-solution of the linear program by defining $d(e) = 1$, if $e \in F$, and $d(e) = 0$, otherwise. Consider a subset $S \subseteq V$ that satisfies $w(S) > \rho \cdot w(V)$, and consider a vertex $v \in S$. We need to show that the constraint corresponding to S and v is satisfied. Let $\mathsf{comp}_F(v)$ denote the connected component that contains v in the graph $G' = (V, E - F)$. Every path from v to a vertex $u \in S - \mathsf{comp}_F(v)$ must contain at least

one edge $e \in F$ whose length equals 1; hence $\mathsf{dist}_V(v,u) \geq 1$. Therefore,

$$\begin{aligned}\sum_{u \in S} \mathsf{dist}_V(v,u) \cdot w(u) &\geq \sum_{u \in S - \mathsf{comp}_F(v)} \mathsf{dist}_V(v,u) \cdot w(u) \\ &\geq w(S - \mathsf{comp}_F(v)) \\ &\geq w(S) - w(\mathsf{comp}_F(v)) \\ &\geq w(S) - \rho \cdot w(V).\end{aligned}$$

The cost of the integral solution induced by a ρ-separator equals the capacity of the ρ-separator. Hence, the cost of an optimal fractional solution of the linear program cannot be greater than the cost of a minimum capacity ρ-separator.

Radius guarantee. Every feasible solution of (P1) satisfies the following radius guarantee.

LEMMA 3.2. *If $S \subseteq V$ satisfies $w(S) > \rho' \cdot w(V)$, then for every vertex $v \in S$,*

$$\mathsf{radius}(v,S) > \frac{\rho' - \rho}{\rho'}.$$

Proof. Fix S and v, and consider the constraint corresponding to them. This constraint gives a lower bound on the weighted sum of the distances from v to the vertices in S. Hence, it provides a lower bound on the weighted average distance from v to the vertices in S. Let $u \in S$ denote a vertex whose distance from v is not less than the weighted average distance of a vertex in S from v. Then,

$$\mathsf{dist}_V(v,u) \quad \geq \quad 1 - \frac{\rho \cdot w(V)}{w(S)} \quad \geq \quad 1 - \frac{\rho \cdot w(V)}{\rho' \cdot w(V)}.$$

Since $\mathsf{dist}_S(v,u) \geq \mathsf{dist}_V(v,u)$, the lemma follows. ∎

Polynomial time computability. The formulation for the linear program (P1) is shorthand for a linear program that contains exponentially many constraints: For every "heavy" subset S, and for every $v \in S$, consider all combinations of paths from v to all other vertices in S, and require that the weighted sum of the lengths of the paths satisfies the corresponding constraint. Since the number of constraints is exponential, naive implementation of known polynomial time LP-solvers would not provide an efficient way of computing spreading metrics. This is because the running time of these solvers is polynomial in both the number of variables and the number of constraints.

We describe below how a spreading metric can be computed in polynomial time using the ellipsoid algorithm [15]. Algorithms for computing spreading metrics with better asymptotic running times are presented in section 7.

Applying the ellipsoid algorithm requires a polynomial-time separation procedure that, given a candidate solution $\{d(e)\}_e$, either finds a violated constraint or proves that it is indeed a solution.

We rewrite the constraints of (P1) as follows:

$$\forall S \subseteq V, \quad \forall v \in S : \sum_{u \in S} (\mathsf{dist}_V(v,u) - 1) \cdot w(u) \geq -\rho \cdot w(V). \tag{3.1}$$

Given a vertex v, the left-hand side of (3.1) is minimized when the subset $S_v = \{u : \mathsf{dist}_V(v,u) \leq 1\}$ is chosen. Therefore, if the constraint corresponding to v and S_v

is satisfied, then all the constraints in which distances are measured from v are also satisfied. This means that if the constraints corresponding to v and S_v are satisfied for every vertex v, then the edge lengths constitute a feasible solution to (P1). Hence, a polynomial-time separation procedure exists.

Since S_v is a sphere of radius 1, it follows that $\mathsf{dist}_V(v,u) = \mathsf{dist}_S(v,u)$ for every $u \in S_v$. Therefore, the linear programs (P1) and (P1$_S$) have the same feasible solutions and the same optima.

4. Finding a ρ'-separator. In this section we describe the approximation algorithm for ρ'-separators. The input consists of a graph $G = (V, E)$ with edge capacities $c(e)$ and vertex weights $w(v)$. The input also contains a spreading metric for a ρ-separator ($\rho' \geq \rho$), represented by edge lengths $\{d(e)\}$ for all $e \in E$.

The algorithm consists of a cut procedure that partitions a subset of vertices whose weight is larger than $\rho' \cdot w(V)$. This procedure cuts off a subset of vertices with weight at most $\rho' \cdot w(V)$, and hence the chopped off pieces need not be further partitioned. Initially, the cut procedure is applied to the whole graph; then it is applied iteratively to the remaining part until its weight is not greater than $\rho' \cdot w(V)$.

The cut procedure presented in this section is identical to the sphere growing procedure in [6]; the only difference is in the parameters used in the definition of the volume and the upper bound on the radius. Our presentation emphasizes the ability to find a cut whose capacity is logarithmic in the volume of the spreading metric when the diameter of the graph is constant (see (4.2)).

4.1. Assigning volumes. Following Garg, Vazirani, and Yannakakis [6] we assign volumes to spheres that are grown around vertices. These volumes will define the credit that is attributed to the spheres in order to pay for the cut disconnecting them from the rest of the graph. Our definition of volume deviates slightly from the definition of [6] so as to reduce the constants.

DEFINITION 4.1. *Let v denote a vertex in a subgraph induced by V'. The* r-sphere centered at v, *denoted by $N(v,r)$, is defined by*

$$N(v,r) \triangleq \{u : \mathsf{dist}_{V'}(u,v) < r\}.$$

Note that $N(v,r)$ includes only vertices whose distance from v is strictly less than r.

Notation. Let $E(v,r)$ denote the set of edges whose endpoints belong to $N(v,r)$, namely, $E(v,r) = E \cap (N(v,r) \times N(v,r))$. Let $\mathsf{cut}(v,r)$ denote the set of edges that belong to the cut $(N(v,r), V - N(v,r))$.

The volume of a sphere is a positive value that we attach to spheres and is the sum of three components: (1) a "seed value" set to $\varepsilon \cdot \tau$, where τ is the cost of the optimal fractional solution, (2) the contribution of edges in $E(v,r)$, and (3) the contribution of edges in $\mathsf{cut}(v,r)$.

DEFINITION 4.2. *The* volume *of $N(v,r)$, denoted by $\mathsf{vol}(v,r)$, is defined by*

$$\mathsf{vol}(v,r) \triangleq \varepsilon \cdot \tau + \sum_{e \in E(v,r)} c(e) \cdot d(e) + \sum_{(x,y) \in \mathsf{cut}(v,r)} c(x,y) \cdot (r - \mathsf{dist}_{N(v,r)}(v,x)),$$

where $\varepsilon = \frac{1}{n \ln n}$.

4.2. The cut procedure. In this section, we describe a procedure for partitioning a subgraph $G' = (V', E')$ of G into two parts, given a spreading metric for a ρ-separator of G. The procedure is applied when $w(V') > \rho' \cdot w(V)$, and it finds a

cut-proc $(V', E', \{c(e)\}_{e\in E'}, \{d(e)\}_{e\in E'})$
$\tilde{r} = \frac{\rho'-\rho}{\rho'}$
choose an arbitrary $v \in V'$.
$T = \{v\}$
v' = closest vertex to T in $V' - T$.
while $c(T, V' - T) > \frac{1}{\tilde{r}} \cdot \ln\left(\frac{\mathsf{vol}(v,\tilde{r})}{\mathsf{vol}(v,0)}\right) \cdot \mathsf{vol}(v, \mathsf{dist}_{V'}(v, v'))$ do
begin
$T = T \cup \{v'\}$
v' = closest vertex to T in $V' - T$.
end
Return T

FIG. 4.1. *The cut procedure.*

sphere $N(v, r)$ that satisfies the following two properties: (1) $w(N(v, r)) \le \rho' \cdot w(V)$, and (2) the ratio between $c(\mathsf{cut}(v, r))$ and $\mathsf{vol}(v, r)$ is logarithmic.

4.2.1. Description. The cut procedure runs Dijkstra's single source shortest paths algorithm from an arbitrary vertex $v \in V'$. In each iteration, before adding the closest vertex $v' \in V'$ to the set of vertices whose distances from v are already determined, the procedure checks whether $r = \mathsf{dist}_{V'}(v, v')$ is a "good" radius. The procedure stops when it finds the first good radius and returns $N(v, r)$ as the set of vertices to be chopped off. The procedure, called "cut-proc," is depicted in Figure 4.1.

THEOREM 4.3. *Given a subgraph $G' = (V', E')$ that satisfies $w(V') > \rho' \cdot w(V)$, and given a spreading metric $\{d(e)\}_e$, procedure cut-proc finds a subset $T \subset V'$ that satisfies $w(T) \le \rho' \cdot w(V)$.*

4.2.2. Proof of Theorem 4.3. Let $v \in V'$ be the vertex chosen by the cut procedure. Consider $\mathsf{vol}(v, r)$ as a function of r, as depicted in Figure 4.2. Note that it is a monotone piecewise linear function whose initial value equals $\varepsilon \cdot \tau$ and whose final value equals $(1 + \varepsilon) \cdot \tau$. The endpoints of the linear segments correspond to distances measured from v to vertices in V'. In other words, if we sort the vertices of V' in ascending distance order from v: $v = v_0, v_1, \ldots, v_n$, then for every $0 \le i < n$ the function $\mathsf{vol}(v, r)$ is linear in the closed interval $r \in [\mathsf{dist}(v_0, v_i), \mathsf{dist}(v_0, v_{i+1})]$. Moreover, the derivate $\mathsf{vol}'(v, r) \triangleq \frac{d\mathsf{vol}(v,r)}{dr}$ in the open interval $(\mathsf{dist}(v_0, v_i), \mathsf{dist}(v_0, v_{i+1}))$ equals $c(\mathsf{cut}(v, r))$. This can readily be seen by observing that in this open interval, only the cut edges contribute to the growth of the volume, and that the coefficient of r equals the sum of the capacities of the cut edges.

The cut procedure searches for a radius r for which the ratio between $\mathsf{vol}'(v, r)$ and $\mathsf{vol}(v, r)$ is logarithmic. We need to show that such a radius $r \le \tilde{r}$ exists and that the procedure finds it. Note that $r \le \tilde{r}$ implies that $w(v, r) \le \rho' \cdot w(V)$ (see Lemma 3.2).

Recall that $\tilde{r} \triangleq \frac{\rho'-\rho}{\rho'}$ and let I_i denote the open interval $(\mathsf{dist}(v_0, v_i), \mathsf{dist}(v_0, v_{i+1}))$. The following claim proves the existence of a good radius.

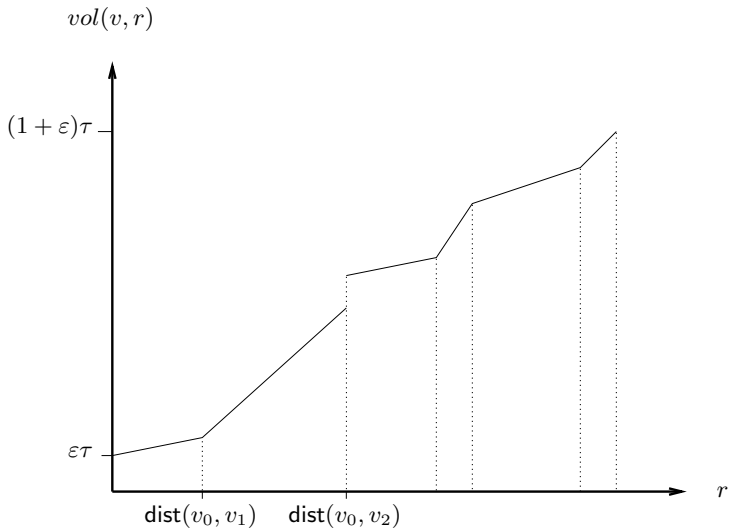

FIG. 4.2. $\mathsf{vol}(v,r)$ *as a function of* r.

Claim 4.4. For every vertex $v \in V'$, there exists an $r \in (0, \tilde{r}] \cap \cup_i I_i$ that satisfies

$$\frac{\mathsf{vol}'(v,r)}{\mathsf{vol}(v,r)} \leq \frac{1}{\tilde{r}} \cdot \ln\left(\frac{\mathsf{vol}(v,\tilde{r})}{\mathsf{vol}(v,0)}\right).$$

Proof. By contradiction, suppose that for every $r \in (0, \tilde{r}] \cap \cup_i I_i$,

$$\frac{\mathsf{vol}'(v,r)}{\mathsf{vol}(v,r)} > \frac{1}{\tilde{r}} \cdot \ln\left(\frac{\mathsf{vol}(v,\tilde{r})}{\mathsf{vol}(v,0)}\right).$$

The left-hand side of the above equation is defined and continuous in the interval $(0, \tilde{r}]$ except for finitely many points. Hence, we may take the integral of both sides, yielding

$$\int_0^{\tilde{r}} \frac{\mathsf{vol}'(v,r)}{\mathsf{vol}(v,r)} dr > \frac{1}{\tilde{r}} \ln\left(\frac{\mathsf{vol}(v,\tilde{r})}{\mathsf{vol}(v,0)}\right) \int_0^{\tilde{r}} dr. \tag{4.1}$$

Using the identity $\int \frac{f'(x)}{f(x)} dx = \ln f(x)$, we can evaluate the left-hand side of inequality (4.1),

$$\begin{aligned}\int_0^{\tilde{r}} \frac{\mathsf{vol}'(v,r)}{\mathsf{vol}(v,r)} dr &= \ln(\mathsf{vol}(v,\tilde{r})) - \ln(\mathsf{vol}(v,0)) \\ &= \ln\left(\frac{\mathsf{vol}(v,\tilde{r})}{\mathsf{vol}(v,0)}\right).\end{aligned}$$

However, the right-hand side of inequality (4.1) also equals the same value (a contradiction) and the claim follows. □

The cut-proc procedure considers only radii in the set $\{\mathsf{dist}_{V'}(v,u)\}_{u \in V'}$. (Note that since T is a sphere in V', it follows that $\mathsf{dist}_{V'}(v,v') = \mathsf{dist}_T(v,v')$ for every vertex $v' \in T$.) In order to enable computability of a good radius, we show that among the

distances $\{\mathsf{dist}_{V'}(v,u)\}_{u\in V'}$ there exists a good radius. The following claim proves this property.

Claim 4.5. Let $v \in V'$ denote an arbitrary vertex. Let r_0 denote the radius whose existence is guaranteed by Claim 4.4. Define r_1 to be

$$r_1 \stackrel{\triangle}{=} \min\left\{\mathsf{dist}_{V'}(v,u) : u \in V' \text{ and } \mathsf{dist}_{V'}(v,u) \geq r_0\right\}.$$

Then, r_1 satisfies

$$c(\mathsf{cut}(v,r_1)) \leq \frac{1}{\tilde{r}} \cdot \ln\left(\frac{\mathsf{vol}(v,\tilde{r})}{\mathsf{vol}(v,0)}\right) \cdot \mathsf{vol}(v,r_1), \tag{4.2}$$

$$w(N(v,r_1)) \leq \rho' \cdot w(V'). \tag{4.3}$$

Proof. Since $N(v,r_1)$ consists of the vertices whose distance from v is strictly less that r_1, it follows that $N(v,r_0) = N(v,r_1)$, and hence these spheres define the same cut. In particular, $c(\mathsf{cut}(v,r_1)) = \mathsf{vol}'(v,r_0)$. Inequality (4.2) follows from Claim 4.4 and from $\mathsf{vol}(v,r_0) \leq \mathsf{vol}(v,r_1)$.

Since $N(v,r_1) = N(v,r_0)$, and since $r_0 \leq \tilde{r}$, Lemma 3.2 implies inequality (4.3), and the claim follows. ∎

Claims 4.4 and 4.5 show that among the set of radii $\{\mathsf{dist}_{V'}(v_0,v_i)\}_i$ there exists a good radius. The cut procedure simply performs an exhaustive search in ascending distance order and stops as soon as it finds the first radius that satisfies inequality (4.2). The found radius also satisfies inequality (4.3) (since it is not greater than r_1), and hence the theorem follows.

4.3. Analysis of the approximation factor. In this section we prove the $O(\log n)$-approximation factor of the proposed algorithm. We also outline how the algorithm may be modified to obtain an $O(\log \tau)$-approximation algorithm.

The cut procedure is called repetitively until the weight of the remaining subset of vertices drops below (or becomes equal to) $\rho' \cdot w(V)$. Each call chops off a sphere, and the chopped off spheres are disjoint. The volume of each sphere consists of the contribution of the edges contained inside, the contribution of the edges of the cut, and the contribution of the seed value. The sum of the contributions of the edges and edges of the cut to the volumes of the chopped off spheres is bounded by τ. The sum of the seed values is bounded by $\varepsilon\tau n$.

The capacity of the cut $(T, V' - T)$ found by the cut procedure satisfies

$$c(T, V' - T) \leq \frac{1}{\tilde{r}} \cdot \ln\left(\frac{\mathsf{vol}(v,\tilde{r})}{\mathsf{vol}(v,0)}\right) \cdot \mathsf{vol}(v, \mathsf{dist}_{V'}(v,v')).$$

But $\mathsf{vol}(v,\tilde{r}) \leq (1+\varepsilon)\tau$ and $\mathsf{vol}(v,0) = \varepsilon\tau$. Hence, the sum of the capacities of the cuts found by the calls to the cut procedure is bounded by

$$\frac{1}{\tilde{r}} \cdot \ln\left(\frac{1+\varepsilon}{\varepsilon}\right) \cdot \tau \cdot (1+\varepsilon n).$$

Plugging in $\varepsilon = \frac{1}{n \ln n}$ yields the following theorem.

THEOREM 4.6. *The algorithm presented above finds a ρ'-separator whose capacity is at most*

$$\left(\frac{\rho'}{\rho' - \rho} + o(1)\right) \cdot \ln n \cdot \tau,$$

where τ is the volume of the spreading metric, and hence is a lower bound on the cost of an optimal ρ-separator.

One could also obtain an $O(\log(\tau/\gamma))$-approximation factor, where γ is the minimum edge capacity. From now on, we assume without loss of generality that the minimum edge capacity is one, and we show how to obtain an $O(\log \tau)$-approximation factor. This is done by the following modifications. (1) Define $\varepsilon = 0$; namely, do not add seed values to the volume of spheres. (2) Let δ denote a positive parameter to be specified later. Start the cut procedure with an initial sphere of radius $\tilde{r}/(1+\delta)$, and substitute all occurrences of $\mathsf{vol}(v, 0)$ with $\mathsf{vol}(v, \tilde{r}/(1+\delta))$. (3) Instead of considering the half-open interval $(0, \tilde{r}]$, consider the half-open interval $(\tilde{r}/(1+\delta), \tilde{r}]$. Now, substitute all occurrences of $\frac{1}{\tilde{r}}$ with $\frac{1+1/\delta}{\tilde{r}}$. (This is the reciprocal of the length of the half-open interval.) After these modifications, the sum of the volumes of the chopped off pieces is bounded by τ. Since $c(e) \geq 1$, for every edge $e \in E$ we have $\mathsf{vol}(v, \tilde{r}/(1+\delta)) \geq \tilde{r}/(1+\delta)$ (otherwise the subgraph is not connected). Thus, the sum of the capacities of the cuts found by the calls to the cut procedure is bounded by

$$\frac{1+1/\delta}{\tilde{r}} \cdot \ln\left(\frac{(1+\delta)\tau}{\tilde{r}}\right) \cdot \tau.$$

Assign, for example, $\delta = e^5 - 1$, and the capacity of the ρ'-separator is bounded by

$$\frac{1.01 \cdot \rho}{\rho' - \rho} \cdot \left(5 + \ln\left(\frac{\rho}{\rho' - \rho} \cdot \tau\right)\right) \cdot \tau.$$

Thus, we obtain an $O(\log \tau)$-approximation factor.

5. ρ'-separators in directed graphs. In this section we describe the approximation algorithm for ρ'-separators in directed graphs when $\rho' \geq 1/2$. This algorithm is very similar to the algorithm for undirected separators; however, our control over the weight of the chopped off pieces is diminished, and we can guarantee only that the weight of chopped off pieces is at most half of the weight of the vertices in the remaining subgraph. Hence, our algorithm is applicable only for values of $\rho' \geq 1/2$ and the approximation factors are larger by a factor of 4. We first define the spreading metrics for directed graphs and later point out the modifications of the undirected ρ-separator algorithm required for directed separators.

5.1. Spreading metrics for directed graphs. The spreading metric in the directed case for a parameter ρ is obtained by the following linear program:

$$\min \sum_{e \in E} c(e) \cdot d(e)$$

$$\text{s.t. } \forall S \subseteq V,\ \forall v \in S:\ \sum_{u \in S} (\mathsf{dist}_V(v,u) + \mathsf{dist}_V(u,v)) \cdot w(u) \geq w(S) - \rho \cdot w(V)$$

$$\forall e \in E:\ 0 \leq d(e) \leq 1.$$

We omit the proofs that an optimal spreading metric is computable in polynomial time and that it is a lower bound on the capacity of an optimal ρ-separator. We also omit the proof that the spreading metric satisfies a modified radius guarantee that is stated below.

LEMMA 5.1. *If $S \subseteq V$ satisfies $w(S) > \rho' \cdot w(V)$, then for every vertex $v \in S$ there exists a vertex $u \in S$ such that*

$$\mathsf{dist}_S(v,u) + \mathsf{dist}_S(u,v) > \frac{\rho' - \rho}{\rho'}.$$

5.2. Finding a ρ'-separator in directed graphs. In each iteration we find a pair of vertices $s,t \in V'$ that achieves the diameter; namely, $\mathsf{dist}_{V'}(s,t) = \max\{\mathsf{dist}_{V'}(u,v) : u,v \in V'\}$. Note that Lemma 5.1 implies that $\mathsf{dist}(s,t) > \frac{\rho'-\rho}{2\rho'}$. After finding s and t, we call the cut procedure twice: the first instance with the remaining subgraph $G' = (V', E')$ and s as the initial vertex, and the second instance with the reversed subgraph $G'_{rev}(V', E'_{rev})$ and t as the initial vertex. (A reversed graph is obtained by reversing the directions of the edges while preserving the edge weights and capacities.) The cut procedure assigns volumes in the same fashion as in the undirected case. However, we modify the definition of $\tilde{r}$ in the cut procedure to be $\tilde{r} = \frac{\rho'-\rho}{4\rho'}$. Let T denote the subset of vertices returned by the first call to the cut procedure, and let T_{rev} denote the subset of vertices returned by the second call. In the following theorem, we claim that $\min\{w(T), w(T_{rev})\} \leq w(V')/2$. If $w(T) \leq W(V')/2$, then we choose the cut $(T, V' - T)$ and chop off T. Otherwise, we choose the cut $(V' - T_{rev}, T_{rev})$ and chop off T_{rev}.

THEOREM 5.2. *Let $G' = (V', E')$ be a directed subgraph that satisfies $w(V') > \rho' \cdot w(V)$. Given a (directed) spreading metric $\{d(e)\}_e$, let $s,t \in V'$ satisfy $\mathsf{dist}(s,t) > \frac{\rho'-\rho}{2\rho'}$. Let T and T_{rev} be the subsets of vertices returned by two calls to the procedure cut-proc: the first with input G' and s as its initial vertex, and the second with input G'_{rev} and t as its initial vertex. Then, the weights $w(T)$ and $w(T_{rev})$ satisfy* $\min\{w(T), w(T_{rev})\} \leq w(V')/2$.

Proof. Let $N = N(s,\tilde{r})$ and $N_{rev} = N_{rev}(t,\tilde{r})$, where $N_{rev}(t,\tilde{r})$ denotes a sphere in the reversed graph (recall that we now use $\tilde{r} = \frac{\rho'-\rho}{4\rho'}$). Since $\mathsf{dist}(s,t) > 2 \cdot \tilde{r}$, it follows that N and N_{rev} are disjoint. Since $w(N) + w(N_{rev}) \leq w(V')$, we conclude that either $w(N)$ or $w(N_{rev})$ is at most $w(V')/2$.

To complete, we show that $T \subseteq N$ and $T_{rev} \subseteq N_{rev}$, and hence $\min\{w(T), w(T_{rev})\} \leq \min\{w(N), w(N_{rev})\} \leq w(V')/2$. This is easy since Claims 4.4 and 4.5 (without inequality (4.3)) are applicable, and hence the theorem follows. ∎

5.3. Approximation factor in directed graphs. In the directed case, the ratio between the capacity of the directed ρ'-separator and the volume of the spreading is four times larger than the corresponding ratio in the undirected case. This is due to the fact that in the directed case $\tilde{r} = \frac{\rho'-\rho}{4\rho}$. Hence the approximation factors increase by a factor of 4 as compared to the approximation factors in the undirected case.

6. Simultaneous separators. In this section we review the modifications that are needed to solve the problem of simultaneous separators with similar approximation factors. As in the other problems, we describe a pseudoapproximation algorithm. The input consists of a graph with edge capacities and vertex weights, a sequence of subsets of vertices $\boldsymbol{U} = \{U_1, U_2, \ldots, U_s\}$, and two sequences of separation parameters $\boldsymbol{\rho} = \{\rho_1, \rho_2, \ldots, \rho_s\}$ and $\boldsymbol{\rho'} = \{\rho'_1, \rho'_2, \ldots, \rho'_s\}$. The required output is a $(\boldsymbol{U}, \boldsymbol{\rho'})$-simultaneous separator, and we compare its cost to an optimal $(\boldsymbol{U}, \boldsymbol{\rho})$-simultaneous separator.

We describe only the undirected case, and the discussion carries over to the directed case if $\rho_i \geq 1/2$, for every $1 \leq i \leq s$.

6.1. A spreading metric for simultaneous separators. The spreading metric for $(\boldsymbol{U}, \boldsymbol{\rho})$-simultaneous separators is obtained by the following linear program:

$$\min \sum_{e \in E} c(e) \cdot d(e)$$

$$\text{s.t. } \forall i, \quad \forall S \subseteq V, \quad \forall v \in S : \sum_{u \in S \cap U_i} \mathsf{dist}(v,u) \cdot w(u) \geq w(S \cap U_i) - \rho_i \cdot w(U_i)$$

$$\forall e \in E : \ 0 \leq d(e) \leq 1.$$

We omit the proofs concerning an optimal spreading metric but state the radius guarantee lemma for this case.

LEMMA 6.1. *If $S \subseteq V$ satisfies $w(S \cap U_i) > \rho_i' \cdot w(U_i)$, then for every vertex $v \in S$*

$$\mathsf{radius}(v, S \cap U_i) > \frac{\rho_i' - \rho_i}{\rho_i'}.$$

The only modification required for finding a simultaneous separator is the definition of $\tilde{r}$. We define $\tilde{r} \triangleq \min_{1 \leq i \leq s} \frac{\rho_i' - \rho_i}{\rho_i'}$. The algorithm proceeds by chopping off parts from the graph using the cut procedure as long as the remaining subgraph does not satisfy the simultaneous separation requirements. The approximation factor obtained is $(1/\tilde{r} + o(1)) \cdot \ln n$. The only difference in the ratio between the capacity of the simultaneous separator and the volume of the spreading metric stems from the definition of $\tilde{r}$.

7. Computing spreading metrics efficiently. Plotkin, Tardos, and Shmoys [16] defined a framework of fractional packing and covering problems and developed fast algorithms for computing approximate solutions therein. Young [18] also devised fast algorithms for finding approximate solutions in this framework. In this section we show how to use this framework to compute spreading metrics efficiently. We note that our results hold only in the case of undirected graphs. We henceforth refer to the algorithm described in [16] as the PST algorithm and to the algorithm described in [18] as the Y algorithm. We first describe the fractional packing setting of [16]. Let $G = (V, E)$ denote a graph, where $|V| = n$ and $|E| = m$. For an optimization problem on graphs, the input consists of the following:

1. A convex set $P \subseteq \mathrm{R}^{\ell}$. (Note that ℓ may be even exponential in n since its influence on the running time is indirect.)
2. A nonnegative linear function $U : P \to \mathrm{R}^m$.

We consider U as m real valued linear functions indexed by the edges of the graph. The goal in the fractional packing problem is to compute λ^* defined by

$$\lambda^* \triangleq \min_{x \in P} \max_{e \in E} U_e(x).$$

Rather than computing λ^* precisely, the PST and Y algorithms do the following. Given an error parameter ε, they find a vector $x' \in P$ such that $U_e(x') \leq (1+\varepsilon)\lambda^*$, for every $e \in E$. Moreover, they also compute a solution to the dual fractional covering problem. This input to the dual problem consists of the following:

1. A convex set $Q \subseteq \mathrm{R}^m$.
2. A nonnegative linear function $U^D : Q \to \mathrm{R}^{\ell}$.

We view each point in Q as an assignment of lengths $d(e)$ to the edges, and we consider U^D as ℓ real valued linear functions. The goal in the fractional covering problem is to compute μ^* defined by

$$\mu^* \triangleq \max_{y \in Q} \min_{1 \le i \le \ell} U_i^D(y).$$

The PST and Y algorithms require the existence of an *optimization oracle*. The input to the optimization oracle is a dual solution which is an assignment of edge lengths $\{d(e)\}_{e \in E}$. The output is a vector $x \in P$ which minimizes the objective function $\sum_{e \in E} U_e(x) \cdot d(e)$. In other words, given a $y \in Q$, the optimization oracle computes an $x \in P$ that minimizes the inner product $y \cdot U(x)$. Both the PST and the Y algorithms still work well even if the optimization oracle returns a suboptimal result. Specifically, if the optimization oracle outputs a vector $x \in P$ for which

$$\sum_{e \in E} U_e(x) \cdot d(e) \le 2 \cdot \min_{x' \in P} \sum_{e \in E} U_e(x') \cdot d(e),$$

then the algorithms find a vector $x' \in P$ such that $U_e(x') \le 2(1+\varepsilon)\lambda^*$, for every $e \in E$.

A key parameter that affects the running time of the PST and Y algorithms is the *width* of the set P with respect to the function U. The width is denoted by $U_{\max}$ and is defined by

$$U_{\max} \triangleq \max_{x \in P} \max_{e \in E} U_e(x).$$

With this setting, the complexities of the PST and Y algorithms are as follows. The complexity of the PST algorithm is

$$O\left(\left(\frac{U_{\max} \cdot \ln(m/\varepsilon) \ln(1/\varepsilon)}{\lambda^* \cdot \varepsilon^2}\right) \cdot (T(\text{compute } U) + T(\text{oracle}))\right),$$

where $T(\text{compute } U)$ denotes the time required to compute $U(x)$ with respect to an intermediate value of x, and $T(\text{oracle})$ denotes the time required by the optimization oracle for answering a single query.

The complexity of the Y algorithm is

$$O\left(\left(\frac{(1+\varepsilon) \cdot U_{\max} \cdot \ln(m)}{\lambda^* \cdot \varepsilon^2}\right) \cdot (T(\text{compute } U) + T(\text{oracle}))\right).$$

Note that ℓ may even be exponentially large without affecting the complexity of the algorithms as long as we can (a) efficiently compute $U(x)$ for the intermediate vectors $x \in P$ that are encountered in the course of running the algorithms, and (b) efficiently compute the oracle.

In the rest of this section we present efficient implementations of the PST and Y algorithms for computing a spreading metric for ρ-separators. We present a deterministic algorithm that has a running time of $\tilde{O}(m^2 n \cdot \frac{\rho'}{\rho' - \rho})$ and a randomized algorithm that has an expected running time of $\tilde{O}(m^2/(\rho' - \rho))$. The following implementation issues are discussed:

- In section 7.1, modification of the linear program (P1) so that it fits the framework of [16], and adjustment of the linear program so that the width of the convex set P is at most $\frac{\rho'}{\rho' - \rho}$.

- In section 7.2, scaling of the problem so that the optimal solution λ^* satisfies $1/\lambda^* = O(m)$.
- In section 7.3, construction of a deterministic optimization oracle that runs in $\tilde{O}(mn)$ time, and a randomized version that succeeds in finding a 2-approximate solution in $\tilde{O}(m/\rho')$ time with high probability.
- In section 7.4, implementation issues such as computing U in $O(m)$ time and deriving a dual solution.

7.1. The modified formulation. In this section we rewrite the linear program (P1$_S$) so that it fits the framework of [16]. This modification will ensure that the width is a constant.

We first define a modified version of (P1$_S$), denoted by (P1′).

$$\text{(P1}') \qquad \min \sum_{e \in E} c(e) \cdot d(e)$$

$$\text{s.t. } \forall S \subseteq V \text{ such that } w(S) > \rho' \cdot w(V), \quad \forall v \in S : \sum_{u \in S} \mathsf{dist}_S(v,u) \cdot w(u) \geq s(w(S))$$

$$\forall e \in E : d(e) \geq 0,$$

where $s(w(S)) = w(S) - \rho \cdot w(V)$.

Observe the following details in (P1′): (a) the constraints that $d(e) \leq 1$ are omitted; (b) the distances $\mathsf{dist}_S(v,u)$ are used; and, most important, (c) we omit the constraints for subsets S whose weight is less than or equal to $\rho' \cdot w(V)$.

Omitting the constraints $d(e) \leq 1$ from (P1$_S$) does not change the cost of an optimal solution. The reason for this is that if $d(e)$ is a feasible solution of (P1$_S$), then so is $d'(e) = \min\{1, d(e)\}$.

It is also easy to show that (i) the cost of an optimal solution of (P1′) is a lower bound on the minimum capacity of a ρ-separator; and (ii) every feasible solution of (P1′) satisfies the radius guarantee as stated in Lemma 3.2. Thus, optimal solutions of (P1′) are also spreading metrics.

We now define a linear program (P2) using the following notation. A *rooted tree* in a graph G is a pair (T, r), where the vertices and edges of the tree T belong to G and r is a designated vertex of T called the root. Removing an edge from T disconnects the tree into two subtrees, where one contains the root r and the other does not contain it. For every edge e in a rooted tree (T, r), define $\omega(T, r, e)$ to be the sum of the weights of the vertices of the subtree of T that are disconnected from the root r by removing edge e. Let $\mathcal{T}$ denote the set of all rooted trees of weight greater than $\rho' \cdot w(V)$.

We define linear program (P2) as follows:

$$\text{(P2)} \qquad \min \sum_{e \in E} c(e) \cdot d(e)$$

$$\text{s.t. for all rooted trees } (T,r) \in \mathcal{T} : \sum_{e \in T} d(e) \cdot \omega(T,r,e) \geq s(w(T))$$

$$\forall e \in E : \; d(e) \geq 0,$$

where $s(w(T)) = w(T) - \rho \cdot w(V)$.

LEMMA 7.1. *The sets of feasible solutions to linear programs* (P1′) *and* (P2) *are equal, and hence their optima are also equal.*

Proof. Consider a rooted tree (T, r), and let $v, u \in T$. Define $\mathsf{dist}_T(v, u)$ to be the distance from v to u in T. It is easy to see that $\sum_{u \in T} \mathsf{dist}_T(r, u) \cdot w(u) = \sum_{e \in T} d(e) \cdot \omega(T, r, e)$. Thus, in (P2) these two expressions are interchangeable.

Given a subset S and a vertex $r \in S$, consider a rooted tree (T, r) of shortest paths in S. For every $u \in S$, it follows that $\mathsf{dist}_S(r, u) = \mathsf{dist}_T(r, u)$. Therefore, every feasible solution of (P2) is also a feasible solution of (P1′).

We now show that every feasible solution of (P1′) is also a feasible solution of (P2). Given a rooted tree (T, r), let S denote the vertex set of T. Let (T', r) denote a shortest-path tree of S. The constraint corresponding to (T', r) is satisfied since it is identical to the constraint corresponding to S and r. Since $\mathsf{dist}_T(r, u) \geq \mathsf{dist}_{T'}(r, u)$, for every vertex $u \in S$, it follows that the constraint corresponding to (T, r) is also satisfied, and the lemma follows. ∎

The *utilization* of edge e by a rooted tree $(T, r) \in \mathcal{T}$ is defined by

$$U_e(T, r) \triangleq \frac{\omega(T, r, e)}{c(e) \cdot s(w(T))}.$$

We define $y(e) \triangleq c(e) \cdot d(e)$ and rewrite the linear program (P2) as follows:

$$\text{(P3)} \qquad \min \sum_{e \in E} y(e)$$

$$\text{s.t. for all rooted trees } (T, r) \in \mathcal{T}\text{: } \sum_{e \in T} y(e) \cdot U_e(T, r) \geq 1$$

$$\forall e \in E : \; y(e) \geq 0.$$

We construct the dual program of (P3) as follows. For every rooted tree $(T, r) \in \mathcal{T}$, define a nonnegative variable $\tilde{x}(T, r)$.

Given a vector $\tilde{x} = \{\tilde{x}(T, r)\}_{(T,r) \in \mathcal{T}}$, define the utilization of edge e by $\tilde{x}$ as follows:

$$U_e(\tilde{x}) \triangleq \sum_{\{(T,r):\; e \in T\}} U_e(T, r) \cdot \tilde{x}(T, r).$$

The dual program of (P3) is defined as follows:

$$\text{(D3)} \qquad \max \sum_{(T,r) \in \mathcal{T}} \tilde{x}(T, r)$$

$$\text{s.t. for all edges } e \in E\text{: } U_e(\tilde{x}) \leq 1$$

$$\text{for all rooted trees } (T, r) \in \mathcal{T}\text{: } \tilde{x}(T, r) \geq 0.$$

We now translate the linear program (D3) into a fractional packing problem (D4) solvable by the PST and Y algorithms. Define a *fractional rooted tree* to be a convex combination of rooted trees. A fractional rooted tree is represented by a nonnegative vector $x = \{x(T, r)\}_{(T,r) \in \mathcal{T}}$ such that $\sum_{(T,r) \in \mathcal{T}} x(T, r) = 1$. Define the convex set $P \subseteq \mathrm{R}^{\ell}$ to be the set of fractional rooted trees, where ℓ denotes the cardinality of $\mathcal{T}$. The fractional packing problem (D4) is to compute an $x^* \in P$ that minimizes $\max_{e \in E} U_e(x)$. The approximate solution $x' \in P$ computed by the

PST algorithm or the Y algorithm satisfies $\max_{e\in E} U_e(x') \leq (1+\varepsilon)\cdot\lambda^*$, where $\lambda^* \triangleq \min_{x\in P}\max_{e\in E} U_e(x)$.

The relation between problems (D3) and (D4) is as follows. Every feasible solution $\tilde{x}$ of (D3) can be scaled to a vector $x \in P$ by setting $x = \tilde{x}/\sum_{T,r}\tilde{x}(T,r)$. The maximum edge utilization of x is bounded by $1/\sum_{T,r}\tilde{x}(T,r)$. Conversely, given a vector $x \in P$ with maximum edge utilization λ, define $\tilde{x} = x/\lambda$ to obtain a feasible solution of (D3) for which $\sum_{T,r}\tilde{x}(T,r) = 1/\lambda$. Thus, every optimal solution of problem (D4) can be scaled to an optimal of (D3) and vice versa. Moreover, this translation by scaling also preserves approximation factors of approximate solutions.

The fractional covering problem (P4) that is dual to (D4) and corresponds to (P3) is defined as follows. Let Q denote the convex set of all vectors $y \in \mathrm{R}^m$ for which $\sum_{e\in E} y(e) = 1$. Define the cost of a rooted tree (T,r) with respect to y by $\mathsf{cost}_y(T,r) \triangleq \sum_{e\in T} y(e)\cdot U_e(T,r)$. Problem (P4) is to find a vector $y \in Q$ that maximizes the cost of a minimum cost tree with respect to y. In other words, define, $\mu^* = \max_{y\in Q}\min_{T,r}\mathsf{cost}_y(T,r)$, and the goal is to find a vector $y \in Q$ for which $\mathsf{cost}_y(T,r) \geq \mu^*$ for all rooted trees (T,r).

To be precise, the PST and Y algorithms find vectors $x \in P$ and $y \in Q$ such that

$$(1+\varepsilon)\cdot\min_{T,r}\mathsf{cost}_y(T,r) \geq \max_{e\in E} U_e(x). \tag{7.1}$$

Combined with linear programming duality, (7.1) implies that the computed costs of the solutions x and y are within a factor of $(1+\varepsilon)$ from the optimum $\lambda^* = \mu^*$. We then scale back the vector y to obtain an approximate solution of linear program (P1′) which constitutes a spreading metric.

We conclude by showing that the width of P with respect to U is constant. Since every point $x \in P$ is a convex combination of rooted trees and since U is linear, it follows that the width is obtained on a single rooted tree.

Claim 7.2. If the capacities of the edges are at least a unit, then the width $U_{\max}$ is at most $\frac{\rho'}{(\rho'-\rho)}$.

Proof. As discussed above,

$$U_{\max} = \max_{(T,r)\in\mathcal{T}}\max_{e\in E} U_e(T,r) = \max_{(T,r,e)}\frac{\omega(T,r,e)}{c(e)\cdot s(w(T))}.$$

Note that $\omega(T,r,e) \leq w(T)$. Since we consider only rooted trees for which $w(T) > \rho'\cdot w(V)$, it follows that $s(w(T)) = w(T) - \rho\cdot w(V) \geq w(T)(1-\rho/\rho')$, and the claim follows. ∎

7.2. Bounding the optimal cost. The running time of the PST and Y algorithms depends on $1/\lambda^*$, where λ^* is the optimal cost of the fractional packing problem (D4). In this section we show how scaling can be used to bound the value of $1/\lambda^*$ by $2m$. Let $\textsc{opt}_\rho$ denote the capacity of an optimal ρ-separator. Since every ρ-separator is a feasible solution to linear program (P1′), it follows that $\textsc{opt}_\rho \geq 1/\lambda^*$. Hence, it suffices to bound $\textsc{opt}_\rho$ by $2m$.

We present a reduction that scales the minimum capacity of a ρ-separator so that it is bounded by $2m$. The cost associated with this reduction is at most $2\cdot\textsc{opt}_\rho$. Namely, the reduction adds edges to the ρ'-separator that we compute, and the sum of the capacities of these edges is at most $2\cdot\textsc{opt}_\rho$. This, of course, suffices for a constant approximation. The overhead of running our reduction is a multiplicative factor of $O(\log m)$, since one needs to execute the PST (or Y) algorithm $O(\log m)$ times.

Suppose that we have a bound t satisfying $\text{OPT}_\rho \le t \le 2\text{OPT}_\rho$. Consider the following scaling. Define

$$\mathsf{Light}_t \triangleq \left\{ e \in E \,:\, c(e) \le \frac{t}{2m} \right\},$$
$$\mathsf{Heavy}_t \triangleq \{ e \in E \,:\, c(e) > t \}.$$

Clearly, edges in Heavy_t do not belong to an optimal ρ-separator. Therefore, contracting edges in Heavy_t does not modify the capacity of an optimal ρ-separator. By contracting we mean that connected components in Heavy_t are merged into a single node, the weight of which equals the sum of the weights of the original vertices, and the capacity of an edge incident to two merged vertices equals the sum of the capacities of the edges connecting the original vertices.

The total capacity of edges in Light_t is bounded by OPT_ρ. Therefore, we can add all the edges in Light_t to our solution, and the overhead of this step is bounded by OPT_ρ. Adding the edges in Light_t to our solution means that we may delete these edges from the graph.

Next, scale the capacities of the remaining edges as follows: $c'(e) = \frac{2m}{t} \cdot c(e)$. Note that the capacities of the remaining edges are between 1 and $2m$.

Let $G' = (V', E')$ denote the graph obtained after contracting edges in Heavy_t, deleting edges in Light_t, and scaling the edge capacities. Let OPT'_ρ denote the capacity of an optimal ρ-separator in G'. The following claims prove the required properties of the reduction from G to G'.

Claim 7.3. The capacity of an optimal ρ-separator in G' satisfies $\text{OPT}'_\rho \le \frac{2m}{t} \cdot \text{OPT}_\rho \le 2m$.

Proof. We show that there is a ρ-separator in G' of capacity at most $2m$. Consider an optimal ρ-separator F in G. Since F is optimal, it does not contain any of the edges in Heavy_t. It follows that if $(u, v) \in F$, $(u, w) \in \mathsf{Heavy}_t$, and $(w, v) \in E$, then $(w, v) \in F$. Therefore, we can transform a ρ-separator F in G into a ρ-separator F' in G' simply by choosing the edges in G' that originate from edges in F. Moreover, $c'(F') \le \frac{2m}{t} \cdot c(F)$. Since $\text{OPT}_\rho \le t$, $\text{OPT}'_\rho \le 2m$. ∎

Claim 7.4. Every $\hat{\rho}$-separator F' in G' can be transformed in linear time into a $\hat{\rho}$-separator F in G such that $c(F) \le \frac{t}{2m} \cdot c'(F') + \text{OPT}_\rho$.

Proof. Every $\hat{\rho}$-separator F' in G' can be transformed into a $\hat{\rho}$-separator in $G - \mathsf{Light}_t$ by choosing the edges in G from which the edges in F' originate. This translation satisfies $c(F) \le \frac{t}{2m} \cdot c'(F)$. Adding the edges of Light_t yields a $\hat{\rho}$-separator in G of cost bounded by $\frac{t}{2m} \cdot c'(F') + \text{OPT}_\rho$. ∎

We conclude from Claims 7.3 and 7.4 that any $\hat{\rho}$-separator F' whose capacity is at most $\alpha \cdot \text{OPT}'_\rho$, for some $\alpha \ge 1$, can be transformed into a $\hat{\rho}$-separator F in G whose capacity is at most $(\alpha + 1) \cdot \text{OPT}_\rho$.

The reduction presented so far enables us to run the approximation algorithms on a graph in which an optimal ρ-separator has capacity at most $2m$. This reduction assumes the existence of 2-approximation for OPT_ρ, which we do not have. Thus, we resort to guessing, starting from $t = 1$ and doubling t for the next guess. Suppose we prescale the graph so that $\text{OPT}_\rho \le m^2$ and all edge capacities remain not less than 1; then only $2 \log m$ guesses are required. For every guess of t, we solve approximately the problem (D4) on the corresponding graph and choose the best solution among the $2 \log m$ solutions. (Note that if our guess of t is "too large," then many edges are contained in Light_t, and Light_t is a ρ-separator. If t is "too small," then Heavy_t spans a subgraph that is too heavy, rendering the problem infeasible.)

We now discuss how to perform prescaling so that $1 \leq \text{OPT}_\rho \leq m^2$. Note that this prescaling keeps all edge capacities not less than 1. After this prescaling, it suffices to consider the "guesses" $1 \leq t = 2^i \leq m^2$ and pick the best solution among the $O(\log m)$ possibilities.

We first order the edges in increasing cost order, namely, $c(e_1) \leq \cdots \leq c(e_m)$. We then compute the index i_0 that satisfies

$$i_0 \triangleq \min\{i \,:\, \{e_1, \ldots, e_i\} \text{ is a } \rho\text{-separator}\}.$$

Note that i_0 can be found using a binary search, and hence it can be computed in $O(m \log m)$ time.

We claim that $c(e_{i_0}) \leq \text{OPT}_\rho \leq i_0 \cdot c(e_{i_0}) \leq m \cdot c(e_{i_0})$. The upper bound follows directly from the definition of i_0. The lower bound follows since if $\text{OPT}_\rho < c(e_{i_0})$, then an optimal ρ-separator would consist of edges in the subset $\{e_1, \ldots, e_{i_0-1}\}$, a contradiction to the definition of i_0.

Following the scaling technique discussed above, define

$$\mathsf{Light} \triangleq \left\{ e \in E \,:\, c(e) \leq \frac{c(e_{i_0})}{m} \right\},$$
$$\mathsf{Heavy} \triangleq \{e \in E \,:\, c(e) > m \cdot c(e_{i_0})\}.$$

Since $c(e_{i_0}) < \text{OPT}_\rho$, the sum of the capacities of the edges in Light is bounded by OPT_ρ, and we add the edges of Light to our solution and delete them from the graph, as before. Since $\text{OPT}_\rho < m \cdot c(e_{i_0})$, the capacity of each edge in Heavy is more than OPT_ρ. Therefore, the edges in Heavy do not belong to an optimal ρ-separator and they can be contracted.

Next, scale the capacities of the remaining edges as follows: $c'(e) = \frac{m}{c(e_{i_0})} \cdot c(e)$. It is easy to see that this achieves the desired prescaling.

7.3. The optimization oracle. The optimization oracle receives as input nonnegative edge lengths $\{d(e)\}_e$ and finds a fractional rooted tree $\tilde{x} \in P$ that minimizes $\sum_{e \in E} d(e) \cdot U_e(\tilde{x})$. Such a vector is called a *min-cost fractional rooted tree* since one may interpret the edge lengths as edge costs.

Claim 7.5. Let $\tilde{x} \in P$ be a min-cost fractional rooted tree. Then, for every rooted tree $(T, r) \in \mathcal{T}$ for which $\tilde{x}(T, r) > 0$,

$$\sum_{e \in (T,r)} d(e) \cdot U_e(T, r) = \sum_{e \in E} d(e) \cdot U_e(\tilde{x}).$$

Proof. Observe that every rooted tree is also a fractional rooted tree. Hence, if there exists a rooted tree (T', r') for which $\tilde{x}(T', r') > 0$ and

$$\sum_{e \in (T',r')} d(e) \cdot U_e(T', r') > \sum_{e \in E} d(e) \cdot U_e(\tilde{x}),$$

then there also exists a rooted tree (T'', r'') for which $\tilde{x}(T'', r'') > 0$ and

$$\sum_{e \in (T'',r'')} d(e) \cdot U_e(T'', r'') < \sum_{e \in E} d(e) \cdot U_e(\tilde{x}),$$

yielding a contradiction to the assumption that $\tilde{x}$ is a min-cost fractional tree. The claim follows. ∎

It follows from Claim 7.5 that in order to compute a min-cost vector, it suffices to find a min-cost tree. Namely, our goal is to find a rooted tree $(T, r) \in \mathcal{T}$ that minimizes

$$\text{cost}(T, r) \triangleq \sum_{e \in (T,r)} \frac{\omega(T, r, e) \cdot d(e)}{c(e) \cdot s(w(T))}.$$

We prove that finding a minimum-cost rooted tree in the case where the vertices have arbitrary weights is NP-complete by a reduction from the SUBSET-SUM problem [5, p. 223].

The input to an instance of the SUBSET-SUM problem consists of a fraction $\alpha \in (0, 1)$ and n positive weights $w_1, w_2, \ldots, w_n$ that satisfy $\sum_{i=1}^{n} w_i = 1$. The question is whether there exists a subset of indices $I \subseteq [1..n]$ such that $\sum_{i \in I} w_i = \alpha$.

The reduction to the weighted optimization oracle is as follows. We choose any pair $\rho' > \rho$ such that $\rho' - \rho = \alpha$. For simplicity, we choose $\rho = (1 - \alpha)/2$ and $\rho' = (1 + \alpha)/2$. Consider a star graph with a center vertex r and n vertices connected to the center, denoted by $v_1, v_2, \ldots, v_n$. Define the edge capacities and the edge lengths all to be 1, namely, $d(r, v_i) = c(r, v_i) = 1$ for all $1 \le i \le n$. Define the vertex weights as follows: $w(v_i) = w_i$ for all $1 \le i \le n$, and $w(r) = \rho/(1 - \rho')$ (which in our case means $w(r) = 1$).

Claim 7.6. The cost of a minimum-cost rooted tree (T^*, r^*) in the instance of the weighted optimization oracle is $1/2$ if and only if the answer to the instance of the SUBSET-SUM problem is affirmative.

Proof. It can readily be verified that since $w(r)$ is relatively large, a minimum-cost tree must be rooted at r. Due to the unit edge lengths and edge capacities, the cost of a rooted tree (T, r) equals

$$\text{cost}(T, r) = \frac{w(T) - w(r)}{w(T) - \rho(1 + w(r))} = \frac{w(T) - 1}{w(T) - 2\rho}.$$

Since $w(r) > \rho(1 + w(r))$, it follows that the cost is minimized when $w(T)$ is minimized, namely, when $w(T) = \rho'(1 + w(r))$. If there exists a tree (T, r) such that $w(T) = \rho'(1 + w(r))$, then its cost is the smallest possible and $\text{cost}(T, r) = 1/2$.

However, there exists such a tree if and only if there exists a subset $I \subseteq [1..n]$ such that

$$w(r) + \sum_{i \in I} w_i = \rho'(1 + w(r)).$$

That occurs if and only if $\sum_{i \in I} w_i = \alpha$, and the claim follows. ∎

The rest of this section is organized as follows:

1. An algorithm for computing the optimization oracle in the case of unit vertex weights is presented. The running time of this algorithm is $\tilde{O}(mn)$.
2. A $(2 + \varepsilon)$-approximation algorithm for the optimization oracle in the case of arbitrary vertex weights is presented. The running time of this algorithm is $\tilde{O}(mn)$.
3. A randomized approximation algorithm for the optimization oracle (for both the weighted and unweighted case) is presented for reducing the running time of the optimization oracle. The randomized algorithm reduces the running time by a factor of $\tilde{O}(n \cdot \rho')$.

7.3.1. Precise optimization oracle for the unit-weight case. We consider here the case where all vertices have unit weight. Define a *k-vertex min-cost tree rooted at* r, denoted by $T(r,k)$, to be a rooted tree whose cost is minimum among the rooted trees (T,r) for which $|T|=k$. We find a min-cost tree by computing, for every root r and for every $1 \le k \le n$, a k-vertex min-cost tree rooted at r. The min-cost tree is then chosen among these n^2 trees. We henceforth focus on computing $T(r,k)$ for a fixed root r. Define

$$\gamma(T,r) \triangleq \mathrm{cost}(T,r) \cdot s(|T|) = \sum_{e \in T} \frac{d(e)}{c(e)} \cdot \omega(T,r,e).$$

Let $d'(e) \triangleq d(e)/c(e)$. Given a rooted tree (T,r), let $\mathsf{dist}'_T(r,u)$ denote the distance in T from r to u with respect to edge lengths $d'(e)$. Clearly,

$$\gamma(T,r) = \sum_{u \in T} \mathsf{dist}'_T(r,u). \tag{7.2}$$

The consequence of (7.2) is that computing $T(r,k)$ reduces to that of computing the k closest vertices to r with respect to edge lengths $d'(e)$. Hence, for a given root r we can compute $T(r,k)$ for all values of k by running Dijkstra's shortest paths algorithm which has complexity $O(m+n\log n)$ [4]. Since we need to run the algorithm for all choices for the root r, we get that the total running time of the min-cost subroutine is $O(mn+n^2\log n)$.

7.3.2. Approximate optimization oracle for the weighted case. First, we extend the definition of $\gamma(T,r)$ from the unweighted case to deal with vertex weights. Define

$$\gamma(T,r) \triangleq \mathrm{cost}(T,r) \cdot s(w(T)) = \sum_{e \in T} \frac{d(e)}{c(e)} \cdot \omega(T,r,e) = d'(e) \cdot \omega(T,r,e).$$

Clearly,

$$\gamma(T,r) = \sum_{u \in T} \mathsf{dist}'_T(r,u) \cdot w(u). \tag{7.3}$$

The optimization oracle in the weighted case searches for a rooted tree $(T,r) \in \mathcal{T}$ that minimizes $\gamma(T,r)/s(w(T))$. The approximate oracle "guesses" an interval for the denominator and searches for rooted trees that minimize the numerator.

Figure 7.1 depicts a $2(1+\varepsilon)$-approximation algorithm for the optimization oracle. Algorithm *apx-opt-oracle* is based on a procedure called apx-min-γ which, given a root r and a threshold t, finds a rooted tree (T,r) of weight at least t such that $\gamma(T,r) \le 2 \cdot \min_{\{(T',r'):w(T') \ge t\}} \gamma(T',r')$. Algorithm apx-opt-oracle calls procedure apx-min-γ from every possible root with a sequence of increasing thresholds and returns a rooted tree of minimum cost among all the computed trees. The following claim summarizes the approximation factor of algorithm apx-opt-oracle.

Claim 7.7. Algorithm apx-opt-oracle finds a $2(1+\varepsilon)$-approximate min-cost rooted tree.

Proof. Consider a min-cost rooted tree (T^*,r^*). Let $t_0,t_1,\ldots$ denote the sequence of thresholds considered by the algorithm. Suppose that $t_i \le w(T^*) < t_{i+1}$. Let (T,r^*) denote the rooted tree that is found by procedure apx-min-γ with respect to threshold t_i and root r^*.

apx-opt-oracle $(V, E, \{w(v)\}_{v\in V}, \{d'(e)\}_{e\in E})$
(assume that ρ, ρ' are known)

Set $(\tilde{T}, \tilde{r})$ to be any rooted tree in $\mathcal{T}$.
$t = \rho' \cdot w(V)$ (set initial threshold to be $\rho' \cdot w(V)$)
while $t \le w(V)$ do
begin
for every root $r \in V$ do
begin
$T =$ *apx-min-*γ $(V, E, \{w(v)\}_{v\in V}, \{d'(e)\}_{e\in E}, r, t)$
if $\frac{\gamma(T,r)}{s(w(T))} < \frac{\gamma(\tilde{T},\tilde{r})}{s(w(\tilde{T}))}$ then $\{\ \tilde{T} = T$ and $\tilde{r} = r\}$
end
$t = (t - \rho \cdot w(V))(1 + \varepsilon) + \rho \cdot w(V)$
end
Return $(\tilde{T}, \tilde{r})$

FIG. 7.1. $2(1+\varepsilon)$-*approximation for min-cost rooted tree.*

The 2-approximation of procedure apx-min-γ implies that $\gamma(T, r^*) \le 2\gamma(T^*, r^*)$. Also, the fact that $w(T^*) < t_{i+1}$ implies that

$$\frac{w(T^*) - \rho \cdot w(V)}{w(T) - \rho \cdot w(V)} < \frac{t_{i+1} - \rho \cdot w(V)}{t_i - \rho \cdot w(V)} = 1 + \varepsilon.$$

Therefore, $\text{cost}(T, r^*) \le 2(1+\varepsilon) \cdot \text{cost}(T^*, r^*)$, and since algorithm apx-opt-oracle returns a rooted tree the cost of which is not greater than $\text{cost}(T, r^*)$, the claim follows. □

We now turn to the procedure apx-min-γ depicted in Figure 7.2. Recall that this procedure finds a rooted tree (T, r) of weight at least t such that $\gamma(T, r) \le 2 \cdot \min_{\{(T',r'):w(T')\ge t\}} \gamma(T', r')$. Note that it is computationally prohibitive to find the exact minimum since for any fixed $t > \rho' \cdot w(V)$, searching for a tree rooted at r of weight at least t that minimizes $\gamma(T, r)$ is NP-hard. The reduction is again from the SUBSET-SUM problem and is analogous to the reduction given above to the problem of searching for a tree rooted at r of weight at least $\rho' \cdot w(V)$ that minimizes $\gamma(T, r)$.

The procedure apx-min-γ grows a shortest-path tree rooted at r. Whenever the total weight of the vertices in the tree exceeds the threshold t, the resulting tree is considered a candidate for a min-cost tree, and the last vertex added to the tree is deleted from the tree. The procedure returns the minimum cost tree among all candidate trees. The following claim summarizes the approximation factor that it obtains.

Claim 7.8. Algorithm apx-min-γ computes a 2-approximate min-cost tree of weight at least t rooted at vertex r.

Proof. Let T^* denote a min-cost tree rooted at r of weight at least t. Given a tree T in *List*, let $last(T)$ denote the last vertex added to T. Consider the first tree T in *List* such that $last(T) \in T^*$. We show that the cost of T is at most twice the cost of T^*.

First, we prove that such a tree T exists. Assume to the contrary that for all the trees T' in *List*, $last(T') \notin T^*$. Since a vertex is added to X only if it is $Last(T')$ for some T' in *List*, we get that $X \cap T^*$ is empty upon termination. Let T_f denote

apx-min-γ $(V, E, \{w(v)\}_{v\in V}, \{d'(e)\}_{e\in E}, r, t)$

```
List = empty list   (list of candidate trees)
X = φ               (set of deleted vertices)
T = {r}             (current tree)
repeat
    let v be a closest vertex to r in the subgraph induced by V − X,
        among all vertices in V − T − X.
    let e = (u, v) be the last edge in a shortest path from r to v
        in the subgraph induced by V − X.          (u ∈ T)
    if w(T) + w(v) ≥ t, then add T ∪ {e} to List and add v to X.
    else add v to T.
until V − T − X is empty
Return min-cost tree in List
```

FIG. 7.2. 2-*approximation for min-cost tree of weight at least* t *rooted at* r.

the last tree that is added to *List*. Since $X \cap T^*$ is empty, it follows that $T^* \subseteq T_f$. Consider the vertex v of T^* that is added last to T_f. After v is added, the weight of the current tree (which is a subtree of T_f) is at least t. Hence, v should be added to X, which is a contradiction.

Consider the following partitioning of $T \cup T^*$ into three sets:

$$A = T - T^*,$$
$$B = (T \cap T^*) - last(T),$$
$$C = (T^* - T) + last(T).$$

We partition T into two: $T - last(T)$ and $last(T)$. Since $last(T) \in T^*$, the cost of $last(T)$ is not greater than the cost of T^*. We show that the cost of $T - last(T)$ is not greater than the cost of T^* as well.

By the definition of T, when T is constructed (before $last(T)$ is added to X), set X does not contain any vertices of T^*. The algorithm adds vertices to T in nondescending order of distance, where the distance is measured in the subgraphs induced by $V - X$. Since $X \cap T = \emptyset$ the distances in these subgraphs are the same as the distances in the whole graph. Therefore, the vertices of A are closer (or at least as close) to r than any vertex in C. Namely, for every $v \in A$, $\mathsf{dist}_V(r, v) \leq \mathsf{dist}_V(r, u)$ for all $u \in C$.

By the definition of T, $w(A) + w(B) < t$. On the other hand, since $T^* = B \cup C$, it follows that $w(B) + w(C) \geq t$. Hence, $w(A) < w(C)$. Together with the fact that the vertices in A are closer to r than any vertex in C, we obtain that the cost of A is smaller than the cost of C, and hence the cost of $T - last(T) = A \cup B$ is smaller than the cost of T^*, and the claim follows. □

The complexity of algorithm apx-min-γ is dominated by the complexity of Dijkstra's shortest paths algorithm which has complexity $O(m+n \log n)$ [4]. The number of iterations in algorithm apx-opt-oracle, for every root, is bounded by $\log(1/\rho')/\log(1+\varepsilon)$ which is at most $O(1/(\rho' \cdot \varepsilon))$. Hence, the total complexity of computing a $2(1+\varepsilon)$-approximate min-cost tree is $\tilde{O}(mn)$.

7.3.3. A randomized algorithm. Consider a tree T, and let c be a root such that the cost (T, c) is minimum among the costs of all rooted trees (T, r), where $r \in T$. The following claim shows that if a root r of T is chosen at random with probability $w(r)/w(T)$, then the expected cost of (T, r) is at most twice the cost of (T, c). Denote the cost of a rooted tree (T, r) by $\mathsf{cost}(T, r)$ and the expected cost by $\mathbf{Exp}[\mathsf{cost}(T, r)]$.

Claim 7.9. If a root r is chosen with probability $w(r)/w(T)$, then $\mathbf{Exp}[\mathsf{cost}(T, r)] \leq 2 \cdot \mathsf{cost}(T, c)$.

Proof. The cost of a tree (T, r) is defined to be

$$\sum_{e \in T} \frac{\omega(T, r, e) \cdot d(e)}{c(e) \cdot s(w(T))}.$$

Suppose that edge e disconnects T into two subtrees, T_1 and T_2, such that $w(T_1) \leq w(T_2)$. Clearly, $\omega(T, c, e) \geq w(T_1)$. On the other hand,

$$\mathbf{Exp}[\omega(T, r, e)] = \frac{2w(T_1) \cdot w(T_2)}{w(T)},$$

yielding the bound $\mathbf{Exp}[\omega(T, r, e)] \leq 2 \cdot \omega(T, c, e)$. Hence, by linearity of expectation,

$$\begin{aligned}\mathbf{Exp}[\mathsf{cost}(T, r)] &= \mathbf{Exp}\left[\sum_{e \in T} \frac{\omega(T, r, e) \cdot d(e)}{c(e) \cdot s(w(T))}\right] = \sum_{e \in T} \frac{\mathbf{Exp}[\omega(T, r, e)] \cdot d(e)}{c(e) \cdot s(w(T))} \\ &\leq \sum_{e \in T} \frac{2 \cdot \omega(T, c, e) \cdot d(e)}{c(e) \cdot s(w(T))} = 2 \cdot \mathsf{cost}(T, c),\end{aligned}$$

completing the proof. ∎

Combining the last claim with the algorithm for computing a min-cost tree rooted at vertex r yields the following randomized algorithm for finding a 2-approximate min-cost tree. The algorithm chooses a vertex $v \in V$ with probability $w(v)/w(V)$ and outputs a min-cost tree T rooted at v. This saves the need to compute min-cost rooted trees for every possible root. Fix an optimal min-cost rooted tree (T^*, r^*). Since $w(T^*) \geq \rho' w(V)$, the probability that $v \in T^*$ is at least ρ', in which case the expected cost of (T, v) is at most twice the cost of (T^*, r^*). With probability bounded by $1 - \rho'$, we fail. To amplify the probability of success, we may need to repeat the above algorithm $\tilde{O}(1/\rho')$ times, yielding that the complexity of the randomized algorithm is $\tilde{O}(m/\rho')$.

7.4. Implementation issues. We first point out how to compute $U(x)$ on the intermediate values of x in $O(m)$ time. The main reason this is possible is that the optimization oracle returns a single rooted tree (T, r). Therefore, the edge utilizations with respect to this rooted tree need to be computed. In the Y algorithm this is all we need, and in the PST algorithm, the new vector x is a weighted average of the old one and the rooted tree returned by the optimization oracle. Since the function U is linear, we simply take the weighted average of the edge utilizations.

Second, we discuss how to scale the vector $y \in Q$ returned by the PST and Y algorithms to obtain a spreading metric. The scaling consists of the following stages:

1. Transform y into a solution y' of (P3) by setting $y'(e) = \frac{y(e)}{\min_{T,r} \mathsf{cost}_y(T,r)}$. Note that in the weighted case, the denominator is only approximated, which adds another error to the approximation factor. (For the deterministic oracle this error is bounded by $2(1 + \varepsilon)$, and for the randomized oracle this error is bounded by $4(1 + \varepsilon)$.)
2. Transform y' into a solution d of (P2) by setting $d(e) = y'(e)/c(e)$.

Acknowledgments. We thank Serge Plotkin and Éva Tardos for their generous help in applying the framework described in [16] for approximating spreading metrics. We thank Naveen Garg for discussions about the constants in previous related approximation algorithms. We thank Neal Young for helpful remarks about his paper [18]. We thank Mark Rosenschein for pointing out the need for a different oracle in the weighted case.

AN OPTIMAL ALGORITHM FOR EUCLIDEAN SHORTEST PATHS IN THE PLANE *

JOHN HERSHBERGER† AND SUBHASH SURI‡

Abstract. We propose an optimal-time algorithm for a classical problem in plane computational geometry: computing a shortest path between two points in the presence of polygonal obstacles. Our algorithm runs in worst-case time $O(n \log n)$ and requires $O(n \log n)$ space, where n is the total number of vertices in the obstacle polygons. The algorithm is based on an efficient implementation of wavefront propagation among polygonal obstacles, and it actually computes a planar map encoding shortest paths from a fixed source point to all other points of the plane; the map can be used to answer single-source shortest path queries in $O(\log n)$ time. The time complexity of our algorithm is a significant improvement over all previously published results on the shortest path problem. Finally, we also discuss extensions to more general shortest path problems, involving nonpoint and multiple sources.

1. Introduction.

1.1. The background and our result.

The Euclidean shortest path problem is one of the oldest and best-known problems in computational geometry. Given a planar set of polygonal obstacles with disjoint interiors, the problem is to compute a shortest path between two points avoiding all the obstacles. Due to its simple formulation and obvious applications in routing and robotics, the problem has drawn the attention of many researchers in computational geometry; we mention only a few papers most relevant to our work [4, 13, 14, 17, 18, 19, 24].

The problem of computing shortest paths in the presence of a single obstacle has received special attention, due to its applications in various geometric problems involving a simple polygon [4, 13, 14, 17]. The roles of free space and obstacle space have traditionally been reversed in this special case: the interior of the polygon represents the *free space* and the boundary of the polygon represents an impenetrable obstacle. After several years of continued efforts, an optimal, linear-time algorithm is now known for computing a shortest path in a simple polygon [13, 14].

The general case of multiple obstacles, however, has proved to be substantially more difficult. There have been two fundamentally different approaches to the problem: the *visibility graph method* and the *shortest path map method*.[1] The visibility graph method is based on constructing a graph whose nodes are the vertices of the

[1] Several authors have also considered approximation algorithms for the shortest path problem [5, 7]; we consider only the exact shortest path problem.

obstacles and whose edges are pairs of mutually visible vertices. The shortest path between two vertices can be found by running any Dijkstra-type algorithm on this graph [8, 9, 11]. This approach fueled intense research on computing visibility graphs, culminating in an optimal $O(n \log n + E)$ time algorithm by Ghosh and Mount [12], where E is the number of edges in the graph. Unfortunately, the visibility graph can have $\Omega(n^2)$ edges in the worst case, and so any shortest path algorithm that depends on an explicit construction of the visibility graph will have a similar worst-case running time [1, 2, 15, 21, 24]. A "holy grail" of this approach is to build and search only the portion of the visibility graph that is relevant to the shortest path computation, but no noteworthy progress has been made on that front.

The second approach tries to solve a more general problem: for a given source point s, build a shortest path map (a subdivision of the plane) so that all points of a region have the same vertex sequence in their shortest path to s. This map is an encoding of shortest paths from s to *all* points of the plane. The shortest path map approach seems inherently more geometric than the graph-theoretic method based on visibility graphs. Nevertheless, most algorithms using the shortest path map approach also have $\Omega(n^2)$ worst-case running times; however, their running times typically have the form $O(n\,k\,g(n))$, where k is the *number* of obstacles and $g(n)$ is a sublinear function, such as the poly-logarithm [15, 18, 23]. Thus, for a small number of obstacles, these bounds approach the time complexity for a single obstacle. Mitchell has recently published an algorithm for computing a shortest path map that runs in $O(n^{3/2+\epsilon})$ time and space [19], for any $\epsilon > 0$, with the constant in the big-Oh notation depending on ϵ. Mitchell's algorithm uses some advanced range searching data structures to compute the vertices of the shortest path map.

The only lower bound known for the shortest path problem is $\Omega(n \log n)$ in the algebraic computation tree model, and so there remained a relatively large gap between the known upper and lower bounds on the problem. (The lower bound follows easily by a reduction from sorting.) Nevertheless, there had been a general belief in the computational geometry community that an almost-linear-time algorithm must be achievable.

In this paper, we validate this belief by presenting an optimal $O(n \log n)$ time algorithm for computing shortest paths in the presence of polygonal obstacles; n denotes the total number of vertices in all the obstacle polygons. Our algorithm takes the shortest path map approach and builds a subdivision of the plane, which after an additional linear-time preprocessing can be used to answer shortest path queries from a fixed point [10, 16].

A key idea in our algorithm is a special, quad-tree-style subdivision of the plane with respect to an arbitrary set of points P. This subdivision, called a *conforming subdivision*, divides the plane into a linear number of cells using horizontal and vertical edges so that the following critical condition holds: each point of P lies in a separate cell, and there are $O(1)$ cells within distance $\alpha|e|$ of every subdivision edge e, where $|e|$ is the length of e and α is a parameter (we choose $\alpha = 2$ for our application). Though a subdivision into square cells with this property can be obtained using a quad-tree construction of Bern, Eppstein, and Gilbert [3], that subdivision has size $O(n \log A)$, where A is the aspect ratio of the Delaunay triangulation of P. Our subdivision achieves its linear upper bound by enforcing a weaker condition; in particular, cells in our subdivision may be nonconvex and the subdivision itself may not be connected. Nevertheless, our conforming subdivision appears to be a useful tool and is likely to have other applications. In particular, we discuss extensions of our

technique that can handle generalized versions of the shortest path problem. These include versions with multiple sources (the "geodesic Voronoi diagram") or nonpoint sources such as line segments or disks.

1.2. An overview of the algorithm. We use a technique dubbed the *continuous Dijkstra method* in the literature [18, 19, 20]. It simulates the expansion of a wavefront from a point source in the presence of polygonal obstacles. The wavefront at time t consists of all points of the plane whose shortest path distance to the source is t. The boundary of the wavefront is a set of cycles, each composed of a sequence of circular arcs. Each arc, called a *wavelet*, is generated by an obstacle vertex already covered by the wavefront; the vertex is called the *generator* of its wavelet. The meeting point between two adjacent wavelets sweeps along a bisector curve, which is either a straight line or a hyperbola. Simulating the wavefront requires processing *events* that change its topology. These events fall into two categories: wavefront-wavefront collisions and wavefront-obstacle collisions. The ability to process these events efficiently is the key to a fast algorithm for the shortest path problem. Detecting and processing these events quickly, however, appears to be quite difficult, and except for the recent result of Mitchell [19], all previous algorithms employing the continuous Dijkstra method have led to no better than an $\Omega(n^2)$ worst-case time bound.

We introduce two new ideas to speed up the implementation of the wavefront propagation method: a quad-tree-style subdivision of the plane, and an approximate wavefront. Our first idea is to recognize that advancing a wavefront from event to event can be difficult without a sufficiently well-behaved subdivision of the plane to guide the propagation. We build a special subdivision of size $O(n)$ on the vertices of the obstacles, temporarily ignoring the line segments between them. Each cell of this subdivision, called a *conforming subdivision*, has a constant number of straight line edges, contains at most one obstacle vertex, and satisfies the following crucial property: for any edge e of the subdivision, there are $O(1)$ cells within distance $2|e|$ of e. We then insert the obstacle line segments into the subdivision, but maintain both the linear size of the subdivision and its conforming property—except now a *nonobstacle* edge e has the property that there are $O(1)$ cells within *shortest path* distance $2|e|$ of the edge. These cells form the units of our propagation algorithm: in each step, we advance the wavefront through one cell. Since each cell has constant descriptive complexity, we are able to do the propagation in a cell efficiently.

Inside a cell, a wavefront-obstacle event is relatively easy to handle. However, a wavefront-wavefront event is more complex. There are two types of wavefront-wavefront events, depending on whether or not the colliding wavelets are neighbors in the wavefront. The collision of neighboring wavelets occurs when a wavelet is engulfed by the expanding wavelets of its two neighbors. This event is easy to detect and process. The collisions between nonneighboring wavelets, however, are more troublesome, and to process them we introduce our second idea—the approximate wavefront.

When trying to propagate the wavefront across a boundary edge of a cell, we abandon the idea of computing the wavefront exactly; instead, we maintain two separate wavefronts approaching the edge from opposite sides. Each of these wavefronts is an *approximate wavefront*, representing the wavefront that hits the edge from only one side.

We use timers to make a conservative estimate of the time each edge is engulfed by the wavefront, and discard any parts of the wavefront arriving at a cell boundary after a timer at that boundary edge goes off. A critical task of these timers is to ensure that the wavefront-wavefront collisions of the true shortest path map are

detected during approximate wavefront propagation in a small neighborhood of their actual location. The algorithm propagates the approximate wavefront, remembering the wavefront-wavefront collisions and updating the wavefront so that it has enough information to act as an approximate wavefront at any time.

At the end of the propagation phase, we collect all the collision information, then use Voronoi diagram techniques in each cell to compute the collision events in that cell precisely. The collisions determine the edges of the final shortest path map.

This paper contains seven sections. Section 2 describes our conforming subdivision of the free space, and section 6 gives the details of its construction. Section 3 presents the key shortest path properties used by our algorithm. Section 4 describes our algorithm for computing a shortest path map. The data structures and finer details of our algorithm are discussed in section 5. We close in section 7 with some discussion and open problems.

2. A conforming subdivision of the free space. The input to our shortest path problem is a source vertex s and a family of obstacles $\mathcal{O} = \{O_1, O_2, \ldots, O_k\}$, where each obstacle is a simple polygon and the closures of any two obstacles are disjoint. (It is not hard to extend our algorithm to handle more general polygonal obstacles, but for convenience we limit our discussion to disjoint, nonnested obstacles.) The total number of vertices in all the obstacles is n. The plane minus the interiors of all obstacle polygons is called the *free space*, and a path is called *legal* if it lies entirely in the free space—that is, a legal path is disjoint from the interiors of all obstacle polygons in the family $\mathcal{O}$. Given two points in the plane, a *Euclidean shortest path* between them is a legal path of minimum total length connecting the two points.

A key ingredient of our shortest path algorithm is a special subdivision of the plane into *cells* of constant descriptive complexity. We construct this subdivision in two steps: the first step builds a subdivision by considering only the vertices of the obstacle polygons; the second step inserts the obstacle edges into the subdivision. Our algorithm for the first step (constructing a conforming subdivision for points) is somewhat complicated and quite independent of our main topic, the shortest paths, and so we have moved its presentation to section 6 at the end of the paper. In the present section, we assume the construction for points, and describe how to modify this subdivision when obstacle edges are inserted. We start with some preliminary definitions.

2.1. The well-covering regions. Our subdivision is inspired by quad-trees, though it is best implemented bottom-up. A crucial property of our subdivision is the *well-covering* of its internal edges. Given a straight-line subdivision $\mathcal{S}$ of the plane, an edge $e \in \mathcal{S}$ is said to be *well-covered with parameter* α if the following three conditions hold:

(W1) There exists a set of cells $\mathcal{C}(e) \subseteq \mathcal{S}$ such that e lies in the interior of their union. The union is denoted $\mathcal{U}(e) = \{c \mid c \in \mathcal{C}(e)\}$.

(W2) The total complexity of all the cells in $\mathcal{C}(e)$ is $O(\alpha)$.

(W3) If f is an edge on the boundary of the union $\mathcal{U}(e)$, then the Euclidean distance between e and f is at least $\alpha \cdot \max(|e|, |f|)$.

The edge is *strongly* well-covered if the stronger condition (W3′) holds:

(W3′) If f is an edge on *or outside* the boundary of the union $\mathcal{U}(e)$, then the Euclidean distance between e and f is at least $\alpha \cdot \max(|e|, |f|)$.

In either case, the region $\mathcal{U}(e)$ is called the *well-covering region of* e. Our wavefront simulation algorithm cares only about the distance between e and the edges on the boundary of $\mathcal{U}(e)$; that is, it requires its subdivision edges to be well-covered, but

not strongly well-covered. The strong condition on the distance between e and the edges outside $\mathcal{U}(e)$ is used only in our construction of the conforming subdivision (cf. Lemma 2.2).

Let V denote the set of vertices of the obstacle polygons, plus the source vertex s. A subdivision $\mathcal{S}$ is called a (*strong*) *α-conforming subdivision for V* if

(C1) Each cell of $\mathcal{S}$ contains at most one point of V in its closure (interior plus boundary),

(C2) Each edge of $\mathcal{S}$ is (strongly) well-covered with parameter α, and

(C3) The well-covering region of every edge of $\mathcal{S}$ contains at most one vertex of V.

The subdivision is called "conforming" because conditions (C1) and (C3) force it to conform to the distribution of points in V. Figure 2.1 shows an example of a well-covering region in a 1-conforming subdivision. The region $\mathcal{U}(e)$, drawn shaded, is not necessarily a minimal well-covering region; rather, it is the region constructed by our algorithm.

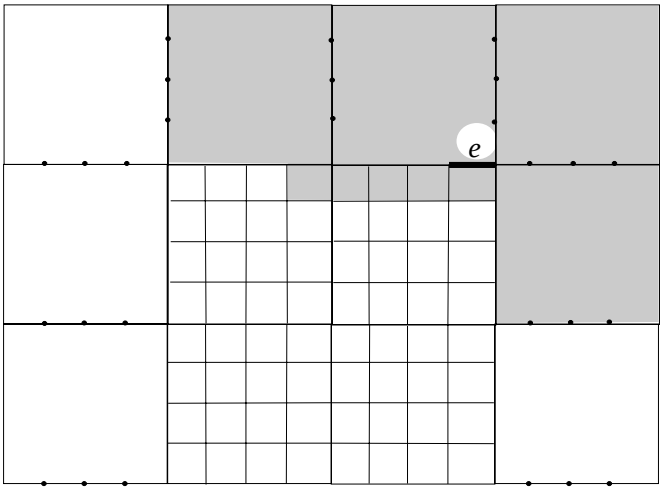

FIG. 2.1. *Part of a strong* 1*-conforming subdivision of a set of points. The shaded region is the union of cells* $\mathcal{U}(e)$ *forming a well-covering region of* e.

Our algorithm is based on a 2-conforming subdivision for V. For convenience, in the rest of the paper we use the term *conforming* to mean 2-conforming; when the conformity parameter is not 2, we state it explicitly.

2.2. Computing a conforming subdivision. Our strong conforming subdivision $\mathcal{S}$ is similar to a quad-tree in that all its edges are horizontal or vertical. However, the cells of $\mathcal{S}$ may be nonconvex and the subdivision itself may be disconnected. Each cell is reasonably well behaved, though there is at most one hole per cell. More specifically, each cell is either a square or a square-annulus (a square minus a square—see Figure 2.2); the boundaries of these squares, however, may be subdivided into a constant number of edges. Each square-annulus also has the following minimum clearance property:

> *Minimum clearance property:* The minimum width of an annulus in the subdivision (the minimum distance from the inner square to the

outer square) is at least one-quarter of the side length of the outer square.

Annuli and square faces are both subject to the uniform edge property:

Uniform edge property:

- Every edge on the outer square of an annulus has length $1/(4\lceil\alpha\rceil)$ times the side length of the outer square. Every edge on the inner square has length $1/(4\lceil\alpha\rceil)$ times the side length of the inner square.
- The lengths of edges on the boundary of a square cell differ by at most a factor of 4.

Our algorithm for computing a strong conforming subdivision of V is presented in section 6; describing it here would cause an unduly long digression. We simply state the main result from section 6.

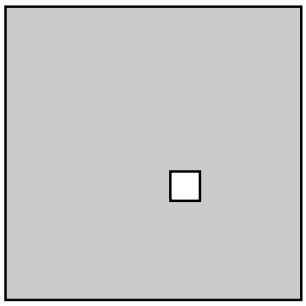

FIG. 2.2. *A square-annulus. The distance from the inner square to the outer square is at least* 1/4 *the side length of the outer square.*

THEOREM 2.1 (Conforming Subdivision Theorem). *For any $\alpha \geq 1$, every set of n points in the plane admits a strong α-conforming subdivision of $O(\alpha n)$ size satisfying the following additional properties:* (1) *all edges of the subdivision are horizontal or vertical,* (2) *each face is either a square or a square-annulus (with subdivided boundary),* (3) *each annulus has the minimum clearance property,* (4) *each face has the uniform edge property, and* (5) *every data point is contained in the interior of a square face. Such a subdivision can be computed in time $O(\alpha n + n \log n)$.*

We modify the strong conforming subdivision of V to accommodate the edges of the obstacles, producing a *conforming subdivision of the free space*. In the modified subdivision, there are two types of edges: the edges introduced by the subdivision construction and the original obstacle edges. To distinguish between them, we call the former *transparent* edges and the latter *opaque* edges; a wavefront can pass through the transparent edges, but it is blocked by the opaque edges. We require that all transparent edges be well-covered in the conforming subdivision of the free space (but not strongly so). Conditions (W1) and (W3) in the definition of well-covering are modified for the subdivision of free space as follows:

($W1_{fs}$) Let e be a transparent edge of $\mathcal{S}$. There exists a set of cells $\mathcal{C}(e) \subseteq \mathcal{S}$ such that e is contained in the closure of the union of cells $\mathcal{U}(e) = \{c \mid c \in \mathcal{C}(e)\}$.

($W3_{fs}$) Let e and f be two transparent edges of $\mathcal{S}$ such that f lies on the boundary of the well-covering region $\mathcal{U}(e)$. Then the shortest path distance between e and f is at least $\alpha \cdot \max(|e|, |f|)$.

Condition ($W3_{fs}$) ensures that e does not touch any transparent boundary edge of $\mathcal{U}(e)$, although it may touch opaque boundary edges.

Figure 2.3 shows an example of a well-covering region with obstacles. Lemma 2.2 shows how to modify a strong conforming subdivision of obstacle vertices to obtain a conforming subdivision of the free space. This subdivision of free space has the additional property that each obstacle vertex is incident to a transparent edge.

Remark. Our shortest path algorithm computes the distance from the source to the endpoints of all the transparent edges. The condition in the following lemma that each obstacle vertex is incident to a transparent edge ensures that the distance to each obstacle vertex is correctly computed.

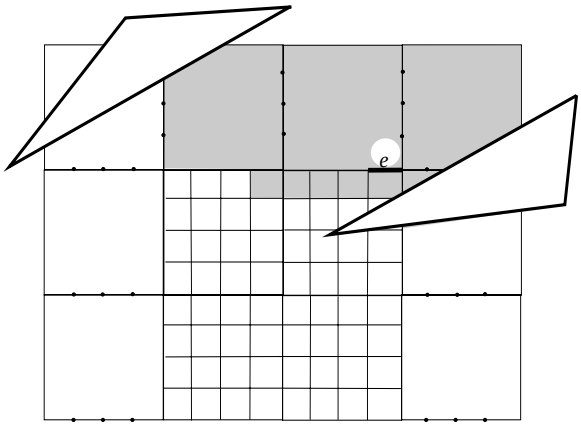

FIG. 2.3. *Part of a* 1*-conforming subdivision of free space. The shaded region is the well-covering region* $\mathcal{U}(e)$.

LEMMA 2.2. *Every family of disjoint simple polygons with a total of* n *vertices admits a* 2*-conforming subdivision of the free space with size* $O(n)$ *in which each obstacle vertex is incident to a transparent edge.*

Proof. Let $\mathcal{S}$ be a strong 2-conforming subdivision for V (the source vertex plus the vertices of the obstacle polygons), constructed according to Theorem 2.1. $\mathcal{S}$ has $O(n)$ vertices, edges, and faces (also referred to as cells), and each face is either a square or a square-annulus. Overlaying the obstacle edges on top of $\mathcal{S}$ cuts the plane into $O(n^2)$ cells. We call a face of this new subdivision $\mathcal{S}_{\text{overlay}}$ *interesting* if its boundary contains an obstacle vertex or a vertex of $\mathcal{S}$. For every vertex of $\mathcal{O}$ and for every vertex of $\mathcal{S}$, we keep intact the cells in $\mathcal{S}_{\text{overlay}}$ to which the vertex is incident (at most four cells per $\mathcal{S}$ vertex and two cells per obstacle vertex). We delete every edge fragment of $\mathcal{S}$ not on the boundary of one of these interesting cells.

Partition each cell containing an obstacle vertex v by extending edges vertically up and down from v. This cuts the cell into at most three convex pieces (since the cell is derived from a square of $\mathcal{S}$). Let c be the square in $\mathcal{S}$ that contains v, and let δ be the length of the shortest edge on the boundary of c. Subdivide each of the added

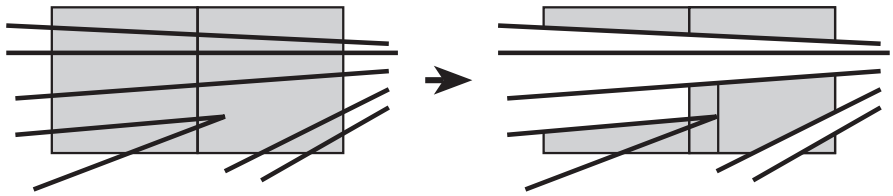

FIG. 2.4. *Constructing a conforming subdivision of the free space, given a strong conforming subdivision for the obstacle vertices. The shaded cells on the right are interesting cells.*

vertical edges incident to v into pieces of length at most δ (this produces $O(1)$ vertical edge fragments, since there are $O(1)$ edges on the boundary of c, all of approximately equal lengths, by the uniform edge property).

In the resulting subdivision, call it $\mathcal{S}'$, all cells are convex except those derived from square-annuli. Every nonconvexity in $\mathcal{S}_{\text{overlay}}$ is derived from a nonconvexity in either $\mathcal{S}$ or $\mathcal{O}$, since each face is the intersection of a face of $\mathcal{S}$ with a face in the arrangement of obstacle segments. Hence all nonconvex faces of $\mathcal{S}_{\text{overlay}}$ are interesting cells. Any face in $\mathcal{S}_{\text{overlay}}$ with an obstacle vertex on the boundary is cut into convex pieces by the vertical edges added through the vertex. The only other nonconvex vertices in $\mathcal{S}_{\text{overlay}}$ are annulus vertices. Each edge fragment that is deleted lies on the common boundary of two uninteresting faces; its deletion creates no new nonconvexities.

If a cell c of $\mathcal{S}$ has p edges on its boundary, then each subcell of c in $\mathcal{S}'$ that contains one of c's vertices has size at most $2p + O(1)$: each convex corner of c may be cut off by an obstacle edge, adding an extra edge; two obstacle edges may enter and exit through the same edge, leaving an obstacle vertex in the cell; and a subcell of an annulus may have up to two additional edges connecting the inner and outer squares. Adding vertical edges through each obstacle vertex splits a cell into at most three subcells, with at most $O(1)$ additional edges shared between them. Because each cell of $\mathcal{S}$ has constant complexity, the same is true of the interesting cells of $\mathcal{S}'$. It follows that the total complexity of the interesting cells is $O(n)$. Each uninteresting cell of $\mathcal{S}'$ (without a vertex of $\mathcal{S}$ or V) has at most eight edges—four edge fragments from $\mathcal{S}$ and four from $\mathcal{O}$. Each vertex in $\mathcal{S}'$ is a vertex of an interesting cell, so $\mathcal{S}'$ has $O(n)$ vertices, and, by planarity, $O(n)$ faces. See Figure 2.4 for a simplified example of the construction of $\mathcal{S}'$. In the remainder of the proof, we show that the portion of $\mathcal{S}'$ outside all obstacles in $\mathcal{O}$ is a *conforming subdivision of the free space*.

Condition (C1) is easily satisfied: each vertex of V lies in its own square cell in $\mathcal{S}$. These cells are interesting, and hence are retained (possibly subdivided) in $\mathcal{S}'$. Each cell of $\mathcal{S}_{\text{overlay}}$ therefore contains at most one vertex of V in its closure.

To show that all transparent edges of $\mathcal{S}'$ are well-covered (condition (C2)), consider such an edge e'. Edge e' may be a fragment of an edge $e \in \mathcal{S}$ (possibly $e = e'$), or it may be a fragment of a vertical edge added incident to an obstacle vertex. In the former case, define $\mathcal{U} = \mathcal{U}(e)$. In the latter case, e' is inside a square c of $\mathcal{S}$; define $\mathcal{U}$ to be the union of $\mathcal{U}(e)$ over all edges of c. Note that the boundary of $\mathcal{U}$ is covered by edge fragments in $\mathcal{S}$ (and hence in $\mathcal{S}_{\text{overlay}}$) but need not be in $\mathcal{S}'$: some edge fragments on the boundary of $\mathcal{U}$ may be erased in the construction of $\mathcal{S}'$. That is, $\mathcal{U}$ is a union of cells of $\mathcal{S}$ (and hence of $\mathcal{S}_{\text{overlay}}$), but not necessarily of $\mathcal{S}'$. Region $\mathcal{U}$ satisfies conditions (W1_{fs}) and (W3_{fs}); the latter holds because $\mathcal{U}$ satisfies condition (W3) for

the transparent edges of $\mathcal{S}$, and hence for those of $\mathcal{S}_{\text{overlay}}$. However, because $\mathcal{U}$ is not necessarily a union of cells of $\mathcal{S}'$, and may be cut into a nonconstant number of pieces by the obstacle polygons, we cannot use it directly as the well-covering region of e' in $\mathcal{S}'$.

We intersect $\mathcal{U}$ with free space. This partitions $\mathcal{U}$ into connected components $R_1, R_2, \ldots$. Exactly one component, call it R_1, contains e'. We show that each R_i is a union of $O(1)$ cells of $\mathcal{S}_{\text{overlay}}$, and hence that it has constant total complexity. We argue that for each cell c in $\mathcal{S}$, only a constant number of $\mathcal{S}_{\text{overlay}}$ subcells of c belong to R_i. If two subcells of c in $\mathcal{S}_{\text{overlay}}$ both belong to R_i, then the obstacle edges separating them must have endpoints either inside $\mathcal{U}$, or contained in one or more holes of $\mathcal{U}$ if $\mathcal{U}$ is multiply connected (see Figure 2.5). If we walk along the boundary of R_i, we visit subcells of c repeatedly. Between each pair of different subcells of c, we traverse the boundary of a different hole of $\mathcal{U}$ (or the outer boundary of $\mathcal{U}$, or the unique obstacle vertex inside $\mathcal{U}$). Because $\mathcal{U}$ has $O(1)$ holes, only $O(1)$ subcells of c belong to R_i.

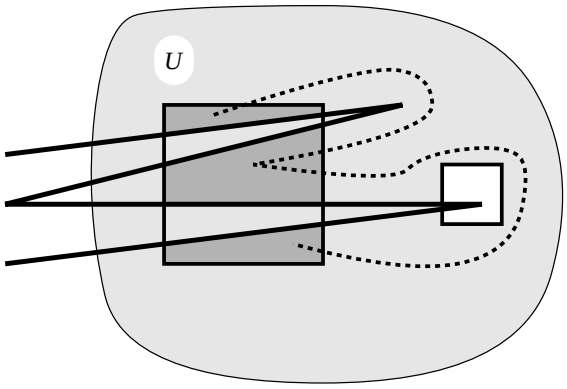

FIG. 2.5. *A cell of $\mathcal{U}$ may be partitioned into many subcells in $\mathcal{S}_{\text{overlay}}$, but only $O(1)$ of them belong to any one R_i.*

For any given component R_i, let $c(R_i)$ be the cells of $\mathcal{S}_{\text{overlay}}$ in R_i; $|c(R_i)| = O(1)$. Corresponding to each $c \in c(R_i)$, there is a unique cell c' in $\mathcal{S}'$ such that $c \subseteq c'$. Cell c is a strict subset of c' if and only if some edge of c was erased during the construction of $\mathcal{S}'$. If c is a strict subset of c', then c' is an uninteresting cell, and hence has at most eight edges. Thus both c and c' have constant complexity. Define

$$c'(R_i) = \{c' \mid c' \in \mathcal{S}' \text{ and } c \subseteq c' \text{ for some } c \in c(R_i)\}.$$

We have $|c'(R_i)| = O(|c(R_i)|) = O(1)$.

If $\mathcal{U}$ is nonconvex, it may be the case that some cell c' of $\mathcal{S}'$ that intersects R_i also intersects another component R_j, that is, $c'(R_i) \cap c'(R_j) \neq \emptyset$ (see Figure 2.6). Let us say that two components are connected, $R_i \sim R_j$, if and only if $c'(R_i) \cap c'(R_j) \neq \emptyset$, and extend $\sim$ to an equivalence relation by transitive closure.

We define $\mathcal{U}' = \mathcal{U}(e')$, the well-covering region for e' in $\mathcal{S}'$, to be the union of $c'(R_i)$ for all R_i in the equivalence class of R_1 under the $\sim$ relation. We argue that $\mathcal{U}'$ has constant complexity. Let $\overline{R}$ be the set of R_i that contain a vertex of $\mathcal{S}$ or $\mathcal{O}$. The set of cells $c'(\overline{R}) = \bigcup_{R_i \in \overline{R}} c'(R_i)$ has $O(1)$ total complexity. Further, if $R_i \notin \overline{R}$, then

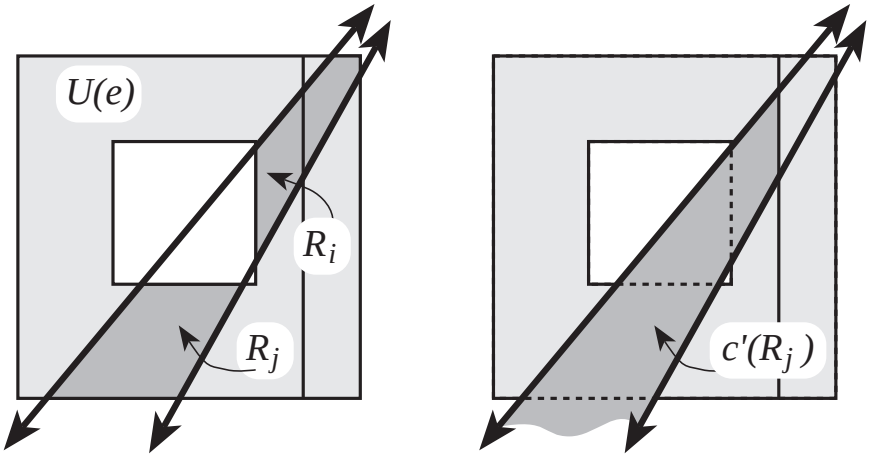

FIG. 2.6. *R_i and R_j are disjoint components of $\mathcal{U}(e)$ in $\mathcal{S}_{\text{overlay}}$. R_i is partitioned by a vertical line inside $\mathcal{U}(e)$, so $c(R_i)$ consists of two cells; $c(R_j)$ is a single cell. $c'(R_j)$ intersects both R_i and R_j, so $R_i \sim R_j$. Note that $c'(R_j)$ may have transparent edges outside $\mathcal{U}(e)$.*

$c'(R_i)$ is a single convex cell with $O(1)$ complexity (because all transparent edges of $c(R_i)$ inside $\mathcal{U}$ have been deleted). If such a cell $c' = c'(R_i)$ does not intersect any component in $\overline{R}$, then the union of $c'(R_j)$ for all $R_j \sim R_i$ is just the single cell c'. On the other hand, if c' does intersect some $R_j \in \overline{R}$, then $c' \cup c'(R_j)$ is identical to $c'(R_j)$. Because edge e' was not deleted, $R_1 \in \overline{R}$. It follows that $\mathcal{U}' \subseteq c'(\overline{R})$, and hence $\mathcal{U}'$ satisfies condition (W2).

The definition of $\mathcal{U}(e')$ implies that every transparent edge f' on the boundary of $\mathcal{U}(e')$ is outside or on the boundary of $\mathcal{U}$. Edge f' is a subset of some edge f of $\mathcal{S}$, so the Euclidean distance from e' to f' is at least $2 \cdot \max(|e'|, |f'|)$. It follows that condition (W3_{fs}) holds. Condition (W1_{fs}) holds by construction.

Let us now establish condition (C3). A well-covering region $\mathcal{U}(e')$ in $\mathcal{S}'$ contains no obstacle vertex that lies outside the well-covering region $\mathcal{U}$ in $\mathcal{S}$ from which $\mathcal{U}(e')$ is derived, since no edges of $\mathcal{S}$ that bound vertex-containing cells are deleted. If e' is a fragment of an edge e of $\mathcal{S}$, then its well-covering region $\mathcal{U}(e')$ in $\mathcal{S}'$ contains at most one obstacle vertex, since the same is true for $\mathcal{U} = \mathcal{U}(e)$ in $\mathcal{S}$. If e' is one of the edges added to $\mathcal{S}'$ inside a vertex-containing square, its well-covering region $\mathcal{U}$ is the union of $O(1)$ well-covering regions of $\mathcal{S}$. Each component region contains the square and its vertex and no other vertex; hence the well-covering region of e' in $\mathcal{S}'$ also satisfies condition (C3).

This completes our proof that $\mathcal{S}'$ is a conforming subdivision of the free space corresponding to the set of obstacles $\mathcal{O}$. □

Our next lemma shows that the conforming subdivision described above can be computed in $O(n \log n)$ time.

LEMMA 2.3. *The linear-size conforming subdivision of free space described in Lemma 2.2 can be built in time $O(n \log n)$.*

Proof. We start with a strong 2-conforming subdivision $\mathcal{S}$ of the obstacle vertices; $\mathcal{S}$ is computed in $O(n \log n)$ time by Theorem 2.1. In $O(n \log n)$ additional time, we build a point-location data structure for the obstacle polygons, so that given a query point q, we can in $O(\log n)$ time find the obstacle edge immediately to the left, right,

above, or below q [10, 16]. The edges of $\mathcal{S}'$ are obstacle edges, transparent edges on the boundary of kept cells, and transparent edges incident to obstacle vertices. To identify the second kind of edges, we trace the boundary of each kept cell separately. Each kept cell is contained in a single cell of $\mathcal{S}$ and has at least one vertex on its boundary, so we trace starting from each vertex. Tracing along an obstacle edge is easy, since the next transparent edge intersected is one of the $O(1)$ edges on the boundary of the current cell in $\mathcal{S}$. We use the point-location structure to trace along transparent edges: the next cell vertex is either a vertex of $\mathcal{S}$ or the first obstacle point hit by the ray that the current point and edge define. This tracing takes $O(n \log n)$ time altogether. The third kind of edges can be computed in $O(n)$ total time by local operations in each cell containing an obstacle vertex. To stitch the three kinds of edges into a single adjacency structure $\mathcal{S}'$, we use an $O(n \log n)$ time plane sweep algorithm [22]. □

This completes our discussion of the conforming subdivision. Our shortest path algorithm, described in section 4, relies heavily on the well-covering property of this subdivision. But first we establish some key geometric properties of shortest paths used by our algorithm.

3. Geometric properties of shortest paths. This section summarizes the properties of shortest paths we use in our algorithm. Most of these definitions and lemmas have appeared earlier [17, 18, 23]; we include them here for completeness.

The triangle inequality implies that a Euclidean shortest path turns only at obstacle vertices. Shortest paths need not be unique, though—for instance, every obstacle polygon O_i has at least one point on its boundary reached by two shortest paths; the two shortest paths together form a cycle enclosing the polygon. We use the notation $\pi(p, q)$ to denote the set of shortest paths connecting two points p and q. The length of any path in $\pi(p, q)$ is the shortest path distance between p and q, denoted $d(p, q)$. (Clearly, if one or both points lie inside an obstacle, there is no legal path between them; their shortest path distance is assumed to be infinite.) If the shortest path between p and q is the line segment $\overline{pq}$, then p and q are said to be mutually *visible*. We occasionally use $d(X, Y)$ to denote the shortest path distance between two sets of points X and Y, which is the minimum $d(x, y)$ over all pairs of points $x \in X$ and $y \in Y$.

We consider the problem of computing shortest paths from a fixed point s to all points of the free space. We define the *weight* of an obstacle vertex to be its shortest path distance to s. Given an arbitrary point p in free space, its *weighted distance* to a visible vertex u is defined as $|\overline{pu}| + d(u, s)$—the straight-line distance from p to u plus the shortest path distance from u to s. Obviously, the shortest path distance $d(p, s)$ is the minimum weighted distance between p and all vertices visible to p.

The *predecessor* of an arbitrary point p is defined as the vertex (or vertices) of V adjacent to p in $\pi(p, s)$; recall that V includes both s and the obstacle vertices. A predecessor of p is necessarily visible from p. (If p and s are mutually visible, then s is a predecessor of p.) The *shortest path map* of a particular source point s, denoted $SPM(s)$, is a subdivision of the plane into two-dimensional regions such that all the points in one region have the same unique predecessor. Points on region boundaries have multiple predecessors. These boundaries are pieces of *bisectors*—a bisector is the locus of points equidistant (by weighted distance) from two obstacle vertices, and it is in general an arc of a hyperbola. Figure 3.1 shows an example of a shortest path map.

The next three lemmas establish some fundamental properties of shortest paths

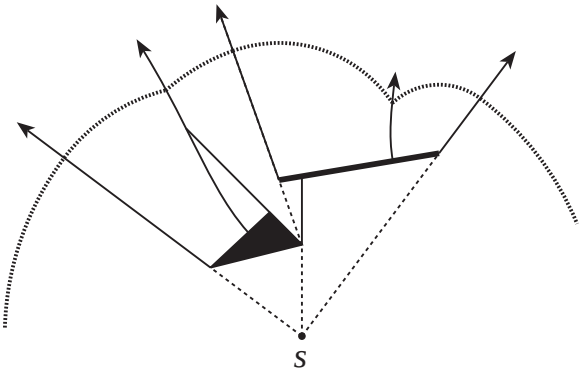

FIG. 3.1. *SPM*(s) *and a wavefront sweeping it.*

and shortest path maps.

LEMMA 3.1. *The set of points in the plane with multiple predecessors has measure zero.*

Proof. A point p with two obstacle vertices u and v as predecessors lies on the bisector of u and v, which is the hyperbola determined by the equation

$$|\overline{pu}| + d(u,s) = |\overline{pv}| + d(v,s).$$

There are at most $O(n^2)$ such hyperbolas, and each has measure zero. □

There are two types of edges in the subdivision *SPM*(s): (portions of) obstacle edges and arcs of hyperbolas determined by pairs of weighted vertices. The hyperbolic arcs may degenerate to straight lines—this happens when the weights of two vertices are equal, or differ by precisely the distance between the vertices; in the latter case the vertex with smaller weight is a predecessor of the other vertex. The vertices of *SPM*(s) are of three types: the obstacle vertices, the intersections of obstacle edges with (bisector) hyperbolic arcs, and the intersections of two or more bisectors; each of the last variety of vertices has three or more predecessors. The following lemma proves a linear upper bound on the total size of a shortest path map.

LEMMA 3.2. *The shortest path map SPM*(s) *has* $O(n)$ *vertices, edges, and faces. Each edge is a segment of a line or a hyperbola.*

Proof. We first observe that each face of *SPM*(s) is star-shaped, with the unique predecessor vertex for the face in its kernel—this follows from Lemma 3.1, which shows that interior points of a face have a unique predecessor.

The key step in the proof is to show that each obstacle vertex is the predecessor vertex for at most one face in *SPM*(s). Consider a vertex u that is the predecessor of a face F, and let *pred*(u) be the set of predecessors of u; observe that $d(u,s) = |\overline{uv}| + d(v,s)$ for any $v \in$ *pred*(u).

By the triangle inequality, if a point p is visible from a vertex $v \in$ *pred*(u), with v, u, p not collinear, then p cannot have u as its predecessor. Consider the subset of the free space that is visible from u but not visible from $v \in$ *pred*(u). Let $R(u,v)$ denote the component of this subset that is incident to u. Then $R(u,v)$ lies in an

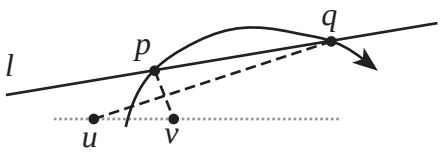

FIG. 3.2. *The intersection of $\overline{qu}$ with $\overline{pv}$ has two predecessors, even though it is not on a bisector—a contradiction.*

angular wedge around u of less than 180°. Define

$$R(u) = \bigcap_{v \in pred(u)} R(u, v).$$

Clearly, $F \subseteq R(u)$. We claim that there is at most one face of $SPM(s)$ in $R(u)$ with u as its predecessor. Suppose there were two faces, F_1 and F_2, both having u as their unique predecessor. The faces F_1 and F_2 have exactly one point in common: the vertex u. In the space between F_1 and F_2, there is a point p arbitrarily close to u with predecessor z such that z is distinct from both u and $pred(u)$. In other words, $|\overline{pu}| + d(u, s) > |\overline{pz}| + d(z, s)$. However, as p moves towards u, the difference in the distance shrinks, and finally $d(u, s) = |\overline{uz}| + d(z, s)$. But then z must be a predecessor of u, contradicting the hypothesis. Thus, a vertex u is a predecessor of at most one face in the shortest path map.

Finally, to prove the linear upper bound on the size of the shortest path map, recall that the number of obstacle vertices is n; the remaining vertices border at least three faces of $SPM(s)$ (for this argument, we count the obstacle polygons as faces of the shortest path map). Since the number of faces is $O(n)$, Euler's formula for planar graphs implies that the total number of vertices is also $O(n)$. This completes the proof. □

LEMMA 3.3. *Let u and v be two obstacle vertices that lie on the same side of a line ℓ. If ℓ intersects the bisector generated by u and v more than once, the intersections lie on opposite sides of the line supporting $\overline{uv}$.*

Proof. If the bisector is a straight line, the claim follows readily. Otherwise, the bisector is a hyperbola, and let us consider an arbitrary point p on this bisector. Every point on $\overline{pu}$ has u as its predecessor, and every point on $\overline{pv}$ has v as its predecessor. Points in the interiors of $\overline{pu}$ and $\overline{pv}$ have only one predecessor since they are not on the bisector (see Figure 3.2). If the half-bisector on one side of $\overline{uv}$ intersects ℓ at two points p and q, then there is an intersection of $\overline{pu}$ with $\overline{qv}$ or $\overline{pv}$ with $\overline{qu}$ that is not on the bisector and yet has two predecessors—a contradiction. □

With these preliminaries in place, we can now describe our shortest path algorithm, which works by propagating a wavefront through the conforming subdivision of the free space.

4. The shortest path algorithm. Our algorithm uses the *continuous Dijkstra method* [18, 19, 20], which simulates a unit-speed wavefront expanding from a point source and spreading among the obstacles. At simulation time t, the wavefront consists of points whose shortest path distance to the source is t. The wavefront is a set of disjoint paths and closed cycles. Each path or cycle is a sequence of circular arcs, called *wavelets*. Each wavelet is centered on an obstacle vertex that is already covered

by the wavefront, called the *generator* of the wavelet. As the wavefront expands, the meeting point of two adjacent wavelets sweeps along a *bisector curve*, which is the hyperbolic bisector of the two wavelets' generators. The endpoints of paths in the wavefront are formed where wavelets meet obstacle boundaries; these endpoints sweep along obstacle boundaries as the wavefront expands. During the wavefront simulation, the topology of the wavefront is changed by *events* of two types: wavefront-wavefront collisions and wavefront-obstacle collisions.

Our shortest path algorithm has two phases: a wavefront propagation phase, followed by a map computation phase. The first phase simulates the wavefront and determines approximate locations of all the wavefront collision events. The second phase uses this information to build the shortest path map in each cell of the conforming subdivision. In the following two subsections, we describe the details of these two phases, deferring the data structures and implementation issues of the propagation until the next section.

4.1. The propagation algorithm. Our algorithm works by propagating the wavefront through the cells of the conforming subdivision of the free space. The wavefront propagates between adjacent cells only across transparent edges; it dies upon meeting an opaque edge.

Propagating the exact wavefront appears to be quite difficult, so we content ourselves with computing two "single-sided" approximations to the wavefront at each transparent edge. Specifically, at each transparent edge, we compute two *approximate wavefronts*, passing through the edge in opposite directions. An approximate wavefront represents the wavefront reaching an edge from one side of the edge only. We can think of an approximate wavefront as labeling each point p on the edge with the time at which the approximate wavefront reaches p. The true distance $d(p, s)$ is the minimum of the two labels from opposite sides of the edge.

Remark. In some cases we can determine that a portion of a wavefront arrives at an edge after the wavefront from the other side of the same edge, and in such cases we drop the part that arrives later. In that sense, an approximate wavefront is not necessarily a complete representation of all the wavelets coming from one side of the edge.

An approximate wavefront at an edge e is represented as a sequence of obstacle vertices weighted with their shortest path distances from s. These vertices are the generators of the wavelets in the approximate wavefront. All the generators in an approximate wavefront sequence lie on the same side of e, since the approximate wavefront passes through e in one direction only. The core of our algorithm is a method for computing an approximate wavefront at an edge e based on the approximate wavefronts of nearby edges. These nearby edges are formalized in the following with the definitions of $input(e)$ and $output(e)$.

We denote by $input(e)$ the set of edges whose approximate wavefronts are used to compute the approximate wavefronts at e. This set consists of the transparent edges on the boundary of $\mathcal{U}(e)$, the well-covering region of e (cf. section 2.1). To compute the approximate wavefront at e, we propagate the approximate wavefronts from $input(e)$ to e inside $\mathcal{U}(e)$. The propagation algorithm introduces bends only at obstacle vertices in the closure of $\mathcal{U}(e)$; that is, the shortest paths corresponding to the wavefront do not bend except at obstacle vertices. Because $\mathcal{U}(e)$ need not be convex (nor even simply connected), nonconvexities of $\mathcal{U}(e)$ may block the wavefronts from some edges of $input(e)$ from reaching e. Typically, the paths corresponding to blocked wavefronts either run into obstacles outside $\mathcal{U}(e)$, or they pass through free

space outside $\mathcal{U}(e)$ and re-enter through other edges of *input*(e).

We denote by *output*(e) the set of edges to which the approximate wavefronts of e will be passed; *output*(e) = *input*$(e) \cup \{f \mid e \in \textit{input}(f)\}$. We set *output*$(e)$ to contain *input*(e) because our algorithm for detecting wavefront collision events depends on *output*(e) having a cycle enclosing e.

LEMMA 4.1. *For any transparent edge e, output(e) contains a constant number of edges.*

Proof. Because $|\mathcal{U}(f)| = O(1)$ for all f, and each $\mathcal{U}(f)$ is a connected set of cells of $\mathcal{S}'$, no edge e can belong to *input*(f) for more than $O(1)$ edges f. □

Our simulation of the wavefront propagation is loosely synchronized. For a transparent edge $e = \overline{ab}$, we define $\tilde{d}(e, s) = \min(d(a, s), d(b, s))$; this is a rough estimate of $d(e, s)$, since $d(e, s) \leq \tilde{d}(e, s) \leq d(e, s) + \frac{1}{2}|e|$. We compute the approximate wavefronts for e at the first time we are sure that e has been completely covered by wavefronts from the edges in *input*(e). This time is $\tilde{d}(e, s) + |e|$, the approximate time at which the expanding wavefront first hits an endpoint of e, plus the length of e. It is a conservative estimate of the time when e is completely run over by the wavefront.

We compute $\tilde{d}(e, s) + |e|$ on the fly for each edge e using a variable *covertime*(e). Initially, for every edge e whose well-covering region $\mathcal{U}(e)$ includes the source point s, we calculate an upper bound on $\tilde{d}(e, s)$ directly, considering only straight-line paths inside $\mathcal{U}(e)$, and set *covertime*(e) to this upper bound plus $|e|$. For all other edges, we initialize *covertime*$(e) = \infty$. Thus *covertime*(e) is not equal to $\tilde{d}(e, s) + |e|$ only for edges $e = \overline{ab}$ such that $\pi(a, s)$ or $\pi(b, s)$ crosses the boundary of $\mathcal{U}(e)$. The simulation maintains a time parameter t, and processes edges in order of their *covertime*$(\cdot)$ values. The main loop of the simulation is as follows:

PROPAGATION ALGORITHM

while there is an unprocessed transparent edge **do**

1. Select the edge e with minimum *covertime*(e), and set $t :=$ *covertime*(e).
2. Compute the approximate wavefronts at e based on the approximate wavefronts from all edges $f \in$ *input*(e) satisfying *covertime*$(f) <$ *covertime*(e). Compute $d(v, s)$ exactly for each endpoint v of e.
3. For each edge $g \in$ *output*(e), compute the time t_g when the approximate wavefront from e first engulfs an endpoint of g. Set *covertime*$(g) :=$ min (*covertime*(g), $t_g + |g|$).

endwhile

The following lemma proves the consistency of our algorithm—it shows that *covertime*() is correctly maintained and that the edges required for processing e are already processed. The details of Step 2 appear in sections 4.1.1 and 4.1.2; the computation of t_g in Step 3 is described in section 5.

LEMMA 4.2. *During the wavefront propagation, the following invariants hold:*

(*a*) *If the wavefront of an edge $f \in$ input(e) contributes to an approximate wavefront of e, then $\tilde{d}(f, s) + |f| < \tilde{d}(e, s) + |e|$.*

(*b*) *The value of covertime(e) is updated a constant number of times.*

(*c*) *The final value of covertime(e) is $\tilde{d}(e, s) + |e|$. This value is reached no later than the simulation clock reaches that time.*

(*d*) *Edge e is processed at simulation time $\tilde{d}(e,s)+|e|$.*

Proof. We establish the invariants separately:

(*a*) Any wavelet that contributes to the approximate wavefront at e must reach e at some time t_e with $d(e,s) \le t_e < \tilde{d}(e,s)+|e|$. Such a wavelet reaches e either by traveling straight from s inside $\mathcal{U}(e)$ or by passing through a transparent edge $f \in \mathit{input}(e)$ at an earlier time t_f, with $d(f,s) \le t_f < \tilde{d}(f,s)+|f|$ and $t_e \ge t_f + d(e,f)$. By condition ($\mathrm{W3_{fs}}$) of a well-covering region with parameter 2, $d(e,f) \ge 2|f|$, and so $t_e \ge d(f,s)+2|f|$. Since $\tilde{d}(f,s) \le d(f,s)+\frac{1}{2}|f|$, we can conclude that $\tilde{d}(f,s)+|f| < \tilde{d}(e,s)+|e|$.

(*b*) The value of $\mathit{covertime}(e)$ is updated only when an edge f is processed such that $f \in \mathit{input}(e)$ or $e \in \mathit{input}(f)$. There are $O(1)$ such edges, by Lemma 4.1.

(*c*), (*d*) We prove these by induction on the simulation clock. Claims (*c*) and (*d*) hold for the edges whose initial $\mathit{covertime}(\cdot)$ values are not infinite. The wavelet that first reaches an endpoint of e (at $t_e = \tilde{d}(e,s)$) passes through some $f \in \mathit{input}(e)$. By induction and the proof of (*a*), f has already been processed before the simulation clock reaches t_e, and so $\mathit{covertime}(e)$ is set to $\tilde{d}(e,s)+|e|$ no later than $t_e = \tilde{d}(e,s)$. The variable $\mathit{covertime}(e)$ cannot be set to any smaller value, because no approximate wavefront can reach the endpoints of e earlier than $\tilde{d}(e,s)$. It follows that e will be processed at simulation time $\tilde{d}(e,s)+|e|$. ∎

LEMMA 4.3. *For every vertex v of our conforming subdivision, the propagation algorithm correctly determines the distance $d(v,s)$ before v is used as a generator in any wavefront.*

Proof. Every vertex v of the conforming subdivision is an endpoint of a transparent edge e. The wavefront that determines $d(v,s)$ either reaches v from s by traveling only inside $\mathcal{U}(e)$, or it passes through an edge $f \in \mathit{input}(e)$ such that $\mathit{covertime}(f) < \mathit{covertime}(e)$. In the former case, initialization computes $d(v,s)$ correctly; in the latter case, Step 2 of the propagation algorithm implies that $d(v,s)$ is correctly computed. If v is an obstacle vertex, it may appear as a generator in a wavefront, but it will not be used until after $d(v,s)$ is computed at time $\tilde{d}(e,s)+|e|$ (Lemma 4.2(*d*)). ∎

While a well-covering region $\mathcal{U}(e)$ has constant complexity, it is not necessarily simply connected; consider, for instance, the case of a square-annulus. Consequently, there may be multiple, topologically distinct paths from a boundary edge $f \in \mathit{input}(e)$ to e. In order to avoid comparing paths of different topologies, we split the wavefront $W(e)$ into topologically equivalent pieces. In particular, let $W(e)$ denote one of the two approximate wavefronts passing through e. In computing $W(e)$ from a set $\{W(f) \mid f \in \mathit{input}(e)\}$, we use topologically constrained versions of the incoming wavefronts, denoted $W(f,e)$. A wavefront $W(f,e)$ is a portion of $W(f)$ that follows a single topological path inside $\mathcal{U}(e)$ from f to e.

If $\mathcal{U}(e)$ contains islands, there are multiple topologically distinct paths from an edge $f \in \mathit{input}(e)$ to e. When we need to refer to multiple topologically distinguished wavefronts from a single edge f to e, we use primed notation: $W(f,e)$, $W(f',e)$, etc.

If two points $p, q \in e$ are hit by a single topologically constrained wavefront $W(f,e)$, then the segments connecting p and q to their predecessors among the generator vertices in $W(f)$ intersect f and e, and the quadrilateral bounded by those segments and f and e is a subset of $\mathcal{U}(e)$. (The paths are not always segments: if an obstacle vertex v lies in the well-covering region of e and the path from f to p turns at v, then the predecessor of p in $W(f,e)$ may be v. Even in this case, the paths from p and q to f can be continuously deformed to each other inside $\mathcal{U}(e)$.) For

any point $p \in e$, the shortest path $\pi(p, s)$ passes through some $f \in \mathit{input}(e)$ (unless $s \in \mathcal{U}(e)$), so constraining the source wavefronts to pass through $\mathit{input}(e)$ does not lose any essential information.

4.1.1. The artificial wavefronts. When we compute the approximate wavefronts at a transparent edge e, we allow limited interaction between waves coming from opposite sides of the edge. This lets us eliminate some waves coming from one side of the edge that are dominated by waves from the other side. The interaction between the wavefronts from two sides is implemented using *artificial wavefronts*. These artificial wavefronts are our only mechanism for pruning the wavefront that arrives second at a transparent edge. We depend on artificial wavefronts to eliminate dominated wavefronts within a constant number of cells of where they first become dominated.

Consider a horizontal transparent edge e, and let v be an endpoint of e. We introduce an *artificial wavefront* with generator v and weight $d(v, s)$ into the computation of both approximate wavefronts at e. The triangle inequality implies that $d(p, s) \leq d(v, s) + |\overline{vp}|$, for any point $p \in e$. If the artificial wavefront reaches $p \in e$ before the wavefront from below e reaches p, then p is surely reached first by the upper wavefront, and so there is no need to propagate the lower wavefront through p. See Figure 4.1 for an illustration. In essence, an artificial wavefront is a convenient mechanism for discarding parts of the actual wavefront that are completely dominated by some other part of the wavefront. A generator of an artificial wavefront is not passed on to $\mathit{output}(e)$ as part of the approximate wavefront, unless it is also a vertex of $\mathcal{O}$.

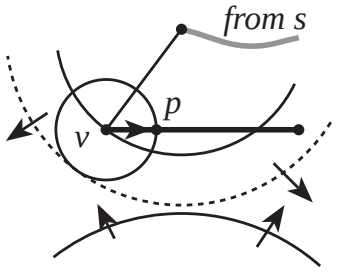

FIG. 4.1. *An artificial wavefront generated by v. If $d(v, s) + |\overline{vp}|$ is less than the time at which the wavefront from below reaches p, then p is reached first by a wavefront from above.*

Remark. An artificial wavefront is just a conceptual device that lets us argue about shortest paths without having to exhibit a specific shortest path. We use this technique in our proofs (e.g., Lemma 4.8) to discard generators at a cell boundary if the wavelet from an artificial wavefront reaches that boundary before the wavelets from those generators. Since the path passing through an artificial generator is no shorter than the true path from the predecessor of the artificial generator, the paths from the losing generators cannot be shortest paths.

When we compute the approximate wavefront passing through e from below (that is, coming from predecessors below e), the contributing wavefronts are the following:

1. All wavefronts $W(f, e)$ for $f \in \mathit{input}(e)$ and f below the line supporting e. (If f intersects the line supporting e, we split $W(f, e)$ in two, and keep only the portion $W(f', e)$ that comes from the part of f below e.)
2. An artificial wavefront expanding from each endpoint of e. An artificial wavefront generator v has weight $d(v, s)$.

The contributing wavefronts for the approximate wavefront passing through e from above are symmetric. The wavefront coming directly from s is handled separately.

The approximate wavefront from below is what the true wavefront would be if we were to block off the wavefront from above by adding extra obstacles. In physical terms, we can imagine replacing the transparent edge e with an (open) opaque obstacle segment. The opaque segment absorbs the wavefront from above, but the open endpoints let the wavefront from above pass through to generate artificial wavefronts. (Open endpoints are needed only to guard against the case in which an actual obstacle segment shares an endpoint of e, in which case replacing e with a closed segment would prevent artificial wavefronts from passing through the endpoint.)

Consider a set of wavefronts that reach e from the same side. We say that a contributing wavefront $W(f)$ *claims* a point $p \in e$ if $W(f)$ reaches p before any other contributor from the same side of e.

LEMMA 4.4. *Let e be horizontal, and let $W(f,e)$ and $W(g,e)$ be two contributors to the approximate wavefront that passes through e from below. Let x and x' be points on e claimed by $W(f,e)$, and let y be a point on e claimed by $W(g,e)$. Then y cannot lie between x and x'.*

Proof. Consider the shortest paths $\pi(x,s)$, $\pi(x',s)$, and $\pi(y,s)$ in the modified environment in which e has been replaced by an open, opaque segment. These paths connect x and x' to f, and y to g, inside $\mathcal{U}(e)$. Shortest paths $\pi(x,s)$, $\pi(x',s)$, and $\pi(y,s)$ do not cross. The subpaths of $\pi(x,s)$ and $\pi(x',s)$ inside $\mathcal{U}(e)$ can be continuously deformed to each other inside $\mathcal{U}(e)$, so g is not between them. It follows that y is not between them, either. ∎

LEMMA 4.5. *Let u and v be two obstacle vertices, both generating wavelets that are considered when the approximate wavefront passing through an edge e from below is computed. Then the bisector generated by u and v intersects e at most once in $SPM(s)$.*

Proof. Suppose the bisector intersects e twice. Without loss of generality assume u lies inside the loop formed by the bisector and e. If the bisector intersects e twice in $SPM(s)$, then the segment from u to its predecessor must intersect e between the two bisector intersections. This means that $d(e,s) < d(u,s)$; in fact, $d(e,s)+2|e| \leq d(u,s)$. Hence $\tilde{d}(e,s) + |e| < d(u,s)$, and u cannot contribute to the approximate wavefront at e: it does not become a generator until after e is processed, contradicting the assumption that both u and v contribute to the approximate wavefront at e. ∎

LEMMA 4.6. *Given $W(f,e)$ for each f below e that contributes to $W(e)$, we can compute the interval of e claimed by each $W(f,e)$ in $O(1+k)$ total time, where k is the total number of generators in all wavefronts $W(f,e)$ that are absent from $W(e)$.*

Proof. For each contributing wavefront $W(f,e)$, we show how to determine the portion of e claimed by $W(f,e)$ if only one other contributing wavefront $W(g,e)$ is present. Lemma 4.4 implies that this portion is contiguous. The intersection of these claimed portions, taken over all other contributors $W(g,e)$, is the part of e claimed by $W(f,e)$ in $W(e)$.

In constant time we determine whether the claim of $W(f,e)$ is left or right of that of $W(g,e)$. If both $W(f,e)$ and $W(g,e)$ reach the left endpoint of e, in constant time, check which one reaches it sooner. Otherwise, one of $W(f,e)$ and $W(g,e)$ reaches a point on e that is left of any point reached by the other, and this point determines the ordering. Without loss of generality, assume that the claim of $W(f,e)$ is left of that of $W(g,e)$.

By Lemma 4.4, we can combine the two wavefronts using only local operations.

Let a denote the generator in $W(f,e)$ claiming the rightmost point on e. Let p_a be the left endpoint of a's interval on e. Similarly, let b denote the generator in $W(g,e)$ claiming the leftmost point on e, and let p_b be the right endpoint of b's interval on e. Compute the bisector of a and b, and let its intersection with e be the point x. (By Lemma 4.5, there is only one intersection point in $SPM(s)$. If the hyperbola generated by a and b intersects e twice, then a is to the left of b at only one of the intersections, and we use that intersection as x.) See Figure 4.2. If x is to the left of p_a, then delete a from $W(f,e)$; if x is to the right of p_b, then delete b from $W(g,e)$; in either case, redefine a, b, p_a, p_b, recompute x, and repeat this test. If p_a is left of p_b and x lies between them, then x is the right endpoint of $W(f,e)$'s claim in the presence of $W(g,e)$.

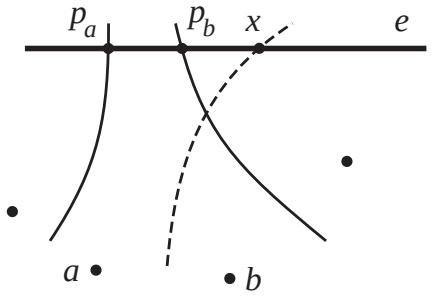

FIG. 4.2. *The contribution of b to $W(e)$ is constrained to be left of p_b and right of x, and therefore does not exist.*

By combining the claimed regions for all contributors $W(f,e)$, we construct the approximate wavefront at e. The time bound follows since we spend constant time per generator that is deleted for each pair of wavefronts, and the total number of wavefronts $W(f,e)$ to be merged is also a constant. This finishes the proof. □

LEMMA 4.7. *Any generator deleted during the construction of an approximate wavefront at edge e does not contribute to the true wavefront at e. Every generator that contributes to the true wavefront at e either is s or belongs to one of the approximate wavefronts at e.*

Proof. The first part is clear—every deleted generator is dominated by some other generator at e. The second part follows by induction from two facts: any wavelet that contributes to the true wavefront at e must come either from s inside $\mathcal{U}(e)$ or through one of the edges in $input(e)$ (by the definition of well-covering). The approximate wavefronts at $input(e)$ are ready before they are needed to construct $W(e)$ (by Lemma 4.2). □

4.1.2. The bisector events. When we propagate an approximate wavefront $W(e)$ to $output(e)$, we may detect bisector events, which are intersections of bisectors with each other or with obstacles. Bisector events are detected in two ways: (1) during the computation of $W(e,g)$ from $W(e)$ for some $g \in output(e)$; (2) during the merging process described in Lemma 4.6.

1. Bisector events of the first kind are detected when we simulate the advance of the wavefront from e to g to compute $W(e,g)$; the details of this simulation are discussed in section 5. In particular, if two generators u and v are nonadjacent in $W(e)$, but become adjacent at any time during the propagation from e to g, then there is a bisector event involving u and v.

2. Bisector events of the second kind are detected during merging. If a generator v contributes to one of the input wavefronts $W(e, g)$ but not to the merged wavefront $W(g)$ at g, then v is involved in a bisector event on the way from e to g. (As a special case, if a generator's claim on $W(g)$ is shortened (but not eliminated) by an artificial wavefront, then that generator is also considered to have a bisector event. This adds at most two extra bisector events for each edge g.)

Our algorithm detects bisector events in a small neighborhood of their actual location in $SPM(s)$. To ensure that all bisector events are properly localized, we *mark* the generators that participate in a bisector event in $O(1)$ cells near where the event is detected: if a generator v is involved in a bisector event in a cell c, then v is guaranteed to belong to a set of marked generators for c. However, the set of marked generators for a cell c may be a superset of the generators that actually participate in bisector events in c. We will show that the total number of generators marked in all the cells is $O(n)$. The precise rules for marking the generators are given below.

Marking Rules for Generators

1. If a generator v lies in a cell c, then mark v in c.
2. Let e be a transparent edge, and let $W(e)$ be the approximate wavefront coming from some generator v's side of e.
   (a) If v claims an endpoint of e in $W(e)$, or if it would do so except for an artificial wavefront, then mark v in all cells incident to the claimed endpoint.
   (b) If v's claim in $W(e)$ is shortened or eliminated by an artificial wavefront, then mark v in the cell on v's side of e.
3. Let e and f be two transparent edges with $f \in output(e)$. Mark v in both the cells that have e as an edge if one of the following events occurs:
   (a) v claims an endpoint of f in $W(e, f)$;
   (b) v participates in a bisector event detected either during the computation of $W(e, f)$ from $W(e)$, or during the merging step at f (Lemma 4.6). (We also mark v as having a bisector event if v's claim on $W(f)$ is shortened by an artificial wavefront.)
4. If v claims part of an opaque edge when it is propagated from an edge e toward $output(e)$, mark v in both cells with e on their boundary.

Rules 2a and 3a both apply when a wavefront claims an endpoint of an edge. The main difference between the two rules is that Rule 2a puts marks in cells near the claimed endpoint, and Rule 3a puts marks in cells near the source edge of the wavefront.

A generator may contribute to a wavefront more than once in the wavefront sequence; each mark applies to only one instance of the generator in the sequence. The following technical lemma is used in the proof of Lemma 4.9 to establish the correctness of the marking rules.

Lemma 4.8. *Let v be a generator that contributes to an approximate wavefront $W(e)$. Suppose there is a point $p \in e$ that is claimed by v in $W(e)$ but not in $SPM(s)$*

(because a wave from the other side of e reaches p first). Then v is marked in the cell c on v's side of e.

Proof. If v is unmarked in c, there must be generators u and w such that u, v, w are consecutive in $W(e)$—otherwise Rule 2 would apply. The bisectors (u, v) and (v, w) must exit from $\mathcal{U}(e)$ through the same transparent edge h—otherwise Rule 3 or 4 would apply. For the same reason, the region bounded by (u, v), (v, w), h, and e is a subset of $\mathcal{U}(e)$—if the region contained a non-$\mathcal{U}(e)$ island, v would claim an endpoint of a boundary edge of that island. Edge h is by definition part of $input(e)$. Consider the point $p \in e$ that is claimed by v in the approximate wavefront $W(e)$ but not in the true wavefront at e, and suppose that the true predecessor of p is $z \neq v$. The vertex z is either an obstacle vertex or the source s. In the former case, z lies outside $\mathcal{U}(e)$ or on its boundary $\partial\mathcal{U}(e)$—by condition (C3), $\mathcal{U}(e)$ contains at most one obstacle vertex, so any vertex not strictly outside $\mathcal{U}(e)$ must be connected to points outside $\mathcal{U}(e)$ by opaque edges. Vertex z may lie strictly inside $\mathcal{U}(e)$ only if $z = s$.

Let us first assume that z lies outside the well-covering region $\mathcal{U}(e)$—the proof simplifies in the other case, which is considered below. Let q denote the intersection point between $\overline{zp}$ and $input(e)$ closest to p (recall that $input(e) \subset output(e)$, and $input(e) \subset \partial\mathcal{U}(e)$). Based on the position of q relative to the bisectors (u, v) and (v, w), we argue that v must have been involved in a bisector event detected by our algorithm, and thus marked in cell c.

First, consider the case in which q lies between the bisectors (u, v) and (v, w) on the edge h. Now, since $|\overline{qp}| \geq |h|$ (by the well-covering property), the endpoints of h are engulfed by a wavefront from z or from some other generator before the wavefront from z reaches p at time $d(z, s) + |\overline{zp}|$. The artificial wavefronts from h's endpoints will cover h before time $d(z, s) + |\overline{zp}| + |h|$. By assumption we have $d(v, s) + |\overline{vp}| > d(z, s) + |\overline{zp}|$. The wavefront from v cannot reach e earlier than $d(v, s) + |\overline{vp}| - |e|$. By well-covering with parameter 2, $d(e, h)$ is at least $|e| + |h|$, and so the wavefront from v reaches h no earlier than $d(v, s)+|\overline{vp}|+|h| > d(z, s)+|\overline{zp}|+|h|$, at which time h is already covered by the artificial wavefront. The claim of v on h is shortened by the artificial wavefront (in fact, v's claim is eliminated completely), and so it must be marked by Rule 3b.

In the second case, q is not between the bisectors (u, v) and (v, w) on h. The segment $\overline{qp}$ must intersect one of the bisectors. Without loss of generality, assume $\overline{qp}$ intersects bisector (u, v). Since every point on $\overline{qp}$ has z as its predecessor in $SPM(s)$, the bisector (u, v) does not reach $\partial\mathcal{U}(e)$ in $SPM(s)$. We show that our propagation and merging algorithms will detect a bisector event for (u, v). Let r be the intersection point between the bisector (u, v) and the edge h. As noted in the discussion after Lemma 4.3, the triangle defined by the segments $\overline{ur}$, $\overline{vr}$, and e is a subset of $\mathcal{U}(e)$. Bisector (u, v) crosses the triangle boundary on e and at r, but nowhere else. The larger region R bounded by e, h, $\overline{ur}$, and bisector (v, w) also is a subset of $\mathcal{U}(e)$, and it contains point p. Because $\overline{qp}$ crosses into R to intersect (u, v), and it does not intersect the (v, w) or h sides of R, $\overline{qp}$ must intersect $\overline{ur}$; let x be the point of intersection. The wavelet from z reaches x before the one from u, so the path $z \to x \to r$, starting at time $d(z, s)$, reaches r before the path $u \to r$, starting at time $d(u, s)$. Observe also that the path $z \to x \to r$ is a legal path—it lies in free space. Now, consider the shortest path from z to r inside the triangle $\triangle zxr$ that does not cross h or any obstacle edge (see Figure 4.3). Because $z \to x \to r$ lies in free space, such a path exists, and is shorter than $z \to x \to r$. This path claims r from the same side as u before the wavelet from u reaches r. (If the path passes through an endpoint of h, then an artificial wavefront claims r; otherwise the last obstacle vertex on the path

claims r.) Thus, a bisector event for (u, v) is detected during the computation of $W(e, h)$ or $W(h)$, and v is marked by Rule 3b.

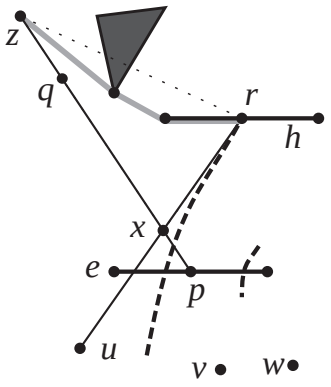

FIG. 4.3. *The shaded path from z to r claims r before the wavelet from u, and from the same side of h as u.*

Next consider what happens if the predecessor vertex z lies on the boundary of the well-covering region $\mathcal{U}(e)$. Let h be a boundary edge of $\mathcal{U}(e)$ incident to z. In this case we detect a bisector event involving v when we advance the wavefront from e to $output(e)$: if z lies between the bisectors (u, v) and (v, w), then v is marked by Rule 3a or 4; if z is not between the bisectors, the segment $\overline{zp}$ intersects one of the bisectors, say (u, v), and we detect a bisector event for (u, v) in advancing the wavefront from e to $output(e)$.

Finally, consider the case in which $z = s$ lies inside $\mathcal{U}(e)$. If z is not between the bisectors (u, v) and (v, w), segment $\overline{zp}$ intersects one of them and the proof is as above. Let r be the intersection of (u, v) with h, and let t be the intersection of (v, w) with h. The convex quadrilateral bounded by subsegments of e, $\overline{ur}$, h, and $\overline{tw}$ is contained inside $\mathcal{U}(e)$. Hence if z is between the bisectors (u, v) and (v, w), the entire segment $\overline{rt}$ is visible from z (that is, $\triangle zrt$ is empty) and so v's claim on h is eliminated by z. Therefore v is marked by Rule 3b. This completes the proof. ∎

LEMMA 4.9. *If a generator v participates in a bisector event of $SPM(s)$ in a cell c, then v is marked in c.*

Proof. If a bisector has an endpoint on an opaque edge of c, it either emanates from an obstacle vertex on the edge, or it is defined by two generators that claim part of the opaque edge. Rules 1 and 4 guarantee that all such generators are marked in c. If a generator v that contributes to an approximate wavefront in c is unmarked, then by Rule 2a there must be transparent edges e and f on the boundary of c such that $W(e)$ and $W(f)$ both contain the generator subsequence u, v, w, for some u and w. Without loss of generality assume $W(e)$ enters c and $W(f)$ leaves c. If v participates in a bisector event of $SPM(s)$ in c, then at least one point p inside the region R bounded by e, f, (u, v), and (v, w) is not claimed by v in $SPM(s)$. Let z be the true predecessor of p. Let r and t be the intersections of (u, v) and (v, w) with f, respectively. Region R is contained in the convex quadrilateral Q bounded by $\overline{ur}$, $\overline{rt}$, $\overline{tw}$, and the line supporting e. Because u, v, w is a subsequence of $W(e)$, no vertex on the same side of e as v claims any point of the side of Q collinear with e; that is, $\overline{zp}$ does not cross that side of Q. If r and t are both claimed by v in $SPM(s)$, then $\overline{ur} \in \pi(s, r)$, and $\overline{wt} \in \pi(s, t)$. In this case $\pi(s, p)$ cannot cross $\overline{ur}$ or $\overline{wt}$, and hence it

must cross $\overline{rt}$. The intersection of $\overline{zp}$ with $\overline{rt}$ is a point q that satisfies the hypothesis of Lemma 4.8, and so v is marked in c. On the other hand, if either r or t is not claimed by v in $SPM(s)$, that vertex satisfies the hypothesis of Lemma 4.8, and so v is marked in c. □

The following technical lemma shows that the approximate wavefronts are not too different from the true wavefronts; this lets us bound the number of marks made by the marking rules.

LEMMA 4.10. *Let B be the set of pairs (e, b) of transparent edges e and bisectors b such that b crosses e in some approximate wavefront, but the same crossing does not occur in $SPM(s)$. Then $|B| = O(n)$.*

Proof. Let (e, b) be a pair in B. Bisector b is defined by two generators u and v. The proof of Lemma 4.8 notes that each generator (except possibly s) is outside or on the boundary of $\mathcal{U}(e)$. That proof also shows that b's intersection with e in some approximate wavefront (that is, the presence of u and v in $W(e)$) is proof that u and v claim points on the boundary of $\mathcal{U}(e)$ (in $input(e)$) in $SPM(s)$. Let $p = b \cap e$. Because (e, b) is not an incident pair in $SPM(s)$, there must be at least one bisector event in $SPM(s)$ that lies in the interior of $\mathcal{U}(e)$ between the line segments $\overline{up}$ and $\overline{vp}$. We can charge the early demise of b to any one of these bisector events.

The segments $\overline{pu}$ and $\overline{pv}$ are disjoint inside $\mathcal{U}(e)$ from the corresponding segments defined by any other pair $(e, b') \in B$—in the modified shortest path problem in which the obstacles are $\mathcal{O} \cup \{e\}$, the segments $\overline{pv}$ and $\overline{pu}$ belong to $\pi(s, p)$, and hence they are disjoint from any other such segments. Thus the sector bounded by $\overrightarrow{pu}$ and $\overrightarrow{pv}$ is disjoint inside $\mathcal{U}(e)$ from the sector defined by any other pair $(e, b') \in B$, so each bisector event inside $\mathcal{U}(e)$ is charged at most once for all pairs in B that have e as the first element of the pair. Each cell in the conforming subdivision belongs to $O(1)$ well-covering regions $\mathcal{U}(e)$. Hence the sum over all transparent edges e of the number of bisector events in $\mathcal{U}(e)$ is only $O(n)$. This total is an upper bound on $|B|$. □

LEMMA 4.11. *The total number of marked generators over all cells is $O(n)$.*

Proof. We begin by defining a *propagation region* for each edge e. For any transparent edge e, let $P(e)$ be the collection of cells through which wavefronts propagate on the way from e to all edges $f \in output(e)$. Clearly $P(e) \subseteq \mathcal{U}(e) \cup \{\mathcal{U}(f) \mid f \in output(e)\}$. The number of cells in $P(e)$ is constant, since $|output(e)|$ is constant, and so is the number of cells in $\mathcal{U}(f)$ for any f. Furthermore, since every cell of $P(e)$ is within a constant number of cells of e, each cell c belongs to $P(e')$ for only a constant number of edges e'.

The total number of generator-cell marks made under Rule 1 is clearly $O(n)$.

Each $P(e)$ has constant complexity, so there are $O(n)$ edge pairs (e, f), where e is transparent and f is either transparent and in $output(e)$, or opaque and inside or on the boundary of $P(e)$. From this it follows that the number of marks made by Rules 2a and 3a is $O(n)$. Similarly, there are $O(n)$ Rule 4 marks in which the wavelet from v claims an endpoint of the opaque edge, or is the first or last nonartificial wavelet in $W(e)$.

Any Rule 4 mark not yet counted involves a generator v that does not reach any opaque edge endpoint when propagated forward from e. Because v is not the first or last nonartificial wavelet in $W(e)$, there is a generator u such that v's claim on e in $W(e)$ is bounded on the left by bisector (u, v). We can assume that (u, v) intersects e in $SPM(s)$; by Lemma 4.10 there are only $O(n)$ bisector-edge pairs that intersect in approximate wavefronts but not in $SPM(s)$. Bisector (u, v) terminates in $P(e)$, either on the opaque edge or in a bisector event before the opaque edge. Let us charge the

marking of v at e to this endpoint of (u, v) in $SPM(s)$. Because each cell belongs to $P(e')$ for a constant number of edges e', each vertex of $SPM(s)$ is charged $O(1)$ times. Since $|SPM(s)| = O(n)$, the number of Rule 4 marks is $O(n)$.

The proofs for Rules 2b and 3b are similar to that for Rule 4. We begin with the proof for Rule 3b. We can assume that the interval claimed by v on e in $W(e)$ is bounded by two bisectors (u, v) and (v, w), for two nonartificial generators u and w; the first and last generators in $W(e)$, counted separately, sum to at most $O(n)$ overall. Furthermore, we can assume that (u, v) and (v, w) both intersect e in $SPM(s)$; there are only $O(n)$ bisector-edge pairs that appear in some approximate wavefront but not in $SPM(s)$ (Lemma 4.10). At least one of the two bisectors fails to reach the boundary of $P(e)$ in $SPM(s)$, because Rule 3b applies, and a detected bisector event implies the existence of an actual bisector event no later than the point of detection; we charge the marking of v to that bisector endpoint. Each bisector event gets charged $O(1)$ times, and there are $O(n)$ bisector events in $SPM(s)$.

To bound the number of Rule 2b marks, consider where the generator v lies. There is at most one generator v inside $\mathcal{U}(e)$, and so $O(n)$ marks for such generators overall. If v lies outside $\mathcal{U}(e)$, there is at least one edge in $input(e)$ where v is marked by Rule 3b because of the shortening of v's claim on e. Charge the Rule 2b mark at e to this Rule 3b mark. There are $O(n)$ Rule 3b marks and hence $O(n)$ Rule 2b marks. □

We defer the finer details of the propagation algorithm to section 5 and instead describe the second phase of the algorithm next, namely, the shortest path map computation.

4.2. Computing the shortest path map. At the end of the propagation phase, approximate wavefronts for all transparent edges have been computed. Furthermore, for every cell c, a set of *marked* generators is known; each marked generator is in the approximate wavefront of one of the boundary edges of c, and all but $O(1)$ of them contribute to a bisector event either in c or in one of $O(1)$ nearby cells. The algorithms of Lemma 4.6 and section 5 let us compute the marked generators in $O(\log n)$ time apiece.

We now show how to break the interior of a cell c into *active* and *inactive* regions such that no vertices of $SPM(s)$ lie in the inactive regions. By Lemma 4.9, no unmarked generator contributes to a bisector event in c. A bisector defined by a marked generator and an unmarked neighbor belongs to $SPM(s)$. All such bisectors are disjoint. They partition c into regions such that each region is claimed only by marked generators or only by unmarked generators. These are the active and inactive regions, respectively (see Figure 4.4). The active regions can be computed in time proportional to the number of marked generators in c, since the order of the generators along the boundary of c is known.

The boundary of an active region consists of $O(1)$ segments. Each segment is a transparent edge fragment, an opaque edge, or a bisector in $SPM(s)$. Let e be a transparent edge fragment bounding an active region, and let $W(e)$ be the wavefront that enters the active region by crossing e. In the absence of wavefronts from other transparent edges, $W(e)$ partitions the active region into pieces we call S-faces, each with a unique predecessor in $W(e)$. These S-faces may not cover the active region, since each point in an S-face must be connected to its predecessor by a segment that intersects e. Denote this partition by $S(e)$. $S(e)$ is essentially a shortest path map, restricted to the active region and considering only generators in $W(e)$. If a point p lies in an S-face of $S(e)$ with predecessor v, then $S(e)$ assigns weight $|\overline{pv}| + d(v, s)$ to

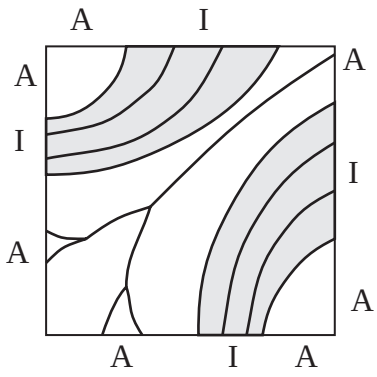

FIG. 4.4. *Active regions (white) and inactive regions (shaded). Each region-bounding bisector is defined by one marked and one unmarked generator.*

p. Points outside any S-face are assigned infinite weight by $S(e)$. We can compute $S(e)$ in $O(m \log m)$ time, where $m = |W(e)|$, by using the propagation algorithm and data structure of section 5.

The following lemma shows how to combine the wavefronts incident to different boundary edges of an active region.

LEMMA 4.12. *Given the approximate wavefronts on the boundary of a cell c and a set of k marked generators in those wavefronts, we can compute the vertices of $SPM(s)$ inside c in time $O(k \log k)$.*

Proof. Consider an active region inside c and two transparent edge fragments e and f on the boundary of this active region. We can use the merge step from a standard divide-and-conquer Voronoi diagram algorithm to compute the portion of the region nearer to $W(e)$ than to $W(f)$, using weighted distance, in time $O(|W(e)| + |W(f)|)$. More specifically, assume that $S(e)$ and $S(f)$ have both been computed. Let $m = |W(e)| + |W(f)|$. Each of $S(e)$ and $S(f)$ defines a distance function on the points of the active region. The pointwise minimum of these two functions determines which points are nearer to $W(e)$ than to $W(f)$ under weighted distance. Consider a point p in the S-face for some generator $v \in W(e)$. Point p belongs to v's S-face in $SPM(s)$ only if all of the segment $\overline{pv}$ is closer to v than to any generator in $W(f)$. The set of points p such that the entire segment from p to its predecessor is closer to $W(e)$ than to $W(f)$ is bounded by a single chain Γ of $O(m)$ hyperbolic arcs. (The number of arcs follows from Lemma 3.2.) To find Γ, first trace along a ray emanating from some generator $v \in W(e)$, marching through $S(e)$ and $S(f)$ simultaneously, until the ray reaches the boundary of c or reaches a point whose weight in $S(f)$ equals its weight in $S(e)$. This takes $O(m)$ time, since a line cuts $O(m)$ edges of $S(e)$ and $S(f)$. Then trace outward from this point along Γ. Each arc of Γ is a hyperbola determined by the generators of the S-faces of $S(e)$ and $S(f)$ containing the current point; trace along the hyperbola until it leaves one of the two S-faces, then follow the hyperbola determined by the next pair of S-faces, etc. This procedure takes $O(1)$ time per arc of Γ, or $O(m)$ time altogether (see Figure 4.5).

The tracing procedure computes the region closer to $W(e)$ than to $W(f)$ for one edge f. Intersecting the results for all such edges f on the boundary of the active region produces the region $R(e)$ claimed by $W(e)$ in $SPM(s)$. Intersecting $R(e)$ with $S(e)$ gives the vertices of $SPM(s)$ to which $W(e)$ contributes. We repeat this computation for each transparent edge fragment to find all the vertices of $SPM(s)$ in

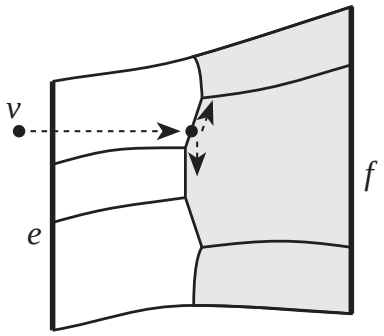

FIG. 4.5. *To find the region closer to $W(e)$ than to $W(f)$ under weighted distance, trace a ray from some $v \in W(e)$ through $S(e)$ and $S(f)$ until it hits a point equidistant from the two wavefronts; then trace outward from the point along the bisector Γ.*

the active region. Applying this algorithm to all active regions finds all vertices of $SPM(s)$ inside c.

The partition $S(e)$ determined by each edge fragment e participates $O(1)$ times in a Voronoi-style merge, so the total cost of merging is $O(k)$. Hence the running time is dominated by the propagation algorithm, which takes $O(k \log k)$ time altogether. □

LEMMA 4.13. *The shortest path map vertices computed cell-by-cell can be combined to build $SPM(s)$ in additional $O(n \log n)$ time.*

Proof. To compute $SPM(s)$, we compute all its edges separately, then use a standard plane sweep to assemble them, as follows. Create a list of the bisector endpoints discovered in the computation of Lemma 4.12, each identified by a key consisting of two generators. Put each three-bisector endpoint into the list three times, once for each bisector. Put each bisector/edge collision in once, labeled with the generators of the bisector. Now sort the list to group together endpoints belonging to each bisector. Take the endpoints belonging to the bisector of a generator pair (v, w) and sort them along the hyperbola determined by the weighted generators v and w. This determines all edges of $SPM(s)$ on the hyperbola. Doing this for all pairs that appear as keys in the sorted list gives all $O(n)$ hyperbolic arcs of $SPM(s)$. Finally, with a standard plane sweep [22], we can combine these arcs with the edges of $\mathcal{O}$ to build the subdivision $SPM(s)$. □

5. An implementation of the wavefront propagation. In this section, we give the implementation details of our algorithm. We describe the data structures used by our algorithm and finer details of the propagation algorithm.

5.1. The data structures. An approximate wavefront is a list of generators (obstacle vertices). Our algorithm performs the following two types of operations on these lists:

1. *Standard list operations:* insert, delete, concatenate, split, find previous and next elements, and search. The search operation locates the position of a query point in the list of bisectors defined by the generators at a particular time.
2. *Priority queue operations:* we assign each generator in the list a priority, and the data structure needs to update priorities and find the minimum priority in the list.

Both of these types of operations can be supported by a data structure based on balanced binary trees, for example, red-black trees, with the generators at the leaves. In particular, the list operations take $O(\log n)$ time each because the maximum list length is $O(n)$. The priority queue operations are supported by adding a priority field to the nodes of the binary tree: each node records the minimum priority of the leaves in its subtree. Each priority queue operation takes $O(\log n)$ time, while the list operations retain their $O(\log n)$ bound.

We also require our data structure to be fully persistent—we need the ability to operate on past versions of any list. Each of the two kinds of operations uses $O(1)$ storage per node of the binary tree, so we can make the data structure fully persistent by path-copying. Each of our operations affects $O(\log n)$ nodes of the tree, including all the ancestors of every affected node. Once we have determined which nodes an operation will affect, and before the operation modifies any node, we copy all of the nodes that will be affected, then modify the copies. This creates a new version of the tree while leaving the old version unchanged. The data structure uses $O(m \log n)$ storage, where m is the total number of data structure operations, and keeps the $O(\log n)$ per-operation time bound quoted above.

LEMMA 5.1. *There is a linear-space data structure that represents an approximate wavefront and supports list operations and priority queue operations in $O(\log n)$ time per operation. The data structure can be made fully persistent at the expense of an additional $O(\log n)$ space per operation.*

5.2. Details of the wavefront propagation. Using the data structures just described, we now show how to propagate an approximate wavefront from edge to edge. In particular, given an approximate wavefront $W(e)$, we show how to compute $W(e, g)$ for every edge $g \in \mathit{output}(e)$. In the process, we also determine the time of first contact between $W(e, g)$ and the endpoints of g.

We describe how to compute $W(e, g)$ for all the transparent edges g on the boundary of e's cell. Because the edges of $\mathit{output}(e)$ belong to a constant number of cells in the neighborhood of e, we can use this primitive to compute $W(e, g)$ for all $g \in \mathit{output}(e)$. When we propagate the wavefront cell-by-cell, we effectively split $W(e, g)$ into multiple pieces, each labeled by the sequence of transparent edges it follows from e to g. We assemble $W(e, g)$ out of these component wavefronts by concatenating pieces that correspond to topologically equivalent paths inside $\mathcal{U}(e)$. (Recall that for a pair e and g, there may be several constrained wavefronts $W(e, g)$, $W(e', g)$, etc., topologically distinguished by the paths they follow among the islands inside $\mathcal{U}(e)$.) Each component piece is a list of generators; adjacent pieces may contain a single duplicate generator, namely, the generator that claims the common endpoint. Before concatenation of the lists, one copy of the duplicate generator is deleted. In Figure 5.1, $W(e, g)$ is assembled from $W(e', g)$ and $W(e'', g)$, where e' and e'' are two edges on the boundary of g's cell.

5.2.1. Preparing the cells for propagation. The propagation algorithm that follows assumes that the cell c is convex. When c is nonconvex, which is the case for subcells of an annulus cell, we temporarily break c into convex subcells by adding transparent edges *parallel to* e through the points of nonconvexity, as illustrated by Figure 5.2.

Let $f \neq e$ be another transparent edge on the boundary of c. Our propagation algorithm assumes the following invariant:

> **Propagation invariant**: When a wavefront $W(e, f)$ is propagated for distance $2|f|$ beyond f, it intersects only a constant number of

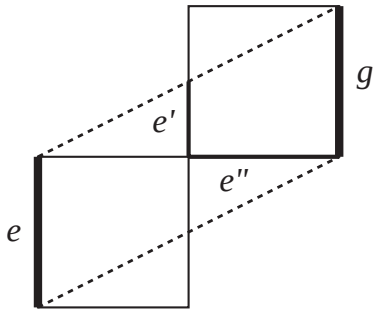

FIG. 5.1. *$W(e, g)$ may reach g via multiple paths.*

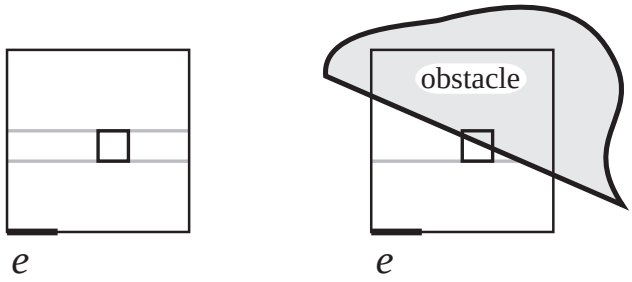

FIG. 5.2. *Preparing nonconvex cells for wave propagation.*

cells of the conforming subdivision of the free space.

The edges of the conforming subdivision $\mathcal{S}'$ already satisfy the propagation invariant, since each edge f is well-covered with parameter 2. However, we need to be more careful in dealing with a cell derived from an annulus. We subdivide each of the newly added, nonconvexity-removing edges into $O(1)$ pieces, each no longer than the edges of $\mathcal{S}$ on the annulus's outer boundary (one-eighth the side length of the outer square, by the uniform edge property of the conforming subdivision). Let H denote the convex hull of e and the inner square of the annulus. If H intersects a newly added edge f, then we further partition $f \cap H$ into pieces no longer than the inner boundary's edges (one-eighth the side length of the inner square). We illustrate this last step in Figure 5.3. Because f is parallel to e, and the inner boundary of the annulus is well separated from the outer boundary (cf. the minimum clearance property of the conforming subdivision $\mathcal{S}$), the total length of edges inside H is proportional to the side length of the inner square. It follows that the partition step creates only $O(1)$ edges.

The subdivided edges satisfy the propagation invariant: for any such edge f, let g' be an edge of c such that $W(e, f)$ leaves c by passing through g'. Edge g' is an edge of $\mathcal{S}'$, the conforming subdivision of free space; it is a fragment of an edge g of $\mathcal{S}$, the conforming subdivision for the vertices. The construction of $\mathcal{S}'$ in Lemma 2.2 ensures that there are $O(1)$ cells of $\mathcal{S}'$ within shortest path distance $2|g|$ of g'. The subdivision of nonconvexity-removing edges guarantees that $|f| \leq |g|$, which implies that the propagation invariant holds for edge f.

5.2.2. Simulating the wavefront propagation across convex cells. So far we have used a wavefront in its static form, namely, as a sequence of generators whose

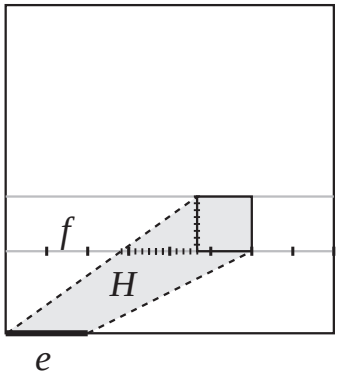

FIG. 5.3. *Subdividing the added edges.*

bisectors intersect an edge in the subdivision. We now describe a dynamic form of the wavefront, in which we track changes in the combinatorial structure of the wavefront as it sweeps across a cell. In particular, we simulate the evolution of a wavefront $W(e)$ as it sweeps across a cell c after entering it through the edge e; the cell c is a convex cell satisfying the propagation invariant. Our simulation detects and processes any bisector events involving the generators of $W(e)$ that may occur inside c. Events are processed in order of increasing distance from s, that is, in simulation time order. Generators are marked as events are processed, though the description below does not necessarily itemize all the marks made.

Let W denote the current dynamic wavefront at any time during the simulation. At the start of the simulation, we have $W = W(e)$, the approximate wavefront that passes through e—it is a list of generators, each claiming some portion of e. Every generator $v \in W$ defines a pair of bisectors with its neighbors in the list. If v is the first generator in the list, then its first bisector is the ray from v through the endpoint of e at v's end of the list; the last bisector for the last generator is defined similarly. If v is an endpoint of e, then there is no first bisector (or last bisector, as appropriate).

To process bisector events in order, we maintain the corresponding generators of W in a priority queue. The *priority* of a generator v is the weighted distance to the point at which the two bisectors defined by v intersect *beyond* e; the priority is infinite if the bisectors do not intersect beyond e. Specifically, if the bisectors defined by v and its neighbors intersect ahead of e, either in c or beyond it, at a point p, then $priority(v) = |\overline{vp}| + d(v, s)$. Our simulation of the wavefront propagation processes these bisector events in order of increasing priority *up to some maximum priority* t_{stop}, which is determined by the shape of c, as explained below. This limit t_{stop} is the minimum of individual $t_{stop}(f)$ values for each transparent edge f on c. Initially, we set $t_{stop} = \infty$ and $t_{stop}(f) = \infty$ for all f. We also initialize an empty set T, which is used to hold generators whose priorities need to be reset after the simulation.

At each step of the simulation, we extract the event with minimum priority from the queue; let v be the generator vertex producing this event. If the event occurs inside c (that is, the intersection point corresponding to the event lies in c), then we delete v from the generator list and recompute the priorities of its neighbors. We mark v in $W(e)$ for the cell c; in addition, we also mark v for a constant number of cells near c to satisfy Rule 3 of section 4.1.2.

If, however, v's event occurs outside c, then we set $priority(v) = \infty$, and add v

to the set T. The generator list is not changed in this case, because we have found the correct intersection between the boundary of c and the wavelet from v, at least locally. If we were to process all the bisector events of W in strict time order, the generators on either side of v might participate in further bisector events outside c before the last bisector event inside c occurred. However, we are not interested in those events now. Setting $priority(v)$ to ∞ avoids processing those events outside c.

We compute the intersection points of the two bisectors defined by v with the boundary of c. If either intersection lies on an opaque edge, or if they lie on different transparent edges with an opaque edge between, mark the generator v for cell c and $O(1)$ neighbors to satisfy Rule 4 of section 4.1.2. If either of the intersection points, say x, lies on a transparent edge, say f, then we update t_{stop} as follows:

$$t_{stop}(f) = \min(t_{stop}(f),\ d(v,s) + |\overline{vx}| + |f|),$$
$$t_{stop} = \min(t_{stop},\ t_{stop}(f)).$$

The second term of the minimum in the first line above is a time at which the wavefront W certainly will have swept over f; it is also no more than $2|f|$ greater than the time at which the wavefront W first contacts f.

When we reach priority t_{stop}, either $t_{stop} = \infty$ and all events inside c have been processed, or $t_{stop} < \infty$ and there is a transparent edge f on the boundary of c with $t_{stop}(f) = t_{stop}$. The definition of $t_{stop}(f)$ ensures that all the bisector events needed to produce $W(e, f)$ have been processed. We compute the static wavefront $W(e, f)$ from the current dynamic wavefront W, as follows. We first locate the endpoints of f in W by searching outward from one of the bisectors in W that intersects f—there is at least one such bisector. At this point we mark the endpoint-claiming generators to satisfy Rule 2. We split the current generator list at the endpoints of f; this breaks up the wavefront into three parts: one that passes through f (in fact, once the generator priorities are reset, this part becomes $W(e, f)$), and the other two that pass on the left and right of f. We continue with the simulation process on the latter two pieces independently, after we have reset t_{stop} in each piece to be the minimum of $t_{stop}(g)$ over the transparent edges g in that piece.

If we stop because $t_{stop} = \infty$, we split the current generator list at all the transparent edge endpoints, producing $W(e, f)$ for each transparent edge f, plus some wavefront pieces that hit only opaque edges.

If no transparent edges remain in some piece, all bisectors in the piece hit an opaque edge. We mark all the generators in that piece for cell c and in $O(1)$ nearby cells to satisfy Rule 4, as well as making all necessary marks for Rules 2 and 3.

When we finish, we reset the priority of each vertex in the temporary set T, based on the bisectors it defines with its neighbors in the (new) list. This ensures that each wavefront fragment $W(e, f)$ has its priorities set properly.

Once we have computed the wavefront $W(e, f)$, we determine the time of first contact between this wavefront and each endpoint of f. Each endpoint p lies in the region claimed by some $v \in W(e)$; v is the first or last generator in $W(e, f)$. The time of first contact is $d(v, s) + |\overline{vp}|$. (Because of visibility constraints, p may not be claimed by any generator in $W(e)$; recall that $W(e, f)$ is constrained to reach f by paths passing through e and contained in $\mathcal{U}(f)$. In this case the time of first contact is infinite.)

The propagation algorithm performs $O(1)$ priority queue and list operations per bisector event processed, plus $O(1)$ per edge of the conforming subdivision. Each operation takes $O(\log n)$ time and space. Because the wavefront data structure is

fully persistent, all the modifications to a single wavefront list $W(e)$ are independent: for example, a wavefront $W(e, f)$ may share generators with a wavefront $W(e, g)$, for $f, g \in \mathit{output}(e)$, but that overlap causes no problems.

We summarize the main result of the preceding discussion in the following lemma.

LEMMA 5.2. *Every bisector event processed in the procedure above either* (1) *lies inside* c, (2) *involves a generator whose region is truncated by an opaque edge of* c, (3) *is associated with* $t_{stop}(f)$ *being set to a finite value for the first time for some transparent edge* f *of* c, *or* (4) *lies within shortest path distance* $2|f|$ *of a transparent edge* f *of* c. *If the number of events is* m, *then the procedure takes* $O(m \log n)$ *time.*

As argued in the proof of Lemma 4.11, our simulation of the wavefront propagation discovers a bisector event for a generator v within a constant number of cells of a true bisector event for v in the shortest path map $SPM(s)$. By the propagation invariant, the bisector events processed during the propagation of a wavefront $W(e)$ across a cell c lie within a constant number of cells near the edge e (cf. Lemma 5.2 (4)). We conclude that a generator v is marked for a constant number of cells in the vicinity of each of the true bisector events involving v. Thus, the total number of events processed and generators marked during the wavefront propagation is $O(n)$. This concludes the proof of our main result.

THEOREM 5.3. *Let* $\mathcal{O}$ *be a family of polygonal obstacles in the plane with pairwise disjoint interiors and a total of* n *vertices. Given a point* s, *we can construct the shortest path map from* s *with respect to* $\mathcal{O}$ *in time* $O(n \log n)$ *and space* $O(n \log n)$.

The shortest path map $SPM(s)$ can be preprocessed for point location, after which a shortest path query from s to any point t in the plane can be answered in time $O(\log n)$ [10, 16]. A shortest path $\pi(s, t)$ can be computed in additional time $O(k)$, where k is the number of edges in the path.

6. Constructing a conforming subdivision. This section contains the proof of Theorem 2.1. It gives an algorithm to construct an α-conforming subdivision for a set V of n points in the plane. The main part of the algorithm constructs a 1-conforming subdivision of size $O(n)$ in $O(n \log n)$ time. The following lemma shows how to transform this subdivision into an α-conforming subdivision of size $O(\alpha n)$ in $O(\alpha n)$ additional time.

LEMMA 6.1. *Let* V *be a set of* n *points, and let* $\mathcal{S}_1$ *be a* 1*-conforming subdivision for* V *of size* $O(n)$. *For any* $\alpha > 1$, *we can build an* α*-conforming subdivision* $\mathcal{S}_\alpha$ *for* V *with complexity* $O(\alpha n)$ *in time* $O(\alpha n)$. *If* $\mathcal{S}_1$ *is a strong* 1*-conforming subdivision, then* $\mathcal{S}_\alpha$ *is a strong* α*-conforming subdivision.*

Proof. Subdivide each edge of $\mathcal{S}_1$ into $\lceil \alpha \rceil$ equal-length pieces. Define the well-covering region of each edge e in $\mathcal{S}_\alpha$ to be the same as the well-covering region in $\mathcal{S}_1$ of the edge of $\mathcal{S}_1$ of which e is a fragment. These operations can be performed in $O(\alpha n)$ time. We show below that the subdivision thus defined satisfies properties (C1)–(C3). Text in [brackets] applies if $\mathcal{S}_1$ is strongly 1-conforming.

- (C1) $\mathcal{S}_\alpha$ has the same set of cells as $\mathcal{S}_1$, so each cell of $\mathcal{S}_\alpha$ contains at most one point of V in its closure.
- (C2) Each internal edge e_α of $\mathcal{S}_\alpha$ is well-covered with parameter α, since it satisfies conditions (W1), (W2), and (W3) [(W3′)]. Let e_1 be the edge of $\mathcal{S}_1$ of which e_α is a fragment. Let $\mathcal{C}_\alpha(e_\alpha)$ be the set of cells of $\mathcal{S}_\alpha$ whose union $\mathcal{U}_\alpha(e_\alpha)$ is the well-covering region of e_α. Define $\mathcal{C}_1(e_1)$ and $\mathcal{U}_1(e_1)$ analogously.
  - (W1) $\mathcal{U}_\alpha(e_\alpha)$ covers the same area as $\mathcal{U}_1(e_1)$, so e_α is contained in its interior.
  - (W2) Each edge of each cell in $\mathcal{C}_1(e_1)$ is divided in $\lceil \alpha \rceil$ pieces in $\mathcal{C}_\alpha(e_\alpha)$, so the total complexity of $\mathcal{C}_\alpha(e_\alpha)$ is $O(\alpha)$.

(W3) [(W3′)]
Let f_α be an edge of $\mathcal{S}_\alpha$ on [or outside] the boundary of $\mathcal{U}_\alpha(e_\alpha)$, and let f_1 be the edge of $\mathcal{S}_1$ from which it is derived. The Euclidean distance between e_α and f_α is at least as large as the distance between e_1 and f_1, which is at least $\max(|e_1|, |f_1|) \geq \max(\alpha|e_\alpha|, \alpha|f_\alpha|)$.

(C3) Well-covering regions in $\mathcal{S}_\alpha$ are the same as in $\mathcal{S}_1$, so each contains at most one vertex of V.

This establishes the lemma. □

Before we describe the construction of the 1-conforming subdivision, we need a few definitions.

6.1. The *i*-boxes and *i*-quads. We fix a Cartesian coordinate system in the plane. For any integer i, an ith-order grid in this coordinate system is the arrangement of all lines $x = k2^i$ and $y = k2^i$, where k ranges over all integers. Each face of this grid is a square of size $2^i \times 2^i$, whose lower-left corner lies at a point $(k2^i, l2^i)$ for a pair of integers k, l. We call each such face an *i-box*.

Any 4×4 array of i-boxes is called an *i-quad*. Though an i-quad has the same size as an $(i+2)$-box, it is not necessarily an $(i+2)$-box because it may not be a face in the $(i+2)$-order grid. The four nonboundary i-boxes of an i-quad form its *core*; that is, the core of an i-quad is a 2×2 array of i-boxes. Observe that an i-box b may have up to four i-quads that contain b in their cores.

Our algorithm for building a 1-conforming partition of the point set V is a bottom-up procedure. The algorithm simulates a growth process in which we grow a square box around each data point, until the entire plane is covered by these boxes. The simulation works in discrete *stages* numbered $-2, 0, 2, 4, \ldots$. It produces a subdivision of the plane into orthogonal cells. The key object associated with a data point p in stage i is an i-quad containing p in its core. In fact, the following stronger condition holds inductively: each $(i-2)$-quad constructed in stage $(i-2)$ lies in the core of some i-quad constructed in stage i.

In each stage, we maintain only a minimal set of quads. The set of quads in stage i is denoted $\mathcal{Q}(i)$. This set is partitioned into equivalence classes under the transitive closure of the *overlap* relation—two quads q and q' are in the same equivalence class if there is a sequence of quads $q = q_0, q_1, \ldots, q_m = q' \in \mathcal{Q}(i)$ such that q_j and q_{j+1} overlap (have a common interior point) for all $j = 0, 1, \ldots, m-1$. Let $\{S_1(i), \ldots, S_k(i)\}$ denote the partition of $\mathcal{Q}(i)$ into equivalence classes in the ith stage, and let $\equiv_i$ denote the equivalence relation.

The region of the plane covered by quads in one class of this partition is called a *component*. Each component in stage i is either an i-quad or the union of i-quads. We can classify each component as either a *simple* component or a *complex* component. A component at stage i is simple if (1) its outer boundary is an i-quad and (2) it contains exactly one $(i-2)$-quad of $\mathcal{Q}(i-2)$ in its interior. Otherwise, the component is complex.

6.2. The invariants. As the algorithm progresses, we draw the boundaries of certain components. Each boundary edge is a straight line segment, parallel to one of the axes, and together these edges subdivide the plane into orthogonal cells. The critical property of our subdivision is the following *conforming property*:

> **Invariant 1:** For any edge e and cell c of the subdivision, c has an interior point within distance $|e|$ of e if and only if c and e are

incident (their closures intersect). Thus there are at most six cells within distance $|e|$ of any edge e.

Our algorithm draws edges of increasing lengths, and so we never need to subdivide previously drawn edges inside a component. In order to help maintain Invariant 1, we will also enforce the following auxiliary invariant.

> **Invariant 2:** The boundary of each complex component in stage i is subdivided into edges of length 2^i that are aligned with the ith-order grid.

Our algorithm does not actually draw the outer boundary of a simple component until just before it merges with another component to form a complex component. Indeed, this is crucial to ensure that the final subdivision has only $O(n)$ size, and not $\Theta(n \log A)$, where A is the maximum aspect ratio of a triangle in the Delaunay triangulation of the input points [3].

There are two main parts to our algorithm—one involves growing the $(i-2)$-quads of stage $(i-2)$ to i-quads of stage i, and the other involves computing and maintaining the equivalence classes and drawing subdivision edges to satisfy Invariants 1 and 2. These tasks are performed by procedures *growth* and *build-subdivision*, respectively. We postpone the discussion of *growth* till later, but introduce the necessary terminology to allow us to describe *build-subdivision*.

Given an i-quad q, $\mathit{growth}(q)$ is an $(i+2)$-quad containing q inside its core. For a family S of i-quads, $\mathit{growth}(S)$ is a minimal set of $(i+2)$-quads satisfying the following:

$$\forall\, q \in S,\ \exists\, \bar{q} \in \mathit{growth}(S) \quad \text{s.t.} \quad \bar{q} = \mathit{growth}(q).$$

As mentioned earlier, up to four $(i+2)$-quads may qualify for the role of $\mathit{growth}(q)$. We will describe later how the procedure *growth* chooses $\mathit{growth}(q)$, but for now we will use $\mathit{growth}(q)$ as a unique $(i+2)$-quad returned by the procedure *growth*. We also use the notation $\bar{q}$ to denote $\mathit{growth}(q)$.

6.3. Details of build-subdivision. By proper scaling and translation of the plane, we assume that either the horizontal or the vertical distance between any two points in V is at least 1, and no point coordinate is a multiple of $1/4$. For every point $p \in V$, we compute a (-2)-quad with p in the upper-left (-2)-box of its core; this choice ensures that quads of different points are disjoint. These quads form the initial set of quads $\mathcal{Q}(-2)$—each quad in $\mathcal{Q}(-2)$ forms its own singleton component under the equivalence class in stage -2. We regard all quads in $\mathcal{Q}(-2)$ as simple components. We draw a (-2)-box around each point p. Each of these (-2)-boxes is contained in the core of its (-2)-quad. (The (-2)-quads are *not* drawn.) Invariants 1 and 2 are both clearly satisfied at this stage. The pseudo-code below describes the details of the algorithm *build-subdivision*. This pseudo-code is correct, but not particularly efficient; an efficient implementation is presented in section 6.5.

ALGORITHM *build-subdivision*

1. Increment i : $\quad i = i + 2$.
2. ($*$ *Compute* $\mathcal{Q}(i)$ *from* $\mathcal{Q}(i-2)$. $*$)
   (a) Initialize $\mathcal{Q}(i) = \emptyset$.
   (b) **for** each equivalence class S of $\mathcal{Q}(i-2)$ **do**
   $\mathcal{Q}(i) = \mathcal{Q}(i) \cup \mathit{growth}(S)$.
   (c) **for** every pair of i-quads $q, q' \in \mathcal{Q}(i)$ **do**
   if $q \cap q' \neq \emptyset$, set $q \equiv_i q'$.
   (d) Extend $\equiv_i$ to an equivalence relation by transitive closure, and compute the equivalence classes.
3. ($*$ *Process simple components of* $\equiv_{i-2}$ *that are about to merge with some other component.* $*$)
   for each $q \in \mathcal{Q}(i-2)$ **do**
   (a) Let $\bar{q} = \mathit{growth}(q)$ as computed in Step 2.
   (b) **if** q *is a simple component of* $\mathcal{Q}(i-2)$
   but $\bar{q}$ *is not a simple component of* $\mathcal{Q}(i)$ **then**
   Draw the boundary box of q and subdivide each of its sides into four edges at the $(i-2)$-order grid lines.
4. ($*$ *Process complex components.* $*$)
   for each equivalence class S of $\mathcal{Q}(i)$ **do**
   Let $S' = \{q \in \mathcal{Q}(i-2)$ s.t. $\mathit{growth}(q) \in S\}$.
   if $|S'| > 1$ **then** ($*$ S *is complex* $*$)
   (a) Let $R_1 = \cup_{q \in S'}$ {the core of $\mathit{growth}(q)$}.
   (b) Let $R_2 = \cup_{q \in S'}$ {the region covered by q}.
   (c) Draw $(i-2)$-boxes to fill the region between the boundaries of R_1 and R_2.
   (d) Draw i-boxes to fill the region between the boundaries of R_1 and S; break each cell boundary with an endpoint incident to R_1 into four edges of length 2^{i-2}, to satisfy Invariant 1.

endwhile

LEMMA 6.2. *The subdivision computed by the algorithm build-subdivision satisfies Invariants* 1 *and* 2.

Proof. We prove by induction that the invariants hold inside the family of quads $\mathcal{Q}(i)$, for all i. The initial family of quads $\mathcal{Q}(-2)$ clearly satisfies the two invariants. We show that no step of the algorithm *build-subdivision* ever violates these invariants. Step 2 computes $\mathit{growth}(S)$ for each equivalence class of $\mathcal{Q}(i-2)$ and then computes $\mathcal{Q}(i)$. No new edges are drawn in this step.

The only edges drawn in Step 3 are on the boundaries of simple components. Let q be an $(i-2)$-quad that is a simple component of $\mathcal{Q}(i-2)$. By definition, the single $(i-4)$-quad of $\mathcal{Q}(i-4)$ contained in q lies in its core and thus is separated from the outer boundary of q by a gap of at least 2^{i-2} on all sides. Hence the edges already drawn in the core satisfy Invariant 1: they have length no more than 2^{i-2} (actually

2^{i-4}, except when $i = 0$), and are separated from the boundary of q by a gap of at least 2^{i-2}. We draw the boundary of q in Step 3; since any previously drawn edges within q lie in its core, the new edges satisfy Invariant 1. Invariant 2 holds vacuously.

Step 4 subdivides the region covered by each complex component S. Again, the boundary of S is separated from any components of $\mathcal{Q}(i-2)$ contained in it by a gap at least the width of an i-box. Step 4(c) adds $(i-2)$-boxes to pad the region covered by $\mathcal{Q}(i-2)$ out to the boundaries of i-boxes. By Invariant 2, the newly drawn boxes satisfy Invariant 1 with respect to the previously drawn edges; they clearly satisfy Invariant 1 with respect to each other's edges. Step 4(d) packs the area between the core and the boundary of S with i-boxes, and breaks the segments incident to previously drawn cells into four pieces to guarantee Invariant 1 with respect to those cells. (The previously drawn edges on the core boundary have length 2^{i-2}, so by induction the cells incident to them have side lengths at least 2^{i-2}. It follows that the cells inside the core satisfy Invariant 1 with respect to the newly drawn segments of length 2^{i-2}.) The segments on the boundary of S are unbroken, so Invariant 2 holds at the next stage of the algorithm. This completes the proof. □

LEMMA 6.3. *The subdivision produced by build-subdivision has size $O(n)$.*

Proof. We show that the algorithm draws a linear number of edges altogether. The number of edges drawn in Step 3 is proportional to the number drawn in Step 4—we draw a constant number of edges in Step 3 for each simple component that merges to form a complex component at the next stage. The number of edges drawn in Step 4 for a complex component S is $O(|S'|)$, the number of $(i-2)$-quads whose growths constitute S. The key observation in proving the linear bound is that the total size of $\mathcal{Q}$ decreases every two stages by an amount proportional to the total number of quads in complex components. This fact, which we prove in the next subsection (Lemma 6.5), can be expressed as follows: If e_i edges are drawn in stage i, then

$$|\mathcal{Q}(i+2)| \;\leq\; |\mathcal{Q}(i-2)| \;-\; \Theta(e_i).$$

That is, there exists an absolute constant β such that

$$\beta e_i \;\leq\; |\mathcal{Q}(i-2)| - |\mathcal{Q}(i+2)|.$$

If we sum this inequality over all even $i \geq 0$, the right-hand side telescopes, and we obtain

$$\beta \sum_i e_i \;\leq\; |\mathcal{Q}(-2)| + |\mathcal{Q}(0)| - 2.$$

Since $|\mathcal{Q}(-2)| = n$, we have $\sum_i e_i \leq (2n-2)/\beta$. The total number of edges in the subdivision is $O(n)$. □

LEMMA 6.4. *The subdivision that build-subdivision produces is strongly* 1*-conforming and satisfies the following additional properties:* (1) *all edges of the subdivision are horizontal or vertical,* (2) *each face is either a square or a square-annulus (with subdivided boundary),* (3) *each annulus has the minimum clearance property,* (4) *each face has the uniform edge property, and* (5) *every point of V is contained in a square face.*

Proof. Strong 1-conformity is a consequence of Invariant 1, as we now show. Condition (C1) is trivially true, since each point is initially enclosed by a square. To establish well-covering (Condition (C2)), let $I(e)$ be the union of the (at most six) cells incident to an edge e. By Invariant 1, the distance from e to any edge outside or

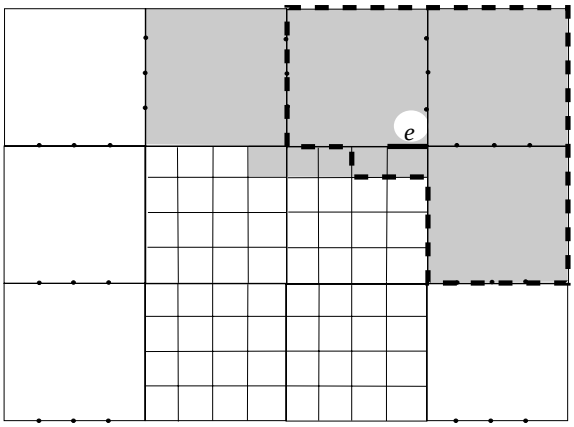

FIG. 6.1. *A well-covering region $\mathcal{U}(e)$. The boundary of $I(e)$ is shown dashed.*

on the boundary of $I(e)$ is at least $|e|$. Edge e may be collinear with other edges of the two cells on whose boundary it lies. We define $\mathcal{C}(e)$ to be the set of cells incident to any of these collinear edges; $\mathcal{U}(e)$, the union of these cells, is a superset of $I(e)$. See Figure 6.1. Because the two cells with e as a boundary edge meet only along edges collinear with e, this definition of $\mathcal{U}(e)$ means that for any edge f on or outside the boundary of $\mathcal{U}(e)$, $I(f)$ does not contain both cells incident to e. But this implies, by Invariant 1, that e is on or outside the boundary of $I(f)$, and hence the distance from e to f is at least $|f|$. Edge e certainly lies in the interior of $\mathcal{U}(e)$ (Condition (W1)). Condition (W2) follows because $\mathcal{C}(e)$ is the union of $I(e')$ for $O(1)$ edges e' collinear with e, $|I(e')| \leq 6$ for each e', and each cell has constant complexity. As noted above, the minimum distance between e and any edge f on or outside the boundary of $\mathcal{U}(e)$ is at least $\max(|e|, |f|)$, which establishes Condition (W3′). Condition (C3) follows from the observation that a well-covering region $\mathcal{U}(e)$ includes a vertex v of V if and only if e is an edge of the square containing v. This is because each vertex-containing square is the inner square of a square-annulus in the subdivision. No edge belongs to two such squares, so Condition (C3) holds.

Properties (1)–(5) hold by construction. This completes the proof. □

6.4. The algorithm *growth*(). In this subsection, we describe our algorithm for computing $growth(S)$ for a set of i-quads S, and prove that the number of quads decreases every two stages by an amount proportional to the total complexity of the complex components. Let $S \subset \mathcal{Q}(i)$ be a set of i-quads forming a complex component under the equivalence relation $\equiv_i$. Recall that $growth(S)$ is a minimal set of $(i+2)$-quads such that each i-quad of S lies in the core of some $(i+2)$-quad in $growth(S)$. We will show that

$$|growth(growth(S))| \;\leq\; \kappa|S|,$$

for an absolute constant $0 < \kappa < 1$. The pseudo-code below describes an unoptimized version of our algorithm for computing $growth(S)$. The algorithm works by building a graph on the quads in S.

In this algorithm, Step 1 builds a graph whose nodes are the i-quads of S; two quads q_1 and q_2 have an edge between them if their union $q_1 \cup q_2$ lies in some 2×2 array of $(i+2)$-boxes. The maximum node degree of this graph is $O(1)$ since only a

ALGORITHM *growth*(S)

0. Set $growth(S) = \emptyset$.
1. **for** each pair of quads $q_1, q_2 \in S$ **do**
   if $q_1 \cup q_2$ can be contained in a 2×2 array of $(i+2)$-boxes, **then**
   Put an edge between q_1 and q_2.
2. Compute a maximal matching in the graph computed in Step 1.
3. **for** each edge (q_1, q_2) in the maximal matching **do**
   Choose an $(i+2)$-quad $\bar{q}$ containing q_1, q_2 in its core.
   Set $growth(q_1) = growth(q_2) = \bar{q}$, and add $\bar{q}$ to $growth(S)$.
4. **for** each unmatched quad $q \in S$ **do**
   Set $growth(q) = \bar{q}$, where $\bar{q}$ is an $(i+2)$-quad containing q in its core.
   Add $\bar{q}$ to $growth(S)$.

constant number of i-quads can touch any i-quad q. Thus, a maximal matching in this graph has $\Theta(|E|)$ edges. Each i-quad at stage i maps to an $(i+2)$-quad at stage $(i+2)$. Since each matching edge corresponds to two i-quads that map to the same $(i+2)$-quad, it clearly follows that

$$|growth(S)| \;=\; |S| - \Theta(|E|).$$

The crucial fact to prove is that $|E|$ is a constant fraction of $|S|$ at stage $(i+2)$.

LEMMA 6.5. *Let $S \subset \mathcal{Q}(i)$ be a set of two or more i-quads such that $growth(S)$ is a complex component under the equivalence relation $\equiv_{i+2}$. Then $|growth(growth(S))| \leq \kappa|S|$, for an absolute constant $0 < \kappa < 1$.*

Proof. We show that either $|growth(S)| < (3/4)|S|$, or at least half of the quads of $growth(S)$ can be contained in a 2×2 array of $(i+2)$-boxes with some other quad of $growth(S)$.

If $|growth(S)| < (3/4)|S|$, then we are done, because the following inequality obviously holds: $|growth(growth(S))| \leq |growth(S)| \leq (3/4)|S|$. Therefore, suppose that $|growth(S)| \geq (3/4)|S|$. Then at least half the i-quads of S are not matched in Step 2 of the function *growth*(), and their growths contribute more than half of the $(i+2)$-quads of $growth(S)$. Consider one such i-quad $q \in S$. Since S is a nonsingleton equivalence class, there exists another i-quad $q' \in S$ that overlaps q. Let $\bar{q} = growth(q)$ and $\bar{q}' = growth(q')$. By assumption, $\bar{q} \neq \bar{q}'$. The cores of $\bar{q}$ and $\bar{q}'$ both contain the overlap region $q \cap q'$, so the cores must overlap. Therefore both cores are contained within a 3×3 array of $(i+2)$-boxes, and both the $(i+2)$-quads $\bar{q}$ and $\bar{q}'$ are contained within a 5×5 array of $(i+2)$-boxes. This ensures that $\bar{q}$ and $\bar{q}'$ are joined by an edge in the graph of $growth(S)$: any two $(i+2)$-quads whose bounding box is contained in a 5×5 array of $(i+2)$-boxes can be covered by a 2×2 array of $(i+4)$-boxes. Hence the number of edges in the maximal matching of $growth(S)$ is $\Omega(|S|)$, which proves the inequality $|growth(growth(S))| \leq \kappa|S|$ for some $\kappa < 1$. □

Since the number of edges drawn at stage i, call it e_i, is proportional to the number of $(i-2)$-quads whose growths belong to complex components, the preceding lemma establishes the earlier claim that

$$|\mathcal{Q}(i+2)| \;\leq\; |\mathcal{Q}(i-2)| \;-\; \Theta(e_i).$$

For any $q, q' \in S$, we have $growth(q) = growth(q')$ only if q and q' are touching—their closures intersect—otherwise q and q' cannot be contained in the core of the

same $(i+2)$-quad. We use this fact to implement the procedure *growth*(S) to run in time $O(|S| \log |S|)$: each quad of S touches at most a constant number of other quads, and we can compute which quads touch using an $O(|S| \log |S|)$ plane sweep algorithm [22]. From the set of touching pairs we can compute the graph edges in Step 1 of *growth*(S) in $O(|S|)$ additional time. All other steps of *growth*(S) take time proportional to the graph size, which is $O(|S|)$.

6.5. An $O(n \log n)$ implementation of build-subdivision. In order to keep the time complexity of *build-subdivision* independent of the aspect ratio of the points, we process a simple component only when it is about to merge with another component. In other words, the amount of processing is proportional to the number of boundary edges drawn at any stage. Except for Step 2(b), which computes growths, and Step 2(c), which detects overlapping i-quads, all other steps can be implemented to run in time proportional to the number of edges drawn in the subdivision. (Steps 3 and 4 use the adjacency information computed in Step 2(c) to run in linear time.)

We maintain the simple components and the complex components of $\mathcal{Q}(i)$ in two separate sets. We compute *growth*(S) explicitly for the complex components, but only implicitly for the simple components. Suppose that q is a singleton component of $\mathcal{Q}(i-2j)$, and *growth*$^j(q) \in \mathcal{Q}(i)$ is the result of applying the *growth*() operator j times. If *growth*$^k(q)$ is simple for all positive $k \leq j$, then *growth*$^j(q)$ can be determined in constant time from q using the floor operation. The set of simple components of $\mathcal{Q}(i)$ is maintained as a set of singletons from earlier stages; when we determine that a simple component is about to merge with another component (Step 2(c)), we compute the simple component explicitly. The transitive closure can be computed in time proportional to the total size of the complex components, which is proportional to the number of edges drawn at this stage. Since the final subdivision has size $O(n)$, all the work except that in Steps 2(b) and 2(c) takes a linear amount of time. In the following we show how to use a minimum spanning tree algorithm to implement Step 2(c) in $O(n \log n)$ time.

6.5.1. The merging of i-quads. Before we present the algorithm, we discuss the distance properties satisfied by points that lie in the same equivalence class in stage i. We say that a quad q is a *containing i-quad* of a point $u \in V$ if $q \in \mathcal{Q}(i)$ and u lies in q's core. A point u *belongs* to an equivalence class $S \in \mathcal{Q}(i)$ if there is a containing i-quad of u in S.

LEMMA 6.6. *Let u be a point of V and let $q \in \mathcal{Q}(i)$ be a containing i-quad of u. Then the minimum L_∞ distance between u and the outer boundary of q is 2^i.*

Proof. The lemma depends on the property that u lies in the core of q. Since q has side length 2^{i+2}, and u lies at least a quarter of this distance away from the outer boundary, the lemma follows. □

In the following, the notation $d_\infty(u, v)$ denotes the distance between the points u and v under the L_∞ norm.

LEMMA 6.7. *Let u and v be two points of V that belong to different equivalence classes of $\mathcal{Q}(i)$. Then $d_\infty(u, v) > 2 \times 2^i$.*

Proof. Let q_u and q_v be two containing i-quads for u and v, respectively. Since u and v lie in different equivalence classes, these i-quads do not intersect. By Lemma 6.6, each of the points lies at least a distance 2^i away from the outer boundaries of their i-quads, which immediately gives the lower bound on $d_\infty(u, v)$ stated in the lemma. □

LEMMA 6.8. *Let $u, v \in V$ be two points and let q_u, q_v, respectively, be two i-quads of $\mathcal{Q}(i)$ containing them. If $q_u \cap q_v \neq \emptyset$, then $d_\infty(u, v) < 6 \times 2^i$.*

Proof. By Lemma 6.6, the maximum distance between u and the outer boundary of q_u is at most 3×2^i. The same holds for v and q_v, which implies the upper bound on $d_\infty(u, v)$. □

6.5.2. Minimum spanning trees. Let V_S be the set of points in the core of some component $S \in \mathcal{Q}(i)$. Our implementation of *build-subdivision* is based on the observation that the longest edge of the L_∞ minimum spanning tree of V_S has length less than 6×2^i. To make this observation more precise, we define $G(i)$ to be the graph on V containing exactly those edges whose L_∞ length is at most 6×2^i, and define $MSF(i)$ to be the minimum spanning forest of $G(i)$.

LEMMA 6.9. *The points contained in any component of $\mathcal{Q}(i)$ belong to a single tree of $MSF(i)$.*

Proof. Let S be a component of $\mathcal{Q}(i)$. By Lemma 6.8, the points contained in S can be linked by a tree with edges shorter than 6×2^i. For any bipartition of the points of V_S, the minimum weight edge linking the two subsets is shorter than 6×2^i. The minimum spanning tree of V_S has all edges shorter than 6×2^i, and therefore V_S belongs to a single tree of $MSF(i)$. □

LEMMA 6.10. *If i-quads q_1 and q_2 belong to different components of $\mathcal{Q}(i)$, then their points belong to different trees of $MSF(i-2)$.*

Proof. Every edge from a point in q_1's component to any point outside that component has length greater than 2×2^i, by Lemma 6.7. The points of quads q_1 and q_2 are in the same tree of $MSF(i-2)$ only if every bipartition of V that separates the points of q_1 from those of q_2 is bridged by an edge of length less than $6 \times 2^{i-2}$. But the bipartition separating the points of q_1's component of $\mathcal{Q}(i)$ from the rest of V has bridge length greater than $2 \times 2^i > 6 \times 2^{i-2}$. □

Our algorithm is based on an efficient construction of $MSF(i)$ for all i such that $MSF(i) \neq MSF(i-2)$. The standard algorithm for computing a geometric minimum spanning tree is well suited to our needs. We compute the L_∞ Delaunay triangulation of V in $O(n \log n)$ time [6], then run Kruskal's MST algorithm [8]. Kruskal's algorithm inserts the $O(n)$ Delaunay edges into the current minimum spanning forest in sorted order from shortest to longest; any edge that joins two trees of the forest is retained, and all other edges are dropped. For each edge e added to the forest, we compute $k = 2\lceil \frac{1}{2} \log_2(|e|/6) \rceil$, which determines the stage k at which e is added to $MSF(k)$. By stopping just before each stage change, we produce $MSF(i)$ for each even i such that $MSF(i) \neq MSF(i-2)$ in $O(n \log n)$ total time.

The implementation of *build-subdivision* below replaces Steps 1 and 2 of *build-subdivision* with more efficient code based on minimum spanning trees. First, we process only stages at which something happens: $MSF(i)$ changes, or there are complex components of $\mathcal{Q}(i)$ whose *growth* computation is nontrivial. (This optimization is not usually significant; it matters only if the ratio of maximum to minimum point separation is greater than 2^n.) Second, we compute $growth(S)$ only for complex components and for simple components that will merge with another component soon, and compute the equivalence classes of $\mathcal{Q}(i)$ only for this same set of quads. Simple components that are well separated from others are not involved in the computation.

The running time of this algorithm is dominated by the $O(k \log k)$ required for a plane sweep [22] of $k = |\mathcal{Q}(i, T)|$ quads in Step 2(c–d). There are $O(k)$ quads in complex components either in $\mathcal{Q}(i, T)$ or in $\mathcal{Q}(i+2, T)$, so there are $O(k)$ edges drawn for these quads at stage i or $i+2$. We amortize this cost by charging $O(\log k)$ per edge of the subdivision, getting $O(n \log n)$ time overall. The computation of the Delaunay triangulation and the minimum spanning forest contributes a term of the

IMPLEMENTATION OF *build-subdivision*

For each $T \in MSF(i)$, maintain the corresponding set of i-quads in $\mathcal{Q}(i)$ that are the containing quads for the vertices of T. Call this set $\mathcal{Q}(i, T)$.

Initialize $i = -2$. Initialize $MSF(-2)$ to be a forest of singleton vertices. For each vertex $v \in V$, $\mathcal{Q}(-2, \{v\})$ is a singleton quad with v in its core.

Maintain a set $\mathcal{N}$ of trees in $MSF(i)$ such that for each $T \in \mathcal{N}$, $|\mathcal{Q}(i, T)| > 1$; that is, T's component is not a singleton quad. Initialize $\mathcal{N} = \emptyset$.

while $|\mathcal{Q}(i)| > 1$ **do**
  $i_{old} = i$;
  if $|\mathcal{N}| > 0$ **then** $i = i + 2$
  else Set i to the smallest even $i' > i$ such that $MSF(i') \neq MSF(i)$.
  foreach edge e of $MSF(i)$ not in $MSF(i_{old})$ **do**
    Let T_1 and T_2 be the trees linked by e.
    foreach $T_x \in \{T_1, T_2\}$ **do**
      if $T_x \in \mathcal{N}$ **then**
        Remove T_x from $\mathcal{N}$.
      else
        Compute the singleton $(i-2)$-quad in $\mathcal{Q}(i-2, T_x)$.

same asymptotic magnitude.

We have established the following lemma.

LEMMA 6.11. *Algorithm build-subdivision can be implemented to run using* $O(n \log n)$ *standard operations on a real RAM, plus* $O(n)$ *floor and base-2 logarithm operations.*

Lemmas 6.1, 6.3, 6.4, and 6.11 establish the main theorem of this section.

CONFORMING SUBDIVISION THEOREM. *For any* $\alpha \geq 1$*, every set of* n *points in the plane admits a strong* α*-conforming subdivision of* $O(\alpha n)$ *size satisfying the following additional properties:* (1) *all edges of the subdivision are horizontal or vertical,* (2) *each face is either a square or a square-annulus (with subdivided boundary),* (3) *each annulus has the minimum clearance property,* (4) *each face has the uniform edge property, and* (5) *every data point is contained in the interior of a square face. Such*

a subdivision can be computed in time $O(\alpha n + n \log n)$.

7. Extensions and concluding remarks. We have presented a worst-case optimal algorithm for the planar, Euclidean shortest path problem. Our algorithm uses the wavefront propagation method and builds a shortest path map, which can be used to answer shortest path queries from a fixed source in logarithmic time. We introduced several new ideas and techniques in order to implement the wavefront propagation optimally. Perhaps the most original contribution of our paper is the idea of a conforming subdivision—it is a quad-tree-like subdivision that seems especially useful for line segments. We expect this subdivision to find other applications in computational geometry.

Our wavefront simulation is highly "local" in the sense that all interactions among bisectors occur within "small" regions (well-covering regions). Obviously, we still require the bisectors to satisfy some global properties, such as the ones stated in Lemmas 3.2 and 3.3, but the locality of processing allows our algorithm to extend to several more general instances of the shortest path problem. These include generalizations involving the shape and number of sources. We sketch below the modifications necessary for some of these extensions.

Nonpoint sources. When the source is not a point, but rather a more complex geometric shape such as a line segment or a disk, then the initial wavelet originating from the source has a more complicated form: it is the Minkowski sum of a disk and the source. However, the intermediate generators are still just the obstacle vertices, and they generate circular wavelets. Thus, except for initialization and propagating the initial wavelets, the rest of the wavefront propagation algorithm does not change. The initialization involves computing "direct" distances to all the cells that are within a constant number of cells of the source, which can be done easily in $O(n \log n)$ time.

Multiple sources. Computing shortest paths in the presence of multiple sources is equivalent to computing a "geodesic Voronoi diagram": a partition of the free space into regions so that all points in a region have the same nearest source and the combinatorial structure of the shortest path to that source is also the same for all points in the region. To help visualize the process, we might imagine that the wavefront of each source has a distinct color; in the end, the region claimed by each source acquires the color of its source.

During the initialization, we compute direct distances between each source and the corners of its well-covering regions; if well-covering regions overlap, we use the Voronoi diagram of the sources to decide which corner is closer to which source. Again, this can be done in $O(n \log n)$ time initially. We maintain a common priority queue for all the sources, and as each obstacle vertex is claimed, it acquires the color of its claiming source. Knowing the color of each generator helps us determine whether a bisector is bounding two regions belonging to the same source or two different sources. In all other respects, the processing of bisectors in cells is the same as in the original algorithm.

Other generalizations. The ideas mentioned above also work for multiple sources with specified release times. In particular, each source has associated with it an initial "delay" and its wavelet is issued after the specified delay. The delays are easily handled by our algorithm: just add the delay time of each source to its initial priority queue entries. The rest of the algorithm proceeds as before.

Open problems. Finally, we conclude with two open problems.

1. Can the space complexity of our algorithm be reduced to linear?
2. Does our wavefront propagation method extend to the shortest path problem on the surface of a convex polytope?

Acknowledgment. We are grateful to an anonymous referee for a thoughtful and thorough review; the referee's suggestions significantly improved the presentation of our results.

TIGHT LOWER BOUNDS FOR *st*-CONNECTIVITY ON THE NNJAG MODEL*

JEFF EDMONDS†, CHUNG KEUNG POON‡, AND DIMITRIS ACHLIOPTAS§

Abstract. Directed *st*-connectivity is the problem of deciding whether or not there exists a path from a distinguished node s to a distinguished node t in a directed graph. We prove a time–space lower bound on the probabilistic NNJAG model of Poon [*Proc. 34th Annual Symposium on Foundations of Computer Science*, Palo Alto, CA, 1993, pp. 218–227]. Let n be the number of nodes in the input graph and S and T be the space and time used by the NNJAG, respectively. We show that, for any $\delta > 0$, if an NNJAG uses space $S \in O(n^{1-\delta})$, then $T \in 2^{\Omega(\log^2(n/S))}$; otherwise $T \in 2^{\Omega(\log^2(\frac{n \log n}{S})/\log\log n)} \times (nS/\log n)^{1/2}$. (In a preliminary version of this paper by Edmonds and Poon [*Proc. 27th Annual ACM Symposium on Theory of Computing*, Las Vegas, NV, 1995, pp. 147–156.], a lower bound of $T \in 2^{\Omega(\log^2(\frac{n \log n}{S})/\log\log n)} \times (nS/\log n)^{1/2}$ was proved.) Our result greatly improves the previous lower bound of $ST \in \Omega(n^2/\log n)$ on the JAG model by Barnes and Edmonds [*Proc. 34th Annual Symposium on Foundations of Computer Science*, Palo Alto, CA, 1993, pp. 228–237] and that of $S^{1/3}T \in \Omega(n^{4/3})$ on the NNJAG model by Edmonds [*Time-Space Lower Bounds for Undirected and Directed ST-Connectivity on JAG Models*, Ph.D. thesis, University of Toronto, Toronto, ON, Canada, 1993]. Our lower bound is tight for $S \in O(n^{1-\delta})$, for any $\delta > 0$, matching the upper bound of Barnes et al.[*Proc. 7th Annual IEEE Conference on Structure in Complexity Theory*, Boston, MA, 1992, pp. 27–33]. As a corollary of this improved lower bound, we obtain the first tight space lower bound of $\Omega(\log^2 n)$ on the NNJAG model. No tight space lower bound was previously known even for the more restricted JAG model.

1. Introduction.

The *st*-connectivity problem (STCON) is a fundamental problem in computer science, as it is the natural abstraction of many search processes. Its space and time–space complexities are of special interest because there are many applications such as game searching, program verification, and databases in which the size of the input graph is too large compared to the size of the internal memory of a machine. In these applications algorithms that run in small space, and preferably in small time simultaneously, are required. STCON is also important in computational complexity theory because it is complete for NSPACE($\log n$) under logarithmic space reductions. Both STCON and the corresponding problem for undirected graphs, USTCON, are hard for DSPACE($\log n$) since any problem solvable deterministically in logarithmic space can be reduced to either problem. (See Lewis and Papadimitriou [22] and Savitch [28].) Thus, showing that there is no deterministic logarithmic space algorithm for STCON that would separate the classes DSPACE($\log n$) and NSPACE($\log n$),

while devising such an algorithm would prove that $\mathrm{DSPACE}(f(n)) = \mathrm{NSPACE}(f(n))$ for any space-constructible function $f(n) \in \Omega(\log n)$ [28]. STCON is also a candidate problem for separating the classes of SC and NC [20]. Below we mention the previous works that are most relevant to our paper. For more information on graph connectivity, we refer the reader to the beautiful survey paper by Wigderson [31].

1.1. Previous work. The most commonly used algorithms for *st*-connectivity, breadth- and depth-first search run in optimal time $O(m+n)$ and use $O(n \log n)$ space. At the other extreme, Savitch [28] provided an algorithm that uses $O(\log^2 n)$ space and requires time exponential in its space bound (i.e., time $n^{O(\log n)}$). Tompa [30] showed that STCON cannot be solved in polynomial time and sublinear space simultaneously by the repeated squaring method. However, Barnes et al. [3] gave a polynomial time algorithm for STCON that uses space $S \in n/2^{\Theta(\sqrt{\log n})}$, providing the first polynomial time, sublinear space algorithm. This shows that the repeated squaring method is too restricted. In fact, their algorithm implies a general time–space upper bound of $T \in 2^{O(\log^2(\frac{n \log n}{S}))} \times n^3$ for $S \in \Omega(\log^2 n)$.

A natural question is whether the upper bounds of Savitch and Barnes et al. are tight. Unfortunately, proving nontrivial lower bounds for natural decision problems on any general model of computation, such as Turing machines and branching programs, appears to be beyond the reach of current techniques. Thus, it is natural to consider *structured* computational models [12] whose basic operations are based on the structure of the input, as opposed to being based on the bits in the input's encoding. A natural structured model for STCON is the "jumping automaton for graphs," or JAG, introduced by Cook and Rackoff [13]. A JAG moves a set of pebbles on the graph. There are two basic operations—moving a pebble along a directed edge in the graph and jumping a pebble from its current location to the node occupied by another pebble. Although the JAG model is structured, it is powerful enough to simulate most known algorithms for STCON and related problems. For example, depth-first and breadth-first search, random walks [1], and the algorithms of Savitch and Barnes et al. can all be simulated on a JAG (see [13, 27]). To our kowledge, all known deterministic or probabilistic algorithms for directed STCON are implementable on a JAG. However, it is not clear how a nondeterministic JAG can simulate Immerman's and Szelepcsényi's $O(\log n)$-space algorithm for directed *st*-nonconnectivity ($\overline{\text{STCON}}$) [19, 29]. This motivated Poon [26] to introduce the more general node-named JAG (NNJAG) model, an extension of the JAG, where the computation is allowed to depend on the names of the nodes on which the pebbles are located. Using this added power, Poon [26] showed how to simulate the Immerman/Szelepcsényi algorithm on a nondeterministic NNJAG.

Cook and Rackoff [13] proved a lower bound of $\Omega(\log^2 n/\log\log n)$ on the space required for a JAG to compute STCON. Within the $\log\log n$ factor, this is tight with Savitch's algorithm. Berman and Simon [7] extended this result to the probabilistic JAG model. More precisely, they showed that any probabilistic JAG that solves STCON within $2^{\log^{O(1)} n}$ expected time requires $\Omega(\log^2 n/\log\log n)$ space. Their probabilistic JAG is allowed to flip a coin in each step and is able to solve STCON with 1-sided error, using $O(\log n)$ space and $O(n^n)$ expected time (see Gill [18]). In the following, we will refer to such a probabilistic machine as a coin-flipping machine. Poon [26] further generalized the bound, showing that $S \in \Omega(\frac{\log^2 n}{\log\log n + \log\log T})$ for any coin-flipping probabilistic NNJAG with space S and expected time T.

Regarding the time–space tradeoff, there are many lower bounds proved for UST-

CON on various weaker variants of the JAG model [6, 11, 13]. Edmonds [15] was the first to prove a time–space lower bound for USTCON on the regular JAG model (with bounded space). All these results apply to (directed) STCON, which contains USTCON as a special case. However, USTCON appears to be easier than STCON both in terms of space and time–space complexity. For example, Nisan, Szemerédi, and Wigderson [24] showed that USTCON can be solved in $O(\log^{1.5} n)$ space on a deterministic Turing machine. There is also a randomized $O(\log n)$ space, polynomial time algorithm (by Aleliunas et al. [1]) and a deterministic $O(\log^2 n)$ space, polynomial time algorithm (by Nisan [23]) for this problem. Although it is not known whether the algorithms in [24, 23] can be simulated on a JAG or NNJAG, USTCON can indeed be solved in $O(\log n)$ space and polynomial time on a JAG due to the existence of polynomial length universal traversal sequences [1]. Thus, one cannot hope to get superpolynomial time lower bounds for STCON by establishing similar bounds for USTCON.

The first nontrivial lower bound explicitly for STCON was given by Barnes and Edmonds [4]. They showed that $ST \in \Omega(n^2/\log n)$ on the JAG model. In fact their result was proved on a more powerful variant of JAG called *many states, big step JAG* which, unlike an ordinary JAG, is capable of traversing trees in $O(\log n)$ space. Using a proof technique completely different from [4], Edmonds [14] showed that $S^{1/3}T \in \Omega(n^{4/3})$ on the NNJAG model. These results still do not yield superpolynomial lower bounds on time no matter how small S is. In view of this large gap between the upper and lower bounds and the fact that the Barnes et al. algorithm was obtained by combining several rather simple ideas, it seemed that further improvements to the upper bound were quite possible.

1.2. New results. Rather surprisingly, in a preliminary version of this paper by Edmonds and Poon [16], a lower bound of $T \in 2^{\Omega(\log^2(\frac{n\log n}{S})/\log\log n)} \times (nS/\log n)^{1/2}$ is obtained. This implies that superpolynomial running time is necessary to solve the problem whenever S is smaller than $(n\log n)/2^{\omega(\sqrt{\log n \cdot \log\log n})}$. The bound also nearly matches the upper bound of $T \in 2^{O(\log^2(\frac{n\log n}{S}))} \times n^3$ (which is superpolynomial for $S \in (n\log n)/2^{\omega(\sqrt{\log n})}$) by Barnes et al. [3]. Here, by a more careful choice of parameters and a tighter analysis, we prove that for any $\delta > 0$, a probabilistic NNJAG with 2-sided error, using space $S \in O(n^{1-\delta})$, requires expected time $T \in 2^{\Omega(\log^2(n/S))}$, matching the upper bound of [3].

In this paper, we define an S-space probabilistic NNJAG as a distribution of S-space deterministic NNJAGs. Hence, the probabilistic NNJAG must use time $T \in 2^{O(S)}$ or else it will cycle. From this fact and the time–space tradeoff, we obtain the first tight space lower bound of $\Omega(\log^2 n)$ on a probabilistic NNJAG with 2-sided error. No tight space lower bound was previously known even for the more restricted JAG model. However, a coin-flipping probabilistic JAG or NNJAG (as defined in [7, 26]) can run usefully for up to $2^{2^{O(S)}}$ expected time. As mentioned before, it can solve STCON with $O(\log n)$ space and $O(n^n)$ expected time. Thus, one can prove only a time–space lower bound on this coin-flipping model. Since a coin-flipping probabilistic NNJAG with space S and time T can be simulated on our probabilistic NNJAG, using time T and space $S + \log T$, our result is valid on the coin-flipping model for $S \in \Omega(\log^2 n)$ (since $\log T \in O(S)$). For space $S \in O(\log^2 n)$, our result still implies a lower bound of $T \in 2^{\Omega(\log^2 n)}$ on the coin-flipping model. However, for $S \in O(\frac{\log^2 n}{\log\log n})$, Poon [26] gives a stronger lower bound of $T \in 2^{(2^{\Omega(\log^2 n/S)})}$. For example, when $S \in O(\log n)$, his result implies that $T \in 2^{n^c}$ for some constant $c > 0$.

This paper borrows a lot of techniques from [14]. The bound is proved for the probabilistic NNJAG model by transforming the machine into a structured branching program, and applying a progress argument introduced by Borodin et al. [10] and also used in many proofs of time–space trade-off lower bounds, including [8, 5, 9, 33]. Roughly, the argument is that for every short path of the computation, the probability that lots of progress is made, conditional on the fact that this computation path is followed, is less than 2^{-S}. (With space S there are at most 2^S different such subcomputations.) Our proof, however, is complicated by the fact that this is not true for some "lucky" computation paths, and hence a number of new techniques are required to overcome this. In addition, the argument is applied recursively, yielding a substantially greater lower bound than would be possible without recursion. We note that similar recursive techniques have also been used in [13, 7, 33, 15, 26].

1.3. Organization of this paper. We first define the NNJAG model in section 2. In section 3, we give the statement of our main result and its corollaries. In sections 4 and 5, we describe the families of graphs used to defeat the NNJAG. In section 6, we define a notion of progress for an NNJAG on such families of graphs. In section 7, we enhance and stylize the NNJAG model to simplify our proof. Sections 8 through 12 contain the technical proof of the lower bound. Section 8 contains the proof of an inductive statement, Lemma 8.3, from which our main result follows. The proof makes forward references to Lemmas 8.1 and 8.2, which are proved in sections 10 through 12 and section 9, respectively. Section 13 gives the conclusion and some open problems.

2. The NNJAG model. A (deterministic) NNJAG [26] J is a finite state automaton with p distinguishable pebbles, q states, and a transition function Δ. The transition function Δ can depend nonuniformly on the size n of the input graph, and the values of p, q can be functions of n. The input to J is a triple (G, s, t), where G is an n-node graph containing nodes s and t. For every node in G, its out-edges are labeled with consecutive integers starting at 0. The nodes in G are also labeled from 0 to $n-1$. We define the *instantaneous description* (id) of J as the pair (Q, Π), where Q is the current state and Π is a mapping of pebbles to nodes, specifying the current location of each pebble in the graph. When J is in id (Q, Π), the transition function Δ determines the next move for J based on (1) the state Q and (2) the mapping Π. A move is either a *walk* or a *jump*. A walk (P, i, Q') consists of moving pebble P along the edge labeled i that comes out of the node $\Pi(P)$ and then assuming state Q'. (If there is no such edge, the pebble just remains on the same node.) A jump (P, P', Q') consists of moving pebble P to the node $\Pi(P')$ and then assuming state Q'. The NNJAG J is initialized to state Q_0 with all its pebbles on node s. It is said to *accept* an input (G, s, t) if it enters an accepting state on this input. An NNJAG solves STCON for n-node graphs if for every input (G, s, t), where G is an n-node directed graph, it accepts the input if and only if there is a directed path from s to t in G. We define the space used by the NNJAG as $p \log n + \log q$, i.e., as the number of bits needed to specify an id. The time used is the number of moves it has made. For simplicity, we assume that the labels of nodes s and t are always fixed (say, as 0 and $n-1$, respectively). Hence, s and t are not part of the input.

A probabilistic NNJAG J is defined as a distribution on deterministic NNJAGs. On a given input, it first chooses probabilistically a deterministic NNJAG from the distribution and then runs this deterministic NNJAG on the input. The space used is taken as the maximum over all the deterministic NNJAGs in the distribution and the expected (worst case) time is the expected (worst case) running time over the

distribution. We say that J solves STCON with 2-sided error if for every input (G, s, t) the probability of J entering an accepting state is at least $3/4$ when there is a path from node s to t and is at most $1/4$ otherwise.

3. Statement of results. Our main result is the following.

THEOREM 3.1. *If J is a probabilistic NNJAG that solves* STCON *on n-node graphs while taking expected time T and using space S, then $T \in 2^{\Omega(\log^2(n/S))}$ when $S \in O(n^{1-\delta})$, where $\delta > 0$ and $T \in 2^{\Omega(\log^2(\frac{n \log n}{S})/\log\log n)} \times (nS/\log n)^{1/2}$ otherwise.*

The proof of Theorem 3.1 follows by applying Yao's lemma [32] to the following theorem.

THEOREM 3.2. *For any δ, $\epsilon > 0$ there is a distribution $\mathcal{D}$ on n-node graphs such that*

1. *$Pr_{G \in \mathcal{D}}[\, G \in$ STCON $\,] = 1/2$, and*
2. *for any deterministic NNJAG, using space $S \in O(n^{1-\delta})$ and (worst case) time $T \notin 2^{\Omega(\log^2(n/S))}$, or $S \in \omega(n^{1-\delta})$ and $T \notin 2^{\Omega(\log^2(\frac{n \log n}{S})/\log\log n))} \times (nS/\log n)^{1/2}$,*

$$\Pr_{G \in \mathcal{D}}[J \text{ is correct on input } G] < \frac{1}{2} + 2\epsilon.$$

Proof of Theorem 3.1. Theorem 3 of [32] states that for any randomized algorithm $\mathcal{J}$ that has probability of error at most λ and any input distribution $\mathcal{D}$, the expected time of $\mathcal{J}$ on the worst case input is at least half the average time of the best deterministic algorithm that errs with probability at most 2λ on random input chosen from $\mathcal{D}$. By Theorem 3.2, the latter quantity is at least $T \times (1 - 2\lambda - \frac{1}{2} - 2\epsilon)$, where $T \in 2^{\Omega(\log^2(n/S))}$ for $S \in O(n^{1-\delta})$ and $T \in 2^{\Omega(\log^2(\frac{n \log n}{S})/\log\log n)} \times (nS/\log n)^{1/2}$ otherwise. Putting λ as some constant less than $\frac{1}{4} - \epsilon$ and since $S \in O(n^{1-\delta})$ for some $\delta > 0$, we get the required lower bound on a probabilistic NNJAG that errs with probability at most λ. □

Theorem 3.2 is strong enough to yield an optimal space lower bound for the deterministic NNJAG model, as an immediate corollary.

COROLLARY 1. *Any probabilistic NNJAG that solves* STCON *requires $\Omega(\log^2 n)$ space.*

Proof. Once the deterministic NNJAG to be used is chosen from the distribution, the probabilistic NNJAG becomes deterministic. Hence, while using space at most S, the NNJAG cannot take more than $2^{O(S)}$ steps without going into an infinite loop. If an NNJAG J uses space $S \notin \Omega(\log^2 n)$, then for sufficiently large n the number of steps it can take is smaller than the lower bound implied by Theorem 3.2 and the result follows. □

4. Layered graphs. From now on, we let δ be a fixed positive constant. A (d, x, f)-*layered graph*, first defined in [4], is a graph consisting of d layers, each containing x nodes. The jth node in layer i is denoted by (and named) $u_{\langle i,j \rangle}$. (Hence, the NNJAG always knows the location of a pebble in terms of i, j.) Every node has at most f outgoing edges to some (not necessarily distinct) nodes in the next layer. Here, we will set $f = \Theta((n \log n/S)^{1/2})$ for $S \in O(n^{1-\delta})$ and $f = 2$ otherwise.

Let $D = \lceil 80 \log n/\log f \rceil$ (so that $f^D \geq n^{80}$). Note that D is constant with respect to n if $S \in O(n^{1-\delta})$ and $D \in \Theta(\log n)$ otherwise. The distribution $\mathcal{B}(x)$ is a distribution on (D, x, f)-layered graphs. Each graph $G \in \mathcal{B}(x)$ will have $x/2$ *hard paths* (to be defined shortly) of length D and is obtained as follows. In each layer i, except the top layer, we pick (without replacement) a sequence of $x/2$ nodes,

uniformly at random. Let us denote the jth node picked as $v_{\langle i,j\rangle}$. (It is the node $u_{\langle i,j'\rangle}$ for some j'.) These nodes are called the *hard nodes*. The remaining $x/2$ nodes in that layer are called the *easy nodes*. For layer 1, we choose the sequence of nodes $u_{\langle 1,1\rangle}, u_{\langle 1,2\rangle}, \ldots, u_{\langle 1,x/2\rangle}$ as the sequence of hard nodes. We shall put in edges so that if an NNJAG walks a pebble $D-1$ steps starting from a hard node in the top layer, then it is difficult for the pebble to be on a hard node when it reaches layer D.

First, the hard nodes are connected by the edges $(v_{\langle i,j\rangle}, v_{\langle i+1,j\rangle})$ for each $i \in [1 \ldots D-1]$ and each $j \in [1..x/2]$. The path from $v_{\langle 1,j\rangle}$ to $v_{\langle D,j\rangle}$ is called the jth *hard path*. The nodes $v_{\langle 1,j\rangle}$ and $v_{\langle D,j\rangle}$ are called the *root* and *goal* of the jth hard path, respectively. Thus, there are $x/2$ hard paths, roots, and goals in G. The edge labels are chosen independently and uniformly from $[0 \ldots f-1]$. Thus, for each root r the vector of edge labels on the hard path rooted at r, denoted $\vec{\ell}_r$, is chosen uniformly at random from $[0..f-1]^{D-1}$.

For each layer $i \in [1..D-1]$, each hard node $v_{\langle i,j\rangle}$ will have further $f-1$ outgoing edges, and each easy node will have f outgoing edges. The destinations of these edges are chosen independently (with replacement) at random from the set of easy nodes in layer $i+1$. In this way, the in-degree of each hard node is kept to 1.

5. Recursively layered graphs. Set $\chi = \Theta((\frac{n^3 S}{\log n})^{1/4})$ for $S \in O(n^{1-\delta})$ and $\chi = \Theta((\frac{nS}{\log n})^{1/2})$ otherwise. Set $K = \lfloor \frac{\log(n/(4\chi))}{\log 2D} \rfloor$. Thus, $K \in \Theta(\log(\frac{n \log n}{S}))$ for $S \in O(n^{1-\delta})$ and $K \in \Theta(\log(\frac{n \log n}{S})/\log\log n)$ otherwise. Moreover, $K \leq \log n$ since $S \geq \log n$. We first construct, recursively, $K+1$ distributions $\mathcal{H}_0, \mathcal{H}_1, \ldots, \mathcal{H}_K$ on layered graphs, where $\mathcal{H}_k$ is a distribution on $(D^k, 2^k\chi, f)$-layered graphs. Each such graph has χ *super goals*. In addition, for $k > 0$, each graph in $\mathcal{H}_k$ has $D^{k-1}2^{k-1}\chi$ hard paths of length D, each one with a goal. Our input distribution $\mathcal{D}$ of n-node graphs in Theorem 3.2 is formed by adding a few nodes and edges to each graph in $\mathcal{H}_K$.

The distribution $\mathcal{H}_0$ contains only one graph, which is simply a layer of χ isolated nodes. These nodes are the super goals. For $k > 0$, a graph G in $\mathcal{H}_k$ is formed as follows. We choose a graph G' from $\mathcal{H}_{k-1}$ and replace each layer i of G' with a graph G_i chosen from $\mathcal{B}(2^k\chi)$. Note that each G_i has $2^k\chi/2 = 2^{k-1}\chi$ hard paths and that each layer of G' has the same number of nodes. We identify the jth hard path of G_i (i.e., the path from $v_{\langle 1,j\rangle}$ to $v_{\langle D,j\rangle}$ of G_i) with the jth node in layer i (i.e., $u_{\langle i,j\rangle}$) of G'. Every edge that goes into $u_{\langle i,j\rangle}$ of G' will now go into $v_{\langle 1,j\rangle}$ of G_i, and every edge that goes out of $u_{\langle i,j\rangle}$ of G' will go out of $v_{\langle D,j\rangle}$ of G_i. The easy nodes in G_i are not connected to any node outside G_i.

Since G is uniquely determined by G' and $G_1, \ldots, G_{D^{k-1}}$ (and viceversa), we often denote G as a tuple $\langle G_1, G_2, \ldots, G_{D^{k-1}}; G'\rangle$. The graph G' is called the *collapsed* graph of G, denoted $C(G)$. The set of hard paths (respectively, roots and goals) of G is the union of all the sets of hard paths (respectively, roots and goals) in $G_1, G_2, \ldots, G_{D^{k-1}}$. Hence, G has $D^{k-1}2^{k-1}\chi$ hard paths (and the same number of roots and goals) in total. The χ super goal nodes in G are the goal nodes of the χ hard paths in $G_{D^{k-1}}$, representing the χ super goal nodes in $G' \in \mathcal{H}_{k-1}$. Note that the super goals are on the bottom level of G and are associated with the χ nodes in the graph from $\mathcal{H}_0$. The edges within each of the G_is are called the *base edges* of G. The other edges, i.e., those connecting the G_is, are in one-to-one correspondence with the edges in the collapsed graph $C(G)$ of G, and hence they are called the *collapsed edges*. Note that graphs in $\mathcal{H}_1$ have base edges but not collapsed edges, and the graph in $\mathcal{H}_0$ does not have any edge at all.

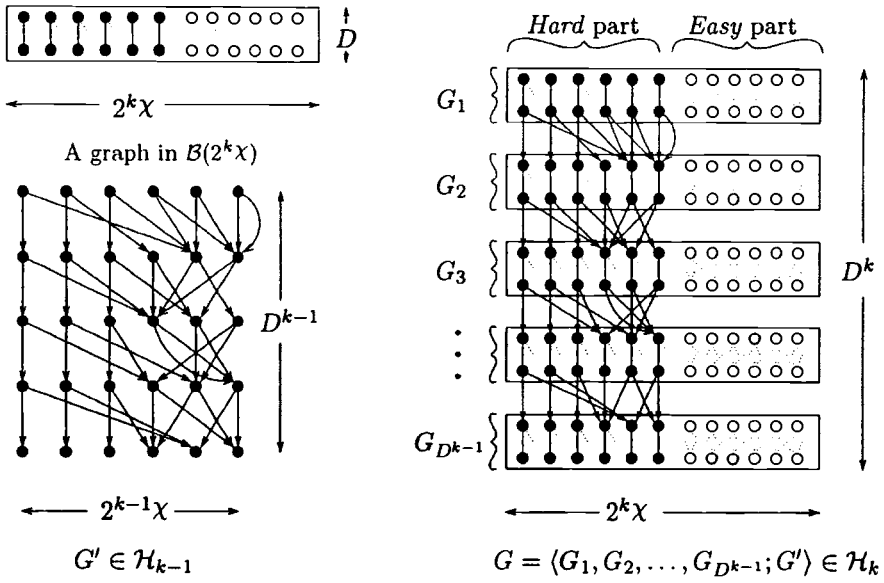

FIG. 1. *An example:* $f = 2$.

Figure 1 shows a graph $G \in \mathcal{H}_k$ on the right and its collapsed graph $C(G) \in \mathcal{H}_{k-1}$ and the symbol for a base graph in $\mathcal{B}(2^k\chi)$ on the left. We rearranged the nodes so that all the hard nodes in the G_i's appear on the left half.

For each $k \in [0..K]$, we obtain a distribution $\mathcal{G}_k$ by adding to each graph in $\mathcal{H}_k$ the following *auxiliary* nodes and edges (see Figure 2):

(A1) a directed path $(s = w_1, w_2, \ldots, w_{2^k\chi})$ with $w_1 = s$ and, for each $j \in [1..2^k\chi]$, an edge from w_j to $u_{\langle 1,j \rangle}$ of G;
(A2) the isolated node t;
(A3) a special isolated node, referred to as the *lost* node;
(A4) a number of isolated nodes so that the total number of nodes in the graph is exactly n.

The lost node is introduced for technical reasons that will become clear in section 7. These auxiliary nodes and edges are fixed for each graph $G \in \mathcal{G}_k$. Hence, for $k > 0$, G can still be specified by a tuple $\langle G_1, G_2, \ldots, G_{D^{k-1}}; G' \rangle$, where $G_1, \ldots, G_{D^{k-1}}$ are in $\mathcal{B}(2^k\chi)$ and G' is in $\mathcal{H}_k$. The *collapsed* graph of G, denoted by $C(G)$, is the graph G' augmented with the auxiliary nodes and edges needed to form a graph in $\mathcal{G}_{k-1}$ from a graph in $\mathcal{H}_{k-1}$. Thus, $C(G)$ is in $\mathcal{G}_{k-1}$. Note that, excluding the nodes added in (A4), each graph in $\mathcal{G}_k$ consists of a $(D^k, 2^k\chi, f)$-layered graph, a path with $2^k\chi$ nodes, the node t and the lost node. These add up to a total of $(2D)^k\chi + 2^k\chi + 2 \leq 4(2D)^k\chi \leq n$ nodes for $k \leq K$ by our choice of χ and K. Hence, we are not adding a negative number of nodes in (A4). Finally, the distribution $\mathcal{D}$ of Theorem 3.2 is defined as follows. First choose a graph $G' \in \mathcal{G}_K$ and then uniformly at random choose one of the χ super goals in G' as the *special node*. With probability $1/2$ connect the special node to the isolated node t to form a graph G. Clearly, $\Pr_{G \in \mathcal{D}}[G \in \text{STCON}] = 1/2$.

6. Defining progress. Consider the computation of an NNJAG J on input G. We will analyze the progress of J during different phases of the computation. In the following definition, a *subcomputation* A refers to a sequence of moves taken by the

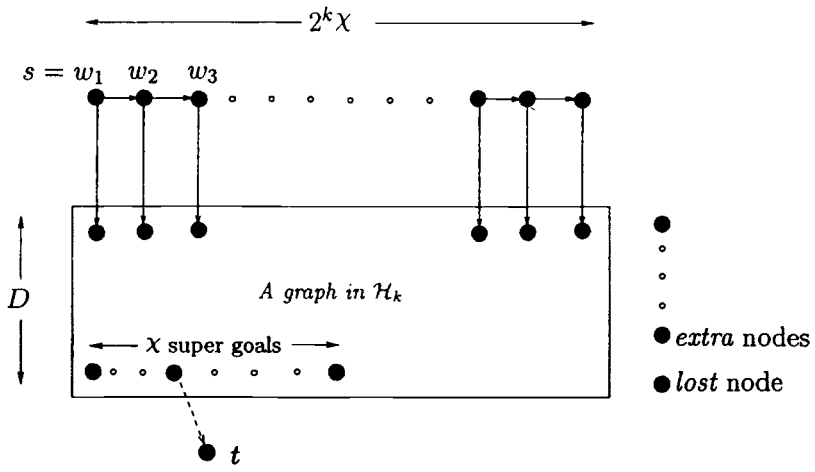

FIG. 2. *A graph in* $\mathcal{G}_k$.

NNJAG, starting from certain id (Q, Π). Once we recast an NNJAG as a branching program in section 7, one can think of A as a subbranching program.

DEFINITION 1. *For any subcomputation A and any input $G \in \mathcal{G}_k$, $w_A(G)$ is the number of different goals in G that were pebbled (i.e., reached by a pebble) at any time during A. Similarly, $w^*_A(G)$ is the number of super goals in G that were pebbled during A.*

Note that when A begins, some pebbles may already be sitting on a goal node. These goals will be counted as progress in $w_A(G)$. However, there can be at most $S/\log n$ such progress. The following lemma shows why reaching the other goals is difficult for an NNJAG.

LEMMA 6.1. *If at some step T' a particular hard path does not contain any pebble and at some later step T'' a pebble arrives at the goal of this path, then each edge in that path must be traversed by some pebble between step T' and T''.*

Proof. Observe that every node on a hard path has in-degree 1 and that in the NNJAG model a pebble can arrive at a node only if the node is already occupied by some pebble or if it walks to the node. □

We point out that it is not necessary for a general computation model to find out the hard path before it can inspect the edge connections of the associated goal node. This is the only significant difference between a general model and an NNJAG model that we will employ in our proof.

Recall that an input $G = \langle G_1, \ldots, G_{D^{k-1}}; G' \rangle \in \mathcal{G}_k$ consists of the collapsed graph $G' \in \mathcal{G}_{k-1}$ and the base graphs $G_1, \ldots, G_{D^{k-1}} \in \mathcal{B}(2^k\chi)$. The NNJAG has to learn both the structure of the base graphs and that of the collapsed graph. Obviously, $w_A(G)$ measures how much A has learned about the base graphs. The following lemma shows that $w_A(G)$ is also a good estimate of the number of different collapsed edges traversed during a subcomputation A.

LEMMA 6.2. *The number of different collapsed edges of an input graph $G \in \mathcal{G}_k$ that can be traversed during a subcomputation A of an NNJAG is at most $f \times w_A(G)$.*

Proof. An NNJAG can traverse an edge (u, v) only if there is a pebble on node u before the traversal. If the edge is a collapsed edge, u must be a goal. Since every goal has out-degree at most f, pebbling one such node allows the NNJAG to traverse

at most f different collapsed edges. □

Lemma 8.3, to follow, uses Lemmas 6.1 and 6.2 recursively to prove that it is hard for an NNJAG to reach the χ super goal nodes. Roughly speaking, the argument goes as follows. Suppose we have proved that it is hard to visit the super goals of graphs chosen from $\mathcal{G}_{k-1}$ within time T_{k-1}. Consider a graph $G = \langle G_1, \ldots, G_{D^{k-1}}; G' \rangle$ in $\mathcal{G}_k$ and an NNJAG J with time T_k. We will prove, using Lemma 6.1, that for any input $G' \in \mathcal{G}_{k-1}$, it is hard for J to visit many goals in the graphs $G_1, \ldots, G_{D^{k-1}} \in \mathcal{B}(2^k\chi)$ within time T_k. In particular, Lemma 6.2 implies that no more than T_{k-1} different edges in G' are traversed. To conclude the argument, we show that J is effectively an NNJAG trying to reach, within time T_{k-1}, the super goals for graphs chosen from $\mathcal{G}_{k-1}$, which is difficult by the inductive assumption.

It should be pointed out that J can traverse the same edge many times (which is natural, since J cannot remember the result of too many edge traversals with limited space). Therefore, we cannot directly claim that J runs in T_{k-1} time on inputs from $\mathcal{G}_{k-1}$. For this reason, we measure the time of an NNJAG using the *s-height*, $h_A()$, of the corresponding branching program A. Precise definitions of *s*-height will be given in section 7. Here, we just state that an NNJAG running in time T will have $h_A(G) \leq T$ for any G. Thus Lemma 8.3 will imply that if J is an NNJAG that uses space $S \in O(n^{1-\delta})$ and time $T \notin 2^{\Omega(\log^2(n/S))}$ or space $S \in \omega(n^{1-\delta})$ and time $T \notin 2^{\Omega(\log^2(\frac{n \log n}{S})/\log\log n)} \times (nS/\log n)^{1/2}$, then for any $\epsilon > 0$, $\Pr_{G \in \mathcal{D}}[\, w^*_J(G) > \epsilon\chi \,] < \epsilon$. Below we show how Theorem 3.2 follows from this last statement.

Proof of Theorem 3.2. Choose $G \in \mathcal{D}$. Recall that this can be done by choosing $G_a \in \mathcal{G}_K$ and then choosing one of its χ super goals to be special, uniformly at random. Let G_b be the same as G_a except with an edge from the special node to t. Then G is uniformly chosen to be G_a or G_b. If G_a is such that $w^*_J(G_a) > \epsilon\chi$, i.e., J reaches a lot of super goals, then assume that J gives the correct answer on G. From Lemma 8.3, the probability of this event is less than ϵ. If J pebbles at most $\epsilon\chi$ super goals, then the probability that J pebbles the special node is at most ϵ because the NNJAG cannot tell that a super goal is special unless it pebbles the node. Finally, if J does not pebble the special node it cannot learn whether there is an edge from the special node to t. Therefore, in this case, the computations on G_a and G_b are the same and hence the probability of giving the correct answer for G is $1/2$. Thus, the probability of giving the right answer for G is less than $1/2 + 2\epsilon$. □

7. An NNJAG as a branching program. We will introduce a variant of the NNJAG model which we call the *pebble location redundant* NNJAG model. The reason is that while the new model maintains all the power of an NNJAG it helps us prove a collapsing lemma. In particular, we shall show that it is helpful to construct a pebble location redundant NNJAG J' for graphs in $\mathcal{G}_{k-1}$ from a pebble location redundant NNJAG J for graphs in $\mathcal{G}_k$. We call this the "collapsing" of J to J'.

An NNJAG is said to be pebble location redundant if the current state always determines the current location of all the pebbles and, hence, the state alone is sufficient to specify the id of the NNJAG. More formally, this means that there is a function $\widehat{\Pi}$ such that if the NNJAG is in state Q, then $\widehat{\Pi}(Q)$ specifies the locations of all the pebbles. As a first step in getting a pebble location redundant NNJAG, we enhance a standard NNJAG as follows. First, we allow it to jump a pebble to the lost node (which is isolated), and for any $j \in [1..2^k\chi]$ to the nodes w_j and $u_{\langle 1,j \rangle}$. We call such a jump a *node-jump*. Note that in the standard NNJAG model a pebble can jump only to (the node occupied already by) another pebble. Also, we modify a step to be

taken from an id (Q, Π) by the NNJAG to consist of the following substeps.
Substep 1. Based on (Q, Π), either it walks a pebble P along the edge with a specified label ℓ, or it node-jumps a pebble P. It can also choose not to move any pebble. Let Π_1 specify the new pebble locations.
Substep 2. Based on (Q, Π) and Π_1, it performs a (possibly empty) sequence of pebble-to-pebble jumps and then assumes some state Q'.
The intuition supporting these modifications is that a sequence of moves of a standard NNJAG can be viewed as a sequence of "macro steps," each of which starts with a walk, followed by a (possibly empty) sequence of jumps. Each such jump causes the standard NNJAG to enter a unique next id. Intuitively, the NNJAG "learns" about the input only by taking walking steps. Each macro step can be performed in one step in the enhanced model. It follows that a time lower bound on this new model implies the same lower bound on the number of walking steps on the original model. For any NNJAG J (modified as above) with p pebbles, q states, and T time, we can construct a pebble location redundant NNJAG J' so that for any possible id (Q, Π) of J, J' will have a state $\langle Q, \Pi \rangle$. In this state, J' will perform the same action as J does on id (Q, Π).[1] Thus, the pebble location redundant NNJAG J' will have p pebbles and $q \times n^p$ states; hence using space $\log(q \times n^p) + p \log n = \log q + 2p \log n$, which is at most twice the space of J. Moreover, it uses no more time than J.

To be able to discuss subcomputations of the NNJAG better, it is convenient to recast the NNJAG as an r-way branching program [8] (defined below). Although an r-way branching program is a general model of computation, the branching program we will examine has "structure" imposed by Lemmas 6.1 and 6.2 regarding NNJAG computations.

A branching program is a directed acyclic graph with a designated source node and a number of sink nodes. Each sink node in the graph is labeled with either *accept* or *reject* and each nonsink node is labeled with an input variable. Furthermore, for each possible value of the input variable that labels a nonsink node, there is a unique out-edge from this nonsink node, labeled with that value. Hence, the out-degree of the graph is at most r, where r is the maximum number of different values possible for an input variable. A *subbranching program* is simply a subgraph rooted at some node.

The nodes in this graph represent the possible states of the machine's memory. In particular, the source node represents the initial memory state. In each step the machine queries an input variable, depending on the current state of its memory, and then changes its memory to another state based on the value returned. Which variable to query and which state to go to, on each possible outcome, are specified by the graph. It is easy to see that for every input, there will be a unique path in the graph from the source node to a sink node. We call such a path the *computation path* followed by the input. We say that a branching program accepts an input if and only if the computation path followed by the input leads to a sink node labeled with accept.

Consider an arbitrary (pebble location redundant) NNJAG J that uses space S, takes time T, and takes inputs from a distribution of n-node graphs with out-degree

[1] Note that in general, a standard NNJAG cannot be made pebble location redundant because, if the move taken from an id (Q_1, Π_1) is a walk, the new pebble location, Π_2, will depend on the input graph. Hence, the NNJAG cannot know which new state Q_2 to move to so that $\widehat{\Pi}(Q_2) = \Pi_2$. In contrast, in the modified NNJAG the pebble location, Π_2, after Substep 2, is uniquely determined by (Q_1, Π_1) and Π'_1. Hence, it is possible for the NNJAG to choose a state Q_2 so that $\widehat{\Pi}(Q_2) = \Pi_2$.

f. The corresponding branching program A has a row of configuration nodes for each of the time steps $t \in [1 \dots T]$. Each row has 2^S configuration nodes (Q, Π, t), one for each NNJAG id (Q, Π). For every id (Q, Π) of J and time step t, there will be a configuration vertex (Q, Π, t) in A. The configuration vertex $(Q_0, \Pi_0, 1)$, where (Q_0, Π_0) is the *start* id of J, is taken as the *start* vertex of A. For each *accept* id (Q_a, Π_a) of J, $(Q_a, \Pi_a, 1), (Q_a, \Pi_a, 1), \dots, (Q_a, \Pi_a, T)$ are *accept* configuration vertices in A, and likewise for the *reject* ids. The input variables labeling the configuration vertices of A are the variables $X_{\langle u,\ell\rangle}$, where $u \in [0..n-1]$ is a node name and $\ell \in [0..f-1]$ is an edge label. The variable $X_{\langle u,\ell\rangle}$ will have value v if there is an edge (u, v) labeled with ℓ in the input graph and the value "undefined" if there is no such edge. Thus, if in id (Q, Π) the first substep of J walks a pebble from node u along the edge with label ℓ, the configuration vertex (Q, Π, t) in A will be labeled with the variable $X_{\langle u,\ell\rangle}$. Furthermore, the vertex will have a directed edge labeled with v to configuration vertex $(Q', \Pi', t+1)$ if for some input graph, $X_{\langle u,\ell\rangle} = v$ (i.e., the queried edge has destination v) and the subsequent jumps taken in Substep 2 by J bring the machine to the id (Q', Π'). If J does not walk any pebble in Substep 1, the configuration vertex will not get any label and will have only one unlabeled out-edge pointing to some configuration vertex $(Q', \Pi', t+1)$, depending on Substep 2 of J.

Note that the branching program A so constructed is *leveled* in the sense that each configuration vertex can be assigned a level number so that edges from level i only go to level $i+1$. Moreover, all the rows in A are identical, because the transition function of the (deterministic) NNJAG does not depend on time. Therefore, the number of distinct subbranching programs of a fixed height is at most 2^S.

Finally, we introduce a variant of branching programs called *sectioned* branching programs. A branching program is said to be sectioned if its vertices are partitioned into sections so that the out-edges of a vertex in section i can only go to vertices in section i or $i+1$. Thus, each computation path will go through each section at most once.

DEFINITION 2. *A branching program A is* properly sectioned *for an input G if it queries at most $\frac{3fS}{\log n}$ different edges of G in each section. If A is properly sectioned for G, then its* s-height *on G, denoted $h_A(G)$, is $\frac{3fS}{\log n}$ times the number of sections A contains; otherwise, $h_A(G)$ is infinite.*

Note that a set of queries to the same edge of the input graph within a section is charged as only one query in the s-height measure. The branching program defined earlier can be viewed as a sectioned branching program with $T/\frac{3fS}{\log n}$ sections, each of which queries at most $\frac{3fS}{\log n}$ different input edges. Moreover, on every input G, A will have s-height $T = (T/\frac{3fS}{\log n}) \times \frac{3fS}{\log n}$.

8. Proof outline. In the rest of this paper, a directed edge from u to v with label ℓ will be denoted by the triple $\langle u, \ell, v\rangle$. Also, by $\mathcal{G}(\mathcal{O})$ we denote the distribution obtained by selecting those graphs in $\mathcal{G}$ that satisfy a condition $\mathcal{O}$. We will derive Lemma 8.3 by induction. Before doing so, we present two lemmas that are central to the proof of that inductive statement. The first mainly concerns traversing base edges of graphs in $\mathcal{G}_k$. It bounds the probability of a machine making a lot of progress within a short period of time.

LEMMA 8.1 (main lemma). *Let A be any sectioned subbranching program derived from some pebble location redundant NNJAG with at most $S/\log n$ pebbles. Then for any $k \in [1..K]$,*

$$\Pr_{G \in \mathcal{G}_k}[w_A(G) \geq 3S/\log n \text{ and } h_A(G) \leq \chi/8] < 2^{-2S}.$$

The intuition behind Lemma 8.1 is as follows. Recall that $w_A(G)$ is the number of goals that get pebbled. We "give away" one such node for each of the (at most) $S/\log n$ pebbles. When $h_A(G) \leq \chi/8$, A queries at most $\chi/8$ different edges in G. Consider the probability of pebbling the goal corresponding to an arbitrary root r, assuming that the hard path rooted at r does not contain any pebble initially. There are f^{D-1} possibilities for the vector, $\vec{\ell}_r$, of edge labels on this hard path. To remind us of its dependency on G, let us use the symbol $\vec{\ell}_r(G)$ instead of $\vec{\ell}_r$ in the following. An NNJAG can move a pebble down from r following some vector $\vec{\ell} \in [0..f-1]^{D-1}$ of edge labels, hoping that $\vec{\ell} = \vec{\ell}_r(G)$. For G drawn from $\mathcal{G}_k$, this probability is $f^{-(D-1)}$. The NNJAG can dynamically choose $\vec{\ell}$ based on the names of the nodes on the path it has traced so far. However, this will not be a lot of help, since the name of the nodes on the hard path are chosen randomly. Recall that $f^D \geq n^{80}$. Since $\chi \in O(n)$, it follows that $f^{D-1} \gg \chi/8$. Clearly, by querying at most $\chi/8$ different edges in the input graph, on the one hand, the NNJAG cannot try many different $\vec{\ell}$s. Hence, the probability of having at least one of them being successful is small.

On the other hand, the NNJAG can eliminate some of the possibilities it needs to consider by detecting "collisions of edges" and hence increase the probability that it succeeds. For example, when it learns that two different edges have the same destination node v, it learns that this node v is not on the hard path since its in-degree is bigger than 1. Hence, any path continuing from node v need not be traversed. However, within $\chi/8$ steps, the probability that an edge traversed by the NNJAG collides with some other traversed edge can be shown to be at most 1/4. (Intuitively, the probability is $\frac{\chi/8}{2^k\chi/2} \leq 1/8$. For the simplicity of the proof, we argue in section 11 that this probability is at most 1/4.) By analyzing a variant of branching processes, we can show that the probability of eliminating a large number of vectors $\vec{\ell} \in [0..f-1]^{D-1}$ in this way, is small. In other words, with high probability, the NNJAG still has a lot of possible $\vec{\ell}$s to try out. This discussion considers only a single root. When there are many roots, we need to take care of the dependencies among them before we can apply some Chernoff-type bounds. The detailed analysis and proof of Lemma 8.1 comprise sections 10, 11, and 12.

The second lemma concerns the traversal of collapsed edges of graphs in $\mathcal{G}_k$. Let E be a fixed set of D^{k-1} base graphs $G_1, \ldots, G_{D^{k-1}} \in \mathcal{B}(2^k\chi)$ (we call such a set of graphs a *complete* set) and $\mathcal{G}_k(E)$ be the distribution of $\mathcal{G}_k$ conditioned on these fixed graphs. The lemma relates the computation of a pebble location redundant NNJAG J on inputs in $\mathcal{G}_k(E)$ to that of a faster (in terms of s-height) pebble location redundant NNJAG J' on inputs in $\mathcal{G}_{k-1}$. For any complete set E of base graphs, define a function C_E from nodes in $G \in \mathcal{G}_k(E)$ to nodes in $C(G) \in \mathcal{G}_{k-1}$ as follows:

$$C_E(v) = \begin{cases} w_i & \text{if } v = w_i \text{ for some } i \in [1..2^{k-1}\chi], \\ u_{\langle i,j \rangle} & \text{if } v \text{ is on the } j\text{th hard path in } G_i, \\ \text{lost} & \text{otherwise.} \end{cases}$$

Note that the function is well defined because for an input $G \in \mathcal{G}_k(E)$, whether a node v is a hard node, an easy node, or an auxiliary node is fixed. For any pebble mapping Π for graphs in $\mathcal{G}_k(E)$, denote $C_E(\Pi)$ as the pebble mapping Π' for graphs in $\mathcal{G}_{k-1}$ such that for any pebble P, $\Pi'(P) = C_E(\Pi(P))$.

LEMMA 8.2 (collapsing lemma). *Let k be any integer in $[1..K]$, J be any pebble location redundant NNJAG with p pebbles and q states, and E be any complete set of base graphs. There exists a corresponding pebble location redundant NNJAG J' with the same number of pebbles and states such that, for any $G \in \mathcal{G}_k(E)$, J is in id (Q, Π)*

in some step on input G if and only if J' is in id $(Q, C_E(\Pi))$ in the same step on input $C(G) \in \mathcal{G}_{k-1}$.

Note that J and J' use the same space. Moreover, J traverses a collapsed edge $\langle u, \ell, v\rangle$ in G if and only if J' traverses the corresponding edge $\langle C_E(u), \ell, C_E(v)\rangle$ in $C(G)$, and J accepts G if and only if J' accepts $C(G)$. The proof of Lemma 8.2 is given in section 9. Having stated Lemmas 8.1 and 8.2, we are ready to state and prove the following inductive statement.

LEMMA 8.3. *For any $\epsilon > 0$ and any $k \in [0..K]$, if $T_k = \epsilon\chi\big(\frac{\chi \log n}{24fS}\big)^k$ and A is a sectioned branching program with no more than $T_k/(\frac{3fS}{\log n})$ sections, derived from a pebble location redundant NNJAG J which uses at most space S, then*

$$\Pr_{G\in\mathcal{G}_k}[w^*_A(G) > \epsilon\chi \text{ and } h_A(G) \le T_k] \le k2^{-S} < \epsilon.$$

Proof of Lemma 8.3.

Base case. When $k = 0$, the branching program A can query at most $T_0 = \epsilon\chi$ different edges. Hence, it cannot discover more than $\epsilon\chi$ super goals.

Inductive step. Assume that the lemma is true for $k-1$. Consider a sectioned branching program A having at most $T_k/\frac{3fS}{\log n}$ sections derived from some pebble location redundant NNJAG J with at most S space. Suppose, for the sake of contradiction, that $\Pr_{G\in\mathcal{G}_k}[\, w^*_A(G) > \epsilon\chi$ and $h_A(G) \le T_k\,] > k2^{-S}$. We will show that in this case there exists some sectioned branching program A' with at most $T_{k-1}/\frac{3fS}{\log n}$ sections corresponding to some pebble location redundant NNJAG J' using at most S space such that $\Pr_{G'\in\mathcal{G}_{k-1}}[\, w^*_{A'}(G') > \epsilon\chi$ and $h_{A'}(G') \le T_{k-1}\,] > (k-1)2^{-S}$. This contradicts the inductive hypothesis.

We break A into at most $T_{k-1}/\frac{3fS}{\log n}$ slices so that slice i consists of section $i(T_k/T_{k-1})$ to section $(i+1)(T_k/T_{k-1}) - 1$, inclusive. (Thus each slice contains $T_k/T_{k-1} = \frac{\chi \log n}{24fS}$ sections.) Let $\mathcal{F}$ be the set of $G \in \mathcal{G}_k$ such that $h_A(G) \le T_k$ and at least one subbranching program $\widehat{A}$, which lies completely within a slice, has $w_{\widehat{A}}(G) \ge 3S/\log n$. Since $h_A(G)$ being finite implies that $\widehat{A}$ is properly sectioned for G, $h_{\widehat{A}}(G) \le (T_k/T_{k-1})(\frac{3fS}{\log n}) = \chi/8$.

Consider the maximal subbranching program $\widehat{A}$ which lies completely within slice i and is rooted at the node through which G first enters slice i. There are at most 2^S such subbranching programs in A. Combining this fact with Lemma 8.1, we have $\Pr_{G\in\mathcal{G}_k}[\, G \in \mathcal{F}\,] < 2^{-S}$. Therefore, $\Pr_{G\in\mathcal{G}_k}[\, w^*_A(G) > \epsilon\chi$ and $h_A(G) \le T_k$ and $G \notin \mathcal{F}\,] > (k-1)2^{-S}$. Let us choose a complete set E of base graphs so that $\Pr_{G\in\mathcal{G}_k(E)}[\, w^*_A(G) > \epsilon\chi$ and $h_A(G) \le T_k$ and $G \notin \mathcal{F}\,] > (k-1)2^{-S}$. By Lemma 8.2, we can construct from the pebble location redundant NNJAG J, another pebble location redundant NNJAG J' that runs on $\mathcal{G}_{k-1}$ with the same number of pebbles and states as J. From J', we can construct a sectioned branching program A' with at most $T_{k-1}/\frac{3fS}{\log n}$ sections, one section for each of the slices of A. This is done by putting a configuration vertex of A' in section i if and only if the corresponding[2] configuration vertex of A is in slice i. In A, edges go only from vertices in slice i to vertices in slice i or $i+1$. Therefore, in A', edges go only from vertices in section i to vertices in section i or $i+1$. Hence, this is a legal way of partitioning the vertices of A' into sections. Now, consider an arbitrary graph $G \in \mathcal{G}_k(E) - \mathcal{F}$. At most $\frac{3S}{\log n}$ progress

[2]There is a one-to-one correspondence between states of J and J'. It is not hard to see that there is also a one-to-one correspondence between configuration vertices of A and A'.

is made in the unique maximal subbranching program that G passes through in each slice of A. By Lemma 6.2, each such subbranching program can query at most $\frac{3fS}{\log n}$ different collapsed edges in G. Hence, each corresponding subbranching program in A' queries at most $\frac{3fS}{\log n}$ different edges in $C(G)$. Therefore, A' is properly sectioned for $C(G)$ for all $G \in \mathcal{G}_k(E) - \mathcal{F}$. Since A has $T_{k-1}/\frac{3fS}{\log n}$ slices, A' has the same number of sections. It follows that $h_{A'}(C(G)) \leq T_{k-1}$ for all $G \in \mathcal{G}_k(E) - \mathcal{F}$. Since $C(G)$ is chosen independent of the G_is, the distribution $\mathcal{G}_k(E)$ is isomorphic to the distribution $\mathcal{G}_{k-1}$. Therefore,

$$\begin{aligned}
&\Pr_{C(G)\in\mathcal{G}_{k-1}}[\, w^*_{A'}(C(G)) > \epsilon\chi \text{ and } h_{A'}(C(G)) \leq T_{k-1}\,] \\
&\geq \Pr_{G\in\mathcal{G}_k(E)}[\, w^*_{A'}(C(G)) > \epsilon\chi \text{ and } G \notin \mathcal{F}\,] \\
&= \Pr_{G\in\mathcal{G}_k(E)}[\, w^*_{A}(G) > \epsilon\chi \text{ and } G \notin \mathcal{F}\,] \\
&\geq \Pr_{G\in\mathcal{G}_k(E)}[\, w^*_{A}(G) > \epsilon\chi \text{ and } h_A(G) \leq T_k \text{ and } G \notin \mathcal{F}\,] \\
&> (k-1)2^{-S}. \qquad \square
\end{aligned}$$

For $k = K$ the above inductive statement implies that any deterministic pebble location redundant NNJAG which uses at most S space and takes $O(T_K)$ time, will pebble more than $\epsilon\chi$ super goals with probability less than $K2^{-S}$. Recall that $T_K = \epsilon\chi\big(\frac{\chi \log n}{24fS}\big)^K$. For $S \in O(n^{1-\delta})$, we set $f = \Theta((n \log n/S)^{1/2})$, $\chi = \Theta((n^3 S/\log n)^{1/4})$, and $K = \Theta(\log(\frac{n \log n}{S}))$. Hence $T_K = 2^{\Omega(\log^2(\frac{n \log n}{S}))} \times (n^3 S/\log n)^{1/4} = 2^{\Omega(\log^2(n/S))}$. For $S \in \omega(n^{1-\delta})$, we set $f = 2$, $\chi = \Theta((nS/\log n)^{1/2})$, and $K = \Theta(\log(\frac{n \log n}{S})/\log\log n)$. Thus, we get $T_K = 2^{\Omega(\log^2(\frac{n \log n}{S})/\log\log n)} \times (nS/\log n)^{1/2}$. For big enough n, $K2^{-S} < \epsilon$, since $K \leq \log n$ and $S \geq \log n$. Thus, if J is an NNJAG that uses space S and time $T \notin \Omega(T_K)$, then for any $\epsilon > 0$, $\Pr_{G\in\mathcal{D}}[\, w^*_J(G) > \epsilon\chi\,] < \epsilon$.

Note that for $S \in O(n^{1-\delta})$, the input graph has out-degree $f = \Theta((\frac{n \log n}{S})^{1/2})$ which is nonconstant. We can convert the graphs of out-degree f into graphs of out-degree 2 by replacing each node with a binary tree of size $O(f)$. This blows up the number of nodes by a factor of f. Hence, our lower bound becomes $T \in 2^{\Omega(\log^2(n/fS))} = 2^{\Omega(\log^2(n/S))}$, where n is the number of nodes in the out-degree 2 graph.

9. Collapsing an NNJAG.

LEMMA 8.2 (repeated). *Let k be any integer in $[1..K]$, J be any pebble location redundant NNJAG with p pebbles and q states, and E be any complete set of base graphs. There exists a corresponding pebble location redundant NNJAG J' with the same number of pebbles and states such that, for any $G \in \mathcal{G}_k(E)$, J is in id (Q, Π) in some step on input G if and only if J' is in id $(Q, C_E(\Pi))$ in the same step on input $C(G) \in \mathcal{G}_{k-1}$.*

Proof. J' will have the same set of states as J. Let $\widehat{\Pi}$ be the function that maps the states of J to its pebble locations. We shall prove, by induction on the number of steps taken, that if J is in state Q in step t on input $G \in \mathcal{G}_k(E)$, then J' is in the same state in step t on input $C(G) \in \mathcal{G}_{k-1}$ and $C_E(\widehat{\Pi}(Q))$ specifies the locations of its pebbles in that step. This proves the claim. Initially, J and J' are at state Q_0. Both $\widehat{\Pi}(Q_0)$ and $C_E(\widehat{\Pi}(Q_0))$ specify that all pebbles are on node s.

Assume that at step t, J is in state Q on input G and that, at the same step, J' is in state Q on $C(G)$ and its pebble locations are specified by $C_E(\widehat{\Pi}(Q))$. The move of J' will be determined by the move of J. For the first substep there are three cases.

Case 1. If J *does nothing*, then J' also does nothing.

Case 2. If J *walks pebble* P *along the edge with label* ℓ, then there are three subcases, depending on the node u that P was on.

(2a) If u is the lost node or the node w_j for some $j \in [1..2^k\chi]$, then the destination, v, of P is fixed and $C_E(v)$ is either the lost node, the node $u_{\langle 1,j\rangle}$, or w_{j+1}. Hence, J' node-jumps pebble P to $C_E(v)$.

(2b) If u is a hard node in layer D of some G_i (i.e., u is a goal node), then the out-edges of u are collapsed edges. In this case, J' walks pebble P along edge ℓ.

(2c) If u is not a goal node, and not an auxiliary node, then the destination, v, is fixed for all $G \in \mathcal{G}_k(E)$. If $C_E(u) \neq C_E(v)$, then u must be a hard node and v must be an easy node. Hence, J' node-jumps pebble P to $C_E(v)$, which is the lost node. If $C_E(u) = C_E(v)$, then J' does nothing.

Case 3. *If* J *node-jumps pebble* P *to node* v, then v must be either the lost node or w_j or $u_{\langle 1,j\rangle}$ for some $j \in [1..2^k\chi]$. Hence $C_E(v)$ is either the lost node, w_j, or $u_{\langle 1,j\rangle}$ for some $j \in [1..2^{k-1}\chi]$. J' just node-jumps pebble P to $C_E(v)$.

Let Π_1 be the pebble locations of J after the first substep and let J assume state Q' in the second substep. In its second substep, J' performs the same sequence of pebble-to-pebble jumps as in the second substep of J and then assumes state Q' if and only if its pebble locations after the first substep is $C_E(\Pi_1)$.

Let us check that in all the above cases the pebble location of J' after the first substep is indeed $C_E(\Pi_1)$. By the inductive hypothesis pebble P of J' was on node $C_E(u)$ before the first substep while pebble P of J was on node u. Since J only moves pebble P from node u to v in the first substep, we just need to show that J' moves P from node $C_E(u)$ to $C_E(v)$ in the first substep. This is obviously true in all the above cases except (2b). In Case (2b), $\langle u, \ell, v\rangle$ is a collapsed edge in G. By the definitions of $\mathcal{G}_k$ and $\mathcal{G}_{k-1}$, $\langle C_E(u), \ell, C_E(v)\rangle$ is an edge in $C(G)$. Hence, pebble P of J' will be on node $C_E(v)$ after the first substep. It follows that J' will also assume state Q' in the second substep. Moreover, in the second substep, J changes the pebble locations from Π_1 to $\widehat{\Pi}(Q')$ by pebble-to-pebble jumps. By construction, J' will also change the pebble locations from $C_E(\Pi_1)$ to $C_E(\widehat{\Pi}(Q'))$. □

10. Proof of the main lemma.

LEMMA 8.1 (repeated). *Let* A *be any sectioned subbranching program derived from some pebble location redundant NNJAG with at most* $S/\log n$ *pebbles. Then, for any* $k \in [1..K]$,

$$Pr_{G\in\mathcal{G}_k}\,[\,w_A(G) \geq 3S/\log n \text{ and } h_A(G) \leq \chi/8\,] < 2^{-2S}.$$

Proof. Recall that every $G \in \mathcal{G}_k$ consists of D^{k-1} graphs, G_1, G_2,..., $G_{D^{k-1}}$, chosen independently from $\mathcal{B}(2^k\chi)$, a graph G' chosen from $\mathcal{H}_{k-1}$ and some fixed auxiliary nodes and edges. Each G_i has $2^{k-1}\chi$ roots. Therefore, there are $(2D)^{k-1}\chi$ roots. Recall as well that $w_A(G)$ denotes how many of the $(2D)^{k-1}\chi$ goals have been discovered and that $h_A(G)$ is a measure of the number of edges queried.

Our proof will concentrate on the traversing of the base edges in G. We assume that G' is fixed and known to A. Hence, the probability is only over the graphs $G_1, \ldots, G_{D^{k-1}} \in \mathcal{B}(2^k\chi)$. Let $\mathcal{B}_k$ be the distribution

$$\{\,\langle G_1, \ldots, G_{D^{k-1}}\rangle \mid G_1, \ldots, G_{D^{k-1}} \in \mathcal{B}(2^k\chi)\,\}.$$

We allow the machine to query any variable $X_{\langle u,\ell\rangle}$ if u is a node in the top layer of a G_i. Moreover, each time a variable $X_{\langle u,\ell\rangle}$ is queried, the following are returned: (1)

the value, v, of $X_{\langle u,\ell\rangle}$; (2) whether v is a goal node; and, if so, (3) its corresponding root node. With these changes, we can assume that the machine does not query any collapsed edge, as there is no need.

Also, we modify A so that it has the following properties: (1) A is a decision tree (i.e., it will not forget the answer to any previous query); (2) A will not repeat any previous query; and (3) each computation path γ in A queries at most $\chi/8$ different (base) edges and discovers at most $3S/\log n$ different goal nodes. (If γ queries more than $\chi/8$ different edges, we will cut it right after it queries the $(\chi/8)$th edge. Similarly, if γ discovers more than $3S/\log n$ different goal nodes, we will cut it right after it discovers the $(3S/\log n)$th node.) It is clear that the modifications will not decrease the probability stated in the lemma. With all the above assumptions and modifications, we just need to show that $\Pr_{G\in\mathcal{B}_k}[\,w_A(G) \geq 3S/\log n\,] \leq 2^{-2S}$.

Just before A starts, each of the $S/\log n$ pebbles may already be partially way down a hard path or even on a goal node. To simplify the analysis, we assume that the goals of those hard paths that initially contain pebbles will be discovered by A. There are at most $S/\log n$ such goals. To pebble the remaining goals, we know, by Lemma 6.1, that the entire hard path must be traversed by the NNJAG. In other words, every edge in the hard path has to be queried by A. Let $w'_A(G)$ be the number of roots such that every edge on its hard path in G has been queried by A. To prove the lemma, it suffices to show that $\Pr_{G\in\mathcal{B}_k}[\,w'_A(G) \geq 2S/\log n\,] < 2^{-2S}$.

Consider an arbitrary computation path γ in A. It can be specified by the sequence of base edges, E_γ, it has queried and the sequence of node names, R_γ, specifying whether a goal node is discovered in each step (and if applicable, its corresponding root). For example, suppose γ queries the variable $X_{\langle u,\ell\rangle}$ which has the value v and then the variable $X_{\langle u',\ell'\rangle}$ which has the value v'. Suppose v is not a goal but v' is the goal node of root r; then $E_\gamma = (\langle u,\ell,v\rangle, \langle u',\ell',v'\rangle)$ and $R_\gamma = (0, r)$ (assuming no root has name 0).

When γ is the computation path followed on input G we will say that "G follows γ." (It might be useful to think of G as being "processed" by A along γ.) First, let us understand what we can deduce about $\vec{\ell}_r(G)$, the sequence of edge labels on the hard path in G rooted at r, given that $G \in \mathcal{B}_k(E_\gamma)$. (Note that G may not actually follow γ, because it might not agree with R_γ.) We say that a node v is a *collision node* with respect to E_γ if E_γ contains two distinct edges $\langle u,\ell,v\rangle$ and $\langle u',\ell',v\rangle$ with the same destination v. Since v has in-degree at least 2, it is known to be an easy node.

In general, we can classify $\vec{\ell} \in [0..f-1]^{D-1}$ according to γ and r as follows. Suppose we trace out a path through the edges in E_γ, starting at the root r and following the sequence of edge labels $\vec{\ell}$ until the next edge to be taken is not contained in E_γ. Then one of the following three possibilities will occur:

1. The path passes through some collision node with respect to E_γ.
2. The path reaches layer D without passing through any collision node with respect to E_γ.
3. The path stops before reaching layer D and does not pass through any collision node with respect to E_γ.

We define $Y_{\langle\gamma,r\rangle}$ and $Z_{\langle\gamma,r\rangle}$ to contain the vectors $\vec{\ell} \in [0..f-1]^{D-1}$ such that when the above procedure is applied, the second and third outcomes occur, respectively.

Claim 1. *For any computation path γ in A, any input graph $G \in \mathcal{B}_k(E_\gamma)$, and any root r, $\vec{\ell}_r(G) \in Y_{\langle\gamma,r\rangle} \cup Z_{\langle\gamma,r\rangle}$.*

Proof. For any $\vec{\ell} \notin Y_{\langle\gamma,r\rangle} \cup Z_{\langle\gamma,r\rangle}$ and any input $G \in \mathcal{B}_k(E_\gamma)$, the path from

the root r labeled with $\vec{\ell}$ in G contains a collision node. Since collision nodes have in-degree at least two in E_γ, they do not lie on the hard path. Thus, $\vec{\ell}_r(G) \neq \vec{\ell}$. ∎

DEFINITION 3. *For any computation path γ and any $G \in \mathcal{B}_k(E_\gamma)$, $Prog_{\langle\gamma,r\rangle}(G)$ is defined as the random variable indicating that all the edges in the hard path in G rooted at r are mentioned in E_γ.*

Obviously, $Prog_{\langle\gamma,r\rangle}(G)$ is true if $\vec{\ell}_r(G) \in Y_{\langle\gamma,r\rangle}$ and false if $\vec{\ell}_r(G) \in Z_{\langle\gamma,r\rangle}$. If G actually follows γ and $Prog_{\langle\gamma,r\rangle}(G)$ is true, then the goal of root r is discovered. Let $y_{\langle\gamma,r\rangle} = |Y_{\langle\gamma,r\rangle}|$ and $z_{\langle\gamma,r\rangle} = |Z_{\langle\gamma,r\rangle}|$. Briefly, the probability that $Prog_{\langle\gamma,r\rangle}(G)$ is true, given that $G \in \mathcal{B}_k(E_\gamma)$ is approximately $\frac{y_{\langle\gamma,r\rangle}}{y_{\langle\gamma,r\rangle}+z_{\langle\gamma,r\rangle}}$, because all $\vec{\ell} \in Y_{\langle\gamma,r\rangle} \cup Z_{\langle\gamma,r\rangle}$ have about the same probability to be chosen as $\vec{\ell}_r(G)$.

Let $D' = D/8$. We say that root r is a *high-collision root* with respect to the computation path γ if $y_{\langle\gamma,r\rangle} + z_{\langle\gamma,r\rangle} \leq f^{D'}$. Otherwise, we say that it is a *low-collision root* with respect to γ. We say that γ is a *high-collision computation* if there are at least $S/\log n$ high-collision roots with respect to γ. Otherwise, we say that it is a *low-collision computation*. Let $\mathcal{C}$ be the set of all high-collision computation paths. Then

$$\begin{aligned}
&\Pr_{G\in\mathcal{B}_k}\left[\, w'_A(G) \geq \frac{2S}{\log n}\,\right] \\
&\leq \sum_{\gamma\in\mathcal{C}} \Pr_{G\in\mathcal{B}_k}\left[\, G \text{ follows } \gamma\,\right] + \sum_{\gamma\notin\mathcal{C}} \Pr_{G\in\mathcal{B}_k}\left[\, w'_A(G) \geq \frac{2S}{\log n} \text{ and } G \text{ follows } \gamma\,\right] \\
&\equiv SUM_1 + SUM_2.
\end{aligned}$$

By Claim 2 in section 11, SUM_1 is at most 2^{-3S}. Consider SUM_2. If both events "$w'_A(G) \geq 2S/\log n$" and "G follows γ" occur, there exist at least $2S/\log n$ roots r such that $Prog_{\langle\gamma,r\rangle}(G)$ is true; i.e., all the edges on the hard path rooted at r in G are in E_γ. For $\gamma \notin \mathcal{C}$, at least $S/\log n$ of these are low-collision roots with respect to E_γ.

DEFINITION 4. *For any computation path γ and any $G \in \mathcal{B}_k(E_\gamma)$, $w''_\gamma(G)$ is defined as the number of roots r such that r is a low-collision root with respect to γ and $Prog_{\langle\gamma,r\rangle}(G)$ is true.*

Then

$$SUM_2 \leq \sum_{\gamma\notin\mathcal{C}} \Pr_{G\in\mathcal{B}_k}\left[\, w''_\gamma(G) \geq \frac{S}{\log n} \text{ and } G \text{ follows } \gamma\,\right].$$

Since "G follows γ" implies "$G \in \mathcal{B}_k(E_\gamma)$,"

$$\begin{aligned}
SUM_2 &\leq \sum_{\gamma\notin\mathcal{C}} \Pr_{G\in\mathcal{B}_k}\left[\, w''_\gamma(G) \geq \frac{S}{\log n} \text{ and } G \in \mathcal{B}_k(E_\gamma)\,\right] \\
&\leq \max_{\gamma\notin\mathcal{C}} \Pr_{G\in\mathcal{B}_k}\left[\, w''_\gamma(G) \geq \frac{S}{\log n} \mid G \in \mathcal{B}_k(E_\gamma)\,\right] \times \sum_{\gamma\notin\mathcal{C}} \Pr_{G\in\mathcal{B}_k}\left[\, G \in \mathcal{B}_k(E_\gamma)\,\right].
\end{aligned}$$

We claim that, for each graph $G \in \mathcal{B}_k$, there are at most 2^{6S} different computation paths γ for which G satisfies E_γ. To see this, observe that every computation path γ in A queries at most $\chi/8$ different base edges and discovers at most $3S/\log n$ different goal nodes, each having at most n name choices for its corresponding root. Hence, there are at most $\binom{\chi/8}{3S/\log n} \times n^{3S/\log n} \leq 2^{6S}$ different sequences R_γ. If there were more than 2^{6S} different computation paths γ's such that G satisfies E_γ, then there

exist two different computation paths γ and γ' such that $R_\gamma = R_{\gamma'}$ and G satisfies both E_γ and $E_{\gamma'}$. For γ and γ' to be different, there must be an edge $\langle u, \ell, v\rangle$ in E_γ and an edge in $\langle u, \ell, v'\rangle$ in $E_{\gamma'}$ such that $v \neq v'$. Then G cannot satisfy both E_γ and $E_{\gamma'}$, a contradiction. Hence, our claim follows. From this claim, we have $\sum_{\gamma \notin \mathcal{C}} \Pr_{G\in\mathcal{B}_k}[\, G \in \mathcal{B}_k(E_\gamma)\,] \leq 2^{6S}$ and thus,

$$SUM_2 \leq \max_{\gamma\notin\mathcal{C}} \Pr_{G\in\mathcal{B}_k}\left[w''_\gamma(G) \geq \frac{S}{\log n} \mid G \in \mathcal{B}_k(E_\gamma)\right] \times 2^{6S}.$$

Claim 4 of section 12 shows that $\Pr_{G\in\mathcal{B}_k}\left[\, w''_\gamma(G) \geq S/\log n \mid G \in \mathcal{B}_k(E_\gamma)\,\right]$ is at most 2^{-9S} for any γ in A. In conclusion,

$$\begin{aligned} SUM_1 + SUM_2 &\leq 2^{-3S} + 2^{-9S+6S} \\ &\leq 2^{-3S+1} \\ &\leq 2^{-2S}, \end{aligned}$$

where all inequalities hold for big enough n. Therefore, Lemma 8.1 (main lemma) follows. ∎

11. Bounding SUM_1. This section bounds the first sum, SUM_1, at the end of the proof for Lemma 8.1 (main lemma).

CLAIM 2. $\sum_{\gamma\in\mathcal{C}} \Pr_{G\in\mathcal{B}_k}[G \textit{ follows } \gamma] \leq 2^{-3S}$.

Proof. We first define two games called the *edge-collision game* and the *branching-process game*. Let S_{ed} and S_{br} be the random variables indicating the success of each game, respectively. We shall show that $\sum_{\gamma\in\mathcal{C}} \Pr_{G\in\mathcal{B}_k}[\, G \text{ follows } \gamma\,] \leq \Pr[\, S_{ed}\,] \leq \Pr[\, S_{br}\,] \leq 2^{-3S}$. ∎

11.1. The edge-collision game. The *edge-collision game* is defined as follows. D^{k-1} graphs $G_1, G_2, \ldots, G_{D^{k-1}}$ are chosen randomly and independently from $\mathcal{B}(2^k\chi)$. The player is informed of the hard path of each root in each G_i. He then queries edges of the G_is one at a time. When the player queries an edge, he specifies $\langle u, \ell\rangle$, where u is a node and $\ell \in [0..f-1]$ is an edge label. The destination node v of the edge $\langle u, \ell, v\rangle$ is then revealed to the player. Based on the result of the previous queries, he chooses the next edge to query. He is allowed to query at most $\chi/8$ edges total.

The aim of the player is to minimize the number of leaves of certain trees associated with the queried edges. To be precise, let E be the sequence of base edges of the input graph G that the player has queried during the game. Recall that in section 10 a node v is called a *collision node* with respect to E if it is the destination of more than one edge in E. In this game, each edge in E will be in one of two conditions: *alive* or *dead*. An edge is said to be dead if its destination node is (1) a collision node or (2) the source of a previously queried edge. Otherwise, it is alive. We shall construct from E a collection of f-ary trees by taking the following steps.

Step 1. If E does not contain a path from any root r to a node v, then delete v from G (along with all its in-edges and out-edges).

Step 2. Delete all the nodes (along with their in-edges and out-edges) that are proper descendents in E of the destinations of the dead edges. The dead edges and their destinations are kept. The remaining edges in E that are alive are called the *y-edges* and their destination nodes are called the *y-nodes*. Each such node has a unique path from some root to it and that path contains no dead edges. Hence, the y-edges form a collection of disjoint f-ary trees.

*Step*3. "Fill up" the above trees so that each node has exactly f outgoing edges. More precisely, for each y-node that does not have exactly f outgoing edges (counting the dead edges), add the missing edges and attach to each such edge a complete f-ary tree, of appropriate depth, such that its leaves are at layer D. The nodes and edges that are added in this way are referred to as the *z-nodes* and the *z-edges*. They do not correspond to actual nodes and edges in the input graph G. Note that each z-node also has a unique path from some root to it and that path contains no dead edges.
We shall measure the performance of the game player by two sets of parameters. They are somewhat similar to $y_{\langle\gamma,r\rangle}$, $z_{\langle\gamma,r\rangle}$ defined in section 10. Define $\tilde{y}_r$ and $\tilde{z}_r$ (the performance parameters) as the number of y- and z-nodes at layer D that are descendents of the root node r. Again, a root r is said to be a *high-collision* root if $\tilde{y}_r + \tilde{z}_r \leq f^{D'}$, where $D' = D/8$ as defined in section 10. The goal of the player is to create as many high-collision roots as possible. More precisely, the player wins if there are more than $S/\log n$ high-collision roots. Let S_{ed} be the indicator variable of this event.

Note that the edge-collision game player can query whatever edges queried by A and hence ensure that $E_\gamma \subseteq E$, where E_γ and E are the set of edges queried by A and the game player, respectively. Consider the conditions for a root to be a high-collision root. In A, a root r is a high-collision root with respect to E_γ if $y_{\langle\gamma,r\rangle} + z_{\langle\gamma,r\rangle} \leq f^{D'}$, i.e., the number of vectors $\vec{\ell} \in Y_{\langle\gamma,r\rangle} \cup Z_{\langle\gamma,r\rangle}$ is small. If a vector $\vec{\ell} \in [0..f-1]^{D-1}$ is not in $Y_{\langle\gamma,r\rangle} \cup Z_{\langle\gamma,r\rangle}$, then the path obtained by following $\vec{\ell}$ from r must contain a collision node in E_γ. The same node will also be a collision node in the edge-collision game, provided $E_\gamma \subseteq E$. It follows that a high-collision root in A will also be a high-collision root in the game. Therefore, $\sum_{\gamma\in\mathcal{C}} \Pr_{G\in\mathcal{B}_k}[\,G \text{ follows } \gamma\,] \leq \Pr[\,S_{ed}\,]$.

11.2. The branching-process game. Before we introduce the branching-process game, we introduce some machinery that will be useful in bounding its probability of success.

Consider a rooted, complete, f-ary tree of depth d. We allow every edge of such a tree to *die* independently of all other edges with a fixed probability α. A node u is said to be *alive* if and only if no edge along the unique path from the root to u is dead. If Z_i denotes the number of alive vertices at level i, then the sequence $Z_0 = 1, Z_1, \ldots, Z_i, \ldots$ forms a branching process [2]. We will be interested in the distribution of the number of live vertices with depth d, i.e., the random variable Z_d. The expected number of live children for an alive node is $(1-\alpha)f$, and the expected value of Z_d is $((1-\alpha)f)^d$. More precisely, the generating function for the offspring distribution in this branching process is $g(x) = (\alpha+(1-\alpha)x)^f$ (i.e., the probability that a node has i out-edges that do not die is the coefficient of x^i in $g(x)$). A well-known fact is that if $(1-\alpha)f > 1$, then $\Pr[\,Z_d = 0\,] = \xi$, where ξ is the unique $x \in (0,1)$ such that $g(x) = x$. Moreover $\eta = g'(\xi) < 1$. The following lemma states that the probability that Z_d is much smaller than its expected value is not much greater than the probability that it is 0.

LEMMA 11.1 (see [25]). *If $(1-\alpha)f > 1$, then for $\tilde{d} \in [1,\ldots,d]$ such that $d-\tilde{d} \to \infty$ and $d \to \infty$,*

$$\Pr\left[Z_d \leq ((1-\alpha)f)^{\tilde{d}}\right] \leq \xi + O(\eta^{d-\tilde{d}}).$$

In the branching-process game we will consider a variant of the above trees defined in section 11.1, with depth D and out-degree f. For these trees, the variation lies in the existence of a *fixed* path from the root to some leaf whose edges are guaranteed

to survive; all other edges die independently with probability 1/4. Such a tree is said to *wither* if it has at most $f^{D'}$ live leaves. We want to bound the probability, ρ, that this happens.

To allow for a uniform treatment we first convert the f-ary trees to binary trees when $f > 2$. In particular, if $f > 2$, then $f = O(n^\epsilon)$ for some $\epsilon > 0$, and hence we can assume that f is a power of 2. Thus, we replace each node v and its f edges/children with a complete binary tree T_v of depth $\log f$, i.e., with f leaves. If v is not on the path that is guaranteed to survive, then all the edges in T_v die independently, with probability 1/4. Otherwise, the edges along a unique path of T_v (the path corresponding to the edge guaranteed to live) are guaranteed to survive while the rest die independently with probability 1/4. It is easy to see, inductively, that for any set of nodes at depth $i \log f$, $i = 0 \ldots D$, in the resulting binary tree, the probability of being alive is no more than that of the corresponding nodes at depth i in the f-ary tree. Moreover, $D = \lceil 80 \log n \rceil / \log f$, for all f, and hence it will suffice to prove the bound for $f = 2$ ($D = \lceil 80 \log n \rceil$).

Let v_i be the node at depth i which is on the path whose edges are guaranteed to survive and let v_i' be the sibling of v_i. Let ρ' be the probability that for all v_i, $i \in [1..2D/3]$, either v_i' is dead or v_i' is alive, but the subtree rooted at v_i', $T_{v_i'}$ has at most $f^{D'}$ live nodes, at depth D. Clearly, $\rho \le \rho'$. Each $T_{v_i'}$, is a complete binary tree of depth $D - i$, where every edge dies with probability 1/4. For $\alpha = 1/4$ and $f = 2$, we have $\xi = 1/9$ and $\eta = 1/2$. As D tends to infinity with n and $T_{v_i'}$ has depth at least $D/3$, we can apply Lemma 11.1 to bound the probability that $T_{v_i'}$ has fewer than $f^{D'}$ live nodes at depth D (given that v_i' is alive) by $1/9 + O((1/2)^{D-i-D'})$. Thus, the probability that $T_{v_i'}$ has at most $f^{D'}$ live leaves at depth D is no more than $1/4 + 1/9 + O((1/2)^{D-i-D'}) \le 1/4 + 1/9 + O((1/2)^{D/3-D'}) = \beta < 1/2$, since $D' = D/8$, $D = \lceil 80 \log n \rceil$ and n can be arbitrarily large. Since the $2D/3$ subtrees grow independently, we get $\rho \le \rho' \le \beta^{2D/3} \in O(n^{-5})$.

In the branching-process game in our graph we say that the root r of the same type of tree above is a *high-collision* root if the tree rooted at r withers. Since there are at most n roots, the expected number of high collision roots is $\mu \le n \times \rho \in O(n^{-4})$. Let S_{br} be the random variable indicating the event that there are more than $S/\log n$ high-collision roots. As each tree grows independently of the others, we can apply the Chernoff bound and prove that

$$\begin{aligned}
&\Pr[\, S_{br} \,] \\
&= \Pr\left[\text{ number of high collision roots } \ge \left(\frac{S}{\mu \log n}\right) \mu \right] \\
&\le 2^{-(\frac{S}{\log n})(\log(\frac{S}{\mu \log n}) - \log e)}.
\end{aligned}$$

Since $\mu \in O(n^{-4})$, $\Pr[\, S_{br} \,] \le 2^{-3S}$.

11.3. Branching-process game versus edge-collision game. This subsection proves the second inequality mentioned in the proof of Claim 2.

LEMMA 11.2. *The success of the edge-collision game is probabilistically dominated by the success of the branching processes game, i.e.,* $\Pr[S_{ed}] \le \Pr[S_{br}]$.

Proof. The edge-collision game starts by random choice of the graphs $G_1, G_2, \ldots, G_{D^{k-1}}$ in $\mathcal{B}(2^k\chi)$. For each $i \in [1..D^{k-1}]$, the first step in choosing G_i according to the distribution $\mathcal{B}(2^k\chi)$ is to randomly partition the $2^k\chi$ nodes at each layer into $2^k\chi/2$ easy nodes and $2^k\chi/2$ hard nodes and to choose the hard path rooted at each root

r. This information is revealed to the player. The edges in these paths correspond to the edges in the branching-process game that are guaranteed to live.

The next step in choosing G_i according to the distribution $\mathcal{B}(2^k\chi)$ is to choose for every remaining edge its destination among the $2^k\chi/2$ easy nodes at the next layer. This needs to be done only for those edges queried by the player. For each $i \in [1..D^{k-1}]$, for each layer $d \in [1..D]$, and for each $\tau \in [1..\chi/8]$, define the variable $v_{\langle i,d,\tau\rangle}$ to uniformly and independently take on a value from $[1..2^k\chi/2]$. Suppose that the player is querying $\langle u, \ell\rangle$, where u is a node at layer d in the graph G_i, and this is the τth query to easy edges at this layer in this graph. Then the variable $v_{\langle i,d,\tau\rangle} \in [1..2^k\chi/2]$ specifies the other endpoint of edge $\langle u, \ell\rangle$ among the $2^k\chi/2$ easy nodes at the next layer.

Consider the edge $\langle u, \ell\rangle$ queried at time t for some $t \in [1..\chi/8]$. Before this query, we do not know in advance which edges will be queried after time t because the player is able to choose them dynamically based on the result of the current query. However, the random variables $v_{\langle i,d,\tau\rangle}$ do tell us the resulting destinations of all the edges queried or to be queried. Together with the knowledge of the source of edges queried before time t, we can tell whether the current edge will die. Specifically, suppose $\langle u, \ell\rangle$ is the τth edge queried at layer d in G_i. Then it will die if either (1) there is another query at this layer $\tau' \in [1..\chi/8]$ with the same destination, i.e., $v_{\langle i,d,\tau\rangle} = v_{\langle i,d,\tau'\rangle}$ for some $\tau' \neq \tau$ or (2) the destination is the source of some edge queried before time t.

In order to compare the success probability of the edge-collision game and the branching-process game, let us first define random variables that will indicate which edges die in the branching-process game. For each root r in each of the graphs G_i, there is a corresponding root in the branching-process game. Consider the complete f-ary tree of height D rooted at such a root r. A specific edge in this tree can be specified by a string $\vec{\ell} \in [0..f-1]^*$. For each such edge, let $x_{\langle r,\vec{\ell}\rangle} \in \{0,1\}$ be the random variable indicating whether this edge dies. If the edge is one of the edges that are guaranteed to live in the branching-process game, i.e., the fixed hard path in the input graph, then $\Pr[x_{\langle r,\vec{\ell}\rangle}] = 0$. Otherwise, $\Pr[x_{\langle r,\vec{\ell}\rangle}] = 1/4$ independent of the other x variables.

Now consider a fixed algorithm for the edge-collision game. For each intermediate time step $t \in [0..\chi/8]$, we define the tth game as follows. The game starts with t time steps of the fixed algorithm for the edge-collision game. Let E_t be the resulting base edges queried. We want these edges to die in the tth game if and only if they die in the edge-collision game. As previously mentioned, the edge associated with $v_{\langle i,d,\tau\rangle}$ is dead if and only if (1) there is another query at this layer $\tau' \in [1..\chi/8]$ with the same destination, i.e., $v_{\langle i,d,\tau\rangle} = v_{\langle i,d,\tau'\rangle}$, or (2) the destination, i.e., $v_{\langle i,d,\tau\rangle}$, is the source of an edge queried before time t. In (1), the query associated with $v_{\langle i,d,\tau'\rangle}$ can occur either before or after time step t. Either way, we consider the edge associated with $v_{\langle i,d,\tau\rangle}$ dead. Given which edges in E_t have died, the set E_t can be transformed, as described in Steps (1) through (3) in section 11.1, into a collection of f-ary trees made up of y-nodes and y-edges (the living ones), z-nodes and z-edges, and some collision nodes and dead edges. The tth game is completed by finishing the branching process on the z-edges. Namely, each such edge will live or die according to the corresponding random variable $x_{\langle r,\vec{\ell}\rangle} \in \{0,1\}$. A node u in the resulting collection of trees is said to be *alive* if all the edges on the path from the root of the tree to u are alive. A root is said to be a *high-collision* root if it has at most $f^{D'}$ living nodes in layer D. The tth game succeeds if there are more than $S/\log n$ high-collision roots. Let S_t be the random variable indicating the success of the game.

Observe that the 0th game is simply the branching-process game and hence $S_{br} = S_0$. The $(\chi/8)$th game differs from the edge-collision game only in that in the edge-collision game all the z-nodes and z-edges added in Step 3 are treated as live while in the $(\chi/8)$th game some of the z-edges may die according to the $x_{\langle r,\vec{\ell}\rangle}$ variables. The additional children at layer D hurt only the edge-collision game player. Therefore, $\Pr\left[\, S_{(\chi/8)} \,\right] \geq \Pr\left[\, S_{ed} \,\right]$. What remains to be proved is that, for every $t \in [1..\chi/8]$, $\Pr\left[\, S_{t-1} \,\right] \geq \Pr\left[\, S_t \,\right]$.

Let $\vec{V}_{(<t)}$ specify a possible computation up to and including the $(t-1)$st query. It will specify the values of $t-1$ of the $v_{\langle i,d,\tau\rangle}$ variables. Which of them are specified will depend dynamically on the computation. The computation $\vec{V}_{(<t)}$ will also specify the set of queried edges in the graph E_{t-1} and the next query $\langle u,\ell\rangle$ made by the player. Let the node u be on layer d of G_i and the query be the τth one at this layer in this graph.

Let us consider the following cases. In the first case, E_{t-1} does not contain a unique path with no dead edges from a root to u. In this case, the descendant nodes and edges of node u will be deleted from the y-node tree, both in the $(t-1)$st game and in the tth game. Hence, whether this edge dies has no effect on either game. In the second case, $\langle u,\ell\rangle$ is on a hard path. For both games, the edge is guaranteed to live.

In the third case, E_{t-1} contains a unique path with no dead edges from a root to u and $\langle u,\ell\rangle$ is not on a hard path. Let r and $\vec{\ell}$ specify the root and the labels in this path. In the $(t$–$1)$st game, whether the edge from $\langle u,\ell\rangle$ dies is specified by the variable $x_{\langle r,\vec{\ell}\rangle} \in \{0,1\}$. In the tth game, the destination of the edge from $\langle u,\ell\rangle$ is specified by the variable $v_{\langle i,d,\tau\rangle}$. Consider one setting $\vec{V}_{(>t)}$ of all the $v_{\langle i',d',\tau'\rangle}$ variables other than those set by $\vec{V}_{(<t)}$ and other than the variable $v_{\langle i,d,\tau\rangle}$. Consider as well one setting $\vec{X}_{(\neq t)}$ of all the x variables other than $x_{\langle r,\vec{\ell}\rangle}$.

Compare $\Pr[S_{t-1} \mid \vec{V}_{(<t)}, \vec{V}_{(>t)}, \vec{X}_{(\neq t)}]$ and $\Pr[S_t \mid \vec{V}_{(<t)}, \vec{V}_{(>t)}, \vec{X}_{(\neq t)}]$. In both cases, the probability is only over the values of $v_{\langle i,d,\tau\rangle}$ and $x_{\langle r,\vec{\ell}\rangle}$. Everything else is fixed by $\vec{V}_{(<t)}$, $\vec{V}_{(>t)}$, and $\vec{X}_{(\neq t)}$. For every value of $v_{\langle i,d,\tau\rangle}$ and $x_{\langle r,\vec{\ell}\rangle}$, which edges die before time step t and which die after time step t is the same for both the $(t-1)$st and the tth game. The only change in the game is whether or not the edge from $\langle u,\ell\rangle$ dies. In the $(t-1)$st game, this edge dies with probability $\Pr[x_{\langle r,\vec{\ell}\rangle} \mid \vec{V}_{(<t)}, \vec{V}_{(>t)}, \vec{X}_{(\neq t)}] = 1/4$. In the tth game, this edge dies if there exists a $\tau' \in [1..\chi/8]$ $(\tau' \neq \tau)$ for which $v_{\langle i,d,\tau\rangle} = v_{\langle i,d,\tau'\rangle}$ or $v_{\langle i,d,\tau\rangle}$ is equal to the source of an edge queried before time t. $\vec{V}_{(<t)}$ and $\vec{V}_{(>t)}$ fix at most $\chi/8-1$ different values of the variables $v_{\langle i,d,\tau'\rangle}$ and at most $t-1 \leq \chi/8-1$ different values as the sources. The value for $v_{\langle i,d,\tau\rangle}$ is chosen uniformly from $[1..2^k\chi/2]$. Therefore, the probability that $v_{\langle i,d,\tau\rangle}$ collides with one of these $\leq 2(\chi/8-1)$ values given $\vec{V}_{(<t)}$, $\vec{V}_{(>t)}$, $\vec{X}_{(\neq t)}$ is at most $1/4$. Having a smaller probability of this edge dying can hurt only the tth game player. We can conclude that

$$\Pr\left[\, S_{t-1} \;\middle|\; \vec{V}_{(<t)}, \vec{V}_{(>t)}, \vec{X}_{(\neq t)} \,\right] \geq \Pr\left[\, S_t \;\middle|\; \vec{V}_{(<t)}, \vec{V}_{(>t)}, \vec{X}_{(\neq t)} \,\right]$$

and hence

$$\Pr\left[\, S_{t-1} \,\right]$$

$$= \sum_{\vec{V}_{(<t)},\vec{V}_{(>t)},\vec{X}_{(\neq t)}} \Pr\left[S_{t-1} \;\middle|\; \vec{V}_{(<t)},\vec{V}_{(>t)},\vec{X}_{(\neq t)} \right] \times \Pr\left[\vec{V}_{(<t)},\vec{V}_{(>t)},\vec{X}_{(\neq t)} \right]$$
$$\geq \sum_{\vec{V}_{(<t)},\vec{V}_{(>t)},\vec{X}_{(\neq t)}} \Pr\left[S_{t} \;\middle|\; \vec{V}_{(<t)},\vec{V}_{(>t)},\vec{X}_{(\neq t)} \right] \times \Pr\left[\vec{V}_{(<t)},\vec{V}_{(>t)},\vec{X}_{(\neq t)} \right]$$
$$= \Pr[\, S_t \,]. \quad \square$$

12. Bounding SUM_2. This section bounds the second sum at the end of the proof of Lemma 8.1. It suffices to show that $\Pr_{G\in\mathcal{B}_k}\left[\, w''_\gamma(G) \geq S/\log n \mid G \in \mathcal{B}_k(E_\gamma) \,\right] \leq 2^{-9S}$. The event $w''_\gamma(G) \geq S/\log n$ happens when at least $S/\log n$ of the low collision roots r have $Prog_{\langle\gamma,r\rangle}(G)$ true. If, for every root r, $Prog_{\langle\gamma,r\rangle}(G)$ were true with a fixed probability independent of the other roots, then we could apply the Chernoff bound directly. However, there are indeed dependencies among different roots. Fortunately, if each event has a low probability of success no matter what outcomes of the other events have, then by the following lemma from Edmonds [14] the Chernoff bound still holds.

LEMMA 12.1 (Lemma 14 of [14]). *Let $\mathcal{R}$ be the set of roots. For each $r \in \mathcal{R}$, let $\hat{x}_r \in \{\,0,1\,\}$ be the random variable indicating the success of the rth trial. For each $r \in \mathcal{R}$ and $\mathcal{O} \in \{\,0,1\,\}^{\mathcal{R}-\{\,r\,\}}$, let $Z_{\langle r,\mathcal{O}\rangle} = \Pr[\hat{x}_r = 1 \mid \mathcal{O}]$, where $\mathcal{O}$ indicates that the other trials have the stated outcomes. If for every r and every possible outcome of the other trials $\mathcal{O}$, $Z_{\langle r,\mathcal{O}\rangle} \leq \rho$, then for every $\delta > 1$, $\Pr[\sum_{r\in\mathcal{R}} \hat{x}_r \geq 2\delta\rho|\mathcal{R}|] \leq 2^{-0.38\delta\rho|\mathcal{R}|}$.*

Proof. Let $\hat{X} = \sum_{r\in\mathcal{R}} \hat{x}_r$. To bound $\Pr[\hat{X} \geq 2\delta\rho|\mathcal{R}|]$, we will consider a sequence of random variables, x_r, $r \in \mathcal{R}$, defined as follows: for x_1, we choose uniformly at random $\lambda_1 \in [0,1]$ and set $x_1 = 1$ if and only if $\lambda_1 \leq \Pr[\,\hat{x}_1 = 1\,]$. In general, if we have set $x_1 = a_1, \ldots, x_i = a_i$, we choose uniformly at random $\lambda_{i+1} \in [0,1]$ and set $x_{i+1} = 1$ if and only if $\lambda_{i+1} \leq \Pr[\,\hat{x}_{i+1} = 1 \mid \hat{x}_1 = a_1 \wedge \cdots \wedge \hat{x}_i = a_i\,]$. Clearly, the sequences $\hat{x}_r$ and x_r are identically distributed and $\Pr[\,x_r = 1\,] \leq \rho$ for all $r \in \mathcal{R}$.

Consider now a sequence of random variables y_r defined by $y_r = 1$ if and only if $\lambda_r \leq \rho$, $r \in \mathcal{R}$, where λ_r is as above. By construction, $x_r \leq y_r$ for all $r \in \mathcal{R}$. Hence, if $X = \sum_{r\in\mathcal{R}} x_r$ and $Y = \sum_{r\in\mathcal{R}} y_r$, then $X \leq Y$. Moreover Y is the sum of $|R|$ independent Boolean random variables. Applying the Chernoff bound we get, for $\delta > 1$,

$$\square\ \Pr\left[\, \hat{X} \geq 2\delta\rho|\mathcal{R}| \,\right] = \Pr[\, X \geq 2\delta\rho|\mathcal{R}|\,] \leq \Pr[\, Y \geq 2\delta\rho|\mathcal{R}|\,] \leq 2^{-0.38\delta\rho|\mathcal{R}|}.$$

In Claim 3, we first show that the probability that $Prog_{\langle\gamma,r\rangle}(G)$ is true is small for low-collision roots r. Then we will apply Lemma 12.1 in Claim 4 to get the desired bound for the second sum.

CLAIM 3. *For any computation path γ in A, any root r, and any subset $\mathcal{O}$ of roots indicating for which roots r' other than r, $Prog_{\langle\gamma,r'\rangle}(G)$ is true,*

$$\Pr_{G\in\mathcal{B}_k}\left[Prog_{\langle\gamma,r\rangle}(G) \mid G \in \mathcal{B}_k(E_\gamma) \text{ and } \mathcal{O} \right] \leq \frac{4}{3}\frac{y_{\langle\gamma,r\rangle}}{y_{\langle\gamma,r\rangle} + z_{\langle\gamma,r\rangle}}.$$

Proof. Let us consider a fixed γ and r. Recall that $\vec{\ell}_r(G)$ is the random variable indicating the vector of edge labels on the hard path rooted at r in graph G drawn from $\mathcal{B}_k$ and that $\vec{\ell}_r(G) \in Y_{\langle\gamma,r\rangle} \cup Z_{\langle\gamma,r\rangle}$. Recall as well that $Prog_{\langle\gamma,r\rangle}(G)$ is true if and only if $\vec{\ell}_r(G) \in Y_{\langle\gamma,r\rangle}$. We shall drop the subscripts in $Y_{\langle\gamma,r\rangle}$, $Z_{\langle\gamma,r\rangle}$, $y_{\langle\gamma,r\rangle}$, $z_{\langle\gamma,r\rangle}$, $\vec{\ell}_r(G)$, $Prog_{\langle\gamma,r\rangle}(G)$, and E_γ, when there is no chance of confusion. We shall also write

$\Pr_{G\in\mathcal{B}_k}[\,\cdot \mid G \in \mathcal{B}_k(E_\gamma)\,]$ as $\Pr[\,\cdot \mid E\,]$. Note that

$$\begin{aligned}
&\Pr[\,\mathit{Prog}(G) \mid E \text{ and } \mathcal{O}\,] \\
&= \frac{\Pr[\,\mathit{Prog}(G) \mid E \text{ and } \mathcal{O}\,]}{\Pr[\,\mathit{Prog}(G) \mid E \text{ and } \mathcal{O}\,] + \Pr[\,\neg\mathit{Prog}(G) \mid E \text{ and } \mathcal{O}\,]} \\
&= \frac{\sum_{\vec{\ell}\in Y} \Pr\left[\,\vec{\ell}(G) = \vec{\ell}\mid E \text{ and } \mathcal{O}\,\right]}{\sum_{\vec{\ell}\in Y} \Pr\left[\,\vec{\ell}(G) = \vec{\ell}\mid E \text{ and } \mathcal{O}\,\right] + \sum_{\vec{\ell}\in Z} \Pr\left[\,\vec{\ell}(G) = \vec{\ell}\mid E \text{ and } \mathcal{O}\,\right]}.
\end{aligned}$$

Let $\vec{\ell}_y$ be the vector in Y that maximizes $\Pr[\vec{\ell}(G) = \vec{\ell}\mid E \text{ and } \mathcal{O}]$ over $\vec{\ell}\in Y$ and let $\vec{\ell}_z$ be the vector in Z that minimizes $\Pr[\vec{\ell}(G) = \vec{\ell}\mid E \text{ and } \mathcal{O}]$ over $\vec{\ell}\in Z$. The above probability is at most

$$\begin{aligned}
&\frac{y \times \Pr\left[\,\vec{\ell}(G) = \vec{\ell}_y \mid E \text{ and } \mathcal{O}\,\right]}{y \times \Pr\left[\,\vec{\ell}(G) = \vec{\ell}_y \mid E \text{ and } \mathcal{O}\,\right] + z \times \Pr\left[\,\vec{\ell}(G) = \vec{\ell}_z \mid E \text{ and } \mathcal{O}\,\right]} \\
&\qquad = \frac{y}{y + \frac{\Pr\left[\,\vec{\ell}(G)=\vec{\ell}_z \mid E \text{ and } \mathcal{O}\,\right]}{\Pr\left[\,\vec{\ell}(G)=\vec{\ell}_y \mid E \text{ and } \mathcal{O}\,\right]} \times z}.
\end{aligned}$$

What remains to be proven is that

$$\frac{\Pr\left[\,\vec{\ell}(G) = \vec{\ell}_z \mid E \text{ and } \mathcal{O}\,\right]}{\Pr\left[\,\vec{\ell}(G) = \vec{\ell}_y \mid E \text{ and } \mathcal{O}\,\right]} \geq \frac{3}{4}.$$

Let $N_y(G)$ and $N_z(G)$, respectively, be the set of edges on the path with label $\vec{\ell}_y$ and $\vec{\ell}_z$ from root r in G. Let $H(G)$ be the random variable specifying the hard path rooted at r in G, i.e., both the nodes and the labels $\vec{\ell}(G)$. The fact that $\vec{\ell}_y \in Y$ means that the path following the edge labels in $\vec{\ell}_y$ is totally contained in E. Therefore, $N_y(G)$ is equal to some fixed value N_y determined by E. Then the statements $\vec{\ell}(G) = \vec{\ell}_y$ and $\vec{\ell}(G) = \vec{\ell}_z$ are equivalent to $H(G) = N_y$ and $H(G) = N_z(G)$, respectively. The possible values N_z for the random variable $N_z(G)$ (i.e., the path in G rooted at r with edge labels $\vec{\ell}_z$) can be divided into two sets. Let $N_z \in \mathcal{A}_z$ if and only if some edge $\langle u, \ell, v\rangle$ in N_z has the same destination with a different edge $\langle u', \ell', v'\rangle$ in E, i.e., $v = v'$ but $\langle u, \ell\rangle \neq \langle u', \ell'\rangle$. In this case, N_z cannot be the hard path. That is, for $N_z \in \mathcal{A}_z$, $\Pr[\,H(G) = N_z \mid E \text{ and } \mathcal{O}\,] = 0$. Now consider an $N_z \notin \mathcal{A}_z$. Given that G contains $E \cup N_z$ and satisfies $\mathcal{O}$, we argue that it is equally likely for $H(G)$ to be N_y or N_z. To see this, first observe that $\mathcal{O}$ does not affect how $H(G)$ can be chosen because $\mathcal{O}$ is a condition on the hard paths of roots other than r. Second, both fixed paths N_y and N_z, started from root r, are contained in $E \cup N_z$. Furthermore, neither N_y nor N_z contains any collision node with respect to $E \cup N_z$. By symmetry, it is equally likely for N_y and N_z to be chosen as $H(G)$. Hence,

$$\begin{aligned}
&\Pr[\,H(G) = N_y \mid N_z(G) = N_z \text{ and } E \text{ and } \mathcal{O}\,] \\
&= \Pr[\,H(G) = N_z \mid N_z(G) = N_z \text{ and } E \text{ and } \mathcal{O}\,].
\end{aligned}$$

Note as well that "$H(G) = N_z$" implies "$N_z(G) = N_z$." Therefore,

$$\Pr[\,H(G) = N_y \text{ and } N_z(G) = N_z \mid E \text{ and } \mathcal{O}\,]$$

$$= \Pr\left[\, H(G) = N_z \text{ and } N_z(G) = N_z \mid E \text{ and } \mathcal{O} \,\right]$$
$$= \Pr\left[\, H(G) = N_z \mid E \text{ and } \mathcal{O} \,\right].$$

The above ratio then becomes

$$\frac{\Pr\left[\, \vec{\ell}(G) = \vec{\ell}_z \mid E \text{ and } \mathcal{O} \,\right]}{\Pr\left[\, \vec{\ell}(G) = \vec{\ell}_y \mid E \text{ and } \mathcal{O} \,\right]}$$
$$= \frac{\sum_{N_z \notin \mathcal{A}_z} \Pr\left[\, H(G) = N_z \mid E \text{ and } \mathcal{O} \,\right]}{\Pr\left[\, H(G) = N_y \mid E \text{ and } \mathcal{O} \,\right]}$$
$$= \frac{\sum_{N_z \notin \mathcal{A}_z} \Pr\left[\, H(G) = N_y \text{ and } N_z(G) = N_z \mid E \text{ and } \mathcal{O} \,\right]}{\Pr\left[\, H(G) = N_y \mid E \text{ and } \mathcal{O} \,\right]}$$
$$= \Pr\left[\, N_z(G) \notin \mathcal{A}_z \mid H(G) = N_y \text{ and } E \text{ and } \mathcal{O} \,\right].$$

The input distribution $\mathcal{B}_k$ first chooses the hard paths. Then every other edge is added independently at random. If $N_z(G)$ is not a hard path, at each level $i \in [2..D]$, its node is chosen from the $2^k\chi/2$ easy nodes at this level. A sufficient condition for $N_z(G)$ not to be in $\mathcal{A}_z$ is that for all its edges not fixed by E, their destinations do not collide with any node mentioned in E. Let h_i be the number of nodes mentioned in E at level i that $N_z(G)$ must avoid. It follows that

$$\Pr\left[\, N_z(G) \notin \mathcal{A}_z \mid H(G) = N_y \text{ and } E \text{ and } \mathcal{O} \,\right]$$
$$\geq \Pi_{i \in [2..D]} \left(1 - \frac{h_i}{2^k\chi/2}\right)$$
$$\geq 1 - \frac{\sum_{i \in [2..D]} h_i}{2^k\chi/2} \;\geq\; 1 - \frac{2 \cdot \chi/8}{2^k\chi/2} \;\geq\; \frac{3}{4}$$

because $\sum_{i \in [2..D]} h_i \leq \chi/8$ and E contains at most $\chi/8$, different edges and each edge involves two nodes. □

CLAIM 4. *For any computation path γ in A,*

$$\Pr_{G \in \mathcal{B}_k}[w''_\gamma(G) \geq S/\log n \mid G \in \mathcal{B}_k(E_\gamma)] \leq 2^{-9S}.$$

Proof. Recall that $w''_\gamma(G)$ is the number of roots r in G such that r is a low-collision root with respect to γ and $Prog_{\langle\gamma,r\rangle}(G)$ is true. Hence, the expected value μ of $w''_\gamma(G)$ is

$$\sum_{\text{low-collision roots } r} \Pr_{G \in \mathcal{B}_k}\left[\, Prog_{\langle\gamma,r\rangle}(G) \mid G \in \mathcal{B}_k(E_\gamma) \,\right],$$

and by Claim 3,

$$\mu \leq \sum_{\text{low-collision root } r} \frac{4}{3} \times \frac{y_{\langle\gamma,r\rangle}}{y_{\langle\gamma,r\rangle} + z_{\langle\gamma,r\rangle}}$$
$$\leq \frac{4}{3} \frac{\sum_{\text{low-collision root } r} y_{\langle\gamma,r\rangle}}{f^{D'}}$$
$$\leq \frac{\chi}{6 \cdot f^{D'}},$$

as $\sum_r y_{\langle\gamma,r\rangle} \leq \chi/8$ (at most $\chi/8$ different edges are queried by γ). Since $\chi \in O(n)$ and $f^{D'} \geq n^{10}$, we have $\mu \in O(n^{-9})$. By Lemma 12.1,

$$\begin{aligned}&\Pr_{G\in\mathcal{B}_k}\left[\, w''_\gamma(G) \geq \frac{S}{\log n} \mid G \in \mathcal{B}_k(E_\gamma)\right]\\ &\leq 2^{-(\frac{S}{\log n})(\log(\frac{S}{\mu \log n})-\log e)}\\ &\leq 2^{-9S}. \qquad \square\end{aligned}$$

13. Conclusion. We have proven that any 2-sided probabilistic NNJAG solving the *st*-connectivity problem for n-node graphs in (expected) time T using space S must have $T \in 2^{\Omega(\log^2(n/S))}$ when $S \in O(n^{1-\delta})$ for some $\delta > 0$, and $T \in 2^{\Omega(\log^2(\frac{n\log n}{S})/\log\log n)} \times (nS/\log n)^{1/2}$ for general $S \in O(n \log n)$. This greatly improves the previous bounds of $ST \in \Omega(n^2/\log n)$ by Barnes and Edmonds [4] and $S^{1/3}T \in \Omega(n^{4/3})$ by Edmonds [14]. Moreover, the bound is tight for $S \in n^{1-\Omega(1)}$. As a corollary, we also obtained a space lower bound of $\Omega(\log^2 n)$ on a probabilistic NNJAG. No such tight lower bound was known before, even in the more restricted JAG model.

An obvious open problem is to close the gap between the upper and lower bounds when $S \notin n^{1-\Omega(1)}$. However, the major open problem is to prove similar lower bounds on a general model of computation. To achieve that, one possible approach is to start with a JAG/NNJAG-like model and add more and more power, pushing our way towards the ultimate model of the branching program. A major complaint regarding a JAG or NNJAG is its restricted access to the inputs. As pointed out in Etessami and Immerman [17], the space lower bounds of [13, 7, 26] are proven on a tree. However, it is easy for a RAM to solve STCON on trees in $O(\log n)$ space. All it needs to do is to walk a "pebble" from node t backward and see if it hits node s.

In response to this, we define a model called the *Stack NNJAG* that can solve STCON for trees in $O(\log n)$ space, and yet on this model we can still prove the same time–space lower bound. In this model, there is a constant number of *stack* pebbles in addition to those regular pebbles. Each stack pebble has a stack which can remember the path that it has traversed since its last jump. More precisely, all the pebbles, whether regular or stack pebbles, are initially on node s. The stack of each stack pebble is empty initially. Whenever a stack pebble walks along an edge (u, v), the node u is pushed onto the stack. Whenever a stack pebble jumps to another pebble P', it empties its stack. If P' is also a stack pebble, then P copies the stack of P' to its own stack. A stack pebble can also backtrack along the path, i.e., to move to the node v if v is the top of the stack and then pop the stack. Note that the pebble is not allowed to visit any arbitrary node. Any node reachable by a stack pebble must be reachable from s by a directed path. The space for storing the stacks is given for free.

To prove the time–space lower bound, observe that the height of the graph used in our paper is $O(\sqrt{(n\log n)/S})$. If $\sqrt{(n\log n)/S} \leq S/\log n$, each stack can store only at most $O(S/\log n)$ nodes. Since a stack NNJAG has a constant number of stack pebbles, it can be simulated by a normal NNJAG with at most $\Theta(S/\log n)$ extra pebbles. The extra pebbles simply jump to and remain on each node that a stack pebble reaches. This increases the space used by the algorithm by at most $\Theta(S)$. If $\sqrt{(n\log n)/S} \geq S/\log n$, then $S \leq n^{1/3}\log n$. In this case, the bound we have for a normal NNJAG is $T = 2^{\Omega(\log^2 n)}$. Now observe that the height of each stack is at most

the height of the graph, i.e., at most $O(\sqrt{n \log n})$. Hence, any stack NNJAG with space S can be simulated by a normal NNJAG with space $O(S + \sqrt{n \log n}) \in O(\sqrt{n \log n})$, and the same lower bound applies.

Note that the stack NNJAG model seems to be incomparable with a branching program because of the way we charge the space. Also, defining an intermediate model between the NNJAG model and branching program seems hard. For example, allowing the model to move a pebble to an arbitrary node or to the next node in some fixed ordering would give the power of branching programs. Within a polynomial factor of time and constant factor of space, so does allowing it to move a pebble backward along any directed edge [6]. The idea is that one can treat the graph as undirected and, using a universal traversal sequence [1], visit any vertex in polynomial time. Hence, whenever the branching program queries the out-edges of a node v, the enhanced NNJAG can place a pebble on node v (by the universal traversal sequence) and perform the same query on v.

Acknowledgments. We are especially grateful to Greg Barnes for his invaluable insights. We thank Allan Borodin, Faith Fich, Charles Rackoff, and Hisao Tamaki for their helpful discussions and support. We also thank the annonymous referees for their careful reading and helpful comments. Last but not the least, we thank Johan Håstad for pointing out a bug in the original proof of Lemma 12.1.

COMPUTING TWO-DIMENSIONAL INTEGER HULLS*

WARWICK HARVEY†

Abstract. An optimal algorithm is presented for computing the smallest set of linear inequalities that define the integer hull of a possibly unbounded two-dimensional convex polygon R. Input to the algorithm is a set of linear inequalities defining R, and the integer hull computed is the convex hull of the integer points of R. It is proven that the integer hull has at most $O(n \log A_{max})$ inequalities, where n is the number of input inequalities and A_{max} is the magnitude of the largest input coefficient. It is shown that the algorithm presented has complexity $O(n \log A_{max})$ and that this is optimal by proving that the integer hull may have $\Omega(n \log A_{max})$ inequalities in the worst case.

Key words. integer convex hull, linear inequalities, continued fractions

1. Introduction and motivation.

In this paper we present an algorithm for finding the integer hull of a possibly unbounded two-dimensional (planar) convex region in polynomial time, given the set of linear inequalities defining the region. By the integer hull of a region we mean the convex hull of the integer points contained in that region. This algorithm grew out of work in the field of constraint logic programming (CLP) [11], specifically integer solvers for CLP. As a result, the algorithm is presented in an incremental formulation (that is, the input is processed one inequality at a time with the integer hull being updated fully after each) because that is what is most suitable for use in a CLP language. While a nonincremental formulation of the algorithm can likely be made to run faster in practice, it will not improve the (worst case) time complexity, since in section 7 we prove our algorithm is optimal.

We see this two-dimensional algorithm as a first step and hope to generalize it to an algorithm for efficiently finding the integer hulls of systems in an arbitrary number of dimensions. There are several reasons why being able to compute the integer hull of a system is useful. The integer hull provides a convenient and concise description of the set of all integer solutions of the input set, which is particularly useful if the number of such solutions is large or even infinite. It also implicitly answers the satisfiability question, which is the basis of constraint solvers for CLP. Thus if incrementally computing the integer hull is efficient enough, it may provide an interesting alternative to the partial solvers for integer CLP used to date (e.g., [7, 4, 10]). Finally, the integer hull allows integer linear optimization to be performed in polynomial time by using real optimization algorithms, though this is likely to be of limited utility unless a number of such optimizations are to be performed on the same feasible set.

In section 2 we discuss existing and related work. In section 3 we discuss some assumptions and notation. Section 4 shows how to find the integer hull of a single pair of inequalities, while section 5 uses this technique to compute the integer hull of

a full set of inequalities. In section 6 we prove a time bound on the algorithm, and in section 7 we prove optimality. Finally, in section 8 we describe areas for future work.

2. Existing and related work. The only other existing algorithm for computing the integer hull of a polyhedron of which we are aware is presented in Schrijver [16, Chap. 23]. The algorithm works by successive approximation of the integer hull and is guaranteed to terminate after a finite number of such approximation steps. Each step involves finding the minimal total dual integral system describing the current approximation. Since such a system can be exponentially large, clearly each step can take exponential time. Moreover, Schrijver presents an example which shows that, even when restricted to the two-dimensional case, the number of steps taken may be exponential in the size of the problem. Our algorithm solves the given example in linear time.

Kannan [12] gave an algorithm for two-dimensional linear integer optimization in polynomial time (assuming the variables are nonnegative). Lenstra [13] showed that linear integer optimization in any fixed number of dimensions could be done in polynomial time. An interesting question is whether a similar result can be found for the problem of computing the integer hull, i.e., whether it can be done in polynomial time for any fixed number of dimensions.

There exist a number of algorithms for computing the convex hull of a finite set of points. Several algorithms and a review of others can be found in [9] and [15]. They include algorithms specifically for two dimensions, as well as algorithms for an arbitrary number of dimensions. Attempting to use these algorithms to help find the integer hull still leaves the problem of constructing the point set to give them and does not allow the handling of infinite solution sets.

Quite a number of algorithms have been developed for finding a (precise) finite description of all solutions of linear Diophantine equations and inequalities. For example, there are algorithms which focus on finding minimal solutions (e.g., [8]), algorithms which focus on finding nonambiguous solutions (e.g., [1]), and algorithms which focus on avoiding introducing slack variables (e.g., [2]). All of these algorithms resort to complete enumeration when the solution space is finite, which is inefficient if it is particularly large. Whether this matters, and whether the integer hull would be a better representation, depends on the end use for the algorithm.

3. Preliminaries. In the following, we assume that the coefficients of the input inequalities are integers; rational coefficients can be handled by appropriate multiplication. Because we are working in two dimensions, any given inequality C_i (for some i) can be written in the form

$$a_i x + b_i y \leq c_i.$$

For each such inequality, we assume that $\gcd(|a_i|, |b_i|) = 1$. If this is not the case (say, $\gcd(|a_i|, |b_i|) = k_i$), then it can be made so by replacing it with

$$\frac{a_i}{k_i} x + \frac{b_i}{k_i} y \leq \left\lfloor \frac{c_i}{k_i} \right\rfloor.$$

Note that the set of integer points satisfying this replacement inequality is exactly the set of integer points satisfying the original inequality.

We also use $C_i^{=}$ to denote the supporting line of C_i, namely,

$$a_i x + b_i y = c_i.$$

We make use of a number of results from the theory of continued fractions. For an introduction to continued fractions, see, for instance, [6] or [3, Chap. 32]. Briefly, any quantity X can be written as

$$a_1+\cfrac{1}{a_2+\cfrac{1}{a_3+\cfrac{1}{a_4+\cdots}}},$$

where the a_k's (called *partial quotients*) are integers and all denominators are positive. The expansion terminates exactly when X is rational. The *principal convergents* of X are rational approximations p_k/q_k to X, obtained by truncating the continued fraction expansion of X after the kth term. p_k and q_k can be computed using the recurrence relations

$$\begin{array}{lll} p_0 = 1; & p_1 = a_1; & p_k = a_k p_{k-1} + p_{k-2},\ k \geq 2; \\ q_0 = 0; & q_1 = 1; & q_k = a_k q_{k-1} + q_{k-2},\ k \geq 2. \end{array}$$

The principal convergents are "good" approximations in that no simpler fraction is as close to X in value as any particular principal convergent. If any $a_k > 1$, then between p_{k-2}/q_{k-2} and p_k/q_k we define *intermediate convergents*

$$\frac{p_{k-2} + jp_{k-1}}{q_{k-2} + jq_{k-1}},\ j = 1 \cdots a_k - 1.$$

4. Finding the integer hull of a pair of inequalities. Before we look at the full integer hull computation, we first show how to compute the integer hull of a pair of inequalities that are adjacent on the (real) hull. This is a key step in computing the integer hull of an arbitrary set of inequalities, which is described in section 5.

Assume the two inequalities are

$$\begin{aligned} a_1 x + b_1 y \leq c_1 \quad (C_1), \\ a_2 x + b_2 y \leq c_2 \quad (C_2). \end{aligned}$$

Let Δ be the determinant of the coefficient matrix (i.e., $\Delta = a_1 b_2 - b_1 a_2$). Without loss of generality, assume that the (counterclockwise) angle between C_1 and C_2 is less than 180 degrees so that $\Delta > 0$ (otherwise, swap C_1 and C_2).

We now compute the intersection point of $C_1^=$ and $C_2^=$, which will be an extreme point of the (real) feasible region. If this point is integral, then clearly we already have the integer hull and we are done. Otherwise, we need to perform cuts to obtain the integer hull, and we now describe how to compute exactly which cuts are needed to completely define the integer hull.

First, we perform a unimodular[1] transformation from x and y to X and Y such that one of the inequalities is transformed into an inequality in only one variable (say, X), specifically, an inequality of the form $X \leq c$. We would also like the other transformed inequality to have a nonpositive X coefficient and a positive Y coefficient to ensure a standard orientation for later parts of the algorithm. The unimodularity of the transformation ensures that computing the integer hull in XY space is equivalent

[1] A unimodular matrix (transformation) is an integral matrix with determinant ± 1. The main property of interest to us here is that both the transformation and its inverse preserve integrality: they both map integer points to integer points.

to doing it in xy space. To determine the transformation matrix, we thus need to solve

$$\begin{bmatrix} a_1 & b_1 \\ a_2 & b_2 \end{bmatrix} \begin{bmatrix} \alpha & \beta \\ \gamma & \delta \end{bmatrix} = \begin{bmatrix} t & u \\ 1 & 0 \end{bmatrix} \tag{4.1a}$$

such that

$$\text{(unimodularity)} \quad \alpha\delta - \beta\gamma = \pm 1, \tag{4.1b}$$

$$t \le 0, \tag{4.1c}$$

$$u > 0. \tag{4.1d}$$

The transformed inequalities will then be

$$tX + uY \le c_1, \tag{4.2a}$$

$$X \le c_2. \tag{4.2b}$$

LEMMA 4.1. *The transformation matrix*

$$\begin{bmatrix} \alpha & \beta \\ \gamma & \delta \end{bmatrix} = \begin{bmatrix} \alpha_0 + kb_2 & b_2 \\ \gamma_0 - ka_2 & -a_2 \end{bmatrix}$$

satisfies the conditions (4.1), *where* α_0 *and* γ_0 *are any integral solution of* $a_2\alpha_0 + b_2\gamma_0 = 1$ *and* $k = \left\lfloor \frac{-a_1\alpha_0 - b_1\gamma_0}{\Delta} \right\rfloor$.

Proof. It is straightforward that (4.1a), (4.1b), and (4.1d) hold. For (4.1c) we have

$$\begin{aligned} t &= a_1\alpha + b_1\gamma \\ &= a_1\alpha_0 + ka_1b_2 + b_1\gamma_0 - kb_1a_2 \\ &= \Delta \left\{ \frac{a_1\alpha_0 + b_1\gamma_0}{\Delta} + \left\lfloor \frac{-a_1\alpha_0 - b_1\gamma_0}{\Delta} \right\rfloor \right\} \\ &\le 0, \text{ since } \Delta > 0. \end{aligned}$$

∎

We now find the integer point on the supporting line of (4.2a) that is immediately on the feasible side of the supporting line of (4.2b), i.e., the point on the line with the largest X coordinate while still being feasible (call it (x_1, y_1)). Given an arbitrary integral point (x_0, y_0) on the supporting line of (4.2a) (which we can find by using, for example, a modified Euclid's algorithm), the point we are after is given by

$$(x_1, y_1) = \left(x_0 + \left\lfloor \frac{c_2 - x_0}{u} \right\rfloor u, y_0 - \left\lfloor \frac{c_2 - x_0}{u} \right\rfloor t \right).$$

We now translate the coordinate system so that this point becomes the new origin:

$$\begin{bmatrix} X' \\ Y' \end{bmatrix} = \begin{bmatrix} X \\ Y \end{bmatrix} - \begin{bmatrix} x_1 \\ y_1 \end{bmatrix}.$$

This means the inequalities (4.2a) and (4.2b) now become

$$tX' + uY' \le 0, \tag{4.3a}$$

$$X' \le c_2 - x_1. \tag{4.3b}$$

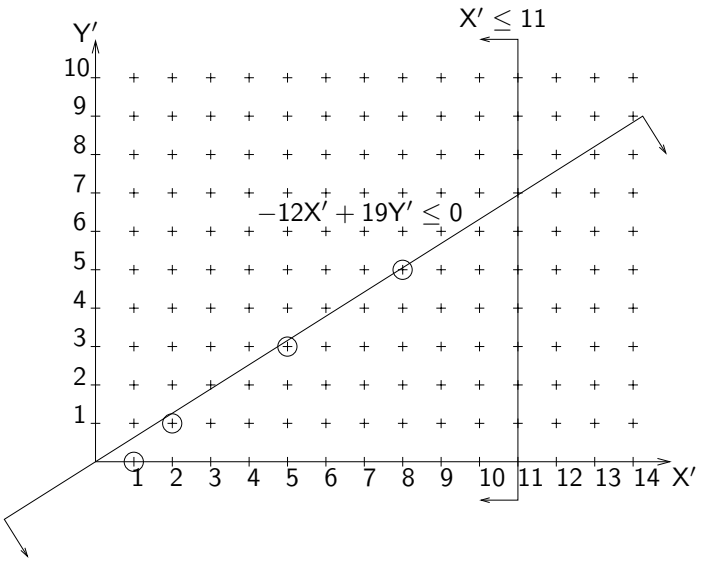

FIG. 4.1. *Two inequality integer hull example: the transformed initial inequalities.*

For example, if the initial inequalities are $5x + 2y \leq 8$ and $-2x + 3y \leq 4$, the transformed inequalities are $-12X' + 19Y' \leq 0$ and $X' \leq 11$, as shown in Figure 4.1.

We are now up to the "interesting" part, where we actually start computing the integer hull. If we think of the boundary of the real region as being a piece of string, and assume each integer point on the plane has a peg in it, finding the integer hull can be thought of as pulling the string tight. To compute this, we essentially need to find the points where the string bends. Due to our construction, there are no integer points on (4.3a) between the origin and where it meets (4.3b), so the first of these articulation points is the origin itself. The main task in finding the next one is determining the gradient of the next segment of "string." This involves rotating this "slack" section of (4.3a) (between the origin and where it meets (4.3b)) clockwise about the origin until it hits the first integer point(s) which satisfy (4.3b). The requirement that it satisfies (4.3b) means we only consider points with X'-coordinate no greater than $c_2 - x_1$. If we look at the problem in terms of the gradients of lines passing through the origin, the feasible integer points correspond to gradients p/q such that $q \leq c_2 - x_1$. Thus we are looking for the fraction p/q which is as close to $-t/u$ as possible (on the "less than" side) with a denominator no greater than $c_2 - x_1$. To find it, we make use of the following theorem.

THEOREM 4.2. *Suppose we are required to find the fraction, whose denominator does not exceed D, which most closely approximates, but is no greater than, the quantity X. If we construct a sequence of fractions containing all the odd principal convergents of X with their corresponding intermediate convergents (if such convergents exist), then the fraction we desire is the element of this sequence with the largest denominator no greater than D.*

Proof. See, for example, [3, Chap. 32, sects. 12–16]. □

Thus the fraction we are looking for can be found by searching the sequence of odd principal convergents for $-t/u$ and the corresponding intermediate convergents (these convergents correspond to the circled points in Figure 4.1). Since the inter-

mediate convergents, if any, have denominators in arithmetic progression between the denominators of the principal convergents on either side, we actually only (construct and) search the sequence of odd principal convergents and then compute the appropriate intermediate convergent directly.

Let p/q be the fraction found by the search. Then this is the gradient of the line from the origin to the first integer point encountered when sweeping the hull segment around. Thus the next segment of the integer hull is given by

$$-pX' + qY' \leq 0. \tag{4.4}$$

Transformed back to the original coordinate system, it is

$$(p\delta + q\gamma)x - (p\beta + q\alpha)y \leq -px_1 + qy_1. \tag{4.5}$$

As the next step in our algorithm, we determine whether this new inequality (4.4) intersects (4.3b) (the vertical inequality) at an integer extreme point. If it does, then we have finished computing the integer hull of the original pair of inequalities. If it does not, then we need to proceed with computing the next cut. If we stay in $X'Y'$ space, this is just the first cut of the integer hull of (4.4) and (4.3b). The inequalities are already oriented appropriately, so we just need to translate them to bring them into our standard form. This involves finding the integer point on the supporting line of (4.4) that has greatest X' coordinate while still being feasible with respect to (4.3b) and moving it to the origin. Note that the "hard" part of finding this integer point, namely, finding an arbitrary point on the line, can be skipped because we already have one: the origin. Thus computing the translation is trivial. We also note that we need not compute the list of convergents for the gradient of (4.4) because it is a prefix of the list of convergents we already computed for $-t/u$ (p/q was basically formed by truncating the continued fraction expansion of $-t/u$).

5. Constructing the full two-dimensional integer hull. We now describe how to find the full two-dimensional integer hull of a set of inequalities in an incremental fashion. Adding the first inequality (to an empty existing set) is straightforward and obvious, so we concentrate on what happens when we add an inequality to an existing integer hull. We keep the inequalities sorted based on orientation (e.g., using the counterclockwise angle between the x-axis and the normal vector of the inequality). The question of what data structure to use to store the inequalities is deferred to section 6, where we analyze the computational complexity of the algorithm.

Since the existing system is an integer hull, we may assume that it is satisfiable and contains no redundant inequalities. Let the inequality being added be $C \equiv ax+by \leq c$. The first thing we do is check whether the augmented system is (real) unsatisfiable. This is equivalent to checking whether $ax + by > c$ (or equivalently $ax + by \geq c + 1$) is (real) redundant with respect to the existing system.

An inequality is (real) redundant if every point that is feasible with respect to every other inequality is also feasible with respect to this inequality. This means that if it is redundant, its supporting line lies on or outside the convex hull of the other inequalities and it is either parallel to the closest edge of the feasible region or there is a closest vertex. For the first case (parallel), we can just check whether there is another inequality with the same orientation and compare right-hand side constants. Otherwise, for the second case, we can find the inequalities that belong just before (C_{i-1}) and just after (C_{i+1}), the inequality being checked (C_i) in the sorted sequence, and see whether these form a vertex which is both feasible with respect to C_i and

also the closest feasible point to $C_i^=$. This is the case if the (counterclockwise) angle between C_{i-1} and C_{i+1} is less than 180 degrees and the intersection of $C_{i-1}^=$ and $C_{i+1}^=$ is feasible with respect to C_i.

If we have discovered that the augmented system is unsatisfiable, then there is no integer hull and we stop. Otherwise, we proceed by checking whether the inequality we are adding is redundant. If it is, then we have nothing to do and the integer hull is unchanged. Otherwise, we proceed to check the inequalities immediately before and after it for redundancy. If the inequality immediately before (after) it is redundant, the redundant inequality is discarded and the next inequality before (resp., after) it is checked. This process continues until an irredundant inequality is found.

Note that at this point the set of inequalities define a convex hull (though most likely not an integer hull), and since all but one inequality (C) was part of the existing integer hull, all the vertices that are not on $C^=$ are guaranteed to be at integral locations.

We consider two cases, depending on whether or not the new inequality has a feasible integer point on its supporting line. The first case is where it does. We can just compute the integer hull of C pairwise with each of the adjacent inequalities, as per section 4 (as long as the relevant angle is less than 180 degrees; if it isn't, the region is unbounded between the inequalities and there are no cuts to compute), and add the resulting cuts to our description of the integer hull. Note that since the new inequality contains a feasible integer point, the pairwise integer hulls are guaranteed not to overlap. This is because at worst there is only one feasible integer point on the supporting line of the new inequality and the two pairwise integer hulls meet at this point. Note that any inequality involved in a nonintegral intersection before the cuts were made may have become redundant (if it only had one feasible integer point on its supporting line to begin with), so this must be checked for and the inequalities must be discarded if they are indeed redundant.

The second case is where there is no feasible integer point on the supporting line of the new inequality. In this case, computing the pairwise integer hulls of the new inequality with the inequalities on either side of it will generate cuts which overlap, and the new inequality is guaranteed to be redundant with respect to the final integer hull. The method described here shows how to deal with these overlapping cuts in a way which ensures that no more than one redundant cut is ever generated.

Let C_i be the new inequality with C_{i-1} and C_{i+1} the inequalities immediately to the clockwise and counterclockwise sides of C_i, respectively. We commence computing the cuts that form the integer hull of C_{i-1} and C_i, as per section 4, and continue until we make a cut (call it C_i') that causes C_i to become (real) redundant.[2] At this point, we now have at most one vertex remaining which is nonintegral, namely, the one at the intersection of C_i' and C_{i+1}. Thus to complete the integer hull, we simply compute the pairwise integer hull of C_i' and C_{i+1}. As before, some of the inequalities need to be checked for (real) redundancy. These are C_{i-1}, C_{i+1}, and C_i' (C_i is guaranteed to be redundant and thus need not be checked, just discarded).

This completes the integer hull algorithm.

6. Computational complexity. We now demonstrate that the algorithm presented has complexity $O(n \log A_{max})$. The time analysis is presented in terms of basic arithmetic operations $(+, -, \times, /)$.

[2] We start with C_{i-1} and C_i rather than C_i and C_{i+1} so that the pairwise hull algorithm generates cuts in an appropriate order ("outside in"), beginning with those adjacent to C_{i-1} and working toward C_i.

We start with the following definitions. Let A_{max} be the maximum absolute value of any coefficient of x or y in any original inequality added to the system.

We start by obtaining bounds for the coefficients of the inequalities that define the integer hull.

In the following, we assume all fractions p/q are in lowest terms (i.e., $\gcd(p,q) = 1$). Let p^+/q^+ (p^-/q^-) be the smallest (resp., largest) rational that is greater than (resp., less than) p/q with a denominator no larger than q.

LEMMA 6.1. *If p_{j-1}/q_{j-1} and p_j/q_j are consecutive principal convergents of p/q, then $p_jq_{j-1} - p_{j-1}q_j = (-1)^j$.*

Proof. See, for example, [3, Chap. 32, sect. 8]. □

LEMMA 6.2. *If p/q and p'/q' are two fractions such that $pq' - p'q = 1$ and $q > 0$, then no fraction can lie between them unless its denominator is greater than the denominator of both of them.*

Proof. See, for example, [3, Chap. 32, Sect. 12]. □

LEMMA 6.3. *Consider the two fractions*

$$\frac{p_{n-1}}{q_{n-1}}, \qquad \frac{p_n - p_{n-1}}{q_n - q_{n-1}}.$$

If $0 < p/q < 1$, then one of these is the closest above approximation (p^+/q^+) of $p/q = p_n/q_n$ and the other is the closest below approximation (p^-/q^-), depending on whether n is odd or even.

Proof. $0 < p/q < 1$ implies that $q > 0$, and also that $n \geq 1$, so that p_{n-1} and q_{n-1} are defined. Thus, using Lemmas 6.2 and 6.1, it is straightforward that these are the closest above and below approximations with denominators no greater than q. If n is odd, then p_{n-1}/q_{n-1} is the above approximation; if n is even, it is the below approximation. □

COROLLARY 6.4. *$pq^+ - p^+q = -1$ and $pq^- - p^-q = 1$ if $0 < p/q < 1$.*

Proof. This is obvious from Lemmas 6.3 and 6.1. □

LEMMA 6.5. *Consider two inequalities C_0 and C_n with $C_1 \cdots C_{n-1}$ being the cuts required to form the pairwise integer hull. Consider any cut C_i ($1 \leq i \leq n-1$). If the magnitude of the larger of the coefficients of C_i is greater than 1, then it is strictly smaller than the largest magnitude coefficient appearing in C_{i-1} and C_{i+1}.*

Proof. If $C_i \equiv a_ix + b_iy \leq c_i$, then we can assume, without loss of generality, that $0 \leq a_i \leq b_i$. However, $b_i > 1$ implies $b_i \neq a_i$ and $a_i \neq 0$ (since $\gcd(a_i, b_i) = 1$), so we have $0 < a_i < b_i$. Let a_i^+/b_i^+ and a_i^-/b_i^- be closest above and below approximations to a_i/b_i, respectively. Let $P_0 = (x_0, y_0)$ and $P_1 = (x_1, y_1)$ be the (integral) intersection points of $C_i^=$ with $C_{i-1}^=$ and $C_{i+1}^=$, respectively, so that $x_0 > x_1$ and $y_0 < y_1$ (see Figure 6.1).Note that $x_0 - x_1 = kb_i$ and $y_1 - y_0 = ka_i$ for some integer $k > 0$. Also note that C_i is the cut required to form the integer hull of C_{i-1} and C_{i+1} and that there are no integer points which are infeasible with respect to C_i that are feasible with respect to C_{i-1} and C_{i+1} (i.e., the introduced cut excludes no feasible integer points). Consider the integer point $P_2 = (x_2, y_2) = (x_0 - b_i^+, y_0 + a_i^+)$. P_2 is infeasible with respect to C_i, so it must be infeasible with respect to at least one of C_{i-1} and C_{i+1}. We consider two possibilities:

1. Suppose P_2 is infeasible with respect to C_{i-1}. This means that the gradient of C_{i-1} must be between $a_i/-b_i$ and $a_i^+/-b_i^+$. By Corollary 6.4 and Lemma 6.2, any gradient that lies between these two has a denominator of magnitude larger than b_i. Since $b_i > a_i$, this means C_{i-1} must have a coefficient (namely, b_{i-1}) larger in magnitude than both a_i and b_i.

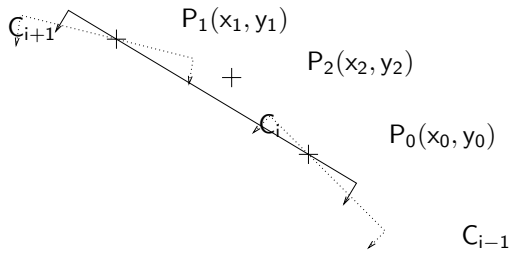

FIG. 6.1. *Determining bounds on the coefficients of adjacent cuts.*

2. Suppose P_2 is infeasible with respect to C_{i+1}. This means that the gradient of C_{i+1} must be between $a_i/-b_i$ and

$$\frac{y_1 - y_2}{-(x_1 - x_2)} = \frac{ka_i - a_i^+}{-(kb_i - b_i^+)}.$$

Again by Corollary 6.4 and Lemma 6.2, any gradient that lies between these two has a denominator of magnitude larger than b_i, which in turn means C_{i+1} must have a coefficient (namely, b_{i+1}) larger in magnitude than both a_i and b_i.

Since at least one of these two possibilities must be true, we have that at least one of C_{i-1} and C_{i+1} must have a coefficient larger in magnitude than those of C_i, as long as at least one of the coefficients of C_i is greater than 1. ∎

THEOREM 6.6. *For the integer hull of a pair of inequalities, the coefficients of the generated cuts are no larger in magnitude than the largest of those of the original inequalities.*

Proof. Let the two inequalities be C_0 and C_n with the generated cuts being $C_1 \cdots C_{n-1}$. Let A_i be the magnitude of the largest coefficient of C_i, $i = 0 \cdots n$. We note that no $A_i = 0$, since that would imply that $C_i \equiv 0x + 0y \leq c_i$. Let j be the smallest i such that A_i is minimal, so that $\forall i, A_i \geq A_j$. If $j > 0$, we have $A_{j-1} > A_j$, so $A_{j-1} > 1$. If $j > 1$, Lemma 6.5 implies $A_{j-2} > A_{j-1}$ since $A_j < A_{j-1}$. Further applications of Lemma 6.5 yield, in turn,

$$A_{j-2} < A_{j-3}, A_{j-3} < A_{j-4}, \ldots, A_1 < A_0.$$

Thus $\forall i \leq j, A_i \leq A_0$.

Let $k = \min\{i : i > j \wedge A_i > A_j\}$. If k is not defined (e.g., $j = n$), then $A_j = A_{j+1} = \cdots = A_n$. Otherwise, we have $A_j = A_{j+1} = \cdots = A_{k-1}$ and $A_k > A_{k-1}$. As before, repeated applications of Lemma 6.5 yield, in turn,

$$A_k < A_{k+1}, A_{k+1} < A_{k+2}, \ldots, A_{n-1} < A_n.$$

Thus $\forall i \geq j, A_i \leq A_n$.

This means that all A_i are no larger than the larger of A_0 and A_n, and the theorem is proved. ∎

THEOREM 6.7. *The coefficients of the inequalities defining an integer hull are no larger in magnitude than the largest coefficient of the input inequalities.*

Proof. Since all the inequalities in the system at any given time are either original input inequalities or are part of a pairwise integer hull of some combination of original

inequalities and inequalities already in the system, the result follows by a simple induction argument on Theorem 6.6. ∎

Now that we have an upper bound on the size of the coefficients in the system, we can obtain an upper bound on the number of inequalities in the system.

LEMMA 6.8. *The integer hull of a pair of inequalities with largest magnitude coefficient A_{max} requires at most $O(\log A_{max})$ inequalities to define it.*

Proof. Each cut generated in the transformed space corresponds to either an odd principal convergent of the gradient $(-t/u)$ of the main transformed inequality or to an intermediate convergent between two such odd principal convergents. To achieve the bound, we start by showing that even if there are many intermediate convergents between two odd principal convergents, only one can correspond to a cut of the integer hull. Consider an intermediate convergent that is used for a cut. If p_{2k-1}/q_{2k-1} and p_{2k+1}/q_{2k+1} are the odd principal convergents it lies between, then it is of the form $\frac{p_{2k-1}+jp_{2k}}{q_{2k-1}+jq_{2k}}$ for some j. Note that j is chosen as large as possible subject to the bound on the denominator, so the "slack" between the denominator and the bound must be less than q_{2k}. Since the translation in preparation for the next cut reduces the bound by (at least) the size of the denominator selected, this means the new bound must be less than q_{2k}. This, in turn, precludes any other intermediate convergents between p_{2k-1}/q_{2k-1} and p_{2k+1}/q_{2k+1} from being used to generate cuts, since such a convergent must have a denominator of at least $q_{2k-1} + q_{2k}$.

Thus we can generate no more than two cuts for each odd principal convergent: one for the odd principal convergent itself and one for a corresponding intermediate convergent.

The number of principal convergents is the same as the number of steps in the Euclidean algorithm for finding g.c.ds, applied to $|t|$ and u. This is $O(\log(\min(|t|, u)))$ [5, p. 811], but

$$\min(|t|, u) \le u = a_1\beta + b_1\delta = a_1b_2 - b_1a_2 = O(A_{max}^2)$$

(this last step by Theorem 6.7). So we have $O(\log A_{max})$ principal convergents and thus $O(\log A_{max})$ cuts generated. ∎

LEMMA 6.9. *When computing the integer hull of n (initial) inequalities with largest magnitude coefficient A_{max}, at most $O(n \log A_{max})$ cuts are added.*

Proof. Each time we add a new inequality to the integer hull, we perform at most two pairwise integer hull computations. By Lemma 6.8, each of these generates $O(\log A_{max})$ inequalities, and so after adding n (initial) inequalities, we can have added no more than $O(n \log A_{max})$ inequalities. ∎

LEMMA 6.10. *The integer hull of a set of any number of inequalities with coefficients of magnitude no larger than A_{max} requires at most $O(A_{max}^2)$ inequalities to define it.*

Proof. If the largest magnitude of an input coefficient is A_{max}, then by Theorem 6.7, the magnitudes of all coefficients in the integer hull are no greater than A_{max}. This means there are at most $O(A_{max}^2)$ different possible combinations of coefficients. Since there are no redundant inequalities in the integer hull, there can be no more than one inequality with a given combination of coefficients, and the result follows. ∎

We now proceed to analyze the time complexity of the algorithm. We start by analyzing the pairwise integer hull, and then we use that analysis to derive a time bound for the full algorithm.

THEOREM 6.11. *Computing the pairwise hull of two inequalities with largest magnitude coefficient A_{max} is $O(\log A_{max})$.*

Proof. To compute the integer hull of a pair of inequalities, the following steps are performed:

1. *If the intersection point is integral, we stop.* Finding the intersection point and determining whether it is integral is $O(1)$.

2. *Determine the transformation matrix.* The main step in determining the transformation matrix is finding a solution to $a_2\alpha + b_2\gamma = 1$; everything else is $O(1)$. Thus this step is $O(\log A_{max})$, using, for instance, a modified Euclid's algorithm to solve the equation.

3. *Compute the odd principal convergents.* We just compute all the principal convergents of $|t/u|$; this is $O(\log(\min(|t|, |u|))) = O(\log A_{max})$.

4. *Repeat the following steps until the intersection point is integral.* Each pass through this loop generates one cut, and so by Lemma 6.8, we loop no more than $O(\log A_{max})$ times.

(i) *Determine the appropriate translation.* The first time we perform this translation we must find an initial integer point on the supporting line of the "main" inequality, which is $O(\log A_{max})$, and then find the correct integer point, which is $O(1)$. All subsequent translation computations start with an integer point given, so we just require the $O(1)$ adjustment.

(ii) *Search for the appropriate principal convergent.* If we do a simple linear search backwards in the list of principal convergents, this is $O(\log A_{max})$. However, no principal convergent checked in one pass needs be checked again in a subsequent pass, so we can amortize the search cost for a total of $O(\log A_{max})$ over all passes through the loop.

(iii) *Compute the appropriate intermediate convergent.* This is $O(1)$.

(iv) *Transform the new cut back to the original coordinate system.* This is $O(1)$.

The result follows directly from the above analysis. □

We now turn to the full integer hull algorithm.

THEOREM 6.12. *Incrementally computing the integer hull of n inequalities with largest magnitude coefficient A_{max} is $O(n \log A_{max})$.*

Proof. For this analysis, we assume the inequalities in the system are stored in a level-linked (a,b)-tree, sorted based on their orientation. Level-linked (a,b)-trees are described in [14], along with proofs of the complexity results used here. Some modification of the standard operations on level-linked (a,b)-trees is required for our purposes, since our data is inherently circular in nature and wraps around from largest to smallest, but these do not affect the results.

Let N_j be the number of inequalities defining the existing integer hull just before we add the jth inequality ($C_j \equiv a_j x + b_j y \le c_j$). By Lemma 6.10, N_j is $O(A_{max}^2)$. In particular, this means that $\log N_j$ is $O(\log A_{max})$, and thus we have bounds for various tree operations (search, split, concatenate) which are independent of the number of inequalities added so far.

To add the inequality to the system and recompute the integer hull, we perform the following steps:

1. *Tighten the inequality being added.* This step consists mainly of computing the g.c.d. of $|a_j|$ and $|b_j|$, which is $O(\log(\min(|a_j|, |b_j|))) = O(\log A_{max})$.

2. *Check satisfiability of augmented system.* This requires searching the data structure to find where the complement of C_j would go and accessing at most two adjacent items. This is $O(\log A_{max})$, and the actual check is $O(1)$.

3. *Eliminate initial redundancy.* This requires searching the data structure to find where C_j would go ($O(\log A_{max})$) and then performing a series of redundancy checks. Since no inequality can be found to be redundant more than once, and at most $O(n \log A_{max})$ inequalities are added to the system for n input inequalities (Lemma 6.9), we have a total of $O(n \log A_{max})$ eliminations performed, summed over all n incremental steps. Since all but a constant number of redundancy checks at each incremental step result in an elimination, this means $O(n \log A_{max})$ redundancy checks are performed in total. Accessing the adjacent inequalities to perform one of these checks is $O(1)$, as is the actual check, which means the total cost of redundancy checks over all n additions is $O(n \log A_{max})$. Since all the inequalities to be eliminated due to redundancy are adjacent to each other, we can delete them all at the same time by performing two splits of the tree, which is $O(\log A_{max})$ (we leave it split until we are ready to insert the new inequalities). Thus this step as a whole, summed over all n additions, is $O(n \log A_{max})$.

4. *Compute the cuts.* We treat this as two instances of finding the integer hull of a pair of inequalities. This is not strictly the case when there are no integer points on the feasible segment of the supporting line of the inequality being added, but the extra redundancy checks required have no bearing on the computational complexity. Thus this step is $O(\log A_{max})$, by Theorem 6.11.

5. *Add the cuts to the system.* Since all the inequalities added will be adjacent to each other, and will be inserted at the point the existing tree was split, we can insert them all at the same time. Constructing a new tree from a sorted set is linear in the number of items in the tree, so this is $O(\log A_{max})$ by Lemma 6.8. Then we just perform two concatenation operations to add the new tree between the two parts created in step 3. This is also $O(\log A_{max})$, so the step as a whole is $O(\log A_{max})$.

6. *Eliminate final redundancy.* This requires at most three redundancy checks and three deletions and hence is $O(\log A_{max})$.

Each step is either $O(\log A_{max})$ for each inequality added or is $O(n \log A_{max})$ summed over all n inequalities. Outputting the inequalities is linear in the number output, which is $O(n \log A_{max})$ by Lemma 6.9. The result follows. ∎

7. Proof of optimality. We now show that our algorithm is optimal by demonstrating a worst case lower bound complexity of $\Omega(n \log A_{max})$. We do this by constructing a family of examples which generate $\Omega(n \log A_{max})$ output constraints.

LEMMA 7.1. *The integer hull of*

$$-2x + y \le -1, \tag{7.1a}$$

$$-F_{2k+5}x + F_{2k+4}y \le -1 \tag{7.1b}$$

has k cuts, where F_n is the nth Fibonacci number (with $F_0 = 0, F_1 = 1$).

Proof. Let $\phi = \frac{1+\sqrt{5}}{2}$ be the golden ratio. The continued fraction representation of ϕ is infinite with all partial quotients 1. Thus the sequence of closest below approximations to ϕ are given by p_{2j+1}/q_{2j+1} for $j \ge 0$, where p_i, q_i satisfy the recurrence relations

$$\begin{array}{lll} p_0 = 1; & p_1 = 1; & p_i = p_{i-1} + p_{i-2}, i \ge 2; \\ q_0 = 0; & q_1 = 1; & q_i = q_{i-1} + q_{i-2}, i \ge 2. \end{array}$$

Clearly, the p_i's and q_i's both form the Fibonacci sequence with $p_i = F_{i+1}$ and $q_i = F_i$. The below approximations are thus given by $F_{2j+2}/F_{2j+1}, j \ge 0$.

If we were to compute the (infinite) integer hull of $-\phi x + y \le 0$ and $-x \le -1$ (see Figure 7.1), then these below approximations clearly define the vertices of the integer

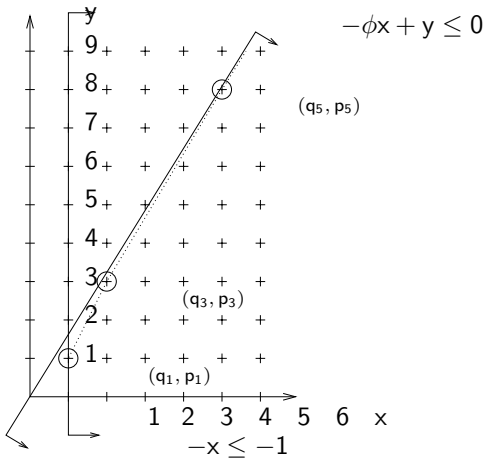

FIG. 7.1. *The infinite integer hull of* $-\phi x + y \leq 0$ *and* $-x \leq -1$.

hull. The inequality defining the jth edge (the edge between the jth and $(j+1)$th vertices) is then

$$-(p_{2j+3} - p_{2j+1})x + (q_{2j+3} - q_{2j+1})y \leq -(p_{2j+3} - p_{2j+1})q_{2j+1} + (q_{2j+3} - q_{2j+1})p_{2j+1},$$

i.e.,
$$-p_{2j+2}x + q_{2j+2}y \leq -p_{2j+2}q_{2j+1} + q_{2j+2}p_{2j+1},$$

i.e.,
$$-F_{2j+3}x + F_{2j+2}y \leq -1$$

(the last step by Lemma 6.1).

Note that we can select any two of these inequalities (say, $j = j_0$ and $j = j_1$), and the cuts needed to form the integer hull of the selected pair consist simply of all the inequalities between them in the above integer hull (namely, $j = j_0 + 1 \ldots j_1 - 1$). In particular, we can choose $j_0 = 0$ and $j_1 = k + 1$ and have the integer hull contain k cuts. The result follows. □

LEMMA 7.2. *It is possible for a system with* $2m$ *inequalities with largest magnitude coefficient* $O(m\phi^{2k})$ *to require at least* mk *cuts to complete the integer hull.*

Proof. We note that we can perform both translations and unimodular transformations on the integer hull used in Lemma 7.1 without altering its basic structure. Applying the unimodular transformation $\left[\begin{smallmatrix} 1 & 0 \\ -i & 1 \end{smallmatrix}\right]$, we obtain

$$-(2+i)x + y \leq -1, \tag{7.2a}$$

$$-(F_{2k+5} + iF_{2k+4})x + F_{2k+4}y \leq -1. \tag{7.2b}$$

Note that, since $F_{2k+5}/F_{2k+4} > 1$, both the inequalities (and all the cuts) have gradients larger than $1 + i$, and no greater than $2 + i$, which means that the range of gradients for one value of i does not overlap with that of another. This means that, with appropriate translation, we can construct a system of $2m$ inequalities, by including a "copy" of (7.2) for all values of i from 0 to $m - 1$, such that the integer hulls of each component do not interfere with each other. By Lemma 7.1, each component has k cuts, so with m noninterfering components, we have (at least) mk cuts (depending on the exact translation used, there may be cuts between each "block").

The magnitude of the largest coefficient of the system is $F_{2k+5} + (m-1)F_{2k+4}$. Using the closed form expression for F_j in terms of ϕ ($F_j = \frac{1}{\sqrt{5}}(\phi^j - (-\phi)^{-j})$), we

have that this is $O(m\phi^{2k+4}) = O(m\phi^{2k})$, and the result follows. ∎

THEOREM 7.3. *It is possible for a system of n inequalities with coefficients of magnitude no larger than A_{max} to have an integer hull consisting of $\Omega(n \log A_{max})$ inequalities.*

Proof. Consider Lemma 7.2 with $k = \Omega(\log m)$. Then $n = 2m$, $A_{max} = O(m\phi^{2k})$, and we have mk cuts. Thus $n \log A_{max} = O(m(k + \log m))$. But $k = \Omega(\log m)$, so $n \log A_{max} = O(mk)$. This means $mk = \Omega(n \log A_{max})$ and we have the result. ∎

THEOREM 7.4. *Our algorithm for computing two-dimensional integer hulls is optimal.*

Proof. By Theorem 7.3, any algorithm must be $\Omega(n \log A_{max})$ on some problem instances. By Theorem 6.12, our algorithm is $O(n \log A_{max})$ on all problem instances, and the result follows. ∎

8. Future work. We have done some work toward developing an integer hull algorithm that works in three dimensions, but we have yet to establish whether this algorithm can be made to be polynomial time. If it can, then we hope to generalize to an arbitrary number of dimensions and tackle the very interesting question of whether such an algorithm is polynomial time for any fixed number of dimensions.

At some stage we also hope to determine whether such algorithms can be usefully employed in a constraint solver for a CLP language by buying enough of a reduction in domain sizes to offset the extra overhead incurred on more than just a few select problem classes.

Acknowledgments. The geometrical interpretation of continued fractions and their convergents used in this paper is from [6, Chap. IV, sect. 12] and appears to be due to Smith [17, Art. 20].

The author would like to thank Peter Stuckey for his comments on many drafts of this paper. The author would also like to thank the anonymous referees for their feedback, advice, and suggestions. In particular, credit must be given to one anonymous referee for a suggestion on how to obtain improved bounds on the coefficients of generated cuts (the bounds presented in an earlier version of this work were messy and not particularly tight, with the proofs hard to follow). While the ideas proposed by the referee are not used in the paper, the bounds yielded were sufficiently good for the whole question of optimality to be addressed and provided the motivation to find the proof of even tighter bounds that is presented in this version of the paper.

Finally, the author would like to thank Gary Eddy for his help in selecting an appropriate data structure for storing the inequalities.
